
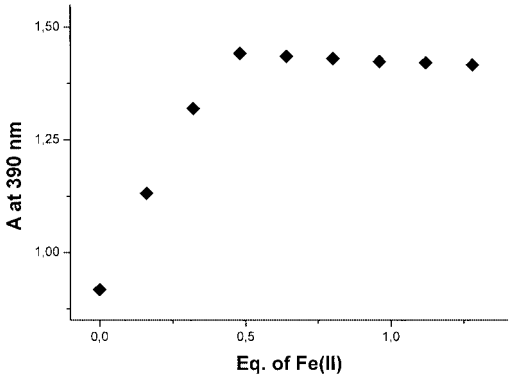

Figure 4. Increase of the 390 nm absorbance upon photometric titration of **L** (5×10^{-5} M) with Fe^{II}-tetrafluoroborate solution at 20 °C and pH 7.0 (spectra correspond to addition of Fe in steps of 0.16 equiv.).

These observations are consistent with fast formation of an $\mathbf{L}_2Fe$ species in which the terpyridine-like tridentate sites of **L** coordinate to the metal ion and slow conversion of this complex to the $\mathbf{L}_4Fe_4$ oligomer occurs. Any attempts to detect the intact $\mathbf{L}_4Fe_4$ complexes by mass spectrometric techniques (FAB, electrospray at variable concentrations, MALDI-TOF) failed, even for fresh solutions of crystalline samples of complexes **1** and **2**.

Complexes of L with Cu^I

While the tetranuclear [2×2] grid structure appears to be favoured with metal ions which can adopt octahedral coordination, **L** might form different types of self-assembled structures when metal ions with a preference for tetrahedral coordination are involved. We therefore explored the reaction of **L** with Cu^I ions which forms both tetrahedral complexes with 2,2′-bipyridyl type ligands and five coordinate complexes with *terpy* ligands, corresponding to the bidentate und tridentate sites of **L**, respectively.

The crystalline Cu^I complexes $[Cu\mathbf{L}(PPh_3)_2]ClO_4\cdot 2(CH_3CN)$ (**6**) and $[Cu_2\mathbf{L}_2(CN)(PPh_3)_2]ClO_4$ (**7**) could be obtained by treatment of **L** with $Cu^I(PPh_3)_3Cl$ followed by addition of $NaClO_4$ in acetone solution. Use of ClO_4^- promoted better crystallisation of the complexes.

The IR spectra of complexes **6** and **7** in the range 4000–400 cm^{-1} are quite similar and, as for **1**, **2**, **3**, **4** and **5**, show all the characteristic ligand peaks. The infrared spectra display bands for $\nu_{(C\equiv N)}$ at 2100 cm^{-1} (acetonitrile solvate) for **6** and 2080 cm^{-1} (bridging CN^-) for **7**, and bands for the perchlorate counterions at 1094 and 1098 cm^{-1} for **6** and **7**, respectively.[13] Crystals of **6** formed in acetonitrile appeared to lose solvent if left to stand in a solvent-free atmosphere.

ESI and MALDI mass spectra of solutions of **6** and **7** gave signals for mononuclear species. Major peaks in the spectra correspond to $[Cu\mathbf{L}]^+$ and $[Cu\mathbf{L}(OH)(OH_2)]^+$ with characteristic isotopic distributions for copper ions. Spectrophotometric titrations of ligand **L** with $[Cu(CH_3CN)_4]BF_4$ also indicate formation of a 1:1 **L**:Cu complex (Figure 5). Sharp isosbestic points were obtained in the range of 0 to 1 equiv. of Cu. The UV absorbance maxima of the complexes (about 330 nm) are shifted toward higher wavelengths relative to the free ligands (about 300 nm).

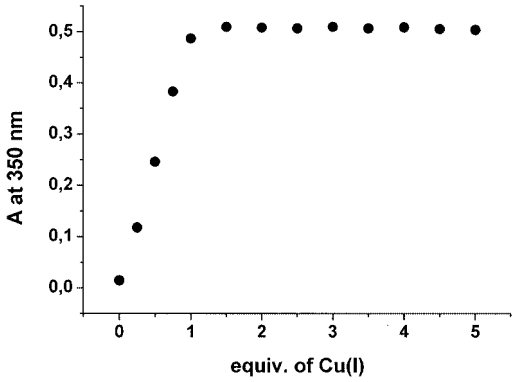

Figure 5. Increase of the 350 nm absorbance upon photometric titration of **L** (1×10^{-5} M) with $[Cu(CH_3CN)_4]BF_4$ solution at 20 °C (spectra correspond to addition of Cu in steps of 0.25 equiv.).

Crystal Structure of $[CuL(PPh_3)_2]ClO_4\cdot 2CH_3CN$ (6)

The solid-state structure of **6** was determined by X-ray crystallography (Table 1). The copper ion is four-coordinate (Figure 6) and bound to the two nitrogen atoms of **L** as well as two phosphorus atoms from PPh_3 groups. The geometry around the copper ion is distorted tetrahedral which is typical for Cu^I compounds, with angles ranging from 79.63(8) to 122.77(3)° (selected distances and angles are given in Table 1). The copper–phosphorus distances are nearly identical at 2.2461(8) and 2.2550(8) Å and are similar to the values in other Cu^I complexes.[14,15] The copper ion binds to the bidentate site of **L** with Cu–N distances of 2.052(2) and 2.083(2) Å. Very similar bonding parameters for the Cu^I ion were found in $[Cu(phen)(PPh_3)_2]^+$ and $[Cu(dmp)(PPh_3)_2]^+$ (where dmp is 2,9-dimethyl-1,10-phenanthroline).[16]

Table 1. Selected bond and lengths [Å] and angles [°] for **6**.

Cu(1)–N(1)	2.052(2)	N(1)–Cu(1)–P(1)	116.21(6)
Cu(1)–N(2)	2.083(2)	N(2)–Cu(1)–P(1)	107.82(6)
Cu(1)–P(1)	2.2461(8)	N(1)–Cu(1)–P(2)	109.08(6)
Cu(1)–P(2)	2.2550(8)	N(2)–Cu(1)–P(2)	113.24(6)
N(1)–Cu(1)–N(2)	79.63(8)	P(1)–Cu(1)–P(2)	122.77(3)

The heterocyclic fragments of **L** containing nitrogens N(3), N(4) and N(5) are coplanar whereas the heterocyclic fragment is tilted by 13.9°. The π-stacking (3.4 and 7.9 Å)

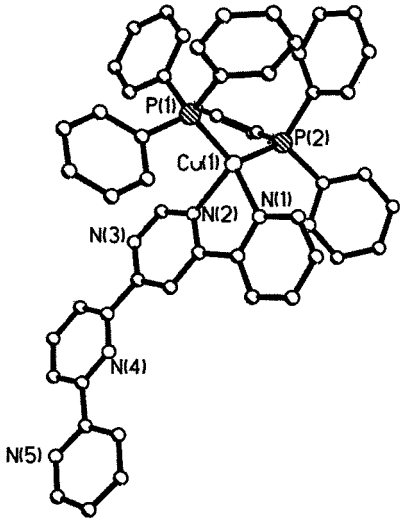

Figure 6. Molecular structure and numbering scheme for **6**. Hydrogen atoms are omitted for clarity.

of Cu**L** fragments can be observed in the crystal structure (Figure 7). The distances of the observed π-stacked units in **6** are approximately 3.4 and 7.9 Å.

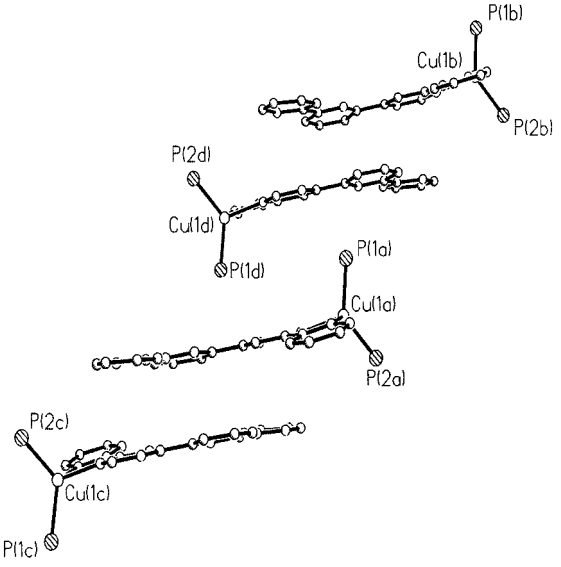

Figure 7. Stacking of complex cations in the crystal of **6**. Phenyl rings are omitted for clarity.

L contains both bi- and tridentate metal binding fragments. Interestingly, Cu^{I} prefers the bidentate bipyridyl-like binding site, although pentacoordinate Cu^{I} complexes with tridentate terpyridine and two monodentate coligands have been reported.[17] In each of the latter complexes, however, the metal ion coordination sphere is strongly distorted with one long metal–nitrogen contact and the complexes are not stable in solution and are spontaneously oxidised by air to the corresponding Cu^{II} complexes. In contrast, reported Cu^{I}-bipy-PPh_3 complexes are air stable in solution for days.[18] These facts indicate that bidentate bipyridyl is a better ligand for Cu^{I} than tridentate terpyridyl and explain the observed structures of **6** and **7** as well as the lack of oligomeric complex formation.

Sauvage and coworkers have designed a ligand system which consists of bidentate bipyridyl and tridentate terpyridyl fragments.[19] It was shown by electrochemical and spectroscopic methods that the preferred coordination mode for Cu^{I} is bidentate bipyridyl whereas for Cu^{II} it is tridentate terpyridyl. Similarly, the observation of a bidentate site preference for Cu^{I} should facilitate the design of mixed-metal self-assembled complexes of **L**.

Crystal Structure of $[Cu_2L_2(CN)(PPh_3)_2]ClO_4$ (7)

This structure (Table 2, Figure 8) reveals that the molecule of **7** contains two copper centres bridged by cyanide, traces of which were possibly present in the MeCN solvent. The bridging CN^- is disordered with respect to C/N coordination. Each copper ion exhibits a distorted tetrahedral geometry by binding to two nitrogen atoms from **L**, a phosphorus atom from PPh_3 and a nitrogen (carbon) atom from the CN group. The angles at the copper(I) atoms range from 78.84(9) to 127.87(7)°. In **7**, the copper–nitrogen distances are different, i.e. 2.089(2) and 2.090(2) Å to the heterocyclic nitrogen atoms and 1.930(2) Å to the nitrile nitrogen. The copper–phosphorus distance is 2.2094(8) Å. The copper–bpy nitrogen and copper–phosphorus distances are close to the corresponding values in **6**. The Cu–N(C)–C(N) angle is 164.5° and the Cu···Cu separation is 4.869 Å.

Table 2. Selected bond and lengths [Å] and angles [°] for **7**.

Cu(1)–N(1C)	1.930(2)	N(1C)–Cu(1)–N(3)	111.44(9)

Conclusions

We have reported here a novel polynucleating ligand which forms [2×2] grids with divalent 3d metals having different electronic structures, i.e. Ni^{II}, Co^{II}, Fe^{II}, Zn^{II} and Cu^{II}. As shown by magnetic measurements and Mössbauer spectroscopy, no significant interactions between metal centres occur in these compounds. We have also shown that the grids are formed only in the presence of NO_3^- ions and with divalent metal ions. Monovalent metal ions (e.g. Cu^I) both in the presence and absence NO_3^- form mono and dinuclear complexes. In both cases Cu^I prefers the bidentate to the tridentate binding site of the ligand.

Experimental Section

Materials and Procedures: Reagents and solvents were obtained from Aldrich, Acros or Fluka and used as received. 6-(2-Pyridyl)-4-[6-(2-pyridyl)-2-pyridyl]pyrimidine (**L**) was synthesized as previously reported.[9] The iron(II) and copper(I) complexes were synthesized and purified using typical high vacuum and/or Schlenk techniques.

Physical Measurements: ^{1}H NMR spectra were recorded on Bruker AC-300 (300.13 MHz) and Bruker AC-400 (400.13 MHz) spectrometers and chemical shifts are reported in ppm. Tetramethylsilane was used as an internal standard. Absorbance UV/Vis spectra of solutions were recorded on a Specord S100 spectrophotometer (Carl Zeiss Jena). IR spectra were obtained on a Perkin–Elmer 983 G spectrometer (as KBr pellets). Matrix-assisted laser desorption ionisation time of flight (MALDI-TOF) and LDI-TOF mass spectra were recorded on a Bruker Biflex III MS spectrometer in negative and positive linear modes. Variable-temperature magnetic susceptibility data (1.7–300 K) were acquired on powdered samples using a Quantum Design MPMS-5 SQUID magnetometer. Corrections for the diamagnetism of the ligand and Co^{II} cations were applied using Pascal's[20] constants; the diamagnetic contribution from the sample holder was also taken into account. The ^{57}Fe Mössbauer measurements were carried out using a conventional constant-acceleration spectrometer and the spectra were fitted using the MOSSFUN program.[21] Elemental analyses were performed by the Microanalytisches Laboratorium des Organisch-Chemischen Instituts der Universität Heidelberg.

Crystallographic Studies: Intensity data were collected at 173 K with a Bruker AXS SMART 100 diffractometer (Mo-K_α radiation, λ = 0.71073 Å, graphite monochromator, ω scans, SADABS 10). Absorption corrections were applied. The structures were solved by direct methods using SHELXS-86[22,23] and refined by least-squares methods based on F^2 with all measured reflections using SHELX-97.[24] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were located and refined (Table 3).

CCDC-246323 (for **6**) and CCDC-246324 (for **7**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Caution! Transition-metal perchlorate complexes are potentially explosive and should be handled with due care and in small quantities!

Synthesis of 1: See ref.[8]

Synthesis of 2: To a stirred solution of **L** (77 mg, 0.246 mmol) in acetone (5 mL) was added a solution of $Co(NO_3)_2{\cdot}4H_2O$ (63 mg, 0.249 mmol) in water (5 mL). A dark-red precipitate formed within 12 h which was filtered, washed with acetone and dried. The complex crystallised from DMF upon layering with a solution of $NaClO_4$ in acetone. Yield: 119 mg, (79%). $C_{88}H_{80}Cl_7Co_4N_{25}O_{35}$ (2451.63) calcd. C 41.75, H 3.19, N 13.83; found C 41.39, H 3.88, N 13.91. MS (MALDI) *m*/*z* (%): 370.2 (100) $[^{59}Co\mathbf{L} + e]^+$, 387.2 (90) $[^{59}Co\mathbf{L}(OH)]^+$. IR (KBr): $\tilde{\nu}$ = 1384 (N=O), 1102 (Cl=O), 1677 (C=O) cm^{-1}.

Synthesis of 3: To a stirred solution of **L** (20 mg, 0.064 mmol) in acetone (5 mL) was added a solution of $Fe(NO_3)_2{\cdot}6H_2O$ (17 mg, 0.064 mmol) in water (5 mL). A solution of $NaClO_4$ in acetone was then added to the resultant dark blue solution over 24 h. Complex **3** started to crystallise from this solution after 24 h and was filtered, washed with diethyl ether and dried in a high vacuum. Yield 34.8 mg (90%). $C_{76}H_{72}Cl_7Fe_4N_{21}O_{41}$ (2407.05): calcd. C 37.92, H 3.01, N 12.22; found C 38.51, H 3.21, N 12.31. MS (MALDI) *m*/*z* (%): 678.5 (100) $[^{56}Fe\mathbf{L}_2 + e]^+$, 791.4 (70) $[^{56}Fe_3\mathbf{L}_2]^+$. IR (KBr): $\tilde{\nu}$ = 1386 (N=O), 1107 (Cl=O) cm^{-1}.

Synthesis of 4: To a stirred solution of **L** (65 mg, 0.21 mmol) in acetone (5 mL) was added a solution of $Zn(NO_3)_2{\cdot}4H_2O$ (58 mg, 0.21 mmol) in water and a solution of $ZnCl_2$ (31mg, 21 mmol) in water (5 mL). The white precipitate which formed was filtered off, washed with diethyl ether and dried in high vacuum. Yield 82.2 mg (79%). $Zn_4C_{76}H_{64}Cl_4N_{24}O_{18}$ (2004.8): calcd. C 45.53, H 3.22, N

IR (KBr): $\tilde{\nu}$ = 1386 and 1378 (N=O), 1105 (Cl=O) cm^{-1}.

Synthesis of 6 and 7: To a stirred solution of **L** (45 mg, 0.14 mmol) in dry acetonitrile (3 mL) was added a solution of $Cu(PPh_3)_3Cl$ (90 mg, 0.15 mmol) in dry acetonitrile (5 mL). The clear orange solution was stirred for 30 min at 40 °C. After 15 min a small amount of a white precipitate started to form. This was filtered off and to the filtrate was added $NaClO_4$ in acetone (1 mL). Complex **6** was filtered off from this solution after 48 h. Complex **7** crystallised from the second solution after 24 h. For **6**: Yield 26 mg (17%). $C_{59}H_{49}ClCuN_7O_4P_2$ (1080.98): calcd. C 65.55, H 4.57, N 9.07; found C 64.75, H 3.98, N 8.51. The d^6 low-spin Mn^I half-sandwich dinuclear complexes of the type [{Mn(MeC_5H_4)($R_2PCH_2CH_2PR_2$)=C=C($SnMe_3$)}$_2${X}] (X = {μ-1,4-C_6H_4}, R = Me, **2a**; X = {μ-1,4-C_6H_4}, R = Et, **2b**; X = {μ-1,3-C_6H_4}, R = Me, **3a**; X = {μ-1,3-C_6H_4}, R = Et, **3b**; X = {μ-4,4-C_6H_4-C_6H_4}, R = Me, **4a**; X = {μ-4,4-C_6H_4-C_6H_4}, R = Et, **4b**; X = {μ-1,4-C_4H_2S}, R = Me, **5a**; X = {μ-1,4-C_4H_2S}, R = Et, **5b**) were obtained by the treatment of [Mn(C_5H_4Me)(η^6-cycloheptatriene)] with 0.5 equiv. of the corresponding acetylene Me_3Sn–C≡C–X–C≡C–$SnMe_3$ (X = {μ-1,4-C_6H_4}, {μ-1,3-C_6H_4}, {μ-4,4-C_6H_4-C_6H_4}, {μ-1,4-C_4H_2S}) and $R_2PCH_2CH_2PR_2$ (R = Me, Et) at 50 °C for 12 h to yield the corresponding dinuclear complexes in very good yields. These dinuclear tin-substituted vinylidene complexes were further treated with an excess of MeOH to give the corresponding dinuclear parent vinylidene complexes of the type [{Mn(MeC_5H_4)($R_2PCH_2CH_2PR_2$)=C=C(H)}$_2${X}] (X = {μ-1,4-C_6H_4}, R = Me, **6a**; X = {μ-1,4-C_6H_4}, R = Et, **6b**; X = {μ-1,3-C_6H_4}, R = Me, **7a**; X = {μ-1,3-C_6H_4}, R = Et, **7b**; X = {μ-4,4-C_6H_4-C_6H_4}, R = Me, **8a**; X = {μ-4,4-C_6H_4-C_6H_4}, R = Et, **8b**). All dinuclear compounds were characterised by NMR and IR spectroscopy and elemental analysis. X-ray diffraction studies were performed on complexes **2b**, **3a**, **4a** and **6a**.

Introduction

Carbon-rich organometallics containing rigid, π-conjugated chains are of increasing interest due to their uses in the synthesis of unsaturated organic species,[1–4] organometallic polymers[5] and π-conjugated di- or multimetallic systems.[3,6–24] In particular, the dinuclear transition metal acetylide complexes offer an interesting perspective for the build-up of organometallic systems as molecular-level single-electron devices and the bottom-up construction of miniaturised components capable of performing specific electronic functions.[8–20] Our ongoing interest in such building blocks is devoted to the synthesis and physical properties of molecular species which might function as wires. Specifically, they should consist of an all-carbon chain capped by two redox-active metal termini.[6–17] We sought to explore reactions of dinuclear vinylidene precursor complexes which would ultimately lead to polyyne ligand containing complexes. We recently reported the chemistry and reactivity of Mn^{II} and Mn^{III} half-sandwich $Me_2PCH_2CH_2PMe_2$ (dmpe) alkynyl complexes and their conversion to (vinylidene)Mn^I species.[21,23,24] The first conclusion of this study was that vinylidene complexes gained considerable stability through the presence of the bis(dimethylphosphanyl)ethane ligand (dmpe) in comparison with the reported CO-substituted species [Mn(Cp)L^1L^2(C=CR_2)] (L^1 = L^2 = CO, PR'_3 or L^1 = CO, L^2 = PR'_3).[25] Although the dinuclear complexes with the CO ligands were reported earlier,[26] these complexes are not expected to possess low-energy work functions which is an important property required for the molecules to function as molecular wires.[23] In contrast, the complexes bearing electron-donating phosphane ligands can be expected to possess suitable electronic properties, i.e. a low energy work function. Similar types of dinuclear vinylidene complexes have been reported with terminal ends capped by various other transition metals such as Ru,[17b] Rh[27] or Fe.[7] We herein report access to new dinuclear half-sandwich complexes of the type [{Mn(MeC_5H_4)($R_2PCH_2CH_2PR_2$) = C=C(H)}$_2${X}] (R = Me, Et) (X = {μ-1,4-C_6H_4}, {μ-1,3-C_6H_4} and {μ-4,4-C_6H_4-C_6H_4}). It has been demonstrated by other groups that similar types of dinuclear vinylidene complexes can serve as valuable starting materials for obtaining access to dinuclear acetylide complexes.

Results and Discussion

A common method for obtaining vinylidene complexes is to make use of the high propensity of terminal acetylide derivatives to rearrange into vinylidene compounds.[28–36] Such principal possibilities have been corroborated by recent studies by our group.[18–23] For such a process to be initiated in half-sandwich Mn^I chemistry, we believed the complex [Mn(C_5H_4Me)(η^6-cycloheptatriene)] (**1**)[37] would be an excellent starting material, since facile cycloheptatriene exchange could be expected to occur with electron donating ligands such as phosphanes or acetylenes.[38,39] Further reactivity with disubstituted tin acetylides was anticipated, thus leading to the desired dinuclear vinylidene species.

The reaction of [Mn(C_5H_4Me)(η^6-cycloheptatriene)] (**1**) with 0.5 equiv. of $Me_3Sn–C\equiv C–X–C\equiv C–SnMe_3$ (X = {μ-1,4-C_6H_4}, {μ-1,3-C_6H_4}, {μ-4,4-C_6H_4-C_6H_4},[40–42] {μ-1,4-C_4H_2S}) and $R_2PCH_2CH_2PR_2$ (R = Me, Et) at 50 °C for 12 h gave the corresponding vinylidene complexes of the type [{Mn(MeC_5H_4)($R_2PCH_2CH_2PR_2$)=C=C($SnMe_3$)}$_2$-{X}] (X = {μ-1,4-C_6H_4}, R = Me, **2a**; X = {μ-1,4-C_6H_4}, R = Et, **2b**; X = {μ-1,3-C_6H_4}, R = Me, **3a**; X = {μ-1,3-C_6H_4}, R = Et, **3b**; X = {μ-4,4-C_6H_4-C_6H_4}, R = Me, **4a**; X = {μ-4,4-C_6H_4-C_6H_4}, R = Et, **4b**; X = {μ-1,4-C_4H_2S}, R = Me, **5a**; X = {μ-1,4-C_4H_2S}, R = Et, **5b**) in quantitative yields (Scheme 1).

These reactions appear to require the initial formation of (alkyne)Mn species.[25] However, NMR studies of the reactions carried out in the temperature range of –70 to 20 °C did not reveal any intermediates. The ^{13}C NMR spectra of complexes **2**–**5** show the C_α and the C_β resonances between δ = 326–330 and 110–140 ppm, respectively. The ^{31}P NMR resonances appear at $\delta \approx 95$ ppm for complexes **2a**–**5a** and are thus comparable with those observed for the related [Mn($C_5H_4R^1$)($Me_2PCH_2CH_2PMe_2$)(=C=CR^2H)] complexes.[24,38,39] However, for complexes **2b**–**5b** a downfield shift to $\delta \approx 115$ ppm was observed in the ^{31}P NMR spectra. The resonances corresponding to the trimethyltin groups were observed in the ^{119}Sn NMR spectra as triplets at $\delta \approx -30$ ppm. The ^{31}P, ^{119}Sn and ^{13}C NMR spectroscopic data for the complexes **2**–**5** are summarised in Table 1.

Table 1. $^{31}P\{^1H\}$, $^{119}Sn\{^1H\}$ and $^{13}C\{^1H\}$ NMR spectroscopic data for compounds **2**–**5**

Compound	^{31}P NMR ($R_2PCH_2CH_2PR_2$) δ (ppm)	^{119}Sn NMR ($SnMe_3$) δ (ppm)	^{13}C NMR Mn=C_α=C_β	Mn=C_α=C_β
2a	94.9 (s)	–30.2 (t)	329.6 (t)	129.1
2b	115.0 (s)	–27.4 (t)	326.3 (t)	129.9
3a	94.3 (s)	–29.8 (t)	328.5 (t)	129.1
3b	115.0 (s)	–29.8 (t)	328.5 (t)	129.1
4a	93.0 (s)	–17.1 (t)	330.5 (t)	129.1
4b	113.5 (s)	–29.2 (t)	328.0 (t)	142.3
5a	93.7 (s)	–27.5 (t)	328.5 (t)	110.1
5b	115.1 (s)	–26.3 (t)	326.8 (t)	141.1

The structure of **2b** was additionally confirmed by an X-ray diffraction study (Figure 1). A pseudo-tetrahedral coordination environment of the manganese centre was revealed. The bond lengths of 1.763(4) Å and 1.345(2) Å for Mn–C11 and C11–C12, respectively, confirm the double-bond character of these bonds. The observed C12–Sn bond length of 2.159(4) Å is similar to that found in the mononuclear vinylidene complexes already reported.[38,39] The bond angles for Mn–C11–C12 and C11–C12–C13 were found to be 175.7(3)° and 125.8(4)°, respectively.

X-ray diffraction analysis confirmed the spectroscopically derived structures of **3a** and **4a** which are closely related to that of **2b** (Figures 2 and 3). The solid-state structures indicated the Mn–C_α and C_α–C_β bond lengths to be 1.769(4) and 1.299(6) Å, and 1.744(4) and 1.358(5) Å, for **3a** and **4a**, respectively. These values confirm the double-bond nature in these vinylidene complexes.

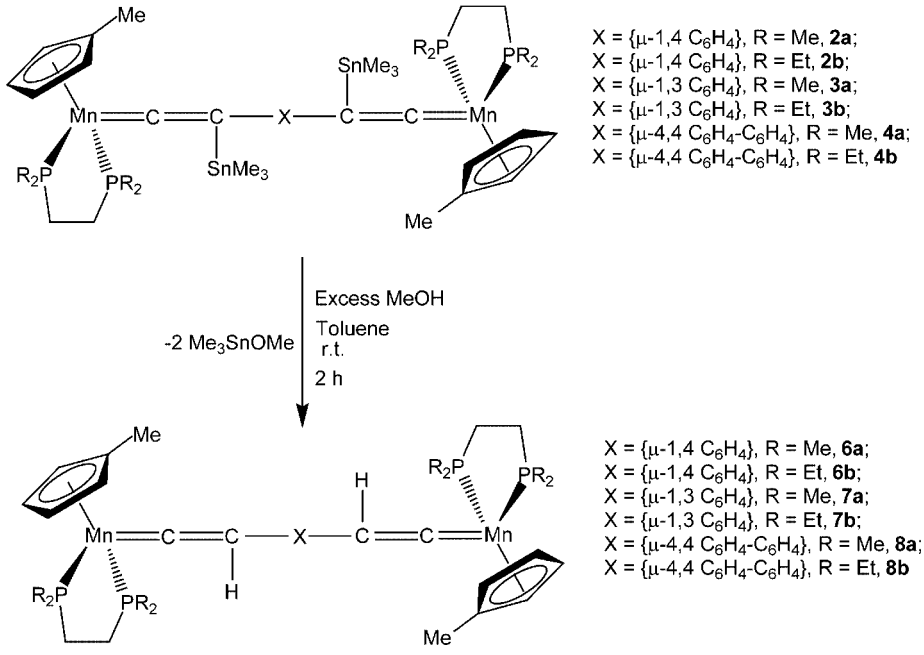
Table 2. $^{31}P\{^1H\}$ and $^{13}C\{^1H\}$ NMR spectroscopic data for compounds **6**–**8**

Compound	^{31}P NMR ($R_2PCH_2CH_2PR_2$) δ (ppm)	^{13}C NMR δ (ppm) Mn=C_α=C$_\beta$	Mn=C$_\alpha$=C_β
6a	96.1 (s)	325.4 (t)	133.9
6b	114.5 (s)	327.4 (t)	133.9
7a	94.9 (s)	343.4 (t)	141.3
7b	114.2 (s)	341.9 (t)	140.4
8a	94.5 (s)	342.2 (t)	139.9
8b	115.1 (s)	345.5 (t)	140.2

teristic triplet resonances at $\delta \approx 6.0$ ppm with $^4J_{P,H}$ values of 8.4 Hz. The ^{13}C NMR spectra of complexes **2**–**5** show the C$_\alpha$ and the C$_\beta$ resonances further downfield between δ = 325–350 and 130–140 ppm, respectively, in comparison with the tin derivatives. The ^{31}P NMR resonances appear at $\delta \approx 97$ ppm for complexes **6a**–**8a** and are thus comparable with those observed for the related $[Mn(C_5H_4R^1)(Me_2PCH_2CH_2PMe_2)(=C=CR^2H)]$ complexes.[24,38,39] However, the ^{31}P NMR resonances for complexes **6b**–**8b** were observed further downfield at $\delta \approx$ 114 ppm. The ^{31}P NMR and ^{13}C NMR spectroscopic data for complexes **6**–**8** are summarised in Table 2.



Scheme 2.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

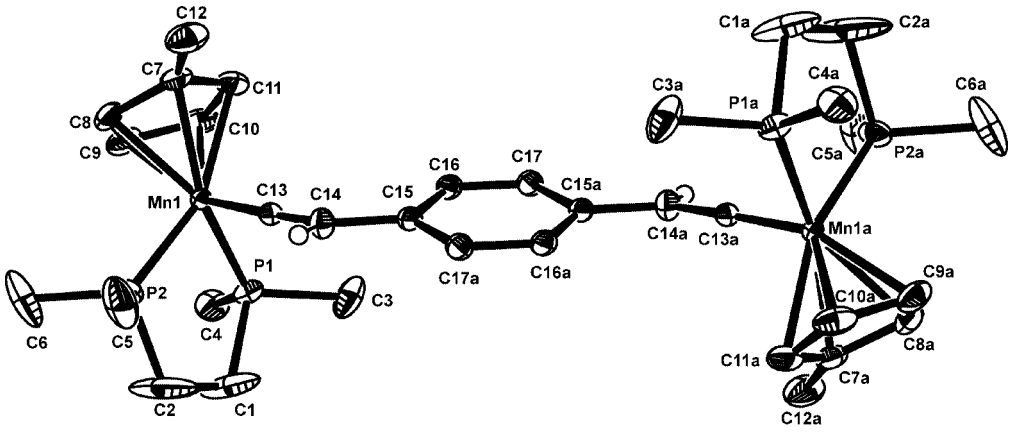


Figure 4. Molecular structure of **6a**; the symmetry operator $a = 2 - x, 2 - y, 1 - z$ represents a centre of inversion in the middle of the benzene ring; the ellipsoids are at the 30% probability level and selected hydrogen atoms are omitted for clarity; selected bond lengths [Å] and bond angles [°]: Mn(1)–C(13) 1.746(2), C(13)–C(14) 1.340(3), C(14)–C(15) 1.466(3), C(1)–C(2) 1.354(5), C(15)–C(16) 1.403(3), Mn1–Cg1 1.7769(3); C(14)–C(13)–Mn(1) 175.09(19), C(13)–C(14)–C(15) 127.8(2), C(14)–C(15)–C(16) 123.1(2), C(5)–P(2)–C(6) 99.17(16), C(3)–P(1)–Mn(1) 120.44(11)

The structure of **6a** was also confirmed by an X-ray diffraction study (Figure 4). A pseudo-tetrahedral coordination environment for each manganese centre was found. The bond lengths of 1.746(4) Å and 1.340(3) Å for Mn1–C13 and C13–C14, respectively, are similar to those found for the previous complexes **2b**, **3a** and **4a** and confirm the double-bond character of these bonds. The bond angles for Mn–C13–C14 and C13–C14–C15 were found to be 175.09(19)° and 127.8(2)°. The latter bond angle suggests that the bending is less pronounced in comparison with the tin derivative.

Conclusions

New dinuclear vinylidenetin complexes and the parent vinylidene complexes capped by Mn^{I} half-sandwich units have been synthesised. A series of these complexes has been structurally characterised. These complexes offer further possibilities for gaining access to the corresponding dinuclear acetylide complexes.

Experimental Section

X-ray Diffraction Studies on 2b, 3a, 4a and 6a: Single-crystal X-ray diffraction data were collected at measurement temperatures of 183(2) K for **2b** and **4a**, and 153(2) K for **3a** and **6a** using an imaging plate detector system (Stoe IPDS) with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). A total of 200, 167, 154 and 200 images were exposed at constant times of 3.0, 5.0, 2.6 and 2.5 min per image for the structures of **2b**, **3a**, **4a** and **6a**.[43] The crystal-to-image distances were set to 50 mm for **3a**, **4a** and **6a** and to 60 mm for **2b** (θ_{max} range: 27.90–30.46°). φ-oscillation (**2b** and **3a**) and rotation modes (**4a** and **6a**) were chosen for the increments of 1.5, 1.2, 1.3 and 1.3° per exposure in each case. Total exposure times were 21, 24, 14 and 22.4 h. The intensities were integrated using a dynamic peak profile analysis and an estimated mosaic spread (EMS) check was performed to prevent overlapping intensities. For the cell parameter refinements, 8000 reflections with intensities $I > 6\sigma(I)$ were selected out of the whole limiting spheres for the four structures. A total of 18043, 53927, 29813 and 13632 reflections were collected of which 5603, 13101, 7610 and 4830 were unique after performing absorption corrections and data reductions (R_{int} = 8.79, 11.04, 8.02 and 3.92%). For the numerical absorption corrections of **2b**, **3a**, **4a** and **6a**, the numbers of indexed crystal faces used were 9, 10, 6 and 10.[44] All measurement procedures were performed using the stoe IPDS software.[43] The measurement temperatures were controlled by an Oxford cryogenic system. It should be noted that the structures of **2b**, **4a** and **6a** have crystallographically imposed inversion symmetry (see Figure 1, Figure 3 and Figure 4). The structures were solved with the unique data sets using the Patterson method of the program SHELXS-97.[45] The structures were refined with the program SHELXL-97.[46] The programs PLATON and PLUTON[47] were used to check the results of the X-ray analyses and also for the completion of the structures by checking the different electron density calculations. Relevant crystallographic data are collected in Table 3.

Preparations

General: Reagent grade benzene, toluene, hexane, pentane, diethyl ether and tetrahydrofuran were dried and distilled from sodium benzophenone ketyl prior to use. Dichloromethane was distilled first from P_2O_5 and then from CaH_2 prior to use. Literature procedures were used to prepare the following compounds: 1,2-bis(dimethylphosphanyl)ethane (dmpe),[48] 1,2-bis(diethylphosphanyl) ethane (depe),[48] [Mn(η^5-MeC_5H_4)(η^6-cycloheptatriene)],[37] Me_3Sn–C≡C–X–C≡C–$SnMe_3$ (X = {μ-1,4-C_6H_4}, {μ-1,3-C_6H_4}, {μ-4,4-C_6H_4-C_6H_4},[40–42] {μ-1,4-C_4H_2S}). *n*BuLi (1.6 M in hexane), MeLi·LiBr (1.5 M in diethyl ether) and Me_3SnCl were used as received. All manipulations were carried out under nitrogen using Schlenk techniques or in a drybox. IR spectra were obtained with a Bio-Rad FTS-45 instrument. NMR spectra were measured with a Varian Gemini-2000 spectrometer at 300 MHz for ^1H and 121.5 MHz for $^{31}P\{^1H\}$ and with a Bruker DRX-500 spectrometer the frequencies were 125.8 MHz for $^{13}C\{^1H\}$ and 186.5 MHz for ^{119}Sn. Chemical shifts for ^1H and ^{13}C NMR spectra are given in ppm with respect to the solvent signals. $^{31}P\{^1H\}$ NMR spectra were referenced to 98% external H_3PO_4 and the $^{119}Sn\{^1H\}$ NMR spectra are relative to $SnBu_4$.

[{Mn(MeC_5H_4)($Me_2PCH_2CH_2PMe_2$)=C=C($SnMe_3$)}$_2$(μ-1,4-C_6H_4)] (2a): To a toluene solution (10 mL) of [Mn(MeC_5H_4)(η^6-cycloheptatriene)] (50 mg, 0.22 mmol) was added a toluene solution

(10 mL) of dmpe (33 mg, 0.22 mmol) and Me_3Sn–C≡C–C_6H_4–C≡C–$SnMe_3$ (50mg, 0.11 mmol). The solution was stirred at 50 °C for 3 h to give a dark red solution. The solvent was removed under vacuum to afford a dark red solid. Then the solid was extracted with diethyl ether and filtered through Celite. The ether fraction was concentrated to give an orange red precipitate. Crystallisation from ether at –35 °C gave single orange-red crystals. Yield: 104 mg, 93%. ^{1}H NMR ([D$_8$]THF, 300 MHz, 20 °C): δ = 6.75 (4 H, C_6H_5), 4.26 (4 H, C_5H_4Me), 4.00 (4 H, C_5H_4Me), 1.98 (6 H, C_5H_4Me), 1.72 (4 H, PCH_2), 1.61 (4 H, PCH_2), 1.22 (24 H, $P[CH_3]_2$), –0.07 ppm (18 H, $SnMe_3$). ^{13}C{^{1}H} NMR ([D$_8$]THF, 125.8 MHz, 20 °C): δ = 329.6 (t, $^2J_{P,C}$ = 35 Hz, Mn-C_α), 136.7 (s, C_i-Ph), 129.1 (m, = C_β), 129.4 (s, 2 C, C_i-C_5H_4Me), 122.2 (s, C_6H_5), 120.5 (s, C_6H_5), 120.2 (s, C_6H_5), 83.9 (s, 4 C, C_5H_4Me), 81.3 (s, 4 C, C_5H_4Me), 32.1 (4 C, PCH_2), 24.5 (PCH_2), 21.9 ($P[CH_3]_3$), 14.8 ($P[CH_3]_3$), –6.1 ($SnMe_3$) ppm. ^{31}P{^{1}H} NMR ([D$_8$]THF, 121.5 MHz, 20 °C): δ = 94.9 (s, 4 P) ppm. ^{119}Sn NMR ([D$_8$]THF, 186.5 MHz, 20 °C): δ = –30.2 (t, J = 76 Hz) ppm. [{Mn(MeC$_5$H$_4$)(Me$_2$PCH$_2$CH$_2$PMe$_2$)=C=C(H)}$_2$(μ-1,4-C$_6$H$_4$)] (6a): To a toluene solution (10 mL) of [{Mn(MeC$_5$H$_4$)(dmpe)=C=C(SnMe$_3$)}$_2$(μ-1,4-C$_6$H$_4$)] (120 mg, 0.17 mmol) was added an excess of methanol. The solution was stirred at room temperature for 2 h to give a dark red solution. The solvent was removed under vacuum to afford a dark red solid which was washed with pentane. The solid was extracted with toluene and filtered through Celite. The toluene fraction was concentrated to give an orange-red precipitate. Crystallisation from a mixture of tetrahydrofuran/ether at –35 °C gave single orange-red crystals. Yield: 105 mg, 90%. ^{1}H NMR ([D$_8$]toluene, 300 MHz, 20 °C): δ = 7.15 (4 H, C$_6$H$_5$), 5.91 (2 H, $^4J_{P,H}$ = 8.4 Hz, = C[H]), 4.30 (4 H, C$_5$H$_4$Me), 3.86 (4 H, C$_5$H$_4$Me), 1.93 (6 H, C$_5$H$_4$Me), 1.49 (4 H, PCH$_2$), 1.11 (12 H, P(CH$_3$]$_2$), 1.02 (4 H, PCH$_2$), 0.74 (12 H, P[CH$_3$]$_2$) ppm. ^{13}C{^{1}H} NMR ([D$_8$]toluene, 125.8 MHz, 20 °C): δ = 325.4 (t, $^2J_{P,C}$ = 37.5 Hz, Mn-*C*$_α$), 133.9 (m, =*C*$_β$), 132.3 (s, *C*$_i$-Ph), 129.4 (s, 2 C, *C*$_i$-C$_5$H$_4$Me), 123.1 (s, C$_6$H$_5$), 122.3 (s, C$_6$H$_5$), 121.9 (s, C$_6$H$_5$), 84.1 (s, 4 C, C$_5$H$_4$Me), 80.4 (s, 4 C, C$_5$H$_4$Me), 31.2 (2 C, PCH$_2$), 23.5 (2 C, PCH$_2$), 21.1 (P[CH$_3$]$_3$), 14.8 (P[CH$_3$]$_3$) ppm. ^{31}P{^{1}H} NMR ([D$_8$]toluene, 121.5 MHz, 20 °C): δ = 96.1 (s, 4 P) ppm. First Complexes of a 4-Alkyl-3,5-di(2-pyridyl)-4*H*-1,2,4-triazole: Synthesis, X-ray Crystal Structures and Magnetic Properties of Dinuclear Cobalt(II), Nickel(II) and Copper(II) Complexes of 4-Isobutyl-3,5-di(2-pyridyl)-4*H*-1,2,4-triazole

Marco H. Klingele,[a] Peter D. W. Boyd,[b] Boujemaa Moubaraki,[c] Keith S. Murray,[c] and Sally Brooker*[a]

Keywords: 1,2,4-Triazole / Bridging ligands / N ligands / Magnetic properties / X-ray diffraction

The reaction of the new, bis(bidentate), potentially dinucleating ligand 4-isobutyl-3,5-di(2-pyridyl)-4*H*-1,2,4-triazole (ibdpt) with $M(ClO_4)_2{\cdot}6H_2O$ (M = Co^{II}, Ni^{II} or Cu^{II}) in a 1:1 molar ratio in MeCN affords the dinuclear complexes $[Co^{II}_2(ibdpt)_2(MeCN)_2(H_2O)_2](ClO_4)_4$ (**1**), $[Ni^{II}_2(ibdpt)_2(MeCN)_4](ClO_4)_4$ (**2**) and $[Cu^{II}_2(ibdpt)_2(MeCN)_2(ClO_4)_2](ClO_4)_2{\cdot}2MeCN$ (**3**). Complex **1** is obtained as a mixture of the red-orange polymorph **1a** and the yellow-orange polymorph **1b**, the main difference between the two forms being the hydrogen bonding patterns between the H_2O co-ligands and the ClO_4^- counterions. The mononuclear complex $[Cu^{II}(ibdpt)_2(ClO_4)_2]$ (**4**) was initially obtained as a minor by-product in the preparation of complex **3** but can also be deliberately prepared from $Cu(ClO_4)_2{\cdot}6H_2O$ and ibdpt in MeCN using a metal-to-ligand molar ratio of 1:2. All five complexes have been structurally characterised by X-ray diffraction. In the dinuclear complexes **1**–**3** the $(N',N^1,N^2,N'')_2$double bridging coordination mode is realised while the mononuclear complex **4** features the common *trans*-$(N',N^1)_2$ coordination mode. In all cases the metal centres reside in distorted octahedral N_4X_2 coordination spheres with axially bound co-ligands (X = H_2O, MeCN or ClO_4^-). The dinuclear complexes **1**–**3** readily lose solvent when taken out of their mother liquors giving rise to partially desolvated materials. Magnetic studies have been carried out on crystalline samples of the resulting complexes that analysed as $Co^{II}_2(ibdpt)_2(ClO_4)_4(MeCN)(H_2O)$ (**5**), $Ni^{II}_2(ibdpt)_2(ClO_4)_4(MeCN)$ (**6**) and $Cu^{II}_2(ibdpt)_2(ClO_4)_4(MeCN)$ (**7**). It was found that in these complexes the two 1,2,4-triazole bridges facilitate antiferromagnetic coupling between the two metal centres (J = –3.76 cm^{-1}, –13.0 cm^{-1} and –105 cm^{-1}, respectively). The coordination compounds described in this paper are the first to incorporate a 4-alkyl-substituted 3,5-di(2-pyridyl)-4*H*-1,2,4-triazole ligand.

Introduction

The strong current interest in the coordination chemistry of 1,2,4-triazole derivatives[1–3] is mainly due to the fact that their ligand strength is in the right region to give complexes with iron(II) salts that show the spin crossover phenomenon.[4–7] Because of their bistability such coordination compounds have potential applications in nano-technology as switches and memory devices, but also as materials for the construction of displays.[8–12] In order for a bistable molecular system to be used in nano-technology it must, however, fulfil certain requirements.[8,9] Most importantly, the transition between the two detectable states should be complete and abrupt with a relatively large thermal hysteresis, centred near room temperature.[13] Such behaviour is associated with cooperative interactions between the metal centres.[14] In mononuclear complexes cooperativity can be conferred by hydrogen bonding, π–π stacking, solvation and the nature of the counterion. These relatively weak interactions pass on the information from one unit to another that the spin transition is occurring. It has been suggested that more pronounced cooperativity could be achieved by the use of ligands capable of bridging metal centres, thus giving rise to oligo- or polynuclear assemblies rather than mononuclear complexes. The employment of mostly 4-substituted 4*H*-1,2,4-triazoles as bridging ligands has allowed the isolation and investigation of various, mainly tri- and polynuclear, spin crossover systems that show promising properties with regard to the requirements outlined above.[4–7] In light of this, we are particularly interested in the synthesis and study of discrete dinuclear iron(II) complexes.[15,16] As a result of these ongoing studies we were recently able to identify the nature of the [low spin–high spin] species of the doubly 1,2,4-triazole-bridged complex $[Fe^{II}_2(PMAT)_2](BF_4)_4{\cdot}DMF$

(PMAT = 4-amino-3,5-bis{[(2-pyridylmethyl)amino]-methyl}-4*H*-1,2,4-triazole) by means of X-ray diffraction[15] and thus to confirm the conclusions drawn by Real, Gütlich and co-workers[17,18] on the basis of magnetic and applied-field Mössbauer data about the pathway of the transition in their two-step spin crossover systems.

Structurally related to the bis(terdentate) ligand PMAT (Figure 1) are the bis(bidentate) 4-substituted 3,5-di(2-pyridyl)-4*H*-1,2,4-triazoles.[2] Within this class of potentially dinucleating ligands only two members, namely 4-amino-3,5-di(2-pyridyl)-4*H*-1,2,4-triazole (NH_2dpt)[19,20] and 3,5-di(2-pyridyl)-4-(1*H*-pyrrol-1-yl)-4*H*-1,2,4-triazole (pldpt)[21–23] (Figure 1), have actually produced dinuclear complexes while no 4-aryl-3,5-di(2-pyridyl)-4*H*-1,2,4-triazoles have ever been reported to do so.[24–29] We therefore hypothesised that the coordination behaviour of these bis(bidentate) ligands, i. e. their ability to bind and bridge two metal centres, is influenced not only by factors such as the reaction stoichiometry and product solubility but also by the electronic effects of the substituent on N^4.[2,22] Given that our goal is the preparation of dinuclear iron(II) complexes, it was desirable to test this hypothesis by investigating the coordination chemistry of the hitherto unknown 4-alkyl-3,5-di(2-pyridyl)-4*H*-1,2,4-triazoles which carry electron-donating substitutents on N^4. We recently succeeded in the synthesis of the first two members of this group, namely 4-methyl-3,5-di(2-pyridyl)-4*H*-1,2,4-triazole (medpt) and 4-isobutyl-3,5-di(2-pyridyl)-4*H*-1,2,4-triazole (ibdpt) (Figure 1).[22,30] In this paper we present the results of our investigation of the dinucleation behaviour of the new ligand ibdpt towards the *d*-block ions cobalt(II), nickel(II) and copper(II).

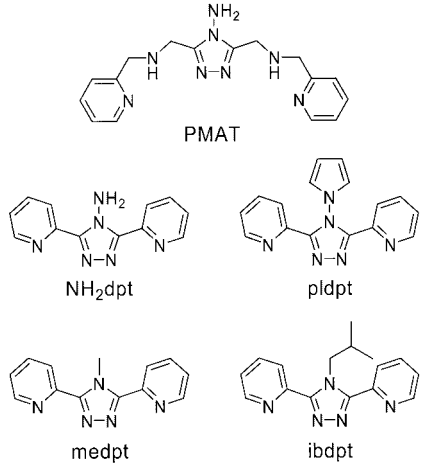

Figure 1. Structural drawings of the ligands 4-amino-3,5-bis{[(2-pyridylmethyl)amino]methyl}-4*H*-1,2,4-triazole (PMAT), 4-amino-3,5-di(2-pyridyl)-4*H*-1,2,4-triazole (NH_2dpt), 3,5-di(2-pyridyl)-4-(1*H*-pyrrol-1-yl)-4*H*-1,2,4-triazole (pldpt), 4-methyl-3,5-di(2-pyridyl)-4*H*-1,2,4-triazole (medpt) and 4-isobutyl-3,5-di(2-pyridyl)-4*H*-1,2,4-triazole (ibdpt).

Results and Discussion

Preparation of the Complexes

The reaction of ibdpt with $M(ClO_4)_2{\cdot}6H_2O$ (M = Co^{II}, Ni^{II} or Cu^{II}) in a 1:1 molar ratio in MeCN produced coloured solutions from which solid products were only obtained upon vapour diffusion of Et_2O. In the case of the cobalt(II) salt this led to the formation of a mixture of red-orange and yellow-orange crystals from the orange reaction mixture in virtually quantitative yield. On the basis of their elemental analyses both crystal types were found to have metal-to-ligand molar ratios of 1:1, not 1:2, and subsequent X-ray diffraction studies showed them to be the two polymorphs **1a** and **1b** of $[Co^{II}_2(ibdpt)_2(MeCN)_2(H_2O)_2](ClO_4)_4$ (**1**). From the purple solution obtained with the nickel(II) salt only one type of purple crystals formed, quantitatively, which were identified by X-ray diffraction as the dinuclear complex $[Ni^{II}_2(ibdpt)_2(MeCN)_4](ClO_4)_4$ (**2**). Using the copper(II) salt instead, blue-green crystals separated from the blue solution which, on prolonged vapour diffusion of Et_2O, were followed by a small amount of steel-blue crystals. Here too, the crystallisation was virtually quantitative. Both crystal types were studied by X-ray diffraction. The blue-green main component was thus identified as the desired dinuclear complex $[Cu^{II}_2(ibdpt)_2(MeCN)_2(ClO_4)_2](ClO_4)_2{\cdot}2MeCN$ (**3**) while the steel-blue minor component was found to be the mononuclear complex $[Cu^{II}(ibdpt)_2(ClO_4)_2]$ (**4**). Complex **4** was readily accessible by the direct reaction of ibdpt with $Cu(ClO_4)_2{\cdot}6H_2O$ in a 2:1 molar ratio in MeCN. Under these conditions it precipitated from the reaction mixture as a blue powder in 48% yield. Vapour diffusion of Et_2O into either the mother liquor or a solution of the powder in MeCN afforded crystals of complex **4** that were identical to those obtained as described above (Table 1).

The dinuclear complexes **1**–**3** readily lost solvent when taken out of their mother liquors. In the case of the yellow-orange polymorph **1b** this was accompanied by a colour change to red-orange while no colour change was observed for the red-orange polymorph **1a**. Subsequent drying of the crystalline samples in vacuo gave rise to partially desolvated materials which were found by elemental analysis to have the compositions $Co^{II}_2(ibdpt)_2(ClO_4)_4(MeCN)(H_2O)$ (**5**) (red-orange), $Ni^{II}_2(ibdpt)_2(ClO_4)_4(MeCN)$ (**6**) (purple) and $Cu^{II}_2(ibdpt)_2(ClO_4)_4(MeCN)$ (**7**) (blue-green). The latter materials were used for further characterisation and magnetic studies.

Description of the Structures

The molecular structures of the red-orange polymorph **1a** (Figure 2) and the yellow-orange polymorph **1b** (Figure S1, Supporting Information) of $[Co^{II}_2(ibdpt)_2(MeCN)_2(H_2O)_2](ClO_4)_4$ (**1**) are very similar, the most obvious difference between them being the orientation of the isobutyl groups of the respective ligand molecule (Figure S2, Supporting Information). The dinuclear $(N',N^1,N^2,N'')_2$ double bridging coordination mode realised in both of these complexes causes distortion of the CoN_5O coordination octahedra and longer Co–N_{pyr} than Co–N_{trz} bond lengths are observed (Table 2 and Table 3). The Co···Co separation in polymorphs **1a** and **1b** are 4.1481(7) and 4.1722(4) Å,

respectively, and thus are somewhat shorter than the corresponding bond length of 4.226(2) Å in $[Co^{II}_2(pldpt)_2(H_2O)_4]Cl_4\cdot 2MeOH\cdot 2H_2O$,[21] the only structurally characterised dinuclear cobalt(II) complex of any 4-substituted 3,5-di(2-pyridyl)-4*H*-1,2,4-triazole previously reported. The torsion angles between the mean planes of the pyridine rings and the central triazole ring in the red-orange polymorph **1a** [8.6(1) and 8.8(1)°] are slightly larger than in the yellow-orange polymorph **1b** [2.3(1) and 8.1(1)°]. In both polymorphs some doming of the ligands is observed. The most significant structural difference between the two polymorphs is found in their hydrogen bonding patterns. In the red-orange polymorph **1a** both ClO_4^- ions form hydrogen bonds to the axial H_2O co-ligand [O(1)···O(11) 2.79 and O(1)···O(21) 2.82 Å] (Figure S3, Supporting Information). In contrast, only one ClO_4^- ion is involved in hydrogen bonding in the yellow-orange polymorph **1b** while the other ClO_4^- ion resides independently within the lattice. A chain of dinuclear units is thus formed with the ClO_4^- ion hydrogen bonding to the H_2O co-ligands of its own and a neighbouring unit in a bridging fashion [O(1)···O(11) 2.76 and O(1)···O(12B) 2.88 Å] (Figure S4, Supporting Information). The shortest bond length between the metal centres of two dinuclear units across this $H_2O\cdots ClO_4^-\cdots H_2O$ link is 8.5770(5) Å while it is only 8.3822(4) Å between the metal centres of two independent chains.

The adoption of the $(N',N^1,N^2,N'')_2$ double bridging coordination mode in $[Ni^{II}_2(ibdpt)_2(MeCN)_4](ClO_4)_4$ (**2**) with MeCN molecules as the axial co-ligands (Figure 3) results in a distorted octahedral N_6 coordination environment about the nickel centres (Table 2 and Table 3). As can be expected for this coordination mode,[2] the Ni–N_{pyr} bond lengths are considerably longer than the Ni–N_{trz} bond lengths [2.139(3)–2.149(3) and 2.023(3)–2.031(3) Å, respectively]. The former are slightly shorter than the corresponding bond lengths observed in $[Ni^{II}_2(NH_2dpt)_2(H_2O)_2Cl_2]Cl_2\cdot 4H_2O$[19] [2.155(1)–2.164(1) Å] while the latter are very similar in both complexes. The Ni···Ni separation in complex **2** is 4.1107(9) Å which is also slightly less than in $[Ni^{II}_2(NH_2dpt)_2(H_2O)_2Cl_2]Cl_2\cdot 4H_2O$ [4.1348(3) Å].[19] The pyridine–triazole–pyridine moiety of the ligand is not completely flat but shows slight doming and torsion angles between the mean planes of the pyridine rings and the central triazole ring of 5.7(2) and 8.7(2)°.

The asymmetric unit of $[Cu^{II}_2(ibdpt)_2(MeCN)_2(ClO_4)_2](ClO_4)_2\cdot 2MeCN$ (**3**) contains two crystallographically independent but structurally very similar complex cations (Table 2 and Table 4), one of which is shown in Figure 4. The Cu···Cu separations in the two cations are 4.0701(10) and 4.0861(9) Å and are thus very similar to one another while they are dramatically shorter than the Cu···Cu separation of 4.415(1) Å found in the only other known dinuclear

above, the pyridine–triazole–pyridine moieties of the ligands are not planar but show some doming and the torsion angles between the mean planes of the pyridine rings and the central triazole rings vary over the range 6.9(2)–9.0(2)°.

The overall architecture of $[Cu^{II}(ibdpt)_2(ClO_4)_2]$ (**4**) (Figure 5) is practically identical to that of $[Cu^{II}(pyppt)_2(ClO_4)_2] \cdot MeCN$ [pyppt = 3-phenyl-5-(2-pyridyl)-4-(4-pyridyl)-4*H*-1,2,4-triazole].[31] As a result of the realisation of the *trans*-$(N',N^1)_2$ coordination mode longer $Cu–N_{pyr}$ bond lengths [2.038(3) Å] than $Cu–N_{trz}$ bond lengths [1.962(3) Å] are observed in complex **4** (Table 2 and Table 4). The respective values are in good agreement with the corresponding bond lengths observed in $[Cu^{II}(pyppt)_2(ClO_4)_2] \cdot MeCN$ [2.045(2) and 1.989(2) Å, respectively]. This is also true for the Cu–O bond length which is 2.471(2) Å in complex **4** and 2.466(3) Å in $[Cu^{II}(pyppt)_2(ClO_4)_2] \cdot MeCN$.[31] The nitrogen atom of the non-coordinated pyridine ring points outwards towards the isobutyl group and the pyridine–triazole–pyridine moiety is almost perfectly planar, with the angles between the mean planes of the coordinated and the non-coordinated pyridine rings relative to the triazole mean plane being very small and identical within experimental error [2.0(2) and 1.9(2)°, respectively].

Magnetic Studies

The curves for the temperature dependence of the molar magnetic susceptibility and the effective magnetic moment for the dinuclear cobalt(II) complex **5** are shown in Figure S5 (Supporting Information). The maximum in susceptibility observed at 18 K (χ_m = 0.05383 $cm^3 mol^{-1}$) is due

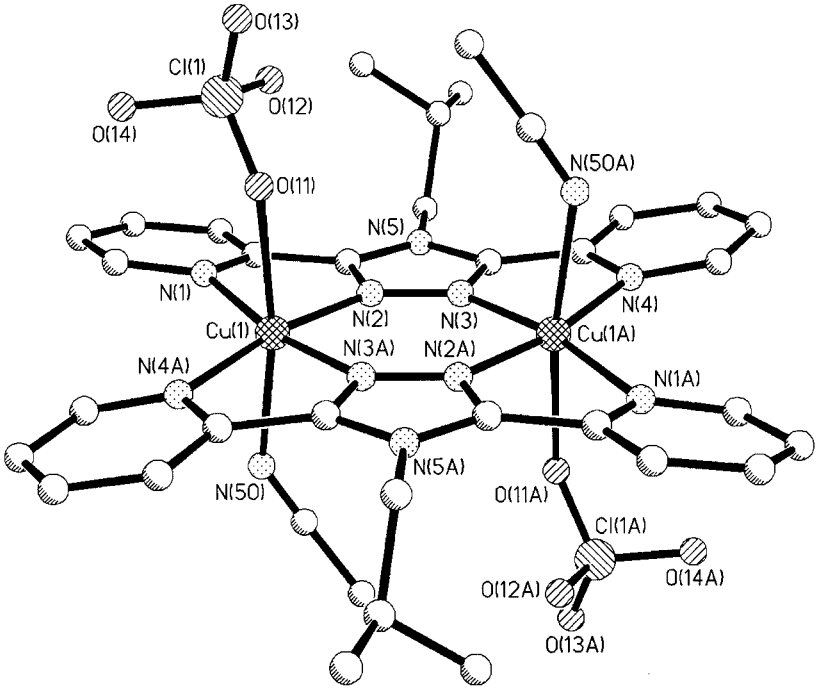

Figure 4. View of the molecular structure of one of the two crystallographically independent cations of $[Cu^{II}_2(ibdpt)_2(MeCN)_2(ClO_4)_2](ClO_4)_2 \cdot 2MeCN$ (**3**). Hydrogen atoms have been omitted for clarity. Symmetry operation used to generate equivalent atoms: (A) $-x + 1, -y, -z + 2$.

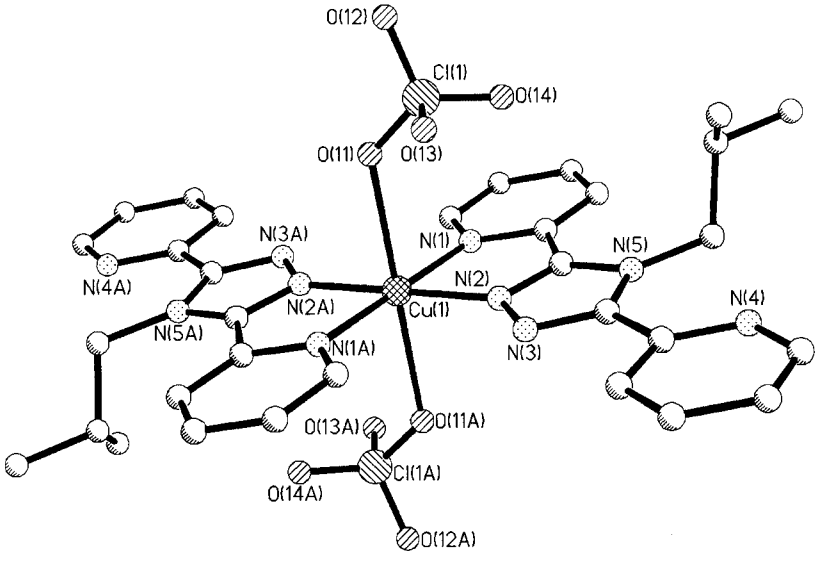

Figure 5. View of the molecular structure of $[Cu^{II}(ibdpt)_2(ClO_4)_2]$ (**4**). Hydrogen atoms have been omitted for clarity. Symmetry operation used to generate equivalent atoms: (A) $-x + 2, -y, -z + 2$.

to antiferromagnetic coupling across the two 1,2,4-triazole bridges. The corresponding magnetic moment data show a μ_{eff} value of 4.64 μ_B at room temperature which is a little reduced from typical weak-field octahedral cobalt(II) centres having $^4T_{1g}$ (d^7) ground states. Low symmetry ligand field effects, combined with spin-orbit coupling, cause splitting of these single-ion states and thus allow for the use of the Heisenberg–Van Vleck exchange Hamiltonian ($-2J\mathbf{S_1 \cdot S_2}$) for an $S = 3/2$ dimer as a reasonable approximation for fitting the data. A good fit was obtained using the parameters $J = -3.76$ cm^{-1}, $g = 2.45$, $TIP = 0$ cm^3 mol^{-1} and 0.2% monomer (in this and in all other cases all parameters were allowed to vary for the best fit except for *TIP* which was fixed). The high g value accounts for spin-orbit and orbital degeneracy effects. The value of J is similar to that obtained for related compounds incorporating NH_2dpt[19] and is somewhat less than observed for pyridazine-bridged systems.[32,33]

The dinuclear nickel(II) complex **6** also exhibits antiferromagnetic coupling. The fitted curve for the molar magnetic

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

susceptibility reaches a maximum at 38 K (χ_m = 0.01142 $cm^3 mol^{-1}$) and the corresponding effective magnetic moment decreases from 2.81 μ_B at room temperature to 0.17 μ_B at 4.2 K (Figure S6, Supporting Information). The data were fitted extremely well to an $S = 1$ dimer–$2J\mathbf{S_1}\cdot\mathbf{S_2}$ model using $J = -13.0\ cm^{-1}$, $g = 2.08$, $TIP = 85\times10^{-6}\ cm^3 mol^{-1}$ and 0.3% monomer. The coupling is slightly stronger than that found in related doubly 1,2,4-triazole-bridged complexes incorporating NH_2dpt[19] but weaker than in doubly pyridazine-bridged derivatives ($J \approx -21\ cm^{-1}$).[33]

The analogous dinuclear copper(II) complex **7** shows quite strong antiferromagnetic coupling. Thus, the maximum in molar magnetic susceptibility is observed at 185 K (χ_m = 0.00093 $cm^3 mol^{-1}$) and the corresponding effective magnetic moment decreases from 1.39 μ_B at room temperature to 0.22 μ_B at 4.2 K (Figure 6). Monomer impurity is clearly evident in the susceptibility plot below ca. 50 K. Fitting to the Bleaney–Bowers $S = 1/2$ dimer model[34] yielded $J = -105\ cm^{-1}$, $g = 1.87$, $TIP = 60\times10^{-6}\ cm^3 mol^{-1}$ and 1.5% monomer. The g value is lower than expected for a tetragonally elongated copper(II) site which is probably due to the loss of the remaining MeCN solvate affecting the molar mass used in the calculation of the molar magnetic susceptibilities. The strong antiferromagnetic coupling is compatible with the triazole p orbitals of the two 1,2,4-triazole nitrogen donors coupling effectively with the $d(x^2–y^2)$ magnetic orbitals of the copper(II) centres within the planar six-membered $(Cu–N_{trz}–N_{trz})_2$ ring. Other doubly 1,2,4-triazole-bridged compounds with symmetrical bis(bidentate) ligands[35–37] have similar values of J while weaker coupling is found in systems incorporating the unsymmetrical anionic 3-(2-pyridyl)-1,2,4-triazolato ligand ($J \approx -50\ cm^{-1}$).[38,39] Interestingly, in $[Cu^{II}_2(NH_2dpt)(H_2O)_2(SO_4)_2]\cdot H_2O$,[20] containing a single 1,2,4-triazole bridge and an additional bridging sulfato co-ligand between the two copper(II) centres, the J value was found to be $-34.5\ cm^{-1}$, i. e. about one third of the value obtained here for the doubly 1,2,4-triazole-bridged system. Clearly, the poor superexchange pathway provided by a bidentate sulfate ion in combination with only one 1,2,4-triazole pathway leads to the diminution in J. The Cu···Cu separation in the present complex is significantly shorter than in the singly 1,2,4-triazole-bridged complex $[Cu^{II}_2(NH_2dpt)(H_2O)_2(SO_4)_2]\cdot H_2O$.[20] The $Cu–N_{trz}–N_{trz}$ angles of ca. 133–134° in the present complex are somewhat smaller than the corresponding angles of ca. 136–138° found in the unsymmetrical singly 1,2,4-triazole-bridged example. Haasnoot and coworkers[39] have concluded that $Cu–N_{trz}–N_{trz}$ angles of ca. 134° in symmetrical doubly 1,2,4-triazole-bridged systems lead to the largest possible coupling with $J \approx -120\ cm^{-1}$. The J value of $-105\ cm^{-1}$ observed here is only a little smaller than the predicted value.

Conclusions

The new ligand ibdpt was used to investigate the coordination chemistry of a 4-alkyl-substituted 3,5-di(2-pyridyl)-4*H*-1,2,4-triazole for the first time. We initially focused on the exploration of the dinucleation behaviour of this ligand. It has been found that, unlike with 4-aryl-substituted 3,5-di(2-pyridyl)-4*H*-1,2,4-triazoles, dinuclear complexes can be readily obtained. This result clearly supports our hypothesis that whether or not dinuclear complexes of bis(bidentate) 4-substituted 3,5-di(2-pyridyl)-4*H*-1,2,4-triazoles can be formed is strongly influenced by the nature of the actual substituent on N^4, including its electronic effect on the 1,2,4-triazole ring. In the resulting dinuclear doubly 1,2,4-triazole-bridged complexes the two metal centres have been found to be antiferromagnetically coupled. In light of these findings the synthesis of exchange-coupled dinuclear iron(II) spin crossover compounds of ibdpt and other 4-alkyl-3,5-di(2-pyridyl)-4*H*-1,2,4-triazoles[30] appears possible. Studies in this direction are currently underway and will be reported in due course.[16]

Experimental Section

General Remarks: All solvents used were laboratory reagent grade. $Co(ClO_4)_2\cdot 6H_2O$, $Ni(ClO_4)_2\cdot 6H_2O$ and $Cu(ClO_4)_2\cdot 6H_2O$ were purchased from Aldrich and used as received. 4-Isobutyl-3,5-di(2-pyridyl)-4*H*-1,2,4-triazole (ibdpt) was prepared as described elsewhere.[22,30] Elemental analyses were carried out by the Campbell Microanalytical Laboratory at the University of Otago. Infrared spectra were recorded over the range 4000–400 cm^{-1} with a Perkin–Elmer Spectrum BX FT-IR spectrophotometer. ESI mass spectra were run with a MicroMass LCT mass spectrometer at the University of Canterbury. X-ray data were collected with a Bruker SMART CCD area detector using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The structures were solved by direct methods with SIR-92[40] and refined against F^2 using all data by full-matrix least-squares techniques with SHELXL-97.[41] Magnetic data were recorded over the range 300–4.2 K with a Quantum Design MPMS5 SQUID magnetometer with an applied field of 1 T.

Caution: While no problems were encountered in the course of this work, ClO_4^- salts are potentially explosive and should be handled with appropriate care!

$[Co^{II}_2(ibdpt)_2(MeCN)_2(H_2O)_2](ClO_4)_4$ (1) and $Co^{II}_2(ibdpt)_2(ClO_4)_4(MeCN)(H_2O)$ (5): An orange solution of $Co(ClO_4)_2\cdot 6H_2O$ (366 mg, 1.00 mmol) in MeCN (5 mL) was added to a colourless solution of ibdpt (279 mg, 1.00 mmol) in MeCN (35 mL). The resulting orange solution was stirred at room temperature for 2 hours before it was subjected to vapour diffusion of Et_2O. This afforded crystalline $[Co^{II}_2(ibdpt)_2(MeCN)_2(H_2O)_2](ClO_4)_4$ (**1**) as a mixture of the red-orange polymorph **1a** and the yellow-orange polymorph **1b** which were both identified by X-ray diffraction. The ratio of the two crystal types was variable and they both readily lost solvent when taken out of their mother liquor which in the case of the yellow-orange polymorph **1b** was accompanied by a colour change to red-orange while no colour change was observed for the red-orange polymorph **1a**. A bulk sample of complex **1** was dried in vacuo to give 541 mg (95%) of $Co^{II}_2(ibdpt)_2(ClO_4)_4(MeCN)(H_2O)$ (**5**) as dull red-orange crystals. This material was used for further characterisation and magnetic studies. $C_{34}H_{39}Cl_4Co_2N_{11}O_{17}$ (1133.43): calcd. C 36.03, H 3.47, N 13.59; found C 35.81, H 3.56, N 13.66. IR (KBr): $\tilde{\nu}$ = 3374, 2966, 1607, 1579, 1511, 1498, 1467, 1436, 1394, 1299, 1280, 1248, 1145, 1117, 1083, 1027, 1002, 940, 928, 793, 760, 744, 709, 688, 668, 636, 626, 515, 417 cm^{-1}. ESI-MS (pos., MeCN): *m*/*z* = 308.1 $[Ni(ibdpt)_2]^{2+}$, 328.7 $[Ni(ibdpt)_2(MeCN)]^{2+}$, 447.7 $[Ni(ibdpt)_3]^{2+}$, 477.1 $[Ni(ibdpt)(MeCN)(ClO_4)]^+$, 715.2 $[Ni(ibdpt)_2(ClO_4)]^+$, 975.0 $[Ni_2(ibdpt)_2(ClO_4)_3]^+$, 994.4 $[Ni(ibdpt)_3(ClO_4)]^+$, 1252.2 $[Ni_2(ibdpt)_3(ClO_4)_3]^+$, 1533.5 $[Ni_2(ibdpt)_4(ClO_4)_3]^+$.

$[Cu^{II}_2(ibdpt)_2(MeCN)_2(ClO_4)_2](ClO_4)_2{\cdot}2MeCN$ (3) and $Cu^{II}_2(ibdpt)_2(ClO_4)_4(MeCN)$ (7): A blue solution of $Cu(ClO_4)_2{\cdot}6H_2O$ (371 mg, 1.00 mmol) in MeCN (5 mL) was added to a colourless solution of ibdpt (279 mg, 1.00 mmol) in MeCN (35 mL). The resulting blue solution was stirred at room temperature for 2 hours before it was subjected to vapour diffusion of Et_2O. This afforded $[Cu^{II}_2(ibdpt)_2(MeCN)_2(ClO_4)_2](ClO_4)_2{\cdot}2MeCN$ (**3**) as blue-green crystals along with a small amount of $[Cu^{II}(ibdpt)_2(ClO_4)_2]$ (**4**) as steel-blue crystals which were both identified by X-ray diffraction. The crystals of complex **3** readily lost solvent when taken out of their mother liquor. A bulk sample of complex **3** was dried in vacuo to give 485 mg (86%) of $Cu^{II}_2(ibdpt)_2(ClO_4)_4(MeCN)$ (**7**) as dull blue-green crystals. This material was used for further characterisation and magnetic studies. $C_{34}H_{37}Cl_4Cu_2N_{11}O_{16}$ (1124.64): calcd. C 36.31, H 3.32, N 13.70; found C 36.53, H 3.24, N 13.73. IR (KBr): $\tilde{\nu}$ = 3454, 2967, 1614, 1586, 1514, 1472, 1442, 1398, 1378, 1280, 1254, 1144, 1119, 1087, 1014, 929, 793, 763, 746, 710, 688, 667, 624, 507, 417 cm^{-1}. ESI-MS (pos., MeCN): *m*/*z* = 310.6 $[Cu(ibdpt)_2]^{2+}$, 331.1 $[Cu(ibdpt)_2(MeCN)]^{2+}$, 450.2 $[Cu(ibdpt)_3]^{2+}$, 482.1 $[Cu(ibdpt)(MeCN)(ClO_4)]^+$, 720.2 $[Cu(ibdpt)_2(ClO_4)]^+$, 983.0 $[Cu_2\text{-}(ibdpt)_2(ClO_4)_3]^+$, 1262.2 $[Cu_2(ibdpt)_3(ClO_4)_3]^+$, 1541.3 $[Cu_2\text{-}(ibdpt)_4(ClO_4)_3]^+$.

$[Cu^{II}(ibdpt)_2(ClO_4)_2]$ (4): A blue solution of $Cu(ClO_4)_2{\cdot}6H_2O$ (185 mg, 0.50 mmol) in MeCN (5 mL) was added to a colourless solution of ibdpt (279 mg, 1.00 mmol) in MeCN (5 mL). The resulting blue solution was stirred at room temperature for 24 hours during which time a precipitate formed. The solid was filtered off and washed with small amount of MeCN. Drying in vacuo gave 198 mg (48%) of $[Cu^{II}(ibdpt)_2(ClO_4)_2]$ (**4**) as a pale blue powder. $C_{32}H_{34}Cl_2CuN_{10}O_8$ (821.14): calcd. C 46.81, H 4.17, N 17.06; found C 46.64, H 4.10, N 16.98. IR (KBr): $\tilde{\nu}$ = 3447, 2971, 1612, 1584, 1497, 1460, 1428, 1395, 1310, 1280, 1247, 1171, 1131, 1054, 1021, 926, 796, 762, 751, 739, 712, 693, 668, 649, 623, 592 cm^{-1}. ESI-MS (pos., MeCN): *m*/*z* = 310.6 $[Cu(ibdpt)_2]^{2+}$, 383.1 $[Cu(ibdpt)(MeCN)]^+$, 621.2. $[Cu(ibdpt)_2]^+$, 785.1 $[Cu_2(ibdpt)_2(ClO_4)]^+$, 900.5 $[Cu(ibdpt)_3]^+$, 1064.3 $[Cu_2(ibdpt)_3(ClO_4)]^+$. Vapour diffusion of Et_2O into the mother liquor or a solution of the powder in MeCN gave steel-blue crystals of $[Cu^{II}(ibdpt)_2(ClO_4)_2]$ (**4**) which were identified by X-ray diffraction.

X-ray Crystallography: All non-hydrogen atoms, except N(90) to C(91) of the disordered MeCN solvate in complex **3**, were refined anistropically. All hydrogen atoms, except H(101) and H(102) of the axial H_2O co-ligands in complexes **1a** and **1b**, were placed at calculated positions using a riding model with thermal parameters 1.2 times the equivalent isotropic thermal parameters of the atom to which they were bonded. The hydrogen atoms of the H_2O co-ligands in complexes **1a** and **1b** were located from the difference maps and allowed to refine freely. In the structure of complex **2** one of the two methyl groups of the isobutyl moiety was disordered

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

over two positions with site occupancy factors of 0.75 and 0.25 for C(17) and C(17′), respectively. One of the ClO_4^- ions was also disordered over two positions with a site occupancy factor of 0.50 for both Cl(2) to O(24) and Cl(3) to O(34). The structure of complex **3** featured two crystallographically independent moieties within the asymmetric unit. In one of the ClO_4^- ions three of the oxygen atoms were disordered over two positions with a site occupancy factor of 0.50 for both O(42) to O(44) and O(42′) to O(44′). One of the MeCN solvates was also disordered over two positions with site occupancy factors of 0.75 for N(80) to C(81) and 0.25 for N(90) to C(91). CCDC-250036 (**1a**), -250037 (**1b**), -250038 (**2**), -250039 (**3**) and -250040 (**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Supporting Information (see also the footnote on the first page of this article): A PDF file (five pages) with Supporting Information for this article is available on the internet under http://www.eurjic.org or from the authors. The file contains a view of the molecular structure of complex **1b** (Figure S1), an overlay of the molecular structures of complexes **1a** and **1b** (Figure S2), illustrations of the hydrogen bonding in complexes **1a** and **1b** (Figures S3 and S4, respectively) and the curves for the molar magnetic susceptibilities and effective magnetic moments of complexes **5** and **6** over the range 300–4.2 K (Figures S5 and S6, respectively).

Acknowledgments

This work was supported by a number of grants from the University of Otago (including a University of Otago Postgraduate Scholarship to MHK and a Bridging Grant) and the Australian Research Council (Discovery Grant). Mr. B. M. Clark (University of Canterbury) is thanked for running the ESI mass spectra and Dr. J. Hausmann (University of Otago) for helpful discussions. SB is grateful for the provision of sabbatical leave which has facilitated the completion of this manuscript and thanks her host Prof. A. K. Powell (University of Karlsruhe) for helpful discussions and the DFG Research Center for Functional Nanostructures (CFN) for the award of a Visiting Professorship.

Keywords: Iron / Rhenium / Molybdenum octahedral clusters / M_6L_{14} units / Hybrid compounds / Inorganic organometallic chemistry / Single-crystal structures

Novel hybrid inorganic/organometallic compounds have been obtained from the crystallization of inorganic anionic clusters units with the [Cp*(dppe)Fe–NCMe]$^+$organometallic entity as the cationic counter part. After dissolution of $Cs_2M_6L_{14}$ (M_6L_{14} = $[Re_6S_6Br_8]^{2-}$, $[Mo_6Br_{14}]^{2-}$ and $[Mo_6I_{14}]^{2-}$) and [Cp*(dppe)Fe–NCMe]Cl precursors in acetonitrile at room temperature, the reaction proceeds by a metathesis of the Cl^- anion by $[M_6L_{14}]^{2-}$ anions and precipitation of CsCl. The crystal structures of the [Cp*(dppe)Fe–NCMe]$_2$[M_6L_{14}] series reveal that inorganic and organic entities can be assembled without any structural modifications to both partners whatever the M_6L_{14} unit. These properties of the M_6L_{14} cluster units could be extended for the crystallization of other novel organometallic cations when usual small counter anions do not lead to any crystallization with the new organometallic cation

Introduction

A wide variety of compounds based on M_6 clusters (M = Re, Mo) have been obtained by solid-state synthesis and extensively investigated.[1–5] Such compounds are built up from M_6L_{14} units (L = halogen, chalcogen) in which the M_6 cluster is face-capped by eight inner ligands (L^i) and six apical ligands (L^a) lie in terminal positions. The developed formula of the unit is then written as $M_6L^i{}_8L^a{}_6$ according to the H. Schäfer notation.[6] The condensation of units by means of apical-inner connections leads to solid-state compounds containing octahedral clusters with various physico-chemical properties such as superconductivity at high critical field,[7] catalytic[8] or redox intercalation behavior.[9] On the other hand, fascinating molecular and supramolecular assemblies based on axially substituted $M_6L^i{}_8$ cluster cores have been reported, particularly in rhenium cluster chemistry.[10] Their synthesis requires soluble cluster precursors with isolated $Re_6L^i{}_8L^a{}_6$ units. Numerous water-soluble cesium salts built up from isolated Re_6L_{14} units have been obtained from solid-state chemistry.[11] After dissolution in distilled water or acidic solutions, the $(TBA)_xRe_6L^i{}_8L^a{}_6$ series can be easily obtained by precipitation after addition of an excess of a TBA halide. The $(TBA)_xRe_6L^i{}_8L^a{}_6$ series, soluble in organic solvents, constitutes a set of relevant precursors for use in coordination chemistry.[1]

In this paper, we report the room-temperature synthesis and characterization of novel hybrid inorganic/organometallic compounds based on $[M_6L_{14}]^{2-}$ anionic units obtained by direct dissolution of $Cs_2M_6L_{14}$ in organic solvents ($[M_6L_{14}]^{2-}$ = $[Re_6S_6Br_8]^{2-}$, $[Mo_6Br_{14}]^{2-}$ and $[Mo_6I_{14}]^{2-}$). It will become evident that $[M_6L_{14}]^{2-}$ anionic units can be used to advantage in organometallic chemistry for the isolataton and characterization of new organometallic cations. Thus, the crystallization of large organometallic cations with small anions usually used in organometallic chemistry (for instance PF_6^-, BF_4^- or BPh_4^-), often affords single crystals with high mosaic spreads and low diffracting powers. Indeed, the quality of the single-crystal X-ray diffraction

data often thwarts a structural solution or gives low reliability factors. The latter condition is the key point for obtaining accurate structural information on bond lengths and angles. In this work, we focused on the crystallization of the $[Cp^*(dppe)Fe–NCMe]^+$ organometallic cation with $[M_6L_{14}]^{2-}$ units ($[Re_6S_6Br_8]^{2-}$, $[Mo_6Br_{14}]^{2-}$ and $[Mo_6I_{14}]^{2-}$). The structures of the resultant $[Cp^*(dppe)Fe–NCMe]_2[M_6L_{14}]$ complexes, determined from single-crystal X-ray diffraction data, indicatee that inorganic and organic entities can be assembled without any structural modifications to both partners whatever the M_6L_{14} unit.

Single-Crystal X-ray Diffraction Analyses

Data Collection

Experimental details for $[Cp^*(dppe)FeNCCH_3]_2[Re_6(S_6Br_2)^iBr_6^a]$ (**1**), $[Cp^*(dppe)FeNCCH_3]_2[Mo_6Br_8{}^iBr_6^a]$ (**2**) and $[Cp^*(dppe)FeNCCH_3]_2[Mo_6I_8{}^iI_6^a]$ (**3**) are given in Table 1. Once the data processing had been performed by the KappaCCD analysis softwares,[12] the lattice constants were refined by least-squares refinements using 33851 reflections ($1.00° < \theta < 27.48°$), 10475 reflections ($2.55° < \theta < 27.48°$) and 14097 reflections ($2.72° < \theta < 30.03°$) for **1**, **2** and **3**, respectively. In each case, an absorption correction based on crystal shape was applied to the data sets with the ANALYTICAL program.[13]

Structure Solution and Refinement

The three compounds are isostructural and crystallize in the monoclinic system. According to the observed systematic extinctions, the structures were solved in the $P2_1/c$ space group (No. 14). The unit-cell parameters, crystal system, space group and refinement details are summarized in Table 1 for the three phases. The structures were solved by direct methods (SIR97 program[14]) combined with Fourier difference syntheses and refined against F using reflections with $I/\sigma(I) > 3$ (CRYSTALS program[15]).

In the case of the $[Cp^*(dppe)Fe–NCMe]_2[Re_6S_6Br_8]$ structure refinement, all ligand sites were at first considered as being occupied by bromine atoms. After several cycles of refinement, it turned out that only the inner sites were not fully occupied by bromine atoms. Sulfur atoms were then introduced to these inner sites with the same positions and the same atomic displacement parameters as those of the bromine atoms and for each crystallographic site the sum of the occupancies was restrained to the value corresponding to a fully occupied position. Afterwards, the two first constraints (on positional and atomic displacement parameters) were progressively relaxed during the convergence, leading to a final position in agreement with reliable Re–

Table 1. Crystallographic data[a] for $[Cp^*(dppe)Fe–NCCH_3]_2[Re_6S_6Br_8]$ (**1**), $[Cp^*(dppe)Fe–NCCH_3]_2[Mo_6Br_{14}]$ (**2**) and $[Cp^*(dppe)Fe–NCCH_3]_2[Mo_6I_{14}]$ (**3**).

Br and Re–S interatomic distances. Therefore, the chemical formula deduced from the X-ray diffraction refinement, $[Cp^*(dppe)Fe–NCMe]_2[(Re_6S^i_{5.9(1)}S^i_{2.1(1)})Br^a_6]$, is in good agreement with the EDS analyses.

All atoms of the cationic unit are located in 4*e* general crystallographic Wyckoff positions and were successfully refined anisotropically for the three structures (Figure 1). The refined formulae for **1**, **2** and **3** are given in Table 1. Atomic positions, equivalent thermal factors and occupancy factors are given in Table 2, Table 4 and Table 6. Meaningful bond lengths are summarized in Table 3, Table 5 and Table 7. All the thermal atomic displacements were refined anisotropically.

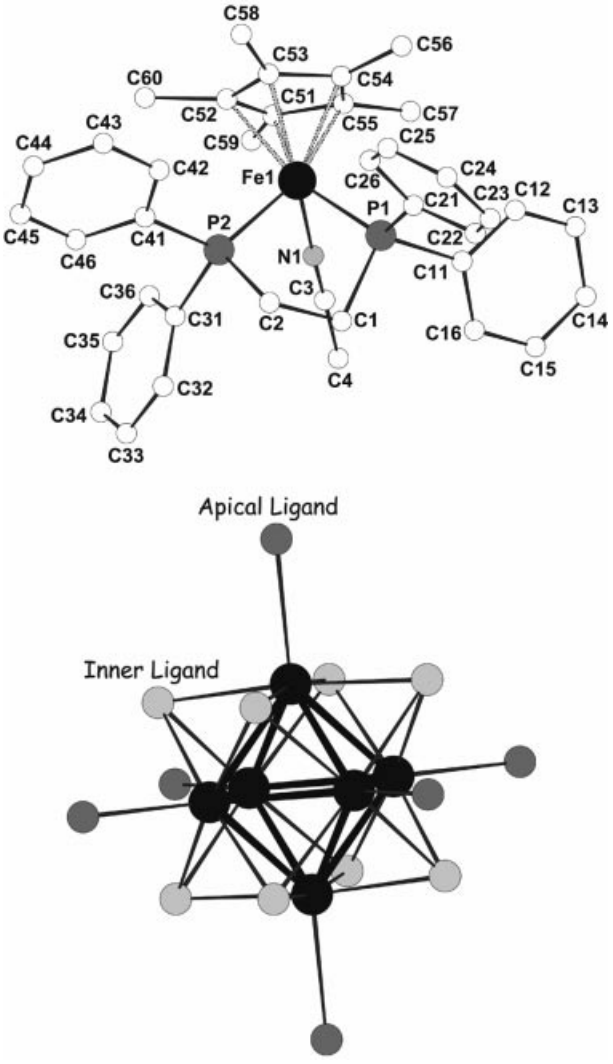

Figure 1. (a) Representation of the $[Cp^*(dppe)Fe–NCCH_3]^+$ cationic complex. The same labelling is used for the three structures. (b) Description of the $[Me_6L_{14}]$ (Me = Re, Mo; L = S, Br, I) anionic cluster entity.

Results

Structure of $[Cp^*(dppe)Fe–NCMe]_2[Re_6S_6Br_8]$

The structure of $[Cp^*(dppe)Fe–NCMe]_2[Re_6S_6Br_8]$ is based on a discrete $[Re_6S^i_6Br^i_2Br^a_6]^{2-}$ centrosymmetric cluster anion with an $(Re_6S^i_6Br^i_2)^{4+}$ cluster core. The Re_6 octahedron is slightly distorted and is inscribed into a cube of eight μ_3-S/Br atoms (inner ligands). Among the four independent inner ligand sites, all are randomly occupied by sulfur and bromine atoms [L^i1 = 0.39(1) S + 0.61(1) Br; L^i2 = 0.807(9) S + 0.193(9) Br; L^i3 = 0.903(8) S + 0.097(8) Br; L^i4 = 0.843(7) S + 0.157(7) Br]. The six apical positions are fully occupied by bromine atoms. The bond length ranges within the cluster unit are 2.5889(5)–2.6157(5) Å for Re–Re; 2.533(1)–2.5386(9) Å for Re–Br^a; 2.49(2)–2.66(5) Å for Re–Br^i and 2.403(7)–2.53(2) Å for Re–S^i (Table 3). These bond lengths correspond, within the s.u.'s, to those observed in the starting $Cs_2Re_6S_8Br_8$ cluster precursor. Indeed the substitution of $[Cp^*(dppe)Fe–NCMe]^+$ for Cs^+ does not influence the Re–Br^a bond length which is the most sensitive to a change in the counter cation in solid-state compounds.[16]

The bond lengths within the $[Cp^*(dppe)Fe–NCMe]^+$ cation in $[Cp^*(dppe)Fe–NCMe]_2[Re_6S_6Br_8]$ corresponds to those found in $[Cp^*(dppe)Fe–NCMe][PF_6]$.[17] The Fe^{II} atom is located in an environment built from a pentamethylcyclopentadienyl (Cp^*: $C_{10}H_{15}$), a P–$(CH_2)_2$–P bridge connected to four phenyl groups (dppe) and a molecule of acetonitrile (NCMe).

The Fe–C interatomic distances [2.097(9)–2.14(1) Å] and C–C bond lengths [1.41(2)–1.44(1) Å and 1.48(2)–1.55 (2) Å for C_5 ring and $C_5(CH_3)_5$, respectively] inside the Cp^* ligand are in good agreement with those generally observed for this kind of aromatic ring (average Fe–C distance equal to 2.11 Å, for example).[18–20]

Other selected interatomic distances are Fe–P [2.228(3)–2.258(3) Å], Fe–$NCCH_3$ [1.909(8) Å], P–C [1.833(9)–1.860(9) Å] and C–C [1.53(1) Å for the bridge, 1.34(2)–1.43(2) Å for aromatic rings inside the –P–$(CH_2)_2$–P– bridge], N–CCH_3 [1.15(1) Å] and NC–CH_3 [1.46(2) Å].

Structure of $[Cp^*(dppe)Fe–NCMe]_2[Mo_6Br_{14}]$

The anionic unit of the $[Cp^*(dppe)Fe–NCMe]_2[Mo_6Br_{14}]$ structure contains a slightly distorted Mo_6 octahedron. All the inner and apical positions of the cluster are occupied by bromine atoms. The chemical formula deduced from the X-ray diffraction refinement is $[Cp^*(dppe)Fe–NCMe]_2$-$[Mo_6Br_{14}]$ which fully corroborates with the EDS analysis. The ranges for the bond lengths within the cluster unit are 2.6358(6)–2.6437(6) Å for Mo–Mo, 2.5921(7)–2.6000(6) Å for Mo–Br^a and 2.5960(6)–2.6103(6) Å for Mo–Br^i (Table 5). Such values are comparable with data previously reported for the starting compound $Cs_2Mo_6Br_{14}$[23] (see Table 8). Indeed, the $[Cp^*(dppe)Fe–NCMe]^+$ cation does not influence the intra-unit bond lengths. The interatomic distances observed within the organometallic partner are very close to those observed in **1**.

Structure of $[Cp^*(dppe)Fe–NCMe]_2[Mo_6I_{14}]$

The structure of $[Cp^*(dppe)Fe–NCMe]_2[Mo_6I_{14}]$ is built from a slightly distorted Mo_6 octahedral cluster surrounded

[a] For inner ligands, these atoms correspond to a split position.

by eight inner iodine ligands and six apical iodine ligands. As expected, owing to the larger ionic radius of iodine face-capping ligands compared with bromine, the Mo–Mo bonds are longer in $[Cp^*(dppe)Fe–NCMe]_2[Mo_6I_{14}]$ than in $[Cp^*(dppe)Fe–NCMe]_2[Mo_6Br_{14}]$. The chemical formula deduced from the X-ray diffraction refinement is $[Cp^*(dppe)Fe–NCMe]_2[Mo_6I_{14}]$ which is fully consistent with the EDS analysis. The bond length ranges within the

anionic unit are 2.6745(5)–2.6878(6) Å for Mo–Mo, 2.8408(5)–2.8467(5) Å for $Mo–I^a$ and 2.7665(5)–2.7889(5) Å for $Mo–I^i$ (Table 7). These distances are in good agreement with those found in the starting compound $Cs_2Mo_6I_{14}$[23] (see Table 8). The interatomic distances within the organometallic cation are identical to the values observed in **1** and **2**.

General Description of the Three Structures

The structures of the three original compounds are based on discrete $[M_6L_{14}]^{2-}$ anions (M = Mo, Re; L = Br, I, S) located at the corners and the centre of two opposite faces of the unit-cell (Figure 2), thus forming a pseudo-*A*-centered monoclinic unit-cell. Owing to the symmetry of the cationic $[Cp^*(dppe)Fe–NCMe]^+$ group, the space group is $P2_1/n$ and the systematic extinctions corresponding to the *A* lattice are not observed. The structural cohesion results from coulombic interactions between anionic inorganic units and cationic entities based on organo–iron molecules.

The structures of the compounds in the $[Cp^*(dppe)Fe–NCMe]_2{\cdot}M_6L_{14}$ series can be described in each case as a succession of $[M_6L_{14}]^{2-}$ anionic units layers and cationic layers. The layers of anionic entities are planar whilst the layers of $[Cp^*(dppe)Fe–NCMe]^+$ cations are puckered along the *a* axis of the unit-cell (Figure 3). The shortest Fe–Fe distances between two consecutive cationic planes are equal to 11.01, 10.98 and 11.12 Å for $[Cp^*(dppe)Fe–NCMe]_2[Re_6S_6Br_8]$, $[Cp^*(dppe)Fe–NCMe]_2[Mo_6Br_{14}]$ and $[Cp^*(dppe)Fe–NCMe]_2[Mo_6I_{14}]$, respectively. The shortest Fe–Fe distances within the puckered plane of cations are 9.44, 9.83 and 9.74 Å for these three compounds, respectively. For comparison, the Fe–Fe distance in $[Cp^*(dppe)Fe–NCMe][PF_6]$ is 9.099 Å.

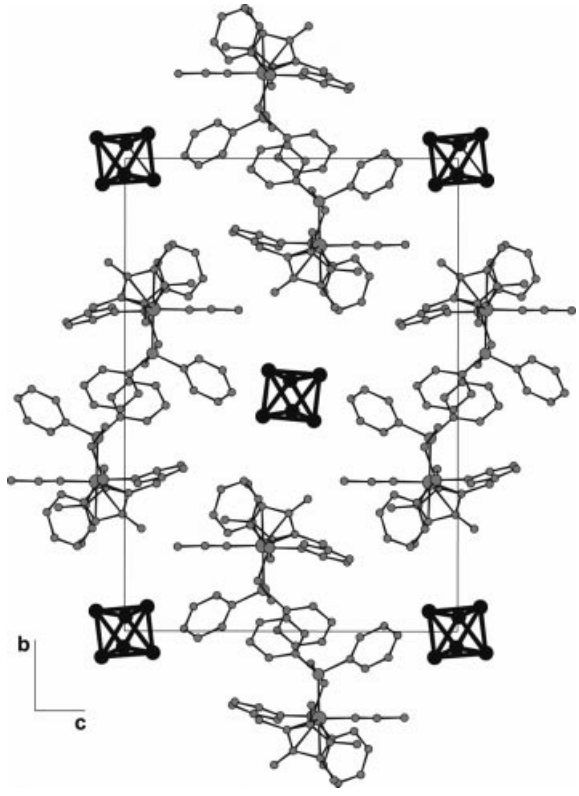

Figure 2. $[Cp^*(dppe)Fe–NCCH_3]_2[Me_6L_{14}]$ (Me = Re, Mo; L = S, Br, I) structure projection in the (*b*,*c*) plane of the unit-cell. For clarity, cluster ligands have been removed.

Discussion and Conclusion

The crystal structures of the $[Cp^*(dppe)Fe–NCMe]_2 \cdot M_6L_{14}$ series reveal that inorganic and organic entities can be assembled without any structural modifications to each-partner whatever the M_6L_{14} unit (Table 8). Indeed, the interatomic distances within the M_6L_{14} units do not significantly vary between the starting $Cs_2M_6L_{14}$ solid-state compound and the final $[Cp^*(dppe)Fe–NCMe]_2 \cdot M_6L_{14}$ series. Furthermore, the interatomic distances within the $[Cp^*(dppe)Fe–NCMe]^+$ entity correspond to those found in the previously reported $[Cp^*(dppe)Fe–NCMe][PF_6]$. The compound $[Cp^*(dppe)Fe–NCMe]PF_6$ was obtained by photolysis of $[Cp^*Fe–(CO)_3]PF_6$ in acetonitrile with 1 equiv. of dppe. After the reaction, single crystals were ob-

tained by slowly cooling the solution to 233K. This procedure cannot guarantee a rigorous control of the crystallization and cannot be extended to brittle entities or those unstable at lowtemperatures. On the other hand, [Cp*(dppe)Fe–NCMe] is easily crystallized at room temperature with M_6L_{14} units. The reaction proposed here for the synthesis of the $[Cp^*(dppe)Fe–NCMe]_2 \cdot M_6L_{14}$ series is based on the exchange, in solution, of the chlorine atom from the Cp*(dppe)FeCl precursor by the more strongly coordinating acetonitrile group.[21] The charge is then compensated for by the M_6L_{14} dianionic unit. Using an organic solvent, it is more easy to separate CsCl than TBACl from $[Cp^*(dppe)Fe–NCMe]_2[Mo_6L_{14}]$. TBACl results from the reaction between [Cp*(dppe)Fe–NCMe]Cl and $(TBA)_2$-Mo_6L_{14} indicating that $Cs_2Mo_6L_{14}$ solid-state compounds must be preferentially chosen instead of the $(TBA)_2Mo_6L_{14}$ series usually used in coordination chemistry. M_6L_{14} anionic units could be used for the crystallization of other novel cationic organometallic entities when usual anionic counterparts give unfruitful results. In particular, the $Cs_2M_6L_{14}$ series could be used to advantage instead of $MReX_6$ salts for the crystallization of organic or organometallic cations from chloride precursors by precipitation of CsCl.

Finally, it is noteworthy that a solubile cation needs to counterbalance an insolubile anion to favour the crystal growing process.

Experimental Section

General: Unless otherwise specified, all reagents and solvents were purchased from commercial suppliers and used without further purification. The complex (η^2-dppe)(η^5-C_5Me_5)FeCl was prepared as described.[21][1]H NMR spectra were recorded with a Bruker Avance 200 (200 MHz) spectrometer. ^1H and ^{31}P NMR chemical shifts are reported in units of parts per million relative to the residual protio solvent and H_3PO_4, respectively.Transmittance-FTIR spectra were recorded with a Bruker IFS28 spectrometer (400–4000 cm^{-1}). $Cs_2Re_6S_6Br_8$, as well as $Cs_2Mo_6Br_{14}$ and $Cs_2Mo_6I_{14}$ were prepared by solid-state reactions as described in refs.[22,23], respectively. Chemical analyses were performed by energy dispersive spectrometry (EDS), using a scanning electron microscope JEOL JSM 6400 equipped with a microprobe EDS Oxford Link ISIS. Single-crystal X-ray diffraction data collections were performed at room temperature with a Nonius KappaCCD diffractometer. CCDC-244494, -250568 {for $[Cp^*(dppe)Fe–NCMe]_2[Re_6S_6Br_8]$, $[Cp^*(dppe)Fe–NCMe]_2[Mo_6Br_{14}]$} and CCDC-250569 {for $[Cp^*(dppe)Fe–NCMe]_2[Mo_6I_{14}]$} contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Synthesis of $[Cp^*(dppe)Fe–NCMe]_2[Re_6S_6Br_8]$ (1): [Cp*(dppe)FeCl] (0.312 g; 0.5 mmol) and $Cs_2Re_6S_6Br_8$ (0.609 g; 0.25 mmol) were separately dissolved in degassed MeCN (10 mL and 50 mL, respectively) in Schlenk tubes. The solutions were then mixed together with magnetic stirring for 1 h. The solvent was subsequently removed. $[Cp^*(dppe)Fe–NCMe]_2[Re_6S_6Br_8]$ was extracted from the resultant product by addition of acetone. The orange solution was then separated from the CsCl precipitate by filtration. After evaporation of acetone, $[Cp^*(dppe)Fe–NCMe]_2[Re_6S_6Br_8]$ was obtained as a brown powder (yield 40 %). Single crystals suitable for X-ray diffraction studies were obtained by diffusion of pentane into an acetone solution. No traces of chlorine or cesium were apparent in the final product from the EDS analysis (experimental atomic percentages: Fe, P, Re, S, Br: 7.0, 17.3, 24.1, 23.8, 27.8; calculated for $[Cp^*(dppe)Fe–CMe]_2[Re_6S_6Br_8]$: 7.7, 15.4, 23.1, 23.1, 30.8). This result is consistent with a complete cationic exchange between $[Re_6S_6Br_8]$ dianionic units and Cl^- with precipitation of CsCl in an organic solvent. In agreement with previous data reported with the related PF_6 salt,[24] the ^{31}P NMR spectrum exhibits only one signal at δ = 91.13 ppm characteristic for the two P atoms of the –P–$(CH_2)_2$–P– chain bridging the central iron atom. The presence of a

unique singlet is evidence the formation of only one organometallic complex with an η^2-dppe ligand. The ^{1}H NMR spectrum exhibits several peaks, i.e. a group between δ = 7.34 and 7.70 ppm (20 hydrogen atoms of the four phenyl groups connected to the two P atoms), a manifold between 2.15 ppm and 2.45 ppm [4 hydrogen atoms of the CH_2 groups of the –P–$(CH_2)_2$–P– bridge], a singlet at δ = 2.15 ppm (3 hydrogen atoms of the $NCCH_3$ solvent molecule connected to the metal atom) and a singlet at δ = 1.38 ppm (15 hydrogen atoms of the methyl groups of the Cp* ligand). In addition, the coordination of an $NCCH_3$ molecule on the iron atom is indicated by the presence of a characteristic ν_{CN} band stretch at 2249 cm^{-1} in the IR spectrum. This value is in agreement with those observed in other iron complexes with this same solvent molecule.[24] FT-IR (Nujol): $\tilde{\nu}$ = 2249 (m, $\nu_{C\equiv N}$) cm^{-1}. ^{1}H NMR (200 MHz $CDCl_3$): δ = 7.70–7.34 (m, 20 H, Ph), 2.45–2.45 (m, 4 H, CH_2dppe), 2.15 (s, 3 H, CH_3CN), 1.90 (s, 15 H, Cp*) ppm. ^{31}P NMR (81 MHz, $CDCl_3$): δ = 91.1 (s, dppe) ppm.

Synthesis of $[Cp^*(dppe)Fe–NCMe]_2[Mo_6Br_{14}]$ (2): [Cp*(dppe)FeCl] (0.115 g, 0.36 mmol) and $Cs_2Mo_6Br_{14}$ (0.360 g, 0.18 mmol) were

separately dissolved in degassed MeCN (10 mL and 50 mL, respectively) in Schlenk tubes. The solutions were then mixed together with magnetic stirring. In contrast to [Cp*(dppe)Fe–NCMe]$_2$[$Re_6S_6Br_8$], [Cp*(dppe)Fe–NCMe]$_2$[Mo_6Br_{14}] is not soluble in acetone. Consequently, the solution volume was reduced to 10 mL in order to precipitate all the CsCl which was then separated by filtration. Subsequently, the solvent was removed to provide [Cp*(dppe)Fe–NCMe]$_2$[Mo_6Br_{14}] as an orange crystalline powder (yield 34 %). Suitable single crystals for X-ray diffraction studies were obtained by diffusion of pentane into an acetonitrile solution. EDS analysis did not indicate any traces of Cl or Cs. Heavy-element analyses are in good agreement with the stoichiometry determined from structural data. Spectroscopic characterization (^{31}P NMR, IR) of [Cp*(dppe)Fe–NCMe]$_2$[Mo_6Br_{14}] was carried out and no significant shifts in the band maxima in the IR spectrum or shifts in the NMR peaks could be observed compared with those of [Cp*(dppe)Fe–NCMe]$_2$[$Re_6S_6Br_8$].

Synthesis of [Cp*(dppe)Fe–NCMe]$_2$[Mo_6I_{14}] (3): [Cp*(dppe)Fe–NCMe]$_2$[Mo_6I_{14}] was prepared according to a similar experimental procedure to that described for [Cp*(dppe)Fe–NCMe]$_2$[Mo_6Br_{14}] using Cp*(dppe)FeCl (0.110 g, 0.18 mmol) and $Cs_2Mo_6I_{14}$ (0.230 g, 0.09 mmol). After drying under vacuum, [Cp*(dppe)Fe–NCMe]$_2$[Mo_6I_{14}] was obtained as an orange powder (yield 50 %). Single crystals suitable for X-ray diffraction studies were obtained by diffusion of pentane into an acetonitrile solution. EDS analysss did not suggest any traces of Cl or Cs. Heavy-element analyses are in good agreement with the stoichiometry determined from structural data. Spectroscopic characterization (^{31}P NMR, IR) of [Cp*(dppe)Fe–NCMe]$_2$[Mo_6I_{14}] was carried out and no significant shifts in the band maxima in the IR spectrum or shifts in the NMR peaks could be observed compared with those of [Cp*(dppe)Fe–NCMe]$_2$[$Re_6S_6Br_8$].

Acknowledgments

This work has been supported in part by three research grants from the French Ministry of Research and Education (F. d. M., K. K., G. P.). We would like to thank the Scanning Electron Microscopy Center at the University of Rennes 1 for microanalyses and the Diffraction Center of the University of Rennes 1 for the data collection with the Nonius KappaCCD X-ray diffractometer. In particular, the useful advice of Dr. Thierry Roisnel is gratefully acknowledged. We are also indebted to the French Research Ministry for "ACI Nanosciences 2001 – No. 18-01" contract and to "Fondation Langlois" for financial support.

Evolution of the Structural Parameters and Magnetic Properties in a Series of Di(μ-hydroxy)bis(nitrilotriacetato)dichromium(III) Complexes

Ghenadie Novitchi,*[a,c] Jean-Pierre Costes,[b] Victor Ciornea,[c] Sergiu Shova,[b,c] Irina Filippova,[d] Yurii A. Simonov,[d] and Aurelian Gulea[c]

Dedicated to Prof. André E. Merbach (EPFL, Lausanne, Switzerland) on the occasion of 65th birthday

Keywords: Chromium / Alkaline earth metals / N,O ligands / Magnetic properties

Four heterometallic complexes $\{Mg(H_2O)_6\}[Cr_2(\mu\text{-}OH)_2(nta)_2]\cdot 4H_2O$ (**I**), $\{Ca(H_2O)_3\}[Cr_2(\mu\text{-}OH)_2(nta)_2]\cdot 3H_2O$ (**II**), $\{Sr(H_2O)_3\}[Cr_2(\mu\text{-}OH)_2(nta)_2]\cdot 3H_2O$ (**III**) and $\{Ba(H_2O)_3dmso\}[Cr_2(\mu\text{-}OH)_2(nta)_2]\cdot 2H_2O$ (**IV**) containing dinuclear *bis*(μ-hydroxo) chromium(III) complex ions, where *nta* is the nitrilotriacetate ligand and *dmso* is dimethyl sulfoxide, have been prepared and crystallographically characterised. Compound **I** displays an ionic type structure, **II** and **III** are 3D coordination polymers and **IV** behaves like a 2D coordination polymer. In these compounds, the chromium(III) dimeric unit exhibits different structural features. It forms a polymeric structure by coordination of alkaline earth metal ions and/or formation of hydrogen-bonding interactions. The temperature dependencies of the magnetic susceptibilities of **I**–**IV** were fitted on the basis of the expression derived from the isotropic Hamiltonian including a biquadratic exchange term, $\hat{H} = -2J(\vec{S}_1\,\vec{S}_2) - j(\vec{S}_1\,\vec{S}_2)^2$. The values of the coupling interaction (J) range from –17.38 cm^{-1} to –5.80 cm^{-1} and the biquadratic terms (j) from +0.71 to 2.02 cm^{-1}. The experimental and theoretical values of J (calculated, using the Glerup–Hodgson–Pedersen model) have been discussed.

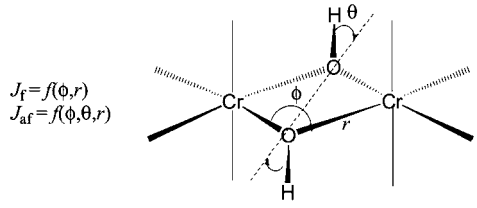
Introduction

The magnetic interactions between the unpaired electrons located at different metal atoms in polynuclear compounds are an important characteristic of magnetic materials.[1] The interest in this arises from the essential contribution of the exchange coupling constant to the magnetic properties of compounds containing coupled paramagnetic centres.[2] Among the transition-metal binuclear complexes known, many bridged complexes of transition metals with a wide variety of bridging ligands such as mono-cyanide[3] (CN^-, $S\text{–}CN^-$, $O\text{–}CN^-$), chloro,[4] azido,[5] oxo,[6,7] hydroxo,[8] oxalato[9] or even more complex bridges have been already described. The magnetic behaviour of these compounds depends on the ligand nature, the metal coordination number and the geometrical structure of the bridge. For closely related complexes such as alkoxo- and hydroxo-bridged $V^{II}O$[10] or oxo-bridged dimers,[11] magneto-structural correlations have been established. Many[12] studies have been devoted to chromium(III) dimers $[Cr_2(\mu\text{-}OH)_2L_x]^y$ with a *bis*(μ-hydroxo) bridge, where L are bidentate or polydentate ligands. For these types of dimer, Hoffmann and coworkers[12a] have characterised the exchange coupling constant J as the sum of ferromagnetic (J_f) and antiferromagnetic (J_{af}) terms where $J = J_{af} + J_f$. The two contributions J_f and J_{af} can be correlated to structural parameters: the metal-oxygen distance r, the in plane bridge angle φ as well as the out-of-plane distortions θ of the hydroxide ligand (Scheme 1).[12]



Scheme 1.

In the development of this correlation, Pedersen and coworkers[12b,12c] demonstrated that the magnetic exchange is highly sensitive to both θ and r or to the hybridisation state of the bridging oxygen atom.

In this paper, we report the synthesis, structures and magnetic characterisation of four chromium(III) alkaline earth heterometallic complexes: $\{Mg(H_2O)_6\}[Cr_2(\mu\text{-}OH)_2(nta)_2]\cdot 4H_2O$, (**I**), $\{Ca(H_2O)_3\}[Cr_2(\mu\text{-}OH)_2(nta)_2]\cdot 3H_2O$ (**II**), $\{Sr(H_2O)_3\}[Cr_2(\mu\text{-}OH)_2(nta)_2]\cdot 3H_2O$ (**III**) and $\{Ba(H_2O)_3\text{-}dmso\}[Cr_2(\mu\text{-}OH)_2(nta)_2]\cdot 2H_2O$ (**IV**) where *nta* is the nitrilotriacetate ligand and *dmso* is dimethyl sulfoxide.

Results and Discussion

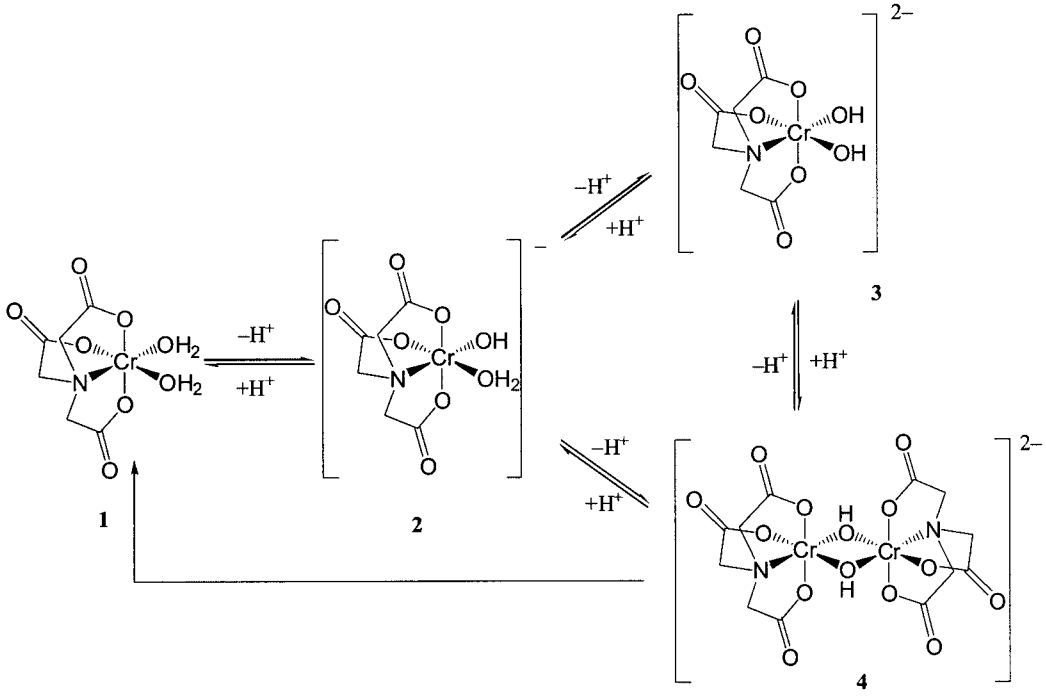
Synthesis and Characterisation of the Complexes

The heterometallic complexes **I**–**IV** containing dinuclear bis(μ-hydroxo)chromium(III) complex ions were prepared by the interaction of $CrCl_3\cdot 6H_2O$ and $M_3(nta)_2$ (where M = Ca^{2+}, Sr^{2+} or Ba^{2+}). The reactions proceed in aqueous solutions and the pH was adjusted with a solution of $M(OH)_2$. $M_3(nta)_2$ was previously obtained by an exchange reaction between MCO_3 and nitrilotriacetic acid (H_3nta). As usual, the formation of the dinuclear complex ion (**4**) (Scheme 2) results from a hydrolysis reaction which is characteristic of chromium(III) ions.[13] The reversibility of the protolytic reaction between **1** and **2** and also between **2** and **3** has already been demonstrated byspectroscopic (UV/Vis, ^2H NMR) and pH-metric investigations of different Co^{III} and Cr^{III}-*nta* complexes.[14]

This work reveals that the dimeric ions (**4**) are broken in an irreversible protonation step to form diaqua complexes (**1**). The very slow dimerisation steps **2**↔**4** and **3**↔**4** proceed over several days.[15] Compound **I** was obtained by an exchange reaction between the barium compound **IV** and $MgSO_4$.

In order to establish the coordination modes of the carboxylic groups of the nitrilotriacetate ligands, the IR absorption spectra of **I**–**IV** were determined. In the IR spectra, the difference between the asymmetric and the symmetric stretching frequencies [$\Delta = \nu_{as}(COO^-) - \nu_s(COO^-)$] characterises the coordination modes of the carboxylic groups.[15] In the IR spectrum of **I**, three intensive bands were found, namely one at ca. 1623 cm^{-1} related to $\nu_{as}(COO^-)$ and two at 1363 and 1335 cm^{-1} attributable to $\nu_s(COO^-)$. The differences between the asymmetric and symmetric frequencies are equal to 260 and 287 cm^{-1}. Differences higher than 250 cm^{-1} indicate two different monodentate modes of coordination for the carboxylate groups. In the IR spectra of compounds **II** and **III**, three intense bands corresponding to carboxylate moieties do exist: for **II** they are $\nu_{as}(COO^-)$ = 1596 cm^{-1} and $\nu_s(COO^-)$ = 1385 and 1345 cm^{-1} whereas for complex **III** these bands appear at 1597, 1386 and 1345 cm^{-1}. The related frequency differences Δ = 252 cm^{-1} and 211 cm^{-1} support the presence of monodentate and bidentate bridging modes of coordination, respectively. The similarities of the values for complexes **II** and **III** suggest isostructural arrangements for the nitrilotriacetate ligands. Two coordination modes are also present in **IV**: monodentate (Δ = 255 cm^{-1}) and bridging or chelating (Δ = 231 cm^{-1}).

The electronic spectra of complexes **I**–**IV** in aqueous solution (in the 300–1100 nm range) show two bands $\nu_1(^4A_{2g}\rightarrow{}^4T_{2g})$ = 17069 cm^{-1} (ε = 40 $L\,mol^{-1}\,cm^{-1}$) and $\nu_2[^4A_{2g}\rightarrow{}^4T_{1g}(F)]$ = 24510 cm^{-1} (ε = 63 $L\,mol^{-1}\,cm^{-1}$), characteristic for an $\{NO_5\}$ octahedral environment for chromium(III) with ligand field parameters $10Dq$ = 17069 cm^{-1} and B = 745 cm^{-1}.[16] The configuration interaction (x) between



Scheme 2.

the $^4T_{1g}(F)$ and $^4T_{1g}(P)$ states of the same symmetry is 6214 cm^{-1}. The similarities in the wave numbers for **I–IV** indicate that the complexes dissociate in solution, keeping the dianionic dichromium structure unchanged.

Structures

A perspective view of the centrosymmetric dinuclear complex anion **I** is shown in Figure 1. A similar $[Cr_2(\mu\text{-}OH)_2(nta)_2]^{2-}$ unit is present in the four complexes **I–IV** as well as in the $Cs_2[M_2(\mu\text{-}OH)_2(nta)_2]\cdot 4H_2O$ entities already reported (M = Cr, Co).[14a,14b] In compounds **II–IV**, the asymmetric part of the unit-cell contains two crystallographically independent nitrilotriacetate molecules which generate two different centrosymmetric dimeric anions (named **A** and **B** hereafter) (Figure 2).The octahedral coordination of the chromium atoms implies four donor atoms from the nta^{3-} ligands (N,O,O,O) and two bridging OH groups. For **I–IV**, the average Cr–N bond length is 2.060 Å [from 2.052(3) to 2.069(2) Å, Table 1] while a more significant dispersion is observed for the Cr–O bonds [from 1.952(1) to 2.015(2) Å]. The nta^{3-} ligand forms three five-membered ring chelates with the central atom. According to ref.[17] these rings can be classified as one *R* ring {N(1) CrO(6)C(6)C(5)N(1)} and two *G* rings (Figure 1). For complexes **I–IV**, the sums of the endocyclic angles vary in the ranges 537.5–540.0° and 524.9–536.2° for the *R* and *G* rings, respectively. Two oxygen atoms from hydroxy groups act as bridges in the $[Cr_2(\mu\text{-}OH)_2(nta)_2]^{2-}$ anion (Figure 1 and Figure 2).The Cr–(μ-OH) bond lengths are in the range 1.942(3)–1.979(1) Å, as in the previously published $Cr_2(\mu\text{-}OH)_2$ fragments.[12,14a,14b,18b] Slight differences characterise the Cr–O(1)–Cr* angles (φ) [96.0(1)–101.2(8)°] (Table 1). As a consequence, the Cr–Cr distances vary from 2.928(1) to 3.014(1) Å. Significant differences can also be observed for the angles defined by the O–H and O(1)–O(1)* vectors (θ angles in Scheme 1 and Table 1). These angles are essential for differentiating the dimeric units and are 51(2)° (dimer **A**) and 8(3)° (dimer **B**) in compound **II.**

[a] Two crystallographically independent *nta* molecules are named as **A** and **B**.

nation polyhedron and induce different assemblies of the dinuclear units in the polymer networks. In **I** the Mg^{2+} ion is surrounded by six water molecules and has an octahedral coordination geometry. The Mg–O distances vary between 2.049(1) Å and 2.072(2) Å, with the O–Mg–O angles close to 90°. Distances and bond angles (Table S2) are similar to those found in other $[Mg(H_2O)_6]^{2+}$ containing compounds.[18] Multiple hydrogen bonds involving coordinated and solvated water molecules link the $[Cr_2(\mu\text{-}OH)_2(nta)_2]^{2-}$ anions with the $[Mg(H_2O)_6]^{2+}$ cations in a 3D network (Figure S1).

The isostructural compounds **II** and **III** are 3D coordination polymers (Figure 3). In this framework, four bridging carboxylic groups ($\eta^1{:}\eta^1{:}\mu_2$) arising from four *G* rings from the **A** type dimers form bonds with seven-coordinate Ca or Sr ions (see a in Figure 2). On the other hand, two *G* and two *R* rings are used for the **B** type dimers (see b in Figure 2). The coordination polyhedron of Ca^{2+} is completed by four carboxylate oxygen atoms belonging to four Cr dimers with Ca–O lengths ranging from 2.395(2) to 2.431(2) Å and by three water molecules with bond lengths ranging from 2.410(2) to 2.427(2) Å (Figure 3). The corresponding bond lengths to the Sr centres in **III** increase with the ionic radius of Sr^{2+}. The Sr–O(*w*) bond lengths are in the range of 2.526(2)–2.573(2) Å and the Sr–O_{carb} distances vary from 2.507(2) to 2.561(2) Å. The 3D structure is stabilised by O–H···O hydrogen bonds (Table S1). The increase in the Sr–O bond lengths in comparison with the Ca–O distances leads to small modifications in the orientations of some of the H-bonds.

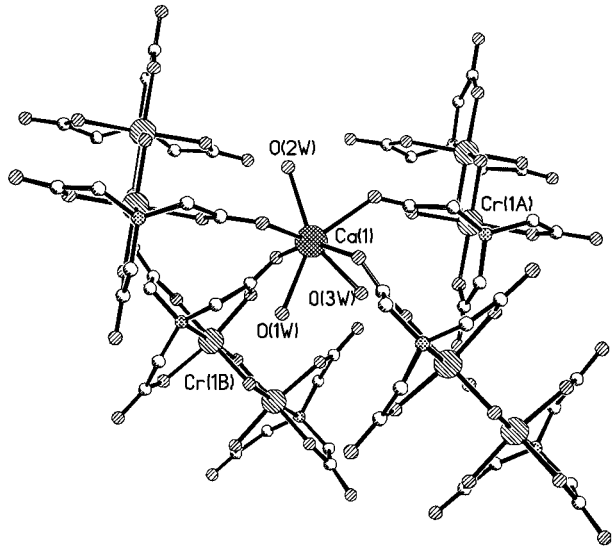

Figure 3. Coordination environment of Ca^{2+} in the 3D network of compound **II**.

In compound **IV**, the **A** type dimers have four *G* carboxylic groups chelating the ten- coordinate Ba^{2+} ions (see c in Figure 2). In **IV-A**, the carboxylic groups exhibit different bridging functions: two are tridentate bridging groups ($\eta^2{:}\eta^1{:}\mu_2$) whereas the other two are tetradentate ($\eta^2{:}\eta^2{:}\mu_2$). In contrast, only two *trans* (*R*) carboxylic bridging groups ($\eta^1{:}\eta^1{:}\mu_2$) are bound to the Ba^{2+} ions in the **B** type dimers, (see d in Figure 2). The coordination sphere of barium is composed of six oxygen atoms from two nta^{3-} ligands [dis-

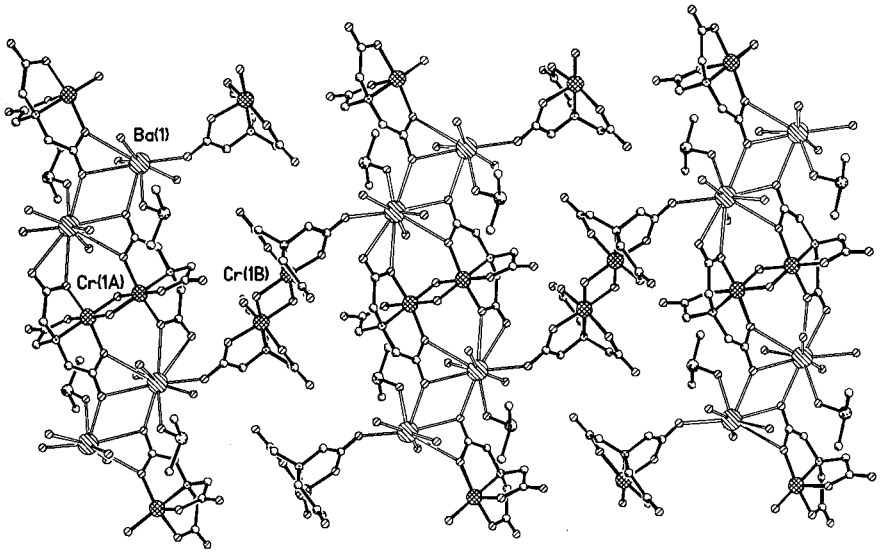

Figure 4. View of the 2D polymeric layer in compound **IV**. Hydrogen atoms and solvated water molecules have been omitted for clarity.

tances: 2.697(2)–3.094(3) Å], one dimethyl sulfoxide molecule [Ba(1)–O(1S) = 2.751(3) Å] and three H_2O molecules [2.786(3)–2.813(3) Å]. A centrosymmetric dimer **B** joins two atoms [Ba(1) and Ba(1*)] through two oxygen atoms [Ba(1)–O(7B) = 2.697(2) Å] whereas the second dimer (**A**) has five short contacts [2.827(2)–3.094(3) Å] with Ba(1). Furthermore, the carboxylate oxygen atoms O(5A) form a bridge between two centrosymmetric Ba^{2+} ions yielding dimers with Ba···Ba distances of 4.691(1) Å (Figure 4). Decadentate chelate-bridging dimeric anions enable the formation of chains with alternating of Cr(1A) and Ba(1) dimers along the *b* axis while Cr(1B)-dimers join the adjacent chains to give 2D polymeric layers (Figure 4). The layers are held together by hydrogen bonds (Table S1).

Magnetic Studies

The magnetic behaviour of compounds **I**–**IV** has been studied in the 2–300 K temperature range. As an example, the magnetic behaviour of **II** is shown in Figure 5 in the form of the thermal variation of χ_M, where χ_M is the molar susceptibility corrected for diamagnetism. At 300 K, χ_M is equal to 1.1×10^{-2} $cm^3 mol^{-1}$ which corresponds to the expected value for two uncoupled metal ($S = {}^3/_2$) ions both in the $^4A_{2g}$ ground state. As usual, the appropriate model for obtaining a fairly good agreement between the theoretical and experimental data may include a biquadratic exchange term [Equation (1)]. The resultant Hamiltonian is:[11e,11f,19]

$$\hat{H} = -2J(\vec{S}_1 \cdot \vec{S}_2) - j(\vec{S}_1 \cdot \vec{S}_2)^2 \quad (1)$$

and this leads to the following expression [Equation (2)].

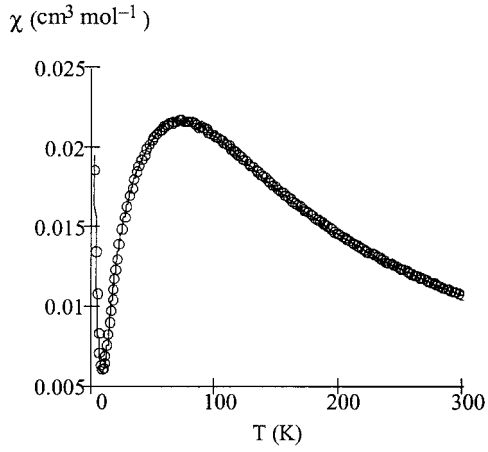

Figure 5. Magnetic susceptibility data for **II**. The solid line corresponds to the best fit for a pair of exchange-coupled $S = {}^3/_2$ spins including biquadratic exchange.

where the variable magnetic parameters *J* and *j* determine triplet, quintet and septet electronic ground states $E(^3A_2'') = -2J + 6.5j$, $E(^5A_1') = -6J + 13.5j$ and $E(^7A_2'') = -12J + 9j$, respectively (Scheme S1). C_{pi} represents the paramagnetic impurity factor. Least-squares fittings of the experimental data lead to the parameters collected in Table 2 with the agreement factors defined by $R = \Sigma(\chi_{calc} - \chi_{obs})^2/\Sigma(\chi_{obs})^2$. The negative *J* value indicates that the main exchange interaction in the dimeric building block fragments is antiferromagnetic. On the contrary, however, the biquadratic exchange *j* is positive but of lower amplitude with a

$$\chi_m = \frac{2Ng^2\mu_B^2(1-C_{pi})}{kT} \cdot \frac{\exp\left[\frac{(2J-6,5j)}{kT}\right] + 5\exp\left[\frac{(6J-13,5j)}{kT}\right] + 14\exp\left[\frac{(12J-9j)}{kT}\right]}{1 + 3\exp\left[\frac{(2J-6,5j)}{kT}\right] + 5\exp\left[\frac{(6J-13,5j)}{kT}\right] + 7\exp\left[\frac{(12J-9j)}{kT}\right]} \quad (2)$$

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

j/2*J* ratio equal to 0.05.[20] In our complexes, a parallel evolution of *J* and *j* can be observed, with an increase of |*J*| occurring as |*j*| increases and a ratio varying from 0.05 to 0.06.

Table 2. Best parameters obtained from magnetic susceptibility data fitting.

Parameters	I	II	III	IV
J	–5.80(1)	–12.59(1)	–13.85(1)	–17.38(1)
j	0.71(2)	1.29(2)	1.31(2)	2.02(2)
Cp	–0.006	–0.039	–0.012	–0.0063
R	7×10^{-5}	7×10^{-5}	9×10^{-7}	9×10^{-7}

The exchange interaction in chromium(III) dimers with $S = 0, 1, 2$ and 3 concerns two coupled $(^4A_{2g})a(^4A_{2g})b$ states derived from the $|t_{2g}^3(a)t_{2g}^3(b)>$ configuration where $^4A_{2g}$ and t_{2g}^3 characterise two d^3-metal centres *a* and *b*. The chromium(III) t_{2g} orbitals containing the unpaired electrons and the p orbitals of the bridging OH-ligands are both involved in the superexchange interactions. In this pathway, the magnetic interactions also depend upon the orientation of the oxygen atom orbitals which determine the dominant contributions between the two paramagnetic centres. The resultant expression for *J* in the Heisenberg's Hamiltonian may be calculated using the Glerup–Hodgson–Pedersen model [Equation (3)].[12]

$$J = J_{af} - J_f = e^{-a(r-1,8)}\left[\frac{b\cdot\cos^4\theta}{\left\{(1-\sin^2\theta)\Big/\tan^2(\phi/2)\right\}^2} - \frac{c\cdot\sin\phi}{(1-\cos\phi)^2}\right] \quad (3)$$

where *r*, φ and θ are defined as represented in Scheme 1. The calculated *J* values with $a = 19$ Å^{-1}, $b = 611$ cm^{-1} and $c = 172$ cm^{-1} [12b] and the experimental ones for **I**–**IV** are presented in Figure 6. Theoretical *J* values with their standard deviations were calculated using distances and angles obtained from X-ray experiments. For compound **I** and for **II-A** and **III-A** type dimers, experimental and theoretical estimations of *J* values are in fair agreement. For dimers **II-B** and **III-B**, the theoretical values are overestimated compared with the experimental measurements. This difference may be explained by a supplementary interaction between dimers through Ca or Sr ions. Indeed, the carboxylate groups bridge Cr and Ca or Sr ions in a *syn-anti* conformation for dimers **A** and in an *anti-anti* conformation for dimers **B**.

The Hamiltonian used in our calculations assumes that the chromium dimers are well isolated from each other. A look at the structural determinations indicates that this assumption is only true for complex **I**. In complexes **II**–**IV**, the Ca, Sr and Ba ions bridge these dinuclear units but we have no experimental evidence to suggest that such bridges are able to transmit magnetic interactions. On the contrary, the quality of the fits obtained for the entire set of complexes agrees with the accuracy of the retained Hamiltonian and the absence of magnetic interactions through the alkaline-earth metal ions.

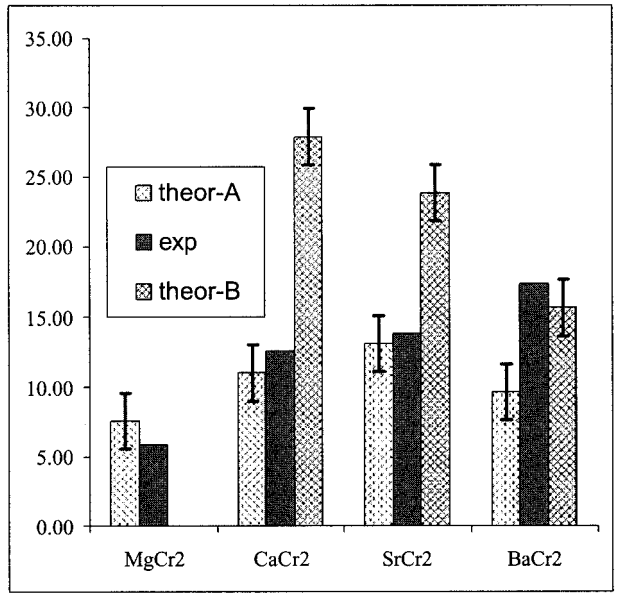

Figure 6. Experimental (best fit of Eq. 2) and theoretical (Glerup–Hodgson–Pedersen model, Eq. 3) *J* values for compounds **I**–**IV** (**theor-A** and **theor-B** correspond to the values calculated with the crystallographic data of the **A** and **B** dimers).

Conclusion

Four new heterometallic chromium nitrilotriacetate complexes have been synthesized and structurally characterised by X-ray analysis. The dinuclear di-(μ-hydroxo) chromium anion $[Cr_2(\mu\text{-}OH)_2(nta)_2]^{2-}$ is present in each complex. Thus, the effect of substitution of one alkaline earth metal with another, while preserving the basic composition and inducing a variation in the number of solvated water molecules, affords dramatic alterations in the molecular structures which range from an ionic type in compound **I** to coordination polymers in **II**–**IV**. This is predetermined by the coordination function of $[Cr_2(\mu\text{-}OH)_2(nta)_2]^{2-}$ and its binding to give 2D or 3D coordination polymers.

The IR spectra confirm, with help of the Δ parameters [$\Delta = \nu_{as}(COO^-) - \nu_s(COO^-)$], that monodentate, bidentate bridging or chelating coordination modes of the carboxylate groups are present. This is consistent with the structural features of the studied complexes.

The magnetic properties of this series of di-μ-hydroxo bridged chromium(III) complexes containing the nitrilotriacetic ligand include antiferromagnetic coupling interactions with *J* values ranging from –5.80 to –17.38 cm^{-1}. A comparison of the best fit magnetic parameters with theoretical values calculated using the Glerup–Hodgson–Pedersen model clearly shows a fair correlation with the structural parameters of the dinuclear units, with only a minute influence from the hydrogen bonds and the alkaline earth metal bridges.

Experimental Section

Materials: All starting materials and solvents were purchased from Aldrich and were used without further purification. Elemental analyses (C, H, N) were carried out by the Service de Microanalyse du Laboratoire de Chimie de Coordination, Toulouse.

Syntheses: Calcium [Di-μ-hydroxy-bis(nitrilotriacetato)dichromium(III)] Hexahydrate $\{Ca(H_2O)_3\}[Cr_2(\mu\text{-}OH)_2(nta)_2]\cdot 3H_2O$ (II): Water (100 mL) was added to a mixture of H_3nta (0.76 g, 4 mmol) and dispersed $CaCO_3$ (0.6 g, 6 mmol). The resultant solution was warmed to 95 °C. After complete dissolution of $CaCO_3$, $CrCl_3\cdot 6H_2O$ (1.07 g, 4 mmol) in water (50 mL) was added to the initial solution (the temperature was maintained at about 95 °C). Heating was stopped after 1 h and a saturated solution of $Ca(OH)_2$ was added dropwise in order to raise the pH value to 6.5–7.0. As a result, the solution changed from violet to navy blue-green. The reaction mixture was filtered and concentrated to 30 mL. After 24 h, the crystals which appeared were separated by filtration, washed with cold water, ethanol and diethyl ether. Yield 70%. $C_{12}H_{26}CaCr_2N_2O_{20}$: calcd. C 21.76, H 3.96, N 4.23; found C 21.63, H 4.03, N 4.21.IR (KBr): $\tilde{\nu}$ = 3318 (br,m) ν(OH), 1596 (vs) $\nu_{as}(CO_2)$, 1455 (w) 1429 (w) $\delta(CH_2)$, 1385 (s) 1345 (s) $\nu_s(CO_2)$, 1272 (m) 1216 (m) $\rho_\omega(CH_2)$, 1098 (m) 1010 (m) ν(CN), 974 (w) ρ_r, 953 (m) 941 (m) ν(CC), 748 (s) $\delta(CO_2)$, 624 (s) $\rho_\omega(CO_2)$ cm^{-1}.

Strontium [Di-μ-hydroxy-bis(nitrilotriacetato)dichromium(III)] Hexahydrate $\{Sr(H_2O)_3\}[Cr_2(\mu\text{-}OH)_2(nta)_2]\cdot 3H_2O$ (III)andBarium [Di-μ-hydroxy-bis(nitrilotriaacetato)dichromium(III)] Dimethyl Sulfoxide Pentahydrate $\{Ba(H_2O)_3dmso\}[Cr_2(\mu\text{-}OH)_2(nta)_2]\cdot 2H_2O$ (IV): The syntheses were analogous to that of **II** except for neutralisation of the reaction mixture (pH = 6.5–7) that was carried out with concentrated NH_4OH.Compound **IV** was recrystallised from dimethyl sulfoxide. $\{Sr(H_2O)_3\}[Cr_2(\mu\text{-}OH)_2(nta)_2]\cdot 3H_2O$ (**III**) Yield 65%. $C_{12}H_{26}Cr_2N_2O_{20}Sr$: calcd. C 20.30, H 3.69, N 3.95; found C 20.35, H 3.89, N 3.71. IR (KBr): $\tilde{\nu}$ = 3319 (m, br) ν(OH), 1597 (vs) $\nu_{as}(CO_2)$, 1455 (w) 1430 (w) $\delta(CH_2)$, 1386 (s) 1345 (s) $\nu_s(CO_2)$, 1274 (m) $\rho_\omega(CH_2)$, 1100 (m) 1011 (m) ν(CN), 941 (m) ν(CC), 744 (s) $\delta(CO_2)$, 621 (s) $\rho_\omega(CO_2)$ cm^{-1}.$\{Ba(H_2O)_3dmso\}[Cr_2(\mu\text{-}OH)_2(nta)_2]\cdot 2H_2O$(**IV**) Yield 55%. $C_{14}H_{30}BaCr_2N_2O_{20}S$: calcd. C 20.51, H 3.69, N 3.42; found C 20.50, H 3.42, N 3.48. IR (KBr): $\tilde{\nu}$ = 3421 (s, br) ν(OH), 1653 (vs) 1617 (vs) $\nu_{as}(CO_2)$, 1456 (w) $\delta(CH_2)$, 1386 (vs) $\nu_s(CO_2)$, 1268 (m) 1212 (w) $\rho_\omega(CH_2)$, 1104 1093 (w) ν(CN), 951 (m) ν(CC), 754 (s) $\delta(CO_2)$, 621 (m) $\rho_\omega(CO_2)$ cm^{-1}.

Magnesium [Di-μ-hydroxy-bis(nitrilotriacetato)dichromium(III)] Decahydrate$\{Mg(H_2O)_6\}[Cr_2(\mu\text{-}OH)_2(nta)_2]\cdot 4H_2O$ (I): $MgSO_4\cdot 7H_2O$ (0.25 g, 1 mmol) was dissolved in water (50 mL) and the crystalline complex **IV** (0.74 g, 1 mmol) was added. The mixture was stirred for 2 h at 70°C. The solution was then filtered and concentrated to a volume of 20 mL. A substance crystallised from the navy blue-green solution over 24 h and this was separated by filtration. The crystals obtained were washed with cold water, alcohol and eventually with acetone and were dried at room temperature. Yield 67%. $C_{12}H_{34}Cr_2MgN_2O_{24}$: calcd. C 20.05, H 4.78, N 3.89; found C 20.91, H 4.56, N 4.05. IR (KBr): $\tilde{\nu}$ = 3356 (s, br) ν(OH), 1623 (vs) $\nu_{as}(CO_2)$, 1457 (w) 1420 (w) $\delta(CH_2)$, 1363 (s) 1335 (s) $\nu_s(CO_2)$, 1268 (m) 1220 (m) $\rho_\omega(CH_2)$, 1107 (m) 1092 (m) ν(CN), 934 (m) ν(CC), 746 (s) $\delta(CO_2)$, 620 (s) $\rho_\omega(CO_2)$ cm^{-1}.

The substances **I–IV** are soluble in water, slightly soluble in DMSO and DMF but insoluble in ethanol and acetone.

Physical Measurements: TheIR spectra (KBr pellets) were recorded on a GX system 2000 Perkin–Elmer spectrophotometer. Electronic absorption spectra were recorded on a Perkin–Elmer UV/Vis-NIR-

Lambda-19 spectrophotometer. Magnetic susceptibility data (2–300 K) were collected on powdered samples using a SQUID-based sample magnetometer on a Quantum Design model MPMS instrument in an applied magnetic field of 0.1 T. All data were corrected for the diamagnetism of the ligands as estimated from Pascal's constants.[21]

Single-Crystal X-ray Analyses: X-ray diffraction data were collected with a KUMA KM4CCD-κ-axis diffractometer for compounds **I** and **II**, anOxford-Diffraction XCALIBUR CCD instrument for **III** and a Stoe Imaging Plate Diffractometer System (IPDS)[22a] for **IV** using graphite-monochromated Mo-K_α radiation. Absorption corrections were introduced for **I**–**IV** using semi-empirical methods from symmetry equivalent reflections.[22b,22c] Crystal data, details of data collections and refinements for **I**–**IV** are given in Table 3. The structures were solved by direct methods with SHELXS-97[22d] and refined on F^2 with SHELXL-97[22e] with an anisotropic approach for non-hydrogen atoms. In the crystal structure of **IV**, two water molecules O(2*w*) and O(4*w*) are disordered over two positions in the unit cell. The ratios of the site occupancy factors of the major and minor components *sof* O(2*w*)/*sof* O(2*w**) and *sof* O(4*w*)/*sof* O(4*w**) are 3:1. The positional parameters for the hydrogen atoms of bridging OH groups in **I**–**IV** were located objectively from the difference syntheses of electronic density and were refined in isotropic approximation. The accuracy of the determinations of H-atom coordinates guarantees that the estimated standard deviations of O–H bonds are no more than 0.05 Å and those of the bond angles no more than 4° (these data are used for interpretation of magnetic properties, see above). Other hydrogen atoms were also located from the difference syntheses of electronic density, except for the H-atoms of the minor components water molecules O(2*w**) and O(4*w**) for **IV**. H-atoms were refined in an isotropic approximation for **I** and **II**, except for the H-atoms of the H_2O molecules of **II**. In all other cases the positions of H atoms were allowed to ride on a pivot atom with isotropic displacement parameters fixed at $1.5 \times U_{eq}$ for H_2O and CH_3, and $1.2 \times U_{eq}$ for CH_2 groups where U_{eq} is the equivalent isotropic displacement parameter for the pivot atom.

CCDC-244108, -244109, -244110 and -244111 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Supporting Information Available: Figure S1. Packing diagram of compound **I**. Hydrogen atoms are omitted for the sake of clarity and hydrogen bonds are indicated by dotted lines. Figure S2. Magnetic susceptibility data for **I**, **III** and **IV**. Table S1. Hydrogen bonding interactions in the crystal structures of **I**–**IV**. Table S2. Bond lengths [Å] in coordination polyhedra of the alkaline-earth metals in structures **I**–**IV**. Scheme S1. Energy level diagram for di(μ-hydroxo)chromium(III) dimers ($S = {}^3/_2$).

Acknowledgments

The authors thank Professor M. Gdaniec (Department of Chemistry, A. Mickiewicz University, Poznań, Poland) for the X-ray structure determinations of compounds **I** and **II**. Gh. Novitchi is grateful to the Swiss Federal Institute of Technology, Lausanne, for financial support. This work was also supported by the Superior Council for Sciences and Technology Developing of the R. Moldova (Project 45.003p).

Selective C–H and C–F Bond Activation Reactions of Pyridine and Fluoropyridines – Formation of Binuclear μ-X Titanocene Complexes (X = H, F) with α-Functionalized N-Heterocycles

Ingmar M. Piglosiewicz,[a] Susanne Kraft,[a] Rüdiger Beckhaus,*[a] Detlev Haase,[a] and Wolfgang Saak[a]

Keywords: Titanium / Bridging ligand / Fluorinated ligands / Nitrogen heterocycles / C–H activation / C–F activation

Titanocene synthons react with pyridine (**2**), fluorosubstituted pyridines [pentafluoropyridine (**3**), 2-fluoropyridine(**4**)] and cyanuric fluoride, by C–H and C–F bond activation, respectively, to afford interesting novel binuclear titanium(III) complexes. C–H bond activation requires high temperatures (110 °C), whereas C–F bond activation occurs at room temperature. X-ray structure analysis showed that the two titanium(III) centres are hydride-bridged when pyridine was reacted with the titanocene fragment and fluoride-bridged if a 2-fluoro-substituted derivative of pyridine was used. The reactivities of a C–F and a C–H bond in the 2-position toward the titanocene fragment have been compared in a competition experiment using 2-fluoropyridine – revealing a preference for C–F bond cleavage. Primary mononuclear C–F bond activation products have been proved in solution by NMR measurements using [$Cp^*_2Ti\{\eta^2$-$C_2(SiMe_3)_2\}$] instead of the non-methylated titanocene source.

Introduction

We recently reported that N-heterocycles such as pyrimidine, pyrazine and triazine may undergo amazing C–C couplings when reacted with the titanocene fragments [Cp_2Ti] or [Cp^*_2Ti].[1] With this kind of reaction we presume a single electron transfer from the titanium(II) centre to the N-heterocycles, as in the case of 2,2′-bipyridine and comparable chelating ligands.[2–4] Here we report reactions of low valent titanium complexes with pyridines. Examples of C–C coupling reactions of pyridine via low valent early transition metal complexes are rare.[5] As well as simple pyridine (C_5H_5N) we also wanted to use fluorinated pyridines. The electronegative fluorine substituents lower the energy of the LUMOs and increase the electron affinities,[6] which could be helpful in C–C coupling reactions. In particular, C–H or C–F bond activation reactions could also be possible.

Carbon–fluorine bond activation of several fluoroaromatics mediated by transition metal complexes has been thoroughly investigated in the last two decades. Especially, late transition metal complexes have been employed to cleave aromatic carbon–fluorine bonds by oxidative addition.[7] There are few examples for C–F bond activation reactions via electron-deficient transition metal complexes.[7–26] For titanium compounds, Burk and co-workers showed, as one of the first examples, that tetrakis(trifluoromethyl)cyclopentadienone reacts with d^0 bis(cyclopentadienyl)-titanacyclobutanes to produce titanium fluoride products.[26] Our group has given an example of complete defluorination of a CF_3 moiety, employing a titanium amide.[18] Kiplinger and Richmond reported the first hydrogenolysis of an aromatic C–F bond at ambient temperature, using an in situ generated, low-valent zirconocene fragment [Cp_2Zr].[25] They also reported the conversion of several saturated perfluorohydrocarbon compounds into the corresponding aromatic derivatives by reductive defluorination, using the Cp_2TiF_2/Al/$HgCl_2$ system.[25] Jones et al. found that zirconocene hydrides ([$Cp_2ZrH_2]_2$, [$Cp^*_2ZrH_2$]) can activate a C–F bond of perfluorobenzene at room temperature.[22,27] They suggested the reaction proceeded by oxidative addition to a low valent zirconocene intermediate[22] and an S_NAr2 of fluorinated aromatics to give either reduced fluoroaromatics or new zirconium-aryl bonds.[12] Metallation of polyfluorinated pyridines and other fluorine-containing N-heterocycles in the 2-position via C–F activation is of special interest. Perutz et al. prepared the nickel complex [$NiF(2\text{-}C_5NF_4)(PEt_3)_2$] by reacting pentafluoropyridine with [$Ni(COD)(PEt_3)_2$][28] and provided new pathways for the synthesis of uncommon tetrafluoropyridines substituted at the 2-position.[29] Substitution reactions of unsubstituted pyridines at the 2-position are common and well known.[30] There are fewer examples of the synthesis of 2-

 DOI: 10.1002/ejic.200400252

substituted pyridines mediated by early transition metal complexes.[31,32] Teuben et al. have also synthesized a 6-substituted 2-methylpyridine by hydrogen transfer using a titanium complex.[33]

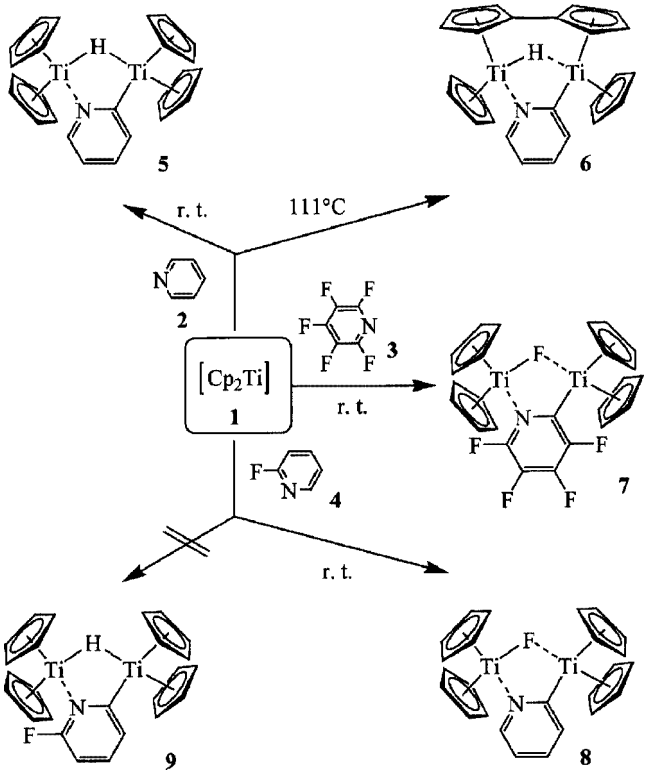
This paper describes the reactions of pyridine (**2**) and fluorosubstituted pyridines [pentafluoropyridine (**3**), 2-fluoropyridine (**4**)] with the titanocene fragments [Cp_2Ti] and [Cp^*_2Ti], generated in situ by using the corresponding bis(trimethylsilyl)acetylene complexes **10** and **13**.[34]

We also report the structure and facile synthesis of complexes **5**–**8** by activation of the 2-C–H and 2-C–F bonds of pyridine (**2**) and the fluorosubstituted pyridines **3** and **4**, respectively, using an in situgenerated titanocene fragment [Cp_2Ti] (**1**). Due to the facile preparation and its versatility the titanocene complex of bis(trimethylsilyl)acetylene (**10**)[34] was used as well as the reaction between magnesium and titanocene dichloride to generate the titanocene fragment.

Results and Discussion

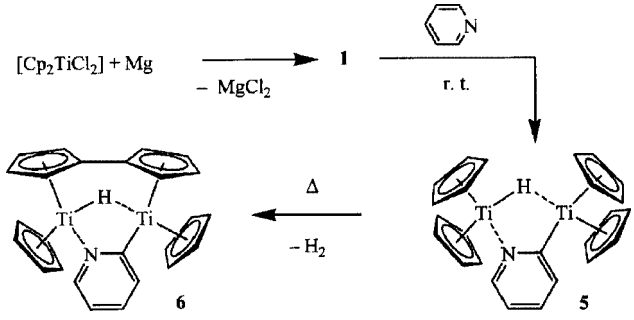
Reactivity

Upon refluxing for 3 h, a solution of [$Cp_2Ti\{\eta^2$-$C_2(SiMe_3)_2\}$] (**10**) and C_5H_4N (**2**) in toluene the color changes from yellow to red-brown. Slow evaporation leads to precipitation of dark brown crystals of the fulvalene titanium complex **6** (Scheme 1). Stirring a suspension of [Cp_2TiCl_2], Mg and an excess of **2** in THF for 48 h yields a brown solution. Brown crystals of the binuclear titanocene complex **5** can then be obtained after filtration from the magnesium chloride pyridine adduct, removal of the solvent and recrystallization of the residue from toluene. Treatment of a solution of **10** in *n*-hexane with pentafluoro- (**3**) and monofluoropyridine (**4**)at ambient temperature leads to a color change from yellow to slightly green and to the slow crystallization of the fluoride-bridged binuclear titanium derivatives **7** and **8**, respectively. All these compounds were isolated as thermally robust solids with high melting points (207–217 °C) but they decomposed rapidly upon exposure to air and moisture. Complexes **5**–**8**, isolated in 25–75% yield, have been characterized by X-ray structure analysis, mass spectrometry and elemental analysis.



Scheme 1. Reaction of **1** (generated in situ from [$Cp_2Ti\{\eta^2$-$C_2(SiMe_3)_2\}$] or [Cp_2TiCl_2]/Mg) with pyridines **2**–**4**.

In all reactions of the in situ generated titanocene fragment **1** and N-heterocycles **2**–**4** we observed C–H or C–F bond activation at the 2-position and transfer of hydrogen or fluorine, respectively, into the titanium coordination sphere. The titanium(III) centres of the resulting dimeric complexes are bridged by a hydride and a fluoride, respectively, and the metallated pyridyl ligand. As expected for compounds with unpaired electrons the ^1H NMR spectra (300 MHz, 25 °C, C_6D_6) of the Ti^{III} complexes show either no or paramagnetically broadened signals. The positions of the signals are reproducible and provide a characteristic fingerprint. For the syntheses of complexes **6**–**8** the titanocene complex of bis(trimethylsilyl)acetylene (**10**) was used as the source of titanocene fragment **1**.[35] The reaction of **10** with pyridine (**2**) requires higher temperatures and results in the coupling of two Cp ligands, leading to fulvalene complex **6**. Conversely, **2** reacts with the titanocene generating system [Cp_2TiCl_2/Mg] at room temperature[36] to give complex **5** with no Cp ligand coupling (Scheme 2).



Scheme 2. Formation of fulvalene-bridged titanocene complex **6**.

Complex **5** has been isolated as an intermediate in the hydrosilylation of pyridines with silanes catalyzed by low valent titanocene complexes.[37] In this reaction the silane provides the bridging hydride of **5**, and the pyridine undergoes the ortho-metallation under liberation of H_2. The reaction between the titanocene fragment (**1**) and pyridine (**2**) shows that **5** can also be synthesized by C–H activation without an external hydride source. Several facts indicate that the reaction to **6** probablyproceeds via a preliminary hydride transfer from the pyridine and a subsequent coupling of the Cp ligands. The mass spectrum of **5** has no molecular peak, but one at [$M^+ - H_2$] (40% intensity) shows that this complex easily loses H_2, which suggests that the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

higher reaction temperature could explain the Cp ligand coupling and the formation of **6** instead of **5** if acetylene complex **10** is used to generate titanocene **1**. This is supported by the spectra of the product isolated after refluxing a solution of **5** for 3 h in toluene. IR and ^{1}H NMR spectra are identical to those of the fulvalene-bridged complex **6**, while the characteristic signals of **5** have vanished. For **5** a broad signal at δ = 31 ppm in the ^{1}H NMR spectrum is consistent with investigations by Harrod and Samuel, who assigned this signal to Cp ligands.[37] The ^{1}H NMR spectrum of **6** shows weaker broad signals at δ = 8.9,9.5, 10.9, 11.1,16.2 and 21.5 ppm. Accordingly, it seems reasonable to propose **5** as an intermediate in the reaction of **10** with **2** to give **6** because the coupling reaction follows its formation if the reaction is carried out at a higher temperature (Scheme 2).

The fact that [$Cp_2Ti\{\eta^2$-$C_2(SiMe_3)_2\}$] (**10**) reacts with perfluorinated pyridine (**3**) to afford complex **7** at room temperature, whereas pyridine only reacts at >100 °C, indicates that fluorine transfer is a favored reaction pathway. This has been confirmed by a C–H/C–F competition experiment with 2-fluoropyridine (**4**), which bears hydrogen as well as fluorine in the 2-position. In this reaction the selective transfer of fluorine occurs, and only the C–F activation product **8** is observed. The alternative C–H activation product **7** is not found. Under preparative conditions **8** could be isolated in 71% yield. A comparison of C–F and C–H bond activation by zerovalent nickel and platinum complexes shows, by DFT calculation, a preferred exothermic C–F bond activation, owing to a strong thermodynamic preference for C–F over C–H bond activation and a relatively low kinetic barrier.[38] Generally, ortho-substituted aryl fluorides undergo C–F bond activation. In such a way [Cp^*_2Zr(o-C_6H_4F)H] reacts by β-fluoride elimination to give [$Cp^*_2Zr(C_6H_5)$F].[20] The selectivity of C–F versus C–H activation depends on the nature of the transition metal system. Late transition metal complexes (Rh,[39] Os[40,41]) often prefer C–H over C–F activation reactions, whereas [Ru(dmpe)$_2H_2$] and partially fluorinated arenes produce only C–F bond activation products.[42] The insertion of tungsten in a C–F bond in the presence of C–H bonds was one of the first examples.[43]

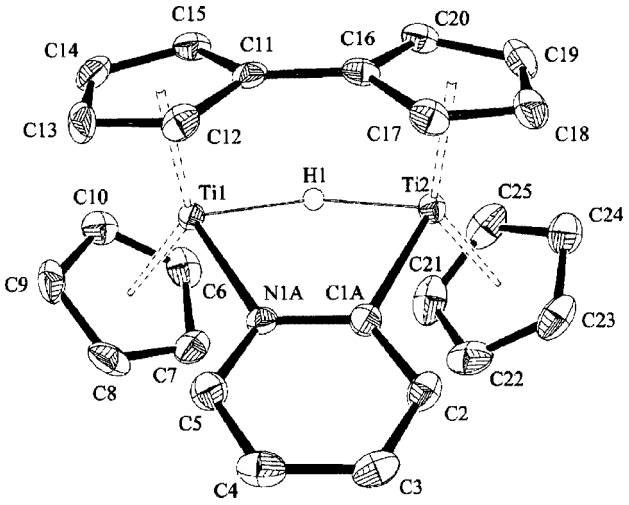


Figure 1. Molecular structure of **6**: ORTEP plot with 50% probability thermal ellipsoids; hydrogen atoms omitted for clarity.Thebridging H-atom has been freely refined. Selected bond lengths [Å] and angles [°]: Ti1–Ti2 3.324, Ti1–H1 1.85(3), Ti1–N1A 2.205(3), Ti2–H1 1.79(3), Ti2–C1A 2.205(3), Ti1–Ct1 2.062, Ti1–Ct2 2.040, Ti2–Ct3 2.050, Ti2–Ct4 2.065; Ct1–Ti1–Ct2 139.79, Ct3–Ti2–Ct4 137.21, H1–Ti1–N1A 84.6(9), H1–Ti2–C1A 84.7, Ti1–H1–Ti2 131.64, Ct1 = centroid of C6–C10, Ct2 = centroid of C11–C15, Ct3 = centroid of C16–C20, Ct4 = centroid of C21–C25.

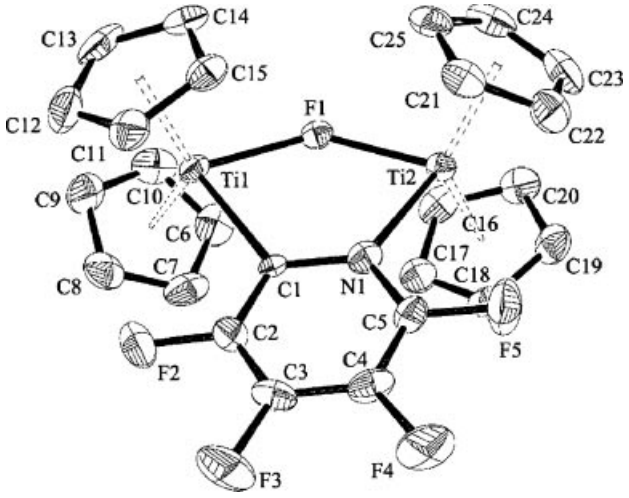

Figure 2. Molecular structure of **7**: ORTEP plot with 50% probability thermal ellipsoids. The asymmetric unit contains two independent molecules A and B; only data for A are given; hydrogen atoms omitted for clarity.Selected bond lengths [Å] and angles [°]: Ti1–Ti2 3.829, Ti1–F1 2.0487(13), Ti1–C1 2.277(2), Ti2–N1 2.288(2), Ti2–F1 2.0448(15), Ti1–Ct1 2.076, Ti1–Cpt 2.075, Ti2–Ct3 2.071, Ti2–Ct4 2.078; Cp1–Ti1–Ct2 132.72, Ct3–Ti2–Ct4 131.86, F1–Ti1–C1 78.31(7), F1–Ti2–N1 77.79(7), Ti1–F1–Ti2 138.62(8), Ct1 = centroid of C6–C10, Ct2 = centroid of C11–C15, Ct3 = centroid of C16–C20, Ct4 = centroid of C21–C25.

Crystal Structures of 6–8

Crystals suitable for X-ray structure analysis were obtained either directly from the reaction mixtures or after recrystallization from toluene for complex **5** and from fluorobenzene for complex **7**. Figure 1, Figure 2 and Figure 3 show the molecular structures of **6**–**8**, respectively.

Due to slight disorder of the pyridyl ligands in **6**–**8**, the Ti1–C1 and Ti2–N1 bond lengths could not be determined reliably. The asymmetric unit of **7** contains two independent molecules, A and B. Since the two molecules do not exhibit significant differences only the structure of A will be discussed. The bridging H-atom of **6** could be freely refined and the bond lengths between titanium and hydrogen, which average 1.82(3) Å, are in the same range as in the published structure of **5**[37] but shorter than in the analogue fulvalene hydrido chloride complex.[44] Ti–F bond lengths for **7** (2.047 Å) and **8** (2.051 Å) (average) are in the range expected for bent bridging Ti–F–Ti bonds.[45–48] The Ti–Ti distance in **6** (3.324 Å) is considerably shorter than in **7** (3.829 Å) and **8** (3.788 Å), probably due to the minor steric

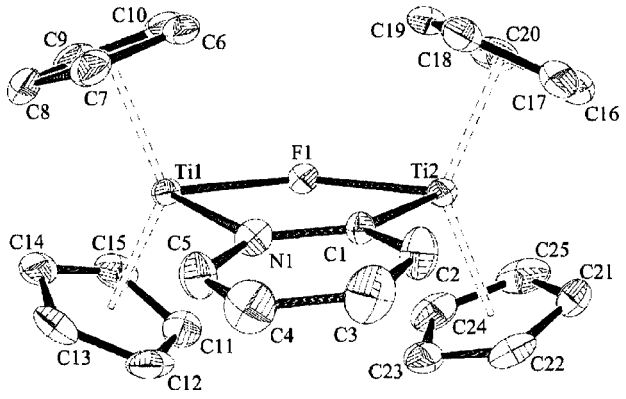

Figure 3. Molecular structure of **8**. ORTEP plot with 50% probability thermal ellipsoids; hydrogen atoms omitted for clarity. Selected bond lengths [Å] and angles [°]: Ti1–Ti2 3.788, Ti1–F1 2.0507(11), Ti1–N1 2.2271(18), Ti2–F1 2.0504(11), Ti2–C1 2.2252(18), Ti1–Ct1 2.081, Ti1–Ct2 2.078, Ti2–Ct3 2.084, Ti2–Ct4 2.083; Ct1–Ti1–Ct2 131.67, Ct3–Ti2–Ct4 132.91, F1–Ti1–N1 79.27(5), F1–Ti2–C1 79.60(6), Ti1–F1–Ti2 134.91, Ct1 = centroid of C6–C10, Ct2 = centroid of C11–C15, Ct3 = centroid of C16–C20, Ct4 = centroid of C21–C25.

demand of the hydride and the presence of the fulvalene bridge. In all three complexes the distance is beyond the range of a direct Ti–Ti interaction.

Reaction of 10 with Cyanuric Fluoride

Reactions between **10** and fluorinated and non-fluorinated triazine further support the cleavage of a C–F bond as a favored pathway in reactions of fluorinated N-heterocycles and low-valent titanium complexes. Scheme 3 shows the two reaction pathways.

Triazine reacts with **10**, through C–C coupling, to give a dimeric chelate ligand,[1] whereas the fluorinated analogue reacts through α-F-activation to form a complex similar to those obtained in the reactions with pyridines (Scheme 3).

Crystal Structure of 11

Figure 4 shows the molecular structure of **11**. Unlike the disordered pyridyl ligands in **6**–**8**,the N-heterocyclic ligand in **11** showed no disorder. The fluoride-bridge in **11** is approximately symmetric. Ti–F distances [Ti1–F1 = 2.0413(18) Å; Ti2–F1 2.0619(18) Å] are typical for fluoride-bridged Ti complexes[45] (Ti–F = 2.046 Å in $[(\eta^5\text{-}C_5H_5)Ti(\mu\text{-}F)]_2(\mu\text{-}\ \eta5\text{:}\ \eta5\text{-}C_{10}H_8)]$;[48] Ti–F = 2.092 Å in $[(C_5H_4Me)_2\text{-}TiF]_2$[49]). The Ti–Ti distance (3.831 Å) is similar to those in **6**–**8**. The Ti2–C1 bond [2.229(3) Å] is slightly shorter than the Ti1–C1 bond [2.293(3) Å]. Generally, **11** has the same structural characteristics as **6**–**8**.

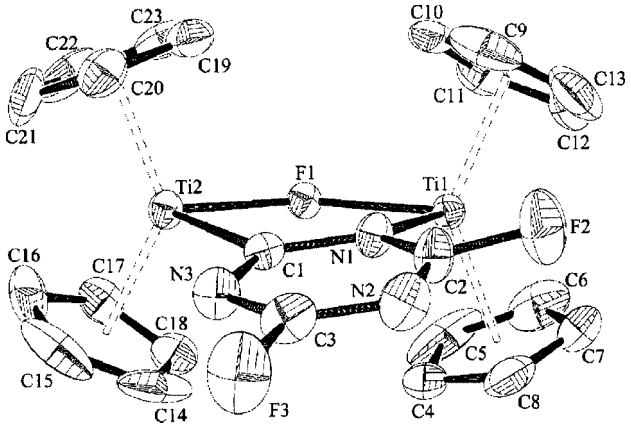

Figure 4. Molecular structure of **11**: ORTEP plot with 50% probability thermal ellipsoids; hydrogen atoms omitted for clarity. Selected bond lengths [Å] and angles [°]: Ti1–Ti2 3.831, Ti1–F1 2.0413(18), Ti1–N1 2.293(3), Ti2–F1 2.0619(18), C1–N1 1.391(4), N1–C2 1.324(4), C2–N2 1.310(4), N2–C3 1.318(5), C3–N3 1.299(4), N3–C1 1.373(4), Ti2–C1 2.229(3), Ti1–Ct1 2.067, Ti1–Ct2 2.073, Ti2–Ct3 2.067, Ti2–Ct4 2.072; Ct1–Ti1–Ct2 132.18, Ct3–Ti2–Ct4 133.66, F1–Ti1–N1 77.39, F1–Ti2–C1 78.62, Ti1–F1–Ti2 138.02(9), Ct1 = centroid of C4–C8, Ct2 = centroid of C9–C13, Ct3 = centroid of C14–C18, Ct4 = centroid of C19–C23.

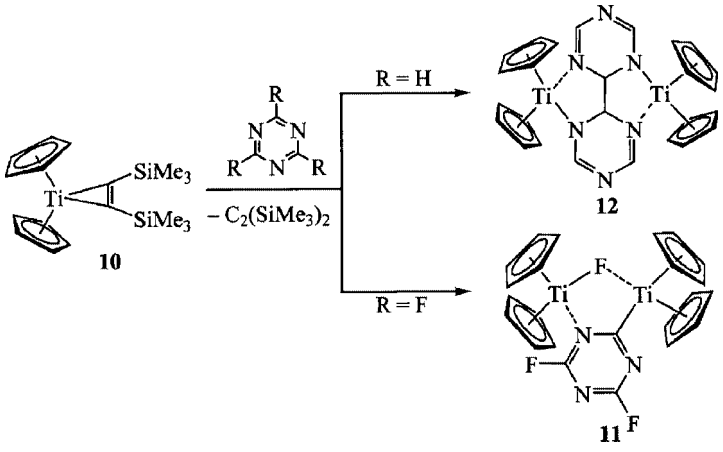
Reactions of $[Cp^*_2Ti\{\eta^2\text{-}C_2(SiMe_3)_2\}]$ (13) with Fluorinated N-Heterocycles

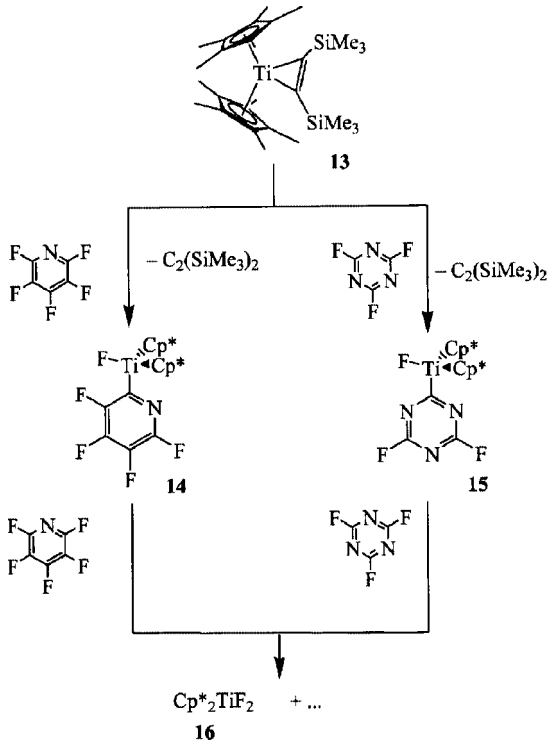
To understand the formation of binuclear complexes **7**, **8** and **11** reactions were performed using the permethylated complex $[Cp^*_2Ti\{\eta^2\text{-}C_2(SiMe_3)_2\}]$ (**13**)[34] instead of the non-methylated analogue **10**.



Scheme 3. Reaction of **10** with triazine and cyanuric fluoride.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Both fluorosubstituted pyridines and cyanuric fluoride react with **13** to give $[Cp^*_2TiF_2]$ (**16**) as the final product and not binuclear, fluoride-bridged titanocene complexes. Mass spectroscopic investigations, as well as ^1H, ^{13}C and ^{19}F NMR experiments, revealed the intermediate formation of mononuclear Ti^{IV} complexes, which react further with fluorinated starting material to form **16** (Scheme 4).



Scheme 4. Reaction of $[Cp^*_2Ti\{\eta^2\text{-}C_2(SiMe_3)_2\}]$ (**13**) with pentafluoropyridine and cyanuric fluoride, with intermediate formation of mononuclear complexes **14** and **15**.

^1H, ^{13}C and ^{19}F NMR spectroscopic data of **14** were obtained by recording NMR spectra of a corresponding reaction mixture. Therefore, the acetylene complex **13** was reacted with pentafluoropyridine for 2 h at 60 °C in *n*-hexane. The volatiles were then removed and the resulting solid was redissolved in C_6D_6. The ^{19}F NMR spectrum of the reaction mixturedisplaysfour multiplets of equal integration in the fluoroaromatic region at δ = –170.31, –147.48, –130.08 and –87.61, which are assignable to the fluoro nuclei of the pyridyl ligand of complex **14**. These δ are in excellent agreement with ^{19}F NMR spectroscopic data given for the complex $[NiF(2\text{-}C_5NF_4)(PEt_3)_2]$, which contains a fluorosubstituted pyridyl ligand with an analogous substitution pattern (δ –173.38, –150.75, –131.33, –84.70).[50] The spectrum also shows a singlet for the metal fluoride of **14** at δ = 128.82. Another ^{19}F resonance at δ = 74.14 was assigned to the final product $[Cp^*_2TiF_2]$ (**16**), which is consistent with the NMR spectroscopic data of pure **16** in C_6D_6 prepared according to the literature.[51] The proton spectrum of the reaction mixture shows a singlet at δ = 1.56, assigned to **14**, and, as expected, a further singlet at δ = 1.82, which was assigned to **16**. The single resonance seen for the protons of **14** reveals that the Cp*–Ti–Cp* plane is orthogonal to that of the pyridyl ligand. Consistently, only two signals assigned to the Cp* ligands of **14** arise in the ^{13}C NMR spectrum, at δ = 11.3 and 124.4, respectively. Two further signals, at δ = 11.2 and 124.9, are as expected for **16**. To determine that **14** is formed as an intermediate that reacts with pentafluoropyridine to give the final product **16** the reaction was monitored by following the increase of the ^1H resonance of **14** at δ = 1.56 as the reaction starts and the decrease of this resonance while that assigned to **16** at δ = 1.82 increases. Analogues NMR investigations revealed the formation of the intermediate complex **15** and, subsequently, **16** in the reaction between **13** and cyanuric fluoride (Scheme 4). Besides **16**, NMR investigations could characterize no further products. The fate of the fluoroaromatic ligands could not be clarified. The fluoroaromatic region of the ^{19}F spectra showed several additional signals of very low intensity, probably due to the formation of multiple compounds in low concentration. Table 1 summarizes the ^1H and ^{19}F NMR spectroscopic data of intermediates **14** and **15**.

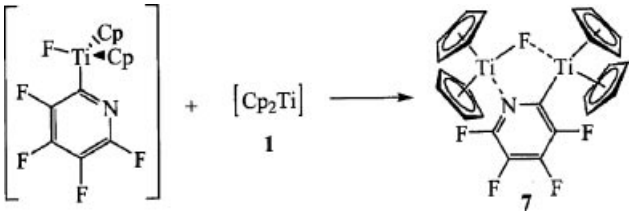
Table 1. NMR spectroscopic data of **14**, **15** (C_6D_6, 298 K).[a]

Complex	^1H	^{19}F
14	1.56 (s, 30 H, CH_3)	128.82 (s, 1 F, Ti–F)
		–87.61 (m, 1 F)
		–130.08 (m, 1 F)
		–147.48 (m, 1 F)
		–70.31 (m, 1 F)
15	1.53 (s, 30 H, CH_3)	128,71 (s, 1 F, Ti–F)
		–41.00 (d, J_{FF} = 12, 1 F)
		–45.31 (d, J_{FF} = 12, 1 F)

[a] Reported in ppm (δ) and *J* values in Hz.

Mass spectra (MS CI, *iso*-butane) of reaction mixtures prepared analogously to those used for the NMR investigations also showed evidence for the intermediate formation of mononuclear Ti^{IV} complexes **14** and **15**. The spectra show the characteristic fragments $[M + 1]^+$, $[M - F]^+$, $[Cp^*_2TiF_2]^+$, $[Cp^*_2TiF]^+$ and $[Cp^*]^+$ (M = molecular mass of **14** and **15**, respectively). Due to their similarly high solubilities, **14** and **15** could not be separated from the final product **16**.

Intermediate formation of mononuclear Ti^{IV} complexes can also be assumed in the reactions to **6**–**8**, and **11**. The Ti^{IV} species might subsequently react further with in situ generated titanocene $[Cp_2Ti^{II}]$ in terms of a comproportion reaction that results in Ti^{III} complexes **6**–**8** and **11** (Scheme 5).



Scheme 5. Proposed formation of binuclear Ti^{III} complex **7**.

The observed preference for C–F activation at the 2-position of the fluoropyridines provides indirect evidence for concerted oxidative addition of the heterocycles via a three-centered transition state, as proposed for nickel-mediated C–F bond activation reactions.[52] A primary electron transfer reaction pathway, as expected from the reducing properties of titanium(II) derivatives, can be excluded due to the absence of reactions at the 4-position, which are found as a result of the formation of ion pairs or Meisenheimer type intermediates.[53–56]

Conclusions

Titanocene-generating systems can selectively activate 2-C–H and 2-C–F bonds of pyridine and fluorosubstituted pyridines, respectively, in reactions that yield dimeric, hydride-bridged Ti^{III} complexes. C–F activation reactions at room temperature between the titanocene source $[Cp_2Ti\{\eta^2\text{-}C_2(SiMe_3)_2\}]$ and the fluorosubstituted N-heterocycles pentafluoropyridine and 2-fluoropyridine, as well as cyanuric fluoride, afforded dimeric, fluoride-bridged titanocene complexes that were isolated in good yields. The reaction of $[Cp_2Ti\{\eta^2\text{-}C_2(SiMe_3)_2\}]$ with 2-fluoropyridine showed that 2-C–F activation is preferred over 2-C–H activation. The ease synthesis of polyfluorinated pyridines metallated at the 2-position, via C–F activation reactions, may offer new opportunities to synthesize polyfluorinated pyridines substituted at the 2-position. Such compounds are very difficult to prepare by either electrophilic or nucleophilic substitution.[53,57–60]

Experimental Section

General Remarks: All operations were performed under nitrogen with rigorous exclusion of oxygen and moisture using glove box or Schlenk techniques. Solvents were thoroughly dried and saturated with nitrogen. ^1H and ^{19}F NMR spectra were recorded with a Bruker AVANCE 300 spectrometer (^1H, 300.1 MHz; ^{19}F, 282.4 MHz). ^1H NMR chemical shifts were referenced to residual protons of the solvent; ^{13}C and ^{19}F NMR spectra were referenced to C_6D_6 and $CFCl_3$ (externally), respectively. Electron impact (EI) mass spectra were recorded with a Finnigan-MAT 95 Spectrometer. IR spectra were recorded with a BIO-RAD FTS-7 Spectrometer using KBr pellets. Elemental analyses were carried out by the Analytischen Laboratorien in Lindlar (Germany). $[Cp_2Ti\{\eta^2\text{-}C_2(SiMe_3)_2\}]$ (**10**) and $[Cp^*_2Ti\{\eta^2\text{-}C_2(SiMe_3)_2\}]$ (**13**) were prepared according to the literature.[34] All heterocyclic compounds (Aldrich) were used as received.

Preparation of Complex 5: A suspension of Cp_2TiCl_2 (1 g, 4 mmol), magnesium (96 mg, 4 mmol) and pyridine (2 mL, excess) in THF (40 mL) was stirred for 48 h. The solution turned dark brown and a white solid precipitated. The mixture was then concentrated and the resultant brown solid was dissolved in toluene (20 mL) and filtered. Concentrating the solution to a few mL afforded 420 mg (48%) of **5** as brown crystals that were washed with *n*-hexane and dried in vacuo. M.p. 217–219 °C; ^1H NMR (C_6D_6): δ = 31.0, 16.3, 14.0, 11.1, 10.9 ppm broad signals. IR (KBr): $\tilde{\nu}$ = 3075, 1601, 1441, 1217, 1067, 1009, 793, 758, 698, 629 cm^{-1}. $C_{25}H_{25}NTi_2$ (435.24 $g\,mol^{-1}$); MS (70 eV): *m*/*z* (rel. intensity) 433 (40) [$M^+ - H_2$], 354 (100) [$M^+ - C_5H_7N_2$], 288 (20), 260 (15), 178 (85) [$Cp_2Ti]^+$, 113 (20) [$CpTi]^+$, 66 (15) [$CpH]^+$ The experimental data, including the molecular structure determined by single crystal X–ray diffraction, agree with published results.[37]

Preparation of Complex 6: A solution of **10** (1 g, 2.87 mmol) and pyridine (2 mL, excess) in toluene (30 mL), heated under reflux for 3 h, turned dark brown. Concentrating the solution to a few mL afforded 150 mg (24%) of **6** as brown crystals that were washed with *n*-hexane and dried in vacuo. M.p. 203–205 °C; ^1H NMR (C_6D_6): δ = 16.2, 11.0, 10.9, 9.5, 8.9 ppm broad paramagnetic signals. IR (KBr): $\tilde{\nu}$ = 3079, 1576, 1520, 1435, 1242, 1042, 1009, 8097, 799, 735, 631, 586 cm^{-1}. MS (70 eV): *m*/*z* (rel. intensity) 433 (50) [M^+], 354 (100) [$M^+ - C_5H_5N$], 288 (25), 260 (18), 178 (25) [$Cp_2Ti]^+$, 113 (25) [$CpTi]^+$. HR-MS: calcd 433.0789; found 433.0793. $C_{25}H_{23}NTi_2$ (433.22 $g\,mol^{-1}$): calcd H 5.35, C 69.31, N 3.23; found H 5.39, C 69.06, N 3.11.

Preparation of Complex 7: 10 (300 mg, 0.86 mmol) and pentafluoropyridine (**3**) (72.8 mg, 0.43 mmol) were dissolved in *n*-hexane (60 mL) at room temperature. After 24 h crystals precipitated, and the reaction was complete after one week. The mixture changed from yellow to slightly green during the reaction. Crystals, separated from the solution by decanting, were washed twice with *n*-hexane (20 mL) and subsequently dried in vacuo. The yield of **7** was 158 mg (70%) as green-yellow crystals. Crystals suitable for X-ray structure analysis were obtained from fluorobenzene. M.p. 207 °C, IR (KBr): $\tilde{\nu}$= 3937, 3090, 2955, 1715, 1620, 1588, 1505, 1478, 1437, 1373, 1252, 1090, 1013, 795, 691, 592, 471, 395, 226 cm^{-1}. MS (70 eV): *m*/*z* (rel. intensity) 328 (95) [$M^+ - Cp_2TiF$], 197 (80) [$Cp_2TiF]^+$, 178 (85) [$Cp_2Ti]^+$, 132 (100) [$CpTiF]^+$. $C_{25}H_{20}F_5NTi_2$ (525.19 $g\,mol^{-1}$): calcd. H 3.84, C 57.18, F 18.09; found H 3.78, C 56.97, F 18.01.

Preparation of Complex 8: 10 (300 mg 0.86 mmol) and 2-fluoropyridine (41.8 mg 0.43 mmol) (**4**) were dissolved in *n*-hexane (60 mL) at room temperature. After one week, the solution was cooled to 0 °C and tawny crystals precipitated. During the reaction the mixture changed from yellow to slightly green. Crystals, separated from the solution by decanting, were washed twice with *n*-hexane (20 mL) and subsequently dried in vacuo. The yield of **8** was 139 mg (71%) as tawny crystals. Crystals suitable for X-ray structure analysis were obtained from the reaction mixture. M.p. 211 °C, IR (KBr): $\tilde{\nu}$= 3090, 2955, 2724, 2367, 2276, 2081, 1651, 1578, 1532, 1449, 1441,1398,1362, 1260, 1154, 1065, 1013, 795, 727, 667, 590, 485, 451, 422, 378 cm^{-1}. MS (70 eV): *m*/*z* (rel. intensity) 256 (100) [$M^+ - Cp_2TiF$], 197 (70) [$Cp_2TiF]^+$, 178 (60) [$Cp_2Ti]^+$, 132 (95) [$CpTiF]^+$. $C_{25}H_{24}FNTi_2$ (453,23 $g\,mol^{-1}$): calcd. H 5.34, C 66.26, F 4.02; found H 5.23, C 65.91, F 4.19.

Preparation of Complex 11: 10 (300 mg, 0.86 mmol) and cyanuric fluoride (**9**) (58.1 mg, 0.43 mmol) were dissolved in *n*-hexane (60 mL) at room temperature. After 6 h a brown solid and dark brown crystals precipitated; the reaction was completed after 3 days. The solid, separated from the solution by decanting, was washed twice with *n*-hexane (20 mL) and subsequently dried in vacuo. The yield of **9** was 148 mg (70%) as a brown solid. Crystals suitable for X-ray structure analysis were obtained from the reaction mixture. M.p. 160 °C (dec.), IR (KBr): $\tilde{\nu}$= 3740, 3104, 2955, 2864, 2733, 2517, 2367, 2338, 1615, 1580, 1495, 1398, 1260, 1094, 1017, 804, 689, 590, 463, 397, 328, 303, 280 cm^{-1}. MS (70 eV): *m*/*z* (rel. intensity) 197 (60) [$Cp_2TiF]^+$, 178 (20) [$Cp_2Ti]^+$, 132 (100) [$CpTiF]^+$, 65 (50) [$Cp]^+$. $C_{23}H_{20}F_3N_3Ti_2$ (491.19 $g\,mol^{-1}$): H 4.10, C 56.24, F 11.60; found H 4.13, C 55.99, F 11.32.

Two Novel Transition-Metal Phosphite Compounds with 4-, 6- and 12-Membered Rings: Hydrothermal Syntheses, Crystal Structures and Magnetic Properties of $Na_2[M(HPO_3)_2]$ (M = Fe, Co)

Wei Liu,[a] Hao-Hong Chen,[a] Xin-Xin Yang,[a] and Jing-Tai Zhao*[a]

Keywords: Synthesis / Structure / Cobalt / Iron / Phosphites / Magnetic properties

Two transition-metal phosphites, $Na_2[M(HPO_3)_2]$ (M = Fe, Co) with a new structure type have been synthesised under mild hydrothermal conditions and the solid-state structures have been elucidated by single-crystal X-ray diffraction studies. The structures are of a new type with the following data: orthorhombic, *Pnma*, a = 12.169(4), b = 5.441(2) and c = 9.146(3) Å for the iron species **1** and a = 12.091(3), b = 5.400(4) and c = 9.115(2) Å for the cobalt compound **2**, with Z = 4. The crystal structures of these compounds are isotypic and built up from a 3D open framework with 4-, 6- and 12-membered polyhedral rings of vertex-linked MO_6 and HPO_3 building units. The inorganic frameworks contains 12-membered ring channel systems in which the sodium ions are located. The topology of this structure type is remarkably similar to that of the aeschynite $CaTa_2O_6$ with much larger channels. Magnetic measurements of $Na_2[Co(HPO_3)_2]$ show different magnetic features in the low-temperature (5–30 K) and high-temperature ranges (100–320 K) suggesting the possible existence of a complex magnetic structure. Antiferromagnetic ordering can be observed as a broadened cusp in χ^{-1} at θ = 2.6 K. For $Na_2[Fe(HPO_3)_2]$, the magnetic behavior follows the Curie–Weiss law with μ_{eff} = 5.41 μ_B, fitted for 100–320 K.

Introduction

Transtion-metal phosphates with open-framework structures are of great interest from both an industrial and an academic point of view due to their applications as catalysts, ion-exchangers and molecular sieves.[1] Although attention has focused initially on the phosphates of aluminium and gallium because of their structural similarities with zeolites and clays, numerous open-framework transition-metal phosphates with novel properties are also known.[2–17] Besides, in the past few years, considerable efforts have been devoted to exploratory work on the possibilities of incorporating the phosphorus atom as a pseudo-pyramidal HPO_3^{2-} hydrogen phosphite group into extended structures and these studies have yielded a structurally diverse range of transition-metal phosphites, e.g. $(VO)(HPO_3)(H_2O)_5$ with isolated single chains,[18] $ZnCa(HPO_3)_2(H_2O)_2$,[19] $Fe(HPO_3H)_3$,[20] $M(HPO_3)(H_2O)$ (M = Co, Ni)[21] and $(NH_4)_2Zn_5(HPO_3)_6(H_2O)_4$[22] with layered structures as well as $NaM(H_2PO_3)_3(H_2O)$ (M = Mn, Co),[23] $[Zn_2(H_2O)_4](HPO_3)_2(H_2O)$,[24] $Na_2Zn_3(HPO_3)_4$[24] and $M_{11}(HPO_3)_8(OH)_6$ (M = Co, Ni, Zn)[25] with 3D structures. A few examples of inorganic-organic hybrid phosphites with transition-metal elements (V, Cr, Co, Mn, Fe) have also been reported in the literature.[26–30] However, phosphites with transition-metal elements have not been studied widely when compared with the related phosphates. In order to further examine the structural chemistry of these types of materials containing the first series of transition elements, we synthesised two new transition-metal phosphites of formula $Na_2[M(PO_3H)_2]$ (M = Fe, Co). The crystal structures of these compounds and their magnetic properties are also reported in this paper.

Results and Discussion

Synthesis

Reactions of phosphorous acid with the transition-metal salts in the presence of NaOH under mild hydrothermal conditions afforded two new isostructural complexes with 3D open-frameworks. According to experimental investigations, we noted that the pH value has a significant influence on the reaction products. To obtain information about the reactive process of $Na_2[M(HPO_3)_2]$ (M = Fe, Co), an in-depth study at various pH values was carried out. Different experiments were performed with the pH = 1.0, 3.0, 5.0, 7.0 and 9.0 but all other conditions were kept constant. The study of the final products by X-ray powder diffraction measurements revealed that when the pH ≤ 5.0, the reactions lead to an unknown powder for $Na_2[Fe(HPO_3)_2]$ (**1**)

 DOI: 10.1002/ejic.200400644

and a known compound, $Co(PO_3H)\cdot H_2O$ (JCPDS: 44-1323) for $Na_2[Co(HPO_3)_2]$ (**2**) while with a pH > 5.0 the title compounds were isolated as pure phases (Scheme 1). When thinking about the synthesis of transition-metal derivatives of this low-oxidation-state phosphorous acid, it becomes necessary to consider the problems resulting from the hydrolytic processes of phosphorous acid which would be essentially controlled by the pH of the solution.[31] In this context, it becomes possible to understand the experimental results obtained when the syntheses of the title compounds were performed. Since the protons of the phosphorous acid are easily removed under alkaline conditions, the phosphorus atom is suitable for simultaneously binding to three M^{II} atoms to form the polyhedral network of alternating MO_6 and PO_3H units in the title compounds. On the contrary, with a decrease in the pH value, less protons from the phosphorous acid can be removed which correspondingly reduces the degree of coordination of the phosphorus atoms to the M^{II} atoms. Therefore, the cationic groups in the solution tend to aggregate themselves under suitable conditions, leading to the resultant cationic network in the final solid $Co(PO_3H)\cdot H_2O$. Similar results have also been reported by Marcos et al. in their synthetic process.[25] For example, they were also able to prepare $M(HPO_3)(H_2O)$ (M = Co, Ni, Zn) at low pH whereas by carrying out the synthesis at intermediate pH values, other compounds with a different structure type were obtained, namely $M_{11}(HPO_3)_8(OH)_6$ (M = Zn, Co, Ni). All the above observations indicate that the pH of the solution indeed plays a crucial role in the reactive process and mainly determines the stability ranges of the various compounds.

Crystal Structures of $Na_2[M(HPO_3)_2]$ (M = Fe and Co)

The crystal structures of the two isotypic compounds both contain a 3D anionic framework made from polyhedral linkages between MO_6 and HPO_3 units sharing common O-corners. Such connectivities between these units produce numerous six-membered rings which connect to each other by sharing common edges giving rise to an infinite honeycomb-like six-membered sheet in the *bc* plane [see Figure 1 (left)]. Pairs of phosphite groups are distributed between these sheets and bridge the sheets into the whole 3D open-framework. An offset between the sheets in the [001] direction destroys the formation of a six-membered ring channel system along the *a* axis [see Figure 1 (right)] but the 4- and 12-membered ring channel systems are distributed alternately in the structure along the *b* axis which is enclosed by the 4- and 6- membered ring walls [see Figure 2 (d)]. The shape of the 12-membered ring channel is close to rhombohedral with the largest length being 12.8 Å and the smallest being 6.8 Å. Therefore, the structures of the title compounds examined here can also be characterised by the presence of an infinite number of 4-, 6- and 12-membered polyhedral rings.

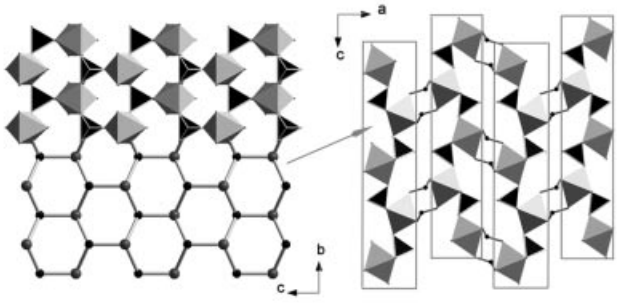

Figure 1. (left) The 6-membered ring polyhedral sheet in the *bc* plane constructed from alternating MO_6 and HPO_3 polyhedra. (right) The parallel stack of 6-membered ring sheets along the [010] direction showing the offset along the *c* axis between the sheets (MO_6, grey octahedron; PO_3H, dark tetrahedron; M atom, gray sphere; P atom, dark sphere).

More importantly, a detailed analysis of the structures allows the entire framework in each case to be described as an assembly of multiple ribbons running along the *b* axis. Such multiple ribbons are built up from two distinct types of single polyhedral ribbons: the linear chain possessing corner-shared four-membered rings [Figure 2(a)] and the ladders with edge-sharing four-membered rings [Figure 2 (b)]. The centred ladder interconnects with two neighbouring linear chains through edge sharing and forms a novel unbranched multiple-chain running along the *b* axis [Figure 2 (c)]. Such multiple-ribbons repeat themselves in parallel along the *c* axis in a zigzag-like manner with an angle of approximately 120° along the *a* axis [Figure 2 (d)], giving rise to a fish backbone-type arrangement in the *bc* plane. Such multiple-chains connect to each other through the M–O–P bridges to form the entire open-framework [Figure 2 (e)].

The guest Na^+ ions occupy the open spaces in the framework to maintain the structural stability and satisfy the charge balance. The $Na(1)^+$ ions are located in the twelve-membered ring channels and the $Na(2)^+$ ions occupy the centres of the six-membered rings, respectively (see Figure 3).

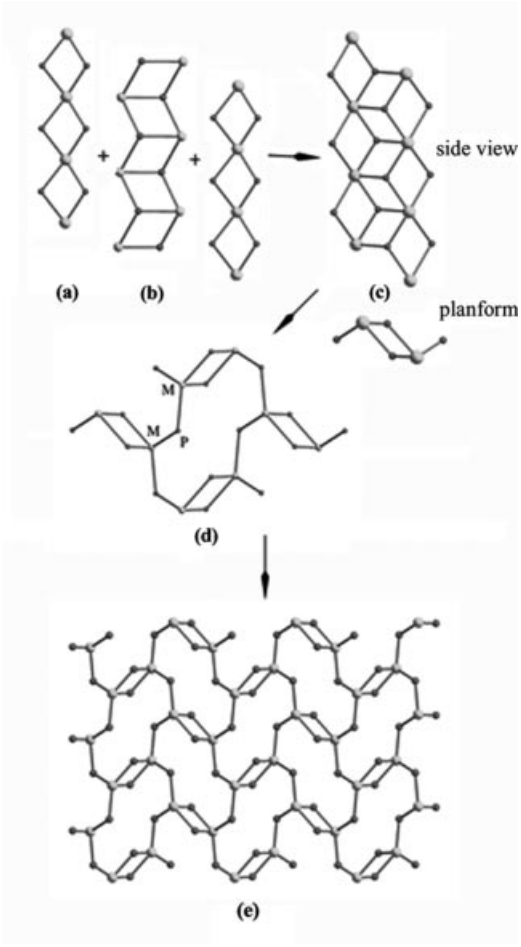

Figure 2. Schematic representation of the formation of the open-framework structure of $Na_2[M(HPO_3)_2]$ (M = Fe, Co). (a) The linear chain possessing corner-shared four-membered rings. (b) The ladders with edge-shared four-membered rings. (c) The loop-branched multiple ribbon. (d) The combination of four multiple ribbons to form a 12-membered ring via the M–O–P bridge. (e) The infinite 3D open-framework.

The topology of this structure is remarkably similar to that of the aeschynite $CaTa_2O_6$ (see Figure 4). According to the concept of scale chemistry,[32,33] the two structures can be considered as though they have the same walls (topology) but are built from different bricks (BUs). The latter has the double rows of TaO_6 octahedra as BUs, while the former has an upper analogue in which the BUs are the multiple ribbons made of corner-shared tetrahedra and octahedra. The *trans* corner linkage of the BUs givs rise to zigzag chains and Na^+ and Ca^{2+}cations are located in similarly oriented tunnels in these phosphites and in the aeschynite, respectively. The augmentation of the 4,6 net in the aeschynite structure largely increases the porosity of the structure. The channels (12.8 × 6.8 Å) in the title compounds are more expanded compared with those (7.67 × 4.93 Å) in the aeschynite as a result of the adoption of larger BUs which is consistent with the principle of scale chemistry, i.e. the larger the brick, the larger the pore. Thus, the present structural type, in addition to being a new member of the family of $CaTa_2O_6$, also demonstrates that many structures can readily be designed and preformed to basic topologies dictated by the shapes (triangle, square, tetrahedron, etc.) and connectivities of the structural building units.

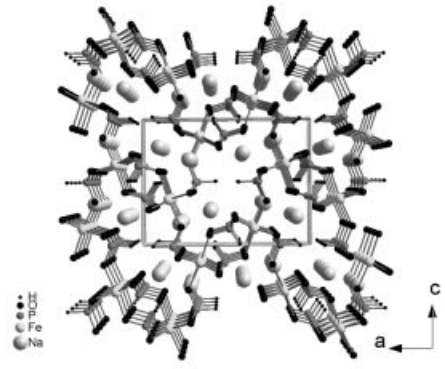

Figure 3. Structure of $Na_2[M(HPO_3)_2]$ (M = Fe, Co) along the [010] direction showing the 4-, 6-, and 12-membered polyhedral rings. The $Na(1)^+$ ions and $Na(2)^+$ ions are located in the channels and the centre of six-membered rings, respectively.

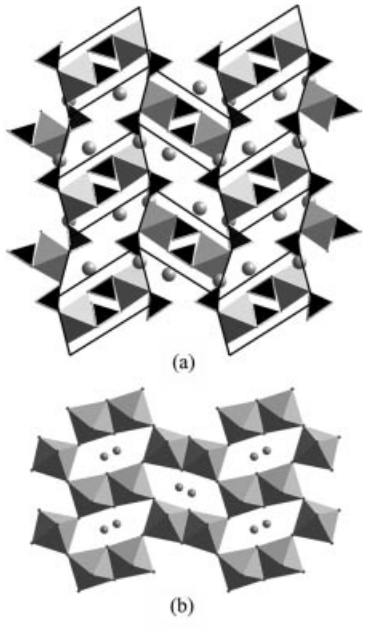

Figure 4. (a) The stacking of the multiple ribbons in $Na_2[M(HPO_3)_2]$ (M = Fe, Co) leading to a aeschynite-like framework. (b) The aeschynite ($CaTa_2O_6$) frameworks (Na atom, large gray sphere; Ca atom, small gray sphere).

For **1**, the FeO_6 octahedra have Fe–O distances in the range of 2.113(2)–2.171(2) Å whereas the *cis* and *trans* bond angles are in the ranges of 84.29(5)–96.04(4)° and 172.39(5)–174.64(7)°, respectively. For **2**, the Co–O distances vary from 2.079(2) Å to 2.147(2) Å and the *cis* and *trans* angles are in the ranges of 83.95(6)–95.77(4)° and 172.57(6)–174.99(7)°, respectively. These values are typical for Fe and Co in an octahedral oxygen environment. The

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tetrahedral P atoms have P–O bond lengths in the ranges of 1.517(2)–1.522(2) Å for **1** and 1.518(2)–1.523(2) Å for **2** and the P–H distances vary between 1.31(7) and 1.46(5) Å [P(1)–H(2) = 1.31(7) Å, P(2)–H(1) = 1.396(1) Å in **1**; P(1)–H(2) = 1.34(7) Å, P(2)–H(1) = 1.46(5) Å in **2**]. These values are within the expected ranges. The Na cations reside in the irregular $Na(1)O_5$ and $Na(2)O_9$ environments and are coordinated to neighbouring phosphite groups by sharing common corners or edges. Additionally, Na(1) bonds to two hydrogen atoms of the HPO_3 groups with distances in the range of 2.608–2.872 Å. The Na–O bond lengths are quite diverse with Na(1)–O in the range of 2.36–2.41 Å and Na(2)–O in the range of 2.29–2.78 Å for compound **1**. For **2** the Na(1)–O distances are in the range of 2.35–2.39 Å and the Na(2)–O distances are in the range of 2.29–2.76 Å.

Magnetic Properties

Magnetic measurements of $Na_2[M(HPO_3)_2]$ (M = Fe, Co) were performed on crystalline samples in the temperature range of 1.8–320 K. The temperature dependence of the inverse molar magnetic susceptibilities, χ^{-1}, of compounds **1** and **2** in the range of 1.8–320 K are show in Figure 5 and Figure 6, respectively. Compound $Na_2[Co(HPO_3)_2]$ displays a magnetic susceptibility not obeying a simple Curie–Weiss law. If one separates the low- and the high-temperature ranges, the Curie–Weiss can be fit in the ranges of 100–320 K (HT) and 5–30 K (LT). For the low-temperature interval, an effective magnetic moment of 4.47 μ_B and θ = –21 K can be obtained. The effective magnetic moment per Co atom obtained from the LT fit is well within the range reported in the literature for octahedrally coordinated Co^{2+} ions (but also near to the value of 4.3 μ_B reported for Co^{3+}).[34] The effective magnetic moment for the high-temperature range is 5.30 μ_B which, while significantly larger than the spin-only value for spin S = centres (3.87 μ_B), indicates especially strong deviations of Co^{2+} from the spin-only value due to strong orbital contributions. A Weiss temperature θ = –50 K can be obtained, demonstrating dominant antiferromagnetic interactions between the magnetic centres at low temperature. The zero-field cooled samples measured under an external field of 100 Oe show a broadened cusp at 1 and 4 K in the χ^{-1} vs T curve, indicating antiferromagnetic ordering at low field [Figure 5 (inset)]. The different magnetic features at low and high temperatures indicate that the magnetic structure is complex. Similar magnetic properties can also be observed in $[Co_3(pyz)(HPO_4)_2F_2]$ and $[Co_3(4,4'\text{-bpy})(HPO_4)_2F_2]\cdot xH_2O$ (Figure 5).[35] For $Na_2[Fe(HPO_3)_2]$, the magnetic behaviour follows the Curie–Weiss law in the temperature range of 100–320 K (Figure 6). A fit in the range of 100–320 K gives an effective magnetic moment of 5.41 μ_B which is well within the range reported in the literature for octahedrally coordinated Fe^{2+} ions.[34] The asymptotic Curie–Weiss temperature θ is equal to –20.3 K, indicating antiferromagnetic exchange in compound **2**. There is possible magnetic ordering observed in fields as low as 1 kOe and above 1.8 K [Figure 6 (inset)].

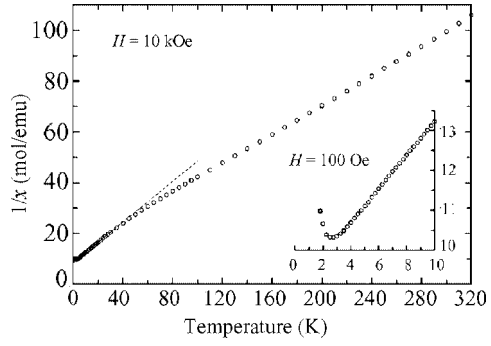

Figure 5. Inverse magnetic susceptibility (χ^{-1}, open circles) plotted as a function of temperature for powder samples of $Na_2[Co(HPO_3)_2]$. The inset shows the antiferromagnetic ordering at low temperature.

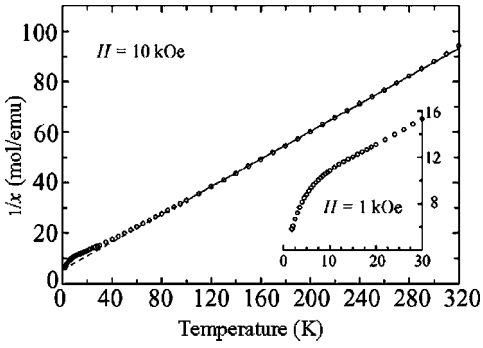

Figure 6. Inverse magnetic susceptibility (χ^{-1}, open circles) plotted as a function of temperature for powder samples of $Na_2[Fe(HPO_3)_2]$. The inset shows the possible magnetic ordering at low temperature.

Conclusions

Two new transition-metal phosphites with 4-, 6- and 12-membered polyhedral rings have been synthesised under mild hydrothermal conditions. Both of the compounds are constructed from strictly alternating MO_6 octahedra and HPO_3 tetrahedra through sharing the O-vertexes. Such connectivities between the units also form 4- and 12-membered ring channel systems in the framework structures in which the sodium ions are located. The topology of this structure is remarkably similar to that of the aeschynite $CaTa_2O_6$ and the augmentation of the BUs largely increases the channel size in the new compounds. Magnetic studies for $Na_2[Co(HPO_3)_2]$ show interesting features suggesting the possible existence of a complex magnetic structure at low temperature. For $Na_2[Fe(HPO_3)_2]$, the magnetic susceptibility obeys the Curie–Weiss law in the temperature range of 100–320 K with μ_{eff} = 5.41 μ_B which indicates Fe^{2+} character.

Experimental Section

General Remarks: All chemicals were obtained from commercial sources and used as received. The products were examined by powder X-ray diffraction (Rigaku D/max 2550V diffractometer, Cu-K_α radiation) in order to confirm their phase identity and purity. IR spectra were recorded with a Digilab-FTS-80 spectrophotometer from 4000 to 400 cm^{-1} using pressed KBr pellets of the samples. The magnetic susceptibility measurements were carried out with a SQUID magnetometer (Quantum-Design, MPMS XL-7) in the temperature range 1.8 K–320 K. The elemental analyses were performed with an ICP-AES (Vista AX ICP-AES) instrument.

$Na_2[Fe(HPO_3)_2]$ (1): $FeCl_2{\cdot}6H_2O$ (0.29 g), NaOH (0.125 g), H_3PO_3 (solid state, 2.56 g) and deionised water (15 mL) were mixed in a molar ratio of 2:2.5:25:667. A solution of $NH_3{\cdot}H_2O$ (40 wt.-%) was added to adjust the pH to 7.0 and the resultant solution was sealed in a 25-mL Teflon-lined stainless steel autoclave and heated under autogenous pressure at 433 K for 5 d. The resultant pink rod-like water-soluble crystals from the reaction were recovered by filtration, washed with ethanol and dried at room temperature. Yield: 0.258 g (80% based on $FeCl_2{\cdot}6H_2O$). $H_2FeNa_2O_6P_2$ (261.79): calcd. Fe 21.3, Na 17.6, P 23.6; found Fe 21.0, Na, 17.7, P 23.2. IR (KBr disk): $\tilde{\nu}$ = 2388 (m), 1170 (s), 1085 (s), 1025 (s), 998 (m), 591 (m), 501 (m) cm^{-1}.

$Na_2[Co(HPO_3)_2]$ (2): $CoCl_2{\cdot}6H_2O$ (0.3 g), NaOH (0.125 g), H_3PO_3 (solid state, 2.56 g) and deionised water (15 mL) were mixed in a molar ratio of 2:2.5:25:667. A solution of $NH_3{\cdot}H_2O$ (40 wt.-%) was added to adjust the pH to 7.0 and the resultant solution was sealed in a 25-mL Teflon-lined stainless steel autoclave and heated under autogenous pressure at 433 K for 5 d. The resultant pink rod-like water-soluble crystals from the reaction were recovered by filtration, washed with ethanol and dried at room temperature. Yield: 0.234 g (70% based on $CoCl_2{\cdot}6H_2O$). $H_2CoNa_2O_6P_2$ (264.87): calcd. Co 22.2, Na 17.4, P 23.7; found Co 21.7, Na 17.0, P 23.3.

IR (KBr disk): $\tilde{\nu}$ = 2383 (m), 1172 (s), 1095 (s), 1025 (s), 995 (m), 586 (m), 493 (m) cm^{-1}.

X-ray Crystallographic Study: Crystals of each compound were selected under a polarising microscope, glued to a thin glass fibre with cyanoacrylate (superglue) adhesive and inspected for singularity. Two of them with regular rod-like shapes were chosen ($0.40 \times 0.20 \times 0.20$ mm for **1** and $0.40 \times 0.15 \times 0.15$ mm for **2**) and data sets were collected with a Nonius Kappa CCD diffractometer (Mo-K_α radiation, λ = 0.71073 Å) at 293 K. For **1**, the θ range for data collection was from 2.79 to 27.12° and an absorption correction was applied with maximum and minimum transmission factors of 0.732 and 0.694, respectively. A total of 2760 reflections were collected with ω scans, yielding 727 unique observed reflections(R_{int} = 0.0233). For **2** the θ range for data collection was from 2.80 to 27.09° and an absorption correction was applied with maximum and minimum transmission factors of 0.702 and 0.661, respectively. A total of 2814 reflections were collected with ω scans, yielding 724 unique observed reflections(R_{int} = 0.0210). The intensity data were corrected for Lorentz and polarisationeffects. The structures were solved by direct methods and refined against $|F^2|$ with the aid of the SHELXTL-PLUS package.[36] The iron, cobalt, sodium, phosphorus and oxygen atoms were initially found and refined. The coordinates of hydrogen atoms on the phosphorus centres were obtained from difference Fourier maps. Additional information concerning the data collection and structure refinements is presented in Table 1 while selected interatomic distances are given in Table 2 and Table 3 for **1** and **2**, respectively. Further details of the crystal-structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany, on quoting the depository numbers CSD-414247 (**1**) and -414248 (**2**).

(Cyanocyclopentadienyl)potassium and -cesium

Eberhardt Herdtweck,[a] Frank H. Köhler,*[a] and Rüdiger Mölle[a]

Keywords: Cyanocyclopentadienide / Crystal structure / ^{133}Cs NMR spectroscopy

(Cyanocyclopentadienyl)potassium and -cesium have been synthesized and subsequently characterized by single-crystal X-ray structure determinations, ^{1}H and ^{13}C NMR spectroscopy in solution as well as by ^{133}Cs NMR spectroscopy in solution and the solid-state. Both salts crystallize in zigzag chains which are crosslinked differently through the cyano substituents. There is significant distortion of the cyanocyclopentadienide ion toward a fulvalene-like structure because the alkali-metal ions do not only interact with the five-membered ring but also with the cyano groups. The ^{133}Cs NMR spectra reflect the bending of the [CpCsCp]$^{-}$ fragments of the chains.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

The cyclopentadienyl (Cp) ligand is ubiquitous in organometallic chemistry and substitution has been widely used for generating special properties of its (transition) metal compounds such as better solubility, increased stability and asymmetry.[1] More recently, donor substituents have been introduced[2] mainly for providing (planar-)chiral[2b,2c] or C_2-symmetric[2a,2d] catalysts. For the latter derivatives, the substituted Cp groups have been designed such that intramolecular coordination of the Cp-attached donor occurs owing to dangling substituents. If intermolecular or bridging coordination is to be achieved, a donor function bonded directly to the Cp ring is advantageous. An example is the cyanocyclopentadienyl ligand (CpCN) which has been synthesised by various routes.[3] As for alkali-metal cyclopentadienides, these may be assumed to be simple compounds but, in fact, there is surprising structural diversity among them[4] and this might be particularly true for structural implications of the cyano substituent in the solid and liquid state. Therefore, we synthesized the title compounds CpCNK and CpCNCs and investigated them by techniques including X-ray diffraction and solid-state ^{133}Cs NMR spectroscopy.

Results and Discussion

Synthesis

When choosing Webster's synthetic approach,[3b] (see Scheme 1) special attention is warranted. Thus, the reaction between CpNa and ClCN is clean if the latter has been freshly prepared. The resultant isomeric cyanocyclopentadienes react almost instantaneously to give dimers (not only those in Scheme 1) which must be cracked thermally just before the reaction with an alkali carbonate. The overall yield (5–6%) of the alkali-metal cyanocyclopentadienides, CpCNK and CpCNCs, according to the sequence in Scheme 1 is mainly limited by interfering polymerization of cyanocyclopentadiene. Both compounds are colorless to brown powders which are air-sensitive and soluble in donor solvents such as propionitrile, DMSO and THF. The ^{1}H and ^{13}C NMR spectra of both salts in solution show similar signal patterns and confirm the expected structure of the anion. An example is the AA′BB′ spin system of the five-membered ring protons which gives rise to two pseudo-triplets. These and other signals of the nuclei in positions 2/5 and 3/4 of the ring could be distinguished by considering the contribution of a fulvene-type limiting structure (cf. discussion below and Figure 2b) and the fact that in fulvenes and the related cyclopentadienones the signal of C-3/4 is always more shifted than that of C-2/5.[5] Nevertheless, this assignment is tentative. The new cesium derivative was characterised in addition by mass spectrometry and IR spectroscopy, and its purity was checked.

Crystal Structures of CpCNK and CpCNCs

An issue which arises during structural work on solid-state alkali-metal cyclopentadienides is whether solvent molecules are incorporated into the lattice or not. Because of the low solubilities of these salts, only few solvent-free structures are known[6] and most of them have been determined from powders. It is, therefore, unsurprising that the rich structural chemistry of alkali cyclopentadienides stems from crystals usually containing solvating amines or ethers. In contrast, the potassium and cesium salts of cyanocyclopentadiene form solvent-free crystals from THF or propionitrile because the anion contains its own donor.

The potassium salt CpCNK forms monoclinic crystals in which the anions and cations are arranged in zigzag chains running almost parallel to the *a* axis as illustrated in Figure 1. The chains can be broken down into inverse sandwich cations $[K(CpCN)K]^+$ highlighted by the broken frame and separated by $CpCN^-$ anions. The corresponding solvated and hence isolated lithium species $[(TMEDA)Li(MeCp)Li(TMEDA)]^+$ has been established previously.[7] Alternatively, the chains may be broken down into bent metallocene anions (solid frame in Figure 1) separated by potassium anions thereby enabling a structural analogy with bent metallocenes such as $[Cp_2Ti(NCCH_3)_2]^+$[8] which are well known in transition-metal organometallic chemistry. As for titanium in $[Cp_2Ti(NCCH_3)_2]^+$, the coordination sphere of potassium in CpCNK is completed by two neutral ligands, i.e. the cyano groups of adjacent CpCN anions. The metallocene bending angles (D–K1–D′ 135.86° and D–K2–D′ 135.14°) are very similar to that in $[Cp_2Ti(NCCH_3)_2]^+$ [134.8(5)°] but the angles N–K–N′ [90.00(4)° for K1 and 88.84(4)° for K2] and N–Ti–N′ [80.6(5)°] are somewhat different. It follows that the cyano groups of CpCNK force bent chains while for the cyclopentadienides of other alkali-metal ions, the chains may be linear or bent[6c–e] depending on the radius of the cation.[4a] When crystallizing with one molecule of diethyl ether, CpK also forms bent chains in which the angle is about 10° wider.[9]

The CpCN···K interaction links neighbouring chains to give a 3D network through slightly distorted squares K1,N,K2,N′ lying approximately in the *bc* plane as shown in Figure 2a. The angles between the best plane of K1,N,K2,N′ and the Cp groups on the left and the right are 22.6°. Unlike in $[Cp_2Ti(NCCH_3)_2]^+$, the metal–Cp bonding in CpCNK should be almost purely ionic as in all alkali-metal cyclopentadienides.[4] This implies a polarisation of the $CpCN^-$ anion in such a way that the negative charge is not only localised in the Cp π system but also at the N atom. Therefore, it can be expected that the limiting electronic structure B in Figure 2b plays a significant role. The crystal structure confirms this in two ways. Firstly, the

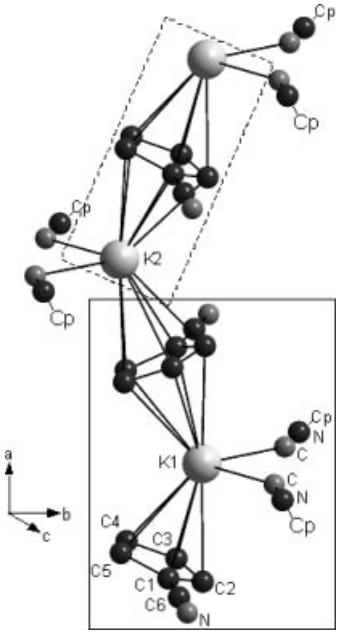

Figure 1. Inverse sandwich motif (broken frame) and bent-metallocene motif (solid frame) within the polymeric chains of CpCNK (detail with three formula units complemented by full coordination at the potassium ion); hydrogen atoms have been omitted for clarity; selected bond lengths [Å]: K1–C1 3.036(1), K1–C2 3.092(2), K1–C3 3.125(2), K1–C4 3.100(2), K1–C5 3.049(2), K2–C1 3.008(1), K2–C2 3.079(2), K2–C3 3.133(2), K2–C4 3.115(2), K2–C5 3.043(2), K1–D 2.840, K2–D 2.835, where D is the centre of gravity of the five-membered ring.

Figure 2.  © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

CNK fragments in Figure 2a are bent rather than linear and secondly, the $CpCN^-$ anion is distorted toward a fulvene-type structure. A comparison of the bond lengths of CpCNK with those of the benzonitrile complex of CuBr[10] in Figure 2c shows that the C–C bond lengths of the phenyl group are very similar, whereas in CpCNK the bonds C3–C2 and C4–C5 are significantly shorter than C1–C2, C3–C4 and C5–C1. Also, compared with $C_6H_5CNCuBr$, C1–C6 of CpCNK is shorter while C6–N is longerand both are towards double bonds. It is worth noting that structure B in Figure 2b is the deprotonation product of the transient species 6-iminofulvene.[11]

The cesium salt CpCNCs forms orthorhombic crystals again featuring zigzag chains (along the *c* direction of the unit cell) which may also be decomposed into inverse sandwich cations (Figure 3, broken frame) or bent sandwich anions (Figure 3, solid frame). However, compared with the potassium salt, there are remarkable differences. The mean metal–Cp distance in CpCNCs is 0.37 Å longer than in CpCNK which is more than the difference of the coordination number adjusted radii of Cs^+ and K^+ (0.23 Å[12]) and which, therefore, points to additional factors contributing to that distance. There is a striking decrease in the sandwich bending angles from 135.14° and 135.86° to 107.3° when passing from CpCNK to CpCNCs. While in the latter salt the angle is still 8.3° smaller than in the isolated anion $[Cp_3Cs_2]^-$[13] and 22.4° smaller than in CpCs,[6c] the bending of the alkali-metal cyclopentadienides is most pronounced for Cs. Bending of Cp sandwich compounds as an intrinsic molecular property has been addressed for main-group element derivatives.[14] In particular, the salts CpCNK and CpCNCs correspond to the general tendency that the deviation from linearity in main-group compounds MX_2 increases when M becomes heavier.[15] In mostly ionic solids, another driving force is the need to optimise coulombic interactions and to complete the coordination spheres of the ions. Incomplete coordination of alkali-metal–organic compounds becomes more critical when the radius of the metal ion increases.[16] In the present case this means that upon additional coordination of the cyano groups, the Cp_2Cs^- fragment bends more strongly than Cp_2K^-.

The linkage of the chains in CpCNCs is also different from that in CpCNK. As can be seen in Figure 4, the CpCN···Cs interaction occurs in such a way that the $CpCN^-$ anions on both sides of the cation chain bridge different pairs of cations, whereas in CpCNK they bridge the same pair (Figure 2a). This does not prevent the CN group of CpCNCs from interacting with two cesium ions, thereby stretching the anion toward a fulvene limiting structure (Figure 2) much in the same way as in the case of CpCNK. An additional linkage between adjacent chains of CpCNCs occurs between one edge of the cyclopentadienyl and Cs′ (see inset of Figure 4). This is indicated by the large angle between the plane formed by C2,C3,Cs and the Cp plane (152.0°), and by the distances Cs′–C2 [3.654(3) Å] and Cs′–C3 [3.654(3) Å] which are only slightly longer than the Cs–C distances within the chains. The contribution of the η^2 interaction to the overall bonding energy of CpCNCs is probably substantial because, for the Cp^- and Li^+ pair, it has been calculated that such η^2 interactions are only about 1.4 times smaller than η^5 interactions.[4a]

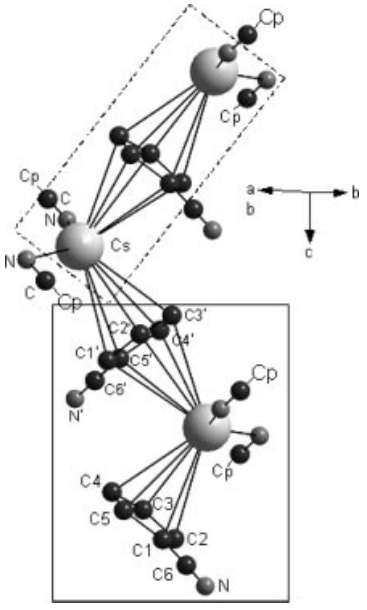

Figure 3. Inverse sandwich motif (broken frame) and bent-metallocene motif (solid frame) within the polymeric chains of CpCNCs (detail with three formula units complemented by full coordination at the potassium ion); hydrogen atoms have been omitted for clarity; selected bond lengths [Å] and angles [°]: Cs–C1 3.541(3), Cs–C2 3.436(3), Cs–C3 3.309(3), Cs–C4 3.334(3), Cs–C5 3.486(3), Cs–C1′ 3.426(3), Cs–C2′ 3.464(3), Cs–C3′ 3.438(3), Cs–C4′ 3.403(3), Cs–C5′ 3.389(3), C1–C6–N 179.4(3), C6–N–Cs 117.7(3), C6′–N′–Cs 149.0(3), Cs–D 3.207, Cs–D′ 3.209, D–Cs–D′ 107.32, where D is the centre of gravity of the five-membered ring.

