Crystallography: Crystallographic data for **8**, **12a**, **12b**, and **13** are given in Table 2. The data collection was performed on a Nonius Kappa-CCD equipped with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) and a nominal crystal-to-area-detector distance of 36 mm. Intensities were integrated using DENZO and scaled with SCALEPACK.[14] Several scans in φ and ω direction were made to increase the number of redundant reflections, which were averaged in the refinement cycles. This procedure replaces an empirical absorption correction. The structures were solved by direct methods (SHELXS-86) and refined against F^2 (SHELX-97).[15] Hydrogen atoms at carbon atoms were added geometrically and refined using a riding model. All non-hydrogen atoms were refined with anisotropic displacement parameters.

The structure determination of **13** was complicated by two crystallographic characteristics. First, several crystals were examined and showed systematic twinning. The best crystal was measured and the 20 worst overlying reflections were omitted in the refinement. Second, the correct determination of the space group because of a possible transformation to bravais lattice higher in symmetry. In the triclinic space group were two identical molecules, which can be transferred into each other by refinement in the monoclinic space group *C*2/*c*. Nevertheless, the space group *C*2/*c* was excluded because the R_{int} value of 0.176 for 8154 symmetry-equivalent reflections is much higher than the R_{int} value of 0.038 for 4919 reflections in the triclinic space group. In addition, the conventional R_1 value of 0.0750 is also higher (0.0542). The unit cell constants of the transformed C-centered lattice are 3958.4, 856.6, 136.39 pm and 90.04, 97.48, 91.42°. The deviation of the angle γ from over 1° to the correct 90° angle is also too high for this monoclinic space group.

CCDC-252740 (for **8**), -252741 (for **12a**), -252742 (for **12b**), and -252743 (for **13**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Syntheses, Structures, and Magnetic Properties of Two 1D, Mixed-Ligand, Metal Coordination Polymers, $[M(C_4O_4)(dpa)(OH_2)]$ ($M = Co^{II}$, Ni^{II}, and Zn^{II}; dpa = 2,2′-dipyridylamine) and $[Cu(C_4O_4)(dpa)(H_2O)]_2\cdot(H_2O)$

Keywords: Hydrogen bonds / Hydrothermal synthesis / Magnetic properties / Self-assembly / Squarate

Two metal coordination polymers with general formula $[M(dpa)(C_4O_4)(H_2O)]$ [M = Co (**1**), Ni (**2**), Zn (**3**); dpa = 2,2′-dipyridylamine] and $[Cu(dpa)(C_4O_4)(H_2O)]_2\cdot H_2O$ (**4**) have been synthesized under hydrothermal conditions. The single-crystal X-ray analyses reveal that compounds **1**–**3** are isostructural and possess distorted octahedral metal centers coordinated by two squarates, one dpa, and two water molecules. A 1D two-legged ladder-like framework is formed by interconnection of the water-bridged $[M(dpa)(\mu_2\text{-}OH_2)]_2^{4+}$ dimeric fragments and $\mu_{1,2}$-squarate ligands. Intra- and intermolecular hydrogen bonds between squarate, water, and dpa ligands, as well as the π-π stacking interaction of the pyridyl ring in the dpa ligands, provide extra forces to stabilize the extended network. Conversely, the molecular structure of compound **4** contains two distorted square-pyramidal Cu^{II} centers coordinated by two squarates, one dpa ligand, and one water molecule. The squarates adopt a $\mu_{1,2}$-binding mode to link the Cu centers and form a 1D helical chain. For compound **2**, the magnetic exchange couplings between metal centers are analyzed with a binuclear magnetic model. The resulting negative magnetic exchange coupling constant indicates an antiferromagnetic interaction within the dimers. The magnetic behavior of compound **4** is typical of paramagnetic Cu^{II} ions.

Introduction

Owing to its attractive topologies and intriguing structural features,[1–4] the crystal engineering of mixed-ligand metal coordination solids with functional building blocks has received much attention. Among various methodologies to construct novel 1-, 2-, and 3D frameworks, the hydrothermal method has been ubiquitously applied to the synthesis of metal–organic coordination polymers[5–9] and hydrogen-bonded systems.[10] Of significant important is the ability of the organic molecules to influence profoundly the structures of synthesized products, and to dictate their formation with particular structural and potential applications, such as magnetism, host-guest chemistry, shape specificity, and catalysis. The squarate dianion, $C_4O_4^{2-}$, has been widely used as a polyfunctional ligand, for example to induce hydrogen bonding or π-π interactions, for the construction of extended frameworks and has also been used as a bridging ligand to bind metal ions in various bonding modes to create many novel networks.[11–26] The most typical coordination modes of the squarate dianion are $\mu_{1,2}$- (*cis*) and $\mu_{1,3}$- (*trans*). Many squarate-bridged metal complexes with $\mu_{1,2}$-, $\mu_{1,3}$-, or $\mu_{1,2,3,4}$-binding modes combined with different nitrogen-based flexible ligands have been structurally characterized,[19–25] and their magnetic investigation shows that $\mu_{1,3}$-coordination gives a negligibly small coupling, while $\mu_{1,2}$-coordination induces a small antiferromagnetic coupling.[19,26] In this contribution, we describe the synthesis and structural characterization of two 1D coordination polymers, $[M(dpa)(C_4O_4)(H_2O)]$ [M = Co (**1**), Ni (**2**), Zn (**3**)] and $[Cu(dpa)(C_4O_4)(H_2O)]_2\cdot H_2O$ (**4**), by using flexible dpa (2,2′-dipyridylamine) and squarate ($C_4O_4^{2-}$) ligands as building units, as well as the studies of their thermal stability and magnetic properties.

Results and Discussion

Synthesis and IR Spectroscopy of Compounds 1–4

Compounds **1**–**4** were synthesized by mixing the divalent metal salt MCl_2 (M = Co, Ni, Cu, Zn), 2,2′-dipyridylamine (dpa), $H_2C_4O_4$, and H_2O. All reactions were carried out in 23-mL, acid-digestion bombs at 180 °C for three days. Low pH values were observed in all reactions (final pH = 2.82–3.91). The resulting products are very stable in air at ambient temperature and insoluble in common solvents such as water, alcohol, and acetonitrile. It is also worthy to note that the synthetic reproducibility is high. The appearance of N–H stretching vibrations in the region of 3000–

3400 cm^{-1} in the IR spectrum is in agreement with that reported for hydrogen bonds between N–H and several H-acceptor groups. The most relevant IR features are those associated with the chelating squarate ligands. The coordinated CO groups are characterized by medium-strength absorptions at around 1664 cm^{-1}. A very strong band centered at around 1480 cm^{-1} is attributed to a combination mode of C–O and C–C stretchings and is in agreement with other $(CO)_n^{2-}$ salts.[27]

Crystal Structures of [M(dpa)(C_4O_4)(H_2O)] Complexes

Compounds **1**–**3** were found to be isostructural; a typical structure of **1** is shown in Figure 1. In **1**–**3**, each metal center is six-coordinate and adopts a slightly distorted octahedral coordination environment, being bonded to two nitrogen atoms from dpa ligands and four oxygen atoms from two squarate ligands and two water molecules. The corresponding M–N, M–O_w and M–O_{sq} bond lengths (see Table 1) are similar to those of relevant squarate-bridged metal complexes.[19–21,28,29] Two metal centers are linked together by two bridging water molecules to form an $[M(dpa)(H_2O)]_2^{4+}$ dimeric fragment (see Figure 1) in the equatorial plane. The squarate ligand adopts a $\mu_{1,2}$-binding mode to connect the neighboring $[M(dpa)(\mu_2\text{-}OH_2)]_2$ fragments at the axial sites, constructing a 1D linear two-legged ladder-like metal–organic framework (MOF) along the *a* axis [see (a) in Figure 2]. The M···M separations via μ_2-O_{water} and $\mu_{1,2}$-$C_4O_4^{2-}$ bridges are 3.459(1) and 7.416(1) Å

for **1**, 3.391(1) and 7.377(1) Å for **2**, and 3.501(1) and 7.458(1) Å for **3**. The corresponding C–C and C–O bond lengths (see Table 1) of the squarate ligands show a roughly D_{4h} delocalized mode and fall in the same range as some analogous squarate-bridged complexes.[19–21,29] It should be noted that adjacent ladders are displaced by half a repeating unit along the *a* and *c* axes. This arrangement effectively prevents steric hindrance between the inter-ladder dpa ligands. As a result, compounds **1**–**3** favor the closer-packed building block shown in Figure 2. The centroids of the pyridine rings in the dpa ligands of adjacent ladders are generally parallel and adopt a face-to-face alignment with a separation distance within the range 3.59–3.82 Å, thus indicating a weak π–π stacking interaction[28,30] that may, in part, contribute to the stabilization of the extended framework. Hydrogen-bond formation is a very important aspect in constructing coordination polymers.[31–35] In compounds **1**–**3**, two strong O–H···O hydrogen bonds [O(5)–H(5a)···O(4) and O(5)–H(5b)···O(3)] are found between uncoordinated oxygen atoms of squarate and the coordinated water molecules, with O···O distances in the range of 2.528–2.600 Å, which are similar to those (2.589–2.748 Å) of O_{sq}···O_w-type hydrogen bonds found in other squarate-bridged compounds.[19–22,28b] In addition, the inter-ladder interactions are through one pair of N–H···O [N(2)–H(2a)···O(4)] and C–H···O [C(11)–H(11a)···O(4)] hydrogen bonds from the same dpa molecule linked to the oxygen atom of squarate in the neighboring ladders to form a mixed N–H···O and C–H···O hydrogen bond (dashed line in Figure 2(b)]. A similar hydrogen-bonding interaction has also been found in complexes such as [Fe(ox)(dpa)][28a] and $[M_2(dpa)_2(C_2O_4)(C_4O_4)]$.[28b] Relevant bond lengths and angles of the O–H···O, N–H···O and C–H···O hydrogen bonds for **1**–**3** are summarized in Table 2.

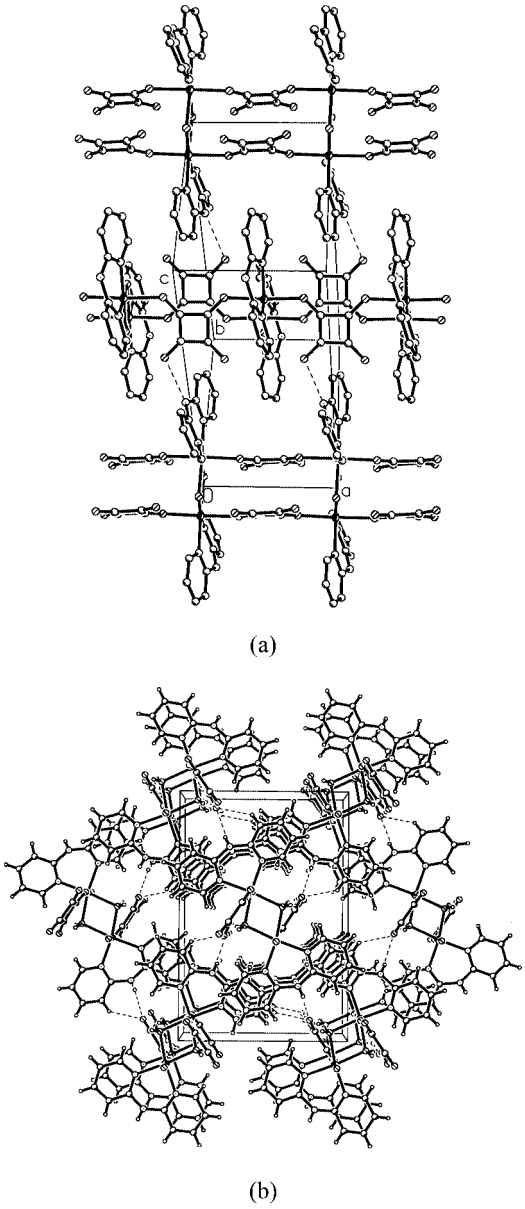

Figure 2. Perspective view of compound **1** along the crystallographic *b* axis (a) and the *a* axis (b).

Crystal Structure of $[Cu(dpa)(C_4O_4)(H_2O)]_2\cdot(H_2O)$ (4)

The asymmetric unit of compound **4** contains two copper ions, two squarates, two dpa ligands, and one solvated, doubly coordinated water molecule. Each of the two independent Cu centers adopts a slightly distorted square-pyramidal coordination environment, but is subject to different environments incorporating squarate and water molecules (Figure 3). In the equatorial plane, Cu(1) is bonded to two nitrogen atoms of dpa and two oxygen atoms of the two squarate ligands, while Cu(2) is bonded to two nitrogen atoms of dpa and two oxygen atoms, one from $C_4O_4^{2-}$ and the other from the water molecule. The axial ligand bonded to Cu(1) is the oxygen atom of a water molecule [O(9)], while that bonded to Cu(2) is an oxygen atom of a squarate [O(6)], forming a distorted square-pyramidal coordination environment. A 1D helical chain is observed in which the copper ions are alternately bridged by equatorial-axial and equatorial-equatorial $\mu_{1,2}$-$C_4O_4^{2-}$ ligands (Figure 4). The Cu···Cu separations across the equatorial-axial and equatorial-equatorial $C_4O_4^{2-}$ bridges are 4.832(4) Å and 5.392(4) Å, respectively. The former is longer than that of 4.328(1) Å in $[Cu(C_4O_4)(C_4H_4N_2)]_n$[36] but shorter than other relevant $\mu_{1,2}$- or $\mu_{1,2,3,4}$-$C_4O_4^{2-}$-bridged Cu complexes.[19a,22,26b,37] As expected, the axial Cu(1)–$O(9)_w$ and Cu(2)–$O(6)_{sq}$ distances of 2.242(2) and 2.174(2) Å are significantly longer than the equatorial Cu(1)–$O(1)_{sq}$ and Cu(1)–$O(5)_{sq}$ bond lengths [2.026(2) and 1.955(2) Å respectively] and the Cu(2)–$O(2)_{sq}$ and Cu(2)–$O(10)_w$ bond lengths [2.013(2) and 1.954(2) Å respectively] due to the Jahn–Teller distortion. The corresponding Cu–O_w, Cu–O_{sq}, and Cu–N bond lengths listed in Table 3 are similar to those found in some other squarate-bridged Cu complexes.[22–26,32,37] Hydrogen bonds also play an important role in the helical chain of compound **4**. These include three O–H···O hydrogen bonds [O(11)–H(11a)···O(8), O(10)–H(10b)···O(11), and O(9)–H(9b)···O(2)] between water molecules and squarate ligands, with O···O distances

in the range 2.588–2.785 Å, similar to those (2.589–2.748 Å) of O_{sq}···O_w-type hydrogen bonds found in other squarate-bridged compounds.[19–22] The inter-chain interactions are through hydrogen bonds between the dpa nitrogen atoms in one chain and uncoordinated squarate oxygen atoms in the adjacent chain, with hydrogen-bonding distances N(2)–H(2a)···O(3)$_{ii}$ of 2.776 Å and N(5)–H(5a)···O(4)$_{iii}$ of 2.961 Å (dashed line in Figure 4). Relevant bond lengths and angles of the O–H···O and N–H···O hydrogen bonds for complex **4** are listed in Table 4.

Magnetic Properties

Compound 2

Plots of the magnetic susceptibility (χ_M and $\chi_M T$) in the temperature range of 5–300 K for **2** are shown in Figure 5. At room temperature, the $\chi_M T$ value is 2.31 emu K mol^{-1}, which, upon cooling, slowly decreases to a value of 2.05 emu K mol^{-1} at 75 K and then drops rapidly from 1.66 emu K mol^{-1} at 30 K to 0.35 emu K mol^{-1} at 5 K. This seems to be characteristic of weakly antiferromagnetic be-

havior. In order to analyze the magnetic exchange coupling interaction in **2**, the susceptibility data was fitted to a binuclear magnetic model, namely a dimer formed by double μ-OH_2 bridges, $[(dpa)Ni(\mu_2\text{-}OH_2)_2Ni(dpa)]^{4+}$. The corresponding molar susceptibility was calculated from the Hei-

senberg model ($H = -2JS_1S_2$, $S_1 = S_2 = 1$) given in Equation (1)[42]

$$\chi'_M = \frac{Ng^2\beta^2}{kT}\frac{2\exp(x)+10\exp(3x)}{1+3\exp(x)+5\exp(6x)} + TIP \quad (1)$$

where N, g, β, and x are the Avogadro number, g factor, Bohr magneton, and J/kT, respectively; TIP is the temperature-independent paramagnetism of the Ni^{2+} ion. The best fitting results for magnetic susceptibility data give $TIP = 4.00\times10^{-4}$ emu mol^{-1}, $g = 2.13$, $J = -3.9$ cm^{-1}, and $R = 2.80\times10^{-5}$ [$R = \Sigma[(\chi_M T)_{obs} - (\chi_M T)_{cal}]^2/\Sigma(\chi_M T)^2_{obs}$]. As shown in Figure 5, the solid lines obtained from the theoretical approach are in good agreement with the experimental results. The negative value of J, according to the crystallographic results, indicates an antiferromagnetic interaction through the water bridges between Ni^{II} ions in the [(dpa)-Ni(μ_2-OH$_2$)$_2$Ni(dpa)] dimer and the spin-orbit coupling contributes trivially to the g factor. The intermolecular exchange interactions through $\mu_{1,2}$-squarate bridges can be ignored since there is only a weak antiferromagnetic interaction through the squarate bridge in [Ni(C$_4$O$_4$)(tren)(H$_2$O)$_2$](ClO$_4$)$_2$ ($J = -0.4$ cm^{-1}).[19]

Compound 4

The temperature dependence of the magnetic susceptibilities of **4** in the form of χ_M and $\chi_M T$ vs. T plots is shown in Figure 6. At room temperature, the $\chi_M T$ value is 0.89 emu K mol^{-1}, which is equal to the spin-only $\chi_M T$ value of 0.89 when $g = 2.18$, expected for a doubly uncoupled $S = 1/2$ system. As the temperature decreases, the $\chi_M T$ value remains nearly unchanged and finally reaches a value of 0.88 emu K mol^{-1} at 5 K. This magnetic behavior indicates the existence of a very weak antiferromagnetic interaction between the Cu^{II} ions. Based on the framework of compound **4**, two possible origins of the magnetic properties are tentatively proposed, namely the magnetism induced from either the equatorial-axial squarate bridge with a separation distance of 4.832(4) Å or the equatorial-equatorial squarate bridge separated by 5.392(4) Å. In either case, the magnetic interaction is mainly dominated by the equatorial-axial squarate bridge. As a result, the magnetic susceptibility data can be fitted with the binuclear magnetic model to give $TIP = 0.0$ emu mol^{-1}, $g = 2.18$, $J = -0.08$ cm^{-1} and $R = 9.24\times10^{-6}$. The solid lines obtained from the theoretical model in Figure 6 demonstrate a good agreement between the theoretical and experimental results. For complex **4**, the magnetic interaction via the squarate bridge is rather small and it can thus be treated as a paramagnetic ion because of the weak overlap between the magnetic orbital through the $\mu_{1,2}$-bis-monodentate squarate bridging ligands.[24] However, the magnetic susceptibility data can be fitted to a Curie–Weiss law with $\theta = +0.224$ K, and $C = 0.444$ emu K mol^{-1}. The Curie constant agrees well with the value of $g = 2.18$ for a copper(II) one-spin electron configuration, which corresponds to a value of $\chi_M T$ per copper ion of 0.89 emu K mol^{-1}. The small, positive Weiss constant does not really reflect a weak ferromagnetic interaction but rather implies that there is a lack of strong metal–metal interactions within the frameworks.

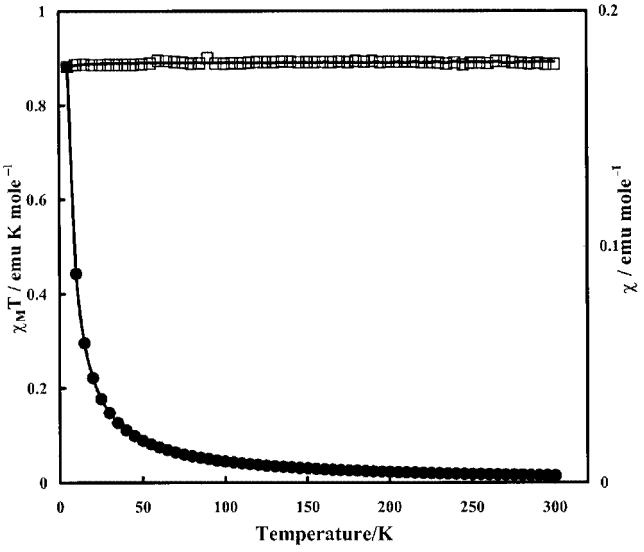

Figure 6. Plots of χ_M (●) and $\chi_M T$ (□) vs. T [K] for **4**. The solid line represents the best theoretical fit.

Compound 1

The magnetic behavior of **1** is illustrated in Figure 7 as a plot of $\chi_M T$ as a function of temperature in the range 5–300 K. At room temperature, the $\chi_M T$ value is 3.94 emu K mol^{-1}, which is close to the value (3.76 cm^3 K mol^{-1}) of a doubly uncoupled $S = 3/2$ spin system. The value of $\chi_M T$ slowly increases as the temperature decreases, and reaches a maximum (4.18 emu K mol^{-1}) near 125 K. It then decreases continuously and finally reaches a value of 1.52 emu K mol^{-1} at 5 K. For a weak-field configuration ($A = 1.5$) the value of $\chi_M T$ (3.94 emu K mol^{-1}) is unexpectedly large. Note that a similar phenomenon has been reported in the case of $CoBr_2$.[39] From the geometry point

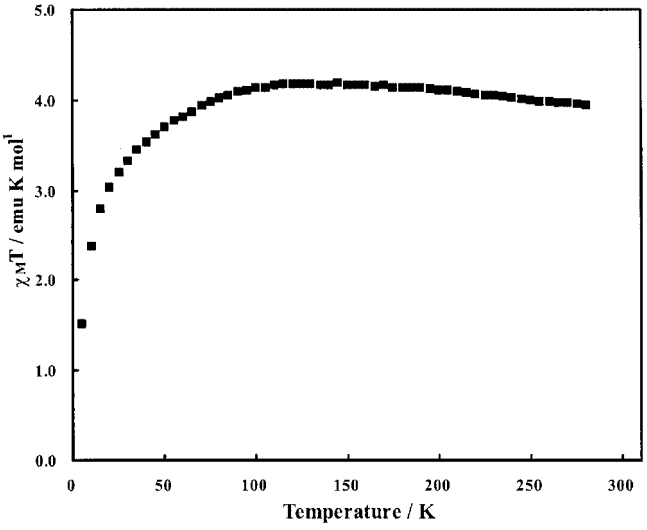

Figure 7. Plots of $\chi_M T$ (■) vs. T [K] for **1**.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of view, the magnetic behavior may originate from the antiferromagnetic dimers $[(dpa)Co(\mu_2\text{-}OH_2)_2Co(dpa)]^{4+}$, bridged by H_2O ligands [Co···Co separation of 3.459(1) Å] similar to that of complex **2**. However, the susceptibility data could not be analyzed by using an expression for the magnetic susceptibility of a dinuclear cobalt(II) system because the dinuclear system does not take into account the effects of the zero-field splitting and/or spin-orbital coupling, which may be significant for cobalt(II) ions.[38,40]

Thermogravimetric Analysis

To assess the thermal stability of compounds **1**–**4** and their structural variation as a function of the temperature, thermogravimetric analysis (TGA) was performed on single-phase polycrystalline samples for each compound. The former three compounds (**1**–**3**) all undergo a continuous, single-step weight-loss process (losing coordinated water, followed by detachment of dpa and squarate groups) and are thermally stable up to at least 175 °C. The on-set temperatures for the weight losses are approximately 175 °C, 258 °C, and 180 °C for **1**–**3**, respectively. The decomposition processes were completed at approximately 454 °C for **1**, 361 °C for **2**, and 436 °C for **3**. These samples are then decomposed completely. The final products of the pyrolysis were identified as Co_3O_4, NiO, and ZnO, with remaining percentages of 20.25, 22.25, and 22.92%. The high thermal stability of these compounds can be mainly attributed to the intra- and intermolecular hydrogen bonds in combination with the π-π stacking interaction.

For compound **4**, the dehydration takes place in a temperature range 50–100 °C with a weight lost of 6.6%, corresponding to the calculated value (7.2%) for loss of one solvated and two coordinated water molecules. The loss of squarate groups occurs in the range 210–260 °C, with the weight loss of 30.0% corresponding to the calculated value of 30.5%. Above 290 °C the dpa ligand is degraded. The final pyrolysis product is CuO, with a remaining percentage of 20.98%.

Conclusions

In conclusion, under hydrothermal conditions, we have successfully synthesized two metal coordination polymer frameworks $[M(dpa)(C_4O_4)(H_2O)]$ [M = Co (**1**), Ni (**2**), Zn (**3**)] and $[Cu(dpa)(C_4O_4)(H_2O)]_2{\cdot}H_2O$ (**4**), the structures of which have been well characterized by X-ray diffraction. The squarate ligands afford a $\mu_{1,2}$-bridging coordination mode as well as hydrogen-bonding capability to build a 1D two-legged ladder-like MOF for compounds **1**–**3** and a 1D helical chain for compound **4**. The magnetic studies indicate a weak antiferromagnetic interaction via H_2O bridges for **1** and **2** and paramagnetism for **4**.

Experimental Section

Materials and Physical Techniques: All chemicals were of reagent grade and were used as received. The IR spectra were recorded on a Nicolet Fourier Transform IR, MAGNA-IR 500 spectrometer in the range of 500–4000 cm^{-1} using the KBr disc technique. The magnetic susceptibilities were measured on polycrystalline samples of compound **1** (Co), **2** (Ni), and **4** (Cu) at a field of 10000 G over a temperature range from 5 to 300 K with a SQUID magnetometer. Diamagnetic corrections were made with Pascal's constants for all constituent atoms, and the magnetic moments were calculated by the equation $\mu_{eff} = 2.828(\chi_M T)^{1/2}$. Thermogravimetric analyses (TGA) of the title compounds were performed on a computer-controlled Perkin–Elmer 7 Series/UNIX TGA7 analyzer. Single-phase powder samples of **1** (4.014 mg), **2** (5.079 mg), **3** (1.532 mg), and **4** (4.406 mg) were loaded into alumina pans and heated with a ramp rate of 5 °C min^{-1} from room temperature to 900 °C under nitrogen.

Synthesis of $[Co(dpa)(C_4O_4)(H_2O)]$ (1): Reaction of anhydrous $CoCl_2$ (0.0131 g, 0.1 mmol), $H_2C_4O_4$ (0.0114 g, 0.1 mmol), dpa (0.0348 g, 0.2 mmol), and deionized water (6 mL) in a molar ratio of 1:1:2:3333 at 180 °C for three days produced red, column-like crystals of **1** in a yield of 0.0198 g (54.9%) based on Co^{II}. The final pH value was 3.28. IR (KBr): $\tilde{\nu}$ = 3319 (w), 3204 (w), 3141 (w), 3041 (w), 1651 (m), 1582 (m), 1540 (s), 1480 (vs), 1425 (s), 1379 (m), 1235 (m), 1160 (m), 1011 (m), 847 (w), 763 (m), 646 (w) cm^{-1}. $C_{14}H_{11}CoN_3O_5$ (360.19): calcd. C 46.69, H 3.08, N 11.67; found C 46.78, H 3.01, N 11.64.

Synthesis of $[Ni(dpa)(C_4O_4)(H_2O)]$ (2): Reaction of $NiCl_2{\cdot}6H_2O$ (0.0241 g, 0.1 mmol), $H_2C_4O_4$ (0.0115 g, 0.1 mmol), dpa (0.0352 g, 0.2 mmol), and deionized water (6 mL) in a molar ratio of 1:1:2:3333 at 180 °C for three days produced light-blue, column-like crystals of **2** in a yield of 0.0194 g (53.9%) based on Ni^{II}. The final pH value was 2.82. IR (KBr): $\tilde{\nu}$ = 3319 (w), 3206 (w), 3143 (w), 3043 (w), 1652 (s), 1601 (s), 1580 (s), 1541 (vs), 1486 (vs, broad), 1434 (vs), 1381 (s), 1276 (m), 1236 (m), 1166 (m), 1160 (s), 1081 (m), 1047 (m), 1015 (m), 900 (m), 851 (m), 789 (m), 763 (m), 648 (w) cm^{-1}. $C_{14}H_{11}N_3NiO_5$ (359.97): calcd. C 46.72, H 3.08, N 11.67; found C 46.87, H 2.92, N 11.76.

Synthesis of $[Zn(dpa)(C_4O_4)(H_2O)]$ (3): Reaction of anhydrous $ZnCl_2$ (0.0136 g, 0.1 mmol), $H_2C_4O_4$ (0.0114 g, 0.1 mmol), dpa (0.0340 g, 0.2 mmol), and deionized water (6 mL) in a molar ratio of 1:1:2:3333 at 180 °C for three days produced light-brown, needle-like crystals of **3** in a yield of 0.0256 g (69.8%) based on Zn^{II}. The final pH value was 3.74. IR (KBr): $\tilde{\nu}$ = 3307 (w), 3210 (w), 3148 (w), 3037 (w), 1644 (m), 1586 (m), 1532 (s), 1483 (vs), 1379 (m), 1272 (w), 1236 (m), 1160 (m), 1013 (m), 765 (m), 648 (w) cm^{-1}. $C_{14}H_{11}N_3O_5Zn$ (366.63): calcd. C 45.86, H 2.02, N 11.46; found C 45.31, H 2.12, N 11.35.

Synthesis of $[Cu(dpa)(C_4O_4)(H_2O)]_2{\cdot}(H_2O)$ (4): Reaction of $CuCl_2{\cdot}6H_2O$ (0.0170 g, 0.1 mmol), $H_2C_4O_4$ (0.0114 g, 0.1 mmol), dpa (0.0170 g, 0.2 mmol), and deionized water (6 mL) in a molar ratio of 1:1:1:3333 at 180 °C for three days produced black, column-like crystals of **4** in a yield of 0.074 g (98.9%) based on Cu^{II}. The final pH value was 2.94. IR (KBr): $\tilde{\nu}$ = 3304 (w), 3204 (w), 3141 (w), 3106 (w), 3041 (w), 1652 (m), 1589 (m), 1520 (vs), 1483 (vs), 1463 (vs), 1434 (m), 1332 (m), 1241 (m), 1157 (m), 1082 (m), 1025 (m), 766 (m), 650 (m) cm^{-1}. $C_{28}H_{24}Cu_2N_6O_{11}$ (747.61): calcd. C 44.98, H 3.08, N 11.67; found C 44.58, H 2.89, N 11.15.

X-ray Crystallographic Study: Single-crystal structure analyses for compounds **1**–**4** were performed on a Siemens SMART diffractometer with a CCD detector with Mo-K_α radiation (λ = 0.71073 Å) at room temperature. A preliminary orientation matrix and unit-cell parameters were determined from three runs of 15 frames each, with each frame corresponding to a 0.3° scan in 10 s, following by spot integration and least-squares refinement. For each structure, data were measured using ω scans of 0.3° per frame

for 20 s until a complete hemisphere had been collected. Cell parameters were retrieved with SMART[41] software and refined with SAINT[42] on all observed reflections. Data reduction was performed with SAINT and corrected for Lorentz and polarization effects. Absorption corrections were applied with the program SADABS.[43] Direct phase-determination and subsequent difference-Fourier map synthesis yielded the positions of non-hydrogen atoms, which were subjected to anisotropic refinements. For **1**–**4**, all hydrogen atoms were generated geometrically (C–H: 0.95) with the exception of the hydrogen atoms of the coordinated water molecules, which were located in the difference Fourier map with the corresponding positions and isotropic displacement parameters being refined. A final full-matrix, least-squares refinement method on F^2 was applied for all observed reflections [$I > 2\sigma(I)$]. All calculations were performed with the SHELXTL-PC V 5.03 software package.[44] Crystal data and details of the data collection and structure refinements for **1**–**4** are summarized in Table 5.

CCDC-205773 (for **1**), -205772 (for **2**), -172057 (for **3**) and -205774 (for **4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

Synthesis, Structure, Coordination Expansion and Theoretical Modelling of Dichlorobis(phenoxo) Titanium(IV) Complexes

Alastair J. Nielson,*[a] Chaohong Shen,[a] Peter Schwerdtfeger,[a] and Joyce M. Waters[a]

Keywords: Complexes / Phenoxo ligands / Structure elucidation / Theoretical structure / Titanium

Thermalisation of $TiCl_4$ and two equivalents of a phenol in toluene is found to be the best preparative method for quantitative yields of a variety of dichlorobis(phenoxo) complexes. $[TiCl_2(OC_6H_4CMe_3\text{-}4)_2]$ (**1**) is monomeric in benzene, a phenoxo-bridged dimer in the solid state and undergoes coordination expansion with 4,4′-dimethyl-2,2′-bipyridine (dmbipy) to give $[TiCl_2(OC_6H_4CMe_3\text{-}4)_2(dmbipy)]$ (**2**). Also monomeric are $[TiCl_2(OC_6H_2Me_3\text{-}2,4,6)_2]$ (**3**) and $[TiCl_2(OC_6H_3iPr_2\text{-}2,6)_2]$ (**5**) which expand their coordination with dmbipy to give $[TiCl_2(OC_6H_2Me_3\text{-}2,4,6)_2(dmbipy)]$ (**4**) and $[TiCl_2(OC_6H_3iPr_2\text{-}2,6)_2(dmbipy)]$ (**6**). In contrast $[TiCl_2(OC_6H_2\{CMe_3\}_2\text{-}2,6\text{-}Me\text{-}4)_2]$ (**7**) is only partially formed by the thermolysis reaction and does not coordinatively expand with dmbipy. $[TiCl_2(OC_6H_3Me_2\text{-}2,4)_2]$ (**8**) is monomeric in benzene and reacts to form $[TiCl_2(OC_6H_3Me_2\text{-}2,4)_2(dmbipy)]$ (**9**). $[TiCl_2(OC_6H_3\{CMe_3\}_2\text{-}2,4)_2]$ (**10**) forms along with the tri-phenoxo complex $[TiCl\{OC_6H_3(CMe_3)_2\text{-}2,4\}_3]$. $[TiCl_2(OC_6H_3CMe_3\text{-}2\text{-}Me\text{-}6)_2]$ (**11**) is monomeric in benzene and forms $[TiCl_2(OC_6H_3CMe_3\text{-}2\text{-}Me\text{-}6)_2(dmbipy)]$ (**12**). 2-Phenylphenol and 1-napthol form $[TiCl_2(OC_6H_4Ph\text{-}2)_2]$ (**13**) and $[TiCl_2(OC_{10}H_9)_2]$ (**14**) which are monomeric in benzene. DFT calculations give structural parameters for monomeric $[TiCl_2(OC_6H_5)_2]$ (**15**) in good agreement with the X-ray data for $[TiCl_2(OC_6H_3Me_2\text{-}2,6)_2]$. Each oxygen of the phenoxo ligand in **15** acts essentially as a 2π donor to titanium and there is substantial $p_\pi(O)\text{-}p_\pi^*(C{=}C)$ backbonding with the phenyl ring, which is absent in $[TiCl_2(OCH_3)_2]$ (**16**). The global minimum for the dimer $[(TiCl_2\{OC_6H_5\}\{\mu\text{-}OC_6H_5\})_2]$ is in almost perfect agreement with the crystal structure obtained for $[(TiCl_2\{OC_6H_5\}\{\mu\text{-}OC_6H_5\})_2]$ or $[(TiCl_2\{OC_6H_4CMe_3\text{-}4\}\{\mu\text{-}OC_6H_4CMe_3\text{-}4\})_2]$ (**1**). The dimerisation energy for **15** is $-26.2\ kJ{\cdot}mol^{-1}$.

Introduction

The relationship between dichlorobis(phenoxo) complexes $[TiCl_2(OAr)_2]$ and titanium metallocences $[TiCl_2Cp_2]$ is now very apparent[1,2] with the phenoxo complexes emerging as promising synthons and catalysts for organic reactions[2,3,4] and catalysts for olefin polymerisation.[5] Alkoxo complexes of titanium often form higher associates than monomers in solution[6] but the solution behavior of the bis(phenoxo) complexes and the coordination expansion properties have not been studied.[7] From the synthetic point of view, complexes containing *tert*-butyl or phenyl groups in the 2,6- positions of the aryloxo ring have received the most attention.[5,8–10] However, little is known about bis(phenoxo) complexes containing ligands which are less sterically demanding. For example, $[TiCl_2(OC_6H_5)_2]$ has a dimeric structure in the solid state[11] and there is conflicting evidence for the structure in solution,[12,13] $[TiCl_2(OC_6H_3Me_2\text{-}2,6)_2]$ has a monomeric solid-state structure,[9] and $[TiCl_2(OC_6H_2Me_3\text{-}2,4,6)_2]$ is monomeric in benzene and expands its co-ordination sphere forming the bis-adducts $[TiCl_2(OC_6H_2Me_3\text{-}2,4,6)_2(L)_2]$ (L = pyridine, $ArNH_2$ and tetrahydrofuran) which have been characterised only by analytical data and IR spectroscopy.[14] We have reported[15] a comprehensive systematic study of the mono(phenoxo) complexes $[TiCl_3(OAr)]$ (Ar = unsubstituted or substituted phenyl group) which included aspects of best synthetic method, co-ordination expansion and theoretical modelling. We report here a similar investigation for complexes of the type $[TiCl_2(OAr)_2]$ where changes are made to the size of the *ortho*-substituents of the phenyl rings. In particular we investigate the nature of the complexes in non-coordinating solvents to ascertain if co-ordinative unsaturation is maintained in solution. Some general comparisons of the bis(phenoxo) complexes with $[TiCl_2Cp_2]$ (Cp = cyclopentadienyl) are also made.

Results and Discussion

Synthetic Studies

Bis(phenoxide) complexes have been prepared by thermalising $TiCl_4$ and the phenol in a non-coordinating solvent[14,16] or more commonly by reacting the lithium phenolate with $TiCl_4$ in diethyl ether.[2–10] We have found that thermalisation in toluene of $TiCl_4$ and the phenol in 1:2 ratio is the best procedure for most phenols [Equation (1)].

$TiCl_4 + 2\ HOAr \rightarrow [TiCl_2(OAr)_2] + 2\ HCl$ (1)

HOAr = $HOC_6H_4CMe_3$-4, $HOC_6H_2Me_3$-2,4,6, $HOC_6H_3iPr_2$-2,6, $HOC_6H_3Me_2$-2,4, $HOC_6H_3(CMe_3)_2$-2,4, $HOC_6H_3CMe_3$-2-Me-6, HOC_6H_4Ph-2, $HOC_{10}H_9$ (naphthyl)

If the reaction is carried out to completion, then solid complexes can be obtained in virtually quantitative yield and in an analytically pure form. It is important to determine the end point of the reaction otherwise gummy materials often result which are difficult to purify. The last traces of HCl gas produced in the reaction are easily detected by a simple but very sensitive test which involves passing the exhaust gases close to concentrated ammonia solution or a liquid organic amine and observing any white hydrochloride cloud. On a 5–10 g scale in vigorously boiling toluene, the reactions are usually complete in less than 14 h and on a 50–100 g scale the reaction times are not much longer.

The crystal structure of $[TiCl_2(OC_6H_5)_2]$ has been determined,[11] but we have found the complex is not suitably soluble in benzene for an accurate cryoscopic molecular weight determination. However, reaction of $TiCl_4$ with 4-*tert*-butylphenol gave highly soluble $[TiCl_2(OC_6H_4CMe_3\text{-}4)_2]$ (**1**) and an X-ray crystal structure determination of the product crystallised from benzene showed a dimeric complex containing a phenoxo bridge in which each titanium atom adopts a distorted pentagonal bipyrimidal coordination geometry (Figure 1). The titanium atoms each have two *cis*-coordinated chloro ligands and two *cis*-coordinated phenoxo ligands, one of which bridges to the adjacent titanium atom where it lies *trans* to a terminal phenoxo ligand.

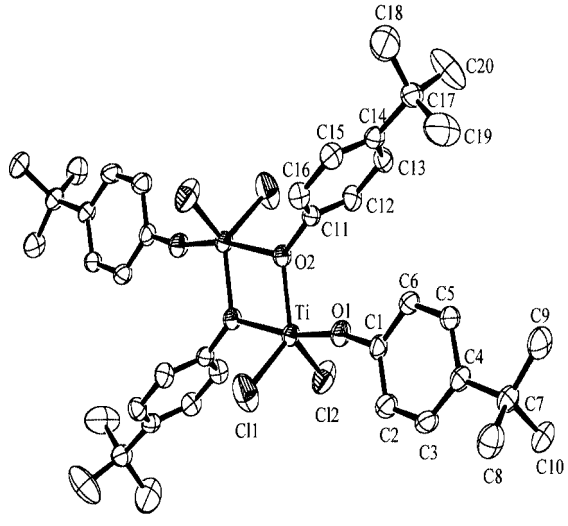

Figure 1.Thermal ellipsoid diagram (at the 50% probability level) for (**1**) showing the numbering system. Hydrogen atoms have been omitted for clarity.

The structure of **1** is essentially similar to that found for dimeric $[TiCl_2(OC_6H_5)_2]$,[11] but is described now in terms of modern bonding concepts. Selected bond lengths and angles are given in Table 1. The Ti–O(1) and O(1)–C(1) bond lengths [1.749(2) and 1.369(3) Å, respectively] and the Ti–O(1)–C(1) bond angle [165.2(2)°] are similar to those found for the mono(phenoxo) complex $[TiCl_3(OC_6H_2\{CMe_3\}_2\text{-}2,6\text{-}Me\text{-}4)]$ [1.750(2), 1.390(2) Å and 163.1°, respectively[15]]. Theoretical calculations on the model complex $[TiCl_3(OC_6H_2Me_3\text{-}2,4,6)]$ show that the terminal phenoxo ligand oxygen atom acts essentially as a 1-σ, 2-π donor to titanium but that there is also some O(2p) donation to the phenyl ring C=C(π*) orbital.[15] The Ti−O(2) bond length in **1** [1.912(2) Å], is significantly longer than the Ti–O(1) bond length [1.749(2) Å] as a consequence of O(2) forming a dative bond to the other titanium atom [Ti–O(2)′ bond length 2.142(2) Å] in the unsymmetrical bridge. The O(2) lone pair donation to Ti occurs *trans* to the strongly π-donating terminal phenoxo ligand so that the potentially π-donating chloro ligands do not have to compete for the same d orbitals. The increased length of the Ti–O(2) bond indicates that O(2)-to-Ti π-donation is much less than for the Ti–O(1) bond. Also the bridging phenoxo ligand O–C bond [O(2)–C(11) bond length 1.406(3) Å] is significantly longer than the terminal phenoxo ligand O–C bond [O(1)–C(1) bond length [1.369(3) Å] indicating there is less O(2p) donation to the phenyl ring C=C(π*) orbital for the bridging mode. This may be a consequence of the phenyl ring π-orbitals being unable to overlap to any significant extent with oxygen orbitals when the two oxygen lone pairs on O(2) are otherwise involved with bonding to Ti [possible O(2)p-to-Ti(1)d π-donation and O(2)p-to-Ti(2)d σ-donation].

Table 1. Selected bond lengths [Å] and angles [°] for **1**. Symmetry transformations used to generate equivalent atoms: #1: $-x + 1$, $-y + 1$, $-z + 1$).

The Ti–Cl(1) and Ti–Cl(2) bond lengths in complex **1** [2.2186(11) and 2.2256(11) Å] are not very different from each other but are slightly longer than those found for

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$[TiCl_3(OC_6H_2\{CMe_3\}_2\text{-}2,6\text{-}Me\text{-}4)]$ [Ti–Cl bond lengths 2.1822(8), 2.1913(8) and 2.1945(9) Å] where π-donation from chloro ligands is needed to increase the overall electron count. The theoretical calculations made on the model complex $[TiCl_3(OC_6H_2Me_3\text{-}2,4,6)]$ show that significant Cl(2p) to Ti(3d) π-donation occurs in these tetrahedral molecules.[15] Assuming that O(2) in complex **1** makes a single π-donor interaction with the titanium atom then the overall (formal) electron count for the complex is 16 so an 18-electron count can be attained if Cl(2p) to Ti(3d) donation occurs.

The X-ray crystal structure indicates complex **1** exists in the solid state as a dimer but a molecular weight determination in benzene, the solvent from which the dimer crystallised, indicates a monomer (Scheme 1). The ^1H NMR spectrum in C_6D_6 shows a single resonance for the *tert*-butyl groups, a doublet for the *meta*-protons of the phenyl ring but a broadened resonance for the *ortho*-protons. In the $^{13}C\{^1H\}$ NMR spectrum the *tert*-butyl group methyl and quaternary carbons appear as single sharp resonances but the aromatic ring C resonances are somewhat broadened. Identical spectra are obtained for the complexes reported here whether the solvent is C_6D_6 or $CDCl_3$ but the resonances are slightly sharper in $CDCl_3$. Cooling $CDCl_3$ or $[D_8]$toluene solutions of **1** produced little change in the broadening observed leaving unclear the nature of any solution dynamics. The spectra are thus consistent with the monomeric structure shown by the molecular weight determination and not the dimer found in the solid state. The *ipso*-C resonance occurs at δ = 166.3 ppm, which lies slightly upfield to that observed for $[TiCl_3(OC_6H_4CMe_3\text{-}4)]$ (δ = 169.6 ppm[15]) and this may represent a small change in the O(2p)–C=C(π*) bonding system associated with the smaller need for tight O(2)p-to-Ti(1)d orbital donation on addition of the second phenoxide ligand which is a better π-bonder than Cl.[15]

Scheme 1.

The coordination expansion properties of complex **1** were studied using 4,4′-dimethyl-2,2′-bipyridine (dmbipy), as this ligand is useful in determining isomer structure by NMR spectroscopy.[15] $[TiCl_2(OC_6H_4CMe_3\text{-}4)_2(dmbipy)]$ (**2**) was readily formed in CH_2Cl_2 and the NMR spectra showed the presence of only one isomer. Both the ^1H and $^{13}C\{^1H\}$ NMR spectra indicate a symmetrical molecule based on a single set of resonances for the relevant position of the phenoxo and dmbipy ligands. Structure **I** (Scheme 2) is the preferred isomer since structure **II** contains *trans*-orientated phenoxo ligands, which would lead to an unfavourable competition for d-metal orbitals and structure **III** is an unsymmetrical molecule. A *trans*-chloro-*cis*-phenoxo configuration has been observed in the X-ray crystal structures $[TiCl_2(OC_6H_3Me_2\text{-}2,6)_2(THF)_2]$[17] [i.e. consistant with structure **I**, Scheme 2], where the THF ligands coordinate *cis* to each other and *trans* to the strongly π-donating phenoxo ligands. The NMR spectra for **2** show sharp resonances, which suggests that solution dynamics are not prevalent. The *ipso*-C resonance occurs at δ = 164.8 ppm, which lies slightly upfield to that observed for complex **1** (δ = 166.3 ppm) and again this may represent a small change in the O(2p)–C=C(π*) bonding system associated with the smaller need for tight O(2)p–to–Ti(1)d orbital donation on addition of the 4-electron donor bipy chelate. (see Table 2 for comparisons of the $^{13}C\{^1H\}$ spectra *ipso*-C resonance positions for complexes of the type $[TiCl_3(OAr)]$, $[TiCl_2(OAr)_2]$ and $[TiCl_2(OAr)_2(dmbipy)]$).

benzene and shows sharper NMR spectra than complex **1** suggesting again that solution dynamics are not prevalent. The complex reacts with dmbipy to give $[TiCl_2(OC_6H_2Me_3\text{-}2,4,6)_2(dmbipy)]$ (**4**) for which the NMR spectra indicate one isomer with a similar structure to **2**. The *ipso*-C resonance in the $^{13}C\{^1H\}$ NMR spectrum of **4** occurs at δ = 164.5 ppm compared with δ = 166.4 ppm in the parent complex **3** (Table 2). Both complexes **3** and **4** did not crystallise, so that comparisons of *ipso*-C resonance position with solid state bond length data cannot be made. However, complex **3** is closely related to $[TiCl_2(OC_6H_3Me_2\text{-}2,6)_2]$ for which an X-ray crystal structure determination has shown a monomeric tetrahedral structure with Ti–O bond lengths of 1.734(7) and 1.736(8) Å, Ti–Cl bond lengths of 2.192(4) and 2.211(4) Å[9] and an *ipso*-C resonance in the ^{13}C NMR spectrum at δ = 167.8 ppm.[8] In the octahedral adduct $[TiCl_2(OC_6H_3Me_2\text{-}2,6)_2(dpeda)]$ [dpeda = (1*S*,2*S*)-diphenylethylenediamine] the Ti–O bond lengths increase to 1.804(4) and 1.787(4) Å, the Ti–Cl bond lengths to 2.353(2) Å and the *ipso*-C resonance is at δ = 166.0 ppm.[7] The standard deviations for the C–O bond lengths do not allow reliable bond length comparisons to be made for these complexes.

The reaction of 2,6-diisopropylphenol with $TiCl_4$ gave an oil which failed to form a solid[9,18,19] but was identified as $[TiCl_2(OC_6H_3iPr_2\text{-}2,6)_2]$ (**5**) on the basis of its NMR spectra (*ipso*-C resonance δ = 165.7, cf. δ = 170.5 ppm for $[TiCl_3(OC_6H_3iPr_2\text{-}2,6)]$,[15] Table 2) being identical to an authentic sample.[19] Reaction of complex **5** with dmbipy gave $[TiCl_2(OC_6H_3iPr_2\text{-}2,6)_2(dmbipy)]$ (**6**) for which the NMR spectra showed one isomer with a similar structure to **2** [structure **I**, Scheme 2] and the *ipso*-C resonance at δ = 162.6 ppm. Refluxing a solution of 2,6-di-*tert*-butyl-4-methylphenol with $TiCl_4$ in toluene for 18 h, at which time HCl production had essentially ceased, gave a gum which NMR spectroscopy showed to be a mixture of $[TiCl_3(OC_6H_2\{CMe_3\}_2\text{-}2,6\text{-}Me\text{-}4)]$,[15] $[TiCl_2(OC_6H_2\{CMe_3\}_2\text{-}2,6\text{-}Me\text{-}4)_2]$[8] (**7**) and unreacted phenol. This indicated that the thermalisation reaction is not successful with this sterically demanding phenol.[8] A sample of $[TiCl_2(OC_6H_2\{CMe_3\}_2\text{-}2,6\text{-}Me\text{-}4)_2]$ prepared by the reaction of $TiCl_4$ and $LiOC_6H_2(CMe_3)_2\text{-}2,6\text{-}Me\text{-}4$[8] did not react with dmbipy and is reported not to react with pyridine.[8] These results indicate that 2,6-di-*tert*-butyl substituents represent the steric limit for coordination expansion about the titanium centre.

Several unsymmetrically substituted phenols were also thermalised with $TiCl_4$ in toluene giving bis(phenoxo) complexes which have not been reported before. $[TiCl_2(OC_6H_3Me_2\text{-}2,4)_2]$ (**8**) (*ipso*-C resonance at δ = 165.2 ppm, cf. δ = 169.9 ppm for $[TiCl_3(OC_6H_3Me_2\text{-}2,4)]$,[15] Table 2) is monomeric in benzene and reacts with dmbipy to give $[TiCl_2(OC_6H_3Me_2\text{-}2,4)_2(dmbipy)]$ (**9**) for which the NMR spectra show a single isomer similar to structure **I**, Scheme 2 and an *ipso*-C resonance at δ = 164.3ppm. Reaction of 2,4-di-*tert*-butylphenol and $TiCl_4$ gave a mixture of $[TiCl_2(OC_6H_3\{CMe_3\}_2\text{-}2,4)_2]$ (**10**) (identified as a monomer by NMR spectroscopy, one set of resonances in the NMR spectra, *ipso*-C resonance at δ = 165.7 ppm) and the tris-(phenoxo) complex $[TiCl(OC_6H_3\{CMe_3\}_2\text{-}2,4)_3]$, which could be crystallised from the solution and has a distinctly different *ipso*-C resonance position (δ = 163.2 ppm). NMR spectroscopy showed that a reaction of two equivalents of $LiOC_6H_3(CMe_3)_2\text{-}2,4$ with $TiCl_4$ in benzene also gave the tris(phenoxo) complex as the major product. The reason for the ease of formation of this tris-product in these reactions is unclear but appears to be related to the presence of the *para*-*tert*-butyl substituent. NMR spectral analysis of the reaction of two equivalents of 2-*tert*-butyl-4-methylphenol with $TiCl_4$ shows the product is exclusively the bis-(phenoxo) complex (*ipso*-C resonance at δ = 165.8 ppm).

Reaction of 2-*tert*-butyl-6-methylphenol and $TiCl_4$ gave $[TiCl_2(OC_6H_3CMe_3\text{-}2\text{-}Me\text{-}6)_2]$ (**11**) (*ipso*-C resonance at δ = 169.3 ppm, cf. δ = 172.8 ppm for $[TiCl_3(OC_6H_3CMe_3\text{-}2\text{-}Me\text{-}6)]$,[15] Table 2) which is monomeric in benzene. The complex is reported to be a liquid when prepared by thermolysis in CH_2Cl_2[18] and is formed in only 50% yield when $[Ti(NEt_2)_2(OC_6H_3CMe_3\text{-}2\text{-}Me\text{-}6)_2]$ is reacted with $SiCl_4$.[4b] Using the present thermolysis method, production of HCl appeared to have ceased after approximately 8 h of vigorous refluxing, but NMR spectroscopy indicated that the reaction was only about 80% complete. Starting the cooled solution refluxing again led to resumption of HCl gas production and further NMR spectral analysis at intervals showed that another 10 h of reaction time was needed for completion. On removing the solvent an oil remained but this solidified on standing. The reaction time can be compared with that when using 2,6-di-*tert*-butyl-4-methylphe-

nol where HCl gas production appeared to cease after about 18 h but NMR spectral analysis showed the presence of $[TiCl_3(OC_6H_2\{CMe_3\}_2\text{-}2,6\text{-}Me\text{-}4)]$, $[TiCl_2(OC_6H_2\{CMe_3\}_2\text{-}2,6\text{-}Me\text{-}4)_2]$ (**7**) and unreacted phenol. This result emphasises the need to correctly identify the end-point of these reactions, especially in cases where the size of both *ortho*-substituents becomes larger. The X-ray crystal structure of **11** shows a distorted tetrahedral structure in the solid state with bond lengths and angles that are not significantly different from those found for $[TiCl_2(OC_6H_3Me_2\text{-}2,6)_2]$ except for the O–Ti–O bond angle which widens by ca. 3.5° in **11**.[4a] Complex **11** reacts readily with dmbipy to form $[TiCl_2(OC_6H_3CMe_3\text{-}2\text{-}Me\text{-}6)_2(dmbipy)]$ (**12**) for which the NMR spectra indicate a similar structure to complex (**2**). The *ipso*-C resonance occurs at δ = 166.4 ppm. $[TiCl_2(OC_2H_4Ph\text{-}2)_2]$ (**13**) and the 1-napthoxo complex $[TiCl_2(OC_{10}H_9)_2]$ (**14**) were also prepared and found to be monomeric in benzene.

Theoretical Studies

Density functional theory (DFT) calculations were carried out on model complexes to study the electronic properties of the phenoxo and chloro ligand interactions with the titanium centre in the monomeric and dimeric complexes shown by the solution and solid-state structures. Unsubstituted phenoxo ligands were used in the models to simplify the calculations. The optimised geometry for the monomers $[TiCl_2(OC_6H_5)_2]$ (**15**) and $[TiCl_2(OCH_3)_2]$ (**16**) (used for comparisons) are shown in Figure 2. Bond lengths and angles for these two structures are given in Table 3 where they are compared with data obtained from the X-ray structure of the monomeric complexes $[TiCl_2(OC_6H_3Me_2\text{-}2,6)_2]$[9] and $[TiCl_2(OC_6H_3CMe_3\text{-}2\text{-}Me\text{-}6)_2]$.[3]

As expected, the ligands in **15** are tetrahedrally coordinated to titanium with the O–Ti–Cl, Cl–Ti–Cl and O–Ti–O bond angles (108.7 , 111.1 , and 111.0°, respectively) being very close to those found in the two X-ray structures. The Ti–O bond lengths in **15** [1.753 Å] are also similar to those found in the X-ray structures [Ti–O bond lengths 1.734(7) and 1.753(4) Å, respectively]. The model structures, however, indicate that the Ti–O bond lengths are longer in phenoxo model **15** (1.753 Å) than in the alkoxo model **16** (1.740 Å). Theoretical calculations have shown previously that a short Ti–O bond length of 1.750(2) Å in $[TiCl_3(OC_6H_2Me_3\text{-}2,4,6)]$ corresponds to a phenoxo ligand acting formally as a 2π-donor to Ti[15] but the Ti–O bonding is clearly stronger in **16**, where there is no $p_\pi(O)$-$p_\pi^*(C{=}C)$ backbonding with a phenyl ring (the C–O bond lengths in **15** and $[TiCl_2(OMe)_2]$ (**16**) are 1.384 and 1.436 Å,

Table 3. Comparison of the bond lengths [Å] and angles [°] for the X-ray structure of $[TiCl_2(OC_6H_3Me_2\text{-}2,6)_2]$ and $[TiCl_2(OC_6H_3CMe_3\text{-}2\text{-}Me\text{-}6)_2]$ with the calculated structures $[TiCl_2(OC_6H_5)_2]$ (**15**) and $[TiCl_2(OCH_3)_2]$ (**16**).

respectively). A similar situation was found for the models $[TiCl_3(OC_6H_2Me_3\text{-}2,4,6)]$ and $[TiCl_3(OMe)]$.[15]

The Ti–Cl bond lengths in **15** [2.249 Å] are somewhat longer than in $[TiCl_2(OC_6H_3Me_2\text{-}2,6)_2]$ [2.192(4) and 2.211(4) Å] and $[TiCl_2(OC_6H_3CMe_3\text{-}2\text{-}Me\text{-}6)_2]$ [2.217(3) and 2.207(3) Å], but this is to be expected from the level of theory applied, and they compare with 2.257 Å in $[TiCl_2(OMe)_2]$ where the strong Ti–O bonding allows the Ti–Cl bond to relax its π-bonding component somewhat when the electron count is maximised.

The Ti–O–C bond angle in model **15** [175.8°] is close to being linear which is also the case in the calculated structure of $[TiCl_3(OC_6H_2Me_3\text{-}2,4,6)]$ [177.7°][15] but the angles are smaller in the X-ray structures [e.g. 167.3(7)° in $[TiCl_2(OC_6H_3Me_2\text{-}2,6)_2]$ and 163.2(4)° in $[TiCl_2(OC_6H_3CMe_3\text{-}2\text{-}Me\text{-}6)_2]$. Ti–O–C bond angle linearity is also favoured by $p_\pi(O)$-$p_\pi^*(C{=}C)$ back bonding with the phenyl ring. However, the Ti–O–C bond angle in the model $[TiCl_2(OMe)_2]$ (**16**) in which there is no $p_\pi(O)$-$p_\pi^*(C{=}C)$ back bonding with a phenyl ring is 178.3°. In this molecule the bond angles about the titanium atom are similar to those in **15**, but more importantly the Ti–O bond lengths are slightly shorter in $[TiCl_2(OMe)_2]$ (1.740 Å, 1.753 Å in **15**), where the oxygen atom can bind to the metal without the influence of π-bonding to an aromatic ring. An angle scan reveals, however, that for the Ti–O–C bond angle in $[TiCl_3(OC_6H_2Me_3\text{-}2,4,6)]$ the energy difference between the calculated angle (177.7°) and the experimental value in the crystal [163.1(1)°] is only 3 kJ·mol^{-1}.[15] The reduced bond angle in the crystal structure is thus due to intermolecular effects similar to those apparent in the related organoimido complexes, where M–N–C bond angles can be as low as 150° without greatly effecting the electronic nature of the multiple bond.[20]

Interestingly, the phenyl rings in **15** face each other with the faces of the phenyl rings inclined to each other at an angle of 92.6°. This fact can be easily explained from electronic arguments. As there is strong π-overlap with both the Ti centre and the phenyl ring carbon atom (cummulene type arrangement), one oxygen atom overlaps with the d_{xz} orbital whilst the other overlaps with the d_{yz} orbital resulting in phenyl rings perpendicular to each other (Figure 3). The $p_\pi(O)$–$p_\pi^*(C{=}C)$ interaction extends the π system in the complexes which accounts for the deep red coloration observed. In comparison, bis(alkoxo) complexes which do not contain this feature are usually colourless.[6]

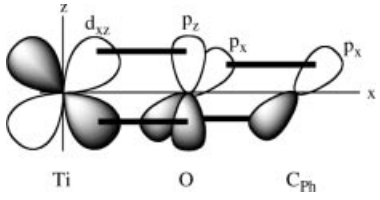

Figure 3. Op_z–Tid_{xz} and Op_x–Cp_x orbital overlaps in the Ti–O–Ar system.

A natural bond orbital (NBO) analysis[21] of **15** using second order perturbation analysis of the Fock matrix, which allows assignment of energetic contributions to individual donor acceptor pairs, shows there is substantial donation from the two oxygen 2p lone pairs on the phenoxo ligands to both the phenyl C=C (π*) orbital (E_2 = 104.6 kJ mol^{-1}) and more importantly to the unoccupied titanium 3d orbitals (E_2 = 376.6 kJ mol^{-1}). Both the $p_\pi(O)$-$p_\pi^*(C{=}C)$ and the $p_\pi(O)$-Ti interactions are stronger than that in the mono(phenoxo) model $[TiCl_3(OC_6H_2Me_3\text{-}2,4,6)]$ (E_2 = 54.4 kJ mol^{-1} and 230 kJ mol^{-1} per lone pair, respectively). Even so these values in **15** are clearly overestimated by the NBO procedure, but nevertheless it clearly points towards Ti–O multiple bonding. The O_{2p}-phenyl C=C (π*) back-bonding is also sufficiently strong to prevent rotation, so that at ambient temperatures the configuration of the two phenoxo ligands is essentially locked. A decrease in the Ti–O–C bond angle diminishes the backbonding into the Ti 3d-orbitals. This bonding situation would leave no orbitals available for π-donation from the two chloro ligands, which could build the electron count formally to 18. However, the perturbation analysis reveals that this picture is too simple as there is some orbital mixing of the Cl(3p) lone-pair on both chlorines via back donation into unoccupied titanium 3d orbitals. In comparison, for the complex $[TiCl_3(OC_6H_2Me_3\text{-}2,4,6)]$ in which there is only one phenoxo ligand and thus a greater need for Cl_p–Ti π-donation, calculations show that two of the lone pairs donate more strongly (E_2 = 108.8 kcal mol^{-1}.[15]) In $[TiCl_2(OMe)_2]$ (**16**) the calculations show that the contribution from the chloro ligands is much less than in **15** as without the $p_\pi(O)$-$p_\pi^*(C{=}C)$ interaction the strong Ti–O bonding allows the Ti–Cl bond to relax its π-bonding component and this is reflected in the longer Ti–Cl bond length in **16**.

Calculations were also carried out on models of the dimeric complex $[(TiCl_2\{OC_6H_4CMe_3\text{-}4\}\{\mu\text{-}OC_6H_4\text{-}CMe_3\text{-}4\})_2]$. For each titanium centre a trigonal bipyramidal arrangement for the ligands with the bridging oxygen atoms in the equatorial position was chosen in agreement with the crystal structure. With the 4-*tert*-butyl substituent replaced by H for computational convenience, a number of different structures according to all possible permutations was obtained. However, all the possible starting geometries optimised to only three different structures and these are shown in Figure 4. The global minimum (Figure 4A) is in almost perfect agreement with the crystal structures $[(TiCl_2\{OC_6H_4CMe_3\text{-}4\}\{\mu\text{-}OC_6H_4\text{-}CMe_3\text{-}4\})_2]$ (complex **1**) and $[(TiCl_2\{OC_6H_5\}\{\mu\text{-}OC_6H_5\})_2]$[11] (see Table 4). In particular the terminal Ti–O bond lengths are 1.747, 1.749 and 1.744 Å, respectively, and the Ti–O bridging bond lengths are 1.908, 1.912 and 1.910 Å, respectively. The C–O_t–Ti bond angles are also in reasonable agreement with experimental data (169.9, 165.2 and 165.9°, respectively) as are the C–O_b–Ti bond angles (126.6, 123.5 and 128.3°, respectively). It is clear that solid state effects and limitations in the computational procedure accounts for the small differences in the geometries. The other two structures (Figure 4 B and C) are 13.2 and 23.3 kJ·mol^{-1} above the global minimum (Figure 4, A). The dimerization energy for the reaction

[i.e. for dimer (A)] is only –26.2 kJ mol^{-1}. This supports the results obtained here indicating complex (**1**) is monomeric in solution but a dimer in the solid state and also gives insight as to why molecular weight studies could indicate either monomeric or dimeric structures in solution.[12,13] In the gas phase only the monomeric compound was found from mass spectroscopic studies.[13]

Conclusions

The results of this work show that a range of dichlorobis(phenoxo)titanium(IV) complexes can be prepared in essentially pure form and in quantitative yield if the end-point of thermalising $TiCl_4$ and two equivalents of a phenol in toluene is determined. This represents a major advance in the ease of preparing these complexes when larger quantities are required. In a non coordinating solvent such as benzene the complexes are monomeric and thus have a four-coordinate geometry typical of $[Cp_2TiCl_2]$ complexes. When there are no substituents in both *ortho*-positions of the phenoxo ligand phenyl rings, a dimeric phenoxo-bridged structure is possible in the solid state. Coordination expansion occurs where a ligand such as dmbipy is used but this ceases when both *ortho*-positions of the phenoxo ligand phenyl ring contain *tert*-butyl substituents. This compares with the dicyclopentadienyl complex $[Cp_2TiCl_2]$ which is not known to undergo coordination expansion easily and can be prepared in the presence of coordinating solvents.[22] The chloro ligands in the six-coordinate bis(phenoxo) adducts are expected to lie *trans* to each other which is not the orientation required for many catalytic reactions. It is thus important to keep potentially coordinating ligands away from the complexes if a *cis*-dichloro geometry is to be maintained. The *ipso*-C resonance position in the ^{13}C NMR spectra of the phenoxo ligand phenyl rings indicate that there is a trend towards less O(2p)-C=C(π^*) bonding component through the series $[TiCl_3(OAr)]$, $[TiCl_2(OAr)_2]$ and $[TiCl_2(OAr)_2(dmbipy)]$) and this would appear to be a sensitive probe for determining O_π-orbital-Ti_d orbital bonding tightness. The comparable feature in cyclopentadienyl complexes is ring slippage which is uncommon and is only found in circumstances where a strong π-donating ligand is

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

able to compete for available metal orbitals.[23] DFT calculations on the model $[TiCl_2(OC_6H_5)_2]$ show that the structural parameters compare well with the X-ray structures of $[TiCl_2(OC_6H_3Me_2\text{-}2,6)_2]$ and $[TiCl_2(OC_6H_3CMe_3\text{-}2\text{-}Me\text{-}6)_2]$ and as already discussed, an NBO analysis indicates substantial donation from the two oxygen 2p lone pairs on the phenoxo ligands to the unoccupied titanium 3d orbitals. This is consistent with each ligand acting formally as a 5-electron donor and gives credence to the analogy with the 5-electron donor Cp ligand.[1] There is also sufficient O(2p)–C=C(π*) interaction to prevent rotation of the phenyl rings about the C–O bond at room temperature. The calculations also show that there is only a small dimerisation energy for $[TiCl_2(OC_6H_5)_2]$ and the global minimum structure is the one observed in the solid state. Overall the bis(phenoxo) complexes show a range of differences compared with $[Cp_2TiCl_2]$ and in the absence of cyclometallation involving the *ortho*-substituents on the aromatic rings[24] these differences may be exploited in tuning stoichiometric and catalytic reactions in organic synthesis. Such metal-mediated reactions are now emerging.[3]

Experimental Section

Syntheses: All preparations and manipulations were carried out under dry, oxygen-free nitrogen using standard bench-top techniques for air-sensitive substances. $TiCl_4$ and the phenols were used as received from commercial sources. 4,4′-Dimethyl-2,2′-bipyridine (dmbipy) was dried under vacuum before use. Light petroleum (b.p. 40–60 °C) and toluene were distilled from sodium wire and dichloromethane from freshly ground CaH_2. ^1H and $^{13}C\{^1H\}$ NMR spectra were recorded at 400 and 100 MHz respectively with a Bruker AM400 spectrometer. $CDCl_3$ and CD_2Cl_2 were dried with, and distilled from, freshly ground CaH_2 and $[D_6]$benzene from sodium wire. Molecular mass values were determined cryoscopically in benzene with a Knauer molecular weight determination apparatus under N_2 gas conditions using concentrations in the vicinity of 5.3×10^{-8} mol·L^{-1}. C, H and N analyses were determined by Dr A. Cunninghame and associates, University of Otago, New Zealand. Chlorine was determined by gravimetric measurements. The production of HCl gas in the thermalisation reactions was monitored by passing the exhaust gases from the nitrogen bubbler over *N*,*N*,*N*′,*N*′-teramethylethylenediamine and observing the white cloud produced.

$[TiCl_2(OC_6H_4CMe_3\text{-}4)_2]$ (1): 4-*tert*-Butylphenol (4.75 g, 31 6 mmol) in toluene (50 cm^3) was added to $TiCl_4$ (3.0 g, 15.8 mmol) in toluene (50 cm^3) and the mixture was refluxed vigorously until the production of HCl gas ceased (9 h). The solution was cooled, filtered and the solvent removed to give a deep red microcrystalline solid which was pumped on for several hours. Yield: 6.57 g, 100%. $C_{20}H_{26}Cl_2O_2Ti$: calcd. C 57.6, H 6.3, Cl 17.0; found C 57.5, H 6.3, Cl 17.3. Cryoscopic mol. mass: found 420.6; required: 417.2. ^1H NMR: δ = 1.25 (s, 18 H, CMe_3), 6.92 (b, 4 H, *o*-H), 7.18 (d, ^3J(H,H) = 7.7 Hz, 4 H, *m*-H) ppm. ^{13}C NMR: δ = 31.4 (CMe_3), 34.4 (C), 118.8 (*o*-C), 125.8 (*m*-C), 148.2 (*p*-C), 166.3 (*ipso*-C) ppm. Recrystallisation of a portion of the solid from benzene gave well formed crystals. [$C_{20}H_{26}Cl_2O_2Ti$: calcd. C 57.6, H 6.3; found C 57.5, H 6.5]. One of these crystals was used in the X-ray analysis.

$[TiCl_2(OC_6H_4CMe_3\text{-}4)_2(dmbipy)]$ (2): Dmbipy (0.24 g, 1.3 mmol) in CH_2Cl_2 (25 cm^3) was added to complex **1** (0.54 g, 1.3 mmol) in CH_2Cl_2 (30 cm^3) and the mixture was stirred for 2 h. The solution was filtered, the solvent removed and the residue allowed to stand under petroleum ether (20 cm^3) overnight giving the complex as a noncrystalline orange solid. Yield: 0.75 g, 97%. $C_{32}H_{38}Cl_2N_2O_2Ti$: calcd. C 63.6, H 6.3, N 4.6; found C 63.5, H 6.2, N 4.9. ^1H NMR: δ = 1.30 (s, 18 H, CMe_3), 2.39 (s, 6 H, Me-dmbipy), 7.23 and 7.27 [2d, (AB quartet),$^3J_{H,H}$ = 8.8 Hz, 8 H, *o*,-*m*-H], 7.27 (d, obsc., H^2-dmbipy), 7.93 (br. s, 2 H, H^4-dmbipy), 8.96 (d,$^3J_{H,H}$ 5.6 Hz, 2 H, H^1-dmbipy) ppm. ^{13}C NMR: δ = 21.5 (Me-dmbipy), 31.4 (CMe_3), 34.3 (C), 118.5 (*o*-C), 122.5 (C^2-dmbipy), 125.8 (*m*-C), 126.9 (C^4-dmbipy), 145.5 (*p*-C), 148.7 (C^1-dmbipy), 150.4 (C^3 or C^5-dmbipy), 152.4 (C^5 or C^3-dmbipy), 164.8 (*ipso*-C) ppm.

$[TiCl_2(OC_6H_2Me_3\text{-}2,4,6)_2]$ (3): 2,4,6-Trimethylphenol (4.31 g, 31.6 mmol) in toluene (50 cm^3) was added to $TiCl_4$ (3.0 g, 15.8 mmol) in toluene (50 cm^3) and the mixture was refluxed vigorously until the production of HCl gas ceased (10 h). The solution was cooled, filtered and the solvent removed to give the complex as a noncrystalline deep red solid. Yield: 5.97 g, 97%. $C_{18}H_{22}Cl_2O_2Ti$: calcd. C 55.6, H 6.1, Cl 18.2; found C 55.6, H 6.1, Cl 18.8. Cryoscopic mol. mass: found 395.4; required: 389.1. ^1H NMR: δ = 2.22 (s, 6 H, *p*-Me), 2.29 (s, 12 H, *o*-Me), 6.75 (s, 4 H, *m*-H) ppm. ^{13}C NMR: δ = 16.8 (*o*-Me), 20.8 (*p*-Me), 127.3 (*o*-C), 128.6 (*m*-C), 134.1 (*p*-C),166.4 (*ipso*-C) ppm.

$[TiCl_2(OC_6H_2Me_3\text{-}2,4,6)_2(dmbipy)]$ (4): Dmbipy (0.33 g, 1.79 mmol) in CH_2Cl_2 (30 cm^3) was added to complex **3** (0.69 g, 1.78 mmol) in CH_2Cl_2 (30 cm^3) and the mixture was stirred for 3 h. The solution was filtered, the solvent removed and the residue allowed to stand under petroleum ether (20 cm^3) overnight giving the complex as a noncrystalline orange solid. Yield: 1.02 g, 100%. $C_{30}H_{34}Cl_2N_2O_2Ti$: calcd. C 62.8, H 6.4, N 4.9; found C 62.4, H 6.4, N 4.8. ^1H NMR: δ = 2.23 (s, 6 H, *p*-Me), 2.38 (s, 6 H, Me-dmbipy), 2.51 (s, 12 H, *o*-Me), 6.75 (s, 4 H, *m*-H), 7.22 (d, $^3J_{H,H}$ 5.5 Hz, 2 H, H^2- dmbipy), 7.90 (br. s, 2 H, H^4-dmbipy), 8.99 (d, $^3J_{H,H}$ 5.5 Hz, 2 H, H^1-dmbipy) ppm. ^{13}C NMR: δ = 18.1 (*o*-Me), 20.6 (*p*-Me), 21.4 (Me-dmbipy), 122.6 (C^2-dmbipy), 126.5 (C^4-dmbipy), 128.9 (*m*-C), 129.3 (*o*-C), 131.6 (*p*-C), 148.6 (C^1-dmbipy), 150.4 (C^3 or C^5-dmbipy),151.9 (C^5 or C^3-dmbipy), 164.5 (*ipso*-C) ppm.

$[TiCl_2(OC_6H_3iPr_2\text{-}2,6)_2]$ (5): 2,6-Diisopropylphenol (3.76 g, 21.1 mmol) in toluene (50 cm^3) was added to $TiCl_4$ (2.0 g, 10.5 mmol) in toluene (50 cm^3) and the mixture was refluxed vigorously until the production of HCl gas ceased (13 h). The solution was cooled, filtered and the solvent removed to give an oil which failed to solidify over time. Yield: 4.96 g. The product gave an identical NMR spectra to a literature complex.[19]

$[TiCl_2(OC_6H_3iPr_2\text{-}2,6)_2(dmbipy)]$ (6): Dmbipy (0.31 g, 1.79 mmol) in CH_2Cl_2 (30 cm^3) was added to complex **5** (0.8 g, 1.79 mmol) in CH_2Cl_2 (30 cm^3) and the mixture was stirred for 3 h. The solution was filtered, the solvent removed and the residue allowed to stand under diethyl ether (50 cm^3) overnight giving the complex as a noncrystalline deep red solid. Yield: 1.03 g, 88%. $C_{36}H_{46}Cl_2N_2O_2Ti$: calcd. C 65.8, H 7.1, N 4.3; found C 65.9, H 7.0, N 4.8. ^1H NMR: δ = 1.10 (d, $^3J_{H,H}$ = 6.7 Hz, 24 H, CMe_2), 2.43 (s, 6 H, Me-dmbipy), 4.20 (sept, $^3J_{H,H}$ = 6.7 Hz, 4 H, CH), 7.07 (m, 6 H, *m*,*p*-H), 7.25 (d, $^3J_{H,H}$ = 5.4 Hz, 2 H, H^2-dmbipy), 7.92 (br. s, 2 H, H^4-dmbipy), 8.89 (d, $^3J_{H,H}$ = 5.4 Hz, 2 H, H^1-dmbipy) ppm. ^{13}C NMR: δ = 21.6 (Me-dmbipy), 24.5 (CMe_2), 26.1 (CH), 122.7 (C^2-dmbipy), 122.9 (*p*-C), 123.6 (*m*-C), 126.4 (C^4-dmbipy), 140.2 (*o*-C), 148.5 (C^1-dmbipy), 150.4 (C^3 or C^5-dmbipy), 151.8 (C^5 or C^3-dmbipy), 162.6 (*ipso*-C) ppm. The complex is slightly soluble in diethyl ether.

[$TiCl_2(OC_6H_3Me_2$-2,4)$_2$] (8): 2,4-Dimethylphenol (5.15 g, 42.2 mmol) in toluene (50 cm^3) was added to $TiCl_4$ (4.0 g, 21.1 mmol) in toluene (50 cm^3) and the mixture was refluxed vigorously until the production of HCl gas ceased (10 h). The solution was cooled, filtered and the solvent removed to give the complex as a noncrystalline deep red solid. Yield: 7.28 g, 96%. $C_{16}H_{18}Cl_2O_2Ti$: calcd. C 54.6, H 5.2, Cl 19.0; found C 54.6, H 5.4, Cl 19.4. Cryoscopic mol. mass: found 376.5; required: 360.0. ^{1}H NMR: δ = 2.23 (s, 6 H, Me), 2.25 (s, 6 H, Me), 6.82 (m, 4 H, *m*-H), 6.98 (d, $^3J_{H,H}$ = 7.2 Hz, 2 H *o*-H) ppm. ^{13}C NMR: δ = 16.5 (Me), 20.8 (Me), 119.3 (*o*-CH), 126.4 (*p*-C), 127.0 and 131.0 (*m*-CH), 134.2 (*o*-C), 165.2 (*ipso*-C) ppm.

[$TiCl_2(OC_6H_3$Me-2,4$)_2$(dmbipy)] (9): Dmbipy (0.25 g, 1.36 mmol) in CH_2Cl_2 (20 cm^3) was added to complex **7** (0.49 g, 1.78 mmol) in CH_2Cl_2 (20 cm^3) and the mixture was stirred for 2 h. The solution was filtered, the solvent removed and the residue allowed to stand under petroleum ether (20 cm^3) overnight giving the complex as a noncrystalline orange solid. Yield: 0.69 g, 93%. $C_{28}H_{30}Cl_2N_2O_2Ti$: calcd. C 61.8, H 5.6, N 5.1; found C 61.4, H 5.9, N 4.9. ^{1}H NMR: δ = 2.27 (s, 6 H, Me), 2.42 (s, 6 H, Me), 2.43 (s, 6 H, Me-dmbipy), 6.74 (d, $^3J_{H,H}$ = 8.1 Hz, $^4J_{H,H}$ = 1.2, 2 H, *m*-H), 6.85 (br. s, 2 H, *m*-H), 7.23 (d, $^3J_{H,H}$ = 5.5 Hz, 2 H, H^2-dmbipy), 7.46 (d, $^3J_{H,H}$ = 8.1 Hz, 2 H, *o*-H), 7.92 (br. s, 2 H, H^4-dmbipy), 8.88 (d, $^3J_{H,H}$ = 5.5 Hz, 2 H, H^1-dmbipy) ppm. ^{13}C NMR: δ = 17.0 (Me), 20.8 (Me), 21.5 (Me-dmbipy), 119.7 (*o*-CH), 122.5 (C^2-dmbipy), 126.9 (C^4-dmbipy), 127.0 (*m*-C), 127.2 (*p*-C), 130.8 (*m*-C), 131.9 (*o*-C), 148.5 (C^1-dmbipy), 150.4 (C^3 or C^5-dmbipy),152.2 (C^5 or C^3-dmbipy), 164.3 (*ipso*-C) ppm.

[$TiCl_2(OC_6H_3\{CMe_3\}_2$-2,4$)_2$] (10) and [$TiCl(OC_6H_3\{CMe_3\}_2$-2,4$)_3$]. Procedure A: 2,4-Di-*tert*-butylphenol (6.53 g, 31.6 mmol) in toluene (60 cm^3) was added to $TiCl_4$ (3.0 g, 15.8 mmol) in toluene (50 cm^3) and the mixture was refluxed vigorously until the production of HCl gas ceased (12 h). The solution was cooled, filtered and the solvent removed to give an oil which solidified on standing overnight. NMR spectroscopy showed the product consisted of complex **10** [^{1}H NMR: δ = 1.33 (s, 18 H, CMe_3), 1.52 (s, 18 H, CMe_3), 7.14–7.25 (m, 4 H, *o*,*m*-H), 7.34 (d, $^4J_{H,H}$ 2.1 Hz, 2 H, *m*-H) ppm. ^{13}C NMR: δ = 30.3 (CMe_3), 31.4 (CMe_3), 34.7 (C), 35.1 (C), 123.3 (*o*-CH), 123.4 (*m*-CH), 124.2 (*m*-CH), 135.8 (*p*-C), 148.0 (*o*-C), 165.7 (*ipso*-C) ppm], and [$TiCl(OC_6H_3\{CMe_3\}_3$-2,4$)_3$], which was crystallised from the mixture by dissolving the reaction product in petroleum ether (100 cm^3), reducing the volume to ca. 50 cm^3 while keeping the solution hot, then allowing it to stand and cool. [$C_{42}H_{63}ClO_3Ti$: calcd. C 72.1, H 9.1; found C 72.7, H 9.4].

Procedure B: A solution of *n*-butyllithium (13.2 cm^3, 1.6 mol·L^{-1}) in hexane was added dropwise to a solution of 2,4-di-*tert*-butylphenol (4.35 g, 21.1 mmol) in benzene (50 cm^3) chilled with ice-water. The cooling bath was removed and the mixture stirred for 1 h. The solution and precipitated solid was added slowly to $TiCl_4$ (2.0 g, 10.5 mmol) in benzene (50 cm^3) via a cannula and the mixture stirred overnight. The mixture was allowed to stand for 24 hours to settle the precipitated LiCl, the solution was filtered and the solvent removed to give a red solid which was shown to be a mixture of complex **10** and [$TiCl(OC_6H_3\{CMe_3\}_3$-2,4$)_3$] by NMR spectroscopy. Crystallisation of the mixture as for procedure A, gave [$TiCl(OC_6H_3\{CMe_3\}_3$-2,4$)_3$] [$C_{42}H_{63}ClO_3Ti$: calcd. C 72.1, H 9.1; found C 71.1, H 9.9] which had identical NMR spectra with the sample prepared under procedure A.

[$TiCl_2(OC_6H_3CMe_3$-2-Me-6$)_2$] (11): 2-*tert*-Butyl-6-methylphenol (5.2 g, 31.7 mmol) in toluene (40 cm^3) was added to $TiCl_4$ (3.0 g, 15.8 mmol) in toluene (30 cm^3) and the mixture was refluxed vigorously until the production of HCl gas ceased (18 h). The solution was cooled, filtered from a small amount of solid and the solvent removed to give the complex as an oil which turned into a noncrystalline orange-red solid on standing. Yield: 6.80 g, 96%. $C_{22}H_{30}Cl_2O_2Ti$: calcd. C 59.3, H 6.8, Cl 15.9; found C 59.3, H 6.7, Cl 15.8. Cryoscopic mol. mass: found 454.4; required: 445.3. ^{1}H NMR: δ = 1.52 (s, 18 H, CMe_3), 2.29 (s, 6 H, Me), 6.93 (t, $^3J_{H,H}$ = 7.6 Hz, 2 H, *p*-H), 7.00 (d, $^3J_{H,H}$ = 7.6, $^4J_{H,H}$ = 1.2 Hz, 2 H, *m*-H), 7.17 (d, $^3J_{H,H}$ = 7.6, $^4J_{H,H}$ = 1.2 Hz, 2 H, *m*-H) ppm. ^{13}C NMR: δ = 18.5 (Me), 30.3 (CMe_3), 35.0 (C), 124.6 (*m*-C), 124.7 (*m*-C), 129.1 (*p*-C), 131.1 [*o*-C(methyl)], 137.7 [*o*-C(*tert*-butyl)], 169.3 (*ipso*-C) ppm.

[$TiCl_2(OC_6H_3CMe_3$-2-Me-6$)_2$(dmbipy)] (12): Dmbipy (0.32 g, 1.75 mmol) in CH_2Cl_2 (25 cm^3) was added to complex **11** (0.78 g, 1.75 mmol) in CH_2Cl_2 (30 cm^3) and the mixture was stirred for 3 h. The solution was filtered, the solvent removed and the residue allowed to stand under petroleum ether (20 cm^3) overnight giving the complex as a noncrystalline orange solid. Yield: 0.60 g, 55%. $C_{34}H_{42}Cl_2N_2O_2Ti$: calcd. C 64.9, H 6.7, N 4.5; found C 64.5, H 7.0, N 4.5. ^{1}H NMR: δ = 1.48 (s, 18 H, CMe_3), 2.46 (s, 6 H, Me-dmbipy), 2.76 (s, 6 H, Me-phenoxo), 6.84 (t, $^3J_{H,H}$ = 7.4 Hz, 2 H, *p*-H), 6.99 (bd, 2 H, *m*-H), 7.17 (bd, 2 H, *m*-H), 7.22 (d, $^3J_{H,H}$ 5.5 Hz, 2 H, H^2-dmbipy), 7.93 (br. s, 2 H, H^4-dmbipy), 8.84 (d, $^3J_{H,H}$ 5.5 Hz, 2 H, H^1-dmbipy) ppm. ^{13}C NMR: δ = 21.5 (Me-dmbipy), 21.8 (Me), 31.7 (CMe_3), 35.6 (C), 122.1(CH), 124.5 (CH), 129.8 (CH), 133.0 [*o*-C(methyl)], 140.8 [*o*-C(*tert*-butyl)], 148.6 (C^1-dmbipy), 150.6 (C^3 or C^5-dmbipy), 151.5 (C^5 or C^3-dmbipy), 166.4 (*ipso*-C) ppm. The complex is slightly soluble in petroleum ether.

[$TiCl_2(OC_6H_4$Ph-2$)_2$] (13): 2-Phenylphenol (5.38 g, 31.6 mmol) in CH_2Cl_2 (60 cm^3) was added to $TiCl_4$ (3.0 g, 15.8 mmol) in CH_2Cl_2 (40 cm^3) and the mixture was refluxed vigorously until the production of HCl gas ceased (12 h). The solution was cooled, filtered and the solvent removed to give the complex as an oil which turned into a noncrystalline deep red solid on standing for several days. Yield: 7.21 g, 100%. $C_{24}H_{18}Cl_2O_2Ti$: calcd. C 63.1, H 4.0, Cl 15.5; found C 63.4, H 4.1, Cl 15.5. Cryoscopic mol. mass: found 471.3; required: 457.2. ^{1}H NMR: δ = 6.91–7.49 (m, 18 H, aromatic-H's) ppm. ^{13}C NMR: δ = 115.9, 120.3, 124.3, 127.5, 128.4, 128.5, 129.0, 129.3, 130.1, 137.0 (*o*-C), 161.9 (*ipso*-C) ppm.

[$TiCl_2(OC_{10}H_9)_2$] (14): 1-Napthol (4.56 g, 31.6 mmol) in toluene (60 cm^3) was added to $TiCl_4$ (3.0 g, 15.8 mmol) in toluene (30 cm^3) and the mixture was refluxed vigorously until the production of HCl gas ceased (12 h). The solution was cooled, filtered and the solvent removed to give the complex as a noncrystalline solid. Yield: 6.8 g, 100%. $C_{20}H_{14}Cl_2O_2Ti$: calcd. C 61.3, H 3.9, Cl 16.4; found C 61.4, H 4.1, Cl 15.9. Cryoscopic mol. mass: found 426.9; required: 405.0. The ^{1}H NMR spectrum shows the product contains a small amount of toluene which is difficult to remove by pumping.

Theoretical: Density functional (DFT) calculations were carried out on the model compound [$TiCl_2(OC_6H_5)_2$] and its possible dimeric structures using a hybrid Becke three parameter function together with the Lee–Yang–Parr correlation function (B3LYP).[25,26] For H, C and O a Dunning/Huzinaga valence double-zeta set was used.[27] For Ti and Cl we applied the pseudopotential approximation using the Hay–Wadt parametrization together with valence double-zeta basis.[28] This resulted in 934 basis functions contracted to 368 for the dimeric species. The geometries were fully optimized until the gradients were below 10^{-5} a.u. which took several months of supercomputer time on a 16-processor SGI. The structures are shown in Figure 2 and Figure 4. All calculations were performed with a parallel version of Gaussian98[29] The bonding situation has

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

been examined using the natural bond orbital (NBO) partitioning of Weinhold and Reed.[21]

X-ray Crystallography: Data were collected with a Siemens Bruker CCD instrument with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) at T = 203(2) K. Crystal decay was monitored by repeating the initial frames at the end of the data collection and analysing the duplicate reflections. This was negligible. Unit cell parameters were obtained by a least-squares fit of all data with $I > 10\ \sigma(I)$. Data were corrected for Lorentz, polarisation and absorption effects.[30] The structures were solved by direct methods and refined on all F^2 by the full-matrix least-squares technique. All non-hydrogen atoms were allowed to assume anisotropic thermal motion. Hydrogen atoms were in calculated positions (C–H, 0.94 Å for phenyl ring H and 0.97 Å for *tert*-butyl H) and refined with a riding model with U_{iso} = 0.08. Programs used were SHELXS[31] for structure solution and SHELXL[32] for refinement. Diagrams were prepared with ORTEP-3 for WINDOWS®.[33]

Crystal Data: [$C_{20}H_{26}Cl_2O_2Ti$], M = 417.21, monoclinic, space group $P\ 2_1/c$, a = 11.265(2), b = 18.603(3), c = 11.491(2) Å, β = 116.59(3)°, V = 2153.4(6) Å^3, Z = 4, $D_{calcd.}$ = 1.287 mg m^3, μ (Mo-K_α) = 0.655 mm^{-1}, crystal size 0.23 × 0.22 × 0.14 mm, ω scans, $\theta_{max.}$ = 28.19°, F(000) = 872, 12833 reflections measured, 4783 unique ($R_{int.}$ = 0.0381), $I_{min.}/I_{max.}$ = 0.8639/0.9139, R_1 = 0.0547 [$I > 2\sigma(I)$], wR_2 = 0.1210 (all data).

CCDC-249718 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Nitrosyl Ruthenium Diolato Complexes[‡]

Michael Barth,[a] Xaver Kästele,[a] and Peter Klüfers*[a]

Keywords: Ruthenium / Nitrosyl / Diols / Carbohydrate complexes

[*mer*-(dien)(NO)Ru(AnErytH$_{-2}$)]BPh_4·2H_2O (**1**), [*mer*-(dien)(NO)Ru(*R*,*R*-ChxdH$_{-2}$)]BPh_4 (**2**), [*mer*-(dien)(NO)Ru(EthdH$_{-2}$)]BPh_4 (**3**), and [*mer*-(dien)(NO)Ru(Me-β-D-Rib*f*2,3H$_{-2}$)]BPh_4·5.5H_2O (**4**) have been synthesized in the form of light pink crystals by the reaction of [*mer*-(dien)(NO)$RuCl_2$]X with the respective diol in aqueous sodium hydroxide solution (dien = diethylenetriamine, AnEryt = anhydroerythritol, Chxd = cyclohexane-1,2-diol, Ethd = ethanediol, Rib = ribose; X = BPh_4 or PF_6). The nitrosyl ligand exhibits a strong *trans* influence which causes the *trans*-bonded oxygen atom of the diolato ligand to form a shorter bond with the Ru centre. Mean values are 2.038 for *cis* and 1.946 Å for *trans* *O*-binding. Back donation is strongly supported by the diolato ligand resulting in low energies for the N–O stretch which can be observed as low as 1805 cm^{-1}. *trans*-Oxygen atoms do not act as hydrogen-bond acceptors in any of the cases.

Introduction

Ruthenium and its compounds are a class of particularly significant catalytically active materials. Carbohydrates on the other hand provide a biogenic, renewable feedstock which, however, is burdened with the problem of "overfunctionalisation". This term emphasises the fact that it is not merely the number but the similarity of the functional groups which causes problems with regioselectivity. Problems of this kind are typically solved in chemistry by means of catalysis. Bearing in mind the aims of the currently topical green chemistry, which promotes both catalytic reactions and the use of renewable resources, it is surprising that there is no structural information on the interaction of ruthenium centres and carbohydrates. This statement holds not only for monosaccharides but also for simple diols which provide the basic functional group of carbohydrates for metal chelation. This paper reports the synthesis and structural characterisation of the first diolato-ruthenium complexes in both the solid-state and solution. As starting materials, we used aqueous solutions of *trans*-dichloro-*mer*-diethylenetriamine-nitrosyl ruthenium(III) salts[1] which contain a nitrosyl ligand linearly bonded to the ruthenium centre thus forming the well-known, tricationic $\{RuNO\}^6$ fragment (for the Enemark–Feltham notation cf. ref.[2]). In the context of the hormonal action of nitrous oxide, the chemistry[3] of $\{RuNO\}^6$-type complexes has recently attracted interest in its own right due to the physiological activity of these species.[4,5]

Results and Discussion

Synthesis of Crystalline [*mer*-(dien)(NO)Ru(DiolH$_{-2}$)] Tetraphenylborates

[*mer*-(dien)(NO)$RuCl_2$]BPh_4 reacts with anhydroerythritol (*cis*-oxolane-3,4-diol, AnEryt) in aqueous alkaline solution over the course of 2 h at 70 °C to yield the tetraphenylborate salt of the complex cation [*mer*-(dien)(NO)Ru(AnErytH$_{-2}$)]$^+$ without concomitant removal of the chloro ligands by special reagents such as silver oxide (method 1 in the Experimental Section). The application of slightly harsher reaction conditions allowed the synthesis of the same product to be initiated directly from nitrosyl-ruthenium chloride, diethylenetriamine and anhydroerythritol (method 2 in the Experimental Section). Method 1 achieved completion as judged by NMR spectroscopy. The precipitate was of a colour similar to the crystals. Method 2, however, results in a more or less brown precipitate which clearly contains by-products. Structural analyses using light pink crystals of the products from both methods revealed the formula [*mer*-(dien)(NO)Ru(AnErytH$_{-2}$)]BPh_4·2H_2O (**1**). Complexes of less acidic diols have been prepared with (*R*,*R*)-cyclohexane-1,2-diol [(*R*,*R*)-Chxd] and ethane-1,2-diol (Ethd). Both diols are less reactive than oxolanediol in terms of the diol remaining uncoordinated after the reaction with the ruthenium starting material in an approximately equimolar ratio according to method 1. Hence, about half of the cyclohexanediol and about one fifth of the ethanediol react in this experimental setup. Crystallisation achieved according to the procedures given in the Experimental Section yielded solvent-free crystals containing the attempted diolato complexes with the formulae [*mer*-(dien)(NO)Ru(*R*,*R*-ChxdH$_{-2}$)]BPh_4 (**2**) and [*mer*-(dien)-(NO)Ru(EthdH$_{-2}$)]BPh_4 (**3**). Attempts to include a carbo-

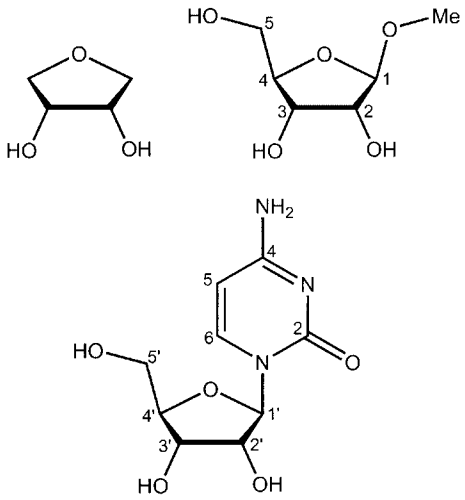
hydrate derivative were successful for methyl-β-D-ribofuranoside which contains the anhydroerythritol core (Scheme 1). Here, red crystals of [*mer*-(dien)(NO)Ru(Me-β-D-Rib*f*2,3H$_{-2}$)]BPh_4·5.5H_2O (**4**) were obtained by applying method 2.



Scheme 1.

The Diolato-{RuNO}^{6} Moiety

The structures of the four complex cations (**1**: Figure 1, **2**: Figure 2, **3**: Figure 3, **4**: Figures 4 and 5) reveal dianionic diolato(2–) ligands bonded to an octahedrally coordinated ruthenium centre. Isomerisation occurred during the course of the reaction: in the starting complex, one nitrogen atom of the dien ligand is *trans* to the nitrosyl group, whereas in the product, all three nitrogen atoms of the *mer*-dien ligand are bonded *cis* to the NO.

parameters have been listed in Table 1. There are some features common to **1**–**4**: (1) the Ru–O(*trans*) distance is always markedly shortened compared with the Ru–O(*cis*) distance, (2) the Ru–O(*trans*)–C angle is always more obtuse than the Ru–O(*cis*)–C angle and, most remarkably, considering the usual features of polyolato-metal structures, (3) the O(*trans*) centre does not act as a hydrogen-bond acceptor in any of the structures. On the other hand, O(*cis*) is a hydrogen-bond acceptor, as is usual.

The energies for the N–O stretching vibration are rather low, the minimum being 1805 cm^{-1} for **2** (cf. 1889 cm^{-1} for the starting material complex [*mer*-(dien)(NO)RuCl_2]BPh_4

with a *trans*-Cl–Ru–NO moiety). Such low values may be expected for *trans* ligands which effectively support electron density donation into the NO π* orbital. Hence, it is not surprising that both the geometric and spectroscopic parameters of **1**–**4** resemble three closely related methoxo and ethoxo complexes which have been reported very recently by Nagoa et al.[6,7] Using pyridine-2-carboxylate (pyca) groups as coligands, these authors reported structural and spectroscopic data for *cis*-[6] and *trans*-[Ru(NO)(OMe)(pyca)$_2$],[7] *cis* and *trans* referring to the orientation of the NO group and the methoxo ligand. These data have been added to Table 1 for comparison. In addition, IR data have been reported on the ethoxo homologue[6] which shares, with our diolates, a low value for the NO stretch of 1815 cm^{-1}. It should be noted that the rules derived by Nagoa et al. regarding the stability of isomers at the {RuNO}^{6} centre are supported by our data. According to these rules, isomers with one of the dien-nitrogen atoms *trans* to the nitrosyl group should be less stable than the species which have been isolated. The number of isomers is thus limited. Due to the equivalence of the hydroxy groups of the parent diols of **1**–**3**, only one isomer can be expected for a diolato complex. In fact, only one ^{13}C signal can be observed for each carbon atom which is part of a ruthenium complex in each of the respective reaction mixtures.

NMR Spectroscopy

One of the reasons for starting the investigation of ruthenium-carbohydrate interactions with {RuNO}^{6} complexes is because of their diamagnetism which enables monitoring of the progress of polyolate binding to the ruthenium centre by NMR spectroscopy. ^{13}C NMR spectra of solutions of **1**–**4** in fact show a marked "coordination-induced shift" (CIS) – a typical down-field shift of the signals of the diol carbon atoms which bear metal-binding oxygens. In addition, the kinetic inertness of the starting material and the product ruthenium complexes is the reason why the signals of metal-bonded and nonbonded diols occur separately in the spectra. This includes the NMR behaviour of possible coordination isomers which, however, are missing for **1**–**3** due to the reasons discussed in the previous paragraph. CIS values are best taken from the spectra of the aqueous reaction mixtures since they contain both the signals of the complex and the free diol (DMSO spectra of the pure products, which are given in the Experimental Section, do not

Table 1. show the free diol signals. Hence, a less realistic reference state must be defined). CIS values range from ca. 8 to 15 ppm for **1**–**3** (**1**: 15.0, 13.7 for diol carbons; 3.4, 3.1 for carbons adjacent to the coordinating diol; **2**: 11.6, 9.1 and 1.3, 1.1 in addition to 0.3, 0.2 for the carbons most distant from Ru; **3**: 9.9, 8.1 ppm). For **4** and the related diol cytidine, the coordination induced shifts are slightly larger (Table 2 and Table 3). It is likely that a connection could be made between the differences in the diol CIS values (**1**: 1.3, **2**: 2.5, **3**: 1.7, **4**: 1.9, 2.0; cytidine: 0.7, 2.0) and *cis* and *trans* bonding to NO. However, no sound assignment is possible on the basis of the present data.

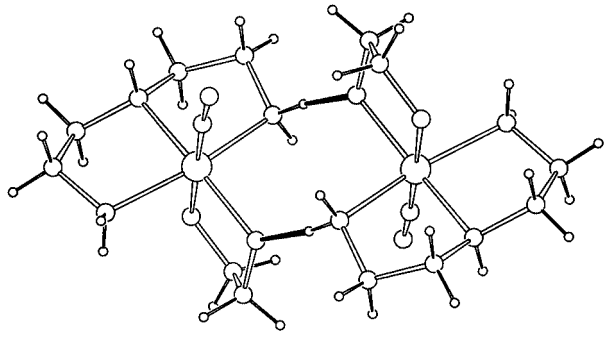

Figure 6. The C_i-symmetric dimer in crystals of **3**. The metric parameters of the hydrogen bond are: N4–H741 0.92, H···O2^{i} 1.76, N4···O2^{i} 2.672(3) Å, N4–H–O2^{i} 170°; symmetry code: ^{i} 1 – *x*, –*y*, –*z*. Similar, but C_1-symmetric dimers are present in the chiral crystals of **2** with the parameters: N3–H732 0.90, H···O5 1.84, N3···O5 2.729(6) Å, N3–H–O5 171°; N7–H771 0.90, H···O1 1.89, N7···O1 2.772(6) Å, N7–H–O1 165°.

Hydrogen Bonds

The individual crystal structures have some special features. Although crystallised from aqueous solution, crystals of **2** and **3** are anhydrous. Hence the N–H functions of the dien ligand are the only possible hydrogen-bond donors. In both structures, only one hydrogen bond is established towards each O(*cis*) acceptor but these bonds are unusually short when compared with N–H···O bonds usually found in polyolato-metal complexes – the shortest one having been observed in **3**: N···O2(*cis*) is 2.672(3) Å. Also, in both structures, two complex cations are linked by two such bonds to form a hydrogen-bonded dimer – a centrosymmetric dimer in **3** (Figure 6) and a similarly assembled dimer of the two symmetrically independent cations of the asymmetrical unit in crystals of the chiral complex **2**.

While there are dimers embedded in an assembly of the large tetraphenylborate counterions in **2** and **3**, the O(*cis*) atoms in **1** and **4** are hydrogen-bonded to water donors and, concomitantly, the complex cations form a structure with the counterions without having close contacts with one another. The structure determination for **1**, which was of a higher quality than that of **4**, reveals typical hydrogen-bonding parameters for the furanoidic ligand with the exception of the lack of such bonds towards the *trans*-oxygen (Table 4). It should be noted that the presence of additional hydrogen-bond acceptors (**1**) or donors and acceptors (**4**) is clearly not the reason for the presence or absence of water molecules in the crystals and the assembly of dimers and vice versa. Using *cis*-cyclopentane-1,2-diol (*cis*-Cptd), which parallels ethanediol and cyclohexanediol in being a simple diol without further functionality, a preliminary structure determination on centrosymmetric triclinic crystals of low quality revealed a hydrated product [*mer*-(dien)(NO)Ru(*cis*-CptdH$_{-2}$)]BPh$_4$·3H$_2$O (**5**). The structure of the complex cation follows the rules presented above. As in **1** and **4**, individual cations and not dimers are embedded in separated counterion surroundings.

Isomers in the Case of Glycoside and Nucleoside Ligation

As mentioned, the hydroxy groups of the diol functions of anhydroerythritol, (*R*,*R*)-cyclohexane-1,2-diol and ethane-1,2-diol are equivalent. Hence no isomers are formed upon rotating the diol functions at the ruthenium centre. The riboside ligand is different in this respect and two iso-

N3	H732	O91[iii]	0.85(3)	2.04(3)	2.874(3)	168(3)

mers can be expected – one in which O2 is the *trans*-oxygen and the other in which O3 occupies that position. Indeed, both isomers are present in crystals of **4**. Formation of the crystals was somewhat unusual. After a brown slurry had precipitated, crystals of **4** grew within this slurry over the course of three days, leaving part of the slurry unchanged. NMR spectra of the redissolved crystals showed the expected number of signals which is twice the number of carbon atoms of the riboside. NMR spectra of the brown residue obtained by washing, filtering and redissolving the slurry in dimethyl sulfoxide, clearly consist of only one half of the signals of the crystalline material. Obviously, the two isomers are not formed in equal amounts during the course of the reaction as expected but there is a main species. Crystallisation proceeds to the point where all of the minor species is spent, leaving the remaining major species in its finely divided state.

Due to the difference in back donation, parameters connected with the {RuNO}^{6} moiety should reflect whether O2 or the slightly more basic O3 atom is *trans* to the ruthenium centre. A measure of this difference is the energy of the N–O stretch. Actually, Figure 7 shows the absorption to be slightly split. Lorentz curve-fitting yields peak values of 1819 and 1838 cm^{-1}. Though the existence of two isomers has been demonstrated from X-ray work as well as NMR and IR spectroscopy, assignment of the spectroscopic data to an individual structure remains uncertain. If higher back donation is assigned to the more basic O3, the main species in the reaction mixture should, hence, be the O3(*trans*) isomer. It should be noted that the quality of the structure analysis did not produce sufficiently sound values for the bond lengths to contribute meaningfully to this study (cf. Experimental Section).

The related nucleosides react differently with the ruthenium starting material. No substantial shift in the ribose signals was observed for uridine and guanosine which bind to ruthenium through the uracil and guanidine residues, respectively. Note that both nucleosides can provide deprotonated amide functions which are obviously stronger ligands for ruthenium than a diolate. With cytidine, however, the ^{13}C NMR spectra closely resemble those of the methyl-β-D-ribofuranoside complexes (cf. the formulae in Scheme 1). The ratio of the major and minor isomers depends on the synthetic procedure chosen. When prepared as described in the Experimental Section by means of microwave heating, there is a distinct difference in the two isomers. Hence, assignment of the signals to one of the isomers is unambiguous. All attempts to crystallise one or both of the isomers have proved unsuccessful so far. The procedure given yielded small needles or platelets both of which were too weakly diffracting for structural analysis.

Conclusions

The {RuNO}^{6} moiety is a well-suited metal fragment for diolate binding. The diolato ligand markedly strengthens back-donation to the nitrosyl ligand. Hence, the energy values for the N–O stretching vibration slightly above 1800 cm^{-1} are at the lower end of those reported in the literature. The applied synthetic methods are suitable for the preparation of complexes of simple diols, nucleosides and other glycosides which are stable under more strongly alkaline conditions and at elevated temperatures. Work is in progress to prepare compounds of this type at conditions which are mild enough such that ruthenium complexes of monosaccharides can also be synthesized.

Experimental Section

trans-Dichloro-*mer*-diethylenetriamine-nitrosyl ruthenium(III) tetraphenylborate (**6**) and *trans*-dichloro-*mer*-diethylenetriamine-

nitrosyl ruthenium(III) hexafluorophosphate (**7**) were prepared according to the literature.[1] The results reported appear to be independent of the supplier of the diols, diethylenetriamine and the salts which provide the counterions. It should be noted, however, that the appearance of $Ru(NO)Cl_3 \cdot H_2O$ differs from one supplier to the other. For **1**, we used $Ru(NO)Cl_3 \cdot H_2O$ from Strem and anhydrous $Ru(NO)Cl_3$ from ABCR. For **4**, $Ru(NO)Cl_3 \cdot H_2O$ from Chempur was used.

For the reactions with cytidine a CEM Discover microwave oven was used.

$^{13}C\{^1H\}$ spectra were recorded using 1 mL of the appropriate filtered aqueous reaction mixture in a 5 mm tube. Reference signals of the free diols were subsequently recorded after addition of the respective diol to the measured reaction mixture. Equipment used: ^{13}C NMR spectroscopy: Jeol EX-400. Mass spectrometry: Jeol JMS-700 (ionisation method: FAB^+). IR spectroscopy: Nicolet 520-FTIR.

The equipment used for the structure determinations was an Enraf Nonius KappaCCD diffractometer in the case of **2**–**4** (rotating anode, 4.125 kW source power, Mo-K_α radiation, graphite monochromator) and a Stoe IPDS instrument (sealed tube, 2.75 kW source power, Mo-K_α radiation, graphite monochromator) for **1**. Crystallographic data are summarised in Table 5.

CCDC-226508 (for **1**), 226509 (for **2**), 226510 (for **3**) and 226511 (for **4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

In the structure determination of **3**, a high residual density of 3.4 e Å^{-1} was calculated at a distance of 1.3 Å from Ru. The reason for this high value remains unclear and the next density was as low as 0.6 e Å^{-1}. The structure determination using a crystal of **4** was complicated by a considerable degree of pseudo-symmetry. Though being built up from a chiral motif, most atoms of the unit-cell keep to a centrosymmetric arrangement. Hence, most of the structure can be described in space group $P\bar{1}$ (instead of $P1$). The origin of the pseudosymmetry of the crystals is the pseudosymmetry of the methyl-β-D-ribofuranoside ligand. Taking the methoxy residue at C1 and the hydroxymethyl substituent at C4 as equivalent (Scheme 1), the riboside exhibits C_s symmetry. It is not usual for this pseudosymmetry to find itself expressed in a crystal structure since a hydroxymethyl residue, being a hydrogen-bond donor, is clearly different from the more hydrophobic methoxy group. However, in the structure of **4**, this rare case is realised and it interferes with the structure refinement.

***mer*-Diethylenetriamine-{*cis*-oxolane-2,3-diolato(2–)}-nitrosyl Ruthenium(III) Tetraphenylborate Dihydrate (1). Method 1:** Compound **6** (667 mg, 1.068 mmol) was dissolved in hot water (350 mL) with vigorous stirring. The pH value was adjusted to 12 by addition of 2 M sodium hydroxide. After addition of anhydroerythritol (111 mg, 1.068 mmol), the solution was heated to 70 °C for 2 h. Upon cooling, an orange-pink precipitate formed which was filtered off, washed with some water and dried under vacuum to yield ca.

200 mg of a pink solid. Dissolving the solid in as small an amount of methanol as possible followed by slow evaporation of the solvent gave light pink crystals of **1**. Compound **1** is slightly soluble in water and ethanol and very soluble in methanol. $C_{32}H_{43}BN_4O_6Ru$ (691.59): calcd. C 55.6, H 6.3, B 1.56, N 8.1, Ru 14.6; found C 56.9, H 6.3, B 1.50, N 8.1, Ru 14.9. ^{13}C NMR (100 MHz, [D_6] DMSO): δ = 164.7–163.2 (4 signals, phenyl, C_{ipso}), 136.1 (phenyl, C_{ortho}), 125.9 (phenyl, C_{meta}), 122.1 (phenyl, C_{para}), 88.1, 87.8 (diol, 2H, CH), 77.1, 75.5 (diol, 2H, CH_2), 50.8, 50.4, 50.2, 49.8 (dien, 4H, CH_2) ppm. MS (FAB^+): *m*/*z* (%) = 337 (15) $[M + H]^+$, 336 (8) $[M]^+$. IR (KBr): $\tilde{\nu}$ = 1825 (vs, N–O), 1579 (vw), 1480 (w), 1453 (w), 1427 (w), 1119 (w), 1052 (sh), 1035 (m), 739 (st), 710 (st), 612 (m) cm^{-1}.

Method 2: Anhydrous nitrosyl-ruthenium(III) chloride (445 mg, 1.87 mmol) or the equivalent amount of nitrosyl-ruthenium(III) chloride monohydrate was dissolved in water (20 mL). The pH value was adjusted to 11 by addition of 2 M sodium hydroxide. A solution of diethylenetriamine (193 mg, 1.87 mmol) and anhydroerythritol (195 mg, 1.87 mmol) in water (5 mL) was added dropwise. The pH value was readjusted to 11 by addition of either 0.1 M hydrochloric acid or 0.1 M sodium hydroxide and the solution was then heated to reflux for 3 h. Excess sodium tetraphenylborate was then added to the hot solution. A pink to light-brown precipitate formed which was filtered off, washed with cold water and recrystallised from methanol to yield light pink crystals of **1**. Both methods yield ca. 10% of the crystalline product.

***mer*-Diethylenetriamine-{*R*,*R*-cyclohexane-1,2-diolato(2–)}-nitrosyl Ruthenium(III) Tetraphenylborate (2):** Compound **6** (580 mg, 0.929 mmol) was dissolved in water (300 mL). The pH value was adjusted to 13 with 2 M sodium hydroxide and (*R*,*R*)-cyclohexane-1,2-diol (324 mg, 2.79 mmol) was added. The resultant solution was heated to reflux at 80 °C for 2 h. After standing overnight, a mixture of yellow-pink crystals of **2** and colourless crystals of unreacted starting material were formed. Compound **2** is poorly soluble in water but freely soluble in methanol. $C_{34}H_{43}BN_4O_3Ru$ (667.61): calcd. C 61.2, H 6.5, B 1.62, N 8.4, Ru 15.1; found C 60.9, H 6.4, B 1.51, N 8.3, Ru 15.0. ^{13}C NMR (100 MHz, [D_6]DMSO): δ = 164.7–163.2 (4 signals, phenyl, C_{ipso}), 136.1 (phenyl, C_{ortho}), 125.9 (phenyl, C_{meta}), 122.1 (phenyl, C_{para}), 89.0, 88.5 (diol, 2 CH), 50.8, 50.4, 50.2, 49.8 (dien, 4 CH_2), 35.6, 34.9 (diol, 2 CH_2), 23.1 (diol, 2 isochronous CH_2); signals of the free diol in water: δ = 73.9 (2 CH; C1, C2), 31.5 (2 CH_2; C3, C6), 22.7 (2 CH_2; C4, C5) ppm. MS (FAB^+): *m*/*z* (%) = 349 (65) $[M + H]^+$, 348 (37) $[M]^+$. IR (KBr): $\tilde{\nu}$ = 1805 (vs, N–O), 1579 (m), 1568 (sh), 1480 (m), 1455 (m), 1427 (m), 1089 (m), 1071(m), 1034 (m), 739 (st), 709 (st), 641 (st), 610 (st) cm^{-1}.

***mer*-Diethylenetriamine-{1,2-ethanediolato(2–)}-nitrosyl Ruthenium(III) Tetraphenylborate (3):** Compound **7** (97 mg, 0.216 mmol) was dissolved in water (10 mL). 1,2-Ethanediol (11 mg, 0.216 mmol) was added, the pH value adjusted to 12.5 by addition of 2 M sodium hydroxide and the reaction mixture heated to 70 °C for 2 h. The cooled solution was then carefully layered with sodium tetraphenylborate solution (5 mL) which had been saturated at room temperature. Reddish-brown prisms of **3** crystallised overnight at the boundary between the layers. Solution behaviour resembles that of **2**. $C_{30}H_{37}BN_4O_3Ru$ (613.52): calcd. C 58.7, H 6.1, B 1.76, N 9.1, Ru 16.5; found C 58.7, H 6.1, B 1.56, N 8.9, Ru 16.3. ^{13}C NMR (100 MHz, H_2O): δ = 72.4, 74.2 (diol, 2 CH_2), 50.7, 50.5, 50.1, 49.8 (dien, 4 CH_2); signal of the free diol in the same solution: δ = 64.3 ppm. MS (FAB^+): *m*/*z* (%) = 293 (19) $[M + H]^+$, 292 (17) $[M]^+$. IR (KBr): $\tilde{\nu}$ = 1823 (vs, N–O), 1578 (w), 1453 (w), 1427 (w), 1073 (m), 1054 (m), 1033 (m), 749 (sh), 736 (st), 710 (st), 614 (m) cm^{-1}.

***mer*-Diethylenetriamine-{methyl-β-D-ribofuranosid-2,3-ato(2–)}-nitrosyl Ruthenium(III) Tetraphenylborate 5.5-Hydrate (4):** $Ru(NO)Cl_3 \cdot H_2O$ (0.256 g, 1.00 mmol) was suspended in water (10 mL) and diethylenediamine (0.103 g, 1.00 mmol) in water (2 mL) was added. A red solution formed immediately. Methyl-β-D-ribofuranoside (0.164 g, 1.00 mmol) dissolved in water (3 mL) was added followed by the dropwise addition of NaOH (1.5 mL, 2 M, pH ≈ 11.5). The reddish-brown solution was heated to 100 °C for 3 h (about half of the free glycoside was left in the reaction mixtures containing a 1:1 molar ratio of the ruthenium starting material and the furanoside; however, in terms of NMR spectra, no more product forms after prolonged reaction times). After cooling, sodium tetraphenylborate (0.342 g, 1.00 mmol) in water (15 mL) was added and a brown slurry precipitated. Over the course of 3 d, red crystals of **4** formed which were separated from the slurry by flotation (16% yield). Compound **4** is insoluble in water, ether and dichloromethane but dissolves in DMSO to yield a light-red solution. ^{13}C NMR (100 MHz, [D_6]DMSO): major isomer: δ = 111.3 (C1), 91.4 (C2), 89.7 (C3), 88.9 (C4), 65.1 (C5), 54.6 (C6); minor isomer: 112.3 (C1), 92.9 (C2), 88.8 (C3), 88.3 (C4), 64.0 (C5), 54.9 (C6); the signals of the phenyl residues of the counterion coincide for both isomers, the dien signals coincide partly: 164.7–163.2 (4 signals, phenyl, C_{ipso}), 136.1 (phenyl, C_{ortho}), 125.9 (phenyl, C_{meta}), 122.1 (phenyl, C_{para}); 50.9, 50.7, 50.5, 50.2, 49.9, 49.7 (dien, 4 CH_2 of 2 isomers) ppm.

Reaction of Cytidine with [*mer*-(dien)(NO)$RuCl_2$]PF_6: [*mer*-(dien)(NO)$RuCl_2$]PF_6 (52 mg, 0.116 mmol) was dissolved in sodium hydroxide (2 mL, 0.1 M, pH = 12.5). After addition of cytidine (56 mg, 0.232 mmol) the solution was heated in a microwave oven (10 min, 100 °C, 200 W with cooling). ^{13}C NMR spectroscopy indicated that about half of the nucleoside was bonded to ruthenium. Of this half, a major and a minor isomer are present in a ratio of about 2:1.

Adducts of Cyclotriphosphorus Complexes with Cyclopentadienyl Ruthenium Fragments: Synthesis, Solid-State Structure and Solution Behaviour

Pierluigi Barbaro,[b] Massimo Di Vaira,[a] Maurizio Peruzzini,[b] Stefano Seniori Costantini,[a] and Piero Stoppioni*[a]

Keywords: Cyclotriphosphorus / Ruthenium / Cyclopentadienyl / Monodentate P ligands

Treatment of the cyclo-P_3 complexes [(triphos)M(η^3-P_3)]-[triphos = 1,1,1-tris(diphenylphosphanylmethyl)ethane; M = Co (**1**), Rh (**2**)] with stoichiometric amounts of [CpRu-$(CH_3CN)_2(PR_3)$]PF_6 [R = Ph (**3**), Me (**4**), Cy (**5**)] in CH_2Cl_2 in the presence of CH_3CN yields the bimetallic adducts [{(triphos)M}($\mu,\eta^{3:1}$-P_3){CpRu(CH_3CN)(PR_3)}]PF_6 [M = Co; R = Ph (**6**), Me (**7**), Cy (**8**); M = Rh; R = Ph, (**9**), Me (**10**), Cy (**11**)]. The rhodium derivatives **9** and **11**, upon treatment with one equivalent of PMe_3, form the complexes [{(triphos)Rh}($\mu,\eta^{3:1}$-P_3){CpRu(PMe_3)(PR_3}]PF_6 [R = Ph (**12**), Cy (**13**)]. On standing in CH_2Cl_2, the rhodium complexes **9** and **10** lose acetonitrile to yield compounds with the formula [{(triphos)Rh}($\mu,\eta^{3:1,1'}$-P_3){CpRu(PR_3)}]PF_6 [R = Ph (**14**), Me (**15**)]. All the compounds have been characterised by elemental analyses and, in solution, by ^{31}P and ^1H NMR spectroscopy. The $^{31}P\{^1H\}$ EXSY NMR spectroscopic data at different temperatures of **11** and **14** have highlighted the occurrence of independent dynamic processes that exchange both the triphos and the cyclo-P_3 phosphorus nuclei. An X-ray structural investigation carried out on **6** has confirmed the occurrence of the $\mu,\eta^{3:1}$-ligating behaviour of the cyclo-P_3 ligand.

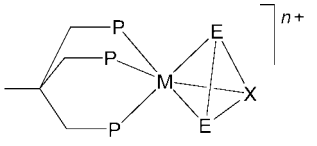
Introduction

"Naked" group 15 ligands stabilised by transition-metal moieties exhibit lone pair electrons, owing to which they are generally endowed with reactivity toward metal fragments with Lewis acid character. Many compounds have been described that result from the addition of metal moieties, mainly carbonyl or cyclopentadienyl carbonyl metal fragments, to the above metal-supported main group atom ligands. The added moieties, depending on their ligating properties, may bind in η^1-, η^2- or η^3 fashion to the main group units to afford bi-, tri- and tetrametallic complexes.[1–5] The solution structures of these multimetallic adducts may usually be assigned by in-depth ^{31}P NMR spectroscopic studies. These NMR studies have often revealed the occurrence of a dynamic behaviour consisting of (i) skeleton rearrangements of multinuclear cluster compounds,[6–12] (ii) relative rotation of parts of the molecule about symmetry- or pseudosymmetry axes,[13–16] and (iii) scrambling of coordinated fragments.[17,18] In our laboratories the reactivity of a series of neutral[19–21] and cationic[22–25] complexes has been investigated, in which a cyclic triatomic E_3 or E_2X (E = P, As; X = S, Se) group isη^3 bound to a metal atom of the cobalt or of the nickel group and is supported by the tripodal tridentate 1,1,1-tris(diphenylphosphanylmethyl)ethane (triphos) ligand (Scheme 1).[26,27]



n = 0 M = Co, Rh, Ir; E = X = P

n = 1 M = Ni, Pd, Pt; E = X = P

n = 1 M = Co; E = P, As; X = S, Se

Scheme 1.

The neutral compounds [(triphos)M(η^3-P_3)] (M = Co, Rh) easily add coordinatively unsaturated metal fragments, such as $M(CO)_5$ (M = Cr, W) or $CpMn(CO)_2$, to yield bi-, tri- and tetrametallic adducts in which the geometry of the P_3 ring is only slightly modified from that in the parent compounds.[19,21,28–31] In contrast, the cationic [(triphos)-M(η^3-E_2X)]$^+$ species (M = Ni; E = X = P. M = Co; E = P, As; X = S, Se) do not add carbonyl fragments, but readily insert the 14e $M(PPh_3)_2$ (M = Pd, Pt) carbene-like moieties into an E–E or E–X bond of the triatomic ring.[31–33] Interestingly, all of these polymetallic compounds exhibit dynamic behaviour at room temperature. Recent studies on a series of complexes resulting from the addition of one me-

[a] Dipartimento di Chimica, Università di Firenze, via della Lastruccia, 3, 50019 Sesto Fiorentino, Firenze, Italy

tal-carbonyl fragment to [(triphos)M(η^3-P_3)] (M = Co, Rh) have definitely shown that two fluxional processes occur in solution, i.e. the scrambling of the metal-carbonyl moiety over the P_3 cyclic system and the relative rotation of the P_3 and {(triphos)M} moieties about their common C_3 axis.[34] Variable-temperature NMR analysis has also established that the rhodium derivatives have a higher rotational barrier than the cobalt derivatives.[34] The scrambling process over cyclo-P_3, which has been blocked at low temperature for both cobalt and rhodium derivatives, has a higher barrier with respect to the {(triphos)M} rotation. Indeed, the latter process has been blocked on the NMR time scale only for the rhodium adduct [{(triphos)Rh}($\mu,\eta^{3:1}$-P_3){$W(CO)_4$-PPh_3}], which is formed with the sterically demanding $W(CO)_4(PPh_3)$ fragment sitting as an end-on ligand on the cyclotriphosphorus unit.[34]

In this work we have investigated the reactivity of [(triphos)M(η^3-P_3)] [M = Co (**1**), Rh(**2**)] toward the [$CpRu(CH_3CN)_2(PR_3)$]PF_6 [R = Ph (**3**), Me (**4**), Cy (**5**)] complexes. These species contain two acetonitrile molecules that can be selectively replaced to generate the 16e [$CpRu(CH_3CN)(PR_3)$]$^+$ and 14e [$CpRu(PR_3)$]$^+$ fragments, respectively.[35] The 16e moieties appear to be particularly suitable, upon reaction with **1** and **2**, to provide further information on the factors affecting the scrambling process of the metal fragment, as they are more sterically hindered than the carbonyl moieties previously employed and, furthermore, their steric demand may be varied by changing the phosphane substituents. Moreover, the lability of the second acetonitrile molecule may further extend the reactivity of the P_3 ring, already activated by the initial end-on coordination of the ruthenium fragment.

Results and Discussion

The dinuclear compounds with the formula [{(triphos)M}($\mu,\eta^{3:1}$-P_3){$CpRu(CH_3CN)(PR_3)$}]PF_6 [M = Co; R = Ph (**6**), Me (**7**), Cy (**8**); M = Rh; R = Ph, (**9**), Me (**10**), Cy (**11**)] are obtained in a straightforward manner by adding a stoichiometric amount of the appropriate [$CpRu(CH_3CN)_2(PR_3)$]PF_6 complex to [(triphos)M(η^3-P_3)] [M = Co (**1**), Rh (**2**)] dissolved in CH_2Cl_2 in the presence of CH_3CN (see the Experimental Section). The complexes **6–11** can be regarded as the mono adducts of the cyclo-P_3 unit in **1** or **2** with 16e [$CpRu(CH_3CN)(PR_3)$]$^+$ (R = Ph, Me, Cy) fragments that readily result from the removal of one labile acetonitrile molecule from [$CpRu(CH_3CN)_2(PR_3)$]PF_6 (Scheme 2). The concentration of CH_3CN is crucial for obtaining **6–11** in both high yield and purity. Actually, **1** and **2** do not react with the ruthenium complexes under conditions of high CH_3CN concentration, which hamper the substitution of the coordinating molecule that occurs through a dissociative pathway.[35] The complexes **6–11** may be handled in air for a limited time; they are soluble in polar organic solvents and their solutions are stable in an inert atmosphere. Solutions of **6–11**, in both $(CH_3)_2CO$ or $CHCl_3$, decompose when heated to 40–50 °C, yielding a mixture of compounds, which could not be characterised.

X-ray Structure Analysis

The structure of **6**, determined by X-ray crystal analysis, consists of [{(triphos)Co}($\mu,\eta^{3:1}$-P_3){$CpRu(CH_3CN)(PPh_3)$}]$^+$ cations (Figure 1), PF_6^- anions, and toluene solvate molecules in a 1:1:2 ratio. Selected values of bond

lengths and angles are given in Table 1. In the dimetal cation, the {CpRu(CH_3CN)(PPh_3)} moiety forms through its metal atom an end-on monoadduct on a phosphorus atom of the CoP_3 core. Such a pseudotetrahedral core exhibits some deviations from the regular geometry of the parent compound **1**, consisting of (i) a moderately shorter Co–P bond formed by the bridging phosphorus atom [P(5)] between the two metal atoms, with respect to the other two Co–P bonds, and (ii) slightly shorter P–P bonds formed by the same P(5) atom than the third P–P bond in the P_3 unit. Consistent deviations from regularity have been detected for metal carbonyl monoadducts of **1** and **2**[34] and similar, although more pronounced, deviations have been found for a methyl adduct.[36] Rationalizations for these trends have already been proposed.[13,34]

[a] Distance and angles formed by the centroid (Ct) of the Cp ring. The Ru–C(Cp) distances are in the range 2.195–2.224 Å.

The ruthenium atom forms a slightly longer bond to the P_3 phosphorus atom than to the phosphane donor atom (Table 1). These two P atoms and the CH_3CN nitrogen atom substantially span a face of an octahedron around the ruthenium atom; the opposite side of the coordination sphere is occupied by the cyclopentadienyl ligand. A similar coordination geometry, although in this case the nitrogen atom of a second CH_3CN ligand replaces the P_3 phosphorus atom, has recently been found for a ruthenium derivative, in which the Ru–P(phosphane) and Ru–C(Cp) mean distances are marginally shorter than the present ones and both Ru–N distances are longer by 0.05 Å.[37]

NMR Properties of the Compounds

The room temperature $^{31}P\{^1H\}$ NMR spectra of the compounds **6–11** recorded in CD_2Cl_2 show resonances that fall into two quite distinct regions: a group of signals at low field (50–2 ppm) is assigned to the phosphorus atoms of triphos and of the phosphane bound to ruthenium (see Experimental Section), while a second group of high-field shifted signals (from –150 to –304 ppm) is assigned to the "naked" P atoms from the cyclo-P_3 ligand. Table 2 presents the NMR spectroscopic data for the latter resonances, and the relevant labelling scheme is shown in Scheme 2. The intensity ratios of the signals agree with the proposed formulae. The resonance for the triphos phosphorus atoms exhibits chemical shifts that are similar to those of the parent [(triphos)M(η^3-P_3)] [M = Co (**1**) and Rh (**2**)][22] compounds and of other end-on carbonyl adducts.[13,34] The phosphorus atom of the PR_3 ligand yields a doublet due to coupling with P_F; both the chemical shift and the coupling constant of the phosphane ligand are in the range observed for [CpRu(PR_3)(PR_3')(L)] complexes.[38] This could indirectly suggest that the donor/acceptor properties of the "naked" phosphorus atoms in the "ligand" [(triphos)M(η^3-P_3)] should be similar to those of the phosphanes. Signals due to the P atoms of the cyclo-P_3 unit are split into three distinct multiplets in the high-field region with integral ratios of 1:1:1. Irrespective of the compound, the signal at lower field appears as a triplet, while the other two, occurring at higher field, consist each of a doublet of doublets, with small differences in their chemical shifts. The overall high-field shifts of the P atoms involved in the cyclo-P_3 ring clearly suggest that this unit has undergone only minor modifications upon coordination to the ruthenium fragment. Indeed, severe rearrangements of the cyclic unit, such as cleavage of one of its P–P bonds, significantly affect the chemical shifts, which move to low field with respect to the signal of the parent compound.[32] The multiplicities of the resonances under discussion allow the safe assignment of the low-field triplet to P_F, which is slightly deshielded by coordination to the ruthenium fragment. Consequently, the two high-field resonances may be safely assigned to the two phosphorus atoms P_M and P_Q that are not coordinated to ruthenium. Such an assignment is strongly supported by the analogous shifts observed in the low-temperature ^{31}P NMR spectra of the monoadducts of [(triphos)M(η^3-P_3)] with metal carbonyl fragments.[34] It is worth noting that while the resonance of the end-on Ru-coordinated P_F atom undergoes a low-field shift with respect to that observed for the parent [(triphos)-

[a] The NMR spectra were recorded in CD_2Cl_2 with a Varian Gemini g300bb spectrometer. Key: d = doublet, t = triplet, m = multiplet, br = broad. The cyclo-P_3 in the parent compounds [(triphos)M(P_3)] yields a broad singlet (δ = –276.2 ppm) for M = Co (**1**) and a doubled quartet [δ = –261.0, ^1J(P–Rh) 13, $^2J(P\text{–}P_{triphos})$ 12 Hz] for M = Rh (**2**).

M(η^3-P_3)] compound, the P_M and P_Q resonances move high field, suggesting an increase of local electron density upon coordination of the ruthenium moiety to the cobalt or rhodium cyclo-P_3 starting material. The inequivalence of P_M and P_Q, that is observed for all of the complexes irrespective of the phosphane substituent, may be ascribed to the chirality of the $[CpRu(CH_3CN)(PR_3)]^+$ fragment, although different environments of the two P atoms are likely to result also from the effects of steric repulsions between the phenyl ends of the {(triphos)M} moiety and the ruthenium fragment. The ^1J coupling constants between P_F, P_M, and P_Q lie in the range spanned by other end-on adducts of cyclo-P_3.[34] Both the triphos and "naked" P atom signals of the cobalt derivatives **6–8** are broadened by the cobalt quadrupole, so that only the largest ^1J coupling constants between the unsubstituted P atoms may be detected. The rhodium complexes **9–11** exhibit broad signals for the triphos P atoms, but sharp patterns for the "naked" phosporus nuclei. Such data point to the occurrence at room temperature of a dynamic process, on the NMR time scale, that involves motion of the triphos ligand with respect to a fixed frame formed by the "naked P" atoms. On the other hand, no dynamic process involving the scrambling motion of the Ru-metal moiety over the P_3 cyclic system is observed at room temperature for **6–11**, irrespective of large differences in the steric requirements of the PR_3 phosphanes employed. This is in contrast with the behaviour of the metal carbonyls previously investigated,[34] which exhibited dynamic behaviour at room temperature, and this suggests that such differences may be influenced by electronic factors, rather than by steric ones. The decomposition of the complexes upon warming their solutions prevented a through investigation of possible dynamic processes involving the Ru-metal moiety and the P_3 cyclic system at higher temperatures. However, the dynamic behaviour of **11** has been carefully investigated at various temperatures by means of ^1H, $^{31}P\{^1H\}$ and 2D $^{31}P\{^1H\}$ EXSY spectroscopic analyses. Sections of selected variable-temperature $^{31}P\{^1H\}$ spectra are shown in Figure 2.

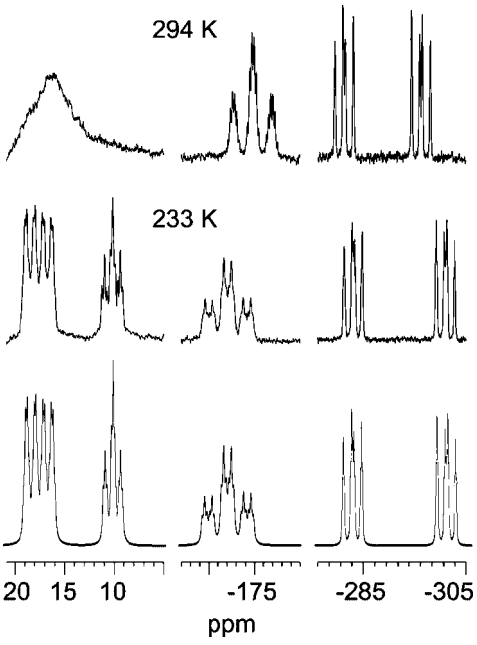

Figure 2. Sections of the $^{31}P\{^1H\}$ NMR spectra of **11** (CD_2Cl_2, 161.95 MHz). Top, experimental spectrum at 294 K; middle, experimental spectrum at 233 K; bottom, simulated spectrum at 233 K. The resonances due to the PCy_3 phosphorus are omitted for clarity.

The rate of the exchange of triphos donor atoms is lowered on cooling the solution. In particular, at 233 K, the triphos phosphorus atoms exhibit separated multiplets centred at 18.45, 16.75 and 10.18 ppm, with coupling constants that range from 29.5 to 130.0 Hz (data obtained by computer simulation) (Table 3). The $^{31}P\{^1H\}$ EXSY spectra recorded at 294 and 248 K are reported in Figure 3. Indeed, two distinct sets of exchange peaks are observed, showing that **11** attains an overall slow motional regime in the above temperature range.[39] A set of exchange peaks is detected at temperatures higher than 260 K, and is relative to the high-field signals due to P_3 (Figure 3, top); the other set, that can be observed below the coalescence point, connects the resonances of the triphos phosphorus atoms (Figure 3, bottom).

This exchange pattern is consistent with the existence of two distinct dynamic processes that have different activation energies; the energy for the process for the P_3 exchange is higher than that for the other one. Such dynamic behaviour

[a] In CD_2Cl_2, 161.95 MHz, 233 K. Data by computer simulation.

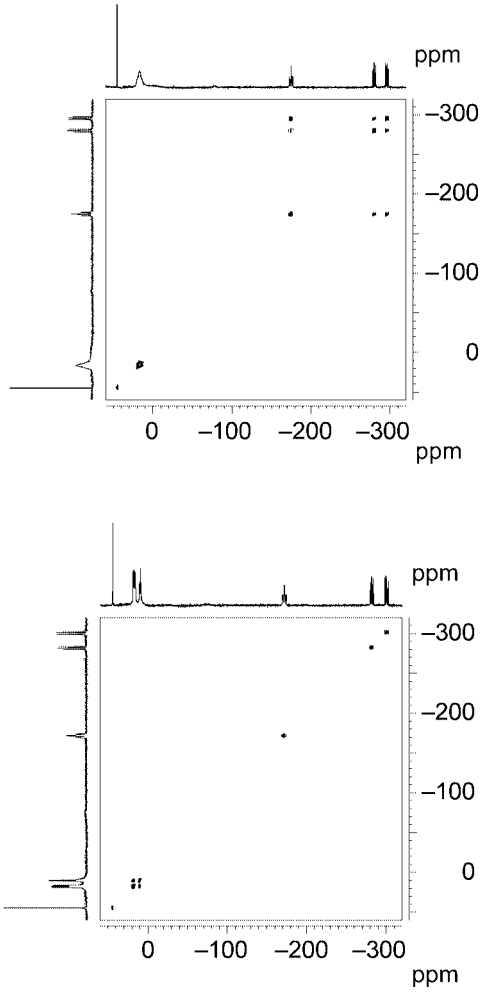

Figure 3. $^{31}P\{^{1}H\}$ EXSY spectra of **11** (CD_2Cl_2, 161.95 MHz, τ_m 0.1 s). Top, spectrum at 294 K; bottom, spectrum at 248 K.

may be accounted for by referring to two types of motion: (i) rotation of the P_3 unit with respect to the other parts of the structure (this motion, shown in Scheme 3 (*i*), involves scrambling of the Ru moiety over the cyclic system and yields the exchange peaks in the 294 K spectrum in Figure 3); and (ii) relative rotation of the {(triphos)M} moiety and the rest of the structure [Scheme 3 (*ii*)] that accounts for the exchange peaks in the EXSY spectrum at 248 K in Figure 3. The two processes are simultaneous and partly related, which makes it impossible, in view of the complex eight-nuclei spin system, to perform any reliable analysis addressing the thermodynamics of each exchange process.

The reactivity of the rhodium derivatives **9–11** has been further investigated, as the fine structure exhibited by the resonances of the "naked" atoms in the ^{31}P NMR spectra may provide more information on the solution behaviour of these dimetallic derivatives. Treatment of **9** and **11** in CH_2Cl_2 with a stoichiometric amount of PMe_3 yields the complexes $[\{(triphos)Rh\}(\mu,\eta^{3:1}\text{-}P_3)\{CpRu(PMe_3)(PR_3)\}]_6$ [R = Ph (**12**), Cy (**13**)] (Scheme 2), which form through replacement of CH_3CN by PMe_3 in the ruthenium coordination sphere. When twice as large an amount of PMe_3 is used, $[(triphos)Rh(\eta^3\text{-}P_3)]$ (**2**) and $[CpRu(PMe_3)_2(PR_3)]PF_6$ (R = Ph, Cy) are formed, which suggests an intrinsic weakness of the cyclo-P_3 coordination to the [CpRu(L)(L′)] unit. The ^{31}P NMR spectra of **12** and **13** (see the Experimental Section and Table 2) exhibit resonances for triphos, PR_3, P_F, P_M, and P_Q with similar features to those observed for **9** and **11**, besides the expected additional resonance for the PMe_3 phosphorus atom that occurs at about 2 ppm as a pseudo triplet; such multiplicity is due to fortuitous coincidence of the coupling constant to both PR_3 (R = Ph, Cy) and P_F. Interestingly, the triphos resonances, which in the parent compounds **9** and **11** appear as a broad signal, occur as a doublet of narrower multiplets, such that the

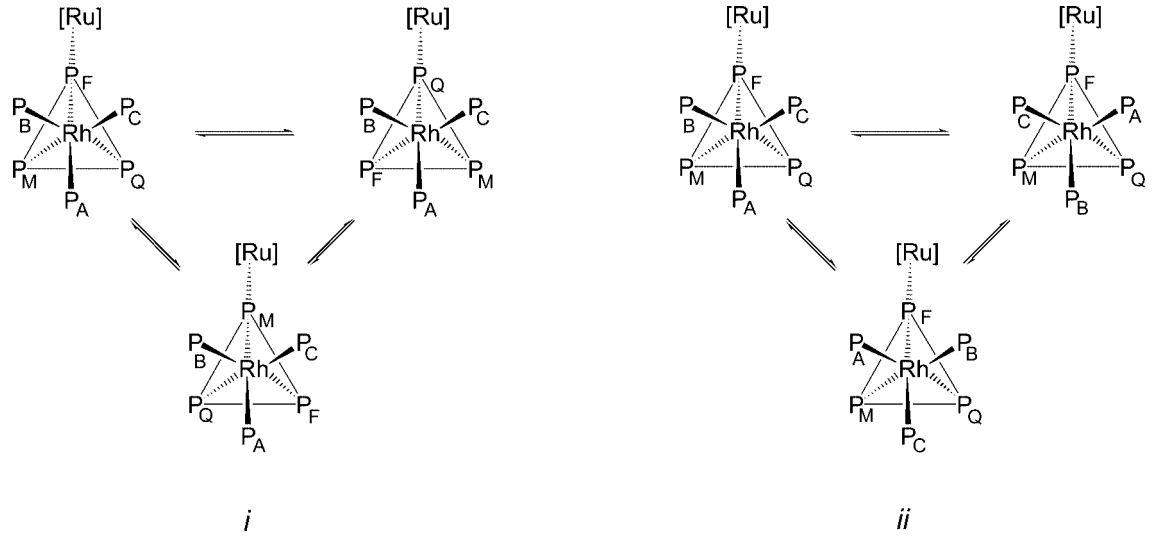

Scheme 3.

$^1J(P_{triphos}–Rh)$ is observed, see Experimental Section. Such a result points to a higher barrier for the type of motion shown in Scheme 3 (*ii*) for **12** and **13** than for **9** and **11**. This in turn may be attributed to the increased steric demand of the ruthenium fragment after replacement of the acetonitrile ligand by trimethylphosphane.

In the absence of acetonitrile, CH_2Cl_2 solutions **9** and **10** are not stable, but slowly transform to compounds with the general formula [(triphos)Rh(P_3){CpRu(PR_3)}]PF_6 [R = Ph (**14**) and Me (**15**)], by releasing the coordinated CH_3CN molecule (Scheme 2). Complexes **14** and **15** have been isolated as brown microcrystals but, in spite of repeated attempts, suitable crystals for X-ray investigations have not been obtained, so their solution structure is proposed on the basis of ^{31}P NMR spectroscopic data. The ^{31}P NMR spectra at room temperature of **14** and **15** (see Experimental Section and Table 2) exhibit resonances for triphos, PR_3, and P_F with similar shifts to those observed for **9** and **10**; the triphos and PR_3 signals are broad; those assigned to P_M and P_Q, on the other hand, appear at significantly lower field than in the parent compounds; the P_F, P_M and P_Q signals still appear as triplets and doublet of doublets, respectively, but their components are broad and only the large ^1J(P–P) coupling constants may be detected. Such data suggest that the dimetal cations in **9** and **10** have undergone minor modifications on the loss of the acetonitrile molecule to yield **14** and **15**, and that the 14e {CpRu(PR_3)} fragment interacts with the P_M and P_Q phosphorus atoms of the P_3 unit. Furthermore, the data are consistent with the rotational motion of the {(triphos)Rh} moiety and, on account of the broad resonances exhibited by the PR_3, P_F, P_M, and P_Q atoms, they point to a further process involving the CpRu(PR_3)P_3 side of the dimetal cation. A type of motion that might account for the latter aspects would be that of the ruthenium fragment, tightly bound to a P_3 phosphorus atom, that shifts between the positions of the other two, and therefore yields a dynamic $\mu,\eta^{3:1,1'}$-P_3 unit. The behaviour of **14** has been investigated at different temperatures by $^{31}P\{^1H\}$ and 2D $^{31}P\{^1H\}$ EXSY spectroscopic data. The $^{31}P\{^1H\}$ spectra show that the rates of exchange decrease on cooling, but even at the lowest reached temperature (230 K), the limiting form is not attained. The $^{31}P\{^1H\}$ EXSY spectra at 294 K and 248 K do not show cross peaks connecting either the triphos or the P_3 phosphorus atoms. These data seem to indicate that the dynamic processes occur with lower barriers than for **9** and **10**. Such a finding is consistent with the suggested geometry in solution; in fact, the ruthenium fragment, on interacting with P_M and P_Q, is expected to move slightly toward the centre of the P_3 unit, thereby releasing some steric repulsions within the cation, which are present in **9** and **10**.

Experimental Section

All reactions and manipulations were performed under dry oxygen-free argon. The solvents were purified according to standard procedures.[40] The ^1H and $^{31}P\{^1H\}$ NMR spectra at room temperature were measured on a Varian Gemini g300bb spectrometer, equipped with a variable-temperature unit, operating at 300 MHz (^1H) and 121.46 MHz (^{31}P). The variable-temperature and EXSY experiments were carried out on a Bruker Avance DRX-400 spectrometer equipped with a variable-temperature control unit accurate to ±0.1 °C and operating at 161.95 and 400.13 MHz. Chemical shifts are relative to tetramethylsilane (^1H) and to H_3PO_4 85 % (^{31}P) as external standards at δ = 0.00 ppm, with downfield values taken as positive; coupling constants are in Hertz. J(P–P) and J(P–Rh) coupling constants of **11** at low temperature were obtained by computer simulation using the gNMR program.[41] 2D NMR spectra were recorded on degassed nonspinning samples using pulse sequences suitable for phase-sensitive representations with TPPI. The 2D $^{31}P\{^1H\}$ EXSY spectra were recorded using a modified NOESY sequence with ^1H decoupling during acquisition: 400 increments of size 3 K (with 400 scans each) covering the full range in both dimensions were collected with a relaxation delay of 0.25 s and mixing times of 50, 100 and 500 ms.[42,43] Analytical data for carbon, hydrogen, nitrogen, and phosphorus were obtained from the Microanalytical Laboratory of the Department of Chemistry of the University of Firenze. The complexes [(triphos)M(η^3-P_3)] (M

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

= Co (**1**), Rh (**2**) and $[CpRu(CH_3CN)_2(PR_3)]PF_6$ [PR_3 = PPh_3 (**3**), PMe_3 (**4**) and PCy_3 (**5**)] were synthesized according to literature methods.[19,20,38] The ^1H NMR spectroscopic data of the dinuclear adducts **6–15** and the $^{31}P\{^1H\}$ resonances of the phosphane ligands (triphos and PR_3) are reported in this section. The uninformative ^1H signals of the aromatic protons of triphos and of the PPh_3 derivatives, occurring in the expected region (7.6–6.9 ppm), are not reported. The labelling used for the different phosphorus nuclei is defined in Scheme 2. The PF_6^- anion yields a septet centred at –143.2 [^1J(P–F) 712 Hz] in all the compounds.

Syntheses

[{(triphos)Co}(μ,η$^{3:1}$-P$_3$){CpRu(CH$_3$CN)(PPh$_3$)}]PF$_6$ (6): To a yellowish orange solution of [(triphos)Co(η^3-P$_3$)] (**1**) [132 mg, 0.17 mmol] in CH_2Cl_2 (40 mL) was added at room temperature whilst stirring one equivalent of $[CpRu(CH_3CN)_2(PPh_3)]PF_6$ (**3**) in CH_2Cl_2 (10 mL). The resulting solution was stirred for 3 h at room temperature, and during this time the colour changed to brown-red. Acetonitrile (1 mL) and toluene (10 mL) were then slowly added to yield reddish brown crystals by slowly evaporating the resulting solution at room temperature. Yield: 201 mg (85 %). $C_{66}H_{62}CoF_6NP_8Ru$ (1390.9): calcd. C 57.0, H 4.5, N 1.0 %; found C 57.1, H 4.8, N 0.9 %. ^1H NMR (CD_2Cl_2, 298 K): δ = 4.14 (s, C_5H_5, 5 H), 2.40 (br., CH_2P, 6 H), 2.20 (br. s, CH_3CN, 3 H), 1.37 (br. s, CH_3C, 3 H) ppm. $^{31}P\{^1H\}$ NMR (CD_2Cl_2, 298 K): δ = 50.2 [d, PPh_3, ^2J(PPh_3–P_F) 36.5, 1P], 34.2 (br., $P_{triphos}$, 3P) ppm.

The compounds [{(triphos)M}(μ,η$^{3:1}$-P$_3$){CpRu(CH$_3$CN)(PR$_3$)}]PF_6 [M = Co; R = Me (**7**), Cy (**8**); M = Rh; R = Ph (**9**), Me (**10**), Cy (**11**)] were prepared by the same procedure as for **6** by adding the equimolar amount of $[CpRu(CH_3CN)_2(PR_3)]PF_6$ [R = Ph (**3**), Me (**4**), Cy (**5**)] to a CH_2Cl_2 solution of [(triphos)M(η^3-P$_3$)] [M = Co (**1**), Rh(**2**)].

[{(triphos)Co}(μ,η$^{3:1}$-P$_3$){CpRu(CH$_3$CN)(PMe$_3$)}]PF$_6$ (7): Yield: 123 mg (60 %). $C_{51}H_{56}CoF_6NP_8Ru$ (1204.7): calcd. C 50.8, H 4.7, N 1.2 %; found C 50.7, H 4.8, N 1.0 %. ^1H NMR (CD_2Cl_2, 298 K): δ = 4.27 (s, C_5H_5, 5 H), 2.37 (br., CH_2P, 6 H), 2.17 (s, CH_3CN, 3 H), 1.65 (d, CH_3P, ^2J(H-P) 9.6, 9 H), 1.39 (s, CH_3C, 3 H) ppm. $^{31}P\{^1H\}$ NMR (CD_2Cl_2, 298 K): δ = 32.7 (br., $P_{triphos}$, 3P), 10.0 [d, PMe_3, ^2J(PMe_3–P_F) 46.0, 1P] ppm.

[{(triphos)Co}(μ,η$^{3:1}$-P$_3$){CpRu(CH$_3$CN)(PCy$_3$)}]PF$_6$ (8): Yield: 204 mg (85 %). $C_{66}H_{80}CoF_6NP_8Ru$ (1409.1): calcd. C 56.2, H 5.7, N 1.0 %; found C 56.1, H 5.8, N 0.8 %. ^1H NMR (CD_2Cl_2, 298 K): δ = 4.27 (s, C_5H_5, 5 H), 2.40–1.40 (br. m, C_6H_{11}, CH_2P, CH_3CN, CH_3C, 45 H) ppm. $^{31}P\{^1H\}$ NMR (CD_2Cl_2, 298 K): δ = 42.2 [d, PCy_3, ^2J(PCy_3–P_F) 39.0, 1P], 32.9 (br., $P_{triphos}$, 3P) ppm.

C 55.2, H 4.3, N 1.0 %; found C 55.1, H 4.5, N 0.9 %. ^1H NMR (CD_2Cl_2, 298 K): δ = 4.20 (s, C_5H_5, 5 H), 2.47 (br., CH_2P, 6 H), 2.20 (s, CH_3CN, 3 H), 1.31 (s, CH_3C, 3 H) ppm. $^{31}P\{^1H\}$ NMR (CD_2Cl_2, 298 K): δ = 51.0 [d, PPh_3, ^2J(PPh_3–P_F) 44.5, 1P], 16.9 (br., $P_{triphos}$, 3P) ppm.

[{(triphos)Rh}(μ,η$^{3:1}$-P$_3$){CpRu(CH$_3$CN)(PMe$_3$)}]PF$_6$ (10): Yield: 138 mg (65 %). $C_{51}H_{56}F_6NP_8RhRu$ (1248.7): calcd. C 49.0, H 4.5, N 1.1; found C 49.3, H 4.6, N 1.0 %. ^1H NMR (CD_2Cl_2, 298 K): δ = 4.42 (s, C_5H_5, 5 H), 2.48 (br., CH_2P, 6 H), 2.21 (s, CH_3CN, 3 H), 1.67 (d, CH_3P, ^2J(H-P) = 9.6, 9 H), 1.52 (s, CH_3C, 3 H) ppm. $^{31}P\{^1H\}$ NMR (CD_2Cl_2, 298 K): δ = 16.8 (br., $P_{triphos}$, 3P), 9.8 [d, PMe_3, ^2J(PMe_3–P_F) 49.5, 1P] ppm.

[{(triphos)Rh}(μ,η$^{3:1}$-P$_3$){CpRu(CH$_3$CN)(PCy$_3$)}]PF$_6$ (11): Yield: 210 mg (85 %). $C_{66}H_{80}F_6NP_8RhRu$ (1453.0): calcd. C 54.5, H 5.5, N 1.0, P 17.0 %; found C 54.3, H 5.7, N 0.8, P 16.8 %. ^1H NMR (CD_2Cl_2, 298 K): δ = 4.23 (s, C_5H_5, 5 H), 2.40–1.4 (br. m, C_6H_{11}, CH_2P, CH_3CN, CH_3C) ppm. $^{31}P\{^1H\}$ NMR (CD_2Cl_2, 298 K): δ = 44.4 [d, PCy_3, ^2J(PCy_3–P_F) 44.5, 1P], 16.0 (br., $P_{triphos}$, 3P) ppm.

[{(triphos)Rh}(μ,η$^{3:1}$-P$_3$){CpRu(PMe$_3$)(PPh$_3$)}]PF$_6$ (12): To an orange solution of [{(triphos)Rh}(μ,η$^{3:1}$-P$_3$){CpRu(CH$_3$CN)-(PPh$_3$)}]PF_6 (**9**) [143 mg, 0.10 mmol] in CH_2Cl_2 (20 mL) was added at room temperature whilst stirring an equimolar amount of neat PMe_3. The resulting solution was stirred for 2 h; toluene (15 mL) was then slowly added; reddish-orange crystals were obtained by slowly evaporating the resulting solution at room temperature. Yield: 200 mg (80 %). $C_{67}H_{68}F_6P_9RhRu$ (1469.9): calcd. C 54.7, H 4.7 %; found C 54.5, H 4.6 %. ^1H NMR (CD_2Cl_2, 298 K): δ = 4.34 (s, C_5H_5, 5 H), 2.41 (br., CH_2P, 6 H), 1.52 (s, CH_3C, 3 H), 1.31 [d, CH_3P, ^2J(H–P) = 9.3, 9 H] ppm. $^{31}P\{^1H\}$ NMR (CD_2Cl_2, 298 K): δ = 50.2 [dd, PPh_3, ^2J(PPh_3–PMe_3) 41.5, ^2J(PPh_3–P_F) 36.5, 1P], 16.5 [br. d, $P_{triphos}$, ^1J($P_{triphos}$–Rh) 130.5, 3P], 2.2 [t, PMe_3, ^2J(PMe_3–P_F) 42.0, 1P] ppm.

[{(triphos)Rh}(μ,η$^{3:1}$-P$_3$){CpRu(PMe$_3$)(PCy$_3$)}]PF$_6$ (13): Complex **13** was prepared as described above for **12** by using **11** instead of **9**. Yield: 202 mg (80 %). $C_{67}H_{86}F_6P_9RhRu$ (1488.1): calcd. C 54.1, H 5.8 %; found C 54.2, H 5.9 %. ^1H NMR (CD_2Cl_2, 298 K): δ = 4.32 (s, C_5H_5, 5 H), 2.40–1.30 (br. m, C_6H_{11}, CH_2P, CH_3C, 42 H), 1.25 [d, CH_3P, ^2J(H–P) 8.7, 9 H] ppm. $^{31}P\{^1H\}$ NMR (CD_2Cl_2, 298 K): δ = 46.0 [t, PCy_3, ^2J(PCy_3–PMe_3) = ^2J(PCy_3–P_F) 39.0, 1P], 15.0 [br. d, $P_{triphos}$, ^1J($P_{triphos}$–Rh) 120.0, 3P], 2.1 [t, PMe_3, ^2J(PMe_3–P_F) 40.0, 1P] ppm.

[{(triphos)Rh}(μ,η$^{3:1,1'}$-P$_3$){CpRu(PPh$_3$)}]PF$_6$ (14): [(triphos)Rh(η^3-P$_3$)] (**2**) and $[CpRu(CH_3CN)_2(PPh_3)]PF_6$ (**3**) were reacted as described for **9** avoiding the subsequent addition of acetonitrile. Brown microcrystals were obtained by adding only toluene, and slowly concentrating the resulting solution. Yield: 154 mg (65 %). $C_{64}H_{59}F_6P_8RhRu$ (1393.8): calcd. C 55.1, H 4.3, P 17.8 %; found C 55.2, H 4.4, P 17.6 %. ^1H NMR (CD_2Cl_2, 298 K): δ = 4.02 (s, C_5H_5, 5 H), 2.37 (br., CH_2P, 6 H), 1.53 (s, CH_3C, 3 H) ppm. $^{31}P\{^1H\}$ NMR (CD_2Cl_2, 298 K): δ = 48.4 (br. s, PPh_3, 1P), 15.5 [dq, $P_{triphos}$, ^1J($P_{triphos}$–Rh) 132.0, ^2J($P_{triphos}$–$P_{cyclo\text{-}P3}$) 21.0, 3P] ppm.

[{(triphos)Rh}(μ,η$^{3:1,1'}$-P$_3$){CpRu(PMe$_3$)}]PF$_6$ (15): Brown microcrystals of **15** were obtained as described above for **14** by reacting [(triphos)Rh(η^3-P$_3$)] (**2**) and $[CpRu(CH_3CN)_2(PMe_3)]PF_6$ (**4**) in a 1:1 ratio in CH_2Cl_2. Yield: 123 mg (60 %). $C_{49}H_{53}F_6P_8RhRu$ (1207.6): calcd. C 48.7, H 4.4, P 20.5 %; found C 48.9, H 4.4, P 20.2 %. ^1H NMR (CD_2Cl_2, 298 K): δ = 4.15 (s, C_5H_5, 5 H), 2.37 (br., CH_2P, 6 H), 1.53 (s, CH_3C, 3 H), 1.50 [d, CH_3P, ^2J(H–P) 9.3] ppm. $^{31}P\{^1H\}$ NMR (CD_2Cl_2, 298 K): δ = 16.2 [dm, $P_{triphos}$, ^1J($P_{triphos}$–Rh) 127.0, 3P], 8.0 (m, PMe_3, 1P) ppm.

Crystal Structure Determination

Obtaining crystals suitable for X-ray analyses on these compounds proved to be difficult; a data set could only be collected with a very small crystal of **6**, grown from a diluted CH_2Cl_2/CH_3CN/C_7H_8 solution, which gave relatively low-angle reflections. Data were collected at room temperature with a Bruker CCD diffractometer, equipped with Göbel mirrors and mounted on a rotating-anode generator, using Cu-K_α radiation (λ = 1.5418 Å). Cell constants were obtained by least-squares refinement of the setting angles of 791 reflections in the range $7° < 2\theta < 55°$. Crystallographic data and details on the structure determination and refinement procedure are summarised in Table 4. Although limited absorption effects were expected, in view of the small size of the crystal, a correction for absorption was applied with SADABS,[44] in an attempt to reduce the effects of absorption by the glass fibre, which caused

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

high R_{int} values. The structure was solved by direct methods with SIR-97[45] and was extended and refined on F^2 with SHELXL-97.[46] In addition to the ions forming the unit formula of **6**, two solvate toluene molecules were located in the asymmetric unit. In the final sets of the refinement cycles, the metal, P and F atoms, as well as the three outermost C atoms of each phenyl ring − those of the cyclopentadiene ligand and of the two solvent molecules − were refined anisotropically, with soft isotropic restraints on temperature factors of the C atom. The phenyl, cyclopentadiene, and toluene rings were refined as rigid groups, and a constraint was also applied on the C–CH_3 distance of one toluene molecule. Hydrogen atoms were in calculated positions, riding on the respective carrier atom, with $U_H = 1.2U_C^{eq}$ ($U_H = 1.5U_C^{eq}$ for methyl hydrogens). A small damping factor was applied. Features in the final difference synthesis were low and devoid of chemical meaning. Computer programs used included PARST[47] for geometry calculations, and ORTEP[48,49] for graphics.

Table 4. Crystal data and structure refinement parameters for **6**.

Empirical formula	$C_{80}H_{78}CoF_6NP_8Ru$
Formula weight	1575.19
Crystal system	orthorhombic
Space group	*Pcab* (no. 61)
a [Å]	22.138(4)
b [Å]	22.955(5)
c [Å]	30.038(7)
V [Å^3]	15265(6)
Z	8
$D_{calcd.}$ [g cm^{-3}]	1.371
μ [mm^{-1}]	5.364
Transmission factors range	0.549–1.000
Crystal size [mm]	0.05 × 0.08 × 0.40
F(000)	6480
θ range [°]	2.94–37.56
Index ranges	$-17 \le h \le 17$, $-18 \le k \le 17$, $-23 \le l \le 23$
Reflections collected	33678
Independent reflections	3873 [$R_{int} = 0.322$]
Independent observed reflections	1507 [$I > 2\sigma(I)$]
Restraints/Parameters	313/572
Final *R* indices [$I > 2\sigma(I)$]	$R_1 = 0.056$, $wR_2 = 0.071$
R indices (all data)	$R_1 = 0.199$, $wR_2 = 0.093$
Goodness of fit on F^2 (all data)	0.806
Largest diff. peak and hole [e·Å^{-3}]	0.316 to –0.250

CCDC-244899 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Binding of Oxovanadium(IV) to Dipeptides Containing Histidine and Cysteine Residues

Eugenio Garribba,*[a] Elzbieta Lodyga-Chruscinska,[b] Giovanni Micera,*[a] Angelo Panzanelli,[a] and Daniele Sanna[c]

Keywords: Vanadium / Peptides / Bioinorganic chemistry / EPR spectroscopy / Coordination modes / Bond theory

The complexation of the oxovanadium(IV) ion with five dipeptides containing L-histidine or L-cysteine (GlyHis, HisHis, HisGly, CysGly, GlyCys) was studied. L-histidinamide ($HisNH_2$) was assumed as a model system for dipeptides with L-histidine in the N-terminal position. The study was performed in aqueous solution through the combined application of potentiometric and spectroscopic (electronic absorption and EPR) techniques. The results indicate that simple dipeptides lacking a strong anchoring group can form mono- and bischelated complexes with the $V^{IV}O$ ion if a suitable "donor" is present in the chain. The ligands behave like amino acids in the acidic and neutral pH range, inhibit the precipitation of hydroxides and suppress the formation of hydrolytic species if at least a fivefold molar excess of ligand is used. In alkaline media all the ligands, except CysGly, promote the deprotonation and N-coordination of the amide group. CysGly forms a bischelated complex with a [2 × (NH_2, S^-)] donor set. The contribution of the deprotonated amide group to the ^{51}V hyperfine coupling constant, A_z, as a function of the total equatorial charge of oxovanadium(IV) ion, is discussed. The results have general validity and are useful to predict the geometry and donor set of complexes involving the bonding of the $V^{IV}O$ ion to the deprotonated amide group.

Introduction

Vanadium is an important element for higher animals and essential for certain organisms including tunicates, some fungi and bacteria.[1] It elicits a number of physiological responses in human organism, e.g. the inhibition of ATPases,[2] phosphotyrosine phosphatase[3] and so forth. One of the most relevant properties of vanadium is its insulin-mimetic activity.[4] To clarify its biological role, it is of primary importance to understand the mechanisms of reaction (ligand-exchange and redox processes) and complexation of vanadium in organisms and to find the target biomolecules. Among the biomolecules present in intra- and extra-cellular fluids, proteins have a special importance because of their high amount in the cellular environment and their possible interaction with metal ions through a number of active sites. For instance, glutathione plays an important role in the processes of reduction of vanadium(V) to oxovanadium(IV) and in the following complexation reactions.[5a,5b]

Detailed studies on synthetic models of the interaction of vanadium with proteins can contribute greatly to our knowledge of its biological activity. Oligopeptides are among the models most closely related to proteins. These ligands can interact with metal ions through various donor groups: terminal amino and carboxylate groups, intermediate peptide groups and side-chain donor groups, e.g. imidazole-N or thiolate-S. Usually, these groups are not strong enough to keep metal ions in solution at the physiological pH. However, they can play the role of "anchoring group" and promote the deprotonation of the amide bond and its coordination in the $-N^-$ form. Various metal ions exhibit this ability, e.g. Pt^{II}, Pd^{II}, Cu^{II}, Ni^{II} and, in some cases, Zn^{II} and Co^{II}.[6]

Recently, the role of anchoring donor groups was studied with $V^{IV}O$ and it was found that their effectiveness in promoting peptide amide deprotonation and coordination follows the order: phenolate-O^- < alcoholate-O^- < thiolate-S^- < carboxylate-COO^- < NH_2.[7]

The interaction with oligopeptides in the physiological pH range, through the coordination of a deprotonated peptide group, was first proved to involve vanadium(V).[8] The amide coordination of a few synthetic ligands to $V^{IV}O$ ion was observed in the solid state too.[9] Costa Pessoa and coworkers suggested the deprotonation and coordination of $V^{IV}O$ by glycine/alanine dipeptides in aqueous solution.[10a,10b] However, the first unambiguous proof for $V^{IV}O$-amide deprotonation and coordination, favoured by

an anchoring donor like the "hard" phenolate group, was obtained with salicylglycine.[11]

The solution speciation and the characterisation of the $V^{IV}O$ complexes of five dipeptides (GlyHis, HisGly, HisHis, GlyCys and CysGly) are reported in this work. Their structures are displayed in Scheme 1. A model system for the dipeptides with L-histidine in the N-terminal position, L-histidinamide ($HisNH_2$), has been included. Though in aqueous solution terminal $–NH_2$ is not a particularly good anchoring donor for the $V^{IV}O$ ion,[7] additional donors, like the imidazole nitrogen and the thiolate sulfur atoms, favour the binding of the ligands.

Results

L-Histidinamide ($HisNH_2$)

The aromatic nitrogen of imidazole is a major binding site of metalloenzymes. The imidazole nitrogen of L-histidine can compete with the amino acid site and significantly enhance the stability of the complexes. Therefore, imidazole side chains play a relevant role in complex formation. However, the effect depends critically on the position of the histidyl residue.

To model peptides with histidine in the N-terminal position, we examined L-histidinamide. The potentiometric titrations of the ligand (H_2L^{2+}, Table 1 and Scheme 1) indicate two deprotonation steps with pK_a of 5.39 ($–N_{im}H^+$) and 7.49 ($–NH_3^+$). The values are in good agreement with those of the literature. For instance, Michailidis and Martin reported values of 5.85 and 7.78 at 0.5 M ionic strength.[12] $HisNH_2$ forms mono- and biscomplexes with the $V^{IV}O$ ion (Table 1). The concentration distribution curves of the $V^{IV}O$ complexes as a function of pH are depicted in Figure 1.

The detection of a series of $V^{IV}O$ complexes at a ligand-to-metal molar ratio (L/M) as low as 7 is in contrast to the findings for other simple amino acids systems. For instance, L/M values of 77 are needed with glycine.[13a,13b] This substantiates a stronger binding mode, due e.g. to a tridentate behaviour for $HisNH_2$ with the involvement of the imidazole nitrogen in metal coordination. The speciation process was inferred by a pH-potentiometric titration of the metal-ligand system (see Experimental Section). Complex formation starts with a VOL species, which predominates at pH 4–5. The biscomplexes VOL_2H and VOL_2 are major

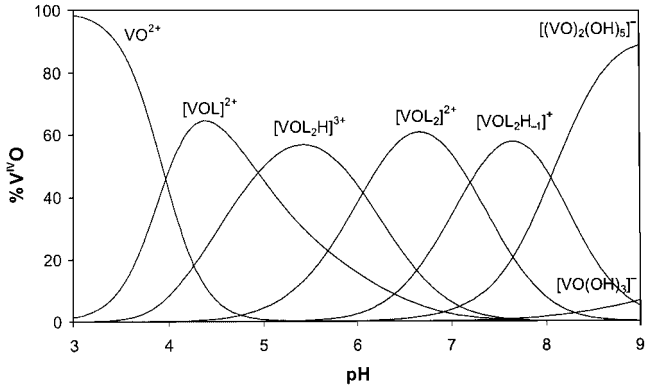

Figure 1. Species distribution for the $V^{IV}O$-$HisNH_2$ system at a metal-to-ligand molar ratio of 1:7 and a $V^{IV}O$ concentration of 1 mM.

species in the pH range 5–7. The log K values for VOL and VOL_2 formation are 7.15 and 4.27, respectively. The "basicity-adjusted" stability constants for the reactions $VO^{2+} + HL^+ \rightarrow [VOL]^{2+} + H^+$ and $[VOL]^{2+} + HL^+ \rightarrow [VOL_2]^{2+} + H^+$ are –0.34 and –3.22, which are greater by about three orders and one order of magnitude, respectively, than those of $V^{IV}O$ complexes of simple amino acids (cf. –3.05 and –4.25 for glycine [14]).

The findings substantiate the involvement of the imidazole nitrogen atom in the coordination of vanadium in VOL. The ligand presumably adopts an equatorial-axial-equatorial (*eq-ax-eq*) binding mode (the two external donor atoms are in the equatorial and the third in the axial position) and this increases the stability of the species. At a pH higher than 5, according to the potentiometric and spectroscopic measurements, a second ligand replaces two water molecules and forms first VOL_2H and then VOL_2. Only two positions of the equatorial plane are available for the second ligand. The pK_a of 6.06 for the VOL_2H to VOL_2 deprotonation, which is very close to that of the free ligand, suggests that the aromatic nitrogen atom of the second ligand molecule does not participate in the coordination. Finally, VOL_2 loses a proton with pK_a = 7.20 to form VOL_2H_{-1} before the start of the processes leading to $[(VO)_2(OH)_5]^-$ and $[VO(OH)_3]^-$. The formation of these hydrolytic species characteristic of $V^{IV}O$ is supported by the potentiometric titrations and by the progressive disappearance of the EPR signal at pH > 8.

The EPR parameters are: g_z = 1.946, A_z = 169×10^{-4} cm^{-1} for VOL, and g_z = 1.950, A_z = 164×10^{-4} cm^{-1} for both VOL_2H and VOL_2 (Table 2). The data are similar to those of the mono- and bischelated complexes of $V^{IV}O$ with L-histidine methyl ester (HisOMe),[15] g_z = 1.946, A_z = 170×10^{-4} cm^{-1} and g_z = 1.950, A_z = 164×10^{-4} cm^{-1}, respectively. Moreover, we compared the EPR spectra with those of the $V^{IV}O$/L-glycine methyl ester (GlyOMe) system at L/M = 500. The stepwise formation of the two species was observed with g_z = 1.946, A_z =

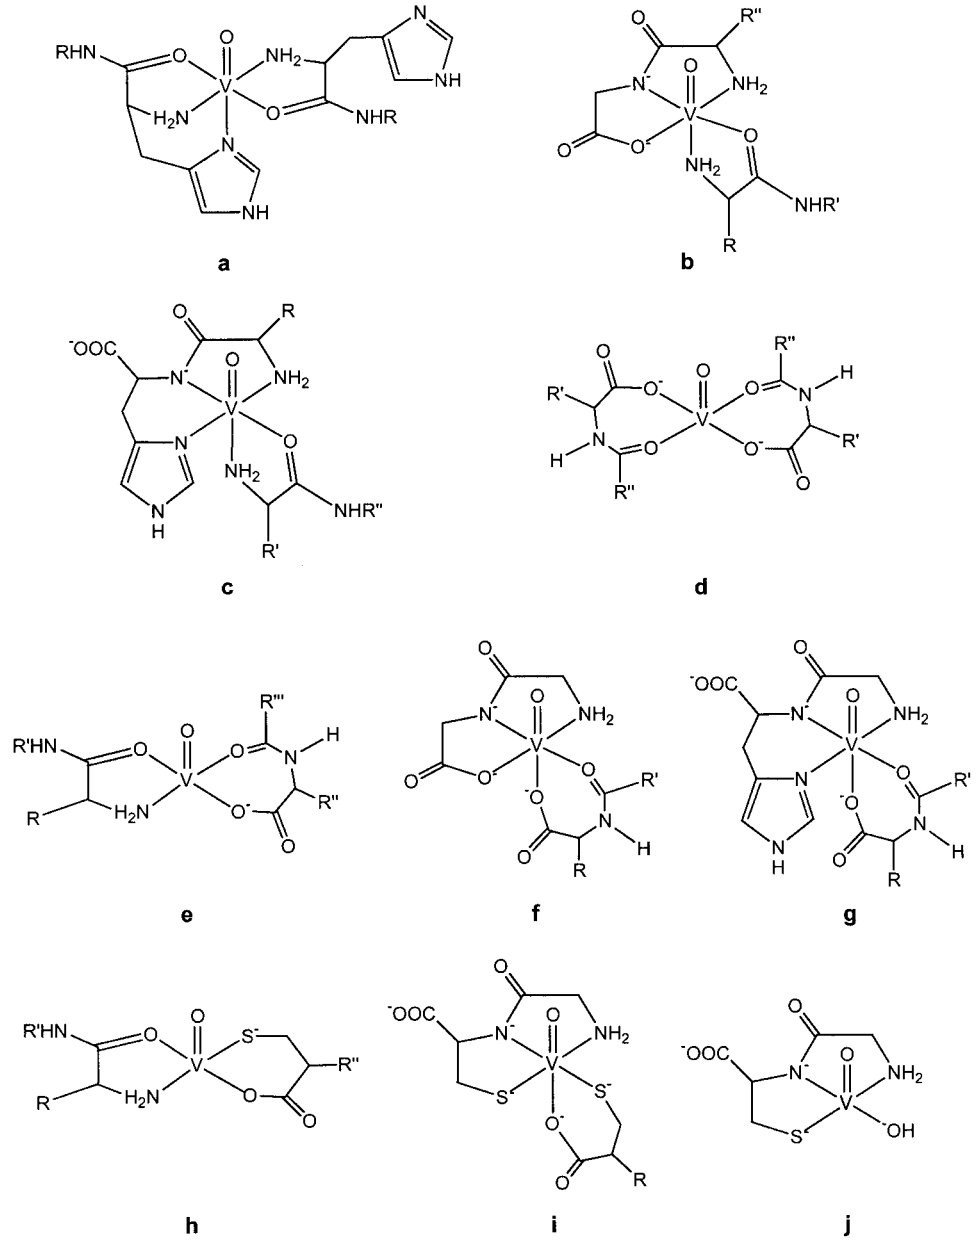
168×10^{-4} cm^{-1} and g_z = 1.951, A_z = 163×10^{-4} cm^{-1}, respectively. They were identified as VOL and VOL_2 with (NH_2, CO) and [2×(NH_2, CO)] coordination modes, respectively. The features suggest that in the monochelated complex, $HisNH_2$ coordinates the metal ion through amino nitrogen and carbonyl oxygen donors in the equatorial plane and the imidazole nitrogen atom in the apical position, which enhances the stability of the species. The resulting donor set is (NH_2, CO, N_{im}^{ax}). The presence of an imidazole nitrogen atom in the axial position does not significantly affect the A_z value, according to the "Chasteen additivity rule", which assumes that only equatorial donors contribute to the parallel hyperfine ^{51}V constant.[16] The second ligand is bound through the (NH_2, CO) donor set: the resulting coordination mode is [(NH_2, CO, N_{im}^{ax}); (NH_2, CO)], as reported in Table 2. The structure is indicated as '**a**' in Scheme 2 with R = H. This scheme explains the rather high stability of the monochelated complex involving a tridentate ligand, compared with the bischelated species (in which a molecule is tridentate and another bidentate).

Potentiometric and spectroscopic studies on the $V^{IV}O$/L-histidine system in aqueous solution indicate that the VOL and VOL_2 species are formed with (NH_2, COO^-, N_{im}^{ax}) and [(NH_2, COO^-, N_{im}^{ax}); (NH_2, COO^-)] donor sets, respectively. The EPR parameters are g_z = 1.945, A_z = 170×10^{-4} cm^{-1} and g_z = 1.944, A_z = 163×10^{-4} cm^{-1}, respectively.[17a,17b]

At pH values higher than 6.5–7, a VOL_2H_{-1} species of $HisNH_2$ is detected by EPR spectroscopy with g_z = 1.956,



Scheme 2. Structures of the oxovanadium(IV) complexes.

$A_z = 160 \times 10^{-4}$ cm^{-1}. In this pH range, potentiometry indicates a deprotonation with a pK_a of 7.20. We can exclude the deprotonation of an equatorial water molecule because all the five coordination sites are occupied by ligand molecules, one bound in *eq-ax-eq* mode and another in *eq-eq* mode. The spectral parameters do not support a complexation scheme similar to that of L-histidine, which forms a mixed species with a [(NH_2, COO^-, N_{im}^{ax}); (NH_2, N_{im})] donor set and $g_z = 1.955$, $A_z = 157 \times 10^{-4}$ cm^{-1}. Therefore, the deprotonation can be ascribed to the amide group, whereas donor sets [(NH_2, CO^-, N_{im}^{ax}); (NH_2, CO)] or [(NH_2, N^-, N_{im}^{ax}); (NH_2, CO)] are equally probable for the complex. Only an X-ray determination could solve the ambiguity. Attempts to obtain single crystals of the complex are in progress. However, the coordination of the amide group through a deprotonated nitrogen atom is most likely if a second chelated ring can be closed, as it happens with dipeptides.[6]

Pecoraro and coworkers demonstrated that the $V^{IV}O$ coordination of a ligand with a terminal amide group, e.g. H_2ada = *N*-(carbamoylmethyl)iminodiacetic acid, takes place through the carbonyl oxygen atom of the deprotonated amide group.[18] This is not surprising if the preference of the $V^{IV}O$ ion for oxygen rather than nitrogen donors is considered. Moreover, Kabanos et al. showed that a dipeptide like Hpycan [Hpycan = *N*-(2-nitrophenyl)pyridine-2-carboxamide] coordinates the VO^{2+} ion in a bidentate mode by adopting the (N_{py}, CO_{amide}) rather than the (N_{py}, N_{amide}) donor set.[19] Analogous results were obtained with vanadium(V).[20] Therefore, we can assume that the first coordination mode is more likely.

Glycyl-L-Histidine (GlyHis), L-Histidylglycine (HisGly), and L-Histidyl-L-histidine (HisHis)

The complex formation of dipeptides containing L-histidine depends on the "hardness" of the metal ion.[6] In N-terminal histidyl peptides, the amino and imidazole nitrogen atoms can give rise to a stable six-membered chelated ring. Histamine-like complexes are formed with "soft" ions, like Cu^{2+}. Histamine-like coordination is less favoured with $V^{IV}O$; suitable donors, possibly oxygen atoms, should be involved in anchoring the metal ion.

In simple dipeptides lacking strong anchoring groups in the N-terminal position, the carboxylate group in the C-terminal position and the amide carbonyl group can interact with $V^{IV}O$ at acidic pH values to form a seven-membered (COO^-, CO) chelated ring.[7,21] This favours the deprotonation and coordination of the amide group at higher pH values.

For HisGly (H_3L^{2+}, Table 1 and Scheme 1), three pK_a values were measured: 2.82 (–COOH), 5.94 ($-N_{im}H^+$) and 7.69 ($-NH_3^+$), which are comparable to those reported by Sóvágó et al.[22] The $V^{IV}O$ complexation scheme is very similar to that of $HisNH_2$ and involves the formation of VOL, VOL_2H and VOL_2 below pH 7 (Figure 2). In the pH range 4–7, EPR spectroscopy shows two species with $g_z = 1.946$, $A_z = 168 \times 10^{-4}$ cm^{-1} and $g_z = 1.951$, $A_z = 165 \times 10^{-4}$ cm^{-1}, values comparable with those measured for $HisNH_2$. This confirms that VOL has a (NH_2, CO, N_{im}^{ax}) coordination (**I** in Figure 3) and VOL_2H, a [(NH_2, CO,N_{im}^{ax}); (NH_2, CO)] donor set (**IIa** in Figure 3 and **a** in Scheme 2). The imidazole nitrogen atom of the second ligand molecule is still protonated in VOL_2H. The proton dissociation yielding VOL_2 (**IIb** in Figure 3) takes place with a pK_a value of 5.91, which is in excellent agreement with the value of the free ligand. In this case too, the deprotonation does not affect the coordination sphere of the vanadium atom. The "basicity-adjusted" stability constants for mono-and bischelated species are –0.69 and –2.69, respectively, which means that the monochelated complex is a little less stable and the bischelated species a little more stable than the corresponding species of $HisNH_2$.

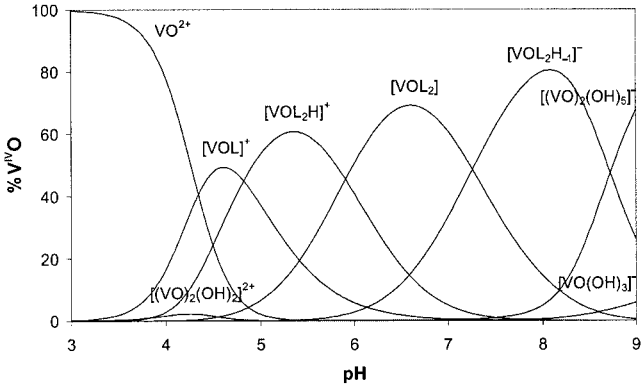

Figure 2. Species distribution for the $V^{IV}O$-HisGly system at a metal-to-ligand molar ratio of 1:10 and a $V^{IV}O$ concentration of 1 mM.

VOL_2 undergoes deprotonation with a pK_a of 7.26 to form a VOL_2H_{-1} species characterised by $g_z = 1.955$, $A_z = 160 \times 10^{-4}$ cm^{-1} (**III** in Figure 3). Also in this case the deprotonation can be attributed to the ligand and we can assign it to the peptide group. However, in contrast with $HisNH_2$, the coordination of a deprotonated nitrogen atom makes the closure of a second chelated ring possible through a bond between the terminal carboxylate group and vanadium. It is commonly accepted that a simple dipeptide coordinates with all the three donor atoms in the equatorial position of a metal ion.[6] Thus, the second molecule of HisGly must change its arrangement from *eq-eq* to *eq-ax*. Since histamine-like coordination is not favoured with the $V^{IV}O$ ion,[17b] we expect that the fourth and fifth coordination sites are occupied by the carbonyl oxygen atom and the amine nitrogen of the N-terminal part, respectively. Therefore, both the donor sets [(NH_2, N^-, COO^-); (CO, NH_2^{ax})] or [(NH_2, N^-, COO^-); (NH_2, CO^{ax})] are acceptable. The following discussion will demonstrate that the first structure, indicated as '**b**' in Scheme 2, is more suitable (vide infra).

HisHis (H_4L^{3+}, Table 1 and Scheme 1) shows four deprotonation steps in the pH range 2–10 with pK_a of 2.61 (–COOH), 5.68 ($-N_{im1}H^+$), 6.85 ($-N_{im2}H^+$) and 7.79 ($-NH_3^+$).[23] The complexation scheme is very similar to

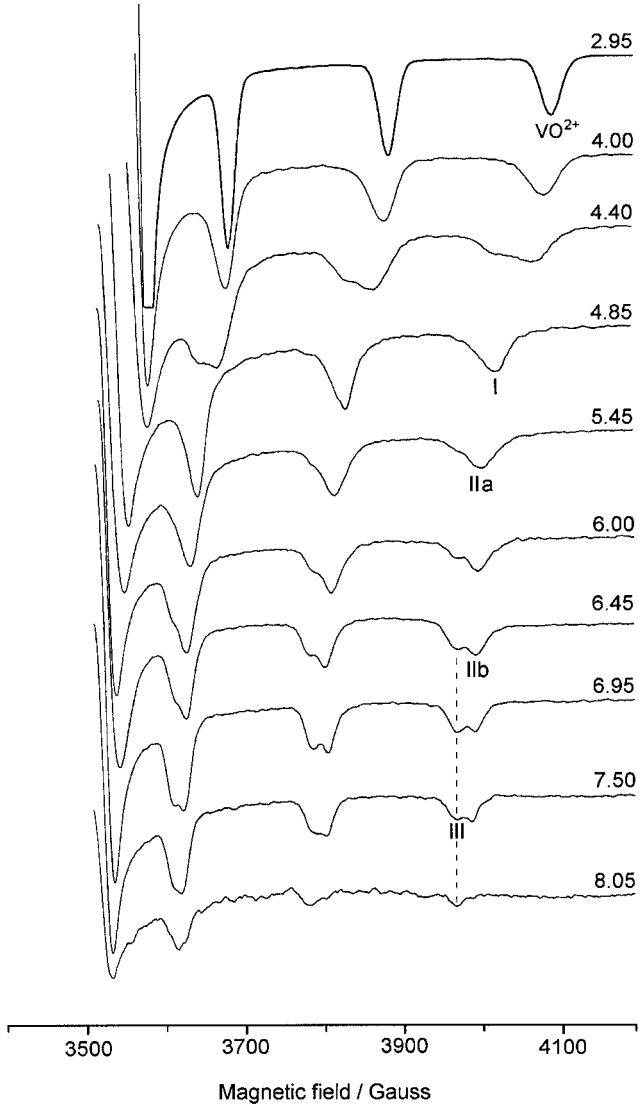

Figure 3. High-field region of the X-Band EPR spectra recorded at 140 K as a function of pH on aqueous solutions of $V^{IV}O$ and HisGly at a metal-to-ligand to molar ratio of 1:10 and a $V^{IV}O$ concentration of 4 mM. The dotted line indicates the high-field resonance of the complex with the deprotonated amide group.

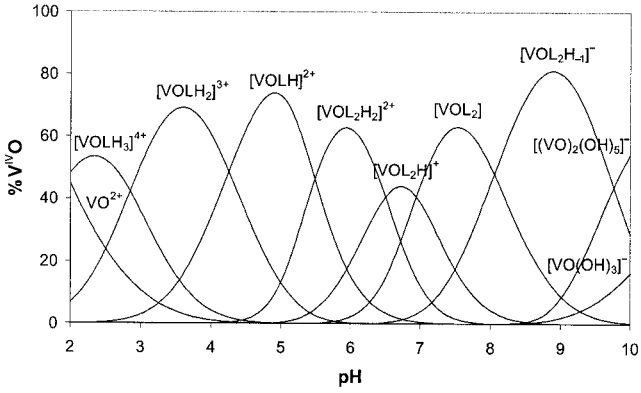

Figure 4. Species distribution for the $V^{IV}O$-HisHis system at a metal-to-ligand molar ratio of 1:3 and a $V^{IV}O$ concentration of 1 mM.

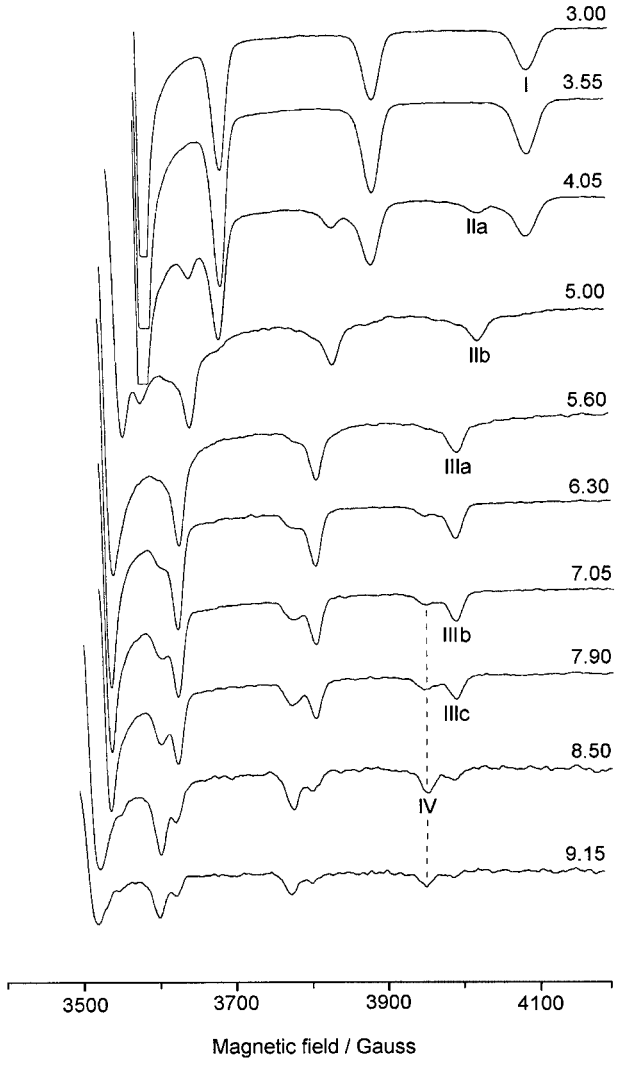

Figure 5. High-field region of the X-Band EPR spectra recorded at 140 K as a function of pH on aqueous solutions of $V^{IV}O$ and HisHis at a metal-to-ligand to molar ratio of 1:3 and a $V^{IV}O$ concentration of 4 mM. The dotted line indicates the high-field resonance of the complex with the deprotonated amide group.

that of $HisNH_2$ and HisGly if the presence of the imidazole ring on the C-terminal part of the dipeptide is taken into account. The distribution curves for this system are shown in Figure 4 and the EPR spectra in Figure 5.The complexation process starts to give $VOLH_3$ through the coordination of the weak carboxylate group (the stronger donor groups, i.e. the two imidazole and the amine nitrogen atoms, are still protonated). EPR and electronic absorption spectra are distinctive of this coordination mode. Indeed, the formation of carboxylate complexes does not change the EPR parameters very significantly (Table 2) relative to the aqua ion, $g_z = 1.934$, $A_z = 178 \times 10^{-4}$ cm^{-1} (**I**, Figure 5). As usual, in the absorption spectra, only a minor shift of the d-d band around 770 nm is observed, accompanied by a better resolution of the shoulder around 640 nm.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$VOLH_2$ and VOLH (**IIa** and **IIb** in Figure 5) exhibit $g_z = 1.947$, $A_z = 169 \times 10^{-4}$ cm^{-1} indicative of a (NH_2, CO, N_{im}^{ax}) coordination of HisHis; they have two and one imidazole rings still protonated, respectively. Analogously, VOL_2H_2 (**IIIa** in Figure 5 and **a** in Scheme 2) shows the [(NH_2, CO, N_{im}^{ax}); (NH_2, CO)] donor set displayed by $HisNH_2$ and HisGly, and keeps two imidazole residues protonated. The findings are confirmed by EPR ($g_z = 1.950$, $A_z = 164 \times 10^{-4}$ cm^{-1}). The deprotonation of the imidazole groups takes place in distinct steps with pK_a values of 6.50 and 6.94, similar to those of the free ligand, to afford VOL_2H and VOL_2 (**IIIb** and **IIIc** in Figure 5). The "basicity-adjusted" stability constant for the formation of VOL_2H_2 complex through the reaction $[VOLH]^{2+} + LH_2^+ \rightarrow [VOL_2H_2]^{2+} + H^+$ is –2.24, which is comparable to that of the complex of HisGly.

At a pH above 6.5, VOL_2H_{-1} (**IV** in Figure 5 and **c** in Scheme 2) is formed from VOL_2 with a pK_a of 8.05. The species is distinguished by $g_z = 1.957$, $A_z = 157 \times 10^{-4}$ cm^{-1}. The higher g_z and lower A_z values, in comparison with the analogous complex of HisGly, suggest that the imidazole nitrogen atom at the C-terminal part takes part in the coordination to the VO^{2+} ion rather than the weaker carboxylate group. Also for this complex as well as for HisGly, two different donor sets, [(NH_2, N^-, N_{im}); (CO, NH_2^{ax})] or [(NH_2, N^-, N_{im}); (NH_2, CO^{ax})], could be proposed; the first one with the carbonyl group in equatorial position is most probable (vide infra).

GlyHis (H_3L^{2+}, Table 1 and Scheme 1) shows three pK_a values in the titratable pH range: 2.45 (–COOH), 6.85 ($-N_{im}H^+$) and 8.33 ($-NH_3^+$).[22] If histidine is in the C-terminal position of a dipeptide, the complexation scheme is completely different to that of $HisNH_2$, HisGly and HisHis. The species distribution curve, shown in Figure 6 for a molar ligand excess of 10, shows the species $VOLH_2$ and VOL_2H_3 in the pH range 2–5. The $VOLH_2$ complex exhibits $g_z = 1.935$, $A_z = 177 \times 10^{-4}$ cm^{-1}. In less acidic solution, the EPR components shift continuously until pH 5 is reached, with a change of A_z from 178×10^{-4} to 173×10^{-4} cm^{-1}, which supports the coordination of a carboxylate group to the $V^{IV}O$ ion. Similar changes were observed with carboxylic[13b] and amino acids[13a] at high ligand excess, also suggesting COO^- and/or (COO^-; COO^-) coordination. The stability constants of these complexes are somewhat higher than expected for pure carboxylate coordination[24] and indicate the binding of extra donors, presumably the amide carbonyl. A (NH_2, CO) donor set can be excluded because the EPR parameters expected for this coordination mode are $g_z = 1.946$, $A_z = 168 \times 10^{-4}$ cm^{-1} (vide supra). Moreover, the exclusive coordination of a monodentate histidine residue in the N-terminal position can be ruled out because in such a case L/M ratios as high as 500 are necessary to suppress the hydrolysis of the vanadyl ion. This suggests that (COO^-, CO) is the coordination set. In $VOLH_2$, the amino and imidazole nitrogen atoms are still protonated. VOL_2H_3 is characterised by $g_z = 1.938$, $A_z = 172 \times 10^{-4}$ cm^{-1} and can be described as a bischelated complex of the [2×(COO^-, CO)] type, see '**d**' in Scheme 2 and Table 2. The amine and imidazole nitrogen atoms in one ligand are still protonated, whilst in another ligand, only the amino nitrogen atom is protonated. The attributions and the EPR parameters are in agreement with recent contributions,[21,25–27] which report EPR hyperfine coupling constants in the range 175–179×10^{-4} cm^{-1} for monochelated and 171–174×10^{-4} cm^{-1} for bischelated species.

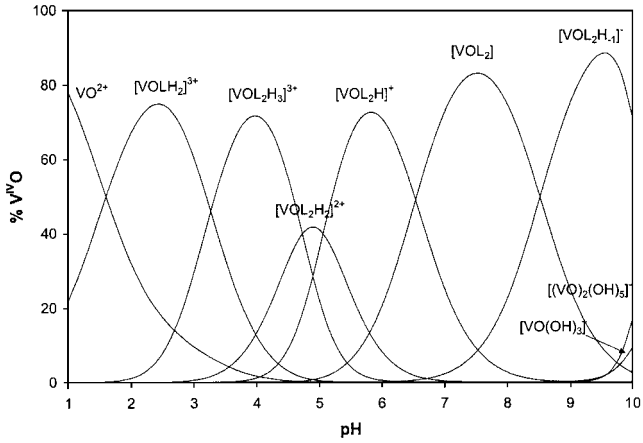

Figure 6. Species distribution for the $V^{IV}O$-GlyHis system at a metal-to-ligand molar ratio of 1:10 and a $V^{IV}O$ concentration of 1 mM.

Upon deprotonation of the first amino group, the dipeptide switches its coordination mode from (COO^-, CO) to (NH_2, CO) and forms a minor VOL_2H_2 species with a [(NH_2, CO); (COO^-, CO)] mixed donor set (**e** in Scheme 2). The EPR parameters ($g_z = 1.943$, $A_z = 166 \times 10^{-4}$ cm^{-1}), intermediate between those of [2×(COO^-, CO)] and [2×(NH_2, CO)], support the coordination mode, whereas potentiometry indicates the presence of this species at around pH 5 (Figure 6).

The coordination of a ligand molecule through (NH_2, CO) hinders hydrolysis and favours the subsequent deprotonation of the amide group to form a VOL_2H species with donor set [(NH_2, N^-, COO^-); (CO, COO^{-ax})], **f** in Scheme 2, which exhibits $g_z = 1.958$, $A_z = 161 \times 10^{-4}$ cm^{-1}. The imidazole and amino groups of the second ligand are still protonated. They undergo deprotonation with pK_a 6.54 and 8.52, respectively; these are both a little higher than for the free ligand. Two new species VOL_2 and VOL_2H_{-1} are formed, and differ only with respect to the protonation of an amino group. Since the same EPR parameters ($g_z = 1.959$, $A_z = 157 \times 10^{-4}$ cm^{-1}) are measured, we suggest a [(NH_2, N^-, N_{im}); (CO, COO^{-ax})] donor set for VOL_2 (**g** in Scheme 2) and [(NH_2, N^-, N_{im}); (CO, NH_2^{ax})] for VOL_2H_{-1} (**c** in Scheme 2). In both species, a carbonyl oxygen atom of the second ligand occupies the equatorial position (vide infra). The coincidence of the hyperfine coupling constants for HisHis and GlyHis complexes supports our conclusion.

Glycyl-L-cysteine (GlyCys), L-Cysteinylglycine (CysGly)

The "soft" deprotonated thiol group of cysteine is very effective as a metal-binding site for transition-metal ions.[6]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Also in this case, the complexation processes depend on the position of the residue in the peptide and on the "hardness" of the metal ion.[6]

With GlyCys the soft Ni^{2+} and Pd^{2+} ions promote the coordination of the deprotonated amide.[28,29] Instead, Co^{2+}, Zn^{2+} and Cd^{2+}[30,31] prefer the coordination of thiol and carboxylate groups in bischelated complexes with various protonated forms because of the presence of the free terminal amino group.

In the case of CysGly a stable cysteine-like (NH_2, S^-) coordination is favourable for a number of metal ions (e.g. Ni^{2+}, Pd^{2+}, Co^{2+}, Zn^{2+} and Cd^{2+}).[28–31] This means that the N-terminal cysteine residue prevents amide deprotonation, and biscomplexes $[MA_2]^{2-}$ are observed.

GlyCys (H_3L^+, Table 1 and Scheme 1) shows three pK_a values in the measured pH range: 2.73 (–COOH), 8.04 ($-NH_3^+$) and 9.48 (–SH).[30] The speciation scheme of GlyCys is more complex than for other systems. The species distribution curves depicted in Figure 7 indicate that at pH 2–4.5 $VOLH_2$ and VOL_2H_4 (**I** and **II** in Figure 8) are formed in strongly overlapping processes. Their EPR parameters are g_z = 1.935, $A_z = 176\times10^{-4}$ cm^{-1} and g_z = 1.940, $A_z = 172\times10^{-4}$ cm^{-1}, very similar to those of $VOLH_2$ and VOL_2H_3 of GlyHis and of $[VO\text{-}(mpg)]^+$ and $[VO\text{-}(mpg)_2]$, where H_2mpg is 2-mercaptopropionylglycine.[21] As for GlyHis, the features support (COO^-, CO) and [2×(COO^-, CO)] coordination modes (**d** in Scheme 2). In both complexes, the amino and thiol groups in each ligand are protonated.

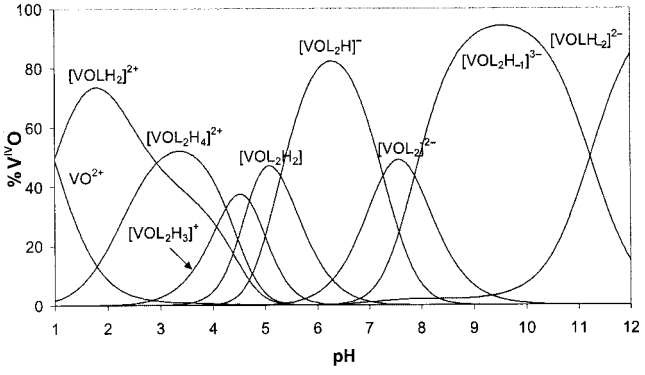

Figure 7. Species distribution for the $V^{IV}O$-GlyCys system at a metal-to-ligand molar ratio of 1:10 and a $V^{IV}O$ concentration of 1 mM.

A two-step deprotonation of the amino groups gives rise to VOL_2H_3 and VOL_2H_2 (**III** and **IV** in Figure 8) at pH 5–6. As suggested by EPR and pH-potentiometry, the first is a minor complex and it is, therefore, a rather hard task to accurately measure the spectral parameters. However, a mixed coordination [(NH_2, CO); (COO^-, CO)] could be proposed (**e** in Scheme 2). The second complex exhibits g_z = 1.950, $A_z = 164\times10^{-4}$ cm^{-1}, indicative of a [2×(NH_2, CO)] coordination.

With increasing pH the first –SH group deprotonates and VOL_2H_2 is replaced by VOL_2H (**V** in Figure 8 and **h** in Scheme 2), presumably a complex with a mixed donor set

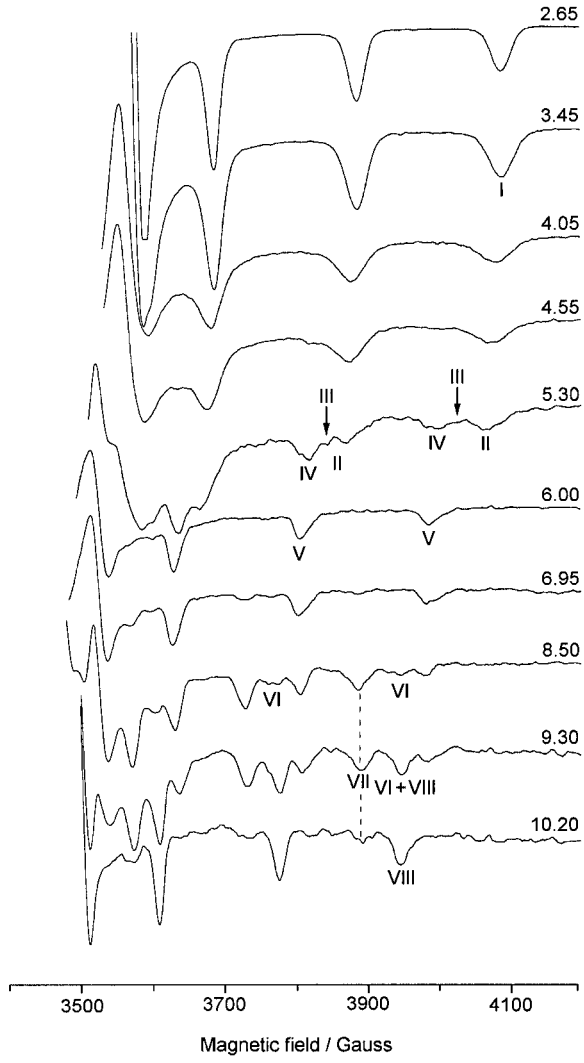

Figure 8. High-field region of the X-Band EPR spectra recorded at 140 K as a function of pH on aqueous solutions of $V^{IV}O$ and GlyCys at metal-to-ligand to molar ratio of 1:10 and a $V^{IV}O$ concentration of 4 mM. The dotted line indicates the high-field resonance of the complex with the deprotonated amide group.

[(S^-, COO^-); (NH_2, CO)]. The conclusion is supported by the EPR parameters, g_z = 1.953, $A_z = 160\times10^{-4}$ cm^{-1}, which are intermediate between those of the [2×(NH_2, CO)] and [2×(S^-, COO^-)] donor sets (g_z = 1.959, $A_z = 155\times10^{-4}$ cm^{-1} for N-acetyl-L-cysteine and g_z = 1.960, $A_z = 154\times10^{-4}$ cm^{-1} for 3-mercaptopropionic acid).[13b] The deprotonation of the thiol group of the second ligand yields VOL_2 (**VI** in Figure 8) with g_z = 1.956, $A_z = 155\times10^{-4}$ cm^{-1} and a [2× (S^-, COO^-)] coordination set.[13b]

At pH values higher than 8, VOL_2 is transformed into VOL_2H_{-1} (**VII** in Figure 8 and **i** in Scheme 2) with a pK_a of 8.43. The EPR parameters are g_z = 1.968, $A_z = 144\times10^{-4}$ cm^{-1}. To this species we attribute a coordination mode of the [(NH_2, N^-, S^-); (S^-, COO^{-ax})] type, according to the assignments for 2-mercaptopropionylglycine.[21]

Finally, at pH >10, a $VOLH_{-2}$ species (**VIII** in Figure 8 and **j** in Scheme 2) exhibits EPR parameters, g_z = 1.956, $A_z = 152\times10^{-4}$ cm^{-1}, which are very similar to those of VOL_2.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

A species with donor set [2×(S⁻, COO⁻)] likely undergoes hydrolysis at pH >9.[13b] Thus, around pH 9, the two species **VI** and **VIII** with similar spectral parameters coexist, whereas only $VOLH_{-2}$ remains in solution at higher pH values. As suggested by potentiometry, most probably this is a hydrolytic species with donor set [(NH_2, N^-, S^-); OH^-], similar to that formed by 2-mercaptopropionylglycine with [(COO^-, N^-, S^-); OH^-] coordination.[21] The difference in the A_z value, 154×10^{-4} cm^{-1} versus 152×10^{-4} cm^{-1} (this work), is attributable to the replacement of a carboxylate by an amino group.

For CysGly (H_3L^+, Table 1 and Scheme 1), three pK_a values were observed by Sóvágó et al.: 3.13 (–COOH), 6.94 (–NH_3^+) and 9.37 (–SH).[30] The complexation behaviour is rather simple because the (NH_2, S^-) donor set can form very stable mono- and bischelated complexes. Besides the aqua ion $[VO(H_2O)_5]^{2+}$, we observe a VOL species around pH 5 with g_z = 1.951, $A_z = 162\times10^{-4}$ cm^{-1}, and another species VOL_2 above pH 6.0 with g_z = 1.966, $A_z = 145\times10^{-4}$ cm^{-1}. The EPR parameters of VOL_2 are very similar to those of the bischelated complexes of cysteamine (g_z = 1.973, $A_z = 144\times10^{-4}$ cm^{-1}) and L-cysteine (g_z = 1.967, $A_z = 144\times10^{-4}$ cm^{-1}) for which a [2×(NH_2, S^-)] donor set was proposed.[13b] To the best of our knowledge, a coordination mode (NH_2, S^-) was never observed: we expect EPR parameters intermediate between those of $[VO(H_2O)_5]^{2+}$ (g_z = 1.933, $A_z = 180\times10^{-4}$ cm^{-1}) and VOL_2. The spectra are consistent with that expected.

The "basicity-adjusted" stability constants for the mono- and bischelated species VOL and VOL_2 in the reactions $VO^{2+} + HL^- \rightarrow [VOL] + H^+$ and $[VOL] + HL^- \rightarrow [VOL_2]^{2-} + H^+$ are –0.06 and –2.08; these are significantly greater than the corresponding complexes of HisGly. This confirms that L-cysteyl is a more efficient anchoring residue than L-histidyl and can hinder the subsequent deprotonation of the amide group (Figure 9).

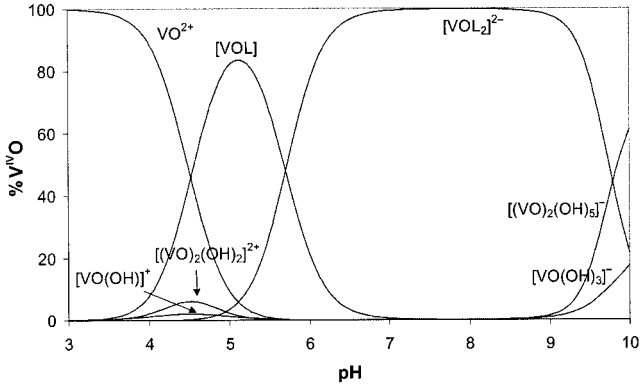

Figure 9. Species distribution for the $V^{IV}O$-CysGly system at a metal-to-ligand molar ratio of 1:10 and a $V^{IV}O$ concentration of 1 mM.

The results for the $V^{IV}O$ complexes of GlyCys and CysGly are similar to those for the Cu^{II} complexes of L-histidyl peptides. In the latter case, amide deprotonation and binding were prevented by an N-terminal side chain and promoted by a C-terminal side chain.[6]

Discussion

Chasteen introduced an "additivity rule" to estimate the parallel ^{51}V hyperfine constant of $V^{IV}O$ complexes, based on the contribution to A_z from each of the four equatorial donor groups.[16] The rule provides a valid criterion for the identification of equatorial donor atoms. Data for amine, carboxylate, alcoholate, phenolate, aromatic nitrogen, hydroxo ion and aliphatic and aromatic thiolate groups were listed by Chasteen (Table 3).[16] Kabanos et al. used values of 44.2 and 43.2×10^{-4} cm^{-1} for Cl^- and SCN^-, respectively.[32] Based on the model $[VO(oxalato)_2]^{2-}$ complex,[33] Kiss and Costa Pessoa changed the COO^- contribution from 42.7 to 41.8×10^{-4} cm^{-1} (Table 3).[21] The mean value for a neutral oxygen atom belonging to an amide CO group is 43.5×10^{-4} cm^{-1}.[18]

Table 3. Contribution of various groups to ^{51}V hyperfine coupling constants A_z.

Donor group	A_z expected[a]	Reference
H_2O	45.6	[16]
COO^-	41.8	[21]
CO	43.5	[18]
OH^-	38.7	[16]
Ar-O^-	38.9	[16]
R–O^-	35.3	[16]
Ar–S^-	35.3	[16]
R–S^-	31.9	[16]
NH_2	40.1	[16]
N(imino)	41.6	this work
N(aromatic)	40.7	[16]
Cl^-	44.2	[32]
SCN^-	43.2	[32]

[a] A_z measured in 10^{-4} cm^{-1} units.

Chasteen did not include the imino nitrogen atom, which, as noticed by Cavaco et al., is certainly different from an aromatic nitrogen atom, e.g. those of 2,2′-bipyridine.[34] On the basis of the EPR parameters of [VO(*N*-salicylidene-glycinato)(bipy)] and [VO(*N*-salicylidene-L-alaninato)(bipy)] Cavaco et al. calculated a value in the range $41.5–43.5\times10^{-4}$ cm^{-1}.[34] From the analysis of the hyperfine coupling constants of twenty three compounds,[34–35] we obtained a more accurate value of $A_z(N_{imino})$; A_z values in the range $38.1–43.7\times10^{-4}$ cm^{-1} were found,[36] with a mean value of 41.6×10^{-4} cm^{-1}, which is in good agreement with those reported by Costa Pessoa.[34,35d] The values used in this work are summarised in Table 3.

With respect to the amide contribution A_z(amide), the values, in the range $29–43\times10^{-4}$ cm^{-1},[37] are sensitive to the balance of the coordination sphere. The A_z(amide) value decreases with increasing donation of electron density from the ligands to the metal ion (Table 4). Tasiopoulos et al. listed the amide contribution for 15 $V^{IV}O$ compounds characterised by X-ray diffraction.[37] They found that A_z(amide) is affected by the charge of the other equatorial donor atoms. If the total charge of the donor atoms in the equatorial plane (TEC) is –2, –3 or 4 (including the –1 charge of the deprotonated peptide nitrogen), the mean A_z(amide) value is 32.2, 36.5 and 40.3×10^{-4} cm^{-1}, respectively.

[b] A_z measured in 10^{-4} cm^{-1} units.

Unfortunately, they analysed only two data for the –3 charge and four for –4 charge, whereas no data for the –1 charge were available.

We included further four solid-state compounds and 18 complexes characterised in solution. Therefore, we have taken into account a total of 37 compounds, nine with a –4 charge, nine with –3, and finally, 19 with a –2 charge.[9,10b,11,21,26,27,32,37–44]

Among 25 $V^{IV}O$ structures involving the coordination of a deprotonated amide group found with a search in the Cambridge Structural Database,[45] we excluded only the octahedral complexes *trans*-[VOX(capca)], where Hcapca is *N*-{2-[(2-pyridylmethylene)amino]phenyl}pyridine-2-carboxamide and X^- (Cl^-, SCN^-, CH_3COO^- and $PhCOO^-$) is an axial ligand,[46] because the authors noticed an anomalous reduction of A_z of about 10% due to the effect of X^-.

On the whole, an evaluation of the contribution of a deprotonated amide group to the hyperfine constant along the *z* axis confirms the results of Kabanos and Deligiannakis.[37] However, the mean values for TEC = –2, –3 and –4 are slightly different: 35.5, 38.3 and 40.9×10^{-4} cm^{-1} in this work versus 32.2, 36.5 and 40.3×10^{-4} cm^{-1}, respectively. As shown in Figure 10, a linear relationship is observed with a correlation coefficient of 0.99. Based on these results, we can obtain the contribution of the amide group with a –1 charge by extrapolation. The calculated value is 32.7×10^{-4} cm^{-1}.

The rather low contribution for an amide group in complexes with TEC = –1 could partially explain the anomalous reduction of the parallel hyperfine coupling constant observed by Kabanos and coworkers and mentioned above.[46] They reported A_z values of $144–148\times10^{-4}$ cm^{-1}

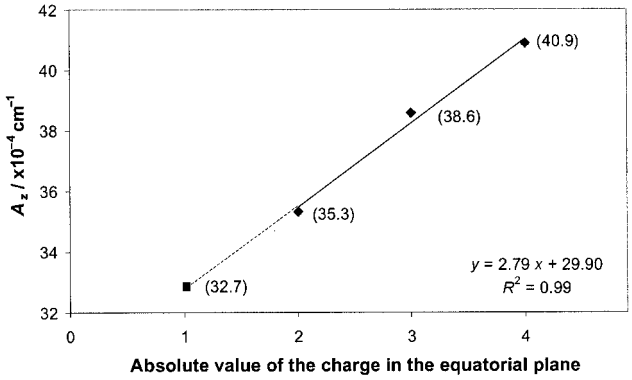

Figure 10. Contribution of a deprotonated amide group to A_z as a function of the absolute value of the charge in the equatorial plane for oxovanadium(IV) complexes.

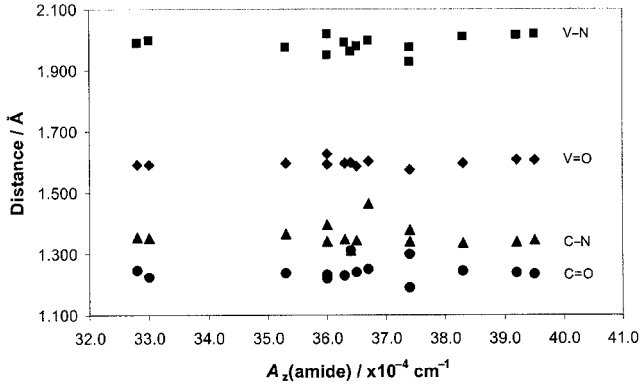

Figure 11. Lengths of V–N, V=O, C–N and C=O bonds as a function of the contribution of the deprotonated amide group to A_z for oxovanadium(IV) complexes. All the solid structures present in literature, for which EPR parameters are reported,[9,32,37,38,40,42–44] were examined.

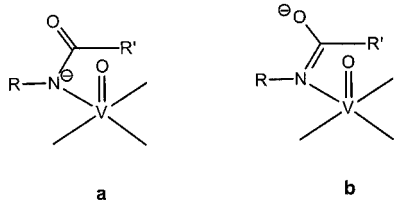
for the complexes [VOX(capca)], where X^- is Cl^-, SCN^-, CH_3COO^- or $PhCOO^-$ and occupies the axial position, relative to 161×10^{-4} cm^{-1} predicted by Chasteen's rule for (N_{ar}, N_{imino}, N^-, N_{ar}) coordination. With the contribution proposed here for this type of complexes we calculate a value of 155.9×10^{-4} cm^{-1}, which is significantly closer to the experimental one.

The wide range of the A_z(amide) contribution was explained [37,44] by assuming two limit resonance structures for an amide group coordinated through the nitrogen atom: one "amide-like", with the nitrogen atom negatively charged and a double bond between the carbon and oxygen atoms of the carbonyl group (**a** in Scheme 3), and another "imine-like", with the carbonyl oxygen atom negatively charged and a double bond between the carbon and nitrogen atoms (**b** in Scheme 3). The predominance of one of these structures depends on the electronic density of the metal ion: particularly, the importance of the **a** form should increase with decreasing the density (and hence TEC value).



Scheme 3. Limit resonance structures for a deprotonated amide group bound to oxovanadium(IV) species: (a) "amide-like" and (b) "imine-like" form.

If this suggestion is correct, one might expect that the C–N bond is longer and the V–N and C=O bonds are shorter as the "amide-like" form becomes prevalent. In the meantime, the contribution of the deprotonated amide group to A_z should be reduced. A comparison of V–N, C–N and C=O bond lengths, shown in Figure 11, does not reveal any apparent correlation. Therefore, the cause for the difference in the contribution of a deprotonated amide group to A_z must be another one.

The hyperfine coupling constant for ^{51}V can be expressed in the following form:[47]

$$A_z = P_d\left[\beta^2\left(-\kappa - \frac{4}{7}\right) + (g_z - 2.0023) + \frac{3}{14}(g_x - 2.0023) + \frac{3}{14}(g_y - 2.0023)\right]$$

In the above equation $P_d = g_N\beta_N g\beta\langle r^{-3}\rangle$ is the dipolar interaction between the unpaired electron and the ^{51}V nucleus, and is determined by the spatial distribution of the d electron.[47] κ is the Fermi contact term, a measure of the unpaired s-electron spin density at the nucleus, and is influenced by the polarisation of the inner s electrons upon interaction with the unpaired electron. The β^2 factor is, to a good approximation, the population of the ground state d orbital containing the unpaired spin; for $V^{IV}O$ species with C_{2v} symmetry or higher, it measures the population of the d_{xy} orbital. A value of 1 for β^2 indicates that the unpaired electron is localised exclusively on the vanadium d orbital and that there is no delocalisation onto the ligands. On the other hand, values of $\beta^2 < 1$ indicate that a $(1 - \beta^2)$ fraction of the spin density is delocalised onto the ligands.

Since the κ term is considered constant for vanadyl complexes,[48] a reduction in the A_z value could be connected to a decrease of P_d or β^2 or both. According to Kabanos et al.,[32] a reduced P_d value implies a larger $\langle r^{-3}\rangle$ value, which means a radial expansion of the $3d_{xy}$ orbital and a reduced electron density on the metal. This reduced electron density is expected to decrease the V=O bond strength.[49] From Figure 11 it can be observed that no correlation between the A_z(amide) values and the length of V=O bond in vanadyl unit is tenable. Thus, this mechanism can be excluded. This confirms that P_d can also be assumed constant for compounds with similar donor sets, as stated by Pecoraro.[48]

Pecoraro et al. proposed that the overlap of the π orbitals of the ligand with the d_{xy} vanadium atomic orbital would increase the covalence of the metal–ligand bond and produce a decrease in the β^2 value.[48] However, this hypothesis too can be ruled out because the π orbitals of the dipeptides

[a] A_z measured in 10^{-4} cm^{-1} units. [b] See Scheme 2.

and d_{xy} of vanadium are not in a favourable position to overlap with each other.

The only mechanism that may reduce the A_z value is a strong covalent bond between the deprotonated nitrogen atom and the $V^{IV}O$ ion. We suggest that if the TEC of amidate complexes is –4, i.e. the electronic density around the vanadium atom is high, the V–N bond exhibits a minor amount of covalent character and remains close to the ionic limit: this means higher β^2 and A_z values. On the other hand, if the TEC of the complex is –1, the V–N bond is more covalent, and this results in the reduction in the electron density at the d_{xy} nonbonding orbital of vanadium, and therefore a decrease in the β^2 and A_z values is observed.

According to Kabanos and Pecoraro,[32,48] we assume $P_d = 125 \times 10^{-4}$ cm^{-1} and $\kappa = 0.85$. Values of β^2 of approximately 0.92 for TEC = –4, 0.86 for TEC = –3, 0.80 for TEC = –2 and 0.74 for TEC = –1 are thus obtained.

Based on the A_z contribution of the amide group calculated in the previous discussion, we can attempt to find the donor set and the geometry for the $V^{IV}O$ species that involves this group. The first obvious observation is that the experimental coupling constants for the VOL_2H_{-1} species formed by two dipeptides with L-histidine in the C-terminal position show similar A_z values (about 157×10^{-4} cm^{-1}), whilst for HisGly, VOL_2H_{-1} exhibits a value of about 160×10^{-4} cm^{-1}. This substantiates the involvement of the imidazole nitrogen atom in metal coordination. Instead, the very low value of A_z for GlyCys suggests the participation of S^- in the bonding. Therefore, three equatorial positions are filled by HisGly, GlyHis, HisHis and GlyCys through (NH_2, N^-, COO^-), (NH_2, N^-, N_{im}), (NH_2, N^-, N_{im}), and (NH_2, N^-, S^-), respectively. The last two remaining sites of the coordination sphere of the $V^{IV}O$ ion are completed, according to the data in Table 5, by the (CO, NH_2) donor set which acts as a moderately strong donor towards the $V^{IV}O$ ion. The comparison of the experimental with calculated values supports that the CO group is in the equatorial position and the amino group is in the axial position.

The structures of the complexes formed upon deprotonation of the amide group are marked with **b**, **c**, **f**, **g**, **i** and **j** in Scheme 2.

Conclusions

Simple dipeptides coordinate the $V^{IV}O$ ion without the assistance of strong "anchoring" groups. The ligands coordinate the metal ion with (NH_2, CO) or (COO^-, CO) donor sets in the acidic and neutral pH range, and avoid the precipitation of the hydroxide if at least a fivefold excess of ligand is used. The presence of L-histidine in the N-terminal position enhances the strength of the (NH_2, CO) donor set. In the alkaline pH range, all the ligands, except CysGly, promote the deprotonation of the amide group. The effect of additional donors, e.g. imidazole and thiolate, can be seen also in species containing deprotonated amide groups. The donor sets (NH_2, N^-, N_{im}) and (NH_2, N^-, S^-) are stronger than the simple (NH_2, N^-, COO^-) donor set.

The composition of the complexes of GlyCys and CysGly depends on the location of the thiolato group. In GlyCys the coordination mode is (NH_2, N^-, S^-) and the C-terminal carboxylate does not take part in complexation. On the other hand, N-terminal cysteine peptides can form a stable five-membered chelated ring with the participation of the amino group, which gives rise to stable bischelated complexes without amide binding.

According to Kabanos and Cornman[37,44] the total charge on the equatorial plane of vanadium(IV) affects the bond type of the deprotonated amide group and determines the contribution of the nitrogen atom to the ^{51}V hyperfine coupling constant. We have demonstrated that the reduction of A_z(amide) observed when the TEC changes from –4 to –1 does not depend on the "shift" of "imine-like" to "amide-like" coordination. Instead, it is attributable to an increase in the covalence of the V–N bond accompanied by a decrease in the electron density at vanadium. Thus, it could be misleading to take into account a mean value for the contribution of the deprotonated amide groups without considering the effect of the total equatorial charge.

A direct application of these theoretical results allows the prediction of the geometry and donor set of the compounds involving the coordination of the amide group examined in this study.

Experimental Section

Chemicals: The ligands were Aldrich products of puriss. quality. Their purity and concentration were determined by the Gran method.[50] VO^{2+} solutions were prepared following literature methods.[51] The concentration of the metal ion was determined by $KMnO_4$ titration and that of H^+ by a potentiometric titration using the appropriate Gran function. The ionic strength was adjusted to 0.1 M with KNO_3. The temperature was 25.0 ± 0.1 °C.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Potentiometric Measurements: The protonation constants for the ligands and the stability constants for the $V^{IV}O$ complexes were determined by pH-potentiometric titrations of 2.0 mL samples. The ligand-to-metal molar ratio was in the range 1:1–5:1. The VO^{2+} concentration was 0.001 M. Titrations were performed by adding 0.1 M NaOH with a calibrated syringe under purified argon. The pH values were recorded with a combination glass electrode (Russel CMAWL/S7) calibrated for hydrogen concentration by the method of Irving et al.[52] The reproducibility of the titration points included in the evaluation was within 0.005 pH units in the whole pH range examined (2–12). As usual, the stability of the complexes is reported as the logarithm of the overall formation constant $\beta_{pqr} = [M_pH_qL_r]/[M]^p[H]^q[L]^r$, where M stands for the metal ion, H is the proton, and L is the deprotonated form of the ligand in the absence of metal coordination and was calculated with the aid of the SUPERQUAD program.[53] Standard deviations were calculated by assuming random errors. The conventional notation has been used. Negative indices for protons indicate either the proton dissociation of groups which do not deprotonate in the absence of coordination of the metal ion, or hydroxo ligands. Hydroxo complexes of VO^{2+} were taken into account in the calculations. The following species were assumed: $[VO(OH)]^+$ ($\log \beta_{1-1} = -5.94$), $[(VO)_2(OH)_2]^{2+}$ ($\log \beta_{2-2} = -6.95$), and the stability constants were calculated from the data of Henry et al.[54] and corrected for the different ionic strengths by use of the Davies equation,[55] $[VO(OH)_3]^-$ ($\log \beta_{1-3} = -18.0$) and $[(VO)_2(OH)_5]^-$ ($\log \beta_{2-5} = -22.0$).[56]

Spectroscopic and Analytical Measurements: Anisotropic EPR spectra were recorded on aqueous solutions with an X-band (9.15 GHz) Varian E-9 spectrometer in the temperature range 120–140 K. As usual for low temperature measurements, a few drops of DMSO were added to the samples to ensure good glass formation. The spectra were simulated with the computer program Bruker WinEPR SimFonia. Electronic spectra were recorded with a Beckman Acta MIV spectrophotometer.

Trinuclear Oxo-Centered Iron and Iron/Nickel Clusters – Ligand-Controlled Homo/Hetero Valency[‡]

Rolf W. Saalfrank,*[a] Andreas Scheurer,[a] Klaus Pokorny,[a] Harald Maid,[a] Uwe Reimann,[a] Frank Hampel,[a] Frank W. Heinemann,[b] Volker Schünemann,[c] and Alfred X. Trautwein[d]

Keywords: Trinuclear complexes / Iron / Nickel / Mixed-valent complexes / Heteronuclear complexes

Cleavage of the all-iron(III) μ_2-O^{2-}-linked dimer $[Fe^{III}_3O(L)_2(OAc)_4]_2O$ (**3**) with lithium chloride yields $[Fe^{III}_3O(L)_2(OAc)_4]Cl$ (**4**) and with sodium benzoate, in combination with complete acetate-to-benzoate coligand exchange, gives $[Fe^{III}_3O(L)_2(OBz)_4]OBz$ (**5**). Reduction of the all-Fe^{III} complex **5** [Fe/L/OBz = 3:2:(4+1)] with sodium iodide affords the homonuclear mixed-valent cluster $[Fe^{II}Fe^{III}_2O(L)_3(OBz)_3]$ (**6**) (Fe/L/OBz = 1:1:1) and requires fundamental coligand-to-ligand exchange. Likewise, when the all-Fe^{III} dimer $[Fe^{III}_3O(L)_2(OAc)_4]_2O$ (**3**) (Fe/L/OAc = 3:2:4) is cleaved with nickel acetate, the mixed-valent heteronuclear complex $[Ni^{II}Fe^{III}_2O(L)_3(OAc)_3]$ (**7**) (M/L/OAc = 1:1:1) is formed.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

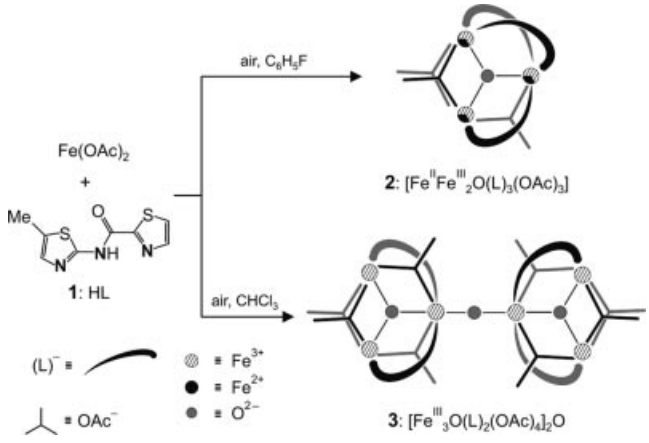
Introduction

Recently, we reported that the reaction of *N*-(5-methylthiazol-2-yl)thiazole-2-carboxamide HL (**1**) with fresh iron(II) acetate in fluorobenzene under aerobic conditions yields the deeply violet μ_3-O^{2-}-centered mixed-valent complex $[Fe^{II}Fe^{III}_2O(L)_3(OAc)_3]$ (**2**), whereas aged $Fe(OAc)_2$ in chloroform under aerobic conditions leads to homovalent dimer $[Fe^{III}_3O(L)_2(OAc)_4]_2O$ (**3**) (Scheme 1).[1–4] Most notably, the metal/ligand/coligand ratio (Fe/L/OAc) in mixed-valent **2** is 1:1:1, whereas the ratio in homo-valent **3** is 3:2:4.

Results and Discussion

All-Iron(III) Complexes

Herein we describe the cleavage of the μ_2-O^{2-}-linked dimer $[Fe^{III}_3O(L)_2(OAc)_4]_2O$ (**3**) in chloroform with lithium chloride or sodium benzoate to give $[Fe^{III}_3O(L)_2(OAc)_4]Cl$ (**4**) or $[Fe^{III}_3O(L)_2(OBz)_4]OBz$ (**5**) (Scheme 2). The cleavage of **3** with benzoate ions to give **5** obviously proceeds with complete acetate-to-benzoate coligand exchange.



Scheme 1. Synthesis of heteroleptic **2** and **3**. In **2**, the mixed valency and its statistical distribution is highlighted by differently marked segments.

The all-iron(III) character of **4** and **5** was confirmed by Mössbauer spectra of their powder samples recorded at 77 K. The spectra exhibit quadrupolar doublets and isomeric shifts consistent with high-spin iron(III) (**4**: ΔE_Q = 0.77 mm s^{-1}, δ = 0.48 mm s^{-1}, and Γ = 0.36 mm s^{-1}; **5**: ΔE_Q = 0.77 mm s^{-1}, δ = 0.51 mm s^{-1}, and Γ = 0.45 mm s^{-1}). The Mössbauer spectrum of **5** is displayed in Figure 1 as an example.

The structure of **4** was unequivocally determined by single-crystal X-ray analysis.[5–7] According to these data, heteroleptic $[Fe^{III}_3O(L)_2(OAc)_4]Cl$ (**4**) is made up of two ditopic, tridentate ligands $(L)^-$ and four bridging acetate coligands, fixing the three Fe^{III} ions in the corners of a triangle with a μ_3-O^{2-} ion in the center. Fe1/2 are linked by

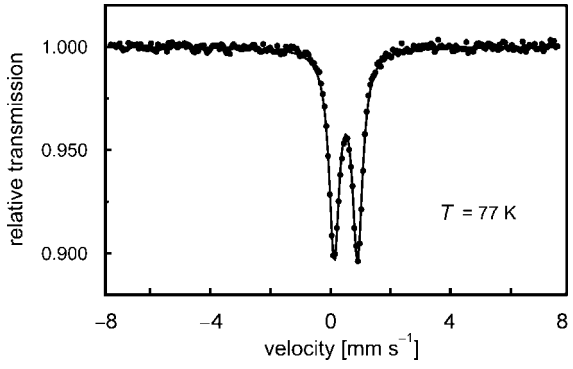

Figure 1. Mössbauer spectrum of **5**.

one ligand $(L)^-$ head-to-tail and Fe2/3 by one ligand $(L)^-$ tail-to-head. Furthermore, Fe1/2 and Fe2/3 are linked by one μ_2-$(OAc)^-$ bridge, each, and Fe1/3 by two μ_2-$(OAc)^-$ bridges. As a consequence, in the all-iron(III) compound **4**, Fe1 and Fe3 are identically octahedrally coordinated. The extra coordination site at Fe2 is occupied by a chloride ion, leading to charge compensation (Figure 2). As with **4**, complexes **2**–**10** were obtained as racemic mixtures.

Since we were not successful in growing single crystals suitable for an X-ray analysis of $[Fe^{III}_3O(L)_2(OBz)_4]OBz$ (**5**), we prepared $[Fe^{III}_3O(L)_2(OBzBr)_4]OBzBr$ (**9**). The all-iron(III) complex **9** was synthesised from iron(II) acetate with an excess of sodium 4-bromobenzoate and *N*-(5-methylthiazol-2-yl)thiazole-2-carboxamide HL (**1**) in chloroform under aerobic conditions, and separated from mixed-valent $[Fe^{II}Fe^{III}_2O(L)_3(OBzBr)_3]$ (**10**) by fractionising crystallization (Scheme 3). According to the X-ray analysis, **9** is isostructural with $[Fe^{III}_3O(L)_2(OAc)_4]Cl$ (**4**) with one μ_1-$(OBzBr)^-$ coligand bound to Fe, necessary for coordination and charge compensation (**9**: $\Delta E_Q = 0.81\ mm\,s^{-1}$, $\delta = 0.48\ mm\,s^{-1}$, and $\Gamma = 0.35\ mm\,s^{-1}$).[6–8]

Mixed-Valent Homonuclear and Mixed-Valent Heteronuclear Complexes

The reversible cyclic voltammograms of redox-active $[Fe^{II}Fe^{III}_2O(L)_3(OAc)_3]$ (**2**) and $[Fe^{II}Fe^{III}_2O(L)_3(OBz)_3]$ (**6**) displayed basically two processes attributable to the reduction of **2** and **6** from $Fe^{II}Fe^{III}_2$ to $Fe^{II}_2Fe^{III}$ and oxidation to the all-Fe^{III} species.[1] The number of electrons transferred at different potentials during this process was determined in acetonitrile vs. Fc/Fc^+ and turned out to be one for the reduction of all-Fe^{III} to $Fe^{II}Fe^{III}_2$ and one for the second reduction to $Fe^{II}_2Fe^{III}$. Further reduction of $Fe^{II}_2Fe^{III}$ to the all-Fe^{II} species is irreversible. Consequently, the cyclic voltammograms of redox-active $[Ni^{II}Fe^{III}_2O(L)_3(OAc)_3]$ (**7**) and $[Ni^{II}Fe^{III}_3O(L)_3(OBz)_3]$ (**8**) represent the reduction of $Ni^{II}Fe^{III}_2$ to $Ni^{II}Fe^{II}Fe^{III}$ and reoxidation to $Ni^{II}Fe^{III}_2$.[1] As determined in acetonitrile vs. Fc/Fc^+, one electron is transferred during this redox process. Further reduction of $Ni^{II}Fe^{II}Fe^{III}$ to the $Ni^{II}Fe^{II}_2$ species is irreversible.

Reduction of the all-iron(III) complex $[Fe^{III}_3O(L)_2(OBz)_4]$-OBz (**5**) in chloroform with 5 equiv. of sodium iodide[9] yields homonuclear mixed-valent cluster $[Fe^{II}Fe^{III}_2O(L)_3(OBz)_3]$ (**6**) (Scheme 2). Worth noting is that reduction of **5** does not simply occur by a one-electron reduction, but rather affords fundamental coligand-to-ligand exchange to give **6**. In order to generate **6** (Fe/L/OBz = 1:1:1), the mono- and bidentate $(OBz)^-$ coligands in **5** [Fe/L/OBz = 3:2:(4+1)] have to be substituted by the ditopic, tridentate ligand $(L)^-$ (Scheme 2). Furthermore, these findings coherently explain the irreversibility of the cyclic voltammograms of **4**, **5**, and **9**.

Likewise, when the all-iron(III) dimer $[Fe^{III}_3O(L)_2(OAc)_4]_2O$ (**3**) (Fe/L/OAc = 3:2:4) is cleaved with nickel acetate in chloroform, the mixed-valent heteronuclear $[Ni^{II}Fe^{III}_2O(L)_3(OAc)_3]$ (**7**) (M/L/OAc = 1:1:1) is formed. This again is a complex reaction and requires the exchange of Fe^{III}-to-Ni^{II} and of $(OAc)^-$ coligand-to-$(L)^-$. Since it was not possible to grow single crystals of acetate **7** suitable for X-ray structure determination, $[Ni^{II}Fe^{III}_2O(L)_3(OBz)_3]$ (**8**) was generated from **7** by exchange of the $(OAc)^-$ coligands with $(OBz)^-$ ions (Scheme 2).

The chelate complexes **6**–**8** are also accessible starting from complex **2**.[1] For example, **6** and **7** were prepared from

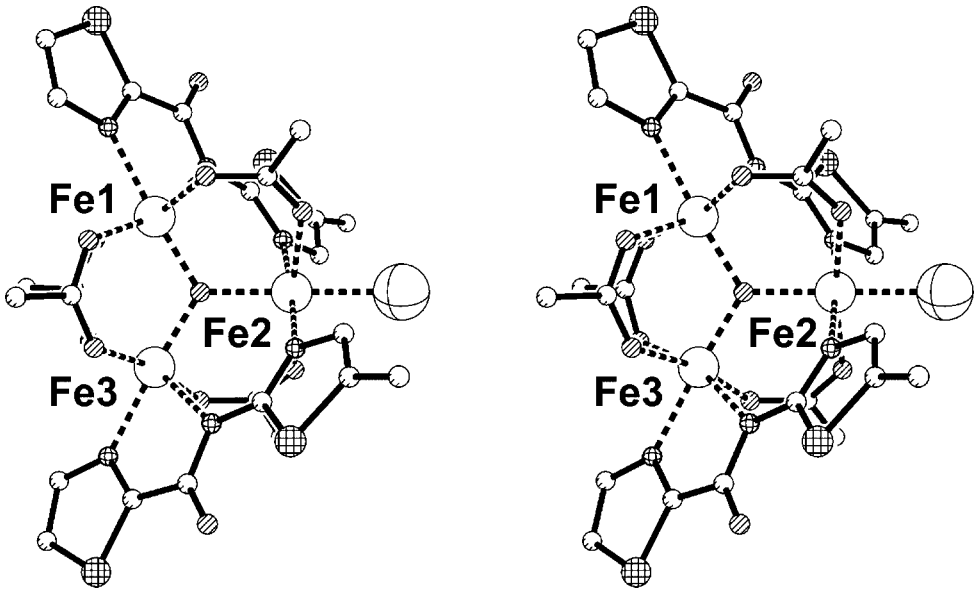

Figure 2. Molecular structure of **4** in the crystal (stereoview, PLUTON presentation, with the numbering of the iron ions, only one stereoisomer shown). H atoms omitted for clarity. C: shaded; N: net; O: diagonal; S: mesh; Fe: void; Cl: cross. Selected bond lengths [Å] and angles [°]: Fe1–μ_3-O 1.87, Fe2–μ_3-O 1.95; Fe1–μ_3-O–Fe2 121.1, Fe1–μ_3-O–Fe3 117.7.

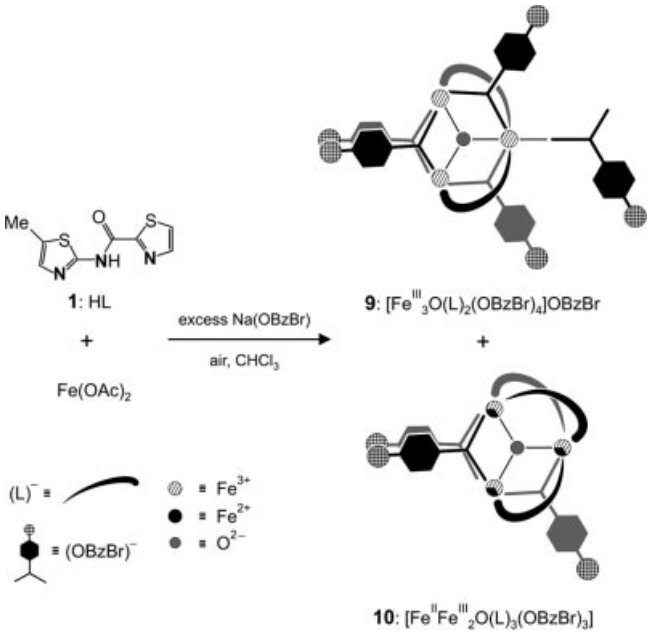

Scheme 3. Synthesis of all-iron(III) complex **9** and mixed-valent species **10**. In **10**, the mixed valency is marked by segments.

mixed-valent homonuclear $[Fe^{II}Fe^{III}_2O(L)_3(OAc)_3]$ (**2**) by mere exchange of the $(OAc)^-$ coligands by $(OBz)^-$ ions and by Fe^{II}-to-Ni^{II} exchange, respectively.

Conclusions

In summary, we have presented the cleavage of dimer **3** into **4**, **5**, and **7** and the interconversion of **5** into **6** and **7** into **8**. Most interestingly, in mixed-valent homonuclear **2** and **6** and in mixed-valent heteronuclear **7** and **8** the metal/ligand/coligand ratio M/L/co-L is 1:1:1, whereas, in homovalent **3**–**5** the ratio is 3:2:4. This result indicates ligand-controlled stabilization of the all-Fe^{III} and mixed-valent species.

Experimental Section

General Methods: IR spectra were recorded from $CHBr_3$ triturations with a Bruker IFS 25 spectrometer. FAB-MS spectra were recorded with a Micromass ZAB-Spec spectrometer. Elemental analyses were performed with an EA 1110 CHNS-Microautomat. The microanalytical data for **4**–**9** deviate from theory due to varying crystal solvents and are not recorded here.

Materials: All reagents and solvents employed were commercially available high-grade purity materials (Fluka, Aldrich), used as supplied without further purification. Ligand HL (**1**) was prepared according to ref.[2] Sodium 4-bromobenzoate was generated by reaction of 4-bromobenzoic acid (1.1 equiv.) with NaH (1.0 equiv.) in dry THF. The precipitate was filtered off, washed with THF and dried in vacuo.

General Procedure: The metal salt (LiCl, NaOBz, $Ni(OAc)_2$, NaI) was added, in one portion, to a solution of complexes **3** or **5** in chloroform. The initially pale violet suspension was stirred at 20 °C for 48 h. After removal of the excess metal salt by filtration through a pad of Celite, the remaining solution was concentrated to dryness.

Compound $[Fe^{III}_3O(L)_2(OAc)_4]Cl$ (4): 3 (131 mg, 0.075 mmol), anhydrous lithium chloride (509 mg, 12 mmol), and chloroform (60 mL). Yield: 110 mg (81%) dark-violet crystals from $CHCl_3$ by vapor diffusion of diethyl ether; m.p. >250 °C (decomp.). IR ($CHBr_3$): $\tilde{\nu}$ = 3137, 3109, 2995, 2923, 1615, 1575, 1556, 1505 cm^{-1}. FAB-MS (*m*-NBA): *m*/*z* (%) = 902 (6) $[M]^+$, 868 (100) $[M - Cl]^+$, 809 (59) $[M - Cl - OAc]^+$, 750 (22) $[M - Cl - 2\ OAc]^+$, 691 (11) $[M - Cl - 3\ OAc]^+$, 644 (33) $[M - Cl - L]^+$, 585 (32) $[M - Cl - OAc - L]^+$, 526 (25) $[M - Cl - 2\ OAc - L]^+$, 470 (21) $[M - Cl - 2\ OAc - L - Fe]^+$, 411 (21) $[M - Cl - 3\ OAc - L - Fe]^+$, 352 (16) $[M - Cl - 4\ OAc - L - Fe]^+$.

Compound $[Fe^{III}_3O(L)_2(OBz)_4]OBz$ (5): 3 (175 mg, 0.1 mmol), sodium benzoate (2.30 g, 16 mmol), and chloroform (80 mL). Yield: 178 mg (72%) dark-violet microcrystalline solid from $CHCl_3$ by vapor diffusion of diethyl ether; m.p. >250 °C (decomp.). IR ($CHBr_3$): $\tilde{\nu}$ = 3127, 3111, 2922, 1615, 1596, 1557, 1539, 1504 cm^{-1}. FAB-MS (*m*-NBA): *m*/*z* (%) = 1237 (3) $[M]^+$, 1116 (91) $[M – OBz]^+$, 1013 (32) $[M – L]^+$, 995 (100) $[M – 2\ OBz]^+$, 892 (60) $[M – OBz – L]^+$, 874 (41) $[M – 3\ OBz]^+$, 771 (73) $[M – 2\ OBz – L]^+$, 650 (76) $[M – 3\ OBz – L]^+$, 529 (35) $[M – 4\ OBz – L]^+$.

Compound $[Fe^{II}Fe^{III}_2O(L)_3(OBz)_3]$ (6): 5 (247 mg, 0.2 mmol), **1** (45 mg, 0.2 mmol), sodium iodide (50 mg, 0.33 mmol), and chloroform (50 mL). Yield: 129 mg (53%) dark-violet crystals from $CHCl_3$ by vapor diffusion of diethyl ether. For analytical data see ref.[1]

Compound $[Ni^{II}Fe^{III}_2O(L)_3(OAc)_3]$ (7): 3 (123 mg, 0.07 mmol), nickel acetate tetrahydrate (174 mg, 0.7 mmol), and chloroform (30 mL). Yield: 68 mg (47%) brown precipitate from $CHCl_3$/*n*-pentane (5 mL/30 mL; once repeated). For analytical data see ref.[1]

Compound $[Ni^{II}Fe^{III}_2O(L)_3(OBz)_3]$ (8): 7 (52 mg, 0.05 mmol), sodium benzoate (432 mg, 3 mmol), and chloroform (10 mL). Yield: 42 mg (68%) brown crystals from $CHCl_3$ by vapor diffusion of diethyl ether. For analytical data see ref.[1]

Compounds $[Fe^{III}_3O(L)_2(OBzBr)_4]OBzBr$ (9), $[Fe^{II}Fe^{III}_2O(L)_3(OBzBr)_3]$ (10): A suspension of iron(II) acetate (348 mg, 2 mmol) and sodium 4-bromobenzoate (6.70 g, 30 mmol) in chloroform (300 mL) was stirred under nitrogen for 2 h. After addition of HL (**1**) (534 mg, 2.4 mmol), the pale violet reaction mixture was stirred in air for a further 48 h. After removal of the excess metal salt by filtration through a pad of Celite, and concentration to dryness, the mixture of **9** and **10** (ratio of ca. 6:1) was purified by fractionizing crystallization from CH_2Cl_2/ether, yielding dark-violet crystals of **9**. Yield: 348 mg (32%); m.p. >250 °C (decomp.). IR ($CHBr_3$): $\tilde{\nu}$ = 3107, 2920, 1589, 1554, 1504, 1411 cm^{-1}. FAB-MS (*m*-NBA): *m*/*z* (%) = 1656 (2) $[M + Na]^+$, 1431 (80) $[M – OBzBr]^+$, 1408 (14) $[M – L]^+$, 1232 (100) $[M – 2\ OBzBr]^+$, 1207 (39) $[M – L – OBzBr]^+$, 1032 (51) $[M – 3\ OBzBr]^+$, 1008 (49) $[M – L – 2\ OBzBr]^+$, 831 (23) $[M – 4\ OBzBr]^+$, 808 (63) $[M – L – 3\ OBzBr]^+$, 752 (24) $[M – Fe – L – 3\ OBzBr]^+$. Complex **10** was characterized by FAB-MS and was not further purified: FAB-MS (*m*-NBA): *m*/*z* (%) = 1458 (65) $[M + H]^+$, 1256 (100) $[M – OBzBr]^+$, 1058 (31) $[M – OBzBr]^+$.

Acknowledgments

[3] Fresh $Fe(OAc)_2$ (Supplier Aldrich 51,793-3; 99.995%); aged $Fe(OAc)_2$ (kept under nitrogen in a Schlenk tube for 6–9 months with occasional opening). We suspect that aging of $Fe(OAc)_2$ leads to the formation of oligonuclear iron species. This assumption is supported by the fact that reaction of ten-membered iron wheel $[Fe^{III}_{10}(OAc)_{10}(OMe)_{20}]$ with HL (**1**) yields a mixture of $[Fe^{II}Fe^{III}_2O(L)_3(OAc)_3]$ (**2**), and $[Fe^{III}_3O(L)_2(OAc)_4]_2O$ (**3**, main product). The Fe^{II} ions in **2** are generated by reduction of Fe^{III} by methanol. We generated $[Fe^{III}_{10}(OAc)_{10}(OMe)_{20}]$ in ≥80% yield simply by stirring $Fe(OAc)_2$ or $FeCl_2$ together with NaOAc in air at 20 °C in methanol for 10 h. The X-ray crystallographic data matched those reported in ref.[10]

New Tris(thioimidazolyl)borate Ligands and Some Zinc Complexes Thereof

Mohamed M. Ibrahim,[a] Mouhai Shu,[a] and Heinrich Vahrenkamp*[a]

Keywords: Alcohol ligands / Alkoxide ligands / S ligands / Tripodal ligands / Zinc

In order to improve the encapsulation of metal ions coordinated by tris(thioimidazolyl)borate ligands, four new such ligands with *o*-substituted phenyl substituents were synthesised as well as ones with *p*-tolyl and cyclohexyl substituents. In order to provide a basis for their bioinorganic zinc complex chemistry, they were converted to some zinc-halide, -carboxylate, -nitrate, -phenolate and -benzylate complexes. They form zinc-perchlorate complexes which are productive starting materials for the attachment of alcohols and alkoxides at zinc, thereby yielding new structural models for the zinc enzyme alcohol dehydrogenase.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Among the zinc enzymes the alcohol dehydrogenases[1] and the thiolate alkylating enzymes[2] have an unusually (cysteine-)sulfur-rich ligand environment of the zinc ion. We[3,4] and others[5–9] have tried to model the structure and function of these enzymes by applying tripodal scorpionate[10] ligands bearing one to three sulfur donors. During these studies Parkin's[5,8,11,12] and our own research group[3,13] have found that the sulfur-rich environment of the tris(thioimidazolyl)borate ligands (Tti^R) enables the attachment of quite unusual and biologically relevant co-ligands X at the zinc ion in an S_3ZnX environment.

During these studies it also became evident that the substituted tris(thioimidazolyl)borates (Tti^R) have one disadvantage in comparison to the widely used tris(pyrazolyl)borates (Tp^R). While the R substituents at the 3-positions of the pyrazolylborates provide an ideal encapsulation of the metal ions bound to the three pyrazole nitrogens due to their orientation, the corresponding R substituents at the 1-nitrogens of the thioimidazolylborates are less efficient in this respect because they point away from the core of the ligands. As encapsulation of the metals is a key feature in the development of ligands for a viable bioinorganic model complex chemistry, there arose the necessity to use Tti^R ligands with sterically more demanding substituents R.

The Tti ligands, which should bear as much potential as the Tp ligands, were introduced by Reglinski in 1996.[14] Remarkably little metal complex chemistry has been done with them in the eight years since, either by Reglinski himself[15–20] or by other research groups.[3,5,8,11–16,21–25] So far only methyl,[14] *tert*-butyl,[3] benzyl,[22] phenyl,[5] *p*-tolyl,[22] mesityl[5] and *p*-cumenyl substituents[3] have been attached at the N^1 nitrogens of the thioimidazolyl moieties, of which only *tert*-butyl and mesityl can be considered as sterically demanding.

Having enjoyed the bioinorganic zinc chemistry of the Tp^R ligands for many years,[26] we trusted the zinc chemistry of the Tti^R ligands to be equally fertile. We therefore set out to lay a basis for it by obtaining Tti^R ligands with improved encapsulation abilities. In order to achieve this we chose *o*-substituted phenyl groups as the substituents R. We prepared two ligands with one *o*-substituent each (**L1**, **L2**), two with two *o*-substituents each (**L3**, **L4**), and we also de-

scribe a variation of the synthesis of *p*-substituted **L5**[22] and the synthesis of cyclohexyl-substituted **L6**. This paper reports the ligand syntheses, some simple zinc complexes, and some alcohol and alkoxide derivatives relevant to the zinc enzyme alcohol dehydrogenase.

Results and Discussion

Ligand Synthesis

While the preparation of tris(pyrazolyl)borates requires high-temperature reactions between KBH_4 and the pyrazoles in a melt, the thioimidazoles react with KBH_4 under milder conditions, typically in boiling toluene. This made the synthesis of ligands **L1**–**L6** an easy, high-yield process, the most time-consuming part of which is actually the two-step synthesis of the substituted thioimidazoles, whose overall yields rarely exceed 50%.

Except for **L2** (ca. 60%) the potassium salts of the ligands **L** were obtained in yields of around 90%. K[**L1**] and K[**L5**] were obtained analytically pure from the reaction solution, K[**L2**] needed a chromatographic purification, and the other K[**L**] complexes were crystallised from methanol. Their characteristic spectral features are the weak ν(BH) band at around 2500 cm^{-1} and a pair of doublets due to the two imidazole protons in the ^1H NMR spectra.

Complexes of Simple Anions

It was already known[3,5,11] that zinc in the sulfur-rich ligand environment of the tris(thioimidazolyl)borate ligands is complemented favourably by oxygen-containing coligands and by the halides. This was verified here for ligands **L1**, **L3** and **L5** in combination with zinc and simple anionic coligands. In order to obtain complexes **1**–**9** the potassium salts of **L** were either treated directly with $ZnCl_2$, ZnI_2, $Zn(NO_3)_2$ or $Zn(CH_3COO)_2$, or they were reacted first with zinc perchlorate and then with the deprotonated forms of thioacetic acid or *p*-nitrothiophenol. The latter was included with the anionic ligands due to its typical UV/Vis absorption, which we intend to exploit for kinetic studies of the alkylation of Zn–OR species in comparison to Zn–SR species.[8,27] Products **1**–**9** were isolated in very good yields as colourless (**1**–**5**) or yellow (**6**–**9**) powders. Except for **1**, **2** and **3** the characteristic ^1H NMR features of the anionic coligands complement the typical spectral characteristics (see above) of their ligands **L**.

L3•Zn-Cl	**L3**•Zn-I	**L3**•Zn-ONO_2
1	**2**	**3**
L1•Zn-$OCOCH_3$	**L3**•Zn-$OCOCH_3$	**L3**•Zn-$SCOCH_3$
4	**5**	**6**
L1•Zn-$OC_6H_4NO_2$	**L3**•Zn-$OC_6H_4NO_2$	**L5**•Zn-$OC_6H_4NO_2$
7	**8**	**9**

The structure determinations of **1**, **3**, **4**, **5** and **9** confirmed the identities of the ligands, the characteristic structural features of the **L**·Zn units and the coligand attachment. Figure 1 displays the complete molecule of **1** as an example; Table 1 lists the important bonding features. There is a quite uniform array of the four donors around the zinc ions. The attachment of the tripod ligands **L** nicely defines a tetrahedral geometry with remarkably constant bond lengths and angles. The coligands' donor atoms (Cl and O), however, are never positioned correctly on the trigonal axis of the complexes, as defined by the B–Zn line. Table 1 displays this in terms of the X–Zn···B angles. These deviate most from 180° in the case of the nitrate and acetate complexes **3**, **4** and **5**, thus reflecting the semi-bidentate nature of their coligands. As a consequence, the X–Zn–S angles in all complexes described in this paper show a considerable spread, typically between 100° and 120°.

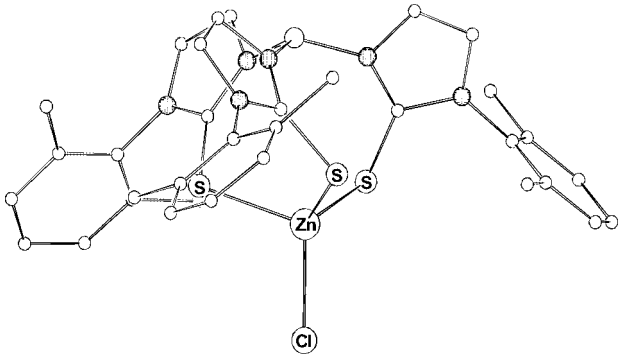

Figure 1. Molecular structure of **1**.

Table 1. Bond lengths [Å] and angles [°] around the zinc ions in complexes **1**, **3**, **4**, **5**, and **9**.

	X	Zn–X	Zn–S(av)	S–Zn–S(av)	X–Zn···B
1	Cl	2.252(2)	2.34(1)	108(2)	175
3	O	2.007(6)	2.33(1)	109(2)	171
4	O	2.005(11)	2.37(1)	107(1)	161
5	O	1.954(5)	2.34(2)	108(1)	172
9	O	1.926(5)	2.33(1)	106(3)	174

The voluminous nature of the tripod ligands **L** somewhat obscures their essential bonding characteristics. Therefore, two views of molecular fragments were chosen to make them visible. One of them is the view along the B···Zn axis (Figure 2), which shows the chiral, screw-like array of the three thioimidazolyl moieties between the boron and zinc atoms that is the most characteristic feature distinguishing the tris(thioimidazolyl)borates from the tris(pyrazolyl)borates. The other is the orientation of the external aromatic substituents (Figure 3). Following the trigonal symmetry of the **L**·Zn units, all three of them are always tilted in the same direction with respect to the thioimidazole rings. The amount of this tilting varies within each complex and between complexes. It places the "down" parts of the aromatic rings in the vicinity of the zinc-bound coligands, thereby providing the encapsulation of the Zn–X units, though in a much less efficient way than in related tris(pyrazolyl)borates. Yet, as Figure 3 shows, the best way to improve this encapsulation should be the attachment of *ortho*-substitu-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ents at the aromatic rings, which, due to the tilting, are most likely to be located in the vicinity of the Zn–X units.

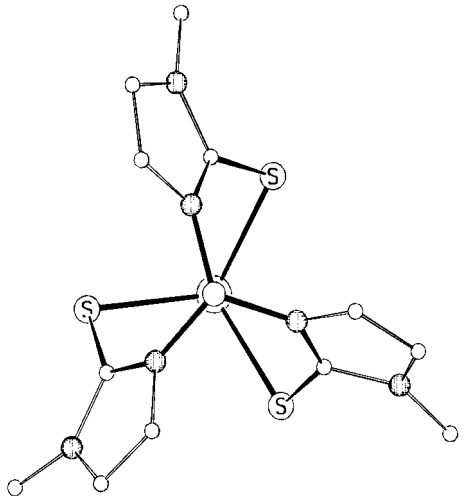

Figure 2. A view of complex **1** down the B···Zn line (aromatic substituents omitted for clarity).

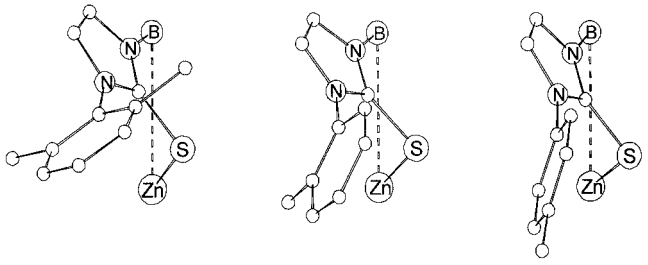

Figure 3. One substituted thioimidazolyl fragment each of complexes **1**, **4** and **21**, viewed perpendicular to the B···Zn line.

Perchlorate Complexes

Quite a number of the complexes described in this paper were prepared by combining a ligand **L** with zinc perchlorate first. This implies that in the intermediate species either perchlorate or the solvent used is coordinated to zinc. Probing this we realized that the **L**·Zn-perchlorate complexes are easily formed and that they can be used as precursors of **L**·Zn complexes with other unusual coligands X. The solvent of choice for this purpose is methanol, which obviously binds less well to zinc than perchlorate. Accordingly, complexes **10**–**14** were obtained from K[**L**] and $Zn(ClO_4)_2$ in methanol.

L1•Zn-$OClO_3$ **10** **L2**•Zn-$OClO_3$ **11** **L3**•Zn-$OClO_3$ **12**

L4•Zn-$OClO_3$ **13** **L6**•Zn-$OClO_3$ **14**

The characteristic feature of **10**–**14**, apart from the weak ν(BH) band, is the very strong perchlorate band in the infrared spectra in the region of 1090 cm^{-1}. The existence of a Zn–$OClO_3$ connection has already been proved by us by the structure determination of tris(*N*-*tert*-butylthioimidazolyl)boratozinc perchlorate.[3] The ease of isolation of **10**–**14** has made it clear now that these complexes are much less labile than originally assumed.

Alkoxide Complexes

In our previous studies of zinc complexes of tris(thioimidazolyl)borate ligands, which were aimed predominantly at modelling alcohol dehydrogenase,[3] alkoxide complexes had evaded us. We now found that they are accessible with the new ligands **L**. In trying to make mononuclear **L**·Zn–OR complexes we learnt that these are still inaccessible with aliphatic alkoxides or with benzylate, but the more electronegative *p*-nitrobenzylate and *p*-(trifluoromethyl)benzylate could be introduced as terminal ligands in complexes **15** and **16**. The procedure which led to them is the reverse of the procedure used for all other complexes: zinc perchlorate and the benzylate are combined first, and only after that is the tripod **L3** attached.

L3•Zn-$OCH_2C_6H_4NO_2$ **15** **L3**•Zn-$OCH_2C_6H_4CF_3$ **16**

The mononuclear nature of **15** and **16** is evident from their solubility in non-polar solvents and from their ^1H NMR spectra, which correspond for the **L3**·Zn unit to those of the other mononuclear **L3**·Zn complexes. In addition the ^1H and ^{19}F NMR spectroscopic data confirm the presence of the benzylate ligands. Unfortunately, complexes **15** and **16** did not yield crystals suitable for a structure determination.

Aliphatic alkoxides could be incorporated using the standard procedure, i.e. first making the intermediate **L**·Zn perchlorate complex and then treating it with the alkoxide. Methoxide, ethoxide and trifluoroethoxide could be combined with **L3**·Zn, but the structure determinations showed that the resulting complexes **17**–**19** are dinuclear and contain bridging alkoxide ligands. The ionic nature of **17**–**19** is reflected by their solubility only in polar solvents. Their ^1H NMR spectra show small but significant shifts compared to those of the mononuclear **L3**·Zn complexes.

[**L3**•Zn-OR-Zn**L3**]ClO_4

17: R = CH_3, **18**: R = C_2H_5, **19**: R = CH_2CF_3

Figure 4 shows the structure of **17** as an example; that of **18** is very similar. In both **17** and **18** the alkoxide bridge is nicely symmetrical with two virtually identical Zn–O distances and Zn–O–C angles each (see Table 2). The Zn–O bond lengths (near 1.95 Å) resemble those for the **L**·Zn nitrophenolates (see above and ref.[3]). We could not find a structurally characterised dizinc complex with a single unsupported alkoxide bridge in the literature, but there are some related complexes with single hydroxide bridges.[28–32] Their Zn–O bond lengths (1.87–2.00 Å) and Zn–O–Zn angles (132–141°) closely resemble those of **17** and **18**. With

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

respect to the **L3**·Zn units, specifically the displacement of the bridging oxygen off the B···Zn line, complexes **17** and **18** are completely analogous to the other **L**·Zn–X complexes reported here.

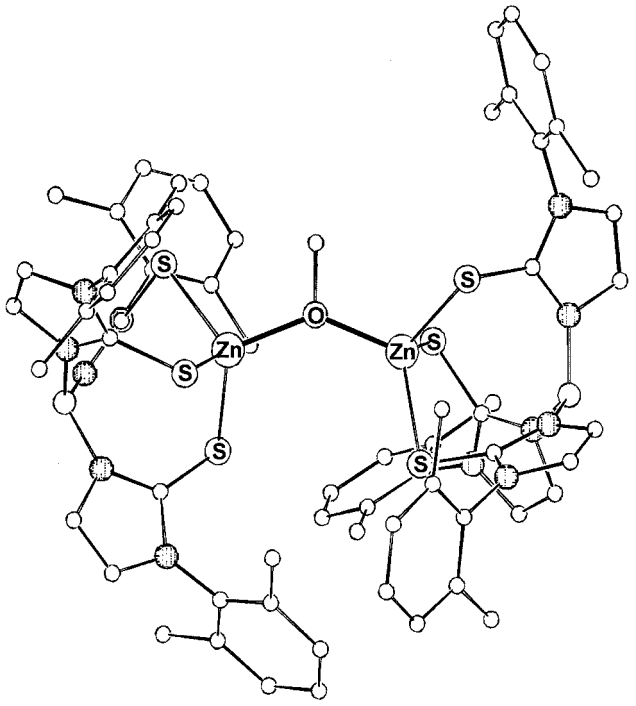

Figure 4. Structure of the dinuclear cation of **17**. See Table 2 for details.

Table 2. Relevant distances [Å] and angles [°] araound the zinc ions in the alkoxide-bridged complexes.

	17	**18**

Complexes with Alcohol and Aldehyde Ligands

We have already shown[3] that the electron-rich nature of the **L**·Zn unit and its favourable combination with oxygen donors allows the attachment of ethanol as a coligand. We could now show that with the ligands **L** used in this paper even the weaker oxygen donor 2-propanol can be attached. The 2-propanol complexes **20** and **21** crystallised when **L3** or **L5** were combined with zinc perchlorate in 2-propanol.

[**L3**•Zn(*i*-C_3H_7OH)]ClO_4 **20**

[**L5**•Zn(*i*-C_3H_7OH)]ClO_4 **21**

Complex **21** was chosen for a structure determination (see Figure 5). There are two formula units of **21** in the asymmetric unit. In one of them the 2-propanol ligand is linked through a hydrogen bond (2.67 Å) to another 2-propanol molecule, and in the other it is linked by a hydrogen bond (2.84 Å) to a perchlorate anion. This attachment of an external hydrogen-bond acceptor seems to be a common feature of all zinc–alcohol complexes with tripodal ligands.[3–5] Likewise, the Zn–O bond lengths in both complex units of **21** (av. 1.98 Å) lie within the small range of such bond lengths observed before (1.97–2.01 Å),[3–5] and they are nearly identical to the one in the pentafluorobenzyl alcohol adduct of alcohol dehydrogenase (ADH).[33] This adds complex **21** to the list of structural models of ADH.

The idea of modelling ADH was also the reason for attaching the two functional phenols salicylic alcohol and salicylic aldehyde as phenolates to the **L3**·Zn unit. The *o*-hydroxymethylphenolate complex **22** and the *o*-formylphenolate complex **23** were obtained by treating the deprotonated phenols first with zinc perchlorate and then with K[**L3**]. It was hoped that the chelate effect would enable a coordination of the alcoholic function in **22** and the aldehydic function in **23** to zinc, thereby generating a pair of complexes that mimic the binding of substrate and product in the active centre of ADH, as we had achieved before with $Zn(SR)_2$ systems.[34]

L3•Zn-OC_6H_4-*o*-CH_2OH **22**

L3•Zn-OC_6H_4-*o*-CHO **23**

While the spectroscopic data of **22** are inconclusive, those of **23** indicate coordination of the aldehyde oxygen to zinc: both the ν(CO) IR band (1671 → 1659 cm^{-1}) and the ^1H NMR formyl signal (δ = 9.99 → 11.03 ppm) undergo shifts in the expected direction relative to those of formylphenolate. The structure determination of **23**, however, disproved this assumption. As Figure 6 shows, the formyl oxygen is

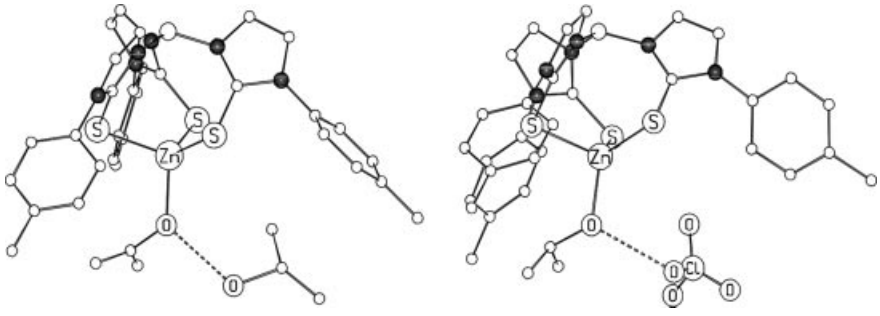

Figure 5. The two crystallographically independent complex cations of **21**. Left (linked to a molecule of 2-propanol): Zn–O 1.979(4), Zn–S 2.307(2), 2.317(2) and 2.332(2) Å. Right (linked to a perchlorate anion): Zn–O 1.984(4), Zn–S 2.309(2), 2.315(2) and 2.332(2) Å.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

oriented away from the zinc ion, thus making **23** a normal phenolate complex comparable to **7**–**9**. Based on this observation, and on the similar non-coordination of the hydroxymethyl group in **24** (see below), it must be concluded that the hydroxymethyl function in **22** is also not coordinated to zinc.

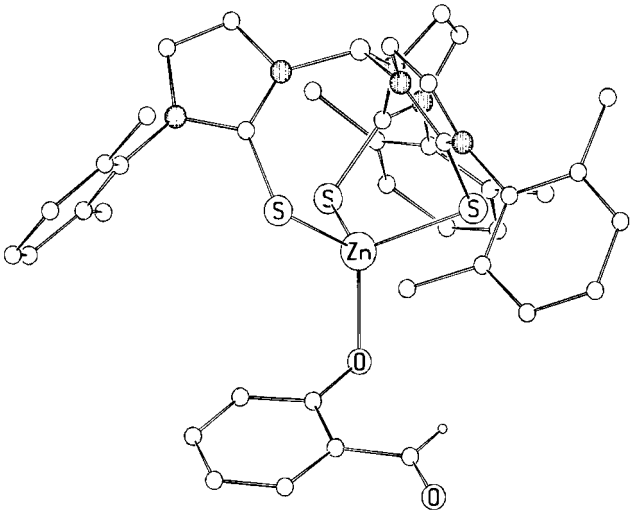

Figure 6. Molecular structure of complex **23**. Zn–O 1.937(2), Zn–S 2.338(1), 2.363(1), and 2.319(1) Å.