^{133}Cs NMR Spectroscopy

Since crystal structures of alkali-metal–organic compounds are sometimes difficult to obtain, we wanted to find out whether ^{133}Cs NMR spectroscopy would be a useful method of characterization. Alkali-metal ions have neither p nor d valence electrons and this makes qualitative signal shift interpretation as straightforward as for proton signals because simple electron density arguments can be used. The disadvantage is that the signal shift range of an alkali-metal nucleus is much smaller than that of its neighbours in the same row of the periodic table. For instance, ^{7}Li NMR signal shifts are much smaller than those of ^{11}B which are in turn smaller than those of ^{19}F. The disadvantage is partly compensated for by the fact that the shift range increases rapidly when passing from a light to a heavy nucleus in a given group. Therefore, ^{133}Cs should be the nucleus of choice for studying small changes of the bonding in alkali-metal cyclopentadienides. Figure 5 shows the ^{133}Cs MAS NMR spectra of microcrystalline samples of CpCNCs and CpCs. The envelope of the spinning sideband pattern corresponds to the typical signal shape of a spin nucleus with low chemical shift anisotropy.[17] At the given spinning frequency, the six satellite transitions flanking the central m = ±½ transition are best seen in the case of CpCs from the modulation of the sideband intensities. At lower spinning frequencies, some chemical shift anisotropy and its orientation relative to the quadrupolar interaction leads to additional spectroscopic features as has been worked out in detail previously.[18] In this study we were interested in the isotropic signal shifts which turned out to be rather different for solid CpCNCs (δ = –128.2 ppm) and CpCs (δ = –247.6 ppm). Similar shifts were found in solution for CpCNCs (δ = –50.7 ppm in MeCN) and CpCs (δ = –253.7 ppm in THF). One may think of attributing the shift difference of both salts to additional CN coordination in CpCNCs. This would be equivalent to solvation which has been shown to actually shift ^{133}Cs NMR signals to high frequency when the solvent is acetonitrile.[19] However, these shifts are much smaller even for fully solvated ions. Another reason for the low-frequency signal shift is the fact that Cs^+ sits above the center of the Cp ring and hence experiences the additional field induced by the π electrons of the aromatic ligand. This scenario applies to mapping protons of transition-metal compounds[20] and to determining the interaction of Li^+ with Cp and Cp-like anions.[21] In fact, for $^{6/7}$Li, as for ^{133}Cs in this work, the metal resonance is shifted to a lower frequency upon interacting with Cp anions and these shifts are much larger than solvation-induced shifts. In the case of ^{133}Cs NMR spectroscopy, the Cp-induced signal shift is so large that structural changes of CpCs derivatives should be visible. On this basis we suggest that the ^{133}Cs NMR signal shift depends on the bending angle α of the $[Cp_2Cs]^-$ fragment (see Figure 1 and Figure 3). When adding the field vectors induced at both Cp groups, the ^{133}Cs NMR signal shift can be expected to behave as cos(180 – α). A linear sandwich fragment can thus be expected to give the largest ^{133}Cs signal shift. Upon bending the sandwich, the angle α decreases and the signal should move to high frequency. This is true for CpCNCs [α = 107.3°, δ(^{133}Cs) = –128.2 ppm] and CpCs [α = 129.7°, δ(^{133}Cs) = –247.6 ppm] although the correlation is not perfect. The reason is that the signal shift also depends on other factors such as the Cp–Cs distance, additional ligands such as the CN groups and the neighbors in the lattice. In solution, the structural parameters may be different and solvation cannot be neglected.

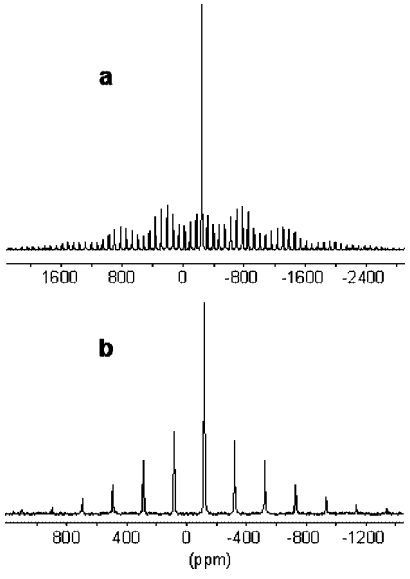

Figure 5. ^{133}Cs MAS NMR spectra of CpCNCs (a) and CpCs (b) at a spinning frequency of 8 kHz and a temperature of 301 K.

Conclusions

The potassium and cesium salts of cyanocyclopentadiene are soluble compounds and yet they do not form solid-state solvates. The arrangement of CpCN anions and alkali-metal cations in the lattice may be viewed as chains or *n*-decker sandwiches which are bent and which consist of linear inverse sandwich (M–Cp′–M) fragments and bent sandwich $[Cp'_2M(NCCp)_2]$ fragments. The chains are crosslinked through CN···M interactions which at the same time polarize the CpCN anion such that it is distorted from a cyclopentadienyl- toward a fulvene-type geometry. Different crosslinking patterns exist for CpCNK and CpCNCs and the latter features an additional η^2 interaction between Cs^+ and $CpCN^-$. ^{133}Cs NMR spectroscopy proved to be a sensitive probe for structural changes of the $[Cp_2Cs]^-$ fragment.

Experimental Section

Caution: *Cyanogen chloride used as reagent in this work is a very toxic gas at room temperature and should be handled with proper precautions!* All manipulations involving alkali-metal cyclopentadienides were carried out under nitrogen using Schlenk tech-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

niques and dry, oxygen-free solvents. Cesium cyclopentadienide was synthesized as described by Harder.[13] The spectroscopic results were obtained with a Varian Mat 50 mass spectrometer, a Perkin–Elmer IR spectrometer 1600 FTIR as well as Jeol JNM GX 400 and Bruker Avance 300 NMR spectrometers for solution and solid-state NMR spectra, respectively. The solid samples were packed in ZrO_2 rotors and sealed with Kel-F caps in a glovebox. All referencing was done relative to TMS except for the ^{133}Cs NMR spectroscopic data which are relative to external CsCl as a solid or highly diluted in water for MAS and solution spectra, respectively. The sample temperature under MAS conditions was obtained from a previous calibration.[22]

Dicyanotricyclo[5.2.1.0^{2,6}]deca-4,8-diene Isomers: By modifying Webster's procedure,[3b] freshly prepared cyanogen chloride[23] (30.0 g, 0.488 mol) was dissolved at –78 °C in THF (150 mL). The colourless solution was warmed to 0 °C and a THF solution of sodium cyclopentadienide (208 mL, 2.35 M, 0.49 mol) was added dropwise while cooling with an ice bath. The reaction was apparent from the immediate formation of a colourless precipitate and colour changes first to yellow and subsequently to red-brown. The reaction mixture was allowed to warm to room temperature and was then stirred for 2 h. After removing the solvent at 10^{-4} bar, the brown solid was dissolved in water (100 mL), the pH was adjusted to 7 using a solution of 0.1 N hydrochloric acid and the product was extracted with diethyl ether (4 × 100 mL). The combined organic phases were dried with sodium sulfate, the solvent was removed under reduced pressure and the resultant deep red oil of cyanocyclopentadiene dimers (60.2 g, 67% yield relative to cyanogen chloride) was subjected immediately to further reaction.

Potassium Cyanocyclopentadienide: Similar to the procedure described previously,[3b] a mixture of dicyanotricyclo[5.2.1.0^{2,6}]deca-4,8-dienes (20.0 g, 0.110 mol) was cracked to cyanocyclopentadienes by heating to 170–180 °C and distilled at 15 mbar by using a short bridge directly into a suspension of potassium carbonate (11.1 g, 0.110 mol) in propionitrile (200 mL). The resultant pink suspension was stirred for 2 h and the solid removed by filtration. The solvent was then removed at 10^{-4} bar leaving behind microcrystalline CpCNK. Yield 1.71 g, yield 6%. Colourless crystals suitable for X-ray analysis were obtained by covering a solution of the solid in THF with hexane at room temperature. ^1H NMR (400 MHz, [D$_6$]DMSO, 305 K): δ = 5.51 (pseudo-t, $^{2+4}J_{H,H}$ = 5.6 Hz, 2 H, 2/5-H), 5.92 (pseudo-t, $^{2+4}J_{H,H}$ = 5.6 Hz, 2 H, 3/4-H) ppm. ^{13}C NMR (100 MHz, [D$_6$]DMSO, 305 K): δ = 80.7 (C-1), 107.7 (C-2/5), 111.4 (C-3/4), 126.4 (CN) ppm.

Cesium Cyanocyclopentadienide: The procedure described for the potassium analogue was carried out with dicyanotricyclo[5.2.1.0^{2,6}]deca-4,8-dienes (9.11 g, 50 mmol) and cesium carbonate (16.3 g, 50 mmol) in propionitrile (100 mL). Crystallization of the resultant powder from acetonitrile at room temperature gave CpCNCs as brown crystals which were analytically pure and suitable for X-ray analysis. Yield 1.11 g, 5%. M.p. 170–175 °C (dec.). IR (KBr): $\tilde{\nu}$ = 3037, 3095 [m, ν(CH)], 2191 [s, ν(CN)] cm^{-1}. CI$^+$ MS: *m*/*z* (%) = 223 (75) [M]$^+$, 196 (10) [M – CHN]$^+$, 133 (78) [M – C_6H_4N]$^+$. ^1H NMR (400 MHz, [D$_6$]DMSO, 305 K): δ = 5.67 (pseudo-t, $^{2+4}J_{H,H}$ = 5.6 Hz, 2 H, 2/5-H), 6.07 (pseudo-t, $^{2+4}J_{H,H}$ = 5.6 Hz, 2 H, 3/4-H) ppm. ^{13}C NMR (100 MHz, [D$_6$]DMSO, 305 K): δ = 84.1 (C-1), 110.3 (C-2/5), 114.0 (C-3/4), 126.5 (CN) ppm. C_6H_4CsN (223.0): calcd. C 32.32, H 1.81, N 6.28; found C 32.79, H 1.91, N 6.18.

Single Crystal X-ray Structure Determination of CpCNK and CpCNCs

CpCNK: Crystal data and details of the structure determination are presented in Table 1. Suitable single-crystals for the X-ray diffraction study were grown from THF/hexane. A clear colorless fragment was stored under perfluorinated ether, transferred to a Lindemann capillary, fixed and sealed. Preliminary examinations and data collection were carried out with an area detecting system (NONIUS, MACH3, κ-CCD) at the window of a rotating anode (NONIUS, FR951) with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The unit-cell parameters were obtained by a full-matrix least-squares refinement of 1331 reflections. Data collection was performed at 173 K within a θ-range of 3.33° < θ < 25.34°. Nine data sets were measured in rotation scan mode with $\Delta\varphi/\Delta\Omega$ = 1.0°. A total number of 16425 intensities were integrated. Raw data were corrected for Lorentz, polarisation and latent decay and absorption effects (arising from the scaling procedure). After merging (R_{int} = 0.042), a sum of 1266 (all data) and 1173 [$I > 2\sigma(I)$] reflections remained and all data were used. The structure was solved by a combination of direct methods and difference Fourier syntheses. All non-hydrogen atoms were refined with anisotropic displacement parameters. All hydrogen atom positions were found in the difference map calculated from the model containing all non-hydrogen atoms. The hydrogen positions were refined with individual isotropic displacement parameters. Full-matrix least-squares refinements with 90 parameters were carried out by minimizing $\Sigma w(F_o^2 - F_c^2)^2$ with the SHELXL-97weighting scheme and the refinements were stopped at shift/err < 0.001. The final residual electron density maps showed no remarkable features. Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the *International Tables for Crystallography.* All calculations were performed with an Intel Pentium II PC with the STRUX-V system including the programs PLATON, SIR92 and SHELXL-97.[24]

CpCNCs: Crystal data and details of the structure determination are presented in Table 1. Suitable single-crystals for the X-ray diffraction study were grown from acetonitrile. A clear light brown fragment was stored under perfluorinated ether, transferred to a Lindemann capillary, fixed and sealed. Preliminary examinations and data collection were carried out with an area detecting system (NONIUS, MACH3, κ-CCD) at the window of a rotating anode (NONIUS, FR951) with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The unit-cell parameters were obtained by a full-matrix least-squares refinement of 759 reflections. Data collection was performed at 173 K within a θ-range of 3.08° < θ < 25.36°. Eight data sets were measured in rotation scan mode with $\Delta\varphi/\Delta\Omega$ = 2.0°. A total number of 13279 intensities were integrated. Raw data were corrected for Lorentz, polarisation and latent decay and absorption effects (arising from the scaling procedure). After merging (R_{int} = 0.046), a sum of 1238 (all data) and 1215 [$I > 2\sigma(I)$] reflections remained and all data were used. The structure was solved by a combination of direct methods and difference Fourier syntheses. All non-hydrogen atoms were refined with anisotropic displacement parameters. All hydrogen atom positions were calculated in ideal positions (riding model). Full-matrix least-squares refinements with 75 parameters were carried out by minimizing $\Sigma w(F_o^2 - F_c^2)^2$ with the SHELXL-97weighting scheme and were stopped at shift/err < 0.001. The final residual electron density maps showed no remarkable features. As shown by Flack's parameter ε = 0.15(3), the crystal is slightly twinned. A correction for extinction was applied using the SHELXL-97 procedure with a final ε value of 0.0125(4). Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the *International Tables for Crystallography.* All calculations were performed with an Intel Pentium II PC with the STRUX-V system including the programs PLATON, SIR92, and SHELXL-97.[24]

Crystallographic Proof of Double Walden Inversion in Nucleophilic Substitution Reactions of Macrocyclic Cyclotriphosphazene Derivatives

Serap Beşli,[a] Simon J. Coles,[b] David B. Davies,[c] Robert J. Eaton,[c] Michael B. Hursthouse,[b] Adem Kılıç,*[a] and Robert A. Shaw[c]

Keywords: Nucleophilic substitution / Inversion of configuration / Cyclotriphosphazenes / Crystal structures / Configuration determination

Using X-ray crystallography it is demonstrated unambiguously that a double Walden inversion reaction occurs for successive nucleophilic substitution of the mono-spiropropanoxyamino derivative of the *cis*-ansa-macrocyclic cyclophosphazene compound $N_3P_3[O(CH_2)_3NH][O(CH_2CH_2O)_4]Cl_2$ (**3**). The spiropropanoxyamino moiety enables groups above and below the plane of the N_3P_3 ring to be distinguished. The first nucleophilic substitution of compound **3** with X^- (e.g., X = 2-naphthoxy) gives $N_3P_3[O(CH_2)_3NH][O(CH_2CH_2O)_4]XCl$ (**4a**), which has a *trans*-ansa-macrocyclic ring as a result of the inversion reaction, and then subsequent reaction of **4a** with the same nucleophile gives $N_3P_3[O(CH_2)_3NH][O(CH_2CH_2O)_4]X_2$ (**5a**), in which the macrocyclic ring is *cis*-ansa again, but it is now on the *opposite side* of the N_3P_3 ring from that of the starting material **3** as a result of the second inversion reaction. Structures stereochemically analogous to compound **5a** were also obtained upon reaction with other monofunctional nucleophiles, such as phenol, pyrrolidine and aniline, to give compounds **5b**, **5c** and **5d**, respectively, and with the difunctional nucleophile 2,2,3,3-tetrafluorobutanediol to give the di-ansa derivative **6**. Compound **3** was also sequentially treated with two different mononucleophiles – phenol and aniline – to give the unsymmetrically disubstituted compound **7**, in which the macrocyclic ring is also *cis*-ansa again and on the *opposite side* of the N_3P_3 ring from that of the starting material, as a result of the double Walden inversion reactions.

Introduction

The Walden inversion[1] has played an important part in the study of reaction mechanisms in organic chemistry.[2] For S_N2 reactions involving four-coordinate carbon atoms, attack by a nucleophile leads to an inversion of configuration, which is usually confirmed by starting with an optically active compound so that the product has the opposite optical rotation.[3] A similar approach has been taken for reactions involving four-coordinate phosphorus atoms; unless pseudorotation or steric constraints intervene, nucleophilic attack generally leads to inversion of configuration, if the reaction is associative, via either a five-coordinate transition state $S_N2(P)$ or intermediate.[4,5] Pentacoordinate intermediates with fluoride ions have been reported for $(NPF_2)_n$ (n = 4, 5 and 6) and crystallographically characterised as the $(N_4P_4F_9)^-$ and $(N_6P_6F_{13})^-$ anions.[6]

Instead of using changes in optical rotation to investigate reaction mechanisms involving inversion of configuration, we have used a different approach involving reactions of *meso* compounds to give racemates, which can react further to give either another *meso* compound or another racemate depending on the second substituent.[7,8] In recent years macrocyclic derivatives of cyclotriphosphazene have been isolated and X-ray crystallographic investigations of the initial products with polyether macrocyclic rings in the ansa configuration have been found, so far without exception, to have *cis*-ansa structures.[9,10] In macrocyclic cyclophosphazene compounds such as **1** (Scheme 1), the two P atoms carrying the macrocyclic ring, P(Om)Cl (where Om = macrocyclic residue), are stereogenic and, because compound **1** is symmetrically substituted, it is the *meso* form.[7] The first reaction of compound **1** with a nucleophile (X^-) takes place at either of the two P(Om)Cl groups to give the P(Om)X moiety, in which the macrocyclic ring now exists in a *trans*-ansa configuration and the molecule is racemic.[7,8] Further reaction with the same nucleophile X^- then converts the second P(Om)Cl group into another P(Om)X moiety and the resulting derivative has regained a *cis*-ansa structure and is *meso* again.[7] On the other hand, reaction of **1** with

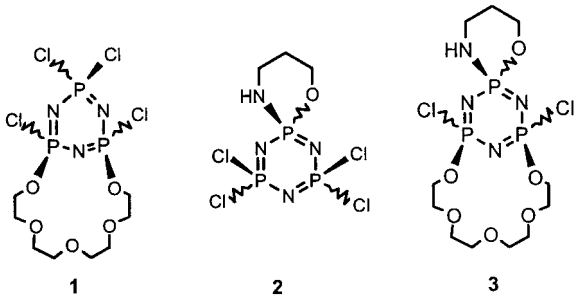
the first nucleophile X^- and then further reaction with a different nucleophile Y^- converts the second P(Om)Cl group into a P(Om)Y moiety and the resulting derivative has regained a *cis*-ansa structure, but is now racemic.[8] These structures have been confirmed crystallographically for single-bridged and double-bridged macrocyclic cyclophosphazene compounds, thus supporting the postulate of Walden inversions for both steps of the reaction.[7] However, only the first step was proven crystallographically; the second was assumed by analogy based mainly on ^{31}P NMR measurements.[7,8]



Scheme 1. Wedge-based structure representation of compounds **1**–**3** in order to emphasise that the macrocyclic ring of compound **3** is in the *cis-ansa* configuration with respect to the cyclophosphazene ring and is *cis* to the NH group of the spirocyclic ring.

Although there is good evidence of inversion of configuration at each step of the reaction, we could not prove by X-ray crystallography that the second Walden inversion led to a *cis*-ansa structure in which the macrocyclic ring was now on the *opposite side* of the N_3P_3 ring to that of the starting material. In order to distinguish groups that are above and below the plane of the N_3P_3 ring, a marker is needed having non-identical substituents on the third phosphorus atom, i.e. the one not involved in the ansa segment. This was achieved by using the mono-spiro derivative $N_3P_3Cl_4[O(CH_2)_3NH]$ (**2**; Scheme 1), whose synthesis[11,12] and crystal structure[12] have been reported previously. The spiropropanoxyamino group is approximately perpendicular to the cyclophosphazene ring[12] and, because it is linked by two different groups (O and NH) to the N_3P_3 ring, a distinction can be be made between the two sides (above and below) of the planar cyclophosphazene ring. Reaction of **2** with the sodium derivative of tetraethylene glycol, $NaO(CH_2CH_2O)_4Na$, gives $N_3P_3[O(CH_2)_3NH][O(CH_2CH_2O)_4]Cl_2$ (**3**), which is a suitable starting material for further nucleophilic substitution reactions of the two remaining P–Cl bonds in a *cis*-ansa relationship. Compound **3** (Scheme 1) was chosen as an easily accessible starting material with no more than two P–Cl bonds in the molecule (to avoid side-reactions) and because the two P–Cl bonds had to exist in a definite *cis* relationship; suitably substituted *cis*-ansa compounds provide such a juxtaposition of bonds.

Scheme 2. Diagrammatic representation of the structure of compound **3** showing the macrocyclic ring in the *cis-ansa* configuration with respect to the cyclophosphazene ring and *cis* to the NH group of the spirocyclic ring. The structure of compound **4** shows the macrocyclic ring in the *trans-ansa* configuration with respect to the cyclophosphazene ring, resulting from one inversion reaction of compound **3** with a mono(nucleophile). The structure of compounds **5**–**7** shows the macrocyclic ring in the *cis-ansa* configuration with respect to the cyclophosphazene ring but it is now *trans* to the NH group of the spirocyclic ring as a result of double inversion reactions.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

However, if the length of the *cis*-ansa chain is too short, reaction could lead to retention of configuration, as recently observed in two systems containing nine-membered ansa rings.[13] Previous work has shown that the sixteen-membered ring of the *cis*-ansa macrocyclic cyclophosphazene derivative **1** is sufficiently large and flexible to take up both *cis* and *trans* configurations as a result of nucleophilic substitution reactions,[7,8] and so this same macrocyclic ring was incorporated into compound **3**. Reaction of compound **3** with a range of mononucleophiles (2-naphthol, phenol, pyrrolidine and aniline) with different steric demands and different nucleophilicities gave examples of the monosubstituted compound **4** (**4a**, X = 2-naphthoxy; **4b**, X = phenoxy) and of the disubstituted compounds **5a**, **5b**, **5c** and **5d**, respectively. Compound **3** was also treated with the difunctional nucleophile 2,2,3,3-tetrafluorobutanediol, to give the diansa derivative **6**, and also treated sequentially with two different mononucleophiles − phenol and aniline − to give the unsymmetrically disubstituted compound **7**. The products (**3**, **4a**, **5a**, **5b**, **5c**, **6** and **7**, summarised in diagrammatic form in Scheme 2) were characterised by X-ray crystallography to show that double Walden inversion reactions had taken place.

Results and Discussion

Macrocyclic cyclophosphazene derivatives are difficult to crystallise and, even when they do, often give rise to disordered structures. Many mono- and disubstituted derivatives (such as **4** and **5**, respectively) remained stubbornly as oils, even though they were shown to be pure by chromatography, elemental analyses, mass spectrometry and ^{31}P NMR spectroscopy. Other derivatives gave solids that were unsuitable for crystallography. The most probable cause of these difficulties is the conformational flexibility of the macrocyclic ring. In particular, the monosubstituted macrocyclic cyclophosphazene derivatives caused major experimental problems, though we eventually succeeded in obtaining a good crystalline product for one compound $\{N_3P_3Cl[O(CH_2CH_2O)_4][NH(CH_2)_3O]X$ (**4a**), X = 2-naphthoxy$\}$. We had more success in crystallisation of the symmetrically disubstituted derivatives $N_3P_3[O(CH_2CH_2O)_4][NH(CH_2)_3O]X_2$ [X = 2-naphthoxy (**5a**), X = phenoxy (**5b**),X = pyrrolidino (**5c**)],though not with X = anilino(**5d**). Crystal structures were also obtained for the symmetrically disubstituted derivative **6**, which is the diansa compound formed from reaction of compound **3** with thedifunctional nucleophile 2,2,3,3-tetrafluorobutanediol, and for the unsymmetrically disubstituted derivative **7**), formed from sequential reaction of compound **3** with phenol and aniline. The X-ray data for compounds **3**, **4a**, **5a**, **5b**, **5c**, **6** and **7** are summarised in the Exp. Sect. and the molecular crystal structures are given below.

Treament of compound **3** with the Na derivative of 2-naphthol gave, successively, the mono- (**4a**) and dinaphthoxy derivatives (**5a**). The same product (**5a**) was obtained in a one-pot reaction with 2 equiv. of thereagent**.** The crystal structure of the starting compound (**3**; Figure 1) shows that the *cis*-ansa macrocyclic ring is on the same side of the cyclophosphazene ring as the NH moiety of the spiropropanoxyamino ring, whereas that for the monosubstituted naphthoxy compound **4a** (Figure 2) shows that the macrocyclic ring is in a *trans*-ansa configuration as a result of a Walden inversion. The crystal structure of the disubstituted naphthoxy compound **5a** (Figure 3) shows that the macrocyclic ring again has a *cis*-ansa configuration as a result of a second Walden inversion, and that the macrocyclic ring is now on the opposite side of the cyclophosphazene ring to the NH moiety of the spiropropanoxyamino ring. These results prove conclusively that we are dealing in this reaction with two successive Walden inversions, which give rise to derivatives with a c*is*-ansa ring on the opposite side of the N_3P_3 ring to that of the starting material. It should be noted that the two P(OR)Cl groups in **3** have the opposite stereogenic configuration and the compound is therefore *meso* (Figure 1).Reaction of a mononucleophile with **3** can take place with equal probability at either P(OR)Cl group to form compound **4a**, which has been shown by X-ray crystallography to have a *trans*-ansa macrocyclic configuration (Figure 2) and exist as a racemate. Further reaction of **4a** with the same nucleophile gives the symmetrical compound **5a**, which has regained a *cis*-ansa structure and is *meso* (Figure 3).

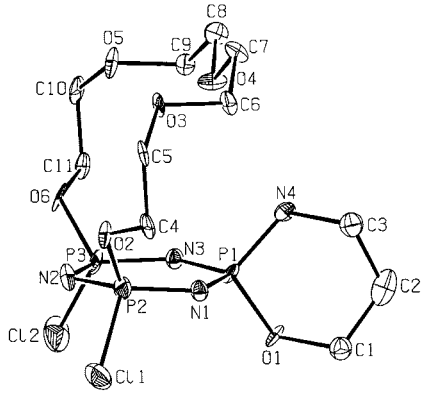

Figure 1. The molecular structure and atomic numbering scheme for one of the independent molecules of compound **3**, with hydrogen atoms (except for NH) and disorder omitted for clarity

In order to ensure that the double Walden inversion reaction does not depend on a bulky, anionic oxygen nucleophile (i.e. 2-naphthol), it was important to show the generality of the phenomenon with a variety of reagents with different steric demands and different nucleophilicities. Therefore we investigated the reaction of **3** with two smaller anionic analogues, phenol, to form the diphenoxide derivative **5b**, and the difunctional aliphatic nucleophile tetrafluorobutanediol, to give the diansa derivative **6**. The crystal structures of **5b** (Figure 4) and **6** (Figure 5) both demonstrate that double inversion has taken place because the macrocyclic ring is found to exist in the *cis*-ansa configuration that was *trans* to the NH group of the spiropropanoxy-

amino group. The investigation was then extended to test the inversion reaction with neutral nucleophiles. Reaction of **3** with the fairly strong nucleophilic secondary aliphatic amine pyrrolidine gave **5c**, whose crystal structure (Figure 6) again showsthat a double inversion has taken place as the macrocyclic ring is on the opposite side of the cyclophosphazene ring compared to the starting compound. It should be noted that reaction of primary amines with the P(OR)Cl group of **1**, which is analogous to **3**, takes place with inversion of configuration,although double inversion could not be conclusively proved in the absence of a stereochemical marker group.[7]

All of the symmetrically disubstituted compounds (**5a**–**c**, **6**; Scheme 2) have the ansa ring in a *cis* configuration and are *meso*. It therefore remained to synthesise an unsymmetrically disubstituted compound, which has a *cis*-ansa ring

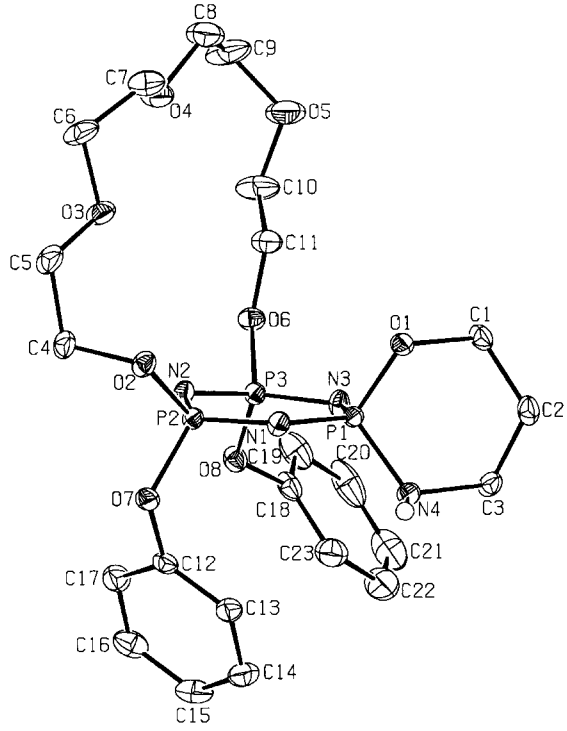

Figure 4. The molecular structure and atomic numbering scheme for compound **5b**, with hydrogen atoms (except for NH) omitted for clarity

but exists as a racemate, by a double Walden inversion reaction. This was achieved by introducing two different substituents, viz. OPh and NHPh in compound **7**, whose molecular structure is shown in Figure 7 and diagrammatic representation in Scheme 2. This compound also confirms that the weak primary aromatic amine aniline reacts with the P(OR)Cl group with inversion of configuration, which could not be proved with the dianilino derivative **5d** because suitable crystals were not obtained.

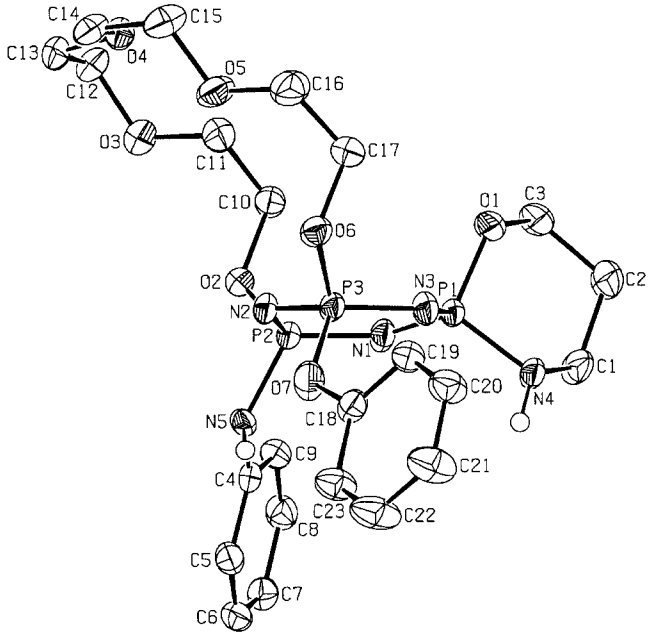

Figure 7. The molecular structure and atomic numbering scheme for compound **7**, with hydrogen atoms (except for NH) and the hydrogen-bonded water molecule omitted for clarity

Discussion of Crystal Structures

In all the crystal structures summarised in Figures 1–7, the bond lengths and bond angles of the N_3P_3 moieties are within the normal range found for cyclophosphazenes.[14] The shape of the cyclophosphazene ring varies from planar in compound **3**,through almost planar in **5b**, **5c** and **7**,to quite puckered in **4a**, **5a** and **6**. The really interesting features in this series of molecules are the hydrogen bonding and the conformation of the macrocyclic substituent with respect to the cyclophosphazene ring. Compound **3** is the only structure reported in this work that exhibits intramolecular hydrogen bonding; the other compounds exhibit intermolecular hydrogen bonding, except **5a**, which does not exhibit any significant hydrogen bonding at all. In compound **3** the macrocycle is pulled back over the N_3P_3 ring, probably because of the intramolecular hydrogen bonding of the NH group of the spiro ring to a central oxygen atom of the macrocycle. In compound **4a**, by contrast, the macrocycle is now pulled away from the N_3P_3 ring and the NH group is involved in intermolecular hydrogen bonding to the ring nitrogen atom of a second molecule to form discrete dimers. The sole 2-naphthoxy group adopts an edge-on conformation with respect to the N_3P_3 ring. A disordered Et_2O molecule is present in the crystal lattice. In the more symmetrical structure of compound **5a** the two 2-naphthoxy groups adopt quite different conformations with respect to the N_3P_3 ring, one being face-on and the other edge-on.The macrocycle is placed over the phosphazene ring, but here no hydrogen bonding is involved and, in fact, there are no close hydrogen bonds in this structure.In compound **5b** the macrocyclic moiety adopts an intermediate position, being neither pulled over or away from the phosphazene ring, even though, as in compound **4a**, the NH group is involved in intermolecular hydrogen bonding to the ring nitrogen atom of a second molecule to form discrete dimers. The structure of compound **5c** resembles that of **5b**,except that the macrocycle is pulled a bit further back from the N_3P_3 ring. In the diansa compound **6** the macrocycle is strongly pulled away from the N_3P_3 ring and the NH group is involved in intermolecular hydrogen bonding to one of the central oxygen atoms of the macrocycle of a second molecule to form infinite chains. In compound **7** the NH group hydrogen bonds intermolecularly to the oxygen atom of the macrocycle of another molecule to again form infinite chains. There is also a molecule of water present, which hydrogen bonds to a ring nitrogen atom and to an oxygen atom of the macrocycle.

Summary

It has been demonstrated by X-ray crystallography that all the nucleophilic reactions so far studied with the macrocyclic cyclophosphazene compound **3**, which contains a sixteen-membered tetraethylene glycol ansa moiety, give rise on monosubstitution, by a Walden inversion, to a racemic *trans*-ansa derivative, and on disubstitution, by a double Walden inversion, to *cis*-ansa compounds. The double

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Walden inversion has been verified with a wide variety of nucleophiles (mono- and difunctional reagents with different steric demands and different nucleophilicities). It is also found that compound **3** is *meso*, the symmetrically disubstituted derivatives of **3** (viz. **5a**, **5b**, **5c** and **6**) are *meso* and the unsymmetrically substituted derivative of **3** (viz. **7**) is, as expected, a racemate.

In all nucleophilic substitution reactions studied in this work, inversion of configuration is the preferred mechanism of reaction, though the possibility cannot be excluded that under some conditions there might be a product with retention of configuration. It has now been demonstrated crystallographically that inversion of configuration takes place in nucleophilic substitution reactions of macrocyclic phosphazene compounds containing a sixteen-membered ansa ring system, whereas retention of configuration occurs in cyclophosphazenes containing nine-membered ansa rings.[13] We are currently investigating analogous *cis*-ansa cyclophosphazene compounds with ring sizes intermediate between nine and sixteen to determine at which point or in which range of ring sizes retention changes to inversion. The work will be greatly facilitated by using a marker, such as the spiro-propanoxyamino group, which can be used to distinguish above and below the plane of the cyclophosphazene ring, and hence to investigate retention versus inversion mechanisms.

Experimental Section

Materials: Hexachlorocyclotriphosphazene (a gift from Shin Nisso Kako Co. Ltd.) was purified by fractional crystallization from hexane. Sodium hydride (60% dispersion in mineral oil, Merck) was washed with dry heptane, followed by decantation, to remove the oil prior to use. 2-Naphthol, phenol, pyrrolidine and aniline were obtained from Merck. 2,2,3,3-Tetrafluorobutanediol was obtained from Aldrich. Tetraethylene glycol (Fluka) and 3-amino-1-propanol (Merck) were dried with molecular sieves (4 Å). All solvents used in this work were purified by conventional methods. THF was distilled from a sodium/potassium alloy under dry argon. All reactions were carried out under dry argon. Products were subjected to separation by column chromatography using silica gel (230–400 mesh, Merck). Deuterated $CDCl_3$ for NMR spectroscopy was obtained from Goss Scientific.

NMR Measurements: 200 MHz ^{31}P NMR spectra of all compounds were recorded at 25 °C in $CDCl_3$ solutions with a Bruker DRX 500 MHz spectrometer using 85% H_3PO_4 as an external reference. In some cases both proton-coupled and proton-decoupled ^{31}P NMR spectra were recorded to aid assignment of spectra.

Synthesis of 3: Compound **2** was synthesised by the reaction of hexachlorocyclophosphazene with 3-amino-1-propanol, as described in the literature.[11,12] Compound **2** (3.5 g, 10 mmol) and tetraethylene glycol (2.91g, 15 mmol) were dissolved in 650 mL of dry THF in a 1-L, three-necked, round-bottomed flask. The reaction mixture was cooled in an ice-bath and NaH (1.2 g, 30 mmol) in 100 mL of dry THF was quickly added to the stirred solution under argon. The reaction mixture was stirred at room temperature for a further 2 h and was followed by TLC on silica gel plates with hexane/THF (1:1) as eluent. The reaction mixture was filtered to remove the sodium chloride formed, the solvent was removed under reduced pressure, and the resulting colourless oil was subjected to column chromatography with THF/hexane (2:1) as eluent. $N_3P_3[O(CH_2)_3NH][O(CH_2CH_2O)_4]Cl_2$ (**3**) was isolated as a colourless oil and crystallised from chloroform/hexane (1:2) to give white crystals, m.p. 137 °C (yield: 0.94 g, 20%). ^{31}P NMR (analysed as A_2X): δ = 13.8 [t, $^2J_{P,P}$ = 65 Hz, 1 P, P(spiro)], 23.4 [d, $^2J_{P,P}$ = 65 Hz, 2 P, P(OR)Cl] ppm. $C_{11}H_{23}Cl_2N_4O_6P_3$ (471): calcd. C 28.04, H 4.92, N 11.89; found C 28.04, H 4.88, N 12.5.

Reaction of 3 with 2-Naphthol To Give 4a: Compound **3** (0.47 g, 1 mmol) and 2-naphthol (0.216 g, 1.5 mmol) were dissolved in 50 mL of dry THF in a 100-mL, three-necked, round-bottomed flask. The reaction mixture was cooled in an ice-bath and NaH (0.06 g, 1.5 mmol) in 25 mL of dry THF was quickly added to the stirred solution under argon. The reaction mixture was stirred at room temperature for a further 4 h and followed by TLC on silica gel plates with hexane/THF (1:1) as eluent. The reaction mixture was filtered to remove the sodium chloride formed, the solvent ws removed under reduced pressure, and the resulting colourless oil was subjected to column chromatography with THF/hexane (1:1) as eluent. $N_3P_3[O(CH_2)_3NH][O(CH_2CH_2O)_4]$(2-naphthoxy)Cl] (**4a**) was isolated as a colourless oil and crystallised from dichloromethane/light petroleum (boiling range 40–60°C) to give white crystals, m.p. 75°C (yield 1.13 g, 60%). ^{31}P NMR (analysed as AMX): δ = 12.8 [dd, 1 P, P(OR)(2-naphthoxy), A], 16.9 [dd, 1 P, P(spiro), M], 26.4 ppm [dd, 1 P, P(OR)Cl, X]; $^2J_{P,P}$ = 79.4 Hz, AM; $J_{P,P}$ = 71.8 Hz, AX; $J_{P,P}$ = 79.4 Hz, MX. $C_{21}H_{30}ClN_4O_7P_3$ (578.8): calcd. C 43.57, H 5.22, N 9.68; found C 43.60, H 5.20, N 9.70.

Reaction of 3 with 2-Naphthol To Give 5a: Compound **3** (0.47 g, 1 mmol) and 2-naphthol (0.3 g, 2.1 mmol) were dissolved in 30 mL of dry THF in a 100-mL, three-necked, round-bottomed flask. The reaction mixture was cooled in an ice-bath and NaH (0.084 g, 2.1 mmol) in 25 mL of dry THF was quickly added to the stirred solution under argon. The reaction mixture was stirred at room temperature for a further 18 h and followed by TLC on silica gel plates with hexane/THF (1:1) as eluent. The reaction mixture was filtered to remove the sodium chloride formed, the solvent was removed under reduced pressure, and the resulting colourless oil was subjected to column chromatography with THF/hexane (1:1) as eluent. $N_3P_3\{[O(CH_2)_3NH][O(CH_2CH_2O)_4](2\text{-Naphthoxy})_2\}$ (**5a**) was isolated as a colourless oil and crystallised from (1:1) chloroform/light petroleum (boiling range 40–60°C) to give white crystals, m.p. 116 °C (yield 0.3 g, 43%). ^{31}P NMR (analysed as A_2X): δ = 18.6 [t, 1 P, P(spiro)], 14.6 ppm [d, 2 P, P(OR)(2-naphthoxy)$_2$]; $^2J_{P,P}$ = 73.1 Hz. $C_{31}H_{37}N_4O_8P_3$ (686.94): calcd. C 54.23, H 5.43, N 8.16; found C 54.21, H 5.40, N 8.10.

Reaction of 3 with Monofunctional Nucleophiles To Give Symmetrically Disubstituted Compounds 5b–d: Compound **3** was treated with phenol, pyrollidine and aniline to give compounds **5b**, **5c** and **5d**, respectively. Experimental and analytical details are provided as Supporting Information.

Reaction of 3 with 2,2,3,3-Tetrafluorobutanediol To Give the Monospiro-diansa Compound 6: Compound **3** (0.95 g, 2 mmol) and 2,2,3,3-tetrafluorobutanediol (0.33 g, 2 mmol) were dissolved in 50 mL of dry THF in a 100-mL, three-necked, round-bottomed flask. NaH (1.2 g, 30 mmol) in 20 mL of dry THF was quickly added to the stirred solution under argon and the reaction mixture was stirred at room temperature for a further 5 d and followed by TLC on silica gel plates with THF as eluent. The reaction mixture was filtered to remove the sodium chloride formed, the solvent was removed under reduced pressure, and the resulting colourless oil was subjected to column chromatography with THF/hexane (3:1) as eluent. The solvent was removed under reduced pressure and the

Sequential Reaction of 3 with Phenol and Aniline To Give the Unsymmetrically Disubstituted Compound 7. (i) Reaction of 3 with Phenol To Give 4b: Compound **3** (0.95 g, 2 mol) and phenol (0.188 g, 2 mmol) were dissolved in 50 mL of dry THF in a 100-mL, three-necked, round-bottomed flask. The reaction mixture was cooled in an ice-bath and NaH (0.08 g, 2 mmol) in 20 mL of dry THF was quickly added to the stirred solution under argon. The reaction mixture was stirred at room temperature for a further 4 h and followed by TLC on silica gel plates with hexane/THF (1:1) as eluent. The reaction mixture was filtered to remove the sodium chloride formed, the solvent was removed under reduced pressure, and the resulting colourless oil was subjected to column chromatography with THF/hexane (1:1) as eluent. $N_3P_3\{[O(CH_2)_3NH][O(CH_2CH_2O)_4](OPh)Cl\}$ (**4b**) was isolated as a colourless oil (yield 0.78 g, 74%). ^{31}P NMR (analysed as AMX): δ = 12.6 [dd, 1 P, P(OR)-(OPh), A], 16.9 [dd, 1 P, P(spiro), M], 26.4 ppm [dd, 1 P, P(OR)Cl, X]; $^2J_{P,P}$ = 79.1 Hz, AM; $J_{P,P}$ = 72.1 Hz, AX; $J_{P,P}$ = 69.3 Hz, MX. $C_{17}H_{28}ClN_4O_7P_3$ (529): calcd. C 38.61, H 5.34, N 10.59; found C 38.65, H 5.35, N 10.55. **(ii) Reaction of 4b with Aniline To Give 7:** Aniline (2.79g, 30mmol) was added dropwise from an addition funnel to a solution of **4b** (0.53 g, 1 mmol) in 15 mL of dry THF in a 50-mL, three-necked, round-bottomed flask. The reaction mixture was heated to reflux for 4 h and followed by TLC on silica gel plates with THF/hexane (2:1) as eluent. The reaction mixture was then cooled to room temperature, filtered and the solvent removed under reduced pressure. Distilled water (30 mL) was added to the reaction mixture and the mixture was extracted with dichloromethane. The organic layer was dried with anhydrous Na_2SO_4 and concentrated to 5 mL. The crude product was poured into 750 mL of hexane to give $N_3P_3\{[O(CH_2)_3NH][O(CH_2CH_2O)_4](OPh)(NHPh)\}$ (**7**) as white crystals, m.p. 76°C (yield 0.38 g 65%). ^{31}P NMR (analysed as ABX): δ = 14.7 [dd, 1 P, P(spiro), A], 14.0 [dd, 1 P, P(OR)(NPh), B], 18.1 ppm [t, 1 P, P(OR)(OPh), X]; $^2J_{P,P}$ = 72.3 Hz, AB; $J_{P,P}$ = 65.2 Hz, AX; $J_{P,P}$ = 65.4 Hz, BX. $C_{23}H_{34}N_5O_7P_3$ (586): calcd. C 47.18, H 5.85, N 11.96; found C 47.18, H 5.86, N 11.90.

X-ray Crystallography: Data were collected at low temperature with a Nonius KappaCCD area-detector diffractometer located at the window of a Nonius FR591 rotating anode X-ray generator, equipped with a molybdenum target (Mo-K_α, λ = 0.71073 Å). Structures were solved and refined using the SHELX-97 suite of programs.[15] Data were corrected for absorption effects by means of comparison of equivalent reflections using the program SORTAV.[16] Non-hydrogen atoms were refined anisotropically; NH hydrogen atoms were determined experimentally, whilst the other hydrogen atoms were generally fixed in idealised positions with their thermal parameters riding on the values of their parent atoms. Compound **3** exhibits 50:50 disorder at many sites in one of the two independent molecules, whilst **5c** and **6** show minor disorder in the macrocycle moiety and compound **4a** contains a disordered Et_2O solvent molecule. The absolute structure of **5a** was confirmed by refinement of the Flack parameter to a value of 0.01(9). The macrocycle moiety of **7** encapsulates a water molecule by means of hydrogen bonding. Details are given in Table 1. CCDC-189494 (**3**), -189495 (**4a**), -189496 (**5a**), -238735 (**5b**), -238736 (**5c**), -238737 (**6**) and-238738 (**7**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Supporting Information: Details of the preparation and analytical data for compounds **5b**, **5c** and **5d** are provided as Supporting Information (see also footnote on the first page of this article).

Synthesis, Structural and Magnetic Characterization of a New Scheelite Related Compound: $Eu_2Mo_3O_{12}$

Khalid Boulahya,[a] Marina Parras,[a] and José M. González-Calbet*[a]

Keywords: Molybdate / X-ray diffraction / High resolution electron microscopy / Magnetic properties

Polycrystalline $Eu_2Mo_3O_{12}$ has been synthesized and characterized by X-ray and electron diffraction, high resolution electron microscopy and magnetic measurements. This oxide shows a complex scheelite superstructure whose essential feature is the existence of isolated Mo tetrahedra. Each Mo atom has four oxygen neighbors at distances ranging from 1.75 to 1.91 Å, whereas each Eu atom has eight oxygen neighbors at 2.43 Å. The temperature dependence of the inverse magnetic susceptibility shows that $Eu_2Mo_3O_{12}$ behaves as a Curie–Weiss paramagnet at high temperature (160–300 K), whereas in the range 100–20 K it shows Van Vleck paramagnetism.

Introduction

Rare earth molybdates constitute a large family of materials with interesting physical properties which depend on the crystal structure, rare earth element and molybdenum oxidation state. Initial interest was developed due to fluorescence properties.[1] Later on, new applications were reported for the molybdenum highest oxidation state (VI). Ferroelectric/ferroelastic properties have been described for $Gd_2Mo_3O_{12}$,[2] whereas La_2MoO_6[3] shows catalytic behavior and $La_2Mo_2O_9$[4] is a fast ionic conductor. More reduced molybdates present some interesting transport properties such as metal–insulator transitions, as is the case of $La_2Mo_2O_7$[5,6] which exhibits short Mo–Mo distances.

The chemical nature of the lanthanide element strongly influences its structural type. For instance, at least three polymorphs have been described for the $Ln_2Mo_3O_{12}$ complex. The $La_2Mo_3O_{12}$[7] structure is formed by a network of corner-sharing square-antiprismatic and tetrahedral sites, with La having eightfold and Mo slightly distorted tetrahedral oxygen coordination. The structure is related to the scheelite ($CaWO_4$) type,[8] from which it can be derived through vacancy ordering of one third of the Ca sites. Nearest-neighbor environments of the cations resemble those of the scheelite. $Gd_2Mo_3O_{12}$[2] presents two polymorphs with different symmetries; both structures contain a network of corner-sharing polyhedra in which Gd and Mo cations are coordinated by seven and four oxygen atoms, respectively. Tb and Mo stabilize the same oxygen environment in $Tb_2Mo_3O_{12}$.[9]

The europium-molybdenum systems are attractive as a result of their structural and compositional variation. Such variation arises from the ability of isolated MoO_4 tetrahedra and Mo_nO_m structural units to be incorporated, in an ordered manner, giving rise to the stabilization of phases with different Eu/Mo ratios. For instance, the crystal structure of $Eu_6Mo_{12}O_{45}$[10] comprises four MoO_4 tetrahedra, and Mo_2O_8 and $Mo_{12}O_{11}$ structural units which, connected by sharing corners, form polymeric $[Mo_4O_{17}]$ chains. $Eu_6Mo_{10}O_{39}$[11] and $Eu_2Mo_5O_{18}$[12] are formed by MoO_4 and Mo_2O_7 units, which are three-dimensionally arranged. $Eu_4Mo_7O_{27}$[11] is a layered compound consisting of MoO_4 and Mo_3O_{11} units, while $EuMoO_4$[13] adopts the scheelite structural type where isolated MoO_4 tetrahedra constitute the three-dimensional structure. Finally, the crystal structure of $Eu_6Mo_{10}O_{39}$[11] is characterized by bioctahedral Mo_{10} clusters forming extended chains.

In this work, we report the synthetic conditions and characterization, by means of X-ray Rietveld refinement, electron diffraction (ED), high resolution electron microscopy (HREM), electrical resistivity and magnetic susceptibility, of a new europium molybdate with the composition $Eu_2Mo_3O_{12}$. The structural relationship between this phase and the scheelite structural type is reported.

Results and Discussion

The cationic composition, as analyzed by energy-dispersive X-ray spectroscopy, is in agreement with the nominal composition, $Eu_2Mo_3O_{12}$. The corresponding X-ray powder diffraction pattern (Figure 1) can be fully indexed on the basis of a monoclinic unit cell with space group, *C*2/*c,* and lattice parameters a = 7.5613(3) Å, b = 11.4685(5) Å, c = 11.5055(5) Å and β = 109.309(3)°, no extra reflections being detected.

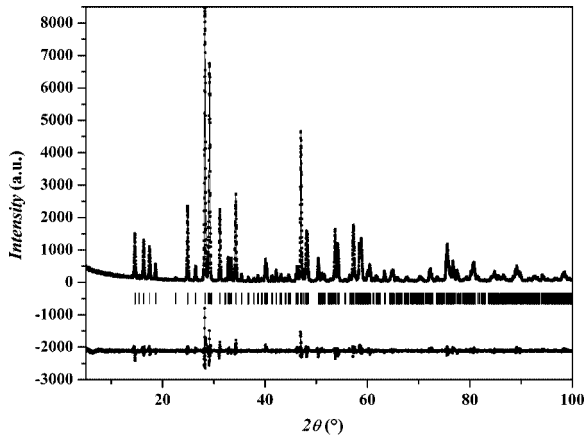

Figure 1. Experimental, calculated and difference X-ray diffraction patterns for $Eu_2Mo_3O_{12}$

The $Eu_2Mo_3O_{12}$ structure has been initially determined by ED and HREM (Figure 2). The HREM micrograph along the [100] zone axis (Figure 2b) shows an apparently well ordered material with d-spacings 5.7 and 3.6 Å, corresponding to d_{020} and d_{003}, respectively. Following the *b* axis, a layer of bright dots alternate with brighter ones in an ordered manner. This contrast can be associated with rows of tetrahedrally coordinated Mo atoms arranged at different heights along the *a* axis. These structural features are those presented by $Eu_2W_3O_{12}$[14] which can be described as a three-dimensional distribution of WO_4 tetrahedra linked by EuO_8 units. Therefore, from the $Eu_2W_3O_{12}$ atomic coordinates, an image calculation was performed in the *C*2/*c* space group. The simulated image (shown in the inset) compare well with the experimental one at Δt = 6 nm and Δf = –70 nm.

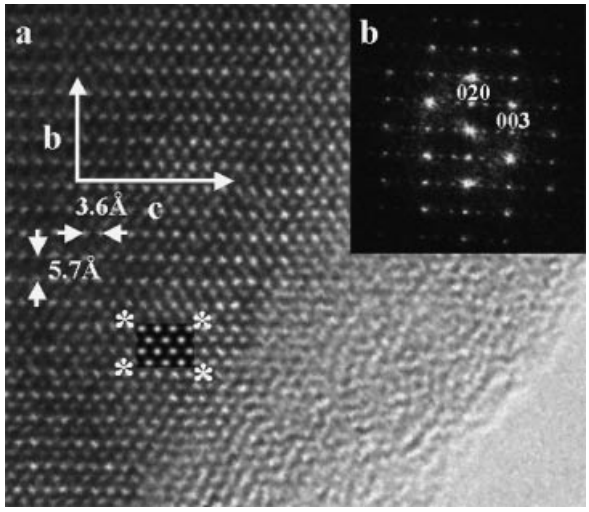

Figure 2. (a) HRTEM image of $Eu_2Mo_3O_{12}$ along [100], (b) corresponding FT. Simulated image is shown in the inset

On the basis of these results, an X-ray profile refinement was performed. The structure was solved in the ***C2/c*** space group taking the $Eu_2W_3O_{12}$ crystallographic data as the starting point. Peak shapes were described by pseudo-Voigt functions. Figure 1 shows the graphic results of the fitting of the experimental X-ray diffraction pattern and the difference between observed and calculated data. The refinement was stable and it was possible to refine the positions of oxygen atoms, provided a temperature factor for each type of atom was used. The structural model is depicted in Figure 3. The final structural parameters are collected in Table 1, whereas Table 2 shows some selected inter-atomic distances. The structure refinement confirms isotypism with $Eu_2W_3O_{12}$.[14] The crystal structure of the $Eu_2Mo_3O_{12}$ is formed by isolated $Mo(1)O_4$ tetrahedra and $Mo_2(2)O_8$ groups constituted by very irregular $Mo(2)O_5$ trigonal bipyramids. Mo1 forms a MoO_4 tetrahedron with M-O average distances of 1.78 or 1.83 Å. The Mo_2O_8 group comprises of two $Mo(2)O_5$ trigonal bipyramids sharing one edge. They are formed by three oxygen neighbors at distances of 1.79, 1.76, and 1.75 Å, a fourth one at 1.91 Å, and a fifth at 2.4 Å. Figure 4 shows a view of the Mo_2O_8 group. Such a dimeric group is also present in isostructural $Eu_2W_3O_{12}$ but, in this case, the distance to the fifth neighbor is smaller, close to 2.19 Å. However, a similar

value (2.39 Å) is observed in the related oxide $Eu_4Mo_7O_{27}$.[11] The Eu atom has eight oxygen neighbors at an average distance of 2.43 Å with a distorted square-antiprismatic coordination as observed in related europium oxides.[11]

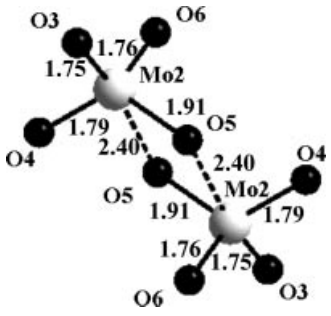

Figure 4. Structural details of the Mo_2O_8 group

The $EuMoO_4$,[13] scheelite related structure is depicted in Figure 5a. The analogy with $Eu_2Mo_3O_{12}$ can be clearly seen by comparing Figures 5a and b. Both structures are formed by similar [MoO_4] units of isolated tetrahedra. The essential structural difference is related to the europium atoms planes. In the scheelite $EuMoO_4$ structure, the three crystallographic Eu planes, indicated by solid lines in Figure 5a, are fully occupied and equidistant along the [120] direction. The ordered elimination of one of every three Eu planes in $EuMoO_4$, leads to the $Eu_2Mo_3O_{12}$ structure (Figure 5b). This Eu elimination process has less influence on the Eu coordination than in the Mo one. Whereas in the scheelite structure Mo only adopts tetrahedral coordination, in the $Eu_2Mo_3O_{12}$ oxide, Mo is also trigonal bipyramidally coordinated.

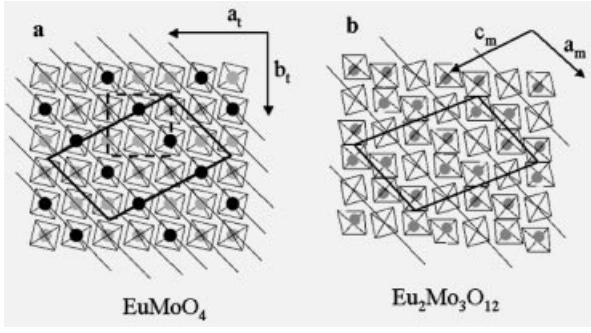

Figure 5. Schematic representation of the structural relationship between (a) $EuMoO_4$ and (b) $Eu_2Mo_3O_{12}$. Both structures are projected along the *c* axis of the scheelite cell, which is outlined by broken lines. Black dots represent the Eu atoms, which are eliminated in $Eu_2Mo_3O_{12}$. The steps involving the $EuMoO_4$ to $Eu_2Mo_3O_{12}$ transformation are shown

From the crystallographic point of view, monoclinic (*C*2/*c*) $Eu_2Mo_3O_{12}$ can be considered as a superstructure of tetragonal ($I4_1/a$) $EuMoO_4$ as depicted in Figure 5a. The monoclinic cell parameters a_m, b_m, and c_m can be related to the tetragonal ones a_t and c_t by means of the expression: $a_m \approx a_t\sqrt{2}$, $b_m \approx c_t$ and $c_m \approx a_t\sqrt{5}$. Furthermore, the symmetry *C*2/*c* is a subgroup of $I4_1/a$.

On the other hand, different physical properties have also been explored. First, from an electrical point of view, $Eu_2Mo_3O_{12}$ behaves as an insulator at room temperature.

The temperature dependence of the molar susceptibility is shown in Figure 6. The curve shape resembles that reported by Holsa et al.[15] but χ is smaller by 14–30% than their data at all the temperatures measured. The χ^{-1} value follows the Curie–Weiss law down to about 160 K and then is constant for the lower temperature range between 100 and 20 K. Finally, below 20 K, a sharp decrease in the inverse susceptibility is observed. This behavior can be qualitatively explained by the exceptional ^7F_J (J = 0–6) ground term energy level Scheme of the Eu^{3+} ion.[16,17] The $^7F_0$–$^7F_1$ energy gap is large enough to induce a *plateau* in the inverse paramagnetic susceptibility curve due to the constant temperature independent paramagnetism, since practically only the ground level $^7F_0$ is populated. The $^7F_0$ ground level is non-magnetic and gives no contribution to the $Eu_2Mo_3O_{12}$ susceptibility at low temperatures. At the higher temperature range, the population of the closely spaced higher ^7F_J (J = 1–6) levels leads to the normal Curie–Weiss paramagnetism. It can be concluded that for Eu^{3+}, the crystal field plays a significant role in the susceptibility. Below 15 K, a sharp decrease in the inverse susceptibility is observed. This has been already been observed with other Eu compounds, as in the oxychloride EuOX (X = Br, Cl),[15,16] and attributedto the presence of a slight amount of Eu^{2+} impurity, since Eu^{2+} with the $^4f_7$ electron configuration has high paramagnetic susceptibility. In order to understand this phenomenon, a study on partially reduced Eu^{3+} samples is in progress.

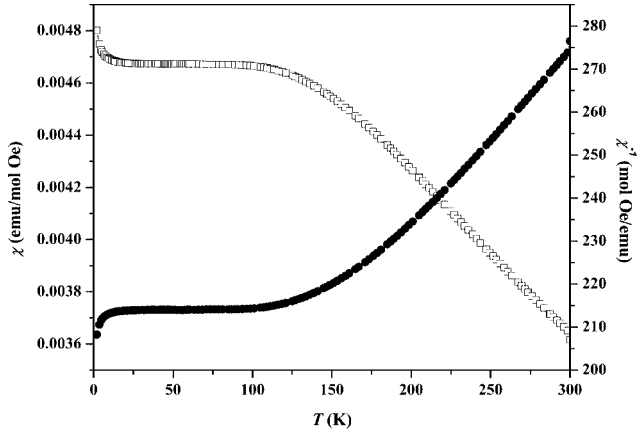

Figure 6. Temperature evolution of the magnetic susceptibility χ (squares) and χ^{-1} (black dots) of $Eu_2Mo_3O_{12}$

Experimental Section

Polycrystalline $Eu_2Mo_3O_{12}$ was synthesised by heating stoichiometric amounts of Eu_2O_3 (Aldrich; 99.98%) and MoO_2 (Aldrich; 99+%) in air at 900 °C for 4 days and then quenched to room temperature.

Powder X-ray diffraction patterns were collected with CuKα radiation at room temperature on a PHILIPS X'PERT diffractometer

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

equipped with a graphite monochromator. Diffraction data were analyzed by the Rietveld method[18] using the Fullprof program.[19]

The sample was characterized by ED and HREM using a PHILIPS CM200 FEG electron microscope, fitted with a double tilting goniometer stage (±40°, ±24°). Local composition was analyzed with an EDAX DX-4 analyzer system attached to the above microscope. Simulated HREM images were calculated by the multislice method using the MacTempas software package. Magnetic properties were measured with a SQUID magnetometer, over the temperature range 2 to 300 K, and magnetic fields up to 5 T.

Reaction Chemistry of the Carbenoid Butadienyl Complex Ion $[CpCo(\sigma,\eta^4\text{-}C_4HMe_4)]^+$ Formed by Protonation of the Cyclobutadiene Complex $[CpCo(C_4Me_4)]$

Mikhail V. Butovskii,[a] Ulli Englert,[a] Gerhard E. Herberich,*[a] and Ulrich Koelle[a]

Keywords: Cobalt / Cyclobutadiene / Butadienyl / Carbene

The protonation of $[CpCo(C_4Me_4)]$ (**1**) with excess acid, which produces the carbenoid ion $\mathbf{3}^+$, is shown to be reversible under conditions of low proton activity. Treatment of $\mathbf{3}^+$ with *one equivalent* of NEt_3 mainly produces **1** (60 %, isolated yield), and in DMSO the solvent acts as base transforming $[\mathbf{3}]BF_4$ into **1** (67 %, isolated yield). Deprotonation of $[\mathbf{3}]BF_4$ with *excess* NEt_3 affords (cyclopentadienyl)[(2–5-η)-(3Z,4Z)-3,4-dimethylhexa-1,2,4-triene]cobalt (**5**) in high yield (83 %). The structure of **5** has been determined by X-ray work. In the reaction of $\mathbf{3}^+$ with pyridine four reaction channels could be unveiled by low-temperature NMR spectroscopy: i) Reversible deprotonation to form **5** in a kinetic shunt; ii) reversible nucleophilic addition at the carbenoid center to form a pyridinium ion complex $\mathbf{6}^+$ as a low-temperature species with a terminal *anti*-Me group; iii) irreversible isomerization of $\mathbf{6}^+$ to the more stable stereoisomer $\mathbf{7}^+$ with a terminal *syn*-Me group; iv) very slow formation of **1**. Using very high concentrations of pyridine (mixing at –60 °C, slowly warming to 20 °C) allowed the preparation of $[\mathbf{7}]BF_4$ in near quantitative yield (97 %). The pyridine rings in $\mathbf{6}^+$ and $\mathbf{7}^+$ display hindered rotation (NMR), and the structure of $[\mathbf{7}]CF_3SO_3$ shows considerable steric crowding. On treatment with a large excess of CF_3CO_2H (≥ 7 equiv.) the hexatriene complex **5** quantitatively reverts to the carbenoid $\mathbf{3}^+$. Reaction of **5** with $(C_5H_5NH)CF_3SO_3$ (–80 °C, 3 weeks) produced $[\mathbf{6}]CF_3SO_3$ with retention of the stereochemistry at C-4 (NMR), while the same reaction at ambient temperature and in presence of a large excess of pyridine is accompanied by stereoisomerization and afforded $[\mathbf{7}]CF_3SO_3$ (94 %). Nucleophilic addition of excess PPh_3 to $\mathbf{3}^+$ gave a phosphonium salt $[\mathbf{8}]BF_4$, again with stereoisomerization, in near quantitative yield (98 %). Addition of CN*t*Bu with concomitant rearrangement produced a (*tert*-butylamino)cobaltocenium salt $[\mathbf{9}]CF_3SO_3$ (90 %). Nucleophilic substitution of the pyridine moiety of $\mathbf{7}^+$ with 4-picoline gave the 4-picoline addition product $[\mathbf{10}]CF_3SO_3$ (96 %). With CN^- a hexa-2,4-dienenitrile complex $[CpCo(\eta^4\text{-}C_4HMe_4CN)]$ (**11**) was obtained (85 %), which on protonation gave an aminocobaltocenium ion $[CpCo\{C_5Me_4(NH_2)\}]^+$ ($\mathbf{12}^+$), isolated as $[\mathbf{12}]BF_4$ (94 %). Acid removes the pyridine moiety from $\mathbf{7}^+$ to produce a carbenoid ion $\mathbf{13}^+$ with a 4-Me group in *syn*-position (a stereoisomer of $\mathbf{3}^+$) which was characterized by NMR spectroscopy. Deprotonation of $\mathbf{13}^+$ affords a hexatriene complex **14** (a stereoisomer of **5**) in good yield (57 %). Thermolyses of **5** and **14** show that **14** is the lower-energy isomer and produce a dinuclear complex $[(\mu\text{-}C_5H_3Me_3)(CoCp)_2\textit{(Co–Co)}]$ (**15**) (91 %) with a bridging penta-2,4-dienylidene ligand.

Introduction

In an earlier communication[1] we described the protonation of (cyclopentadienyl)(tetramethylcyclobutadiene)cobalt [CpCoCb*] (Cb* = C_4Me_4) (**1**).[1,2] According to a DFT study this protonation takes place from the *endo*-side to give a primary agostic intermediate $\mathbf{2}^+$. This intermediate rearranges by way of a stereospecific ring-opening reaction to give a carbenoid cation $\mathbf{3}^+$ with a σ,η^4-butadienyl substructure and an *anti*-Me group. While $\mathbf{2}^+$ has not been observed experimentally, the rearranged cation $\mathbf{3}^+$ was isolated as tetrafluoroborate in quantitative yield (97%) and has fully been characterized.[1]

If this protonation reaction is performed with a large excess of acid (for instance with 9 equivalents of HBF_4 in Et_2O at –50 °C or in neat CF_3CO_2H), product formation is fast and clean. At lower proton activity some solid material is formed, possibly by some decomposition processes. These observations suggest that the protonation reaction of **1** might be reversible, but only in this paper can we present straightforward experimental evidence for the reversibility of the sequence $\mathbf{1} \rightarrow \mathbf{2}^+ \rightarrow \mathbf{3}^+$.

The carbenoid cation $\mathbf{3}^+$ is a highly reactive species. At temperatures above –10 °C it undergoes thermal rearrangement with formation of [(cyclopentadienyl){η^5-(2*Z*,3*Z*,4*E*)-

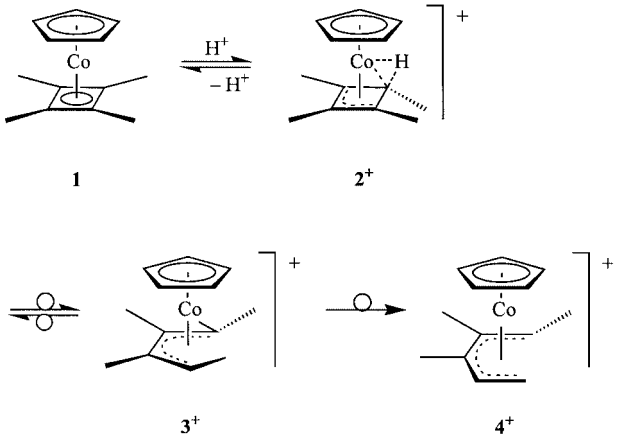


Scheme 1. Primary protonation equilibrium/rearrangement.

3,4-dimethylhexa-2,4-dienyl}cobalt] cation (**4**$^+$), a half-open cobaltocenium ion. This chemistry is summarized in Scheme 1.[1]

Early papers on (cyclobutadiene)(cyclopentadienyl)cobalt derivatives describe electrophilic H/D-exchange as well as some other electrophilic aromatic substitution reactions as characteristic reactions in this family of complexes,[3] the most notable examples being the parent complex [CpCo(C_4H_4)][4] and the tetraphenyl derivative CpCo(C_4Ph_4).[5] The boratabenzene analogue of **1**, [Cb*Co(C_5H_5BMe)],[6] which is less electron-rich than **1**, displays similar reactivity with very fast H/D exchange, but ring opening of the Cb* ring has never been observed. We conclude that only the most electron-rich complexes of the [CpCoCb]-type can undergo the protonation/rearrangement sequence of Scheme 1.

Complexes with σ,η^4-butadienyl-type ligands are known in some variety, for instance of the fragments CpRu,[7] Cp*Ru,[8] CpRe,[9] and CpMo[10] as well as of other complexes of Nb,[11] Mo,[12] and W.[12] To the best of our knowledge, cation **3**$^+$ is the first such complex of a 3d metal. Since the ion **3**$^+$ originates from a protonation reaction, it seemed particularly interesting to study its reactions with bases and/or nucleophiles. During our work, it quickly turned out that the reactions of **3**$^+$ depend in a subtle manner on the nature of the attacking reagents and on the reaction conditions. In this paper we describe the deprotonation of **3**$^+$, conditions which result in a reversal of the ring opening of complex **1** (in Scheme 1), furthermore nucleophilic addition to **3**$^+$, and some closely related chemistry of the products obtained.

Results and Discussion

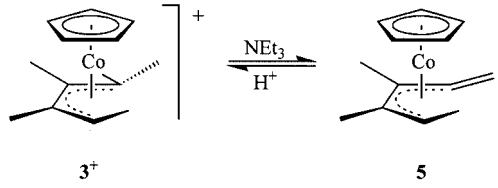
Deprotonation of the Carbenoid Complex 3$^+$

Reaction of [**3**]BF_4 in dichloromethane with a large excess of triethylamine effects deprotonation and produces (cyclopentadienyl)[(2–5-η)-(3*Z*,4*Z*)-3,4-dimethylhexa-1,2,4-triene]cobalt (**5**). For instance, an NMR experiment with a 1:5 ratio of the reactants showed the formation of the hexatriene complex **5** as the sole complex product and of $NHEt_3^+$; no further change was seen at ambient temperature after 16 h. Preparative runs yielded **5** as air-sensitive, low-melting, orange-red crystals. Other strongly basic reagents, as for instance allylmagnesium chloride in ether, gave the same product **5**. Note that **5** is an isomer of **1**, but does not spontaneously convert to **1** under the conditions given here.

^{1}H NMR spectra of **5** show that the terminal MeCH= moiety of **3**$^+$ with an *anti*-Me group is retained in **5** and that one methyl group is now replaced with a noncoordinated methylene function. This result was later confirmed by a single-crystal structure determination (see below). Marked C–H acidity at a carbon atom ß to a carbene center is well known for Fischer carbene complexes,[13] and has previously been observed for some of the known σ,η^4-butadienyl complexes.[10,14]

When **3**$^+$ was deprotonated with NEt_3 in a 1:1 ratio, i.e. under conditions where a low proton activity is retained, some unidentified solid material was deposited. The ^{1}H NMR of the solution, recorded without delay, indicated the presence of two complex products, the hexatriene complex **5** and the cyclobutadiene complex **1** in roughly a 1:1 ratio. Upon standing at ambient temperature, the concentration of **1** grew at the expense of **5**, and after 16 h, complex **1** had become the sole complex product. Conventional workup of the NMR tube contents including chromatography on alumina with hexane as eluent afforded a 60% yield of spectroscopically pure **1**. In a related experiment [**3**]BF_4 was dissolved in CH_2Cl_2/DMSO (2:1, v/v) and kept at 30 °C for 30 min; in this case the basicity of the medium is sufficient to allow the transformation of **3**$^+$ into complex **1** which was isolated in 67% yield.

These observations imply reversibility of the deprotonation of **3**$^+$ (Scheme 2) and of the ring-opening reaction of **1** (Scheme 1). Protonation of **5** by protic reagents other than the relatively weak acid $NHEt_3^+$ will be described below.



Scheme 2. Protonation/deprotonation equilibrium.

We summarize and conclude: i) In strongly acidic medium the stable complex species is the carbenoid ion **3**$^+$ which is formed either from the cyclobutadiene complex **1** (Scheme 1)[1] or from the hexatriene complex **5** (Scheme 2). ii) In strongly basic medium, i.e. with a large excess of base or with strong bases, a kinetically controlled deprotonation of **3**$^+$ affords the hexatriene complex **5**. iii) Under conditions of low, but noticeable proton activity reversibility comes into play. The product now is the cyclobutadiene complex **1**, both in the reaction of **3**$^+$ with bases and in the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

protonation of **5**; thus the cyclobutadiene complex **1** is seen to be thermodynamically more stable than its isomer **5**.

Structure of 5

The structure of **5** was determined by single-crystal X-ray diffraction (Figure 1) and confirms the presence of an η^4-bonded vinylallene-type ligand and the *anti*-position of the terminal Me group. Related structures are known for $[Fe(CO)_3]$[16] and CpRu compounds[14c] and a $[RhCl(PPh_3)]$ complex.[17] We note the short bond length C3–C4 [1.408(11) Å] of the central diene bond, which is now shorter than the former diene double bonds C2–C3 [1.449(9) Å] and C4–C5 [1.438(11) Å], furthermore the remarkably short bond length Co–C2 [1.883(5) Å], and the bond angle C1–C2–C3 [137.2(6)°]; the methyl group at C5 is bent away from the metal. These details are all indicative of pronounced metal-to-ligand back-bonding, as expected for a complex which belongs to the CpCo(diene) family in a broad sense.

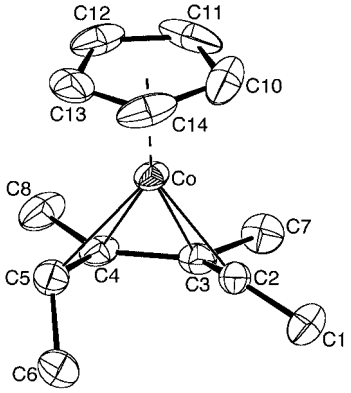


Figure 1. Molecular structure of **5** in the crystal (PLATON plot[15] at the 30% probability level); selected bond lengths (Å) and angles (°): Co–C2 1.883(5), Co–C3 1.988(5), Co–C4 1.979(5), Co–C5 2.050(6), Co–C(Cp) 2.053 (av.), C1–C2 1.316(8), C2–C3 1.449(9), C3–C4 1.408(11), C4–C5 1.438(11); C1–C2–C3 137.2(6), C4–C5–C6 126.3(6), C2–C3–C4–C5 9.5, C3–C4–C5–C6 56.3, C1–C2–C3–C4 147.1.

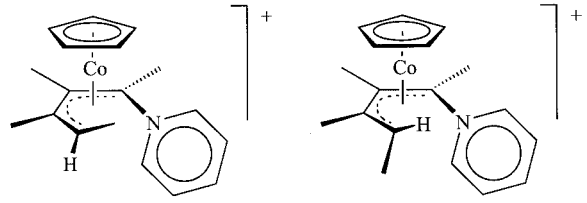
Nucleophilic Addition to the Carbenoid Complex 3^+

In this chapter we describe nucleophilic addition reactions which are the preferred reactions for weak bases such as pyridine, PPh_3, and CN*t*Bu. The case of pyridine addition, which revealed an unexpected complexity of the reaction system, was investigated by means of low-temperature NMR experiments and by varying the substrate/base ratio.

Addition of Pyridine

In one NMR tube experiment pyridine (1 equiv.) was added to a solution of $[\mathbf{3}]BF_4$ in CD_2Cl_2 at –80 °C and the reaction mixture was kept at this temperature for several days. Four different cobalt complexes were observed as products: i) The hexatriene complex **5**, ii) a primary addition product $[\mathbf{6}]BF_4$, iii) an isomeric addition product $[\mathbf{7}]BF_4$, and iv) the cyclobutadiene complex **1**. In the early stages of the reaction (up to 30 h) the major product was the hexatriene complex **5**; after 30 h at –80 °C the product ratios (normalized to 100%) were $\mathbf{5}:\mathbf{6}^+:\mathbf{7}^+:\mathbf{1}$ = 53:37:8:2. Later the primary addition product $\mathbf{6}^+$ grew at the expense of **5** and amounted to 80% of the product mixture after 7 days; the product ratios now were $\mathbf{5}:\mathbf{6}^+:\mathbf{7}^+:\mathbf{1}$ = 5:80:10:6. It is remarkable that **1** already appears at –80 °C with its concentration very slowly increasing with time at this temperature.



$\mathbf{6}^+$ $\mathbf{7}^+$

In a second NMR tube experiment the temperature of the reaction mixture ($\mathbf{3}^+/C_5H_5N$, 1:1) was increased in steps of 10 K. Under these conditions the hexatriene complex **5** was the major product up to –60 °C, but had disappeared completely below –30 °C. The primary addition product $\mathbf{6}^+$ reached its maximum concentration at –30 °C. At higher temperatures the concentration of **1** grew quickly at the expense of $\mathbf{6}^+$; at 10 °C ratios of $\mathbf{5}:\mathbf{6}^+:\mathbf{7}^+:\mathbf{1}$ = 0:0:14:86 were observed. A similar experiment with a higher pyridine concentration ($\mathbf{3}^+/C_5H_5N$, 1:7) differed in two respects. Above –50 °C the isomerization $\mathbf{6}^+ \rightarrow \mathbf{7}^+$ was clearly seen and was the main process above –25 °C, while the formation of **1** was markedly slowed down; at 10 °C ratios of $\mathbf{5}:\mathbf{6}^+:\mathbf{7}^+:\mathbf{1}$ = 0:1.5:76:23 were reached. In all these experiments the primary addition product $\mathbf{6}^+$ seemed to be the sole source for the formation of **1**. We may conclude i) that the pyridine addition to $\mathbf{3}^+$ is reversible allowing the formation of **1**, and ii) that the isomerization $\mathbf{6}^+ \rightarrow \mathbf{7}^+$ is an irreversible reaction (Scheme 3).

Scheme 3. Pyridine addition equilibrium and stereoisomerization.

The primary addition product $[\mathbf{6}]BF_4$ could, of course, only be characterized by its ^1H NMR and ^{13}C NMR spectra. For the preparation of the more stable isomeric addition product $[\mathbf{7}]BF_4$ a very high concentration of pyridine $[CH_2Cl_2/C_5H_5N$, 1:1 (v/v)] has to be used. Mixing the reagents at –60 °C effected an immediate color change from dark red to orange-red; while the temperature was slowly increased the color began to deepen and was burgundy at ambient temperature. From this solution the product was isolated in near quantitative yield.

The ^1H NMR spectra of the isomeric ions $\mathbf{6}^+$ and $\mathbf{7}^+$ are rather similar, but differ conspicuously in the doublet/quartet pattern of the terminal MeCH= moiety [for $\mathbf{6}^+$: δ = –0.49 ppm (d, J = 7.6 Hz, 4-Me) and 3.76 ppm (q, J = 7.6 Hz, 4-H); for $\mathbf{7}^+$: δ = 1.18 (d, J = 6.1 Hz, 4-Me) and –0.37 ppm (q, J = 6.1 Hz, 4-H)]. These data show that $\mathbf{6}^+$

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

still possesses an *anti*-Me group (with a negative chemical shift) which has become a *syn*-Me group in **7**$^+$. This result is in agreement with the structure determination of [**7**]CF_3SO_3 (see below). In contrast to **6**$^+$ the cation **7**$^+$ displays an additional long-range coupling (^4J = 0.7 Hz) between the proton 4-H_{anti} and the methyl group 3-Me which are in a zigzag arrangement in this isomer. Both ions **6**$^+$ and **7**$^+$ display separate signals for the proton pairs 2-H/6-H and 3-H/5-H of the pyridine ring. This indicates hindered rotation of the pyridine ring. When the solution of [**7**]BF_4 in $MeNO_2$ was warmed, five sharp lines were observed up to 50 °C; at higher temperatures the spectra deteriorated due to decomposition, but even at 80 °C five signals were seen. Hindered rotation of pyridine ligands has occasionally been observed, albeit only at low temperatures.[18] We comment on the origin of this barrier in the context of the structure description of the structure of [**7**]CF_3SO_3.

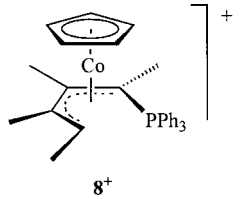
We noted above that low concentration of pyridine and higher temperatures favor the formation of the cyclobutadiene complex **1** while very high concentrations of pyridine favor the stereoisomerization **6**$^+$ → **7**$^+$. Excess pyridine and low temperature will suppress the dissociation of the primary addition product **6**$^+$ → **3**$^+$ and hence the formation of **1** (cf. Scheme 1 and Scheme 3). As a consequence, the slow stereoisomerization can come into play. Note also, that in the preparation of [**7**]BF_4 mixing at low temperature and slow warm up are features which are essential for the excellent yields obtained. We consider this interpretation as the most likely one. However, in the absence of kinetic data we cannot exclude that pyridine does actively participate in the stereoisomerization; in such a case high pyridine concentrations would directly accelerate the formation of **7**$^+$.

Addition of Triphenylphosphane

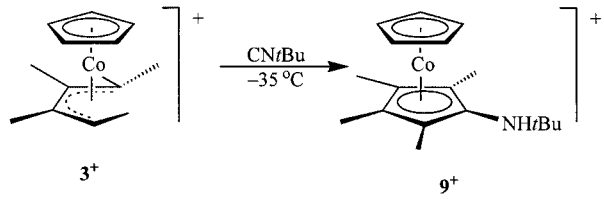
Under the same reaction conditions used for the preparation of [**7**]BF_4, the carbenoid complex [**3**]BF_4 reacts with excess PPh_3 (7 equiv.) to undergo nucleophilic addition, again with stereoisomerization of the diene chain. The resulting complex phosphonium ion **8**$^+$ was isolated as tetrafluoroborate [**8**]BF_4 in quantitative yield. The ion **8**$^+$ has a remarkably small direct coupling constant $^1J_{PC}$ = 46.0 Hz as has the related ion [CpCo{η^4-$C_4HPh_4(PPh_3)$}]$^+$ ($^1J_{PC}$ = 36.6 Hz).[19] If only 1 equivalent of PPh_3 was used the familiar complications appeared again: Formation of **1** and of insoluble material. Trimethylphosphane reacted unselectively to produce several unidentified [CpCo(PMe_3)] species (NMR).

Addition of tert-Butyl Isocyanide

The reaction of [**3**]CF_3SO_3 with CN*t*Bu is fast at –35 °C, showing a fast color change from dark red to yellow, and produced the (*tert*-butylamino)cobaltocenium derivative [**9**]CF_3SO_3 (Scheme 4). The new cobaltocenium ion was readily identified and characterized by its simple NMR spectra which show effective lateral symmetry for the cation. This fascinating ring formation has precedence in M. Green's chemistry,[19] and will be discussed below.



8$^+$



3$^+$ **9**$^+$

Scheme 4. Reaction with CN*t*Bu.

Protonation of the Hexatriene Complex 5

The protonation of **5** (Scheme 2) had first been deduced from the evolution of the system **3**$^+$/C_5H_5N with time, but can be confirmed by independent experiments. Indeed, when **5** was treated with a large excess CF_3CO_2H (≥ 7 equiv., NMR tube experiment), the reverse protonation reaction took place and produced **3**$^+$ in a very clean reaction; no species other than **3**$^+$ and CF_3CO_2H were seen. With only stoichiometric quantities (**5**/CF_3CO_2H, 1:1) we found again formation of **1** and of insoluble material.

The protonation of **5** by the pyridinium salt (C_5H_5NH) CF_3SO_3 in CD_2Cl_2 was monitored by low-temperature NMR spectroscopy. When the reaction mixture was kept at –80 °C, the main process was the slow formation of [**6**]CF_3SO_3, and both [**7**]CF_3SO_3 and **1** remained trace products. After 3 weeks at –80 °C the product ratios were **5**:**6**$^+$:**7**$^+$:**1** = 0:93:5:2. In contrast to this low-temperature situation, the synthetic version of this experiment required high concentrations of pyridine in CH_2Cl_2 (4:6 v/v) to ensure high chemoselectivity, and at ambient temperature afforded the complex triflate [**7**]CF_3SO_3 in excellent yield (94%).

Structure of [7]CF_3SO_3

The structure determination of [**7**]CF_3SO_3 confirms the constitution of **7**$^+$ and specifically the *syn*-position of the Me group at C4 (in chemical notation C-4′) and the *anti*-stereochemistry of the pyridinio substituent at C1 (Figure 2). Thus, the cation **7**$^+$ is a CpCo(diene) derivative with the unusual feature of a positively charged substituent in the terminal *anti*-position of the diene ligand. The short central bond of the diene substructure [C2–C3 1.384(4) Å] and the long former double bonds [C1–C2 1.441(3) and C3–C4 1.443(4) Å] show again that metal-to-diene back bonding is rather pronounced as in **5**. We also note that the bond N–C1 [1.498(3) Å] is longer than expected. A search in the CSD database[20] for structures with comparable ge ometry[21] resulted in 692 hits with an average C–N distance

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of 1.392(1) Å; only six of the 692 matches showed a C–N distance longer than the one observed in **7**$^+$. We explain the unusual length of the N–C1 bond by a steric labilization caused by two short interactions between the pentadienyl chain and the pyridinium N atom, namely N···H5–C5 of 2.61 and N···H4–C4 of 2.19 Å. Of course, we cannot exclude an additional electronic effect due to the neighboring metal center.

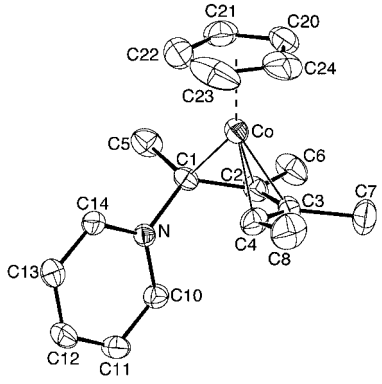


Figure 2. Structure of the ion **7**$^+$ in the crystal of [**7**]CF_3SO_3 (PLATON plot[15] at the 30% probability level); selected bond lengths (Å) and angles (°): Co–C1 1.975(2), Co–C2 1.971(2), Co–C3 1.966(3), Co–C4 2.053(3), Co–C(Cp) 2.057 (av.), N–C1 1.498(3), C1–C2 1.441(3), C2–C3 1.384(4), C3–C4 1.443(4); C2–C1–N 118.5(2), C2–C1–C5 120.8(2), N–C1–C5 106.31(19); C1–C2–C3–C4 2.1, N–C1–C2–C3 59.0, C5–C1–N–C10 100.6, C5–C1–N–C14 76.6.

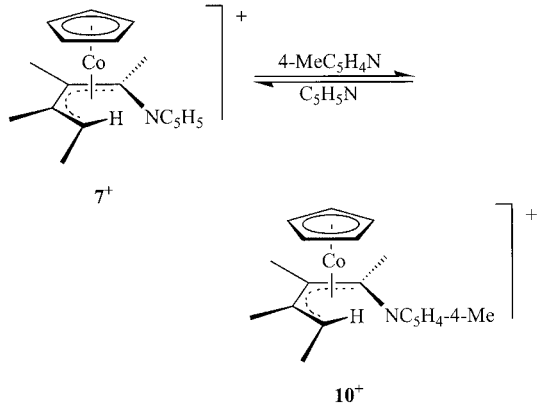
If the (trimethylpentadienyl)pyridinium ligand of **7**$^+$ were planar we would have a prohibitively strong repulsive 1,6-interaction between a C atom in the *ortho*-position of the pyridinium ring and C4 of the pentadienyl chain. In the structure this 1,6-interaction is reduced by a bending of the ring out of the pentadienyl plane and away from the metal [dihedral angle N–C1–C2–C3 59.0°] and by a near orthogonal rotational position of the ring. This situation explains the unusually high barrier to internal rotation of the pyridine ring which is seen in the NMR spectra.

Nucleophilic Substitution of the Pyridine Moiety of 7$^+$

In the system **3**$^+$/pyridine we had observed the slow formation of the cyclobutadiene complex **1** from the pyridine addition product **6**$^+$, most likely via the carbenoid ion **3**$^+$ (cf. Scheme 1 and Scheme 3). Given the low thermal stability of **6**$^+$, it would be difficult to verify the reversibility of the pyridine addition to **3**$^+$ directly. However, the more stable isomer **7**$^+$ is prone to reactions which suggest that pyridine can dissociate from the complex.

A Pyridine/4-Picoline Exchange Reaction

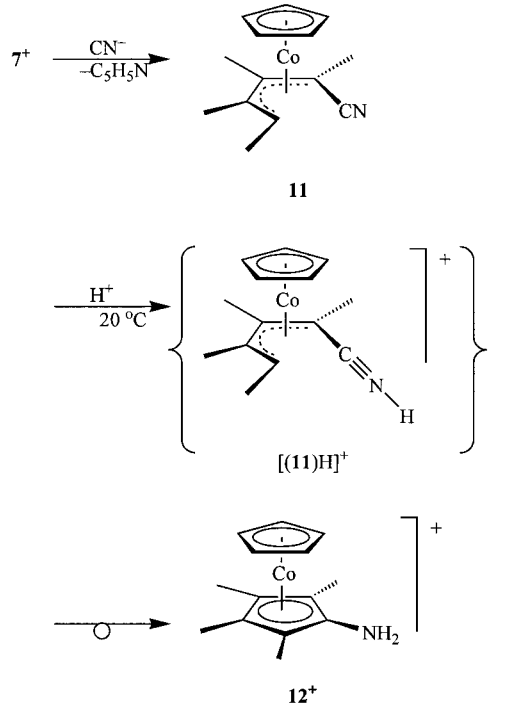
When 4-picoline (4-methylpyridine) was added to a solution of [**7**]CF_3SO_3 in CD_2Cl_2 a new species **10**$^+$ was seen in a slow exchange reaction at ambient temperature (NMR, two Cp signals) with a slight preference of **3**$^+$ for 4-picoline over pyridine (Scheme 5). The pure 4-picoline addition product [**10**]BF_4 could be prepared in CH_2Cl_2 by repeated removal of the volatiles and addition of fresh CH_2Cl_2 and 4-picoline.



Scheme 5. Pyridine/4-picoline exchange.

Substitution Reaction of 7$^+$ with Cyanide

Attempted nucleophilic addition of cyanide to **3**$^+$ produced the hexatriene complex **5** because of the high basicity of CN^- in an aprotic medium. However, the reaction of **7**$^+$ with $(NBu_4)CN$ resulted in a smooth substitution of pyridine with cyanide and afforded the neutral complex **11** as a robust crystalline compound (Scheme 6). This nitrile **11** could readily be protonated in an NMR tube experiment. The reaction with CF_3CO_2H (3 equiv.) in CD_2Cl_2 effected a fast color change from red to yellow. The cation so formed was precipitated from aqueous solution as hexafluorophosphate [**12**]PF_6 (Scheme 6). A synthetically more



Scheme 6. Cyanide reaction, protonation, rearrangement.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

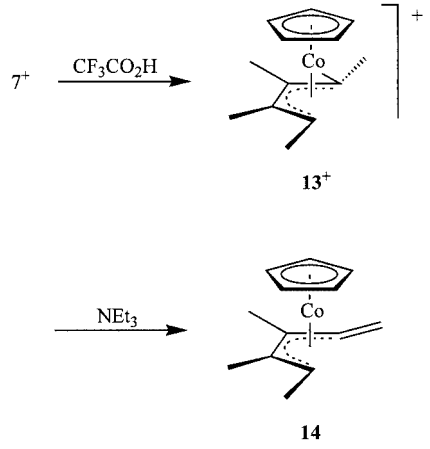
convenient reaction with HBF_4 in ether afforded [**12**]BF_4 in near quantitative yield. Mechanistically, this transformation is thought to involve protonation at the nitrilic nitrogen of **11** forming a nitrilium intermediate [(**11**)H]$^+$, which by way of an electrocyclic ring closure and subsequent proton migration rearranges into the aminocobaltocenium cation **12**$^+$. Details of the metal-participation involved and potential further intermediates must at present remain undefined.

Substitution Reaction of 7$^+$ with tert-Butyl Isocyanide

Isocyanides are much less basic than cyanide ion. Therefore, the direct nucleophilic addition of CN*t*Bu to **3**$^+$ described above was feasible. We then found that [**7**]CF_3SO_3 also reacts with CN*t*Bu, though much slower than **3**$^+$, and also gave the (*tert*-butylamino)cobaltocenium derivative [**9**]CF_3SO_3. Both reactions, that of CN*t*Bu with **3**$^+$ (Scheme 4) and that with **7**$^+$ follow the same mechanistic pattern exemplified Scheme 6.

Abstraction of Pyridine from the Pyridinium Ion 7$^+$

The demonstrated lability of the pyridine moiety in **7**$^+$ suggested that acid should be able to remove pyridine from **7**$^+$, thereby producing the carbenoid ion **13**$^+$, the alternative stereoisomer of **3**$^+$. Indeed, treatment of the triflate [**7**]CF_3SO_3 with a large excess of CF_3CO_2H (1:7) at ambient temperature resulted in the formation of **13**$^+$ and pyridinium ion $C_5H_5NH^+$ (Scheme 7). The new complex ion is labile and decomposes above –20 °C. It could be characterized by its NMR spectra by recording the spectra a few minutes after mixing the reagents. The ^{1}H NMR spectra of **13**$^+$ and **3**$^+$ are remarkably similar, except for the doublet/quartet patterns of the terminal MeCH= moiety [for **13**$^+$: δ = 2.37 (d, J = 6.6 Hz, 4-Me) and 3.13 ppm (q, J = 6.6 Hz, 4-H); for **3**$^+$: δ = 0.55 (d, J = 6.7 Hz, 4-Me) and 6.49 ppm (q, J = 6.7 Hz, 4-H)] which readily distinguish the two stereoisomers. In the ^{13}C NMR spectrum of **13**$^+$ a signal at very high chemical shift [for **13**$^+$$\delta$ = 288.4 and for **3**$^+$$\delta$ = 292.1 ppm] indicates the presence of a carbenoid center at C-1 as in **3**$^+$, and small shifts to lower chemical shifts for 3-Me, C-4, and C-5 reflect the presence of steric strain in **3**$^+$, but not in **13**$^+$.



Scheme 7. Reaction with acid / deprotonation.

One would expect that the new isomer **13**$^+$ should be amenable to deprotonation in the same way that was successful in the case of **3**$^+$. To verify this expectation [**7**]BF_4 was treated with excess of CF_3CO_2H (1:8) and subsequently with a very large excess of NEt_3. Workup afforded the hexatriene complex **14** (57%), the alternative stereoisomer of **5**, as a low-melting red solid (Scheme 7). As may be verified by inspection, the NMR spectra of **14** and **5** are largely similar and, as discussed above in detail for the pair **13**$^+$/**3**$^+$, allow a straightforward distinction of the respective stereochemistries.

Thermolysis Reactions of the Hexatriene Complexes 5 and 14

It is intuitively clear that complex **14** with its terminal methyl group in *syn* position should be more stable than its stereochemical counterpart **5** with a terminal *anti*-Me group. Experimental support for this notion comes from the thermal behavior of **5**. Monitoring a solution of **5** in [D_8]-toluene showed the onset of a slow thermolysis reaction around 80 °C. Complex **5** partially isomerized to produce its stereoisomer **14**, and partially decomposed with formation of a new dinuclear complex **15** and free olefins. After three days at 80 °C the molar product ratio amounted to **5**:**14**:**15** = 2.8:3.4:4.8 and after seven days it was 0.3:4.2:6.1. This result demonstrates that **14** is indeed more stable than **5**. Unfortunately it was not possible to selectively produce the isomer **14** by a meticulous choice and control of the reaction temperature. A stereoisomerization related to the transformation **5** → **14** has been described for vinylallene complexes of the [RhCl(PPh_3)] fragment.[17] M. Murakami et al. argue that the isomerization occurs via a 14e complex with a 2,5-σ^2-coordinated vinylallene (1,2,4-pentatriene) ligand and present an example where this arrangement becomes the groundstate of the molecular system. Most likely the isomerization **5** → **14** follows the same path.

Thermolysis of **14** in [D_8]toluene was found to be markedly slower and again produced the dinuclear complex **15** and free olefins. Complex **5** was not found in the product mixtures. For the practical synthesis of **15** the more readily accessible complex **5** was used as starting material. Heating **5** in toluene at 110 °C for 4 days gave, after workup, **15** as black crystals in high yield (91%) (Scheme 8).

The ^{1}H NMR spectrum of **15** displayed two singlets of equal intensity for two CoCp moieties, three doublets of doublets for a coordinated vinyl group, and three singlets for methyl groups. These observations suggested the presence of a 1,2,3-trimethylpenta-2,4-dien-1-ylidene ligand in a dinuclear complex. The ^{13}C NMR spectrum of **15** was in agreement with this conclusion, and the signal with the highest chemical shift (δ = 166.1 ppm) indicated that the ylidene carbon was in a bridging position between the two metal centers. It was then found that complexes of this type have previously been obtained from the thermolysis of (cyclopentadienyl)[(1–4-η)-(2Z,3*E*)-1,3,5-hexatriene]cobalt and have structurally been characterized.[22]

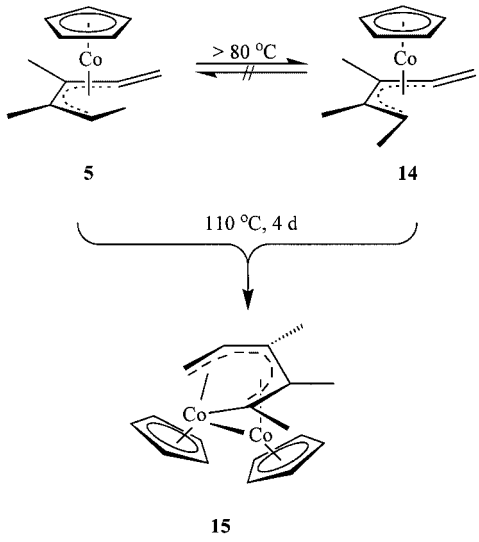

Scheme 8. **5** → **14** + **15** and **14** → **15** at higher temperature.

Conclusion

In this paper we have demonstrated that the carbenoid complex ion **3**$^+$ can react to give the cyclobutadiene complex **1**. Thus we have now a kind of acid/base equilibrium between **1** and **3**$^+$ as already expressed in Scheme 1. According to our earlier theoretical analysis by means of DFT calculations the forward reaction consists of a protonation step followed by a ring-opening step.[1] The principle of microscopic reversibility suggests that the reverse transformation begins with a ring closure (**3**$^+$ → **2**$^+$), and subsequent deprotonation (**2**$^+$ → **1**) gives the cyclobutadiene complex **1**.

As we have seen the experimental situation is much more complicated. i) At temperatures above –20 °C the acid **3**$^+$ rearranges irreversibly to give the half-open cobaltocenium ion **4**$^+$ (Scheme 1). ii) Bases effect reversible deprotonation of **3**$^+$ with formation of the hexatriene complex **5** (Scheme 2) at a rate which is higher than the rate of the reverse reaction of Scheme 1; alternatively they may undergo competing nucleophilic addition reactions (Scheme 3). iii) The formation of **3**$^+$ from **1** is a clean reaction only under strongly acidic conditions. Likewise the formation of **5** from **3**$^+$ is a clean reaction only under strongly basic conditions. Whenever the acid **3**$^+$ is allowed to coexist for some time (minutes to several hours at ambient temperature) with its deprotonated forms (**1** or **5**) we observed undefined decomposition.

The irreversible isomerization of the low-temperature pyridine addition product **6**$^+$ with formation of the more robust stereoisomer **7**$^+$ (Scheme 3) opened a route to sterically less crowded complexes with the terminal methyl group in *syn*-position. Thus we have pairs of stereoisomers, the pyridine addition products **6**$^+$ and **7**$^+$, the carbenoid complex ions **3**$^+$ and **13**$^+$, and the hexatriene complexes **5** and **14**. In the cases **6**$^+$/**7**$^+$ and **5**/**14**, the species with the *syn*-Me group are the more stable isomers, in agreement with expectation.

Experimental Section

General: All manipulations were carried out under nitrogen by means of standard Schlenk techniques. THF and Et_2O were distilled from sodium benzophenone ketyl and CH_2Cl_2 was distilled from CaH_2. Hexane was distilled from potassium and toluene from sodium. Alumina for chromatography was deactivated with 5% water. Elemental analyses were performed by Analytische Laboratorien, 51789 Lindlar, Germany. Melting points were determined with a Büchi 510 melting point apparatus and are uncorrected. NMR spectra were recorded with a Varian 200 (^{1}H, 200.0 MHz; ^{13}C{^{1}H}, 50.29 MHz; ^{31}P{^{1}H}, 80.96 MHz), with a Varian Unity 500 (^{1}H, 499.6 MHz; ^{13}C, 125.6 MHz; ^{31}P{^{1}H}, 202.2 MHz) or with a Varian Inova 400 (^{1}H, 400.0 MHz; ^{13}C, 100.6 MHz). Chemical shifts are given in ppm; they were measured at ambient temperature and are referenced to internal TMS for ^{1}H and ^{13}C, and relative to H_3PO_4 (85%) as external reference for ^{31}P. IR spectra were measured with a Nicolet Avatar 360 FT-IR instrument.

Deprotonation of [3]BF$_4$ and Synthesis of (Cyclopentadienyl)[(2–5-η)-(3*Z*,4*Z*)-3,4-dimethylhexa-1,2,4-triene]cobalt (5): Triethylamine (20 mL) was added to [**3**]BF_4 (1.28 g, 4 mmol) in CH_2Cl_2 (30 mL) at –60 °C. The color of the solution changed immediately from deep wine-red to orange. After dilution with hexane (150–200 mL) the reaction mixture was filtered through a short column of alumina at –80 °C. Thorough removal of all volatiles under vacuum left **5** (0.775 g, 83%) as orange-red crystalline product. The product was recrystallized by cooling Et_2O or hexane solutions to –80 °C; m.p. 37–39 °C. $C_{13}H_{17}Co$ (232.21): calcd. C 67.24, H 7.38; found C 67.07, H 7.42. ^{1}H NMR (500 MHz, CD_2Cl_2): δ = 0.47 (d, J = 7.02 Hz, 5-Me), 1.83 (s, 3-Me), 2.09 (s, 4-Me), 3.37 (q, J = 7.02 Hz, 5-H), 4.68 (s, Cp), 4.72 (d, J = 2.14 Hz, 1-H$_{anti}$), 4.95 (d, J = 2.14 Hz, 1-H$_{syn}$) ppm. ^{13}C{^{1}H} NMR (126 MHz, CD_2Cl_2): δ = 17.9 (3-Me), 18.5 (5-Me), 21.1 (4-Me), 49.4 (C-5), 77.2 (C-3), 82.6 (Cp), 97.5 (C-1), 99.0 (C-4), 175.6 (C-2) ppm.[23]

Deprotonation of 3$^+$ by an Allyl Grignard Reagent: Allylmagnesium chloride (0.87 mL, 1.74 mmol, 2 M solution in THF) was added with stirring to [**3**]BF_4 (279 mg, 0.87 mmol) in CH_2Cl_2 (20 mL) at –90 °C. After warming to ambient temperature overnight, evaporation to dryness, extraction of the residue with hexane, filtration of the combined extracts through a plug of alumina, and finally removal of the hexane afforded **5** (165 mg, 81%) which was identified by its ^{1}H NMR spectrum.

Deprotonation of 3$^+$ with One Equivalent of NEt$_3$ and Formation of the Cyclobutadiene Complex 1: In an NMR tube a sample of [**3**]BF_4 (109 mg, 0.34 mmol) was dissolved in CD_2Cl_2 (0.7 mL). One equivalent of NEt_3 (47 μL, 0.34 mmol, d = 0.73 g·mL^{-1}) was added at ambient temperature. After shaking the mixture vigorously some insoluble material was separated utilizing a centrifuge. The ^{1}H NMR (200 MHz, CD_2Cl_2) spectrum, recorded without delay, displayed three species in the mixture: the cyclobutadiene complex **1** and the hexatriene complex **5** in roughly equal amounts, and $NHEt_3^+$ [δ = 1.32 (t, Me), 3.18 (q, CH_2), 6.75 (broad, H) ppm]. After 16 h **5** had disappeared completely. Chromatography of the reaction mixture on alumina (20 cm) with hexane, followed by removal of the eluent under vacuum gave **1** (47 mg, 60%) as deep yellow crystalline solid.

Deprotonation of 3$^+$ in CH$_2$Cl$_2$/DMSO and Formation of the Cyclobutadiene Complex 1: A Schlenk tube was charged with [**3**]BF_4 (253 mg, 0.79 mmol), CH_2Cl_2 (10 mL), and finally with dimethylsulfoxide (5 mL) at ca. –40 °C. Then the solution was warmed to 30 °C and stirred for 30 min. Concentrating the solution under vacuum, extraction of the yellow product with hexane, followed by

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

filtration of the combined extracts through short plug of alumina, and finally removal of the hexane afforded **1** (124 mg, 67%) as deep yellow crystalline solid.

The System [3]BF_4/C_5H_5N in the NMR Tube: A solution of [**3**]BF_4 (26 mg, 0.08 mmol) in CD_2Cl_2 (0.7 mL) was prepared in an NMR tube at –50 °C. The ^1H NMR spectrum of the sample showed the spectrum of [**3**]BF_4 and impurity signals due to traces of Et_2O and of [**4**]BF_4. One equivalent of pyridine (6.5 μL, 0.08 mmol, d = 0.98 g·mL^{-1}) was then added at –80 °C. The reagents were mixed utilizing an ultrasonic bath at –80 °C. ^1H NMR spectra were recorded on a 200 MHz spectrometer. In one experiment the temperature was kept below –70 °C for 7 d. In a second experiment the temperature was increased in 10 K steps over the range from –80 to 10 °C, and the sample was kept at the chosen temperature for 10 minutes before the spectrum was recorded. Integral intensities of the pertinent Cp ring signals were measured using the signal of the residual solvent protons as internal standard.

Data for 6^+: ^1H NMR (200 MHz, CD_2Cl_2, –30 °C): δ = –0.45 (d, J = 7.6 Hz, 4-Me), 1.95 (s, Me), 2.12 (s, Me), 2.20 (s, Me), 3.78 (q, J = 7.6 Hz, 4-H), 4.90 (s, Cp); pyridine: 7.61 (t, J = 6.4 Hz, 1 H, β-H_{exo}), 7.97 (t, J = 6.4 Hz, 2 H, β-H_{endo} + α-H_{exo}), 8.23 (t, J = 7.8 Hz, γ-H), 9.26 (d, J = 5.6 Hz, 1 H, α-H_{endo}) ppm; partial assignments by analogy to 7^+. Multiplets at δ = 8.08 (t), 8.47 (t), 8.83 (d) ppm were assigned to the pyridine/pyridinium mixture. For $^{13}C\{^1H\}$ NMR spectroscopic data see below.

Synthesis of [(Cyclopentadienyl){*N*-[η^4-(1′*Z*,2′*Z*,3′*E*)-1′,2′,3′-trimethylpenta-1′,3′-dienyl]pyridinium}cobalt] Tetrafluoroborate ([7]BF_4): Pyridine (10 mL) was added to a solution of [**3**]BF_4 (640 mg, 2.00 mmol) in CH_2Cl_2 (10 mL) at –60 °C. The reaction mixture was warmed to ambient temperature overnight. Addition of Et_2O precipitated a raw product which was purified by re-precipitation from CH_2Cl_2 solutions yielding [**7**]BF_4 (775 mg, 97%) as deep red, crystalline solid; m.p. 112 °C (dec). $C_{18}H_{23}BCoF_4N$ (399.12): calcd. C 54.17, H 5.80, N 3.51; found C 54.09, H 5.70, N 3.71. ^1H NMR (500 MHz, CD_2Cl_2): δ = –0.37 (qq, J = 6.1, 0.7 Hz, 4-H), 1.18 (d, J = 6.1 Hz, 4-Me), 1.94 (s, 1-Me), 2.17 (d, J = 0.7 Hz, 3-Me), 2.21 (s, 2-Me), 4.82 (s, Cp); pyridine: 7.52 (t, J = 6.7 Hz, β-H_{exo}), 7.66 (d, J = 6.1 Hz, α-H_{exo}), 8.00 (t, J = 6.7 Hz, β-H_{endo}), 8.23 (t, J = 7.6 Hz, γ-H), 9.34 (d, J = 6.1 Hz, α-H_{endo}) ppm. Note the ^4J coupling between 4-H and 3-Me which can be observed under favorable conditions and which is absent in 6^+; the coupling constant was measured applying digital filtering with a Lorentz Gauss function. $^{13}C\{^1H\}$ NMR (126 MHz, CD_2Cl_2): δ = 16.0 (3-Me), 16.3 (2-Me), 20.2 (4-Me), 32.3 (1-Me), 53.7 (C-4), 80.4 (C-2), 81.8 (C-1), 84.6 (Cp), 100.0 (C-3); pyridine: 126.8 (β-C_{exo}), 129.3 (β-C_{endo}), 143.3 (α-C_{exo}), 143.9 (γ-C), 147.6 (α-C_{endo}) ppm.[23]

Synthesis of [(Cyclopentadienyl){*P*,*P*,*P*-triphenyl-*P*-[η^4-(1′*Z*,2′*Z*,3′*E*)-1′,2′,3′-trimethylpenta-1′,3′-dienyl]phosphonium}-cobalt] Tetrafluoroborate ([8]BF_4): Triphenylphosphane (3.67 g, 14 mmol) in CH_2Cl_2 (50 mL) was added to [**3**]BF_4 (640 mg, 2.00 mmol) in CH_2Cl_2 (10 mL) at –60 °C. The reaction mixture was warmed to ambient temperature overnight. The solution was concentrated to a small volume (ca.10 mL) and THF (100 mL) was added. A raw product precipitated, which was purified by re-precipitation from CH_2Cl_2 solution to give [**8**]BF_4 (1.14 g, 98%) as a dark red powder; m.p. 145 °C, dec. 150 °C. $C_{31}H_{33}BCoF_4P$ (582.30): calcd. C 63.94, H 5.71; found C 64.00, H 5.70. ^1H NMR (500 MHz, CD_2Cl_2): δ = 0.85 (d, J = 6.4 Hz, 4-Me), 1.24 (q, J = 6.4 Hz, 4-H), 1.34 (d, $^3J_{PH}$ = 16.2 Hz, 1-Me), 1.83 (s, 3-Me), 2.56 (d, $^4J_{PH}$ = 2.4 Hz, 2-Me), 4.76 (s, Cp); PPh_3: 7.63 (m, α-H), 7.73 (m, β-H), 7.75 (m, γ-H) ppm. $^{13}C\{^1H\}$ NMR (126 MHz, CD_2Cl_2): δ = 14.9 (3-Me), 17.5 (2-Me), 18.4 (4-Me), 29.0 (C-1) 30.0 (d, $^2J_{PC}$ = 12.4 Hz, 1-Me), 52.1 (C-4), 85.2 (Cp), 92.3 (C-2), 97.3 (C-3); PPh_3: 122.4 (d, $^1J_{PC}$ = 80.6 Hz, C_i), 129.9 (d, $^2J_{PC}$ = 11.5 Hz, C_o), 134.0 (d, $^3J_{PC}$ = 8.6 Hz, C_m), 134.2 (d, $^4J_{PC}$ = 2.8 Hz, C_p) ppm. $^{13}C\{^1H\}$ NMR (50 MHz, CD_2Cl_2): δ = 14.8 (3-Me), 17.4 (d, $^3J_{PC}$ = 2.75 Hz, 2-Me), 18.3 (4-Me), 29.4 (d, $^1J_{PC}$ = 46.0 Hz, C-1), 29.9 (d, $^2J_{PC}$ = 13.05 Hz, 1-Me), 52.0 (d, J_{PC} = 3.43 Hz, C-4), 84.9 (Cp), 92.0 (d, $^2J_{PC}$ = 1.48 Hz, C-2), 97.0 (d, $^3J_{PC}$ = 1.96 Hz, C-3); PPh_3: 122.1 (d, $^1J_{PC}$ = 80.23 Hz, C_i), 129.7 (d, $^2J_{PC}$ = 11.9 Hz, C_o), 133.8 (d, $^3J_{PC}$ = 8.45 Hz, C_m), 134.0 (d, $^4J_{PC}$ = 2.98 Hz, C_p) ppm. $P\{^1H\}$ NMR (202 MHz, CD_2Cl_2): δ = 25.91 (PPh_3) ppm.

Synthesis of [{1-(*tert*-Butylamino)-2,3,4,5-tetramethylcyclopentadienyl}(cyclopentadienyl)cobalt] Trifluoromethanesulfonate ([9]CF_3SO_3): A solution of [CpCoCb*] (**1**) (237 mg, 1.02 mmol) in CH_2Cl_2 (10 mL) was treated with CF_3SO_3H (90 μL, 1.02 mmol, d = 1.708 g·mL^{-1}) at –35 °C. After 5 min *tert*-butyl isocyanide (0.12 mL, 1.06 mmol, d = 0.736 g·mL^{-1}) was added to the solution of [**3**]CF_3SO_3 so obtained, resulting in an immediate color change from dark red to yellow. Addition of Et_2O (35 mL) and cooling to –80 °C overnight gave a yellow powder which was recrystallized from CH_2Cl_2 to afford analytically pure [**9**]CF_3SO_3 (430 mg, 90%) as yellow powder; m.p. 274–276 °C (dec.). $C_{19}H_{27}CoF_3NO_3S$ (465.42): calcd. C 49.03, H 5.85, N 3.01; found C 48.69, H 5.87, N 2.98. ^1H NMR (500 MHz, CD_3CN): δ = 1.41 (s, *t*Bu), 2.08 (s, 3-/4-Me), 2.26 (s, 2-/5-Me), 5.53 (s, Cp), 9.34 (s, N*H*) ppm. $^{13}C\{^1H\}$ NMR (126 MHz, CD_3CN): δ = 10.9 (3-/4-Me), 12.0 (2-/5-Me), 26.7 (C*Me*$_3$), 70.9 (*C*Me$_3$), 89.2 (Cp), 94.7 (C-2,5), 100.4 (C-3,4), 97.3 (C-1) ppm; in CD_2Cl_2 solution some C atoms were not observed.[23]

The System 5/(C_5H_5NH)CF_3SO_3 in the NMR Tube: A solution of **5** (22 mg, 0.095 mmol) in CD_2Cl_2 (0.8 mL) was added into an NMR tube containing [C_5H_5NH]CF_3SO_3 (21 mg, 0.095 mmol) at –80 °C. The reagents were mixed utilizing an ultrasonic bath at this temperature. ^1H NMR spectra were recorded after one, two, and three weeks at –80 °C. As some solid [C_5H_5NH]CF_3SO_3 had formed, the mixing process was repeated. After three weeks the product ratio was **5**:6^+:7^+:**1** = 0:93:5:2, and a good ^{13}C NMR spectrum of 6^+ could be recorded from this reaction mixture.

^{13}C NMR Data for 6^+: $^{13}C\{^1H\}$ NMR (50.3 MHz, CD_2Cl_2, –80 °C): δ = 13.2 (4-Me), 17.2 (Me), 24.2 (Me), 35.6 (1-Me), 49.3 (C-4), 82.7 (C-2), 83.8 (Cp), 87.8 (C-1), 100.0 (C-3); pyridine: 128.0 (β-C_{exo}), 128.3 (β-C_{endo}), 143.1 (α-C_{exo}), 144.0 (γ-C), 147.7 (α-C_{endo}) ppm; tentative and partial assignments by analogy to the case of 7^+.

Addition of Pyridinium Triflate to the Hexatriene Complex 5 and Synthesis of [7]CF_3SO_3: To a mixture of **5** (649 mg, 2.79 mmol) and (C_5H_5NH)CF_3SO_3 (640 mg, 2.79 mmol) was added pyridine (10 mL) and thereafter CH_2Cl_2 (15 mL). The reaction mixture was stirred for 1 h. Concentrating the solution and addition of Et_2O precipitated the raw product, which was purified by re-precipitation from CH_2Cl_2 solution to give [**7**]CF_3SO_3 (1.21 g, 94%) as spectroscopically pure, red, microcrystalline powder, with ^1H NMR spectroscopic data identical to those for [**7**]BF_4.

Pyridine/4-Picoline Exchange of [7]BF_4 and Synthesis of [10]BF_4: A sample of the pyridinium derivative [**7**]BF_4 (112 mg, 0.28 mmol) was dissolved in CH_2Cl_2 (10 mL) and 4-picoline (1 mL) was added with stirring. After 20 min the solution was concentrated to a small volume and Et_2O was added to precipitate the complex salts which were dried in a vacuum for 0.5 h. This procedure was repeated three more times to give a spectroscopically pure sample of [**10**]BF_4 (111 mg, 96%). ^1H NMR (200 MHz, CD_2Cl_2): δ = –0.36 (q, J = 6.1 Hz, 4-H), 1.17 (d, J = 6.1 Hz, 4-Me), 1.89 (s, 1-Me), 2.15 (s, 3-Me), 2.19 (s, 2-Me), 4.80 (s, Cp); 4-picoline: 2.48 (s, 4-Me), 7.27 (dd, J = 6.22, 1.95 Hz, α-H_{exo}), 7.48 (dd, J = 6.22, 1.46 Hz, β-H_{exo}), 7.75 (dd, J = 6.22, 1.95 Hz, α-H_{endo}), 9.13 (dd, J = 6.22, 1.46 Hz,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

β-H_{endo}) ppm; assignments by analogy with the assignments for [7]BF_4.

Nucleophilic Substitution of Pyridine in [7]BF_4 with Cyanide and Synthesis of (Cyclopentadienyl)[η⁴-(2*Z*,3*Z*,4*E*)-2,3,4-trimethylhexa-2,4-dienenitrile]cobalt (11): A solution of [7]BF_4 (395 mg, 0.99 mmol) in CH_2Cl_2 (10 mL) was mixed with a solution of $(Bu_4N)CN$ (531 mg, 1.98 mmol) in CH_2Cl_2 (10 mL) at –80 °C. The mixture was stirred and warmed to ambient temperature within 24 h. Then all volatiles were removed. The residue was extracted several times with a hexane/ether (4:1) mixture. The combined extracts were filtered through a layer of alumina (2 cm). Removal of the volatiles and crystallization from CH_2Cl_2/hexane at –80 °C yielded **11** (218 mg, 85%) as dark red crystalline solid; m.p. 90–91 °C, dec. 126 °C. $C_{14}H_{18}CoN$ (259.23): calcd. C 64.86, H 6.99, N 5.40; found C 64.92, H 7.08, N 5.37. ^{1}H NMR (500 MHz, CD_2Cl_2): δ = 1.33 (d, J = 6.1 Hz, 5-Me), 1.43 (s, 2-Me), 1.84 (q, J = 6.1 Hz, 5-H), 2.06 (s, 4-Me), 2.15 (s, 3-Me), 4.61 (s, Cp) ppm. ^{13}C{^{1}H} NMR (126 MHz, CD_2Cl_2): δ = 15.6 (4-Me), 16.2 (3-Me), 19.7 (5-Me), 24.2 (C-2), 25.7 (2-Me), 51.2 (C-5), 83.2 (Cp), 88.4 (C-3), 95.0 (C-4), 125.5 (C-1) ppm.[23] IR (CH_2Cl_2): $\tilde{\nu}$(CN) = 2183.0 cm^{-1}.

Synthesis of [(1-Amino-2,3,4,5-tetramethylcyclopentadienyl)(cyclopentadienyl)cobalt] Salts: a) Trifluoroacetic acid CF_3CO_2H (25 μL, d = 1.48 g·mL^{-1}, 0.33 mmol) was added to a solution of the nitrile complex **11** (30 mg, 0.11 mmol) in CD_2Cl_2 (0.7 mL). The color of the reaction mixture rapidly changed from dark red to lemon-yellow. Removal of the volatiles and precipitation from aqueous solution (10 mL) with NH_4PF_6 (57 mg, 0.33 mmol) gave, after recrystallization from CH_2Cl_2/Et_2O, [**12**]PF_6 (42 mg, 90%) as a yellow powder. b) A solution of HBF_4 in Et_2O (87 μL, 54%, d = 1.18 g·mL^{-1}, 0.636 mmol) was added to a solution of the nitrile complex **11** (55 mg, 0.212 mmol) in CH_2Cl_2 (10 mL). The color immediately changed to lemon-yellow and a precipitate formed within seconds. Ether (30 mL) was added to complete the precipitation. The solid was collected on a frit, thoroughly washed with diethyl ether, and reprecipitated several times from acetone/ether to yield [**12**]BF_4 (69 mg, 94%) as a yellow powder. $C_{14}H_{19}BCoF_4N$ (347.05): calcd. C 48.45, H 5.52, N 4.04; found C 48.39, H 5.59, N 4.13.

Data for [12]PF_6: ^{1}H NMR (500 MHz, CD_2Cl_2): δ = 1.98 (s, 3-/4-Me), 1.99 (s, 2-/5-Me), 4.25 (s, NH), 4.97 (s, Cp) ppm. ^{13}C{^{1}H} NMR (126 MHz, CD_2Cl_2): δ = 9.5 (3-/4-Me), 10.4 (2-/5-Me), 79.7 (C-2/-5), 85.6 (Cp), 92.4 (C-3/-4), 122.7 (C-1) ppm.[23]

Reaction of [7]CF_3SO_3 with Excess CF_3CO_2H and Formation of the Carbenoid Cation 13⁺: In an NMR tube a solution of [7]CF_3SO_3 (93 mg, 0.20 mmol) in CD_2Cl_2 (0.7 mL) was combined with CF_3CO_2H (109 μL, d = 1.48 g·mL^{-1}, 1.41 mmol) at ambient temperature and kept for several minutes. NMR spectra were then measured with a 500 MHz spectrometer at –20 °C. ^{1}H NMR (500 MHz, –20 °C, CD_2Cl_2): δ = 1.80 (s, 2-Me), 2.37 (d, J = 6.6 Hz, 4-Me), 2.53 (s, 1-Me), 2.56 (s, 3-Me), 3.13 (q, J = 6.6 Hz, 4-H), 5.36 (s, Cp) ppm. ^{13}C{^{1}H} NMR (126 MHz, –20 °C, CD_2Cl_2): δ = 11.5 (2-Me), 17.5 (3-Me), 20.0 (C-5 = 4-Me), 31.3 (1-Me), 77.6 (C-4), 88.7 (Cp), 100.3 (C-2), 117.3 (C-3), 288.4 (C-1) ppm.[23]

Synthesis of (Cyclopentadienyl)[(2–5-η)-(3*Z*,4*E*)-3,4-dimethylhexa-1,2,4-triene]cobalt (14): A large excess of CF_3CO_2H (3.1 mL, 40 mmol) was added to [7]BF_4 (2.02 g, 5.06 mmol) in CH_2Cl_2 (20 mL) at 0 °C. The mixture was stirred for 30 min and then added slowly to a slurry of alumina (ca. 30 g) in NEt_3/hexane (22 mL/80 mL) at 0°. After stirring for 30 min the orange-red solution was filtered with the help of a plug of alumina (2–3 cm). Removal of the volatiles in a vacuum left a red oil which was crystallized from a minimal amount of hexane at –80 °C overnight to give the hexatriene complex **14** (0.668 g, 57%) as red crystalline material; m.p. 30 °C. $C_{13}H_{17}Co$ (232.21): calcd. C 67.24, H 7.38; found C 67.01, H 7.26. ^{1}H NMR (500 MHz, CD_2Cl_2): δ = 0.50 (q, J = 6.45 Hz, 5-H), 1.31 (d, J = 6.47 Hz, 5-Me), 1.86 (s, 3-Me), 2.18 (s, 4-Me), 4.63 (s, Cp), 4.72 (d, J = 2.08 Hz, 1-H_{anti}), 4.88 (d, J = 2.08 Hz, 1-H_{syn}) ppm. ^{13}C{^{1}H} NMR (126 MHz, CD_2Cl_2): δ = 14.0 (4-Me), 16.9 (3-Me), 19.2 (5-Me), 49.6 (C-5), 72.4 (C-3), 83.2 (Cp), 97.2 (C-4), 97.3 (C-1), 171.9 (C-2) ppm.[23]

Synthesis of Bis(cyclopentadienyl)[μ-2(1–3-η):1(4,5-η)-(1*Z*,2*Z*,3*Z*)-1,2,3-trimethylpenta-2,4-dien-1-ylidene-1κ(*C*¹)]dicobalt(*Co–Co*)] (15): A solution of **5** (694 mg, 2.98 mmol) in toluene (15 mL) was heated to 110 °C for 4 d. Then all volatiles were removed in a vacuum leaving a black oily residue which was chromatographed on alumina (35-cm column) using hexane as eluent. Removal of the solvent afforded spectroscopically pure **15** (487 mg, 91%) as black microcrystalline solid; m.p. 67 °C. $C_{18}H_{22}Co_2$ (356.23): calcd. C 60.69, H 6.22; found C 61.28, H 6.25. ^{1}H NMR (500 MHz, CD_2Cl_2): δ = –0.43 (dd, $^2J_{5anti,5syn}$ = 1.1, $^3J_{4,5anti}$ = 10.01 Hz, 5-H_{anti}), 1.28 (s, 2-Me), 1.58 (dd, $^2J_{5anti,5syn}$ = 1.1, $^3J_{4,5syn}$ = 6.72 Hz, 5-H_{syn}), 2.00 (s, 3-Me), 2.59 (s, 1-Me), 3.05 (dd, $^3J_{4,5anti}$ = 10.01, $^3J_{4,5syn}$ = 6.72 Hz, 4-H), 4.60 [s, Cp(Co-2)], 4.87 [s, Cp(Co-1)] ppm. ^{13}C{^{1}H} NMR (126 MHz, CD_2Cl_2): δ = 14.5 (2-Me), 23.0 (3-Me), 26.8 (C-5), 30.5 (1-Me), 55.0 (C-4), 69.5 (C-3), 81.7 [Cp(Co-2)], 85.0 [Cp(Co-1)], 87.1 (C-2), 161.1(C-1) ppm.[23]

X-ray Crystal Structure Determinations: Suitable crystals of **5** were obtained by slow vacuum sublimation (40–50 °C, 1–2 days) as orange-red platelets. Crystallization of [7]CF_3SO_3 from acetone/ether afforded well-shaped red rods. Geometry and intensity data were collected with ENRAF-Nonius CAD4 diffractometers

Table 1. Crystal data, data collection parameters, and convergence results for **5** and [7]CF_3SO_3.

COVER PICTURE

The cover picture shows a high-yield, one-step synthesis of end-on bridged dinuclear titanium–dinitrogen complexes using Cp^*TiCl_3, N_2 and pentafulvenes under reductive conditions. The Cp* as well as the fulvene ligands are arranged in a stereoregular manner along the Ti–N≡N–Ti axis, both in the solid state as well as in solution, as proved by extensive NMR measurements. Details are discussed in the article by R. Beckhaus et al. on p. 1003ff. In a similar way a nitrogen-free, low-coordinated titanium complex is obtained by using sterically demanding benzofulvenes. We thank the Fonds der Chemischen Industrie for a kindly granted scholarship (A. S.).

Iron-Assisted Oxidative Radical C–C Bond Cleavage

Laurent Bénisvy,[a,c] Jean-Claude Chottard,[a] Jérôme Marrot,[b] and Yun Li*[a]

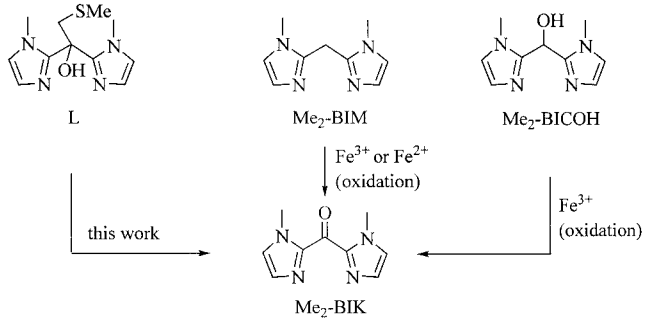
Keywords: Iron / Multidentate ligand / Imidazole ligand / Thioether ligand / Radical fragmentation / X-ray diffraction

The N_2SO ligand, bis(*N*-methylimidazol-2-yl)-2-methylthioethanol (**L**), when coordinated to Fe^{3+} or Fe^{2+}, undergoes a radical C–C bond cleavage in air, to form bis(*N*-methylimidazol-2-yl) ketone (Me_2-BIK).

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Model complexes play an important role in the comprehension of mechanistic studies of metalloproteins. Iron complexes with polyimidazole and benzimidazole ligands are commonly used to mimic the active sites of various iron-containing proteins with histidine residues.[1,2] A variety of protein residues other than His also coordinate a metal ion in enzyme active sites. For example, a relatively unusual metal site [$N_2SM^{II}(H_2O)$] (N = Histidine, S = Cysteine, M = Zn, Co, Ni and Fe) is found in peptide deformylase (PDF).[3,4] Peptide deformylase (PDF) is responsible for the hydrolysis of an N-terminal formyl group during bacterial protein synthesis and has been under investigation as a new target for antibiotics. Our initial goal was to look at the coordination behavior of a mixed N,S,O multidentate ligand to Fe^{2+} or Fe^{3+}. However, because of the frustrating propensity of thiolato (RS^-) ligands to yield sulfur-bridged polymeric metal species and disulfide derivatives by radical coupling reactions, we chose to work with thioethers to avoid undesired side reactions. We have prepared the new tripodal N_2SO ligand, bis(*N*-methylimidazol-2-yl)-2-methylthioethanol (**L**, see Scheme 1), comprising donor atoms from *N*-methylimidazole, methylthioether and alcohol functionalities. **L** is an analogue of the previously reported N_2S ligands (N = imidazole, S = thiolate), that have been studied for Hg^{2+}, Cu^{2+}, Zn^{2+} and Fe^{2+} coordination.[5,6] These thiolato ligands presented both synthetic difficulties and the above-mentioned undesirable side reactions. In principle, **L** could coordinate to $Fe^{2+/3+}$ as a tridentate (N_2S or *NOS*), or as a bidentate (N_2 or *NO*). We have found that in aerated MeOH, in the presence of Fe^{2+} or Fe^{3+}, this ligand was converted into bis(*N*-methylimidazol-2-yl) ketone (Me_2-BIK). This reaction could be compared to the iron-catalyzed oxidations of bis(*N*-methylimidazol-2-yl)methanol (Me_2-BICOH)[7] and bis(*N*-methylimidazol-2-yl)methane (Me_2-BIM)[8] into Me_2-BIK. However, in the case of **L**, the formation of Me_2-BIK requires a carbon–carbon bond scission (Scheme 1).



Scheme 1. Different pathways for the formation of Me_2-BIK.

Results and Discussion

The synthesis of **L** was straightforward and was achieved in only one step by condensation of the anion of *N*-methylimidazole with ethyl (methylthio)acetate ($MeSCH_2COOEt$).

Under argon, the reaction of **L** with $Fe(ClO_4)_2{\cdot}xH_2O$ in degassed MeOH in a 3:1 ratio, led to a pale-yellow Fe^{II} complex (EPR silent). Its cyclic voltammogram in MeOH clearly shows the formation of an Fe^{II} complex, as there is an irreversible oxidation peak at ca. 0.180 V (vs. Fc^+/Fc) (Figure S1, see Supporting Information). In the presence of air, the Fe^{II} complex oxidized into a yellow, paramagnetic Fe^{3+} species. Its EPR spectrum in MeOH at 10 K is typical of rhombic high-spin Fe^{3+} species (g = 4.25). The cyclic voltammogram of this yellow complex in MeOH exhibits an irreversible reduction wave at –0.62 V (vs. Fc^+/Fc), con-

[c] Present address: Max-Planck Institut für Bioanorganische Chemie, Stiftstrasse 34-36, 45470 Mülheim, Germany
Supporting information for this article is available on the WWW under http://www.eurjic.org or from the author.

firming the +3 oxidation state (Figure S1 top, see Supporting Information). This yellow complex turned blue at room temperature. After several days, deep-blue crystals precipitated. The IR spectrum of the solid indicates the presence of a ketone function ($\nu_{C=O}$ = 1637 cm^{-1}). The cyclic voltammogram in CH_3CN solution shows a fully reversible one-electron oxidation process at $E_{1/2}$ = 0.44 V (vs. Fc^+/Fc) (Figure S2, see Supporting Information).

The X-ray structural determination of the blue complex revealed it to be $[Fe^{II}(Me_2\text{-}BIK)_3](ClO_4)_2$. The Me_2-BIK ligand resulted obviously from the fragmentation of the CH_2SMe arm during the oxidation of **L**. An ORTEP[9] view of the $[Fe(Me_2\text{-}BIK)_3]^{2+}$ cation at 298 K is shown in Figure 1. The unit cell includes eight mononuclear complex molecules. The iron is hexacoordinated in an N_6 environment with a distorted octahedral geometry. The six nitrogen donors originate from three Me_2-BIK molecules. The significant departure of the FeN_6 core from octahedral geometry is evidenced by the values of the bond angles, e.g. 83.91° for the N(26)–Fe–N(15) angle. The Fe–N distances range from 2.123 to 2.159 Å, clearly demonstrating that the iron is high-spin (HS, S = 2). For low-spin (LS, S = 0) octahedral $[Fe^{II}N_6]$ complexes, the average bond lengths are ca. 1.97 Å.[10] Moreover, the paramagnetism of $[Fe^{II}(Me_2\text{-}BIK)_3](ClO_4)_2$ was also observed in the ^{1}H NMR spectrum (250 MHz, CN_3CN, 300 K), which spread over the range from 17 to 4 ppm (see Experimental Section).

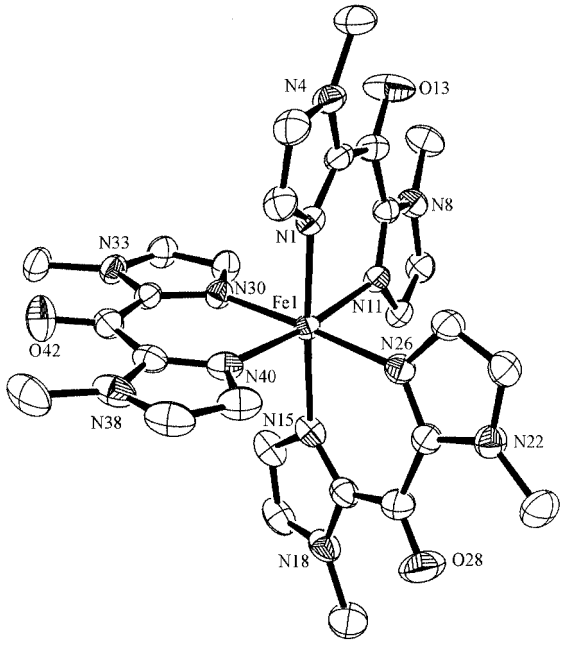

Figure 1. ORTEP view (ellipsoid at the 30% probability level) of $[Fe(Me_2\text{-}BIK)_3]^{2+}$. H atoms are omitted for clarity. Selected bond distances (Å): Fe–N(1) 2.143(2), Fe–N(11) 2.125(2), Fe–N(15) 2.159(3), Fe–N(26) 2.132(2), Fe–N(30) 2.140(2), Fe–N(40) 2.123(3). Selected bond angles (°): N(1)–Fe–N(11) 84.53(9), N(1)–Fe–N(26) 92.88(9), N(1)–Fe–N(15) 176.61(9), N(1)–Fe–N(40) 90.56(9), N(1)–Fe–N(30) 91.02(9), N(11)–Fe–N(26) 91.07(9), N(11)–Fe–N(15) 94.45(8), N(11)–Fe–N(40) 172.67(9), N(11)–Fe–N(30) 88.92(8), N(26)–Fe–N(15) 83.91(9), N(26)–Fe–N(40) 94.62(9), N(26)–Fe–N(30) 176.09(9), N(15)–Fe–N(40) 90.75(9), N(15)–Fe–N(30) 92.19(9), N(40)–Fe–N(30) 85.71(9).

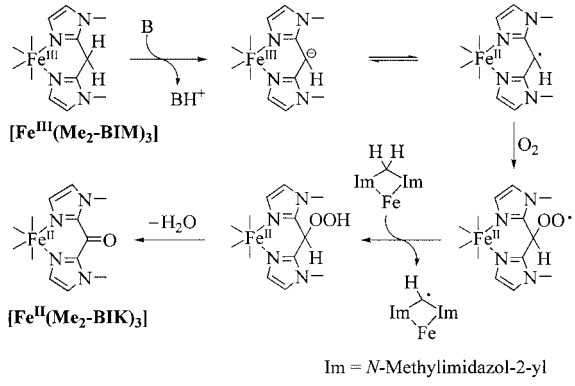
It is well-known that some octahedral iron(II)-N_6 complexes exhibit temperature-dependent "spin-equilibrium" (LS ↔ HS) behavior. This active research area has been widely reviewed.[11] The spin-crossover property of $[Fe(Me_2\text{-}BIK)_3](BF_4)_2$, prepared classically from $Fe(BF_4)_2$ and 3 equiv. of Me_2-BIK[12] in CH_3CN, has been investigated earlier by Mössbauer spectroscopy in cooperation with our group.[13]

When Fe^{3+} or Fe^{3+}/Et_3N (3 equiv.) in MeOH were used instead of Fe^{2+}, the same cleavage reaction was observed. The addition of Et_3N accelerated the reaction and gave a better yield.

It has been previously reported that $[Fe(Me_2\text{-}BIK)_3]^{2+}$ was a side-product formed during the complexation of Fe^{3+} by the N_2OH ligand (Me_2-BICOH) (Scheme 1).[7] We have also found that Me_2-BIM was converted into Me_2-BIK by $Fe^{2+/3+}$ under oxygen upon base catalysis (Scheme 2).[8] A comparable reaction has been observed with Cu^{II}-catalyzed oxidation of *bis*(*N*-methylbenzimidazol-2-yl)methane and *bis*(2-pyridyl)methane into the corresponding ketones.[14,15] In all these cases, the ligands present "benzylic"-type oxidizable hydrogen atom(s), and the mechanism involves most likely the "benzylic" radicals. However, the mechanism ought to be different in the present instance, since the "benzylic" carbon is fully substituted.



Scheme 2. Iron-assisted oxidation of Me_2-BIM into Me_2-BIK upon base catalysis (ref.[8]).

When the reaction was run under $^{18}O_2$ instead of air, no ^{18}O atom incorporation was found by electrospray mass spectroscopy. This result means that the oxygen atom in $[Fe^{II}(Me_2\text{-}BIK)_3]^{2+}$ comes from the ligand. We suggest a radical mechanism for this C–C bond fragmentation which involves the following sequence (Scheme 3): [1] oxidation of the very unstable Fe^{II} complex **1** by O_2 to generate the intermediate Fe^{III} complex **2** with a switch of ligand in the coordination sphere, in agreement with the preference of Fe^{III} for the alcoholate rather than the imidazole ligand; [2] homolytic C–C bond cleavage, forming the (methylthio) methyl radical, assisted by the homolytic fragmentation of the Fe^{III}–O bond, to give the corresponding ketone function. The (methylthio)methyl radical is stabilized by the presence of the sulfur atom in the α-position of the radical and dimerizes into $CH_3SCH_2CH_2SCH_3$. The latter was detected in the mother liquor after the reaction, by electro-

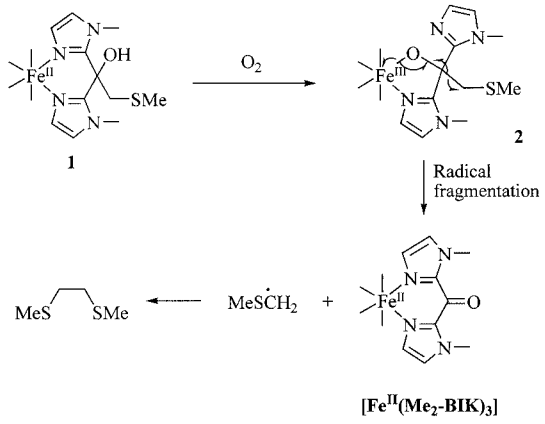
spray MS (m/z = 123, M + H^+) and ^1H NMR spectroscopy ($CDCl_3$, δ = 2.653, and 2.151 ppm in a 2:3 ratio); the spectrum agreed with the literature data.[16] The driving force of the fragmentation likely results from the stability of $[Fe(Me_2\text{-BIK})_3]^{2+}$ ($E_{1/2}$ = +0.44 V vs. Fc^+/Fc, CH_3CN), as well as the relative stability of the thioether α-carbon radicals.



Scheme 3. Proposed iron-assisted radical fragmentation mechanism for the formation of Me_2-BIK.

Conclusion

This study has shown that whatever the substituents on the "benzylic" type bridge of the bis(*N*-methylimidazol-2-yl)methane core, either H/H, H/OH or OH/CH_2SMe, its Fe(III)-catalyzed oxidation takes an appropriate pathway to form bis(*N*-methylimidazol-2-yl) ketone (Me_2-BIK). To avoid this fragmentation, a new ligand with one more carbon in the side arm (CH_2CH_2SMe instead of CH_2SMe) was synthesized. Its complexation towards Fe^{2+} and Fe^{3+} is under investigation.

Experimental Section

Synthesis of Ligand L: A solution of *n*BuLi (1.6 M *in* hexane, 7.3 mL, 11.7 mmol) was added dropwise to a solution of *N*-methylimidazole (0.96 g, 11.7 mmol) in anhydrous THF (10 mL) cooled to 0 °C. After 30 min at 0 °C under argon, $MeSCH_2CO_2Et$ (0.5 mL, 520 mg, 3.9 mmol) was added dropwise to the yellow solution at 0 °C. The temperature was allowed to rise slowly to room temperature and maintained at room temperature for 1 night. The mixture was extracted with EtOAc (3 × 50 mL), and the combined organic layers were washed with saturated aq. NaCl (2 × 50 mL), dried ($MgSO_4$), and the solvents evaporated to dryness. The crude product was filtered through silica gel (MeOH-CH_2Cl_2-conc. aq. NH_3 = 5:95:0.25 as the eluent). The pale-yellow solid obtained was recrystallized from EtOAc/cyclohexane (1:1) to give **L** as colorless crystals (403 mg, 41%). M.p. (EtOAc/cyclohexane) 133 °C. MS (CI, NH_3): m/z = 253 (M + 1). ^1H NMR (250 MHz, $CDCl_3$): δ = 6.97 (s, 2 H, H_{im}), 6.80 (s, 2 H, H_{im}), 5.40 (s, 1 H, D_2O exchangeable, OH), 3.66 (S, 2 H, CH_2), 3.29 (s, 6 H, NMe), 1.92 (s, 3 H, SMe) ppm. ^{13}C NMR (63 MHz, $CDCl_3$): δ = 146.6 (C-2_{im}), 126.3 + 123.5 (C-4_{im} + C-5_{im}), 77.8 (C-OH), 44.6 (CH_2), 33.5 (NCH_3), 17.1 (SCH_3) ppm. $C_{11}H_{16}N_4OS$ (252.34): calcd. C 52.36, H 6.39, N 22.20, S 12.71; found: C 52.47, H 6.47, N 22.12, S 12.57.

$[Fe^{II}(Me_2BIK)_3](ClO_4)_2$: A solution of **L** (83 mg, 0.33 mmol) and $Fe^{II}(ClO_4)_2.xH_2O$ (37 mg, 0.11 mmol) in degassed MeOH (2.5 mL) was stirred under Ar. The initial pale-yellow solution turned yellow after 10 min at room temperature. Stirring was continued for 15 h, and the solvent was evaporated to dryness under reduced pressure. The yellow-brown solid was dissolved in MeOH (6 mL). Et_2O (12 mL) was carefully added to the surface of the MeOH solution, and the mixture was left unperturbed for 24 h. The blue precipitate was filtered, rinsed with Et_2O and vacuum-dried to afford $[Fe^{II}(Me_2BIK)_3](ClO_4)_2$ as a crystalline powder (40 mg, 44%). UV/Vis (CH_3CN): λ_{max} (ε) = 591 (4305), 329 (40200), 284 (21607), 236 nm (15185 $M^{-1}cm^{-1}$). IR [KBr (cm^{-1})]: 1637 (ν_{CO}). ^1H NMR (250 MHz, CD_3CN, 300 K): δ = 17.00 (1 H, H_{im}), 7.22 (3 H, NCH_3), 4.06 (1 H, H_{im}) ppm. $C_{27}H_{30}Cl_2FeN_{12}O_{11}$ (825.35): calcd. C 39.29, H 3.66, N 20.36; found: C 39.12, H 3.81, N 20.53.

To produce the crystals of $[Fe^{II}(Me_2BIK)_3](ClO_4)_2$, the same procedure was used without addition of Et_2O. The MeOH solution was kept at room temperature for 1 week and deep-blue single crystals suitable for X-ray diffraction were collected.

X-ray intensity data were collected on a Bruker X8-APEX2 CCD area-detector diffractometer using Mo-K_α radiation (λ = 0.71073 Å). Seven sets of narrow data frames were collected using 0.5° increments of ω or φ. Data reduction was accomplished with SAINT V7.03.[17] The substantial redundancy in the data allowed a semi-empirical absorption correction (SADABS V2.10)[17] to be applied, on the basis of multiple measurements of equivalent reflections. The structure was solved by direct methods, developed by successive-difference Fourier syntheses, and refined by full-matrix least-squares on all F^2 data using SHELXTL V6.12.[18] Hydrogen atoms were included in calculated positions and allowed to ride on their parent atoms.

Crystal Data for $[Fe^{II}(Me_2BIK)_3](ClO_4)_2$: $C_{27}H_{30}Cl_2FeN_{12}O_{11}$, M = 825.35, blue parallelepipeds, orthorhombic, space group *pbca*, a = 15.2718(3), b = 11.8490(2), c = 38.3903(7) Å, Z = 8, $\alpha = \beta = \gamma$ = 90.00°, V = 6946.9(2) $Å^3$, D_c = 1.578 $g\,cm^{-3}$, T = 298 K, Mo-K_α radiation (λ = 0.71073 Å), 95217 reflections were measured, 6373 independent reflections [5466 $I > 2\sigma(I)$] were used in all calculations. R = 0.0492, R_w = 0.1385. G.O.F. = 1.038.

CCDC-240407 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Low-Valent Titanium–Pentafulvene Complexes − Formation of Dinuclear Titanium–Nitrogen Complexes

Axel Scherer,[a] Kay Kollak,[a] Arne Lützen,[a] Marion Friedemann,[a] Detlev Haase,[a] Wolfgang Saak,[a] and Rüdiger Beckhaus*[a]

Dedicated to Prof. Dr. Jan H. Teuben

Keywords: Titanium / Bridging ligands / Nitrogen / Metallocenes / Fulvene ligands

Sodium amalgam reduction of $[(\eta^5\text{-}C_5Me_5)TiCl_3]$ (**1**) in the presence of the pentafulvenes $\{C_5H_4{=}CR_2$, R: *p*-tol (**2**), *p*-FPh (**3**), CR_2: adamantyl (**4**)$\}$ under nitrogen smoothly produces dark green or dark blue dinuclear low-valent titanium complexes $[\{(\eta^5\text{-}C_5Me_5)Ti(\eta^6\text{-}C_5H_4{=}CR_2)\}_2(\mu_2,\eta^1,\eta^1\text{-}N_2)]$ {R: *p*-tol (**6**), *p*-FPh (**7**), CR_2: adamantyl (**8**)}, characterized by a bridging end-on coordinated dinitrogen ligand, in high yield. In the same way, the nitrogen-free, low-coordinated complex $[(\eta^5\text{-}C_5Me_5)Ti(\eta^6\text{-}C_9H_6{=}C(p\text{-tol})_2)]$ (**10**) is obtained by using the more sterically demanding benzofulvene $C_9H_6{=}C(p\text{-tol})_2$ (**5**) instead of **2**–**4**. The solid-state structures of the dinitrogen compounds reveal weakly activated end-on bound N_2 ligands with identical N–N distances of 1.160(3) Å (**6**) and 1.160(5) Å (**8**). The dinitrogen complexes **6**, **7** and **8** show diamagnetic behaviour, which allowed a complete NMR spectroscopic characterization. So a correlation between the situation in solution, measured by NMR, and in the solid state (X-ray diffraction) becomes possible and shows a congruent picture. A broad range of reactions can be imagined concerning the easily replaceable dinitrogen ligand as well as the known reactivity of fulvene ligands in complexes of early transition metals.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Low-valent titanium complexes are of great importance in the complexation and activation of molecular nitrogen. Different bonding modes are found in early transition metals, depending on the nature of the other ligands.[1–5] Titanocene- as well as zirconocene-based systems have been and are still being extensively investigated. It was found that the cyclopentadienyl substituent patterns have a strong influence on the N_2 coordination and activation modes.[6–11] In such a way, for example, the permethylated $[(\eta^5\text{-}C_5Me_5)_2Zr]$ fragment coordinates the N_2 molecules by end-on bridging as well as in a terminal mode.[12–14] On the other hand, using the tetramethylcyclopentadiene ligand instead of the pentamethyl derivative, a side-on bridging coordination mode, characterized by an efficient N_2 activation, is found.[15,16] Results like this initiated further studies in order to obtain a detailed understanding of the field of N_2 activation reactions. In addition to the metallocene-based systems, Cp alternatives based on multidentate anionic ligands bearing N, O and P donor atoms were successfully used in order to obtain nitrogen complexes.[17–25] It was also shown that the introduction of nitrogen into organic substrates becomes possible under reductive conditions.[26–29]

Recently we were able to demonstrate that pentafulvene complexes of early transition metals are easily available from the reaction of titanium halides, reducing agents (Mg, Na/Hg), and free pentafulvenes.[30] Using fulvenes exhibiting asymmetric exocyclic carbon centres, a diastereoselective complexation of the fulvene ligand at different cyclopentadienyltitanium fragments is possible.[31]

Here we wish to report the one-step formation of dinitrogen-containing titanium complexes by reactions of $[(\eta^5\text{-}C_5Me_5)TiCl_3]$ (**1**) with the pentafulvenes **2**, **3**, **4** and Na/Hg as reducing agent in the presence of dinitrogen. Using the bulky benzofulvene **5**, a low-coordinated mononuclear titanium compound is formed.

Results and Discussion

Treatment of a THF solution of equimolar amounts of $[(\eta^5\text{-}C_5Me_5)TiCl_3]$ (**1**) [Equation (1)] and **2**, **3**, or **4** with three equivalents of Na (20% Na/Hg) under nitrogen leads to intensely coloured solutions. After removal of

the solvent, addition of *n*-hexane to the residue and separation from the insoluble NaCl and mercury by filtration, **6**, **7**, and **8** can be isolated as dark green (**6**, **7**) or dark blue (**8**) crystals showing a fascinating cupric lustre. All complexes were isolated in high yields (**6**, **8** 90%; **7** 80%). It is also possible to use magnesium as the reducing agent, but the products could only be isolated in lower yields (40%), because the formation of $MgCl_2$ containing adducts with the dinitrogen complexes made it difficult to separate $MgCl_2$ quantitatively. All three dinitrogen complexes are thermally stable; melting points are found at 125 °C (**6**), 138–140 °C (**7**), and 175 °C (**8**). They are easily soluble in inert solvents like ethers and saturated or aromatic hydrocarbons.

Suitable crystals for X-ray diffraction were obtained from *n*-hexane/toluene (1:1) (**6**) or *n*-hexane (**8**) solutions at ambient temperature. In the case of **6** the asymmetric unit contains a disordered *n*-hexane molecule, which was refined on 3 positions (1/3, 1/3, 1/3) in idealised geometry; **8** shows two independent molecules in the asymmetric unit. Figure 1 and Figure 2 show ORTEP plots of the molecules with 50% probability ellipsoids, the hydrogen atoms, solvent molecules and the second molecule in the asymmetric unit (**8**) are omitted for clarity. Due to similarities of the structural values, we will limit our discussion mainly on the data of molecule one (Ti1, Ti2). Selected structural data are given in Table 1 and Table 2. The dinuclear structures consist of two [(η^5-C_5Me_5)(η^6-C_5H_4=CR_2)Ti] moieties bridged by N_2 in an almost linear Ti–N≡N–Ti arrangement. However, a deviation from linearity of about 9–10° was found (**6** Ti1–Ti2–N2 9.4°, Ti2–Ti1–N1 9.0°; **8** Ti1–Ti2–N2 9.9°, Ti2–Ti1–N1 10°). In accordance with this observation, the Ti–N–N angles were found to be slightly smaller than 180° [**6** 171.0(2)°, 169.1(2)°; **8** 170.0(4)°, 169.6(4)°]. These values correspond well to the lower range of values found in comparable μ_2,η^1,η^1-N_2 titanium complexes (168–180°, Table 1). The N–N bond lengths of 1.160(3) Å (**6**) and 1.160(5) Å (**8**) are also consistent with a just slightly activated N_2 molecule, since the N–N distance is not significantly different from that of free N_2 (1.0976 Å[32]). Thus, these values are in good agreement with metallocene type dinitrogen–titanium complexes (Table 1). Also, the Ti–N bond lengths are in the range of end-on coordinated dinitrogen–titanocene complexes [**6** 1.997(3), 2.001(3) Å; **8** 2.012(4), 2.003(4) Å]. Only in non-titanocene–nitrogen complexes derived from titanium amides are shorter Ti–N and longer N–N bonds found (Ti–N av. 1.72–1.76 Å, N–N 1.26–1.29 Å[17,24,25]).

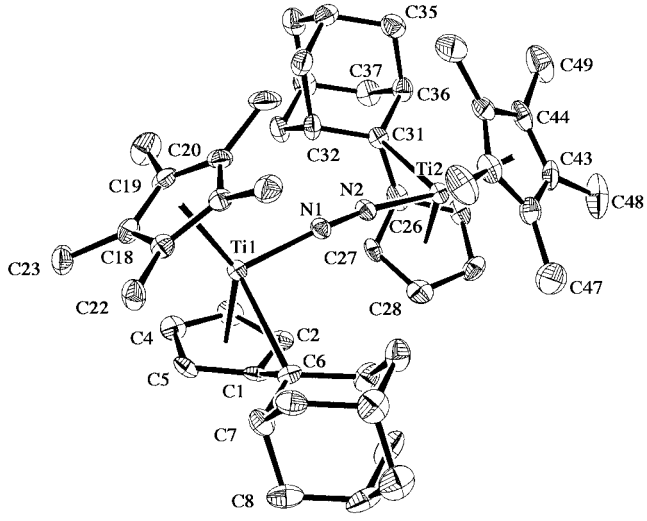

Figure 2. Solid state structure of **8** (50% probability ellipsoids). Selected bond lengths [Å] and angles [°]: Ti(1)–C(1) 2.179(5), Ti(1)–C(2) 2.301(5), Ti(1)–C(5) 2.291(5), Ti(1)–C(3) 2.424(5), Ti(1)–C(4) 2.426(5), Ti(1)–C(6) 2.511(5), C(1)–C(6) 1.441(6), C(1)–C(2) 1.437(6), C(1)–C(5) 1.448(7), C(2)–C(3) 1.413(8), C(4)–C(5) 1.419(7), C(3)–C(4) 1.397(7), Ti(1)–N(1) 2.012(4), N(1)–N(2) 1.160(5), Ti(1)–Ct(1) 2.061(4), Ti(1)–Ct(2) 1.986(4), Θ 30.4, Ct(1)–Ti(1)–Ct(2) 138.8 [Ct(1) = Centroid of Cp*, Ct(2) = centroid of the fulvene ring, Θ = tilt of C(6) out of the plane of C(1)–C(5)].

6 as well as **8** show similarities but also some marked differences compared with titanocene complexes. Probably the most striking point is the well-defined arrangement of the pentafulvene ligands which are located on the same side of the molecule. In general, a selective *trans* orientation of

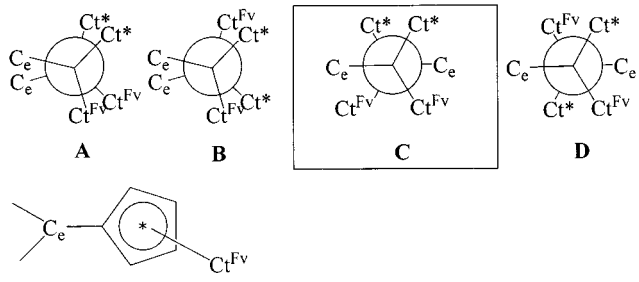
the non-Cp-type ligands is found in dinuclear, μ_2,η^1,η^1-dinitrogen-bridged titanocene complexes with tetrahedral coordinated titanium centres like $[\{(\eta^5\text{-}C_5H_5)_2Ti(p\text{-tol})\}_2(\mu_2,\eta^1,\eta^1\text{-}N_2)]$[11] and $[\{(\eta^5\text{-}C_5H_5)_2Ti(PMe_3)\}_2(\mu_2,\eta^1,\eta^1\text{-}N_2)]$.[9] In the case of **6** and **8**, in principle, four different stereoisomers are possible with respect to the position of the exocyclic fulvene carbon atoms (C_e) to each other (Scheme 1). Again, the formation of the "*cis* isomers" **A** and **B** was not observed, whereas of the two possible "*trans* isomers" **C** was found to be formed exclusively. This was confirmed not only in the solid state but also in solution (vide infra).



Scheme 1. Possible isomers of $[\{(\eta^5\text{-}C_5Me_5)(\eta^6\text{-}C_5H_4{=}CR_2)Ti\}_2(\mu^2,\eta^1,\eta^1\text{-}N_2)]$ complexes (Ct*: ring centroid of C_5Me_5; Ct^{Fv}: ring centroid of Ci, C_a, C'_a, C_b, C'_b; C_e *exo*-cyclic carbon of the fulvene ligand, see also Table 2).

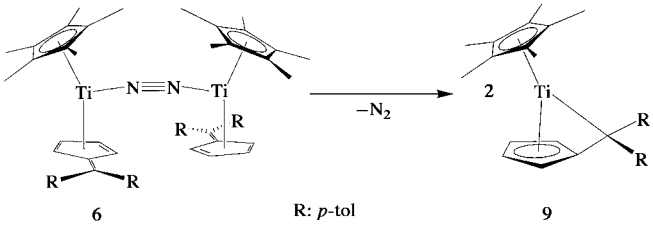
The formal titanocene moieties $[(\eta^5\text{-}C_5Me_5)Ti(\eta^6\text{-}C_5H_4{=}CR_2)]$ are canted towards each other, forming a dihedral angle of 3.2° in **6** and 19.1° in **8** between the planes defined by the metallocene wedges, respectively (a value of 20.0° was found for the second molecule of **8** in the asymmetric unit). This is again in the same range as it was observed for similar complexes as, for example, in the case of $[\{(\eta^5\text{-}C_5H_3(SiMe_3)_2)_2Ti\}_2(\mu_2,\eta^1,\eta^1\text{-}N_2)]$ where a dihedral angle of 9.6° was found.[7]

However, this behaviour is different from that of the Ti(II) dinitrogen complexes showing twisted metallocene units $[\{(\eta^5\text{-}C_5Me_5)_2Ti\}_2(\mu_2,\eta^1,\eta^1\text{-}N_2)]$ (av. 90°)[33] and $[\{(\eta^5\text{-}C_5H_5)_2Ti(PMe_3)\}_2(\mu_2,\eta^1,\eta^1\text{-}N_2)]$ (P–Ti–Ti–P 109°).[9] A nearly perpendicular twist was found also for tantalum–dinitrogen complexes $[\{(\eta^5\text{-}C_5Me_5)_2TaCl\}_2(\mu_2,\eta^1,\eta^1\text{-}N_2)]$ (90.8°).[34] Nevertheless, structural parameters that are com-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

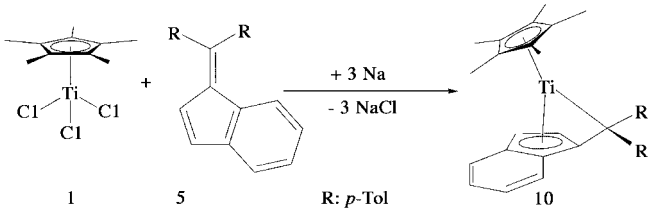
parable to those of **6** and **8** were found in the case of the diamagnetic Ti^{III} derivative $[\{(\eta^5\text{-}C_5H_5)_2Ti(p\text{-Tol})\}_2(\mu_2,\eta^1,\eta^1\text{-}N_2)]$[11] exhibiting a coplanar arrangement of both aryl groups and the centrosymmetric titanocene complex $[\{(\eta^5\text{-}C_5Me_4H)_2Ti\}_2(\mu_2,\eta^1,\eta^1\text{-}N_2)]$.[8]

Indeed, the N_2 coordination in our complexes is comparatively weak, and nitrogen is thus released quantitatively under reduced pressure or vacuum (0.49 moles per mole of Ti), forming the paramagnetic fulvene complex **9** [Equation (2)], characterized by elementary analysis ($C_{30}H_{33}Ti$ (M_τ = 441.47 g mol^{-1}): calcd. C 81.62, H 7.53; found: C 81.46, H 7.42). This observation is confirmed by MS analysis (EI, 70 eV) of **6**, **7**, and **8**, where only the monomeric $[(\eta^5\text{-}C_5Me_5)Ti(\eta^6\text{-}C_5H_4{=}CR_2)]$ units are detectable.



(2)

Unfortunately, crystals of **9** suitable for X-ray diffraction were not available up to now. However, using **5** instead of **2** under the reaction conditions described in Equation (1), the nitrogen-free fulvene complex **10** became available in a one-step synthesis. The low-coordinated complex **10** [Equation (3)] was isolated in the form of black, needle-shaped crystals (85%). In the mass spectrum, the peak of the molecular ion (*m*/*z* 491) was observed as the base peak. Suitable crystals for X-ray structure determination were obtained from *n*-hexane solutions at –20 °C. Due to the paramagnetic behaviour of the complex caused by the odd number of electrons at the titanium, it was not possible to record NMR spectra with distinct signals.



(3)

The molecular structure of **10** is given in Figure 3. The structure of the free ligand **5** was determined for comparison by X-ray diffraction (Figure 4). Selected structural parameters are summarized in Table 2.

Due to the two quite different π-ligands, (η^5-C_5Me_5) and (η^6-$C_5H_4{=}CR_2$), in **6** and **8** the bonding situation is remarkably different compared to bent-titanocene-derived dinitrogen complexes. The complexation of pentafulvenes to low-valent titanium fragments is generally assumed to be accompanied by electron transfer to the π-acceptor ligand. This leads to a situation that can probably be best described

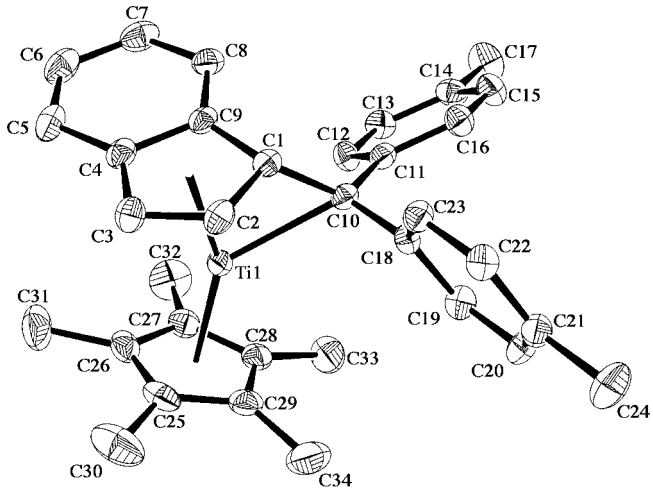


Figure 3. Solid-state structure of **10** (50% probability ellipsoids). Figure 4. Solid-state structure of **5** (50% probability ellipsoids). Selected bond lengths [Å] and angles [°]: C(1)–C(10) 1.359(2), C(1)–C(2) 1.467(2), C(1)–C(9) 1.488(2), C(2)–C(3) 1.340(3), C(3)–C(4) 1.454(2), C(4)–C(5) 1.390(3), C(4)–C(9) 1.416(2), C(5)–C(6) 1.382(3), C(6)–C(7) 1.387(3), C(7)–C(8) 1.390(3), C(8)–C(9) 1.387(2).

by the formation of a dianionic fulvene ligand coordinated in a π-η^5:σ-η^1 manner.[31,30] Thus, the five-membered ring of the pentafulvene becomes aromatic, the C_i–C_e bond is elongated, and the C_e atom is bent out of the ring plane (Θ, see footnote Table 2). A comparison of the structural data of the free ligands **2**,[30] **4**[35] and **5** with the titanium complexes **6**, **8** and **10** is given in Table 2. The exocyclic C_i–C_e distances in **2** [1.359(2) Å], **4** [1.342(2) Å][35] and **5** [1.359(2) Å] are elongated to av. 1.436 Å (**6**), av. 1.434 Å (**8**) and 1.465(3) Å (**10**) after complexation. The strongest

elongation and, simultaneously, the shortest Ti–C_e bond lengths [2.351(2) Å] were observed in the mononuclear titanium complex **10**. On the other hand, the Ti–C_e distances in **6** and **8** were found to be av. 2.606 Å and av. 2.491 Å. A comparable value was found for [(η^5-C_5Me_5)Ti(η^6-C_5H_4=C(*p*-tol)$_2$)Cl] [2.535(5) Å].[30] In fulvene complexes substituted with one or two protons at the C_e-atom of the fulvene ligand, Ti–C_e distances close to typical bond lengths between titanium and sp^3-hybridized C-atoms were found as in [(η^5-C_5Me_5)Ti(η^6-C_5Me_4=CH_2)] [2.281(14) Å][36] and [(η^5-C_5Me_5)Ti(η^6-C_5H_4=CH(*t*Bu))Cl] [2.355(2) Å].[31] The fulvene ligands in **6**, **8** and **10** show characteristic deviations (Θ) of the C_e-atom from the plane of the five-membered ring (**6** av. 28.3°, **8** av. 31.6°, **10** 34.9°). The Ct*–Ti–Ct^{Fv} angles of **6** (av. 138.8°) and **8** (138.8°) were found in a typical range of bent-titanocene derivatives[37] {Ti^{IV}: [(η^5-C_5Me_5)(η^5-C_5H_5)$TiCl_2$] 132.0°,[38] Ti^{III}: [(η^5-C_5Me_4H)$_2$TiCl] 139.1°,[39] [(η^5-C_5Me_5)$_2$TiCl] 143.6°[40]}. In contrast, the Ct*–Ti–Ct* angles in permethylated titanium(II) complexes are usually significantly larger {[{(η^5-C_5Me_5)$_2$Ti}$_2$(μ_2,η^1,η^1-N_2)] 145.7(3)°,[33] [(η^5-C_5Me_5)$_2$Ti(CO)$_2$] 147.9°[41]}. Also, in the case of the bulky fulvene complex **10** a larger value of 150.9° was found. Compared to free fulvene **5**, the two double bonds of the six-membered ring are significantly shortened from av. 1.39 Å to av. 1.36 Å in **10** and therefore seem to be more localised, indicating a loss of aromaticity. This is in agreement with an η^5 complexation mode of the five-membered ring, thus no hints for a typical indenyl effect are found.[42,43]

The isolated dinitrogen complexes **6**, **7**, and **8** showed diamagnetic behaviour, which allowed a complete NMR spectroscopic characterization (Table 3). The magnetic behaviour is comparable to the titanium(III)–dinitrogen complex [{(η^5-C_5H_5)$_2$Ti(*p*-tol)}$_2$(μ_2,η^1,η^1-N_2)].[44] On the other hand the titanium(II)–dinitrogen complexes like [{(η^5-C_5Me_5)$_2$Ti}$_2$(μ_2,η^1,η^1-N_2)] are often paramagnetic compounds (μ_{eff} = 2.18 BM per titanium atom[33]), showing broad downfield-shifted signals at room temperature[45] and dynamic properties in solutions. In such a way, detailed ^{1}H NMR measurements of [{(η^5-C_5Me_5)$_2$Ti(N_2)}$_2$(μ_2,η^1,η^1-N_2)] in [D_8]toluene at low temperatures (–78 to –42 °C) are in full accord with an η^5-C_5Me_5 ring site exchange.[13]

However, strong upfield shifts of proton and carbon signals, e.g. of up to 3 ppm for H_a of **8**, clearly show the presence of low-valent titanium complexes. This is especially pronounced for the exocyclic fulvene carbon atoms of all titanium complexes compared to the free ligands. Interestingly, the signals for these carbons were found at almost the same chemical shifts in all complexes although the free fulvenes do show significant differences. Furthermore, a complete loss of symmetry indicated by separated signals for all protons and carbons of the fulvenes in the dinuclear titanium complexes compared to the highly symmetrical fulvenes themselves and the absence of saturation transfer phenomena clearly show the formation of conformationally rigid dinitrogen complexes in benzene solution at room temperature. This is in sharp contrast to the conformational behaviour found for the mononuclear fulvene complexes [(η^5-C_5Me_5)Ti(η^6-C_5H_4=C(*p*-tol)$_2$)Cl][30] and [(η^5-C_5Me_5)-Ti(η^6-C_5H_4=C(*p*-C_6H_4F)$_2$)Cl][46], where a fast rotation of the fulvene ligand was observed under similar conditions. Obviously, a free rotation of the fulvene ligand is hindered by the dimeric structure, although the Ti–C_e distances are in a similar range. NOE measurements at room temperature indicate that the favoured isomer C (Scheme 1) in the solid state is also found in benzene solution because strong NOE contacts were observed between fulvene ring protons H'_b–H'_a of **8** which do not only result from the interaction of these protons attached to one fulvene ring but also from the interaction of protons attached to different fulvenes.

Table 3. Selected ^{1}H- (C_6D_6, 500 MHz, 300 K) and ^{13}C NMR spectroscopic data (C_6D_6, 125 MHz, 300 K) of **6**, **7** and **8**, compared with **2**,[30] **3** and **4**[47] (assignment of the proton and carbon signals in accordance with footnote[b] in Table 2).

Conclusion

An efficient type of one-step synthesis of end-on bridged dinuclear cyclopentadienyltitaniumfulvene complexes was presented. These complexes are formed in high yields from [(η^5-C_5Me_5)$TiCl_3$], bulky substituted pentafulvenes, and sodium amalgam as reducing agent under nitrogen. Along the Ti–N≡N–Ti axis the C_5Me_5 as well as the fulvene ligands are arranged in a stereoregular manner. The weak activation of the dinitrogen ligand suggests that the dinuclear [(η^5-C_5Me_5)Ti(η^6-C_5H_4=CR_2)] dinitrogen complexes serve as synthons for interesting titanocenes, derived from the displacement of the nitrogen molecule in combination with the known possibilities to functionalize the strongly nucleophilic exocyclic carbon atom of the fulvene ligand by electrophilic attack.

Experimental Section

General Remarks: All operations were performed under nitrogen with rigorous exclusion of oxygen and moisture by using glove box or Schlenk techniques. Solvents were thoroughly dried and saturated with nitrogen. ^{1}H- and ^{13}C NMR spectra were recorded with a Bruker AVANCE 500 spectrometer (^{1}H, 500.1 MHz; ^{13}C

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

125.8 MHz) or a Bruker AVANCE 300 spectrometer for ^{19}F- (282.4 MHz) and ^{1}H- or ^{13}C nuclei. The ^{1}H NMR chemical shifts were referenced to residual protons of the solvent. The ^{13}C NMR spectra were referenced to the signals of the solvent. The ^{19}F NMR spectra were referenced externally to $CFCl_3$. Assignment of the signals was done on the basis of ^{1}H, ^{13}C, H,H-COSY, HMQC, HMBC, and sel-1D NOESY NMR experiments.[48] Electron impact (EI) mass spectra were taken with a Finnigan-MAT 95 Spectrometer. IR spectra were recorded with a BIO-RAD FTS-7 Spectrometer by using KBr pellets. Elemental analyses were carried out by the Analytischen Laboratorien in Lindlar (Germany). [(η^5-C_5Me_5)$TiCl_3$] (**1**) was prepared according to the literature.[49] Sodium amalgam was purchased as 20% pellets from Aldrich. The fulvenes **2** and **3** were prepared according to general literature procedures.[48,50] **5**[48,51] was obtained in a similar way under only slightly modified conditions. Compound **4** was prepared according to the literature.[47,48]

[Bis{[η^6-6,6-bis(*p*-tolyl)pentafulvene](η^5-pentamethylcyclopentadienyl)titanium}-μ^2,η^1,η^1-dinitrogen] (6): Sodium amalgam (2.38 g, 20% Na, 20.73 mmol Na), di-*para*-tolylfulvene (**2**) (1.78 g, 6.91 mmol) and [(η^5-C_5Me_5)$TiCl_3$] (**1**) (2.00 g, 6.91 mmol) were placed in a Schlenk tube. At a temperature of 0 °C (ice bath) of THF (100 mL) was added under an excess nitrogen pressure of 200 mbar. The reaction mixture was stirred for 16 h. A colour change from red to dark green occurred. The reaction mixture was filtered twice (first P4/Celite, then P5). Removing the solvent under vacuum led to a brown residue, which became dark green again after adding N_2. After recrystallisation from of *n*-hexane (50 mL) at –20 °C, complex **6** could be isolated as dark green crystals showing a cupric lustre. Yield: 2.83 g (90%). M.p. 125 °C. ^{1}H NMR (500.1 MHz, C_6D_6, 300 K):[48] δ = 1.69 [s, 30 H, $C_5(CH_3)_5$], 2.14 (s, 6 H, outer CH_3), 2.16 (s, 6 H, inner CH_3), 3.98 (m, 2 H, H′$_a$), 4.07 (m, 2 H, H′$_b$), 4.38 (m, 2 H, H$_a$), 4.79 (m, 2 H, H$_b$), 6.83 (m, 4 H, inner C_6H_4), 6.92 (m, 4 H, outer C_6H_4), 6.98 (m, 4 H, inner C_6H_4), 7.28 (m, 4 H, outer C_6H_4) ppm. ^{13}C NMR (125.8 MHz, C_6D_6, 300 K):[48] δ = 12.5 [$C_5(CH_3)_5$], 21.0 (each C_6H_4-CH_3), 104.0 (C$_a$), 106.5 (C′$_a$), 108.4 (C′$_b$), 108.5 (C$_e$), 111.9 (C$_b$), 113.5 [$C_5(CH_3)_5$], 125.6 (Ci), 126.3 (outer C_6H_4), 128.5 (outer C_6H_4), 128.8 (inner C_6H_4), 132.0 (outer *i*-C_6H_4-C6), 132.2 (inner C_6H_4), 133.9 (inner *i*-C_6H_4-CH_3), 141.7 (outer *i*-C_6H_4-C6), 144.1 (inner *i*-C_6H_4-C6) ppm. IR (KBr): $\tilde{\nu}$ = 2915 (m), 2859 (m), 2745 (m), 1894 (w), 1746, 1605, 1505 (s), 1460 (s), 1375 (s), 1296, 1260 (w), 1159, 1103, 1067, 1020 (m), 905, 804, 731 cm^{-1}. MS (70 eV): *m*/*z* (%) = 441 (100) [M^+ – N_2 – Cp*Ti(*p*-Tolfv)], 307 (28). $C_{60}H_{66}N_2Ti_2$ (910.56): calcd. C 79.11, H 7.30, N 3.08; found C 78.93, H 7.42, N 3.05.

[Bis{[η^6-6,6-bis(*p*-fluorophenyl)pentafulvene](η^5-pentamethylcyclopentadienyl)titanium}-μ^2-η^1,η^1-dinitrogen] (7): Sodium amalgam (2.38 g, 20% Na, 20.73 mmol Na), di-*para*-fluorofulvene **3** (1.84 g, 6.91 mmol) and [(η^5-C_5Me_5)$TiCl_3$] (**1**) (2.00 g, 6.91 mmol) were placed in a Schlenk tube. At a temperature of 0 °C (ice bath) THF (100 mL) was added under an excess nitrogen pressure of 200 mbar. The reaction mixture was stirred for 16 h. A colour change from red to dark green occurred. The reaction mixture was filtered twice (first P4/Celite, then P5). Removing the solvent under vacuum led to a brown residue, which became dark green again after adding N_2. After recrystallisation from *n*-hexane (20 mL) at –20 °C, **7** could be isolated as dark green crystals with a cupric lustre. Yield: 2.56 g (80%). M.p. 138–140 °C. ^{1}H NMR (500.1 MHz, C_6D_6, 300 K):[48] δ = 1.56 [s, 30 H, $C_5(CH_3)_5$], 3.87 (m, 2 H, H′$_a$), 4.17 (m, 4 H, H$_a$ and H′$_b$), 4.86 (m, 2 H, H$_b$), 6.68 [m, *J* = 8.1 Hz, 4 H, ^{3}J(H,F) = 8.5 Hz, inner C_4H_6F], 6.75 (m, *J* = 8.4 Hz, 4 H, $^{3}J_{H,F}$ = 8.5 Hz, outer C_4H_6F), 6.81 (m, 4 H, inner C_4H_6F), 7.05 (m, 4 H, outer C_4H_6F) ppm. ^{13}C NMR (125.8 MHz, C_6D_6, 300 K):[48] δ = 12.4 [$C_5(CH_3)_5$], 104.1 (C$_a$), 105.7 (C$_{exo}$), 105.9 (C′$_a$), 108.0 (C′$_b$), 112.3 (C$_b$), 114.0 [$C_5(CH_3)_5$], 114.6 (outer C_4H_6F, d, $^{2}J_{C,F}$ = 21 Hz), 114.7 (inner C_4H_6F, d, $^{2}J_{C,F}$ = 21 Hz), 125.4 (Ci), 133.5 (outer C_4H_6F, d, $^{3}J_{C,F}$ = 8 Hz), 133.5 (inner C_4H_6F, d, $^{3}J_{C,F}$ = 8 Hz), 140.4 (outer *i*-C_6H_4-C6, d, $^{4}J_{C,F}$ = 3 Hz), 142.8 (inner *i*-C_6H_4-C6, d, $^{4}J_{C,F}$ = 3 Hz), 159.9 (outer *i*-C_6H_4-F, d, $^{1}J_{C,F}$ = 244 Hz), 162.2 (inner *i*-C_6H_4-F, d, $^{1}J_{C,F}$ = 244 Hz) ppm. ^{19}F NMR (282.4 MHz, C_6D_6, 303 K): δ = –115.8 (2F) ppm.- MS (CI, isobutane): *m*/*z* (%) = 938 (65) [469 × 2], 469 (100) [M^+ – N_2 – Cp*Ti(*p*-Ffv) + HF], 450 (20) [M+ – N_2 – Cp*Ti(*p*-Ffv) + H]. $C_{56}H_{54}F_4N_2Ti_2$ (926.81): calcd. C 72.57, H 5.87, N 3.02; found C 72.16, H 6.11, N 2.37.

[Bis{(η^6-adamantylidenepentafulvene)(η^5-pentamethylcyclopentadienyl)titanium}-μ^2-η^1,η^1-dinitrogen] (8): Sodium amalgam (2.38 g, 20% Na, 20.73 mmol Na), adamantylidenepentafulvene **4** (1.37 g, 6.91 mmol) and [(η^5-C_5Me_5)$TiCl_3$] (**1**) (2.00 g, 6.91 mmol) were placed in a Schlenk tube. At a temperature of 0 °C (ice bath) THF (100 mL) was added under an excess nitrogen pressure of 200 mbar. The reaction mixture was stirred for 16 h. A colour change from red to dark blue occurred. The reaction mixture was filtered twice (first P4/Celite, then P5). Removing the solvent under vacuum led to a turquoise residue, which became dark blue again after adding N_2. After recrystallisation from *n*-hexane (20 mL) at –20 °C, **8** could be isolated as dark blue crystals with a cupric lustre. Yield: 2.46 g (90%). M.p. 175 °C. ^{1}H NMR (500.1 MHz, C_6D_6, 300 K):[48] δ = 1.75 (s, 30 H, $C_5(CH_3)_5$), 1.48–2.53 (m, 28 H, $H_{Adamantyl}$), 3.64 (m, 2 H, H$_a$), 4.20, (m, 2 H, H′$_a$), 5.10 (m, 2 H, H$_b$), 5.69 (m, 2 H, H′$_b$) ppm. ^{13}C NMR (125.8 MHz, C_6D_6, 300 K):[48] δ = 12.3 [$C_5(CH_3)_5$], 29.2, 30.2, 34.1, 34.9, 38.2, 38.8, 39.0, 43.4, 45.4 ($C_{Adamantyl}$), 103.2 (C$_a$), 103.7 (C′$_b$), 104.5 (C′$_a$), 113.3 (C$_b$), 107.9 (C$_e$), 112.8 [$C_5(CH_3)_5$], 125.2 (Ci) ppm. MS (70 eV): *m*/*z* (%) = 381 (100) [M^+ – N_2 – Cp*Ti{$C_5H_4(C_{10}H_{14})$}]. $C_{50}H_{66}N_2Ti_2$ (790.85): calcd. C 75.94, H 8.41, N 3.54; found C 75.76, H 8.45, N 3.47.

[{η^6-10,10-Bis(*p*-tolyl)benzofulvene}(η^5-pentamethylcyclopentadienyl)titanium] (10): Sodium amalgam (2.38 g, 20% Na, 20.73 mmol Na), di-*p*-tolylbenzofulvene (**5**) (2.13g, 6.91 mmol) and [(η^5-C_5Me_5)$TiCl_3$] (**1**) (2.00 g, 6.91 mmol) were placed in a Schlenk tube. At a temperature of 0 °C (ice bath) THF (100 mL) was added under an excess nitrogen pressure of 200 mbar. The reaction mixture was stirred for 16 h. A colour change from red to brownish green occurred. The reaction mixture was filtered twice (first P4/Celite, then P5). Removing the solvent under vacuum led to a brown residue, which was recrystallised from *n*-hexane (20 mL) at –20 °C. Compound **10** could be isolated as black needle-shaped crystals. Yield: 2.8 g (85%). M.p. 115 °C. MS (70 eV): *m*/*z* (%) = 491 (100) [M^+], 308 (80) [di-*para*-tolylbenzofulvene$^+$]. $C_{34}H_{35}Ti$ (491.51): calcd. C 83.08, H 7.18; found C 83.04, H 7.21.

Di-*p*-tolylbenzofulvene (5): During 30 minutes, *n*BuLi (40.5 mL, 1.6 M) was added dropwise to a cooled solution (0 °C) of freshly distilled indene (9.8 mL, 0.082 mol) in THF (170 mL). The mixture was cooled to –60 °C, and 4,4′-dimethylbenzophenone (17.24 g, 0.082 mol) dissolved in THF (120 mL) was added. The reaction mixture was stirred overnight at room temperature. Then, water and diethyl ether were added, and the ether phase was extracted with water until pH 7 was reached. The ether phase was dried with $MgSO_4$, and the solvent was evaporated. After that the residue was dissolved in *n*-hexane (200 mL) and cooled rapidly. The precipitated crystalline solid was filtered and dried. Finally, the product could be isolated as orange crystals after recrystallisation from *n*-hexane/dichloromethane (2:1). Yield: 19.0 g (75%). M.p. 130–131 °C. ^{1}H NMR (500 MHz, $CDCl_3$, 300 K):[48] δ = 2.46 (s, 3 H, H-20), 2.52 (s, 3 H, H-15), 6.75 (m, 1 H, H-2), 6.79 (m, 1 H, H-8),

X-ray Crystallographic Study: Data for the structures **6**, **8**, **10** and **5** were collected on a STOE-IPDS diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). A summary of crystal data and intensity collection and refinement parameters is reported in Table 4. Intensity measurements were performed at 193(2) K. The structure of all complexes was solved by direct phase determination (SHELXL 97) and refined on F^2 (SHELXL 97)[52] with anisotropic thermal parameters for all non-hydrogen atoms.

Additionally crystallographic data for the structures **6**, **8**, **10**, and **5** have been deposited. CCDC-161093 (**6**), -252794 (**8**), -252795 (**10**), and -252796 (**5**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

New Insights into the Stoichiometric and Catalytic Reactivity of Unsaturated $Pd_3(dppm)_3CO^{n+}$ Clusters (n = 0, 1) Towards Halocarbons – First Evidence for Inorganic By-Products

Dominique Lucas,*[a] Frédéric Lemaître,[a,b] Beatriz Gallego-Gómez,[a] Cyril Cugnet,[a] Philippe Richard,[a] Yves Mugnier,[a] and Pierre D. Harvey*[b]

Keywords: Palladium cluster / Alkyl halide / Reduction / Electrocatalysis / Alkyl radicals

The title clusters, $Pd_3(dppm)_3(CO)^+$ and $Pd_3(dppm)_3(CO)^0$ can be electrochemically generated from the 1- and 2-electron reductions, respectively, of the $Pd_3(dppm)_3(CO)^{2+}$ cluster [dppm = bis(diphenylphosphanyl)methane; Pd_3^{2+}]. Pd_3^+ reacts in a stoichiometric ratio with methyl iodide, MeI, and benzyl bromide, BzBr, in THF to provide the corresponding $Pd_3(X)^+$ adducts (X = I, Br respectively) as inorganic products. Other products are Bz_2 and PhMe for BzBr but, for MeI, no organic product was observed (since they are too volatile). In the presence of the same substrates, Pd_3^0 also reacts in a stoichiometric ratio to form the same organics and the $Pd_3(X)^+$ adducts (X = I and Br). However for MeI, the major inorganic product is the A-frame $Pd_2(dppm)_2(Me)_2I^+$ binuclear complex. For BzBr, the corresponding A-frame complex $Pd_2(dppm)_2(Bz)_2Br^+$ could not be detected. The spin-trap agents, 2,2,6,6-tetramethylpiperidin-1-oxyl (TEMPO) and 5,5′-dimethyl-1-pyrroline *N*-oxide (DMPO), have been used to demonstrate the intermediacy of the radical Bz˙. The catalytic generation of "Bz˙" was performed using two methods, i.e. 1) using a copper anode as the working electrode [$Pd_3(Br)^+ + Cu - e^- \rightarrow Pd_3^{2+} + CuBr$ (s)] and 2) using a carbon cathode as the working electrode [$Pd_3(Br)^+ + 2e^- \rightarrow Pd_3^0 + Br^-$]. The chemical yields for Bz_2 vary between 50 and 56 % and the Faradic yield is of the order of 90 % for method 1 and between 52 and 59 % for method 2 [taking into account the quantity of electricity necessary to reduce the catalyst $Pd_3(Br)^+$]. The X-ray structure of $Pd_3(dppm)_3(CO)(Br)^+$ is presented and the following parameters were recorded: monoclinic space group $P2_1/n$, a = 10.6546(2), b = 37.1091(7), c = 21.2714(7) Å, β = 91.55(1)°, V = 8407.3(4) Å^3, Z = 4, R_1 = 0.0581 [$I > 2\sigma(I)$], wR_2 = 0.1478 (all data).

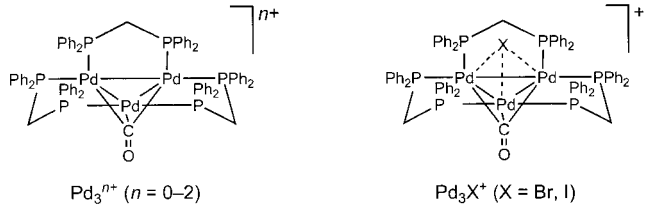
Introduction

The C–X bond activation is an important process in organic synthesis.[1–7] In this respect, our groups have investigated numerous thermal and electrochemical reactions between $Pd_3(dppm)_3(CO)^{2+}$ (**1**; Pd_3^{2+})[8–10] and halocarbons (RX) and some important electrochemically induced organic catalyses have been reported.[11–13] The direct thermal reaction (Pd_3^{2+} + RX) quantitatively produces the corresponding adducts $Pd_3(X)^+$ and "R^+".

The elucidation of the mechanism of C–X bond cleavage for alkyl halides and acid chlorides has been studied in some detail.[14] However, whereas the reactivity of Pd_3^{2+} towards RX has been fully investigated under both stoichiometric and catalytic conditions, the corresponding reduced species Pd_3^+ and Pd_3^0 have only been briefly studied under catalytic conditions.



Pd_3^{n+} (n = 0–2) Pd_3X^+ (X = Br, I)

We now wish to report the reactivity of the Pd_3^+ and Pd_3^0 species under stoichiometric conditions towards MeI and BzBr and evidence for the slow formation of the d^8–d^8 A-frame $Pd_2(dppm)_2(Me)_2I^+$ complex during the Pd_3^0 + MeI reactions has been obtained for the first time, indicating the presence of a parallel process which may explain the catalyst poisoning in some cases.

The use of BzBr was made since the presence of the potential Bz^+ and Bz˙ intermediates can easily be deduced from the lesser volatile products, hence providing key information on the mechanism. Similarly, the MeI substrate is well known to undergo facile oxidative addition with Pd species in the low oxidation states, often resulting in the

formation of a Pd–Me bond.[15–18] Finally, the efficient catalytic generation of "Bz˙" was examined.

Results and Discussion

Stoichiometric Reactivity of Pd_3^+

As reported earlier,[11,14,19] Pd_3^+ can be quantitatively obtained from a 1-electron reduction of the corresponding dicationic compound. Its RDE voltammogram is depicted in Figure 1 (trace a) and exhibits two closely spaced waves for oxidation and reduction labelled A'_1 and A_2, respectively [$E_{1/2}$ (A_1') = –0.24 V and $E_{1/2}$ (A_2) = –0.51 V vs. SCE]. Line 1b results from the addition of an excess of methyl iodide to Pd_3^+. The disappearance of waves A'_1 and A_2 can be observed, demonstrating that the Pd_3^+ complex has completely reacted. On the other hand, the current waves A_3 and A_4 indicate the formation of the previously known iodide coordination cluster $Pd_3(I)^+$ [$E_{1/2}$ (A_3) = –0.80 V and $E_{1/2}$ (A_4) = –1.25 V vs. SCE] which was confirmed by ^{31}P NMR spectroscopic analysis of the reaction solution in which only the signal of $Pd_3(I)^+$ can be seen (δ = –6.4 ppm).[20–22]

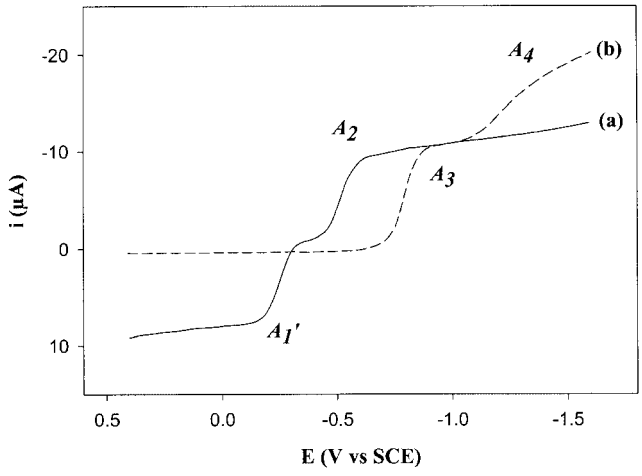

Figure 1. RDE voltammogram of Pd_3^+ (0.81 mM) in THF with 0.2 M Bu_4NPF_6: (a) alone, (b) immediately after addition of 1.1 molar equiv. of CH_3I.

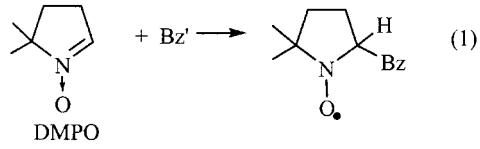
Addition of BzBr (1.1 equiv.) to Pd_3^+ produces $Pd_3(Br)^+$ as confirmed by the comparison of the electrochemical [$E_{1/2}$ = –0.7 V (A_3)] and ^{31}P NMR spectroscopic data (δ = –6.14 ppm in [D_6]acetone) as well as the formation of Bz_2 (44% based upon GCMS data) and PhMe.[23] During the course of this investigation, crystals of $Pd_3(Br)^+$ suitable for X-ray analysis were obtained and investigated (see below). The organic products indicate a radical-type reactivity involving the "Bz˙" species which produces Bz_2 by homocoupling and PhMe by hydrogen abstraction from the solvent.[24] The addition of an excess of the spin trap agent 5,5′-dimethyl-1-pyrroline *N*-oxide (DMPO, 10 equiv.) to the Pd_3^+/BzBr reaction yields the stable Bz-DMPO spin adduct as readily observed by EPR spectroscopy which exhibits the expected 6-line signal:[25] a_β^H = 20.66 G, a^N = 14.16 G.[26,27] The absence of Bz_2 in reaction (1) suggests a quantitative reaction.



The two possible mechanisms for the production of the organic radical [$Pd_3^+ + RX \rightarrow Pd_3(X)^+ + R^{\cdot}$] are 1) an outer-sphere electron transfer from Pd_3^+ to RX, followed by X^- elimination from the intermediate $R–X^{\cdot-}$ (X^- is then trapped by the resultant Pd_3^{2+}) or 2) a halide abstraction process occurring within a host-guest $Pd_3\cdots(RX)^+$ assembly in which the homolytic C–X bond cleavage takes place, as described by reactions (2) and (3).

$$Pd_3^+ + RX \rightleftharpoons Pd_3\text{---}(XR)^+ \quad (2)$$

$$Pd_3\text{---}(XR)^+ \longrightarrow Pd_3(X)^+ + \text{"R}^{\cdot}\text{"} \quad (3)$$

The driving force in reaction (3) is the formation of the very stable $Pd_3(X)^+$ adduct. The former outer-sphere mechanism is highly unlikely since the oxidation ($E_{1/2}$ = –0.29 V) and reduction potentials ($E_{1/2} \approx$ –2.5 V vs. SCE)[28,29] for Pd_3^+ and R–X, respectively, are not thermodynamically favourable for such a process. On the other hand, the second proposal is more likely to occur based upon the well-established mechanism reported for the Pd_3^{2+} cluster [$Pd_3^{2+} + RX \rightarrow Pd_3\cdots(XR)^{2+} \rightarrow Pd_3(X)^+ +$ "R^+"].[11–14]

Going back to the Pd_3^+/MeI reaction, the absence of observed organics is due to their high volatility and, based on the observation made for the Pd_3^+/BzBr reaction, one can suggest that these are Me_2 and MeH.

Reactivity with Pd_3^0

The 2-electron reduction of Pd_3^{2+} leads to Pd_3^0 quantitatively. Addition of an excess of MeI to the electrochemically generated Pd_3^0-containing solution monitored by RDE voltammetry (Figure 2) results in the complete disappearance of the two 1-electron oxidation waves of the Pd_3^0 species (waves A_1' and A_2') and the appearance of waves A_3 and B_1 (–1.18 V vs. SCE) which are due to the anticipated $Pd_3(I)^+$ species and the known dinuclear d^8–d^8 A-frame complex $Pd_2(dppm)_2(Me)_2I^+$, respectively.[30] Based upon the current amplitudes of waves A_3 and B_1 and the relative intensity of the corresponding ^{31}P NMR signals (at –6.40 and +19.76 ppm), the relative proportions are ≈ 20–25% and ≈ 80–75%, respectively. This result is different from that of Pd_3^+ for which no A-frame complex was observed and

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

suggests the presence of oxidative addition of MeI to Pd_3^0 as a parallel pathway.

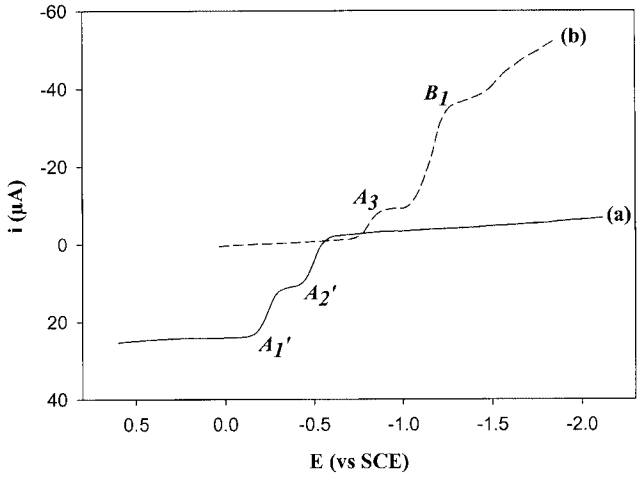


Figure 2. RDE voltammogram of Pd_3^0 (1.2 mM) in THF with 0.2 M Bu_4NPF_6: (a) alone, (b) immediately after addition of an excess (4 molar equiv.) of CH_3I.

The addition of BzBr (2 equiv.) to a Pd_3^0-containing solution leads to a slower reaction with respect to that of a similar reaction with Pd_3^+ (as monitored by the RDE method; Figure 3) but the presence of Bz_2 (GC-MS yields $\approx$ 44%) and PhMe as organic products could be detected in about the same relative amount.

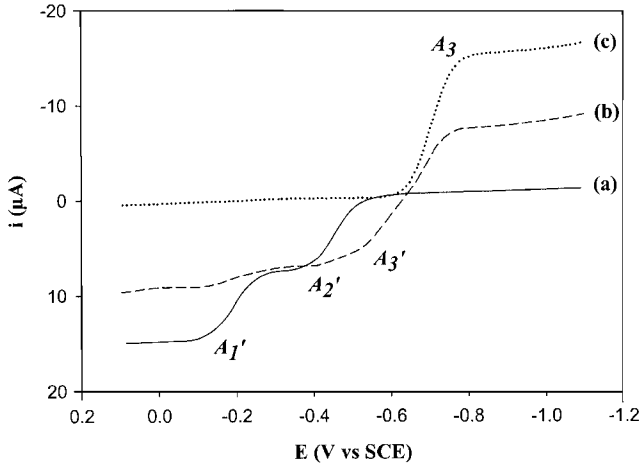

Figure 3. RDE voltammogram of Pd_3^0 (0.75 mM) in THF with 0.2 M Bu_4NPF_6: (a) alone, (b) immediately after addition of 2 molar equiv. of $PhCH_2Br$, (c) after 15 min at room temperature.

On the other hand, $Pd_3(Br)^+$ was quantitatively obtained and no trace of the d^8–d^8 $Pd_2(dppm)_2(Bz)_2Br^+$ complex was detected on this occasion (see below). The addition of DMPO to the solution prior to reaction leads to the same spin adduct as described above and no Bz_2 was observed, also suggesting completion of the spin-trap reaction. The overall reaction for the radical formation can be written as in reaction (4).

$$Pd_3^0 + 2\,RX \longrightarrow Pd_3(X)^+ + 2\,R^{\cdot} + X^- \quad (4)$$

A similar mechanism to that for Pd_3^+ can be proposed; see reaction (7).

$$Pd_3^0 + RX \rightleftharpoons Pd_3\text{---}(XR)^0 \quad (5)$$

$$Pd_3\text{---}(XR)^0 \longrightarrow Pd_3(X)^0 + \text{"}R^{\cdot}\text{"} \quad (6)$$

$$Pd_3(X)^0 \longrightarrow Pd_3^+ + X^- \quad (7)$$

The halocarbon molecule penetrates inside the cluster cavity forming a transient reactive host-guest complex $Pd_3\cdots(XR)^0$ [reaction (5)], in which a homolytic C–X bond cleavage takes place, giving the corresponding alkyl radical "$R^{\cdot}$" [reaction (6)]. The resultant $Pd_3(X)^0$ intermediate is unstable and eliminates X^- to form Pd_3^+ [reaction (7)]. This latter process is well known and has been previously established for X^- = Br^- and I^-.[8,22] Finally, the paramagnetic Pd_3^+ cluster undergoes reactions (2) and (3).

A second mechanism can also be considered and this involves the heterolytic C–X bond cleavage of the species $Pd_3\cdots(RX)^0$ followed by the reductive elimination of "$R^{\cdot}$"; see reactions (8) and (9).

$$Pd_3\text{---}(RX)^0 \longrightarrow Pd_3(R)^+ + X^- \quad (8)$$

$$Pd_3(R)^+ \longrightarrow Pd_3^+ + \text{"}R^{\cdot}\text{"} \quad (9)$$

Again, Pd_3^+ undergoes reactions (2) and (3). Reaction (8), which differs from reaction (6), finds its driving force from the electrostatic attraction of a potential carbocation "R^+" with the electron-rich Pd_3^0 centre. However, reactions 8 and 9 are both unlikely. The postulated $Pd_3(R)^+$ intermediate exhibits a Pd_3^{2+} centre and a carbanion which follows the octet rule similar to the Pd_3X^+ adducts. Its dissociation into Pd_3^+ and "$R^{\cdot}$" [reaction (9)] would be far too high in energy. In addition, the formation of the $Pd_3(R)^+$ species would prove difficult since the approach of the Pd_3^0 cluster towards the alkyl carbon atom in BzBr is sterically encumbered. Finally, such alkyl adducts of Pd_3^{2+} have never been observed and appear highly reactive.[31]

In order to support this hypothesis, DFT computations were performed on the model compounds $Pd_3(H_2PCH_2PH_2)_3(CO)(Me)^+$ and $Pd_3(H_2PCH_2PH_2)_3(CO)(Br)^+$. The first observation is that the computed total energies are –17067.91 and –19590.39 a. u. (arbitrary units), respectively, indicating the greater stability of the $Pd_3(Br)^+$ species. The second observation pointing in the same direction is that the computed energies for individual MOs are systematically higher for the $Pd_3(Me)^+$ species. As an example, a partial comparative MO diagram for the LUMO and HOMO is presented in Figure 4. The MO's have been described previously elsewhere and this is not within the scope of this work.[32,33] In conclusion, DFT supports the hypothesis that $Pd_3(Me)^+$ is a less stable species than $Pd_3(Br)^+$, Br^- or Pd_3^{2+}.

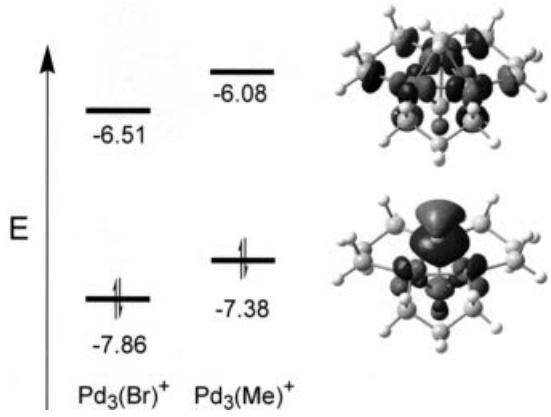

Figure 4. Left: Partial MO diagram of the HOMO and LUMO of the model compounds $Pd_3(H_2PCH_2PH_2)_3(CO)(Me)^+$ and $Pd_3(H_2PCH_2PH_2)_3(CO)(Br)^+$. Right: MO drawing for the HOMO and LUMO for $Pd_3(H_2PCH_2PH_2)_3(CO)(Me)^+$.

Two new questions now arise. Firstly, why can the radical Bz˙ intermediate be observed in quantitative amounts (based upon observed Bz_2 and PhMe) for both Pd_3^0 and Pd_3^+ species and, secondly, why can two inorganic products be observed for the Pd_3^0/MeI reaction (Pd_3 adduct and A-frame) while the Pd_3^+/MeI reaction leads to only one inorganic product (Pd_3 adduct)? These observations imply that another competitive process must occur which can be formalised as shown in reaction (10).

$$Pd_3(dppm)_3(CO)^0 + 3\ MeI \longrightarrow 3/2\ Pd_2(dppm)_2(Me)_2(I)^+ + CO + 3/2\ I^- \quad (10)$$

The answer to the first question can be found in the considerable stability of the $Pd_3(X)^+$ adducts[22] [reaction (3)] which readily drives the reactions. Thus, the same driving force may be present in the case of Pd_3^+. The answer to the second question can be found in the synthesis of Pd_3^0 itself.[34] The reduction of $Pd(dppm)Cl_2$ or $Pd_2(dppm)_2Cl_2$ leads to the zero-valent "$Pd_2(dppm)_2$" species. In the presence of a source of CO, this very reactive binuclear complex provides Pd_3^0.[35,36] On the other hand, the synthesis of $Pd_2(dppm)_2(Me)_2(I)^+$ can be performed by addition of MeI to $Pd_2(dppm)_3$[37] and the latter can dissociate into "$Pd_2(dppm)_2$" and dppm.[38] These previous results suggest that Pd_3^0 should dissociate to form the highly reactive species "$Pd_2(dppm)_2$" which would react with MeI.

On the other hand, the absence of reactivity in the case of BzBr, to form the A-frame product, suggests an important difference between the rates of the Pd_3^0/BzBr and "$Pd_2(dppm)_2$"/BzBr reactions which would favour the first reaction. It should be noted that the A-frame product $Pd_2(dppm)_2(Bz)_2(Br)^+$ has been previously reported in the literature[39] but the synthesis was not through the BzBr oxidative addition pathway as for MeI. This method was attempted but with no success which is consistent with our results. The preferred route was the reaction between $Pd(dppm)Br_2$ and the Grignard reagent BzMgBr.

Some questions remain such as how does the structure of the halogenated substrate affect the occurrence of the A-frame product? What is the main factor between the halogen and the alkyl group? In order to address these points, Pd_3^0 was treated with a slight excess of BzI in a cross experiment. This led to quantitative formation of $Pd_3(I)^+$ meaning that reaction (4) proceeds solely.

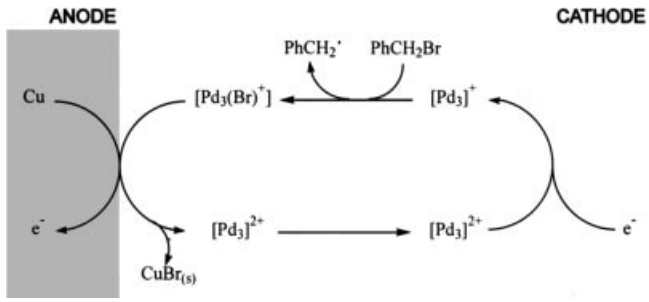
Thus, the steric hindrance of the alkyl group is likely playing an important role in the oxidative addition of RX to Pd_3^0. In order to confirm this proposal, a series of alkyl iodides, RI, were tested in the reaction with Pd_3^0 (R = Et, *i*Pr, *t*Bu). In no case was the A-frame product observed and $Pd_3(I)^+$ was always the sole inorganic product. Hence, reaction (10) may be extremely sensitive to the steric encumbrance of the alkyl group since it operates only when R = Me.

Catalytic Formation of "Bz˙" Radicals

The chemistry of free radicals has experienced an important growth in recent years[40,41] but the use of organotin compounds such as R_3SnH remains the first choice for radical generation.[42] However, because their use must be stoichiometric, their toxicity has encouraged chemists to find alternate and more environmentally friendly methods.[43] Thus, the indirect reduction of RX using an electron transfer catalyst mediating the RX conversion to "R˙" is appealing.[44]

$$RX + e^- \longrightarrow "R^{\cdot}" + X^- \quad (11)$$

In an attempt to render the stoichiometric reactions for "Bz˙" described above catalytic, two methodologies were examined. The first involves $Pd_3(Br)^+$ as a precatalyst in a single compartment electrochemical cell equipped with a copper anode as the controlled-potential working electrode, a platinum cathode as the counter-electrode and CH_2Cl_2 as the solvent. The electrolysis proceeds as shown in Scheme 1. The 1-electron oxidation at the copper anode produces CuBr(s) and Pd_3^{2+} from $Pd_3(Br)^+$. Pd_3^{2+} diffuses towards the cathode where it is reduced to Pd_3^+ which itself diffuses in the solution and reacts with BzBr to generate $Pd_3(Br)^+$ and "Bz˙". Bz_2 is the sole organic product observed and no PhMe is formed. The reason is that, unlike THF, CH_2Cl_2 is not an H-donor. Table 1 summarises the results (entry



Scheme 1.

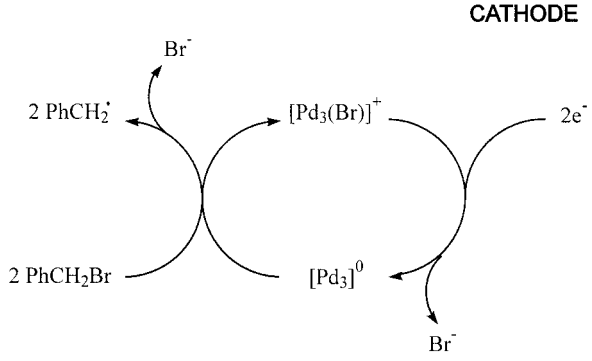
Table 1. Controlled-potential electrolysis of $Pd_3(Br)^+$ in the presence of BzBr.

Entry	Working electrode (WE)	E_{WE} (V vs. SCE)	Solvent[a]	Molar ratio BzBr/cluster	Q (F per mol of BzBr)	Spin trap	Product(s)	% Chemical yield	% Faradic yield[b]
1	Cu anode[c]	+0.6	CH_2Cl_2	25	0.84	none	dibenzyl	76[d]	90
2	C cathode[e]	–0.9	THF	14	1.24	none	dibenzyl	70[d]	56
3	C cathode[e]	–1.3	THF	14	1.21	none	dibenzyl	60[d]	50
4	C cathode[e]	–0.9	THF	14	1.14	DMPO[f]	spin adduct	[g]	
5	C cathode[e]	–0.9	THF	14	1.09	TEMPO[f]	dibenzyl	42[d]	38
							spin Adduct	30[h]	28

[a] In the case of entry 1, CH_2Cl_2 was used as the solvent and no PhMe was observed; for entries 2–5, THF was used and PhMe was detected by GC–MS but not quantified because of strong overlap with the solvent peak in the chromatogram. [b] Faradic yield = Chemical Yield/Q. [c] The platinum counter-electrode was not separated, being directly immersed in the solution in order for it to electrolyse. [d] Measured by gas chromatography. [e] Standard assembly with an isolated platinum counter-electrode located in a separate compartment. [f] Quantity = 1 molar equivalent with respect to BzBr. [g] Only observed by ESR with no quantification. [h] Isolated yield.

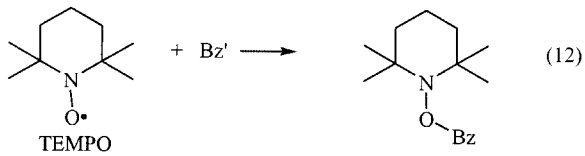
1). Both the chemical (76%) and Faradic (90%) yields are good.

The second method involves the use of a carbon cathode where the single 2-electron reduction of $Pd_3(Br)^+$ in Pd_3^0 (at about –1 V vs. SCE) occurs in THF. The catalytic cycle is shown in Scheme 2 based on the findings of the stoichiometric reactions above. This method leads to slightly lower chemical yields of Bz_2 and the presence of PhMe was noted. The data are summarised in Table 1.



Scheme 2.

The addition of the spin trap DMPO to the solution during catalysis (entry 4) leads to the formation of the spin adduct as shown in reaction (1). On the other hand, addition of 2,2,6,6-tetramethylpiperidin-1-oxyl (TEMPO) [45–48] (entry 5) leads to a partial trapping where Bz_2 and the diamagnetic spin adduct can be observed [reaction (12)].



(12)

X-ray Structure of $Pd_3(Br)^+$

This compound completes the series for $Pd_3(X)^+$ (Figure 5 and Table 2) where X = Cl[49,50] and I.[21] A comparison of the skeleton (Table 3) indicates a fairly robust core in which the nature of the halide does not perturb the bond distances within the experimental uncertainties. In all cases, the Pd–X distances indicate strong ionic interactions and vary as expected (Cl < Br < I).

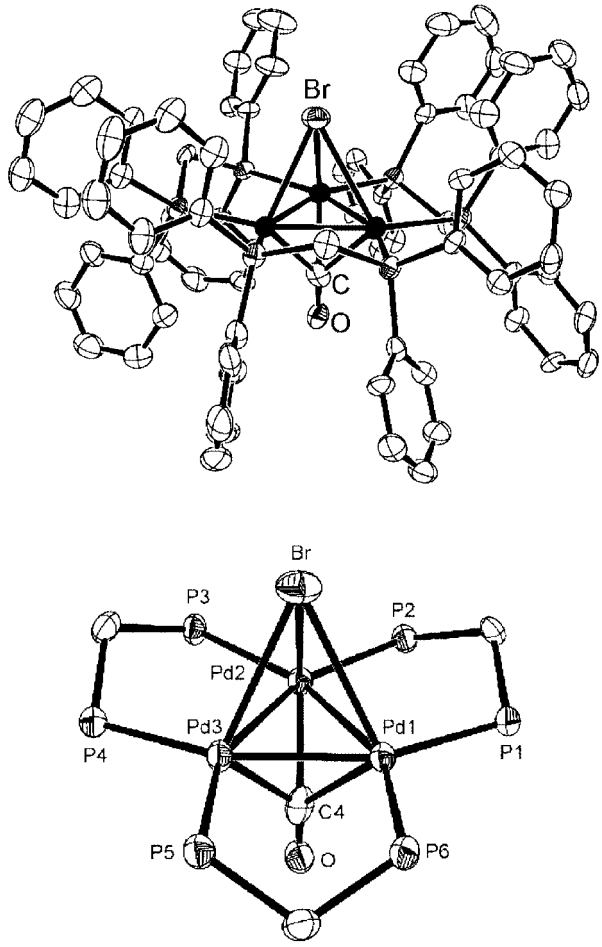


Figure 5. Top: ORTEP representation of $Pd_3(Br)^+$. The PF_6^- counter-anion, crystallisation toluene molecules and H-atoms are not shown for clarity. The ellipsoids are shown at the 50% probability level. Bottom: Drawing showing the skeleton of the cluster and the atom numbering.

Conclusions

The stoichiometric reactivity toward halocarbons of the Pd_3^+ and Pd_3^0 species has been investigated for the first

[a] The uncertainties are based on the maximum difference between the average value and experimental data.

time and has allowed the discovery of a new reactivity, particularly with respect to the inorganic products evolved from the Pd_3^0 species. The resultant A-frame product is stable since its reduction potential is higher than that for Pd_3^+ and Pd_3^0. Although there is no evidence in this work, the parallel pathway leading to the A-frame product may cause catalyst poisoning. Moreover, the catalytic generation of free radicals has been performed in good yields and the electrochemical methods may represent interesting alternatives to other stoichiometric reagents such as R_3SnH which may exhibit some undesired toxicity. Applications of such species in organic syntheses, especially those relative to C–X bond activation, are many. Due to the nature of the radical-type reactions that these species lead to, many other applications should be possible.

Experimental Section

Materials: The $[Pd_3(dppm)_3(CO)](PF_6)_2$ complex was prepared according to the literature.[20,51] Dichloromethane was distilled under Ar over P_2O_5 and tetrahydrofuran (THF) was distilled under Ar over Na (Aldrich). Benzyl bromide (BzBr), methyl iodide (MeI) and the spin trap agents TEMPO (2,2,6,6-tetramethylpiperidin-1-oxyl) and DMPO (5,5′-dimethyl-1-pyrroline *N*-oxide) were purchased from Aldrich and used as received. Benzyl iodide (BzI) was prepared according to a literature method.[52] The Bu_4NPF_6 salt was synthesized by mixing stoichiometric amounts of Bu_4NOH (40% in water) and HPF_6 (60% in water). After filtration, the salt was recrystallised twice from ethanol and dried at 80 °C for at least two days.

Apparatus: NMR spectra were measured on a Bruker WM 300 spectrometer (^{31}P NMR: 121.497 MHz). The chemical shifts are reported with respect to H_3PO_4 (^{31}P NMR). The GC–MS data were collected on a Hewlett–Packard 6890 Series instrument. EPR measurements were carried out on a Bruker ESP 300 spectrometer; field calibration was made with DPPH (g = 2.0037).

Electrochemical Experiments: All manipulations were performed using Schlenk techniques in an atmosphere of dry oxygen-free argon. The supporting electrolyte was degassed under vacuum before use and then dissolved to a concentration of 0.2 M. For cyclic voltammetry experiments, the concentration of the analyte was almost 10^{-3} M. Voltammetric analyses were carried out in a standard three-electrode cell with a Tacussel PJT24–1 potentiostat connected to a Tacussel GSTP4 waveform generator. The reference electrode was a saturated calomel electrode(SCE)separated from the solution by a sintered glass disk. The auxiliary electrode was a platinum wire. For all voltammetric measurements, the working electrode was a vitreous carbon electrode (φ = 3 mm). Under these conditions, when operating in THF, the formal potential for the ferrocene$^{+/-}$ couple was found to be +0.56 V versus the SCE. The controlled potential electrolysis was performed with an Amel 552 potentiostat coupled with an Amel 721 electronic integrator. High scale electrolyses were performed in a cell with three compartments separated with fritted glasses of medium porosity. Carbon gauze was used as the working electrode, a platinum plate as the counter-electrode and a saturated calomel electrode as the reference electrode. The electrolyses corresponding to the copper method were performed with a copper plate as the working electrode (anode), a platinum plate as the counter-electrode (cathode) and a saturated calomel electrode as the reference electrode, the latter being separated from the others in a two-compartment cell.

Procedures for the Electrochemical Experiments. Conventional High-Scale Electrolysis: The $[Pd_3(dppm)_3(CO)](PF_6)_2$ cluster (12.5 mg, 7×10^{-3} mmol, 6 mol-% per mol of BzBr) and BzBr (12.45 μL, 0.105 mmol) were added to the cathodic compartment of the cell containing a 0.2 M solution of Bu_4NPF_6 in THF (10 mL). The anodic compartment and the reference electrode compartment were filled with the Bu_4NPF_6–THF solution. The potential was set to –0.9 V vs. SCE. The electrolysis was stopped after the current had dropped to less than 0.5 mA. After filtration of the mixture, the solvent was removed and the residue extracted with diethyl ether (3× 5 mL). The internal standard method was used to measure the GC yields of the products. These were identified by comparison of the GC–MS spectra and GC retention times with those of available authentic samples. The electrolysis was also performed in the presence of TEMPO (in an equimolar amount to BzBr) which led to the isolation of the spin adducts Bz–DMPO (30%) and Bz_2 (42%). These were separated by column chromatography (solvent: CH_2Cl_2) and identified by mass spectrometry, ^1H NMR spectroscopy and by comparison with literature data.[53]

High-Scale Electrolysis. The Copper Method: Pd_3^{2+} cluster (11.6 mg, 6.5×10^{-3} mmol, 4 mol-% per mol of BzBr) and BzBr (20 μL, 0.168 mmol) were added to the anodic compartment containing a 0.2 M solution of Bu_4NPF_6 in CH_2Cl_2 (10 mL). The Bu_4NPF_6–CH_2Cl_2 solution (10 mL) was poured into the reference electrode compartment. The copper anode potential was set to +0.6 V vs. SCE and the electrolysis was stopped after one Faraday

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

per mol of BzBr had passed. The quantification procedure was the same as described above.

Theoretical Computations: The Density Functional Theory calculations (DFT) were performed using the commercially available Gaussian 98[54] software and a Pentium 4 (1.6 GHz) computer. The computations were performed at the RB3LYP level [Becke's three parameter hybrid functional[55] using the LYP (Lee–Yang–Parr) correlation functional].[56,57] The basis set for the polarisation and diffuse function was the 3-21G* set.[58–60] To save computation time, $H_2PCH_2PH_2$ was selected instead of dppm. In order to test the methodology, the computed bond distances and angles of the model cluster $Pd_3(H_2PCH_2PH_2)_3(CO)(Br)^+$ were checked against those of the crystal structure of $Pd_3(dppm)_3(CO)(Br)^+$ [denoted as $Pd_3(Br)^+$ in the text]. The comparison was satisfactory.

X-ray Structure of $[Pd_3(dppm)_3(CO)Br](PF_6)$: Single crystals of Pd_3Br^+ (as its PF_6^- salt) were obtained from acetone/toluene/hexane, mounted in inert oil and transferred to the cold gas stream (110 K) of a Nonius Kappa CCD diffractometer located at the Université de Bourgogne. The structure was solved by the heavy atoms method (SHELXS-97) and refined by full-matrix least-squares methods (SHELXL-97)[61] with the aid of the WINGX program.[62] The capping CO molecule and the capping Br atom were found to be slightly disordered (inversion of both ligands with respect to the Pd_3 plane), the occupancies converged to 0.93/0.07. The minor component of the disorder was isotropically refined with some least-squares restraints to ensure equivalent geometrical parameters for both components. Among the three toluene solvate molecules, only one was anisotropically refined, the others were each refined with an overall isotropic thermal parameter and one of them, close to an inversion centre, was refined with an occupancy of 0.5. All other non-hydrogen atoms were anisotropically refined and the hydrogen atoms were included using a riding model. Crystallographic data are reported in Table 4.