The same reasoning as above, together with the knowledge that the **L**·Zn units, unlike the TpZn units, easily bind uncharged nitrogen ligands,[3,5,12,13] led us to the application of 1-methyl-2-hydroxymethylimidazole. It was hoped that the coordination of both its 3-nitrogen and the hydroxymethyl oxygen to zinc would be favoured by the formation of a five-membered chelate ring. The desired complex **24** was formed by treating the intermediate **L5**·Zn perchlorate with the imidazole.

[**L5**•Zn(1-methyl-2-hydroxymethylimidazole)]ClO_4

24

The structure determination of **24** again eliminated the assumption of Zn–OH coordination. Just as observed for $Zn(SR)_2$ complexes of 1-methyl-2-hydroxymethylimidazole and 1-methyl-2-formylimidazole,[34] only the imidazole nitrogen is coordinated to zinc. As Figure 7 shows, complex **24** is essentially an imidazole adduct of [**L5**·Zn]$^+$ with a nicely symmetrical arrangement of the NS_3donor set.

Conclusions

This paper has about doubled the number of available tris(thioimidazolyl)borate ligands and underlined their suitability for a biomimetic zinc complex chemistry. Although they still lack the major advantage of the tris(pyrazolyl)borates, i.e. the ease of encapsulating the metal ion by properly placed substituents, an approach seems to be emerging to achieve this. As the structural dispositions exemplified by Figures 2 and 3 show, voluminous substituents at the *ortho*-positions of phenyl rings at the thioimidazole's N3 nitro-

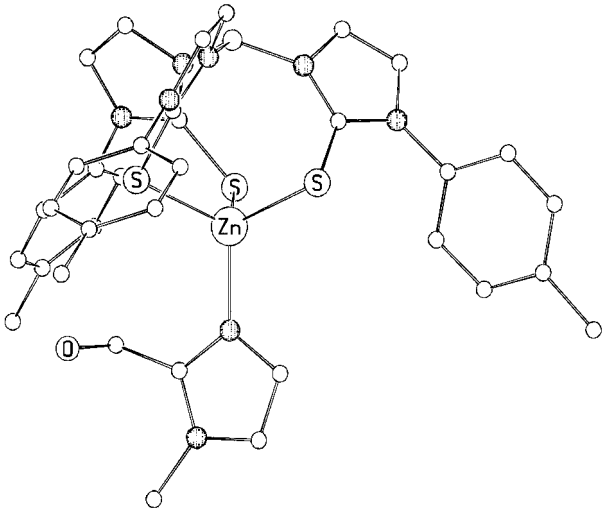

Figure 7. Structure of the complex cation of **24**. Zn–N 1.991(4), Zn–S 2.315(2), 2.325(2), and 2.333(2) Å. S–Zn–S 105.6–109.8(1)°, S–Zn–N 108.0–113.1(1)°.

gens should be oriented towards the neighbourhood of the metal ions and thereby create the desired cavity for them.

We have already observed[3] that the very soft environment of the zinc ion provided by these S_3 tripods results in a reluctance of zinc to bind a fourth soft donor, for instance an alkanethiolate. Conversely, hard oxygen donors are bound very well, as exemplified here by acetate, nitrate and *p*-nitrophenolate. Particularly noteworthy in this respect is the ease of formation of perchlorate complexes, which promise to be good starting materials for further labile **L**·Zn complexes of ligands **L1**–**L6**.

The latter was exemplified by the formation of the 2-propanol complexes **20** and **21**. Thus, 2-propanol is preferred over perchlorate as a donor here. In contrast, methanol is not, as all the perchlorate complexes described here were prepared in methanol. There seems to be a delicate balance of stabilities which is controlled by the substituents on the thioimidazole rings: with R = mesityl Parkin isolated a methanol complex,[5] with R = *tert*-butyl we obtained an ethanol complex,[3] and now with R = 2,6-xylyl and *p*-tolyl the 2-propanol complexes were obtained. We consider it likely that equilibrium mixtures of alcohol and perchlorate complexes exist in solution.

With respect to the modelling of alcohol dehydrogenase some new insights are provided by this work too. One of them is the accessibility of the alcohol complexes. Another is the accessibility of alkoxide complexes. Although the latter could only be obtained with a singly bridging alkoxide for methanol and ethanol, they resulted as monomers with terminal alkoxide ligands for *para*-substituted benzyl alcohol. As before[3] our attempts failed to induce alcohol or aldehyde coordination by the chelate effect: the hydroxymethyl and formyl side-arms of the coligands in complexes **22**–**24** remain uncoordinated. Nevertheless, complexes **20/21** and **15/16** represent the first chemical reproduction of the enzymatic situation where first the alcohol and then the alkoxide are bound to the same **L**·Zn unit.

Experimental Section

For general working and measuring procedures, see ref.[35] All procedures for the ligand synthesis were performed under an inert gas. The isolation procedures described below yielded the new complexes spectroscopically pure. Samples for elemental analyses were recrystallised from methanol and/or dichloromethane. All *N*-substituted mercaptoimidazoles were prepared from bromoacetaldehyde diethylacetal, the amine RNH_2 and HSCN according to the established procedure.[36,37] They were characterised by ^{1}H NMR spectroscopy in $CDCl_3$ as follows:

R = *o*-tolyl: δ = 2.21 (s, 3 H, Me), 6.72 (d, *J* = 2.3 Hz, 1 H, Im), 6.84 (d, *J* = 2.3 Hz, 1 H, Im), 7.26–7.44 (m, 4 H, Ph), 10.94 (br. s, 1 H, NH) ppm.

R = *o*-biphenylyl: δ = 6.40 (d, *J* = 2.1 Hz, 1 H, Im), 6.62 (d, *J* = 2.1 Hz, 1 H, Im), 7.29–7.43 (m, 4 H, Ph), 7.45–7.65 (m, 5 H, Ar), 12.15 (s, 1 H, NH) ppm.

R = 2,6-xylyl: δ = 2.12 (s, 6 H, Me), 6.72 (d, *J* = 2.2 Hz, 1 H, Im), 6.98 (d, *J* = 2.2 Hz, 1 H, Im), 7.20 [d, *J* = 6.4 Hz, 2 H, Ph(3,5)], 7.29 [t, *J* = 5.6 Hz,, 1 H, Ph(4)], 12.34 (s, 1 H, NH) ppm.

R = 2,6-di(isopropyl)phenyl: δ = 1.12 (d, *J* = 6.9 Hz, 6 H, Me), 1.30 (d, *J* = 6.9 Hz, 6 H, Me), 2.61 (m, *J* = 6.7 Hz, 2 H, CH), 6.64 (d, *J* = 2.2 Hz, 1 H, Im), 6.85 (d, *J* = 2.2 Hz, 1 H, Im), 7.28 [d, *J* = 7.8 Hz, 2 H, Ph(3,5)], 7.43 [t, *J* = 7.3 Hz, 1 H, Ph(4)], 12.20 (s, 1 H, NH) ppm.

R = *p*-tolyl: 2.41 (s, 3 H, Me), 6.80 (d, *J* = 1.6 Hz, 1 H, Im), 6.84 (d, *J* = 1.6 Hz, 1 H, Im), 7.28 (m, 2 H, Ph), 7.45 (m, 2 H, Ph) ppm.

R = cyclohexyl: δ = 1.17–1.56 [p, *J* = 9.8 Hz, 4 H, CH_2(3,5-cyclohexyl)], 1.73–1.85 [q, *J* = 10.8 Hz, 4 H, CH_2(2,6-cyclohexyl)], 1.91 [m, 2 H, CH_2(4-cyclohexyl)], 4.66 (m, *J* = 4.00 Hz, 1 H, CH), 6.71 (d, *J* = 2.3 Hz, 1 H, Im), 6.73 (d, *J* = 2.3 Hz, 1 H, Im), 10.75 (s, 1 H, NH) ppm.

Ligand Synthesis. General Procedure: The *N*-substituted thioimidazole and KBH_4 were ground very finely. Toluene (100 mL) was added and the mixture refluxed for one week. After cooling to room temperature the precipitate was filtered off, washed with toluene and dried in vacuo.

L1: From 11.4 g (60.0 mmol) of *N*-(*o*-tolyl)thioimidazole and 1.08 g (20.0 mmol) of KBH_4. The precipitate was analytically pure. Yield 11.5 g (93%) of **L1** as a colourless powder, m.p. 200 °C (dec.). $C_{30}H_{28}BKN_6S_3$ (618.70): calcd. C 58.24, H 4.56, N 13.58, S 15.55; found C 59.10, H 5.08, N 13.87, S 15.80. ^{1}H NMR ($CDCl_3$): δ = 2.10 (s, 9 H, Me), 6.47 (d, *J* = 2.2 Hz, 3 H, Im), 6.70 (d, *J* = 2.2 Hz, 3 H, Im), 7.29 (m, 12 H, Ph) ppm. IR (KBr): $\tilde{\nu}$ = 2520 w (BH) cm^{-1}.

L2: From 4.92 g (19.50 mmol) of *N*-(*o*-biphenylyl)thioimidazole and 0.35 g (6.50 mmol) of KBH_4. Purification of the ligand required column chromatography over silica gel with methanol/dichloromethane (1:10). Yield 3.26 g (62%) of **L2** as a colourless powder, m.p. 215 °C (dec.). $C_{45}H_{34}BKN_6S_3$ (804.91): calcd. C 67.15, H 4.26, N 10.44, S 11.95; found C 64.73, H 4.49, N 10.02, S 11.73. ^{1}H NMR ($CDCl_3$): δ = 5.77 (d, *J* = 2.0 Hz, 3 H, Im), 6.37 (d, *J* = 2.0 Hz, 3 H, Im), 7.09–7.20 (m, 12 H, Ph), 7.31–7.46 (m, 15 H, Ar) ppm. IR (KBr): $\tilde{\nu}$ = 2482 w (BH) cm^{-1}.

L3: From 4.80 g (23.5 mmol) of *N*-(2,6-xylyl)thioimidazole and 0.42 g (7.8 mmol) of KBH_4. Recrystallisation from methanol yielded 4.57 g (88%) of **L3** as a colourless powder, m.p. 220 °C (dec.). $C_{33}H_{34}BKN_6S_3{\cdot}H_2O$ (660.78 + 18.01): calcd. C 58.39, H 5.35, N 12.38, S 14.17; found C 57.87, H 5.38, N 12.25, S 14.00. ^{1}H NMR ($CDCl_3$): δ = 2.08 (s, 18 H, Me), 6.59 (d, *J* = 2.2 Hz, 3 H, Im), 6.63 (d, *J* = 2.2 Hz, 3 H, Im), 7.15 [d, *J* = 7.4 Hz, 6 H, Ph(3,5)], 7.26 [t, *J* = 6.3 Hz,, 3 H, Ph(4)] ppm. IR (KBr): $\tilde{\nu}$ = 2555 w (BH) cm^{-1}.

L4: From 8.38 g (32.2 mmol) of *N*-(2,6-diisopropylphenyl)thioimidazole and 0.58 g (10.7 mmol) of KBH_4. Recrystallisation from methanol yielded 7.45 g (84%) of **L4** as a colourless powder, m.p. 255 °C (dec.). $C_{45}H_{58}BKN_6S_3$ (829.10): calcd. C 65.19, H 7.05, N 10.14, S 11.60; found C 65.22, H 7.41, N 9.46, S 10.81. ^{1}H NMR ($CDCl_3$): δ = 1.12 (d, *J* = 6.8 Hz, 18 H, Me), 1.30 (d, *J* = 6.8 Hz, 18 H, Me), 2.58 (m, *J* = 6.7 Hz, 6 H, CH), 6.64 (d, *J* = 2.29 Hz, 3 H, Im), 6.85 (d, *J* = 2.3 Hz, 3 H, Im), 7.28 [d, *J* = 7.8 Hz, 6 H, Ph(3,5)], 7.46 [m, 3 H, Ph(4)] ppm. IR (KBr): $\tilde{\nu}$ = 2533 w (BH) cm^{-1}.

L5: From 9.12 g (0.48 mmol) of *N*-(*p*-tolyl)thioimidazole and 0.86 g (0.16 mmol) of KBH_4. The precipitate was analytically pure. Yield 8.61 g (87%) of **L5** as a colourless powder, m.p. 215 °C (dec.). $C_{30}H_{28}BKN_6S_3$ (618.70): calcd. C 58.24, H 4.56, N 13.58, S 15.55; found C 57.55, H 4.80, N 13.57, S 15.37. ^{1}H NMR (CD_3OD): δ = 2.38 (s, 9 H, Me), 6.70 (d, *J* = 2.2 Hz, 3 H, Im), 6.98 (d, *J* = 2.2 Hz, 3 H, Im), 7.26 (d, *J* = 8.2 Hz, 6 H, Ph), 7.45 (d, *J* = 8.2 Hz, 6 H, Ph) ppm. IR (KBr): $\tilde{\nu}$ = 2495 w (BH) cm^{-1}.

L6: From 7.25 g (40.0 mmol) of *N*-cyclohexylthioimidazole and 0.72 g (13.3 mmol) of KBH_4. Recrystallisation from methanol yielded 7.15 g (91%) of **L6** as a colourless powder, m.p. 220 °C (dec.). $C_{27}H_{37}BKN_6S_3{\cdot}2H_2O$ (591.74 + 36.03): calcd. C 51.65, H 6.58, N 13.39, S 15.32; found C 51.74, H 6.98, N 13.35, S 15.39. ^{1}H NMR (CD_3OD): δ = δ = 1.27–1.49 [p, *J* = 12.3, 12 H, CH_2(3,5-cyclohexyl)], 1.49–1.78 [q, *J* = 5.3, 12 H, CH_2(2,6-cyclohexyl)], 1.86 [m, 6 H, CH_2(4-cyclohexyl)], 4.64 (m, *J* = 3.5 Hz, 3 H, CH-cyclohexyl), 6.31 (d, *J* = 2.2 Hz, 3 H, Im), 6.79 (d, *J* = 2.2 Hz, 3 H, Im) ppm. IR (KBr): $\tilde{\nu}$ = 2514 w (BH) cm^{-1}.

Simple Zinc Complexes

1: A solution of 264 mg (0.40 mmol) of **L3** in 10 mL of absolute methanol was added dropwise with stirring to a solution of 55 mg (0.40 mmol) of anhydrous $ZnCl_2$ in 10 mL of absolute methanol. After stirring for 4 h the volume of the solution was reduced to 10 mL in vacuo. The precipitate was filtered off and the filtrate evaporated to dryness. The residue was taken up in 10 mL of dichloromethane, filtered and the solvents evaporated to dryness again, to give 276 mg (96%) of **1** as a colourless powder, m.p. 265 °C (dec.). $C_{33}H_{34}BClN_6S_3Zn$ (722.52): calcd. C 54.86, H 4.74, N 11.63, S 13.31, Zn 9.05; found C 54.07, H 4.97, N 11.29, S 12.89, Zn 8.76. ^{1}H NMR ($CDCl_3$): δ = 1.99 (s, 9 H, Me), 2.10 (s, 9 H, Me), 6.83 (d, *J* = 2.0 Hz, 3 H, Im), 7.08 (d, *J* = 2.0 Hz, 3 H, Im), 7.11 [d, *J* = 4.6 Hz, 6 H, Ph(3,5)], 7.26 [t, *J* = 3.8 Hz, 3 H, Ph(4)] ppm. IR (KBr): $\tilde{\nu}$ = 2438 w (BH) cm^{-1}.

2: Like **1** from 200 mg (0.30 mmol) of **L3** and 97 mg (0.30 mmol) of ZnI_2. Yield 232 mg (94%) of **2** as a colourless powder, m.p. 300 °C (dec.). $C_{33}H_{34}BIN_6S_3Zn$ (813.97): calcd. C 48.69, H 4.21, N 10.32, S 11.82, Zn 8.03; found C 47.77, H, 4.27, N 10.09, S 11.64, Zn 7.91. ^{1}H NMR ($CDCl_3$): δ = 1.99 (s, 9 H, Me), 2.08 (s, 9 H, Me), 6.84 (d, *J* = 2.1 Hz, 3 H, Im), 7.14 (d, *J* = 2.1 Hz, 3 H, Im), 7.16 [d, *J* = 7.6 Hz, 6 H, Ph(3,5)], 7.25 [t, *J* = 7.5 Hz, 3 H, Ph(4)] ppm. IR (KBr): = $\tilde{\nu}$ = 2437 w (BH) cm^{-1}.

3: Like **1** from 200 mg (0.30 mmol) of **L3** and 80 mg (0.30 mmol) of $Zn(NO_3)_2{\cdot}4H_2O$. Yield 194 mg (85%) of **3** as a colourless powder, m.p. 235 °C (dec.). $C_{33}H_{34}BN_7O_3S_3Zn$ (749.08): calcd. C 52.91, H 4.57, N 13.09, S 12.84, Zn 8.72; found C 52.53, H 4.70, N 12.96, S 12.63, Zn 8.58. ^{1}H NMR ($CDCl_3$): δ = 1.95 (s, 9 H, Me), 2.17 (s, 9 H, Me), 6.86 (d, *J* = 2.1 Hz, 3 H, Im), 7.09 (d, *J* = 2.1 Hz, 3

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

H, Im), 7.14 [d, J = 7.2 Hz, 6 H, Ph(3,5)], 7.25 [t, J = 7.4 Hz, 3 H, Ph(4)] ppm. IR (KBr): $\tilde{\nu}$ = 2426 w (BH) cm^{-1}.

4: Like **1** from 206 mg (0.33 mmol) of **L1** and 62 mg (0.34 mmol) of $Zn(CH_3COO)_2{\cdot}2H_2O$. Yield 156 mg (67%) of **4** as a colourless crystals, m.p. 265 °C (dec.). $C_{32}H_{31}BN_6O_2S_3Zn$ (704.03): calcd. C 54.59, H 4.4, N 11.94, S 13.66, Zn 9.29; found C 54.48, H 4.34, N 12.00, S 13.59, Zn 9.14. ^1H NMR ($CDCl_3$): δ = 1.76 [s, 3 H, Me(acetate)], 2.1 (s, 9 H, Me), 6.96 (d, J = 2.0 Hz, 3 H, Im), 7.16 (d, J = 2.0 Hz, 3 H, Im), 7.28 (m, 12 H, Ph) ppm. IR (KBr): $\tilde{\nu}$ = 2412 w (BH) cm^{-1}.

5: Like **1** from 264 mg (0.40 mmol) of **L3** and 88 mg (0.40 mmol) of $Zn(CH_3COO)_2{\cdot}2H_2O$. Yield 250 mg (84%) of **4** as a colourless powder, m.p. 235 °C (dec.). $C_{35}H_{37}BN_6O_2S_3Zn$ (746.12): calcd. C 56.34, H 5.00, N 11.27, S 12.89, Zn 8.76; found C 55.40, H 5.30, N 11.85, S 11.85, Zn 8.73. ^1H NMR ($CDCl_3$): δ = 1.82 [s, 3 H, Me(acetate)], 1.99 (s, 9 H, Me), 2.17 (s, 9 H, Me), 6.82 (d, J = 2.2 Hz, 3 H, Im), 7.11 (d, J = 2.2 Hz, 3 H, Im), 7.17 [d, J = 7.6 Hz, 6 H, Ph(3,5)], 7.22 [t, J = 7.4 Hz, 3 H, Ph(4)] ppm. IR (KBr): $\tilde{\nu}$ = 2412 w (BH), 1598 s ($OCOCH_3$) cm^{-1}.

6: A solution of 200 mg (0.30 mmol) of **L3** in 10 mL of methanol was added dropwise with stirring to a solution of 112 mg (0.30 mmol) of $Zn(ClO_4)_2{\cdot}6H_2O$ in 10 mL of methanol. After stirring for 2 h the resulting $KClO_4$ was filtered off. In a separate flask a solution of 33 mg (0.30 mmol) of CH_3COSH was deprotonated with 0.30 mmol of a 0.5 M solution of sodium methoxide in methanol. The two solutions were combined and stirred for 15 h. Then, all volatiles were removed in vacuo, the residue taken up in 15 mL of dichloromethane and filtered again. The filtrate was evaporated to dryness to give 161 mg (70%) of **6** as a yellow powder, m.p. 225 °C (dec.). $C_{35}H_{37}BN_6OS_4Zn$ (762.19): calcd. C 55.19, H 4.89, N 11.03, S 16.83, Zn 8.58; found C 54.76, H 4.96, N 10.87, S 15.72, Zn 8.46. ^1H NMR ($CDCl_3$): δ = 1.75 [s, 3 H, Me(thioacetate)], 1.92 (s, 9 H, Me), 2.04 (s, 9 H, Me), 6.74 (d, J = 2.1 Hz, 3 H, Im), 7.02 (d, J = 2.1 Hz, 3 H, Im), 7.03 [d, J = 7.6 Hz, 6 H, Ph(3,5)], 7.18 [t, J = 7.4 Hz, 3 H, Ph(4)] ppm. IR (KBr): $\tilde{\nu}$ = 2430 w (BH) cm^{-1}.

7: Like **6** from 200 mg (0.32 mmol) of **L1** and 45 mg (0.32 mmol) of *p*-nitrophenol. Yield 197 mg (78%) of **7** as a yellow powder, m.p. 225 °C (dec.). $C_{36}H_{32}BN_7O_3S_3Zn$ (783.09): calcd. C 55.22, H 4.12, N 12.52, S 12.88, Zn 8.35; found C 54.92, H 4.11, N 12.47, S 12.59, Zn 8.56. ^1H NMR ($CDCl_3$): δ = 2.11 (s, 9 H, Me), 6.44 [d, J = 9.1 Hz, 2 H, nitro(2,6)], 6.97 (d, J = 2.2 Hz, 3 H, Im), 7.16 (d, J = 2.2 Hz, 3 H, Im), 7.29–7.42 (m, 12 H, Ph), 7.81 [d, J = 9.1 Hz, 2 H, nitro(3,5)] ppm. IR (KBr): $\tilde{\nu}$ = 2442 w (BH).

8: Like **6** from 213 mg (0.32 mmol) of **L3** and 45 mg (0.32 mmol) of *p*-nitrophenol. Yield 236 mg (89%) of **8** as a yellow powder, m.p. 200 °C (dec.). $C_{39}H_{38}BN_7O_3S_3Zn$ (825.17): calcd. C 56.77, H 4.64, N 11.88, S 11.66, Zn 7.92; found C 55.41, H 4.65, N 12.68, S 11.38, Zn 7.74. ^1H NMR ($CDCl_3$): δ = 2.02 (s, 18 H, Me), 6.51 [d, J = 8.9 Hz, 2 H, nitro(2,6)], 6.89 (d, J = 2.2 Hz, 3 H, Im), 7.13 [d, J = 7.2 Hz, 6 H, Ph(3,5)], 7.17 (d, J = 2.2 Hz, 3 H, Im), 7.27 [t, J = 7.4 Hz, 3 H, Ph(4)], 7.83 [d, J = 8.9 Hz, 2 H, nitro(3,5)] ppm. IR (KBr): $\tilde{\nu}$ = 2440 w (BH).

9: Like **6** from 206 mg (0.38 mmol) of **L5** and 54 mg (0.38 mmol) of *p*-nitrophenol. Yield 193 mg (73%) of **9** as a yellow powder, m.p. 205 °C (dec.). $C_{36}H_{34}BN_7O_3S_3Zn$ (785.11): calcd. C 55.07, H 4.36, N 12.49, S 12.25, Zn 8.33; found C 54.84, H 4.27, N 12.59, S 11.83, Zn 8.22. ^1H NMR ($CDCl_3$): δ = 2.40 (s, 9 H, Me), 6.36 [d, J = 9.3 Hz, 2 H, nitro(2,6)], 7.04 (d, J = 2.2 Hz, 3 H, Im), 7.11 (d, J = 2.2 Hz, 3 H, Im), 7.22 (s, 12 H, Ph), 7.66 [d, J = 9.3 Hz, 2 H, nitro(3,5)] ppm. IR (KBr): $\tilde{\nu}$ = 2345 w (BH) cm^{-1}.

Perchlorate Complexes

10: A solution of 45 mg (0.07 mmol) of **L1** in 5 mL of methanol was slowly added dropwise with stirring into a solution of 27 mg (0.07 mmol) of $Zn(ClO_4)_2{\cdot}6H_2O$ in 5 mL of methanol. After stirring for 2 h the solvent was removed in vacuo. The residue was picked up in 10 mL of dichloromethane and filtered. Evaporation to dryness gave 44 mg (81%) of **10** as a colourless powder, m.p. 220 °C (dec.). $C_{30}H_{28}BClN_6O_4S_3Zn$ (744.44): calcd. C 48.40, H 3.79, N 11.29, S 12.92, Zn 8.78; found C 48.42, H 4.12, N 10.96, S 12.48, Zn 8.48. ^1H NMR ($CDCl_3$): δ = 2.13 (s, 9 H, Me), 6.96 (br, 3 H, Im), 7.16 (br, 3 H, Im), 7.22–7.37 (m, 12 H, Ph) ppm. IR (KBr): $\tilde{\nu}$ = 2448 w (BH), 1105vs. (ClO_4) cm^{-1}.

11: Like **10** from 310 mg (0.38 mmol) of **L2** and 143 mg (0.38 mmol) of $Zn(ClO_4)_2{\cdot}6H_2O$. Yield 245 mg (68%) of **11** as a colourless powder, m.p. 230 °C (dec.). $C_{45}H_{34}BClN_6O_4S_3Zn$ (930.65): calcd. C 58.08, H 3.68, N 9.03, S 10.34, Zn 7.03; found C 56.67, H 4.07, N 8.74, S 10.16, Zn 6.91. ^1H NMR ($CDCl_3$): δ = 6.63 (br, 3 H, Im), 6.78 (br, 3 H, Im), 6.98–7.16 (m, 12 H, Ph), 7.32–7.41 (m, 15 H, Ar) ppm. IR (KBr): $\tilde{\nu}$ = 2437 w (BH), 1090 s (ClO_4^-) cm^{-1}.

12: Like **10** from 264 mg (0.40 mmol) of **L3** and 149 mg (0.40 mmol) of $Zn(ClO_4)_2{\cdot}6H_2O$. Yield 257 mg (82%) of **12** as a colourless powder, m.p. 245 °C (dec.). $C_{33}H_{34}BClN_6O_4S_3Zn$ (786.52): calcd. C 50.39, H 4.36, N 10.69, S 12.23, Zn 8.31; found C 49.27, H 4.51, N 11.12, S 11.79, Zn 8.03. ^1H NMR ($CDCl_3$): δ = 1.98 (s, 9 H, Me), 2.06 (s, 9 H, Me), 6.89 (d, J = 2.1 Hz, 3 H, Im), 7.10 [d, J = 7.4 Hz, 6 H, Ph(3,5)], 7.16 (d, J = 2.1 Hz, 3 H, Im), 7.25 [t, J = 7.4 Hz, 3 H, Ph(4)] ppm. IR (KBr): $\tilde{\nu}$ = 2448 w (BH), 1991 s (ClO_4^-) cm^{-1}.

13: Like **10** from 200 mg (0.24 mmol) of **L4** and 90 mg (0.24 mmol) of $Zn(ClO_4)_2{\cdot}6H_2O$. Yield 193 mg (84%) of **13** as a colourless powder, m.p. 230 °C (dec.). $C_{45}H_{58}BClN_6O_4S_3Zn$ (954.84): calcd. C 56.61, H 6.12, N 8.80, S 10.07, Zn 6.85; found C 56.29, H 6.48, N 8.73, S 10.04, Zn 6.82. ^1H NMR ($CDCl_3$): δ = 0.82 (d, J = 6.6 Hz, 3 H, Me), 0.98 (d, J = 6.6 Hz, 9 H, Me), 1.16 (d, J = 6.6 Hz, 24 H, Me), 2.28 (m, J = 6.7 Hz, 3 H, CH), 2.58 (m, J = 6.7 Hz, 3 H, CH), 6.90 (d, J = 1.6 Hz, 3 H, Im), 7.21 [d, J = 7.6 Hz, 6 H, Ph(3,5)], 7.25 (d, J = 1.6 Hz, 3 H, Im), 7.45 [m, 3 H, Ph(4)] ppm. IR (KBr): $\tilde{\nu}$ = 2449 w (BH), 1102 s (ClO_4^-) cm^{-1}.

14: Like **10** from 178 mg (0.30 mmol) of **L6** and 112 mg (0.30 mmol) of $Zn(ClO_4)_2{\cdot}6H_2O$. Yield 182 mg (84%) of **14** as a colourless powder, m.p. 230 °C (dec.). $C_{27}H_{37}BClN_6O_4S_3Zn{\cdot}CHCl_3$ (717.47 + 119.38): calcd. C 40.19, H 4.58, N 10.04, S 11.50, Zn 7.81; found C 41.15, H 5.19, N 10.32, S 11.63, Zn 8.27. ^1H NMR (CD_3OD): δ = 1.17–1.31 [p, J = 10.2 Hz, 12 H, CH_2(3,5-cyclohexyl)], 1.38–1.58 [q, J = 5.3 Hz, 12 H, CH_2(2,6-cyclohexyl)], 1.78 [m, 6 H, CH_2(4-cyclohexyl)], 4.53 (m, J = 3.8 Hz, 3 H, CH), 6.99 (d, J = 1.9 Hz, 3 H, Im), 7.23 (d, J = 1.9 Hz, 3 H, Im) ppm. IR (KBr): $\tilde{\nu}$ = 2435 w (BH), 1091 s (ClO_4^-) cm^{-1}.

Alkoxide Complexes

15: A solution of 46 mg (0.30 mmol) of *p*-nitrobenzyl alcohol in 5 mL of methanol was treated dropwise, with stirring, first with 0.30 mmol of a 0.5 M solution of $NaOCH_3$ in CH_3OH, then with 112 mg (0.30 mmol) of $Zn(ClO_4){\cdot}6H_2O$ in 10 mL of methanol, and finally with 200 mg (0.30 mmol) of **L3** in 10 mL of methanol. After stirring for 12 h the solvent was removed in vacuo, the residue taken up in 20 mL of dichloromethane and filtered. After evaporation to dryness, 205 mg (81%) of **15** was isolated as a yellow powder, m.p. 200 °C (dec.). $C_{40}H_{40}BN_7O_3S_3Zn$ (839.2): calcd. C 57.25, H 4.80, N 11.68, S 11.46, Zn 7.79; found C 57.72, H 5.36, N 11.71, S 11.54, Zn 7.86. ^1H NMR ($CDCl_3$): δ = 1.99 (s, 18 H, Me), 4.84

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(s, 2 H, CH_2), 6.58 (d, J = 2.1 Hz, 1 H, Im), 6.81 (d, J = 2.1 Hz, 3 H, Im), 6.84 (d, J = 2.1 Hz, 2 H, Im), 6.89 [d, J = 6.2 Hz, 6 H, Ph(3,5)], 7.19 [t, J = 7.6 Hz, 3 H, Ph(4)], 7.53 [d, J = 8.7 Hz, 2 H, nitro(2,6)], 8.22 [d, J = 8.7 Hz, 2 H, Nitro(3,5)] ppm. IR (KBr): $\tilde{\nu}$ = 2444 w (BH) cm^{-1}.

16: Like **15** from 53 mg (0.30 mmol) of *p*-(trifluoromethyl)benzyl alcohol, 112 mg (0.30 mmol) of $Zn(ClO_4)_2 \cdot 6H_2O$ and 200 mg (0.30 mmol) of **L3**. Yield 214 mg (82%) of **16** as a colourless powder, m.p. 180 °C. $C_{41}H_{40}BF_3N_6OS_3Zn \cdot 0.25CH_2Cl_2$ (862.20 + 21.23): calcd. C 56.08, H 4.62, N 9.52, S 10.88, Zn 7.40; found C 56.43, H 4.88, N 9.42, S 10.13, Zn 6.89. ^{1}H NMR ($CDCl_3$): δ = 2.00 (s, 18 H, Me), 4.78 (d, J = 2.8 Hz, 2 H, CH_2), 5.29 (s, 0.5 H, CH_2Cl_2), 6.58 (d, J = 2.1 Hz, 1 H, Im), 6.81 (d, J = 2.1 Hz, 3 H, Im), 6.89 (d, J = 2.1 Hz, 2 H, Im), 7.01 [d, J = 6.6 Hz, 6 H, Ph(3,5)], 7.19 [t, J = 7.4 Hz, 3 H, Ph(4)], 7.48 [d, J = 8.2 Hz, 2 H, trifluoromethyl(2,6)], 7.61 [d, J = 8.2 Hz, 2 H, trifluoromethyl(3,5)] ppm. ^{19}F NMR ($CDCl_3$): δ = 61.21 ppm. IR (KBr): $\tilde{\nu}$ = 2441 w (BH) cm^{-1}.

17: A solution of 200 mg (0.30 mmol) of **L3** and 10 mL of methanol was added dropwise with stirring to a solution of 112 mg (0.30 mmol) of $Zn(ClO_4)_2 \cdot 6H_2O$ in 10 mL of methanol. After stirring for 2 h the resulting $KClO_4$ was filtered off. The filtrate was treated with 0.3 mmol of a 0.25 M solution of $NaOCH_3$ in CH_3OH. After stirring for another 8 h the solvent was removed in vacuo, the residue taken up in 20 mL of dichloromethane and filtered. After evaporation to dryness 161 mg (71%) of **17** was isolated as a colourless powder, m.p. 255 °C (dec.). $C_{67}H_{71}B_2ClN_{12}O_5S_6Zn_2$ (1504.63): calcd. C 53.48, H 4.76, N 11.17, S 12.79, Zn 8.69; found C 53.35, H 4.88, N 11.07, S 12.67, Zn 8.61. ^{1}H NMR ($CDCl_3$): δ = 1.58 (s, 18 H, Me), 1.99 (s, 18 H, Me), 2.10 (s, 3 H, OMe), 6.57 (d, J = 2.1 Hz, 3 H, Im), 6.80 (d, J = 2.1 Hz, 6 H, Im), 6.87–7.09 [d, J = 6.8 Hz, 12 H, Ph(3,5)], 7.13 (d, J = 2.1 Hz, 3 H, Im), 7.19 [t, J = 7.5 Hz, 6 H, Ph(4)] ppm. IR (KBr): $\tilde{\nu}$ = 2439 w (BH), 1095 s (ClO_4^-) cm^{-1}.

18: Like **17** (all operations in absolute ethanol) from 200 mg (0.30 mmol) of **L3**, 112 mg (0.30 mmol) of $Zn(ClO_4)_2 \cdot 6H_2O$ and 0.30 mmol of $NaOC_2H_5$. Yield 180 mg (78%) of **18** as a colourless powder, m.p. 250 °C (dec.). $C_{68}H_{73}B_2ClN_{12}O_5S_6Zn_2$ (1518.65): calcd. C 53.78, H 4.84, N 11.07, S 12.67, Zn 8.61; found C 52.86, H 4.80, N 11.14, S 12.87, Zn 8.75. ^{1}H NMR ($CDCl_3$): δ = 1.24 [t, J = 7.0 Hz, 3 H, Me(Ethyl)], 1.58 (s, 18 H, Me), 2.05 (s, 18 H, Me), 3.72 [q, J = 5.2 Hz, CH_2(Ethyl)], 6.82 (d, J = 2.2 Hz 3 H, Im), 6.84 (d, J = 2.2 Hz, 6 H, Im), 6.88–7.10 [d, J = 6.8 Hz, 12 H, Ph(3,5)], 7.14 (d, J = 2.2 Hz, 3 H, Im), 7.20 [t, J = 7.4 Hz, 6 H, Ph(4)] ppm. IR (KBr): $\tilde{\nu}$ = 2417 w (BH), 1096 s (ClO_4^-) cm^{-1}.

19: Like **17** (all operations in absolute ethanol) from 200 mg (0.30 mmol) of **L3**, 112 mg (0.30 mmol) of $Zn(ClO_4)_2 \cdot 6H_2O$ and 0.30 mmol of $NaOCH_2CF_3$. Yield 166 mg (70%) of **19** as a colourless powder, m.p. 260 °C (dec.). $C_{68}H_{70}B_2ClF_3N_{12}O_5S_6Zn_2$ (1572.62): calcd. C 51.94, H 4.49, N 10.69, S 12.23, Zn 8.32; found C 52.23, H 4.93, N 11.61, S 12.85, Zn 8.73. ^{1}H NMR ($CDCl_3$): δ = 1.58 (s, 18 H, Me), 1.99 (s, 18 H, Me), 2.07 (s, 2 H, CH_2), 6.81 (br, 6 H, Im), 6.84 (br, 3 H, Im), 6.87–7.13 [d, J = 7.2 Hz, 12 H, Ph(3,5)], 7.14 (d, J = 2.1 Hz, 3 H, Im), 7.23 [t, J = 6.0 Hz, 6 H, Ph(4)] ppm. ^{19}F NMR ($CDCl_3$): δ = 77.81 ppm. IR (KBr): $\tilde{\nu}$ = 2490 w (BH), 1097 s (ClO_4^-) cm^{-1}.

Complexes with Alcohol and Aldehyde Ligands

20: A solution of 200 mg (0.30 mmol) of **L3** in 10 mL of absolute 2-propanol was added dropwise with stirring to a solution of 112 mg (0.30 mmol) of $Zn(ClO_4)_2 \cdot 6H_2O$ in 10 mL of absolute 2-propanol. After stirring for 4 h the volume of the solution was reduced to 10 mL in vacuo, the precipitate filtered off, and the filtrate evaporated to dryness. The residue was taken up in 10 mL of dichloromethane, filtered, and the filtrate evaporated to dryness again to give 150 mg (62%) of **20** as a colourless powder, m.p. 275 °C (dec.). $C_{36}H_{42}BClN_6O_5S_3Zn$ (846.62): calcd. C 51.07, H 5.00, N 9.93, S 11.36, Zn 7.72; found C 49.28, H 4.95, N 9.89, S 11.34, Zn 7.71. ^{1}H NMR ($CDCl_3$): δ = 1.12 [d, J = 6.2 Hz, 6 H, Me(*i*Pr)], 1.91 (s, 9 H, Me), 1.97 (s, 9 H, Me), 4.02 [m, J = 6.2 Hz, 1 H, CH(*i*Pr)], 6.82 (d, J = 2.0 Hz, 3 H, Im), 7.07 [d, J = 7.6 Hz, 6 H, Ph(3,5)], 7.09 (d, J = 2.0 Hz, 3 H, Im), 7.19 [t, J = 7.4 Hz, 3 H, Ph(4)] ppm. IR (KBr): $\tilde{\nu}$ = 2448 w (BH), 1101 s (ClO_4^-) cm^{-1}.

21: Like **20** from 206 mg (0.33 mmol) of **L5** and 124 mg (0.33 mmol) of $Zn(ClO_4)_2 \cdot 6H_2O$. Yield 149 mg (56%) of **21** as a

colourless powder, m.p. 215 °C (dec.). $C_{33}H_{36}BClN_6O_5S_3Zn$ (804.54): calcd. C 49.27, H 4.51, N 10.45, S 11.96, Zn 8.13; found C 49.45, H 4.89, N 9.97, S 11.19, Zn 7.98. ^{1}H NMR ($CDCl_3$): δ = 1.16 [d, J = 6.0 Hz, 6 H, Me(*i*Pr)], 2.38 (s, 6 H, Me), 2.41 (s, 3 H, Me), 4.03 [m, J = 6.0 Hz, 1 H, CH(*i*Pr)], 7.07 (br, 2 H, Im), 7.09 (d, J = 2.2 Hz, 2 H, Im), 7.14 (br, 2 H, Im), 7.22 (m, 12 H, Ph) ppm. IR (KBr): $\tilde{\nu}$ = 2452 w (BH) cm^{-1}.

22: A solution of 37 mg (0.30 mmol) of 2-hydroxybenzyl alcohol in 5 mL of methanol was treated dropwise with stirring first with 0.30 mmol of a 0.25 M solution of $NaOCH_3$ in CH_3OH, then with a solution of 112 mg (0.30 mmol) of $Zn(ClO_4)_2$·$6H_2O$ in 10 mL of methanol, and finally with a solution of 200 mg (0.30 mmol) of **L3**. After stirring for 12 h the solvent was removed in vacuo, the residue taken up in 10 mL of dichloromethane, filtered and the filtrate evaporated to dryness again to give 218 mg (89%) of **22** as a colourless powder, m.p. 180 °C (dec.). $C_{40}H_{41}BN_6O_2S_3Zn$·$0.5CH_2Cl_2$ (810.20 + 42.46): calcd. C 57.05, H 4.96, N 9.86, S 11.28, Zn 7.67; found C 57.52, H 5.11, N 9.19, S 10.54, Zn 8.07. ^{1}H NMR ($CDCl_3$): δ = 1.99 (s, 18 H, Me), 4.48 (m, 1 H, OH), 4.85 (s, 2 H, CH_2), 5.30 (s, 1 H, CH_2Cl_2), 6.82 (d, J = 2.0 Hz, 3 H, Im), 6.86 (d, J = 2.0 Hz, 3 H, Im), 7.03 [d, J = 5.0 Hz, 6 H, Ph(3,5)], 7.13 [m, 2 H, Ph(3,5-phenolate)], 7.16 [t, J = 6.6 Hz, 3 H, Ph(4)], 7.26 [m, 2 H, Ph(4,6-phenolate)] ppm. IR (KBr): $\tilde{\nu}$ = 2442 w (BH) cm^{-1}.

23: Like **22** from 38 mg (0.30 mmol) of salicylic aldehyde, 112 mg (0.30 mmol) of $Zn(ClO_4)_2$·$6H_2O$ and 200 mg (0.30 mmol) of **L3**. Yield 202 mg (83%) of **23** as a colourless powder, m.p. 180 °C (dec.). $C_{40}H_{39}BN_6O_2S_3Zn$ (808.19): calcd. C 59.45, H 4.86, N 10.40, S 11.90, Zn 8.09; found C 58.23, H 4.83, N 10.99, S 11.87, Zn 8.07. ^{1}H NMR ($CDCl_3$): δ = 1.99 (s, 18 H, Me), 6.82 (d, J = 2.0 Hz, 3 H, Im), 6.85 (d, J = 2.0 Hz, 3 H, Im), 7.02 [d, J = 8.0 Hz, 6 H, Ph(3,5)], 7.13 [m, 2 H, Ph(3,5-salicyl)], 7.20 [t, J = 4.8 Hz, 3 H, Ph(4)], 7.54 [m, 2 H, Ph(4,6-salicyl)], 9.91 [s, 1 H, CHO] ppm. IR (KBr): $\tilde{\nu}$ = 2460 w (BH), 1659 m (CO) cm^{-1}.

24: Equimolar amounts of **L5** and $Zn(ClO_4)_2$ were converted into the **L5**·Zn-$OClO_3$ complex as described above for **10**. Then, a solution of 245 mg (0.33 mmol) of this complex in 5 mL of dichloromethane was treated with a solution of 37 mg (0.33 mmol) of 2-(hydroxymethyl)-1-methylimidazole in 5 mL of dichloromethane. After stirring for 6 h the product was precipitated by addition of 30 mL of petroleum ether (60–70). Filtration and recrystallisation from dichloromethane/petroleum ether yielded 150 mg (53%) of **24** as colourless crystals, m.p. 210 °C (dec.). $C_{35}H_{36}BClN_8O_5S_3Zn$ (856.57): calcd. C 49.08, H 4.24, N 13.08, S 11.23, Zn 7.63; found C 48.10, H 4.54, N 13.18, S 10.18, Zn 7.67. ^{1}H NMR ($CDCl_3$): δ = 22.38 (s, 9 H, Me), 3.62 [s, 3 H, Me(imidazole)], 4.46 [s, 2 H, CH_2(imidazole)], 6.67 (s, 1 H, imidazole), 6.87 (s, 1 H, imidazole), 7.10 (d, J = 2.2 Hz, 6 H, Im), 7.16 (d, J = 8.6 Hz, 6 H, Ph), 7.26 (d, J = 8.6 Hz, 6 H, Ph) ppm. IR (KBr): $\tilde{\nu}$ = 2454 w (BH) cm^{-1}.

Structure Determinations:[38] Crystals of **1**, **3**, **4**, **5**, **17** and **23** were obtained by recrystallisation from methanol/dichloromethane mixtures, those of **18** from ethanol/dichloromethane, those of **9** from acetonitrile/dichloromethane, those of **21** by layering a dichloromethane/2-propanol (1:4) solution with petroleum ether, and those of **24** by layering a dichloromethane solution with petroleum ether. Diffraction data were recorded at room temperature (**10**, **12**), at –50 °C (**3**, **5**, **17**, **18**), at –80° (**1**, **23**, **24**) or at –140 °C (**4**) with a Bruker Smart CCD diffractometer. Empirical absorption corrections were applied to all data sets except those of **9** and **17**. The structures were solved by direct methods and refined anisotropically with the SHELX program suite.[39] Hydrogen atoms were included with fixed distances and isotropic temperature factors 1.5-times those of their attached atoms. Parameters were refined against F^2. The R values are defined as $R_1 = \Sigma|F_o - F_c|/\Sigma F_o$ and $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]\Sigma[w(F_o^2)^2]\}^{1/2}$. Drawings were produced with SCHAKAL.[40] Tables 3 and 4 list the crystallographic data.

Acknowledgments

This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We are indebted to Drs. W. Deck and H. Brombacher for their help with the structure determinations.

Zinc Thiolate Complexes of (N,N,S)-Tridentate Ligands for the Modeling of Thiolate Alkylating Enzymes

Mian Ji[a] and Heinrich Vahrenkamp*[a]

Keywords: Bioinorganic chemistry / S ligands / Tridentate ligands / Zinc

Zinc thiolate complexes of three tridentate (N,N,S) ligands were prepared as models for the structure and function of thiolate alkylating zinc enzymes. *N*-(2-Mercaptoisobutyl)(2-pyridin-2-yl-methyl)amine (**L^1**) forms isobutylthiolate-bridged dinuclear complexes with ZnN_2S_3 coordination. *N*-(2-Mercaptoisobutyl)(2-pyridin-2-yl-ethyl)amine (**L^2**) yields isobutylthiolate-bridged dinuclear complexes in which the pyridine donor is not coordinated to zinc, resulting in a $ZnNS_3$ coordination. Only *N*-(2-mercaptoisobutyl)(2-pyridin-2-yl-ethyl)methylamine (**L^3**) forms the desired mononuclear complexes with ZnN_2S_2 coordination. The latter react with the alkylating agents CH_3I and $PO(OCH_3)_3$ in a two-step process. In the first step the isobutylthiolate function is methylated and its position in the ligand sphere of zinc is taken by I^- or $OPO(OCH_3)_2^-$, respectively, and in the second step the additional thiolate ligand is methylated and replaced by a second iodide or dimethyl phosphate anion.

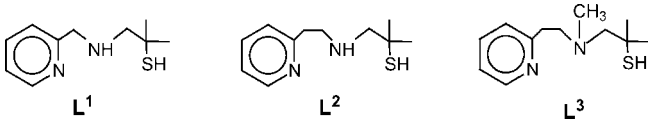
Introduction

In recent years a number of thiolate alkylating enzymes have been identified that contain zinc in their active centers,[1] the most prominent of which is cobalamine-independent methionine synthase.[2] An unusual feature of these enzymes is that they contain zinc in a sulfur-rich ligand environment, which can typically be represented as NS_2ZnX or N_2SZnX, where N and S stand for the side-chains of histidine and cysteine and X is the coordination position of the substrate. It is believed that the thiol substrates, for example homocysteine, are attached to zinc as thioalates prior to alkylation, for example to methionine. An open mechanistic question is whether the alkylation, typically a methylation by methyl tetrahydrofolate, takes place at the zinc-bound or at the free thiolate.

We[3–5] and others[6–11] have attempted to reproduce this biological process with zinc thiolate complexes of various polydentate ligands, using methyl iodide, dimethyl sulfate, or trimethyl phosphate as methylating agents. In most cases the coligands were bidentate chelators or tripodal donors offering only N coordination. In those cases where mechanistic studies were performed it was found that the thiolate is alkylated in the zinc-bound state. Thus, a reasonable approximation to a functional modeling of the enzymes has been achieved, albeit with rather low reaction rates and not in a catalytic fashion.

At this point the major challenges concern a better structural modeling of the enzymes, which may also be a way to achieve higher reactivities of the zinc thiolate model complexes. This requires modeling the protein environment of zinc by tridentate or tripodal ligands with N_2S and NS_2 donor sets, of which N is part of a nitrogen heterocycle representing histidine's imidazole and S is a thiolate sulfur representing cysteine's thiolate. We are not aware of a model study employing such an NS_2 ligand, and so far just one type of such N_2S ligands seems to have been used for thiolate alkylation in zinc complexes.[8,9]

We have reported various tridentate N_2S ligands[12–15] as well as pyrazolylborate-derived NS_2[16] and N_2S tripods.[17] While we have previously focused on modeling hydrolytic enzymes or alcohol dehydrogenase with their zinc complexes, we are at present using their zinc thiolate complexes for studies of thiolate alkylation. This paper reports our results with the tridentate N_2S systems **L^1**–**L^3**. The goal of our study was to find out whether mononuclear tetrahedral **L**·Zn–SR complexes of **L^1**–**L^3** are accessible and how they behave toward alkylating reagents.



Results and Discussion

All three ligands in their free form are aliphatic thiols and by design are good chelators. They are disubstituted at

the α-carbon of the thiolate function with the purpose of introducing some steric strain in order to reduce their tendency to bridge. Their synthesis consists in the ring opening of 2,2-dimethylthiirane by the corresponding pyridine-substituted aliphatic amine. The two methyl substituents and the CH_2 group of their mercaptoethylamine functions make it easy to identify the complexes of **L¹**–**L³** by ^{1}H NMR spectroscopy. The zinc thiolate complexes of **L¹**–**L³** could be expected to have a ZnN_2S_2 coordination, which in almost all cases − in coordination compounds as well as in zinc-containing proteins − was found to imply mononuclear species with a tetrahedral coordination of zinc.

N-(2-Mercaptoisobutyl)(2-pyridin-2-ylmethyl)amine (L¹)

Ligand **L¹** and some of its zinc complexes have been described previously by us.[14] We observed that the isobutylthiolate function of **L¹** has a high bridging tendency and that the zinc ions in the resulting oligonuclear complexes have coordination numbers of 5 or 6. Yet, except for the thiolate sulfur only hard donor atoms (N and O) are present in these complexes and the N_2S_2 donor composition has not been tested.

This was done now. The thiophenolate complex **1** was generated in a one-step synthesis from deprotonated **L¹**, zinc nitrate, and potassium thiophenolate. The NMR spectroscopic data of **1** are inconclusive in terms of composition and structure in solution, but in the crystalline state **1** was found to be dimeric with a ZnN_2S_3 coordination.

L¹•Zn-SC$_6$H$_5$
1

Figure 1 shows the centrosymmetrical dinuclear molecular units of **1** in which the isobutylthiolate groups function as bridging ligands as observed before.[14] The perfectly planar central Zn_2S_2 unit of the complex is close to being a square. The coordination of the zinc ions is roughly trigonal bipyramidal (85% TBP according to the dihedral angle method of Holmes[18]). This is not so evident from the S1–Zn–N1 angle of 159°, but clearly so from the fact that the axial bonds Zn–S1 and Zn–N1 are considerably longer than their equatorial counterparts Zn–S1′, Zn–S2, and Zn–N2. Complex **1** therefore closely resembles the **L¹**·Zn-acetate complex.[14]

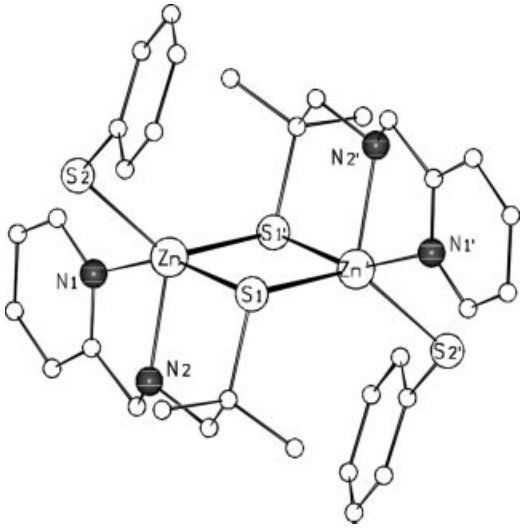

Figure 1. Structure of **1** in the solid state. Relevant bond lengths [Å]: Zn–S1 2.514(2), Zn–S1′ 2.370(2), Zn–S2 2.321(2), Zn–N1 2.305(4), Zn–N2 2.134(4).

One reason for the inaccessibility of tetrahedral zinc complexes with ligand **L¹** seems to be the fact that, upon complexation with **L¹**, two five-membered chelate rings are formed. These enforce two small bond angles and therefore encourage trigonal bipyramidal or octahedral coordination despite the high sulfur content in the ligand sphere of the metal. The investigations with ligand **L¹** were therefore abandoned in favor of those with **L²** and **L³**.

N-(2-Mercaptoisobutyl)(2-pyridin-2-ylethyl)amine (L²)

This ligand has not been described before. We now found that it is easily accessible from 2,2-dimethylthiirane and 2-(2-aminoethyl)pyridine as a colorless liquid with typical ^{1}H NMR resonances for its aliphatic constituents.

While we found it difficult to obtain zinc alkanethiolate complexes of **L²**, aromatic thiolates could easily be incorporated. Again, they resulted from a one-pot synthesis using deprotonated **L²**, $Zn(NO_3)_2$, and the corresponding thiolate. Complexes **2a**–**d** were obtained in reasonable yields as colorless, crystalline materials, except for yellow **2c**.

L²•Zn-SAr

	2a	**2b**	**2c**	**2d**
Ar	C$_6$H$_5$	*p*-CH$_3$C$_6$H$_4$	*p*-NO$_2$C$_6$H$_4$	C$_6$F$_5$

The spectroscopic data of all four complexes **2** are similar enough to justify the statement that they all have a structure like the one that was determined for **2a** (see Figure 2). Again, the complexes crystallize as centrosymmetrical dimers with bridging isobutylthiolate functions.

The unusual feature of this structure is the noncoordination of the pyridine donor of **L²**. Thus, while the expected coordination number 4 is achieved for zinc, this is not due to the lengthening of the ligand arm between the two nitrogen donors but due to the fact that thiolate bridging is preferred over pyridine coordination. Therefore, with three thiolate ligands bound to zinc, anything but a tetrahedral coordination is unlikely, and the $ZnNS_3$ coordination pattern ensues. The coordination geometry of zinc is extremely distorted tetrahedral. The two smallest bond angles (S1–Zn–S1′ and S1–Zn–N2) are enforced by the Zn_2S_2 diamond and the chelate ring, respectively. The opening in the ligand sphere resulting from this then allows the very large S1–

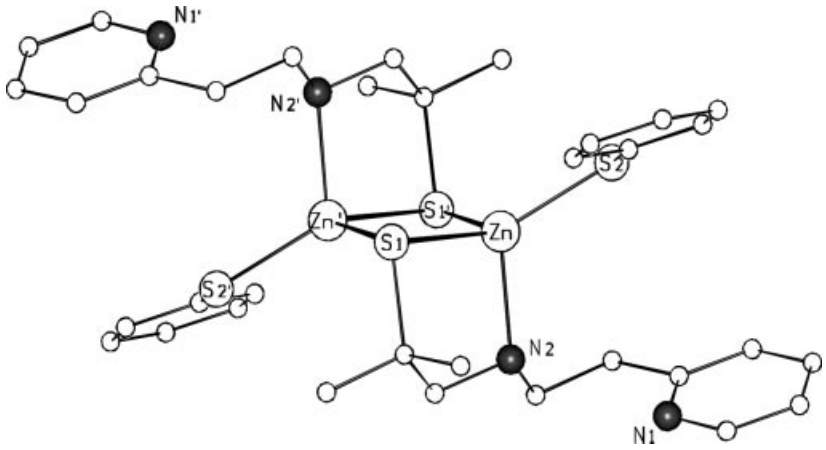

Figure 2. Structure of **2a** in the solid state. Relevant bond lengths [Å] and angles [°]: Zn–S1 2.375(4), Zn–S1′ 2.377(4), Zn–S2 2.254(3), Zn–N2 2.101(5); S1–Zn–S1′ 99.3(1), Zn–S1–Zn′ 80.7(1), S1–Zn–N2 90.1(1), S1–Zn–S2 130.0(1).

Zn–S2 angle. Neither of the structural features of **2a** is unprecedented. A similar dimeric structure with severe bond-angle deviations has been described by Kellogg for an NS_2 chelate ligand,[19] and we have observed the noncoordination of the pyridine arm in the ZnL_2 complex of $\mathbf{L^1}$.[17]

N-(2-Mercaptoisobutyl)(2-pyridin-2-ylethyl)methylamine ($\mathbf{L^3}$)

While ligands $\mathbf{L^1}$ and $\mathbf{L^2}$ yielded zinc complexes that are not suitable for the intended thiolate alkylation studies, ligand $\mathbf{L^3}$, which differs from $\mathbf{L^2}$ only by the methyl group on the central nitrogen atom, did allow the formation of mononuclear tetrahedral **L**·Zn–SR complexes. $\mathbf{L^3}$ was first described by Goldberg et al. and used for zinc chemistry unrelated to thiolate alkylation,[20–22] and these authors had already noted that the larger chelate ring size in relation to that provided by ligands like $\mathbf{L^1}$ favors the formation of four-coordinate complexes.[21] We verified the ability of $\mathbf{L^3}$ to form tetrahedral **L**·Zn–X complexes with soft donors X by preparing $\mathbf{L^3}$·ZnCl from zinc chloride. The molecular structure of $\mathbf{L^3}$·ZnCl (Figure 3) shows that in the mononuclear complexes of these ligands the tetrahedral coordination is also severely distorted due to the small bond angles between the chelate donors and, subsequently, the large bond angle between the two soft donors Cl and S.

$\mathbf{L^3}$•Zn-SR

	3a	**3b**	**3c**
R	CH_2CF_3	$CH_2C_6H_5$	$CH_2C_6H_4Cl$
	3d	**3e**	**3f**
R	C_6H_5	*p*-$NO_2C_6H_4$	C_6F_5

Just like $\mathbf{L^2}$, ligand $\mathbf{L^3}$ did not facilitate access to simple zinc alkanethiolate complexes. However, the trifluoroe-

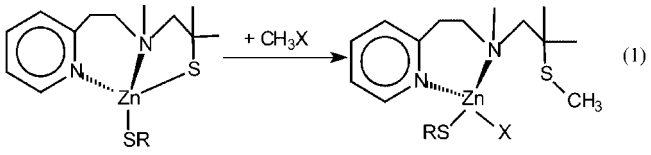
thanethiolate complex **3a**, the benzylthiolate complexes **3b** and **3c**, as well as the arenethiolate complexes **3d–f** could be synthesized from L^3·ZnBr[21] and the corresponding thiolates. Complexes **3a–f** were isolated in good yields. Except for yellow **3e** they form colorless crystals.

The structures of **3d**, **3e**, and **3f** were determined. They are very similar, making it sufficient to discuss that of **3d**. As Figure 4 shows, the ZnN_2S_2 coordination pattern in the thiolates very much resembles the ZnN_2SCl coordination pattern in the chloride (see Figure 3): the bond angles for the two chelate rings are far below the tetrahedral angle, and the S–Zn–S angle is far above it. Complex **3d** shares these features with our (N_2S-chelate)Zn–SR complex derived from the N_2S-chelate ligand MPPA.[13] The Zn–N and Zn–S distances of the L^3·Zn–SR complexes are in the normal range, comparing well with those both in (N_2S-chelate)[12–14] and in (N_2S-tripod)Zn–SR complexes.[23,24]

The coordination pattern of zinc in complexes **3** is close enough to that in the thiolate alkylating enzymes to justify the investigation of alkylating reactions. They were performed for **3d–f** using methyl iodide and for **3d** using trimethyl phosphate. It was found that both thiolate units attached to zinc are alkylated. However, the alkanethiolate function which is part of ligand L^3 reacts first, according to Equation (1).

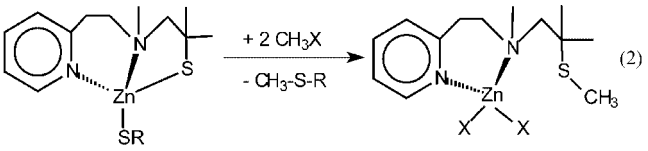


3d: R = C_6H_5
3e: R = $C_6H_4NO_2$
3f: R = C_6F_5

4d: R = C_6H_5, X = I
4e: R = $C_6H_4NO_2$, X = I
4f: R = C_6F_5, X = I
5d: R = C_6H_5, X = $OPO(OMe)_2$

Equimolar amounts of **3d–f** and methyl iodide react smoothly at room temperature in nonpolar solvents. The conversion of ligand L^3 into its methylated form Me-L^3 was evident from the ^{1}H NMR spectra (see Experimental Section), which also indicate by the chemical shifts of the SCH_3 units that in the isolated complexes **4d–f** the thioether functions are not coordinated to zinc, as observed before for a related (N_2S)Zn–SR system and proved by a structure determination.[8] While this could not be proved here by a structure determination it corresponds to the experience that, after alkylation, the sulfur donor is released from zinc and replaced by the anionic constituent of the alkylating agent.[3–5] Actually, the weak donor qualities of thioethers toward zinc, and hence their easy removal from the metal, provide an important part of the driving force for thiolate alkylation by zinc enzymes.[1,2] For complexes **3d–f**, however, the preferred alkylation at the alkanethiolate function corresponds to a partial blocking of ligand L^3, thereby hampering its quality as a model ligand for biomimetic chemistry.

The preference for alkylation at the isobutylthiolate function was not so large as to prevent alkylation at the benzenethiolate function entirely. The NMR spectra of the reaction solutions showed the presence of the aromatic thioethers before the alkylation of the aliphatic thiolate functions was complete. In accord with this the use of a large excess of the alkylating agent brought the reactions to completion according to Equation (2) under the same reaction conditions as for Equation (1).



3d: R = C_6H_5
3e: R = $C_6H_4NO_2$
3f: R = C_6F_5

6: X = I
7: X = $OPO(OMe)_2$

The aromatic thioethers ($CH_3SC_6H_5$ from **3d**, $CH_3SC_6H_4$-*p*-NO_2 from **3e**, $CH_3SC_6F_5$ from **3f**) were isolated and identified from their ^{1}H NMR spectra. The product complexes **6** and **7** bearing the partially blocked ligand Me-L^3 offer no special features; they have the conventional ZnN_2Hal_2 and ZnN_2O_2 compositions. The assumption that the thioether function in these complexes is not coordinated to zinc is backed by the fact that there is not a single structure of a complex of ZnN_2Hal_2 coordination known which has any other donor coordinated to zinc.

The alkylation of **3d** with trimethyl phosphate was included in this investigation to test the ability of complexes **3** to model the function of the Ada protein, a zinc enzyme that repairs damaged DNA by transferring alkyl groups from its phosphate units to thiolates.[1,25] Yet, as observed before,[1,5] trimethyl phosphate is so much less reactive than methyl iodide that rather forcing reaction conditions had to be applied for the alkylation process. While the reactions with CH_3I proceeded smoothly in chloroform at room temperature, for the $PO(OMe)_3$ reactions the reagents had to be heated to 80 °C in DMSO for 10–20 days before the formation of **5d** or **7** was complete, and the products could not be isolated pure due to partial decomposition. This supports the notion that alkylations by trimethyl phosphate and by methyl iodide occur by different mechanisms. The facile alkylation by methyl iodide in nonpolar media, and mechanistic evidence from kinetic data,[3–5] support the assumption that it occurs as an intramolecular process at the zinc-bound thiolates. The forcing conditions and the polar environment needed for alkylation by trimethyl phosphate, as well as mechanistic information from related alkylations of $Zn(SR_4)^{2-}$ species by trimethyl phosphate in very polar solvents,[26] make it likely that the thiolates dissociate from zinc before they react.

Conclusions

In our series of investigations on the modeling of thiolate alkylating enzymes by zinc complexes the ligands L^1–L^3

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

provide a coordination environment for zinc which more closely than before resembles that in the enzymes. While the studies have shown that **L[1]**–**L[3]** are viable tridentate N_2S donors, they have also made clear that the peculiarities of the coordination chemistry of zinc call for a still better control of the donor arrangement and its functionality around the metal center.

The most striking example of this is the fact that despite their high similarity all three ligands yield zinc thiolate complexes **L**·Zn–SR of completely different structure. Although the ZnN_2S_3 pattern in **1**, the $ZnNS_3$ pattern in **2**, and the ZnN_2S_2 pattern in **3** can subsequently be explained, they came as a surprise; the prevention of thiolate bridging on going from **2** to **3** simply by attaching a methyl group on the remote side of the coordination sphere is particularly noteworthy. Likewise, the preferred alkylation at the aliphatic thiolate function of ligand **L[3]** rather than the aromatic thiolate functions of the "substrates" SAr is explainable by the simple fact that aliphatic thiolates are more nucleophilic than aromatic ones. Yet it was not predictable, as the chelate effect should have resulted in a reduced reactivity of the intact zinc-bound **L[3]**. This sheds light on the delicate balance of stability and reactivity in the thiolate alkylating zinc enzymes, specifically cobalamine-independent methionine syntheses.[1,2] In this enzyme the substrate to be methylated is homocysteine while the protein fixes zinc by two cysteine residues which obviously are not to be methylated. Certainly model chemistry still needs some efforts to reproduce this.

Experimental Section

General: For general working and measuring procedures, see ref.[27] Organic starting materials were obtained commercially. Ligands **L[1]**[14] and **L[3]**[20] were prepared according to the published procedures.

Ligand L[2]: 2-(2-Aminoethyl)pyridine (1.95 g, 16.0 mmol) and 2,2-dimethylthiirane (1.77 g, 20.0 mmol) were refluxed for 30 h in 30 mL of toluene. After cooling to room temp. and filtration the solvent was removed in vacuo and the residue distilled to give 1.08 g (32%) of **L[2]** as a colorless liquid, b.p. 89–90 °C/10^{-1} mbar. $C_{11}H_{18}N_2S$ (210.34): calcd. C 62.81, H 8.63, N 13.32; found C 62.87, H 8.52, N 13.74. IR (film): $\tilde{\nu}$ = 1587 s, 1568 s cm^{-1} (C=N). ^1H NMR ($CDCl_3$): δ = 1.39 (s, 6 H, CH_3), 1.74 (s, 1 H, SH), 2.70 (s, 2 H, CH_2), 2.98–3.18 (m, 4 H, CH_2), 7.13–7.22 (m, 2 H, Ar), 7.64 (m, 1 H, Ar), 8.58 (d, J = 3.8 Hz, 1 H, Ar) ppm.

1: A solution of $Zn(NO_3)_2·6H_2O$ (0.440 g, 1.48 mmol) in 50 mL of methanol was added dropwise, with stirring, within 2 h to a solution of **HL[1]** (0.291 g, 1.48 mmol) and 1.48 mmol of $KOCH_3$ in 50 mL of methanol. Then, a solution of KSC_6H_5 (0.219 g, 1.48 mmol) in 50 mL of methanol was added and the mixture stirred for 15 h. The solvent was removed in vacuo, the residue was taken up in 40 mL of chloroform, and filtered. The solvent was removed in vacuo again and the residue crystallized from chloroform/hexane (1:1) to give 0.35 g (64%) of **1** as off-white crystals, m.p. 198 °C. $C_{16}H_{20}N_2S_2Zn·CHCl_3$ (369.87 + 119.38): calcd. C 41.73, H 4.33, N 5.73, S 13.11; found C 43.15, H 4.58, N 7.30, S 12.60. IR (KBr): $\tilde{\nu}$ = 1604 s, 1575 s cm^{-1} (C=N). ^1H NMR ($CDCl_3$): δ = 1.28 (br. s, 6 H, CH_3), 2.18 (br. s, 1 H, CH_2), 2.78 (br. s, 1 H, CH_2), 3.91 (br. s, 1 H, CH_2), 4.06 (br. s, 1 H, CH_2), 6.76–6.91 (m, 3 H, Ar), 7.14–7.36 (m, 5 H, Ar), 7.71 (m, 1 H, Ar), 8.36 (br. s, 1 H, Ar) ppm.

2a: A solution of $Zn(NO_3)_2·4H_2O$ (0.447 g, 1.71 mmol) in 40 mL of methanol was added dropwise, with stirring, over a period of 1 h to a solution of **HL[2]** (0.360 g, 1.71 mmol) and 1.71 mmol of $NaOCH_3$ in 50 mL of methanol. Then, a solution of KSC_6H_5 (0.254 g, 1.71 mmol) in 40 mL of methanol was added and the mixture stirred for 15 h. The solvent was removed in vacuo and the residue taken up in 30 mL of chloroform and filtered. The solvent was then removed in vacuo again and the product crystallized from chloroform/hexane (1:1) to give 0.312 g (48%) of **2a** as colorless crystals, m.p. 191 °C. IR (KBr): $\tilde{\nu}$ = 1594 s, 1577 s cm^{-1} (C=N). ^1H NMR ($CDCl_3$): δ = 1.09 (br. s, 3 H, CH_3), 1.41 (br. s, 3 H, CH_3), 2.51–3.06 (br. m, 6 H, CH_2), 6.77–6.91 (m, 3 H, Ar), 7.11 (t, J = 7.4 Hz, 2 H, Ph), 7.20–7.29 (m, 2 H, Ar), 7.58 (m, 1 H, Ar), 8.33 (br. s, 1 H, Ar) ppm.

2b: Like **2a** from $Zn(NO_3)_2·4H_2O$ (0.307 g, 1.17 mmol), **HL[2]** (0.247 g, 1.17 mmol), and HSC_6H_4-*p*-CH_3 (0.145 g, 1.17 mmol). Yield 0.246 g (53%) of **2b** as colorless crystals, m.p. 191 °C. $C_{18}H_{24}N_2S_2Zn$ (397.92): calcd. C 54.33, H 6.08, N 7.04, S 16.12; found C 53.94, H 6.01, N 7.34, S 16.00. IR (KBr): $\tilde{\nu}$ = 1594 s, 1567 m cm^{-1} (C=N). ^1H NMR ($CDCl_3$): δ = 1.12 (br. s, 3 H, CH_3), 1.40 (br. s, 3 H, CH_3), 2.11 (s, 3 H, CH_3), 2.42–3.05 (m, 6 H, CH_2), 6.67 (d, J = 7.8 Hz, 2 H, Ar), 7.07–7.17 (m, 4 H, Ar), 7.59 (m, 1 H, Ar), 8.35 (s, 1 H, Ar) ppm.

2c: Like **2a** from $Zn(NO_3)_2·4H_2O$ (0.468 g, 1.79 mmol), **HL[2]** (0.377 g, 1.79 mmol), and HSC_6H_4-*p*-NO_2 (0.346 g, 1.79 mmol). Yield 0.353 g (46%) of **2c** as colorless crystals, m.p. 182 °C. $C_{17}H_{21}N_3O_2S_2Zn$ (428.89): calcd. C 47.61, H 4.93, N 9.80, S 14.95; found C 47.52, H 4.98, N 9.78, S 14.87. IR (KBr): $\tilde{\nu}$ = 1570 s cm^{-1} (C=N). ^1H NMR ($CDCl_3$): δ = 1.28 (s, 3 H, CH_3), 1.44 (s, 3 H, CH_3), 2.54–3.20 (m, 6 H, CH_2), 7.11–7.18 (m, 2 H, Ar), 7.45 (d, J = 8.6 Hz, 2 H, Ar), 7.56–7.73 (m, 3 H, Ar), 8.34 (br. s, 1 H, Ar) ppm.

2d: Like **2a** from $Zn(NO_3)_2·4H_2O$ (0.439 g, 1.68 mmol), **HL[2]** (0.353 g, 1.68 mmol), and HSC_6F_5 (0.336 g, 1.68 mmol). Yield 0.358 g (45%) of **2d** as colorless crystals, m.p. 206 °C. $C_{17}H_{17}F_5N_2S_2Zn$ (473.85): calcd. C 43.09, H 3.62, N 5.91, S 13.53; found C 43.04, H 3.48, N 6.04, S 13.53. IR (KBr): $\tilde{\nu}$ = 1598 s, 1570 s cm^{-1} (C=N). ^1H NMR ($CDCl_3$): δ = 1.29 (br. s, 3 H, CH_3), 1.40 (br. s, 3 H, CH_3), 2.53–3.33 (m, 6 H, CH_2), 4.73 (br. s, 1 H, NH), 7.20–7.27 (m, 2 H, Ar), 7.71 (t, J = 7.6 Hz, 1 H, Ar), 8.49 (d, J = 4.6 Hz, 1 H, Ar) ppm. ^{19}F NMR ($CDCl_3$): δ = –134.0 (s, 2 F), –163.2 (s, 1 F), –165.1 (s, 2 F) ppm.

L[3]·ZnCl: A solution of **HL[3]** (0.122 g, 3.04 mmol) in 15 mL of methanol was treated dropwise with stirring first with NaOH (0.122 g, 3.04 mmol) in 5 mL of methanol and then with $ZnCl_2$ (0.414 g, 3.04 mmol) in 5 mL of methanol. The mixture was stirred for 20 h, filtered, and the filtrate evaporated to dryness. Recrystallization of the residue from methanol yielded 0.374 g (38%) of **L[3]**·ZnCl as colorless crystals, m.p. 203 °C. $C_{12}H_{19}ClN_2S_2Zn$ (324.20): calcd. C 44.46, H 5.91, N 8.64; found C 43.52, H 5.88, N 8.28. IR (KBr): $\tilde{\nu}$ = 1610 s, 1569 s cm^{-1} (C=N). ^1H NMR ($CDCl_3$): δ = 1.42 (s, 3 H, CH_3), 1.60 (s, 3 H, CH_3), 2.55 (d, J = 13.0 Hz, 1 H, CH_2), 2.78 (s, 3 H, NCH_3), 2.87–3.74 (m, 5 H, CH_2), 7.33 (d, J = 7.8 Hz, 1 H, Ar), 7.47 (t, J = 6.5 Hz, 1 H, Ar), 7.88 (m, 1 H, Ar), 8.81 (d, J = 5.0 Hz, 1 H, Ar) ppm.

3a: A solution of $HSCH_2CF_3$ (0.058 g, 0.50 mmol) and 1 mL of a 0.5 M solution of $NaOCH_3$ in methanol (0.50 mmol) in 30 mL of methanol was added dropwise, with stirring, to a solution of

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

L^3·ZnBr (0.184 g, 0.50 mmol) in 60 mL of methanol. After stirring overnight the solvent was removed in vacuo. The residue was taken up in 30 mL of chloroform and filtered. After removal of the solvent in vacuo the product was recrystallized from methanol to yield 32 mg (16%) of **3a** as colorless crystals, m.p. 125 °C. $C_{14}H_{21}F_3N_2S_2Zn$ (403.85): calcd. C 41.64, H 5.24, N 6.94, S 15.88; found C 41.68, H 4.56, N 6.45, S 15.44. IR (KBr): $\tilde{\nu}$ = 1608 s, 1571 s cm^{-1} (C=N). ^{1}H NMR ($CDCl_3$): δ = 1.40 (s, 3 H, CH_3), 1.57 (s, 3 H, CH_3), 2.47 (d, J = 13.0 Hz, 1 H, CH_2), 2.77 (s, 3 H, NCH_3), 2.80–3.59 (m, 7 H, CH_2), 7.31 (d, J = 7.8 Hz, 1 H, Ar), 7.45 (t, J = 6.5 Hz, 1 H, Ar), 7.86 (m, 1 H, Ar), 8.87 (d, J = 4.4 Hz, 1 H, Ar) ppm. ^{19}F NMR ($CDCl_3$): δ = –67.29 (s) ppm.

3b: $HSCH_2C_6H_5$ (0.124 g, 1.00 mmol) in 50 mL of methanol was treated with 2.00 mL (1.00 mmol) of a 0.5 M methanol solution of $NaOCH_3$ and then added dropwise, with stirring, to a solution of **L^3·**ZnBr (0.369 g, 1.00 mmol) in 80 mL of methanol. After stirring overnight the solvent was removed in vacuo, the residue taken up in 25 mL of chloroform, and filtered. The filtrate was evaporated to dryness and the product washed with diethyl ether and dried in vacuo. Recrystallization from hexane/chloroform (2:1) yielded 0.239 g (58%) of **3b** as a colorless powder, m.p. 139 °C. $C_{19}H_{26}N_2S_2Zn$ (411.95): calcd. C 55.40, H 6.36, N 6.80, S 15.57; found C 55.14, H 6.20, N 6.67, S 14.74. IR (KBr): $\tilde{\nu}$ = 1607 s, 1568 m cm^{-1} (C=N). ^{1}H NMR ($CDCl_3$): δ = 1.34 (s, 3 H, CH_3), 1.61 (s, 3 H, CH_3), 2.50 (d, J = 13.0 Hz, 1 H, CH_2), 2.67 (s, 3 H, NCH_3), 2.76–3.50 (m, 5 H, CH_2), 3.87 (m, 2 H, CH_2), 7.07–7.28 (m, 6 H, Ar), 7.42 (t, J = 4.2 Hz, 1 H, Ar), 7.76 (m, 1 H, Ar), 8.31 (d, J = 5.4 Hz, 1 H, Ar) ppm.

3c: Like **3b** from $HSCH_2C_6H_4Cl$ (0.159 g, 1.00 mmol), 1.00 mmol of $NaOCH_3$, and **L^3·**ZnBr (0.369 g, 1.00 mmol). Yield 0.331 g (74%) of **3c** as a colorless powder, m.p. 164 °C. $C_{19}H_{25}N_2S_2ClZn$ (446.39): calcd. C 51.12, H 5.84, N 6.28, S 14.37; found C 51.08, H 5.55, N 6.13, S 13.48. IR (KBr): $\tilde{\nu}$ = 1606 s, 1566 s cm^{-1} (C=N). ^{1}H NMR ($CDCl_3$): δ = 1.35 (s, 3 H, CH_3), 1.60 (s, 3 H, CH_3), 2.51 (d, J = 13.0 Hz, 1 H, CH_2), 2.55 (s, 3 H, NCH_3), 2.77–3.48 (m, 5 H, CH_2), 3.84 (m, 2 H, CH_2), 7.16–7.39 (m, 6 H, Ar), 7.79 (m, 1 H, Ar), 8.38 (d, J = 5.2 Hz, 1 H, Ar) ppm.

3d: Like **3b** from HSC_6H_5 (0.115 g, 1.00 mmol), 1.00 mmol of $NaOCH_3$, and **L^3·**ZnBr (0.369 g, 1.00 mmol). Yield 0.224 g (56%) of **3d** as colorless crystals, m.p. 122 °C. $C_{18}H_{24}N_2S_2Zn$ (397.92): calcd. C 54.33, H 6.08, N 7.04, S 16.12; found C 54.30, H 6.29, N 6.99, S 15.43. IR (KBr): $\tilde{\nu}$ = 1608 s, 1578 s cm^{-1} (C=N). ^{1}H NMR ($CDCl_3$): δ = 1.18 (s, 3 H, CH_3), 1.38 (s, 3 H, CH_3), 2.49 (d, J = 13.0 Hz, 1 H, CH_2), 2.66 (s, 3 H, NCH_3), 2.74–3.20 (m, 5 H, CH_2), 6.90–6.95 (m, 3 H, Ar), 7.31–7.44 (m, 4 H, Ar), 7.92 (m, 1 H, Ar), 8.58 (d, J = 5.2 Hz, 1 H, Ar) ppm.

3e: Like **3c** from $HSC_6H_4NO_2$ (0.103 g, 0.66 mmol), 0.66 mmol of $NaOCH_3$, and **L^3·**ZnBr (0.244 g, 0.66 mmol). Yield 0.202 g (69%) of **3e** as yellow crystals, m.p. 81 °C. $C_{18}H_{23}N_3S_2O_2Zn$ (442.92): calcd. C 48.81, H 5.23, N 9.49, S 14.48; found C 48.50, H 5.05, N 9.30, S 14.28. IR (KBr): $\tilde{\nu}$ = 1609 s, 1569 s cm^{-1} (C=N). ^{1}H NMR ($CDCl_3$): δ = 1.34 (s, 3 H, CH_3), 1.47 (s, 3 H, CH_3), 2.54 (d, J = 13.0 Hz, 1 H, CH_2), 2.73 (s, 3 H, NCH_3), 2.80–3.47 (m, 5 H, CH_2), 7.33 (d, J = 7.8 Hz, 1 H, Ar), 7.44 (t, J = 6.5 Hz, 1 H, Ar), 7.73 (d, J = 8.8 Hz, 2 H, Ar), 7.84–7.93 (m, 3 H, Ar), 8.72 (d, J = 1.0 Hz, 1 H, Ar) ppm.

3f: Like **3c** from HSC_6F_5 (0.100 g, 0.50 mmol), 0.50 mmol of $NaOCH_3$, and **L^3·**ZnBr (0.184 g, 0.50 mmol). Yield 0.145 g (59%) of **3f** as colorless crystals, m.p. 110 °C. $C_{18}H_{19}F_5N_2S_2Zn$ (487.88): calcd. C 44.31, H 3.93, N 5.74, S 13.15; found C 44.12, H 3.46, N 5.37, S 11.88. IR (KBr): $\tilde{\nu}$ = 1611 s, 1571 m cm^{-1} (C=N). ^{1}H NMR ($CDCl_3$): δ = 1.26 (s, 3 H, CH_3), 1.57 (s, 3 H, CH_3), 2.53 (d, J = 13.0 Hz, 1 H, CH_2), 2.81 (s, 3 H, NCH_3), 2.85–3.53 (m, 5 H, CH_2), 7.31 (d, J = 7.8 Hz, 1 H, Ar), 7.46 (t, J = 6.3 Hz, 1 H, Ar), 7.80 (t, J = 7.2 Hz, 1 H, Ar), 8.85 (d, J = 5.0 Hz, 1 H, Ar) ppm. ^{19}F NMR ($CDCl_3$): δ = –163.3 (s, 2 F), –161.9 (s, 1 F), –133.9 (s, 2 F) ppm.

4d: A solution of **3d** (0.100 g, 0.25 mmol) in 15 mL of chloroform was treated with methyl iodide (0.036 g, 0.25 mmol). After stirring for 3 d the solvent was removed in vacuo, the residue washed with diethyl ether, and dried in vacuo to give 0.078 g (57%) of **4d** as a colorless powder, m.p. 128 °C. $C_{19}H_{27}IN_2S_2Zn$ (539.86): calcd. C 42.27, H 5.04, N 5.19, S 11.14; found C 39.26, H 5.19, N 5.56, S 12.04. IR (KBr): $\tilde{\nu}$ = 1609 s, 1569 m cm^{-1} (C=N). ^{1}H NMR ($CDCl_3$): δ = 1.26 (s, 3 H, CH_3), 1.38 (s, 3 H, CH_3), 2.03 (s, 3 H, SCH_3), 2.50 (d, J = 9.2 Hz, 1 H, CH_2), 2.81 (s, 3 H, NCH_3), 2.84–3.48 (m, 5 H, CH_2), 6.96–7.00 (m, 3 H, Ar), 7.10–7.44 (m, 4 H, Ar), 7.83 (br. d, J = 6.2 Hz, 1 H, Ar), 8.87 (br. s, 1 H, Ar) ppm.

4e: Like **4d** from **3e** (0.090 g, 0.20 mmol) and methyl iodide (0.029 g, 0.20 mmol). Yield 0.064 g (54%) of **4e** as a yellow powder, m.p. 53 °C. $C_{19}H_{26}IN_3O_2S_2Zn$ (584.86): calcd. C 39.02, H 4.48, N 7.18, S 10.97; found C 39.30, H 4.64, N 7.02, S 10.67. IR (KBr): $\tilde{\nu}$ = 1611 s, 1570 m cm^{-1} (C=N). ^{1}H NMR ($CDCl_3$): δ = 1.34 (s, 3 H, CH_3), 1.44 (s, 3 H, CH_3), 2.06 (s, 3 H, SCH_3), 2.54 (s, 1 H, CH_2), 2.65 (s, 3 H, NCH_3), 2.79–3.18 (m, 5 H, CH_2), 7.28 (d, J = 7.2 Hz, 1 H, Ar), 7.61 (d, J = 8.8 Hz, 2 H, Ar), 7.68–7.84 (m, 2 H, Ar), 8.18 (d, J = 9.0 Hz, 2 H, Ar), 8.66 (br. s, 1 H, Ar) ppm.

4f: Like **4d** from **3f** (0.101 g, 0.21 mmol) and methyl iodide (0.030 g, 0.21 mmol). Yield 0.077 g (58%) of **4f** as a colorless powder, m.p. 58 °C. $C_{19}H_{22}F_5IN_2S_2Zn$ (629.81): calcd. C 36.23, H 3.52, N 4.45, S 10.18; found C 34.78, H 3.27, N 5.13, S 9.72. IR (KBr): $\tilde{\nu}$ = 1610 s, 1571 m cm^{-1} (C=N). ^{1}H NMR ($CDCl_3$): δ = 1.36 (s, 3 H, CH_3), 1.48 (s, 3 H, CH_3), 2.11 (s, 3 H, SCH_3), 2.48 (s, 1 H, CH_2), 2.83 (s, 3 H, NCH_3), 2.95–3.66 (m, 5 H, CH_2), 7.27–7.47 (m, 2 H, Ar), 7.68–7.80 (m, 1 H, Ar), 8.67 (br. s, 1 H, Ar) ppm. ^{19}F NMR ($CDCl_3$): δ = –163.1 (s, 2 F), –161.9 (s, 1 F), –132.9 (s, 2 F) ppm.

5d: A solution of **3d** (0.116 g, 0.29 mmol) and $PO(OMe)_3$ (0.041 g, 0.29 mmol) in 15 mL of DMSO was stirred at 80 °C for two weeks. The solvent was then removed by distillation in vacuo. The residue was washed with diethyl ether and dried in vacuo to give 0.116 g (74%) of **5d** as a slightly yellow wax which could not be purified further and hence was identified only by ^{1}H NMR spectroscopy in $CDCl_3$: δ = 1.40 (br. s, 6 H, CH_3), 1.73 (s, 3 H, SCH_3), 2.55–3.39 (m, 9 H, NCH_3/CH_2), 3.63 (d, J = 11.0 Hz, 6 H, OCH_3), 6.90–7.10 (m, 3 H, Ar), 7.32–7.52 (m, 4 H, Ar), 7.86 (t, J = 7.6 Hz, 1 H, Ar), 8.83 (br. s, 1 H, Ar) ppm. ^{31}P NMR ($CDCl_3$): δ = 0.91 ppm.

Complex 6. a) From 3d: A solution of **3d** (0.120 g, 0.30 mmol) and methyl iodide (0.214 g, 1.50 mmol) in 15 mL of chloroform was stirred for 3 d. The solvent was then removed in vacuo and the residue extracted with two 10-mL portions of diethyl ether. The remaining product was dried in vacuo to give 0.148 g (88%) of **6** as a colorless powder, m.p. 59 °C. $C_{13}H_{22}I_2N_2SZn$ (557.59): calcd. C 28.00, H 3.98, N 5.02, S 5.75; found C 27.48, H 3.97, N 5.53, S 5.27. IR (KBr): $\tilde{\nu}$ = 1610 s, 1570 m cm^{-1} (C=N). ^{1}H NMR ($CDCl_3$): δ = 1.53 (s, 6 H, CH_3), 2.18 (s, 3 H, SCH_3), 2.91 (s, 3 H, NCH_3), 3.18 (br. s, 2 H, CH_2), 3.41–3.52 (m, 4 H, CH_2), 7.41–7.50 (m, 2 H, Ar), 7.90 (m, 1 H, Ar), 8.87 (br. s, 1 H, Ar) ppm.

The diethyl ether phase was evaporated to dryness and the remaining $CH_3SC_6H_5$ identified by ^{1}H NMR ($CDCl_3$): δ = 2.47 (s, 3 H, CH_3), 7.12–7.28 (m, 5 H, Ph) ppm.

b) From 3e: As before from **3e** (0.100 g, 0.23 mmol) and methyl iodide (0.326 g, 2.30 mmol). Yield 0.113 g (88%) of **6**. Identifica-

tion of $CH_3SC_6H_4$-*p*-NO_2 by ^{1}H NMR ($CDCl_3$): δ = 2.47 (s, 3 H, CH_3), 7.19–7.25 (m, 2 H, Ar), 8.03–8.10 (m, 2 H, Ar) ppm.

c) From 3f: As before from **3f** (0.050 g, 0.10 mmol) and methyl iodide (0.142 g, 1.00 mmol). Yield 0.047 g (84%) of **6**. Identification of $CH_3SC_6F_5$ by ^{1}H NMR ($CDCl_3$): δ = 2.47 (CH_3) ppm.

Complex 7: Complex **3d** (0.122 g, 0.31 mmol) and trimethyl phosphate (0.317 g, 1.55 mmol) in 15 mL of DMSO were stirred at 80 °C for two weeks. The solvent was then removed by distillation in vacuo. The residue was extracted with two 10-mL portions of diethyl ether and dried in vacuo to give 0.121 g (71%) of **7** as an impure, waxy material which was identified by ^{1}H NMR ($CDCl_3$): δ = 1.45 (s, 6 H, CH_3), 2.06 (d, J = 2.6 Hz, 3 H, SCH_3), 2.61 (s, 3 H, NCH_3), 2.72–3.05 (m, 4 H, CH_2), 3.32 (s, 2 H, CH_2), 3.64 (d, J = 11.0 Hz, 12 H, OCH_3), 7.15–7.23 (m, 2 H, Ar), 7.46 (t, J = 8.0 Hz, 1 H, Ar), 7.72 (d, J = 6.0 Hz, 1 H, Ar) ppm. ^{31}P NMR ($CDCl_3$): δ = 0.55 ppm.

The diethyl ether phase was evaporated to dryness and the remaining $CH_3SC_6H_5$ identified by ^{1}H NMR spectroscopy as above.

Structure Determinations:[28] Crystals were obtained as described above. Diffraction data were recorded at room temp. for **3d** and **3f** and at 220 K for **1**, **2a**, **3e**, and **L^3**·ZnCl with a Bruker Smart CCD diffractometer. Empirical absorption corrections (SADABS) were applied for **1**, **2a**, and **L^3**·ZnCl. The structures were solved and refined anisotropically with the SHELX program suite.[29] Hydrogen atoms were included with fixed distances and isotropic temperature factors 1.5-times those of their attached atoms. Parameters were refined against F^2. The R values are defined as $R_1 = \Sigma|F_o - F_c|/\Sigma F_o$ and $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]\Sigma[w(F_o^2)^2]\}^{1/2}$. Drawings were produced with SCHAKAL.[30] Table 1 lists the crystallographic data.

Acknowledgments

This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We are indebted to Drs. W. Deck and H. Brombacher for help with the structure determinations and to Mr. B. Benkmil for assistance in the laboratory.

Luminescence from Lanthanide(3+) Ions in Solution

Anders Døssing*[a]

Keywords: Lanthanides / Luminescence / Fluorescent probes

An overview of recent work dealing with luminescence properties in solution of complexes of the lanthanide(3+) ions Nd^{3+}, Eu^{3+}, Tb^{3+}, Er^{3+} and Yb^{3+} in which an organic chromophore is attached to the metal centre as a sensitizer is given. The various factors that influence the metal-centred luminescence lifetime and intensity are discussed and illustrated with own results and recent literature examples. The VIS emitting metal ions Eu^{3+} and Tb^{3+} require sensitizers that absorb light in the UV or near UV range whereas VIS absorbing sensitizers can be used for the NIR emitting ions Nd^{3+}, Er^{3+} and Yb^{3+}. The latter type of complexes is currently of great interest because of potential applications as luminescent markers in biological systems.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Complexes of the trivalent lanthanide ions (Ln^{3+}) that display a metal-centred luminescence in solution have attracted an increased attention in the recent years owing to their potential use as luminescent tags in biological systems e.g. fluoroimmunoassays.[1] The emission from the excited state Ln^{3+} ions is characterized by narrow emission bands in the NIR to UV range and long emission lifetimes, up to milliseconds, characteristic of the individual metal ion. The energy levels, $^{(2S+1)}L_J$, of selected Ln^{3+} ions are shown in Figure 1.[2] These characteristics are caused by the parity forbidden, and in many cases spin forbidden, nature of the 4f → 4f transitions and the fact that the 4f electrons, being effectively shielded by 5p and 6s electrons, are not involved in chemical bonding.

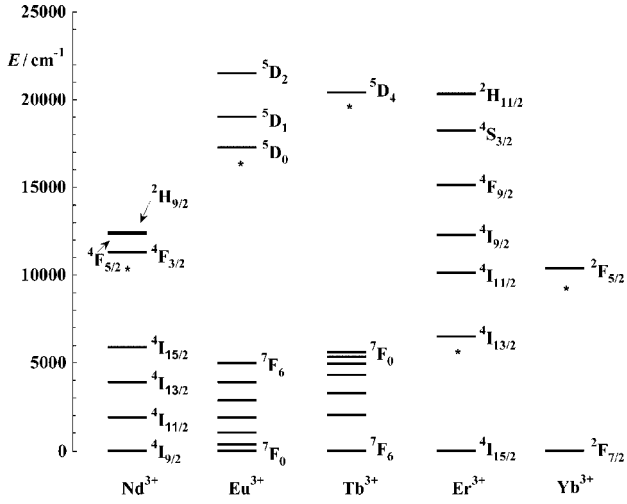

Figure 1. Lower energy levels of selected lanthanide(3+) aqua ions.[2] The luminescent level is marked with an asterisk.

Concerning potential applications of such complexes the parity-forbidden nature of the 4f → 4f transitions is a major draw back. The 4f → 4f transitions have very low molar absorption coefficients ($\varepsilon < 1\ M^{-1}cm^{-1}$), and population of

Anders Døssing was born in 1962 in Denmark and received his Ph.D. degree in 1990 from the University of Copenhagen in chemistry under the supervision of Prof. Peter Andersen in the field of hydroxo-bridged, dinuclear chromium(III) complexes. In 1991 he did postdoctoral work in Prof. Peter C. Ford's group at University of California, Santa Barbara where he investigated the photophysical properties of polynuclear copper(I) complexes. In 1992–1994 he worked with Prof. Hans Toftlund at Odense University (Denmark) in the field of lanthanide-polypyridyl complexes. In 1994 he returned to University of Copenhagen as an Assistant Professor and in 1997 he became an Associate Professor.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

the excited state(s) of the emitting metal ion by direct excitation is consequently inefficient. One way to overcome this problem is to include a highly absorbing chromophore in the ligand coordinated to the metal centre, which is illustrated in the Jablonski diagram in Figure 2. The chromophore absorbs efficiently the excitation energy followed by an energy transfer to the metal centre, and finally a metal-centred, sensitized luminescence occurs. Such a process, where light is harvested by a strongly absorbing chromophore (or sensitizer), is usually referred to as the "antenna effect". The energy transfer from the chromophore to the metal centre in principle can take place either from the singlet excited state S_1 or from the triplet excited state T_1 after an intersystem crossing. It is, however, generally believed that the energy transfer in most cases occurs from T_1 rather than from S_1.[3] Competitive to the intersystem crossing and the subsequent energy transfer is fluorescence, phosphorescence and thermal decay to the ground state S_0. The energy transfer is mediated by two mechanisms. The first is the so-called Förster mechanism,[4] a dipole−dipole mechanism that operates through space with a chromophore–metal distance (r) dependence of r^{-6} and displays a strong dependence on spectral overlap between emission spectrum of the chromophore (T_1) and the absorption spectrum of the metal centre. The selection rule for this mechanism is $\Delta J = 2$, 4, 6. The second is the Dexter mechanism,[5] where energy transfer is mediated through orbitals with ΔJ being 0 or 1 ($0 \leftrightarrow 0$ excluded) and with a distance dependence of e^{-r}. It follows, that the energy difference between T_1 of the chromophore and $^{2S'+1}L'_{J'}$ of the metal centre should not be too large with the energy of T_1 being the higher in energy. On the other hand, a too small energy gap will lead to back energy transfer from $^{2S'+1}L'_{J'}$ to T_1 and possible bimolecular quenching of T_1 by dioxygen (vide infra).

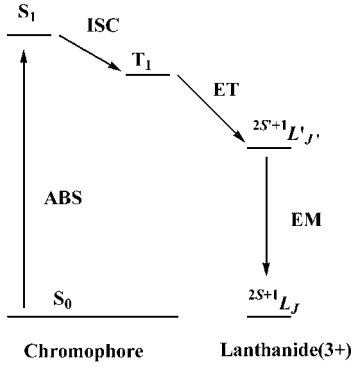

Figure 2. Jablonski diagram illustrating the absorption (ABS) of incident light on the sensitizing chromophore followed by intersystem crossing (ISC) from the singlet (S_1) to the triplet state (T_1) on the chromophore and energy transfer (ET) to the $^{2S'+1}L'_{J'}$ level on the lanthanide(3+) centre from which deactivation to the ground state $^{2S+1}L_J$ by emission of light (EM) occurs.

The metal centre being in the excited state $^{2S'+1}L'_{J'}$ as a result of energy transfer from the chromophore can undergo radiative or nonradiative deactivation to the ground state $^{2S+1}L_J$. The latter is promoted by the high-frequency vibrational modes of coordinated X–H oscillators, such as coordinated water or amine ligands (ν_{OH} = 3300–3500 cm^{-1}, ν_{NH} = 3100–3300 cm^{-1}). The extent of this nonradiative deactivation pathway, which results in luminescence quenching, is inversely proportional to the energy gap between the excited state and the ground state manifold. By inspection of Figure 1 it is seen that the energy gap between $^5D_0$ and $^7F_6$ in Eu^{3+} of 12300 cm^{-1} matches the 2nd vibrational overtone of an O–H oscillator. For Tb^{3+} a gap of 14800 cm^{-1} matches the 3rd overtone, and the vibrational deactivation is therefore less efficient owing to a smaller Frank-Condon overlap between the two wavefunctions. Going to Er^{3+} with an energy gap of only 6500 cm^{-1}, the emission is effectively quenched by coordinated water ligands. The spacing between the vibrational levels in X–D oscillators is smaller than in X–H oscillators and vibrational luminescence quenching is accordingly much less pronounced and can often be neglected. This has been done by Horrocks,[6] who proposed a correlation (1) to estimate the number of coordinated water ligands coordinated to the metal centre, n_{H_2O}, with an alleged uncertainty of 0.5.

$$n_{H_2O} = A\,(k_H - k_D) \quad (1)$$

Here k_H and k_D are the first-order rate constant (in ms^{-1}) for deactivation of the excited state metal in water and D_2O solution, respectively, and A an empirically determined constant being 1.05 ms, 4.2 ms and 0.9 μs for Eu^{3+}, Tb^{3+} and Yb^{3+}, respectively (for Yb^{3+} k_H and k_D should be in units of μs^{-1}). Correlation (1) can be extended to work in methanol solution. The number of coordinated methanol ligands can be estimated by measuring the rate constants in CH_3OH and CD_3OD solution and by use of values of A that are twice the above mentioned, since a methanol ligand only contains one O–H oscillator compared to two in a water ligand. A later and more sophisticated treatment of this subject by Parker[7] has resulted in the modified correlation (2):

$$n_{H_2O} = A'\,(k_H - k_D - B) \quad (2)$$

Here the term B accounts for interaction between the metal centre and outer sphere O–H oscillators. Values for A' in aqueous solution are 1.2 ms, 5 ms and 1.0 μs and for B 0.25 ms^{-1}, 0.06 ms^{-1} and 0.2 μs^{-1} for Eu^{3+}, Tb^{3+} and Yb^{3+}, respectively. The uncertainty of n_{H_2O} in correlation (2) is believed to be smaller than in correlation (1). Attempts to make similar expressions for complexes including other oscillators were made by Parker.[7]

Recently,[8] on the basis of a study of luminescence lifetimes in aqueous solution with 25 Eu^{3+} complexes of ligands not containing any X–H oscillators, Horrocks has proposed correlation (3):

$$n_{H_2O} = 1.11\text{ ms}\,(k_H - k_D - 0.31\text{ ms}^{-1}) \quad (3)$$

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

This result in combination with Parkers work[7] that included other X–H oscillators in a series of macrocyclic complexes, gives correlation (4) for Eu^{3+} complexes of ligands containing hydroxo, amine and amide oscillators coordinated to the metal centre:

$$n_{H_2O} = 1.11\ ms\ (k_H - k_D - 0.31\ ms^{-1} + 0.45\ ms^{-1}\ n_{OH} + 0.99\ ms^{-1}\ n_{NH} + 0.075\ ms^{-1}\ n_{O=CNH}) \quad (4)$$

For Nd^{3+} correlation (5) has been proposed by Faulkner[9a]

$$n_{H_2O} = 130\ ns\ (k_H - k_D) - 0.4 \quad (5)$$

with the rate constants in ns^{-1}. Kimura[9b] proposed for Sm^{3+} and Dy^{3+} correlation (6):

$$n_{H_2O} = Ak_H - B \quad (6)$$

with A being $0.026\ ms^{-1}$ and $0.024\ ms^{-1}$ and B being 1.6 and 1.3 for Sm^{3+} and Dy^{3+}, respectively. Obtaining noninteger values of n_{H_2O} by use of the correlations above is not necessarily wrong, since there could be several more or less aquated species coexisting in solution. In summary, a complex that efficiently converts incident light (UV or VIS) to metal-centred, emitted light (VIS or NIR) should fulfil the following conditions: (i) The ligand includes a highly absorbing chromophore, (ii) energy transfer from the ligand-centred excited states is fast and efficient, (iii) X–H oscillators are excluded from the first coordination sphere of the metal, (iv) the complex is thermodynamically stable and kinetically inert. In the following a brief overview of lanthanide complexes that display VIS and NIR luminescence will be given.

VIS Emitters

The most intense emitters in the VIS range among the Ln^{3+} ions are Eu^{3+} and Tb^{3+} with the weaker ones being Sm^{3+} and Dy^{3+}. The energy of the emitting state in Eu^{3+}, $^5D_0$, is ca. 17300 cm^{-1} and in Tb^{3+}, $^5D_4$, is ca. 20500 cm^{-1} as seen in Figure 1. The energy of the triplet state of the sensitizer has, as mentioned above, to be larger and useful sensitizers for Eu^{3+} and Tb^{3+} centred emission should consequently absorb in the UV or near UV range. Heteroaromatic compounds such as bipyridine, phenanthroline, quinoline, terpyridine or benzimidazole have been used in this regard.[10–15] Numerous complexes of the above mentioned compounds have been isolated in the solid state and structurally characterized. However, these compounds coordinate only weakly to the Ln^{3+} ions and the complexes dissociate readily in coordinating solvents such as water or alcohols. This obstacle can be overcomed by incorporating the chromophores as part of larger chelating ligands with podand, macrocyclic or cage type structure. Examples of such ligands are shown in Figure 3 (**1**–**7**). Apart from including the heteroaromatic sensitizers, these ligands more or less exclude solvent molecules from the first coordination sphere, which, as mentioned above, suppresses the nonradiative deactivation pathway.

A widely used ligand structure is based on the cyclic amine 1,4,7,10-tetraazacyclododecane (cyclen) with neutral or anionic donors such as $-CH_2COO^-$ attached as pendant arms to the nitrogen atoms.[16] The ligand DOTA (**8**) forms complexes of very high thermodynamic and kinetic stability. Concerning the influence of the radius of the Ln^{3+} ion on the thermodynamic stability of such complexes, a study by Sherry[17] showed that the Ln^{3+} ions with an ionic radius less than 0.94 Å (Gd^{3+} or later) are more stable. By including UV absorbing sensitizers in the pendant arm(s), sensitized emission from the metal centre has been observed in numerous cases. One interesting example of this was reported by Parker et al.[18] who attached a phenanthridine chromophore to the cyclen unit as seen in **9**. In the Tb^{3+} and Eu^{3+} complexes of **9** a pH and oxygen concentration dependence of the intensity of the metal-centred emission was observed. The pH dependence was explained in terms of protonation equilibria involving the nitrogen atom in the sensitizing phenanthridine chromophore.

In the use of the Eu^{3+} ion as the emitter there is a major draw back resulting from its redox properties. It is well known that the Eu^{3+} ions is the lanthanide ion most readily reduced to the oxidation state 2+ with the standard electrode potential $E^{\circ}_{Eu^{3+}/Eu^{2+}} = -0.35$ V in aqueous solution.[19] The second most readily reduced ion is the Sm^{3+} ion with $E^{\circ}_{Sm^{3+}/Sm^{2+}} = -1.5$ V.[19] In the case of Eu^{3+}, electron transfer from the excited state (S_1) chromophore to the metal centre might then compete with the intersystem crossing (and subsequent energy transfer) with a reduction of the Eu^{3+} to Eu^{2+} as a result. An *rough* estimate of the free energy of the excited-state electron transfer, ΔG°_{el}, can be found by use of correlation (7):

$$\Delta G^{\circ}_{el} = FE^{\circ}_{sens^+/sens} - FE^{\circ}_{Eu^{3+}/Eu^{2+}} - E_{sens*} \quad (7)$$

Here $E^{\circ}_{sens^+/sens}$ is the standard electrode potential for $sens^+$/sens couple, E_{sens*} the energy of the excited state of the sensitizer and F the Faraday constant. A small correction term for charge redistribution has been omitted. As a result of the intramolecular electron transfer, a LMCT excited state will be populated from which a nonradiative deactivation to the ground state is likely to occur. To suppress this deactivation pathway, the sensitizing chromophores should have high values of $E^{\circ}_{sens^+/sens}$, namely, they should be difficult to oxidize. One way achieving that could be done by attaching electron withdrawing substituents to the aromatic rings.

Returning to the energy gap between the sensitizer T_1 state and the acceptor state(s) of the metal centre Latva et al.[14] has systematically studied the emission quantum yield of a large series of Tb^{3+} and Eu^{3+} complexes of heteroaromatic ligands with T_1 energies in the range 18600–27000 cm^{-1}. They found that in the case of Eu^{3+} there was no clear correlation between the T_1 energy and the emission quantum yield. It was concluded that the Eu^{3+} centre is able to accept energy, not only with the $^5D_0$ level but also with the higher ^5D_J levels. In the case of Tb^{3+} there was a clear correlation between the emission quantum yield and the T_1 energy. With an energy gap between the T_1 state and the $^5D_4$ state larger than 1850 cm^{-1} the quantum yields were found in the range 0.12–0.58. Below 1850 cm^{-1}, the quantum yields dropped dramatically to 0.01 or less. One possible explanation for this behaviour is that with small energy gaps, back energy transfer from the metal centre to the sensitizer might occur with a reduction of the emission quantum yield as a result. However, in the case of a small energy gap the energy transfer from the sensitizer T_1 state to dioxygen, which is present in the solution, might compete with the energy transfer to the metal centre efficiently. Again, this resulted in a reduction of the metal-centred emission quantum yield. An example of this phenomenon was observed in the Tb^{3+} complex of the Lehn-cryptand (**1**). Here, the T_1 state of the bipyridine chromophore has an energy of 21600 cm^{-1}. A temperature dependence of the emission quantum yield and a bimolecular quenching of the metal-centred emission by dioxygen was observed[10] with a second-order rate constant $k_q = 3.9 \times 10^6$ $M^{-1}s^{-1}$. This was interpreted in terms of back energy transfer.

The sensitizing chromophores in the ligands **1**–**7** and **9** require irradiation at $\lambda < 400$ nm. A very interesting example of an Eu^{3+} complex that displays a metal-centred luminescence at irradiation wavelengths *above* 400 nm was recently reported by Verhoeven et al.[20] The coordinatively unsaturated tris(β-diketonate) complex [Eu(fod)$_3$] (fod = 6,6,7,7,8,8,8-heptafluoro-2,2-dimethyloctane-3,5-dione) forms in the non-coordinating solvent benzene a 1:1 complex with Michler's ketone [4,4′-bis(dimethylamino)benzophenone, **10**). The compound **10** is a so-called push-pull chromophore, and an intense absorption band at 350 nm ($\varepsilon \approx$ 16000 cm^{-1} M^{-1}) has some charge-transfer character, where electron density is moved from the dimethylamino groups to the carbonyl group. The formation of a bond between the carbonyl oxygen atom on **10** and the Eu^{3+} centre yielding [Eu(fod)$_3$(**10**)] results in a bathochromic shift of this charge-transfer band to 414 nm. Irradiation of such a solution with light gave intense red luminescence at wavelengths up to 450 nm with an emission quantum yield of 0.17 in an aerated solution. From phosphorescence measurements of the complex [Gd(fod)$_3$(**10**)] the triplet energy of coordinated **10** was estimated to be 19600 cm^{-1}, which is only 2300 cm^{-1} above the $^5D_0$ level on Eu^{3+} centre. However, the bond between the carbonyl oxygen and the metal centre is so weak that it is broken in coordinating solvents, which limits the potential applications of this system.

Ln^{3+} complexes of the cage ligand **1** were among the early systems to be investigated.[10] Luminescence lifetime measurements revealed by use of correlation (1) the presence of 2–3 water molecules coordinated to the metal centre in aqueous solution. A later[21] crystal structure determination of the Tb^{3+} complex of **1** showed an open structure (Figure 4) with bond lengths to the bipyridine groups A, B and C being 2.90, 2.55 and 2.74 Å, respectively. Tb^{3+}–bipyridine bond lengths fall typically in the range 2.5–2.6 Å,[22,23] so the cavity size in **1** is obviously too large. Furthermore, a water molecule and a chloride anion are coordinated to the metal centre. This prompted us to investigate Ln^{3+} complexes of the related and more flexible pod-and type ligand **2**.[11] The ligand **2** can be imagined to be the result of hydrogenolysis of the 2,2′ C–C bonds in two of the bipyridine groups. Therefore, the more flexible ligand **2** should enclose the metal centre more efficiently than **1**. Single crystals of the Gd^{3+} complex of **2** were grown from an ethanol solution and the structure is shown in Figure 5.[11a] It is seen that one of the pyridine groups is dangling uncoordinated, and that two chloride anions are coordinated to the metal centre. Therefore, the complex cation should be formulated as $[Gd(\mathbf{2})Cl_2]^+$. Moreover, the complex cation is chiral with the nitrogen atoms N1–N2–N3–N4–N5–N6 forming a helix. The unit cell contains two complex cations of opposite chirality. In collaboration with J. Legendziewicz's group more detailed studies of the luminescence properties of Ln^{3+} complexes of **2** have been done.[11b,11d] From the phosphorescence spectrum of $[Gd(\mathbf{2})Cl_2]^+$ in CH_3OH solution at 77 K the energy of the T_1 state

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

in the bipyridine chromophore was found to be 21900 cm^{-1}.[11b] In water or CH_3OH solution the Eu^{3+} and Tb^{3+} complex of **2** displays luminescence on irradiation with UV light. In the case Eu^{3+} the energy of $^5D_0 \rightarrow {}^7F_0$ transition depends on the ligand field, and the presence of more than one peak is therefore indicative of more than one species in the solution. A close scrutiny of the $^5D_0 \rightarrow {}^7F_0$ transition at 77 K in the solid state and in various solvents shows indeed the presence of two components in water and in CH_3OH solution (Figure 6).[11b] In CH_3CN solution and in the solid state the stoichiometry of the complex is likely to be $[Eu(\mathbf{2})Cl_2]^+$, and in water and CH_3OH solution a partly solvatized species, such as $[Eu(\mathbf{2})Cl(CH_3OH)]^{2+}$, is present as well. In agreement with this, luminescence lifetime measurements in CH_3OH and CD_3OD gave in each solvent two luminescence lifetimes τ_1 and τ_2, and by use of correlation (1) it was found that the two species contains 0.0 and 0.6 coordinated CH_3OH molecules, respectively. Investigations of the Tb^{3+} complex of **2** indicated that back energy transfer took place.[11d]

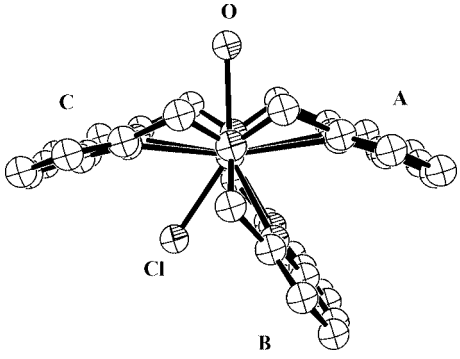

Figure 4. ORTEP drawing of the cation $[Tb(\mathbf{1})(OH_2)Cl]^{2+}$ prepared by Lehn et al.[21] viewed along the axis comprised by the two aliphatic nitrogen atoms. Drawn using coordinates taken from Cambridge Crystallographic Database. Tb–N bond lengths are 2.90 Å (A), 2.55 Å (B) and 2.74 Å (C).

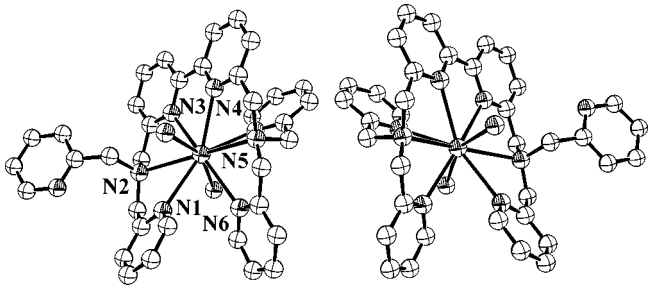

Figure 5. ORTEP drawing of the two complex cations in the unit cell of $[Gd(\mathbf{2})Cl_2]Cl{\cdot}2H_2O{\cdot}\frac{1}{2}EtOH$ prepared by Døssing et al.[11a]

Complexes of La^{3+} are diamagnetic and the structure and dynamics of such complexes in solution can conveniently be studied by use of NMR spectroscopy. The complex $[La(\mathbf{2})]Cl_3{\cdot}4H_2O$ has been studied in CD_3OD and

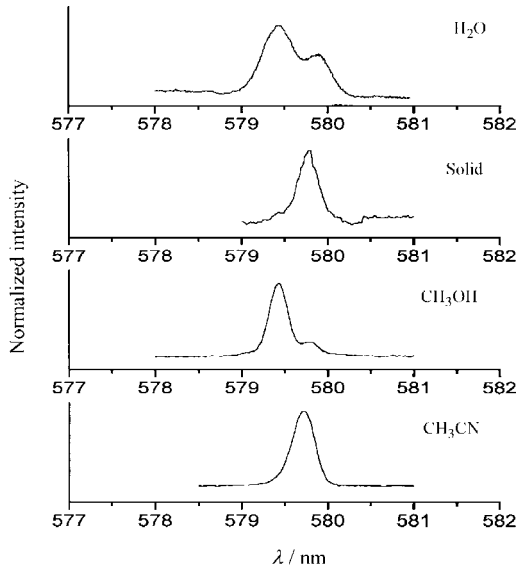

Figure 6. $^5D_0 \rightarrow {}^7F_0$ emission spectra of $[Eu(\mathbf{2})Cl_2]Cl{\cdot}1.5H_2O$ in different solvents at 77 K (λ_{ex} = 320 nm) Redrawn from ref.[11b] with permission from Elsevier.

CD_3CN solution, and the ^1H NMR spectrum in the latter solvent is shown in Figure 7 along with the assignment obtained by help of two-dimensional COSY spectroscopy.[11c] The figure shows that the four pyridine groups exist in two pair-wise equivalent groups and that the bipyridine group is symmetric. The presence of six methylene groups that give rise to the three AX spin systems (α1, α2), (β1, β3) and (β2, β4) of equal intensity shows that the pyridine rings 1 and 3 (and, 2 and 4) are symmetry related, and the complex ion has therefore twofold symmetry. The ^1H NMR spectrum of $[La(\mathbf{2})]Cl_3{\cdot}4H_2O$ in CD_3OD is very similar except for a number of additional low-intensity peaks, which shows the existence of an other species in low concentration. This is not surprising, since this is also the case in Eu^{3+} complexes of **2** in methanol solution (see Figure 6). At higher temperatures the peaks corresponding to the protons in the four pyridine groups are broadened, which indicates that a slow interchange between the two pairs of symmetric pyridine groups takes place. Moreover, the peaks corresponding to the α1 and α1′ protons broadens. No broadening was observed for the peaks corresponding to the protons in the bipyridine group. From the two-dimensional EXSY spectrum showed in Figure 8 the presence of the cross peaks between the four protons in the pyridine groups clearly confirms the interchange. Moreover, cross peaks between primed and unprimed protons in the methylene groups are present. The exchange rates in CD_3CN solution were measured in the temperature range 270–315 K with the first-order rate constant, k, for the interconversion at 300 K being 1.78(5) s^{-1} with $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ being 69(1) $kJ\,mol^{-1}$ and –9(2) $J{\cdot}mol^{-1}{\cdot}K^{-1}$, respectively. In CD_3OD solution the behaviour was similar with $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ being 71(2) $kJ{\cdot}mol^{-1}$ and 4(6) $J{\cdot}mol^{-1}{\cdot}K^{-1}$, respectively. The pseudo-first-order rate constants for substitution of unidentate ligands in the first coordination sphere of the

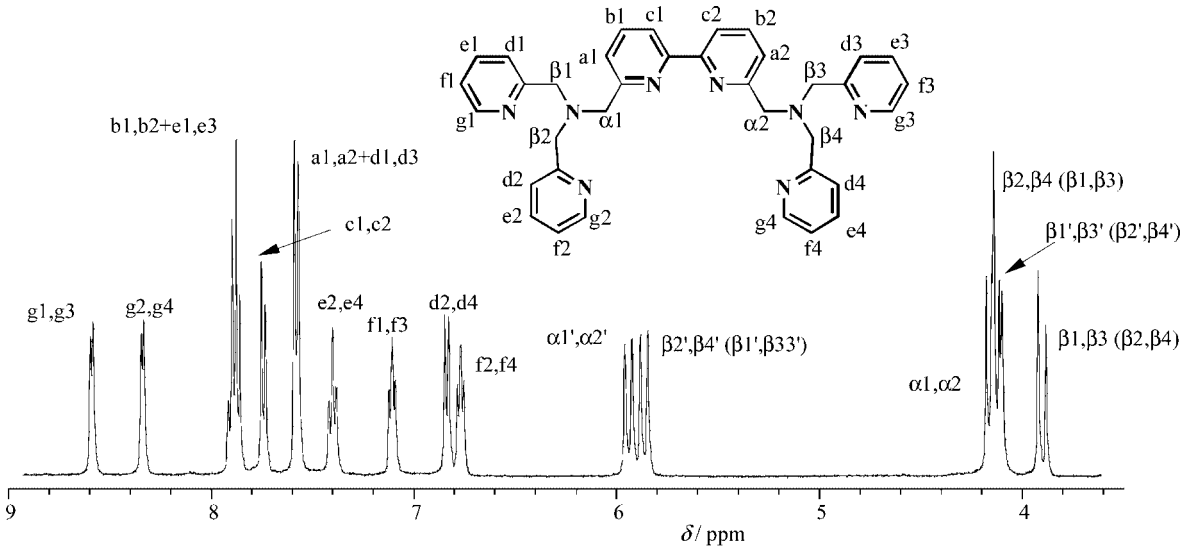

Figure 7. One dimensional ^{1}H NMR spectrum of [La(**2**)]Cl_3·4H_2O in CD_3CN solution at 298 K with assignments. The primed and unprimed methylene protons refer to chemically and magnetically inequivalent protons bound to the same carbon atom. For reasons of clarity the La^{3+} centre has been omitted in the labelling figure.

lanthanide(3+) ions have been found in the range 10^5–10^9 s^{-1},[24] several orders of magnitude higher than the interconversion rate, k. The interconversion process is therefore unlikely to be either an exchange between dangling (uncoordinated) and coordinated pyridine groups or a solvento/chloro ligand exchange but rather a concerted twist. With twofold symmetry the cation could be chiral having a C_2 axis or achiral having a mirror plane. The interconversion is in the first case a conformational change during which the chirality changes and in the second case a mirror-image conformational change through a plane orthogonal to the symmetry plane of the complex. The NMR spectroscopic data did not allow any distinction between the two cases.

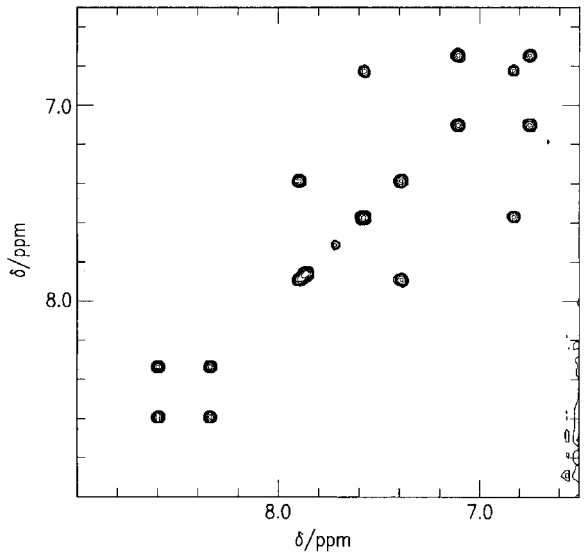

Figure 8. The EXSY spectrum recorded of [La(**2**)]Cl_3·4H_2O in CD_3CN solution at 300 K in the range 6.6–9.0 ppm with an exchange delay of 1.0 s.

One way to clarify if a solution of a luminescent Ln^{3+} complex consists of a racemic mixture of two interconverting enantiomers is by use of circularly polarized (CP) excitation light. A racemic mixture may on excitation with CP light be enantiomerically enriched in the excited state. The metal centre may subsequently display a circularly polarized luminescence (CPL). An excellent review of this technique has been given by J. P. Riehl.[25] The requirement for the detection of a CPL signal is, however, that the rate of the racemization in the excited state (which is probably very close to the racemization rate in the ground state) is slower than the rate of the decay from the metal-centred excited state. In collaboration with J. P. Riehl, Tb^{3+}, Eu^{3+} and Dy^{3+} complexes of **2** have been studied by this technique.[11d] A CPL signal was indeed seen for the $^4F_{9/2} \rightarrow {}^6H_{13/2}$ transition in the Dy^{3+} complex in aqueous solution at room temperature. The $^4F_{9/2}$ excited state lifetime was found to be 10 μs under such conditions. In the cases of Tb^{3+} and Eu^{3+} with the much longer excited state lifetimes in H_2O (1.53 ms and 0.78 ms) no CPL was detected.

In conclusion, CH_3CN solutions of complexes between **2** and Ln^{3+} ions consist of interconverting enantiomers of [Ln(**2**)Cl_2]$^+$ species with **2** being heptadentate as shown in Figure 5 for Ln^{3+} = Eu^{3+}, Gd^{3+}, Tb^{3+} and Dy^{3+} and octadentate in the case of the larger La^{3+} ion. In water and CH_3OH solution solvento ligands partly displace the chloro ligands.

NIR Emitters

The Ln^{3+} ions emitting in the NIR range are Nd^{3+}, Er^{3+}, and Yb^{3+}. For Nd^{3+} the typical emission lines are located around 890 nm ($^4F_{3/2} \rightarrow {}^4I_{9/2}$), 1060 nm ($^4F_{3/2} \rightarrow {}^4I_{11/2}$) and 1350 nm ($^4F_{3/2} \rightarrow {}^4I_{13/2}$), for Er^{3+} around 1540 nm ($^4I_{13/2} \rightarrow {}^4I_{15/2}$) and for Yb^{3+} around 980 nm ($^2F_{5/2} \rightarrow {}^2F_{7/2}$). For

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

many reasons luminophores based on the three metal ions have attracted large interest in the recent years. One reason is that this gives the opportunity to use sensitizers that absorb in the VIS range. This gives an advantage in their use as luminescent tags in biological systems compared to tags based on Eu^{3+} and Tb^{3+}, since biological tissue is more transparent to VIS excitation light than UV excitation light, and since cheap light sources such as diode lasers can be used then. Although this review deals with luminescence in solution, in this context it should be mentioned that the Nd^{3+} and Er^{3+} ions complexed by organic groups and doped in polymer waveguides may find use as optical amplifiers of 1300 nm and 1500 nm light, respectively, two standard wavelengths used in telecommunication.[26]

There are some drawbacks in the use of luminophores based on the three above mentioned Ln^{3+} ions. Firstly, the luminescence intensities are low and the luminescence lifetimes are short, typically in the range 10^{-7}–10^{-5} s, which is about 3 orders of magnitude lower than lifetimes in Eu^{3+} and Tb^{3+} complexes. Secondly, the low energy gap between the emitting level and the ground state manifold on the metal centre has the result, that the luminescence is quenched, not only by O–H or N–H oscillators directly bound to the metal centre, but also unbound C–H oscillators nearby, with an r^{-6} distance dependence. The energy gap in Er^{3+} is 6500 cm^{-1} which is resonant with the 1st overtone of the C–H oscillator ($\nu \approx 2950\ cm^{-1}$ in aliphatic groups), but the quenching can be somewhat reduced by deuteration ($\nu_{CD} \approx 2200\ cm^{-1}$). To illustrate this, it was shown by Parker[7] that each CH_2COO^- pendant arm in **8** contributes by 13000 s^{-1} to the first-order deactivation rate constant of the complex $[Yb(\mathbf{8})]^-$, while the contribution in the corresponding Eu^{3+} complex is 45 s^{-1}.

Metal-centred emission from the three above-mentioned lanthanide ions can be sensitized by UV absorbing chromophores such as bipyridine,[9] terpyridine,[27] pyrene[28] (**11**) or dansyl[29] (**12**) (see Figure 9). The accepting energy level(s) on the metal ions Nd^{3+} and Er^{3+} are therefore located higher than the emitting level. However, the most interesting aspects are connected with the use of sensitizers that absorb in the VIS range. Therefore, the following will deal with such ligands.

As light harvesters absorbing in the VIS range, the chromophore fluorescein **13** (Figure 9) has been used extensively. Fluorescein absorbs strongly around 500 nm (depending of the nature of the solvent) with $\varepsilon \approx 80000\ M^{-1}cm^{-1}$ and is widely used as a (green) fluorescent probe in biology.[30]

Reinhoudt et al. described one of the first systems where a Nd^{3+} or Er^{3+} ion is bound to a ligand that is covalently bound to a VIS absorbing organic sensitizer.[31] The metal complexes of **14** in which fluorescein is attached to a calix[4]arene ring (Figure 10) displayed NIR luminescence in CD_3OD and dimethyl sulfoxide (dmso) solution. The luminescence intensity was found to depend on the spacer length with the highest luminescence intensity with the C_3 spacer ($x = 3$). In the case of Er^{3+}, only the fluorescein sensitized the emission whereas in the Nd^{3+} case, also the UV absorbing calix[4]arene moiety was able to sensitize the emission. In another study, a fluorescein chromophore was attached to the chelating ligand diethylenetriaminepentaacetic acid (**15**).[32] This ligand forms 1:1 metal complexes and NIR luminescence of such complexes in aqueous solution was observed. The emission intensity for the Yb^{3+} was found to be much lower than for the Nd^{3+} and Er^{3+} complexes. To explain this we must look at Figure 1, which shows that the two latter ions have several higher lying accepting states above the emitting level and thus a better spectral overlap with the T_1 state (located at 15900 cm^{-1}) of the fluorescein chromophore. The emission was, however, found to be quenched by dissolved molecular dioxygen, and this shows that the energy transfer is rather inefficient. A more efficient energy transfer was observed in metal complexes of **16**,[33] where the binding site of the metal ion is much closer to the sensitizer than in **15**. The attached iminodiacetic acid groups ensures a thermodynamic and kinetic stability of the 1:1 complexes that equals the corresponding EDTA complexes, and NIR emission was observed in aqueous solution. Moreover, the NIR emission is *not* quenched by dissolved dioxygen. The Yb^{3+} complex of **16** is so long-lived (1.91 μs in water), that it is possible to distinguish it from background fluorescence from organic groups in biological systems. Systems with fluorescein (**17**)[34] or its derivatives (**18, 19**)[35] attached to a terphenyl moiety have been studied by Reinhoudt and van Veggel. In the ligands **18** and **19** the two VIS absorbing chromophores (lissamine and Texas Red, respectively) absorb strongly in the near-UV to VIS range with absorption maxima at 568 nm ($\varepsilon = 8.8\times10^4\ M^{-1}cm^{-1}$) and 590 nm ($\varepsilon = 8.5\times10^4\ M^{-1}cm^{-1}$), respectively. They were found to be able to sensitize emission from the Nd^{3+} ion in $[D_6]$dmso solution with luminescence lifetimes close to 2 μs. The triphenylmethane derivative xylenol orange (**20**) is widely used as an indicator for complexometric determination of metal ions. It has been reported that 1:1 complexes with the Ln^{3+} ions were formed, and interestingly, it is able to sensitize emission

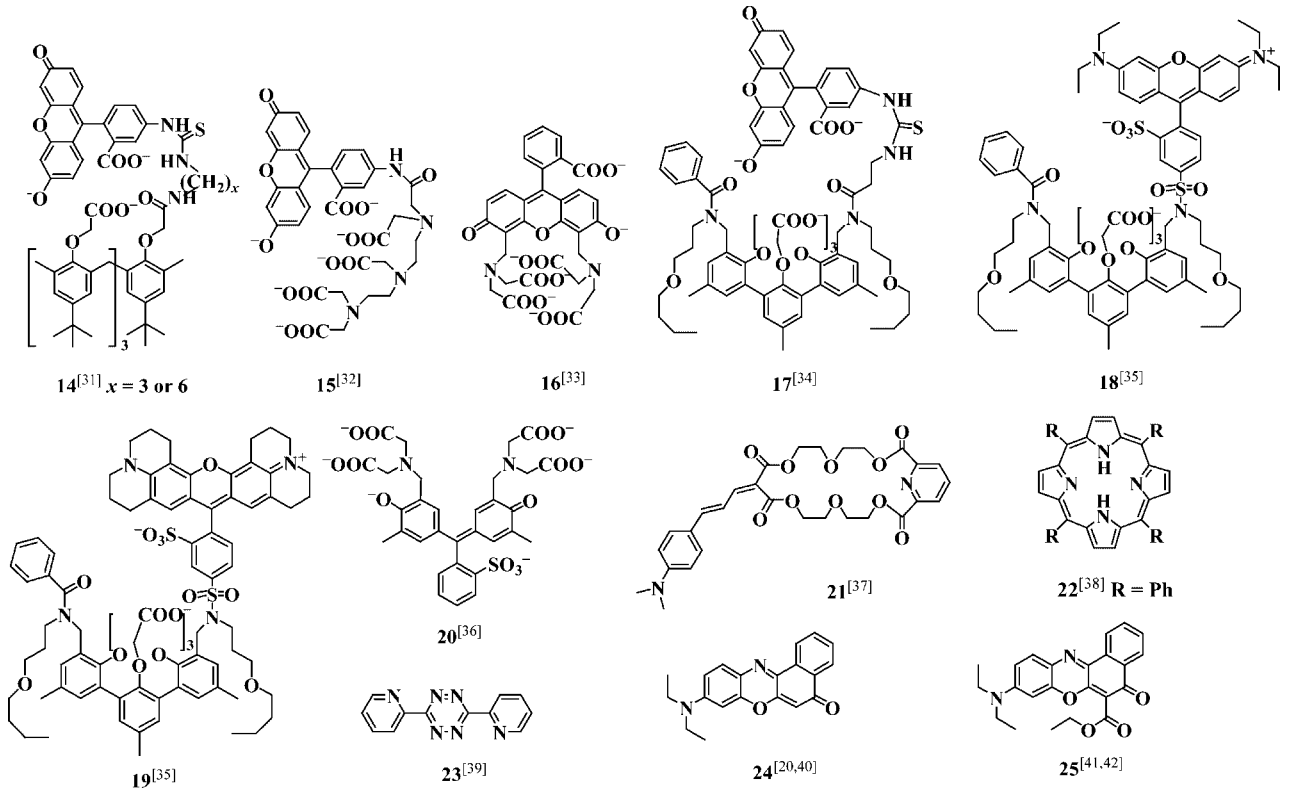

Figure 10. Structure of different VIS absorbing ligands.

from the Nd^{3+} and Yb^{3+} ions.[36] In ligand **21** an oligoene sensitizer is incorporated in a crown ether. The Er^{3+} complex of **21** absorbs VIS light between 400 and 600 nm and displays NIR luminescence in dmso solution.[37] Boncella reported the isolation and structural characterization of tetraphenylporphyrinate, tpp, (**22**, R = Ph) Ln^{3+} complexes capped with multidentate additional ligands such as the tridentate hydridotris(1-pyrazol)borate (tp).[38] The intense Soret bands of the porphyrin group and the low lying T_1 state makes the porphyrin group suitable as sensitizer for the NIR emitting Ln^{3+} ions. The complexes were found to be stable in the solid state in air, but they are sensitive to hydrolysis during which cleavage of the Ln–N bond occurs. The crystal structure of [Yb(tpp)(tp)] is shown in Figure 11, and it is seen that the cavity size of the porphyrin ring is too small for the metal ion to fit in. The ligand field caused the $^2F_{5/2} \rightarrow {}^2F_{7/2}$ transition to be split into multiple bands in the [Yb(tpp)(tp)] complex. The coordinatively unsaturated complex [Ln(tta)$_3$] [Htta = thenoyl(trifluoro)acetone] been found to form complexes with the potentially bis-bidentate bridging imine ligand 3,6-bis(2-pyridyl)tetrazin, bptz (**23**).[39] The crystal structure of a dinuclear complex [{Yb(tta)$_3$}$_2$(μ-bptz)] is shown in Figure 12. The Yb^{3+}, Er^{3+} and Nd^{3+} complexes have an absorption band around 500 nm and exhibit NIR luminescence in CH_2Cl_2 solution.

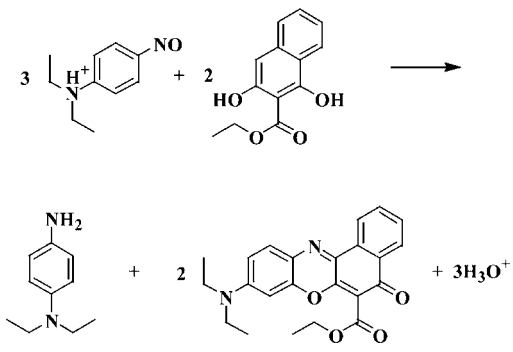
The compound **24** (Nile Red) is a highly fluorescent laser dye.[40] It is, like **10**, a push-pull chromophore with a strong solvent polarity dependence on the absorption and emission band maxima. The position of the absorption maximum has been found in a wide range moving from 484 nm in pentane to 629 nm in trifluoroacetic acid with values of ε around 35000 $M^{-1}cm^{-1}$,[40a] and the compound has thus been used as a polarity probe in chemical and biophysical environments. This solvatochromic effect has its origin in the fact that the dipole moment in the first excited state is significantly higher than in the ground state.[40b,40c] Verhoeven[20] found that **24** forms a complex (through the carbonyl oxygen atom) in benzene solution with the lewis acids [Ln(fod)$_3$], and that coordinated **24** was able to sensitize NIR emission for Ln = Er or Yb. The complex formation is, however, weak and does not occur in more coordinating solvents. In our laboratory we have tried to circumvent this obstacle by using the derivative of Nile Red **25**. This compound, along with a whole range of other Nile Red derivatives, was first described by Meng and co-workers,[41] and it was conveniently prepared as shown below (Scheme 1).



Scheme 1.

The compound **25** is able to form chelate metal complexes as shown in Figure 13 with an increased stability compared to the complexes of **24**. Preliminary experiments[42] showed indeed the complex formation between Ln^{3+} ions and **25** even in coordinating solvents such as CH_3CN or CH_3OH as seen in Figure 14. From an CH_3CN solution of La(OSO$_2$CF$_3$)$_3$ and **25** single crystals of [La(**25**)$_2$(OSO$_2$CF$_3$)$_3$(OH$_2$)$_2$] were grown. A crystal structure determination showed that **25** does coordinate bidentately to the metal centre (Figure 13). The luminescence properties of the Nd^{3+}, Er^{3+}, and Yb^{3+} complexes of **25** are under current investigation.

Outlook

Despite the fact that the detection of NIR light requires specialized equipment, it seems very interesting to develop luminescent probes based on the NIR emitting metal ions Nd^{3+}, Er^{3+} and Yb^{3+}. However, the very low overall quantum yields (typically 10^{-4}–10^{-3}) of the metal-centred emission from complexes of the three metal ions in solution has been a disadvantage. The efficiency of the energy transfer from the VIS-absorbing to the metal centre is a bottleneck in that regard, and a better understanding of the mechanism for the energy transfer is needed in order to optimize the ligand design. It is crucial that the ligand enclose the metal centre efficiently so that water molecules are excluded from its first coordination sphere, and that the complex is stable in solution. Moreover, deuteration of the ligand, in proximity to the metal centre, increases the quantum yield significantly. Thus there is much room for improvement of the ligand design, and there are definitely many challenges ahead for synthetic chemists.

Cu^{I} and Cu^{II} Complexes Containing Nitrite and Tridentate Aromatic Amine Ligand as Models for the Substrate-Binding Type-2 Cu Site of Nitrite Reductase

Hiroshi Yokoyama,[a] Kazuya Yamaguchi,*[a] Manabu Sugimoto,[b] and Shinnichiro Suzuki[a]

Keywords: Bioinorganic chemistry / Copper / N ligands / Tridentate ligands

Cu^{I} and Cu^{II} complexes containing a tridentate aromatic amine compound [bis(6-methyl-2-pyridylmethyl)amine, Me_2bpa] in the absence and presence of nitrite have been prepared as models for the active site of dissimilatory copper-containing nitrite reductase (CuNIR). $[Cu^{II}(Me_2bpa)(H_2O)(ClO_4)]ClO_4$ (**1**), $[Cu^{II}(Me_2bpa)(NO_2)(ClO_4)]$ (**2**), $[Cu^{I}(Me_2bpa)(CH_3CN)]PF_6$ (**3**) and $[Cu^{I}(Me_2bpa)(NO_2)]_2\cdot[(Ph_3P)_2NPF_6]$ (**4**) were prepared. The X-ray crystal structural analyses of **1**, **2**, and **4** reveal that the geometries of the Cu centers are distorted square pyramidal, distorted octahedral, and tetrahedral, respectively. The coordination modes of the nitrite ligands in **2** and **4** depend on the oxidation state of the copper ion: nitrite is coordinated to Cu^{II} and Cu^{I} through two oxygen atoms (*O*,*O*′-coordination mode) and one nitrogen atom (*N*-coordination mode), respectively. A comparison of the absorption spectra of **1** and **2** in acetone solution indicates that the 387-nm absorption band (ε = 780 $M^{-1}cm^{-1}$) of **2** is a charge-transfer transition. The broad absorption band at around 320 nm ($\varepsilon \approx 5000\ M^{-1}cm^{-1}$) of **4** in dichloromethane is also due to a charge-transfer transition. Functional modeling of CuNIR has been accomplished by treating solutions of **4** with acid; the nitrite-binding Cu^{I} complex quantitatively gives the one-electron reduction product,NO. The nitrite reduction of **4** in dichloromethane obeys a second-order rate law, suggesting that the rate-determining step would be protonation of the nitrite ligand of **4**. Electronic structure calculations of the Cu^{I} and Cu^{II} complexes containing Me_2bpa and nitrite by the density functional theory method demonstrate that the net charge of nitrite in $Cu^{I}(Me_2bpa)$(nitro) is larger than that in $Cu^{I}(Me_2bpa)$(nitrito). The mechanism of the nitrite reduction is discussed in comparison with the enzyme reaction mechanism of CuNIR.

Introduction

The global inorganic nitrogen cycle sustained by bacteria plays an important role in the animal and plant kingdoms. Dinitrogen is introduced into the biosphere by the biological fixation of dinitrogen, and is removed from there into the atmosphere again by denitrification. Denitrification is the dissimilatory reduction of nitrate or nitrite to produce dinitrogen by prokaryotic organisms. Nitrite reductase (NIR), a key enzyme of denitrification, catalyzes the reduction of nitrite to nitrogen monoxide. Cu-containing NIR (CuNIR) is a 110-kDa homotrimer in which a monomer contains one each of type-1 Cu (blue copper) and type-2 Cu (nonblue copper).[1–3] The interatomic distance between the two Cu sites is 12.5 Å. The type-2 Cu site shows a distorted tetrahedral geometry and is bound by three His residues and one solvent water; the active site pocket containing the Cu site lies at the bottom of a 16.5 Å cavity formed at the interface between two adjacent monomers. X-ray crystal structure analyses of nitrite-soaked oxidized NIRs have demonstrated that the substrate is coordinated to type-2 Cu^{II} in an asymmetric bidentate fashion through two oxygen atoms instead of the water ligand,[4–6] and an enzymatic mechanism has been proposed.[7,8] In the very recent X-ray crystal structure of nitrite-soaked oxidized *Alcaligenes faecalis* CuNIR at 1.4 Å resolution, NO_2^- coordinates to the Cu primarily by one O atom, whereas the other O atom interacts more weakly with the metal center.[9] Moreover, the plane defined by the Cu and the two O atoms and the plane defined by the N and the two O atoms form a 75° angle and the NO_2^- binds to the Cu with an almost face-on interaction. Several nitrite adducts of Cu^{II} complexes have been reported as model complexes for the active site of CuNIR.[10–14] Tolman et al. have reported the nitrite-binding copper(I) complexes $L^{iPr_3}Cu(NO_2)$ (L^{iPr_3} = 1,4,7-triisopropyl-1,4,7-triazacyclononane) and $[(L^{iPr_3}Cu)_2(\mu\text{-}NO_2)]^{2+}$ as structural and functional models for the nitrite-binding type-2 Cu site and have discussed a mechanism for NO generation involving these Cu^{I} complexes.[15,16]

Supporting information for this article is available on the WWW under http://www.eurjic.org or from the author.

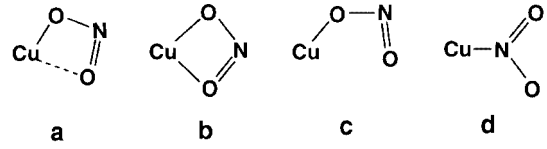
We report here the spectral and structural characterization of Cu^{I} and Cu^{II} complexes containing nitrite and a tridentate aromatic amine [bis(6-methyl-2-pyridylmethyl) amine (Me_2bpa)] as a substrate-binding type-2 Cu site model of CuNIR. Moreover, the nitrite reduction mechanism of the Cu^{I} complex is discussed based on the parameters of activation of the transition state. The enzymatic reduction mechanism of nitrite at the type-2 Cu is also proposed in comparison with the present model complexes and the binding mode of nitrite observed in the native and mutant CuNIRs from *Alcaligenes faecalis* S-6 by X-ray crystal structure analysis.[9]

Results and Discussion

Structural and Spectral Aspects of the Cu^{II} Model Complex Containing NO_2^-

The reaction of $[Cu^{II}(Me_2bpa)(H_2O)(ClO_4)]ClO_4$ (**1**) with one equivalent of $NaNO_2$ in H_2O at room temperature gives $[Cu^{II}(Me_2bpa)(NO_2)(ClO_4)]$ (**2**), which was recrystallized from aqueous methanol solution as green crystals. Figure 1 shows the X-ray crystal structures of **1** and **2**.

The geometry of Cu^{II} in **1** is distorted square pyramidal with three nitrogen atoms of the Me_2bpa ligand and one oxygen atom from each of H_2O and ClO_4^-; a 15.0° upside deviation of the O(1) ligating atom of H_2O from the N(1) N(2)N(3) plane of Me_2bpa is observed. The structure of **2** reveals the replacement of the H_2O ligand by nitrite and asymmetric *O*,*O*′-nitrite chelation to the distorted octahedral Cu^{II} ion along with the Me_2bpa and ClO_4^- ligands. The equatorial O(2) coordinating atom deviates from the N(1)N(2)N(3) plane of Me_2bpa by 19.6° and the O(1) ligating atom binds axially to the Cu^{II} ion. The structural studies of nitrite-binding Cu^{II} complexes have shown that nitrite has a variety of coordination modes to a Cu^{II} center (Scheme 1).[17] Complex **2** exhibits two distinct Cu^{II}–$O_{nitrite}$ bond lengths [Cu(1)–O(1) = 2.47(3) Å, Cu(1)–O(2) = 1.98(2) Å] and the coordination mode of NO_2^- (**a** in Scheme 1) is similar to those of the Cu^{II}–NO_2^- model complexes[10–14] and the nitrite-binding type-2 Cu^{II} site in nitrite-soaked NIR at 1.4 Å resolution (Cu–O = 2.29–2.38, 2.04–2.08 Å).[9] The Cu, N(4), and two O(1 and 2) atoms lie in the same plane. The N–O bond lengths [N(4)–O(1) = 1.24(4) Å, N(4)–O(2) = 1.28(4) Å] and the O(1)–N(4)–O(2) angle [115.8(27)°] are similar to those in the free nitrite ion [O–N–O = 114.9(5)° and N–O = 1.240(3) Å].[18]



Scheme 1.

The electronic absorption spectrum of **1** in acetone solution (Figure 2) shows one band at 675 nm (ε = 190 $M^{-1}cm^{-1}$), which is assigned to a ligand field transition. Complex **2** exhibits two bands at 378 nm (ε = 780 $M^{-1}cm^{-1}$) and 671 nm (ε = 200 $M^{-1}cm^{-1}$), which are ascribed as a nitrite → Cu^{II} charge transfer (LMCT) and a d-d transition, respectively. The small blue shift of the d-d band from 675 nm to 671 nm is due to the *O*-nitrite coordination of nitrite. Moreover, the 77-K EPR spectra of **1** and **2** in ace-

tone solution reveal the typical axial signals ($g_{\|} > g_{\perp}$) of a tetragonal Cu^{II} chromophore having a $d_{x^2-y^2}$ground state (Figure S1, Supporting Information). The parameters for **2** ($g_{\|}$ = 2.25, $g_{\perp}$ = 2.09, $A_{\|}$ = 16.8 mT) exhibit a slight decrease in the $g_{\|}$ and $A_{\|}$ values with respect to the precursor complex **1** ($g_{\|}$ = 2.27, $g_{\perp}$ = 2.07, $A_{\|}$ = 17.2 mT). The difference between the parameters of these Cu^{II} complexes suggests the weak apical coordination [Cu(1)–O(3)] of nitrite in **2**.

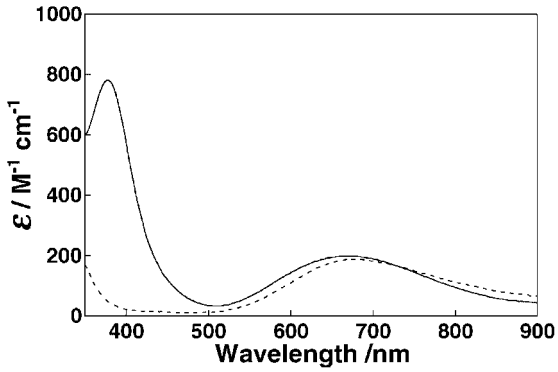

Figure 2. Electronic absorption spectra of **1** (broken line) and **2** (solid line) in acetone at room temperature.

Structural and Spectral Aspects of the Cu^{I} Model Complex Containing NO_2^-

The reduced complex of **1**, the pale-yellow crystalline solid $[Cu^{I}(Me_2bpa)(CH_3CN)]PF_6$ (**3**), was prepared by treatment of $[Cu(CH_3CN)]PF_6$ with Me_2bpa in methanol. The nitrite-binding copper(I) complex, $[Cu(Me_2bpa)(NO_2)]_2\cdot[(Ph_3P)_2NPF_6]$ (**4**) was obtained as a yellow powder from an equimolar mixture of $[Cu(CH_3CN)]PF_6$, Me_2bpa, and $[(Ph_3P)_2N]NO_2$ in acetone under nitrogen. The X-ray crystal structure of **4** (Figure 3) reveals the *N*-nitrite coordination (**d** in Scheme 1) to the Cu^{I} center that adopts a distorted tetrahedral geometry. Although such a binding mode of nitrite in **4** is similar to that of $L^{iPr_3}Cu(NO_2)$, some important structural aspects are different.[15,16] The N–O bond lengths [1.253(5) and 1.238(5) Å] and the O–N–O angle [116.6(4)°] of nitrite in $L^{iPr_3}Cu(NO_2)$[16] are almost the same as those of free nitrite ion,[18] but the nitrite N–O distances [O(1)–N(4) = 1.076(8) Å and O(2)–N(4) = 1.039(8) Å] and the O(1)–N(4)–O(2) angle [133.6(8)°] of **4** are different from the corresponding values of free nitrite. The Cu(1)–N(4) bond length of **4** is 2.053(4) Å, which is longer than the value of 1.903(4) Å in $L^{iPr_3}Cu(NO_2)$.[16] Unfortunately, the large temperature factor of the O-atoms of the nitrite in **4** suggest the rotation/vibration of the NO_2^- ligand and lead to serious errors in the parameters of nitrite bound to Cu^{I} ion.[19] Therefore, it is difficult to discuss the structure of nitrite-binding copper(I) complex in detail on the basis of our present results.

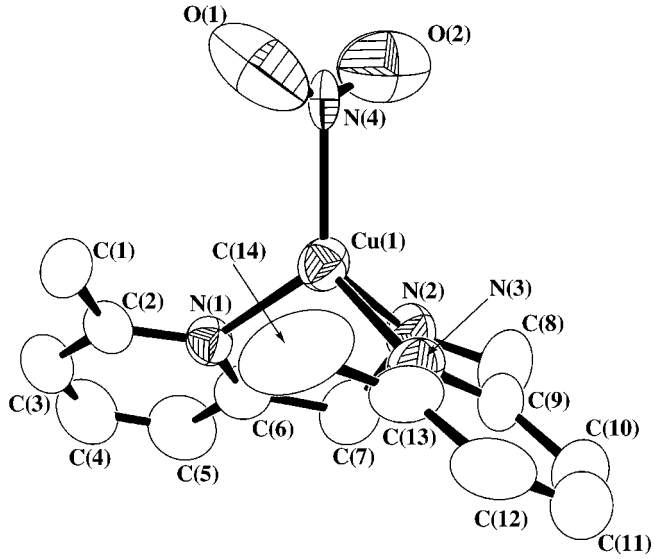

Figure 3. ORTEP plots of the Cu^{I} complex in **4** with 50% probability thermal ellipsoids. The hydrogen atoms and $[(Ph_3P)_2NPF_6]$ have been omitted for clarity. Selected distances [Å] and angles [°] for **4** are follows: Cu(1)–N(1) 2.053(4), Cu(1)–N(2) 2.168(5), Cu(1)–N(3) 2.033(5), Cu(1)–N(4) 2.087(5), O(1)–N(4) 1.076(8), O(2)–N(4) 1.039(8); N(1)–Cu(1)–N(2) 82.4(2), N(1)–Cu(1)–N(3) 111.7(2), N(2)–Cu(1)–N(3) 81.0(2), N(1)–Cu(1)–N(4) 121.9(2), N(2)–Cu(1)–N(4) 118.8(2), N(3)–Cu(1)–N(4) 124.2(2), Cu(1)–N(4)–O(1) 111.5(5) Cu(1)–N(4)–O(2) 114.8(5), O(1)–N(4)–O(2) 133.6(8).

The electronic absorption spectra of **3** and **4** in CH_2Cl_2 are shown in Figure 4. These Cu^{I} complexes have no absorption band in the visible region. Complex **4** exhibits an intense broad band around 320 nm ($\varepsilon \approx 5000\ M^{-1}cm^{-1}$), which is assigned to a $Cu^{I} \rightarrow NO_2^-$ MLCT transition.[10–14] Tolman et al. have reported that $L^{iPr_3}Cu(NO_2)$ exhibits an intense MLCT band at 308 nm (ε = 3800 $M^{-1}cm^{-1}$) in CH_2Cl_2. The shift of the MLCT band could be due to the different electronic structures of **4** and $L^{iPr_3}Cu(NO_2)$.

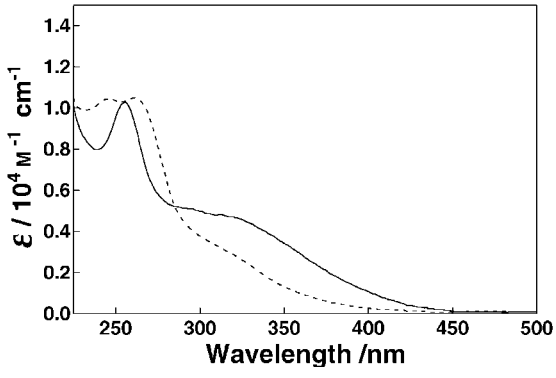

Figure 4. Electronic absorption spectra of **3** (broken line) and **4** (solid line) in CH_2Cl_2 at room temperature.

Nitrite Reductase Reactivity of the Cu^{I} Model Complex Containing NO_2^-

The cyclic voltammogram of **2** in H_2O shows a response with $E_{1/2}$ = –95 mV vs. Ag/AgCl and a peak-to-peak sepa-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ration, ΔE, of 74 mV in the presence of 500 mM $NaNO_2$ (a in Figure 5). The ΔE value indicates a quasi-reversible electron-transfer process. Addition of acid to the aqueous solution of **2** brings about a strong catalytic current due to the reduction of NO_2^- (b in Figure 5). Thus, **2** serves as an electrocatalyst in the reduction of NO_2^- at pH 5.5.

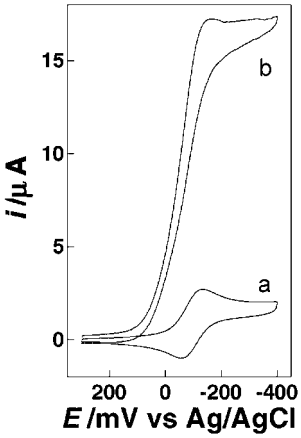

Figure 5. Voltammetric behavior of **2** (a) and after addition of $HClO_4$ (b) in 0.1 M $TBAClO_4$ aqueous solution at 25.0 °C (**2**: 0.5 mM; $NaNO_2$: 500 mM; scan rate: 10 mV s^{-1}).

When four equivalents of trifluoroacetic acid was added to a CH_2Cl_2 solution of **4** at room temperature, the color of the solution was changed from pale yellow to blue and the stoichiometric evolution of NO gas (>95% vs. **4**) was observed by gas chromatography (Figure S2, Supporting Information). No N_2O gas was detected, and [$Cu(Me_2bpa)(OCOCF_3)_2$] was isolated from the reaction mixture. The reaction of **4** with proton was monitored either by recording the transient absorption spectra at one-second intervals or by recording absorption vs. time at a fixed wavelength (320 nm). At 213.0 K, the 320-nm band of **4** was observed to be a sharp peak as shown in Figure 6. Introduction of four equivalents of trifluoroacetic acid to the solution under an Ar atmosphere induced a decrease in the absorbance at 320 nm and a slight increase in the absorbance at about 700 nm. As shown in the inset of Figure 6, the reaction of **4** with proton was found to be first-order both in [**4**] and in [acid] ($v = k_{obs}$[**4**][acid]) at 213.0, 223.0, and 231.8 K. The rate constants (k_{obs}) are listed in Table 1. The activation parameters (Table 2) were estimated from Arrhenius–Eyring plots of the data ($\ln k_{obs} = \ln A - E_a/RT$, $\ln(hk_{obs}/k_BT) = \Delta S^{\neq}/R - \Delta H^{\neq}/RT$; Figure S3, Supporting Information).

The mechanism of nitrite reduction of **4** with proton is illustrated in Scheme 2. The kinetic data of the reaction of **4** with trifluoroacetic acid suggest that the rate-determining step is the first protonation of the nitrite ligand. Since a negative value of $\Delta S^{\neq}$ generally corresponds to the additional loss of freedom of motion by the solvating molecule, the negative $\Delta S^{\neq}$ value (–51 J K^{-1} mol^{-1}) means that protonated **4** will be an active intermediate. The positive $\Delta H^{\neq}$ suggests that **4** is more stable than protonated **4**. The resonance structure of the nitrite ligand in **4** (O=N–O^- ↔ $^-$O–N=O) might contribute to the stability of **4**.

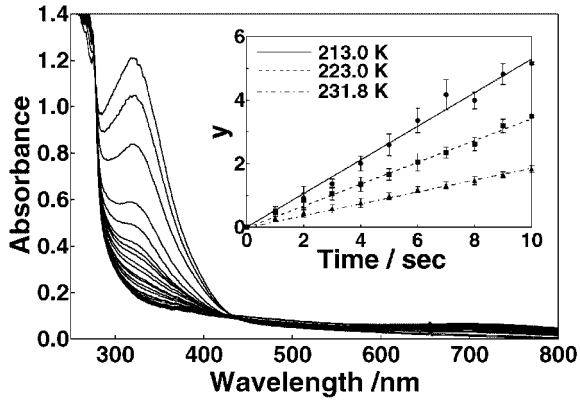

Figure 6. Spectral changes observed during the anaerobic reaction of **4** with trifluoroacetic acid in CH_2Cl_2 at 213.0 K. The subsequent traces, with progressively decreasing absorbance at 320 nm, refer to spectra taken every second Inset: plots of the second-order rate law for the reactions of **4** with CF_3COOH at 213.0, 223.0, and 231.8 K. The *y*-axis is $(1/[\mathbf{4}]_0[acid]_0)\ln([acid]_0[\mathbf{4}]_x/[\mathbf{4}]_0[acid]_x)$.

Table 1. Second-order rate constants for nitrite reduction of **4**.

T [K]	$k_{obsd.}$ [M^{-1} s^{-1}]
231.8	0.53 ± 0.04
223.0	0.34 ± 0.03

Electronic-Structure Calculations of the Cu^I and Cu^{II} Complexes Containing Me_2bpa and Nitrite by the Density Functional Theory (DFT) Method

Electronic-structure calculations of the Cu^I and Cu^{II} complexes containing Me_2bpa and nitrite were carried out with the DFT method using the Gaussian 98 program.[20] The X-ray crystal data of **2** and **4** were employed for initial geometries. The $Cu^{II}(Me_2bpa)$ complex binding nitrite asymmetrically through two oxygen atoms (Cu^{II}–ONO^-, *O,O′*-nitrite coordination) is stabilized by 13.1 kcal mol^{-1} relative to that binding nitrite through one nitrogen atom (Cu^{II}–NO_2^-, *N*-nitrite coordination), while Cu^I–NO_2^- is less stable than Cu^I–ONO^- (1.0 kcal mol^{-1}). Therefore, nitrite is preferentially coordinated to Cu^{II} through two oxygen atoms (Cu^{II}–ONO^-), whereas the Cu^I complex could have two nitrite-binding forms (Cu^I–ONO^- and Cu^I–NO_2^-). These findings are consistent with the experimental data

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

that the two L^{iPr_3}-containing Cu^{I} complexes are bridged by nitrite through both nitrogen and oxygen atoms in the dicopper(II) complex $[(L^{iPr_3}Cu)_2(\mu\text{-}NO_2)]PF_6$.[16] The Cu–nitrite bond energies of Cu^{I}–NO_2^- and Cu^{I}–ONO^- were estimated to be 103.2 and 104.2 kcal mol^{-1}, respectively, whereas those of Cu^{II}–NO_2^- and Cu^{II}–ONO^- were calculated to be 200.7 and 213.8 kcal mol^{-1}, respectively. The binding of nitrite to Cu^{II} in both the *N*-nitrite and the *O*,*O*′-nitrite coordination is energetically favored over that of nitrite to Cu^{I} in the two forms. The net charges of the nitrite ligands of Cu^{I}–NO_2^-, Cu^{I}–ONO^-, Cu^{II}–NO_2^- and Cu^{II}–ONO^- were evaluated to be –0.649, –0.562, –0.314, and –0.403, respectively, suggesting that the *N*-coordinated nitrite ligand of Cu^{I}–NO_2^- will be most easily attacked by proton to produce NO and H_2O.

Proposed Mechanism of Nitrite Reductases

According to the crystallographic studies of the nitrite-binding Cu^{II} complexes[10–16] and the nitrite-soaked oxidized CuNIR,[4–6] nitrite preferentially binds to the oxidized type-2 Cu by asymmetric *O*,*O*′-coordination. We have proposed a catalytic mechanism for CuNIR incorporating roles for Asp98 hydrogen-bonded to the substrate and His255 hydrogen-bonded to Asp98 through H_2O, of which both the residues form a hydrogen-bonding network around the type-2 Cu.[8] In an intermediate species during nitrite reduction, one of the two oxygen atoms of nitrite coordinated to type-2 Cu is probably hydrogen-bonded by both the protonated Asp98 and His255 residues. Very recently, Murphy et al. have reported that the nitrite-bound CuNIR crystal structure shows an angular orientation of nitrite bound to the type-2 Cu; the N atom is out of the plane defined by the two O atoms and the Cu atom, which forms a 75° angle with the plane defined by the N and the two O atoms.[9] Therefore, they proposed that electron transfer (ET) from the type-1 Cu reduces the type-2 Cu to trigger a rearrangement of NO_2^- (from *O*,*O*′-coordination to *N*-coordination) to release water and form a Cu^{I}–NO^+ intermediate, that is, the proximity of the N atom of nitrite to the Cu in the substrate-soaked structure will facilitate this rearrangement step. The present studies of the X-ray crystal structure, nitrite reduction kinetics, and electronic-structure calculation of **4** also suggest that nitrite is initially coordinated to the oxidized type-2 Cu by the *O*,*O*′-coordination and then is converted into *N*-coordination by the reduction of the type-1 Cu. As shown in Figure 7, nitrite displaces a water ligand, which leaves a proton on Asp98 and is released as OH^- (I → II). When the type-2 Cu is reduced by an electron from the type-1 Cu, the binding mode of nitrite is changed from *O*,*O*′-coordination to *N*-coordination and the proton of His255, which has an imidazolium group, is donated to the oxygen of *N*-coordinated nitrite (II → III → IV → V). *N*-Coordination of nitrite to the Cu^{I} ion and protonation to the nitrite ligand are supported by the kinetic analysis of **4** and the electronic-structure calculations of **2** and **4**. Finally, the electron transfer from the reduced type-2 Cu to NO_2H would facilitate the N–O bond cleavage to produce NO gas through a Cu^{I}–NO^+ intermediate (V → VI).

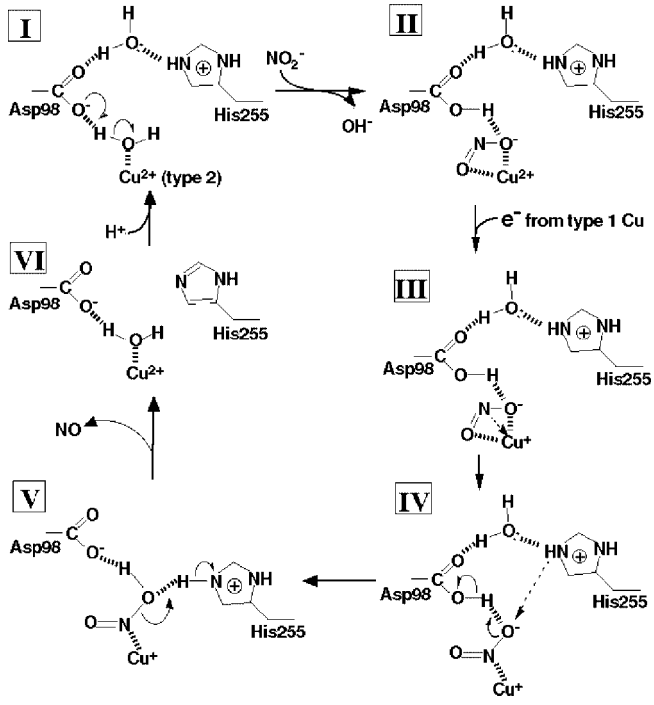

Figure 7. Revized enzymatic reaction mechanism of CuNIR containing type-1 Cu and type-2 Cu (cf. ref.[7]).

Conclusions

Cu^{I} and Cu^{II} complexes containing a tridentate aromatic amine compound (Me_2bpa) and nitrite have been prepared as models for the active site of dissimilatory copper-containing nitrite reductase (CuNIR). The X-ray crystal structural analyses of **2** and **4** reveal that the geometries of the Cu centers are distorted octahedral and tetrahedral, respectively, and the coordination modes of nitrite are *O*,*O*′-coordination and *N*-coordination, respectively. The spectroscopic data of these complexes are consistent with their structural data. The reduction of nitrite by proton donation to **4** gives NO. These findings imply that both structural and functional modeling of CuNIR are achieved with Cu^{I} and Cu^{II} complexes containing the same aromatic amine ligand, Me_2bpa. The kinetic results of the reaction of **4** with acid suggest that the rate-determining step is protonation of the nitrite ligand of **4** and the resultant protonated species is the active intermediate. Moreover, electronic-structure calculations of the Cu^{I} and Cu^{II} complexes containing Me_2bpa and nitrite demonstrate that nitrite is preferentially coordinated to Cu^{II} through two oxygen atoms, but could bind to Cu^{I} by both *O*,*O*′- and *N*-coordination. Since the *N*-coordinated nitrite ligand of **4** will be more easily attacked than the *O*,*O*′-coordinated one by proton, the nitrite reduction of **4** probably occurs through the *N*-coordination of nitrite to Cu^{I}. According to the model complex studies for the active site of CuNIR, we have proposed a revised catalytic mechanism[7] for CuNIR.

Experimental Section

General Remarks: All reagents used were of the highest grade available. Solvents were dried and distilled under N_2. Bis(6-methyl-2-pyridylmethyl)amine (Me_2bpa),[21] $[Cu(CH_3CN)_4]PF_6$, and $[(Ph_3P)_2N]NO_2$[22] were synthesized according to the published procedures. All air-sensitive reactions were performed by using standard Schlenk and vacuum-line techniques. Electronic absorption spectra were recorded on a Shimadzu UV-2200 spectrophotometer. Low-temperature absorption spectra were obtained with a Shimadzu Multi-Spec 1500 spectrophotometer. X-band EPR spectra were recorded on a JEOL JES-FE1X spectrometer at 77 K. Gas chromatography was performed by using a Shimadzu GC14B analyzer with TCD detector (3-m molecular sieve 13X column, 23.5 mL min^{-1} flow rate, helium carrier gas, and at 50 °C). Cyclic voltammetric analyses were carried out using a Bioanalytical Systems Model CV-50W voltammetric analyzer with a three-electrode system consisting of a Ag/AgCl reference electrode, a gold wire counter electrode, and a glassy carbon working electrode under an Ag atmosphere at 25 °C.

$[Cu^{II}(Me_2bpa)(H_2O)(ClO_4)]ClO_4$ (1): A solution of $Cu(ClO_4)_2 \cdot 6H_2O$ (3.71 g, 10 mmol) in methanol (5 mL) was added to a solution of Me_2bpa (2.27 g, 10 mmol) in methanol (50 mL). The resultant solution was stirred for 1 h and stored for a few days at room temperature to give blue crystals of **1** (4.39 g, 86.5%). $C_{14}H_{19}Cl_2CuN_3O_9$ (507.8): calcd. C 33.11, H 3.78, N 8.28; found C 33.11, H 3.68, N 8.30.

$[Cu^{II}(Me_2bpa)(NO_2)(ClO_4)]$ (2): A solution of $NaNO_2$ (0.069 g, 1 mmol) in H_2O (10 mL) was added to a solution of **1** (0.51 g, 1 mmol) in H_2O (25 mL). The resultant solution was stirred for 1 h at room temperature to give **2** as a green precipitate. The green complex **2** was recrystallized from methanol/H_2O (0.362 g, 83.0%). $C_{14}H_{17}ClCuN_4O_6$ (436.3): calcd. C 38.54, H 3.93, N 12.84; found C 38.37, H 3.95, N 12.83.

$[Cu^{I}(Me_2bpa)(CH_3CN)]PF_6$ (3): $[Cu(CH_3CN)_4]PF_6$ (0.167 g, 0.5 mmol) was added as a solid, under an N_2 atmosphere, to a solution of Me_2bpa (0.114 g, 0.5 mmol) in methanol (5 mL). After stirring at 60 °C for 10 min, the resultant solution was stored at –20 °C. The pale-yellow crystalline solid thus obtained was filtered off, washed with dry diethyl ether, and dried under N_2 (0.196 g, 82.2%). $C_{16}H_{20}CuF_6N_4P$ (476.9): calcd. C 40.29, H 4.24, N 11.75; found C 40.09, H 4.23, N 11.89.

$[Cu^{I}(Me_2bpa)(NO_2)]_2 \cdot [(Ph_3P)_2NPF_6]$ (4): $[Cu(CH_3CN)_4]PF_6$ (0.167 g, 0.5 mmol) was added as a solid, under an N_2 atmosphere, to a solution of Me_2bpa (0.114 g, 0.5 mmol) in acetone (3.5 mL). $[(Ph_3P)_2N]NO_2$ (0.292 g, 0.5 mmol) was then added to the resultant solution, under an N_2 atmosphere. After stirring for 1 h **4** precipitated as a yellow powder (0.301 g, 88.7%). For X-ray analysis, yellow crystals of **4** were obtained from CH_2Cl_2/acetone. $C_{64}H_{64}Cu_2F_6N_9O_4P_3$ (1357.3): calcd. C 56.63, H 4.76, N 9.29; found C 56.64, H 4.90, N 9.41.

Measurement of NO Generated from 3: A solution of **4** (10 mg, 7.5 μmol) in CH_2Cl_2 (0.45 mL) was prepared in a small vial capped with a rubber septum. A degassed solution of CF_3COOH (6 μL) in CH_2Cl_2 (0.05 mL) was then introduced with a syringe at room temperature. The solution changed immediately from yellow to blue. Analysis of the head-space gas by a GC analyzer indicated that NO had been generated (7.3 ± 0.2 μmol).

Kinetics: The kinetic studies of nitrite reduction of **4** in CH_2Cl_2 were carried out by monitoring the intensity decrease of the 320-nm band. The absorbance was detected by a fiber-optics quartz probe (0.2-cm path-length) immersed in a small vessel containing a 5 mL CH_2Cl_2 solution of **4** (3.4 mg, 2.5 μmol) under an Ar atmosphere. The reaction was started with the addition of 100 μL of a CH_2Cl_2 solution containing CF_3COOH (10 μmol), which had been degassed with N_2 beforehand.

X-ray Crystallographic Study of $[Cu^{II}(Me_2bpa)(H_2O)(ClO_4)]ClO_4$ (1) and $[Cu^{II}(Me_2bpa)(NO_2)(ClO_4)]$ (2): The X-ray experiment was carried out on a MAC Science MXC18 diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71069 Å). A blue (**1**) or green (**2**) crystal was mounted on a glass capillary. The reflection intensities were monitored by three standard reflections at every 150 measurements, and the decay of intensities was within 2%. The unit-cell parameters used for the refinement were determined by least-square calculations on the setting angles for 22 carefully centered reflections. An absorption correction was applied. Diffraction data were corrected for both Lorentz and polarization effects. The structure was solved by direct methods SIR92[23] using the CRYSTAN-GM program system[24] and refined anisotropically for non-hydrogen atoms by full-matrix least-squares calculations. Each refinement was continued until all shifts were smaller than one-third of the standard deviations of the parameters involved. Atomic scattering factors and anomalous dispersion terms were taken from the literature.[25] All hydrogen atoms were located at their calculated positions. The fundamental crystal data and experimental parameters for structure determination are given in Table 3.

$[Cu^{I}(Me_2bpa)(NO_2)]_2[(Ph_3P)_2NPF_6]$ (4): The X-ray experiment was carried out at –70 °C on a Rigaku Mercury CCD area detector coupled with a Rigaku AFC-7R diffractometer with graphite monochromated Mo-K_α radiation (λ = 0.71069 Å). The pale-yellow crystal was mounted on a glass capillary. The data were corrected for Lorentz and polarization effects, but not for secondary extinction. An empirical absorption correction was applied. The structure was solved by direct methods using the Crystal Structure crystallographic software package[26] and refined anisotropically for non-hydrogen atoms by full-matrix least-squares calculations. Each refinement was continued until all shifts were smaller than one-third of the standard deviations of the parameters involved. Atomic scattering factors and anomalous dispersion terms were taken from the literature.[25] All hydrogen atoms were located at their calculated positions. The maximum and minimum peaks on the final difference Fourier map corresponded to 0.73 and –0.52 e Å^{-3}, respectively. The fundamental crystal data and experimental parameters for structure determination are given in Table 3.

CCDC-251363 (for **1**), -251364, (for **2**) and -251365 (for **4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Electronic-Structure Calculations: Electronic-structure calculations of the Cu^{I} and Cu^{II} complexes containing Me_2bpa and nitrite were carried out with the DFT method in the Gaussian 98 program.[27] For all molecules, the geometries were fully optimized without any constraints. The three-parameter Becke–Lee–Yang–Parr (B3LYP) functional was adopted as the exchange-correlation functional.[28] The core electrons of Cu were replaced with the effective core potential (ECP) of Hay and Wadt.[29] The basis set for Cu was the split-valence set (LANL2DZ[21]) for the ECP. The Huzinaga–Dunning (9s5p)/[4s2p] and (4s)/[2s] basis sets were used for the first row elements and hydrogen, respectively.[30]

Supporting Information (see also footnote on the first page of this article): Further figures illustrating the ESR spectra of **1** and **2**, the GC chart, and the Arrhenius–Eyring plot for the reaction of **4** with proton are provided.

An Exploration of the Structural and Bonding Variability in Mixed-Ligand Benzimidazole-2-thione(bromo)(triarylphosphane)dicopper(I) Complexes with Diamond-Shaped $Cu_2(\mu\text{-}X)_2$ Core Structures

Sotiris K. Hadjikakou,*[a] Constantinos D. Antoniadis,[a] Paraskevas Aslanidis,[b] Philip J. Cox,[c] and Athanassios C. Tsipis*[a]

Keywords: Bridging ligands / Copper / Density functional calculations / S ligands

Reaction of copper(I) bromide with benz-1,3-imidazole-2-thione ($bzimtH_2$) in the presence of one equivalent of triphenylphosphane (PPh_3), tri-*meta*-tolylphosphane (tmtp) or tri-*para*-tolylphosphane (tptp) in acetonitrile/methanol solvent afforded dinuclear complexes formulated as $[CuBr(bzimtH_2)(PR_3)]_2$. The new complexes were characterized by IR, UV/Vis, and ^1H NMR spectroscopy, while the crystal structures of $[\{CuBr(\mu_2\text{-}S\text{-}bzimtH_2)(PPh_3)\}_2]_{0.78}[\{Cu(\mu_2\text{-}Br)(PPh_3)(bzimtH_2)\}_2]_{0.22}$ (**1**), $[CuBr(\mu_2\text{-}S\text{-}bzimtH_2)(tmtp)]_2$ (**2**) and $[CuBr(\mu_2\text{-}S\text{-}bzimtH_2)(tptp)]_2$ (**3**) were determined by single-crystal X-ray diffraction methods. In complex **1**, with spectator PPh_3 ligands, the unit cell of the crystal consists of two different half-molecules, both corresponding to the formula $[CuBr(bzimtH_2)(PPh_3)]_2$. One of the two molecules (molecule **A**) is a symmetrical dicopper(I) complex in which the exocyclic thione S-atoms serve as bridges between the Cu^I ions. The second one (molecule **B**) is disordered and can be resolved into two separate entities, one μ_2-S dicopper(I) complex, similar to molecule **A** (molecule **B1**), and another one (molecule **B2**) involving μ_2-Br bridges. In contrast, in complexes **2** and **3**, with spectator tmtp and tptp ligands, only the $bzimtH_2$-bridged dicopper complexes are formed. Density functional calculations at the B3LYP level of theory provided a satisfactory description of the structural, bonding, electronic and related properties of all dicopper complexes exhibiting the "diamond-shaped" $Cu_2(\mu\text{-}X)_2$ (X = S or Br) core structures and account well for their structural preferences.

Introduction

Polynuclear metal–sulfur coordination sites formed by metal ions with a d^{10} configuration constitute the active sites in a super-family of ubiquitous cysteine-rich, low-molecular-weight proteins or polypeptides called metallothioneins.[1,2] Investigations directed to explore the structure and chemistry of metallothioneins in detail are extremely important taking into account that nature makes use of them as multipurpose proteins. Considering that obtaining precise structural information on metallothioneins is a very difficult task, it appears to be appropriate to study the coordination behavior of copper in model complexes reaching from mononuclear to higher nuclearities. All of them might act as structural and spectroscopic models for copper thioneins and might contribute to the understanding of the thionein structure and function. The most useful ligands for modeling cysteine bonding are undoubtedly thiolates. Heterocyclic thiones are an important class of such ligands, and therefore their coordination properties with many transition metals have been studied extensively. Although the coordination chemistry of heterocyclic thiones is characterized by a wealth of coordinating possibilities, studies on their coordination with copper(I) metal centers have revealed that monodentate coordination through the exocyclic thione sulfur atom is the preferred bonding mode of the ligands. Within this class of coordination compounds, the tendency of heterocyclic thiones to bridge metal centers to form oligo- or polymeric species is also well established.[3] In the oligonuclear complexes, which are normally prepared from Cu^I or Cu^{II} salts and thiolates under various reaction conditions in a variety of solvents, the ligands are normally bridging. In the course of our research on the coordination chemistry of copper(I) halides with a variety of thiones and tertiary arylphosphanes we have reported the synthesis and structural studies of symmetrical binuclear species, with the thione ligand coordinated through the exocyclic sulfur atom in a μ_2-S bridging mode.[4–6] However, in many other cases the reaction of copper(I) halides with thione ligands yielded dicopper(I) complexes with a "diamond-shaped" $Cu_2(\mu\text{-}X)_2$ core structure involving the halide as bridging ligands, particularly for the "soft" iodide rather than the "hard" chloride ligand.[4,7]

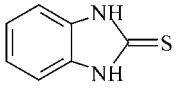
Thus, the coordination behavior (terminal or bridging) of the thione and halide ligands seems to be determined primarily by the choice of the halide ligand, although the nature of the thione and, to a lesser extent, of the spectator phosphane ligand might also play a significant role. In order to further investigate trends in the formation of these two different types of binuclear copper(I) halide complexes of the general formula $[CuX(thione)(PR_3)]_2$ involving either a double halide or a double thione-sulfur bridge, we report in this work the results of a detailed experimental and quantum chemical (DFT) study of three new, mixed-ligand dinuclear complexes of copper(I) with bromide, benz-1,3-imidazole-2-thione ($bzimtH_2$) and triphenylphosphane (PPh_3), tri-*m*-tolylphosphane (tmtp) or tri-*p*-tolylphosphane (tptp) as ligands pursuing a threefold objective: (i) the examination of the preferred μ_2-S or μ_2-Br bridging mode; (ii) the exploration of the role played by the spectator phosphane ligands, which exert different steric effects while they differ slightly in their basicity; and (iii) the understanding of the role of the bromide ligands, which have a donor capacity on the border between "soft" and "hard", in forming either μ_2-S or μ_2-Br bridges in the dicopper(I) complexes.



$bzimtH_2$

Results and Discussion

Synthesis

The reaction of equimolar quantities of copper(I) bromide and triphenylphosphane, tri-*m*-tolylphosphane or tri-*p*-tolylphosphane followed by the addition of one equivalent of 1,3-benzimidazole-2-thione ($bzimtH_2$) in dry acetonitrile/methanol solution at 25 °C afforded pale-yellow microcrystalline solids which, on analysis and spectroscopic measurements (IR, ^1H NMR), were found to correspond to the formulae $[\{CuBr(\mu_2\text{-S-}bzimtH_2)(PPh_3)\}_2]_{0.78}[\{Cu(\mu_2\text{-Br})(PPh_3)(bzimtH_2)\}_2]_{0.22}$ (**1**), $[CuBr(\mu_2\text{-S-}bzimtH_2)(tmtp)]_2$ (**2**) and $[CuBr(\mu_2\text{-S-}bzimtH_2)(tptp)]_2$ (**3**). Compounds **1**–**3** are air-stable, diamagnetic, crystalline materials that are soluble in polar solvents such as acetonitrile and dimethyl sulfoxide, slightly soluble in chloroform and dichloromethane, and insoluble in water, diethyl ether and tetrahydrofuran.

The infrared spectra recorded in the range of 4000–250 cm^{-1} show distinct strong vibrational bands due to the phosphane ligand, which remain practically unshifted upon coordination to the metal center. Moreover, the spectra of **1**–**3** contain the usual four "thioamide bands" required by the presence of the heterocyclic thione ligand, as well as the characteristic ν(NH) stretching vibration observed at about 3220 cm^{-1}. The observed shifts of these bands enforced by coordination, in conjunction with the lack of the ν(SH) stretching vibration band, signifies the exclusive S-coordination mode of the 1,3-benzimidazole-2-thione ligand.

The ^1H NMR spectra, recorded in $CDCl_3$, are dominated by the presence of multiplets in the region of δ = 7.45–7.03 ppm attributed to the phenyl protons of the phosphane ligands as well as to the aromatic protons of the thione ligand. The extent of overlapping does not allow resolution between these signals, making assignment of the splitting pattern for the individual thione resonances very difficult. Upon coordination, the methyl protons of the tri-*p*-tolyl- and tri-*m*-tolylphosphane ligands are shifted slightly upfield by 0.09 and 0.08 ppm respectively. Furthermore, the observation of a broad singlet at around δ = 11 ppm due to the proton resonance of the NH groups, and the absence of a signal due to the proton resonance of the SH moiety, strongly suggest that the thione ligand is coordinated to the metal center in its thionato form.

It is well known that deviation from the common four-coordination in copper(I) complexes can be induced by an increase of the bulkiness of the ligands. In this context, according to our previous experience with the use of triarylphosphanes in mixed-ligand Cu^I halide complexes, triphenylphosphane as well as tri-*m*-tolyl- and tri-*p*-tolylphosphane turned out to be relatively small; a coordination number of three could be achieved only for the bulkier tri-*o*-tolylphosphane.[8,9] Similarly, the steric requirements of the neutral heterocyclic thiones used do not affect the coordination number of the complexes, since terminal or bridging S-coordination has been observed but always around a tetrahedrally coordinated copper atom. Thus, on the basis of the chemical composition of the new compounds, we assumed that complexes **1**, **2** and **3** are doubly bridged (μ_2) binuclear complexes. In order to verify our assumption and to confirm the nature of the bridge, we determined the structures of the three complexes by single-crystal X-ray diffraction methods.

Description of the Structures

$[\{CuBr(\mu_2\text{-S-}bzimtH_2)(PPh_3)\}_2]_{0.78}[\{Cu(\mu_2\text{-Br})(PPh_3)(bzimtH_2)\}_2]_{0.22}$ (1)

The unit cell of the crystal consists of two different half-molecules, both corresponding to the formula $[CuBr(bzimtH_2)(PPh_3)]_2$. One of the two molecules (molecule **A**, Figure 1) is a symmetrical dicopper(I) complex in which the thione S-atoms serve as bridges between the Cu^I ions. The second one (molecule **B**, Figure 2) is disordered and can be resolved into two separate entities, one μ_2-S dicopper(I) complex, similar to molecule **A** (molecule **B1**), and another one (molecule **B2**) involving μ_2-Br bridges. The disordered atoms are Br(2), (Br2′), (S2), (S2′), N(4), N(4′), H(4), (H4′), C(26) and (C26′), while the other atoms are considered to overlap. Due to this disorder the hydrogen atoms attached to N(3), C(28) and C(32) in molecule **B** were omitted from the calculations. The six-membered ring C(27)–C(32) has high displacement parameters due to the disorder. Selected bond lengths and angles for **1** are given in Table 1 and ORTEP views showing the atom numbering schemes of molecules **A**, **B1** and **B2** are given in Figures 1

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and 2. Molecule **B1** consists of the atoms Cu(2), Br(2), P(2), S(2), N(3), N(4) and C(26)–C(50) (unprimed, 56% occupancy), while the atoms Cu(2), Br(2′), P(2), S(2′), N(3), N(4′), C(26′), C(27)–C(50) (primed, 44% occupancy) belong to the Br-bridged molecule **B2**. The basic structural unit of molecules **A** and **B1** corresponds to a "diamond-shaped" $Cu_2(\mu\text{-}S)_2$ core formed by the operation of an inversion center. The doubly bridging S atoms and the Cu^I metal centers constitute a strictly planar Cu_2S_2 core in which each copper(I) center displays a distorted tetrahedral environment, with the other two positions of the tetrahedra being occupied by a P donor atom of the PPh_3 ligand and a bromide ligand. The two bromide ligands in *trans* positions stabilize the complex further through the formation of two short, symmetrical, intramolecular hydrogen bonds

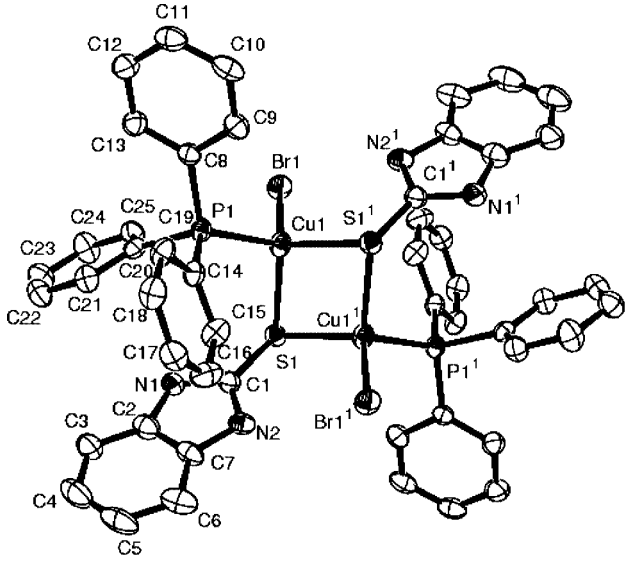


Figure 1. ORTEP view showing the metal environment and the atom labelling scheme in compound **1** (Molecule **A**). Displacement ellipsoids are shown at the 50% probability level.

(Table 1). In general, there are small but definite differences in bond lengths and angles within the central cores of molecules **A** and **B1**. In both structures the bridging sulfur atoms and the two copper atoms form a parallelogram with two short and two longer Cu–S bonds. Although each of these two individual Cu–S distances is not far from the values in other copper(I) complexes with equivalent bonds, the asymmetry in the bridging Cu–S distances is the largest among the thione-S coordinated copper(I) complexes structurally characterized by us so far.

The Cu–P bond lengths in the three individual molecules lie in the range normally found in analogous dicopper(I) complexes with halide or sulfur bridging ligands. In contrast, the significant differences in the corresponding Cu–Br bond lengths are noteworthy. In general terms, the bridging Cu–Br distances are somewhat longer than those found previously in other mixed-ligand dicopper(I) complexes containing bromide, phosphane and heterocyclic thione ligands, but are shorter than those found in $[CuBr(tzdtH)(tmtp)]_2$.[5]

In all three structures the interbond angles around the central copper(I) atoms show remarkable deviations from idealized tetrahedral geometry, with the Br(1)–Cu(1)–S(1) bond angle of 93.89(5)° in molecule **A** representing the most significant distortion. Finally, the S–Cu–S (Br–Cu–Br) and Cu–S–Cu (Cu–Br–Cu) bond angles in the "diamond-shaped" Cu_2S_2 (or Cu_2Br_2) cores are close to the calculated ideal values (109.5 and 70.5°) for a symmetric dimer.

$[CuBr(\mu_2\text{-}S\text{-}bzimtH_2)(tmtp)]_2$ (2) and $[CuBr(\mu_2\text{-}S\text{-}bzimtH_2)(tptp)]_2$ (3)

Selected bond lengths and angles for compounds **2** and **3** are given in Tables 2 and 3 and the molecular structures are displayed in Figures 3 and 4, respectively.

The basic structural unit of both complexes is a dicopper(I) unit with the two copper(I) atoms doubly bridged by two S atoms of the thione ligands to form a strictly planar,

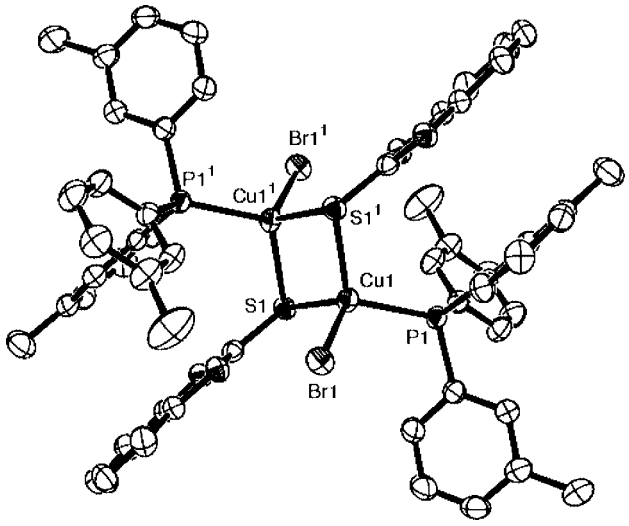

Figure 3. ORTEP view showing the metal environment and the atom labelling scheme in compound **2**. Displacement ellipsoids are shown at the 50% probability level.

four-membered Cu_2S_2 core. The distorted tetrahedral coordination environment around the central copper(I) atoms is completed by one P atom from the phosphane ligand and one bromide ligand. Complex **2** (Figure 3) crystallizes in the monoclinic space group $P2_1/c$ with the unit cell containing two discrete dinuclear species, whereas compound **3** (Figure 4) crystallizes in the triclinic space group $P\bar{1}$. Its structure contains one discrete molecule per unit cell, as well as two CH_3CN, three H_2O and one half CH_3OH lattice molecules; the latter solvate molecules do not interact specifically with the dimer and therefore will not be discussed further.

The Cu–P bond length of 2.2552(7) Å in **2** does not differ significantly from that found in **3** [2.233(6) Å], both values lying in the range normally found for analogous halide- or sulfide-bridged dicopper(I) complexes.[4,7,10] On the other hand, the Cu–Br bonds in **2** and **3** differ remarkably, the latter being shorter by 0.0512 Å. The Cu–Br bond lengths, which are typical for a bromide ligand in the tetrahedral coordination environment of Cu^I complexes, are shorter than those of 2.5693(12) and 2.5369(4) Å found in $[CuBr(dppe)(py2SH)]_2$ [dppe = 1,2-bis(diphenylphosphanyl)ethane][11] and [CuBr(dppb)(pymtH)][12] [dppp = 1,2-bis(diphenylphosphanyl)propane], respectively, but are longer than that found in [CuBr(dppet)(mftztH)].[13] Moreover, both structures exhibit the usual asymmetric $Cu_2(\mu\text{-}S)_2$ core with Cu–S bond lengths in the range found for other dicopper(I) complexes containing bromide, phosphane and heterocyclic thione ligands. Finally, it should be noted that the S–Cu–S and Cu–S–Cu bond angles in the $Cu_2(\mu\text{-}S)_2$

core of **2** and **3** closely resemble those of an ideal symmetric dimer.

Electronic Structure Calculations

The structural properties, such as geometrical data, as well as the energetic and spectroscopic properties of the model dicopper complexes $[CuBr(PH_3)(\mu\text{-}S)(imtH_2)]_2$ (**4**) and $[Cu(PH_3)(\mu\text{-}Br)(imtH_2)]_2$ (**5**), which exhibit "diamond-shaped" $Cu_2(\mu\text{-}X)_2$ (X = S or Br) core structures, were examined by electronic structure calculation methods. In order to obtain reliable data it is of outmost importance to find a method/basis set combination that allows the accurate description of the molecules studied herein. In a first attempt, we therefore employed DFT computational techniques at the B3LYP level of theory using a variety of basis sets to reproduce the structure of the $Cu_2(\mu\text{-}X)_2$ (X = S or Br) core of the "real" complexes, the main focus being on the structural parameters of the $Cu_2(\mu\text{-}X)_2$ core in **4** and **5**. The results are compiled in the Supporting Information (Table S1). In all cases the basic structural features of the model compounds **4** and **5** were satisfactorily reproduced by taking into account the different electronic and steric effects of the ligands used to represent the ligands in the "real" complexes. In general terms, the best estimate of the energetic data is that obtained using the larger TZVP and 6-31G(d,p) basis sets. However, more reliable structural data (overall closer to the experiment) were obtained using the DZVP and TZVP rather than the 6-31G(d,p) basis sets. Interestingly, even the smaller SDD basis set performs well with respect to the structural parameters of the model compounds, but could not provide meaningful energetic data. Note that a reliable structure is indispensable for the evaluation of the relative stability of the isomeric species.

Equilibrium Geometries of the Model Compounds

The equilibrium structures of $[CuBr(PH_3)(\mu\text{-}S)(imtH_2)]_2$ (**4**) and $[Cu(PH_3)(\mu\text{-}Br)(imtH_2)]_2$ (**5**) and their monomeric species $[CuBr(PH_3)(imtH_2)]$ (**6**), along with selected structural parameters, computed at the B3LYP/DZVP level of theory are depicted schematically in Figure 5.

Searching the potential energy surface (PES) of the monomeric species $[CuBr(PH_3)(imtH_2)]$ (**6**) we located two stationary points corresponding to two rotamers involving the bromide ligand in a *syn* (**6a**) and *anti* (**6b**) configuration with respect to the imidazole ring. The *syn* rotamer corresponds to the global minimum, while the *anti* one is a local minimum that is 14.7 kcal mol^{-1} higher in energy. The *syn* (**6a**) → *anti* (**6b**) isomerization proceeds across a barrier of 15.1 kcal mol^{-1} through a product-like transition structure $\mathbf{TS_{6a\rightarrow 6b}}$ (Figure 5) with a P–Cu–S–C torsion angle of 57.2°, while the dominant motion of the vibrational mode corresponding to the imaginary frequency (ν_i = 24 cm^{-1}) involves the rotation around the Cu–S bond. Note that the *syn* rotamer is stabilized by the formation of an N–H···Br hydrogen bond. Both rotamers adopt a trigonal planar stereochemistry of C_s symmetry, with the central copper(I) atom and the three donor atoms being coplanar with the imidazole ring. The bending coordination mode of the thione ligand with the Cu^I central atom is noteworthy; the Cu^I–S–C bond angles are 104.3° and 107.6° in the *syn* and *anti* rotamers, respectively. The bending coordination mode of the thione ligand is that expected on the grounds of the bonding interactions between the Cu^I and thione ligand orbitals, which will be discussed later on.

The equilibrium geometries of the dimeric species $[CuBr(PH_3)(\mu\text{-}S)(imtH_2)]_2$ (**4**) and $[CuS(PH_3)(\mu\text{-}Br)(imtH_2)]_2$ (**5**) correspond to a "diamond-shaped" $Cu_2(\mu\text{-}X)_2$ (X = S or Br) core structure where the copper(I) atoms display a distorted tetrahedral coordination environment. The $Cu_2(\mu\text{-}X)_2Cu$ (X = S or Br) parallelogram is perfectly planar with two long and two short asymmetric Cu–X bonds, in line with the available X-ray crystal structure data. The asymmetry in the Cu–X bond lengths of the $Cu_2(\mu\text{-}X)_2Cu$ parallelogram is more pronounced for X = S rather than for X = Br, the difference in the Cu–X bond lengths being 8.4 and 4.5 pm, respectively. The intermetallic Cu···Cu distance is 322.3 and 316.0 pm for the μ_2-S and μ_2-Br dimers, respectively. On the other hand, the X···X distance is equal to 384.9 and 416.2 pm for **4** and **5**, respectively. No cross-ring interactions are possible in either **4** or **5** due to the long Cu···Cu or X···X distances, in agreement with the framework-electron counting (FEC) rule introduced by Alvarez et al.[14] to account for the formation or breaking of transannular bonds in dimetal systems that contain a simple "diamond-shaped" $M_2(\mu\text{-}X)_2$ core structure.

At all levels of theory the μ_2-Br-bridged dimer **5** is predicted to be slightly more stable than the μ_2-S-bridged dimer **4** by 2.5–5.4 kcal mol^{-1}. The computed dimerization energy for **4** and **5** was found to be 18.8 and 21.7 kcal mol^{-1}, respectively, at the B3LYP/TZVP level of theory. The dimerization and relative energies of the model complexes **4** and **5** computed at the B3LYP level of theory using a variety of basis sets are given in detail in the Supporting Information (Table S2). The low computed dimerization energy indicates that **4** and **5** correspond to loose associations of the mono-

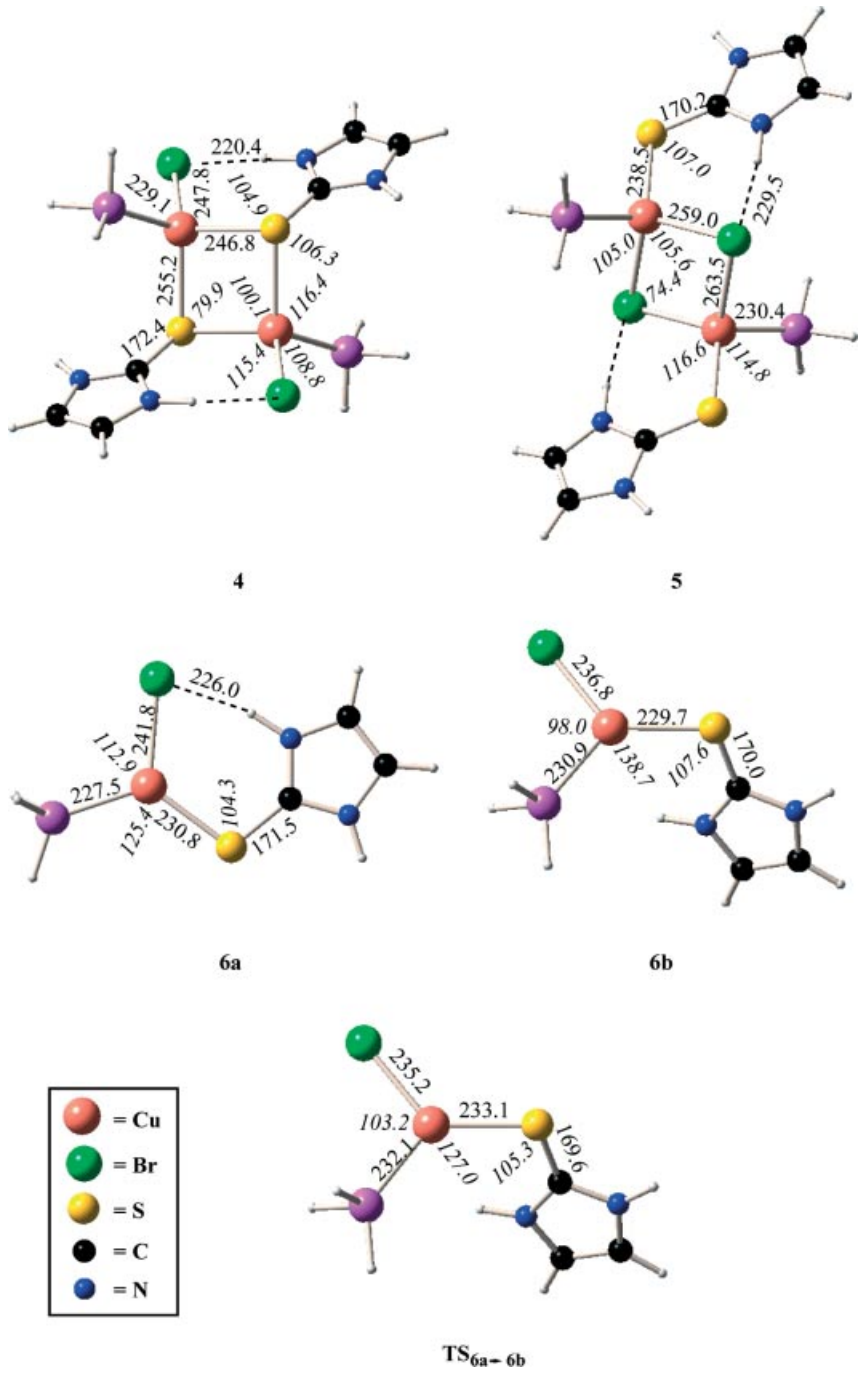

Figure 5. Equilibrium geometries of $[CuBr(PH_3)(\mu\text{-}S)(imtH_2)]_2$ (**4**), $[CuS(PH_3)(\mu\text{-}Br)(imtH_2)]_2$ (**5**) and the monomeric species $[CuBr(PH_3)(imtH_2)]$ in the *syn* (**6a**) and *anti* (**6b**) configurations computed at the B3LYP/DZVP level of theory.

meric species **6a** and strongly suggests that both isomers could be formed during the synthesis. Moreover, because of the low dissociation energy of the dimers they are expected to be in equilibrium with their monomers, therefore the two isomers and their monomeric species could coexist in the solid state, in line with the experiment. The interconversion of the two isomers should follow a dissociative (S_N1) mechanism, as shown in Scheme 1. According to this mechanism the dimer dissociates to the monomer, which then re-associates with a different orientation. The total energies given are those computed at the B3LYP/TZVP level of theory.

Electronic Structure and Bonding Description of the Model Compounds

In order to gain insight into the electronic and bonding properties of the monomer **6** and the dimers **4** and **5** the relevant molecular orbitals (MOs) and the Mulliken population analyses were extracted from the B3LYP/DZVP cal-

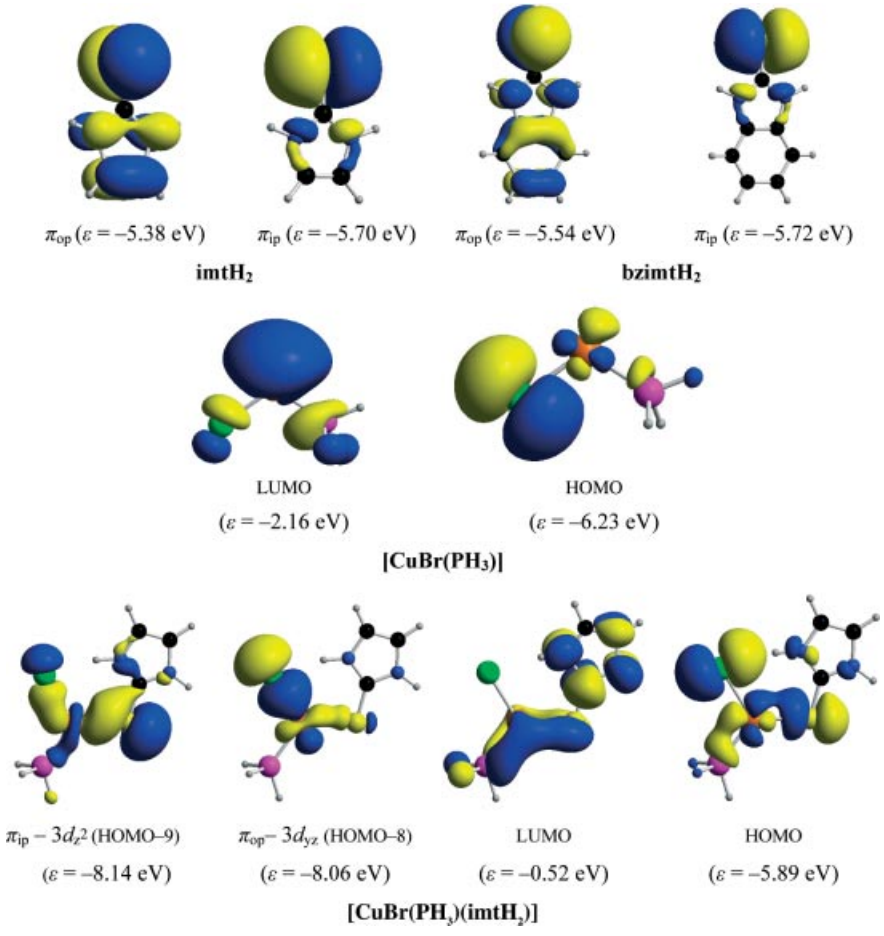
culations. Both the $imtH_2$ and $bzimtH_2$ ligands possess two occupied frontier molecular orbitals (HOMO and HOMO-1) with high sulfur 3p-orbital character (Scheme 2), which are the orbitals primarily involved in the formation of the Cu–S coordination bond. The two π-type MOs were labeled as π_{ip} and π_{op} following the nomenclature previously established by Solomon et al.[15] for phenolate and by Halfen et al.[16] for thiophenolate ligands. The π_{ip} orbital lies in the plane of the imidazole ring, while the π_{op} orbital is perpendicular to this plane. In light of the perfect planarity of the $[CuBr(PH_3)(imtH_2)]$ model compound it is the π_{ip} MO of the thione ligand which participates in the bonding interactions with a vacant metal orbital [a 4s orbital of Cu^I hybridized by mixing with the 4p orbitals in the bent



Scheme 2. The most relevant MOs of the $imtH_2$ and $bzimtH_2$ thione ligands and the model $[CuBr(PH_3)]$ and $[CuBr(PH_3)(imtH_2)]$ complexes.

$CuBr(PH_3)$ fragment, the LUMO in Scheme 2] to form the σ Cu^I–S coordination bond. In order to achieve maximum overlap the π_{ip} MO should point primarily along the Cu^I–S bond, which nicely explains the Cu^I–S–C bending (Cu–S–C bond angle of 104.3°). The π_{op} is perpendicular to the Cu^I–S vector and therefore interacts in a π fashion with a vacant metal orbital.

According to the natural bond orbital (NBO) population analysis the bonding σ(Cu–S) interaction between the Cu and S atoms is constructed from an s NAO (93.29% s-character) on a Cu atom interacting with a p NAO (89.36% p-character) on a sulfur atom, and thus has the form $\sigma(Cu–S) = (0.2868)s_{Cu} + (0.9580)p_S$.

The Mulliken population analysis data given in Table 4 indicate that there is a charge transfer of about 0.14 charge units of electron density from the sulfur donor atom to the central Cu^I atom upon coordination of the thione ligand to the Cu^I metal center of the $[CuBr(PH_3)]$ fragment. This charge transfer increases to 0.20 charge units of electron density upon dimerization of the monomeric species **6**, when sulfur bridges are formed, but remains unchanged when bromide bridges are formed. The charge transfer from sulfur to Cu^I, which is a result of both σ-dative and π-back-bonding interactions, results in the weakening of the C=S bond of the thione ligand, which thus acquires a partial double-bond character that is reflected in the bond overlap population (*bop*) values (Table 4), which correlate well with the charge transferred from S to Cu^I. Moreover, the Cu–S *bop* values indicate that the Cu–S···Cu bridge is not symmetric, while the Cu–S bonds are remarkably weakened upon dimerization.

Based upon the nature of the FMOs of the monomeric species $[CuBr(PH_3)(imtH_2)]$ (**6**; Scheme 2) it can be envisaged that the monomers **6** could be dimerized through favorable HOMO–LUMO interactions that form either weak μ-S or μ-Br bridges. On the other hand, the high HOMO–LUMO energy gap of 5.37 eV illustrates the high stability of the monomer, which should coexist in equilibrium with the dimers. It should be noted that copper is normally monovalent in its thiolate complexes and the coordination is normally trigonal planar, although a number of linearly coordinated examples are known. In oligonuclear complexes, which are normally prepared from Cu^I or Cu^{II} salts and thiolates under various reaction conditions in solvents such as methanol, the ligands are normally bridging. In the series of dinuclear copper thiolates only a few cases are known with a central four-membered Cu_2S_2 unit, probably because of the closed-shell d^{10}···d^{10} Cu···Cu and ligand···ligand repulsions. Examples are $[Cu_2(mimtH)_6]^{2+}$ (mimtH = 1-methylimidazoline-2-thione),[17] the thione complex $[Cu_2\text{-}(SNC_5H_5)_6]Cl_2$,[18] and the thiolate complex $[Cu_2(SC_6H_4\text{-}o\text{-}Me)_2(1,10\text{-phen})_2]$ with phenanthroline as co-ligand.[19]

Single-Point Calculations on the "Real" Complexes

For the single-point calculations, the geometries were based on the corresponding X-ray crystal structures. Moreover, calculations were performed on the monomeric species $[CuBr(PPH_3)(bzimtH_2)]$ (**7**), $[CuBr(tmtp)(bzimtH_2)]$ (**8**) and $[CuBr(tptp)(bzimtH_2)]$ (**9**) resulting from the adiabatic dissociation of the dimers for the dissociation energy to be estimated. The energetic and electronic properties of the "real" complexes and their monomeric species, computed at the B3LYP/DZVP level, are compiled in Table 5.

It can be seen that complex **1A**, which contains μ_2-S bridges, is more stable than its isomeric complex **1B**, which contains μ_2-Br bridges, by about 121 kcal mol^{-1} at the B3LYP/DZVP level. The predicted higher stability of isomer **1A** accounts well for the estimated experimental occupancy of **1A** in the unit cell of the crystal (about 78%). The coexistence of the thermodynamically less stable isomer **1B** in the solid state could be attributed to steric and crystal-packing effects. The dimerization energy of **1A** was predicted to be 52.3 kcal mol^{-1}, thus illustrating that the sulfur bridges are relatively weak. In contrast, the dimerization energy of **1B** was predicted to be only 2.4 kcal mol^{-1}, thus indicating that **1B** corresponds practically to the three-coordinate monomer **7B**. It should be noted that **7B** is stabilized with respect to its isomer **7A** by 35.6 kcal mol^{-1} at the B3LYP/DZVP level. The higher stability of **7B** is also reflected in the higher HOMO–LUMO energy gap (4.37 vs. 3.40 eV). The weak association of the monomer **7B** to form **1B** is also mirrored in the relatively small change of the electron-density distribution introduced by the association of the monomers through the formation of the μ_2-Br bridges.

Finally, complex **2**, which contains the spectator tmtp ligand, is slightly more stable than isomer **3**, which contains

tptp, by about 8.2 kcal mol^{-1}. The same holds also true for the corresponding monomeric species. The monomer **8** is more stable than monomer **9** by about 18.3 kcal mol^{-1} at the B3LYP/DZVP level. The dimerization energies for **8** and **9** were predicted to be 12.8 and 41.3 kcal mol^{-1}, respectively.

Concluding Remarks

We have reported the synthesis of a new series of dinuclear copper(I) complexes formulated as [CuBr-(bzimtH$_2$)(PR$_3$)]$_2$ formed by treatment of copper(I) bromide with benz-1,3-imidazole-2-thione (bzimtH$_2$) in the presence of one equivalent of triphenylphosphane (PPh$_3$), tri-*meta*-tolylphosphane (tmtp) or tri-*para*-tolylphosphane (tptp) in acetonitrile/methanol solvent. The crystal structures of the new complexes [{CuBr(μ_2-S-bzimtH$_2$)(PPh$_3$)}$_2$]$_{0.78}$[{Cu-(μ_2-Br) (PPh$_3$)(bzimtH$_2$)}$_2$]$_{0.22}$ (**1**), [CuBr(μ_2-S-bzimtH$_2$)-(tmtp)]$_2$ (**2**) and [CuBr(μ_2-S-bzimtH$_2$)(tptp)]$_2$ (**3**) have been determined by single-crystal X-ray diffraction methods. Depending on the spectator phosphane ligands either μ_2-S- or μ_2-Br-bridged dimers are formed. In some cases the monomeric three-coordinate Cu^I complexes seem to be stable as well. Thus, for the simple PH$_3$ ligand (a strong σ-donor) both dimeric species are predicted to be formed in equal proportions upon treatment of copper(I) bromide with the thione ligand in the presence of PH$_3$. On the other hand, with the PPh$_3$ ligand (a weaker σ-donor and stronger π-acceptor ligand than PH$_3$) the two isomeric forms involving μ_2-S or μ_2-Br bridges coexist in the solid state, with the former being favored (about 78%). In contrast, with the spectator tmtp and tptp ligands (with comparable electronic effects to those of PPh$_3$, but differing significantly in their steric effects) only the μ_2-S-bridged dicopper complexes are formed. Density functional calculations at the B3LYP level of theory provide a satisfactory description of the bonding, electronic and related properties of the "real" and model dicopper complexes exhibiting the "diamond-shaped" Cu$_2$(μ-X)$_2$ (X = S or Br) core structures and account well for their structural preferences. In all complexes the coordination of the thione ligand is further stabilized by Br···H–N bond formation, which is more pronounced in the μ_2-S bridged dimers. No Cu^I···Cu^I interactions are predicted to occur either in the μ_2-S- or μ_2-Br- bridged dicopper complexes.

Experimental Section

Materials and Instruments: Copper(I) bromide, triphenylphosphane, tri-*m*-tolylphosphane, tri-*p*-tolylphosphane and solvents are commercially available and were used as obtained, while benz-1,3-imidazole-2-thione was recrystallized from hot ethanol prior to use. Elemental analyses for C, H and N were carried out with a Carlo Erba EA MODEL 1108. Melting points were measured in open tubes with a STUART scientific apparatus and are uncorrected. IR spectra in the region of 4000–370 cm^{-1} were obtained in KBr discs while far-IR spectra in the region of 400–50 cm^{-1} were obtained in polyethylene discs, with a Perkin–Elmer Spectrum GX FT-IR spectrometer. ^{1}H NMR spectra were recorded on a Bruker 400 MHFT NMR instrument in CDCl$_3$ solutions with chemical shifts given in ppm relative to internal TMS.

Synthesis of the Complexes 1–3: The appropriate phosphane (0.5 mmol) was added to a suspension of copper(I) bromide (71.7 mg, 0.5 mmol) in 30 mL of dry acetonitrile, and the mixture was stirred for 2 h at ambient temperature during which time a white precipitate of [CuBr(PR$_3$)$_n$]$_m$ [PR$_3$ = triphenylphosphane (PPh$_3$), tri-*p*-tolylphosphane (tptp) or tri-*m*-tolylphosphane (tmtp)] formed. A solution of benz-1,3-imidazole-2-thione (75 mg, 0.5 mmol) in 20 mL of methanol was added dropwise to the reaction mixture whereupon the white precipitate gradually disappeared. After stirring at ambient temperature overnight, the resulting clear solution was filtered off and left to evaporate. The microcrystalline solid that deposited upon standing for several days was filtered off and dried in vacuo.

X-ray Structural Determinations: Single crystals suitable for crystal structure analysis were obtained by slow evaporation of acetonitrile/methanol solutions of the complexes at room temperature. X-ray diffraction data were collected on a Bruker-Nonius Kappa CCD area-detector diffractometer. The programs DENZO[20] and COLLECT[21] were used in data collection and cell refinement. Details of crystal and structure refinement are shown in Table 6. The structures were solved with SIR97[22] and refined with SHELX-97.[23] Molecular plots were obtained with ORTEP-3.[24]
CCDC-241984 (**1**), -241985 (**2**) and -241986 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Computational Details: The structural, electronic and energetic properties of all compounds were computed with Becke's three-parameter hybrid functional[25,26] combined with the Lee–Yang–Parr[27] correlation functional (B3LYP level of density functional theory) using several basis sets, such as the SDD basis set, which describes valence electrons with an [8s,7p,6d/6s,5p,3d] valence basis set and Stuttgart–Dresden relativistic ECPs;[28] the larger all-electron double-zeta (DZVP) basis set;[29] the split-valence 6-31G(d) basis set; the LANL2DZ basis set, which describes valence electrons with a [5s,6p,4d/3s,3p,2d] valence basis set and Los Alamos ECPs;[30–32] the LANL2DZ basis set for copper combined with the 6-31G(d) basis for the non-metal atoms. The hybrid B3LYP functional was used since it gives acceptable results for molecular energies and geometries, as well as proton donation, and weak and strong H-bonds.[33–38] No constraints were imposed on the geometry. Full geometry optimization was performed for each structure using Schlegel's analytical gradient method,[39] and the attainment of the energy minimum was verified by calculating the vibrational frequencies that result in an absence of imaginary eigenvalues. All the stationary points were identified for minima (number of imaginary frequencies NIMAG = 0) or transition states (NIMAG = 1). All calculations were performed using the GAUSSIAN 03 series of programs.[40] Moreover, the qualitative concepts and the graphs derived from the Chem3D program suite[41] highlight the basic interactions found from the DFT calculations. Because of the computational cost due to the relatively big size of the compounds under consideration, to obtain a computationally convenient size we used

models resulting from substitution of the phenyl groups of the spectator phosphane ligands by H atoms, while the benzimidazole-2-thione was replaced by the imidazole-2-thione ($imtH_2$) ligand. The use of such models does not alter the description of the "core" region of the compounds and is ultimately the most efficient and productive route for modeling the electronic structure and related properties of relatively large transition metal coordination compounds. Single point energy calculations on the "real" dicopper(I) complexes were also performed at the B3LYP/LANL2DZ level using the X-ray structural parameters of the two isomeric forms that coexist in the solid state.

Reactivity of Lewis Acid/Base Stabilized Phosphanyl- and Arsanylboranes towards a Platinum(0) Complex

Ulf Vogel,[a] Karl-Christian Schwan,[a] Petra Hoemensch,[a] and Manfred Scheer*[a]

Dedicated to Prof. M. Meisel on the occasion of his 65th birthday

Keywords: Arsenic / Boron / Phosphorus / Reactivity / Platinum

The Lewis acid/base stabilized phosphanylboranes and -arsanes [$(CO)_5W(H_2EBH_2{\cdot}NMe_3)$] (**1a**: E = P; **1b**: E = As) have been shown to react with the platinum(0) complex [$(Ph_3P)_2Pt(C_2H_4)$] under oxidative addition of the E–H bond to the platinum center. The complexes *cis*-[$(Ph_3P)_2Pt(H)(\mu\text{-}EHBH_2{\cdot}NMe_3)W(CO)_5$] (**2a**: E = P; **2b**: E = As) are formed. Complex **2a** is unstable in solution at room temperature and slowly reacts with loss of carbon monoxide to form [$(Ph_3P)_2Pt(\mu\text{-}H)(\mu\text{-}EHBH_2{\cdot}NMe_3)W(CO)_4$] (**3a**: E = P). An analogous complex **3b** (E = As) is formed from **2b** only by refluxing in CH_2Cl_2. The reaction of **2a** to **3a** can be reversed by addition of CO, whereas the arsenic compound **3b** does not show this reactivity pattern. All new compounds have been comprehensively characterized by spectroscopy and X-ray crystallography.

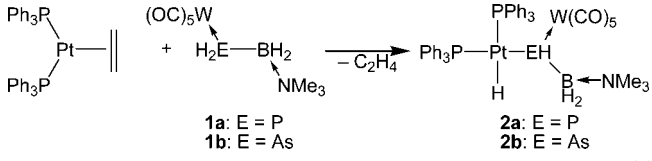
Introduction

A large number of phosphanylboranes $(R_2BPR'_2)_n$ have been synthesized over the years,[1] whereas only some arsanylboranes $(R_2BAsR'_2)_n$ are known so far.[2] Monomeric compounds of both types have up to now been stabilized exclusively by bulky substituents at the group 13 and group 15 elements. Otherwise an intermolecular oligomerisation occurs by the lone pair of the group 15 element and the acceptor orbital of the boron atom. For the experimentally unobserved parent compounds H_2BPH_2 and H_2BAsH_2 we have recently found a novel method of stabilization by the coordination of a Lewis acid and a Lewis base. Thus, the phosphanyl- and arsanylborane complexes [$(CO)_5W(EH_2BH_2{\cdot}NMe_3)$] (**1a**: E = P; **1b**: E = As) were synthesized by a salt elimination route starting from $Li[(CO)_5WEH_2]$ and $ClBH_2{\cdot}NMe_3$.[3] Herein we report on the reactivity of **1** towards the platinum(0) complex [$(Ph_3P)_2Pt(C_2H_4)$] and the CO elimination/addition reactions of the products.

Results and Discussion

The reaction of [$(CO)_5W(H_2EBH_2{\cdot}NMe_3)$] (**1a**: E = P; **1b**: E = As) with the platinum(0) complex [$(Ph_3P)_2Pt(C_2H_4)$] at ambient temperature results in an initial oxidative addition of the platinum center to the E–H bond of **1**, and the complexes *cis*-[$(Ph_3P)_2Pt(H)(\mu\text{-}EHBH_2{\cdot}NMe_3)W(CO)_5$] (**2a**: E = P; **2b**: E = As) are formed [Equation (1)].



1a: E = P
1b: E = As

2a: E = P
2b: E = As

(1)

For the arsenic substituted compound **2b** the reaction is complete at this stage and **2b** can be isolated as a pure compound. In contrast, even under these conditions **2a** tends to lose 1 equiv. of CO and forms the complex [$(Ph_3P)_2Pt(\mu\text{-}H)(\mu\text{-}PHBH_2{\cdot}NMe_3)W(CO)_4$] (**3a**) bearing a bridging hydrogen ligand. For a full conversion the reaction mixture has to be heated to yield pure **3a** [Equation (2)]. Although pure crystalline **2a** can be isolated from the reaction (1) by fractional crystallization, if it is redissolved it tends to lose CO with formation of complex **3a**.

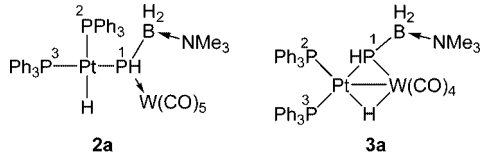
Only by heating a CH_2Cl_2 solution of the arsenic complex **2b** the formation of **3b** was detected, and the product could be isolated in pure form. Furthermore, the formation of **3a** from **2a** by loss of carbon monoxide is reversible. On saturation of a solution of **3a** with carbon monoxide, **2a** together with minor amounts of **3a** could be identified by NMR spectroscopy. In contrast, this feature has never been observed for **2b**.

Interestingly, only the diorgano-substituted phosphane complexes of the type $[(CO)_5M(PPh_2H)]$ show a similar reaction behavior of **1** when treated with $[(C_2H_4)Pt(PPh_3)_2]$. Here, initially the complexes *cis*-$[(CO)_5M(\mu\text{-}PPh_2)\text{-}Pt(H)(PPh_3)_2]$ (M = Cr, Mo, W) are formed, which have a strong tendency to lose CO, resulting in the compounds $[(CO)_4M(\mu\text{-}PPh_2)(\mu\text{-}H)Pt(PPh_3)_2]$. For these complexes the initial oxidative addition products could only be identified by NMR spectroscopy.[4] In contrast, the complexes $[(Ph_3P)_2Pt(H)(\mu\text{-}EH_2)W(CO)_5]$ (E = P, As)[5] and $[(Ph_3P)_2\text{-}Pt(H)(\mu\text{-}PRH)M(CO)_5]$ (R = Ph, cyclohexyl; M = Cr, Mo, W),[6] which are structurally more closely related to **2** and are formed in a manner similar to that for **2**, both show no loss of carbon monoxide even at elevated temperatures. Thus, the occurrence of this CO loss does not seem to be caused by steric factors. Furthermore, the complexes $[(Ph_3P)_2Pt(H)(\mu\text{-}EH_2)W(CO)_5]$ (E = P, As)[5] show a *cis*/*trans* isomerization, whereas for **2a** and **2b** only the *cis*-addition products are detected in solution. It is interesting to note that in a related reaction of the phosphane–borane adducts $PhRPH{\cdot}BH_3$ (R = H, Ph) with $Pt(PEt_3)_3$ an oxidative addition of the P–H bond to the platinum center occurs, but in this case the *trans*-substituted complexes $[(Et_3P)_2\text{-}Pt(H)(PPhR{\cdot}BH_3)]$ (R = H, Ph) are formed exclusively.[7]

Complexes **2** are colorless compounds and moderately soluble in CH_2Cl_2 and toluene, whereas complexes **3** are orange crystalline complexes readily soluble in CH_2Cl_2 and toluene. In the vibrational spectra all products show bands for the CO, PH and BH functional groups. The EI mass spectra do not show the molecular ion peaks, but decomposition products including $[(CO)_5W(PPh_3)]$ and $[(CO)_5\text{-}W(H_2EBH_2{\cdot}NMe_3)]$ (E = P, As) can be identified.

In its $^{31}P\{^1H\}$ NMR spectrum **2a** shows a signal at δ = –174.8 ppm ($^1J_{P1,Pt}$ = 1286, $^2J_{P1,P3}$ = 223 Hz) for the P^1 atom of the phosphido group which is only slightly shifted to lower field when compared with free **1a** (δ = –184.2 ppm). The signal is very broad because of the quadrupolar moment of the neighboring boron atom, which is directly bound to the phosphorus atom. Upon recording a $^{31}P\{^{11}B,^1H\}$ NMR spectrum, the coupling to the tungsten atom and to the P^2 atom *cis* to P^1 (see Scheme 1) is also revealed ($^2J_{P1,P2}$ = 11, $^1J_{P1,W}$ = 153 Hz). The P^2 atom shows a pseudo-triplet at δ = 29.4 ppm ($^1J_{P2,Pt}$ = 2099, $^2J_{P2,P1}$ = 11, $^2J_{P2,P3}$ = 14 Hz) and P^3 is detected as a doublet of doublets at δ = 25.9 ppm ($^1J_{P3,Pt}$ = 2199, $^2J_{P3,P2}$ = 14, $^2J_{P3,P1}$ = 223 Hz). This coupling pattern clearly shows the *cis* arrangement of the phosphanidoboranyl ligand relative to the hydrido ligand. The latter ligand is detected in the ^1H NMR spectrum of **2a** as a doublet of doublets of doublets at δ = –4.48 ppm showing platinum satellites. The PH proton appears as a doublet at δ = 2.38 ppm. A signal for the BH_2 protons could not be assigned, as this resonance is too broad to be clearly identified from the background in the spectrum.



Scheme 1.

Complex **3a** shows a similar $^{31}P\{^1H\}$ NMR spectrum, which is depicted in Figure 1. Here, the P^1 atom shows a broad doublet at δ = –8.7 ppm. Upon additional boron decoupling the signal shows a doublet of doublets bearing platinum satellites. The large downfield shift of the signal compared to **2a** can be explained by the bridging position of the phosphidoboranyl ligand.[8] Also the phosphorus–platinum coupling constant (951 Hz) is much smaller than in **2a** (1286 Hz). A coupling to the tungsten atom is not obvious, but it is presumably hidden under the main signals. Signals for the P^2 and P^3 atoms appear at δ = 15.7 and 19.5 ppm, respectively, and show the same coupling pattern as in **2a**. In its ^1H NMR spectrum **3a** shows a doublet of doublet of doublets with platinum satellites at δ = –7.43 ppm (Figure 1). Due to the small intensity of the hydride signals, the expected tungsten satellites cannot be clearly differentiated from the background noise. The resonance for the PH protons appears as a doublet at δ = 2.60 ppm. As in the case for **2a** the BH_2 signal for **3a** could not be detected.

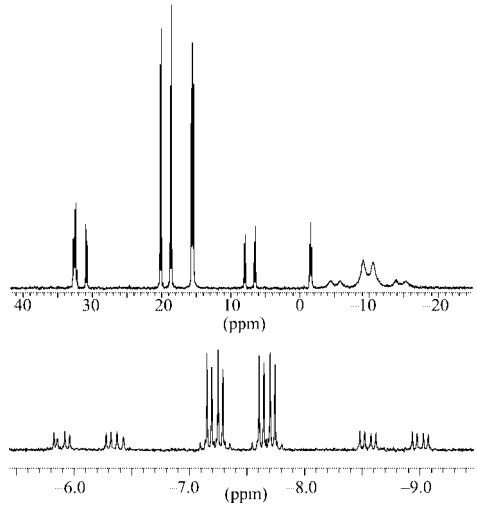


Figure 1. $^{31}P\{^1H\}$ NMR spectrum of **3a** (top). Hydride region of the ^1H NMR spectrum of **3a** (bottom).

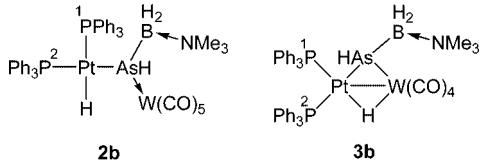
The $^{31}P\{^1H\}$ NMR spectrum of compound **2b** (Scheme 2) shows two doublets at δ = 30.7 ppm and 23.6 ppm, both bearing platinum satellites ($^2J_{P1,P2}$ = 13, $^1J_{P1,Pt}$ = 2145Hz, $^1J_{P2,Pt}$ = 2531Hz). In its ^1H NMR spectrum **2b** displays a doublet of doublets at δ = –4.76 ppm with platinum satellites for the hydrido ligand bound to the platinum atom ($^2J_{H,P1}$ = 177, $^2J_{H,P2}$ = 19 Hz). In accord-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ance with the $^{31}P\{^1H\}$ NMR spectrum this coupling pattern shows the *cis* arrangement of the phosphane ligands around the platinum center. In the ^1H NMR spectrum the protons bound to the arsenic atom give rise to a complex signal centered at δ = –1.27 ppm.



Scheme 2.

In the $^{31}P\{^1H\}$ NMR spectrum complex **3b** (Scheme 2) shows two doublets with platinum satellites at δ = 15.2 ppm and 16.9 ppm ($^2J_{P1,P2}$ = 16, $^1J_{P1,Pt}$ = 2657, $^1J_{P2,Pt}$ = 3433 Hz) for both non-equivalent phosphorus atoms. The ^1H NMR spectrum of **3b** shows the same characteristic signals as that of complex **3a**. The hydrido ligand bound to the platinum atom gives rise to a doublet of doublets with platinum satellites at δ = –6.74 ppm ($^2J_{H,P1}$ = 116, $^2J_{H,P2}$ = 24, $^1J_{H,Pt}$ = 669 Hz). Signals for the nine protons of the trimethylamine group and the 30 protons of the phenyl groups are detected at δ = 1.95 ppm and 6.8–7.6 ppm, respectively.

In order to confirm the proposed structures of **2** and **3** X-ray crystal structure determinations have been performed on all compounds. Single crystals of complex **2** could be obtained from CH_2Cl_2 solutions. Whereas **2b** crystallizes as a dichloromethane solvate, for **2a** no solvent molecule was found in the unit cell. As an example the molecular structure of **2a** is depicted in Figure 2; in Table 1 the bond lengths and angles are compared.

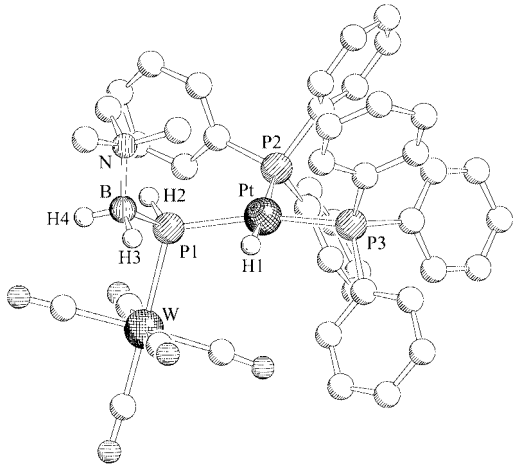


Figure 2. Molecular structure of **2a** in the crystal. Hydrogen atoms at the carbon atoms are omitted for clarity.

The key structural feature of **2** is a central platinum atom which shows an almost perfect planar coordination sphere. Two phenylphosphane ligands are in *cis* arrangement to each other. A hydrido and the phosphanidoboranyl or arsanidoboranyl ligand (**2a** or **2b**) complete the coordination sphere of the 16-electron complexes. The sum of the bond angles around the platinum atom are close to 360° [**2a**: 359.87(5)°; **2b**: 359.01(7)°]. Despite the planar coordination around the platinum atom the bond angles are far from 90° required for a square-planar coordination. All ligands are shifted towards the hydrido ligand to alleviate steric crowding. The Pt–P bond lengths in both compounds are comparable and in a range usually found for such bonds. In comparison to the starting material the B–E [**1a**: 195.5(4); **2a**: 198.1(6): **1b**: 206.7(9): **2b**: 209.4(9) pm] and the E–W bonds [**1a**: 254.2(2); **2a**: 260.5(1); **1b**: 263.5(1); **2b**: 270.15(8) pm] are elongated.[3] The elongation of the E–W bond can be explained by the back-bonding of the E atom to two metal atoms instead of one metal atom as in compound **1**. The same effect can be observed for $[(CO)_5W(\mu\text{-}PH_2)PtH(PPh_3)_2]$ [W–P 260.3(3) pm] in comparison to $[(CO)_5WPH_3]$ [W–P 249.1(2) pm].[5] The change of the electron density at the E atom in **2** and **3** can also explain the elongation of the E–B bond.

Table 1. Comparison of selected bond lengths [pm] and angles [°] in **2a** and **2b**.

Bond lengths[a]	**2a**	**2b**
Pt–E	233.0(2)	243.6(1)
Pt–P_{cis}	233.1(1)	232.1(2)
Pt–P_{trans}	231.0(2)	229.9(2)
E–W	260.5(1)	270.2(1)
E–B	198.1(6)	209.4(9)
B–N	161.8(7)	162(1)
Angles	**2a**	**2b**
E–Pt–P_{cis}	98.29(5)	100.06(5)
E–Pt–P_{trans}	159.71(5)	157.60(5)
P_{cis}–Pt–P_{trans}	101.87(5)	101.35(7)
Pt–E–W	111.20(5)	112.07(3)
Pt–E–B	118.1(3)	116.0(3)
W–E–B	106.1(2)	106.3(3)
E–B–N	116.4(4)	115.2(6)

[a] **2a**: E = P1, P_{cis} = P2, P_{trans} = P3; **2b**: E = As, P_{cis} = P1, P_{trans} = P2.

The compounds **3a** and **3b** are isostructural and crystallize in the triclinic space group $P\bar{1}$ as the dichloromethane solvates. As an example the molecular structure of **3a** is depicted in Figure 3; in Table 2 the bond lengths and angles are compared.

The essential feature of the structures is a $(CO)_4WPt(PPh_3)_2$ moiety which is bridged by a hydrido ligand and a phosphanidoboranyl and an arsanidoboranyl ligand (**3a** or **3b**), respectively. Like in the compounds **2** the platinum atoms show a nearly planar coordination geometry [sum of bond angles **3a**: 357.74(7)°; **3b**: 357.49(7)°]. The long distance between the platinum and the tungsten atom [**3a**: 302.8(1); **3b**: 307.72(9) pm] implies indirect multi-centered bonding through the bridging ligands, rather than a direct metal–metal bond, as was discussed for the structurally related compound $[(CO)_4Cr(\mu\text{-}PPh_2)(\mu\text{-}H)Pt(PEt_3)_2]$.[4b] The E–B distances [**3a**: 197.5(8); **3b** 207.3(8) pm] are comparable to **2a** and **2b**, respectively. In comparison to **2a** and **2b**, respectively, the E–W bond lengths in **3a** and **3b** are significantly reduced [**3a**: 246.0(1); **3b**: 255.57(9) pm] but in a range normally found for similar complexes {$[(CO)_4$-

Conclusions

The results have shown that the Lewis acid/base stabilized phosphanylborane and arsanylborane undergo oxidative addition reactions at a Pt^0 center only at the P–H bond. Initially we had expected that the B–H bond also shows some addition behavior, as it is known for Rh and Ir complexes.[10] However, the boranyl substituent in **1** only functions as an electron-withdrawing substituent at the group 15 atom. Furthermore, in comparison to organo-substituted PH-containing phosphanes, the boranyl-substituted complexes **1** show a similar reaction behaviour toward Pt^0 centers. Oxidative addition of the E–H bond leads to exclusive formation of *cis*-substituted Pt^{II} complexes, which can lose CO to form a complex with a bridging hydrido and pnicogenido substituent, respectively.

Experimental Section

General Remarks: All manipulations were carried out under dinitrogen using standard Schlenk techniques. All solvents were dried using standard procedures and distilled freshly before use. $[(CO)_5W(H_2EBH_2{\cdot}NMe_3)]$ (**1a**: E = P; **1b**: E = As)[3] and $[(Ph_3P)_2Pt(C_2H_4)]$[11] were prepared according to the literature. All NMR spectra were recorded with a Bruker AC 250 with δ referenced to external $SiMe_4$ (^{1}H), $F_3B{\cdot}OEt_2$ (^{11}B) or H_3PO_4 (^{31}P), respectively. IR spectra were measured with a Bruker IFS-28, Raman spectra with a Bruker FRA 106 spectrometer. All mass spectra were recorded with a Varian MATR 711.

***cis*-$[(Ph_3P)_2Pt(H)(\mu\text{-}PHBH_2{\cdot}NMe_3)W(CO)_5]$ (2a):** A mixture of $[W(CO)_5(H_2PBH_2{\cdot}NMe_3)]$ (**1a**) (467 mg, 1.09 mmol) and $[(C_2H_4)Pt(PPh_3)_2]$ (814 mg, 1.09 mmol) was stirred in toluene (20 mL) at room temperature for 14 h. The solution turned to an orange color during this time and a yellow precipitate was formed. The precipitate was separated by filtration and dissolved in a minimum amount of CH_2Cl_2 (ca. 4–5 mL). After 2 d, **2a** was obtained at 4 °C as colorless crystals (if the solution is too concentrated, orange crystals of **3a** crystallize additionally). Yield: 638 mg (51%). $C_{44}H_{43}BNO_5P_3PtW$ (1148.45): calcd. C 46.02, H 3.77, N 1.22; found C 46.23, H 3.87, N 1.14. Raman (solid state) $\tilde{\nu}$ = 3061 (vs), 3006 (w), 2949 (w), 2370 (w), 2295 (w), 2048 (s), 1951 (vs), 1895 (m), 1873 (s), 1518 (s), 1573 (m), 1097 (m), 1029 (m), 1002 (vs), 789 (w), 461 (m), 439 (m), 260 (w), 174 (w), 114 (s) cm^{-1}. ^{1}H NMR (250 MHz, CD_2Cl_2): δ = –4.48 (ddd, $^1J_{Pt,H}$ = 971, $^2J_{P,H}$ = 176, $^2J_{P,H}$ = 33, $^2J_{P,H}$ = 22 Hz, 1 H, HPt), 2.38 (m, $^1J_{P,H} \approx$ 300 Hz, 1 H, PH), 2.49 (s, 9 H, NMe_3), 7.0–7.5 (m, 30 H, PPh_3) ppm. ^{31}P{^{1}H} NMR (101 MHz, CD_2Cl_2): δ = –174.8 (br. d, $^2J_{P,P}$ = 223, $^1J_{Pt,P}$ = 1286 Hz, $PHBH_2$), 25.9 (dd, $^2J_{P,P}$ = 223, $^2J_{P,P}$ = 14, $^1J_{Pt,P}$ = 2199 Hz, PPh_3), 29.4 (t, $^2J_{P,P}$ = 14, $^1J_{Pt,P}$ = 2099 Hz, PPh_3) ppm. ^{31}P{^{11}B,^{1}H} NMR (101 MHz, CD_2Cl_2): δ = –174.8 (dd, $^2J_{P,P}$ = 11 Hz $^2J_{P,P}$ = 223, $^1J_{W,P}$ = 153, $^1J_{Pt,P}$ = 1286 Hz, $PHBH_2$), 25.9 (dd, $^2J_{P,P}$ = 223, $^2J_{P,P}$ = 14, $^1J_{Pt,P}$ = 2199 Hz, PPh_3), 29.4 (t, $^2J_{P,P}$ = 14, $^1J_{Pt,P}$ = 2099 Hz, PPh_3) ppm. X-ray Crystallographic Study: Data were collected with a STOE IPDS area-detector diffractometer using Ag-K_α (λ = 0.56087 Å) radiation. Machine parameters, crystal data and data collection parameters are summarized in Table 3. The structures were solved by direct methods using SHELXS-97,[12a] full-matrix-least-squares

refinement on F^2 in SHELXL-97[12b] with anisotropic displacement for non-H atoms, hydrogen atoms placed in idealized positions and refined isotropically according to the riding model. The H atoms at the heavy atoms were found as residue electron densities and could be freely refined except for the H atom at the As atom in **2b**, which was placed in an idealized position. The use of restraints was necessary for the refinement of **3b** to fix the Cl atoms at the solvent molecule in appropriate distances. CCDC-249065 to -249068 (**2a**,**b** and **3a**,**b**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Acknowledgments

Cobalt(II) Complexes with Substituted Salen-Type Ligands and Their Dioxygen Affinity in *N*,*N*-Dimethylformamide at Various Temperatures

Andreas Huber,[a] Lutz Müller,[a] Horst Elias,*[a] Robert Klement,[b] and Marian Valko[c]

Keywords: Cobalt / Oxygen / Schiff bases / Substituent effects / Thermodynamics

Several unsymmetrically substituted salen-type cobalt(II) Schiff-base complexes CoL [H_2L = 1,6-bis(2-hydroxyphenyl)-3,3-dimethyl-2,5-diaza-1,5-hexadiene (**1**); 1,6-bis(2-hydroxyphenyl)-3,3-dimethyl-2,5-diaza-1,5-heptadiene (**2**); 1-(3-*tert*-butyl-2-hydroxy-5-methylphenyl)-6-(2-hydroxyphenyl)-3,3-dimethyl-2,5-diaza-1,5-heptadiene (**3**); 1-(2-hydroxyphenyl)-6-methyl-2,5-diaza-1,5-nonadien-8-one (**4**); 1-(3-*tert*-butyl-2-hydroxy-5-methylphenyl)-6-methyl-2,5-diaza-1,5-nonadien-8-one (**5**); 1-(2-hydroxyphenyl)-3,3,6-trimethyl-2,5-diaza-1,5-nonadien-8-one (**6**); 1-(3-*tert*-butyl-2-hydroxy-5-methylphenyl)-3,3,6-trimethyl-2,5-diaza-1,5-nonadien-8-one (**7**)] were prepared and characterized by their UV/Vis absorption spectra, magnetic moments, and oxidation potentials. Except for complex **4** (irreversible oxidation with $t_{½} \approx 3$ h), complexes **1**–**3** and **5**–**7** are remarkably resistant against irreversible auto-oxidation in air-saturated *N*,*N*-dimethylformamide (DMF) at ambient temperature. To characterize the Lewis acidity of the cobalt center in **1**–**7**, the equilibrium constant K_{py} was determined for monoadduct formation with pyridine (CoL + py ⇌ CoL·py). An O_2-sensitive optode was used to determine the Henry constant, K_H, for the system O_2/DMF in the temperature range 298–228 K. The formation of 1:1 adducts of complexes **1**–**7** with O_2 in DMF, as characterized by the equilibrium constant K_{O_2}, was followed spectrophotometrically in the temperature range 298–228 K. The parameters ΔH^o, ΔS^o, and K_{O_2} are reported. At 298 K, K_{O_2} ranges from 21.9 M^{-1} (**5**) to 155 M^{-1} (**7**). The overall spectroscopic information, including EPR spectra obtained with frozen solutions of **3** and **7** in O_2-saturated DMF, confirm that the 1:1 adducts CoL·O_2 are cobalt(III) superoxo compounds. The symmetrically substituted salen complex **8** [H_2L = 1,6-bis(3-*tert*-butyl-2-hydroxy-5-methylphenyl)-3,3,4,4-tetramethyl-2,5-diaza-1,5-hexadiene in **8**] is shown to catalyze the oxidation of triphenylphosphane and 2,6-di-*tert*-butylphenol by O_2 in DMF at ambient temperature. The correlation of the data obtained for K_{O_2}, K_{py}, and the oxidation potential $E_{½}$ is discussed.

Introduction

In 1938 Tsumakis discovered the reversible binding of dioxygen to the cobalt(II) complex Co(salen).[1] Since then there has been a continuous and increasing interest in this complex and its derivatives as well as in other dioxygen-binding Schiff-base cobalt(II) complexes such as Co(acacen) and Cobaloxime. This interest arises from the potential application of these compounds as solids for the storage of dioxygen and for dioxygen-separation processes.[2,3] Furthermore, solutions of these complexes have been widely studied as dioxygen carriers and as catalysts for oxidation processes under mild conditions.[2] Martell and coworkers have prepared a number of derivatives of Co(salen) by introducing substituents in the 3- and/or 5-position of the aromatic rings of the ligand salen and by modifying the CH_2-CH_2 bridge connecting the two nitrogen donor atoms.[3,4] They investigated the formation of dioxygen adducts in systems CoL/O_2/B (CoL = salen-type Co^{II} complex; B = base) in solution at various temperatures and reported the corresponding equilibrium constants K_{O_2} and how they are affected by the nature of the base B coordinated to the cobalt center in the axial position. Busch and coworkers have prepared and studied O_2-binding cobalt(II) complexes with pentadentate salen-type ligands offering a (O∩N)∩N∩(N∩O) set of donor atoms, with the central N atom occupying an axial position at the cobalt center as an internal base.[5]

Co(salen) and Co(acacen) can be classified as four-coordinate chelate Co^{II} complexes with an N_2O_2 set of donor atoms. As shown by the cobaloximes[6] and by Co^{II} complexes with N_4 macrocyclic ligands[7] or with aliphatic N_x and N/O chelate ligands,[8,9] an affinity of the cobalt center for dioxygen is also generated by planar N_4 donor systems. For all the O_2-binding complexes CoL, where L is an N_2O_2- or N_4-type ligand, it is generally found that the interaction

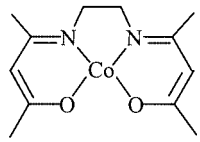
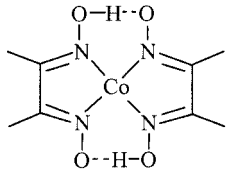
Co(salen) ("Salcomine")



Co(acacen)



Cobaloxime

of the cobalt with dioxygen is more or less favored by an additional base B (such as pyridine, for example) coordinated in one of the axial positions to form five-coordinate CoL·B.

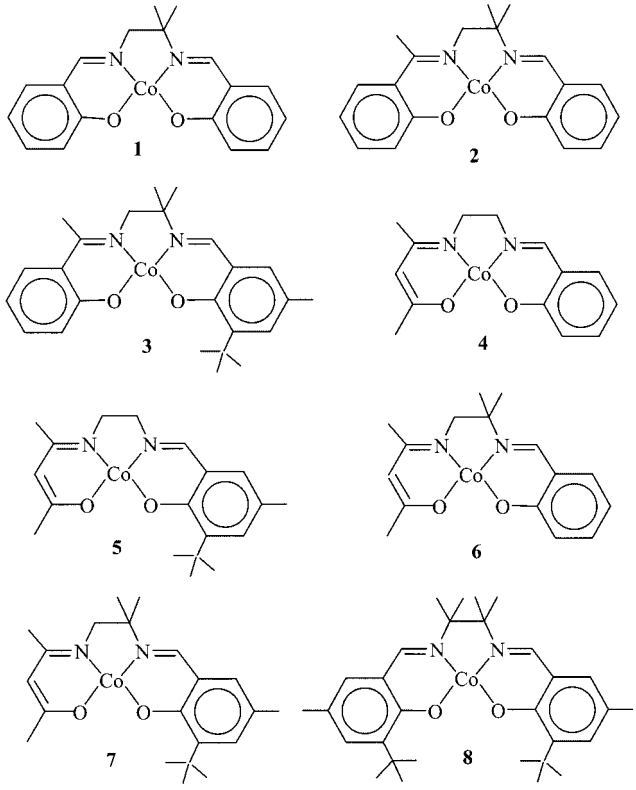
The ligand salen can be easily modified by the introduction of electron-releasing or electron-withdrawing substituents and sterically demanding groups. The electronic and steric properties of a given set of substituents on modified ligands salen* can drastically effect the electron density at the cobalt in Co(salen*) as well as the accessibility of the axial positions. An aerated solution of Co(salen), for example, is irreversibly auto-oxidized within hours. We found that, in contrast to Co(salen), an aerated solution of the cobalt salen complex **8**, which contains a number of methyl and *tert*-butyl groups (see Scheme 1), is stable for weeks. Nevertheless, complex **8** is a weak catalyst for oxidation reactions with O_2 (see Results and Discussion section).

The ligand salen is "symmetric" in the sense that it consists of two identical halves, as indicated by the dashed line in the structural formula of Co(salen) shown above. This sort of ligand symmetry is also typical for most of the derivatives of Co(salen) reported so far.[3,4] To provide a finer tool for property tuning, we decided to prepare a number of salen-type Co^{II} complexes **1**–**7** with "unsymmetric" ligands and to determine the corresponding equilibrium constants K_{O_2}. Compared to Co(salen), the two halves of the ligands in complexes **1**–**7** are no longer identical.

The present contribution summarizes the results obtained by investigating the effect of the various ligands in complexes **1**–**7** on the dioxygen affinity of the complexes in DMF at various temperatures, as characterized by equilibrium constants K_{O_2} according to Equation (1), on the Lewis acidity of the cobalt center, as characterized by equilibrium constants K_{py} according to Equation (2), and on the oxidation potential, $E_{1/2}$, of complexes **1**–**7**, according to the reaction $Co^{II}L \rightleftharpoons Co^{III}L^+ + e^-$.

$$CoL + O_2 \overset{K_{O_2}}{\rightleftharpoons} CoL{\cdot}O_2 \quad (1)$$

$$CoL + py \overset{K_{py}}{\rightleftharpoons} CoL{\cdot}py \quad (2)$$



Scheme 1. Structural formulae of the cobalt(II) complexes.

Results and Discussion

Preparation and Properties of the Complexes

Compared to salen and "symmetrically" substituted salen ligands such as the one in complex **8**, the synthesis of "unsymmetric" salen-type ligands is not at all simple. The ligands for the preparation of complexes **2**–**7** were obtained according to an efficient two-step procedure developed earlier.[10] On the basis of the known structure of complexes **3**[10] and **8**[11] one can extrapolate that, in all of the complexes **1**–**8**, the CoN_2O_2 core is nearly planar, with the plane of at least one of the two phenyl rings in **1**–**3** being almost co-planar with the CoN_2O_2 core. The UV/Vis spectra of complexes **1**–**8** are characterized by two intense charge-transfer (CT) bands at approximately 360 nm and 420 nm and by a weak d-d absorption (shoulder) at approximately 500 nm (see Table S1). The absorptivities of complexes **4**–**7** are smaller due to reduced conjugation. The magnetic moments of complexes **1**–**8** at 298 K were found to lie in the range μ_{exp} = 2.31–2.60 μ_B,[11,12] which is typically observed for low-spin d^7 systems of the present type.[13]

Auto-Oxidation of the Complexes in Solution

In air-saturated DMF solution at ambient temperature, the stability of complexes **1**–**8** towards irreversible auto-oxidation can be described by the following order: **8** > **1**–**3** > **5**–**7** > **4**. More specifically, a solution of complex **8** is stable for weeks and the solutions of **1**–**3** are stable for several

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

days, whereas those of complexes **5**–**7** change slowly within 24 h (<10%). Complex **4**, the least stable one, undergoes irreversible oxidative decomposition with a $t_{½}$ of about 3 h, which is close to the auto-oxidation rate of the parent complex Co(salen) in air-saturated DMF solution in the absence of bases such as pyridine.[14] One should note, however, that at –40 °C, adduct formation with dioxygen according to Equation (1) was shown to be reversible for all of the complexes **1**–**8**.

Potentials for the Oxidation Step $Co^{II} \rightarrow Co^{III}$

The data obtained for the potential $E_{½}$ in acetonitrile, which describes the quasi-reversible step $Co^{II} \rightarrow Co^{III}$, range from 183 to 274 mV (Table 1). The potential reported for unsubstituted Co(salen) in acetonitrile (258 mV)[15a,15b] lies within this range.

Table 1. Oxidation potentials, $E_{½}$, for complexes **1**–**8** in acetonitrile at 293 K.[a]

Complex	$E_{½}$ [mV][b]	Complex	$E_{½}$ [mV][b]
1	263	**6**	234
2	210	**7**	223
3	183	**8**	274
4	196	Co(salen)	258[c]
5	193	Co(salen)[d]	–33[e]

[a] $E_{½}$ referenced to SCE. [b] The peak separation, $E_p^c - E_p^a$, was in the range 82–144 mV. [c] The value presented is based on $E_{½}$ = –195 mV, as reported for acetonitrile and referenced to Fc/Fc^+ (Fc = ferrocene);[15a] conversion to SCE was achieved according to: $E(SCE) = E(Fc/Fc^+) + 453$ mV.[15b] [d] Solvent DMF. [e] The value presented is based on $E_{½}$ = –466 mV, as reported for DMF and referenced to Fc/Fc^+ (Fc = ferrocene);[15c] conversion to SCE was achieved according to: $E(SCE) = E(Fc/Fc^+) + 433$ mV.[15b]

The qualitative order of stability towards auto-oxidation (**8** > **1**–**3** > **5**–**7** > **4**), as obtained by spectrophotometric monitoring, does not correlate with the parameter $E_{½}$. The most positive oxidation potential (274 mV) is indeed found for the most stable complex **8**, but within the group of complexes **1**–**3**, which show the same sort of stability, the potential drops by 80 mV from 263 mV (**1**) to 183 mV (**3**). Moreover, within the group of complexes **4**–**7** complex **5** is found to be as stable as complexes **6** and **7**, but the potential of **5** (193 mV) is as low as **4** (196 mV), which is the least stable complex. As pointed out above, the instability of **4** resembles that of Co(salen), although the potentials differ by 64 mV.

The lack of a correlation between $E_{½}$ and the observed complex stability is not unexpected. The parameter $E_{½}$ is a measure of the energy needed to abstract an electron from the cobalt. The observed stability towards irreversible auto-oxidation, however, reflects a multi-step process that is probably initiated by docking of the O_2 molecule at the cobalt, followed by electron transfer from the cobalt to O_2, and followed by a further series of reactions that lead finally to the destruction of the complex. All of these steps can be subject to electronic and steric substituent effects in a specific way.

Adduct Formation with Pyridine

The cobalt center in complexes **1**–**8** is weakly Lewis acidic. As an example, Figure 1 shows the spectral changes associated with the stepwise titration of complex **3** with pyridine in toluene. The (A,[py]) data follow the relationship in Equation (6), which describes monoadduct formation according to Equation (2). The occurrence of a sharp isosbestic point indicates that there is no additional diadduct formation. The data obtained for the equilibrium constant K_{py} range from 6.3 M^{-1} for **1** to 0.3 M^{-1} for **7** (Table 2).

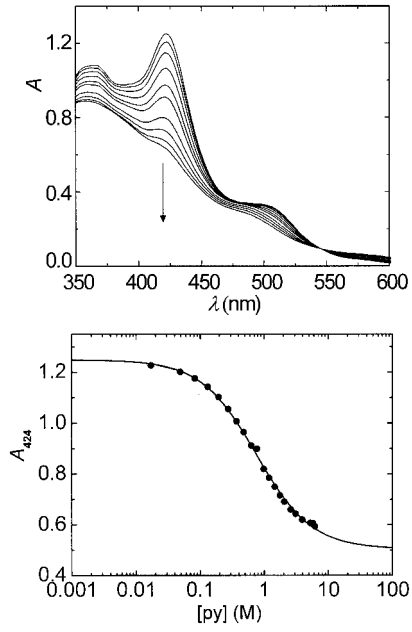


Figure 1. Spectral changes and titration curve describing the stepwise titration of complex **3** with pyridine in toluene at 298 K [solid line obtained by fitting Equation (6) to the (A_{424},[py]) data].

Table 2. Equilibrium constants, K_{py}, for adduct formation of complexes **1**–**8** with pyridine in toluene according to Equation (2) at 298 K.

Complex	K_{py} [M^{-1}]	Complex	K_{py} [M^{-1}]
1	6.3 ± 0.7	**5**	0.50 ± 0.01
2	3.0 ± 0.3	**6**	0.55 ± 0.10
3	1.3 ± 0.1	**7**	0.32 ± 0.01
4	1.3 ± 0.2	**8**	0.47 ± 0.01; 0.06 ± 0.01[a]

[a] The solvent was DMF instead of toluene.

For comparison of the K_{py} data, complexes **1**–**8** should be divided into two groups: in group **A** (complexes **1**–**3** and **8**), the ligand skeleton is that of salen, whereas in group **B** (complexes **4**–**7**) one half of the ligand is based on acetylacetone instead of salicylaldehyde. The fact that $K_{py}(\mathbf{1}) > K_{py}(\mathbf{6})$ reflects clearly that, independent of additional substituent effects, the acetylacetone-containing ligand system of complexes **4**–**7** is a stronger electron donor than that of salen.

In more detail, the analysis of the K_{py} data leads to the following conclusions: (i) the order observed for group **A** complexes, $K_{py}(\mathbf{1}) > K_{py}(\mathbf{2}) > K_{py}(\mathbf{3}) > K_{py}(\mathbf{8})$, reflects the combined electronic and steric effects of an increasing

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

number of methyl and *tert*-butyl groups, respectively, which increase the electron density and decrease the accessibility of the cobalt center; (ii) the order observed for group **B** complexes, $K_{py}(\mathbf{4}) > K_{py}(\mathbf{5}) \approx K_{py}(\mathbf{6}) > K_{py}(\mathbf{7})$, is due to the same sort of effects; (iii) the finding that $K_{py}(\mathbf{4}) > K_{py}(\mathbf{6})$ and $K_{py}(\mathbf{5}) > K_{py}(\mathbf{7})$ demonstrates the (probable) steric effect of two methyl groups on the CH_2-$C(CH_3)_2$ bridge of **6** and **7**, which reduce the accessibility of the cobalt; and (iv) the finding that $K_{py}(\mathbf{2}) > K_{py}(\mathbf{3})$, $K_{py}(\mathbf{4}) > K_{py}(\mathbf{5})$, and $K_{py}(\mathbf{6}) > K_{py}(\mathbf{7})$ can be ascribed to the combined electronic and steric substituent effects of the methyl group and *tert*-butyl group, respectively, in the *para*- and *ortho*-position to the phenolic oxygen.

For complex **8**, the addition of pyridine was measured in toluene (K_{py} = 0.47 M^{-1}) as well as in DMF (K_{py} = 0.06 M^{-1}). The apparently lower Lewis acidity in DMF confirms that, in DMF, complexes CoL form CoL(DMF) adducts with the solvent. The base pyridine has to compete for axial coordination according to Equation (3).

$$CoL(DMF) + py \rightleftharpoons CoL(py) + DMF \quad (3)$$

Henry Constant, K_H, for the System O_2/DMF at Various Temperatures

The determination of the temperature dependence of the equilibrium constant K_{O_2} for adduct formation according to Equation (1) requires a knowledge of the Henry constant, K_H, for the temperature range studied. An O_2-sensitive optode was used to determine $[O_2]$, the equilibrium concentration of dioxygen in O_2-saturated DMF at various temperatures (see Experimental Section and Figure S1, Supporting Information). The data obtained for K_H are presented in Table 3.

Table 3. Henry constant, K_H, for the system O_2/*N*,*N*-dimethylformamide in the temperature range 298–223 K.

T [K]	$K_H \times 10^6$ [M Torr^{-1}][a]	T [K]	$K_H \times 10^6$ [M Torr^{-1}][a]
298	6.4	243	7.4
283	6.6	238	7.5
273	6.8	233	7.6
263	7.0	228	7.7
253	7.2		

[a] The error limits for K_H are approximately ±10%.

Equilibrium Constant, K_{O_2}, for Adduct Formation with Dioxygen at Various Temperatures

The Henry constant, K_H, for the system O_2/DMF increases with decreasing temperature (see Table 3) and so does the equilibrium concentration of dioxygen in DMF. As a consequence, adduct formation according to Equation (1) and, correspondingly, the UV/Vis spectra of complexes **1**–**7** in O_2-saturated DMF are shifted towards the dioxygen adducts CoL·O_2. As an example, Figure 2 shows a selection of spectra obtained for the system **1**/O_2/DMF at various temperatures. There are a number of sharp isosbestic points indicating that, in addition to the formation of the 1:1 adduct, there is no further formation of a 1:2 adduct. In line with this, the absorbance data at 406 nm can be well fitted with Equation (8) (see Figure 2, bottom), as derived for monoadduct formation. The fitting procedure finally leads to data for ΔH^o, ΔS^o, and K_{O_2} for complexes **1**–**3** and **5**–**7** (Table 4). The results for complex **4** are missing due to the limited stability of **4** against auto-oxidation.[16]

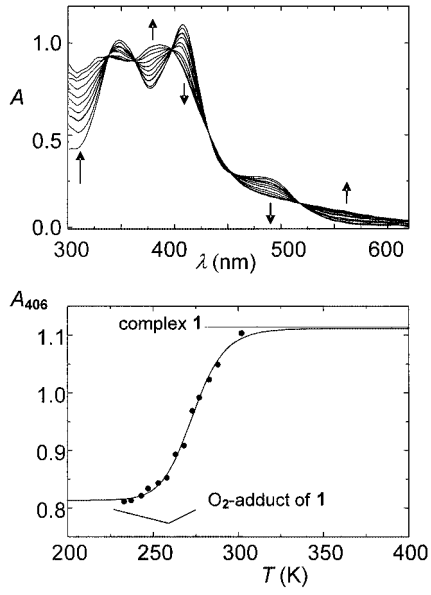

Figure 2. UV/Vis spectra of complex **1** in O_2-saturated *N*,*N*-dimethylformamide at various temperatures (upper diagram; the arrows indicate spectral changes associated with decreasing temperature) and the dependence of the absorbance at 406 nm on the temperature in the range 298–228 K [lower diagram; the fitting curve was obtained by fitting Equation (8) to the (A_{406},T) data].

To have a different experimental method for control, complex **3** in Ar-saturated DMF was titrated with dioxygen at 288 K. The observed spectral changes led to (A_{412},$[O_2]$) data (A_{412} = absorbance at 412 nm) that could be satisfyingly fitted with Equation (9) (see Figure S2, Supporting Information). The equilibrium constant K_{O_2} = 96 ± 9 M^{-1}, as obtained at 15 °C by this titration method (see Table 4), agrees within the limits of error with K_{O_2} = 130 ± 25 M^{-1}, as calculated for 15 °C from the data obtained at various temperatures.

In O_2-saturated DMF, the UV/Vis spectra of complexes **1**–**7** show absorption bands at about 340, 380, and 550 nm (shoulder), even at ambient temperature. These bands can be assigned to M→L charge-transfer processes in the adducts CoL·O_2 and superoxo species $CoL^+ \cdot O_2^-$, respectively (see also EPR data below).[19] In the case of complex **8**, spectral changes associated with the formation of the O_2 adduct were not observed at ambient temperature, but clearly at 223 K.

It follows from Table 4 that complexes **1**–**3** and **5**–**7** do not differ drastically in their dioxygen affinity. At 25 °C, K_{O_2} ranges from 21.9 M^{-1} for **5** to 155 M^{-1} for **7**. The thermo-

dynamic data indicate that the driving force for dioxygen complex formation is the favorable enthalpy of reaction, corresponding to metal–dioxygen bond formation and, as a consequence, a strengthening of the coordinate bonds between the metal and the ligand donor atoms. As characteristically observed for all oxygenation processes,[4] the entropies of oxygenation are seen to be negative, due to the loss of the translational entropy of the O_2 molecule and the increase in ligand rigidity.

The general expectation is that an increase of the electron density on the cobalt, as introduced by substituents on the ligand, should favor the reaction described by Equation (1) and increase K_{O_2}. Since the methyl and *tert*-butyl groups on the salicylaldehyde unit and the methyl groups on the diamine bridge in complexes **1**–**3** and **5**–**7** can have steric as well as electronic effects, there is no simple prediction concerning their effect on the electron density on the cobalt. The equilibrium constant K_{py}, however, which describes adduct formation with pyridine (see Table 2), is a useful experimental measure of both the electron density on the cobalt and its accessibility. K_{py} should therefore correlate inversely with K_{O_2}. For group **A** complexes **1**–**3**, this correlation is indeed observed with $K_{py}(\mathbf{1}) > K_{py}(\mathbf{2}) > K_{py}(\mathbf{3})$ vs. $K_{O_2}(\mathbf{1}) < K_{O_2}(\mathbf{2}) < K_{O_2}(\mathbf{3})$. In the case of group **B** complexes **5**–**7**, the order $K_{O_2}(\mathbf{5}) < K_{O_2}(\mathbf{6}) < K_{O_2}(\mathbf{7})$ is less well reflected by the finding $K_{py}(\mathbf{5}) \approx K_{py}(\mathbf{6}) > K_{py}(\mathbf{7})$. The inverse correlation between K_{py} and K_{O_2} confirms convincingly that the reaction of the cobalt(II) complexes CoL with O_2 according to Equation (1) is not at all a simple nucleophilic addition reaction. Obviously, electron abstraction and formation of the species $Co^{III}L^+$ is the driving force, with the latter following the electron density on the cobalt, as determined by the ligand L.[20] The order in the oxidation potential, $E_{1/2}(\mathbf{1}) > E_{1/2}(\mathbf{2}) > E_{1/2}(\mathbf{3})$ (Table 1), is paralleled by the reverse order in dioxygen affinity, $K_{O_2}(\mathbf{1}) < K_{O_2}(\mathbf{2}) < K_{O_2}(\mathbf{3})$. This means that the more easily the cobalt(II) is oxidized, the stronger is the interaction with O_2. The corresponding data obtained for group **B** complexes **5**–**7**, however, are not in line with this sort of correlation.

For comparison, Table 4 lists data for pressure-based equilibrium constants $K_{O_2}(\text{Torr}^{-1})$, as reported for a number of "symmetric" salen-type cobalt(II) complexes that form 1:1 adducts with dioxygen. Neglecting possible solvent effects, one learns that the range of dioxygen affinities obtained for complexes **1**–**3** and **5**–**7** [$K_{O_2} \approx (0.1–1) \times 10^{-3}$ Torr^{-1}] covers the K_{O_2} data reported for Co(saltmen),[21] Co(acacen), and Co(salMeDPT).[21] The range of affinities reported for Co(salophen),[21] Co(salen), and Co(α-CH_3-salen)[21] is approximately one order of magnitude higher [$K_{O_2} \approx (2–6) \times 10^{-3}$ Torr^{-1}], but, as a rule, increased affinity means reduced resistance against oxidative attack.

To summarize: (i) compared to Co(salen), the "unsymmetric" salen-type ligands of the present study lead to cobalt(II) complexes with slightly reduced dioxygen affinities, and (ii) the loss in dioxygen affinity is paralleled by an increase in resistance towards irreversible auto-oxidation. Depending on the type of substitution (substituents on the CH_2-CH_2 bridge and/or on the phenyl rings), complexes **1**–**3** and **5**–**7** are O_2-active cobalt(II) compounds with interesting intermediate properties concerning sufficient dioxygen affinity (and possible catalytic activity) on the one hand and

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

limited susceptibility to auto-oxidation on the other hand. As an example, in the case of complex **3** the binding constant for O_2 (in DMF) is five times smaller than in the case of Co(salen) (in DMSO). Compared to Co(salen), complex **3** is, however, far more auto-oxidation resistant (at ambient temperature, air-saturated solutions of **3** in DMF are stable for several days). The affinity constant K_{O_2} = 65 M^{-1} for **3** means that, in an O_2-saturated solution of **3** in DMF at 25 °C, not less than 24% of the complex is present in the form of the O_2 adduct.

EPR Spectra of the Dioxygen Adducts of Complexes 3 and 7 in Frozen DMF

We reported earlier that in frozen O_2-saturated solution the O_2 adducts of cobalt(II) complexes with "symmetrically" substituted salen ligands show EPR spectra with well-resolved hyperfine structures.[22] As confirmed by the investigation of complexes **3** and **7**, the "unsymmetrically" substituted cobalt(II) complexes of the present study behave analogously. As an example, Figure 3 shows the experimental and simulated ESR spectrum of the 1:1 dioxygen adduct of complex **3** in O_2-saturated frozen DMF. The EPR data, as obtained by computer simulation, are summarized in Table 5.

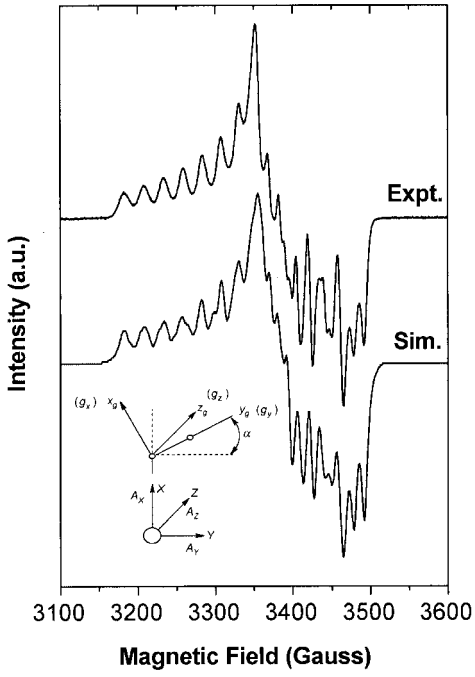

Figure 3. Experimental and simulated X-band ESR spectrum of the dioxygen adduct of complex **3** in O_2-saturated frozen DMF [inset: coordinate system for Zeeman and hyperfine terms of ESR spectra of CoL·O_2 adducts. The principal g axes are x_g, y_g, and z_g, and the principal A axes are X, Y and Z. According to the Smith and Pilbrow notation:[24a] $X(z)$, $Y(y)$ and $Z(x)$, $A_x(Z) = A_Z$, $A_y(Y) = A_Y$, $A_z(X) = A_X$].

As documented earlier, the unpaired electron density in the 1:1 adducts resides mostly on the O_2 moiety.[22] The g-values lie close to the free-electron value and the hyperfine structure arising from the cobalt nucleus (I^{Co} = 7/2) is still present but, compared to CoL Schiff-base complexes in the absence of dioxygen, is strongly reduced in magnitude. The oxygenation of complexes **3** and **7** was found to be complete and the results obtained are in agreement with the general experience that the stability of such 1:1 adducts is enhanced by additional coordination of a base B (in the present system, B = DMF) in the sixth (axial) position *trans* to O_2.