Synthesis and Structural and Spectroscopic Characterization of New Ru^{II}-dmso Precursors with Face-Capping Ligands for Use in Self-Assembly Reactions

Elisabetta Iengo,[a] Ennio Zangrando,[a] Edi Baiutti,[a] Fabio Munini,[a] and Enzo Alessio*[a]

Keywords: Facial coordination / Ruthenium / Self-assembly / Tridentate ligands / Tripodal ligands

The aim of this work is the preparation of new, easy-to-make, octahedral Ru^{II} precursors with facial geometry to be used in self-assembly reactions. We chose dmso as a leaving group and 1,4,7-trithiacyclononane ([9]aneS$_3$), tris(pyrazolyl)methane [CH(pz)$_3$, pz = pyrazol-1-yl], or triphos [CH$_3$C(CH$_2$PPh$_2$)$_3$] as the face-capping ligand (fcl). We describe here the preparation and structural characterization of three new dicationic Ru^{II} complexes (as triflate salts) of the type *fac*-[Ru(fcl)(solv)$_3$]$^{2+}$, namely *fac*-[Ru([9]aneS$_3$)(dmso-O)(dmso-S)$_2$]$^{2+}$ (**3b**), which equilibrates in solution with the linkage isomer *fac*-[Ru([9]aneS$_3$)(dmso-O)$_2$(dmso-S)]$^{2+}$ (**3a**), *fac*-[Ru{CH(pz)$_3$}(dmso-O)(dmso-S)$_2$]$^{2+}$ (**7**), and *fac*-[Ru(triphos)(dmso-O)$_2$(H$_2$O)]$^{2+}$ (**9**). In all cases the preferred synthetic procedure involved coordination of the face-capping ligand to *cis*-[RuCl$_2$(dmso)$_4$] first, followed by replacement of the chlorides with dmso (or water) molecules assisted by addition of AgCF$_3$SO$_3$ (AgOTf). NMR investigations showed that hydrolysis of the dmso ligands occurs very easily for **3** in water and for **9** in chloroform, while for complex **7** only the O-bound dmso ligand is replaced in water. In the course of this work, the following complexes were also isolated and structurally characterized: *fac*-[Ru([9]aneS$_3$)Cl(dmso-S)$_2$][OTf] (**2**), *trans*,*cis*,*cis*-[RuCl$_2$(dmso-S)$_2${CH(pz)$_2$(pz)}] (**4**), *trans*,*cis*,*cis*-[RuCl$_2$(dmso-S)$_2$(pzH)$_2$] (**5**), *fac*-[Ru{CH(pz)$_3$}Cl$_2$(dmso-S)] (**6**), *fac*-[Ru([9]aneS$_3$)(py)$_3$][OTf]$_2$ (**11**), *fac*-[Ru([9]aneS$_3$)(py)$_2$(CH$_3$CN)][OTf]$_2$ (**13**), and *fac*-[Ru([9]aneS$_3$O)(dmso-O)$_2$(dmso-S)][OTf]$_2$ ([9]aneS$_3$O = 1,4,7-trithiacyclononane 1-oxide); in **4** the tripodal tris(pyrazolyl)methane acts as a bidentate ligand.

Introduction

Metal-mediated synthetic procedures involving the self-assembly of electron-donor building blocks (polytopic organic ligands) and electron-acceptor components (naked ions or coordination compounds with some labile ligands) are increasingly being exploited for the preparation of stable, shape-persistent supramolecular assemblies of nanoscopic dimensions.[1] Fascinating three-dimensional systems have been reported by several groups.[2,3] Compared to naked ions, in which the number of available coordination sites for self-assembly and their geometry is determined by the nature of the ion, the use of suitable coordination compounds allows, in principle, a better control of the number and geometry of such sites. In addition, useful properties can be introduced into the supramolecular systems by the nonparticipating ligands. Also, the solubility of the products can be largely influenced by the nature of the ancillary ligands at the metal centers.

However, a literature survey shows that, while a large number of polytopic organic ligands have been employed for the construction of metal-mediated supramolecular assemblies, the number of metal-containing components is relatively limited. Most frequently used are the square-planar complexes [Pd(en)(ONO$_2$)$_2$] (en = ethylenediamine),[3e–3g,3k,4] [Pd(bipy)(ONO$_2$)$_2$] (both soluble in water),[5] and [Pd(dppp)(OTf)$_2$] [soluble in chlorinated solvents, dppp = 1,2-bis(diphenylphosphanyl)propane, OTf = CF$_3$SO$_3$, triflate],[3d,6] which yield *cis* bifunctional dicationic metal fragments after dissociation of the two weakly coordinated anions. Square-planar complexes with labile neutral ligands, such as *cis*-[PtCl$_2$(PhCN)$_2$] and *trans*-[PdCl$_2$(PhCN)$_2$], which yield the bifunctional metal fragments *cis*-PtCl$_2$ and *trans*-PdCl$_2$, respectively, have also been employed in self-assembly reactions.[7] The use of octahedral coordination complexes is more rare and, in most cases, concerns complexes such as [ReX(CO)$_5$] (X = Cl, Br)[8] or *trans*-[RuCl$_2$(dmso)$_2$(L)$_2$] (L = CO, dmso)[9] that yield the *cis* bifunctional neutral fragments *fac*-ReX(CO)$_3$ and *trans*,*cis*-RuCl$_2$(L)$_2$, respectively.

Even though the two coordination sites available in these metal fragments define a linear or planar geometry, 3D adducts have been obtained; tridimensionality can be induced by flexible organic polytopic ligands or by a noncoplanar mutual orientation of planar rigid fragments. In general, in both cases, the shape of the 3D product is rarely predictable a priori.

We believe that the field of coordination-driven self-assembly would greatly benefit from the introduction of new,

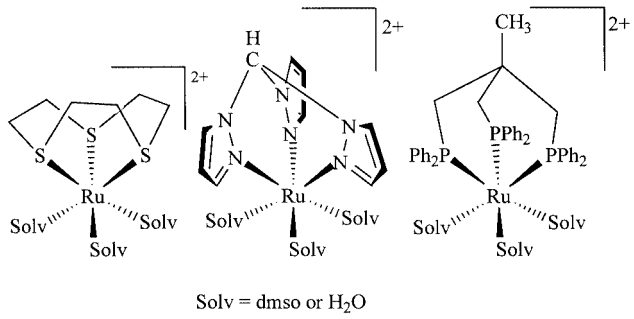
easy-to-make, coordination compounds having three (or more) readily available coordination sites for self-assembly. In particular, we are interested in the development of low-valent metal fragments with three sites in facial geometry occupied by good leaving groups, either weak neutral ligands (e.g. solvent molecules) or weakly coordinating anions. In such cases the tridimensionality of the adduct would be inherently determined by that of the metal fragment. The remaining three positions must be firmly held by nonparticipating ligands, so that neither dissociation nor isomerization occur during the substitution reaction with the bridging building blocks. Thus, the three permanent facial atoms may be conveniently embedded in a face-capping ligand (fcl), either a heterocycle,[10–12] a tripodal ligand,[13,14] or an organometallic fragment such as η^5-cyclopentadienyl or η^6-arene.[15]

Even though most of the low-valent, half-sandwich complexes described in the literature were not specifically developed for use in self-assembly reactions (for example, they have been widely investigated as homogeneous catalysts),[16] there are some remarkable exceptions.[3a,12,17] For example, Ru^{II}-, Rh^{III}-, and Ir^{III}-arene fragments have been exploited as building blocks for the construction of supramolecular cubes and metallamacrocyclic complexes.[3a,17] One striking example with a nonorganometallic fragment is that of the molecular cube $[\{Ru([9]aneS_3)\}_8(\mu\text{-}4,4'\text{-bipy})_{12}][OTf]_{16}$ ([9]aneS$_3$ = 1,4,7-trithiacyclononane), which is obtained by treatment of *fac*-[Ru([9]aneS$_3$)Cl$_2$(dmso-S)] with the linear ditopic ligand 4,4′-bipy in an 8:12 stoichiometry in noncoordinating solvents. The *fac*-Ru([9]aneS$_3$) and 4,4′-bipy fragments form the corners and edges of the cube, respectively.[12a] However, this synthetic procedure requires prolonged reaction times and heating (four weeks in nitromethane at refluxing temperature), and the addition of AgOTf to remove chlorides. In an ideal metal-mediated self-assembly process, two (or more) components are mixed in solution in the appropriate ratio and react spontaneously with each other to afford the desired product; external interventions, such as addition of silver salts to remove coordinated halides and filtration of precipitates (other than the product), should be avoided. Therefore, precursors with more-labile leaving ligands, such as those mentioned above, would be much preferred for self-assembly purposes.

In this work we report our results concerning the preparation of three new, easy-to-make [Ru(fcl)(solv)$_3$][OTf]$_2$ complexes {fcl = [9]aneS$_3$, tris(pyrazolyl)methane [CH-(pz)$_3$, pz = pyrazol-1-yl], or triphos [CH$_3$C(CH$_2$PPh$_2$)$_3$]; solv = dmso or H$_2$O} (Scheme 1); dmso was chosen as, in our experience with ruthenium precursors, it is normally a better leaving group than the widely used CH$_3$CN. The three face-capping ligands were chosen with the aim of investigating a range of electronic, steric, and solubility properties; in addition, they are either commercially available or very easily prepared and, unlike the organometallic fragments, their reactions do not require the use of Schlenk techniques. In the case of triphos, we partially revisited the work of Venanzi and co-workers on the Ru/dmso/triphos systems.[13]



Scheme 1. Schematic representations of the Ru^{II} complexes with face-capping ligands discussed in this work.

Results

The main ruthenium precursor used in this work is the well known complex *cis*-[RuCl$_2$(dmso)$_4$]. Several examples in the literature indicate that the reaction of *cis*-[RuCl$_2$(dmso)$_4$] with one equivalent of a neutral, face-capping ligand usually leads to *fac*-[Ru(fcl)Cl$_2$(dmso-S)] complexes after replacement of three facial sulfoxides (one O-bonded and two S-bonded).[18] Treatment of *fac*-[Ru(fcl)-Cl$_2$(dmso-S)] with two equivalents of a soluble silver salt, such as AgOTf, in a weakly coordinating solvent (solv) is expected to yield the desired *fac*-[Ru(fcl)(solv)$_3$][OTf]$_2$ complexes.[11a,13,18] For example, the reaction of *fac*-[Ru([9]-aneS$_3$)Cl$_2$(dmso-S)] (**1**) with AgOTf in refluxing acetonitrile produces *fac*-[Ru([9]aneS$_3$)(CH$_3$CN)$_3$][OTf]$_2$ in excellent yield.[11a]

As an alternative, in some cases we also employed the dicationic precursor *fac*-[Ru(dmso-S)$_3$(dmso-O)$_3$][OTf]$_2$. In this synthetic approach removal of the chlorides from *cis*-[RuCl$_2$(dmso)$_4$] occurred first and was followed by coordination of the face-capping ligand (see also Scheme 5).

Compounds with 1,4,7-Trithiacyclononane ([9]aneS$_3$)

The complex *fac*-[Ru([9]aneS$_3$)Cl$_2$(dmso-S)] (**1**), despite being an excellent precursor for inorganic synthesis,[11,12] is not suitable *as such* for facial self-assembly reactions with neutral, monodentate bridging ligands, as chloride replace-

ment needs the assistance of Ag^+.[12d–12f] For example, *fac*-[Ru([9]aneS$_3$)(L)$_3$][PF$_6$]$_2$ complexes (L = py or 4,4′-bipy) can be obtained by treatment of **1** with $AgPF_6$ and a large excess of ligand (L/Ru = in the range from 14 to 25) in refluxing ethanol/water mixtures.[12b,12c]

With the aim of preparing *fac*-[Ru([9]aneS$_3$)(dmso)$_3$][OTf]$_2$, we found that the reaction of **1** with two equivalents of AgOTf in refluxing acetone in the presence of dmso afforded a crystalline product (**2**) that, according to spectroscopic investigations and X-ray diffraction analysis, was established to be the monocationic complex *fac*-[Ru([9]aneS$_3$)Cl(dmso-S)$_2$][OTf] (**2**) (Scheme 2, Figure 1).[19] The same product was also obtained when the above reaction was performed in pure dmso at 100 °C.

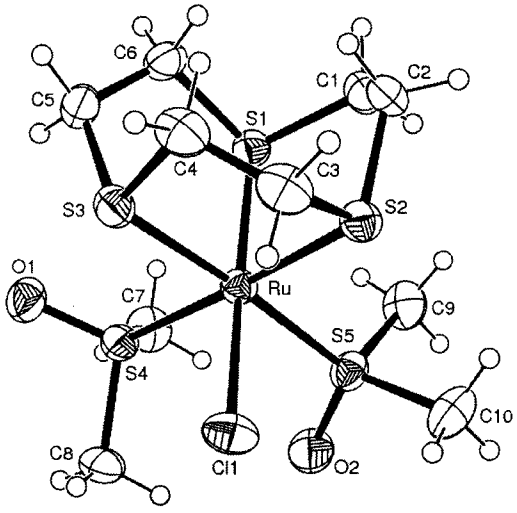

Figure 1. Molecular structure of the cation of *fac*-[Ru([9]aneS$_3$)Cl(dmso-S)$_2$][OTf] (**2**) with thermal ellipsoids at the 40% probability level. Selected bond lengths [Å] and angles [°]: Ru–S(1) 2.313(1), Ru–S(2) 2.346(1), Ru–S(3) 2.351(1), Ru–S(4) 2.325(1), Ru–S(5) 2.339(1), Ru–Cl(1) 2.420(1); S(2)–Ru–S(4) 174.69(3), S(3)–Ru–S(5) 175.21(3), S(1)–Ru–Cl(1) 173.03(3).

Replacement of both chlorides of **1** with dmso molecules was accomplished by performing the reaction with a slight excess of AgOTf in refluxing methanol in the presence of dmso (Scheme 2).

The IR spectrum of the product, which analyzed correctly for [Ru([9]aneS$_3$)(dmso)$_3$][OTf]$_2$ (**3**), showed the presence of both S-bonded (S=O stretching at $\tilde{\nu}$ = 1088 cm^{-1}) and O-bonded (S=O stretching at $\tilde{\nu}$ = 933 and 914 cm^{-1}) dmso molecules. The ^{1}H NMR spectrum of **3** in noncoordinating solvents (e.g. CD_3NO_2 or [D$_6$]acetone), besides many, low-intensity multiplets for the [9]aneS$_3$ protons between δ = 2.8 and 3.4 ppm, contains two sets of signals in an approximate 2.5 to 1 ratio in the region of dmso resonances; the most abundant has two singlets for dmso-O and one for dmso-S ligands, while the less abundant one has one singlet for dmso-O and two for dmso-S ligands (Figure 2). These two sets were attributed to the linkage isomers *fac*-[Ru([9]aneS$_3$)(dmso-O)$_2$(dmso-S)]$^{2+}$ (**3a**) and *fac*-[Ru([9]aneS$_3$)(dmso-O)(dmso-S)$_2$]$^{2+}$ (**3b**), respectively. In each isomer there are two equivalent dmso ligands with diastereotopic methyl groups; accordingly, their NMR resonances are slightly broader than that of the other dmso because of the long-range coupling ($^4J_{H,H} \approx 0.5$ Hz).[20]

X-ray structural determinations performed on crystals selected both from the raw material and from a sample recrystallized from acetone (at room temperature, upon addition of diethyl ether) gave the same results: in both cases the solid-state structure corresponded to *fac*-[Ru([9]aneS$_3$)(dmso-O)(dmso-S)$_2$][OTf]$_2$ (**3b**), i.e. the less-abundant isomer in solution (Figure 3).[21] It is noteworthy that the Ru–S distance in **3b***trans* to dmso-O [2.298(1) Å] is shorter than the values observed for the other S atoms of [9]aneS$_3$ [mean value 2.352(1) Å].

Dissolution of the crystals in CD_3NO_2 or [D$_6$]acetone afforded the usual NMR spectrum, with the same ratio between **3a** and **3b**, thus suggesting that an equilibrium between the two linkage isomers occurs in solution. However, saturation of the dmso resonances of one isomer did not result in any appreciable transfer of saturation to those of the other one, thus indicating that the equilibrium must be quite slow on the NMR timescale. As progressive hydrolysis

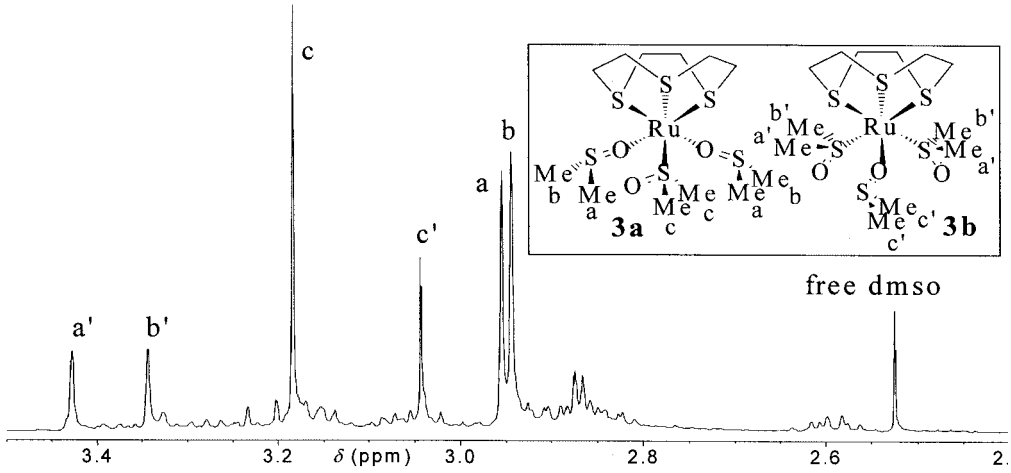

Figure 2. ^{1}H NMR spectrum (CD_3NO_2) of the mixture of the two linkage isomers **3a** and **3b**; dmso singlets are labeled (see insert for labeling scheme). The other small resonances belong to [9]aneS$_3$ protons.

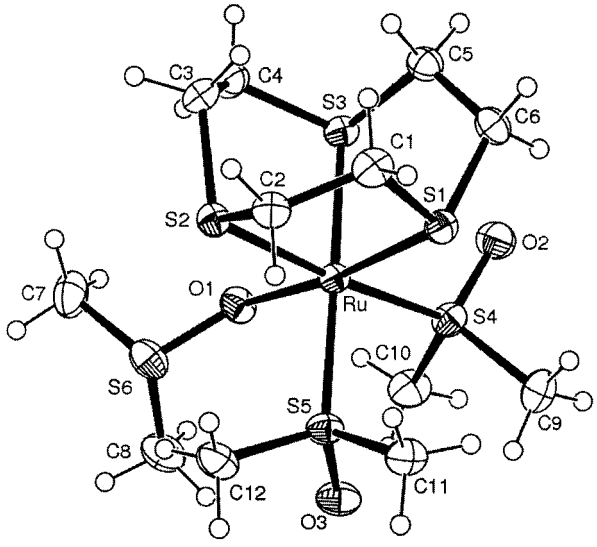

Figure 3. Molecular structure of the cation of *fac*-[Ru([9]aneS$_3$)(dmso-O)(dmso-S)$_2$][OTf]$_2$ (**3b**) with thermal ellipsoids at the 40% probability level. Selected bond lengths [Å] and angles [°]: Ru–O(1) 2.169(3), Ru–S(1) 2.298(1), Ru–S(2) 2.350(1), Ru–S(3) 2.355(1), Ru–S(4) 2.326(1), Ru–S(5) 2.307(1); O(1)–Ru–S(1) 171.49(10), S(2)–Ru–S(4) 174.15(5), S(3)–Ru–S(5) 176.64(5).

of coordinated dmso was observed (minutes), it was not possible to perform a saturation-transfer experiment (and/or line-shape analysis) above room temperature.

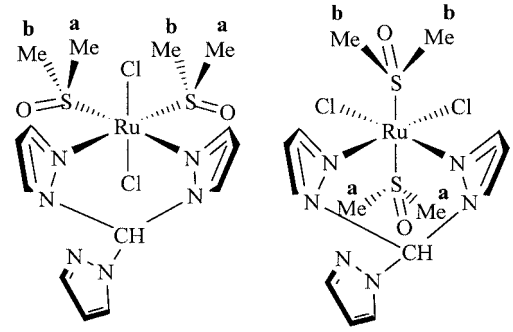
We also found that the reaction of *fac*-[Ru(dmso-S)$_3$(dmso-O)$_3$][OTf]$_2$ with *one* equivalent of [9]aneS$_3$ in a number of refluxing solvents (nitromethane, methanol, chloroform, and chloroform/acetone mixtures) yielded only mixtures of the unreacted precursor and of the fully substituted product [Ru([9]aneS$_3$)$_2$][OTf]$_2$, identified by elemental analysis and by comparison with the NMR spectrum reported in the literature.[22]

The ^{1}H NMR spectrum of *fac*-[Ru([9]aneS$_3$)(dmso)$_3$]$^{2+}$ (mixture of the two isomers) in D$_2$O showed that hydrolysis of the dmso ligands occurs within minutes after dissolution (the resonance of a species with one coordinated dmso-S, δ = 3.31 ppm, that integrates for 1/3 of the free dmso appears and remains unchanged for longer observation times, up to 2 days). Under the same conditions only very slow hydrolysis of acetonitrile from *fac*-[Ru([9]aneS$_3$)(CH$_3$CN)$_3$]$^{2+}$ was observed (ca. 30% after one week at ambient temperature).

Compounds with Tris(pyrazolyl)methane [CH(pz)$_3$]

The reaction of *cis*-[RuCl$_2$(dmso)$_4$] with tris(pyrazolyl)methane, CH(pz)$_3$, has not been described so far. We found that treatment of *cis*-[RuCl$_2$(dmso)$_4$] with one equivalent of CH(pz)$_3$ in refluxing methanol yielded a yellow precipitate and large, deep-orange crystals. The mixture was found to contain three products, **4**–**6**, in approximately equimolar amounts (NMR ratio measured in [D$_6$]DMSO, in which the mixture is well soluble), which were separated and obtained in pure form (see Experimental Section).

The elemental analysis of compound **4** was consistent with the formula [RuCl$_2$(dmso)$_2$CH(pz)$_3$], and the solid-state IR spectrum indicated the presence of S-bonded dmso exclusively. The ^{1}H NMR spectrum of **4** in CDCl$_3$ shows two singlets for dmso-S, integrating for six protons each, which is consistent with two geometries, each featuring a bidentate coordination for the tris(pyrazolyl)methane, CH(pz)$_2$(pz): either *trans,cis,cis*-[RuCl$_2$(dmso-S)$_2${CH(pz)$_2$(pz)}] or *cis,trans,cis*-[RuCl$_2$(dmso-S)$_2${CH(pz)$_2$(pz)}] (Scheme 3).[23] In the first hypothesis the two dmso-S ligands are equivalent but have diastereotopic methyls, while in the second hypothesis the two *trans* dmso-S ligands have enantiotopic methyl groups but are not equivalent as the N$_2$Cl$_2$ plane is not a plane of symmetry for the complex.



Scheme 3. The two possible geometries of compound **4** that are compatible with the observed ^{1}H NMR spectrum.

A *cis,cis,cis* geometry can be excluded since four methyl resonances for the two sulfoxides would be expected. The *trans,cis,cis*-[RuCl$_2$(dmso-S)$_2${CH(pz)$_2$(pz)}] geometry was eventually confirmed by an X-ray structural investigation (Figure 4), which showed that the tris(pyrazolyl)methane in **4** indeed acts as a bidentate ligand, with a chelating angle of 81.61(13)°.

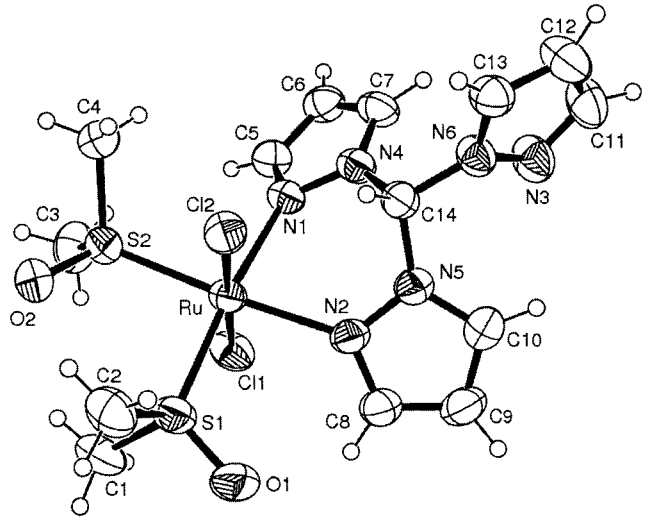


Figure 4. Molecular structure of *trans,cis,cis*-[RuCl$_2$(dmso-S)$_2${CH(pz)$_2$(pz)}] (**4**) with thermal ellipsoids at the 40% probability level. Selected bond lengths [Å] and angles [°]: Ru–N(1) 2.119(3), Ru–N(2) 2.148(4), Ru–S(1) 2.278(1), Ru–S(2) 2.262(1), Ru–Cl(1) 2.402(1), Ru–Cl(2) 2.416(1); N(1)–Ru–N(2) 81.61(13), N(1)–Ru–S(1) 173.84(10), N(2)–Ru–S(2) 176.01(9), Cl(1)–Ru–Cl(2) 179.04(5).

Complex **4** was also selectively prepared in good yield by reaction of *trans*-[$RuCl_2$(dmso-S)$_4$] with one equivalent of $CH(pz)_3$ in chloroform at ambient temperature. It is in fact well known that *trans*-[$RuCl_2$(dmso-S)$_4$] replaces two *cis* dmso-S ligands to affording the *trans,cis*-$RuCl_2$(dmso-S)$_2$ fragment selectively.[24]

The ^{1}H NMR spectrum of **5** in $CDCl_3$ is very simple (see Experimental Section), suggesting that the complex must be highly symmetrical and that, most likely, simple pyrazole ligands (pzH), derived from the decomposition of tris(pyrazolyl)methane, are bound to ruthenium. X-ray analysis confirmed this hypothesis, indicating that the molecular structure of **5** is *trans,cis,cis*-[$RuCl_2$(dmso-S)$_2$(pzH)$_2$] (see Supporting Information). Complex **5**, which had been already prepared by Taqui Khan and co-workers by treatment of *cis*-[$RuCl_2$(dmso)$_4$] with two equivalents of pyrazole in acetonitrile at 60 °C,[25] is structurally similar to **4**, as it contains two *cis* pyrazole ligands instead of the two *cis* pyrazole units belonging to $CH(pz)_3$ found in **4**.

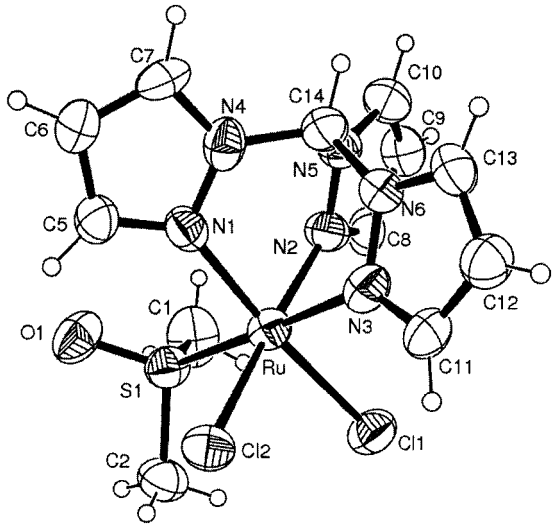

Figure 5. Molecular structure of *fac*-[Ru{CH(pz)$_3$}Cl$_2$(dmso-S)] (**6**) with thermal ellipsoids at the 40% probability level. Selected bond lengths [Å] and angles [°]: Ru–N(1) 2.052(9), Ru–N(2) 2.049(11), Ru–N(3) 2.078(10), Ru–S(1) 2.251(4), Ru–Cl(1) 2.419(3), Ru–Cl(2) 2.406(3); N(1)–Ru–N(2) 87.8(4), N(1)–Ru–N(3) 84.4(4), N(2)–Ru–N(3) 83.3(4), N(1)–Ru–Cl(1) 174.8(4), N(2)–Ru–Cl(2) 172.4(3), N(3)–Ru–S(1) 177.1(3).

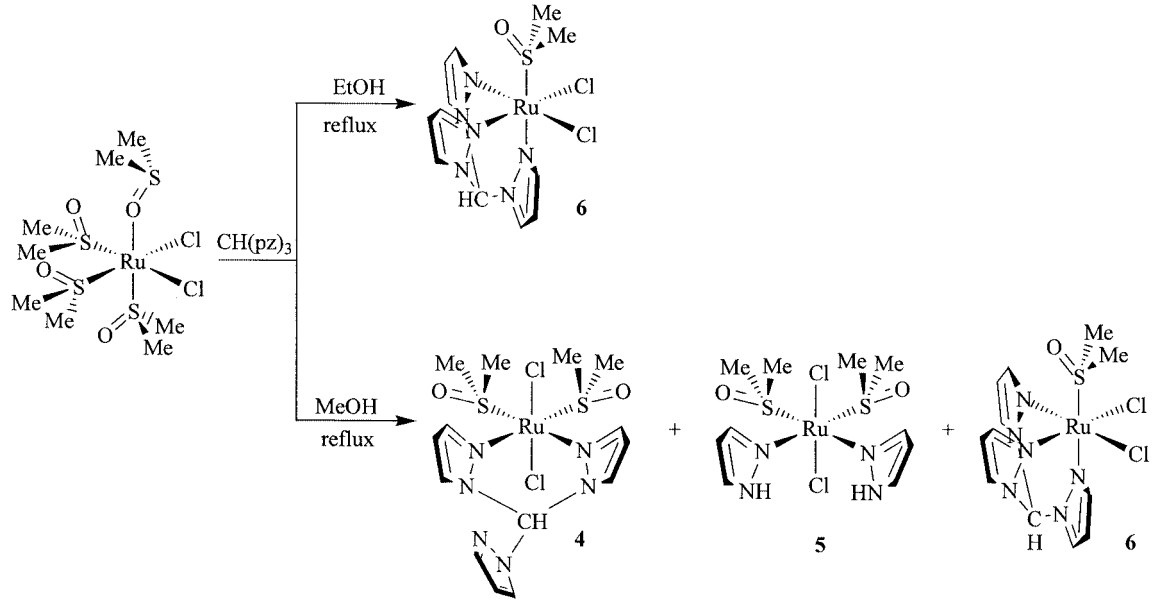
Elemental analysis of the third product, **6**, suggested an [$RuCl_2$(dmso)CH(pz)$_3$] stoichiometry. The pattern of the downfield region of the ^{1}H NMR spectrum of **6** in noncoordinating solvents (CD_3NO_2) is similar to that of complex **4**, as it shows two sets of pyrazole resonances with a 2:1 intensity ratio and a singlet at δ = 8.87 ppm for the CH proton of tris(pyrazolyl)methane. The region of the dmso resonances contains one singlet for dmso-S (δ = 3.41 ppm), integrating for six protons. The NMR spectrum of **6** is thus consistent with a *fac*-[Ru{CH(pz)$_3$}Cl$_2$(dmso-S)] geometry in which the two pz units *trans* to the chlorides are equivalent and the methyl groups of dmso-S are enantiotopic. This geometry was confirmed by an X-ray investigation (Figure 5).

As anticipated in the Introduction, complex **6** is the product expected from the reaction of *cis*-[$RuCl_2$(dmso)$_4$] with one equivalent of a face-capping ligand. We found that compound **6** can also be obtained in almost pure form and in good yield by performing the reaction between *cis*-[$RuCl_2$(dmso)$_4$] and $CH(pz)_3$ at slightly higher temperature (in refluxing ethanol rather than methanol), as the product precipitates spontaneously from the reaction mixture. The reactivity of *cis*-[$RuCl_2$(dmso)$_4$] towards $CH(pz)_3$ is summarized in Scheme 4.

Treatment of **6** with two equivalents of AgOTf in refluxing methanol in the presence of dmso afforded *fac*-[Ru{CH(pz)$_3$}(dmso-O)(dmso-S)$_2$][OTf]$_2$ (**7**; Scheme 5). The IR spectrum of **7** clearly indicates the presence of both



Scheme 4.

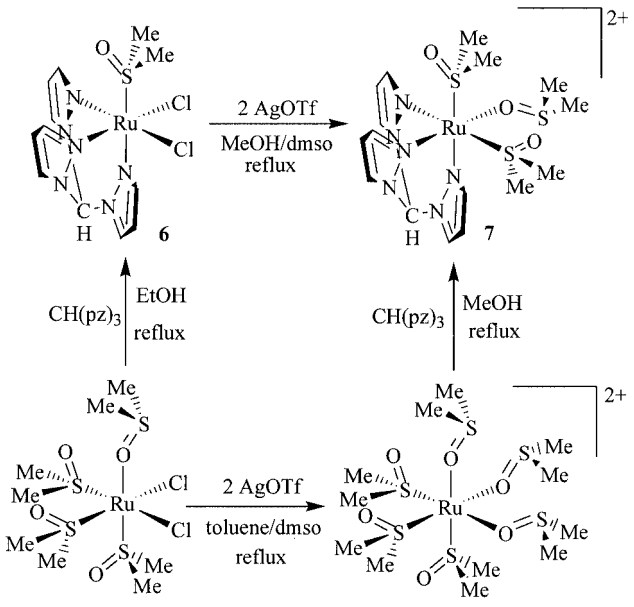
S-bonded (S–O stretching at $\tilde{\nu}$ = 1155 cm^{-1}) and O-bonded (S–O stretching at $\tilde{\nu}$ = 938 cm^{-1}) dmso ligands. Its ^1H NMR spectrum in noncoordinating solvents ([D_6]acetone or CD_3NO_2) shows three singlets for the dmso ligands, integrating for six protons each, one O-bonded and two S-bonded; the resonances for coordinated $CH(pz)_3$ consist of two sets of pyrazole protons with a 2:1 intensity ratio and a singlet for the CH proton. X-ray diffraction studies confirmed the molecular structure of complex **7** (Figure 6); the two equivalent dmso-S ligands have diastereotopic methyl groups, which are responsible for the two NMR resonances in the dmso-S region.



Scheme 5.

When **7** was dissolved in D_2O the O-bonded dmso was rapidly and completely hydrolyzed as, in this solvent, the dmso-O resonance was replaced by the signal of free dmso at δ = 2.72 ppm; hydrolysis of the dmso-S ligands was not observed. In addition, in D_2O the resonance of the CH proton of coordinated $CH(pz)_3$ decreased rather rapidly (minutes) because of exchange with the deuterated solvent. This result suggests that, as might be expected, the acidity of this proton in **7** is greater than in the neutral precursor **6**, for which this phenomenon was not observed.

As an alternative, complex **7** was also obtained by reaction of *fac*-[Ru(dmso-S)$_3$(dmso-O)$_3$][OTf]$_2$ with one equivalent of $CH(pz)_3$ in refluxing methanol (Scheme 5). In this case, unlike with [9]aneS_3 (see above), we found no evidence of the formation of the homoleptic sandwich adduct *fac*-[Ru{$CH(pz)_3$}$_2$][OTf]$_2$.

The structural characterizations indicated that the metal in complexes **4**–**7** displays a distorted octahedral geometry with coordination bond lengths falling in a range already observed for similar ruthenium species.[26] Interestingly, the mean Ru–N bond length found in *fac*-[Ru{$CH(pz)_3$}Cl_2(dmso-S)] (**6**) is shorter (by about 0.1 Å) than those found in the other structures, but similar to that *trans* to the dmso-O in *fac*-[Ru{$CH(pz)_3$}(dmso-O)(dmso-S)$_2$][OTf]$_2$ (**7**).

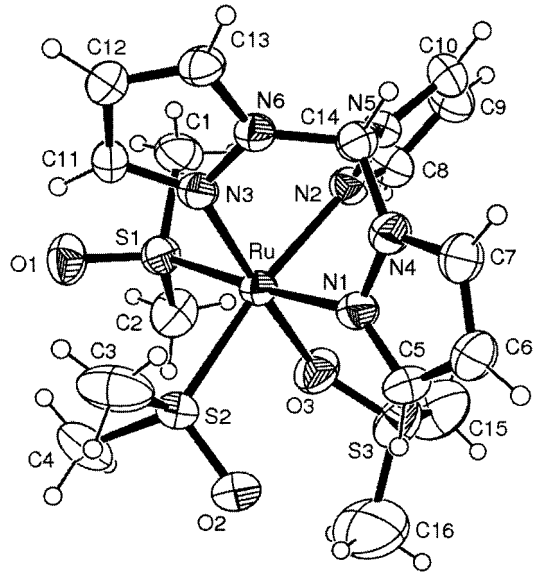


Figure 6. Molecular structure of the cation of *fac*-[Ru{$CH(pz)_3$}(dmso-O)(dmso-S)$_2$][OTf]$_2$ (**7**) with thermal ellipsoids at the 40% probability level. Selected bond lengths [Å] and angles [°]: Ru–N(1) 2.130(5), Ru–N(2) 2.123(4), Ru–N(3) 2.051(4), Ru–S(1) 2.272(2), Ru–S(2) 2.283(2), Ru–O(3) 2.110(4); N(1)–Ru–N(2) 81.89(17), N(1)–Ru–N(3) 86.70(18), N(2)–Ru–N(3) 85.42(17), N(3)–Ru–O(3) 174.32(18), N(1)–Ru–S(1) 175.61(12), N(2)–Ru–S(2) 169.52(13).

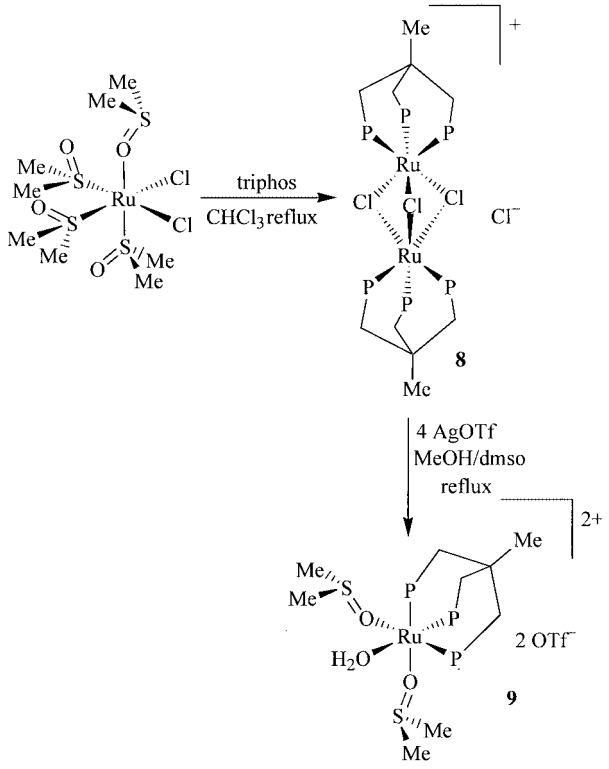
The different binding mode of $CH(pz)_3$ in **4** (bidentate) compared to **6** and **7** (tripodal) is reflected in the values of the Ru–N–N and Ru–N–C bond angles. Those found in **4** (131.0° and 123.6°, respectively) are quite different from those found in **6** and **7** (mean values of 136.6° and 118.0°, respectively).

Compounds with $CH_3C(CH_2PPh_2)_3$ (triphos)

We reinvestigated the reaction between *cis*-[$RuCl_2$-(dmso)$_4$] and $CH_3C(CH_2PPh_2)_3$ with the aim of obtaining a more detailed characterization of the *fac*-[Ru(triphos)(dmso)$_3$]$^{2+}$ and *fac*-[Ru(triphos)(dmso)$_2$(H_2O)]$^{2+}$ complexes described by Venanzi and co-workers.[13] Initially, we found that the reaction of *cis*-[$RuCl_2$(dmso)$_4$] with one equivalent of triphos, even when performed under milder conditions than those reported in the literature (4 h in refluxing chloroform vs. 24 h in refluxing toluene),[13] led to the isolation of the dinuclear species [(triphos)Ru(μ-Cl)$_3$Ru(triphos)]Cl (**8**) exclusively (Scheme 6). Formation of the mononuclear complex *fac*-[$RuCl_2$(triphos)(dmso-S)] was not observed. Then, we found that treatment of **8** with four equivalents of AgOTf in refluxing methanol in the presence of dmso led exclusively to the isolation of crystalline *fac*-[Ru(triphos)(dmso-O)$_2$(H_2O)][OTf]$_2$ (**9**) in good yield (Scheme 6).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 6.

The molecular structure of **9** was determined by X-ray analysis (Figure 7). The dimensions of the triphos ligand reflect a small degree of geometrical distortions, with Ru–P distances of 2.272(2), 2.296(2), 2.280(2) Å (the latter *trans* to the aqua ligand), and P–Ru–P bond angles that average 87.4°. Overall, the structural parameters of the tripodal ligand are very similar to those found in the dinuclear complex cation $[(triphos)Ru(\mu\text{-}Cl)_3Ru(triphos)]^+$.[13]

We found no evidence of the formation of *fac*-[Ru(triphos)(dmso-O)$_3$][OTf]$_2$ (**10**); compound **9** was the only product that we isolated, even under the conditions (dmso at 110 °C) that, according to the literature,[13] should afford **10**. Our synthetic procedure leading to **9** is simpler than that described by Venanzi and co-workers[13] in that it avoids the tedious removal of dmso. Several attempts to prepare either **9** or **10** by reaction of *fac*-[Ru(dmso-S)$_3$(dmso-O)$_3$][OTf]$_2$ with triphos in a number of refluxing solvents (e.g. acetone, methanol, toluene) were unsuccessful and led to the isolation of small amounts of unreacted precursor only.

Complex **9** was found to be insoluble in water but soluble in a range of organic solvents, including chloroform. The ^{1}H NMR spectrum of **9** in $CDCl_3$ shows, besides the resonances of coordinated triphos, only the singlet of free dmso at δ = 2.62 ppm, thus indicating that both dmso-O ligands are rapidly released and probably replaced by water molecules. The ^{31}P NMR spectrum shows a singlet at δ = 38.2 ppm, in agreement with the equivalence of the three P atoms in the hydrolyzed species.

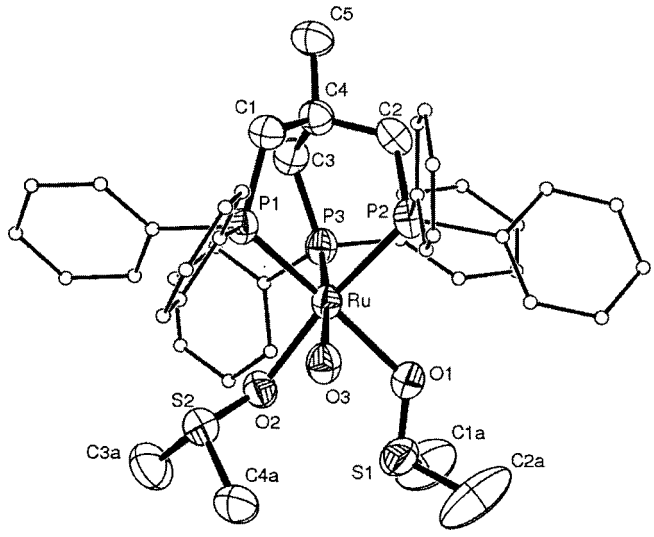


Figure 7. Molecular structure of the cation of *fac*-[Ru(triphos)(dmso-O)$_2$(H_2O)][OTf]$_2$ (**9**) with thermal ellipsoids the 40% probability level. For the sake of clarity the phenyl carbon atoms are indicated as spheres of fixed radius. Selected bond lengths [Å] and angles [°]: Ru–O(1) 2.215(4), Ru–O(2) 2.190(4), Ru–O(3) 2.197(4), Ru–P(1) 2.272(2), Ru–P(2) 2.296(2), Ru–P(3) 2.280(2); O(1)–Ru–P(1) 173.25(12), O(2)–Ru–P(2) 172.80(12), O(3)–Ru–P(3) 174.41(12).

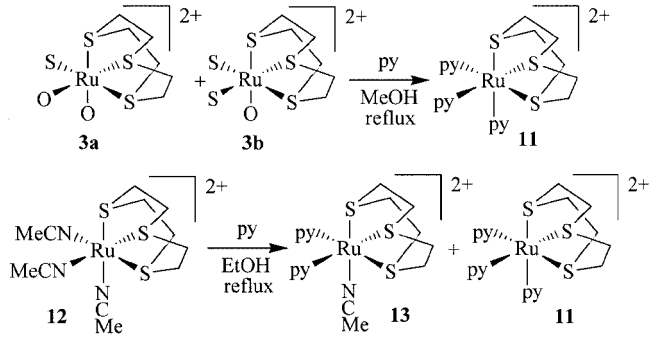
Reactivity of the New Precursors

The reactivity of the new precursors with facial geometry, **3**, **7** and **9**, is currently being investigated in our laboratory and will be the subject of a subsequent paper. We report here only one example concerning the reactivity of the [9]aneS$_3$ complex **3** towards the model ligand pyridine.

The reaction between **3** and a slight excess of pyridine (py/Ru = 4) in refluxing methanol led selectively to the isolation of *fac*-[Ru([9]aneS$_3$)(py)$_3$][OTf]$_2$ (**11**) in excellent yield (Scheme 7). As expected from literature data,[12d–12f] reaction of **1** with pyridine under the same conditions did not yield complex **11**. By comparison, we found that the reaction between the known acetonitrile-containing precursor *fac*-[Ru([9]aneS$_3$)(CH_3CN)$_3$][OTf]$_2$ (**12**) and pyridine, despite being performed at higher temperature (refluxing ethanol) and with a larger excess of ligand (py/Ru = 8), always led to mixtures of **11** and of the disubstituted species *fac*-[Ru([9]aneS$_3$)(py)$_2$(CH_3CN)][OTf]$_2$ (**13**; Scheme 7); both



Scheme 7. For simplicity, in **3a** and **3b** O = dmso-O and S =dmso-S.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

products were isolated in pure form and characterized spectroscopically and by X-ray diffraction analysis (see Supporting Information).[27]

Thus, owing to the greater lability of dmso than acetonitrile bound to the $Ru([9]aneS_3)^{2+}$ fragment (see above), complex **3** proved to be a better precursor than **12** in reactions involving the selective replacement of all three leaving groups with monodentate ligands.

Discussion and Conclusions

In summary, we have prepared and structurally characterized three new, easy-to-make, complexes of the type *fac*-$[Ru(fcl)(solv)_3][OTf]_2$, namely *fac*-$[Ru([9]aneS_3)(dmso\text{-}O)(dmso\text{-}S)_2][OTf]_2$ (**3b**), which equilibrates in solution of noncoordinating solvents with the linkage isomer *fac*-$[Ru([9]aneS_3)(dmso\text{-}O)_2(dmso\text{-}S)]^{2+}$ (**3a**), *fac*-$[Ru\{CH(pz)_3\}(dmso\text{-}O)(dmso\text{-}S)_2][OTf]_2$ (**7**), and *fac*-$[Ru(triphos)(dmso\text{-}O)_2(H_2O)][OTf]_2$ (**9**). In all cases the preferred synthetic procedure involves coordination of the face-capping ligand to *cis*-$[RuCl_2(dmso)_4]$ first, followed by replacement of chlorides with dmso (or water) molecules assisted by addition of AgOTf. The isolated yields of compounds **3** and **9** were satisfactory {ca. 80% for **3**, and ca. 50% for **9**, both calculated with respect to *cis*-$[RuCl_2(dmso)_4]$}, while that of **7** was quite low (18–24% depending on the synthetic route). In addition, unlike $[9]aneS_3$ and triphos, tris(pyrazolyl)methane is not commercially available and it is the only fcl, among the three tested, that undergoes decomposition rather easily and shows a tendency to coordinate in a bidentate rather than a tridentate manner.

It should be noted that while in the dications **3b** and **7** there are two S-bonded and one O-bonded dmso ligands, in **9** both dmso ligands are bonded through oxygen and, according to Venanzi and co-workers,[13] the third one also binds in the same manner when it replaces the water molecule to give **10**. The preferential O-bonding of dmso in **9** might be due to both steric and electronic reasons: the steric bulk of the phenyl groups of coordinated triphos might favor coordination of dmso through oxygen, as dmso-O is less sterically demanding than dmso-S. In addition, dmso might coordinate through oxygen to avoid competition for π-electrons with the *trans* phosphane, as is already well established for the coordination of dmso *trans* to other strong π-accepting ligands such as CO and NO.[18]

A comparison of the structural data of the dmso ligands in the three dicationic species *fac*-$[Ru([9]aneS_3)(dmso\text{-}S)_2(dmso\text{-}O)]^{2+}$ (**3b**), *fac*-$[Ru\{CH(pz)_3\}(dmso\text{-}O)(dmso\text{-}S)_2]^{2+}$ (**7**), and *fac*-$[Ru(triphos)(dmso\text{-}O)_2(H_2O)]^{2+}$ (**9**) shows the following trend for Ru–O(dmso) distances: *trans* to N [2.110(4) Å in **7**] < *trans* to S [2.169(3) Å in **3b**] < *trans* to P [2.202(4) Å, mean value in **9**]. In addition, the Ru–S(dmso) bonds *trans* to pyrazole N atoms in **7** are also significantly shorter (0.04 Å) than the corresponding bonds *trans* to the S atoms in **3b**. As both coordinated $CH(pz)_3$ and $[9]aneS_3$ have a small steric bulk in the region of space occupied by the dmso ligands, the reason for the longer Ru–dmso bond distances in **3b** compared to **7** might be found in the greater *trans* influence of trithiacyclononane than tris(pyrazolyl)methane. This consideration might also explain why the S/O linkage isomerization of one sulfoxide was observed for the trithiacyclononane complex **3**, but not in the case of the corresponding tris(pyrazolyl)methane complex **7**.

As the new complexes were prepared with the aim of being employed in self-assembly reactions, the lability of the coordinated dmso molecules is an important parameter to be assessed. NMR investigations showed that hydrolysis of the dmso ligands occurred very easily from **3** in waterand from **9** in chloroform. In the case of complex **7**, only the O-bound dmso ligand was found to be replaced in water. In general, the lability of the dmso ligands of the three dicationic precursors reflects the trend of Ru–dmso bond distances. In addition, NMR investigations of the two similar complexes *fac*-$[Ru([9]aneS_3)(dmso)_3]^{2+}$ (**3**) and *fac*-$[Ru([9]aneS_3)(CH_3CN)_3]^{2+}$ (**12**) in coordinating solvents such as water have shown that coordinated dmso is much more labile than acetonitrile. Accordingly, replacement of the three dmso ligands of **3** with pyridine occurs more easily than that of the acetonitrile ligands of **12**.

In conclusion, a number of experimental results (total yield, structural considerations in the solid state, the lability of the dmso ligands in solution, preliminary results on the reactivity towards model ligands) agree that *fac*-$[Ru([9]aneS_3)(dmso)_3][OTf]_2$ (**3**) and *fac*-$[Ru(triphos)(dmso\text{-}O)_2(H_2O)][OTf]_2$ (**9**) are the most promising complexes for further use in self-assembly reactions with polytopic ligands. Their solubility, a fundamental parameter to be considered in self-assembly reactions, is strongly influenced by the nature of the face-capping ligand. Taken together, they cover a broad range of solvents: while both complexes are soluble in nitromethane, acetone and methanol, **3** is also well soluble in water, while **9** is soluble in chloroform.

It may be argued that the steric demand of triphos in **9** might disfavor coordination of bulkier ligands in place of the dmso and water molecules; however, the steric bulk of dppp, which may be considered as the bidentate analog of triphos, has not prevented the use of $Pd(dppp)^{2+}$ and $Pt(dppp)^{2+}$ fragments in the construction of many 2D and 3D supramolecular adducts through self-assembly procedures.[3d,6]

Experimental Section

Infrared spectra (KBr) were obtained on a Perkin–Elmer 2000 NIR FT-Raman spectrometer. ^1H and $^{31}P\{^1H\}$ NMR spectra were collected at room temperature at 400 and 161.9 MHz, respectively, on a Jeol Eclipse 400 FT spectrometer, with 2,2-dimethyl-2,2-silapentane-5-sulfonate (DSS) as an internal standard for D_2O solutions and the residual non-deuterated solvent signal as reference for spectra recorded from [D_6]acetone (δ = 2.04 ppm), CD_3NO_2 (δ = 4.33 ppm), and $CDCl_3$ (δ = 7.26 ppm) solutions. ^{31}P NMR spectra were referenced to external H_3PO_4 set at δ = 0 ppm. ES-MSdata were obtained on a Perkin–Elmer AP1 spectrometer. Samples were dissolved in acetonitrile; the spectra were recorded in the positive-ion mode at 5.6 kV accelerating potential. Elemental analyses were

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

performed at the Dipartimento di Scienze Chimiche, University of Trieste.

Trithiacyclononane, triphos, and deuterated solvents were purchased from Aldrich and used as received. Tris(pyrazolyl)methane,[28] *fac*-[Ru([9]aneS$_3$)(CH$_3$CN)$_3$][OTf]$_2$ (**12**),[11a] *fac*-[Ru([9]aneS$_3$)Cl$_2$(dmso-S)] (**1**),[11a] *cis*-[RuCl$_2$(dmso)$_4$],[29] and *trans*-[RuCl$_2$(dmso)$_4$][29] were prepared as described in the literature. *fac*-[Ru(dmso-O)$_3$(dmso-S)$_3$][OTf]$_2$ was prepared by an improved method compared to those reported in the literature for similar *fac*-[Ru(dmso-O)$_3$(dmso-S)$_3$][X]$_2$ (X = ClO$_4$, BF$_4$) compounds:[30,31] *cis*-[RuCl$_2$(dmso)$_4$] (0.48 g, 1 mmol) was treated with a slight excess of AgOTf in refluxing toluene in the presence of dmso (dmso/Ru = 4) for 30 min; the precipitate was extracted with methanol. Solvent removal afforded the product, which was recrystallized from acetone upon addition of diethyl ether. Yield: 0.6 g (70%).

***fac*-[Ru([9]aneS$_3$)Cl(dmso-S)$_2$][OTf] (2):** *fac*-[Ru([9]aneS$_3$)Cl$_2$(dmso-S)] (**1**; 0.18 g, 0.41 mmol) was dissolved in acetone (10 mL); dmso (75 μL, 1 mmol) and AgOTf (0.21 g, 0.82 mmol) were added and the light-protected mixture was heated to reflux for 1 h. After removal of AgCl by filtration through fine paper, the yellow solution was concentrated in vacuo to ca. 3 mL and stored at room temperature after dropwise addition of diethyl ether until saturation. A light-yellow precipitate formed within 24 h and was removed by filtration, washed with diethyl ether, and vacuum dried. Yield: 55 mg (20%). $C_{11}H_{24}ClF_3O_5RuS_6$ (622.19): calcd. C 21.2, H 3.88; found C 21.6, H 3.63. Selected IR (Nujol): $\tilde{\nu}$ = 1093 (s, νSO dmso-S), 428 cm^{-1} (w, νRu–S). ^{1}H NMR (400 MHz, D_2O, 25 °C): δ = 3.3–2.8 (m, 12 H, [9]aneS$_3$), 3.38 (s, 6 H, dmso-S), 3.46 (s, 6 H, dmso-S) ppm. ^{1}H NMR (400 MHz, CD_3NO_2, 25 °C): δ = 3.3–2.8 (m, 12 H, [9]aneS$_3$), 3.29 (s, 6 H, dmso-S), 3.38 (s, 6 H, dmso-S) ppm.

Crystals suitable for X-ray diffraction were obtained by diffusion of diethyl ether into an acetone solution of **2**.

***fac*-[Ru([9]aneS$_3$)(dmso)$_3$][OTf]$_2$ (3):** *fac*-[Ru([9]aneS$_3$)Cl$_2$(dmso-S)] (**1**; 0.43 g, 1 mmol) was partially dissolved in MeOH (10 mL); dmso (250 μL, 3.5 mmol) and AgOTf (0.60 g, 2.3 mmol) were added and the light-protected mixture was heated to reflux for 3 h. After removal of AgCl by filtration, the yellow solution was concentrated in vacuo to ca. 5 mL. A yellow crystalline precipitate was obtained within 24 h from the solution stored at room temperature after dropwise addition of diethyl ether until saturation. It was removed by filtration, washed with diethyl ether, and vacuum dried. Yield: 0.71 g (88%). $C_{14}H_{30}F_6O_9RuS_8$ (813.93): calcd. C 20.6, H 3.71; found C 20.7, H 3.77. Selected IR (Nujol): $\tilde{\nu}$ = 1088 (s, νSO dmso-S), 933 and 914 (s, νSO dmso-O), 517 (w, νRu–O), 418 cm^{-1} (w, νRu–S). ^{1}H NMR (400 MHz, CD_3NO_2, 25 °C): δ = 2.94 (s, 6 H, dmso-O **3a**), 2.96 (s, 6 H, dmso-O **3a**), 3.04 (s, 6 H, dmso-O **3b**), 3.18 (s, 6 H, dmso-S **3a**), 3.34 (s, 6 H, dmso-S **3b**), 3.43 (s, 6 H, dmso-S **3b**), 3.4–2.8 (m, 12 H, [9]aneS$_3$) ppm. ^{1}H NMR (400 MHz, [D$_6$]acetone, 25 °C): δ = 3.03 (s, 6 H, dmso-O **3a**), 3.04 (s, 6 H, dmso-O **3a**), 3.13 (s, 6 H, dmso-O **3b**), 3.22 (s, 6 H, dmso-S **3a**), 3.42 (s, 6 H, dmso-S **3b**), 3.49 (s, 6 H, dmso-S **3b**), 3.5–2.7 (m, 12 H, [9]aneS$_3$) ppm. Recrystallization: the product was dissolved in acetone and then diethyl ether was added dropwise until saturation.

***trans*,*cis*,*cis*-[RuCl$_2$(dmso-S)$_2${CH(pz)$_2$(pz)}] (4) and *trans*,*cis*,*cis*-[RuCl$_2$(dmso-S)$_2$(pzH)$_2$] (5):** *cis*-[RuCl$_2$(dmso)$_4$] (0.20 g, 0.41 mmol) was partially dissolved in MeOH (15 mL); CH(pz)$_3$ (0.09 g, 0.41 mmol) was added and the mixture was heated to reflux for 2 h. The resulting orange solution was concentrated in vacuo to ca. 2 mL and stored at room temperature after dropwise addition of diethyl ether until saturation. A yellow microcrystalline precipitate containing big orange crystals formed within 12 h. It was removed by filtration, washed with diethyl ether, and vacuum dried (yield: 0.15 g). The mixture was found to contain approximately equimolar amounts of **4**, **5**, and **6** by NMR spectroscopy. The orange crystals of **4** were manually separated under a microscope, washed with cold methanol and diethyl ether, and vacuum dried. $C_{14}H_{22}N_6Cl_2O_2RuS_2$ (542.46): calcd. C 31.0, H 4.09, N 15.49; found C 31.4, H 4.01 N 15.23. Selected IR (Nujol): $\tilde{\nu}$ = 1086 (s, νSO dmso-S), 424 (w, νRu–S), 341 cm^{-1} (m, νRu–Cl). ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C): δ = 3.45 (s, 6 H, dmso-S), 3.47 (s, 6 H, dmso-S), 6.39 (m, 2 H, H4 bound pz), 6.60 (m, 1 H, H4 unbound pz), 7.79 (m, 2 H, H5 bound pz), 8.03 (m, 2 H, H3 + H5 unbound pz), 8.26 (m, 2 H, H3 bound pz), 10.97 (s, 1 H, C*H*) ppm.

The remaining yellow solid, according to ^{1}H NMR analysis, was a mixture of **5** and **6** (and some residual **4**). Treatment of the mixture with chloroform (twice 5 mL) afforded a small amount of almost pure **6** as an insoluble solid residue (see below). Diffusion of diethyl ether into the chloroform solution afforded yellow crystals of **5**. $C_{10}H_{20}N_4Cl_2O_2RuS_2$ (464.39): calcd. C 25.8, H 4.34, N 12.06; found C 25.3, H 4.18, N 12.02. ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C): δ = 3.21 (s, 12 H, dmso-S), 6.38 (m, 2 H, H4 pzH), 7.63 (m, 2 H, H5 pzH), 7.98 (m, 2 H, H3 pzH), 12.6 (br. s, 2 H, N*H* pzH) ppm.

***trans*,*cis*,*cis*-[RuCl$_2$(dmso-S)$_2${CH(pz)$_2$(pz)}] (4):** As an alternative, complex **4** was selectively prepared in good yield by the following route: *trans*-[RuCl$_2$(dmso-S)$_4$] (0.1 g, 0.2 mmol) was dissolved in $CHCl_3$ (20 mL) and CH(pz)$_3$ (45 mg, 0.21 mmol) was added. After standing 24 h at room temperature, the resulting orange solution was concentrated in vacuo to ca. 5 mL and stored at room temperature after dropwise addition of diethyl ether until saturation. Orange crystals formed within 24 h and were removed by filtration, washed with diethyl ether, and vacuum dried. Yield: 65 mg (60%). See above for elemental analysis and spectroscopic characterization.

***fac*-[Ru{CH(pz)$_3$}Cl$_2$(dmso-S)] (6):** *cis*-[RuCl$_2$(dmso)$_4$] (0.30 g, 0.62 mmol) was partially dissolved in absolute EtOH (20 mL); CH(pz)$_3$ (0.14 g, 0.62 mmol) was added and the mixture was heated to reflux for 2 h. A yellow precipitate formed from the hot orange solution. After cooling the mixture to room temperature, it was removed by filtration, washed with cold ethanol and diethyl ether, and vacuum dried. Yield: 0.13 g (45%). Concentration of the mother liquor and addition of diethyl ether afforded a further yellow precipitate that, according to ^{1}H NMR spectroscopy, was a mixture of **5** and **6**. Recrystallization: the product was dissolved in the minimum amount of dmso (e.g. 0.15 g of **6** in 0.5 mL dmso), the solution was diluted with acetone (5 mL) and diethyl ether was added dropwise until saturation. Crystals of **6** suitable for X-ray diffraction were obtained by diffusion of diethyl ether into the dmso/acetone solution. $C_{12}H_{16}N_6Cl_2ORuS$ (464.33): calcd. C 31.0, H 3.47, N 18.09; found C 30.9, H 3.37, N 17.85. Selected IR (Nujol): $\tilde{\nu}$ = 1078 (s, νSO dmso-S), 424 cm^{-1} (w, νRu–S). ^{1}H NMR (400 MHz, D_2O, 25 °C): δ = 3.49 (s, 6 H, dmso-S), 6.56 (m, 2 H, H4), 6.65 (m, 1 H, H4), 8.01 (m, 2 H, H5), 8.23 (m, 1 H, H5), 8.36 (m, 2 H, H3), 8.40 (m, 1 H, H3), 9.47 (s, 1 H, C*H*) ppm. ^{1}H NMR (400 MHz, CD_3NO_2, 25 °C): δ = 3.41 (s, 6 H, dmso-S), 6.49 (m, 2 H, H4), 6.60 (m, 1 H, H4), 8.07 (m, 2 H, H5), 8.23 (m, 1 H, H5), 8.28 (m, 2 H, H3), 8.31 (m, 1 H, H3), 8.87 (s, 1 H, C*H*) ppm.

***fac*-[Ru{CH(pz)$_3$}(dmso-O)(dmso-S)$_2$][OTf]$_2$ (7):** This complex was prepared by two different routes: a) by treatment of **6** with two equivalents of AgOTf in the presence of dmso; b) by reaction of *fac*-[Ru(dmso-S)$_3$(dmso-O)$_3$][OTf]$_2$ with CH(pz)$_3$. The yield of **7** with respect to the common precursor *cis*-[RuCl$_2$(dmso)$_4$] is similar in the two procedures: 18% via route a, and 24% via route b.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Route a: *fac*-[Ru{CH(pz)$_3$}Cl$_2$(dmso-S)] (**6**; 0.10 g, 0.21 mmol) was dissolved in MeOH (5 mL); dmso (46 μL, 0.65 mmol) and AgOTf (0.11 g, 0.43 mmol) were added and the light-protected mixture was heated to reflux for 3 h. After removal of AgCl by filtration, the yellow solution was concentrated in vacuo to ca. 2 mL and stored at room temperature after dropwise addition of diethyl ether until saturation. A pale-yellow microcrystalline precipitate formed within 24 h and was removed by filtration, washed with diethyl ether, and vacuum dried. Yield: 72 mg (40%). $C_{18}H_{28}N_6F_6O_9RuS_5$ (847.82): calcd. C 25.5, H 3.33, N 9.91; found C 25.0, H 3.12, N 9.76. Selected IR (Nujol): $\tilde{\nu}$ = 1092 (s, νSO dmso-S), 938 (s, νSO dmso-O), 518 (w, νRu–O), 428 cm^{-1} (w, νRu–S). ^{1}H NMR (400 MHz, [D$_6$]acetone, 25 °C): δ = 2.94 (s, 6 H, dmso-O), 3.27 (s, 6 H, dmso-S), 3.35 (s, 6 H, dmso-S), 6.75 (m, 1 H, H4 pz *trans* to dmso-O), 6.83 (m, 2 H, H4 pz *trans* to dmso-S), 8.22 (m, 1 H, H5 pz *trans* to dmso-O), 8.69 (m, 2 H, H5 pz *trans* to dmso-S), 8.75 (m, 3 H, H3), 10.19 (s, 1 H, C*H*) ppm. ^{1}H NMR (400 MHz, CD_3NO_2, 25 °C): δ = 2.83 (s, 6 H, dmso-O), 3.17 (s, 6 H, dmso-S), 3.22 (s, 6 H, dmso-S), 6.68 (m, 1 H, H4 pz *trans* to dmso-O), 6.75 (m, 2 H, H4 pz *trans* to dmso-S), 8.09 (m, 1 H, H5 pz *trans* to dmso-O), 8.46 (m, 2 H, H5 pz *trans* to dmso-S), 8.62 (m, 3 H, H3), 9.61 (s, 1 H, C*H*) ppm. ^{1}H NMR (400 MHz, D_2O, 25 °C): δ = 2.72 (s, 6 H, free dmso), 3.20 (s, 6 H, dmso-S), 3.29 (s, 6 H, dmso-S), 6.71 (m, 1 H, H4 pz *trans* to dmso-O), 6.75 (m, 2 H, H4 pz *trans* to dmso-S), 8.03 (m, 1 H, H5 pz *trans* to dmso-O), 8.42 (m, 2 H, H5 pz *trans* to dmso-S), 8.53 (m, 3 H, H3), 9.84 (s, 1 H, C*H*) ppm.
Route b: *fac*-[Ru(dmso-S)$_3$(dmso-O)$_3$][OTf]$_2$ (0.10 g, 0.11 mmol) was dissolved in MeOH (5 mL); CH(pz)$_3$ (25 mg, 0.11 mmol) was added and the mixture was heated to reflux for 30 min. During reflux the initially colorless solution turned yellow; it was then concentrated in vacuo to ca. 1.5 mL and stored at room temperature after dropwise addition of diethyl ether until saturation. A pale-yellow microcrystalline precipitate formed within a few days and was removed by filtration, washed with diethyl ether, and vacuum dried. Yield: 32 mg (35%). $C_{18}H_{28}N_6F_6O_9RuS_5$ (847.82): calcd. C 25.5, H 3.33, N 9.91; found C 26.0, H 3.23, N 10.06. Crystals suitable for X-ray diffraction were obtained by diffusion of diethyl ether into an acetone solution of **7** (15 mg in 2 mL).

[(triphos)Ru(μ-Cl)$_3$Ru(triphos)]Cl (8): *cis*-[RuCl$_2$(dmso)$_4$] (0.48 g, 1 mmol) was dissolved in CHCl$_3$ (20 mL); triphos (0.62 g, 1 mmol) was added and the mixture was heated to reflux for 4 h under a stream of Ar. A yellow precipitate formed from the hot orange solution. After cooling the mixture to room temperature, this precipitate was removed by filtration, washed with diethyl ether, and vacuum dried. Yield: 0.6 g (75%). $C_{82}H_{78}Cl_4P_6Ru_2$ (1593.29): calcd. C 61.8, H 4.93; found C 60.5, H 4.90. ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C): δ = 1.59 (br. s, 6 H, CH_3), 2.40 (br. s, 12 H, CH_2), 6.83 (m, 24 H, *m*-Ph), 7.18 (t, 12 H, *p*-Ph), 7.37 (t, 24 H, *o*-Ph) ppm.

***fac*-[Ru(triphos)(dmso-O)$_2$(H$_2$O)][OTf]$_2$ (9):** [(triphos)Ru(μ-Cl)$_3$Ru-(triphos)]Cl (**8**; 0.20 g, 0.12 mmol) was dissolved in MeOH (10 mL); dmso (60 μL, 0.84 mmol) and AgOTf (0.13 g, 0.52 mmol) were added and the light-protected mixture was heated to reflux for 2 h. AgCl was removed by filtration and thoroughly washed with MeOH. The pale-orange solution was concentrated in vacuo to ca. 2 mL and stored at room temperature after dropwise addition of diethyl ether until saturation. A pale-yellow microcrystalline precipitate formed within 24 h and was removed by filtration, washed with diethyl ether, and vacuum dried. Yield: 0.2 g (70%). $C_{47}H_{53}F_6O_9P_3RuS_4$ (1198.1): calcd. C 47.1, H 4.46; found C 46.4, H 4.56. ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C): δ = 1.63 (br. s, 3 H, CH_3), 2.40 (br. s, 6 H, CH_2), 2.61 (s, 12 H, free dmso), 7.13 (m, 12 H, *m*-Ph), 7.27 (m, 18 H, *o*+*p*-Ph) ppm. ^{31}P{^{1}H} NMR (161.9 MHz, $CDCl_3$, 25 °C): δ = 38.2 ppm.

***fac*-[Ru([9]aneS$_3$)(py)$_3$][OTf]$_2$ (11) and *fac*-[Ru([9]aneS$_3$)(py)$_2$-(CH$_3$CN)][OTf]$_2$ (13):** *fac*-[Ru([9]aneS$_3$)(CH$_3$CN)$_3$][OTf]$_2$ (**12**; 0.1 g, 0.14 mmol) was partially dissolved in EtOH (20 mL); pyridine (92 μL, 1.13 mmol) was added and the mixture was heated to reflux for 4 h. The resulting yellow-green solution was filtered through fine paper to remove a small amount of a dark precipitate and then concentrated in vacuo to ca. 2 mL and stored at room temperature after dropwise addition of diethyl ether until saturation. A yellow crystalline precipitate containing two types of crystals (big prisms and small needles) formed within 24 h and was then removed by filtration, washed with chloroform and diethyl ether, and vacuum dried (yield 80 mg). The precipitate was shown to be an approximate 1:3 mixture of **11** and **13** by ^{1}H NMR spectroscopy. The large yellow prisms were manually separated from the mixture under a microscope and were found to be **13** (by X-ray diffraction and ^{1}H NMR spectroscopy). $C_{20}H_{25}N_3F_6O_6RuS_5$ (778.80): calcd. C 30.8, H 3.23, N 5.39; found C 31.0, H 3.17, N 5.41. ^{1}H NMR (400 MHz, D_2O, 25 °C): δ = 2.52 (s, 3 H, CH_3CN), 2.80 (m, 8 H, [9]aneS$_3$), 3.05 and 2.85 (m, 2 H each, [9]aneS$_3$), 7.45 (m, 4 H, *m*H py), 7.98 (t, 2 H, *p*H py), 8.61 (d, 4 H, *o*H py) ppm.

Recrystallization of the remaining mixture from ethanol by diffusion of diethyl ether afforded yellow crystals of pure **11**. $C_{23}H_{27}N_3F_6O_6RuS_5$ (816.85): calcd. C 33.8, H 3.33, N 5.14; found C 33.9, H 3.27, N 5.27. ^{1}H NMR (400 MHz, D_2O, 25 °C): δ = 2.80 (s, 12 H, [9]aneS$_3$), 7.44 (m, 6 H, *m*H py), 7.98 (t, 3 H, *p*H py), 8.48 (d, 6 H, *o*H py) ppm.

As an alternative, *fac*-[Ru([9]aneS$_3$)(py)$_3$][OTf]$_2$ (**11**) was selectively prepared as follows: *fac*-[Ru([9]aneS$_3$)(dmso)$_3$][OTf]$_2$ (**3**; 0.1 g, 0.12 mmol) was dissolved in MeOH (5 mL); pyridine (41 μL, 0.5 mmol) was added and the mixture was heated to reflux for 2 h. The resulting yellow-green solution was concentrated in vacuo to ca. 2 mL and stored at room temperature after dropwise addition of diethyl ether until saturation. A yellow crystalline precipitate formed within 24 h and was then removed by filtration, washed with chloroform and diethyl ether, and vacuum dried. Yield: 68 mg (70%). $C_{23}H_{27}N_3F_6O_6RuS_5$ (816.85): calcd. C 33.8, H 3.33, N 5.14; found C 34.3, H 3.41, N 5.22. ^{1}H NMR (400 MHz, CD_3NO_2, 25 °C): δ = 2.89 (m, 12 H, [9]aneS$_3$), 7.52 (m, 6 H, *m*H py), 8.04 (t, 3 H, *p*H py), 8.50 (d, 6 H, *o*H py) ppm. ES-MS: *m*/*z* (calcd.) = 667.8 (667.8) [M – OTf]$^+$, 259.4 (259.2) [M – 2OTf]$^{2+}$.

X-ray Crystallography: All diffraction data, with the exception of **3b** [150(2) K] were collected at room temperature on a Nonius DIP-1030H system with graphite-monochromated Mo-K_α radiation. For each crystal, a total of 30 frames were collected (exposure time of 15–30 min, rotation angle of 6° about φ, with the detector at a distance of 80–90 mm from the crystal). Cell refinement, indexing, and scaling of the data sets were done using the programs Mosflm and Scala.[32] All the structures were solved by Patterson and Fourier analyses and refined by the full-matrix least-squares method based on F^2 with all observed reflections.[33] The choice of the non-centrosymmetric space group $Pna2_1$ for **7** was confirmed by the successful final refinement; the Flack parameter of 0.49(10) indicates racemic twinning of the crystal. A difference Fourier map of **6** revealed a molecule of dmso and one of water. A residual in **3b** was assigned to a water oxygen (occupancy = 0.5, H atoms omitted). All the calculations were performed using the WinGX System, Ver. 1.64.05.[34]

CCDC-238841 (for **13**), -238842 ... -238847 (for **2**–**8**) and -238848 (for **9**) contain the supplementary crystallographic data forthis paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Supporting Information: The molecular structures of *trans,cis,cis*-[$RuCl_2$(dmso-S)$_2$(pzH)$_2$] (**5**) and the cations of *fac*-[Ru([9]aneS_3)(py)$_3$][OTf]$_2$·CH_3OH (**11**), *fac*-[Ru([9]aneS_3)(py)$_2$(CH_3CN)][OTf]$_2$ (**13**), and of one of the two crystallographically independent cations of *fac*-[Ru([9]aneS_3O)(dmso-O)$_2$(dmso-S)][OTf]$_2$ are reported. Of these, only the data for compounds **5** and **13** have been deposited, as the other structures are of poor resolution mainly because of the disordered triflate anions. The preparation of *fac*-[Ru([9]aneS_3O)(dmso-O)$_2$(dmso-S)][OTf]$_2$ is also reported (see also footnote on the first page of this article).

Acknowledgments

Acknowledgments are made for financial support to the donors of The Petroleum Research Fund, administered by the ACS, (grant ACS PRF# 38892-AC3), to MIUR (PRIN no. 2003035553), and to Regione Autonoma Friuli-Venezia Giulia (L. R. 3/98). We wish to thank Engelhard Italiana S.p.A. for a generous loan of hydrated $RuCl_3$.

Synthesis and Physicochemical Characterization of Bis(macrocycles) Involving a Porphyrin and a *meso*-Substituted Corrole – X-ray Crystal Structure of a [(Free-base porphyrin)–corrole]bis(pyridine)cobalt Complex

Jean-Michel Barbe,*[a] Fabien Burdet,[a] Enrique Espinosa,[a] and Roger Guilard*[a]

Keywords: Bis(macrocycles) / Porphyrins / Corroles / Synthetic methods / X-ray diffraction

A very efficient, simple synthesis of face-to-face porphyrin–corrole free-bases bearing substituents at the *meso* positions of the corrole ring is reported. Starting from the (porphyrin–aldehyde)zinc species **1Zn**, porphyrin–corrole free-bases (**3M**, **3C**) are obtained in two steps, in fairly good yields (40–43 %), compared to 11 steps for their corrole β-pyrrole-substituted counterparts. Moreover, the possibility to directly synthesize the free-base (porphyrin–corrole)cobalt complex (**5M** or **5C**) allows for the further preparation of heterodimetallic derivatives. Crystals of the bis(pyridine) adduct of **5M** have been grown; the molecular structure clearly shows that the two pyridine molecules are coordinated to the cobalt ion in *endo* and *exo* positions, leading to an open-mouth geometry of the bis(macrocycle). The structure of **5M(py)$_2$**also shows intermolecular π–π interactions along the [1 0 0] direction, leading to stacking of the complexes.

Introduction

Enzyme mimics have always been of great interest. For example, considerable studies of heme/copper terminal oxidases have led to several models of the active site. In addition, several reviews have been published recently.[1–3] Concurrently, cofacial bis(porphyrins) were proposed as synthetic models of the dioxygen reduction site and, particularly, face-to-face bis(porphyrin)bis(cobalt) complexes appeared to be very efficient catalysts for the four-electron reduction of O_2 to water in acidic media.[1,2,4,5] Cofacial heterodimetallic bis(porphyrins) containing one cobalt atom were later reported, and also proved to be good catalysts for O_2 reduction.[1,6–8] Numerous studies on the synthetic models indicate that the catalytic activity originates from intermetallic cooperation between the two metal atoms of the bis(porphyrin) complex, tuned by the nature of the spacer.[1,5] Moreover, the Lewis acid character of one of the two metals in the bis(porphyrin) complex is a key factor in stabilizing the dioxygen adduct during catalysis.[1]

Our research in this domain has focused on cofacialbis(-macrocycles) where a porphyrin and a corrole are held together by a rigid spacer.[9,10] The originality of this approach lies in the difference in coordination properties between the porphyrin and the corrole rings. Indeed, corroles can coordinate metal ions in higher oxidation states than porphyrins.[11,12] Therefore, complexation of the bis-(macrocycle) by a cobalt ion could directly generate the active species in the O_2 four-electron catalytic cycle, i.e. cobalt(II) in the porphyrin and cobalt(III) in the corrole ring.[13] We recently demonstrated that this mixed-valence species is a good catalyst for the 4e reduction of O_2 to water.[14]

Most investigated porphyrin–corrole bis(macrocycles) were substituted at the β-pyrrole positions by electron-donating groups.[9] However, recent syntheses of *meso*-substituted corroles allow significant variation of the substituents on the corrole ring, particularly at the *meso* positions.[15–23] Electron-withdrawing substituents on the bis(macrocycle) corrole ring enhance the Lewis acid character of the complexed metal ion [namely cobalt(III)], the main parameter in stabilizing the dioxygen adduct. Therefore, the stability of the dioxygen adduct formed during the catalytic process increases with the Lewis acid character of the corrole-coordinated metal ion. By adapting the new procedures, involving the reaction of dipyrromethanes with an aromatic aldehyde, we could prepare new porphyrin–corrole derivatives with the corrole counterpart substituted at the *meso* positions with mesityl or 2,6-dichlorophenyl groups. Moreover, the corrole ring is formed in only two steps, allowing for the synthesis of gram quantities of these model catalysts.

Here we describe the synthesis of these new bis(macrocycles), and show the possibility of selectively metalating the corrole ring by cobalt (or another metal) to access heterodimetallic derivatives.

Results and Discussion

Synthesis and Physicochemical Characterization

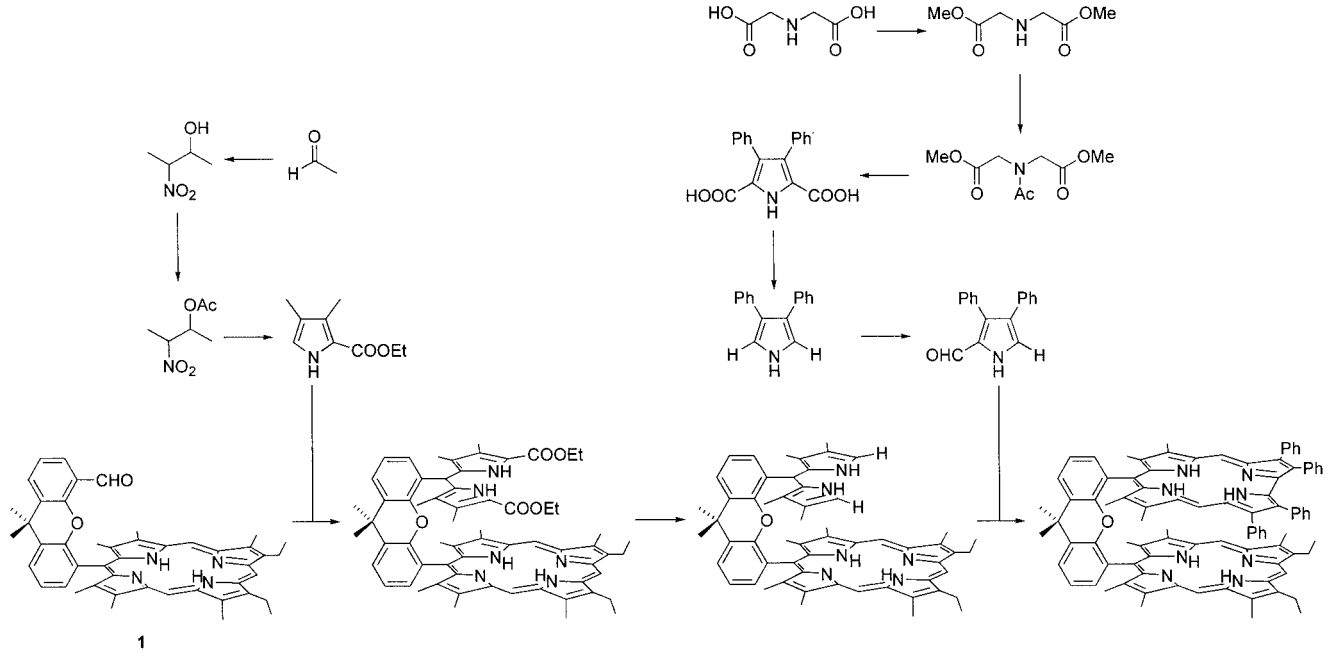
We recently reported a significant improvement in the syntheses of β-substituted porphyrin–corrole and bis(corrole) bis(macrocycles), allowing the yield in final free-bases to be almost tripled.[10] However, even if one can introduce electron-withdrawing substituents (i.e. phenyl groups) at the β-pyrrole positions of the corrole ring, the synthetic pathway affording the final free-bases is somewhat long. As an example, Scheme 1 shows the synthesis of a β-phenyl-substituted porphyrin–corrole derivative.

When starting from the porphyrin–aldehyde precursor (**1** in Scheme 1), the target compound is obtained in 11 steps due to the step-by-step nature of this approach, which firstly requires the formation of a dipyrromethane. This dipyrromethane is then coupled with a pyrrole–aldehyde to obtain the final corrole ring by formation of an *a*,*c*-biladiene. Each pyrrole precursor is obtained in three to five steps, depending upon the substitution at the β-pyrrole positions (Scheme 1). Notably, a symmetrical corrole ring is prepared in only eight steps since only one pyrrole derivative is needed. Another drawback of this multistep synthetic route is that any variation in the structure of the desired bis(macrocycle) requires the synthesis of a new pyrrole precursor (Scheme 1). Nevertheless, this is still the only method that allows the insertion of electron-donating substituents at the β-pyrrole positions of the corrole ring.[9,10]

An alternative to these β-substituted derivatives would be the *meso*-substituted ones. Indeed, the new methods leading to *meso*-substituted corrole rings[15–23] can be adapted to the synthesis of porphyrin–corrole derivatives. In the present case, starting from **1Zn**, the porphyrin–corrole bis(macrocycle) is obtained in only two steps. Scheme 2 gives the overall procedure.

5-Mesityldipyrromethane and 5-(2,6-dichlorophenyl)dipyrromethane were obtained from a previously described procedure[24] and used for reaction with **1Zn**. **1Zn** was used in the condensation instead of **1** since the reaction requires the presence of trifluoroacetic acid (TFA), which can protonate the porphyrin moiety. For **1**, larger quantities of TFA must be used for the condensation reaction, and acidolysis of the reacting dipyrromethane can occur. Therefore, **1Zn** is a more appropriate precursor because no protonation of the porphyrin core can occur and the final derivatives **2M** and **2C** are much easier to purify by column chromatography than their non-metalated counterparts.

1Zn was obtained in 87% yield in classical conditions by simple metalation of **1** by zinc acetate dihydrate in chloroform/methanol (Scheme 2). The remaining aldehyde function of **1Zn** was treated further, with either 5-mesityldipyrromethane or 5-(2,6-dichlorophenyl)dipyrromethane, in dichloromethane in the presence of a catalytic amount of TFA (aldehyde/TFA = 17:1.3 mmol).[19] Under the best experimental conditions, in which dipyrromethane was added in twice the stoichiometric amount (66 mmol, 4 equiv.) with respect to **1Zn**, both **2M** and **2C** were obtained in yields close to 30% compared to ca. 6% for stoichiometric amounts (33 mmol, 2 equiv.).[19] To recover **2M** and **2C**, the final reoxidation process was performed using 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) after a 25× dilution in dichloromethane.[21] **2M** and **2C** were isolated in 27 and 33% yield, respectively. Corrole ring formation is easily evidenced in MALDI/TOF by a distribution of peaks centered at 1253.92 (**2M**) and 1307.34 (**2C**), and by ^{1}H NMR resonance signals of the corrole (Table 1). Notably, no signal



Scheme 1.

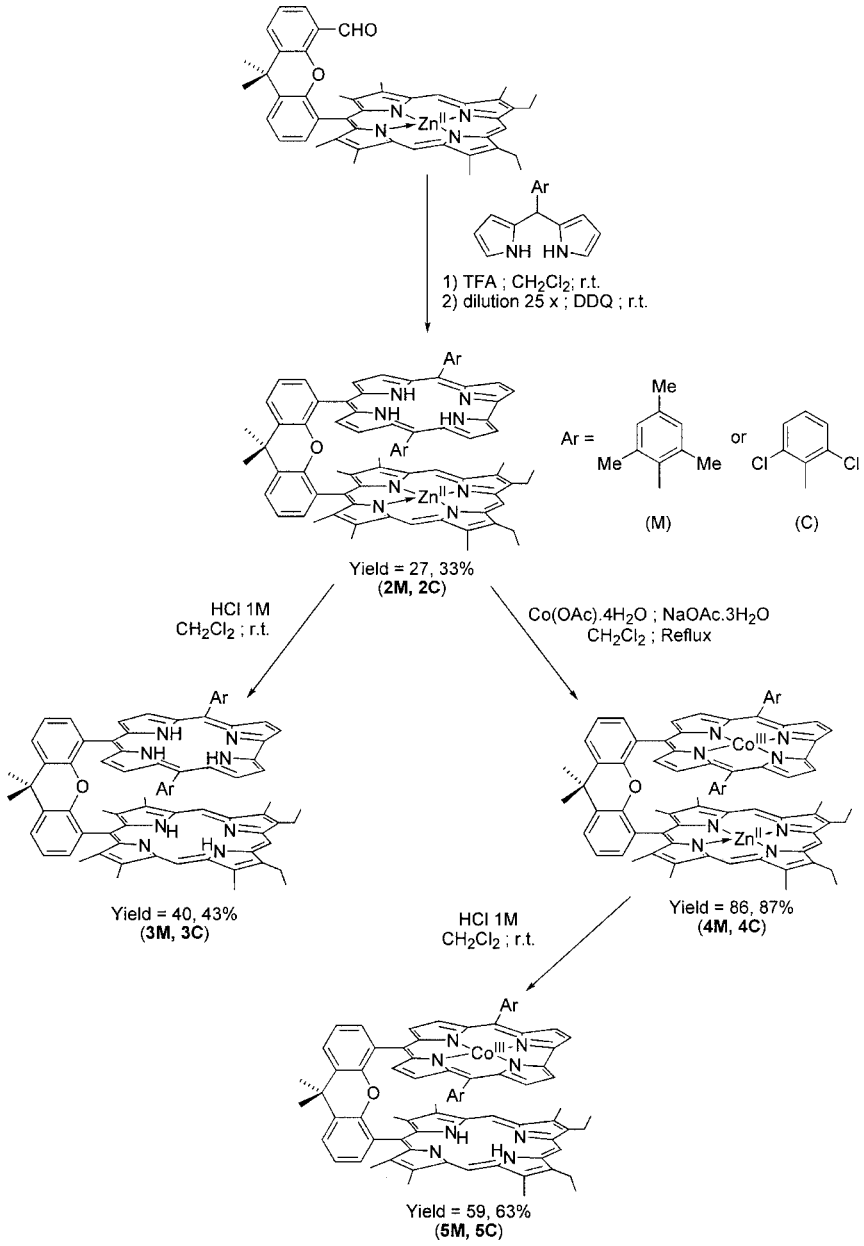

Scheme 2.

could be attributed to the inner NH protons of the corrole ring.

Similarly, the corrole ring is evidenced in UV/Vis spectroscopy by two extra Q bands at 610 and 638 nm, and 617 and 636 nm for **2M** and **2C**, respectively. At the same time, the unique Soret band is slightly blue-shifted by 7 nm for both derivatives compared to that of **1Zn** (Table 2). This shift is generally interpreted in terms of the mutual influence of the porphyrin and corrole rings, thus increasing the HOMO–LUMO gap and therefore shifting the transition at lower wavelengths.[25,26]

Corrole ring formation is further indicated by the disappearance of the C=O stretching band at 1680 cm^{-1} of the aldehyde function of **1Zn** and the concomitant appearance of a new band around 3360 cm^{-1} relative to the vibration of the NH groups of the corrole ring of **2M** and **2C** (see Exp. Sect.).

2M and **2C** can be demetalated by washing with one molar hydrochloric acid solution to afford the free bases **3M** and **3C** in 43 and 40% yield, respectively (Scheme 2). UV/Vis spectroscopy reveals **3M** and **3C** formation by one extra Q band at ca. 510 nm when compared to **2M** and **2C** (Table 2). ^{1}H NMR spectra of **3M** and **3C** feature two signals corresponding to the NH protons of the porphyrin free-base at δ = –5.43 and –4.69 ppm, and at δ = –5.63 and –4.97 ppm, for **3M** and **3C**, respectively. Again, no signal is observed for the same protons in the corrole ring.

When treated with excess cobalt acetate tetrahydrate and sodium acetate in dichloromethane/methanol, **2M** and **2C** lead to **4M** and **4C** in ca. 85% yield, as confirmed by the

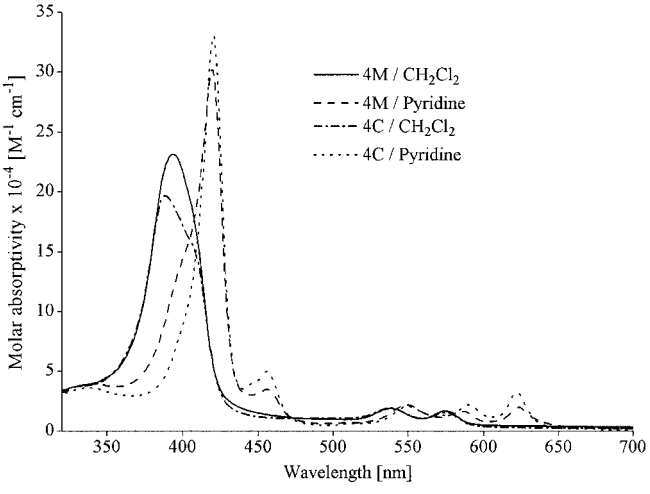

Figure 1. UV/Vis spectra of **4M** and **4C** recorded in CH_2Cl_2 and pyridine.

hypsochromic shift of the Soret band and by the presence of only two major Q bands (Scheme 2 and Table 2). The spectra of the two species recorded in pyridine are interesting (see Exp. Sect. for data). Figure 1 shows the UV/Vis spectra of both **4M** and **4C** in CH_2Cl_2 and pyridine. In dichloromethane, the data are close to those of pure zinc monoporphyrins, the only difference being the shoulder on the Soret band of the porphyrin corresponding to that of the corrole ring. In contrast, major differences arise when pyridine is used as a solvent. For example, all Q bands are red-shifted and a new absorption appears in the range 620–625 nm. Such a band is specific of the coordination of two pyridine molecules on the cobalt(III) ion of the corrole moiety.[10,27–29] Therefore, the coordination of two pyridine molecules is expected on the cobalt atom in *endo* and *exo* positions. The spectra in pyridine exhibit another band, at 456 nm, for both **4M** and **4C** complexes, corresponding to the Soret band of the corrole ring. In ^{1}H NMR spectra recorded in deuterated pyridine all resonance signals appear

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

in the diamagnetic region (δ = 0–10 ppm) while in non-coordinating solvents ($CDCl_3$ or C_6D_6) broad signals appear over a wider range for the corrole counterpart. This behavior is attributed to the presence, in non-coordinating solvents, of a high-spin Co^{III} (S = 1) species while in coordinating solvents a low-spin Co^{III} (S = 0) is expected.[11] A detailed study of these spectral characteristics will be published separately.[30]

Demetalation of **4M** and **4C** using 1 M hydrochloric acid affords **5M** and **5C** in yields ranging from 59 to 63% (Scheme 2). No demetalation of the (corrole)cobalt moiety occurs, as demonstrated in MALDI/TOF mass spectrometry by single ionic patterns at m/z = 1246.98 and 1300.8, which correspond to the **5M** and **5C** molecular ions, respectively. The relative "protective action" of the cobalt-containing corrole ring during metalation is interesting. Indeed, direct demetalation from **2M** and **2C** affords **3M** and **3C** in lower yields (around 40%). Other porphyrin–corrole and bis(corrole) bis(macrocycles) show such behavior; the free-bases exhibiting instability relative to the metalated derivatives.[31,32]^{1}H NMR spectra of **5M** and **5C**, recorded in [D_5]-pyridine, do not differ significantly from those of **4M** and **4C**, apart from the NH proton resonances of the porphyrin pyrrole units, which are centered at δ = –3.72 and –3.38 ppm for **5M**, and δ = –4.10 and –3.49 ppm for **5C** (Table 1). The UV/Vis spectrum of **5M** recorded in CH_2Cl_2 closely resembles that of **5C** (Figure 2). Due to the lower molar absorptivity of the absorption bands on the corrole, both spectra exhibit characteristic features of free-base monoporphyrins, with four Q bands between 500 and 630 nm and a Soret band at 389 nm. This latter band is broadened slightly by overlap with the Soret band of the corrole ring. With pyridine as solvent, similar UV/Vis spectra are again obtained for **5M** and **5C** (Figure 2). The band close to 620–625 nm increases in intensity, in accordance with the coordination of two pyridine molecules on the cobalt atom in the corrole. As observed for **4M** and **4C**, **5M** and **5C** exhibit a band at 456 nm in pyridine corresponding to the Soret band of the corrole moiety. Finally, crystallization of **5M** in cyclohexane/pyridine furnished crystals of **5M(py)$_2$**.

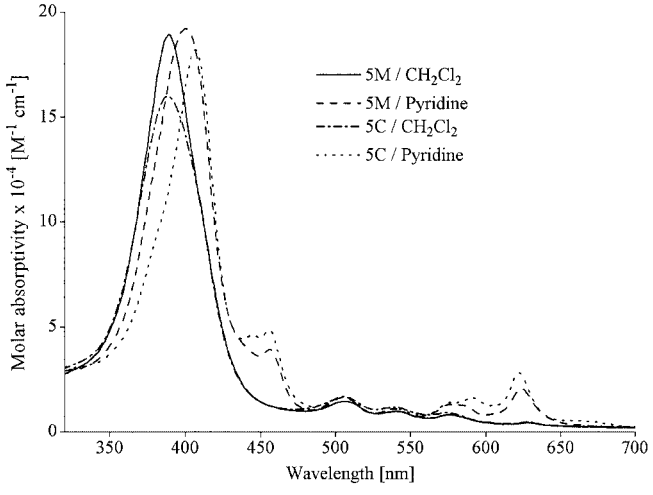

Figure 2. UV/Vis spectra of **5M** and **5C** recorded in CH_2Cl_2 and pyridine.

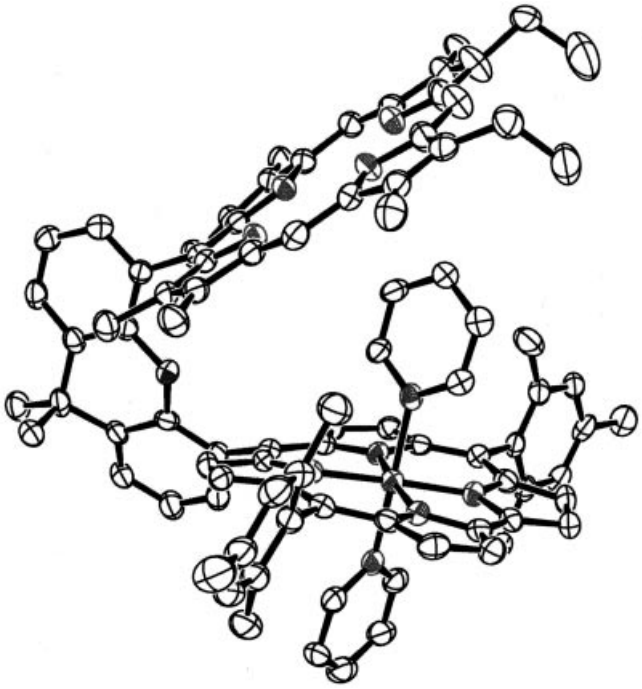

Figure 3. ORTEP view of the **5M(py)$_2$** complex. Ellipsoids drawn at 50% probability level; hydrogen atoms omitted for clarity.

Structural Study

A single-crystal X-ray diffraction analysis of **5M(py)$_2$** revealed the molecular structure of the monometallic cobalt(III) complex (Figure 3). The Co^{III} ion is coordinated to the four pyrrole nitrogen atoms ($4N_{pyrrole}$) in a planar conformation (the metal ion is only 0.011 Å out of the $4N_{pyrrole}$ mean plane), lying slightly out of the $4N_{pyrrole}$ centroid Ct_1 at 0.070 Å. Two kinds of Co–$N_{pyrrole}$ distances are observed in the complex [1.869(4)–1.875(4) and 1.896(4)–1.898(4) Å, each group involving the nitrogen atoms in *trans* positions], indicating a slightly distorted $4N_{pyrrole}$ square coordination. In addition, two pyridine (py) nitrogen atoms (N_{py}) are in apical positions from the metal centre at 1.969(4) and 1.978(4) Å, completing a close square-bipyramidal coordination geometry. These coordination distances and geometry are very similar to those reported for related complexes. Thus, for the [5,10,15-tris-(pentafluorophenyl)corrole]cobalt(III) complex,[33] M–$N_{pyrrole}$ and M–N_{py} distances are 1.873–1.900 and 1.994 Å for the monomer, and 1.868–1.899 and 1.989–2.000 Å for the dimer. In the face-to-face homodimetallic bis(corrole) complex [(BCA)$Co_2(py)_3$],[28] bearing three coordinated pyridine molecules (one inside and two out of the complex cavity), M–$N_{pyrrole}$ and M–N_{py} distances are 1.879–1.905 and 1.976–1.979 Å for the hexacoordinate metal centre. In this latter structure, the coordination distances of the pentacoordinate metal centre, [1.875(4)–1.894(4) for $N_{pyrrole}$ and 1.946(5) Å for N_{py}], compare well with those of the mono-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

metallic (corrole–porphyrin)cobalt(III) complex, where the spacer is a biphenylenyl unit, [(PCB)H_2Co(py)],[10] which binds one pyridine molecule out of the complex cavity. The corresponding distances were 1.882(3)–1.902(3) ($N_{pyrrole}$) and 1.945(4) Å (N_{py}). Thus, from penta- to hexacoordinate (corrole)cobalt(III) species having pyridine in apical positions, the most relevant difference in coordination geometry concerns: (i) elongation of M–N_{py} by about 0.03 Å and (ii) displacement of the metal centre towards the $4N_{pyrrole}$ mean plane (<$4N_{pyrrole}$>); the Co···<$4N_{pyrrole}$> distance being 0.202(1) and 0.252(1) Å for pentacoordinate cases in [(PCB)H_2Co(py)] and [(BCA)$Co_2(py)_3$] and 0.009(1) and 0.011(1) Å for hexacoordinate ones in [(BCA)$Co_2(py)_3$] and **5M(py)$_2$**.

In the molecular structure of the **5M(py)$_2$**complex both macrocycles exhibit a small distortion from planarity, the root mean square deviation of the 23 and 24 atoms from the corrole and porphyrin least-squares planes being 0.112 and 0.078 Å, respectively. While the corrole macrocycle shows a ruffled conformation, as indicated by the displacements of the alternated *meso*-carbon atoms above and below the corrole mean plane, the porphyrin moiety is closely planar. Thus, for the corrole ring, the *meso*-carbon atom C10 lies 0.210(4) Å above the mean plane, whereas C5 and C15 lie –0.159(4) and –0.175(4) Å below this plane. With the porphyrin, only five atoms lie more than 0.1 Å out of the mean plane [C55, C60, C61, C68, and C71 at 0.128(4), –0.108(4), –0.122(4), –0.105(4), and –0.207(4) Å, respectively]. [(BCA)$Co_2(py)_3$] and [(PCB)H_2Co(py)] complexes have similar macrocycle conformations.[10,28]

Both H(–N) hydrogen atoms were found unambiguously in the porphyrin cavity, on N7 and N5, and are involved in hydrogen-bonding interactions with N6 and N8 pyrrole nitrogen atoms [d(N–H) = 0.95(5) and 0.99(5) Å, d(H···N) = 2.23(5) and 2.11(5) Å and α(N–H···N) = 120(4) and 127(4)°, respectively].

The coordination of one of the pyridine molecules within the complex cavity leads to a large open-mouth face-to-face geometry (the interplanar angle between the macrocycle mean planes β is 43.2°) due to the important steric effects with the porphyrin moiety. Nevertheless, the spacer is folded through the Csp^3–O direction (the dihedral angle between both half parts is 28.9°), allowing for a short pyridine–porphyrin contact that balances the repulsive steric effect by the attractive (C_{py}–)H···π-system interaction (the $4N_{pyrrole}$ porphyrin centroid Ct_2 distance to the closest H_{py} atom is 2.22 Å, and the four H···Ct_2···$N_{pyrrole}$ angles range between 80 and 100°). The anchored sites of both macrocycles at the spacer and at the corrole–porphyrin moieties are 4.64 and 4.79 Å, respectively, apart. The small difference in distances (0.15 Å) suggests that, while steric repulsion mainly drives the corrole macrocycle orientation (leading to the large β angle), both the spacer folding and the attractive H···π–porphyrin interaction avoid a larger difference. Further support for both this attractive interaction and the role of the spacer follows from a comparison of the molecular structures of (BCA)$Co_2(py)_3$ and **5M(py)$_2$**, where the distances from the hexacoordinate metal centre to the centroid of the other macrocycle are 7.23 and 6.86 Å, respectively. Thus, the latter complex exhibits a short "macrocycle-to-macrocycle" distance due to the folding of its spacer, which in the relaxed planar conformation corresponds to the distance observed for the anthracenyl moiety. Therefore, thanks to its flexibility, the dimethylxanthene spacer is of great interest for tuning potential metal···metal or metal···molecule···metal interactions in face-to-face macrocyclic complexes.

In **5M(py)$_2$**, the slip angle α, defined as the average angle between the vector joining Ct_1···Ct_2 and the unit vectors normal to the two macrocyclic least-squares planes [$\alpha = (\alpha_1 + \alpha_2)/2$], is 24.0° and the lateral shift $L = \sin\alpha \cdot d(Ct_1 \cdots Ct_2)$ is 2.80 Å [$d(Ct_1 \cdots Ct_2)$ = 6.90 Å]. These values are larger than those found in [(BCA)$Co_2(py)_3$] (α = 14.7°, L = 1.84 Å), even if α and L slightly differ in their definitions in the two complexes.[28]

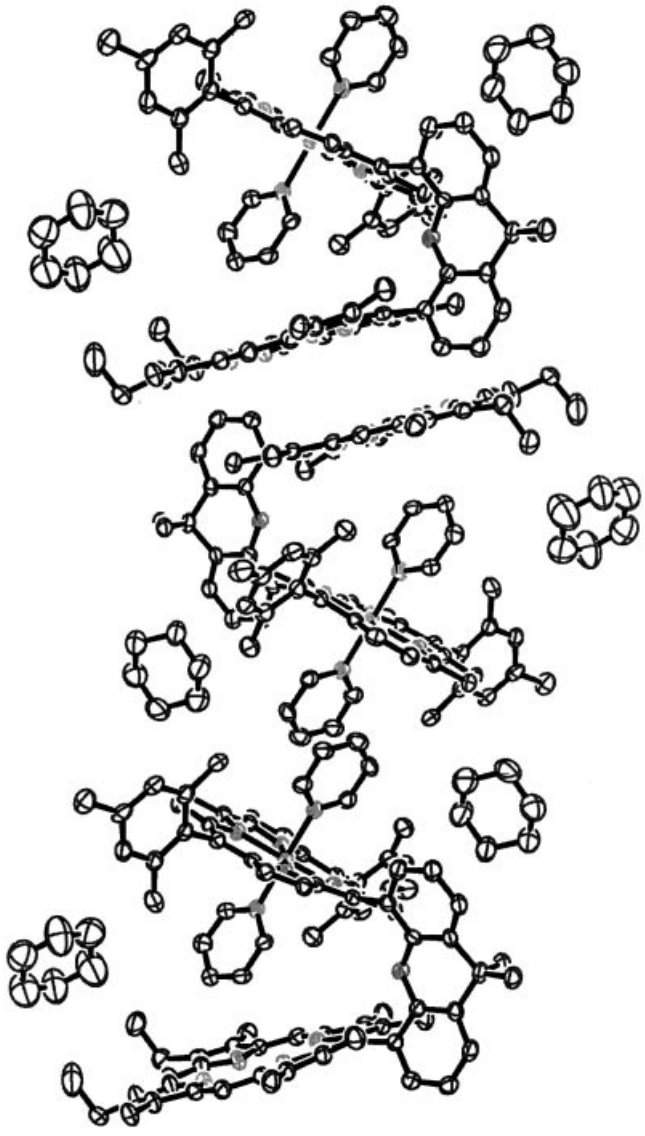

Figure 4. Stacking of **5M(py)$_2$** complexes along the [1 0 0] direction, including solvent molecules. Ellipsoids drawn at 50% probability level; hydrogen atoms omitted for clarity.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Moreover, the pyridine molecules are almost staggered around the metal centre; the dihedral angle between their mean planes being 87.9°. While this almost perpendicular orientation has also been observed in [(BCA)$Co_2(py)_3$] (88.2°)[28] and [(Me_4Ph_5Cor)Co$(py)_2$] (83.7°),[27] in the [5,10,15-tris(pentafluorophenyl)corrole]cobalt(III) complex a mutually parallel arrangement between both pyridine molecules is found for the monomer and dimer.[33]

In the **5M(py)$_2$** crystal structure, the stacking of complexes is driven by two kinds of π–π interactions along the [1 0 0] direction (Figure 4). Hence, while the porphyrin ring interacts with the adjacent equivalent moiety of another molecule (the shortest distance is 3.57 Å for two equivalent *meso*-C atoms), at the other side of the complex the outer pyridine molecule makes a π–π interaction with an equivalent molecule of the closest complex (the shortest C–C distance being 3.33 Å). In the former case, the centroid–centroid distance is quite large (7.50 Å), indicating an important lateral shift between the macrocycles. In the second case, the centroid–centroid distance is 3.63 Å, reflecting significant overlap between the π-systems of both pyridine molecules.

The relative orientation of the inner pyridine in front of two methyl groups of the mesityl substituents (C_{methyl}···Ct_{py}···C_{methyl} = 160°) seems to indicate a further stabilisation by two quite weak C–H···aromatic ring interactions (H···Ct_{py} distances are 3.83 and 4.41 Å). A variable ^{1}H NMR analysis down to 220 K, to visualize tentatively any interaction involving a methyl proton of a mesityl group with a pyridine molecule, found no significant variation in signal shape or chemical shift for the protons concerned.

Summary and Conclusion

1Zn reacts with an aryldipyrromethane to afford good yields of (free-base corrole–porphyrin)zinc complexes (**2M** and **2C**). Further metalation of the corrole ring by cobalt followed by demetalation of the porphyrin moiety gives the (free-base porphyrin–corrole)cobalt complex, which is a precursor of heterodimetallic derivatives. The "protective" effect of the zinc ion in the porphyrin ring is evidenced throughout the synthetic pathway and, especially, during the first step, leading to the formation of the corrole, where lower amounts of TFA are required than for the reaction carried out from **1**. Therefore, acidolysis of the dipyrromethane reactant avoided, and reaction yields in bis(macrocycle) are obviously increased.

In the presence of pyridine, the bis(pyridine) adduct of **5M** crystallized. The structure of **5M(py)$_2$**was solved, exhibiting coordination of the two pyridine molecules on the cobalt atom of the corrole ring in *endo* and *exo* positions. Another interesting feature is that the complexes are stacked along the [1 0 0] direction through π–π interactions.

Work towards the preparation of heterodimetallic complexes and their use as catalysts for the reduction of dioxygen is being carried out.

Experimental Section

General Remarks: All analytical grade reagents, obtained from commercial suppliers, were used without further purification. 5-Mesityldipyrromethane, 5-(2,6-dichlorophenyl)dipyrromethane,[24] 5-(13,17-diethyl-2,3,7,8,12,18-hexamethylporphyrin-5-yl)-4-formyl-9,9-dimethylxanthene[13,31,32] (**1**) were synthesized according to reported procedures. ^{1}H NMR spectra were recorded at 500 MHz with a Bruker DRX-500 Avance spectrometer of the "Centre de Spectrométrie Moléculaire de l'Université de Bourgogne" of the FR 2604. Chemical shifts are expressed in ppm relative to residual peaks of chloroform (δ = 7.26 ppm), pyridine (δ = 7.19, 7.55, 8.71 ppm) or benzene (δ = 7.16 ppm). UV/Vis spectra were collected with a Varian Cary 1 spectrophotometer in dichloromethane solution. Infrared spectra were measured in the attenuated total reflectance mode (ATR) with a Bruker Vector 22 Fourier transform spectrometer. MALDI/TOF mass spectra were obtained with a Bruker ProFLEX III spectrometer using dithranol as matrix. Microanalyses were performed with a Fisons EA 1108 CHNS instrument.

[13,17-Diethyl-5-(5-formyl-9,9-dimethylxanthen-4-yl)-2,3,7,8,12,18-hexamethylporphyrin]zinc(II) (1Zn): A solution of porphyrin **1** (0.200 g, 0.291 mmol, 1 equiv.), zinc acetate dihydrate (0.128 g, 0.582 mmol, 2 equiv.), and sodium acetate trihydrate (0.396 g, 2.91 mmol, 10 equiv.) in a chloroform (35 mL)/methanol (15 mL) mixture was heated to reflux for 15 min. After cooling to room temperature, dichloromethane (50 mL) was added. The reaction mixture was then washed with water (3 × 100 mL), dried with magnesium sulfate, filtered and the solvents were evaporated. The resulting solid was chromatographed on silica gel using first toluene as eluent and then dichloromethane to collect a pink fraction. After concentration, the solid was recrystallized from dichloromethane/heptane. **1Zn** was obtained in 87% yield (0.190 g, 0.253 mmol). ^{1}H MNR ($CDCl_3$, 300 K): δ = 1.88 (t, $^3J_{H,H}$ = 7.85 Hz, 6 H, $CH_3$$CH_2$-porphyrin), 1.92 (s, 6 H, CH_3-dimethylxanthene) 2.48 (s, 6 H, CH_3-porphyrin), 3.48 (s, 6 H, CH_3-porphyrin), 3.63 (s, 6 H, CH_3-porphyrin), 4.08 (m, 4 H, $CH_3$$CH_2$-porphyrin), 7.05 (t, $^3J_{H,H}$ = 7.68 Hz, 1 H, H-dimethylxanthene), 7.30 (dd, $^3J_{H,H}$ = 7.39, $^4J_{H,H}$ = 1.19 Hz, 1 H, H-dimethylxanthene), 7.51 (s, 1 H, CHO), 7.60 (t, $^3J_{H,H}$ = 7.71 Hz, 1 H, H-dimethylxanthene), 7.71 (dd, $^3J_{H,H}$ = 7.90, $^4J_{H–H}$ = 1.43 Hz, 1 H, H-dimethylxanthene), 7.87 (d, $^3J_{H,H}$ = 6.40 Hz, 1 H, H-dimethylxanthene), 7.93 (dd, $^3J_{H,H}$ = 7.95, $^4J_{H,H}$ = 1.01 Hz, 1 H, H-dimethylxanthene), 10.02 (s, 1 H, H_{meso}-porphyrin), 10.12 (s, 2 H, H_{meso}-porphyrin). MS (MALDI/TOF): *m*/*z* = 747.30 [M – H]$^+$; 748.28 calcd. for $C_{46}H_{44}N_4O_2Zn$. UV/Vis (CH_2Cl_2): λ_{max} ($\varepsilon \times 10^{-3}$ L mol^{-1} cm^{-1}) = 332.0 (23.6), 406.0 (346), 536.1 (16.9), 572.1 (16.0) nm. IR $\tilde{\nu}$ = 2959 (C–H), 2923 (C–H), 2861 (C–H), 1680 (C=O) cm^{-1}. $C_{46}H_{44}N_4O_2Zn$ (750.27): calcd. C 73.64, H 5.91, N 7.47; found C 73.63, H 6.07, N 7.48.

{5-[5-(5,15-Dimesitylcorrol-10-yl)-9,9-dimethylxanthen-4-yl]-13,17-diethyl-2,3,7,8,12,18-hexamethylporphyrin}zinc(II) (2M): (Porphyrin)zinc complex **1Zn** (0.20 g, 0.27 mmol, 1 equiv.) and mesityldipyrromethane (0.28 g, 1.07 mmol, 4 equiv.) were dissolved in 16 mL of a solution of trifluoroacetic acid (0.02 mmol, 0.08 equiv.) in CH_2Cl_2 (10 μL of TFA in 100 mL of CH_2Cl_2). The reaction mixture was then stirred for 5 h, diluted 25× with CH_2Cl_2 (400 mL) and a solution of 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ; 0.182 g, 0.80 mmol, 3 equiv.) in toluene (4 mL) was added with stirring. After a further 5 min, the reaction mixture was chromatographed on silica gel and eluted with CH_2Cl_2. The first collected, violet, fraction was concentrated, washed with pentane and dried under vacuum, yielding 0.091 g (27%, 0.07 mmol) of **2M**. ^{1}H MNR (C_6D_6, 330 K): δ = 0.93 (s, 6 H, CH_3-mesityl), 1.48 (s, 6 H,

{10-[5-(13,17-Diethyl-2,3,7,8,12,18-hexamethylporphyrin-5-yl)-9,9-dimethylxanthen-4-yl]-5,15-dimesitylcorrole}cobalt(III) (5M): A solution of **4M** (35 mg, 26.7 μmol) in dichloromethane (35 mL) was vigorously stirred with hydrochloric acid (1 M; 3 × 50 mL) in a separating funnel. The organic layer was then washed with distilled water (3 × 50 mL), dried with magnesium sulfate, filtered and the solvents were evaporated under vacuum. The resultant solid residue was chromatographed on basic alumina and eluted with dichloromethane/methanol (98:2). The first eluting fraction was concentrated and then recrystallized from dichloromethane/methanol, yielding **5M** (59%, 0.020 g, 0.016 mmol). ^{1}H NMR (C_5D_5N, 330 K): δ = –3.72 (br. s, 1 H, NH-porphyrin), –3.38 (br. s, 1 H, NH-porphyrin), 0.71 (s, 6 H, CH_3-mesityl), 1.68 (t, $^3J_{H,H}$ = 7.59 Hz, 6 H, CH_3CH_2-porphyrin), 2.17 (s, 6 H, CH_3-mesityl), 2.29 (s, 6 H, CH_3-dimethylxanthene), 2.65 (s, 6 H, CH_3-mesityl), 2.93 (s, 6 H, CH_3-porphyrin), 3.33 (s, 6 H, CH_3-porphyrin), 3.49 (s, 6 H, CH_3-porphyrin), 3.89 (m, 4 H, CH_3CH_2-porphyrin), 6.62 (m, 2 H, H-dimethylxanthene), 7.29 (t, $^3J_{H,H}$ = 7.57 Hz, 1 H, H-dimethylxanthene), 7.33 (m, 5 H, 4 H_{meta}-mesityl + 1 H-dimethylxanthene), 7.96 (dd, $^3J_{H,H}$ = 8.01, $^4J_{H,H}$ = 1.53 Hz, 1 H, H-dimethylxanthene), 8.08 (dd, $^3J_{H,H}$ = 7.53, $^4J_{H,H}$ = 1.54 Hz, 1 H, H-dimethylxanthene), 8.23 (d, $^3J_{H,H}$ = 3.88 Hz, 2 H, H_β-corrole), 8.55 (d, $^3J_{H,H}$ = 4.64 Hz, 2 H, H_β-corrole), 8.73 (d, $^3J_{H,H}$ = 4.01 Hz, 2 H, H_β-corrole), 8.96 (d, $^3J_{H,H}$ = 4.56 Hz, 2 H, H_β-corrole), 9.94 (s, 3 H, H_{meso}-porphyrin) ppm. MS (MALDI/TOF): *m/z* = 1246.98 $[M]^{+\cdot}$; 1246.54 calcd. for $C_{82}H_{78}N_8O$. X-ray Crystallography: X-ray diffraction experiment and data processing: Dark green single-crystals of prismatic morphology were grown in a mixture of pyridine and cyclohexane. A specimen of good quality was selected for low-temperature [T = 115(2) K] X-ray diffraction. The X-ray source was graphite-monochromatized Mo-K_α radiation (λ = 0.71073 Å) from a sealed tube. Data were collected with a Nonius KappaCCD diffractometer, equipped with a nitrogen jet-stream low-temperature system (Oxford Cryosystems).[34] Lattice parameters were obtained by a least-squares fit to the optimised setting angles of all collected reflections observed up to the maximum diffraction angle $2\theta_{max}$ = 48°. Intensity data were recorded as φ and ω scans with κ offsets. Data reduction was performed using the DENZO program.[35] Table 3 shows crystal data and some experimental details. Structure solution and refinement: The structure was solved by direct methods using the SIR97 program.[36] Refinements were carried out by full-matrix least squares on F^2 using the SHELXL97 program[37] and the complete set of reflections. The applied weighting scheme was $w = 1/[\sigma^2(F_o^2) + (AP)^2 + BP]$ where $P = (F_o^2 + 2F_c^2)/3$, A and B being updated parameters (at convergence, A = 0.0715 and B = 4.8787). Anisotropic thermal parameters were used for non-H atoms. Most hydrogen atoms were observed from Fourier synthesis. Hydrogen atoms were placed at calculated positions using a riding model [except both H(–$N_{pyrrole}$) atoms belonging to the free porphyrin moiety, for which the structural parameters were refined]. All H atoms were refined with a global isotropic thermal factor. One ethyl group belonging to the porphyrin moiety was disordered over two positions, showing sites occupation factors of 0.58(2)/0.42(2). Two cyclohexane solvent molecules co-crystallized with the complex. CCDC-240510 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK, Fax: +44-1223/336-033, E-mail: deposit@ccdc.cam.ac.uk].

Stereoisomerism in Pentaerythritol-Bridged Cyclotriphosphazene Tri-Spiranes: Spiro and Ansa 1,3-Propanediyldioxy Disubstituted Derivatives

Aylin Uslu,*[a] Simon J. Coles,[b] David B. Davies,[c] Robert J. Eaton,[c] Michael B. Hursthouse,[b] Adem Kılıç,[a] and Robert A. Shaw[c]

Keywords: Cyclotriphosphazene derivatives / Trispiranes

Four isomeric products were isolated and purified from the reaction of 1,3-propanediol with the tri-spirane cyclophosphazene-organophosphate compound **1**: viz. the di-monospiro (**2a**), di-monoansa (**2b**) and two monospiro-monoansa derivatives (**2c** and **2d**). It is shown by ^{31}P NMR spectroscopy on addition of a chiral solvating agent (CSA) that both the di-monospiro **2a** and di-monoansa **2b** derivatives are racemates, as expected, whereas no splitting of NMR signals occurred on addition of CSA to solutions of **2c** and **2d**. It is found by X-ray crystallography that the two monospiro-monoansa spirane derivatives, **2c** and **2d**, are *meso* diastereoisomers, which represent a new case of the stereochemistry of bis(disubstituted) cyclophosphazene derivatives of **1**. It is also observed from the ^{31}P NMR spectrum of the reaction mixture, supported by the yields of pure compounds, that formation of a spiro group is about 4.5 times more likely than that of an ansa moiety under the conditions of the reaction.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Difunctional reagents with cyclophosphazenes can give rise to four structural types: spiro, ansa, bridged and open chain.[1] For example, the reaction of 1,3-propanediol with cyclotriphosphazene, $N_3P_3Cl_6$, gave spiro, $N_3P_3[O(CH_2)_3O]_xCl_{6-x}$ (x = 1,2,3); ansa, $N_3P_3[O(CH_2)_3O]Cl_4$; spiro-ansa, $N_3P_3[O(CH_2)_3O]_2Cl_2$; open chain, $N_3P_3[O(CH_2)_3OH]Cl_5$ and bridged, $N_3P_3Cl_5[O(CH_2)_3O]N_3P_3Cl_5$ compounds, in which spiro derivatives are by far the major product.[2] It is known that reaction of cyclotriphosphazene with a tetrafunctional alcohol such as pentaerythritol, $C(CH_2OH)_4$, gives a spirane-bridged compound **1**, whose structure (Figure 1) consists of four six-membered rings, each joined by a tetrahedral atom (phosphorus or carbon atom) to the next ring, with each six-membered ring being orthogonal to its neighbours.[3] The stereochemistry of bis(disubstituted) cyclophosphazene derivatives of **1** has recently been elucidated;[4] it was shown that racemates were observed for bis(geminal) derivatives, as well as for non-geminally disubstituted *cis* and *trans* (the latter has two diastereoisomers) derivatives. In the present work, the reaction of the spirane-bridged compound **1** with 1,3-propanediol was investigated and four isomeric disubstituted spiro and ansa derivatives **2a**–**d** were isolated (Figure 1).

Two of the products **2a**–**b** gave rise to chiral compounds corresponding to cases observed previously [bis(disubstitution that is geminal or *cis* non-geminal],[4] whereas the other two derivatives **2c**–**d** have geminal disubstitution in one cyclophosphazene ring and *cis* non-geminal disubstitution in the other cyclophosphazene ring, giving rise to a new case of chirality in such systems, in which both compounds are *meso* diastereoisomers.

Results and Discussion

The spirane-bridged compound **1**, was allowed to react with 1,3-propanediol in a 1:2 mol ratio to give four disubstituted isomers **2a**–**d**, which were separated by column chromatography. Overall, there was a yield of about 25% with compound **2a** (14.9%) being the major product, and with minor yields of **2b** (2.5%) **2c** (4%) and **2d** (3.5%). The products were characterised by elemental analysis, mass spectrometry and ^{31}P NMR spectroscopy. Elemental analysis and mass spectrometry give the same results for the four compounds, as expected for isomers.

The proton-decoupled ^{31}P NMR spectra of **2a** and **2b** are observed (Figure 2, a and b, respectively) as ABX spin systems resulting from the two phosphazene rings in each compound having the same substitution pattern. However, the two ABX spin systems are quite different as in **2a** the X-part is ca. 26–27 ppm and the AB portion is 8–11 ppm, whereas the X-part of **2b** is ca. 11 ppm and the AB portion is 30–32 ppm. The assignment of signals of **2a** was assisted

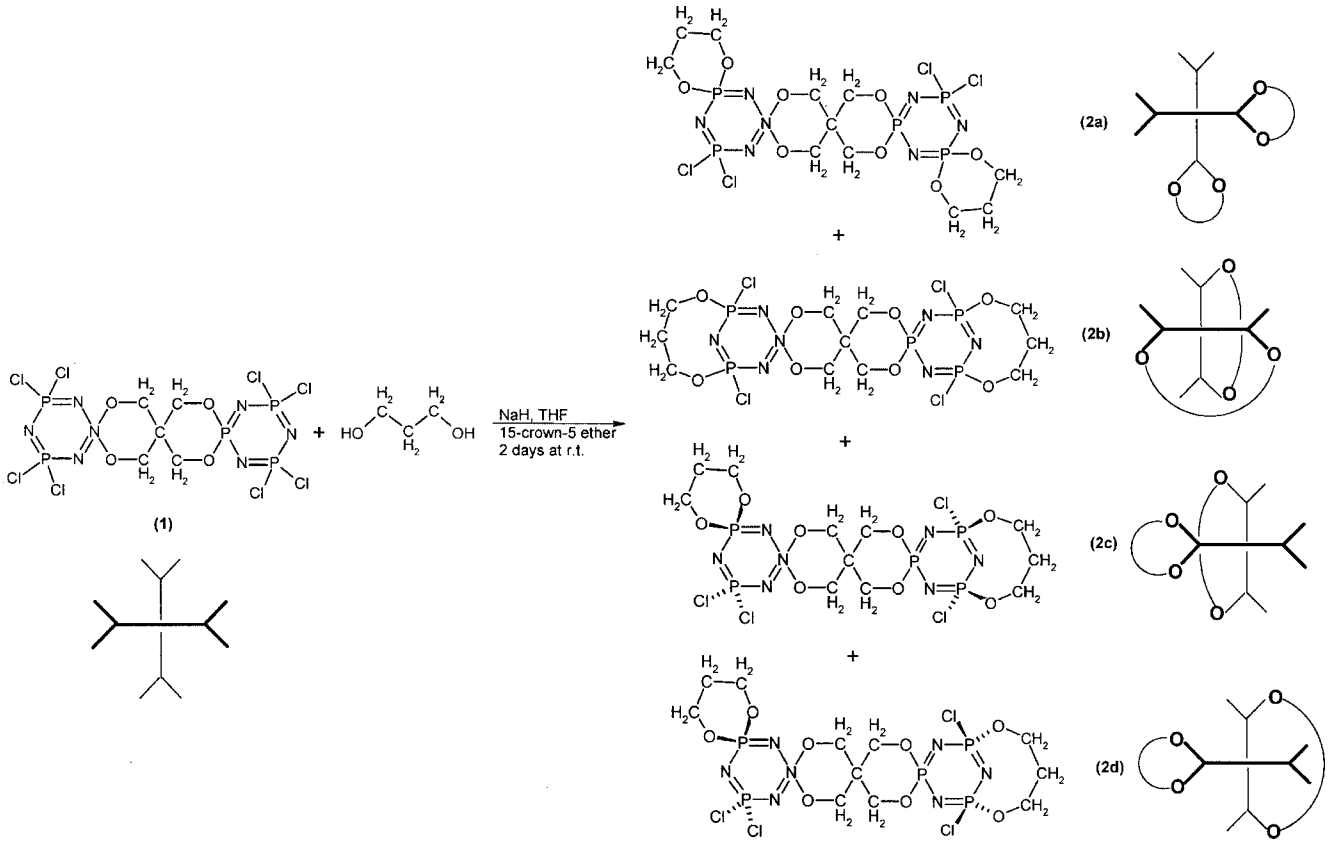

Figure 1. Structures of spirane-bridged unsubstituted, **1**, and disubstituted cyclotriphosphazene derivatives; di-monospiro **2a**, di-monoansa **2b**, and two monospiro-monoansa derivatives (**2c**, *syn*) and (**2d**, *anti*). A diagrammatic representation is also shown for compounds **1** and **2a**–**2d**. For clarity the inner organophosphate rings have been omitted and the outer cyclophosphazene rings, which are orthogonal to each other, are shown in the same projection with the ring to the front in bold type.

by proton-coupled ^{31}P NMR spectra [not shown], which indicates that the 26–27 ppm signal corresponds to a $>PCl_2$ group (no coupling) and the AB portion results from the >P(bridge) and >P(spiro) groups. The ^{31}P NMR spectrum of **2b** at 30–32 ppm is characteristic of a cyclotriphosphazene dioxy-ansa derivative with a relatively small ansa ring[5] and the signal at δ = 11 ppm is given by the >P(bridge) group; the ansa moiety is observed as an AB spin system because **2b** is a chiral diastereoisomer (see below). The ^{31}P NMR spectra are consistent with **2a** being the di-monospiro compound and **2b** being the di-monoansa compound. The ^{31}P NMR spectra of **2c** and **2d** (Figure 2, c and d, respectively) are very similar to each other and consist of five multiplets resulting from the superposition of an A_2X and an ABX spin system; the ABX spin system is similar to that for the spiro derivative **2a**, and the A_2X has similar chemical shifts and coupling constants to those found for the ansa derivative **2b**, but is A_2 rather than AB because compounds **2c** and **2d** are a *meso* diastereoisomers (see below). ^{31}P NMR indicates that both, **2c** and **2d**, are monospiro-monoansa compounds, having slightly different chemical shifts and coupling constants, especially for the spiro-substituted ring. The ^{31}P NMR spectroscopic data for compounds **2a**–**2d** are summarised Table 1.

By analogy with previous work on the stereochemistry of bis(disubstituted) cyclophosphazene derivatives of **1**,[4] it is expected that both compounds **2a** and **2b** are chiral and exist as racemates. The di-monospiro compound **2a** is the case of a bis(geminal) derivative and the di-monoansa compound **2b** has non-geminal disubstitutents that are *cis*.[4] On addition of a chiral solvating agent [CSA, (*S*)-(+)-2,2,2-trifluoro-1-(9′-anthryl)ethanol] it was found that all the ^{31}P NMR signals of compounds **2a** and **2b** exhibit chemical shift changes indicating complexation with the CSA, and that all signals, except the >P(bridge) group of compound **2b**, separate into two lines of equal intensity consistent with compounds **2a** and **2b** existing as racemates. The change in ^{31}P NMR chemical shifts and separation of signals of compounds **2a** and **2b** at a 20:1 mol ratio of CSA:**2a** or **2b** are summarised Table 1. Addition of CSA to compounds **2c** and **2d** also caused changes in chemical shifts of each signal (Table 1), but no separation of signals even at higher mol ratios of 50:1 (**2c**) and 40:1 (**2d**). These results indicate that CSA complexes to compounds **2c** and **2d** in solution, and that both molecules may be *meso*, because CSA does not cause extra splitting of the NMR peaks. Such a caveat needs to be made, in the first instance, because previous NMR work has shown splitting of peaks for *meso* com-

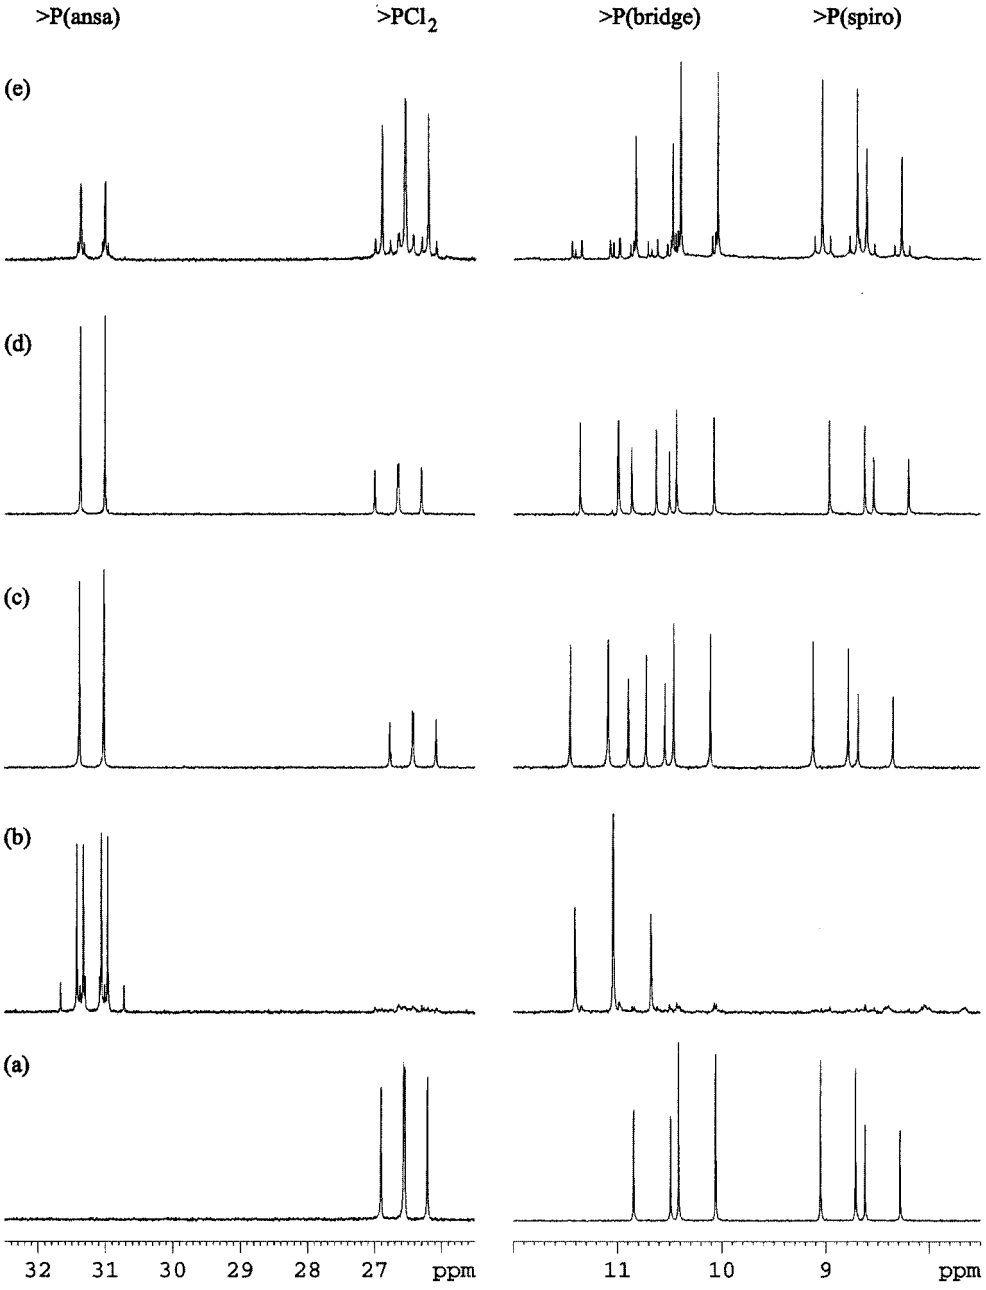

Figure 2. ^{31}P NMR spectra of the reaction mixture and the isolated four isomers of 1,3-propanediyldioxy derivatives of pentaerythritol-bridged cyclotriphosphazenes. (a) **2a**, spiro-spiro, (b) **2b**, ansa-ansa, (c) **2c**, *syn*-spiro-ansa, (d) **2d**, *anti*-spiro-ansa, (e) reaction mixture.

pounds with remote stereogenic centres on addition of CSA (and Chiral Shift Reagents, CSR).[6] However, in the case of compounds **2c** and **2d** the centres of chirality in the cyclophosphazene ansa moiety are part of the same ring and only two bonds apart and so complexation with CSA will affect both centres at the same time, as is normally found for other analogous systems,[6] i.e. the anomalous ^{31}P NMR effect with CSA is not expected for compounds **2c** and **2d** and so both are expected to be *meso* compounds.

Although NMR spectroscopy has been used to show that both compounds **2c** and **2d** are different monospiro-monoansa derivatives, such data cannot be used to assign an absolute structure and hence compounds **2c** and **2d** were characterised by X-ray crystallography.

The crystal structures of **2c** and **2d** (Figure 3) show that both molecules contain six rings, two phosphazene units bridged by a pentaerythritol molecule in a spirane arrangement, a spiro-$O(CH_2)_3O$ unit in one cyclophosphazene ring and an ansa-$O(CH_2)_3O$ moiety in the *cis*-configuration in the other cyclophosphazene ring.[7]

In both **2c** and **2d** the cyclophosphazene ring is essentially planar for the spiro-containing moiety, whereas for the ansa-substituted moiety the cyclophosphazene ring is non-planar, indicating strain which is relieved by the ring

[a] 202.45 MHz ^{31}P NMR measurements in $CDCl_3$ solutions at 298K. CSA is chiral solvating agent, (*S*)-(+)-2,2,2-trifluoro-1-(9′-anthryl) ethanol. [b] AB coupling for ^2J(P,P)/Hz in ansa ring. [c] $\Delta\delta$ is the difference in chemical shift (ppb) of racemic signals at a mol ratio of CSA:**2** of 20:1. [d] No separation of signals observed up to a mol ratio of CSA:**2** of 50:1. [e] No separation of signals observed up to a mol ratio of CSA:**2** of 40:1.

nitrogen atom containing the ansa moiety being significantly out of plane; 0.262 Å **2c** and 0.289 Å **2d**.[8] The difference between the two structures is that in **2c** the ansa- and spiro-propanediyldioxy units are in a *syn* arrangement, whereas in **2d** there is an *anti* arrangement of the ansa- and spiro-propanediyldioxy units. The *syn* and *anti* structures are shown in Figure 1 for **2c** and **2d**, respectively, from which it can be clearly seen that both molecules have a plane of symmetry and so are not chiral, confirming the ^{31}P NMR results. The stereochemistry of bis(disubstituted) cyclophosphazene derivatives of **1** has recently been elucidated[4] and compounds **2c** and **2d** give rise to a new case of stereochemistry of these spirane derivatives.

The ^{31}P NMR spectrum of the reaction mixture of compound **2** is shown in Figure 2(e). Using the NMR spectroscopic data in Table 1, it is possible to assign all the ^{31}P NMR signals in the reaction mixture to the four disubstituted compounds **2a**–**2d** (i.e. there is no evidence of the starting material, mono-substituted or higher substituted compounds). Assuming similar relaxation times for ^{31}P NMR signals of phosphorus nuclei with similar substitution patterns, the analysis gives spiro-spiro **2a** (ca. 70%), *syn*-spiro-ansa **2c** = *anti*-spiro-ansa **2d** (ca. 12%) and ansa-ansa **2b** (ca. 6%), which corresponds to the formation of a spiro being about 4.5 times more likely than that of an ansa moiety. This was confirmed by the similar relative distribution of compounds observed as a result of isolation and purification after column chromatography (**2a**, ca. 60%; **2b** ca. 10%; **2c** ca. 16%; **2d** ca.14%), though the results do not match exactly, because there are likely to be small differences in the efficiency of isolation and purification of the four compounds. The preference for spiro over ansa 1,3-propanediyldioxy derivatives of cyclophosphazene is not surprising given that the spiro ring is a six-membered thermodynamically stable chair form, in contrast to the eight-membered strained ansa ring.[8] In fact, it is somewhat surprising that significant quantities of the ansa derivatives are formed. However, in the reactions of cyclophosphazenes with diols in THF solution it has been observed[9–12] that the formation of ansa derivatives is promoted by using the more reactive sodium alkoxides (rather than the less reactive neutral pentaerythritol and tertiary base used previously[3]). It was also expected[11,12] that addition of 15-crown-5 ether (which should make the nucleophilic alkoxide more reactive by reducing ion-pairing) might also assist in the formation of ansa derivatives with 1,3-propanediol in this work. The reaction conditions for the formation of spiro and ansa derivatives of cyclophosphazenes with diols are currently being investigated.

Experimental Section

Materials: Hexachlorocyclotriphosphazene (Shin Nisso Kako Co Ltd.) was purified by fractional crystallisation from hexane. The following chemicals were obtained from Merck: Pentaerythritol (> 98%), 1,3-propanediol (> 98%), silica gel 60, tetrahydrofuran (≥ 99.0%), dichloromethane (≥ 99.0%), ethyl acetate (≥ 99.0%), *n*-hexane (>96%), sodium hydride (> 60%), 15-crown-5 ether (> 98%). The deuteriated solvent ($CDCl_3$) for NMR spectroscopy was obtained from Apollo Scientific and the chiral solvating agent (CSA), (*S*)-(+)-2,2,2-trifluoro-1-(9′-anthryl)ethanol, from Aldrich Chem. Co.

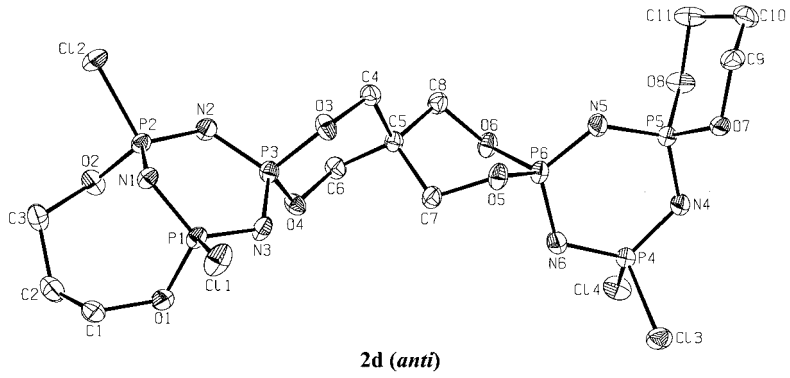
2c (*syn*)



2d (*anti*)

Figure 3. X-ray crystal structures of the two monospiro-monoansa derivatives **2c** and **2d**.

Methods: Elemental analyses were obtained with a Carlo–Erba 1106 Instrument. Mass spectra were recorded with a VG Zab Spec GC-MS spectrometer using the fast atom bombardment (FAB) method (35 kV) with MNBA as the matrix; ^{35}Cl values were used for calculated masses. Analytical thin layer chromatography (TLC) was performed on Merck Silica gel plates (Merck, Kieselgel 60, 0.25 mm thickness) with F_{254} indicator. Column chromatography was performed on silica gel (Merck, Kieselgel 60, 230–400 mesh; for 3 g. crude mixture, 100g. silica gel was used in a column of 3 cm in diameter and 60 cm in length). ^{31}P NMR spectra were recorded in $CDCl_3$ solutions with a Bruker DRX 500 MHz spectrometer using 85% H_3PO_4 as an external reference for ^{31}P. In order to assign the signals of some compounds both proton-coupled and proton-decoupled ^{31}P NMR spectra were recorded. Experiments involving the chiral solvating agent (CSA) were performed by addition of small aliquots of a concentrated solution of CSA in the solvent used for NMR spectroscopy and the proton-decoupled ^{31}P NMR spectrum recorded at each addition.

X-ray Crystallography: X-ray structure determination and crystallographic data were collected by means of combined phi and omega scans with a Bruker–NoniusKappaCCD area detector situated at the window of a rotating anode (λ, Mo-K_α = 0.71073 Å). The structures were solved by direct methods, SHELXS-97 and refined by using SHELXL-97.[13] Hydrogen atoms were included in the refinement, but thermal parameters and geometry were constrained to ride on the atom to which they are bonded. The data were corrected for absorption effects using SORTAV.[14] The structure of **2c** exhibits crystallographic disorder about the mirror axis in the space group. In addition a disordered solvent molecule was also present, but was too disordered to resolve and was therefore removed from the model using the SQUEEZE[15] procedure from within the PLATON[16] suite of programs (Table 2).

Reaction of Compound 1 with 1,3-Propanediol To Give Compounds 2a–d: Compound **1** was prepared as in the literature.[3] To a stirred solution of compound **1** (2 g, 2.92 mmol) dissolved in dry tetrahydrofuran (20 mL) at –15 °C under argon was first added dropwise 1,3-propanediol (0.4 g, 5.84 mmol) in dry tetrahydrofuran (20 mL), then sodium hydride (0.28 g, 11.68 mmol) in dry tetrahydrofuran (20 mL) was added dropwise and finally 15-crown-5 (0.5 g) was

added. The reaction mixture was stirred for a further 2 days at room temperature and the reaction was followed by TLC indicating four products and no starting material remaining. The precipitated salt (NaCl) was then filtered off, the solvent was removed under reduced pressure and four products were isolated by column chromatography [silica gel 60 (70–230 mesh) as adsorbent and ethyl acetate/*n*-hexane (1:2) as eluent]. The order of compounds eluted is **2d**, **2b**, **2a** and **2c** . Compound **2c** was crystallized from benzene and **2d** was crystallized from dichloromethane/hexane (3:1). **2a:** Yield 0.30 g (14.85%), m.p. 208 °C. (found: C 18.96, H 2.85, N 12.05. MS: *m*/*z* = 690.8 $[M + 1]^+$). **2b:** Yield 0.05 g (2.47%), decomp. 200 °C, (found: C 21.06, H, 2.86, N 12.11. MS: *m*/*z* = 691.0 $[M + 1]^+$). **2c:** Yield 0.08 g (3.97%), m.p. 170 °C, (found: C 20.25, H 2.89, N 12.12. MS: *m*/*z* = 690.7 $[M + 1]^+$). **2d:** Yield 0.07 g (3.47%), decomp. 140 °C, (found: C 20.21, H 2.74, N 11.96. MS: *m*/*z* = 690.7 $[M + 1]^+$). $C_{11}H_{20}Cl_4N_6O_8P_6$: calcd. [7] The starting material, compound **1**, is a linear tri-spirane, in which all the organophosphate and cyclotriphosphazene spirane moieties are six-membered and the shape of the ring system may be described as planar/chair/chair/planar. The introduction of spiro substituents creates further six-membered spirane rings, whereas ansa substituents form eight-membered rings giving rise to fused bicyclic systems. Thus the spiro-spiro derivative, **2a**, is a penta-spirane with the two terminal spirane rings at an angle to the linear central four. The ansa-ansa compound, **2b**, is a tri-spirane with both ends having fused bicyclic units. The two spiro-ansa isomers, **2c** and **2d**, are tetra-spiranes and have one end with a fused bicyclic structure. The ring system of the *syn* compound **2c** may be described as chair/planar/chair/disordered-chair/fused-envelope and the *anti* compound **2d** as chair/planar/twisted-chair/chair/fused-envelope. All the CH_2 groups are staggered with respect to their nearest neighbours and eclipsed with those two bonds away, except in the twisted chair, where they are staggered.

[8] The fused bicyclic ansa structures exhibit a boat-chair form. The ring N atom sandwiched between the two P–O ansa segments is forced out of the rest of the plane of the N_2P_3 ring to such an extent that it is nearly parallel with the adjacent P–Cl bonds. This distortion causes a ring compression. The respective non-bonded P···P distances for the spiro and ansa N_3P_3 rings for these two diastereoisomers are for the *syn* compound **2c** (spiro 2.724, 2.729 and 2.763 Å and ansa **2.636**, 2.725 and 2.726 Å) and for the *anti* compound **2d** (spiro 2.745, 2.760 and 2.764 Å and ansa **2.637**, 2.735 and 2.741 Å).

Solution, Structural and Catalytic Studies of Neutral MCl_2 (M = Pd, Pt) Complexes of the N/E Mixed-Donor Ligands 2-$(RECH_2)C_5H_4N$ (RE = MeS, PhS, MeSe)

Roderick C. Jones,[a] Rachael L. Madden,[a] Brian W. Skelton,[b] Vicki-Anne Tolhurst,*[a] Allan H. White,[b] Alan M. Williams,[a] Adele J. Wilson,[a] and Brian F. Yates[a]

Keywords: Palladium / Platinium / N,S ligands / Homogeneous catalysis / Fluxional processes

The reaction of MCl_2 (M = Pd, Pt) with one mole-equivalent of **L** [**L** = 2-$(MeSCH_2)C_5H_4N$ (**L**^{1}), 2-$(PhSCH_2)C_5H_4N$ (**L**^{2}), 2-$(MeSeCH_2)C_5H_4N$ (**L**^{3})] in MeCN gave the monomeric complexes [MCl_2**L**] in good yields. Single-crystal X-ray diffraction studies of [MCl_2**L**^{2}] confirmed the complexes to be monomeric with square-planar geometry about the metal centre. Variable-temperature NMR spectroscopy showed that the complexes undergo fluxional processes in solution, which were confirmed, by DFT calculations, to be (*E*)-pyramidal inversion at the chalcogen centre rather than ring-flip or (*E*)-dissociation processes. The calculations showed that the barrier to inversion increases in the order S<Se<Te. All complexes were characterised using ^{1}H NMR, UV/Vis and IR spectroscopy and microanalysis.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Palladium(II) and platinum(II) complexes containing dithioether ligands have been extensively studied in recent years,[1–3] leading to an understanding of the *S*-pyramidal inversion process in solution. Reports of similar compounds containing diselenoether and ditelluroether ligands are now more prevalent and include solution properties ascertained by using multinuclear NMR spectroscopy.[4] In contrast, complexes containing mixed-N/S or N/Se donor groups have not been as extensively studied, nor have these studies generally included systematic investigations into the complexes' behaviour in solution.

The use of hemilabile ligands in catalysis is gaining interest, as these ligands are thought to give better catalyst stability and higher yields compared to catalysts containing homoleptic ligands.[5] It has been suggested that the enantioselectivity observed in Pd-catalysed enantioselective allylic alkylation may be related to the pyramidal inversion at the sulfur donor atom in complexes containing thioether ligands.[6] Organo-palladium(II) complexes containing the mixed-donor ligand 2-$(RSCH_2)C_5H_4N$ (R = Me, Ph) undergo allene insertion into Pd–C bonds.[7,8]

Herein we report the preparation of a number of palladium(II) and platinum(II) complexes containing the mixed-donor ligands 2-$(RECH_2)C_5H_4N$ [E = S, R = Me (**L**^{1}), Ph (**L**^{2}); E = Se, R = Me (**L**^{3})] and the single-crystal structure determinations of isomorphous [$PdCl_2$**L**^{2}] and [$PtCl_2$**L**^{2}]. We have investigated the solution behaviour of these complexes using variable-temperature NMR spectroscopy. Density Functional Theory calculations have been employed to determine the likely processes being observed. Trends in (*E*)-pyramidal inversion barriers for the complexes have been compared with those associated with Pd^{II} and Pt^{II} complexes containing homoleptic dithio- and diselenoether ligands. Studies into the solid-state structures and solution properties are important for understanding the usefulness of these complexes as catalysts as they infer information on the strength of the ligand-metal interactions. We also report the catalytic activity of the Pd^{II} complexes [$PdCl_2$**L**^{1}] and [$PdCl_2$**L**^{2}] in the Heck reaction, by using various aryl halides and olefins. The efficiencies of these complexes in this reaction are compared to those for the analogous complexes containing the homoleptic ligands 2,5-dithiahexane ($MeS(CH)_2SMe$) and bipyridine (bipy).

Results and Discussion

Neutral [MCl_2L] Complexes (M = Pd, Pt)

The reactions of **L**^{1}, **L**^{2} and **L**^{3} with $PdCl_2$ or $PtCl_2$ in MeCN at ambient temperature afforded the complexes

$[MCl_2L]$ {M = Pd, **L** = $\mathbf{L^1}$ (**1a**), $\mathbf{L^2}$ (**2a**), $\mathbf{L^3}$ (**3a**); M = Pt, **L** = $\mathbf{L^1}$ (**1b**), $\mathbf{L^2}$ (**2b**), $\mathbf{L^3}$ (**3b**)} in good to high yields as yellow powders (Scheme 1). All complexes were air stable and had poor solubility in most solvents except DMSO. Liquid-secondary-ionisation (LSI) mass spectra of all complexes exhibited ions corresponding to the molecular ion with loss of one halide atom. The IR spectra for all compounds showed all observed stretches corresponding to those of the coordinated ligand. The UV/Vis spectra of these compounds exhibited peaks consistent with square-planar geometries.

Scheme 1. Preparation of Pd(II) and Pt(II) chloride complexes.

Room-temperature ^{1}H NMR spectra of the complexes in [D_6]DMSO exhibit resonances between 9.13–6.63 ppm, ascribed to the pyridyl rings of the ligands. A second-order AB spin system is observed for the methylene protons of the α-carbon upon coordination to the metal centre for each compound. This is due to the formation of a new stereogenic centre at each chalcogen upon coordination. The methyl protons in complexes **1(a,b)** and **3(a,b)** are obscured by the [D_6]DMSO resonance.

Fluxional Behaviour and Theoretical Calculations

The appearance of a second-order AB spin system at ambient temperature in the ^{1}H NMR spectra for all complexes led us to undertake variable-temperature ^{1}H NMR studies. On warming the complexes in solution, the resonances of the methylene protons coalesced for most complexes to form broad singlets. Coalescence temperatures of the methylene protons in the complexes are listed in Table 1. Three fluxional processes can occur in these complexes: (a) conformational changes of the chelate ring (ring flip, Figure 1a) where the transition state contains a nearly flat five-membered chelate ring which is quasi-coplanar with the coordination plane of the metal, (b) pyramidal inversion at the chalcogen, where the transition state has a planar five-membered ring, and the terminal substituent is also in the same plane as the coordination plane of the metal centre (Figure 1b), and (c) dissociation of the chalcogen donor atom from the palladium centre (Figure 1c). Variable-temperature NMR studies of palladium(II) and platinum(II) complexes containing chelating dichalcogenoether ligands have established that the coalescence of resonances at high temperatures is due to pyramidal inversion at the chalcogen.[2,3,9,10]

Table 1. Coalescence temperatures for compounds.

Complex	Coalescence temperature [°C]
$\mathbf{L^1}$ 2-$(MeSCH_2)C_5H_3N$	
$PdCl_2L$	95
$PtCl_2L$	>160
$\mathbf{L^2}$ 2-$(PhSCH_2)C_5H_3N$	
$PdCl_2L$	90
$PtCl_2L$	157
$\mathbf{L^3}$ 2-$(MeSeCH_2)C_5H_3N$	
$PdCl_2L$	82
$PtCl_2L$	110[a]

[a] Decomposes at this temperature in solution.

Density Functional Theory (DFT) calculations confirm that the fluxional process observed for the complexes described here is not a ring-flip process, which has a calculated activation energy of 2.7 kJ mol^{-1} for the complex $PdCl_2\mathbf{L^1}$ (in contrast, sulfur-pyramidal-inversion and sulfur-dissociation processes for $PdCl_2\mathbf{L^1}$ have calculated activation energies of 71.7 and 92.0 kJ mol^{-1}, respectively). This suggests that the ring inversion process is already occurring at room temperature, thus explaining the presence of only one AB spin system rather than two, as would be expected for two possible conformers given the similar energies of the two.

The calculated energy difference between the two conformers, the barrier to (*E*)-pyramidal inversion and the barrier to (*E*)-dissociation for $[MCl_2L]$ {M = Pd, Pt; **L** = 2-$(MeECH_2)C_5H_4N$ where E = S ($\mathbf{L^1}$), Se ($\mathbf{L^3}$), Te ($\mathbf{L^4}$)} are listed in Table 2. All $\Delta H^{\ddagger}$ values listed here have been zero-point corrected for enthalpy. Structures **II** and **III** are enantiomers, so the energy for only one enantiomer was calculated, as both are of equal energy.

Trends observed in the calculated energy barriers to (*E*)-pyramidal inversion for the Pd^{II} and Pt^{II} complexes containing the mixed-donor ligands are similar to those seen for the analogous complexes containing dichalcogenoether ligands. Pyramidal inversion at the chalcogen centres of the palladium complexes occurs at lower energies relative to those of the platinum compounds, consistent with a stronger Pt–E bond compared with Pd–E, as is also observed in the solid-state structures of $[MCl_2\mathbf{L^2}]$ (**2a**, **2b**). There is also an increase in the barrier to chalcogen pyramidal inversion in the order S < Se < Te. This trend is also observed in the compounds containing the homoleptic ligands. However, the relative increase in the energy barrier is considerably larger for the heteroleptic complexes compared with the homoleptic complexes. For instance, the energy difference between the complexes $[PtClMe\{MeS(CH_2)_2SMe\}]$ and $[PtClMe\{MeSe(CH_2)_2SeMe\}]$ is 10.9 kJ mol^{-1} where inversion occurs *trans* to the coordinated methyl group,[2] whereas the increase in inversion energy between the complexes $[PtCl_2\mathbf{L^1}]$ and $[PtCl_2\mathbf{L^3}]$ calculated here is 29.8 kJ mol^{-1}. However, this could be consequent on the difference in the *trans*-effect of the methyl compared to the chloride group on the chalcogen.

Energies associated with the full dissociation of the chalcogen donor atom from the metal centre are generally

$PdCl_2$L	2.2	97.5	95.3
$PtCl_2$L	2.0	119.1	131.1
2-($MeTeCH_2$)C_5H_3N (**L**^{4}) [b]			
$PdCl_2$L	3.5	118.7	119.2
$PtCl_2$L	1.75	141.2	150.8

[a] Energy relative to **I** (0 kJ mol^{-1}). [b] Synthesis of **L**^{4} and its compounds have not been reported. [c] Energy of **I** relative to **III** (0 kJ mol^{-1}).

higher than those of the (*E*)-inversion processes by 10–40 kJ mol^{-1} except for [$PdCl_2$**L**] (**L** = **L**^{3}, **L**^{4}) where the two processes have similar energies. This is consistent with the better orbital overlap between the softer selenium and tellurium donor atoms with platinum compared to the harder palladium centre affording stronger M–Se and M–Te bonds for platinum.

Structures of [$PdCl_2$**L**^{2}] (2a) and [$PtCl_2$**L**^{2}] (2b)

The solid-state structures of **2a** and **2b** are isomorphous, with both complexes crystallising in the monoclinic space group $P2_1/n$, and the molecules being discrete monomers, one comprising the asymmetric unit of each. The structure of [$PdCl_2$**L**^{2}] is shown in Figure 2. Crystallographic data of

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

2a and **2b** are listed in Table 3, with important bond distances and angles given in Table 4. The molecules of **2a** and **2b** contain four-coordinate metal centres with square-planar geometry with slight tetrahedral distortion, with the ligand acting as a bidentate.

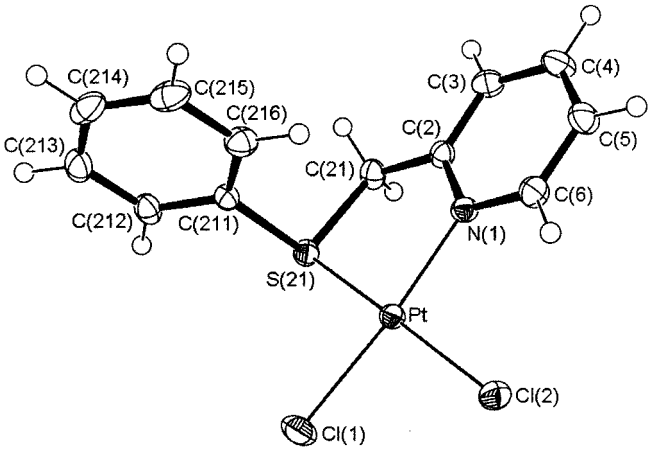

Figure 2. Molecular projection of $[PtCl_2\mathbf{L^2}]$ showing the atom labelling scheme. Thermal ellipsoids are drawn at the 50% probability level. $[PdCl_2\mathbf{L^2}]$ is isostructural.

C(2)–C(21)–S(21)–M	–20.1(1)	–21.4(3)

The Pd–N bond distance of 2.045(1) Å is shorter than that found in $[Pd(\eta^3\text{-allyl})\mathbf{L^2}](ClO_4)$ (2.088(5) Å).[11] This can be attributed to the difference in the *trans* effect of the chloride ion compared to that of the allyl group. The Pd–S bond distance of 2.2540(5) Å is similar to those observed in the similar compounds $[PdClMe(2\text{-}(MeSCH_2)C_5H_4N)]$ (2.257(5), 2.255(6) Å)[8] and $[PdClMe(2\text{-}(t\text{Bu}SCH_2)C_5H_4N)]$ (2.2589(13) Å)[7], where the sulfur atom is *trans* to a chloride group. The Pd–Cl bond distances of 2.2887(6) and 2.3162(5) Å, are similar to those seen in complexes where chloride is *trans* to nitrogen and sulfur, respectively.[12–14]

Pt–Cl bond distances of 2.296(1) and 2.316(1) Å, are again similar to those seen in complexes where the chloride atom is *trans* to nitrogen and sulfur, respectively.[14] They are also similar to those seen in the palladium complex **2a**, which is not surprising given that the ionic radii of Pd^{II} and Pt^{II} are the same within experimental error. The Pt–N bond distance of 2.034(3) Å is also similar to that in complex **2a** within experimental error. Interestingly, the Pt–S bond distance of 2.235(1) Å is significantly shorter than the Pd–S bond distance observed in **2a** [Δ_S = –0.019 Å, where Δ_S = *d*(Pt–S)-*d*(Pd–S)] while the Pt–Cl bond for the chloride *trans* to the sulfur atom is the same as the analogous Pd–Cl bond [2.316(1) vs 2.3162(5) Å]. Similar trends in bond distances in isomorphous structures of palladium and platinum complexes containing homoleptic and heteroleptic ligands have been observed, and theoretical calculations have been performed to explain the trend.[14–19] Results from theoretical calculations for the geometry optimisations of the complexes $[MMe_3\{(H_2C{=}N{-}NH)_3CH\}]^+$ compared well with the X-ray studies of isostructural $[MMe_3\{(pz)_3CH\}]^+$ (M = Pd, Pt), where the M–C bond distances are identical or slightly shorter for palladium and platinum while the Pd–N bonds are longer than the Pt–N bonds.[19] The explanation for this trend is attributed to the softer acidity of platinum compared with palladium. Steric influences on the trends in bond lengths, which were previously suggested as having an additional effect,[16,17] were eliminated after similar trends were found in the optimised geometries of *trans*-$[M(H)_2(CH_3)(NH_3)]^-$.[19]

The five-membered chelate ring formed by the bidentate ligand in both the palladium and the platinum complexes is puckered, with the sulfur atom lying out of the M, N, C(2), C(21) plane [χ^2 205 (Pd), 28 (Pt)] by 0.415(2) and 0.434(5) Å, respectively. This distortion and the larger Cl(2)–M–N(1) bond angle [94.50(3) (Pd), 94.2(1)° (Pt)] offset the smaller angles about the metal centre, including the small bite angle of the ligand [86.32(3) (Pd), 86.6(1)° (Pt)]. The ligand chelates the metal centre, with the pyridyl ring

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of the ligand lying almost in the same plane as the coordination plane of the metal centre {τ[M–N–C(6)–C(5)] 179.70(1) (Pd), 179.5(3)° (Pt)} and the phenyl substituent of the thioether almost perpendicular to this plane {τ[N–M–S(21)–C(211)] –93.12(6) (Pd), –92.5(2)° (Pt)}.

Catalytic Activity of $[PdCl_2L^1]$ (2a) and $[PdCl_2L^2]$ (2b)

The catalytic activity of $[PdCl_2\mathbf{L}]$ in the Heck reaction was investigated. The versatility of the compounds in this reaction was tested by using both an activated and deactivated aryl bromide, and terminal mono- and disubstituted alkenes, and an internal alkene. The catalytic results are listed in Table 5 and Table 6.

Table 5. Catalytic data for the Heck reaction of various aryl halides and alkenes.[a]

Aryl halide	Alkene	Conversion (%)[b]	TON
		>99	1,000,000[c]
		>99	1,000,000[c]
		94	94[d]
		>99	100[d]

[a] The reactions were carried out with 1.5 mol aryl halide, excess alkene, 2.2 mol NaOAc in 7 mL DMAc for 48 h. [b] Determined by GC (standard: diethylene glycol monobutyl ether). [c] Reaction carried out at 100 °C with 0.001 mol-% $[PdCl_2\mathbf{L^2}]$. [d] Reaction carried out at 120 °C with 1 mol-% $[PdCl_2\mathbf{L^2}]$.

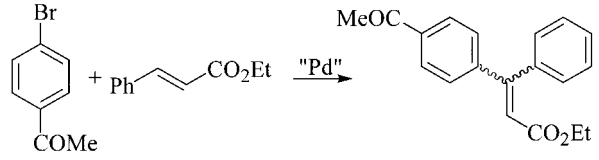
Table 6. Catalytic data for the Heck reaction of 4-bromoacetophenone and ethyl *trans*-cinnamate.[a]

Catalyst	Time [h]	Conversion [%][b]	*E*/*Z* Ratio[c]
$[PdCl_2\mathbf{L^1}]$	6	68	4.3:1
$[PdCl_2\mathbf{L^2}]$	6 (3)	83 (>99[d])	4.2:1 (>99:1)
$[PdCl_2(bipy)]$	6 (6)	56 (46)	4.3:1 (>99:1)
$[PdCl_2(MeS(CH_2)_2SMe)]$	6 (6)	64 (90)	4.6:1 (>99:1)

[a] The reactions were carried out with 1.5 mol 4-bromoacetophenone, 4.2 mol ethyl *trans*-cinnamate, 1 mol-% catalyst, 2.2 mol NaOAc in 7 mL DMAc at 140 °C for 6 h. Data in brackets correspond to reactions carried out with addition of 1.1 equiv. nBu$_4$NCl, 1.1 equiv. HCO_2Na at 80 °C for 6 h. [b] Determined by GC (standard: diethylene glycol monobutyl ether). [c] Determined by GC. [d] Conversion after 3 h.

The complex $[PdCl_2\mathbf{L^2}]$ was found to facilitate high turnover numbers (1,000,000) in the reaction between 4-bromoacetophenone and both *n*-butylacrylate and *n*-butylmethacrylate. In both reactions, only one product was observed by using GC. These turnover numbers are comparable to those of Herrmann's palladacycle, $\{Pd_2[P(o\text{-tol})_3]_2(\mu\text{-OAc})_2\}$, although this reaction is undertaken at 130 °C.[20] The reaction between 4-bromotoluene and *n*-butylacrylate and *n*-butylmethacrylate resulted in excellent conversion of the aryl halide with 94 and >99 % conversion achieved, respectively; however, the turnover number for neither reaction was as good as those for 4-bromoacetophenone.

More significantly, the reaction between 4-bromoacetophenone and ethyl *trans*-cinnamate was undertaken to see if the complexes facilitated the reaction using 1,2-disubstituted alkenes (Scheme 2). Intermolecular Heck reactions of internal alkenes are not often due to their low reactivity using typical catalysts.[21–23] The difficulty of this reaction is reflected in the high catalyst loadings and long reaction times required as well as other complications such as the possibility of both (*E*)- and (*Z*) isomers of the product being formed because of the high temperatures often required to undertake the reaction. Full conversion of 4-bromoacetophenone is achieved within 3 hours with $[PdCl_2\mathbf{L^2}]$, resulting in the formation of (*E*)-ethyl-3-(4-acetylphenyl)-3-phenyl-2-propenoate regio- and stereoselectively. This occurs at lower catalyst loadings relative to other similar reactions reported in the literature.[21,22] Fu and Littke have reported the reaction of deactivated aryl bromides with methyl *trans*-cinnamate at room temperature achieving 80 % isolated yield after 72 h with >20:1 *E*/*Z* selectivity by using 1.0 mol-% $Pd_2(dba)_3$ and 2.0 mol-% P(tBu)$_3$.[21]



Scheme2. Reaction of 4-bromoacetophenone and ethyl *trans*-cinnamate.

Modification of the hemilable ligands also results in significant differences in activity. When the reaction shown in Scheme 2 is conducted without the aid of phase-transfer agents and reducing agents, the phenylthioether-containing complex, $[PdCl_2\mathbf{L^2}]$, achieves higher conversion of the 4-bromoacetophenone (83 %) compared to the methylthioether-containing complex, $[PdCl_2\mathbf{L^1}]$ (68 %) after 16 hours at 140 °C, suggesting that the presence of a softer S-donor atom enhances the reactivity. This is consistent with theoretical calculations investigating the electronic and steric ligand effects on the activity of the Heck reaction, by using a substituted phenylpalladium(II) diimine complex.[24] Similar reactivity comparisons have been observed for the insertion reaction of allenes into Pd–C bonds.[7,8]

We also compared the catalytic activity in the Heck reaction of the heteroleptic complex $[PdCl_2\mathbf{L^2}]$ with that of $[PdCl_2(bipy)]$ (bipy = 2,2′-dipyridyl), a complex containing a homoleptic bidentate N-donor ligand, and $[PdCl_2(MeS(CH_2)_2SMe)]$, a complex containing a homoleptic bidentate S-donor ligand, again using the reaction shown in Scheme 2. As mentioned previously, the complex $[PdCl_2\mathbf{L^2}]$ facilitates the full conversion of 4-bromoacetophenone in 3 hours to form (*E*)-ethyl-3-(4-acetylphenyl)-3-phenyl-2-propenoate regio- and stereoselectively. In contrast, complexes containing the homoleptic nitrogen and sulfur ligands only achieved 46 and 90 % conversion, respectively, after 6 hours under the same conditions. If the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

reaction is done at higher temperatures, Pd black is produced in the two homoleptic systems, with significant amounts in the [$PdCl_2(MeS(CH_2)_2SMe)$] catalysed system, which indicates that catalyst degradation occurs readily. Degradation of catalysts containing the hemilable ligands was also observed, but probably occurred after the reaction was complete.

Conclusions

Neutral palladium(II) and platinum(II) complexes have been prepared containing the mixed-N/E donor ligands 2-$(RECH_2)C_5H_4N$ [E = S, R = Me (**L**^{1}), Ph (**L**^{2}); E = Se, R = Me (**L**^{3})].

DFT calculations have shown that the process observed in variable-temperature ^{1}H NMR studies is most probably due to either the (*E*)-pyramidal inversion process or (*E*)-dissociation processes rather than ring flip. For all platinum complexes and the palladium complex [$PdCl_2$**L**^{1}] the fluxionality is most probably due to the (*E*)-pyramidal inversion process, which is 10–40 kJ mol^{-1} lower in energy than the (*E*)-dissociation process. The cause of the fluxional process for the complexes [$PdCl_2$**L**] (**L** = **L**^{2}, **L**^{3}) is not as clear based on the DFT calculations. Both the (*E*)-pyramidal inversion and (*E*)-dissociation processes involve a weakening of the M–E bond. In the case of the heavier chalcogenoether-containing palladium complexes, the orbital overlap between the softer chalcogen atom and the harder palladium atom becomes mismatched, leading to a destabilising effect on the Pd–E bond during the processes. As a result, it is plausible that full (*E*)-dissociation may occur in these complexes rather than just a partial weakening of the Pd–E bond during the (*E*)-pyramidal inversion process. The trends observed in the barrier to (*E*)-pyramidal inversion for the complexes containing the mixed-donor ligand complexes reported here are the same as those observed for complexes containing homoleptic dichalcogenoether ligands. These include the barrier to (*E*)-inversion increasing in the order S<Se<Te, and Pd<Pt.

The isomorphous solid-state structures of [MCl_2**L**^{2}] (M = Pd, Pt) show that the thioether functional group is more strongly bound to the platinum than to the palladium as seen by a shorter Pt–S bond compared to the Pd–S bond, probably due to the softness of the platinum centre.

The complexes [$PdCl_2$**L**] (**L** = **L**^{1}, **L**^{2}) were found to facilitate the Heck reaction of various aryl bromides with terminal and internal alkenes with excellent conversions. In the case of the reaction of 4-bromoacetophenone with ethyl *trans*-cinnamate, full conversion of the aryl bromide is achieved to form (*E*)-ethyl-3-(4-acetylphenyl)-3-phenyl-2-propenoate regio- and stereoselectively. The complex [$PdCl_2$**L**^{2}] was found to have higher catalytic activity compared to [$PdCl_2$**L**^{1}], suggesting that activity is promoted by the presence of the softer ligand. Both complexes containing the hemilabile ligands had higher catalytic activity than complexes containing homoleptic N- and S-donor containing ligands. At this stage it can not be discounted that the difference in catalytic activities is due to a difference in induction period and/or the efficiency in the reduction of the complexes to a Pd^0 catalytically active species. This is under further investigation.

Experimental Section

General Remarks: All reactions were done under nitrogen gas using standard Schlenk techniques. Palladium(II) chloride and platinum(II) chloride were obtained as a loan from Johnson Matthey, and used without purification. The ligands 2-$(RECH_2)C_5H_4N$ [E = S, R = Me (**L**^{1}), Ph (**L**^{2}); E = Se, R = Me (**L**^{3})] were prepared according to literature procedures.[25,11] All solvents were degassed prior to use. Infrared spectra were recorded as a KBr disc on a Bruker IF55 Infra-Red Spectrometer. LSIMS mass spectra of the complexes were recorded on a Kratos Analytical Concept ISQ mass spectrometer. ^{1}H NMR spectra were recorded on a Varian Gemini (200 MHz) or Unity (400 MHz) NMR spectrometer, in deuterated dimethylsulfoxide and referenced to the residual resonances of the solvent (δ = 4.33 ppm). Microanalyses (C,H,N,S) were determined by The Microanalysis Services, Central Science Laboratory, University of Tasmania.

[$PdCl_2$L**^{1}] (1a):** **L**^{1} (43 mg, 0.309 mmol) was added to a degassed solution of $PdCl_2$ (50 mg, 0.28 mmol) in MeCN (20 mL), and the reaction was stirred at room temperature for 16 hours. An orange precipitate formed over this time. The MeCN volume was reduced in vacuo (to about 2 mL) to afford a yellow precipitate. The solid was collected and washed with Et_2O (56 mg, 62 %). ^{1}H NMR (200 MHz, [D_6]DMSO): δ = 4.51, 4.85 (AB spin system, 2 H, CH_2), 7.60 (m, 1 H, C_6H_4N), 7.78 (m, 1 H, C_6H_4N), 8.13 (m, 1 H, C_6H_4N), 9.13 (m, 1 H, C_6H_4N) ppm. IR (KBr): $\tilde{\nu}$ = 3079 (m), 2987 (m), 2945 (vs), 2902 (s), 1606 (vs), 1481 (s), 1446 (s), 1381 (m), 1320 (w), 1274 (s), 1166 (s), 1111 (m), 1060 (m), 1030 (m), 978 (m), 863 (w), 825 (w), 769 (vs), 657 (w), 428 (w) cm^{-1}. *m*/*z* = 280 (M-Cl)$^+$ [^{106}Pd($^{12}C_7H_9N^{32}S$)^{35}Cl 280]. UV/Vis (DMSO)/cm^{-1}: $\tilde{\nu}_{max}$ (ε_{mol}/dm^3 mol^{-1} cm^{-1}) = 26170 (1113), 33600 (3537). $C_7H_9Cl_2PdNS$ (316.51): calcd. C 26.56, H 2.87, N 4.43; found C 26.99, H 2.83, N 4.63.

[$PtCl_2$L**^{1}] (1b):** The procedure described above using $PtCl_2$ afforded an off-white solid (75 %). ^{1}H NMR (200 MHz, [D_6]DMSO): δ = 4.50, 4.78 (AB spin system, 2 H, CH_2), 7.60 (m, 1 H, C_6H_4N), 7.87 (m, 1 H, C_6H_4N), 8.22 (m, 1 H, C_6H_4N), 9.45 (m, 1 H, C_6H_4N) ppm. IR (KBr): $\tilde{\nu}$ = 3116 (w), 3087 (m), 3000 (m), 2959 (vs), 2903 (s), 1612 (s), 1475 (s), 1427 (s), 1397 (m), 1321 (m), 1272 (m), 1168 (s), 1113 (w), 1063 (w), 996 (m), 977 (m), 901 (w), 773 (vs), 710 (w), 473 (w), 435 (w) cm^{-1}. *m*/*z* = 369 (M-Cl)$^+$ [^{195}Pt($^{12}C_7H_9N^{32}S$)^{35}Cl 369]. UV/Vis (DMSO)/cm^{-1}: $\tilde{\nu}_{max}$ (ε_{mol}/dm^3 mol^{-1} cm^{-1}) = 34400 (2502). $C_7H_9Cl_2NPtS$ (405.21): calcd. C 20.75, H 2.43, N 3.46; found C 20.91, H 2.26, N 3.44.

General Procedure for Heck Reactions: A degassed solution of aryl halide in dimethylacetamide (5.0 mL, 0.30 mol L^{-1}) was added to the alkene (0.70 mL), NaOAc (2.2 mmol), catalyst, $n$$Bu_4NCl$ (1.1 equiv.) and HCO_2Na (1.1 equiv.) in a Schlenk vessel under argon. The reaction was heated at the appropriate temperature for 3–48 hours. The reaction was then cooled to room temperature, after which 0.20 mL diethylene glycol monobutyl ether was added. An aliquot (1.00 mL) was taken from the reaction, diluted with CH_2Cl_2, and washed three times with a saturated aqueous solution of NaCl. The organic layer was dried over $MgSO_4$. The conversion of aryl halide and the *E*/*Z* product ratio of ethyl 3-(4-acetylphenyl)-3-phenyl-2-propenoate were then determined by GC.

X-ray Crystallographic Study: Suitable crystals for X-ray diffraction studies of [$PdCl_2$**L^2**] and [$PtCl_2$**L^2**] were grown from $MeNO_2$/Et_2O (vapour diffusion). Spheres of CCD area-detector diffractometer data for [$PdCl_2$**L^2**] and [$PtCl_2$**L^2**] were measured (Bruker AXS, ω-scans, monochromatic Mo-K_α radiation, λ = 0.7107$_3$ Å, $2\theta_{max}$ = 75°). $N_{t(otal)}$ reflections merging to N unique (R_{int} cited) after "empirical"/multiscan absorption correction (proprietary software), N_o with $F > 4\sigma(F)$ being considered "observed" and used in the full-matrix least-squares refinements. (x, y, z, U_{iso})$_H$ were refined for **2a** only, constrained in **2b**. Neutral atom complex scattering factors were employed within the context of the Xtal 3.7 program system.[26] Pertinent results are given above and in the Tables and Figures, the latter showing the 50 % probability amplitude displacement ellipsoids for the non-hydrogen atoms, hydrogen atoms having arbitrary radii of 0.1 Å.

Computational Methods: Full geometry optimisations were carried out with the use of the B3LYP[27,28] density functional level of theory combined with the LANL2DZ basis set (which incorporates the Hay and Wadt[29,30] small-core relativistic effective core potential and double-zeta valence basis set on palladium, platinum, sulphur, selenium and tellurium together with the Dunning/Huzinaga[31] double zeta basis set on other atoms). Sets of five d-functions were used in the basis sets throughout these calculations. For the optimised geometries, harmonic vibrational frequencies were calculated at the B3LYP level. All transition structures possessed one and only one imaginary frequency, and they were further characterised by following the corresponding normal mode towards each product and reactant. Single-point energies on B3LYP/LANL2DZ optimised geometries were calculated at the B3LYP level with the LANL2augmented:6-311+G(2d,p) basis set,[32] which incorporates the LANL2 effective core potential and augmented basis sets on the metals (the large f-polarised valence basis set of Bauschlicher and coworkers[33] was used for palladium and the LANL2TZ+(3f) basis set for platinum[34]) together with the 6-311+G(2d,p) basis set[35–37] on all other atoms (3–11G basis set was used for tellurium). Energies from these single-point calculations were combined with the zero-point vibrational energy corrections from the lower level of theory to yield ΔH_0 numbers. Unless otherwise noted all computed energies quoted in this paper refer to these final ΔH_0 numbers. All calculations were carried out with the Gaussian 03[38] program.

CCDC-228118 and CCDC-228119 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

XYZ Cartesian coordinates for all optimised structures described in this article are available as Supporting Information (see also the footnote on the first page of this article).

Acknowledgments

We acknowledge the Australian Research Council for funding this project. We also thank Johnson-Matthey for the generous loan of $PtCl_2$ and $PdCl_2$, and Prof. W. Levason and Dr. G. Reid for the [$PdCl_2$(MeS(CH_2)$_2$SMe)] sample.

Investigations into the Reactivity of Organoelement Gallium and Indium Subhalides – Syntheses of Digallium and Diindium Acetylacetonates

Werner Uhl,*[a] Abdelhakim El-Hamdan,[a] and Andreas Lawerenz[a]

Keywords: Gallium / Indium / Subvalent compounds / Acetylacetonate ligands

The organoelement subhalides $R_2Ga_2I_2$ (**1**) and $[R_2In_2Cl_2]_2$ (**2**) [R = $C(SiMe_3)_3$] react with silver acetylacetonate Ag(acac) (acac = $[OC(CH_3)]_2CH$) and lithium acetylacetonate Li(acac), respectively, to yield the di(acetylacetonato)dielement compounds $R_2E_2(acac)_2$ (**3**: E = Ga; **4**: E = In). Both products possess E–E single bonds with relatively long E–E distances of 251.1 (Ga–Ga) and 278.0 pm (In–In). The gallium or indium atoms are terminally coordinated by an alkyl and a bidentate acetylacetonato group. Similar reactions of the subhalides **1** and $[R_2In_2Br_2]_2$ with lithium diphenyltriazenide $LiN_3(C_6H_5)_2$ did not result in the formation of dielement compounds analogous with **3** and **4** but in the cleavage of the E–E bonds with formation of element(III) compounds of the type R–E(X)$[N_3(C_6H_5)_2]$ (E = Ga, In; X = Br, I).

Introduction

Organoelement subhalides of the heavier elements of the third main-group, i.e. aluminum, gallium, indium and thallium form an interesting class of compounds. They possess the elements in unusually low oxidation states with direct E–E interactions and are valuable starting materials for the generation of secondary products by salt elimination reactions. Their synthesis can be accomplished by several different methods such as (i) the treatment of tetrahalogenosubhalides of the type $X_2(L)E–E(L)X_2$ with aryl or silyl alkali-metal compounds in molar ratios of 1:1 or 1:2[1–4] (ii) the reduction of organogallium(III) compounds by alkali metals[5] (iii) the treatment of GaBr or "GaI" with organo lithium or sodium compounds accompanied by disproportionation of the third main-group element[1,6,7] (iv) the reduction of an indium(III) compound with an aminoborole[8] (v) the insertion of AlCp* into Al–I bonds of the aluminum triiodide dimer[9] and (vi) the careful oxidation of tetragallium or tetraindium clusters $E_4[C(SiMe_3)_3]_4$ with halogens or halogen donors.[10–13] The last method was introduced by our group and affords subhalides possessing different structures in reasonable yields. The transfer of one bromine molecule to the tetrahedral tetraindium cluster affords the compound $In_4Br_2[C(SiMe_3)_3]_4$ in which the tetrahedral arrangement of the indium atoms is retained but one triangular face of the In_4 tetrahedron and one edge of that face are bridged by bromine atoms.[11] The oxidation of all element(I) atoms of the starting clusters to an oxidation state of +II yields the element(II) halides R(X)E–E(X)R (E = Ga, In; X = Cl, Br, I) which possess E–E single bonds.[11–13] They remain monomeric even in the solid state for gallium whereas they form dimers with all halogen atoms in bridging positions for the indium derivatives. A chain of three indium atoms connected by two In–In single bonds was observed for the subhalide $In_3I_2[C(SiMe_3)_3]_3$[10] which resulted from the oxidation of the tetraindium cluster with elemental iodine in the presence of AlI_3.

These subhalides proved to be very effective starting compounds for the synthesis of secondary products by salt elimination reactions. For instance, several transition-metal gallium or indium compounds possessing quite different and interesting structures can be obtained by such a route on treatment with transition-metal carbonylate anions such as $[Fe(CO)_4]^{2-}$ or $[Fe_2(CO)_8]^{2-}$.[14–17] Silver or lithium carboxylates give dialkyldicarboxylatodielement compounds in which the carboxylato ligands occupy bridging positions across the relatively short E–E bonds.[18] Whereas the corresponding digallium compounds are easily available by the direct treatment of a tetraalkyldigallium(4) derivative $R_2Ga–GaR_2$ [R = $CH(SiMe_3)_2$] with carboxylic acids,[19–24] the In–In bonds of the diindium analogue $R_2In–InR_2$ are completely cleaved by oxidation of the indium atoms under similar conditions.[25] Thus, the reactions of these organoelement subhalides of gallium and, in particular, indium seem to offer a valuable route for the syntheses of new compounds which contain the elements in unusually low oxidation states and are not accessible by other methods. The behaviour of the dielement compounds $R_2E–ER_2$ towards acetylacetones is similar to that described for carboxylic acids. While substituent exchange with retention of the Ga–Ga bonds was observed for the digallium derivative, oxidation and cleavage of the In–In bond occurred with the diindium compound.[26,27] Diindium acetylacetonates containing an In–In bond may, however, be accessible by use

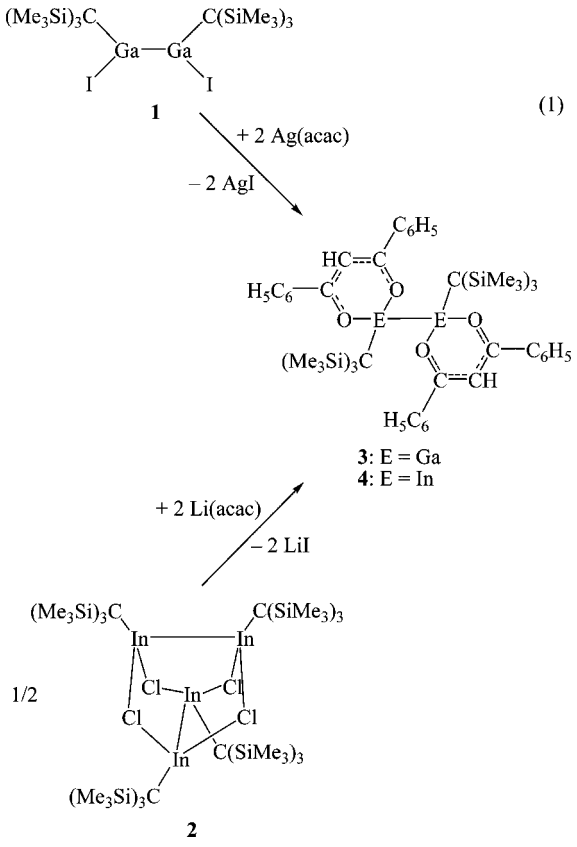
of the corresponding subhalides. We report here on the continuation of our systematic investigations into the reactivities of these subhalides and on their reactions with acetylacetonate and diphenyltriazenide anions.

Results and Discussion

Syntheses and Molecular Structures of the Di(acetylacetonato)digallium and-diindium Compounds 3 and 4

Treatment of the monomeric dialkyldigallium subiodide $R_2Ga_2I_2$ (**1**) [R = $C(SiMe_3)_3$] with lithium acetylacetonate gave a mixture of unknown products, none of which could be isolated in a pure form. We therefore employed silver acetylacetonate in order to enhance the driving force of the reaction with the formation of silver iodide. A suspension of the silver salt was treated with **1** at low temperature (–90 °C) and it appeared that the reaction was complete upon warming to –70 °C. Filtration was carried out at that temperature and subsequent workup yielded yellow crystals of the product **3** in 67% yield [Equation (1)]. In contrast, the corresponding reaction of the dimeric diindium subchloride $(R_2In_2Cl_2)_2$**2** with silver acetylacetonate gave decomposition only. Probably, the In–In bond was cleaved by oxidation of the indium atoms with the formation of unknown products. A silver mirror formed at the glass wall of the Schlenk tube. Lithium acetylacetonate now gave a clean reaction although reproducible yields after reasonable reaction times were obtained only upon warming of the mixtures in toluene to 50 °C. Pale yellow crystals of the product **4** were isolated in 66% yield after recrystallisation from *n*-hexane. The chemical shifts of the trimethylsilyl protons of both products **3** and **4** (δ = 0.44 and 0.42 ppm, respectively) are in the characteristic range for $C(SiMe_3)_3$ groups attached to Ga–Ga or In–In single bonds possessing coordinatively saturated Ga or In atoms (about δ = 0.4 to 0.5 ppm).[11,18] The integration ratios in the ^{1}H NMR spectra, too, were in accordance with the formulae given schematically in Equation (1) with intact Ga–Ga or In–In bonds and the replacement of both halogen atoms of the starting dielementdihalides by chelating acetylacetonato groups. We were not able to detect the resonance of the inner carbon atoms of the $C(SiMe_3)_3$ groups attached to the In–In bond, probably as a result of the quadrupole moment of indium. The corresponding ^{13}C NMR signal of the gallium compound appeared at δ = 5.0 ppm which is characteristic of compounds possessing coordination numbers of four at their gallium atoms. Usually, tetraalkyl- or tetraaryldielement compounds of the type R_2E–ER_2 (E = Ga, In) containing Ga–Ga or In–In single bonds and an empty p-orbital at each Ga or In atom are deeply coloured.[28] However, upon coordinative saturation of the central gallium atoms by introduction of chelating ligands such as a carboxylato[19–24] or imidotetraphenyldiphosphinato groups,[29] colourless digallium products were isolated. Colours observed for those compounds in some cases are caused by transitions within ligands which possess electronically delocalised bonding systems such as diphenyltriazenide.[30,31] Similar to the acetylacetonato digallium derivatives[26,27] cited in the introduction, compounds **3** and **4** are yellow. The longest wavelengths were observed at 345 and 355 nm, respectively, the absorption of the gallium compound **3** is broader than that of the diindium diacetylacetonate **4**. The mononuclear E(III) compounds $E(acac)_3$ (E = Al, Ga, In) were reported to be colourless to orange.[32–34] Absorptions in the UV/Vis spectra were assigned to π-π transitions within the ligands.[35]



The molecular structures of **3** and **4** determined by single-crystal X-ray diffraction studies are depicted in Figure 1 and Figure 2. The compounds are not isostructural. While the molecules of **3** are in general positions, the molecules of **4** reside on crystallographic twofold rotation axes. The chelating acetylacetonato ligands of both compounds are terminally coordinated to the gallium or indium atoms of the unsupported Ga–Ga or In–In single bonds. Each central atom is further attached to an alkyl group so that coordination numbers of four result. Although an approach to the *trans* arrangement of the ligands is observed for both structures, the molecules deviate more or less significantly from an ideal centrosymmetric conformation. The torsion angles across the E–E bonds (C–E–E–C) are 151.4(3)° and 146.4(1)°, respectively. The Ga–Ga and In–In bond lengths (251.1 and 278.0 pm) are relatively long and similar to those of tetraalkyldielement derivatives R_2E–ER_2 [R = $CH(SiMe_3)_2$].[28,36,37] Thus, the shortening usually detected

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

upon coordination of electronegative atoms to the E–E bonds[28] is not observed in these cases. Two dialkyldigallium compounds containing terminal acetylacetonato groups attached to their Ga–Ga bonds have been reported in the literature.[26,27,38] They show shorter Ga–Ga bond lengths of 244.3 pm on average. Owing to the smaller alkyl groups employed in these compounds [$CH(SiMe_3)_2$ compared with $C(SiMe_3)_3$ in **3** and **4**], we suppose that the long E–E distances of **3** and **4** may be caused by some steric interactions between their very bulky substituents. Accordingly, the Ga–C distances are longer in the tris(trimethylsilyl)methyl compounds described here (199 versus 204 pm). In contrast, the Ga–O distances are unaffected by the different alkyl groups and, at 195 pm,are almost indistinguishable between the compounds. An analogous dialkyldiindium compound was not obtained before so that a sound comparison of bond distances is difficult. However, the In–C bonds appear to be relatively long (221.2 pm).[37]

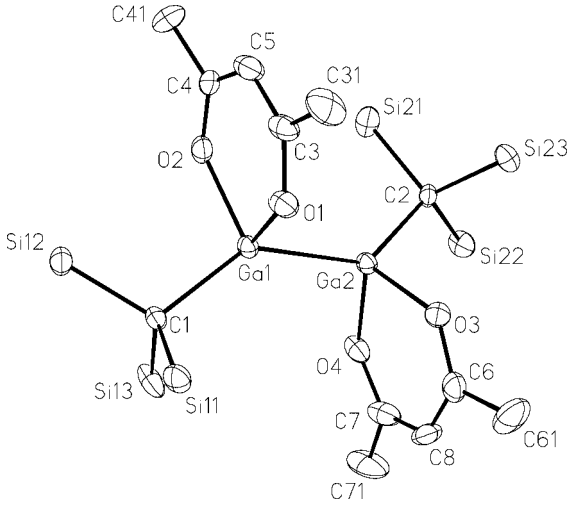


Figure 1. Molecular structure and numbering scheme of compound **3**. Thermal ellipsoids are drawn at the 40% probability level. Methyl groups of $SiMe_3$ substituents and hydrogen atoms are omitted. Selected bond lengths [pm] and angles [°]: Ga1–Ga2 251.12(8), Ga1–C1 204.0(5), Ga2–C2 204.5(6), Ga1–O1 195.1(3), Ga1–O2 195.7(4), Ga2–O3 195.1(3), Ga2–O4 195.1(4), Ga1–Ga2–C2 134.1(1), Ga2–Ga1–C1 133.8(1), O1–Ga1–O2 91.3(2), O3–Ga2–O4 91.3(2).

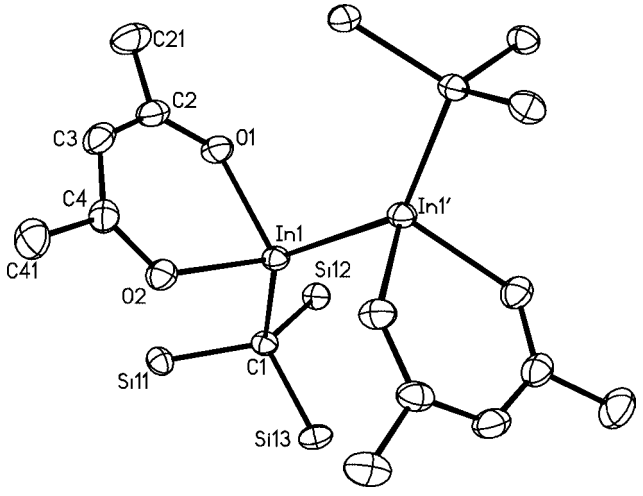

Figure 2. Molecular structure and numbering scheme of compound **4**. Thermal ellipsoids are drawn at the 40% probability level. Methyl groups of $SiMe_3$ substituents and hydrogen atoms are omitted. Selected bond lengths [pm] and angles [°]: In1–In1′ 278.04(7), In1–C1 221.3(2), In1–O1 216.3(1), In1–O2 216.0(1), In1′–In1–C1 136.73(5), O1–In1–O2 85.31(5); In1′ generated by $-x, y, -z + 1/2$.

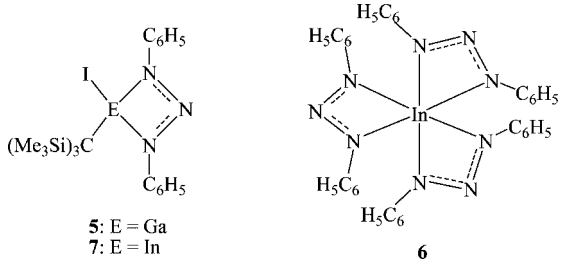
Reactions of the Subhalides with Lithium Diphenyltriazenide

As was shown before, the subhalides of gallium and indium are excellent starting compounds for the generation of secondary products containing Ga–Ga or In–In bonds. Carboxylato and acetylacetonato ligands could be introduced by such a route and the products were generally isolated in reasonable yields. Another ligand which is able to stabilise the Ga–Ga bond of bis(trimethylsilyl)methyl compounds is diphenyltriazenide. However, the direct reaction of $R_2Ga–GaR_2$ [$R = CH(SiMe_3)_2$] with diphenyltriazene by release of two equivalents of bis(trimethylsilyl)methane gave partial cleavage of the Ga–Ga bond as an undesired side-reaction and the separation of both products by recrystallisation did not succeed.[30] Owing to their different colours, the crystalline products could be separated in very small quantities under a microscope only. Later, the bis(triazenido)digallium compound containing a Ga–Ga bond was isolated in an almost quantitative yield by the reaction of an acetato derivative, $R_2Ga_2(\mu\text{-}O_2C\text{-}CH_3)_2$ [$R = CH(SiMe_3)_2$], with lithium diphenyltriazenide.[31] The driving force was the precipitation of lithium acetate. Such a procedure is similar to the method described here. Diindium compounds bearing triazenido ligands are unknown and so we tried to introduce triazenido groups into digallium or diindium compounds starting with our subhalides. Treatment of the digallium subhalide $R_2Ga_2I_2$**1** with lithium diphenyltriazenide (easily obtained by deprotonation of diphenyltriazene with *n*-butyllithium) in *n*-hexane afforded a mixture of products. Recrystallisation from diisopropyl ether yielded a small quantity of orange crystals of compound **5** which was identified from a crystal structure determination (see below) as the mononuclear compound $IGa[C(SiMe_3)_3][N_3(C_6H_5)_2]$ (Scheme 1) possessing gallium atoms in the +III oxidation state. Compound **5** was formed by the cleavage of the Ga–Ga bond. Although the ^1H NMR spectrum of the crude product of the reaction showed that **5** (δ = 0.31 ppm, $SiMe_3$) had formed in a considerable amount, no second fraction could be isolated after concentration and cooling of the mother liquor. Furthermore, a second main product was detected (δ = 0.25 ppm) which could not be isolated in a pure form at all. Its constitution remains unknown and we do not have any suitable information to allow a sound discussion of the reaction course. A similar situation holds for the reactions of the diindium subhalides $(R_2In_2X_2)_2$ [X = Cl: **2**; X = Br] with lithium diphenyltriazenide. Mixtures were formed in which $HC(SiMe_3)_3$ and the protonated triazenide $N_3(C_6H_5)_2H$

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

could be detected by NMR spectroscopy. Both compounds may indicate the occurrence of radical intermediates. Another product formed was indium tris(diphenyltriazenide) **6** (Scheme 1) which could be isolated as yellow crystals in a low yield from the reaction of the dibromide but was also clearly identified in the NMR spectrum of the crude product from the reaction of **2**. The mother liquor remaining after the separation of **6** showed one resonance of relatively high intensity in the trimethylsilyl range of the ^{1}H NMR spectrum at δ = 0.22 ppm which is characteristic of $C(SiMe_3)_3$ groups attached to gallium or indium in the +III oxidation state. It may result from the cleavage of the In–In bond and, in accordance with the integration ratio, may be described as $BrIn[C(SiMe_3)_3][N_3(C_6H_5)_2]$ similar to the gallium compound **5** described before. We did not succeed in isolating this compound in a pure form. However, a few crystals of a similar indium compound were isolated from the reaction of lithium diphenyltriazenide with the triindium subiodide $In_3I_2[C(SiMe_3)_3]_3$. This product, $InI[C(SiMe_3)_3][N_3(C_6H_5)_2]$ **7**, was identified by a crystal structure determination (see below) and by ^{1}H NMR spectroscopy (δ = 0.28 pm for the trimethylsilyl groups). It was obtained as well as $HC(SiMe_3)_3$ and several other compounds. The main resonances in the ^{1}H NMR spectrum of the crude product were observed at δ = 0.22, 0.50 and 0.68 ppm. We did not succeed in isolating any of these components in a pure form.



Scheme 1.

Three triazenido compounds (**5**, **6** and **7**) were characterised by single-crystal X-ray diffraction studies. The structure of the tris(triazenido)indium compound **6**, containing an indium atom coordinated by six nitrogen atoms in a distorted octahedral coordination sphere, was determined before.[39] We observed the occurrence of another space group and crystal system (monoclinic instead of orthorhombic). Therefore, we include some details of the structure determination in Table 1 but omit a pictorial presentation of the molecular structure. The bond parameters (In–N 224.1 pm on average; N–In–N within the chelate 56.4° on average; N–N–N 108.6° on average) are almost identical to those reported in the literature and do not need a further discussion. The structures of compounds **5** and **7** (Figures 3 and 4) are quite similar but they do not crystallise isotypically. They possess central gallium or indium atoms with oxidation numbers of +III which are coordinated by an iodine atom, a tris(trimethylsilyl)methyl group and a chelating triazenido ligand. The E–I distances (Ga–I 252.7 pm; In–I 269.5 pm) are in the expected ranges for terminal Ga–I or In–I bonds (some examples are given in refs.[12,40–54]). The same holds for the E–C (197.7 and 217.3 pm, respectively) and E–N distances (203.9 and 223.7 pm, respectively).[30,31,39,55,56] The N–N bond lengths of the triazenido groups are almost indistinguishable in both compounds (130.4 pm on average) while the N–N–N angle is slightly enlarged in the indium derivative **7** (107.5 compared with 109.6°) which may be caused by the larger covalent radius of indium.

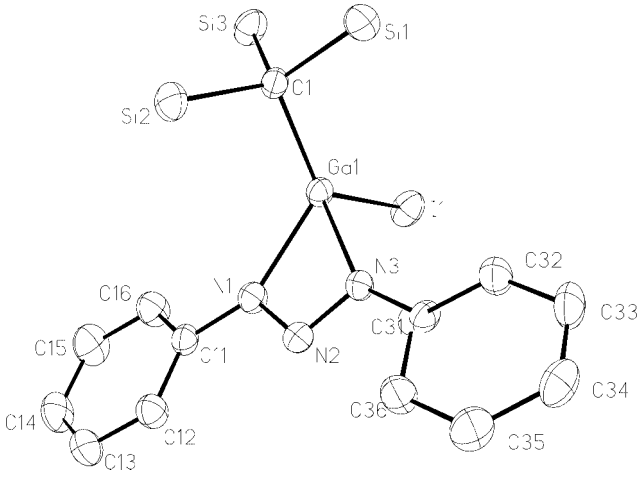


Figure 3. Molecular structure and numbering scheme of compound **5**. Thermal ellipsoids are drawn at the 40% probability level. Methyl groups of $SiMe_3$ substituents and hydrogen atoms are omitted. Selected bond lengths [pm] and angles [°]: Ga1–I1 252.7(1), Ga1–C1 197.7(4), Ga1–N1 203.6(3), Ga1–N3 204.2(3), N1–N2 130.7(5), N2–N3 130.0(4), N1–Ga1–N3 62.1(1), N1–N2–N3 107.5(3).

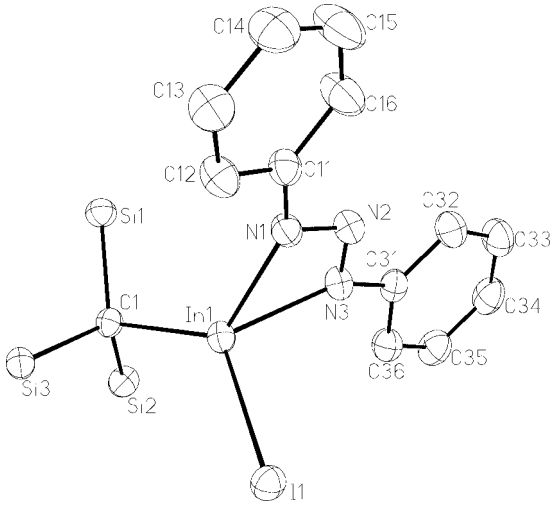

Figure 4. Molecular structure and numbering scheme of compound **7**. Thermal ellipsoids are drawn at the 40% probability level. Methyl groups of $SiMe_3$ substituents and hydrogen atoms are omitted. Selected bond lengths [pm] and angles [°]: In1–I1 269.49(3), In1–C1 217.3(2), In1–N1 223.8(2), In1–N3 223.6(2), N1–N2 130.5(3), N2–N3 130.2(3), N1–In1–N3 56.85(9), N1–N2–N3 109.6(2).

Experimental Section

General: All procedures were carried out under purified argon in dried solvents (toluene and diisopropyl ether over Na/benzophenone; *n*-hexane and cyclopentane over $LiAlH_4$; 1,2-difluorobenzene over molecular sieves). The compounds $R_2Ga_2I_2$ (**1**),[12] $(R_2In_2Cl_2)_2$ (**2**),[11] $(R_2In_2Br_2)_2$[11] and $R_3In_3I_2$[10] were synthesised according to literature procedures. Commercially available silver acetylacetonate Ag(acac) (STREM), acetylacetone acacH (Aldrich) and diphenyltriazene (Aldrich) were employed without further purification. Lithium diphenyltriazenide was prepared by treatment of diphenyltriazene with an equimolar quantity of *n*-butyllithium in *n*-hexane. The insoluble product was filtered off and dried in vacuo.

Synthesis of $R_2Ga_2(acac)_2$ (3) [R = C(SiMe$_3$)$_3$]: A suspension of silver acetylacetonate (68 mg, 0.328 mmol) in toluene (25 mL) was cooled to –90 °C and treated with the diiodide **1** (141 mg, 0.165 mmol) dissolved in toluene (10 mL). The mixture was stirred and warmed to –70 °C (20 min). The precipitate was filtered off at –70 °C and the solvent was subsequently removed in vacuo at room temperature. The yellowish solid residue was recrystallised from cyclopentane (temp. range +20 to +8 °C). Yield: 89 mg of yellow crystals, 67%. M.p. (argon, sealed capillary): 194 °C (dec.). ^{1}H NMR (C_6D_6, 300 MHz, 298 K): δ = 0.44 (s, 27 H, $SiMe_3$), 1.64 (s, 6 H, acac-Me), 5.03 (s, 1 H,acac-CH) ppm. ^{13}C NMR (C_6D_6, 75.5 MHz, 298 K): δ = 5.0 (GaC), 6.2 ($SiMe_3$), 27.7 (acac-Me), 103.1 (acac-C, inner), 192.2 (CO) ppm. IR (CsBr, paraffin): $\tilde{\nu}$ = 1644 (vw), 1580 (w), 1555 (vw), 1525 (w, νCO, νCC), 1461 (vs), 1377 (vs, paraffin), 1304 (vw), 1260 (s, νCO, δCH_3), 1125 (s), 1095 (s), 1026 (s, δCH, νCC), 934 (vw), 843 (s), 804 [s, ρCH_3(Si)], 720 (w, paraffin), 699 (w), 677 (w), 659 (vw, ν_{as}SiC), 618 (vw, ν_sSiC), 514 (w), 464 (vw), 404 (vw), 390 (vw, νGaC, νGaO) cm^{-1}. UV/Vis (*n*-hexane): λ_{max} (log ε) = 250 (4.0), 275 (sh, 3.7), 345 (sh, 3.0) nm.

Synthesis of $R_2In_2(acac)_2$ (4) [R = C(SiMe$_3$)$_3$]: Acetylacetone (27.5 mg, 0.275 mmol) was dissolved in toluene (10 mL), cooled to –30 °C and treated with a solution of *n*-butyllithium (1.6 M, 17.2 μL) in *n*-hexane. After warming to room temperature the mixture was stirred for 30 min. A solution of the diindium dichloride (**2**) (105 mg, 0.138 mmol) in toluene (15 mL) was then added at room temperature. After stirring for 1 h the mixture was heated in a prewarmed oil-bath at 50 °C for a further hour. The solvent was removed in vacuo and the residue was treated with *n*-hexane. After filtration, the solution was cooled to –15 °C to give the solid, yellowish product **4**. Yield: 81 mg of yellowish crystals, 66%. M.p. (argon, sealed capillary): 178–182 °C. ^{1}H NMR (C_6D_6, 300 MHz, 298 K): δ = 0.42 (s, 27 H, $SiMe_3$), 1.71 (s, 6 H, acac-Me), 5.09 (s, 1 H, acac-CH) ppm. ^{13}C NMR (C_6D_6, 75.5 MHz, 298 K): δ = 6.3 ($SiMe_3$), 29.0 (acac-Me), 102.7 (acac-C, inner), 193.0 (CO) ppm, InC not detected. IR (CsBr, paraffin): $\tilde{\nu}$ = 1577 (s), 1543 (m), 1517 (s, νCO, νCC), 1459 (vs), 1375 (vs, paraffin), 1260 (s), 1248 (s, νCO, δCH_3), 1019 (ν_{as}Me-CO), 927 (ν_sMe-CO), 858 (vs), 777 [s, ρCH_3(Si)], 724 (w, paraffin), 676 (m), 653 (m, ν_{as}SiC), 615 (w), 600 (m, ν_sSiC), 555 (w), 417 (w), 399 (w, νInC, νInO) cm^{-1}. UV/Vis (*n*-hexane): λ_{max} (log ε) = 250 (3.4), 300 (sh, 3.6), 355 (3.7) nm.

Reaction of $R_2Ga_2I_2$ 1 with Lithium Diphenyltriazenide: A cooled (–80 °C) mixture of lithium diphenyltriazenide (57 mg, 0.281 mmol) and *n*-hexane (20 mL) was treated with a solution of **1** (117 mg, 0.137 mmol) in *n*-hexane (10 mL). The suspension was warmed to room temperature and stirred overnight. After filtration and evaporation of the solvent, the red residue was recrystallised twice from diisopropyl ether (temp. range +20 to –45 °C) to afford a small quantity of the pure compound IGa[C(SiMe$_3$)$_3$][N$_3$(C$_6$H$_5$)$_2$] (**5**) as orange crystals. ^{1}H NMR (C_6D_6, 300 MHz, 298 K): δ = 0.31 (s, 27 H, $SiMe_3$), 6.92 (pseudo-t, 2 H, *para*-PhH), 7.09 (pseudo-t, 4 H, *meta*-PhH), 7.52 (pseudo-d, 4 H, *ortho*-PhH) ppm.

^{13}C NMR (C_6D_6, 75.5 MHz, 298 K): δ = 5.2 ($SiMe_3$), 6.0 (GaC?), 120.0, 126.4, 129.6 and 144.0 (phenyl) ppm.

Reaction of $(R_2In_2Br_2)_2$ with Lithium Diphenyltriazenide: Diphenyltriazene (69 mg, 0.35 mmol) was dissolved in *n*-hexane (20 mL), cooled to –30 °C and treated with a solution of *n*-butyllithium (0.2 mL, 1.6 M, 0.32 mmol) in *n*-hexane. The resultant suspension was stirred for 30 min at room temperature, cooled again to –30 °C and treated with a solution of the dibromide (130 mg, 1.53 mmol based on the monomeric formula) in *n*-hexane (25 mL). The mixture was warmed to room temperature and stirred for 30 min. A black precipitate formed which probably contained elemental indium. After filtration, the yellow-orange solution was concentrated and cooled to –30 °C. Only a few crystals of $In[N_3(C_6H_5)_2]_3$ (**6**) sufficient for a crystal structure determination could be isolated. All attempts to crystallise a second component from the reaction mixture failed.

Reaction of $R_3In_3I_2$ with Lithium Diphenyltriazenide: A cooled (–80 °C) suspension of lithium diphenyltriazenide (35 mg, 0.172 mmol) in *n*-hexane (25 mL) was treated with a solution of the triindiumdiiodide (101 mg, 0.078 mmol) in *n*-hexane (10 mL). The mixture was stirred for 1 h at room temperature. After filtration, the red solution was concentrated and cooled to –15 °C. Only a few crystals of $InI[C(SiMe_3)_3][N_3(C_6H_5)_2]$ (**7**) could be isolated. ^1H NMR (C_6D_6, 200 MHz, 298 K): δ = 0.28 (s, 27 H, $SiMe_3$), 6.92 (pseudo-t, 2 H, *para*-PhH), 7.10 (pseudo-t, 4 H, *meta*-PhH), 7.46 (pseudo-d, 4 H, *ortho*-PhH) ppm.

Crystal Structure Determinations: Single crystals of the compounds **3** to **7** were obtained by cooling solutions in cyclopentane (temp. range from +20 to +8 °C, **3**), *n*-hexane (temp. range from +20 to +8 °C, **4**), diisopropyl ether (temp. range from +20 to –45 °C, **5**), 1,2-difluorobenzene (temp. range from +20 to –30 °C, **6**) or *n*-hexane (temp. range +20 to 0 °C, **7**). Crystal data and structure refinement parameters are given in Table 1.[59] The molecules of compound **4** reside on a crystallographic twofold rotation axis. The crystals of **6** contain one molecule of 1,2-difluorobenzene per formula unit of **6**. These solvent molecules are strongly disordered.

Titanium Complexes of Chelating, Dianionic O,S,O-Bisphenolato Ligands: Syntheses, Characterisation, and Catalytic Activity

Zofia Janas,*[a] Lucjan B. Jerzykiewicz,[a] Katarzyna Przybylak,[a] Piotr Sobota,[a] Krzysztof Szczegot,[b] and Dorota Wiśniewska[a]

Keywords: Polymerization / Titanium / O,S ligands

Titanium complexes based on 2,2′-thiobis[4-(1,1,3,3-tetramethylbutyl)phenolato] (tbop) are prepared by reaction of $TiCl_4$ or $Ti(NMe_2)_4$ with the parent biphenol. Three new complexes are reported: $[Ti_2(\mu\text{-tbop-}\kappa^3O,S,O)(\mu\text{-tbop-}\kappa^2O,O)(\text{tbop-}\kappa^3O,S,O)Cl_2]$ (**1**)·2CH_3CN, $[Ti_2(\mu\text{-tbop-}\kappa^3O,S,O)_2Cl_4]$ (**2**) and $[Ti(\text{tbop-}\kappa^3O,S,O)_2]$ (**3**). Substitution of the chlorides in **1** and **2** by 2,6-diisopropylphenolato and imido (N*t*Bu) ligands generates the new compounds $[Ti_2(\mu\text{-tbop-}\kappa^3O,S,O)_2Cl_2(dipp)_2]$ (**4**)·Et_2O and $[Ti_2(\mu\text{-tbop-}\kappa^3O,S,O)_2(N\text{t}Bu)_2(NH_2\text{t}Bu)_2]$ (**5**), respectively. Treatment of **5** with crude Me_3SiCl, containing Me_3SiOH, produces $[Ti(\text{tbop-}\kappa^3O,S,O)Cl(OSiMe_3)(NH_2\text{t}Bu)]$ (**6**). Reaction of **2** with an excess of $NHiPr_2$ provides a mixture of compounds: ionic $[NH_2iPr_2][Ti(\text{tbop-}\kappa^3O,S,O)Cl_3]$ (**7**)·CH_2Cl_2 and molecular $[Ti_2(\mu\text{-tbop-}\kappa^3O,S,O)_2Cl_2(NiPr_2)_2]$ (**8**). The structures of **1**–**8** were confirmed by NMR spectroscopy; complexes **1**, **5**, **6** and **7** were further investigated by X-ray crystallography. Compounds **1**, **2**, **4** and **5**, when supported on $MgCl_2$ and activated with alkylaluminiums, effectively polymerise ethene.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Titanium complexes $[Ti_2(\mu\text{-}X)_2X_2(\text{tbmp-}\kappa^3O,S,O)_2]$ derived from the sulfide-linked bisphenol $\text{tbmp}H_2$ [$\text{tbmp}H_2$ = 2,2′-thiobis(6-*tert*-butyl-4-methylphenol); X = Cl, O*i*Pr] were first reported by Kakugo et al. to be highly active for the polymerisation of ethene, propene, styrene and dienes, as well as the copolymerisation of ethene with styrene, upon activation with methylalumoxane (MAO).[1–3] These titanium complexes were found to be an order of magnitude more active than the methylene-bridged chelating aryloxide complexes of the type $[TiX_2(\text{mbmp})]$ [mbmp = 2,2′-methylenebis(6-*tert*-butyl-4-methylphenolato)].[4] This is in qualitative agreement with theoretical studies that showed the S-bridged chelating phenolates to have lower insertion barriers than their methylene-bridged or directly bridged analogues.[5–7] Although the Ti–S interaction in $[Ti_2(\mu\text{-}X)_2X_2(\text{tbmp-}\kappa^3O,S,O)_2]$ is weak, it is likely to be of importance in stabilizing the active cationic species, facilitating its formation from the former and MAO and making the coordination of the counterion less tight.[8] Bisphenolato- and bisnaphtholatotitanium complexes have been well characterised both structurally and spectroscopically, and the kinetics and thermodynamics of intra- and intermolecular rearrangement in bisnaphtholates has been described as well.[9,10] However, there are very few reports of structural data on S-bridged titanium analogues, especially of their ligand modifications.[5,11,12] This encouraged us to investigate the titanium compounds with the tridentate O,S,O-thiobisphenolato ligand 2,2′-thiobis[4-(1,1,3,3-tetramethylbutyl)phenolato] (tbop). In addition to the S bridge, the tbop ligand seemed to have one more attractive feature: the long, sterically hindered auxiliary group on the thiobisphenolato ligand sufficiently increases solubility of the catalyst in hydrocarbons.

Recently we described the synthesis and structural characterisation of the mixed-ligand complexes $[Ti_2(\mu\text{-}OR)_2(X)_2(\text{tbop-}\kappa^3O,S,O)_2]$ (R = Me, Et; X = OR or Me).[13] In these complexes the tbop ligand was found to coordinate to the titanium in a *fac* fashion. $[Ti_2(\mu\text{-}OR)_2(X)_2(\text{tbop-}\kappa^3O,S,O)_2]$ complexes supported on $MgCl_2$ and activated with $AlEt_2Cl$ or $AlEt_2Cl/AlEt_3$ show very high activity in ethene polymerisation. The narrow molecular-weight distribution obtained for these systems is indicative of the operation of typical heterogeneous single-site catalyst behaviour.

We have been exploringthe use of the tbop ligand for the preparation of new titanium complexes that might serve as catalysts for the ethene polymerisation process. We report here their syntheses and structures, along with catalytic behaviour in ethene polymerisation.

Results and Discussion

The reaction between $TiCl_4$ and $\text{tbop}H_2$ in *n*-hexane, depending on the stoichiometry (1:1.5 and 1:1), produces

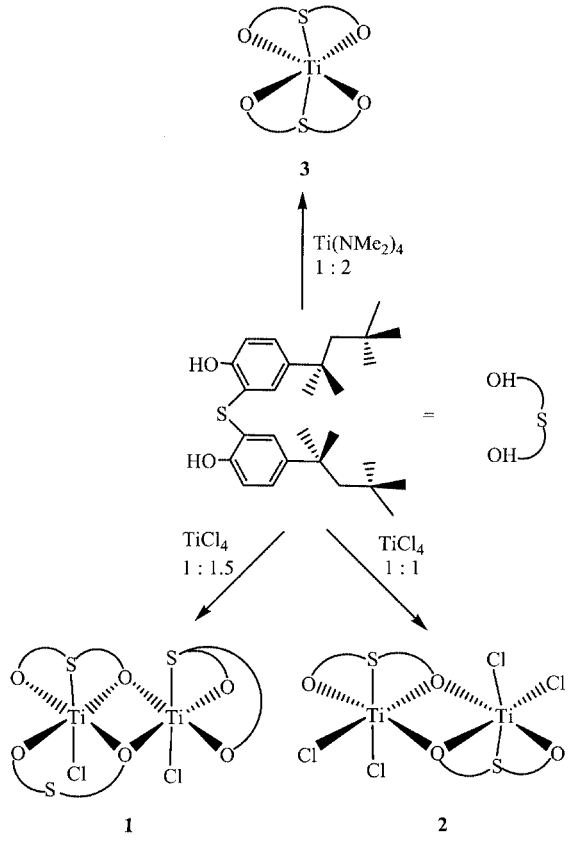
compounds [Ti_2(μ-tbop-κ^3O,S,O)(μ-tbop-κ^2O,O)(tbop-κ^3O,S,O)Cl_2] (**1**·2CH_3CN and [Ti_2(μ-tbop-κ^3O,S,O)$_2Cl_4$] (**2**) with concomitant elimination of three and two equivalents of HCl, respectively (Scheme 1). Surprisingly, reaction of $TiCl_4$ with two equivalents of $tbopH_2$ in diethyl ether did not lead to the anticipated [Ti(tbop-κ^3O,S,O)$_2$] (**3**) but to a good yield of complex **2**. Fortunately, compound **3** is available by simple addition of $tbopH_2$ to [$Ti(NMe_2)_4$]. When the reaction of $tbopH_2$ with neat $TiCl_4$ is carried out in toluene, a mixture of **1**, **2** and **3** is formed, from which only compound **1** could be isolated as an analytically pure product. The IR spectra of **1** and **2** show characteristic modes for terminal coordinated chlorides at 380 and 378 cm^{-1}, respectively.



Scheme 1.