The electronic structure of the O_2 adducts of cobalt(II) complexes is usually discussed in terms of a spin-pairing model, which interprets the cobalt hyperfine structure, observed in the EPR spectra of the adducts, as originating from a direct or indirect (spin-polarization) mechanism.[23] The rather low values of $A_y(Y)$ and $A_x(Z)$ (see Table 5) for the O_2 adducts of complexes **3** and **7** in DMF, which acts as a weak base, and the significant reduction in $A_y(Y)$ and $A_x(Z)$ for the dioxygen adduct of complex **3** in the presence of pyridine, which acts as a strong base, are most probably due to the peculiar balance between the direct and indirect (spin-polarization) contributions to the ^{59}Co hyperfine coupling constants.

In discussing the relationship between g-values and the electronic structure of the O_2 adducts of **3** and **7**, one has to consider the fact (see Table 5) that the g_x and g_z values are close to the free-electron value (2.0023), whereas the data for g_y (along O–O bond) are somewhat greater. This increase in g_y can be rationalized in terms of the energy separation of the dioxygen π*-orbitals.[23,24] According to Equation (4), the size of g_y is controlled by the oxygen spin-orbit coupling parameter, λ, and by the energy separation, Δ, between the π*-dioxygen orbitals. An increase in g_y corresponds to decreasing values of Δ. This points to a lower energy separation of the oxygen π*-orbitals in the O_2 adducts of the CoL(B) complexes, with B being the weak base DMF. The size of Δ could well be related to the strength of the Co–O_2 interaction.[25] An increase in Δ, due to a strong σ-bond interaction between the cobalt d_{z^2} and oxygen π*-orbital leads to an increased strength of the Co–O_2 bond as well. On the other hand, the increased values of g_y observed for the dioxygen adducts of complexes **3** and **7** in DMF (see Table 5) imply lower Δ values. This may in turn suggest a weaker Co–O_2 interaction of these complexes,

Table 5. Evaluated EPR spin-Hamiltonian parameters for the dioxygen adducts of complexes **3** and **7** in O_2-saturated DMF at 77 K.

Complex	g_x[a]	g_y	g_z	$-A_X^{Co}$[a,b]	$-A_Y^{Co}$	$-A_Z^{Co}$	α [°]
3	2.011	2.092	1.985	23	78	36	25

compared to the O_2 adducts of complexes CoL(B) with a strong base such as pyridine.

$$g_y = 2.0023 + 2\left[\frac{\lambda^2}{\lambda^2 + \Delta^2}\right]^{1/2} \quad (4)$$

Complex 8 as O_2-Activating Catalyst

In O_2-saturated DMF, the symmetrically substituted salen complex **8** is remarkably resistant to irreversible auto-oxidation (see above). At ambient temperature, the UV/Vis spectrum of **8** in O_2-stripped DMF solution does not change upon addition of O_2. At –40 °C, however, reversible adduct formation of **8** with dioxygen according to Equation (1) is observed. This means that, compared to complexes **1**–**7**, the dioxygen affinity of **8** is small. Despite this comparatively limited interaction with dioxygen, complex **8** was found to be a weak catalyst for the O_2-oxidation of triphenylphosphane and 2,6-di-*tert*-butylphenol (DTBP). As shown in Table 6, at ambient temperature 35% of DTBP is oxidized to the corresponding quinone within 24 hours. In the case of PPh_3, 84% of this substrate is oxidized under the same conditions. Although the observed catalytic activity of **8** is very limited, it points to interesting catalytic properties to be expected for complexes **1**–**3** and **5**–**7**. From the point of practical application in catalysis, one is interested in O_2-activating cobalt(II) complexes with intermediate properties concerning the interplay between dioxygen affinity (corresponding to superoxo complex formation) and auto-oxidation rate. Complexes **1**–**3** and **5**–**7** can be suggested as promising candidates.

Table 6. Oxidation of triphenylphosphane (PPh_3) and 2,6-di-*tert*-butylphenol (DTBP) in O_2-saturated *N*,*N*-dimethylformamide according to Equation (10) in the presence of complex **8** as catalyst.

Substrate S	[S] [mM]	[**8**] [mM]	*T* [K]	*t*[a] [h]	Product distribution (%) substrate	oxid. substrate
DTBP	5	0.5	293	24	65	35[b]

PPh_3	10	1	295	24	16	84[c]

[a] Reaction time. [b] 2,6-Di-*tert*-butyl-1,4-benzoquinone. [c] Ph_3PO.

Conclusions

Complexes **1**–**7** are unsymmetrically substituted cobalt(II) complexes of the Co(salen)-type. In solution, all of these complexes behave like Co(salen) in that they interact with dioxygen, according to Equation (1), to form monoadducts with O_2. Due to steric crowding of the ligands, the formation of dinuclear species, as observed for "normal" Co(salen), is obviously suppressed. The spectroscopic information obtained (UV/Vis and EPR) is in line with the interpretation that the monoadducts, $CoL{\cdot}O_2$, are cobalt(III) superoxo compounds.

The resistance against auto-oxidation is ligand-dependent. In air-saturated DMF at ambient temperature, complexes **1**–**3** are stable for several days, **5**–**7** change slowly within one day, and **4** undergoes oxidative decomposition within hours.

The dioxygen affinity of the complexes in DMF, as characterized by the equilibrium constant K_{O_2} for adduct formation with dioxygen, ranges from $K_{O_2} = 21.9\ M^{-1}$ for **5** to $K_{O_2} = 155\ M^{-1}$ for **7** at 298 K. The data obtained for K_{O_2} correlate inversely with the Lewis acidity of the cobalt center, as characterized by the equilibrium constant K_{py} for adduct formation with the base pyridine. As an example, the dioxygen affinity of $K_{O_2} = 65$ for complex **3** means that, in O_2-saturated DMF at 25 °C, not less than 24% of **3** is present in the form of the superoxo species. There is experimental evidence to suggest that the remarkably oxidation-resistant complexes **1**, **2** and **3** in particular are useful catalysts for the oxidation of organic substrates with dioxygen in homogeneous solution under mild conditions.

Experimental Section

Chemicals: The commercially available aldehydes, ketones, and amines needed for ligand synthesis and the salt $Co(AcO)_2{\cdot}4H_2O$ (reagent grade) were used without further purification. Reagent grade *N*,*N*-dimethylformamide (DMF), toluene, and acetonitrile used as solvents for spectrophotometric titrations and CV measurements were stored under Ar.

Ligands: The salen-type ligands used for the preparation of complexes **1**,[26] **3**,[10] and **8**[11] were synthesized according to the literature. The ligands for complexes **2** and **4**–**7** were obtained by a two-step procedure, as developed for the preparation of the "unsymmetric" ligand of complex **3**.[10] In the first step, the corresponding ketone (2′-hydroxyacetophenone or 2,4-pentanedione) was treated with the corresponding diamine (1,2-diamino-2-methylpropane or 1,2-diaminoethane) in a 1:1 ratio to form a tridentate mono Schiff base. In the second step, the mono Schiff base was finally turned into the tetradentate salen-type ligand H_2L by reaction with salicylaldehyde or 3-*tert*-butyl-5-methylsalicylaldehyde. More details concerning the application of this two-step procedure to the preparation of the ligands for complexes **2** and **4**–**7** can be found in the literature.[12]

Complexes: Complex **8** was prepared and characterized as described earlier.[11] To avoid oxidation, the preparation of complexes **1**–**7** according to Equation (5) was carried out under Ar.

$$H_2L + Co(AcO)_2 \rightleftharpoons CoL + 2\ AcOH \quad (5)$$

General Procedure: A solution of 2 mmol of $Co(AcO)_2{\cdot}4H_2O$ in 25 mL of ethanol was added dropwise to a warm solution of 2 mmol of the ligand H_2L in 20–30 mL of ethanol whilst stirring. The red solution was refluxed for 30 min. Upon cooling, the red or red-orange cobalt complex precipitated. Recrystallization was carried out from ethanol (yield: 60–95%).

3: $C_{24}H_{30}CoN_2O_2$ (437.44): calcd. C 65.90, H 6.91, N 6.40; found C 65.82, H 7.09, N 6.44.

4: $C_{14}H_{16}CoN_2O_2$ (303.22): calcd. C 55.46, H 5.32, N 9.24; found C 55.06, H 5.34, N 9.04.

5: $C_{19}H_{26}CoN_2O_2$ (373.36): calcd. C 61.12, H 7.02, N 7.50; found C 61.07, H 7.26, N 7.48.

7: $C_{21}H_{30}CoN_2O_2$ (401.42): calcd. C 62.84, H 7.53, N 6.98; found C 62.87, H 7.62, N 7.00.

The identity of complexes **1** and **6** was based on the purity of the ligands applied (CHN, ^{1}H NMR) and on the spectroscopic properties of the complexes (IR, UV/Vis). The visible absorption data of complexes **1**–**8** are presented in Table S1.

Instrumentation: UV/Vis spectra: diode array spectrophotometer (HP, type 8451A). Cyclic voltammetry: CV setup as described earlier.[11] Determination of dioxygen dissolved in DMF: optode (= dioxygen sensor), based on fluorescence quenching.[27] EPR spectra: Bruker SRC 200 D spectrometer, operating at X-band, with variable-temperature unit. An Ar-filled glove box was used for the preparation of O_2-stripped solutions.

Stability of the Complexes in Solution: The stability of complexes **1**–**8** in solution in air-saturated DMF was followed by monitoring the change of the UV/Vis spectra with time at ambient temperature.

Determination of Equilibrium Constant K_{py}: The stepwise titration of freshly prepared solutions of complexes **1**–**8** in toluene (Ar-saturated) with pyridine (Ar-saturated) according to Equation (2) was followed spectrophotometrically at 298 K in the range λ = 350–600 nm. Least-squares fitting of Equation (6) to the (A,[py]) data led to the equilibrium constant K_{py} (A = absorbance).

$$A = (A_o + A_\infty K_{py}\,[py])/(1 + K_{py}\,[py]) \quad (6)$$

The parameters A_o and A_∞ refer to the absorbance of the complexes CoL and CoL·py, respectively, at the initial concentration of CoL, $[CoL]_o$.

Cyclic Voltammetry: The measurements were carried out in O_2-stripped (Ar) acetonitrile (0.1 M $[Bu_4N]ClO_4$) at 293 K with [complex] = 1 mM. The scan rate was 100 mV s^{-1}.

EPR Spectroscopy: Solutions of **3** and **7** in DMF (1 mM) were filled into cylindrical quartz tubes and then purged with O_2 or Ar at ambient temperature before cooling to 77 K. The reversibility of dioxygen binding was checked by warming up the oxygenated frozen solutions, purging with Ar, and repeating the low-temperature measurement.

Henry Constant, K_H, for the System O_2/DMF at Various Temperatures: An O_2-sensitive optode[27] was used to determine $[O_2]$ in O_2-saturated DMF in the temperature range 298–228 K at atmospheric pressure. Calibration of the optode was achieved by determining its signal at 228 K in O_2-saturated DMF ($[O_2]_{rel}$ = 100%) and O_2-stripped (Ar) DMF ($[O_2]_{rel}$ = 0%), respectively. As shown in Figure 1S, $[O_2]_{rel}$ increases linearly with T^{-1}. On the basis of $[O_2] = 4.8 \times 10^{-3}$ M, as reported for O_2-saturated DMF at 298 K,[28] the data shown in Figure S1 lead to Equation (7).

$$[O_2] = 1.42 \times 10^{-3} + 1.01 \cdot T^{-1}\ (M) \quad (7)$$

This equation gives the equilibrium concentration of dissolved dioxygen, $[O_2]$, for O_2-saturated DMF at any temperature in the range 298–228 K. The Henry constant, K_H, follows from $[O_2]$ according to $K_H = [O_2]/p_{O_2}$ (in the present system, $p_{O_2} = 760 - p_{DMF}$; p_{DMF} = vapor pressure of DMF in Torr units).

Determination of Equilibrium Constant K_{O_2} for Adduct Formation with Dioxygen at Various Temperatures: A reaction vessel containing 70 mL of the freshly prepared solution of the complex CoL in Ar-saturated DMF ([CoL] ≈ 10^{-4} M) was placed into a thermostat/cryostat for temperature control. The experimental setup allowed us to saturate the solution with either O_2 or Ar. Spectra of the solution (λ = 300–650 nm) were recorded with a specially designed quartz cell (1 cm path length), immersed in the solution. The cell was equipped with flexible quartz fiber cables for connection to a diode array spectrophotometer. For each CoL/O_2 system, spectra were recorded stepwise at 8–12 temperatures in the range T = 310–230 K. In the first step, the solution was thermostatted at a given temperature in the range 25–35 °C and equilibrated with O_2 for 5 min. After that, the first spectrum was recorded. In the next step, the temperature was lowered by approximately 10 °C and the procedure of thermostatting and equilibrating with O_2 for 5 min was repeated to take the second spectrum. To guarantee O_2-equilibration, there was a continuous flow of O_2 through the solution during all steps. Least-squares fitting of Equation (8) to the observed (A,T) data[29] led to the parameters $m = -\Delta H^o/R$, $b = \Delta S^o/R$, A_{CoL}, and A_{add}. The equilibrium constant K_{O_2} was calculated according to van't Hoff.

$$A = \{(A_{CoL} + A_{add}\,[O_2]\exp(mT^{-1} + b)\}/\{(1 + [O_2]\exp(mT^{-1} + b)\} \quad (8)$$

where A_{CoL} and A_{add} refer to the absorbance of the complex CoL and of its dioxygen adduct, CoL·O_2, respectively, at the initial concentration of CoL, $[CoL]_o$.

The reversibility of adduct formation according to Equation (1) was confirmed by repeatedly running the cycle Ar-saturation/O_2-saturation at a given temperature and recording the corresponding spectra. For a given complex CoL, these experiments led to identical spectra for the O_2-saturated solution and for the Ar-saturated solution.

Determination of Equilibrium Constant K_{O_2} by Titration with Dioxygen: In an alternative approach, K_{O_2} at 288 K was determined by stepwise titration of a freshly prepared solution of complex **3** in Ar-saturated DMF with O_2. The titration was carried out in a spherical reaction vessel equipped with an inlet and with a glass tube, the end of which was sealed with a quartz cell fitting into the cell holder of the spectrophotometer. In an Ar-operated glove box, the solution of CoL in Ar-saturated DMF was filled into the reaction vessel. After that, the inlet was sealed with a septum through which twenty portions of O_2 were successively added with a gastight syringe. After each addition, the system was equilibrated at 288 K and a spectrum was recorded. Least-squares fitting of Equation (9) to the observed (A,$[O_2]$) data led to the equilibrium constant K_{O_2}. The data for $[O_2]$ were obtained from the partial pressure of O_2, p_{O_2}, and the Henry constant, K_H, according to $[O_2] = K_H \cdot p_{O_2}$.

$$A = (A_{CoL} + A_{add}\,K_{O_2}\,[O_2])/(1 + K_{O_2}\,[O_2]) \quad (9)$$

Analytical Procedure for Monitoring the Catalytic O_2-Oxidation of Substrates: The oxidation of substrates S according to Equation (10), as catalyzed by **8**, was studied with S = triphenylphosphane and 2,6-di-*tert*-butylphenol. The formation of the oxidation products, $(Ph_3)PO$ and 2,6-di-*tert*-butyl-1,4-benzoquinone, was

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

monitored by ^{31}P NMR and ^{1}H NMR spectroscopy, respectively.[14]

$$S + O_2 \xrightarrow{CoL} S\ (oxid.) \qquad (10)$$

Supporting Information Available (see also footnote on the first page of this article): Table S1, provides visible absorption data of complexes **1**–**8**. Figure S1 presents the calibration curve for the relative concentration of O_2 in DMF at various temperatures, and Figure S2 presents a plot of the (A_{412},[O_2]) data obtained by spectrophotometric monitoring of the titration of complex **3** with O_2 in DMF.

[16] The spectral changes observed during the equilibration of complex **4** with O_2 were clearly affected by partial auto-oxidation of the complex, especially at temperatures above 293 K, and did not allow a reliable determination of K_{O_2}. One can estimate, though, that the dioxygen affinity of complex **4** corresponds to an equilibrium constant $K_{O_2} \geq 200\ M^{-1}$ at 298 K.

[20] For a detailed thermodynamic description of the reaction described by Equation (1) one has to consider the following scheme: $Co^{II}L(DMF) \rightleftharpoons Co^{III}L(DMF)^+ + e^-$ (step 1), $O_2 + e^- \rightleftharpoons O_2^-$ (step 2), $Co^{III}L(DMF)^+ + O_2^- \rightleftharpoons \{Co^{III}L(DMF)^+\}\text{-}\{O_2^-\}$ (step 3). Obviously, the overall reaction, CoL(DMF) + $O_2 \rightleftharpoons$ CoL(DMF)·O_2, is governed by step 1.
[21] The nature of this modified salen ligand is described in Table 4.

[23] Both mechanisms, i.e. the direct delocalization of the unpaired spin density into the cobalt 3d orbitals (inducing positive spin density on the cobalt orbitals) as well as the indirect spin-polarization of the 3d orbitals (inducing negative spin density on the cobalt orbitals), contribute to the cobalt anisotropic hyperfine structure. Since the two mechanisms put spin of opposite sign in the d orbitals, the contribution to the ^{59}Co hyperfine splitting constant stemming from the direct mechanism may cancel the one from the indirect mechanism or vice versa. Synthesis of Palladium(II) and Platinum(II) Complexes with Crown Ether Phosphane Ligands: Stille Coupling of Aryl Iodides in Water

Jorge Fresneda,[b] Ernesto de Jesús,*[a] Pilar Gómez-Sal,[a] and Carmen López Mardomingo[b]

Keywords: Aqueous-phase catalysis / Crown compounds / C–C coupling / Palladium / Phosphane ligands

The crown ether phosphanes $PAr^{\star}Ph_2$ (**1**) and $PAr^{\star}{}_2R$ [$Ar^{\star}$ = 3,4-(18-crown-6)-phenyl; R = Me (**2**); R = Ph (**3**)], prepared from PCl_2R and $Ar^{\star}Li$, have been studied. The syntheses and characterization of their oxides (**4**–**6**), and their BH_3 (**7**–**9**), $PdCl_2$ (**10**–**12**), and $PtCl_2$ (**13**–**15**) complexes are reported. The molecular structure of the borane complex $PAr^{\star}{}_2Ph{\cdot}BH_3$ (**9**) has been determined by X-ray structural analysis. Spectroscopic data suggest that phosphanes **1**–**3** have similar electronic properties and steric requirements to the corresponding phenylphosphane ligands PPh_2Me and PPh_3. Crown ether methylphosphane **2** and its complexes are remarkably water soluble, but **1** and **3** are only slightly soluble. Palladium(II) complexes **14** and **15** have been tested as catalysts in the Stille coupling of phenyltrichlorostannanes and aryl iodides in water.

Introduction

The synthesis and study of metal complexes for aqueous-phase homogeneous catalysis is currently an active research area in organometallic chemistry.[1] Aryl- and alkyl-substituted tertiary phosphanes are among the most common ligands present in transition-metal catalysts, but they are hydrophobic and lack water solubility. Hydrophilicity can be introduced into a phosphane by making use of polar substituents, usually anionic or cationic functions, such as sulfonate or ammonium groups.[2,3] Water solubility has also been achieved with nonionic phosphanes, for example with hydroxyalkyl or polyether substituents but, in general, nonionic phosphanes have attracted less attention than ionic phosphanes. Since the first report by Shaw et al. in 1978,[4] several examples of hybrid crown ether phosphane ligands have appeared in the literature.[5–11] Okano and coworkers have reported the synthesis of mono[3,4-(crown)-phenyl]diphenylphosphane ligands $PAr^{*}Ph_2$ with crown heterocycles of different sizes.[6] The water solubility of these phosphanes is low but the crown cavity acts as an extractant and phase-transfer agent for biphasic catalysis.[5,6,12,13] Crown ether phosphanes contain a secondary site for coordination that can play an important role in catalytic processes.[9,10,14] Here, we report the synthesis of bis[3,4-(18-crown-6)-phenyl] analogs of methyldiphenyl- and triphenylphosphane and the preparation of their $PdCl_2$ and $PtCl_2$ complexes. The palladium complexes are tested as catalysts in Stille carbon–carbon couplings[15,16] in an aqueous medium.[17]

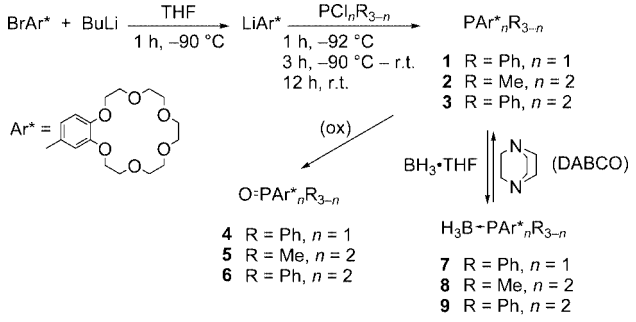
Results and Discussion

Synthesis and Characterization of Crown Ether Phosphanes and Their Complexes

The synthesis of phosphanes $PAr^{*}{}_nR_{3-n}$ [Ar* = 3,4-(18-crown-6)-phenyl, R = Me, *n* = 2 (**2**); R = Ph, *n* = 2 (**3**)] is based on the lithiation of bromo-3,4-(18-crown-6)-benzene and the subsequent reaction of the lithium crown-aryl LiAr* with the corresponding chlorophosphane PCl_nR_{3-n} (Scheme 1), according to the procedure reported previously for the synthesis of $PAr^{*}Ph_2$ (**1**).[6] The main drawback of this procedure lies in the thermal instability[4] of LiAr*, which requires keeping the temperature carefully below the decomposition point (–90 °C) until the reaction with the chlorophosphane is completed, and to use a low concentration of reactants to avoid the formation of a slush at this temperature.[9] In our hands, moderate to high yields (60–90%) were obtained only when the temperature was maintained below –90 °C for at least one hour before and one hour after the addition of the chlorophosphane. The main impurities contaminating the crude product are 1,2-(18-crown-6)-benzene and butylphosphanes derived from unreacted *n*BuLi and chlorophosphanes. In the case of **3**, these are readily removed by crystallization from ethanol/methanol (9:1). In contrast, all our efforts to purify methylphos-

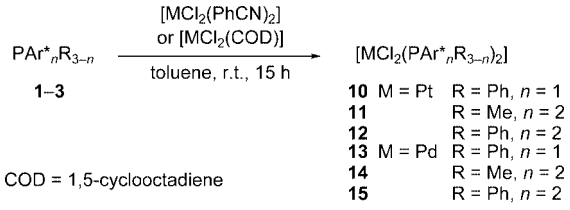
phane **2** by crystallization failed because of its high solubility in water and polar organic media (see below). Moreover, only the oxide **5** was collected from chromatography columns of silica gel or alumina even if an inert atmosphere and deoxygenated solvents were employed. Although triarylphosphanes are more stable, both **1** and **3** were transformed quantitatively into their oxides **4** or **6** when stirred under an air atmosphere for three days at room temperature.



Scheme 1.

The formation of borane adducts is a classical method for the protection of phosphanes against oxidation during purification or synthetic steps (the borane group also plays an activation role in the latter).[18] For the synthesis of the borane complexes **7**–**9**, an equimolar solution of BH_3·THF was treated with the purified phosphanes (only for **1** and **3**) or, alternatively, added directly to the crude product obtained during their preparation. In both cases pure samples of **7**–**9** were obtained in high yields as white, air-stable solids after crystallization from ethanol/methanol. The deprotected phosphanes **1**–**3** were recovered from their borane adducts **7**–**9** by decomplexation with an excess of the diamine ligand 1,4-diazabicyclo[2.2.2]octane (DABCO). A mixture of phosphane, DABCO, and DABCO·BH_3 composed the crude product, from which the phosphanes **1** and **3** were easily separated by crystallization. Again, the properties of **2** complicated the purification of this phosphane, although almost pure samples could be obtained by repeated washings with hexane and long high-vacuum treatments. In practice, we limited the purification step to a short high-vacuum treatment until complete sublimation of the DABCO. Samples thus obtained consisted of a 1.6:1 mixture of phosphane **2** and DABCO·BH_3 and were appropriate for the synthesis of the complexes described here. A clear difference was observed in the complexation/decomplexation process between triarylphosphanes **1** and **3** and methylphosphane **2**. Complexation of the former with BH_3·THF is slower (at room temperature, 24 h for **1** and **3**, and 4 h for **2**) but decomplexation seems to be easier (4 h at 40 °C and 1.2 equiv. of DABCO for **1** and **3**, 5 h at THF reflux and 3.5 equiv. of DABCO for **2**). The enhanced strength of the P–B bond in the more electron-rich phosphane **2** is presumably responsible for these observations. It has been pointed out that BH_3 decomplexation by amine exchange can be an inefficient process for electron-rich, sterically hindered phosphanes.[19]

The platinum (**10**–**12**) and palladium (**13**–**15**) complexes $[MCl_2(PAr^*_nR_{3-n})_2]_2$ were prepared by the displacement of the labile ligand in $[MCl_2(COD)]$ or $[MCl_2(PhCN)_2]$ (Scheme 2). Palladium complex **13** has already been reported[5,6] and is described here only for comparative purposes. The platinum complexes are white solids containing only the *cis* isomers, whereas the palladium ones are yellow and were obtained as *cis*-*trans* mixtures. The *cis*-*trans* ratios obtained (*cis* amount: traces for **13**, 60% for **14**, and 30% for **15**) are independent of the starting material, $[PdCl_2(COD)]$ or $[PdCl_2(PhCN)_2]$. The *cis* and *trans* isomers of **15** were separated on the basis of their different solubility in toluene. The assigned stereochemistry is in agreement with the following experimental data and observations: (*a*) the order of the $^2J(^{31}P\text{-}^{31}P)$ coupling constant, estimated from second-order analysis of the ^1H NMR methyl resonance of PAr^*_2Me complexes,[20] and the ring ^{13}C signals (see below); (*b*) the number of ν(M–X) IR absorptions, two (A_1 + B_1) for *cis*, but one (B_{1u}) for *trans*; (*c*) in square-planar $[MCl_2(PR_3)_2]$ complexes, it has been observed that lower field phosphorus chemical shifts correspond to *cis* and higher field chemical shifts to *trans* isomers in Pd^{II} complexes, whereas the reverse is true for Pt^{II}; (*d*) the estimated phosphorus chemical shift value employing the reported[21] empirical correlation between the chemical shifts of free and coordinated phosphanes; estimated/experimental values are δ = 34.7/33.0 (*cis*-**13**), 23.3/24.1 (*trans*-**13**), 18.4/19.7 (*cis*-**14**), 9.0/7.7 (*trans*-**14**), 35.1/33.4 (*cis*-**15**), and 23.7/23.8 ppm (*trans*-**15**); (*e*) for Pt complexes, yellow colors are typical of *trans* isomers whereas *cis* isomers are usually white;[22] the $^1J(^{31}P\text{-}^{195}Pt)$ value is typically in the range of 2200–2500 Hz for *trans* and 3500–3700 Hz for *cis*-$[PtCl_2(PR_3)_2]$ complexes (3641–3673 Hz for *cis* **10**–**12**).[23]



Scheme 2.

Spectroscopic and analytical data for compounds **2**–**15** are given in the Experimental Section. For the assignment of ^1H and ^{13}C NMR signals and the determination of coupling constants, we applied a combination of selective and broadband ($\{^1H\}$ and $\{^{31}P\}$) decoupling techniques together with the simulation of second-order spectra. The ^{31}P nuclei of the crown ether aryl derivatives **2**–**15** resonate almost at the same position as their parent phenyl analogs (PPh_2Me and PPh_3). For example, the ^{31}P NMR chemical shifts for the pair PAr^*_2Me (**2**)/PPh_2Me are as follows (in $CDCl_3$): δ = –25.6/–28 ppm for the free phosphane,[24] δ = 0.9/–1.2 ppm for the *cis* platinum complex,[25] and δ = 7.7/7.8 ppm for the *trans* palladium complex.[26] Therefore, the steric requirements and electronic properties imposed by the Ar* group to the phosphane ligand are possibly very

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

similar to those of a Ph group. In fact, Storhoff et al.[11] have evaluated the donor/acceptor characteristics of several crown ether containing phosphanes, including **1**, from the A_1 ν(CO) bands for $[Ni(CO)_3L]$ complexes.[27] They reported that the PPh_2Ar^* complex absorbs 0.6 cm^{-1} lower than the PPh_3 analog, thus indicating that the donor ability of crown ether phosphane **1** is apparently only slightly greater than that of triphenylphosphane. The steric bulk of phosphanes is typically expressed in terms of cone angles, usually the Tolman cone angle, θ_{Tol}, originally derived from space-filling models,[28] or the Musco cone angle, θ_{Mus}, derived from phosphane X-ray diffraction data.[29] The estimation of these angles from the ^{31}P NMR spectroscopic data of *trans*-$[PdCl_2(PR_3)_2]$ complexes is possible because an empirical linear relationship has been demonstrated between the ^{31}P chemical shift and θ.[30] As remarked above, chemical shifts of crown ether complexes *trans*-$[PdCl_2(PAr^*_{3-n}R_n)_2]$ [δ = 24.1 (**13**), 7.7 (**14**), and 23.8 ppm (**15**)] match almost exactly those of the related non-crown ether *trans*-$[PdCl_2L_2]$ [δ = 24.4 (L = PPh_3),[31] 7.8 ppm (L = PPh_2Me)[26]]. Thus, it is predicted that Ar* phosphanes should have identical cone angles to Ph phosphanes. The estimated[32] values are θ_{Tol} = 131° and 147°, and θ_{Mus} = 126° and 134° for methyldiaryl and triarylphosphanes, respectively (actual values for PPh_2Me and PPh_3 are θ_{Tol} = 136° and 145°,[28] respectively).

The magnitude of the ^{13}C–^{31}P coupling constants is highly dependent on structural parameters, such as the coordination state of the P atom.[33] One-bond coupling constants between *ipso* Ph or Ar* carbon-13 and phosphorus-31 appear in a well-defined range for each type of compound: $^1J(^{13}C\text{-}^{31}P)$ = 9–11 (**2** and **3**), 105–108 (**4**–**6**), 58–63 (**7**–**9**), 68–71 (*cis*, **10**–**12**), 55–65 (*cis*, **13**–**15**), and 45–55 Hz (*trans*, **13**–**15**). The pattern of the ^{13}C NMR signals is a source of information about the magnitude of $^2J(^{31}P\text{-}^{31}P)$ coupling constants and serves to elucidate the *cis*-*trans* stereochemistry of square-planar $[MCl_2(PR_3)_2]$ complexes. The Me, Ar*, or Ph ^{13}C nuclei in **10**–**15** constitute the X part of an AA′X spin system,[34] where A and A′ are, respectively, the nearest and the most distant ^{31}P nuclei, for which five symmetrically disposed spectral lines are expected. If we assume $J(^{13}C\text{-}^{31}P_{A'})$ to be essentially zero, the actual appearance of the ^{13}C resonance lies between two limiting cases depending on the relative values of $J(^{13}C\text{-}^{31}P_A)$ and $^2J(^{31}P_A\text{-}^{31}P_{A'})$:[23] (*a*) a triplet produced by the weakening of the two outer lines (resonances marked as *pseudo triplets* in the Experimental Section), favored by larger $^2J(^{31}P_A\text{-}^{31}P_{A'})$ values; (*b*) lower $^2J(^{31}P_A\text{-}^{31}P_{A'})$ values favor an apparent doublet of doublets (or a doublet in the limiting case) due to the vanishing of the central line (*pseudo dd* or *d* in the experimental section). For *cis*-Pd complex **15**, all the carbons are split into doublets when coupled with ^{31}P, as expected for $^2J(^{31}P_A\text{-}^{31}P_{A'}) \approx 0$. For *cis*-Pt complexes, the carbons coupled to ^{31}P appear as pseudo triplets, except those with the largest $J(^{13}C\text{-}^{31}P_A)$ (*ipso* Ph, *ipso* Ar*, and Me carbons), which are observed as pseudo dd or d [a quantitative analysis of *ipso* Ph and *ipso* Ar* resonances gives an estimation for $^2J(^{31}P_A\text{-}^{31}P_{A'})$ of 10–14 Hz]. Finally, pseudo triplets for *ipso* Ph, *ipso* Ar*, or Me carbons are observed in the *trans* complexes, according to the larger P–P coupling constants. The simulated spectra of the Ar* protons match the experimental ones satisfactorily when P–P couplings of 0 (for *cis*-Pd), approx. 12 Hz (for *cis*-Pt), and >100 Hz (for *trans*-Pd) are considered in the second-order interpretation.

The solubility of catalysts in water is a relevant parameter when considering processes in this media. Triarylphosphanes **1** and **3** are only slightly soluble in water. Within this reduced solubility, the affinity for water increases with the number of crown-ether aryl groups as shown by the measured water/toluene distribution constants (7.4×10^{-3} for **1**, 1.46×10^{-3} for **3**). In contrast, the methylphosphane **2** is exceptionally water soluble. These differences are reflected in their metal complexes; for example, the palladium triarylphosphane complex **10** is poorly soluble in water (0.002 g/100 mL), whereas the palladium methyldiarylphosphane complex **11** has a remarkable solubility (>10 g/100 mL).

Crystal Structure of Borane–Phosphane 9

The molecular structure of borane complex $PAr^*_2Ph{\cdot}BH_3$ (**9**) based on X-ray structural analysis is given in Figure 1. In spite of the presence of two 18-crown-6 ether rings, the bond distances and angles around the phosphorus atom, which are listed in Table 1, are almost equal to those of $Ph_3P{\cdot}BH_3$.[35] For example, the mean P–C_{ipso} and P–B distances and C_{ipso}–P–C_{ipso} and B–P–C_{ipso} bond angles are, respectively, 1.811(4) and 1.917(5) Å, and 106.0(2)° and 112.6(2)° in **9**, compared with 1.818 and 1.917 Å, and 106.3° and 112.6° in $Ph_3P{\cdot}BH_3$. Complex **9** adopts a three-fold rotor conformation, according to the Dance and Scudder nomenclature,[36] with B–P–C_{ipso}–C_{ortho} torsion angles within the range 30.4–41.5° (mean: 36.8°). In contrast, the conformation of $Ph_3P{\cdot}BH_3$ is irregular, with two rotor rings and the other parallel to the P–B bond. The crown ether ring O(1)–O(6) is folded toward a face of the phenyl ring with an angle between crown and phenyl mean planes of 129.3(1)°, whereas the disposition of the crown ether O(7)–O(12) is almost coplanar [angle between mean planes = 172.4(1)°]. With respect to the plane defined by the *ipso* carbon atoms [C(1), C(17), and C(33)], the crown O(1)–O(6) is placed completely within the semispace opposite the P–B bond (*endo* orientation), whereas O(7)–O(12) has an *exo* orientation, with half of the crown atoms situated in each semispace. The crystallographic cone angle calculated[37] for the phosphane PAr^*_2Ph (**3**) in the solid-state structure of complex **9** is very large (175°). However, single crystallographic cone angles of ligands with significant conformational freedom are not relevant in describing steric effects in solution and are only representative of the conformation adopted in the particular structure. In this sense, the conformation adopted by the crown ether groups in the solid structure of **9** (*exo*-*endo*) is better ascribed to crystal-packing forces than to intermolecular interactions; chang-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ing the conformation to an *endo-endo* disposition reduces the cone angle to 160°. This value is only slightly larger than that of PPh_3 in $Ph_3P{\cdot}BH_3$ (155°).[38]

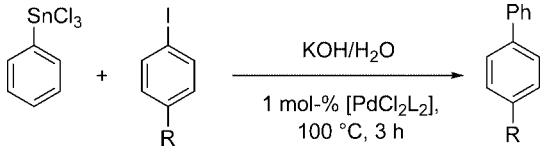
Palladium-Catalyzed Stille Couplings of Phenyltrichlorostannanes and Aryl Halides in Aqueous Solution

In 1993, Zhang and Daves[39] reported the achievement of Stille coupling reactions in aqueous media that they had been unable to accomplish in nonaqueous solvents. However, reactions carried out in water alone gave very low yields owing to the limited solubility of the reactants. Beletskaya[40] and Collum[41] independently reported successful couplings in water alone, thanks to the application of alkyltrichlorostannanes instead of tetraorganotin compounds; the former are less toxic and expensive, and produce water-soluble anionic alkylhydroxostannates in situ in aqueous alkaline solution. The catalyst employed was $PdCl_2$ with or without the addition of sulfonated water-soluble phosphane ligands such as P(*m*-$C_6H_4SO_3Na)Ph_2$[40] or P(*m*-$C_6H_4SO_3Na)_2Ph$,[41] or, in a recent paper by Wolf, $P(OH)(tBu)_2$.[42]

We chose the coupling of $PhSnCl_3$ and *p*-iodotoluene or *p*-iodoaniline, under the Belestkaya–Collum conditions (Scheme 3), to test the efficiency of the palladium complexes **14** and **15** as aqueous-phase catalysts. [$PdCl_2$(COD)] and [$PdCl_2(PPh_3)_2$] were also tested as a reference. Table 2 summarizes our results. Yields were especially high (>86%) for both crown catalysts **14** or **15**, but the less-soluble catalyst **15** gave quantitative yields whereas those of the highly soluble **14** were a bit lower (may be because of the lower stability of methyldiarylphosphane towards oxidation). Surprisingly, Beletskaya and co-workers[40] reported yields of about 85% when employing 1:2 mixtures of $PdCl_2$ and the monosulfonated phosphane P(*m*-$C_6H_4SO_3Na)Ph_2$. Reactions with [$PdCl_2$(COD)] and [$PdCl_2(PPh_3)_2$] proceed in 62 to 75% yields, normally with decomposition of the catalysts and formation of Pd^0.[43]



Scheme 3.

Table 2. Yields in reactions of ArI with $PhSnCl_3$ in the presence of palladium complexes **14** and **15** in aqueous alkaline medium.

Aryl iodide	Product	Catalyst[a]	Yield[b]
p-$NH_2C_6H_4I$	*p*-$NH_2C_6H_4$-C_6H_5	[$PdCl_2$(COD)]	62%

p-$CH_3C_6H_4I$	*p*-$CH_3C_6H_4$-C_6H_5	[$PdCl_2(PAr^*_2Me)_2$] (**14**)	86%
p-$CH_3C_6H_4I$	*p*-$CH_3C_6H_4$-C_6H_5	[$PdCl_2(PAr^*_2Ph)_2$] (**15**)	98% [c]

[a] 1.0 mol-% with respect to the aryl iodide. See Experimental Section for details. [b] Yield of isolated product based on starting ArI. Differences up to 100% were mainly due to unchanged ArI. [c] The reaction proceeded quantitatively and neither starting aryl iodide nor by-products were detected by ^1H NMR spectroscopy or TLC.

Conclusions

We have synthesized the new hybrid phosphane crown ether molecules PAr^*_2Me (**2**) and PAr^*_2Ph (**3**), where Ar* = 3,4-(18-crown-6)-phenyl, and their BH_3, $PtCl_2$, and $PdCl_2$ complexes. Because of the conformational flexibility of the crown ether substituents, the available data suggest that compounds **1–3** are isosteric to the corresponding phenylphosphane ligands (PPh_2Me or PPh_3). If we consider, in addition, the electronic similarity between crown and non-crown ligands, we can conclude that **1–3** are good alternatives to PPh_2Me and PPh_3 when working in aqueous medium. Moreover, the methylphosphane PAr^*_2Me (**2**) furnishes to their complexes a water solubility comparable to those of sulfonated phosphanes. However, solubility is not the only parameter to be considered, as shown by the fact that the only slightly water-soluble phenylphosphane PAr^*_2Ph (**3**) gives the best yields in the Stille coupling reactions in water here studied. Taking into account these preliminary but promising results in catalysis, the work here undertaken is being pursued with the synthesis of new crown ether phosphanes and a more detailed study of Stille and other C–C coupling reactions in water.

Experimental Section

Reagents and General Techniques: All operations were performed under an argon atmosphere by using Schlenk or dry-box tech-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

niques. Solvents were dried and distilled under argon and degassed prior to use, as described elsewhere.[44] Unless otherwise stated, reagents were obtained from commercial sources and used as received. PAr^*Ph_2 (**1**),[6,9] $[PtCl_2(COD)]$, and $[PdCl_2(COD)]$[45] were prepared according to reported procedures. ^1H, ^{13}C, ^{31}P, and ^{11}B NMR spectra were recorded on Varian Unity 300 or 500 Plus spectrometers. Chemical shifts (δ, ppm) are relative to $SiMe_4$ (^1H, ^{13}C), 85% H_3PO_4 (^{31}P), or $F_3B{\cdot}OEt_2$ (^{11}B), and were measured by internal referencing to the deuterated solvent (^{13}C and residual ^1H resonances), or by the substitution method (^{31}P and ^{11}B references). Coupling constants (J) are given in hertz. The ring-numbering system employed in the description of NMR spectroscopic data is given in Figure 2. In ^{13}C NMR, $J_{P\ virtual}$ of *pseudo triplets* (see Results and Discussion) corresponds to $J(^{13}C–^{31}P_A) + J(^{13}C–^{31}P_{A'})$. IR spectra were recorded on a Perkin–Elmer Spectrum 2000 FT-IR spectrometer and data are given in cm^{-1}. The Analytical Services of the Universidad de Alcalá performed the C, H, and N analyses in a Heraeus CHN-O-Rapid microanalyzer, and the MS-ESI+ mass spectra in an Automass Multi, ThermoQuest. MALDI-TOF mass spectra were recorded by the Analytical Services of the Universidad Autónoma de Madrid.

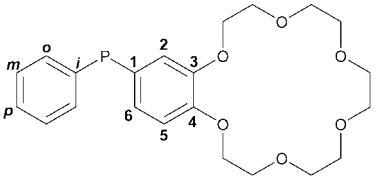

Figure 2. Selected $^{13}C\{^1H\}$ chemical shifts (in ppm) and coupling constants (in Hz) for compounds **2**–**15**, with the ring-labeling scheme employed in the Experimental Section.

PAr^*_2Me (2): The procedure described below for **3** was used for the synthesis of phosphane **2** (0.28 g, 65%) as a colorless oil starting from 4-bromobenzo-3,4-(18-crown-6) (0.500 g, 1.28 mmol), a 1.6 M hexane solution of *n*-butyllithium (0.88 mL, 1.41 mmol), and a 1.0 M solution of dichloromethylphosphane in hexane (0.70 mL, 0.70 mmol). However, this phosphane could not be purified by crystallization as described for **3**, because of its high solubility in water and polar organic media such as methanol or THF. ^1H NMR ($CDCl_3$, 500 MHz): δ = 6.93 [td, J_P = 7.0, J_{H5} = 7.8, J_{H2} = 1.7, 2 H, Ar*(H^6)], 6.87 [dd, J_P = 7.5, 2 H, Ar*(H^2)], 6.82 [dd, J_P = 1.3, 2 H, Ar*(H^5)], 4.12 (m, 4 H, CH_2 crown), 4.07 (m, 4 H, crown), 3.90 (m, 4 H, crown), 3.87 (m, 4 H, crown), 3.74 (m, 8 H, crown), 3.70 (m, 8 H, crown), 3.66 (s, 8 H, crown), 1.51 (d, J_P = 3.3, 3 H, Me) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 75 MHz): δ = 149.53 [s, Ar*(C^4)], 148.38 [d, J_P = 8.1, Ar*(C^3)], 132.23 [d, J_P = 10.3, Ar*(C^1)], 125.46 [d, J_P = 19.9, Ar*(C^2)], 118.02 [d, J_P = 21.4, Ar*(C^6)], 114.00 [d, J_P = 8.1, Ar*(C^5)], 70.85, 70.78, 70.75, 69.65, 69.61, 69.30, 69.03 (s, CH$_2$ crown), 13.24 (d, $J_{C,P}$ = 8.1, Me) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 202 MHz): δ = –25.6 ppm.

PAr^*_2Ph (3): In a 100-mL round-bottomed flask equipped with a low-temperature thermometer, a magnetic stirrer, and a dropping funnel, 4-bromobenzo-3,4-(18-crown-6) (0.500 g, 1.28 mmol) was dissolved in freshly distilled THF (60 mL) and cooled in a methanol/liquid nitrogen slush. The temperature was lowered to –95 °C and then a 1.6 M hexane solution of *n*-butyllithium (0.88 mL, 1.41 mmol) was added dropwise to the cooled and stirred solution, keeping the temperature below –92 °C. The stirring was continued for 90 min while the temperature was carefully maintained in the stated range. Then, dichlorophenylphosphane (0.10 mL, 0.73 mmol) dissolved in THF (1 mL) was added gradually to the stirred mixture over a period of 10 min. The temperature was kept below –90 °C over a period of 60 min and then the reaction mixture was allowed to warm up to room temperature in the course of 3 h. Stirring was continued overnight. The solvent was removed in vacuo and the resulting residue was extracted with dichloromethane (3 × 30 mL). The dichloromethane was removed under reduced pressure to provide a colorless oil. Pure **3** (0.390 g, 83%) was obtained by crystallization of the crude from a mixture of absolute ethanol and methanol (9:1). $C_{38}H_{51}O_{12}P$ (730.79): calcd. C 62.46, H 7.03; found C 62.21, H 6.89. ^1H NMR ($CDCl_3$, 500 MHz): δ = 7.28 (m, 3 H, Ph), 7.22 (m, 2 H, Ph), 6.81 (m, 6 H, Ar*), 4.13 (m, 4 H, CH_2 crown), 4.01 (m, 4 H, crown), 3.91 (m, 4 H, crown), 3.83 (m, 4 H, crown), 3.75 (m, 4 H, crown), 3.74–3.68 (m, 12 H, crown), 3.67 (s, 8 H, crown) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 75 MHz): δ = 149.68 [s, Ar*(C^4)], 148.84 [d, J_P = 9.0, Ar*(C^3)], 138.13 [d, J_P = 10.6, Ar*(C_{ipso})], 133.18 [d, J_P = 18.9, Ph(C_{ortho})], 128.98 [d, J_P = 8.7, Ph(C^1)], 128.38 [s, Ph(C_{para})], 128.33 [d, J_P = 6.7, Ph(C_{meta})], 127.31 [d, J_P = 20.0, Ar*(C^6)], 119.10 [d, J_P = 22.5, Ar*(C^2)], 113.73 [d, J_P = 8.3, Ar*(C^5)], 70.90, 70.79, 70.75, 69.68, 69.57, 69.05, 68.91 (s, CH$_2$ crown) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 202 MHz): δ = –4.4 ppm.

$P(O)Ar^*Ph_2$ (4): Phosphane PAr^*Ph_2 (**1**) (0.15 g, 0.30 mmol) was dissolved in $CHCl_3$ (10 mL). The solution was stirred at room temperature for 3 d under an air atmosphere. Subsequently, the solvent was evaporated to dryness and the residue crystallized from ethanol at –25 °C to give pure oxide **4** as a white solid (0.13 g, 84%). $C_{28}H_{33}O_7P$ (512.54): calcd. C 65.62, H 6.49; found C 65.71, H 6.42. ^1H NMR ($CDCl_3$, 300 MHz): δ = 7.62 [m, J_P = 11.9, 4 H, Ph(H_{ortho})], 7.50 [m, 2 H, Ph(H_{para})], 7.42 [m, 4 H, Ph(H_{meta})], 7.22 [dd, J_P = 12.1, J_{H6} = 1.8, 1 H, Ar*(H^2)], 7.03 [ddd, J_P = 12.1, J_{H5} = 8.1, 1 H, Ar*(H^6)], 6.86 [dd, J_P = 3.1, 1 H, Ar*(H^5)], 4.16 (m, 2 H, CH_2 crown), 4.08 (m, 2 H, crown), 3.91 (m, 2 H, crown), 3.84 (m, 2 H, crown), 3.77–3.66 (m, 12 H, crown) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 75 MHz): δ = 152.09 [s, Ar*(C^4)], 148.90 [d, J_P = 14.7, Ar*(C^3)], 132.89 [d, J_P = 104.7, Ph(C_{ipso})], 131.89 [d, J_P = 14.0, Ph(C_{ortho})], 128.41 [d, J_P = 11.8, Ph(C_{meta})], 131.79 [d, J_P = 2.9, Ph(C_{para})], 126.27 [d, J_P = 11.6, Ar*(C^6)], 124.12 [d, J_P = 108.4, Ar*(C^1)], 116.87 [d, J_P = 11.1, Ar*(C^2)], 112.81 [d, J_P = 14.7, Ar*(C^5)], 70.98, 70.94, 70.83, 70.75, 70.68, 69.49, 69.41, 69.23, 68.94 (s, CH$_2$ crown) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 202 MHz): δ = 30.5 ppm.

$P(O)Ar^*_2Me$ (5) and $P(O)Ar^*_2Ph$ (6): The procedure described above for **4** was used for the synthesis of phosphane oxides **5** (0.084 g, 55%) from **2** (0.150 g, 0.224 mmol), and **6** (0.138 g, 90%) from **3** (0.150 g, 0.205 mmol). The latter was obtained as an oil which was purified by chromatography on a silica gel column using a 1:1 mixture of toluene and ethanol as the mobile phase.

5: $C_{33}H_{49}O_{13}P$ (684.72): calcd. C 57.89, H 7.21; found C 57.95, H 7.08. MS (ESI+): m/z = 707.3 (calcd. for MNa^+: 707.0). ^1H NMR ($CDCl_3$, 500 MHz): δ = 7.19 [dd, J_P = 12.3, J_{H6} = 1.9, 2 H, Ar*(H^2)], 7.13 [ddd, J_P = 12.0, J_{H5} = 8.0, 2 H, Ar*(H^6)], 6.87 [dd, J_P = 2.9, 2 H, Ar*(H^5)], 4.15 (m, 4 H, CH_2 crown), 4.13 (m, 4 H, crown), 3.91 (m, 4 H, crown), 3.89 (m, 4 H, crown), 3.78 (m, 8 H, crown), 3.73 (m, 8 H, crown), 3.65 (s, 8 H, crown), 1.91 (d, J_P = 13.2, 3 H, Me) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 126 MHz): δ = 151.81 [s, Ar*(C^4)], 148.85 [d, J_P = 14.5, Ar*(C^3)], 125.95 [d, J_P = 106.2, Ar*(C^1)], 124.30 [d, J_P = 10.6, Ar*(C^2)], 115.49 [d, J_P = 11.7, Ar*(C^6)], 112.87 [d, J_P = 15.0, Ar*(C^5)], 70.87, 70.81, 70.75, 70.67, 70.66, 70.60, 69.42, 69.32, 69.15, 68.82 (s, CH$_2$ crown), 16.99 (d, J_P = 75.5, Me) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 202 MHz): δ = 31.5 ppm.

6: $C_{38}H_{51}O_{13}P$ (746.79): calcd. C 61.12, H 6.88; found C 60.97, H 6.82. ^1H NMR ($CDCl_3$, 300 MHz): δ = 7.60 [m, J_P = 12.1, 2 H,

Ph(H_{ortho})], 7.50 [m, 1 H, Ph(H_{para})], 7.43 [m, 2 H, Ph(H_{meta})], 7.21 [dd, J_P = 12.5, J_{H6} = 1.7, 2 H, Ar*(H^2)], 7.00 [ddd, J_P = 12.1, J_{H5} = 8.2, 2 H, Ar*(H^6)], 6.86 [dd, J_P = 2.9, 2 H, Ar*(H^5)], 4.13 (m, 4 H, CH_2 crown), 4.01 (m, 4 H, crown), 3.91 (m, 4 H, crown), 3.83 (m, 4 H, crown), 3.75 (m, 4 H, crown), 3.74–3.67 (m, 12 H, crown), 3.66 (s, 8 H, crown) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 126 MHz): δ = 151.82 [s, Ar*(C^4)], 148.87 [d, J_P = 14.5, Ar*(C^3)], 132.92 [d, J_P = 12.4, Ph(C_{ortho})], 131.52 [d, J_P = 2.6, Ph(C_{para})], 130.01 [d, J_P = 105.6, Ph(C_{ipso})], 128.55 [d, J_P = 11.5, Ph(C_{meta})], 126.68 [d, J_P = 12.0, Ar*(C^6)], 124.02 [d, J_P = 106.9, Ar*(C^1)], 117.52 [d, J_P = 12.1, Ar*(C^2)], 113.03 [d, J_P = 14.3, Ar*(C^5)], 70.93, 70.83, 70.80, 70.67, 70.65, 70.42, 69.45, 69.18, 68.89 (s, CH$_2$ crown) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 202 MHz): δ = 31.3 ppm.

Ar*Ph$_2$P·BH$_3$ (7): PAr*Ph$_2$ (**1**; 0.11 g, 0.22 mmol) was dissolved in THF (20 mL) and a 1.0 M solution of BH_3·THF in THF (0.22 mL, 0.22 mmol) was added with a syringe. The mixture was stirred at room temperature for 24 h. The solvent was subsequently removed under vacuum to give a white solid. Pure borane complex **7** (0.097 g, 85%) was obtained after crystallization of the crude product from a mixture of absolute ethanol and methanol (18:1) at –25 °C. $C_{28}H_{36}BO_6P$ (510.38): calcd. C 65.89, H 7.11; found C 66.01, H 7.08. MS (ESI+): m/z = 534.0 (calcd. for MNa^+: 533.2), 520.0 (calcd. for MNa^+ – BH_3: 519.2). ^1H NMR ($CDCl_3$, 300 MHz): δ = 7.52 [m, J_P = 10.8, 4 H, Ph(H_{ortho})], 7.47 [m, 2 H, Ph(H_{para})], 7.43 [m, 4 H, Ph(H_{meta})], 7.10 [dd, J_P = 11.4, J_{H6} = 1.8, 1 H, Ar*(H^2)], 7.05 [ddd, J_P = 10.4, J_{H5} = 8.2, 1 H, Ar*(H^6)], 6.87 [dd, J_P = 2.4, 1 H, Ar*(H^5)], 4.15 (m, 2 H, CH_2 crown), 4.05 (m, 2 H, crown), 3.91 (m, 2 H, crown), 3.84 (m, 2 H, crown), 3.74 (m, 2 H, crown), 3.71 (m, 2 H, crown), 3.70 (m, 2 H, crown), 3.68 (m, 2 H, crown), 3.65 (s, 4 H, crown), 1.5–0.6 (very broad, BH_3) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 126 MHz): δ = 151.64 [d, J_P = 2.2, Ar*(C^4)], 148.98 [d, J_P = 12.8, Ar*(C^3)], 133.03 [d, J_P = 9.5, Ph(C_{ortho})], 132.04 [d, J_P = 2.2, Ph(C_{para})], 129.65 [d, J_P = 57.8, Ph(C_{ipso})], 128.67 [d, J_P = 10.0, Ph(C_{meta})], 127.38 [d, J_P = 9.5, Ar*(C^6)], 120.07 [d, J_P = 62.3, Ar*(C^1)], 118.21 [d, J_P = 12.8, Ar*(C^2)], 113.28 [d, J_P = 12.23, Ar*(C^5)], 70.94, 70.89, 70.80, 70.71, 70.67, 69.45, 69.37, 69.17, 68.88 (s, CH$_2$ crown) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 202 MHz): δ = 21.5 ppm.

Ar*$_2$MeP·BH$_3$ (8): The procedure described above for **7** was used for the synthesis of borane complex **8** starting from the crude product **2** (0.35 g, 0.52 mmol) and a 1.0 M solution of BH_3·THF in THF (0.52 mL, 0.52 mmol). In this case, the reaction time was reduced to 4 h, and the crude product was recrystallized three times from a mixture of absolute ethanol and methanol (18:1) at –25 °C to provide 0.21 g (60%) of an analytically pure solid which was identified as **8**. $C_{33}H_{52}BO_{12}P$ (682.55): calcd. C 58.07, H 7.68; found C 58.30, H 7.63. MS (ESI+): m/z = 706.0 (calcd. for MNa^+: 705.3). IR (KBr pellets): ν(BH) = 2371 s. ^1H NMR ($CDCl_3$, 500 MHz): δ = 7.19 [dd, J_P = 12.3, J_{H6} = 1.9, 2 H, Ar*(H^2)], 7.13 [ddd, J_P = 12.0, J_{H5} = 8.0, 2 H, Ar*(H^6)], 6.87 [dd, J_P = 2.9, 2 H, Ar*(H^5)], 4.15 (m, 4 H, CH_2 crown), 4.13 (m, 4 H, crown), 3.91 (m, 4 H, crown), 3.89 (m, 4 H, crown), 3.78 (m, 8 H, crown), 3.73 (m, 8 H, crown), 3.65 (s, 8 H, crown), 1.74 (d, J_P = 10.3, 3 H, Me), 1.3–0.5 (very broad, BH_3) ppm. $^{11}B\{^1H\}$ NMR ($CDCl_3$, 160 MHz): δ = –39 ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 126 MHz): δ = 151.52 [s, Ar*(C^4)], 148.97 [d, J_P = 13.3, Ar*(C^3)], 125.52 [d, J_P = 8.9, Ar*(C^6)], 122.20 [d, J_P = 60.5, Ar*(C^1)], 117.25 [d, J_P = 11.8, Ar*(C^2)], 113.55 [d, J_P = 13.3, Ar*(C^5)], 70.91, 70.85, 70.77, 70.68, 69.50, 69.39, 68.94 (s, CH$_2$ crown), 12.5 (d, J_P = 41.3, Me) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 202 MHz): δ = 10.2 ppm.

Ar*$_2$PhP·BH$_3$ (9): The procedure described above for **7** was used for the synthesis of borane complex **9** (0.308 g, 90%) from **3** (0.250 g, 0.342 mmol). The presence of 1 equiv. of MeOH in the crystalline white solid is suggested by the elemental analyses and confirmed by NMR spectra (resonances of the methanol are omitted in the spectroscopic data below). $C_{38.5}H_{56}BO_{12.5}P$ (760.65, includes 1/2 a molecule of methanol): calcd. C 60.79, H 7.42; found C 60.74, H 7.36. ^1H NMR ($CDCl_3$, 500 MHz): δ = 7.49 [m, J_P = 10.8, 2 H, Ph(H_{ortho})], 7.47 [m, 1 H, Ph(H_{para})], 7.38 [m, 2 H, Ph(H_{meta})], 7.08 [dd, J_P = 11.4, J_{H6} = 1.8, 2 H, Ar*(H^2)], 7.00 [ddd, J_P = 8.6, J_{H5} = 8.4, 2 H, Ar*(H^6)], 6.85 [dd, J_P = 2.6, 2 H, Ar*(H^5)], 4.15 (m, 4 H, CH_2 crown), 4.05 (m, 4 H, crown), 3.91 (m, 4 H, crown), 3.84 (m, 4 H, crown), 3.75 (m, 4 H, crown), 3.74–3.67 (m, 12 H, crown), 3.66 (s, 8 H, crown), 1.5–0.6 (very broad, BH_3) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 75 MHz): δ = 151.50 [s, Ar*(C^4)], 148.98 [d, J_P = 13.3, Ar*(C^3)], 132.89 [d, J_P = 9.6, Ph(C_{ortho})], 130.95 [d, J_P = 3.0, Ph(C_{para})], 130.11 [d, J_P = 58.2, Ph(C_{ipso})], 128.60 [d, J_P = 10.3, Ph(C_{meta})], 127.17 [d, J_P = 8.9, Ar*(C^6)], 120.57 [d, J_P = 62.7, Ar*(C^1)], 117.97 [d, J_P = 12.5, Ar*(C^2)], 113.17 [d, J_P = 12.5, Ar*(C^5)], 70.90, 70.82, 70.78, 70.69, 70.63, 70.41, 69.36, 69.12, 68.84 (s, CH$_2$ crown) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 202 MHz): δ = 21.0 ppm.

Decomplexation of Phosphane–Borane Complex 7: This was carried out as described below for complex **9**.

Decomplexation of Phosphane–Borane Complex 8: Complex **8** (0.044 g, 0.065 mmol) and 1,4-diazabicyclo[2.2.2]octane (DABCO) (0.0174, 0.16 mmol) were dissolved in THF (5 mL). The mixture was refluxed at 85 °C for 5 h and then allowed to cool to room temperature. The solvent was removed under reduced pressure and complete decomplexation was evidenced by ^1H NMR spectroscopy. The excess of DABCO was completely eliminated under high vacuum at room temperature and the DABCO·BH_3 formed in the reaction was partially removed in this treatment. The final product was found to be a mixture of phosphane **2** and DABCO·BH_3 (1.6:1, ^1H NMR).

Decomplexation of Phosphane–Borane Complex 9: Complex **9** (0.22 g, 0.30 mmol) and the DABCO ligand (0.040, 0.36 mmol) were dissolved in toluene (20 mL). The mixture was stirred at 40 °C for 4 h. The solvent was removed under reduced pressure and the crude product was identified as a 1:1 mixture of phosphane **3** and complex BH_3·DABCO (^1H NMR), showing that decomplexation was complete. Phosphane **3** (0.20 g, 90%) could be purified by crystallization of the crude mixture with ethanol at –25 °C.

[PtCl$_2$(PAr*Ph$_2$)$_2$] (10): The procedure described below for **12** was used for the synthesis of platinum complex **10** starting from phosphane **1** (0.067 g, 0.13 mmol) and [$PtCl_2$(PhCN)$_2$] (0.028 g, 0.059 mmol). Complex **10** was obtained as a pure white solid containing only the *cis* isomer (0.062 g, 83%). $C_{56}H_{66}Cl_2O_{12}P_2Pt$ (1259.07): calcd. C 53.42, H 5.28; found C 53.11, H 5.31. MS (ESI+): m/z = 1281.0 (calcd. for MNa^+: 1280.3). IR (Nujol): ν(Pt–Cl) = 318, 292. ^1H NMR ($CDCl_3$, 500 MHz): δ = 7.44 [m, 8 H, Ph(H_{ortho})], 7.28 [m, 4 H, Ph(H_{para})], 7.14 [m, 8 H, Ph(H_{meta})], 7.09 [m, J_P = 10.5, J_{H6} = 2.0, 2 H, Ar*(H^2)], 6.93 [m, $J_P \approx$ 8, 2 H, Ar*(H^6)], 6.59 [dd, J_P = 2.2, J_{H5} = 8.3, 2 H, Ar*(H^5)], 4.10 (m, 4 H, CH_2 crown), 3.90 (m, 4 H, crown), 3.76 (m, 8 H, crown), 3.74 (m, 8 H, crown), 3.69 (m, 8 H, crown), 3.66 (s, 8 H, crown) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 75 MHz): δ = 151.07 [d, J_P = 2.2, Ar*(C^4)], 147.67 [pseudo t, $J_{P\,virtual}$ = 14.4, Ar*(C^3)], 134.44 [pseudo t, $J_{P\,virtual}$ = 9.6, Ph(C_{ortho})], 130.47 [s, Ph(C_{para})], 130.01 [pseudo dd, $J_{apparent}$ = 68.0 and 2.4, Ph(C_{ipso})], 129.01 [pseudo t, $J_{P\,virtual}$ = 9.6, Ar*(C^6)], 127.66 [pseudo t, $J_{P\,virtual}$ = 11.6, Ph(C_{meta})], 120.09 [pseudo dd, $J_{apparent}$ = 68.0 and 1.6, Ar*(C^1)], 120.39 [pseudo t, J_P = 12.6, Ar*(C^2)], 112.03 [pseudo t, J_P = 12.8, Ar*(C^5)], 70.93, 70.90, 70.79, 70.69, 70.58, 69.32, 68.92, 68.79 (s, CH$_2$ crown) ppm.

$^{31}P\{^1H\}$ NMR ($CDCl_3$, 202 MHz): δ = 15.1 (s with ^{195}Pt satellites, J_{Pt} = 3669 Hz).

[$PtCl_2$(PAr*$_2$Me)$_2$] (11): Phosphane–borane complex **8** (0.044 g, 0.065 mmol) and DABCO (0.0174 g, 0.15 mmol) were refluxed in THF for 5 h. The solvent was removed and the residue was treated with 1 equiv. of [$PtCl_2$(PhCN)$_2$] (0.015 g, 0.032 mmol) in toluene (5 mL). The mixture was stirred at room temperature for 15 h. Subsequently, the solvent was removed in vacuo and the residue washed with hexane. The crude product thus obtained, a mixture of *cis*-**11** and BH_3·DABCO, was chromatographed on a neutral alumina column using a 9:1 mixture of toluene and ethanol as mobile phase. Complex **11** was obtained as a solid and the *cis* isomer (0.032 g, 63%). $C_{66}H_{98}Cl_2O_{24}P_2Pt$ (1603.42): calcd. C 49.44, H 6.16; found C 49.20, H 6.08. MS (MALDI-TOF): *m*/*z* = 1624.4 (calcd. for MNa^+: 1624.48). IR (Nujol): ν(Pt–Cl) = 312, 285. ^1H NMR ($CDCl_3$, 500 MHz,): δ = 7.08 [m, J_P = 12.1, 4 H, Ar*(*H*^{2})], 6.99 [m, $J_P \approx$ 8, 4 H, Ar*(*H*^{6})], 6.71 [dd, J_{H5} = 8.3, J_P = 2.0, 4 H, Ar*(*H*^{5})], 4.12 (m, 8 H, CH_2 crown), 4.00–3.83 (m, 16 H, CH_2 crown), 3.74–3.67 (m, 32 H, CH_2 crown), 3.65 (s, 16 H, CH_2 crown), 1.79 (d, J_P = 10.3, 6 H, Me) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 126 MHz): δ = 151.35 [s, Ar*(*C*^{4})], 148.46 [pseudo t, $J_{P\ virtual}$ = 13.4, Ar*(*C*^{3})], 126.65 [pseudo t, $J_{P\ virtual}$ = 11.2, Ar*(*C*^{6})], 122.23 [d, J_P = 68.4, Ar*(*C*^{1})], 118.26 [pseudo t, $J_{P\ virtual}$ = 14.4, Ar*(*C*^{2})], 112.81 [pseudo t, $J_{P\ virtual}$ = 14.4, Ar*(*C*^{5})], 70.91, 70.84, 70.79, 70.74, 70.67, 70.62, 69.41, 69.38, 68.90 (s, *C*H_2 crown), 17.71 (d, J_P = 47.8, Me) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 202 MHz): δ = 0.9 (s with ^{195}Pt satellites, J_{Pt} = 3641 Hz).

[$PtCl_2$(PAr*$_2$Ph)$_2$] (12): Phosphane **3** (0.185 g, 0.25 mmol) and [$PtCl_2$(PhCN)$_2$] (0.060 g, 0.125 mmol) were dissolved in toluene (5 mL). The mixture was stirred at room temperature for 15 h. Then, the solvent was removed in vacuo, the residue washed several times with hexane, and crystallized by addition of absolute methanol to afford **12** as a white solid (0.198 g, 90%). Alternatively, the reaction time was reduced to 1 h when [$PtCl_2$(COD)] (COD = 1,5-cyclooctadiene) was used instead of [$PtCl_2$(PhCN)$_2$]. In both cases, only the *cis* isomer was detected. $C_{76}H_{102}Cl_2O_{24}P_2Pt$ (1727.56): calcd. C 52.84, H 5.95; found C 52.78, H 5.98. IR (Nujol): ν(Pt–Cl) = 317, 290. ^1H NMR ($CDCl_3$, 300 MHz): δ = 7.42 [m, J_P = 9.0, 4 H, Ph(*H*$_{ortho}$)], 7.27 [m, 2 H, Ph(*H*$_{para}$)], 7.15 [m, 4 H, Ph(*H*$_{meta}$)], 7.09 [m, J_P = 12.0, J_{H6} = 1.8, 4 H, Ar*(*H*^{2})], 6.86 [m, J_P = 10.2, 4 H, Ar*(*H*^{6})], 6.57 [dd, J_{H5} = 8.5, J_P = 2.3, 4 H, Ar*(*H*^{5})], 4.11 (m, 8 H, CH_2 crown), 3.90 (m, 8 H, crown), 3.75 (m, 16 H, crown), 3.70 (m, 16 H, crown), 3.67 (m, 16 H, crown), 3.65 (s, 16 H, crown) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 75 MHz): δ = 151.02 [s, Ar*(*C*^{4})], 147.75 [pseudo t, $J_{P\ virtual}$ = 15.2, Ar*(*C*^{3})], 134.25 [pseudo t, $J_{P\ virtual}$ = 9.4, Ph(*C*$_{ortho}$)], 131.00 [pseudo dd, $J_{apparent}$ = 62.4 and 2.3, Ph(*C*$_{ipso}$)], 130.38 [s, Ph(*C*$_{para}$)], 128.88 [pseudo t, $J_{P\ virtual}$ = 10.6, Ar*(*C*^{6})], 127.62 [pseudo t, J_P = 11.4, Ph(*C*$_{meta}$)], 120.85 [pseudo dd, $J_{apparent}$ = 70.6 and 1.5, Ar*(*C*^{1})], 120.40 [pseudo t, J_P = 13.2, Ar*(*C*^{2})], 112.04 [d, J_P = 13.2, Ar*(*C*^{5})], 70.91, 70.85, 70.79, 70.72, 70.69, 70.56, 69.38, 69.31, 68.97, 68.79 (s, *C*H_2 crown) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 202 MHz): δ = 14.8 (s with ^{195}Pt satellites, J_{Pt} = 3673 Hz).

[$PdCl_2$(PAr*Ph_2)$_2$] (13): This complex has been previously reported by Okano et al.[6] We employed the same procedure as described above for **12**. The crude product contains traces of the *cis* isomer (δ_P = 33.0 ppm), but after crystallization complex **13** was obtained as a pure yellow solid containing only the *trans* isomer (90%). $C_{56}H_{66}Cl_2O_{12}P_2Pd$ (1170.41): calcd. C 57.47, H 5.68; found C 57.80, H 5.63. MS (ESI+): *m*/*z* = 1193.6 (calcd. for MNa^+: 1192.2). IR (Nujol): ν(Pd–Cl) = 359. ^1H NMR ($CDCl_3$, 300 MHz): δ = 7.62 [m, 8 H, Ph(*H*$_{ortho}$)], 7.45 [td, $J_{P\ virtual}$ = 12.0, J_{H6} = 1.9, 2 H, Ar*(*H*^{2})], 7.40–7.30 [m, 12 H, Ph(*H*$_{meta}$) and Ph(*H*$_{para}$) overlapping], 7.14 [m, $J_{P\ virtual}$ = 10.4, J_{H5} = 8.4, 2 H, Ar*(*H*^{6})], 6.82 [br. d, $J_{P\ virtual} \approx$ 2.0, 2 H, Ar*(*H*^{5})], 4.14 (m, 4 H, CH_2 crown), 4.00 (m, 4 H, crown), 3.91 (m, 4 H, crown), 3.79 (m, 4 H, crown), 3.74 (m, 4 H, crown), 3.70–3.68 (m, 12 H, crown), 3.65 (s, 8 H, crown) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 75 MHz): δ = 151.03 [s, Ar*(*C*^{4})], 148.16 [pseudo t, $J_{P\ virtual}$ = 14.8, Ar*(*C*^{3})], 134.79 [pseudo t, $J_{P\ virtual}$ = 11.8, Ph(*C*$_{ortho}$)], 130.33 [s, Ph(*C*$_{para}$)], 130.21 [pseudo t, J_P = 50.1, Ph(*C*$_{ipso}$)], 128.94 [pseudo t, $J_{P\ virtual}$ = 11.8, Ar*(*C*^{6})], 127.90 [pseudo t, $J_{P\ virtual}$ = 8.8, Ph(*C*$_{meta}$)], 121.08 [pseudo t, $J_{P\ virtual}$ = 14.8, Ar*(*C*^{2})], 120.80 [pseudo t, $J_{P\ virtual}$ = 53.2, Ar*(*C*^{1})], 112.76 [pseudo t, $J_{P\ virtual}$ = 5.6, Ar*(*C*^{5})], 70.97, 70.83, 70.79, 70.75, 70.66, 69.46, 69.05, 68.84 (s, *C*H_2 crown) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 202 MHz): δ = 24.1 ppm.

[$PdCl_2$(PAr*$_2$Me)$_2$] (14): The procedure described above for **11** was used for the synthesis of palladium complex **14** starting from **8** (0.064 g, 0.094 mmol), DABCO (0.041 g, 0.37 mmol), and [$PdCl_2$(COD)] (0.012 g, 0.042 mmol). Although complex **14** was formed in greater than 95% yield (^1H NMR evidence) as a pair of *cis*/*trans* isomers (1:0.75), the resultant oil could not be purified by crystallization or chromatography and was used in this form in further catalytic studies. In the NMR spectroscopic data of the unpurified *cis*/*trans* mixture that follows, resonances corresponding to the BH_3·DABCO impurity are omitted, and the *cis*/*trans* ratio has been taken into account in integral values. IR (Nujol): ν(Pd–Cl) = 356 (*trans*), 287, 276 (*cis*). ^1H NMR ($CDCl_3$, 500 MHz,): δ = 7.223 and 7.216 [overlapping m, $J_P \approx$ 10–14, 8 H, Ar*(*H*^{6}) and Ar*(*H*^{2}) *trans* isomer], 7.07 [dd, J_P = 12.4, J_{H6} = 1.9, 4 H, Ar*(*H*^{2}) *cis* isomer], 6.97 [ddd, J_P = 11.8, J_{H5} = 8.3, 4 H, Ar*(*H*^{6}) *cis* isomer], 6.86 [br. d, J_{H6} = 8.4, J_P not observed, 4 H, Ar*(*H*^{5}) *trans* isomer], 6.72 [dd, J_P = 2.6, 4 H, Ar*(*H*^{5}) *cis* isomer], 4.15–3.66 (overlapped m, 80 H, CH_2 crown, *cis* and *trans* isomers), 1.96 (pseudo t, $J_{P\ virtual}$ = 7.1, 6 H, Me *trans* isomer), 1.91 (d, J_P = 11.1, 3 H, Me *cis* isomer) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 126 MHz): δ = 151.49, 150.93 [s, Ar*(*C*^{4})], 148.65 [d, J_P = 14.3, Ar*(*C*^{3}) *cis* isomer], 148.36 [pseudo t, $J_{P\ virtual}$ = 14.1, Ar*(*C*^{3}) *trans* isomer], 126.8 [m, Ar*(*C*^{6}) *cis* and *trans* overlapping], 123.61 [pseudo t, $J_{P\ virtual}$ = 52.0, Ar*(*C*^{1}) *trans* isomer], 122.78 [d, J_P = 57.5, Ar*(*C*^{1}) *cis* isomer], 118.78 [pseudo t, $J_{P\ virtual}$ = 14.4, Ar*(*C*^{2}) *trans* isomer], 118.22 [d, J_P = 13.8, Ar*(*C*^{2}) *cis* isomer], 113.00 [m, Ar*(*C*^{5}) *cis* and *trans* overlapping], 70.97, 70.95, 70.85, 70.82, 70.76, 70.69, 70.64, 69.48, 69.41, 69.24, 68.91, 68.85 (s, *C*H_2 crown), 18.6 (overlapping d and m, Me) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 202 MHz): δ = 19.7 (*cis*), 7.7 (*trans*).

[$PdCl_2$(PAr*$_2$Ph)$_2$] (15): The procedure described above for **12** was used for the synthesis of palladium complex **15** starting from phosphane **3** (0.168 g, 0.25 mmol) and [$PdCl_2$(PhCN)$_2$] (0.048 g, 0.125 mmol). A yellow solid was obtained (0.20 g, 98%) that was identified by NMR spectroscopy as a 3:7 mixture of *cis*/*trans* isomers of complex **15**. Both isomers were easily separated because of their different solubility in toluene. The soluble *cis* isomer was extracted in this solvent and subsequently crystallized from methanol whereas the insoluble residue containing the *trans* isomer was crystallized from CH_2Cl_2/toluene. Both were obtained as deep-yellow solids.

***trans*-15:** $C_{76}H_{102}Cl_2O_{24}P_2Pd$ (1638.90): calcd. C 55.70, H 6.27; found C 55.54, H 6.20. 3.68 (m, 24 H, crown), 3.67 (s, 16 H, crown) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 75 MHz): δ = 150.93 [s, Ar*(C^4)], 148.98 [pseudo t, $J_{P\ virtual}$ = 14.8, Ar*(C^3)], 134.59 [pseudo t, $J_{P\ virtual}$ = 11.8, Ph(C_{ortho})], 130.81 [pseudo t, $J_{P\ virtual}$ = 45.4, Ph(C_{ipso})], 130.19 [s, Ph(C_{para})], 128.78 [pseudo t, $J_{P\ virtual}$ = 11.8, Ar*(C^6)], 127.82 [pseudo t, J_P = 10.4, Ph(C_{meta})], 121.25 [pseudo t, $J_{P\ virtual}$ = 53.0, Ar*(C^1)], 120.86 [m, Ar*(C^2), overlapping with Ar*(C^1)], 113.17 [d, J_P = 12.5, Ar*(C^5)], 70.98, 70.94, 70.85, 70.78, 70.65, 69.49, 69.13, 68.85 (s, CH_2 crown) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 202 MHz): δ = 23.8 ppm.

***cis*-15:** $C_{76}H_{102}Cl_2O_{24}P_2Pd$ (1638.90): calcd. C 55.70, H 6.27; found C 55.78, H 6.19. IR (Nujol): ν(Pd–Cl) = 287, 276. ^1H NMR ($CDCl_3$, 300 MHz): δ = 7.63 [m, J_P = 12.6, 4 H, Ph(H_{ortho})], 7.45 [m, 2 H, Ph(H_{para})], 7.38 [m, 4 H, Ph(H_{meta})], 7.29 [dd, J_P = 13.2, J_{H6} = 1.8, 4 H, Ar*(H^2)], 7.05 [ddd, J_P = 12.1, J_{H5} = 8.4, 4 H, Ar*(H^6)], 6.80 [dd, J_P = 2.5, 4 H, Ar*(H^5)], 4.15 (m, 8 H, CH_2 crown), 4.07 (m, 8 H, crown), 3.92 (m, 8 H, crown), 3.80 (m, 8 H, crown), 3.75 (m, 8 H, crown), 3.71–3.68 (m, 24 H, crown), 3.67 (s, 16 H, crown) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 75 MHz): δ = 151.89 [d, $J_P \approx$ 1.0, Ar*(C^4)], 148.30 [d, J_P = 15.5, Ar*(C^3)], 134.40 [d, J_P = 11.6, Ph(C_{ortho})], 131.51 [s, Ph(C_{para})], 128.76 [d, J_P = 3.9, Ar*(C^6)], 128.31 [d, J_P = 12.2, Ph(C_{meta})], 128.28 [d, J_P = 54.7, Ph(C_{ipso})], 120.09 [d, J_P = 14.9, Ar*(C^2)], 118.31 [d, J_P = 64.7, Ar*(C^1)], 112.45 [d, J_P = 15.5, Ar*(C^5)], 71.01, 70.95, 70.86, 70.73, 70.71, 70.58, 69.39, 69.34, 69.26, 68.83 (s, CH_2 crown) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 202 MHz): δ = 33.4 ppm.

Water Solubility of Complexes 10 and 11: The extent of water solubility was assessed by placing a small, accurately weighted quantity of the compound in a vial, followed by slow addition of water, with stirring, from a 50 μL syringe. Solubility measurements were repeated several times to give an average value. Measured solubility in water at 25 °C: 0.002 g/100 mL (**10**) and 10 g/100 mL (**11**).

Distribution Coefficients Between Toluene and Water for Phosphanes 1 and 3: Previously, the UV spectra of phosphanes **1** and **3** were registered in ethanol at several concentrations (from ca. 1×10^{-5} to 1×10^{-4} M). Two absorption bands were observed at λ_{max} = 203 and 261 nm for **1**, and 208 and 283 nm for **3**. Fits of *c* versus *A* plots showed a linear correlation in the entire range of concentrations considered only in the case of the second maximum absorption ($R^2 > 0.999$). Thus, the absorptions at 261 nm (ε = 12100) for **1**, and 283 nm (ε = 13300) for **3** were used as follows in the determination of distribution coefficients. A small, accurately weighted quantity of phosphane (approx. 0.02 mmol) was added to a 1:1 mixture of toluene and water (5 + 5 mL) that was stirred for 20 min at 25 °C. An aliquot of the aqueous solution (2 mL) was removed with a pipette, evaporated to dryness, and dissolved in ethanol (3 mL). The original water-phase concentration was determined by measuring the concentration of phosphane in the ethanol solution by UV spectroscopy, using the *c* versus *A* plots previously obtained. At 25 °C, distribution constants, defined as $[phosphane]_{aq}/[phosphane]_{toluene}$, are 7.4×10^{-3} for **1**, and 1.46×10^{-2} for **3**.

Palladium-Catalyzed Stille Couplings: We used similar conditions to those previously described.[40,41] In a typical experiment, $PhSnCl_3$ (0.31 mL, 1.824 mmol) was dissolved in 2 mL of degassed water. The solution was treated with 5.5 mL of aqueous KOH (1 M) and stirred for several minutes. The *p*-iodoaniline (0.339 g, 1.52 mmol) and the Pd catalyst **14** (0.023 g, 0.0152 mmol) were then added and the mixture was stirred for 3 h at 100 °C under argon. The product was extracted with diethyl ether and dried with sodium sulfate. The solution was filtered off and the solvent removed in vacuo to give a solid. The crude product was analyzed by HPLC-MS and ^1H NMR spectroscopy (95% 4-aminobiphenyl, 5% *p*-iodoaniline) and purified by flash chromatography on silica gel with toluene/ethanol (9:1) to give pure 4-aminobiphenyl (0.244 g, 95%).

X-ray Structure Determinations: White, needle-shaped crystals of **9** were obtained from methanol/ethanol at –25 °C. A summary of crystal data, data collection, and refinement parameters for the structural analysis is given in Table 3. The crystal was glued to a glass fiber and mounted on a Kappa-CCD Bruker–Nonius diffractometer with area detector, and data were collected using graphite monochromated Mo-K_α radiation (λ = 0.71073 Å). Data collection was performed at 200 K, with an exposure time of 24 s per frame (3 sets; 247 frames). Raw data were corrected for Lorenz and polarization effects. The structure was solved by direct methods, completed by subsequent difference Fourier techniques, and refined by full-matrix least-squares on F^2 (SHELXL-97).[46] Anisotropic thermal parameters were used in the last cycles of refinement for the non-hydrogen atoms. Most of the hydrogen atoms were found in the final Fourier map and were refined with isotropic thermal displacement parameters, others were introduced in the last cycle of refinement from geometrical calculations and refined using a riding model. A molecule of methanol with important disorder was located; the hydrogen atoms of the methyl group are not included. All the calculations were made using the WINGX system.[47]

CCDC-253624 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

An Efficient Keim-Type Catalyst Based on an Electron-Poor *P,O*-Chelate; Tuning the Selectivity of Ethylene Oligomerisation towards Short α-Olefins

Pierre Kuhn,[a] David Sémeril,[a] Catherine Jeunesse,[a] Dominique Matt,*[a] Pierre Lutz,*[b] and Richard Welter[c]

Keywords: Nickel *P,O* complexes / 4-Phosphanylpyrazolonate / Oligomerisation / Phosphorus ylides / Electron-withdrawing ligands / X-ray diffraction

The tertiary phosphane Ph_2P-pzONa, in which the phosphorus atom is substituted by an electron-withdrawing pyrazolonato unit, reacts with *trans*-[NiPhCl(PPh_3)$_2$] to afford quantitatively *trans-P,P′*-[NiPh(Ph_2P-pzO)(PPh_3)] (**4**), the first Keim-type catalyst derived from an amide. In the absence of any cocatalyst, complex **4** converts ethylene in high selectivity and activity into α-olefins. The product distribution is drastically shifted towards lower oligomers when compared to the outcome of the reaction carried out with the conventional SHOP catalyst. Thus, when operating at 1 bar, over 99 wt.-% of the oligomers formed are C_4–C_{16} oligomers. In ethylene-free solvents, **4** was shown to slowly undergo reductive elimination to produce the stabilised phosphorus ylide Ph_3P-pzO (**5**). Both compounds (**4** and **5**) were characterised by single-crystal X-ray diffraction analyses.

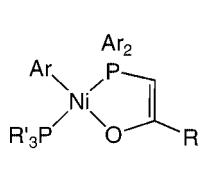
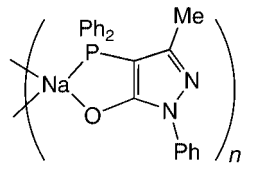
Introduction

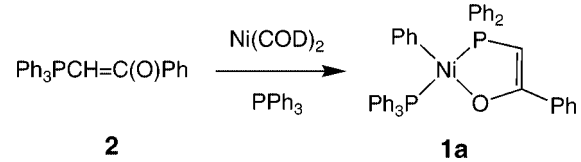
Square-planar nickel(II) complexes of the general formula *trans-P,P′*-[NiAr{Ar_2PCH=C(O)R′}(PR_3)] (**1**; R, R′ = aryl, alkyl) have been extensively studied over the last 25 years, mainly because of their ability to oligomerise ethylene into α-olefins under mild conditions.[1–7] The discovery of this catalyst type stretches back to the early seventies, when researchers at SHELL discovered that mixing Ni^0 complexes with phosphorus ylides, e.g. Ph_3PCH=C(O)Ph (**2**), produced highly active oligomerisation catalysts.[8] Later, Keim et al. showed that reaction of **2** with Ni(cod)$_2$ in the presence of PPh_3 resulted in an oxidative addition reaction with cleavage of a P–Ph(ylide) bond and subsequent formation of the phosphanyl-enolato complex [NiPh{Ph_2PCH=C(O)Ph}(PPh_3)] (**1a**), known as Keim's oligomerisation catalyst.[9] Since Keim's pioneering studies, a number of related *P,O*-nickel complexes (*P,O* = 3-electron chelate) have been prepared and studied, but surprisingly little is known about variants in which the *P,O*-chelate behaves as an electron-poor donor, although the complex [NiH{$Ph_2PCH_2C(CF_3)_2O$}PCy_3] was reported to be inactive. Note that several recent publications have focussed on nickel complexes with electron-rich *P,O*-chelates,[10,11] while a few nickel complexes in which the *P,O* ligand behaves as a neutral 4-electron donor have also been studied.[12]



1 R = alkyl, aryl



[Na(Ph_2P-pzO)]$_n$ (**3**•Na)



2 **1a**

We now describe the convenient, direct synthesis of the new Keim-type catalyst **4** starting from a P^{III} derivative, namely the sodium pyrazolonato-phosphane Ph_2P-pzONa (**3**•Na).[13] Our investigations show how the presence of the strong electron-withdrawing pyrazolonato ring,[14] known to be stronger than CF_3, drastically drives the product distribution towards shorter olefins. The present study furthers demonstrates that "Keim catalysts" may undergo reductive elimination with formation of a phosphorus ylide. The reported complex **4** is the first example of a Keim-type catalyst derived from an amide.

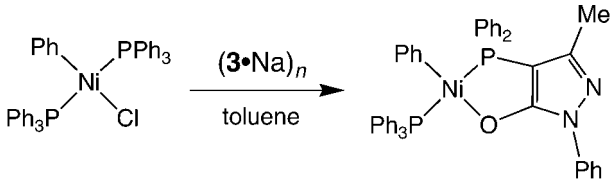
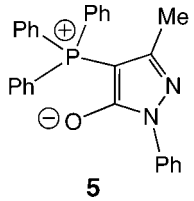
Results and Discussion

Reaction of [NiPhCl(PPh_3)$_2$] with one equiv. of Ph_2P-pzONa in toluene afforded complex **4** in ca. 90% yield. It is noteworthy that this reaction constitutes a rare case in which a **1a**-analogue was obtained from a phosphanylenolate rather than a phosphorus ylide. The ^{31}P NMR spectrum of **4** displays an AB quartet (δ_A/δ_B = 20.2/–8.6 ppm) with a J(PP′) coupling constant of 280 Hz, typical for *trans*-arranged phosphorus atoms. The phosphorus signal of the P-enolato moiety (δ = –8.6 ppm) is strongly shifted to high field with respect to that of other diphenylphosphanylenolates reported in the literature, thus reflecting the high electron-withdrawing nature of the pyrazolonato ring. The solid-state structure of **4** was elucidated by an X-ray diffraction study (Figure 1), which reveals a significant deviation from the usual square-planar coordination geometry observed in other [NiPh(*PO*)PPh_3] complexes. Thus, while the C(23) and oxygen atoms lie on one side of the mean-squares coordination plane, the two P atoms are turned towards the other side [distances to the plane: C(23) –0.154(1); O –0.160(1); P1 +0.184(1); P2 +0.185(1) Å]. Consistent with the electronic features of the pyrazolonato ring, the Ni–O and the Ni–P(1) bonds [1.955(1) Å and 2.210(1) Å, respectively] are somewhat longer than their counterparts in **1a** (1.914 Å; 2.168 Å). The shortness of the P(1)–C(2) bond [1.770(2) Å] is in keeping with electron delocalisation within the *PO* chelate.



4

Interestingly, we noted that on standing, colourless crystals slowly formed from toluene solutions containing **4**. An X-ray analysis of the product reveals the formation of the phosphorus ylide **5** (Figure 2). Surprisingly, a similar reductive elimination reaction had not been reported for **1a**. A careful reinvestigation of the latter complex showed that, in fact, **1a** undergoes the same slow transformation in toluene, resulting in the formation of $Ph_3PCH{=}C(O)Ph$. Possibly, this transformation is triggered by the presence of trace amounts of air, since we found that bubbling air through a C_6D_6 solution of **4** rapidly produced **5**.



5

Typically for a Keim-type catalyst, complex **4** displays high activity in the low pressure oligomerisation of ethylene without requiring any activating agent to trigger the reaction. Turnover frequencies (TOF) as high as

6600 $mol_{ethylene}{\cdot}mol_{Ni}^{-1}{\cdot}h^{-1}$ were observed when operating in toluene at 70 °C under a constant ethylene pressure of 5 bar and a nickel concentration of 0.25 μmol/mL (cf. TOF = 7500 for **1a**) [2 h experiments]. At this pressure, the selectivity in the α-olefins surpassed 95% (Table 1).

The most striking feature of **4** involves the product distribution which considerably shifts towards lower oligomers in comparison with the outcome of Keim's catalyst. Thus, under the conditions outlined above, ca. 72 wt.-% of the oligomers produced after 60 min were C_4–C_{16} olefins; this fraction represents only 15 wt.-% of the total amount of

[a] Batch experiments, toluene 20 mL, 70 °C.

oligomers produced with **1a** in the same period of time. When applying a constant ethylene pressure of 1 bar, this ratio rose to 99 wt.-% (versus 60% for **1a**). The performances of **4** and **1a** were also compared with those in batch experiments carried out at higher pressures. Thus, when applying an initial pressure of 20 bar ([Ni] = 0.25 μmol/mL), the amount of C_4–C_{16} olefins produced with **4** after 1 h was 25 wt.-% of the total amount of oligomers, versus only 9.6% for **1a**. It must be mentioned here that a SHOP catalyst in which the oxygen atom was involved in hydrogen bonding has been reported to also favour β elimination, hence the formation of shorter oligomers, but not to such an extent.[2] Interestingly, the observed effect can be drastically enhanced by using BF_3 as an additive. For example, in experiments where stoichiometric amounts of BF_3 were used (batch autoclave, $P_{initial}$ = 20 bar, [**4**] = 0.25 μmol/mL), the fraction of C_4–C_{16} olefins obtained after 1 h represented 97% of all oligomers formed. It appears plausible that the BF_3 unit binds to the pyrazole ring, probably through a nitrogen atom,[15] hence increasing the electron deficiency of the nickel atom. Overall, the effect observed by adding BF_3 is reminiscent of the properties of [Ni{$Ph_2PC_6H_4C(O)O$}(Me-2-allyl)],[16] which upon addition of $B(C_6F_5)_3$ shifts ethylene oligomerisation towards the formation of low-weight olefins (butene and hexene).[17]

Finally, we noted that mixing complex **4** with $Ni(cod)_2$ in excess afforded, as expected,[11,18,19] a catalyst which polymerises ethylene. Its activity compares with that of **1a**, but analysis of the polymer reveals that the polyethylene chains are considerably shorter (M_w = 650 g mol^{-1}) than those obtained with **1a** (M_w = 4500 g mol^{-1}) under similar conditions. These findings confirm the remarkable electronic properties of the phosphanyl-pyrazolonato ligand. Further investigations are in progress which aim at the use of electron poor *P,O* chelators that allow the controlled production of industrially relevant α-olefins in the absence of any cocatalyst.

Experimental Section

General: All manipulations were performed in Schlenk-type flasks under dry nitrogen. Solvents were dried by conventional methods and distilled immediately prior to use. $CDCl_3$ was passed down a 5 cm-thick alumina column and stored under nitrogen over molecular sieves (4 Å). IR spectra were measured with a Perkin–Elmer 1605 spectrometer. Routine ^1H and $^{31}P\{^1H\}$ spectra were recorded with FT Bruker instruments (AC-300 or Bruker AM–400). $^{13}C\{^1H\}$ were recorded with an FT Bruker AC-200 spectrometer. ^1H NMR spectra are referenced to residual protiated solvents (δ =7.26 ppm for $CDCl_3$ and 5.32 ppm for CD_2Cl_2); ^{13}C chemical shifts are reported relative to deuterated solvents (δ =77.0 ppm for $CDCl_3$ and 53.8 ppm for CD_2Cl_2); ^{31}P NMR spectroscopic data are given relative to external H_3PO_4. The catalytic solutions were analysed with a Varian 3900 gas chromatograph equipped with a WCOT fused silica column (25 m, 0.32 mm inside diameter, 0.25 mm film thickness). High temperature size exclusion chromatography (HT SEC) measurements were performed at 150 °C with a "PL220" apparatus (Column set HT-MixedB-TCB-01) in 1,2,4-trichlorobenzene (with 0.2% Irganox). Calibration was made with linear PS samples. Ph_2P-pzONa[13] and [NiPhCl-(PPh_3)$_2$][20,21] are reported according to procedures reported in the literature.

[NiPh{Ph_2P-pzO}(PPh_3)] (4): To a stirred suspension of Ph_2P-pzONa (0.766 g, 2.14 mmol) in toluene (30 mL) was added a solution of [NiPhCl(PPh_3)$_2$] (1.491 g, 2.14 mmol) in toluene (40 mL). After stirring for 4 h, the mixture was filtered through Celite in order to remove NaCl. The solution was concentrated to ca. 10 mL. On standing, dark yellow crystals formed overnight. After removal of the supernatant solution, the crystals were washed successively with cold toluene (5 mL) and pentane (10 mL), and then dried in vacuo. Yield: 1.088 g, 60%. Addition of pentane to the mother liquor afforded further amounts of **4** as a yellow powder which increases the yield to 90 %. $C_{46}H_{38}N_2NiOP_2 \cdot C_7H_8$ (M_r = 755.46 + 92.14 = 847.60): calcd. C 75.1, H 5.47, N 3.31; found C 74.6, H 5.39, N 3.34. IR (KBr): 1592.6 (m), 1515.5 (s), 1495.0 (s), 1425.8 s cm^{-1}. ^1H NMR (300 MHz, C_6D_6): δ = 8.25–6.44 (35 H, arom. H), 2.02 (s, 3 H, CH_3) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, $CDCl_3$): δ = 140.76–118.06 (arom. C), 89.83 (d, J(P,C) = 63 Hz, PCH), 14.77 (s, CH_3) ppm. $^{31}P\{^1H\}$ NMR (121 MHz, $CDCl_3$): δ = 20.2 and –8.6 (AB spin system, J(PP′) = 280 Hz).

Ph_3P-pzO (5): [NiPh{Ph_2P-pzO}(PPh_3)] (**4**; 0.100 g, 0.13 mmol) was dissolved in toluene (5 mL). Upon standing in air, crystals of Ph_3P-pzO appeared after 48 h. The supernatant was removed by suction, and the crystals were dried under high vacuum. Yield: 0.056 g, 70%. $C_{28}H_{23}N_2OP$ (M_r = 434.48): calcd. C 77.41, H 5.34, N 6.45; found C 77.49, H 5.38, N, 6.41. $^{31}P\{^1H\}$ NMR (121 MHz, $CDCl_3$): δ = 10.6 ppm (lit.: 12.6[22])

concentrated toluene solution of the complex. Data were collected on a Nonius KappaCCD diffractometer (graphite Mo-K_α radiation, λ = 0.71073 Å). The structure was solved by direct methods with the SHELXS-97 program and refined by full-matrix least-squares techniques (SHELXL-97) on F^2.[23] Hydrogen atoms were located by using the geometric method. The crystal data and structural refinement details are listed in Table 2. The compound was found to crystallise with one molecule of toluene (CCDC 242626).

X-ray Crystal Structure Determination of 5·benzene: Single crystals of **5** suitable for X-ray diffraction analysis were obtained from a toluene solution of the complex on standing in air. Data collection and structure solution were as for compound **4**. The compound crystallised with one molecule of benzene. The benzene molecules occupy special positions (–1). CCDC-242627 and CCDC-242626 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Catalytic runs

Ethylene oligomerisation: The low pressure catalytic runs (≤5 bar) were carried out in a Büchi miniclave (200 mL) equipped with a Teflon-coated magnetic stirrer. For higher pressures, a stainless steel autoclave was used (100 mL). Both reactors were dried under vacuum at 100 °C for 1 h before use. In a typical procedure, a Schlenk flask was charged with the complex (7.5 μmol) and toluene (10 mL). The resulting solution was injected into the autoclave together with additional toluene (20 mL). The autoclave was then pressurised with ethylene and heated at 70 °C. After completion of the reaction, the autoclave was cooled with an ice bath and depressurized over 1 h. The solution was analysed by GC. Heptane (200 μL) was used as internal reference. For details see Tables S1–S3.

Ethylene Polymerisation: Polymerisations were carried out in a mini-Büchi glass reactor (200 mL), equipped with a Teflon-coated magnetic stirrer and heating (temperature-controlled oil bath), at constant ethylene pressure. The autoclave was heated at 100 °C under vacuum for 1 h before use and purged with ethylene. The reaction temperature refers to the bath temperature.

In a typical run, the reactor was charged at ambient temperature under an ethylene atmosphere, with a solution of catalyst (7.5 μmol) in toluene (15 mL), followed by a solution of Ni(cod)$_2$ (75 μmol) in toluene (15 mL). The autoclave temperature was raised to 70 °C, and pressurised to 5 bar. The reaction was quenched by venting the autoclave, and the reaction mixture was subsequently poured into a stirring solution of methanol (300 mL) and concentrated HCl (10 mL) to precipitate the polymer. The white powder was isolated by filtration, washed with methanol, and dried in vacuo at 50 °C. By using Keim's catalyst (**1a**), 1.80 g of a polymer was obtained and was characterised by M_w = 4500 g·mol^{-1} and M_w/M_n = 1.87 (Catalyst activity: 240 g·mmol$_{cat}^{-1}$·h^{-1}). The polymer (1.51 g) obtained with **4** has the following characteristics: M_w = 650 g·mol^{-1} and M_w/M_n = 1.31 (Activity: 201 g·mmol$_{cat}^{-1}$·h^{-1}).

Supporting Information Available: See also footnote on the first page of this article. Ethylene oligomerisation with the Keim-type complex **1a** (constant pressure) (Table S1). A Copper-Metalated, Hybrid Inorganic–Organic Polymer as an Oxidative Nuclease

Vadapalli Chandrasekhar,*[a] Arunachalampillai Athimoolam,[a] Venkatasubbaiah Krishnan,[a] Ramachandran Azhakar,[a] C. Madhavaiah,[a] and Sandeep Verma*[a]

Dedicated to Professor S. S. Krishnamurthy on the occasion of his 63rd birthday

Keywords: Chemical nucleases / Phosphazenes / Pendant polymers / Copper complexes / Phosphate ester hydrolysis / Heterogeneous catalysis

This study describes nucleolytic activity of a copper-metalated, multisite-coordinating, hybrid polymer **CPPL-Cu** under oxidative conditions. Rapid relaxation of supercoiled plasmid DNA was observed and mechanistic probing by chemical and enzymatic assays revealed involvement of singlet-oxygen-derived reactive species. The heterogeneous nature of the catalyst allowed a facile recycling of the artificial nuclease.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

As many phosphate-ester-modifying enzymes depend on metal ions for their catalytic activities, it is not surprising to find that numerous artificial phosphatases and nucleases-containing metal ions have been reported over the past few decades for possible biochemical applications ranging from chemotherapy to synthetic restriction enzymes.[1] These model systems employ a wide range of transition and inner-transition-metal ions coordinated to ligands of natural and synthetic origin. Although enzyme-like substrate recognition, efficiency, and high turnover remain elusive with such systems, they provide incisive insight to the study of the role of metal ions for phosphate ester modification in natural enzymes.[2–5]

Among the many transition-metal ions, copper-based artificial systems have received considerable focus perhaps due to their variable mechanism of reactivity: they can modify natural and non-natural phosphate esters either through an oxidative route or a hydrolytic pathway. The former activity can be attributed to the redox cycling of copper in the presence of exogenously added oxidants or reductants, which leads to in situ formation of reactive species.[6]

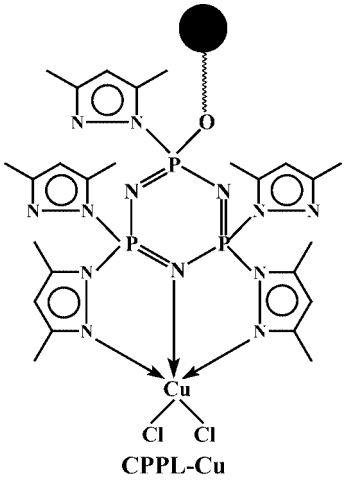
Polyphosphazenes, $[N{=}PR_2]_n$, are the most versatile and well-studied family of inorganic polymers.[7] One of the remarkable features of this class of polymers is that individual polymer properties can be readily modulated by a variation of the substituent on the phosphorus center.[8–10] Several applications of these polymers in diverse fields[11–14] are known, including the use of these polymers as matrices for stabilizing gold nanoparticles.[15] A closely related class of hybrid inorganic–organic polymers contains an intact cyclophosphazene ring as a pendant group attached at regular intervals to the backbone of an organic polymer.[16–18] Although much less studied, these polymers also show considerable promise particularly in the design of polymeric ligands.[19–20] We have recently utilized this approach to design new polymeric catalysts, which show applications in phosphate ester hydrolysis[21] or in the Heck arylation reaction.[22] In the following account we report the first application of these hybrid inorganic–organic polymers in DNA cleavage under heterogeneous reaction conditions.

Results and Discussion

A number of inner and outer-transition-metal ions are known for their catalytic assistance towards nucleic acid cleavage, either by a hydrolytic pathway[23–31] or through oxidative damage.[32–35] In particular, copper complexes afford facile nucleic acid oxidative cleavage in the presence of oxidizing and reducing agents,[36–43] in addition to the hydrolytic mechanism.[23,27,29] Most of these artificial phosphatases and nucleases offer homogeneous catalysis, while

only limited applications of heterogeneous catalysts have been reported.[44–52]

We have utilized copper-metalated, pyrazolylcyclotriphosphazene-containing, cross-linked polymeric catalyst CPPL-Cu (Scheme 1) for the oxidative damage to supercoiled plasmid in the presence of oxidizing agents such as magnesium monoperoxyphthalate (MMPP) and oxone. To the best of our knowledge, this is the first instance where an inorganic–organic hybrid polymer, and more specifically, a polyphosphazene-appended polymeric system has been used as a synthetic nuclease. The molecular structure of CPPL-Cu, has been previously established by us.[21] Briefly, the EPR spectrum of CPPL-Cu at 77 K is of the axial type and the parameters obtained viz., $g_{II} = 2.27$, $g_{\perp} = 2.10$, and $A_{II} = 130.5 \times 10^{-4}\ cm^{-1}$, compare very well with that of model compounds $N_3P_3(3,5\text{-}Me_2Pz)_5(O\text{–}C_6H_4\text{–}C_6H_4\text{–}CH{=}CH_2)\cdot CuCl_2$ [$g_{II} = 2.28$, $g_{\perp} = 2.05$, and $A_{II} = 130.5 \times 10^{-4}\ cm^{-1}$] and $N_3P_3(3,5\text{-}Me_2Pz)_5(O\text{–}C_6H_4\text{–}CHO)\cdot CuCl_2$ [$g_{II} = 2.28$, $g_{\perp} = 2.06$, and $A_{II} = 122.0 \times 10^{-4}\ cm^{-1}$].



CPPL-Cu

Scheme 1.

The X-ray crystal structure of the model compound $N_3P_3(3,5\text{-}Me_2Pz)_5(O\text{–}C_6H_4\text{–}CHO)\cdot CuCl_2$ has been determined and shows a five-coordinate environment around Cu^{II} containing a cyclophosphazene ring nitrogen atom, two pyrazolyl nitrogen atoms and two chlorine atoms. Further, the diffuse reflectance spectrum of CPPL-Cu shows peaks at 845, 351, 318, 304, and 251 nm. These peak positions are similar to those observed in the solution spectrum of the model compounds. On the basis of this cumulative data, it is suggested that the coordination environment around copper contains two chlorides along with two nongeminal pyrazolyl nitrogens and one cyclophosphazene-ring nitrogen. From the nitrogen analysis it is concluded that every gram of the polymer contains 0.33 g of the cyclophosphazene monomer corresponding to 4.09×10^{-4} moles. From the AAS analysis the amount of copper present per gram of CPPL-Cu was found to be 21.7 mg.[21]

Plasmid (pBR322) modification assisted by the CPPL-Cu complex was studied in the presence of exogenously added co-oxidants MMPP and oxone. Initial experiments were performed using a varying amount of polymer in the presence of MMPP to study the concentration-dependent cleavage of pBR322. These experiments revealed a dependence of polymer concentration on the DNA cleavage (Figure 1). The concentration of catalyst for all subsequent experiments was optimized at 50 μg/20 μL for a 20-min cleavage reaction to set complete relaxation of plasmid DNA.

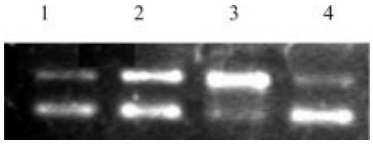


Figure 1. pBR322 cleavage with CPPL-Cu in presence of different amounts of copper polymer [lane 1: DNA + 10 μg of catalyst + MMPP (25 min); lane 2: DNA + 20 μg of polymer + MMPP (25 min); lane 3: DNA + 30 μg of polymer + MMPP (25 min); lane 4: DNA alone].

Both of the peracids effectively activated CPPL-Cu and a complete conversion of supercoiled plasmid DNA, from form I to nicked form II, and linear form III was observed (Figure 2, lanes 6 and 8). Control experiments with unmetalated ligand complex and peracid alone did not produce any detectable strand scission (Figure 2, lanes 2, 3, 5, and 7 respectively). However, the addition of EDTA afforded complete inhibition of plasmid cleavage, thus indicating the crucial role of coordinated copper ions in the cleavage reaction (Figure 2, lane 4).

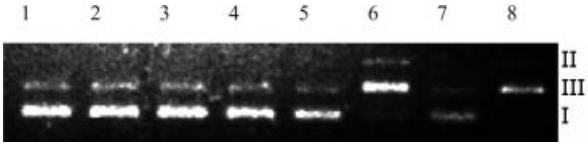

Figure 2. pBR322 cleavage by CPPL-Cu in the presence of MMPP and oxone (lane 1: DNA alone; lane 2: DNA + CPPL; lane 3: DNA + CPPL-Cu; lane 4: DNA + CPPL-Cu + EDTA + MMPP; lane 5; DNA + MMPP; lane 6: DNA + CPPL-Cu + MMPP; lane 7: DNA + oxone; lane 8: DNA + CPPL-Cu + oxone).

The nature of the reactive species responsible for DNA cleavage was probed by performing the reactions in the presence of hydroxyl-radical scavengers such as *tert*-butyl alcohol, dimethyl sulfoxide, and D-mannitol. These reagents partially inhibited the cleavage reaction (Figure 3; lanes 3–5), thus suggesting the possible involvement of reactive radical species in DNA cleavage. The extent of inhibition is limited probably because of the insoluble nature of the catalyst, which may shield the reactive species from freely diffusing out in the solution. Such protection has recently been observed with a trinuclear copper(II) complex where the presence of standard free-radical scavengers failed to reveal any interference against oxidative DNA cleavage.[53] As discussed in the literature, abstraction of C-4′ hydrogen appears to be the most likely mechanism of action for the reactive species so generated, leading to backbone scission.[54]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

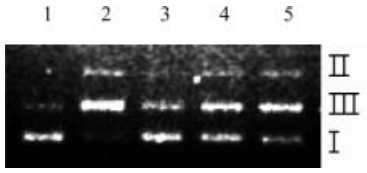

Figure 3. pBR322 cleavage by CPPL-Cu in the presence of radical scavengers (lane 1: DNA alone; lane 2: without the radical scavenger; lane 3: with *t*BuOH; lane 4: with DMSO; lane 5: with D-mannitol).

Enzymatic scavengers such as superoxide dismutase and catalase failed to provide any inhibition of the reaction, thereby suggesting a lack of involvement of the superoxide radical anion and the peroxide species in the cleavage (Figure 4, lanes 3, 4). Curiously, sodium azide afforded almost complete inhibition of plasmid relaxation, and the deployment of anaerobic conditions resulted in partial plasmid modification (Figure 4, lanes 5, 6). Taken together, these observations point towards a possible role of singlet oxygen in DNA modification as sodium azide is an effective quencher of singlet oxygen and some other reactive oxygen species. These results are similar to those of the hydroquinone/Cu^{II} system where the DNA strand cleavage was partially inhibited by HO·scavengers, whereas a greater degree of protection was offered by singlet-oxygen scavengers.[55] This clearly suggests localized generation and attack of singlet oxygen or a related species, because of the possible formation of a copper-peroxide complex, rather than the predominance of HO·in DNA cleavage. A dual mechanism involving hydroxyl radicals and singlet oxygen for DNA cleavage using photoactivated copper-based catalysts has been recently reported by Chakravarty and coworkers.[56]

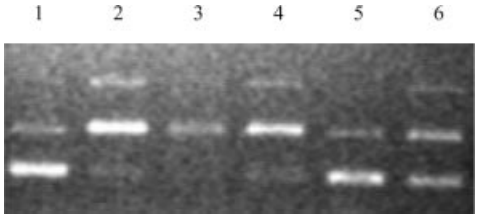

Figure 4. Lane 1: DNA alone; lane 2: DNA + CPPL-Cu + MMPP; lanes 3–5: DNA + CPPL-Cu + MMPP + SOD, catalase, sodium azide, respectively; lane 6: DNA + CPPL-Cu + MMPP under anaerobic conditions.

Growing interest in the development of heterogeneous nucleolytic reagents[44–46,48,51] and their possible application as recyclable catalytic systems has prompted us to explore CPPL-Cu for multiple cleavage reactions. Typically, reaction mixtures were centrifuged after completion of a reaction to leave the catalyst in the form of a pellet. After the removal of the supernatant, the pellet was repeatedly washed with cacodylate buffer (4×100 μL) to ensure complete removal of DNA and then reused for subsequent plasmid modification. Gel electrophoretic tracking was used to detect the complete removal of plasmid and cleaved fragments. CPPL-Cu was recycled for three consecutive reactions and each time a complete conversion of supercoiled form I to linear form III was observed (Figure 5) thus making an emphatic statement about the robust nature of the CPPL-Cu catalytic system.

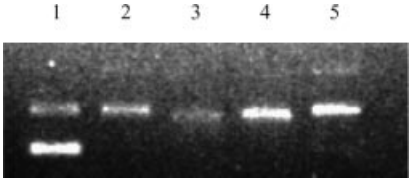

Figure 5. Recycling experiment [lane 1: DNA alone; lane 2: DNA + CPPL-Cu + MMPP (fresh); lane 3: first recycle; lane 4: second recycle; lane 5: third recycle].

We therefore perceive that the role of the cross-linked polymeric matrix is twofold: firstly, stabilization of the coordination complex by providing a suitable hydrophobic environment and secondly, providing an accessible, insoluble embedded metal complex scaffold for participation in the catalytic reactions. The latter property manifests itself in the facile recycling of the catalyst. As this catalyst relaxes plasmid superhelicity, it can also be considered to act as an artificial DNA topoisomerse. Such enzymes catalyze DNA strand scission releasing superhelical stress and religating activities in order to modulate nucleic acid architectures.[57] However, unlike topoisomerases our catalyst has not been optimized for the religation activity and thus, a direct comparison of their respective cleavage/ligation activities will not be meaningful.

Conclusions

In summary, we have demonstrated a novel, effective, and hitherto unreported nucleolytic activity of hybrid polymers with biomolecules, the cleavage of supercoiled plasmid with **CPPL-Cu** by an oxidative mechanism. It was further verified that **CPPL-Cu** is an extremely robust and stable catalyst, and it can be recycled several times over because of the heterogeneous nature of the catalysis. This represents the first application of the cyclophosphazene pendant polymeric system in a biological milieu. It is possible to harness this motif efficiently for the coordination of diverse metal ions to create a set of heterogeneously active catalytic reagents for chemico-biological applications.

Experimental Section

General Remarks: Solvents and other general reagents used in this work were purified according to the standard literature procedures.[58] CPPL and CPPL-Cu were prepared according to the reported procedures.[21] Elemental analyses were carried out with a Carlo–Erba CHNSO 1108 elemental analyzer. The amount of copper present in the polymeric catalyst was determined by atomic absorption spectrometry (AAS) with an Integra XL AAS spectrometer. EPR spectra were recorded with a Varian 109E Line Century Series, X-band spectrometer, at liquid nitrogen temperature. IR spectra of KBr pellets were recorded with a Bruker Vector 22 FTIR spectrophotometer operating from 400 to 4000 cm^{-1}. Ab-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

sorption spectra were recorded with a Shimadzu UV-160 spectrophotometer.

Preparation of CPPL: To a solution of $N_3P_3(3,5\text{-}Me_2Pz)_5(OC_6H_4\text{-}p\text{-}C_6H_4\text{-}p\text{-}CH{=}CH_2)$ (1.0 g, 1.2 mmol) in 1,2-dichloroethane (15 mL) was added 1,4-divinylbenzene (80%, mixture of isomers, 0.4 g, 2.5 mmol) and AIBN (0.03 g, 0.2 mmol). The solution was purged with argon for 45 min and was subsequently heated at 80 °C for 36 h. The cross-linked polymer obtained was filtered and washed with toluene (3 × 20 mL), dichloromethane (3 × 20 mL), methanol (3 × 20 mL), and acetone (3 × 20 mL), and dried thoroughly under vacuum at 40 °C. Yield: 1.04 g. IR (KBr) cm^{-1}: 3397 (s), 2923 (s), 1604 (s), 1573 (s), 1493 (s), 1443 (s), 1412 (s), 1372 (m), 1301 (s), 1218 (vs), 1089 (m), 1023 (m), 967 (m), 902 (m), 824 (m), 796 (m), 711 (w), 597 (m), 525 (m). Found: C 64.98, H 6.2, N 9.32. From the nitrogen analysis it was concluded that every gram of the polymer contained 0.54 g of the cyclophosphazene monomer which corresponded to 6.7×10^{-4} moles.

Preparation of CPPL-Cu: To a solution of anhydrous cupric chloride (0.09 g, 0.7 mmol) in ethanol CPPL (1.0 g, 0.67 mmol of the monomer) was added and stirred for 24 h. The resulting metalated polymer was washed thoroughly with methanol (5 × 20 mL) to remove any unreacted cupric chloride and dried under vacuum at 40 °C. Yield: 1.2 g. IR (KBr) cm^{-1}: 3420 (m), 3020 (m), 2923 (s), 2853 (m), 1649 (w), 1603 (w), 1570 (w), 1492 (m), 1454 (m), 1418 (m), 1374 (w), 1240 (vs), 1187 (vs), 1047 (m), 964 (w), 903 (m), 824 (m), 795 (m), 709 (w), 588 (w), 540 (w). Found: C 55.40, H 5.21, N 6.39. From the nitrogen analysis it was concluded that every gram of the polymer contained 0.33 g of the cyclophosphazene monomer which corresponded to 4.09×10^{-4} moles. From the AAS analysis the amount of copper present per gram of CPPL-Cu was found to be 21.7 mg. EPR (solid, 77 K): $g_{II} = 2.27$; $g_{\perp} = 2.10$; $A_{II} = 130.5 \times 10^{-4}\,cm^{-1}$. Diffuse reflectance UV/Vis [λ_{max}/nm (absorbance)]: λ_{max} = 845 (0.355), 351 (0.294), 318 (0.891), 304 (0.878), 251 (0.920).

pBR322 Cleavage Assay: Plasmid cleavage reactions (20 min) were performed in sodium cacodylate buffer (10 mM, pH 7.5, 20 μL, 30 °C) containing supercoiled plasmid DNA pBR322 (9 ng/μL, New England Biolabs), CPPL-Cu (the concentration of copper was 0.85 mM, if the catalyst was completely soluble in buffer), and an oxidizing agent [magnesium monoperoxyphthalate (100 μM) or oxone (100 μM)]. Individual reactions were quenched by adding the gel loading buffer (5 μL) containing EDTA (100 mM), loaded onto agarose gel (0.7%), containing ethidium bromide (1 μg/mL), and were electrophoresed for 1.5 h (60 mA). Gels were imaged with the Bio-Rad Gel Documentation System 2000. Recycle experiments were performed in a similar fashion except that they were performed for 25 min to ensure complete conversion of the supercoiled form to the relaxed form.

Synthesis, Structure, and Luminescent Properties of Guanidinate-Based Terbium Complexes

Xingan Pang,[a] Hongmei Sun,[a] Yong Zhang,[a] Qi Shen,*[a,b] and Hongjie Zhang[c]

Keywords: Terbium complex / Guanidinate / Luminescence / Lanthanides

Two guanidinate-based terbium complexes [*i*PrNC(N*i*Pr$_2$)-N*i*Pr]$_m$TbCl$_{3-m}$ [m = 3 (**1**), 2 (**2**)] were synthesized, and the crystal structure of **1** was determined by single-crystal X-ray diffraction. Complexes **1** and **2** were further characterized by elemental analysis, IR, and ^{1}H NMR spectroscopy. In complex **1** the guanidinate ligand coordinates to the terbium atom through the nitrogen atoms in a bidentate chelating coordination mode. As a result of an efficient energy transfer from the guanidinate ligand to the central Tb^{3+}, both **1** and **2** have been found to exhibit strong green emission corresponding to Tb^{3+} $^5D_4$-^7F_J (J = 6, 5, 4, 3) transitions. Among them, the emission $^5D_4$-$^7F_5$ (550 nm) is the most prominent. The lifetimes of the $^5D_4$ Tb^{3+} excited levels of the two complexes were determined to be around 0.90 ms.

Introduction

The luminescence properties of lanthanide ions (i.e., narrow emission peak, high quantum yield, and long decay time), in particular Tb^{3+} and Eu^{3+}, make them useful in luminescence probes for chemical or biological systems.[1] The strong luminescence of lanthanide complexes depends on the energy-level structure of the ligands and the central metal ions. Therefore, considerable efforts have been made to design and assemble lanthanide complexes with organic ligands such as β-diketones,[2] cryptands,[3] aromatic carboxylic acids,[4] and heterocyclics[5]. Lately, guanidinate anions, $[(RN)_2CNR'_2]^-$, whose steric and electronic effects can be easily modified by the variation of substituents on the N-atoms, have attracted considerable attention in organometallic chemistry,[6] and their application in organolanthanide complexes has led to the synthesis of a series of guanidinate derivatives of lanthanides.[6–14] Moreover, these complexes with guanidinate as the auxiliary ligands have many uses in catalytic chemistry. For example, the guanidinate aryloxy lanthanum complex can act as the catalyst for the ring-opening polymerization of lactide.[10] The guanidinate–methyl complexes of lanthanides are effective initiators not only for the polymerizations of MMA and ε-caprolactone,[11] but also for styrene polymerization.[12] The homoleptic triguanidinate lanthanides can also efficiently initiate the ring-opening polymerization of ε-caprolactone[14] and cyclocarbonate.[15] However, to our best knowledge, the photophysical properties of the guanidinate derivatives of lanthanides still remain unexplored. More recently, our group found that the Tb complex with β-diketiminate as a ligand showed a strong green emission band due to an efficient energy transfer from the β-diketiminate to the central Tb^{3+}.[16] Considering the similar structural characteristics of guanidinate and β-diketiminate, it is interesting to investigate the photoluminescence behavior of the guanidinate complex of lanthanides. Accordingly, two guanidinate complexes of terbium {[*i*PrNC(N*i*Pr$_2$)N*i*Pr]$_m$TbCl$_{3-m}$, m = 3 (**1**), 2 (**2**)} were synthesized and their luminescence spectra were determined. Both of them exhibited strong green emission corresponding to Tb^{3+} $^5D_4$-^7F_J (J = 6, 5, 4, 3) transitions. Herein, we would like to report the results.

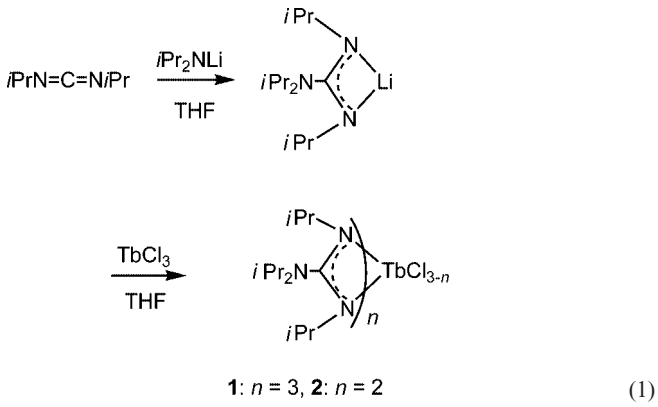
Results and Discussion

Synthesis of (*i*PrNC(N*i*Pr$_2$)N*i*Pr)$_m$TbCl$_{3-m}$ [m = 3 (1), 2 (2)]

The complexes **1** and **2** can be easily synthesized by the reaction of freshly-prepared lithium guanidinate with $TbCl_3$. The reaction of $TbCl_3$ with lithium guanidinate in 1:3 and 1:2 mole ratios, respectively, after work up at room temperature, gave the two expected complexes as white crystals [Equation (1)]. The complexes are air- and moisture-sensitive and soluble in THF, diethyl ether, and toluene. The initial characterization of complexes **1** and **2** were supported by elemental analysis and IR spectroscopy. In their IR spectra, no signal of C=N=C near 2110 cm^{-1} was ob-

 DOI: 10.1002/ejic.200400750 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

served, and a strong absorption at approximately 1640 cm^{-1} assigned to the C=N stretch appeared. The IR data indicated that the electrons within the double bonds of the N–C–N linkage are delocalized in the two complexes



1: n = 3, **2**: n = 2 (1)

Crystal-Structure Analysis of Complex 1

Crystals of complex **1** suitable for X-ray crystallographic analysis were obtained by recrystallization from THF solution at –15 °C. The crystal-structure analyses revealed that complex **1** is a monomer in the solid state. Figure 1 depicts the molecular structure of complex **1**. Selected bond lengths and angles are given in Table 1. The terbium ion in the complex is coordinated to six nitrogen atoms of the three bidentate guanidinate anions and the geometry around the center metal can be best described as a distorted octahedron. The sum of the three angles C(1)–Tb(1)–C(14) [119.36(19)°], C(14)–Tb(1)–C(27) [120.8(2)°], and C(27)–Tb(1)–C(1) [119.87(19)°] equals 360.03°, which indicates that the terbium ion is located in a plane defined by the three central carbon atoms of the guanidinate moieties. All of the C–N bond lengths for the N–C–N moiety of each guanidinate group are intermediate between the C–N and C=N bond lengths. The results indicated the delocalization of the π bond in the N–C–N unit, while the C(1)–N(3), C(14)–N(6), and C(27)–N(9) bond lengths are 1.452(10), 1.411(9), and 1.422(9), respectively; these values fall into the normal C–N single bond-length range. The Tb–N bond lengths range from 2.380 Å to 2.411 Å. The average Tb–N bond length (2.393 Å) is comparable to those for $[(i\mathrm{PrN})_2\mathrm{CN}i\mathrm{Pr}_2]_3\mathrm{Nd}$ (2.464 Å) and $[(\mathrm{CyN})_2\mathrm{CN}i\mathrm{Pr}_2]_3\mathrm{Nd}$ (2.458 Å)[14] when the difference in the ionic radii of Nd and Tb is considered. The angles of the three N–C–N units are slightly different, ranging from 114.0(6)° to 117.2(7)°, which are also comparable to those for $[(i\mathrm{PrN})_2\mathrm{CN}i\mathrm{Pr}_2]_3\mathrm{Nd}$ (115°) and $[(\mathrm{CyN})_2\mathrm{CN}i\mathrm{Pr}_2]_3\mathrm{Nd}$ (114°). The N–Tb–N angle in each TbN_2C moiety is about 56.4°, which is slightly larger than that in the analogous complexes of $[(\mathrm{CyN})_2\mathrm{CN}i\mathrm{Pr}_2]_3\mathrm{Nd}$ (54.5°) and $[(i\mathrm{PrN})_2\mathrm{CN}i\mathrm{Pr}_2]_3\mathrm{Nd}$ (54.2°).

Photoluminescence Properties of Complexes 1 and 2

Figure 2 shows the excitation spectra of complex **1** in the solid state at room temperature (a), in THF solution at 77 K (b), and of complex **2** in the solid state at room temperature (c). The spectra were monitored by the Tb^{3+} green emission at 550 nm ($^5D_4$-$^7F_5$) and recorded in a range of 200 to 500 nm. The three excitation spectra are very similar and all of them display broad bands: from 230 to 400 nm with a maximum at 345 nm in the solid state at room temperature and at 304 nm in THF at 77 K for complex **1**, and from 250 to 410 nm with a maximum at 355 nm in the solid state for complex **2**. In the excitation spectra of both complexes, determined in the solid state at room temperature (see **a** and **c** in Figure 2), there is a shoulder at 488 nm and a broad band from 200 to 410 nm, which can be attributed to the f-f excitation transition ($^7F_6$-$^5D_4$) within the Tb^{3+} $4f^8$ electron configuration.[17] The wide excitation band observed can be attributed to the π-π* transition of the guanidinate ligand, in accordance with its broad character and strong intensity. Upon excitation into the absorption of the ligand at 345 nm and 350 nm in the solid state at room temperature. for complexes **1** (see **a** in Figure 3) and **2** (see **b** in

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Figure 3), and at 306 nm in the THF solution at 77 K for complex **1** (Figure 4), almost the same emission spectra were obtained. All of the spectra display strong green luminescence with four emission bands at 485, 546, 585, and 624 nm. The broad band from the ligand in the range of 230 to 410 nm was also not observed. These results indicated that an efficient energy transfer from the guanidinate ligand state to the emitting $^5D_4$ level of the Tb^{3+} ion occurs. These bands correspond to the characteristic emission from the $^5D_4$-^7F_J (J = 6, 5, 4, 3) transition of the Tb^{3+} ion. Among them the $^5D_4$-$^7F_5$ transition is the strongest one. The splits of the emission bands corresponding to $^5D_4$-$^7F_6$, $^5D_4$-$^7F_5$, and $^5D_4$-$^7F_4$ are 2, 3, and 4, respectively, which is caused by the crystal field splitting.[18] We can also see that the emission intensity of complex **1** (see **a** in Figure 3) is stronger than that of complex **2** (see **b** in Figure 3), which shows the number of the ligands affects the luminescent intensity of the guanidinate Tb complexes.

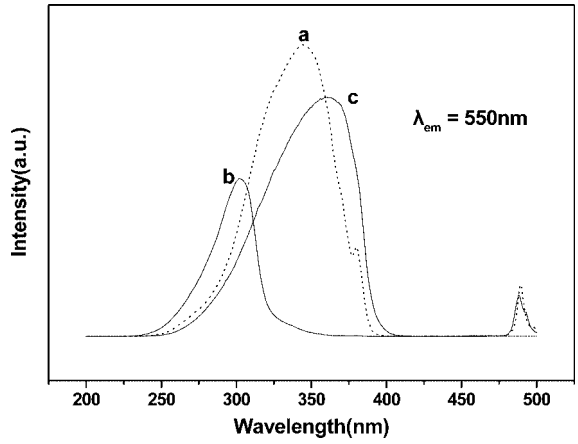

Figure 2. Excitation spectra (a) of complex **1** in the solid state at room temperature; (b) of complex **1** in THF solution at 77 K, and (c) of complex **2** in the solid state at room temperature.

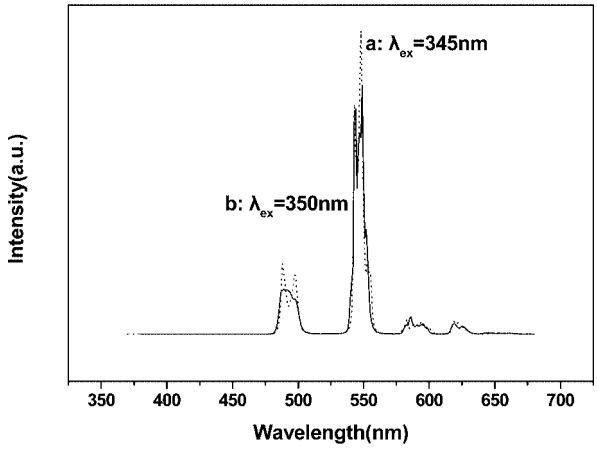

Figure 3. Emission spectra of complexes **1** (a) and **2** (b) in the solid state at room temperature.

The luminescence decay curves of Tb^{3+} ($^5D_4$-$^7F_5$ at 546 nm) in complex **1** were obtained under different excitation wavelengths at room temperature. The decay curves under the excitation wavelengths 546, 485, and 624 nm are

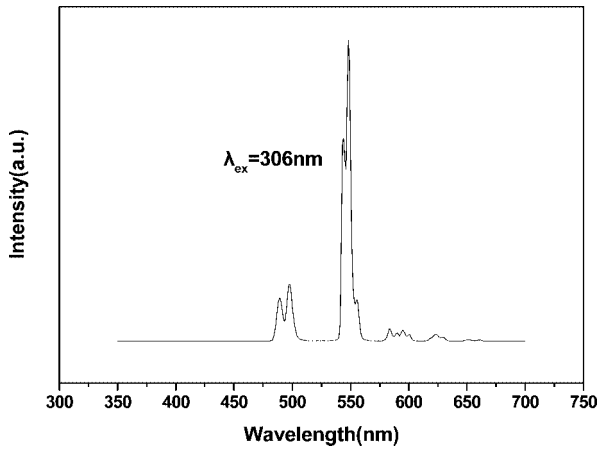

Figure 4. Emission spectrum of complex **1** in THF solution at 77 K.

shown in Figure 5 and Figure 6. It is clear that the luminescence of Tb^{3+} in complex **1** shows simple decay behavior. The decay curves fitted well into a singly exponential function as $I = I_0 \exp(-t/\tau)$ (τ is 1/e lifetime of the rare earth ion), indicating that all the Tb ions occupy the same average local environment. The lifetime of the Tb^{3+} ion (τ) is determined to be 0.91, 0.87, and 0.95 ms for $^5D_4$-$^7F_5$, $^5D_4$-$^7F_6$, and $^5D_4$-$^7F_3$, respectively. This result means that the ligands are efficiently shielding the Tb ion. The lifetime of the $^5D_4$ Tb^{3+} excited level in complex **2** was determined to be 0.86 ms, as shown in Figure 7. This value is very close to that of complex **1**; evidently, the number of ligands in the complex does not influence the lifetime.

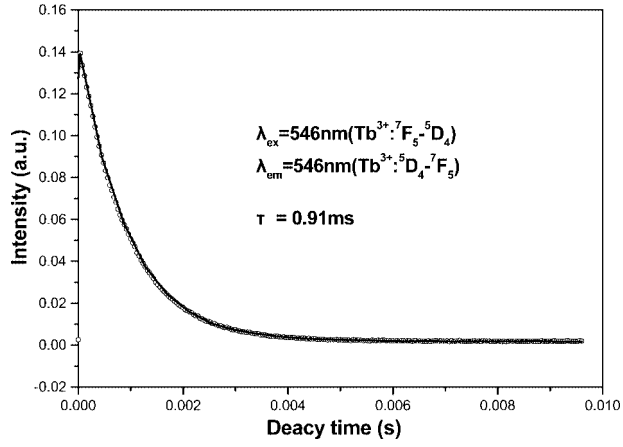

Figure 5. The decay curve for the luminescence of Tb^{3+} in complex **1** under an excitation wavelength of 546 nm.

Conclusions

In summary, bis- and tris-guanidinate terbium complexes can be easily prepared in good yield by the metathesis reaction of lithium guanidinate with anhydrous terbium trichloride at different mole ratios. The structural features of homoleptic terbium guanidinate (**1**) have been determined by X-ray diffraction. Interestingly, both of the two com-

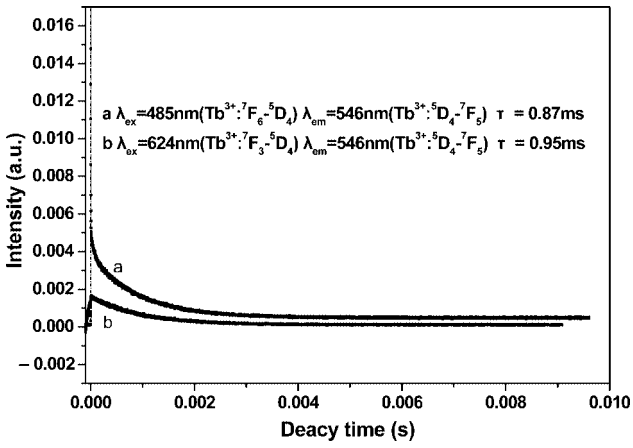

Figure 6. The decay curves for the luminescence of Tb^{3+} in complex **1** under the excitation wavelengths of 485 and 624 nm.

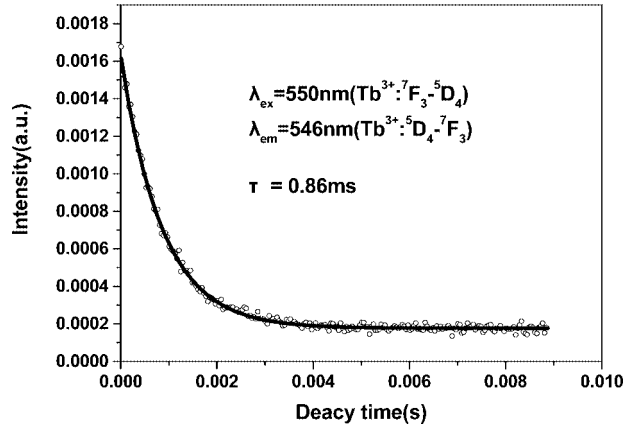

Figure 7. The decay curve for the luminescence of Tb^{3+} in complex **2** under an excitation wavelength of 550 nm.

plexes show rich luminescent properties at room temperature or 77 K. The lifetimes of the $^5D_4$ Tb^{3+} excited levels of the guanidinate complexes were determined to be around 0.90 ms. These results suggest that guanidinate could be used as a novel type of ligand for the synthesis of lanthanide-based luminescent complexes.

Experimental Section

General Procedures: All manipulations were performed under pure Ar with rigorous exclusion of air and moisture by the standard Schlenk techniques. Solvents were distilled from Na/benzophenone ketyl prior to use. Anhydrous $TbCl_3$[19] was prepared according to the literature procedures. *N*,*N*′-diisopropylcarbodiimide was purchased from Aldrich and purified by distillation under reduced pressure. Metal analyses were carried out by complexometric titration. Carbon, hydrogen, and nitrogen analyses were performed by direct combustion with a Carlo–Erba EA-1110 instrument. The IR spectra were recorded with a Magna-IR 550 spectrometer. ^{1}H NMR spectra were measured with a Unity Inova-400 spectrometer. The excitation and emission spectra were obtained with a SPEX FL-2T2 spectrofluorimeter with a 0.8 mm slit and equipped with a 450-W lamp as the excitation source. Luminescence lifetimes were measured with a Lecroy Wave Runner 6100 Digital Oscilloscope (1 GHz) using a 350-nm Ar ion laser (pulse width = 4 ns) as the excitation source (Continuum Sunlite OPO).

Synthesis of [*i*PrNC(*i*Pr$_2$N)N*i*Pr]$_3$Tb (1): A freshly-prepared solution of lithium guanidinate [(*i*PrN)$_2$CN*i*Pr$_2$]Li (2.2 g, 10 mmol) in THF (40 mL) was cannula-transferred into a Schlenk tube (100 mL) containing a solution of $TbCl_3$ (0.88 g, 3.33 mmol) in THF (20 mL) at 0 °C. The reaction mixture was stirred for 20 min at 0 °C and then stirred for 48 h at room temperature. The solvent was removed in vacuo, and the residue was extracted with toluene (45 mL) and LiCl was removed by centrifugation. After the extracts were concentrated and cooled to –15 °C for crystallization, colorless microcrystals were obtained (1.84 g, 66%). ^{1}H NMR (400 MHz, C_6D_6, 25 °C): δ = 2.88–3.76 [m, 12 H, C*H*(CH$_3$)$_2$], 0.68–1.76 [m, 72 H, CH(C*H*$_3$)$_2$] ppm. $C_{39}H_{84}N_9Tb$ (838.07): calcd. C 55.89, H 10.08, N 15.03, Tb 19; found: C 55.77, H 10.12, N 14.98, Tb 19.08. IR [KBr pellet (cm^{-1})]: 2969 (s), 2863 (s), 2709 (m), 2617 (m), 1651 (s), 1450 (s), 1361 (s), 1317 (s), 1210 (s), 1058 (s), 1018 (m), 975 (m), 930 (m), 861 (m), 667 (m), 576 (m) cm^{-1}.

Synthesis of [*i*PrNC(*i*Pr$_2$N)N*i*Pr]$_2$TbCl(THF) (2): Following a procedure similar to the synthesis of **1**, using [(*i*PrN)$_2$CN*i*Pr$_2$]Li (1.74 g, 8 mmol), $TbCl_3$ (1.06 g, 4 mmol), and THF (60 mL), followed by crystallization from THF yielded white crystals (1.72 g, 60%). ^{1}H NMR (400 MHz, C_6D_6, 25 °C): δ = 2.80–3.82 [m, 8 H, C*H*(CH$_3$)$_2$], 0.68–1.80 [m, 48 H, CH(C*H*$_3$)$_2$] ppm. $C_{30}H_{64}N_6ClOTb$ (718.42): calcd. C 50.11, H 8.9, N 11.69, Tb 22.13; found: C 49.98, H 8.86, N 11.98, Tb 22.54. IR [KBr pellet (cm^{-1})]: 2972 (s), 2865 (s), 2612 (s), 2463 (m), 1634 (s), 1473 (s), 1449 (s), 1367 (s), 1322 (s), 1173 (m), 1118 (m), 1014 (m), 922 (m), 866 (m), 809 (m), 722 (m), 661 (s) cm^{-1}.

X-ray Structural Determination of Complex 1: Suitable single crystals of complex **1** were each sealed in a thin-walled glass capillary, and intensity data were collected with a Rigaku Mercury CCD equipped with graphite-monochromated Mo-*Kα* (λ = 0.7107 Å) radiation. Details of the intensity data collection and crystal data are given in Table 2. The crystal structure was solved by direct methods and expanded by Fourier techniques. Atomic coordinates and ther-

Selectivity of Asymmetric Macrocyclic Compartmental Lanthanide(III) Complexes towards Alkali and Alkaline-Earth Metal Ions

Alessandro Barge,[a] Mauro Botta,[b] Umberto Casellato,[c] Sergio Tamburini,*[c] and P. Alessandro Vigato[c]

Keywords: Lanthanides / Schiff bases / Shift reagents / ^{23}Na NMR / Macrocyclic ligands

The asymmetric macrocyclic compartmental ligand H_2L, derived from the [1+1] condensation of 3,3′-(3-oxapentane-1,5-diyldioxy)bis(2-hydroxybenzaldehyde) with 1,5-diamine-3-azamethylpentane, forms the complexes $[LnNa(L)(Cl)_2(CH_3OH)]$ (Ln = La–Nd, Sm–Lu) where the lanthanide(III) ion resides in the N_3O_2 Schiff base coordination site and the sodium ion is located in the O_3O_2 crown-like cavity. The new heterodinuclear complexes $[LnCa(L)(Cl)_2(CH_3OH)(H_2O)]Cl$ (Ln = Tb, Dy, Tm, Yb) were prepared and characterised by single-crystal X-ray diffraction, IR, ^{1}H and ^{13}C NMR spectroscopy and their homogeneity and stoichiometry (Ln:Ca:Cl = 1:1:3 molar ratio) were ascertained by SEM-EDS analysis. The single-crystal X-ray structure of $[YbCa(L)(Cl_2)(EtOH)(H_2O)]\cdot Cl\cdot 2H_2O$ has been determined. The complex is monoclinic, space group $P2_1/c$, with a = 10.033(2), b = 11.702(2), c = 27.796(6) Å and β = 105.51(3)°. The ytterbium ion is seven-coordinate within the N_3O_2 site and is in a pentagonal bipyramidal environment and bonded, in the axial positions, to two chloride ions. The calcium ion is seven-coordinate within the O_3O_2 site and is bonded to the ethyl alcohol oxygen and to one water molecule. The significant contact between the calcium ion and the chloride ions increases the coordination number of the metal ion to eight in a square antiprismatic environment. The selectivity of the etheric site towards alkali and alkaline-earth metal ions has been quantitatively assessed by evaluating, with ^{23}Na NMR spectroscopy, the transmetallation reaction involving the coordinated Na^+ ion in the complexes $[LnNa(L)(Cl)_2(CH_3OH)]$ (Ln = Tb, Dy, Tm and Yb) and Li^+, K^+ and Ca^{2+}. The affinity constants follow the general order $K_{Ca} >> K_{Li} \geq K_K$. Quantitative kinetic analyses were performed on the complex $[TmNa(L)(Cl)_2(CH_3OH)]$ using variable temperature ^{23}Na NMR spectroscopy in CD_3OD. It was ascertained that the exchange rate Na_{bound}/Na_{free} is independent of the presence of increasing amounts of water in the methanolic solution.

Introduction

In recent years asymmetric compartmental macrocyclic ligands have been designed and extensively studied since they are endowed with two well-defined and different recognition processes at two adjacent sites.[1,2] In these studies, Schiff-base ligands have often been used due to their well known coordinating ability. For the preparation of these systems, appropriate formyl-, keto- or amine-precursors have been condensed under suitable experimental conditions.[3]

Recently we prepared [1+1] cyclic Schiff bases by the condensation of 3,3′-(3-oxapentane-1,5-diyldioxy)bis(2-hydroxybenzaldehyde) or 3,3′-(3,6-dioxaoctane-1,8-diyldioxy)bis(2-hydroxybenzaldehyde) with 1,2-diaminoethane, 1,3-diaminopropane or 1,5-diamine-3-azamethylpentane.[4] These ligands contain one N_2O_2 or N_3O_2 Schiff base site and one O_3O_2 or O_4O_2 crown ether-like site. The N_2O_2 and N_3O_2 sites are particularly suitable for the coordination of transition-metal ions while alkali and alkaline-earth metal ions invariably prefer the O_3O_2 or O_4O_2 sites.[5,6] The 4f-metal(III) ions also prefer the crown ether-like chamber irrespective of the shape and donor atoms of the Schiff base site, as ascertained from X-ray structural determinations.[7,8] However, when this cavity is already filled by an alkali metal ion, the incoming lanthanide(III) ion coordinates to the adjacent chamber if the latter is large enough to accommodate the large 4f-metal ion. This occurs in the N_3O_2 chamber of the above mentioned ligand H_2L, derived from the 1:1 condensation of 3,3′-(3-oxapentane-1,5-diyldioxy)bis(2-hydroxybenzaldehyde) and 1,5-diamine-3-azamethylpentane. Thus, heterodinuclear complexes of the type $[LnNa(L)(Cl)_2(CH_3OH)]$ can be easily prepared.[9] When 1,2-diaminoethane or 1,3-diaminopropane was used, the resultant N_2O_2 site is too small for lanthanide(III) encapsulation although the N_3O_2 group is suitable for such coordination.

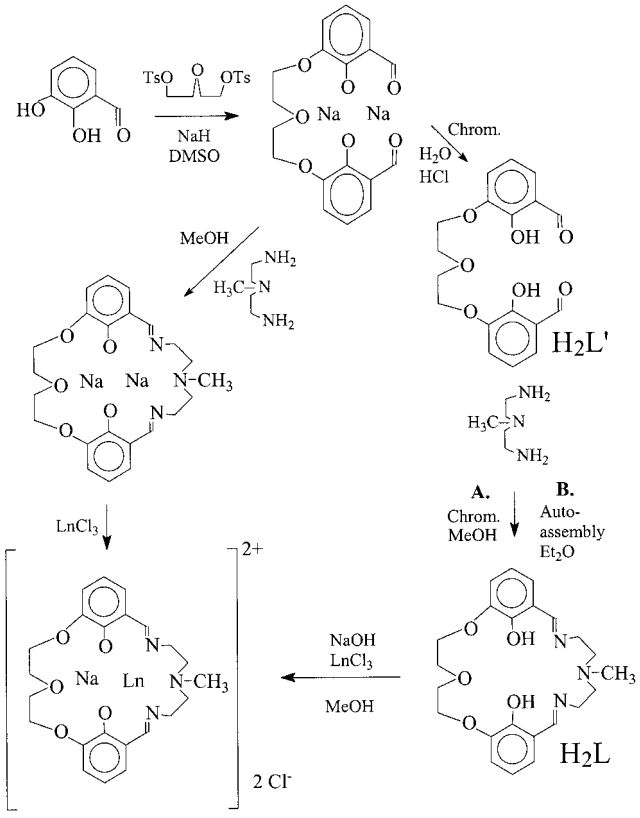
In these complexes, the lanthanide ion coordinated in the N_3O_2 chamber is able to induce a strong paramagnetic shift (LIS) on the Na^+ ion coordinated in the O_3O_2 site. In the case of the Tb, Dy and Tm complexes, the bound shifts are of the order of several hundred ppm (in methanol) which is more than one order of magnitude higher than the values estimated (in water) for the shift reagents currently available.[10–12,15]

These properties make the heterodinuclear Ln-Na complexes very promising candidates for the development of highly effective shift reagents for metal cations of biological interest. The study of the stability of these complexes in solution and the selectivity of the O_2O_3 chamber towards other alkali or alkaline-earth metal ions thus becomes of paramount importance.

In this work, for the complexes $[LnNa(L)(Cl)_2(CH_3OH)]$, we have investigated the rate of exchange between Na_{bound} and Na_{free} (Ln = Tb, Dy, Tm, Yb) and the transmetallation reaction of Na^+ with K^+, Li^+ and Ca^{2+} (Ln = Tm). Furthermore, the heterodinuclear $[LnCa(L)(Cl)_2(CH_3OH)(H_2O)]Cl$ (Ln = Tb, Dy, Tm, Yb) complexes have been prepared and characterised by single-crystal X-ray diffraction, IR, ^1H and ^{13}C NMR spectroscopy and their homogeneity and stoichiometry ascertained by SEM and EDS analyses.



Scheme 1.

Results and Discussion

Preparation and Properties of the Macrocycle H_2L and Related Complexes

The H_2L [1+1] macrocyclic ligand and its homo- and heterodinuclear complexes have been prepared according to Scheme 1.

The diformyl precursor 3,3′-(3-oxapentane-1,5-diyldioxy)bis(2-hydroxybenzaldehyde) H_2L' and its related disodium derivative Na_2L' were prepared as pale yellow air-stable and organic solvent soluble solids by the reaction of the appropriate ditosilate with 2,3-dihydroxybenzaldehyde in anhydrous dimethyl sulfoxide in the presence of NaH. Pure H_2L' was obtained by chromatographic workup on silica gel using $CHCl_3$ as the eluent. The IR spectrum of H_2L' shows a strong ν(C=O) absorption at 1659–1646 cm^{-1}. The ^1H NMR ($CDCl_3$) spectrum consists of a singlet at δ = 9.94 ppm due to CH=O protons, a singlet at δ = 10.96 ppm assignable to the phenolic oxygens and multiplets at δ = 7.15, 4.26 and 3.96 ppm associated with the aromatic and the aliphatic protons of the crown ether chain, respectively. The IR and ^1H NMR spectra of Na_2L' are analogous to those of H_2L'.

The [1+1] macrocyclic ligand H_2L was synthesised by self-condensation of H_2L' with 1,5-diamine-3-azamethylpentane (1:1 molar ratio) in methanol. Alternatively, H_2L can be obtained by the same condensation reaction in the presence of $Ba(ClO_4)_2$ as a templating agent. By following this route, the yellow [1+1] macrocyclic complex $[Ba(H_2L)](ClO_4)_2$ can be demetallated by guanidinium sulphate and the resultant macrocycle H_2L extracted from water with $CHCl_3$. Finally, H_2L can be conveniently prepared in high yield by the condensation of H_2L' and 1,5-diamine-3-azamethylpentane in diethyl ether using the high dilution technique. The latter synthetic route was the chosen method since it gives the macrocyclic ligand in high yield without the need for any further purification. H_2L is a yellow solid and its [1+1] cyclic nature was inferred from the presence of the parent peak $[M - H]^+$ at m/z = 428 in the mass spectrum and by the presence, in the IR spectrum, of a strong ν(C=N) band at 1634 cm^{-1}. The bands attributable to ν(C=O) or ν(NH_2) completely disappeared. Moreover the ^1H NMR spectrum in $CDCl_3$ shows a singlet at δ = 8.19 ppm for the iminic protons, multiplets at δ = 6.75 ppm assignable to the aromatic protons and peaks at δ = 4.20 and 3.95 ppm which can be assigned to the methylenic protons of the crown ether chain. Peaks at δ = 3.63 and 2.78 ppm are due to methylenic protons of the iminic chain and a singlet at δ = 2.32 ppm can be assigned to the methyl group. The ^1H NMR spectrum of Na_2L, obtained from the condensation of the acyclic derivative Na_2L' with $H_2N(CH_2)_2N(CH_3)(CH_2)_2NH_2$, is significantly different from that of H_2L owing to the coordination of the Na^+ ions in the N_3O_2 and O_3O_2 coordination chambers.

By treating Na_2L with the appropriate lanthanide(III) trichloride in methanol in a 1:1 molar ratio, the heterodinuclear complexes $[LnNa(L)(Cl)_2(CH_3OH)]$ were obtained. Alternatively, the macrocycle H_2L can be treated with NaOH and the subsequent addition of $LnCl_3$ yields the same heterodinuclear complexes. The complexes are yellow

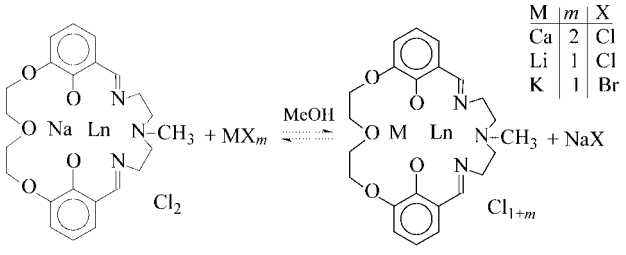
solids which are stable in the solid-state and in solution and yield well formed crystals when recrystallised from alcoholic solutions. The homogeneity of the obtained crystals and the occurrence of the correct Ln/Na/Cl ratio (1:1:2) were checked by electron microscopy and EDS analysis.The IR spectra of $[LnNa(L)(Cl)_2(CH_3OH)]$ show a lower frequency for the ν(C=N) band at 1617–1632 cm^{-1} compared with the free ligand (1634 cm^{-1}). Noticeably, the ν(C=N) resonance lies at 1635–1660 cm^{-1} for the mononuclear complexes $[Ln(H_2L)Cl(H_2O)_4](Cl)_2$ in which the Ln^{3+} ion occupies the O_3O_2 site, with a relevant shift ($\Delta\tilde{\nu}$ = 29–38 cm^{-1}) towards higher wavelengths compared with H_2L. The differences in the C=N stretching frequencies are clearly related to the change in the coordination mode of the lanthanide(III) ion on going from the mononuclear to the heterodinuclear complex.The $[LnCa(L)(Cl)_2(CH_3OH)(H_2O)]Cl$ complexes were prepared by the transmetallation route of $[LnNa(L)(Cl)_2(CH_3OH)]$ with an equimolar quantity of $CaCl_2$ in methanol followed by crystallisation of the resultant powder to eliminate the sodium chloride formed (Scheme 2).



Scheme 2.

The formation of the LnCa(L) complexes was highlighted by elemental analyses as well as IR and NMR spectroscopic measurements and further confirmed by SEM-EDS investigations which indicated the complete disappearance of sodium and the correct Ln:Ca:Cl ratio of 1:1:3. The BSE micrography and the EDX spectra of the complex $[TbCa(L)(Cl)_2(CH_3OH)H_2O]Cl$ are reported in Figure 1.

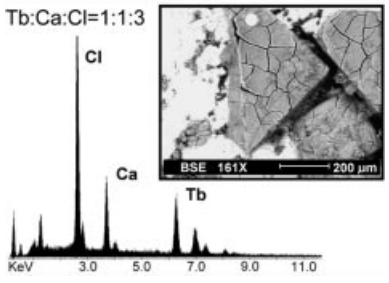


Figure 1. BSE micrography and EDX spectra of the complex $[TbCa(L)(Cl)_2(CH_3OH)H_2O]Cl$.

The ^1H NMR spectra of the paramagnetic calcium complexes closely resemble those of the corresponding sodium complexes. These spectra consist of thirteen resonances spanning a very large chemical shift range. The strict similarity, in terms of chemical shift and bandwidth, between the set of proton resonances for LnCa(L) and LnNa(L) strongly suggests that in both cases the lanthanide ion is coordinated at the N_3O_2 Schiff base site. The IR data also confirm this hypothesis. The ν(C=N) stretching for LnCa(L) is only 2–10 cm^{-1} higher than that of the Ln-Na complex.

Crystal Structure of $[YbCa(L)(Cl)_2(EtOH)(H_2O)]Cl\cdot 2H_2O$

Crystals of $[YbCa(L)(Cl)_2(EtOH)(H_2O)]Cl\cdot 2H_2O$ were obtained by slow diffusion of Et_2O into an ethanol solution of $[YbCa(L)(Cl)_2(CH_3OH)(H_2O)]Cl\cdot H_2O$. ORTEP representations of the complex and its coordination geometries are shown in Figure 2 (see parts a and b).

The macrocyclic ligand accommodates the ytterbium ion in the O_2N_3 chamber and the calcium ion in the O_2O_3 site. The presence of the calcium ion, as already seen with alkaline ions, forces the coordination of the lanthanide at the iminic site although this is generally unfavourable. The heptacoordination around the lanthanide ion is completed by two chloride ions *trans* to each other and the resultant coordination geometry can be described as pentagonal bipyramidal with the two chlorine atoms [Cl(1) and Cl(2)] in the apical positions. Another chlorine atom and two water molecules are not coordinated and are not reported in the figures. The calcium ion, which is heptacoordinated, is bonded to the two phenolic oxygen atoms which act as a bridge to the ytterbium ion, the three etheric oxygen atoms of the ligand as well as one ethanol and one water molecule. A significant contact is also present between the calcium ion and the chlorine atom Cl(2), [Ca···Cl(2) 3.135(6) Å, the sum of ionic radii being 2.80Å] and this increases the coordination number of the calcium ion to eight. The coordination polyhedron can now be described as a square antiprism.

The Yb–O(phenol) distances are 2.205 Å (mean), the Yb–N(iminic) distances are 2.45 Å (mean) and the Yb–N(2) (aminic) distance is 2.49(1) Å. The difference between the two Yb–Cl distances [2.623(4) Å for Cl(1) and 2.639(4) Å for Cl(2)] is due to the interaction of Cl(2) with the calcium ion. The distance between the two metal ions is 3.565(3) Å. The calcium ion is encapsulated into the O_2O_3 ligand site and the Ca–O(phenol) distances are 2.39(1) Å (mean). The Ca–O(ether) distances are longer and vary between 2.48 and 2.56 Å.

A comparison between this complex [YbCa(L)] and the sodium analogue [YbNa(L)] already published[13] indicates remarkable differences in spite of the very similar ionic radii of the two metal ions (0.97 and 0.99 Å for Na^+ and Ca^{2+}, respectively). Clearly, the charge difference plays an important role. The distances involving the ytterbium ion are comparable in the two complexes as well as the contact distances Yb–Na [3.540(2) Å] and Yb–Ca [3.565(3) Å]. The most important structural difference relates to the coordination geometries of the Na^+ and Ca^{2+} ions. In the former the geometry is pentagonal pyramidal whereas for the latter it is square antiprismatic.

Different spatial arrangements of the ligands are present in the two compounds, although both are in a butterfly-like

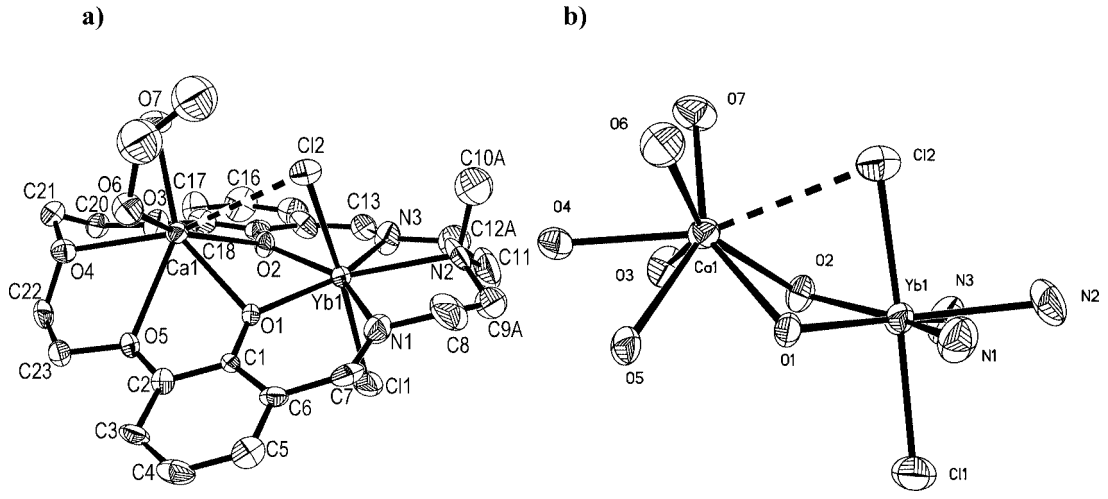

Figure 2. ORTEP representation of (a) the molecular structure of the complex $[YbCa(L)(Cl)_2(EtOH)H_2O]Cl$ and (b) the coordination geometries.

arrangement. The two wings (the two benzene rings) subtend a dihedral angle of 40.7° in the YbNa(L) complex and 32.2° in the YbCa(L) complex. Dissimilar dihedral angles involving the central metals are present and the dihedral angle between Na–O(1)–Yb and Na–O(2)–Yb is 21.1° whereas it increases to 49.3° for the angle between Ca–O(1)–Yb and Ca–O(2)–Yb. A noticeable dissimilarity between the Na–O(etheric) and Ca–O(etheric) bond distances and the torsion angles of the ligand (O–C–C–O and N–C–C–N) is present in the complexes. The conformations of the torsion angles O(3)–C(20)–C(21)–O(4) and O(4)–C(22)–C(23)–O(5) are g^+ and g^- in the Na complex and g^- and g^- in the Ca compound. The conformations of the torsion angles N(1)–C(8)–C(9)–N(2) and N(2)–C(11)–C(12)–N(3) are g^- and g^+ for the Na complex and g^+ and g^- for the Ca complex [because of the presence of disorder, we used the C(9A) and C(12A) atomic positions which show higher population parameters]. The Na–O(etheric) bond distances are 2.38 Å (mean) whereas the corresponding Ca–O(etheric) bond distances are 2.52 Å (mean). The hydrogen bonding networks in the crystal structures of these complexes are remarkable and involve the three chloride anions and all the coordinated and uncoordinated water molecules.

NMR Solution Studies

Selectivity of [LnNa(L)(Cl)$_2$(CH$_3$OH)] towards Li$^+$, K$^+$ and Ca^{2+} Ions

The LnNa(L) complexes appear to be stereochemically rigid on the NMR timescale and their proton spectra are characterised by sharp and well-separated resonances over a wide interval of temperatures.[9] On the other hand, the ^{23}Na NMR spectra show single resonances assignable to the coordinated sodium cation and markedly shifted from the positions of the free ions. Following addition to the methanolic solution of KBr, LiCl or $CaCl_2$, a transmetallation reaction occurs which can be revealed by the appearance, in the ^{1}H NMR spectra, of a second set of resonances closely corresponding to those of the LnNa(L) complex.[9] Alternatively, the course of the reaction can be followed by monitoring the decrease in the intensity of the ^{23}Na NMR peak of the coordinated sodium cations and the concomitant increase of a new resonance due to the free sodium ions (Figure 3). Thus, the replacement of Na^+ by alkali and alkaline-earth metal ions does not modify the structure or the stereochemical rigidity of the complex.

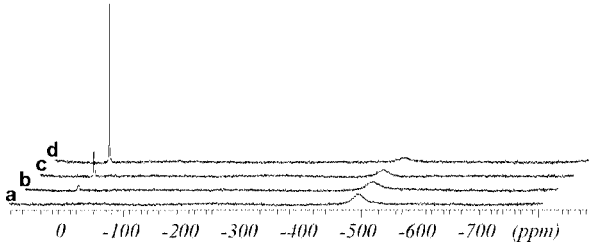

Figure 3. ^{23}Na NMR spectra of $[TbNa(L)(Cl)_2(MeOH)]$ in CD_3OD at 9.4 T and 273 K before (a) and after the addition of equimolar amounts of KBr (b), LiCl (c) and $CaCl_2$ (d).

We have recorded the ^{23}Na NMR spectra of the LnNa(L) complexes (Ln = Tb, Dy, Tm and Yb) in the presence of equimolar amounts of LiCl, KBr and $CaCl_2$ at different temperatures. When LnNa(L) and the lithium, potassium or calcium salts are added together in equimolar amounts, the transmetallation reaction described in Equation (1) assumes a simplified form [Equation (2)] particularly suitable for an NMR study.

$$LnNa(L) + M \leftrightarrow LnM(L) + Na \quad (1)$$

$$K = \frac{[LnM(L)][Na]}{[LnNa(L)][M]} \Rightarrow K = \frac{[Na]^2}{[LnNa(L)]^2} \quad (2)$$

In fact, the equilibrium constant K can be directly assessed by measuring the areas of the ^{23}Na NMR signals

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

corresponding to the free and bound sodium cations. For the different lanthanides investigated, we observed different affinities for the complexes towards alkali and alkaline-earth metal ions. Table 1 reports the *K* values for the transmetallation reactions of involving the LnNa(L) complexes (Ln = Tb, Dy, Tm, Yb) with Li^+, K^+ and Ca^{2+}.

Table 1. Equilibrium constants for reaction (1) obtained from ^{23}Na NMR spectroscopic data at 9.4 T and 293 K.

Ln	K_{Li}	K_K	K_{Ca}
Tb	4.3×10^{-2}	1.1×10^{-2} [a]	2.4
Dy	2.7×10^{-2}	3.8×10^{-2} [a]	2.7
Tm	3.2×10^{-1}	7.3×10^{-2}	1.2
Yb	6.4×10^{-2}	1.9×10^{-3}	7.6

[a] Measured at 273 K.

The values of the equilibrium constants follow the general order $K_{Ca} >> K_{Li} \geq K_K$. This behaviour is likely to be related to the ionic radii of the metal ions and the dimension of the O_2O_3 coordination site. Both Na^+ (97 pm) and Ca^{2+} (99 pm) fit rather well into the crown-ether cavity whereas Li^+ (76 pm) and K^+ (138 pm) are either too small or too large. On the other hand, a well defined trend as a function of the ionic radius of the lanthanide ion was not observed. The equilibrium constants for the transmetallation reactions with Li^+ and K^+ are higher for Tm than for the other lanthanide cations, whereas the highest affinity for Ca^{2+} is shown by the Yb complex. Clearly, the affinity of the different Ln^{III} cations towards a given alkali or alkaline-earth metal ion is not simply dictated by the variation of the charge density across the lanthanide series. Although this behaviour cannot easily be rationalised in terms of the available data, it could arise from small structural variations of the complexes which occur on passing from the Tb to the Yb complexes involving primarily the crown-ether site. A powder X-ray diffraction analysis on the Dy complex, obtained from a different solvent, was carried out using a Philips X'Pert system in the range 4–90° (2θ). The resultant diffraction pattern is not analogous with that of the Yb analogue and this is consistent with the differences in the structural details.

The selectivity of the complexes to sodium appears greater than that observed for $TmDOTP^{5-}$ [$DOTP^{8-}$ = tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetrakis(methylphosphonate)], the most effective shift reagent currently available.[14] This latter complex forms very stable 1:1 adducts with Ca^{2+} (and Mg^{2+}) and the ^{23}Na shift is significantly reversed for a $Ca^{2+}/TmDOTP^{5-}$ ratio close to 1. Under similar experimental conditions 48% of the sodium remains bound to the Tm complex in our case (20 °C). On the other hand, the Dy complex with a polyoxa tetraaza macrocyclic tetraacetate ligand shows a higher selectivity for Na^+ than for Ca^{2+} although the paramagnetic shift is much smaller.[15]

Determination of the Na^+ Exchange Rate

The rate of exchange of the Na^+ ion between the coordination site of the complex and the solution is of primary importance for the development of efficient shift reagents for biomedical applications. The exchange rate needs to be sufficiently rapid so as to give rise to an exchange-averaged ^{23}Na NMR signal well shifted from the diamagnetic position and to allow a clear discrimination of the peaks of the Na^+ ions present in two different compartments. The ^{23}Na NMR spectra of the LnNa(L) complexes in methanol can be characterised, at low temperature, by the presence of a broad, highly shifted resonance (–614, –157, +340 and –40 ppm for Tb, Dy, Tm and Yb, respectively, at 253 K and 9.4 Tesla) corresponding to the coordinated Na^+ ion and another narrow peak at 0 ppm corresponding to the free ion.[9,13] The magnitudes of the shifts are very large when compared with common lanthanide-based shift reagents. One possible reason is the presence of a very short Ln–Na distance (ca. 3.5–3.6 Å) which is in contrast to the case of the polyaminocarboxylic complexes in which the ion-paired adducts are characterised by Ln–Na distances of about 4.0 Å and the LnDOTA chelate bearing a crown-ether moiety able to bind sodium where the distance is 5.3 Å.[15] In the complexes discussed here, however, the presence of a contact (through bond) contribution to the shift through the bridging phenolic oxygen atoms cannot be excluded. On the other hand, an accurate evaluation of this contribution is not possible because of the lack of an isostructural trend along the lanthanide series.[12]

The narrow resonance arises from the presence of NaCl which cocrystallises during the recrystallisation of the complexes. By increasing the temperature, the paramagnetically shifted resonance begins to sharpen and shift towards the peak corresponding to the free sodium ions. Exchange-averaged signals can be observed at about 320 K (at ca. +80 and –15 ppm for the Tm and Yb complexes, respectively) which sharpen further upon a further increase in temperature. The lanthanide-based shift reagents currently available produce a shift in the ^{23}Na NMR signal which does not exceed 10 ppm in the compartment in which they distribute.[10–12] These heterodinuclear LnNa(L) complexes are much more effective since they show chemical shifts of hundreds of ppm for the "bound" sodium cation. However, their solubility in water is very poor and, at present, this limits their use for biomedical studies. Clearly, a modification of the ligand is necessary in order to improve the solubility in aqueous media. In this work we have recorded a series of ^{23}Na NMR spectra for the TmNa(L) complex, in the presence of an equimolar amount of NaCl, as a function of temperature and increasing amounts of water. We then calculated the rate of sodium exchange. The complex:NaCl:D_2O molar ratios used were as follows: 1:1:0, 1:1:0.2, 1:1:0.4, 1:1:0.7, 1:1:1.4 and 1:1:2.9. Over a wide range of temperatures, from 263 to 315 K, the resonances due to the coordinated (B) and free (F) Na^+ ions are well separated (large $\Delta\nu_{BF}$) and the system is in the slow exchange regime. These two conditions allows us to assume the validity of the following expression: $1/\tau_B \leq \Delta\nu_{BF}/5$, where $1/\tau_B = k_{ex}$.[16] In this case, the transverse relaxation rate of the resonance of Na_F, calculated from the bandwidth at half-height, $\Delta\nu_F$, can be expressed in terms of Equation (3).[16]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$$1/T_{2F} = 1/T_{2F}^{ref} + P_B \times k_{ex} \quad (3)$$

where $1/T_{2F}$ and $1/T_{2F}^{ref}$ (given by: $\Delta\nu_F \times \pi$) are the transverse relaxation rates of the free Na^+ ions in the presence and in the absence of chemical exchange, respectively, P_B is the molar fraction of the coordinated sodium ion [P_B = [B]/([B]+[F])] and k_{ex} is the rate constant of the exchange process. A similar expression holds for the transverse relaxation rate of the resonance of Na_B, see Equation (4).

$$1/T_{2B} = 1/T_{2B}^{ref} + P_F \times k_{ex} \quad (4)$$

The temperature dependence of k_{ex} is given by the Arrhenius equation, see Equation (5).

$$k_{ex}^T = k_{ex}^{298} \times T/298.15 \times \exp[\Delta H^{\#}/R \times (1000/298.15 - 1000/T)] \quad (5)$$

where T is the temperature, k_{ex}^T is the exchange rate constant at the temperature T, $\Delta H^{\#}$ (kJ mol^{-1}) is the enthalpy of activation of the exchange process and R is the gas constant. Finally, the temperature dependence of the transverse relaxation rate of the NMR signal in the absence of exchange is given by Equation (6).

$$1/T_2^{ref} = (1/T_2^{ref})^{298} \times \exp[E_a/R \times (1000/T - 1000/298.15)] \quad (6)$$

where E_a represents the activation energy of the process.

With the use of Equations 3–6, we have analysed the temperature dependence of the bandwidth of the ^{23}Na peak of the bound sodium ion for the six different solutions and calculated the rate of chemical exchange. The value of k_{ex} was found to be 600 s^{-1} (at 298 K) for all the solutions investigated and is thus independent of the molar fraction of added water. Thus, the derivatisation of the ligand aimed at increasing the solubility of the complexes in water should not compromise their promising properties as ^{23}Na NMR shift reagents, provided that the chemical modification does not affect the structure and rigidity of the coordination cage.

Conclusions

The transmetallation reactions of the complexes [LnNa(L)(Cl)$_2$(CH$_3$OH)] (Ln = Tb, Dy, Tm and Yb) by Li^+, K^+ and Ca^{2+} ions have been investigated by ^{23}Na NMR spectroscopy in methanolic solutions. The affinities of the macrocyclic complexes towards the alkali and alkaline-earth metal ions are primarily dictated by the match of the ionic radii with the size of the crown-like cavity of the ligand. Interaction of the cation in the O_2O_3 site with the anions may also contribute to the stabilities of the complexes. Large variations were observed in the affinity of a given metal ion for different lanthanide complexes. Small structural changes which may occurs across the lanthanide series seem to have a strong influence on the stabilities of the heterodinuclear complexes. Clearly, further investigations involving a systematic variation of the crown ether cavity are necessary in order to understand the relationship between the selectivity and the structural details of the complexes. The exchange of sodium between the coordination site and the solution is fast enough at physiological temperatures to cause an exchange averaged NMR signal strongly shifted from the diamagnetic position. The rate of exchange is not influenced by the addition of variable amounts of water to the methanolic solution. This property is promising for the development of water soluble derivatives as highly effective shift reagents for cations of biological relevance for diagnostic applications.[11]

Experimental Section

Materials: All solvents, reagents and the lanthanide chlorides, $LnCl_3 \cdot 6H_2O$, were purchased from Aldrich and Fluka and used without further purification.

Physico-Chemical Measurements: Elemental analyses were carried out by using a Fison 1108 analyser. IR spectra were recorded as KBr pellets on a Mattson FTIR spectrometer. The ^1H and ^{13}C NMR spectra for the diamagnetic complexes were recorded on a Bruker AMX300 spectrometer equipped with a broadband multinuclear probe and a variable temperature unit. ^{23}Na spectra were recorded on the same spectrometer on 15–25 m^m solutions of the Ln^{III} complexes (Ln = Tb, Dy, Tm, Yb) in CD_3OD. Typically, 2000 transients were necessary to obtain a satisfactory signal to noise ratio. The data were processed using a line broadening of 20 Hz and a baseline correction. ^{23}Na chemical shifts were measured in relation to the ^{23}Na signal of a 5 M solution of NaCl in CD_3OD. Downfield induced shifts are denoted as positive. The chemical shifts (^{23}Na) and the peak widths were determined by fitting the signals to a Lorenzian line function. All the samples examined were dissolved in deuterated methanol which was also used as an internal reference.

XRD investigations were performed on a Philips X'Pert PW3710 diffractometer using Cu-K_α radiation (40 kV, 30 mA), a high-resolution graphite monochromator, rotating sample holder and a proportional detector. Measurements were carried out in the range 4° $< 2\theta <$ 90° with a step of 0.02°. The morphology, homogeneity and the lanthanide/alkali or alkaline-earth/chlorine ratios of the complexes were investigated using a Philips XL40 model scanning electron microscope equipped with an EDAX DX PRIME X-ray energy dispersive spectrometer.[17] The solvent contents (H_2O or MeOH) were evaluated from thermal analysis curves recorded using Netzsch STA 429 thermoanalytical equipment. The tests were performed under nitrogen (flux rate 250 mL min^{-1}, heating rate 5 °C min^{-1}) and in air under the same conditions. Neutral alumina (Carlo–Erba, Milano, Italy) was used as reference material. All mass spectrometric measurements were performed on a VG ZAB 2F instrument (VG Analytical Ltd.) operating under fast atom bombardment (FAB) conditions (8 keV Xe atoms bombarding a nitrobenzyl alcohol solution of the sample). Also, ESI-MS spectra were recorded using an LQC mass spectrometer (Finnigan) and methanolic solutions of the samples (10^{-5} M).[18]

Preparation of H_2L' and Na_2L': The diformyl precursor 3,3′-(3-oxapentane-1,5-diyldioxy)bis(2-hydroxybenzaldehyde) (H_2L') and the disodium derivative (Na_2L') were prepared by a modification of the literature procedure.[6,7,19–21]

Preparation of H_2L and $[LnNa(L)(Cl)_2(CH_3OH)]$ (Ln = Y, La, Ce, Nd, Sm, Eu, Gd, Tb, Dy, Ho, Er, Tm, Yb and Lu): The asymmetric [1+1] macrocycle 18-methyl-3,5,8-trioxa-15,18,21-triazacyclo-[21.3.1.1[9,13]]octacosa-1(27),9(28),10,12,14,21,23,25-octaene-27,28-diol (H_2L) and its heterodinuclear complexes $[LnNa(L)(Cl)_2(CH_3OH)]$ were prepared according to a literature procedure.[9]

Preparation of $[LnCa(L)(Cl)_2(CH_3OH)(H_2O)]Cl$ (Ln = Tb, Dy, Yb): $[LnNa(L)(Cl)_2(CH_3OH)]$ (Ln = Tb, Dy, Yb) (1 mmol) in methanol (50 mL) was added to an equimolar methanolic solution (50 mL) of $CaCl_2$. The pale brown solution was stirred for 24 h at room temperature. The mixture was then cleared by filtration and the solvent was evaporated to dryness under reduced pressure. The pale yellow residue was treated with *n*-propanol (30 mL), filtered, dried in vacuo and recrystallised by slow diffusion of diethyl ether into a methanol solution which yielded well-formed yellow crystals suitable for X-ray analysis.

$[TbCa(L)(Cl)_2(CH_3OH)(H_2O)]Cl{\cdot}H_2O$: IR (KBr): $\tilde{\nu}$ = 1631 cm^{-1} (C=N). $C_{24}H_{35}CaCl_3N_3O_8Tb$: calcd. C 36.08, H 4.42, N 5.26; found C 35.82, H 4.71, N 5.02.

$[TmCa(L)(Cl)_2(CH_3OH)(H_2O)]Cl{\cdot}H_2O$: IR (KBr): $\tilde{\nu}$ = 1630 cm^{-1} (C=N). $C_{24}H_{35}CaCl_3N_3O_8Tm$: calcd. C 35.64, H 4.36, N 5.19; found C 35.43, H 4.97, N 4.89.

$[DyCa(L)(Cl)_2(CH_3OH)(H_2O)]Cl\,H_2O$: IR (KBr): $\tilde{\nu}$ = 1630 cm^{-1} (C=N). $C_{24}H_{35}CaCl_3DyN_3O_8$: calcd. C 35.92, H 4.40, N 5.24; found C 35.51, H 4.62, N 4.98.

$[YbCa(L)(Cl)_2(CH_3OH)(H_2O)]Cl{\cdot}H_2O{\cdot}0.5NaCl$: IR (KBr): $\tilde{\nu}$ = 1627 cm^{-1} (C=N). $C_{24}H_{35}CaCl_{3.5}N_3Na_{0.5}O_8Yb$: calcd. C 34.23, H 4.19, N 4.99; found C 34.98, H 4.22, N 4.64.

X-ray: Diffraction data were collected at room temperature on a Philips PW1100 automatic four-circle diffractometer (FEBO System) using graphite monochromated Mo-K_α radiation and the ω-2θ scan method. Lattice parameters were obtained from least-squares refinements of the setting angles of 30 reflections with $9° \leq 2\theta \leq 23°$. No sign of crystal deterioration was revealed by monitoring three standard reflections after every 200 measurements. The structure was solved by standard Patterson methods and subsequently completed by a combination of least-squares techniques and Fourier syntheses with the SHELX program.[22,23] All benzene rings were refined as rigid bodies, the hydrogen atoms were included in idealised positions with fixed C–H distances (C–H = 0.93Å) and isotropic temperature factors fixed to 1.2 times *U*(eq) of the corresponding carbon atom. Table 2 shows a summary of the crystallographic data and structure refinement. The poor quality of the crystals did not give very good data but the data were, however, very useful in understanding the structure and the connectivity of this complex. In particular, serious disorder was found around N2 and for the coordinated ethanol molecule. Two possible positions for C9, C10, C12 and C25 were refined together with the corresponding population parameters. Additional crystallographic data, atomic coordinates, anisotropic thermal parameters and full listings of bond lengths and angles are available as supplementary material from the CCDC. Final geometrical calculations and drawings were carried out with the PARST program[24] and the XP utility of the Siemens package,[25] respectively, running on a DIGITAL ALPHA-AXP 300 computer.

Two New Diphenoxo-Bridged Discrete Dinuclear $Cu^{II}Gd^{III}$ Compounds with Cyclic Diimino Moieties: Syntheses, Structures, and Magnetic Properties

Rajesh Koner,[a] Gene-Hsiang Lee,[b] Yu Wang,[b] Ho-Hsiang Wei,*[c] and Sasankasekhar Mohanta*[a]

Keywords: Magnetic properties / Compartmental ligands / Gadolinium(III) / Ferromagnetic / Heterometallic complexes

Two Schiff base compartmental ligands, H_2L^1 and H_2L^2, derived from the condensation of 3-ethoxysalicylaldehyde with 1,2-diaminocyclohexane and orthophenylenediamine, respectively, have been utilized to isolate two diphenoxo-bridged discrete dinuclear $Cu^{II}Gd^{III}$ complexes, $[Cu^{II}(H_2O)L^1Gd^{III}(NO_3)_3]$ (**3**) and $[Cu^{II}L^2Gd^{III}(NO_3)_3]$ (**4**). This is the first report on the 3d-4f compounds derived from compartmental Schiff base ligands with cyclic diamines. The compounds **3** and **4** crystallize in the triclinic $P\bar{1}$ and orthorhombic *Pna*2(1) space groups, respectively, with the following unit cell parameters – **3**: a = 8.8713(2) Å, b = 12.8399(3) Å, c = 14.0067(3) Å, α = 80.6649(5)°, β = 77.4059(5)°, γ = 76.8879(5)°, and Z = 2; **4**: a = 9.2210(1) Å, b = 16.5407(2) Å, c = 19.9248(4) Å, and Z = 4. Structural analysis reveals that both are discrete dinuclear complexes. In **3**, one water molecule is coordinated to the copper(II) ion to result in a square-pyramidal coordination geometry, while the geometry of the coppe(II) center in **4** is square planar. In both complexes, the gadolinium(III) center has an O_{10} coordination environment. In contrast to expectation, although the N_2O_2 cavity affords a better planar environment for the copper(II) center in **4**, the bridging moiety in complex **3** is more planar than that in **4** or in most of the previously reported examples (the dihedral angle between two CuO_2Gd planes: 2.1° for **3** and 7.1° for **4**). Variable-temperature and variable-field magnetic measurements reveal that the metal centers in both the complexes are ferromagnetically coupled (J values: 6.3 cm^{-1} for **3** and 5.4 cm^{-1} for **4**; $H = -2JS_{Cu}\cdot S_{Gd}$). Interestingly, complex **3** exhibits strongest ferromagnetic interaction among the related compounds.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

With the exception of a few examples of carboxylate-bridged dimers,[1] all other reported discrete dinuclear 3d-4f complexes have been derived from Schiff base ligands.[2–19] In these Schiff base compounds, the steric effects imposed by complete encapsulation of the dinuclear core,[2,3] alkyl substituents on the lateral diiminoalkane chain,[4–16] the presence of an apical fifth ligand (1-methyl imidazole, methanol or acetone) coordinated to the square-planar copper(II) center,[6,17] or the distortion of the copper(II) environment from a square plane to tetrahedron have been argued to be the governing factors that stabilize the discrete dinuclear cores.[18]

Costes et al. reported a number of discrete 3d-4f compounds derived from the compartmental Schiff base ligands obtained on condensation of 3-methoxy/ethoxysalicylaldehyde with diaminoalkanes that have alkyl substituents on the lateral alkane chain.[4–16] There is also a recent example in which a discrete $Cu^{II}Gd^{III}$ compound has been synthesized by using the planar diamino chain provided by *S*-methylisothiosemicarbazide.[19] We reported a $Cu^{II}Gd^{III}$ compound derived from *N*,*N*′-ethylenebis(3-ethoxysalicylaldimine) with no alkyl substituent on the lateral chain.[20] In this complex, although the metal ions are well separated, there exists a weak intermolecular antiferromagnetic interaction, probably due to the semicoordination of one nitrate oxygen of one molecule to the copper(II) center of another dinuclear unit. The studies of the reported compounds reveal that although the nature of interaction is ferromagnetic in most cases,[2–20] the ferromagnetic behavior is not intrinsic; it depends on the environment of the metal ions and the structural parameters, and the behavior may also be antiferromagnetic.[14,15] It has also been realized that the dihedral angle between the CuO_2 and LnO_2 planes plays the crucial role in determining the nature and magnitudes of the exchange interactions.[10,17]

Although several acyclic diamines have been used to prepare Schiff base ligands that can stabilize discrete 3d-4f

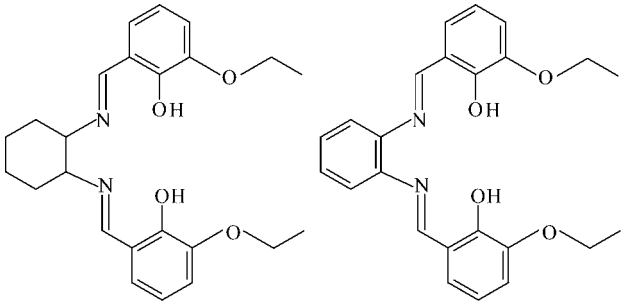
complexes, cyclic diamines such as 1,2-diaminocyclohexane or orthophenylenediamine have still not been utilized. By using two compartmental Schiff base ligands, H_2L^1 and H_2L^2, derived from the condensation of 3-ethoxysalicylaldehyde with 1,2-diaminocyclohexane and orthophenylenediamine, respectively, we have isolated two new heteronuclear $Cu^{II}Gd^{III}$ complexes, $[Cu^{II}(H_2O)L^1Gd^{III}(NO_3)_3]$ (**3**) and $[Cu^{II}L^2Gd^{III}(NO_3)_3]$ (**4**) (Scheme 1). We were particularly interested in the designed syntheses of 3d-4f systems that exhibit ferromagnetic interactions of different strengths.



Scheme 1. Chemical structures of H_2L^1 and H_2L^2.

Results and Discussion

Description of the Structures of 3 and 4

The X-ray crystal structures of the two complexes show that both are dinuclear neutral complexes of copper(II) and gadolinium(III). ORTEP representations of **3** and **4** along with atom labels are shown in Figure 1 and Figure 2, respectively. The selected bond lengths and angles are listed in Table 1. In **3**, the cyclohexane moiety exists in a diequatorial *trans* configuration indicating that the condensation takes place with the diequatorial *trans* form of the diamine. The metal centers in both the complexes are doubly bridged by two phenoxo oxygen atoms provided by the ligands. The inner N_2O_2 cavity is occupied by copper(II), while gadolinium(III) occupies the open and larger position of the dinucleating compartmental ligands, $[L^1]^{2-}$ or $[L^2]^{2-}$. Because of the significant difference in size, the bond lengths of copper(II) and gadolinium(III) with bridging phenoxo oxygen atoms are significantly different [**3**: Cu–O(1) = 1.915(2), Cu–O(2) = 1.909(2), Gd–O(1) = 2.380(2), Gd–O(2) = 2.343(2) Å; **4**: Cu–O(1) = 1.884(4), Cu–O(2) = 1.903(5), Gd–O(1) = 2.368(5), Gd–O(2) = 2.419(4) Å].

The gadolinium(III) ion in both compounds has an O_{10} coordination environment. In addition to the phenoxo groups, two ethoxy oxygen atoms coordinate to this metal center. Two oxygen atoms each from the three nitrate groups chelate to gadolinium(III) to complete the decacoordination geometry. There are, as usual, three sets of Gd–O bond lengths.[4–13,18] The shortest and longest bonds involve the linking of the lanthanide with the bridging phenoxo oxygen atoms [**3**: Gd–O(1) = 2.380(2), Gd–O(2) = 2.343(2) Å; **4**: Gd–O(1) = 2.368(5), Gd–O(2) = 2.419(4) Å] and the ethoxy moieties [**3**: Gd–O(3) = 2.712(2), Gd–O(4) = 2.568(2) Å; **4**: Gd–O(3) = 2.544(4), Gd–O(4) = 2.701(4) Å], respectively, while the Gd–O(nitrates) separations [**3**: 2.450(3)–2.554(3) Å; **4**: 2.441(6)–2.551(5) Å] are of intermediate length. The Gd–O (ethoxy, nitrate or phenoxo) bond lengths are almost similar to the bond lengths observed in previously reported examples.[6–15,20]

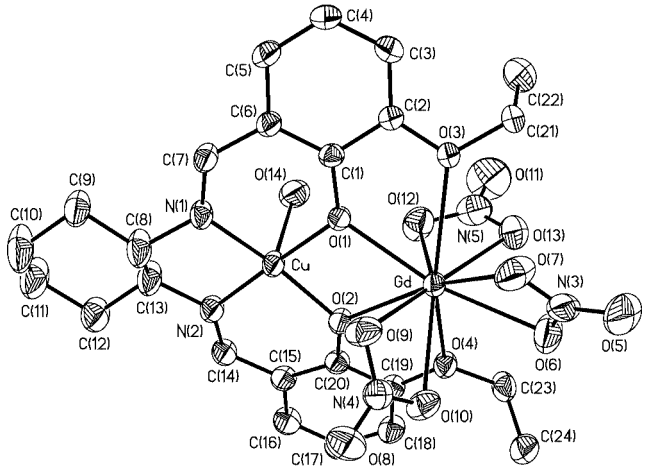


Figure 1. ORTEP representation (40% thermal ellipsoids) of **3** with atom-labeling schemes.

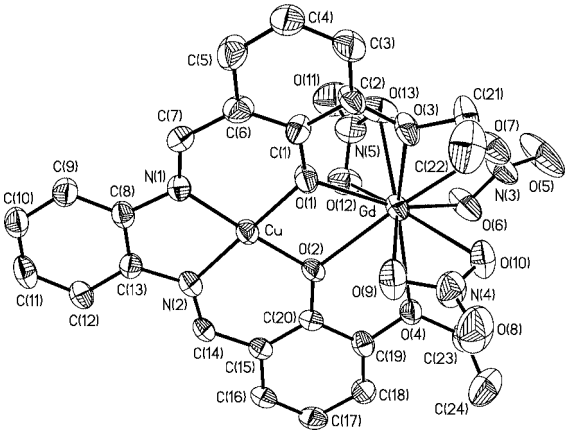

Figure 2. ORTEP representation (40% thermal ellipsoids) of **4** with atom-labeling schemes.

As mentioned before, copper(II) occupies the N_2O_2 cavities of the compartmental ligands in **3** and **4**. The ranges of the *cisoid* [84.23(9)°–96.82(11)°] and *transoid* [178.41(11)° and 168.44(12)°] angles in the N_2O_2 cavity, and the dihedral angles between the CuN(1)N(2) and CuO(1)O(2) planes (δ_1, 11.5°) or the CuN(1)O(1) and CuN(2)O(2) planes (δ_2, 11.7°) indicate that the N_2O_2 moiety affords an approximate square plane to copper(II) in **3**; the donor centers are alternatively above and below the mean N_2O_2 plane by an average of 0.086 Å, while the copper(II) is 0.1 Å below this square plane. In contrast, the N_2O_2 environment in **4** is more planar. Although the range of the *cisoid* angles [83.0(2)°–96.1(2)°] in **4** is similar to that in **3**, the *transoid*

δ_1[a]	11.5	1.8
δ_2[a]	11.7	1.9
Cu···Gd[b]	3.401	3.449
Cu···Cu[b]	6.469	6.695
Cu···Gd[b]	7.657	7.192
Gd···Gd[b]	8.871	9.221

[a] δ, δ_1, δ_2 are the dihedral angles between CuO(1)O(2) and GdO(1)O(2), CuN(1)N(2) and CuO(1)O(2), and CuN(1)O(1) and CuN(2)O(2) planes, respectively. [b] Intramolecular interaction. [c] Shortest intermolecular interaction.

angles deviate only by a small degree from 180°. In addition, the dihedral angles δ_1 (1.8°) and δ_2 (1.9°) are close to 0°, which indicates an almost planar copper(II) environment afforded by the hexadentate ligand in **4**; the deviations of the donor centers and the metal ion is 0.01 Å (average). As expected, the copper(II) environment in the N_2O_2 cavity is more planar in **4**. However, interestingly, the planarity of the bridging moieties does not parallel our expectation; the dihedral angles (δ) between the CuO(1)O(2) and GdO(1)O(2) planes in **3** and **4** are 2.1° and 7.1°, respectively. Among the diphenoxo-bridged $M^{II}Ln^{III}$ complexes reported so far, the bridging moiety in one $Cu^{II}Gd^{III}$ complex that has a δ value of 1.7° is more planar than that in **3**.[10] The dihedral angles in other related compounds range from 4.7° to 47.4°.[7–16,20]

In addition to the four donor centers provided by the Schiff base ligand, one water molecule is coordinated to the apical position of the copper(II) center in **3** to result in a square-pyramidal coordination environment. As expected, due to Jahn–Teller distortion, the Cu–O(water) bond length [2.535(3) Å] is much longer than the bond lengths [1.909(2)–1.922(3) Å] of the metal ion with the donor centers in the equatorial plane. The bond angles of the Cu–O(water) axis with the planar Cu–N or Cu–O bonds lie between 89.56(10)° and 96.82(11)° indicating the square-pyramidal geometry of the copper(II) ion in **3**. In contrast, the coordination environment in **4** is square planar.

There exist several types of common intra- and intermolecular hydrogen bonds in both **3** and **4** that result in self-assembled supramolecular structures (one-dimensional for **4** and two-dimensional for **3**; see supporting information for discussion and figures). However, the shortest intermolecular metal···metal distances in **3** (Gd···GdA = 8.871 Å, Cu···GdA = 7.657 Å, Cu···CuC = 6.469 Å; symmetry: A, $x-1, y, z$; C, $1-x, -y, 1-z$) or **4** (Cu···CuA = 6.695 Å, Cu···GdA = 7.192 Å, Gd···GdB = 9.221 Å; symmetry: A, $x-0.5, 0.5-y, z$; B, $x-1, y, z$) are long enough to consider the dinuclear cores in both complexes as discrete.

Magnetic Properties

The variable-temperature (2–300 K) magnetic behavior of **3** and **4** are shown in Figure 3 and Figure 4, respectively, in the form of $\chi_M T$ versus T plots. The $\chi_M T$ values at 300 K for both complexes (8.51 $cm^3 mol^{-1} K$ for **3** and 8.34 $cm^3 mol^{-1} K$ for **4**) are slightly higher than the calculated value (8.25 $cm^3 mol^{-1} K$) for two uncoupled spins with $g = 2$. With a decrease in temperature from 300 K to 85 K, the $\chi_M T$ values slowly increase to reach 8.80 $cm^3 mol^{-1} K$ and 8.55 $cm^3 mol^{-1} K$ for **3** and **4**, respectively. On further lowering of the temperature, $\chi_M T$ increases sharply to 10.31 $cm^3 mol^{-1} K$ at 10 K for **3** and 9.97 $cm^3 mol^{-1} K$ at 2 K

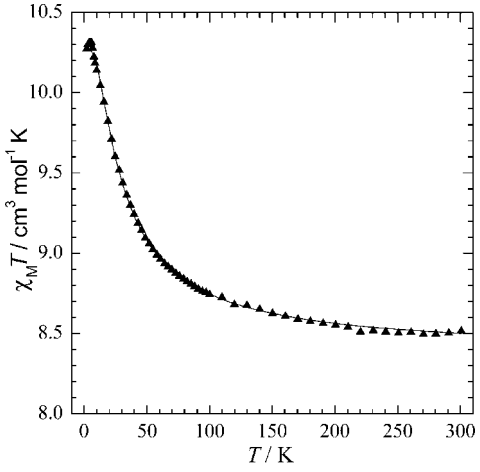

Figure 3. Experimental (triangles) and calculated (solid lines) $\chi_M T$ vs. T plots for $[Cu^{II}(H_2O)L^1Gd^{III}(NO_3)_3]$ (**3**).

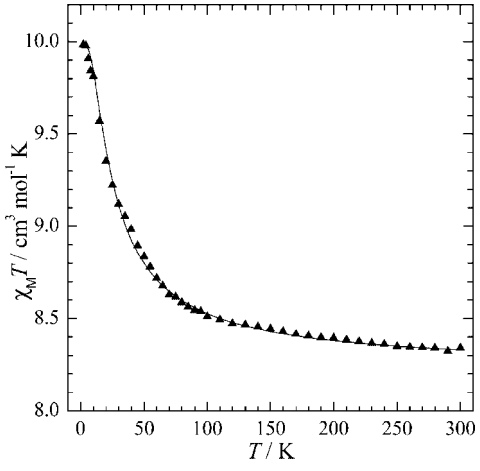

Figure 4. Experimental (triangles) and calculated (solid lines) $\chi_M T$ vs. T plots for $[Cu^{II}L^2Gd^{III}(NO_3)_3]$ (**4**).

for **4**. Below 10 K, the $\chi_M T$ values of **3** are practically constant. As there is no orbital contribution in the ground state of Gd^{III}, the trends for the magnetic behavior indicate a ferromagnetic interaction between the metal centers in both complexes. The higher value of $\chi_M T$ at 300 K is also consistent with the ferromagnetic interaction between the spin carriers. For **4**, the larger value of $\chi_M T$ at 300 K is also associated with the larger value of g_{Cu} (vide infra).

Using the spin-only HDVV Hamiltonian [$H = -2JS_{Cu}\cdot S_{Gd} + \beta(g_{Cu}\cdot S_{Cu} + g_{Gd}\cdot S_{Gd})H$], the theoretical expression of χ_M for the $Cu^{II}Gd^{III}$ system may be derived as:

$$\chi_M = \frac{4N\beta^2}{k(T-\theta)} \times \frac{7g_3^{\,2} + 15g_4^{\,2}\exp(8J/kT)}{7 + 9\exp(8J/kT)} \quad (1)$$

where g_4 and g_3 are the g values of the pair states $S_T = 4$ and $S_T = 3$, respectively, which, in turn, are related to the local g values as:

$$g_3 = \frac{9g_{Gd} - g_{Cu}}{8}$$

$$g_4 = \frac{7g_{Gd} + g_{Cu}}{8}$$

Least-squares fitting of the experimental data with Equation (1) leads to $J = 6.3\ cm^{-1}$, $g_{Gd} = 2.008$, $g_{Cu} = 2.15$ for **3** and $J = 5.4\ cm^{-1}$, $g_{Gd} = 1.997$, $g_{Cu} = 2.0$ for **4**;[21] the agreement factor defined as $[\sum\{(\chi_M T)_{obs} - (\chi_M T)_{calc}\}^2 / \sum(\chi_M T)_{obs}^2]$ is 1.9×10^{-3} and 2.9×10^{-3} for **3** and **4**, respectively.

The field dependence of magnetization (up to 60000 G for **3** and 55000 G for **4**) at 5 K was measured. In Figure 5 and Figure 6, the magnetization data have been compared with the sum of the Brillouin functions of isolated Gd^{III} and Cu^{II}, as well as with the Brillouin function of the $S_T = 4$ state. The experimental magnetization is always greater than the sum of the noncorrelated spin system and matches well with the calculated values of the $S_T = 4$ state. The analysis confirms the existence of ferromagnetic exchange interactions between Cu^{II} and Gd^{III} in both complexes.

Kahn suggested that because the coupling is dependent on the exchange transfer integral between the 3d orbital of copper(II) and the 4f orbitals of gadolinium(III), the magnitude of J in systems with a CuO_2Gd moiety, like in **3** and **4**, should be a function of the dihedral angle (δ) between the CuO_2 and GdO_2 planes.[17] Later, on analyzing the coupling constants of a limited numbers of structurally characterized diphenoxo-bridged complexes, Costes proposed an exponential relationship, $2J = Ae^{-B\delta}$ ($A = 11.5$, $B = 0.054$).[10] According to this correlation, J should be $5.15\ cm^{-1}$ for **3** ($\delta = 2.1°$) and $3.9\ cm^{-1}$ for **4** ($\delta = 7.1°$). The experimental values of $6.3\ cm^{-1}$ (**3**) and $5.4\ cm^{-1}$ (**4**) are not very different from this hypothesis. For the $Cu^{II}Gd^{III}$ complex with the smallest dihedral angle (1.7°) reported so far, J is $5\ cm^{-1}$.[10] However, compound **4** with a dihedral angle of 2.1° exhibits the strongest ferromagnetic interaction among the reported examples.

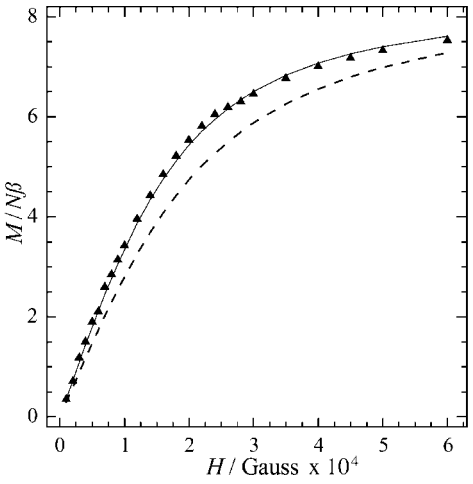

Figure 5. Field dependence of the magnetization at 5 K for $[Cu^{II}(H_2O)L^1Gd^{III}(NO_3)_3]$ (**3**). The solid and dashed lines represent the theoretical magnetization curves for the $S_T = 4$ state and the isolated spin system, respectively.

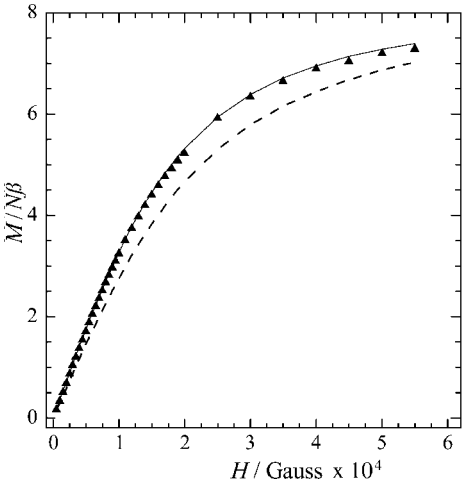

Figure 6. Field dependence of the magnetization at 5 K for $[Cu^{II}L^2Gd^{III}(NO_3)_3]$ (**4**). The solid and dashed lines represent the theoretical magnetization curves for the $S_T = 4$ state and the isolated spin system, respectively.

Conclusions

Two Schiff base compartmental ligands, H_2L^1 and H_2L^2, derived from the condensation of 3-ethoxysalicylaldehyde with 1,2-diaminocyclohexane and orthophenylenediamine, respectively, have been utilized to isolate two diphenoxo-bridged dinuclear $Cu^{II}Gd^{III}$ complexes, $[Cu^{II}(H_2O)L^1Gd^{III}(NO_3)_3]$ (**3**) and $[Cu^{II}L^2Gd^{III}(NO_3)_3]$ (**4**). Cyclic diamines have for the first time been utilized to obtain discrete dinuclear 3d-4f complexes. We expected that **3** would be a discrete $Cu^{II}Gd^{III}$ complex with high δ value that would exhibit a weak ferromagnetic interaction. In contrast, as $[L^2]^{2-}$ should afford a better square plane to copper(II), we expected a more planar bridging moiety in **4** so that this complex would exhibit a stronger ferromagnetic interaction. In contrast to our expectation, although the N_2O_2 cavity affords a better square plane to the copper(II) center in **4**, the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

bridging moiety in complex **3** is more planar than that in **4** or in most of the previously reported examples. Complex **3** exhibits the strongest ferromagnetic interaction (J = 6.3 cm^{-1}; $H = -2JS_{Cu}\cdot S_{Gd}$) among the related compounds reported so far.

Experimental Section

Materials and Physical Methods: All the reagents and solvents were purchased from commercial sources and used as received. Elemental (C, H, N) analyses were performed with a Perkin–Elmer 2400 II analyzer. IR spectra were recorded in the region 400–4000 cm^{-1} on a Perkin–Elmer RXIFT spectrophotometer with samples as KBr disks. Variable-temperature (2–300 K) magnetic susceptibility measurements under a fixed field strength of 0.5 T and the field-dependence magnetization experiments (up to 60000 G for **3** and 55000 G for **4**) at 5 K were carried out with a Quantum Design MPMS SQUID magnetometer. Diamagnetic corrections were estimated from Pascal's constants.

Synthesis of the Complexes

[Cu^{II}L^{1}]·H$_2$O (1): A methanol solution (10 mL) of an equimolar mixture of *cis*- and *trans*-1,2-diaminocyclohexane (0.475 g, 5 mmol) was mixed with a methanol solution (30 mL) of 3-ethoxysalicylaldehyde (1.66 g, 10 mmol), and the mixture was refluxed for 30 min. After cooling to room temperature, an aqueous solution (10 mL) of copper(II) acetate monohydrate (1.0 g, 5 mmol) was added dropwise to the resulting brown solution with stirring. An ash-colored precipitate was separated immediately. After stirring for 1 h, the compound was collected by filtration and air dried. Recrystallization from dimethylformamide resulted in a brown crystalline compound. Yield: 2.1 g (86%). $C_{24}H_{30}N_2O_5Cu$ (490.06): calcd. C 58.82, H 6.17, N 5.71; found C 58.68, H 6.25, N 5.83. IR (cm^{-1}, KBr): ν_{OH}(water), 3541 (m), 3501 (m); ν_{CH}(cyclohexane), 3048 (w), 2985 (w), 2931 (m), 2867 (w); $\nu_{C=N}$, 1623 (s).

[Cu^{II}L^{2}]·H$_2$O (2): This compound was prepared in a similar way to **1**, except with *o*-phenylenediamine instead of 1,2-diaminocyclohexane. Color: brown. Yield: 2.18 g (90%). $C_{24}H_{24}N_2O_5Cu$ (484.01): calcd. C 59.55, H 4.99, N 5.78; found C 59.67, H 4.90, N 5.71. IR (cm^{-1}, KBr): ν_{OH}(water), 3506 (w), 3461 (w); $\nu_{C=N}$, 1606 (s).

[Cu^{II}(H$_2$O)L^{1}Gd^{III}(NO$_3$)$_3$] (3): To a stirred suspension of 1 (0.122 g, 0.25 mmol) in acetone (20 mL) was added a methanol solution (10 mL) of gadolinium(III) nitrate hexahydrate (0.135 g, 0.3 mmol). The color of the solution changed to red. After 20 min of stirring, the solution was filtered to remove the suspended particles and was kept at room temperature for slow evaporation. After a few days, an orange crystalline compound containing diffractable single crystals appeared that was collected by filtration and air dried. Yield: 0.1 g (48%). $C_{24}H_{30}N_5O_{14}CuGd$ (833.32): calcd. C 34.59, H 3.63, N 8.40; found C 34.70, H 3.55, N 8.31. IR (cm^{-1}, KBr): ν_{OH}(water), 3500 (w), 3480 (w); $\nu_{C=N}$, 1632 (s); $\nu_{Nitrate}$, 1393 (s).

[Cu^{II}L^{2}Gd^{III}(NO$_3$)$_3$] (4): This compound was prepared in a similar way to **3**, except with **2** instead of **1**. Color: orange. Yield: 0.14 g (69%). $C_{24}H_{22}N_5O_{13}CuGd$ (809.26): C 35.62, H 2.74, N 8.65; found: C 35.53, H 2.81, N 8.72. IR (cm^{-1}, KBr): $\nu_{C=N}$, 1608 (s); $\nu_{Nitrate}$, 1388 (s).

Crystal Structure Determination: Pertinent crystallographic data of both complexes are summarized in Table 2. Diffraction data for **3** and **4** were collected on a Bruker SMART CCD and a NONIUS Kappa CCD diffractometer, respectively, in the ω–2θ scan mode using graphite monochromated Mo-K_α radiation with λ = 0.71073 Å. The accurate unit cells were obtained by means of least-squares fittings of 25 centered reflections. The intensity data were corrected for Lorentz and polarization effects, and semiempirical absorption corrections were made from ψ-scans. A total of 20780 reflections were collected for **3** in the range 2θ = 3.0–55.0° with $-11 \le h \le 11$, $-16 \le k \le 16$, and $-18 \le l \le 18$, of which 6930 independent reflections (R_{int} = 0.0275) were used for structure determinations. In the case of **4**, among 18891 of the total reflections collected in the 2θ range of 4.92–55.0° with $-11 \le h \le 11$, $-21 \le k \le 21$, and $-25 \le l \le 25$, 6767 were independent (R_{int} = 0.0612). The structures were solved by direct and Fourier methods and refined by full-matrix least-squares methods based on F^2 with the programs SHELXS-97 and SHELXL-97.[22,23] The final least-squares refinements ($R1$) based on $I > 2\sigma(I)$ converged to 0.0255 for **3** and 0.0425 for **4**. CCDC-250133 (**3**) and CCDC-250132 (**4**) contain the supple-

Mixed f-d Metallomesogens with an Extended Rigid Core

Koen Binnemans,*[a] Katleen Lodewyckx,[a] Bertrand Donnio,[b] and Daniel Guillon[b]

Keywords: Copper / Lanthanides / Liquid crystals / Metallomesogens / Nickel

The liquid-crystalline behaviour of copper(II) and nickel(II) complexes of a mesogenic Schiff-base ligand derived from *N*,*N*′-disalicylidene-1,2-phenylenediamine (salophenH_2) and of the corresponding trinuclear mixed copper(II)/lanthanum(III) and nickel(II)/lanthanum(III) complexes was investigated. High-temperature X-ray diffraction studies revealed that both the parent transition metal complexes and the mixed f-d complexes exhibit a hexagonal columnar phase (Col_h) over an extended temperature range. Complex formation with lanthanum(III) nitrate resulted in an increase of the transition temperatures. The geometrical parameters (lattice parameters and column cross-section) of all the metal complexes are very similar, which indicates that the local organisation in the mesophase is the same despite their structural differences.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Liquid-crystalline metal complexes (metallomesogens) combine the unique properties of both transition metals or rare-earth metals and liquid crystals, and these compounds form an intriguing class of new materials.[1] In this way, it is, for instance, possible to obtain paramagnetic liquid crystals,[2] or redox-active liquid crystals.[3] Nearly all metallic elements of the periodic table have been used to create metallomesogens, but examples of liquid crystals that contain both an f-block metal ion (lanthanide or rare-earth ion) and a d-block metal ion are rare. The first examples of such mixed f-d metallomesogens have been reported recently (Figure 1).[4] A copper(II) complex of a mesogenic 2,2′-*N*,*N*′-bis(salicylidene)ethylenediamine (salen) derivative was used to form adducts with lanthanide(III) nitrates. This work was extended further in the sense that the copper(II) was replaced by nickel(II) (Figure 2), and that the influence of the chain length on the transition temperatures was investigated.[5] In all cases, both the parent transition metal complexes and the f-d complexes exhibit a hexagonal columnar mesophase (Col_h). It should be noticed that salen-type ligands are of interest not only for preparing liquid-crystalline f-d complexes, but also for the design of many types of liquid-crystalline transition metal complexes.[6] The salen-type Schiff-base complexes are important as catalysts.[7]

In this paper we have modified the salen-type ligand that has been used in earlier studies on f-d metallomesogens by replacing 1,2-ethylenediamine as the linking group by 1,2-diaminobenzene. The aim of the work was to investigate the influence of the extension of the rigid part of the core of the ligand on the thermal behaviour of the ligand and metal complexes. Four mesogenic metal complexes were prepared, namely two copper(II) and nickel(II) ones, and two binuclear copper(II)/lanthanum(III) and nickel(II)/lanthanum(III) complexes (Figure 3). Their liquid-crystalline properties were investigated in detail by X-ray diffraction.

Results and Discussion

The synthesis of the *N*,*N*′-disalicylidene-1,2-phenylenediamine (salophenH_2) Schiff-base ligand (H_2L) and of the metal complexes is outlined in Scheme 1. The first step is the synthesis of 3,4,5-tris(tetradecyloxy)benzoic acid by alkoxylation of 3,4,5-trihydroxybenzoic acid ethyl ester (Williamson ether synthesis), followed by formation of the free acid by saponification of the ethyl ester and acidification of the carboxylate salt. The second step is the coupling of 3,4,5-tris(tetradecyloxy)benzoic acid to the 4-position of 2,4-dihydroxybenzaldehyde by an ester bond (with DCC, DMAP). The aldehyde was transformed into the Schiff-base ligand by condensation with 1,2-diaminobenzene in toluene. The water formed during the condensation reaction was removed azeotropically in a Dean–Stark trap. The copper(II) complex CuL and the nickel(II) complex NiL were formed by reaction between the Schiff-base H_2L and copper(II) acetate monohydrate and nickel(II) acetate tetrahydrate, respectively, in a methanol/chloroform mixture.

The acetate ions act as the base to deprotonate the Schiff-base ligand. The copper(II)/lanthanum(III) complex CuLaL and the nickel(II)/lanthanum(III) complex NiLaL were prepared by reaction between the copper(II) complex CuL or the nickel(II) complex NiL and lanthanum(III) nitrate hexahydrate in acetone. The metal complexes were characterised by infrared spectroscopy and by elemental analysis. Both the copper(II)/lanthanum(III) complex CuLaL and the nickel(II)/lanthanum(III) complex NiLaL were found to be trinuclear species consisting of two transition metal ions [either copper(II) or nickel(II)] and one trivalent lanthanum(III) ion per molecule. The nitrogen content of the lanthanum(III) complexes, as determined by CHN microanalysis, is lower than the calculated value. This discrepancy is due to a systematic error in the CHN microanalysis procedure, and can be attributed to incomplete reduction of the nitrates to dinitrogen gas or to the formation of lanthanum(III) oxonitrides. Although we could not obtain single crystals of our compounds for X-ray structure determination, we can nevertheless deduce some data about the coordination sphere of the lanthanum(III) by referring to the crystal structures published by Kahn et al. for f-d complexes of the salen ligand.[8] The three nitrate ions are coordinated to the lanthanum(III) ion in a bidentate fashion. The coordination number of lanthanum(III) is ten, with six oxygen atoms from the three nitrate groups and four oxygen atoms of the two copper(II) salophen complexes [or nickel(II) salophen complexes]. The coordination polyhedron of lanthanum(III) is irregular and cannot be approximated by a highly symmetric coordination polyhedron. Coordination number 10 is rather unusual for lanthanide complexes, but can in this case be achieved by the small bite angle of the nitrate groups.

The Schiff-base ligand H_2L is not mesomorphic, and it melts directly to an isotropic liquid at 67 °C. All the metal complexes are enantiotropic liquid crystals. The mesophases were studied by polarising optical microscopy (POM), differential scanning calorimetry (DSC) and by high-temperature X-ray diffraction. For the copper and nickel complex, a typical texture of a hexagonal columnar mesophase (Col_h) could be seen by POM upon slow cooling from the isotropic liquid. Only atypical textures were observed for the trinuclear complex CuLaL and for the trinuclear complex NiLaL, so that it was impossible to determine the mesophase unambiguously by POM. Observation of the texture of the copper/lanthanum complex CuLaL was also hampered by the thermal decomposition of the complex in the mesophase before the clearing point was reached. Just above the melting point, the viscosity of the samples is quite high, but the viscosity decreases with increasing temperature. Because no well-resolved DSC curves could be recorded (a problem also encountered in the past for similar complexes),[4] no enthalpy data could be obtained. These problems could be due to the high viscosity of the complexes, and to the low crystallinity of the complexes in the solid phase. The transition temperatures of the complexes were determined by optical microscopy, and the values are given in Table 1.

Table 1. Transition temperatures and mesophase behaviour of the Schiff-base complexes.

Complex	Transition temperatures [°C][a]
CuL	Col_{ho} · 39 · Col_h · 170 · I

The mesophase behaviour of the metal complexes was studied in detail by temperature-dependent X-ray measurements. The results of the X-ray measurements are summarised in Tables 2–5. X-ray patterns of the complexes are shown in Figures 4–8. X-ray diffractograms were recorded at 30 °C (Figure 4) and at 50 °C and 100 °C (Figure 5) for

the mononuclear copper complex CuL (Table 2) and the mononuclear nickel complex NiL (Table 3), and at 100 °C (Figure 6) and 150 °C for the trinuclear copper/lanthanum complex CuLaL (Figure 7, Table 4) and the nickel/lanthanum complex NiLaL (Figure 8, Table 5). All the samples gave similar X-ray patterns when the experiments were performed in the mesomorphic temperature ranges. The X-ray patterns consist of: (a) a diffuse scattering halo (*h2*) in the wide-angle region, corresponding to the liquid-like disorder

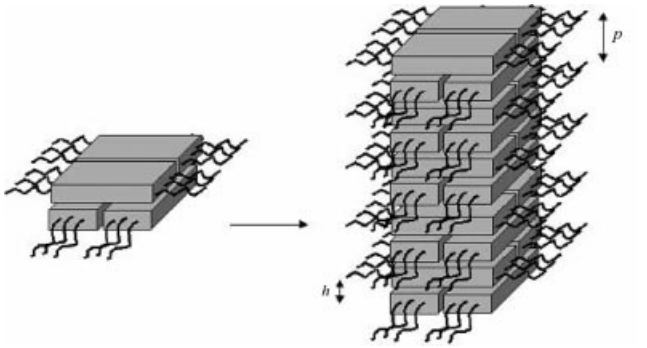

Figure 9. Molecular organisation of the copper(II) complex CuL and the nickel(II) complex NiL within the hexagonal columnar mesophase. The columnar repeat unit is given by $<p>$, and $<h>$ is the average distance between adjacent molten chains.

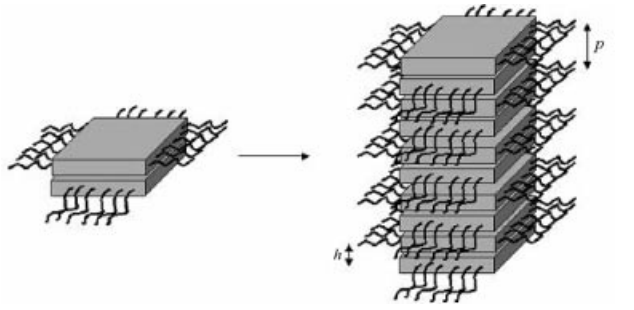

Figure 10. Molecular organisation of the copper(II)/lanthanum(III) complex CuLaL and the nickel(II)/lanthanum(III) complex NiLaL within the columnar mesophase. The columnar repeat unit is given by $<p>$, and $<h>$ is the average distance between adjacent molten chains.

ratio 1, $\sqrt{3}$, $\sqrt{4}$ and $\sqrt{7}$, corresponding to the indexation [*hk*] = [10], [11], [20] and [21], respectively. Such features are characteristic of a two-dimensional hexagonal packing of columns; that is, a hexagonal columnar mesophase (Col_h). The phase is disordered since there is no long-range correlation order within the columns, as evident from the absence of a sharp peak in the wide-angle region which would have corresponded to a more regular stacking along the columnar axis. However, for the copper complex CuL, an ordered columnar mesophase with a hexagonal symmetry (Col_{ho}) was observed below 39 °C. A typical feature in the X-ray diffractogram of this compound is the sharp diffraction peak in the wide-angle region at about 4.1 Å (Figure 4). The corresponding nickel complex NiL is crystalline at temperatures below 61 °C, and undergoes a crystal-to-crystal transition between 35 and 40 °C. The crystalline character of this compound at ambient temperature is evident from the large number of sharp diffraction peaks in the X-ray pattern. For the complexes in the mesophase, the lattice parameter, *a*, and the column cross-section, *s*, were determined from the positions of the small angle diffraction peaks (10), (11), (20) and (21): $a = 2/\sqrt{3}[1/4(d_{10} + \sqrt{3}d_{11} + 2d_{20} + \sqrt{7}d_{21})]$ and $s = 2/\sqrt{3}[1/4(d_{10} + \sqrt{3}d_{11} + 2d_{20} + \sqrt{7}d_{21})]$.[2] The lattice parameters and thus the column cross-sections of all the complexes are very similar. This similarity indicates that the local organisation within the mesophase is the same despite the structural differences. The hexagonal symmetry of the columnar mesophase implies that the hard, columnar core (i.e. the aromatic part) is cylindrical, and that therefore the cross-section is circular. These hard columns are separated from one another by the liquid paraffinic continuum formed by the molten alkyl chains. As far as the copper(II)/lanthanum(III) complex and the nickel(II)/lanthanum(III) complex are concerned, they both have a square-like shape, and it is evident that upon their stacking into an alternated orthogonal fashion (the halo *h1* corresponds to a dimerisation, as shown in Figure 10) and due to the free rotation around the molecular axis, the apparent cross-sections of the columns will appear circular, thus satisfying the geometrical requirements for the formation of the Col_h phase. Moreover, and in agreement with this proposal, we found that the molecular volume considering a density of about 0.95 for each of these two trinuclear compounds corresponds exactly to the volume of one single columnar stratum with a thickness of 4.5–4.6 Å (or to two complexes per portion of column with a thickness of 9.2–9.4 Å). Note also that the molecular dimensions of these two mixed complexes are in good agreement with the lattice parameters of the Col_h phases, and thus they both lie almost flat in the 2D hexagonal lattice. However, due to the lath-like shape of the mononuclear copper and nickel complexes, it is probable that they initially associate into face-to-face dimers (Figure 9) approximating the shape of a large, flat square, which then self-organise into columns as for the trinuclear complexes (Figure 9). Again, considering a density close to unity for both the complexes, it was found that the volume of a portion of column with a thickness of about 4.5 Å can contain two mononuclear complexes, and that the length of the complexes is of the order of the diameter of the columns, *a*. As mentioned above, the presence of the halo *h1* at about 9.4 Å in the X-ray patterns of the mesophases indicates that the repeating unit along the columnar axis $<p>$ is about twice the thickness of the complexes. Thus, the repeating unit is formed by two molecules stacked on top of each other (dimeric structures). A similar behaviour was also observed for the copper complexes and for the copper/lanthanide complexes we reported previously.[4] Structural models for the different metal complexes are shown in Figures 9 and 10. Moreover, a change of the linking group formed by ethylenediamine to a linking group formed by 1,2-diaminobenzene in the Schiff-base ligand has a negligible effect on the column lattice parameters. This is not unexpected due to the presence of the (disordered) alkyl chains in the complexes in the mesophase. For all the complexes, the lattice parameter *a* decreases with increasing temperature.

Conclusions

We have studied the mesophase behaviour of new copper(II), nickel(II), copper(II)/lanthanum(III) and nickel(II)/lanthanum(III) complexes of a mesogenic *N*,*N*′-disalicylidene-1,2-phenylenediamine (salophenH_2) ligand. The cop-

per(II)/lanthanum(III) and the nickel(II)/lanthanum(III) complexes are trinuclear. All the Schiff-base complexes exhibited a hexagonal columnar mesophase (Col_h). X-ray diffraction measurements on samples in the mesophase indicate that the geometrical parameters (lattice parameter *a* and column cross-section *s*) are largely independent of the type of complex. This indicates that the structure of the mesophase is more or less identical for all the complexes. The metal has an influence on the transition temperatures: higher transition temperatures have been observed, and thus a substantial enhancement of the mesophase stability achieved, for the mixed f-d metallomesogens with respect to the parent transition metal complexes. The replacement of the ethylenediamine linking group present in the first type of mixed f-d metallomesogens by a more rigid 1,2-diaminobenzene linking group has a negligible influence on the mesophase behaviour. This is probably due to the fact that the linking group constitutes only a small part of the total ligand. One could have expected that the enhanced π-π stacking of the aromatic cores would result in higher transition temperatures, but this is not the case. The difference between the copper(II) or nickel(II) ion as the d-block metal is reflected in the thermal stability of the f-d complexes, in the sense that the nickel(II)/lanthanum(III) complex is thermally more stable than the corresponding copper(II)/lanthanum(III) complex. The presence of the rigid linking group is not a sufficient condition to induce a mesophase in the Schiff-base ligand.

Experimental Section

Equipment: The NMR spectra were recorded on a Bruker Avance 300 spectrometer (operating at 300 MHz) and Bruker AMX-400 (operating at 400 MHz), using $CDCl_3$ as solvent and tetramethylsilane (TMS) as internal standard. FTIR spectra were recorded on a Bruker IFS-66 spectrometer, using the KBr pellet method. Elemental analyses were obtained on a CE-Instrument EA-1110 elemental analyzer. The optical textures of the mesophases were observed with an Olympus BX60 polarizing microscope equipped with a LINKAM THMS600 hot stage and a LINKAM TMS93 programmable temperature-controller. DSC traces were recorded with a Mettler–Toledo DSC821e module. The XRD patterns were obtained with two different experimental set-ups, and in all cases the powdered sample was filled in Lindemann capillaries of 1 mm diameter. A linear monochromatic Cu-K_{α_1} beam (λ = 1.5405 Å) obtained with a sealed-tube generator (900 W) and a bent quartz monochromator were used (both generator and monochromator were manufactured by Inel). One set of diffraction patterns was registered with a curved counter Inel CPS 120, for which the sample temperature was controlled to within ±0.05 °C; periodicities up to 60 Å could be measured. The other set of diffraction patterns was registered on an Image Plate detector. The cell parameters were calculated from the position of the reflection at the smallest Bragg angle, which is in all cases the most intense. Periodicities up to 90 Å could be measured, and the sample temperature was controlled to within ±0.3 °C.

Synthesis of 3,4,5-Tris(tetradecyloxy)benzoic Acid: Ethyl 3,4,5-trihydroxybenzoate (19.82 g, 0.1 mol), K_2CO_3 (55.28 g, 0.4 mol), tetrabutylammonium bromide (TBAB, phase-transfer catalyst) (1.61 g, 5 mmol), methyl isobutyl ketone (MIBK; 300 mL) and 1-bromotetradecane (97.05 g, 0.35 mol), were added to a 1 L flask. Subsequently, the reaction mixture was heated to reflux and stirred overnight. The brown mixture was cooled below 100 °C, and water (300 mL) was added. The aqueous layer was separated, and the organic layer was washed with water (300 mL), dilute HCl solution (300 mL, 1.0 M), and water (300 mL) again. The solvent was removed on a rotary evaporator and the crude product was recrystallised from acetone. This product was redissolved in an ethanol solution of NaOH (16 g, 0.4 mol) and refluxed for 4 h. After allowing the solution to cool to room temperature, the reaction mixture was poured into cold water. The solution was acidified with dilute HCl. The precipitate was filtered off, recrystallised from dichloromethane and washed with ethanol. Yield: 57% (42.67 g), m.p. 72 °C. $C_{49}H_{90}O_5$ (749.24): calcd. C 77.52, H 11.95; found C 77.56, H 11.98. ^{1}H NMR ($CDCl_3$, 300 MHz): δ = 0.89 (t, J = 6.3 Hz, 9 H, CH_3), 1.27 (m, 30 H, CH_2), 1.49 (m, 6 H, CH_2CH$_2$CH$_2$O), 1.81 (m, 6 H, CH_2CH$_2$O), 4.03 (t, J = 6.3 Hz, 6 H, CH_2O), 7.33 (s, 2 H, H-aryl) ppm.

Synthesis of 3-Formyl-4-(hydroxyphenyl)-3,4,5-tris(tetradecyloxy)-benzoate: 3,4,5-Tris(tetradecyloxy)benzoic acid (15.16 g, 0.02 mol) and DMAP [4-(dimethylamino)pyridine; 0.24 g, 0.002 mol) were added to a mixture of 2,5-dihydroxybenzaldehyde (2.76 g, 0.02 mol) and *N*,*N*′-dicyclohexylcarbodiimide (DCC; 4.60 g, 0.022 mol) in 600 mL of dichloromethane. The solution was stirred at room temperature for 24 h. The precipitated *N*,*N*′-dicyclohexylurea was filtered off and washed with a saturated $NaHCO_3$ solution (2×400 mL) and water (2×400 mL). The aqueous layers were back-extracted with dichloromethane (200 mL). The combined organic layers were dried with $MgSO_4$ and the solvent was removed on a rotary evaporator. The crude compound was purified by column chromatography (silica, with dichloromethane as the eluent). Yield: 49% (8.60 g), m.p. 70 °C. $C_{56}H_{94}O_7$ (879.34): calcd. C 76.49, H 10.77; found C 76.56, H 10.83. ^{1}H NMR ($CDCl_3$, 300 MHz): δ = 0.89 (t, 9 H, CH_3), 1.27 (m, 30 H, CH_2), 1.50 (m, 6 H, CH_2CH$_2$CH$_2$O), 1.81 (m, 6 H, CH_2CH$_2$O), 4.05 (t, 6 H, CH_2O), 7.06 (d, J_o = 9.15 Hz, 1 H, H-aryl), 7.36 (dd, J_o = 8.91, J_m = 2.84 Hz, 1 H, H-aryl), 7.40 (s, 2 H, H-aryl), 7.44 (d, J_m = 2.58 Hz, 1 H, H-aryl), 9.89 (s, 1 H, CHO), 10.96 (s, 1 H, OH) ppm.

Synthesis of the Schiff-Base Ligand H_2L: 1,2-Diaminobenzene (54 mg, 0.5 mmol) and five drops of glacial acetic acid (as the catalyst) were added to a solution of 3-formyl-4-(hydroxyphenyl)-3,4,5-tris(tetradecyloxy)benzoate (0.88 g, 0.001 mol) in 150 mL of toluene. The mixture was heated for 3 h at reflux, and the water formed by the reaction was removed azeotropically (Dean–Stark trap). After allowing the solution to cool to room temperature, the solvent was removed under reduced pressure. The crude product was purified by recrystallisation from absolute ethanol. Yield: 92% (0.84 g), m.p. 67 °C. $C_{118}H_{192}N_2O_{12}$ (1830.8): calcd. C 77.41, H 10.57, N 1.53; found C 76.94, H 10.57, N 1.54. IR (KBr): $\tilde{\nu}$ = 1626 cm^{-1} (C=N), 1209 (C–O). ^{1}H NMR ($CDCl_3$, 300 MHz): δ = 0.88 (t, 18 H, CH_3), 1.26 (m, 60 H, CH_2), 1.49 (m, 12 H, CH_2CH$_2$CH$_2$O), 1.83 (m, 12 H, CH_2CH$_2$O), 4.05 (m, 16 H, CH_2O, CH_2N), 6.80–7.45 (m, 14 H, H-aryl), 8.59 (s, 2 H, CH=N), 13.01 (s, 2 H, OH) ppm.

Synthesis of the Copper(II) Complex CuL: A hot solution of copper(II) acetate monohydrate, (30 mg, 0.15 mol) in methanol was added dropwise to a hot solution of the Schiff-base ligand H_2L (0.24 g, 0.13 mmol) in chloroform. The reaction mixture was refluxed overnight. After allowing the solution to cool to room temperature, the solvent was removed under reduced pressure. The crude product was crystallised from ethyl acetate, washed with methanol and dried in vacuo. Yield: 92% (0.23 g). IR (KBr): $\tilde{\nu}$ =

1606 cm^{-1} (C=N), 1203 (C–O). $C_{118}H_{196}CuN_2O_{15}$ (1892.3): calcd. C 72.82, H 10.15, N 1.44; found C 72.88, H 10.24, N 1.49.

Synthesis of the Nickel(II) Complex NiL: A hot solution of nickel(II) acetate tetrahydrate (70 mg, 0.28 mol) in methanol was added dropwise to a hot solution of the Schiff-base ligand H_2L (0.46 g, 0.25 mmol) in chloroform. The reaction mixture was heated at reflux temperature overnight. After allowing the solution to cool to room temperature, the solvent was removed under reduced pressure. The crude product was crystallised from ethyl acetate, washed with methanol and dried in vacuo. Yield: 86% (0.41 g). IR (KBr): $\tilde{\nu}$ = 1606 cm^{-1} (C=N), 1203 (C–O). $C_{118}H_{190}N_2NiO_{12}$ (1887.5): calcd. C 75.09, H 10.15, N 1.48; found C 74.68, H 10.28, N 1.50.

Synthesis of the Copper(II)/Lanthanum(III) Complex CuLaL: A solution of lanthanum(III) nitrate hexahydrate (0.048 g, 0.11 mmol) in acetone was added to a solution of the copper complex CuL (0.189 g, 0.1 mmol) in acetone. The reaction mixture was stirred at room temperature for 24 h. The precipitate was filtered off, washed with cold methanol and dried in vacuo. Yield: 40% (164 mg). IR (KBr): $\tilde{\nu}$ = 1629 cm^{-1} (C=N), 1306 (C–O). $C_{236}H_{380}Cu_2LaN_7O_{33}$ (4105.59): calcd. C 68.98, H 9.33, N 2.39; found C 68.45, H 9.23, N 1.97.

Synthesis of the Nickel(II)/Lanthanum(III) Complex NiLaL: A solution of lanthanum(III) nitrate hexahydrate (0.048 g, 0.11 mmol) in acetone was added to a solution of the nickel complex NiL (0.189 g, 0.1 mmol) in acetone. The reaction mixture was stirred at room temperature for a period of 24 h. The precipitate was filtered off, washed with cold methanol and dried in vacuo. Yield: 46% (187 mg). IR (KBr): $\tilde{\nu}$ = 1627 cm^{-1} (C=N), 1205 (C–O). $C_{236}H_{380}LaN_7Ni_2O_{33}$ (4095.60): calcd. C 69.15, H 9.35, N 2.39; found C 69.23, H 9.36, N 2.06.

Chiral Indenes and Group-4 Metallocene Dichlorides Containing α- and β-Pinenyl-Derived Ligand Substituents: Synthesis and Catalytic Applications in Polymerization and Carboalumination Reactions

Satu Silver,[a] Arto Puranen,[b] Rainer Sjöholm,[a] Timo Repo,[b] and Reko Leino*[a]

Keywords: Homogeneous catalysis / Indenyl ligands / Metallocenes / Olefin polymerization / Carboalumination

The synthesis and characterization of chiral bis(indenyl)zirconium dichlorides containing β-pinenyl-derived ligand substituents is reported. Unbridged metallocene complexes having the {[(1*S*,2*S*,5*S*)-6,6-dimethylbicyclo[3.1.1]hept-2-yl]methyl}dimethylsilyl substituent in both 1- and 2-positions of the indenyl moiety were prepared and isolated in moderate to low yields by reaction of the corresponding indenyllithium salts with $ZrCl_4$ followed by work-up and crystallization procedures. The corresponding tetrahydroindenyl complexes were obtained in excellent yields by catalytic hydrogenation of the indenyl six-membered rings. In a complementary approach, a synthetic route to α-pinenyl-substituted indenyl ligand analogues was briefly evaluated, which however, suffered from low yields. Selected β-pinenyl-substituted indenyl complexes were scanned as catalysts for the dehydropolymerization of phenylsilane upon activation with *n*BuLi, for polymerization of ethylene and propylene upon activation with methylaluminoxane (MAO) as well as for enantioselective carboalumination of 1-octene with triethyl- and trimethylaluminum. The bis(indenyl) complexes catalyzed the carboalumination reaction, albeit only low yields (8–16%) and low enantioselectivities (*ee* = 0.5–10%) were obtained. The 2-substituted bis(indenyl)zirconocene/MAO catalyst system produced atactic low-molecular weight polypropylene with low polymerization activity whereas both 1- and 2-substituted complexes showed high activities in ethylene polymerization producing polyethylenes with high molecular weights ($M_w > 440000$).

Introduction

Chiral group-4 metallocenes are widely used catalysts or catalyst precursors for the stereoselective polymerization of α-olefins,[1–3] and enantioselective cyclopolymerization of nonconjugated dienes,[4,5] and are employed in various enantioselective organic transformations[6,7] including carbon–carbon,[8–13] carbon–hydrogen[14–18] and carbon–oxygen[19,20] bond formation. Commonly employed chiral precatalysts are the conformationally constrained racemic *ansa*-metallocenes and their resolved single enantiomers,[21] but also unbridged bis(indenyl)metallocenes containing chiral substituents[22–27] have been utilized previously in a number of applications in stereo- and/or enantioselective synthesis.

In a recent communication, we presented a simple route to new chirally substituted indenes by reaction of indenyllithium or 2-indenylmagnesium bromide with a β-pinenyl-derived chlorosilane.[28] As a continuation of the previous work, we report here a detailed study on the utilization of these new chiral ligand precursors for the preparation of new chiral group-4 metallocene complexes as well as a brief evaluation of the chiral metallocenes formed for catalytic applications in olefin polymerization, dehydropolymerization of phenylsilane and enantioselective carboalumination reactions. As a complementary approach, the low-yield synthesis of some α-pinenyl-substituted ligand analogues is briefly described.

Results and Discussion

Ligand Precursor and Metallocene Synthesis

The chiral zirconocene dichloride **2** was prepared by deprotonation of the previously described chiral indene **1**[28] with *n*BuLi followed by reaction with 0.5 equiv. $ZrCl_4$ in toluene (Scheme 1). Subsequent work-up and crystallization from pentane at –20 °C provided pure **2** in 37% isolated yield. Due to the position of the chiral substituent, the π-faces of the indenyl ligand are equivalent (i.e., homotopic) and only one product can be formed upon metallation. Complex **2** was further hydrogenated at 50 bar H_2 in dichloromethane in the presence of PtO_2 catalyst to provide the corresponding chiral tetrahydroindenyl complex **3** in 86% isolated yield. The parent compound **2** is obtained as

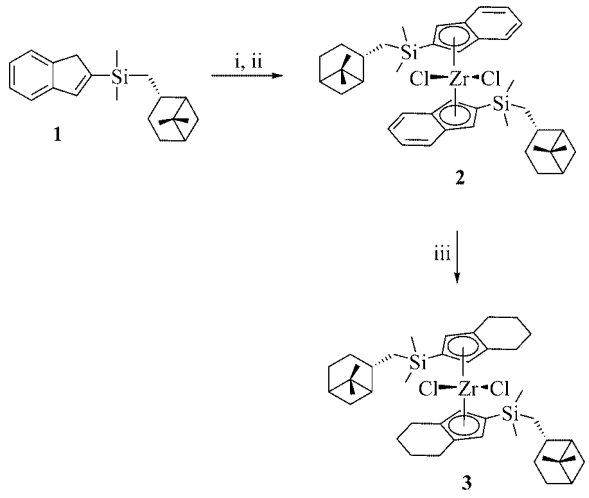
a yellow powder, whereas the hydrogenated congener **3** is a noncrystalline, pale green oil. Apparently, because of the large aliphatic pinenyl substituent, both complexes are remarkably soluble in all common organic solvents including pentane and hexane. Consequently, all our attempts to grow single crystals suitable for X-ray structure determination from either one of the complexes **2** or **3** failed.



Scheme 1. Synthesis of the chiral metallocenes **2** and **3**. (i) *n*BuLi, Et_2O, 0 °C. (ii) $ZrCl_4$, toluene, 50 °C, 37%. (iii) H_2/50 bar/PtO_2, CH_2Cl_2, 86%.

The change in the position of the chiral substituent from 2- to 1- or 3-indenyl renders the π-faces of the ligand precursor inequivalent [planar chirality: (*pR*) vs. (*pS*)] thus potentially resulting in the formation of three isomeric metallocene complexes [combinations of (*pR*)/(*pR*), (*pS*)/(*pS*) and (*pR*)/(*pS*)] upon metallation with group-4 metal tetrahalides (Figure 1).

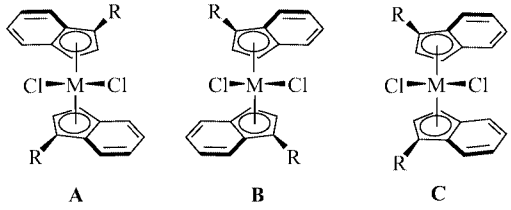


Figure 1. Metallocene diastereomers obtained upon metallation of indenyl ligands with enantiotopic or diastereotopic ligand π-faces [combinations of (*pR*)/(*pR*), (*pS*)/(*pS*) (**A** and **B**) and (*pR*)/(*pS*) (**C**).

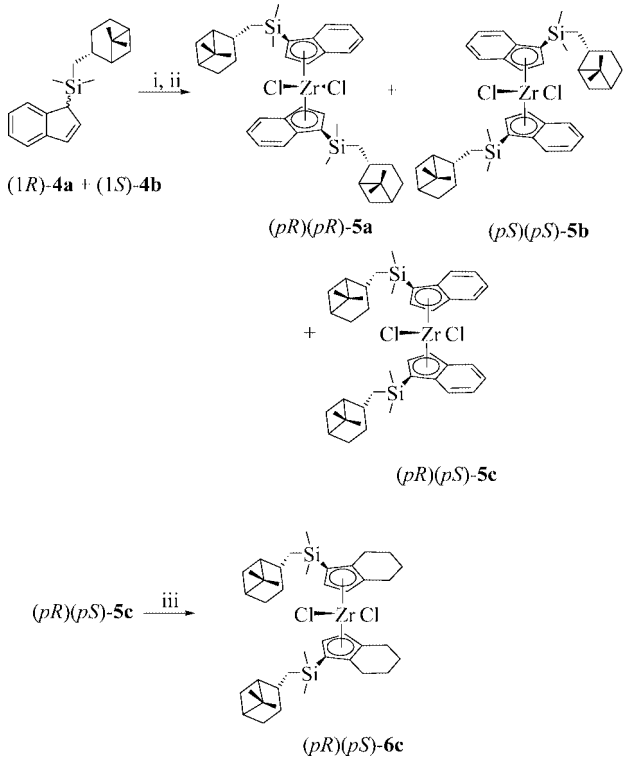
If the 1- or 3-indenyl substituent is achiral (*enantiotopic* ligand π-faces), a C_2 symmetric racemic pair of two equienergetic enantiomers (**A** and **B** in Figure 1) is obtained together with a C_s symmetric *meso* form (**C**). A statistical 1:1:2 ratio of the three isomers is observed in most cases. When, as in the present case, the 1- or 3-indenyl substituent is chiral (*diastereotopic* ligand π-faces), a mixture of three diastereomers, two C_2 symmetric "pseudo-racemic" or "racemic-like" complexes (**A** and **B**) and one C_1 symmetric "*meso*-like" diastereomer (**C**), is formed in a ratio depending on the relative energies of the π-face metallation (*pR*) vs. (*pS*) and the mono(indenyl)metallocene trichlorides initially formed.

Thus, when the previously described 1:1 diastereomeric mixture of the chiral 1-substituted indenes (1*R*)-**4a** and (1*S*)-**4b**[28] was deprotonated with *n*BuLi and the resulting chiral indenyl anion lithium salt metallated with 0.5 equiv. of $ZrCl_4$ (Scheme 2), a mixture of the metallocene complexes **5a-c** was obtained in variable ratios depending on the solvent employed in the metallation step, as shown by ^{1}H NMR analyses of the metallocene crude products (Table 1, Figure 2). In all solvents investigated (toluene, Et_2O, THF), the molar ratio between the C_2-symmetric diastereomers (*pR*)(*pR*)-**5a** and (*pS*)(*pS*)-**5b** remained equimolar, consistent with their "pseudo-racemic" character. Formation of the *meso*-like C_1-symmetric diastereomer (*pR*)(*pS*)-**5c** was more favored in the coordinating solvents Et_2O and THF. As observed for the 2-substituted analogue **2**, also complexes **5a**–**c** displayed unusually high solubilities in all common organic solvents rendering their isolation and purification very difficult. The pure, least soluble C_1-symmetric diastereomer (*pR*)(*pS*)-**5c** was, however, obtained in 11% isolated yield as a bright yellow powder from the reaction carried out in Et_2O after subsequent work-up and crystallization from dichloromethane at –20 °C. The *meso*-like diastereomer (*pR*)(*pS*)-**5c** is easily distinguished from the C_2-symmetric diastereomers (*pR*)(*pR*)-**5a** and (*pS*)(*pS*)-**5b** by its ^{1}H and ^{13}C NMR spectra where, unlike in the cases of **5a** and **5b**, separate signal sets are observed for each of the (*pR*)- and (*pS*)-indenyl ligands coordinated to the central metal atom. The corresponding tetrahydroinde-



Scheme 2. Synthesis of the chiral metallocenes **5a**–**c** and **6c**. (i) *n*BuLi, Et_2O, 0 °C. (ii) 0.5 $ZrCl_4$, toluene, 50 °C; or 0.5 $ZrCl_4$, Et_2O, room temp.; or 0.5 $ZrCl_4$·2THF, –80 °C. (iii) H_2/50 bar/PtO_2, CH_2Cl_2, 82%.

nyl analogue (*pR*)(*pS*)-**6c** was then obtained in 82% yield after hydrogenation at 50 bar over PtO_2 catalyst in dichloromethane. Again, despite several attempts, crystals suitable for X-ray structure determination could not be grown from either one of the highly soluble complexes **5c** and **6c**.

Table 1. Relative ratios of the metallocene diastereomers **5a–c** formed in different solvents.

Solvent	*rac*-like **5a**	*rac*-like **5b**	*meso*-like **5c**
Toluene	42.4%	42.4%	15.2%
THF	22.6%	22.6%	54.8%
Et_2O	28.4%	28.4%	43.2%

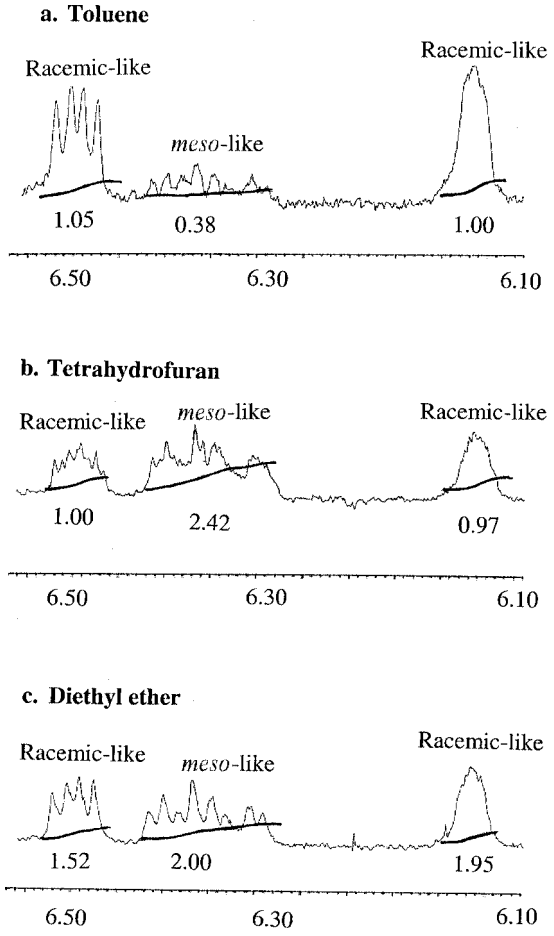

Figure 2. Expansions of the crude product indenyl CH regions of the ^{1}H NMR spectra of complexes **5a–c.**

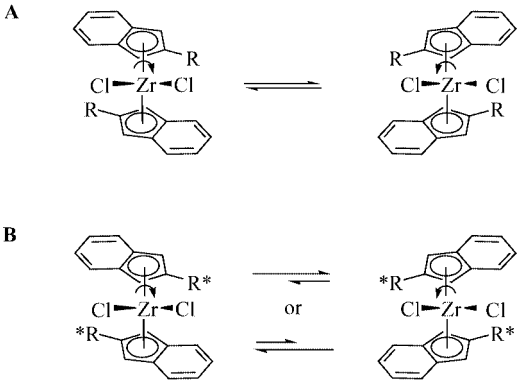
Unbridged bis(indenyl)zirconocenes with bulky equatorial or σ-ligand substituents may exhibit dynamic behavior in their NMR spectra at subambient temperatures resulting from partially hindered rotation around the Zr–Cp(centroid) axis (Scheme 3).[29] For complexes with achiral ligand substituents the observed interconversion is likely to take place between two C_2 symmetric enantiomeric conformations becoming frozen on the NMR time scale to form a racemic mixture of the interconverting conformational isomers.[30–32] If, however, the ligand substituent is chiral, the interconverting conformational isomers become diastereomeric, one of which could be favored by proper choice of the ligand substitution pattern. Such complexes in turn could prove promising candidates for applications in enantioselective catalysis. In a previous work, Halterman and coworkers demonstrated that for the chiral bis(2-menthyl-4,7-dimethylindenyl)zirconium dichloride one diastereomeric conformation is slightly favored at 223 K (60:40) with a rotational activation barrier of 12.5 ± 0.5 kcal/mol.[25]



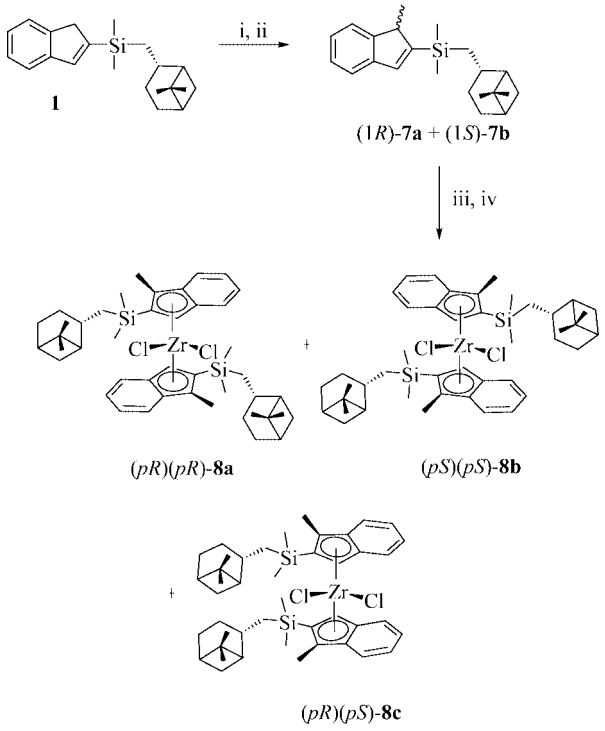
Scheme 3. Conformational equilibration of unbridged bis(indenyl) zirconocenes with (**A**) achiral substituents (enantiomeric conformations), and (**B**) chiral substituents (diastereomeric conformations).

At ambient temperature, the ^{1}H NMR spectra of complexes **2** and **5c** are consistent with unhindered ligand rotation. Upon lowering the monitoring temperature to 213–163 K, complex **2** displays dynamic behavior as indicated by the broadening of the aromatic CH resonances at δ = 5.92 and 5.96 ppm in the five-membered indenyl ring. At the estimated coalescence temperature of 163 K, the signals start to split to the individual resonances resulting from the equilibration of the two C_2 symmetric diastereomeric conformers. However, due to the operational limits of the NMR instrument at such low temperatures, neither the exact point of coalescence nor the associated rotational energy barrier and the eventual predominance of either one of the conformers could be reliably determined.

Next, as an attempt to modify the steric properties of the complex family and as a further extension of the use of the pinenyl group as a chiral indenyl ligand substituent, we prepared the monomethylated analogues of compounds **1** and **4a/b**. Thus, deprotonation of **1** with *n*BuLi and the subsequent reaction of the lithium salt formed with excess methyl iodide provided a diastereomeric mixture of the chiral indenes (1*R*)-**7a** and (1*S*)-**7b** in 74% isolated yield after purification by flash chromatography. Deprotonation of **7a/7b** with *n*BuLi and the subsequent reaction with 0.5 equiv. $ZrCl_4$ formed the expected mixture of the diastereomeric metallocene complexes (*pR*)(*pR*)-**8a**, (*pS*)(*pS*)-**8b** and (*pR*)(*pS*)-**8c** in good yield, as evidenced by ^{1}H NMR analysis of the crude product. All attempts to purify/isolate any of the complexes **8a–c** by fractional crystallization techniques failed due to their extremely high solubilities in all common organic solvents. When, however, the crude product was subjected to flash column chromatography using silanized silica gel[33] under argon, elution with pentane provided a mixture of the pure metallocenes **8a–c** in 53%

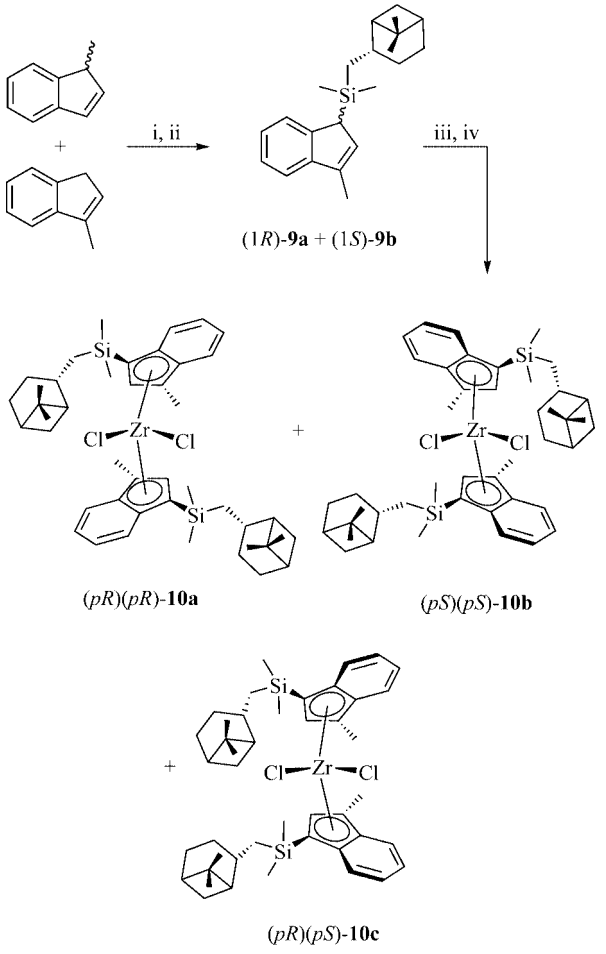
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

yield (all fractions combined) as a yellow oil. Despite their very similar solubility properties, the diastereomers eluted at slightly different retention times yielding fractions consisting of both **8a/8b** and **8a/8b/8c** in variable ratios. Small differences in the elution properties were observed even between the racemic-like diastereomers **8a** and **8b**, however, due to their high solubilities even in pentane, complete separation was impossible to achieve. Combination of all fractions containing only the racemic-like diastereomers gave an isolated yield of 18% for **8a/8b** obtained as a yellow oil. Crystallization of this mixture from cold pentane (–60 °C) gave 54 mg (3%) of yellow crystals enriched in one of the racemic-like diastereomers in a 53:47 ratio (Scheme 4).



Scheme 4. Synthesis of the chiral indenyl ligand precursor **7a/7b** and the chiral metallocenes **8a**–**c**. (i) *n*BuLi, THF, 0 °C. (ii) MeI, 74%. (iii) *n*BuLi, Et_2O, 0 °C. (iv) 0.5 $ZrCl_4$, 53% (isolated mixture **8a**–**c**), 18% (isolated mixture **8a/8b**).

A diastereomeric mixture of the 3-methyl-substituted chiral indenes (1*R*)-**9a** and (1*S*)-**9b** was in turn obtained in 53% isolated yield by deprotonation of a 1-methylindene/3-methylindene mixture with *n*BuLi followed by quenching with excess chloro{[(1*S*,2*S*,5*S*)-6,6-dimethylbicyclo[3.1.1]-hept-2-yl]methyl}dimethylsilane, work-up and purification by flash chromatography. Deprotonation of **9a/9b** with *n*BuLi and the subsequent reaction with 0.5 equiv. $ZrCl_4$ formed the expected mixture of the diastereomeric metallocene complexes (*pR*)(*pR*)-**10a**, (*pS*)(*pS*)-**10b** and (*pR*)(*pS*)-**10c** in good, approximately 70% yield, as evidenced by ^{1}H NMR analysis of the crude product. All attempts to purify/isolate any of the complexes **10a**–**c** by crystallization failed due to their high solubilities in all common organic solvents. In contrast to complexes **8a**–**c**, the 1-silyl-substituted zirconocenes **10a**–**c** were also unstable under the flash column chromatographic conditions (silanized silica gel under argon atmosphere), yielding ligand precursor as the main decomposition product upon elution with pentane (Scheme 5).



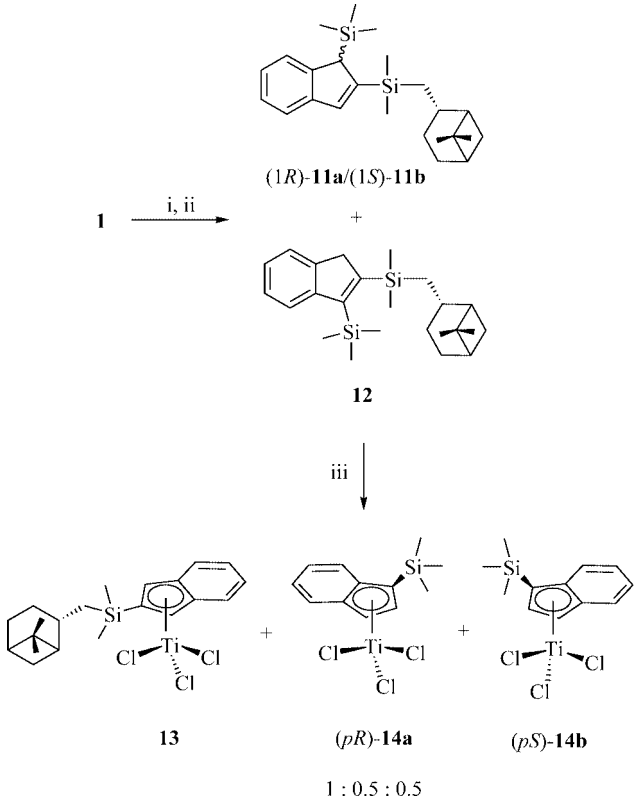
Scheme 5. Synthesis of the chiral indenyl ligand precursor **9a/9b** and the chiral metallocenes **10a**–**c**. (i) *n*BuLi, THF, 0 °C. (ii) Chloro{[(1*S*,2*S*,5*S*)-6,6-dimethylbicyclo[3.1.1]hept-2-yl]methyl}dimethylsilane, 53%. (iii) *n*BuLi, Et_2O, 0 °C. (iv) 0.5 $ZrCl_4$, product not isolated.

In addition, we briefly evaluated the metalation of the ligand percursors **1** and (1*R*)-**4a**/(1*S*)-**4b** with other group-4 metals. Treatment of the from **1** and (1*R*)-**4a**/(1*S*)-**4b** generated lithium salts with 0.5 equiv. $HfCl_4$ in diethyl ether or toluene yielded the desired metallocene complexes in moderate (approximately 30%) yields as shown by ^{1}H NMR analyses of the corresponding crude products. In contrast to their zirconium analogues, these hafnium complexes proved highly unstable resulting in decomposition upon all purification attempts, even when manipulated under strictly inert atmosphere.

From both compounds **1** and (1*R*)-**4a**/(1*S*)-**4b**, a mixture of the trimethylsilyl-substituted derivatives (1*R*)-**11a**/(1*S*)-**11b** and **12** and mixtures of (1*R*)-**15a**/(1*S*)-**15b**/(1*R*)-**16a**/(1*S*)-**16b** were obtained in high yields by quenching the corresponding lithium salts with chlorotrimethylsilane (Scheme 6 resp. Scheme 7). Treatment of these with one

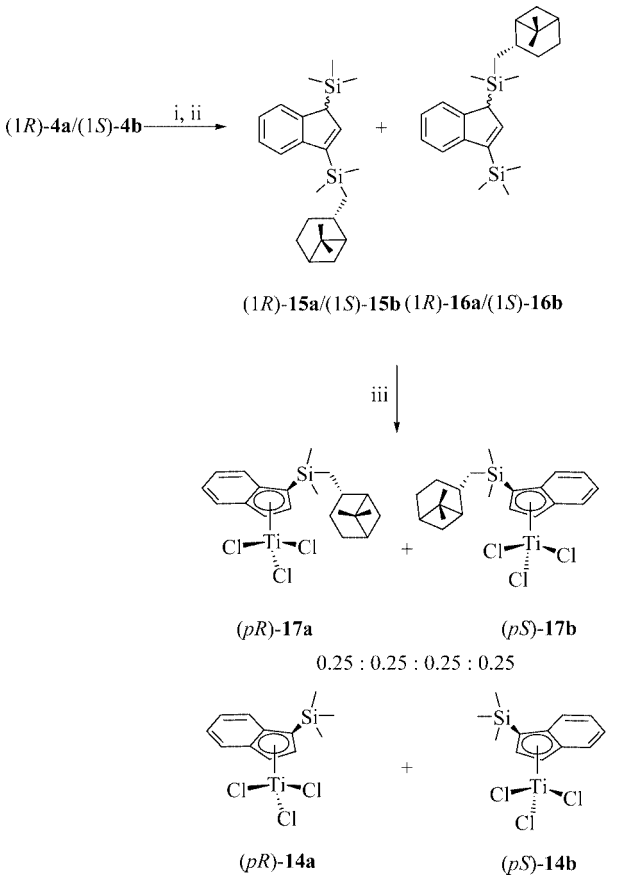
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

equivalent of $TiCl_4$ in dichloromethane at –78 °C resulted in competing elimination of both the trimethylsilyl- and the pinenyl-substituted silyl groups providing approximately 1:1 mixtures of the mono(indenyl)titanium trichlorides carrying either a trimethysilyl [(*pR*)-**14a**/(*pS*)-**14b**] or {[(1*S*,2*S*,5*S*)-6,6-dimethylbicyclo[3.1.1]hept-2-yl]methyl}-dimethylsilyl substituent [**13** and (*pR*)-**17a**/(*pS*)-**17b**, respectively]. In the case of the mixture of (1*R*)-**11a**/(1*S*)-**11b** and **12**, conversion of the ligand to mono(indenyl)metallocene appears to be nearly quantitative as evidenced by ^{1}H NMR, whereas in the case of (1*R*)-**15a**/(1*S*)-**15b**/(1*R*)-**16a**/(1*S*)-**16b** the yield of the metallation step is approximately 30%. Due to the similar solubilities of the (trimethylsilylindenyl)-titanium trichloride and the {{[(1*S*,2*S*,5*S*)-6,6-dimethylbicyclo[3.1.1]hept-2-yl]methyl}dimethylsilylindenyl}titanium trichlorides formed, these metallocene mixtures proved inseparable by fractional crystallization techniques.



Scheme 6. Attempted synthesis of 2-chirally substituted mono(indenyl)titanium trichlorides. (i) *n*BuLi, THF, 0 °C. (ii) Chlorodimethylsilane, 71%. (iii) $TiCl_4$·CH_2Cl_2, –78 °C, not purified.

When the lithium salts generated from **1** and (1*R*)-**4a**/(1*S*)-**4b** were treated with 0.5 equiv. $FeCl_2$, the desired ferrocenes were formed in approximately 25% and 40% yields, respectively, as evidenced by ^{1}H NMR spectroscopy. Also these compounds proved to have extremely high solubilities in all common organic solvents rendering their purification by crystallization impossible. All attempts to purify the oily crude products by silica gel column chromatography likewise failed due to the apparent high sensitivity of these iron complexes.



Scheme 7. Attempted synthesis of 1-chirally substituted mono(indenyl)titanium trichlorides. (i) *n*BuLi, THF, 0 °C. (ii) Chlorodimethylsilane, 76%. (iii) $TiCl_4$·CH_2Cl_2, –78 °C, not purified/isolated.

In our previous communication,[28] we also described the preparation of the ethylene-bridged bis(indenyl) ligand analogues of **1** and **4a**/**4b** (compounds **18** and **19**), as well as the 1,3-chirally disubstituted indene analogue **20** (Figure 3). When the dilithium salt of **18** was reacted with $ZrCl_4$ in Et_2O, no metallocene could be detected by ^{1}H NMR or EIMS analysis of the crude product. Reaction of the dilithium salt of **19** with $ZrCl_4$ in THF showed no formation of the desired bis(indenyl)metallocenes. By carrying out the metallation in toluene only traces of zirconium complex diastereomers could be detected together with large amounts of impurities. In Et_2O, however, metallation of **19**-Li_2 with $ZrCl_4$ consumed all of the ligand precursor and formation of zirconocene diastereomers could be proven by both ^{1}H NMR and EIMS analyses, the latter of which gave the observed isotope peak distibutions for [M^+] in matching ratios with the theoretically calculated values. Unfortunately, again apparently due to the very high solubilities of the metallocene complexes formed, all attempts to isolate pure compounds by crystallization from Et_2O, iPr_2O, hexane, THF, toluene and dichloromethane failed.

All our attempts to metallate either the lithium or potassium salt of the 1,3-disubstituted indene **20** with $ZrCl_4$ in Et_2O, toluene and dichloromethane under various reaction conditions failed. In none of the attempts could we observe

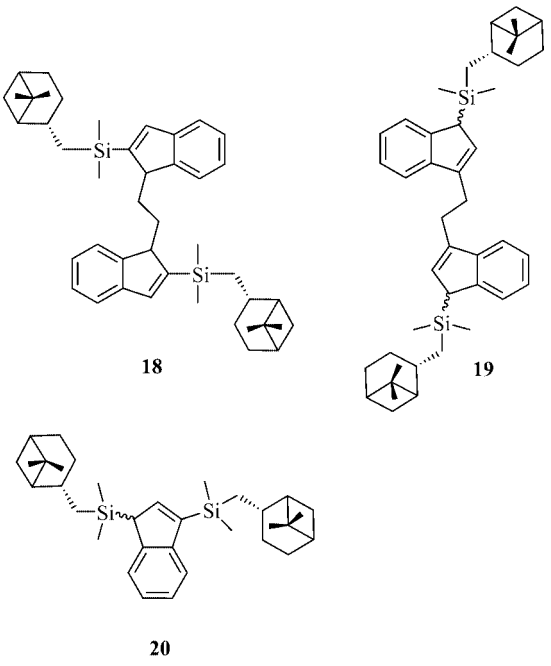

Figure 3. Ethylene-bridged and 1,3-chirally disubstituted ligand precursors **18**–**20**.

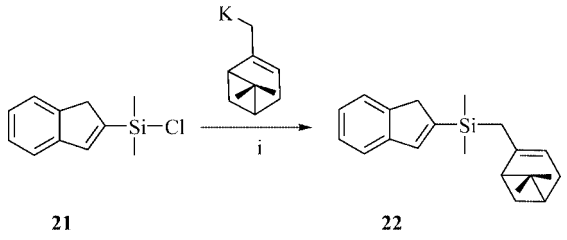
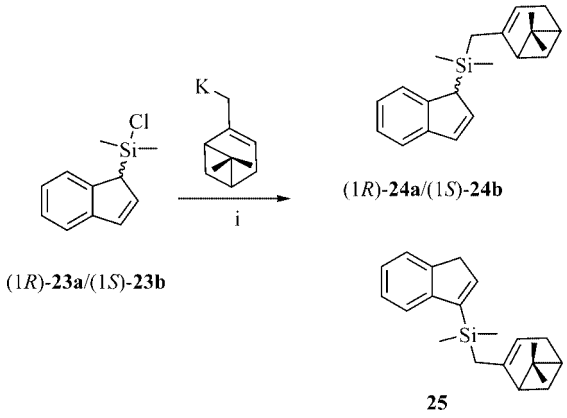


Scheme 8. Synthesis of the 2-chirally substituted indenyl ligand precursor **22**. (i) THF, –72 °C, 3%.



Scheme 9. Synthesis of the 1-chirally substituted indenyl ligand precursors (1*R*)-**24a**/(1*S*)-**24b**/**25**. (i) THF, –72 °C, 21%.

any formation of the desired bis(indenyl)metallocene complex. Considering that the analogous 1,3-bis(trimethylsilyl)-indenyl and other 1,3-bis(trialkyl/arylsilyl)indenyl-derived anions were recently successfully complexed with zirconium and iron in moderately high yields by Chirik and co-workers,[34,35] the observation here is quite surprising and hardly explained by steric factors only. Other examples of both 1,2- and 1,3-trimethylsilyl-substituted bis(indenyl)-iron(II) complexes have also been reported recently.[36]

Finally, in a complementary approach, we investigated the possibility of using α-pinene as the chiral indenyl substituent. By deprotonation of α-pinene with *n*BuLi/*t*BuOK at 50 °C using excess α-pinene[37] and the subsequent reaction of the obtained α-pinenyl potassium salt with 2-(chlorodimethylsilyl)indene[38] **21** or 1-(chlorodimethylsilyl)-indene[39] (1*R*)-**23a**/(1*S*)-**23b**, the corresponding 1- and 2-chirally substituted indenes **22** and (1*R*)-**24a**/(1*S*)-**24b**/**25** were obtained in low (3% and 21%, respectively) yields (Scheme 8 and Scheme 9). The amount of the 3-silyl isomer **25** in the **24a**/**24b**/**25** mixture was estimated to 15% by ^{1}H NMR spectroscopy. All attempts to react α-pinenyl potassium with either 2-indanone or 2-bromoindene failed. Due to the low isolated yields and preparations in small scale, further attempts to utilize the compounds **22** and (1*R*)-**24a**/(1*S*)-**24b**/**25** as ligand precursors for transition metal complexes were not pursued.

Dehydropolymerization of Phenylsilane

Dehydropolymerization of phenylsilane to poly(phenylsilane) with *n*BuLi activated transition-metal catalysts is a well-known reaction.[40,41] Harrod and co-workers reported in 1985 the first effective transition-metal catalyst for silane dehydrocoupling[42] and during the past 20 years a number of metallocene-based catalyst systems have been reported to polymerize phenylsilane.[43–50] Several shortcomings are, however, still to be overcome. Firstly, catalysts producing polyphenylsilanes with narrower polydispersities and with higher molecular weights than the presently existing systems, which seldom yield polymers with M_w's exceeding 5×10^3, would be desirable. Secondly, cleaner reaction mixtures not containing intractable oligo-/polysilane mixtures are required. Finally, the issue of stereocontrol in phenylsilane polymerization remains largely unsolved and only essentially atactic polymers are obtained regardless of chirality/achirality of the initiating catalyst system.

During the course of the present investigation, the chiral metallocenes **2**, **3**, (*pR*)(*pS*)-**5c** and (*pR*)(*pS*)-**6c** were briefly evaluated as catalysts for the dehydropolymerization of phenylsilane using zirconocene dichloride ([Cp_2ZrCl_2]) as reference catalyst (Scheme 10). The polymerization reactions were carried out in neat phenylsilane under argon by activation of 1 mol-% of the metallocene dichloride with 2 mol-% of *n*BuLi. The results are summarized in Table 2.

With the exception of the 1-substituted *meso*-like chiral complex (*pR*)(*pS*)-**5c**, the silane polymerization activities of the pinenyl-substituted systems were significantly lower than obtained with the zirconocene dichloride reference. The 2-substituted bis(indenyl) complex **2** gave polysilane with similar molecular weight to the reference catalyst whereas both 1-substituted complexes **5c** and **6c** and the 2-substituted tetrahydroindenyl analogue **3** produced lower molecular weight polymers. All catalysts investigated pro-

duced atactic polysilanes as confirmed by $^{29}Si\{^1H\}$ NMR analysis. As the sole significant difference between zirconocene dichloride and the investigated pinenyl-substituted complexes, it could be shown by ^1H NMR analysis of the polysilanes produced that catalysts **2**, **3**, **5c** and **6c** produced only linear polysilanes whereas mixtures of cyclic and linear poly-/oligomers were obtained with the Cp_2ZrCl_2/*n*BuLi catalyst system. The formation of oligomers and other coupling products was further investigated with GC-MS with compounds detected shown in Figure 4. All by-products **26**–**29** were detected in polymerizations catalyzed by complexes **2** and (*pR*)(*pS*)-**5c**, whereas complex **3** only yielded compounds **26** and **27** and complex **6c** yielded compound **26**. In the reaction catalyzed by the reference catalyst only compounds **26** and **29** were formed.