The structure of **1** (Figure 1) consists of discrete molecules of dimer [Ti_2(μ-tbop-κ^3O,S,O)(μ-tbop-κ^2O,O)(tbop-κ^3O,S,O)Cl_2] together with two MeCN molecules of crystallisation. The coordination environment about the Ti centres bridged by two oxygen atoms of tbop ligands is best described as highly distorted octahedral. The major distortions from idealised octahedral geometry are for the O(41)–Ti(1)–O(61), O(21)–Ti(1)–S(1), O(31)–Ti(2)–O(61), O(41)–Ti(2)–O(61) and O(61)–Ti(2)–S(3) angles, with values of 71.88(11)°, 75.72(9)°, 149.18(12)°, 71.54(10)° and 74.19(8)°, respectively. Two tbop ligands in **1** bridge titanium centres and the third one is facially coordinated to Ti(1). All the oxygen atoms of the tbop ligands are engaged in the formation of the equatorial planes, while the terminal chlorides and two sulfur links [S(1), S(3)] of the tbop ligands occupy the apical sites. The third sulfur atom [S(2)] isnot bonded to any Ti atom. The average titanium–sulfur bond length of 2.735(2) Å is longer than those found in other complexes, for example[Ti_2(μ-O*i*Pr)$_2$(O*i*Pr)$_2$(tbmp-κ^3O,S,O)$_2$] [tbmp = 2,2′-thiobis(6-*tert*-butyl-4-methylphenolato; 2.719(1) Å],[Ti(tbmp-κ^3O,S,O)($C_6H_4CH_2NMe_2$-2-κ^2C,N)Cl] [2.704(1) Å]and [Ti(tbmp-κ^3O,S,O)Cl(O*i*Pr)(HO*i*Pr)] [2.693(1) Å],[5,11] and shorter than those in [Ti_2(μ-OEt)$_2$(OEt)$_2$(tbop-κ^3O,S,O)$_2$] [2.800(1) Å] and [{Ti_2(μ-OEt)$_2$(tbop-κ^3O,S,O)$_2$}$_2$-(μ-O)$_2$] [2.762(2) Å].[13] The average Ti–O distances of 1.832(3) Å and 2.040(3) Å are in the expected range for Ti^{IV} complexes with non-bridging and bridging aryloxo ligands, respectively.[4] The terminal Ti–Cl distances of 2.254(2) Å and 2.265(2) Å are slightly shorter (by less than 0.01 Å) than those in [Ti_2(μ-Cl)$_2Cl_2$(tbmp-κ^3O,S,O)$_2$].[12]

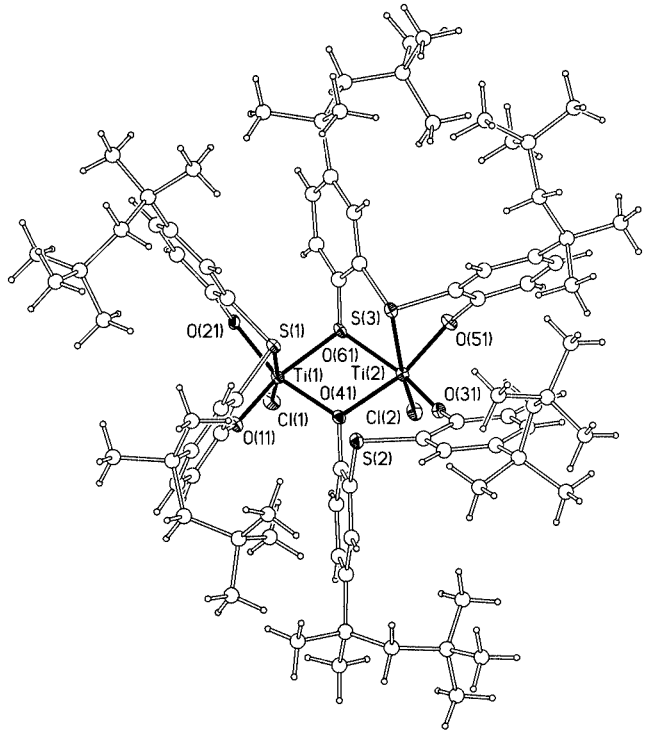


Figure 1. Molecular structure of **1**·2CH_3CN. Selected bond lengths [Å] and angles [°]: Ti(1)–O(11) 1.833(3), Ti(1)–O(21) 1.839(3), Ti(1)–O(41) 2.024(3), Ti(1)–O(61) 2.048(3), Ti(1)–Cl(1) 2.254(2), Ti(1)–S(1) 2.752(2), Ti(2)–Cl(2) 2.265(2), Ti(2)–O(31) 1.793(3), Ti(2)–O(41) 2.041(3), Ti(2)–O(51) 1.863(3), Ti(2)–O(61) 2.048(3), Ti(2)–S(3) 2.728(2); O(41)–Ti(1)–O(61) 71.88(11), O(21)–Ti(1)–S(1) 75.72(9), O(31)–Ti(2)–O(61) 149.18(12), O(41)–Ti(2)–O(61) 71.54(10), O(61)–Ti(2)–S(3) 74.19(8).

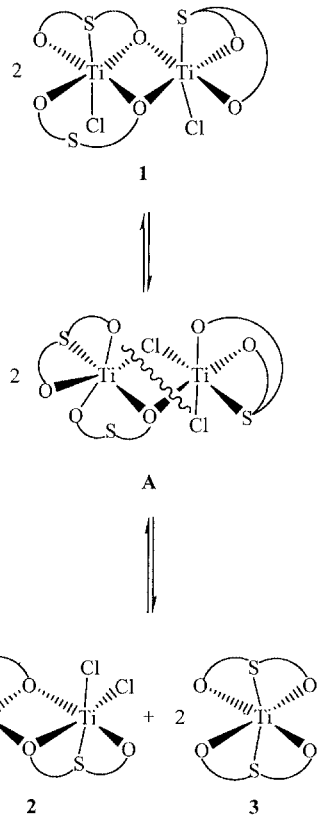
The ^1H NMR spectra of **1** in C_6D_6 show more peaks corresponding to the tbop ligand than would be expected from the crystal structure. These data suggest that the structure of **1** does not stay intact in solution at room temperature. It is most likely that compound **1** undergoes an intramolecular rearrangement in solution probably to the chloride- and oxygen-bridged dinuclear derivative **A** (Scheme 2). This closely corresponds to the well-documented mechanism for intramolecular exchange in [(R_2bino)Ti(O*i*Pr)$_2$]$_2$

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(R_2bino = 3,3′-disubstituted-1,1′-bi-2-naphtholates)[10] and [(tartrate)Ti(O*i*Pr)$_2$]$_2$ proposed by Sharpless and Finn.[14]

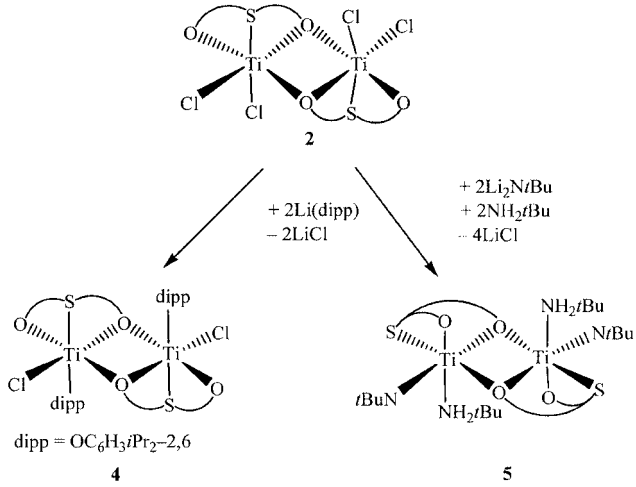


Scheme 2.

Fragmentation of **A** through the interruption of chloride and oxygen bridges would produce compounds [Ti$_2$(μ-tbop-κ^{3}O,S,O)$_2$Cl$_4$] (**2**) and [Ti(tbop-κ^{3}O,S,O)$_2$] (**3**). All these compoundscould participate in a facile equilibrium involving the interconversion of chemically distinct compounds. Partial confirmation of this hypothesis is the fact that compound **1** gives the same products upon substitution of its chlorides as **2** (described below). The presence of compound **3** was confirmed from the ^{1}H NMR spectrum.

Attempts to grow crystals of **2** suitable for X-ray diffraction proved unsuccessful. Therefore, we tried to examine its structure by indirect methods, by investigating the products of substitution of the chlorides in **2** (Scheme 3).

We found that the reaction of **2** with Li(dipp) (dipp = 2,4-diisopropylphenolato) in diethyl ether provides orange-red crystals of [Ti$_2$(μ-tbop-κ^{3}O,S,O)$_2$Cl$_2$(dipp)$_2$] (**4**)·Et$_2$O in good yield. The ^{1}H NMR spectrum of **4** contains septet and doublet resonances for the isopropyl substituents of the dipp groups and similar resonance sets for the tbop ligand to those detected for **2**, together with resonances corresponding to the free diethyl ether. Single-crystal X-ray diffraction of **4** showed it to be composed of dimeric [Ti$_2$(μ-tbop-κ^{3}O,S,O)$_2$Cl$_2$(dipp)$_2$] and one Et$_2$O molecule of crystallisation. Two titanium centres are linked by a double bridge formed from the oxygen atoms of the tbop ligands. The chloride atoms and dipp ligands are terminally coordinated to each titanium atom to complete the octahedral



Scheme 3.

coordination sphere. Unfortunately, the poor-quality X-ray data for **4** do not allow a discussion of bond lengths and angles.[15]

Treatment of **2** with one equivalent of Li$_2$N*t*Bu and NH$_2$*t*Bu per titanium atom in diethyl ether produced [Ti$_2$(μ-tbop-κ^{3}O,S,O)$_2$(N*t*Bu)$_2$(NH$_2$*t*Bu)$_2$] (**5**) in high yield. The coordination of both amine (NH$_2$*t*Bu) and imido (N*t*Bu) ligands to the titanium centres is implied by the presence of two inequivalent *t*Bu groups and the broad resonance for the NH$_2$ group in the ^{1}H NMR spectrum and by ν(NH) bands in the IR spectra (see Experimental Section). Single-crystal X-ray diffraction clearly confirms (Figure 2) that **5** contains an approximately linear Ti=N*t*Bu linkage [166.4(3)°], with a Ti–N$_{imido}$ distance [1.710(3) Å] consistent with a formal metal–nitrogen triple bond ($\sigma^2\pi^4$),[16] and a

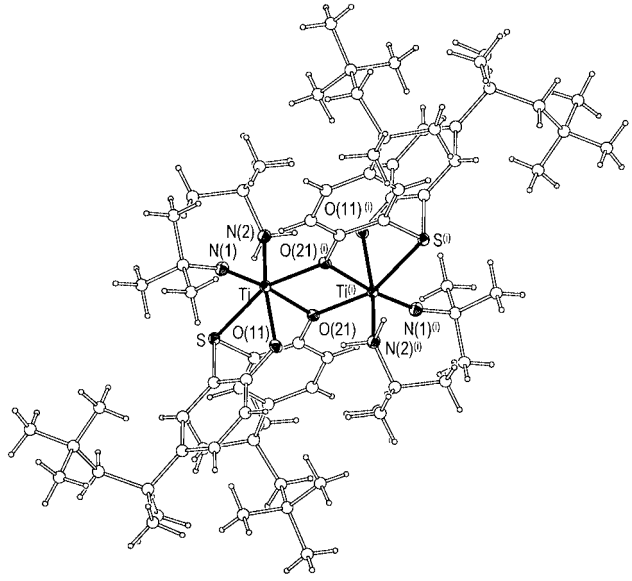


Figure 2. Molecular structure of **5**. Selected bond lengths [Å] and angles [°]: Ti–N(1) 1.710(3), Ti–O(11) 2.013(2), Ti–O(21)^i 2.010(3), Ti–N(2) 2.255(3), Ti–O(21) 2.298(2), Ti–S 2.587(2); Ti–N(1)–C(51) 166.4(3), Ti–N(2)–C(61) 126.5(2). Symmetry operation: (*i*) –*x* + 1, –*y*, –*z*.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

bent Ti–NH_2tBu unit with a Ti–N bond length and a Ti–N–C angle of 2.255(3) Å and 126.5(2)°, respectively.

The amine and imido groups are terminally coordinated to the titanium centres. A similar coordination of both amine and imido groups to the titanium centres is found in the tetramer $[Ti_4(\mu\text{-}Cl)_4(\mu^3\text{-}Cl)_2Cl_2(NtBu)_4(NH_2tBu)_4]$, which is obtained from the direct reaction of $TiCl_4$ and four equivalents of tBuN(H)$SiMe_3$.[17] The octahedral titanium centres in **5** are bridged by two oxygen atoms [O(21), O(21)$^{(i)}$] of the tbop ligands. These two oxygens form the equatorial planes together with sulfur and imido nitrogen atoms, while the remaining oxygens [O(11), O(11)$^{(i)}$] and amine nitrogens [N(2) and N(2)$^{(i)}$] occupy the apical sites. The Ti–S bond length of 2.587(2) Å is significantly shorter than that in **1** and is one of the shortest Ti–S lengths so far reported in the literature of titanium S-bridged bisaryloxo complexes.[5,11–13] Typically, it is observed that the Ti-μ-O_{Ar} distances are a minimum of 0.1 Å longer than terminal Ti–O_{Ar} bonds, as was found for **1**. However, the Ti–O bond distances in **5** do not reveal this tendency and show a significant variation. These variations could be caused by the *trans* interactions of bridging O(21) and O(21)$^{(i)}$ atoms with imido N(1), N(1)$^{(i)}$ atoms and S, S$^{(i)}$ atoms, respectively, as well as terminal O(11) and O(11)$^{(i)}$ atoms situated in axial positions with amine N(2) and N(2)$^{(i)}$ atoms, respectively. On the other hand, an increased axial Ti–O distance is expected, because axial ligands generally engender more severe steric interactions and experience greater competition for empty dπ-bonding orbitals than analogous equatorial ligands.[18] These two effects sufficiently influence the variation in Ti–O bond distances, although the influence of crystal packingcannot be excluded.

On the basis of structures **4** and **5** it seems most likely that complex **2** is a dimer in which the titanium centres are doubly bridged by oxygen atoms of the tbop ligands and the chlorides are coordinated terminally. This is in contrast to $[Ti_2(\mu\text{-}Cl)_2Cl_2(tbmp\text{-}\kappa^3O,S,O)_2]$, reported by Nakamura and Okuda, which has a chloro-bridged binuclear structure with tbmp ligands facially coordinated to each titanium centre,[12] probably because of the bulky tBu substituents in the tbmp ligands.

Addition of four equivalents of crude Me_3SiCl to **5** in diethyl ether led unexpectedly to yellow crystals of [Ti(tbop-κ^3O,S,O)Cl($OSiMe_3$)(NH_2tBu)] (**6**) in low yield. The X-ray structure of **6** (Figure 3) displays a distorted octahedral geometry around the titanium centre with the tbop ligand coordinated in a *fac* fashion. The oxygen atom [O(3)] of the $OSiMe_3$ ligand and the sulfur atom of the tbop group occupy the apical positions, while oxygens atoms O(1) and O(2) of the tbop ligand, together with the nitrogen atom of NH_2tBu, occupy the equatorial plane. The Ti–S distance of 2.757(1) Å is similar to those found in **1** and significantly longer than those detected in **5**. The Ti–$O_{aryloxo}$ [av. 1.87(2) Å], Ti–O_{alkoxo} [1.7758(2) Å] and Ti–Cl [2.385(1) Å] distances are in the expected range for Ti^{IV} complexes with non-bridging aryloxo[4] and alkoxo ligands[12] and terminal chlorides.Interestingly, intramolecular N–H···Cl [d(N···Cl): 3.4179 Å; N–H–Cl: 169.00°] and C(44)–H(44C)···O(2) [d(C···O): 3.3033 Å; C–H–O: 136.00°]hydrogen bonds are observed. One may suppose that compound **6** might be an-intermediate species in the Ti=NtBu linkage formation.

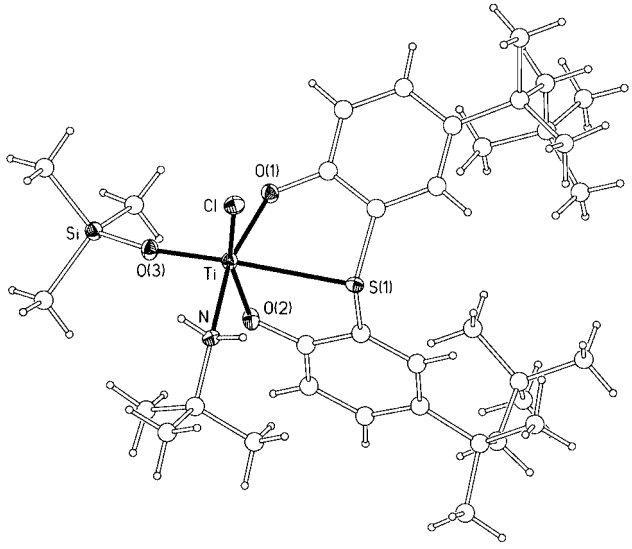

Figure 3. Molecular structure of **6**. Selected bond lengths [Å] and angles [°]: Ti–Cl 2.385(1), Ti–S(1) 2.757(1), Ti–N 2.232(2), Ti–O(1) 1.866(2), Ti–O(2) 1.874(2), Ti–O(3) 1.7758(2); S(1)–Ti–O(3) 174.32, O(2)–Ti–Cl 159.18(6), N–Ti–O(1) 158.69(9), Ti–N–C(41) 130.43(17).

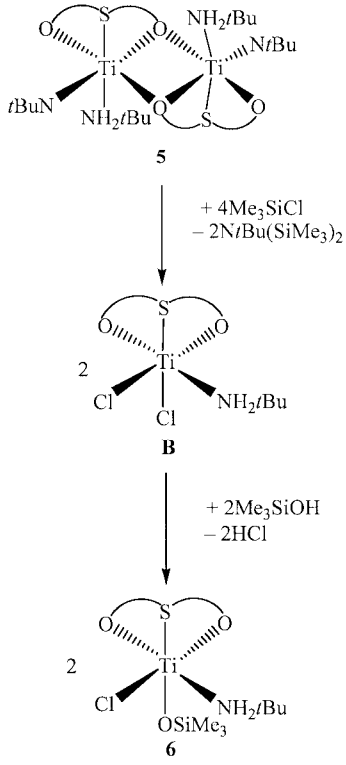
We suggest that the interaction of **5** with crude Me_3SiCl generates a monomeric compound **B** (Scheme 4), which immediately reacts with Me_3SiOH (a product of the hydrolysis of Me_3SiCl that is present in the crude sample) to form **6**

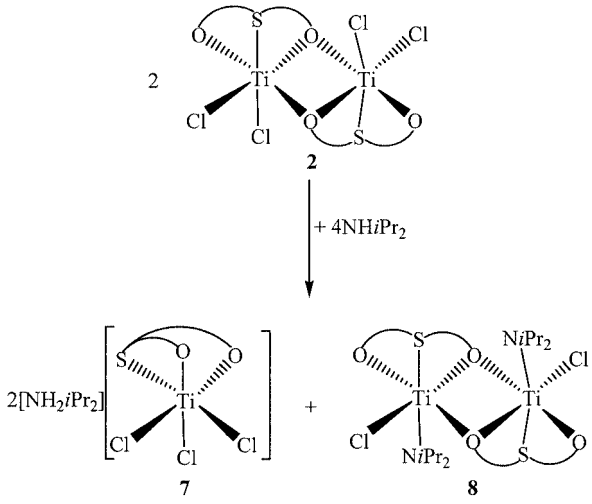


Scheme 4.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

with elimination of HCl. However, when freshly distilled Me_3SiCl was used, no formation of **6** was observed and a mixture of **B**, $NH_2tBu{\cdot}HCl$, amido and imido products was identified by ^1H NMR and IR spectroscopy.

The reaction of **2** with two equivalents of $NHiPr_2$ in diethyl ether results in the formation of two products: the ionic complex $[NH_2iPr_2][TiCl_3(tbop\text{-}\kappa^3O,S,O)]$ (**7**) and the molecular complex $[Ti_2(\mu\text{-}tbop\text{-}\kappa^3O,S,O)_2Cl_2(NiPr_2)_2]$ (**8**) (Scheme 5).



Scheme 5.

Crystals of **7** consist of $[NH_2iPr_2]^+$ cations and $[Ti(tbop\text{-}\kappa^3O,S,O)Cl_3]^-$ anions in a 1:1 ratio and one CH_2Cl_2 molecule of crystallisation. The molecular structure of the $[Ti(tbop\text{-}\kappa^3O,S,O)Cl_3]^-$ anion in **7** is shown in Figure 4. This anion evidently maintains a mononuclear octahedral environment with a facially capped tbop ligand. The oxygen atom O(12) of the tbop ligand and chloride Cl(2) occupy an apical coordination sphere, while the remaining donor atoms form the equatorial plane. The Ti–O distances of 1.863(2) and 1.884(2) Å are relatively short and comparable to the terminal aryloxide oxygens found in **1** and **5**. The Ti–Cl bond lengths, disposed *trans* to Ti–O and Ti–S, vary from 2.270(2) to 2.380(2) Å, presumably due to the *trans* influence. The structure of the cation $[NH_2iPr_2]^+$ is well known.[19]

The ^1H NMR spectrum of compound **8** shows similar sets of resonances for the tbop ligand to **5** and additional resonances (septet and doublet) for the deprotonated amido $NiPr_2$ groups. The IR spectrum of **8** also confirms the lack of the ν(NH) frequencies in the expected region. In compounds **1**–**7** thetitanium atom prefers to be six-coordinate. This suggests that complex **8**, which is isolated from non-donor solvents, might be a dimer, as shown in Scheme 5. By analogy to **5**, we propose that the titanium atoms in **8** are joined through the oxygen donors of the tbop ligand rather than the amido $NiPr_2$ groups. Terminal coordination of the amido $NiPr_2$ group to the titanium centre has been observed and crystallographically characterised in $[CpTiCl_2(NiPr_2)]$[20] and $[Li(tmeda)][TiPh_2(NiPr_2)_2]$.[21]

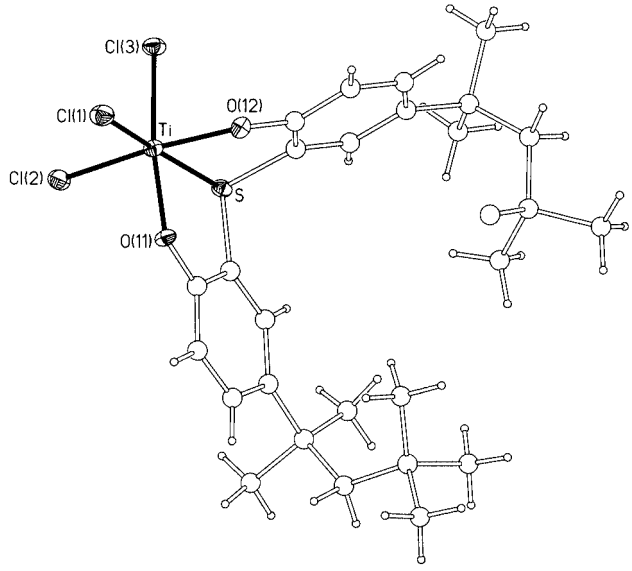


Figure 4. Molecular structure of the $[Ti(tbop\text{-}\kappa^3O,S,O)Cl_3]^-$ anion in **7**·CH_2Cl_2. Selected bond lengths [Å]: Ti–Cl(1) 2.270(2), Ti–Cl(3) 2.369(2), Ti–Cl(2) 2.380(2), Ti–S 2.652(2), Ti–O(11) 1.863(2), Ti–O(12) 1.884(2).

Complexes **1**, **2**, **4** and **5** were tested in ethene polymerisation. Catalysts based on these compounds were prepared in *n*-hexane by milling (see Experimental Section) a slurry of $[MgCl_2(THF)_2]$ with the titanium compound (10:1) and $AlEt_2Cl$ as cocatalyst. Prior to the polymerisation, ethene was passed through a suspension of the catalyst. Then, an additional amount of organoaluminium compound [$Al(iBu)_3$ or MAO] was added to the catalyst dispersed in the prepolymer to form a highly active catalyst. Thus, the polymerisation of ethene was performed in a two-step process. The aim of the first step (very low Al:Ti molar ratio, normal pressure of monomer, very low rate of polymerisation) was to prepare granules of polymer containing dispersed catalyst. These granules act as a "microreactor" in the second step of the polymerisation with a high rate (Granular Reactor Technology). This method gave PE yields twice as high as those obtained with a one-stage activation process. The ethene polymerisation results and polymer characterisation data are summarised in Table 1.

Table 1.Ethylene polymerisation.[a]

Entry	Complex	Cocatalyst	Activity[b]	M_w/M_n
1	**1**	MAO	110	3.73
2	**1**	$Al(iBu)_3$	345	4.23
3	**2**	MAO	465	4.36
4	**2**	$Al(iBu)_3$	322	4.67
5	**4**	MAO	357	3.05
6	**4**	$Al(iBu)_3$	707	5.48
7	**5**	MAO	207	3.32
8	**5**	$Al(iBu)_3$	402	4.74
9	$[Cp_2TiCl_2]$	MAO	137	2.80
10	$[Cp_2TiCl_2]$	$Al(iBu)_3$	123	3.16

[a] Polymerisation conditions: for MAO $[Ti]_0$ = 0.05 mmol dm^{-3}, [Al]/[Ti] = 4000; for $Al(iBu)_3$ $[Ti]_0$ = 0.01 mmol dm^{-3}, [Al]/[Ti] = 2000, time 30 min. [b] kg PE/g Ti/h.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

For comparison of catalyst activities, titanocene dichloride [Cp_2TiCl_2] was used as a reference under the same conditions (Table 1, entries 9 and 10). It turned out that the catalyst based on complex **4** (entry 6) exhibits the highest catalytic activity (707 kg PE/g Ti/h) for ethene polymerisation. This is about two- and sevenfold more than catalysts basedon[$Ti_2(\mu\text{-}OEt)_2(Me)_2(tbop\text{-}\kappa^3O,S,O)_2$] (344 kg PE/g Ti/h; 323 K, 0.5 MPa, 0.005 mmol catalyst)[13]and the species formulated as [Ti(tbmp)X_2] (100 kg PE/g Ti/h; 293 K, 3 MPa, 0.2 mmol catalyst, 25 mmol MAO, toluene),[2b] respectively, but is comparable with [Ti(tbmp)X_2]/MAO (820 kg PE/g Ti/h for X = Cl and 677 kg PE/g Ti/h for X = O*i*Pr; 293 K, 3 MPa, 0.001 mmol catalyst, 5.17 mmol MAO, toluene) originally reported by Kakugo.[1b,1c] The molecular weights of the polymers produced with complexes **1**, **2**, **4** and **5** under these conditions range from 924 000 to 1 269 000.The polydispersities, M_w/M_n, for **1**, **2**, **4** and **5** (see Table 1) are narrower than those reported for ethylenepolymerisation with catalysts based on [$Ti_2(\mu\text{-}OEt)_2(OEt)_4$-(maltolato-$\kappa^2O,O)_2$] (6.11)[22] and [Ti(tbmp)X_2] (11.9).[2b] It would appear that for polymerisation of ethene, activation of these systems affords a single, well-defined active species. This indicates that the cocatalyst does not abstract the tbop ligand from the titanium centre.

The preliminary polymerisation results on our Ziegler–Natta-like systems are promising on account of the production of a polymer with a sufficiently narrow particle-size distribution.

Conclusions

Reaction of $TiCl_4$ with $tbopH_2$ results in the formation of dimeric, mixed-ligand complexes **1** and **2** depending on the stoichiometry. Analytically pure compound **3** can be only obtained by the protonolysis reaction of $tbopH_2$ with [$Ti(NMe_2)_4$]. The extremely high solubility of **3** makes its isolation in the solid state difficult. Treatment of **1** and **2** with Li(dipp) or Li_2NtBu leads to the partial or complete substitution of chlorides to form dimeric compounds **4** and **5**, respectively. The monomeric complex **6** is a casual product of the reaction of **5** with crude Me_3SiCl containing Me_3SiOH. The use of the secondary amine $NHiPr_2$ in the reaction with **2** produces a mixture of the ionic compound **7** and the molecular species **8**. The solid-state crystal structures of **1**, **4** and **5** showthat their dimeric nature is due to oxygen bridges from the tbop ligands. This is in contrast to the complexes containing a tbmp ligand. It is likely that the bulky substituents in the *ortho* positions of the tbmp ligand are the main reason why chloride bridges are favoured in [$Ti_2(\mu\text{-}Cl)_2Cl_2(tbmp\text{-}\kappa^3O,S,O)_2$].

The complexes **1**, **2**, **4** and **5** are highly effective ethene polymerisation catalysts upon activation with alkylaluminium compounds. The narrow molecular-mass distribution for these systems suggests the operation of heterogeneous, well-defined, single-site catalysts.

Experimental Section

General Remarks: All operations were carried out under a dry dinitrogen atmosphere using standard Schlenk techniques. All the solvents were distilled under dinitrogen from the appropriate drying agents prior to use. The compounds $TiCl_4$, $Al(iBu)_3$, MAO, NH_2tBu, $NHiPr_2$, Me_3SiCl and 2,2′-thiobis[4-(1,1,3,3-tetramethylbutyl)phenol] ($tbopH_2$) were obtained from the Aldrich Chemical Co. and used without further purification, unless stated otherwise. Infrared spectra were recorded on a Perkin–Elmer 180 spectrophotometer in Nujol mulls. NMR spectra were performed on a Bruker ARX 300 spectrometer. Microanalysis was conducted with a ASA-1 (GDR, Carl-Zeiss-Jena) instrument (in-house).

[$Ti_2(\mu\text{-}tbop\text{-}\kappa^3O,S,O)(\mu\text{-}tbop\text{-}\kappa^2O,O)(tbop\text{-}\kappa^3O,S,O)Cl_2$](1)·2$CH_3CN$: $tbopH_2$ (6.05 g, 13.67 mmol) was addedto a solution of $TiCl_4$ (1.73 g, 9.11 mmol) in *n*-hexane (60 mL), and the mixture was stirred at room temperature until the evolution of HCl had ceased (48 h). All volatiles were then removed under reduced pressure. The resulting brown solid was washed with *n*-hexane (60 mL), and then the brown precipitate was filtered off, washed with *n*-hexane (3 × 5 mL) and dried under vacuum. The resultant solid was dissolved in warm CH_3CN, from which bright-red crystals suitable for the structure determination were isolated after standing at room temperature for two days. Yield: 5.83 g (86%). $C_{84}H_{120}Cl_2O_6S_3Ti_2$ (1488.67): calcd. C 67.80, H 8.13, Cl 4.70, S 6.45; found C 68.01, H 8.26, Cl 5.32, S 6.13. IR (Nujol mull): $\tilde{\nu}$ = 380 (s), 412 (w), 438 (s), 454 (w), 488 (w), 546 (m), 580 (s), 628 (s), 682 (m), 734 (w), 766 (m), 828 (s), 890 (m), 1060 (w), 1100 (w), 1144 (w), 1250 (s), 1288 (s), 1592 (w) cm^{-1}. ^1H NMR (300 MHz, C_6D_6, 25 °C): δ = 7.78–5.98 (m, 3 H, C_6H_3), 1.54–0.71 [multiplet, signals of $C(CH_3)_2$-$CH_2C(CH_3)_3$] ppm. The crystal structure shows the presence of two CH_3CN molecules in the unit cell. However, the elemental analysis indicates that these are absent from the powder sample analysed; they are presumably removed by the vacuum drying to which the sample was subjected.

[$Ti_2(\mu\text{-}tbop\text{-}\kappa^3O,S,O)_2Cl_4$] (2): $tbopH_2$ (4.05 g, 9.11 mmol) was added to a solution of $TiCl_4$ (1.73 g, 9.11 mmol) in Et_2O or *n*-hexane (60 mL) and the mixture was refluxed until the evolution of HCl had ceased (48 h). The resulting dark-red solid was filtered off, washed with cold Et_2O (3 × 5 mL), and dried under vacuum. Yield: 4.07 g (80%). $C_{56}H_{80}Cl_4O_4S_2Ti_2$ (1118.99): calcd. C 60.20, H 7.22, Cl 12.53, S 5.73; found C 60.86, H 6.96, Cl 12.02, S 5.92. IR (Nujol mull): $\tilde{\nu}$ = 324 (vw), 340 (vw), 378(vs, sh), 420 (s), 448 (m), 466 (m), 500 (w), 542 (w), 568 (m), 578 (m), 628 (vw), 670 (vw), 720 (m), 748 (w), 780 (m), 824 (s), 840 (vs), 888 (m), 916 (m), 936 (vs), 1048 (w), 1064 (w), 1100 (w), 1150 (w), 1192 (m), 1262 (vs), 1324 (m), 1588 (w) cm^{-1}. ^1H NMR (300 MHz, C_6D_6, 25 °C): δ = 7.71–6.89 (m, 12 H, C_6H_3), 1.58 [s, 8 H, $C(CH_3)_2CH_2C(CH_3)_3$], 1.19 [s, 24 H, $C(CH_3)_2CH_2C(CH_3)_3$], 0.77 [s, 36 H, $C(CH_3)_2$-$CH_2C(CH_3)_3$] ppm.

[Ti(tbop-$\kappa^3O,S,O)_2$] (3): $tbopH_2$ (2.19 g, 5.44 mmol) was added to a solution of [$Ti(NMe_2)_4$] (0.5 g, 2.72 mmol) in hexane (30 mL). After refluxing the reaction mixture for 6 h, all volatiles were evaporated in vacuo and the residue was dissolved in *n*-hexane (10 mL). The resulting solution was allowed to stand at room temperature for several days, upon which orange microcrystals of **3** separated. Yield: 0.4 g (15.8%). The extremely good solubility of this complex in organic solvents did not allow us to separate pure **3** with higher yield. Removal of solvent under vacuum gave a sticky product. $C_{56}H_{80}O_4S_2Ti$ (929.30): calcd. C 72.38, H 8.68, S 6.90; found C 71.99, H 8.65, S 7.11. IR (Nujol mull): $\tilde{\nu}$ = 446 (m), 460 (m), 502 (w), 539 (w), 566 (m), 575 (m), 627 (vw), 669 (vw), 722 (m), 747 (w), 781 (m), 822 (s), 838 (vs), 882 (m), 915 (m), 934 (vs), 1046 (w),

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

1060 (w), 1100 (w), 1151 (w), 1190 (m), 1260 (vs), 1320 (m), 1588 (w) cm^{-1}. ^1H NMR (300 MHz, C_6D_6, 25 °C): δ = 8.35–6.24 (m, 12 H, C_6H_3), 1.70 [br, 8 H, $C(CH_3)_2CH_2C(CH_3)_3$], 1.40 [br, 24 H, $C(CH_3)_2CH_2C(CH_3)_3$], 0.95, 0.90, 0.84 [s, 36 H, $C(CH_3)_2CH_2C(CH_3)_3$] ppm.

[Ti$_2$(μ-tbop-κ^{3}O,S,O)$_2$Cl$_2$(dipp)$_2$] (4)·Et$_2$O: A solution of Li(dipp) (0.50 g, 2.70 mmol) in diethyl ether (20 mL) was added to a solution of **2** (2.52 g, 2.70 mmol) in diethyl ether (30 mL). The mixture was stirred over a period of 12 h and then filtered to remove LiCl. Reduction of the filtrate volume to 10 mL and storage at 253 K for 1 week provided red crystals of complex **4**. Yield: 1.24 g (65%). $C_{80}H_{114}Cl_2O_6S_2Ti_2$ (1402.65): calcd. C 68.54, H 8.20, Cl 4.99, S 4.57; found C 67.99, H 8.01, Cl 5.05, S 4.68. IR (Nujol mull): $\tilde{\nu}$ = 350 (m), 386 (s), 416 (m), 428 (m), 456 (m), 488 (m), 544 (w), 572 (m), 588 (m), 616 (w), 628 (w), 640 (w), 684 (m), 724 (s), 736 (s), 748 (s), 796 (m), 830 (s), 890 (m), 922 (s), 976 (w), 1044 (w), 1050 (m), 1100 (m), 1122 (m), 1146 (s), 1194 (s), 1250 (m), 1274(s), 1326 (s) cm^{-1}. ^1H NMR (300 MHz, C_6D_6, 25 °C): δ = 8.5–7.15 (m, 18 H, C_6H_3), 3.21 [sept, 4 H, $C_6H_3\{CH(CH_3)_2\}_2$], 1.43 [s, 8 H, $C(CH_3)_2CH_2C(CH_3)_3$], 1.35 [d, 24 H, $C_6H_3\{CH(CH_3)_2\}_2$], 0.95 [s, 24 H, $C(CH_3)_2CH_2C(CH_3)_3$], 0.77 [s, 36 H, $C(CH_3)_2CH_2C(CH_3)_3$] ppm. The crystal structure shows the presence of one Et_2O molecule in the unit cell. However, the elemental analysis indicates that this is absent from the powder sample analysed; presumably it is removed by the vacuum drying to which the sample was subjected.

[Ti$_2$(μ-tbop-κ^{3}O,S,O)$_2$(N*t*Bu)$_2$(NH$_2$*t*Bu)$_2$] (5): BuLi (2.19 mL, 3.52 mmol) was added to a cooled (233 K) solution of NH_2tBu (0.13 g, 1.76 mmol) in diethyl ether (40 mL). The mixture was allowed to warm to room temperature. After 3 h of stirring, **2** (0.98 g, 0.88 mmol) was added. The orange mixture was stirred for 24 h and then filtered to remove LiCl. Then, NH_2tBu (0.13 g, 1.76 mmol) was added to the filtrate and stirred for 2 h. Concentration of the reaction mixture to 10 mL gave yellow crystals of **5** after standing at room temperature for 2 d. These were filtered off and dried in vacuo. Yield: 0.86 g (76%). $C_{72}H_{120}N_4O_4S_2Ti_2$ (1265.64): calcd. C 68.33, H 9.56, N. 4.43, S, 5.07; found C 68.98, H 10.16, N 4.31, S 5.37. IR (Nujol mull): $\tilde{\nu}$ = 346 (vw), 402 (w), 420 (w), 444 (w), 492 (w), 530 (w), 560 (w), 574 (w), 604 (w), 672 (m), 748 (m), 758 (m), 824 (vs), 886 (m), 874 (s), 1018 (s), 1060 (s), 1112 (s), 1146 (s), 1194 (m), 1232 (s), 1260 (vs), 1308 (vs), 1536 (w), 1592 (m), 3104 (m), 3180 (w) cm^{-1}. ^1H NMR (300 MHz, C_6D_6, 25 °C): δ = 7.94–6.60 (m, 12 H, C_6H_3), 4.22 [br. s, 4 H, $NH_2C(CH_3)_3$], 1.48 [s, 8 H, $C(CH_3)_2CH_2C(CH_3)_3$], 1.27 [s, 18 H, $NH_2C(CH_3)_3$], 1.26 [s, 24 H, $C(CH_3)_2CH_2C(CH_3)_3$], 1.04 [s, 18 H, $NC(CH_3)_3$], 0.73 [s, 36 H, $C(CH_3)_2CH_2C(CH_3)_3$] ppm.

[Ti(tbop-κ^{3}O,S,O)Cl(OSiMe$_3$)(NH$_2$*t*Bu)] (6): Crude Me_3SiCl (0.86 g, 7.90 mmol) was added to a solution of **2** (2.5 g, 1.97 mmol) in diethyl ether (30 mL). The reaction mixture was stirred at room temperature, upon which the solution changed colour from orange to dark red. After filtration the solution was concentrated to 10 mL and allowed to stand at room temperature for 4 d. After that time red crystals of **6** suitable for X-ray structural analysis separated. Yield: 1.73 g (72%). $C_{35}H_{60}ClNO_3SiSTi$ (686.34): calcd. C 61.28, H 8.82, Cl 5.10, N 2.04, S 4.67; found C 61.91, H 8.53, Cl 5.28, N 2.16, S 5.03%. IR (Nujol mull): $\tilde{\nu}$ = 340 (vw), 472 (w), 492 (w), 584 (m), 622 (w), 680 (m), 736 (m), 762 (s), 836 (s), 892 (s), 928 (vs), 1028 (m), 1056 (m), 1148 (m), 1248 (s), 1280 (s), 1296 (s), 1568 (m), 3216 (s), 3280 (s) cm^{-1}. ^1H NMR (300 MHz, C_6D_6, 25 °C): δ = 7.38–6.79 (m, 6 H, C_6H_3), 4.15 [br. s, 2 H, $NH_2C(CH_3)_3$], 1.47 [s, 4 H, $C(CH_3)_2CH_2C(CH_3)_3$], 1.21 [s, 9 H, $NH_2C(CH_3)_3$], 1.09 [s, 12 H, $C(CH_3)_2CH_2C(CH_3)_3$], 0.65 [s, 18 H, $C(CH_3)_2CH_2C(CH_3)_3$], 0.13 [s, 9 H, $Si(CH_3)_3$] ppm.

[NH$_2$*i*Pr$_2$][Ti(tbop-κ^{3}O,S,O)Cl$_3$] (7)·CH$_2$Cl$_2$ and [Ti$_2$(μ-tbop-κ^{3}O,S,O)$_2$Cl$_2$(N*i*Pr$_2$)$_2$] (8): $NHiPr_2$ (0.16 mL, 1.94 mmol) was addedto a solution of **2** (1.09 g, 1.94 mmol) in toluene (20 mL) and the mixture was stirred for 12 h. Then, solvent was removed under vacuum and the residue extracted with Et_2O. CH_2Cl_2 (5 mL) was added to the dark-red ether solution, and left at room temperature for a few days. After that time red crystals of **7** suitable for X-ray analysis had settled out. They were filtered off and dried under vacuum. Yield: 0.89 g (66%). $C_{34}H_{56}Cl_3NO_2STi$ (697.10): calcd. C 58.68, H 8.12, Cl 15.09, N 2.01, S 4.60; found C 58.58, H 8.09, Cl 14.89, N 1.96, S 4.48. IR (Nujol mull): $\tilde{\nu}$ = 316 (s), 352 (m), 416 (m), 450 (m), 468 (m), 492 (m), 578 (s), 588 (m), 680 (m), 740 (s), 754 (m), 834 (s), 879 (m), 892 (m), 1100 (w), 1140 (w), 1248 (s), 1258 (s), 1272 (s), 1290 (s), 1334 (s), 1568 (m), 1579 (m) cm^{-1}. ^1H NMR (300 MHz, C_6D_6, 25 °C): δ = 7.75 (br., 2 H, NH_2iPr_2), 7.63–6.50 (m, 6 H, C_6H_3), 2.88 [m, 2 H, $NCH(CH_3)_2$], 1.63 [s, 4 H, $C(CH_3)_2CH_2C(CH_3)_3$], 1.28 [d, 12 H, $NCH(CH_3)_2$], 1.25 [s, 12 H, $C(CH_3)_2CH_2C(CH_3)_3$], 0.81 [s, 18 H, $C(CH_3)_2CH_2C(CH_3)_3$] ppm. The crystal structure shows the presence of one CH_2Cl_2 molecule in the unit cell. However, the elemental analysis indicates that this is absent from the powder sample analysed; presumably it is removed by the vacuum drying to which the sample was subjected.

The dark-orange, solid residue from the separation of **7** was dissolved in toluene (20 mL) and Et_2O (20 mL) was added. After standing for 2 d at room temperature, orange microcrystals of **8** precipitated. These were filtered off, washed with Et_2O and dried under vacuum. Yield: 0.58 g (48%). $C_{68}H_{108}Cl_2N_2O_4S_2Ti_2$ (1248.47): calcd. C 65.42, H 8.72, Cl 5.68, N 2.24, S 5.14; found C 65.02, H 8.41, Cl 5.52, N 2.01, S 5.21. IR (Nujol mull): $\tilde{\nu}$ = 338 (w), 456 (m), 486 (m), 576 (s), 625 (w), 675 (m), 735 (s), 750 (s), 799 (s), 879 (s), 890 (m), 1105 (w), 1139 (w), 1245 (s), 1251 (s), 1269 (s), 1287 (s), 1330 (s), 1579 (m) cm^{-1}. ^1H NMR (300 MHz, C_6D_6, 25 °C): δ = 7.63–6.50, (m, 6 H, C_6H_3), 3.37 [sept, 2 H, $N\{CH(CH_3)_2\}_2$], 1.63 [s, 4 H, $C(CH_3)_2CH_2C(CH_3)_3$], 1.28 [s, 12 H, $C(CH_3)_2CH_2C(CH_3)_3$], 1.01 [d, 12 H, $N\{CH(CH_3)_2\}_2$], 0.81 [s, 18 H, $C(CH_3)_2CH_2C(CH_3)_3$] ppm.

Polymerisation Test: A slurry of [$MgCl_2(THF)_2$] (10 mmol) in *n*-hexane was milled under argon in a glass mill (capacity 250 mL, with 20 balls of diameter 5–15 mm) at room temperature for 6 h. Then, the titanium compound (1 mmol) and *n*-hexane (50 mL) were added, and the mixture was milled for a further 24 h. The sample of precatalyst suspension (containing 0.01 mmol of titanium) was activated with $AlEt_2Cl$ (Al:Ti = 120) for 15 min at 323 K under argon. Prior to polymerisation, ethene was passed through the suspension of the catalyst (10 mL) in a Schlenk ampoule for 15 min at room temperature and normal pressure to form the prepolymer (about 1 g). An additional amount of organoaluminium compound [$Al(iBu)_3$ or MAO] was then added to the catalyst dispersed in the prepolymer (Al:Ti = 2000) to form a highly active catalyst. The polymerisation of ethylene was carried out in *n*-hexane at 323 K in a stainless-steel reactor (1 L), equipped with a stirrer, at 0.5 MPa pressure. The polymerisation was quenched with a 5% solution of HCl in methanol and dried under vacuum.

Crystal Data and Refinement Details for 1·2CH$_3$CN, 5, 6, and 7·CH$_2$Cl$_2$: Preliminary examination and intensity data collections were carried out on a CCD KUMA KM4 κ-axis diffractometer with graphite-monochromated Mo-K_α. Data were corrected for Lorentz, polarisation and absorption effects. The structures were solved by direct methods and refined by the full-matrix least-squares method on all F^2 data using the SHELXTL-NT v. 5.1 software package.[23] Carbon-bound hydrogen atoms were included in calculated positions and refined in the riding mode. Other hydrogen

Chiral Iron(II) and Cobalt(II) Complexes with Biphenyl-Bridged Bis(pyridylimine) Ligands – Syntheses, Structures and Reactivities

Christoph Vedder,[a] Frank Schaper,[a] Hans-Herbert Brintzinger,*[a] Mika Kettunen,[b] Sebastian Babik,[c] and Gerhard Fink[c]

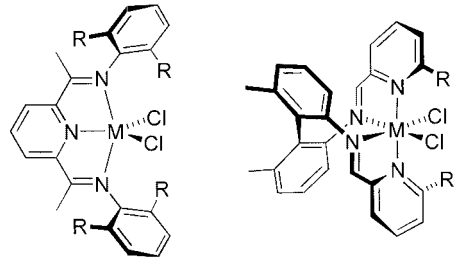
Keywords: Iron(II) / Cobalt(II) / Bianiline / Pyridylimine

A new class of iron(II) and cobalt(II) complexes with neutral, tetradentate bis(pyridylimine) chelate ligands bridged by a chiral 6,6′-dimethylbiphenyl backbone has been synthesized. Their dihalogen derivatives gave spectral, magnetic and X-ray diffraction results in agreement with a C_2-symmetric, approximately octahedral geometry with *cis*-positioned halide ligands and high-spin d-electron configuration. ^{1}H NMR signals of these paramagnetic complexes were assigned by correlating line widths with reciprocal proton-metal distances. Methyl substitution in 6-position of the pyridyl rings lead to a different, presumably square-pyramidal coordination geometry under dissociation of one chloride ion. Fe^{II} dimethyl and diisocyanide derivatives were shown to have low-spin configuration and C_1-symmetric geometry. With respect to MAO-activated olefin polymerization, significant catalytic activities were reproducibly obtained only under conditions, where the original complex structure was degraded.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Complexes of late transition metals such as Pd, Ni, Fe, or Co are interesting targets for olefin polymerization catalysis,[1,2] none the least since these catalysts are relatively tolerant towards polar substrates and might thus allow copolymerization of α-olefins with polar monomers.[3] Iron-based catalysts in particular have shown activities for ethene polymerization which are comparable to those of the most active group(IV) metallocene catalysts. The excellent stereoselectivity of metallocene-catalyzed propene polymerization,[4] however, is still lacking for late transition metal catalysts. Low-temperature polymerizations have afforded polypropene with only partially syndiotactic or isotactic microstructures induced by chain-end stereocontrol.[5]

Most iron- or cobalt-based polymerization catalysts employ symmetric tridentate pyridyldiimine ligands, which form C_{2v}-symmetric bipyramidal complex species with homotopic coordination sites (Scheme 1).[1c,2c] Enantiotopic coordination sites, as required for olefin insertion under catalytic-site control, might be obtained by use of axially chiral, tetradentate ligands, from which C_2-symmetric octahedral complexes would be generated on coordination to MX_2 (Scheme 1). Chiral complexes with two N ligand atoms have previously been applied in enantioselective homogeneous catalysis.[6] Here we report on the synthesis of chiral Fe^{II} and Co^{II} complexes with C_2-symmetric, bianiline-bridged tetradentate nitrogen ligands, and on the properties of these complexes in homogeneous olefin polymerization.



Scheme 1. Pyridyldiimine complexes with C_{2v} symmetry (left) and biphenyl-bridged bis(pyridylimine) complexes with axial C_2 symmetry (right)

Results and Discussion

Ligand Syntheses

The neutral, potentially tetradentate ligands *N*,*N*′-(biphenyl-2,2′-diyl)bis(2-pyridylmethyl)diimine (**1**), and *N*,*N*′-(6,6′-dimethylbiphenyl-2,2′-diyl)bis[(6-R′′-2-pyridyl)methyl]diimine [R′′ = H (**2**), Me (**3**)], were prepared by condensation of the known *N*,*N*′-(biphenyl-2,2′-diyl)diamines **4** and **5**,[7] with the appropriate heteroaromatic aldehyde in

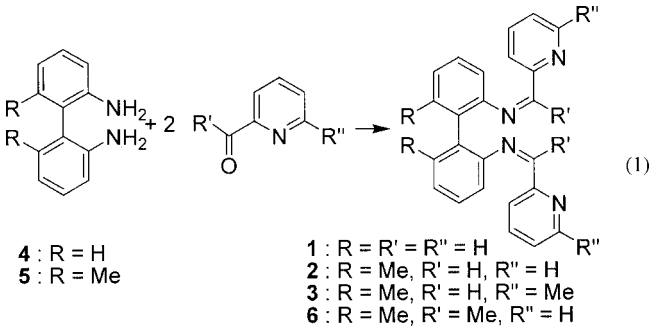
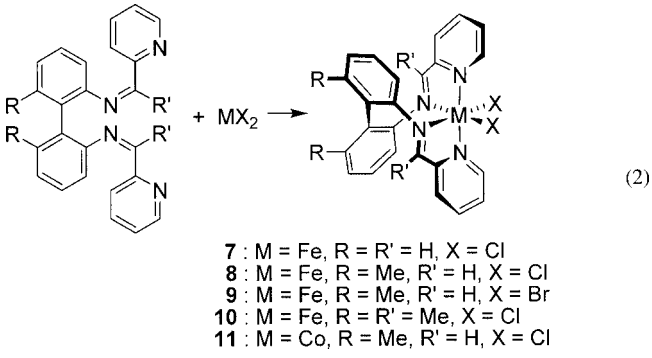
ethanol at room temperature [Equation (1)]. Ligand **1** was reacted directly, without prior isolation, with iron(II) chloride (vide infra). Reaction of **5** with 2-acetylpyridine, be it in ethanol, methanol or dichloromethane with catalytic amounts of acetic, formic or hydrochloric acid, or in benzene over molecular sieves or in diethyl ether/pentane mixtures in the presence of excess $TiCl_4$, did not afford the desired ligand **6**. Refluxing a toluene solution of **5** and 2-acetylpyridine with a catalytic amount of *p*-toluenesulfonic acid in a Dean–Stark apparatus, however, yielded after three days a mixture which contained, apart from the starting materials, *N*,*N*′-(6,6′-dimethylbiphenyl-2,2′-diyl)bis[1-(2-pyridyl)ethane]diimine (**6**), in ca. 45% yield as determined by ^{1}H NMR spectroscopy. This reaction mixture was used without purification for further complex syntheses.



(1)

Complex Syntheses, Structures, and Spectroscopic Properties

Reaction of $FeCl_2$ or $FeBr_2$ with the dipyridyldiimine ligands **1**, **2**, or **6** in THF afforded, after evaporation of solvent and extraction with CH_2Cl_2, the blue to turquoise iron(II) complexes **7**–**10** [Equation (2)].[8] Since **7**–**10** were found to be insoluble in non-chlorinated solvents, excess ligand (and starting materials of the ligand synthesis in the case of **6**) was removed by washing with diethyl ether and pentane to yield analytically and spectroscopically pure products. The light brown cobalt(II) complex **11** was obtained by an analogous reaction of $CoCl_2$ with **2**.



(2)

Single crystals of the dichloro complexes **8** and **11** were obtained by layering their dichloromethane solutions with pentane or toluene, respectively. The complexes are isostructural and crystallize in the monoclinic space group *C*2/*c* with cell constants deviating by less than 0.2 Å and less than 0.5° (Figure 1, Table 1). The distorted octahedral complexes, with *cis*-positioned chlorine atoms, both possess crystallographic C_2-symmetry. Co–N bonds are approximately 0.05 Å shorter than their Fe–N counterparts (Table 1), presumably a consequence of higher nuclear charge and more strongly contracted metal d-orbitals of cobalt. Fe–N distances are within the range generally observed in neutral, octahedral iron complexes.[9] The bond angles ∠N1–M–Cl1, ∠N2–M–Cl1 and ∠N2–M–Cl1A (M = Fe, Co) at each of the metal centers deviate by less than 2° from each other and from the value of 90° expected for octahedral coordination. The bite angles of the twisted seven-membered chelate ring, ∠N1–M–N1A = 73–74°, and of the five-membered chelate rings, ∠N1–M–N2 = 73–74°, however, are both significantly smaller than 90° and lead to a distortion of the octahedral coordination, i.e. to an opening of the angle ∠Cl1–M–Cl1A to a value of 110–112° (Table 1). Due to the twisted bianiline backbone, the planes formed by N1, N1A, and M and by M, Cl1, and Cl1A deviate from each other by 26–28°.

For the magnetic moments of complexes **8** and **11**, high-spin values of μ_{eff} = 5.47 μ_B and μ_{eff} = 4.96 μ_B, respectively, were measured by the SQUID method at 300 K. No indication for any thermally induced spin-crossover between 90 K and 300 K was obtained in either case. In this regard, complex **8** falls in line with related Fe^{II} complexes such as [bis(bipyridyl)$FeCl_2$] or bis(phenanthrolin)$FeCl_2$, for which high-spin configurations have likewise been reported.[10]

In the ^{1}H NMR spectrum of the paramagnetic iron(II) complex **8** in $CDCl_3$ solution, nine signals are detected over a range of nearly 190 ppm (Figure 2), in agreement with a time-averaged C_2-symmetric complex geometry. Based on the observed signal intensities, the resonance at δ = –6.72 ppm is clearly identified as being due to the methyl groups. Since no signal above δ = 120 is displayed in the NMR spectrum of complex **10**, which contains, instead of the aldimine ligand **2**, the analogous ketimine ligand **6**, we can conclude that the resonance of complex **8** at $\delta \approx$ 180 ppm must be due to its aldimine protons.

Assignments of further signals are based on their relative line widths: Up to a distance of ca. 5 Å from the metal center, relative line widths of two nuclei A and B depend reciprocally on the ratio of their distances from the metal center, $v_2(A)/v_2(B) \approx (d_B/d_A)^6$.[11] The remaining signals can thus be assigned as shown in Figure 2 and Table 2.

^{1}H NMR spectra of complexes **7** and **9**–**11** in $CDCl_3$ solution, which are likewise in agreement with time-averaged C_2 symmetry, were assigned in a manner similar to that used for **8** (see Exp. Sect.). Complexes **7**, **9**, and **10**, for which crystal structure determinations are not available, could in principle adopt the C_2-symmetric geometries indicated by their ^{1}H NMR spectra with their two chlorine ligands either in *trans*- or in *cis*-configuration. In order to ascertain, whether these complexes have the same *cis*-halide geometry as found for **8** and **11**, we have characterized these complexes also by their far-infrared vibrational spectra.

For a C_{2v}-symmetric complex of the type [*cis*-N_4FeCl_2], four Fe–N and two Fe–Cl vibrations are expected to be IR-active. For [*trans*-N_4FeCl_2] with approximate D_{4h} symmetry, however, only one Fe–N and one Fe–Cl vibration would be IR-active, if no distinction is made between imine and pyridine N atoms.[12] In the IR spectra of solid **8**, **9**, and **11**

Two further strong peaks are observed at 244 and 144 cm^{-1} for complex **8** and at 174 and 104 cm^{-1} for its dibromo homologue **9**. The 1.4:1 ratio of these wavenumbers, which is close to the theoretical value of 1.5 estimated from the ratio of reduced masses of Fe–Cl and Fe–Br, supports the assignment of these bands to the symmetric and asymmetric stretching modes of a *cis*-FeX_2 unit. The Co–Cl vibrations of **11** were found at 242 and 135 cm^{-1}, as expected only slightly below those of **8**. Analogous assignments hold for **7** and **10**. Complexes **7**–**11** thus all contain *cis*-coordinated halogen ligands in the solid state.

While the chiral, C_2-symmetric complexes **7**–**11** have the *cis*-positioned homotopic sites required for enantioselective olefin insertion, substituents bigger than hydrogen would be desirable in the 6-positions of the pyridine rings, so as to transfer the axial chirality of the biphenyl backbone most effectively to the coordination sites of the complex (Figure 3).

In order to obtain a homologue of complex **8** with methyl substituents in both pyridyl 6-positions, $FeCl_2$ was reacted with ligand **3**. Reactions in THF yielded **12**·THF as a brown solid. The same product, without THF, was obtained from reactions in CH_2Cl_2. In contrast to complexes **7**–**11**, complex **12** gives a ^1H NMR spectrum with only three broad signals centered at δ = 3.45, –4.91, and –11.39. Only two strong and one medium vibration at 367, 319, and 268 cm^{-1}, respectively, are apparent in its far-infrared spectrum, again in contrast to complexes **7**–**11**, where four M–N and two M–X vibrations have been observed. The C_2-symmetric geometry found for these complexes is thus unlikely to be adopted by complex **12**.

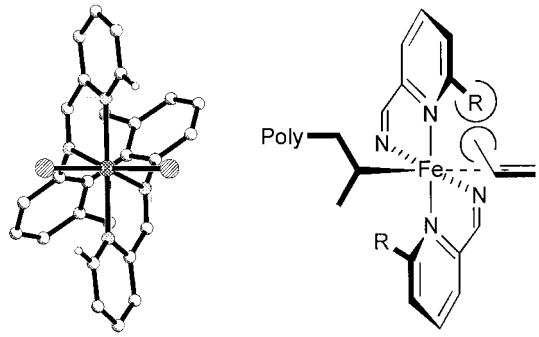

Figure 3. Front view of complex **8** (left) and of a putative Fe-polymeryl π complex (right) with propene coordinated by its disfavored enantioface (biphenyl bridge omitted for clarity)

The only useful structural clue is derived from SQUID measurements, which yielded for complex **12** an effective magnetic moment of μ_{eff} = 3.41 μ_B, indicative of 2–3 unpaired electrons, i.e. of a configuration with partly paired electron spins. The ligand field separation ΔE = 10 *Dq* of the octahedral complexes **7**–**11** is clearly insufficient to induce any spin pairing, and the same holds, a fortiori, for tetrahedral or trigonal bipyramidal geometries (Figure 4). The only plausible coordination geometry, which would be in agreement with the partial spin pairing observed for **12**, is that of a square pyramidal complex, e. g. of a species [(**3**)FeCl]$^+$Cl$^-$, in which one of the chloride ligands has been eliminated from the metal center due to steric repulsions by the methyl-substituted pyridyl ligands. To reach a square pyramidal geometry, at least three of the four N ligand atoms must be positioned in the square base plane of the complex (Scheme 2). Rearrangements between alternative connectivities, which are likely to occur quite rapidly, as well as chloride dissociation and re-association equilibria would plausibly explain the observed broadening of the NMR signals of **12**.[14]

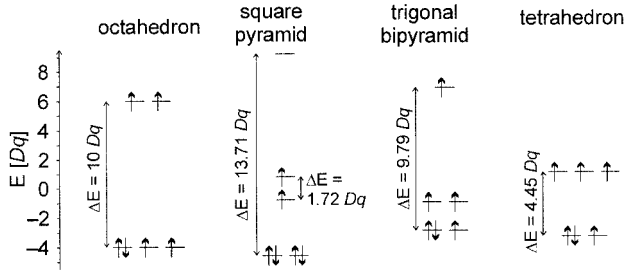

Figure 4. Effects of different complex geometries with moderately strong ligand field on d^6 electron configurations (values taken from ref.[15])

In order to obtain also bona-fide low-spin complexes with the bianiline-bridged ligand framework under consideration, complex **8** was reacted with methylmagnesium chloride [Equation (3)]. The diamagnetic dimethyl complex **13** was obtained from this reaction as a brown powder.[16] Its ^1H NMR spectrum revealed a C_1-symmetric geometry in solution. The same geometry was also found for its counterpart with isocyanide instead of methyl ligands. This sec-

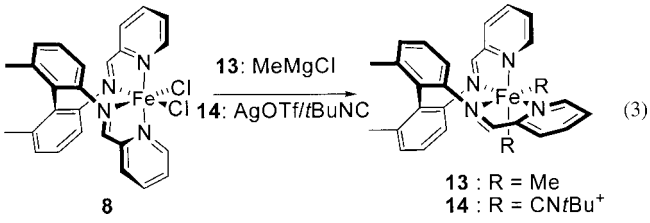
Scheme 2. Structure proposed for complex **12**

ond low-spin derivative, the orange-red complex **14** was obtained by reaction of complex **8** with two equivalents each of AgOTf and *tert*-butyl isocyanide [Equation (3)].[17] The ^{1}H NMR spectrum of **14** (see Exp. Sect.) confirmed the coordination of two isocyanide ligands, and indicated, again, a C_1-symmetric geometry.



(3)

This structural assignment is supported by the results of an X-ray diffraction study (Figure 5, Table 4): In the cationic diisocyanide complex **14**, three of the four N ligand atoms reside in one meridional plane; in the second meridional plane, one of the pyridyl moieties and the two *tert*-butyl isocyanide ligands are coordinated to the iron center.[18]

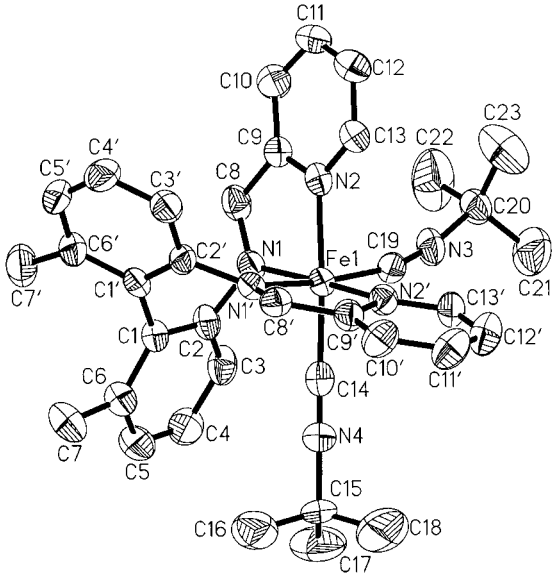


Figure 5. Crystal structure of the complex cation **14**; hydrogen atoms, triflate anions and co-crystallized solvent omitted for clarity, thermal ellipsoids drawn at the 50% probability level

The overall C_1 symmetry of this complex appears to be stabilized by one or more of the following factors: Close

adherence to idealized octahedral geometry and a shortening of the Fe–N bonds, which is presumably required by the low-spin configuration of **14**, is more easily adopted by a C_1- than by a C_2-symmetric geometry, as indicated by the ligand–metal–ligand bite angles in **14** (Table 4), which are much closer to 90° than those of the C_2-symmetric complex **8** (Table 1). In addition, the pyridyl ligands are likely to prefer a *cis* over a *trans* arrangement in order to utilize different d orbitals for backdonation. A possible preference of isocyanide ligands to coordinate *trans* to pyridine, finally, can be satisfied, for at least one of the isocyanide ligands, only in the C_1-symmetric geometry shown in Figure 5.[19]

Polymerization Experiments

Reaction conditions suitable for catalytic polymerization of ethene were sought in particular using complex **8** as precatalyst. When very finely dispersed suspensions of 10–20 mg (ca. 20–40 μmol) of turquoise **8** in 120 mL of toluene, prepared by extended exposure to an ultrasound bath, were reacted with a toluene solution of methylalumoxane (MAO) in a glass-walled reactor, with [Al]/[Fe] ratios varying between 30:1 and 1000:1, dark green solutions were obtained. Exposure of such a solution to 2–4 bar of ethene or propene yielded only miniscule flakes of polymer (if any), which escaped any isolation attempts. Neither particularly careful exclusion of air and moisture from the reaction mixture nor its deliberate exposure to the atmosphere or even addition of oxidizing reagents, such as $[NO][BF_4]$ or Meerwein salt, which are capable of oxidizing Fe^{II} complexes,[20] gave any more positive results, nor was this the case when the Fe^{III} complex $[\mathbf{8}]^+Cl^-$ was separately synthesized (see Exp. Sect.) and tested with regard to its catalytic activity after reaction with MAO or with trityl perfluorotetraphenyl borate and $(i\text{Bu})_3\text{Al}$.[21]

Remarkably, however, significant amounts of polymer were obtained, when 20–50 mg (ca. 40–100 μmol) of solid complex **8** in toluene were activated, *without* being finely dispersed by ultrasound treatment, by addition of a toluene solution of MAO, at [Al]/[Fe] ratios of ca. 55–85:1. When the black viscous tar, obtained from this activating procedure, was introduced into a stainless-steel reactor and then immediately exposed to 30 bar of ethene at reaction temperatures of 0–40 °C, yields of 40–160 mg polyethene

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

were reproducibly isolated after a reaction time of 4 hours,[22] corresponding to productivities of ca. 160–1000 g polymer/(mol Fe≅h) (Table 5). In analogous experiments with complexes **10** and **12**, no polymer was obtained although these experiments followed a protocol which had proven successful for complex **8**.

Table 5.Conditions and results of olefin polymerization reactions[a]

Run	Catalyst [μmol]	MAO [Al]:[Fe]	T_p [°C]	Monomer [bar]	Ultra-sound treatment	Polymer yield
1	**8**, 38.7	30:1	20	ethene, 4	yes	traces

13	**12**, 42.2	120:1	25	ethene, 30	no	0

[a] Reaction conditions: 120 mL of toluene; reaction time, 4 hours; 1–5 min. pre-incubation with cocatalyst. [b] Trityl (perfluorotetraphenyl)borate (1 equiv.) and triisobutylaluminum (0.5 mL).

Conclusions

The results described above indicate that complex **8** undergoes some transformation upon exposure to MAO; this does not lead to an active species, capable of inducing catalytic olefin polymerization, however, when the reaction is conducted in homogeneous solution. While no direct clues indicate the nature of the green species formed under these conditions, we can surmise, in analogy to results obtained with related reaction systems,[23] that metal alkyl cations of the type N_4FeMe^+, most likely stabilized by uptake of a MAO-derived $AlMe_3$ unit, dominate in these solutions and would thus be responsible for the strongly red-shifted UV/Vis absorption of these reaction systems. If indeed present in these solutions, these species are obviously not capable of inducing chain growth by olefin insertion. Their 16-valence electron configuration is apparently not sufficiently electron-deficient to coordinate and insert an olefin substrate, in distinction to related 14-electron cations of the type N_3FeMe^+, which are considered to be catalytically active in MAO-activated Fe^{II} pyridyldiimine systems.[23]

The reaction of MAO with solid particles of complex **8**, on the other hand, seems to favour some other reaction paths, most likely some intermolecular ligand exchange reaction. Formation of the viscous, tarry product is likely to arise from a transfer of some of the N ligand atoms, e. g. of a pyridyl moiety, from one complex molecule to another, such that the resulting oligomeric or polymeric complex species now contains metal centers, which are coordinated to less than four N ligand atoms. More likely than not, such a reaction would lead to a collection of different coordination patterns each with its own catalytic property, rather than to a unique complex geometry.

In accord with this assumption, a gel-permeation chromatography (GPC) analysis of the polyethene samples obtained from runs 10–12 reveals in all cases a molecular mass distribution with three distinct fractions (see Supporting Information) with M_n values of 130–180 ($M_w/M_n \approx 1.25$), ca. 3600–7000 ($M_w/M_n \approx 1.7$) and ca. 160000–320000 ($M_w/M_n \approx 6.2–7.1$), respectively. Clearly, several catalytic species contribute to chain growth in these reaction systems. The component with highest M_n is remarkably similar, in its mean chain length as well as in its rather broad molar mass distribution, to polyethene samples obtained with typical MAO-activated iron pyridyldiimine complexes,[1c,2d] in agreement with the assumption that some related catalyst species with reduced coordination number might be generated from complex **8** by the heterogeneous activation procedure described above. The observations presented here, in particular the lack of reactivity of any of our reaction systems vis-à-vis propene,[21] let the probability of observing catalytic-site-controlled, stereoselective olefin polymerization by precatalyst structures of the type investigated in this report, appear rather remote.

Experimental Section

All preparations were performed under an argon atmosphere using standard Schlenk techniques. Solvents were dried prior to use by refluxing over and distillation from sodium (THF, hydrocarbons) or calcium hydride (dichloromethane). Deuterated solvents were dried over 4-Å molecular sieves. All other chemicals were commercially obtained and used without further purification. Melting points were determined with a Sanyo–Gallenkamp MFB-600–010F thermometer, magnetic susceptibilities with a Quantum Design Superconducting Quantum Interference Device (SQUID) MPMS-XL5. NMR spectra were collected on Bruker AC 250 FT NMR or Bruker Avance DRX 600 spectrometers, IR spectra measured with a Perkin–Elmer 2000 FT-IR spectrometer, either as KBr or polyethene (PE) pellets, UV spectra of 1.0 mM solutions in a 1-cm cuvette with a Varian–Cary 50 and mass spectra with Finnigan MAT 312 (EI) or Finnigan AMD MAT 312/AMD 5000 (FAB) mass spectrometers. Elemental compositions were analyzed with an Elementar Vario EL device. Ligands **2** and **3** were prepared as described earlier.[24]

***N,N′*-(Biphenyl-2,2′-diyl)bis(2-pyridylmethyl)diimine (1):** A solution of **4** (361 mg, 1.96 mmol) in ethanol (10 mL) was stirred for 1 h with pyridine-2-carbaldehyde (373 μL, 420 mg, 3.92 mmol). After evaporation of solvent, **1** was obtained as a solid residue in almost quantitative yield. ^{1}H NMR (250 MHz, $CDCl_3$, ppm): δ = 7.11 [d, ^3J (H-H) = 7.9 Hz, 2 H; Ar-H], 7.23–7.48 (m, 8 H, Ar-H), 7.66 [t, ^3J (H-H) = 7.3 Hz, 2 H; Ar-H], 7.79 [d, ^3J (H-H) = 7.9 Hz, 2 H; Ar-H], 8.34 (s, 2 H, N=CH), 8.49 [d, ^3J (H-H) = 4.3 Hz, 2 H; 6′′-H]. Since **1** was not obtainable in powdered form, the solid residue was dissolved in THF and used for further reactions.

***N,N′*-(6,6′-Dimethylbiphenyl-2,2′-diyl)bis[1-(2-pyridyl)ethyl]diimine (6):** To a solution of **5** (4.45 g, 21.0 mmol) in toluene (100 mL) was added 2-acetylpyridine (4.70 mL, 5.08 g, 41.9 mmol) and *para*-toluenesulfonic acid hydrate (797 mg, 4.19 mmol). After refluxing the reaction mixture in a Dean–Stark aparatus for 3 days, the solvent

was evaporated. The residue was suspended in 200 mL of diethyl ether, freed from solids by filtration and the solids washed with diethyl ether. The combined ether fractions were extracted with diluted sodium hydroxide solution (200 mL) and subsequently dried with $MgSO_4$. After evaporation of solvent, a brown crude product was obtained (6.97 g), which contained, according to its ^1H NMR, 24% toluene, 6% **5**, 12% 2-acetylpyridine, 21% of the mono condensation product, and 37% of **6**. Attempted purification by column chromatography on silica gel lead to decomposition of **6** to the starting materials. Since this crude ligand was suitable for complex formation, no further attempts were undertaken to purify it. Yield (calculated on ^1H NMR basis) 2.58 g (6.16 mmol, 29%). ^1H NMR (250 MHz, $CDCl_3$, ppm): δ = 2.14 (s, 6 H, 6-CH_3/6′-CH_3), 2.28 (s, 6 H, N=C–CH_3), 6.57 [d, ^3J (H-H) = 7.9 Hz, 2 H; 3-H/3′-H], 7.03 [d, ^3J (H-H) = 7.3 Hz, 2 H; 5-H/5′-H], 7.15–7.30 (m, 4 H, 4-H/4′-H, 5′′-H), 7.56–7.67 (m, 4 H, 3′′-H, 4′′-H), 8.55 [d, ^3J (H-H) = 4.9 Hz, 2 H; 6′′-H].

General Procedure for the Synthesis of Dihalogeno Metal(II) Complexes 7–11: To a stirred suspension of the metal halide in THF (10 mL/mmol), a solution of 1.02 equiv. of the ligand in THF (10 mL/mmol) was slowly added. After stirring overnight, the solvent was evaporated and the residue extracted four times with CH_2Cl_2 (4 × 20 mL/mmol). The combined extracts were evaporated to dryness and the remaining solids suspended in diethyl ether (15 mL/mmol). The complex was collected by filtration, washed with diethyl ether (3 × 5 mL/mmol), once with pentane (5 mL/mmol), and finally dried in vacuo.

Dichloro[*N*,*N*′-(biphenyl-2,2′-diyl)bis(2-pyridylmethyl)diimine]-iron(II)·0.5 CH_2Cl_2 (7·0.5 CH_2Cl_2): A solution of **1**, obtained from **4** (361 mg, 1.96 mmol) and pyridine-2-carbaldehyde (373 µL, 420 mg, 3.92 mmol), in THF (20 mL) was reacted, following the general procedure, with $FeCl_2$ (246 mg, 1.94 mmol) to yield blue **7**·0.5 CH_2Cl_2 (858 mg, 1.61 mmol, 83%). ^1H NMR (600 MHz, $CDCl_3$, ppm): δ = –8.29 (s, $\Delta\nu_{1/2}$ = 72.3 Hz, 2 H; 4-H/4′-H or 5-H/5′-H or 4′′-H), –4.20 (s, $\Delta\nu_{1/2}$ = 179 Hz, 2 H; 3-H/3′-H), 5.34 (s, $\Delta\nu_{1/2}$ = 61.5 Hz, 1 H; CH_2Cl_2), 6.42 (s, $\Delta\nu_{1/2}$ = 78.8 Hz, 2 H; 6-H/6′-H), 11.07 (s, $\Delta\nu_{1/2}$ = 76.9 Hz, 2 H; 4-H/4′-H or 5-H/5′-H or 4′′-H), 17.61 (s, $\Delta\nu_{1/2}$ = 94.9 Hz, 2 H; 4-H/4′-H or 5-H/5′-H or 4′′-H), 55.12 (s, $\Delta\nu_{1/2}$ = 119 Hz, 2 H; 3′′-H or 5′′-H), 56.01 (s, $\Delta\nu_{1/2}$ = 113 Hz, 2 H; 3′′-H or 5′′-H), 116.53 (s, $\Delta\nu_{1/2}$ = 575 Hz; 2 H), 180.40 (s, $\Delta\nu_{1/2}$ = 230 Hz, 2 H; N=CH). ^{13}C NMR (151 MHz, $CDCl_3$, ppm): δ = 14.59, 71.37 (C-6/C-6′), 160.91 (C-4/C-4′ or C-5/C-5′ or C-4′′), 193.84, 193.95, 198.96, 218.13 (C-4/C-4′ or C-5/C-5′ or C-4′′), 244.74, 421.96 (C-3′′ or C-5′′), 544.79 (C-3′′ or C-5′′), other expected ^{13}C signals were not observable due to the low solubility and the low intensity of the broad ^{13}C signals. IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3054, 3045, 3019 (m, m, w, Ar-H), 2978, 2964 (m, w, C–H), 1632, 1593, 1564 (s, s, m, C=N, C=C), 1471 (m, C–H_{def}), 1304 (m), 1011 (m). IR (PE, cm^{-1}): $\tilde{\nu}$ = 560 (m), 542 (m), 503 (m), 495 (m), 451 (m), 419 (m), 397 (w), 328 (w, Fe–N), 295 (m, Fe–N_{imine}), 251 (vs, Fe–Cl), 214 (w), 202 (w), 146 (m, Fe–Cl). Further $\tilde{\nu}$(Fe–N) bands could not be identified. UV/Vis (CH_2Cl_2): λ_{max} (ε) = 653 (1290). $C_{24.5}H_{19}Cl_3FeN_4$ (531.65): calcd. C 55.35, H 3.60, N 10.54; found C 55.24, H 3.75, N 10.58 (%).

Dichloro[*N*,*N*′-(6,6′-dimethylbiphenyl-2,2′-diyl)bis(2-pyridylmethyl)-diimine]iron(II) (8): Following the general procedure, **2** (2.10 g, 5.38 mmol) and $FeCl_2$ (668 mg, 5.27 mmol) yielded turquoise **8** (2.54 g, 4.91 mmol, 93%). SQUID: μ_{eff} = 5.47 μ_B. ^1H NMR (600 MHz, $CDCl_3$, ppm): δ = –7.62(s, $\Delta\nu_{1/2}$ = 30.3 Hz, 2 H; 4-H/4′-H or 5-H/5′-H or 4′′-H), –6.72 (s, $\Delta\nu_{1/2}$ = 28.7 Hz, 6 H; CH_3), –2.65 (s, $\Delta\nu_{1/2}$ = 149 Hz, 2 H; 3-H/3′-H), 11.35 (s, $\Delta\nu_{1/2}$ = 36.3 Hz, 2 H; 4-H/4′-H or 5-H/5′-H or 4′′-H), 17.08 (s, $\Delta\nu_{1/2}$ = 42.1 Hz, 2 H; 4-H/4′-H or 5-H/5′-H or 4′′-H), 52.77 (s, $\Delta\nu_{1/2}$ = 66.4 Hz, 2 H; 3′′-H or 5′′-H), 54.20 (s, $\Delta\nu_{1/2}$ = 56.6 Hz, 2 H; 3′′-H or 5′′-H), 116.21 (s, $\Delta\nu_{1/2}$ = 520 Hz, 2 H; 6′′-H), 180.74 (s, $\Delta\nu_{1/2}$ = 172 Hz, 2 H; N=CH). ^{13}C NMR (151 MHz, $CDCl_3$, ppm): δ = –181.44, 0.41, 39.30 (CH_3), 71.79 (C-4/C-4′ or C-5/C-5′ or C-4′′), 80.22, 157.30 (C-4/C-4′ or C-5/C-5′ or C-4′′), 194.91 (C-4/C-4′ or C-5/C-5′ or C-4′′), 195.76, 199.13, 232.31, 418.95, 533.17, 908.63 (C=N). IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3065, 3012 (w, w, Ar–H), 2962, 2916, 2850 (w, w, w, C–H), 1627, 1594, 1563 (m, s, m, C=N, C=C), 1475, 1450 (m, m, C–H_{def}), 1012 (m). IR (PE, cm^{-1}): $\tilde{\nu}$ = 590 (w), 555 (m), 536 (w), 515 (m), 488 (m), 474 (m), 437 (w), 416 (s), 386 (w), 337 (m, Fe–N), 300 (s, Fe–N_{imine}), 271 (w), 244 (vs, Fe–Cl), 192 (m, Fe–N), 144 (s, Fe–Cl), one $\tilde{\nu}$(Fe–N) was probably hidden by $\tilde{\nu}$ = 244 cm^{-1}. UV/Vis (CH_2Cl_2): λ_{max} (ε) = 641 (1140). MS (FAB): *m*/*z* (%): 516/518/520 (11/8/2) [M^+], 481/483 (100/43) [M^+ – Cl], 446 (22) [481/483 – Cl]; for $C_{26}H_{22}Cl_2FeN_4$ (517.24). calcd. MS (FAB): *m*/*z* (%): 483/481 (64/33) [M^+ – CH_2Cl_2 – 2 Cl], 446 (93) [481/483 – Cl], 391 (100) [446 – Fe + H]. $C_{27}H_{24}Cl_5FeN_4$ (637.63): calcd. C 50.86, H 3.79, N 8.79; found C 50.87, H 3.94, N 8.88 (%).

Diffractometric Structure Determination: Diffraction data for complexes **8**, **11**, and **14** were collected on a Siemens P4 diffractometer by using graphite-monochromatized Mo-*Kα* radiation with λ = 0.71073 Å (Table 6). Three check reflections were measured every 97 reflections. The structures were solved by direct methods (SHELXS97).[25] All non-hydrogen atoms were refined based on F_{obs}^2 (SHELXL97),[25] while hydrogen atoms were refined on calculated positions with fixed isotropic *U*, using riding model techniques.

Supporting Information: Far-infrared spectra of compounds **2**, **8**, **9**, **12**, and **12b**, temperature dependence of paramagnetic NMR shifts for complex **8**, GPC elution diagrams of polyethene samples obtained from entries 9–11 in Table 5.

Acknowledgments

For contributions to this work at the University of Konstanz we thank Anke Friemel (for 2D NMR spectra), Marie-Jose Quelle and Klaus Hägele (for EI and FAB mass spectra) and Dirk Haffke (for elemental analyses). For helpful comments we thank Professor Ulrich Steiner, for diffractometric structure determinations Dr. Ulrich Wieser (both University of Konstanz) and Dr. Christian Eichhorn (University of Würzburg). Encouragement for this work byProfessor Wolf-Dieter Schenk (University of Würzburg) and by Professor Markku Leskälä (University of Helsinki) and financial support by BMBF and BASELL GmbH are gratefully acknowledged.

[13] The Fe–N vibration of **8** at ca. 223 cm^{-1} is probably obscured by the broad and intense peak at 244 cm^{-1}.

[14] When brown **12** or **12**·THF was stirred overnight in an apolar solvent such as toluene or diethyl ether, it was transformed to a pink-colored solid (**12b**). Stirring **12b** in THF or CH_2Cl_2 regenerates brown **12**. Complex **12b** has a high-spin value of $\mu_{eff} = 5.23\ \mu_B$. Formation of **12b** in non-polar solvents indicates that both chloride ligands are coordinated, but **12b** differs from the C_2-symmetric complexes **7**–**11** in its FIR bands at 327 (s), 269 (m) and 202 (m) cm^{-1}. In the absence of suitable single crystals, its coordination geometry cannot be reliably assigned.

[16] We were not able to obtain satisfactory elemental analyses for complex **13**. Although no other species were detected in its NMR spectra, elemental analysis consistently gave carbon values too low by 3–4%; this might be caused by the presence of small amounts of $MgCl_2$.

[17] Reactions of **8** with 2 equiv. of silver triflate gave the analytically pure bistriflate derivative (see Exp. Sect.). A diffractometric structure determination revealed a C_2-symmetric geometry rather similar to that of **8** (for details see CCDC-229183).

[18] Vibrations of the isocyanide ligands were observed at 2160 and 2184 cm^{-1}, significantly higher than $\nu_{CN} = 2138\ cm^{-1}$ measured for free isocyanide. Back-bonding from the metal to the isocyanide ligand thus appears negligible.

[19] Coordination of both σ-donors *trans* to pyridine is prohibited by the obligatory *cis*-coordination of the diimine nitrogen atoms.

[21] Further propene polymerization experiments with **8**/MAO, **12**/MAO, or **13**/MAO in CH_2Cl_2 or toluene, at temperatures between 40 and 80 °C, propene pressures ranging from 2 to 10 bar and polymerization times up to 23 hours failed in all cases to produce even traces of polypropene.

[22] We assume that the unexpected formation of 60 mg of polyethene in polymerization run no. 2 (and in occasional other polymerization experiments) is caused by incomplete homogeneous dispersion of **8** due to insufficient exposure to the ultrasound pretreatment.

Alternative Coordination Modes in Palladium(II)-Diimino-Bispyridine Complexes with an Axially Chiral Biphenyl Backbone

Mika Kettunen,[a] Christoph Vedder,[b] Hans-Herbert Brintzinger,[b] Ilpo Mutikainen,[a] Markku Leskelä,[a] and Timo Repo*[a]

Keywords: Chiral biaryl ligands / Palladium imino complexes / Binuclear complexes

The chiral biphenyl-bridged diimino-bispyridine ligands *N*,*N*′-(6,6′-dimethylbiphenyl-2,2′-diyl)bis(2-pyridylmethyl)-diimine(**1**)and *N*,*N*′-(6,6′-dimethylbiphenyl-2,2′-diyl)bis[(6-methyl-2-pyridyl)methyl]diimine (**2**) react with Pd(COD)Cl_2 to give, depending on the reaction conditions, either mono- or binuclear $PdCl_2$ complexes. In the binuclear complex **1**-$(PdCl_2)_2$, the Pd nuclei are held at a distance of 3.37 Å by the ligand backbone. *N*,*N*′-(6,6′-dimethylbiphenyl-2,2′-diyl) bis[(5-methyl-2-furyl)methyl]diimine (**3**), with furyl instead of pyridyl rings, gives mononuclear, C_2-symmetric complexes only. Reactions of $[Pd(NCCH_3)_4]^{2+}(BF_4^-)_2$ with ligand **1** or **3** give the C_2-symmetric cations [**1**-Pd]$^{2+}$or [**3**-Pd$(NCCH_3)_2]^{2+}$, respectively, as their BF_4^- salts. Solid-state structures of the chloride complexes **1**-$PdCl_2$, **1**-$(PdCl_2)_2$ and **3**-$PdCl_2$, and of the complex cations [**1**-Pd]$^{2+}$ and [**3**-Pd$(NCCCH_3)_2]^{2+}$ with tetradentate and bidentate ligand coordination, respectively, all show square-planar coordination, with some distortion toward tedrahedral geometry due to the twisted biaryl-backbone. Preliminary observations on norbornene polymerization with the catalysts **1**-$PdCl_2$/MAO, **2**-$PdCl_2$/MAO and [(**3**-Pd$(NCCH_3)_2]^{2+}$ suggest that a certain degree of stereoregularity of the polymers is induced by these chiral catalysts.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Considerable attention has lately been focused on binuclear organometallic compounds, based on expectations that their reactivity in synthesis and catalysis may differ significantly from that of analogous mononuclear species.[1] Interactions between closely adjacent metal centers might cause increased reaction rates or transformations not occurring with monometallic species, as was recently shown for copolymerization of styrene and ethene by binuclear titanocene complexes.[2] The distance between two metal centers and their orientation to each other can be important for catalytic performance, as had been noted for binuclear rhodium hydroformylation catalysts[3] and for palladium complexes that catalyze hydration reactions.[4] Additional oxidation states might also be accessible in binuclear complexes as a result of stabilizing metal–metal interactions.[5]

Late transition metal complexes with nitrogen-based ligands have found a wide range of applications in homogeneous catalysis including polymerization of olefins or acrylates as well as hydrogenation reactions.[6] Pyridylimine-Pd^{II} chelates as dendrimeric complexes and binuclear Pd^{II} complexes with long aliphatic spacers have recently been described as effective catalyst precursors for Heck coupling[7] and for ethene polymerization,[8] respectively, as well as with shorter chiral spacers to produce optically active polyketones.[9] Palladium complexes with chiral bidentate bis(oxazoline) ligands have been shown to be efficient in asymmetric allylic alkylation,[10] while biaryl Schiff base Cu complexes catalyze the aziridination of alkenes.[11]

With a structurally rigid 6,6′-disubstituted biaryl ligand backbone, the configuration of the ligand is fixed and its axial chirality can efficiently be transmitted to the stereotopicity of the active site.[12] Biphenyl-bridged ligands form, in general, mononuclear complexes,[13] but binuclear complexes, e. g. with Cu^{II}, have also been reported.[14] Tetradentate N_4, N_2O_2 and N_2P_2 ligands are known to form both mono- and binuclear Pd^{II} complexes,[15,16,17] but only few of these have chiral biaryl backbones.[16a,17c]

Since cationic Pd^{II} complexes bearing diimine ligands with bulky substituents have been discovered to catalyze copolymerizations of α-olefins with functional vinyl monomers,[18] significant amounts of research have been aimed at tuning the electronic and steric properties of these ligands. Bulky aryls disfavor associative displacement and chain transfer reactions by steric protection of the electrophilic metal center; ligands with labile donor atoms like oxygen or sulfur in their side arms might likewise hinder β-H elimination by temporarily occupying a vacant site on the metal center.[19] Interesting featuresmight thus be expected for C_2-symmetric Pd^{II} diimine complexes with side-arm donors bridged by a chiral ligand backbone.

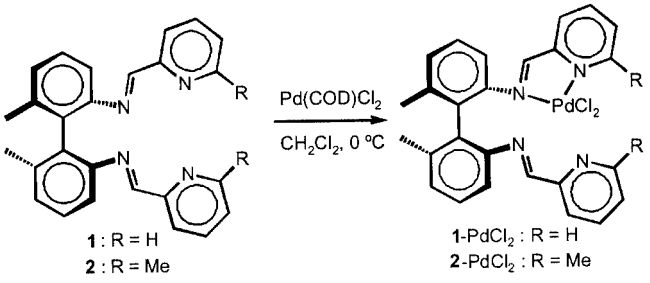
In previous contributions, we have studied complexes of tetradentate 6,6′-dimethylbianiline-based ligands with metals such as Zr, Fe, Co or Cr in regard to their structures and catalytic activities.[20] In this work, we extend these studies to mono- and bimetallic Pd^{II} complexes bearing chiral diimino ligands with a biphenyl backbone.

Results and Discussion

Ligands **1**, **2** and **3** were prepared, as described earlier,[20] by imine condensation of *N*,*N*′-(6,6′-dimethylbiphenyl-2,2′-diyl)diamine with the required aldehydes. Reaction of *N*,*N*′-(6,6′-dimethylbiphenyl-2,2′-diyl)bis(2-pyridylmethyl)di-imine (**1**) with one equivalent of $Pd(COD)Cl_2$ at 0 °C gave **1**-$PdCl_2$, which precipitated from the reaction mixture in almost quantitative yield [Equation (1)]. When the reaction was repeated in an NMR tube, starting at 0 °C and continuing at room temperature, the rate of the reaction was found to be quite fast; 95% of the $Pd(COD)Cl_2$ was consumed after 30 minutes. Ligand **2** likewise reacted readily with $Pd(COD)Cl_2$ under similar reaction conditions, but **2**-$PdCl_2$ was isolated with lower yield due to its higher solubility.



(1)

A single-crystal X-ray structure analysis of **1**-$PdCl_2$ confirms an approximately square-planar coordination of the Pd^{II} *cis*-dichloro unit to one of the pyridylimine moieties of ligand **1** (Figure 1), which thus forms a five-membered pyridylimine chelate, with Pd–N and Pd–Cl distances (Table 1) close to values reported for similar complexes.[15–17] In the solid state, the non-coordinated pyridylimine moiety lies on the backside of the biphenyl bridge, pointing away from the $PdCl_2$ unit.

The ^1H NMR spectrum of **1**-$PdCl_2$ in [D_6]DMSO solution reveals, instead of two singlets expected for the non-equivalent methyl groups in 6- and 6′-positions of the biaryl backbone, three sharp CH_3 signals at δ = 1.82, 2.02 and 2.23 ppm with an integral ratio of 1:2:1.[21] The occurrence of these three CH_3 signals, as well as non-integer ratios for the aromatic proton signal integrals (see Experimental section), indicate the presence of two isomers in [D_6]DMSO solution of **1**-$PdCl_2$, each with one Pd-coordinated and one non-coordinated ligand moiety. Related phenomena in connection with possible isomers of **1**-$(PdCl_2)_2$ will be discussed below.

For **2**-$PdCl_2$ in [D_6]DMSO solution, however, only two singlets are observed, in agreement with the presence of a

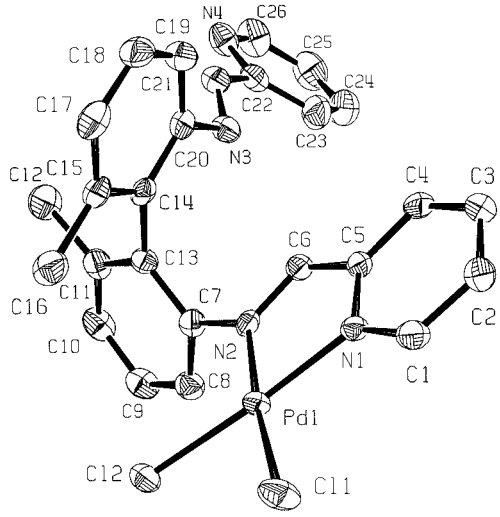


Figure 1. Crystal structure of **1**-$PdCl_2$ (ORTEP plot, thermal ellipsoids drawn at 50% probability, H atoms and CH_2Cl_2 solvent molecules omitted for clarity).

Table 1. Selected bond lengths (Å) and angles [°] for **1**-$PdCl_2$ (c.f. Figure 1).

Pd(1)–N(1)	2.022(3)	N(1)–Pd(1)–N(2)	80.38(12
Pd(1)–N(2)	2.037(3)	N(1)–Pd(1)–Cl(2)	175.56(9)
Pd(1)–Cl(2)	2.2893(11)	N(2)–Pd(1)–Cl(2)	95.26(9)
Pd(1)–Cl(1)	2.2916(11)	N(1)–Pd(1)–Cl(1)	93.28(9)
		N(2)–Pd(1)–Cl(1)	173.61(9)

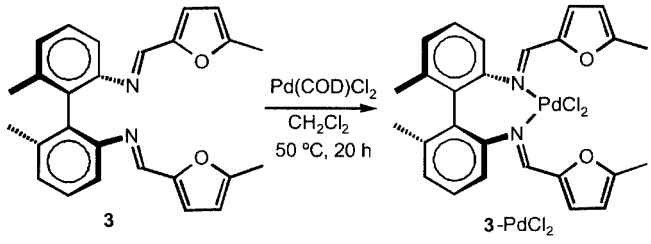
Pd-coordinated and an uncoordinated ligand moiety, for the methyl groups at the biphenyl bridge (1.96 and 2.05 ppm), for the methyl groups in 6-position of each pyridyl ring (2.47 and 2.80 ppm) and for the imine protons (8.21 and 8.69 ppm).



(2)

With ligand **3**, where the side-arm pyridyl groups are replaced by furyl rings, a significantly longer reaction time (20 h) was required for complex formation with $Pd(COD)Cl_2$ [Equation (2)]. As shown by the crystal structure of **3**-$PdCl_2$ (Figure 2, Table 2), ligand **3** is bound in a bidentate manner again. Here, however, the two imino nitrogens form a seven-membered chelate with the *cis*-dichloro Pd unit to give an approximately square-planar and C_2-symmetric geometry. Due to the dihedral angle of 67° between the phenyl rings of the biphenyl bridge, the ligand plane at the Pd center is somewhat distorted, with an angle of 5.9(2)° spanned by the planes Cl1–Pd–N1 and Cl2–Pd–N2. The furyl oxy-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

gen atoms are located at non-bonding distances of 5.0 and 5.1 Å from the Pd center, from which the side arms are pointing away.[22] The preference of the Pd center for N over O ligand atoms obviously overrides its preference for five-membered over seven-membered chelate rings to such an extent that a C_2-symmetric geometry becomes favored for **3**-$PdCl_2$ over the C_1-symmetric structures of **1**-$PdCl_2$ and **2**-$PdCl_2$.

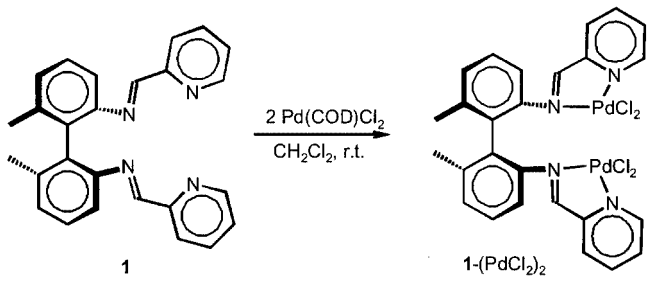
$CDCl_3$ solutions of **3**-$PdCl_2$ give ^1H NMR spectra in agreement with an apparent C_2 symmetry, with a singlet at δ = 1.88 ppm due to the two methyl groups in the biphenyl backbone, another singlet at δ = 2.18 ppm due to the methyl groups at the furyl rings, and a singlet at δ = 8.32 ppm assigned to the imine protons. These signals are accompanied, however, by a set of smaller signals located slightly up-field, at δ = 1.82, 2.12 and 8.29 ppm, which integrate to ratios of ca. 1:10 relative to the respective main peaks. The observation of this additional signal set in solutions of **3**-$PdCl_2$ would indicate that some minor isomer is present, in addition to the structure represented in Figure 2. From our data it is not clear, which alternative geometry prevails in this isomer, whether (and how) e. g. furyl oxygen atoms might be coordinated to the Pd^{II} center.[19]



(3)

In **1**-$PdCl_2$ one halve of ligand **1** remains available for further coordination and provides a possibility for the preparation of bimetallic complexes. The dipalladium complex **1**-$(PdCl_2)_2$ was indeed isolated in 97% yield when ligand **1** was treated with two equivalents of $Pd(COD)Cl_2$ at room temperature [Equation (3)].[23] In the solid-state structure of binuclear **1**-$(PdCl_2)_2$, one $PdCl_2$ unit is coordinated, as expected, to each of the biphenyl-bridged pyridylimine moieties (Figure 3, Table 3). The two square-planar N_2PdCl_2 units are almost parallel to each other, stacking under an angle of 7.40(2)°. Viewed along the Pd–Pd axis, the two $PdCl_2$ units are rotated by an angle of 104.9° relative to each other. The Pd(1)–Pd(2) distance of 3.37 Å is in the range of quite a number of binuclear Pd^{II} complexes with relatively short (2−4 atom) bridging ligands.[24] Apparently a similarly favorable situation for a close $Pd^{II}\cdots Pd^{II}$ contact is created by the preference of the biaryl bridge for a twist angle of ca. 70°. In addition, some attractive interaction between Pd–Cl dipoles might contribute to keep the Pd centers at a distance close to the sum of their van-der-Waals radii.

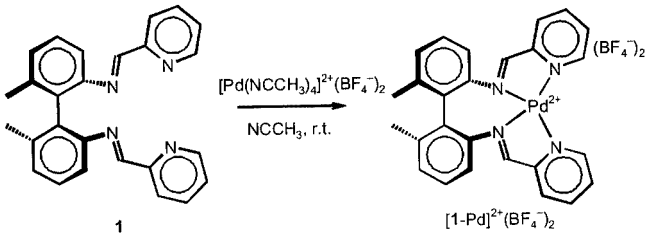
tioned protons of the pyridyl rings likewise appear as two doublets at 8.83 and at δ = 9.04 ppm representing one proton each and the other aromatic and imine signals are also grouped in a manner incompatible with a C_2-symmetric complex. These observations can be explained either by the occurrence of two diastereomers, e.g. *meso*- and *rac*-like conformers of the two complex moieties, in a ratio of ca. 1:1 or by some nonequivalence of the two complex moieties in solution, caused e.g. by co-ordination of a solvent molecule to one of the Pd centers. Our data do not allow us to estimate the lifetimes of isomers of this kind.

The *cis*-$PdCl_2$ unit considered so far obviously favors formation of a five-membered pyridyl-imine chelate over that of a seven-membered diimine chelate; complexes such as **1**-$PdCl_2$ or **2**-$PdCl_2$ are thus of C_1 symmetry. In order to synthesize complexes which fully exploit the axialsymmetry inherent in the biaryl backbone to generate C_2-symmetric complexes suitable for asymmetric catalysis,[25] we have sought to induce tetradentate coordination of ligands **1** and **2** with formation of cationic complexes by use of the more electron-deficient Pd precursor $[Pd(NCCH_3)_4]^{2+}(BF_4^-)_2$ [Equation (4)].



(4)

Reaction of ligand **1** with one equivalent of $[Pd(NCCH_3)_4]^{2+}(BF_4^-)_2$ in acetonitrile at room temperature gave the ion pair $[\mathbf{1}\text{-Pd}]^{2+}(BF_4^-)_2$ in high yield. The expected tetradentate coordination of ligand **1** in $[\mathbf{1}\text{-Pd}]^{2+}(BF_4^-)_2$ was verified by single-crystal structure determination (Figure 4). The Pd center forms an approximately C_2-symmetric seven-membered chelate ring with the biphenyl-bridged imine nitrogens and one five-membered chelate ring with each of the pyridylimine moieties, with Pd–N distances (Table 4) in the range reported for other Pd-imino complexes.[15–17] Due to the dihedral angle of 71° in the 2,2′-dimethyl-substituted biphenyl backbone, the square-planar coordination at the Pd atom shows some tetrahedral distortion, so that the planes N1–Pd–N2 and N3–Pd–N4 span an angle of 12.9(5)°.[26]

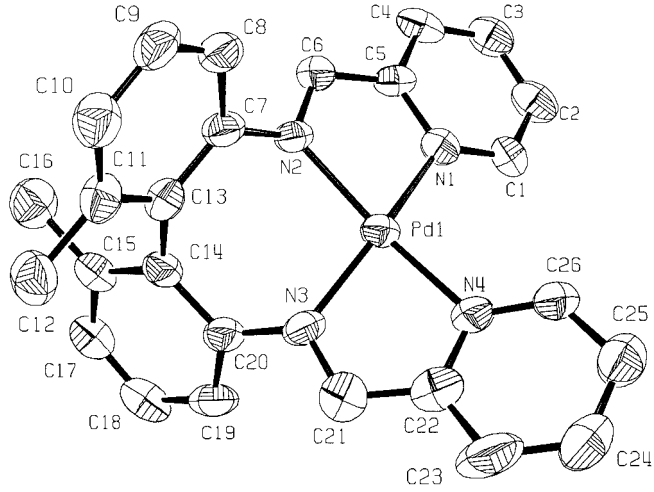


Figure 4. Crystal structure of $[\mathbf{1}\text{-Pd}]^{2+}(BF_4^-)_2$ (ORTEP plot, thermal ellipsoids drawn at 50% probability, H atoms, 0.5 H_2O and BF_4^- omitted for clarity).

Table 4. Selected bond lengths (Å) and angles [°] for $[\mathbf{1}\text{-Pd}]^{2+}(BF_4^-)_2$ (c.f. Figure 4).

Pd(1)–N(1)	2.044(7)	N(3)–Pd(1)–N(1)	164.5(3)
		N(2)–Pd(1)–N(1)	79.7(3)
		N(4)–Pd(1)–N(1)	105.6(3)

^{1}H NMR spectra in CD_3CN solution indicate, again, some deviations of the cation $[\mathbf{1}\text{-Pd}]^{2+}$ from the approximate C_2 symmetry found in the solid state. The 6,6′-positioned methyl groups of the ligand backbone give rise to a multiplet with two maxima at δ = 1.72 and 1.76 ppm, and the aromatic protons are likewise grouped in multiplets which do not appear to be compatible with an overall C_2 symmetry. Even though we do not have any direct evidence in this regard, we would assume that the equivalence of both halves of the complex molecule might be destroyed, as in the cases discussed above, by coordination of a solvent molecule.

In order to test whether a tetradentate coordination similar to that achieved for ligand **1** might also be accessible for the furyl-substituted ligand **3**,[27] the latter was likewise reacted with $[Pd(NCCH_3)_4]^{2+}(BF_4^-)_2$ in acetonitrile solution. The reaction proceeded fast and with high yield, but gave, instead of a product with tetracoordinate ligand **3**, $[\mathbf{3}\text{-Pd}]^{2+}(BF_4^-)_2$, the bis(acetonitrile) adduct $[\mathbf{3}\text{-Pd-}(NCCH_3)_2]^{2+}(BF_4^-)_2$ [Equation (5)].

(5)

In the crystal structure of [**3**-Pd(NCCH$_3$)$_2$]$^{2+}$(BF$_4^-$)$_2$ (Figure 5, Table 5), square-planar coordination at the cationic Pd center is found to involve two *cis*-positioned acetonitrile ligands and the two imino nitrogen atoms of ligand **3**; as in **3**-PdCl$_2$, the ligand **3** forms again a seven-membered chelate ring with the Pd center. In distinction to **3**-PdCl$_2$, however, where the furyl oxygen atoms point away from the Pd center, they are now turned towards the latter and lie rather close to it, in pseudo-axial positions at Pd–O distances of 3.0(1) Å. Some (presumably weak) coordination or dipolar attraction of the furyl oxygen atoms to the Pd^{II} center thus appears to be stabilized by the cationic nature of the metal.[27,28]

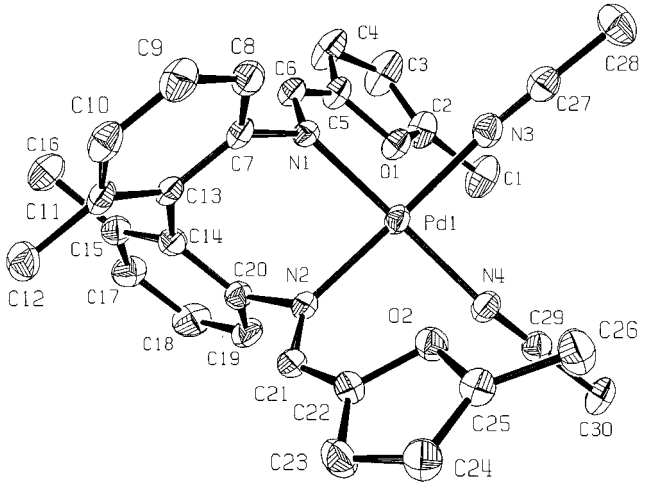

Figure 5. Crystal structure of [**3**-Pd(NCCH$_3$)$_2$]$^{2+}$(BF$_4^-$)$_2$ (ORTEP plot, thermal ellipsoids drawn at 50% probability, H atoms, CH$_3$CN solvent molecule and BF$_4^-$ omitted for clarity).

Table 5. Selected bond lengths (Å) and angles [°] for [**3**-Pd(NCCH$_3$)$_2$]$^{2+}$(BF$_4^-$)$_2$ (c.f. Figure 5).

Pd(1)–N(1)	2.006(2)	N(1)–Pd(1)–N(4)	171.03(8)

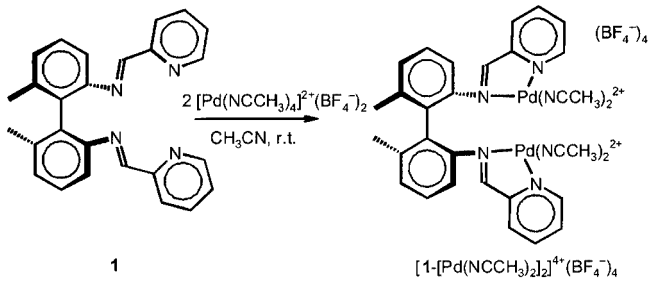
Pd(1)–N(2)	2.016(2)	N(4)–Pd(1)–N(2)	93.37(9)
Pd(1)–N(3)	2.022(2)	N(1)–Pd(1)–N(3)	91.97(9)
		N(4)–Pd(1)–N(3)	89.15(9)
		N(2)–Pd(1)–N(3)	174.21(8)

The ^{1}H NMR spectrum of [**3**-Pd(NCCH$_3$)$_2$]$^{2+}$ is entirely in agreement with the overall C_2 symmetry expected from its solid-state structure. Its NCCH$_3$ ligands and its biphenyl and furyl methyl substituents give rise to only one singlet signal each, at δ = 2.08, 2.20 and 2.63 ppm, respectively. Apparently, the binding of the furyl groups to the cationic Pd^{II} center, however weak, protects the latter from interaction with a solvent donor, which might otherwise destroy the overall C_2 symmetry of the complex molecule in solution.

Since two nitrogen ligand atoms are sufficient for the formation of a cationic di-acetonitrile complex, ligand **1** was also treated with two equivalents of [Pd(NCCH$_3$)$_4$](BF$_4$)$_2$ to prepare the binuclear cationic complex **1**-([Pd(NCCH$_3$)$_2$]$^{2+}$)$_2$(BF$_4^-$)$_4$ [Equation (6)]. The reaction yielded an oily product, the elemental analysis and ^{1}H NMR spectra of which indicated formation of the expected complex. As no crystals suitable for X-ray diffraction were obtained, it was not possible to study the effect of the increased charges on the mutual arrangement of the metal centers in this binuclear complex.



(6)

Preliminary data concerning catalytic activities of the new Pd^{II} complexes described above were obtained with regard to polymerization of norbornene at room temperature.[29] When activated by addition of methylaluminoxane (MAO), the dichloro complexes **1**-PdCl$_2$, **2**-PdCl$_2$ and **3**-PdCl$_2$ gave polymers which were insoluble in organic solvents such as trichlorobenzene even at elevated temperatures. The cationic complex [**3**-Pd(NCCH$_3$)$_2$]$^{2+}$(BF$_4^-$)$_2$ gave, without activation by MAO,[29] polymers with good solubility, e.g. in toluene or chloroform, in moderate yield. For these polynorbornenes, a molar mass of 33800 g/mol and a polydispersity index of 1.26 were determined. Complex [**1**-Pd]$^{2+}$(BF$_4^-$)$_2$, in which the Pd center is bound to all four N atoms of the tetradentate ligand, was found to be inactive for polymerization of norbornene at room temperature.

Decomposition temperatures, determined by thermogravimetric analysis, of the polymers obtained with MAO-activated **1**-PdCl$_2$, **2**-PdCl$_2$ and **3**-PdCl$_2$ as well as of those obtained with [(**3**-Pd(NCCH$_3$)$_2$]$^{2+}$(BF$_4^-$)$_2$, were found to be exceptionally high (ca. 450 °C), i.e. more than 100 °C higher than that (335 °C) determined for the polymer obtained with [Pd(NCCH$_3$)$_4$](BF$_4$)$_2$.[29] This might suggest that a certain degree of stereoregularity is induced in the polymer by the chiral ligands of the catalysts **1**-PdCl$_2$/MAO, **2**-PdCl$_2$/MAO, **3**-PdCl$_2$/MAO and [(**3**-Pd(NCCH$_3$)$_2$]$^{2+}$.[30]

Conclusions

Axially symmetric, biphenyl-bridged diimino ligands with additional pyridyl or furyl side arms are highly versatile with respect to Pd^{II} complex formation. Depending on the Pd precursors and the reaction conditions used, mononuclear-bidentate complexes of C_1 or C_2 symmetry, as well as binuclear and mononuclear-tetradentale Pd^{II} complexes can be obtained in a controlled manner and with high yields. Preliminary observations indicate distinctly different properties of cationic species derived from them as norbornene polymerization catalysts.

Experimental Section

All complex preparation and polymerization reactions were performed under argon atmosphere using standard Schlenk techniques. *N,N′*-(6,6′-Dimethylbiphenyl-2,2′-diyl)diamine,[31] the ligands **1**–**3**[20] and dichloro(1,5-cyclooctadiene)palladium(II) [Pd(COD)Cl_2],[32] were prepared as reported earlier. Solvents were dried prior to use by refluxing over and distillation from sodium (hydrocarbons), magnesium (alcohols), P_2O_5 (acetonitrile) or calcium hydride (dichloromethane). Deuterated solvents were dried over 4-Å molecular sieves. All other chemicals were purchased from commercial suppliers and used without further purification. Elemental analyses were performed with an EA 1110 CHNS-O CE instrument. NMR spectra were collected with a Varian Gemini 200 spectrometer. Polymer molar mass and molar mass distributions were measured by gel permeation chromatography (GPC) relative to polystyrene standards.

***N,N′*-(6,6′-Dimethylbiphenyl-2,2′-diyl)bis(2-pyridylmethyl)-diimine-$PdCl_2$ (1-$PdCl_2$):** A solution of ligand **1** (0.59 g, 1.52 mmol) and Pd(COD)Cl_2 (0.39 g, 1.38 mmol) in CH_2Cl_2 (25 mL) was stirred at 0 °C. The product started to precipitate as a light yellow powder after 1 h. After stirring for another 20 h at room temperature, the product was filtered, washed with diethyl ether and dried in vacuo. action solution with diethyl ether at ambient temperature. Crystals of **3**-$PdCl_2$ were obtained at 4 °C; at room temperature, **3**-$PdCl_2$ gave crystals with a different unit cell. Crystals selected for X-ray measurements were mounted on a glass fiber using the oil-drop method. Data were collected on a Nonius–Kappa CCD diffractometer using Mo-*Kα* radiation (71.073 pm) and a graphite monochromator. Structures were solved by direct methods. All non-hydrogen atoms were refined anisotropically.[33] Hydrogen atoms were introduced at calculated positions and refined with fixed geometry with respect to their carrier atoms. Cell parameters and data collection parameters are summarized in Table 6. CCDC-243264 (for **1**-$PdCl_2$), CCDC-243267 and CCDC-243268 (for **3**-$PdCl_2$, two crystals with different structures), CCDC-243265 (for **1**-$(PdCl_2)_2$), CCDC-243266 (for [**1**-Pd]$^{2+}$(BF_4^-)$_2$) and CCDC-243269 (for [**3**-Pd($NCCH_3$)$_2$]$^{2+}$(BF_4^-)$_2$) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Norbornene Polymerizations: The dichloro complexes **1**-$PdCl_2$, **2**-$PdCl_2$ and **3**-$PdCl_2$ (20 μmol) were suspended in toluene (60 mL), MAO (4 mL, 20 mmol) and 2-norbonene (2.1 g, 22.3 mmol) were added and the reaction solution stirred at room temperature for 1 h. Conversions measured from the isolated products were 64, 71 and 38%, respectively. In the case of complexes [**1**-Pd]$^{2+}$(BF_4^-)$_2$, and [**3**-Pd($NCCH_3$)$_2$]$^{2+}$(BF_4^-)$_2$ norbornene was added to a solution of the complex (50 mg, 66 μmol) in CH_2Cl_2 (50 mL), chlorobenzene (5 mL) and nitrobenzene (1 mL) and stirred at room temperature for 1 h. Conversions were 0 and 44%, respectively. After quenching the reaction by addition of methanol (200 mL), acidified with HCl (1 mL), the precipitate was collected by filtration, washed with methanol and dried at 60 °C. Decomposition points were determined with thermogravimetric balance under N_2 flow. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 0.87−2.23 (br. m, 10 H) ppm. ^{13}C NMR (50 MHz, $CDCl_3$): δ = 28−44 (br. m), 48−55 ppm (br. m).

[21] The ratio of the integrals of the methyl proton signals changed gradually when the NMR sample was heated. DMSO as a solvent did not allow low-temperature NMR studies.

[22] When grown from CH_2Cl_2/Et_2O solution at room temperature, **3**-$PdCl_2$ crystallized in another modification without a solvent molecule in the unit cell. The coordination geometry of this modification is practically superimposable to that of **3**-$PdCl_2$ described above, but it contains one of the uncoordinated furyl side arms in a different orientation.

[23] When ligand **1** was reacted with one equivalent of Pd(COD)Cl_2 at room temperature, complex **1**-$[PdCl_2]_2$didprecipitate first under partial consumption of the ligand, while mononuclear **1**-$PdCl_2$ was isolated later by recrystallization.

Novel Mercury Phosphanylamides

Marcus L. Cole,[a,b] Glen B. Deacon,*[a] Peter C. Junk,[a] Kristina Konstas[a] and Peter W. Roesky[c]

Keywords: Mercury / Redox transmetallation / Phosphanylamide ligands / Subvalent complexes / P Donors

The reactions of bis(pentafluorophenyl)mercury, bis(diphenylphosphanyl)amine and neodymium or erbium metal in toluene yielded the subvalent mercury(1.33) complex $[Hg_3\{\mu_2\text{-}(Ph_2P)_2N\}_4]\cdot 3C_7H_8$ (**1**·3 C_7H_8) as a toluene solvate. The complex was also prepared in high yield from $Hg(C_6F_5)_2$, $(PPh_2)_2NH$ and mercury metal in toluene at room temperature. From reaction of $Hg(C_6F_5)_2$ and $HN(PPh_2)_2$ in toluene with no added metal, $[Hg_2\{\mu_2\text{-}(Ph_2P)_2N\}_2\{(Ph_2P)(OPPh_2)N\}_2]\cdot 2C_7H_8$ (**3**·2 C_7H_8) has been obtained, and **3**·2 $C_4H_{10}O_2$ has also been isolated in low yield. From a related reaction, a solution of the product in $CDCl_3$ deposited $[Hg_2\{\mu_2\text{-}(Ph_2P)_2N\}_3Cl]\cdot 3/2\,CDCl_3$ (**4**·3/2 $CDCl_3$). The structure of **1**·3 C_7H_8 contains a Hg–Hg bonded Hg_3 triangle with adjacent metals bridged (P,P′) by either one or two phosphanylamide ligands. One mercury is four coordinate, and the other two are five coordinate. In $[Hg_2\{\mu_2\text{-}(Ph_2P)_2N\}_2\{(Ph_2P)(OPPh_2)\text{-}N\}_2]\cdot 2S$ [S = C_7H_8 or $C_4H_{10}O_2$ (1,2-dimethoxyethane)], the mercury atoms are bridged (P,P′) by two phosphanylamide ligands, whilst the hemi-oxidised ligands are chelating (O,P) in a *transoid* disposition to each other leading to four coordination. There is unsymmetrical ligation in $[Hg_2\{\mu_2\text{-}(Ph_2P)_2N\}_3Cl]\cdot 3/2\,CDCl_3$ (**4**·3/2 $CDCl_3$) with one mercury four coordinate and the other three. Three phosphanylamide ligands bridge (P,P′) the metals with a non-bonding Hg···Hg separation of 3.0042(7) Å. Each HgP_3 array has a triangular arrangement, little affected in one case by the attachment of a chloride approximately normal to HgP_3.

Introduction

In recent years the bidentate bis(diphenylphosphanyl) amine (Hdppa) ligand has received considerable attention.[1] This interest partly emanates from the electronic and structural similarity to the widely used and hugely successful bis(diphenylphosphanyl)methane (dppm) ligand,[2] which gives a wide range of binuclear and metal cluster complexes with transition metals.[3] Such diphosphane ligands are attractive due to their ability to bridge or flexibly chelate (for dppm an aspect furnished by distortion of the central sp^3 hybridised methylene PCP angle), offering coordination geometries that can be tailored to the metal at hand. This often permits short metal–metal contacts, thereby increasing the likelihood of high nuclearity metal complexes.[2,4] Deprotonation of bis(diphenylphosphanyl) amine is readily achieved by treatment with group 1 alkyls (e.g. butyllithium) or alkoxides.[5] The resulting bis(diphenylphosphanyl)amide ligand is an isoelectronic analogue of dppm that has so far demonstrated an ability to bridge, chelate or act as a terminal ligand for transition metals[5–7] and, more recently, lanthanoid metals by coordination through the amide and the phosphorus donor sets.[1b,8]

Another interesting feature of the bis(diphenylphosphanyl)amine ligand is the ability of the phosphorus atoms to be sequentially oxidised by selected chalcogen elements (E = O, S, Se), thereby forming the new derivatives $(PPh_2)[P(E)Ph_2]NH$ and $[P(E)Ph_2]_2NH$.[7] The neutral ligands, or their anionic forms generated by deprotonation,[1a] can also behave as unidentate N/P/E-bonded, E,E/P-chelating or E,E/P-bridging ligands. This class of ligand is capable of acting simultaneously as both a hard and soft Lewis base donor.[1c] Herein we report the synthesis and structures of some unusual and unexpected mercury complexes resulting initially from redox transmetallation/ligand exchange reactions involving lanthanoid metals, bis(pentafluorophenyl)mercury and bis(diphenylphosphanyl)amine. These reactions normally provide a "one-pot" route to numerous organo, organoamido and aryloxo complexes of the lanthanoids[9–10] and appeared attractive for bis(diphenylphosphanyl)amide complexes as a complementary synthesis to the existing metathesis and protolysis routes.[1b,8]

Results and Discussion

Synthesis

The preparation of lanthanoid (Ln) complexes with chelating phosphanylamide ligands was attempted using redox

transmetallation/ligand exchange with bis(pentafluorophenyl)mercury and bis(diphenylphosphanyl)amine [Equation (1); Ln = Nd].

$$Ln + 1.5[Hg(C_6F_5)_2] + 3(Ph_2P)_2NH \rightarrow [Ln\{(Ph_2P)_2N\}_3] + 1.5\,Hg + 3\,C_6F_5H \quad (1)$$

Treatment of neodymium metal [Equation (1); Ln = Nd) with the reactants in the non-coordinating solvent toluene, did not yield the target $[Nd\{(Ph_2P)_2N\}_3]$ but rather an orange crystalline product that was identified as a subvalent mercury complex, $[Hg_3\{\mu_2\text{-}(Ph_2P)_2N\}_4]\cdot 3\,C_7H_8$ (**1**·3 C_7H_8), by an X-ray structure determination (Figure 1 and i in Scheme 1). Compound **1**·3 C_7H_8 was also characterised by $^{31}P\{^1H\}$ NMR, ^1H NMR and infrared spectroscopy (below). Despite repeated attempts, $[Nd\{(Ph_2P)_2N\}_3]$ could not be isolated. A similar attempt with erbium metal [Equation (1); Ln = Er] also gave no isolable lanthanoid complex. The $^{31}P\{^1H\}$ NMR spectra of the reaction mixture indicated the presence of the same trinuclear complex **1**. Single crystals isolated from the Er reaction mixture were also identified by X-ray crystallography as **1**·3 C_7H_8 (see Experimental Section: Method 2). Attempts to effect reaction (1) were accompanied by formation of insoluble precipitates containing Ln and F.

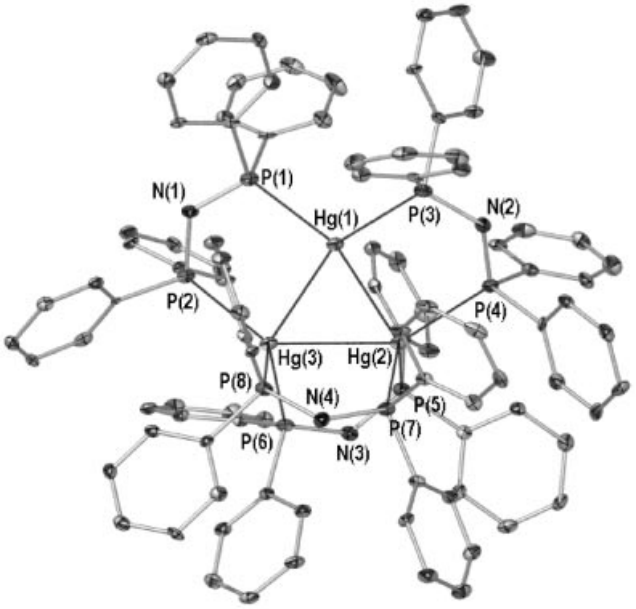

Figure 1. The molecular structure of $[Hg_3\{\mu\text{-}(Ph_2P)_2N\}_4]\cdot 3\,C_7H_8$ (**1**·3C_7H_8). POV-Ray graphic (www.povray.org), 40% thermal ellipsoids. All solvent molecules are removed for clarity.

As mercury metal is a sufficient reductant to give the subvalent $[Hg_3(\mu\text{-dmpm})_4][O_3SCF_3]_4$ [dmpm = bis(dimethylphosphanyl)methane] complex,[11] the reaction of $Hg(C_6F_5)_2$ with $(Ph_2P)_2NH$ was attempted in the presenceof mercury metal (and no lanthanoid) [see i in Scheme 1 and Equation (2)] and compound **1**·3 C_7H_8 was isolated in excellent yield.

$$2[Hg(C_6F_5)_2] + 4(Ph_2P)_2NH + Hg^0 \rightarrow [Hg_3\{\mu_2\text{-}(Ph_2P)_2N\}_4] + 4\,C_6F_5H \quad (2)$$

Since the first step in redox transmetallation/ligand exchange reactions with Nd or Er can be formulated as in Equation (3), the mercury metal produced may well be the reductant in reactions with lanthanoid metals.

$$2\,Ln + 3[Hg(C_6F_5)_2] \rightarrow 2[Ln(C_6F_5)_3] + 3\,Hg^0 \quad (3)$$

Independent attempts to prepare $[Ln(C_6F_5)_3]$ by Equation (3) resulted in decomposition to LnF_3,[9,12] by contrast with isolation of $[Ln(C_6F_5)_2(THF)_n]$ (Ln = Eu, n = 5; Ln = Yb, n = 4),[13] and decomposition of such species accounts for the formation of intractable Ln/F containing precipitates in attempted reaction (1).

Although no direct reaction could be induced between Nd metal and $(Ph_2P)_2NH$ in toluene, it was evident that the amine reacts with $Hg(C_6F_5)_2$ at room temperature since an immediate orange colour developed. When this reaction was carried out on a 2:1 mole ratio, pentafluorobenzene was formed, indicative of ligand exchange. However, the expected exchange product $[Hg\{(Ph_2P)_2N\}_2]$ **2** (see iv in Scheme 1) was not isolated but instead a partly oxidised species, $[Hg_2\{\mu_2\text{-}(Ph_2P)_2N\}_2\{(Ph_2P)(OPPh_2)N\}_2]\cdot 2\,C_7H_8$ (**3**·2 C_7H_8), (Figure 2 and ii in Scheme 1), which was initially identified by X-ray crystallography.

$$2[Hg(C_6F_5)_2] + 4(Ph_2P)_2NH \xrightarrow{O_2} [Hg_2\{\mu_2\text{-}(Ph_2P)_2N\}_2\{(Ph_2P)(OPPh_2)N\}_2] + 4\,C_6F_5H \quad (4)$$

Multiple preparations of **2** were attempted under dry anaerobic conditions but all resulted in the isolation solely of **3**·2 C_7H_8, which was additionally characterised by $^{31}P\{^1H\}$ NMR, ^1H NMR and IR spectroscopy (below). Since four phosphane sites are unaffected by oxidation, the amount of oxygen present must have been extremely small. This compound was also isolated as a DME solvate in low yield from DME washings of a similar reaction mixture involving Nd metal, and was identified by X-ray crystallography as $[Hg_2\{\mu_2\text{-}(Ph_2P)_2N\}_2\{(Ph_2P)(OPPh_2)N\}_2]\cdot 2\,C_4H_{10}O_2$ (**3**·2 $C_4H_{10}O_2$).

Protolysis (see iv in Scheme 1) implies that the phosphanylamine ligand is more acidic than pentafluorobenzene (pK_a = 25.6, in THF),[9,14] but this reaction is highly unexpected given that bis(pentafluorophenyl)mercury is very resistant to electrophilic attack, as evidenced by successful recrystallisation from concentrated sulphuric acid and the very slow reaction with bromine.[15] By contrast bis(pentafluorophenyl)mercury is prone to nucleophilic attack, being readily cleaved by nucleophiles, for example by I^- to give $[HgI_4]^{2-}$ and pentafluorobenzene,[16] (see also recent isolation of a $[Hg(C_6F_5)_2I]^-$ intermediate).[17] This may suggest that coordination of the neutral $(Ph_2P)_2NH$ ligand through phosphorus provides nucleophilic assistance for

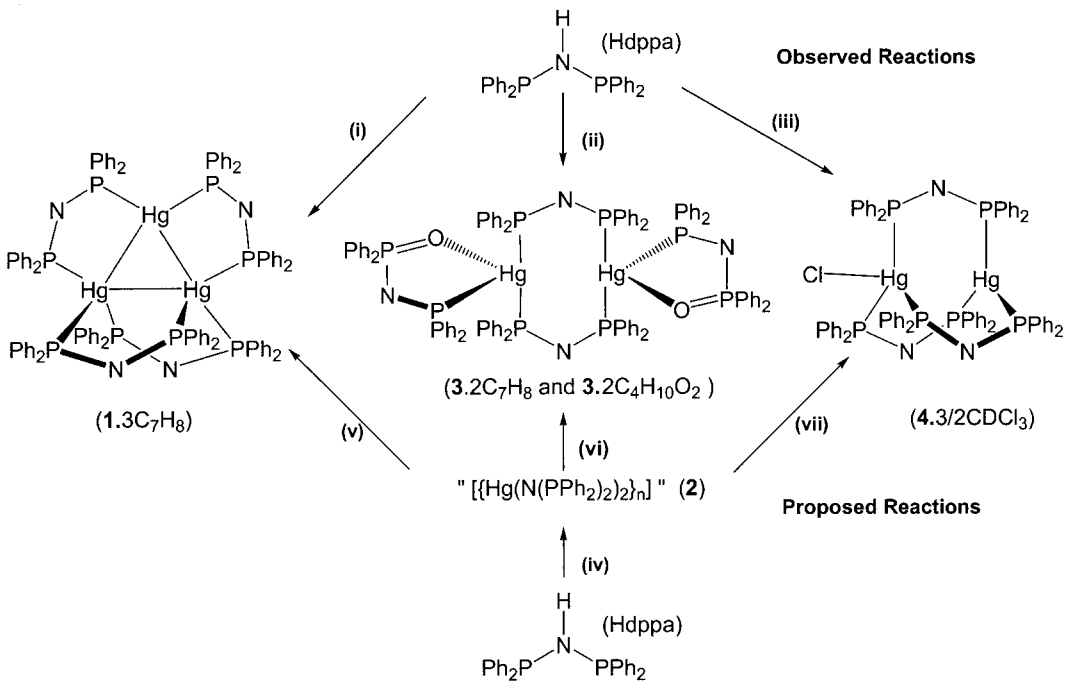

Scheme 1. (i) $Hg(C_6F_5)_2$, Er, Nd, Hg metal, toluene, 20 °C (ii) $Hg(C_6F_5)_2$, toluene, trace of O_2, 20 °C or DME extraction after (i), (iii) $Hg(C_6F_5)_2$, toluene, 20 °C, and crystallisation from $CDCl_3$ (iv) $Hg(C_6F_5)_2$ (v) Hg (vi) trace of O_2 (vii) $CHCl_3/CDCl_3$, $-(Ph_2P)_2NH$.

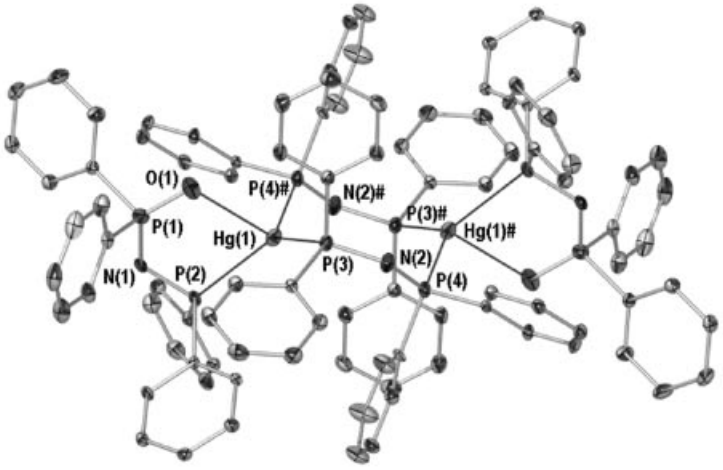

Figure 2. The crystal structure of $[Hg_2\{\mu_2\text{-}(Ph_2P)_2N\}_2\{(Ph_2P)(OPPh_2)N\}_2]\cdot 2C_4H_{10}O_2$ (**3**·$2C_4H_{10}O_2$), (POV-Ray, 40% thermal ellipsoids). All solvent molecules are removed for clarity.

protolysis by generation of partial carbanion character in the C_6F_5 group. Complexation of $Hg(C_6F_5)_2$ by phosphanes is known though the coordination is weak.[15,18] In previous studies of redox transmetallation/ligand exchange, blank reactions between $Hg(C_6F_5)_2$ and the protic ligand have failed, but no soft donor has been present to support X–H scission.[19]

In an attempt to stem the oxidation of **2** that yields **3** (see vi in Scheme 1) the preparation of **2** was attempted under even more strenuously anaerobic conditions (see Experimental Section) and spectroscopic characterisation of the initially deposited material was undertaken rapidly. Attempts to dissolve this material in C_4D_8O or C_7D_8 gave poor data, due to sparing solubility. Thus deuteriochloroform was employed, and gave NMR spectra suggesting a species with two separate ligand environments of equal resonance intensity, see below, as well as $(PPh_2)_2NH$ and the still persistent **3**. Slow evaporation of the NMR solution rendered a deep orange crystalline material suitable for X-ray structure analysis. This indicated the formation of a non-oxidised mercury(II) phosphanylamide chloride complex; $[Hg_2\{\mu_2\text{-}(Ph_2P)_2N\}_3Cl]\cdot 3/2\,CDCl_3$, **4**·$3/2\,CDCl_3$ (Figure 3, iii in Scheme 1). Further crystallization from the reaction mixture filtrate gave **3**·$2C_7H_8$.

X-ray Crystal Structures and Characterisation

Compound **1**·3 C_7H_8 crystallises in the triclinic space group $P\bar{1}$ with three Hg metal ions and four deprotonated ligands in the asymmetric unit (Figure 1, Table1 and Table 2). The structure is a neutral homoleptic trinuclear complex with mercury atoms in a triangular array and considered to be linked by metal–metal bonds (below). This core is supported by four bridging phosphanylamide ligands. Hg(1) is coordinated by two phosphorus atoms [P(1,3)] from two ligands, while Hg(2) and Hg(3) are coordinated to three phosphorus atoms [P(2,5,7) and P(4,6,8)], respectively, from three different ligands. Including Hg–Hg bonds, Hg(2) and Hg(3) are five-coordinate and Hg(1) is four-coordinate. Different bond lengths are observed for all Hg–P contacts; these range from 2.526(2)–2.630(2) Å. Mercury to phosphorus interactions associated with Hg(2) and Hg(3) have an average length of 2.560 Å. Counterintuitively, this is smaller than to the analogous bonds of lower coordinate Hg(1) (mean 2.598 Å), as lower coordination numbers are usually associated with shorter bond lengths.[20] A similar dmpm based compound,[11] $[Hg_3(\mu\text{-dmpm})_4][O_3SCF_3]_4$, with a triangular Hg_3 cation and similar connectivity to the neutral compound **1**·3 C_7H_8 has a mean Hg–P bond length of 2.539 Å. Neutrality and the increased steric bulk at phosphorus of **1**·3 C_7H_8 results in lengthening of the Hg–P interactions overall. In $[Hg_3(\mu_2\text{-}(Ph_2P)_2NH)_3][O_3SCF_3]_4$,[21] a decrease in the number of ligands and the cationic nature offset lack of deprotonation leading to shorter Hg–P bond lengths (2.506–2.536 Å) than in **1**·3 C_7H_8.

Overall charge neutrality indicates that the formal oxidation state of Hg in **1**·3 C_7H_8 is +4/3. The Hg–Hg bond

lengths vary within the complex, the shortest being 2.7785(10) Å [Hg(1)–Hg(3)] and the longest 3.0721(8) Å [Hg(2)–Hg(3)]. The upper value is larger than the Hg–Hg bond lengths in $[Hg_3(\mu\text{-dmpm})_4][O_3SCF_3]_4$ (2.767(1) to 2.955(1) Å],[11] owing to the uncharged nature of **1** and greater crowding. The van der Waals radius of Hg (1.73 Å)[22] gives an upper limit of 3.46 Å for a dimercury bonding contact. Reported Hg^I–Hg^I bonds range from 2.48 to 2.60 Å,[23] while the closed shell configuration of Hg^{2+} does not favour participation in Hg^{II}–Hg^{II} bonds. Thus, the Hg–Hg bond lengths of **1**·3C_7H_8, are indicative of subvalent mercury between Hg^I and Hg^{II} oxidation states. With a $Hg^{4/3+}$ oxidation state there are two electrons in excess of the d^{10} Hg^{II} configuration. These electrons bind the trinuclear core of **1**·3 C_7H_8, and presumably occupy a molecular orbital within the triangle. For the Hg_3^{4+} ion of $[Hg_3(dppm)_3(SO_4)_2]$,[24a] the bonding electrons are considered to occupy a molecular orbital from overlap of the 6s orbitals of the mercury atoms.[24b,24c] The Hg–Hg distances suggest the bonding electrons are more associated with Hg(1) than Hg(2,3), and greater Hg^I character might explain the longer Hg–P bonds to Hg(1). The triangular planes described by the triphosphorus donor ensembles [P(2,6,8) and P(4,5,7)] lie roughly perpendicular [76.24(5) and 85.97(5)°, respectively] to the plane of the trinuclear core. Hg(2) resides 0.7659(14) Å out of its triphosphorus plane [P(4,5,7)] and Hg(3) 0.7168(14) Å out of the analogous plane [P(2,6,8)]. The neutral homoleptic compound **1**·3 C_7H_8 is the first crystallographically characterised triangular mercury complex of a phosphanylamide ligand. The P–N distance (1.606–1.647 Å) shows values between P–N single and double bond range as in phosphazines, (range of 1.60–1.65 Å).[25]

Examination of **1**·3 C_7H_8 by $^{31}P\{^1H\}$ NMR spectroscopy indicates three very broad signals at 130.4, 95.6 and 81.9 ppm, which are characteristic of $[Hg_3(\mu\text{-dmpm})_4][O_3SCF_3]_4$[11] but at much higher chemical shifts than observed for $[Hg_3\{(\mu\text{-}Ph_2P)_2NH\}_3][O_3SCF_3]_4$.[21] The highest frequency resonance is attributed to the phosphorus atoms [P(1,3)] from two different ligands bound to the mercury of lowest coordination number. The next is assigned to the other two phosphorus atoms P(2,4) of these ligands, and the lowest frequency signal to P(5–8) of the two equivalent ligands linking Hg(2,3). These assignments are supported by intensities. Low solubility precluded low temperature measurements and resulted in very broad resonances, hence ^{199}Hg satellites could not be detected. The ^1H NMR spectrum of **1**·3 C_7H_8 shows three broad peaks situated at δ = 7.42, 6.91 and 6.81 ppm resulting from aromatic resonances associated with the ligands, as well as toluene resonances from lattice solvent. The IR spectrum of **1**·3 C_7H_8 is devoid of an N–H stretching band at 3300–3400 cm^{-1}, thus eliminating the possibility of remnant starting material or protonation of any of the coordinated ligands. Distinct bands at 1147 and 1229 cm^{-1} can be assigned as PNP stretching, which are typically found in the range of 1100 to 1300 cm^{-1}.[26] This is consistent with deprotonation of $(Ph_2P)_2NH$, resulting in delocalisation of the anionic charge across the PNP backbone. Characterisation of **1**·3 C_7H_8 by ^{199}Hg NMR spectroscopy proved unsuccessful due to insufficient solubility of this compound in suitable solvents.

Discussion of the structures of **3**·2 C_7H_8 and **3**·2 $C_4H_{10}O_2$ is centred on the latter, as it gave a more precise refinement than compound **3**·2 C_7H_8. Both contain the same complex and differ only in solvation. The crystallographic data are in Table 2 and selected bonds lengths and angles for **3**·2 $C_4H_{10}O_2$ in Table 3, whilst geometric values for **3**·2 C_7H_8 have been deposited.

Compound **3**·2 $C_4H_{10}O_2$ crystallises as a centrosymmetric dimer (triclinic, space group $P\bar{1}$) and consists of two mercury atoms bridged by two unoxidised phosphanylamide ligands. The metal coordination is completed by two terminal $[(Ph_2P)(OPPh_2)N]^-$ ligands which are *transoid* across the centre of symmetry (Figure 2). The Hg atom resides

0.0893(15) Å out of the plane defined by the three associated P atoms with the O atom in an apical position completing four coordination. Thus, the geometry of mercury is best described as a distorted triangular-based pyramid [P(3)–Hg(1)–P(4*) 124.14(3)°, P(3)–Hg(1)–P(2) 126.10(4)°, P(4*)–Hg(1)–P(2) 109.37(4)°]. Unlike $\mathbf{1}\cdot 3C_7H_8$, the Hg···Hg distance in $\mathbf{3}\cdot 2C_4H_{10}O_2$ of 4.487(2) Å is well outside the sum of the van der Waals radii (3.46 Å).[22]

Comparison with the structure of $[Hg\{(OPPh_2)NPPh_2\}_2]$, which has two chelating diphenylphosphanyl(diphenylphosphoryl)amide ligands, shows this has much shorter Hg–P distances, 2.4042(7) Å, but longer Hg–O lengths, 2.7135(15) Å.[27] This arises from the different stereochemistry (square planar) which is skewed towards two short and two long bonds in accordance with the preference of mercury for digonal two coordination.[23,28] Similarly Hg–P distances in the dinuclear phosphanylamine complex $[Hg_2\{\mu\text{-}(Ph_2P)_2NH\}_2(O_3SCF_3)_4]$ are short [2.421(1)–2.426(1) Å] with longer Hg–O bond lengths [2.679(4)–2.893(5) Å],[27] again owing to the tendency of mercury to have two short colinear bonds. This factor is not in evidence in $\mathbf{3}\cdot 2C_7H_8$ and $\mathbf{3}\cdot 2C_4H_{10}O_2$ with the three soft P and one hard O donors giving rise to the trigonal pyramidal geometry.

The $^{31}P\{^1H\}$ NMR spectrum of bulk $\mathbf{3}\cdot 2C_7H_8$ exhibits three broad resonances at δ = 60.1, 28.3 and 12.4 ppm with intensities in approximately a 2:4:2 ratio, corresponding to the three types of phosphorus atoms in the structure. The oxidised phosphorus P(1) should resonate at the highest chemical shift, since P^V centres are more deshielded than P^{III} centres. The ^{31}P resonance of the P=O group in the free (protonated) ligand, $(Ph_2P)(OPPh_2)NH$ occurs at δ = 21.4 ppm,[29] and the large shift of P(1) (60.1 ppm) can be attributed to chelation as observed for other phosphorus based systems that have five membered chelate rings.[30] The larger intensity indicates the middle resonance should be assigned to the four bridging phosphorus atoms [P(3,4,3#,4#)]. This leaves the remaining resonance to be assigned to P(2) (δ =12.4 ppm). The ^1H NMR spectrum of $\mathbf{3}\cdot 2C_7H_8$ is unremarkable, while the IR spectrum exhibits a band at 1128 cm^{-1} characteristic of an *O*-coordinated phosphoryl group.[31] Other characteristic features include bands at 1228 and 1148 cm^{-1} attributed to P=N stretching.[26]

The structure of $\mathbf{4}\cdot 3/2CDCl_3$ (Figure 3) consists of two mercury atoms bridged by three phosphanylamide ligands with a chloride coordinated to Hg(1). Each mercury is coordinated by three phosphorus atoms, Hg(1) being four coordinate and Hg(2) three coordinate. The latter has an average Hg–P bond length of 2.482 Å and four coordinate Hg(1) has an average Hg–P bond length of 2.593 Å (Table 4). This is consistent with the higher coordination of Hg(1). The Hg(1)–Cl(1) terminal bond length in $\mathbf{4}\cdot 3/2CDCl_3$, 2.624(2) Å, is considerably extended relative to those in $[HgCl_4]^{2-}$ complexes, which possess an average Hg–Cl bond length of 2.472 Å,[32] but well inside the sum (3.58 Å) of the van der Waals radii of Hg and Cl. In $[Hg_2(\mu\text{-}dppm)_2(\mu\text{-}Cl)Cl_2][Cl]\cdot H_2O$[33] which has a somewhat similar structural core to $\mathbf{4}\cdot 3/2CDCl_3$, the mean terminal Hg–Cl bond length is 2.587 Å, similar to that of $\mathbf{4}\cdot 3/2CDCl_3$.

The HgP_3 geometry of Hg(1) and Hg(2) can be considered equilateral triangular with all P–Hg–P angles close to 120° (Table 4). Hg(1) is 0.3280 (14) Å out of the P(1,3,5) plane, *exo* to the Hg···Hg vector. The chloride ligand lies perpendicular to this plane. Overall the stereochemistry for Hg(1) is trigonal pyramidal. Hg(2) is 0.1260(13) Å out of the analogous P(2,4,6) plane being *endo* to the Hg···Hg vector and has triangular geometry. The two triphosphorus donor P(1,3,5) and P(2,4,6) ensembles are very close to coplanar with an interplanar angle of 0.68(3)°. Although the Hg···Hg distance [3.0042(7) Å] is well within two van der Waals radii (3.46 Å),[22] this does not indicate the presence of a mercury–mercury bond as there are no valence electrons available for bonding, unless some electron density is transmitted from the *trans* Hg–Cl bond. A closer nonbonding Hg···Hg contact has been reported in $[Hg_2(1,8\text{-}C_{10}H_6)_2]$ [2.797(1) Å],[34] whilst Hg···Hg [3.2805(7) Å] of $[Hg_2\{\mu\text{-}(Ph_2P)_2NH\}_2(O_3SCF_3)_4]$ is not considered bonding.[27] It has been claimed on the basis of a low frequency

Raman absorption (46 to 48 cm^{-1}) assigned to ν(Hg–Hg) that there is a weak mercury–mercury bond in $[Hg_2(\mu\text{-dppm})_2(\mu\text{-Cl})Cl_2][Cl]\cdot H_2O$, where the separation is 3.343(3) Å.[33] We find this difficult to sustain for an $Hg^{II}\cdots Hg^{II}$ interaction, unless electron density is transmitted from Hg–Cl bonds.

The crude product from which crystals of **4**·3/2 $CDCl_3$ were obtained was characterised by $^{31}P\{^1H\}$ NMR and ^1H NMR spectroscopy. Two equal intensity and very broadened resonances in the $^{31}P\{^1H\}$ NMR spectrum at δ = 71.0 and 37.2 ppm, can be assigned to P(2,4,6) on the lower coordinate mercury and P(1,3,5) of **4** respectively. There is also a resonance at δ = 45.8 ppm attributable to (protonated) $(Ph_2P)_2NH$,[5] in the appropriate ratio to **4** consistent with the formation of **4**·3/2 $CDCl_3$ by protolysis/deuterolysis (see vii in Scheme 1). The ^1H NMR spectrum of the crude product displays solely the expected protons from phenyl groups (7.8 to 6.9 ppm) and a resonance attributable to the amine proton of $(Ph_2P)_2NH$ (δ = 3.1 ppm).

Conclusions

The attempted synthesis of homoleptic lanthanoid chelating phosphanylamide complexes by redox transmetallation/ligand exchange, gave instead the unusual subvalent mercury compound **1**·3 C_7H_8, attributable to formation of intermediate $[Hg\{(Ph_2P)_2N\}_2]$ **2** followed by reduction by mercury metal. Consistent with this, reaction of $Hg(C_6F_5)_2$ with $(Ph_2P)_2NH$ in the presence of mercury metal provided a higher yielding route to **1**·3 C_7H_8. Attempted preparation of **2** yielded **3**·2 C_7H_8 and **3**·2 $C_4H_{10}O_2$ containing hemi-oxidised phosphanylamide as well as the unoxidised phosphanylamide ligands.

Experimental Section

Mercury complexes, lanthanoid metal filings and the phosphanylamine ligand were handled and stored under purified nitrogen (activated BASF R3/11 copper oxide "catalyst" and 4-Å molecular sieves). Toluene, tetrahydrofuran, 1,2-dimethoxyethane and hexane were pre-dried with sodium wire and then distilled from sodium benzophenone under purified nitrogen. The reagents $Hg(C_6F_5)_2$ and $(Ph_2P)_2NH$ were prepared as reported.[35] The former was recrystallised from hot methanol/water, followed by drying under reduced pressure for several hours. The latter was shown free of P=O species by ^{31}P NMR spectroscopy. $^{31}P\{^1H\}$, ^{19}F and ^1H nuclear magnetic resonance (NMR) spectra were recorded with a Bruker AC 300 spectrometer. ^{199}Hg NMR could not be recorded due to the low solubility of the mercury compounds. Deuterated solvents (C_6D_6 and C_4D_8O) were dried with calcium hydride (powdered) for 24 h. Deuterated $CDCl_3$ was dried with 4-Å molecular sieves. All dried deuterated solvents were degassed by three cycles of freezing, evacuating, and backfilling with nitrogen and thawing and were then vacuum transferred and stored under nitrogen. Infrared spectra (4000–650 cm^{-1}) of Nujol mulls (prepared in a drybox) were recorded with a Perkin–Elmer 1600 Fourier transform infrared spectrometer. Melting points were determined in sealed glass capillaries under nitrogen. Elemental analyses were by the Campbell Microanalytical Laboratory, University of Otago, New Zealand. The complicated isolation/preparation and solvation of **4**·3/2 $CDCl_3$ frustrated all attempts to obtain satisfactory elemental analyses.

$[Hg_3\{\mu_2\text{-}(Ph_2P)_2N\}_4]\cdot 3\,C_7H_8$(1·3 C_7H_8).Method1: Bis(diphenylphosphanyl)amine (1.01 g, 2.56 mmol) and $Hg(C_6F_5)_2$ (0.68 g, 1.28 mmol) were dissolved in toluene (40 mL). Nd metal (1.23 g, 8.5 mmol) was added and the mixture was stirred at 80 °C for 96 h. The resulting suspension was filtered through a cannula and a light green/blue precipitate remained. This was subsequently washed with 2 × 10 mL of toluene. The orange-coloured solution was then evaporated under reduced pressure to yield a bright orange solid. Dissolution in a mixture of toluene (15 mL) and hex-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ane (5 mL) and concentration to 5 mL gave single rectangular orange crystals. These were filtered off, washed with hexane (5 mL) and dried in vacuo giving $[Hg_3\{\mu_2\text{-}(Ph_2P)_2N\}_4]\cdot 3C_7H_8$ (**1**·3C$_7$H$_8$). Yield 0.70 g (26%), and the crystals were used for the structure determination. EDAX analysis of the green/blue precipitate detected C, F, O, Nd, P and no Hg.

Method 2: A suspension of bis(diphenylphosphanyl)amine (0.10 g, 0.25 mmol), $Hg(C_6F_5)_2$ (0.07 g, 0.13 mmol) and Er metal (0.14 g, 0.85 mmol) in toluene (30 mL) was stirred for 15 d at room temperature. The resulting suspension was filtered through a cannula and a yellow/blue precipitate remained. The orange filtrate was evaporated under reduced pressure to yield a bright orange solid. Crystallisation from toluene/hexane gave a few orange crystals which were identified by X-ray crystallography as $[Hg_3\{\mu_2\text{-}(Ph_2P)_2N\}_4]\cdot 3C_7H_8$ (**1**·3C$_7$H$_8$). Yield 0.068g (22%), m.p. 253 °C. Unit cell data: a = 13.17, b = 18.79, c = 21.04 Å, α= 88.43, β= 84.61, γ= 77.52°. V = 5063.83 Å^3. $^{31}P\{^1H\}$ NMR (C$_7$H$_8$, 25 °C): δ = 80.5 (br. s, 4 P), 95.8 (br. s, 2 P), 130.1 (br. s, 2 P) ppm. The IR spectrum was in agreement with that of the analytically pure sample (Method 3).

Method 3: To bis(diphenylphosphanyl)amine (0.31 g, 0.80 mmol) dissolved in toluene (40 mL) was added $Hg(C_6F_5)_2$ (0.21 g, 0.40 mmol) and the solution turned yellow. Two drops of liquid mercury were added. The solution became bright orange, was left at room temperature overnight under nitrogen and filtered. The solvent was evaporated to 20 mL and left to crystallise, yielding **1**·3C$_7$H$_8$ (0.69 g, 80%). M.p. 250–252 °C. Unit cell data: a = 13.15, b = 18.76, c = 21.06 Å, α= 88.40, β= 84.61, γ= 77.53°. V = 5064.53 Å^3. ^{1}H NMR (300 MHz, C$_6$D$_6$, 25 °C): δ = 2.11 (s, 9 H, *Me*Ph), 6.83–6.89 (m, 15 H, *Ph*Me), 6.81 [br. m, 16 H, *p*-H (PhP)], 6.91 [br. m, 32 H, *m*-H (PhP)], 7.42 [br. m, 32 H, *o*-H (PhP)] ppm. $^{31}P\{^1H\}$ NMR (C$_6$D$_6$, 25 °C): δ = 81.9 (br. s, 4 P, P5,6,7,8), 95.6 (br. s, 2 P, P2,4), 130.4 (br. s, 2 P, P1,3) ppm. IR (Nujol): $\tilde{\nu}$ = 3020 m, 1229 s, 1147 s, 1098 m, 1025 w, 950 w, 755 m, 697 s cm^{-1}. $C_{117}H_{104}Hg_3N_4P_8$ (2415.57): calcd. C 58.17, H 4.34, N 2.32; found C 57.95, H 4.86, N 2.95.

$[Hg_2\{\mu_2\text{-}(Ph_2P)_2N\}_2\{(Ph_2P)(OPPh_2)N\}_2]\cdot 2C_7H_8$ (3·2C$_7$H$_8$): To bis(diphenylphosphanyl)amine (0.31 g, 0.80 mmol) dissolved in toluene (50 mL) was added $Hg(C_6F_5)_2$ (0.21 g, 0.40 mmol) and the solution turned yellow. After 1 h the yellow solution became bright orange and was left at room temperature overnight under nitrogen. Yellow crystals formed and were filtered from the mother liquor and characterised by X-ray crystallography as $[Hg_2\{\mu_2\text{-}(Ph_2P)_2N\}_2\{(Ph_2P)(OPPh_2)N\}_2]\cdot 2C_7H_8$ (**3**·2C$_7$H$_8$). Yield 0.60 g (77%). M.p. 242–245 °C. ^{1}H NMR (300 MHz, C$_4$D$_8$O, 25 °C): δ = 2.04 (s, 6 H, *Me*Ph), 6.8–8.2 (m , 90 H, PhP and *Ph*Me) ppm. $^{31}P\{^1H\}$ NMR (C$_4$D$_8$O, 25 °C): δ = 12.4 (s, 2 P, Hg–P chelating) 28.3 (s, 4 P, Hg–P bridging) 60.1 (s, 2 P, PO) ppm. IR (Nujol): $\tilde{\nu}$ = 3055 w, 1228 br. s, 1178 w, 1149 m, 1128 m, 1101 m, 1080 m, 1063 m, 1026 m, 998 m, 793 s, 731 m, 694 vs cm^{-1}. $C_{110}H_{96}Hg_2N_4O_2P_8$ (2154.9): calcd. C 61.31, H 4.49, N 2.60; found C 60.60, H 4.65, N 2.84. The presence of C_6F_5H in the filtrate was established by ^{19}F NMR spectroscopy.[36]

$[Hg_2\{\mu_2\text{-}(Ph_2P)_2N\}_2\{(Ph_2P)(OPPh_2)N\}_2]\cdot 2C_4H_{10}O_2$ (3·2C$_4$H$_{10}$O$_2$): Bis(diphenylphosphanyl)amine (0.10 g, 0.26 mmol) and $Hg(C_6F_5)_2$ (68 mg, 0.13 mmol) were dissolved in toluene (30 mL). Nd metal (12 mg, 0.09 mmol) was added and the mixture sonicated for 4 d. The resulting suspension was filtered through a cannula and a light green/blue precipitate remained. Evaporation of the filtrate yielded a bright orange solid, which on crystallisation from toluene/hexane gave single crystals, which were unsatisfactory for X-ray diffraction. The precipitate was washed with 1,2-dimethoxyethane (20 mL) which on partial evaporation deposited single crystals of $[Hg_2\{\mu_2\text{-}(Ph_2P)_2N\}_2\{(Ph_2P)(OPPh_2)N\}_2]\cdot 2C_4H_{10}O_2$ (**3**·2C$_4$H$_{10}$O$_2$). Yield 0.04 g (16%). IR (Nujol): $\tilde{\nu}$ = 1230 s, 1149 m, 1128 m, 1101 m, 1080 m, 983 w, 939 m, 830 w, 780 w-m, 754 m-s, 698 s, 668 s, 648 w cm^{-1}.

$[Hg_2\{\mu_2\text{-}(Ph_2P)_2N\}_3Cl]\cdot 3/2CDCl_3$ (4·3/2CDCl$_3$): Solid bis(diphenylphosphanyl)amine (0.39 g, 1.0 mmol) and $Hg(C_6F_5)_2$ (0.27 g, 0.50 mmol) were mixed in the dry box (O_2 < 0.1 ppm) whereupon onset of reaction was indicated by a developing yellow colour. After connection to a vacuum/N_2 line with a recently regenerated purification train, addition of toluene (50 mL) gave a yellow solution which intensified to orange in 10 min. After 24 h an orange solid deposited, m.p. 205–208 °C. IR (Nujol): $\tilde{\nu}$ = 3034 w, 1495 m, 1164 s, 1097 m, 1025 s, 998 s, 769 s, 727 s, 692 s, 525 w cm^{-1}. This material when dissolved in $CDCl_3$ was shown to be a mixture of **3**, **4** and $(Ph_2P)_2NH$ by $^{31}P\{^1H\}$ NMR ($CDCl_3$, 25 °C): δ = 15.7 (s, 2 P, Hg–P chelating of 3), 26.7 (s, 4 P, Hg–P bridging of 3), 37.2 (br. m, 3 P, P1,3,5 of **4**) 45.8 [s, $(Ph_2P)_2NH$], 64.0 (m, 2 P, PO of **3**), 71.03 (br. m, 3 P, P2,4,6 of **4**), together with further minor impurity signals. Single crystals formed in the $CDCl_3$ solution and were identified by X-ray crystallography as **4**·3/2CDCl$_3$. The mother liquor was evaporated to 5 mL. The resulting orange precipitate was dissolved on gentle heating and slow cooling deposited crystals of **3**·2C$_7$H$_8$ (unit cell data a = 12.19, b = 12.61, c = 16.19 Å, α= 101.53, β= 96.07, γ= 101.52°, V = 2370.3 Å^3).

X-ray Crystallography: Crystalline samples of compounds $[Hg_3\{\mu\text{-}(Ph_2P)_2N\}_4]\cdot 3C_7H_8$ (**1**·3C$_7$H$_8$), $[Hg_2\{\mu_2\text{-}(Ph_2P)_2N\}_2\{(Ph_2P)\text{-}(OPPh_2)N\}_2]\cdot 2C_7H_8$ (**3**·2C$_7$H$_8$), $[Hg_2\{\mu_2\text{-}(Ph_2P)_2N\}_2\{(Ph_2P)\text{-}(OPPh_2)N\}_2]\cdot 2C_4H_{10}O_2$ (**3**·2C$_4$H$_{10}$O$_2$), and $[Hg_2\{\mu_2\text{-}(Ph_2P)_2N\}_3Cl]\cdot 3/2CDCl_3$ (**4**·3/2CDCl$_3$) were mounted on glass fibres, in viscous hydrocarbon oil. Crystal data were obtained using an Enraf–NoniusKappa CCD at –150 °C (123 K). X-ray data were processed using the DENZO program.[37] Structural solution and refinement was carried out using the SHELX suite of programs[38,39] with the graphical interface X-Seed.[40] All hydrogen atoms were placed in calculated positions using the riding model.

CCDC-241398 (for **1**·3C$_7$H$_8$), CCDC-241399 (for **3**·2C$_4$H$_{10}$O$_2$), CCDC-241400 (for **3**·2C$_7$H$_8$) and CCDC-241401 (for **4**·3/2CDCl$_3$) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Compound $[Hg_3\{\mu\text{-}(Ph_2P)_2N\}_4]\cdot 3C_7H_8$ (1·3C$_7$H$_8$): For compound $[Hg_3\{\mu\text{-}(Ph_2P)_2N\}_4]\cdot 3C_7H_8$ (**1**·3C$_7$H$_8$), one toluene molecule of solvation was disordered "tip-to-toe" over two sites of partial occupancy. These were satisfactorily modelled with half occupancy. No hydrogen atoms were appended to this disordered molecule and an ISOR 0.01 refinement was used to obtain satisfactory thermal parameters for atoms C(112), C(114), C(118) and C(120).

Compound $[Hg_2\{\mu_2\text{-}(Ph_2P)_2N\}_2\{(Ph_2P)(OPPh_2)N\}_2]\cdot 2C_7H_8$ (3·2C$_7$H$_8$): For compound $[Hg_2\{\mu_2\text{-}(Ph_2P)_2N\}_2\{(Ph_2P)(OPPh_2)N\}_2]\cdot 2C_7H_8$ (**3**·2C$_7$H$_8$), the poor R_1 value (see Table 2) can be attributed to a peak of residual electron density (20.086) located 0.829 Å from Hg(1). Incorporation of this density led to extension of the Hg(1)–O(1) and Hg(1)–P(2) bonds (lesser occupancy relative to greater Hg(1) occupancy) of greater than 0.16 and 0.80 Å, respectively. Accordingly, the disorder was not modelled.

Compound $[Hg_2\{\mu_2\text{-}(Ph_2P)_2N\}_2\{(Ph_2P)(OPPh_2)N\}_2]\cdot 2C_4H_{10}O_2$ (3·2C$_4$H$_{10}$O$_2$): For compound $[Hg_2\{\mu_2\text{-}(Ph_2P)_2N\}_2\{(Ph_2P)(OPPh_2)N\}_2]\cdot 2C_4H_{10}O_2$ (**3**·2C$_4$H$_{10}$O$_2$), a peak of residual electron density (3.97) is located 0.882 Å from Hg(1). Modelling of this electron density as a partial Hg occupancy led to extension of the original

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Hg(1)–O(1) and Hg(1)–P(2) bonds, new occupancy less relative to Hg(1) of greater than 0.12 and 0.8 Å, respectively. Accordingly, the disorder was not modelled.

Compound $[Hg_2\{\mu_2\text{-}(Ph_2P)_2N\}_3Cl]\cdot 3/2\,CDCl_3$ ($4\cdot 3/2\,CDCl_3$): For compound $[Hg_2\{\mu_2\text{-}(Ph_2P)_2N\}_3Cl]\cdot 3/2\,CDCl_3$ ($\mathbf{4}\cdot 3/2\,CDCl_3$), ISOR 0.01 refinement was required for atoms C(25), C(55) and N(1) in order to obtain satisfactory thermal parameters. Due to computational constraints the deuterium atoms of the lattice solvent were refined as hydrogen.

A Bicyclic P–P-Bridged 1,3,2,4-Diphosphadiboretane Cation and an Imino(phosphinidene)borane–$AlBr_3$ Adduct[‡]

Klaus Knabel,[a] Thomas M. Klapötke,[a] Heinrich Nöth,*[a] Robert T. Paine,[b] and Ingo Schwab[a]

Dedicated to Prof. Dr. Alfred Schmidpeter on the occasion of his 70th birthday

Keywords: 1,3-Di(*tert*-butyl)-2,4-bis(2,2,6,6-tetramethylpiperidino)-1,3,2,4-diphosphadiboretane / 1-*tert*-Butyl-2,4-bis(2,2,6,6-tetramethylpiperidino)-1,3-diphospha-2,4-diborabicyclo[1.1.0]butane cation / 2,2,6,6-Tetramethylpiperidino-*tert*-butylphosphinideneborane–$AlBr_3$ adduct / X-ray structures / ab initio calculations

Depending on reaction conditions the 1,3,2,4-diphosphadiboretane **1** reacts with $AlBr_3$ to give the unstable adduct tmp=B=P(*t*Bu)$AlBr_3$, **3**, and/or the somewhat more stable salt $[(tmpB)_2(PtBu)P]^+[AlBr_4]$, **2**. The X-ray structure determination of **3** shows an almost linear NBP array with BN and BP double bonds resembling an allene type structure. NBO analysis shows the presence of BN- and BP-π-bonds. On the other hand, the cation of compound **2** has a bicyclic structure with a long P–P bond [2.349(2) Å]. The B–P bonds to the phosphonium type P2 atom [av. 1.939(5) Å] are longer than those to the tri-coordinated P1 atom [1.889(6) Å]. NBO analysis of the model compound $(H_2NB)_2(PMe)P^+$, **9**, show that the P–P bond in **2** is formed from *p*-orbitals.

Introduction

In contrast to boron nitrogen chemistry, the development of the chemistry of B–P compounds began much later, but has attracted increasing attention during the last two decades. The state of the art has been summarized in a review.[2] Particularly 1,3,2,4-diphosphadiboretanes[3–11] offer many interesting aspects as ligands as well as a source for amino-phosphinidene-boranes $R_2N{=}B{=}PR$[8,11] having a boron atom of coordination number 2 and B=N as well as B=P double bonds. They also react with many Lewis acids often in rather unusual ways,[12] and we report here on the reaction of $[tmpB\text{-}PtBu]_2$, **1**, (tmp = 2,2,6,6-tetramethylpiperidino) with $AlBr_3$.

Results

Synthesis and Reactions

The chemistry of 1,3,2,4-diphosphadiboretanes is well developed. Many derivatives have been synthesized, characterized, and their chemistry studied to some extent.[2] For example, in most cases reactions with metal carbonyl fragments lead simply to coordination of the P atoms of the intact four-membered ring.[6,7] More interesting are reactions where cycloreversion produces phosphinidene boranes with dicoordinated B atoms as shown for $(tmpB\text{-}PCEt_3)_2$,[11] which gives the complex tmp=B=PR–$Cr(CO)_5$.[5] This suggests that other Lewis acidic compounds or fragments might behave similarly. Another ideal candidate for cycloreversion reactivity is the diphosphadiboretane $(tmpB\text{-}PtBu)_2$, **1**. The synthesis of this compound has already been reported.[4] We now find that the reaction sequence Equation (1) allows the synthesis of **1** in a one pot reaction with yields of up to 81%.

The subsequent reaction of **1** with $AlBr_3$ in a 1:2 ratio in toluene solution at room temperature proceeds unexpectedly by P–C bond cleavage, according to Equation (2), to give compound **2**, which crystallized from toluene at –30 °C as yellow prisms. The compound is stable for more than a week in toluene below –20 °C. However, compound **2** is not the primary reaction product. Monitoring the reaction by ^{31}P and ^{11}B NMR spectroscopy at –30 °C we find that the primary reaction leads to the yellow 1:1 adduct tmp=B=P*t*Bu·$AlBr_3$, **3**, on rapid addition of an excess of $AlBr_3$ to **1** (ratio 2:1) as shown in Equation (3). Compound **3** quickly converts, at room temperature, from a solid into an orange oil which finally yields the golden yellow compound **2** after addition of toluene. At low temperatures (below –20 °C) both **2** and **3** are stable for some hours in tolu-

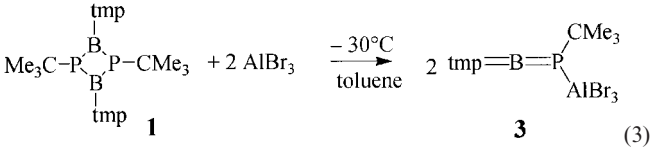
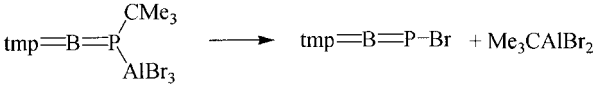
(2)

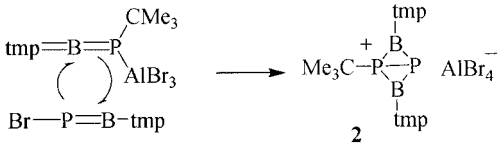
ene. In the solution of **2** the formation of tBuAlBr$_2$ was detected by its ^{27}Al NMR signal at δ = 152.5 ppm. Compound **2** is nearly insoluble in pentane but reacts with $CDCl_3$ and more slowly in CD_2Cl_2 solution.



(3)



(4)



(5)

There are at least two conceivable mechanisms for the formation of the salt **2**. We prefer the one that is shown in Equation (4) and Equation (5) as **3** is one of the isolated products, i.e. we assume a decomposition of **3** with elimination of tBuAlBr$_2$ [Equation (4)] and cycloaddition of the proposed intermediate BrP=Btmp with **3** [Equation (5)].

The reaction of **1** with $AlCl_3$ in toluene produced a yellow powder that was insoluble in nonpolar solvents. Elemental analyses of products from several experiments ranged from 6.74 to 8.38% for Al, and from 29.80 to 34.70% for Cl. These data show that the Cl:Al ratio is close to 3. However, IR data are not conclusive as to whether the product is an analogue of **2** or **3** or something else**.** With $GaCl_3$ the same observation was made for toluene solutions. The colorless powder which forms decomposes at about 185°C. The ^{11}B NMR spectrum of the solution showed the presence of tmpBCl$_2$ (δ^{11}B = 33.8 ppm) besides a signal at δ^{11}B = 44.5 ppm. In the ^{31}P NMR spectrum of the $GaCl_3$ reaction five signals are observed at –181.4 [d, $J(^1H^{31}P)$= 110 Hz], –148.7 [d, $J(^1H^{31}P)$= 110 Hz], 91.9, 7.9, and 1.8 ppm, indicating that no single species is present in solution. In contrast, $InCl_3$ in the toluene suspension did not react at all with **1**. This demonstrates the unique behavior of $AlBr_3$.

NMR Spectra

The rapid decomposition of **3** made the recording and interpretation of the NMR spectra difficult, particularly for the ^{1}H and ^{13}C NMR spectra due to the presence of **2** and other by-products.

It is surprising to note that the shielding of the ^{11}B nucleus in **3** is only 4.6 ppm, less than in the starting diphosphadiboretane **1** in spite of the fact that the boron atom is now dicoordinate. However, in agreement with this, the line width has increased from 400 (for, **1**) to 530 Hz for **3**. The small amount of deshielding is most likely due to the presence of BN- and weaker BP-π-bonding which leads to a comparatively high electron density at the boron atom (see results of calculations). Moreover, the δ^{11}B value is very close to those of tmp=B=P(tBu)M(CO)$_5$ (M = Cr, W)[5] which are 67.0 and 62.9 ppm. The ^{31}P NMR signal of **3** is broad ($h_{1/2}$ = 900 Hz) and found at δ = –59.8 ppm. This P atom environment is better shielded than in the M(CO)$_5$ complexes (δ^{31}P = –32.7 and –45.3 ppm for M = Cr and W, respectively). Its ^{27}Al NMR spectrum contains a doublet at δ = 98.3 ppm due to AlP coupling with $^1J(^{31}P^{27}Al)$ = 140 Hz. The small line width of 20 Hz, as well as the chemical shift, is typical of a tetracoordinate Al atom.

Due to the low solubility the ^{13}C NMR spectroscopic data of **3** could not be recorded in deuterated benzene. Reliable assignment of the ^{1}H NMR spectrum was also not possible. Similarly, the very low solubility of **2** in deuterobenzene or deuterotoluene resulted in the detection of ^{1}H NMR resonances only for the *tert*-butyl group. In $CDCl_3$ rapid decomposition of **2** occurred. In CD_2Cl_2 the decomposition was slow enough to allow the measurement of several NMR resonances. Nevertheless, even under these circumstances the compound decomposed completely within 15 to 20 min. Thus, the measurements had to be done very quickly with as few pulses as possible. For this reason we were unable to get ^{13}C NMR spectroscopic data of compound **2**, and only the ^{1}H resonance for the tBu group could be reliably assigned as a doublet due to $^3J(^{31}P^1H)$ = 11 Hz.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The boron atoms in the cation of **2** are more shielded by 30 ppm compared with **3.** As expected, the line width is much smaller (280 Hz) since the B atoms are tricoordinate. The observed two ^{31}P signals were doublets with $^{1}J(^{31}P^{31}P)$ = 62 Hz in accordance with the calculations, and the shift difference of 40 ppm is 6 ppm from the calculated value.[13] The small coupling constant suggests that the bond between the two P atoms does not represent a normal P–P single bond as found e.g. in 3-(diisopropylamino)-4-(dimethylamino)-1,2-di(*tert*-butyl)-1,2,3,4-diphosphadiboretane.[14] The presence of the tetrabromoaluminate anion in **2** is manifested by a sharp ^{27}Al NMR signal at δ = 80.3 ppm.[15]

The IR spectrum of **3** is characterized by two strong bands at 1633 and 1590 cm^{-1}. These heteroallene bands are 26 and 23 cm^{-1} higher than those observed for tmp=B=P(*t*Bu)M(CO)$_5$[5] indicating stronger BN and BP bonds. In tmp=B=N(*t*Bu)$AlBr_3$ these bands are found at 1800 and 1850 cm^{-1}.[16] This is due to a better coupling of the two BN vibrations, and obviously stronger BN bonds.

The mass spectrum of **3** shows few peaks, and there is no peak for the molecular ion. The most intense peak is found at *m*/*z* = 298. It can be assigned to the $PAlBr_3$ fragment due to the isotopic pattern. A peak at *m*/*z* = 426 (22%) results from loss of a Br atom from the molecular ion. Loss of a Me group from this ion, either from the *t*Bu group or the tmp substituent, leads to a peak at *m*/*z* = 411 (35%).

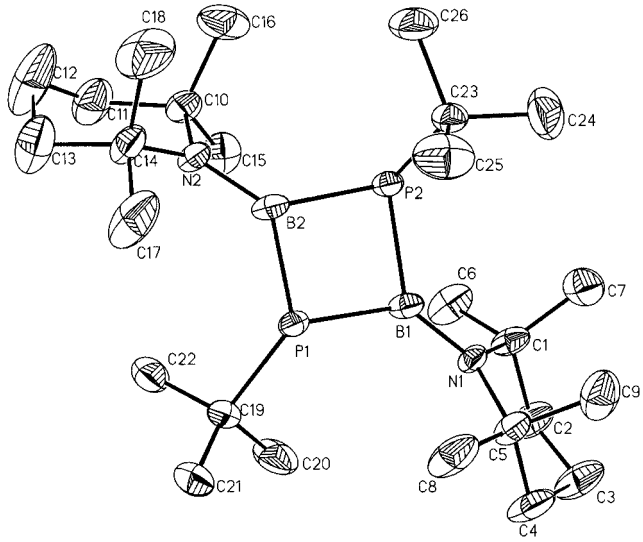


Figure 1. The molecular structure of **1** in ORTEP description. Thermal ellipsoids are represented on a 25% probability level. Selected bond lengths (Å): P1–B1 1.876(9), P1–B2 1.865(6), P1–C19 1.895(7), P2–B2 1.943(8), P2–B1 1.948(6), P2–C23 1.880(7), B1–N1 1.408(8), B2–N2 1.419(8), N1–C1 1.503(7), N1–C5 1.492(7), N2–C10 1.494(8), N2–C14 1.492(7). Selected bond angles (°): B1–P1–B2 90.1(3), B1–P1–C19 124.1(3), B2–P1–C19 124.9(3), B1–P2–B2 85.9(3), B1–P2–C23 111.1(3), B2–P2–C23 112.1(3), N1–B1–P1 134.7(5), N1–B1–P2 133.5(6), P1–B1–P2 91.6(3), P1–B2–P2 92.1(3), N2–B2–P2 133.3(5), N2–B2–P1 134.4(6), B1–N1–C1 118.5(5), B1–N1–C5 122.8(5), C1–N1–C5 118.4(5), B1–N2–C10 118.5(5), B2–N2–C14 143.8(5), C10–N2–C14 118.1(5).

Molecular Structures

Figure 1 shows the molecular structure of the diphosphadiboretane **1**. The compound crystallizes in orange prisms in the monoclinic system, space group $P2_1/c$ with Z = 4. The four-membered ring is asymmetric with unequal B–P bond lengths spanning a range from 1.865(6) to 1.948(6) Å. This results in endocyclic bond angles also being different with P–B–P angles of 91.6(2)° at B1 and 92.1(3)° at B2 and B–P–B bond angles of 90.1(3)° at P1, and 85.9(3)° at P2. As expected, the B and N atoms reside in planar environments, e.g. the sum of bond angles for N1 is 359.7°, and 359.8° for N2. The B–N bonds are on the upper end of the range of B(sp^2)–N(sp^2) bonds in monoaminoboranes. The reason for this is that the tmp groups are twisted against the respective P_2B planes by 47.8° for the C1N1C5 plane and by 51.1° for the C10N2C14 plane. This twisting is due to steric repulsion of the bulky organyl groups. Actually, the BN bond lengths found for **1** are intermediate with those determined for (tmpB-$PCEt_3$)$_2$ (1.431 Å)[11] and (tmpB-$PH)_2$ (1.405 Å).[7] In contrast to most other 1,3,2,4-diphosphadiboretanes, the four-membered ring of **1** is not planar whereas calculations (v. i.) predict a planar ring structure: the two P_2B planes are bent by 7.1° (roof angle 172.9°). The angle that the PC bonds form with their respective P_2 bonds are also unusual: for P2–P1–C19 this angle is 149.7° while an angle of 126.7° is found for P2–P1–C23.

The molecular structure of **3** is depicted in Figure 2. This compound also crystallizes in the monoclinic system, space group $P2_1/n$ with Z = 4. The molecule is characterized by a dicoordinated B atom and by tricoordinate N and P atoms. The plane C1N1C5 lies almost perpendicular to the plane Al1P1C10 as expected for an allene type configuration. This is in agreement with an N–B–P bond angle of 170.4(3)°. Similar deviation from the ideal linearity has been observed for compounds of type tmp=B=N(*t*Bu)(Cr[CO)$_5$[16] or tmp=B=N(*t*Bu)ECl_3 (E = Ga, In).[17] While atom N1 sits in the center of the C1C5B1 plane, the sum of bond angles at atom P1 is only 334.4°. Thus, the geometry about the P1 atom is pyramidal. The bond angle C10–P1–Al1 is 118.2(2)° and the other two angles, B1–P1–C10 and B1–P1–Al1 are 110.6(2) and 105.6(2)°, respectively. This corresponds with a distorted trigonal pyramid. Consequently, this geometry is not optimal for BP-π-bonding. One can indeed note that the B–P bond length in **3** [1.787(4) Å] is somewhat longer than in tmp=B=P(*t*Bu)Cr(CO)$_5$[5] [1.742(5) Å] where the P atom resides in a planar environment. Nevertheless, the B–P bond length in **3** is shorter than expected for B–P single bonds for which a range from 1.81 to 1.91 Å has been determined in agreement with covalent radii and taking the Shoemaker–Stevenson correction into account.[18] It should be noted, however, that in most cases a covalent bond length increases as the coordination number of an atom decreases, thus the B–P bond in **3** can still be considered to have multiple bond characteristics. However it does not show the

geometry of a classical pp–π-bond in contrast to the model compound $Me_2N{=}B{=}P(Me)AlBr_3$ (**10**), see below.

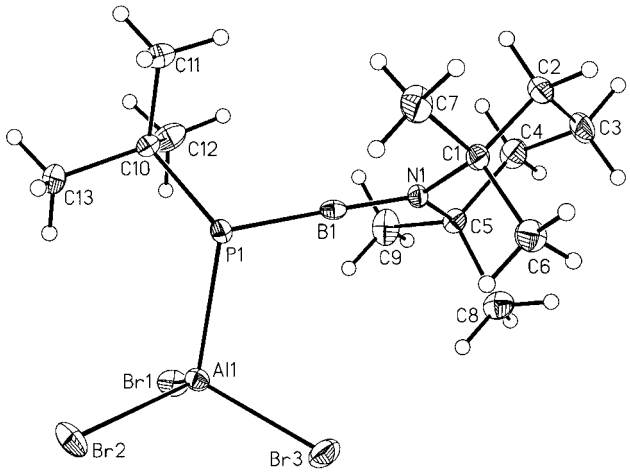

Figure 2. The molecular structure of **3** in ORTEP description. Thermal ellipsoids are shown on a 25% probability level. Selected bond lengths (Å): Al1–Br1 2.279(1), Al1–Br2 2.302(1). Al1–Br3 2.281(1), Al1–P1 2.67(1), P1–B1 1.787(4), P1–C10 1.892(3), N1–B1 1.331(4), N1–C1 1.529(4), N1–C5 1.527(4). Selected bond angles (°): Br1–Al1–Br2 109.40(4), Br1–Al1–Br3 112.49(4), Br1–Al1–P1 111.95(4), Br2–Al1–P1 107.66(5), Br3–Al1–P1 104.36(4), B1–P1–C10 110.6(2), B1–P1–Al1 105.6(1), Al1–P1–C10 118.2(1), N1–B1–P1 170.4(3), B1–N1–C1 119.5(3), B1–N1–C5 119.7(3), B1–N1–C5 120.7(2).

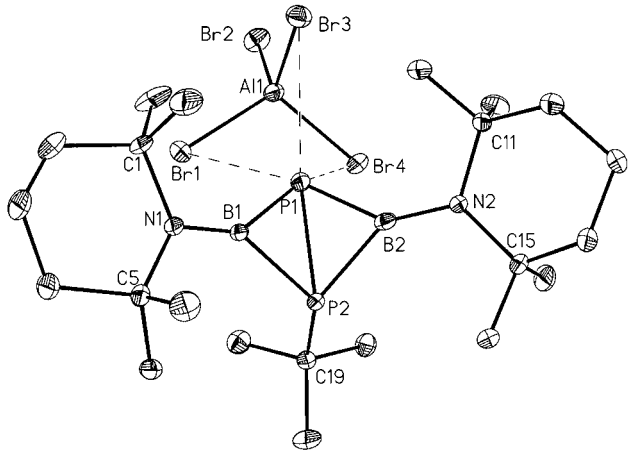

Figure 3. The molecular structure of **2** in ORTEP description. Thermal ellipsoids are depicted on a 25% probability level. Selected bond lengths (Å): Al1–Br1 2.310(2), Al1–Br2 2.293(2), Al1–Br3 2.297(2), Al1–Br4 2.308(2), P1–P2 2.315(2), P1–B1 1.894(6), P2–B1 1.944(5), P1–B2 1.884(7), P2–B2 1.931(6), B1–N1 1.360(6), B2–N2 1.377(8), N1–C1 1.532(6), N1–C5 1.534(6), N2–C10 1.537(6), N2–C14 1.519(6). Selected bond angles (°): B1–P1–B2 90.4(3), B2–P1–P2 53.6(2), B1–P1–P2 53.9(2), B1–P2–B2 87.6(2), B2–P2–P1 51.7(2), B1–P2–P1 51.9(2), B1–P2–C19 123.9(3), B2–P2–C19 124.6(2), N1–B1–P1 143.9(4), N1–B1–P2 141.9(4), P1–B1–P2 74.2(2), P1–B2–P2 74.7(2), N2–B2–P1 142.1(4), N2–P–B2–P2 142.9(4), B1–N1–C1 118.0(4), B1–N1–C5 121.8(4), C1–N1–C5 118.5(4), B2–N2–C10 118.3(4), B2–N2–C14 122.1(4), C10–N2–C14 118.8(4), P1–P2–C110.1(4).

The molecular structure of compound **2** is shown in Figure 3. The bicyclic ring has a butterfly configuration with the P atoms at the roof and an angle of 123.4° between the two P_2B planes. This fold angle differs enormously from that in **1** (172.9°), but corresponds with the bicyclo[1.1.0]-butane structure with a "roof" angle of 126°.[19] The B and N atoms of **2** have a planar environment, demonstrating their sp^2 type character which allows good BN-π-bonding. This is not only shown by short BN bonds [1.360(6) Å for B1–N1, and 1.377(8) Å for B2–N2] but also by the fact that the torsion angles τ of C1–N1–B1–P1 and C14–N2–B2–P2 are only 16.3 and 15.4°, respectively.

The P–B bonds in the cation of **2** are shorter for P1 (1.894(6) and 1.884(7) Å) than those at atom P2 which show bond lengths of 1.944(5) and 1.931(6) Å. These longer bonds are in line with the higher coordination number at atom P2. Of particular interest is the P1–P2 distance, 2.315(2) Å. This is longer than the usual P–P single bond length, 2.15(2) Å, but compared with the PP separation in the related diphosphadiboretane (tmpB-P*t*Bu)$_2$, **1**, there is a shortening by 0.427 Å. This is consistent with the presence of a weak P–P bond in **2**. The two B–P–B bond angles are close to 90° [90.4(3)° for P1 and 87.6(2)° for P2]. On the other hand, we find the P–B–P bond angle at B1 to be 74.2(2)°, and 74.7(2)° for B2, while the B1–P1–P2 and B2–P1–P2 angles are 53.9(2)° and 53.6(2)°.

Twhere is a very weak interaction of atom P1 with the bromine atom Br3 of the tetrabromoaluminate anion (P1···Br3 3.720 Å). The other two "contacts", P1···Br1 and P1···Br4 show distances of 3.965 and 4.166 Å, respectively. The Al–Br bonds lie in the range of 2.293 to 2.310 Å and the Br–Al–Br bond angles range from 108.6 to 110.1°. The Br3···P1 interaction has no elongating effect on the Al1–Br3 bond (Al1–Br3 2.297 Å).

Theoretical Studies

The formation of the $(tmpB)_2P_2tBu^+$ cation in **2** is not only unusual but also of interest considering bonding situation and structure. Therefore, we performed ab initio and density functional calculations at various levels not only for the gas phase structure of compound **2** but also for the model compounds **5** to **10**, **5** being a model for the cation in compound **2**. Moreover, ELF calculations were performed for the model compounds **9** and **10** (see Figures 7 and 8, molecule **8** is not depicted but calculations have been performed for comparison).

Compound **1** is an analogue of **7**. While **1** has a slightly bent ring structure and shows two differently *trans*-oriented P–C bonds with respect to the P1/P2 atoms, the calculations for model **7** in the *trans*-configuration reveal a planar ring structure with longer P–B bonds, and, more noticeably, the P–B–P bond angle is 8° larger than that calculated for the *cis*-isomer of **7** (see Figure 4). Compound **1** has only been observed as the *trans*-isomer which is obviously the more stable structure, and this has been ascertained for *cis*-**7** which is 611.6 kJ/mol less stable than the *trans*-isomer. Figure 5 shows the results of the calculations for the *trans*-isomer.

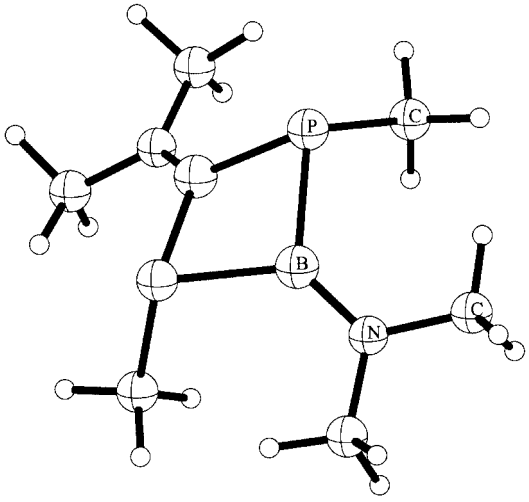

Figure 4. Optimized structure for the model compound *cis*-[$(Me_2B)_2$-$(PMe)_2$], **7** (C_{2v}) at the RI-MP2/TZVP level of theory. Bond lengths (Å) and angles (°): P–B 1.943, P–C 1.885, B–N 1.399*N*–C 1.455; P–B–P 98.60, B–P–B 74.15, B–P–C 106.51, P–B–N 130.67, B–N–C 123.71; torsion angle P–B–B–P 143.9.

Table 1 contains calculated data for compound **6** and experimental data for compound **4**, respectively. It also shows selected experimental and calculated data for the cation in compound **2** as well as calculated values for the model **5**

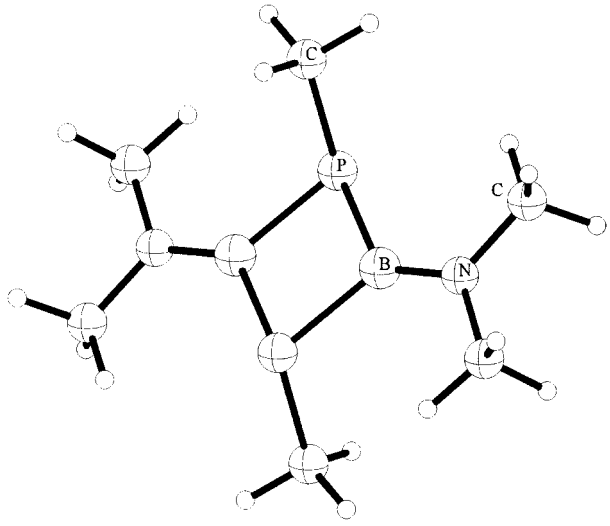

Figure 5. Optimized structure for the model compound *trans*-[$(Me_2B)_2(PMe)_2$], **7** (C_1) at the RI-MP2/TZVP level of theory. Bond lengths (Å) and angles (°): P–N 1.924, P–C 1.875, B–N 1.395, N–C 1.452; P–B–P 97.95, B–P–B 82.05, B–P–C 114.26, P–B–N 131.03, B–N–C 123.28; torsion angle 0.01.

(C_1 and C_s; see also Figure 6). It also contains experimental and calculated ^{31}P chemical shifts. The ^{31}P spectrum of the cation of **2** showed two doublets with $^1J(^{31}P^{31}P)$ = 62 Hz and a separation of the two signals by 40 ppm. These data are roughly in agreement with the calculated values for the model cation **5** with C_1 or C_s symmetry. The largest deviation between experimental and calculated data results for the bond angle P1–P2–C, most likely a result of the different steric requirements of the tmp and Me_2N groups.

Selected data from the NBO analysis of **9** and **10** are listed in Table 2 and Table 3. It is noteworthy that the P–P bond in **9** is built almost exclusively from the *p*-orbitals of the phosphorus atoms. While the P1–B bond results from a boron sp^2 and a phosphorus *p*-orbital (86% p character),

Table 1. Experimental parameters from X-ray diffraction and ^{31}P NMR shifts for compounds **2** and **4** together with the calculated parameters of the cation of **2** and the model compounds **5** and **8**.

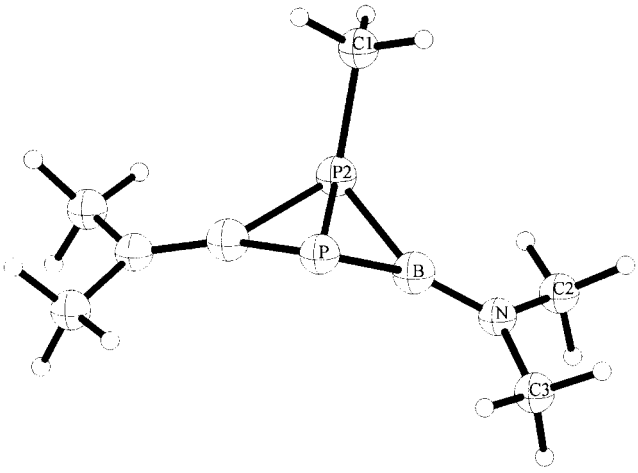

Figure 6. Optimized geometry (C_s) for the model cation **5** at the RI-MP2/TZVP level of theory. Bond lengths (Å) and angles (°): P–P2 2.385, P–B 1.890, P2–B 1.925, P2–C1 1.846, B–N 1.366, N–C2 1.466, N–C3 1.468; P–P2–B 50.66, P–B–P2 77.37, B–P–P2 51.97, P–P2–C1 110.42, P–B–N 137.83, B–N–C2 124.17, B–N–C3 122.13

the P2–B bond is formed from a boron sp^3 orbital and a phosphorus sp^2 orbital. The positive charge of the cation resides mainly on the tetracoordinate P atom (see data in Figure 6). As expected, the B–N bonds are double bonds.

A similar situation is present in the $AlBr_3$ adduct **10**. Both, the B–N and the B–P bonds are double bonds.

Finally, the bonding situation in **2** and **3** as calculated for the model compounds **9** and **10** is illustrated by the use of topological ELF analysis (electron localization function),[20] as depicted in Figure 7 and Figure 8, calculated for C_s and C_1 symmetry, respectively. There are four B–P bonds and a weak P–P bond that form the B_2P_2 core of **9**. The corresponding attractors are above the two BP_2 planes. The disynaptic basins of these attractors are merged in the case of the alkyl-substituted atoms P2. Regarding the location of positive charges: the tetracoordinate atom P2 carries a higher positive charge than atom P1, which is almost neutral, and as expected the boron atoms also carries a positive charge while negative charges are primarily located at the N atoms. Figure 8, on the other hand, clearly shows the allene type structure of the $AlBr_3$ adduct **10** (orthogonal attractor positions) and also reveals BN- and BP-π-bonding.

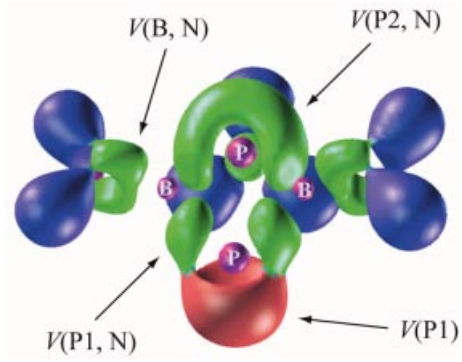

Figure 7. Rendered *ELF* isosurface and basin assignment for $[(H_2NB)_2(PMe]P)]^+$ (**9**C_s) with disynaptic basins (green) and monosynaptic basin *V*(P1) (red). Representation at η = 0.80, 150^3 grid points, core basins in purple, protonated basins in blue. The *V*(P1, P2) for the weak interaction between the two phosphorus atoms has a maximum *ELF* value of 0.645 and is therefore difficult to visualize. AIM basin populations (charges): P1 15.04 (–0.04), P2 14.76 (+0.24), B1/B2 3.89 (+1.11), N 8.54 (–1.54).

Discussion

1,3,2,4-Diphosphadiboretanes (RB–PR′)$_2$ are more readily accessible than the six-membered 1,3,5,2,4,6-triphosphatriboranes but need bulky groups R for stabilization. The 2,2,6,6-tetramethylpiperidino is such a group as shown e.g. by (tmpB-PH)$_2$.[17] Another one is the mesityl group

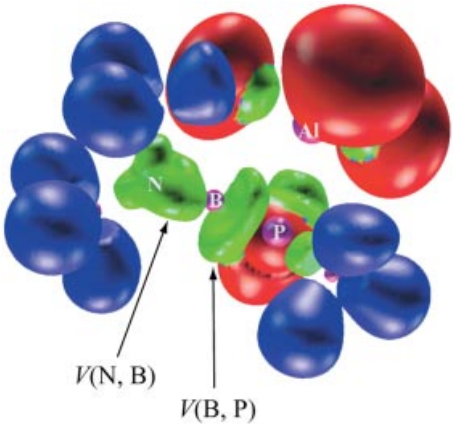

Figure 8. Rendered *ELF* isosurface and basin assignment for $AlBr_3$ adduct (**10**) with disynaptic basins (green). Representation at η = 0.75, grid increment 0.2 Å, core basins in purple, protonated basins in blue. The *ELF* surface illustrates the allene type character of the N–B–P moiety. Attractor distances (Å): P–*V*(P, Al)–Al: 1.026, 1.503; P–V(P, B)–B: 1.083, 0.775; P–V(P, C)–C: 1.024, 0.859; B–V(B, N)–N: 0.738/0.747, 0.701/0.718. AIM basin populations (charges): N 8.37 (–1.37), B 4.41 (+0.59), P 14.66 (+0.34), Al 11.02 (+1.98).

attached to the B atom.[21,22] Table 4 lists some typical structural features as well as ^{11}B and ^{31}P NMR spectroscopic data of some 2,4-diamino-1,3,2,4-diphosphadiboretanes. A more complete survey is given in a review.[2] A small range is observed for the B–P bond lengths (1.865 to 1.97 Å) which is typical for a B–P single bond between tricoordinate B and P atoms. In almost all cases the BN bonds are close to 1.4 Å with extremes of 1.37(1) to 1.431(2) Å. It appears that the B–P bond lengths are influenced by the steric requirements of the amino groups at the boron atoms: the smaller the amino group the longer is the B–P bond. This is coupled with the lengths of the B–N bonds and coplanarity of the C_2N plane with the BP_2 plane, e.g. the strength of the BN bond. Moreover, this also becomes apparent in the respective $\delta^{11}B$ values where deshielding is noted for the diphosphadiboretanes (tmpB-PR)$_2$ with an increasing steric demand of the R substituents (R = H, $\delta^{11}B$ = 47.1 ppm; R = CMe_3, $\delta^{11}B$ = 50.2 ppm; R = CEt_3,$\delta^{11}B$ = 66.1 ppm). Most of the four-membered rings are planar, and many of them show C_i point group symmetry. Therefore, the nonplanar rings of **1** as well as (tmpB-PSiMe$_3$)$_2$[4] are exceptional, particularly in comparison with the planar ring in (tmpB-PCEt$_3$)$_2$ where the P substituent is more bulky.[11] Nonplanarity is also observed for the two B_2P_2 rings of $Et_3CP(Btmp)_2P$–P(tmpB)$_2$PCEt$_3$,[23] whose angles between the P_2B planes are 157.2° within a bicyclic ring, and 98.4° between adjacent rings. The P–P bond length joining the two four-membered rings is 2.189(1) Å. In compound **4**, which results from the photolysis of (tmpB-PCEt$_3$)$_2$ [Equation (6)], the P–P distance is 2.349(2) Å, while in compound **2** a length of 2.315(2) Å is observed. The shrinking is significant and obviously due to the positive charge.

A noteworthy feature of diphosphadiboretanes (see Table 4) is that the sum of bond angles at the P atoms (average values of the two P atoms) is decreasing with increasing steric requirement of the organyl group as shown

Table 4. Selected NMR spectroscopic data of 2,4-amino-1,3-diorganyl-(silyl or hydrido)-1,3,2,4-diphophadiboretanes.

by the following data: R = CEt_3, 329.2°; R = CMe_3, 323.1°; $SiMe_3$ = 287.9°. On the other hand, in the series of compounds $(R_2NB\text{-}PtBu)_2$ this sum of bond angles decreases in the series from R_2N = tmp (332.8°) > iPr_2N (313.5°) > Me_2N (309°). Thus, the *p*-character at the P atoms increases. The result of the ring of compound **1** being nonplanar in contrast to $(tmpB\text{-}PCEt_3)_2$ is puzzling. In the latter compound the higher steric requirement of the CEt_3 group is compensated by a stronger twist of the tmp group which obviously allows ring planarity while in compound **1** the structure prefers a stronger BN bond at the expense of loss of planarity. Although the solid-state structure of **1** has two nonequivalent P atoms, in solution only one ^{31}P NMR signal is observed as well as only one each for the protons of the CMe_3 group but two ^{13}C resonances for this group. Therefore, the two P atoms are equivalent in solution.

It has been shown that $(tmpB\text{-}PCEt_3)_2$ reacts with $M(CO_5)$ fragments to yield $tmp{=}B{=}P(CEt_3)M(CO)_5$ (M = Cr, MoW).[5] In analogy, **1** reacts with $AlBr_3$ to give **3**. In contrast to compounds $tmp{=}B{=}N(tBu)EX_3$ (E = Al, Ga, In; X = Cl, Br),[17] **3** is unstable and decomposes to **2** which, however, is more conveniently obtained from **1** and $AlBr_3$ at ambient temperature followed by rapid cooling to prevent decomposition. The formation of Me_3CAlBr_2 in this process indicates that this is most likely not a radical reaction although this has not been proven definitely.

Experimental Section

All experiments were performed under anhydrous conditions using Schlenk techniques. Solvents were dried by conventional methods. $TmpBCl_2$,[23] LiPH*t*Bu,[24] and $NaN(SiMe_3)_2$[25] were prepared by literature methods. $AlBr_3$ was freshly sublimed before use. NMR: Bruker WP 200 and JEOL EX 400, IR: Nicolet FT-IR, MS: Atlas CH-7 (70 eV), X-ray: Siemens P4 four circle diffractometer operated with Mo-*Kα*-radiation, graphite monochromator, CCD detector, and the low temperature device Siemens LT2. NMR references: $SiMe_4$ for ^1H and ^{13}C; $BF_3{\cdot}OEt_2$ (ext. for ^{11}B), 1 M aqueous $HAlCl_4$ solution (ext.), 85% H_3PO_4 (ext.) for ^{31}P.

***tert*-Butylchlorophosphanyl-(2,2,6,6-tetramethylpiperidino)borane and 1,3-Di(*tert*-butyl)-2,4-(2,2,6,6-tetramethylpiperidino)-1,3,2,4-diphosphadiboretane (1):** LiPH(*t*Bu) (9.2 g, 95.8 mmol) were dissolved in diethyl ether (100 mL) – slight warming of the stirred suspension may be necessary. The clear, yellowish solution was then cooled to –60 °C, and a solution of $tmpBCl_2$, (21.2 g, 95.5 mmol) in hexane (300 mL) was added over a period of 3 h under rapid stirring. Stirring was continued overnight. After allowing the suspension to attain room temperature the orange solution was separated by a cannula from the white precipitate which was washed twice with hexane (50 mL). All solvent was evaporated in vacuo from the solution, which contained only tmpBCl–PH*t*Bu ($\delta^{11}B$ = 45.6 ppm, $\delta^{31}P$ = –52.6 ppm), leaving behind a very viscous to waxy material to which benzene (100 mL) was added. The solution was then treated with a solution of $NaN(SiMe_3)_2$ (20.9 g, 114 mmol) in benzene (200 mL). Within a few minutes a white precipitate formed. After stirring overnight the benzene was removed in vacuo and the residue treated with hexane (200 mL). According to NMR data ($\delta^{11}B$ = 63.8 ppm, $\delta^{31}P$ = 4.6 ppm) the filtrate contains only compound **1**. After reduction of the filtrate by 2/3 of its volume and cooling to –30 °C orange crystals separated within 2 d. Yield: 18.4 g of **1** (81%), m.p. 129–131 °C. ^1H NMR (C_6D_6): δ = 1.42 [t, *N* = 11 Hz, 18 H, $C(CH_3)_3$], 1.52 [m, 8 H, βCH_2], 1.61 [s, br., 16 H, γCH_2 + $C(CH_3)_2$], 1.67 [s, 12 H, $N(CH_3)_2$] ppm. ^{13}C NMR: δ = 17.1 [s, γCH_2], 32.4 [t, *N* = 6 Hz, $C(CH_3)_2$], 33.2 [t, *N* = 9 Hz, $C(CH_3)_2$], 36.1 [t, *N* = 6 Hz, $C(CH_3)_2$),], 38.6 [d, $^1J(^{31}P^{13}C)$ = 16 Hz, $C(CH_3)_3$], 54. [t, *N* = 8 Hz, $N(CH_3)_2$] ppm. ^{11}B NMR: δ = 63.8 ($h_{1/2}$ = 400 Hz) ppm. ^{31}P NMR: δ = 4.6 ($h_{1/2}$ = 90 Hz) ppm. MS: (*m*/*z*, rel. %) 421 (100), 365 (54), 316 (6), 239 (25), 224 (11), 182 (29), 126 (36), 70 (55), 57 (56). $C_{26}H_{54}B_2N_2P_2$ (478.27): calcd. C 65.29, H 11.38, N 5.86; found C 64.28, H 11.44, N 5.81

***tert*-Butylphosphinidene-2,2,6,6-tetramethylpiperidino-borane Aluminium Tribromide (3):** A solution of $AlBr_3$ (1.28 g, 4.80 mmol) in toluene (30 mL) was rapidly added to a stirred solution of compound **1** (1.12 g, 2.34 mmol, dissolved in toluene, 30 mL) at –30 °C. The mixture turned deep yellow. About 2/3 of the solvent was then removed in vacuo. From the solution, which was kept at –30 °C, golden yellow prisms separated (most of them as single crystals) within a few hours. Yield: 1.23 g, (47%), m.p. 112 °C. Additional material was retained in the filtrate including an excess of $AlBr_3$ (NMR). The compound decomposed on standing at room temperature to give an orange oil. Treatment of the oil with toluene resulted in a deep yellow solution. At –20 °C yellow crystals of **3** separated. ^1H NMR (C_6D_6): δ = 0.48, 1.40, 1.46, 1.53, 1.55 ppm. ^{13}C NMR: δ = 16.3 [s, γ-CH_2], 31.3 [s, ß-CH_2], 34.8 [d, $^2J(^{31}P^{13}C)$ = 7 Hz $C(CH_3)_3$], 37.4 [s, $N(CH_3)_2$], 57.2 [s, $C(CH_3)_2$]), 58.2 [d, $^1J(^{31}P^{13}C)$ = 8 Hz $C[CH_3)_3]$ ppm. ^{11}B NMR: δ = 68.4 ($h_{1/2}$ = 530 Hz) ppm. ^{31}P NMR: δ = –59.8 ($h_{1/2}$ = 900 Hz) ppm. MS: (*m*/*z*, rel. %) 426 (22), 411 (35), 298 (100). $C_{13}H_{27}AlBBr_3NP$ (505.85): calcd. C 30.87, H 5.38, N 2.77; found C 29.92, H 4.87, N 2.79

1-*tert*-Butyl-2,4-bis(2,2,6,6-tetramethylpiperidino)-1-phosphonia-3-phospha-2,4-dibora-bicyclo[1.1.0]butane Tetrabromoaluminate (2): A solution of $AlBr_3$ (1.0 g, 3.8 mmol) in toluene (20 mL) was slowly (1 h) added to a stirred solution of 1 (0.90 g, 1.9 mmol) in toluene (15 mL) at ambient temperature. During addition the color of the solution became light yellow. The solution was reduced in volume to about 20 mL and then stored at –20 °C. Within two weeks golden yellow crystals of **2** separated. Yield (0.2 g, 16%). Most of the crystals had single crystal quality. At room temperature the crystals turned into an oily material within a few hours. The crystals were insoluble in hexane, only slightly soluble in benzene, and dissolved in $CDCl_3$ and CD_2Cl_2 with decomposition within several minutes. ^1H NMR (CD_2Cl_2): δ = 1.41 [9 H, $^3J(^{31}P^1H)$ = 11 Hz, $C(CH_3)_3$)], 1.47, 1.56 [24 H, $N(CH_3)_2$)], 1.60, 1.61 (appr. 12 H) ppm. ^{11}B NMR: δ = 37.8 ($h_{1/2}$ = 280 Hz) ppm. ^{27}Al NMR: δ = 80.3 ($h_{1/2}$ = 50 Hz) ppm. $C_{22}H_{45}AlB_2Br_4N_2P_2$ (767.78): calcd. C 34.42, H 5.19, N 3.65; Br 41.63, found C 29.25, H 5.45, N 1.27, Br 40.9 (C and N values were always too low due to possible formation of AlN).

X-ray Structure Analysis: Single crystals were selected under perfluoro ether oil and mounted on the a glass fiber. Graphite-monochromatized Mo-*Kα* radiation was used in all cases. Compound **1** was measured on a Siemens P4 diffractometer with a scintillation counter and an LT2 low-temperature device at –80 °C in the ω/2θ mode. For compounds **2** and **3** a CCD detector was applied, and data collection was performed in the hemisphere mode.[26] For data reduction the program SAINT was used.[27] The structures were solved by direct methods implemented in SHELXTL Plus.[27] This program was also used in the refinement and SADABS for absorption correction. Non-hydrogen atoms were refined in anisotropic description, and although most H atom positions were found in the difference Fourier they were placed in calculated positions and

incorporated into the refinement as riding on their respective C atoms. Table 5 contains the relevant information related to the crystallography, data acquisition and structure solution. CCDC-237980 to -237982 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Computational Details: Geometries of the model compounds and **2** were optimized with internal redundant coordinates (total energy converged to $\le 1\times10^{-7}$ a. u., max norm of BP86/MP2/CC2 energy gradient converged to $\le1\times10^{-4}$ a. u.) with TURBOMOLE5.[29–32] using density functional (Becke–Perdew86 exchange correlation functional[33,34] for **2** and second order Møller-Plesset theory (frozen core) as well as a second-order approximated coupled cluster model for the model compounds **5**, **6**, **7** and **10** with the resolution of the identity (RI) approximation employing TZVP sets for all atoms.[35,36] For all structures, frequency calculations with SNF (MPI-parallel for **2**[37] or TURBOMOLE[38] (for the model compounds) were carried out. The geometries were re-optimized until the imaginary no imaginary frequencies remained (NIMAG = 0). NMR shift calculations were performed with the MPSHIFT module of TURBOMOLE.[39,40] ELF and AIM analyses were performed with the ToPMoD package,[41] NBO(NPA analysis with Gaussian 03 at the equilibrium geometries).[42]

Acknowledgments

We thank the University of Munich and Fonds der Chemischen Industrie as well as Chemetall GmbH for financial support. We also thank Dr. T. Seifert, and Prof. I. Krossing for recording X-ray data sets and for their help in determining the X-ray structures, Mr. P. Mayer for NMR spectra, and Mrs. D. Ewald for the MS spectra.

A Surprisingly Stable 1-(Chlorosilyl)-2-phosphaethenyllithium Compound, $RCl_2SiC(Li)=PMes^*$

Gabriela Cretiu Nemes,[a,b] Henri Ranaivonjatovo,[b] Jean Escudié,*[b] Ioan Silaghi-Dumitrescu,[a] Luminita Silaghi-Dumitrescu,[a] and Heinz Gornitzka[b]

Keywords: Phosphaalkenes / (Chlorosilyl)phosphaethenyllithium / Chlorophosphasilaallene / Molecular modelling / Cation-π interaction

$RCl_2Si–C(Li)=PMes^*$ (**1**) (R = 9-methylfluoren-9-yl, Mes* = 2,4,6-tri-*tert*-butylphenyl), considered as a key intermediate in the synthesis of the heteroallene $RClSi=C=PMes^*$, was obtained from $RCl_2Si–C(Cl)=PMes^*$ by lithium/chlorine exchange with *n*BuLi and evidence for its identity was obtained by hydrolysis. Remarkably, however, it failed to undergo a lithium salt elimination to form the corresponding chlorophosphasilaallene, $RClSi=C=PMes^*$, even under prolonged heating in toluene. As shown by theoretical studies (RHF/3-21G* and RHF/6-31G**//RHF/3-21G* level), interactions between the lithium ion and the π-systems of the substituents at the phosphorus and silicon atoms could partly account for this stability. The lithium compound **1** reacts with methanol or chlorotrimethylsilane leading to new silylphosphaalkenes. The reaction of the lithium derivative **1** with benzaldehyde gave a four-membered heterocycle with an exocyclic P=C bond which virtually corresponds to the product of a [2+2] cycloaddition between the Si=C and C=O double bonds.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Silenes, the silicon counterparts of olefins, have challenged chemists for many years. Although the initial claim for producing an Si=C linkage dates back to 1912,[1] isolation of a stable silene was first achieved in 1981.[2] This major breakthrough, combined with the syntheses of the stable disilene $Mes_2Si=SiMes_2$ (Mes = 2,4,6-trimethylphenyl)[3] and diphosphene Mes*P=PMes* (Mes* = 2,4,6-tri-*tert*-butylphenyl)[4] paved the way for the remarkable and thriving chemistry of heavier multiple-bonded main group elements from which other bonding patterns such as heterocumulative double-bond systems have emerged.[5] A stable 1-silaallene >Si=C=C<, in which the carbon atom involved in the double bond to the silicon atom adopts sp-hybridisation, was reported a decade later.[6] We have been interested in 1,3-phosphasilaallenes, i.e. compounds with phosphorus and silicon atoms (thus, two heavier group 14 and 15 elements) at the terminal positions of the heteroallene skeleton and reported the hitherto unique >Si=C=P– derivative some years ago.[7] The latter readily undergoes dimerisation above –30 °C. Clearly, the steric shielding of the bulky groups in PhTipSi=C=PMes* (Tip = 2,4,6-triisopropylphenyl) is not sufficient to prevent the target molecule from coupling with itself and, consequently, the study of its chemical behaviour was limited. Due to the presence of three reaction sites (the Si=C and P=C double bonds as well as the phosphorus lone pair), such compounds should be extremely interesting from a synthetic point of view. Various cycloadducts could be obtained with unsaturated species, making these allenic derivatives powerful building blocks in heterocyclic and organometallic chemistry. In order to increase the synthetic utility of such compounds, we have tried to attach a chlorine atom to the silicon atom which could allow functionalisation of SiCP systems. Thus, it seemed interesting to prepare a phosphasilaallene, the main objective being to obtain a stable derivative to facilitate the study of its reactivity.

Herein we describe the synthesisof the stable chloro-lithio compound $RCl_2Si–C(Li)=PMes^*$ (R = 9-methylfluoren-9-yl) **1** from dichlorophosphasilapropene **2**, along with its characterisation showing that it exhibits a chemical behaviour which could be theoretically expected from the target phosphasilaallene $RClSi=C=PMes^*$ **3**.

Results and Discussion

Vicinal dihalophosphametallapropenes >M(X)–C(Cl)=P– (X = F, Cl; M = Si,[7] Ge[8]) are suitable precursors to the corresponding heteroallenes. Lithiation of the central carbon atom occurs smoothly at low temperature through a lithium/halogen exchange and the subsequent

lithium salt elimination gives rise to a metal–carbon double bond adjacent to the existing P=C bond which remains intact throughout the whole procedure. The final step in the synthesis of stable 1-silaallenes also involves lithium salt elimination from the closely related 3-fluoro-2-lithio-3-silapropenes >Si(F)–C(Li)=C<.[5e,6,9]

The above-described synthetic approach was applied for the target chlorophosphasilaallene. Substitution with the 9-methylfluorenyl group at the silicon atom was intended to provide extra steric protection for the desired double bond. The coupling of the carbenoid Cl(Li)C=PMes*[10] with trichloro(9-methylfluoren-9-yl)silane[11] afforded the anticipated trichlorophosphasilapropene **2** in good yield. A ^{31}P NMR analysis of the reaction mixture suggested that only one isomer of compound **2** was formed (δ_P = 328.1 ppm). Because of the severe steric hindrance of the Mes* group, the more accessible *trans*-chlorine atom in Cl_2C=PMes* can be expected to undergo an easier lithium/halogen exchange with *n*BuLi. This favours the formation of the (*E*)-carbenoid Cl(Li)C=PMes* which hence led to the (*Z*)-phosphasilapropene **2** when mixed with the starting trichlorosilane. The (*Z*) configuration of derivative **2** was confirmed by an X-ray diffraction study (Figure 1). The P=C distance [1.669(3) Å] matches the average value reported for such bonds (1.67 Å).[5c]

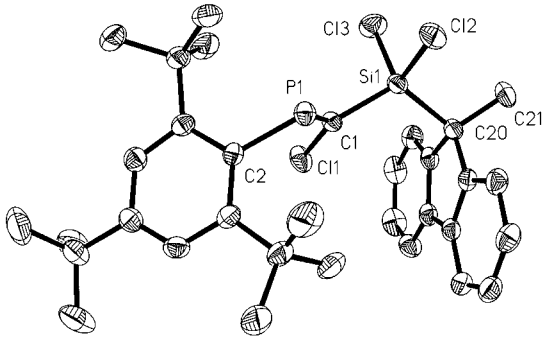

Figure 1. Molecular structure of **2** (thermal ellipsoids at the 50% probability level; H atoms are omitted for clarity); selected bond lengths [Å] and angles [°]: C(1)–P(1) 1.669(3), C(1)–Cl(1) 1.747(2), C(1)–Si(1) 1.850(3), P(1)–C(2) 1.833(3), Si(1)–C(20) 1.883(3), Si(1)–Cl(2) 2.0404(9), Si(1)–Cl(3) 2.0524(10); P(1)–C(1)–Cl(1) 125.92(15), P(1)–C(1)–Si(1) 119.65(14), C(1)–P(1)–C(2) 104.42(11), C(1)–Si(1)–C(20) 115.89(11), C(20)–Si(1)–Cl(2) 109.47(8), C(20)–Si(1)–Cl(3) 109.97(8)

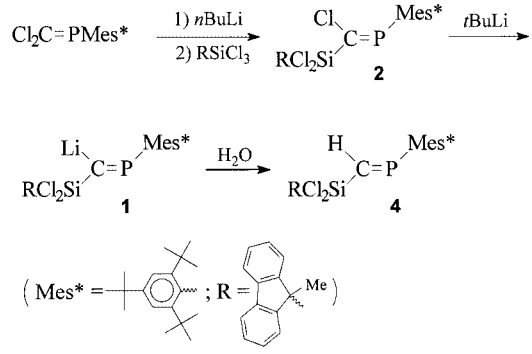
Treatment of **2** with *tert*-butyllithium resulted in the expected metallation and caused the ^{31}P NMR signal to shift downfield (δ_P = 441.4 ppm). Further evidence for the ensuing lithium derivative $RCl_2SiC(Li)$=PMes* **1** was obtained by formation of its hydrolysis product (Scheme 1).

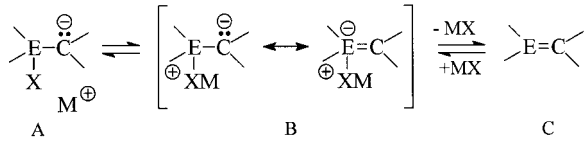
Compound **1** is stable under a rigorously maintained inert gas at room temperature and fails to eliminate lithium chloride to give **3** even under prolonged heating at reflux in toluene. However, attempts to isolate the highly air- and moisture-sensitive **1** by crystallisation at –30 °C led to the hydrolysis product **4** due to adventitious water. The (*E*) isomer was exclusively obtained, as expected from the configuration of starting **1** and was proved by the $^1J_{P=C}$ coupling



Scheme 1.

constant (67.9 Hz). A similar value (66.4 Hz) was reported by Bickelhaupt et al. for the (*E*) isomer of Mes*P=C(H)$SiMe_3$[10a] whereas the coupling constant for the (*Z*) isomer is smaller (54.4 Hz).

According to Wiberg, the 1,2-elimination of LiX to form an Si=C double bond involves dipolar intermediates B (Scheme 2).[12]



Scheme 2.

In our case, the non-elimination of LiCl means that the position of the equilibrium is shifted to form A, probably because of the presence of two chlorine atoms on the silicon atom. The natural charges on the carbon atom in the model carbanions $[Cl_{3-x}H_xSi–C=PH]^-$ at the RHF/6-31+G** level (Table 1) show that by increasing the number of chlorine atoms on the silicon atom, the negative charge on the carbon atom increases. This in turn favours the A form in Scheme 2.

Table 1.Natural charges on the carbon atom in the $[Cl_{3-x}H_xSi–C=PH]^-$ anions

Model	Natural charge on the carbon atom
$[H_3Si–C=PH]^-$	–1.224
$[ClH_2Si–C=PH]^-$	–1.315
$[Cl_2HSi–C=PH]^-$	–1.362
$[Cl_3Si–C=PH]^-$	–1.393

In order to obtain a deeper understanding of the observed reluctance of **1** to lose LiCl, molecular orbital calculations on various conformers of the model $Cp'Cl_2SiC(Li)$=PMes* system (Cp′ = 1-methylcyclopentadienyl) were carried out at the RHF/3-21G* level of theory, with full optimisation of the geometry. Note that this model retains the main steric and electronic features of **1** (through the Mes* group on P and the Cp′ group on Si). The influence of the solvent on the relative stability of these conformers has been inferred from single point calculations with the PCM solvation model of Tomasi by using two sol-

Table 2. Relative energies [kJ mol^{-1}] and natural charges on Li in **1a** and **1b**

Conformer	Gas phase		DMSO		Toluene	
	Relative energy	Natural charge	Relative energy	Natural charge	Relative energy	Natural charge
1a	30.00	0.897	47.00	0.900	40.42	0.898
1b	0.0	0.885	0.0	0.887	0.0	0.886

vents (DMSO and toluene). The two lowest energy conformers (**1a** and **1b**) are shown in Figure 2. Table 2 includes the relative energies of these conformers calculated in the gas phase and in the two solvents as well as the natural charges on Li.

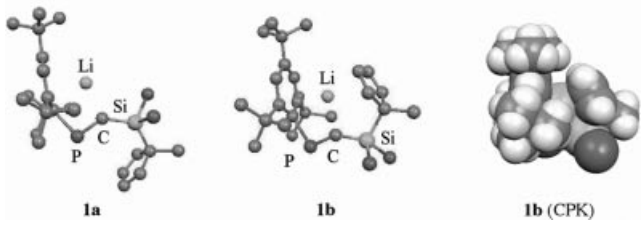

Figure 2. Lowest energy conformers of Cp′Cl_2SiC(Li)=PMes* (hydrogen atoms omitted); note the special position of Li in **1b** allowing for strong cation–π interactions

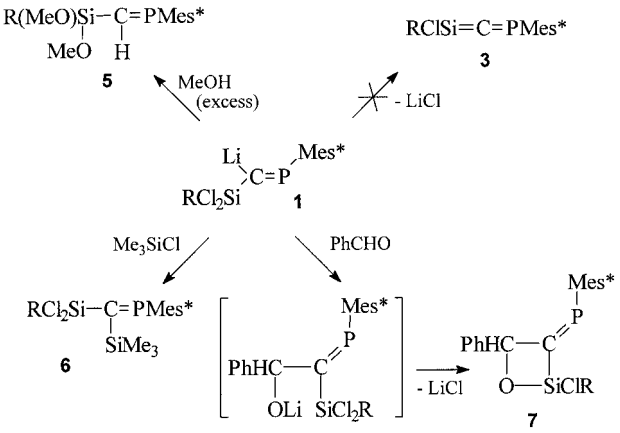
The lowest energy conformer **1b** exhibits strong electrostatic interactions between Li and both π systems (Mes* and Cp′) as shown by the following distances: Li–*ipso*-C(Mes*) 2.357 Å, Li–centroid(Mes*) 2.380 Å, Li–*ipso*-C(Cp′) 2.325 Å, Li–centroid(Cp′) 2.247 Å. These distances are in good agreement with those determined from X-ray analyses of similar interactions.[13]

The chlorine atoms in **1b** are located in unfavourable positions for intramolecular elimination of LiCl. Intermolecular condensation is also quite improbable due to the very efficient steric protection of the Li cation (see the CPK representation of **1b** in Figure 2). Note also that because of these cation···π interactions, the natural charge on Li does not change on going from gas phase to DMSO or toluene solution. Conformer **1a** is higher in energy both in the gas phase and in solution and, presumably, this arrangement is more difficult to achieve in the real system **1**. This order is also maintained at the RHF/6-31G**//RHF/3-21G* level where **1a** is still higher by 15.22 kJ mol^{-1}. Thus, cation···π interactions between Li and the Mes* and fluorenyl groups in **1** could account for its failure to eliminate lithium chloride. Such interactions have been recently highlighted by an X-ray diffraction analysis of a lithium (difluorosilyl)phosphide –Si(F_2)–P(Li)– which failed to undergo lithium fluoride elimination up to 100 °C.[14]

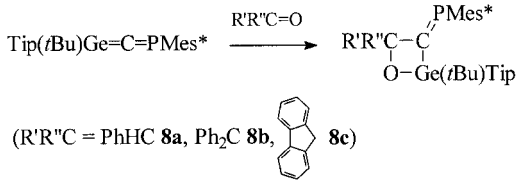
Lithium···π interactions in the case of $RCl_2SiC(Li)$=PMes* **1** also favour a shift in the position of the equilibrium to form A in accordance with the calculations and this could also explain the lack of elimination of LiCl. A similar reluctance to form an Si=C double bond by salt elimination has been previously reported.[15]

The lithio compound **1** reacts with excess methanol or chlorotrimethylsilane to give the silylphosphaalkenes **5** and **6**, respectively. The same derivatives should also be obtainable from the chlorophosphasilaallene **3** with these reactants (Scheme 3).