Olefin Polymerization

Complexes **2** and (*pR*)(*pS*)-**5c** were activated with methylaluminoxane (MAO) for polymerization of propylene in toluene (T = 50 °C, P = 5.34 bar, [Al]:[Zr] = 2000:1). The results are summarized in Table 3. Under the conditions investigated, the 2-pinenyl-substituted **2**/MAO catalyst system produced only low molecular weight atactic polypropylene (*a*PP) (colorless oil) with low activity, whereas the 1-substituted **5c**/MAO was totally inactive toward propylene intake, most likely due to its greater steric hindrance toward monomer coordination in the vicinity of the metal site induced by placement of the bulky substituents. The experimental pentad distribution for the *a*-PP obtained with **2**/MAO as determined by quantitative ^{13}C NMR with inverse gated ^1H-decoupling is as follows: [*mmmm*] = 5.5%, [*mmmr*] = 8.8%, [*rmmr*] = 5.5%, [*mmrm*] + [*rmrr*] = 25.3%, [*mrmr*] = 16.5%, [*rrrr*] = 8.8%, [*rrrm*] = 11.0% and [*mrrm*] = 7.7%. End group analysis by ^{13}C NMR indicated the presence of *n*-propyl, vinylidene, isobutenyl, *cis*-2-butenyl and *trans*-2-butenyl chain ends (Figure 5).

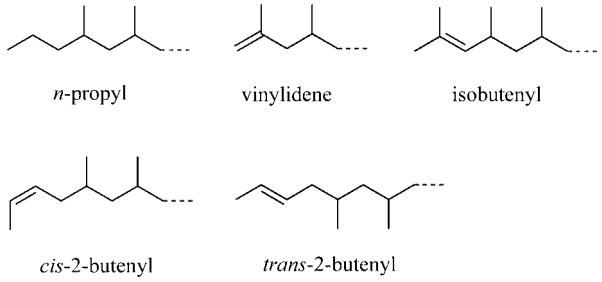

Figure 5. End groups present in the atactic polypropylene produced with **2**/MAO

The MAO-activated bis(indenyl) complexes **2** and (*pR*)(*pS*)-**5c** were further tested in the polymerization of ethylene in toluene (T = 50 °C, P = 3.95 bar, [Al]:[Zr] = 2000:1). In contrast to the propylene polymerization experiments, both catalysts **2**/MAO and **5c**/MAO polymerized ethylene with fairly high activities (2300–2550 kg PE/mol Zr/h) to high molecular weight polyethylene (M_w > 440000), the latter being slightly more active of the two. The polymerization results and characterization data are collected in Table 4 with results of IR-analyses of the poly-

mer end group composition in Table 5. Both catalysts produced polyethylenes with vinylidene, terminal vinyl and *trans*-vinylene end groups (Figure 6) in slightly different ratios. The fact that the **5c**/MAO catalyst polymerizes ethylene with comparable activity to that of **2**/MAO further suggests that its inactivity toward propylene is most likely of steric origin and a consequence of the orientation of the 1-indenyl substituents over the metal center.

Table 4. Polymerization of ethylene over **2**/MAO and (*pR*)(*pS*)-**5c**/MAO.

Catalyst[a]	A[d]	M_w[e]	M_n[e]	M_v[e]	PDI[f]	T_m[g]

Carboalumination Reactions

Catalytic asymmetric carboalumination of unactivated terminal alkenes using chiral zirconocene catalysts has considerable synthetic potential as oxidation of the organoaluminum products with molecular oxygen potentially provides access to the corresponding chiral alcohols.[9–13] Recently, this reaction, initially developed by Negishi and coworkers, has been applied successfully e.g., in natural product synthesis via the obtained chiral polypropionate building blocks.[51–53] Of several zirconocene catalysts evaluated previously, high yields and moderate enantioselectivities are almost exclusively obtained by use of the chiral unbridged bis(1-neomenthylindenyl)zirconium dichloride [$(NMI)_2ZrCl_2$], initially developed by Erker and co-workers.[22] Accordingly, we felt motivated to briefly investigate the applicability of the easily prepared chiral zirconocenes **2**, **3**, (*pR*)(*pS*)-**5c** and (*pR*)(*pS*)-**6c** as catalysts for carboalumination reactions. Thus, by reaction of 1-octene with triethylaluminum or trimethylaluminum in the presence of catalytic amounts of the chiral zirconocene complexes **2** and (*pR*)(*pS*)-**5c**, 2-ethyl-1-octanol and 2-methyl-1-octanol were indeed obtained after oxidation with O_2, albeit in disappointingly low yields ranging from 8 to 18% (Scheme 11). Also enantiomeric excesses were low ranging from marginal to 10% as determined by ^{1}H and ^{19}F NMR analysis of the corresponding Mosher esters.[54] By measuring the optical rotations of the enantiomeric product mixtures it could be deduced that the 2-substituted complex **2** produced, in both cases, a slight excess of the (+)-enantiomer of 2-alkyl-1-octanols whereas a slight excess of the (–)-enantiomers was obtained with (*pR*)(*pS*)-**5c**. The hydrogenated congeners **3** and (*pR*)(*pS*)-**6c** proved totally inactive as carboalumination catalysts.

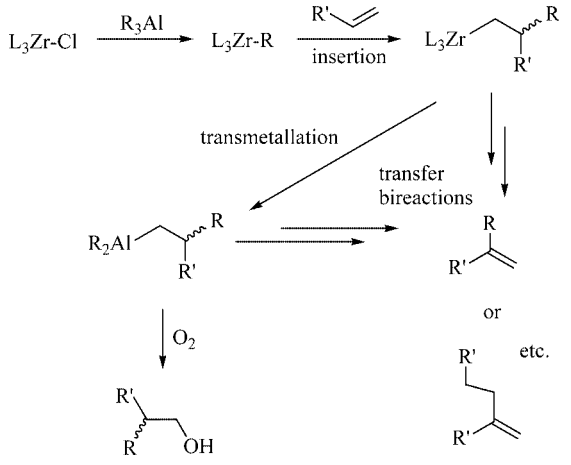
Scheme 11. Carboalumination of 1-octene with chiral zirconocene catalysts. (i) Et_3Al or Me_3Al, **2** or (*pR*)(*pS*)-**5c**, dichloromethane. (ii) O_2.

A simplified mechanistic scheme of the carboalumination reaction is displayed in Scheme 12. Based on the previous work by Negishi, Waymouth and others, the NMI_2ZrCl_2 catalyst appears to have an optimal disposal of the chiral ligands coupled with conformational flexibility driving the reaction towards the carboalumination product which in turn can be oxidized to the chiral alcohol. With other catalysts investigated previously, larger amounts of alkene products resulting from hydrometalation/carbometalation and/or hydrogen transfer sequences are often produced. The ligands in **2** and (*pR*)(*pS*)-**5c** are apparently not bulky enough for efficient blocking of the side reactions resulting in low carboalumination yields and selectivities.



Scheme 12. Simplified mechanism for zirconocene catalyzed carboalumination.

Nevertheless, some enantiocontrol was obtained with the simple ligand design presented in this work and the results obtained could be considered promising. Unfortunately our attempts to modify the steric properties of these precatalysts by additional methyl substituents were hampered by the difficult (or impossible) isolation and purification of complexes **8a**–**c** and **10a**–**c**. Furher variations in ligand structure are currently in progress.

Summary and Conclusions

In this paper we have reported the synthesis of some new indenes containing a β-pinenyl-derived, chiral substituent and investigated the metallation of these ligand precursors, as well as some previously described ligand analogues,[28] with group-4 metals. Due to the simple accessibility of the ligand precursors and the successful metallations in some of the cases, the route appears attractive for the preparation of new chiral transition metal complexes. The main drawback of the complexes described are the high solubilities of both the ligand precursors and the corresponding metallocenes in nearly all common organic solvents which render their isolation and purification unusually difficult in many cases. The high solubilities in turn are likely a consequence of the high rotational and conformational freedom of the pinenyl part in these molecules.

In addition, we have investigated the catalytic activity of selected metal complexes in polymerization and carboalumination reactions. Metal complexes **2** and (*pR*)(*pS*)-**5c** polymerized ethylene with high activity and polyethylene with high molecular weight was obtained whereas only complex **2** was active in propylene polymerization producing atactic polypropylene with low molecular weight. All of the catalysts investigated produced atactic poly(phenylsilane) with low molecular weight. In catalytic carboalumination reactions, complexes **2** and (*pR*)(*pS*)-**5c** showed to induce some (0.5–10% *ee*) enantioselectivity in the carboalumination of 1-octene with triethyl- and trimethylaluminum whereas their tetrahydroindenyl analogues **3** and (*pR*)(*pS*)-**6c** were not active at all. Nevertheless, we believe that the simple chiral catalyst structures described herein, may prove valuable starting points for further developoment by structural modifications.

Experimental Section

General Comments: All air and moisture sensitive reactions were conducted under argon using standard techniques. Commercially available reagents were used without further purification. Methylindene,[55] α-pinenylpotassium,[37] 2-(chlorodimethylsilyl)indene[38] and 1-(chlorodimethylsilyl)indene[39] were synthesized essentially according to literature procedures. Chloro{[(1*S*,2*S*,5*S*)-6,6-dimethylbicyclo[3.1.1]hept-2-yl]methyl}dimethylsilane was prepared by hydrosilylation of β-pinene with chlorodimethylsilane in the presence of Karstedt's catalyst.[56,57] Diethyl ether and tetrahydrofuran were distilled from sodium/benzophenone ketyl prior to use. Dichloromethane was distilled from calcium hydride and toluene was purified by passage through a series of activated 3-Å molecular sieves and copper catalyst columns. Flash chromatography was performed on silica gel 60 (40–63 μm). Silanized silica gel was prepared according to a literature procedure.[33] NMR spectra were recorded at 298 K with a Bruker Avance 600 (^{1}H NMR 600 MHz, ^{13}C NMR 150.9 MHz), Jeol JNM-A500 (^{1}H NMR 500 MHz, ^{13}C 125.8 MHz), Jeol L-400 (^{1}H NMR 400 MHz, ^{13}C 100.6 MHz, ^{29}Si 79.5 MHz) or Bruker 250 MHz (1H NMR 250 MHz) NMR spectrometer. ^{1}H NMR were referenced against residual ^{1}H-impurities in the solvent and ^{13}C NMR to the solvent signals. In the ^{29}Si NMR experiments TMS was used as external reference. The NMR spectra were recorded in δ values with $CDCl_3$ or CD_2Cl_2 as the solvent. Mass spectra were recorded with a high-resolution mass spectrometer (Fison's ZapSpec). A Hewlett–Packard Series II 5890/Hewlett Packard 5971A Mass selective detector was used in GC-MS analysis. Molecular weights and molecular weight distributions of polysilanes were measured at 30 °C in THF by size exclusion chromatography (GPC) relative to polystyrene standards using a Waters 515 high-pressure liquid chromatography pump, GPC fitted with Styragel columns HR 2, HR 4, and HR 6, a UV detector Waters 2487 and a refractive-index detector Waters 2410. Melting intervals were measured with Perkin–Elmer DSC 7. Polyethylene end group analyses were carried out with a Perkin–Elmer FT-IR spectrometer Spectrum 1000. The optical rotation measurements were made using Perkin–Elmer Polarimeter 241. The molecular weights of the polyethylene and polypropylene samples were determined using a Waters Alliance 2000 GPC equipped with a refractometer, viscometer, and three Waters Styragel HMW columns covering the molecular weight range from 10^2 to 10^8 g/mol. 1,2,4-Trichlorobenzene was used as solvent and the chromatograms were collected at 140 °C. The molecular weights were calculated with the universal calibration based on 11 narrow polystyrene standards.

Bis{2-[(7,7-dimethylnorpinanylmethyl)dimethylsilyl]indenyl}-zirconium Dichloride (2): To 2-[(7,7-dimethylnorpinanylmethyl)dimethylsilyl]indene (**1**) (2.4076 g, 7.8 mmol) in diethyl ether (35 mL) at 0 °C was added *n*BuLi (2.5 M in *n*-hexane, 3.2 mL, 7.8 mmol). The yellow solution was stirred at room temperature for 4 h. The solvent was removed under vacuum leaving a pale yellow foam. Next, $ZrCl_4$ (0.9634 g, 4.1 mmol) was added and the solids were mixed a few minutes before 50 mL of toluene was added. After stirring at 50 °C for 18 h, the suspension was filtered and the filtrate was concentrated under vacuum. The product was crystallized from *n*-pentane at –20 °C yielding 1.1157 g (37%) of pure **2** as a yellow powder. ^{1}H NMR (400 MHz, CD_2Cl_2, 25 °C): δ = 7.81 (m, 4 H, arom. CH in six-membered ring), 7.30 (m, 4 H, arom. CH in six-membered ring), 5.97 (dd, J = 0.92 Hz, 2.14 Hz, 2 H, arom. CH in five-membered ring), 5.94 (dd, J = 0.76 Hz, 2.14 Hz, 2 H, arom. In the EIMS mass spectrum parent ions of composition $C_{42}H_{66}Cl_2Si_2Zr^+$ were observed in the appropriate ratios at m/z = 786–794.

A Diastereomeric Mixture of (6,6-dimethylbicyclo[3.1.1]hept-2-ylmethyl)dimethyl(1-methyl-1*H*-inden-2-yl)silanes (7a/7b): To **1**[28] (3.4065 g, 11.0 mmol) in tetrahydrofuran (50 mL) at 0 °C was added *n*BuLi (2.5 M in *n*-hexane, 4.5 mL, 11.1 mmol). The orange solution was stirred at room temperature for 3.5 h and to this solution was added dropwise methyl iodide (1.4 mL, 21.9 mmol) at 0 °C. The resulting red reaction mixture was stirred at room temperature for 1.5 h before saturated aqueous NH_4Cl solution (50 mL) was added. The layers formed were separated and the aqueous layer was further extracted with diethyl ether (30 mL). The combined organic layers were dried with Na_2SO_4, filtered and the solvents evaporated to dryness. The crude product was purified with silica gel column chromatography using hexane as eluent providing 2.6259 g (74%) of **7a/7b** (a mixture of two diastereomers) as a colorless oil. ^{1}H NMR (600 MHz, $CDCl_3$, 25 °C): δ = 7.45 (m, 1+1 H, arom. CH), 7.39 (m, 1+1 H, arom. CH), 7.28 (m, 1+1 H, arom. CH), 7.22 (m, 1+1 H, arom. CH), 7.06 (m, 1+1 H, olefinic CH in five-membered ring), 3.59 (m, 1+1 H, aliph. CH in five-membered ring), 2.21 (m, 1+1 H, CH in pinenyl ring), 2.05 (m, 1+1 H, CH in pinenyl ring), 1.88 (m, 1+1 H, CH in pinenyl ring), 1.74 (m, 3+3 H, CH in pinenyl ring), 1.68 (m, 1+1 H, CH in pinenyl ring), 1.42 (m, 1+1 H, CH in pinenyl ring), 1.39 (m, 3+3 H, CH_3 attached to five-membered ring), 1.30 (m, 1+1 H, CH in pinenyl ring), 1.21 (s, 3 H, CH_3 in pinenyl ring), 1.20 (s, 3 H, CH_3 in pinenyl ring), 0.85 (m, 1+1 H, bridging CH between Si and pinenyl ring), 0.84 (s, 3 H, CH_3 in pinenyl ring), 0.83 (s, 3 H, CH_3 in pinenyl ring), 0.75 (m, 1+1 H, bridging CH between Si and pinenyl ring), 0.28 (m, 6+6 H, CH_3 attached to Si) ppm. ^{13}C NMR (150.9 MHz, $CDCl_3$, 25 °C): δ = 155.20 (C_q), 155.14 (C_q), 152.51 (C_q), 152.48 (C_q), 144.36 (2 C_q), 140.01 (olefinic CH in five-membered ring), 140.00 (olefinic CH in five-membered ring), 126.48 (2 arom. CH), 124.98 (2 arom. CH), 122.58 (2 arom. CH), 120.84 (2 arom. CH), 49.51 (CH in pinenyl ring), 49.37 (CH in pinenyl ring), 49.33 (aliph. CH in five-membered ring), 49.32 (aliph. CH in five-membered ring), 40.79 (CH in pinenyl ring), 40.77 (CH in pinenyl ring), 39.69 (2 C_q in pinenyl ring), 31.39 (CH in pinenyl ring), 31.38 (CH in pinenyl ring), 27.07 (2 CH_3 in pinenyl ring), 25.81 (CH_2 in pinenyl ring), 25.69 (CH_2 in pinenyl ring), 24.92 (2 CH_2 in pinenyl ring), 24.35 (bridging CH_2 between Si and pinenyl ring), 24.22 (bridging CH_2 between Si and pinenyl ring), 23.13 (2 CH_2 in pinenyl ring), 20.18 (2 CH_3 in pinenyl ring), 17.24 (CH_3 attached to five-membered ring), 17.20 (CH_3 attached to five-membered ring), –0.78 (CH_3 attached to Si), –1.02 (CH_3 attached to Si), –1.17 (CH_3 attached to Si), –1.38 (CH_3 attached to Si) ppm. ^{29}Si NMR (119.3 MHz, $CDCl_3$, 25 °C): δ = –8.30, –8.43 ppm. EIMS (70 eV) calcd. for $C_{22}H_{32}Si$ 324.2273, found 324.2273.

Bis{2-[(7,7-dimethylnorpinanylmethyl)dimethylsilyl](1-methyl-indenyl}zirconium Dichlorides [(*pR*)(*pR*)-8a, (*pS*)(*pS*)-8b, (*pR*)(*pS*)-8c]: To a mixture of **7a/7b** (1.2887 g, 4.0 mmol) in diethyl ether (30 mL) at 0 °C was added *n*BuLi (2.5 M in *n*-hexane, 1.6 mL, 4.0 mmol). The yellow solution was stirred at room temperature for 4 h. The reaction mixture was cooled to 0 °C and $ZrCl_4$ (0.4626 g, 2.0 mmol) was added. After stirring the suspension at room temperature for 18 h, the solvents were removed under vacuum. The residue was dissolved in dichloromethane, filtered and the filtrate was concentrated. The crude product was purified with silanized silica gel column chromatography under argon using pentane as eluent providing 0.8499 g (53%) of a mixture of **8a**–**c** as a yellow oil. Combination of fractions containing only the racemic-like diastereomers (*pR*)(*pR*)-**8a** and (*pS*)(*pS*)-**8b** yielded 0.2938 g (18%) of a such mixture. When to this mixture was added cold pentane at –60 °C a small sample (0.054 g, 3%) of **8a/8b** was obtained as yellow crystals enriched in one of the racemic-like diastereomers in a 57:43 ratio. ^{1}H NMR (600 MHz, $CDCl_3$, 25 °C): δ = 7.97 (m, 4 H, arom. CH in **8a** and **8b**), 7.59 (m, 4 H, arom. CH in **8a** and **8b**), 7.33 (m, 4 H, arom. CH in **8a** and **8b**), 7.20 (m, 4 H, arom. EIMS (70 eV) calcd. for $C_{22}H_{32}Si$ 324.2273, found 324.2275.

Bis{3-[(7,7-Dimethylnorpinanylmethyl)dimethylsilyl]-1-methylindenyl}zirconium Dichlorides [(*pR*)(*pR*)-10a, (*pS*)(*pS*)-10b, (*pR*)(*pS*)-10c]: To a mixture of **9a/9b** (0.5294 g, 1.6 mmol) in diethyl ether (10 mL) at 0 °C was added *n*BuLi (2.5 M in *n*-hexane, 660 μL, 1.7 mmol). The pale orange solution was stirred at room temperature for 4 h. The reaction mixture was cooled to 0 °C and $ZrCl_4$ (0.2011 g, 0.9 mmol) was added. After stirring the suspension at room temperature for 20 h, the solvent was removed under vacuum. The residue was dissolved in dichloromethane, filtered and the filtrate was evaporated. The residue was dried in vacuo and the crude product was analyzed with 600 MHz ^{1}H NMR spectroscopy. ^{1}H NMR (600 MHz, $CDCl_3$, 25 °C): δ = 7.71 (m, 4 H, arom. CH in **10a** and/or **10b** and/or **10c**), 7.54 (m, 4 H, arom. CH in **10a** and/or **10b** and/or **10c**), 7.47 (m, 4 H, arom. CH in **10a** and/or **10b** and/or **10c**), 7.38 (m, 2 H, arom. CH in **10a** and/or **10b** and/or **10c**), 7.29 (m, 2 H, arom. CH in **10a** and/or **10b** and/or **10c**), 7.22 (m, 8 H, arom. CH in **10a** and/or **10b** and/or **10c**), 6.41 (m, 2 H, olefinic CH in five-membered ring in **10a** and/or **10b** and/or **10c**), 5.92 (m, 4 H, olefinic CH in five-membered ring in **10a** and/or **10b** and/or **10c**), 2.51 (m, 6 H, CH_3 attached to five-membered ring in **10a** and/or **10b** and/or **10c**), 2.31 (m, 12 H, CH_3 attached to five-membered ring in **10a** and/or **10b** and/or **10c**), 1.10 (m, 18 H, CH_3 in pinenyl ring in **10a** and/or **10b** and/or **10c**), 0.72 (m, 12 H, bridging CH between Si and pinenyl ring in **10a** and/or **10b** and/or **10c**), 0.64 (m, 18 H, CH_3 in pinenyl ring in **10a** and/or **10b** and/or **10c**), 0.38 (m, 36 H, CH_3 attached to Si in **10a** and/or **10b** and/or **10c**), 1.95–1.12 (m, 54 H, aliph. CH in pinenyl ring in **10a** and/or **10b** and/or **10c**), signals from the aliph. protons in pinenyl ring in **10a**, **10b** and **10c** are overlapping with each other and other signals in the region 1.95–1.12 ppm. From the Cp-H (5.92, 6.28 and 6.41 ppm) and Cp-CH_3 signals (2.21, 2.31 and 2.51 ppm) it could be calculated that the amount of the mixture of formed metallocenes was approximately 70%.

Mixture of a Diastereomeric Mixture of 2-[6,6-(Dimethylbicyclo[3.1.1]hept-2-ylmethyl)dimethylsilyl]-1-trimethylsilyl-1*H*-indenes (11a/11b) and 2-[(6,6-dimethylbicyclo[3.1.1]hept-2-ylmethyl)dimethylsilyl]-3-trimethylsilyl-1*H*-indene (12): To **1** (3.3786 g, 10.9 mmol) in tetrahydrofuran (40 mL) at 0 °C was added *n*BuLi (2.5 M in *n*-hexane, 4.4 mL, 11.0 mmol). The orange solution was stirred at room temperature for 3 h and to this solution was added dropwise chlorodimethylsilane (1.4 mL, 10.9 mmol) in tetrahydrofuran (10 mL) at 0 °C. The resulting brownish-orange reaction mixture was stirred at room temperature for 1.5 h before saturated aqueous NH_4Cl solution (50 mL) was added. The layers formed were separated and the aqueous layer was further extracted with diethyl ether (30 mL). The combined organic layers were dried with Na_2SO_4, filtered and the solvents evaporated to dryness. The crude product was purified with silica gel column chromatography using hexane as eluent providing 2.9362 g (71%) of a mixture of **11a/11b** (a mixture of two diastereomers) and **12** as an orange oil. The chemical shifts are largely overlapping both in the ^{1}H NMR and in the ^{13}C NMR spectrum. ^{1}H NMR (600 MHz, $CDCl_3$, 25 °C): δ = 7.53–6.70 (m, 14 H, arom. CH in six-membered ring and olefinic CH in five-membered ring in **11a**, **11b** and **12**), 3.77–3.49 (m, 4 H, aliph. CH in five-membered ring in **11a**, **11b** and **12**), 2.06–1.30 (m, 27 H, aliph. CH in pinenyl ring in **11a**, **11b** and **12**), 1.20 (m, 9 H, CH_3 in pinenyl ring in **11a**, **11b** and **12**), 0.95–0.77 (m, 15 H, CH_3 in pinenyl ring in **11a**, **11b** and **12** and bridging CH between Si and pinenyl ring in **11a**, **11b** and **12**), 0.32 (m, 18 H, CH_3 attached to Si in **11a**, **11b** and **12**), 0.05 (m, 27 H, CH_3 attached to Si in **11a**, **11b** and **12**) ppm. ^{13}C NMR (150.9 MHz, $CDCl_3$, 25 °C): δ = 151.09, 150.95, 149.14, 148.99, 144.83 (10 overlapping C_q in **11a**, **11b** and **12**), 140.26–140.07 and 124.77–120.78 (12 arom. 12), 39.68–39.58 (C_q in **11a**, **11b** and **12**), 31.39–30.65 (aliph. CH in pinenyl ring in **11a**, **11b** and **12**), 27.04 (CH_3 in pinenyl ring in **11a**, **11b** and **12**), 24.93–22.79 (aliphtic CH in pinenyl ring in **11a**, **11b** and **12**), 20.17–20.08 (CH_3 in pinenyl ring in **11a**, **11b** and **12**), 0.74 – (–2. 42) (CH_3 attached to Si in **11a**, **11b** and **12**) ppm. EIMS (70 eV) calcd. for $C_{24}H_{38}Si_2$ 382.2512, found 382.2510.

Mixture of [2-({[(1*S*,2*S*5*S*)-6,6-Dimethylbicyclo[3.1.1]hept-2-yl]-methyl}dimethylsilyl)indenyl]titanium Trichloride (13) and [1-(Trimethylsilyl)indenyl]titanium Trichlorides (14a and 14b): To a solution of a mixture of **11a**, **11b** and **12** (0.6153 g, 1.6 mmol) in dichloromethane (4 mL) at –78 °C was added $TiCl_4$·DCM (1.6 mL, 1.6 mmol) in drops. The resulting dark red reaction mixture was gradually warmed to room temperature and after stirring the reaction mixture at room temperature for 19 h the solvent was removed. The reaction product was crystallized from *n*-pentane at –78 °C yielding a 1:1:1 mixture of **13**, **14a** and **14b** as a black solid. ^{1}H NMR (250 MHz, $CDCl_3$, 25 °C): δ = 7.79 (m, 6 H, arom. CH in **13** and/or **14a** and/or **14b**), 7.51 (m, 6 H, arom. CH in **13** and/or **14a** and/or **14b**), 7.37 (6 H, olefinic CH in five-membered ring in **13**, **14a** and **14b**), 2.12 (m, 1 H, aliph. CH in pinenyl ring in **13**), 1.99 (m, 1 H, aliph. CH in pinenyl ring in **13**), 1.84 (m, 1 H, aliph. CH in pinenyl ring in **13**), 1.75 (m, 2 H, aliph. CH in pinenyl ring in **13**), 1.87 (m, 3 H, aliph. CH in pinenyl ring in **13**), 1.33 (m, 1 H, aliph. CH in pinenyl ring in **13**), 1.12 (s, 3 H, CH_3 in pinenyl ring in **13**), 0.85 (m, 2 H, bridging CH_2 between Si and pinenyl ring in **13**), 0.76 (s, 3 H, CH_3 in pinenyl ring in **13**), 0.46 (m, 24 H, CH_3 attached to Si in **13**, **14a** and **14b**).

Mixture of Diastereomeric Mixtures of 3-[(6,6-Dimethylbicyclo[3.1.1]hept-2-ylmethyl)dimethylsilyl]-1-trimethylsilyl-1*H*-indenes (15a/15b) and 1-[(6,6-Dimethylbicyclo[3.1.1]hept-2-ylmethyl)dimethylsilyl]-3-trimethylsilyl-1*H*-indenes (16a/16b): To a diastereomeric mixture of 1-[dimethyl(7,7-dimethylnorpinanylmethyl)silyl]indene (**4a/4b**) (2.9742 g, 9.6 mmol) in tetrahydrofuran (30 mL) at 0 °C was added *n*BuLi (2.5 M in *n*-hexane, 3.9 mL, 9.7 mmol). The orange solution was stirred at room temperature for 3 h and to this solution was added dropwise chlorodimethylsilane (1.3 mL, 9.6 mmol) in tetrahydrofuran (8 mL) at 0 °C. The resulting yellowish-brown reaction mixture was stirred at room temperature for 1.5 h before saturated aqueous NH_4Cl solution (50 mL) was added. The layers formed were separated and the aqueous layer was further extracted with diethyl ether (30 mL). The combined organic layers were dried with Na_2SO_4, filtered and the solvents evaporated to dryness. The crude product was purified with silica gel column chromatography using hexane as eluent providing 2.3547g (76%) of a mixture of the diastereomeric mixtures **15a/15b** and **16a/16b** as an orange oil. The chemical shifts are largely overlapping both in the ^{1}H NMR and in the ^{13}C NMR spectrum. ^{1}H NMR (600 MHz, $CDCl_3$, 25 °C): δ = 7.56–7.18 (m, 16 H, arom. CH in **15a**, **15b**, **16a** and **16b**), 6.93–6.67 (m, 4 H, olefinic CH in five-membered ring in **15a**, **15b**, **16a** and **16b**), 3.62–3.43 (m, aliph. CH in five-membered ring in **15a**, **15b**, **16a** and **16b**), 2.23–1.30 (m, 36 H, aliph. CH in pinenyl ring in **15a**, **15b**, **16a** and **16b**), 1.16 (m, 12 H, CH_3 in pinenyl ring in **15a**, **15b**, **16a** and **16b**), 0.83 (m, 8 H, CH_2 bridging between Si and pinenyl ring in **15a**, **15b**, **16a** and **16b**), 0.78 (m, 12 H, CH_3 in pinenyl ring in **15a**, **15b**, **16a** and **16b**), 0.33 (m, 24 H, CH_3 attached to Si in **15a**, **15b**, **16a** and **16b**), –0.04 (m, 36 H, CH_3 attached to Si in **15a**, **15b**, **16a** and **16b**) ppm. ^{13}C NMR (150.9 MHz, $CDCl_3$, 25 °C): δ = 147.65, 146.58, 141.57 (12 overlapping C_q in **15a**, **15b**, **16a** and **16b**), 145.73–145.58 (4 overlapping olefinic CH in five-membered ring in **15a**, **15b**, **16a** and **16b**), 124.88–121.13 (16 overlapping aromatic CH in **15a**, **15b**, **16a** and **16b**), 49.48–46.44, 40.81–40.74, 31.50–31.14 (16 overlapping aliph. CH in five-membered ring and in pinenyl ring in **15a**, **15b**, **16a** and **16b**), 39.69 (4 C_q in pinenyl ring in **15a**, **15b**, **16a** and **16b**), 27.07 (4 CH_3 in pinenyl ring in **15a**, **15b**, **16a** and **16b**), 25.89–22.56 (12 overlapping CH_2 in pinenyl ring in **15a**, **15b**, **16a** and **16b**), 20.18 (4 CH_3 in pinenyl ring in **15a**, **15b**, **16a** and **16b**), –0.66 – (–3.09) (20 overlapping CH_3 attached to Si in **15a**, **15b**, **16a** and **16b**). EIMS (70 eV) calcd. for $C_{24}H_{38}Si_2$ 382.2512, found 382.2518.

Mixture of {1-{{[(1*S*,2*S*5*S*)-6,6-Dimethylbicyclo[3.1.1]hept-2-yl]-methyl}dimethylsilyl}indenyl}titanium Trichloride (17a and 17b) and [1-(Trimethylsilyl)indenyl]titanium Trichlorides (14a and 14b): To a solution of a mixture of **15a**, **15b**, **16a** and **16b** (0.6045 g, 1.6 mmol) in dichloromethane (4 mL) at –78 °C was added $TiCl_4$·DCM (1.6 mL, 1.6 mmol) in drops. The resulting dark red reaction mixture was gradually warmed into room temperature and after stirring the reaction mixture at room temperature for 19 h the solvent was removed. The crude product was analyzed with ^{1}H NMR (600 MHz, $CDCl_3$, 25 °C): δ = 7.90, 7.82, 7.57, 7.46, 7.38, 7.22 (m, 12 H, overlapping signals from aromatic CH in **17a** and **17b** and olefinic CH in five-membered ring in **17a** and **17b**), 7.82 (m, 4 H, arom. CH in **14a** and **14b**), 7.53 (m, 4 H, arom. CH in **14a** and **14b**), 7.38 (m, 4 H, olefinic CH in five-membered ring in **14a** and **14b**), 2.21–1.24 (m, 18 H, overlapping signals from aliph. CH in pinenyl ring in **17a** and **17b**), 1.18 (s, 3 H, CH_3 in pinenyl ring in **17a** or **17b**), 1.12 (m, 3 H, CH_3 in pinenyl ring in **17a** or **17b**), 0.88 (m, 4 H, bridging CH_2 between Si and pinenyl ring in **17a** or **17b**), 0.82 (s, 3 H, CH_3 in pinenyl ring in **17a** or **17b**), 0.73 (m, 3 H, CH_3 in pinenyl ring in **17a** or **17b**), 0.52 (m, 24 H, CH_3 attached to Si in **17a**, **17b**, **14a** and **14b**), 0.40 (m, 6 H, CH_3 attached to Si in **17a** and **17b**) ppm.

(6,6-Dimethylbicyclo[3.1.1]hept-2-en-2-ylmethyl)-(1*H*-inden-2-yl)dimethylsilane (22): To α-pinene potassium salt (4.4 mmol) in α-pinene (2.1 mL, 13.1 mmol) were added THF (2 mL) and 2-(chlorodimethylsilyl)indene (**21**) (0.9141g, 4.4 mmol) in THF (2 mL) at –72 °C. The resulting brown reaction mixture was taken into room temperature and stirred for 1 h before saturated aqueous NH_4Cl solution (50 mL) was added. The layers formed were separated and the aqueous layer was further extracted with diethyl ether (30 mL). The combined organic layers were dried with Na_2SO_4, filtered and the solvents evaporated. The excess α-pinene was separated from the crude product by distillation under reduced pressure. The residue was further purified with silica gel column chromatography using hexane as eluent providing 0.0378 g (3%) of **22** as a colorless oil. ^{1}H NMR (600 MHz, $CDCl_3$, 25 °C): δ = 7.49 (m, 1 H, arom. CH), 7.41 (m, 1 H, arom. CH), 7.28 (m, 1 H, arom. CH), 7.19 (m, 1 H, arom. CH), 7.12 (m, 1 H, olefinic CH in five-membered ring), 5.06 (m, 1 H, olefinic CH in pinenyl ring), 3.46 (m, 2 H, aliph. EIMS (70 eV) calcd. for $C_{21}H_{28}Si$ 308.1960, found 308.1965.

Dehydropolymerization of Phenylsilane. General Procedure: A tube was charged with 1 mol-% of the metallocene catalyst, evacuated and backfilled with argon. Phenylsilane was added by syringe and the reaction mixture was degassed three times. The catalyst was activated at room temperature by addition of 2 mol-% of *n*BuLi. The reaction mixture was stirred at room temperature for 24 h. The formed viscous solution was dissolved in tetrahydrofuran and filtered through kiselguhr. The filtrate was concentrated in vacuo to leave the polysilane. The polymer obtained was analyzed by GC-MS, ^{1}H NMR, ^{29}Si{^{1}H} NMR and GPC.

Polymerization of Phenylsilane with [Cp_2ZrCl_2]: By applying the general procedure, [Cp_2ZrCl_2] (0.0111 g, 0.04 mmol), *n*BuLi (31 μL, 0.08 mmol) and phenylsilane (480 μL, 3.86 mmol) gave 0.41 g (98%) of polysilane as a yellow, highly viscous oil.

Polymerization of Phenylsilane with 2: By applying the general procedure, **2** (0.0943 g, 0.12 mmol), *n*BuLi (97 μL, 0.24 mmol) and phenylsilane (1.5 mL, 12.1 mmol) gave 1.26 g (97%) of polysilane as a yellow oil.

Polymerization of Phenylsilane with 3: By applying the general procedure, **3** (0.060 g, 0.08 mmol), *n*BuLi (62 μL; 0,16 mmol) and phenylsilane (950 μL, 7.64 mmol) gave 0.38 g (46%) of polysilane as a pale yellow oil.

Polymerization of Phenylsilane with (*pR*)(*pS*)-5c: By applying the general procedure, (*pR*)(*pS*)-**5c** (0.0261 g, 0.03 mmol), *n*BuLi (27 μL, 0.07 mmol) and phenylsilane (420 μL, 3.34 mmol) gave 0.33 g (90%) of polysilane as a yellow oil.

Polymerization of Phenylsilane with (*pR*)(*pS*)-6c: By applying the general procedure, (*pR*)(*pS*)-**6c** (0.0125 g, 0.02 mmol), *n*BuLi (13 μL, 0.03 mmol) and phenylsilane (198 μL, 1.59 mmol) gave 0.04 g (25%) of polysilane as a yellow oil.

Polymerization of Ethylene and Propylene: The olefin polymerization reactions were performed in a steel reactor rinsed with 200 mL of a 0.3% methylaluminoxane (MAO) solution in toluene prior to use. After evacuation of the steel reactor, 200 mL of dry toluene was cannulated in. MAO was added to the reactor by syringe. The system was saturated with the gas (monomer) and after complete saturation and thermal equilibrium of the system (50 °C) the polymerization was started by adding the prepared catalyst solution (in toluene) to the reactor. Gas (monomer) was continuously added

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and the pressure was kept constant during the polymerization reaction and the gas consumption was monitored. The polymerization was quenched by adding the reaction mixture to a dilute hydrochloric acid/methanol mixture. The produced polyethylene, which was insoluble in toluene, was washed with a dilute hydrochloric acid/methanol mixture, filtered, washed further with methanol, filtered and dried at 60 °C overnight. The polypropylene produced was mixed with a dilute hydrochloric acid/methanol mixture and the formed layers were separated and the polypropylene was further washed two times with methanol. The oily polypropylene obtained was dried under vacuum.

Methyl- and Ethyl- Carboalumination of 1-Octene. General Procedure: In a glove box, trimethylaluminum or triethylaluminum was placed in a reaction vessel followed by addition of a catalyst solution in dichloromethane (3 mL) under argon atmosphere. To this mixture was then added 1-octene and the reaction mixture was stirred at room temperature for 19 h. After cooling to 0 °C, oxygen was bubbled through the solution until all volatiles were evaporated. The resulting yellow oil was treated with 15% aqueous NaOH solution and extracted with diethyl ether (40 mL). The organic layer was dried with $NaSO_4$, filtered and the solvents evaporated to dryness. The crude product was purified by silica gel column chromatography (eluent: 1:1 diethyl ether/hexane).

Synthesis of 2-Methyl-1-octanol Using 2 or (*pR*)(*pS*)-5c: By applying the general procedure, 1-octene (157 μL, 1 mmol), trimethylaluminum (96 μL, 1 mmol) and **2** (0.0623 g, 0.08 mmol) or (*pR*)(*pS*)-**5c** (0.0623 g, 0.08 mmol) gave after purification by column chromatography 2-methyl-1-octanol as a colorless oil in 8% (11.7 mg) and 18% (26.2 mg) yields, respectively. ^{1}H NMR (600 MHz, $CDCl_3$, 25 °C): δ = 3.49 (m, 1 H, CH next to OH), 3.40 (m, 1 H, CH next to OH), 2.03 (br. s, 1 H, OH), 1.60 (m, 1 H, CH), 1.38 (m, 2 H, 2 CH), 1.25 (m, 7 H, 3 CH_2 and CH), 1.08 (m, 1 H, CH), 0.90 (d, J = 6.7 Hz, 3 H, CH_3), 0.86 (t, J = 6.9 Hz, 3 H, CH_3) ppm. ^{13}C NMR (150.9 MHz, $CDCl_3$, 25 °C): δ = 68.64 (CH_2–OH), 35.98 (CH), 33.23 (CH_2), 31.96 (CH_2), 29.71 (CH_2), 27.04 (CH_2), 22.88 (CH_2), 16.69 (CH_3), 14.29 (CH_3). EIMS (30eV) calcd. for $C_{19}H_{20}O$ 144.1514, found 144.1499 (reaction using **2**), found 144.1487 (reaction using (*pR*)(*pS*)-**5c**). Enantiomeric excesses were determined from the ^{1}H NMR spectra of the esters formed with (*S*)-(+)-MTPA-Cl using a literature procedure.[54] For the reaction catalyzed by complex **2**: *ee* = 0.5%, $[a]_D^{24}$ = +0.09 (c = 0.0117 g/mL $CHCl_3$). For the reaction catalyzed by (*pR*)(*pS*)-**5c**: *ee* = 3%, $[a]_D^{24}$ = –0.6 (c = 0.0120 g/mL $CHCl_3$).

Synthesis of 2-Ethyl-1-octanol Using 2 or (*pR*)(*pS*)-5c: By applying the general procedure, 1-octene (157 μL, 1 mmol), triethylaluminum (137 μL, 1 mmol) and **2** (0.0623 g, 0.08 mmol) or (*pR*)(*pS*)-**5c** (0.0623 g, 0.08 mmol) gave after purification by column chromatography 2-ethyl-1-octanol as a colorless oil in 11% (16.8 mg) and 16% (26.0 mg) yields, respectively. ^{1}H NMR (600 MHz, $CDCl_3$, 25 °C): δ = 3.54 (m, 2 H, CH_2 next to OH), 1,37 (m, 3 H, CH and CH_2 in ethyl), 1,27 (m, 11 H, 5 CH_2 and OH), 0,88 (m, 6 H, 2 CH_3) ppm. ^{13}C NMR (150.9 MHz, $CDCl_3$, 25 °C): δ = 65.55 (CH_2–OH), 42.24 (CH), 32.03 (CH_2), 30.62 (CH_2), 29.89 (CH_2), 27.02 (CH_2), 23.48 (CH_2 in ethyl), 22.82(CH_2), 14.30 (CH_3 in ethyl), 11.58 (CH_3). EIMS (30eV) calcd. for $C_{10}H_{22}O$ 158.1671, found 158.1639 (reaction using **2**), found 158.1655 (reaction using (*pR*)(*pS*)-**5c**). Enantiomeric excesses were determined from the ^{1}H NMR spectra of the esters formed with (*S*)-(+)-MTPA–Cl using a literature procedure.[54] For the reaction catalyzed by complex **2**: *ee* = 10%, $[a]_D^{24}$ = +0.48 (c = 0.00084 g/mL $CHCl_3$). For the reaction catalyzed by (*pR*)(*pS*)-**5c**: *ee* = 5%, $[a]_D^{24}$ = –0.18 (c = 0.0109 g/mL $CHCl_3$).

Acknowledgments

Financial support from the Neste Research Foundation is gratefully acknowledged. We also thank Mr. Markku Reunanen, Mrs. Päivi Pennanen, Mr. Mattias Roslund, Mr. Esa Kokko and Mr. Mikko Lankinen for their assistance with the ESIMS, EIMS, NMR and GPC-analyses.

Dinuclear Copper(II) Complexes of Two Homologous Pyrazine-Based Bis(terdentate) Diamide Ligands

Julia Klingele (née Hausmann),[a] Boujemaa Moubaraki,[b] Keith S. Murray,[b] John F. Boas,[c] and Sally Brooker*[a]

Keywords: N ligands / Copper / Amides / Pyrazine / Hexafluorosilicate

The 1:1 reactions of the new bis(terdentate) diamide ligand *N*,*N*′-bis(2-pyridylmethyl)pyrazine-2,5-dicarboxamide ($H_2\mathbf{L^1}$) and its higher homologue *N*,*N*′-bis[2-(2-pyridyl)ethyl]-pyrazine-2,5-dicarboxamide ($H_2\mathbf{L^2}$) with $Cu(BF_4)_2{\cdot}4H_2O$ in the absence of added base have consistently afforded dicopper(II) complexes of the doubly deprotonated ligands $(\mathbf{L^1})^{2-}$ and $(\mathbf{L^2})^{2-}$. The complex $[Cu^{II}_2(\mathbf{L^2})(H_2O)_2(MeCN)_2](BF_4)_2$ (**2a**) has been structurally characterised. Subsequently, reactions employing a correct stoichiometric 2:1 metal-to-ligand ratio in MeCN have afforded bulk samples of the dinuclear complexes. The compounds $[Cu^{II}_2(\mathbf{L^1})(MeCN)_2(H_2O)_2](BF_4)_2{\cdot}H_2O$ (**1a**·H_2O) and $[Cu^{II}_2(\mathbf{L^2})(H_2O)_4(BF_4)_2]{\cdot}2H_2O$ (**2b**·$2H_2O$) have been structurally characterised. While complex **1a**·H_2O of the lower ligand homologue exhibits very weak antiferromagnetic spin coupling ($J = -0.24$ cm^{-1}), complex **2b** of the higher ligand homologue exhibits very weak ferromagnetic spin coupling ($J = +0.67$ cm^{-1}). EPR studies have been carried out on polycrystalline powders and frozen DMF solutions of **1a**·H_2O and **2b**·$2H_2O$. The EPR spectra of the polycrystalline powders indicate the presence of dipolar broadening and weak intermolecular exchange, while those of the frozen DMF solutions are characteristic of dipolar-coupled Cu^{II} pairs within the dinuclear molecules, with no evidence of intra- or intermolecular exchange. The spectral simulations confirm that the binuclear structure and the Cu···Cu distances are retained in frozen solution. Dinuclear SiF_6^{2-} containing compounds, $[Cu^{II}_2(\mathbf{L^1})(H_2O)_4](SiF_6)$ (**1b**) and $\{[Cu^{II}_2(\mathbf{L^1})(H_2O)_2(\mu\text{-}SiF_6)]{\cdot}4H_2O\}_\infty$ (**1c**·$4H_2O$), were obtained serendipitously, in nearly quantitative yield, by the 2:1 reaction of $Cu(BF_4)_2{\cdot}4H_2O$ with $H_2\mathbf{L^1}$ in H_2O. The unexpected SiF_6^{2-} anions were generated in the course of the reaction by partial hydrolysis of the BF_4^- anions employed, thus forming traces of HF which reacted with the glassware.

Introduction

For the formation of grid-type complexes relatively rigid ligand systems with a repeating linear array of bi- or terdentate binding pockets are necessary.[1] With regard to advanced materials, grid-type complexes containing octahedral rather than tetrahedral metal ions are expected to give rise to a broader range of potentially useful properties. The design of ligands with terdentate rather than bidentate binding pockets is therefore desirable. Grid-type complexes of relatively simple pyrimidine-bridged bis(terdentate) ligands, which exhibit intriguing electronic[2] or magnetic properties,[3] for example, have been reported by Lehn and co-workers. The use of amide-based ligands for the formation of grid-type complexes offers advantages over other systems as amides can usually be synthesised relatively easily. Apart from their ability to coordinate to metal ions, amide groups also reduce the degrees of freedom in a given ligand system.[4]

The two homologous pyrazine-based diamide ligands *N*,*N*′-bis(2-pyridylmethyl)pyrazine-2,5-dicarboxamide ($H_2\mathbf{L^1}$) and *N*,*N*′-bis[2-(2-pyridyl)ethyl]pyrazine-2,5-dicarboxamide ($H_2\mathbf{L^2}$) are relatively rigid, bis(terdentate) chelates with antiparallel coordinate vectors, and in theory they should be able to form [2 × 2] grid-type complexes of octahedral transition metal ions. Indeed, we have recently reported a cobalt(III) [2 × 2] grid-type complex of the doubly deprotonated ligand $(\mathbf{L^2})^{2-}$.[5] Likewise, copper(II)[6] and nickel(II)[7] [2 × 2] grid-type complexes of the ligand *N*,*N*′-bis(2-pyridylmethyl)pyrazine-2,3-dicarboxamide ($H_2\mathbf{L^3}$), which is isomeric to the lower ligand homologue $H_2\mathbf{L^1}$, have been reported recently. However, it has been found that attempts to isolate similar copper(II) [2 × 2] grid-type complexes of either $H_2\mathbf{L^1}$ or $H_2\mathbf{L^2}$, in the presence of base, consistently produced amorphous solids, which analysed as $[CuH\mathbf{L}]^{n+}{}_n$ (1 equivalent of base per ligand strand) and $[Cu_x\mathbf{L}_x]$ (2 equivalents of base per ligand strand) species.[8] These rather intractable solids have not been further characterised. In contrast, in the absence of added base, reactions

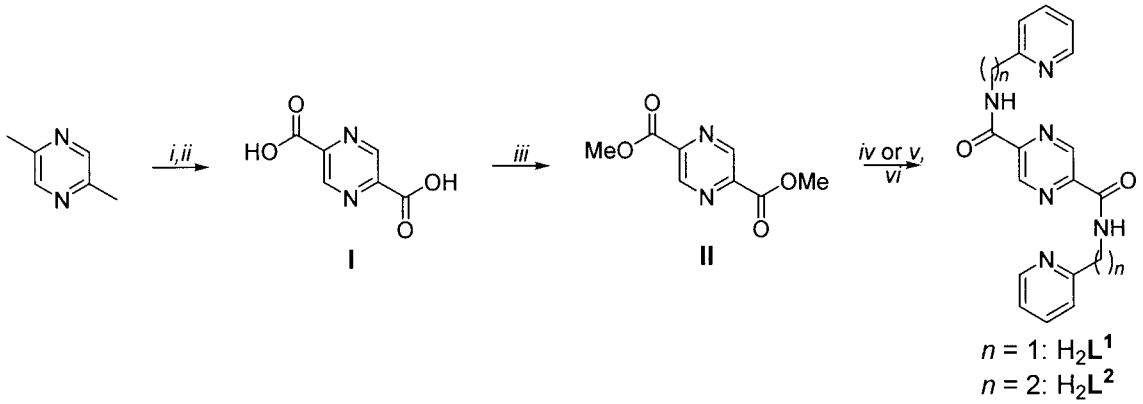

Scheme 1. Synthesis of the ligands $H_2\mathbf{L^1}$ and $H_2\mathbf{L^2}$. Reagents and conditions: (*i*) SeO_2, pyridine/H_2O, (10:1), reflux; (*ii*) H_2O, filtration; (*iii*) $SOCl_2$, MeOH, reflux; (*iv*) 2.2 equiv. 2-(aminomethyl)pyridine, MeOH, 80–90°, open flask; (*v*) 2.2 equiv. 2-(2-aminoethyl)pyridine, MeOH, 80–90°C, open flask; (*vi*) filtration.

of copper(II) with these ligands consistently resulted in the isolation of crystalline samples of dinuclear complexes of a single ligand strand, of the type $[Cu^{II}_2(\mathbf{L^1})(\text{co-ligand})_n]^{2+}$ or $[Cu^{II}_2(\mathbf{L^2})(\text{co-ligand})_n]^{2+}$, which are related to the dinuclear copper(II) complexes obtained by Fleischer and co-workers with the isomeric ligand *N*,*N*′-bis[2-(2-pyridyl)ethyl]pyrazine-2,3-dicarboxamide ($H_2\mathbf{L^4}$).[9,10] In this paper, we report the synthesis of the homologous diamide ligands $H_2\mathbf{L^1}$ and $H_2\mathbf{L^2}$ and describe the X-ray crystal structures of the five dinuclear copper(II) complexes $[Cu^{II}_2(\mathbf{L^1})(MeCN)_2(H_2O)_2]$-$(BF_4)_2\cdot H_2O$ (**1a**·H_2O), $[Cu^{II}_2(\mathbf{L^1})(H_2O)_4](SiF_6)$ (**1b**), $\{[Cu^{II}_2(\mathbf{L^1})(H_2O)_2(\mu\text{-}SiF_6)]\cdot 4H_2O\}_\infty$ (**1c**·$4H_2O$), $[Cu^{II}_2(\mathbf{L^2})(H_2O)_2(MeCN)_2](BF_4)_2$ (**2a**) and $[Cu^{II}_2(\mathbf{L^2})(H_2O)_4(BF_4)_2]\cdot 2H_2O$ (**2b**·$2H_2O$). The magnetic properties and EPR data of **1a**·H_2O and **2b** are also presented.

Results and Discussion

Ligand Syntheses

The ligand precursor, dimethyl pyrazine-2,5-dicarboxylate (**II**),[11,12] was synthesised, by modifying the literature procedure, from commercially available 2,5-dimethylpyrazine in a one-pot two-step procedure (Scheme 1). The first step consisted of the oxidation of the *α*-methyl groups with SeO_2 in aqueous pyridine to afford pyrazine-2,5-dicarboxylic acid (**I**).[11–13] The diacid **I** was not isolated in pure form as the crude product could be esterified with MeOH and $SOCl_2$ yielding analytically pure diester **II** as a crystalline material.

The potentially bis(terdentate) diamide ligands $H_2\mathbf{L^1}$ and $H_2\mathbf{L^2}$ were obtained by reacting the diester **II** with 2-(aminomethyl)pyridine or 2-(2-aminoethyl)pyridine, respectively, in a 1:2.2 molar ratio (Scheme 1). The reactions were carried out in MeOH solutions in open flasks, thus allowing most of the solvent to evaporate. The ligands $H_2\mathbf{L^1}$ and $H_2\mathbf{L^2}$ were obtained by filtration in ca. 80 and 70% yield, respectively, as colourless solids. Both compounds proved to be virtually insoluble in all common solvents at room temperature, but some solubility was observed in $CHCl_3$ and CH_2Cl_2 at room temperature and in MeOH, MeCN and DMF at reflux. However, the poor solubility of these two ligands did not preclude successful complexations being carried out (see below).

Dinuclear Copper(II) Complexes

Complexations of $H_2\mathbf{L^1}$ and $H_2\mathbf{L^2}$ with $Cu(BF_4)_2\cdot 4H_2O$ in a metal-to-ligand ratio of 1:1 in MeCN resulted in the isolation of 2:1 complexes of the doubly deprotonated ligands. Single crystals of $[Cu^{II}_2(\mathbf{L^2})(H_2O)_2(MeCN)_2](BF_4)_2$ (**2a**) suitable for an X-ray crystal structure determination were obtained by the vapour diffusion of Et_2O into the 1:1 MeCN reaction solution (Figure 1, Table 1, Table 2, Table 3 and Table 4).

Complex **2a** features two crystallographically independent but chemically very similar centrosymmetric dinuclear molecules. In each molecule the doubly deprotonated ligand acts as an $(N_3)_2$ bis(terdentate) chelate. Each copper(II) centre is in a distorted N_4O square-pyramidal coordination environment (τ[14] = 0.24, 0.41). The coordination sphere is made up of the equatorially coordinating N_3 terdentate coordination site of the deprotonated amide ligand, an H_2O co-ligand in the remaining equatorial position and a MeCN co-ligand at the apex. As observed in related amide complexes,[6,7,10,15–18] the $Cu–N_{amide}$ distances of **2a** [Cu(1)–N(2) 1.936(2) Å and Cu(2)–N(12) 1.929(2) Å] are shorter than the $Cu–N_{heterocycle}$ distances [$Cu–N_{py}$: Cu(1)–N(3) 2.011(3) Å, Cu(2)–N(13) 1.992(3) Å; $Cu–N_{pz}$: Cu(1)–N(1) 2.027(2) Å, Cu(2)–N(11) 2.021(2) Å]. The canting angles, formed between the mean plane of the pyridine ring and the mean plane of the pyrazine ring, are 33.4(1)° and 39.5(1)° for the two independent molecules Cu(1) and Cu(2), respectively. The intramolecular Cu···Cu distances [Cu(1)···Cu(1A) 6.784(2) Å and Cu(2)···Cu(2B) 6.756(2) Å] across the pyrazine bridge are about 0.1 Å shorter than that found in a related dicopper(II) complex of the chemically related ligand *N*,*N*′-bis(2-pyridylmethyl)pyrazine-2,3-dicarboxamide ($H_2\mathbf{L^3}$).[7] In complex **2a** the independent dinuclear subunits are $O_{water}–H\cdots O_{amide}$ intermolecularly hy-

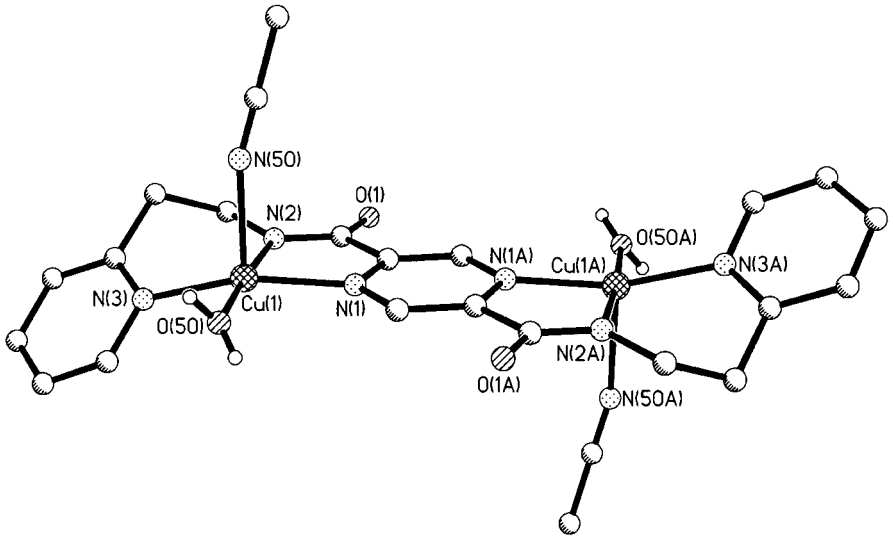

Figure 1. Molecular structure of one of the two independent cations, $[Cu^{II}_2(\mathbf{L^2})(H_2O)_2(MeCN)_2]^{2+}$, of complex **2a**. Hydrogen atoms, except those of the H_2O co-ligands, have been omitted for clarity. Symmetry operation used to generate equivalent atoms: (A) $1 - x$, $2 - y$, $1 - z$.

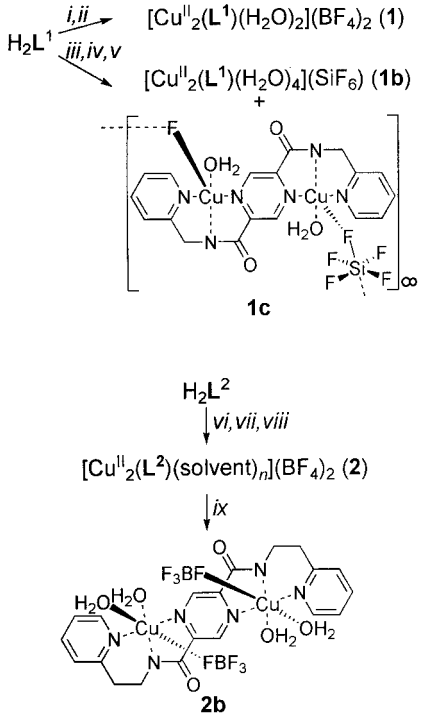
drogen-bonded, forming a 2D ribbon-like structure [$O_{water}\cdots O_{amide}$ 2.598 Å and 2.595 Å]. Parallel ribbons are connected through O_{water}–H···F–BF_2–F···H–O_{water} hydrogen bonds (Figure S1, Supporting Information; $O_{water}\cdots$F 2.738 Å and 2.801 Å).

As reactions, in the absence of base, employing metal-to-ligand ratios of 1:1 consistently afforded 2:1 products, the complexations of $H_2\mathbf{L^1}$ and $H_2\mathbf{L^2}$ were repeated using 2:1 molar metal-to-ligand ratios to isolate bulk materials (Scheme 2).

Vapour diffusion of Et_2O into the reaction solution containing the lower ligand homologue $H_2\mathbf{L^1}$ and $Cu(BF_4)_2\cdot 4H_2O$ in a 1:2 molar ratio in MeCN afforded the dinuclear compound $[Cu^{II}_2(\mathbf{L^1})(H_2O)_2](BF_4)_2$ (**1**) in 60% yield as a dark turquoise microcrystalline solid (Scheme 2). Single crystals of $[Cu^{II}_2(\mathbf{L^1})(MeCN)_2(H_2O)_2](BF_4)_2\cdot H_2O$ (**1a**·H_2O) (Figure 2, Table 1, Table 2, Table 3 and Table 4) suitable for an X-ray crystal structure determination were obtained by slow evaporation of the reaction solution.

The copper(II) coordination sphere in the centrosymmetric dinuclear complex in **1a**·H_2O is N_4O square-pyramidal, exhibiting only a slight distortion from the perfect geometry ($\tau^{[14]} = 0.06$). As in **2a**, the doubly deprotonated $(N_3)_2$ bis-(terdentate) ligand $(\mathbf{L^1})^{2-}$ in **1a**·H_2O encapsulates each copper(II) ion in an equatorial manner. Again, the copper(II) coordination sphere is completed by a MeCN and an H_2O co-ligand. Compared to complex **2a**, however, these co-ligands have switched their positions, so that in complex **1a**·H_2O the H_2O co-ligand coordinates axially and the MeCN co-ligand coordinates in the equatorial position. Owing to the increase in ligand rigidity due to the methylene instead of the ethylene linkers, the ligand backbone of complex **1a**·H_2O is much flatter than that in **2a**, showing a mean deviation of only 0.048 Å from the mean plane made up of all non-hydrogen atoms of the ligand, and a maximum deviation of only 0.082(4) Å for $C(10)_{(4\text{-}py)}$. The



Scheme 2. Synthesis of the complexes **1**, **1b**, **1c**, **2** and **2b**. Reagents and conditions: (*i*) 2 equiv. $Cu(BF_4)_2\cdot 4H_2O$, MeCN, room temp.; (*ii*) Et_2O (vapour diffusion); (*iii*) 2 equiv. $Cu(BF_4)_2\cdot 4H_2O$, H_2O, room temp.; (*iv*) 2 equiv. NEt_3; (*v*) slow evaporation; (*vi*) 2 equiv. $Cu(BF_4)_2\cdot 4H_2O$, MeCN, 60 °C; (vii) room temp., 10 h; (*viii*) filtration; (*ix*) MeCN/EtOH (1:1) (slow evaporation).

Cu···Cu distance of the equivalent copper(II) centres [Cu(1)···Cu(1A) 6.811(3) Å] is slightly longer than that found in complex **2a**. A stair-like chain structure is formed through hydrogen bonding of the axial H_2O co-ligand to the amide oxygen atom of a neighbouring dinuclear subunit [$O_{water}\cdots O_{amide}$ 2.714 Å]. The H_2O co-ligand forms a second

hydrogen bond, to the BF_4^- anion [$O_{water}\cdots F$ 2.745 Å]. The amide oxygen atom is also involved in another hydrogen bond, to the H_2O solvate molecule [$O_{amide}\cdots O_{solvate}$ 2.907 Å] (Figure S2, Supporting Information).

The 2:1 molar reaction of $Cu(BF_4)_2$·$4H_2O$ with the higher ligand homologue $H_2\mathbf{L^2}$ in MeCN afforded the complex $[Cu^{II}_2(\mathbf{L^2})(solvent)_n](BF_4)_2$ (**2**) in ca. 50% yield in the form of a bottle-green microcrystalline solid, that precipitated from the reaction mixture after several hours of stirring (Scheme 2). Recrystallisation of complex **2** from MeCN/EtOH (1:1) afforded single crystals of $[Cu^{II}_2(\mathbf{L^2})(H_2O)_4(BF_4)_2]$·$2H_2O$ (**2b**·$2H_2O$) suitable for an X-ray crystal structure determination (Figure 3, Table 1, Table 2, Table 3 and Table 4).

The overall molecular structure of the centrosymmetric molecule of complex **2b**·$2H_2O$ is very similar to that of complex **2a**. The major difference is the N_3O_2F distorted octahedral coordination environment about the copper(II) ions in **2b**·$2H_2O$, the two axial positions being elongated and occupied by an H_2O and a BF_4^- co-ligand. The Cu–F_{ax} distance [Cu(1)–F(13B) 2.598(3) Å] is, as expected, somewhat longer than the Cu–O_{ax} distance [Cu(1)–O(60) 2.516(5) Å]. Although BF_4^- ions are commonly regarded as "non-coordinating" a number of structures with coordi-

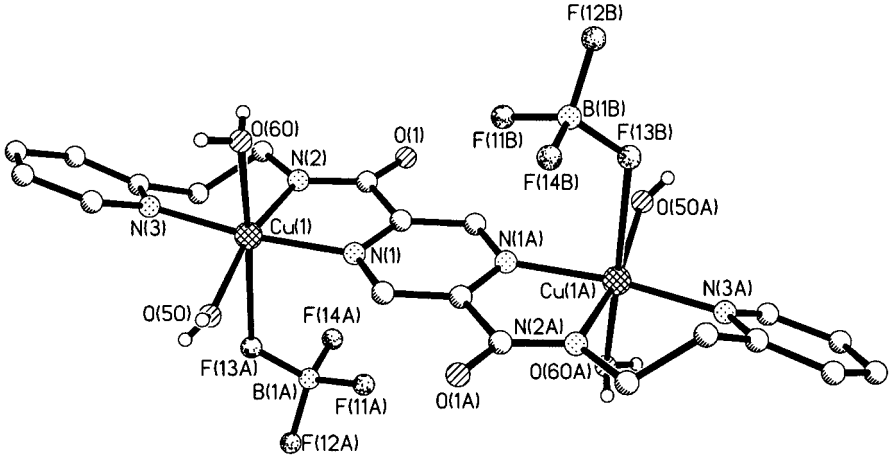

Figure 3. Molecular structure of the complex $[Cu^{II}_2(\mathbf{L^2})(H_2O)_4(BF_4)_2]$ (**2b**·2H_2O). The H_2O solvates and hydrogen atoms, except those of H_2O co-ligands, have been omitted for clarity. Symmetry operations used to generate equivalent atoms: (A) $1-x, 1-y, 1-z$; (B) $x-1, y, z$.

nated BF_4^- ions are known.[19,20] In copper(II) complexes with coordinated BF_4^- ions, Cu–F distances between 2.07 Å[21] and 2.85 Å[22] have been observed, but mostly the distances lie in the range 2.40–2.71 Å. In complex **2b**·2H_2O a 3D network is formed by hydrogen bonds, involving the amide oxygen atoms, both H_2O co-ligands, the BF_4^- co-ligands and the H_2O solvates (Figure S3, Supporting Information).

Dinuclear copper(II) compounds unexpectedly incorporating SiF_6^{2-} as counterions were obtained by reacting $Cu(BF_4)_2$·4H_2O with the lower ligand homologue $H_2\mathbf{L^1}$, in a 2:1 metal-to-ligand ratio, using H_2O as the solvent and a glass vial as the reaction and crystallisation vessel (slow evaporation of the solvent in air). Reactions carried out without base resulted in the isolation of blue-green crystal blocks, along with yellow crystals which, on the basis of elemental and IR analyses, are believed to be $(H_4\mathbf{L^1})$-$(BF_4)_2$. The blue-green crystal blocks were identified as a mixture of the complexes $[Cu^{II}_2(\mathbf{L^1})(H_2O)_4](SiF_6)$ (**1b**) and $\{[Cu^{II}_2(\mathbf{L^1})(H_2O)_2(\mu\text{-}SiF_6)]$·4$H_2O\}_\infty$ (**1c**·4H_2O) by X-ray crystallography (Figure 4 and Figure S4, Supporting information, Table 1, Table 2, Table 3 and Table 4). The formation of the yellow crystals could be prevented by the addition of two equivalents of NEt_3 as a base (Scheme 2), which also resulted in an increased yield (ca. 70–80% yield) of the desired SiF_6^{2-} compounds. The occurrence of SiF_6^{2-}

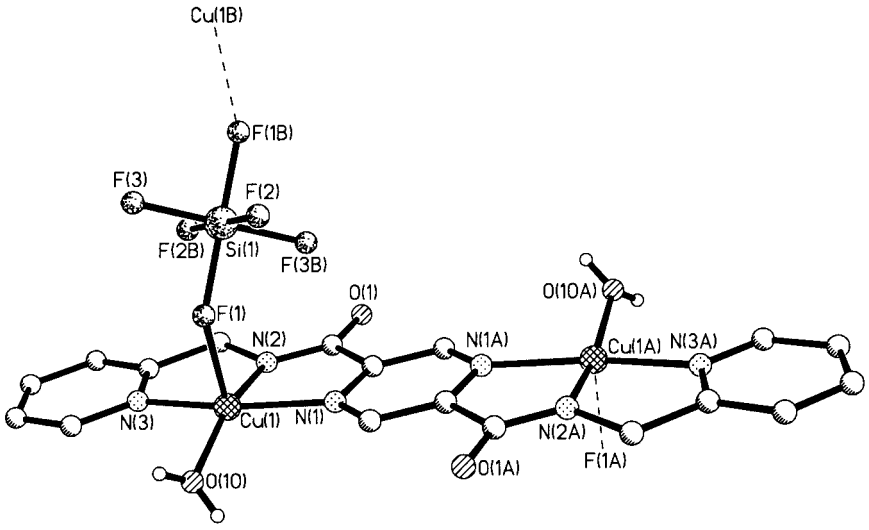

Figure 4. View of the $[Cu^{II}_2(\mathbf{L^1})(H_2O)_2(\mu\text{-}SiF_6)]$ subunit of the polymeric chain structure of the cation of complex **1c**·4 H_2O, emphasising the coordination environment about Cu(1). Hydrogen atoms, except those of H_2O co-ligands, have been omitted for clarity. Symmetry operations used to generate equivalent atoms: (A) $-x, -y - 1, -z$; (B) $-x, -y, -z$.

ions in these compounds, rather than BF_4^- ions, was unexpected but was readily confirmed by the negative ion ESI mass spectrum, which showed a peak at m/z = 123.0 corresponding to the SiF_5^- anion, and the IR spectrum, which showed an intense broad split band (with peaks at 780 and 750 cm^{-1}) typical of the SiF_6^{2-} ion. It has been reported that SiF_6^{2-} anions can arise in compounds originally containing BF_4^- ions as partial hydrolysis of the latter in the presence of moisture can generate traces of HF, which then react with the glassware to form SiF_6^{2-} ions.[23–27]

The molecular structure of the hexafluorosilicate complex **1b** (Figure S4, Supporting Information, Table 1, Table 2, Table 3 and Table 4) is very similar to the structure of the analogous tetrafluoroborate complex **1a**·H_2O. In the centrosymmetric complex **1b** an N_3O_2 distorted square-pyramidal coordination environment about the copper(II) ion is achieved by equatorially and axially coordinated H_2O co-ligands ($\tau_{Cu(1)}$[14] = 0.03). Hydrogen bonding, involving the amide oxygen atom and the equatorial H_2O co-ligand of two neighbouring subunits [$O_{amide}\cdots O_{water}$ 2.603 Å] and both of the H_2O co-ligands with the SiF_6^{2-} anions [$F_{anion}\cdots O_{water}$ 2.760–3.377 Å], is also a feature of this structure.

The related compound **1c**·4 H_2O, obtained from the same reaction mixture, features bridging SiF_6^{2-} co-ligands. The coordination environment about the copper(II) ion is therefore best described as N_3OF square-pyramidal (Figure 4; τ[14] = 0.00).

A polymeric chain structure is formed by the SiF_6^{2-} bridges, which connect two apical positions of two neighbouring dinuclear subunits (Figure 5). The first crystal structure of a chain compound containing bridging SiF_6^{2-} co-ligands, $[Co^{II}(\mathbf{viz})_4(SiF_6)]_\infty$ (**viz** = *N*-vinylimidazole), was reported in 1982 by Reedijk and co-workers.[28] Even now polynuclear compounds with bridging SiF_6^{2-} ions are not very common and all reported compounds incorporate six-coordinate metal ions and mononuclear subunits.[24,29–31] To the best of our knowledge, complex **1c**·4 H_2O is the first polymeric chain compound incorporating square-pyramidal metal ions bridged by SiF_6^{2-} ions and, at the same time, it is the first polymeric compound featuring discrete dinuclear subunits that are bridged by SiF_6^{2-} ions. The Cu–F bond length in complex **1c**·4 H_2O [Cu(1)–F(1) 2.235(1) Å] is around 0.3 Å shorter than in the dimeric complexes $[\{Cu^{II}(H\mathbf{sabh})(H_2O)\}_2(SiF_6)]\cdot 2H_2O$ (H_2**sabh** = salicylaldehyde benzoylhydrazone) (2.522 Å)[32] or $[\{Cu^{II}(H\mathbf{spca})(H_2O)\}_2(SiF_6)]\cdot 2H_2O$ (H_2**spca** = N^3-salicyloylpyridine-2-carboxamidrazone) (2.528 Å),[25] the only crystal structures reported to date that contain square-pyramidal copper(II) ions bridged by the apical positions by SiF_6^{2-} ions. The intermolecular Cu···Cu distance in complex **1c**·4 H_2O is 7.166(1) Å and thus is in between the distances reported for $[\{Cu^{II}(H\mathbf{sabh})(H_2O)\}_2(SiF_6)]\cdot 2H_2O$ (6.04 Å)[32] and $[\{Cu^{II}(H\mathbf{spca})(H_2O)\}_2(SiF_6)]\cdot 2H_2O$ (7.951 Å).[25] The Cu–F–Si angle in complex **1c**·4 H_2O is only 130.45(7)° and is thus smaller than in both $[\{Cu^{II}(H\mathbf{sabh})(H_2O)\}_2(SiF_6)]\cdot 2H_2O$ (144.0°)[32] and $[\{Cu^{II}(H\mathbf{spca})(H_2O)\}_2(SiF_6)]\cdot 2H_2O$ (140.1°)[25] and considerably smaller than in the six-coordinate polymeric chain structures, where the M–F–Si angles range from 152° to 180°.[24,28,33] In complex **1c**·4 H_2O the parallel polymeric strands are interconnected through hydrogen bonds involving the equatorial H_2O co-ligand and the amide oxygen atom [O(10)···O(1C) 2.662 Å]. Furthermore, the two H_2O solvates per asymmetric unit are involved in a network of hydrogen bonds involving all non-coordinated fluorine atoms of the SiF_6^{2-} ligand and the equatorial H_2O co-ligand (Figure 5).

In all of the above structures the Cu–N_{ligand} bond lengths follow the same general trend, specifically Cu–N_{am} < Cu–N_{py} < Cu–N_{pz} (Table 2). Another general, and expected, trend is that in each case on deprotonation and coordination to copper(II) the υ_{CO} band of the free ligand moves to

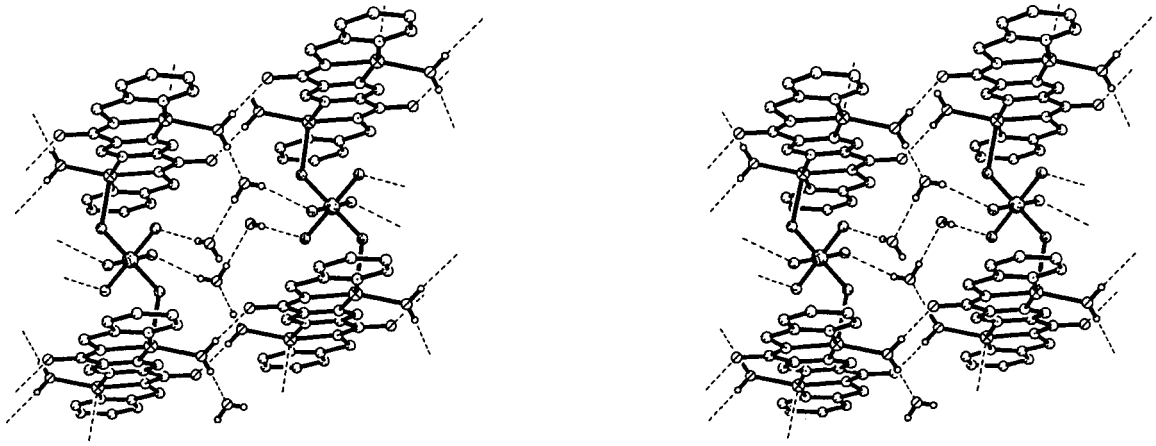

Figure 5. Stereo view of a section of the 3D structure of $\{[Cu^{II}_2(\mathbf{L^1})(H_2O)_2(SiF_6)]\cdot 4H_2O\}_\infty$ (**1c**·4 H_2O). Hydrogen atoms not involved in hydrogen bonds have been omitted for clarity.

lower energy [1681 cm^{-1} for $H_2\mathbf{L^1}$ to 1628–1634 cm^{-1} for the complexes of $(\mathbf{L^1})^{2-}$; 1659 cm^{-1} for $H_2\mathbf{L^2}$ to 1607 cm^{-1} for the complexes of $(\mathbf{L^2})^{2-}$].

Magnetic and EPR Studies

The temperature dependence of the magnetic susceptibility was measured for the two complexes **1a**·H_2O and **2b** over the range 300–4.2 K. The plots of the temperature dependence of μ_{eff} and χ_m are given in the Figures S5–S8 (Supporting Information).

Complex **1a**·H_2O showed Curie-like behaviour at higher temperatures (μ_{eff} = 1.91 μ_B) and only at temperatures below 5 K a small, rapid decrease was observed. Consequently, χ_m increased and no maximum was observed in the plot χ_m vs. *T*. The best fit to the Bleaney–Bowers equation[34] was obtained from the parameters J = –0.24 cm^{-1}, g = 2.2, $TIP = 60\times10^{-6}$ cm^3mol^{-1}. Setting J at zero gave a calculated line that did not reproduce the decrease in μ_{eff} values below 5 K. Calculations of μ_{eff} using the thermodynamic form of susceptibility, applicable to low temperature/high field combinations, rather than the Bleaney–Bowers equation, show that the small decrease is partly, but not wholly, due to Zeeman level depopulation (saturation) effects in the field used (1 T). Nevertheless, the antiferromagnetic coupling interaction was less than that (–7.5 cm^{-1}) of a related dicopper(II) complex of the isomeric ligand *N*,*N*′-bis(2-pyridylmethyl)pyrazine-2,3-dicarboxamide ($H_2\mathbf{L^3}$).[7] In the 2,3-dicarboxamide compound, an internal O···H···O=C hydrogen-bond was present in the $(H\mathbf{L^3})^-$ form of the bridging ligand and the terminal ligands to each copper(II) centre were different to those in **1a**·H_2O. However, the Cu···Cu distances, τ values and *trans-axial* copper(II) geometries were very similar in both cases (vide infra). DFT calculations made on the 2,3-dicarboxamide complex yielded spin densities and spin populations on the pyrazine N-donor atoms compatible with weak antiferromagnetic superexchange coupling of the $Cu^{II}(d_{x^2-y^2})$ orbitals across the pyrazine ring.[7] Thus, while **1a**·H_2O and this 2,3-dicarboxamide analogue are both very weakly antiferromagnetically coupled, there is no clearly identifiable feature which explains this difference in *J* values. For complex **2b** the χ_m values follow Curie behaviour while μ_{eff} is constant at 1.86 μ_B down to 50 K, then increases to 1.92 μ_B at 4 K. Fitting to a dinuclear model gave g = 2.14 and J = +0.67 cm^{-1}. The observed very weak ferromagnetic spin coupling was unexpected, as the main difference between the complexes **2b** and **1a**·H_2O is only the more flexible ethylene containing ligand arm and weak Cu–F coordination in complex **2b**. Furthermore, antiferromagnetic spin coupling has been observed for various copper(II) complexes of the ligands *N*,*N*′-bis(2-pyridylmethyl)pyrazine-2,3-dicarboxamide ($H_2\mathbf{L^3}$)[7] and *N*,*N*′-bis[2-(2-pyridyl)ethyl]pyrazine-2,3-dicarboxamide ($H_2\mathbf{L^4}$),[35] which are isomeric to $H_2\mathbf{L^1}$ and $H_2\mathbf{L^2}$, respectively.

The EPR spectrum of a polycrystalline powder of **1a**·H_2O at 120 K shows a strong resonance near g = 2, with no hyperfine structure being resolved on the parallel feature (Figure S9, Supporting Information). Simulations give $g_\parallel$ = 2.24 and $g_\perp$ = 2.06. An extremely weak resonance of similar shape is observed at $g \approx 4$ (Figure S10, Supporting Information). The spectrum of a polycrystalline powder of **2b**·2 H_2O at both 260 K and 150 K (Figure S11, Supporting Information) shows an asymmetric resonance near g = 2, with the features associated with $g_\parallel$ being unresolved and tailing off to low field. The g-values are estimated as $g_\parallel$ = 2.23 and $g_\perp$ = 2.05. Again, a weak resonance is observed near g = 4 (Figure S12, Supporting Information). None of the polycrystalline powder spectra showed a dependence on temperature between 120 K and 295 K. The appearance of the resonances in the $g \approx 2$ and $g \approx 4$ regions is indicative of the presence of dipolar and weak exchange interactions between the copper(II) ions.[36] The former give rise to spectral broadening while the latter result in exchange narrowing, as is observed here. The effect of the different magnitudes of exchange interaction on the spectra is shown by the collapse of the hyperfine interaction in **1a**·H_2O and the smearing out of the differences in g-value due to a larger exchange interaction in **2b**·2 H_2O.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The observation of resonances at $g \approx 4$ in the polycrystalline powder systems is additional evidence for interaction between the copper(II) ions. These resonances are not due to Fe^{III} impurities in either the cavity background or in the powders themselves. Although in a three-dimensional extended lattice the $g \approx 4$ resonances are expected to be smeared out unless E_d, $E_{ex} << E_0$,[37] this inequality does not hold in the present case, where the Zeeman energy $E_0 \approx 0.3\ cm^{-1}$, the dipolar coupling energy $E_d \approx 0.01\ cm^{-1}$ and E_{ex} is $-0.24\ cm^{-1}$ for **1a**·H_2O and $+0.67\ cm^{-1}$ for **2b**·2 H_2O. However, this condition is relaxed for low-dimensional magnetic systems. Thus the observation of resonances near $g = 4$ for both complexes implies the existence of low-dimensional intermolecular exchange interactions in the solid state.[37,38]

The EPR spectra of **1a**·H_2O and **2b**·2 H_2O in frozen DMF solution (ca. 1 mM) at 130 K were identical and showed well resolved resonances at $g \approx 2$ and $g \approx 4$ as shown in Figure 6 and Figure 7 respectively. These resonances are typical of those observed for many dinuclear copper(II) complexes in dilute frozen solution[36] and are attributed to the coupling of two copper(II) ions, each with electron spin $S = ½$, by dipole–dipole and exchange interactions to give a triplet state ($S = 1$) and a singlet state ($S = 0$). The resonances in the $g \approx 2$ region are due to the $\Delta M_s = 1$ transitions within the triplet state and those near $g \approx 4$ ("half field") to the "forbidden" or $\Delta M_s = 2$ transitions between the $M_s = \pm 1$ levels of the triplet state.

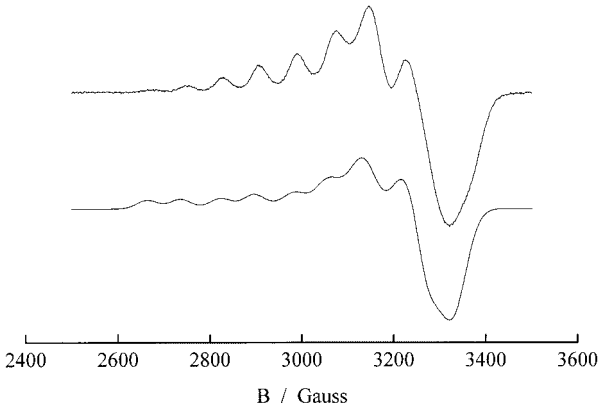

Figure 6. EPR spectrum in the $g = 2$ region of **2b**·2 H_2O in frozen DMF solution at 130 K (approximately 1 mM). Experimental spectrum (top): microwave frequency 9.424 GHz; microwave power 2 mW; 100 kHz modulation amplitude 1 G; receiver gain 2.0×10^4; scan time 167 s; time constant 82 ms. Simulated spectrum (bottom): computed using the parameters referred to in the text.

The spectra can be simulated as shown in Figures 6 and 7 with the following spin Hamiltonian parameters $g_{\|} = 2.290\ (\pm 0.005)$, $g_{\perp} = 2.080\ (\pm 0.005)$, $A_{\|} = 170\ (\pm 5) \times 10^{-4}\ cm^{-1}$, $A_{\perp} = 5\ (\pm 5) \times 10^{-4}\ cm^{-1}$. A $Cu^{II} \cdots Cu^{II}$ distance of 6.9 (± 0.1) Å is obtained with the inter-nuclear vector in the xy plane of the magnetic axes of the copper(II) ions (to within 15°), i.e. perpendicular to the z or symmetry axis of the individual ions. The best fit of experimental and simulated spectra is found with an isotropic exchange interaction $J = 0$. The uncertainties, given in parentheses, represent the range of parameters for which acceptable agreement is found between experimental and simulated spectra. There is no inherent contradiction between the value of $J = 0$ found from the simulation of the frozen solution spectra and the small values of J found by magnetic susceptibility measurements, as the latter may arise from intermolecular interactions in the solid state. Intermolecular exchange is not expected to be significant in dilute frozen solution.

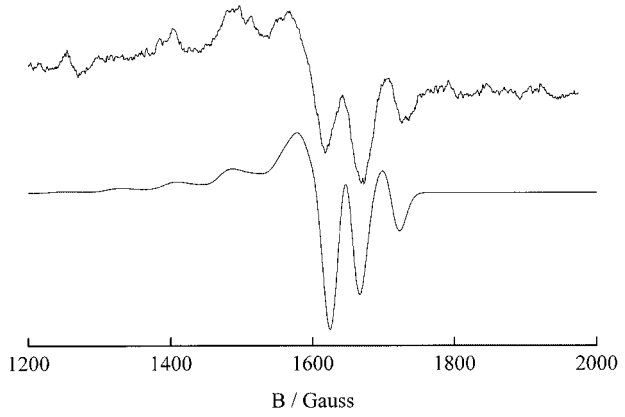

Figure 7. Half-field portion of EPR spectrum of **2b**·2 H_2O in frozen DMF solution at 130 K. Experimental spectrum (top): microwave frequency 9.424 GHz; microwave power 10 mW; 100 kHz modulation amplitude 10 G; receiver gain 5.0×10^5; scan time 84 s; time constant 328 ms; average of 17 scans. Simulated spectrum (bottom): computed using the parameters referred to in the text.

The spin Hamiltonian parameters from the simulation of the frozen solution spectra can be taken as being those of the individual copper(II) ions and give $g_{av} = 2.14$. This value may be compared with the values of g_{av} from the solid-state powder spectra of 2.12 (**1a**·H_2O) and 2.11 (**2b**·2 H_2O) and from magnetic susceptibility of 2.20 (**1a**·H_2O) and 2.14 (**2b**·2 H_2O). The g values of the solid-state powder spectra and those from magnetic susceptibility measurements are subject to significant sources of uncertainty. Nevertheless, the magnetic susceptibility and EPR measurements show that the copper(II) ions retain the $Cu^{II}(d_{x^2-y^2})$ orbital ground state even in solution, consistent with the distorted square pyramidal or octahedral coordination shown by the X-ray crystallographic analysis.

Conclusions

The pyrazine-based bis(terdentate) diamide ligands $H_2\mathbf{L^1}$ and $H_2\mathbf{L^2}$ can be used for the formation of grid-type metal complexes.[5] However, it has been found that on complexation with $Cu(BF_4)_2 \cdot 4H_2O$ both ligands prefer to form dicopper(II) complexes of the type $[Cu^{II}_2(\mathbf{L^1})(\text{co-ligand})_4]^{2+}$ or $[Cu^{II}_2(\mathbf{L^2})(\text{co-ligand})_4]^{2+}$ featuring doubly deprotonated ligands and varying co-ligands. Unlike their isomeric ligands *N*,*N*′-bis(2-pyridylmethyl)pyrazine-2,3-dicarboxamide ($H_2\mathbf{L^3}$)[6] and *N*,*N*′-bis[2-(2-pyridyl)ethyl]pyrazine-2,3-dicarboxamide ($H_2\mathbf{L^4}$),[35] where the addition of base is required to even monodeprotonate the ligand for complexation, no additional base is required to form complexes of

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the doubly deprotonated ligand species $(\mathbf{L^1})^{2-}$ and $(\mathbf{L^2})^{2-}$. All of the complexes described in this paper, except compound **2b**·2 H_2O, feature distorted square-pyramidal coordination spheres for the copper(II) ions. A distorted octahedral coordination sphere with BF_4^- coordination is observed in complex **2b**·2 H_2O. In all cases the central pyrazine ring bridges the metal ions. Very weak antiferromagnetic spin coupling is observed in magnetic studies on complex **1a**·H_2O which features N_4O five-coordinate copper(II) ions, whereas very weak ferromagnetic spin coupling is observed in studies of complex **2b**, which features N_3O_2F six-coordinate copper(II) ions. X-band EPR studies confirm the very weak exchange coupling in the solid state. The frozen solution spectra are interpreted in terms of dipolar coupling with no intramolecular exchange and intra-cluster Cu···Cu separations similar to those obtained by crystallography. Serendipitous formation of SiF_6^{2-} ions, and the almost quantitative crystallisation of the corresponding SiF_6^{2-} compounds **1b** and **1c**·4 H_2O, has been observed when reacting $H_2\mathbf{L^1}$ with $Cu(BF_4)_2$·4 H_2O in H_2O as the solvent and using a glass vial as both the reaction and crystallisation vessel. Complex **1c**·4 H_2O was found to be a rare example of a structure featuring five-coordinate dicopper(II) subunits bridged by SiF_6^{2-} ions.

Experimental Section

General Remarks: Elemental analyses were performed by the Campbell Microanalytical Laboratory at the University of Otago. Melting points were determined with a Gallenkamp melting point apparatus in open-glass capillaries and are uncorrected. ^1H and ^{13}C NMR spectra were recorded with a Varian INOVA-300 or with a Varian INOVA-500 spectrometer at 25 °C. Chemical shifts are given relative to tetramethylsilane (TMS). IR spectra were recorded with a Perkin–Elmer Spectrum BX FT-IR spectrophotometer over the range 4000–400 cm^{-1}. UV/Vis/NIR spectra were recorded with a Varian CARY 500 Scan UV/Vis/NIR spectrophotometer over the range 200–1400 nm. Molar conductivities were measured using 1 mM solutions with a Suntex SC-170 conductivity meter. ESI mass spectra were recorded with a MicroMass LCT spectrometer. For all compounds MeCN was used as the solvent. Magnetic data were recorded over the range 300–4.2 K using a Quantum Design MPMS5 SQUID magnetometer with an applied field of 1 T. Single-crystal X-ray data were collected with a Bruker SMART CCD area detector diffractometer (λ = 0.71073 Å). The structures were solved by direct methods using SHELXS-97[39,40] and refined against F^2 using full-matrix least-squares techniques with SHELXL-97.[41] Continuous wave (CW) EPR spectra were obtained with a Bruker ESP380FT/CW X-band spectrometer at Monash University, using the standard rectangular TE_{012} cavity. Temperatures below room temperature (295 K) down to 120 K were achieved with a Bruker nitrogen flow insert in the cavity. The microwave frequency was measured with an EIP microwave 548A frequency counter and the *g* factors were determined by proton NMR and with reference to the F^+ line in CaO (2.0001 ± 0.0001).[42] Spectrum simulations were performed with either the Bruker SIMFONIA software or (for Figure 6 and Figure 7) with the SOPHE software described by Griffin and co-workers.[43]

Dimethyl Pyrazine-2,5-dicarboxylate (II): A solution of 2,5-dimethylpyrazine (8.11 g, 75.0 mmol) in pyridine/H_2O (10:1) (165 mL) was treated with solid SeO_2 (37.5 g, 337.5 mmol) and the resulting suspension was refluxed for 18 hours. The resulting dark red-brown mixture was evaporated to dryness under reduced pressure. H_2O (250 mL) was added and the solid elemental selenium was filtered off. After evaporation of the red solution to dryness, the resulting dark red brown solid was taken up in MeOH (150 mL), treated with $SOCl_2$ (3.5 mL) and refluxed for 8 hours. The resulting suspension was then filtered whilst hot and the solid was washed with CH_2Cl_2 (5 × 20 mL). The combined organic layers were reduced in volume under reduced pressure (to ca. 100 mL) to give the product in the form of pale yellow-orange feathery crystals. The solid was filtered off and washed with ice-cold MeOH (20 mL) to give 8.98 g (45.8 mmol, 61%) of analytically pure **II**. M.p. 167–168 °C. $C_8H_8N_2O_4$ (196.16): calcd. C 48.98, H 4.11, N 14.28; found C 49.24, H 3.87, N 14.25. TLC (SiO_2, CH_2Cl_2/10% MeOH): R_f = 0.83. ^1H NMR (300 MHz, $CDCl_3$): δ = 9.39 (s, 2 H, pz*H*), 4.07 (s, 6 H, CH_3) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, $CDCl_3$): δ = 163.6 (pz*C*O), 145.6 (*pz*H), 145.3 (*pz*CO), 53.6 (O*C*H_3) ppm. IR (KBr, disk): $\tilde{\nu}$ = 3549, 3472, 3417, 3077, 3015, 2960, 2853, 1720, 1637, 1618, 1472, 1431, 1359, 1279, 1202, 1181, 1144, 1020, 959, 824, 759, 616 495, 466, 425 cm^{-1}.

***N,N′*-Bis(2-pyridylmethyl)pyrazine-2,5-dicarboxamide ($H_2\mathbf{L^1}$):** A suspension of **II** (1.96 g, 10.0 mmol) in MeOH (70 mL) was treated with a solution of 2-(aminomethyl)pyridine (2.38 g, 22.0 mmol) in MeOH (30 mL) and the resulting solution was kept in an open flask at 80–90 °C for 4 hours, allowing most of the solvent to evaporate. Filtration of the resulting suspension gave 2.92 g (8.38 mmol, 84%) of $H_2\mathbf{L^1}$ in the form of an analytically pure colourless powder. M.p. 205–206 °C. $C_{18}H_{16}N_6O_2$ (348.36): calcd. C 62.06, H 4.63, N 24.12; found C 61.94, H 4.66, N 24.30. TLC (SiO_2, CH_2Cl_2/10% MeOH): R_f = 0.60. ^1H NMR (500 MHz, $CDCl_3$): δ = 9.39 (s, 2 H, 2 × pz*H*), 8.88 (t, *J* = 5.0 Hz, 2 H, 2 × N*H*), 8.62 (ddd, $^3J_{6,5}$ = 5.0, $^4J_{6,4}$ = 2.0, $^5J_{6,3}$ = 1.0 Hz, 2 H, 2 × 6-py*H*), 7.69 (dt, $^3J_{4,5}$ = $^3J_{4,3}$ = 7.5, $^4J_{4,6}$ = 2.0 Hz, 2 H, 2 × 4-py*H*), 7.34 (td, $^3J_{3,4}$ = 7.5, $^4J_{3,5}$ = $^5J_{3,6}$ = 1.0 Hz, 2 H, 2 × 3-py*H*), 7.23 (ddd, $^3J_{5,4}$ = 7.5, $^3J_{5,6}$ = 5.0, $^4J_{5,3}$ = 1.0 Hz, 2 H, 2 × 5-py*H*), 4.82 (d, *J* = 5.0 Hz, 4 H, 2 × pyCH_2) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, $CDCl_3$): δ = 162.6 (pz*C*O), 156.0 (2-*py*), 149.5 (6-*py*), 146.4 (*pz*CO), 142.4 (*pz*H), 136.9 (4-*py*), 122.6 (5-*py*), 122.1 (3-*py*), 44.7 (*C*H_2) ppm. sulting dark bottle-green solution was left at this temperature for 10 minutes and was then cooled to room temperature. By vapour diffusion of Et_2O into the reaction mixture, 106 mg (155 μmol, 64%) of complex **1** were obtained in the form of a dark turquoise solid. Single crystals of $[Cu^{II}_2(\mathbf{L^1})(MeCN)_2(H_2O)_2](BF_4)_2{\cdot}H_2O$ (**1a**·H_2O) suitable for X-ray analysis were obtained by slow evaporation of the reaction solution, obtained as described above. $[Cu^{II}_2(\mathbf{L^1})(H_2O)_2](BF_4)_2$ ($C_{18}H_{18}B_2N_6O_4F_8Cu_2$) (683.08): calcd. C 31.65, H 2.66, N 12.30; found C 31.86, H 2.23, N 12.30. IR (KBr, disk): $\tilde{\nu}$ = 3424, 3110, 2897, 1634, 1567, 1485, 1449, 1436, 1416, 1361, 1350, 1335, 1288, 1214, 1190, 1167, 1083, 1062, 923, 772, 743, 715, 656, 635, 585, 556, 533, 521, 465, 415 cm^{-1}. ESI-MS (pos, MeCN): *m*/*z* (fragment) = 571.5 ($[Cu^{I}Cu^{II}(\mathbf{L^1})(H_2O)(MeCN)_2]^+$), 531.7 ($[Cu^{I}Cu^{II}(\mathbf{L^1})(H_2O)(MeCN)]^+$), 450.7 ($[Cu^{II}(H\mathbf{L^1})(MeCN)]^+$), 276.9 ($[Cu^{II}_2(\mathbf{L^1})(MeCN)_2]^{2+}$), 237.9 ($[Cu^{I}_2(H_2\mathbf{L^1})]^{2+}$), 225.9 ($[Cu^{II}(H_2\mathbf{L^1})(MeCN)]^{2+}$). UV/Vis/NIR (MeCN): $\lambda_{max.}$ (ε) = 212 (34100), 261 (20500), 349 (4200), 641 nm (204 $M^{-1}cm^{-1}$). Λ_m (MeCN) = 231 $\Omega^{-1}mol^{-1}cm^2$.

$[Cu^{II}_2(\mathbf{L^1})(H_2O)_4](SiF_6)$ (1b) and $\{[Cu^{II}_2(\mathbf{L^1})(H_2O)_2(\mu\text{-}SiF_6)]\cdot 4H_2O\}_\infty$ (1c·4H_2O): Solid $H_2\mathbf{L^1}$ (40.1 mg, 115 μmol) was treated with a solution of $Cu(BF_4)_2{\cdot}4H_2O$ (71.1 mg, 230 μmol) in H_2O (5 mL) and the resulting dark bottle green solution was further treated with a solution of NEt_3 (23.3 mg, 230 μmol) in H_2O (3 mL). The resulting blue-green solution was transferred into a sample vial (SAMCO specimen tubes, soda glass, 75 × 25/26 mm, ISO 9002) and was left to slowly evaporate. After 4 weeks 66 mg (96 μmol, 83%) of huge blue-green crystal blocks were isolated by filtration. The crystal blocks analysed as $[Cu^{II}_2(\mathbf{L^1})](SiF_6){\cdot}4H_2O$. Single crystals suitable for X-ray crystal structure determinations, $[Cu^{II}_2(\mathbf{L^1})(H_2O)_4](SiF_6)$ (**1b**) and $\{[Cu^{II}_2(\mathbf{L^1})(H_2O)_2(\mu\text{-}SiF_6)]\cdot 4H_2O\}_\infty$ (**1c**·4H_2O), were selected from these blocks before filtration. $[Cu^{II}_2(\mathbf{L^1})](SiF_6){\cdot}4H_2O$ ($C_{18}H_{22}N_6O_6F_6SiCu_2$) (687.58): C 31.44, H 3.23, N 12.22; found C 31.45, H 3.23, N 12.08. IR (KBr, disk): $\tilde{\nu}$ = 3442, 3084, 2872, 1628, 1563, 1481, 1449, 1407, 1352, 1289, 1214, 1193, 1163, 1111, 1083, 1060, 1026, 981, 961, 923, 780, 750, 651, 556, 512, 472, 417 cm^{-1}. ESI-MS (pos, MeCN): *m*/*z* (fragment) = 451.1($[Cu^{II}(\mathbf{L^1})(MeCN)_2]^+$), 349.2 ($[H_3\mathbf{L^1}]^+$). ESI-MS (neg, MeCN): *m*/*z* (fragment) = 123.0 ($[SiF_5]^-$).

$[Cu^{II}_2(\mathbf{L^2})(solvent)_n](BF_4)_2$ (2): This compound was synthesised in an analogous manner to the preparation of complex **1**, using $H_2\mathbf{L^2}$ (75.3 mg, 200 μmol) instead of $H_2\mathbf{L^1}$. After 10 hours stirring at room temperature complex **2** could be filtered off as a microcrystalline solid. Yield: 74.2 mg (104 μmol, 52%). Single crystals of $[Cu^{II}_2(\mathbf{L^2})(H_2O)_4(BF_4)_2]{\cdot}2H_2O$ (**2b**·2H_2O) suitable for X-ray crystal structure analysis were obtained by recrystallisation of compound **2** from MeCN/EtOH, 1:1. Single crystals of $[Cu^{II}_2(\mathbf{L^2})(H_2O)_2(MeCN)_2](BF_4)_2$ (**2a**) suitable for X-ray crystal structure analysis were obtained by vapour diffusion of Et_2O into the reaction filtrate of an analogous 1:1 molar reaction of ligand to $Cu(BF_4)_2{\cdot}4H_2O$. $[Cu^{II}_2(\mathbf{L^2})(MeCN)_{0.5}(H_2O)](BF_4)_2$ ($C_{21}H_{21.5}B_2N_{6.5}O_3F_8Cu_2$) (713.65): calcd. The First Sandwich-Type Heteropolytungstates Consisting of Trivacant Gallium(III)-Substituted Keggin Fragments

Daniel Drewes,[a] Eva Melanie Limanski,[a] and Bernt Krebs*[a]

Keywords: Gallium / Heteropolytungstates / Polyoxometalates / Tungsten

The new polyoxotungstates $(NH_4)_5Na_9[Cu_4(H_2O)_2(GaW_9O_{34})_2]\cdot 22H_2O$ (**1**) and $(NH_4)_{14}[Zn_4(H_2O)_2(GaW_9O_{34})_2]\cdot 37H_2O$ (**2**) were synthesized in aqueous solution and characterized by IR and Raman spectroscopy, energy dispersive X-ray fluorescence and single-crystal X-ray analysis. Compounds **1** and **2** contain the trivacant α-B-$(GaW_9O_{34})^{11-}$ Keggin fragment, which is structurally characterized for the first time. The lacunary $(GaW_9O_{34})^{11-}$ structure exhibits a centered Ga^{III} atom, which is bound to four oxygen atoms and thus achieves a tetrahedral coordination sphere. The synthesis of **1**–**2** enlarges the class of sandwich-type polyoxoanions and enables the syntheses of a new series of gallium(III)-substituted polyoxotungstates.

Introduction

Polyoxotungstates and -molybdates[1] have been investigated extensively over the last years. Owing to their unique properties, they attract current attention in view of their potential in medicine, material science, and catalysis.[2,3] Beyond the numerous applications, polyoxoanions exhibit impressing and fascinating large structures.[4] Complex and largely unknown self-assembly reaction mechanisms are responsible for the formation of polyoxometalates and make it difficult to develop a straightforward reaction route for their syntheses. It is therefore an important challenge to synthesize polyoxoanions with novel structural features to provide an insight into building reactions. For the exact description of polyoxometalate structures, single-crystal X-ray structure analysis is the most powerful tool as the standard analytical techniques like IR, UV/Vis and elemental analysis are often insufficient.

Within the class of polyoxotungstates, the Keggin anion $(XW_{12}O_{40})^{(8-x)-}$ (where X is the central atom and x its oxidation state) and its defect fragments are the basis for an enormous number of structurally different polyoxoanions. In our work, we focused on the systematic synthesis of sandwich-type polyoxotungstates containing As, Sb and Bi.[5] Sandwich-type polyoxoanions of the $M_4X_2W_{18}$-type constitute a class of structurally interesting compounds in which two trivacant α-*B*-$(XW_9O_{34})^{n-}$ Keggin fragments (X = P^V, As^V, Si^{IV}, Ge^{IV} etc.) are connected via a belt of four transition metals M. The first anion of this type, $[Co_4(H_2O)_2(PW_9O_{34})_2]^{10-}$, was reported in 1973 by Weakley et al.,[6] and the corresponding nickel-substituted anion was published in 1999.[7] Some analogous structures with As^V were described with M = Zn^{II}, Mn^{II}, Co^{II}, Cu^{II}, Cd^{II}, Ni^{II}.[8,5i] Kortz et al. were able expand the number of polyoxoanions of the $M_4X_2W_{18}$ structure type by synthesizing the first examples of silicotungstates $[M_4(H_2O)_2(SiW_9O_{34})_2]^{12-}$ (M = Mn^{II}, Cu^{II}, Zn^{II}) and germanotungstates $[M_4(H_2O)_2(GeW_9O_{34})_2]^{12-}$ (M = Mn^{II}, Cu^{II}, Zn^{II}, Cd^{II}).[9] Our group reported two novel anions of the $M_4X_2W_{18}$-type in which the transition metal M also can be found in the center of the α-*B*-$(XW_9O_{34})^{n-}$ fragment (M = X = Cu^{II}, Fe^{III}).[10]

The selective incorporation of diverse metals M or X is an important aim in polyoxometalate chemistry and makes it possible to modify the properties of the polyoxoanions. For example, the influence on the magnetic properties of transition metals M[11] or main group metals X[12] has been investigated during the last years as well as the effects on the polyoxoanions' catalytic properties.[5a,13] Most of the known structures contain divalent or trivalent transition metals M. Recently, some main-group substituted anions which contain In^{III} and Sn^{II} have been reported.[5h,5j,14] In this paper, we report for the first time on anions consisting of trivacant $(GaW_9O_{34})^{11-}$ Keggin fragments. Only little research was done to date on polyoxometalates containing gallium as a heteroatom. Ga^{III} is used as heteroatom, e.g. in the monovacant Keggin-type anions $[GaW_{11}Ga(OH)O_{39}]^{7-}$[15] and $[GaW_{11}O_{39}Pb]^{7-}$.[16] A Chinese group reported on polyoxoanions of the general formula $[GaW_9M_3O_{40}]^{n-}$ (with M = Mn^{II}, Co^{II}, Ni^{II}, Fe^{III}, V^V), but these compounds were not investigated by X-ray diffraction studies.[17] In 1982 Zonnevijlle characterized POMs of the general formula α-$XM^{III}(OH_2)W_{11}O_{39}^{n-}$ (X = B, Si, Ge, P,

As; M = Al, Ga, In, Tl) and $X_2M^{III}(OH_2)W_{17}O_{61}^{7-}$ (X = P, As; M = Al, Ga, In, Tl) by elemental analysis, UV/Vis and vibrational spectroscopy.

Results and Discussion

The new polyoxotungstates $(NH_4)_5Na_9[Cu_4(H_2O)_2(GaW_9O_{34})_2]\cdot 22\,H_2O$ (**1**) and $(NH_4)_{14}[Zn_4(H_2O)_2(GaW_9O_{34})_2]\cdot 37\,H_2O$ (**2**) were synthesized in aqueous solution by reaction of WO_4^{2-}, Ga^{3+} and the divalent transition metals Cu^{2+} and Zn^{2+}, respectively. The syntheses of **1** and **2** succeeded using $Ga(NO_3)_3\cdot 9\,H_2O$ as well as Ga_2O_3 as starting material. After adding a 1 M solution of NH_4NO_3 or NH_4Cl, single crystals suitable for X-ray diffraction can be obtained by slow evaporation of the solvent. Although in most cases a stoichiometric molar ratio is the best way to synthesize polyoxoanions, we were only able to get single crystals suitable for X-ray diffraction when using an excess of gallium and tungsten.

Figure 1 shows the $[Cu_4(H_2O)_2(GaW_9O_{34})_2]^{14-}$ anion of **1.** The tetranuclear sandwich clusters $[M_4(H_2O)_2(GaW_9O_{34})_2]^{14-}$ (M = Cu^{II}, Zn^{II}) consist of two analogous α-*B*-$(GaW_9O_{34})^{11-}$ subunits, which are connected by a system of four divalent transition metal atoms. The two trivacant subunits can formally be derived from the Keggin structure by removal of three adjacent edge-sharing WO_6 octahedra. The W–O bond lengths and O–W–O bond angles summarized in Table 1 show typical values and differ only slightly from known structures of the $M_4X_2W_{18}$ type. The center of each lacunary anion is occupied by a Ga^{III} atom that is surrounded by four oxygen atoms. The Ga–O bond are in the range of 1.82(1) and 1.84(1) Å for **1** and 1.84(1) and 1.89(1) Å for **2**. We used bond valence calculations to affirm that a gallium atom is situated in the center of the Keggin fragments and to exclude an occupation of this position by the divalent transition metals. The calculated bond valences for the Ga atoms of 3.1 for **1** and 2.7 for **2** are in good agreement with the formal oxidation state +III of the gallium atoms. Modeling these atoms as copper or zinc atoms, respectively, bond valences of 2.7 for **1** and 2.5 for **2** were calculated which are obviously too high for the divalent metal atoms. The results of the elemental analyses confirm that both compounds contain gallium and copper or zinc, respectively, at a ratio of 2:4. However, we cannot exclude a slight disorder of Ga and Zn in **2** as the Ga–O bond lengths are elongated in comparison to **1**.

The two $(GaW_9O_{34})^{11-}$ Keggin fragments are connected through a $M_4O_{14}(H_2O)_2$ belt (M = Cu^{II}, Zn^{II}). The two crystallographically independent Cu atoms in **1** have a distorted octahedral coordination sphere. For Cu(1), each of the subunits provides three oxygen atoms. Cu(2) is bound to one water molecule, two oxygen atoms of one $(GaW_9O_{34})^{11-}$ subunit and three oxygen atoms of the second $(GaW_9O_{34})^{11-}$ subunit. All Cu–O distances are in the range between 1.92(1) and 2.28(1) Å. The O–Cu–O bond angles summarized in Table 1 show the distortion of the CuO_6 octahedra. In **2**, the Zn^{II} atoms are coordinated in the same way and show also an octahedral coordination sphere. The Zn^{II}–O bond lengths range between 2.00(1) and 2.19(1) Å and show that the ZnO_6 octahedra are less distorted than the CuO_6 octahedra. Figure 2 shows the Cu_4 belt in **1** and its linkage to the Ga^{III} atoms of the $(GaW_9O_{34})^{11-}$ Keggin fragments.

The –14 charge of the gallium-substituted polyanions is balanced by nine sodium cations and five ammonium ions in **1** and 14 ammonium ions in **2**. The exact positions of the ammonium ions could not be identified by X-ray diffraction methods as they could not be distinguished from water molecules. However, the results of the elemental analyses are in complete agreement with the formulas of **1** and **2**. In addition, bond valence calculations gave no hints for protonation of the anions.[18]

In both compounds, the anions are linked by an extensive hydrogen bond network. Although the hydrogen atoms

have not been located during the refinement, the OW···O and OW···OW distance indicates the linkage of the anions by hydrogen bonds.[18] Even though the anions in **1** and **2** contain transition metals with different chemical characteristics, the metal−metal distances in the $X_2M_4O_{20}(H_2O)_2$ belt show great similarities. The distances given in Table 2 show that these distances differ only slightly in **1** and **2**. In the rhombic M_4O_{16} (M = Cu^{II}, Zn^{II}) fragments, the side lengths of the M_4 unit differ by less than 0.1 Å for both compounds.

The synthesis of **1** and **2** enables the syntheses of a new series of gallotungstates with the general formula $[M_4(H_2O)_2(GaW_9O_{34})_2]^{n-}$. As the two crystal structures show the synthesis of the $(GaW_9O_{34})^{11-}$ Keggin defect fragments to be reproducible, we think that further anions with M = Co^{II}, Ni^{II}, Mn^{II} or Cd^{II} as heteroatoms can be synthesized.

Conclusions

Two new polyoxotungstates, $(NH_4)_5Na_9[Cu_4(H_2O)_2(GaW_9O_{34})_2]\cdot 22H_2O$ (**1**) and $(NH_4)_{14}[Zn_4(H_2O)_2(GaW_9O_{34})_2]\cdot 37H_2O$ (**2**), were synthesized and characterized by single-crystal X-ray analysis. The present work shows that the class of $M_4X_2W_{18}$ sandwich-type polyoxotungstates can be enlarged by new family of anions with $(GaW_9O_{34})^{9-}$ trivacant lacunary Keggin fragments, which has been synthesized and characterized for the first time. The two exponents of this family with M = Cu^{II} and Zn^{II} establish a new series of tungstates comparable to the known series with X = P^V, As^V, Si^{IV} and Ge^{IV}.

Experimental Section

All starting materials and chemicals were used without further purification.

Preparation of $(NH_4)_5Na_9[Cu_4(H_2O)_2(GaW_9O_{34})_2]\cdot 22H_2O$ (1): $Na_2WO_4\cdot 2H_2O$ (3 g, 9.09 mmol) was dissolved in 20 mL H_2O. The pH value of the solution was adjusted to 7 with concentrated hydrochloric acid. A solution of $Ga(NO_3)_3\cdot 9H_2O$ (0.42 g, 1 mmol) in 2 mL distilled water was added. After stirring the reaction mixture at 70 °C for 15 minutes, a solution of $Cu(CH_3COO)_2\cdot H_2O$ (0.35 g, 1.8 mmol) in 2 mL water was added dropwise. The solution was stirred at 70 °C for one hour. After cooling to room temperature, a greenish residue was removed by filtration and 1 mL of a NH_4NO_3 solution (c = 1 mol/L) was added. Green needles of **1** were obtained on slow evaporation. Yield: 388 mg (16%, based on Cu). IR: $\tilde{\nu}$ (cm^{-1}) = 3477 vs, 1627 s, 1406 m, 931 vs, 882 s, 741 s, 520 w, 455 s. Raman: $\tilde{\nu}$ (cm^{-1}) = 954 s, 780 w, 743 w, 702 w, 628 w 570 w, 512 w, 438 w, 393 w, 327 w, 217 m, 154 m, 106 m. EDX: $Cu_4Ga_2H_{68}N_5Na_9O_{92}W_{18}$ (5505.85): calcd. Cu 4.00, Ga 2.00, W 18.00; found Cu 3.80, Ga 2.15, W 18.00.

Preparation of $(NH_4)_{14}[Zn_4(H_2O)_2(GaW_9O_{34})_2]\cdot 37H_2O$ (2): $Na_2WO_4\cdot 2H_2O$ (4 g, 12.13 mmol) and NaOH (1.0 g, 25 mmol) were dissolved in 50 mL H_2O. A solution of Ga_2O_3 (0.125 g, 0.67 mmol), dissolved in 5 mL of boiling concentrated hydrochloric acid, was added dropwise and the pH was adjusted to 7. The solution was heated to 80 °C and vigorously stirred for two hours. Afterwards, the solution was cooled to room temperature and $Zn(NO_3)_2\cdot 6H_2O$ (446.2 mg, 1.5 mmol), dissolved in 6 mL of water, was added. After 20 minutes, the solution was filtered and 3 mL of a NH_4Cl solution (c = 1 mol/L) was added. Colorless single crystals of **2** were obtained on slow evaporation. Yield: 531 mg (25%, based on Zn). IR: $\tilde{\nu}$ (cm^{-1}) = 3448 vs, br, 2361 w, 2087 w, 1630 s, 1384 m, 925 s, 875 s, 738 s, 451 s. Raman: $\tilde{\nu}$ (cm^{-1}) = 949 s, 900 m, 532 w, 445 w, 351 w, 225 m, 154 m, 107 m. EDX: $Ga_2H_{134}N_{14}O_{107}W_{18}Zn_4$ (5749.40): calcd. Zn 4.00, Ga 2.00, W 18.00; found Zn 4.11, Ga 2.15, W 18.00.

Instrumentation and Analytical Procedures: IR spectra were measured with a Perkin–Elmer 683 spectrometer as KBr pellets. Raman spectra were performed with a Bruker-IFS 113-V-spectrometer. The atomic ratios of the heavy elements were determined by energy dispersive X-ray fluorescence analysis (EDX).

X-ray Crystallography and Data Collection: Diffraction experiments were performed with a STOE IPDS imaging plate system (for **1**) and a Bruker Smart Apex diffractometer with CCD detector (for **2**), both using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Structures were solved by direct methods (for **1**) or Patterson Synthesis (for **2**) with the SHELXS-97[19] and refined with the SHELXL-97 program.[20] No hydrogen atoms were included. Nitrogen atoms of ammonium cations were modeled as oxygen atoms because nitrogen atoms could not be distinguished from oxygen atoms. All metal atoms and oxygen atoms of the anions were refined anisotropically by full-matrix least-squares calculations based on F^2, the crystal water molecules were refined isotropically. The programs SADABS[21] (for **2**) and DECAY[22] (for **1**) were applied as absorption correction. As usual for polyoxometalates, the crystal structures show disorder in the crystal water molecules. Crystallographic data for **1** and **2** are summarized in Table 3.

Further details on the crystal structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, 76344 Eggenstein-Leopoldhafen, Germany; Fax: +49-7247-808-666, E-mail: crysdata@fiz-karlsruhe.de, on quoting the depository number CSD-414617 (for **1**) and CSD-414618 (for **2**).

Keywords: Polyoxometalates / Cyclic voltammetry / Molybdenum / Iron / Tungsten

An isomerically pure form of the molybdenum-rich polytungstate, $[\alpha_1\text{-}As_2Mo_5W_{12}O_{61}]^{10-}$, was prepared by adding 5 equivalents of Mo^{VI} to $[\alpha\text{-}H_2As_2W_{12}O_{48}]^{12-}$, in the presence of Li^+. The α_2-isomer, $[\alpha_2\text{-}As_2Mo_5W_{12}O_{61}]^{10-}$, was prepared by mild alkaline ($KHCO_3$) degradation of $[\alpha\text{-}As_2Mo_6W_{12}O_{62}]^{6-}$. Both $[\alpha_1\text{-}As_2Mo_5W_{12}O_{61}]^{10-}$ and $[\alpha_2\text{-}As_2Mo_5W_{12}O_{61}]^{10-}$ react with Fe^{III} in aqueous solution to give $[\alpha_1\text{-}As_2(FeOH_2)Mo_5W_{12}O_{61}]^{7-}$ (**1**) and $[\alpha_2\text{-}As_2(FeOH_2)Mo_5W_{12}O_{61}]^{7-}$ (**2**), respectively. The parent complex, $[\alpha\text{-}As_2Mo_6W_{12}O_{62}]^{6-}$, was characterized by X-ray crystallography as a mixed potassium-sodium salt [a = 12.8412(17) Å, b = 14.8145(19) Å, c = 19.913(3) Å, α = 70.058°, β = 81.055(5)°, γ = 64,495°, triclinic, $P\bar{1}$, R_1 = 4.99 % based on 9709 reflections]. All of the complexes were characterized by infrared spectroscopy, cyclic voltammetry, and elemental analyses. ^{183}W NMR studies confirm that **1** and **2** are isomerically pure compounds.

Introduction

Polyoxometalates (POMs) are a versatile family of molecular metal oxide clusters with applications in catalysis as well as in medicine and material science.[1–4] Interest in the preparation of isomerically pure polytungstate complexes from lacunary (i.e. tungsten-deficient) precursors continues to be at the center of much of this ongoing research. The first coordination complexes derived from the Wells-Dawson anion, $[\alpha\text{-}P_2W_{18}O_{62}]^{6-}$, were prepared using the monotungsten-vacant derivatives, $[\alpha_1\text{-}P_2W_{17}O_{61}]^{10-}$ and $[\alpha_2\text{-}P_2W_{17}O_{61}]^{10-}$.[5] Later, the tri- and hexatungsten-vacant species ($[\alpha\text{-}P_2W_{15}O_{56}]^{12-}$ and $[\alpha\text{-}H_2P_2W_{12}O_{48}]^{12-}$, respectively) were used.[6,7]

Among the various derivatives prepared by metal incorporation into $[\alpha\text{-}P_2W_{15}O_{56}]^{12-}$ and $[\alpha\text{-}H_2P_2W_{12}O_{48}]^{12-}$, those containing Mo^{VI} or simultaneously Mo^{VI} and a first-row transition metal cation are of particular interest for their electrocatalytic properties.[8,9] It is well established that the presence of one or more molybdenum centers in the polytungstate framework can significantly improve the catalytic properties of the complex. For example, electrocatalysis of NO reduction with $[\alpha_2\text{-}P_2MoW_{17}O_{62}]^{6-}$ was observed at a potential which was 0.270 V more positive than that necessary to carry out the same process with $[\alpha\text{-}P_2W_{18}O_{62}]^{6-}$.[10,11]

Substantial changes in the electrochemical properties of the complexes were also observed upon introducing Fe^{III} centers into a mixed-molybdenum-tungsten framework.[12–14] In a pH 2 medium, the Mo^{VI} centers in $[\alpha\text{-}P_2Mo_3W_{15}O_{62}]^{6-}$ are reduced through three diffusion-controlled one-electron waves. In contrast, $[\alpha_2\text{-}P_2(FeOH_2)Mo_2W_{15}O_{61}]^{7-}$ displays a single three-electron wave in a pH 2 medium as a result of pH-induced merging of the molybdenum and iron waves.

As part of an ongoing program designed to prepare new electrocatalysts for multi-electron transfer reactions,[12,15,16] we now report the isomerically pure preparations of the molybdenum-rich polytungstates, $[\alpha_1\text{-}As_2(FeOH_2)Mo_5W_{12}O_{61}]^{7-}$ (**1**) and $[\alpha_2\text{-}As_2(FeOH_2)Mo_5W_{12}O_{61}]^{7-}$ (**2**). These complexes are formed by the reaction of Fe^{III} with the lacunary precursors, $[\alpha_1\text{-}As_2Mo_5W_{12}O_{61}]^{10-}$ and $[\alpha_2\text{-}As_2Mo_5W_{12}O_{61}]^{10-}$, respectively. Both of these species are structurally derived from $[\alpha\text{-}As_2Mo_6W_{12}O_{62}]^{6-}$ (**3**),[17] which is now characterized by X-ray crystallography. The focus of this manuscript will remain exclusively with the As^V species (rather than the complete isomerically pure P^V series) since $[\alpha_1\text{-}P_2(FeOH_2)Mo_5W_{12}O_{61}]^{7-}$ has not yet been prepared and the first several voltammetric waves of the complexes are driven to more positive potentials by the presence of As^V.[18]

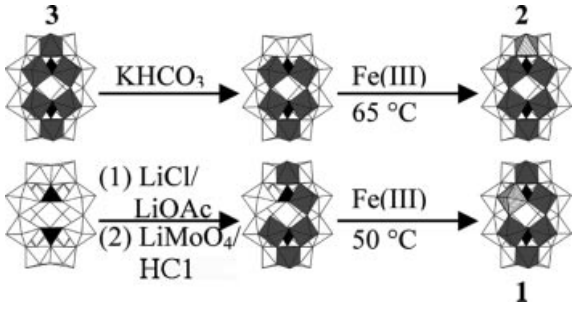
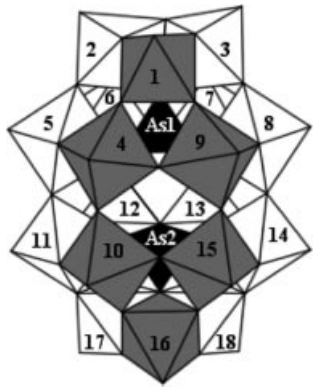
Results and Discussion

Syntheses: Recently we reported the stereospecific synthesis of $[\alpha\text{-}As_2Mo_6W_{12}O_{62}]^{6-}$ (**3**).[17] Three parameters were identified in order to achieve high yield and high purity. First, the synthesis must be performed in highly acidic media. Second, a 25% molar excess of molybdate (relative to $[\alpha\text{-}H_2As_2W_{12}O_{48}]^{12-}$) must be used in order to prevent the formation of byproducts. Finally, the order of the addition of reactants is important (i.e. solid $K_{12}H_2[\alpha\text{-}As_2W_{12}O_{48}]$ must be slowly added to the molybdate solution in order to keep the Mo concentration as high as possible). Pure complex **3** was the precursor required for the synthesis of $[\alpha_2\text{-}As_2Mo_5W_{12}O_{61}]^{10-}$ (Scheme 1). In contrast, the synthesis of $[\alpha_1\text{-}As_2Mo_5W_{12}O_{61}]^{10-}$ was achieved by adding 5 equivalents of Mo to $[\alpha\text{-}H_2As_2W_{12}O_{48}]^{12-}$, in the presence of Li^+. Syntheses of $[\alpha_1\text{-}As_2(FeOH_2)Mo_5W_{12}O_{61}]^{7-}$ (**1**) and $[\alpha_2\text{-}As_2(FeOH_2)Mo_5W_{12}O_{61}]^{7-}$ (**2**) were straightforward and involved the gentle heating of aqueous mixtures of Fe^{III} and $[\alpha_1\text{-}As_2Mo_5W_{12}O_{61}]^{10-}$ or $[\alpha_2\text{-}As_2Mo_5W_{12}O_{61}]^{10-}$, respectively (Scheme 1). In the case of **1**, excessive heating must be avoided in order to prevent the conversion of **1** to **2** (by "hole migration").[19]



Scheme 1. Synthesis of complexes **1** and **2** from $[\alpha\text{-}H_2As_2W_{12}O_{48}]^{12-}$ and **3**, respectively.

Crystallographic Studies: X-ray quality crystals of $[\alpha\text{-}As_2Mo_6W_{12}O_{62}]^{6-}$ (Scheme 2) were grown by allowing an aqueous solution of the POM (in 1 M NaCl) to slowly evaporate in air over two months. However, over this time period the complex starts to decompose. As a result, the crystals that are obtained are a mixture of 50% $[\alpha\text{-}As_2Mo_6W_{12}O_{62}]^{6-}$ and 50% $[\alpha\text{-}As_2W_{18}O_{62}]^{6-}$. The data show that a contiguous longitudinal strip of six MO_6 (M = metal) sites (one on each cap position and two on each belt position)[20] are 50% MoO_6 and 50% WO_6 (positions 1, 4, 9, 10, 15, and 16 in Scheme 2). The remaining 12 MO_6 sites are 100% WO_6 (two on each cap position and four on each belt position). This assignment is confirmed by elemental analyses which show that the ratio of As:Mo:W is 2:3:15. A thermal ellipsoid plot with 50% probability surfaces is provided in the Supporting Information.



Scheme 2. Numbering scheme for $[\alpha\text{-}As_2Mo_6W_{12}O_{62}]^{6-}$. The MoO_6 octahedra are shown in gray, the WO_6 octahedra are shown in white, and the AsO_4 tetrahedra are shown in black.

Spectroscopic Studies: The infrared spectrum of **3** has a slight shift of the frequencies toward lower wave numbers relative to $[\alpha\text{-}As_2W_{18}O_{62}]^{6-}$ as a result of the weakening of bond force constants imposed by the substitution of Mo^{VI} for W^{VI}.[17] A similar trend is observed for the substitution of Fe^{III} for Mo^{VI} in **1** and **2**. In addition, the incorporation of Fe^{III} into the vacant sites of $[\alpha_1\text{-}As_2Mo_5W_{12}O_{61}]^{10-}$ and $[\alpha_2\text{-}As_2Mo_5W_{12}O_{61}]^{10-}$ partially restores the symmetry in the substituted molecules. The infrared spectra of **1** and **2** are quite similar, but they are clearly distinguishable from their lacunary precursors $[\alpha_1\text{-}As_2Mo_5W_{12}O_{61}]^{10-}$ and $[\alpha_2\text{-}As_2Mo_5W_{12}O_{61}]^{10-}$ (see Supporting Information).

Table 1 gives the ^{183}W NMR chemical shift values for **1**, **2**, and **3** in aqueous buffer solutions. The substitution of a paramagnetic Fe^{III} center into the mixed-molybdenum-tungsten framework of **1** and **2** results in a substantial broadening of the signals for the two most structurally proximal W^{VI} centers such that they are not observed in the spectrum. Previously it was established (primarily by ^{31}P NMR studies) that the presence of paramagnetic metal centers results in dramatic chemical shift changes and/or substantial broadening of signals.[5b] Low solubility and low stability prevented the acquisition of ^{183}W NMR spectroscopic data on the lacunary precursors $[\alpha_1\text{-}As_2Mo_5W_{12}O_{61}]^{10-}$ and $[\alpha_2\text{-}As_2Mo_5W_{12}O_{61}]^{10-}$.

Electrochemical Studies: The electrochemical properties of **3** were previously studied in a pH = 0.33 medium suitable for its stability.[17] The observed pattern consists of three chemically reversible waves featuring three quasi-reversible two-electron processes. The cyclic voltammograms of **1**, **2**, $[\alpha_1\text{-}As_2Mo_5W_{12}O_{61}]^{10-}$, and $[\alpha_2\text{-}As_2Mo_5W_{12}O_{61}]^{10-}$ were

run at a scan rate of 10 mV s^{-1} in a 1 M CH_3COOLi/CH_3COOH (pH = 5) medium. The electrolyte was chosen to ensure the stability of all four of the compounds. Given the fact that the Mo^{VI} and Fe^{III} waves of $[\alpha_2\text{-}P_2(FeOH_2)Mo_2W_{15}O_{61}]^{7-}$ merge in a pH = 2 medium but become increasingly split at higher pH values,[12,13] similar behavior was anticipated for **1** and **2**. Figure 1 compares the cyclic voltammograms of **1** and **2** with those of their lacunary precursors, $[\alpha_1\text{-}As_2Mo_5W_{12}O_{61}]^{10-}$ and $[\alpha_2\text{-}As_2Mo_5W_{12}O_{61}]^{10-}$, respectively. The patterns were restricted to those waves for which derivatization of the electrode surface is not expected. The superposition of the waves highlights their differences, and in analogy with previous work,[12,13,15b,16,17,21,22] facilitates the assignments of the first several waves. In addition, assignment of the waves is further facilitated by the fact that it is well established that the first electron transfer should occur on one of the "belt" atoms.[9b] With these guidelines in mind, each of the first two waves of **1** and $[\alpha_1\text{-}As_2Mo_5W_{12}O_{61}]^{10-}$ moving toward less positive potentials features a one-electron quasi-reversible process, with Mo^{VI} being more easily reduced than the Fe^{III} center. The apparent redox potential of this first wave, estimated as the average between the cathodic and anodic peak potentials, was +0.134 V vs. SCE. In contrast, the first two one-electron redox processes of $[\alpha_2\text{-}As_2Mo_5W_{12}O_{61}]^{10-}$ are almost completely merged, while those of **2** are well separated with an apparent redox potential of +0.096 V (vs. SCE) for the first wave of the latter. Thus electrochemistry establishes clear differences between all four of the POMs in a pH = 5 medium, at least regarding the location of the potential of the first wave and/or the number of electrons consumed on this first wave. Finally, as anticipated, there is a close similarity observed between the present As^V-based POMs and the corresponding P^V-based complex, $[\alpha_2\text{-}P_2(FeOH_2)Mo_5W_{12}O_{61}]^{7-}$.[16]

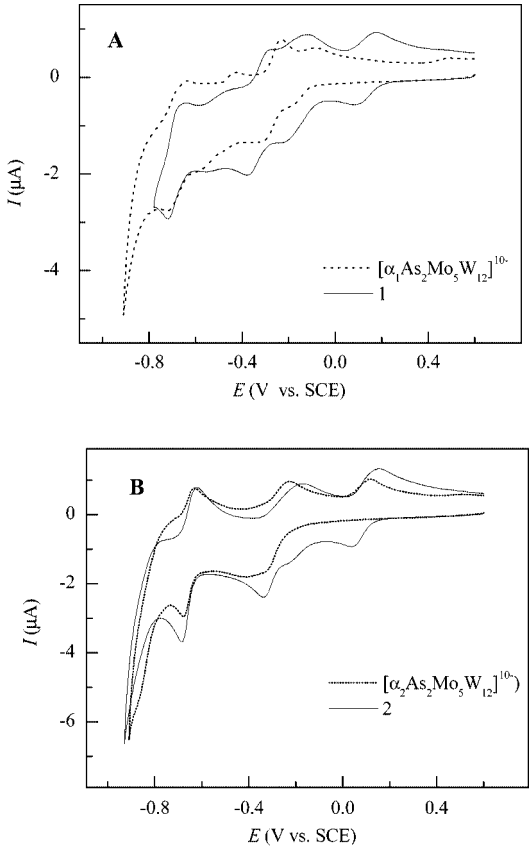

Figure 1. Cyclic voltammograms of 0.2 mM solutions of (**A**) **1** and $[\alpha_1\text{-}As_2Mo_5W_{12}O_{61}]^{10-}$ and (**B**) **2** and $[\alpha_2\text{-}As_2Mo_5W_{12}O_{61}]^{10-}$ in a 1 M CH_3COOLi/CH_3COOH (pH = 5) buffer solution. The working electrode was glassy carbon, the reference electrode was SCE, and the scan rate was 10 mV·s^{-1}.

Conclusions

Molybdenum-rich polytungstates are of proven value in electrocatalysis. However, the preparation of isomerically pure complexes is challenging, in part, due to the high lability of the Mo^{VI} centers. Isomerically pure preparations of $[\alpha_1\text{-}As_2(FeOH_2)Mo_5W_{12}O_{61}]^{7-}$ (**1**) and $[\alpha_2\text{-}As_2(FeOH_2)Mo_5W_{12}O_{61}]^{7-}$ (**2**) were achieved by the reaction of Fe^{III} with the lacunary precursors, $[\alpha_1\text{-}As_2Mo_5W_{12}O_{61}]^{10-}$ and $[\alpha_2\text{-}As_2Mo_5W_{12}O_{61}]^{10-}$, respectively. Both of these species are structurally derived from $[\alpha\text{-}As_2Mo_6W_{12}O_{62}]^{6-}$ (**3**), which is now characterized by X-ray crystallography. The results show that positions 1, 4, 9, 10, 15, and 16 in Scheme 2 are 50% MoO_6 and 50% WO_6. Electrochemical studies reveal that complexes **1** and **2** (and their lacunary precursors) are all clearly distinguishable by cyclic voltammetry.

Experimental Section

General Methods and Materials: $K_6[\alpha\text{-}As_2Mo_6W_{12}O_{62}]\cdot 12H_2O$ and $K_{12}H_2[\alpha\text{-}As_2W_{12}O_{48}]\cdot 23H_2O$ were obtained by published procedures.[17,19,23] Elemental analyses were performed by Kanti Labs (Mississauga, Ontario), and the analysis of W was confirmed by a modified literature method.[24] The water content of the samples was determined by standard methods. Infrared spectra (2% sample in KBr) were recorded with a Perkin–Elmer Spectrum One FT-IR spectrometer. NMR spectra were recorded with a Bruker 400 instrument operating at 16.67 MHz. The ^{183}W chemical shifts were measured with respect to an external 2 M Na_2WO_4 solution in alkaline D_2O.