Scheme 3.

Interestingly, compound **1** readily reacts with benzaldehyde to afford oxasiletane **7** with an exocyclic P=C double bond in the form of one isomer as shown by ^{31}P NMR spectroscopy (δ_P = 339.4 ppm) (Scheme 3). From the $^2J_{P,CO}$ coupling constant (10.2 Hz) it seems that **7** exists as the (*E*) isomer (Mes* and Si *trans* to each other). This stereochemistry is in agreement with the postulated configuration of **1** and the mechanism of the reaction. Similar values were obtained by Appel and Bickelhaupt [16] for $^2J_{P,C}$ in Mes*P=C–C systems [(*E*) isomer 10–15 Hz, (*Z*) isomer 20–60 Hz]. In the closely related germanium compound **8c**, the structure of which was established by an X-ray determination, a $^2J_{P,CO}$ coupling constant of 38.7 Hz was observed for the (*Z*) isomer (Scheme 4). In the absence of an X-ray structural study, the stereochemistry of the four-membered ring (Ph and Cl in *cis* or *trans* positions) could not be determined.



Scheme 4.

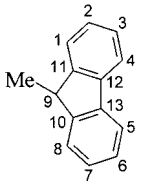
Though the latter reaction likely proceeds through an addition/elimination pathway, the four-membered ring **7** virtually conforms to the cycloaddition product of the Si=C double bond of the corresponding chlorophosphasilaallene with the starting aldehyde without participation of the contiguous P=C double bond as was found earlier for the Ge congener *t*BuTipGe=C=PMes*.[8]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Similarly, a silenoid, >Si(Cl)–C(Li)<, has already been observed to behave as a synthetic equivalent of the corresponding silene in its reaction with carbonyl compounds.[15e] The study of the chemical behaviour of **1** towards various unsaturated species is now under investigation.

Experimental Section

General Remarks: All manipulations were carried out under N_2 or Ar using standard Schlenk techniques with solvents freshly distilled from sodium/benzophenone. ^1H, ^{13}C and ^{31}P NMR spectra were recorded in $CDCl_3$ with a Bruker AC 200 instrument at 200.1, 50.1 and 81.01 MHz, respectively, except for compound **1** which was measured in [D_8]toluene with a Bruker AC 400 spectrometer at 100.6 MHz. Mass spectra were recorded with a Hewlett–Packard 5989 A spectrometer by EI at 70 eV. Melting points were determined using a Leitz microscope heating stage 250. Elemental analyses were performed by the "Service de Microanalyse de l'Ecole de Chimie de Toulouse". The carbon atoms of the fluorenyl group are numbered as shown in Scheme 5.



Scheme 5.

Synthesis of RCl_2Si–C(Cl)=PMes* (2): A sample of Cl_2C=PMes* (1.14 g, 3.18 mmol) was dissolved in THF (15 mL) and cooled to –80 °C. Under nitrogen, *t*BuLi (2 mL of a 1.7 M hexane solution, 1 equiv.) was added to form ClLiC=PMes*. This solution was slowly added to a solution of trichloro(9-methylfluoren-9-yl)silane (1.00 g, 3.18 mmol) in THF (10 mL) at –80 °C. The mixture was slowly warmed to room temperature with magnetic stirring over 2 h. After filtration, the solution was concentrated in vacuo and pentane (10 mL) was added. Cooling to –20 °C led to **2** as a crystalline product. Yield 1.49 g (78%). M.p. 131 °C. ^1H NMR ($CDCl_3$): δ = 1.12 (s, 18 H, *o*-CMe_3), 1.23 (s, 9 H, *p*-CMe_3), 1.88 (s, 3 H, Me), 7.28–7.85 (m, 10 H, arom. H of R and *m*-CH of Mes*) ppm. ^{13}C NMR ($CDCl_3$): δ = 21.4 (br., Me), 30.3 (br., C*Me*$_3$), 35.0 (*p*-*C*Me_3), 37.8 (*o*-*C*Me_3), 46.2 (C-9), 120.3 and 122.0 (C-4, -5 and *m*-CH of Mes*), 125.2 and 127.2 (C-1–3, C-6–8), 134.0 (d, $J_{P,C}$ = 63.0 Hz, *i*-C of Mes*), 141.1 and 146.1 (C-10–13), 151.0 and 153.1 (*o*- and *p*-C of Mes*), 155.7 (d, $J_{P,C}$ = 83.5 Hz, P=CCl) ppm. ^{31}P NMR ($CDCl_3$): δ = 328.1 ppm. MS (EI): *m*/*z* (%) = 602 (5) $[M]^+$, 587 (10) $[M – Me]^+$, 565 (5) $[M – Cl]^+$, 423 (30) $[M – R]^+$, 179 (95) $[R]^+$, 57 (100) $[t\text{Bu}]^+$. $C_{33}H_{40}Cl_3PSi$ (602.09): calcd. C 65.83, H 6.70; found C 66.10, H 6.91.

Synthesis of RCl_2Si–C(Li)=PMes* (1): A solution of RCl_2Si–C(Cl)=PMes* (1.30 g, 2.16 mmol) in diethyl ether (20 mL) was cooled to –80 °C under nitrogen. To the stirred solution was slowly added *t*BuLi (1.27 mL of a 1.7 M hexane solution, 1 equiv.) and the solution was then warmed to room temperature with magnetic stirring over 2 h. ^{13}C and ^{31}P NMR spectroscopic analyses of the brown solution showed nearly quantitative formation of **1**. ^{13}C NMR (400 MHz, [D_8]toluene): δ = 18.6 (Me), 31.2 and 33.9 (C*Me*$_3$), 33.3 (*C*Me_3), 38.4 (C-9), 120.0 (C-4, -5), 124.7, 126.7 and 127.1 (C-1–3, C-6–8), 141.0 and 145.7 (C-10–13), 144.4 (d, $J_{P,C}$ = 74.6 Hz, P=C or *i*-C of Mes*), 149.1 and 151.6 (*o*- and *p*-C of Mes*) ppm. ^{31}P NMR (Et_2O, [D_8]toluene): δ = 441.4 ppm.

Formation of RCl_2Si–C(H)=PMes* (4): A white waxy solid of **4** (95% purity) was obtained due to hydrolysis when a solution of the lithium compound **1** in Et_2O, prepared as described previously from **2** (1.00 g, 1.66 mmol), was kept at –30 °C for a week. Yield 0.85 g (90%). ^1H NMR ($CDCl_3$): δ = 1.25 (s, 18 H, *o*-CMe_3), 1.32 (s, 9 H, *p*-CMe_3), 1.85 (s, 3 H, Me), 6.75 (d, $^2J_{P,H}$ = 22.5 Hz, 1 H, CH), 7.28–7.91 (m, 10 H, arom. H of R and *m*-CH of Mes*) ppm. ^{13}C NMR ($CDCl_3$): δ = 19.1 (br. s, Me), 31.6 and 34.3 (br., C*Me*$_3$), 35.0 and 35.2 (*o*- and *p*-*C*Me_3), 38.1 (C-9), 120.2 and 122.0 (C-4, -5 and *m*-CH of Mes*), 124.9 and 127.2 (C-1–3, C-6–8), 141.0, 146.0, 150.2 and 152.6 (*o*- and *p*-C of Mes*, C-10–13), 156.6 (d, $^1J_{P,C}$ = 67.9 Hz,P=C) ppm. ^{31}P NMR ($CDCl_3$): δ = 375.3 ($^2J_{P,H}$ = 22.5 Hz) ppm.

Synthesis of $R(OMe)_2Si$–C(H)=PMes* (5): RCl_2Si–C(Li)=PMes* (1.66 mmol) prepared as previously described was treated with excess methanol (1 mL). The reaction mixture was filtered and the solution concentrated in vacuo followed by addition of pentane. Cooling to –20 °C gave **5** as a white solid (90% purity). Yield 0.87 g (88%). ^1H NMR ($CDCl_3$): δ = 1.28 (s, 18 H, *o*-CMe_3), 1.34 (s, 9 H, *p*-CMe_3), 1.66 (s, 3 H, Me), 3.27 (s, 6 H, OMe), 6.98 (d, $^2J_{P,H}$ = 22.0 Hz, 1 H, CH), 7.20–7.80 (m, 10 H, arom. H of R and *m*-CH of Mes*) ppm. ^{13}C NMR ($CDCl_3$): δ = 19.1 (Me), 31.5 and 33.8 (br., C*Me*$_3$), 35.1, 38.1 and 38.9 (*o*- and *p*-*C*Me_3, C-9), 45.5 (br., OMe), 119.9 (br., C-4, -5 and *m*-CH of Mes*), 124.8 and 126.5 (C-1–3, C-6–8), 140.4, 145.8, 152.2 and 153.1 (*o*- and *p*-C of Mes*, C-10–13) ppm. ^{31}P NMR ($CDCl_3$): δ = 362.2 (d, $^2J_{P,H}$ = 22.0 Hz) ppm. MS (EI): *m*/*z* (%) = 558 (5) $[M]^+$, 527 (1) $[M – OMe]^+$, 379 (40) $[M – R]^+$, 323 (33) $[M – R – t\text{Bu} + 1]^+$, 179 (100) $[R]^+$.

Synthesis of RCl_2Si–C($SiMe_3$)=PMes* (6): RCl_2Si–C(Li)=PMes* (1.66 mmol) in Et_2O (10 mL) was treated with excess chlorotrimethylsilane (0.5 mL) at room temperature. The lithium salt was removed by filtration and the solution concentrated in vacuo followed by addition of pentane. Cooling to –20 °C afforded **6** as a white solid. Yield 0.90 g(85%). M.p. 116 °C. ^1H NMR ($CDCl_3$): δ = –0.33(s, 9 H, $SiMe_3$), 1.12 (s, 18 H, *o*-CMe_3), 1.28 (s, 9 H, *p*-CMe_3), 1.92 (s, 3 H, Me), 7.23–7.91 (m, 10 H, arom. H of R and *m*-CH of Mes*) ppm. ^{13}C NMR ($CDCl_3$): δ = 0.4 ($SiMe_3$), 19.6 (Me), 29.9 and 31.6 (br., C*Me*$_3$), 37.1 and 37.6 (*o*- and *p*-*C*Me_3), 45.3 (C-9), 118.3 and 119.6 (C-4, -5 and *m*-CH of Mes*), 125.1 and 127.2 (C-1–3, C-6–8), 141.0, 146.0, 150.1 and 153.2 (*o*- and *p*-C of Mes*, C-10–13), 177.2 (d, $^1J_{P,C}$ = 90.5 Hz, P=CSi) ppm. ^{31}P NMR ($CDCl_3$): δ = 433.7 ppm. MS (EI): *m*/*z* (%) = 638 (15) $[M]^+$, 623 (15) $[M – Me]^+$, 566 (20) $[M – SiMe_3 + 1]^+$, 459 (20) $[M – R]^+$, 403 (15) $[M – R – t\text{Bu} + 1]^+$, 275 (22) $[ArP – 1]^+$, 179 (65) $[R]^+$, 57 (100) $[t\text{Bu}]^+$. $C_{36}H_{49}Cl_2PSi_2$ (638.83): calcd. C 67.58, H 7.72; found C 67.81, H 7.88.

Synthesis of Oxasiletane 7: A solution of RCl_2Si–C(Li)=PMes*, prepared from **2** (1.00 g, 1.66 mmol) in diethylether (20 mL), was cooled to –60 °C under nitrogen. To the stirred solution was slowly added benzaldehyde (0.19 g, 1.75 mmol). The solution was warmed to room temperature with magnetic stirring over 2 h. The reaction mixture was then filtered to remove LiCl and the solution concentrated in vacuo. Addition of pentane and cooling to –20 °C gave a waxy yellow solid which could not be obtained completely pure (90% purity) but was unambiguously identified as **7** by NMR spectroscopy and mass spectrometry. Yield 0.85 g (77%). ^1H NMR ($CDCl_3$): δ = 1.35 (br., 27 H, CMe_3), 1.80 (s, 3 H, Me), 5.80 (d, $^3J_{P,H}$ = 13.6 Hz, 1 H, OCH), 6.75–8.10 (m, 15 H, Ph, arom. H of R and *m*-CH of Mes*) ppm. ^{13}C NMR ($CDCl_3$): δ = 13.8 (Me), 31.4 and 33.6 (br., C*Me*$_3$), 37.1 and 38.3 (*o*- and *p*-*C*Me_3) 47.7 (C-

9), 113.1 (d, $^2J_{P,CO}$ = 10.2 Hz, OCH), 120.2–130.0 (C-1–8 and *m*-CH of Mes*), 140.8–154.0 (*o*- and *p*-C Mes*, C-10–13) ppm. ^{31}P NMR ($CDCl_3$): δ = 339.4 (d, $^3J_{P,H}$ = 13.6 Hz) ppm. MS (EI): *m*/*z* (%) = 636 (2) $[M]^+$, 545 (3) $[M - PhCH - 1]^+$, 456 (5) $[M - R - 1]^+$, 394 (3) $[M - ClSiR]^+$, 379 (3) $[ArP{=}CCHPh]^+$, 350 (8) $[ArP{=}C{-}SiCl + 1]^+$, 179 (35) $[R]^+$, 105 (30) $[PhCO]^+$, 57 (100) $[t\text{Bu}]^+$.

Computational Details: A complete search of the conformational space of **1** was carried out using Spartan02[17] and the conformers thus obtained were further subjected to complete geometry optimisation at the RHF/3-21G* level with the same package. Single point calculations, taking into account the effect of solvents with the PCM model of Tomasi,[18] were performed using the G98 system Gaussian98, revision A.11.3.[19] The NBO analysis[20] was carried out within the NBO module implemented in G98.

Crystal Data for 2: $C_{33}H_{40}Cl_3PSi$, M = 602.06, monoclinic, $C2/c$, a = 16.661(2) Å, b = 10.730(1) Å, c = 36.380(3) Å, β = 90.284(2)°, V = 6504.0(11) Å^3, Z = 8, T = 193(2) K. 18162 reflections (6577 independent, R_{int} = 0.0340) were collected at low temperature using an oil-coated shock-cooled crystal with a Bruker-AXS CCD 1000 diffractometer with Mo-K_α radiation (λ = 0.71073 Å). The structure was solved by direct methods (SHELXS-97)[21] and all non-hydrogen atoms were refined anisotropically using the least-squares method on F^2.[22] Largest electron density residue: 0.403 e·Å^{-3}, $R_1[I > 2\sigma(I)]$ = 0.0511 and wR_2 (all data) = 0.1187 with $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $wR_2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{0.5}$. CCDC-233371 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: +44-1223-336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis, Characterization and Coordination Chemistry of Some Selenium-Containing Macrocyclic Schiff Bases

Arunashree Panda,[a] Saija C. Menon,[a] Harkesh B. Singh,*[a] Christopher P. Morley,[b] Robert Bachman,[c] T. Matthew Cocker,[c] and Ray J. Butcher[d]

Keywords: Macrocycles / Selena-aza macrocycles / Palladium / Nickel / Cobalt

The condensation of bis(*o*-formylphenyl) selenide with 1,2-diaminoethane or 1,3-diaminopropane yielded the new macrocyclic ligands **1** and **2** in very good yields. Crystals of **1** are monoclinic, space group $P2_1/c$ with a = 10.0648(10) Å, b = 37.390(4) Å, c = 8.0073(11) Å, Z = 4 and those of **2** are triclinic, space group $P\bar{1}$ with a = 7.200(3), b = 9.137(3), c = 12.780(6) Å, Z = 1. The coordination chemistry of **1** and **2** has been studied with the "soft" metal ion Pd^{II} and "hard" metal ions Ni^{II} and Co^{II}. Reaction of $[PdCl_2(COD)]$ with 1 mol-equiv. of **1** or **2** in refluxing methanol and addition of NH_4PF_6 afforded the Pd^{II} complexes **5** and **6**, respectively. Compound **5** is an unexpected partially hydrolyzed complex. It crystallizes in the tetragonal space group $P4_12_12$ with a = 10.7737(10) Å, b = 10.7737(10) Å, c = 28.190(5) Å, Z = 4. The structure shows the Pd^{II} ion coordinated to a square-planar arrangement of two selenium and two nitrogen atoms. Reaction of $NiCl_2{\cdot}6H_2O$ with **1** or **2** and NH_4PF_6 yielded complexes **7** and **8**, respectively. The assignment of octahedral geometries to $[Ni(L)](PF_6)_2]$ (**7**: L = **1**; **8**: L = **2**) follows from their paramagnetism [μ_{eff} = 3.23 (**7**), 1.81 (**8**) B.M.] and their UV/Vis spectra. This was also confirmed by single-crystal X-ray studies. The crystal structures of **7** and **8** showed a distorted octahedral nickel center coordinated by two selenium and four nitrogen atoms. **7**: Monoclinic, space group $P2_1/c$; a = 9.979(2) Å, b = 18.901(4) Å, c = 19.333(4) Å; Z = 4. **8**:Orthorhombic, space group $Pna2_1$; a = 20.277(5), b = 20.865(5), c = 9.416(2) Å; Z = 4. The cyclic voltammograms of **7** and **8** in MeCN solution show well-behaved quasi-reversible Ni^{III}/Ni^{II} couples. The analogous Co^{II} complex, $[Co(\mathbf{1})](PF_6)_2]$ (**9**) also shows a quasi-reversible Co^{III}/Co^{II} couple.

Introduction

Currently, a great deal of attention is being focused on macrocyclic ligands because they play an important role in many aspects of chemistry, medicine and the chemical industry.[1] The contrast-enhancing properties of their lanthanide complexes in NMR imaging,[2] their suitability as antibiotics in radioimmunotherapy,[2] their high selectivity in the binding of metal ions,[1,2] and nucleotide bases,[3] and their unique structural features as spacers for crystal engineering[4] are some of the notable applications. In seeking optimum efficiency in their existing and potential applications, numerous macrocyclic ligands with a wide spectrum of electronic and structural features have been designed and synthesized. To date, the majority of these synthetic cyclic ligands contain oxygen,[5] nitrogen,[6] phosphorus[7] and sulfur[8] donor atoms.

The chemical and structural features of macrocyclic metal complexes can be tuned by incorporating different "soft" and "hard" donor atoms in the chelating ring, thereby promoting the stabilization of both low and high oxidation states of the metal center, as well as forcing metal ions to adopt an atypical coordination geometry. In this context, thia[8] and mixed aza-thia[9] crown ethers have been the subject of intense interest in the last few years, particularly as their complexes are useful model compounds for biological systems.[10]

Pinto and co-workers pioneered work on the synthesis of the cyclic selenium ligands. They have reported a series of selena crowns, including [14]aneSe$_4$, [16]aneSe$_4$, and [24]aneSe$_4$.[11] The Pd^{II} complex $[Pd([16]aneSe_4)]^{2+}$ has been shown to possess the *c*,*c*,*c* configuration by Pinto et al.[12] They have also reported the complexes of Cu^{I} and Cu^{II} with [16]-aneSe$_4$ and some new selenium-containing coronands.[13] Reid et al. have reported complexes with a variety of platinum metal centers, viz. $[M([16]aneSe_4)]^{2+}$ (M = Pd or Pt),[14] $[PtX_2([16]aneSe_4)]^{+}$ (X = Cl, Br),[15] $[MX_2([16]-aneSe_4)]^{+}$ (M = Rh or Ir),[16,17] $[RuX_2([16]aneSe_4)]^{n+}$ (n = 0 or 1), and $[MX(PPh_3)([16]aneSe_4)]^{+}$ (M = Ru or Os).[18] There are limited examples on Ni^{II}[19] and Co^{II}[17] complexes of these selenoethers. Reid et al. have also reported a range of complexes of Cr,[20] Mo, W, Mn, Re Cu, Ag and

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim **DOI: 10.1002/ejic.200400757**

Au involving [8]aneSe_2(1,5-diselenacyclooctane), 1,6-diselena-3,4-benzocyclononane, and [16]aneSe_4,[21,22] The main group metal complexation of these selenoethers are only reported for As^{III}, Sb^{III} and Bi^{III}.[23] Recently, Levason et al. have developed some mixed donor selenoether and telluroether macrocyclic ligands and studied their complexation property towards various metal ions.[24]

Cyclic polyselenoethers have also been prepared and their extraction abilities towards transition metal and heavy metal cations determined.[25] The first host molecule containing an Se–Se bond has been synthesized by Tomoda et al.[26] Muralidharan et al. have described a selenium-containing cyclophane and also studied its complexation.[27] Another novel tetraselenide macrocycle has been synthesized by Furukawa and co-workers.[28] Polyselenoether macrocycles have also been synthesized from 3,3-dimethylselenatane which is cyclooligomerized catalytically at 115 °C in the presence of $[Re_2(CO)_9(SeCH_2CMe_2CH_2)]$.[29] Jackson and co-workers have designed and synthesized a novel macrobicyclic cage incorporating N/Se (N_3Se_3) atoms and its Co^{III} complex.[30] Meunier et al. have reported the synthesis of a diselena crown ether[31] and tetraselena crown ethers of three different sizes incorporating several oxygen atoms in the bridge.[32] The complexation of these selenoethers has been achieved by their reaction with mercury(II) iodide. Very recently, they have reported the preparation of new cationic palladium complexes binding to two selena macrocyclic ligands.[33] Zeng et al. has synthesized a calix[4]diselena crown ether which has been tested as sensor for ion selective electrodes.[34] Meng et al. have synthesized a phospha-selena macrocycle and studied their complexation with $Pd^{II}Cl_2$.[35]

In continuation of our work on tellurium-[36] and selenium-containing aza macrocycles[37] we report here the facile synthesis, structure and reactivity of the new 22- and 24-membered Schiff-base macrocycles **1** and **2** along with their coordination chemistry. We also compare their structural behavior and relative donor abilities with their tellurium analogs.

Results and Discussion

Macrocyclic Schiff-Base Ligands

The 22- and 24-membered macrocyclic Schiff bases **1** and **2** with N and Se donor sets were isolated in 91 and 89% yield as colorless solids by use of the [2+2] condensation reaction of bis(*o*-formylphenyl) selenide[37] with 1,2-diaminoethane or 1,3-diaminopropane, respectively, in CH_3CN at room temperature without recourse to a metal ion template (Scheme 1). Secondary intramolecular Se···N interaction (vide infra) plays an important role in the formation of the macrocycles by reducing the unfavorable lone pair−lone pair repulsion between nitrogen atoms. These compounds are soluble in $CHCl_3$ and CH_2Cl_2 but show poor solubility in other common organic solvents and in polar solvents like CH_3OH and DMSO. They could be recrystallized from a $CHCl_3/CH_3CN$ (1:1) mixture.

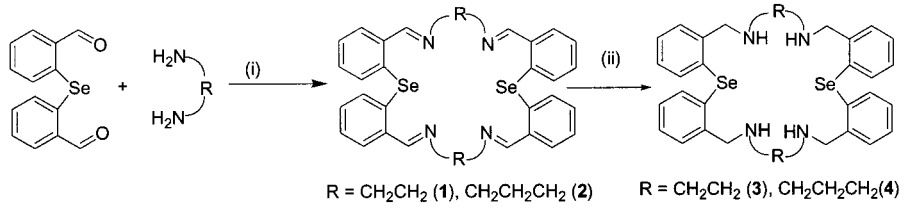
The IR spectra of the crystals of **1** and **2** showed that cyclization had occurred; an imine C=N stretch was present at 1636 and 1632 cm^{-1}, respectively, and no absorptions corresponding to unreacted carbonyl or primary amine were observed. Both the ^1H and ^{13}C NMR spectra of compounds **1** and **2** show resonances corresponding to one quarter of the molecule, suggesting very symmetric structures for the macrocyles. The CH=N proton signals were observed at δ = 8.52 and 8.46 ppm, respectively, being shifted ca.1.8 ppm upfield of the signal of the formyl proton in the starting bis(*o*-formylphenyl) selenide[37] (δ = 10.28 ppm).

The observation of a single signal in the ^{77}Se NMR spectra of the macrocycles confirms the equivalence of the two selenium atoms in **1** and **2**. On comparing the values for **1** and **2** (δ = 407, 413 ppm) with those for the corresponding saturated compounds **3** and **4** (δ = 329, 326 ppm), prepared as shown in Scheme 1, a considerable decrease in ^{77}Se chemical shift is noticed. This indicates poorer shielding of the selenium nucleus in the former cases, due to the delocalization of the selenium lone pairs in the five-membered ring formed by the strong Se···N interactions. In **3** and **4**, the Se···N interactions are not significant and hence delocalization of the electron pair is not possible.

The fast electron bombardment (FAB) mass spectra of **1** and **2** were recorded in order to confirm the formation of the [2+2] cyclocondensation products. The selenium-containing fragments could easily be recognized because of their characteristic isotope distribution pattern. In addition to the molecular ion peaks at m/z = 627 and 657 as the base peaks, the FAB mass spectra clearly show peaks due to the successive loss of groups from the macrocyclic framework.

Crystal Structures of 1 and 2

The crystal structure of **1** consists of discrete molecules and the unit cell contains four of them. The bond lengths and bond angles for a representative molecule are given in



Scheme 1. (i) $NH_2CH_2CH_2NH_2$ or $NH_2CH_2CH_2CH_2NH_2$; (ii) $NaBH_4$, EtOH, reflux.

C(2D)–C(1D)–Se(2)	123.1(5)	C(6D)–C(1D)–Se(2)	117.9(5)
N(1D)–C(7D)–C(6D)	122.5(7)	N(1D)–C(8D)–C(8B)	111.5(6)

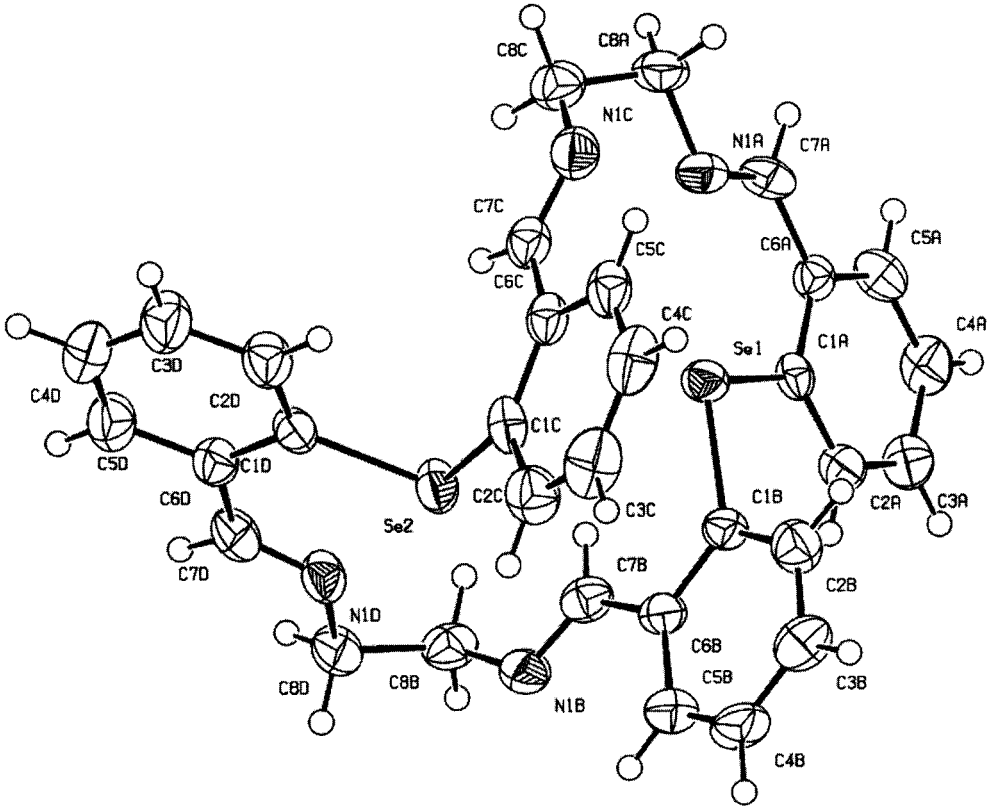

Figure 1. ORTEP diagram for **1**.

Table 1, and the ORTEP diagram is shown in Figure 1. The Se(1)···N(1A) and Se(2)···N(1C) intramolecular distances of 2.723 Å and 2.729 Å are shorter than the sum of the van der Waals radii of Se (2 Å) and sp^2-hybridized N (1.5 Å).[38] Although there are equal chances of coordination of N(1A), N(1B) to the Se(1) atom and N(1C), N(1D) to the Se(2) atom, the N(1B) and N(1D) atoms are not coordinated to Se(1) and Se(2), respectively. Thus, the solid-state geometry of the molecule indicates the presence of only one attractive interaction per selenium atom, i.e. it corresponds to the structure of 10-Se-3 selenurane. The bond configuration at the selenium atom is T-shaped. The C(1B)–Se–C(1A) angle is 100.2(3)°.

The transannular Se···Se distance (3.808 Å) is shorter than the sum of the van der Waals radii (4 Å). Interestingly, the transannular Te···Te bond length (4.979 Å)[36] in the case of the tellurium analog is greater than the sum of the van der Waals radii (4.4 Å). However, the transannular Se···Se distance in **1** is comparable to the Se1···Se2 distance of 3.9315(8) Å in 22-diselenasapphyrin.[39]

Compound **2** crystallized in the triclinic space group $P\bar{1}$. The unit cell contains one molecule. Selected bond lengths

N(1B)–C(8B)–C(9)#1	110.0(7)		

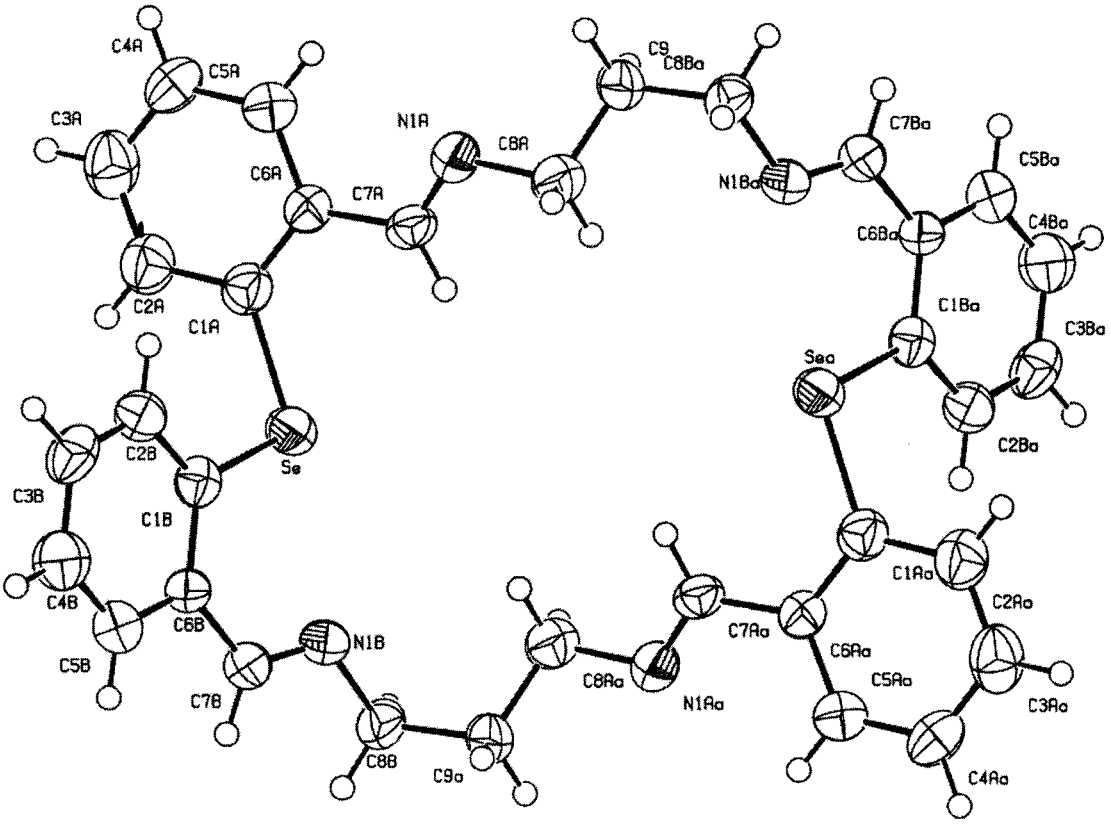

Figure 2. ORTEP diagram for **2**.

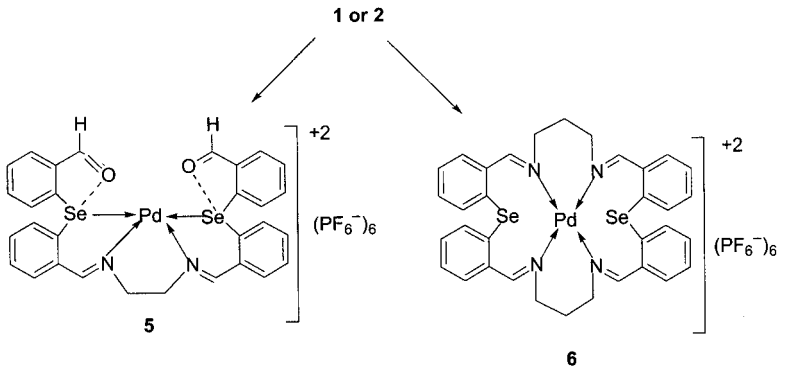
and angles are provided in Table 2. The ORTEP view is given in Figure 2. The solid-state geometry of the molecule indicates the presence of only one attractive Se···N interaction per selenium atom, i.e. it corresponds to the structure of 10-Se-3 selenurane. The intramolecular Se···N(1B) distance is 2.773 Å slightly longer than the equivalent distances in **1**. The geometry around the selenium atom is T-shaped, with the C(1B)–Se(1)–C(1A) angle being 97.7(4)°. The transannular Se···Se distance (7.229 Å) is much longer than the sum of van der Waals radii (4 Å) and also greater than the corresponding Se···Se distance (3.808 Å) observed in the 22-membered macrocycle **1**.

Reactions of 1 and 2 with Pd^{II}

The reaction of **1** or **2** with 1 equiv. of $[PdCl_2(COD)]$ (COD = 1,5-cyclooctadiene) in refluxing methanol afforded a yellow solution, which gave a yellow precipitate of complex **5** or **6**, respectively, in quantitative yield upon addition of PF_6^- counterions (Scheme 2). Slow concentration of an MeCN solution of **5** yielded yellow crystals of the complex. These complexes are air-stable in the solid state. They are insoluble in chlorinated solvents and hydrocarbons but soluble in MeCN, $MeNO_2$, acetone, DMF and DMSO.

The IR spectra of the complexes confirm the presence of PF_6^- anion {836 [ν(P–F)], 556 [δ(F–P–F)] cm^{-1}} and display the characteristic ν(C=N) stretching frequency around 1640 and 1637 cm^{-1}, respectively, shifted slightly compared with the ν(C=N) stretching frequencies of 1650 (**1**) and 1653 cm^{-1} (**2**) for the free ligands. The ^1H NMR spectrum of **5** shows a peak at δ = 10.1 ppm corresponding to two aldehydic protons and at δ = 8.89 ppm corresponding to two azomethine protons. The IR spectrum also shows a peak corresponding to ν(C=O) stretching at 1667 cm^{-1}, which implies that of the four CH=N bonds, two are hydrolyzed to −CHO groups. This hydrolysis may be due to excessive strain in the ring due to the planar geometry en-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 2. Reagents: (i) $Pd(COD)Cl_2$, MeOH, reflux; (ii) NH_4PF_6.

forced by the metal ion. However, a similar reaction of the Pd^{II} precursor with the 22-membered tellurium analog gives the cationic complex $[Pd(L)](PF_6)_2$ [L = macrocycle derived from bis(*o*-formylphenyl) telluride and 1,2-diaminoethane] without any hydrolysis.[36] This may be due to the larger hole size of the tellurium analog. The ^{77}Se NMR spectrum of **5** exhibits a single signal at δ = 411 ppm showing that the selenium atoms are equivalent. The FAB mass spectrum of the complex shows peaks with the correct isotope distribution pattern at *m*/*z* = 855, 709, 605 corresponding to [**5** − PF_6], [**5** − 2PF_6] and [**5** − Pd − 2 PF_6]. The formulation of the product **5** as $[Pd\{(C_6H_4(CHO)SeC_6H_4CHNCH_2)_2\}](PF_6)_2$ was confirmed by a crystal structure determination (vide infra).

The elemental analysis data for **6** were in accordance with the formation of a 1:1 product. The ^1H NMR spectrum of **6** shows a single peak at δ = 8.66 ppm for the azomethine protons and the ^{13}C NMR spectrum shows a peak at δ = 170 ppm for the azomethine carbon atoms, confirming the equivalence of the four azomethine groups. The quintuplet and the triplet for the CH_2–C*H*$_2$–CH_2 and the NH–C*H*$_2$–CH_2 protons are found in the deshielded region at δ = 3.64 and 4.83 ppm compared with δ = 2.00 and 3.61 ppm for the free ligand **2**, thus confirming the coordination of all the nitrogen atoms to the Pd^{II} ion. The large ring size of **2** (24-membered and Se···Se distance 7.229 Å) probably mitigates against coordination of the selenium atoms to Pd^{II}. A single signal was observed in the ^{77}Se NMR spectrum at δ = 441 ppm, which confirmed the identical environment around each selenium atom. The molecular ion peak was not observed in the FAB mass spectrum of **6**. However, the highest recorded peak was found at *m*/*z* = 905, corresponding to [$\mathbf{6}^+$ − PF_6]. Similar observations have been reported by Reid et al.,[14,17] The peak at *m*/*z* = 761 was assignable to [**6** – 2 PF_6]. The base peak at *m*/*z* = 434 corresponded to $[(CH_2)_2N{=}CH(C_6H_4)Se(C_6H_4)CH{=}NCH_2Pd]$. In addition, the spectrum clearly shows peaks due to the fragmentation of the macrocyclic framework. The crystal structure of **6**, which was isolated as yellow needles, could not be solved due to a crystallographic problem. The formulation of **6** as $[Pd(\mathbf{2})](PF_6)_2$ is, however, assured on the basis of the analytical data, IR, ^1H, ^{13}C, ^{77}Se NMR spectroscopy and mass spectrometry.

Crystal Structure of 5

Complex **5** crystallizes in a tetragonal crystal system with four molecules in the unit cell. Figure 3 shows the structure of a representative molecule and confirms the hydrolysis of two of the azomethine bonds in the starting material **1**. Selected bond lengths and angles are given in Table 3. The structure of **5** shows that the palladium ion is bound to two selenium and two nitrogen atoms. The average Pd–N distance, 2.019(6) Å, is in excellent agreement with the sum of the Pauling single bond covalent radii for palladium (1.31 Å) and nitrogen (0.7 Å).[38] The average Pd–Se bond length 2.3973(11) Å is close to that reported in a range of other palladium complexes of selenium-containing ligands.[40–42] It is also comparable to the Pd–Se distances [2.4191(5), 2.4183(5) Å] in $[PdL](PF_6)_2$ (L = diselena macrocycle),[33] although shorter than the Pd–Se bond lengths of 2.428(1) Å and 2.435(2) Å in $[Pd([16]aneSe_4)](PF_6)_2{\cdot}2\,MeCN$.[14] The Se–Pd–N and N–Pd–Se angles are 93.3(2)° and 169.7(2)°, respectively, which implies that the complex has a distorted square-planar geometry. The Se···O distance 2.855 Å shows that selenium atom is weakly coordinated to the oxygen atom. This bond length can be compared to the selenium···oxygen contacts 2.888(3) Å in α-selenazofurin.[44] The geometry around the Se atom is V-shaped. The C(1A)–Se–C(1B) angle of 96.7(4)° is 3.5° smaller than the C(1A)–Se–C(1B) angle (100.2(3)°] in **1**.

Reactions of 1 and 2 with Ni^{II}

The reaction of $NiCl_2{\cdot}6H_2O$ with 1 equiv. of **1** or **2** in refluxing methanol followed by the addition of an excess of PF_6^- afforded air-stable, brown and greenish yellow paramagnetic complexes **7** or **8**, respectively (Scheme 3). Complex **7** could be recrystallized by the slow diffusion of diethyl ether into an MeCN solution. Complex **8** was isolated as green needles from methanol. The compounds are soluble in MeCN, $MeNO_2$, acetone, DMSO and DMF. The elemental analysis data of the complexes **7** and **8** suggested the formation of a 1:1 product in each case. The infrared spectroscopic measurements showed the presence of the PF_6^- anion. The $\nu_{C=N}$ absorption for **7** and **8** was found at 1650 and 1628 cm^{-1}, respectively. The electronic spectra of

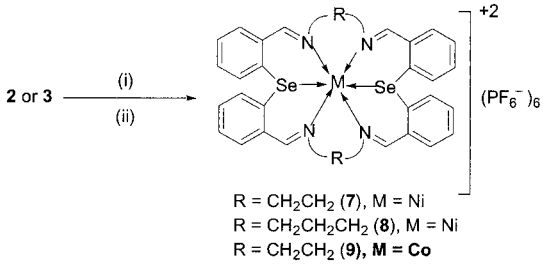
the complexes **7** and **8** were recorded at room temperature in CH_3CN in the range of 190–900 nm. The solution-phase electronic spectra (> 200 nm) of the ligands **1** and **2** consist of two intense bands centered at 290 and 335 nm which can be assigned to π–π* transitions. The intense peak found at 295 nm in each case may be attributed to a charge-transfer transition. Three spin-allowed transitions are expected for d^8 Ni^{II} complexes in an octahedral field. For the complex **7** there are three intense bands at 310, 452, and 804, which may be assigned to the interligand π–π* and d–d transitions. The solid-state UV/Vis spectrum also shows similar peaks at 800, 458, and 312 nm confirming the stability of the complex in the solution state. Complex **8** shows peaks at 872 (7.3), 560 (8.2) and 446 (24.3) nm in acetonitrile solution. These may be assigned to a combination of intraligand π–π* and d–d transitions. The solid-state UV/Vis spectra shows peaks at 866, 552 and 452 nm confirming the stability of complex in solution.



Scheme 3. Reagents: (i) $NiCl_2 \cdot 6H_2O$ or $CoCl_2 \cdot 6H_2O$; (ii) MeOH, reflux, NH_4PF_6.

In the FAB mass spectrum the highest recorded peak for complex **7** was found at *m*/*z* = 997. This was assigned to [**7** + H_2O]. The peak at *m*/*z* = 831 corresponds to [**7** − PF_6]. The base peak was found at *m*/*z* = 686 and can be assigned to [**7** – 2 PF_6]. For complex **8** a peak at *m*/*z* = 733 was found as the base peak, which can be assigned to [**8** − 2

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

PF_6 + H_2O]. A peak at m/z = 712 corresponds to [**8** – 2 PF_6]. The cyclic voltammograms of **7** and **8** revealed well-behaved quasi-reversible (ΔE = 100 mV at scan rate = 100 $mV \cdot s^{-1}$) Ni^{III}/Ni^{II} couples, with $E_{1/2}$ = 1.42 V and 1.55 V, respectively.

The assignment of octahedral geometries to [Ni(**1**)]-$(PF_6)_2$ (**7**) and [Ni(**2**)]$(PF_6)_2$ (**8**) follows from their paramagnetism, μ_{eff} = 3.06 and 3.25 B.M., respectively, which indicates S = 1. This was confirmed by single-crystal X-ray studies (vide infra).

Crystal Structures of 7 and 8

Complex **7** crystallizes as a monohydrate in the monoclinic system (space group $P2_1/c$) with four molecules in the

unit cell. Selected bond lengths and bond angles for a representative molecule are listed in Table 4. The ORTEP diagram is shown in Figure 4. The structure shows the nickel(II) ion occupying the macrocyclic cavity, bound through the four nitrogen and two selenium donor atoms. The angles around the nickel ion lie in the range 84.57(14)–98.24(3)° and 164.32(14)–177.7(2)° deviating only slightly from those expected for regular octahedral geometry. The two selenium atoms are mutually *cis* to each other. The Ni–Se distances [2.489(10) and 2.552(10) Å] are significantly

different, but comparable to those in [NiPyPySe$_2$(H$_2$O)$_2$](ClO$_4$)$_2$ [2.479(2), 2.477(2) [Å][27] and *trans*-[NiCl$_2$(MeSeCH$_2$CH$_2$SeMe)$_2$] [2.5581(9), 2.5536(9) Å],[19] respectively.

The single-crystal X-ray structure determination of **8** alsoshowed a distorted octahedral arrangement of the four nitrogen atoms and two selenium atoms around the central metal ion. Figure 5 shows the coordination sphere around the Ni^{II} ion and Table 5 summarizes selected bond lengths and bond angles. The complex crystallizes in a chiral space group *Pna*2$_1$ with four molecules in the unit cell. The Ni–Se distances [2.558(2), 2.578(3) Å] are slightly longer than those in **7**, and resemble those [2.568(2), 2.567(2) Å] in [(CO)$_3$Mn(μ-2-SC$_4$H$_3$S)$_3$Ni(μ-SePh)$_3$Fe(CO)$_3$]$^-$.[45] The C(1A)–Se(1)–C(1B) angle of 97.1(7)° deviates slightly (0.6°) from that in the ligand **2**.

Reaction of 1 with Co^{II}

The reaction of CoCl$_2$·6H$_2$O with 1 equiv. of **1** in refluxing methanol afforded a black solution. Addition of excess NH$_4$PF$_6$ yielded a black crystalline precipitate of complex **9** (Scheme 3). The air-stable complex **9** is insoluble in chlorocarbons and hydrocarbons. However, it dissolves in coordinating solvents such as MeCN, DMF, or DMSO. Rapid decomposition by displacement of the aza-selena macrocycle **1** occurs in the solvent DMSO. This was confirmed by ^{1}H NMR spectroscopic studies on the compound in [D$_6$]DMSO. A similar type of observation has been made by Reid et al. for the seven-coordinate Mo^{II} and W^{II} species derived from the selenoether ligands 1,5,9,13-tetraselenacyclohexadecane ([16]aneSe$_4$) and 1,6-diselena-3,4-benzocyclononane.[21] The elemental analysis data confirmed a 1:1 stoichiometry for the complex. The peaks at 838 and 554 cm^{-1} in the infrared spectrum were assigned to ν(P–F), δ(F–P–F). The peak at 1644 cm^{-1} was due to ν(C=N) stretching. In the UV/Vis spectrum of **9** an intense band was found centered at 290 nm, which may be due to a charge-transfer transition. Two further bands at 340 and 515 nm may be attributed to a combination of π–π* and d–d transitions. The FAB mass spectrum shows a low-intensity peak at *m*/*z* = 975 corresponding to the molecular ion [M]. The peak at *m*/*z* = 832 is for [**9** − PF$_6$]. The base peak at *m*/*z* = 687 corresponds to [**9** − 2 PF$_6$].

A powder sample of the paramagnetic black Co^{II} complex had μ_{eff} = 1.81 B.M., which indicates that it has a low-spin configuration (S = 1/2). Elemental analysis data, IR, UV/Vis, ^{77}Se NMR and FAB mass spectra, and magnetic susceptibility data are consistent with the formula of the complex **9** being [Co(**1**)](PF$_6$)$_2$. Cyclic voltammetry in acetonitrile solution reveals a well-behaved quasi-reversible (ΔE = 72 mV) Co^{III}/Co^{II} couple having $E_{1/2}$ = 0.17 V.

Conclusions

The Schiff-base condensation reaction of 1,2-diaminoethane or 1,3-diaminopropane with bis(*o*-formylphenyl) selenide yields the 22- and 24-membered [2+2] ligands **1** and **2**, respectively. Here the Se···N intramolecular interaction acts as a template in the formation of the ring. Macrocycles **1** and **2** have contrasting conformations. Whereas the transannular Se···Se distance in **1** is 3.808 Å, in **2** the distance is 7.229 Å. The Pd^{II} complex of **1** is isolated as a partially hydrolyzed complex. This is in contrast to the tellurium analog where the macrocycle is intact. The hydrolysis probably occurs due to the ring strain imposed by the square-planar geometry. The Ni^{II} complexes of **1** and **2** also show contrasting behavior. The former crystallises in an achiral space group ($P2_1/c$) whereas the latter crystallises in a chiral space group (*Pna*2$_1$).

Experimental Section

General: Bis(*o*-formylphenyl) selenide[37] and [PdCl$_2$(COD)][46] were prepared according to reported procedures. Air-sensitive reactions were carried out under inert conditions. Solvents were purified by standard techniques and were freshly distilled prior to use. 1,2-Diaminoethane (en) and 1,3-diaminopropane (pn) were reagent grade and were distilled prior to use. Melting points were recorded in capillary tubes and are uncorrected. IR spectra were recorded as KBr pellets with a Nicolet Impact 400 FT-IR spectrometer (4000–400 cm^{-1}). Electronic absorption spectra were obtained in CHCl$_3$/CH$_3$CN at 25 °C in a 1-cm quartz cuvette with a thermostatted Shimadzu UV-2100 apparatus and reflectance spectra was recorded with a UV-160A spectrophotometer. ^{1}H, ^{13}C and ^{77}Se NMR spectra were recorded with a Varian VXR 300S spectrometer at the indicated frequencies. Chemical shifts cited were referenced to TMS (^{1}H, ^{13}C NMR) as internal, Me$_2$Se (^{77}Se) as external standard. Elemental analyses were performed with a Carlo–Erba model 1106 elemental analyzer. Fast atom bombardment (FAB) mass spectra were recorded at room temperature with a JEOL SX 102 DA-6000 mass spectrometer/data system using xenon (6 kV, 10 mV) as the bombarding gas. The acceleration voltage was 10 kV and *m*-nitrobenzyl alcohol was used as the matrix with positive-ion detection. In the case of clusters due to the presence of more than one isotope, the value given is for the most intense peak. Magnetic susceptibilities of powdered samples were determined at room temperature with a Faraday balance, standardized with mercury tetracyanocobaltate(II) [$\chi = 16.44 \times 10^{-6}$ cm^3·mol^{-1}]. The molar susceptibilities were corrected for diamagnetism using Pascal's constants. The effective magnetic moments were calculated using the expression $\mu_{eff} = 2.83(\chi_m \times T)^{1/2}$. Cyclic Voltammetry (CV) experiments were performed with a Scanning Potentiostat EG and G PARC Model 362 instrument which consists of a one-compartment cell with platinum working and counter electrodes and a standard Ag/AgCl reference electrode. Tetrabutylammonium tetrafluoroborate (Aldrich) was used as the supporting electrolyte. All solutions were purged with nitrogen before the CV data were recorded. Measurements were conducted in 0.1 mol·dm^{-3} Bu$_4$NBF$_4$ in acetonitrile with sample concentration 0.05 mM. Ferrocene was taken as standard.

Synthesis of Macrocyclic Schiff Base 1: A solution of bis(*o*-formylphenyl) selenide (0.15g, 0.5 mmol) in acetonitrile (100 mL) was added to a stirred solution of 1,2-diaminoethane (0.030 g, 0.5 mmol) in acetonitrile (100 mL) over a period of 1 h. The mixture was stirred overnight and the precipitated colorless powder was filtered off, washed with acetonitrile and recrystallized from CHCl$_3$/CH$_3$CN (1:1). Yield: 0.14g, 91%. M.p. 218–220 °C. C$_{32}$H$_{28}$N$_4$Se$_2$ (627.31): calcd. C 61.35, H 4.50, N 8.94; found C

Synthesis of Macrocyclic Schiff Base 2: This was prepared as described for **1** from bis(*o*-formylphenyl) selenide (0.15g, 0.5 mmol) and 1,3-diaminopropane (0.037g, 0.5 mmol). The colorless powder was washed with acetonitrile and recrystallized from $CHCl_3$/CH_3CN (1:1). Yield: 0.15 g, 89%. M.p. 225–227 °C (dec.). $C_{34}H_{32}N_4Se_2$ (654.57): calcd. C 62.39, H 4.93, N 8.56; found C 62.18, H 5.04, N, 8.69. IR (KBr): $\tilde{\nu}$ = 1653 ν(C=N), 1632 ν(C=N) cm^{-1}. ^1H NMR (300 MHz, $CDCl_3$): δ = 8.46 (s, −C*H*=N−, 4 H), 7.64–7.16 (m, 16 H, aromatic H), 3.61 (t, 8 H, N–CH_2–CH_2), 2.01 (quint, 4 H, –CH_2–CH_2–CH_2–) ppm. ^{13}C NMR (75.42 MHz, $CDCl_3$): δ = 162.58 (azomethine C), 136.92, 134.34, 133.78, 130.60, 130.18, 127.18 (aromatic C), 56.87 (N–*C*H_2–CH_2), 30.07 (N–CH_2–*C*H_2–) ppm. ^{77}Se NMR (57.22 MHz, $CDCl_3$): δ = 413 ppm. MS (FAB): m/z = 657 [M^+], 327, 307, 284, 245, 204, 165, 154, 136, 117, 107, 91, 77, 65, 41.

Synthesis of Complex 5: The ligand **1** (0.1 g, 0.16 mmol) was taken up in a two-necked round-bottomed flask with 20 mL of methanol. This was brought to reflux and then [$PdCl_2$(COD)] (0.045 g, 0.16 mmol) was added. The suspension immediately changed color to a clear yellow solution. This was allowed to reflux for an additional 15 min. Then it was filtered and an excess of NH_4PF_6 was added to the filtrate. Immediately a yellow powder precipitated. This could be recrystallized by slow concentration of an MeCN solution of the complex. Yield: 0.12 g, 76%. M.p. 208–210 °C (dec.). $C_{30}H_{24}F_1N_2O_2P_{22}PdSe_2$ (998.78): calcd. C 36.08, H 2.42, N 2.80; found C 35.92, H 2.46, N 2.55. IR (KBr): $\tilde{\nu}$ = 1667 ν(C=O), 1640 ν(C=N) cm^{-1}. ^1H NMR (300 M Hz, [D_6]DMSO): δ = 10.05 (s, 2 H, aldehydic H), 8.88 (s, 2 H, azomethine H), 8.34–6.61 (m, 16 H, aromatic H), 3.81–3.52 (m, 4 H, =NCH_2–CH_2N=) ppm. ^{77}Se NMR (57.22 M Hz, [D_6]DMSO): δ = 411 ppm. MS (FAB): m/z = 855 [M^+− PF_6], 709 [M^+ – 2 PF_6], 525, 495, 467, 439, 420, 391, 329, 307, 289, 245.

Synthesis of Complex 6: This was prepared as described for **5** by the addition of [$PdCl_2$(COD)] (0.043 g, 0.15 mmol) to the ligand **2** (0.1 g, 0.15 mmol) in methanol. Recrystallization by the slow diffusion of diethyl ether into a nitromethane solutionas afforded **6** as yellow needles. Yield: 0.14 g, 87.5%. M.p. 220–222 °C (dec.). $C_{34}H_{32}F_{12}N_4P_2PdSe_2$ (1050.90): calcd. C 38.86, H 3.07, N 5.33; found C 39.11, H 2.93, N 5.39. IR (KBr): $\tilde{\nu}$ = 1637 ν(C=N), 836 ν(P–F), 556 δ(F–P–F) cm^{-1}. ^1H NMR (300 MHz, [D_6]DMSO): δ = 8.66 (s, 4 H, azomethine H), 7.60–8.06 (m, 24 H, aromatic H), 3.64 (quint, 4 H, NCH_2–CH_2–CH_2N), 4.82 (t, 8 H, NCH_2–CH_2–CH_2N) ppm. ^{13}C NMR (75.42 MHz, [D_6]DMSO): δ = 170.18 (azomethine C), 137.60, 135.38, 135.18, 131.84, 130.75, 119.08 (aromatic C), 62.46 (N–*C*H_2–CH_2), 32.22 (CH_2–*C*H_2–CH_2) ppm. ^{77}Se NMR (57.22 MHz, [D_6]DMSO): δ = 441 ppm. MS (FAB): m/z = 905 [M^+ − PF_6], 761 [M^+ − 2 PF_6], 577, 551, 539, 512, 487, 469, 434 (base peak), 247.

Synthesis of Complex7: The ligand **1** (0.1 g, 0.16 mmol) was added to methanol (20 mL) under nitrogen. This was brought to reflux and then $NiCl_2 \cdot 6H_2O$ (0.038 g, 0.16 mmol) was added. The suspension changed to a clear red solution within 5 min. It was allowed to reflux for an additional 15 min. The solution was filtered and to the filtrate an excess of NH_4PF_6 was added. Immediately a brown precipitate was obtained which was filtered and washed with methanol. Yield: 0.15 g, 96%. M.p. 258–260 °C (dec). $C_{32}H_{28}F_{12}N_4NiP_2Se_2 \cdot H_2O$ (993.17): calcd. C 38.70, H 3.04, N 5.64; found C 38.25, H 3.04, N 5.95. IR (KBr): $\tilde{\nu}$ = 1650 ν(C=N), 830 ν(P–F), 555 δ(F–P–F) cm^{-1}. UV/Vis (MeCN): $\lambda_{max.}$ (ε) = 295 (14 330), 345 (2950), 435 (579), 805 nm (58 $mol^{-1} \cdot dm^3 \cdot cm^{-1}$); μ_{eff} = 3.23 B.M.. MS (FAB): m/z = 831 [M^+ − PF_6], 686 [M^+ − 2 PF_6], 372, 343, 291, 273, 242, 178, 153, 120.

Synthesis of Complex 8: This was prepared similarly from ligand **2** (0.1 g, 0.15 mmol) and $NiCl_2{\cdot}6H_2O$ (0.036 g, 0.15 mmol). It was recrystallized by the slow diffusion of diethyl ether into a nitromethane solution. Yield: 0.13 g, 87%. M.p. 258–260 °C (dec.). $C_{34}H_{32}F_{12}N_4NiP_2Se_2{\cdot}H_2O$ (1021.23): calcd. C 39.99, H 3.30, N 5.48; found C 39.57, H 3.22; N 5.98. IR (KBr): $\tilde{\nu}$ = 1628 ν(C=N) 834, 753, 557 cm^{-1}. UV/Vis (MeCN): $\lambda_{max.}$ (ε) = 295 (12 200), 335 (3650), 565 nm (24 mol^{-1}·dm^3·cm^{-1}); μ_{eff} = 3.25 B.M.. MS (FAB): m/z = 733 [M$^+$ − PF_6 + H_2O], 712 [M$^+$ − PF_6], 577, 407, 386, 327, 306, 251, 224.

Synthesis of Complex 9: This was prepared according to the method used for the preparation of the complex **7** by adding $CoCl_2{\cdot}6H_2O$ (0.038 g, 0.16 mmol) to the ligand **1** (0.1 g, 0.16 mmol) in 20 mL methanol. Yield: 0.12 g, 75%. M.p. 226–228 °C (dec.). $C_{32}H_{28}CoF_{12}N_4P_2Se_2$ (975.38): calcd. C 39.41, H 2.89, N 5.74; found C 38.50, H 2.96, N 5.66. IR (KBr): $\tilde{\nu}$ = 1644 ν(C=N), 838 ν(P–F), 554 (δ(F–P–F) cm^{-1}. UV/Vis: (MeCN): $\lambda_{max.}$ (ε) = 290 (13 240), 340 (6640), 515 nm (1100 mol^{-1}·dm^3·cm^{-1}); μ_{eff} = 1.81 B.M. MS (FAB): m/z = 975 [M$^+$], 832 [M$^+$ − PF_6], 687 [M$^+$ − 2 PF_6, base peak], 373, 343, 309, 291, 242, 152, 120.

X-ray Crystallographic Study: The diffraction measurements for compound **1**, **2**, **5**,**7** and **8** were performed at room temperature (293 K) with a Siemens R3m/V diffractometer using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The unit cell was determined from 25 randomly selected reflections using the automatic search index and least-squares routine. The data were corrected for Lorentz, polarization and absorption effects. A semiempirical absorption correction from ψ-scans was applied to the data of **5** and **7**. The maximum and minimum transmission values of the correction factors for compounds **5** and **7** were 0.2761 and 0.2170 and 0.5048 and 0.4442, respectively. The structures were solved by routine heavy-atom (using SHELXS[47]) and Fourier methods and refined by full-matrix least squares, the non-hydrogen atoms with anisotropic and the hydrogen atoms with fixed isotropic thermal parameters of 0.07 Å^2 using SHELXL93.[48] The hydrogen atoms were partially located from difference electron-density maps and the rest were fixed at calculated positions. Scattering factors were from common sources.[49] Some details of data collection and refinement are given in Tables 6 and 7. CCDC-148626 (**1**), -148627 (**2**), -148630 (**5**), -148631 (**7**) and -148632 (**8**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Acknowledgments

We are grateful to the Department of Science and Technology (DST), New Delhi and Board of Research in Nuclear Sciences (BRNS), Department of Atomic Energy, Bombay for funding this work. Additional help from the Regional Sophisticated Instrumentation Center (RSIC), Indian Institute of Technology (IIT), Bombay for 300 MHz NMR spectroscopy, and RSIC, CDRI Lucknow for mass spectrometry, is gratefully acknowledged. R. J. B. wishes to acknowledge the DOD-ONR program for funds to upgrade the diffractometer.

Structural Studies of Rare Earth/Transition Metal Complex Ion Systems as a Basis for Understanding Their Thermal Decomposition to Mixed Oxides

Philippa A. Brayshaw,[a] Annegret K. Hall,[a] William T. A. Harrison,[a,b] Jack M. Harrowfield,*[a,c] Dierdre Pearce,[a] Todd M. Shand,[a] Brian W. Skelton,[d] Claire R. Whitaker,[a,e] and Allan H. White[d]

Keywords: Dipicolinates / Rare earths / Crystal structures / Mixed oxides / Thermochemistry

Thermal decomposition in air of the series of complexes $[Co(NH_3)_6][Ln(dipic)_3]\cdot x H_2O$, $[Cr(en)_3][Ln(dipic)_3]\cdot y H_2O$ and $[Cr(urea)_6][Ln(dipic)_3]\cdot z H_2O$ (Ln = La – Lu, excluding Pm but plus Y; dipic = 2,6-pyridinedicarboxylate) to give oxide phases has been examined. The products were characterised by powder X-ray diffraction, magnetic and surface area measurements. From the Co-containing species, either Co_3O_4 + Ln_2O_3 or perovskite ($CoLnO_3$) products result, while the Cr-containing species provide $CrLnO_4$ phases in addition, the monazite form of $CrNdO_4$ being detected for the first time in this way. Underpinning consideration of the solid state decomposition mechanisms, single-crystal X-ray structure determinations have been performed on $[Co(NH_3)_6][Ln(dipic)_3]\cdot n H_2O$ across the Ln series, defining differing phases (all triclinic $P\bar{1}$) for n = 5 (encompassing Ln = La–Pr), n = 8(.5) (Ln = Tm – Eu) and n = 10 (Ln = Pr – Er, including Y), and also on one of the low-temperature decomposition products, $[Co(NH_3)_6]Cl\cdot dipic\cdot 2H_2O$ (**1**). The structure of **1** provides evidence that conventional π-stacking of the dipicolinate anions may be of some importance in determining the solid state array, whereas consideration of all structures involving $[Ln(dipic)_3]^{3-}$ anions indicates that "edge-to-face" interactions between dipicolinate ligands of adjacent complex anions may also be determinants of the formation of sheet-like arrays of the trianions commonly observed in these compounds.

Introduction

In the hope of gaining some understanding of the complicated events which must be involved in the thermal decomposition reactions of mixed-metal solids in which a transition metal is present in a cationic complex and a lanthanide (Ln) in an anionic complex, we have conducted a detailed crystallographic study of one family of reactants, $[Co(NH_3)_6][Ln(dipic)_3]\cdot x H_2O$, [dipic = dipicolinate = 2,6-pyridinedicarboxylate; x = 5, 8(.5), 10] and some related materials. Solids containing tris(dipicolinato)lanthanide(III) anions ($[Ln(dipic)_3]^{3-}$) have been of interest for many reasons,[1–5] but thermal decomposition reactions of their derivatives with transition metal cations to give "mixed" oxides have not been investigated. Analogous reactions, however, have been explored in numerous systems[6–11] and frequently have been found superior to those based on reactions between separate solid phases such as the monometallic oxide constituents (or their simple precursors). While mixed lanthanide/transition metal oxides have long been of interest in regard to their structural, spectroscopic, magnetic and catalytic properties, which are consequently rather well understood,[12] there remains a need to provide more efficient syntheses and better methods of control of particle size.[13] We provide herein evidence that this need may be met to some extent through the use of thermal decomposition of solids containing $[Ln(dipic)_3]^{3-}$ in association with cobalt(III) or chromium(III) complex cations. One reason for studying compounds involving a cation such as $[Co(NH_3)_6]^{3+}$ in the presence of $[Ln(dipic)_3]^{3-}$ anions was to see if the aspects of three-fold symmetry present in both species would lead to particular modes of association in their lattices which might be seen to control solid-state reactions. Interpretation of features of the supramolecular chemistry of these lattices which may be deduced from detailed analysis of their structures is enhanced by structural studies of $[Co(NH_3)_6]dipic\cdot Cl\cdot 2H_2O$ and $[Eu(dipicH)(dipic)(OH_2)_2]\cdot 4H_2O$, the latter being a member of a known

series of lanthanide complexes,[14] though both complexes were presently isolated through unintended solution decomposition reactions of two of the mixed-oxide precursor species, $[Co(NH_3)_6][La(dipic)_3]\cdot x\,H_2O$ and $[Cr(urea)_6][Eu(dipic)_3]\cdot x\,H_2O$, respectively.

Results and Discussion

1. Cobalt/Rare Earth Systems

Structure Determinations: Various hydrates, $[Co(NH_3)_6][Ln(dipic)_3]\cdot x\,H_2O$, are obtained when $[Co(NH_3)_6]^{3+}$ is precipitated from aqueous solutions by the addition of tris(dipicolinato)lanthanate(III) anions, $[Ln(dipic)_3]^{3-}$. Any given lanthanide may be a member of more than one hydrate family, thus rendering extremely complicated any attempt to fully characterise the systems. This situation is exacerbated by the fact that, although the very insoluble compounds may be readily recrystallised, the crystals obtained are often small and needle-like, thus being less than optimal for diffraction studies. To find that some adducts, slowly crystallised over periods as long as years, underwent apparent desolvation within seconds of separation from their supernatant solution was a further significant handicap. In combination, these difficulties were more acute for the heavier than the lighter rare earths. Overall, nonetheless, the gamut of the rare earth array (including Y) appears to be encompassed within three dominant series, a pentahydrate ($x = 5$) phase being defined for La – Pr, a decahydrate form for Pr – Er, Y, and an octahydrate (more precisely, an 8.5-hydrate) for Tm − Lu, these limiting members (with some intermediates) being structurally characterised herein. A broader survey, focussed particularly on hydrogen bonding in these hydrates and defining further sporadic phases, will be reported elsewhere.[15]

In all $[Co(NH_3)_6][Ln(dipic)_3]\cdot x\,H_2O$, a triclinic $P\bar{1}$ cell obtains, with one formula unit comprising the asymmetric unit of the structure. The space group $P\bar{1}$ necessarily implies a racemic mixture of the chiral anions in each case. In the penta- and "octa-"hydrate phases, the asymmetric unit of the structure is devoid of any symmetry but in the decahydrate phase, the cations lie with their cobalt atoms disposed on crystallographic inversion centres, there being two such independent species. The similarity between crystallographic *a*, *b*, *c* of the deca- and "octa"-hydrate species is noted but, seemingly, carries no deeper significance (see below). The geometries of the $[Co(NH_3)_6]^{3+}$ cations are "normal"[16] and do not justify further comment. The anions, one representative being shown in Figure 1, are also of a form already known from studies of the sodium salts,[17–20] as well as from more recent work,[1–5] with the three ligands tridentate through ONO donor atoms about the metal, making up a three-bladed propeller array of putative *32* symmetry. Their geometries are tabulated comparatively and in summary in Table 1, the most obvious trend being that expected of the "lanthanide contraction", <Ln−N> diminishing by ca. 0.22 Å across the series, and <Ln−O> by rather less, ca. 0.18 Å. The components of the geometries vary rather widely, particularly in the angles and particularly at the lighter end of the series, where it might be expected that, in the context of nine-coordination throughout, the constraints on the packing of the three ligands about the metal are less demanding. The carboxylate groups are essentially coplanar with their parent pyridine rings, albeit not rigidly so, and out-of-plane Ln deviations are substantial, even relative to the pyridine ring and most particularly among the complexes containing the lighter rare earths. There is no association of the cations and anions into intimate pairs or columns of alternating species which simply reflects common aspects of threefold symmetry.

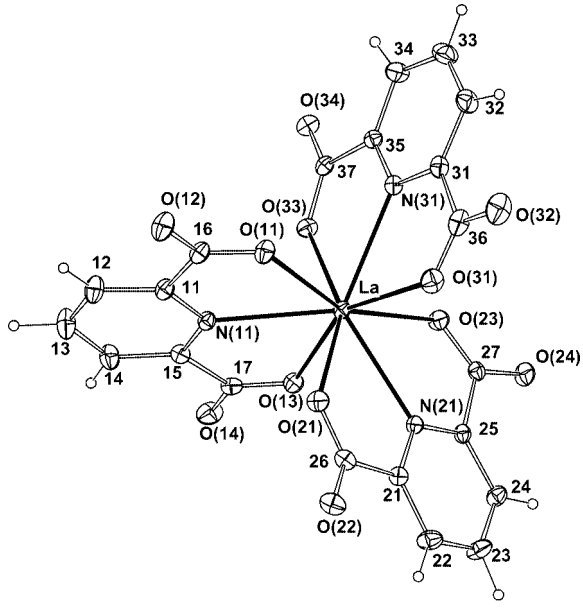

Figure 1. A view of the $[La(dipic)_3]^{3-}$ anion present within the lattice of $[Co(NH_3)_6][La(dipic)_3]\cdot 5\,H_2O$ (**2**), showing the numbering system which provides the basis for Table 1.

The component water molecules are described with variable definitiveness, those in the penta- and deca-hydrate families, respectively, being most and least precisely defined. The first structure solved was that of the pentahydrate phase of the Ce species **3**, a significant result at the time in confirming the Ce^{III} oxidation state, since the orange colour of the precursor $Na_3[Ce(dipic)_3]\cdot 15\,H_2O$ complex had led to some suspicion that it might in fact be a Ce(IV) species (as has been obtained, apparently, with a Ca^{II} counter cation[21]). A superior structural characterisation of the pentahydrate phase was ultimately obtained for the Pr (**4a**) species, where the precision of the determination is such that all hydrogen atoms in the structure have been resolved and refined in (x, y, z, U_{iso}) and are taken as indicative of the basic hydrogen bonding scheme for this family, the La species making up a third member. Powder XRD studies (see below) indicate, however, that the pentahydrate phase may well be common to the whole rare earth series, upon partial desolvation of the higher hydrates.

The decahydrate phase has been structurally characterised for Pr (**4b**), Sm (**5**), Tb (**6**), Er (**7**) and Y (**8**) and is

presumed accessible to at least the intervening rare earths (Table 1). For this family, site occupancy refinement of water molecule oxygen sites is indicative of full occupancy of all postulated sites across the series; for all, however, the displacement parameters, possibly a foil for minor disorder, are high for a number of these, and for some no hydrogen atom locations were definitively established. Throughout the x = 8(.5) series also, solvent displacement parameters generally are high, possibly indicative of or associated with the difficulties in the crystallisation of adducts containing heavy Ln, with site occupancy refinement suggestive of some fragment populations. Unit cell projections for the various phases are shown in Figures 2(a)–(c), representative in general for each phase, although there may be variations in the fine detail of the modelling of the hydration. The complex anions, as in other structures (discussed ahead), may be considered to be disposed in homochiral columns lying side-by-side, with chirality alternating, to form sheets, viewed edge-on here, interspersed by layers of cations and associated water molecules, the two systems being interconnected by hydrogen bonds between cation, solvent and anions, in the last via the uncoordinated carboxylate oxygen atoms. In the "octa"-hydrates, the cations lie in between translation-related anions in projection down *b*, generating a CoLn column up that axis. In similar projections of the penta- and deca-hydrates, the cations lie between the anions with the axes of the Co and Ln chains parallel but not collinear. A similar motif of parallel-column/sheet formation

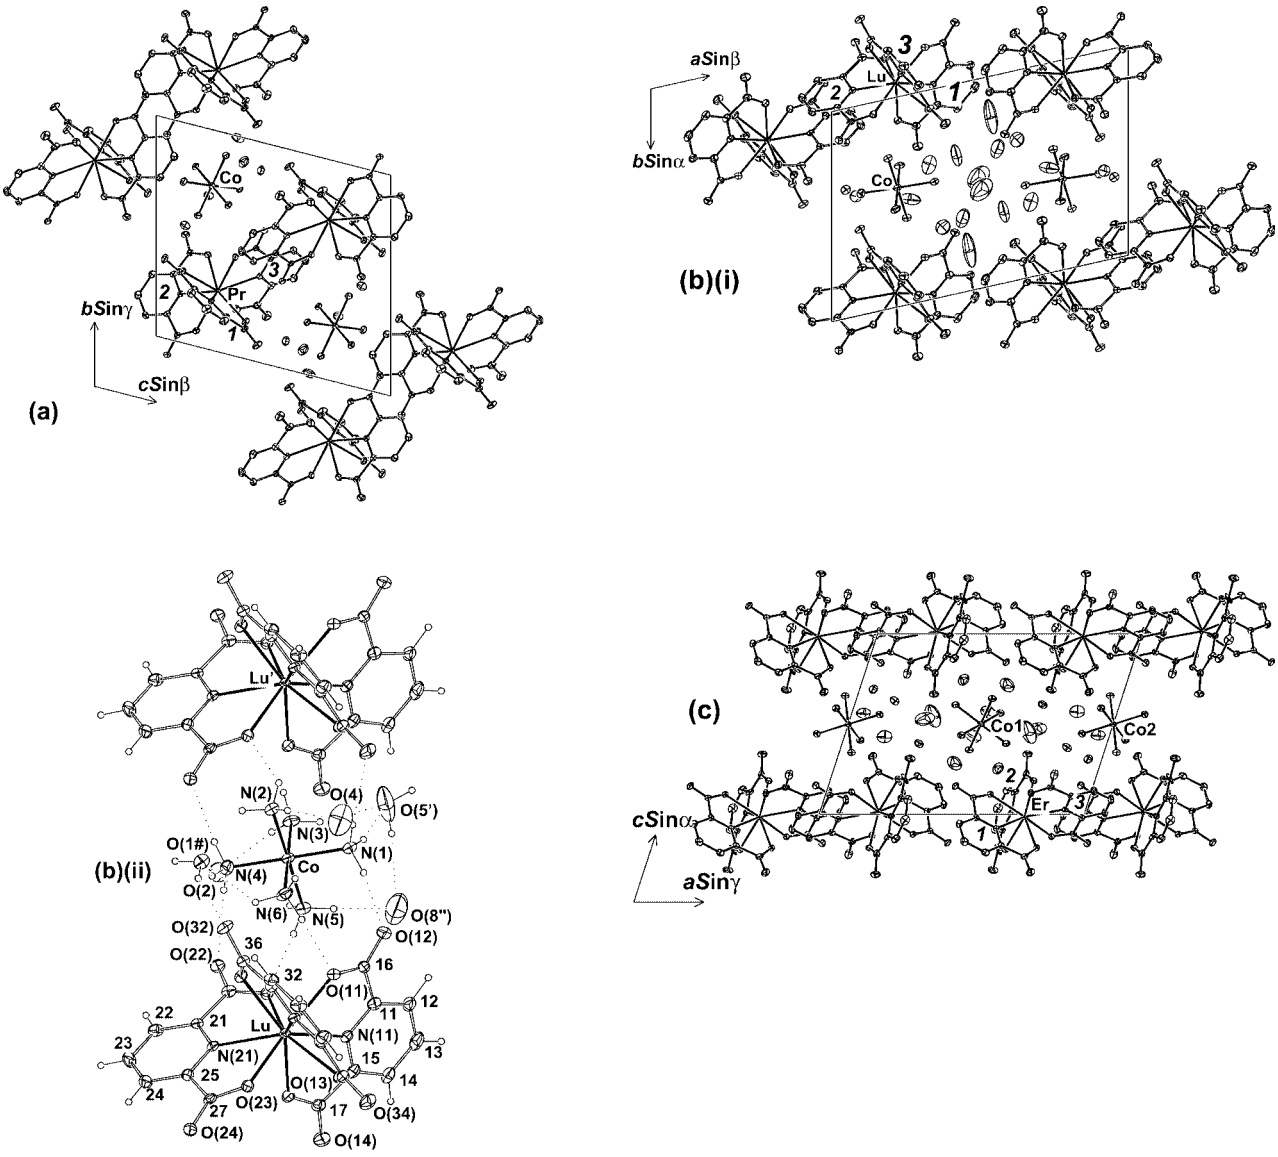

Figure 2. Representative unit cell projections for the various hydrate types $[Co(NH_3)_6][Ln(dipic)_3]\cdot x\,H_2O$, x = 5, 8(.5), 10. (a) Ln = Pr, x = 5 (**4a**), down *a*; (b) Ln = Lu, x = 8.5 (**10**), (i) down *c* and (ii) down *b*, showing the column stacking; (c) Ln = Er, x = 10 (**7**), down *b*.

is seen for the more highly charged anions of the complex $Na_5[Gd(chelidamate)_3]\cdot 16\,H_2O$[22] (chelidamic acid = 4-hydroxy-2,6-pyridinedicarboxylic acid), where approaches between anions of opposite chirality involve chelate units on the separate centres very closely parallel but with no atom separations for these rings being <3.9 Å and the closest atom approaches (3.1–3.2 Å) in fact being between uncoordinated carboxylate-*O* and C(2) of a near-orthogonal chelate ring on the adjacent centre. (Contact between anions of the same chirality appears to be mediated by H-bonding involving the 4-phenol/phenoxide groups.) In terms of the details of possible interactions, the present systems exhibit similarities but with further complications.

Thus, in the precisely defined pentahydrate-phase structure of $[Co(NH_3)_6][Pr(dipic)_3]\cdot 5\,H_2O$, the anion sheets (in planes parallel to [0,−1,1]), seen edge-on in the view down *a* [Figure 2(a)], involve each anion having two near neighbours (as part of a column) of the same chirality, with Pr···Pr 10.4500(7) Å (= *a*; homochiral contact), and three near-neighbours of opposite chirality, with Pr···Pr 8.4476(4), 8.6449(4) and 9.3568(4) Å (heterochiral contacts). The homochiral pairs are rather remote, with the only close approaches involving atoms in near orthogonal chelate units, so that they are perhaps best described as of a "edge-to-face" type,[23] (or possibly as a bent CH···O interaction) involving O(uncoordinated)···C(2) 3.458(4) Å and O(coordinated)···C(3) 3.576(4) Å. For the heterochiral pairs, interpenetration of the coordination spheres involves pairs of chelates being closely parallel but this is duplicitous evidence for stacking in that either ring atoms are not overlapped in projection or the ring planes are separated by >3.6 Å. Thus, both the 8.4476 and 8.6449 Å pairs involve

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

parallel rings for which only the C–O(uncoordinated) units overlap in projection, involving C···O separations of 3.020(3) and 2.911(3) Å, respectively. For the 9.3568 Å pair, while the parallel ring overlap in projection is more extensive, all interatomic separations are >3.6 Å and possible edge-to-face interactions involving coordinated-*O* to C(4) and C(3) of a nonparallel ring lead to significantly shorter contacts [3.566(3) and 3.585(3) Å, respectively]. In an "octa"hydrate species such as $[Co(NH_3)_6][Lu(dipic)_3]\cdot 8.5H_2O$, where the anion sheets are seen edge-on in the view down *c* [Figure 2(b)], both homochiral [10.419(5) Å] and heterochiral [8.571(4), 8.860(5) and 9.328(4) Å] unit separations involve quite similar juxtapositioning of the anions to those in the Pr pentahydrate compound, though involving differences in specific interatomic approaches consistent with a very complicated balance of forces being involved. The closest contact in the homochiral pair, 3.291(2) Å, is that of a dipicolinate C(3) to an uncoordinated-*O* of a near-orthogonal chelate unit, again possibly an edge-to-face aromatic or a bent CH···O interaction. The adjacent C(4) is 3.46(1) and 3.58(2) Å, respectively, from uncoordinated- and coordinated-*O* of the same carboxylate and these are the only contacts which could be termed close. For the heterochiral pair at 8.571 Å, stacking C···O contacts are apparent at 3.24(1) Å but the 8.860 Å pair is less like its Pr analogue in that the closest (stacking) contacts are C(aromatic)···C(carboxylate) at 3.406(2) Å and two C(aromatic)···C(aromatic) at 3.461(2) Å. The closest contact in the heterochiral 9.328 Å pair is a C(4)···O(coordinated) separation of 3.461(2) Å, again involving atoms in nonparallel rings. In a decahydrate such as $[Co(NH_3)_6][Er(dipic)_3]\cdot 10H_2O$, where the anion sheets are seen edge-on in the view down *b* [Figure 2(c)], there are no contacts <3.7 Å between atoms in the homochiral pairs [11.227(1) Å = *b* apart] and while in the closest heterochiral pair [8.468(9) Å apart], there are stacking contacts C(carboxylate)···O(uncoordinated) of 3.422(8) Å, the closest atomic separation is 3.310(7) Å for O(uncoordinated)···O(coordinated). For the more remote pair 8.588(7) Å apart, the parallel ring positions are very similar but just sufficiently different to those of the 8.468 Å pair for C(carboxylate)···O(uncoordinated) at 3.226(8) Å to now be shorter than C(carboxylate)···O(uncoordinated) (3.313(8) Å] and O(uncoordinated)···O(coordinated) [3.346(8) Å]. For the longest heterochiral pair separation [9.269(9) Å], despite two rings being closely parallel and having significant overlap in projection, no interatomic separations are <3.6 Å, though several are close to this value. All these subtleties in the detail of what can be grossly termed "aromatic-aromatic" interactions can also be discerned in many structures of simpler materials such as metal nitrophenoxides and other aza-aromatic carboxylates,[24,25] as well as in structures of complexes of neutral aza-aromatic ligands.[23] How significant particular separations may be and how they may be related to lattice energies are nontrivial issues but the individual interaction energies are presumably small[23] and it may be noted that, across the various $[Co(NH_3)_6][Ln(dipic)_3]\cdot xH_2O$ phases, the cell dimensions are not too dissimilar, suggestive of a relatively facile passage from one form to another, possibly with rather minimal energy differences, in the course of crystallisation.

While the segregation of $[Ln(dipic)_3]^{3-}$ anions into sheet-like structures in all the cases described above might be taken as indicative of energetically important interactions, particularly those involving heterochiral pairs, between the anions, it is instructive to apply a similar analysis to the structures of other known derivatives. First structurally characterised were the sodium compounds and in $Na_3[Nd(dipic)_3]\cdot 15H_2O$,[18] for example, while again anion sheets generated from a side-by-side, alternating arrangement of homochiral columns can be discerned, one heterochiral pair involves closely parallel rings but with no ring atom separations <4 Å and another closely parallel rings with no separation <3.5 Å, suggesting any stacking to be of minimal importance. For the closest homochiral pair [10.353(15) Å = *a* apart], the only close contacts are C(3)···O(uncoordinated) and C(4)···C(carboxylate) of 3.25 and 3.30 Å, respectively. In the monoclinic form of $Na_3[Yb(dipic)_3]\cdot 13H_2O$,[17] racemic anion sheets are present but can no longer be regarded as built up from side-by-side positioning of homochiral columns containing anions in a common orientation. Concomitantly, heterochiral pairs involve closely parallel ring arrangements but none of this apparent stacking involves atomic approaches <3.6 Å and only for one pair is there a close edge-to-face contact [C(3)···O(uncoordinated)] of 3.37 Å. The closest homochiral pair involves a relative orientation unlike that in the Nd compound which results in one C(4)···C(4′) contact of 3.46 Å. In orthorhombic $Na_3[Yb(dipic)_3]\cdot 14H_2O$,[17] an anion sheet built up of adjacent homochiral columns is recovered but no pair within it involves short interatomic contacts aside from C(4)···C(carboxylate) and C(4)···O(uncoordinated), both close to 3.5 Å in the heterochiral pair 9.76 Å apart. In the similar anion sheet of $Na_4[Yb(dipic)_3][ClO_4]\cdot 10H_2O$,[19] close contacts are again rare, only edge-to-face C(3,5)···O(uncoordinated) at 3.31 Å in the homochiral pair 10.37 Å apart being obvious. Such results may mean that the anion sheet is a flexible motif, adjusting to restraints imposed by other components of the lattice. Consistent with this is the presence of homochiral sheets in $Cs_3[Eu(dipic)_3]\cdot 9H_2O$[1a] [with closest interatomic contacts being C(3,5)···O(uncoordinated) 3.44(2) Å] and the presence of racemic sheets in $[Co(sar)][Eu(dipic)_3]\cdot 13H_2O$[1a] (sar = "sarcophagine" = 3,6,10,13,16,19-hexaazabicyclo[6.6.6]icosane) where there is no evidence of any significant stacking. $[N(CH_2CH_3)_4]_3[Eu(dipic)_3]\cdot 4H_2O$[1c] provides a complicated system in which sheets of anions can be discerned which alternate in the sense that the orientations of the anion, common within a sheet, are nearly orthogonal from one sheet to the next. In one sheet, only homochiral pairs involve any close interatomic approaches, very similar to those in $Na_4[Yb(dipic)_3][ClO_4]\cdot 10H_2O$, with C(3,5)···O(uncoordinated) 3.33 Å. In the other sheet, homochiral pair contacts are similar, with a separation of 3.39 Å but the heterochiral pairs 10.29 Å apart appear to involve stacking, with C(3)···C(3′) 3.42 and C(4)···C(4′) 3.43 Å. The tet-

raethylammonium cation is, of course, unlike all other countercations discussed so far in that it is formally neither an H-bond donor nor a coordinating centre, properties shared with cations such as $[Co(bipy)_3]^{3+}$ and $[Co(phen)_3]^{3+}$. These cations also give $[Ln(dipic)_3]^{3-}$ derivatives with rather different anion arrays, their properties being described in detail elsewhere.[26] $[NEt_4]^+$ is not like these cations in having an aliphatic exterior and there are approaches indicating possible CH···O interactions with dipicolinate carboxylate-*O*, as in fact there are for the butyl chain in the complex $[Co(3\text{-butyldiamsar})][Sm(dipic)_3]\cdot 15H_2O$ ("diamsar" = 1,8-diaminosarcophagine).[27]

Of the various forces in addition to anion−anion (aromatic) interactions which may determine the lattice arrays, important in the present systems would appear to be familiar H-bonding (discussed in more detail elsewhere[15]) and metal ion coordination. In addition to the columnar arrays of anions referred to above, it is possible to discern in many instances columns in which anions are bridged by cations and/or water. In all $[Co(NH_3)_6][Ln(dipic)_3]\cdot x H_2O$, as well as $Na_3[Nd(dipic)_3]\cdot 15H_2O$,[17] $Na_3[Yb(dipic)_3]\cdot NaClO_4\cdot 10H_2O$[19] and $Cs_3[Eu(dipic)_3]\cdot 9H_2O$,[1a] the metal ions align in such a way that the lanthanide and the other cation alternate in a chain, with the C_3 axes of the $[Ln(dipic)_3]^{3-}$ anions being oriented along the chain and with the structural indications being that coordination (of an alkali metal) or H-bonding (of Co–NH_3) to the "*exo*" dipicolinate oxygens atoms determines or assists this feature of the total crystalline array. In orthorhombic $Na_3[Yb(dipic)_3]\cdot 14H_2O$,[17] however, no such "mixed" chains are found and the C_3 axes of the anions appear to lie in the *bc* plane with alternating tilts towards Na^+ columns parallel to *c*. This may be associated with size differences between Nd^{3+} and Yb^{3+} in this hydrate series, where it is apparent also that the $[Yb(dipic)_3]^{3-}$ species is significantly distorted from true D_3 symmetry and the Yb columns can be regarded as forming pairs parallel to *b*. The Yb environment appears more symmetrical in monoclinic $Na_3[Yb(dipic)_3]\cdot 14H_2O$[19] and the C_3 axes of the complex anions seem more closely aligned (here, parallel to *a*) but again sodium cations are not directly interposed between Yb ions in columns. Although it is possible for $[Co(NH_3)_6]^{3+}$ to orient three NH bonds on a trigonal face parallel to the threefold axis of the octahedron, it does not adopt this mode to interact with the threefold symmetric dipicolinate *exo*-O_3 array of a given anion, presumably because of dimensional mismatching, but it is nonetheless apparent from the structure of $[Co(sar)][Eu(dipic)_3]\cdot 13H_2O$[1a] that in this case the fixed orientations of the NH bonds of the cation away from its C_3 axis are the likely cause of the juxtaposition (down *b*) of columns of the cations adjacent to columns of the anions (with their C_3 axes oriented down *b*). A similar feature is apparent in the structure of the $[Cr((NH_2)_2sar)][Ln(dipic)_3]\cdot 8H_2O$ series,[1b] even though here some differences might be expected because of the presence of the terminal primary amino groups. In both cases, anyway, the interactions between a given cation-anion pair are only part of an extended structure involving lattice water as well. Any asymmetry in the overall formal charge distributions on the cation and anion must of course be considered as another influence on cation-anion orientation and the rather beautiful sinusoidally undulating cation and anion sheets observed in $[Cr((NH_3)NH_2sar)][Cr((NH_3)_2sar)][La(dipic)_3]_3\cdot 32H_2O$[1b] provide evidence of its possible effects.

A specific aspect of interest in the solid-state structures of mixed transition metal/rare earth compounds is the influence of particular features of the structure on the separation and consequent degree of interaction between the different metal centres. The least separation of the Co and Ln centres within the asymmetric units of the present series varies from 5.752(3) Å in the 8.5 hydrate of the Lu species to 6.169(4) Å in the pentahydrate of the La species, all such Co···Ln separations being significantly shorter than the Cr···Ce separation in $[Cr\{(NH_2)_2sar\}][Ce(dipic)_3]\cdot 8H_2O$ (7.054(2) Å)[1b] and the Co–Eu separation in $[Co(sar)][Eu(dipic)_3]\cdot 13H_2O$ [6.733(3) Å – note an incorrect minimum of 7.408(3) Å was quoted in ref.[1a]], though still much longer than the Cs–Eu separation in $Cs_3[Eu(dipic)_3]\cdot 9H_2O$ [4.584(2) Å][1a] (where the Cs is directly coordinated to dipicolinate oxygen atoms). The relatively short Co···Ln approaches in the present compounds (and note that, for all, there is another only slightly longer) presumably reflects the fact that some of the coordinated ammonia ligands appear to be involved in direct hydrogen bonding to dipicolinate oxygen atoms though, as indicated by the Co···Pr separations in the pentahydrate and decahydrate species, 6.1629(6) and 5.9143(9) Å, respectively, water also acts as a "glue" which is more effective the greater its abundance. It is also notable that in the series of hydrated sodium salts, $Na_3[Ln(dipic)_3]\cdot x H_2O$,[17–20] the shorter Ln..Ln separations occur in the lattices of the earlier and larger Ln^{3+} ions, again in association with a (here, slightly) higher degree of hydration. The subtleties of these issues are further illustrated by the facts that: (i) in the $[Cr\{(NH_2)_2sar\}][Ln(dipic)_3]\cdot 8H_2O$ series,[1b] Cr···Lu [7.097(5) Å] is longer than its counterpart Cr···La [7.051(7) Å], while Cr···La (x, $y-1$, z), at 7.097(9) Å contracts to a counterpart Cr···Lu value of 6.991(6) Å; (ii) that in the present $[Co(NH_3)_6][Ln(dipic)_3]\cdot 10H_2O$ family, the minimum Co···Ln [5.9143(5) (Pr), 5.880(1) (Sm), 5.8747(9) (Tb), 5.8719(4) Å (Er)] decreases in agreement with the lanthanide contraction but by an amount which is les than half the change in Ln-donor atom bond lengths. The lanthanide-transition metal ion separations observed in the present system must be close to the minima possible if both metals are to retain independent coordination environments but they considerably exceed the separations found between lanthanide ions in binuclear calixarene complexes where significant but very weak metal-metal interactions can be detected.[28]

Crystals of $[Co(NH_3)_6]dipic\cdot Cl\cdot 2H_2O$ (**1**) were first isolated as a result of decomposition reactions occurring during first attempts to recrystallise $[Co(NH_3)_6][La(dipic)_3]$, though it was discovered after the structural study had been completed that orange, needle-like crystals of the same material slowly deposited on simply mixing solutions of $[Co(NH_3)_6]Cl_3$ and disodium dipicolinate. A representation

of the structure, viewed down *a*, is given in Figure 3(a). An unusual feature is that three formula units constitute the asymmetric unit. Viewed parallel to the *a* axis, the three inequivalent units appear to be related by pseudo-2_1-screw operations parallel to *c* but this is only approximately true for one of the units, and both the number of "observed" reflections and systematic absences are inconsistent with a smaller cell. Throughout the cell, in a sheet about $y = 0.5$,

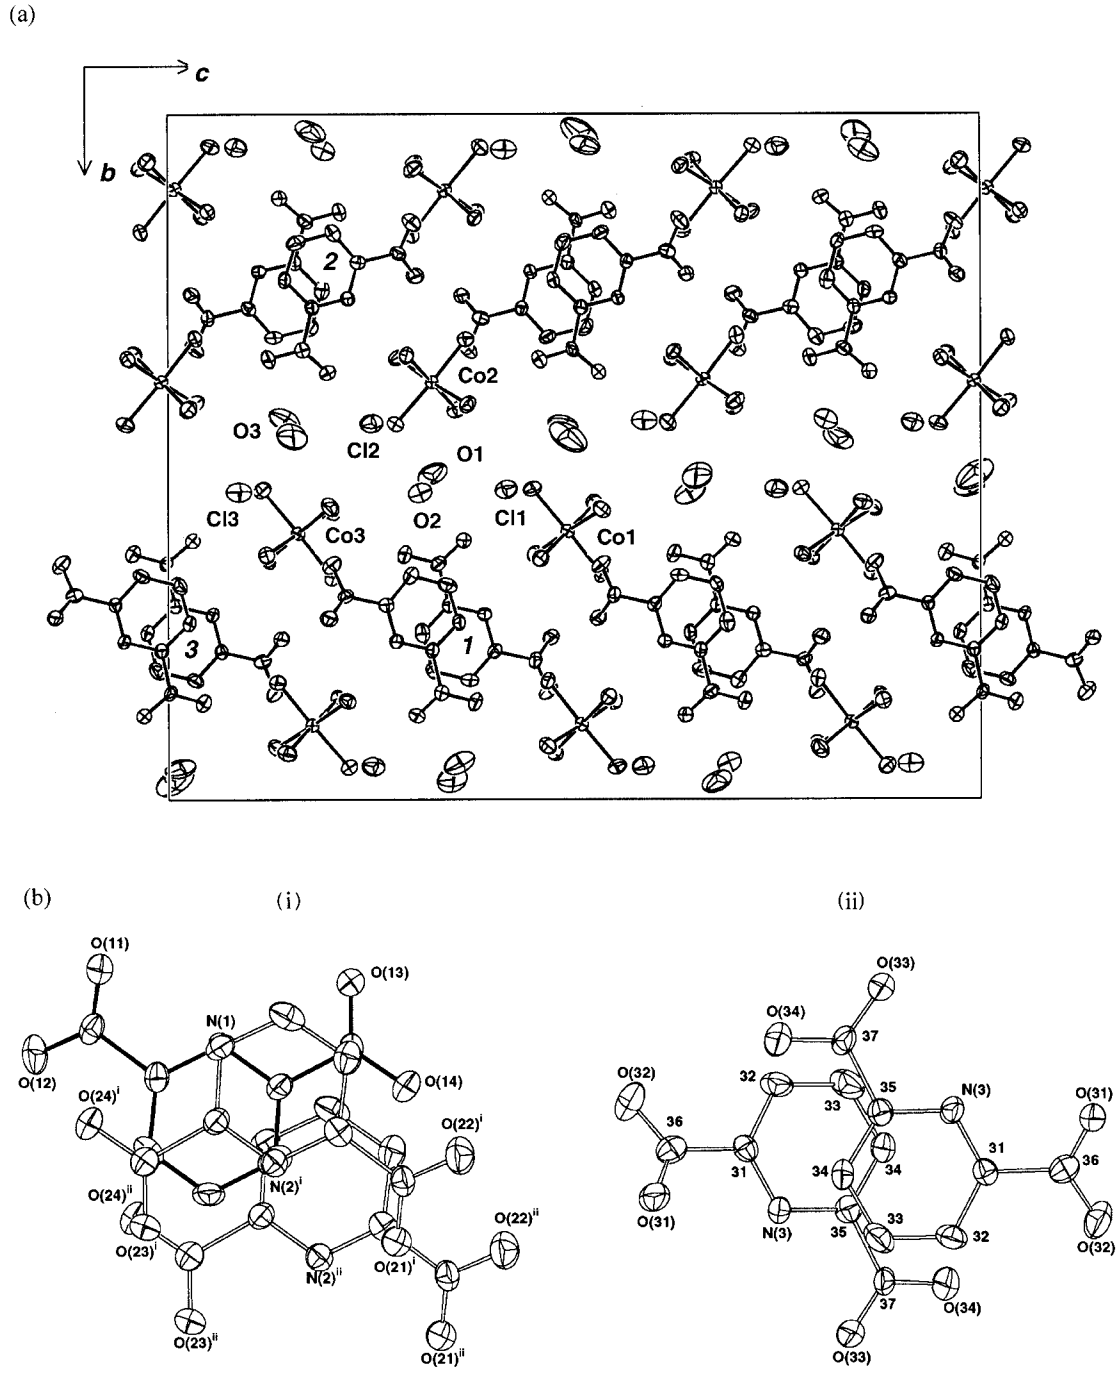

Figure 3. (a) Unit cell contents of $[Co(NH_3)_6]$dipic·Cl·$2H_2O$ (**1**), projected down *a*. (b) Interanion overlaps between; (i) anions 1 and 2, perpendicular to the aromatic plane of anion 1 (i: $1 - x$, $^1/_2 + y$, $^1/_2 - z$; ii: $2 - x$, $^1/_2 + y$, $^1/_2 - z$). N(1) contacts C(Ar) of ligand 2^i at 3.360(9), N(2^i) C(Ar) of ligand 1 at 3.387(9), the latter also contacting C(Ar) of ligand 2^{ii} at 3.54(1) Å.; (ii) anion 3 and its image ($x - ^1/_2$, $^3/_2 + y$, $\bar{z}$); C(34)···C(35) is 3.496(9) Å.

there is a complicated hydrogen-bonding network involving the water molecules, chloride and carboxylate anions and the ammonia groups of the cations. This is a common situation in "crystallised ion pairs" of polycarboxylate anions and amine complexes[29] and the very complicated nature of the system contrasts with the rather elegant simplicity of other systems incorporating polyamidinium cations and polycarboxylates.[30] by (presumed) hydrogen-bonding interactions, the "inner" oxygen atoms of a dipicolinate anion *quasi*-chelate one hexamminecobalt(III) cation while the outer oxygen atoms bridge to other hexammine cations. In the view presented in Figure 3(a), it is apparent that the dipicolinate entities lie in columns, with one molecule projecting upon the next in its column in a manner suggestive of π-stacking interactions, consistent with the fact that when viewed down *b*, the dipicolinates form undulating sheets *a*/2 = 3.56 Å apart. This is to ignore some subtleties of the array, however, in that there are dipicolinate columns down *a* of three types, two with the dipicolinate ring planes close to parallel but with their ring plane vectors oppositely oriented relative to *a* and one where the ring plane orientations alternate down the column between those of the other columns. These are associated with three types of adjacent ring projections and thus different short interatomic approaches, as shown in Figure 3(b). The anion array is quite reminiscent of that known for the sodium complex, [Na(dipicH)(dipicH$_2$)(OH$_2$)$_3$],[31] where layers are separated by *a*/2 = 3.44 Å. Dipicolinate stacking is also apparent in the lattice of [Eu(dipicH)(dipic)(OH$_2$)$_2$] and its congeners.[14]

Powder Diffraction Studies of Hydration

The powder diffraction pattern predicted[32–34] from the single crystal structure determined for [Co(NH$_3$)$_6$][Ce(dipic)$_3$]·5H$_2$O (**3a**) was in good agreement with that observed for the bulk sample rapidly crystallised from water and stored under ambient (low humidity) conditions, indicating that the pentahydrate phase may be readily isolated. On the first occasion that several members of the complete [Co(NH$_3$)$_6$][Ln(dipic)$_3$]·*x*H$_2$O series were isolated under essentially identical conditions, the La (**2**), Ce (**3**) and Pr (**4a**) compounds all gave this powder pattern. However, a clearly different powder pattern was observed for the Sm (**5**) and Eu derivatives and yet another for the Dy, Ho and Yb derivatives. The 2θ angles of the most intense peak in these powder spectra were found to be 8.70–8.80° for La, Ce, Pr, 8.25–8.30° for Sm and Eu, and 9.35–9.40° for Dy, Ho and Yb but after the Sm and Ho compounds, for example, had been heated at 50 °C under vacuum for several hours, both provided a powder pattern with the most intense peak having 2θ = 8.75°. Extended, later studies of the complete series showed that if the samples were thoroughly ground prior to the recording of powder diffraction spectra (so, presumably, allowing rapid equilibration of crystal hydrate water with atmospheric humidity), the powder patterns for all compounds were close to that predicted for the pentahydrate phase. The facts that subsequent crystal structure determinations (described above and to be reported elsewhere) showed that other (higher) hydrates could be isolated at least as larger crystals and that the predicted powder pattern for the Lu species[33] closely corresponded to that first observed for the Dy, Ho and Yb compounds we interpret, in conjunction with the first observations, as indicating that the [Co(NH$_3$)$_6$][Ln(dipic)$_3$] compounds may precipitate as various hydrate mixtures but that the pentahydrate phase is preferred for the solid materials stored under ambient conditions.

Thermogravimetry

Qualitatively, thermograms over the range of ca. 25–800 °C obtained for all the [Co(NH$_3$)$_6$][Ln(dipic)$_3$]·*x*H$_2$O compounds were identical, showing the features expected from the behaviour of related, simpler compounds. Data for the Ln = La and Lu compounds are shown in Figure 4(a). The major mass change between 400–470 °C is associated with evolution of heat and corresponds with the major exotherm observed for [Co(NH$_3$)$_6$]dipic·Cl·2H$_2$O (**1**), so that

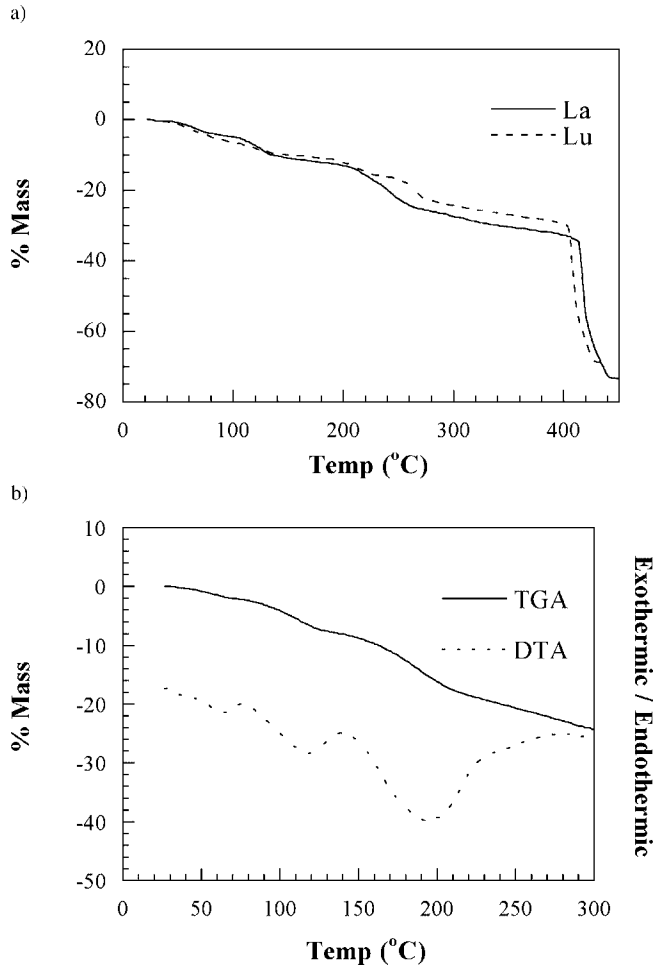

Figure 4. (a) Mass changes during thermal decomposition of [Co(NH$_3$)$_6$][Ln(dipic)$_3$]·*x*H$_2$O (Ln = La, Lu) in air. (b) Initial mass changes during thermal decomposition of [Co(NH$_3$)$_6$][Ce(dipic)$_3$] ≈ 6H$_2$O in air.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

we assume it to reflect the oxidative decomposition of dipicolinate.[10] The significantly endothermic events occurring between ca.200 and 300 °C are similar to those of both **1** and $[Co(NH_3)_6]Cl_3$ in this range (note that the latter complex displays no strong exotherm at higher temperatures) and are thus associated with at least the final steps in the decomposition of the $[Co(NH_3)_6]^{3+}$ moiety. The mass changes below ca. 200 °C, all of them associated with weak endotherms, were of particular interest given the crystallographic characterisation of different hydrates across the rare earth series but from observation of the mass changes alone and without monitoring of the evolved gases, it is not possible to clearly distinguish water and ammonia loss processes in this range. However, the most readily induced changes (below 100 °C) can be reversed by exposure of the solids to humid air, so that it is assumed that these are simply associated with reversible dehydration. A thermogram for the Ln = Ce compound between ambient temperature and 250 °C is shown in Figure 4(b). The starting material for this experiment was previously equilibrated in air of 75% relative humidity (298 K)[36] to ensure a reproducible composition, though microanalyses (C, H, N) indicated a formulation intermediate between that of a hexahydrate and a pentahydrate and presumably the bulk sample may have contained several phases. Repetitive thermograms provided the mean results of a near mass plateau at 75 ± 10 °C corresponding to a weight loss of 4.8 ± 0.9% (i.e., ≈ $2H_2O$) and another at 113 ± 5 °C corresponding to a total weight loss of 12.2 ± 1.4% (i.e., ≈ $6H_2O$ overall, though a contribution from ammonia loss cannot be excluded). The stepwise loss of water is consistent with the fact that the crystal structure determination on the pentahydrate shows that the lattice water molecules are in inequivalent sites, so that some differences in their rates of thermal release would be expected.

After being heated to 600 °C or higher in air, all the $[Co(NH_3)_6][Ln(dipic)_3]\cdot x H_2O$ solids were converted to black powders for which microanalysis showed negligible carbon and nitrogen contents. Powder diffractometry (see below) confirmed that these powders were metal oxides. Scanning electron micrographs of the products obtained after ca. 15 min at 600 °C from the Pr and Lu compounds showed the different products to have different particle morphologies but with a similar mean particle size ca.2 μm.

Powder Diffractometry of Thermal Decomposition Products

Phase equilibria in Co/Ln/O systems have been thoroughly studied,[12] so that it was anticipated that perovskite, $CoLnO_3$, materials might be observed as the products of the thermal decomposition reactions. Powder diffractometry showed this expectation to be justified, though, again as expected, generation of the perovskite phase from the separate monometallic oxides appeared to become more difficult in progressing from the lighter to the heavier rare earths. Thus, under the conditions of our experiments, only Co_3O_4 and Ln_2O_3 could be detected as products for Ln = Yb, Lu. In fact, Co_3O_4 and Ln_2O_3 were the initial products in all cases, indicating that there could be no particular advantage to synthesis of the perovskites by thermal decomposition of $[Co(NH_3)_6][Ln(dipic)_3]\cdot x H_2O$ rather than by direct reaction of the oxides. This initial formation of separate oxide phases may be consistent with the observed decomposition during attempted recrystallisation in that dipicolinate release could result from the (solid state) hydrolysis reaction

$$[Ln(dipic)_3]^{3-} + 3H_2O \rightarrow [Ln(OH)_3] + 3Hdipic^-$$

giving a separate rare earth phase prior to any decomposition of the $[Co(NH_3)_6]^{3+}$ unit. The self-association of "free" dipicolinate units through π-stacking may be a factor favouring the early occurrence of this reaction. The kinetic inertness and high stability of the $[Co(NH_3)_6]^{3+}$ cation is probably another reason why a dipicolinate-bridged Co/Ln species which might smoothly transform to a mixed oxide is not formed.

2. Chromium/Rare Earth Systems

The $[Cr(en)_3][Ln(dipic)_3]\cdot x H_2O$ solids are all light-sensitive and the initially clear-yellow crystals precipitated from aqueous solution turn violet within several hours on exposure to normal ambient levels of illumination. For this reason, we have made a study of only a few members of the series to ensure that there are no dramatic differences in thermal behaviour from that of their $[Cr(urea)_6][Ln(dipic)_3]\cdot x H_2O$ analogues (which, as expected, are much less light-sensitive). The green $[Cr(urea)_6][Ln(dipic)_3]\cdot x H_2O$ compounds are particularly insoluble, precipitating very rapidly as powders, and we have been unable yet to grow crystals suitable for single-crystal structure determinations. However, their powder diffractograms show a common pattern of lines for the whole series, indicating a common hydrate stoichiometry (x = 7 on the basis of microanalysis).

Thermogravimetry

Weight losses and heat exchanges occurring on heating samples of both $[Cr(en)_3][Ln(dipic)_3]$ and $[Cr(urea)_6][Ln(dipic)_3]$ compounds are unremarkable and, as with the $[Co(NH_3)_6][Ln(dipic)_3]$ compounds, the most prominent feature of the thermograms is the major mass loss and exotherm initiated near 450 °C, again assumed to be associated with decomposition of the dipicolinate units. The chemical properties of the oxide products obtained at this point appeared to be independent of the particular precursor used (at least in the cases of Ln = La, Pr, Eu, Yb and Y) but the changes occurring on further heating at higher temperatures were considerably more complicated than in the Co systems. They were studied in detail for the products from the $[Cr(urea)_6][Ln(dipic)_3]$ precursors using powder diffractometry of the solids after periods of oven-heating at various temperatures between 450 and 900 °C.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Powder Diffractometry of Thermal Decomposition Products

Phase equilibria are again well-characterised for Cr/Ln/O systems,[12] so that the formation of both "chromate", $LnCrO_4$, and "chromite" (perovskite), $LnCrO_3$, solids was expected. Excepting only $[Cr(urea)_6][Ce(dipic)_3]$, which gave rise to a stable mixture of CeO_2 and Cr_2O_3, this was the case for all the compounds studied. A significant difference from the Co systems, however, was that the separate monometallic oxide phases could not be detected as intermediate products prior to the formation of the chromate or chromite phases. This may reflect a greater lability of the Cr^{III} cations compared to $[Co(NH_3)_6]^{3+}$, so that a dipicolinate-oxygen-bridged species, say, may be produced early on in the decomposition, although another significant observation is that the chromates, formally containing a Cr^{V} species, appear to be produced prior to the chromites, formally containing Cr^{III} (as in the reactant). It is difficult to establish the exact sequence of events near the actual point of oxide formation, since the product formed between 450 and 500 °C (following the major dipicolinate exotherm) is black or very dark green in colour and apparently amorphous, giving very broad lines in its X-ray diffraction pattern and an increase in temperature and/or prolonged heating are required to form materials giving identifiable powder diffraction lines. In general, nonetheless, the amorphous black initial product undergoes a conversion to a dark green, crystalline chromate phase (which is dimorphic) and then to an olive-green, crystalline chromite phase. Table 2 contains a summary of observations across the full series of compounds. Included are our measurements made to date of surface areas of the oxides, showing that high surface area materials can be readily produced through these decomposition reactions. Also interesting in relation to catalytic activity of the mixed oxides is the fact that in early experiments conducted in crucibles with (loose fitting) lids, the chromate species were observed to persist to higher temperatures. Assuming the lid to cause retention of CO_2 generated during the dipicolinate decomposition, this may indicate that the oxides effectively catalyse the CO_2/CO interconversion.

In the particular case of the thermal decomposition of $[Cr(urea)_6][Nd(dipic)_3]$, careful observation of the powder patterns of the products produced between 450 °C and 550 °C provided evidence for the hitherto unknown monazite phase of neodymium chromate being produced along with the known zircon phase. Rietveld refinement confirmed the presence of both monoclinic monazite-type [a = 6.9226(7), b = 7.1148(7), c = 6.6088(6) Å, β = 105.318(6)°, V = 313.94(7) Å^3] and tetragonal zircon-type [a = 7.3101(3), c = 6.3982(3) Å, V = 341.91(4) Å^3] in a sample prepared

under optimum conditions of one hour's heating at 530 °C. These well-known ABO_4-type structures, which consist of alternating [001] stacks of AO_9 polyhedra and BO_4 tetrahedra (monazite) or AO_8 and BO_4 groups (zircon) have been described in detail elsewhere.[37,38] In both structures, which are nominally related by tetrahedral rotations about [001], the O atoms are three coordinate to two rare earth cations and one tetrahedral cation. This is the first report of the monazite form of $NdCrO_4$, though the precision of the atomic positional parameters and derived geometrical data is only mediocre and neutron diffraction data would be required for a high-precision structure determination of monoclinic $NdCrO_4$. The tetragonal $NdCrO_4$ cell parameters are in good accordance with those determined earlier (a = 7.315, c = 6.399 Å) from X-ray powder data.[39] Comparison of phase fraction scale factors indicated that the ratios of the two phases in the mixture analysed was approximately 1:1. So far, we have not been able to prepare the monazite form in greater purity.

Thus, the monazite structure is now confirmed for $LnCrO_4$ (Ln = La, Pr and Nd) and the zircon structure for Ln = Pr to Yb (excluding Pm and Tm). A plot[40] of ^3V (V = unit cell volume) vs. ionic radius of the rare earth cations (Figure 5) shows smooth, approximately linear relationships for each of the two structure types. The overall trend for the $LnCrO_4$ phases is comparable to the situation for the $LnPO_4$ family,[37] where the break point between the large lanthanide (monazite) and small lanthanide (xenotime/zircon) structures occurs between Gd and Tb. Unlike the phosphates, two of the chromates, $PrCrO_4$ and $NdCrO_4$, show polymorphism between these two forms. The monazite-type polymorphs of $PrCrO_4$ and $NdCrO_4$ have smaller unit cell volumes (by ≈ 8.4 and 9.0%, respectively) than their zircon modifications, even though the rare earth cations have a higher coordination number in the monazite phases. This phenomenon has also been observed for the monazite and zircon polymorphs of thorium silicate, $ThSiO_4$, and correlated with void space and short O..O contacts in the zircon-type phase.[41] Another phase which shows polymorphism between monazite and zircon forms is $CeVO_4$.[38] The stable room-temperature polymorph of this material is monazite, with the zircon form stable above ≈ 1300 °C at ambient pressure. Under more extreme conditions ($T >$ ≈ 500 °C, $P >$ ≈ 27 kbar), $CeVO_4$ transforms again to the scheelite ($CaWO_4$) structure.

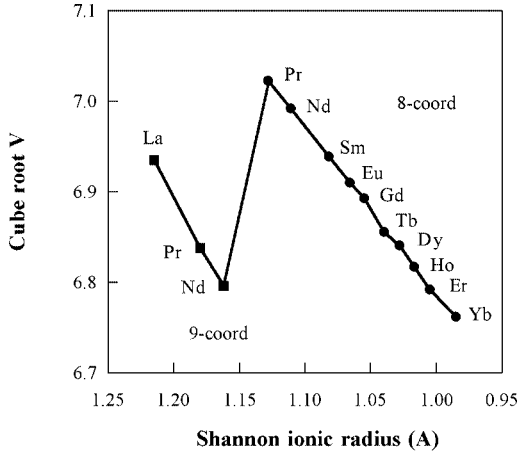

Figure 5. The relationship between unit cell volume and estimated cation radius for the monazite and zircon families of rare earth chromates.

Oxide Phase Magnetic Properties

Measurements (deposited as Supporting information; for supporting information see also the footnote on the first page of this article) of magnetic susceptibility on a selection for both the Co and Cr containing mixed oxides provided no evidence of significant differences from known data[42] for the same oxides prepared by conventional methods, and hence were not pursued in detail.

Conclusions

The work described herein provides evidence that the dipicolinate anion, whether coordinated to the proton or to metal ions, can undergo self-association through mechanisms[22–24] associated with its aromatic character, which do not directly involve the formally recognised donor and acceptor groups (N, O and hydroxy H atoms). There is, of course, very substantial evidence in solid-state structures[1,5,17–21,28,43] of its capacity to promote oligomerisation through bridging coordination of the carboxylate groups, and facts such as the solvatochromism of the complex $[Fe(dipic)_2]^{2-}$[31] show that at least some other association mechanisms must remain effective in solution. A substantial remaining problem, recently recognised in general terms for both solid[23] and solution[44] systems, is to conduct a quantitative partitioning of the factors operative in any particular case of "supermolecule" formation. The present work provides at least circumstantial evidence that the energies of inter-dipicolinate interactions are sufficiently great to influence solid state reaction rates.

Experimental Section

General: Thermogravimetry: Weight loss and associated thermal changes resulting when ca. 20 mg samples of the complexes were heated between ca. 25 and 800 °C under air were monitored with a Rigaku "Thermoflex" instrument. Magnetometry: Measurements were made with a SQUID magnetometer (Quantum Design MPMS-7) at a magnetic field strength of 12 T in the temperature range 5–300 K. Samples were formed as small discs by compression of the powdered solids. Surface Area Determination: Surface areas for nitrogen adsorption were determined by the BET method on a Micrometer Gemini 2360 Surface Area Analyser, with a free space correction made using He.

Synthesis of the Precursor Complexes: Precipitation of $[Ln(dipic)_3]^{3-}$ anions from aqueous solution by the addition of cations such as $[Co(NH_3)_6]^{3+}$, $[Cr(en)_3]^{3+}$ and $[Cr(urea)_6]^{3+}$ is very efficient and we have previously described[1] the very simple syntheses of the resulting microcrystalline materials. In early attempts to prepare larger crystals of the various $[Co(NH_3)_6][Ln(dipic)_3]\cdot x\,H_2O$ solids

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

by digestion in the preparative supernatant solution and by recrystallisation from water, the Ln = La compound, in particular, was observed to be rather readily decomposed. In one apparently decomposed sample, however, orange crystals were found to be present and were then identified through crystallographic study as $[Co(NH_3)_6]$dipic·Cl·2 H_2O (**1**). In fact, this material is rather readily precipitated by simple addition of a molar equivalent of Na_2dipic to an aqueous solution of $[Co(NH_3)_6]Cl_3$, analysis of the bulk solid suggesting a slightly higher degree of hydration than deduced from the structure solution. (Found C 20.8, H 6.3, N 24.4; calculated for $C_7H_{21}ClCoN_7O_4$·2 H_2O: C 21.14, H 6.34, N 24.65; for $C_7H_{21}ClCoN_7O_4$·2.5 H_2O: C 20.67, H 6.44, N 24.11.)

Attempts, by numerous variations on liquid and vapour diffusion procedures, to obtain diffraction quality specimens of $[Co(NH_3)_6]$-$[Ln(dipic)_3]$·x H_2O for the full Ln series in an effort to systematically define phases present and their domains of existence yielded results that are erratic, the factors which determine the form of the solids remaining obscure. The principal method adopted for the growth of quite large crystals (sometimes 1 mm on edge) of all the $[Co(NH_3)_6][Ln(dipic)_3]$·$x$ H_2O compounds was to form a solution of the initial precipitate by slow addition of dilute HCl to its slurry with water until dissolution just occurred. (This was readily achieved with all the compounds up to Ln = Nd but with the heavier lanthanides it was apparent that an acid insoluble species, probably $[Ln(dipicH)(dipic)(OH_2)_2]$,[14] was formed, so that the initial solution, even when as dilute as 20 mg in 10 mL, was slightly cloudy. Fortunately, this did not seem to affect the quality of the crystals ultimately formed, though removal of this faint precipitate presumably decreased the recovery). After gravity filtration, this solution was then placed in a vapour diffusion cell with dilute aqueous ammonia in the outer compartment and the system allowed to stand under ambient conditions for extended periods. Several of the crystals used (particularly those involving the heavier rare earths, where there was a tendency for very long, thin needles to form) in the present structural studies were obtained only after more than a year of standing in contact with their supernatant solutions. Even then, for some elements no useful material was obtained at all.

Attempts to apply the above procedure for the growth of larger crystals of the $[Cr(urea)_6][Ln(dipic)_3]$ series were successful to the extent that materials obviously crystalline to the naked eye could be obtained but the crystals remained too small for single-crystal X-ray studies. Prolonged standing in the reaction mixture was to no advantage due to the hydrolysis of the $[Cr(urea)_6]^{3+}$ cation, which caused the initially deposited green crystals to redissolve and colourless crystalline solids to form under a violet supernatant solution. In the case of $[Cr(urea)_6][Eu(dipic)_3]$, a crystal drawn from the final product mass was characterised as [Eu(dipicH)(dipic)-$(OH_2)_2$]·4 H_2O, at the time of its isolation a new member of this Ln series, though its structure has since been determined.[14]

Powder Diffractometry: Measurements were made with a Siemens "Kristalloflex" D5000 diffractometer. For determination of the neodymium chromate structure, step-scan powder data were collected for 15°< 2θ < 100° (step size 0.02°, 8 s counting time per point) with Cu-K_α radiation, $\lambda = 1.5417_8$ Å, $T = 298(2)$ K. Rietveld refinement was carried out using the GSAS[35] suite of programs, with starting atomic models for the monazite (space group $P2_1/n$) and zircon (space roup $I4_1/amd$) forms of $NdCrO_4$ taken from the structures of monoclinic $PrPO_4$[37] and tetragonal $NdCrO_4$,[45] repectively. The profile (unit cells, zero-point error, 6-term background polynomial descriptors, pseudo-Voigt peak-shape parameters) and atomic parameters were progressively added to the model as variables in the usual fashion. The refinement converged to yield residuals, as defined in ref.[35] of $R_p = 8.75\%$, $R_{wp} = 11.94\%$, $R(F^2) = 5.78\%$ and $\chi^2 = 2.33$ (50 parameters, 424 reflections, 4248 profile points). The final observed, calculated and difference profiles are illustrated in Figure 6.

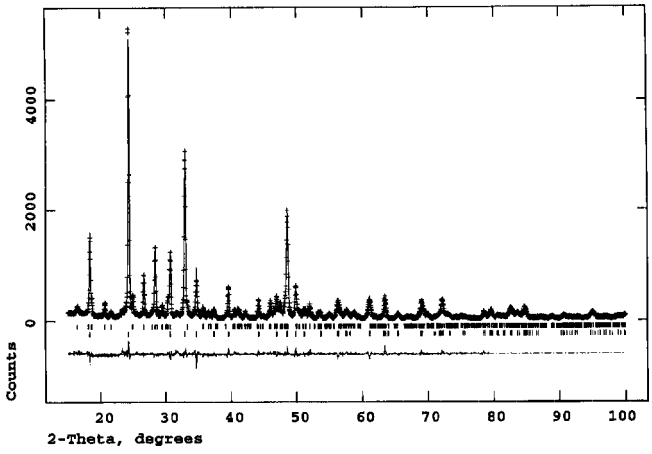

Figure 6. Observed, calculated (Rietveld) and difference intensity profiles for the powder X-ray diffraction pattern of $NdCrO_4$.

Room Temperature Single Crystal X-ray Structure Determinations: The structures of $[Co(NH_3)_6]$dipic·Cl·2 H_2O (**1**) and $[Co(NH_3)_6]$-$[Ce(dipic)_3]$·5 H_2O (**3a**) were determined first in Barcelona. Data sets (Enraf–Nonius CAD4 diffractometer; ω-scan mode; graphite-filtered Mo-K_α radiation, $\lambda = 0.7107_3$ Å) were measured at 293(2) K, with ψ-scan absorption corrections.

Structural studies of the $[Co(NH_3)_6][Ln(dipic)_3]$·$x$ H_2O series were extended in Western Australia (Ln = La(**2**), Ce(**3**), Pr(**4a**) (x = 5); Ln = Pr(**4b**), Sm(**5**), Tb(**6**), Er(**7**), Y(**8**) (x = 10); Ln = Tm(**9**), Lu(**10**) (x = 8.5). The frequent assumption that arrays of rare earth complexes can be adequately represented by studies of a single member or, alternatively, "early" and "late" members, has been effectively demolished as a reasonable presumption by studies of series such as the picrates[47–50] or chloride/terpyridyl[51] complexes (which is not to say that there are not series, such as the triflates,[52] which are represented by a single invariant, unambiguous structural type). The present array is no exception, offering suggestions of a series of subtlety comparable to that of the picrates, though more severe practical difficulties in respect of accessing appropriately crystalline specimens intrude here. As noted above, the gadolinium, terbium and lutetium specimens, for example, were grown by digestion at room temperature on a time scale of years (following slow precipitation over days by pH variation), and in most other cases several months' wait was involved. For several early samples, room temperature, single counter "four circle" diffractometer data sets were measured ($2\theta_{max}$ as specified; $2\theta/\theta$ scan mode; monochromatic Mo-K_α radiation, $\lambda = 0.7107_3$ Å; $T \approx$ 295 K), $N_{t(otal)}$ symmetry-equivalent reflections (where appropriate) being merged to N_r (unique) (R_{int} as quoted), N_o with $I > 3\sigma(I)$ being considered "observed" and used in the full-matrix, least-squares refinement on $|F|$ after Gaussian absorption correction. Conventional residuals R, R_w [statistical weights derivative of $\sigma^2(I) = \sigma^2(I_{diff}) + 0.0004\sigma^4(I_{diff})$] are quoted at convergence, neutral atom complex scattering factors being employed, computation using the Xtal 3.4 program system.[53] Significant nontrivial difference map residues were modelled as water molecule oxygen fragments, site occupancies being established by refinement; not infrequently, hydrogen atom dispositions could not be established with any cer-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tainty in association with fractionally occupied or "thermally smeared" fragments. For the extrema of the three major families, pertinent results are presented in the Figures and Tables, the latter showing the displacement envelopes for the non-hydrogen atoms at the 50% probability amplitude level, hydrogen atoms (where shown) having arbitrary radii of 0.1 Å.

A number of the determinations presented here were only finally accessible with the advent of an area-detector facility (Bruker AXS CCD instrument), spheres of data being measured at $T \approx 300$ K; preliminary data processing was carried out using proprietary software incorporating "empirical"/multiscan absorption correction, refinement using the Xtal 3.7 program system.[53]

Crystal/Refinement Data

1: $[Co(NH_3)_6]$dipic·Cl·2 H_2O, $C_7H_{25}ClCoN_7O_6$, M = 397.7, orthorhombic, space group $P2_12_12_1$ (D_2^4, No. 19), Z = 12, a = 7.123(1), b = 24.099(1), c = 28.670(2) Å, V = 4921 Å^3. $D_{calcd.}$ = 1.61$_1$ g cm^{-3}; μ_{Mo} = 12.5 cm^{-1}; specimen: 0.54 × 0.31 × 0.10 mm; $T_{min./max.}$ = 0.84. $2\theta_{max.}$ = 61°; N_t = 8408, N_r = 8623 (R_{int} = 0.107), N_o = 6408; R = 0.048, R_w = 0.121; n_v = 493, $|\Delta\rho_{max}|$ = 0.78 e Å^{-3}, $x_{abs.}$ = 0.24(2).

$[Co(NH_3)_6][Ln(dipic)_3]\cdot x\,H_2O$, $C_{21}H_{27}CoLnN_9O_{12}\cdot x\,H_2O$, triclinic, space group $P\bar{1}$ (C_i^1, No. 2), Z = 2.

(a) x = 5

2: Ln = La. M = 885.4. a = 10.454(5), b = 12.593(9), c = 13.438(7) Å, α = 102.69(5), β = 94.48(4), γ = 104.39(5)°, V = 1655 Å^3. $D_{calcd.}$ = 1.77$_6$ g cm^{-3}; μ_{Mo} = 18.6 cm^{-1}; specimen: 0.58 × 0.32 × 0.65 mm; $T_{min/max}$ = 0.63. $2\theta_{max}$ = 55°; N_t = 10703, N_r = 7591 (R_{int} = 0.025), N_o = 7064; R = 0.026, R_w = 0.037; n_v = 575, $|\Delta\rho_{max}|$ = 1.4 e Å^{-3}.

Variata: (x, y, z, U_{iso})$_H$ were refined throughout, except O(4,5) (water), for which they could not be definitively established. A further hemisphere of data was measured to $2\theta_{max}$ = 45°, hence R_{int} is quoted.

3: Ln = Ce. M = 886.6. a = 10.432(2), b = 12.583(2), c = 13.427(4) Å, α = 102.72(2), β = 94.32(2), γ = 104.27(2)°, V = 1651 Å^3. $D_{calcd.}$ = 1.78$_4$ g cm^{-3}; μ_{Mo} = 19.5 cm^{-1}; specimen: 0.24 × 0.19 × 0.14 mm; $T_{min/max}$ = 0.79 × $2\theta_{max}$ = 61°; N_t ($2\theta_{max}$ = 61°) = 10430, N_r = 9929, N_o = 4197; R = 0.071, R_w = 0.153; n_v = 448, $|\Delta\rho_{max}|$ = 1.4 e Å^{-3}.

Variata: Study of this complex (and of $[Co(NH_3)_6]$dipic·Cl·2 H_2O), undertaken in Barcelona, initiated the present series of determinations, the precision of which is improved for other Ln extending the domain of this phase. One attempt to improve crystal quality for the Ce species yielded better material but of a new, nonahydrate phase, described elsewhere.[15]

4a: Ln = Pr. M = 887.4. a = 10.4500(7), b = 12.5988(8), c = 13.4262(9) Å, α = 102.750(1), β = 94.180(1), γ = 104.305(1)°, V = 1655 Å^3. $D_{calcd.}$ = 1.78$_0$ g cm^{-3}; μ_{Mo} = 20.4 cm^{-1}; specimen: 0.30 × 0.20 × 0.12 mm; $T_{min/max}$ = 0.77. $2\theta_{max}$ = 58°; N_t (CCD data) = 22325, N_r = 8116 (R_{int} = 0.021), N_o [$F > 4\sigma(F)$] = 6830; R = 0.024, R_w = 0.030; n_v = 590, $|\Delta\rho_{max}|$ = 1.4 e Å^{-3}.

Variata: (x, y, z, U_{iso})$_H$ (all H) were refined. The unit cell dimensions of the Pr derivative are surprisingly similar to those of the La derivative, notwithstanding the clear and expected differences found in the Ln-N,O distances of the Ln coordination environments.

(b) x = 10

4b: Ln = Pr. M = 977.5. a = 16.416(1), b = 11.374(1), c = 11.0082(7) Å, α = 88.300(1), β = 72.577(1), γ = 70.863(1)°, V = 1847 Å^3. $D_{calcd.}$ = 1.75$_7$ g cm^{-3}; μ_{Mo} = 18.5 cm^{-1}; specimen: 0.29 × 0.20 × 0.18 mm; $T_{min/max}$ = 0.59 × $2\theta_{max}$ = 58°; N_t (CCD data) = 20623, N_r = 8994 (R_{int} = 0.068), N_o [$F > 4\sigma(F)$] = 7160; R = 0.078, R_w = 0.100; n_v = 481, $|\Delta\rho_{max}|$ = 5.9 e Å^{-3}.

Variata: Determinations of the members of this phase, although generally with larger specimen size, are inherently less precise than those of some other phases. Displacement parameters throughout the water molecules are generally high, some being modelled only with difficulty; associated hydrogen atoms were defined with reasonable certainty [though not for O(5,9)] but not refined, for the Ln = Er study, the present heavy and most precisely defined extremum.

5: Ln = Sm. M = 986.9. a = 16.302(6), b = 11.237(2), c = 10.978(2) Å, α = 88.26(1), β = 72.54(2), γ = 71.07(2)°, V = 1810 Å^3. $D_{calcd.}$ = 1.81$_1$ g cm^{-3}; μ_{Mo} = 21.6 cm^{-1}; specimen: 0.50 × 0.15 × 0.30 mm; $T_{min/max}$ = 0.83. $2\theta_{max}$ = 50°; N_t (sphere) = 12239, N_r = 6351 (R_{int} = 0.041), N_o [$I > 3\sigma(I)$] = 5735; R = 0.054, R_w = 0.074; n_v = 491, $|\Delta\rho_{max}|$ = 3.4 e Å^{-3}.

6: Ln = Tb. M = 995.5. a = 16.250(3), b = 11.227(1), c = 10.977(2) Å, α = 88.36(1), β = 72.48(2), γ = 71.23(1)°, V = 1803 Å^3. $D_{calcd.}$ = 1.83$_3$ g cm^{-3}; μ_{Mo} = 25.0 cm^{-1}; specimen: 0.55 × 0.18 × 0.45 mm; $T_{min/max}$ = 0.64. N_t (hemisphere to $2\theta_{max}$ = 50°, further hemisphere to 40°) = 11179, N_r = 8356 (R_{int} = 0.079), N_o [$I > 3\sigma(I)$] = 6851; R = 0.052, R_w = 0.068; n_v = 494, $|\Delta\rho_{max}|$ = 2.2 e Å^{-3}.

Variata: Hydrogen atoms were located in association with water molecule oxygen atoms O(1–3) only, for this adduct and for O(6–8) in addition for the Er adduct, for the Pr, Y and Sm adducts not at all.

7: Ln = Er. M = 1003.8. a = 16.216(2), b = 11.225(1), c = 10.982(1) Å, α = 88.377(2), β = 72.414(2), γ = 71.307(2)°, V = 1800 Å^3. $D_{calcd.}$ = 1.85$_2$ g cm^{-3}; μ_{Mo} = 28.8 cm^{-1}; specimen: 0.74 × 0.40 × 0.15 mm; $T_{min/max}$ = 0.54. $2\theta_{max}$ = 58°; N_t (CCD data) = 20903, N_r = 8768 (R_{int} = 0.035), N_o [$F > 4\sigma(F)$] = 7851; R = 0.039, R_w = 0.049; n_v = 491, $|\Delta\rho_{max}|$ = 3.0 e Å^{-3}.

8: Ln = Y. M = 925.5. a = 16.259(2), b = 11.275(1), c = 10.981(1) Å, α = 88.370(2), β = 72.389(2), γ = 71.239(2)°, V = 1811.$_5$ Å^3. $D_{calcd.}$ = 1.69$_7$ g cm^{-3}; μ_{Mo} = 21.5 cm^{-1}; specimen: 0.50 × 0.30 × 0.30 mm; $T_{min/max}$ = 0.66. $2\theta_{max}$ = 58°; N_t (CCD data) = 20168, N_r = 8886 (R_{int} = 0.036), N_o [$F > 4\sigma(F)$] = 5187; R = 0.060, R_w = 0.067; n_v = 491, $|\Delta\rho_{max}|$ = 2.1 e Å^{-3}.

(c) x = 8.5

9: Ln = Tm. M = 978.5. a = 16.250(6), b = 11.584(4), c = 10.449(4) Å, α = 110.905(9), β = 104.743(9), γ = 96.206(9)°, V = 1733 Å^3. $D_{calcd.}$ = 1.87$_5$ g cm^{-3}; μ_{Mo} = 31.2 cm^{-1}; specimen: 0.17 × 0.11 × 0.07 mm; $T_{min/max}$ = 0.79. $2\theta_{max}$ = 76°; N_t (CCD data) = 34830, N_r = 17907 (R_{int} = 0.033), N_o [$F > 4\sigma(F)$) = 12897; R = 0.041, R_w = 0.043; $|\Delta\rho_{max}|$ = 1.9 e Å^{-3}.

10: Ln = Lu. M = 984.5. a = 16.242(9), b = 11.591(5), c = 10.419(5) Å, α = 110.87(4), β = 104.96(5), γ = 96.05(4)°, V = 1728 Å^3. $D_{calcd.}$ = 1.91$_4$ g cm^{-3}; μ_{Mo} = 34.2 cm^{-1}; specimen: 0.18 × 0.30 × 0.35 mm; $T_{min/max}$ = 0.76. $2\theta_{max}$ = 50°; N_t (sphere) = 12081, N_r = 6091 (R_{int} = 0.069), N_o [$I > 3\sigma(I)$] = 4337; R = 0.048, R_w = 0.061; n_v = 480, $|\Delta\rho_{max}|$ = 2.9 e Å^{-3}.

Variata: The crystal decomposed isotropically by ca. 10% (as determined by periodic measures of standards), compensated by scaling. Water molecule hydrogen atoms were located in association with water molecule oxygen atoms O(1,5) only. O(9) has site occupancy 0.5; in the model for the Tm analogue, O(3–7) were modelled in terms of pairs of resolved fragments, with an additional fragment, "O(10)", hydrogen atoms only being located in association with O(1,2).

11: $[Eu(dipicH)(dipic)(OH_2)_2]_{(\infty|\infty)}\cdot 4H_2O = C_{14}H_{19}EuN_2O_{14}$, M = 591.3. Monoclinic, space group $P2_1/c$ (C_{2h}^5, No. 14), a = 14.002(1), b = 11.2293(9), c = 12.845(1) Å, β = 102.492(1)°, V = 1972 Å^3. $D_{calcd.}$ (Z = 4) = 1.99$_1$ g cm^{-3}; μ_{Mo} = 32.6 cm^{-1}; specimen: 0.15 × 0.15 × 0.15 mm; $T_{min/max}$ = 0.84. $2\theta_{max}$ = 50°; N_t (CCD data) = 21787, N_r = 4999 (R_{int} = 0.025), N_o [$F > 4\sigma(F)$] = 4290; R = 0.025, R_w = 0.019; $|\Delta\rho_{max}|$ = 1.15(6) e Å^{-3}.

Variata: (x, y, z, U_{iso})$_H$ (all H) were refined. At the time of this determination, cell and coordinate settings were based upon those of the known La analogue.[14a,14b] In the present, Eu–N are 2.566(2), 2.564(2) Å, Eu−O(dipic) 2.433(2)–2.512(2) and Eu−O(water) 2.390(2)–2.440(2) Å.

CCDC-252240 to -252251 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Acknowledgments

We thank Dr Jordi Rius (Barcelona) for calculation of the powder X-ray diffraction pattern expected for $[Co(NH_3)_6][Ce(dipic)_3]\cdot 5H_2O$, and the Australian Research Council for partial support of this work.

In vitro Relaxometric and Luminescence Characterization of P792 (Gadomelitol, Vistarem®), an Efficient and Rapid Clearance Blood Pool MRI Contrast Agent

Luce Vander Elst,[a] Isabelle Raynal,[b] Marc Port,[b] Pierre Tisnès,[c] and Robert N. Muller*[a]

Keywords: P792 / MRI contrast agent / NMRD / Luminescence / Oxygen-17 relaxometry

P792 (Gadomelitol, Vistarem®), a hydrophilic high molecular weight (MW = 6473 g/mol) derivative of DOTA-Gd is a rapid clearance blood pool agent (RCBPA) characterized by high proton relaxivities r_1 and r_2 at 310 K in the current range of clinical imaging magnetic fields. Luminescence data of the Eu^{III} complex, as expected for this type of DOTA derivative, agree with the presence of one water molecule in the first coordination sphere of the lanthanide ion. The stability of the water proton longitudinal relaxation rate in the presence of zinc(II) and phosphate ions showed that the transmetallation by Zn^{II} ions is negligible. The temperature dependence of the water oxygen-17 transverse relaxation rate gave a τ_M smaller than 100 ns at 310 K. No significant increase of longitudinal or transverse relaxation rates in serum or HSA solution was noticed, precluding association with high molecular weight blood components. The proton Nuclear Magnetic Relaxation Dispersion (NMRD) profile of the water solution showed a maximum of longitudinal relaxivity between 20 and 40 MHz ($r_1 \approx 40\ s^{-1}\,mM^{-1}$ at 310 K). Fitting of the proton NMRD curve by the classical outersphere and innersphere models, including or not additional second sphere water molecules, gave a rotational correlation time of approximately 2 to 3 ns and a large value of the electronic relaxation time at low field ($\tau_{SO} \approx 500$ ps).
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

The development of new paramagnetic MRI contrast agents with high relaxivity usually involves the decrease of their rotational mobility by covalent or non-covalent binding to endogenous or exogenous macromolecules.[1–5] The resulting bulky contrast agents are confined in the vascular space and their renal excretion is reduced. Recently, medium molecular weight ($MW > 5000$ g/mol) contrast agents based on the DOTA-Gd structure tetra-substituted by hydrophilic arms have been developed. For example, P760 (MW = 5.3 kDa) is a low diffusion agent which extravasates at a slow rate through the vascular endothelium but is freely excreted by the kidneys.[6–8] Due to a long rotational correlation time ($\tau_R \approx 2$ ns at 310 K) its proton relaxivity is quite large, with a maximum around $25\ s^{-1}\,mM^{-1}$ observed between 0.35 and 1.4 T.[9]

Another macromolecular DOTA-Gd structure, P792 (Gadomelitol, Vistarem®, MW = 6.47 kDa) has proved also to be a rapid clearance blood pool agent (RCBPA) (Figure 1) with a limited diffusion across the normal endothelium.[6,8] It is mainly excreted by glomerular filtration and has been reported to be well suited for high-quality first-pass and equilibrium-phase MR angiography,[10] visualization of the coronary arteries and their branches,[11] assessment of viability of infarcted myocardium,[12] differentiation of tumor-bearing lymph nodes from reactive inflammatory and normal nodes,[13] and for the distinction between metastatic and relatively benign cancers.[14] A phase I clinical trial has established its safety in humans.[15] In a previous study,[8] some physicochemical parameters were reported like its high proton relaxivity at 20, 40, and 60 MHz and at body temperature. This work aims at extending these preliminary data with a comprehensive in vitro physicochemical characterization encompassing luminescence and oxygen-17 relaxometry and an investigation of the possible non-covalent interaction with blood proteins as well as the analysis of the proton NMRD profile and the determination of related physical parameters.

Results and Discussion

Luminescence of the Europium Complex

According to Horrocks and Sudnick,[16] the difference in the decay rate of Eu^{3+} luminescence in H_2O ($1/\tau_{H_2O(ms)}$) and

 DOI: 10.1002/ejic.200400919

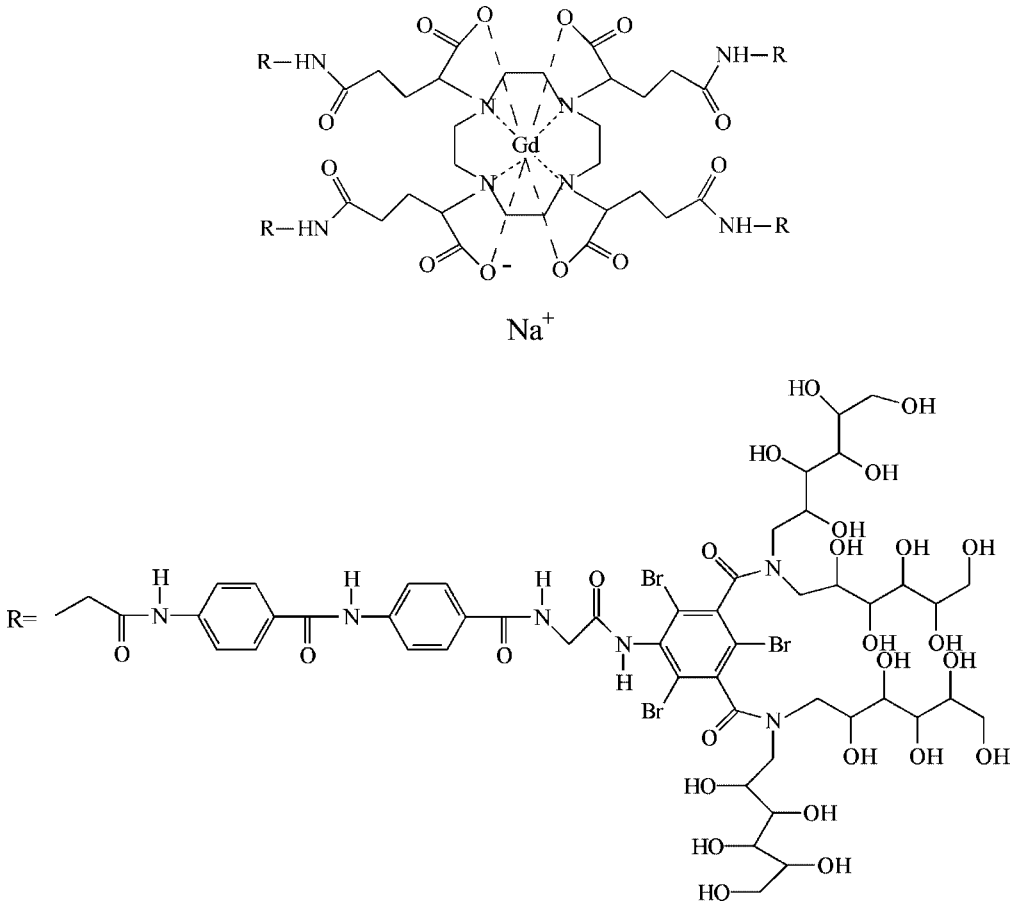

Figure 1. Chemical structure of P792.

D_2O ($1/\tau_{D_2O(ms)}$) solutions depends on the number of water molecules (q) in the first coordination sphere of the complex [Equation (1)]. More recently, Beeby et al.[17] included in the relevant equation the contribution from water molecules diffusing close to the Ln^{3+} complex and from other protons behaving as exchangeable oscillators [Equation (2)]. The measured luminescence lifetimes of P792-Eu in H_2O and D_2O were 0.71 ms and 2.32 ms, respectively. The corresponding calculated q values are 1.02 using Horrock's equation or 0.87 according to Beeby et al.

$$q = 1.05 \cdot \left(\frac{1}{\tau_{H_2O}} - \frac{1}{\tau_{D_2O}}\right) \quad (1)$$

$$q_{corr} = 1.2 \cdot \left(\frac{1}{\tau_{H_2O}} - \frac{1}{\tau_{D_2O}} - 0.25\right) \quad (2)$$

where τ is the lifetime (in ms) of the complex in H_2O and D_2O.

These values agree with the q value reported for the precursor P730.[18,19] As expected, the Gd^{III} ion is thus coordinated to the four nitrogen atoms of the macrocycle, the four carboxylate groups, and one water molecule.

Oxygen-17 Relaxometry of the Gadolinium Complex

The residence time of the coordinated water molecule is a very important parameter likely to limit the innersphere relaxivity of gadolinium complexes and more particularly of bulky structures. In such complexes, the expected enhancement in relaxivity resulting from the slow tumbling of the complex can indeed be quenched by a too slow water exchange.

It is well established that the exchange rate of the water molecule in the first coordination sphere of Gd^{3+} can be determined by analyzing the temperature dependence of the paramagnetic transverse relaxation rate ($R_2p = 1/T_2p$) of the oxygen-17 NMR signal of the aqueous solution.[20–22] The temperature dependence of ^{17}O R_2 was, therefore studied from 290 K to 357 K (Figure 2). Lower temperatures were not investigated to avoid problems related to an increase in viscosity. The qualitative analysis of the transverse relaxation rate data indicates that the water exchange

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

is quite fast. Moreover, the much larger values obtained for the longitudinal relaxation rates of P792 as compared to those of DOTA-Gd[22] agree with a complex of higher molecular weight.

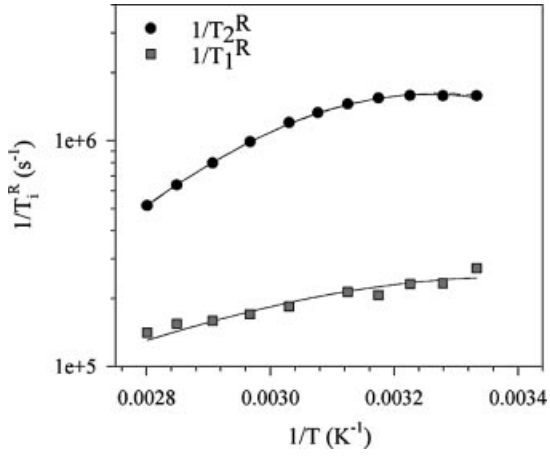

Figure 2. Reduced transverse $\{1/T_2R = 55.55/(T_2p^*[Gd\ complex])\}$ and longitudinal ^{17}O relaxation rate of water in P792 solution as a function of the reciprocal of temperature.

Quantitative analyses of the experimental data were performed with or without quadrupolar contribution, leading to 2 sets of values (Table 1). The first fitting of the experimental data was performed on the transverse relaxation rates with a model where the transverse relaxation rate of the bound nuclei of ^{17}O ($1/T_{2M}$) results mainly from scalar interaction with the gadolinium ion as described in ref.[20]. The second fitting was performed simultaneously on the transverse and longitudinal relaxation rate data with a model taking into account quadrupolar and dipolar contributions for $1/T_{1M}$ and quadrupolar and scalar contributions for $1/T_{2M}$.[9]

Table 1. Parameters obtained from the fitting of the transverse and longitudinal relaxation rates of oxygen-17.

	Without quadrupolar contribution	With quadrupolar contribution
τ_V^{298} [ps]	11.8 ± 0.3	12.8 ± 1.1
B [10^{20} s^{-2}]	4.06 ± 0.10	3.45 ± 0.41
E_v [kJ/mol]	0.9 ± 44.0	1.4 ± 1.5
$2\pi A/h$ [10^6 rad s^{-1}]	–4.46 ± 0.03	–3.95 ± 0.36
$\Delta H^{\#}$ [kJ/mol]	46.3 ± 0.09	46.9 ± 0.3
$\Delta S^{\#}$ [J/mol·K]	40.3 ± 1.3	40.6 ± 0.3
τ_M^{310} [ns]	79.6 ± 5.0	95.7 ± 14.9
τ_R^{298} [ns]		3.2 ± 0.2
τ_R^{310} [ns]		2.4 ± 0.2
E_R [kJ/mol]		17.0 ± 0.2
χ [MHz]		6.60 ± 0.35

The following parameters are simultaneously determined:
i) The hyperfine coupling constant between the oxygen-17 nucleus and the electronic spin of Gd^{3+} ($2\pi A/h$);
ii) the parameters related to the electronic relaxation times (τ_{S1} and τ_{S2}), i.e. the correlation time for the modulation of the zero field splitting (τ_V), the activation energy for this process (E_V), and B which depends on the trace of the square of the zero field splitting tensor (Δ^2) and on the electron spin S ($B = \Delta^2\{4S(S + 1) - 3\}/25$);
iii) the parameters of the water exchange rate, i.e. the enthalpy ($\Delta H^{\neq}$) and the entropy ($\Delta S^{\neq}$) of activation;
iv) the rotational correlation time τ_R and the activation energy for the rotation (E_R), as well as a term related to the quadrupolar coupling constant and the asymmetry parameter of ^{17}O ($\chi = [1 + \eta^2/3]^{1/2}[2\pi e^2qQ/h]$) when the quadrupolar contribution is taken into account.

The fitted value of τ_M obtained with the first model is approximately 80 ns at 310 K, a value close to that of the parent complex DOTA-Gd ($\tau_M^{310} \approx 97$ ns[22]). When the quadrupolar contribution is taken into account, the data from both longitudinal and transverse relaxation rates were fitted simultaneously and the distance between the gadolinium ion and the oxygen nucleus of the coordinated water molecule was set to 0.25 nm.[22] The fitted value of τ_M^{310} was then slightly larger (≈ 96 ns) and the τ_R^{310} value was equal to 2.4 ns, a value slightly larger than that obtained for P760 a compound of rather similar size and shape.[9] Such values of τ_M^{310} although not optimal to ensure a maximum relaxivity are not too large and, if any, their influence on the proton relaxivity should be small or moderate.

Transmetallation by Zn^{2+} Ions

The suitability of paramagnetic complexes as MRI contrast agents depends not only on their relaxivity but also on various other factors, among which is their inertness towards transmetallation by endogenous ions like Zn^{2+}. This can be assessed in vitro by H-1 relaxometry since, as already reported, transmetallation of gadolinium complexes by Zn^{2+} ions induces a release of Gd^{3+} ions which are trapped in a buffered solution containing phosphate ions. The subsequent decrease of the water proton relaxation rate quantitatively reflects the extent of the transmetallation process.[23] In the context of this protocol, the relaxation rate of macrocyclic gadolinium complexes like DOTA-Gd, HPDO3A-Gd [tris(carboxymethyl)-10-(2-hydroxypropyl)-1,4,7,10-tetraazacyclododecane gadolinium(III)], and P760 does not vary, whereas R_1p drops to about 53% of its initial value for DTPA-Gd, 18% for DTPA-BMA-Gd, and 85% for MS-325 after 1900 minutes showing that a significant transmetallation takes place for these open-chain gadolinium complexes.[9,23,24] For P792, lower concentrations of the complex and of Zn^{2+} were used (0.8 mM and 0.87 mM, respectively, instead of 2.5 mM in the original protocol). The data were thus compared to those obtained for DTPA-Gd at identical concentration ([DTPA-Gd] = 0.8 mM and [Zn^{2+}] = 0.87 mM). No significant evolution of the proton paramagnetic relaxation rate was observed for P792 over a period of more than 3000 minutes. This agrees with the absence of transmetallation by Zn^{2+} ions. In the same conditions, the R_1p of DTPA-Gd decreased by about 60% during the same period (Figure 3). These data confirm the very high kinetic and thermodynamic stabilities of DOTA-like

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

complexes of gadolinium as compared to DTPA-like complexes.[23,24]

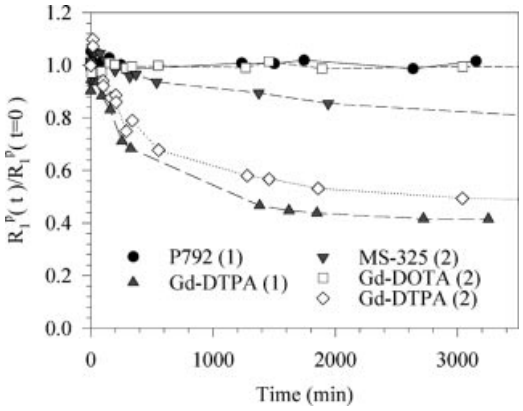

Figure 3. Evolution of the ratio $R_1p(t)/R_1p(t = 0)$ with time for solutions containing $ZnCl_2$ and P792 (circles), DTPA-Gd (up triangles and diamonds), MS-325 (down triangles), DOTA-Gd (squares). The experimental conditions are: (1): $ZnCl_2$ (0.87 mM) and complex-Gd (0.80 mM) at pH 7.0 and 37 °C (B_0 = 0.47 T) and (2): $ZnCl_2$ 2.5 mM and complex-Gd (2.5 mM) at pH 7.0 and 310 K (B_0 = 0.47 T).

Proton NMRD Profile

The proton longitudinal relaxation rates were measured at 310 K between 0.01 MHz and 300 MHz on 0.285 mM and 1 mM solutions of P792; the transverse relaxation rates were measured at 20 MHz, 60 MHz and 300 MHz. The calculated relaxivities (the relaxation rate enhancement brought by one millimol per liter of the gadolinium complex) vs. proton Larmor frequencies (proton NMRD profile) are shown on Figure 4.

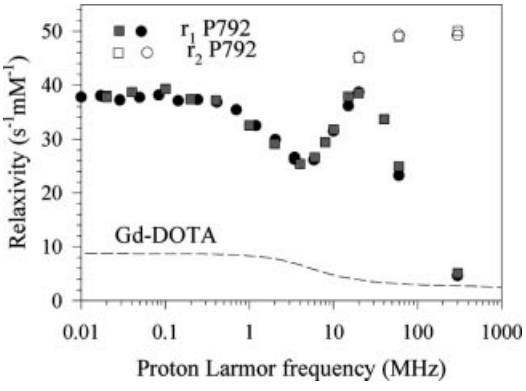

Figure 4. Proton NMRD data obtained at 310 K on a 0.285 mM solution (closed squares: r_1, open squares: r_2) and on a 1 mM solution (closed circles: r_1, open circles: r_2). The proton NMRD profile of DOTA-Gd (dashed line) has been added for comparison.

The longitudinal relaxivities show a hump at high magnetic fields in good agreement with the large size of the gadolinium complex and thus with its slow rotation. The values are remarkably larger, not only as compared to the parent complex DOTA-Gd, but also with respect to another large molecular weight derivative, the P760.[9] Longitudinal relaxivity reaches its maximum (38–40 s^{-1} mM^{-1}) between 15 and 40 MHz (0.35 and 0.94 T) while the transverse relaxivity levels off above 50 MHz (1.18 T).

In a first approach, ^1H NMRD curves were fitted according to the classical innersphere model described by Solomon[25] and Bloembergen[26] and to the outersphere model described by Freed.[27] In these fittings, the number of water molecules coordinated to the Gd^{3+} ion was fixed to 1 in agreement with the luminescence data. Some other parameters were also fixed: r, the distance between the proton nuclei of the innersphere water molecule and the Gd^{3+} (0.31 nm); D, the relative diffusion constant (3×10^{-9} $m^2 s^{-1}$); and d, the distance of closest approach for the outersphere contribution (0.36 nm[28,29]). τ_V and τ_{SO} (the electronic relaxation time at zero field), describing the elec-

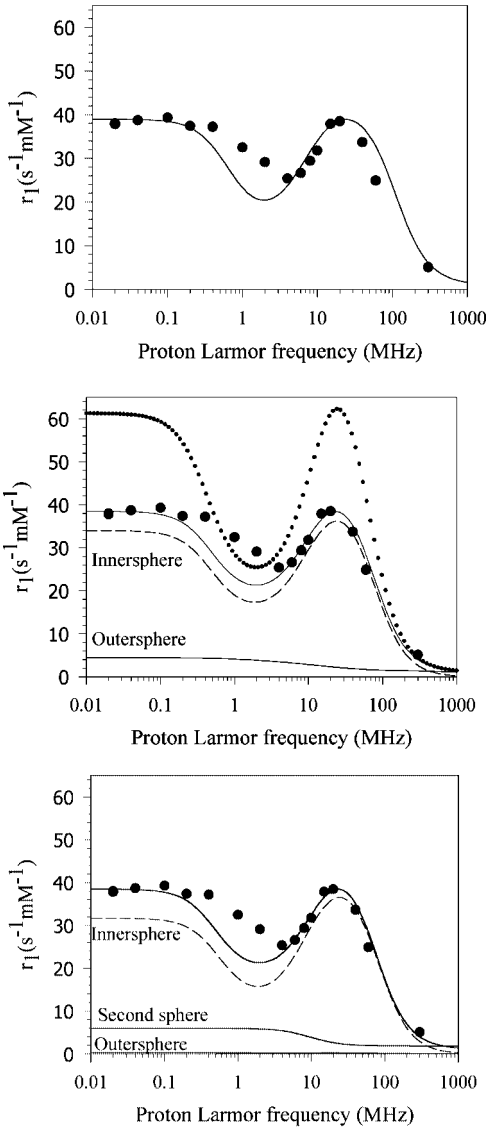

Figure 5. Theoretical fittings of the proton NMRD data obtained at 310 K using outersphere and innersphere models with τ_M fixed to 96 ns or τ_M adjusted (top and middle graphs; respectively) and using outersphere and innersphere models with second sphere water molecules included (bottom graph). The dotted line in the middle graph corresponds to the theoretical optimal relaxivity calculated with τ_M optimum (τ_M = 20–30 ns).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tronic relaxation times, were optimized for the outersphere and the innersphere contributions simultaneously. τ_R was allowed to fluctuate around the values obtained by ^{17}O NMR and τ_M was fixed to 96 ns. A $\tau_R{}^{310}$ value of 1.7 ns and a τ_{SO} value of 538 ps were obtained but in the high field region, the fitted values are larger than the experimental ones (Figure 5 and Table 2). A second adjustment was therefore performed in which τ_M was adjusted. A satisfactory fit of the data could be obtained at low fields and at high fields with a $\tau_R{}^{310}$ value of 3.2 ns and a τ_M value of 240 ns (Figure 5 and Table 2). These values are significantly larger than those determined by ^{17}O NMR (2.4 ns and 80–96 ns, respectively). The τ_{SO} value is also larger than that reported for the parent compound DOTA-Gd ($\tau_{SO}{}^{310}$ = 480 ps).[22] These discrepancies could be explained by the fact that the model used to fit the ^1H NMRD curve is not the most appropriate to describe the behavior of slowly tumbling paramagnetic molecules.[30] They also could result from the presence of a second sphere of water molecules due to the hydrophilic nature of the substituents of the macrocyclic core of P792.

Table 2. Parameters obtained from the fitting of the proton NMRD profile of P792 at 310 K.

	Theoretical model with innersphere and outersphere water molecules; τ_M set to 96 ns	Theoretical model with innersphere and outersphere water molecules; τ_M adjusted	Theoretical model with innersphere, outersphere and second sphere water molecules
d [nm]	0.36	0.36	0.45
D [10^{-9} m^2 s^{-1}]	3.0	3.0	3.0
r [nm]	0.31	0.31	0.31
τ_R [ns]	1.7	3.2	2.7
τ_M [ns]	96	240	200
τ_{SO} [ps]	538	730	520
τ_V [ps]	40	26	29
τ_{SS} [ps]			25
r_{ss} [nm]			0.40
q_{ss}			10

In a third approach, the interaction between the gadolinium ion and water molecules in its second sphere was therefore included in the theoretical model.[31] The hydrogen atoms of these water molecules were assumed to be at a distance of 0.4 nm and the distance of closest approach was set to 0.45 nm. The experimental data were fitted, as shown in Figure 5, with a $\tau_R{}^{310}$ value of 2.7 ns which is similar to the value obtained above by the analysis of the paramagnetic longitudinal rate of oxygen-17. The value found for τ_M (200 ns) is closer to the value obtained by oxygen-17 NMR spectroscopy. The τ_{SO} (520 ps) and τ_V (29 ps) values are also in better agreement with those reported for the parent compound DOTA-Gd. In this fitting, 10 water molecules are found in the second sphere. Their interaction with the paramagnetic center is modulated by a correlation time called τ_{SS} which depends on the rotational correlation time and on the residence time of the second sphere water molecules. A value of 25 ps was found. However, it should be pointed out that both last fittings give similar results and that the choice of the "best" theoretical model is quite subjective.

Nevertheless, it emerges from these data that the rotational correlation time is approximately equal to 2–3 ns at 310 K and that the value of the electronic relaxation rate at low fields is similar to that of the parent complex DOTA-Gd.

Finally, it can be calculated that the observed relaxivity is not optimal and that values of the order of 60 s^{-1} mM^{-1} between 20–60 MHz could be obtained if the water residence time was of the order of 20–30 ns (Figure 5).

Interaction of P792 with Blood Proteins

When small gadolinium complexes bind non-covalently to HSA, an increase of their paramagnetic relaxation rate is usually observed at magnetic fields ranging from 10 to 60 MHz due to the slowing down of the rotational motion of the bound complex. Proton relaxation rate measurements were thus performed at 20 and 60 MHz and 310 K on P792 (0.46 mM) solutions in human serum (Table 3). The increase of the longitudinal and transverse apparent relaxivities is minimal and can be explained by the slight increase in viscosity of the medium as compared to water solution. Alternatively, these data show either the absence of interaction between P792 and blood proteins, or that there is an interaction but that the rotational correlation time of the paramagnetic center is not significantly modified by the binding.

Table 3. Apparent relaxivities in water and human serum solutions of 0.46 mM of P792 at 310 K.

	20 MHz	60 MHz
r_1 [s^{-1} mM^{-1}] (water)	42 ± 1.5	26.7 ± 0.6
$r_1$app [s^{-1} mM^{-1}] (serum)	47.7 ± 1.0	26.9 ± 0.5
r_2 [s^{-1} mM^{-1}] (water)	50 ± 1.4	53.3 ± 2.9
$r_2$app [s^{-1} mM^{-1}] (serum)	59.4 ± 1.3	65.1 ± 1.5

The influence of HSA 4% on the longitudinal and transverse NMRD profiles was also investigated (Figure 6). The

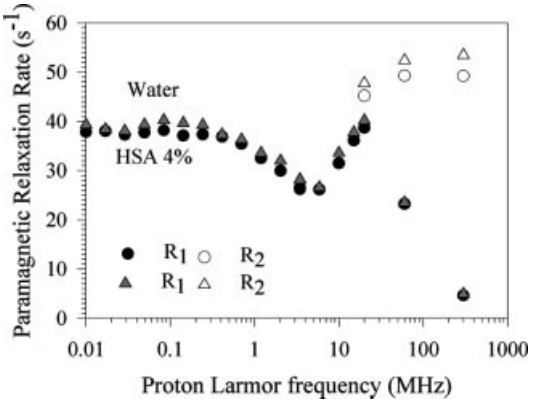

Figure 6. Proton NMRD data obtained at 310 K on a 1 mM solution in water (closed circles: R_1p, open circles: R_2p) and HSA 4% (closed triangles: R_1p, open triangles: R_2p).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

similarity of the paramagnetic R_1 data over the whole range of magnetic fields and of the paramagnetic R_2 data at high fields confirms that P792 does not bind to serum albumin.

The absence of a significant interaction with blood proteins must be related to the observed relatively fast clearance of P792 from mice plasma ($t_{1/2}\beta$ = 22 min)[6] or from rabbit plasma ($t_{1/2}\beta$ = 41 min)[8] as compared to the much larger values reported for MRI contrast agents like MS-325 ($t_{1/2}\beta$ = 155 min in rabbits)[32] and MP2269 ($t_{1/2}\beta$ = 142 min in rabbits);[33] known for their interaction with HSA.

Conclusions

P792, a new tetra-substituted macromolecular DOTA-Gd derivative, is a very interesting MRI contrast agent due to its hydrophilic properties, its very high longitudinal and transverse relaxivities in the imaging magnetic fields (> 30 $s^{-1}mM^{-1}$), and its very high stability with respect to Zn^{II} transmetallation. This complex, which does not bind significantly to serum proteins, is consequently cleared very rapidly by the kidneys. On the other hand, its in vivo relaxivity is independent of concentration; unlike what is observed for contrast agents binding to serum albumin.[34,35]

Experimental Section

Chemicals: All commercial chemicals [$ZnCl_2$ (Merck) and Titrisol buffer pH 7.0 (Merck)] were used without further purification. Non-defatted human albumin (fraction V) was purchased from Sigma (Bornem, Belgium). The synthesis of P792 has been described previously.[7]

Luminescence Studies on the Eu Complex: The Eu^{III} phosphorescence emission spectra were acquired with an LS-50B Perkin–Elmer spectrofluorimeter equipped with a pulsed Xenon lamp and a Hamamatsu R928 photomultiplier tube operating in time-resolved mode. 7×10^{-3} M and 5.5×10^{-3} M solutions of the Eu^{III} complex in H_2O and D_2O, respectively, were used in these experiments. Lifetimes (τ) were obtained by monitoring the emission intensity at 616 nm, resulting from pulsed excitation at 395 nm. Excitation and emission slit widths of 5 nm and 20 nm were used, respectively, and the gate time was 0.4 ms. 160 (H_2O) or 260 (D_2O) different delay times were used. The decays of the europium emitting state were fitted by an equation of the form $I(t) = I(0)\exp(-t/\tau)$ using a current software fitting procedure (Excel). High correlation coefficients were observed in each case (typically 0.999). Error limits on the lifetime are equal to 5%. The number of water molecules (q) bound to the inner coordination sphere of the europium ion was quantified by using either the original equation proposed by Horrocks and Sudnick[16] or the equation reported by Beeby et al.[17]

NMR Spectroscopy: Proton Nuclear Magnetic Relaxation Dispersion (NMRD) profiles extending from 0.24 mT to 1.2 T were recorded with Field Cycling Relaxometers (Field Cycling Systems, Oradell, New Jersey, USA and Stelar, Mede, Italy) on 0.6 mL solutions contained in 10-mm o.d. tubes. Proton relaxation rates were also measured at 0.47 T, 0.94 T, 1.5 T and 7.05 T with Minispec PC-120, PC-140, mq-60 and AMX-300 spectrometer. All these instruments were from Bruker (Karlsruhe, Germany). ^1H NMRD data were fitted according to the theoretical innersphere model described by Solomon[25] and Bloembergen[26] and to the outersphere contribution described by Freed.[27] Calculations were performed with previously described software.[36,37]

Transmetallation by Zn^{II} ions was evaluated at 310 K by the decrease of the water proton longitudinal relaxation rate at 20 MHz (Bruker Minispec PC 120) of buffered solutions (pH 7, phosphate buffer: [KH_2PO_4] = 26 mM, [Na_2HPO_4] = 41 mM) containing the gadolinium complex and Zn^{II} according to a procedure previously described.[23]

^{17}O spectra were recorded on 2 mL samples (10-mm o.d. tubes) on a Bruker AMX-300 spectrometer (Bruker, Karlsruhe, Germany) using a broadband probe and a Bruker BVT-2000 unit for temperature control. ^{17}O transverse relaxation times of distilled water (pH = 6.5) were measured using a CPMG sequence and a subsequent two parameters fit of the data points. The 90° and 180° pulse lengths were respectively 25 μs and 50 μs. ^{17}O T_2 of water in P792 ([P792] = 7 mM, pH = 6.0–7.0) was obtained from linewidth measurement. All ^{17}O spectra were proton decoupled. The procedures for the analysis of the ^{17}O data have been described elsewhere.[20]

All T_1 measurements at 7.05 T (^1H, ^{17}O) were performed with an inversion recovery or fast inversion recovery Fourier transform technique and a subsequent three parameters fit of the peak heights.

Acknowledgments

The authors thank Mrs Patricia de Francisco for her help in preparing the manuscript, and Dr. Claude Picard and Dr. Chantal Galaup (UMR, 5068 Toulouse) for their contribution to luminescence studies. This work was supported by the FNRS and the ARC Program 00/05–258 of the French Community of Belgium. The support and sponsorship concerted by COST Action D18 "Lanthanide Chemistry for Diagnosis and Therapy" are kindly acknowledged.

Keywords: Manganese clusters / Self-assembly / Mixed valency / X-ray diffraction / Cyclic voltammetry

Upon reaction of *N*-substituted diethanolamines H_2L^{2-4} (**4**, **6**, **7**) with cesium carbonate and bis(tetraethylammonium) tetrachloromanganate(II) in acetonitrile in the presence of air, the metal-centered mixed-valent manganese wheels $[NEt_4]\{Mn^{II}\subset[Mn^{II}_3Mn^{III}_3Cl_6(L^{2-4})_6]\}$ (**8**–**10**) were generated. X-ray crystallographic structure analyses revealed, that **8**–**10** are principally isostructural and consist of an alternating ring of three Mn^{II} and three Mn^{III} ions, centered by an additional Mn^{II} ion. The cyclic voltammograms of **8** and **10** displayed three quasi-reversible oxidation processes, which are attributed to the subsequent one electron-oxidations of the three peripheral Mn^{II} ions to Mn^{III}. Oxidation of the central Mn^{II} ion is not observed within the applied potential.

Introduction

Despite their unpredictable nature, polyoxometalates have become the focus of intense research activities.[2] Recently, distinct supramolecular metal clusters have become accessible by rational design rather than by serendipity[3] and oxo-bridged polynuclear iron and manganese metal clusters have been the subject of numerous detailed magnetic studies, which have been rewarded by the discovery of single molecule magnets (SMMs).[4,5] In this context, we reported on the template-mediated self-assembly of six- and eight-membered iron-coronates, $\{Na\subset[Fe_6(L^1)_6]\}^+$ (**2**) and $\{Cs\subset[Fe_8(L^1)_8]\}^+$ (**3**), which were prepared from triethanolamine H_3L^1 (**1**) with iron(III) chloride and sodium hydride or cesium carbonate, respectively (Scheme 1).[6] A common feature of complexes **2** and **3** is that the μ_1-oxygens of the $(L^1)^{3-}$ ligands do not participate in the formation of the hexa- or octanuclear structures. They solely function as ligands for the coordinative saturation of the iron centers. For this reason, further mono-anionic donors, such as chloride ions, should also be candidates for this function. Therefore, reaction of *N*-methyldiethanolamine H_2L^2 (**4**) with cal-

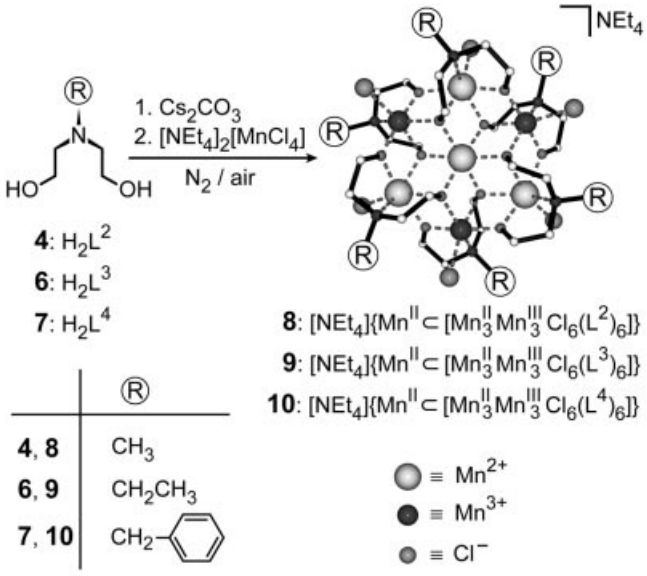
cium hydride and iron(III) chloride yielded the unoccupied neutral iron coronand $[Fe_6Cl_6(L^2)_6]$ (**5**) (Scheme 1).[6] In **5**, the μ_2-oxygen donors of the $(L^2)^{2-}$ ligands are structure determining, whereas their *N*-methyl groups are not. In addition, six chloride coligands are necessary for coordinative saturation at the iron centers and for charge compensation. Consequently, a series of ferric wheels was generated with *N*-substituted diethanolamines.[1,7]

In this communication we report on the synthesis of metal-centered, heptanuclear, mixed-valent manganese wheels **8**–**10**.

Results and Discussion

Synthesis

The metal-centered, heptanuclear, mixed-valent, six-membered manganese wheels **8**–**10** were generated in good yields in a one-pot reaction. For that purpose, *N*-substituted diethanolamines **4**, **6** and **7** were deprotonated with cesium carbonate in acetonitrile under nitrogen for 1 h. After addition of soluble bis(tetraethylammonium) tetrachloromanganate(II), the resulting reaction mixture was stirred for an extra 4 d. Workup in air, and crystallization from suitable solvent systems afforded black parallelepipeds (Scheme 2).



Scheme 2. Synthesis of manganese wheels **8**–**10** with *N*-substituted diethanolamines.

X-ray Analyses

X-ray crystallographic structure determinations were carried out for **8**–**10** (Table 2).[8,9] According to these analyses all three clusters are principally isostructural with idealized S_6 molecular symmetry, and for that reason, only the structure of **8** is discussed in detail. In the crystal, **8** is present as a cyclic manganese complex, consisting of an alternating ring of three Mn^{II} and three Mn^{III} ions[10] centered by an additional Mn^{II} ion, and tetraethylammonium is the counterion. Charge considerations and bond valence calculations require six doubly deprotonated methyldiethanolate amine ligands and six chloride ions. For the idealized consideration, the six equivalent manganese ions of the centrosymmetric anion $\{Mn^{II} \subset [Mn^{II}_3 Mn^{III}_3 Cl_6(L^2)_6]\}^-$ of **8** are located in the corners of a regular hexagon. The Mn–Mn distance is 3.3 Å. The diameter of the hexagon, defined as

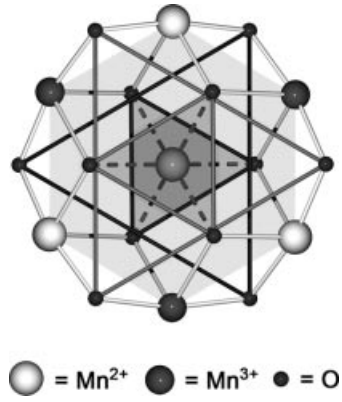


Figure 1. Schematic presentation of the central $[Mn^{II}_3 Mn^{III}_3 \mu_2\text{-}O_6]$ scaffold of $[\mathbf{8}]^-$ together with the octahedral μ_3-O environment of the encapsulated Mn^{II} ion. View along the idealized molecular S_6 axis, neglecting the valency of manganese.

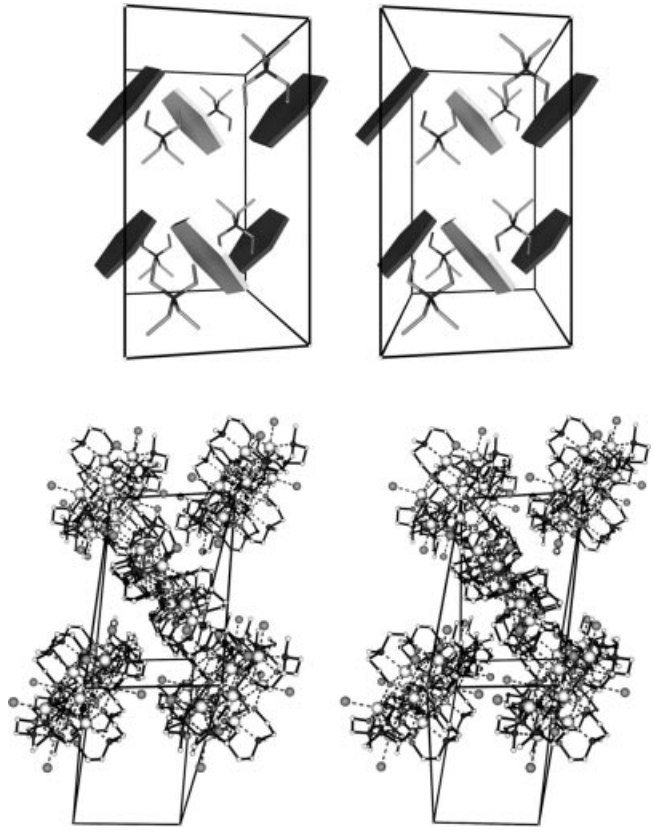

Figure 2. Top: Schematic stereo presentation of the crystal packing of **8** along the *a* axis. Bottom: Stereo view of the crystal packing of manganese wheel **8** along the *a*,*b* plane diagonal of the unit cell.

the distance between two opposite manganese ions, is 6.6 Å. The distorted octahedral coordination sphere of the manganese ions is composed of one nitrogen donor, two μ_2- and two μ_3-oxygen donors and one chloride ion. Consequently, doubly deprotonated methyldiethanolate amine acts as a tetratope tridentate ligand and links three manganese ions. There is a set of six outer μ_2-O donors and a set of six inner μ_3-O donors. The six oxygen donors of each set are located at the corners of a pair of regular triangles, rotated by 60° relative to each other. The pairs of triangular faces are arranged parallel and equidistant in pairs from the central one, with one plane above and one below this hexagonal plane, generated by the peripheral manganese ions. These two pairs of six oxygen donors are related by an S_6 axis. The Mn^{II} ion located in the center of $[\mathbf{8}]^-$ has a distorted octahedral coordination sphere with respect to the six μ_3-O donors (Figure 1). The diameter of the cavity d[11] marked by opposite μ_3-O donors almost corresponds to double the ionic radius of Mn^{II}.

Manganese wheel $[NEt_4]\{Mn^{II}\subset[Mn^{II}_3Mn^{III}_3Cl_6(L^2)_6]\}$ (**8**) crystallizes with four molecules in the unit cell. The disklike clusters are all arranged in parallel (shortest midpoint distance d = 11.2 Å), but in two orientations (mean included angle φ = 85°), and are piled in cylindrical columns, with all the manganese centers superimposed (Figure 2).

Cyclic Voltammetry

The cyclic voltammogram of **8** and **10** were recorded under anaerobic and aprotic conditions and displayed three quasi-reversible oxidation processes, which are attributed to the subsequent one-electron oxidations of the three Mn^{II} ions to Mn^{III}, which are located at the ring positions (Figure 3, Table 1). Oxidation of the central Mn^{II} ion is not observed within the applied potential range.[12] In multisweep experiments under thin layer conditions the first oxidation shows complete reversibility over several cycles, whereas the second and third oxidations lead to degradation of the complex indicating irreversible chemical side reactions. The large potential displacement between the individual oxidations of several hundred mV is indication of a strong electronic coupling between the crystallographically equivalent manganese ions, whereas in a noncoupled system a simultaneous threefold oxidation within one oxidation wave would have been expected.

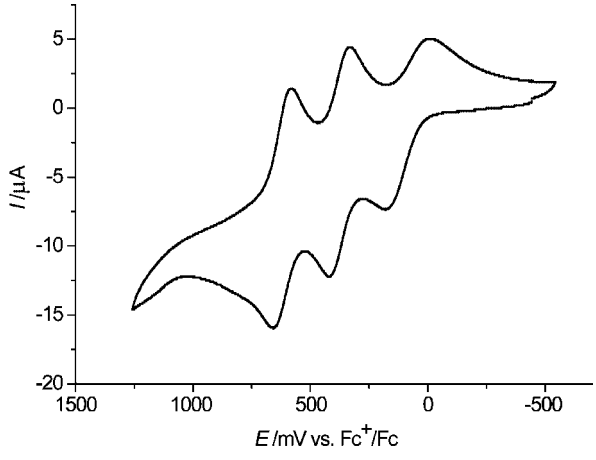

Figure 3. Cyclic voltammogram of **8**.

Table 1. Data of the cyclic voltammogram of **8** and **10** in CH_3CN {0.1 M $[(n\text{Bu})_4N](PF_6)$} versus Fc/Fc^+ at 20 °C; scan rate 200 mV s^{-1}.

Complex	$E_{1/2}{}^1$ [mV]	$E_{1/2}{}^2$ [mV]	$E_{1/2}{}^3$ [mV]
8	85	375	630
10	119	396	650

Conclusion

We are still far from understanding the template effect on the mysterious rules of the self-assembling processes leading to metallic wheels. Whereas triethanolamine with iron(III) chloride affords homovalent metal-centered cationic wheels like $\{Na\subset[Fe_6(L^1)_6]\}^+$ (**2**), methyldiethanolamine yields the unoccupied neutral homovalent species $[Fe_6Cl_6(L^2)_6]$ (**5**). However, when manganese(II) instead of iron(III) was reacted under aerobic conditions with methyldiethanolamine, the mixed-valent metal-centered anionic wheel $\{Mn^{II}\subset[Mn^{II}_3Mn^{III}_3Cl_6(L^2)_6]\}^-$ $(\mathbf{8})^-$ was formed.

Experimental Section

General Techniques: Metal salts, and H_2L^2[2,3] (**4**, **6**) were used as obtained from Aldrich. All solvents used were purified and dried according to standard procedures. $[NEt_4]_2[MnCl_4]$ and H_2L^4 (**7**) were prepared according to literature methods.[13,7] IR spectra were recorded from KBr pellets with a Bruker IFS 25 spectrometer. FAB-MS spectra were recorded with a Micromass ZAB-Spec spectrometer. Elemental analyses were performed with an EA 1110 CHNS-Microautomat. Single-crystal X-ray structure analyses: details for crystal data, data collection and refinement are given in Table 2. X-ray data for **8**–**10** were collected with a Nonius Kappa CCD area detector, using Mo-K_α radiation (λ = 0.71073 Å). Scalepack absorption correction was employed. The structure was solved by direct methods with SHELXS-97 and refined with full-matrix least-squares against F^2 with SHELXL-97.[8]

General Method: Methyldiethanolamine H_2L^2 (**4**) (1.7 mmol, 0.200 g), ethyldiethanolamine H_2L^3 (**6**) (1.7 mmol, 0.230 g), or benzyldiethanolamine H_2L^4 (**7**) (1.7 mmol, 0.330 g) were added to a suspension of Cs_2CO_3 (2 mmol, 0.650 g) in CH_3CN (70 mL). After stirring for 1 h at room temperature $[NEt_4]_2[MnCl_4]$ (2 mmol, 0.915 g) was added. The reaction mixture was stirred for 4 d at room temperature. For **8** and **9**, the resulting black precipitate was filtered off, extracted with $CHCl_3$ (100 mL) and concentrated. Black crystals were obtained from $CHCl_3/Et_2O$ (for **8**) or CH_3CN/Et_2O (for **9**). For **10**, the resulting black suspension was filtered, and the filtrate was concentrated in vacuo to dryness. A mixture of Et_2O (5 mL) and EtOH (5 mL) was added. After standing for 12 h, the black precipitate that had formed was filtered off and extracted with $CHCl_3$ (100 mL). Black crystals were obtained from $CHCl_3/Et_2O$.

Incorporation of Aluminium and Iron into the Zeolite MCM-58

Gabriela Košová,[a] Stefan Ernst,[b] Martin Hartmann,[b] and Jiří Čejka*[a]

Keywords: Acidity / Aluminum / Iron / Kinetics / Zeolites

The hydrothermal synthesis of zeolite MCM-58 is investigated with *N*-benzylquinuclidinium bromide as a structure-directing agent in order to isomorphously substitute aluminium or iron for silicon. Al-MCM-58 was synthesised in a wide range of n_{Si}/n_{Al} ratios (from 19 to 56), and Fe-MCM-58 was successfully prepared in a narrower range of n_{Si}/n_{Fe} ratios (from 18 to 36). The obtained products were characterised by XRD, SEM, ^{27}Al MAS NMR, ^{29}Si MAS NMR, FTIR, and ESR spectroscopy. Two different calcination procedures, viz. in a stream of nitrogen and air or in a stream of ammonia, were used in order to modify the acid sites in the zeolite. FTIR spectroscopy before and after the adsorption of [D_3]acetonitrile and pyridine was employed to determine the concentration and type of the acid sites. The acid forms of Al(Fe)-MCM-58 are characterised by the vibrations of bridging Si–OH–Al(Fe) groups at 3628 cm^{-1} and 3564 cm^{-1} (Al-MCM-58) or 3646 cm^{-1} and 3520 cm^{-1} (Fe-MCM-58). The acid sites of both zeolites Al-MCM-58 and Fe-MCM-58 are accessible for [D_3]acetonitrile and pyridine, and all materials contain substantial numbers of Lewis sites (Al-MCM-58: 50 % of the total acid sites; Fe-MCM-58: 90 %) over the whole range of n_{Si}/n_{Al} (n_{Si}/n_{Fe}) ratios studied. Only a small increase in the concentration of Brønsted acid sites was achieved after calcination of the as-synthesised samples in a flow of ammonia.

Introduction

Zeolite-based molecular sieves are a very important group of inorganic materials with a variety of applications, such as adsorption, ion-exchange and, particularly, heterogeneous catalysis.[1,2] The catalytic activity and selectivity of zeolites is attributed to their large internal surface, with active sites that are accessible through uniformly sized pores. The shape and the size of the pore system influence the diffusion of reactants and products and also the path of the reaction. The successful substitution of trivalent heteroatoms into the silicate framework results in a negative charge compensated by protons that are essential for the catalytic activity of zeolites in acid-catalysed reactions. The hydrophobic/hydrophilic properties of high silica zeolites can be varied enormously by suitable variation of the concentration and location of the trivalent cations. Several detailed studies of the feasibility of trivalent cation incorporation into zeolite frameworks, the distribution of these cations among different sites and the location of the charge compensating metal cations in high silica zeolites have been reported that combine experimental and theoretical approaches.[3–6] In the past decade, isomorphous substitution of trivalent cations into various zeolite structures has been reported.[7,8] In addition to aluminosilicate zeolite, ferrisilicate analogues have already been commercially applied as catalysts.[9] Ferrisilicates are less acidic than aluminosilicates, which results in improved selectivity in some acid-catalysed reactions, such as oligomerisation of C_2-C_4 olefins and catalytic dewaxing. Ferrisilicate analogues of molecular sieves can also serve as precursors for the preparation of redox catalysts with a homogeneous distribution of active iron oxide particles, for example in the synthesis of phenol from benzene.[10]

Nowadays, more than 130 framework types have been described[11] and it is still a big challenge to rationally design the synthesis of new structural types of zeolites.[12] The synthesis of zeolites is usually performed under hydrothermal conditions in the presence of various organocationic structure-directing agents (SDA). It is believed that the size and shape of the SDA predefine the shape and dimensions of the zeolite pore system.[13] The synthesis efforts using novel types of SDA in many laboratories around the world have resulted recently in the successful synthesis of new types of zeolites, for example ITQ-21, a large-pore, three-dimensional zeolite,[14] ITQ-13, with 9- and 10-membered rings,[15] a zeolite having 8-, 10- and 12-membered rings,[16] SSZ-58, a zeolite with previously unseen double 5-ring subunits,[17] MCM-68, in which 12-membered-rings channel are intersected by two independent tortuous 10-membered-ring channel systems,[18] or the novel, extra-large-pore zeolites SSZ-53 and SSZ-59, which possess 14-membered rings in a one-dimensional channel system.[19] Other strategies have been developed for the synthesis of micro/meso-composite molecular sieves.[20,21]

Zeolite MCM-58, which was described for the first time in 1994 by Valyocsik as a high-silica zeolite, can be synthesised with n_{Si}/n_{Al} ratios from 15 to 50.[22] Zeolite MCM-58 (IZA structure code IFR) is isostructural with SSZ-42 and ITQ-4 and is characterised by an undulating, one-dimensional, 12-membered-ring channel system.[23] Due to the relatively large pore diameter of 0.64 nm at the narrowest point and a cage at the widest point with a diameter of 1.0 nm, zeolite MCM-58 could be an interesting catalyst for the conversion of relatively bulky molecules. For example, MCM-58 has been used as catalyst in the gas-phase alkylation of toluene with propylene giving large amount of *n*-propyltoluenes,[24] or ethylbenzene disproportionation and hydroconversion of *n*-decane.[25] Several organic SDAs have been used for the synthesis of MCM-58, including benzyltropanium salts, *N*-benzyl-1-azabicyclo[2.2.2]octane cations (benzylquinuclidinium) and *N*-benzyl-1,4-diazabicyclo[2.2.2] cations.[22]

In the present work, we report on the synthesis of aluminosilicate MCM-58 with n_{Si}/n_{Al} ratios from 20 to 60 and of ferrisilicate MCM-58 with n_{Si}/n_{Fe} ratios from 20 to 40 using *N*-benzylquinuclidinium bromide (BQ) as the templating agent. In particular, we were interested in the isomorphous substitution of iron for silicon in the framework of MCM-58, which has not yet been described. The kinetics of the crystallisation and the effect of incorporated trivalent atoms on concentrations and types of acid sites of this zeolite were also investigated.

Results and Discussion

The progress of crystallisation of MCM-58 from molar gel compositions of $(0.016–0.025)\,Al_2O_3$:SiO_2:$38\,H_2O$:$0.30\,K_2O$:$0.10\,BQ$ for Al-MCM-58 and $(0.0125–0.025)\,Fe_2O_3$:SiO_2:$38\,H_2O$:$0.30\,K_2O$:$0.20\,BQ$ for Fe-MCM-58 was followed by X-ray powder diffraction. By optimising the synthesis conditions and time at 170 °C it was possible to reproducibly synthesise highly crystalline zeolite Al-MCM-58 (Figure 1) with initial n_{Si}/n_{Al} ratios from 20 to 60. Because BQ, which is used as an SDA in the synthesis of MCM-58, is relatively expensive, the amount of BQ in the reaction mixture for Al-MCM-58 was further lowered from the original BQ/SiO_2 molar ratio of 0.2 to 0.1. Even with a reduced amount of SDA, MCM-58 can be synthesised without any loss of quality. When the BQ/SiO_2 ratio is lower then 0.1, or BQ is omitted completely, α-quartz is obtained as a pure phase.[26] A similar effect occurs when the amount of aluminium in the reaction mixture is decreased. When the initial n_{Si}/n_{Al} ratio exceeds 60, α-quartz begins to crystallise as well. Valyocsik has reported that mordenite can be formed as an impurity phase if either the n_{Si}/n_{Al} ratio is less then 10 in the initial gel or sodium cations are used instead of potassium cations in the synthesis gel.[27]

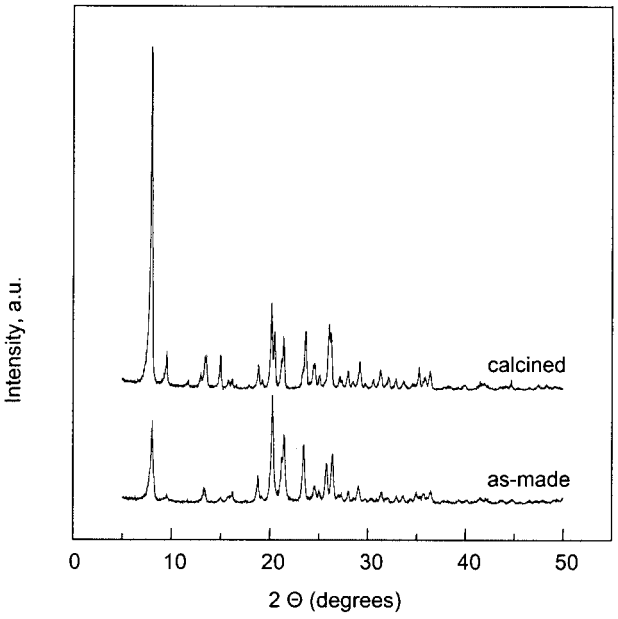

Figure 1. X-ray powder-diffraction patterns of as-synthesised and calcined Al-MCM-58 (n_{Si}/n_{Al} = 36).

The MCM-58 reflections were first observed after three days of synthesis (Figure 2) and the crystallisation was complete after six to eight days, depending on the n_{Si}/n_{Al} ratio (n_{Si}/n_{Al} = 60, 40, 30 and 20, respectively). The rate of crystallisation increases with decreasing amount of aluminium. A relative decrease in the crystallisation rate with reduced aluminium concentration in the synthesis gel has also been reported for other zeolites, such as Al-ZSM-12.[28]

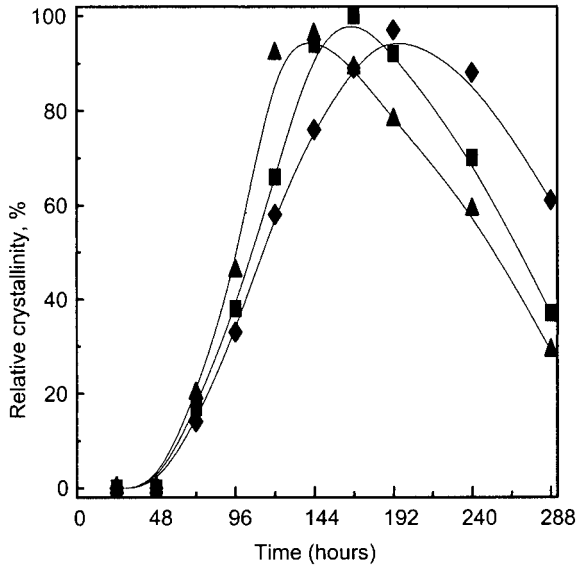

Figure 2. The dependence of relative crystallinity of Al-MCM-58 on the initial n_{Si}/n_{Al} ratio. Temperature: 170 °C; n_{Si}/n_{Al} = 20 (▲), 30 (■), 40 (♦).

In contrast to the synthesis of Al-MCM-58, which was carried out at 170 °C and yielded the phase-pure zeolite, in the case of Fe-MCM-58 it was not possible to synthesise

this zeolite as a pure phase under the same conditions: the sample was always contaminated with α-quartz. After six days, α-quartz was the sole product (see Figure 3). To prevent the formation of α-quartz, the reaction temperature for the synthesis of Fe-MCM-58 was lowered to 155 °C and the synthesis time was optimised. The optimal synthesis time was found to be between 4.5 and 5.5 days independent of the n_{Si}/n_{Fe} ratio in the gel. The molar ratio BQ/SiO_2 was kept at 0.2 as in the original recipe for Al-MCM-58. It was not possible to lower it as in the synthesis of Al-MCM-58. Under these conditions, pure Fe-MCM-58 was synthesised. Moreover, we found that the silicon source is of uttermost importance in order to obtain phase-pure Fe-MCM-58. Three different silica sources were tested, namely Ludox AS-30, Ludox AM-30 and Levasil, all of them as 30 wt-% SiO_2 solutions in water. Phase-pure zeolite Fe-MCM-58 was obtained only with Levasil as the silica source (Figure 3). The shape of the crystallisation curves (Figure 4) reveals that crystallisation starts after two days and increases to 70–80% after 96 h. The crystallisation curves for Fe-MCM-58 are characterised by a sharp maximum at about 120 h irrespective of the n_{Si}/n_{Fe} ratio. Thereafter, α-quartz starts to be formed as well, and later on Fe-MCM-58 is completely transformed into α-quartz, which is the thermodynamically most stable phase. The zeolite synthesis obeys the Ostwald ripening law. As described for zeolite A, the initial metastable phase is converted into a thermodynamically more stable sodalite until the most stable SiO_2 is formed.[29] Thus, the successful synthesis of Fe-MCM-58 requires the control of the optimum synthesis time, which was found to be close to 5.5 days for the conditions used (Figure 5).

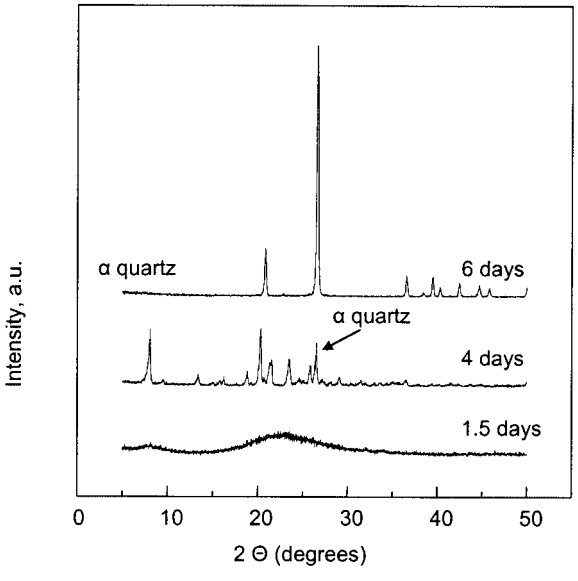

Figure 3. X-ray powder diffraction pattern of Fe-MCM-58 (n_{Si}/n_{Fe} = 28, T = 170 °C). After six days α-quartz is formed.

The scanning electron micrographs (Figure 6) of Al-MCM-58 (n_{Si}/n_{Al} = 36) and Fe-MCM-58 (n_{Si}/n_{Fe} = 36) show that no amorphous phase is present. Crystals of Al-

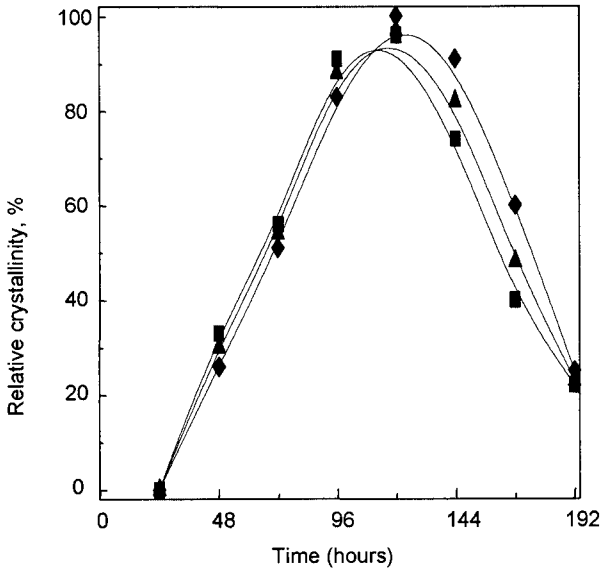

Figure 4. The dependence of relative crystallinity of Fe-MCM-58 on the initial n_{Si}/n_{Fe} ratio. Temperature: 155 °C; n_{Si}/n_{Fe} = 20 (▲), 30 (■), 40 (♦).

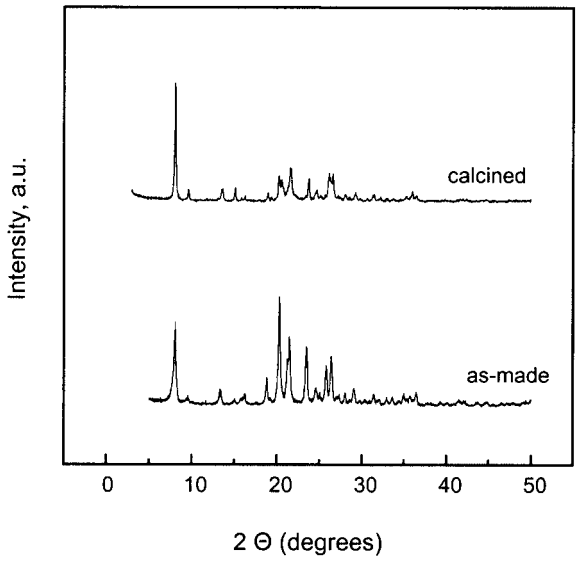

Figure 5. X-ray powder-diffraction pattern of Fe-MCM-58 (n_{Si}/n_{Fe} = 28; T = 155 °C; crystallisation time: 5 days).

MCM-58 (A and B) are represented by elongated particles with lengths ranging from 1 to 5 μm depending on the n_{Si}/n_{Al} ratio in the synthesis gel. The size of the crystals increases with a decreasing amount of aluminium in the reaction mixture. No uniform distribution of crystal sizes was observed for Al-MCM-58. The crystals of Fe-MCM-58 (n_{Si}/n_{Fe} = 36) (see C,D in Figure 6) are smaller than those of Al-MCM-58, with sizes between 0.5 and 3.0 μm. Some agglomeration of Fe-MCM-58 crystals to form stars was found (see C in Figure 6), which is also typical for Fe-ZSM-12.[28]

In agreement with our previous data,[25,31] two resonance signals at about δ = 58 and 61 ppm, reflecting tetrahedrally coordinated Al atoms, are observed in the ^{27}Al MAS NMR

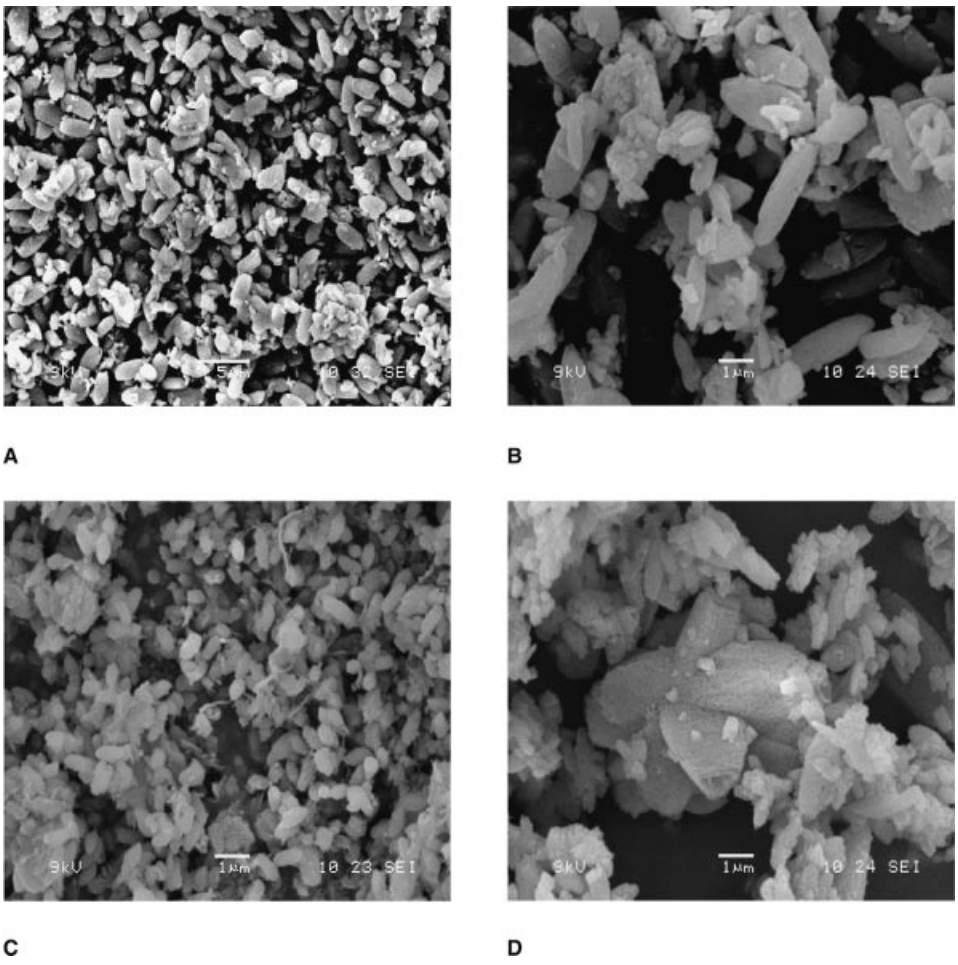

Figure 6. Scanning electron micrographs of zeolites Al-MCM-58 (A, B) and Fe-MCM-58 (C, D).

spectra of Al-MCM-58 with n_{Si}/n_{Al} ratios from 19 to 56 (Figure 7). No resonance around δ = 0 ppm, corresponding to octahedrally coordinated aluminium at extra-framework positions, was observed. This indicates that only tetrahedrally coordinated aluminium is present in Al-MCM-58. The two resonances in the tetrahedral region are explained by the presence of two crystallographically inequivalent aluminium atoms in T1–T4 sites.[31,37] The relative amount of the two different kinds of aluminium (δ = 60.9 and 58.2 ppm) changes with the n_{Si}/n_{Al} ratio: with increasing amount of aluminium in the zeolite, the intensity of the resonance at δ = 60.9 ppm decreases.

The ^{29}Si NMR spectrum of Al-MCM-58 (n_{Si}/n_{Al} ratio = 56) is composed of two broad, complex bands centred around δ = –110 and –102 ppm corresponding to tetrahedrally coordinated silicon atoms with different local environments (see a in Figure 8). The band around δ = –110 ppm can be attributed to Si(4Si) atoms, and is a superposition of four resonances at δ = –107.7, –109.3, –110.7 and –111.8 ppm. These resonances correspond to Si(4Si) atoms at four crystallographically inequivalent positions (T1–T4). The observed chemical shifts are in good agree-

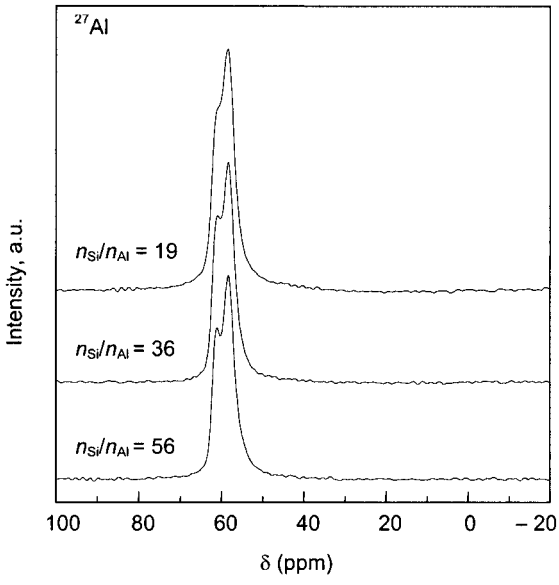

Figure 7. ^{27}Al MAS NMR spectra of Al-MCM-58 samples with different n_{Si}/n_{Al} ratios.

ment with those reported for ITQ-4, which is isostructural with MCM-58 (δ = –108.0, –109.7, –110.9 and –111.5 ppm).[30] The higher resolution of the ^{29}Si NMR spectrum of Al-MCM-58 than that in the literature[31,37] is explained by the decrease in the perturbation of the Si environment due to a lower framework aluminium content. The broad band centred at δ = –102 ppm is ascribed to a superposition of the resonances corresponding to Si(3Si, 1Al) atoms and Si(3Si,OH) atoms. Decomposition of the spectrum to the Gaussian curves (not shown) indicated the presence of two resonances at δ = –101.1 and –104.0 ppm. The resonance at δ = –101.1 ppm can be attributed to Si(3Si, OH) atoms, as indicated by a CP experiment (see a in Figure 8). The resonance at δ = –104.0 ppm corresponds to Si(3Si, 1Al) atoms. Note that the intensity correction factor of Si(3Si, OH) is 1, compared to a value of 0.25 for Si(3Si, 1Al). Thus the relatively high intensity of the resonance at δ = –101.1 ppm compared to that at δ = –104.0 ppm indicates a higher amount of silanol groups than framework Al in the sample. A high amount of silanol groups has also been reported in previous papers from Ernst et al.[31,37]

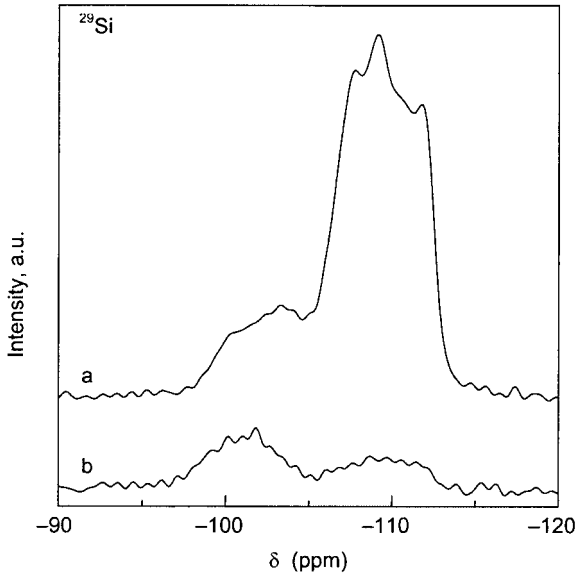

Figure 8. ^{29}Si HP (a) and CP (b) MAS NMR spectra of hydrated Al-MCM-58 (n_{Si}/n_{Al} = 56).

The type and concentration of the acid sites were determined after adsorption of probe molecules such as [D_3]acetonitrile and pyridine on the activated zeolites Al-MCM-58 and Fe-MCM-58, respectively. The spectra of Al-MCM-58 in the region of OH groups before and after adsorption of [D_3]acetonitrile are depicted in part A of Figure 9. The absorption band at 3746 cm^{-1} belongs to terminal Si–OH groups and the two bands at 3630 and 3564 cm^{-1} are characteristic of bridging OH groups. After the interaction with [D_3]acetonitrile, the bands of the hydroxyls groups are significantly reduced and new bands at 2327 cm^{-1} (Lewis sites) and 2297 cm^{-1} (Brønsted sites) are formed (see B in Figure 9).

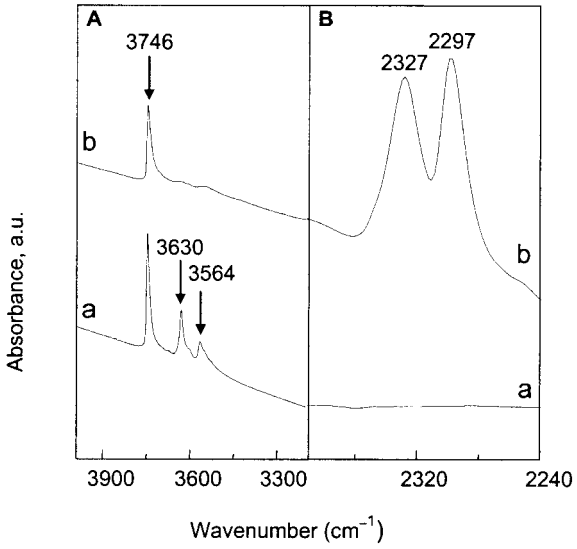

Figure 9. IR spectra of hydroxyl vibration region of Al-MCM-58 with n_{Si}/n_{Al} = 36 before (a) and after (b) [D_3]acetonitrile adsorption (A) and spectra of acetonitrile region before (a) and after (b) its adsorption (B).

In the case of Fe-MCM-58, absorption bands with maxima at 3746 cm^{-1} for terminal Si–OH groups and 3646 and 3520 cm^{-1} for bridging Si–OH–Fe groups (see A,a in Figure 10) were detected. Pyridine adsorption leads to the consumption of all bridging Si–OH–Fe groups (see A,b in Figure 10) and the formation of a band at 1545 cm^{-1} characteristic of the presence of the pyridinium ion, which reflects the interaction of pyridine with Brønsted sites. The band at 1448 cm^{-1} originates from coordinatively bonded pyridine on Lewis sites (see B,b in Figure 10).

The type, strength and concentration of acid sites control the rate and pathway of acid-catalysed reactions such as hydrocarbon cracking and rearrangement. It is evident that Lewis and Brønsted acid sites play a role in catalytic processes; however, their role is still not completely clear. In *n*-butene skeletal isomerisation, it has been shown that an increasing concentration of Lewis sites enhances the rate of deactivation.[32] We tried to modify the concentration of different types of acid sites in MCM-58 by using different methods of calcination. Besides the classical two-step calcination procedure in a stream of nitrogen and air at a calcination temperature of 540 °C, calcination in a stream of ammonia at a temperature of 450 °C was also used. The latter procedure has been described for zeolite beta by Kunkeler et al.,[33] who showed that this treatment results in a reduced formation of Lewis acid sites. They supposed that ammonia ions substitute the leaving organic template cations occluded in the channel system of the zeolite and thus stabilise the zeolite structure. Furthermore, Bourgeat-Lami et al.[34] have proposed that ammonium cations could hinder the formation of octahedrally coordinated aluminium and thus stabilise the structure of the zeolite. In the case of Al-MCM-58 (n_{Si}/n_{Al} = 19), the relative concentration of Brønsted acid sites amounts to about 47% and that of Lewis acid sites to bout 53%. After calcination of this zeolite in a stream of ammonia (5% of NH_3 in N_2) the relative concentration of Brønsted sites increased to 53%. Similar trends were also observed for Fe-MCM-58 (Table 1).

Table 1. n_{Si}/n_{Al} and n_{Si}/n_{Fe} ratios of zeolites Al-MCM-58 and Fe-MCM-58 in the initial gel and in the synthesised zeolite, as determined by X-ray fluorescence (XRF) and FTIR spectroscopy, and the relative amounts of Lewis and Brønsted acid sites.

[a] Initial n_{Si}/n_M ratio in the reaction gel. [b] Adsorption of acetonitrile. [c] Adsorption of pyridine.

The determined concentrations of Brønsted and Lewis acid sites for Al- and Fe-MCM-58 are summarised in Table 1. From a comparison of the n_{Si}/n_{Al} (n_{Si}/n_{Fe}) ratios in the initial reaction mixture and in the synthesised zeolite we found that the obtained product was always richer in aluminium (iron) than the initial gel. The increase in the Al (Fe) content in the zeolite is more notable for Fe-MCM-58 than for Al-MCM-58.

The concentration of the Brønsted acid sites in Al-MCM-58 is practically constant despite the n_{Si}/n_{Al} ratio, while it decreases slightly with an increasing n_{Si}/n_{Fe} ratio. In other words, the higher the concentration of trivalent atoms in the zeolite, the higher the concentration of Lewis sites. The concentration of Brønsted sites depends strongly on the type of trivalent cation. While about 50% of the acid sites are of the Brønsted type in the Al-containing MCM-58 samples, only about 8–16% of the total acid sites are Brønsted sites in Fe-MCM-58. On one side, the concentration of trivalent cations in the synthesised sample is larger for Fe than for Al, whereas the concentration of Brønsted sites is significantly lower for Fe-MCM-58 than for Al-MCM-58. Due to the relatively large ionic radius of Fe^{3+} (0.063 nm) compared to Si^{4+} and Al^{3+} (0.040 nm and 0.053 nm,[35] respectively), the incorporation of iron into the framework is expected be much more complicated. Some evidence for the incorporation of iron into the Fe-MCM-58 framework can be obtained from the ESR spectra. The X-band EPR spectra (not shown) recorded at –196 °C for the calcined Fe-MCM-58 materials with different n_{Si}/n_{Fe} ratios show a sharp signal at g = 4.3 with shoulders at g = 9.1 and g = 2.3 and an intense broad signal at g = 2. The relative proportion of the signal at g = 4.3 decreases from n_{Si}/n_{Fe} = 40 to 20. The signal intensity is directly proportional to the iron content in the materials with different n_{Si}/n_{Fe} ratio. The assignment of the EPR signals to various species is still a matter of debate and is beyond the scope of this paper. Details can be found in our subsequent publication.[36]

Conclusions

Zeolite MCM-58 containing trivalent metal cations such as Al and Fe in the framework can be readily synthesised with *N*-benzylquinuclidinium bromide as the structure directing agent and Levasil (30% SiO_2 in water) as the silica source. The synthesis of Al-MCM-58 was accomplished at an SiO_2/BQ concentration of 0.1 in a wide range of initial n_{Si}/n_{Al} ratios (20 to 60) under dynamic conditions at 170 °C.

Incorporation of iron into the zeolite framework is not as straightforward. The synthesis requires a lower temperature, higher concentration of the template, and the suitable range of initial n_{Si}/n_{Fe} ratios is narrower (20 to 40). The synthesis was carried out with a SiO_2/BQ ratio of 0.2, under dynamic conditions at 155 °C.

The acid forms of both Al-MCM-58 and Fe-MCM-58 contain substantial amounts of Brønsted and Lewis acid sites. After calcination in a stream of ammonia, the amount of Brønsted sites was slightly greater than after conventional calcination in nitrogen and air.

Experimental Section

Abbreviations: BQ = *N*-benzylquinuclidinium bromide, CP = cross polarisation.

The syntheses of MCM-58 with n_{Si}/n_{Al} ratios in the initial synthesis gel ranging from 20 to 60 and n_{Si}/n_{Fe} ratios ranging from 20 to 40 were investigated under hydrothermal conditions in Teflon-lined, stainless-steel autoclaves (35 and 90 mL) under autogenous pressure. *N*-Benzylquinuclidinium bromide (BQ) was used as structure-directing agent in a modified version of the procedure for the synthesis of zeolite MCM-58 described previously.[37]

N-Benzylquinuclidinium bromide was prepared by refluxing an equimolar mixture of benzyl bromide (from Fluka) and quinuclidine (from Fluka) in ethanolic solution for 24 h. Crystals were recovered after cooling the reaction mixture in an ice bath. The chemical composition and structure of the template were confirmed by elemental analysis and NMR spectroscopy.

The synthesis gels were prepared in polyethylene beakers at ambient temperature. In a typical synthesis of Al-MCM-58, 3.69 g of $Al_2(SO_4)_3 \cdot 18\,H_2O$ (from Fluka) was dissolved in 88.00 g of distilled water. To this solution, 3.24 g of KOH (from Lachema, CZ) and subsequently 4.02 g of *N*-benzylquinuclidinium bromide (as made) were added whilst stirring. Later on, 30.00 g of colloidal silica sol (30 wt.-% SiO_2 in water, Ludox AS-30, from Aldrich) was added slowly with vigorous stirring to the reaction mixture, which was finally homogenised for 2 min. The resulting gel was loaded into 90-mL, Teflon-lined, stainless steel autoclaves. The synthesis was carried out with agitation at 170 °C for Al-MCM-58 and at 155 °C for Fe-MCM-58 for 4 to 9 days. For the synthesis of Fe-MCM-58, the aluminium source was replaced by $Fe(NO_3)_3 \cdot 9\,H_2O$ (from Fluka) and instead of Ludox AS-30, Levasil VP 4038 (30% SiO_2 in water, from Bayer AG) was used. After crystallisation, the autoclaves were cooled to room temperature by quenching in cold water; the solid product was recovered by filtration, washed with distilled water, and dried at 80 °C overnight.

To remove the template, the as-synthesised sample was heated to 200 °C in a stream of nitrogen with a temperature ramp of 1 °C min^{-1} and kept at the same temperature for 4 h. Thereafter, the sample was heated to 540 °C with the same heating rate and kept for 2 h at this temperature. Finally, the material was calcined for 24 h in a stream of air at 540 °C.

In a second set of experiments the as-synthesised sample was treated in a stream of ammonia at 470 °C for 8 h with a heating rate of 1 °C min^{-1}. The samples were then ion-exchanged twice with a 0.5 M $NaNO_3$ solution for 8 h and once with 1.0 M $NaNO_3$ for 8 h using 100 mL of solution per gram of zeolite at room temperature. Finally, the sample was calcined again as described above.

The ammonium forms of both zeolites were prepared by fourfold repeated ion-exchange of the zeolite in a 0.5 M aqueous solution of ammonium nitrate at ambient temperature.

X-ray powder diffraction was used for identification of as-synthesised zeolites and the determination of their crystallinity to follow the kinetics of the crystallisation process. The XRD patterns were collected on a Siemens D5005 X-ray powder diffractometer equipped with a graphite monochromator and scintillation counter using Cu-K_α radiation in Bragg–Brentano geometry. Relative crystallinity is defined as the intensity of the peak at $2\theta = 20.53°$ compared to that of the MCM-58 sample with the highest crystallinity obtained in this study.

^{29}Si and ^{27}Al MAS NMR experiments were performed on a Bruker Avance 500 MHz (11.7 T) Wide Bore spectrometer operating at Larmor frequencies of 130.3 MHz for aluminium and 99.35 MHz for silicon using 4 mm and 7 mm o.d. rotors, respectively. Prior to the NMR experiments, all calcined samples were ion-exchanged three times with a 0.5 M NaCl solution for 8 h using 100 mL of solution per gram of zeolite at room temperature. In order to monitor Si coordination and local environment in the samples, ^{29}Si MAS NMR high-power decoupling (HPDec) and cross-polarisation (CP) experiments were carried out. In the case of high-power decoupling, pulse sequences with a $\pi/6$ (1.7 μs) excitation pulse and relaxation delay of 30 s were applied. 1024 FIDs were accumulated to obtain a sufficiently good signal-to-noise ratio. In the case of cross-polarisation spectra, pulse sequences with 50% ramp CP pulse, contact time 2 ms, high-power decoupling and a relaxation delay of 5 s were applied. 10 240 FIDs were accumulated to obtain the spectrum. Rotors were spun at a speed of 5 kHz; chemical shifts are referenced to the chemical compound Q8M8 as a standard. ^{29}Si high-power decoupling spectra were decomposed to the Gaussian bands using Microcall Origin 4.1 software (Microcall Software Inc., U.S.A.).

In order to measure the ^{27}Al MAS NMR spectra, high-power decoupling pulse sequences with a $\pi/12$ (0.7 μs) excitation pulse and relaxation delay of 1 s were applied; 1024 FIDs were accumulated to obtain the spectrum. Rotors were spun at a speed of 12 kHz;chemical shifts are referenced to an aqueous solution of $Al(NO_3)_3$.

The shape and the size of zeolite crystals were determined by scanning electron microscopy (JEOL, JSM-03). X-ray fluorescence spectroscopy was employed to estimate the chemical composition of Al- and Fe-MCM-58.

The concentrations of Brønsted and Lewis acid sites in Al-MCM-58 and Fe-MCM-58 were determined after the adsorption of [D_3]-acetonitrile and pyridine, respectively, followed by FTIR spectroscopy using a Nicolet FTIR Protégé 460 spectrometer. For this purpose, the zeolite powders were pressed binder-free into self-supporting wafers with a density from 4.0 to 10.0 mg cm^{-2}. [D_3]Acetonitrile was degassed by repeated freeze-thaw cycles before use. Prior to the adsorption of [D_3]acetonitrile, the zeolites were activated in situ by overnight evacuation at 400 °C. All measured spectra were recalculated to a normalised wafer thickness of 10 mg cm^{-2}. For a quantitative characterisation of the Brønsted acid sites (B), the C≡N–B vibration at about 2296 cm^{-1} was used with an extinction coefficient of $\varepsilon_B = 2.05 \pm 0.1$ cm μmol^{-1}. For a quantitative evaluation of Lewis acid sites (L), the C≡N–L vibration at 2323 cm^{-1} was used with an extinction coefficient of $\varepsilon_L = 3.6 \pm 0.1$ cm μmol^{-1}.[38] To determine the concentrations of acid sites in Fe-MCM-58, pyridine was used as a probe molecule. From the integral intensities of individual bands at 1545 cm^{-1} (Brønsted sites) and at 1448 cm^{-1} (Lewis sites) and using extinction coefficients of $\varepsilon_L = 1.67 \pm 0.1$ and $\varepsilon_B = 2.22 \pm 0.1$ cm μmol, respectively, concentrations of both types of acid sites were calculated according to ref.[39]

Crosslinking Mechanism of Boric Acid with Diols Revisited

Marcel Rietjens*[a,b] and Peter A. Steenbergen[a,c]

Keywords: Boric acid / Borate / Diols / Guaran / Crosslinking / Rheology

Complex formation of boric acid with diol functional groups is well known and many papers have been published assuming borate is the reactive species. Based on the high reactivity of boric acid towards nucleophiles, this paper assumes boric acid is the reactant. We prove this hypothesis by presenting a study of the reaction of the polymer guaran with boric acid under various conditions. A thermodynamic analysis of the underlying reactions does not show any differences between either crosslinking species. Thermodynamics shows that the concentration of the 2:1 crosslinks, that give rise to the enhanced viscosity, is proportional to [B], the boric acid concentration, [X^2], the concentration of available crosslink sites and inversely proportional to [H^+]. These predictions were all confirmed by experiment. However, a difference between the mechanisms is demonstrated in a kinetic analysis: Longer gel times are predicted with the mechanism based on boric acid as the pH of the fluid increases, that is exactly what is observed in practice. Evidence is provided from visco-elastic measurements. A new approach to describe inter- and intramolecular crosslink formation is introduced and evidence for the correctness of this description is provided.

Introduction

Gelled fluids based on the natural polysaccharide guaran, crosslinked with for example borate, are generally used to fracture oil and gas wells to improve productivity. These fractures start at the well bore and can extend up to several hundred meters into the formation. Basically, this process tremendously increases the surface area of the well bore. In the preparation of borate crosslinked gels, pH (control) is crucial to the success of fracture treatments. The effects of pH and temperature on borate equilibriums have been well described and summarized by Harris.[1] Interestingly, when these gels are prepared the crosslink time depends on the pH of the solution: the higher the pH, the longer it takes to form a gel. At a pH value of 12 and above, the crosslink time may be an hour or longer. This cannot be explained by assuming borate as the reactive species. An additional interesting feature of borate crosslinked gels is their self-healing property: i.e. when exposed to high shear stresses, the network breaks up (shear thinning) but reheals quickly when it comes to rest.[1–3]

Guaran consists of a (1→4) linked mannosepyranosyl backbone with single galactosepyranosyl units connected by (1→6) linkages. The ratio between mannose and galactose is about 2:1.[4,5] Both monomers are capable of forming complexes with boric acid. The complex formation constant strongly depends on the stereochemistry of the diol functionality and their relative positions, 1,2 or 1,3. These aspects have been treated in detail by van den Berg et al.[6] Nuclear Magnetic Resonance (NMR) experiments have shown that complex formation constants of 1,2-diols are larger than 1,3-diols whereas 1,2 complex formation constants of mannose and galactose 1:1 complexes are comparable.[7,8] Combined with the known ratio of mannose to galactose in guaran, boric acid preferentially forms crosslinks with mannose in a ratio of 2:1 in agreement with experiment.[5]

Many authors have assumed borate is the reactive species[1,2,5,8–15] while others have assumed cations to be involved.[14] In a few cases boric acid was proposed as the reactant but merely because the reactions took place at very low pH values.[13] Tetraborate was assumed to be the crosslinking reactant by Khomutov et al., which is more in line with the proposed mechanism covered in this paper because it contains trivalent boron.[16] Van Duin[17,18] realized, based on similar arguments as given below, that boric acid could also be the reactive species and takes both boric acid and borate into account in the reaction equations.

In principle, reaction of an alcoholic group with borate is similar to the formation of an ether and requires dehydration. These types of reactions require time and specific conditions such as heat, to overcome the activation energy, and the removal of water. Properties like self-healing and the fact that equilibrium between boric acid and borate is faster than the NMR time scale can only be explained provided the reactions are fast, in contradiction with the above observations for ether formation. Thus the reaction must

[c] Current address: Panterra Geoconsultants,
Leiderdorp, The Netherlands
E-mail: p.steenbergen@panterra.nl

have a very low activation energy. A determination of this latter value shows that it is indeed low and was reported to be 20.5 kJ/mol.[15] The trivalent B atom in boric acid has an empty p orbital that is very electrophilic in nature; it rapidly reacts with various nucleophiles to form complexes.[19] Therefore, a much more likely alternative mechanism is to assume boric acid as the reactant.

Theory

First, the two models based on boric acid and based on borate will be described. We assume that all crosslink sites are available for reaction and, for the moment, we do not differentiate between inter- and intramolecular crosslinks (Mxl). This issue will be dealt with later because we are primarily interested in the concentration of inter-Mxls because these give rise to visco-elasticity. We further assume similar behavior of guar (G) and hydroxypropylguar (HPG). Thus values for K_1 and K_2 are expected to be similar in magnitude. In the equations below, the following abbreviations are used:

X: Free crosslink site on guar polymer chain

B: $B(OH)_3$

B^-: $B(OH)_4^-$

X_1B/X_1B^-: 1:1 Complex with B in the boric acid/borate form crosslinked with one guar chain.

X_2B^-: 2:1 Complex in which two guar chains are crosslinked by one borate molecule and which is always negatively charged. X_2B^- includes both inter- and intramolecular crosslinks.

Boric Acid as the Reactive Species. Thermodynamics: The fundamental equilibriums are:

$$B + H_2O \rightleftarrows B^- + H^+ \quad (1a)$$

$$B + X \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} X_1B^- + H^+ + H_2O \quad (2a)$$

$$X_1B^- + H^+ \rightleftarrows X_1B + H_2O \quad (3a)$$

$$X_1B + X \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} X_2B^- + H^+ + H_2O \quad (4a)$$

Further, the mass balance is given by:

$$[B_{total}] = [B_t] = [B] + [B^-] + [X_1B] + [X_1B^-] + [X_2B^-] \quad (5a)$$

When substituting the expressions for B^-, X_1B^- etc. into Equation (5a) and rearranging we get:

$$[B_t] = [B]\cdot\left[1 + \frac{K_a}{[H^+]} + \frac{K_1\cdot[X]}{[H^+]} + \frac{K_1\cdot[X]}{K_a^{1:1}} + \frac{K_1\cdot K_2\cdot[X^2]}{[H^+]\cdot K_a^{1:1}}\right] = [B]\cdot M \quad (6a)$$

here K_a is the acid dissociation constant of boric acid, $K_a^{1:1}$ the acid dissociation constant of the complex X_1B, K_1 the equilibrium constant for the formation of the 1:1 complex and K_2 the formation constant of the 2:1 complex. The concentration of 2:1 complexes is then given as:

$$[X_2B^-] = \frac{K_1\cdot K_2\cdot[B_t]\cdot[X^2]}{[H^+]\cdot K_a^{1:1}\cdot M} \quad (7a)$$

Equation (7a) is the fundamental thermodynamic expression that describes the concentration of the 2:1 crosslinked products as a function of X, B and pH.

Borate Anion as the Reactive Species. Thermodynamics: In this case Equation (2a) and (4a) are defined as:

$$B^- + X \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} X_1B^- + 2H_2O \quad (2b)$$

$$X_1B^- + X \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} X_2B^- + 2H_2O \quad (4b)$$

The mass balance is now defined as:

$$[B_t] = [B^-]\cdot\left[\frac{[H^+]}{K_a} + 1 + \frac{K_1\cdot[H^+]\cdot[X]}{K_a^{1:1}} + K_1\cdot[X] + K_1\cdot K_2\cdot[X^2]\right] = [B^-]\cdot N \quad (6b)$$

The concentration of 2:1 complexes is now given by:

$$[X_2B^-] = \frac{K_1\cdot K_2\cdot[B_t]\cdot[X^2]}{N} \quad (7b)$$

Equation (7a) and (7b) show $[X_2B^-]$ is linear in $[X^2]$ and $[B_t]/M$ or $[B_t]/N$ in both models. In fact Equation (7a) and (7b) are exactly equivalent and therefore thermodynamics *cannot* differentiate between both mechanisms.

Boric Acid as the Reactive Species. Kinetics: The basic general rate equations for the formation of 1:1 and 2:1 complexes are:

$$Rate = \frac{d([X_2B^-])}{dt} = k_2\cdot[X_1B]\cdot[X] - k_{-2}\cdot[X_2B^-]\cdot[H^+] \quad (8a)$$

$$\frac{d([X_1B])}{dt} = k_{-a}^{1:1}\cdot[X_1B^-]\cdot[H^+] - k_a^{1:1}\cdot[X_1B] - k_2\cdot[X]\cdot[X_1B] + k_{-2}\cdot[X_2B^-]\cdot[H^+] \quad (9a)$$

$$\frac{d([X_1B^-])}{dt} = k_1\cdot[B]\cdot[X] - k_{-1}\cdot[X_1B^-]\cdot[H^+] - k_{-a}^{1:1}\cdot[X_1B^-]\cdot[H^+] + k_a^{1:1}\cdot[X_1B] \quad (10a)$$

A steady state is assumed for the formation of X_1B and X_1B^-. In other words $d([X_1B])/dt = d([X_1B^-])/dt = 0$. The justification for these assumptions is that reaction rates in-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

volving free boric acid, which is a small molecule, are much greater than reaction rates involving two polymer chains.

An expression for $[X_1B]$ in terms of [B], [X] and $[X_2B^-]$ can now be derived from Equation (9a) and (10a). Substitution in Equation (8a) yields:

$$\frac{d([X_2B^-])}{dt} = C_1 + C_2 \cdot [X_2B^-] \quad (11a)$$

with

$$C_1 = \frac{k_{-a}^{1:1} \cdot k_1 \cdot k_2 \cdot [B] \cdot [X^2]}{k_{-1} \cdot k_a^{1:1} + k_{-1} \cdot k_2 \cdot [X] + k_{-a}^{1:1} \cdot k_2 \cdot [X]} \quad (12a)$$

and

$$C_2 = \frac{(k_{-1} \cdot k_{-2} + k_{-a}^{1:1} \cdot k_{-2}) \cdot k_2 \cdot [X] \cdot [H^+]}{k_{-1} \cdot k_a^{1:1} + k_{-1} k_2 \cdot [X] + k_{-a}^{1:1} \cdot k_2 \cdot [X]} - k_{-2} \cdot [H^+] \quad (13a)$$

After applying the initial condition $X_2B^- = 0$ for $t = 0$, the solution of Equation (11a) is:

$$[X_2B^-] = \left(e^{C_2 \cdot t} - 1\right) \cdot (C_1 / C_2) \quad (14a)$$

Borate Anion as the Reactive Species. Kinetics: The derivation is very similar and the solution of the differential equations has the same form with C_1 and C_2 expressed as:

$$C_1 = \frac{k_1 \cdot k_2 \cdot [B^-] \cdot [X]^2}{k_{-1} + k_2 \cdot [X]} \quad (12b)$$

$$C_2 = \frac{k_2 \cdot k_{-2} \cdot [X]}{k_{-1} + k_2 \cdot [X]} - k_{-2} \quad (13b)$$

As t approaches infinity, both kinetic expressions yield the thermodynamic relation. The main difference is that the term C_2 is independent of pH in the borate model whereas it is a function of pH in the boric acid model.

Results and Discussion

In the calculations and discussions that follow we introduce [X*], the critical concentration of crosslink sites in mol/L, similarly defined as the critical overlap concentration of a polymer, [P*]. Likewise, the concentrations of 1:1 and 2:1 complexes are expressed in mol reacted crosslink sites/L. In plots or when dealing with critical concentrations, we sometimes use the polymer concentrations [P] and [P*] in g/L because these are more familiar in use. No precautions were made to minimize effects due to charge repulsion by the addition of salt.

Chemistry of Borate Complexes: Both 1,2- and 1,3-diols can form 1:1 and 2:1 complexes with boric acid. Each reaction is assumed to proceed in two steps, and because the second step, ring closure, is relatively fast due to the chelate effect, the first step is rate limiting.[17] Paál[20,21] discusses effects of induction, solvation, and H-bonding, in the case that multiple OH groups are present, on the value of K_1. Boric acid complexes with 1,2-diols are well known to possess higher acidities as opposed to 1,3-diols.[15,21,22] The stronger acidity is primarily caused by ring strain. Complexes formed from 1,3-diols form six rings and are slightly more acidic compared to boric acid[15,22] but complexes from 1,2-diols are five rings and have considerable ring strain. In the neutral form, the hybridization of the B nucleus is sp^2 vs. sp^3 in the borate form. In the transition to the borate form, the ring strain is relieved and the activation energy decreases to even lower values.

The stability of 1:1 and 2:1 borate complexes has been shown to be optimum in a certain pH range. Below and above this range no complexes are formed.[17,23] The reason that has been forwarded at high pH values, > 13, is charge repulsion because of deprotonation of the diol group.[13,23] Although we propose compounds containing trivalent boron, B and X_1B, as the reactant species, B and X_1B are still in rapid equilibrium with B^- and X_1B^- respectively. As a consequence, the boron nucleus will be negatively charged on average and therefore subject to charge repulsion.

Inter/intramolecular Crosslinking: In the derivation of the equations above no account was given to inter- and intra-Mxls. Because visco-elasticity is a function of the concentration of inter-Mxl only this must be incorporated in the model. We assume that the polymer coils have a fixed radius of gyration that is independent of the polymer concentration. Thus at [P] > [P*] the coils mix instead of compressing each other. The first step, formation of the 1:1 complex, is the same for both inter- and intra-Mxls. Basically, this formation is a reaction between a crosslink site and boric acid. Because the latter is able to move freely throughout the fluid, all potential crosslink sites are available for reaction. The concentration of 1:1 complexes is than proportional to [X]·[B].

The formation of 2:1 intra-Mxl complexes is a reaction between a 1:1 complex and a free crosslink site in the same polymer chain. At [P] < [P*], the available number of crosslink sites equals the number of crosslink sites within the individual coil. Effectively, this is the same (bulk) concentration as when the coils just touch each other, i.e. at [P] = [P*]. Therefore, the effective concentration of crosslink sites within each coil is equal to [X*]. For intra-Mxls, this relation applies also to concentrations above [P*] because we have assumed the radius of gyration as constant and because reaction with other coils are counted separately as inter-Mxls. Therefore, the concentration of intra-Mxls is proportional to [X]·[X*].

At [P] > [P*] coils of different polymer chains touch each other and reactions between different polymer coils lead to inter-Mxls. Formation of inter-Mxls are assumed to commence at [P] > [P*]. As with intra-Mxls, inter-Mxls are the reaction products from a 1:1 complex and an available crosslink site. Now the number of available crosslink sites is proportional to ([X] – [X*]) because only that portion is able to react with other coils. It follows that the concentration of inter-Mxls is proportional to [X]·{[X] – [X*]}. The ratio of inter- and intra-Mxls is then simply calculated as {[X] – [X*]}/[X*] and is > 0 at [P] > [P*]. However, at polymer concentrations higher than P* deviations can be

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

anticipated. For example, due to excluded volume effects, compression of the coils can be expected to some extent. This leads to an effective higher concentration of P*. Overall, the concentration of 2:1 complexes can be calculated as the sum of inter- and intra-Mxls and is proportional to $[X]^2$ [see Equation (7a)]. The fractions F of the inter- and intra-Mxls are calculated as:

$$F_{Inter} = \frac{P - P^*}{P} \quad (15a)$$

$$F_{Intra} = \frac{P^*}{P} \quad (15b)$$

having a ratio of

$$\frac{Inter}{Intra} = \frac{P - P^*}{P^*} \quad (15c)$$

Pezron et al. derived a different equation for the ratio between inter- and intra-Mxls.[9] They relate a critical concentration C_0 to the average size of a loop or an intra-Mxl. The ratio inter/intra is calculated as $(C/C_0)^{5/4}$. For guar of similar molecular weight they assessed a value for C_0 of 4%. In their view, the concentration of inter-Mxls is always > 0, assuming a $[P] > 0$, and steadily grows. However, even at a polymer concentration twice as large as [P*], the ratio is barely 0.05, whereas in our case it is 1, that is twenty times as large. This issue is further discussed in the model parameter section that follows. We do agree with the statement of Pezron et al. that the ratio inter/intra is dependent on the flexibility of the polymer coils. The more flexible, the closer the segments are to each other favoring intra-Mxl. In our view this is accounted for in the higher value of [P*] because a more flexible coil has a smaller radius of gyration.

Model Parameters: We have deduced the model parameters from first principles and available date of equilibrium constants published in the literature. Further, we have applied the concept of reduced diffusion coefficient in analogy with the reduced mass and is defined as: $D_{reduced} = D_1 + D_2$, where D_1 and D_2 are the diffusion coefficients of the species 1 and 2.

***K*$_a$:** The equilibrium between boric acid and borate is known to be very fast, even faster then the NMR time scale. The reverse rate constant, k_{-a}, was determined by Gilkerson as $1.3 \cdot 10^{10}$ L·mol^{-1}·s^{-1}.[24] Based on this value and the known value of K_a of boric acid,[25] $5.8 \cdot 10^{-10}$ mol·L^{-1}, the forward rate constant, k_a, is calculated as 7.5 s^{-1}. The value of k_{-a} will be used as a basis for the rate constants k_{-1} and k_{-2}.

[P], [P*]: The critical concentration P* was determined by measuring G' as a function of [P] down to the lowest measurable concentration of 1.7 g/L, with and without additional crosslinker. The value of [P*] was taken as the concentration where the two curves merge and was assessed at 2.04 g L^{-1}. This value is in good agreement with published values.[5]

[X], [X*]: At a polymer concentration of 3 g/L, the concentration of [X] is calculated as $0.73 \cdot 3/179 = 0.012$ mol·L^{-1}. The average Mw of a monomer in HPG is about 179 and 0.73 is the fraction of crosslink sites available per monomer due to the HP groups. The value of X* is 0.0083 mol·L^{-1}.

***K*$_1$, *k*$_{-1}$, *k*$_1$:** The value for k_{-1} is deduced from k_{-a}. Three effects influence its value: 1) Compared to the borate anion, which has four OH groups, the 1:1 complex has two OR groups thus a statistical chance of 2/4 to become protonated followed by elimination of H_2O. 2) Compared to OH groups, OR groups have a twofold lower basicity thus have equally less chance to become protonated.[26] 3) The 1:1 complex dissociates into boric acid and a polymer chain and, compared to water, as in the reverse reaction of B^- to B, boric acid has a roughly threefold smaller diffusion coefficient. In summary, the value of k_{-1} is calculated as $1.3 \cdot 10^{10}/(2 \cdot 2 \cdot 3) = 1.08 \cdot 10^9$ L·mol^{-1}·s^{-1}. The value of the equilibrium constant K_1 is calculated from literature data based on dialysis measurements: $K'_1 = 11$ L·mol^{-1} and is defined as $K'_1 = [X_1B^-]/([B^-] \cdot [X])$.[8] In this paper K_1 is defined as $K_1 = [X_1B^-] \cdot [H^+]/([B] \cdot [X])$. Because $K_1 = K'_1 \cdot K_a$ its value is $6.4 \cdot 10^{-9}$. The value of k_1 is then calculated as 6.9 L·mol^{-1}·s^{-1}.

***K*$_a^{1:1}$, *k*$_{-a}^{1:1}$, *k*$_a^{1:1}$:** The acidity of the (neutral) 1:1 complex is defined by $K_a^{1:1}$. Its value is required to calculate K_2. It is well known that the acidity of boric acid increases upon the addition of a 1,2-diol. Sugars such as mannitol and sorbitol are widely used for this purpose in analytical chemistry. Based on titration data with these sugars, apparent K_a values were calculated for boric acid complexes.[27] Based on these data, we estimate an apparent $K_a^{1:1}$ value for the 1:1 complex of $1 \cdot 10^{-5}$ mol·L^{-1}. The absolute value is in fact not relevant for the calculated crosslink density because $K_a^{1:1}$ cancels out in the equation for $[X_2B^-]$. However, it does point out that X_1B complexes are much more acidic and that the concentration of the neutral 1:1 complex decreases very rapidly with increasing pH. The value of $k_{-a}^{1:1}$ is based on the value of k_{-a}. Because there are two OH groups vs. four in borate, the statistical factor is 2/4. We neglect any effect on the basicity of the OH groups due to the complexed diol. Because the values of $k_a^{1:1}$ and $k_{-a}^{1:1}$ are of no concern for the result, ring strain caused by complexation with an 1,2-diol is accounted for only in an increase in the value of $k_a^{1:1}$, not in $k_{-a}^{1:1}$. The reduced diffusion coefficient is that for water and does not change. The value for $k_{-a}^{1:1}$ is then $1.3 \cdot 10^{10}/2 = 6.5 \cdot 10^9$ L·mol^{-1}·s^{-1} and $k_a^{1:1} = K_a^{1:1} \cdot k_{-a}^{1:1} = 6.5 \cdot 10^4$ s^{-1}.

***K*$_2$:** Similar to K_1 we can express K_2 as $K'_2 \cdot K_a^{1:1}$. Pezron[8] defined K'_2 as $K'_2 = [X_2B^-]/([X_1B^-] \cdot [X])$. Two sets of data are available that should allow for the calculation of K_2, NMR spectroscopic data and rheological data. Because the NMR spectroscopic data have a high level of uncertainty, we used the data based on rheological experiments.[2] A critical note to place is that these data have not been corrected for physical crosslinks (see below). The value of K'_2 was obtained from the slope of G' vs. $[P]^{2.6} \cdot [B^-]$ (Figure 6 in ref.[2]), although it is unclear why they have used a power

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of 2.6 instead of 2. The same analysis, but based on a power of 2, yields a slightly better fit. Further, they state that the slope is equal to $2{\cdot}K'_2{\cdot}RT$ but substitution of the appropriate definitions for $[X_2B^-]$ in Equation (16) below, results in $2{\cdot}K'_1{\cdot}K'_2{\cdot}RT$. Using a power of 2.6 the value of K'_2 yields 0.43 mol·L^{-1} whereas with a power of 2 the value of K'_2 is only 0.09 mol·L^{-1}. Model calculations with a value of K'_2 = 0.09 mol·L^{-1} give smaller values for G' than observed experimentally and consequently the deviations, see Table 1, are < 1. The strange observation we then make is that the deviations become even larger (thus $<< 1$) in tests with higher polymer concentrations, whereas at higher polymer concentrations a gel behaves more rubber-like in line with model requirements. Therefore we have decided to use the value of 0.43 mol·L^{-1} instead. The value of K_2 is calculated as $4.3{\cdot}10^{-6}$.

In calculating the value of k_{-2}, the statistical factor is now 4/4 = 1, because there are four possibilities to break a bond of a diol as in B^-. The basicity is still twofold smaller than OH in B^-. At this point dissociation is between two polymer chains that have considerably smaller diffusion coefficients. From data of Brandrup,[28] the value of D for a guar sample with a M_w of 657.000 is $0.54{\cdot}10^{-11}$ m^2·s^{-1}. The molecular weight of the sample we used is approximately $2.0{\cdot}10^6$. Based on the data given in Brandrup, an empirical relation between D and M_w could be set up and based on this relation a value of D for the HPG sample used is calculated as 0.10 10^{-11} m^2·s^{-1}. Compared to the value for water ($D = 2.26{\cdot}10^{-9}$ m^2·s^{-1}), this value is about 2000-fold smaller. The value of k_{-2} is then calculated as $1.3{\cdot}10^{10}/(2{\cdot}2000) = 3.2{\cdot}10^6$ L·mol^{-1}·s^{-1}. From K_2 and k_{-2}, k_2 is finally calculated as 14 L·mol^{-1}·s^{-1}.

Physical Crosslinking: Solutions of guaran are very viscous and possess some degree of visco-elasticity caused by physical crosslinks or entanglements.[29] Because the model outlined above is based on chemical crosslinks, G' data must be corrected for contributions due to physical crosslinks (G'_{phys}). Experiments showed that physical crosslinks form very fast as plateau values were attained within few minutes. The value of G'_{phys} can be expected to be a function of polymer concentration and pH.[29] Figure 1 shows that the value of G'_{phys} is constant up to a pH of about 12, after which it decreases with increasing pH.

This observation is in line with data presented by Goycoolea et al.,[29] and is thought to be caused by charge up on the polymer chain due to deprotonation. In principle, the polymer behaves like a polyelectrolyte at very high pH values.[30] Assuming a pK_a value of 14.7 for the OH groups, it can be calculated that about 1% is dissociated at a pH value of 12.5.[26,30] The acquired charge leads to repulsion between chains, and therefore, partial disruption of the weak physical crosslinks. Charge up of the polymer is also caused by 1:1 complexes (the concentration of 2:1 complexes is relatively small). In the determination of the values for G'_{phys}, fructose was added to mask boric acid. A consequence is that 1:1 complexes are also not formed, whereas they are formed in the other experiments. This means that the values for G'_{phys} are overestimated, and therefore G′ values for chemical crosslinks are overcorrected. Model calculations, however, show that at the highest polymer and borate concentrations used, the concentration of 1:1 complexes is only 0.4% (relative to the total number of crosslink sites) so the magnitude of the overcorrection should be small. This observation is in agreement with calculations by Ochiai.[31] The effect of polymer concentration on G'_{phys} is shown in Figure 2.

In principle, one could expect G'_{phys} to be proportional to [P]·{[P] – [P*]}, the reason being similar to chemical

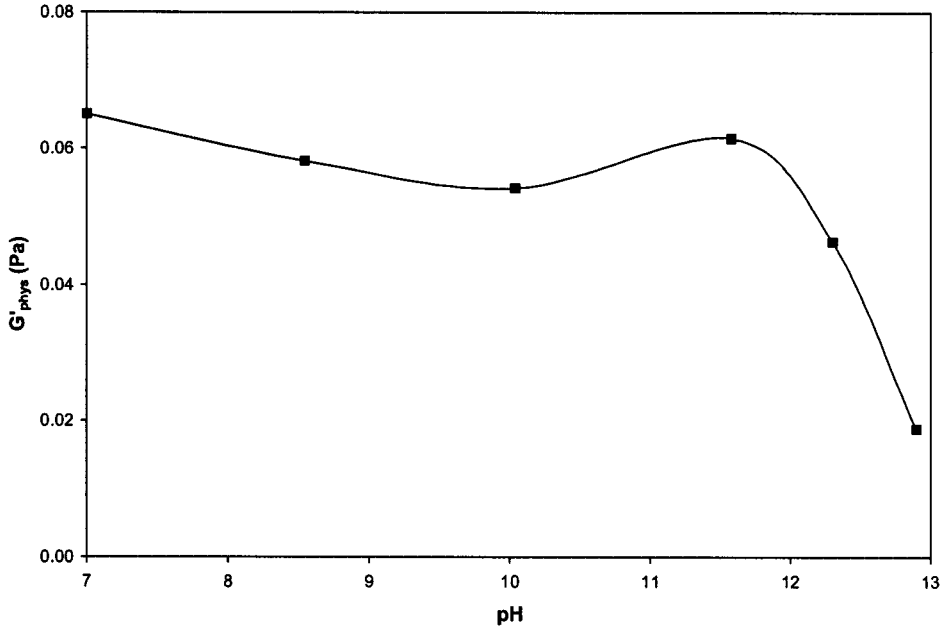

Figure 1. Effect of pH on visco-elasticity due to physical crosslinking.

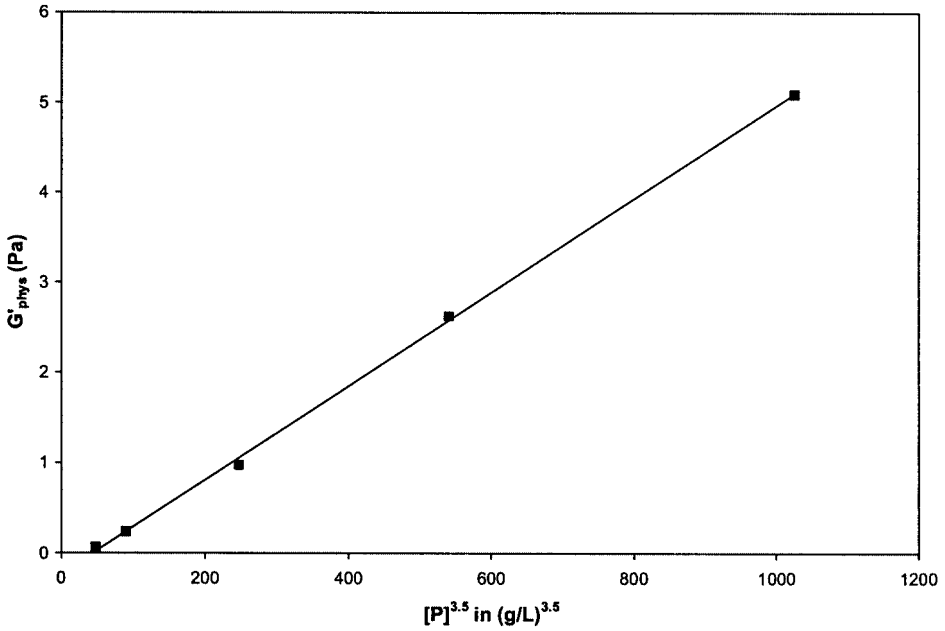

Figure 2. Effect of polymer concentration on visco-elasticity due to physical crosslinking.

crosslinking. This was not confirmed by an analysis, instead we found excellent correlations with the relations $G'_{phys} \approx [P]^{3.5}$ and $G'_{phys} \approx [P]^2 \cdot \{[P] - [P^*]\}$.

Model Validation. Thermodynamics: The dependence of G' as a function of total boron concentration is shown in Figure 3. Because these experiments were run at the same pH value, no account needed to be given to M. A straight line is observed in agreement with theory and published data.[2,3,14]

Equation (7a) further predicts a linear relationship between G' and $[P] \cdot \{[P] - [P^*]\}$. This relation is shown in Figure 4. This curve is clearly not linear but has some curvature because we assume

$$G' = 2\,[X_2B^-]_{Inter}RT \quad (16)$$

to be valid at very low values of G'. Schultz and Myers,[3] however, indicate that a minimum value for $[X_2B^-]_{inter}$ is required for this relation to be valid. Thus Equation (16) is true only if the gel behaves like an ideal rubber. The gels in our experiments have a very low crosslink density and cannot be considered a real rubber. However, this argument

is equally true for the data shown Figure 3. Because the corrections due to physical crosslinks in Figure 4 were up to 50% and were not a constant value, as opposed to data in Figure 3, and are subject to error also, the observed curvature may be misleading. Note that similar deviations from ideal behavior are shown in data published by Pezron et al. in gels with low B_t content and low polymer concentration: compare parts a–d in Figure 5 in ref.[2]

In Figure 5, G' is plotted as a function of pH at fixed concentrations of polymer and $[B_t]$. In the same Figure, the calculated model curve is included as well using a deviation factor of 3.6 (see later). Although there is some scatter in the experimental data at high pH values, the match with the theoretical curve is quite reasonable. Effects of deprotonation of the polymer chain could be anticipated at the highest pH value tested, 12.8, but because of the amount of scatter, it is difficult to state that the experimental curve drops below the theoretical curve. Experiments by van Duin et al.[23] do show that at deprotonation conditions, 0.5 M NaOH, the complex formation constant K_2 drops to zero

and estimates that effects of pH are noticeable at a pH > 13.

The data are summarized in Table 1. The deviation factor, defined as the ratio of calculated and observed values, is 3.6 on average but decreases to 1.2 in the experiments with the highest polymer concentration.

In Table 2 some data points published by Pezron et al.[2] are shown that were calculated through also. We used a molecular mass of $2.2\cdot10^6$ Daltons, a [P*] of 1.5 $g\cdot L^{-1}$, and assumed one crosslink site per monomer, each with a M_w of 156.[2] Even though the gels examined in their case were reasonably representative of a true rubber, the deviations from model calculations are quite similar to our results.

Model Validation. Kinetics: Figure 6 shows the results of model calculations of the concentration of X_2B^- vs. time. The calculated gel times vary from 100 seconds at a pH of 7 up to $10\cdot10^6$ seconds at a pH of 13. Compared to experimental data these numbers are about two orders in magnitude too large and are likely to be due to the estimated value for the diffusion coefficient D of polymer segments. The constant C_1 in Equation (14a) contains two terms but is in fact dominated by the last term: $k_{-2}\cdot H^+$. The value of k_{-2} is proportional to $D_{reduced}$ and the value used for guaran was calculated from sedimentation experiments. In such experiments, the entire molecule settles in a gravitational field, whereas the mobility of chain segments is expected to be

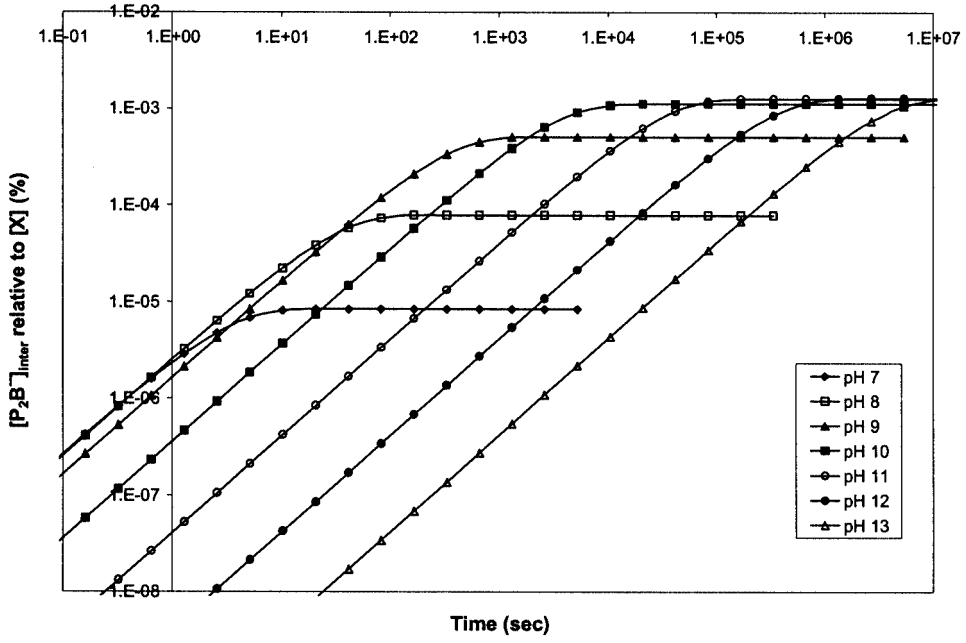

Figure 6. Results of calculated concentrations of $[X_2B^-]$ relative to the concentration of available crosslink sites X vs. time. Curves for pH values from 7 up to 13 are shown.

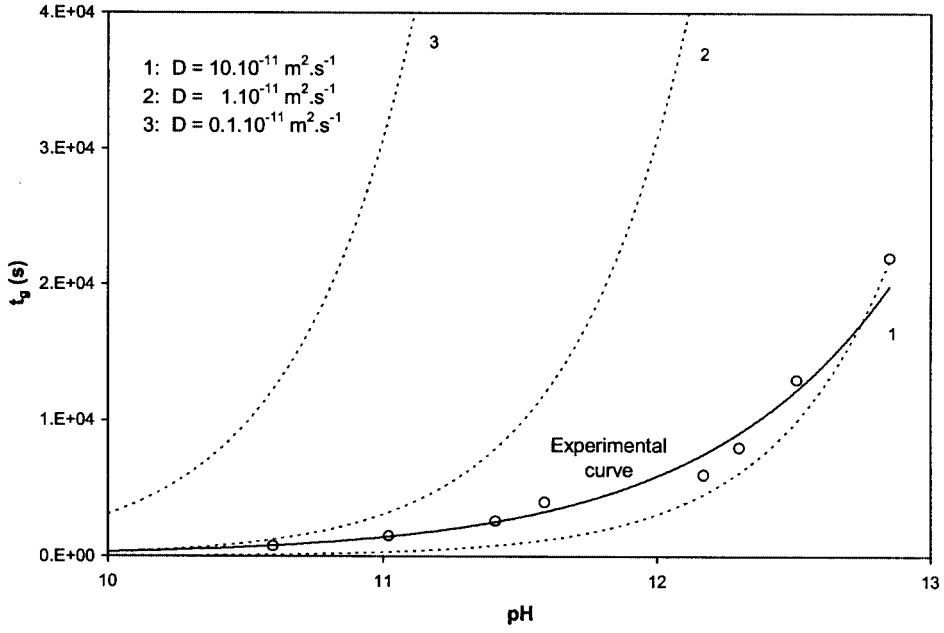

Figure 7. Results of experimental gel times as a function of pH and diffusion coefficient. Three curves (dashed) are shown based on diffusion coefficients ranging from $0.1 \cdot 10^{-11}$ $m^2 \cdot s^{-1}$ up to $10 \cdot 10^{-11}$ $m^2 \cdot s^{-1}$. The solid curve is based on experimental data.

greater. Leibler et al.[32] have made detailed calculations of these effects in reversible networks. Crosslink reactions take place between chain segments with a value for D of roughly two orders greater than the value based on sedimentation, in line with experimental data shown in Figure 7.

On the other hand, as more crosslinks form, the network becomes more rigid and consequently the mobility of the chain segments decreases.[32] As exemplified in Table 1, network formation is not much of an issue here, but it should be taken into account in experiments with more rigid gels.

The time it takes for the gel to reach maximum viscoelasticity is called the gel time, t_g, and can be calculated theoretically. The curves in Figure 6 all show the same value of the slope in a log-log plot. The value of the slope is derived by taking the ln of Equation (14a) and calculating the derivative to ln(t). Using the approximation $e^{C_2 t} \approx 1 +$

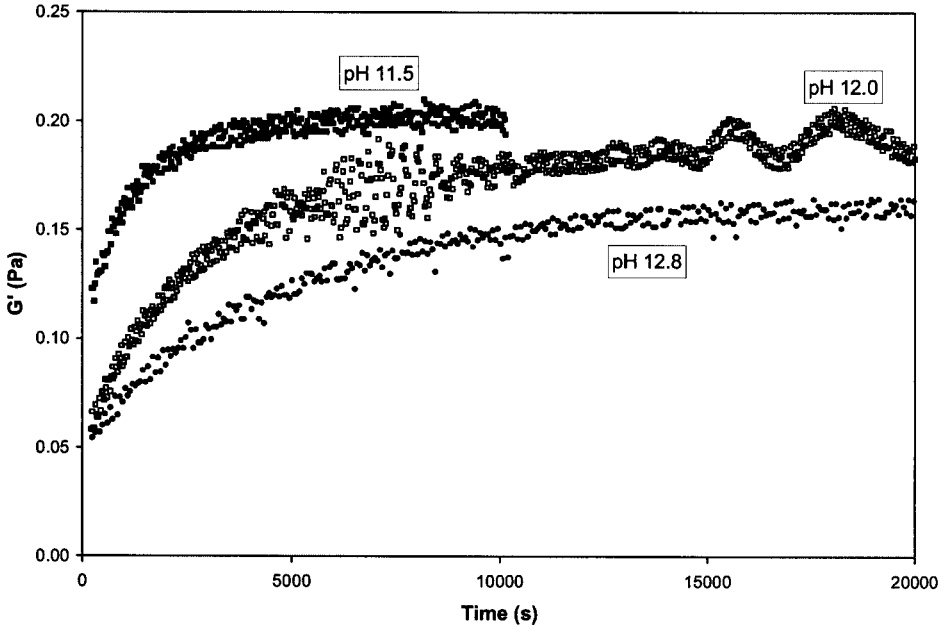

Figure 8. Results of experimental G' values as a function of time. Only a few curves measured at different pH values are shown as examples. Note that only the initial parts of the curves at pH values of 12.0 and 12.8 are shown.

$C_2 \cdot t$, it turns out that the slope is exactly 1. In Figure 6 we can draw two imaginary lines, one through the first part of the curve with a slope of 1 and one through the horizontal part with a slope of zero. The gel time is defined as the intersection of the two lines and yields:

$$t_g = \frac{1}{k_{-2} \cdot [H^+]} \tag{17}$$

These results can be translated to gel times as a function of pH and D_{guaran}. In Figure 7, three curves (dashed) are shown for different diffusion coefficients of chain segments (0.1-, 1- and $10 \cdot 10^{-11}$ $m^2 \cdot s^{-1}$). The resemblance with the experimental curve is quite reasonable, with a value of D close to $10 \cdot 10^{-11}$ $m^2 \cdot s^{-1}$, i.e., about 2 orders in magnitude greater than based on the sedimentation value but in agreement with calculations published by Leibler et al.[32]

Example experimental gel time curves are shown in Figure 8 to demonstrate the increase of gel times in tests at higher pH values. A log-log plot of the initial part of these curves shows a straight line as shown in Figure 9. The re-

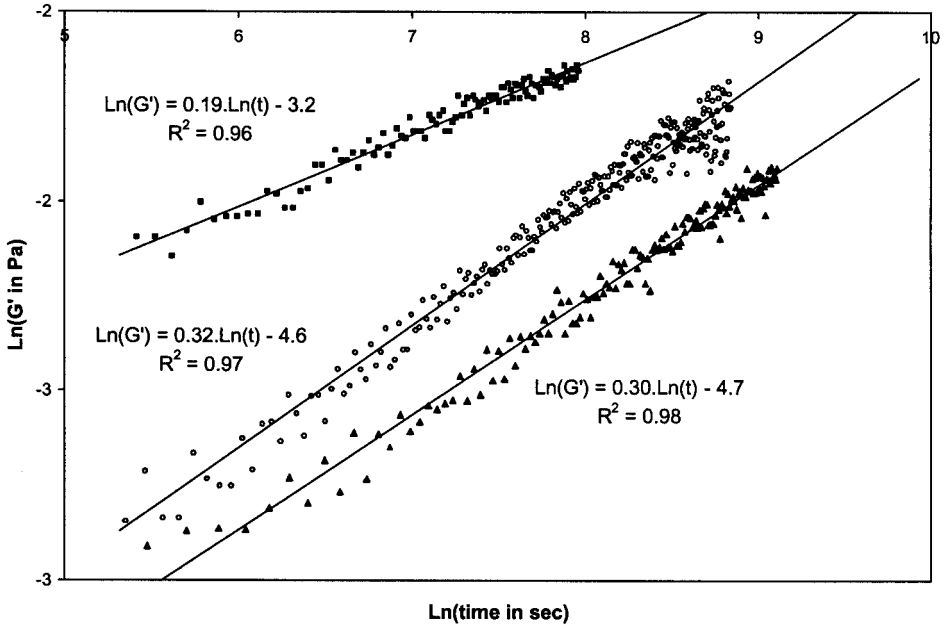

Figure 9. Calculations of the slopes of the initial parts of the curves for the examples shown in Figure 8.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

sults for the gel times and the slopes of tests run at pH values >10.5, which have sufficiently long gel times, are shown in Table 3 (corrected for physical crosslinking).

Table 3. Values of the slopes of the initial part of the experimental curves and the gel times t_g

pH	Slope	Gel time (s)
10.60	0.12	750
11.02	0.19	1500
11.41	0.16	2600
11.59	0.19	4000
12.17	0.32	6000
12.30	0.30	8000
12.51	0.24	13000
12.85	0.30	22000

Compared to the theoretical value of the slope, which is exactly 1, the experimental values are < 1. The slopes of the lines increase as the pH increases but level off at a pH around 12. At low pH values, the gel time is short, and therefore the slopes could have already leveled off to some extent. This is also true in the theoretical curves. At high pH values, 12 for instance, where deprotonation of the polymer is not expected to play any role and where the network is not built up fully because the gel time is at least one hour, the value of the slope is only 0.3. This reason for this discrepancy is not clear.

Data presented in a paper by Pezron et al.[2] provide further indication of the overall correctness of the proposed mechanism. They measured G' curves as a function of frequency for gels with pH values of 8.7, 9.2, and 11. At the highest pH value tested, the plateau extends to lower frequencies and indicates longer life times of the crosslinks, in accordance with the proposed model.

Verification of Assumptions and Improvements: In the derivation of Equation (14a), the steady state assumption was applied to d([X_1B])/dt and d([X_1B^-])/dt. Using the appropriate values for k_1, k_{-1} and others the forward and reverse reaction rates were calculated for reactions 1a through 4a at pH values of 9 and 13. Compared to the B/B^- equilibrium, the relative reaction rates for the forward and reverse reactions of reaction (2a) is two orders slower, and for reaction (3a), one order slower. The forward and reverse reaction rates for reaction (4a) are five orders slower relative to the B/B^- equilibrium. Thus the assumption that the formation of X_2B^- is rate-limiting was indeed valid. Note that X_1B is replenished rapidly because X_1B^- is present in excess. A second assumption made, was constancy of [X] and [B]. As with X_1B, the concentration of B is small relative to [B^-] and readily replenished. A problem could be the amount of free available crosslink sites because a relatively large part is in the form of X_1B^-. However, relative to concentrations of available crosslink sites, model calculations show that [X_1B^-] is not even 1% at a polymer concentration of 10 g/L and a [B_t] of $1\cdot10^{-3}$M. However, in rigid gels reduction of available crosslink sites X needs to be taken into account.

Although the model has been shown to be reasonably accurate, it does have a few shortcomings: 1) in the calculation of k_{-2} application of the diffusion coefficient based on the entire polymer is unrealistic, 2) no effects due to network formation are taken into account 3) effects for the charge up of the polymer chain due to 1:1 complexes and deprotonation are not accounted for and, 4) the relation between G' and [X_2B^-] is not well defined in weakly crosslinked gels.

Verification with Results by Pezron et al.:[10] Interesting results have been compiled by Pezron et al. for borate complexes with poly(glyceryl methacrylate) by using NMR spectroscopy. This polymer was shown to have a critical polymer concentration of 20 g/L. It was observed that the ratio [X_1B^-]/[B_t] varied linearly with [P] whereas the ratio

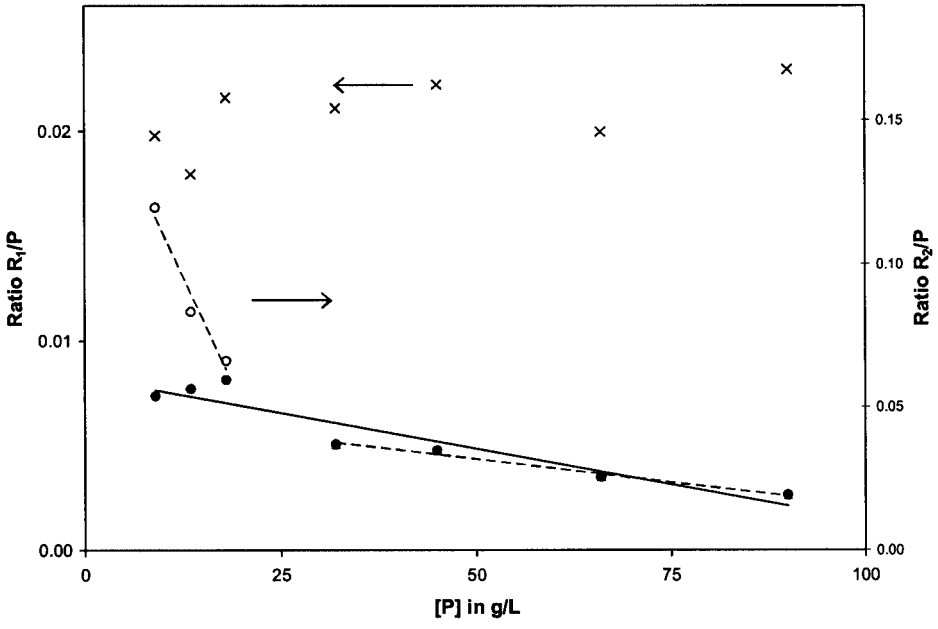

Figure 10. Results of an analysis of data published by Pezron et al.[10]; see text for details.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$[X_2B^-]/[X_1B^-]$ was independent of [P] at [P] < [P*] but dependent on [P] at [P] > [P*]. These observations are in agreement with the proposed theory, and the latter observation is especially convincing evidence for the proposed scheme of inter/intra-Mxl formation. Note that NMR does not distinguish between inter- and intra-Mxl. Thus the peak representing free boron is the sum of [B] and $[B^-]$ and the peak representing the 1:1 complex is the sum of $[X_1B^-]$ and $[X_1B]$. The first relation, $[X_1B^-]/[B_t]$, is calculated as:

$$R_1 = \frac{[X_1B^-]}{([B]+[B^-])} = \left(\frac{K_1}{K_a+[H^+]}\right)\cdot[X] \quad (18)$$

Thus R_1 divided by [P] is constant as shown in Figure 10. The second ratio R_2 is calculated as:

$$R_2 = \frac{[X_2B^-]}{[X_1B^-]+[X_1B]} = \left(\frac{K_2}{K_a^{1:1}+[H^+]}\right)\cdot[X] \quad (19)$$

and therefore R_2/[P] is constant also. However, note that the concentration of X in Equation (18) originates from the formation of 1:1 complexes and is always [X] whereas the concentration of X in Equation (19) is based on the formation of 2:1 complexes and is [X*] at [P] < [P*] and [X] at [P] > [P*], in agreement with Pezron's observations.

The dashed lines in Figure 10 represent the uncorrected data, that is, the value of [P] is used in Equation (19) for all data points. The solid line represents the corrected data, i.e., for the first three data points [P*] was used and for the remaining data points [P]. The slight decrease of the slope could be due to a reduction of the dielectric constant of the solvent at high polymer concentrations.[15]

The data shown by Pezron et al. for 1,2-propanediol are in perfect agreement with Equation (18) and (19). In this case the value of [P] can be used throughout because small molecules are able to diffuse through the entire fluid as 1:1 and as 2:1 complexes.

Verification with Results by Pizer et al.:[11–13] Attempts to clarify the mechanism have been undertaken by the group of Pizer. One observation that can be explained directly from the mechanism above is the relation between the acidity of boric acid derivatives and the value of K_1. Some data published by Pizer et al.[11] are shown graphically in Figure 11 including the results from regression analysis. A linear relationship between the pK_1 and the pK_a is observed with a slope of almost equal to 1. Note that the 95% confidence interval for the slope is quite broad and about ±0.3. Thus even though smaller slopes are suggested, its values are not statistically different from 1, the theoretical value. This latter value is readily seen if we express K_1 as $K'_1 \cdot K_a$ or $\log K_1 = \log K_a + \log K'_1$. Of course, deviations can be expected in case boron is hybridized differently.

Experimental Section

Materials: Hydroxpropyl guaran (HPG) with a molecular weight of about $2.0 \cdot 10^6$ Daltons and an MS of 0.4 was used. The HPG sample is coated with a small amount of Na-borate to improve its dispersability in water. The B-content was determined with Inductively Coupled Plasmaspectrometry (ICP) as 0.328 mg B/g polymer. As a borate source $Na_2B_8O_{13} \cdot 4H_2O$ was used in a concentration of exactly 6 g/100 g in deionized water. This solution has a density of 1.036 g/mL and contains 13.97 g B/L. For the preparation of gels, tap water was used which contains small amounts of Na^+, K^+, Mg^{2+}, Ca^{2+} and B. The content of these elements, as determined with ICP, were 49.5, 4.10, 10.2, 49.0, and 0.624 mg/L, respectively. It is known that Ca^{2+}, and probably Mg^{2+} as well, can be sequestered by 2:1 polysaccharide-borate complexes. This leads to increased values of the complex formation constant K_2. However, at these low concentrations, the effect is negligible and is therefore of no concern.[33] In the calculations, the total B content was taken into account from all three sources: tap water, polymer coating, and crosslinker solution. A 25% (w/v) solution of NaOH was used for pH adjustments. $NaHCO_3$ was added to the gels as a buffer in

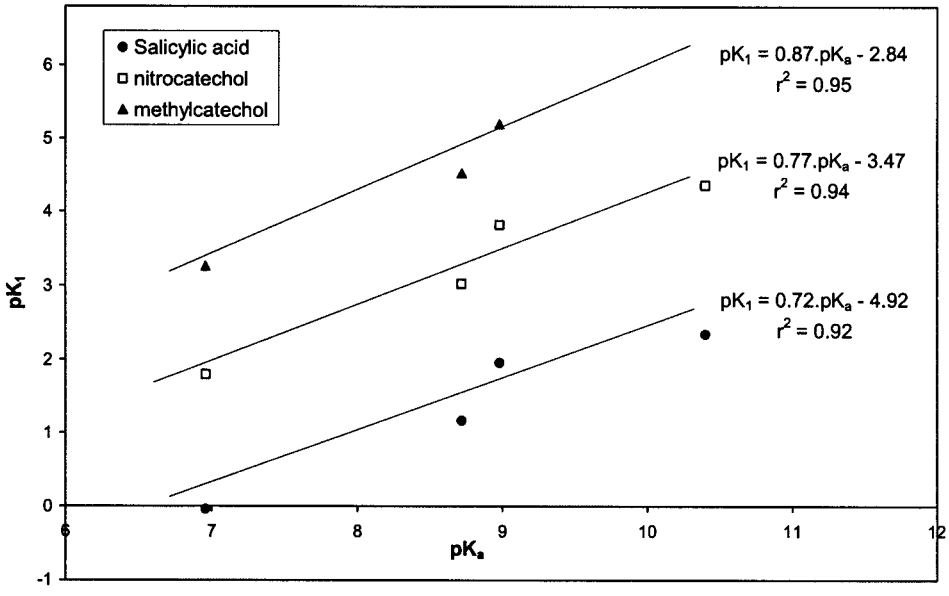

Figure 11. Results of an analysis of data published by Pizer et al.[11]; see text for details.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

a concentration of exactly 3 g/kg. The reagents mentioned above were all of technical purity.

ICP Analysis: ICP was used to analyze the polymer for B and the tap water for Na^+, K^+, Mg^{2+}, Ca^{2+}, and B. The measurements were performed on a Philips PU7000 ICP. Plastic measure flaks were used to minimize the uptake of B from glassware. Exactly 10 mL of a 30% HNO_3 (p.a. quality) solution was added to the tap water samples together with 1.000 mL of a 1000 mg/L solution in Y (Merck) as an internal standard. The HPG sample was analyzed by adding 50.00 g of a base gel containing exactly 3 g/kg in DI water to a measure flask of 100 mL and adding HNO_3 and Y as above. These samples were mixed and, prior to work up, the polymer was allowed to de-polymerize in the course of about two days.

Gel Preparation: Base gels were prepared using a blade stirrer to first disperse the polymer. HPG masses from 15 to 36 g, but exactly known, were mixed in 5.000 kg tap water To initiate hydration of the polymer, the Na-borate coating was removed by adding acetic acid until a pH value of 6.5. The gel was allowed to hydrate for 15 minutes while being stirred before the sample was put in a refrigerator to further hydrate overnight. Then, the gel was homogenized and approximately 950 g of the base gel was added to a Waring blender followed by the required amount of crosslinker solution (see above), usually 500 μL. After 1 minute of stirring, 3.000 g of $NaHCO_3$ was added as a buffer, and after dissolution the pH was adjusted to the desired value with a 25% NaOH solution. In cases where gel formation was followed at high pH values (>11.5) about 75% of the required amount of NaOH was added very quickly to prevent premature gel formation. The Waring blender was then weighted off to exactly 1 kg with base gel and allowed to fully homogenize for 2 more minutes. Then the timer was started, and a sample was injected into the cup of the rheometer. Only in cases where the pH > 10.5 and the [polymer] > 3 g/L, volume and density effects due to additions of NaOH and polymer were signficant and corrected for.

The procedure above is similar for the determination of visco-elasticity due to physical crosslinks but no additional crosslinker was added and 10.0 g fructose per kg base gel was added to absolutely ascertain masking of present borate. The complex formation constant of borate with fructose (F) was determined at K'_1 = 6000 L/mol, defined as $[F_1B^-]/([B^-]\cdot[F])$, which is much higher than the constant for mannose.[6] Effective masking of borate by fructose was verified experimentally by adding 500 μL crosslinker solution to these gels: no crosslinking took place. The data were corrected for volume and density effects caused by fructose addition.

Rheology: A Reologica Stresstech rheometer was used. After the cylindrical cone plate bob was positioned, the sample was covered with a thin layer of aliphatic oil (Shellsol D90) to prevent dehydration of the gel. The gel properties G', G'' and the viscosity were followed in time by oscillating the bob at a frequency of 1 Hz and a strain of 0.3. Previous work by Pezron[2] has shown that a frequency of 1 Hz is sufficiently fast compared to the live time of the crosslinks, i.e., $(\omega.\tau)^2 >> 1$ and G' values are determined at the plateau level in all experiments. The temperature was fixed at 25.0 °C ± 0.2. The gels prepared contained relatively low concentrations of B and polymer to extend reaction times as much as possible.

A Tetranuclear Hydroxo-Bridged Copper(II) Complex with Primary *N*-Acylamidines as Ligands: Preparation, Structural, and Magnetic Characterisation

Jan K. Eberhardt,[a] Thorsten Glaser,*[b] Rolf-Dieter Hoffmann,[b] Roland Fröhlich,[a] and Ernst-Ulrich Würthwein*[a]

Keywords: *N*-Acylamidines / Copper(II) complexes / Magnetic susceptibility / N ligand / O ligand

The reaction of *N*-pivaloylbenzamidine (**1a**) and tetrakis(acetonitrile)copper(I) hexafluorophosphate in the presence of air yields a hydroxo-bridged copper(II) complex (**4**). The product was characterised by X-ray diffraction analysis and found to be a cubane-like dimeric complex consisting of two square dimers with the formula $[\{(\mathbf{1a})_2Cu_2(OH)_2\}_2](PF_6)_4 \cdot 4\,CH_2Cl_2$ ($\mathbf{4}\cdot 4\,CH_2Cl_2$) with cupric ions and hydroxyl oxygen atoms at alternating vertices of a cube. The complex can be described as consisting of two [ligand-Cu-$(OH)_2$-Cu-ligand] units held together by long out-of-plane Cu–O bonds, creating a tetrameric entity with a $Cu_4(OH)_4$ core. Each cupric ion is essentially square-pyramidally coordinated, being bound to three OH bridges, one N atom of the amidine and one *N*-acylamidine O atom. The magnetic properties of this compound have been studied in the 2–300 K temperature range. The measurements revealed that the cupric ions in the cube are antiferromagnetically coupled. This observation has been rationalised on the basis of the structural data.

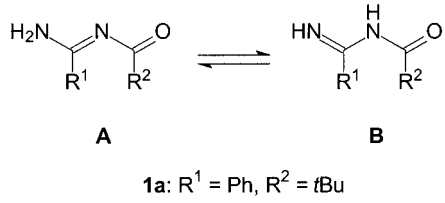
Introduction

Alkoxo-bridged Cu^{II} tetramers with cubane-like Cu_4O_4 cores are well-known. A number of complexes with this moiety have been reported and their magnetic properties have been compared with those of the corresponding binuclear compounds.[1–7] These studies have shown that oxygen-bridged tetrameric copper(II) complexes may exhibit ferromagnetic[8] as well as antiferromagnetic interactions. The correlation between structural parameters and magnetic properties seems to be well established.[9]

In contrast to the alkoxy-bridged complexes, hydroxo-bridged $Cu_4(OH)_4$ tetramers are rather rare. To the best of our knowledge, which is based on a recent CCDC database search, only two examples have been structurally characterised, one containing bidentate 2,2′-bipyridyl ligands[10] and the other bearing tris(2-pyridyl)amine in a bidentate coordination mode.[11]

We report here the synthesis and solid-state molecular structure of a cubane-like hydroxo-bridged *N*-acylamidine copper(II) complex of formula $[\{(\mathbf{1a})_2Cu_2(OH)_2\}_2](PF_6)_4$ (**4**) as well as its magnetic properties measured down to 2 K. The organic ligand employed for the synthesis of this copper complex is *N*-pivaloyl benzamidine (**1a**). *N*-Acylamidines (**1**) offer coordination sites for the formation of six membered chelates, namely the oxygen atom of the acyl functionality and the nitrogen atom of the amino group. Compounds **1** carrying an $-NH_2$ (primary *N*-acylamidines) or an -NHR group (secondary *N*-acylamidines) undergo tautomerism involving 1,3 proton shifts (tautomer **A** and **B**, Scheme 1).



Scheme 1. *N*-Acylamidine **1**, Tautomerism **A/B**.

Spectroscopic data[12] as well as crystal structure determinations[13,14] show that the tautomer **A** dominates, while the other tautomer **B** with the two protons located on different nitrogen atoms plays, if at all, only a minor role in the equilibrium.

In earlier work we were able to characterise four monomeric copper(II) complexes with these ligands which display rather versatile coordination chemistry depending on the ligand-to-metal ion stoichiometry, the charges on the complexes and the properties of the solvents used for the syntheses (Scheme 2).[13] For example, the reaction of *N*-piva-

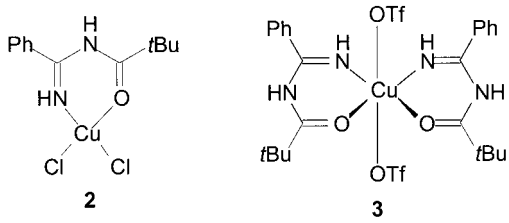
loyl benzamidine (**1a**) with $CuCl_2 \cdot 2H_2O$ in acetonitrile and diethyl ether yielded a mononuclear 1:1 complex **2** consisting of a neutral *N*-acylamidine in its C=NH tautomeric form complexed to a central copper(II) ion. The reaction of two equivalents of *N*-pivaloyl benzamidine (**1a**) with one equivalent of $Cu(CF_3SO_3)_2$ in acetonitrile and diethyl ether led to the formation of the mononuclear 2:1 copper(II) complex **3**. In complex **2** the copper(II) ion is four coordinate leading to a distorted tetrahedral structure. The 2:1 compound **3** possesses an approximate square plane around the central metal ion. Two oxygen atoms of the triflate counterions complement the coordination sphere of the copper(II) ion in axial positions.



Scheme 2. Two *N*-Pivaloyl benzamidine-Cu complexes from ref.[13]

In another publication we presented experimental and theoretical results concerning the complexation of substituted *N*-acylamidine ligands **1** towards palladium(II), the structures of the complexes as well as their catalytic properties in cross-coupling reactions.[15]

Results and Discussion

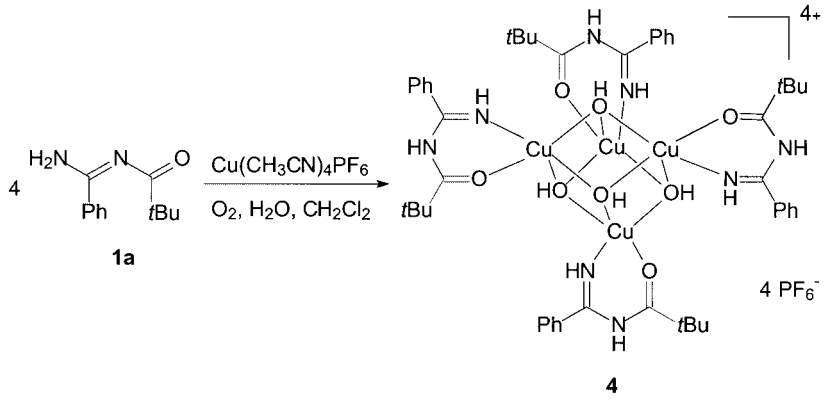
Synthesis

N-Acylamidines (**1**) are interesting yet rarely used ligands for metal complexation. They resemble β-dialkylamino-acroleine derivatives which have found various applications in coordination chemistry.[16] The nitrogen atom in the 3-position of *N*-acylamidines (**1**) has a distinct influence on the electronic properties and on the reactivity of these ligands towards metal ions. A major advantage of the *N*-acylamidines (**1**) is that they are easily prepared by simple acylation of the corresponding amidines with acyl chlorides in yields of up to 97%.[12,17] Amidines are readily available from the reactions of nitriles with amines.[18,19]

In a new experiment, we studied the reaction of *N*-pivaloyl benzamidine (**1a**) with copper(I) hexafluorophosphate. Equimolar amounts of **1a** and tetrakis(acetonitrile)copper(I) hexafluorophosphate were dissolved in dichloromethane, resulting in a colourless solution. A small amount of water was then added. The reaction was stirred without protection from the air leading to oxidation of the copper(I). The solution slowly turned blue due to the formation of a copper(II) complex.

Addition of an excess of diethyl ether yielded blue crystals of $[\{(\mathbf{1a})_2Cu^{II}_2(OH)_2\}_2](PF_6)_4 \cdot 4CH_2Cl_2$ (**4**·$4CH_2Cl_2$) (Scheme 3, 43% yield). The crystals lose solvent molecules indicating that the dichloromethane molecules of solvation are only weakly bound. Elemental analysis of a sample of **4**·$4CH_2Cl_2$ dried in air indicated the loss of one dichloromethane molecule. In a SQUID magnetometer, a high vacuum is applied to the sample to remove water and paramagnetic dioxygen. Thus, it is important to know the exact nature of the sample which is measured after the application of the high vacuum. For this purpose, it is routine to study the behaviour of samples which loose solvents of crystallization under a high vacuum before measuring such a sample in a SQUID magnetometer. Thus, a sample of **4**·$4CH_2Cl_2$ was dried in a high vacuum and subsequent elemental analysis indicated the presence of two molecules of dichloromethane. Detailed infrared spectroscopy indicated that no structural changes occurred in the tetranuclear complexes. Thus, the formula **4**·$2CH_2Cl_2$ was used for the calculation of the molecular mass and the diamagnetic correction for the analysis of the magnetic data.

The hexafluorophosphate counterion is bound to **4** via weak H–F interactions (see below). It possibly acts as a template favouring the formation of polynuclear entities. In contrast to the copper(II) chloride complex **2**, the copper ions in **4** are able to use two more coordination sites to interact with other molecules rather than with the counterions. In one of the other known examples (Sletten et al.) of a hydroxo-bridged $Cu_4(OH)_4$ tetramer, hexafluorophosphate counterions were also used.[10] In this case the hexafluorophosphate ions bridge two copper atoms within the



Scheme 3. Synthesis of **4**.

dinuclear units through loose Cu–F interactions. The tetramer reported by Marks, Ibers et al. has triflate counterions bridging two copper(II) centres.[11]

The complexes **2** and **3** were precipitated from acetonitrile using diethyl ether. In contrast, **4** was synthesized in the less strongly coordinating solvent dichloromethane (with traces of water) and again precipitated using diethyl ether. Thus, dichloromethane offers better possibilities for interactions between metal ions and polynuclear entities are formed more easily.

From these three examples it is clear that there is a strong influence on the complex composition and molecular structure by the counterion and the solvent.

Description of the Structure

The crystal structure of $[\{(\mathbf{1a})_2Cu^{II}_2(OH)_2\}_2](PF_6)_4 \cdot 4CH_2Cl_2$ was determined by single-crystal X-ray diffraction. Figure 1 and Figure 2 show the molecular structure of the tetranuclear tetracation in crystals of $\mathbf{4}\cdot 4CH_2Cl_2$. Two dinuclear copper(II) entities are connected by long axial Cu–(OH) bonds forming a tetranuclear entity with a cubane-like $Cu_4(OH)_4$ core. The Cu^{II} ions and the oxygen atoms of the hydroxy groups are located at alternating corners of a pseudo-cube.

The copper atoms are (4+1)-coordinated showing an approximate square-pyramidal geometry. One oxygen atom and one nitrogen atom from the bidentate organic ligand **1a** and two hydroxide oxygen atoms act as equatorial donors. The equatorial Cu–OH bonds are short (1.930 Å), as are the bonds to the *N*-acylamidine ligand (Cu–O 1.978 Å, Cu–N 1.935 Å). The N–Cu–O bond angles amount to 89.11°. Hence, a rhombic dimeric $Cu_2(OH)_2$ entity results which interacts with a second dimer to form the observed cubane-like structure through longer axial Cu–OH bonds (2.359 Å). In the other known $Cu_4(OH)_4$ cubanes, the equatorial Cu–OH distances were 1.947–1.971 Å, while the axial distances were slightly longer at 2.382–2.585 Å[10,11] when compared with those in **4**. Within each binuclear unit, the Cu–O–Cu bridging angle is 98.84° which is similar to the values found in the literature.[10,11] There is a slight bending within the units, the dihedral angle between the O–Cu–O planes being 6.5°.

In the $Cu_4(OH)_4$ core there is one short Cu1–Cu2 separation of 2.953 Å (within the dimeric entity) and one long distance of 3.226 Å. The long separation is an interdimer copper–copper distance measured along a plane parallel to the $\bar{4}$ axis.

In compound **4**, four neutral *N*-acylamidines (**1**) in their C=NH tautomeric form **B** coordinate to one copper(II) ion each (analogous to **2** and **3**). As in the former examples (see Scheme 2), conjugated six-membered chelate rings are formed by coordination of the oxygen atoms and terminal nitrogen atoms of the *N*-acylamidines (**1**) to the metal centre. Due to the complexation, the former amino group of the ligand is transformed into an imine moiety by a formal 1,3-shift of one of the amino hydrogen atoms to the nitro-

gen atom N(3). The lone pair of the sp^2 hybridised imine type nitrogen atom N(5) acts as the coordination site. Thus, the ligand **1a** presents as a conjugated 6π/5z ligand, carrying a central planar sp^2 amino group. This result is in good agreement with former experiments.[13]

The hexafluorophosphate ions are weakly coordinated to the cationic cluster via N–H···F hydrogen bonds (2.215 Å). The H atoms of the OH groups are at a distance of 2.404 Å from the closest fluorine atom of the PF_6^- counterion, the O–H–F bond angle amounts to 146.3°.

Infrared and UV/Vis Spectra

The IR spectra of hydroxo-bridged copper(II) compounds have been studied thoroughly.[20] The IR spectrum of **4** (KBr pellet) exhibits a characteristic doublet at 3620 and 3615 cm^{-1} which can be assigned to the bridging OH stretch in full accordance with the literature. Three sharp absorptions at 3390, 3380 and 3340 cm^{-1} can be assigned to the =NH and –NH stretching vibrations (isomer **B** of the *N*-acylamidine). In contrast, the free ligand shows bands at 3320 and 3160 cm^{-1} which can be attributed to the asymmetric and symmetric NH_2 stretching vibrations (isomer **A**), respectively.[13] The other absorptions of the complex can be observed at common frequencies. A signal at 970 cm^{-1} has been described in the literature as a bending OH vibration.[20] A very intense band at 845 cm^{-1} can be assigned to the stretching and bending modes of the hexafluorophosphate anions. Low intensity UV absorptions may be observed at 625 nm. These are due to d→d transitions at the metal ion which cause the blue colour of solutions of **4**.

Magnetic Susceptibility

Magnetic susceptibility data of complex **4**·2 CH_2Cl_2 were measured on a microcrystalline sample in the temperature range 2–300 K with an applied field of 1 T. Note that the sample for the susceptibility measurements was dried in vacuo resulting in loss of two solvent molecules and no structural changes of **4** as demonstrated by infrared spectroscopy. A composition **4**·2 CH_2Cl_2 was used for the calculation of the molecular mass and the diamagnetic correction based on elemental analysis.

Figure 3 shows the effective magnetic moment, μ_{eff}, calculated per tetranuclear unit as a function of the temperature. The temperature dependence shows a monotonic decrease from 3.60 μ_B at 300 K to 2.10 μ_B at 50 K. Below 50 K, a change in the curvature occurs. The value at 2 K is 0.66 μ_B. This behaviour is in accordance with an antiferromagnetically coupled spin-system and a total spin ground state of $S_t = 0$. The magnetic properties of the core of **4**, $[Cu^{II}_4(OH)_4]^{4+}$, were analysed with the spin Hamiltonian for four coupled spins $S_i = ½$ including the isotropic Heisenberg–Dirac–van Vleck (HDvV) exchange Hamiltonian and the single-ion Zeeman interaction using a full-matrix diagonalisation approach [Equation (1)].[21]

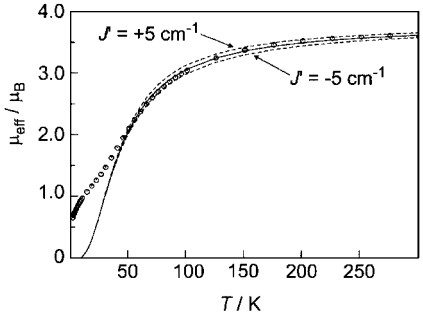

Figure 3. Temperature dependence of the effective magnetic moment, μ_{eff}, of **4**·2 CH_2Cl_2 at 1 T. The solid line represents a simulation using the spin-Hamiltonian given in the text with $J = –41$ cm^{-1}, $J' = 0$, $g = 2.21$ and $\chi_{TIP} = 500 \times 10^{-6}$ $cm^3 mol^{-1}$. The dashed lines represent simulations using the same parameter set but using $J' = +5$ cm^{-1} and $J' = –5$ cm^{-1}, respectively.

$$H = H_{HDvV} + \sum_{i=1}^{4} \mu_B g_i S_i B \quad (1)$$

The spin topology of the $[Cu^{II}_4(OH)_4]^{4+}$ cubane is shown in Figure 4. The crystallographically imposed S_4 axes lead to the equivalence of $J = J_{13} = J_{24}$ as well as $J' = J_{12}$, J_{14}, J_{23} and J_{34}. Thus, the HDvV part of the Hamiltonian becomes [Equation (2)].

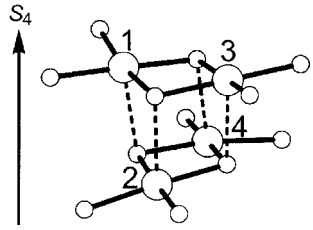

Figure 4. Spin system of **4** imposed on its molecular structure. Copper centres 1 and 3 as well as 2 and 4 both form subdimeric units. The S_4 axes yield the equivalence of the coupling constants J_{13} and J_{24} as well as the coupling constants J_{12}, J_{14}, J_{23} and J_{34}. Note that the magnetic orbitals of the Cu^{II} ions ($d_{x^2-y^2}$) are oriented in the subdimer plane perpendicular to the bond of the apical ligands.

$$H_{HDvV} = -2J(\mathbf{S_1S_3} + \mathbf{S_2S_4}) - 2J'(\mathbf{S_1S_2} + \mathbf{S_1S_4} + \mathbf{S_2S_3} + \mathbf{S_3S_4}) \quad (2)$$

The coupling constant J describes the interactions in the dinuclear subunits (intradimer exchange), whereas J' describes the interactions between the dimeric subunits (interdimer exchange). Dinuclear $Cu^{II}(\mu_2\text{-}OH)_2Cu^{II}$ cores are classics in magnetochemistry. A magneto-structural correlation describing the coupling constant J as a function of the Cu–O–Cu angle was established by Hodgson, Hatfield and coworkers.[22] Applying this correlation to the dimeric subunits of complex **4** with an angle of 98.84° results in $J = –44$ cm^{-1}. The overall spin topology of the tetramer $[Cu^{II}_4(OH)_4]^{4+}$ has been found in several complexes with a

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

central $[Cu^{II}_4(OR)_4]^{4+}$ cubane core.[4–7,9–11] Reasonable values have been established for the intradimer coupling constants depending on the subdimer geometry. Differing magnitudes and signs have been reported for the interdimer coupling constant J'.[4–7,9] Fallon et al. already pointed out that the interdimer interaction should be very small due to the large interdimer Cu–O distances (apical Cu–O bond of a square-pyramidal coordination geometry) when compared with the shorter intradimer Cu–O distances (equatorial Cu–O bonds of a square-pyramidal coordination geometry).[4] They were able to fit their magnetic data only without the use of an interdimer coupling constant. Moreover, by explicitly using the appropriate tetramer model, they obtained an interdimer coupling constant of zero.[4]

Simulation of the magnetic data of **4** using only the intradimer coupling constant J, i.e. $J' = 0$, results in a good reproduction of the experimental data above 50 K with $J = -41\ cm^{-1}$, $g = 2.21$ and $\chi_{TIP} = 500 \times 10^{-6}\ cm^3\,mol^{-1}$ (solid line in Figure 3). The value of J pleasingly corroborates the value obtained from the magneto-structural correlation (vide supra). The resultant spin ladder consists of an $S_t = 0$ spin ground state, two $S_t = 1$ spin states at $+82\ cm^{-1}$, one $S_t = 0$, one $S_t = 1$ and one $S_t = 2$ spin state at $+164\ cm^{-1}$ (Figure 5, centre). Incorporation of an interdimer coupling constant J' does not result in a splitting of the first two excited $S_t = 1$ states but only in a splitting of the excited states at $+164\ cm^{-1}$. Inclusion of $J' = -5\ cm^{-1}$ splits them into $S_t = 0$ at $+144\ cm^{-1}$, $S_t = 1$ at $154\ cm^{-1}$ and $S_t = 2$ at $+174\ cm^{-1}$ (Figure 5, left). On the other hand, inclusion of $J' = +5\ cm^{-1}$ splits them into $S_t = 2$ at $+154\ cm^{-1}$, $S_t = 1$ at $174\ cm^{-1}$ and $S_t = 0$ at $+184\ cm^{-1}$ (Figure 5, right). These splittings do not affect the population of the spin levels at low temperatures. Thus, even taking into account an interdimer coupling, it is not possible to explain the unusual curvature of μ_{eff} below 50 K.

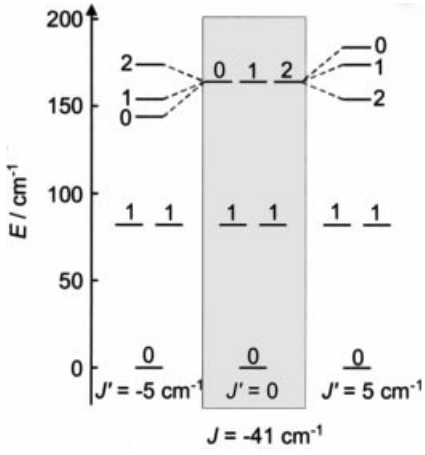

Figure 5. Spin ladder of **4** using $J = -41\ cm^{-1}$. Incorporation of $J' = -5\ cm^{-1}$ (left) or $J' = +5\ cm^{-1}$ (right) only induces a splitting of the degenerate spin states $S_t = 0$, 1 and 2 at $164\ cm^{-1}$ above the spin ground state.

It seems that the deviation of μ_{eff} below 50 K originates from a paramagnetic impurity. Taking into account a paramagnetic impurity leads to minor changes in J ($\pm 2\ cm^{-1}$) and g (± 0.02). However, this uncertainty prohibits a detailed analysis of the influence of J'. Simulations using a constant intradimer coupling constant $J = -41\ cm^{-1}$ and interdimer couplings constants $J' = +5\ cm^{-1}$ and $J' = -5\ cm^{-1}$, respectively, (dashed lines in Figure 3) indicate that the interdimer coupling should be restricted to the range $-5\ cm^{-1} < J' < +5\ cm^{-1}$. Hence, the coupling between the two dimers appears to be small.

This is in agreement with the argument of Fallon et al. whereby the interdimer distances are larger than the intradimer distances which leads to weaker superexchange pathways (vide supra).[4] The interdimer Cu–O distances in **4** are larger (2.36 Å) when compared with the intradimer Cu–O distances ($\approx$ 1.95 Å). Independent of the distance point of view, the orientation of the magnetic orbitals leads to weak couplings. The magnetic orbital of each Cu^{II} ($d_{x^2-y^2}$) is oriented towards the four ligands of the dimeric subunit (Figure 4). This leads to an effective superexchange pathway across the bridging hydroxides of the subdimer. On the other hand, the magnetic orbital of each Cu^{II} ($d_{x^2-y^2}$) is of δ-type symmetry with regard to the Cu–O interaction with its apical ligand. Since these oxygen atoms do not have δ-type symmetry orbitals, there is no interaction with the magnetic orbitals of the Cu^{II} ions. Hence, the superexchange pathway through the apical ligand must be rather weak.

Conclusions

Copper(I) ions, which are important as catalysts in both enzymatic and non-enzymatic chemical systems,[23,24,25] can be easily oxidised by molecular oxygen to Cu^{II}. Consequently, during the reaction of *N*-acylamidine **1a** with tetrakis(acetonitrile)copper(I) hexafluorophosphate in the presence of oxygen, copper(I) is transformed into copper(II) to form the tetrameric Cu^{II} complex **4** with its cubane like structure. The magnetic properties of this compound have been studied in the 2–300 K temperature range. The measurements reveal that the cupric ions in the cube are antiferromagnetically coupled.

This observation can be rationalised on the basis of the structural data. These examples clearly demonstrate that *N*-acylamidines (**1**) are very versatile ligands for copper(II) complexation. In general, they tend to form thermodynamically favourable cyclic six-membered chelates. In earlier work we found that independent of the stoichiometry used, ligand **1a** forms mononuclear 1:1 (**2**) and 2:1 (**3**) complexes with copper(II) chloride and copper(II) triflate, respectively,[13] whereas complex **4** is formed when tetrakis(acetonitrile)copper(I) hexafluorophosphate is used. Besides the counterions, the solvent has a pronounced influence on the nature of the complexes, since the application of acetonitrile leads to complexes **2** and **3**, whereas **4** was obtained using dichloromethane.

To summarise, this series of closely related Cu^{II} complexes demonstrates well the ability of the *N*-acylamidine ligand to form structurally quite diverse copper(II) com-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

plexes and underlines the intriguing role of the counterions and solvents used for the structures obtained.

Experimental Section

Materials and Methods: Compound **1a** was prepared as described previously.[15,26] Commercially available solvents (p.a. quality) were used without further purification. The CHN analysis was performed with a Vario El III (Elementar) instrument. The melting point was measured with a differential scanning calorimeter type 910 (DuPont Instruments) with a Thermal Analyst 2000 (TA Instruments) instrument. IR spectra were recorded on a Nicolet 5DXC FTIR spectrometer as KBr pellets. UV/Vis spectra were recorded on a Cary 1 Bio spectrometer (Varian). The ^{1}H spectrum was obtained by using a Bruker WM 300 spectrometer.

***N*-Pivaloylbenzamidinecopper(II) Hexafluorophosphate Hydroxide Tetramer (4·4 CH_2Cl_2):** *N*-Pivaloylbenzamidine (**1a**, 20 mg, 0.100 mmol) was treated at room temperature with tetrakis(acetonitrile)copper(I) hexafluorophosphate (37 mg, 0.100 mmol) in dichloromethane (5.0 mL). Deionised water (0.1 mL) was then added. After stirring for 10 min, a slight precipitate was removed by filtration. Diethyl ether (7.0 mL) was carefully added to the filtrate to form an upper layer. After five days blue crystals of **4**·4 CH_2Cl_2 were collected. Yield: 22 mg, 0.011 mmol (43%). X-ray Crystal Structure Analysis for 4·4 CH_2Cl_2:[27] Formula $C_{48}H_{68}Cu_4N_8O_8$·4 PF_6·4 CH_2Cl_2, M = 2058.84, blue crystal 0.40 × 0.30 × 0.30 mm, a = 17.585(1), c = 13.726(1) Å, V = 4244.5(5) Å^3, ρ_{calc} = 1.611 g cm^{-3}, μ = 14.17 cm^{-1}, empirical absorption correction (0.601 ≤ T ≤ 0.676), Z = 2, tetragonal, space group $I\bar{4}$ (No. 82), λ = 0.71073 Å, T = 198 K, ω and φ scans, 7923 reflections collected (±h, ±k, ±l), sinθ/λ = 0.66 Å^{-1}, 4633 independent (R_{int} = 0.032) and 4332 observed reflections [$I \geq 2\sigma(I)$], 256 refined parameters, R = 0.048, wR_2 = 0.124, max. residual electron density 069 (–0.66) e Å^{-3} close to the disordered CH_2Cl_2 molecules, hydrogen atoms at N3, N5 and O11 from difference Fourier calculations, others calculated and all refined as riding atoms.

Magnetic Measurements: Temperature-dependent magnetic susceptibilities of a sample of **4**·4 CH_2Cl_2, dried in a high vacuum, were measured in a gelatine capsule using a SQUID magnetometer (Quantum Design) at 1.0 T in the temperature range 2–300 K. This sample was analysed as **4**·2 CH_2Cl_2 indicating the loss of two solvated dichloromethane molecules. Infrared spectroscopic analyses before and after the drying process exhibited no changes, i.e. no structural change in the tetranuclear entity in **4** is associated with the loss of the two dichloromethane molecules. For calculations of the molar magnetic susceptibility, χ_M, the measured susceptibilities were corrected for the susceptibilities of the sample holder and for the underlying diamagnetism of the sample using tabulated Pascal's constants and for the temperature independent paramagnetism (χ_{TIP}) which was obtained by a fitting procedure.

A Novel Two-Dimensional Layer Structure Built from a Tetracobalt(II)-*p*-sulfonatothiacalix[4]arene Cluster Unit

Daqiang Yuan,[a] Yanqing Xu,[a] Maochun Hong,*[a] Wenhua Bi,[a] Youfu Zhou,[a] and Xing Li[a]

Keywords: *p*-Sulfonatothiacalix[4]arene / Cobalt / Magnetic properties / Coordination polymer

The novel coordination polymer $[Co_4(TCAS)(\mu_4\text{-}SO_4)(4,4'\text{-}Hbipy)_2]_n$ (TCAS = the octaanion of *p*-sulfonatothiacalix[4]arene) (**1**) has been synthesized hydrothermally and characterized. X-ray diffraction analyses reveal a two-dimensional (2D) layer structure built from the $[Co_4(TCAS)(\mu_4\text{-}SO_4)]^{2-}$ unit. The tetranuclear cobalt(II) clusters bridged by the μ_4-SO_4^{2-} and phenoxy groups of the same TCAS provide a unique trapeziform magnetic mode; magnetic studies in the temperature range 2–300 K show weak antiferromagnetic interactions between the four cobalt(II) centers.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Water-soluble *p*-sulfonatocalix[4]arene (H_4CAS^{4-}, Scheme 1) is a versatile host for molecules of relevance in areas of materials science such as separation technology, biomimetics, and structural biology.[1] As a multifunctional supramolecular synthon, H_4CAS^{4-} can form capsules, nano-scale spheres, tubes and bi-layer structures with cavities.[2] A new water-soluble *p*-sulfonatothiacalix[4]arene (H_4TCAS^{4-}, Scheme 1) was then obtained by replacing the methylene junctions with thioether sulfur.[3] The sulfur donor atoms in H_4TCAS^{4-} add four new potential coordination sites and has provided a new type of complex.[4] Although many metal-TCAS complexes have been synthesized and studied by X-ray crystallography,[5] complexes possessing a polynuclear structure seem to have been almost neglected.[6] Currently, there is much interest in transition-metal coordination polymers as magnetic, electronic or photooptical molecular materials.[7] One strategy used to obtain such interesting new materials is to increase the structural dimensionality by combining recognizable polynuclear repeating units to form chains, layers or three-dimensional (3D) networks.[8,9] We recently introduced $TCAS^{8-}$ as a polydentate ligand to synthesize polynuclear clusters, and expected the clusters to link into novel structural coordination polymers with special properties. Fortunately, we have successfully synthesized a novel 2D layer coordination polymer with a tetranuclear cobalt(II) cluster unit $[Co_4(TCAS)(\mu_4\text{-}SO_4)(4,4'\text{-}Hbipy)_2]$ (**1**) (4,4′-Hbipy = monocation of 4,4′-H-bipyridine). Herein, we report its synthesis, structural analysis and magnetic properties.

160 °C for 3 days afforded red crystalline compound **1**, which is insoluble in water and common organic solvents. The preparation is summarised in Equation (1).

$$4n\ CoSO_4{\cdot}6\ H_2O + n\ Na_4H_4TCAS + 2n\ 4,4'\text{-bipy} \xrightarrow[T = 160\ ^\circ C]{pH = 3} [Co_4(TCAS)(SO_4)(4,4'\text{-Hbipy})_2]_n + 2n\ Na_2SO_4 + n\ H_2SO_4 + 24n\ H_2O \quad (1)$$

Structural Description

An X-ray structure analysis showed that **1** exhibits a 2D layer structure built from the $[Co_4(TCAS)(\mu_4\text{-}SO_4)]^{2-}$ anion complex unit and 4,4′-Hbipy cation (Figure 1). Table 1 lists selected bond lengths and bond angles. The structure of the anion complex unit, like a bowl, consists of a trapezoid of four cobalt(II) centers between one TCAS unit and one sulfate ligand. In the complex unit, there is only one $TCAS^{8-}$ ligand arranged about the metal cluster, which differs greatly from the metal-thiacalix[4]arene clusters.[4] Furthermore, a mirror plane is imposed on the complex unit and passes through S(3), S(5), S(6), O(1), O(2), O(8), O(9), O(11), O(12), C(1), C(4), C(12), and C(15). A disordered water molecule is included within the cavity of the $TCAS^{8-}$ unit. The fully deprotonated $TCAS^{8-}$ unit, maintaining a conventional cone conformation, utilizes its phenoxy groups as μ_2-phenoxy bridges to bind four cobalt(II) ions to form the tetracobalt cluster with an average $Co–O_{(phenoxy)}$ distance of 2.073(4) Å. The array of four cobalt(II) ions is close to an isosceles trapezoid, and the Co(1)···Co(2), Co(1A)···Co(2A), Co(1)···Co(1A), and Co(2)···Co(2A) distances are 3.645(1), 3.645(1), 3.604(2), and 3.285(2) Å, respectively. Interestingly, at the lower rim of $TCAS^{8-}$, the $\mu_4\text{-}SO_4^{2-}$ anion binds with the four Co^{II} ions in a rare tridentate coordination mode to form the base of the bowl. There are two types of coordination environments for the four cobalt(II) ions: Co(1) and Co(1A) are in a O_5S octahedral geometry, while Co(2) and Co(2A) are in a NO_4S donor-atom environment. Co(1)–S(1) and Co(2)–S(2) have bond lengths of 2.445(2) and 2.499(2) Å, respectively. The oxygen atoms from sulfonate and sulfate oxygen and/or nitrogen atoms from 4,4′-Hbipy complete the six-coordinate cobalt(II) spheres with average $Co–O_{(sulfonate)}$ $Co–O_{(sulfate)}$, and Co–N distances of, respectively, 2.132(5), 2.124(5) and 2.107(6) Å. The 4,4′-Hbipy acts as terminal ligand rather than common bridging ligand, in which uncoordiated nitrogen is protonated, for charge balance, and shows hydrogen bonding with sulfonate and sulfate oxygen [$N···O_{(sulfonate)}$ 3.161(11) Å; $N···O_{(sulfate)}$ 2.851(12) Å]. Notably, further aggregation of the tetracobalt clusters is directed by the coordination of sulfonate groups of $TCAS^{8-}$ in **1**, where the sulfonate groups adopt two types of coordination modes, one half in monodentate and the other half in O,O′-η^1:η^1:μ_2 bridging bidentate mode (Scheme 2).

with four other $TCAS^{8-}$ units within the crystal lattice at ring centroid separations of 3.34, 4.48, 3.34, and 4.48 Å.[10] To date, although many reports have described TCAS complexes, this is the first example showing a 2D layer structure with tetranuclear Co^{II} clusters from $TCAS^{8-}$.

It is pertinent to mention that a disordered water molecule that resides in the cavity of the $TCAS^{8-}$ is located by the OH–aromatic π-hydrogen bonds between the water and aromatic rings, and the O···π centroid distances are 3.45, 3.83, 3.68 and 3.79 Å. Aromatic π-hydrogen bonding to water has been reported for the complex $Na_4H_4CAS{\cdot}13.5\,H_2O$ in which the O···π centroid distances are 3.48, 3.83, 4.78, 4.00 Å.[11] The water molecule penetrates 2.582 Å into the cavity, as measured by how far the water molecule is from the plane of the thiacalix[4]arene bridging sulfur atoms.

Thermal Stability

Thermogravimetric analysis (TGA) was performed on polycrystalline samples of **1**, under nitrogen, to study their stability. The data show two weight loss steps (Figure 3). The first occurs from 30 to 130 °C, with a weight loss of 6.83%, which corresponds to the loss of water molecules. The weight then remains almost unchanged in the plateau from 130 to 510 °C. The second step occurs in the range 510 to 595 °C (weight loss of 29.25%), corresponding to the loss of the 4,4′-bipyridine ligands and the SO_4^{2-}. The compound begins to decompose at 595 °C. The thermogravimetric results demonstrate that the compound is rather stable under nitrogen.

Magnetic Properties

The temperature-dependent magnetic susceptibility of complex **1** was investigated in the range 2–300 K at a 10 kOe applied field. The χ_m and $\chi_m T$ per four Co^{II} ions versus T curves are shown in Figure 4. At 300 K, $\chi_m T$ is 9.80 $cm^3\,mol^{-1}\,K$, which is larger than the expected 7.50 $cm^3\,mol^{-1}\,K$ for four magnetically isolated high-spin Co^{II} ions (S_{Co} = 3/2, g = 2.0). This larger value is the result of contributions to the susceptibility from orbital angular

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

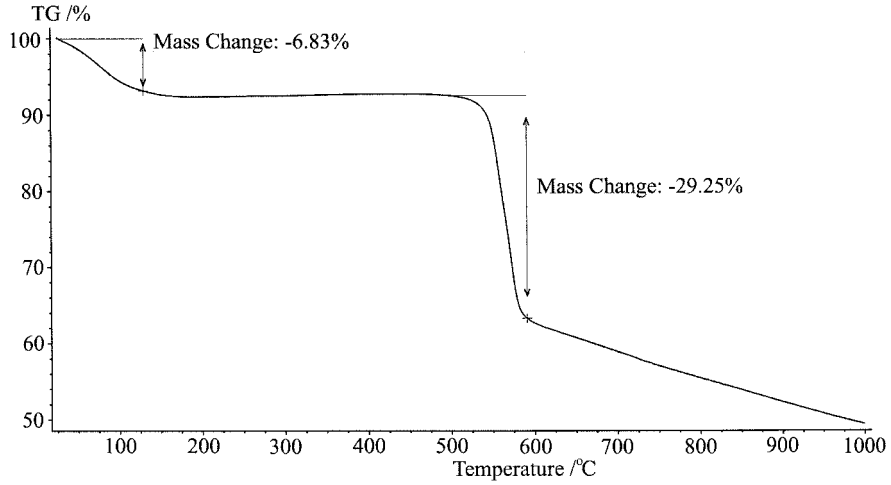

Figure 3. TGA plot for **1** between 30 and 1000 °C.

momentum at high temperature. As the temperature is lowered χ_m increases, reaching a maximum at ca. 14 K. Between 50 and 300 K, χ_m follows the Curie–Weiss law, $\chi_m = C_m/(T - \theta)$, with $C_m = 2.71 \pm 0.01$ cm^{3}kmol (per Co) and $\theta = -28.9 \pm 0.4$ K. These results indicate the antiferromagnetic interactions between cobalt(II) centers.

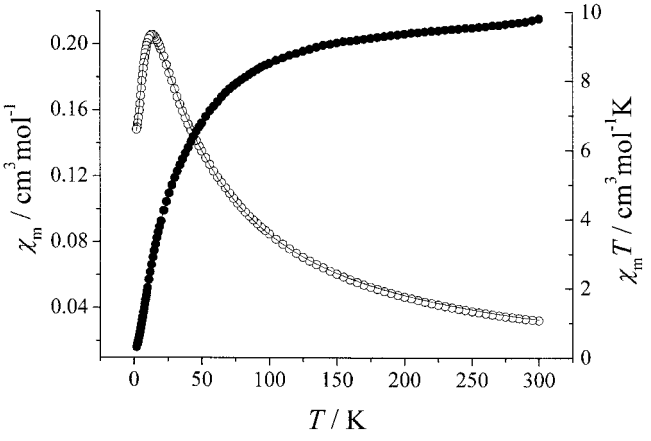

Figure 4. Experimental temperature dependences of χ_m (○) and $\chi_m T$ (●) for **1**; solid lines correspond to the best fit obtained for **1**.

Considering cluster topology and connectivity (Figure 5), an exchange pathway of four cobalt(II) centers of **1** was taken into account. However, we failed to fit the behavior of an array of four orbital degeneration Co^{II} centers by means of an effective spin-Hamiltonian, proposing a four-*J* model, due to the large magnetic anisotropy and spin–orbit coupling of these ions.[12] Therefore, the simplest treatment was carried, considering only isotropic exchange interactions and assuming $J_1 = J_2 = J_3$. The magnetic data were analyzed with the spin Hamiltonian shown in Equation (2).

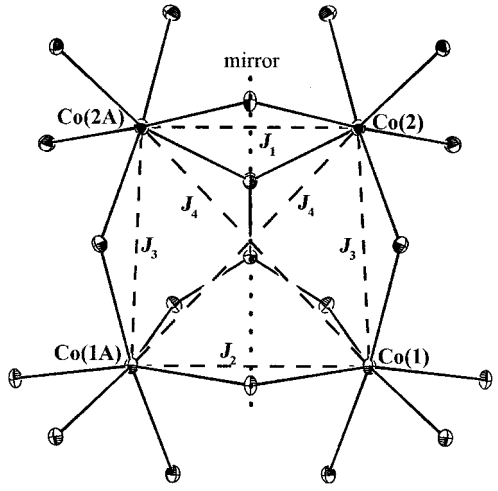

Figure 5. Spin topology for **1** assuming four different *J* values.

The total spin states (S_T) and their energies [$E(S_T)$] can be obtained using the vector-coupling method of Kambe,[13] and substituted into the Van Vleck equation in Equation (3). A Weiss-like temperature correction (θ') to account for intermolecular exchange effects has been applied. The magnetic data were fitted to Equation (3), and gave best-fit parameters of $g = 2.40 \pm 0.01$, $J_1 = -3.07 \pm 0.02$ cm^{-1}, $J_4 = -1.36 \pm 0.06$ cm^{-1}, $\theta' = 1.66 \pm 0.01$ K and an agreement factor $R = 6.12 \times 10^{-6}$. These results show the presence of two kinds of weak antiferromagnetic interactions (J_1 and J_4) associated with the interactions of μ_2-PhO$^-$ and μ_4-SO_4^{2-}. The antiferromagnetic interactions between Co(1) and Co(2) or Co(1) and Co(1A) or Co(2) and Co(2A) through the μ_2-PhO$^-$ originate, presumably, from the high Co–O–Co angles of 121.2° or 119.3° or 108.8°, which differ considerably from 90°.[14]

$$\hat{H}_{ex} = -2J_1(\hat{S}_{Co(2A)}\hat{S}_{Co(2)} + \hat{S}_{Co(1A)}\hat{S}_{Co(1)} + \hat{S}_{Co(2A)}\hat{S}_{Co(1A)} + \hat{S}_{Co(2)}\hat{S}_{Co(1)}) - 2J_4(\hat{S}_{Co(2A)}\hat{S}_{Co(1)} + \hat{S}_{Co(2)}\hat{S}_{Co(1A)}) \quad (2)$$

$$\chi_m = \frac{N\beta^2 g^2}{3k(T-\theta')} \frac{\sum S_T(S_T+1)(2S_T+1)e^{-E(S_T)/kT}}{\sum (2S_T+1)e^{-E(S_T)/kT}} \quad (3)$$

Conclusions

We have successfully used $TCAS^{8-}$ to produce a novel 2D coordination polymer consisting of antiferromagnetically coupled tetranuclear Co^{II} building units. This work suggests that the TCAS-based anion is a versatile ligand with various advantages, including high-nuclearity cluster formation, linking of cluster into polymer arrays, mixed-metal chemistry and ferromagnetic exchange interaction.

Experimental Section

General Remarks: Na_4H_4TCAS was prepared according to a literature method.[3] All other starting chemicals and solvent were commercially available with analytical purity and were used as received. IR spectra were recorded on a Magna 750 FT-IR spectrophotometer (using KBr disks). C, H and N elemental analyses were determined on an Elementary Vario ELIII elemental analyzer and the Co content was determined by atomic absorption. Thermogravimetric analyses (TGA) were performed with a NETSCHZ STA-449C thermoanalyzer under N_2 (30–1000 °C) at a heating rate of 10 °C min^{-1}. Temperature-dependent magnetic-susceptibility measurements on powdered solid samples were performed on Quantum Design MPMS-7 SQUID magnetometer in the range 2–300 K. The magnetic field applied was 10 kOe. Observed susceptibility data were corrected for underlying diamagnetism using Pascal's constants.[15]

Synthesis of 1: The pH of an aqueous mixture (15 mL) containing Na_4H_4TCAS (90.48 mg, 0.1 mmol), 4,4′-bipyridine (31.20 mg, 0.2 mmol) and $CoSO_4{\cdot}6H_2O$ (105.2 mg, 0.4 mmol) was preadjusted to about 3 with 0.1 M H_2SO_4 aqueous solution. The mixture was then transferred to a Teflon-lined stainless vessel (20 mL) that was sealed, heated in an autoclave to 160 °C for 72 h, and then cooled to room temperature at 10 °C h^{-1}. Red crystal of $1{\cdot}3.5H_2O$ were obtained (79.24 mg, yield 52.2% based on Co). Anal. calcd. for $1{\cdot}3.5H_2O$, $C_{44}H_{33}N_4O_{23.5}S_9Co_4$ (1518.00): C 34.81, H 2.19, N 3.69, Co 15.54; found: C 34.53, H 2.11, N 3.82, Co 15.27. IR (KBr): $\tilde{\nu}$ = 3464, 3222, 3116, 3066, 3033, 1637, 1614, 1454, 1423, 1247, 1157, 1141, 1029, 881, 804, 754, 613 cm^{-1}.

X-ray Crystallography Determination: A block crystal (ca. 0.28 × 0.22 × 0.18 mm) of **1** was selected for X-ray diffraction analysis. Data collection was performed on a Siemens SMART-CCD diffractometer equipped with a graphite monochromated Mo-K_α radiation (λ = 0.71073 Å), using the ω-scan mode at 293 K. All absorption corrections were applied using the SADABS program.[16] Structures were solved by direct methods, the metal atoms were located from the E-maps, and other non-hydrogen atoms were derived from successive difference Fourier syntheses. Hydrogen atoms were positioned geometrically, and allowed to ride on their parent C or N atoms. The structure was refined on F^2 by full-matrix least-squares using the SHELXTL-97 program package.[17] Crystallographic data of **1** is summarized in Table 2, and selected bond lengths and bond angles are listed in Table 1. CCDC-221212 (for **1**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Acknowledgments

We are grateful for financial support from NSFC (No. 20231020), the Natural Foundation of Fujian Province and the key project of CAS. We also thank Professor Song Gao for collecting the magnetism data.

COVER PICTURE

The cover picture shows the crystal structures of free radicals of the type $(t\mathrm{Bu_2MeSi})_3\mathrm{E}^{\cdot}$ (E = Si, Ge, Sn) representing the first stable tricoordinate acyclic radicals of the heavier group 14 elements. All of these radicals have a perfect trigonal-planar geometry, being truly π radicals, both in the crystalline form and in solution, accommodating an odd-electron on the p_z(E) orbitals. The synthesis of such stable radicals has been achieved nearly a century after the historical discovery of the first free radical species, triphenylmethyl $\mathrm{Ph_3C}^{\cdot}$ by Gomberg in 1900. The recent developments in the field of stable Si-, Ge-, and Sn-centered free radicals include the synthesis and physico-chemical characterization of the neutral (cyclic and acyclic radicals) and charged (anion radicals of heavy carbene analogues, heavy alkene analogues and heavy alkyne analogues) compounds. The details of this chemistry are described and discussed in the Microreview by V. Ya. Lee and A. Sekiguchi on p. 1209 ff.

Si-, Ge-, and Sn-Centered Free Radicals: From Phantom Species to Grams-Order-Scale Materials

Vladimir Ya. Lee[a] and Akira Sekiguchi*[a]

Keywords: Free radicals / X-ray diffraction / EPR spectroscopy / Silicon / Germanium / Tin

Recent developments in the field of the stable free radicals of heavier group 14 elements are reviewed, covering both neutral and charged radical species. The electronic and crystal structural features of these radicals, both in the solid state and in solution, are compared with each other. The most important parameters affecting the stability, geometry and electronic configuration of the radicals are discussed on the basis of the latest experimental and computational data.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

1. Introduction

Free radicals, that is, compounds featuring a trivalent carbon atom having only seven valence electrons, have been known for more than one hundred years, since the groundbreaking discovery of the triphenylmethyl radical. Such a departure from the fundamental octet rule causes an intrinsic electronic unsaturation of the radical species expressed in the existence of the unpaired electron, resulting in the extremely high reactivity of free radicals compared with that of normal tetravalent carbon compounds.[1] Together with carbocations and carbanions (and later, carbenes), the most fundamental species in organic chemistry, free radicals were always among the most desired and challenging synthetic goals. The two most historically significant discoveries are worth mentioning in this review. The first one commemorates the starting point of free radical chemistry: in 1900 Gomberg provided convincing evidence for the existence of $Ph_3C^{\cdot}$ species obtained by the treatment of triphenylmethyl chloride with metallic silver.[2] This was the first representative of a new class of organic compounds, which were later named free radicals. At the beginning of the era of free radical chemistry, another fundamental breakthrough was achieved by Paneth, who reported in 1929 the first proof for the generation of the simplest methyl radical by the thermal decomposition of tetramethyllead.[3] Since then, and during the last one hundred years, a great deal of experimental information supporting the real existence and participation in chemical reactions of free radical species has been developed. In the early stage, free radicals were speculated to be reactive intermediates with

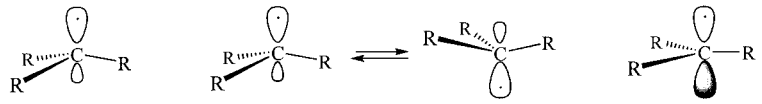
Vladimir Ya. Lee was born in Russia (Sakhalin). He graduated from the chemistry department of the Far-Eastern State University in 1982. He received his Ph.D. degree in chemistry from the Institute of Organic Chemistry of the Academy of Sciences of the USSR (Moscow) in 1987. He has then worked as a postdoctoral researcher at the Korea Institute of Science and Technology (Korea) in 1996 and at the Université Paul Sabatier (France) in 1997. Since 1998 he is working at the University of Tsukuba. His research interests lie in the field of highly reactive species: carbene analogues, cations, free radicals, anions, multiply bonded compounds and small rings.

Akira Sekiguchi is Professor of Organic Chemistry at the University of Tsukuba. He was born in Gunma, Japan, in 1952. He obtained his B. Eng. and M. Eng. from Gunma University in 1974 and 1976, respectively. He received his D. Sc. from the University of Tsukuba in 1981. He became a research fellow in 1978, an assistant in 1981, and an assistant professor in 1982 at the University of Tsukuba. In 1987, he moved to the organosilicon research laboratory at Tohoku University as an associate professor. He worked as a research fellow at the University of Wisconsin, Madison in 1985–1986. In 1996, he returned to the University of Tsukuba as a full professor. He received the Japan IBM Science Award in 1996, the Divisional Award of the Chemical Society of Japan (Organic Chemistry) in 1997, and the Alexander von Humboldt Research Award in 2004. His research interests are organosilicon and organolithium chemistry, organogermanium chemistry, and reactive intermediates.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.



Scheme 1. Geometry of organic free radicals.

very short lifetimes, often undetectable by physico-chemical methods. However, researchers quickly realized that such ephemeral radical species could gain extra stability through the electronic and steric effects of substituents. This greatly extended the lifetime of those radicals, enabling them to be detected and identified directly by means of spectroscopic methods, mainly by EPR and CIDNP techniques.[1] Many so-called persistent radicals have been prepared and characterized since then, and a review dealing with this topic has been published.[4] As a major development in this field, one should mention the synthesis of stable free radicals, whose isolation and structural identification has been possible in a limited number of cases in the past few years.[5]

One of the most fundamental characteristics of free radicals, directly associated with their ground-state electronic structure, is their geometry in the solid state and in solution. It is now well-established that free radicals can adopt one of three possible geometries, known as rigid pyramidal (**A**), flexible pyramidal (**B**), and planar (**C**) (Scheme 1).[1] Planar radicals are also flexible.

In the first two cases, the unpaired electron is accommodated in an orbital with some degree of s-character (tetrahedral configuration), whereas in the latter case the SOMO (singly occupied molecular orbital) is represented by an orbital with essentially p-character (trigonal-planar configuration). The arrangement of the odd electron in an orbital of either s- or p-character is totally governed by the substitution pattern at the radical center. For example, the structure of the methyl radical was found by EPR studies to be either planar or in the form of a very shallow pyramid,[6] whereas the trifluoromethyl radical was found to be markedly pyramidal.[7] The general tendency of the σ-accepting and π-donating substituents to favor the pyramidal structure is explained by the attractive interaction of the SOMO and the central element–electronegative substituent antibonding σ* orbital, increasing the electron density on the more electronegative atom. Accordingly, electropositive σ-donating and π-accepting substituents (such as silyl groups) have the opposite influence on the geometry of the radical center, causing a significant flattening of the radical structure. A great deal of information about the geometry and consequently the electronic structure of free radicals in solution can be obtained from their EPR spectra. The geometry of free radicals in solution can thus be reliably elucidated on the basis of the value of the hyperfine coupling constant (hfcc), since the latter arises from the spin density in the *n*s-orbitals, markedly increasing with increased s-character of the SOMO.[8] In other words, the higher the hfcc value, the more pyramidal is the radical (σ-type radical), the lower the hfcc value, the more planar is the radical (π-type radical).

The chemistry of the heavy analogues of free radicals, centered on the Si, Ge, Sn, and Pb atoms, was developed much later than its carbon counterpart, although the participation of radicals of the type $R_3E^{\cdot}$ (E = heavier group 14 element) in a number of organometallic reactions was postulated and debated several decades ago.[9] Later, the right combination of both steric and electronic stabilizing effects of substituents enabled the preparation of heavier group 14 element centered radicals with lifetimes long enough to be detected directly by EPR spectroscopy.[10] Such compounds have been known since the important publication of the first EPR spectrum of the persistent stannyl radical $[(Me_3Si)_2CH]_3Sn^{\cdot}$ by Lappert et al. nearly 30 years ago.[11] The progress in this field, made after this first discovery, was thoroughly described in a most recent review, to which we refer our readers.[12] The culmination of this steady progress in the field of heavier group 14 element centered radicals was reached just in the past few years, expressed in the publication of the papers describing the first crystal structures of the Si-, Ge- and Sn-centered free radicals. In this review we will deal with the chemistry of such stable (that is, isolable) compounds only, leaving the vast area of the transient and limitedly stable radical species outside the framework of the present article.

The chemistry of stable free radicals centered on the heavier group 14 elements (Si, Ge, Sn, Pb) can be divided into two main areas: the first one concerns the chemistry of the stable *neutral* radical species, whereas the second one is devoted to the *charged* radical species, that is, ion radicals (namely, anion radicals). Below, we will deal with the radicals of both groups, emphasizing the synthetic methods for each class as well as their structural peculiarities, first of all geometry and electronic structure. A remark concerning the terminology used throughout the text: In the literature two main terms for the long-lived radical species are currently used: **persistent** radicals, with a relatively long lifetime enabling them to be detected either by spectroscopic means or chemically, and **stable** radicals, which are indefinitely stable and isolable.[4,12] However, such confusing terminology, particularly with respect to the "relatively" or "indefinitely" long lifetime, may cause conflicting situations when the same radicals are sometimes treated as persistent ones, and sometimes as stable ones. In order to avoid such contradictions, in our review we will use only the term "stable" for those radical species that can be isolated and characterized as individual compounds, in the majority of cases by means of X-ray crystallography.

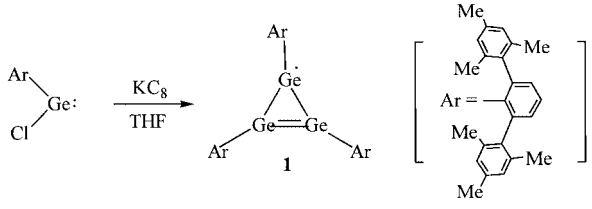
2. Neutral Si-, Ge- and Sn-Centered Radicals

The area of neutral radical species of heavier group 14 elements can be subdivided into the chemistry of cyclic and acyclic compounds. The electronic composition, structural features and stability of these two subgroups differ from each other greatly, since the cyclic radicals can gain extra stability from the cyclic π delocalization of the odd electron over the cyclic π-bond system, whereas the simple acyclic tricoordinate silyl-substituted radicals mainly take advantage of the stabilization through the σ delocalization of the odd electron over the σ* orbitals of the neighboring silyl substituents. The chemistry of both of these groups of neutral radicals will be considered below.

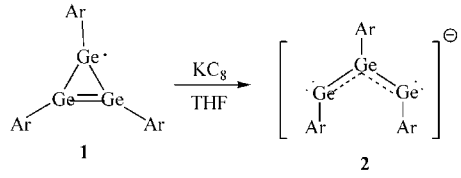
2.1 Cyclic Neutral Radicals

The first example of a stable compound featuring a radical center on a heavier group 14 element, the cyclotrigermenyl radical **1** stabilized by the very bulky 2,6-Mes_2–C_6H_3 groups, was reported by Power's group in 1996.[13] Compound **1** was synthesized by the reduction of chlorogermylene :Ge(Cl)(2,6-Mes_2–C_6H_3)[14] with KC_8 in THF (Scheme 2). Although the exact structural determination of **1** was prevented by skeletal disorder problems, its structure was reliably refined to reveal a Ge analogue of the cyclopropenyl radical, that is, a three-membered ring involving a double bond between the two Ge atoms and an odd electron on the remaining Ge atom.



Scheme 2. Synthesis of cyclotrigermenyl radical **1**.

The EPR spectrum of **1** displayed a resonance with a *g* value of 2.0069 and an hfcc, $a(^{73}Ge)$, of 1.6 mT, suggesting a location for the unpaired electron in an orbital of π symmetry, which in turn means essential planarity at the Ge radical centers. Further reduction of radical **1** resulted in the formation of the corresponding anion species accompanied with the ring-opening process to produce finally the acyclic trigermaallyl anion **2** (Scheme 3).[13]



Scheme 3. Synthesis of trigermaallyl anion **2**.

The cyclic silicon analogue of the delocalized allyl radical, cyclotetrasilenyl radical **3**, was recently reported by Sekiguchi et al.[15] This compound, representing the first stable Si-centered radical, was synthesized by the one-electron reduction of the precursor compound, cyclotetrasilenylium ion **4**,[16] with either silylsodium tBu_3SiNa or KC_8 in Et_2O (Scheme 4).

X-ray crystallography disclosed the free radical structure of **3** (Figure 1). As expected, the four-membered-ring core of **3** was nearly planar (folding angle 4.7°) in contrast to the precursor cation **4**,[16] which had a largely folded cyclic skeleton (folding angle 46.6°) due to the homoaromatic 1,3-

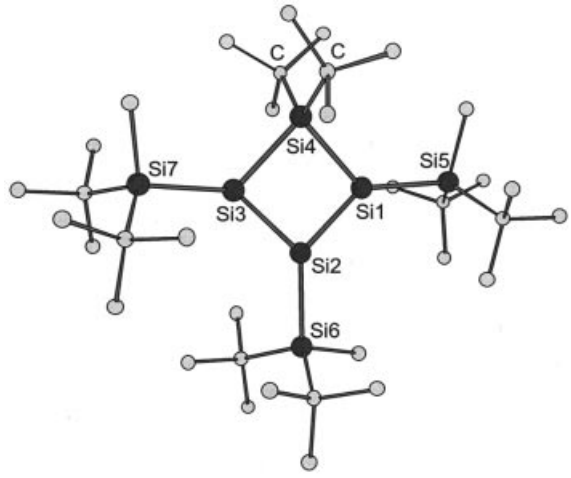


Figure 1. Crystal structure of cyclotetrasilenyl radical **3**.

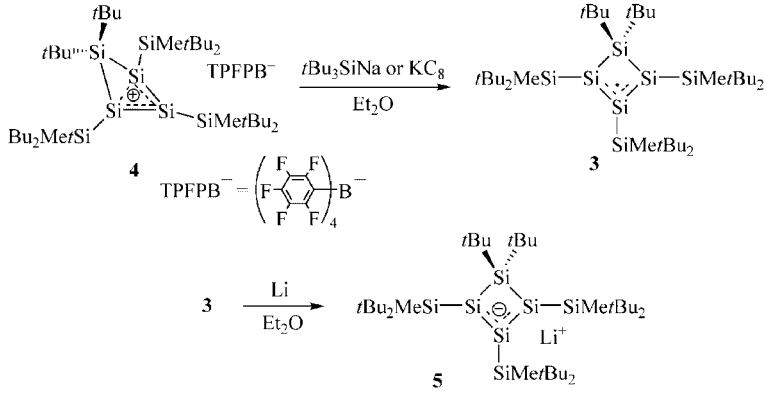


Scheme 4. Synthesis of cyclotetrasilenyl radical **3**.

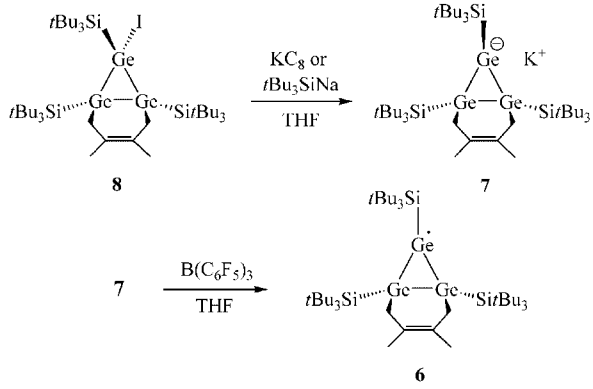
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

orbital interaction. The Si1–Si2 and Si2–Si3 bond lengths were slightly different [2.226(1) and 2.263(1) Å, respectively]. This was consistent with some insignificant pyramidalization of the Si3 atom (the sum of the bond angles was 356.2°). However, the lengths of both the Si1–Si2 and the Si2–Si3 bonds were intermediate between those of the typical Si–Si single and Si=Si double bonds, which proved the allylic-radical-type structure of **3**.

The EPR spectrum of **3** displayed a strong signal with a *g* value of 2.0058 (typical for silyl-substituted silyl radicals: 2.0053–2.0063).[10i–10l] The three pairs of satellite signals with the largest spin densities [hfcc values: $a(^{29}Si)$ = 4.07, 3.74, and 1.55 mT] were assigned to the coupling of an unpaired electron with the terminal Si1, terminal Si3, and the central Si2 nuclei, respectively, which also agreed well with the delocalized-allylic-type structure of radical **3**. The small values of the hfcc's are consistent with the planarity of the radical unit, that is, the planarity of the four-membered ring of **3** is also retained in solution. The cyclic radical **3** can be smoothly reduced with metallic Li in Et_2O to form the corresponding cyclotetrasilenide ion **5**, which preserves the allylic-type structure of its predecessor (Scheme 4).[17] Such stability of the four-membered ring of **3** upon reduction is amazing, in contrast to the above-mentioned ring-opening reduction of the cyclotrigermenyl radical **1**.[13]

The first, and still the sole, example of a stable bicyclic radical of heavier group 14 elements was reported just recently by Sekiguchi et al.[18] Such a Ge-centered free radical, 1,6,7-trigermabicyclo[4.1.0]hept-3-en-7-yl (**6**), was synthesized by the selective one-electron oxidation of the corresponding precursor, bicyclic anion **7**, generated by the reduction of iodide **8**, with tris(pentafluorophenyl)boron in THF (Scheme 5).

The crystal structure of **6** was determined by means of X-ray crystallographic analysis (Figure 2), which showed that the radical center was specifically accommodated on the Ge3 atom having a nearly planar geometry (sum of the bond angles: 357°). The bridgehead Ge1–Ge2 bond was slightly longer than the bridging Ge1–Ge3 and Ge2–Ge3 bonds: 2.4864(4) Å vs. 2.4254(5) and 2.4326(4) Å. A particularly important observation is that compound **6** has *endo* conformation, in contrast to all other structurally



Scheme 5. Synthesis of bicyclic germyl radical **6**.

characterized compounds of this type, which have exclusively *exo* conformation.[19] This fact indicates some degree of intramolecular Ge radical–π(C=C) interaction in **6**; this is deduced from the relative proximity of the two species: the interatomic distance between the Ge radical and the C=C bond is 3.632 Å, which lies in the range of van der Waals interactions.

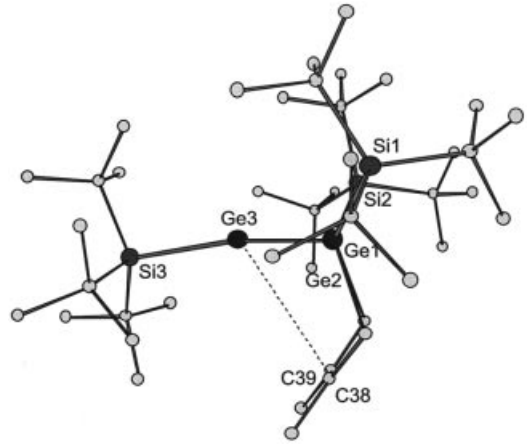


Figure 2. Crystal structure of bicyclic germyl radical **6**.

Surprisingly, the EPR spectrum of **6** revealed two signals of almost identical intensity, with *g* values of 2.0210 and 2.0223. Again, as in all of the above cases of cyclic radicals,

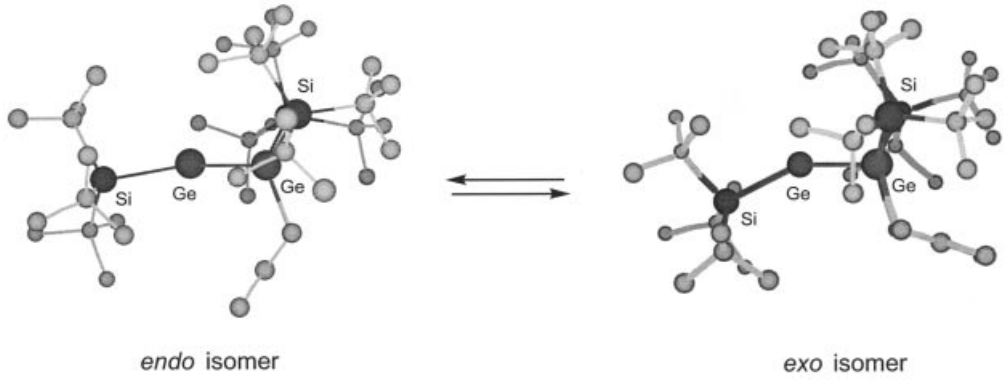

Figure 3. *endo–exo* isomerization of bicyclic germyl radical **6**.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the planarity of these Ge radical centers was maintained also in the condensed phase, which was clearly manifested by their small hfcc's (3.4 and 2.6 mT, respectively), indicating also the sp^2-type hybridization of the Ge radical center. The existence of two signals in the EPR spectrum was explained in terms of the *endo–exo* isomerization taking place in the solution of **6** on the EPR time scale (Figure 3).[18] Apparently, in the solid state such isomerization is suppressed in favor of the *endo* isomer, stabilized by the intramolecular Ge radical–C=C interaction, which was supported by theoretical calculations (the *endo* isomer is more stable than the *exo* isomer by 0.59 kcal/mol).

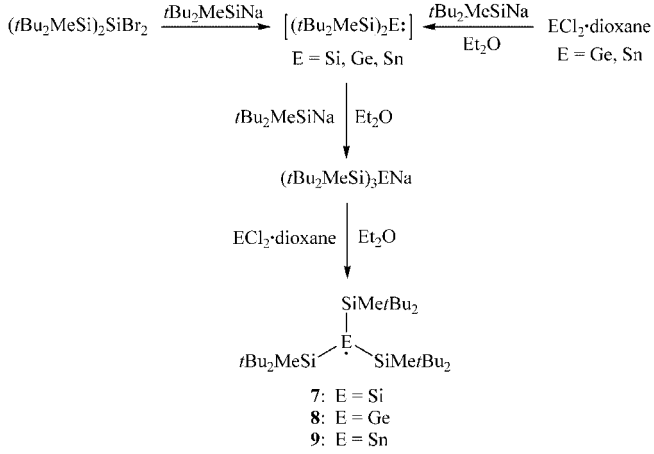
One can easily notice that, in contrast to the allylic-type cyclotrigermenyl radical **1**[13] and cyclotetrasilenyl radical **3**,[15] the bicyclic radical **6**[18] has a localized structure caused by the absence of the π bond in the proximity necessary for effective through-bond interaction and by the insufficiency of the through-space interaction with the C=C double bond to enable the remarkable delocalization of the odd-electron density.

2.2 Acyclic Tricoordinate Neutral Radicals

Although the above-mentioned cyclic Si- and Ge-centered radicals were synthesized as the remarkable first representatives of this class of organometallic compounds, their structural features were significantly affected by their particular and unique cyclic skeletons. However, the properties and stability of the acyclic radicals of the type $R_3E^{\cdot}$ (E = heavier group 14 element) without stabilization through cyclic π delocalization were expected to be greatly different and even more challenging. Therefore, despite the evident progress in the development of the stable-free-radical chemistry described in the previous section, the search for stable, tricoordinate, acyclic radicals of heavier group 14 elements turned out to be a problem of great importance.

The first breakthrough in the development of such chemistry was achieved just a couple of years ago by Sekiguchi et al., who reported the synthesis and structural identification of the first stable acyclic silyl, germyl, and stannyl radicals lacking conjugation with π bonds. Of particular importance was the fact that all compounds were prepared by a similar and very simple method, which demonstrated the generality of the synthetic approach. All synthesized $R_3E^{\cdot}$ (E = Si, Ge, Sn) radicals had the same silyl substituents (R = SiMe*t*Bu$_2$), which provided a unique possibility to prepare a homologous series of the compounds and trace the regularities and tendencies inside this series, on descending group 14.

The tris(silyl)substituted silyl radical **7** was synthesized by the oxidation of the in situ generated silylsodium derivative (*t*Bu$_2$MeSi)$_3$SiNa, prepared by the reaction of dibromosilane (*t*Bu$_2$MeSi)$_2$SiBr$_2$ and silylsodium *t*Bu$_2$MeSiNa with dichlorogermylene–dioxane complex GeCl$_2$·dioxane in Et$_2$O (Scheme 6).[20]



Scheme 6. Synthesis of tris(di-*tert*-butylmethylsilyl)-substituted silyl-, germyl-, and stannyl radicals **7**, **8**, and **9**.

Radical **7** has a trigonal-planar configuration of the Si radical center, implying that the odd electron is accommodated in the 3p$_z$ orbital of the Si atom (Figure 4). Both steric and electronic factors contribute significantly to the planarity of the radical center: Sterically, for example, all methyl substituents at the peripheral Si atoms are arranged in a clockwise manner exactly in the Si1–Si2–Si3–Si4 plane, thus minimizing the steric repulsion of the bulky *t*Bu groups. Electronically, electropositive silyl substituents significantly lower the inversion barrier at the Si radical center, also resulting in its planarization. On the other hand, the bulky substituents sterically protect the free-radical species, enabling it to be isolated. Another important factor enhancing the stability of **7** is the possibility of delocalization of the unpaired-electron density over the antibonding σ* orbitals of the Si–C(*t*Bu) bonds (hyperconjugation effects).

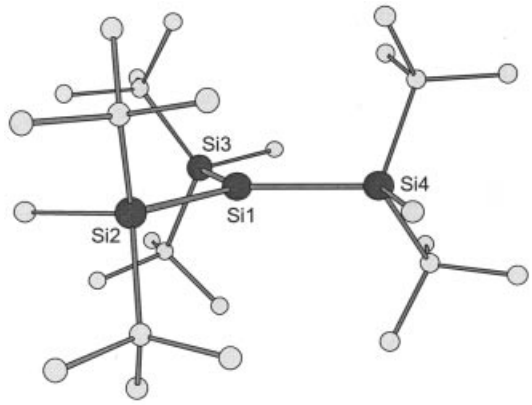


Figure 4. Crystal structure of tris(di-*tert*-butylmethylsilyl)silyl radical **7**.

Radical **7** exhibited an intense signal in the EPR spectrum with a *g* value of 2.0056 and two pairs of satellite signals with the hfcc's $a(^{29}Si)$ = 5.80 mT (α-Si) and 0.79 mT (β-Si) (Figure 5). The small coupling with the central Si atom of 5.80 mT definitely manifests the arrangement of the unpaired electron in an orbital of predominantly p-character, implying that the Si radical center is sp^2-hy-

bridized and planar. Thus, both in the solid state and in solution the persilyl-radical **7** behaves as a π radical, whose SOMO is mainly represented by the $3p_z$(Si) orbital.

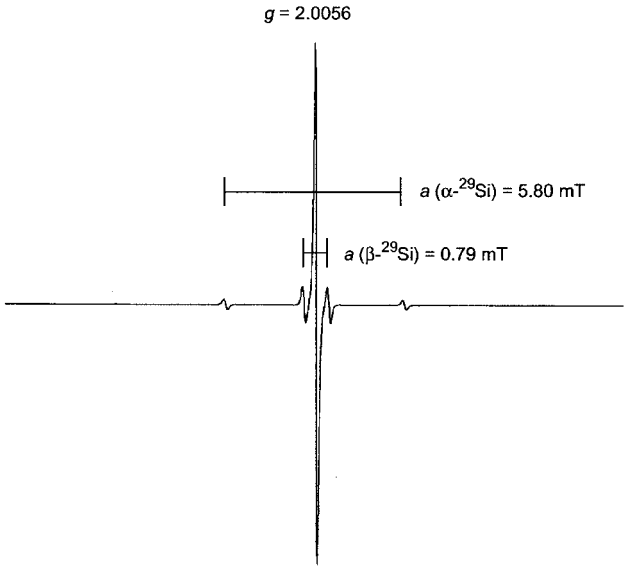

Figure 5. EPR spectrum of tris(di-*tert*-butylmethylsilyl)silyl-radical **7**.

The corresponding Ge analogue (tBu$_2$MeSi)$_3$Ge· (**8**) was prepared in a similar, and even simpler, procedure: by the direct reaction of tBu$_2$MeSiNa with GeCl$_2$·dioxane in Et$_2$O (Scheme 6).[20] At first, the intermediate germylene (tBu$_2$MeSi)$_2$Ge**:** was generated in situ, followed by the formation of the germylsodium derivative (tBu$_2$MeSi)$_3$GeNa, and its subsequent oxidation with a second equivalent of GeCl$_2$·dioxane. It is worth mentioning that in the above reactions the GeCl$_2$·dioxane complex behaved as a very mild and selective oxidizing reagent, whose high oxidizing ability was documented in the previous electrochemical studies [$E_{1/2}$(red) = –0.41 V].[21]

Being a heavy homologue of silyl radical **7**, germyl radical **8** exhibited quite similar structural and electronic features. Its crystal structure was isomorphous to that of **7**: an absolutely planar configuration of the Ge center with the same in-plane and clockwise arrangement of the methyl groups.[20] The EPR spectrum of **8** displayed a strong central signal (*g*-factor = 2.0229) with the very characteristic picture of ten satellite signals with the hfcc a(^{73}Ge) = 2.00 mT (Figure 6). Again, one should recognize that Ge radical **8** is a planar π radical, parallel to the above case of silyl radical **7**.

Employing the same synthetic approach, Sekiguchi et al., recently succeeded in the preparation of the first stable Sn-centered radical, (tBu$_2$MeSi)$_3$Sn· (**9**), by the reaction of tBu$_2$MeSiNa with SnCl$_2$·dioxane in Et$_2$O (Scheme 6).[22] The crystal structure of **9** is identical to those of the silyl and germyl radicals **7** and **8** discussed above: a planar Sn radical center with the same orientation of the silyl substituents. The EPR spectrum of **9** revealed a central signal with a *g* value of 2.0482 and two pairs of satellite signals with the hfcc a(^{119,117}Sn) = 32.9 mT (Figure 7).

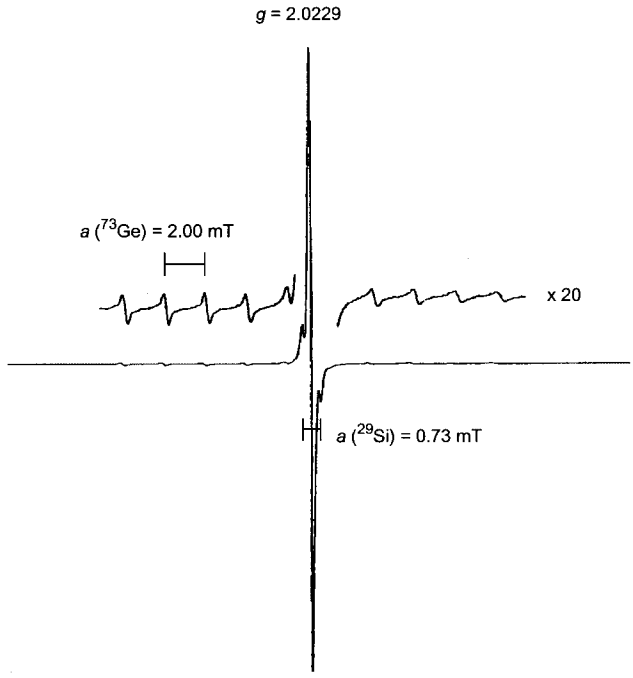

Figure 6. EPR spectrum of tris(di-*tert*-butylmethylsilyl)germyl radical **8**.

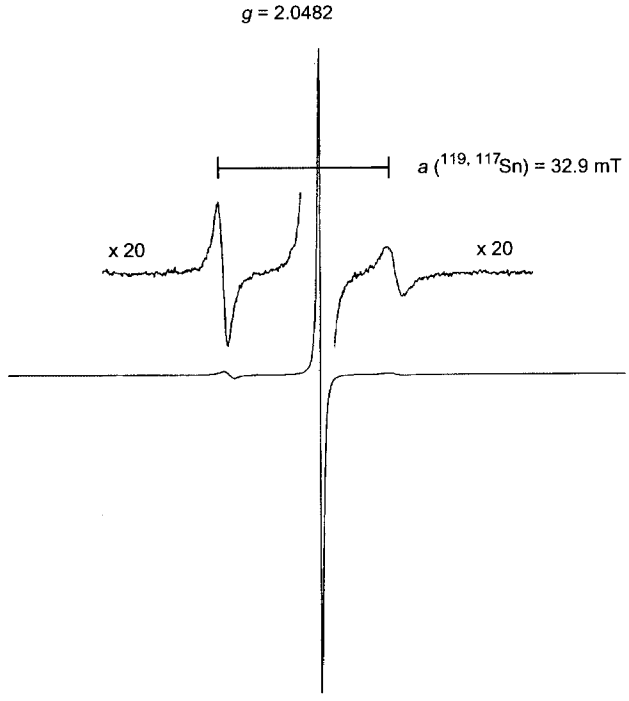

Figure 7. EPR spectrum of tris(di-*tert*-butylmethylsilyl)stannyl-radical **9**.

Most importantly, in the series of silyl, germyl and stannyl radicals **7**, **8**, and **9** the structural features are absolutely identical both in the solid state and in solution, that is, all radicals should be described as truly π radicals with the characteristic sp^2-hybridization and trigonal-planar configuration of the central element. Since the substitution

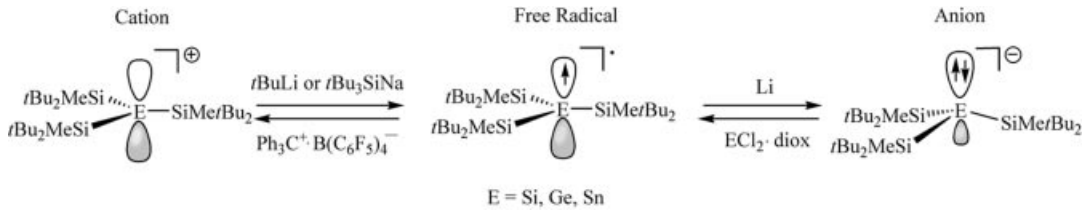

Scheme 7. Reversible redox system of the $(t\mathrm{Bu_2MeSi})_3\mathrm{E}$ (E = Si, Ge, Sn) species: cations–free radicals–anions.

pattern is the same in all cases, one should attribute such uniform behavior of the $(t\mathrm{Bu_2MeSi})\mathrm{E}^{\cdot}$ (E = Si, Ge, Sn) radical homologues to the determining influence of the bulky electropositive silyl substituents, in contrast to simple alkyl and aryl substituents causing a highly pronounced pyramidalization around the metal radical centers, in which the unpaired electron occupies the orbital with a high degree of s-character (σ radicals).

In addition to the evident simplicity of the preparation and hence the easy accessibility of radicals **7**, **8**, and **9**, another striking peculiarity of these compounds is their reactivity. All these radicals easily and quantitatively undergo one-electron oxidation or reduction to form the corresponding cation and anion species (Scheme 7).[23,24] This allowed the synthesis of the first stable free germyl and stannyl cations $(t\mathrm{Bu_2MeSi})_3\mathrm{Ge}^+$ and $(t\mathrm{Bu_2MeSi})_3\mathrm{Sn}^+$, recently described by Sekiguchi et al.[23b,23c]

3. Charged Si-, Ge-, and Sn-Centered Radicals

Another name for charged radicals is ion radicals, either anion radicals or cation radicals of the heavier group 14 elements. Although the existence of such molecules as transient species has been discussed for a long while, being sometimes experimentally demonstrated by special spectroscopic techniques such as low-temperature EPR spectroscopy,[25] significant progress in this field has been achieved only in the last few years, with the synthesis of stable representatives of this class of highly reactive compounds. In reviewing these latest developments, we will also subdivide these radicals into two groups: cyclic and acyclic ones.

3.1 Cyclic Ion Radicals of Heavier Group 14 Elements

Only one example of a stable cyclic anion radical of heavier group 14 elements has been reported very recently, the cyclotetrasilane anion radical **10**.[26] This compound was formed, together with the more extensively reduced species, the cyclotetrasilane dianion **12**, upon reduction of the heterocyclic dichlorosilane precursor **11** with metallic potassium in THF (Scheme 8).

In the crystal state of **10** the potassium ion is solvent-separated from the anion radical part (Figure 8). The four-membered Si_4 ring is square-planar with endocyclic Si–Si bond lengths of 2.347(2) Å, which are slightly shorter than those of known cyclopolysilanes.[27] The EPR spectrum of **10** showed a multiplet signal with $g = 2.0025$ and $a(^{14}\mathrm{N}) = 0.35$ mT, consisting of 15 of the expected 17 lines due to

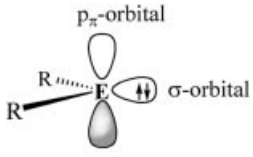
coupling of the unpaired electron with the eight ^{14}N nuclei ($I = 1$). Such an EPR spectrum pattern agrees well with the formulation of odd-electron delocalization over the Si_4 ring, which is supported by the EPR spectrum simulation.

3.2 Acyclic Ion Radicals of Heavier Group 14 Elements

Until now, no examples of stable cation radicals based on the heavier group 14 elements have been reported in the scientific literature. As for stable anion radicals, there were just a few papers devoted to this subject, published mainly in the past few years. Among them, one can recognize the following subtopics: (1) anion radicals of heavy carbene analogues, (2) anion radicals of heavy alkene analogues, (3) anion radicals of heavy alkyne analogues. Each one will be briefly considered below.

3.3 Anion Radicals of Heavy Carbene Analogues

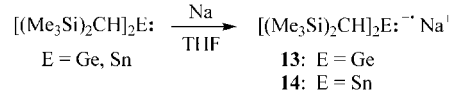
It is now well established that the heavy analogues of carbenes, that is, silylenes, germylenes, stannylenes and plumbylenes, have a singlet ground state with a σ^2 electronic configuration, implying that the two paired electrons are accommodated in the orbital of σ symmetry, corresponding to the a $^1A_1$ electronic ground state (Scheme 9).[28] However, upon either oxidation or reduction, the electronic configuration of heavy carbene analogues may be changed or may be retained depending on the substitution pattern. For example, the silylene cation radical was experimentally found to be a σ-type radical, whereas the silylene anion radical was calculated to be a π radical.[29] The anion radicals of dichlorogermylene, as well as its complexes with Lewis bases, were also calculated to be π radicals, in contrast to their cation radicals of σ type.[21]



Scheme 9. Electronic configuration of the heavy analogues of carbenes.

Although experimental data on the stable (isolable) anion radicals of heavy carbene analogues are still lacking in the scientific literature, there were several papers on the generation of such anion-radical species with lifetimes long enough to be detected and identified by EPR. The first report on the generation of anion radicals of heavy carbene analogues was published by Sita et al., who described the room-temperature EPR spectrum of the reaction mixture obtained upon the reduction of hexakis(2,6-diethylphenyl)-cyclotristannane with potassium amalgam in THF.[30] This EPR signal, exhibiting an $^{119,117}Sn$ hyperfine coupling of 15.2 mT, was reasonably assigned to the bis(2,6-diethylphenyl)stannylene anion radical; however, the assignment was not unambiguously proved. More recent developments in the field involve the direct reduction of the stable heavy carbene analogues (silylenes, germylenes, and stannylenes) with the alkali metals, providing more convincing evidence for the generation of the relatively stable anion-radical species of the heavy carbenes. The latter achievements will be briefly overviewed below.

The first paper on the generation of germylene and stannylene anion radicals was published by Egorov and Gaspar in 1995.[31] These anion radicals were prepared by the reduction of Lappert's germylene $[(Me_3Si)_2CH]_2Ge$**:** and stannylene $[(Me_3Si)_2CH]_2Sn$**:** with sodium mirror in THF (Scheme 10). Although both germylene anion radical **13** and stannylene anion radical **14** were not indefinitely stable in solution at room temperature (the lifetime for **13** was about 1.5 h, whereas for **14** it was several minutes), it was possible to characterize them by EPR spectroscopy. Germylene anion radical **13** exhibited a strong EPR resonance ($g = 2.0125$) as a triplet due to the coupling of the unpaired electron with the two α-protons of the alkyl substituents [$a(^1H) = 0.26$ mT]. The characteristic coupling with the ^{73}Ge nuclei was manifested in the observation of eight (of the total of ten) weak satellite signals with $a(^{73}Ge) = 1.25$ mT. The disappearance of the anion radical **13** in solution obeys second-order kinetics, implying that **13** dimerizes to form the diamagnetic dianion species.



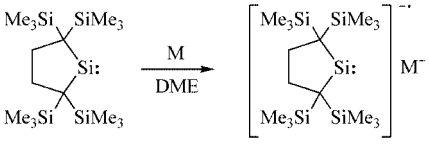
Scheme 10. Generation of the germylene and stannylene anion radicals **13** and **14**.

The stannylene anion radical **14** was also identified by its EPR spectrum, which revealed a broad singlet ($g = 2.0177$) having a pair of unresolved satellite signals arising from the coupling of the unpaired electron with both ^{119}Sn and ^{117}Sn nuclei [$a(^{119,117}Sn) = 11.6$ mT].[31] The small values of the hfcc's [$a(^{73}Ge) = 1.25$ mT and $a(^{119,117}Sn) = 11.6$ mT] make possible a reliable assignment of both anion radicals **13** and **14** to a class of π radicals with the $^2B_1$ ground electronic state.

A study on the generation of the silylene anion radical was published several years later than that for germylene and stannylene anion radicals. The silylene anion radical **15** with a lifetime of about 20 minutes at room temperature was generated similarly by the direct reduction of the stable silylene **16** with potassium mirror in dimethoxyethane (Scheme 11).[32] The one-electron reduction of **16** to form anion radical **15** was also achieved by reduction with other alkali metals such as Li, Na, Rb, and Cs, to produce essentially the same EPR spectra (Scheme 11). The identification and assignment of **15** was made on the basis of its EPR spectrum, which revealed a multiplet signal ($g = 2.0077$) composed of more than 20 lines due to the coupling of the unpaired electron with the 36 protons of the Me_3Si groups [$a(^1H) = 0.0189$ mT] and the 4 protons of the CH_2 groups

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of the cyclopentane skeleton [$a(^1H)$ = 0.0378 mT]. The satellite signals due to the coupling with ^{29}Si nuclei were observed as three sets of doublets, corresponding to the coupling with the central Si atom [$a(^{29}Si)$ = 2.99 mT] and the two types of Si atoms of the Me_3Si groups [$a(^{29}Si)$ = 1.66 and 1.30 mT]. These EPR parameters of **15** are similar to those of the transient silylene anion radical $[(iPr_3Si)_2LiSi]^{-\cdot}$, generated together with other silyl-radical species by the photolysis of $[(iPr_3Si)_2Li(THF)_2Si]_2Hg$, g = 2.0073, $a(^{29}Si_\alpha)$ = 3.20 mT.[33]



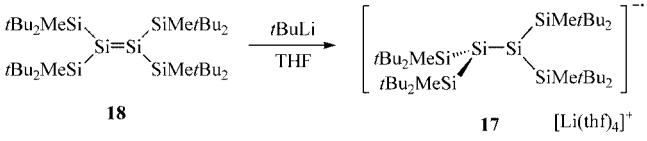
16 **15**

Scheme 11. Generation of the silylene anion radical **15**.

3.4 Anion Radicals of Heavy Alkene Analogues

The heavy analogues of alkenes of the type >E=E< (E = Si, Ge, Sn and Pb) are expected to be oxidized or reduced much more easily than the corresponding alkenes >C=C< because of the high-lying HOMOs and low-lying LUMOs of the former relative to those of the latter. There have been several reports on the formation and EPR identification of the anion radicals of heavy alkene analogues generated either by the reduction of the 1,2-dichlorodisilane precursors or by the direct reduction of disilenes with alkali metals. Weidenbruch et al. reported in 1985 the generation of the first representatives of disilene anion radicals of the type $[R_2Si{=}SiR_2]^{-\cdot}$ (R = *i*Pr, *t*Bu), which were generated by the reduction of the 1,2-dihalo precursors $R_2(X)Si{-}Si(X)R_2$ with alkali metals in THF.[34] The assignment of a lifetime of several minutes at room temperature to the above-mentioned anion radical species was based on its EPR spectrum, which had an hfcc, $a(^{29}Si)$, of 3.36 mT. Following this original report, Kira et al. briefly commented on the generation of disilene anion radicals by the direct reduction of stable tetrasilyldisilenes with potassium in DME; the EPR spectral parameters for these radicals were listed.[35] However, the final isolation and unambiguous structural elucidation of anion radicals of the heavy alkene analogues were achieved only in 2004.

The first virtually stable disilene anion radical **17** was synthesized by the reduction of the disilene $(tBu_2MeSi)_2Si{=}Si(SiMetBu_2)_2$ (**18**) with *t*BuLi in THF (Scheme 12).[36]



18 **17**

Scheme 12. Synthesis of the disilene anion radical **17**.

The crystal structure analysis of **17** revealed a solvent-separated ion pair with a highly twisted (88°) central Si–Si bond with a bond length of 2.341(5) Å (about 4% longer than that of the neutral precursor **18**) (Figure 9). The geometry around the two central Si atoms was different, nearly planar at Si2 (sum of the bond angles 359.9°) and pyramidal at Si1 (sum of the bond angles 352.7°), implying that the odd electron and the negative charge were separated, hence the radical character of Si2 and the anionic character of Si1. The EPR spectrum of **17** exhibited a central signal with g = 2.0061 accompanied by a pair of satellites due to the coupling of the unpaired electron with the ^{29}Si nuclei, $a(^{29}Si)$ = 2.45 mT (Figure 10). However, this hfcc is less than half that of the structurally very similar tris(di-*tert*-butylmethylsilyl)silyl radical **7** (5.80 mT).[20] This variation in magnitude was explained by the delocalization of the unpaired-electron-spin density over the Si1 and Si2 atoms of **17** on the EPR time scale (Scheme 13). At low temperature (120 K), the observed coupling constant in the EPR spectrum of **17** increased to 4.50 mT, indicating that the fast spin exchange was suppressed under glass matrix conditions.

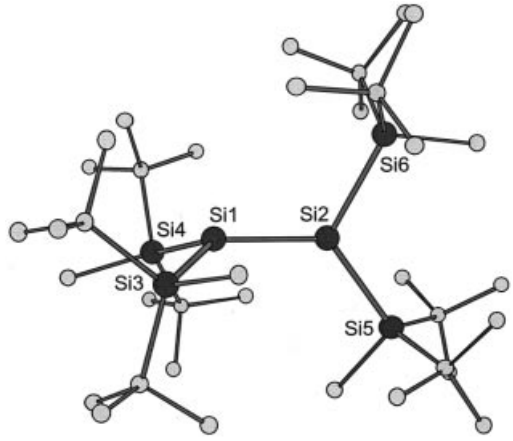


Figure 9. Crystal structure of disilene anion radical **17**.

The tin homologue of the above-mentioned compound, distannene anion radical **19**, was also synthesized by Sekiguchi et al., using the same synthetic protocol, that is, the direct reduction of the precursor distannene $(tBu_2MeSi)_2Sn{=}Sn(SiMetBu_2)_2$ (**20**) with potassium mirror in THF in the presence of [2.2.2]cryptand (Scheme 14).[37]

The crystal structure of **19** is reminiscent of that of the silicon analogue **17**:[36] a highly twisted (74°) Sn–Sn skeleton with a bond length of 2.8978(3) Å, which is 0.2295 Å longer than that in the starting distannene **20** because of the decrease in bond order upon one-electron reduction (Figure 11). As in the case of **17** mentioned above, the geometry around the two Sn atoms is different: one of them is essentially planar (355.4°), whereas the other one is highly pyramidal (323.2°), again assuming that the negative charge and the unpaired electron are effectively separated between the two Sn atoms. However, in contrast to disilene anion radical **17**,[36] such charge–electron separation is also maintained in the solution of distannene anion radical **19**. This was demonstrated by the EPR spectrum of **19** showing a signal (g = 2.0517) with two distinct pairs of $^{119,117}Sn$-satel-

lite signals with hfcc values of 34.0 mT ($^{119,117}Sn_{\alpha}$) and 18.7 mT ($^{119,117}Sn_{\beta}$), respectively, implying that the odd electron localized on only one of the two Sn atoms (Figure 12).[37]

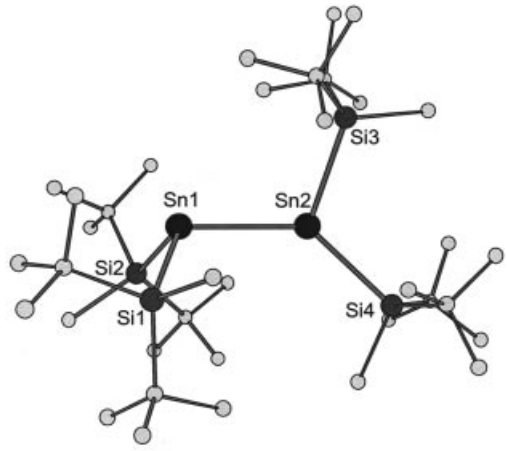

Figure 11. Crystal structure of distannene anion radical **19**.

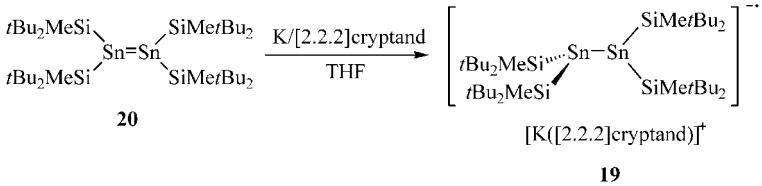
3.5 Anion Radicals of Heavy Alkyne Analogues

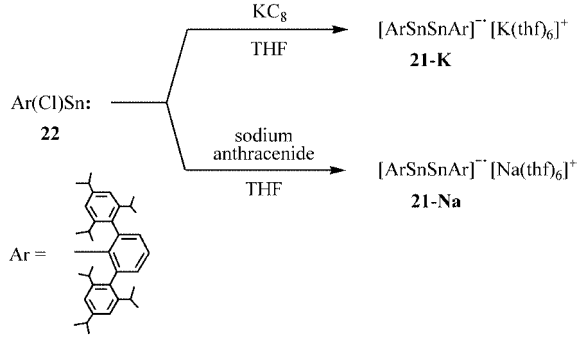
Further increasing the degree of unsaturation of the precursors, one can imagine the triply bonded compounds of heavier group 14 elements as possible candidates for one-electron reduction to produce their corresponding anion radicals. However, until very recently such heavy alkyne analogues were not available as stable species because of their intrinsic instability and high reactivity. Just a few years ago, the first compounds of this class containing a formal triple bond between elements heavier than carbon were synthesized, making possible the study of their reduction.[38] The synthesis of the first, and still the only, example of a singly reduced heavy alkyne analogue was recently reported by Power et al. This product, compound **21-K**, representing the anion radical of the valence isomer of distannyne, was produced by reduction of the precursor chlorostannylene **22** with potassium graphite in THF (Scheme 15).[39]



20 **19**

Scheme 14. Synthesis of the distannene anion radical **19**.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 15. Synthesis of the distannyne valence isomer anion radicals **21-K** and **21-Na**.

The crystal-structure analysis of **21-K** revealed a highly *trans*-bent configuration of the substituents at both Sn atoms with an Sn–Sn–C bond angle of 95.20(13)° and an Sn–Sn bond length of 2.8123(9) Å (Figure 13). The EPR spectrum of **21-K** displayed a signal with g = 2.0069 and hyperfine coupling with both ^{119}Sn and ^{117}Sn nuclei, which were simulated to produce the values $a(^{117}Sn)$ = 0.83 mT and $a(^{117}Sn)$ = 0.85 mT. The small hfcc values provide evidence for the localization of the unpaired electron in an orbital of π symmetry. Such structural and spectral properties of **21-K** are most consistent with the *trans*-bent structure **23**, in which each tin atom bears a lone pair and the unpaired electron is accommodated in a (5p-5p) π orbital of the tin atoms (Figure 14). The species **23**, with a formal Sn–Sn bond order of 1.5 and highly pronounced *trans*-bending of substituents, was suggested to have little hybridization between the tin atoms, implying poor overlap of the 5p-orbitals to form a weak π bond.

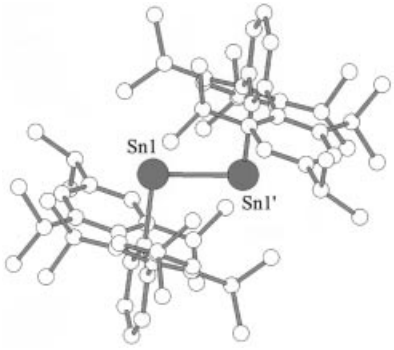


Figure 13. Crystal structure of the distannyne valence isomer anion radical **21-K** (only the anionic part of the molecule is shown).

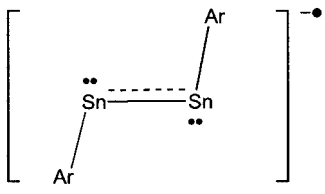

Figure 14. Bonding model of [ArSnSnAr]$^{-\cdot}$ anion radical **23** (Ar = 2,6-Tip$_2$C$_6$H$_3$).

The anion radical **21-Na**, having a sodium counterion, was also prepared by the reduction of chlorostannylene **22** with sodium anthracenide in THF (Scheme 15).[40] Although **21-Na** was isolated as a contact ion pair, in contrast to the potassium salt **21-K** obtained as a solvent-separated ion pair,[39] the EPR spectral and X-ray structural parameters of the two salts were almost completely identical, not being notably affected by the difference in their counterions. Thus, although the Sn–Sn–C bond angles in **21-Na**[40] were just a little bit wider than those in **21-K**:[39] 98.0(4) vs. 95.20(13)°, the Sn–Sn bond lengths in **21-Na** and **21-K** were practically the same, 2.8107(13) vs. 2.8123(9) Å, respectively. That is, the bonding model description **23** is fully applicable to the sodium derivative **21-Na**.

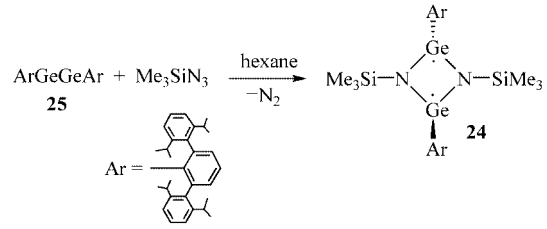
4. Heavier Group 14 Elements Centered Biradicals

The last class of free radicals based on the heavier group 14 elements has just very recently become synthetically accessible and is represented by compounds featuring the singlet biradical character. Such biradicals (or, more precisely speaking, biradicaloids, that is, the closed-shell derivatives of singlet biradicals exhibiting a weak partial coupling between the radical centers) were expected to be more stable than their carbon analogues.[41] Although several papers devoted to the stable carbon- and boron-centered biradicaloids incorporated in four-membered rings have been reported in the scientific literature since 1995,[42] there are very few examples of the stable compounds of heavier group 14 elements with some degree of biradical character. The two latest examples of stable biradicaloids, representing very attractive heteroatom analogues of the classical organic cyclobutane-1,3-diyl, were simultaneously reported in 2004 by research groups of Power and Lappert.[43,44] Both compounds have similar four-membered-ring skeletons composed of the two 1,3-nitrogen atoms and the 2,4-heavier group 14 elements (Ge in Power's paper and Sn in Lappert's paper) with the two radical centers localized on the group 14 elements. In this review, we will highlight the properties of only these two latter compounds.

The first biradicaloid, 1,3-diaza-2,4-digermacyclobutane-1,3-diyl **24**, was synthesized by the reduction of the digermyne **25** with trimethylsilyl azide in hexane (Scheme 16).[43] The crystal structure of **24** revealed a perfectly planar Ge_2N_2 four-membered ring, in which both nitrogen atoms are trigonal-planar [359.97(8)°], whereas the two germanium atoms are pyramidal [322.10(7)°] and the two aryl substituents at the germanium atoms are *trans* to each other (Figure 15). The Ge–Ge separation of 2.755 Å is nearly 0.3 Å longer than the typical Ge–Ge single bond (av. 2.44 Å),[45] indicating no Ge–Ge bonding in the Ge_2N_2 skeleton of **24**. Such tricoordination of both Ge atoms is consistent with the localization of the unpaired electrons on them, that is, with the formulation of **24** as a singlet biradicaloid. Accordingly, no signals were detected in the EPR spectrum of **24** in the temperature range 77–300 K, whereas the usual NMR spectra were observed. The biradical structure of **24** was supported by theoretical calculations, which revealed

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the absence of the Ge–Ge bonding, showing that the HOMO of the molecule consisted mainly of a nonbonding combination of the two lone-pair p-orbitals centered on the two Ge atoms.



Scheme 16. Synthesis of 1,3-diaza-2,4-digermacyclobutane-2,4-diyl **24**.

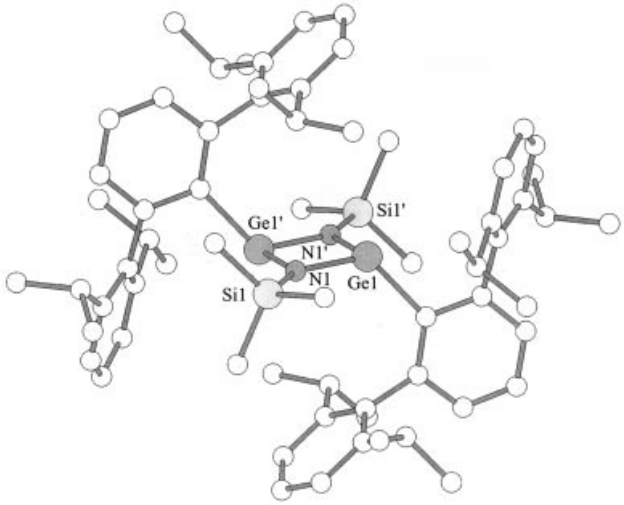


Figure 15. Crystal structure of 1,3-diaza-2,4-digermacyclobutane-2,4-diyl **24**.

The second biradicaloid, 1,3-diaza-2,4-distannacyclobutane-1,3-diyl **26**, was prepared by the rather unusual reaction of the chloro(amino)stannylene dimer $[Sn\{N(SiMe_3)_2\}(\mu\text{-}Cl)]_2$ (**27**) and AgOCN in diethyl ether (Scheme 17).[44] This compound featured an unusual solvent-dependent behavior of its ^{119}Sn NMR chemical shift: δ = –87 (C_6D_6), –83 (toluene/C_6D_6), –102 (CD_2Cl_2), –140 (THF/C_6D_6), –285 (HMPA/toluene/C_6D_6). This was explained by the increasing electron-donating ability of the solvents to the Sn centers in the order C_6D_6 < toluene < CD_2Cl_2 < THF < HMPA, which progressively shifted the ^{119}Sn NMR resonance to higher field. Similar to the above-mentioned Ge_2N_2 biradicaloid **24**, the four-membered ring of **26** is planar, the two *trans*-silyl substituents are nearly in the same plane, and the two Cl atoms are positioned perpendicular to this Sn_2N_2 plane (Figure 16). The central Sn–Sn separation of 3.398 Å is well outside the range of covalent interaction, which indicates the absence of transannular 2,4-bonding. Such pyramidalization and tricoordination of both Sn atoms implies that each Sn atom represents a radical center, therefore simple electron counting provides the overall value of six electrons for the Sn_2N_2 ring: each N atom contributes two electrons (lone pair) to the ring and each Sn atom one (odd) electron. Thus, the most appropriate bonding description of **26** is a six-π-electron-four-center system. The biradicaloid **26** is diamagnetic, being EPR-silent both in the solid state and in solution, which is typical for singlet biradicaloids. Indeed, the theoretical calculations have demonstrated that the singlet state of **26** is more stable than its triplet state with a singlet–triplet energy separation [Δ(S–T)] of 13.6 kcal/mol. This is in agreement with the recent calculations on 2,4-diphosphacyclobutane-1,3-diyl, which revealed that the σ-donating substituents at the phosphorus atoms increase the Δ(S–T) value in favor of the singlet ground state.[46] As one can see, the structural and bonding peculiarities of both 1,3-diaza-2,4-digermacyclobutane-1,3-diyl **24** and 1,3-diaza-2,4-distannacyclobutane-1,3-diyl **26** are very similar to each other, and both of them can be reliably included in the new class of singlet biradicaloids of heavier group 14 elements.

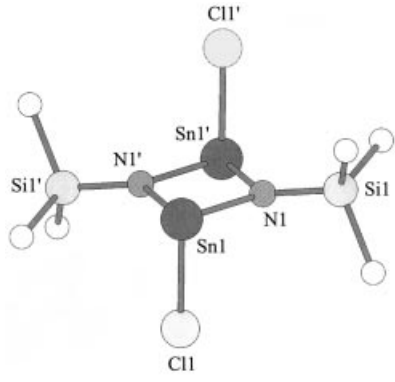

Figure 16. Crystal structure of 1,3-diaza-2,4-distannacyclobutane-2,4-diyl **26**.

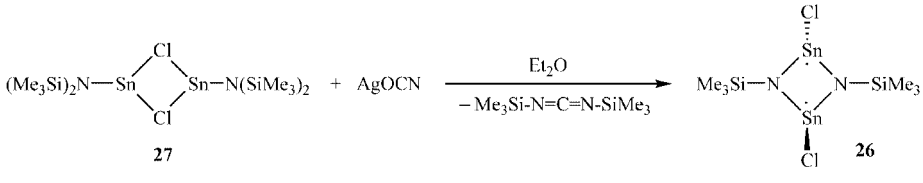
5. Summary and Outlook

The evolution of our knowledge of free radicals centered on group 14 elements heavier than carbon is rather spectacular: those molecules which were originally treated several decades ago as very short-lived elusive transient species



Scheme 17. Synthesis of 1,3-diaza-2,4-distannacyclobutane-2,4-diyl **26**.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

only, were later stabilized as "persistent" radicals with a *relatively* long lifetime, and were finally synthesized as absolutely stable crystalline individual compounds, whose identity was unambiguously verified by X-ray structural determination. The latest developments in the field of stable free radicals of heavier group 14 elements enable the relatively easy synthesis, isolation, and investigation of compounds of this type in the preparative (sometimes in the order of grams) scale. The most prominent achievements in this area, offering deep insight into the electronic and crystal structure of the stable radical species (primarily by means of X-ray crystallography and EPR spectroscopy accompanied by theoretical calculations), should stimulate further interest in this field of organometallic chemistry. Despite the evident and important progress that has been made in this area in just the past few years, there are still many "white spots" to be uncovered on the spacious "map" of free radical chemistry. This concerns, first of all, the synthetic availability of the stable radicals of heavier group 14 elements: these compounds are still not widespread in organometallic chemistry. More general and sophisticated synthetic methods for the preparation of stable Si-, Ge-, Sn-, and Pb-centered radicals are definitely required; for the Pb radicals such experimental procedures should be discovered for the first time, since no stable examples of such compounds have been reported to date. Another great challenge is the synthesis of the charged radical compounds: cationic and anionic. Both stable cation radicals and anion radicals of low-coordinated species, such as heavy carbene analogues or heavy alkene analogues, are among the research goals of primary importance. Deeper and more fundamental theoretical elucidation of the structural peculiarities, bonding nature, multiplicity, and hybridization of free radical species of group 14 elements, both already synthesized and theoretically predicted, is certainly necessary to verify and clarify the recent experimental findings. In the very young and promising field of stable biradicals of group 14 elements (or their combinations with group 13 or 15 elements), new synthetic breakthroughs are also expected in the near future, which could even be extended to the chemistry of stable polyradicals. As one of the most logical and very important developments in the field, the possible applications of stable radicals and polyradicals in the design of new advanced materials with a variety of prospective (for example, magnetic) properties can also be anticipated as an impressive example of the real interplay between fundamental and applied organometallic chemistry.

Acknowledgments

We wish to thank all our coworkers, whose names are listed in the references, for their important experimental contribution to this work. We are also grateful for the permanent financial support of the Ministry of Education, Science, and Culture of Japan (Nos. 147078204, 16205008), and COE (Center of Excellence) program funds.

Co^{II} Complexes of Triazine-Based Tridentate Ligands with Positive and Attractive $Co^{II/III}$ Redox Couples

Elaine A. Medlycott,[a] Isabelle Theobald,[a] and Garry S. Hanan*[a]

Keywords: Tridentate N ligands / Cobalt complexes / Electrochemistry / Triazine

Co^{II} complexes based on the triazine ligand 2,4-di(2′-pyridyl)-6-(*p*-R-C_6H_4)-1,3,5-triazine have been synthesized and characterized. Cyclic voltammetry shows that the $Co^{II/III}$ redox couple is more positive than previously described Co complexes of tridentate ligands. The $Co^{II/III}$ redox couple may be varied depending on the nature of the substituent on the phenyl ring of the triazine ligand.

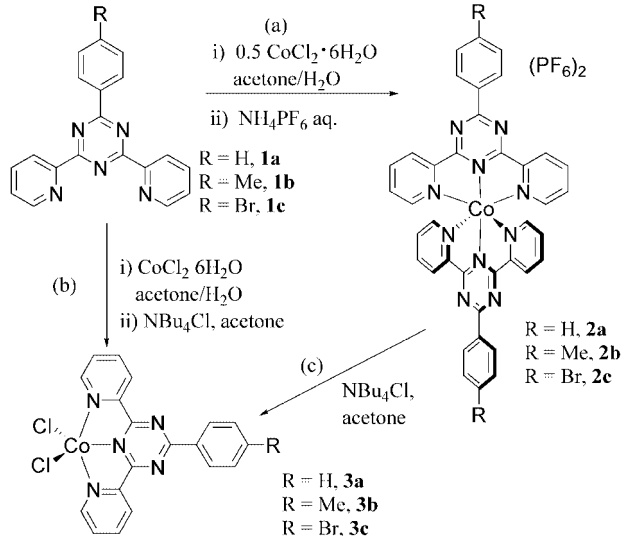
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Dye-sensitized solar cells (DSSCs) have been intensely studied in the last fifteen years since Grätzel published his landmark work.[1,2] In order to advance the field, many groups have focused their efforts on improving the excited-state properties of the polypyridine Ru^{II} complexes that act as the photosensitizers in the Grätzel cell.[3] Much less attention has been paid to the redox mediator, even though it contributes directly to the maximum photocurrent attainable by the DSSC.[2,3] Whereas the classic redox mediator in such systems is the volatile and corrosive I^-/I_3^- couple, its redox potential is fixed and, therefore, cannot be varied to improve the efficiency of the DSSC.[4] Recently, Co^{II} complexes of heterocyclic ligands have been shown to be effective redox mediators in DSSCs, as they are non-corrosive, non-volatile and modifiable.[5–7] Herein we report on a new family of Co^{II} complexes based on tridentate triazine ligands that are easily synthesized and modified. Their considerably more positive $Co^{II/III}$ redox couples than previously reported Co^{II} complexes of polypyridine ligands favors their use in DSSCs.[5,6]

Results and Discussion

The synthesis of triazines ligands **1a**[8] and **1b**[9] has previously been reported. Ligand **1c** was synthesized by the addition of *p*-bromobenzonitrile to a solution of $LiNMe_2$ in anhydrous diethyl ether.[9,10] The amidinate intermediate that forms reacts with two equivalents of 2-cyanopyridine to afford ligand **1c** after loss of dimethylamide. A series of homoleptic Co^{II} complexes of ligands **1a**–**c** were synthesized by allowing the ligands to react with $CoCl_2{\cdot}6H_2O$ followed by precipitation of complexes **2a**–**c** from the reaction mixture by the addition of NH_4PF_6 [see (a) in Scheme 1].[11] Heteroleptic complexes **3a**–**c** may be obtained directly by treating ligands **1a**–**c** with one equivalent of $CoCl_2{\cdot}6H_2O$ in the presence of tetrabutylammonium chloride (Bu_4NCl) [see (b) in Scheme 1] or indirectly when Bu_4NCl is introduced into an acetone solution of complexes **2a**–**c** [see (c) in Scheme 1].[12] It has previously been established that an equilibrium exists between the homo- and heteroleptic state of Co^{II} complexes of 2,4,6-tripyridyl-*s*-triazine in acidic solution.[13] In this case, heteroleptic Co^{II} complexes **3a**–**c** could be obtained by the addition of Bu_4NCl to complexes **2a**–**c**.



Scheme 1. Synthesis of Co^{II} homo- and heteroleptic complexes.

The ^1H NMR chemical shifts of the homoleptic complexes are typical of paramagnetic Co^{II} complexes that are low spin, with chemical shifts ranging over approximately

[a] Département de Chimie, Université de Montréal,

E-mail: garry.hanan@umontreal.ca

110 ppm (Table 1).[14] The signals are broadened considerably, and therefore no coupling constants could be obtained from the spectra. The greatest shifts are observed for the protons *ortho* to the pyridine nitrogen atoms and, therefore, closest to the paramagnetic Co^{II} center. The protons farthest from the paramagnetic center, those on the phenyl ring, have the smallest shift as compared to the free ligands.[9]

Table 1. ^1H NMR chemical shifts of homoleptic complexes **2a**, **2b** and **2c** in CD_3CN.

	δ [ppm]						
	Pyridyl				Phenyl		CH_3
1c	8.99	8.87	8.74	7.60	8.74	7.73	
2a	115.08	80.09	37.54	22.87	13.51	6.17	
2b	113.39	78.56	37.13	21.99	13.27	6.13	5.83
2c	111.88	79.38	36.28	22.96	13.36	6.66	

The X-ray crystal structure of **2c** is shown in Figure 1.[15] The Co^{II} ion is bound by two orthogonal ligands **1c** in a pseudo-octahedral coordination environment as the peripheral pyridines in each ligand pinch in to form N–Co–N angles of 151.79°. The Co–N bond length to the central triazine (1.986 Å) is shorter than the Co–N bond length in homoleptic terpyridine complex (2.022 Å) and the homoleptic triazine complex of 2,4,6-tris(2′-pyridyl)-1,3,5-triazine ligand (2.058 Å).[16,17] The Co–N bond lengths to the peripheral pyridine rings range from 2.134 Å to 2.158 Å, similar to those found in terpyridine complexes of Co^{II}.

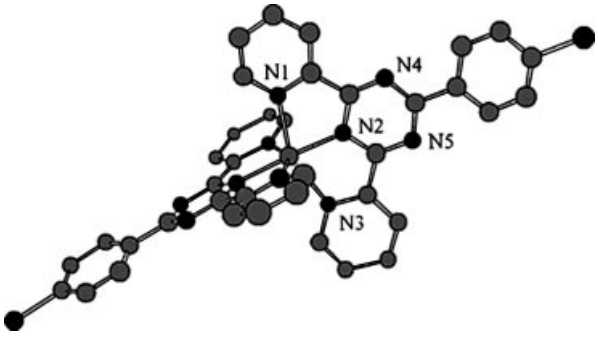

Figure 1. Ball-and-stick representation of the X-ray crystal structure of **2c**. The counteranions and solvent of crystallization have been omitted for clarity.

The phenyl ring is twisted by 13.3° relative to the central triazine ring (Figure 1). This near planar arrangement is due to favorable N-to-CH hydrogen bonding interactions between the N lone pairs and the hydrogen atoms *ortho* to the interannular bond. The slight twist in the interannular bond is a result of edge-to-face packing between the phenyl rings in different molecules of **2c**, which are separated by 3.514 Å (Figure 2). A planar arrangement should easily be adopted in solution which would permit greater electron delocalization between the triazine and the phenyl ring. The two PF_6 counterions are found above and below the planes of the triazine rings and do not interfere with the phenyl packing arrangement, consistent with other extended packing arrangements in the solid state.[18] There is also a short Br1···Br2′ distance of 3.395 Å between adjacent molecules which is indicative of favorable van der Waals interactions which give rise to a linear one-dimensional tape in the solid state (Figure 2).

In the electronic spectra of complexes **2a**–**c**, a very weak metal-centered transition is found at approximately 470 nm (Figure 3). The $\lambda_{max.}$ for these d–d transitions are difficult to identify due to the low energy tail from the ligand-based transitions but the extinction coefficients are in the order of 500 M^{-1} cm^{-1} for all three complexes. For applications in DSSC, a low extinction coefficient is desirable so as to minimise the competition between the redox mediator and sensitiser for absorption in the visible region.[5–7] Intense ligand-based $\pi\rightarrow\pi^*$ transitions are observed in the UV region. Lower energy $\pi\rightarrow\pi^*$ transitions are observed for the Me- and Br-substituted complexes as compared to the complex with R = H. In **2b**, the electron donating methyl groups destabilise the ligand π orbitals to a greater extent than the ligand π^* orbitals. Conversely, in **2c** the ligand π^* orbitals

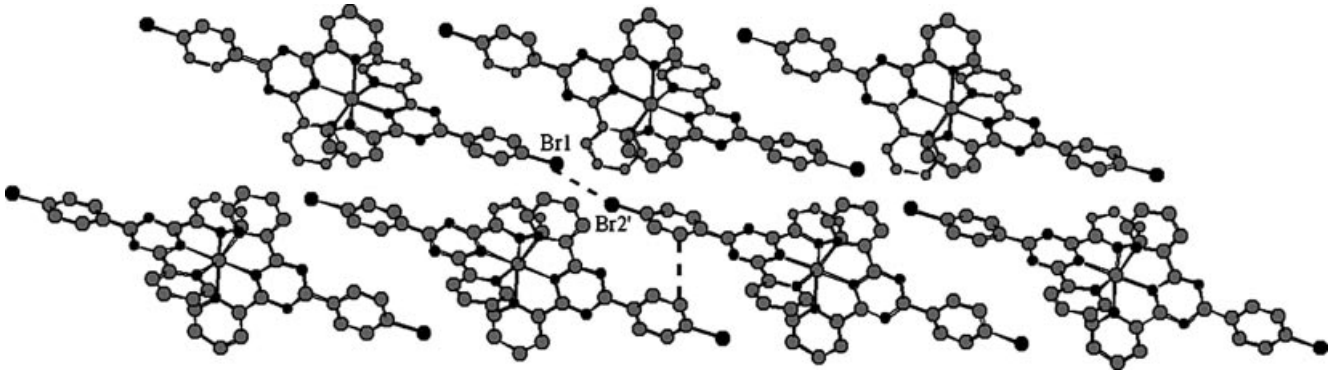

Figure 2. Intermolecular packing forces in the solid-state structure of **2c**. Phenyl-to-phenyl distance = 3.514 Å and the Br1···Br2′ distance = 3.395 Å. The PF_6 counteranions and solvent of crystallization have been removed for clarity.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

are stabilized to a greater extent than ligand π orbitals due to the electron withdrawing nature of the bromine substituent.

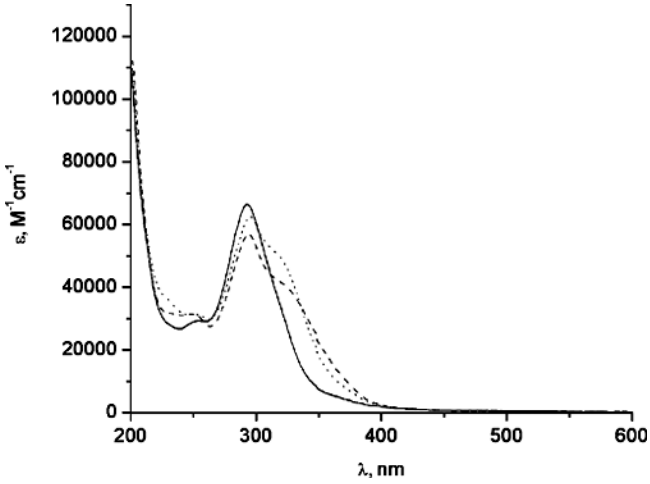

Figure 3. Electronic absorption spectra of complexes **2a** (solid line), **2b** (dashed line) and **2c** (dotted line).

The electrochemical parameters of complexes **2a**, **2b** and **2c** were measured in acetonitrile vs. tetrabutylammonium PF_6 using a Pt electrode and ferrocene as the internal standard. The data (reported vs. SCE) are gathered in Table 2. The $Co^{II/III}$ couples are centered at approximately +0.75 V, which is considerably more positive than previously reported Co^{II} of heterocyclic ligands.[5–7] In each case, oxidative processes are irreversible, which may be a result of limited solubility of the Co^{III} species. It had previously been noted that irreversibility of the $Co^{II/III}$ couple does not necessarily translate into inefficient redox mediators, but sometimes give rise to the most efficient redox mediators.[6] The more positive oxidation potential of **2a**–**c** as compared to terpyridine complexes of Co^{II} is favorable with respect to an increased photocurrent in DSSCs.[7] The $Co^{II/III}$ couple is only slightly affected by substituent on the phenyl ring, with complex **2c** being the most difficult to oxidise as a result of the electron withdrawing Br substituent and **2b** being the easiest as a result of the electron donating Me substituent. The $Co^{II/I}$ couple is also affected by the various substitutents, with **2b** being the hardest to reduce and **2c** the easiest to reduce. The greater variability in the $Co^{II/I}$ reduction potential is a reflection of the increased backbonding of the metal center to the ligand upon reduction. The two remaining reductions are independent triazine-based reductions and follow the electron-withdrawing effect of the substitutents.

Table 2. Electrochemical redox potentials for complexes **2a**–**c** in argon-purged acetonitrile solutions (vs. SCE).

Compound	$E_{1/2}$ (V) [ΔE_p (mV)] $Co^{II/III}$	$Co^{II/I}$	Triazine reductions	
2a	0.76 [irr]	–0.42 [73]	–1.06 [72]	–1.47 [85]
2b	0.74 [irr]	–0.47 [64]	–1.11 [66]	–1.52 [64]
2c	0.77 [irr]	–0.40 [52]	–1.04 [56]	–1.46 [66]

Conclusions

Co^{II} complexes of tridentate triazine-based ligands, either heteroleptic or homoleptic, are readily synthesized and isolated. The electrochemical properties of the homoleptic complexes indicate that the $Co^{II/III}$ redox couples are more positive and more favorable for DSSC than those of Co^{II} terpyridine-based complexes. The $Co^{II/III}$ couple exhibits small shifts in oxidation potential upon modification of the phenyl ring substituents, whereas the $Co^{II/I}$ reduction potential is more readily modified. Further modifications to substitute electron withdrawing and donating groups directly on the triazine ring will be reported in due course.

[10] Synthesis of 2,4-di(2′-pyridyl)-6-(*p*-bromophenyl)-1,3,5-triazine **1c:** *para*-bromobenzonitrile (0.68 g, 3.73 mmol) was added to a stirred mixture of $LiNMe_2$ (0.19 g, 3.73 mmol) in anhydrous diethyl ether. After 30 min, 2-cyanopyridine (0.77 g, 7.46 mmol) was added to the mixture. After an hour the reaction mixture was diluted with H_2O (250 mL) and the precipitate was collected. Recrystallization of the solid from ethanol afforded **1c** (0.90 g, 62%) as a white solid. ^1H NMR ($CDCl_3$): δ = 8.99 (d, J = 4.1 Hz, 2 H), 8.87 (d, J = 7.8 Hz, 2 H), 8.74 (d, J = 8.4 Hz, 2 H), 8.0 (t, J = 7.1 Hz, 2 H), 7.73 (d, J = 8.4 Hz, 2 H), 7.60 (t, 2 H, J = 5.0 Hz) ppm.
[11] General procedure for the synthesis of homoleptic Co^{II} complexes **2a**, **2b**, **2c**: The triazine ligand (0.42 mmol) was stirred in acetone (25 mL) and added to a solution of $CoCl_2 \cdot 6H_2O$ (0.38 mmol, 91 mg). After heating at reflux for 75 min and precipitation in aqueous NH_4PF_6, complexes **2a** (110 mg, 54%), **2b** (127 mg, 61%) and **2c** (103 mg, 43%) were collected.
[12] Synthesis of heteroleptic complexes **3a**, **3b** and **3c** followed the same procedure for complexes **2**. After heating for 75 min the acetone/water mix was removed under reduced pressure and the solution was dissolved in a small amount of acetone and precipitated by the addition of Bu_4NCl. Complexes **3a** (44%), **3b** (33%) and **3c** (23%) were collected. **3a**·$2H_2O$: calcd. C 47.82, H 3.59 N 14.68; found C 47.67, H 3.33, N 14.66. **3b**·H_2O: calcd. C 50.76, H 3.62, N 14.80; found C 51.38, H

Reduction of CCl_4 by Iron Powder in Aqueous Solution

Irena Rusonik,[a] Haim Cohen,[a,b] and Dan Meyerstein*[a,b]

Keywords: Carbon tetrachloride / Reduction / Iron / Mechanism

$^{\cdot}CCl_3$ radicals formed in the first step of the CCl_4 degradation react with iron powder to form an intermediate with an Fe–C σ bond. In the absence of iron powder, $^{\cdot}CCl_3$ radicals formed by γ-irradiation react with 2-propanol in a chain reaction toward dechlorination. When the irradiated solution contains iron powder, the iron scavenges the $^{\cdot}CCl_3$ radicals, thus inhibiting the chain reaction. The minor product of the dechlorination of CCl_4 by iron powder in aqueous solution is CH_4, contrary to the results reported in the literature for the electrochemical reduction of CCl_4 on iron electrodes.

Introduction

The widespread use of chlorinated solvents in commerce has led to considerable groundwater contamination. Halocarbons, including carbon tetrachloride, have a cumulative toxicity and are carcinogenic. Research on the biological degradation of carbon tetrachloride has received much attention.[1,2] Nevertheless, the microbial degradation of CCl_4 can be relatively slow[3] and may be inhibited by the toxicity of CCl_4.

Many recent studies have focused on the abiotic transformation of CCl_4[4,5] and other ground-water pollutants[6,7] by naturally occurring soil minerals such as iron sulfide (FeS). This weak reducing agent reacts slowly with some halo-aliphatic compounds.[8] However, the mechanism of the process has not been elucidated.[8] Consequently, abiotic reductive dechlorination with reduced metals has received increased attention. The use of zero-valent metals has been an active research area[9–11], and most efforts have been concentrated on iron because of the success encountered with iron subsurface permeable walls[12] and the acceptance of zero-valent iron as being safe for the environment. The results indicate that significant CCl_4 reduction occurred at pits rather than on the passive oxide film on the metal.[13] Least-oxidized Fe^0 is the most reactive in CCl_4 degradation.[14]

The combination of ultrasound and Fe^0 has a positive synergistic effect on the dehalogenation of CCl_4. A mechanism involving the formation of $^{\cdot}CCl_3$ radicals was proposed.[15]

The electrochemical reduction of CCl_4 on Fe^0 electrodes was reported to yield CH_4 directly without the formation of $CHCl_3$, CH_2Cl_2, and CH_3Cl as intermediates,[16] though the latter compounds are reduced slower than CCl_4 by the Fe^0 electrode.[9,17–19] Iron is a reasonably strong reducing agent, thus it is not surprising that iron powder can reduce chloro-organic compounds.[20] Therefore it was of interest to investigate the mechanism of the dechlorination reaction of CCl_4 by iron powder, as this method is economically preferable to the electrochemical one.

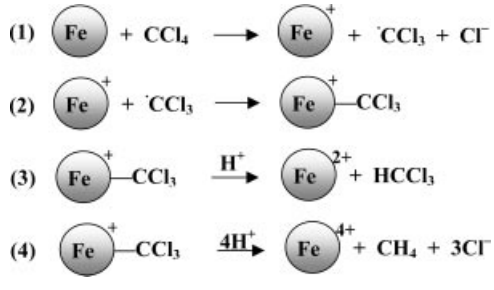
Results and Discussion

The mechanism proposed to explain the latter results, involves the formation of carbenes.[16] However, this mechanism seems to be too complicated, and alternative simpler mechanisms can be proposed. In principle, the following mechanism is proposed (Scheme 1).



Scheme 1. Plausible mechanism of reduction of CCl_4 by iron powder immersed in aqueous solution.

The first reaction in this scheme is identical to that proposed in the literature.[16] However the second one is different; it is proposed that the radical formed in the first reaction, that is, the one near the iron surface, reacts with the resultant $\mathbf{1}^+$ particle to form an intermediate having an Fe–C σ bond, that is, a $–CCl_3$ bound to the iron powder.

1
Fe powder particles

Analogous transients are formed in the fast reaction of Fe^0 powder with CH_3.[21] The intermediate $\mathbf{1^+–CCl_3}$ thus formed might decompose by two alternative mechanisms:
1. Heterolysis of the Fe–C bond, reaction (3), as observed[21] for $\mathbf{1^+–CH_3}$.
2. The iron particle can be considered as a microelectrode that can supply many electrons, which can reduce the $–CCl_3$ substituent directly to form methane, reaction (4).

In order to check the relative contribution of reactions (3) and (4) it was decided to study the reaction of $^{\cdot}CCl_3$ radicals with iron powder and measure the relative yields of $Cl^–$ and CH_4. The radicals were formed by γ-irradiating an aqueous solution containing CCl_4 (0.01 M) and 2-propanol (2.6 M). This solution was placed between the grains of iron powder.

$^{\cdot}CCl_3$ radicals formed in the first step of the CCl_4 degradation might react by two pathways:
1. Initiate a chain reaction by hydrogen abstraction from 2-propanol.[22–24]

$$^{\cdot}CCl_3 + HC(CH_3)_2OH \rightarrow HCCl_3 + {}^{\cdot}C(CH_3)_2OH$$
$$^{\cdot}C(CH_3)_2OH + CCl_4 \rightarrow C(CH_3)_2O + {}^{\cdot}CCl_3 + Cl^– + H_3O^+$$

2. React with the iron powder surface to form $CHCl_3$ or directly CH_4, as proposed in Scheme 1.

Therefore, dehalogenation of CCl_4 was investigated in three different systems (Table 1). Two of them contained iron powder and an aqueous solution containing CCl_4 and 2-propanol. One of these samples was irradiated, and the second served as a thermal blank. The light alkanes formed in the latter samples are due to traces of carbon in the analytical iron.[21] The main idea was to study the reaction of $^{\cdot}CCl_3$ radicals with the iron powder, where, in the nonirradiated system, the source of radicals is the dehalogenation process, and in the irradiated system, $^{\cdot}CCl_3$ radicals are derived from γ-irradiation in addition to the dehalogenation process. The third system contained the aqueous solution of CCl_4 and 2-propanol in the absence of iron powder and was irradiated. The latter blank system contributes to the investigation of the reaction of $^{\cdot}CCl_3$ radicals with 2-propanol in aqueous solution. The results of this blank experiment clearly demonstrate (Table 1) that indeed the chain process occurs, as the yield of $Cl^–$ is $G \sim 50–60$, even though the total primary radical yield is $G(\text{radicals}) \sim 6$.[25] G is defined as the number of molecules of each product per 100 eV of radiation absorbed by the solution. When the same solution is brought in contact with the iron powder, the yield of methane is approximately 1% of the $Cl^–$ yield (Table 1). This result clearly demonstrates that CH_4 is not the major product of the thermal dechlorination reaction and suggests that this process involves reactions (1), (2), and (3) in Scheme 1. This result clearly differs from that reported for the reduction of CCl_4 on Fe^0 electrodes.[16]

When the solution is irradiated in contact with the iron powder, the results (Table 1) point out that the $Cl^–$ yield is considerably smaller than the sum of the two blank experiments. The irradiation of the Fe^0-containing system adds only about 3×10^{-4} M to the $Cl^–$ yield when compared to the

nonirradiated sample, that is, $G(Cl^-)$ under these conditions is $G(Cl^-) = 7.6$. This result clearly demonstrates that the Fe^0 powder scavenges the $\cdot CCl_3$ and partially the $\cdot C(CH_3)_2OH$ radicals, thus inhibiting the chain reaction. Also under these conditions where $G(\cdot CCl_3) \geq 2.5$, as all the e^-_{aq} is expected to react with CCl_4, $G(CH_4) \leq 2\%$ of $G(Cl^-)$. This result clearly proves that reaction (4) in Scheme 1 is at most a side reaction in the process, and that reaction (3) is the major pathway.

The results are pH-independent in the range pH 3–7 (Table 1). Therefore, it was decided to omit the phosphate buffer from the solution. This action slightly increased the radiolytic yield of Cl^-. This result suggests that one of the reactions,

$\cdot C(CH_3)_2OH + H_2PO_4^- \rightarrow (CH_3)_2CHOH + HPO_4^{\cdot -}$

$\cdot CCl_3 + H_2PO_4^- \rightarrow HCCl_3 + HPO_4^{\cdot -}$

probably the latter, shortens the chain reaction. The effect of phosphate on the reduction of CCl_4 by Fe^0 is probably due to the precipitation of $Fe_3(PO_4)_2$ or $Fe(PO_4)$ on the surface of the iron particles, which decreases their activity.[21]

Finally it is suggested that, in the electrochemical reduction of CCl_4[16] on Fe^0, the potential of the cathode was negative enough to reduce the $-CCl_3$ groups bound to the surface by reaction (4). The redox potential of the iron particle is smaller; therefore $CHCl_3$ is obtained as the main product of the reduction of CCl_4 by the iron powder. This conclusion is highly complementary to the early studies of the reductive dehalogenation of CCl_4 by elementary iron.[9]

Experimental Section

The metal powder used in this study was Fe^0 powder Merck 99%, ≤10 μm. The solution was deaerated by bubbling He through it for 15 min by the syringe technique. The solution (2.5 mL) was then added over 2 min to a glass bulb (15 mL) sealed with a rubber septum and containing the Fe^0 powder (10 g), which was previously activated by H_2SO_4 (0.1 M), and then washed with water (7–8×8 mL). The bulb was also deaerated with He prior to the injection of the solution. Some of the samples were irradiated for 2 h in a ^{60}Co γ source with a dose rate of 3.3 Gy/min, within a 3-h reaction time span. After 3 h of reaction, the gas phase above the metal was analyzed with an HP 5890 GC fitted with an FID detector [Porapak QS GC column, 10 ft, 1/8 in; He (30 mL/min), T = 70 °C]. Concentrations of chloride ions were analyzed by a colorimetric method.[26]

Acknowledgments

This study was supported in part by a grant from the Budgeting and Planning Committee of The Council of Higher Education and the Israel Atomic Energy Commission. D. M. wishes to express his thanks to Mrs. Irene Evens for her ongoing interest and support.

Tapes of Cyclic Water Tetramers in the Double-Helical Complex $[Cd_2(bpa)_2Cl_4]\cdot 6H_2O$

Bao-Hui Ye,*[a] Ai-Ping Sun,[a] Tong-Fei Wu,[a] Yan-Qin Weng,[a] and Xiao-Ming Chen*[a]

Keywords: Cadmium / Helical structures / N ligands / Water

The new complex $[Cd_2(bpa)_2Cl_4]\cdot 6H_2O$ [bpa = *N*,*N*′-bis(picolinamide)azine] has been synthesized in which each bpa ligand is twisted into a spiral-like conformation and the two Cd^{II} ions are ligated by two bpa ligands to form a double-stranded binuclear helicate. Unprecedented water chains featuring cyclic water tetramers composed of three independent water molecules are trapped by $[Cd_2(bpa)_2Cl_4]$ double helicates by hydrogen bonds. The binuclear chiral helicates are interlinked into homochiral layers by hydrogen bonds with the water tapes. The layers are alternately stacked in a heterochiral fashion to yield the final racemic structure. The complex shows an endotherm at 65.7 °C in the DSC due to loss of water molecules, giving an enthalpy value of 47 kJ mol^{-1} per water molecule.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Considerable attention has been paid in the past decades to theoretical and experimental studies of small water clusters.[1,2] These studies facilitate an understanding of the structures and functions of liquid water and ice.[3] Among the water clusters, the cyclic $(H_2O)_4$ is very interesting as it is a simple two-structure model for liquid water.[4] Moreover, water chains are of great interest since many fundamental biological processes[5] and material properties[6] appear to depend on the unique properties of water chains. Structural studies have shown that water chains exist in gramicidin A membrane channels,[7] bacteriorhodopsin,[8] and α-amylase[9] for rapid transport of protons and act as "proton wires". The observation of water chains in porous materials[10] and organic hosts[11] exhibiting supramolecular interactions has significantly advanced the understanding of the structures and functions of water chains in biological systems. Furthermore, the homochiral units could assemble into higher dimensionalities and yield a conglomerate with coordination bonds[12] and/or hydrogen bonds.[13] Herein, we report the crystal structure of the double-helical complex $[Cd_2(bpa)_2Cl_4]\cdot 6H_2O$ (**1**) [bpa = *N*,*N*′-bis(picolinamide)azine], in which the lattice water molecules form an unprecedented water tape involving cyclic $(H_2O)_4$ units. Such a tape is relatively rare[14] and is further stabilized by hydrogen bonds to the host molecules. The chiral binuclear helicates are assembled into homochiral layers by the water tapes.

Results and Discussion

Complex **1** was obtained by the reaction of $CdCl_2$ and bpa in the molar ratio of 1:1 in a methanol/water solution. The crystal structure reveals that complex **1** consists of a neutral $[Cd_2(bpa)_2Cl_4]$ molecule and six lattice water molecules. As shown in Figure 1, each bpa ligand is twisted into a spiral-like conformation and the two Cd^{II} ions are ligated by two bpa ligands to form a double-stranded binuclear helicate. Two chloride anions complete a distorted octahedral coordination in a *cis* arrangement for each Cd^{II}, featuring potential chirality.

The two octahedra are bridged by two N–N single bonds in a twisted arrangement (Cd–N–N–Cd = 86.0° and Cd···Cd = 4.817 Å) with the diazine nitrogen atoms [Cd(1)–N(3) = 2.409(1) Å] in the metal equatorial plane and the pyridine nitrogen atoms [Cd(1)–N(1) = 2.421(1) Å] in the axial positions, resulting in a double helicate with each metal coordination environment having the same helicity (delta-delta or lambda-lambda), although both optical isomers coexist in the lattice. Notably, these binuclear chiral units are interlinked into homochiral units through hydrogen bonds [Cl···O(3w) = 3.23 Å] between the water chains, as shown in Figure 2.

The layers are alternately stacked in a heterochiral fashion to yield the final racemic structure. Although the bpa ligand bearing two bidentate sites have been used to construct binuclear triple helicates,[15] only three examples of double helicates have been prepared with competing counteranions and/or solvent molecules such as NO_3^-, N_3^- and H_2O.[16] The chloride ions arranged in the *cis* fashion in **1** not only serve as ligands, but also form hydrogen bonds with the water tapes. The homochiral helicates are interlinked into homochiral layers through the water tapes. This

is markedly different from the related complex $[Cd_2(bpa)_2(NO_3)_2(H_2O)_2](NO_3)_2{\cdot}4H_2O$, in which no water chain was found due to the involvement of the NO_3^- anion in hydrogen bonds with water molecules.[16b]

Interestingly, infinite water tapes involving cyclic $(H_2O)_4$ units consisting of three types of water molecules extended along the *a* axis (Table 1, Figure 3) are observed in the solid state.

To the best of our knowledge, such an arrangementhas not been experimentally observed so far, althoughcyclic $(H_2O)_4$ units consisting of two[4c,4e,4g–4i,14] andfour[4a,4b,4d,4f] independent water molecules have been reported. However, cyclic water pentamers and hexamers containing three independent water molecules have been observed.[17,18] Both the O(1w) and O(2w) atoms are located on the axis of the water chain and are hydrogen bonded to four neighboring O(3w) water molecules [O(1w)···O(3w) = 2.969 or 2.919 Å, and O(2w)···O(3w) = 2.854 or 2.829 Å at 293 or 173 K] in a tetrahedral arrangement [∠O(3w)–O(1w)–O(3wc) = 91.3° and ∠O(3w)–O(2w)–O(3wc) = 96.1°, symmetry code c: *x*, 3/2 – *y*, 1/2 + *z*] to form a cyclic water tetramer. In contrast, the O(3w) molecule is trigonally distorted, in which hydrogen atom H(1wa) has a full occupancy and is hydrogen bonded to Cl(1d) [Cl(1d)···O(3w) = 3.23 Å, symmetry code d: –*x*, 1 – *y*, 1 – *z*]. The other hydrogen atoms H(1wb) and H(1wc) are positionally disordered and were treated as half occupancy atoms during the refinement. The average hydrogen bond length [2.912 (293 K) or 2.874 (173 K) Å] within the water tetramer in **1** is shorter than that (2.950 Å) observed in tac·3H$_2$O (tac = 1,4,7,10-tetraazacyclododecane),[14] but significantly longer than those in other known cases (2.768–2.834 Å).[4f,4g,4i,4j] The four oxygen atoms in the tetramer are coplanar, with nonbonding dis-

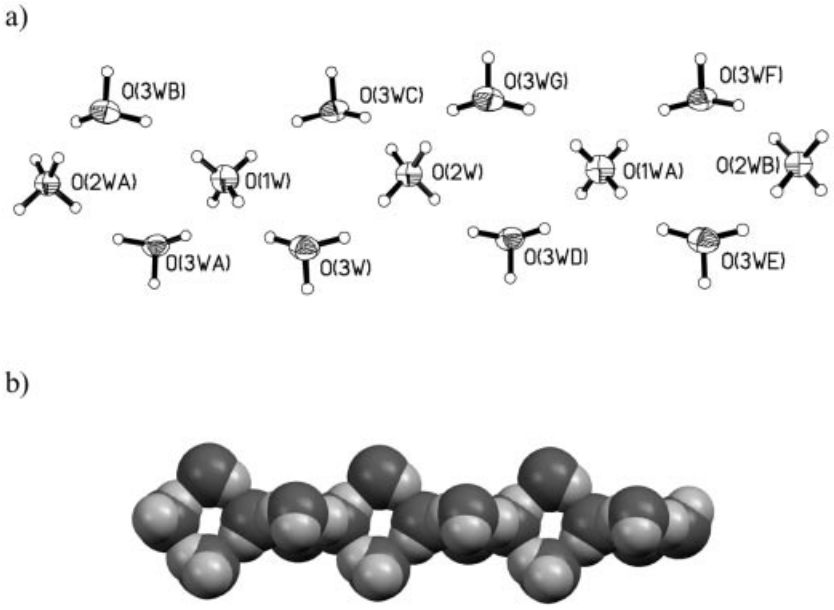

Figure 3. ORTEP (top) and CKP (bottom) plots showing a water chain involving the cyclic water tetramers running along the *a* axis. Symmetry codes: A: 1/2 – *x*, 3/2 – *y*, *z*; B: 1/2 – *x*, *y*, 3/2 – *z*; C: *x*, 3/2 – *y*, 1/2 – *z*; D: –1/2 – *x*, *y*, 3/2 – *z*; E: –1 + *x*, *y*, *z*; F: –1 + *x*, 3/2 – *y*, 3/2 – *z*; G: –1/2 – *x*, 3/2 – *y*, *z*.

tances O(1w)···O(2w) = 3.984 (293 K) or 3.947 (173 K) and O(3w)···O(3wc) = 4.254 (293 K) or 4.177 (173 K) Å, and an O(1w)–O(3w)–O(2w) angle of 92.3° (293 K) or 86.7° (173 K). Adjacent tetramers lie in a perpendicular fashion and are further assembled into a water tape by sharing corners. In fact, the water tape in **1** is very different from the only other example of a water tape involving cyclic water tetramers, which consists of two independent water molecules (O···O = 2.896 Å) that are further bridged by the third type of water molecule by hydrogen bonds (O···O = 3.004 Å) into a water chain with each water molecule tetracoordinate.[14] The nonbonding distances in the cyclic tetramer (O···O = 3.968 Å) and the successive tetramer (O···O = 4.923 Å) are markedly longer than those observed here. These differences may arise from the different hosts and the organization of the water molecules. This observation can help us understand the structure and formation of water clusters and tapes. Another significant phenomenon in **1** is that the water chains arranged in this unique fashion link the homochiral helicates into homochiral layers.

Thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC) (Figure 4) were also performed to observe the thermal stability of the water chain in **1**.

The TGA curve shows a weight loss of 11.0% in the temperature range 25–130 °C, which is consistent with the theoretical value of 11.3% for the loss of six water molecules. The DSC measurement done at 0–150 °C heating at a rate of 5 °C min^{-1} shows a single, sharp endotherm centered at 65.5 °C. The enthalpy is 47 kJ per water molecule, which is larger than that observed in infinite water chains (16 and 36 kJ mol^{-1}),[11e,11g] but similar to those in 4,4′-methylenebis(2,5-dimethylimidazole) dihydrate (44 kJ),[11e] tripeptides hydrates (53 kJ),[19] and theophylline monohydrate (47.3 kJ).[20] Obviously, these data can be correlated to the

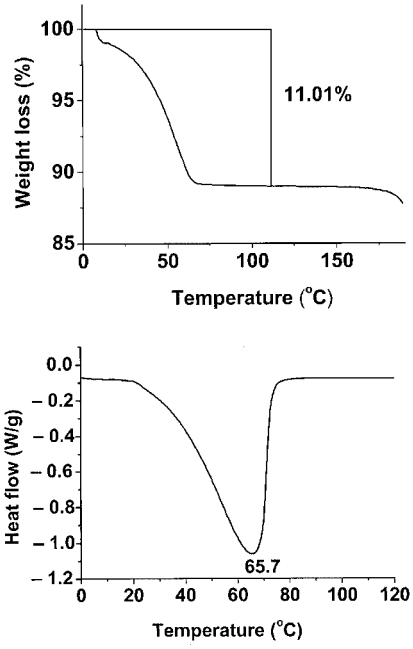

Figure 4. TG plot showing the weight loss of the sample on increasing the temperature (top) and a DSC plot displaying an endotherm for the loss of water molecules (bottom).

number and strength of hydrogen bonds per water molecule. In comparison with the IR spectrum of the free ligand (around 3464 and 3275 cm^{-1}), the peaks at 3234 and 3182 cm^{-1} of the complex can be assigned to the O–H stretching vibration of the water molecules of the tapes. These bands are close to the value reported for ice (3220 cm^{-1}),[21] but lower than those observed for the helical water chain in [Ni(Hsglu)$(H_2O)_2$]·3 H_2O [3368 and 3429 cm^{-1}, H_2sglu = *N*-(2-hydroxybenzyl)-L-glutamic acid][11h]

and the cyclic tetramer water in $[Fe_3(\mu_3\text{-}O)(\mu_2\text{-}CH_3COO)_6(2\text{-pyridone})_2(H_2O)]ClO_4{\cdot}4H_2O$ (3500 cm^{-1}).[4f]

Conclusions

In conclusion, we have described a new water tape featuring cyclic $(H_2O)_4$ units consisting of three independent water molecules, which is trapped by double-helical hosts through hydrogen bonds that link homochiral helicates into homochiral layers. This observation may provide an insight into the formation of water clusters and chains in nature and biological systems, and help our understanding of the mechanism of proton transport in living systems.

Experimental Section

General Remarks: The reagents and solvents employed were commercially available and used as received without further purification. The C, H and N microanalyses were carried out with a Vario EL elemental analyzer. The FT-IR spectra were recorded from KBr pellets in the range 4000–400 cm^{-1} on a Bruker Equinox 55 FT-IR spectrometer. ^1H NMR spectra were recorded on a Varian 300 MHz spectrometer at 25 °C. ESI-MS was carried out with a LCQ DECA XP. TGA analysis was performed on a NETZSCH TG 209 thermal analyzer under nitrogen atmosphere at a scan rate of 10 °C min^{-1}. The DSC curve was obtained with a NETZSCH DSC 204 Differential Scanning Calorimeter at a scan rate of 5 °C min^{-1}.

Synthesis of bpa: The bpa ligand was synthesized in accordance with a published procedure.[22] $C_{12}H_{12}N_6$ (240.11): calcd. C 59.99, H 5.03, N 34.98; found C 59.94, H 5.14, N 34.94. FT-IR (KBr): $\tilde{\nu}$ = 3464 cm^{-1} (vs), 1610 (vs), 1559 (vs), 1465 (s), 376 (s), 799 (s), 746 (vs), 672 (s). ^1H NMR (300 MHz, CD_3OD): δ = 8.58 (d, J = 3.0 Hz, 2 H), 8.34 (d, J = 5.1 Hz, 2 H), 7.84 (t, 2 H), 7.41 (t, 2 H) ppm. ^{13}C NMR (300 MHz, CD_3OD): δ = 1532, 150.8, 148.2, 136.0, 124.3, 120.7 ppm.

Synthesis of 1: $CdCl_2{\cdot}2.5H_2O$ (0.3 mmol) and bpa were added in a 1:1 molar ration to a methanol/water solution (8:2 v/v) and the solution was stirred for 30 min. Crystals of **1** were obtained after one week (48% yield). $C_{24}H_{36}Cl_4Cd_2N_{12}O_6$ (955.27): calcd. C 30.18, H 3.80, N 17.60; found C 29.79, H 3.59, N 17.21. FT-IR (KBr): $\tilde{\nu}$ = 3396 cm^{-1} (m), 3303 (m), 3224 (m), 3182 (m), 1625 (vs), 1604 (s), 1582 (s), 1563 (s), 1483 (m), 1412 (vs), 1301 (m), 1011 (m), 796 (m),749 (m), 678 (m). ESI-MS: m/z = 810.67 $[Cd_2(bpa)_2Cl_3]^+$.

X-ray Crystallographic Study: Diffraction intensities of **1** were collected on a Bruker Smart Apex CCD diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) at 293 and 173 K. Absorption corrections were applied using SADABS.[23] The structures were solved by direct methods and refined with a full-matrix least-squares technique based on F^2 using the SHELXTL program package.[24] Crystal data at 293 K: orthorhombic, space group *Pnnn*, a = 7.9680(4), b = 13.4830(7), c = 16.9690(8) Å, V = 1823.02(16) Å^3, Z = 2, D_c = 1.740 g cm^{-3}, F_{000} = 952, μ(Mo-K_α) = 1.514 mm^{-1}. Of the 2188 independent reflections ($1.9° \le \theta \le 28.3°$), 2022 reflections were observed [$I \ge 2\sigma(I)$]. On the basis of all reflections and 111 refined parameters, $R1$ = 0.0207, $wR2$ = 0.0521, and GOOF on F^2 of 1.06 were obtained. At 173 K: orthorhombic, space group *Pnnn*, a = 7.8940(12), b = 13.418(2), c = 16.911(3) Å, V = 1791.2(5) Å^3, Z = 2, D_c = 1.771 g cm^{-3}, F_{000} = 952, μ(Mo-K_α) = 1.541 mm^{-1}. Of the 2097 independent reflections ($1.9° \le \theta \le 28.3°$), 1815 reflections were observed [$I \ge 2\sigma(I)$]. On the basis of all reflections and 140 refined parameters, $R1$ = 0.0309, $wR2$ = 0.0761, and GOOF on F^2 of 1.04 were obtained. Anisotropic thermal parameters were applied to all non-hydrogen atoms. The organic hydrogen atoms were generated geometrically (C–H = 0.96 Å) and refined with isotropic temperature factors. The hydrogen atoms of the water molecule are disordered. One full-occupancy hydrogen atom H(3wa) and two half-occupancy hydrogen atoms H(3wb) and H(3wc) were located by difference maps and refined isotropically in a trigonal arrangement about O(3w). Water molecules O(1w) (1/4, 3/4, 3/4) and O(2w) (–1/4, 3/4, 3/4) are located on special positions with 0.25 occupancy; only two hydrogens [H(1w) and H(2w)] were located by difference map and refined isotropically as half-occupancy atoms and restrained using the DFIX command.

CCDC-253594 (at 293 K) and -253595 (at 173 K) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Relationship between the Molecular Structure and the π–π* Transition Energy of a Lattice-Framework Disilene: A DFT Study

Hiromasa Tanaka,*[a] Eunsang Kwon,[a] Shinobu Tsutsui,[a] Shigeki Matsumoto,[a] and Kenkichi Sakamoto*[a,b]

Keywords: Density functional calculations / Disilenes / UV/Vis spectroscopy / Electronic structure / Electron transition

The origin of a significantly red-shifted π–π* transition observed in a unique lattice-framework disilene, 2,3,4,6,7,8,2′,3′,4′,6′,7′,8′-dodeca-*tert*-butyl[5,5′]bi{1,5-disilatricyclo[4.2.0.0^{1,4}]octylidene}-2,7,2′,7′-tetraene, has been elucidated by time-dependent density functional calculations and MO energy calculations. An intramolecular through-space interaction between the $\pi^*_{Si=Si}$ orbital and the $\pi^*_{C=C}$ orbitals in the lattice framework strongly stabilizes the LUMO, resulting in a small HOMO–LUMO energy gap.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Silicon–silicon doubly-bonded species (disilenes)[1–4] are pale yellow to red-orange, while carbon–carbon doubly bonded species, such as ethylene, are colorless. The longest wavelength absorptions of disilenes, which correspond to the HOMO–LUMO transition, are generally assigned to the $\pi_{Si=Si}$–$\pi^*_{Si=Si}$ transition and are responsible for the color of the disilenes. It has been postulated that the π–π* transition energy of disilenes is governed by both geometric and electronic effects. For example, steric repulsion caused by the bulkiness of the substituents and electron delocalization between the Si=Si bond and substituents result in a shift of the π–π* absorption wavelength of the disilenes.[4] Substituent effects on the geometry and bond energy of disilenes are of particular interest in theoretical calculations, because of large the differences in the bonding nature between the Si=Si bond and the C=C bond.[5–11] However, to the best of our knowledge, there are few theoretical investigations on the relationship between molecular structures and electron-transition energies of disilenes.[12,13]

Very recently, we reported the synthesis of a novel lattice-framework disilene **1** (Scheme 1).[14] An X-ray crystallographic analysis of **1** reveals that the geometry around the Si=Si bond is almost planar (177.8° for the Si···Si=Si angle) and the Si=Si bond is relatively long (2.262 Å) and slightly twisted (12.1°). Surprisingly, this unique tetraalkyldisilene has the π–π* absorption maximum at 493 nm (2.52 eV) in hexane, which is significantly red-shifted relative to the absorption maximum of tetramethyldisilene (344 nm or 3.60 eV)[15] measured in an argon matrix. The small π–π* transition energy of **1** suggests that the lattice framework surrounding the Si=Si bond should strongly influence the energy levels of the HOMO and LUMO. In this study, to elucidate factors controlling the π–π* transition energy of **1**, we have performed density functional theory (DFT) calculations. The electron transition energies of **1** are evaluated by using a time-dependent DFT (TD-DFT) calculation. The HOMO and LUMO energies of **1** are compared with those of four model disilenes **2**–**5** (Scheme 1).

Results and Discussion

As described in our previous report, **1-opt** reproduces the experimental crystal structure of **1** well.[16] The result of the TD-DFT calculation of **1-opt** is shown in Figure 1, together with the experimental UV/Vis absorption spectrum of **1**. It is noteworthy that the TD-B3LYP calculation of **1-opt** with moderate-size basis sets quantitatively reproduce not only

the positions of the absorption bands but also the relative intensity of the bands.[17] Also, this calculation demonstrates that the longest-wavelength absorption of **1** is assigned to the π–π* transition.

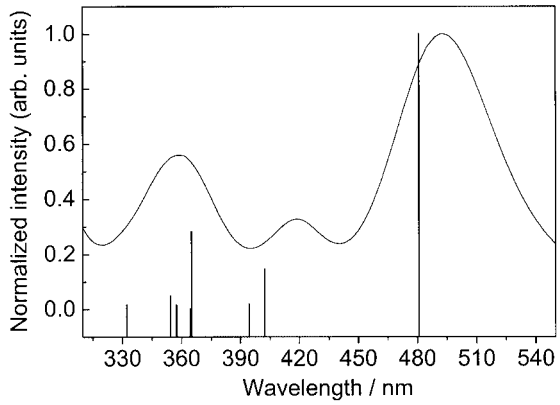

Figure 1. Electron transition energies of **1-opt** calculated by the TD-B3LYP method (vertical line). The UV/Vis spectrum of **1**, in which the intensities are nomalized, is also shown for comparison. Normalized oscillator strengths are used for the calculated intensities.

Although the red-shifted π–π* absorption of **1** was successfully reproduced using the TD-B3LYP method, this calculation does not give information on the factors determining the small π–π* transition energies of **1**. Here we chose four model disilenes **2**–**5** (Scheme 1) and compared the MO energies of the model disilenes with those of **1**. The π–π* transition energies calculated by the TD-B3LYP method are listed in Table 1. The HOMO–LUMO energy gaps (HLGs) as well as the HOMO and LUMO energies are also summarized in Table 1.

Table 1. π–π* transition energies, MO energies, and HOMO–LUMO energy gaps (HLGs) of disilenes **1**–**5** (in eV).

Disilene	π–π* Transition energy[a]	HOMO energy[b]	LUMO energy[b]	HLG
1-fix	2.58[c] (2.52)[d]	–4.18 (0)	–1.24 (0)	2.94
2-fix	2.63	–4.40 (–0.22)	–1.38 (–0.14)	3.03
3-fix	2.56	–4.62 (–0.44)	–1.89 (–0.65)	2.89
4-fix	3.53	–4.77 (–0.59)	–1.15 (+0.09)	3.47
5-fix	4.07	–4.85 (–0.67)	–1.18 (+0.06)	3.67
5-opt	3.45 (3.60)[e]	–4.85 (–0.67)	–1.31 (–0.07)	3.54

[a] Obtained by the TD-B3LYP method. The employed basis sets are described in the text. Experimental values are presented in parentheses. [b] Calculated at the B3LYP/6-311+G(d,p) level. The MO energies relative to **1-fix** are presented in parentheses. [c] Calculated for **1-opt**. [d] Ref.[14] [e] Ref.[15]

Firstly, the result of the DFT calculations for disilenes **1**–**3** are compared in order to evaluate electronic properties depending on the bulkiness of the substituents R (R = *tert*-butyl, CH_3, H). Disilenes **2-fix** and **3-fix** have a structure in which the geometric parameters for the lattice framework are fixed to those of **1-fix**. All the *tert*-butyl groups in **1-fix** are replaced by methyl groups in **2-fix** and by hydrogen atoms in **3-fix**. The π–π* transition energies of **1-fix** (2.58 eV) are almost similar to those of **2-fix** (2.63 eV) and **3-fix** (2.56 eV). The HLGs of these molecules are also very similar to each other, while both the HOMO and LUMO energy levels gradually become lower as the size of the substituents increases in all the molecules. The order of the lowering of the MO energy levels corresponds to the order of the electron-donating ability of the substituents (*tert*-butyl group > methyl group > hydrogen atom). Thus, reducing the size of the substituent R lowers the energy levels of the HOMO and LUMO, whereas it does not change the π–π* transition energy and the HLGs.

Secondly, to discuss how the lattice-framework structure influences the MO energy levels and the π–π* transition energy, the results for **3-fix** are compared with those for **4-fix**, **5-fix** and **5-opt**. Disilene **4-fix** has a lattice-framework structure like **3-fix**, but the C=C bonds are replaced by CH–CH bonds. In **4-fix**, the geometric parameters for doubly bonded silicon atoms and four carbon atoms bound to the silicon atoms are fixed to the parameters of **1-fix** during optimization. Tetramethyldisilene **5-fix** has a structure in which the Si=Si and Si–C bond lengths as well as the C–Si–C bond angle are fixed to those of **1-fix**. The other parameters are optimized in **5-fix**. Tetramethyldisilene **5-opt** has the lowest-energy structure with a trans-bent Si=Si bond.

For a comparison between **3-fix** and **4-fix**, the HLG of **4-fix** (3.47 eV) is significantly larger than that of **3-fix** (2.89 eV), due to the increasing LUMO energy of **4-fix** (+0.71 eV relative to **3-fix**). Thus, the presence of the C=C bonds in the lattice framework is essential for reproducing the small π–π* transition energy observed for **1**. The HOMO and LUMO energies of **4-fix** are calculated to be –4.77 and –1.15 eV, respectively. These values are comparable with the HOMO and LUMO energies of **5-fix** (–4.85 and –1.18 eV, respectively) and **5-opt** (–4.85 and –1.31 eV, respectively). This comparison reveals that geometric changes around the Si=Si bond, such as elongation, flattening, and twisting of the Si=Si bond, play a minor role in changing the HOMO and LUMO energies. Also, replacement of the methyl groups in **5** by the condensed four-membered ring has only a slight influence on the shift in the

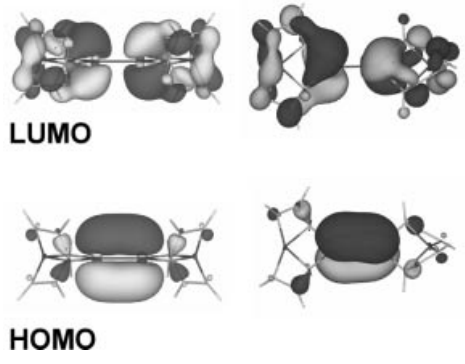

Figure 2. Spatial distribution of the HOMO and LUMO of **3-fix**. Both the side-view (left) and top-view (right; tilted by 60°) images are presented to clarify the interaction between the Si=Si bond and the C=C bonds in the lattice framework.

HOMO and LUMO energies. To explain the large difference in the π–π* transition energy between **3-fix** and **4-fix**, the frontier orbitals of **3-fix** are shown in Figure 2. In the LUMO of **3-fix**, an intramolecular through-space interaction can be found between the Si=Si bond and the four C=C orbitals surrounding the Si=Si bond. The $\pi^*_{C=C}$ orbital overlaps with the $\pi^*_{Si=Si}$ orbitals, as depicted in Figure 3. This π*–π* overlap strongly stabilizes the LUMO of **3-fix**. In the HOMO of **3-fix**, on the other hand, no significant interactions are found between the Si=Si bond and the lattice framework. Because the shape of the frontier orbitals of **1-fix** (or **1-opt**) is almost similar to **3-fix** and the calculated π–π* transition energy of **1-opt** is very close to that of **3-fix**,[18] we can conclude that the stabilization of the LUMO significantly contributes to the small π–π* transition energy of **1**.

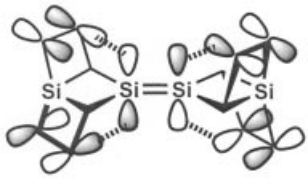

Figure 3. Schematic view of an intramolecular through-space interaction between $\pi^*_{Si=Si}$ and $\pi^*_{C=C}$ orbitals in the LUMO of **1**.

Conclusions

The TD-B3LYP calculation of the lattice-framework disilene **1** combined with moderate-size basis sets quantitatively reproduces the experimental UV/Vis spectrum. The TD-B3LYP calculation would be useful for a full characterization of the electron transitions of "real" disilenes. The red-shifted π–π* absorption maximum observed for **1** can be ascribed to the stabilization of the LUMO. A comparison of the MO energies of **1** and model disilenes **2-5** reveals that an intramolecular through-space interaction between the $\pi^*_{Si=Si}$ and $\pi^*_{C=C}$ orbitals lowers the LUMO energy of **1**. This π*–π* overlap is effectively achieved in **1**, because the four C=C bonds surrounding the Si=Si bond locate nearly perpendicularly to the Si=Si bond. Geometric changes around the Si=Si bond play a minor role in shifting the energy levels of the HOMO and LUMO of **1**.

Computational Methods

All calculations were carried out with the Gaussian98 program.[19] The optimized structure of **1** (**1-opt**) was computed with the B3LYP hybrid functional.[20,21] The 6-31G(d) basis sets were used for the Si and C atoms, except for the atoms consisting of 12 *tert*-butyl groups. For the C and H atoms included in the *tert*-butyl groups, the 3-21G basis sets were employed. The TD-B3LYP calculation[22–25] for **1-opt** was performed at the same level of theory. For model disilenes **2**–**5**, all calculations including the TD calculations were performed at the B3LYP/6-311+G(d,p) level.[25] The MO energies of **1** were also obtained with the B3LYP/6 311+G(d,p) level calculation at the geometry of the experimental crystal structure[14] (represented as **1-fix**). The MO energy calculation of **1** required large basis sets to give converged results, unlike the TD-B3LYP calculation.

$[H_2bpy]_2[\{Cu(btepy)_2\}Mo_5P_2O_{23}]\cdot 4H_2O$: A Three-Dimensional Framework Built from Transition-Metal Coordination Polymer Sheets Pillared by Polyoxomolybdophosphate Clusters

Ying Lu,[a] Yangguang Li,[a,b] Enbo Wang,*[a] Jian Lü,[a] Lin Xu,[a] and Rodolphe Clérac*[b]

Keywords: Coordination polymers / Magnetic properties / Hydrothermal synthesis / Polyoxometallates

$[H_2bpy]_2[\{Cu(bpy)_2\}Mo_5P_2O_{23}]\cdot 4H_2O$ (**1**; bpy = 4,4′-bipyridine) contains the first three-dimensional framework based on two-dimensional transition metal coordination polymer sheets pillared by polyoxomolybdophosphate clusters. It crystallises in the *C*2/*c* monoclinic space group with a = 17.630(4) Å, b = 13.670(3) Å, c = 25.111(5) Å, and β = 106.61(3)°. Thermogravimetric analysis shows that guest molecules (H_2O and free bpy ligands) can be easily removed from **1** by simple heat treatment without losing the three-dimensional framework. Moreover, the paramagnetic properties of the $\{Cu(bpy)_2\}$ arrays, make this material an interesting magnetic solid based on polyoxometallate clusters.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Porous materials have attracted much attention due to their potential applications in gas storage, ion exchange or heterogeneous catalysis.[1] A promising approach toward the synthesis of these porous materials is the design of metal–organic frameworks built from transition metal ions and bridging organic ligands.[2] In this field, the synthesis of robust three-dimensional (3D) frameworks with high porosity and thermal stability has become an important issue.[3] Pillared-layer structures have been proven to be an effective route to design 3D frameworks with large channels. In the known pillared-layer structure, bidentate linear organic ligands such as 4,4′-bipyridine, pyrazine and 1,2-bis(4-pyridyl)ethylene play the role of pillars.[4] An alternative choice of pillars may be the polyoxometallate (POM) clusters. Indeed, the occupation of their surface by oxygen atoms offers the possibility of coordination to other transition metals[5] and hence their use as pillars to link transition metal coordination polymer sheets. In addition, POMs possess interesting properties, for example in catalysis, magnetism and nonlinear optics,[6] and also have a higher thermal stability than organic ligands, which may strengthen the thermal stability of the pillared-layer structures formed. Hence, the combination of POMs and transition metal coordination polymer appears to be an appealing route to design multifunctional porous hybrid materials. Unfortunately, this strategy remains unexplored due to the difficulties in combining appropriate POM clusters and 2D transition metal coordination polymer networks while controlling their interactions to form a three-dimensional architecture.

Among the possible POMs, polyoxomolybdophosphate clusters of general formula, $[H_xMo_5P_2O_{23}]^{(6-x)-}$ (x = 0, 1, 2)[7] have recently proved their ability to form organic–inorganic hybrid materials through their coordination to transition-metal complexes.[5c,8] Although the number of organic–inorganic hybrid materials based on these clusters is limited in the literature, $[H_xMo_5P_2O_{23}]^{(6-x)-}$ clusters can be regarded as valuable building units due to their ability to link transition-metal complexes in diverse coordination modes[5c,8] and their chemical versatility − they can easily be modified at the molecular level by substitution of phosphate groups by organophosphate functions.[9] In our quest for the right polyoxometallate cluster to assemble two dimensional arrays into 3D porous materials, $[H_xMo_5P_2O_{23}]^{(6-x)-}$ clusters appeared to be good candidates. This idea was reinforced by the chemistry of these clusters, which can be easily performed under hydrothermal conditions by mixing Na_2MoO_4 (or MoO_3) and H_3PO_4 in water; they are also stable over a wide pH range (3–6).

We report here the novel compound $[H_2bpy]_2[\{Cu(bpy)_2\}Mo_5P_2O_{23}]\cdot 4H_2O$ (**1**; bpy = 4,4′-bipyridine) which exhibits a 3D framework of 1D channels built from $\{Cu(bpy)_2\}_n^{2n+}$ coordination polymer sheets pillared by $[Mo_5P_2O_{23}]^{6-}$ clusters.

Results and Discussion

Synthesis

The successful isolation of compound **1** depends on the exploitation of hydrothermal techniques. Hydrothermal synthesis has recently been proved to be a particularly useful technique in the preparation of inorganic–organic hybrid materials.[10] In the hydrothermal environment, the reduced viscosity of the solvent results in enhanced rates of solvent extraction of solids and crystal growth from solution. Furthermore, since different solubility problems can be minimised, a variety of organic and inorganic precursors can be introduced. However, hydrothermal synthesis is still a relatively complex process because many factors can influence the outcome of reaction, such as the type of initial reactants, starting concentrations, pH values, reaction time and temperature.[11]

Compound **1** was separated from the hydrothermal reaction of $Na_2MoO_4{\cdot}2H_2O$, H_3PO_4, $Cu(MeCO_2)_2{\cdot}H_2O$, 4,4′-bpy and water in the molar ratio of 4:4:1:1:550 at 160 °C for six days. Parallel experiments showed that the pH value of the reaction system is crucial for the crystallisation of compound **1**: blue crystals of compound **1** could only be obtained in the pH range 4–5. At pH 3–4 no crystalline phase was formed and the products were a mixture of blue and white powders. However, at lower pH (2.5–3) another novel compound reported by our group could be synthesised, which shows a two dimensional structure constructed from interconnecting polyoxomolybdate chains $\{HPCuMo_{11}O_{39}\}_n^{4n-}$ and transition metal coordination polymer chains $\{Cu(bpy)\}_n^{n+}$.[5a] In addition, the nature of the divalent transition metal is crucial for the formation of the pillared-layer structure of compound **1**. We tried to replace $Cu(MeCO_2)_2{\cdot}H_2O$ with $Co(MeCO_2)_2{\cdot}4H_2O$, $Ni(MeCO_2)_2{\cdot}4H_2O$ or $Zn(MeCO_2)_2{\cdot}2H_2O$ in the synthesis of compound **1**, but no isostructural compounds were obtained.

Crystal Structure

A single-crystal X-ray diffraction analysis was performed on **1**; the basic motif of the structure is shown in Figure 1. The $[Mo_5P_2O_{23}]^{6-}$ cluster can be described as a ring of five distorted MoO_6 octahedra with two capped PO_4 tetrahedra on each side. Each phosphate subunit shares three oxo groups with the molybdate ring. One of these oxo-groups (O8) adopts a μ_2-bridging mode, linking Mo1 to P1, and the two others (O2 and O6) adopt a μ_3-bridging mode, linking Mo2, Mo3 (or Mo1) and the P1 site. The fourth oxygen (O3) of the PO_4 is dangling. The Cu1 site adopts a "4+2" axially distorted geometry, characteristic of a d^9 Jahn–Teller distortion.[8b,12] Its equatorial and axial positions are occupied by four nitrogen donors from the four distinct bpy ligands and two oxo groups (O5) from adjacent $[Mo_5P_2O_{23}]^{6-}$ clusters, respectively. The Cu–N and Cu–O bond lengths are 2.062 Å (Cu1–N1), 2.041 Å (Cu1–N2) and 2.423 Å (Cu1–O5).

The three-dimensional structure of **1** is composed of square-grid $\{Cu(bpy)_2\}_n^{2n+}$ layers pillared by $[Mo_5P_2O_{23}]^{6-}$ clusters. The $\{Cu(bpy)_2\}_n^{2n+}$ layers lie parallel to the *ab* plane (Figure 2). Each layer consists of a square lattice of Cu^{II} and bpy located at the corners and the edges, respec-

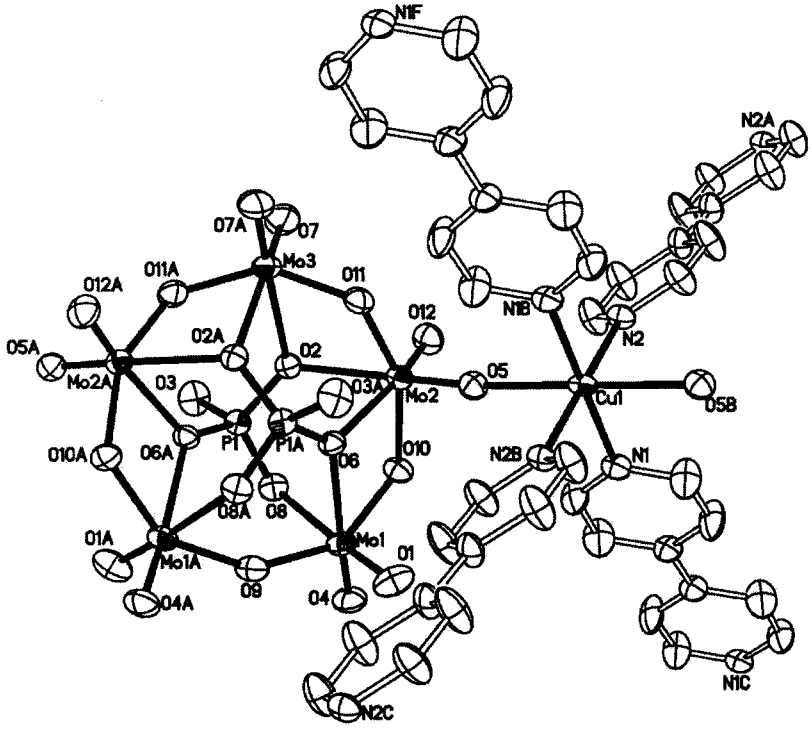

Figure 1. ORTEP drawing of the basic crystallographic unit in **1**. All the hydrogen atoms, H_2bpy^{2+} and H_2O have been omitted for clarity.

tively. As observed in related materials,[13] this type of arrangement leads to a square cavity of about 11.2×11.2 Å^2. Moreover, it is noteworthy that the layers are perfectly planar with the equatorial plane of the Cu coordination sphere. Adjacent square-grid layers are connected by $[Mo_5P_2O_{23}]^{6-}$ clusters through the axial positions of the Cu site to form the 3D open framework (Figure 3). This organisation leads to the formation of channels in two directions: along the *c* axis the channels have an elliptical shape of about 11.2×6.5 Å^2 (Figure 4) and along the *b* axis rectangular channels can be observed with dimensions of about 10.0×3.7 Å^2. Free bipyridine and H_2O molecules are located in these channels. According to the consideration of the charge balance and weak acidic conditions of the synthesis, the free bipyridines are doubly protonated.

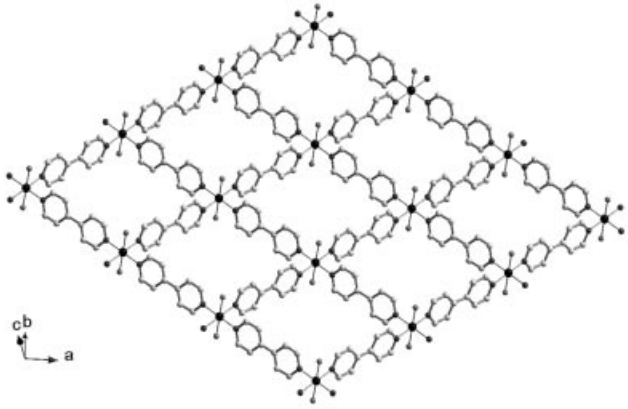

Figure 2. View of the 2D square-grid layer in **1**.

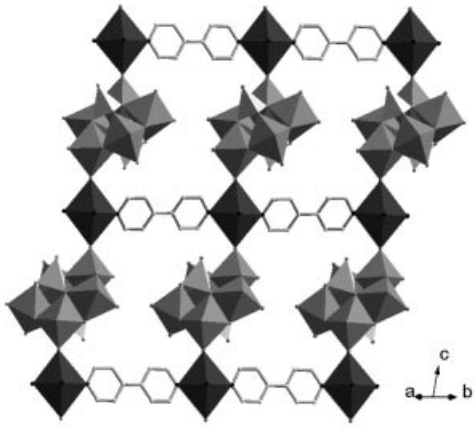

Figure 3. Polyhedral representation of the 3D network in **1**. Guest molecules included in the channels have been omitted for clarity.

Thermogravimetric analysis (TGA) was performed in air at a heating rate of 10 °C min^{-1} on a polycrystalline sample of **1** (Figure 5). A first weight loss of 4.4% occurred between 40 and 150 °C, corresponding to the loss of four water molecules (calcd. 4.3%). In the range 240–340 °C, a second weight loss of 18.6% is observed corresponding to the loss of two free bpy molecules (calcd. 18.8%). Between 390 and 610 °C a weight loss of 19.5% is due to loss of the

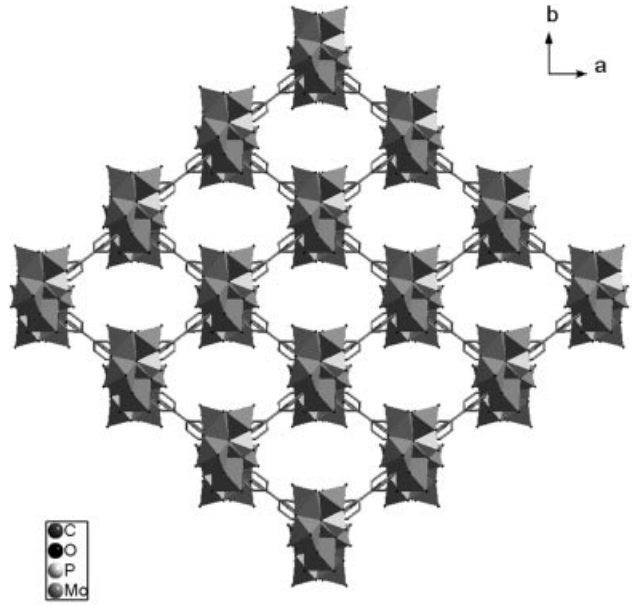

Figure 4. View of the 3D network along the *c* aixs. Guest molecules included in the channels have been omitted for clarity.

coordinated bpy ligands. Above 610 °C and up to 750 °C no further weight loss is observed. Over the whole range of temperature explored, the total weight loss (42.5%) agrees well with the calculated value (41.8%). The final product was found to be amorphous by powder X-ray diffraction.

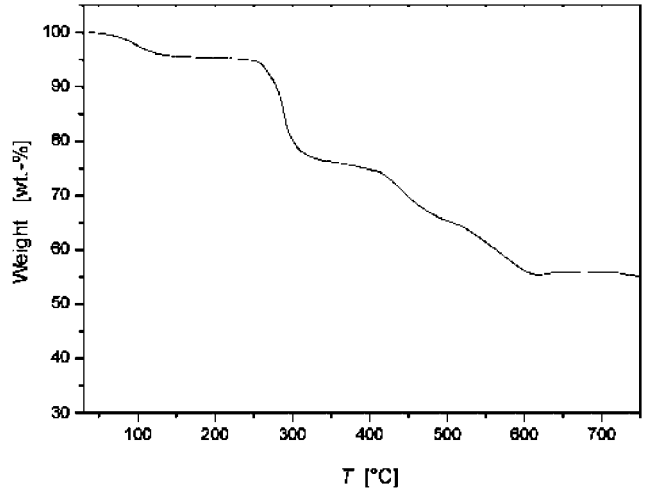

Figure 5. Thermogravimetric analysis curve of **1**.

Based on the TG analysis, **1** was heated in air at 350 °C for six hours to remove the free bpy ligands and water molecules and form **1′**. The elemental analysis of **1′** (C 18.9, H 1.5, N 4.6) agrees well with the expected formula for the opened $[H_4\{Cu(bpy)_2\}Mo_5P_2O_{23}]$ network (calcd. C 18.6, H 1.6, N 4.3). The TG curve of **1′** also confirms that water molecules and free bpy ligands have been removed (Supporting Information, Figure S1). The X-ray powder diffraction spectra of **1** and **1′** (Figure S2) were compared and found to be very similar, thereby confirming that the framework of **1** is retained after the loss of the guest molecules.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

This phenomenon, where a compound retains its framework structure after guest organoamine molecules have been removed, has been reported by several groups.[14]

Magnetic Properties

The magnetic susceptibility of **1** was studied from 300 K to 1.83 K at 1000 Oe on a polycrystalline sample. The χT vs. T plot, shown in Figure 6, decreases continuously from 0.42 $cm^3 K mol^{-1}$ at 300 K to reach 0.24 $cm^3 K mol^{-1}$ at 1.83 K. Based on the structure analysis, the spins are carried by the Cu^{II} centres, which are organized into well-separated, 2D square arrays. Therefore, the magnetic susceptibility was analysed using an $S = 1/2$ Heisenberg 2D square lattice model. A high temperature series-expansion for the susceptibility of this model has been reported by Rushbrooke and Wood.[15a] To fit the experimental data, the compact expression of Lines[15b] was used, with the following spin Hamiltonian:

$$H = -2J \sum_{<i,j>} S_i S_j$$

$$\frac{Ng^2\mu_B^2}{2\chi J} = 3\theta + \sum_{n=1}^{6} \frac{C_n}{\theta^{n-1}}$$

where $\theta = k_B T/|2J|S(S + 1)$, $C_1 = 4$, $C_2 = 2.667$, $C_3 = 1.185$, $C_4 = 0.149$, $C_5 = -0.191$, $C_6 = 0.001$ and N, g, and μ_B have their usual meanings. The best set of parameters are $J/k_B = -0.53(1)$ K and $g = 2.11(1)$. The fitting procedure was performed down to 1.83 K as the validity condition $k_B T \approx 0.9JS(S + 1)$ for this model was not reached.[15b] The J value obtained confirms that the interaction through the bridging bpy is weak, in agreement with the large Cu–Cu distance (ca. 11.2 Å).

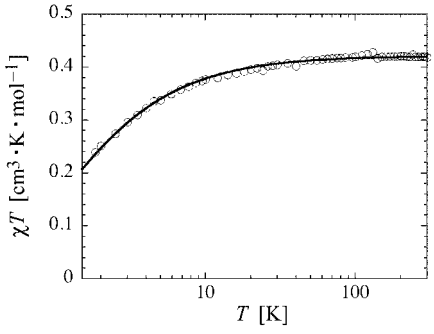

Figure 6. Temperature dependence of the χT product measured at 1000 Oe in the temperature range 1.83–300 K. The solid line is the best fit obtained with the $S = 1/2$ Heisenberg two-dimensional antiferromagnetic square lattice model.[15]

The room-temperature EPR spectrum of **1** (Supporting Information, Figure S3) shows a typical Cu^{2+} signal in an elongated octahedral coordination geometry, as expected from the crystal structure. The eigenvalues of the g tensor can be calculated as $g_{\parallel} = 2.1538(1)$ and $g_{\perp} = 2.0539(1)$; they are in relatively good agreement with the average value ($g = 2.11$) found by susceptibility measurements.

Conclusion

In summary, we have reported here the first 3D structure based on a transition-metal coordination polymer sheet linked by polyoxomolybdophosphate clusters. The successful synthesis of **1** provides an interesting illustration of the use of polyoxometallate clusters to obtain new magnetic materials. Since chemical modifications of the polyoxometallate cluster and the transition-metal coordination polymer sheet may be easily achieved, a complete new family of magnetic solids should be accessible in the near future.

Experimental Section

Materials and General Methods: Reagents were purchased commercially and used without further purification. Elemental analyses (C, H and N) were performed on a Perkin–Elmer 2400 CHN Elemental Analyzer. Mo, Cu and P were determined with a Leeman inductively coupled plasma (ICP) spectrometer. The IR spectrum was obtained on an Alpha Centaurt FT/IR spectrometer with pressed KBr pellet in the 4000–400 cm^{-1} regions. A Perkin–Elmer TGA7 thermogravimetric analyzer was used to obtain TGA curves under N_2 with a temperature increasing rate of 10 °C min^{-1}. X-ray powder diffraction (XRPD) patterns were recorded on a Siemens D5005 diffractometer with Cu-K_α (λ = 1.5418 Å) radiation. The EPR spectrum was recorded on a Bruker ER 200D spectrometer at room temperature. The magnetic susceptibility data were measured with a Quantum Design SQUID magnetometer MPMS-XL.

Synthesis of 1: In a typical synthesis of compound **1**, $Cu(MeCO_2)_2 \cdot H_2O$ (1 mmol) and 4,4′-bpy (1 mmol) were added to a stirred solution of $Na_2MoO_4 \cdot 2H_2O$ (4 mmol) and H_3PO_4 (4 mmol) in water (10 mL). The resultant mixture was sealed in a 23-mL, Teflon-lined autoclave and heated at 160 °C for 6 d. The initial pH value of the reaction solution was ca. 4.6 and the final pH value was ca. 5.5. Blue, block-like crystals of **1** were obtained from the solid product in a yield of 60% (0.65g) with respect to 4,4′-bpy. $C_{40}H_{44}CuMo_5N_8O_{27}P_2$ (1674.0): calcd. C 28.70, H 2.65, Cu 3.80, Mo 28.66, N 6.69, P 3.70; found C 28.58, H 2.59, Cu 3.67, Mo 28.81, N 6.65, P 3.62. IR (KBr pellet): $\tilde{\nu}$ = 3448 (s), 3100 (w), 1607

(m), 1535 (w), 1512 (w), 1488 (w), 1411 (w), 1126 (m), 1066 (w), 1032 (m), 1012 (m), 914 (vs), 884 (s), 827 (w), 803 (w), 700 (vs), 671 (vs), 558 (m) cm^{-1} (see Supporting Information, Figure S4).

X-ray Crystallography: A blue single crystal of **1** was carefully selected under a polarizing microscope and glued to the tip of a thin glass fibre with cyanoacrylate (super glue) adhesive. Single-crystal structure determination by X-ray diffraction was performed on an R-axis RAPID IP diffractometer equipped with a normal focus, 18 kW sealed tube X-ray source (Mo-K_α radiation, λ = 0.71073 Å) operating at 50 kV and 200 mA. Data processing was accomplished with the RAXWISH processing program.[16] An empirical absorption correction was applied. The structure was solved by direct methods and refined by full-matrix least-squares on F^2 using the SHELXL 97 software.[17] All the non-hydrogen atoms were refined anisotropically. The hydrogen atoms were located from difference Fourier maps. Further details of the X-ray structural analysis are given in Table 1. Selected bond lengths and angles are listed in Table 2.

CCDC-239758 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Supporting Information Available (see also footnote on the first page of this article): The TG curve of **1′**, the XRPD patterns for **1** and **1′**, IR and ESR spectra for **1**, space-filling diagram of the three-dimensional framework of **1** and a view of the 3D network of **1** along the *b* axis.

Thermal Properties of $[M_{10}Se_4(SePh)_{12}(PR_3)_4]$ (M = Zn, Cd, Hg) Cluster Molecules – Synthesis and Structure of $[Cd_{32}Se_{14}(SePh)_{36}(L)_4]$; L = $OPPh_3$, OC_4H_8

Andreas Eichhöfer*[a]

Keywords: Cluster compounds / Cadmium / Selenium / X-ray structure analysis / Thermogravimetric analysis

A series of four different M_{10} selenide cluster molecules of the general formula $[M_{10}Se_4(SePh)_{12}(PR_3)_4]$ (M = Zn, Cd, Hg; R = organic group) have been synthesized by the reaction of metal chlorides MCl_2 (M = Zn, Cd, Hg) with phosphanes PR_3, $Se(SiMe_3)_2$ and $PhSeSiMe_3$ in organic solvents. The investigations of the thermal properties by thermogravimetric analysis (TGA) reveal that $[Zn_{10}Se_4(SePh)_{12}(PnPr_2Ph)_4]$, $[Cd_{10}Se_4(SePh)_{12}(PEt_3)_4]$, $[Cd_{10}Se_4(SePh)_{12}(PnPr_3)_4]$ and $[Hg_{10}Se_4(SePh)_{12}(PnPrPh_2)_4]$ form the corresponding bulk chalcogenides in mainly two- or three-step processes. From the intermediate product of the first step of the vacuum thermolysis of $[Cd_{10}Se_4(SePh)_{12}(PnPr_3)_4]$ we were able to obtain in solution the larger cluster molecule $[Cd_{32}Se_{14}(SePh)_{36}(OC_4H_8)_4]$ and upon addition of $OPPh_3$ its homologue $[Cd_{32}Se_{14}(SePh)_{36}(OPPh_3)_4]$. The structures of both molecules have been determined by single-crystal XRD. Obviously, the smaller Cd_{10} cluster grows upon thermal treatment in the solid state to form larger cluster cores. However, optical spectra and dynamic light scattering of the dissolved residues reveal that this growth is not totally specific.

Introduction

Semiconductor cluster molecules that are composed of a defined number of atoms are of particular interest for investigations concerning the variation of properties related to a change in size. For example, recent optical studies have shown that CdSe cluster molecules can be seen, not only with respect to their structure but also to their electronic properties, as molecular models for the bulk semiconductor.[1–4] But although a few well-defined molecular clusters formed by group 12 and 16 elements do exist, these tend to be on the smaller end of the size spectrum. Up to now the largest CdSe cluster compound that has been synthesized and characterized by single-crystal X-ray analysis contains thirty two cadmium atoms with the common formula $[Cd_{32}E_{14}(E'R)_{36}(L)_4]$ (E = Se, S; E′ = Se, S; L = neutral ligand).[5–7] Weller and coworkers found evidence from extended X-ray absorption fine structure (EXAFS) and UV/Vis[8] that the next stable cluster molecule in size is $[Cd_{54}Se_{32}(SeR)_{52}]^{8-}$, but no crystal structure from single-crystal XRD has been reported to date. It is therefore, a major goal to find new synthetic routes to enlarge the number of species in this class of materials. Most of the cluster syntheses are done in solution, but especially for one of the largest clusters $[Cd_{32}S_{14}(SC_6H_5)_{36}(DMF)_4]$, Herron et al. developed a combined solid-state/solution process in which a smaller cluster, namely $(NMe_4)_2[Cd_{10}S_4(SPh)_{16}]$, acts as a precursor for the synthesis of the larger compound.[5,9] With regard to the synthesis of 12–16 nanomaterials, Cumberland et al. have shown recently that similar smaller cluster molecules can also act in solution as convenient single-source precursors for controlled preparation of 2–9 nm CdSe and CdSe/ZnS nanocrystals.[10]

This paper reports on the investigations of the thermal properties of a series of four different M_{10}-selenide cluster molecules of the general formula $[M_{10}Se_4(SePh)_{12}(PR_3)_4]$ (M = Zn, Cd, Hg; R = organic group) by TGA. Recrystallisation of the intermediate product of the first step of the vacuum thermolysis of $[Cd_{10}Se_4(SePh)_{12}(PnPr_3)_4]$ led to the isolation of the larger cluster molecules $[Cd_{32}Se_{14}(SePh)_{36}(L)_4]$ (L = $OPPh_3$, OC_4H_8), which were characterised by single-crystal XRD.

Results and Discussion

Synthesis and Structure of the Precursor Cluster Molecules

The reaction of MCl_2 (M = Zn, Cd, Hg) with PR_3 (R = organic group), $PhSeSiMe_3$ and $Se(SiMe_3)_2$ in organic solvents results, according to Scheme 1, in the formation of crystals of $[Zn_{10}Se_4(SePh)_{12}(PnPr_2Ph)_4]$ (**1**), $[Cd_{10}Se_4(SePh)_{12}(PnPr_3)_4]$ (**2**),[1] $[Cd_{10}Se_4(SePh)_{12}(PEt_3)_4]$ (**3**, **3a**) and $[Hg_{10}Se_4(SePh)_{12}(PnPrPh_2)_4]$ (**4**).[11]

Scheme 1.

Figure 1 shows, as an example, the molecular structure of a $[M_{10}Se_4(SePh)_{12}(PR_3)_4]$ (M = Zn, Cd, Hg; R = organic group) cluster core; these have been determined for all four compounds by single-crystal X-ray diffraction (Table 1). The cluster core, which comprises four adamantane cages each of which is formed by six selenium and four group 12 metal atoms, is a macrotetrahedral fragment of the sphalerite structure, which can be found in ZnSe, CdSe and HgSe. The four phosphane atoms occupy the apex positions of the resultant tetrahedron. The metal atoms are all four coordinate with distorted tetrahedral coordination geometry. Whilst most of them are bonded to either μ_3-Se^{2-}- or μ_2-$SePh^-$ ligands, those at the apex positions are also coordinated to phosphorus atoms. Mean interatomic distances vary in **1–4** because of the increasing covalent radii of zinc, cadmium and mercury (Table 2). The solution absorption spectrum for cluster **1** in THF features one maximum in the UV region at 246 nm ($\varepsilon = 2.9 \cdot 10^5\ M^{-1}\,cm^{-1}$).

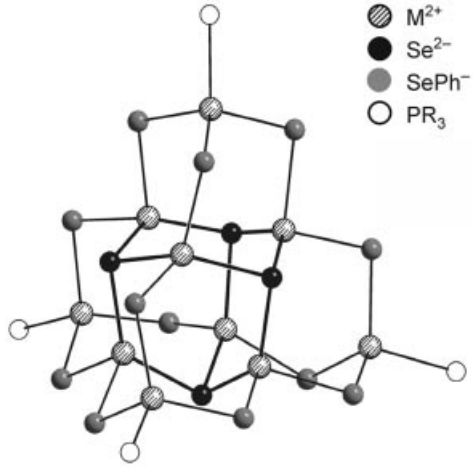

Figure 1. The $M_{10}Se_{16}P_4$ cluster core as a section of the molecular structures of $[M_{10}Se_4(SePh)_{12}(PR_3)_4]$; M = Zn (**1**), Cd (**2**, **3**, **3a**), Hg (**4**); R = organic group.

Thermogravimetric Analysis

The decomposition of **1–4** upon heating was followed by combined thermogravimetric analysis (TGA) and mass spectrometry (Figure 2). In the DTG, the mass change of **1** shows one sharp feature at 204 °C immediately followed by two further steps at 262 °C and 334 °C. The weight change in the first step corresponds to the cleavage of four $PPhnPr_2$ (calcd. 21.5%), while the added mass loss of the second and third step is equivalent to six $SePh_2$ (calcd. 38.7%) leading to the formation of ZnSe. A powder diffraction pattern proves the cubic structure of the formed material.

Thermogravimetric analysis of **2** in vacuo shows that the thermal decomposition occurs in two successive steps represented by two well-resolved peaks in the DTG curve (Figure 2). While the peak at 175 °C displays only one maximum, the other is split into two closely neighbouring maxima at 282 °C and 308 °C. The mass change of the first reaction corresponds to 16.9% which is equivalent in mass to four $PnPr_3$ (calcd. 16.2%) and some additional toluene incorporated in the crystal lattice. The intermediate product '$Cd_{10}Se_4(SePh)_{12}$' then undergoes a second reaction, beginning at around 220 °C. The mass loss is equivalent to six $SePh_2$ (calcd. 35.4%), leaving a solid residue with the formula CdSe. X-ray diffraction indicates that this solid is phase-pure CdSe in the zincblende structure. This interpretation is in good agreement with simultaneously recorded mass spectra. Starting from 40 °C, two peaks at *m/e* = 91, 92 evolve, which indicate small amounts of remaining toluene in the crystal powder. The principal product of the low-temperature weight loss event is identified to be $PnPr_3$ (*m/e* = 161, 133, 104/105, 91, 77, 62, 41, 27). The highest peaks in mass in the spectra of the second step are located between *m/e* = 150–161 and can be assigned to $(C_6H_5)_2$ (*m/e* = 154), HSePh (*m/e* = 158) and 'SePh' as a fragmentation product of $SePh_2$, although molecular peaks (*m/e* = 234; 312) of this latter compound were not detected. Therefore, the volatile products of the second step of the vacuum thermolysis of **5** were collected in a cool trap and investigated by GC-MS as a solution in THF. $SePh_2$ was found to be the main product accompanied by HSePh, $(C_6H_5)_2$ and PhSe–SePh, all with lower concentrations by approximately one-tenth.

Nearly the same decomposition sequence is observed for **3**; the second step that corresponds to the cleavage of six $SePh_2$ (calcd. 36.96%) is quite similar to that of **2** (Figure 2). However, the differential peak for the first event in the TGA of **3** appears to be much broader than that of **2** with an indicated splitting into two subprocesses. As a consequence the mean temperature for the cleavage of four PEt_3 (calcd. 12.49%) is found to be by approximately 30 °C higher than that of $PnPr_3$ in **2**. Therefore, the two steps of the thermolysis of **3** are not as well separated as for **2**. Accordingly the measured weight loss in the mass spectra indicate that PEt_3 (*m/e* = 118) and 'SePh' (*m/e* = 157) are the main decomposition products of either step 1 (low temperature) and step 2 (high temperature).

The investigations of the thermal properties of **4** reveal that it decomposes rapidly in a two-step process between 40 °C and 140 °C to yield a black residue of 12% in mass of the starting cluster with C: 0.61% and H: 0.04% (Figure 2). Powder X-ray diffraction analysis shows it to be HgSe in its cubic form, which then further decomposes at a mean

temperature of 226 °C; this is in rough agreement with the reported value for the beginning of the sublimation of HgSe in an evacuated quartz crucible at 226 °C.[12] However, the observed mass changes in the three-step TGA of **4** cannot be simply assigned to the cleavage of a certain amount of product like in **1–3**, as a theoretical cleavage of four PPh_2nPr (calcd. 17.88%) and six $SePh_2$ (calcd. 27.4%) should yield a residue of 54.72 mass-% of HgSe. Similar to observations of Corrigan et al. on the TGA of $[Hg_{15}Cu_{20}S_{25}(PnPr_3)_{18}]$,[13] we assume that more complex redox processes including the reduction of Hg^{2+} may take place during the thermal treatment of **4**. For the first step, the recorded mass spectra only display the peaks associated to the fragmentation products of PPh_2nPr (m/e = 152 = PPh*n*Pr and 108 = PPh). Starting with the second step, a group of peaks between m/e = 150 and 161 evolves, which is indicative of the cleavage of SePh groups. Any other products could not be clearly identified in the mass spectra.

Characterization of the Intermediate '$Cd_{10}Se_4(SePh)_{12}$'

Bulk samples of the yellow '$Cd_{10}Se_4(SePh)_{12}$' were prepared according to Scheme 2 in a porcelain boat inside a glass tube, connected to a high vacuum pump.

The X-ray powder pattern of the yellow crude powder (Figure 3) shows one strong peak at d = 1.78 nm in the low 2θ range, and three further broad and weaker peaks at higher angles (25.4°, 43.3°), the latter of which has a distinct shoulder at 47.8°. The pattern of the three weaker peaks can be successfully fitted on the basis of the cubic bulk structure of CdSe, and the broad peaks indicating the small sizes of the crystallites. An estimation of the particle size on the basis of the Scherrer equation[14] yields a mean diameter of 1.5 nm, which suggests a growth of the originally 0.7-nm sized CdSe cluster cores in **2** (size is taken as the distance of the cadmium atom at one vertex to the opposite tetrahedral face; see Figure 1). The peak at d = 1.78 nm depicts some long-range order in the powder, which most probably originates from the nanostructuring of the material.

Yellow '$Cd_{10}Se_4(SePh)_{12}$' dissolves fairly well in THF, whilst the solubility is enhanced upon addition of aliquots of tertiary phosphanes. By comparison of the UV/Vis spectra of **2** and '$Cd_{10}Se_4(SePh)_{12}$' in THF it can clearly be seen that the absorption features of **2** have changed upon thermal treatment (Figure 4a). While the characteristic peaks for **2** at 297 nm and 316 nm have disappeared, new, weakly resolved absorption maxima are detected at higher wave-

lengths suggesting a growth of the original CdSe cluster cores of **2**, which is in agreement with the particle sizes derived from powder X-ray data.

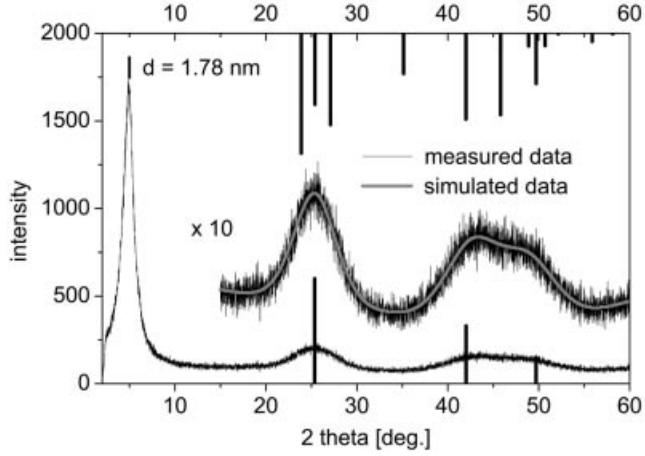

Figure 3. Powder XRD pattern for the intermediate product '$Cd_{10}Se_4(SePh)_{12}$' formed by TGA of $[Cd_{10}Se_4(SePh)_{12}(PnPr_3)_4]$ (**2**). The solid line represents a fit to the experimental data based on the peaks of cubic CdSe. Also shown are the peak patterns of cubic (downward sticks) and hexagonal (upward sticks up) CdSe.

Similar observations are made in a dynamic light scattering experiment (Figure 4b). For solutions of '$Cd_{10}Se_4(SePh)_{12}$' in THF, a broad peak for the hydrodynamic radius (resulting from the fit of the autocorrelation function) is observed, which is shifted by 0.7 nm relative to that of the precursor cluster **2** (the total diameter of **2** is estimated from a space-filling model to be 2.2 nm).[15] The increased width of the peak for the '$Cd_{10}Se_4(SePh)_{12}$' solutions results from a distribution of particle sizes, which is in agreement with the detection of several weakly resolved maxima in the UV/Vis spectrum. The shift of the peak maxima however supports the suggested growth of the '$Cd_{10}Se_4(SePh)_{12}$' cluster cores of **2** during thermal treatment.

Synthesis and Structure of $[Cd_{32}Se_{14}(SePh)_{36}(L)_4]$; L = OC_4H_8 (5), $OPPh_3$ (6)

Dissolution of the crude yellow powder resulting from the thermal treatment of **2** with the formal composition '$Cd_{10}Se_4(SePh)_{12}$' in THF yields pale yellow crystals after one night. Although some of these crystals appear to be perfect, they diffract only up to 25° in 2θ, and the determination of a hexagonal cell was only possible on the basis of 60% of the reflections being indexed ($a = b = 3929.1$, $c = 3017.1$ pm). Additionally, one axis shows a superstructure splitting of the reflections, which altogether makes a solution of the structure impossible. The separation of the supernatant solution from the crystals and subsequent concentration by evaporation of more than half of the solvent yielded other more suitable crystals for X-ray analysis, with the composition $[Cd_{32}Se_{14}(SePh)_{36}(OC_4H_8)_4]$ (**5**) (Scheme 3). Immediate addition of six equiv. triphenylphosphineoxide during the dissolution of '$Cd_{10}Se_4SePh_{12}$' inTHF avoided the formation of the initially formed weak diffracting crystals. Instead, pale yellow pinlike crystals of $[Cd_{32}Se_{14}(SePh)_{36}(OPPh_3)_4]$ (**6**) grew upon indirect layering of the solution with acetone (Scheme 3). However, the theo-

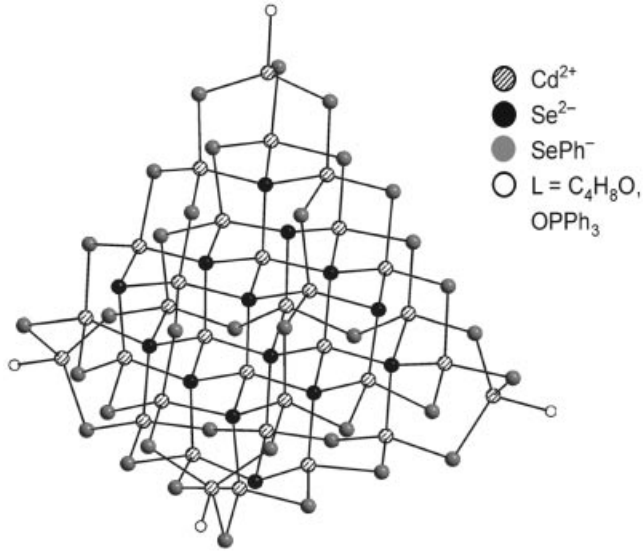

Figure 5. The $Cd_{32}Se_{50}O_4$ cluster core as a section of the molecular structures of $[Cd_{32}Se_{14}(SePh)_{36}(OC_4H_8)_4]$ (**5**) and $[Cd_{32}Se_{14}(SePh)_{36}(OPPh_3)_4]$ (**6**).

retical stoichiometric formation of **5** and **6** from '$Cd_{10}Se_4SePh_{12}$' produces a slight excess of cadmium atoms and phenylselenolate ligands with respect to the composition of the precursor compound, which suggests the formation of unidentified by-products in the reaction as represented by the unknown crystals (see also discussion of powder XRD and UV/Vis below).

Both compounds, **5** which crystallises in the space group $R\bar{3}c$ and **6** which crystallises in $C2/c$, exhibit the same tetrahedral cluster core structure $[Cd_{32}Se_{14}(SePh)_{36}L_4]$, with either C_4H_8O (**5**) or $OPPh_3$ (**6**) at the apex positions (Figure 5). This cluster framework is built up of 13-fused CdSe adamantane cages with four barrelene CdSe cages at each of the corners. Adamantane cages are the building blocks of the cubic zincblende structure of CdSe, while barrelene cages are those of the hexagonal wurtzite type. Thus, it is similar to the known M_{32} chalcogenide cluster molecules such as $[Cd_{32}S_{14}(SPh)_{36}(DMF)_4]$ (DMF = *N*,*N*-dimethylformamide),[5] $[Cd_{32}S_{14}(SCH_2CH(OH)CH_3)_{36}(H_2O)_4]$[6] and $[Hg_{32}Se_{14}(SePh)_{36}]$,[7] but slightly different to the closely related cluster $[Cd_{32}Se_{14}(SePh)_{36}(PPh_3)_4]$[7] and distinctly dif-ferent to a recently characterized cluster of composition $[Hg_{34}Te_{16}(SePh)_{36}(PPhnPr_2)_4]$.[16] The difference in structure in relative to that found in **5** and **6** (Figure 6) lies with the build up of the CdSe framework. A rotation of a corner part of the structure in **5** or **6** that consists of one barrelene cage and three adamantane cages by 120° (around the threefold axis pointing from this corner to the opposite triangular face) converts these three adamantane cages into three barrelene cages and thus leads to the structure of

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$[Cd_{32}Se_{14}(SePh)_{36}(PPh_3)_4]$ without changing the stoichiometry and the overall charge of the cluster. This cluster therefore comprises an increased number of seven barrelene cages and only ten adamantane cages in comparison to the numbers found in **5** and **6**. In principle this twisting should be possible at all four corners of the '$Cd_{32}Se_{14}(SePh)_{36}$' cluster core, which would result in a build up of one adamantane cage and 16 barrelene cages, a structure which has not yet been synthesized and characterized. The problems in crystallizing these compounds are maybe due to this geometric isomerism which reflects the dimorphism of bulk CdSe, together with a huge theoretical amount of isomeric-structures caused by the two possible positions for the phenyl groups of each μ_2-SePh$^-$ ligand.[17] Another tetrahedral cluster composed of elements of group 12 and 16 with a closely related composition and size but different structure is $[Hg_{34}Te_{16}(SePh)_{36}(PPhnPr_2)_4]$.[16] The '$Hg_{34}Te_{16}Se_{36}$' cluster core is completely formed by 20 adamantane cages and can be considered as an idealized fragment of the cubic sphalerite lattice, but with a mercury vacancy in the centre. Although the cluster cores of **5** and **6** are also formed by adamantane cages, except the barrelane cages at the four corners, both structures differ in their geometric centres. Whilst at the centre of $[Hg_{34}Te_{16}(SePh)_{36}(PPhnPr_2)_4]$, there is a mercury vacancy on what should be a formal atomposition, the centre of **5** and **6** lies within the centre of theinner adamantane cage and thus on a tetrahedral hole. This situation shows, in principle, the two possibilities of nucleation of a CdSe crystal, one where it grows regularly on all sides from a preformed 'Cd_4Se_6' adamantane cage and the other from a tetrahedral '$HgTe_4$' unit. The CdSe bond distances for **5** and **6** listed in Table 3 display slightly different ranges for the different bridging modes of the selenium ligands, either μ_4-Se^{2-}, μ_3-Se^{2-} or μ_2-Se^-, which are in analogy to those ranges found in the similar cluster, $[Cd_{32}Se_{14}(SePh)_{36}(PPh_3)_4]$.[7]

A comparison of the measured and calculated X-ray powder diffraction patterns for **5** and **6** reveal their reason-

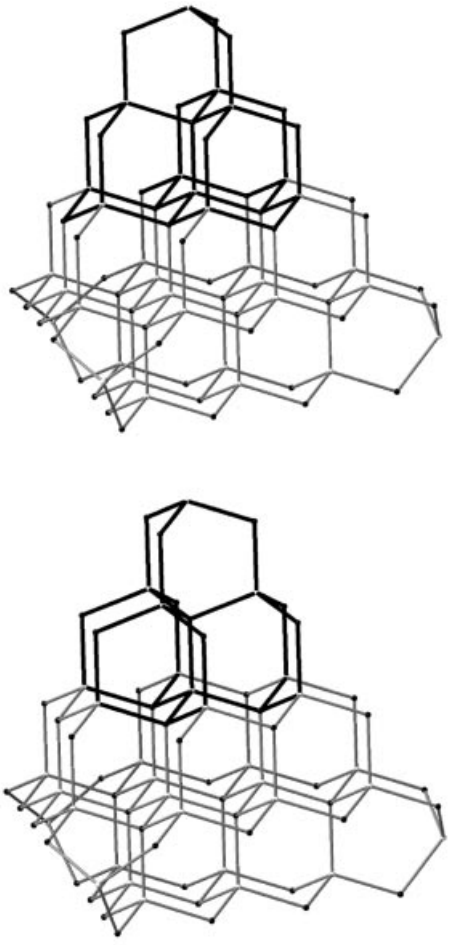

Figure 6. Schematic drawing of the different build up of the $Cd_{32}Se_{50}$ cluster cores in $[Cd_{32}Se_{14}(SePh)_{36}(OC_4H_8)_4]$ (**5**), $[Cd_{32}Se_{14}(SePh)_{36}(OPPh_3)_4]$ (**6**) (above) and $[Cd_{32}Se_{14}(SePh)_{36}(PPh_3)_4]$[7] (below) with the differing part highlighted in black.

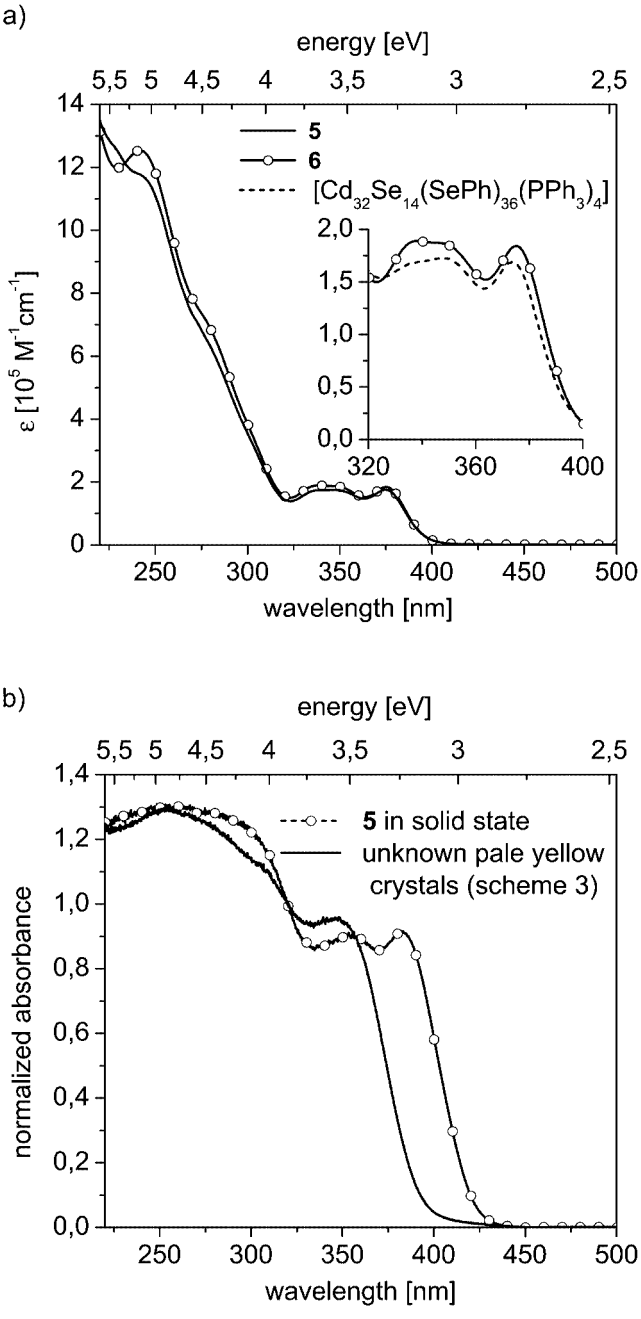

Figure 8. a) UV/Vis spectra of $[Cd_{32}Se_{14}(SePh)_{36}(OC_4H_8)_4]$ (**5**) and $[Cd_{32}Se_{14}(SePh)_{36}(OPPh_3)_4]$ (**6**) in THF. The inset displays a magnification of the absorption bands of **5** between 320 and 400 nm relative to the bands of the very similar cluster $[Cd_{32}Se_{14}(SePh)_{36}(PPh_3)_4]$; b) UV/Vis spectra of **5** and the unknown pale yellow crystals (see Scheme 3) in solid state.

able crystalline purity with respect to the formation of a mixture of compounds (Figure 7), although weak additional reflections in the patterns of **5** and **6** indicate cocrystallisation of small amounts of an unknown crystalline product in both compounds. However, the location of the strong reflections in the powder pattern of these unknown crystals at low 2θ values reflect long-range ordering in a size range comparable to **5** and **6**.

The UV/Vis spectra in THF (Figure 8a) are quite similar for **5** and **6**. Starting from higher wavelengths, the first absorption maximum is observed at 375 nm (3.3 eV) [the extinction coefficient for **5** in THF is $1.84 \cdot 10^5$ $M^{-1}cm^{-1}$ and for **6**, $1.76 \cdot 10^5$ $M^{-1}cm^{-1}$] followed by a broad peak centred at 343 nm (3.6 eV) which most probably consists of two closely neighbouring transitions at either 338 nm (3.7 eV) and 348 nm (3.6 eV). The following increase in absorbance in the region from 321 nm to 210 nm indicates further weakly resolved maxima and shows a last peak for **5** at 241 nm (5.12 eV) and a related shoulder for **6** at a similar position. The inset in Figure 8a displays a comparison of the spectra of **5** and the very similar cluster $[Cd_{32}Se_{14}(SePh)_{36}(PPh_3)_4]$, which has a slightly shifted first absorption maximum at 373 nm. In contrast to **5**, the unknown crystalline pale yellow product according to Scheme 3 is mostly insoluble in THF. The solid-state UV/Vis spectrum in Figure 8b shows the lowest energy absorption peak at 346 nm (3.58 eV), while under similar conditions, the spectrum for **5** shows the first maximum at 383 nm (3.24 eV). Therefore, the position of the lowest-energy transition between that of **2** and **5** points to an intermediate cluster size, for example, a cluster cage with 17 cadmium atoms such as '$Cd_{17}Se_4(SePh)_{24}$', which was found in $[Cd_{17}Se_4(SePh)_{24}(PnPr_2Ph)_4]^{2+}$.[1] The low solubility suggests an ionic or polymeric species. These findings are also in agreement with the elemental analysis (C: 30.2, H: 2.1%) of the preliminary crystallizing powder, which displays higher values than those calculated for **5** (C: 26.3, H 2.0%).

Experimental Section

Synthesis

Standard Schlenk techniques were employed throughout the syntheses using a double manifold vacuum line with high purity dry nitrogen. The solvents tetrahydrofuran (THF), dimethylethyleneglycol (DME) and benzene were dried over sodium benzophenone, and toluene, over $LiAlH_4$, and distilled under nitrogen. Anhydrous $ZnCl_2$, $CdCl_2$ and $HgCl_2$ were purchased from Aldrich. $PhSeSiMe_3$[18] and $Se(SiMe_3)_2$[19] were prepared according to stan-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

dard literature procedures. $Se(SinBu_3)_2$ was prepared according to the synthesis of $Se(SiMe_3)_2$ with $ClSinBu_3$ instead of $ClSiMe_3$.

1: $ZnCl_2$ (0.28 g, 2.05 mmol) was dissolved in benzene (50 mL) with the addition of $PPhnPr_2$ (0.43 mL, 2.05 mmol). $PhSeSiMe_3$ (0.55 mL, 2.87 mmol) was then added, and the resulting clear solution was stirred for 2 h. Addition of $Se(SiMe_3)_2$ (0.18 mL, 0.82 mmol) led to the formation of some droplets of colourless oil, which dissolves again upon standing for two days. Layering with *n*-pentane leads to the formation of colourless crystals of $[Zn_{10}Se_4(SePh)_{12}(PnPr_2Ph)_4]$ (**1**). Yield: 0.66 g, 80%. $C_{120}H_{136}Zn_{10}P_4Se_{16}$ (3619.45): calcd. C 39.82, H 3.79; found C 40.06, H 3.74%.

2: according to ref.[1].

3, **3a:** $CdCl_2$ (0.32 g, 1.75 mmol) was dissolved in DME (30 mL) with the addition of PEt_3 (0.64 mL, 4.36 mmol). $PhSeSiMe_3$ (0.54 mL, 2.8 mmol) was then added at 0 °C, and the resulting clear solution was stirred for 2.5 h. Addition of $Se(SiMe_3)_2$ (0.12 mL, 0.53 mmol) at 0 °C and subsequent standing at room temperature led to the formation of a mixture of colourless crystals of $[Cd_{10}Se_4(SePh)_{12}(PEt_3)_4]$ (**3**, **3a**). Yield: 0.50 g, 76%. $C_{96}H_{120}Cd_{10}P_4Se_{16}$ (3785.36): calcd. C 30.46, H 3.20; found C 30.43, H 3.31%.

4: according to ref.[11].

'$Cd_{10}Se_4(SePh)_{12}$': Bulk samples of the intermediate '$Cd_{10}Se_4(SePh)_{12}$', identified from the TGA experiments, were prepared by heating **2** in a porcelain boat inside a glass tube connected to a high vacuum pump via a cool trap. Samples of **2** (up to 0.5 g) were heated at 3 °C/min to 210 °C and then immediately cooled down by opening of the oven. The originally white/colourless crystals changed to give an intense-coloured yellow powder. $C_{72}H_{60}Cd_{10}Se_{16}$ (3312.73): calcd. C 26.11, H 1.82; found C 26.01, H 1.87%.

5: '$Cd_{10}Se_4(SePh)_{12}$' (0.043 g, 0.013 mmol) was dissolved in THF (12 mL). Hexagonal shaped crystals of poor diffraction quality were obtained after overnight standing. After two days the clear supernatant solution was separated from the crystals and this flask connected to another flask which contains Diglyme (50 mL). Slow evaporation of more than half of the THF solution into the Diglyme solution over a period of 3 weeks yielded pale yellow crystals of $[Cd_{32}Se_{14}(SePh)_{36}(C_4H_8O)_4]$ (**5**) as well as small amounts of the hexagonal ones with unknown composition. Yield: 0.018 g, 45% calculated for reaction of 3.5 equiv. '$Cd_{10}Se_4(SePh)_{12}$' to yield 1 equiv. **5**, according to Scheme 3. $C_{232}H_{212}Cd_{32}O_4Se_{50}$ (10609.35): calcd. C 26.27, H 2.01; found C 26.11, H 2.02%.

6: '$Cd_{10}Se_4(SePh)_{12}$' (0.097 g, 0.0293 mmol) was dissolved in THF (10 mL). Then $OPPh_3$ (1.21 mL of a 0.176 M solution in THF) was added and layered with acetone through slow diffusion by evaporation via a connected flask to give pale yellow crystals of $[Cd_{32}Se_{14}(SePh)_{36}(OPPh_3)_4]$ (**6**). Yield: 0.048 mg, 50% calculated for reaction of 3.5 equiv. '$Cd_{10}Se_4(SePh)_{12}$' to yield 1 equiv. **6** according to Scheme 3. $C_{288}H_{240}Cd_{32}O_4P_4Se_{50}$ (11434.09): calcd. C 30.25, H 2.12; found C 29.95, H 2.09%.

Crystallography

Crystals suitable for single-crystal X-ray diffraction were taken directly from the reaction solutions of the compounds and then selected in perfluoroalkylether oil.

Single-crystal X-ray diffraction data were collected with the use of graphite-monochromatised Mo-K_α radiation (λ = 0.71073 Å) on a STOE IPDS II (Imaging Plate Diffraction System) equipped with a Schneider rotating anode. The structures were solved with the direct methods program SHELXS[20] of the SHELXTL PC suite programs, and were refined with the use of the full-matrix least-squares program SHELXL.[20] Molecular diagrams were prepared by using the program SCHAKAL 97[21] and DIAMOND.[22]

All Zn, Cd, Se and P atoms were refined with anisotropic displacement parameters, whilst all C and O atoms were refined isotropically with the exception of **6** where the O atoms were treated anisotropically. Some of the phenyl rings were refined with a model of disorder **1**: C43–C48 and C103–C108, **3a**: C43–C48 and C91–C96, **5**: C1–C6 and C55–C60. The phenyl group C67–C72 in **5** could only be refined as a rigid group with half occupancy. One THF ligand (O2, C77, C78) in **5**, which coordinates to Cd2 at one apex position of the cluster core resides on a threefold axis. It was refined as a threefold degenerate solvent molecule but could also in general indicate a twinning of the crystals. Only two of the solvent THF molecules in **6** were refined with half occupancy. Residual electron density in the difference Fourier map of **1**, **5** and **6** indicates the existence of additional disordered solvent molecules in the crystal lattice that could not be refined successfully. Problems in the X-ray structural analysis of **5** arise from the very long *c* axis of the unit cell. In order to avoid an overlapping of reflections, a maximum detector distance (200 mm, $2\Theta_{max}$ = 40°) was chosen during the measurement together with a small effective mosaic spread and a small reflection box in the integration.

CCDC-250987 (**1**), CCDC-250988 (**3**), CCDC-250989 (**3a**), CCDC-250990 (**5**) and CCDC-250991 (**6**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

X-ray powder diffraction patterns (XRD) were measured on a STOE STADI P diffractometer (Cu-K_α radiation, Germanium monochromator, Debye–Scherrer geometry) in sealed glass capillaries. Theoretical powder diffraction patterns for **1** and **2** were calculated on the basis of the atom coordinates obtained from single-crystal X-ray analysis by using the program package STOE WinXPOW.[23]

Physical Measurements

UV/Vis absorption spectra of cluster molecules in solution were measured on a Varian Cary 500 spectrophotometer in quartz cuvettes. Solid-state spectra were measured as micron-sized crystalline powders in mineral oil between quartz plates with a Labsphere integrating sphere.

Light scattering experiments were carried out with an ALV-NIBS particle sizer. The time correlation functions were measured with an ALV-5000/E Multiple Tau Digital Correlator. The light source a 3 mW He/Ne-Laser (632.8 nm) is therein combined with a focusing optic and a highly sensitive single photon detector in back-scattering geometry. All of the measurements were carried out at a temperature of 25 °C ± 0.1 °C in quartz cuvettes sealed with a septum to avoid decontamination of the samples with oxygen and water.

Thermogravimetric analyses were run on a thermobalance STA 409 from Netzsch in vacuo (heating rate 2 K/min). The balance was coupled with a quadrupole mass spectrometer QMG 422 from Balzers.

GC-MS spectra were performed on an Agilent Technologies 6869N Network GC System equipped with an Agilent 5973 Network Mass Selective Detector using 30 m DB5 columns.

Acknowledgments

Pyrazole-Tethered Heteroditopic Ligands and Their Transition Metal Complexes: Synthesis, Structure, and Reactivity

Anuradha Mukherjee,[a] U. Subramanyam,[b] Vedavati G. Puranik,[c] Thekke P. Mohandas,[b] and Amitabha Sarkar*[a]

Keywords: Pyrazole / Hemilabile ligands / Nickel / Copper / Cobalt / Oligomerization

Various pyrazole-based P,N (**2a–c**) and N,N (**3a–b**) ligands have been synthesized. Using representative ligands, Ni^{II}, Co^{II}, Cu^{II}, and Cu^{I} complexes have been prepared and structurally characterized by crystallography. During complexation of Co^{II} and Cu^{II} salts, the phosphane part of the P,N ligand oxidized to phosphane oxide. For N,N donor ligands, a dimeric chloro-bridged Ni^{II} complex was obtained. Ni^{II} complex **4** is an active catalyst for ethylene oligomerization. (© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Trofimenko[1] introduced pyrazole as a unique donor in coordination chemistry as tris(pyrazolyl)borate (Tp) and related ligands during late 1960s and early 1970s. A rich and parallel chemistry of Tp and its analogs[2] (often called 'scorpionates') developed subsequently in relation to metal-cyclopentadienyl complexes. Bidentate bis-pyrazolyl ligands are also known[3] and mixed donor ligands (pyrazole in combination with another type of donor atom or group) are currently gaining prominence, especially for their ability to stabilize different metals in diverse oxidation states.

The use of hemilabile ligands in coordination and organometallic chemistry has increased recently because of their potential application in catalysis. They are multidentate ligands that feature one weakly coordinating donor. This donor atom readily dissociates from the metal during catalysis, to accommodate reacting groups on the metal, but recombines with the metal when a coordinative unsaturation develops to stabilize the catalytic intermediate. Mixed ligands containing phosphorus along with oxygen, nitrogen or sulfur donor atoms have been designed in catalytic reactions such as ethylene polymerization,[4] the Heck reaction,[5] Suzuki coupling.[6] Hybrid P,N-type ligands confer high reactivity and selectivity in several catalytic reactions.[7] In continuation of our interest in developing pyrazole-based chelates,[8] we initiated a program for the design and synthesis of mixed donor ligands featuring substituted pyrazoles.

We intended to examine a set of new ligands for late transition elements, especially those relevant for catalysis of C–C (polymerization, Suzuki, Heck, Sonogashira) and C–N (aromatic amination) bond formation. We recently reported preliminary results of Suzuki and amination reactions featuring pyrazole-tethered phosphanes.[9a] Here, we report in detail the synthesis and complete characterization of those ligands and their late transition metal complexes, and initial observations on the application of a typical nickel complex in ethylene oligomerization.

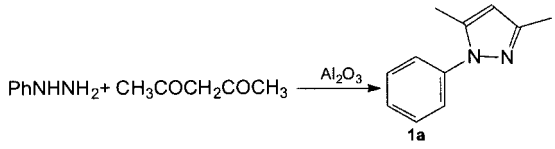
Results and Discussions

Synthesis of Ligands

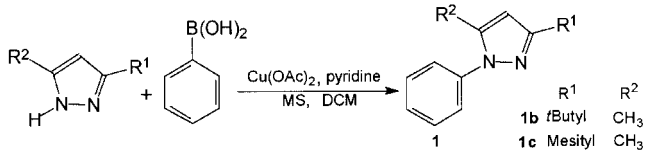
Of the two sets of bidentate ligands used in the present study, one has a phosphane (**2a–c)** and other an amine (**3a–b**) in combination with pyrazole moiety.

3,5-Dimethyl-*N*-phenylpyrazole was synthesized by the action of acetylacetone with phenylhydrazine[10] (Scheme 1). This method was suitable when 3 and 5 substituents of pyrazole were identical. To synthesize unsymmetrically substituted pyrazoles (**1b** and **1c**) we followed an alternative route whereby substituted pyrazoles are coupled with phenylboronic acid by copper acetate in the presence of pyridine[11] (Scheme 2). This procedure provided regiochemically pure derivatives – the bulky substituent (*t*Bu or mesityl) is confined to 3-position of the pyrazole. Compounds **1a–c**, were characterized unambiguously by their ^{1}H and ^{13}C NMR spectroscopic data.



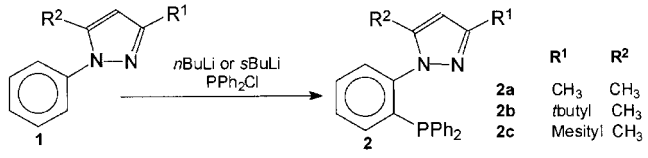
Scheme 1.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim DOI: 10.1002/ejic.200400818



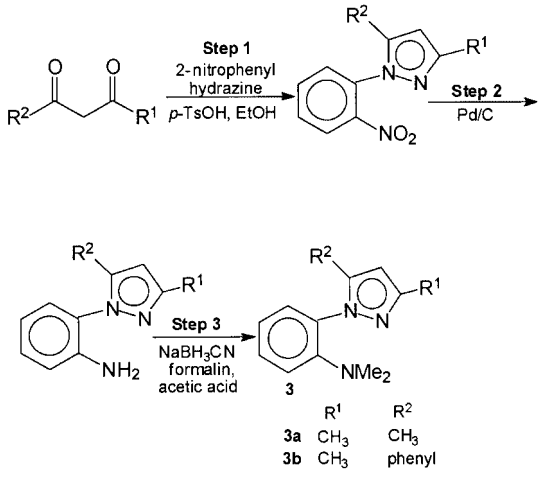
Scheme 2.

Directed lithiation on **1a** and **1b** at 0 °C using *n*BuLi and quenched with PPh_2Cl afforded the potentially bidentate ligands **2a** and **2b** (Scheme 3). Lithiation of **1c** proved difficult and required *s*BuLi. Compounds **2a**–**c** are solids that were purified by column chromatography or crystallization and characterized by spectroscopic data and elemental analysis.[9b] ^{31}P NMR absorptions appear at –23.89 (**2a**), –13.23 (**2b**) and –20.70 (**2c**) ppm.



Scheme 3.

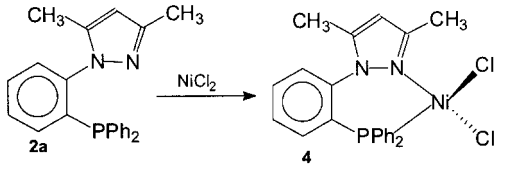
To prepare a set of ligands with nitrogen as a donor in place of phosphane we treated 2-nitrophenylhydrazine with acetylacetone or benzoylacetone followed by reduction of the nitro group with Pd/C. Reductive methylation of the resulting amine afforded the desired ligand (**3**) (Scheme 4). Reaction of benzoylacetone yielded only one product regioisomer, indicating that the hydrazine preferentially attacks the acetyl group.



Scheme 4.

Preparation of Metal Complexes

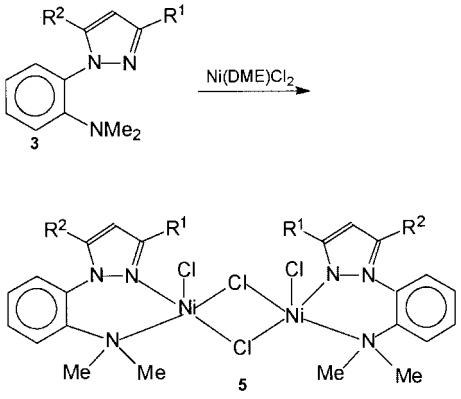
Ligand **2a** was used to synthesize representative transition metal complexes. Addition of a solution of ligand **2a** in acetonitrile to anhydrous $NiCl_2$ dissolved in acetonitrile resulted in a change of colour from yellow to violet after refluxing for 6 h, affording a violet precipitate as product. Complex **4** was isolated by filtration and recrystallized from acetonitrile to provide an analytically pure sample (Scheme 5). The NMR spectrum of this high-spin complex could not be recorded.



Scheme 5.

A single crystal of complex **4** suitable for structure analysis was grown in acetonitrile solution. Figure 1 depicts an ORTEP view of the so-determined molecular structure of **4**. A distorted tetrahedral geometry is seen around the nickel in a six-membered ring. It is strongly similar to a phosphanylaryl oxazoline complex[12] in terms of geometrical parameters, except that the difference in bond lengths of two Ni–halide bonds [0.021 Å between Ni–Cl1, 2.180(2) Å, and Ni–Cl, 2 2.201(2) Å] in **4** is more pronounced than in the reported complex (0.008 Å).

Nickel(II) complexes **5a** and **5b** were synthesized by the addition of ligands **3a** and **3b** to a solution of [Ni(DME)-Cl_2] in dichloromethane, resulting in an instant colour change from yellow to bright orange. A reddish orange solid was then filtered off and purified by crystallization from acetonitrile (Scheme 6). The crystal structure of **5b** (Figure 2) was then determined, revealing a bridged dinuclear species. The N3–Ni–Cl2A [170.4(4)°] bond angle is close to 180° while N1–Ni–N3 [83.18(5)°], Ni–Cl2–Ni1A [91.44(2)°] and N3–Ni–Cl1 [94.74(4)°] are close to 90°, establishing a square-pyramidal structure of complex **5b**. The Ni–Ni1A bond is 3.44 Å long.



Scheme 6.

Addition of a solution of ligand **2a** in acetonitrile to anhydrous $CoCl_2$ dissolved in acetonitrile resulted in an instant color change, from pale blue to deep blue. The reaction mixture was then stirred and heated under reflux for 6 h. Complex **6** was collected by filtration and crystallized from hot acetonitrile to afford blue needle-shaped crystals. The NMR spectra could not recorded, as the product was paramagnetic. Ligand **2a** reacts with anhydrous $CuCl_2$ in

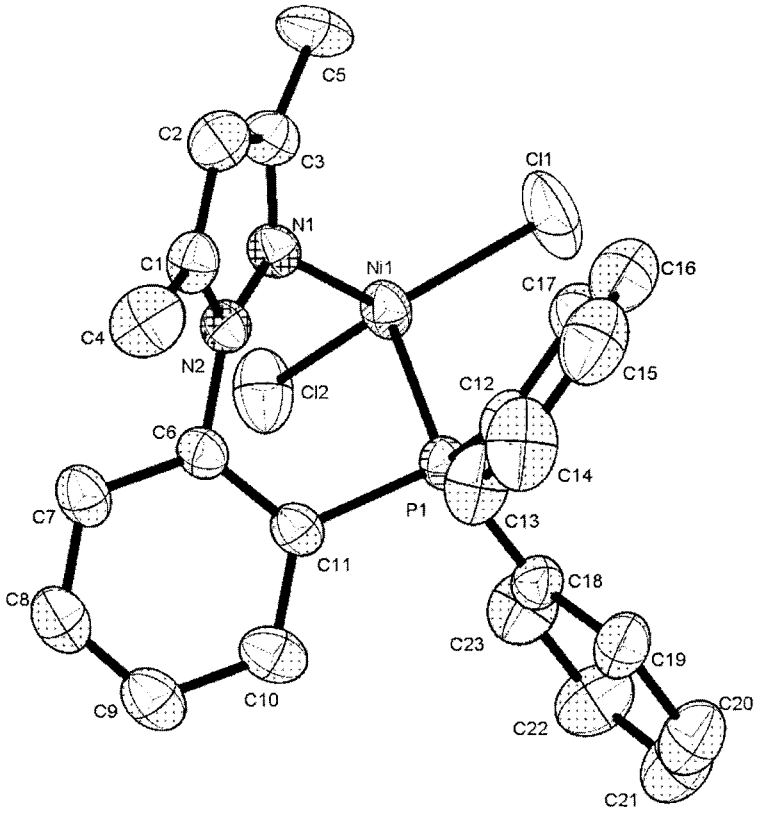

Figure 1. ORTEP diagram of Ni^{II} complex 4; ellipsoids drawn at 50% probability. Selected bond lengths [Å] and bond angles [°]: N1–N2 1.373(5), Ni–N1 2.003(4), Ni–Cl1 2.180(2), Ni–Cl2 2.201(2), Ni–P1 2.281(2). N1–Ni–P1 88.22(12), Cl1–Ni–Cl2 121.29(8), N2–N1–Ni 123.0(3), N1–Ni–Cl1 123.82 (14), N1–Ni–Cl2 104.07(13).

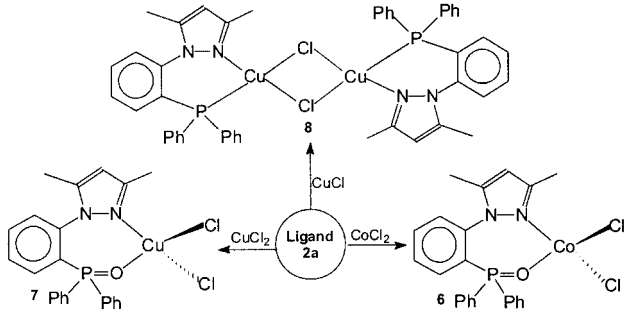
acetonitrile under identical conditions to furnish bright green, paramagnetic crystals of complex **7** (Scheme 7). Conversely, the reaction of ligand **2a** with CuCl in acetonitrile took 12 h to ensure a substantial reaction. Product **8** was obtained as a pale yellow powder, which was recrystallized from acetonitrile to obtain X-ray grade crystals.



Scheme 7.

Crystal structures of complexes **6**–**8** were determined. Interestingly, the Co^{II} and Cu^{II} complexes **6** and **7** are both seven-membered chelates, where the phosphane has been converted into phosphane oxide and the ligand **2a** is coordinated to the metal through the oxygen rather than phosphorus (Figure 3 and Figure 4). For complex **7**, the angle Cu–O–P [122.40(11)°] is suggestive of an sp^2-hybridized oxygen, unlike in $Cu(TPPO)_2Cl_2$ where the angle is considerably greater [Cu–O–P 150.9(3)°].[13a] The Co–O–P bond angle in **6** is 121.72(6)°, which is comparable with that in **7**, but smaller than the Co–O–P angle (153°) in $CoCl_2(OPPh_3)_2$.[13b] Co–O [1.991(11) Å] and P–O [1.507(12) Å] bond lengths in **6** are also comparable with those in **7** {Cu–O [1.995(18) Å] and P–O [1.506(18) Å]}. The P–O bonds of **6** [1.507(12) Å] and 7 [1.506(18) Å] are longer than that of free Ph_3PO [1.46(1) Å].

The Cu^I complex **8**, however, revealed a chloro-bridged, dimeric structure (Figure 5) that has an inversion symmetry overall, and a molecule of the solvent acetonitrile. The copper centers of **8** are 3.101 Å apart, which is comparable with the Cu–Cu′ bond length [3.066(1) Å] of the complex $[(PCy_3)CuCl]_2$.[13c] The Cu–P bond length [2.220(9) Å] of **8** is longer than Cu–P [2.183(2) Å] that of $[(PCy_3)CuCl]_2$. The ^1H NMR spectrum of this diamagnetic complex **8** displays sharp signals – three-proton methyl signals appear at different positions compared to the parent ligand (2.40 and 1.81 ppm in **8** vis-a-vis 2.19 and 2.00 ppm in ligand **2a**). One of the methyl signals in the complex is broad, indicating stereochemical non-rigidity in the molecule. The relative shielding of the methyl signal (δ = 1.81 ppm vs. 2.00 ppm) is possibly a reflection of the anisotropic effect – one methyl group lies in the shielding zone of a neighboring phenyl ring The pyrazole-4H appears at δ = 5.69 ppm, shifted upfield

compared to 5.86 in the free ligand **2a**. Similarly, the ^{31}P NMR of **8** is at –16.37 ppm, compared with δ = –23.89 ppm for the free ligand **2a**. The relative shielding of the pyrazole-4H signal with respect to corresponding signal in the parent ligand can possibly be attributed to the π-acceptor property of pyrazole in combination with a d^{10} metal nucleus.

Since complexation was performed under argon, the oxidation of phosphane was not anticipated. Elemental analyses of complexes **6** and **7** were not consistent with the formulation of the desired phosphane complexes. After the crystal structures were determined, the presence of phosphane oxide as ligand was established beyond doubt. The observed P=O absorption bands, it was then realized, were typical of a bent M–O–P structure, which differs from that of a complex with linear M–O–P arrangement.[14]

The mechanism of oxidation by a trace amount of oxygen is probably akin to the oxidation of tributylphosphane catalyzed by Co^{II} reported earlier. Yet, the facile oxidation of triarylphosphane in this instance presents an intriguing contrast to a previous report that described difficulty in oxidizing Ph_3P by $Co(acac)_2$.[15]

The unpaired electron of such a metal center (d^7 or d^9) probably readily interacts with the paramagnetic oxygen molecules present in trace amounts to generate the reactive intermediate that eventually transfers oxygen to the phosphane.[16] Once the structures were known, the reactions were repeated in an open vessel and yields were improved considerably (up to 90%).

Complexation of $CoCl_2$ and $CuCl_2$ was repeated using fourfold an excess of the ligand **2a**. Recovered ligand showed no evidence of oxidation while the complexes indeed featured the P=O group. This suggests that these metals do not catalytically oxidize the phosphorus to phosphane oxide.

Cu^{II} coordination chemistry is dominated by N or O as donor atom followed by chlorine, bromine and sulfur. The soft donor atom P is uncommon for Cu^{II} despite its frequent occurrence in Cu^{I} coordination chemistry. In a dimeric structure, phosphane can be present as a ligand, as seen in the dinuclear complex $[Cu_2(MeCO_2)_4(PPh_3)_2]$.[17] For mononuclear complexes, this is indeed rare. Therefore, complex **7** attains stability by oxidation of the phosphane to a phosphane oxide in the presence of oxygen. To the best of our knowledge, no precedent for such an oxidation within the coordination sphere of the Cu^{II} exists. Conversely, the dimeric structure of the Cu^{I} complex **7** is unexceptional.

Ethylene Oligomerization

Several nickel or palladium complexes are efficient catalysts for the oligomerization of ethylene.[18a] The degree of branching in ethylene oligomers is an important parameter for catalyst optimization since highly branched oligomers in the C_6–C_{20} range find wide use in lubrication and other applications. Mohring and Fink reported[18b] that aminobis(imino)phosphorane nickel complexes polymerize ethylene to low molecular weight branched polyethylene. More recently, Brookhart and co-workers described a neutral, SHOP-type catalyst, featuring an anionic P–N chelating ligand,[19] that can produce branched polymers/oligomers. The synthesis and coordination behavior of new P,N ligands, therefore, continues to attract interest,[20–22] owing to the possibility of independently tuning the steric and electronic attributes of different donor groups.

Our new nickel complex **4**, featuring a chelating pyrazole ligand, is an active catalyst for ethylene oligomerization. It efficiently polymerizes ethylene under mild conditions in the presence of methylaluminoxane (MAO) to yield highly branched oligomers with a relatively narrow molecular weight distribution. Table 1 and Table 2 display the results. Nickel complexes **5a** and **5b** show no activity for ethylene polymerization in the presence of MAO.

Table 1. Oligomerization of ethylene using a nickel-based catalyst system.

Entry	Ethylene [bar]	Catalyst [mol] × 10^5	MAO [mol] × 10^2	[Al/Ni]	Temp. [°C]	Yield [mg]	TOF[a]

Preliminary experiments indicate that the turnover frequency marginally increases with increasing ethylene pressure (entries 1 and 2), polymerization temperature (entries 2 and 3) and MAO concentration (entries 1 and 4).

The degree of polymerization (DP) and degree of branching were determined from the ^{1}H NMR spectrum of the oligomers following a reported method.[4a,19] The oligomers feature predominantly internal alkenes (ca. 90%), while the rest consists of 1-alkenes and some with CH_2=C(Me)C– end groups. An average of 125 branches per 1000 carbon atoms, a significant number, is estimated from the ^{1}H and ^{13}C NMR spectra (Table 2).

The average chain length of C_{60}–C_{80} and extensive branching are two noteworthy features of this new nickel catalyst. Extensive branching probably results from the 'chain running' behavior[4a] of nickel.

Conclusions

Two sets of new pyrazole-tethered bidentate ligands can form stable complexes with late transition metals such as Co^{II}, Cu^{II}, Ni^{II}, and Cu^{I}. Representative complexes were structurally characterized by crystal structure determination. For the first two metal ions, the phosphane of the ligand was readily oxidized to phosphane oxide, presumably within the metal coordination sphere. The new nickel complex activated by MAO is a highly active catalyst for ethylene oligomerization. Pyrazole-derived ligands seem to offer an alternative and viable motif for ligand design. The results are encouraging and warrant a systematic variation of donor groups and tuning of steric and electronic factors on this ligand skeleton in relation to catalytic performance and microstructure of polymer products, which is currently being pursued in our laboratory.

Experimental Section

General Procedure: All manipulations were carried out under argon. Dried solvents were used. Reagents and chemicals were used as received from Aldrich and Lancaster. M.p.s (°C) (recorded on a Thermonik Campbell melting point apparatus) are uncorrected. IR spectra were recorded on a Shimadzu FTIR-8400 spectrometer. NMR spectra (^{1}H, ^{13}C and ^{31}P) were recorded on Bruker AC200, MSL300 or DRX500 spectrometers. All crystal data were corrected for Lorentzian, polarization and absorption effects. SHELX-97 (ShelxTL)[24] was used for structure solution and full-matrix least-squares refinement on F^2 (see also Table 3 and Table 4). Hydrogen atoms were included in the refinement as per the riding model. CCDC-250550 (for **5b**), -250551 (for **6**), -250552 (for **7**), -250553 (for **8**) and -250554 (for **4**) contain supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Oligomerization of Ethylene: Toluene (S.D. Fine Chemicals, India) was refluxed over sodium/benzophenone and distilled under nitrogen before use. Polymerization grade ethylene was obtained from the gas cracker complex of the Indian Petrochemical Corporation, Nagothane, India. Methylaluminoxane from Witco, Germany, was used as received. NMR Spectroscopy: ^{1}H and ^{13}C NMR spectra are recorded on a high-resolution Bruker 500 MHz spectrometer. Samples were dissolved in $CDCl_3$ in 5 mm tubes at 30 °C. Quantitative ^{13}C NMR spectra were recorded with a 40° flip angle and a delay of 8 s. GC: Gas Chromatograms were obtained on a Perkin–Elmer GC 2001. The following parameters were used for analysis of oligomer. Column: Poly Wax. Operating conditions: over: 100–300 °C, ramp rate: 7 °C min^{-1}, injector: 300 °C, detector: 320 °C, carrier gas (nitrogen): 0.7 psi. GPC: molecular weight and molecular weight distribution (MWD) of the oligomers were determined using a Thermofinnigan gel permeation chromatograph equipped with a refractive index detector and μ-styraged columns (10^5 to 50 Å), based on polystyrene standards, at 25 °C using chloroform as solvent with a 1 mL min^{-1} flow rate. Data were processed using the software PSS WinGPC scientific.

Preparation of Ligand 2a: nBuLi (15 mL 1.41 M, 21.15 mmol) was added dropwise at 0 °C to a solution of N-phenyl-3,5-dimethylpyrazole (**1a**)[10] (3.44 g, 20 mmol) in dry THF (40 mL). The solution was, initially, yellow but changed successively to blue, yellow, and brown. The reaction mixture was then stirred for 4 to 5 h followed by addition of PPh_2Cl (3.6 mL, 20 mmol) at 0 °C. Stirring was continued for an additional 3 h. The reaction was quenched with water and extracted with ethyl acetate (40 mL × 3). The combined organic phase was dried over Na_2SO_4 and concentrated. Crude semi-solid product was purified by flash chromatography followed by crystallization to obtain **2a** as a yellowish white solid (4 g, 56%). M.p. 110 °C. IR (Nujol): 1552 cm^{-1}. ^{1}H NMR ($CDCl_3$, 200 MHz): δ = 2.00 (s, 3 H, CH_3), 2.19 (s, 3 H, CH_3), 5.86 (s, 1 H, PzH), 7.31 (br. s, 14 H, PhH) ppm. ^{13}C NMR ($CDCl_3$, 50.32 MHz): δ = 11.4, 13.2, 105.1, 127.7, 127.9, 128.1, 128.4, 129.1, 133.5, 133.9, 134.0, 135.9, 136.1, 137.4, 137.8, 139.9, 142.8, 143.2, 147.7 ppm. ^{31}P

NMR ($CDCl_3$, 81.02 MHz): δ = –23.89 ppm. $C_{23}H_{21}N_2P$ (356.40): calcd. C 77.52, H 5.89, N 7.26; found C 77.29, H 5.64, N 7.24.

Preparation of 1b: First we prepared pivaloylacetone, which on reaction with hydrazine hydrate yielded 3(5)-*tert*-butyl-5(3)-methylpyrazole.[23] Copper acetate (3.32 g, 16.62 mmol), pyridine (1.8 mL, 22.17 mmol), phenyl boronic acid (2.67 g, 22.17 mmol) and molecular sieve, dichloromethane (30 mL) were then added to the mixture of 3(5)-*tert*-butyl-5(3)-methylpyrazole (1.53 g, 11.08 mmol), and the resultant mixture was stirred for 2 days under air. Crude product was purified by column chromatography. Yield: 1.6 g (70%). ^{1}H NMR ($CDCl_3$, 200 MHz): δ = 1.43 [s, 9 H, $C(CH_3)_3$], 2.32 (s, 3 H, CH_3), 6.12 (s,1 H, PzH), 7.36–7.48 (m, 5 H, PhH). ^{13}C NMR ($CDCl_3$, 50.32 MHz): δ = 12.4, 30.5, 32.0, 103.6, 124.7, 126.9, 128.8, 138.6, 140.2, 162.0. $C_{14}H_{18}N_2$ (214.31): calcd. C 78.5, H 8.41, N 13.08; found: C 78.3, H 8.39, N 13.07.

Preparation of Ligand 2b: *n*BuLi (2.3 mL of 1.6 M, 2.55 mmol) was added dropwise to *N*-phenyl-3-*tert*-butyl-5-methylpyrazole (0.53 g, 2.48 mmol) in THF (3 mL) at 0 °C. The ice bath was removed after addition of *n*BuLi. The reaction mixture gradually changed to yellow and then brown, and stirring was continued for 6 h. PPh_2Cl (0.56 mL, 2.55 mmol) was then added at 0 °C and stirring continued for another 4 h. After the usual work up, semi-solid product was obtained that was purified by column chromatography. Yield: 0.47 g (48%); m.p. 99.5 °C. IR (neat): 1552 cm^{-1}. ^{1}H NMR ($CDCl_3$, 200 MHz): δ = 1.22 [s, 9 H, $C(CH)_3$], 2.21 (s, 3 H, CH_3), 6.04 (s, 1 H, PzH), 7.29–7.46 (m, 14 H, PhH) ppm. ^{13}C NMR ($CDCl_3$, 50.32 MHz): δ = 11.9, 30.3, 31.8, 102.2, 127.8, 128.2, 128.5, 129.3, 133.7, 134.2, 134.7, 136.9, 137.6, 137.9, 139.3, 143.6, 144.1, 161.3 ppm. ^{31}P NMR ($CDCl_3$, 81.02 MHz): δ = –13.23 ppm. $C_{26}H_{27}N_2P$ (398.48): calcd. C 78.39, H 6.78, N 7.03; found C 78.32, H 6.67, N 6.98.

Preparation of Compound 1c: 3-Mesityl-5-methyl-*N*-phenylpyrazole (**1c**) was prepared by *N*-phenylation of 3(5)-mesityl-5(3)-methylpyrazole (0.759 g, 3.79 mmol) using phenyl boronic acid (0.918 g, 7.59 mmol) following the above procedure [copper acetate (1.14 g, 5.68 mmol), pyridine (0.61 mL, 7.59 mmol)]. Yield: 0.9 g (86%); m.p. 73–75 °C. ^{1}H NMR ($CDCl_3$, 300 MHz): δ = 2.24 (s, 6 H, $2CH_3$), 2.34 (s, 3 H, CH_3), 2.46 (s, 3 H, CH_3), 6.14 (s, 1 H, PzH), 6.95 (s, 2 H, PhH), 7.03–7.58 (m, 5 H, PhH) ppm. ^{13}C NMR ($CDCl_3$, 75.47 MHz): δ = 12.7, 20.5, 21.0, 108.1, 118.8, 122.4, 123.2, 124.5, 128.0, 128.3, 128.9, 129.7, 137.2, 137.4, 138.8, 140.0, 151.0 ppm. $C_{19}H_{20}N_2$ (276.38): calcd. C 82.60, H 7.24, N 10.14; found C 81.90, H 7.44, N 10.12.

Preparation of Ligand 2c: The lithiation procedure was the same as that mentioned above, using 3-mesityl-5-methyl-*N*-phenylpyrazole (0.2 g, 0.72 mmol), *s*BuLi (1.5 M, 0.5 mL, 0.72 mL) and PPh_2Cl: (0.13 mL, 0.72 mmol). Yield: 0.065 g (26%); m.p. 107 °C. ^{1}H NMR ($CDCl_3$, 300 MHz): δ = 2.02 (s, 6 H, 2 CH_3), 2.13 (s, 3 H, CH_3), 2.28 (s, 3 H, CH_3), 6.04 (s, 1 H, PzH), 7.10–7.52 (m, 14 H, PhH) ppm. ^{13}C NMR ($CDCl_3$, 75.47 MHz): δ = 12.6, 20.5, 20.9, 108.1, 122.3, 124.4, 125.9, 126.0, 126.9, 127.9, 128.2, 128.4, 128.5, 128.8, 129.3, 130.8, 137.0, 137.3, 138.3, 138.7, 139.9, 140.2, 141.4, 149.2, 150.9 ppm. ^{31}P NMR ($CDCl_3$, 202.46 MHz): δ = –20.70 ppm.

$C_{31}H_{29}N_2P$ (460.55): calcd. C 80.86, H 6.30, N 6.08; found C 80.53, H 5.97, N 6.23.

Preparation of 3,5-Dimethyl-1-(2-nitrophenyl)-1*H*-pyrazole: A solution of 2-nitrophenylhydrazine (1.5 g, 9.98 mmol), one pinch of *p*-toluenesulfonic acid and acetylacetone (1.5 mL, 14.98 mmol) in dry EtOH (50–60 mL) were refluxed for 20–24 h (reaction monitored by TLC). The reaction mixture was then cooled to room temperature and the solvent was evaporated. The resultant residue was taken up in ethyl acetate and washed with aq. $NaHCO_3$ and brine. The organic layer was dried over Na_2SO_4, concentrated and purified by column chromatography using 10% acetone/petroleum ether. Yield: 2 g (62%); m.p. 178–181 °C. IR (KBr): 790, 1529, 1355 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$) δ = 2.17 (s, 3 H, CH_3), 2.23 (s, 3 H, CH_3), 6.01 (s, 1 H, PzH), 7.45–7.59 (m, 2 H, PhH), 7.65–7.73 (m, 1 H, PhH), 7.94–7.98 (m, 1 H, PhH) ppm. ^{13}C NMR (50.32 MHz, $CDCl_3$): δ = 11.2, 13.4, 106.8, 125.0, 129.3, 129.4, 132.9, 133.2, 141.0, 146.3, 150.3 ppm. $C_{11}H_{11}N_3O_2$ (217.22): calcd. C 60.82, H 5.07, N 19.35; found: C 60.11 H 5.37, N 19.18.

Preparation of 2-(3,5-Dimethylpyrazol-1-yl)phenylamine: Dry ethanol (10 mL) was added to a mixture of 3,5-dimethyl-1-(2-nitrophenyl)-1*H*-pyrazole (0.4 g, 1.84 mmol) and 10% Pd–C (45 mg) and the resultant mixture was stirred under hydrogen until the starting material was consumed (3 h, monitored by TLC). The catalyst was filtered off and the solvent was evaporated. The reaction mixture was extracted with ethyl acetate and washed with water. Subsequent removal of the solvent afforded a yellow solid. The product was pure enough to proceed to the next step. Yield: 0.28 g (70%); m.p. 75–77 °C. IR (KBr) 1629, 1550, 3207, 3315, 3413 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$) δ = 2.67 (s, 3 H, CH_3), 2.85 (s, 3 H, CH_3), 4.60 (br., 2 H, NH), 6.53 (s, 1 H, PzH), 7.24–7.31 (m, 2 H, PhH), 7.58–7.70 (m, 2 H, PhH). ^{13}C NMR (50.32 MHz, $CDCl_3$) δ = 10.9, 13.1, 105.1, 116.0, 117.2, 124.8, 127.0, 128.9, 140.2, 143.1, 148.7. $C_{11}H_{13}N_3$ (187.24): calcd. C 70.59, H 6.95, N 22.45; found C 70.27, H 6.80, N 22.42.

Preparation of [2-(3,5-Dimethylpyrazol-1-yl)phenyl]dimethylamine (Ligand 3a): Sodium cyanoborohydride (0.215 g, 3.42 mmol), and then acetic acid, were added dropwise to a solution of 2-(3,5-dimethylpyrazol-1-yl)phenylamine (0.213 g, 1.14 mmol) in acetonitrile (4 mL) and formalin (37%) (0.912 mL, 11.40 mmol). Stirring was continued for 3 h (monitored by TLC). The reaction mixture was then poured into diethyl ether (20 mL) and then washed with brine solution. The so-obtained liquid compound was purified by column chromatography. Yield: 0.161 g (66%). ^1H NMR (300 MHz, $CDCl_3$): δ = 2.06 (s, 3 H, CH_3), 2.26 (s, 3 H, CH_3), 2.46 [s, 6 H, $N(CH_3)_2$], 5.91 (s, 1 H, PzH), 6.89–6.94 (m, 2 H, PhH), 7.19–7.28 (m, 2 H, PhH) ppm. ^{13}C NMR (50.32 MHz, $CDCl_3$): δ = 10.8, 13.3, 41.5, 105.0, 117.3, 120.2, 128.9, 129.4, 130.6, 140.9, 148.5. $C_{13}H_{17}N_3$ (215.29): calcd. C 72.56, H 7.91, N 19.53; found C 72.44, H 7.88, N 19.43.

Preparation of 3-Methyl-1-(2-nitrophenyl)-5-phenyl-1*H*-pyrazole: The same procedure as above was used; this time with benzoyl acetone (2 g, 12.34 mmol) and 2-nitrophenylhydrazine: (1.26 g, 8.23 mmol). Yield: 1 g (45%); m.p. 169–171 °C. IR: 765, 1350, 1527 cm^{-1}. ^1H NMR (300 MHz, $CDCl_3$): δ = 2.35 (s, 3 H, CH_3), 6.34 (s, 1 H, PzH), 7.19–7.28 (m, 6 H, PhH), 7.30–7.52 (m, 2 H, PhH), 7.54 (d, J = 2 Hz, 1 H, PhH) ppm. ^{13}C NMR (50.32 MHz, $CDCl_3$): 13.5, 107.6, 118.3, 124.9, 128.0, 128.3, 128.4, 128.5, 129.1, 129.3, 129.4, 133.0, 133.6, 144.9, 150.9 ppm. $C_{16}H_{13}N_3O_2$ (279.29): calcd. C 68.82 H 4.65, N 19.35; found 68.37, H 4.62, N 19.18.

Preparation of 2-[3-Methyl-5-phenylpyrazol-1-yl)]phenylamine: Using the same procedure as above, 3-methyl-1-(2-nitrophenyl)-5-phenyl-1*H*-pyrazole (0.280 g) and 10% Pd/C (30 mg) were used to obtain the desired product in 96% yield (0.240 g). M.p. 73–75 °C. IR: 1504, 1635, 3209, 3321, 3450 cm^{-1}. ^1H NMR (300 MHz, $CDCl_3$): δ = 2.40 (s, 3 H, CH_3), 3.97 (br., 1 H, NH), 6.37 (s, 1 H, PzH), 6.59–6.64 (m, 1 H, PhH), 6.79–6.85 (m, 2 H, PhH), 7.11–7.29 (m, 6 H, PhH) ppm. ^{13}C NMR (75.47 MHz, $CDCl_3$): δ = 13.6, 106.1, 116.7, 118.1, 128.0, 128.2, 129.1, 130.1, 142.7, 144.7, 149.8 ppm. $C_{16}H_{15}N_3$ (249.31): calcd. C 77.08, H 6.06, N 16.85; found C 77.19, H 6.14, 16.01.

Preparation of Dimethyl[2-{3-methyl-5-phenylpyrazol-1-yl)}-phenyl]amine (Ligand 3b): Ligand **3b** was prepared, by the same procedure as the previously, from 2-[3-methyl-5-phenylpyrazol-1-yl)]phenylamine (0.180 g, 0.72 mmol), $NaBH_3CN$ (0.14 g, 2.16 mmol) and formalin (7.2 mmol, 0.6 mL) in 95% yield (0.19 g). IR (neat): 1552 cm^{-1}. ^1H NMR (300 MHz, $CDCl_3$): δ = 2.07 (s, 6 H, NMe_2), 2.27 (s, 3 H, CH_3), 6.21 (s, 1 H, PzH), 6.67–6.84 (m, 2 H, PhH), 6.86–7.14 (m, 6 H, PhH), 7.28–7.31 (s, 1 H, PhH) ppm. ^{13}C NMR (75.47 MHz, $CDCl_3$) δ = 13.7, 41.9, 103.8, 116.6, 122.3, 124.9, 125.0, 126.5, 127.0, 132.8, 134.5, 136.4, 154.6 ppm. $C_{18}H_{19}N_3$ (277.16): calcd. C 77.97, H 6.86, N 15.16; found C 77.85, H 6.89, N 15.13.

Preparation of Nickel Complex 4: A solution of ligand **2a** (0.356 g, 1 mmol) in acetonitrile (15 mL) was added to a yellow suspension of anhydrous $NiCl_2$ (0.128 g, 1 mmol) in acetonitrile (15 mL) at room temperature. The suspension initially turned red, and during reflux over 6–8 h a violet precipitate was formed, which was filtered off and dried under vacuum to afford violet, crystalline complex **4** (0.3 g, 62%). X-ray grade crystals were obtained from a dilute solution of the complex **4** in acetonitrile. M.p. >240 °C. $C_{23}H_{21}Cl_2N_2NiP$ (485.69): calcd. C 56.26, H 4.28, N 5.70; found C 55.74, H 4.41, N 5.41.

Preparation of Nickel Complex 5a: A solution of ligand **3a** (0.17 g, 0.8 mmol) in dichloromethane (10 mL) was added to a hazy yellow solution of $Ni(DME)Cl_2$ (0.17 g, 0.8 mmol) in dry dichloromethane (5 mL); the resultant solution immediately turned violet, and gradually changed to yellowish violet. Stirring was continued for 12 h. After removal of solvent, an orange solid was obtained, which was purified by recrystallization from hot acetonitrile. Yield: 0.199 g (82%); m.p. >240 °C. IR (Nujol): 1504, 1556 cm^{-1}. $C_{13}H_{17}Cl_2N_3Ni$ (309.2): calcd. C 50.45, H 5.49, N 13.58; found C 50.57, H 5.46, N 13.29.

Preparation of Nickel Complex 5b: A solution of **3b** (0.190 g, 0.685 mmol) in dichloromethane (10 mL) was added to a hazy yellow solution of $Ni(DME)Cl_2$ in dry dichloromethane (5 mL); immediately, the hazy yellow solution turned violet and then orange. Stirring was continued for 12 h. After removal of solvent, an orange solid was obtained that was purified by recrystallization from hot acetonitrile. Yield: 0.453 g (79%); m.p. >240 °C. IR (Nujol): 1506, 1562 cm^{-1}. $C_{36}H_{38}Cl_4N_6Ni_2 \cdot 0.5CH_3CN$ (833.9): calcd. C 53.24, H 4.74, N 10.9; found C 52.99, H 4.32, N 10.88.

Preparation of Co Complex 6: An acetonitrile solution of **2a** (0.7 g, 1.93 mmol) was added to a solution of anhydrous $CoCl_2$ (0.25 g, 1.93 mmol) in acetonitrile (10 mL); the resultant solution become deep blue and, immediately, a blue precipitate formed. After 6 h of reflux reaction, the mixture was filtered, the residue was collected and dried under vacuum to give blue solid **6** (0.5 g, 51%). X-ray quality crystals were obtained from slow evaporation of acetonitrile. When the reaction was carried out in air the yield was better (0.83 g, 84%). M.p. >240 °C. IR ($CHCl_3$): 1215, 1438, 1477 cm^{-1}. $C_{23}H_{21}Cl_2CoN_2OP$ (502.25): calcd. C 55.00, H 4.21, N 5.57; found C 55.13, H 4.21, N 5.78.

Preparation of Cu^{II} Complex 7: An acetonitrile solution (20 mL) of **2a** (0.712 g, 2 mmol) was added to a brownish yellow solution of

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

anhydrous $CuCl_2$ (0.27 g, 2 mmol) in acetonitrile (10 mL) at room temperature. Immediately, the solution was change color, to light yellow. It was then refluxed for 6 h; the solution turned greenish yellow. After removal of solvent, greenish compound **7** (0.42 g, 41%) was formed, which was purified by recrystallization from acetonitrile. When the reaction was performed under air the yield was improved (0.95 g, 94%). M.p. >240 °C. IR (Nujol) 1132, 1554, 1589 cm^{-1}. Microanalysis $C_{23}H_{21}Cl_2CuN_2OP$ (506.86): calcd. C 54.50, H 4.17, N 5.52; found C 54.42, H 4.32, N 5.51.

Preparation of Cu^I Complex 8: An acetonitrile solution (10 mL) of **2a** (0.356 g, 1 mmol) was added to a suspension of CuCl (0.093 g, 1 mmol) in acetonitrile (12 mL). The reaction mixture was refluxed for 12 h. The reaction slurry was filtered and the filtrate was concentrated under vacuum to give yellow solid **8** (0.40 g, 44%). Crystals suitable for X-ray analysis were obtained from an acetonitrile solution of Cu^I complex **8**. M.p. >240 °C. IR (Nujol): 1552, 1587 cm^{-1}. ^1H NMR ($CDCl_3$, 200 MHz): δ = 1.81 (s, 3 H, CH_3), 2.40 (br. s, 3 H, CH_3), 5.69 (s, 1 H, pzH), 7.24–7.54 (m, 14 H, PhH) ppm. ^{13}C NMR ($CDCl_3$, 50.32 MHz): δ = 11.90, 14.00, 107.77, 128.13, 128.76, 129.20, 130.15, 131.22, 133.68, 142.02, 150.92 ppm. ^{31}P ($CDCl_3$, 80.02 MHz): δ –16.37 ppm. $C_{46}H_{42}Cl_2Cu_2N_4P_2{\cdot}CH_3CN$ (951.87): calcd. C 60.57, H 4.76, N 7.36; found C 60.46, H 4.69, N 7.02.

Ethylene Polymerization: Ethylene polymerization was performed in a 100-mL Büchi AG miniclave. Catalyst was suspended in dry toluene (30 mL) and the solvent was saturated with ethylene. Polymerization was initiated by addition of a toluene suspension of MAO. After 60 min, polymerization was terminated by the addition of methanol (5 mL). The resultant oligomeric mixture, obtained as an oil, was dried under vacuum.

Platinum Complexes with Only One Purine Ligand (Guanine, Deoxyguanine, or Adenine) Flanked by Two *cis*-NH(CH_3) Groups – Informative Models for Assessing the Interaction of Purine C6 Substituents with *cis*-Amines

Maria Carlone,*[a] Luigi G. Marzilli,[a] and Giovanni Natile[b]

Keywords: Penciclovir / Platinum / Anticancer drugs

syn-(*R*,*S*)-Me_3dienPtL complexes (Me_3dien = *N*,*N*′,*N*′′-trimethyldiethylenetriamine; L = a guanine, a 6-deoxyguanine, or an adenine derivative) represent useful models for assessing the influence of the purine C6 substituent on the rate of rotation about the Pt–N7 bond. Because of the unsymmetric nature of the *syn*-(*R*,*S*)-Me_3dien carrier ligand with respect to the coordination plane (all *N*–Me groups on one side of this plane), two rotamers are possible; they are defined as *endo* or *exo* for the six-membered ring of the purine on the same or opposite side of the coordination plane as the *N*–Me groups, respectively. The derivatives of guanine (Pen), 6-deoxyguanine (deoxy-Pen), and adenine (MeA) used are distinguished by their C6 substituent (O, H, or NH_2, respectively). At ambient temperature the rate of rotation of the purine about the Pt–N7 bond is slow on the NMR time scale for all three complexes. However, for Pen and deoxy-Pen, an increase of the temperature from 293 to 353 K led to coalescence of the ^{1}H NMR signals, indicating fast interconversion between rotamers and allowing evaluation of the rate constants and activation parameters ($\Delta H^{\neq}$ and $\Delta S^{\neq}$) for rotation. In contrast, for MeA raising the temperature to 353 K caused only a very slight broadening of the NMR signals, thus precluding a kinetic analysis of this complex by NMR methods. The rate of interconversion between the rotamers was comparable for the Pen and deoxy-Pen complexes, notwithstanding the greater bulk of the C6 substituent in the Pen complex. On the other hand, the far slower rate of rotation for MeA, as compared to Pen, cannot be explained solely on the basis of C6 substituent bulk. Activation parameters for rotation (average values for the two rotamers: $\Delta H^{\neq}$ = 57 ± 4 and 108 ± 3 kJ·mol^{-1}, $\Delta S^{\neq}$ = –18 ± 11 and 170 ± 11 J·K^{-1}·mol^{-1} for Pen and deoxy-Pen, respectively) suggest a plausible explanation for the observed trend.

Introduction

Cisplatin[1–3] and related drugs (carboplatin,[4] nedaplatin,[5] oxaliplatin[6–7]) are effective anticancer drugs widely used in the treatment of several human carcinomas. Nevertheless, limitations due to low activity toward some very common tumors (such as breast and colon carcinomas[6,8]), a variety of adverse side effects, and the development of resistance after an initial sensitivity to the treatment have fostered the search for new platinum drugs having improved therapeutic properties. There is a consensus that the antitumor efficacy of cisplatin stems from interaction with DNA and formation of intrastrand cross-links involving adjacent purines.[9–12]

Complexes of platinum with antiviral agents containing purine bases have also been investigated as potential drugs.[13–17] Although the antiviral potency of these compounds did not appear to increase with respect to that of the free base, very promising results were obtained from the viewpoint of antitumor activity. In particular, the complex *cis*-[PtCl(NH_3)$_2$(Acv)]Cl [Acv = Acyclovir = 9-(2-hydroxyethoxymethyl)guanine] proved to be active against sensitive and cisplatin-resistant tumor cells in mice.[18,19] Penciclovir {9-[4-hydroxy-3-(hydroxymethyl)butyl]guanine, Pen}, an agent similar to Acyclovir, is also used as an antiviral drug. 6-Deoxy-Penciclovir (deoxy-Pen) is similar to Penciclovir but carries a hydrogen atom instead of the oxo group on position six of the purine. Cellular enzymes can oxidize the C6 position, introducing an oxygen atom; therefore, deoxy-Pen can be considered a pro-drug of Pen (Scheme 1).[20,21] Having available Pen, deoxy-Pen, and 9-methyladenine (MeA), we used these three bases for investigating the role of the C6 substituent in the interaction between a coordinated purine base and the *cis*-amine(s), a possible key factor affecting the formation and stability of platinum adducts with DNA.

Moreover, in order to simplify the investigation, we looked for a model system having just one purine base and symmetrical *cis*-amine groups. MedienPtL (Medien = 4-

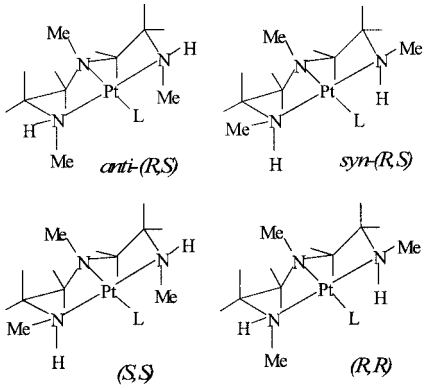
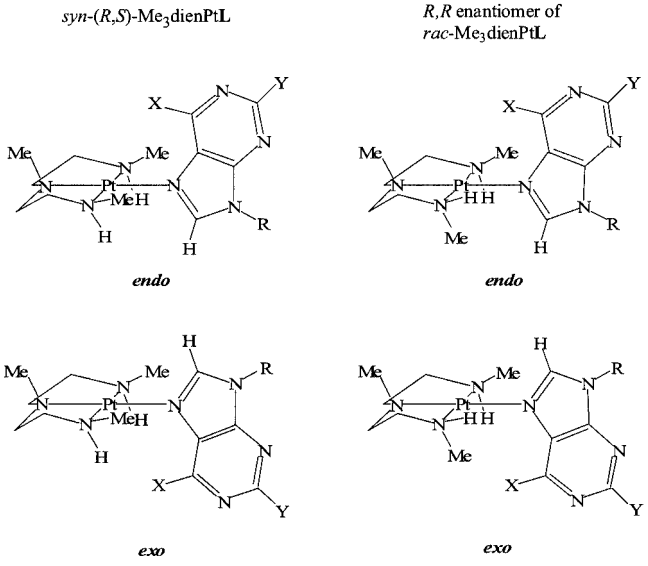
methyl-1,4,7-triazaheptane = *N*′-methyldiethylenetriamine) was the first candidate. However, the system was too dynamic for investigation by NMR (fast rotation about the Pt–N7 bond even at the lowest temperature). The rotation could be slowed by introducing methyl substituents on the terminal nitrogen atoms, and this led to the synthesis of Me_3dienPtL complexes.

The Me_3dien ligand can assume four different configurations when coordinated to the platinum atom (Scheme 2),



Scheme 2. Possible configurations for Me_3dien coordinated to platinum.

two of these are symmetrical [C_{2v} symmetry; *syn*-(*R*,*S*) and *anti*-(*R*,*S*), respectively], and two are non-symmetrical [C_s symmetry; (*R*,*R*) and (*S*,*S*), respectively].[22] [Pt(Me_3dien)-(NO_3)](NO_3) can be isolated, in the solid state, as the pure *syn*-(*R*,*S*) isomer,[23] and under acidic conditions no change of ligand configuration is observed in aqueous solution after several days at 300 K. Because of the unsymmetrical nature of the Me_3dien ligand with respect to the coordination plane, two possible rotamers are observable for restricted rotation of a coordinated purine base about the Pt–N7 bond. The two rotamers are designated as *endo* or *exo* for the six-membered ring of the purine and the central *N*–Me on the same side or on opposite sides with respect to the platinum coordination plane (Scheme 3).



Scheme 3. Possible rotamers for a coordinated purine (L) in Me_3dienPtL complexes (L = Pen, deoxy-Pen, and MeA).

In previous studies we reported the preparation and characterization by ^{1}H NMR spectroscopy of Me_3dienPtG complexes (G = guanine or inosine derivatives).[22,24] These studies established the great relevance of H-bond formation between the NH group of the carrier ligand and the 5′-phosphate of a guanine nucleotide, in comparison with a negligible interaction between an amine NH group and the guanine O6 atom. The latter interaction becomes significant only at basic pH, when deprotonation at N1 takes place.

In the present work we have chosen the same platinum substrate to investigate the effect of the substituent in position 6 of a purine base (L) upon the stability and dynamic behavior of Me_3dienPtL complexes, and we have assessed how steric, solvation, and electronic factors influence the stability and dynamic behavior.

Results

Me_3dienPtPen

The reaction of *syn*-(*R*,*S*)-[Pt(Me_3dien)(NO_3)](NO_3) with a slight excess of Pen (D_2O, pH* = 1 and 6; the asterisk denotes that no correction was made for the deuterium effect) was complete after 5 d at 298 K. At pH* = 6 (Figure 1) partial isomerization of the Me_3dien ligand from its original *syn*-(*R*,*S*) configuration to the (*S*,*S*) + (*R*,*R*) configurations (*rac*-Me_3dien) also takes place. Assignment of the resonance peaks to the *syn*-(*R*,*S*) or *rac* configurations could be performed easily by comparison with the analogous experiment performed at pH* = 1, in which case the initial *syn*-(*R*,*S*) configuration is preserved (Figure 2 for the H8 region).

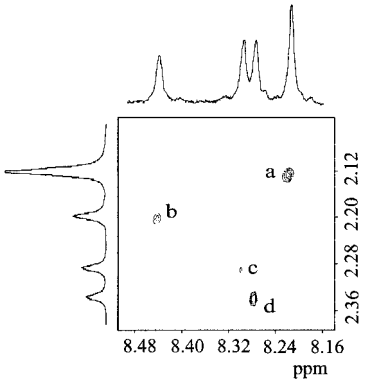

Figure 1. Selected regions of the ROESY spectrum (263 K, pH* = 6) for Me_3dienPtPen. NOE cross-peaks between purine H8 and terminal *N*–Me signals of Me_3dien are labeled. *syn*-(*R*,*S*) isomer: **a** = H8/*N*–Me for *endo* rotamer, **b** = H8/*N*–Me for *exo* rotamer. *rac* Isomer: **c** = H8/*syn*-*N*–Me for *exo* rotamer, **d** = H8/*anti*-*N*–Me for *endo* rotamer.

For both the *syn*-(*R*,*S*) and *rac* isomers two rotamers are possible (Scheme 3). The *endo* rotamer has the six-membered ring of the purine on the same side as the central *N*–Me group of Me_3dien with respect to the platinum coordination plane. In contrast, the *exo* rotamer has the six-membered ring of the purine on the opposite side of the central *N*–Me group with respect to the coordination plane. At 263 K (20% CD_3OD added to the D_2O solution) the exchange between rotamers is slow on the NMR time scale for both isomers; therefore, two relatively sharp and well-separated H8 signals are observed for each isomer (Figure 1, Table 1).

syn-(*R*,*S*)-Me_3dienPtPen has one major and one minor rotamer. In the ROESY spectrum (Figure 1) the H8/*N*–Me-(terminal) cross-peak for the major rotamer (a) was twice the size of that for the minor rotamer (b).

The H8/*N*–Me distance is expected to be shorter in the *exo* rotamer (H8 near the *N*–Me groups) than in the *endo* rotamer; however, in the present case the size of each cross-peak is proportional to the intensity of the parent resonances and therefore cannot be diagnostic for the *endo* or *exo* conformation of a given rotamer. However, for *syn*-(*R*,*S*)-Me_3dienPtG complexes, extensively investigated in a previous work, it was demonstrated that the H8 resonance at higher field (the most intense) belongs to the *endo* rotamer while the resonance at lower field (the less intense) belongs to the *exo* rotamer.[22,24] Thus, on this basis, the major rotamer has the *endo* conformation.

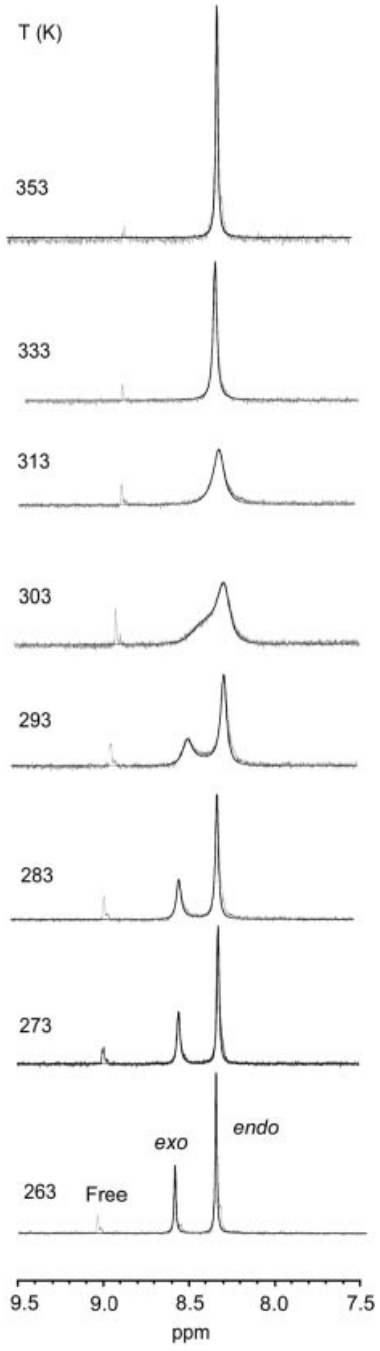

Figure 2. Experimental (pH* = 1, gray line) and simulated (dark line) NMR spectra in the H8 region for *syn*-(*R*,*S*)-Me_3dienPtPen at sample temperatures indicated.

For the adduct with the *rac* configuration of Me_3dien, the two rotamers were formed in equal amounts (equal intensity of the H8 signals). *rac*-Me_3dien has one terminal *N*–Me on the same side of the coordination plane (*syn*-*N*–Me) and the other on the opposite side (*anti*-*N*–Me) as the cen-

[a] pH* = 6, 263 K, proton signal of HOD set at δ = 5.1 ppm. [b] pH* = 5.3, 258 K, proton signal of HOD set at δ = 5.2 ppm. [c] pH* = 1, 278 K, proton signal of HOD set at δ = 5.0 ppm.

tral *N*–Me. An NOE cross-peak between the central *N*–Me and one terminal *N*–Me (δ = 2.29 ppm) assigns the latter signal to the *syn*-*N*–Me; the remaining terminal *N*–Me signal at δ = 2.34 ppm is consequently assigned to the *anti*-*N*–Me. The *endo* rotamer is expected to give an H8/*anti*-*N*–Me NOE cross-peak (both groups on the same side of the coordination plane), while the *exo* rotamer is expected to give a cross-peak between the H8 and the *syn*-*N*–Me signals. The H8 signal at δ = 8.30 ppm has a cross-peak with the *syn*-*N*–Me signal at δ = 2.29 ppm (c in Figure 1), while the H8 signal at δ = 8.28 ppm has a cross-peak with the *anti*-*N*–Me signal at δ = 2.34 ppm (d in Figure 1). Therefore, the signal at δ = 8.30 ppm is assigned to H8 of the *exo* rotamer and that at δ = 8.28 ppm to H8 of the *endo* rotamer.

Cross-peak d is considerably more intense than cross-peak c (Figure 1), indicating that when the six-membered ring of the guanine is adjacent to the "quasi equatorial" *syn*-*N*–Me (*endo* rotamer), the H8 atom can come close to the "quasi axial" *anti*-*N*–Me. In contrast, when the six-membered ring of the guanine is adjacent to the "quasi axial" *anti*-*N*–Me (*exo* rotamer), the H8 atom is kept at some distance from the "quasi equatorial" *syn*-*N*–Me. This finding is in line with a recent observation indicating that there is greater steric interaction between O6 (of an N7-coordinated guanine) and a "quasi axial" *N*–Me than between O6 and a "quasi equatorial" *N*–Me.[25]

In *syn*-(*R*,*S*)-Me_3dienPtPen, rate constants and activation parameters for interconversion between rotamers were evaluated by simulation of ^{1}H NMR spectra recorded at pH* = 1 and at various temperatures between 258 and 353 K (Figure 2, Table 2). The enthalpy and entropy of activation ($\Delta H^{\neq}$ and $\Delta S^{\neq}$, respectively) were estimated from plots of $\ln(k/T)$ vs. $1/T$, which were linear within experimental error (Supporting information; for Supporting information see also the footnote on the first page of this article, Table 4). With respect to the transition state, the *endo* rotamer is lower in enthalpy by 61 ± 2 kJ·mol^{-1} and slightly higher in entropy by 8 ± 2 J·K^{-1}·mol^{-1}. Also the *exo* rotamer is lower in enthalpy by 54 ± 2 kJ·mol^{-1} but significantly higher in entropy by 29 ± 2 J·K^{-1}·mol^{-1}.

From the activation parameters, it is possible to calculate the difference in enthalpy (ΔH) and entropy (ΔS) between *endo* and *exo* rotamers. Compared to the *exo* rotamer, the *endo* rotamer is lower in both enthalpy and entropy (by 7 ± 2 kJ·mol^{-1} and 21 ± 2 J· K^{-1}·mol^{-1}, respectively).

Me_3dienPtdeoxy-Pen

The reaction of *syn*-(*R*,*S*)-[Pt(Me_3dien)(NO_3)](NO_3) with deoxy-Pen in D_2O solution at 298 K was performed at pH* = 1 and 6 for 5 d. In the experiment performed at the higher pH partial isomerization of the Me_3dien ligand from its original *syn*-(*R*,*S*) configuration to the *rac* configuration was observed. Assignment of the resonance peaks to the *syn*-(*R*,*S*) and *rac* isomers was facilitated by comparison with the results of the analogous experiment performed at pH* = 1, for which no isomerization of the *syn*-(*R*,*S*) ligand configuration took place (Figure 4). In order to distinguish between the H6 and H8 set of signals, an aliquot of the NMR samples was heated at 70 °C for several hours to allow H8 exchange with D_2O. The signals that disappeared were assigned as H8 signals.

Coordination of deoxy-Pen took place only through N7 at both pH* values. This conclusion is supported by several pieces of evidence such as: i) formation of the platinum adduct under conditions (pH* = 1) in which the N1 atom is fully protonated ($pK_a \approx 4.3$ as determined by NMR experiments); ii) upfield shift (ca. 0.25 ppm) of the H6 signal (but not of the H8 signal, which instead remained constant) as the pH* was raised from 1 to 6 (reflecting deprotonation at N1); iii) coalescence of the two H6 signals and of the two H8 signals of each isomer [only the *syn*-(*R*,*S*) isomer for the experiment performed at pH* = 1; the *syn*-(*R*,*S*) and the *rac* isomers for the experiment performed at pH* = 6] as the temperature was raised from 255 to 353 K. Coalescence could not be possible if the two H6 signals or the two H8 signals originated from isomers with a different mode of coordination of deoxy-Pen (N7- and N1-coordination).

The coordination, at the same pH* = 6 (where N1 is not protonated), of deoxy-Pen exclusively through N7 and of MeA through both N7 and N1 can be easily understood if we consider the position of the NH_2 substituent on the six-membered ring. In deoxy-Pen the NH_2 substituent is on position 2 of the ring and it can inhibit Pt binding at N1 but not N7; thus N7 binding is preferred. In MeA, in contrast, the NH_2 substituent is on position 6 and it can inhibit Pt binding at both N1 and N7. Thus, binding at both sites is still competitive, and two isomers that cannot interchange rapidly are formed.

The assignment of proton signals to the *endo* and *exo* conformers of each isomer [*syn*-(*R*,*S*) and *rac*] has been achieved by a ROESY experiment carried out at pH* = 5.3 and 258 K (30% CD_3OD added to the D_2O solution); the

353	2230.00	2240.00	50.11	49.89

low temperature ensures the observation of relatively sharp signals (Figure 3). The most upfield signals in the aliphatic region (δ = 2.0–2.2 ppm) are assigned to the terminal *syn*-*N*–Me signals, all of them having NOE cross-peaks with the central *N*–Me signals falling in the δ = 3.0–3.2 ppm region (Supporting information). The signals at δ = 2.17 and 2.18 ppm (one signal for each rotamer) belong to the *syn*-(*R*,*S*) isomer, while the signals at δ = 2.08 and 2.10 ppm (one signal for each rotamer) belong to the *syn*-*N*–Me of the *rac* isomer. The *anti*-*N*–Me signals of the two rotamers of *rac*-Me_3dienPtdeoxy-Pen overlap at δ = 2.37 ppm. Terminal *N*–Me signals were used to assign the signals of the aromatic protons. The a,b and a′,b′ pairs of resonances in the 1D trace (Figure 3) belonging to the *syn*-(*R*,*S*) isomer are assigned to the H8 and H6 protons, respectively, because of the presence of EXSY cross-peaks between a and b and between a′ and b′ resonances (not shown). The more intense pair of signals (a,a′) is characterized by having a stronger NOE between the H6 and terminal *N*–Me signals (cross-peak a′ in the 2D spectrum) than between the H8 and terminal *N*–Me signals (cross-peak a); therefore, this intense pair is assigned to the *endo* rotamer (H6 adjacent to *N*–Me groups). The weaker pair of signals (b,b′) is thus assigned to the *exo* rotamer. The *endo*/*exo* ratio is ca. 1.4.

For the *rac* isomer, again two rotamers of slightly different abundances are observed (pairs of H8,H6 signals, c,c′ and d,d′). For the more intense pair of signals (c,c′) the H8 signal (c) has a cross-peak to the *anti*-*N*–Me signal, and the H6 signal (c′) has a cross-peak to the *syn*-*N*–Me signal; thus, c,c′ are assigned to the *endo* rotamer. In contrast, for the weaker pair of signals (d,d′) the H8 signal (d) has a cross-peak to the *syn*-*N*–Me signal, and the H6 signal (d′) has a cross-peak to the *anti*-*N*–Me signal; therefore d,d′ are assigned to the *exo* rotamer.

Within the set of H8 signals for the two isomers (Figure 3), the most upfield signals belong to *endo* rotamers, while the most downfield signals belong to *exo* rotamers, as found previously.[24] In contrast, the H6 signals show the reverse trend (the most upfield signals belong to the *exo* rotamers, while the most downfield signals belong to the *endo* rotamers).

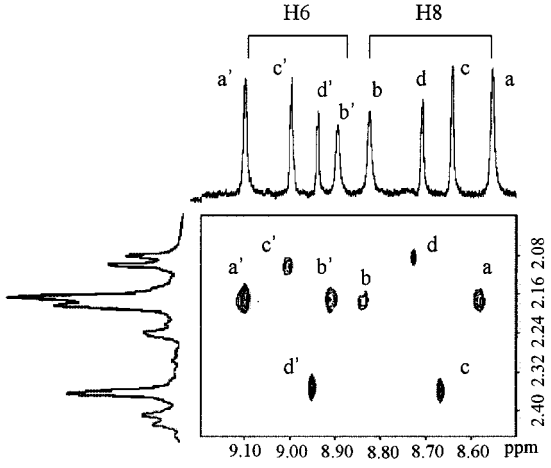

Figure 3. Selected regions of the ROESY spectrum (258 K, pH* = 5.3) for Me_3dienPtdeoxy-Pen. Protons H8 (a−d) and H6 (a′−d′) are labeled.

For *syn*-(*R*,*S*)-Me_3dienPtdeoxy-Pen, the rate constants for interconversion between rotamers were evaluated by spectral simulation between 255 K and 353 K performed at pH* = 1 (Figure 4, Table 3).

It is noteworthy that for the *exo* rotamer the chemical shifts of the H8 and H6 signals are rather close. One-dimensional NMR experiments show that a change of pH* from 1 (protonated N1) to 5.3 (non-protonated N1) causes a change in the relative positions of these two resonances (the H8 signal downfield to the H6 signal at pH* = 1 and upfield at pH* = 5.3). ROESY experiments performed at the two pH* values confirmed the correctness of all 1D assignments.

The enthalpy and entropy of activation ($\Delta H^{\neq}$ and $\Delta S^{\neq}$, respectively) were estimated from plots of ln(k/T) vs. 1/T, which were linear within experimental error (Supporting information, Table 4). With respect to the transition state, both the *endo* and *exo* rotamers are lower in enthalpy (by

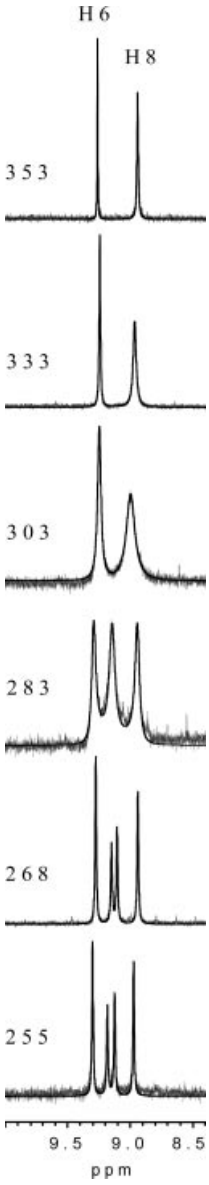

Figure 4. Experimental (pH* = 1, gray line) and simulated (dark line) NMR spectra in the H8 region for *syn*-(*R*,*S*)-Me_3dienPtdeoxyPen at sample temperatures indicated.

111 ± 2 and 105 ± 2 kJ·mol^{-1}, respectively) and entropy (by 181 ± 4 and 159 ± 4 J·K^{-1}·mol^{-1}, respectively). The *endo* rotamer is lower in enthalpy (6 kJ·mol^{-1}) and entropy (22 J·K^{-1}·mol^{-1}) than the *exo* rotamer. An analogous trend was already noted for the Pen complex (ΔH of 7 kJ·mol^{-1} and ΔS of 21 J·K^{-1}·mol^{-1}).

Me_3dienPtMeA

The reaction of *syn*-(*R*,*S*)-[Pt(Me_3dien)(NO_3)](NO_3) with a slight excess of MeA (molar ratio 1:1.4) was carried out in D_2O, pH′ = 1. The low pH ensures not only the absence of isomerization of the carrier ligand from its original *syn*-(*R*,*S*) configuration, but also coordination of adenine through N7 because N1 is fully protonated (pK_a = 4.3).[26] After 3 d at 298 K, 80% of the initial platinum complex had reacted, and another aliquot of MeA was added (Figure 5).

On the basis of their different intensities, the resonances can be grouped into two sets. The most intense set includes signals at δ = 3.82, 8.53, and 8.94 ppm; the second set, less intense, includes signals at δ = 3.84, 8.51, and 9.19 ppm. The intensity ratio between the two sets is ca. 3. The presence of two sets of resonances can be explained by the presence of two rotamers.

For each set of resonances the intensity of the most downfield signal decreased with time (δ = 8.94 and 9.19 ppm, respectively). Such a decrease in intensity is expected to take place for signals belonging to H8 protons, which are known to undergo exchange with deuterium of the solvent.[27,28] The downfield shift of the H8 and H2 resonances, consequent to coordination to the platinum atom (ca. 0.7 and 0.15 ppm, respectively), and the differences in chemical shift between the two H8 ($\Delta\delta$ = 0.25 ppm) and the two H2 resonances ($\Delta\delta$ = 0.02 ppm) are in agreement with N7 coordination of MeA. In fact, the H8 proton, being much closer to the donor atom (N7) than H2, will not only be more deshielded by the metal center, but will also experience more different chemical environments in the two rotamers.

The correct assignment of the H8 and H2 resonances was also confirmed by an inversion recovery experiment (Supporting information): the longitudinal relaxation time (T_1) of the H2 protons was about three times longer than that of the H8 protons, as previously reported for adenine derivatives.[29]

Although the coordinated *syn*-(*R*,*S*)-Me_3dien configuration is rather stable at low pH, a sample of Me_3dienPtMeA kept at 298 K for 30 d showed partial isomerization from the initial *syn*-(*R*,*S*)-Me_3dienPtMeA to the *rac*-Me_3dienPtMeA. A NOESY experiment was performed on this sample (pH* = 1, 278 K) in order to assign the *endo* or *exo* conformation to the two rotamers of the *syn*-(*R*,*S*) and *rac* species.

NOE cross-peaks between central and terminal *N*–Me signals (Figure 6 A) allow us to distinguish between *syn*- and *anti*-*N*–Me groups. For *syn*-(*R*,*S*)-Me_3dienPtMeA the NOE cross-peaks between central and terminal *N*–Me resonances (labeled a) fall at δ = 2.33/3.21 ppm (for the minor rotamer) and at δ = 2.34/3.24 ppm (for the major rotamer). For the *rac* isomer, the terminal *N*–Me signal at δ = 2.28 ppm gives an NOE cross-peak with the central *N*–Me signal at δ = 3.16 ppm (coincident peaks for the two rotamers, b); therefore, the resonance at δ = 2.28 ppm is assigned to the *syn*-*N*–Me group of both rotamers. As a consequence, the resonances of the terminal *N*–Me groups at δ = 2.51 and 2.54 ppm (two distinct signals for the two rotamers), which do not give NOE cross-peaks with the central *N*–Me resonances, are assigned to the *anti*-*N*–Me signals of the minor and major rotamer of the *rac* isomer, respectively.

For *syn*-(*R*,*S*)-Me_3dienPtMeA the minor rotamer has an intense NOE cross-peak between H8 and the terminal *N*–Me signals (δ = 9.30/2.33 ppm, c in Figure 6 B). In contrast, the major rotamer (H8; δ = 9.03 ppm) lacks such a cross-

Table 4. Activation enthalpy [kJ·mol^{-1}] and entropy [J·K^{-1}·mol^{-1}] for interconversion between rotamers in *syn*-(*R*,*S*)-Me_3dienPtL, at pH′ = 1.

L	$\Delta H^{\neq}_{endo}$	$\Delta H^{\neq}_{exo}$	$\Delta S^{\neq}_{endo}$	$\Delta S^{\neq}_{exo}$
Pen	61 ± 2	54 ± 2	–8 ± 2	–29 ± 2
EtG[24]	65 ± 2	56 ± 2	2 ± 2	–28 ± 2
deoxy-Pen	111 ± 2	105 ± 2	181 ± 4	159 ± 4

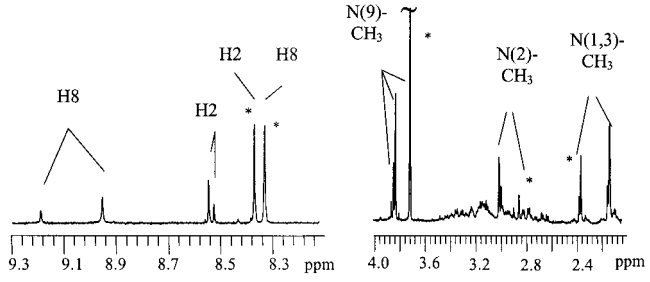

Figure 5. ^{1}H NMR spectrum (295 K, pH* = 1) of *syn*-(*R*,*S*)-Me_3dienPtMeA in the presence of an excess of MeA and some unchanged *syn*-(*R*,*S*)-$[Pt(Me_3dien)(H_2O)]^{2+}$ substrate (signals labeled with an asterisk).

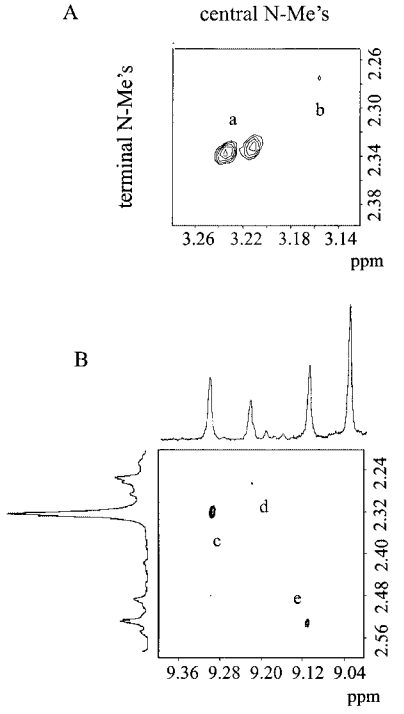

Figure 6. Selected regions of the NOESY spectrum (278 K, pH* = 1) of Me_3dienPtMeA. Spectrum A: Equatorial *N*–Me/central *N*–Me region; NOE cross-peaks are labeled a and b for the *syn*-(*R*,*S*) and *rac*-Me_3dienPtMeA, respectively. Spectrum B: Terminal *N*–Me/aromatic proton region; NOE cross-peaks are labeled c, d, and e for the *exo* rotamer of *syn*-(*R*,*S*)-Me_3dienPtMeA and for the *exo* and *endo* rotamers of the *rac* isomer, respectively.

peak. Thus, it is possible to assign the *exo* conformation to the minor rotamer (H8 near the terminal *N*–Me group with respect to the coordination plane) and the *endo* conformation to the major rotamer.

For *rac*-Me_3dienPtMeA, NOE cross-peaks were observed between the H8 signal of the minor rotamer and the *syn*-*N*–Me signal (δ = 9.22/2.28 ppm, d in Figure 6 B), and between the H8 signal of the major rotamer and one *anti*-*N*–Me signal (δ = 9.11/2.54 ppm, e in Figure 6 B); therefore, the *exo* form is assigned to the minor rotamer and the *endo* form to the major rotamer.

For *syn*-(*R*,*S*)-Me_3dienPtMeA, ^{1}H NMR spectra recorded between 268 and 353 K did not show significant broadening of the resonance peaks, indicating that the rotation around the Pt–N7 bond is slow on the NMR time scale, even at 353 K.

Discussion

In a previous study the Me_3dienPtL system (L = 9-ethylguanine, 5′-guanosine monophosphate, and 3′-guanosine monophosphate; EtG, 5′-GMP, and 3′-GMP, respectively) was used to investigate the effect of the substituent in position 9 of a guanine base upon the rotamer ratio and the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

rate of rotamer interconversion. The most interesting result of that investigation was the great tendency of the 5′-phosphate to form an H bond to the NH group of a *cis*-amine when phosphate and N–H are on the same side of the platinum coordination plane. As a consequence, the *endo* rotamer was the exclusive form for the *syn*-(*R*,*S*) species (at neutral and basic pH). In contrast, for the EtG and 3′-GMP complexes, in which such an interaction cannot take place, the *endo* and *exo* rotamers were present in comparable amounts with a slight preference for the *endo* rotamer. Moreover, in one case (EtG complex) the rate of interconversion between *endo* and *exo* rotamers was investigated by ^{1}H NMR and the activation parameters ($\Delta H^{\neq}$ and $\Delta S^{\neq}$) evaluated. Because the rate of rotation is expected to be very much dependent upon the substituent in position 6 of the ring system, we looked for purine bases differing in the nature of this substituent. Penciclovir, deoxy-Penciclovir, and 9-methyladenine appeared to be most appropriate because two of them have moderately bulky hydrophilic substituents of opposite surface charge (electron-rich oxygen in Penciclovir and electron-poor amine protons in adenine), and deoxy-Penciclovir has a sterically much less demanding H substituent.

Factors Influencing Rotation Around the Pt–N(7) Bond

Most notably, the behavior of the Pen derivative is very similar to that of the EtG derivative previously investigated.[24] The Pen and EtG complexes have not only very similar ratios between *endo* and *exo* rotamers, but also very similar rate constants and activation parameters for interconversion (Table 4). This finding indicates that the different nature of the N9 substituents [Et and 4-hydroxy-3-(hydroxymethyl)butyl for EtG and Pen, respectively] does not influence the ratio and interconversion rate of rotamers. The N9 substituents project in a direction opposite to that of the platinum core, and there is little chance for interaction with the *cis*-amine groups [except in the case of 5′-phosphate-(deoxy)ribo derivatives].

Quite surprising are the comparable rates of rotation observed in the compounds with Pen and deoxy-Pen. We expected a much faster rate of rotation in the deoxy-Pen derivative because of the much smaller steric bulk of the proton, as compared to an oxygen atom, at position 6 of the purine system. A possible explanation for this apparent paradox is suggested by the activation parameters for rotation about the Pt–N7 bond. In the deoxy-Pen complex the transition state is much higher in both enthalpy (average 108 ± 3 kJ·mol^{-1}) and entropy (average 170 ± 11 J·K^{-1}·mol^{-1}), with respect to the *endo* and *exo* ground states, than in the Pen complex (average $\Delta H^{\neq}$ and $\Delta S^{\neq}$ of 57 ± 4 kJ·mol^{-1} and -18 ± 11 J·K^{-1}·mol^{-1}, respectively). It is therefore rather surprising that in the case of Pen, carrying a rather bulky substituent in position 6 of the purine ring (O), the enthalpy of activation is ca. 50 kJ·mol^{-1} lower than in the case of deoxy-Pen, carrying a much smaller group (H).

We believe that the charge of the C6 substituent, in addition to its steric bulk, is very important also. It has been observed that the H8 of a purine carries a partial positive charge and also H6 (in the case of deoxy-Pen), although to a lesser extent, is likely to carry a partial positive charge.[30] In contrast, the O6 of Pen is electron rich. In the transition state, the purine is dragged through the platinum coordination plane, and H8 and X6 (X = O or H) approach the *cis*-amines. Because of the electronegativity of the nitrogen atom, the amine H and Me groups are expected to bear a partial positive charge. For Pen the opposite charge of O6 and of the *cis*-amine substituents (H or Me) evidently favors the bulky O6 group passing through the coordination plane. In other words, the O6 of Pen is an H bond acceptor while the amine group is an H-bond donor, and the attractive interaction between the two groups is likely to lower the rotational barrier. Pen also has very little entropy of activation. If, as we believe for an intramolecular process, the entropy of activation is mainly related to solvation/desolvation phenomena, we must conclude that in the present case (attractive interaction between the two groups passing by) there is only a reorganization of the solvation shells, without release of water molecules.

For deoxy-Pen, the purine H6 and the *cis*-amine substituents (H or Me) both carry a partial positive charge. The electrostatic repulsion between the two positively charged moieties, coming close to one another, will increase the rotational barrier, notwithstanding the small size of H6 compared to O6 of Pen. Moreover, deoxy-Pen (unlike Pen) has a very large entropy of activation (average 170 ± 11 J·K^{-1}·mol^{-1}). We propose that, in the presence of an electrostatic repulsion between the two groups passing by, there is a large desolvation process with consequent release of water molecules. This desolvation process will result in a large activation entropy and a further increase of activation enthalpy.

The explanation given above for the Pen and deoxy-Pen complexes fully accounts for the behavior of the MeA derivative, in which the substituent in position 6 of the purine ring is bulky (even more than O6 of Pen) and positively charged (like the substituents on the *cis* amine). Under these circumstances the barrier to rotation is expected to be far greater than that observed for Pen or deoxy-Pen, with the consequence that the interconversion between rotamers remains slow on the NMR time scale, even at the highest temperature explored (353 K).

Strong support in favor of the explanation given above comes from a parallel investigation regarding the rotation of guanine or adenine derivatives in platinum substrates in which the groups *cis* to the purine are H bond acceptors rather than H bond donors. In this case the trend is reversed and rotation is faster for adenine than guanine.

Factors Determining Conformer Distribution

The rotamer distribution found for the Me_3dienPtPen complex is, as expected, identical to that observed for Me_3-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

dienPtEtG.[24] For the *syn*-(*R*,*S*) isomer, the preference is for the *endo* rotamer having the bulky six-membered ring on the same side of the platinum coordination plane as the *N*–Me groups (*endo*/*exo* ratio of 2 at 273 K). The *exo* conformation, which could form H bonds between the N–H group of *cis*-amines and O6 of the purine, is less favored. This evidence is contrary to a long-held belief that H bonds between purine derivatives and the NH group of platinum-carrier ligands are of primary importance in stabilizing the complexes in solution.[31] On the other hand, for the *rac*-Me_3dienPtPen isomer the *endo*/*exo* ratio is 1, as observed for the *rac* isomer of the complex with EtG. The *rac* isomer has one N–H and one *N*–Me group on each side of the platinum coordination plane; therefore, it is plausible that the two rotamers have similar stability.

In the Me_3dienPtdeoxy-Pen complex, the *syn*-(*R*,*S*) isomer again has a slight preference for the *endo* rotamer (*endo*/*exo* ratio of 1.3 at 273 K). Therefore, in this case also the *endo* rotamer, in which the six-membered ring of Pen is on the more crowded side of the platinum coordination plane, is more favored. Moreover, this *endo*/*exo* ratio of 1.3 is also observed for the *rac* isomer.

The *endo*/*exo* ratio, which is in the range of 2–2.5 for G derivatives (Pen and EtG complexes), is ca. 2.9 for the MeA complex (Table 1). In the case of MeA, the racemic isomer also shows a net preference for the *endo* rotamer (*endo*/*exo* ratio of ca. 2.2), while such a preference is much smaller for G complexes (*endo*/*exo* ratio in the range 1–1.2). Moreover, because for MeA the interconversion between rotamers is still very slow (on the NMR time scale) at the highest temperature explored, we do not know if the observed *endo*/*exo* ratio represents the thermodynamic equilibrium or is a kinetically determined composition.

In summary, at 298 K all complexes show a preference for the more crowded *endo* rotamer; moreover, the preference for such a rotamer appears to increase as the size of the substituent in position 6 of the purine ring system increases, independently of its charge. We do not have a good explanation for such a preference; however, we wish to point out that, in terms of free energy, the difference between the two rotamers is very small (less than 2.5 kJ·mol^{-1} at 300 K) and thus very difficult to account for.

For cases in which it has been possible, from kinetic data, to evaluate the difference in ΔH and ΔS between *endo* and *exo* rotamers (EtG, Pen, and deoxy-Pen complexes), the *endo* rotamer is lower in both enthalpy and entropy with respect to the *exo* rotamer (average 7 ± 2 kJ·mol^{-1} and 26 ± 4 J·K^{-1}·mol^{-1} for ΔH and ΔS, respectively). For the *syn*-(*R*,*S*)-Me_3dienPtEtG complex[24] we hypothesized that in the less abundant *exo* rotamer, interference between solvation shells of the purine C6 substituent and the *cis*-amine NH groups could lead to release of water molecules with a consequent slight increase in enthalpy and entropy. The stabilizing effect of the greater ΔS would not compensate for the destabilizing effect of the greater ΔH. The same explanation could also apply to the present case. We hope to gain a deeper insight in the *endo*/*exo* preference of rotamers by extending the investigation to purine bases carrying different substituents in position 8 of the purine ring system, so as to counterbalance the effect of substituents in position 6 of the purine.

Experimental Section

Materials: [Pt(Me_3dien)(NO_3)](NO_3) was prepared as previously reported.[22] Penciclovir [9-(4-hydroxy-3-hydroxymethylbut-1-yl) guanine, Pen] and 6-deoxy-Penciclovir (deoxy-Pen) were a gift of the Institute of Chemistry of Ljubljana, Slovenia. 9-Methyladenine (MeA) was prepared according to a literature method.[32]

Preparation of Adducts: Solutions of the adducts were prepared by treatment of [Pt(Me_3dien)(NO_3)](NO_3) (5 mM solution in D_2O at pH* = 1 or ca. 6) with a stoichiometric amount of L (L = Pen, deoxy-Pen, or MeA). Reactions were monitored by ^{1}H NMR until the disappearance of free L (or constant intensity ratio between free and complexed L in the case of an excess of L). Standard DNO_3 and NaOD solutions (in D_2O) were used to adjust the pH* of each sample directly in the NMR tube when necessary. 1D NMR studies were normally performed at 295 K. NOESY experiments were performed at 263 K (solvent D_2O/CD_3OD, 80:20 v/v) or 258 K (solvent D_2O/CD_3OD, 70:30 v/v).

1D NMR Spectroscopy: 1D NMR spectra were collected with a Varian Unity 600 spectrometer (spectral width, 6 kHz). The residual HOD peak was used as reference. In a typical experiment, a selective presaturation pulse (10 dB) was applied for 1 s to the residual HOD resonance. The FID was accumulated for 64 transients in blocks containing 16 K data points. Before Fourier transformation, the FIDs were baseline-corrected for DC offset before an exponential multiplication apodization function with a 0.2 Hz line broadening was applied. Selected ^{1}H chemical shifts of the purine base and the Me_3dien ligand are reported in Table 1.

2D NMR Spectroscopy: 2D NMR spectra (512×2048 matrices with a spectral window of 6–7 kHz in each dimension) were recorded with a Varian Unity 600 Spectrometer.[33] For the NOESY and ROESY experiments, a 500-ms mixing time was used. A 1-s presaturation pulse was typically used to saturate the HOD resonance. Spectra were processed using Felix 97.0 (MSI) with a Silicon Graphics INDY R4400 workstation. Typical processing involved zero filling of the t_1 dimension to 2048 points, exponential multiplication (0.4 Hz line broadening) in t_2, and applying a sine bell function shifted 90° over all points in t_1.

Line-Shape Analysis: For *syn*-(*R*,*S*)-Me_3dienPtL complexes (L = Pen or deoxy-Pen), the rate constants for interconversion between the *endo* and *exo* rotamers at different temperatures were calculated from line-shape analyses of ^{1}H NMR spectra collected with a Bruker AVANCE 300 MHz spectrometer. The simulation of the spectra was performed in the temperature range 255–353 K using DNMR6, a dynamic NMR spectra simulation FORTRAN code.[34] Rate constants for interconversion at different temperatures are reported in Table 2 and Table 3 for Pen and deoxy-Pen complexes, respectively. By applying the Eyring equation, the enthalpy and the entropy of activation ($\Delta H^{\neq}$ and $\Delta S^{\neq}$) were evaluated (Table 4).[35] In order to avoid ligand isomerization, a pH* value of 1 was used.

Supporting Information: See also footnote on the first page of this article. ln(k/T) as a function of 1/T for *syn*-(*R*,*S*)-Me_3dienPtPen at pH* = 1; selected regions of the ROESY spectrum (258 K, pH* = 5.3) for Me_3dienPtdeoxy-Pen; ln(k/T) as a function of 1/T for *syn*-(*R*,*S*)-Me_3dienPtdeoxy-Pen at pH* = 1; inversion recovery experiment for *syn*-(*R*,*S*)-Me_3dienPtMeA at pH* = 1.

Endohedral Metallocenophanes of Rhodium and Cobalt

Carsten Schaefer,[a] Gerald Scholz,[a] Rolf Gleiter,*[a] Thomas Oeser,[a] and Frank Rominger[a]

Dedicated to Professor Paul von Ragué Schleyer on the occasion of his 75th birthday

Keywords: Cage compounds / Sandwich complexes / Alkynes / Rhodium / Cobalt

The synthesis of seven endohedral metallocenophanes of rhodium (**7b**, **8b**) and cobalt (**1d**−**h**) with a cyclopentadienyl unit as one of the π-systems and a cyclobutadiene or cyclopentadienone unit as the second π-system is described, including the synthesis of the unsubstituted parent compound of the [CpCo(cbd)]-derived endohedral phanes, [3.3]-η^5-(1,1′,3,3′)-cyclopentadienyl–η^4-(cyclobutadienophane)cobalt(I) (**1h**). This compound could be obtained by deprotection of the corresponding trimethylsilyl-substituted endohedral phane **1g**. The X-ray structures of **7b**, **1e**, **1g** and **1h** could be obtained. This paper compares their structural properties to the complexes reported in previous short communications.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

In [*n.n*]phanes[1−4] the cyclic conjugated π-systems which are held in place by at least two bridges, such as hydrocarbon chains, offer a variety of bonding modes for metal centres. The cage structures of these phanes exhibit an inside and an outside face leading to two binding modes for a metal atom or metal fragment to the π-systems: inside the cage (endohedral, **A**) or outside the cage (exohedral, **B**) as shown in Figure 1.[5]

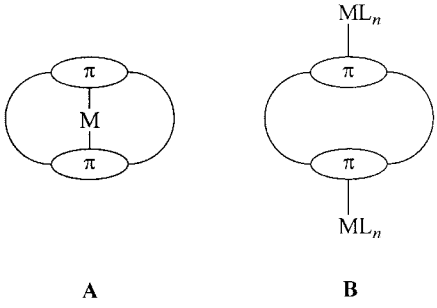

Figure 1. Endohedral (**A**) and exohedral (**B**) bonding modes of metallocenophanes.

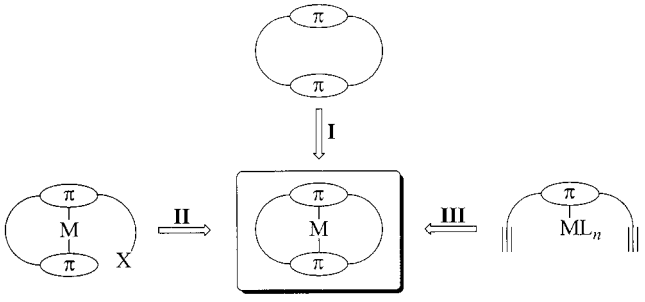
In comparison to the numerous examples of the exohedral metallocenophanes reports of endohedral phanes are much rarer because of their limited accessibility. However, they deserve special interest because the hydrocarbon cage is able to stabilize low oxidation states of the incorporated metals. This has been demonstrated by complexing Ga^{I} and Ge^{II} in [2.2.2]paracyclophane.[6] In the literature there are reports of two protocols for the synthesis of endohedral metallocenophanes:

Either by reacting metal atoms or metal ions directly with the appropriate cyclophanes (path **I** in Scheme 1),[6,7] or by building the tethers on a metallocene in a stepwise fashion (path **II**).[8] Recently, we developed a third path (**III**) by utilizing substituted half-sandwich complexes which are able to form the second π-system by an intramolecular metal mediated cyclization of alkyne units (Scheme 1).[9]



Scheme 1. Protocols **I**–**III** for the synthesis of endohedral metallocenophanes.

Using this third synthetic pathway we were able to synthesize the cobalt and rhodium complexes **1a**−**h**, **2c**, **3a**–**b**, **4a**–**b**, **5a**, and **6a** (Figure 2), of which **1a**, **1b**, **1e**, **1g**, **1h**, **5a**, and **6a** were investigated by X-ray diffraction.[9,10]

In this paper we report the synthesis of two endohedral rhodium phanes **7b** and **8b** (Figure 3), four endohedral co-

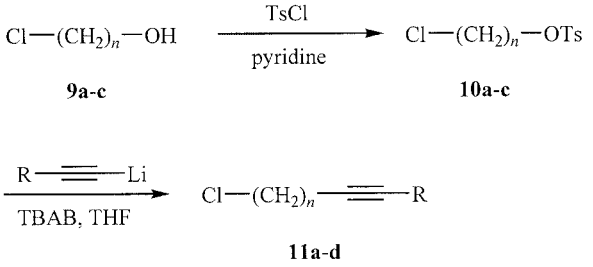
Results and Discussion

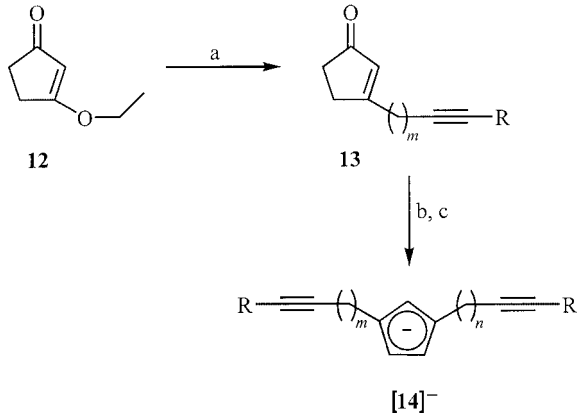
Synthesis

The synthesis of the ω-haloalkynes **11a**–**d** necessary as building blocks for the tethers in the endohedral phanes was achieved by the substitution of tosylated ω-chloro alcohols **10a**–**c** by lithiated *tert*-butylacetylene or (trimethylsilyl)acetylene, respectively (Scheme 2).



Scheme 2. Synthesis of ω-haloalkynes **11a**–**d** [$n = 3$, R = *t*Bu (**a**); $n = 4$, R = *t*Bu (**b**); $n = 5$, R = *t*Bu (**c**); $n = 3$, R = $SiMe_3$ (**d**)] from ω-hydroxy alcohols **9a**–**c** [$n = 3$, R = *t*Bu (**a**); $n = 4$, R = *t*Bu (**b**); $n = 5$, R = *t*Bu (**c**)].

The disubstituted cyclopentadiene derivatives that we used as ligands for the half-sandwich complexes were synthesized by a two step procedure (Scheme 3).[9] In the first step the first alkyne substituent was introduced by treatment of 3-ethoxycyclopent-2-ene-1-one (**12**) with a Grignard reagent of an ω-chloroalkyne **11**. Acidic workup of the reaction mixture yielded the respective 3-alkynylcyclopent-2-enones **13**. The second alkyne substituent was introduced in a similar reaction and again acidic workup led to the desired disubstituted cyclopentadienes. The resulting cyclopentadiene derivatives were deprotonated with *n*-butyllithium in THF shortly before their complexation with metal dicarbonyl fragments.



Scheme 3. Two step synthesis of 1,3-difunctionalized cyclopentadienyllithium salts [**14b**]⁻ ($n = m = 4$, R = *t*Bu) and [**14d**–**g**]⁻ [$n = 3$, $m = 4$, R = *t*Bu (**d**); $n = 3$, $m = 5$, R = *t*Bu (**e**); $n = 4$, $m = 5$, R = *t*Bu (**f**); $m = n = 3$, R = $SiMe_3$ (**g**)]. Reagents: (a) $ClMg–(CH_2)_mC{\equiv}CR$ in THF, then HCl (aq); (b) $ClMg–(CH_2)_nC{\equiv}R$ in THF, then HCl (aq); (c) *n*-butyllithium in THF.

In the case of the rhodium complexes, the lithium salt [**14b**]⁻ was treated with the dicarbonyl(chloro)rhodium dimer in THF to yield the dicarbonyl rhodium complex **15b** (Scheme 4) as an orange oil in 77% yield.

The thermolytic reaction of the dicarbonyl rhodium complex **15b** in refluxing cyclooctane yielded two isomeric endohedral products, **7b** and **8b** (Figure 3). While **7b** was formed in an acceptable yield of 16%, **8b** was only produced in minor quantities (0.5% yield). We were able to grow single crystals of **7b** which were suitable for X-ray diffraction analysis. This allowed us to confirm the structure

Scheme 4. Synthesized dicarbonyl metal complexes **15b** (n = m = 4, R = tBu) and **16d**–**g** [n = 3, m = 4, R = tBu (**d**); n = 3, m = 5, R = tBu (**e**); n = 4, m = 5, R = tBu (**f**); m = n = 3, R = $SiMe_3$ (**g**)].

of **7b** and also to assign the structure of **8b**. For the isomeric endohedral products six isomers are possible, of which four are C_s and two C_1 symmetric. The NMR spectroscopic data for **7b** and **8b** prove the C_1 symmetry of both isolated complexes **7b** and **8b**. As we were able to confirm the structure of **7b** by X-ray analysis the structure of **8b** could also be assigned unambiguously.

Until now only endohedral cobalt phanes bearing alkyl chains of the same length (m = n) had been synthesized.[9,10] To investigate the amount of distortion resulting from two different alkyl chains, the endohedral cobalt phanes **1d** (m = 3, n = 4, R = tBu), **1e** (m = 3, n = 5, R = tBu), **1f** (m = 4, n = 5, R = tBu) were envisaged. To obtain the dicarbonyl cobalt complexes **16d**–**f** we reacted the deprotonated cyclopentadiene derivatives [**14d**–**f**]$^-$ with $[Co_2(CO)_8]/I_2$. The thermolytic reaction of these half-sandwich complexes in refluxing cyclooctane resulted in the formation of the endohedral complexes **1d**–**f** in 5% (**1d**), 30% (**1e**) and 15% (**1f**) yield.

For the synthesis of the parent compound **1h** of the recently published endohedral [3.3]phane **1a** we made use of TMS as protecting groups on the cyclobutadiene unit (Scheme 5).[11] The twofold TMS substituted phane **1g** was obtained in 35% yield analogously to **1a** by refluxing the dicarbonyl cobalt complex **16g** in cyclooctane. The removal of the TMS groups was achieved in 74% yield by stirring a solution of **1g** with Me_4NF at 80 °C.

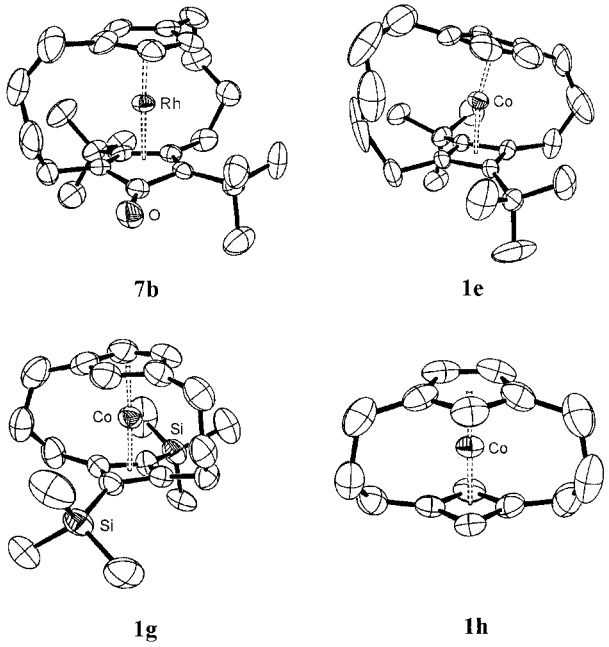
Scheme 5. Synthesis of unsubstituted phane **1h** by deprotection.

Structural Investigations

Crystals suitable for X-ray crystallographic studies could be obtained for the complexes **7b**, **1e**, **1g** and **1h**. In Figure 4, the molecular structures of these endohedral phanes are shown.



7b 1e

1g 1h

Figure 4. ORTEP plots (50% ellipsoid probability) of the molecular structures of **7b**, **1g** (left), **1e** and **1h** (right).

Including the previously described molecular structures,[9,10] a total number of eight crystallographically studied endohedral phanes synthesized with our protocol are available and can now be compared. Selected structural properties of these complexes are listed in Table 1.

Table 1. Structural properties of endohedral metallocenophanes **1a**, **1b**, **1g**, **1h**, **5a**, **6a** and **7b**.[a]

	Interplanar angle α [°]	Angle β [°]	(η^5-Cp)–M distance [Å]	M–(η^4-ligand) distance [Å]
1a[9]	6.6	174.2	1.604	1.645
1b[9]	4.0	178.3	1.670	1.692
1e	13.6	166.9	1.677	1.678
1 g[b]	6.8/7.2	173.6/173.1	1.609/1.604	1.645/1.650
1h	9.9	170.8	1.590	1.631
5a[10]	4.3	175.6	1.777	1.742
6a[10]	22.2	170.9	1.806	1.751
7b	5.1	174.8	1.857	1.791

[a] For the calculation of angles and centroids, all five C atoms of the Cp rings were used, but only the four coordinated C atoms of the η^4-ligands (cyclopentadienone or cyclobutadiene). [b] The two different values refer to two independent molecules in the unit cell.

The larger atomic radius of rhodium results in larger distances between the metal centre and the coordinated η^5-Cp ligand as well as the η^4-coordinated unit. While these distances for the rhodium complexes range from 1.78–1.86 Å [(η^5-Cp)···M distance] and 1.74–1.79 Å [M···(η^4-ligand) distance], the cobalt complexes show values of 1.59–1.68 Å [(η^5-Cp)···M distance] and 1.63–1.69 Å [M···(η^4-ligand) distance]. Within these limits the distances vary ac-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

cording to the lengths of the alkyl chains and to the substitution pattern. First, the structural features of the rhodium complexes shall be compared. Generally there exist six possible isomers for endohedral [*n.n*]phanes with a Cp and a cyclopentadienone unit, namely two C_1- and four C_s-symmetric. Of these six isomers three are represented by the complexes **5a** (C_1), **6a** (C_s) and **7b** (C_1). Because of the shorter alkyl bridges the two [3.3]phanes **5a** and **6a** are more strained than the [4.4]phane **7b**, which has the largest distances between the rhodium centre and the π-ligands. The two [3.3]phanes also differ in the strain of the carbon cage. The substitution pattern of the π-ligands in the C_s-symmetric phane **6a** allows the molecule to reduce the strain by increasing the interplanar angle α (22.2°), which is the largest of all the investigated complexes (Figure 5). The C_1-symmetric [3.3]phane **5a** does not have that much flexibility to reduce strain because of the substitution pattern of the alkyl chains and, therefore, shows a small interplanar angle (α = 4.3°) as well as the shortest rhodium···π-ligand distances.

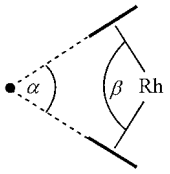


Figure 5. Illustration of the interplanar angle α and angle β.

In the row of the cobalt complexes the shortest bonding lengths between the cobalt centre and the π-ligands are found in the unsubstituted [3.3]phane **1h** [1.590 Å (η^5-Cp)−M distance, 1.631 Å M−(η^4-ligand) distance]. These distances are shorter than those reported for the unbridged species [(η^5-Cp)−M 1.660 Å and M−(η^4-ligand) 1.681 Å].[12] Addition of sterically demanding substituents on the cbd-unit increases these distances, with TMS groups [1.609/1.604 Å (η^5-Cp)−M distance, 1.645/1.650 Å M−(η^4-ligand) distance] having practically the same effect as *t*Bu groups [1.604 Å (η^5-Cp)−M distance, 1.645 Å M−(η^4-ligand) distance]. The metal-ligand distances for **1b** and **1e** are rather close to the parent system.[12] All the symmetrically bridged endohedral cobalt phanes (*n* = *m*) **1a**, **1b**, **1g** and **1h** show nearly parallel π-systems, with the interplanar angles α ranging from 4.0 to 9.9°. In the unsymmetrically bridged **1e** the distortion leads to an enlarged interplanar angle α (13.6°) and to a remarkably small angle β (166.9°), the smallest in all investigated phanes.

Conclusions

Our method of synthesizing metallocenophanes in situ by generating one ligand out of tethered precursors provided us with endohedral complexes of cobalt and rhodium. The yields were low (5%) to moderate (35%). In the case of the cobalt complexes, the generation of a cyclobutadiene or a cyclopentadienone ring is dependent on the reaction temperature. From the dicarbonyl rhodium complexes only the cyclopentadienone ligand was generated. A comparison of five endohedral (η^5-Cp)Co(η^4-Cbd) metallocenophanes revealed the anticipated shortest metal–ligand distances for the [3.3]cyclophane, whereas the other bridges led to metal−ligand distances close to the unbridged species. The relatively short metal−ligand distances for the [3.3]bridged species are also encountered in the case of the rhodium species **5a** and **6a**.

Experimental Section

General Remarks: All melting points are uncorrected. Elemental analyses were carried out by the Mikroanalytisches Laboratorium der Universität Heidelberg. UV/Vis absorption data were recorded with a Hewlett Packard HP 8452A Diode Array-spectrometer. IR spectra were recorded with a Bruker Vector 22 FT-IR spectrometer. The NMR spectra were measured with a Bruker WH 300 or Avance 500 spectrometer (^{1}H NMR at 300 or 500 MHz and ^{13}C NMR at 75 or 125 MHz) using the solvent as internal standard (δ). Standard symbols for signal multiplicities are used; p = pseudo. FAB and FD mass spectra refer to data from a Jeol JMS-700 instrument. All reactions were carried out in dried glassware under argon using dried and oxygen-free solvents.

X-ray Crystallographic Study: Data were collected with a Bruker Smart CCD-diffractometer at 200 K (**7b** and **1e**) and a Bruker Smart Apex-diffractometer at 295 K (**1g** and **1h**). Relevant crystal and data collection parameters are given in Table 2. The structures were solved by direct methods and refined against F^2 with a full-matrix least-square algorithm by using SHELXTL[13] software. In all cases an absorption correction was applied by using SADABS,[14] based on the Laue symmetry of the reciprocal space.

CCDC-249232 (for **1e**), -249234 (for **1g**), -249233 (for **1h**), and -249231 (for **7b**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

General Procedure for the Preparation of ω-Chloroalkynes 11a−d: A dry 100-mL flask was charged with the respective 4-toluenesulfonate, dry THF and *tert*-butylammonium bromide (TBAB) and the mixture was cooled to 0 °C. Alkynyllithium (prepared by the addition of *n*-butyllithium to 1-alkyne in THF) was then added with a cannula. The mixture was stirred at 0 °C (1 h) then allowed to reach room temp. overnight. The solvent was removed, water was added to the residue and the solution was extracted with diethyl ether. The organic layer was washed with brine, dried ($MgSO_4$), filtered and the solvent was evaporated under reduced pressure. The products were purified by distillation.

1-Chloro-6,6-dimethylhept-4-yne (11a): Reaction mixture: 3-chloropropyl-1-tosylate (**10a**) (2.49 g, 10 mmol) and TBAB (3.22 g, 10 mmol) in THF (20 mL), 3,3-dimethylbut-1-yne (0.82 g, 10 mmol) and *n*-butyllithium (3.6 mL, 2.8 M) in THF (20 mL). Yield 1.19 g (75%). Colorless liquid, b.p. 49 °C (2 mbar). ^{1}H NMR (300 MHz, $CDCl_3$): δ = 1.18 (s, 9 H, CH_3), 1.90 (pquint, ^3J = 6.6 Hz, 2 H, CH_2), 2.31 (t, ^3J = 6.8 Hz, 2 H, CH_2), 3.63 (t, ^3J = 6.5 Hz, 2 H, CH_2) ppm. ^{13}C NMR (75 MHz, $CDCl_3$): δ = 16.9 (CH_2), 28.0 (C), 32.0 (CH_3), 32.6 (CH_2), 44.5 (CH_2), 77.0 (C), 90.8 (C) ppm. IR (film) $\tilde{\nu}$ = 2968, 2929, 2867, 1477, 1456 cm^{-1}. HRMS (positive EI) calcd. for $C_9H_{15}Cl$ ([M]$^+$), 160.0833; found, 160.0875 (+4.2 mmu).

1-Chloro-7,7-dimethyloct-5-yne (11b): Reaction mixture: 4-chlorobutyl-1-tosylate (**10b**) (2.63 g, 10 mmol) and TBAB (3.22 g,

General Procedure for the Synthesis of Cyclopent-2-enones 13a–c: In a dry 50-mL flask a Grignard reagent was prepared from chloroalkyne and magnesium in dry THF. The resulting solution was cooled to 0 °C and 3-ethoxycyclopent-2-enone, dissolved in dry THF, was added dropwise. The reaction mixture was stirred at 0 °C (1 h) and then warmed to room temp. overnight. The reaction mixture was poured into ice, and the solution was acidified with 5% hydrochloric acid to pH 5. After extraction with diethyl ether the organic layer was washed with brine, dried ($MgSO_4$), filtered and the solvent was evaporated under reduced pressure. The products were purified by flash column chromatography (silica gel, petroleum ether/diethyl ether, 3:1).

3-(6,6-Dimethylhept-4-ynyl)cyclopent-2-enone (13a): Reaction mixture: 1-chloro-6,6-dimethylhept-4-yne (**11a**) (6.03 g, 38 mmol) and magnesium (0.92 g, 38 mmol) in THF (10 mL), 3-ethoxycyclopent-2-enone (3.0 g, 23.8 mmol) in THF (10 mL). Yield 3.11 g (64%). Colorless oil. ^{1}H NMR (300 MHz, $CDCl_3$): δ = 1.17 (s, 9 H, CH_3), 1.68–1.76 (pquint, ^3J = 7.1 Hz, 2 H, CH_2), 2.19 (t, ^3J = 6.9 Hz, 2 H, CH_2), 2.38 (m, 2 H, CH_2), 2.47–2.52 (m, 2 H, CH_2), 5.94 (s, 1 H, CH) ppm. ^{13}C NMR (125 MHz, $CDCl_3$): δ = 18.3 (CH_2), 26.4 (CH_2), 27.3 (C), 31.3 (CH_3), 31.5 (CH_2), 32.3 (CH_2), 35.2 (CH_2), 77.3 (C), 90.1 (C), 129.6 (CH), 182.3 (C), 210.0 (C) ppm. IR (film) $\tilde{\nu}$ = 2967, 2866, 1710, 1675, 1616, 1437, 1361 cm^{-1}. HRMS (positive

EI) calcd. for $C_{14}H_{20}O$ ([M]$^+$), 204.1514; found, 204.1511 (–0.3 mmu). $C_{14}H_{20}O$ (204.31): calcd. C 82.30, H 9.87, found C 82.02, H 10.32.

3-(7,7-Dimethyloct-5-ynyl)cyclopent-2-enone (13b): Reaction mixture: 1-chloro-7,7-dimethyloct-5-yne (**11b**) (6.56 g, 38 mmol) and magnesium (0.92 g, 38 mmol) in THF (10 mL), 3-ethoxycyclopent-2-enone (3.0 g, 23.8 mmol) in THF (10 mL). Yield 2.65 g (51%). Colorless oil. ^{1}H NMR (300 MHz, $CDCl_3$): δ = 1.14 (s, 9 H, CH_3), 1.44–1.49 (m, 2 H, CH_2), 1.62–1.68 (m, 2 H, CH_2), 2.13 (t, ^3J = 6.9 Hz, 2 H, CH_2), 2.34–2.41 (m, 4 H, CH_2), 2.53–2.55 (m, 2 H, CH_2), 5.91–5.92 (m, 1 H, CH) ppm. ^{13}C NMR (75 MHz, $CDCl_3$): δ = 19.0 (CH_2), 26.6 (CH_2), 27.9 (C), 29.2 (CH_2), 32.0 (CH_3), 32.1 (CH_2), 33.6 (CH_2), 35.9 (CH_2), 78.2 (C), 90.2 (C), 130.2 (CH), 183.4 (C), 210.7 (C) ppm. IR (film) $\tilde{\nu}$ = 2966, 2930, 2864, 1710, 1675, 1616, 1437, 1361 cm^{-1}. UV/Vis (CH_2Cl_2): $\lambda_{max.}$ (log ε) = 276 (2.56), 310 (1.82) nm. HRMS (positive EI) calcd. for $C_{15}H_{22}O$ ([M]$^+$), 218.1671; found, 218.1672 (+0.1 mmu). $C_{15}H_{22}O$ (218.33): calcd. C 82.52, H 10.16; found C 82.11, H 10.36.

3-[5-(Trimethylsilyl)pent-4-ynyl]cyclopent-2-enone (13g): Reaction mixture: (5-chloropent-1-ynyl)trimethylsilane (**11d**) (6.64 g, 38 mmol) and magnesium (0.92 g, 38 mmol) in THF (10 mL), 3-ethoxycyclopent-2-enone (3.0 g, 23.8 mmol) in THF (10 mL). Yield 4.14 g (79%). Colorless oil. ^{1}H NMR (500 MHz, $CDCl_3$): δ = 0.14 (s, 9 H, CH_3), 1.79 (pquint, ^3J = 7.3 Hz, 2 H, CH_2), 2.28 (t, ^3J = 6.9 Hz, 2 H, CH_2), 2.39–2.41 (m, 2 H, CH_2), 2.51 (t, ^3J = 7.7 Hz, 2 H, CH_2), 2.57–2.59 (m, 2 H, CH_2), 5.94–5.96 (m, 1 H, CH) ppm. ^{13}C NMR (125 MHz, $CDCl_3$): δ = 0.2 (CH_3), 19.6 (CH_2), 26.0 (CH_2), 31.7 (CH_2), 32.5 (CH_2), 35.4 (CH_2), 85.9 (C), 106.0 (C), 129.9 (CH), 181.9 (C), 210.0 (C) ppm. HRMS (positive EI) calcd. for $C_{13}H_{20}OSi$ ([M]$^+$), 220.1283; found, 220.1283 (±0.0 mmu). IR (film) $\tilde{\nu}$ = 2957, 2174, 1710, 1675, 1616, 1438, 1409, 1249, 1183, 842, 760 cm^{-1}. $C_{13}H_{20}OSi$ (220.38): calcd. C 70.85, H 9.15; found C 70.91, H 9.32.

General Procedure for the Synthesis of Cyclopentadienes 14b and 14d–g: In a dry 50-mL flask a Grignard reagent was prepared from chloroalkyne and magnesium in dry THF. The resulting solution was cooled to 0 °C, cyclopent-2-enone dissolved in dry THF, was added. The mixture was stirred at 0 °C (1 h) and then allowed to reach room temp. overnight. The reaction mixture was poured into ice, the solution was acidified with 5% hydrochloric acid to pH 5 and extracted with diethyl ether. The organic layer was washed with brine, dried ($MgSO_4$), filtered and the solvent was evaporated under reduced pressure. The product was purified by flash column chromatography [alox III (neutral), petroleum ether] and used directly for the complexation after the removal of solvent.

1,3-Bis(7,7-dimethyloct-5-ynyl)cyclopentadiene (14b): Reaction mixture: 1-chloro-7,7-dimethyloct-5-yne (**11b**) (5.01 g, 29 mmol) and magnesium (0.70 g, 29 mmol) in THF (6 mL), 3-(7,7-dimethyloct-5-ynyl)cyclopent-2-enone (**13b**) (3.21 g, 14.7 mmol) in THF (10 mL). Yield 3.19 g (64%).

1-(6,6-Dimethylhept-4-ynyl)-3-(7,7-dimethyloct-5-ynyl)cyclopentadiene (14d): Reaction mixture: 1-chloro-7,7-dimethyloct-5-yne (**11b**) (5.01 g, 29 mmol) and magnesium (0.70 g, 29 mmol) in THF (6 mL), 3-(7,7-dimethylhept-4-ynyl)cyclopent-2-enone (**13a**) (3.00 g, 14.7 mmol) in THF (10 mL). Yield 0.91 g (19%).

1-(6,6-Dimethylhept-4-ynyl)-3-(8,8-dimethylnon-6-ynyl)cyclopentadiene (14e): Reaction mixture: 1-chloro-8,8-dimethylnon-6-yne (**11c**) (5.41 g, 29 mmol) and magnesium (0.70 g, 29 mmol) in THF (6 mL), 3-(7,7-dimethylhept-4-ynyl)cyclopent-2-enone (**13a**) (3.00 g, 14.7 mmol) in THF (10 mL). Yield 3.53 g (71%).

1-(7,7-Dimethyloct-5-ynyl)-3-(8,8-dimethylnon-6-ynyl)cyclopentadiene (14f): 1-Chloro-8,8-dimethylnon-5-yne (**11c**) (5.41 g, 29 mmol) and magnesium (0.70 g, 29 mmol) in THF (6 mL), 3-(7,7-dimethyloct-5-ynyl)cyclopent-2-enone (**13b**) (3.21 g, 14.7 mmol) in THF (10 mL). Yield 2.44 g (47%).

1,3-Bis[5-(trimethylsilyl)pent-4-ynyl]cyclopentadi-ene (14g): (5-Chloropent-1-ynyl)trimethylsilane (**11d**) (5.07 g, 29 mmol) and magnesium (0.70 g, 29 mmol) in THF (6 mL), 3-[5-(trimethylsilyl) pent-4-ynyl]cyclopent-2-enone (**13g**) (3.24 g, 14.7 mmol) in THF (10 mL). Yield 2.37 g (64%).

Dicarbonyl-η^5-[1,3-bis(7,7-dimethyloct-5-ynyl)cyclopentadienyl]rhodium(I) (15b): *n*-Butyllithium (2.6 mL, 1.6 M in hexane, 2.68 mmol) was added to a solution of cyclopentadiene **14b** (1.12 g, 3.30 mmol) in 10 mL of THF at –40 °C. After warming up to room temperature the solution was added to a solution of dicarbonyl(chloro) rhodium(I) dimer (0.50 g, 0.83 mmol) in 100 mL of THF and stirred for 24 h. The solvents were removed under vacuum and the products purified by flash column chromatography on silica gel using pentanes/diethyl ether (20:1) as eluent. Yield 636 mg (77%). Orange oil. ^{1}H NMR (500 MHz, $CDCl_3$): δ = 1.17 (s, 18 H, CH_3), 1.50 (m, 4 H, CH_2), 1.58 (m, 4 H, CH_2), 2.13 (m, 4 H, CH_2), 2.25 (m, 4 H, CH_2), 5.25 (ps, 2 H, CH), 5.38 (ps, 1 H, CH) ppm. ^{13}C NMR (125 MHz, $CDCl_3$): δ = 18.5 (CH_2), 27.4 (C), 27.9 (CH_2), 28.9 (CH_2), 31.4 (CH_2), 31.5 (CH_3), 78.0 (C), 86.0 (CH, $J_{Rh,C}$ = 3.8 Hz), 89.1 (CH, $J_{Rh,C}$ = 3.8 Hz), 89.5 (C), 110.6 (C, $J_{Rh,C}$ = 3.8 Hz), 192.7 (CO, $J_{Rh,C}$ = 83.8 Hz) ppm. IR (film) $\tilde{\nu}$ = 2967, 2862, 2034, 1969, 1476, 1456, 1361 cm^{-1}. UV/Vis (CH_2Cl_2): $\lambda_{max.}$ (log ε)= 240 (4.18), 296 (3.62) nm. MS (positive FD): m/z = 468 ([M – CO]$^+$).

General Procedure for the Synthesis of Dicarbonylcobalt Complexes 16d–g: A dry flask was charged with [$Co_2(CO)_8$] and dry THF, I_2 was added and the green mixture stirred at room temp. for 1 h. The green solution was cooled to 0 °C and a solution of cyclopentadienyllithium (prepared by the addition of *n*-butyllithium to a solution of cyclopentadiene in dry THF at –40 °C) was added. The brown mixture was stirred at 0 °C (1 h), then allowed to warm to room temp. overnight. The solvent was evaporated under reduced pressure and the product was purified by flash column chromatography [alox III (neutral), petroleum ether].

Dicarbonyl-η^5-[1-(6,6-dimethylhept-4-ynyl)-3-(7,7-dimethyloct-5-ynyl)cyclopentadienyl]cobalt(I) (16d): Reaction mixture: [$Co_2(CO)_8$] (402 mg, 1.2 mmol) and I_2 (299 mg, 1.2 mmol) in THF (25 mL), 1-(6,6-dimethylhept-4-ynyl)-3-(7,7-dimethyloct-5-ynyl)cyclopentadiene (**14d**) (0.9 g, 2.8 mmol) and *n*-butyllithium (2.4 mL, 1.6 M in hexane) in THF (5 mL). Yield 285 mg (55%). Orange oil. ^{1}H NMR (300 MHz, C_6D_6): δ = 1.32 (s, 9 H, CH_3), 1.34 (s, 9 H, CH_3), 1.50–1.64 (m, 6 H, CH_2), 2.10–2.56 (m, 8 H, CH_2), 4.57 (s, 2 H, CH), 4.70 (s, 1 H, CH) ppm. ^{13}C NMR (75 MHz, C_6D_6): δ = 18.7 (CH_2), 18.9 (CH_2), 27.4 (CH_2), 27.7 (C), 28.0 (CH_2), 29.2 (CH_2), 30.1 (CH_2), 30.3 (CH_2), 31.7 (CH_3), 78.1 (C), 78.5 (C), 83.5 (CH), 83.6 (CH), 85.6 (CH), 89.5 (C), 90.0 (C), 105.4 (C), 106.1 (C) ppm. IR (film) $\tilde{\nu}$ = 2964, 2862, 2044, 1952, 1475, 1453, 1360 cm^{-1}. UV/Vis (CH_2Cl_2): $\lambda_{max.}$ (log ε)= 252 (6.71), 336 (2.76), 360 (2.49).

Dicarbonyl-η^5-[1-(6,6-dimethylhept-4-ynyl)-3-(8,8-dimethylnon-6-ynyl)cyclopentadienyl]cobalt(I) (16e): Reaction mixture: [$Co_2(CO)_8$] (388 mg, 1.1 mmol) and I_2 (288 mg, 1.1 mmol) in THF (25 mL), 1-(6,6-dimethylhept-4-ynyl)-3-(8,8-dimethylnon-6-ynyl)cyclopentadiene (**14e**) (1.0 g, 3.0 mmol) and *n*-butyllithium (2.6 mL, 1.6 M in hexane) in THF (5 mL).Yield 130 mg (25%). Orange oil. ^{1}H NMR (500 MHz, C_6D_6): δ = 1.20 (s, 9 H, CH_3), 1.25 (s, 9 H, CH_3), 1.35–1.53 (m, 6 H, CH_2), 2.03–2.40 (m, 10 H, CH_2), 4.49 (s, 1 H, CH), 4.50 (s, 1 H, CH), 4.61 (s, 1 H, CH) ppm. ^{13}C NMR (125 MHz, C_6D_6): δ = 18.7 (CH_2), 19.0 (CH_2), 27.4 (CH_2), 27.7 (C), 28.3 (CH_2), 28.8 (CH_2), 29.2 (CH_2), 30.2 (CH_2), 30.3 (C), 30.6 (CH_2),

Dicarbonyl-η⁵-[1-(7,7-dimethyloct-5-ynyl)-3-(8,8-dimethylnon-6-ynyl)cyclopentadienyl]cobalt(I) (16f): Reaction mixture: [$Co_2(CO)_8$] (458 mg, 1.3 mmol) and I_2 (340 mg, 1.3 mmol) in THF (28 mL), 1-(7,7-dimethyloct-5-ynyl)-3-(8,8-dimethylnon-6-ynyl)cyclopentadiene (**14f**) (1.1 g, 3.2 mmol) and *n*-butyllithium (1.8 mL, 2.5 M in hexane) in THF (6 mL).Yield 250 mg (40%). Orange oil. ^1H NMR (300 MHz, C_6D_6): δ = 0.80–0.87 (m, 4 H, CH_2), 1.24 (s, 18 H, CH_3), 1.30–1.50 (br., 6 H, CH_2), 1.86–1.91 (m, 4 H, CH_2), 2.01–2.09 (m, 4 H, CH_2), 4.48 (s, 2 H, CH), 4.60 (s, 1 H, CH) ppm. ^{13}C NMR (75 MHz, C_6D_6): δ = 18.9 (CH_2), 19.1 (CH_2), 27.7 (C), 28.0 (CH_2), 28.4 (CH_2), 28.9 (CH_2), 29.2 (CH_2), 29.3 (CH_2), 30.1 (C), 30.3 (CH_2), 30.6 (CH_2), 31.6 (CH_3), 31.7 (CH_3), 78.6 (C), 78.8 (C), 83.4 (CH), 83.5 (CH), 85.6 (CH), 89.3 (C), 89.6 (C), 106.0 (C), 106.2 (C) ppm. IR (film) $\tilde{\nu}$ = 2967, 2930, 2860, 2016, 1955, 1475, 1455, 1388 cm^{-1}. UV/Vis (CH_2Cl_2): $\lambda_{max.}$ (log ε) = 246 (4.27), 294 (2.87) nm.

Dicarbonyl-η⁵-[1,3-bis(5-trimethylsilylpent-4-ynyl)cyclopentadienyl]-cobalt(I) (16g): Reaction mixture: [$Co_2(CO)_8$] (1.2 g, 3.5 mmol) and I_2 (896 mg, 3.5 mmol) in THF (75 mL), 1,3-bis[5-(trimethylsilyl) pent-4-ynyl]cyclopentadiene (**14g**) (2.7 g, 7.8 mmol) and *n*-butyllithium (6.3 mL, 1.6 M in hexane) in THF (15 mL). Yield 696 mg (57%). Orange oil. ^1H NMR (300 MHz, C_6D_6): δ = 0.17 (s, 18 H, CH_3), 1.37–1.46 (m, 4 H, CH_2), 1.94–2.07 (m, 8 H, CH_2), 4.40 (s, 2 H, CH), 4.48 (s, 1 H, CH) ppm. ^{13}C NMR (75 MHz, C_6D_6): δ = 0.4 (CH_3), 19.8 (CH_2), 27.3 (CH_2), 29.7 (CH_2), 83.5 (CH), 85.4 (CH), 85.5 (C), 105.1 (C), 106.9 (C) ppm. IR (film) $\tilde{\nu}$ = 2858, 2174, 2046, 2016, 1955, 1427, 1326 cm^{-1}. UV/Vis (CH_2Cl_2): $\lambda_{max.}$ (log ε) = 250 (4.03), 330 (3.21) nm.

Synthesis of Endohedral Rhodium Complexes 7b and 8b: A dry 250-mL flask was charged with cyclopentadienyl(dicarbonyl)rhodium (**15b**, 636 mg, 1.28 mmol) and 120 mL cyclooctane. The solution was refluxed (72 h). The solvent was evaporated under reduced pressure and the products were purified by column chromatography [alox III (neutral)]. After eluting the column with petroleum ether in the beginning, dichloromethane was used to elute first complex **7b** and then complex **8b** as yellow bands.

Complex 7b: Yield 95 mg (16%). Yellow solid. ^1H NMR (500 MHz, $CDCl_3$): δ = 1.49 (s, 9 H, CH_3), 1.51 (s, 9 H, CH_3), 1.56 (m, 2 H, CH_2), 1.73 (m, 2 H, CH_2), 1.79 (m, 2 H, CH_2), 1.90 (m, 2 H, CH_2), 2.19 (m, 2 H, CH_2), 2.22 (m, 2 H, CH_2), 2.58 (m, 2 H, CH_2), 2.71 (m, 2 H, CH_2), 5.15 (ps, 1 H, CH), 5.28 (ps, 1 H, CH), 5.35 (ps, 1 H, CH) ppm. ^{13}C NMR (75 MHz, $CDCl_3$): δ = 26.0 (CH_2), 27.0 (CH_2), 27.2 (CH_2), 29.1 (CH_2), 29.7 (CH_2), 30.0 (CH_2), 30.8 (CH_2), 31.6 (CH_3), 32.1 (CH_2), 33.4 (C), 33.9 (C), 34.5 (CH_3), 83.2 (CH, $J_{Rh,C}$ = 5.6 Hz), 84.0 (CH, $J_{Rh,C}$ = 6.5 Hz), 85.7 (C, $J_{Rh,C}$ = 8.8 Hz), 86.2 (CH, $J_{Rh,C}$ = 6.8 Hz), 93.5 (C, $J_{Rh,C}$ = 9.3 Hz), 93.9 (C, $J_{Rh,C}$ = 10.1 Hz), 106.1 (C, $J_{Rh,C}$ = 5.5 Hz), 106.4 (C, $J_{Rh,C}$ = 6.3 Hz), 111.1 (C, $J_{Rh,C}$ = 11.4 Hz), 163.2 (CO) ppm. MS (positive FAB): *m*/*z* = 468 $[M]^+$. IR (KBr) $\tilde{\nu}$ = 2922, 2857, 2232, 1733, 1598, 1485, 1448, 1388 cm^{-1}. UV/Vis (CH_2Cl_2): $\lambda_{max.}$ (log ε) = 266 (5.05), 348 (4.42) nm. HRMS (positive FAB) calcd. for $C_{26}H_{37}ORhNa$ ($[M + Na]^+$), 491.1797; 491.1804 found, (+0.7 mmu).

Complex 8b: Yield 3 mg (0.5%). Yellow oil. ^1H NMR (500 MHz, $CDCl_3$): δ = 1.41 (s, 9 H, CH_3), 1.58 (s, 9 H, CH_3), 1.91–2.62 (m, 16 H, CH_2), 5.33 (ps, 1 H, CH), 5.38 (ps, 1 H, CH), 5.50 (ps, 1 H, CH) ppm. MS (positive FD): *m*/*z* = 468 $[M]^+$. IR (film) $\tilde{\nu}$ = 2925, 2856, 1562, 1446, 1362, 1261, 1029 cm^{-1}. HRMS (positive FAB) calcd. for $C_{26}H_{38}ORh$ ($[M]^+$), 469.1978; found, 469.1939 (–3.9 mmu).

General Procedure for the Synthesis of Endohedral Cobalt Complexes 1d–g: A dry 250-mL flask was charged with the dicarbonylcobalt complex and cyclooctane. The solution was refluxed (12 h). The solvent was evaporated under reduced pressure and the products were purified by column chromatography (alox III).

[3.4]-η⁵-(1,1′,3,3′)-Cyclopentadienyl-η⁴-[2,4-bis(*tert*-butyl)cyclobutadienophane]cobalt(I) (1d): Reaction mixture: complex **16d** (140 mg, 0.40 mmol) in cyclooctane (80 mL). Yield 20 mg (5%). Yellow solid, m.p. 110 °C. ^1H NMR (500 MHz, C_6D_6): δ = 1.20 (s, 18 H, CH_3), 1.54–1.81 (br., 8 H, CH_2), 2.03–2.12 (br., 4 H, CH_2), 2.24–2.27 (m, 1 H, CH_2), 2.53–2.61 (m, 1 H, CH_2), 4.56 (s, 1 H, CH), 4.79 (s, 1 H, CH), 5.00 (s, 1 H, CH) ppm. ^{13}C NMR (125 MHz, C_6D_6): δ = 23.5 (CH_2), 24.3 (CH_2), 29.3 (CH_2), 29.6 (CH_2), 29.7 (CH_2), 31.2 (CH_2), 31.6 (CH_3), 32.4 (C), 32.7 (C), 33.0 (CH_3), 39.0 (CH_2), 66.1 (C), 80.9 (CH), 81.1 (C), 81.3 (CH), 81.8 (CH), 92.7 (C), 93.2 (C), 95.3 (C), 95.5 (C) ppm. IR (KBr) $\tilde{\nu}$ = 3079, 2953, 2910, 2849, 1622, 1478, 1460, 1442, 1391 cm^{-1}. UV/Vis (CH_2Cl_2): $\lambda_{max.}$ (log ε) = 268 (4.16), 302 (3.24), 342 (2.80) nm. HRMS (positive EI) calcd. for $C_{24}H_{35}Co$ ($[M]^+$), 383.2071; found, 383.2057 (–1.4 mmu). $C_{24}H_{35}Co$ (382.47): calcd. C 75.37, H 9.22; found C 75.47, H 8.99.

[3.5]-η⁵-(1,1′,3,3′)-Cyclopentadienyl-η⁴-[2,4-bis(*tert*-butyl)cyclobutadienophane]cobalt(I) (1e): Reaction mixture: complex **16e** (130 mg, 0.29 mmol) in cyclooctane (50 mL). Yield 34 mg (30%). Yellow solid, m.p. 140 °C. ^1H NMR (300 MHz, C_6D_6): δ = 1.14 (s, 9 H, CH_3), 1.16 (s, 9 H, CH_3), 1.37–1.74 (m, 8 H, CH_2), 1.82–1.88 (m, 4 H, CH_2), 2.19–2.23 (m, 1 H, CH_2), 2.39–2.43 (m, 1 H, CH_2), 2.59–2.62 (m, 2 H, CH_2), 4.58 (s, 1 H, CH), 4.70 (s, 1 H, CH), 4.78 (s, 1 H, CH) ppm. ^{13}C NMR (125 MHz, C_6D_6): δ = 22.9 (CH_2), 23.1 (CH_2), 24.0 (CH_2), 24.3 (CH_2), 25.0 (CH_2), 26.1 (CH_2), 31.4 (CH_3), 32.1 (CH_3), 32.4 (C), 32.6 (C), 37.7 (CH_2), 66.4 (C), 73.4 (C), 78.8 (CH), 81.0 (CH), 81.3 (CH), 90.7 (C), 92.1 (C) 93.5 (C), 94.2 (C) ppm. IR (KBr) $\tilde{\nu}$ = 2955, 2919, 2855, 1478, 1455, 1372 cm^{-1}. UV/Vis (CH_2Cl_2): $\lambda_{max.}$ (log ε) = 270 (4.49), 300 (3.54), 374 (3.20) nm. HRMS (positive EI) calcd. for $C_{25}H_{37}Co$ ($[M]^+$), 396.2227; found, 396.2238 (+1.1 mmu). $C_{25}H_{37}Co$ (396.49): calcd. C 75.37, H 9.41; found C 75.37, H 9.28.

[4.5]-η⁵-(1,1′,3,3′)-Cyclopentadienyl-η⁴-[2,4-bis(*tert*-butyl)cyclobutadienophane]cobalt(I) (1f): Reaction mixture: complex **16f** (165 mg, 0.35 mmol) in cyclooctane (60 mL). Yield 22 mg (15%). Photocontrol of Complexation of Neutral and Cationic Species by *p-tert*-Butylcalix[4]arene Tetraethyl Ester

Bernadette S. Creaven,*[a] Mary Deasy,[a] Catherine McKenna,[a] Brian A. Murray,[a] and Darren Tobin[a]

Keywords: Calixarene / Photocontrol / Anion effect / Solvent effect / Sodium complexes

A number of sodium salt complexes of *p-tert*-butylcalix[4]arene tetraethyl ester (**1**) were isolated both with and without upper-rim encapsulated acetonitrile or methanol. Upon dissolution in $CDCl_3$, **1** remained largely complexed to the sodium cation but ca. 90 % of the upper-rim bound solvent was released, reflecting the relative values of the binding constants for complexation of the two guest species. Selective decomplexation of lower-rim bound sodium cations could be successfully achieved using low-pressure light sources, triggering the immediate expulsion of the upper-rim bound solvent. The extent of decomplexation at both rims is controlled both by the oxidation of the counter-anionic species at the lower rim and by the fate of the photoproducts generated. The calixarene host molecule, **1**, remains intact during the decomplexation process.

Introduction

Calixarenes are a widely studied class of macrocyclic ligands, obtained from the base-catalysed condensation reaction between *para*-substituted phenols and formaldehyde. The general structure of a calixarene is shown in Figure 1. Functionalisation at the lower rim of parent calixarenes (Figure 1, R = H) has led to a variety of derivatives, which have found use in a number of industrial and analytical applications.[1–3] We have been interested in the calix[4]arene esters in particular as their well-defined hydrophobic region, defined by the upper-rim aromatic moieties and lower-rim hydrophilic regions, allows for complexation of both neutral and cationic guests, respectively.[4–7] There have been a limited number of studies carried out on calixarene complexes, which bind guests at the upper and lower rims simultaneously. In one such study, Pochini et al. have shown that a conformationally mobile calixarene host did not show significant upper-rim complexation of a guest whereas its sodium complex, which is more rigid, strongly interacts with the same guest.[8] Stibor et al. investigated the factors influencing the stability of inclusion complexes of calix[4]arene derivatives with neutral molecules, specifically acetonitrile (MeCN). *p-tert*-Butylcalix[4]arene tetraethyl ester (**1**) (Figure 1: R = $CH_2COOCH_2CH_3$) was included in this study, and Stibor found that the presence of a sodium cation at the lower rim of the calixarene significantly enhanced the binding of neutral guests at the upper rim.[9] Stibor's work correlates well with thermodynamic studies in solution of compound **1** with a series of alkali metal salts in MeCN, MeOH, and benzonitrile carried out by other groups. This latter work had concluded that MeCN was seen to produce an "allosteric effect", whereby the interaction of MeCN with the hydrophobic cavity of **1** preorganises the hydrophilic cavity to interact with cations, and the authors had noted the increased stability of sodium complexes of **1** in MeCN.[10–15]

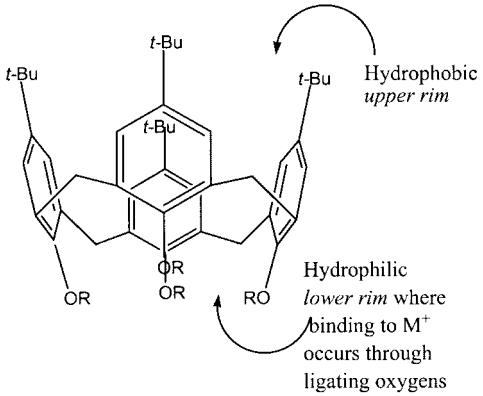

Figure 1. Structural formula of calixarene **1** indicating how it can bind guests.

Our main interest lies in the controlled decomplexation of alkali metal complexes of calixarene esters, specifically the sodium complexes. We have previously reported photodecomplexation studies on sodium iodide and tetraphen-

ylborate complexes of calixarenes in $CDCl_3$, including those of compound **1**,[16,17] and found the % decomplexation to be anion-dependent. Moreover, the decomplexation reaction did not appear to involve a structural change in the calixarene macrocycle. Most photoresponsive macrocyclic systems in the literature employ an *all or nothing* reaction, whereby complexation is controlled by a photoisomerisable moiety within the macrocycle. For example, Shinkai and his colleagues synthesised an azobenzene-containing crown ether, the *cis* form of which bound K^+, Rb^+, and Cs^+, whereas the *trans* isomer preferentially bound Li^+ and Na^+.[18] Our previous work had shown that decomplexation could be controlled to a pre-determined level for the complexes studied and hence was comparable to an analogue control mechanism or analogue switch. This work also showed that for complexes isolated from acetonitrile, rather than chloroform, the overall % decomplexation of the complexes was reduced by up to 20%.[17] The difference in % decomplexation was thought to be due to the inclusion of MeCN in the upper rim of the complexes, exerting a stabilising or allosteric effect on complexation of sodium at the lower rim.

While our previous work had noted both the anion dependency as well as the dependency on solvent inclusion on the extent of photodecomplexation of complexes of **1**, the exact reasons for either dependency were not fully understood. The present study details photodecomplexation studies on a range of sodium complexes of **1**, prepared with several different counter anions, which were isolated from a number of solvents. Our previous studies had also indicated that photodecomplexation of NaI-**1** and $NaBPh_4$-**1** only occurred in chloroform and not in methanol or acetonitrile. The photoreactivity of the complexes in the nonpolar solvent was though to be related to the existence of ion pairs in this solvent, which would allow for efficient energy transfer from the calixarene macrocycle to the associated counter anion. The role of the photolysis solvent in the decomplexation process was therefore also investigated in this study.

Results and Discussion

NMR Studies on NaX-1 and NaX-1·MeCN Complexes

The sodium salt complexes of **1**, NaX-**1** (X = iodide, thiocyanate, perchlorate, periodate, and tetraphenylborate) were isolated from a series of solvents. While it has been reported that calix[4]arenes tightly bind chloroform, benzene, toluene, xylene, anisole and acetonitrile,[19–23] the limited stability of the sodium complexes in some of these solvents precluded their use.[24] Microanalysis of the isolated complexes indicated that for each of the NaI, NaSCN, $NaIO_4$ and $NaBPh_4$ complexes isolated from MeCN, a solvent molecule was also present and these complexes are henceforth denoted as NaX-**1**·MeCN (X = I^-, SCN^-, BPh_4^-, IO_4^-). The integration of the ^1H NMR signals confirmed that the ratio of NaX-**1**:MeCN was 1:1 in all samples. However, the ^1H NMR signal of the methyl group in MeCN was moved upfield relative to free MeCN in $CDCl_3$. Solid-state studies have shown that an interaction between the calixarene and MeCN occurs possibly via a CH_3-π interaction where the methyl group of the MeCN is orientated toward the hydrophobic upper cavity resulting in a significant shielding effect on the MeCN alkyl hydrogen atoms.[23,25] The $NaIO_4$ complex of **1** isolated from MeOH also had an upper-rim bound solvent molecule, henceforth denoted as $NaIO_4$-**1**·MeOH. No encapsulated chloroform or dichloromethane complexes of **1** could be isolated and such complexes are denoted as NaX-**1** in this study. Sodium salt complexes of **1** have been widely reported in the literature[4,9–15] and NMR assignments in $CDCl_3$ were based on these reports (Table 1). All of the reported NMR spectra, including the ones reported here, and additional X-ray crystallo-

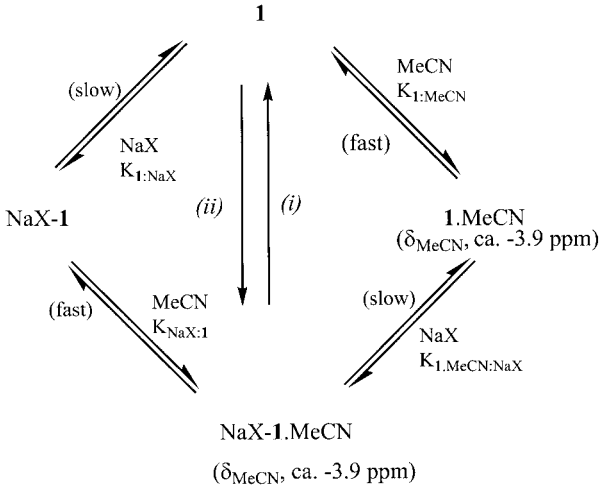
graphic studies have indicated that the sodium complexes are in a fixed cone conformation in the solid and solution states. The complexation-induced shifts noted in Table 1 would indicate that the ion-pair interaction at the lower rim (as evidenced by ^{1}H NMR signals of the $OCH_2COCH_2CH_3$ and $OCH_2COCH_2CH_3$ moieties and the methylene bridges) was relatively similar for all the anions except for tetraphenylborate. This may be an indication that ion pairing with tetraphenylborate was weakest, which is consistent with the "non-coordinating" nature of this ligand, or that the phenyl groups of the anion are having an additional shielding effect at the lower rim.

^{1}H NMR signals at δ = 1.67 ppm, 1.50 ppm and 1.43 ppm in the ^{1}H NMR spectra of NaI-**1**·MeCN, NaSCN-**1**·MeCN, and $NaBPh_4$-**1**·MeCN, respectively, were assigned to MeCN in the upper rim of the complexes. In $CDCl_3$, free MeCN is known to have a chemical shift of 2.1 ppm.[26] The presence of MeCN resulted in small downfield shifts in the *tert*-butyl and aromatic signals for these complexes, relative to when MeCN was absent.

Stibor's study of the complexation of **1** with neutral molecules including MeCN in the presence and absence of sodium thiocyanate sets the context for our photolytic study of the same system in $CDCl_3$.[9] Scheme 1 shows the complexation equilibria that are set up when NaX-**1**·MeCN is dissolved in $CDCl_3$. The processes in which neutral guest MeCN complexes with **1** are fast on the NMR timescale, while Na^+ complexation processes are slow. However, the thermodynamics of these processes are reversed: Na^+ complexes very strongly with **1** with both $K_{\mathbf{1}:NaX}$ and $K_{\mathbf{1}\cdot MeCN:NaX}$ being of the order of 10^6–10^7 M^{-1}.[27] In contrast, the 1:1:1 complex formed from NaX-**1** and MeCN has a binding constant of 31 M^{-1}, while MeCN binds **1** extremely weakly with $K_{\mathbf{1}:MeCN} << 1$ M^{-1}.[9] Stibor has also determined the ^{1}H NMR properties of included MeCN in the ternary complex: from a free position of 2.1 ppm (i.e. δ_G^{MeCN}), the methyl group moves strongly upfield to a limiting value of δ_{GH}^{MeCN} = –3.9 ppm (associated with anisotropic shielding as the methyl group is inserted "head-first" into the upper rim of calixarene cavity and down into the inter-aryl space). This very large complexation-induced shift (CIS) of –6.0 ppm is probably also present in **1**·MeCN, as the geometry of NaX-**1**·MeCN and **1**·MeCN are similar, although the very weak binding precludes observation of this. If it is assumed that $K_{\mathbf{1}:MeCN}$ is < 0.3 M^{-1}, then the ratio $K_{NaX–\mathbf{1}:MeCN}/K_{\mathbf{1}:MeCN}$ is > 100; i.e. complexation of sodium at the lower rim favours complexation of MeCN at the upper rim by at least 11 kJ mol^{-1} in free energy terms.



Scheme 1. Complexation equilibria established in $CDCl_3$ solution upon dissolution of NaSCN-**1**·MeCN. Processes (*i*) and (*ii*) are discussed in the text.

We can now:
(a) Estimate the position these equilibria will attain when 4.0 mmol of NaX-**1**·MeCN is dissolved per litre of $CDCl_3$;
(b) predict the expected ^{1}H NMR behaviour of the methyl signal of MeCN; and
(c) subsequently use this information to rationalize the effect of photolytic decomplexation of $Na^+(X^-)$ on (a) and (b).

Firstly consider the equilibrium:

NaX-**1** + MeCN ⇋ NaX-**1**·MeCN

with $K_{NaX–\mathbf{1}:MeCN}$ = 31 M^{-1}, dissolving compound to 4 mM will result in net dissociation of ca. 90%, leaving f_c^G (fraction of guest, MeCN, complexed) = 0.10, and $\delta_{obsd.}^G$ = 1.50 ppm, i.e. 10% of the way from 2.1 to –3.9 ppm. Neither complex should dissociate its sodium significantly; f_c^{Na} will be > 98%, assuming $K_{\mathbf{1}:NaX}$ and $K_{\mathbf{1}\cdot MeCN:NaX}$ are ca. 10^6 M^{-1}. Finally, any **1**·MeCN present will be 99.9% dissociated. Thus there will be effectively only two environments for MeCN: In the form of NaX-**1**·MeCN or free in solution.

Figure 2(a) shows the predicted ^{1}H NMR binding curve, based on Stibor's data, i.e. the movement of the MeCN methyl protons for a range of stoichiometric or initial concentrations of NaSCN-**1**·MeCN dissolved in $CDCl_3$. At low concentrations of NaSCN-**1**·MeCN, it shows linear behaviour (asymptotically). This is shown in the expansion of the range 0–5 mM in Figure 2(b) i.e $\delta_{obsd.}^G - \delta_G^{MeCN}$ (the observed CIS) is approximately proportional to $[NaSCN\text{-}\mathbf{1}\cdot MeCN]_{initial}$ in this region. When [NaSCN-**1**·MeCN] = 4.0 mM, the ternary complex is 90% dissociated and we observe δ_G^{MeCN} = 1.50 ppm, exactly as predicted by Stibor's data.

If we assume that the values of $K_{NaX\text{-}\mathbf{1}:MeCN}$ are of comparable magnitude, then all of the NaX-**1**·MeCN complexes would behave similarly once dissolved in $CDCl_3$, and $\delta_{obsd.}^{MeCN}$ for each of the complexes should also be of similar magnitude. In fact $\delta_{obsd.}^{MeCN}$ = 1.47, 1.43, 1.50 and 1.67 ppm upon dissolution of 4 mM $NaIO_4$-**1**·MeCN, $NaBPh_4$-**1**·MeCN, NaSCN-**1**·MeCN and NaI-**1**·MeCN, respectively.

The presence of encapsulated MeOH was also observed in $NaIO_4$-**1** complexes with a chemical shift of 3.39 ppm. Free MeOH in $CDCl_3$ has a chemical shift of 3.64 ppm.[25] Although crystals of suitable quality have not been isolated for solid-state structure analysis, a potassium complex of a calixarene tetraamide has been reported with a molecule of MeOH in its hydrophobic cavity.[28]

Photodecomplexation Studies of NaX-1, NaX-1·MeCN and $NaIO_4$-1·MeOH

Our previous work had shown that irradiation of $NaBPh_4$-**1** in $CDCl_3$ generated products consistent with the photooxidation of the tetraphenylborate anion.[17] In this study, we monitored the fate of the other anions upon photoexcitation of the macrocyclic complexes. The choice of excitation source was a low-pressure mercury lamp operating at room temperature, which emits primarily one band of radiation at 253.6 nm. Exposure of calixarene complexes to this wavelength leads to extensive photochemical reaction and breakdown of the host compound. However, the output of low-pressure mercury lamps includes a number of weak lines above 280 nm, including 289.4, 296.7, 302.2 and 312.6 nm. Use of this lamp with an appropriate UV filter, in this case a pyrex NMR tube, ensured that all photochemical decomplexations were clean and could be monitored over reasonable time-scales. Figure 3 shows the absorption spectra of the calixarene host compound **1** and some of its complexes, together with the transmission characteristic of a typical pyrex NMR tube.

The pyrex NMR tube effectively cuts out all radiation at the main excitation wavelength of the lamp and is only 10% transmitting at 280 nm, but increases thereafter. With this experimental set-up, decomplexation of the complexes of **1** could be monitored with good reproducibility over reasonable time scales.[29] The presence of the tetraphenylborate and iodide anions do alter the UV/Vis spectrum of its complexes, but for the remaining complexes the two main absorption bands of the calixarene varied little in position upon coordination; however, they varied somewhat in intensity. Table 2 gives the absorption data of free calixarene and its complexes at a number of wavelengths.

Table 2. UV/Vis absorbance data for host compound, **1**, and its NaI, NaSCN, and $NaIO_4$ complexes in $CDCl_3$.

Compound	λ (nm)	ε (cm^{-1} mol^{-1}) × 10^3
1	275	3.49

$\rightarrow S_1$ transition of the aryl ether moiety.[30,31] The primary wavelengths of excitation, centred around 308nm, correspond to the shoulder of the $S_0 \rightarrow S_1$ transition and the anion-centred absorptions. Photoexcitation of aryl ethers usually leads to the ejection of an electron from the arene excited (π,π^*) state and the formation of a radical cation. The subsequent activation of the aromatic ring is primarily at the *para* position but also at the *ortho* position.[32] In our case, a *tert*-butyl and a methylene group occupy these two positions, and so the expected further reactions would be inhibited. The other chromophoric species in solution are the counter-anionic species i.e. the iodide, thiocyanate, tetraphenylborate or periodate ions that have weak absorptions at these wavelengths (perchlorate ions have no absorption bands in this region).[33]

The % decomplexations of NaX-**1** complexes upon irradiation in $CDCl_3$ at timed intervals are shown in Table 3. The values for % decomplexation are calculated from the ^{1}H NMR spectra of the photolysed solutions by the integration of the aryl protons of the free and complexed species, as distinct signals can be seen for both species in the spectrum. These results indicated a significant anion dependence on the extent of decomplexation with up to 85% decomplexation being achieved with BPh_4^- and SCN^- as anions, but no decomplexation occurring for the sodium perchlorate complex and little for the periodate complex (14%). There was no apparent relationship between the extent of ion pairing at the lower rim and the extent of photodecomplexation, a factor we had previously thought to be important.[17] If this were the case, a $NaBPh_4$-**1** complex, which from the NMR results looks to be the least ion-paired of the complexes, would show the least % decomplexation. However, this was not the case. If fresh solutions of salt were added to the NMR tubes, full recomplexation of **1** occurred, indicating the integrity of the calixarene host was maintained during decomplexation. The presence of encapsulated MeCN within the upper cavity reduced the initial % photodecomplexation of the tetraphenylborate and periodate complexes. In all cases at extended irradiation times, where MeCN was present in the sample, recomplexation was seen to occur to some extent. Irradiation over a two-hour period of the free host, **1**, showed that the calixarene remained intact throughout.

Interesting decomplexation behaviour was noticed upon irradiation of NaX-**1**·MeCN complexes. Figure 4 illustrates the relationship between the amount of calixarene remaining complexed to a sodium cation and the chemical shift of the ^{1}H NMR peak for MeCN measured for three sodium complexes. At the concentrations of NaX-**1**·MeCN used in these experiments, ca. 4.0 mM, the ternary complex is 90% dissociated. As stated earlier, for the NaSCN-**1**·MeCN complex we observe $\delta_G^{MeCN} = 1.50$ ppm. Photolysis now causes net decomplexation of Na^+, and the rapid nature of the reaction

1 + MeCN ⇋ **1**·MeCN

means MeCN dissociates too. Thus the degree to which the sodium is decomplexed can be represented as a movement up the binding curve shown in Figure 2(b): 50% decomplexation will cause $\delta_{obsd.}^{MeCN}$ to move to 1.80 ppm (halfway back to 2.1 ppm) while 100% decomplexation will completely free all the MeCN ($\delta_{obsd.}^{MeCN} = \delta_G^{MeCN} =$ 2.1 ppm). This is represented by process (i) of Figure 2(b) and in Scheme 1. The ordinate-intercept value of the graphs is consistent within experimental error with the value 2.1 ppm for free MeCN in $CDCl_3$,[26] although experimentally 100% decomplexation was not observed in any of the complexes studied. This is because on the slower timescale of many minutes post-photolysis, the sodium will recomplex, moving the acetonitrile position back down the binding curve, represented by process (ii) of Figure 2(b) and in

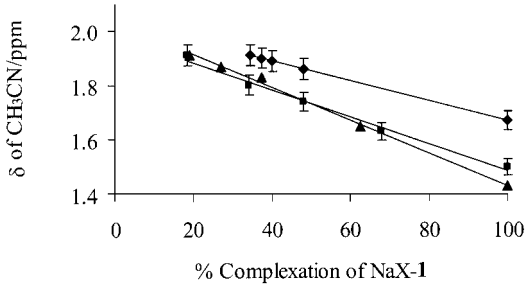

Figure 4. The relationship between the % complexation of NaX-**1** and the chemical shift, δ, of upper-rim bound acetonitrile; NaSCN-**1** (■), NaI-**1** (♦), $NaBPh_4$-**1** (▲). Concentration of each solution is 4 mM and each value is an average of 3 replicate experiments.

Table 3. Decomplexation (%) of NaX-**1** complexes (typical concentration 4.5 mM), before and after irradiation in $CDCl_3$ as determined by ^{1}H NMR spectroscopy. Each value is the average of 6 replicate experiments. Complexes with encapsulated MeCN and MeOH are indicated by NaX-**1**·MeCN or NaX-1·MeOH, respectively.

Scheme 1. This recomplexation can be accelerated by adding fresh excess NaX.

The behaviour of the other anions should be similar with any variability being due to variation in $K_{NaX-1:MeCN}$ values due to the anion. This variability is reflected in the differing slopes of the plots in Figure 4 and Figure 5(b). Such variations would be expected to be small based on the observed values for $\delta_{obsd.}^{MeCN}$ for the four complexes isolated in this study. Determination of the value of K for NaX-**1** with MeCN in the presence of different anions at the lower rim is now a feature of a further study by our group.

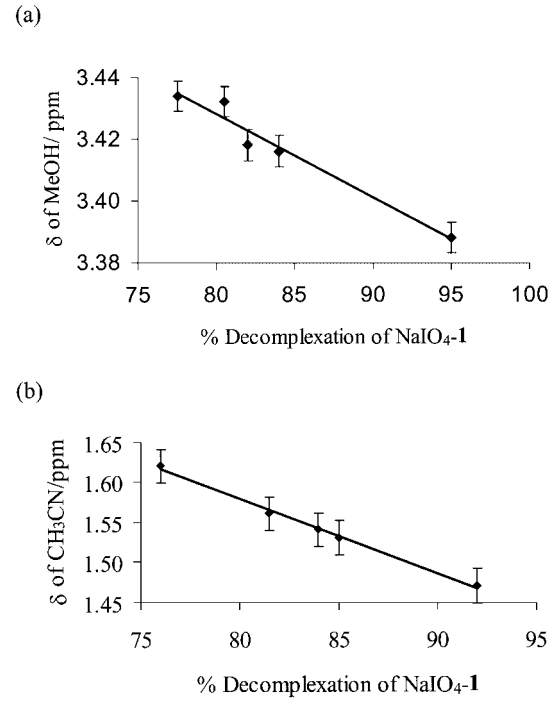

Figure 5. The relationship between (a) the % complexation of $NaIO_4$-**1**·MeOH and the chemical shift, δ, of upper-rim bound methanol and (b) the % complexation of $NaIO_4$-**1**·MeCN and the chemical shift, δ, of upper-rim bound acetonitrile. Concentration of each solution is 4 mM and each value is an average of 3 replicate experiments.

$NaIO_4$-**1** complexes with encapsulated solvent were also examined. The extent of decomplexation noted here was considerably less than in the thiocyanate, tetraphenylborate and iodide complexes. After irradiation of $NaIO_4$-**1**·MeOH, the MeOH peak shifted marginally downfield, consistent with the small extent of decomplexation noted for this anion, but again was found to be linearly dependent (presumably asymptotically) upon the extent of photodecomplexation [(a) in Figure 5]. A similar result was found for the corresponding $NaIO_4$-**1**·MeCN complex [(b) in Figure 5]. Stability constants for ternary complexes with methanol have not been determined yet but the behaviour of theses complexes upon irradiation would appear to be similar to the acetonitrile complexes of NaI-**1**, NaSCN-**1** and $NaBPh_4$-**1**.

From Table 3 it can be seen that the *extent* of neutral guest decomplexation depended on the identity of the counter anion at the lower rim, and the role of this anion in the decomplexation process was important to determine.

Photoreactivity of the Counter Anions of NaX-1

Potentiometric titration of aqueous extracts of the irradiated $CDCl_3$ solutions of NaI-**1** and NaI-**1**·MeCN (Table 4) indicated that the concentration of iodide was reduced upon irradiation, but that reduction did not correlate exactly with the decomplexation of the calixarene. In fact, while most of the iodide had reacted after 10 minutes, partial complexation of the calixarene at this and later times indicated the presence of another anion in solution. UV/Vis analysis indicated that triiodide was produced, presumably from the initial reaction of iodine radicals to form iodine followed by further reaction with iodide to form triiodide.[34] Chloride was also detected in reasonable concentrations (Table 4). A white precipitate isolated from the photolysed solutions was identified as NaCl. If a fresh source of counter anion, in the form of *tert*-butylammonium iodide was added to the NMR tubes, full recomplexation of **1** occurred. *tert*-Butylammonium is a cation that is too large to fit into the lower-rim hydrophilic cavity of **1**, and thus recomplexation of **1** must be with any sodium cation present (Table 4).

Replicate 1-mL samples of chloroform were irradiated for up to 90 minutes, under the same conditions described above, and in each case, no chloride was detected. Solutions of **1** in $CDCl_3$, irradiated for 60 minutes, showed no degradation of the calixarene. However, a potentiometric titration showed that chloride was present in these solutions, but at a significantly reduced level (1.69 ± 0.04 mM) than that recorded following irradiation of the sodium complexes of **1**. In a separate series of experiments *tert*-butylammonium iodide (TBAI) was irradiated for timed intervals and

Table 4. Autotitration results for NaI-**1** complexes before irradiation, and after irradiation for 10 (*) and 45 (#) minutes. Results are average of six replicate experiments (n.d. = not detectable).

analysed by both ^{1}H NMR and potentiometry; TBA cation has no absorption bands above 280 nm. After just 15 minutes no iodide could be detected in solution and chloride, in an equivalent amount to that of iodide initially present, was detected [(a) in Figure 6]. The presence of triiodide in these solutions was confirmed by UV/Vis spectroscopy. The results confirmed that direct photooxidation of the anion could result in the production of triiodide from iodide and lead to the generation of chloride from the solvent.

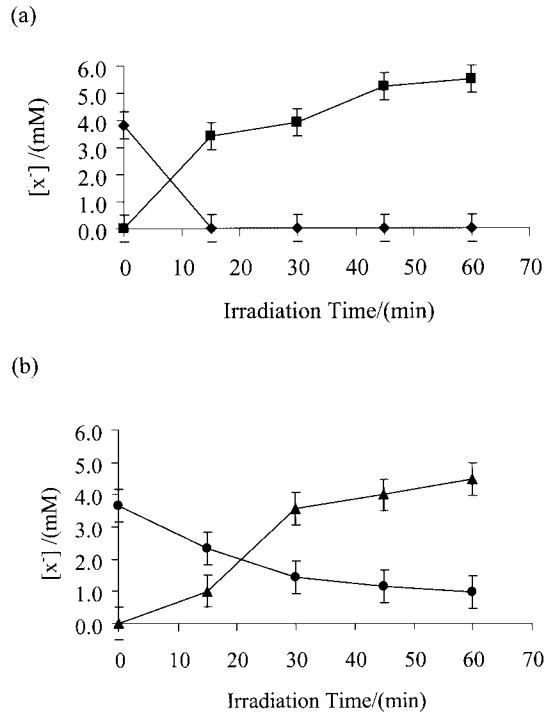

Figure 6. Plots showing (a) the relationship between concentration in mmol of iodide (♦) and chloride (■) ions in $CDCl_3$ solution on irradiation of 3.8 mmol TBAI at 15 minute intervals and (b) the relationship between concentration in mmol of thiocyanate (●) and chloride (▲) ions in solution on irradiation at 15 minute intervals of ca. 3.7 mmol TBASCN. Each value is an average of 3 replicate experiments.

GC and GC-MS analysis of the irradiated $CDCl_3$ solutions of both the calixarene and TBA iodide complexes showed that the primary organic products formed were deuterio-dichloromethane and -dichloroiodomethane ($CDCl_2I$) and traces of deuterio-1,1,2,2-tetrachloroethane. It is known that reduction of chloroform generates short-lived radical anions which eject chloride immediately upon formation.[35] The generated radicals can undergo disproportionation and recombination processes as well as further attack on solvent and this is evidenced by the photoproducts identified above. In all cases the photolysis by-products were present in much larger quantities for experiments carried out on the complexes rather than on the free ligand. In addition no organic photoproducts were identified upon extended irradiation of $CDCl_3$ solutions (or CD_2Cl_2 solutions, vide infra). In other studies, UV/Vis irradiation of metal coordination complexes where iodide is present either as an axial ligand or as a counter anion leads to the generation of an I$^{\cdot}$ radical, with concomitant reduction of the solvent by charge transfer to solvent (CTTS).[36–44] For those studies carried out in chlorinated solvents generation of iodide radicals has resulted in the production of chloride from chlorinated solvents.[40,41]

The pattern of destruction of counter anion and production of chloride can be seen again in the irradiation of NaSCN-**1** and NaSCN-**1**·MeCN This was shown firstly by quantitative FT-IR spectroscopy which indicated that irradiation of the NaSCN-**1** solutions resulted in the concentration of thiocyanate anions falling to undetectable levels after 30 minutes. A similar pattern was noted by potentiometric studies as shown in Figure 7. However, the complexes were once again noted by ^{1}H NMR spectroscopy to be only partially decomplexed over the same time period. The main anion present from photolysis of thiocyanate solutions, as detected by potentiometry, was again chloride and NaCl could be recovered as a precipitate from solution. Elemental sulfur also precipitated out of solution and was identified by microanalysis.

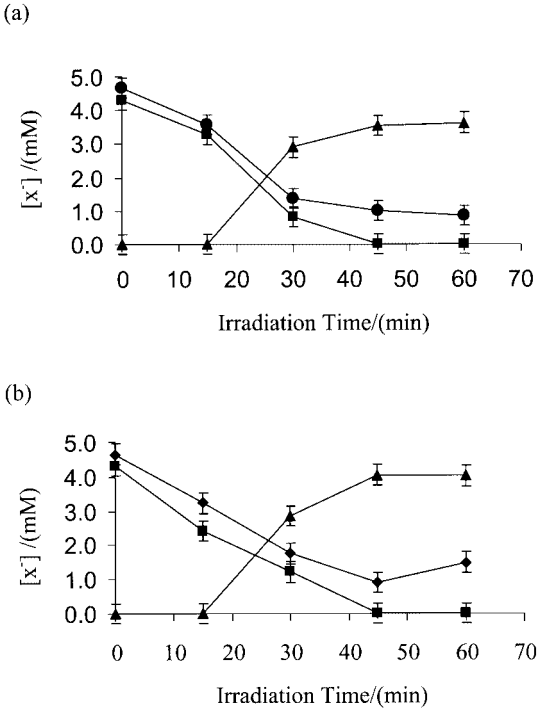

Figure 7. The relationship between (a) the concentration of NaSCN-**1** (●) and (b) the concentration of NaSCN-**1**·MeCN (♦) and those of chloride (▲) and thiocyanate (■) upon irradiation of the respective complexes in $CDCl_3$ at timed intervals. Each value is the average of six replicate measurements.

Irradiation of *tert*-butylammonium thiocyanate (TBASCN) over 60 minutes in $CDCl_3$ also showed the destruction of the SCN anion, though at lower levels than recorded for NaSCN-**1** [(b) in Figure 6]. Thus again the production of chloride in solution could be linked to the photoreaction of the counter-anionic species. GC-MS analysis of irradiated solutions of both TBASCN and NaSCN-**1** showed the formation of mainly deuterated dichloromethane as a photoproduct of the solvent.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

These results confirm what other workers have noted on irradiation of thiocyanate complexes in nonaqueous solvents.[39,40,42] Initially irradiation leads to production of thiocyanate radicals which can then form sulfur and cyanide anion. The proposed reaction is:

$$SCN^- + h\nu \rightarrow SCN^{\cdot} + e^-_{solvated} \quad (1)$$

$$SCN^- + h\nu \rightarrow S + CN^- \quad (2)$$

followed by complex reactions in which cage recombination and further reactions with SCN^- are central:

$$SCN^- + SCN^{\cdot} \leftrightharpoons (SCN)_2^{\cdot -} \quad (3)$$

$$2\ (SCN)_2^{\cdot -} \rightarrow (SCN)_2 + 2\ SCN^- \quad (4)$$

$$S + SCN^- \rightarrow S_2 + CN^- \quad (5)$$

$$2\ SCN^{\cdot} \rightarrow (SCN)_2 \quad (6)$$

Elemental sulfur was recovered following photolysis of both NaSCN-**1** and TBASCN, but there was no evidence for the presence of cyanide from auto-titration or FT-IR studies. The cyanide anion itself can be further photolysed to the cyano radical, which can oxidise the solvent or form cyanogen gas, and this may be what has happened here.[42]

Electrochemical Studies

The experiments on the thiocyanate and iodide complexes, taken together with our previous work on tetraphenylborate, has confirmed that the oxidation of the counter-anionic species is critical to the decomplexation process. The non-reaction of perchlorate and minimal reaction of periodate complexes would support this. The electrochemical oxidation of the anions in $CDCl_3$, as TBAX salts and as the complexes NaX-**1**, was examined by cyclic voltammetry. The results indicated that the iodide, thiocyanate and tetraphenylborate anions in the form of the TBAX salts had oxidation potentials at 0.86, 1.20 and 0.85 V, respectively. In the corresponding calixarene NaX-**1** complexes, these oxidation potentials were recorded at 0.55, 0.95, and 0.80 V, respectively. Thus complexation with the calixarene lowers the oxidation potential of the anion which is consistent with the anion being effectively shielded from the bound cation. The relative ease of electrochemical oxidation of the anions was approximately in the same order as their photochemical oxidation (taking irradiation results after 15 minutes in Table 3, which is before equilibrium is reached).

Irradiation of NaX-1 in Other Deuterated Solvents

The % decomplexation of NaI-**1** and NaSCN-**1** were recorded after irradiation in CD_3OD, CD_3CN, and CD_2Cl_2 (Figure 8). No decomplexation of the complexes occurred in CD_3OD or CD_3CN. While ion pairing is minimised in these solvents it should also be noted that these solvents are not easily reduced by CTTS. The extent of decomplexation of both complexes was significantly less in CD_2Cl_2 than in $CDCl_3$ and both autotitration and IR measurements indicated that, while destruction of the anions had occurred, it was to a far lesser extent than in $CDCl_3$. Although the extent of ion pairing would be similar for these solvents, this difference in reactivity is thought to reflect the relative ease of reduction of these solvents [chloroform, –1.67 V ($E_{1/2}$) vs. dichloromethane –2.33 V ($E_{1/2}$)][45] resulting in the formation of chloride as well as other photoproducts.

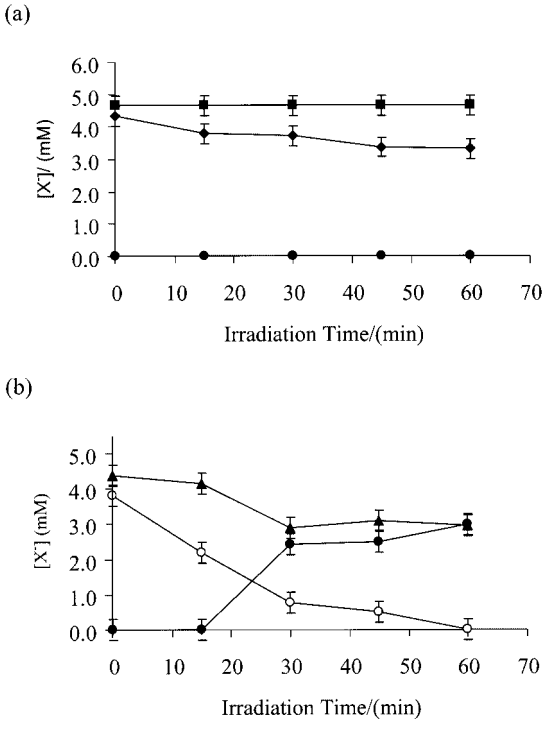

Figure 8. Variation in the concentrations of (a) NaSCN-**1** (■), thiocyanate (♦) and chloride (●) and (b) NaI-**1** (▲), iodide (○) and chloride (●) upon photolysis of the sodium complexes in CD_2Cl_2. Each value is an average of six replicate measurements.

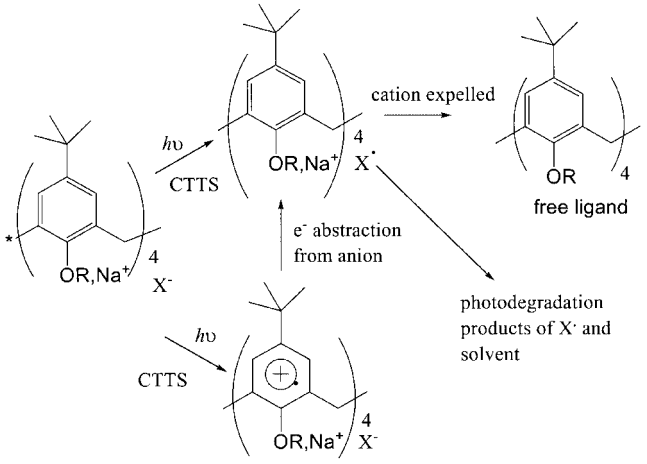
Proposed Mechanism

In Scheme 2 the proposed mechanism for the decomplexation process is shown. Irradiation of NaX-**1** in $CDCl_3$ results in the possible generation of two excited species, a radical aryl cation and the direct oxidation of the counter-anionic species. While the experiments with TBA salts

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

would indicate that excitation of the counter anion predominates, some excitation of the aryl cation does occur as evidenced by the production of chloride ions, albeit at low levels, from the solvent upon irradiation of **1** on its own. However, although a radical aryl cation may be generated initially, abstraction of an electron from the counter anion or solvent is likely to have occurred quickly, as no photoproducts of the host compound were detected in any of the experiments.



R = $CH_2OCOCH_2CH_3$

X = I^-, SCN^-, BPh_4^-

Scheme 2. Proposed decomplexation mechanism for the sodium salt complexes of **1**. Encapsulated solvent is omitted for clarity.

Excitation of the counter-anionic species resulted in a charge transfer to solvent with the subsequent generation of a number of photoproducts of both the solvent and anion. The generation of a radical from the anion leads to the break-up of the ion pair and the subsequent expulsion of the sodium cation. This cation remains available for recomplexation if a suitable counter anion is added to solution post-photolysis or indeed is generated during the photolysis process, i.e. triiodide, chloride.

The products of iodide oxidation were ultimately triiodide and iodine, sulfur was isolated from irradiated thiocyanate solutions, and chloride ion was generated from CTTS to the solvent in both cases. The poor solubility of sodium chloride in chloroform, even in the presence of the macrocycle, precluded full recomplexation. The NMR spectrum recorded after irradiation showed the complex peaks to be at slightly shifted positions relative to the initial complex and these positions are consistent with the complex being present as NaY-**1** (Y = product anion i.e. I_3^-, Cl^-).[17] While photoproducts of the solvent, including the deuterated forms of 1,1,2,2-tetrachloroethane, dichloromethane and dichloroiodomethane, could be detected by GC-MS, there were no photoproducts of the macrocycle itself indicated by NMR or GC-MS.

Conclusions

This study involved the irradiation of a series of sodium salt complexes of **1**. Some of the complexes were isolated in the solid sate with a moleclue of solvent bound at the upper rim. Upon dissolution, however, the upper-rim guest largely dissociated, with about 10% of the solvent molecule remaining associated with the upper rim at any given time. Decomplexation of the sodium cation and immediate subsequent expulsion of upper-rim bound guest could be triggered by the oxidation of the counter anion at the lower rim and the extent of decomplexation varied as a function of the anion. The lower the oxidation potential of the anion the greater the extent of initial decomplexation, with iodide, thiocyanate and tetraphenylborate complexes being easily decomplexed whereas the perchlorate complex was unreactive, as expected. Addition of fresh solutions of anion (in the form of *tert*-butylammonium iodide/thiocyanate etc.) allowed full recomplexation to occur, indicating that the integrity of both the cation and macrocycle were maintained during irradiation.

Potentiometric studies of the inorganic species in solution indicated that there was not a linear correlation between photooxidation of the anion and decomplexation of the calixarene. Photolysis of the anions resulted in the production of other anionic species which could allow recomplexation to occur to some extent. The overall % decomplexation measured was found to be determined by the amount of NaY-**1** present *in solution* at the end of the experiment.

These studies have also helped to understand the relationship between a guest binding at the lower rim of a calixarene and the "allosteric effect" that this confers on upper-rim binding of neutral species.[8,9,25,46] In the example studied here the difference in binding constant for the two guests confers essentially a "one-way allosterism" and removal of the lower-rim bound guest, in this case by photodecomplexation, results in the immediate expulsion of the upper-rim guest. Thus the possibility for a novel control mechanism for the complexation of neutral guest at the upper rim of calixarenes, by choice of lower rim counter anion or level of irradiation, has been identified. Importantly, the photoreaction of the nonchromophoric TBA salts followed similar patterns to the calixarene complexes suggesting that controlled photodecomplexation of bound guests by other macrocyclic systems such as cryptands or resorcinarenes should be possible. The development of high level control of switching systems is obviously desirable and such a system offers potential as an analogue switching device for the control of complexation of neutral species. The dependence of the binding constants at the upper and lower rim as a function of the nature of the counter anion, cation and upper-rim guest is currently being investigated.

Experimental Section

Complexes of *p-tert*-Butylcalix[4]arene Tetraethyl Ester: This calixarene was synthesised and supplied as pure from Prof. M. A. McKervey, Queen's University Belfast and from Loctite (Irl) Ltd. All salts used in this study were supplied by Sigma–Aldrich and were dried overnight at 110 °C prior to use. The following solvents were used in this study: HPLC MeCN, HPLC MeOH (Riedel de

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Haan); and HPLC chloroform, HPLC dichloromethane, [D_3]-MeCN, [D]chloroform, [D_2]dichloromethane and [D_4]MeOH (Aldrich). Anhydrous chloroform was supplied by Sigma–Aldrich. Hydrogen, air, nitrogen and helium were supplied by Air Products.

The complexes were prepared by mixing equimolar amounts of ligand and salt (typically 0.5 mmol) in ca.50 mL of MeCN, chloroform, dichloromethane or MeOH overnight in the dark. The solvent was allowed to evaporate naturally and passing a stream of N_2 over the complex dried the isolated salt. Full complexation was verified from ^{1}H NMR and FTIR data. Micro-analytical data, recorded at the micro-analytical laboratory at the National University of Ireland, Dublin, showed that the solid-state complexes, that contained solvent within the upper cavity, contained 1:1 mol ratios of solvent to complex in all cases.

Spectroscopic Techniques: Solutions of the analytes were typically 10^{-4} mol·L^{-1}. UV/Vis spectra were recorded with a double beam Shimadzu 160A Spectrophotometer. Their spectra were measured using a 10-mm path-length quartz cell. Infrared spectra were recorded with a Nicolet Impact 410 FTIR Spectrometer and the spectra processed on an attached PC using Omnic v.3.1a software. NMR spectra were recorded with a JEOL 300 MHz FT NMR spectrometer. Typically 20 mg of analyte was dissolved in 0.5 mL of a deuterated solvent and placed in a precision pyrex NMR tube.

Irradiation Procedure: The photolysis lamp used in this study was a Pen-Ray 5.5-Watt low-pressure cold cathode mercury vapour lamp with a 150 V (60 Hz) power supply. An external transformer was added to enable direct use of the mains power supply (220 V, 50 Hz). Previous irradiation studies with this lamp showed that a UV filter needed to be used in order to avoid ligand decomposition.[17] This filter was simply a glass NMR tube into which the irradiation sample was placed. Typically, 1 mL of a 4.5 mM solution of a complex in an appropriate solvent was placed into a Pyrex NMR tube. Another 1 mL aliquot of the irradiation sample was placed in the dark during the irradiation time as a reference sample. Before irradiation the solution was degassed for ca. 10 minutes to remove any dissolved oxygen from the sample.

Potentiometric Titration: A 1 mL aliquot of a 4 mM irradiated solution, in chloroform or dichloromethane, was washed with 5 mL ultra-pure water in order to extract all water-soluble inorganic species from the organic solvent. The aqueous layers were collected and transferred to a 50 mL plastic beaker where 2 mL of 2 M HNO_3 was added. The volume in the beaker was made up to ca. 25 mL with doubly distilled water. The solution was then titrated with 0.01 M $AgNO_3$ using a Metrohm 702 SM Titrino autotitrator with a Metrohm 703 Ti stand. The end point was determined potentiometrically using a combined silver ring electrode.

GC-MS Analysis: A GC method was developed using a Shimadzu GC system incorporating a GC-14A gas chromatograph fitted with an FID detector and a Supelco SBP-5 fused silica capillary column (15 m × 0.20 mm, 0.20 μm film thickness). Spectra were obtained from a Shimadzu C-R5A integrator. Samples were introduced to the GC with a Hamilton 10 μL syringe. A GC-MS method was developed using a Shimadzu GC system incorporating a GC-17A gas chromatograph, fitted with an FID detector and a Supelco SBP-5 fused silica capillary column (30 m × 0.25 mm, 0.25 μm film thickness), and a QP-5000 mass spectrometer. Spectra were obtained using the "Class-5000" software package, and samples were introduced to the system with a Shimadzu AOC-20i auto injector.

Electrochemical Analysis: A CHI630A Electrochemical Analyser was used with a Pt wire as the auxillary electrode, a Ag/Ag^+ non-aqueous reference electrode, and a glassy carbon working electrode. A 0.1 M solution of *tert*-butylammonium hexafluorophosphate in chloroform was used as the electrolyte. 0.1 M solutions of *tert*-butylammonium thiocyanate and iodide were prepared in chloroform, and the solution to be analysed contained 6 mL of the electrolyte + 1 mL of the individual anion solutions. A 1 mM solution of *tert*-butylammonium tetraphenylborate was prepared in the electrolyte and was analysed undiluted. All solutions were degassed using nitrogen for 10 minutes prior to analysis. The technique used was CV, sweeping in a positive direction, looking at oxidation between 0 and 1.8 V, and the reverse as far as –0.6 V. The scan rate was 0.1 V/s, four segments were carried out (two full sweeps forward and reverse from –0.6 to 1.8 V), and the sensitivity was 2×10^{-5} A/V.

Acknowledgments

We would like to thank Prof. M. A. McKervey and Loctite Ireland Ltd. for calixarene samples used in this work and J. McGinley for useful discussions. We would also like to thank E. M. Dempsey and T. McCormac for use of the electrochemical analyser. D. T. would like to thank Enterprise Ireland for financial assistance. C. McK. would like to thank the Postgraduate R&D Skills programme (Technological Sector Research, Strand I) and the PhD continuation fund of IT Tallaght for funding.

[27] The values reported were typically determined in acetonitrile or methanol where ion-pairing is minimised (see refs.[10–15] above). The determination of binding constants in media of low dielectric constant, particularly chloroform, is complicated by the phenomenon of ion-pairing in this solvent and binding constants are likely to be higher in these solvents for charged species.

[29] A more logical choice of lamp might appear to be a medium pressure lamp, given the absorption spectra of the ligand and complexes detailed in Table 2 and shown in Figure 3. However use of such lamps resulted in complete photoreaction in short times, which would not allow for a comparison of extent of decomplexation as a function of time.

[33] All of the salts studied were soluble only in their complexed form in $CDCl_3$, but solutions of the salts in MeOH determined that they did have weak excitation spectra above 280 nm.
[34] UV/Vis spectra of the unphotolysed Na**I**-**1** complexes were recorded and had two main absorption bands at 274 nm and 283 nm. In the irradiated complexes a new peak at 368 nm was observed which was concomitant with the destruction of iodide and was assigned as an I_3^- absorption band by comparison with an authentic sample. Quantification of triiodide proved difficult due to the dilution effect on the equilibrium position between poly-iodide and monomeric iodide species in solution. Dilution to record UV/Vis spectra was necessary in order to compare NMR, UV/Vis and potentiometric readings on the same sample. While halides can form polyatomic species the likelihood of this occurring depends on the size of the counter cation and higher species than I_3^- are unlikely to occur with sodium cations in aqueous solution. However dilution in non-aqueous solution does affect the equilibrium between iodide, iodine and triiodide.

Heterobimetallic Systems Containing Organometallic and Classical Coordination Sites: Effects of Subtle Changes in the Werner-Type Site

Tianlu Sheng,[a] Sebastian Dechert,[a] A. Claudia Stückl,[a] and Franc Meyer*[a]

Keywords: Bridging ligands / Cyclopentadienyl ligands / Heterometallic complexes / N ligands / Manganese / Zinc

Several highly unsymmetrical heterodinuclear Mn/Zn complexes are reported, in which an organometallic $CpMn(CO)_2$ fragment and a classical Werner-type zinc coordination unit are arranged in close proximity by means of a bridging pyrazolate. Ligand scaffolds differing in the chelate size of the tripodal tetradentate $\{N_4\}$ binding site, and different co-ligands for zinc are employed. Both the zinc-devoid precursor compounds and the bimetallic complexes with zinc(II) nested in the tris(pyridylalkyl)amine type $\{N_4\}$ compartment have been characterized by X-ray crystallography. Structural and spectroscopic features as well as the redox potentials of the Mn^I/Mn^{II} couple indicate slight effects of the redox-inactive Werner-type subunit on the properties of the organometallic site. Oxidation is highly localized at the organometallic manganese site, as is evidenced by IR and EPR spectroscopy and supported by DFT calculations.

Introduction

Complexes of cyclopentadienyl (Cp) ligands bearing functional amino or amido side-chains are currently receiving enormous attention in organometallic chemistry.[1,2] While the donor substituent tethered to the Cp moiety might serve an intramolecular function, for example acting as a (sometimes hemilabile) chelate donor in generic type **A** complexes (Scheme 1),[3,4] it may also serve an intermolecular function, for example by anchoring to a solid support or providing solubility.[3] A further possibility is the introduction of a potentially bridging moiety that will lead to highly preorganized bimetallic systems formally composed of a type **A** Cp∩N fragment and an adjacent second metal ion. In this respect we have recently developed a synthetic approach for the construction of type **B** bimetallic complexes where a pyrazolate group linking two Cp units functions both as an intramolecular N-donor and as a bridging unit spanning two metals.[5,6] The dimanganese complex **1** has been studied in detail and has been shown to undergo two sequential, one-electron, metal-centered oxidations with fast intramolecular thermal-electron transfer ($k_{ET} \approx 2.6\times10^{10}\ s^{-1}$ at 298 K) in the mixed-valent Mn^IMn^{II} species.[6] In an extension of this concept, a first access to highly unsymmetrical heterobimetallic type **D** scaffolds has recently been developed.[7] These can be formally viewed as a combination of one type **A** and one type **C** subunit, i.e. as an assembly of both a Werner-type and an organometallic fragment in a preorganized bimetallic array. This description is corroborated by the structural characterization of the only such complex reported to date (**2**),[7] since inspection of its individual subunits reveals close similarities to related mononuclear complexes. In particular, the zinc subunit of **2** is reminiscent of the well-known $[(tmpa)ZnCl]^+$ complex, where tmpa is tripodal tetradentate tris(pyridylmethyl)amine. Oxidation of **2** occurs at around –0.66 V (versus the ferrocene couple), and IR spectroscopic evidence showed it to be Mn-centered.[7]

These findings suggest to probe type **D** systems in metal-mediated reactions that proceed by coordination of substrates to the M^2 metal ion in the classical Werner-type site, with the $CpMn(CO)_2$ subunit serving as an electron reservoir, but without direct involvement of the manganese in substrate binding. In the case of redox-active metal ions in the $\{N_4\}$ site, this approach may lead to well-defined systems capable of novel "one-site-addition-two-metal-oxidation" reactions.[8] Two characteristics of type **D** complexes are noteworthy in this regard: firstly, the rigid chelate arrangement precludes dissociation of the organometallic fragment from the bridging pyrazolate, and secondly, the π plane of the heterocycle roughly coincides with the mirror plane of the $Mn(CO)_2$ moiety. The latter situation is most favorable for Mn-pyrazolate π-interactions and hence for electronic communication between the Mn site and the second metal ion.[6,9,10]

It seems particularly attractive that type **D** compounds offer the potential to introduce various different ligand environments for the Werner-type coordination site. Fundamental to an understanding of bimetallic chemistry of those complexes is the knowledge of how different Werner-type

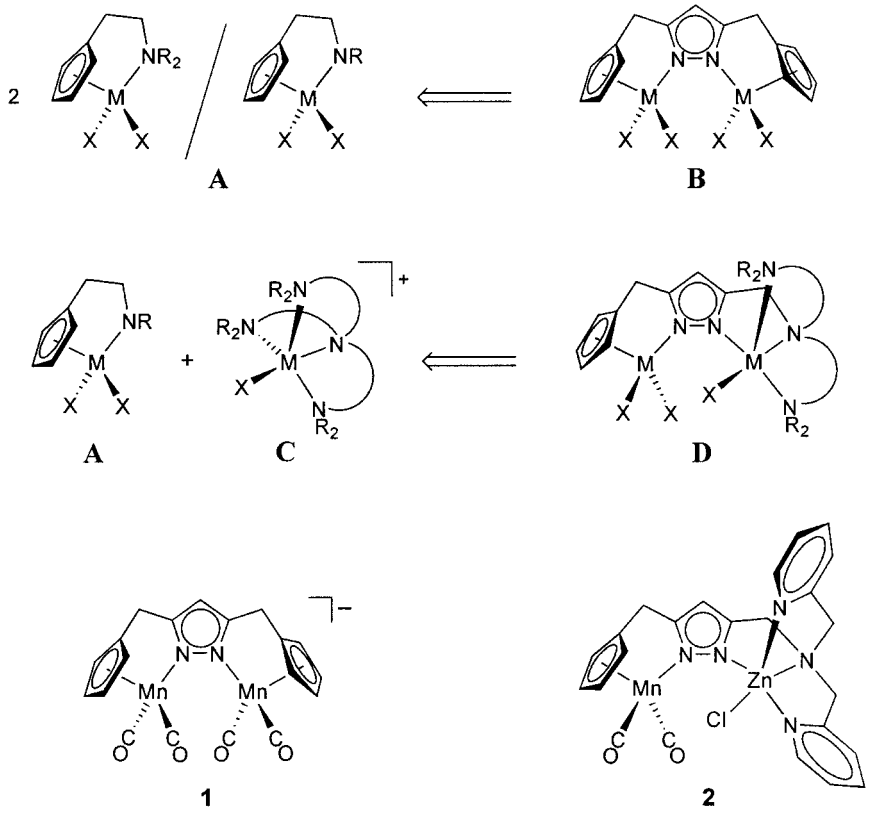

Scheme 1.

sites influence the properties of the redox-active $CpMn(CO)_2$ subunit, even in the absence of any M^2 or in the case of a redox-inactive M^2 ion such as zinc(II). The present contribution now reports two (Cp∩pyrazolate)$Mn(CO)_2$ systems with different chain lengths in the bis(pyridylalkyl) amine side-arms and several zinc complexes thereof. Effects of the different ligand side-arms and different anionic co-ligands (either coordinating or noncoordinating) on structural and electrochemical properties are investigated.

Results and Discussion

Synthesis and Structural Characterization of Complexes

The synthesis of pyrazole derivative **5a** with appended cyclopentadienyltricarbonylmanganese and bis(pyridylmethyl)amine substituents has been communicated previously and had been used for the direct synthesis of **2**.[7] Following the same synthetic strategy we have now prepared the analogous compound **5b** with a longer bis(pyridylethyl)amine side-arm (Scheme 2).

Starting from **3**, which is readily available in five steps from 3,5-dimethylpyrazole,[5,11] the $CpMn(CO)_3$ moiety was first introduced in a palladium-catalyzed cross-coupling reaction and the bis(pyridylmethyl)amine arm was subsequently attached to give 2-tetrahydropyranyl (thp)-protected **5b**. The thp group was then removed under acidic conditions. Irradiation of **5a**,**b** leads to elimination of one CO and intramolecular coordination of the pyrazole-N.[12] This reaction can be conveniently followed by IR spectroscopy. The resulting complexes **6a**,**b** were isolated and fully characterized, including by X-ray crystallography. Their molecular structures are depicted in Figure 1 and Figure 2, respectively, together with selected atom distances and bond angles.

The geometric parameters for the $CpMn(CO)_2$ fragments of **6a**,**b** are very similar to those of **1** and **2** reported previously.[6,7] The proton bound to the pyrazole-N(2) is involved in hydrogen bonding to the N-atoms of the pendent pyridine side-arms. Interestingly, it forms an intramolecular hydrogen bond in the case of **6b** [d{N(2)···N(5)} = 2.977(2) Å; Figure 2], while intermolecular hydrogen bonding that leads to a polymeric chain structure in the solid state is observed for **6a** [d{N(2)···N(5′)} = 2.825(2) Å; Figure 3]. Involvement of the pyrazole-NH in H-bonding has recently also been found to be crucial for unidentate pyrazole coordination.[13]

Heterobimetallic complexes with zinc ions in the $\{N_4\}$ donor compartment are best prepared in a one-pot procedure starting from **5a**,**b**. Thus, solutions of **6a**,**b** prepared in situ were treated with one equivalent of KO*t*Bu and one equivalent of $Zn(OAc)_2{\cdot}2H_2O$. Single crystals of **7a**·DMF·H_2O and **7b** (Scheme 3) were finally obtained by slow diffusion of Et_2O into DMF or CH_2Cl_2 solutions of the products, respectively. The constitution of both complexes was elucidated by X-ray crystallography. Molecular

Selected atom distances [Å] and angles [°] [Cg(1) defines the centroid of the Cp ring atoms]: Mn(1)–Cg(1) 1.7686(9), Mn(1)–N(1) 2.006(2), Mn(1)–C(23) 1.772(2), Mn(1)–C(24) 1.771(2), C(23)–O(1) 1.167(2), C(24)–O(2) 1.162(2); Cg(1)–Mn(1)–N(1) 111.24(5), Cg(1)–Mn(1)–C(23) 125.84(7), Cg(1)–Mn(1)–C(24) 125.04(7), C(23)–Mn(1)–C(24) 90.81(9), C(23)–Mn(1)–N(1) 102.15(8), C(23)–Mn(1)–N(1) 95.98(7), O(1)–C(23)–Mn(1) 173.5(2), O(2)–C(24)–Mn(1) 178.2(2).

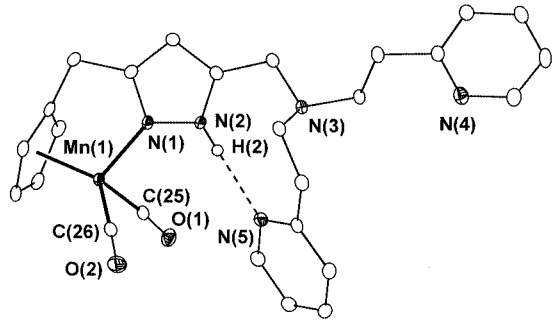

Figure 2. ORTEP plot (30% probability thermal ellipsoids) of the molecular structure of **6b**. For the sake of clarity all hydrogen atoms, except H(2), have been omitted. Selected atom distances [Å] and angles [°] [Cg(1) defines the centroid of the Cp ring atoms]: Mn(1)–Cg(1) 1.772(1), Mn(1)–N(1) 2.020(2), Mn(1)–C(25) 1.767(2), Mn(1)–C(26) 1.775(2), C(25)–O(1) 1.165(3), C(26)–O(2) 1.163(3); Cg(1)–Mn(1)–N(1) 111.16(6), Cg(1)–Mn(1)–C(25) 123.87(8), Cg(1)–Mn(1)–C(26) 127.21(8), C(25)–Mn(1)–C(26) 89.4(1), C(25)–Mn(1)–N(1) 100.45(8), C(26)–Mn(1)–N(1) 99.29(8), O(1)–C(25)–Mn(1) 174.8(2), O(2)–C(26)–Mn(1) 176.2(2); N(2)–H(2) 0.83(3), H(2)···N(5) 2.15(3), N(2)···N(5) 2.977(2); N(2)–H(2)···N(5) 170(2).

structures are depicted in Figure 4 and Figure 5, respectively, together with selected atom distances and bond angles.

The zinc ions in both **7a** and **7b** are nested in the classical $\{N_4\}$ coordination site and the pyrazolate bridge spans the $CpMn(CO)_2$ fragment and the zinc(II), as anticipated. Due to the rigid chelating ligand framework, the N(1)–Mn–CO bond angles of all complexes studied in this work are somewhat widened [95.2(1)–103.1(1)°]. A CSD search revealed that complexes of $CpMn(CO)_2$ fragments with N-donor ligands not tethered to the Cp usually have N–Mn–CO bond angles in the range 92.6–99.4°.

In **7a**, the zinc is five-coordinate with the bridgehead-N(3) and the carboxylate-O(3) in the apical positions of a distorted trigonal bipyramid [N(3)–Zn(1)–O(3) = 170.2(1)°; τ = 0.77].[14] This situation closely resembles the molecular structure of the mononuclear zinc benzoate complex of tmpa.[15] The remaining O(4) atom of the acetate in **7a** is involved in hydrogen bonding to a water molecule included in the crystal lattice (the water is further hydrogen bonded to a DMF solvent molecule; see Figure S1 in the Supporting Information). In contrast, the acetate ligand in **7b** adopts a semi-bidentate binding mode with one short and one significantly longer Zn–O bond [d\{Zn(1)–O(3)\} = 2.049(3) Å, d\{Zn(1)–O(4)\} = 2.447(2) Å]. This is accompanied by an increase in the metal–metal separation [d\{Mn(1)–Zn(1)\} = 4.1423(9) Å in **7a** versus d\{Mn(1)–Zn(1)\} = 4.3915(6) Å in **7b**] and a more drastic displacement of the metal ions out of the plane of the pyrazolate.

Selected atom distances [Å] and angles [°] [Cg(1) defines the centroid of the Cp ring atoms]: Mn(1)–Cg(1) 1.767(2), Mn(1)–N(1) 2.034(2), Mn(1)–C(25) 1.771(3), Mn(1)–C(26) 1.764(3), Mn(1)···Zn(1) 4.3915(6), Zn(1)–O(3) 2.049(2), Zn(1)–O(4) 2.447(2), Zn(1)–N(2) 2.088(2), Zn(1)–N(3) 2.176(2), Zn(1)–N(4) 2.068(2), Zn(1)–N(5) 2.290(3), O(1)–C(25) 1.160(4), O(2)–C(26) 1.174(4); Cg(1)–Mn(1)–N(1) 112.48(9), Cg(1)–Mn(1)–C(25) 122.4(1), Cg(1)–Mn(1)–C(26) 125.0(1), C(25)–Mn(1)–C(26) 93.2(1), C(25)–Mn(1)–N(1) 95.2(1), C(26)–Mn(1)–N(1) 103.1(1), O(1)–C(25)–Mn(1) 175.5(3), O(2)–C(26)–Mn(1) 172.7(3), N(2)–Zn(1)–N(3) 78.21(9), N(2)–Zn(1)–N(4) 103.0(1), N(2)–Zn(1)–N(5) 160.16(9), N(2)–Zn(1)–O(3) 105.18(9), N(2)–Zn(1)–O(4) 91.98(9), N(3)–Zn(1)–N(4) 99.97(9), N(3)–Zn(1)–N(5) 86.03(9), N(3)–Zn(1)–O(3) 158.66(9), N(3)–Zn(1)–O(4) 101.35(8), N(4)–Zn(1)–N(5) 91.4(1), N(4)–Zn(1)–O(3) 99.72(9), N(4)–Zn(1)–O(4) 156.03(9), N(5)–Zn(1)–O(3) 85.32(9), N(5)–Zn(1)–O(4) 79.27(9), O(3)–Zn(1)–O(4) 57.82(8).

Apparently, the six-membered chelate rings leave more space for anion coordination and allow for greater flexibility of the zinc coordination sphere. The different acetate binding modes are also discernible in the IR spectra, where **7a** features a high-energy $\nu_{as}(CO_2^-)$ vibration at $\tilde{\nu}$ = 1663 cm^{-1}, while $\nu_{as}(CO_2^-)$ of **7b** occurs around $\tilde{\nu}$ = 1607 cm^{-1}. The $\nu_s(CO_2^-)$ absorptions (expected around $\tilde{\nu}$ = 1400 cm^{-1})[16] cannot be clearly identified because of various other bands in that region.

The only known mononuclear zinc(II) complex of tris(pyridylethyl)amine (tpea), which provides longer alkyl spacers than tpma, is [(tpea)Zn](ClO$_4$)$_2$.[17] In contrast to the related zinc(II) complexes of tpma, however, the cationic portion of [(tpea)Zn](ClO$_4$)$_2$ contains four-coordinate zinc while the perchlorate remains uncoordinated. A similar sit-

uation is now found in the heterobimetallic complex **8**, which was obtained from **6b** and $[Zn(H_2O)_6](ClO_4)_2$. The molecular structure of the cation of **8** is depicted in Figure 6, together with selected atom distances and bond angles.

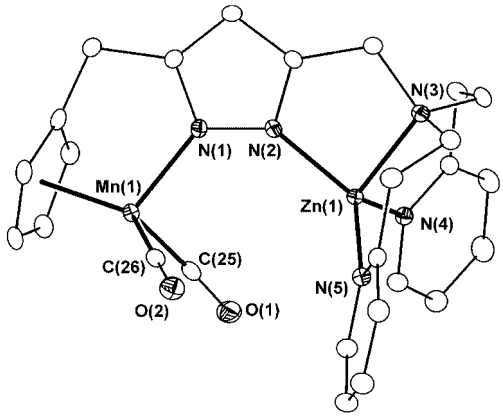

Figure 6. ORTEP plot (30% probability thermal ellipsoids) of the molecular structure of **8**. In the interests of clarity all hydrogen atoms and the ClO_4^- anion have been omitted. Selected atomic distances [Å] and angles [°] [Cg(1) defines the centroid of the Cp ring atoms]: Mn(1)–Cg(1) 1.773(1), Mn(1)–N(1) 1.991(2), Mn(1)–C(25) 1.761(3), Mn(1)–C(26) 1.774(3), Mn(1)···Zn(1) 4.0601(5), Zn(1)–N(2) 1.941(2), Zn(1)–N(3) 2.079(2), Zn(1)–N(4) 1.999(2), Zn(1)–N(5) 2.002(2), O(1)–C(25) 1.167(3), O(2)–C(26) 1.168(3); Cg(1)–Mn(1)–N(1) 110.81(7), Cg(1)–Mn(1)–C(25) 126.29(9), Cg(1)–Mn(1)–C(26) 128.3(1), C(25)–Mn(1)–C(26) 90.5(1), C(25)–Mn(1)–N(1) 99.16(9), C(26)–Mn(1)–N(1) 94.62(9), O(1)–C(25)–Mn(1) 177.2(2), O(2)–C(26)–Mn(1) 179.5(2), N(2)–Zn(1)–N(3) 85.24(8), N(2)–Zn(1)–N(4) 124.58(8), N(2)–Zn(1)–N(5) 114.46(8), N(3)–Zn(1)–N(4) 101.93(8), N(3)–Zn(1)–N(5) 103.88(8), N(4)–Zn(1)–N(5) 116.61(8).

The coordination geometry of Zn(1) in **8** is distorted tetrahedral, the strongest distortion resulting from the presence of an acute angle in the five-membered chelate ring [N(2)–Zn(1)–N(3) = 85.24(8)°]. Both the zinc and the manganese ions are located roughly within the plane of the pyrazolate heterocycle [out-of-plane displacement: 0.317(1) Å for Zn and 0.269(1) Å for Mn], indicating a relaxed bonding situation. The closest distance between Zn(1) and a CO ligand is almost 3.5 Å, which is clearly out of the bonding range.[18] Due to the absence of any coordinating counteranion, the Mn···Zn distance [4.0601(5) Å] is clearly shorter than in **7b**. Comparison of the structures of **7b** and **8** reveals that binding of small substrate molecules to the zinc ion in **8** should be feasible.

Spectroscopic and Electrochemical Trends

Incorporation of zinc in the $\{N_4\}$ compartment of **6a**,**b** to give **7a**,**b** induces a slight shift of the ν(CO) stretching frequencies to lower wavenumbers (Table 1; spectra of KBr pellets), thereby indicating an increase in π-backbonding from the manganese ion to the CO ligands. This is also reflected by a slight decrease of the $Mn–C_{CO}$ distance (mean value for **6a**,**b**: 1.771 Å; mean value for **7a**,**b**: 1.766 Å) and a slight increase of the C–O distance (mean value for **6a**,**b**: 1.164 Å; mean value for **7a**,**b**: 1.171 Å). The effects are less pronounced for **8**, which can be ascribed to the cationic charge of its MnZn entity. While mainly located at zinc, to a small extent the electronic unsaturation in **8** is apparently transmitted also towards the manganese.

Table 1. IR absorptions in the CO stretching range, along with *g* values and isotropic coupling constants derived from EPR spectra of the oxidized species.

	DMF solution [cm^{-1}]		KBr pellets [cm^{-1}]		g_{iso}	$a(^{55}Mn)_{iso}$ [mT]

8$^+$	2021	1935	–	–	–	–

The higher electron density at the manganese ions in **7a**,**b** should correspond to a more facile oxidation of manganese(I) in the heterobimetallic complexes than for the zinc-devoid precursors, which was confirmed by cyclic voltammograms of **6a**,**b** and **7a**,**b** (the cyclic voltammogram of **7a** is shown in Figure 7 as an example). The zinc-devoid compounds exhibit a reversible, one-electron oxidation wave at around $E_{1/2}$ = –0.35 V (versus the ferrocene/ferrocenium couple), while oxidation of the heterobimetallic complexes occurs around $E_{1/2}$ = –0.60 V (Table 2). This shift to more negative potentials is probably due to the higher electron-donating power of the ligand towards manganese as a consequence of the deprotonation of the pyrazole. In accordance with the spectroscopic results discussed above, the electron-poor **8** is clearly more difficult to oxidize than the corresponding acetate complex **7b** with a potential intermediate between those of **6b** and **7b** (the redox process is only quasi-reversible in the case of **8**).

The oxidation potentials of $CpMn(CO)_2L$ complexes are known to vary over a potential range of more than 2 V, depending on the nature of the ligand L.[9,10,19] The rather low oxidation potentials of **6a**,**b** and **7a**,**b** indicate significant stabilization of the Mn^{II} state by the anionic pyrazolate ligand and reflect the high nucleophilicity of the N-heterocycle, in particular in the heterobimetallic species.[19] However, a considerable cathodic shift is observed upon binding of the zinc ions. Zinc itself is redox inactive, but comparison of **7a** and **7b** reveals that the different Werner-type coordination subunits do indeed influence the redox properties of the $CpMn(CO)_2$ group, even though the effects are only minor (difference in $E_{1/2}$ of about 30 mV between **7a** and **7b**). Also, a certain degree of information about the type of coligand at zinc is transmitted to manganese, resulting in slight shifts in the Mn^I/Mn^{II} redox potential (**7b** versus **8**).

Chemical oxidation with $[Cp_2Fe]PF_6$ in DMF solution allowed the IR spectroscopic determination of the ν(CO) absorptions of the oxidized species (Table 1, Figure 8).

Table 2. Formal potentials for the Mn^{II}/Mn^{I} couple in DMF/0.1 M Bu_4NPF_6. Values are given in volts versus Fc/Fc^+.

6a	–0.33
6b	–0.35
7a	–0.61
7b	–0.58
8	–0.44 (quasi rev.)

Within minutes at room temperature, however, these bands gradually vanished without concomitant rise of any new bands in the CO stretching region, thus indicating irreversible decomposition of the oxidized $Mn^{II}Zn^{II}$ complexes. Solution EPR spectra at this point show an isotropic six-line signal around g = 2.009 with $a(^{55}Mn)_{iso}$ = 9.43 mT, suggesting extrusion of the manganese(II) ions and formation of $[Mn(DMF)_6]^{2+}$.[20] Unambiguous EPR characterization of the oxidized Mn^{II} (**6a**$^+$, **6b**$^+$) and $Mn^{II}Zn^{II}$ species (**7a**$^+$, **7b**$^+$, **8**$^+$) after chemical oxidation with $[Cp_2Fe]PF_6$ in a THF/DMF mixture was hampered by the immediate formation of a dominant signal for the $[Mn(DMF)_6]^{2+}$ decomposition product. In CH_2Cl_2 the product of decomposition seems to form less rapidly and is insoluble, which allows EPR spectroscopic characterization of the oxidized species (**6a**$^+$, **6b**$^+$, **7a**$^+$, **7b**$^+$) in solution. All EPR spectra after chemical oxidation with a substoichiometric amount of $[Cp_2Fe]PF_6$ in CH_2Cl_2 solution show a six-line pattern with only slightly differing g values around 2.040 and isotropic coupling constants around 6.12 mT (Table 1; the spectrum of **6b**$^+$ is shown in Figure 9 as an example). The magnitude of $a(^{55}Mn)_{iso}$ is typical for a $[CpMn^{II}(CO)_2L]^+$ species and suggest that the unpaired electron is mainly localized at the manganese atom, in accordance with electronic-structure calculations (see below). The spectrum of a frozen solution of **6b**$^+$ (Figure 9) compares well with those of other $[CpMn^{II}(CO)_2L]^+$ compounds with approximate axial symmetry of the g tensor and anisotropic hyperfine coupling to a single ^{55}Mn nucleus.[21] However, decomposition of the oxidized species occurred after a few minutes at room temperature. The product of decomposition in CH_2Cl_2 shows a very broad unstructured signal centered around g = 1.994. No EPR spectrum of the oxidized $Mn^{II}Zn^{II}$ species **8**$^+$ could be recorded because of the poor solubility of **8** in CH_2Cl_2.

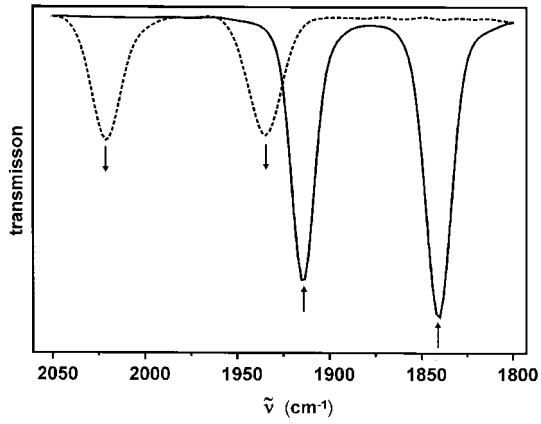

Figure 8. Stretching frequencies ν(CO) of **6b** (solid line) and after oxidation with $[Cp_2Fe]PF_6$ (**6b**$^+$, dashed line) in DMF.

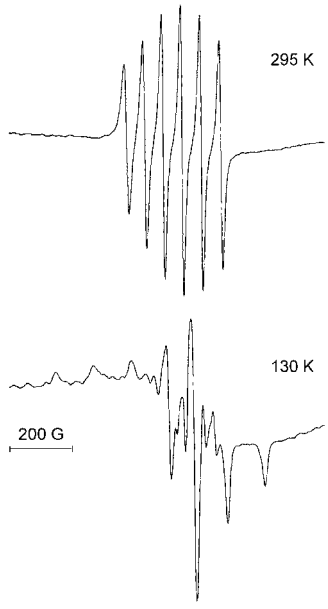

Figure 9. EPR spectra of **6b**$^+$ in CH_2Cl_2 at 295 and 130 K.

Since structural information about the oxidized species is not available, and in order to corroborate the spectroscopic findings, DFT calculations[22] were carried out for the doublet state of **8**$^+$. The geometry was DFT-minimized starting from the X-ray structure atomic coordinates for **8** to give the geometric information listed in Figure 10. The $Mn–N^{pz}$ and $Mn–C_{C\equiv O}$ bonds in **8**$^+$ were calculated to be 1.95 and 1.84 Å, respectively, which is clearly longer than the corresponding values of the $Mn^{I}Zn^{II}$ complex **8**. At the same time, the C–O distances of the Mn-bound carbonyls are significantly shortened at 1.15 Å, in agreement with diminished π-backbonding in the oxidized species and the observed shift of the IR stretching vibrations. The SOMO of **8**$^+$ is depicted in Figure 10, from which it is apparent that

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the SOMO has predominant Mn 3d character with some antibonding admixture from the π-pyrazolate system.

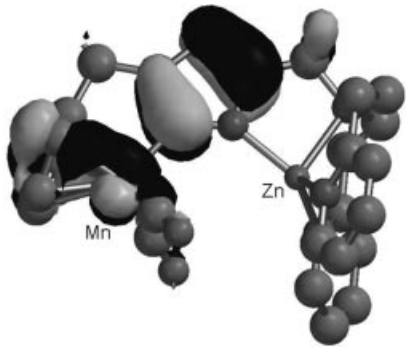

Figure 10. Calculated shape of the SOMO of **8**$^{+}$ (DFT, Spartan 02, UB3LYP/LACVP*). Selected structural parameters: Mn–N^{pz} 1.95 Å; Mn–$C_{C\equiv O}$ 1.84 Å; C–O 1.15 Å; Zn–N^{pz} 2.03 Å; Mn–N–N 139.2°; $C_{C\equiv O}$–Mn–N 98.1/98.2°; Zn–N–N 139.2°.

According to a Mulliken population analysis the spin is almost perfectly localized on manganese (ρMn = 1.017), while spin density on the pyrazolate-N is found to be negligible (ρN^{pz} = 0.009/–0.013), in accordance with the lack of any ^{55}Mn–^{14}N hyperfine coupling in the EPR spectra.

Conclusions

Highly unsymmetrical heterodinuclear Mn/Zn type **D** complexes based on a bridging pyrazolate with variable ligand environments for the classical Werner-type coordination site are accessible by the versatile synthetic approach outlined in Scheme 2. Structural characteristic of the two metal-containing subunits of the systems studied here are reminiscent of their corresponding mononuclear analogues, which supports the description of the present type **D** systems as hybrids of an organometallic $CpMn(CO)_2$ fragment and a classical Werner-type tris(pyridylalkyl)amine type $\{N_4\}$ metal site. Oxidation is highly localized at the organometallic manganese site, as is evidenced by IR and EPR spectroscopy and supported by DFT calculations. However, slight effects of the redox-inactive, Werner-type subunit of the Mn^{I}/Mn^{II} redox properties and of spectroscopic signatures of the organometallic site are revealed by comparing the zinc-devoid manganese compounds and the bimetallic Mn/Zn complexes, as well as by assessing the influence of the chelate size of the tripodal tetradentate $\{N_4\}$ binding site and of different coligands at zinc. Future work will focus on bimetallic type **D** complexes with a second redox-active metal ion other than zinc. It is hoped that application of the principles delineated in this work will allow modulation of the relative redox properties of the two distinct metal sites, and as a consequence will enable a tuning of the bimetallic redox reactivity of the "one-site-addition-two-metal-oxidation" type.

Experimental Section

General Remarks: All reagents were obtained from commercial sources (Aldrich, Fluka, or VWR) and used as received. Compounds **3**, **4**, and **5a** (Scheme 2) were prepared according to the literature methods.[5,7] Solvents were dried under reflux (CaH_2 for dichloromethane, Na/K alloy for diethyl ether and THF) and distilled prior to be used. All reactions were carried out under nitrogen using standard Schlenk techniques. IR spectra were recorded with a Digilab Excalibur, UV/Vis/NIR spectra with a Cary 5000, EPR spectra with a Bruker ELEXSYS 500. Cyclic voltammetry was performed with a potentiostat/galvanostat Perkin–Elmer Model 263A instrument with glassy-carbon working electrode and platinum reference and counter electrodes, in 0.1 M tetra-*n*-butylammonium hexafluorophosphate/DMF. Ferrocene (the potential being 0.45 V in DMF against SCE)[23] was used as internal standard. Elemental analyses were measured by the analytical laboratory of the Institut für Anorganische Chemie der Universität Göttingen using a Heraeus CHN-O-RAPID instrument.

Complex 5b(thp): Na_2CO_3 (4.0 g, 37 mmol) was dried at 100 °C under vacuum for 1 h. After cooling to room temperature, a solution of **4** (1.50 g, 3.60 mmol) and bis[2-(2-pyridyl)ethyl]amine (1.13 g, 3.80 mmol) in MeCN (100 mL) was added. The suspension was stirred overnight at 75 °C in the dark, then filtered and the residue washed several times with small portions of MeCN. Evaporation of the combined organic phases produced a red-brown oil that was purified by Kugelrohr distillation under vacuum to remove all volatile impurities and to give **5b(thp)** (yield 1.62 g, 89%). ^{1}H NMR ($CDCl_3$): δ = 1.55–1.66 (m, 3 H, CH_2^{thp}), 1.92 (d, J = 12.3 Hz, 1 H, CH_2^{thp}), 2.09 (br. s, 1 H, CH_2^{thp}), 2.41 (m, 1 H, CH_2^{thp}), 2.94 (s, 8 H, $PyCH_2CH_2N$), 3.61 (s, 2 H, CH_2Cp), 3.74 (s, 2 H, $PzCH_2$), 3.98 (d, J = 11.0 Hz, 1 H, CH_2^{thp}), 4.63 (d, J = 6.2 Hz, 2 H, CH^{Cp}), 4.69 (s, 2 H, CH^{Cp}), 5.21 (d, J = 8.7 Hz, 1 H, $CH^{thp,2}$), 5.87 (s, 1 H, $CH^{pz,4}$), 7.06 (br. s, 4 H, $CH^{py,3/5}$), 7.49 (t, J = 7.1 Hz, 2 H, $CH^{py,4}$), 8.46 (s, 2 H, $CH^{py,6}$) ppm; NH not observed. ^{13}C NMR ($CDCl_3$): δ = 22.4 ($CH_2^{thp,4}$), 24.3, 24.7 ($CH_2^{thp,5}$, CH_2Cp), 29.3 ($CH_2^{thp,3}$), 35.7 (NCH_2), 51.0, 53.5 ($PzCH_2$, $PyCH_2$), 67.2 ($CH_2^{thp,6}$), 81.4, 81.7, 83.1, 83.2 (CH^{Cp}), 84.4 ($CH^{thp,2}$), 101.9 (C^{Cp}), 106.1 ($CH^{pz,4}$), 120.6 ($CH^{py,5}$), 123.1 ($CH^{py,3}$), 135.7 ($CH^{py,4}$), 141.2 ($C^{pz,5}$), 148.8 ($CH^{py,6}$), 149.6 ($C^{pz,3}$), 160.6 ($C^{py,2}$), 224.6 (CO) ppm. MS (ESI): m/z (%) = 608 (50) [M^+], 501 (100) [M^+ – $pyCH_2CH_3$], 439 (80) [M^+ – 3CO – THP]. $C_{32}H_{34}MnN_5O_4$ (607.59): calcd. C 63.26, H 5.64, N 11.53; found C 62.86, H 5.82, N 11.34.

Complex 5b: A solution of **5b(thp)** (1.62 g, 2.67 mmol) in EtOH (20 mL) was treated with ethanolic HCl (10 mL) and stirred overnight in the dark. Addition of Et_2O (100 mL) caused precipitation of the hydrochloride salt of **5b** as a brownish solid. This was separated by filtration, neutralized with aqueous Na_2CO_3, and extracted with several portions of CH_2Cl_2. After drying the combined organic phases with $MgSO_4$, the solvent was evaporated to give the crude product as a red-brown oil that was purified by Kugelrohr distillation under vacuum to remove all volatile impurities (yield 1.28 g, 91.6%). ^{1}H NMR ($CDCl_3$): δ = 2.89 (br. s, 4 H, CH_2N), 2.99 (br. s, 4 H, $PyCH_2$), 3.59 (s, 2 H, CH_2Cp), 3.83 (br. s, 2 H, $PzCH_2$), 4.59 (s, 2 H, CH^{Cp}), 4.71 (s, 2 H, CH^{Cp}), 5.95 (br. s, 1 H, $CH^{pz,4}$), 6.97 (m, 2 H, $CH^{py,3}$), 7.07 (m, 2 H, $CH^{py,5}$), 7.51 (t, J = 7.2 Hz, 2 H, $CH^{py,4}$), 8.48 (s, 2 H, $CH^{py,6}$) ppm; NH not observed. ^{13}C NMR ($CDCl_3$): δ = 27.2, (CH_2Cp), 35.4 (NCH_2), 49.5 ($PzCH_2$), 54.0 ($PyCH_2$), 81.6, 83.2 (CH^{Cp}), 102.8 (br., $CH^{pz,4}$), 104.7 (C^{Cp}), 121.3 ($CH^{py,5}$), 123.5 ($CH^{py,3}$), 136.5 ($CH^{py,4}$), 148.9 ($CH^{py,6}$), 159.7 ($CH^{py,2}$), 225.1 (CO) ppm; $C^{pz,3/5}$ not observed. MS (ESI): m/z (%) = 524 (100) [M^+], 439 (43) [M^+ – 3CO – 1] 439. $C_{27}H_{26}MnN_5O_3$ (523.47): calcd. C 61.95, H 5.01, N 13.38; found C 62.78, H 5.36, N 13.14.

Complex 6a: A solution of **5a** (0.25 g, 0.50 mmol) in THF (200 mL) was irradiated with a high-pressure mercury lamp in a quartz tube

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

at –40 °C. Within about 1 h the color of the solution had changed from light yellow to yellow. The solution was allowed to warm to room temperature and the solvent was removed under reduced pressure. The residue was extracted with 10 mL of CH_2Cl_2 and filtered. Slow diffusion of Et_2O into the red solution gradually gave red crystals of the product **6a** (yield 73 mg, 31%). IR (KBr): $\tilde{\nu}$ = 3060 w, 2920 w, 2849 w, 1910 vs, 1827 vs, 1592 m, 1571 m, 1474 m, 1435 m, 1231 m, 771 m, 657 m, 612 m, 585 m cm^{-1}. $C_{24}H_{22}MnN_5O_2 \cdot 0.5\,H_2O$ (476.42): calcd. C 60.51, H 4.65, N 14.70; found C 60.56, H 4.77, N 14.58.

Complex 6b: A solution of **5b** (0.26 g, 0.50 mmol) in THF (200 mL) was irradiated with a high-pressure mercury lamp in a quartz tube at –40 °C. After about 1 h the color of the solution had changed from light yellow to yellow. The solution was allowed to warm to room temperature and the solvent was removed under vacuum. The residue was extracted with 10 mL of CH_2Cl_2 and filtered. Slow diffusion of Et_2O into the red solution gradually gave red crystals of **6b**, which were filtered, washed with Et_2O, and dried under vacuum (yield 85 mg, 34%). IR (KBr): $\tilde{\nu}$ = 3127 w, 3061 w, 2968 w, 2851 w, 1912 vs, 1838 vs, 1595 m, 1568 m, 1465 m, 1433 m, 1352 m, 1260 m, 827 m, 803 m, 758 m, 658 m, 610 m, 590 m, 507 w, 472 w cm^{-1}. $C_{26}H_{26}MnN_5O_2$ (495.46): calcd. C 63.03, H 5.29, N 14.13; found C 62.69, H 5.41, N 14.23.

Complex 7a: A solution of **5a** (0.25 g, 0.50 mmol) in THF (200 mL) was irradiated with a high-pressure mercury lamp in a quartz tube at –40 °C. After about 1 h the color of the solution had changed from light yellow to yellow, and the solution was allowed to warm to room temperature. KO*t*Bu (0.056 g, 0.50 mmol) and Zn(OAc)$_2$·2H$_2$O (0.11 g, 0.50 mmol) were then added. The mixture was stirred overnight to give a yellow precipitate. The precipitate was separated by filtration, washed with light petroleum, and dried under vacuum. The crude material was dissolved in DMF (6 mL) to give an orange solution. Orange crystals of **7a**·DMF·H$_2$O were obtained by slow diffusion of Et_2O into that solution. The crystals were separated by filtration, washed with Et_2O, and dried under vacuum (yield 74 mg, 22%). IR (KBr): $\tilde{\nu}$ = 2926 w, 2855 w, 1901 vs, 1831 vs, 1663 s, 1606 s, 1582 m, 148 m, 1430 m, 1406 s, 1387 s, 1340 m, 1254 m, 1218 w, 1157 m, 1094 m, 1057 m, 1019 m, 918 w, 948 w, 889 w, 823 w, 774 m, 660 m, 611 m, 585 m, 412 m cm^{-1}. $C_{26}H_{24}MnN_5O_4Zn \cdot DMF$ (663.93): calcd. C 52.46, H 4.71, N 12.66; found C 52.08, H 4.75, N 12.59.

Complex 7b: A solution of **5b** (0.26 g, 0.50 mmol) in THF (200 mL) was irradiated with a high-pressure mercury lamp in a quartz tube at –40 °C. After about 1 h the color of the solution had changed from light yellow to yellow and the solution was allowed to warm to room temperature. KO*t*Bu (0.056 g, 0.50 mmol) and Zn(OAc)$_2$·2H$_2$0 (0.11 g, 0.50 mmol) were added and the mixture was stirred for 48 h. After removal of the solvent under reduced pressure, the residue was washed with light petroleum and dried under vacuum. Slow diffusion of Et_2O into a solution of the crude material in CH_2Cl_2 (8 mL) gradually gave orange-yellow crystals. These were separated by filtration, washed with Et_2O, and dried under vacuum (yield 57 mg, 19%). IR (KBr): $\tilde{\nu}$ = 308 w, 2975 w, 2911 w, 2850 w, 1898 vs, 1823 vs, 1607 m, 1578 m, 1483 w, 1443 m, 1416

m, 1331 w, 1256 m, 1161 m, 1112 m, 1059 m, 1017 m, 836 w, 764 m, 664 m, 592 m, 419 w cm^{-1}. $C_{28}H_{28}MnN_5O_4Zn·0.5H_2O$ (627.89): calcd. C 53.56, H 4.66, N 11.15; found C 53.41, H 4.67, N 11.15.

Complex 8: A solution of **5b** (0.26 g, 0.50 mmol) in THF (200 mL) was irradiated with a high-pressure mercury lamp in a quartz tube at –40 °C. After about 1 h the color of the solution had changed from light yellow to yellow. It was allowed to warm to room temperature, and KO*t*Bu (0.056 g, 0.50 mmol) and $Zn(ClO_4)_2·6H_2O$ (0.185 g, 0.50 mmol) were then added. The mixture was stirred overnight to give a yellow precipitate. The precipitate was separated by filtered, washed with light petroleum, and dried under vacuum. Orange crystals were obtained after several days by slow diffusion of diethyl ether into a DMF solution (10 mL) of the crude product. The crystals were separated by filtration, washed with diethyl ether, and dried under vacuum (yield 127 mg, 39%). IR (KBr): $\tilde{\nu}$ = 3098 w, 2917 w, 2883 w, 1906 vs, 1833 vs, 1613 m, 1569 w, 1492 m, 1447 m, 1329 w, 1310 w, 1102 s, 772 m, 659 w, 624 m, 593 w, 423 w cm^{-1}. $C_{26}H_{25}ClMnN_5O_6Zn·H_2O$ (677.31): calcd. C 46.11, H 4.02, N 10.34; found C 45.33, H 3.96, N 10.29.

X-ray Crystallographic Study: X-ray data were collected on a STOE IPDS II diffractometer (graphite-monochromated Mo-K_α radiation, λ = 0.71073 Å) by use of ω scans at –140 °C (Table 3). The structures were solved by direct methods and refined on F^2, using all reflections, with SHELX-97.[24] The non-hydrogen atoms were refined anisotropically. Hydrogen atoms which were not involved in hydrogen bonding were placed in calculated positions and assigned an isotropic displacement parameter of 0.08 $Å^2$. The positional and isotropic thermal parameters of the nitrogen-bonded hydrogen atom H(2) in **6a** and **6b** were refined without constraints. A DFIX (0.83 Å) restraint was applied to the H–O distances of the H_2O molecule in **7b** and the hydrogen atoms were refined with an isotropic displacement parameter of 0.08 $Å^2$. Face-indexed absorption corrections were performed numerically with the program X-RED.[25] The geometrical aspects of the structures were analyzed with the PLATON program.[26]

CCDC-248451 (for **6a**), -248452 (for **6b**), -248453 (for **7a**·DMF·H_2O), -248454 (for **7b**), and -248455 (for **8**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Supporting Information Available (see also the footnote on the first page of this article): View of the hydrogen-bonding interactions of **7a**·DMF·H_2O (Figure S1).

Effect of Conformation and Combination of 1,3-Bis(4-pyridylthio)propan-2-one upon Coordination Architectures: Syntheses, Characterizations and Properties

Benlai Wu,[a] Daqiang Yuan,[a] Feilong Jiang,[a] Lei Han,[a] Benyong Lou,[a] Caiping Liu,[a] and Maochun Hong*[a]

Keywords: Coordination polymer / Interpenetration / Conformation analysis / Magnetic property / Fluorescence

Self-assemblies of the conformationally labile ditopic ligand 1,3-bis(4-pyridylthio)propan-2-one (L) with square-planer nodes Co^{II}, Ni^{II} and with linear nodes Ag^{I} have afforded three new coordination polymers, $\{[Ni(L)_2Cl_2]\}_\infty$ (**1**), $\{[Co(L)_2(SCN)_2]\cdot(DMF)_2\}_\infty$ (**2**) and $\{[AgL]NO_3\}_\infty$ (**3**), respectively. Structural analyses of these polymers and conformational analyses of L have revealed that metal-assisted conformational selectivity and unique combinations of conformational isomers of L around the metal nodes probably play the key role in determining the structural topologies. In **1**, a C_2 symmetric array of two sorts of conformational isomers of L around Ni^{II} centers results in a 3D interpenetrating framework, while in **2** a combination of two types of conformational isomers of L around the inversion center Co^{II} provides a 3D interpenetrating architecture of $CdSO_4$-like topology. In **3**, L presents only a typical conformation, with higher steric energy, that links linear nodes Ag^{I}, leading to a 1D U-like chain. The magnetic properties of **1** and **2**, as well as the interesting fluorescent properties of **3**, have also been investigated.

Introduction

Flexible ditopic or multitopic organic ligands that encode more variable chemical information, such as their flexibility and conformational freedoms, have attracted increasing interest in crystal engineering.[1–11] A combination of selective metal ions with tailored flexible ligands is very fruitful in building a large assortment of coordination polymers with unique architectures,[12–19] sometimes with interpenetrations[20–24] and interesting material properties.[25–29] Moreover, some conformational isomers of a flexible ligand in solution may be induced, enhanced, recognized and stabilized by numerous factors, especially by metal coordination preferences in a self-assembly process, providing additional opportunities to design and build unique coordination motifs as well as to separate an unfavorable conformation. This is clearly highlighted by Stang's rational design based on the conformationally defined dihedral angle of 4,4′-dithiodipyridine,[30] although such cases are still comparatively rare.

Recently, we have concentrated on the coordination chemistry of flexible ligands, particularly on metal-based supramolecular architectures of N-containing heterocyclic thioethers with various arene bridges, and have obtained several unique structural motifs.[31–34] While this work was in progress several reports of new Ag^{I} polymers coordinated by related N-containing heterocyclic thioethers with alkane bridges appeared.[35,36] Pursuing our work in this area, we deliberately designed dithioether ligand 1,3-bis(4-pyridylthio)propan-2-one (L) (Scheme 1). The advantages of this ligand are (i) as arene bridges are displaced by propan-2-one groups, the conformational transformation barrier is so low that some conformations of L may be induced by weak forces, such as solvent and electrostatic effects, and recognized by metal-coordination and further stabilized in crystallization; (ii) the relative rigidity resulting from the permanent planar requirement of the propan-2-one group, needed for sp^2 hybridization of its central carbon, enlarges conformational otherness, resultining in differences from analogs with simple alkane bridges; (iii) incorporating the ketone group into the alkane chain endows the ligand with a hydrogen-bond receptor, which will functionalize the resultant architecture. Consequently, using L to assemble with the square-planar nodes Ni^{II} and Co^{II} in solvothermal methanol or DMF/diethyl ether systems, we were able to prepare two new 3D interpenetrating polymers with distinctive topologies, owing to metal-assisted conformational selectivity and unique combinations of ligand L. In contrast, the assembly of L with linear node Ag^{I} in a three-layered diffusion system produced a 1D U-like polymer, where nitrate anions template both the architecture of the polymer and the typical conformation of L. We report here the resultant structures of $\{[Ni(L)_2Cl_2]\}_\infty$ (**1**), $\{[Co(L)_2(SCN)_2]$

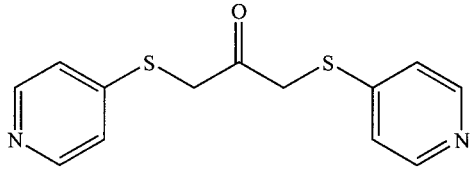
·$(DMF)_2\}_\infty$ (**2**) and $\{[AgL]NO_3\}_\infty$ (**3**), along with conformational analysis of L. Furthermore, we also report quantitative magnetic characterizations of complexes **1** and **2**, and the fluorescence properties of ligand L and complex **3**.



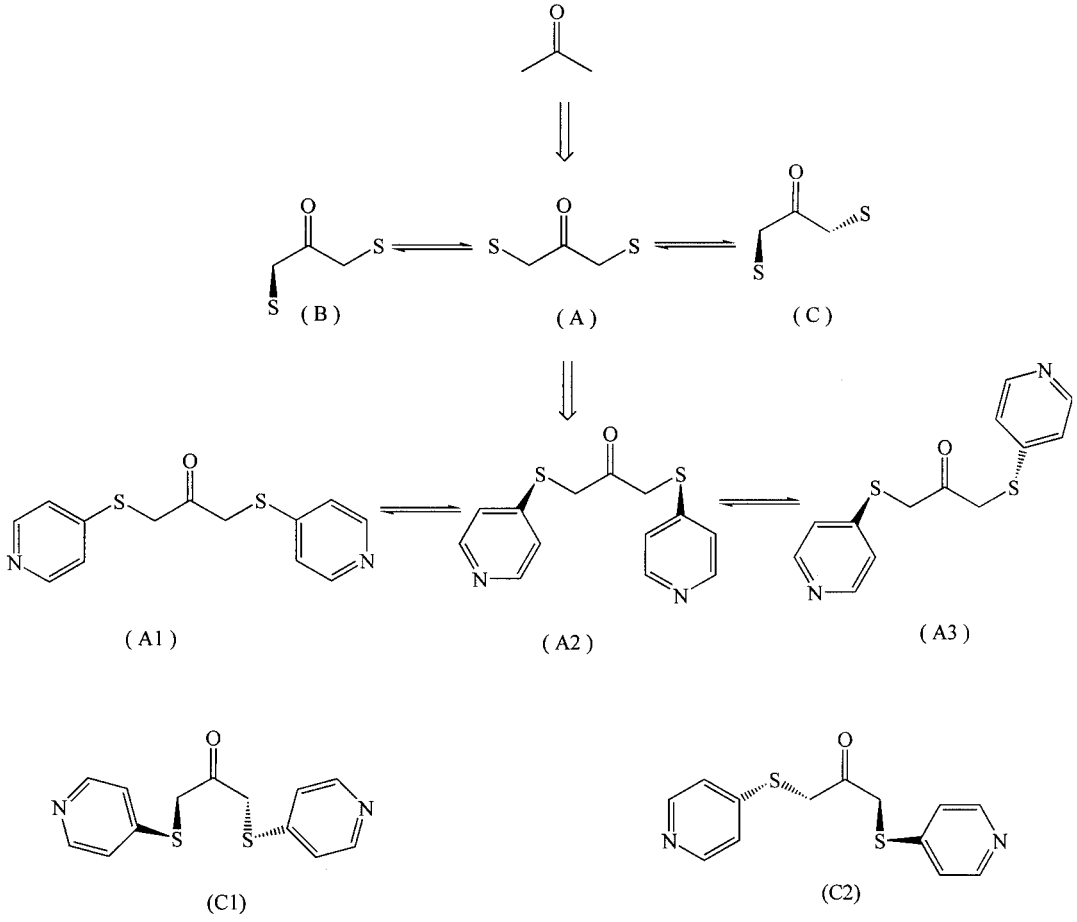
Scheme 1. Ligand L.

Results and Discussion

Synthesis and Conformational Analysis of 1,3-Bis(4-pyridylthio)propan-2-one (L)

Ligand L was prepared by the substitution reaction of 1,3-dichloro-2-propanone and sodium methylate, following the strategy we utilized previously to synthesize N-containing heterocyclic thioether ligands;[31–34] however, the separation of L from the oil phase was a key problem. Ultimately, the pure solid-phase of L was obtained through subtle use of its temperature-dependent solubility in water in the separation and purification process.

Propan-2-one is a planar molecule that shows no conformation due to sp^2 hybridization of its central carbon atom. However, as sulfur atoms are introduced at the 1 and 3 carbon atoms, the substituted compound displays three typical conformations, namely A, B and C isomers. In addition, as two 4-pyridyl groups are bound to the two sulfur atoms, three typical conformational isomers are expected, e.g. A1, A2 and A3 of conformation A (Scheme 2). Thus the resulting ligand L can adopt many conformational isomers. Generally, these conformational isomers will be balanced in solution due to their lower steric and larger solvation energy. Among them, five types of conformational isomers of L were obtained through assembly of L with tailored metal nodes (Scheme 2). The common feature of isomers A1, A2 and A3 is that the two sulfur atoms linked to propan-2-one group are almost coplanar with propan-2-one group (namely plane SCCCS). For the A1 conformation, the two nitrogen atoms of pyridyl groups are also located in the SCCCS plane, similar to the optimized conformational isomer L_{ideal} by Gaussian 03.[37] However, the combination of two pyridyl groups at either the same or each side of the SCCCS plane will afford isomer A2 or A3, respectively. For C1 and C2 isomers, their two 4-mercaptopyridine groups bind to each side of the propan-2-one plane to form the trans conformations, but the obvious distinction shown in



Scheme 2. Formation process of conformational isomers of L (with the A form as example) and representation of conformational isomers of ligand L obtained in its coordination complexes.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 2 defines them as different conformations. Furthermore, using Gaussian 03 we calculated quantitatively their conformational energies (Table S1). Compared with the optimized conformational isomer L_{ideal} (the energy of L_{ideal} is arbitrarily regarded as the standard of zero), their steric energies (kJ mol^{-1}) are evaluated as $E^{A1}{}_{steric}$ 400.94, $E^{A2}{}_{steric}$ 411.65, $E^{A3}{}_{steric}$ 406.01, $E^{C1}{}_{steric}$ 389.86 and $E^{C2}{}_{steric}$ 724.51. Clearly, the energy gaps between those conformational isomers range from 5 to 22 kJ mol^{-1}, except for $E^{C2}{}_{steric}$ which is notably higher due to the relatively low statistical distribution of propan-2-one groups in this L. But as we will show, metal-induced conformational isomers A1, A2, C1 and C2 and their unique combinations around metal centers may play a crucial role in pre-defining the resultant polymeric architectures.

Crystal Structures of $\{[Ni(L)_2Cl_2]\}_\infty$ (1) and $\{[Co(L)_2(SCN)_2]\cdot(DMF)_2\}_\infty$ (2)

Complex **1** was obtained from a solvothermal methanol system. An X-ray structural analysis discloses that it crystallizes in orthorhombic space group *Ibca* and is a 3D sixfold interpenetrating diamondoid framework. Each Ni^{II} center is in a distorted octahedral environment surrounded by four pyridines that occupy equatorial sites in a paddlewheel array and two Cl^- that occupy axial sites (see a in Figure 1). The Ni–N bond distances range from 2.123(8) to 2.128(8) Å and Ni–Cl is 2.398(3) Å, while the in-plane andaxis-transition angles are 179.4(3) and 179.33(17)°, respectively. The Ni^{II} centers are linked by four L and act as square-planar nodes in the network. Exo-bidentate spacers L in **1** display A1 and C1 conformational isomers, and the unique array in A1A1C1C1 form around the metal centers produces a C_2 axis that passes through the Ni^{II} center and equally bisects the equatorial plane N1–N1A–N2A–N2. Furthermore, neighboring L around the Ni1 center extend above or below the equatorial plane, resulting in the sharp deviation of binding sites N1B, N1C, N2B and N2C from the least-squares plane N1–N1A–N2A–N2–Ni1, with deviation distances of N1B, N1C, N2B and N2C from the least-squares plane of 4.98771, –4.98771, –6.0371 and 6.0371 Å, respectively. Clearly, the four nickel(II) nodes bonded by N1B, N1C, N2B and N2C atoms are expected to be at the vertexes of a distorted tetrahedron. In this manner, a 3D diamondoid framework forms (b in Figure 1), which is indicative of a distinctive difference from widely encountered 2D grids constructed by square-planar nodes with other ditopic ligands.[38–41] Adjacent $Ni^{II}\cdots Ni^{II}$ bridged by A1 and C1 are separated by 16.435 and 14.869 Å, respectively (b in Figure 1). The long spacers between coordination sites result in large cavities within the diamondoid cages. However, due to the absence of large guest molecules to fill the void space, the potential voids are filled through mutual interpenetration of five independent equivalent frameworks, generating a sixfold interpenetrating 3D architecture (c in Figure 1).

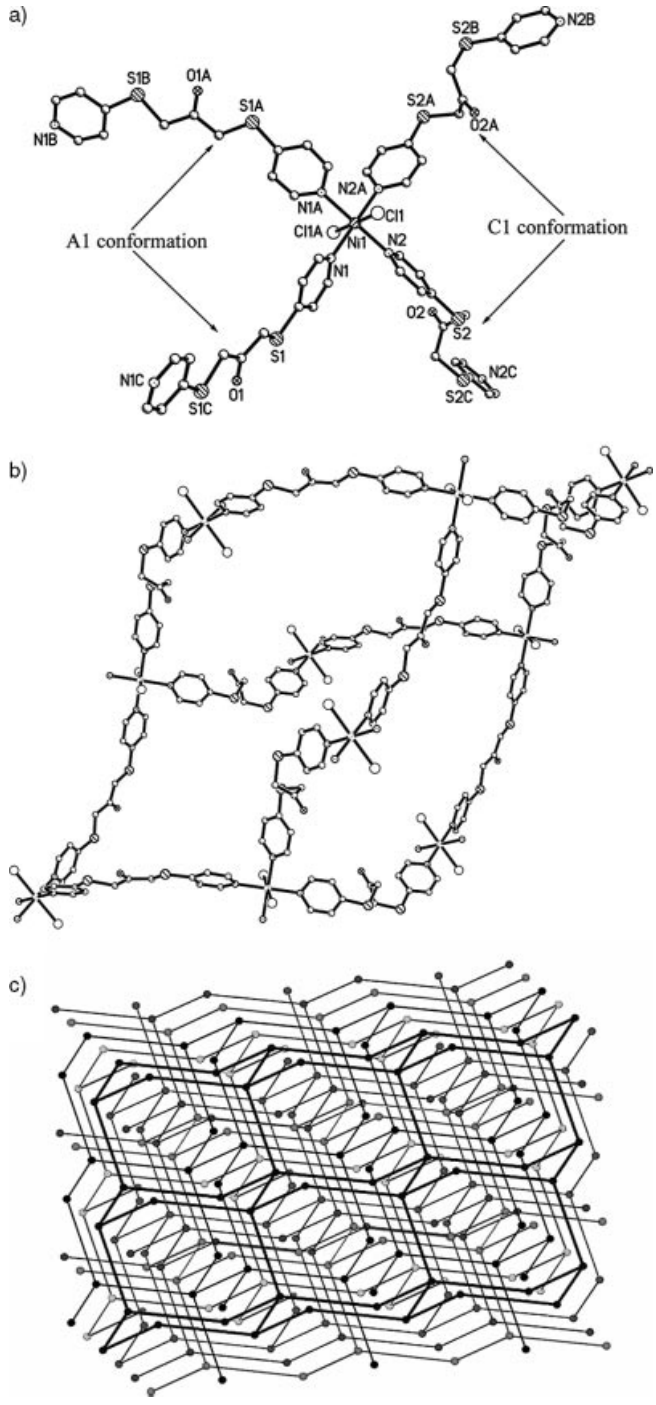


Figure 1. Views of the C_2 symmetric array of conformational isomers A1 and C1 around six-coordinate Ni^{II} centers (a), the single diamondoid cage generated through twelve L (six A1 and six C1) bridging ten Ni^{II} centers (b), and the sixfold interpenetrating diamondoid network with bridging and terminal ligands L and Cl^- omitted for clarity (c) in **1**.

Complex **2**, assembled in a DMF/diethyl ether system, crystallizes in monoclinic space group *C*2/*c* and possesses a 3D threefold interpenetrating network with $CdSO_4$-like topology. Each Co^{II} center in **2** is also in a compressed octahedral environment surrounded by four pyridines, which occupy equatorial sites, and by two SCN^- that occupy axial

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

sites (a in Figure 2). The Co–N bond distances range from 2.087(6) to 2.210(5) Å while the in-plane and axis-transition angles are 180.0(3) and 180.0(2)°, respectively. In complex **2**, each Co^{II} center, linked by four L, plays the role of square-planar node, in the same way as the Ni^{II} node in complex **1**. Exo-bidentate spacers L in **2**, however, display A1 and C2 conformational isomers and array in A1C2A1C2 form around the inversion center Co^{II}. Moreover, two A1 isomers bound to the Co1 center extend either above or below the least-squares plane N1–N2–N1A–N2A–Co1, with their binding sites N1B and N1C deviating sharply from the least-squares plane, by –8.1064 and 8.1064 Å, respectively. In contrast the N2B and N2C binding sites of the two C2 isomers deviate comparatively slightly from the least-squares plane, by –1.9237 and 1.9237 Å, respectively. Consequently, the architecture of **2** is completely different from that of **1** with the diamondoid framework. As clearly shown in part b of Figure 2, the combination of A1 isomers and Co^{II} nodes forms 1D undulating chains, which are further alternately connected along two perpendicular directions by the coordination of C2 isomers with Co^{II} nodes. Consequently, a 3D network with a $CdSO_4$-type topology is generated. Furthermore, the $CdSO_4$-like architecture produces large channels that have an opening of about 30.720×14.722 $Å^2$ (see b and c in Figure 2). Part d in Figure 2 shows the threefold interpenetration of $CdSO_4$-like architecture in the crystal, which effectively reduces the void space. Even so, it has a porous rather than a close-packed structure, such that DMF molecules are entrapped within it.

A combination of four-connected nodes and ditopic ligands can provide 2D grids or novel 3D nets, some interesting architectures of which have been exploited recently.[42,43] Notably, both complex **1** and **2** are 3D nets bridged by the

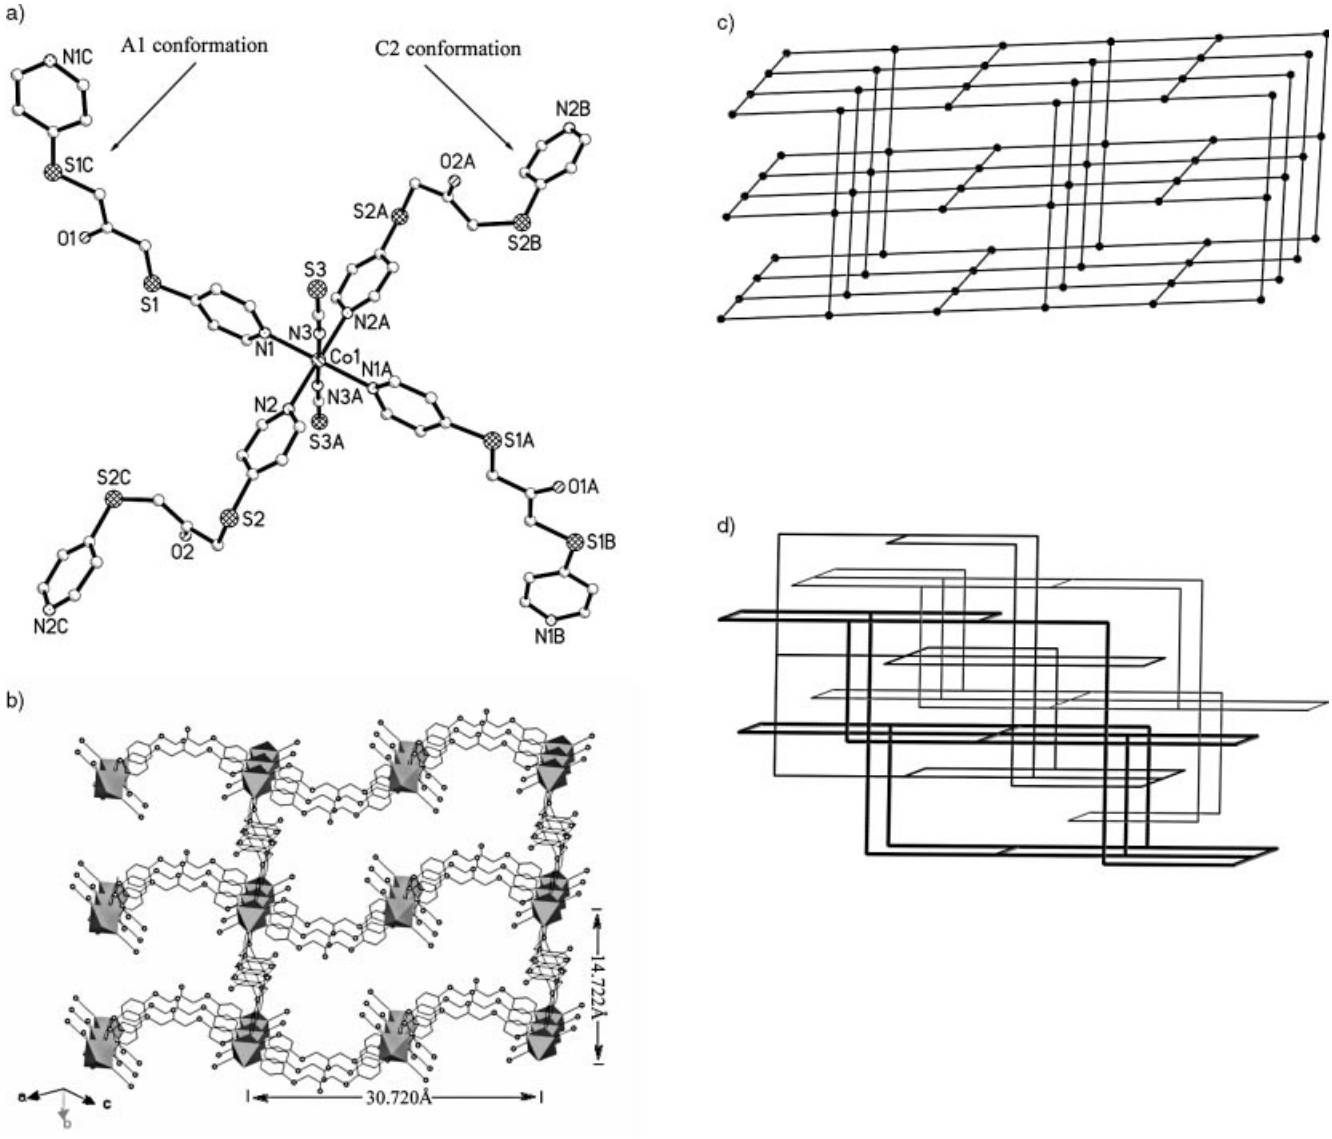

Figure 2. Combination of conformational isomers A1 and C2 around the inversion center of the six-coordinate Co^{II} (a), the 3D open framework containing large tunnels (b), schematic of the $CdSO_4$-like topology (c) and the 3D threefold interpenetrating network with bridging and terminal ligands L and SCN^- omitted for clarity (d) in **2**.

same ditopic ligands L bonded to four-connected nodes Co^{II} or Ni^{II}, but possess different topologies. Although many factors are involved, conformational isomers of L and their unique combination around metal centers, as depicted above, presumably play the key role in determining the structural topologies.

Crystal Structure of $\{[AgL]NO_3\}_\infty$ (3)

Complex **3**, obtained through a three-layered diffusion method, crystallizes in orthorhombic space group *Pnma* and possesses a 1D U-like chain architecture. The Ag^I ion in **3** shows linear coordination, in which the N1–Ag1–N1A angle is 180.0(3)° and Ag1–N1 and Ag1–N1A bond lengths are 2.151(7) Å (Figure 3). Each L, similar to other dithioether ligands containing 4-pyridyl groups in Ag^I complexes we reported previously,[34] acts as an *exo*-bidentate ligand and bridges two Ag^I centers with its two pyridyl nitrogen atoms to construct a 1D chain structure. Interestingly, L in **3** only presents an A2-typical conformation with higher steric energy than that of isomers A1 and A3. The inversion array of A2 around Ag^I centers results in the unique U-like framework, with the $Ag^I\cdots Ag^I$ distance and deep length of the "U" chain (S···S) being 7.283 and 13.365 Å, respectively, which differ from the structures found in Ag^I and N-containing heterocyclic thioethers.[34,36] Notably, nitrate ions located in "U" chains stabilize the A2-typical conformation of L through weak interactions between its oxygen atoms and Ag^I (O3···Ag1A and O3···Ag1, 2.872 Å).

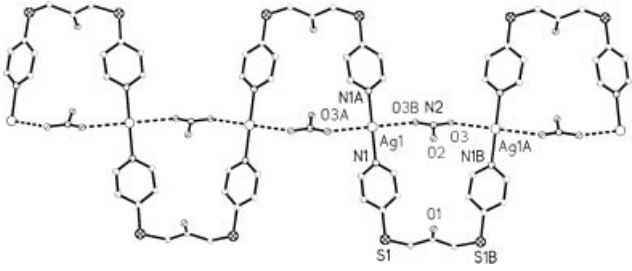

Figure 3. 1D U-like chain architecture in **3**, showing the weak interactions between the counter-anion and Ag^I as well as the template of counter-anions.

Magnetic Properties of Complexes 1 and 2

The temperature (T) dependencies of the magnetic susceptibility (χ_M) of complexes **1** and **2** were measured in the range 2–298 K under fixed fields of 5 and 10 kG, respectively; Figures 4 (see a and b) show the corresponding χ_M vs. T and μ_{eff} vs. T plots. For **1**, μ_{eff} decreases very slowly from 3.45 μ_B at 298 K to 3.29 μ_B at 8 K and then rapidly decreases to 2.53 μ_B at 2 K. The μ_{eff} of 3.45 μ_B per Ni^{II} at room temperature is larger than that calculated for the spin-only case (2.83 μ_B), revealing a significant orbital contribution, which always causes zero-field splitting. The magnetic behavior of complex **1** can be explained by large zero-field splitting, as well as a weak ferromagnetic interaction under the molecular field approximation. The best fit of Equation (1) to the data was achieved with $g = 2.31$, $D/k = 12.25$ K, $\theta = 0.94$ and $R = 4.5\times10^{-6}$ [$R = \sum(\chi_{obsd}-\chi_{cacld})^2/\sum\chi_{obsd}^2$].

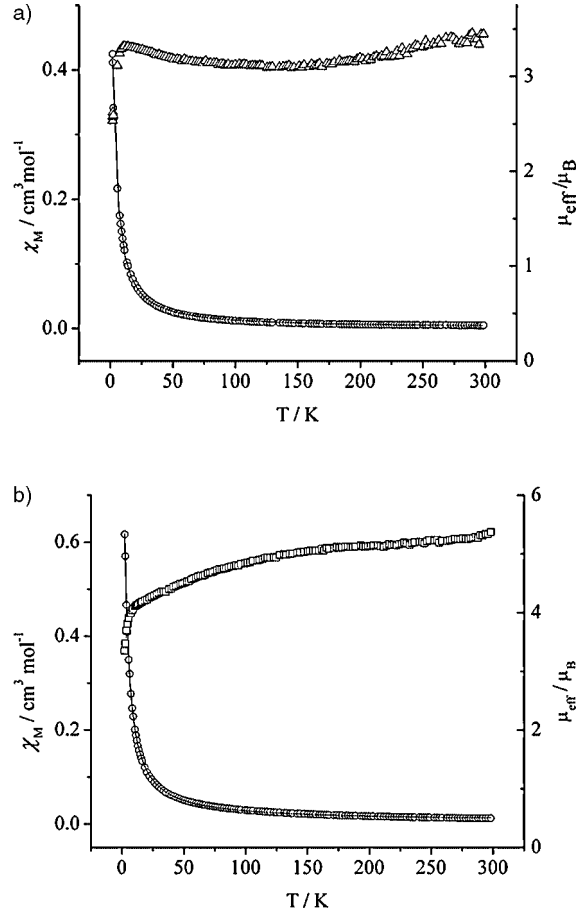

Figure 4. χ_M (○) and μ_{eff} (Δ) vs T with the theoretical fit (−) for **1** (a), and χ_M (○) and μ_{eff} (□) vs. T with the theoretical fit (−) for **2** (b).

$$\chi_M = \frac{2Ng^2\beta^2}{3k(T-\theta)}\left[\frac{2kT/D - 2kT\exp(-D/kT)/D + \exp(-D/kT)}{1+2\exp(-D/kT)}\right] \quad (1)$$

For complex **2**, the experimental μ_{eff} per Co^{II} ion at room temperature is ca. 5.38 μ_B, which is larger than that calculated for the spin-only case (3.87 μ_B), indicating a typical contribution of the orbital momentum for the $4T^1{}_g$ ground state.[44] Upon cooling, μ_{eff} gradually decreases to 4.06 μ_B at 9 K and then dramatically decreases to 3.35 μ_B at 2 K. The χ_M^{-1} vs. T plot is essentially linear, and least-squares fitting of the data to the Curie–Weiss law gives $C = 3.62$ cm^3 mol^{-1} K and $\theta = -17.50$ K. The negative value of θ may be attributed to antiferromagnetic interactions between Co^{II} ions. To date, quantitative magnetic analyses of cobalt(II) complexes have been a challenge due to the complexity of magnetic anisotropy originating from spin–orbit

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

coupling and axial distortion. However, when cobalt(II) ions are located in a perfect or slightly distorted octahedral ligand field, the isotropic model proves to be preferable for describing the magnetic data.[45] As indicated in the structure description, each Co^{II} center in **2** is ligated by six nitrogen atoms in a slightly distorted octahedral geometry and these metal nodes are linked by long spacers L to build a 3D $CdSO_4$-like framework. Thus, a simplified analysis of this coupling system is based on considering the exchange coupling between two adjacent paramagnetic centers in an infinite chain and interchain interaction (zJ) under the molecular field approximation. Assuming an isotropic exchange between Co^{II} ions, the magnetic susceptibility per Co^{II} ion can be expressed as:

$$\chi_M^{J+J'} = \frac{\chi_M^{J}}{1-(2zJ'\times\chi_M^{J})/N\beta^2g^2}$$

$$\chi_M^{J} = \frac{N\beta^2g^2S(S+1)}{3kT}\frac{1+u}{1-u} \quad u = \coth\left[\frac{JS(S+1)}{kT}\right]-\left[\frac{kT}{JS(S+1)}\right] \qquad (2)$$

The best fit (assuming $zJ = 0$) of the experimental data to Equation 2 yields $J = -0.36\ cm^{-1}$, $g = 2.28$, with an agreement factor $R = \sum(\chi_{obsd}-\chi_{cacld})^2/\sum\chi_{obsd}^2) = 2.0\times10^{-5}$. It seems that the spin-only model gives quite a good fit.

On the basis of the molecular structures and the magnetic calculations of complexes **1** and **2**, we conclude that the interaction via the bridge L is very weak – indicative of the long and unconjugated ligand L being unfavorable for the electronic interactions needed for efficient superexchange between paramagnetic metal centers.

Fluorescence Properties of Ligand L and Complex 3

Figure 5 depicts solid-state photoluminescent spectra of **3** and free ligand L at room temperature. Free ligand L is strongly photoluminescent and exhibits intense green emission with a single broad band at λ_{max} = 537 nm, corresponding to an excitation at λ_{max} = 370 nm. The emission properties of **3** are complicated and very interesting. Although several Ag^I polymers that emit photoluminescence at room temperature have been reported,[46–49] complex **3** shows, unusually, multiple emission bands. When excited at 365 nm, it displays two weaker blue emission bands at λ_{max} = 416 and 442 nm and one stronger, broad, green emission band at λ_{max} = 541 nm. The low-energy band of 541 nm for **3** is very similar to that found for free ligand L in terms of position and band shape. Therefore, it is assigned to a silver(I)-perturbed intraligand transition. Perhaps, the two higher energy emission bands with weaker intensities, indicative of a slight modification in the photoluminescent activity in **3**, could be ascribed tentatively to either ligand-to-metal (LMCT) or metal-to-ligand charge-transfer transitions (MLCT), but further exact assignments have not carried out. Notably, free ligand L and its Ag^I complex **3** display useful photoluminescent activity in the blue/green region.

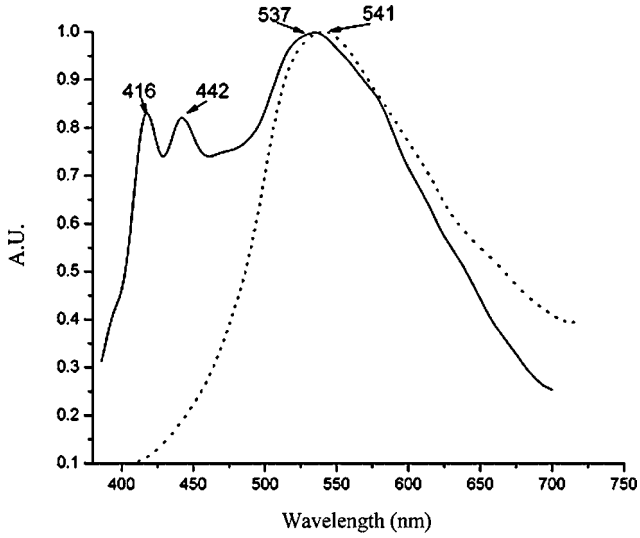

Figure 5. Fluorescence spectra of ligand L excited at 370 nm (dotted line) and complex **3** excited at 365 nm (solid line) in the solid state at room temperature.

Conclusions

We have synthesized flexible ligand L [L = 1,3-bis(4-pyridylthio)propan-2-one] and its three new coordination polymers $\{[Ni(L)_2Cl_2]\}_\infty$ (**1**), $\{[Co(L)_2(SCN)_2]\cdot(DMF)_2\}_\infty$ (**2**) and $\{[AgL]NO_3\}_\infty$ (**3**). Assemblies of L with four-connected square-planar nodes Ni^{II} and Co^{II} lead to two 3D interpenetrating nets with distinct topologies due to the metal-assisted conformational selectivity and unique combinations of ligand L around the metal centers. In **3**, L only presents a typical conformation, with higher steric energy, that links linear nodes Ag^I, leading to a 1D U-like chain, where counter-anions template both the architecture of the polymer and the A2-typical conformation of L. Clearly, L presents conformational lability that can be utilized in metal-assisted assemblies to affect the coordination architectures. Magnetic studies on complexes **1** and **2** show that the long, unconjugated ligand L is unfavorable for the electronic interactions needed for efficient superexchange between paramagnetic metal centers. Interestingly, complex **3** displays unusual fluorescent emission with multiple bands in the blue/green region. Moreover, as the ketone group incorporated into the ligand will functionalize the resultant architecture, further exploitation of such ligands in crystal engineering and material is underway.

Experimental Section

WARNING! Although we experienced no problems in handling these perchlorate compounds, they should be treated with great caution due to their potential for explosion.

General Remarks: All materials, reagents and solvents were purchased from commercial sources and used as received. Elemental

analyses were determined on an Elementary Vario ELIII elemental analyzer. IR spectra were measured as KBr pellets on a Nicolet Magna 750 FT-IR spectrometer in the range 400–4000 cm^{-1}. The NMR spectrum was recorded on a Varian Inova-500 spectrophotometer at room temperature and chemical shifts are quoted in δ (ppm) relative to the deuterated solvent used. Fluorescent spectra were measured with an Edinburgh FL-FS90 TCSPC system. Temperature-dependent magnetic measurements were determined on a Quantum Design SQUID-XL7 magnetometer.

Synthesis of 1,3-Bis(4-pyridylthio)propan-2-one (L): L was synthesized under nitrogen. Sodium methylate (0.540 g, 10 mmol) and 4-pyridinethiol (1.11 g, 10 mmol) were vigorously stirred in MeOH (50 mL) for 1 h before a quantitative amount of 1,3-dichloro-2-propanone (0.635 g, 5 mmol) was added. The resulting solution was heated at 60 °C for 12 h and then filtered after cooling to room temperature. Removal of the solvent from the resultant red filtrate gave a brown oil that afforded yellow needle crystals after recrystallization from warm water. The crystalline product was redissolved in warm water (20 mL) and neutralized with $NaHCO_3$ powder. The so-obtained pale yellow precipitate was filtered off, washed with cold water and a little methanol, and then dried in air to give 0.773 g (2.80 mmol) of L (56%). $C_{13}H_{12}N_2OS_2$ (276.4): calcd. C 56.50, H 4.38, N 10.14, S 23.20; found: C 56.42, H 4.35, N 10.00, S 23.05. ^{1}H NMR (500 MHz, [D$_6$]DMSO): δ = 8.481 [d, *J* (HH) = 6.0 Hz, 4 H, H^{2,6}py], 7.519 [d, *J* (HH) = 5.0 Hz, 4 H,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$H^{3,5}$py], 4.594 (m, 4 H, -CH_2-) ppm. IR (KBr): $\tilde{\nu}$ = 3032 (w), 2942 (w), 1730 (vs), 1575 (vs), 1538 (s), 1482 (m), 1409 (vs), 1381 (s), 1220 (m), 1028 (s), 801 (vs), 702 (s), 497 (m) cm^{-1}.

Synthesis of $\{[Ni(L)_2Cl_2]\}_\infty$ (1): Solvothermal treatment of $NiCl_2 \cdot 6H_2O$ (0.024 g, 0.1 mmol), L (0.055 g, 0.2 mmol) and methanol (10 mL) at 80 °C for 1 day gave yellow-green prismatic crystals of **1** (0.048 g, 0.07 mmol, 70%). $C_{26}H_{24}Cl_2N_4NiO_2S_4$ (682.34): calcd. C 45.77, H 3.54, N 8.21, S 18.80; found: C 45.50, H 3.60, N 8.20, S 18.57. IR (KBr): $\tilde{\nu}$ = 3060 (w), 2916 (m), 1720 (m), 1601 (vs), 1535 (w), 1484 (s), 1417 (s), 1216 (m), 1072 (m), 806 (m), 718 (m), 502 (w) cm^{-1}.

Synthesis of $\{[Co(L)_2(SCN)_2]\cdot(DMF)_2\}_\infty$ (2): KSCN (0.019 g, 0.2 mmol) in DMF (5 mL) was added to a solution of $Co(ClO_4)_2 \cdot 6H_2O$ (0.037 g, 0.1 mmol) and L (0.055 g, 0.2 mmol) in DMF (5 mL) with stirring. The resulting mixture was stirred for 1 h and then filtered. Slow diffusion of diethyl ether (25 mL) into the blue filtrate for three weeks gave block orange crystals of **2** (0.065 g, 0.074 mmol, 74%). $C_{34}H_{38}CoN_8O_4S_6$ (874.01): calcd. C 46.72, H 4.38, N 12.82, S, 22.01; found: C 46.30, H 4.45, N 12.79, S 21.77. IR (KBr): $\tilde{\nu}$ = 3099 (w), 3059 (w), 2928 (w), 2873 (m), 2065 (vs), 1718 (w), 1664 (s), 1593 (vs), 1537 (w), 1485 (m), 1417 (m), 1221 (m), 1065 (m), 807 (m), 720 (m), 627 (w), 501 (m) cm^{-1}.

Synthesis of $\{[AgL]NO_3\}_\infty$ (3): A mixture of DMF (5 mL), methanol (5 mL) and CH_3CN (5 mL) was added dropwise along the wall of tube (50 mL) that contained a solution of $AgNO_3$ (0.017 g, 0.1 mmol) and DMF (5 mL) as the bottom layer. A solution of L (0.028 g, 0.1 mmol) and methanol (10 mL) as the top layer was then transferred into the tube in the same way. After slowly diffusing for two weeks, the mesosphere gave khaki needle crystals of **3** (0.023 g, 0.052 mmol, 52%). $C_{13}H_{12}AgN_3O_4S_2$ (446.25): calcd. C 34.99, H 2.71, N 9.42, S 14.37; found: C 35.10, H 2.64, N 9.17, S 14.50. IR (KBr): $\tilde{\nu}$ = 3091 (w), 2916 (w), 1720 (m), 1597 (s), 1535 (w), 1489 (m), 1422 (m), 1371 (vs), 1232 (m), 1114 (m), 1062 (m), 1026 (m), 806 (m), 718 (m), 636 (w), 487 (m) cm^{-1}.

X-ray Structure Determinations: Single-crystal data were collected on a Rigaku Mercury-CCD diffractometer at room temperature for **1** and **3,** and at 130 K for **2**, using graphite-monochromated Mo-K_α radiation (λ = 0.7107 Å). The structures were solved by direct methods and refined on F^2 by full-matrix least-squares procedures using the SHELXTL software suite.[50] All non-hydrogen atoms were refined anisotropically and the hydrogen atoms were treated as idealized contributions. For complex **2**, the propan-2-one groups of half L were split into two equivalent parts and the accommodated DMF solvent was treated as disordered; the maximum and minimum peaks in the final difference maps were 1.678 and –0.511 e $Å^{-3}$, respectively, and the largest residual density peak was close to the sulfur atom of SCN^-. Table 1 summarizes the crystallographic data of **1**–**3** and Table 2 lists selected bond lengths and angles. X-ray crystallographic data in CIF format for **1**–**3** have also been deposited. CCDC-247593 to -247595 (for **1**–**3)** contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Luminescent Iridium(III)-Terpyridine Complexes – Interplay of Ligand Centred and Charge Transfer States

Lucia Flamigni,*[a] Barbara Ventura,[a] Francesco Barigelletti,*[a] Etienne Baranoff,[b] Jean-Paul Collin,*[b] and Jean-Pierre Sauvage*[b]

Keywords: Iridium / Photochemistry / Luminescence / Charge transfer / Electron transfer

Electrochemical properties, ground state absorption spectra, luminescence spectra and lifetimes (at room temperature and 77 K) as well as transient absorption spectra are reported herein for newly synthesized iridium(III) complexes in which benzamide units are appended to the coordinated terpyridine fragments. The nature of the luminescent excited states ($\Phi < 2\times10^{-3}$ and τ in the microsecond range, in air-equilibrated acetonitrile at 298 K) is discussed with regards to the ligand-centred (^{3}LC) or charge transfer (^{3}CT) nature. At room temperature, the excited state, a predominantly ligand-centred triplet (^{3}LC) for the iridium(III) terpyridine compounds, is switched for the benzamide-containing complexes to a charge transfer state (^{3}CT). Intense absorption in the visible range, high energy content, long excited states lifetimes at 298 and 77 K and good luminescence yields make these complexes very promising as photosensitisers (P). The CT nature of the excited states of the benzamide-containing complexes makes them ideal components for the construction of rigid, linear arrays of the Donor-P-Acceptor type for charge separation.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Iridium(III) complexes of polypyridine ligands are increasingly being employed in relevant applications.[1–5] For iridium(III) terpyridine (2,2′:6′,2′′-terpyridine, tpy) complexes some interesting perspectives concern their use as biological labelling reagents[6] as well as the building up of dyads and triads as models for photoenergy conversion schemes.[7–9] $[Ir(tpy)_2]^{3+}$ and derivatives like those of the $Ir(ttpy)_2]^{3+}$ family (ttpy = 4′-tolyl-tpy) exhibit favourable optical properties which include intense luminescence ($\Phi \approx 10^{-2}$) and lifetimes in the μs time range.[10] Furthermore, the luminescent levels for these complexes come at ca. 2.5 eV so that they have potential to act as efficient photosensitisers. Indeed, the possibility of developing linear arrays by attaching suitable groups at the 4′-position of tpy groups coordinated at the Ir^{III} ion is very appealing.[8,9,11] The use of geometrically opposite photoactive and electroactive units (e.g. D and A, electron donor and acceptor units, respectively) has proven to be of importance within energy conversion schemes.[7] So far, the $[Ir(tpy)_2]^{3+}$ unit integrated within linear triad arrays has been used both as an electron relay[8a] and as a photosensitiser.[9] Whereas it has proven to be rather effective as an electron relay, its properties as a photosensitiser (P) are less satisfactory. For this latter role, in fact, in dyads (D-P and P-A) and triads (D-P-A) designed to perform photoinduced charge separation, it is relevant to gain control over the early events triggered by light absorption at P. In fact, primary formation of the lowest-lying charge transfer (CT) states within P could favour subsequent intercomponent hole and electron migration towards the D and A interacting partners, once the thermodynamic requirements are met. In contrast, for ligand centred (LC) excited states, holes and electrons reside in physically coincident sites and the expected intercomponent charge shift steps could be slowed down and be less competitive towards other processes, e.g. energy transfer.[9]

For the iridium(III) complexes of tpy derivatives studied up to now, the luminescent state has been found to be predominantly ligand centred, ^{3}LC.[10,11,13,14] This is in contrast to what happens for the closely investigated polypyridine complexes of transition metals such as ruthenium(II), osmium(II) and rhenium(I)[12] which are currently being employed as photosensitisers and the emitting states of which are triplet metal-to-ligand states (^{3}MLCT) in nature. In only one case, a scarcely emissive excited state in a 4-aminobiphenyl-substituted Ir(tpy) reported by Williams et al. was attributed to an intraligand charge transfer state, ILCT, where the appended group acts as a donor and the metal-

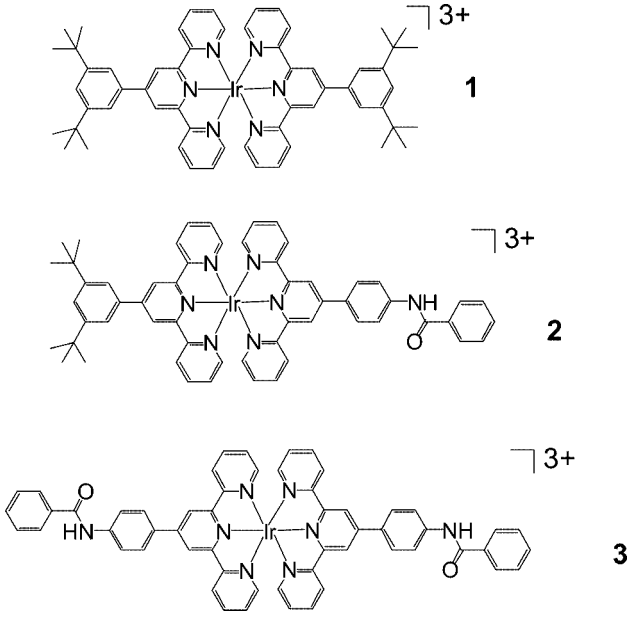
bond terpyridyl unit behaves as an acceptor.[11] The poor tendency of Ir(tpy) derivatives to form MLCT excited states can be understood on the basis of their electrochemical behaviour which is in contrast to that found for polypyridine complexes of transition metals such as ruthenium(II) and some others.[12] For the latter complexes, the free energy for the reaction of the one-electron oxidised and reduced forms, $\Delta E_{1/2}$, correlates with the energy of the lowest-lying absorption and emission bands. These are MLCT in nature as evaluated from the longest-wavelength portions of absorption spectra (^{1}MLCT) and from the characteristics of the emission spectra (^{3}MLCT).[15] For instance, for $[Ru(tpy)_2]^2$, the metal centred oxidation, $E_{1/2}^{ox}$ (3+/2+), and the ligand centred reduction, $E_{1/2}^{red}$ (2+/+), are +1.30 and –1.24 V, respectively, with respect to the SCE in MeCN.[16] The emission level, E_{em}, is ca. 2.0 eV so that $E_{em} \approx \Delta E_{1/2} - 0.5$ eV. On the other hand, for $[Ir(tpy)_2]^{3+}$, $E_{1/2}^{red}$ = –0.77 V but the oxidation of Ir(III) to Ir(IV) is not observed and $E_{1/2}^{ox} \geq +2.4$ V.[10] Based on these electrochemical results and the above correlation, the ^{3}MLCT level for $[Ir(tpy)_2]^{3+}$ can be estimated higher ($\geq$ 2.7 eV) than the luminescent ^{3}LC level which is ca. 2.5 eV.[1] It is worth mentioning here that a ligand-to-ligand excited state, LLCT, was identified as the emitting state in a related cyclometallated complex recently reported.[17]

We show below that newly prepared Ir(III)-tpy type species with appended *N*-phenyl-benzamide fragments, **2** and **3** Scheme 1, also feature ^{3}CT emission properties. Among other things, this CT character causes a low-energy shift of the main absorption bands in complexes **2** and **3** (bright yellow) in comparison with that observed in the prototype $[Ir(tpy)_2]^{3+}$ complex or **1** (colourless or yellowish). This makes this series more promising for the conversion of solar light into chemical energy.



Scheme 1.

Results and Discussion

Synthesis and Electrochemistry

Complexes **1** and **2** were prepared as previously reported.[8,10] Complex **3** was synthesized straightforwardly in one step from 4′-(benzamidophenyl)-2,2′:6′,2"-terpyridine (bap-tpy) and $IrCl_3$.

The redox characteristics of complexes **1**, **2** and **3** examined by cyclic voltammetry in acetonitrile (MeCN) are reported in Table 1. The working electrode used was a glassy carbon electrode since irreproducible and poorly defined signals were obtained with a platinum electrode due to adsorption phenomena. Two reversible ligand-centred[10] one-electron waves followed by an irreversible peak at more negative potential were observed for the three complexes. As indicated by the values of the potentials, complex **1** is slightly more difficult to reduce than **2** and **3**. In fact, the presence of one (in **2**) or two (in **3**) benzamide groups leads to a very similar LUMO energy level in these two complexes. This fact is in agreement with the various spectroscopic properties observed for the three complexes (see below). Thus complex **1** has distinct characteristics compared with **2** and **3** which, in turn, are very similar to one another.

Table 1. Cyclic voltammetric data[a] for the complexes **1**, **2** and **3**.

	$E_{1/2}$ (V vs. SCE)		
	tpy/tpy$^-$	tpy$^-$/tpy^{2-}	tpy^{2-}/tpy^{3-}
1	–0.79	–0.93	–1.80[b]
2	–0.76	–0.92	–1.68[b]
3	–0.76	–0.92	–1.65[b]

Optical Spectroscopy

Figure 1 shows the absorption spectra in MeCN solutions for the complexes shown in Scheme 1. For complex **1**, the absorption onset is at 400 nm and the UV features are due to intraligand ^{1}LC transitions as previously established.[10] The spectra of complexes **2** and **3** are characterised by an additional, unstructured broad band extending

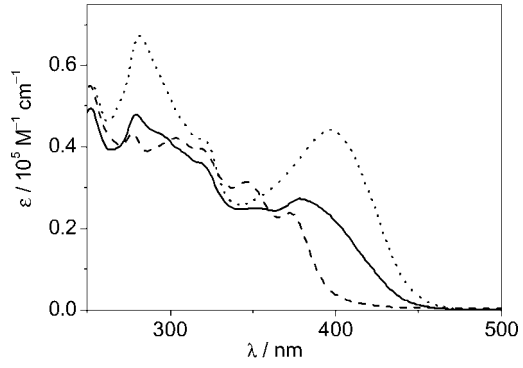

Figure 1. Absorption spectra in MeCN of **1** (dashed), **2** (solid) and **3** (dotted).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

well beyond 400 nm. This band is about twice as intense in **3** as it is in **2** with ε_{398nm} ca. 45000 $M^{-1}cm^{-1}$ and ε_{380nm} ca. 27000 $M^{-1}cm^{-1}$, respectively (see Figure 1).

Figure 2 shows the room temperature luminescence spectra in air-free MeCN. In the inset, the luminescence decays at 298 K of **2** and **3** are also displayed. While a structured luminescence profile can be observed for **1** at 298 K, a broad unstructured band was recorded for both **2** and **3**. The luminescence lifetimes at room temperature of **2** and **3**, which are 800 and 1990 ns, respectively, are shorter than the lifetime of 6800 ns for **1**. The poor solubility of **2** and **3** limits the use of solvents with different dielectric constants which could be helpful in the assignment of the nature of the luminescent state at room temperature. A comparison of emission data in MeCN (dielectric constant = 36), methanol (dielectric constant = 33) and acetone (dielectric constant = 21) shows band maxima in the range 566–570 nm and does not provide any clear evidence of the effect of solvent polarity on the luminescent state energy levels.

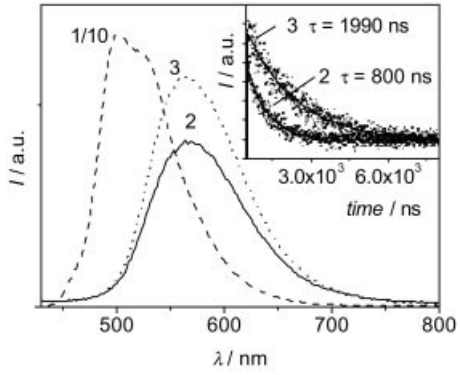

Figure 2. Corrected luminescence spectra (λ_{exc} = 379 nm) at 298 K of optically matched solutions in air-free MeCN of **1** (dashed), **2** (solid) and **3** (dotted). In the inset the luminescence decay in air-free MeCN for **2** and **3** is reported with the exponential fitting.

In contrast to room temperature data, the luminescence spectra at 77 K in glassy butyronitrile (BuCN) illustrated in Figure 3 display rather similar spectroscopic profiles for **1**, **2** and **3**. The luminescence lifetimes detected at 77 K in BuCN for **2** and **3** are 80 and 85 μs, respectively, as shown in the insets of Figure 3. These are longer than the lifetime of 39 μs for **1** under the same conditions. Luminescence data in aerated and air-free MeCN at 298 K and in BuCN at 77 K are collected in Table 2. The room temperature reaction rate constants with oxygen (O_2 solubility in air equilibrated MeCN is 1.9×10^{-3} M[18]) can be derived from the lifetime data shown in Table 2 and are 2.5×10^{8} $M^{-1}s^{-1}$, 4.2×10^{8} $M^{-1}s^{-1}$ and 6.4×10^{8} $M^{-1}s^{-1}$ for **1**, **2** and **3**, respectively, in agreement with previous reports.[19]

We noticed that complexes **2** and **3** exhibit spectroscopic features, both in the low-energy regions of the absorption spectra and in the luminescence spectra at room temperature, which suggest an electronic nature other than neat LC for the excited states involved in the concerned transitions. Thus, the absorption profile for these complexes, see Figure 1, is characterised by a broad, unstructured band extending beyond 400 nm with ε_{max} of the order of

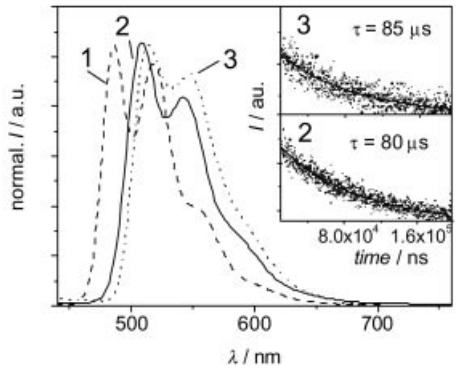

Figure 3. Normalised luminescence at 77 K in BuCN of **1** (dashed), **2** (solid) and **3** (dotted). In the inset the luminescence decay at 77 K in BuCN for **2** and **3** is reported with the exponential fitting.

Table 2. Luminescence data[a] for the complexes **1**, **2** and **3**.

	298 K					77 K			
	λ_{max} nm	Φ[b] $\times10^2$	τ[b] ns	Φ[c] $\times10^2$	τ[c] ns	λ_{max} nm	τ μs	E_0[d] eV	HS[e] cm^{-1}
1	506	9.3	6800	2.2	1600	486	39	2.55	810
2	570	0.55	800	0.21	490	510	80	2.43	2060
3	566	0.76	1990	0.27	580	514	85	2.41	1790

[a] Solvent is MeCN at room temperature, BuCN at 77 K; excitation performed at 379 and 373 nm for the luminescence spectra and lifetimes, respectively. [b] Air-free MeCN. [c] Air-equilibrated MeCN. [d] Estimated energy content of the emitting level from the energy of the emission maximum at 77 K. [e] Hypsochromic shift for the emission band maximum on going from 298 to 77 K.

10^4 $M^{-1}cm^{-1}$. These absorption features are consistent with a CT character for the implied electronic transitions. From the luminescence properties of the complexes at room temperature, further indications about the CT nature of the luminescent state can similarly be drawn, as discussed below.

The room temperature luminescence spectroscopic profiles of complexes **2** and **3** look fairly unstructured as opposed to that of complex **1**, Figure 2. For the latter complex, the extended conjugation at the phenyl-tpy ligand coupled with nuclear rearrangements at the torsional angle between the aromatic rings[20] is known to affect the spectroscopic profile.[10,11] For complexes **2** and **3**, therefore, it seems that further electronic effects must be taken into account. With regard to the low-temperature results, complex **1** on one hand and **2** and **3** on the other hand exhibit different behaviour in terms of the hypsochromic shift (HS) on going from fluid (298 K) to frozen (77 K) solvent, Table 2. Actually, HS amounts to 810 cm^{-1} for **1** but 2060 and 1790 cm^{-1} for **2** and **3**, respectively. The difference between the luminescence profiles of **1**, **2** and **3** recorded in frozen solvents appears less important (Figure 3) but some difference in peak positions and luminescence lifetimes still appears.

Inspection of Table 2 confirms that the luminescent behaviour of **1** at room temperature is different from that of **2** and **3**. Actually, the luminescence lifetimes at room temperature of **2** and **3**, which are 800 and 1990 ns, respectively, (O_2-free case) are well shorter than the lifetime of 6800 ns

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

for **1** but still quite remarkable in comparison with other transition metal complexes widely used for light energy conversion, being of the same order of magnitude or greater than the prototype complex $[Ru(bpy)_3]^{2+}$.[21] The luminescence quantum yield, Φ (Table 2, room temperature, O_2-free) for **1** is one order of magnitude larger than for **2** and **3**. Furthermore, use of Φ and τ values from Table 2 yields radiative rate constants k_r of 1.4×10^4 s^{-1} for **1** (for $[Ir(tpy)_2]^{3+}$, k_r is 2.5×10^4)[10] and ca. 5×10^3 s^{-1} for **2** and **3**. This also points to a different nature for the emissive state at room temperature. Based on all these observations, we ascribe the luminescence of **2** and **3** to an excited state with CT character.

An assessment of the nature of the excited states responsible for the luminescence and the type of vibrations affecting their deactivation can further be obtained by studying the luminescence spectroscopic profiles in terms of Franck–Condon envelopes.[22–27] According to Equation (1a,b)[22–23] (see Experimental Section), vibronic analyses for complexes **1**, **2** and **3** reveal similarities and differences between them. Figure 4 provides a direct comparison of results obtained both at room temperature and at 77 K. Derived estimates for the indicated parameters are further listed in Table 3 (for **1**, at room temperature, no satisfactory analysis could be applied). The luminescence profiles at 77 K for **1**, **2** and **3** exhibit the same vibrational progression, with a frequency $\hbar\omega_v$ in the range 1200–1280 cm^{-1}, Table 3. The displacement parameter along this frequency, S, was found to be 0.90, 0.75 and 0.84 for **1**, **2** and **3**, respectively. The 0–0 energy of the luminescent level, E_0, is ≈ 2.8 eV for **1** and ≈ 2.7 eV for both **2** and **3**. This indicates that at 77 K, the luminescent state is deactivated via coupling with the same type of vibrational modes, which are likely to be C–N or C–C skeleton vibrations,[24–27] with a similar extent of electronic delocalisation for all three cases. According to previous assignments for the ^{3}LC emission for **1**,[1,10,11] this suggests that at 77 K the nature of the emitting state in **2** and **3** is likewise ^{3}LC.

With regards to the room temperature cases, analysis of the broad and unstructured luminescence shape for complexes **2** and **3** (Figure 4 and Table 3) yields a displacement parameter $S > 2$, supporting the view of a quite localised emitting level, with a coupled vibration $\hbar\omega_v \approx 600$–$700$ cm^{-1}. Because of their CT character, on passing from room temperature to the frozen solvent (77 K), these levels can be expected to be highly destabilised which explains why the luminescence of **2** and **3** in the glass has ^{3}LC origin, as for **1** (see Figure 4). This is supported by the large HS observed for **2** and **3** against a much smaller one for **1** on passing from room temperature to 77 K. We notice that the room temperature luminescence spectrum for **1** was not amenable to a profile analysis which might be explained by a *mixed* nature for the emission (presumably LC-CT) of this complex at this temperature.

Other interesting spectroscopic features which help to define useful spectroscopic differences among the investigated complexes are the excited state absorption spectra (ESA). Figure 5 shows the end of pulse spectra determined with

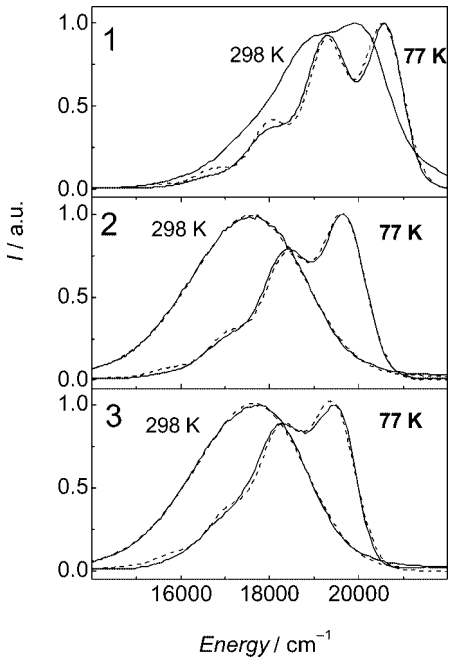

Figure 4. Vibronic analysis [dashed line, Equation (1a,b) of Experimental Section] of the corrected luminescence profiles (full line, an energy scale is employed) of complexes **1**, **2** and **3** as obtained in MeCN (room temperature) and BuCN (77 K); excitation was at 379 nm. For **1** at room temperature, the fit of the experimental profile was unsuccessful.

Table 3. Data from vibronic analyses of the luminescence spectra.[a]

	298 K		77 K		
	2	**3**	**1**	**2**	**3**
$\hbar\omega_v$ [cm^{-1}]	610	700	1270	1275	1190
λ_V [cm^{-1}]	1580	1450	1140	960	1000
λ_S [cm^{-1}]	1720	1430	1830	2270	2210
E_0 [eV]	2.57	2.52	2.78	2.72	2.69
S[b]	2.59	2.07	0.90	0.75	0.84

[a] According to Equation (1a,b) in the Experimental Section.[22,23] Solvent: MeCN at room temperature, BuCN at 77 K; excitation performed at 379 nm. The room temperature spectra of **1** could not be analysed. [b] Displacement parameter, $S = \lambda_V/\hbar\omega_v$, see text.

picosecond resolution upon excitation with a 355 nm laser pulse of the complexes in air-equilibrated MeCN. The ESA profiles are quite different. Complex **1** shows a peak at 670 nm whereas both **2** and **3** display more intense and broad bands peaking at 780 nm. This is indicative of the fact that excited states of a different nature are involved in the transitions of **1** on one hand and **2** and **3** on the other, i.e. a ^{3}LC state is involved in **1** and a ^{3}CT in is involved in both **2** and **3**. The time evolution of the transient absorption in aerated and air-free solutions, as determined by a nanosecond flash photolysis experiment for **2** and **3**, is reported in Figure 6. The decay has a lifetime of 440 ns in air-equilibrated and 740 ns in air-free solutions for **2** and 530 ns in air-equilibrated and 1.75 μs in air-free solutions for **3**. The good agreement[28] with the luminescence lifetimes indicates that the states responsible for the absorption are the same as those displaying luminescence. The molar

absorption coefficient of the triplet state for **2** and **3** was determined against a benzophenone in benzene actinometer (see experimental section for details) and ε_{780nm} was of the order of 15 000 $M^{-1}cm^{-1}$. The characteristic and very strong ESA feature for **2** and **3**, in a spectroscopic region free from the absorbance of most D and A components, will prove very useful as a spectroscopic fingerprint during the study of the sequential events in the D-P-A arrays currently being designed.

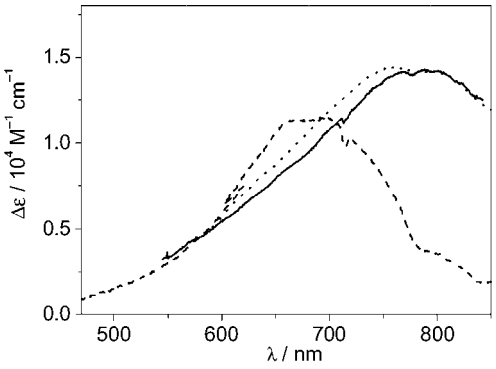

Figure 5. Excited state absorption spectra detected at the end of a laser pulse (35 ps, 355 nm, 3.5 mJ per pulse) in MeCN solutions. Symbols are: **1** (dashed), **2** (solid) and **3** (dotted).

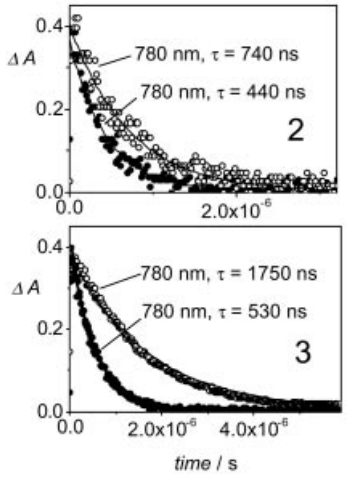

Figure 6. Time decay of excited state absorption spectra (full line results from exponential fit) detected at λ = 780 nm in air-free (o) and air-equilibrated (●) optically matched solutions of **2** (upper panel) and **3** (lower panel) in MeCN following nanosecond laser excitation (18 ns, 355 nm, 1.9 mJ per pulse)

All the above observations are consistent with a predominantly ^{3}LC-type emission for **1** whereas **2** and **3** qualify better at room temperature as ^{3}CT emitters. The differences between **1** on the one hand and **2** and **3** on the other tend to disappear at 77 K, indicating a common nature for the emitting states in frozen solutions. This can be easily understood if one keeps in mind that the rigid environment, which prevents molecular reorientation, effectively destabilises CT states whereas this effect is only minor for LC states. In fact, our results suggest that at 77 K the three complexes exhibit an LC emission. In this respect, the lower and lower energy of emission at 77 K upon passing from **1** to **2** and **3** could reflect a stabilisation induced by an increased delocalisation within the LC manifold.

While it is somewhat tempting to identify the CT state as a metal-to-ligand charge transfer, MLCT, in analogy to other photo- and electro-active transition metal complexes,[12] an ILCT state should in fact also be considered. An ILCT state with the appended benzamide group acting as a donor while the metal-bond terpyridyl unit functions as an acceptor, similar to that postulated by Williams et al. for a 4-aminobiphenyl-substituted $Ir(tpy)_2$ complex,[11] appears unlikely given the electrochemical inertness of the benzamide group which is rather difficult to oxidise.[29] Another possible source of an ILCT excited state could be connected with the intrinsic properties of the ligand, in particular of the benzamide unit. It is therefore useful to recall the spectroscopic properties of *N*-phenylbenzamide. The latter material has been investigated by Lewis at al. in aromatic solvents and at room temperature it displays dual fluorescence which can be assigned to an ^{1}n–π* transition (λ_{max} = 433 nm) and a twisted intramolecular charge transfer state, ^{1}TICT (λ_{max} = 510 nm), originating from a relaxed, higher energy ^{1}π–π* state.[30,31] The extended conjugation at the ligand, which occurs when benzamide units are appended to the tpy fragment coordinated to the metal centre, and the polar solvent could further stabilise the latter state so as to match the detected luminescent level in the present complexes. Accordingly, the low-lying CT transitions detected in the benzamide appended complexes **2** and **3** could be intra-ligand charge transfer in nature (^{3}ILCT) and localised on the *N*-phenyl benzamide fragment. This hypothesis, however, cannot explain the extremely large bathochromic shift, from 265 nm to ca. 400 nm, in the low energy absorption bands detected in these complexes with respect to *N*-phenylbenzamide.

So it seems that Ir^{III} to pab-tpy MLCT transitions could better explain the observed spectroscopic behaviour. However, we lack support from the electrochemistry for the occurrence of such CT transitions at low energy. As discussed above, with reference to the redox properties of $[Ir(tpy)_2]^{3+}$, estimated levels for an Ir^{III} →L CT emission could be too high in energy in comparison with experimental findings. Nonetheless, the estimated energy gap between ^{3}MLCT and luminescent levels is not exceedingly large and thermal redistribution might well mix some ^{3}MLCT character into the luminescent level at room temperature.

Conclusions

New Ir^{III}-bisterpyridine type complexes exhibiting a low-lying excited state with ^{3}CT nature at room temperature have been synthesized and spectroscopically characterised. The lifetimes of the excited states of these complexes are long, $\tau \approx$ 1–2 μs, given the CT nature of the excited species. In a rigid matrix at 77 K the emission, which is ^{3}LC in character, exhibits lifetimes $\tau \approx 10^2$ μs which is longer than recorded for other $[Ir(tpy)_2]^{3+}$ derivatives. In addition, with respect to previously investigated Ir^{III}-tpy type complexes,

complex **2** and, even more, complex **3** feature an absorption spectrum the lowest-energy portion of which is shifted towards the visible region of the spectrum and is characterised by a high molar absorption coefficient. Because of their spectroscopic and photophysical properties, complexes **2** and **3** appear promising as photosensitisers and assembling units in D-P-A arrays designed for exploring photoinduced charge separation. In fact, they combine an advantageous geometry which allows the construction of linear and rigid arrays with the presence of a CT excited state (at room temperature) which, being characterised by a separation of charges with respect to an LC excited state, is much better suited to initiate a multistep electron transfer required to achieve charge separation over long distances.

Experimental Section

The syntheses and characterisations of **1** and **2** have been reported elsewhere.[8,10] Complex **3** was synthesized according to the following procedure: $IrCl_3$ and two equiv. of bap-tpy were heated at 196 °C in degassed ethylene glycol in the dark for 20 min. After precipitation with an aqueous solution of KPF_6, crude **3** was purified by column chromatography (silica, CH_3CN / water / saturated KNO_3 solution 100:10:1) to give **3** in 40% yield as a yellow solid. ^1H NMR (CD_3CN,300 MHz): δ = 9.17 (s, 2H, NH), 9.09 (s, 4H, $H_{3'5'}$), 8.73 (d, ^3J = 7.5 Hz, 4H, $H_{33''}$), 8.27 (d, ^3J = 8.9 Hz, 4H, H_{o1}), 8.25 (m, 4H, $H_{44''}$), 8.18 (d, ^3J = 8.9 Hz, 4H, H_{m2}), 8.04 (d, ^3J = 8.9 Hz, 4H, H_{o2}), 7.72 (d, ^3J = 8.8 Hz, 4H, $H_{66''}$), 7.66–7.57 (m, 6H, H_{m2}, H_{p2}), 7.51 (ddd, ^3J = 6.9 and ^4J = 1.2 Hz, 4H, $H_{55''}$) ppm. ES-MS, *m*/*z* (calcd.): 349.75 (349.76) $[M - 3PF_6]^{3+}$.

Spectrophotometric grade acetonitrile or butyronitrile solvents were used. Absorption and luminescence spectra were measured with a Perkin–Elmer Lambda 5 UV/Vis spectrophotometer and a Spex Fluorolog II spectrofluorimeter, respectively. Solutions were purged of air by bubbling with argon for 10 min. The samples were contained in home designed 10 mm fluorescence cells. Luminescence quantum yields (Φ) were evaluated, after correcting for the photomultiplier response, with reference to air-equilibrated $[Ir(ttpy)_2](PF_6)_3$ in aerated acetonitrile as a standard (Φ = 0.029).[10] Luminescence lifetimes (τ) were obtained with an IBH single photon counting instrument upon excitation at 373 nm from a pulsed diode source. Transient absorption spectra were determined by a pump-probe spectrograph with 30 ps resolution based on a Nd-YAG laser (355 nm, 10 Hz).[32] The lifetime of the absorbing excited state was determined by a laser flash photolysis system based on a Nd-YAG laser (355 nm, 18 ns pulse) previously described.[33] Molar absorption coefficients of the excited states were determined with the same nanosecond apparatus using the benzophenone in benzene actinometer (λ = 530 nm, ε = 7 220 M^{-1} cm^{-1}, Φ_T = 1).[34] The experimental uncertainty in the absorption and luminescence maxima is 2 nm. The uncertainties in the τ values and the Φ values are 10 and 20%, respectively.

The vibronic band profiles of the corrected luminescence spectra, $I(E)$, on an energy scale [E (cm^{-1})] were analysed according to Equations (1a) and (1b) which describe the relation between the Frank–Condon envelope, $FC(E)$, and some other pertinent parameters.[22–23]

$$I(E) = \cos t \times FC(E) \quad \text{(1a)}$$

$$FC(E) = \sum_{J=0}^{\infty} F_j (4\pi\lambda_s k_B T)^{-1/2} \exp\left(-\frac{(E - E_0 + j\hbar\omega_v + \lambda_s)^2}{4\lambda_s k_B T} \right) \quad \text{(1b)}$$

with $F_j = \exp(-S)\frac{S^j}{j!}$; and $S = \frac{\lambda_v}{\hbar\omega_v}$

In this equation, E_0 is the energy of the 0–0 transition (the energy gap between the 0–0 vibrational levels in the excited and ground states), j is a vibrational quantum number for high-frequency modes, $\hbar\omega_v$ (in practice an upper limit j = 5 is taken into account), λ_v and λ_s are internal and solvent reorganisation parameters, S is a displacement parameter and k_B is the Boltzmann constant. A nonlinear least-squares fit of Equation (1a,b)[35] to the experimental spectra provides estimates for E_0, λ_v, λ_s and the displacement parameter S along the $\hbar\omega_v$ vibrational mode (predominantly contributing to deactivation of the excited level). The magnitude of S (the electron-vibrational coupling constant or Huang–Rhys factor) is related to the relative intensities of the individual components in the vibrational progression. Analysis according to Equation (1a,b) allows, among other things, an assessment of the extent of delocalisation of the luminescent level which undergoes deactivation because of coupling with ground state $\hbar\omega_v$ vibrational modes. High values for S (typically in the range 0.7 to 1 and more)[27] indicate that the excited state is significantly distorted along the concerned vibrational mode because of electronic *localisation* effects. On the contrary, when the exited state undergoes extended electronic *delocalisation*, low S values are obtained (typically in the range 0.2 to 0.6)[24,36] indicating that the electronic curve for the excited level is not displaced much relative to that for the ground state.

[28] It should be noticed that the absorbing species lifetimes detected by laser flash photolysis are, in general, shorter than those of the same luminescent species determined by single photon techniques. This is caused by the much higher photon flux which is used in laser flash photolysis experiments and this, increasing the concentration of excited states, introduces a second order component due to self annihilation in the decay which tends to shorten the lifetime compared with low intensity determinations.

Di- and Trivalent Lanthanide Complexes Stabilized by Sterically Demanding Aminopyridinato Ligands

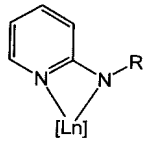
Natalie M. Scott[a] and Rhett Kempe*[a,b]

Keywords: Aminopyridinato ligands / Lanthanides / Neodymium / N ligands / Olefin polymerization / Samarium / Ytterbium

Deprotonation of Ap*H {Ap*H = (2,6-diisopropylphenyl)-[6-(2,4,6-triisopropylphenyl)pyridin-2-yl]amine} and Ap′H {Ap′H = (2,6-diisopropylphenyl)-[6-(2,6-dimethylphenyl)pyridin-2-yl]amine} using KH leads to polymeric $[Ap^*K]_n$ and $[Ap'K]_n$ which undergo clean salt metathesis reactions with $NdCl_3$ in THF forming $[Nd(Ap^*)Cl_2(THF)_2]_2$ and $[Nd(Ap')_2Cl(THF)]$, respectively. Ethylene polymerization activities of the two chloro complexes (after activation with MAO) were studied. Derivatization of the chloro compounds proceeds without ate complex formation, for instance the reaction of $[Nd(Ap')_2Cl(THF)]$ with one equiv. of $[K\{N(SiMe_3)_2\}]$ leads to the "THF-free" silylamide $[Nd(Ap')_2\{N(SiMe_3)_2\}]$. Furthermore rare examples of heteroleptic amido-iodo complexes of selected divalent lanthanides can be stabilized by deprotonated Ap*H. Reaction of $[Ap^*K]_n$ with $[LnI_2(THF)_3]$ (Ln = Yb, Sm) in THF leads, after workup in hexane, to $[Yb(Ap^*)I(THF)_2]_2$ and $[Sm(Ap^*)I(THF)_2]_2$. All lanthanide complexes, four of them are paramagnetic, were characterized by X-ray crystal structure analysis. These compounds exhibit an excellent solubility in nonpolar solvents like hexane.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

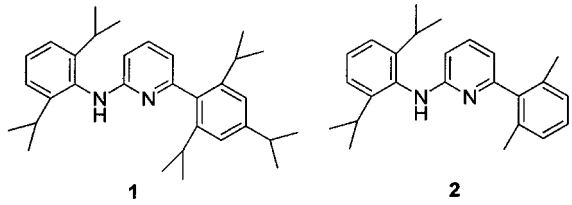
Introduction

During the renaissance[1] of amido[2] metal chemistry, aminopyridinato ligands (Ap)[3] have been used extensively to stabilize lanthanide (Ln) complexes. These compounds (Scheme 1) have been shown to exhibit unusual stoichiometric and catalytic reactivity.[4]



Scheme 1. An aminopyridinato ligand in its strained η^2 binding mode, typical for early transition metals and lanthanides ([Ln] = lanthanide moiety; R = aryl, silyl or alkyl substituent).

The size of the aminopyridinato ligands used thus far has been relatively small, resulting in a low steric demand of the metal, especially in the plane perpendicular to the pyridine moiety. This, in turn, gives rise to highly nitrogen-coordinated lanthanide complexes. Recently, we described the preparation of bulky aminopyridinato ligands by the introduction of 2,6-alkylphenyl substituents at the amido-N atom and also in the 6-position of the pyridine ring (Scheme 2).[5] Here, we report on synthesis, structure and reactivity of lanthanide complexes stabilized by deprotonated **1** and **2**.



Scheme 2. Proligands Ap*H (**1**) and Ap′H (**2**).

The maximum atom-to-atom distance in deprotonated **1** (determined from its Li salt[5] is 15 Å (vector **a** in Scheme 3, top). Approximately perpendicular to it is vector ***b*** = 8 Å. Comparing these measurements with those of the bulky, η^5-coordinated Cp*-ligand[6] (Cp* = pentamethylcyclopentadienyl) (Scheme 3, bottom), which has a distance of **a** = ***b*** = 6.2 Å, indicates that deprotonated **1** would be effective for the protection of large metal ions such as lanthanides. Furthermore, the stabilization of mono-amide [mono-(aminopyridinato)] complexes, in which ligand redistribution is blocked, should become possible.

The size of deprotonated **2** is somewhat smaller than deprotonated **1** with ***a*** = 13 Å and ***b*** = 8 Å.

Results and Discussion

Synthesis and Structure of Neodymium Complexes

The reactions of the lithium salts of **1** or **2** (prepared by deprotonation in situ with BuLi) with $NdCl_3$ did not result

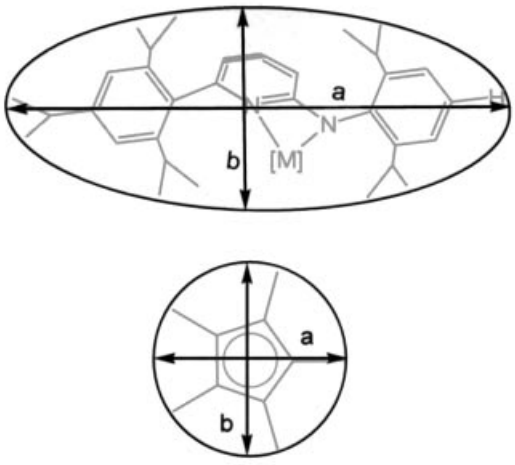
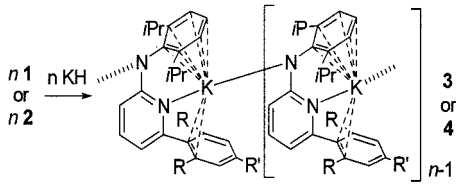


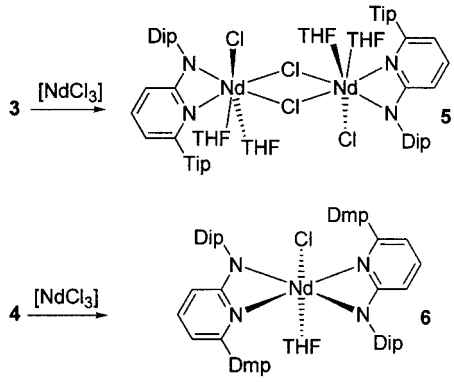
Scheme 3. Description of the steric demand of deprotonated **1** in comparison to Cp*.

in the isolation of a neodymium complex (only starting material was recovered). Deprotonation of **1** or **2** using KH gives rise to polymeric products **3** and **4**, as shown in Scheme 4.[5]



Scheme 4. Synthesis of **3** (R, R′, *i*Pr = isopropyl) and **4** (R = methyl, R′ = H).

Compounds **3** and **4** react with [$NdCl_3$] in a salt metathesis reaction affording **5** and **6**, see Scheme 5. No ate complex formation was observed. Compounds **5** and **6** were characterized by X-ray crystal structure analysis. Experimental details are summarized in Table 1. The molecular structure of **5** is shown in Figure 1.



Scheme 5. Synthesis of **5** and **6** (Dip = 2,6-diisopropylphenyl, Tip = 2,4,6-triisopropylphenyl, Dmp = 2,6-dimethylphenyl).

These investigations revealed **5** to be a dinuclear mono(aminopyridinato) complex. Reacting K to Nd ratios of 1:1 or 2:1 gave rise to the same product. The steric bulk of deprotonated **1** seems to favor the formation of a one to one Ap to Ln ratio. The N–Nd–N angle (53°) underlines the strained nature of the aminopyridinato coordination and the different Nd–N distances indicate a localization of the anionic function of the ligand at the amido-N atom – a classic amido−metal bond and a standard pyridine–neodymium bond. The amido-*N*···neodymium distance (2.380 Å) is in accordance with the reported values from the literature (standard value 2.356 Å[7]), as is the pyridine-N···neodymium distance at 2.659 Å (standard value 2.670 Å[8]). This is in contrast to the coordination of silylaminopyridinato lanthanide complexes, where a delocalized binding mode, including equivalent metal···nitrogen distances, has been observered in all compounds described so far.[4] The molecular structure of **6** is shown in Figure 2.

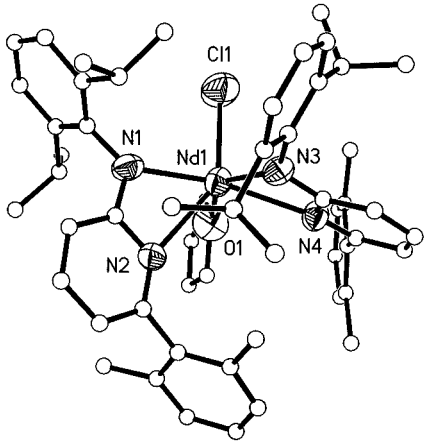

Figure 2. Molecular structure of **6** (ellipsoids correspond to the 50% probability level); selected bond lengths [Å] and angles [°]: Nd1−N1 2.361(6), Nd1−N3 2.386(7), Nd1−O1 2.442(7), Nd1−N4 2.569(6), Nd1−Cl1 2.599(3), Nd1−N2 2.622(6), Nd1−C1 2.936(8); N3−Nd1−N4 54.9(2), N1−Nd1−Cl1 90.50(17), N3−Nd1−Cl1 103.37(16), N4−Nd1−Cl1 107.91(15), N1−Nd1−N2 54.1(2), Cl1−Nd1−N2 142.91(14).

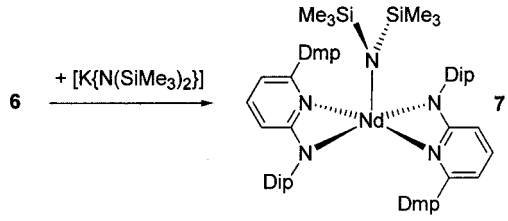
In contrast to **5** a bis(aminopyridinato) complex is formed which is monomeric in the solid state. Despite the fact that the differences of the steric bulk of deprotonated **1** and **2** are rather small in comparison to the size of the ligands, selective formation of mono- or bis(aminopyridinato) complexes are observed. The neodymium···N distances of **6** are indicative of a localization of the anionic function. This appears to be a general phenomenon and is illustrated by the 90° dihedral angle between the pyridine plane and arylamido plane. It is probable that the two alkyl substituents prevent an interaction between the two π-systems. In silylaminopyridinato lanthanide complexes the pyridine π-system may interact with the silicon atom to cause further delocalization. This delocalization may go some way to explain the parity of two N–Ln bonds in silylaminopyridinato ligands. Compound **5** and **6** are soluble in nonpolar solvents such as hexane and salt metathesis reactions proceed in this solvent without ate complex formation. The reaction of **6** with one equiv. of [K{N(SiMe$_3$)$_2$}] leads to the silylamide **7**, uncoordinated by THF (Scheme 6).



Scheme 6. Synthesis of **7**.

Compound **7** was characterized by X-ray crystal structure analysis. Experimental details are summarized in Table 1. The molecular structure of **7** is shown in Figure 3.

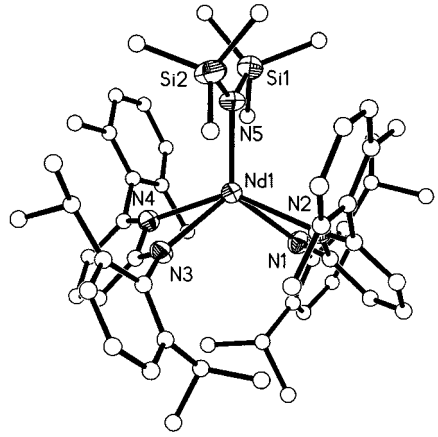


Figure 3. Molecular structure of **7** (ellipsoids correspond to the 50% probability level); selected bond lengths [Å] and angles [°]: Nd1−N5 2.280(2), Nd1−N3 2.407(2), Nd1−N1 2.414(2), Nd1−N2 2.544(2), Nd1−N4 2.552(2); N5−Nd1−N3 123.78(8), N5−Nd1−N1 125.18(8), N5−Nd1−N2 108.02(8), N1−Nd1−N2 54.56(7), N5−Nd1−N4 110.50(8), N3−Nd1−N4 54.57(7).

The coordination can be described as rectangular pyramidal with the four aminopyridinato-N atoms forming the rectangle. As far as we are aware the silylamido–Nd bond length represents the shortest observed so far and should indicate a highly Lewis-acidic metal center. Compounds **5** and **6** were tested as catalysts for ethylene polymerization after activation with MAO. The complexes were dissolved in toluene and treated with MAO (aluminium to catalyst ratio = 250:1). A 1-L laboratory autoclave was charged with the catalyst solution and an ethylene overpressure of 10 bar was applied at 60 °C for 30 minutes. Compounds **5** and **6** showed activities of 51.4 and 42.4 $kg_{polyethylene}\,mol_{cat}^{-1}\,h^{-1}\,bar^{-1}$, respectively. These moderate activities[9] indicate the potential of these compounds in olefin polymerization. Detailed studies of olefin insertion into neutral or cationic lanthanide complexes are underway.

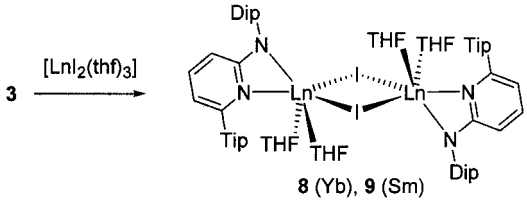
Synthesis and Structure of the Heteroleptic Ytterbium and Samarium Complexes

Pioneering work by Evans and coworkers[10,11] has shown that divalent lanthanide complexes exhibit a particularly rich reaction chemistry owing to the accessibility of different oxidation states;[12] for example, although $[Cp^*_2Sm]$ and $[Cp^*_2Sm(THF)_2]$ do not possess a metal–carbon bond they both show polymerization activity towards ethylene[13,14] The majority of this chemistry has been carried out utilizing homoleptic Cp* complexes. However, complexes incorporating a single Cp* ligand and a second anionic ligand (heteroleptic compounds), which may allow for further tuning of the reactivity, have received inadequate attention. This is partially due to the low stability of the mono-ligated starting materials. For example, the compounds $[(Cp^*)Sm(\mu\text{-}I)(THF)_2]_2$ [15] and $[(Me_3Si)_2NSm(\mu\text{-}I)(DME)(THF)]_2$ [16] (DME = dimethoxyethane) have been described and are reported to undergo facile ligand redistribution to give $[SmI_2(THF)_x]$ and $[SmL_2]$ [L = Cp*, $(Me_3Si)_2N$]. Divalent "heteroleptics" have been well documented in the case of donor-functionalized Cp-ligands but rarely described for alkoxy and amido ligands.[16,17] We expected deprotonated **1** to be an excellent candidate for the stabilization of such divalent complexes. The reaction of **3** with $[LnI_2(THF)_3]$ (Ln = Yb, Sm) in THF leads, after workup in hexane, to mono-iodido complexes, which prove to be binuclear in the solid state (Scheme 7). Experimental details of the X-ray crystal structure analyses are summarized in Table 1.



Scheme 7. Synthesis of **8** and **9**.

The molecular structures of **8** and **9** are shown in Figure 4 and Figure 5, respectively. The coordination of the two Yb centers of **8** is best described as octahedral with a dihedral angle of 95.1° between the Yb1–Yb1A–I1–I1A plane and the pyridine planes. Proton NMR spectra of **8** ([D_8]THF, [D_8]toluene) show a single signal set with well-resolved signals for the isopropyl groups in $C_6D_5CD_3$.

Since the paramagnetic nature of **9** prevents structural characterization by NMR spectroscopy, X-ray analysis was performed. Only very weak diffracting crystals of **9** could be obtained. However, the connectivity could be established. Owing to the low quality of structural data, a detailed discussion of bond length and angles is waived. The molecular structure of **9** is similar to that of **8** but the structures are not isomorphous.

Conclusions

Deprotonated **1** is an excellent ligand for the stabilization of mono(aminopyridinato) complexes of di- and trivalent lanthanides. The steric demands of this ligand result in a reduction of ligand redistribution during synthesis. Structurally, its lanthanide complexes can be compared to that of other bulky amide-containing compounds, such as troponiminate or amidate complexes but the chemistry should be somewhat different owing to higher ligand asymmetry. Surprisingly, deprotonated **2** gives selectively a bis(aminopyridinato) complex for neodymium, despite the relatively small difference in the structural size when compared with **1**. This study underlines the importance of fine-tuning, even surely in the "nano range".

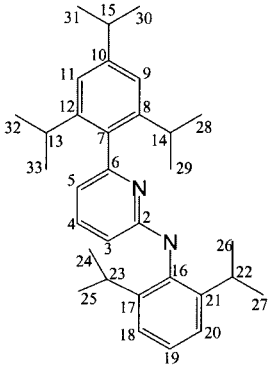
Experimental Section

General Procedures: All reactions and manipulations with air-sensitive compounds were performed under dry argon, using standard Schlenk and drybox techniques. Solvents were distilled from sodium benzophenone ketyl. Deuterated solvents were obtained from Cambridge Isotope Laboratories and were degassed, dried (CaH_2) and distilled prior to use. NMR spectra were obtained using either a Bruker ARX 250, Bruker DRX 500, Varian Unity Inova 400 or 300 spectrometer. Chemical shifts are reported in ppm relative to the deuterated solvent. Elemental analyses were carried out with an Elementar Vario EL III. **1**, **2**, **3**, and **4**[5] as well as [$LnI_2(THF)_3$] (Ln = Yb, Sm)[18] were synthesized following literature procedures. Other starting materials were purchased from commercial suppliers. X-ray crystal structure analyses were performed with a STOE-IPDS I or II equipped with an Oxford Cryostream low-temperature unit. Structure solution and refinement was accomplished using SIR97,[19] SHELXL97,[20] and WinGX.[21] CCDC-251807 (for **5**), -251808 (for **6**), -251809 (for **7**), -251810 (for **8**), and CCDC-251811 (for **9**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Preparation of the Lanthanide Complexes



[Nd(Ap*)Cl_2(THF)$_2$]$_2$ (5): [$NdCl_3$] (0.38 g, 1.50 mmol), **3** (0.75 g, 1.50 mmol) and THF (40 cm^3) were added to a flask, and the mixture was stirred for 15 h. The solvent was removed under vacuum and hexane was added (30 cm^3). The light blue reaction mixture was filtered and on standing at room temperature for 2 h pale blue crystals of the title complex formed (0.80 g, 48%). $C_{80}H_{118}Cl_4N_4Nd_2O_4$ (1630): calcd. C 58.94, H 7.30, N 3.44; found C 58.95, H 7.14, N 3.05. Highly resolved NMR spectroscopic data could not be obtained. (2:1 Ligand/Nd reaction resulted in the formation of **5**.)

[Nd(Ap′)$_2$Cl(THF)] (6): [$NdCl_3$] (0.34 g, 0.93 mmol), **4** (0.74 g, 1.87 mmol) and THF (40 cm^3) were added to a flask, and the mixture was stirred for 24 h. The solvent was removed under vacuum and hexane was added (30 cm^3). The light blue reaction mixture was filtered and the filtrate allowed to stand at room temperature for 2 h whereupon small green-blue crystals of the title complex formed (0.37 g, 64%). $C_{54}H_{66}ClN_4NdO$ (967): calcd. C 67.08, H 6.88, N 5.79; found C 66.85 H 7.17, N 5.61. Highly resolved NMR spectroscopic data could not be obtained.

[Nd(Ap′)$_2${N(SiMe$_3$)$_2$}]•(hexane) (7): Hexane (30 cm^3) was added to **6** (0.11 g, 0.11 mmol) and [K{N(SiMe$_3$)$_2$}] (0.02 g, 0.11 mmol) and the mixture was stirred for 15 h. The reaction mixture was filtered and the filtrate concentrated to ca. 15 cm^3. The reaction mixture was cooled to –20 °C and on standing for 12 h pale blue crystals of the title complex were afforded (0.06 g, 42%). $C_{68}H_{104}N_5NdSi_2$ (1192): calcd. C 68.52, H 8.79, N 5.88; found C 68.85, H 7.98, N 6.31. Highly resolved NMR spectroscopic data could not be obtained.

[Yb(Ap*)I(THF)$_2$]$_2$ (8): [$YbI_2(THF)_3$] (0.70 g, 1.09 mmol), **3** (0.54 g, 1.09 mmol) and THF (40 cm^3) were added to a flask, and the mixture was stirred for 15 h. The solvent was removed under vacuum and a mixture of toluene (20 cm^3)/hexane (10 cm^3) was added. The red suspension was filtered and upon standing at –20 °C for 48 h, dark red crystals (suitable for X-ray analysis) of the title complex formed (0.80 g, 82%). $C_{80}H_{118}I_2N_4O_4Yb_2$ (1798): calcd. C 53.39, H 6.61, N, 3.11; found C 52.85, H 6.38, N 2.96. ^{1}H NMR (400 MHz, C_7D_8, 298 K): δ = 1.22 (d, ^3J = 7.0 Hz, 12 H, $H^{28,29,32,33}$), 1.27 (d, ^3J = 7.0 Hz, 6 H, $H^{24,25,26,27}$), 1.34 (d, ^3J = 7.0 Hz, 6 H, $H^{30,31}$), 1.35 (br, 8 H, β-CH_2, THF), 1.48 (d, ^3J = 7.0 Hz, 6 H, $H^{24,25,26,27}$), 2.78 (sept, ^3J = 7.0 Hz, 1 H, H^{15}), 3.28 (sept, ^3J = 7.0 Hz, 2 H, $H^{13,14}$), 3.41 (br, 8 H, α-CH_2, THF), 3.85 (sept, ^3J = 7.0 Hz, 2 H, $H^{22,23}$), 5.65 (d, ^3J = 8.4 Hz, 1 H, H^3), 5.85 (d, ^3J = 6.8 Hz, 1 H, H^5), 6.76 (dd, ^3J = 8.4 Hz, ^3J = 6.8 Hz, 1 H, H^4), 7.04 (s, 2 H, $H^{9,11}$), 7.11 (vt, ^3J = 8.0 Hz, 1 H, H^{19}), 7.23 (d, ^3J = 8.0 Hz, 2 H, $H^{18,20}$) ppm. ^{13}C NMR (100.5 MHz, C_7D_8, 298 K): δ = 25.3 (s, $C^{30,31}$), 25.7 (s, $C^{24,25,26,27}$), 26.3 (s, β-CH_2, THF), 26.5 (s, $C^{28,29,32,33}$), 26.6 (s, $C^{24,25,26,27}$), 26.7 (s, $C^{28,29,32,33}$), 28.9 (s, $C^{22,23}$), 31.3 (s, $C^{13,14}$), 35.7 (s, C^{15}), 70.1 (s, α-CH_2, THF), 108.5 (s, C^3), 109.0 (s, C^5), 121.7 (s, $C^{9,11}$), 123.5 (s, C^{19}), 124.7 (s, $C^{18,20}$), 138.3 (s, C^4), 139.3 (s, C^7), 144.8 (s, $C^{17,21}$), 147.9 (s, C^{10}), 149.26 (s, $C^{8,12}$), 149.32 (s, C^{16}), 156.9 (s, C^6), 171.0 (s, C^2) ppm.

[Sm(Ap*)I(THF)$_2$]$_2$ (9): THF (40 cm^3) was added to the solids [$SmI_2(THF)_3$] (0.62 g, 1.00 mmol) and **3** (0.99 g, 1.00 mmol) and the mixture was stirred for 15 h. The solvent was removed in vacuo and hexane (10 cm^3) was added. The dark blue suspension was filtered and on standing at –20 °C for 72 h small dark blue crystals (suitable for X-ray analysis) of the title complex formed (0.23 g, 26%). $C_{80}H_{118}I_2N_4O_4Sm_2$ (1754): calcd. C 54.77, H 6.78, N 3.19; found C 53.72, H 6.67, N 3.30. Highly resolved NMR spectroscopic data could not be obtained.

Polymerization of Ethylene: The complex (≈ 20 mg) was dissolved in 15 cm^3 of toluene and treated with MAO solution (30% in toluene; aluminium to catalyst ratio = 250:1). The catalyst mixture was transferred to a larger flask and *n*-pentane (250 cm^3) was added. A BÜCHI laboratory autoclave (1 L) was charged with the catalyst solution and an ethylene overpressure of 10 bar was applied at 60 °C for 30 minutes. The reaction was stopped by relieving the pressure in the reactor. The polymers were washed with hydrochloric acid and acetone and then air-dried.

Acknowledgments

We thank Wolfgang Milius for his support in the X-ray lab and Christine Denner for her help during the polymerization studies. Financial support from the Alexander von Humboldt Stiftung (N. M. S.), the Deutsche Forschungsgemeinschaft (Schwerpunktprogramm 1166 "Lanthanoidspezifische Funktionalitäten in Molekül und Material") and the Fonds der Chemischen Industrie is gratefully acknowledged.

Heteroditopic Imino N-Heterocyclic Carbenes and Their Sulfur, Selenium, and Tungsten Tetracarbonyl Derivatives

Georg Steiner,[a] Holger Kopacka,[a] Karl-Hans Ongania,[b] Klaus Wurst,[a] Peter Preishuber-Pflügl,[c] and Benno Bildstein*[a]

Keywords: Carbene ligands / N ligands / Selenium / Sulfur / Tungsten

New heterditopic imino N-heterocyclic carbenes for use as chelating ligands in homogeneous catalysis are the focus of this contribution. The synthesis of the corresponding imidazolium precursors is accomplished in three steps by alkylation of imidazole with ketoalkyl bromides, imination of the carbonyl functionality with anilines, either by conventional methods or by an aluminum-assisted condensation, and methylation using highly electrophilic methyl triflate. Deprotonation of the imidazolium triflates with potassium hydride gives a different outcome depending on the substitution pattern of the iminomethyl moiety: iminomethyl N-heterocyclic carbenes containing a methylene group between the imino moiety and the N-heterocycle are unstable because of tautomerization to the corresponding methylene-deprotonated ylides. In contrast, iminoisopropyl N-heterocyclic carbenes, where the acidic site of the methylene group is blocked by two methyl groups, are stable in solution, as proven by ^{1}H and ^{13}C NMR spectroscopy. First derivatives of these new [N,C]-ligands include their sulfur and selenium oxidation products (iminoisopropylimidazolin-2-thione and -selenone, respectively) as well as a tungsten tetracarbonyl complex with a six-membered [N,C] chelating moiety. All new products were fully characterized by multinuclear NMR (^{1}H, ^{13}C, ^{77}Se, ^{183}W) and IR spectroscopy, mass spectrometry, as well as by X-ray single crystal structures.

Introduction

The chemistry of N-heterocyclic carbenes (NHCs) and their metal complexes[1] is of great current interest for applications in homogeneous catalysis. The advantages of NHCs as steering ligands of catalytically active transition metal complexes arise from their synthetic, thermodynamic, and technical features. Synthetically, NHC ligands may be designed and more or less easily synthesized in great structural variety, including multidentate and chiral representatives. Thermodynamically, the metal–carbon bond of NHC complexes is stronger than the metal–phosphorus bond of phosphane complexes, which suggests that replacement of phosphanes by NHC ligands will lead to catalysts with improved stability and performance. Technically, NHC complexes are often quite stable towards oxygen and thereby allow catalytic reactions under noninert conditions without catalyst degradation. Up to now, successful applications of NHC catalysts include carbon-carbon cross-coupling reactions, olefin metathesis,[2] hydrosilylation, and CO/ethylene copolymerization.[1] In contrast, the use of NHC-derived catalysts for olefin homopolymerizations[3] have met with rather limited success so far. Established ligand lead structures in late transition metal olefin polymerization catalysis[4] include, inter alia, 1,2-diimines containing bulky peripheral imine donors (type **A**, Scheme 1). We therefore set out to explore new ligand architectures that combine the steric bulk of appropriately substituted imine donors with an electronically favorable NHC moiety.

In earlier work we showed that NHCs with a directly N-bonded imine group of type **B** (Scheme 1) are unstable because of a [1,2] rearrangement of the imidoyl moiety.[5] To avoid this difficulty, we reasoned that an electronically decoupled imine group with a spacer should be compatible with an NHC carbon. Note that type **B** ligands should form five-membered [N,C]-metal chelate rings, whereas type **C** ligands will form six-membered [N,C]-metal chelates due to the C_1 spacer unit. In this contribution we show that such [N,C] ligands are indeed accessible provided that the methylene hydrogens of the C_1 spacer are blocked by two additional methyl groups (type **D**), and we report on their group 6 metal carbonyl complexes and on their thio and seleno derivatives. In a comparable approach, Tilset and coworkers[6] as well as Coleman and coworkers[7] have recently published similar chemistry of type **C** ligands focusing on their monodentate silver and their labile κ^1/κ^2 palladium complexes.

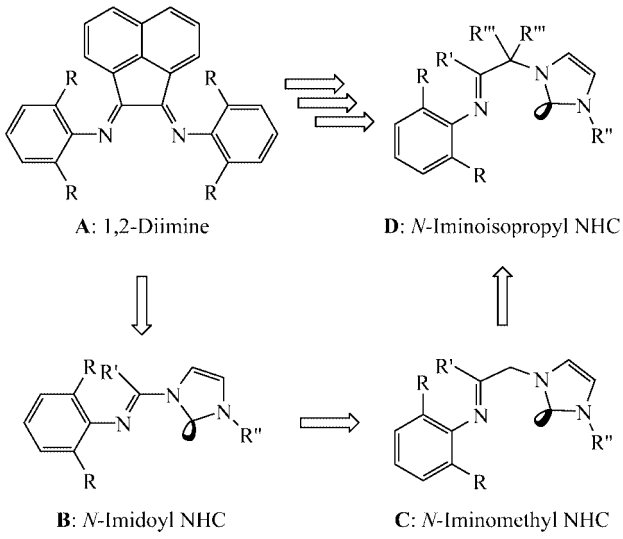


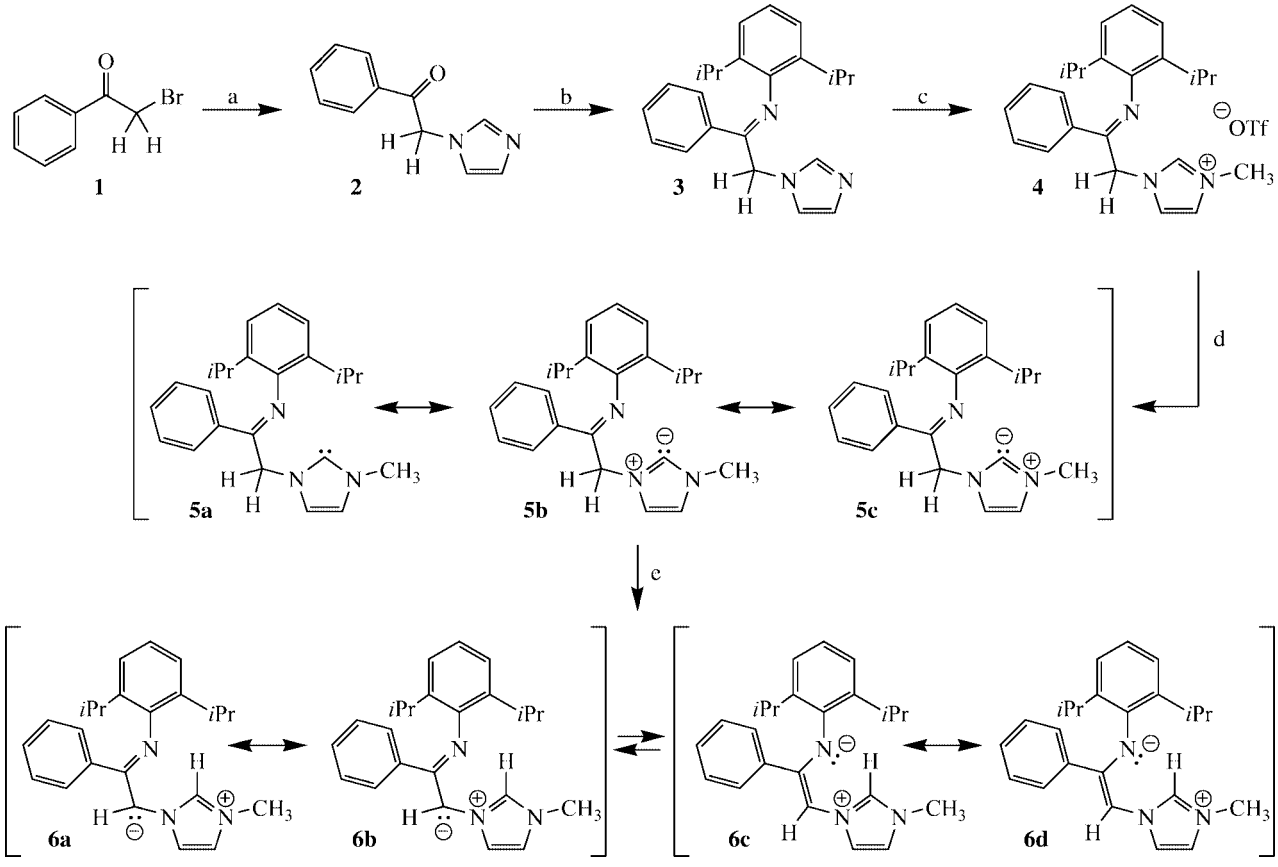
Scheme 1. Design concept for novel [N,C]-ligands.

Results and Discussion

N-Iminomethyl N-Heterocyclic Carbenes

In general, NHC ligands are generated most easily from their corresponding azolium salts (e.g. imidazolium salts) by deprotonation with suitable strong bases.[1] To get access to imino NHCs of type **C** (Scheme 1), the corresponding iminomethylimidazolium progenitors are therefore obvious synthetic targets. Such compounds may be obtained in a straightforward manner, as outlined in Scheme 2. First, a simple alkylation of imidazole with α-bromoacetophenone (**1**) afforded benzoylmethylimidazole **2** in a reasonable yield of 48%; for simplicity, one additional equivalent of imidazole was used as the base to bind the hydrogen bromide formed during the reaction. Secondly, conventional condensation of the carbonyl moiety of **2** with 2,6-diisopropylaniline with azeotropic removal of water gave iminomethylimidazole **3** as a yellow, air-stable oil. Finally, alkylation by the strongly electrophilic methyl trifluoromethanesulfonate afforded air-sensitive imidazolium triflate **4** in 29% overall yield starting from imidazole. Pertinent key NMR spectroscopic data of **4** include characteristic low-field signals for the imidazolium C(2)-bonded hydrogen [$\delta(^1H)$ = 9.17 ppm] as well as for the imine carbon [$\delta(^{13}C)$ = 161.2 ppm], observation of an imidazolium methyl group [$\delta(^1H)$ = 3.94 ppm, $\delta(^{13}C)$ = 35.8 ppm] and of an acceptor-substituted imidazolium methylene group [$\delta(^1H)$ = 5.85 ppm, $\delta(^{13}C)$ = 64.9 ppm], and detection of diastereotopic methyl groups of the isopropyl substituents [$\delta(^1H)$ = 0.83 and 0.91 ppm, $\delta(^{13}C)$ = 21.7 and 23.5 ppm] due to hindered rotation of the bulky 2,6-diisopropylphenyl substituent.

With the NHC precursor iminomethylimidazolium triflate **4** in hand, we anticipated that formation of the corresponding iminomethyl NHC would be easy to accomplish.



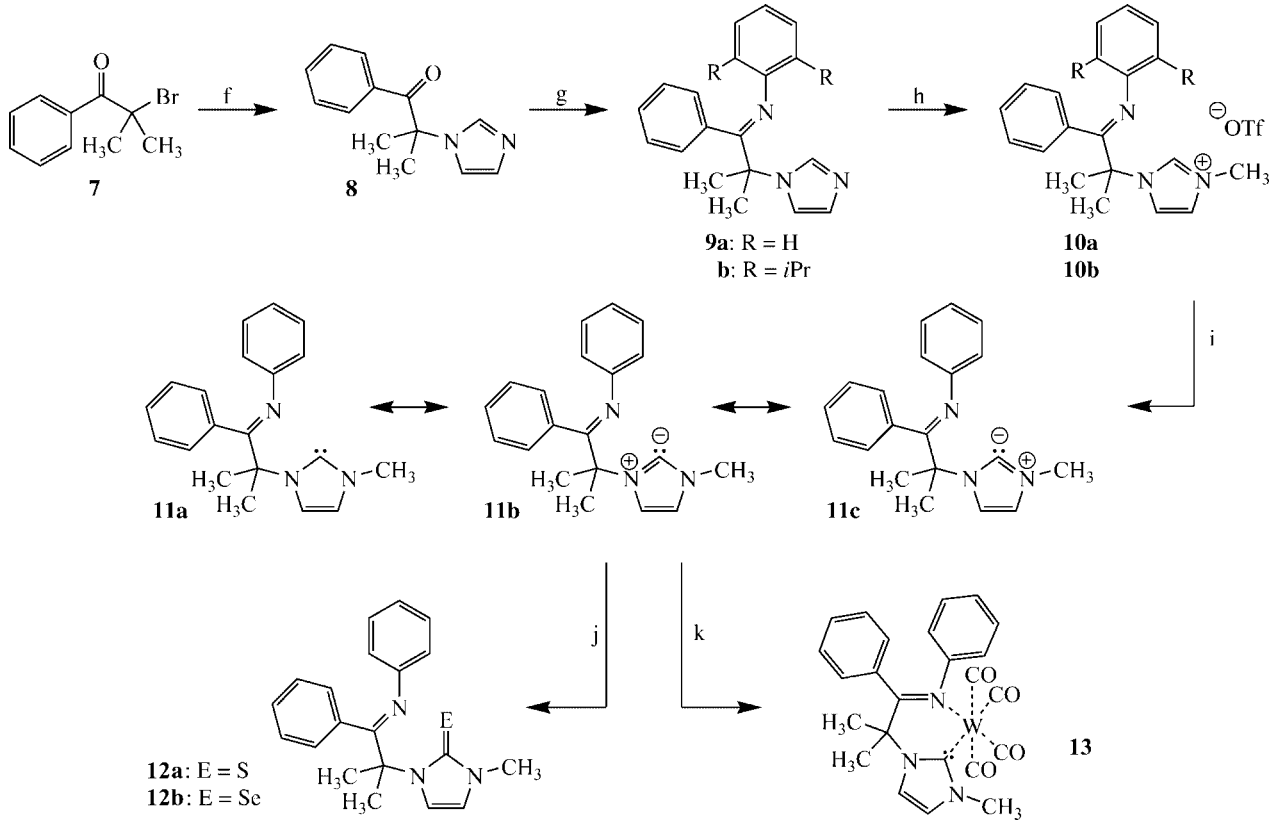
Scheme 2. Synthetic route to *N*-iminomethyl NHC ligands. Conditions: (a) imidazole; (b) 2,6-diisopropylaniline, H^+, reflux; (c) methyl triflate; (d) potassium hydride; (e) tautomerization.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

However, this is not the case. Upon reaction of **4** with one equivalent of potassium hydride as proton-abstracting reagent dihydrogen evolution was observed, as expected, and a dark red solution was obtained, presumably containing NHCs **5a**–**c**. Hydrolysis of this solution followed by TLC analysis showed that only the starting material **4** was present, indicating that deprotonation must have occurred without any decomposition, in contrast to earlier work[6] where intractable reaction mixtures were obtained on attempted deprotonation of iminomethylimidazolium salts. Closer inspection of the reactivity of this red solution indicated that no NHC was present, but instead its formal tautomer **6a**,**b** and/or its ylidic enamine **6c**,**d** must have been formed by deprotonation of the methylene group instead of the imidazolium C(2)-hydrogen. The intense red color of this new ylide is obviously due to the spread of charge over six unsaturated atoms, as indicated by formulas **6a**–**d**. In retrospect, this undesired deprotonation at the "wrong" site is not too surprising because similar behavior has been reported for some other imidazolium salts containing acidic methylene groups.[6–8] Based on these results we conclude that the free iminomethyl NHCs **5a**–**c** are unstable or rearrange to their tautomers. However, we note that such carbene ligands have been successfully incorporated into some silver and palladium complexes[6–8] using in situ deprotonation/complexation procedures which avoid the free carbenes as intermediates.

N-Iminoisopropyl N-Heterocyclic Carbenes

The problems associated with the acidic methylene hydrogens in NHCs of type **C** (Scheme 1) may be overcome by the use of appropriate protecting groups. As the most simple and sterically not too demanding groups we chose two methyl groups for this purpose, selecting NHCs of type **D** as our synthetic targets (Scheme 3). First, imidazole was alkylated with 2-bromo-2-methylpropiophenone (**7**) under reflux for three days in ethanolic solution to affording benzoylisopropylimidazole (**8**) in 61% yield. The longer reaction period and the increased temperature compared to the preparation of **2** reflect the steric shielding imposed by the two additional methyl groups. Besides the spectroscopic data, which are in line with expectations, the identity of **8** was further corroborated by a single crystal structure analysis (Table 2, Figure 1). In the second step, condensation of the carbonyl moiety of **8** with anilines was necessary to introduce the imine functionality. Attempts to perform this conversion under common condensation conditions (proton-catalyzed azeotropic removal of water) failed completely, but applying an aluminum-assisted protocol that was developed by us earlier for difficult substrates[9] worked nicely also in this case, affording iminoisopropylimidazoles **9a** and **9b** in over 75% yield. In the third step, imidazoles **9a** and **9b** were alkylated with methyl triflate to give the



Scheme 3. Synthesis of *N*-iminoisopropyl NHC ligands and their derivatives. Conditions: (f) imidazole, reflux; (g) aniline or 2,6-diisopropylaniline, trimethylaluminum, reflux; (h) methyl triflate; (i) potassium hydride; (j) elemental sulfur or selenium; (k) $(CO)_5W(THF)$, hv.

imidazolium salts **10a** and **10b** in over 40% overall yield starting from imidazole.

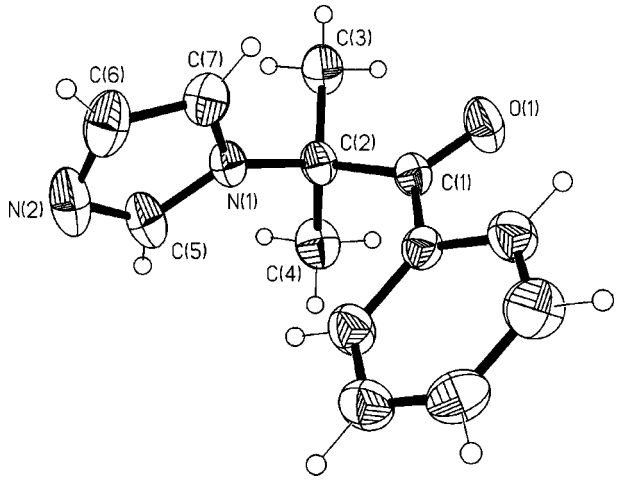

Figure 1. Molecular structure of **8**. Selected bond lengths (pm): C(5)–N(1) 135.24(17), C(5)–N(2) 131.1(2), N(1)–C(7) 137.36(17), N(2)–C(6) 137.4(2), C(6)–C(7) 134.7(2), N(1)–C(2) 147.49(16), C(2)–C(1) 154.95(17), C(1)–O(1) 121.61(15). Selected angles [°]: N(1)–C(5)–N(2) 112.66(13), N(1)–C(2)–C(1) 109.73(9), C(3)–C(2)–C(4) 109.52(11), C(2)–C(1)–O(1) 117.33(11).

Both imidazolium triflates **10a** and **10b** are yellow, slightly air-sensitive powders. Structurally, they differ only in the substitution pattern of the N-bonded aryl group. Because all further chemistry in this contribution was investigated with **10a** as precursor (vide infra), we will discuss only this triflate salt in more detail. Table 1 lists some key NMR spectroscopic data in comparison to its derivatives discussed below. Imidazolium salt **10a** shows a characteristic low-field resonance for the imidazolium C(2)-bonded hydrogen [$\delta(^1H)$ = 8.84 ppm] and an imine carbon signal [$\delta(^{13}C)$ = 171.6 ppm] in the expected range. The two methyl "protecting" groups of the isopropyl moiety are regular, nonshielded alkyl groups [$\delta(^1H)$ = 1.36 ppm, $\delta(^{13}C)$ = 25.7 ppm] as intended, ruling out a deprotonation at this site upon reaction with a strong base. The signals of the imidazolium *N*-methyl group [$\delta(^1H)$ = 3.33 ppm, $\delta(^{13}C)$ = 35.9 ppm] are similar in value to those observed for iminomethylmidazolium salt **4** containing a methylene spacer moiety (vide supra).

Imidazolium triflate **10a** serves as the precursor for the corresponding imino NHC **11a**–**c**. Treatment of **10a** with an equimolar amount of potassium hydride in THF solution caused effervescence due to dihydrogen evolution and the initially yellow solution gradually changed color to orange, which is notably different from the dark-red color of the deprotonation product of **4**. Performing this reaction on a small scale in deuterated THF solution and analyzing the outcome by NMR spectroscopy showed clearly that the desired imino-N-heterocyclic carbene **11a**–**c** had indeed been formed in quantitative yield (Table 1): the ^1H signal of the imidazole-C(2)-bonded hydrogen is absent and the ^{13}C resonance of the imidazole-C(2) carbon is detected at low field [$\delta(^{13}C)$ = 216.3 ppm] in the typical range [$\delta(^{13}C)$ = 205.9 to 231.5 ppm] of imidazolin-2-ylidene carbenes.[1e] All other NMR signals, including the imine carbon resonance [$\delta(^{13}C)$ = 175.0 ppm], are more or less similar to those of the formal conjugate acid **10a**, thus proving that carbene **11a**–**c** exists in solution. Some attempts were undertaken to crystallize NHC **11a**–**c**, but so far no suitable single crystals for an X-ray structure analysis have been obtained.

N-Iminoisopropyl N-Heterocyclic Carbene Derivatives

Having achieved a clean synthesis of the first free imino NHC **11a**–**c**, we explored its chemistry (Scheme 3). Oxidation with elemental sulfur afforded imidazolin-2-thione (**12a**) in 74% yield after workup. Spectroscopically, the sulfur-carbon double bond is clearly evident from the ^{13}C signal at δ = 161.0 ppm (Table 1) and an intense IR absorption ($\nu_{C=S}$ = 1224 cm^{-1}). The carbon resonance of the imine functionality [$\delta(^{13}C)$ = 173.3 ppm] is almost unshifted in comparison to **11a**–**c**, as expected. In addition, the C=N bond manifests itself by a strong IR band ($\nu_{C=N}$ = 1647 cm^{-1}). Further structural proof for **12a** was obtained from a single crystal structure analysis (Table 2, Figure 2); relevant bond lengths and angles are given in the caption.

Carbene **11a**–**c** reacts analogously with elemental selenium to afford the corresponding air-stable imidazolin-2-selenone (**12b**) in 43% isolated yield after workup. As expected, the spectroscopic features of **12b** are quite similar to those of its homologous thione **12a**. Due to the spin-1/2 ^{77}Se isotope further structural proof by ^{77}Se NMR spectroscopy was possible [$\delta(^{13}C)_{C=Se}$ = 153.8 ppm, $^1J(^{13}C\text{-}^{77}Se)$ = 232 Hz; $\delta(^{77}Se)$ = –1182 ppm; $\delta(^{13}C)_{C=N}$ = 172.8 ppm; $\nu_{C=Se}$ = 1222 cm^{-1}; $\nu_{C=N}$ = 1644 cm^{-1}]. These selenium NMR spectroscopic data compare well with those of the few other known imidazolin-2-selenones.[10] In the solid

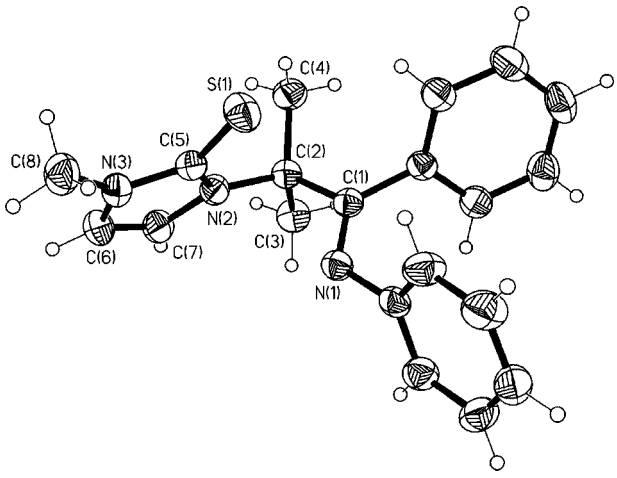

Figure 2. Molecular structure of **12a**. Selected bond lengths (pm): S(1)–C(5) 168.1(2), C(5)–N(2) 137.2(3), C(5)–N(3) 135.8(3), N(2)–C(7) 138.4(3), N(3)–C(6) 137.9(3), C(6)–C(7) 133.4(3), N(3)–C(8) 145.8(3), N(2)–C(2) 148.1(3), C(2)–C(1) 153.5(3), C(1)–N(1) 127.3(3). Selected angles [°]: N(2)–C(5)–N(3) 105.46(17), N(2)–C(2)–C(1) 108.49(16), C(3)–C(2)–C(4) 108.85(18), C(2)–C(1)–N(1) 116.60(18).

state, selenone **12b** (Table 2, Figure 3) is isomorphous with thione **12a**; only some minor differences in bond lengths and angles are observed. Most notable of these is the carbon-selenium bond length [184.0(2) pm] as compared to the shorter C=S bond [168.1(2) pm] of thione **12a**. The rather long C=Se bond length is similar in value to that of an imidazolinselenone published earlier[10] and suggests a reduced bond order due to significant contribution of the zwitterionic C^+-Se^- valence structure.

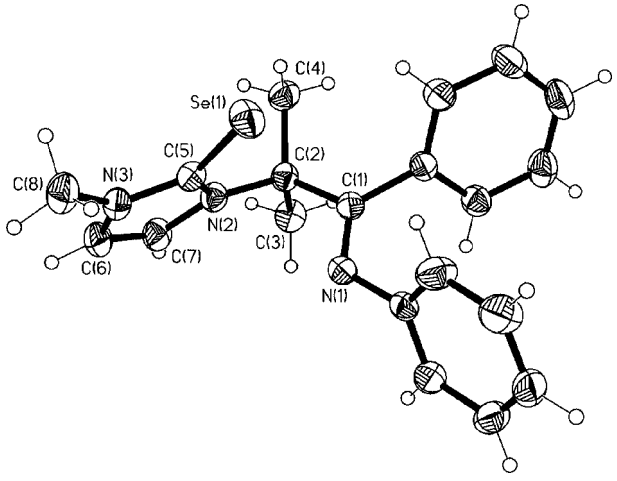

Figure 3. Molecular structure of **12b**. Selected bond lengths (pm): Se(1)–C(5) 184.0(2), C(5)–N(2) 136.7(2), C(5)–N(3) 135.4(3), N(2)–C(7) 138.7(3), N(3)–C(6) 137.5(3), C(6)–C(7) 133.7(3), N(3)–C(8) 146.0(3), N(2)–C(2) 148.2(3), C(2)–C(1) 153.9(3), C(1)–N(1) 127.2(2). Selected angles [°]: N(2)–C(5)–N(3) 105.84(17), N(2)–C(2)–C(1) 108.76(16), C(3)–C(2)–C(4) 108.55(17), C(2)–C(1)–N(1) 116.56(17).

In principal it would be interesting to synthesize the next higher homologue, iminoisopropylimidazolin-2-tellurone, by oxidation of carbene **11a**–**c** with elemental tellurium. However, because of the known sensitivity of such compounds at room temperature and towards sunlight,[11] and because of the obnoxious stench associated with organic tellurium compounds in general, we refrained from attempting this reaction. However, we note that both compounds **12a** and **12b** represent new heteroditopic [N,S]- and [N,Se]-ligands whose coordination chemistry remains unexplored at the moment.

As outlined in the introduction, carbene **11a**–**c** was designed as a member of a new family of heteroditopic [N,C]-imino NHC ligands for application in homogeneous catalysis. Consequently, it was of prime interest to study its coordination chemistry. Reaction with simple metal halides ($PdCl_2$, CuCl, AgCl, $NiCl_2$ etc.) gave, in general, polar products that are obviously [N,C]-bound metal complexes. Full characterization proved quite difficult, however, and the growth of suitable crystals for an unambiguous structural proof by single crystal structure analysis has not yet been possible. In contrast, the reaction with photochemically generated $W(CO)_5$(THF) afforded the air-stable tungsten complex **13**, which was fully characterized in solution by a range of spectroscopic methods as well as in the solid state by single crystal structure analysis. Its ^{13}C NMR spectrum (Table 1) shows the carbene carbon signal at δ = 192.4 ppm, with a one-bond ^{13}C-^{183}W coupling constant of 95 Hz, thereby proving the direct connectivity of the NHC-carbon to the metal center. The imine carbon is shifted to low field [$\delta(^{13}C)$ = 184.2 ppm] in comparison to the free carbene **11a**–**c** [$\delta(^{13}C)$ = 175.0 ppm], thus reflecting the coordination of the imine moiety to the tungsten metal center. The four carbonyl groups are evident from their strong IR absorptions and from three ^{13}C signals with ^{183}W satellites, indicating two magnetically equivalent axial carbonyl groups [$\delta(^{13}C)$ = 205.3 ppm, $^1J_{C,W}$ = 129 Hz] and two different equatorial CO ligands [$\delta(^{13}C)$ = 210.1 ppm, $^1J_{C,W}$ = 146 Hz; $\delta(^{13}C)$ = 218.2 ppm, $^1J_{C,W}$ = 169 Hz] due to the heteroditopic nature of the imino NHC ligand **11a**–**c**. The observation of only one ^{13}C signal for the two axial CO groups indicates rapid interconversion in solution of the two possible boat conformations of the six-membered chelate ring, which is further supported by the two isochronous methyl groups of the isopropyl moiety [$\delta(^{13}C)$ = 27.6 ppm, $\delta(^1H)$ = 1.80 ppm] (Table 1). Several NHC tungsten carbonyl complexes have been reported in the literature,[12] but only for one $(CO)_5$W(NHC) complex[12d] has a direct coupling of the NHC-carbon to the tungsten metal center been reported [$\delta(^{13}C)$ = 176.4 ppm, $^1J_{C,W}$ = 99 Hz];[12d] these data are in good agreement with ours. In addition, we were able to detect for the first time the ^{183}W chemical shift of an NHC-tungsten complex: **13** shows a weak but nevertheless significant ^{183}W signal at δ = –2569 ppm vs. aqueous Na_2WO_4 solution. In general, transition metal NMR spectroscopic data of tungsten metal complexes are very limited due to the unfavorable receptivity of ^{183}W (R^C = 0.0589), and only about 30 organometallic compounds have been investigated by this technique so far. Although the body of ^{183}W chemical shifts is therefore quite small for comparative purposes, the shift of **13** compares well with those of

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

vinylidene-tungsten complexes $[(dppe)CO]_3W{=}C{=}CHR$] with signals in the range of δ = –2548 to –2596 ppm.[13]

In the solid state (Figure 4, Table 2), complex **13** shows the expected κ^2-coordination of the [N,C]-ligand in a boat conformation, with tungsten and the isopropylmethyl group occupying the apical sites. Pertinent bond lengths and angles are given in the caption of Figure 4. Due to geometrical constraints of the six-membered chelate ring, the coordination angle at the formally octahedral tungsten center is only 78.0° as compared to the idealized normal angle. In addition, due to the steric requirements of the [N,C]-ligand, the tungsten center shows a slightly distorted octahedron, indicated by an "umbrella-like" back-bending of the four carbonyl ligands. The W–N [226.5(8) pm] and W–C [221.8(9) pm] bond lengths of the tungsten-coordinated imino NHC ligand are in the normal range of other tungsten-imino and tungsten-NHC complexes.[12] As a consequence of the boat conformation of the [N,C] six-membered chelate the two axial carbonyl groups at the tungsten center are inequivalent. However, this is just a solid-state effect; in solution, a rapid ring flip process occurs as indicated by the simplicity of the NMR spectra discussed above. Overall the X-ray structure of **13** shows the desired heteroditopic imino NHC chelate metal structure and indicates that steric tuning will easily be possible in the future by altering the substitution pattern of the N-bonded aryl moiety.

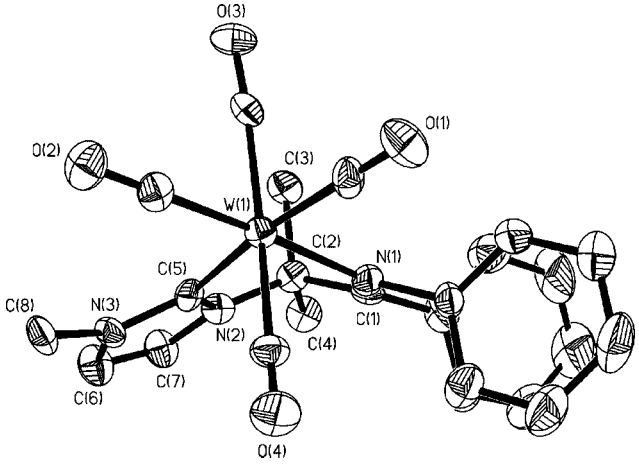

Figure 4. Molecular structure of **13**. Hydrogen atoms have been omitted for clarity. Selected bond lengths (pm): W(1)–C(5) 221.8(9), W(1)–N(1) 226.5(8), W(1)–C(01) 196.5(11), W(1)–C(02) 194.3(11), W(1)–C(03) 201.3(12), W(1)–C(04) 204.5(11), C(01)–O(1) 116.3(13), C(02)–O(2) 119.0(13), C(03)–(O3) 115.0(13), C(04)–O(4) 112.3(13), C(5)–N(2) 137.5(13), C(5)–N(3) 136.1(13), N(2)–C(7) 137.4(13), N(3)–C(6) 138.1(14), C(6)–C(7) 131.2(17), N(3)–C(8) 147.8(14), N(2)–C(2) 147.9(14), C(2)–C(1) 153.6(14), C(1)–N(1) 129.8(12). Selected angles [°]: N(1)–W(1)–C(5) 78.0(3), C(01)–W(1)–C(02) 88.3(4), C(03)–W(1)–C(04) 166.0(4), N(2)–C(5)–N(3) 102.7(8), N(2)–C(2)–C(1) 111.3(8), C(3)–C(2)–C(4) 106.8(9), C(2)–C(1)–N(1) 120.7(9).

Conclusions

New heteroditopic ligands combining the advantageous properties of N-heterocyclic carbenes and imine donors with *N*-aryl groups have been investigated. Such imino NHC systems can be prepared by alkylation of imidazole with a ketoalkyl bromide, condensation of the carbonyl group with anilines, alkylation of the iminoalkylimidazole with methyl trifluoromethanesulfonate, and deprotonation of the *N*-iminoalkyl-*N*′-methylimidazolium triflate with potassium hydride. For a successful generation of the imino NHC it is necessary to block the methylene group between the heterocycle and the imine group by two methyl substituents, otherwise deprotonation at this undesired "wrong" site occurs and an ylidic non-NHC product is observed. Spectroscopically, the imino NHC ligand is characterized by a typical low-field ^{13}C chemical shift of the NHC-carbene carbon together with an imine carbon signal. The chemical reactivity of the imino NHC comprises oxidation by elemental sulfur and selenium to afford the corresponding imidazolin-2-thione and selenone, which were fully characterized by solid state structures and multinuclear NMR spectroscopy, including ^{77}Se spectroscopy. A first transition metal complex of the imino NHC ligand was obtained by treatment with tungsten hexacarbonyl; the resulting [N,C] $W(CO)_4$ complex shows the anticipated six-membered metal [N,C] chelate in solution and in the solid state, as proven by an X-ray structure and by multinuclear NMR spectroscopy, including ^{183}W spectroscopy.

Experimental Section

General: Commercially available starting materials were used as obtained. Solvents were dried, deoxygenated, and saturated with argon according to standard procedures in organometallic chemistry. Reactions of air-sensitive materials were performed in Schlenk glassware under an atmosphere of argon using techniques common in organometallic chemistry.

Imidazole 2 (CA registry no. 24155-34-8): A round-bottomed flask was charged with imidazole (4.3 g, 62.8 mmol), α-bromoacetophenone (**1**; 5 g, 25.1 mmol), and 100 mL of THF. The yellow solution was stirred overnight at ambient temperature to give a yellow suspension of the product with precipitated imidazolium bromide. Aqueous workup and recrystallization from methanol/diethyl ether yielded pure, yellow **2** (2.24 g, 12 mmol, 48%). M.p.: 117–119 °C. IR (KBr): $\tilde{\nu}$ = 2965 cm^{-1} (w), 2919 (w), 1696 (vs), 1597 (s), 1503 (s), 1451 (s), 1360 (s), 1344 (m), 1288 (m), 1227 (vs), 1107 (s), 1074 (s), 1038 (s), 984 (s), 906 (s), 816 (s), 762 (s), 746 (vs), 692 (vs). ^1H NMR (300 MHz, CD_2Cl_2): δ = 5.43 (s, 2 H, CH_2), 6.94–7.99 (m, 8 H, C_6H_5, $C_3H_3N_2$) ppm. ^{13}C NMR (75.432 MHz, CD_2Cl_2): δ = 52.9 (CH_2), 120.7, 128.2, 129.3, 134.6, and 138.5 (C_6H_5, $C_3H_3N_2$), 192.4 (C=O) ppm.

Imidazole 3: A Dean–Stark apparatus was charged with **2** (940 mg, 5.05 mmol), 2,6-diisopropylaniline (2.80 mL, 15.1 mmol), *p*-toluenesulfonic acid monohydrate (2.9 g, 15.1 mmol), and 100 mL of toluene. The mixture was refluxed for 3 d, followed by aqueous workup. Chromatography on alumina with diethyl ether/*n*-hexane (v/v = 1:1) as eluent removed the excess of aniline, and elution with methanol yielded pure **3** (1.07 g, 3.1 mmol, 61.4%) as a yellow oil. MS (EI): *m*/*z* = 345.3 $[M]^+$. ^1H NMR (300 MHz, CD_2Cl_2): δ = 0.87–1.23 (m, 12 H, CH_3), 2.67 (m, 2 H, CH), 4.90 (s, 2 H, CH_2), 6.64–7.88 (m, 11 H, C_6H_5, C_6H_3, $C_3H_3N_2$) ppm. ^{13}C NMR (75.432 MHz, CD_2Cl_2): δ = 22.1, 23.7, and 28.8 [$CH(CH_3)_2$], 44.7 (CH_2), 119.4, 120.2, 123.2, 123.5, 124.2, 124.7, 127.6, 128.7, 129.1, 129.7, 130.2, 131.3, 135.7, 136.1, 136.9, 137.8, 138.2, and 145.1

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(C_6H_5, C_6H_3, $C_3H_3N_2$), 162.2, 162.9 (C=N) ppm. $C_{23}H_{27}N_3$ (345.48): calcd. C 79.96, H 7.88, N 12.16; found C 80.11, H 7.86, N 12.13.

Imidazolium Triflate 4: A Schlenk tube was charged with **3** (392 mg, 1.13 mmol) and dry dichloromethane (40 mL). The solution was cooled to –80 °C and methyl trifluoromethanesulfonate (124 μL, 1.13 mmol) was added from a syringe. After 90 min stirring at –80 °C, the cooling bath was removed and the mixture was stirred for a further 90 min. Workup: all volatile materials were removed on a vacuum line, the solid yellow residue was washed with two portions of dry diethyl ether, and dried in vacuo to afford 570 mg of **4** as a yellow, air-sensitive powder in 99% yield. MS (FAB): *m*/*z* = M of cation not observed due to hydrolysis. ^{1}H NMR [300 MHz, $(CD_3)_2SO$]: δ = 0.83 [d, $^3J_{H,H}$ = 6.9 Hz, 6 H, $CH(CH_3)_2$], 0.91 [d, $^3J_{H,H}$ = 6.6 Hz, 6 H, $CH(CH_3)_2$], 2.65 [m, 2 H, $2\times CH(CH_3)_2$], 3.94 (s, 3 H, CH_3), 5.85 (s, 2 H, CH_2), 6.95–7.82 (m, 10 H, C_6H_5, C_6H_3, $C_3H_3N_2$), 9.17 (s, 1 H, $C_3H_3N_2$) ppm. ^{13}C NMR [75.432 MHz, $(CD_3)_2SO$]: δ = 21.7, 23.5, and 27.4 [$CH(CH_3)_2$], 35.8 (N-CH_3), 64.9 (CH_2), 118.6, 122.6, 122.8, 123.2, 123.8, 124.1, 127.2, 128.5, 128.8, 130.4, 133.6, 134.8, 137.8, and 144.0 (C_6H_5, C_6H_3, $C_3H_3N_2$), 161.2 (C=N) ppm. The weak ^{13}C signals for the triflate anion [δ = 121 ppm, q, $^1J(^{13}C\text{-}^{19}F)$ = 322 Hz] were not observed due to insufficient concentration and/or too short an acquisition period. $C_{25}H_{30}F_3N_3O_3S$ (509.59): calcd. C 58.92, H 5.93, N 8.25; found C 58.69, H 5.95, N 8.22.

Imidazole 8: A round-bottomed flask was charged with imidazole (3.40 g, 49.9 mmol), 2-bromo-2-methylpropiophenone (**7**; 4 mL, 23.8 mmol), and 40 mL of ethanol. The yellow solution was refluxed for 3 d. Aqueous workup yielded a yellow oil which crystallized in the freezer. Recrystallization from dichloromethane/*n*-hexane (1:2) afforded pure, colorless **8** (3.11 g, 14.5 mmol, 61%). MS (EI): *m*/*z* = 214.1 $[M]^+$. IR (KBr): $\tilde{\nu}$ = 3145 cm^{-1} (w), 3000(w), 1672(vs), 1599(m), 1576(w), 1493(m), 1470(m), 1451(m), 1393(w), 1375(m), 1339(w), 1285(w), 1261(s), 1240(vs), 1177(s), 1167(s), 1153(m), 1082(s), 1013(s), 976(s), 906(s), 893(s), 820(s), 750(s). ^{1}H NMR [300 MHz, $(CD_3)_2SO$]: δ = 1.80 (s, 6 H, CH_3), 6.94–7.87 (m, 8 H, C_6H_5, $C_3H_3N_2$) ppm. ^{13}C NMR [75.432 MHz, $(CD_3)_2SO$]: δ = 26.6 and 64.7 [$C(CH_3)_2$], 118.1, 128.0, 128.5, 129.1, 132.6, 134.8, and 135.6 (C_6H_5, $C_3H_3N_2$), 199.3 (C=O) ppm. $C_{13}H_{14}N_2O$ (214.26): calcd. C 72.87, H 6.59, N 13.07; found C 72.95, H 6.57, N 13.03.

Imidazole 9a: A Schlenk tube was charged with aniline (524 μL, 5.75 mmol), 40 mL of toluene, and 2.87 mL of a 2.0 M toluene solution of trimethylaluminum (5.75 mmol). The stirred solution was heated to 80 °C. After 90 min methane evolution was complete and the solution was cooled to ambient temperature. Under protection from air, imidazole **8** (560 mg, 2.61 mmol) was added in one portion. The mixture was stirred overnight at ambient temperature and then heated to 80 °C for a further three hours to afford a bright-yellow solution. Workup: the solution was cooled to 0 °C, the mixture was carefully hydrolyzed with crushed ice, the organic product was extracted with three portions of dichloromethane, the combined organic layers were washed with three portions of a 5% aqueous NaOH solution, the dichloromethane solution was washed with two portions of water, the organic phase was dried with Na_2SO_4, and all volatile materials were removed in vacuo on a rotary evaporator to afford the crude product together with aniline. Chromatography on alumina with diethyl ether/*n*-hexane (v/v, 1:1) as eluent followed by methanol afforded 651 mg of pure **9a** in 86% yield as a yellow oil. MS (FAB): *m*/*z* = 290.2 $[M + H]^+$. ^{1}H NMR (300 MHz, CD_2Cl_2): δ = 1.85 (s, 6 H, CH_3), 6.39–7.53 (m, 13 H, C_6H_5, $C_3H_3N_2$) ppm. ^{13}C NMR (75.432 MHz, CD_2Cl_2): δ = 26.7 and 63.1 [$C(CH_3)_2$], 117, 8, 120.2, 123.6, 127.8, 128.1, 128.5, 128.7, 129.6, 134.6, 135.6, and 150.3 (C_6H_5, $C_3H_3N_2$), 173.0 (C=N) ppm. $C_{19}H_{19}N_3$ (289.37): calcd. C 78.86, H 6.62, N 14.52; found C 78.99, H 6.59, N 14.48.

Imidazole 9b: A Schlenk tube was charged with 2,6-diisopropylaniline (2.96 mL, 15.7 mmol), 40 mL of toluene, and 7.84 mL of a 2.0 M toluene solution of trimethylaluminum (15.7 mmol). The stirred solution was heated to 80 °C. After 90 min methane evolution was complete and the solution was cooled to ambient temperature. Under protection from air, imidazole **8** (1.12 g, 5.23 mmol) was added in one portion. The mixture was stirred overnight at ambient temperature and heated to 80 °C for a further three hours to afford a bright-yellow solution. Workup as described above for **9a** afforded 1.46 g of pure **9b** in 75% yield as a yellow oil. MS (EI): *m*/*z* = 373.3 $[M]^+$. ^{1}H NMR (300 MHz, CD_2Cl_2): δ = 1.06 [d, $^3J_{H,H}$ = 6.94 Hz, 6 H, $CH(CH_3)_2$], 1.14 [d, $^3J_{H,H}$ = 6.61 Hz, 6 H, $CH(CH_3)_2$], 2.74 [m, 2 H, $2\times CH(CH_3)_2$], 6.38–7.49 (m, 11 H, C_6H_5, C_6H_3, $C_3H_3N_2$) ppm. ^{13}C NMR (75.432 MHz, $CDCl_3$): δ = 21.3, 23.9, and 28.7 [$CH(CH_3)_2$], 27.3 and 63.4 [$C(CH_3)_2$], 117.8, 122.7, 126.4, 127.6, 128.0, 128.8, 129.5, 134.7, 135.5, 136.9, and 145.0 (C_6H_5, C_6H_3, $C_3H_3N_2$), 170.4 (C=N) ppm. $C_{25}H_{31}N_3$ (373.53): calcd. C 80.39, H 8.37, N 11.25; found C 80.52, H 8.34, N 11.20.

Imidazolium Triflate 10a: A Schlenk tube was charged with **9a** (650 mg, 2.25 mmol) and dry dichloromethane (40 mL). The solution was cooled to –80 °C and methyl trifluoromethanesulfonate (246 μL, 2.25 mmol) was added with a syringe. After 90 min stirring at –80 °C, the cooling bath was removed and the mixture was stirred for a further 90 min. Workup: all volatile materials were removed on a vacuum line, the solid yellow residue was washed with two portions of dry diethyl ether, and dried in vacuo to afford 920 mg of **10a** as a yellow, slightly air-sensitive powder in 90% yield. MS (FAB): *m*/*z* = 304.1 $[M]^+$ of cation. ^{1}H NMR [300 MHz, $(CD_3)_2SO$]: δ = 1.36 (s, 6 H, CH_3), 3.33 (s, 3 H, CH_3), 6.03–7.54 (m, 12 H, C_6H_5, $C_3H_3N_2$), 8.84 (s, 1 H, $C_3H_3N_2$) ppm. ^{13}C NMR [75.432 MHz, $(CD_3)_2SO$]: δ = 25.7 and 66.7 [$C(CH_3)_2$], 35.8 (N-CH_3), 119.4, 121.6, 121.8, 123.3, 123.6, 123.8, 127.8, 127.9, 128.3, 128.5, 128.6, 128.8, 133.4, 136.5, and 149.3 (C_6H_5, $C_3H_3N_2$), 171.6 (C=N), 120.7 (q, $^1J_{C,F}$ = 322 Hz, CF_3 of triflate) ppm. $C_{21}H_{22}F_3N_3O_3S$ (453.48): calcd. C 55.62, H 4.89, N 9.27; found C 55.34, H 4.91, N 9.24.

Imidazolium Triflate 10b: A Schlenk tube was charged with **9b** (1.47 g, 3.94 mmol) and dry dichloromethane (40 mL). The solution was cooled to –80 °C and methyl trifluoromethanesulfonate (432 μL, 3.94 mmol) was added with a syringe. After 90 min stirring at –80 °C, the cooling bath was removed and the mixture was stirred for a further 90 min. Workup: all volatile materials were removed on a vacuum line, the solid yellow residue was washed with two portions of dry diethyl ether, and dried in vacuo to afford 2.00 g of **10b** as a yellow, slightly air-sensitive powder in 95% yield. MS (FAB): *m*/*z* = 388.4 $[M]^+$ of cation. ^{1}H NMR [300 MHz, $(CD_3)_2SO$]: δ = 0.91 [d, $^3J_{H,H}$ = 6.61 Hz, 6 H, $CH(CH_3)_2$], 1.05 [d, $^3J_{H,H}$ = 6.93 Hz, 6 H, $CH(CH_3)_2$], 2.00 [s, 6 H, $C(CH_3)_2$], 2.65 [m, 2 H, $2\times CH(CH_3)_2$], 3.87 (s, 3 H, CH_3), 6.82–8.10 (m, 10 H, C_6H_5, C_6H_3, $C_3H_3N_2$), 8.94 (s, 1 H, $C_3H_3N_2$) ppm. ^{13}C NMR [75.432 MHz, $(CD_3)_2SO$]: δ = 21.2, 23.6, and 27.7 [$CH(CH_3)_2$], 26.1 and 66.9 [$C(CH_3)_2$], 35.8 (N-CH_3), 121.7, 122.2, 123.4, 123.8, 126.1, 126.8, 127.3, 127.5, 128.0, 129.1, 133.6, 134.6, 136.8, 143.7, and 143.8 (C_6H_5, C_6H_3, $C_3H_3N_2$), 170.5 (C=N), 120,7 (q, $^1J_{C,F}$ = 322 Hz, CF_3 of triflate) ppm. $C_{27}H_{34}F_3N_3O_3S$ (537.64): calcd. C 60.32, H 6.37, N 7.82; found C 60.04, H 6.40, N 7.78.

Imino N-Heterocyclic Carbene 11a–c: A small Schlenk tube was charged with imidazolium triflate **10a** (50 mg, 0.110 mmol) dis-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

solved in 1 mL of dry, deuterated THF. Under protection from air, potassium hydride (4.4 mg, 0.110 mmol) was added in one portion. The mixture was stirred at ambient temperature for 2 h. Dihydrogen evolution was observed and a white precipitate of potassium triflate formed during this period. The orange suspension was transferred under an atmosphere of argon to an NMR tube and analyzed spectroscopically: ^{1}H NMR (300 MHz, [D$_8$]THF): δ = 1.83 (s, 6 H, CH_3), 3.69 (s, 3 H, CH_3), 6.55–7.12 (m, 12 H, C_6H_5, $C_3H_2N_2$) ppm. ^{13}C NMR (75.432 MHz, [D$_8$]THF): δ = 28.4 and 64.8 [$C(CH_3)_2$], 38.2 (N-CH_3), 118.1, 120.7, 121.0, 123.3, 127.8, 128.2, 128.7, 129.4, 136.7, and 151.9 (C_6H_5, $C_3H_2N_2$), 175.0 (C=N), 216.3 (carbene C) ppm.

Imidazolin-2-thione 12a: A Schlenk tube was charged with imidazolium triflate **10a** (165 mg, 0.364 mmol), 40 mL of THF, and potassium hydride (15 mg, 0.364 mmol). The mixture was stirred for 2 h at ambient temperature. Dihydrogen evolution occurred during this period and the mixture gradually changed in color from yellow to orange. Elemental sulfur (93 mg, 0.364 mmol) was added to the stirred mixture and the reaction was allowed to proceed overnight at ambient temperature. Chromatography on alumina with diethyl ether/*n*-hexane (v/v, 1:1) and methanol as eluents afforded air-stable, yellow **12a** (90 mg, 0.268 mmol, 74%). MS (FAB): *m*/*z* = 335.0 [M]$^+$. IR (KBr): $\tilde{\nu}$ = 3140 cm^{-1} (w), 3071 (w), 2979 (w), 2928 (w), 1647 (vs) ($\nu_{C=N}$), 1591 (s), 1478 (s), 1453 (s), 1403 (s), 1386 (vs), 1362 (s), 1292 (m), 1265 (m), 1224 (vs) ($\nu_{C=S}$), 1149 (m), 989 (m), 778 (s), 704 (s), 697 (vs), 670 (vs). ^{1}H NMR [300 MHz, $(CD_3)_2SO$]: δ = 1.83 (s, 6 H, CH_3), 3.49 (s, 3 H, CH_3), 6.62–7.37 (m, 12 H, C_6H_5, $C_3H_2N_2$) ppm. ^{13}C NMR [75.432 MHz, $(CD_3)_2SO$]: δ = 26.3 and 64.6 [$C(CH_3)_2$], 34.5 (CH_3), 115.6, 117.9, 119.6, 122.4, 127.5, 128.0, 128.1, 128.6, 135.6, and 150.9 (C_6H_5, $C_3H_2N_2$), 161.0 (C=S), 173.3 (C=N) ppm. $C_{20}H_{21}N_3S$ (335.47): calcd. C 71.61, H 6.31, N 12.53; found C 71.34, H 6.33, N 12.48.

Imidazolin-2-selenone 12b: A Schlenk tube was charged with imidazolium triflate **10a** (220 mg, 0.485 mmol), 40 mL of THF, and potassium hydride (20 mg, 0.485 mmol). The mixture was stirred for 2 h at ambient temperature. Dihydrogen evolution occurred during this period and the mixture gradually changed in color from yellow to orange. Elemental selenium (40 mg, 0.507 mmol) was added to the stirred mixture and the reaction was allowed to proceed overnight at ambient temperature. Chromatography on alumina with diethyl ether/*n*-hexane (v/v, 1:1) and methanol as eluents afforded air-stable, yellow **12b** (80 mg, 0.209 mmol, 43%). MS (FAB): *m*/*z* = 383.1 [M]$^+$. IR (KBr): $\tilde{\nu}$ = 3141 cm^{-1} (w), 3072 (w), 2979 (w), 1644 (vs) ($\nu_{C=N}$), 1591 (s), 1478 (s), 1452 (vs), 1377 (vs), 1296 (s), 1222 (vs) ($\nu_{C=Se}$), 1131 (s), 938 (m), 778 (s), 733 (m), 697 (vs). ^{1}H NMR [300 MHz, $(CD_3)_2SO$]: δ = 1.91 (s, 6 H, CH_3), 3.59 (s, 3 H, CH_3), 6.70–7.48 (m, 12 H, C_6H_5, $C_3H_2N_2$) ppm. ^{13}C NMR [75.432 MHz, $(CD_3)_2SO$]: δ = 26.7 and 65.7 [$C(CH_3)_2$], 36.5 (CH_3), 118.2, 119.6, 119.8, 122.3, 127.4, 127.9, 128.8, 135.5, and 150.8 (C_6H_5, $C_3H_2N_2$), 153.8 ($^1J_{C,Se}$ = 232 Hz, C=Se), 172.8 (C=N) ppm. ^{77}Se NMR (57.203 MHz, $(CD_3)_2SO$, vs. H_2SeO_3): δ = –1182 (C=Se) ppm. $C_{20}H_{21}N_3Se$ (382.36): calcd. C 62.82, H 5.54, N 10.99; found C 62.62, H 5.56, N 10.95.

Tungsten Complex 13: A Schlenk tube was charged with imidazolium triflate **10a** (768 mg, 1.69 mmol), 50 mL of THF, and potassium hydride (86 mg, 1.69 mmol). The mixture was stirred for 2 h at ambient temperature. Dihydrogen evolution occurred during this period and the mixture gradually changed in color from yellow to orange. Tungsten hexacarbonyl (596 mg, 1.69 mmol) was added to