Synthesis of $K_9Li[\alpha_1\text{-}As_2Mo_5W_{12}O_{61}]\cdot 28H_2O$: A sample of pure α-$K_{12}H_2[As_2W_{12}O_{48}]\cdot 23H_2O$ (12 g; 3 mmol) was dissolved in a solution containing 150 mL of 1 M LiCl and 50 mL of 0.5 M CH_3COOLi (pH ≈ 4.7). This relatively cloudy solution was treated with 15 mL of 1 M $LiMoO_4$ (15 mmol) and 30 mL of 1 M HCl to keep the pH constant (≈ 4.7). The resulting clear, very faintly yellow solution was treated with 60 mL of a saturated KCl solution. The off-white precipitate was filtered (by suction filtration), washed twice with ethyl alcohol and twice with ethyl ether, and dried in air. The amount of pure compound obtained was 13.50 g (yield 96.5% relative to the starting material, α-$K_{12}H_2[As_2W_{12}O_{48}]\cdot 23H_2O$). $K_9Li[\alpha_1\text{-}As_2Mo_5W_{12}O_{61}]\cdot 28H_2O$ (4675): calcd. As 3.19, K 7.45, Mo 9.76, W 46.9; found As 3.21, K 7.52, Mo 10.26, W 47.2. IR (cm^{-1}): $\tilde{\nu}$ = 943.3 (s), 855.3 (w), 823.3 (w), 782.8 (vw), 743.1 (w), 513.7 (vw), 497.9 (w), 419.5 (vw).

Synthesis of $K_{10}[\alpha_2\text{-}As_2Mo_5W_{12}O_{61}]\cdot 21H_2O$: A sample of pure α-$K_6[As_2Mo_6W_{12}O_{62}]\cdot 12H_2O$ (10 g; 2.3 mmol) was dissolved in

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

25 mL of de-ionized water. A 22 mL aliquot of 1 M $KHCO_3$ (22 mL; 22 mmol) was then added to the clear solution. A yellow precipitate formed progressively and was left to settle for ca. 45 min, after which it was filtered, washed twice successively with ethyl alcohol and ethyl ether, and dried in air. The amount of pure compound was 10.00 g (yield 94.9% relative to the starting material, α-$K_6[As_2Mo_6W_{12}O_{62}]\cdot 12H_2O$). $K_{10}[\alpha_2\text{-}As_2Mo_5W_{12}O_{61}]\cdot 21H_2O$ (4581): calcd: As 3.31; K 8.61; Mo 10.7, W 48.3; found As 3.27, K 8.54, Mo 10.47, W 48.2. IR (cm^{-1}): $\tilde{\nu}$ = 938.6 (s), 862.5 (s), 818.8 (m), 784.1 (m), 711.0 (s), 519.6 (w), 498.7 (w), 419.1 (w).

Synthesis of $K_7[\alpha_1\text{-}As_2(FeOH_2)Mo_5W_{12}O_{61}]\cdot 22H_2O$: A sample of $Fe(NO_3)_3\cdot 9H_2O$ (0.30 g; 0.75 mmol) was dissolved in 40 mL of deionized water. Then, solid $K_9Li[\alpha_1\text{-}As_2Mo_5W_{12}O_{61}]\cdot 28H_2O$ (3.0 g; 0.64 mmol) was added in small portions. The mixture was heated very gently on a water bath (≈ 50 °C) to enhance solubility. After ca. 20 min, the pale yellow solution was filtered and treated with 5 g of solid KCl. The yellow precipitate that formed was filtered off, washed successively (twice with a saturated KCl solution and twice with ethyl alcohol), and dried in air. The amount of pure compound obtained was 1.70 g (yield 58.2% relative to the starting material, $K_9Li[\alpha_1\text{-}As_2Mo_5W_{12}O_{61}]\cdot 28H_2O$). $K_7[\alpha_1\text{-}As_2(FeOH_2)Mo_5W_{12}O_{61}]\cdot 22H_2O$ (4538): calcd. As 3.26, Fe, 1.25, K 6.12, Mo 10.6, W 48.5, found As 3.29, Fe 1.22, K 6.01, Mo 10.53, W 48.4. IR (cm^{-1}): $\tilde{\nu}$ = 957.0 (s), 882.9 (w), 854.7 (w), 823.3 (w), 762.9 (s), 520.6 (w), 495.7 (w), 420.1 (m).

Synthesis of $K_7[\alpha_2\text{-}As_2(FeOH_2)Mo_5W_{12}O_{61}]\cdot 19H_2O$: A sample of $Fe(NO_3)_3\cdot 9H_2O$ (0.30 g; 0.75 mmol) was dissolved in 40 mL of deionized water. Then, solid $K_{10}[\alpha_2\text{-}As_2Mo_5W_{12}O_{61}]\cdot 21H_2O$ (3.0 g; 0.65 mmol) was added in small portions. The mixture was heated gently on a water bath (≈ 65 °C) to enhance solubility. After ca. 20 min, the pale yellow solution was filtered and treated with 5 g of solid KCl. The yellow precipitate that formed was filtered off, washed successively (twice with a saturated KCl solution and twice with ethyl alcohol), and dried in air. The amount of pure compound obtained was 2.60 g (yield 89.3% relative to the starting material, $K_{10}[\alpha_2\text{-}As_2Mo_5W_{12}O_{61}]\cdot 21H_2O$). $K_7[\alpha_2\text{-}As_2(FeOH_2)Mo_5W_{12}O_{61}]\cdot 19H_2O$ (4484): calcd. K 6.19, As 3.37, Fe 1.32, Mo 10.9, W 50.3, found As 3.37, Fe 1.25; K 6.15, Mo 10.79, W 49.6. IR (cm^{-1}): $\tilde{\nu}$ = 954.1 (s), 882.8 (w), 854.5 (vw), 823.3 (vw), 763.1 (s), 655.3 (w), 522.6 (m), 490.9 (m), 421.7 (s).

Crystallographic Studies of $K_2Na_4[\alpha\text{-}As_2Mo_6W_{12}O_{62}]_{0.5}[\alpha\text{-}As_2W_{18}O_{62}]_{0.5}\cdot 11H_2O$: Single-crystal X-ray crystallographic analysis of $[\alpha\text{-}As_2Mo_6W_{12}O_{62}]^{6-}$ was performed at 173 K with a Bruker D8 SMART APEX CCD sealed tube diffractometer with graphite-monochromated Mo-K_α (0.71073 Å) radiation. Data collection, indexing, and initial cell refinements were performed using SMART software.[25] Frame integration and final cell refinements were performed using SAINT software.[26] Final cell parameters were determined from least-squares refinement on 9709 reflections. Absorption corrections were applied using SADABS.[27] The structure was determined using Direct Methods and difference Fourier techniques. No H atoms associated with the eleven water molecules of $[\alpha\text{-}As_2Mo_6W_{12}O_{62}]^{6-}$ were located in the difference Fourier maps. The final R_1 scattering factor and the anomalous dispersion correction were taken from International Tables for X-ray Crystallography.[28] Structure solution, refinement, and generation of publication materials were performed using SHELXTL V6.12 software. Additional details are provided in Table 2, and may also be obtained from the Fachinformationszentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany; Fax: +49-7247-808-666, E-mail: crysdata@fiz-karlsruhe.de, on quoting the depository number CSD-414645. Elemental analyses (As, K, Mo, Na and W) on the crystals were performed by Desert Analytics (Tucson, Arizona). $K_2Na_4[\alpha\text{-}As_2Mo_6W_{12}O_{62}]_{0.5}[\alpha\text{-}As_2W_{18}O_{62}]_{0.5}\cdot 11H_2O$ (4556): calcd. As 3.29, K 1.72, Mo 6.32, Na 2.02, OH_2 4.3, W 60.5, found As 3.27, K 1.69, Mo 6.34, Na 2.10, OH_2 4.3, W 59.8.

Table 2. Crystallographic data and structure refinement for $K_2Na_4[\alpha\text{-}As_2Mo_6W_{12}O_{62}]_{0.5}[\alpha\text{-}As_2W_{18}O_{62}]_{0.5}\cdot 11H_2O$.

Electrochemical Studies: Cyclic voltammetry studies were performed in a pH 5 acetate (1.0 M CH_3COOLi/CH_3COOH) medium. Solutions were de-aerated with Ar for at least 30 min prior to measurements and kept under positive pressure at all times. The source, mounting, and polishing of the glassy carbon electrodes (GC, Tokai, Japan, 3 mm diameter) have been described in previous work.[21] The electrochemical apparatus was a EG and G 273A under computer control (M270 software). The counter electrode was a platinum gauze of large surface area. All experiments were performed at ambient temperature, and potentials are quoted against a saturated calomel electrode (SCE).

[20] a) The same substitution pattern was reported for the structure of $[\alpha\text{-}P_2(NbO_2)_6W_{12}O_{56}]^{12-}$ (see ref. [7c]); b) Six of the 18 metal sites were initially assigned and refined as 100% W, but the thermal parameters were too low to support this assignment. Given the fact that elemental analyses suggested that the ratio of Mo to W in the crystals was 3 to 15, the occupancy of the six sites was set at 50% Mo and 50% W. This change resulted in normal thermal parameters for the six metal sites (i. e. positions 1, 4, 9, 10, 15, and 16 in Scheme 2). The remaining 12 metal sites refined as 100% W with normal thermal parameters. Furthermore, the presence of 50% $[\alpha\text{-}As_2Mo_6W_{12}O_{62}]^{6-}$ and 50% $[\alpha\text{-}As_2W_{18}O_{62}]^{6-}$ in these crystalline samples was confirmed by cyclic voltammetry.

Co-Adsorption of Copper(II) and 3-Amino-1,2,4-triazole at a Water–Natural Macromolecular Compound Interface: Molecular Structure from Adsorption Isotherms Combined with X-ray Absorption Measurements

Karine Flogeac,[a] Emmanuel Guillon,*[a] and Michel Aplincourt[a]

Keywords: Adsorption / Environmental chemistry / Pesticides / Structure elucidation / Surface chemistry / X-ray absorption spectroscopy

The co-adsorption of Cu^{II} and amitrole at a water–natural macromolecular compound interface was studied by means of batch adsorption experiments, Fourier transform infrared, and X-ray absorption spectroscopy. The binary systems, aqueous amitrole–Cu^{II} complex, and amitrole and Cu^{II} adsorbed on the surface of the solid were studied. The ternary system was investigated over the pH range 2–10 and at varying metal concentrations. The combination of macroscopic and molecular information shows that Cu^{II} and amitrole interact directly at the water–solid interface to form ternary surface complexes. A two-step mechanism is proposed whereby initial formation of a Cu^{II}–amitrole aqueous complex is followed by the sorption of this complex onto the surface. The structure of the ternary complex was elucidated. Copper(II) is bound to the surface in an inner-sphere mode, while two amitrole ligands simultaneously bonded in a monodentate fashion to Cu^{II} to form a six-membered coordination sphere around the metal cation. The copper coordination sphere is completed by two water molecules. This structure and the mechanism proposed are supported by a combination of potentiometric data, IR and UV/visible spectroscopies and XAS measurements.

Introduction

The monitoring and control of pollutants in the aquatic environment is becoming of increasing concern. Detailed investigations of the interactions between both naturally occurring and anthropogenic species found in the environment have provided information regarding their chemical structure and speciation, and thus the transport, bio-availability and potential toxicity of pollutants.[1–3] In order to fully understand the chemical processes that occur in groundwater, soils and surface waters, it is important to study the role of the solid–water interface as well as the interactions in the aqueous phase. With this aim in mind, this paper investigates ternary surface complexes formed during the adsorption of copper(II) and an organic ligand, 3-amino-1,2,4-triazole (amitrole), onto soil organic matter (SOM). Indeed, there is a lack of mechanistic molecular-level understanding due to the limited knowledge of the speciation and the reactivity of amitrole at the solid–water interface. In this respect, fundamental studies of a simplified model system play an important role since they can provide detailed information about the composition, structure and reactivity of amitrole surface species formed. This information then forms the basis of molecular-level interpretations of observations made on real soils.

It is now widely accepted that SOM, and notably lignin materials, plays a key role in the regulation of metal ions and other pollutants in the environment.[4–7] Lignin is a natural polymer that is produced biologically by random polymerisation processes, which make its study complicated.[8] It is a cross-linked, phenolic polymer built from three basic phenyl propane monomers (*p*-hydroxycinnamyl, coniferyl, and sinapyl alcohols), which are responsible for its chemical heterogeneity. Thus, the solid studied as a model for SOM is a lignocellulosic substrate (LS) extracted from wheat straw by acid/base treatments.

Amitrole is a herbicide that is widely used all over the world. It is used as a systematic herbicide for total weed control in vineyards, orchards, forests, non-crop areas and in aquatic environments such as marshes and drainage ditches.[9] Amitrole is quickly absorbed through the leaves and then migrates into plant tissues to inhibit several biochemical pathways. Moreover, it is often associated with other well-known herbicides such as glyphosate or paraquat. Several studies have been devoted to the adsorption of amitrole in soils but they were essentially focused on quantitative aspects.[10–15] The primary objective of this work is to identify the molecular mechanism(s) of Cu^{II}–amitrole coadsorption on LS. We present new data for the ternary Cu^{II}/amitrole/LS system. Conclusions are drawn based on a comparison of new XAS spectroscopic data and quantita-

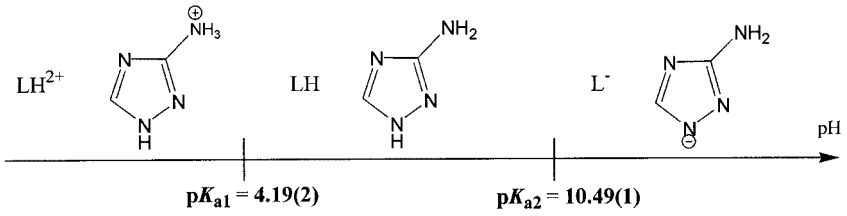

Scheme 1. Different steps of amitrole (LH) deprotonation and their corresponding acidity constants.

tive adsorption data for the three binary systems: aqueous amitrole–Cu^{II}, amitrole–LS and Cu^{II}–LS. We will emphasise how the adsorption characteristics and surface speciation of amitrole are affected by the presence of Cu^{II}, and vice versa. This is the first time that spectroscopic results have been presented for this ternary system, and they allow a good understanding of the molecular mechanism of amitrole retention by SOM in the presence of Cu^{II}.

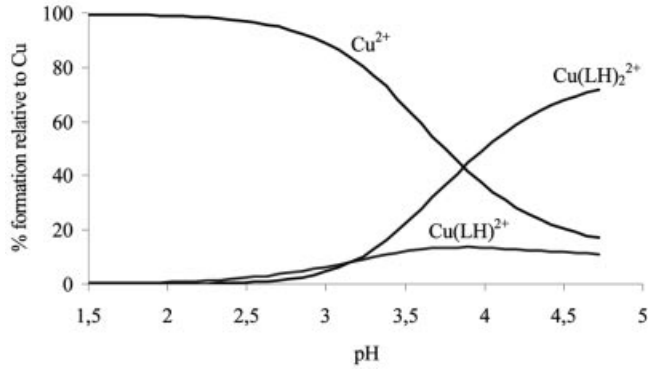

Figure 1. Distribution curves. $C_L = 1.2 \times 10^{-2}$ mol L^{-1}, $C_M = 2.4 \times 10^{-3}$ mol L^{-1}.

Results and Discussion

Binary Systems

The deprotonation reactions of amitrole were studied in KNO_3 (0.1 mol L^{-1}) in the pH range 2–12. The two acidity constants and the deprotonation steps of amitrole are reported in Scheme 1. The constant pK_{a1} corresponds to the deprotonation of the exocyclic nitrogen atom and the constant pK_{a2} to the deprotonation of the endocyclic nitrogen atom. These values are close to the ones obtained by Pichon and Hennion,[16] and Boraei and Mohamed[17] under similar conditions.

The first binary system, Cu^{II}–amitrole, was then studied in aqueous solution by titration with 0.1 mol L^{-1} KOH (ionic strength = 0.1 mol L^{-1}) at variable C_L/C_{Cu} ratios (total ligand to total copper concentration; R). The ligand concentration, C_L, was kept constant (1.2×10^{-2} mol L^{-1}) and the ratio R ranged from 1.08 to 5. The experimental data are shown as distribution curves in Figure 1. It is obvious from this figure that Cu^{II} complexation becomes significant at pH values above 2.5. As formation constant calculations can only be made in a homogeneous medium, the precipitation of a mixed hydroxo-amitrole copper complex since around pH 5 prevents any calculations above this value. Unfortunately, this precipitated complex could not be obtained as a pure compound, but the presence of amitrole was identified by IR spectroscopy. Calculations showed that the best fit between the calculated curves and the experimental data (volume of KOH added, pH) was obtained with two successive complexes having the compositions $Cu(LH)^{2+}$ and $Cu(LH)_2^{2+}$. The logarithmic values of the overall formation constants (log β_n) for these two species are equal to 12.5 and 26.0, respectively. The overall constants $\beta_n = [Cu(LH)_n^{2+}]/[Cu^{2+}][L^-]^n[H^+]^n$ correspond to the general equilibrium $Cu^{2+} + nH^+ + nL^- \rightleftharpoons Cu(LH)_n^{2+}$.

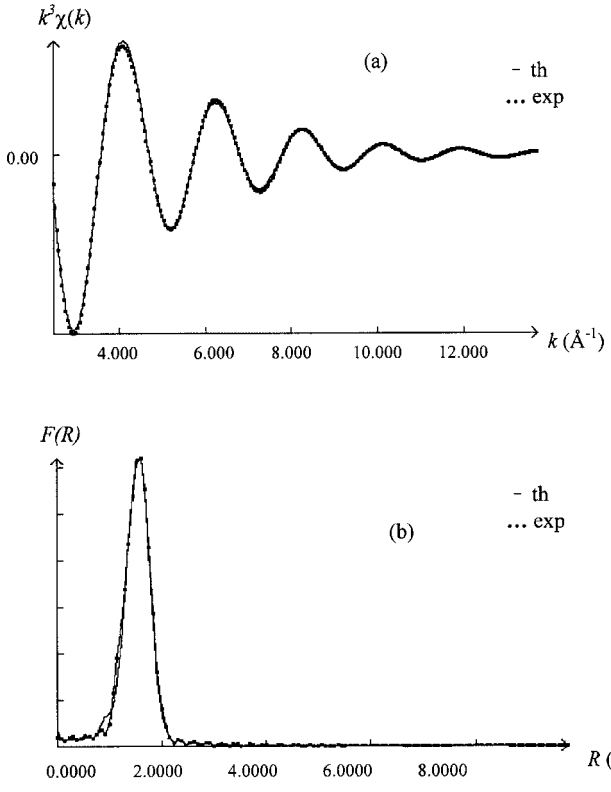

Figure 2. (a) Experimental and fitted first shell (0.96–2.10 Å^{-1}) EXAFS k space spectra of Cu-amitrole solution complex. (b) Fourier transform of the EXAFS signal [$k^3\chi(k)$] at the copper K edge.

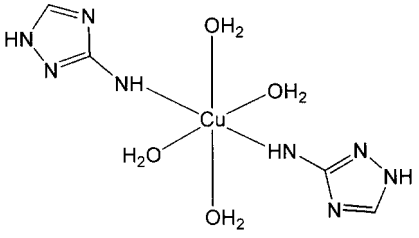
The overall stability constants combined with acidity constants lead to the successive complexation constants K_n, which correspond to the equilibrium $Cu^{2+} + n$LH $\rightleftharpoons$ $Cu(LH)_n^{2+}$.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The logarithmic values of the constants K_n are equal to 2.0 (n = 1) and 3.0 (n = 2). The unexpected variation of these constants ($\log K_1 < \log K_2$) is probably due to a geometric change of the complex or to the Jahn–Teller effect.

In order to obtain structural information about the copper–amitrole complex in solution, UV/visible spectroscopy and XAS experiments were carried out. In the visible region, the absorption spectrum exhibits a broad non-symmetric band centred around 15335 cm^{-1} characteristic of a tetragonal elongated octahedral environment around copper(II) with a CuN_2O_4 chromophore.[18] The structure of the complex in solution was also studied by EXAFS spectroscopy. The first shell was best fit with four oxygen/nitrogen atoms (Figure 2) at an average distance of 2.04 Å from the absorbing copper atom. These four atoms are most likely positioned in the equatorial plane of a Jahn–Teller-distorted, elongated octahedron, similar to the arrangement described for $Cu(OH)_2$.[19] The two axial oxygens of the octahedron are more distant from the copper atom and form weaker bonds, giving rise to higher thermal disorder. These atoms are therefore not expected to contribute significantly to the EXAFS signal. Attempts to fit oxygen at axial positions indeed resulted in high Debye–Waller factors for these atoms (>0.015), and there was no improvement in the fit, compared to including only equatorial oxygen/nitrogen atoms. These EXAFS results combined with those obtained by UV/visible spectroscopy clearly show that the copper in the $Cu(LH)_2^{2+}$ complex is surrounded in the equatorial plane by two nitrogen atoms from amitrole and two water oxygen atoms. The axial position is occupied by two other water molecules. This structure is represented in Scheme 2.



Scheme 2. Molecular structure of $Cu(LH)_2^{2+}$ in solution.

In a second step, we studied the amitrole sorption onto LS as a function of pH. Surprisingly, amitrole was not retained by LS in the pH range 2–12 (Figure 3). This result is unexpected since analogous pesticides are well known to bond to the SOM surface through electrostatic bonds.[20–22] This means that amitrole in a soil with a high content of organic matter such as lignin will be leached towards the surface- and groundwater.

The last binary system is the Cu^{II}–LS system. Copper retention on the solid has been studied previously and the results published in terms of quantitative data[23] and a molecular approach.[24] Briefly, copper is quantitatively sorbed (4.2 mg g^{-1}) at the LS surface. It is surrounded by four oxygen atoms at 1.93 Å and two other ones at 2.41 Å, which corresponds to a tetragonal-distorted octahedral geometry.

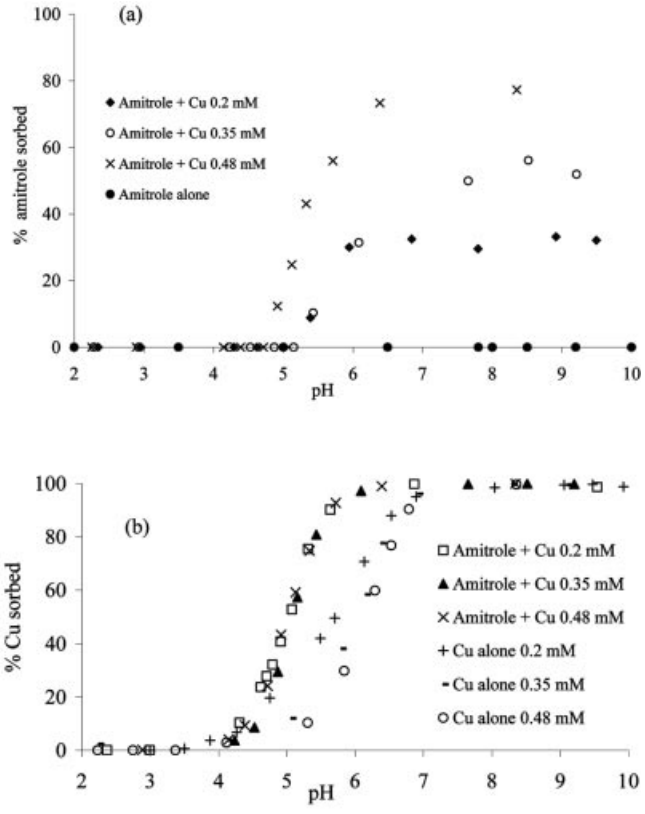


Figure 3. Adsorption of amitrole and Cu^{II} on the LS surface as a function of pH. $C_{amitrole}$ = 0.5 mmol L^{-1}.

Ternary System

The ternary system involving LS, Cu^{II} and amitrole was then studied by means of batch adsorption experiments combined with spectroscopic studies to obtain molecular-level information with the aim of understanding the coadsorption process. Figure 3 shows the adsorption of amitrole, Cu^{II} and both amitrole and Cu^{II} as functions of pH at three different total concentrations of Cu^{II}. The amount of amitrole adsorbed in the presence of Cu^{II} increases proportionally with the introduced copper concentration (Figure 3a). At the same time, all the copper added (three different concentrations) is adsorbed even in the presence of amitrole (Figure 3b). Indeed, in the presence or absence of amitrole, 100% of the copper introduced is sorbed above pH 7. This is in accordance with a mechanism of formation of a ternary complex in two steps: formation of the copper–amitrole complex $Cu(LH)_2^{2+}$ in solution followed by the sorption of this complex onto the LS surface, which leads to the Cu^{II}–amitrole–LS ternary complex, since amitrole alone is not adsorbed onto the LS surface. Moreover, as expected for the three copper concentrations studied, the amount of ligand, copper and copper–amitrole complex adsorbed increases with increasing pH. This enhancement is characteristic of the sorption of a cationic species [$Cu(LH)_2^{2+}$] on a surface, which confirms the mechanism previously proposed for the retention of amitrole in the presence of copper through ternary surface complex formation.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

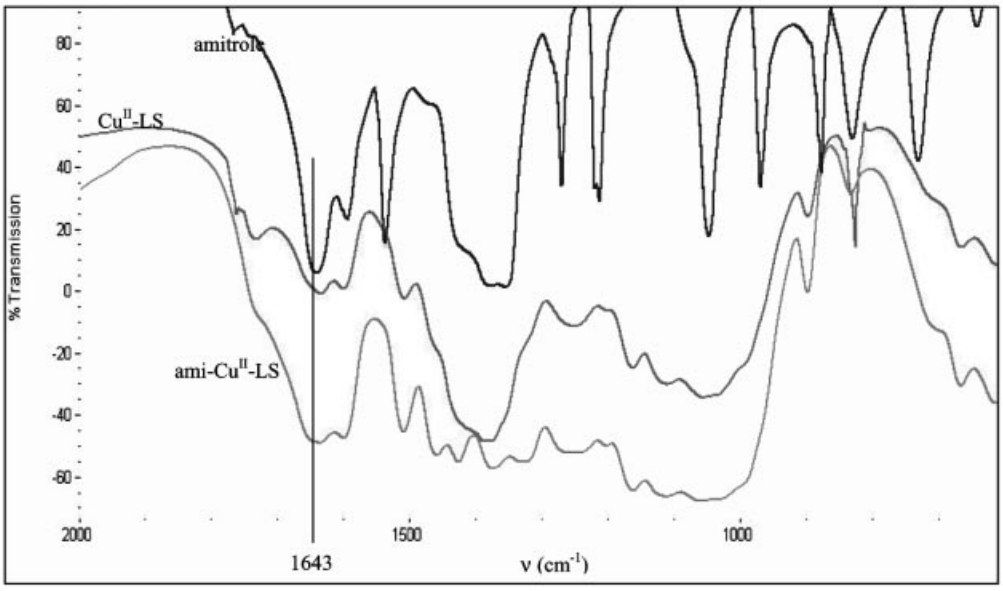

Figure 4. IR spectra of amitrole alone and the Cu^{II}-LS and ami-Cu^{II}-LS systems.

Moreover, the formation of 1:1 [Cu(LH)$^{2+}$] metal/ligand surface complexes cannot be ruled out, since the distribution curves (Figure 1) show the presence of 10% of the Cu(LH)$^{2+}$ species around pH 4–5.

The latter was confirmed by spectroscopic studies, from which structural information were obtained. The IR spectrum of amitrole shows several characteristic absorption bands, in particular the band at 1643 cm^{-1}, which corresponds to the C–N stretching band of the C–NH$_2$ exocyclic group, and the one at 1537 cm^{-1} corresponding to the conjugated ring C=N stretching vibration.[15] The IR spectrum of the Cu^{II}–amitrole–LS sample shows the disappearance of the latter, probably due to the low amitrole concentration on LS. The formation of a ternary complex was confirmed by the presence of a supplementary very weak band characteristic of amitrole at 1643 cm^{-1}, as compared to the Cu^{II}–LS spectra (Figure 4).

XAS experiments were carried out in order to obtain structural information about the ternary surface complex. The *K*-edge XANES spectrum and its first derivative are shown in Figure 5. They are typical of copper(II) complexes with a very weak 1s→3d transition pre-edge feature centred around 8978 eV, which is facilitated by p-d mixing,[25] and an absorption edge centred around 8996 eV. The most important feature of the spectrum at the copper edge is that the low-energy side of the edge exhibits the characteristic shoulder of copper(II) in an elongated tetragonal surrounding.[26] In Figure 5b, in addition to the very weak pre-edge peak, there is a splitting of peaks α and β in the first derivative Cu XANES spectrum. This first derivative can reveal detailed information that is not obvious in this XANES spectrum. The peak α corresponds to the 1s→4p$_{x,y}$ transitions. The second main peak (β) represents the main absorption transition (1s→continuum). The energy gap between the α and β peaks is equal to 6.2 eV. This value gives an estimate of the destabilization of the 4p$_z$ metal orbital (z being the elongation axis). Indeed, it has been suggested that in elongated tetragonal copper(II) complexes, the further the apical site from the metal ion the more displaced this shoulder is towards low energies.[27] The average axial distance around the copper atom was estimated at approximately 2.4 Å by comparison with reference compounds.[24]

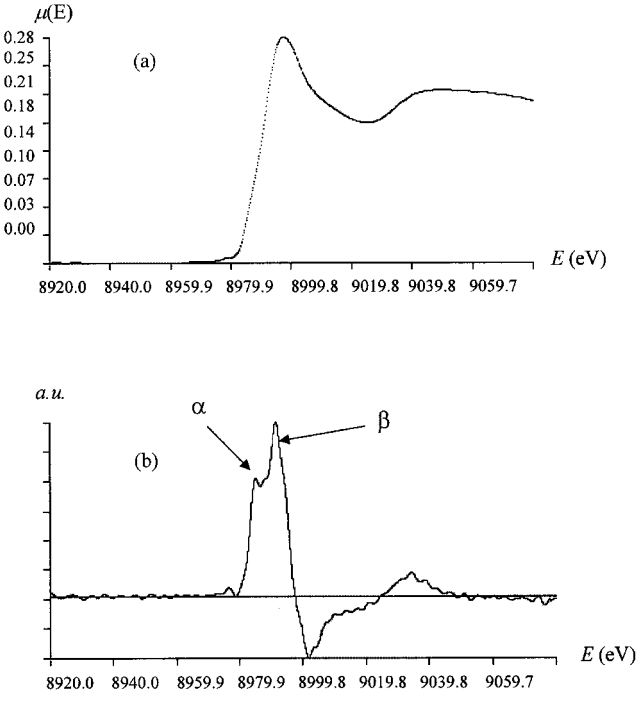

Figure 5. Cu *K*-edge XANES spectrum of the Cu-amitrole-LS ternary complex (a), and its first derivative (b).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The experimental data and the fitted functions of the ternary system first shell are shown in k space as well as by Fourier transformations in real space in Figure 6. In agreement with the previous results, we found four copper–oxygen/nitrogen average distances of 2.01 Å (σ = 0.001 Å^2) from the adsorbing copper atom. Attempts were made to determine also the two longer axial distances, and two Cu–OH_2 distances equal to 2.36 Å (σ = 0.008 Å^2) were found. These data are consistent with those obtained from the XANES spectrum, i.e. a tetragonally distorted octahedral coordination around copper(II), according to the Jahn–Teller effect. The weak scattering contribution from low-Z elements beyond the first shell to the EXAFS, seen as minor Fourier peaks, prevents a more detailed analysis. However, a structure for the ternary surface complex can be proposed (Scheme 3). In Figure 7, for comparison, the k^3-weighted EXAFS spectra and Fourier transforms are reported for Cu^{II} adsorbed together with amitrole on LS, the $Cu(LH)_2^{2+}$ aqueous complex, and Cu^{II} adsorbed onto LS. Even the EXAFS spectra seem identical, although a faint difference can be observed on the first beating of the sinusoid around 4 Å^{-1}, which is also observed for the Cu^{II}–O/N distances. Indeed, the Cu–O/N distance in the Cu-LS surface complex is equal to 1.93 Å,[24] that in the $Cu(LH)_2^{2+}$ aqueous complex to 2.04 Å, and that in the ternary complex to 2.01 Å. The intermediate value obtained for the ternary complex leads to the proposed structure in which two copper–amitrole and two copper–LS bonds are in the equatorial plan, and two water molecules are in the axial positions. This also rules out a surface precipitation of a mixed hydroxo-amitrole copper complex (see solution chemical study). Moreover, the Fourier transform of the ternary surface complex corresponds to the weighted sum of the Fourier transforms of $Cu(LH)_2^{2+}$ and Cu-LS complexes (Figure 7).

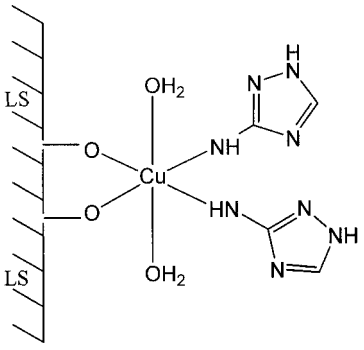

Scheme 3. Proposed structure of the ternary Cu^{II}–amitrole–LS surface complex.

Conclusions

By simultaneously using quantitative and spectroscopic methods we have shown that Cu^{II} and amitrole form ternary complexes on soil organic matter. The retention of amitrole is only possible in the presence of copper. A lack of copper leads to the leaching of the pesticide to surface- and/or groundwater. Potentiometric titrations have underlined the existence of a predominating complex, $Cu(LH)_2$, which was confirmed by IR spectroscopy. Adsorption isotherms and XAS data indicate a molecular structure where copper(II) bonds to the surface in an inner-sphere mode. According to solution studies combined with adsorption and XAS experiments, we have proposed a possible structure for the ternary complex. Two amitrole ligands are probably monodentately bound to Cu^{II} and the copper coordination sphere is completed by two water molecules to form a six-membered coordination sphere around the metal cation (Scheme 3). Finally, it is now obvious that metal ions have a significant influence on the molecular surface speciation of amitrole. The new structure identified is potentially important for elucidating the bio-availability and mechanisms of amitrole degradation in soils. The results obtained in this study are currently being used with modelling software to establish predictive systems for the retention of pesticides in soils in the presence of metallic cations.

Experimental Section

Reagents: All solvents and chemicals from commercial sources were of the highest available purity and were used without further purification. The metal-ion stock solutions were prepared from copper(II) nitrate reagents (Fluka) of the highest purity (>99%). The concentration was determined by EDTA titration {with PAN [1-(2-pyridyl-azo)-2-naphthol] as indicator}. The LS was extracted from

wheat straw by two successive acid-base treatments,[24] and was fully characterized.[28]

Protometric: Potentiometric titrations were carried out as described previously.[29] Briefly, they were performed with a Metrohm 665 Dosimat and a Metrohm 654 pH-meter. The combined glass electrode was standardized with nitric acid (10^{-2} mol L^{-1}; pH 2.00). All measurements were performed at 20 °C under a nitrogen stream. The curves obtained were fitted with the refining program PROTAF[30] in order to obtain the overall stability constants. The ionic product of water, pK_w, was determined to be 13.78. The concentration of copper(II) varied from 1.09×10^{-2} to 0.24×10^{-2} mol L^{-1}, the concentration of the ligand from 8×10^{-3} to 2×10^{-2} mol L^{-1} and the ratio C_L/C_M from 1.08 to 5. The ionic strength was kept constant (0.1 mol L^{-1}) by addition of potassium nitrate.

Sorption Experiments: Adsorption experiments were conducted as a function of pH using batch experiments at room temperature (293 K). The LS (2 g L^{-1}) was immersed in 15 mL of background electrolyte (0.1 mol L^{-1} KNO_3) solution and stirred with a magnetic stir bar for 24 h, which corresponds to the hydration time of the solid. After this pre-equilibration step, the amitrole (5×10^{-4} mol L^{-1}) was added simultaneously with copper (2×10^{-4}, 3.5×10^{-4} and 4.8×10^{-4} mol L^{-1}), and the pH was incrementally adjusted to a fixed value by dropwise addition of 0.1 mol L^{-1} HNO_3 or 0.1 mol L^{-1} KOH. The final volume was adjusted to 25 mL. The sorption equilibrium (12 h) was predetermined by kinetic experiments in which different contact times from 10 min to 48 h between the sorbents and the solid were applied. When two successive curves were superimposed, the equilibrium time was considered to have been reached. The flasks were then shaken at 293 K for 12 h with an automatic shaker to ensure complete sorption. The experimental pH was taken to be the pH measured after a 12 h reaction time. After filtration through a 0.20 μm polyamide membrane, the supernatants were separated into two fractions. In the first fraction, the solution was acidified and the unsorbed metal-ion concentration was measured with a Varian ICP-AES spectrometer. The amount of copper sorbed was deduced from the initial concentration. The amount of amitrole was determined from the second fraction using the spectrophotometric method described by Sund.[10]

The solid studied by spectroscopic techniques was prepared at pH 5.7 with a copper concentration equal to 2×10^{-4} mol L^{-1} and an amitrole concentration of 5×10^{-4} mol L^{-1}. This pH value was chosen in order to have a maximum copper amount adsorbed and to prevent copper hydroxide precipitation (pH 6.8).

Spectroscopy: The electronic spectra in aqueous solutions were recorded in a 1.00-cm quartz cell with a Perkin–Elmer Lamba-6 UV/Visible spectrophotometer. IR spectra were obtained in pellets with a Nicolet Avatar 320 spectrophotometer.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

EXAFS and XANES Data: The XAS experiments were performed on the XAS 4 beamline of the storage ring DCI (positron energy 1.85 GeV; mean current 300 mA) at LURE (Laboratoire d'Utilisation du Rayonnement Electromagnétique, Paris-Sud University). Data were recorded at the Cu *K* edge (8979 eV) using a channel-cut monochromator Si(111) for EXAFS and Si(311) for XANES. The solids and the aqueous copper(II) solutions were measured at room temperature in the transmission mode with two air-filled ionisation chambers. Internal calibration was made with a copper metal foil and fixed at 8979 eV for the first inflection point. Four scans were summed for the samples. The XANES spectra were recorded step-by-step, every 0.3 eV, with a 2 s accumulation time per point. The spectrum of the 5 μm metallic foil was recorded just before the unknown XANES spectrum to check the energy calibration, thus ensuring an energy accuracy of 0.25 eV. The EXAFS spectra were recorded over 1000 eV, with 2 eV steps, from 8900 to 9900 eV. Data analysis was performed by means of the "EXAFS pour le Mac" package.[31] The $\chi(k)$ functions were extracted from the data with a linear pre-edge background, a combination of polynomials and spline atomic-absorption background, and normalised using the Lengeler–Eisenberg method.[32] The energy threshold, E_0, was taken at the middle of the absorption edge and was corrected for each spectrum in the fitting procedure. The k^3 weighted $\chi(k)$ function was Fourier transformed from k = 2–14 Å^{-1}, by means of a Kaiser–Bessel window with a smoothness parameter equal to 3 (k is the photoelectron wave number). In this work, all Fourier transforms were calculated and presented without phase correction. The peaks corresponding to the first coordination shell were then isolated and back-Fourier transformed into k space to determine the mean coordination number, N, the bond length, R, and the Debye–Waller factor, σ. The resulting EXAFS functions were curve-fitted by calculated model functions using ab initio calculated EXAFS phase $|\varphi_i(k,R_i)|$ and amplitude $|f_i(k,R_i)|$ parameters from FEFF7 code.[33] The errors in the first shell bond lengths (R) were estimated to be ±0.02 Å and coordination numbers (N) were accurate to ±20%.

Acknowledgments

We are grateful to the "Région Champagne-Ardenne" for a grant to K.F. The authors also wish to acknowledge S. Belin (Université Paris Sud, LURE, France) for her help in recording EXAFS and XANES data.

Crystal Structure and Magnetism of the Double Perovskite $Sr_3Fe_2MoO_9$: A Neutron Diffraction Study

María C. Viola,[a] José A. Alonso,*[b] José C. Pedregosa,[a] and Raul E. Carbonio[c]

Keywords: Double perovskite / Neutron diffraction / Antiferromagnetic ordering

The $Sr_3Fe_2MoO_9$ double perovskite has been prepared in polycrystalline form by heat treatment, in air, from previously decomposed citrate precursors. This material has been studied by X-ray (XRD), neutron powder diffraction (NPD) and magnetic measurements. At room temperature, the crystal structure is tetragonal, space group *I*4/*m*, with $a = b = 5.5608(2)$ Å, $c = 7.8471(4)$ Å. It is convenient to write the crystallographic formula as $Sr_2Fe(Fe_{1/3}Mo_{2/3})O_6$, according to the usual nomenclature for double perovskites $A_2B'B''O_6$. The structure contains alternating FeO_6 and $(Fe,Mo)O_6$ octahedra, tilted by 3.9° in the basal *ab* plane. Magnetic measurements indicate a weak ferromagnetic behavior below $T_C = 280$ K. Ideally, the $Sr_3Fe_2MoO_9$ double perovskite only contains Fe^{3+} and Mo^{6+} cations, in such a way that superexchange interactions between neighboring Fe^{3+} spins are the only nominal mechanism accounting for the magnetism of this material. Our main finding is that this intrinsically "disordered" sample, containing a random distribution of Fe and Mo at the B′′ positions, exhibits a strong magnetic scattering on the low-angle Bragg positions, originating from naturally occurring groups of Fe^{3+} cations in which strong antiferromagnetic (AFM) Fe–O–Fe superexchange interactions are promoted, similar to those existing in the $LaFeO_3$ perovskite.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

In the search for new colossal magnetoresistant materials, some members of the family of double perovskites of composition $A_2B'B''O_6$ (A = alkaline earths; B′, B′′ = transition metals) have been proposed as half-metallic ferromagnets (best described as ferrimagnets), with T_C values well above room temperature, as an alternative to perovskite manganites.[1–5] The revival of interest in this family was triggered by a report on Sr_2FeMoO_6,[1] demonstrating that in the electronic structure only minority spins are present at the Fermi level: this material was shown to exhibit intrinsic tunnelling-type magnetoresistance (TMR) at room temperature.

TMR has also been described for double perovskites containing transition metals other than Mo, such as A_2FeReO_6 (A = Ca, Sr, Ba), which present a half-metallic ground state concomitant with the ferrimagnetic coupling of Fe^{3+} and Re^{5+} ($5d^2$, $S = 2/2$) magnetic moments, and show MR at room temperature. Also, Fe can be replaced by Co, as we have recently shown in Sr_2CoMoO_6,[6] where CMR properties were induced upon chemical reduction, by topotactical removal of oxygen atoms. Both examples illustrate the appealing possibility of searching for new CMR materials within the large family of double perovskite oxides.

The family of materials of the type $A_3B'_2B''O_9$ (A = Ca, Sr, Ba; B′ = transition metal and B′′ = Mo, W, Te or U) has recently attracted our attention. These compounds are also double perovskites whose crystallographic formula could be re-written as $A_2B'(B'_{1/3}B''_{2/3})O_6$. They, thus, display an intrinsic partial disordering over half of the perovskite ($B'_{1/3}B''_{2/3}$) positions. We have prepared different materials with A = Ca, Sr; B′ = Fe and B′′ = Mo, W, Te or U and with X-ray diffraction and Mössbauer spectroscopy we have shown that all the compounds are tetragonal and can be refined in the space group *I*4/*m*.[7] This is the same symmetry and space group found for Sr_2FeMoO_6 or Sr_2CoMoO_6. Additionally, an increase in the disorder of B′′ among the Wyckoff sites 2*a* and 2*b* in the sequence Mo < U < Te < W was found. This degree of disorder is observed as an increase in the width of the Mössbauer lines.[7] The sextuplet displayed in the Mössbauer spectra implies a room-temperature magnetic order for B′′ = U, Te and W. For B′′ = Mo two iron sites are observed as two different doublets, indicative of iron occupying the two different positions (2*a* and 2*b*).

These data have now been complemented with microscopic neutron powder diffraction (NPD) data on $Sr_3Fe_2MoO_9$. In this paper we report on the results of a

high-resolution NPD study, giving a detailed description of the crystal structure as well as its thermal evolution down to 2 K. This study also gives insight on the magnetic structure of this material, which shows an intrinsically high magnetic disordering over the B′′ = Fe/Mo positions. Macroscopic magnetic measurements are also reported and discussed. We show that, in spite of small saturation magnetization exhibited by $Sr_3Fe_2MoO_9$, the magnetic neutron scattering is surprisingly strong for such a magnetically disordered sample. We ascribe the observed scattering to Fe-rich regions, where strong Fe–O–Fe superexchange interactions give rise to the antiferromagnetic (AFM) ordering of the neighboring Fe spins.

Results

$Sr_3Fe_2MoO_9$ was obtained as a black, well-crystallized powder. The XRD pattern is characteristic of a perovskite structure, showing the splitting of certain reflections, characteristic of a tetragonal distortion [for instance, (004) and (220) reflections]. Minor amounts of $SrMoO_4$ were detected from either XRD or NPD data.

Magnetic Data

The magnetic susceptibility vs. temperature curves are displayed in Figure 1. Below 280 K the zero-field-cooled (ZFC) and field-cooled (FC) curves exhibit a distinct evolution. The FC curve shows a progressive increment of the susceptibility as temperature decreases, reminiscent of the spontaneous evolution characteristic of a ferromagnet, although a very small saturation magnetization is reached at low temperatures, of only 0.004 μ_B/f.u. with a measuring field of H = 1000 Oe. The ZFC curve shows a less pronounced susceptibility increment as temperature decreases, and exhibits a broad maximum increment centered at 60 K, suggesting the establishment of a long-range AFM ordering below this temperature. The magnetization vs. magnetic field curves at 2, 100, and 300 K are plotted in Figure 2. Even at the lowest temperature, the magnetization is very far from saturation for the maximum applied field of H = 3 T, reaching a maximum value of 0.15 μ_B/f.u. The hysteretic behavior is characteristic of a weak ferromagnetic system.

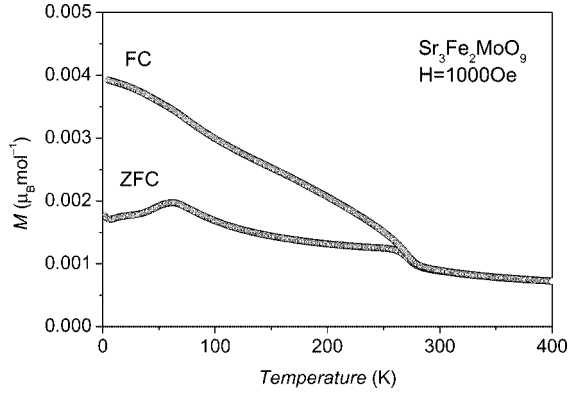

Figure 1. Field-cooled (FC) and zero-field-cooled (ZFC) magnetic susceptibility vs. temperature curves for $Sr_3Fe_2MoO_9$.

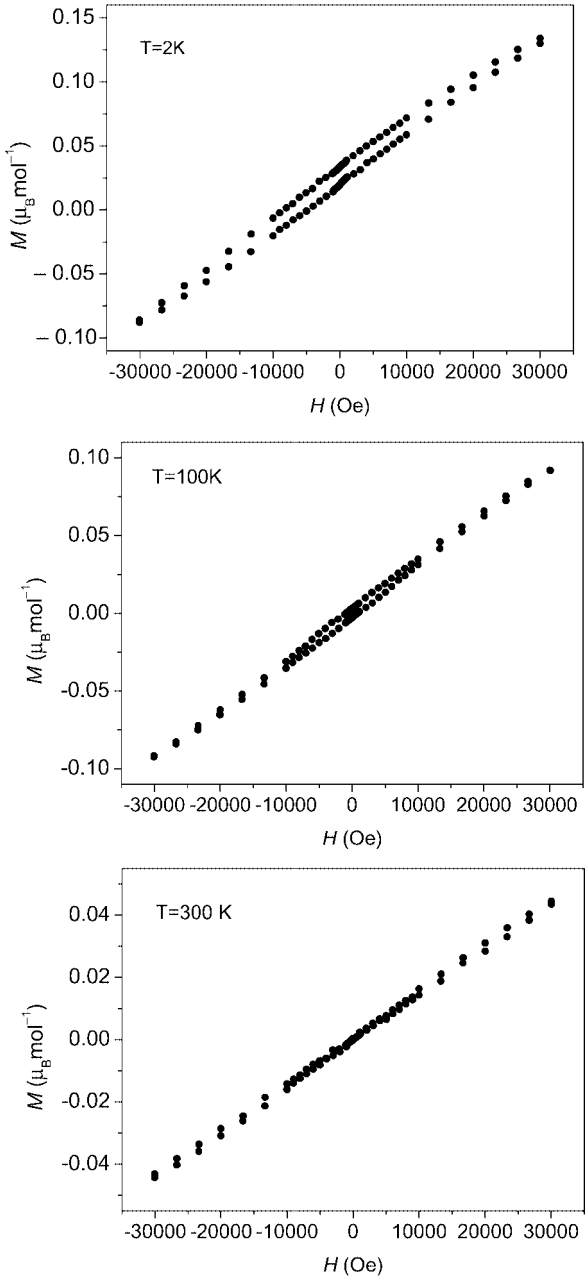

Figure 2. Magnetization vs. magnetic field isotherms (T = 2, 100, and 300 K) for $Sr_3Fe_2MoO_9$.

Structural Refinement

The structural refinement of $Sr_3Fe_2MoO_9$ from room-temperature high-resolution NPD data was performed in the *I*4/*m* space group (No. 87), with unit-cell parameters related to a_0 (ideal cubic perovskite, a_0 = 3.9 Å) as $a = b \approx 2^{1/2} \cdot a_0$ and $c \approx 2a_0$. Sr atoms were located at 4*d* (0,1/2,1/4) positions, Fe/Mo at 2*a* (0,0,0) and Fe at 2*b*(0,0,1/2) sites, and oxygen atoms at 4*e* (0,0,*z*) and 8*h* (*x*,*y*,*z*) positions.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$SrMoO_4$ was included in the refinement as a second phase, defined[8] in the space group $I4_1/a$ (10.87% of this phase from the scale factors). No *anti*-site disordering was detected, by assuming that some Mo from the 2*a* positions could randomly replace some Fe at the 2*b* positions. In the final refinement, the Fe/Mo occupancy over the 2*a* positions was also allowed to change from the nominal Fe/Mo = 2:1 stoichiometry; no departure from this nominal occupancy was detected within the standard deviations (Table 1). An excellent agreement between observed and calculated NPD profiles was obtained for this model, as illustrated in Figure 3. Table 1 includes the final atomic coordinates and discrepancy factors after the refinement. Table 2 lists the main interatomic distances and angles. A drawing of the structure is shown in Figure 4. The structure contains alternating FeO_6 and $(Fe,Mo)O_6$ octahedra, tilted in *anti*-phase in the basal *ab* plane (along the [001] direction of the pseudocubic cell). This corresponds to the $a^0a^0c^-$ Glazer's notation as derived by Woodward[9] for 1:1 ordering of double perovskites, consistent with space group *I*4/*m*.

Table 1. Positional and thermal parameters for $Sr_2Fe(Fe_{1/3}Mo_{2/3})O_6$ after the Rietveld refinement[a] from NPD data taken at 298 K, space group: *I*4/*m*, $Z = 2$. Unit-cell parameters: $a = b = 5.5608(2)$ Å, $c = 7.8471(4)$ Å, $V = 242.65(2)$ Å^3.

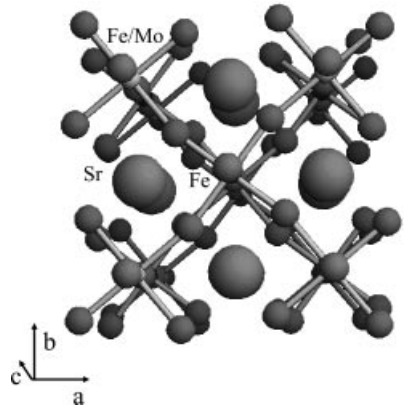

Figure 4. View of the structure of tetragonal $Sr_2Fe(Fe_{1/3}Mo_{2/3})O_6$ approximately along the *c* axis. Large spheres represent Sr; corner-sharing FeO_6 (dark) and $(Fe,Mo)O_6$ octahedra are tilted in *anti*-phase along the *c* axis, in order to optimize Sr–O bond lengths.

allowed Bragg positions ($k = 0$), mainly on the (011) reflection (Figure 5), suggesting a ferro- or ferrimagnetic long-range ordering. This is surprising in this strongly disordered sample, taking into account that the saturation magnetization is very small, of hardly 0.15 μ_B/f.u. with an applied field of 3 T. We would have expected that the structural disordering at the B positions of the perovskite had led to the absence of long-range magnetic ordering between Fe and Mo magnetic moments. As it will be discussed later, we believe that this magnetic scattering originates from Fe-rich patches in which neighboring Fe^{3+} spins exhibit AFM superexchange interactions via Fe–O–Fe paths. We have thus modeled the magnetic structure as a perfect AFM arrangement of Fe spins with alternating directions, occupying all the B positions of a perovskite structure with the same unit-cell and positional parameters as the host $Sr_3Fe_2MoO_9$ perovskite. We have constrained the scale factors of both structural and magnetic models, and refined the magnitude of the Fe magnetic moments. The goodness of the fit is shown in Figure 6, where both structural and magnetic contributions to the scattering have been in-

cluded. The thermal variation of the magnitude of the ordered Fe magnetic moments is displayed in Figure 7.

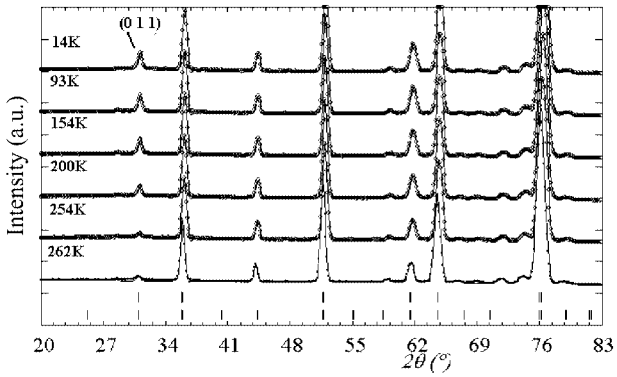

Figure 5. Thermal evolution of the NPD patterns dynamically collected with the high-flux D20 diffractometer, highlighting the appearance at low temperatures of a magnetic contribution to the scattering on the low-angle reflections, especially on the (011) Bragg position.

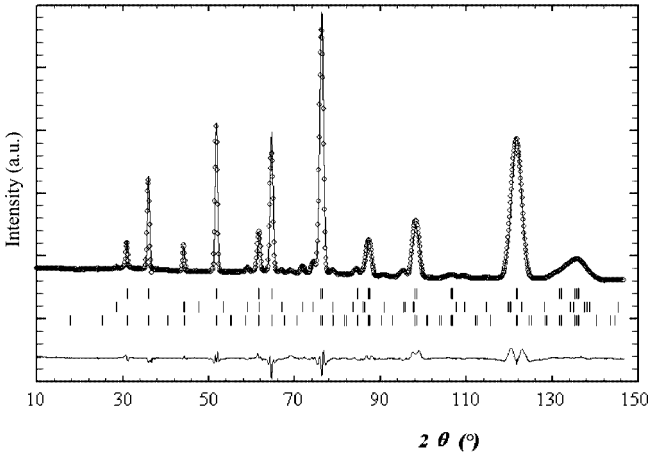

Figure 6. Observed (open circles) and calculated (full line) NPD profiles at 2 K. The three series of allowed Bragg reflections correspond to the crystallographic phase, the $SrMoO_4$ impurity and the magnetic structure for the AFM model described in the text. Unit-cell parameters are $a = b = 5.5346$, $c = 7.8553$ Å; discrepancy factors: $R_{wp} = 3.03\%$, $R_{bragg} = 4.49\%$; $R_{mag} = 11.4\%$.

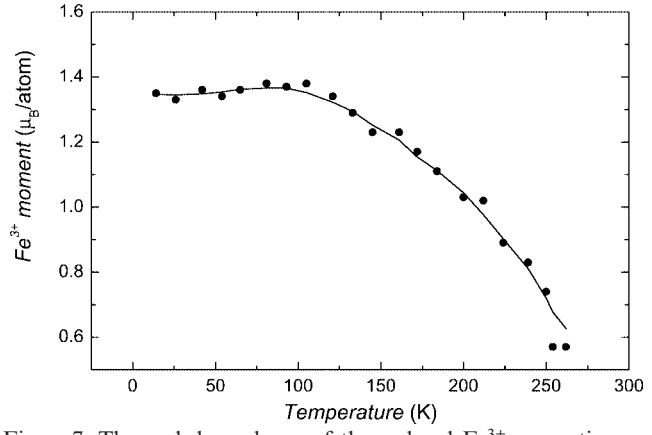

Figure 7. Thermal dependence of the ordered Fe^{3+} magnetic moments sequentially refined from D20 NPD data.

Discussion

Recently, Woodward[9] has described the possible tilting systems for $A_2B'B''O_6$ ordered perovskites, predicting the space groups for each system. When the A cation is large enough, the well-known $(NH_4)_3FeF_6$ structure is adopted by the 1:1 B-site ordered perovskites, such as Ba_2FeMoO_6, which can be described in the cubic space group $Fm\bar{3}m$. For slightly smaller A cations, only a small deformation of the lattice takes place, implying the tilting of the octahedra only along the *c* axis. This tilting means a reduction in symmetry from cubic to tetragonal. The structure of $Sr_3Fe_2MoO_9$, which can ideally be rewritten as $Sr_2Fe(Fe_{1/3}Mo_{2/3})O_6$, is defined in the space group *I*4/*m*, and can be described as the result of a single *anti*-phase octahedral tilting along the *c* axis. Figure 4 illustrates this particular feature. A tilting of 3.9° at room temperature can be derived from the B′–O2–B′′ angle.

The refinement of the occupancy factors of Fe and Mo over the B′′ sites from NPD data indicates a Fe/Mo = 2:1 ratio (within the standard deviations), and no *anti*-site disordering effect was detected, excluding the possibility that some Mo cations could partially replace Fe cations at the 2*b* positions; the actual crystallographic formula is $Sr_2(Fe)_{2b}(Fe_{0.33(3)}Mo_{0.67(3)})_{2a}O_6$. In contrast with Sr_2FeMoO_6, which must be prepared under reducing conditions in order to provide a mixed valence Fe^{3+}–Fe^{2+}/Mo^{5+}–Mo^{6+} state, the present $Sr_3Fe_2MoO_9$ perovskite has been synthesized in air, in such a way that, from the chemical point of view, we should assign a nominal hexavalent oxidation state to the Mo cations, making all Fe cations nominally trivalent. From this point of view, the electronic configuration for this sample would be $Fe^{3+}(3d^5)$–$Mo^{6+}(4d^0)$.

On reinvestigating the example of Sr_2FeMoO_6, electronic band calculations show that the up-spin band, placed below the Fermi level, is mainly occupied by five Fe 3d electrons forming localized spins on the Fe sites. The down-spin band, which has density of states at the Fermi level, is composed mainly of hybridized Mo 4d t_{2g} and Fe 3d t_{2g} states. Thus, the Mo electron which occupies the down-spin band is itinerant and it is shared among Fe and Mo sites.[10–12] The high degree of itinerancy of the Mo electron is responsible for the high conductivity; the superexchange interaction between the localized Fe moment and the partially localized Mo moment accounts for the ferrimagnetic behavior of Sr_2FeMoO_6. Ideally, a perfectly ordered Sr_2FeMoO_6 perovskite should exhibit a saturation magnetization of 4 μ_B/f.u.; in reality, 3.6–3.8 μ_B/f.u. values are obtained due to *anti*-site disordering effects.[13]

In the present $Sr_3Fe_2MoO_9$ material, nominally containing only Fe^{3+} and Mo^{6+}, the lack of an itinerant Mo electron would prevent the magnetic coupling across Fe–O–Mo paths, in such a way that the only possible magnetic superexchange mechanism would take place via Fe–O–Fe paths, in Fe-rich areas of the crystal containing neighboring Fe^{3+} spins. Figure 8 shows a simplified image of the magnetic ordering in this disordered sample; only one layer of B cations is shown for the sake of simplicity. A perfect ferrimag-

netic coupling between up Fe^{3+} spins at 2*b* sites (black in Figure 8) and down Fe^{3+} spins at 2*a* positions (grey in Figure 8) would ideally give $5\cdot(1 - 1/3) = 2.66\ \mu_B$/f.u., but this would require perfect coherence between Fe-rich patches, as illustrated in Figure 8. Notice that the total absence of coherence between isolated Fe-rich patches would lead, on average, to a null saturation magnetization. In fact, in contrast with Sr_2FeMoO_6, in the double perovskite $Sr_3Fe_2MoO_9$ we observe a strong suppression of the global FM properties although there is a remanent weak FM effect which corresponds to the statistical coherence: for a cubic lattice where B′ = Fe and B′′ is statistically occupied by 1/3 Fe, the long-range magnetic connections through B′–B′′(Fe)–B′ exceed the 31% percolation limit of a simple cubic lattice. The tetragonal distortion observed here does not change these considerations. Only $(2/3)^6 = 9\%$ of the B′ site Fe atoms are not connected to at least one B′′ site Fe^{3+}; these nonconnected atoms are labeled as "?" in Figure 8.

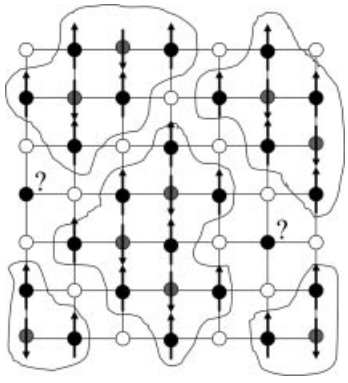

Figure 8. Ideal schematic view of the magnetic coupling in $Sr_2Fe(Fe_{1/3}Mo_{2/3})O_6$. This double perovskite contains Fe at 2*b* positions (black atoms and spins) and randomly distributed Fe (grey atoms and spins) and Mo (white atoms) at 2*a* positions. AFM magnetic coupling is via Fe–O–Fe paths (along the lines). Naturally occurring Fe-rich patches are antiferromagnetically coupled, and there is magnetic coherence between some adjacent patches.

One of the main issues to be addressed in this paper is the origin of the magnetic scattering on the sample showing an important component of intrinsic Fe/Mo disordering. We have been able to accurately fit the magnetic contributions to the neutron scattering by modeling an AFM structure consisting of a perfect arrangement of Fe cations occupying all of the B positions of a perovskite structure with the same unit-cell parameters as the crystallographic $Sr_3Fe_2MoO_9$ phase. The refinement of the magnitude of the magnetic moments on the Fe positions, at 2 K, gives an ordered magnetic moment of 1.4 μ_B, with constrained scale factors for the crystal and magnetic structure. Notice that this is only the average ordered component of the magnetic moment over all the B positions of the perovskite. Our picture thus shows a disordered Fe/Mo pattern in which the Fe–O–Fe superexchange AFM interactions are comparable to those existing in $RFeO_3$ ferrites (R = rare earths). As illustrated in Figure 8, the coupling between near-neighbor Fe–O–Fe cations is always AFM; the important fact is that the coherence between the magnetic ordering of isolated Fe–O–Fe patches is statistically maintained across the solid; the long-range coherence is naturally weaker than that corresponding to a completely ordered compound. Only below temperatures around 30–60 K would the super-superexchange mechanism across Fe–O–Mo–O–Fe paths trigger a complete long-range AFM ordering, as it happens in the antiferromagnet Sr_2FeWO_6 below $T_N = 37$ K.[14] Moreover, we could assign the maximum observed in the ZFC susceptibility curve at 60 K to the onset of these super-superexchange interactions, in addition to the interactions coming from the statistical connections between Fe-rich patches. The thermal variation of the magnetic moment on Fe positions (Figure 7) exhibits an abrupt decay at 250 K, which corresponds to the vanishing of the long-range antiferromagnetic ordering of Fe^{3+} spins, in agreement with the magnetic susceptibility curve.

Conclusions

$Sr_3Fe_2MoO_9$ perovskite is a weak ferromagnet by virtue of the partial long-range coherence established between antiferromagnetically ordered patches of Fe^{3+} spins, composed by some tenths of atoms, naturally arising from the statistical disordering exhibited by this material. The crystal structure, refined from NPD data in the *I*4/*m* space group, contains two kinds of B positions; one of them is fully occupied by Fe^{3+} cations whereas the second one contains a random distribution of Fe^{3+} and Mo^{6+} cations. Below 280 K, the superexchange Fe–O–Fe interactions within naturally occurring Fe-rich patches account for the observed magnetic behavior and the appearance of a significant contribution to the magnetic scattering on the low-angle Bragg reflections. The coherence between isolated Fe-rich patches is statistically provided; only 9% of Fe atoms are magnetically isolated. At lower temperatures, around 60 K, super-superexchange Fe–O–Mo–O–Fe interactions contribute to the long-range AFM ordering of the majority of Fe^{3+} spins. The thermal variation of the ordered Fe^{3+} magnetic moments shows an abrupt decay above 250 K, in agreement with the macroscopic magnetic properties.

Experimental Section

The $Sr_3Fe_2MoO_9$ perovskite was prepared as a black polycrystalline powder from citrate precursors obtained by soft chemistry procedures. Stoichiometric amounts of analytical grade $Sr(NO_3)_2$, $Fe(C_2O_4)\cdot 2H_2O$, and $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ were dissolved in citric acid. The citrate, nitrate and oxalate solutions were slowly concentrated, leading to organic resins containing a random distribution of the cations involved at an atomic level. These resins were first dried at 120 °C and then slowly decomposed at temperatures up to 600 °C. All the organic materials and nitrates were eliminated in a subsequent treatment at 800 °C in air, for 2 h. This treatment gave rise to highly reactive precursor materials. The resulting black powder was then treated in air at 1000 °C for 24 h and 1150 °C for 48 h.

The initial characterization of the product was carried out by laboratory X-ray diffraction (XRD) measurements (Cu-K_α, λ =

1.5418 Å). For the structural refinements, a room-temperature NPD pattern was collected with the high-resolution D2B neutron diffractometer (ILL-Grenoble, France). The high-flux mode was used. About 4 g of sample was contained in a vanadium can; the counting time was 3 h. A wavelength of 1.594 Å was selected from a Ge monochromator. The variable-temperature NPD patterns in the range 2–262 K were collected at the D20 high-flux neutron diffractometer (ILL, Grenoble, France), using a wavelength of 2.42 Å, in order to obtain information about the low-temperature magnetic structure and its thermal variation. A standard cryostat was used for the sequential collections. A collimation of 27" was selected. Once cooled to 2 K, the sample was heated at 2 K min^{-1} and the NPD patterns were sequentially collected with counting times of 2 min.

All the patterns were refined by the Rietveld method by using the FULLPROF refinement program.[15] A pseudo-Voigt function was chosen to generate the line shape of the diffraction peaks. The minor $SrMoO_4$ impurity (with scheelite structure) was included as a second crystallographic phase in the refinements. In the final runs, the following parameters were refined: scale factors for the main and impurity phases, background coefficients, zero-point error, unit-cell parameters, pseudo-Voigt corrected for asymmetry parameters, positional coordinates, isotropic thermal factors, *anti*-site disorder for Fe/Mo and occupancy factors for oxygen atoms. The coherent scattering lengths for Sr, Fe, Mo, and O were 7.02, 9.45, 6.72, and 5.803 fm, respectively.

Kinetic and Thermodynamic Studies of the Disproportionation of Hydrogen Peroxide by Dimanganese(II,II) and -(II,III) Complexes of a Bridging Phenolate Ligand[‡]

Lionel Dubois,[a] Dao-Feng Xiang,[a] Xiang-Shi Tan,[a] and Jean-Marc Latour*[a]

Keywords: Manganese / Catalase / H_2O_2 disproportionation / Kinetics

The dimanganese(II,II) complexes $[Mn_2(L)(OAc)_2(CH_3OH)](ClO_4)$ (**1a**) and $[Mn_2(L)(OBz)_2(H_2O)](ClO_4)$ (**1b**) as well as the dimanganese(II,III) complex $[Mn_2(L)(OAc)_2(CH_3OH)](ClO_4)_2$ (**2a**), where HL is the asymmetric phenol ligand 2-[bis(2-pyridylmethyl)aminomethyl]-6-{[(benzyl)(2-pyridylmethyl)amino]methyl}-4-methylphenol, react with hydrogen peroxide in acetonitrile solution. The initial reaction rates and their temperature and acid/base dependencies were investigated by monitoring the dioxygen evolution. These studies revealed a first-order dependence on both the catalyst and H_2O_2 and a strong influence of the carboxylate. Electrospray ionisation mass spectrometry as well as EPR and UV/Vis spectroscopy were used to monitor the reaction catalysed by **2a**. The same bis(μ-oxo)dimanganese(III,IV) and (μ-oxo)dimanganese(II,III) active species as found for **1a** were detected in the catalytic medium. The EPR spectra recorded during the catalase-like reaction revealed the accumulation of the magnetically uncoupled dimanganese(II,III) precursor of the active bis(μ-oxo)dimanganese(III,IV) species which dominates the spectra in the case of **1a**. This difference can be attributed to the different pH conditions generated by the reaction and reflects differences in the initiation phases for the two catalysts. Overall, the kinetic and thermodynamic studies of H_2O_2 disproportionation by these dimanganese complexes are fully consistent with the mechanism deduced from our previous extensive spectroscopic studies.

Introduction

Although it is a product of aerobic respiration, hydrogen peroxide is potentially toxic since its reduction produces the highly deleterious hydroxyl radical. To prevent formation of HO· and related oxidative stress, cells possess very efficient enzymatic machineries in which the catalase enzymes play an essential role.[1,2] These enzymes eliminate H_2O_2 by means of its disproportionation into harmless dioxygen and water. Most of these enzymes are haemoproteins but a few of them of bacterial origin[3–5] possess a dimanganese active site.[6,7] The two manganese atoms are triply bridged by the carboxylate group of a glutamate and two water-derived ligands, as revealed by the crystallographic studies of the enzymes from *Thermus thermophilus*[8] and *Lactobacillus plantarum*.[9]

Very limited information is available on their mechanism of action. Biochemical[10] and spectroscopic[11] studies have shown that during catalysis, the carboxylate-capped Mn_2O_2 diamond core shuttles between the oxidation states $Mn^{II}Mn^{II}$ and $Mn^{III}Mn^{III}$. However, the fast kinetics of the enzymatic reaction ($k_{cat} \approx 10^5$ s^{-1})[8] and the fact that the oxidised and the reduced forms both react with the same substrate (H_2O_2) have precluded a precise description. As a consequence, most mechanistic proposals have been based on studies of biomimetic compounds.[12–14] The most detailed of these studies were performed on complexes of ligands involving either alkoholates[14,15] or phenolates[13,16] which stabilise the dimanganese unit by providing it with an internal bridge. Depending upon the Mn ligands, all oxidation states of the pair from $Mn^{II}Mn^{II}$ to $Mn^{IV}Mn^{IV}$ have been implicated in the catalysis. In the case of dimanganese complexes of pentadentate bis(aminoalkylimino)phenol ligands, the involvement of oxomanganese(IV) species has been demonstrated by Okawa et al.[16,17] through the observation, in DMF, of a characteristic vibronically split electronic absorption of the $Mn^{IV}(O)$ unit. On the other hand, Nishida et al. provided EPR evidence of the formation of a bis(μ-oxo)dimanganese(III,IV) species in the reaction of hydrogen peroxide with dimanganese complexes of heptadentate hexaaminophenols but did not establish definitely whether this species is a catalytic intermediate or a mere by-product.[18]

As part of our continuing interest in the physical properties and reactivity of dimanganese compounds,[19] we reported the synthesis of the dimanganese(II,II) complexes

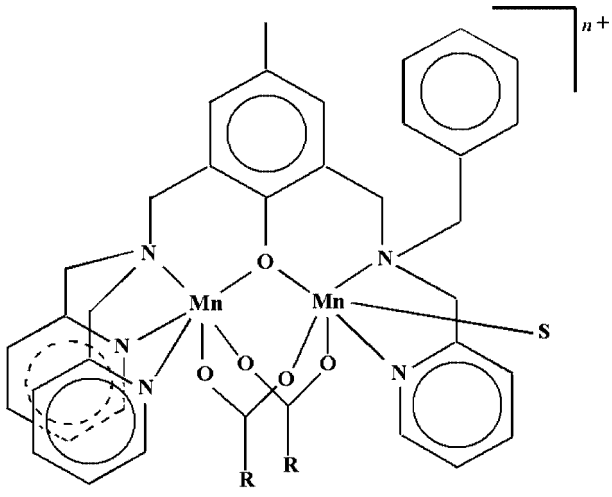
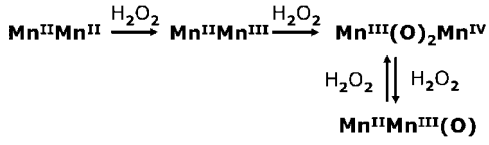
[‡] Binuclear Manganese Compounds of Potential Biological Significance, 3. Part 2: Ref.[21]

$[Mn_2(L)(OAc)_2(CH_3OH)](ClO_4)$ (**1a**) and $[Mn_2(L)(OBz)_2(H_2O)](ClO_4)$ (**1b**) derived from the asymmetric phenolate ligand 2-{[bis(2-pyridylmethyl)amino]methyl}-6-{[(benzyl)-(2-pyridylmethyl)amino]methyl}-4-methylphenol (HL, Scheme 1).[20] We also showed that the hydrogen peroxide disproportionation induced by these complexes involves two intermediates, namely a (μ-oxo)dimanganese(II,III) species $[Mn_2(L)(OAc)(O)]^+$ and a bis(μ-oxo)dimanganese(III,IV) complex $[Mn_2(L)(OAc)(O)_2]^+$ which were characterised by a combination of electrospray ionisation mass spectrometry (ESI-MS) and EPR spectroscopy.[21] In addition, we described the independent synthesis of the bis(μ-oxo)dimanganese(III,IV) complex and its characterisation by X-ray absorption spectroscopy and we showed that the initial reaction of *tert*-butyl hydroperoxide (and probably H_2O_2 also) with the dimanganese(II,II) complexes is a one-electron oxidation to their dimanganese(II,III) analogue.[21] These results are summarised in Scheme 2.



1a: R = Me, **S** = CH_3OH, n = 1
1b: R = Ph, **S** = H_2O, n = 1
2a: R = Me, **S** = H_2O, n = 2

Scheme 1. Complexes used in this study.



Scheme 2. Overall mechanism of the disproportionation of H_2O_2 by **1a**.

In the present article, we report kinetic and thermodynamic studies of the reaction of H_2O_2 with complexes **1a** and **1b** and the analogous dimanganese(II,III) compound $[Mn_2(L)(OAc)_2(H_2O)](ClO_4)_2$ (**2a**).[20] In addition, spectroscopic monitoring of the reaction of H_2O_2 with **2a** shows that the same intermediates are formed, therefore providing a consistent mechanistic picture for all complexes.

Results

Solvent Influence

Many different solvents were used in previous studies of the catalase-like reaction. In a few cases, solvent effects on the rate of dioxygen evolution were considered but the observed effects were found to depend on the catalyst.[18,23–25] It was also reported that even the mechanism of the reaction can change between DMF and acetonitrile.[18] These observations from the literature prompted us to investigate the solvent influence on the kinetics of dioxygen evolution upon reaction of H_2O_2 with **1a**. Figure 1 illustrates the data obtained at 0 °C in DMF, methanol and acetonitrile. In DMF, the reaction was very slow (0.012 mL min^{-1}) and only a small part (ca. 10%) of hydrogen peroxide was disproportionated. In methanol and acetonitrile, the reaction was faster (1.3 and 1.2 mL min^{-1}, respectively) and H_2O_2 was fully disproportionated. Although the initial rates of reaction are very similar, the reaction in methanol slowed down as it approached completion which is possibly due to the limited stability of the catalyst. For this reason, all subsequent measurements were performed in acetonitrile.

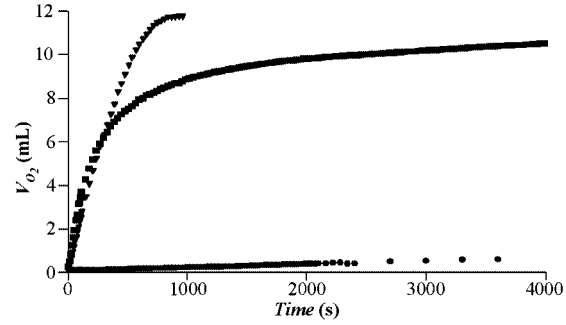


Figure 1. Time dependence of dioxygen evolution upon reaction of **1a** with H_2O_2 in different solvents: methanol (■), acetonitrile (▼) and DMF (●); [**1a**] = 1.0 mM, [H_2O_2] = 460 mM, T = 0 °C.

Comparison of the Catalysts – Stability

The activities of the different catalysts **1a**, **1b** and **2a** were studied under the same conditions as above and the kinetic results are illustrated in Figure 2. The most active catalyst was **2a** with an initial rate of O_2 evolution of 9 mL min^{-1} which can be compared with 1.2 and 0.9 mL min^{-1} for **1a** and **1b**, respectively. In each case, H_2O_2 underwent quantitative disproportionation. At the end of the reaction, the addition of another aliquot of 460 equiv. of hydrogen peroxide gave rise to a new evolution of dioxygen. In the case of **1a**, the rate increased from 1.2 mL min^{-1} for the first H_2O_2 batch to 3.45 mL min^{-1} for the second and 4.5 mL min^{-1} for the third. A sharp decrease in the rate of 2.0 and 0.2 mL min^{-1} was noted for the fourth and the fifth batches, respectively. In the case of **2a**, the rate of O_2 evolution was divided by a factor of 1.8 for the second addition and continued to decrease for the third and the fourth additions where the initial rate became very small (a lag phase was observed in this case).

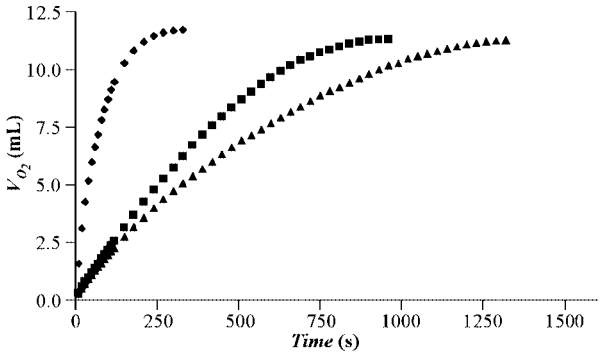

Figure 2. Time dependence of dioxygen evolution upon reaction of H_2O_2 with **1a** (■), **1b** (▼) and **2a** (♦) in acetonitrile; [catalyst] = 1.0 mM, [H_2O_2] = 460 mM, T = 0 °C.

Order of the Reaction

The order of the reaction with respect to the catalyst and hydrogen peroxide was investigated. In the case of **1a**, Figure 3 and Figure 4 show the influence of the complex and hydrogen peroxide concentrations on the reaction rate, respectively. After the initial rate determination, the curve of the Ln(initial rate) = f(concentration) gave a slope of 1.16 (r^2 = 0.998) with respect to the catalyst concentration and 1.12 (r^2 = 0.988) for hydrogen peroxide. It is worth noting that at low H_2O_2 concentrations ([H_2O_2] ≤ 115 mM), an initiation phase was observed over a period of ca. 100 s. In the case of **2a**, the slopes of the curve of the Ln(initial rate) = f(concentration) were 1.17 (r^2 = 0.991) and 0.95 (r^2 = 0.99998) for the catalyst and the hydrogen peroxide concentrations, respectively. Interestingly, no lag phase was detected whatever the H_2O_2 concentration. These results indicate that for **1a** and **2a**, the reaction follows a first-order dependence on both the hydrogen peroxide and the catalyst concentrations.

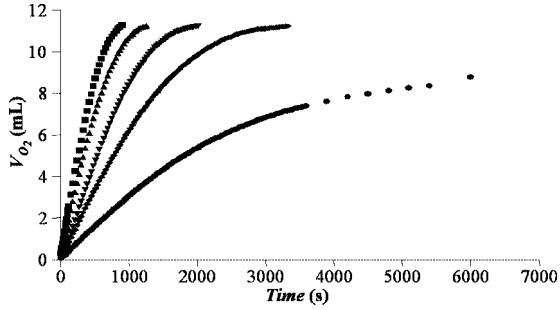

Figure 3. Time dependence of dioxygen evolution upon reaction of H_2O_2 with different concentrations of **1a** in acetonitrile: 1 mM (■), 0.8 mM (▼), 0.6 mM (▲), 0.4 mM (♦), 0.2 mM (●); [H_2O_2] = 460 mM, T = 0 °C.

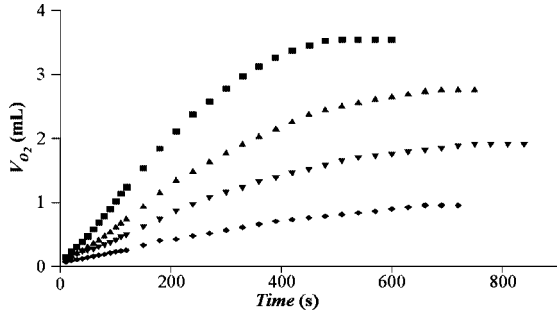

Figure 4. Time dependence of dioxygen evolution upon reaction of **1a** with different concentrations of H_2O_2 in acetonitrile: 115 mM (■), 86 mM (▼), 57 mM (▲), 29 mM (♦); [**1a**] = 1 mM, T = 0 °C.

Temperature Dependence

The determination of the thermodynamic parameters of the catalase-like reaction for the complexes **1a**, **1b** and **2a** was carried out by investigating the rate of dioxygen evolution at different temperatures over the range of –30 °C to +30 °C. After the initial rate determination, the curves Ln(initial rate) = $f(1/T)$ were plotted (Figure 5). For every catalyst, linear regression analysis proved satisfactory thereby indicating that the Arrhenius law is obeyed in all cases. The linear regression analysis provided the activating energy E_a and the preexponential factor k_0 and these parameters are summarised in Table 1. It is noteworthy that the complexes follow a trend in activation energy (**2a** > **1a** > **1b**) which parallels their activities. In other words, the highest activation energy is associated to the most active catalyst (**2a**). This observation contradicts the general view that the higher activity of a catalyst corresponds to a lower activating energy. It follows that the preexponential term k_0 is indeed the dominant factor.

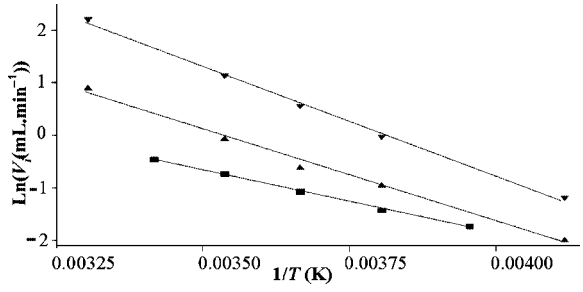

Figure 5. Temperature dependence of the initial rate of the catalase-like reaction in the form of the curve Ln(initial rate) vs. $1/T$ for **1a** (▼), **1b** (■) and **2a** (▲) in acetonitrile; [catalyst] = 1.0 mM, [H_2O_2] = 460 mM.

Table 1.Activation energies and preexponential factors for the reactions of **1a**, **1b** and **2a** with H_2O_2 in acetonitrile.

Catalyst	E_a [kJ mol^{-1}]	ln(k_0)	r^2
2a	35 ± 1	25.2 ± 0.5	0.992
1a	29 ± 1	22.0 ± 0.6	0.997
1b	20.0 ± 0.5	16.2 ± 0.2	0.998

Effect of Acid and Base Addition

In order to further assess the large differences in the abilities of **1a** and **1b** to disproportionate hydrogen peroxide, we decided to study the effect of acid and base addition on

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the reaction rate. Figure 6 shows the effect, on the initial reaction rate in the case of **1a**, upon addition of perchloric acid or triethylamine. Upon addition of triethylamine, the rate increased and this effect reached a maximum at 3 equiv. (per complex) at which point the rate was 3 times higher. A more important effect was observed upon addition of 1 equiv. of perchloric acid and at this concentration the rate of dioxygen evolution was 7 times higher (4.2 mL min^{-1}) than in the absence of perchloric acid. Moreover, it is worth noting that, at this point, the rate is very close to that measured for **2a** (4.5 mL min^{-1} under the same conditions). Further addition of perchloric acid caused a decrease of the initial rate. For **2a**, no change was observed after addition of perchloric acid while addition of base induced its disproportionation into Mn^{II} and $Mn^{III}Mn^{IV}$ species (see below) as shown by EPR spectroscopy.

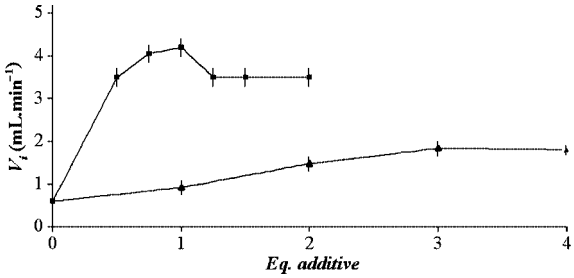

Figure 6. Effect of acid and base addition in the rate of the catalase-like reaction of **1a**: addition of triethylamine (▼), addition of perchloric acid (■).

Spectroscopic Monitoring of Hydrogen Peroxide Disproportionation by 2a

We have previously reported spectroscopic investigations of the mechanism of the reaction of hydrogen peroxide with **1a** and **1b**. We completed this study by monitoring the same reaction for **2a** by combining spectroscopic (UV/Vis, EPR) and mass spectrometric experiments.

UV/Vis Monitoring

When **2a** was treated with hydrogen peroxide in acetonitrile, its characteristic visible spectrum with maxima at 380, 485 and 627 nm[20] disappeared very rapidly (ca. 30 s.) and was replaced by three poorly resolved absorptions at 460, 550 and 630 nm. These absorptions are the signature of a bis(μ-oxo)$Mn^{III}Mn^{IV}$ complex[26] and were similarly observed previously and assigned to the active species in the disproportionation of H_2O_2 by **1a** and **1b**.[21] This spectrum was observed during the whole reaction and tended to disappear at times longer than 5 min.

EPR Monitoring

Figure 7 shows the EPR spectra recorded during the reaction of **2a** with H_2O_2. The initial spectrum (Figure 7a) consists of a large featureless signal between 150 mT and 500 mT with a characteristic poorly resolved 6-line signal superimposed on the central line, as already described.[20] This 6-line signal departs from that of the solvated Mn^{2+} ion and is characteristic of a Mn^{2+} centre bound to the ligand. After addition of H_2O_2 (460 mM, Figure 7b), the signal of **2a** disappeared rapidly (ca. 1 min) and was replaced by a well-resolved 6-line spectrum centred near 350 mT (g = 2). On both the high- and low-field sides of this signal, another weak signal could be detected also with a 16-line pattern which corresponds to a bis(μ-oxo)$Mn^{III}Mn^{IV}$ complex. At longer times (Figure 7c), these two signals decreased in intensity and were replaced by a new poorly resolved 6-line signal at 350 mT (g = 2). After ca. 30 min (Figure 7d), this last signal was the only one observed.

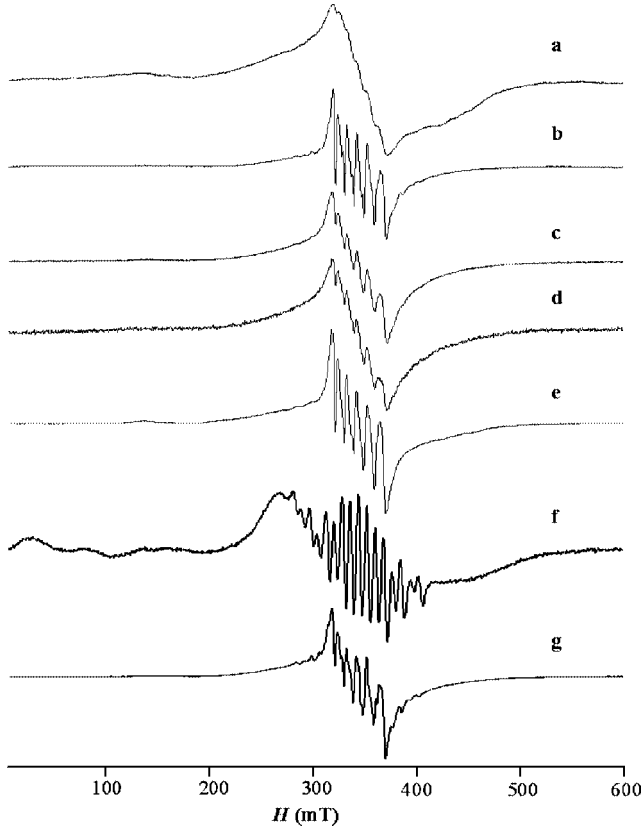

Figure 7. EPR spectra of the reaction of **2a** in acetonitrile with H_2O_2 and after addition of perchloric acid or triethylamine. Spectra a–d: reaction times 0, 1, 8 and 30 min; reaction conditions: [**2a**] = 1 mM, [H_2O_2] = 460 mM, T = –40 °C; spectrum e: **2a** + 1 equiv. perchloric acid; spectrum f: **2a** + 1 equiv. triethylamine; spectrum g: **1a** + 1 equiv. percloric acid + 460 equiv. H_2O_2. Reaction conditions [**1a**] = 1 mM, [H_2O_2] = 460 mM, T = 0 °C.

To further substantiate the effect of addition of acid or base to an acetonitrile solution of **2a**, its EPR spectrum was recorded in the presence of 1 equiv. of perchloric acid (Figure 7e). This spectrum possesses a better resolved 6-line signal centred at 350 mT (g = 2) which is completely different from that of **2a**. This spectrum is very similar to that of **1a** + 1 equiv. of perchloric acid (see Figure 4a in ref.[21]). The spectrum shown in Figure 7f was recorded after addition of 1 equiv. of triethylamine to **2a**. It consists of two signals, one with a 16-line pattern centred at 350 mT (g = 2) corresponding to a bis(μ-oxo)$Mn^{III}Mn^{IV}$ complex. The second one, composed of several transitions between 0 and 5500 G is characteristic of **1a**.[20] These results indicate that

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

2a is not stable in a basic medium and disproportionates into **1a** and a bis(μ-oxo)$Mn^{III}Mn^{IV}$ derivative. Spectrum 7 g was recorded during the reaction of **1a** with H_2O_2 after addition of 1 equiv. of perchloric acid. We can notice than this spectrum is very close to that of **2a** without perchloric acid (Figure 7b).

Mass Spectrometry Monitoring

To obtain a better characterisation of the reaction medium during the reaction of **2a** with hydrogen peroxide, it was monitored by ESI-MS. The results obtained are reported in Figure 8. The starting compound **2a** (Figure 8a) appeared in the form of 3 peaks at *m/z* = 854.8, 756.2 and 378.1 which correspond, respectively, to $[Mn^{II}Mn^{III}(\mu\text{-L})(\mu\text{-OAc})_2](ClO_4)]^+$, $[Mn^{II}Mn^{II}(\mu\text{-L})(\mu\text{-OAc})_2]^+$ and $[Mn^{II}Mn^{III}(\mu\text{-L})(\mu\text{-OAc})_2]^{2+}$. The second ion at *m/z* = 756 was formed by reduction of the starting material (or other related species) during the ionisation process and this can be confirmed by its absence in the corresponding EPR spectrum.[20] After addition of hydrogen peroxide (Figure 8b), new peaks appeared at *m/z* = 713.1, 729.2 and 742.3. All these signals were also observed during the reaction of **1a** with hydrogen peroxide[21] and labelling experiments enabled us to assign them to the two intermediates $[Mn^{II}Mn^{III}(\mu\text{-L})(\mu\text{-O})(\mu\text{-OAc})]^+$ and $[Mn^{III}Mn^{IV}(\mu\text{-L})(\mu\text{-O})_2(OAc)]^+$, and the oxidation product $[Mn^{II}Mn^{II}(\mu\text{-L})(\mu\text{-OAc})(\mu\text{-HCOO})]^+$, respectively. After ca. 17 min, the starting compound had been fully consumed as revealed by the spectrum depicted in Figure 8c showing that the peaks of the initial complex had disappeared.

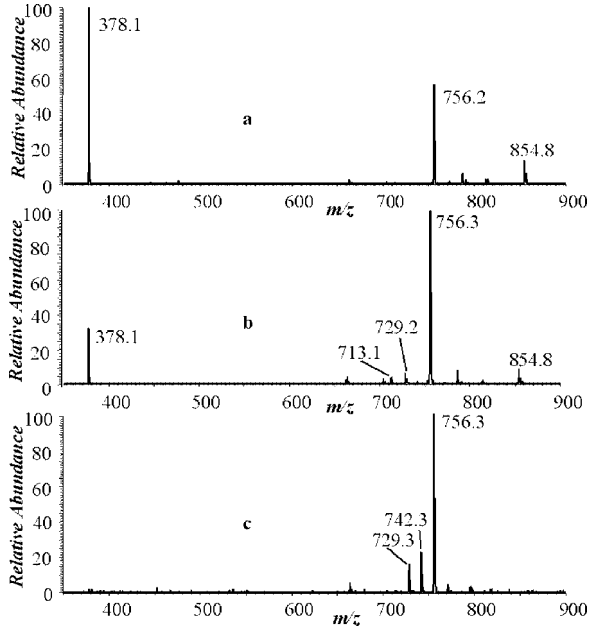

Figure 8. ESI-MS spectra of the reaction of **2a** with H_2O_2 in acetonitrile: spectra a–c: reaction times 0, 1 and 17 min; reaction conditions [**2a**] = 0.6 mM, $[H_2O_2]$ = 460 mM, *T* = –40 °C.

Discussion

Scheme 2 summarises the overall mechanism of H_2O_2 disproportionation by **1a** which emerged from our previous investigations of the reaction by a combination of UV/Vis, EPR, X-ray absorption spectroscopy and ESI mass spectrometry.[21] This mechanism involves an initiation phase in which **1a** is oxidised to the dimanganese(II,III) state with cleavage of the phenoxo bridge. A 6-line EPR signal centred at *g* = 2 is associated with this species. This compound can be viewed as the precursor to the catalytic species since it is further oxidised to the active bis(μ-oxo)dimanganese(III,IV) complex. In the catalase-like reaction, this complex oxidises H_2O_2 and is transformed into the (μ-oxo)dimanganese(II,III) species which is then able to reduce H_2O_2 to water. The present kinetic and thermodynamic studies of dioxygen evolution are fully consistent with this mechanistic scheme. In particular, a lag phase extending over ca. 100 s can be observed at low H_2O_2 concentrations in the case of **1a**. This lag phase more than likely corresponds to the required oxidation process to generate the precursor of the active species. Consistently, no lag phase was observed for **2a** or for **1a** at higher H_2O_2 concentrations. The present kinetic and thermodynamic studies provide a few observations which can valuably improve the understanding of the mechanism.

Firstly, we observed that on the first three successive additions of H_2O_2, the reaction rate of **1a** increased and eventually approached that of **2a**, while the latter did not show such a rate increase. This can be explained if the initiation process is slower than the disproportionation reaction. If this were the case, the disproportionation would start developing before all **1a** had entered the catalytic cycle. Successive additions would therefore bring more of **1a** into the active form. This view is supported by the observation that the less reactive **1b** persists longer than **1a** in the catalytic medium.[21]

Secondly, the kinetic measurements show that the initial rate of the catalase-like reaction is dependent on the nature of the bridging carboxylates. A similar observation was made by Okawa et al.[16,27,28] This result may indicate that at least one of the carboxylate groups remains in the coordination sphere of the active species. This conclusion is perfectly consistent with the results of our previous ESI-MS analyses of **1a** and **1b** which indicated the presence of one carboxylate in both active species.

Thirdly, the thermodynamic analysis of the reaction revealed similar trends (**2a** > **1a** > **1b**) in the activation energies and the preexponential terms. This trend in activation energy is opposite to the reaction efficiency but it is noteworthy that it parallels the bond strengths between the carboxylate ligands and the catalysts. It may then reflect the need to dissociate a carboxylate during the catalysis to make a coordination site available to hydrogen peroxide.

ESI-MS monitoring of the reaction of **2a** with H_2O_2 has shown that the bis(μ-oxo)$Mn^{III}Mn^{IV}$ and the (μ-oxo)Mn^{II}-Mn^{III} intermediates are involved as in the case of **1a**. Nevertheless, the EPR spectra recorded during the course of the reaction were dominated by the 6-line signal of the precursor. It is worth noting that such a species was transiently formed upon reaction of **1a** with H_2O_2.[21] Protonation experiments coupled with EPR spectroscopy showed that the same 6-line EPR spectrum can be obtained upon addition

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of 2 equiv. of $HClO_4$ to **1a** or 1 equiv. to **2a**. This enhanced proton sensitivity of **2a** was attributed to the fact that its Mn^{II}–$O_{phenoxo}$ bond is significantly elongated (2.245 Å) and weakened with respect to the same bonds in **1a** (2.105–2.107 Å)[20] and therefore more susceptible to break in solution. This cleavage of the phenoxide bridge makes the dimanganese unit appear as the individual ions: an EPR-silent Mn^{III} and a mononuclear Mn^{II} with a 6-line signature. The influence of protonation on the reactivity experiments supports this view. Firstly, the rate of the catalase-like reaction of **1a** + 1 equiv. of perchloric acid is very close to that of **2a** without perchloric acid. Secondly, the EPR spectrum recorded during the catalase-like reaction of **1a** + 1 equiv. of perchloric acid and **2a** without perchloric acid are very similar and include a dominating contribution of the precursor (6-line signal at $g \approx 2$) and traces of a bis(μ-oxo)-$Mn^{III}Mn^{IV}$ complex (16-line signal at $g \approx 2$). It appears then that a unique mechanism is likely to be in operation for **1a** and **2a** but the different EPR signatures observed during the catalase-like reaction may reflect different proportions of EPR active species present in solution. Indeed, in the case of **1a**, the EPR spectrum is dominated by the 16-line signal of the active bis(μ-oxo)$Mn^{III}Mn^{IV}$ intermediate and the characteristic EPR signal of **1a** slowly disappears during the reaction. In contrast, in the case of **2a**, the spectrum of the precursor dominates and that of the active bis(μ-oxo)$Mn^{III}Mn^{IV}$ intermediate appears weak. This difference may have its origin in the different proton sensitivities of the starting complexes reinforced by the chemical processes required to form the active bis(μ-oxo)$Mn^{III}Mn^{IV}$ intermediate. Indeed, in the case of **1a**, the reaction requires $^3/_2$ H_2O_2 molecules and generates a single H^+ [Equation (1)].

$$Mn^{II}Mn^{II} + 3/2\ H_2O_2 \rightarrow Mn^{III}Mn^{IV}(\mu\text{-}O)_2 + H_2O + H^+ \quad (1)$$

In contrast, for **2a**, a single H_2O_2 molecule is needed but two H^+ ions are released [Equation (2)].

$$Mn^{II}Mn^{III} + H_2O_2 \rightarrow Mn^{III}Mn^{IV}(\mu\text{-}O)_2 + 2\ H^+ \quad (2)$$

The increased acidity of the medium may be responsible for the higher proportion of the precursor species.

Here we have shown that complexes **1a**, **1b** and **2a** are able to disproportionate 100% of the initial hydrogen peroxide in acetonitrile or methanol solution by means of a first-order reaction with respect to catalyst and hydrogen peroxide. This observation departs from the results of Okawa[13,28] who claimed that the complexes of dissymmetric pentadentate imine/amine-phenolato ligands are able to disproportionate only 65% of the initial hydrogen peroxide, while the symmetric ones disproportionate all the hydrogen peroxide. Nevertheless, the present hexadentate amine ligands and probably also the heptadentate ligand used by Nishida[25] appear flexible enough to accommodate the bis(μ-oxo)dimanganese(III,IV) cores by allowing a phenolate shift which frees some coordination position.[21] Such a situation may not be easily achievable with more conjugated ligands involving imine donors. When the dioxygen evolution rates are compared, our best catalyst (**2a**) is around 9 times more active than the comparable phenolato-bridged complexes described in the literature (after converting initial rates to the same conditions).[13,25] Nevertheless, they appear much less active than the dimanganese(II,II) complexes of tripodal ligands recently reported.[29]

Conclusions

The present kinetic and thermodynamic studies fully support our initial mechanistic investigations of the catalase-like reaction by dimanganese(II,II) complexes. A unique mechanism seems to be operative which is based on shuttling between a (μ-oxo)dimanganese(II,III) and a bis(μ-oxo)dimanganese(III,IV) species. This illustrates the fact that to efficiently disproportionate H_2O_2 the system uses the Mn_2 pairs, the redox potentials of which are the most adapted whatever the initial oxidation states of the Mn ions. The systems differ by the initiation process required to enter the catalytic cycle and the sensitivity to protonation which appears to significantly alter the composition of the medium and the kinetics.

Experimental Section

General: All solvents and reagents were of the highest quality available and were used as received unless noted otherwise. The concentration of the hydrogen peroxide stock solution (30% w/w) was determined monthly by permanganate titration. The ligand HL was prepared according to the literature procedure.[22]

Syntheses: The complexes **1a**, **1b** and **2a** where synthesised according to the procedure described before.[20]

Caution: Perchloric acid and perchlorate salts are potentially dangerous and explosive and must be handled with care and in small quantities.

Spectroscopic Measurements: Electronic absorption spectra were recorded with a Hewlett Packard HP 89090A diode array spectrophotometer. Electrospray ionisation mass spectra were obtained with an LCQ Finnigan Thermoquest ESI source spectrometer with an ion trap and an octupolar analyser. EPR spectra at X band were recorded with an EMX Bruker spectrometer equipped with an Oxford Instruments cryostat ESR900. All spectra presented were recorded with the following set of conditions: T = 10 K, P = 0.2 mW, modulation F = 100 kHz, I = 9 G.

Kinetic Measurements: The rate determinations of the catalase-like reactions were performed by volumetric measurements of the evolved dioxygen. The whole apparatus, constructed from borosilicate glass, was kept at a constant temperature (±0.2 °C) using a thermostatted ethanol circulation bath (Haake FQ-4). In a standard procedure, catalyst solution (2 mL) was placed in the kinetic apparatus. The solution was stirred for 30 min to reach a stable temperature. The chosen volume of hydrogen peroxide stock solution was added and the volume of evolved dioxygen was then measured as a function of time. To compare the kinetics at different temperatures, the volume of the gas was converted to a reference temperature (273 K) using the ideal gas law. The volume was also corrected for the vapour pressure of the solvent at the working temperature using the expression $V_{corr} = V_{mes}*(P_{atm}–P_{vap})/P_{atm}$ where V_{corr} is the corrected volume, V_{mes} the measured volume,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

P_{atm} the atmospheric pressure and P_{vap} the vapour pressure of the solvent at the working temperature. In most cases, the initial rates were obtained by measuring the slopes of the tangents of the curve $v(O_2)$ vs. time at 0 s. When a lag phase was present (i.e. experiments with **1a** at low H_2O_2 concentrations), the largest slope after the initiation phase was used.

One-Dimensional Chains Formed by First-Row Transition Metal(II) Nitrates and Pyrimidine – Influence of Water Coordination on Structural Reliability

Sarah A. Barnett,[a] Neil R. Champness,*[a] and Claire Wilson[a]

Keywords: Coordination frameworks / Coordination polymer / Crystal structure / Metal nitrates / Pyrimidine

An isostructural family of one-dimensional coordination polymers, $[M(NO_3)_2(pym)(H_2O)_2]_\infty$ [M = Mn (**1**), Co (**2**), Ni (**3**), Zn (**4**); pym = pyrimidine], has been prepared and their phase purity assessed. It is shown that in contrast to other $M(NO_3)_2$–pyrimidine coordination polymers, **1**–**4** show a surprising preference for the structure reported herein rather the wide variety of other possible product architectures. It is also shown that a related complex $[Ni(NO_3)_2(pym)(MeCN)_2]_\infty$ (**5**), in which water ligands observed in **1**–**4** are replaced by MeCN molecules, can also be prepared. However, **5** is highly hygroscopic and readily converts to **3** in the presence of atmospheric water. The implication of the uniformity of structure is discussed in relation to the serendipitous coordination of water molecules to the metal centres.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

The construction of coordination frameworks is an extremely topical area of inorganic and materials chemistry.[1] The strong interest in this area arises because the synthetic procedure used to construct these materials allows, in principle, a high degree of design. New materials with tuneable properties have been developed from coordination frameworks over recent years and as synthetic procedures become more advanced so the properties of these materials become more highly evolved.[1] The targeted synthesis of coordination polymers requires an appreciation of not only the variety of possible coordination framework materials that can be prepared, but also an appreciation of which structures are more favourable. An assessment of phase purity of coordination polymers is both valuable from the point of view of material properties, but also gives insight into the structural reliability[2] of a given set of starting building-blocks. We,[3,4] amongst others,[5] have been interested in the use of $M(NO_3)_2$ species as building blocks in coordination polymer construction due to their structural diversity that gives rise to a variety of fascinating coordination framework architectures. We have previously commented on the lack of structural reliability of $M(NO_3)_2$ as a coordination polymer node, and in general they can be viewed as structurally unreliable due to the large number of metal nodes that are generated from such species, but also because of the variety of coordination frameworks that can be generated even when the same $M(NO_3)_2$ node configuration is adopted.[2,3]

Herein, we report a family of isostructural one-dimensional coordination polymers, $[M(NO_3)_2(pym)(H_2O)_2]_\infty$ [M = Mn (**1**), Co (**2**), Ni (**3**), Zn (**4**)], which interestingly form a single phase under the conditions of synthesis used. The serendipitous coordination of water molecules to the metal centres leads to the formation of a hydrogen-bonded array that may contribute to the favourable formation of the observed product.

Results and Discussion

Reaction of $M(NO_3)_2{\cdot}xH_2O$ salts [M = Mn (**1**), Co (**2**), Ni (**3**), Zn (**4**)] dissolved in either MeCN or *i*PrOH with a solution of pyrimidine (pym) in CH_2Cl_2 leads to the formation of insoluble precipitates which are found to have the stoichiometry $[M(NO_3)_2(pym)(H_2O)_2]_\infty$ by elemental analysis. In the case of $Ni(NO_3)_2$ with pym in CH_2Cl_2/MeCN an alternative product $[Ni(NO_3)_2(pym)(MeCN)_2]_\infty$ (**5**) can also be isolated but readily undergoes conversion to **3** in the presence of atmospheric moisture. Single crystals were grown by slow diffusion of the layered solutions of the metal salt and pyrimidine in their respective solvents.

Structural characterisation of **1**–**4** by single-crystal X-ray diffraction showed the formation of one-dimensional coordination polymers with the formula $[M(NO_3)_2(pym)(H_2O)_2]_\infty$. All four compounds are isostructural and crystallize in the space groups *I*2/*a* [non-standard setting of *C*2/*c* (no. 15)]. Each M^{II} centre is pseudo-octahedral and coordinated by two pyrimidine ligands, two η^1-nitrate anions and two water molecules (Figure 1; Table 1). The bridging nature of the pyrimidine ligand results in the formation of a one-dimensional zigzag chain, which is achiral, and runs parallel to the *c* axis (Figure 2).

In addition to these coordination bonds, however, extensive hydrogen bonding interactions are observed within the structure (Figure 3). These occur between the hydrogen atoms of the coordinated water molecules and the oxygen atoms of the nitrate anions on adjacent chains. Both of the hydrogen atoms of each water molecule participate in a hydrogen bond. However, only one oxygen atom of any given

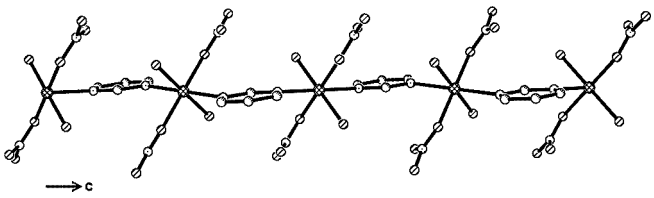

Figure 2. The one-dimensional chain formed by $[Mn(NO_3)_2(pym)(H_2O)_2]_\infty$ (**1**). Compounds **2**–**4** form analogous chains. Mn cross hatch; N dotted; O left hatch.

nitrate anion is involved in hydrogen bonding and, in fact, interacts with two hydrogen atoms from separate, symmetry-equivalent, water molecules. Two crystallographically distinct types of $OH\cdots O(NO_3)$ hydrogen bonds are observed (Table 2); one type links $[M(NO_3)_2(pym)(H_2O)_2]_\infty$ chains parallel to the *a* axis and the second links chains in the direction of the *b* axis. Thus, the hydrogen-bonding interactions form an undulating two-dimensional hydrogen-bonded sheet parallel to the *ab* plane. Each metal node is connected to six adjacent nodes within the sheet using a total of eight hydrogen bonds, utilising all four water hydrogen atoms (two for each H_2O), and both coordinated NO_3^- anions participating in two hydrogen bonds each. These hydrogen-bonded sheets are then crosslinked by the pyrimidine ligands into a three-dimensional network of $3^6.4^{18}.5^3.6$ topology (Figure 4).

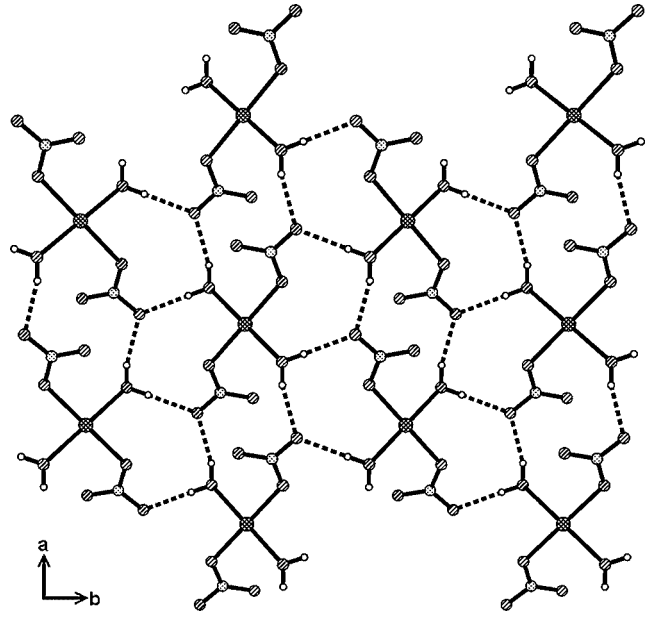

Figure 3. The hydrogen-bonded sheet formed by $[Mn(NO_3)_2(H_2O)_2]$ units viewed in the *ab* plane. $OH\cdots O(NO_3)$ hydrogen bonds indicated by dashed lines. Mn cross hatch; N dotted; O left hatch.

A single-crystal diffraction study of **5** revealed a highly related structure to that observed in **1**–**4**. Thus, each Ni^{II} centre is pseudo-octahedral and coordinated by two pyrimidine ligands, two η^1-nitrate anions and two MeCN molecules replacing the water ligands present in **1**–**4** (Figure 5; Table 1). In the absence of the water ligands no interchain

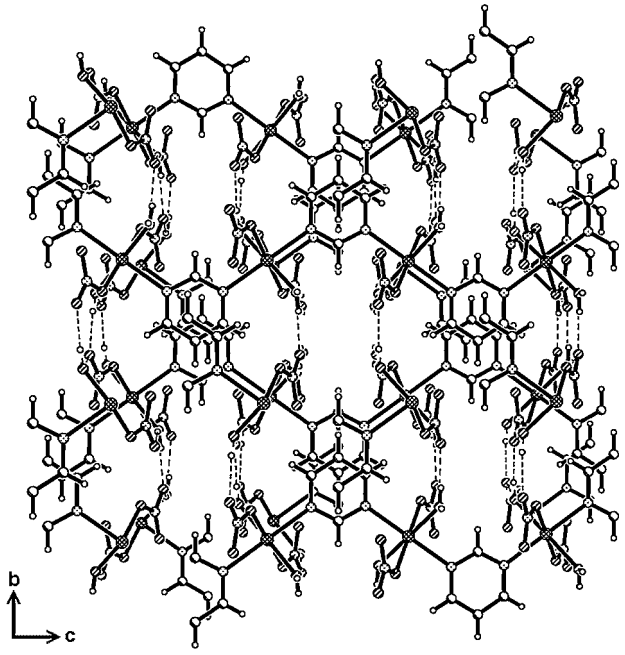

Figure 4. A view of the three-dimensional structure formed by $[Mn(NO_3)_2(pym)(H_2O)_2]_\infty$. Mn cross hatch; N dotted; O left hatch.

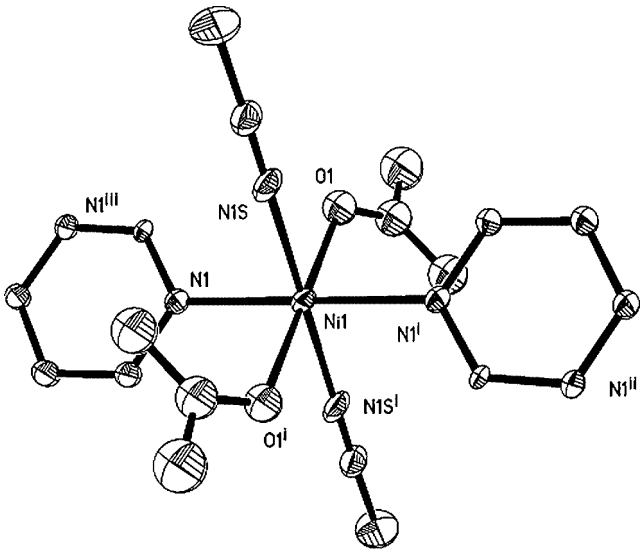

Figure 5. The Ni^{II} coordination environment observed in $\{[Ni(NO_3)_2(pym)(MeCN)_2](MeCN)\}_\infty$ (**5**) showing the numbering scheme used. Displacement ellipsoids drawn at the 50% probability level. Hydrogen atoms are omitted for clarity. Symmetry codes: (i) $-x, -y, 1 - z$; (ii) $x, -y, -1/2 + z$; (iii) $-x, y, 3/2 - z$.

hydrogen bonds are observed and therefore the extended structure observed in **1**–**4** is not present in **5**.

In order that phase purity of these products could be assessed, bulk samples of **1**–**4** were prepared. This is particularly important in the case of metal(II) nitrate bridging N-donor coordination polymers due to the wide variations previously observed in the products of such compounds.[3] Powders were prepared initially by L/M starting ratios of 1:1 in either an $MeCN/CH_2Cl_2$ (**1**, **2**, **4**) or an *i*PrOH/CH_2Cl_2 (**3**) solvent mixture. On comparing the results of X-ray powder diffraction with the calculated powder diffraction patterns using the single-crystal X-ray data, all the samples were confirmed to be pure single phases of the respective complexes (see Figure 6 for example).

The reaction of $Ni(NO_3)_2$ with pym in $MeCN/CH_2Cl_2$ affords crystals of both **3** and **5**. Indeed isolation of samples that contain **5** is difficult as this species proves to be highly hygroscopic, rapidly taking up atmospheric moisture and converting to **3**. All attempts to prepare bulk samples of **5** or to observe its presence in bulk samples of the reaction

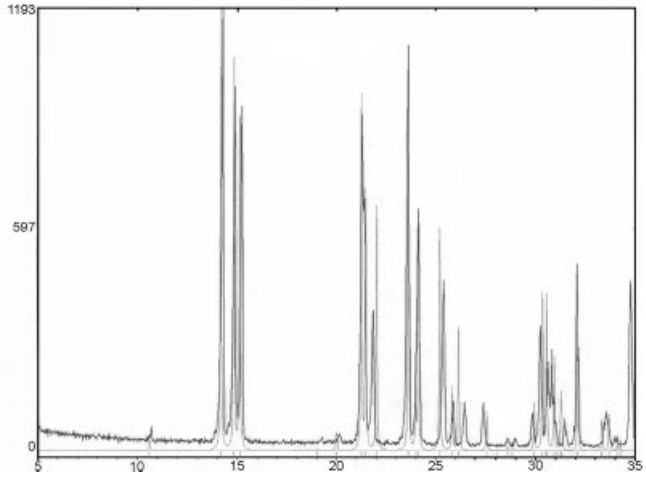

Figure 6. Comparison of the powder diffraction pattern recorded for the bulk product (black line) and that calculated from the single-crystal X-ray diffraction data (grey line) for $[Mn(NO_3)_2(pym)(H_2O)_2]_\infty$ (**1**).

products were unsuccessful with only identification of pure samples of **3**.

The structure of **1**–**4** observed here has been previously observed in the products of the reactions of other transition metal salts with pyrimidine. Indeed, compounds isostructural with **1**–**4** have previously been observed for $[Cu(NO_3)_2(pym)(H_2O)_2]_\infty$[6] and $[Cd(NO_3)_2(pym)(H_2O)_2]_\infty$.[7] However, it is worth noting that in the case of $Cu(NO_3)_2$ and $Cd(NO_3)_2$ other products with pyrimidine[8,9] are also observed indicating that these metal centres are perhaps less predictable in their behaviour than the transition metal salts reported here. The lack of structural predictability is not particular surprising for either $Cu(NO_3)_2$ or $Cd(NO_3)_2$ considering the Jahn–Teller distortion expected for Cu^{II} and the highly malleable coordination sphere of Cd^{II}.[2,3] Indeed, it is perhaps more surprising that such a uniform, isostructural family of compounds are observed for the system reported here. The uniformity of product clearly reflects the greater stability of this product in comparison to other hypothetical competing structures, but also may be attributed, in part, to the coordination of water molecules to the metal centres in **1**–**4**, which arises due to the use of hydrated $M(NO_3)_2$ starting reagents. The coordination of water molecules to the metal centres has two major effects on the resultant coordination polymer structure. Firstly, by occupying two of the coordination sites of the metal centre the number of pyrimidine ligands that can be coordinated and subsequently bridge metal centres is restricted leading to the formation of the one-dimensional chains that are observed. Secondly, the ability of water to act as a hydrogen-bond donor allows the formation of hydrogen-bonding interactions between adjacent chains undoubtedly strengthening the formation of the observed structure. The relative stability of the structure observed in **1**–**4** is further indicated by the rapid conversion of **5** to **3** by replacement of the MeCN ligands in **5** by water molecules.

In summary, a family of one-dimensional coordination polymers has been prepared and their phase purity assessed. The implications of the uniformity of structure observed have been discussed, and it can be concluded that the preferential formation of the observed products can be attributed, at least in part, to the serendipitous coordination of water molecules to the metal centres.

Experimental Section

General: Infrared spectra were measured as KBr disks with a Nicolet Avatar 380 FT-IR spectrometer over the range 400–4000 cm^{-1}. Microanalyses were performed by the University of Nottingham Chemistry Department microanalytical service with a Perkin–Elmer 240B analyser. Powder X-ray diffraction patterns (PXD) data were collected with a Philips XPERT θ-2θ diffractometer with Cu-K_α radiation. Samples were mounted on flat glass plate sample holders. Ca. 50-min scans were run for each sample to assess phase purity. Short scans were run over the range $5° \leq 2\theta \leq 80°$ with step size $2\theta = 0.02°$ and times per step of 0.65 s. The simulated powder pattern was generated using the PC software packages APD, part of the Philips software package and POWDERCELL,[10] taking the single-crystal structural data for the compound as a model. For details see Supporting information (see footnote on the first page of this article). All chemicals were purchased from Aldrich Chemicals and used without further purification. All single-crystal X-ray experiments were performed with either a Bruker AXS SMART1000 CCD detector diffractometer (**1**–**5**) equipped with an Oxford Cryosystems open flow cryostat[11] [graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å); ω scans] or with an Enraf–Nonius FAST TV Detector diffractometer [graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å)] (**3**). Absorption corrections were applied by a semi-empirical approach (**1**, **2**, **4**, **5**). Other details of crystal data, data collection and processing are given in Table 3. CCDC-258503 (**1**), -258504 (**2**), -258505 (**3**), -258506 (**4**), -258507 (**5**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif. All of the single-crystal structures were solved by direct methods using SHELXS-97[12] and all non-hydrogen atoms were located using subsequent difference-Fourier methods.[13] In all cases, hydrogen atoms were placed in calculated positions and thereafter allowed to ride on their parent atoms, except for water hydrogen atoms which were located from the difference Fourier map. The water hydrogen atoms were refined, with suitable O–H and H···H distance re-

straints. During the refinement of the structure of **5** a region of poorly defined solvent was accounted for using SQUEEZE,[14] which calculated 87 electrons per unit cell, approximating to 4 molecules of MeCN (88 electrons) which were included in the formula. One oxygen atom and the nitrogen atom of the nitrate anion showed disorder and were modelled isotropically over two sites with occupancies 0.6 and 0.4. A large peak of residual electron density remained in a chemically nonsensical position. This may be due to some form of twinning, however, the original data all indexed cleanly using the assigned cell and application of various twin laws did not result in any improvement.

$[Mn(NO_3)_2(pym)H_2O)_2]_\infty$ (1): A solution of $Mn(NO_3)_2{\cdot}xH_2O$ (224 mg, 0.83 mmol) in MeCN (15 cm^3) was added to a solution of pym (67 mg, 0.83 mmol) in CH_2Cl_2 (2 cm^3). The colourless crystals which formed over a 24 h period were filtered off and dried in vacuo. Yield 70% (171 mg). $C_4H_8MnN_4O_8$ (295.1): calcd. C 16.28, H 2.74, N 18.99; found C 16.21, H 2.60, N 18.66. IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3423 w, 3109 w, 3074 w, 1763 w, 1594 s, 1568 w, 1467 s, 1389 s, 1221 m, 1177 m, 1144 w, 1078 s, 1024 m, 825 m, 805 w, 694 s, 656 m. Crystals suitable for single-crystal X-ray diffraction were grown as above.

$[Co(NO_3)_2(pym)(H_2O)_2]_\infty$ (2): A solution of $Co(NO_3)_2{\cdot}6H_2O$ (315 mg, 1.08 mmol) in MeCN (15 cm^3) was added to a solution of pym (87 mg, 1.08 mmol) in CH_2Cl_2 (2 cm^3). The dark pink precipitate was filtered off and dried in vacuo. Yield 87% (281 mg). $C_4H_8CoN_4O_8$ (299.1): calcd. C 16.06, H 2.70, N 18.74; found C 16.08, H 2.60, N 18.62. IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3416 m, 3112 w, 3084 w, 1763 w, 1630 w, 1596 s, 1568 w, 1466 s, 1383 s, 1221 m, 1180 m, 1145 w, 1082 m, 1028 m, 825 m, 802 w, 691 s, 663 m. Single crystals were grown by slow diffusion of layered solutions of $Co(NO_3)_2{\cdot}6H_2O$ in MeCN over pym in CH_2Cl_2.

$[Ni(NO_3)_2(pym)(H_2O)_2]_\infty$ (3): A solution of $Ni(NO_3)_2{\cdot}6H_2O$ (240 mg, 0.83 mmol) in *i*PrOH (15 cm^3) was added to a solution of pym (66 mg, 0.83 mmol) in CH_2Cl_2 (2 cm^3). The light blue precipitate was filtered off and dried in vacuo. Yield 94% (233 mg). $C_4H_8N_4NiO_8$ (298.8): calcd. C 16.08, H 2.70, N 18.75; found C 16.10, H 2.65, N 18.31. IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3405 m, 3118 w, 3091 w, 1767 w, 1636 w, 1597 s, 1570 w, 1467 m, 1386 s, 1221 w, 1182 m, 1145 w, 1085 m, 1048 w, 1031 w, 833 m, 801 w, 692 m, 666 m. Single crystals were grown by slow diffusion of layered solutions of $Ni(NO_3)_2{\cdot}6H_2O$ in *i*PrOH over pym in CH_2Cl_2.

$[Zn(NO_3)_2(pym)(H_2O)_2]_\infty$ (4): A solution of $Zn(NO_3)_2{\cdot}6H_2O$ (133 mg, 0.45 mmol) in MeCN (15 cm^3) was added to a solution of pym (36 mg, 0.45 mmol) in CH_2Cl_2 (2 cm^3). The colourless crystals that formed over a 24 hour period were filtered off and dried in vacuo. Yield 64% (88 mg). $C_4H_8N_4O_8Zn$ (305.5): calcd. C 15.73, H 2.65, N 18.35; found C 15.73, H 2.54, N 18.00. IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3449 w, 3111 w, 1763 w, 1597 s, 1570 w, 1466 m, 1385 s, 1221 w, 1180 w, 1146 w, 1082 m, 1028 w, 825 m, 801 w, 690 s, 661 m. Crystals suitable for single-crystal X-ray diffraction were grown as above.

$[Ni(NO_3)_2(pym)(MeCN)_2]_\infty$ (5): A solution of $Ni(NO_3)_2{\cdot}6H_2O$ (101 mg, 0.35 mmol) in MeCN (10 cm^3) was added to a solution of pym (28 mg, 0.35 mmol) in CH_2Cl_2 (2 cm^3). The light blue precipitate was filtered off and dried in vacuo. Yield ca. 60% (ca. 70 mg). CHN elemental analysis, powder X-ray diffraction and IR spectroscopic studies confirmed that **5** rapidly converted to **3** on exposure to atmospheric moisture. Single crystals were grown by slow diffusion of layered solutions of $Ni(NO_3)_2{\cdot}6H_2O$ in MeCN over pym in CH_2Cl_2. Crystals were rapidly transferred from the reaction solution into drops of oil prior to data collection.

Synthesis and Characterization of Magnesium-Aluminum Layered Double Hydroxides Containing (Tetrasulfonated porphyrin)cobalt

César A. S. Barbosa,[a] Ana Maria D. C. Ferreira,[a] and Vera R. L. Constantino*[a]

Keywords: Composites / Intercalations / Layered compounds / Organic–inorganic hybrid composites / Porphyrins

We report the synthesis and characterization of a magnesium-aluminum layered double hydroxide (LDH) containing [5,10,15,20-tetrakis(4-sulfonatophenyl)porphyrinato]cobalt(II) (CoTPhsP) by two routes: (i) CoTPhsP intercalation by structure reconstruction of the calcined pristine LDH [$Mg_{2.8}Al$-$(CoTPhsP)_{int}$] and (ii) adsorption of the CoTPhsP on the external surfaces of the noncalcined pristine LDH [$Mg_{3.0}Al$-$(CoTPhsP)_{ads}$]. The intercalation and adsorption of CoTPhsP in the LDHs were evaluated using different techniques, such as X-ray diffraction, thermogravimetry, scanning electronic microscopy, and surface area and porosity analysis. Further characterization by electron spin resonance and UV/Vis spectroscopy showed that the CoTPhsP molecules adsorbed and intercalated in the LDHs are present as two predominant species: the complex formed with molecular oxygen (CoTPhsP–O_2) and the corresponding deoxy monomeric species (CoTPhsP). The stability and reactivity of the CoTPhsP immobilized in the LDHs were evaluated in the presence of hydrogen peroxide solution. CoTPhsP in homogeneous conditions is deactivated by molecular aggregation and/or oxidative self-destruction in the presence of H_2O_2. On the other hand, CoTPhsP stability and reactivity were improved when adsorbed and intercalated in the LDHs. $Mg_{3.0}Al(CoTPhsP)_{ads}$ is more active than $Mg_{2.8}Al(CoTPhsP)_{int}$ in the decomposition of hydrogen peroxide to H_2O and O_2. A porosity analysis carried out by N_2 adsorption-desorption experiments for the intercalated material exhibited a type-IV isotherm characteristic of nonmicroporous materials. Hence, the CoTPhsP molecules located in the LDH galleries are not acessible to the H_2O_2, while the metal centers in the $Mg_{3.0}Al(CoTPhsP)_{ads}$ sample are more available, which may explain the enhanced reactivity.

Introduction

The intercalation of guest species in crystalline layered host matrices is considered to be a versatile synthetic method for the synthesis of nanostructured hybrid materials. The intercalated materials are particularly attractive because different synthetic approaches provide routes to tune the material properties by mediating the chemical composition of the host matrices and the intercalated species.[1,2]

Among two-dimensional matrices, layered double hydroxides (LDHs) have been found to be an interesting system for intercalation of different species.[3,4] The LDH composition is represented by the general formula $[M^{II}_{(1-x)}M^{III}_{x}(OH)_2](A^{n-})_{x/n}\cdot zH_2O$, where A^{n-} is the interlayer anion and M^{II} and M^{III} are di- and trivalent metals, respectively, located in the positively charged brucite-like layers.[5] LDHs with different compositions can be synthesized by varying the nature of M^{II}, M^{III}, and A^{n-}. This versatility has allowed the isolation of LDH materials with varied functionalities, including their use as catalysts,[6] reinforced fillers in organic polymers,[7] ion-exchangers for environmental remediation,[8] and, more recently, as drug[9] and gene carriers.[10]

Synthetic metalloporphyrins are a well-known class of macrocyclic complexes that have been widely studied as catalysts for organic reactions based on their selective activity in catalyzed oxidations by heme enzymes such as, for example, cytochrome P-450 and peroxidases.[11] However, the reactivity of many synthetic metalloporphyrins is greatly reduced due to their molecular aggregation or oxidative self-destruction in the reaction media. In the presence of hydrogen peroxide these porphyrins are used for catalytic oxidation during important organic conversions due to the formation of a high-valent oxometal–porphyrin active complex.[11] Nevertheless, synthetic metalloporphyrins can lead to the undesired homolytic cleavage of H_2O_2 with generation of hydroxyl radical (Fenton-type reaction), which is a strong, nonselective oxidant of organic substrates and can decompose the metalloporphyrin.[12]

In order to overcome these disadvantages, synthetic metalloporphyrins have been immobilized in different inorganic and organic host networks.[13] In addition to the improved stability and reactivity of the metalloporphyrin catalyst, the immobilization in host matrices has been pointed out as an interesting route for their "heterogenization", facilitating the catalyst separation and recovery from the final reaction mixture.[14]

Sulfonated and carboxylated metalloporphyrins intercalated into LDHs have been prepared by several synthetic

routes, with various M^{2+} and M^{3+} ions and molar ratios in the LDH composition, and also with different transition metals in the porphyrin core.[15–22] Furthermore, nonmetallated anionic porphyrins have also been used to prepare intercalated LDHs.[23–25] These nanostructured hybrid materials have shown interesting properties as catalysts in organic conversions,[15,18,19] sensitizers in photochemical assemblies,[16] and asymmetric charge-carriers for the development of solar-energy conversion devices.[20]

We report in this work the synthesis of magnesium-aluminum LDHs containing [5,10,15,20-tetrakis(4-sulfonatophenyl)porphyrinato]cobalt(II) (CoTPhsP) through two synthetic routes: (i) the structure reconstruction of the calcined $Mg_{3.0}Al(OH)_{8.0}(CO_3)_{0.5}{\cdot}xH_2O$ pristine LDH in the presence of the anionic porphyrin (reconstruction method); (ii) adsorption of the anionic metalloporphyrin onto the external surfaces of the pristine LDH (Figure 1). To the best of our knowledge this is the first report regarding the synthesis and characterization of CoTPhsP adsorbed in a magnesium-aluminum LDH and its successful intercalation into the inorganic matrix by the reconstruction method. The isolated materials were characterized by X-ray diffraction (XRD), surface area and porosity analysis, thermogravimetry (TGA), scanning electronic microscopy (SEM), electron spin resonance (ESR), and infrared (IR) and electronic (UV/Vis) spectroscopy. In addition, the stability and longevity of the immobilized porphyrins (adsorbed and intercalated in the LDHs) were evaluated in the presence of hydrogen peroxide.

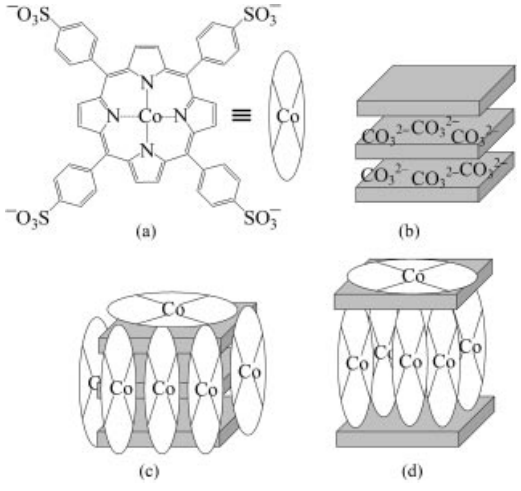

Figure 1. Schematic representation of CoTPhsP (a), $Mg_{3.0}Al\text{-}CO_3$ LDH (b) and idealized immobilization of CoTPhsP in the LDHs through adsorption (carbonate ions located between the layers are omitted for clarity) (c) or intercalation (d).

Results and Discussion

Materials Characterization

A typical XRD pattern was found for $Mg_{3.0}Al\text{-}CO_3$ prepared by coprecipitation (a profile similar to those presented by hydrotalcite-like compounds): sharp and symmetric peaks related to 00*l* reflections and broad and less symmetric peaks related to 0*kl* reflections (Figure 2a). The peaks were indexed in a hexagonal cell with rhombohedral symmetry, where c_0 = 23.4 Å and a_0 = 3.06 Å. From the c_0 parameter, which corresponds to three times the distance between adjacent layers, an interlayer distance of 7.80 Å could be calculated, which is typical for hydrotalcite-like materials containing carbonate anions.[26]

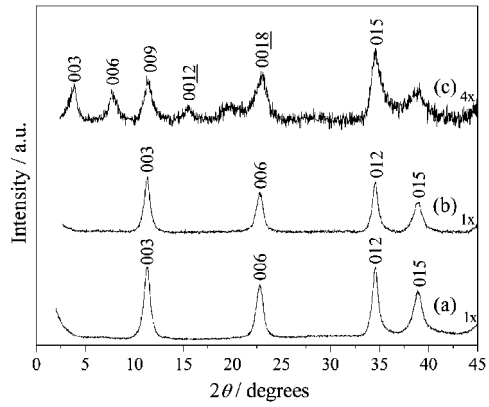

Figure 2. XRD patterns of $Mg_{3.0}Al\text{-}CO_3$ (a), $Mg_{3.0}Al(CoTPhsP)_{ads}$ (b), and $Mg_{2.8}Al(CoTPhsP)_{int}$ (c).

In relation to $Mg_{3.0}Al(CoTPhsP)_{ads}$ which contains the CoTPhsP adsorbed on the LDH external surfaces, the XRD pattern is identical to the $Mg_{3.0}Al\text{-}CO_3$ precursor (Figure 2b). This result shows, as expected, that the anionic porphyrin is not ion-exchanged with carbonate anions in the LDH.

The intercalated material isolated from the synthesis of $Mg_{2.8}Al(CoTPhsP)_{int}$ shows an XRD pattern different from the $Mg_{3.0}Al\text{-}CO_3$ precursor: a lower crystallinity and new peaks observed in the 2θ range 2.5–20° (Figure 2c).

Considering the same crystalline system used to assign the LDH precursor peaks, we find cell dimensions of c_0 = 70.2 Å and a_0 = 3.06 Å. The former corresponds to an interlayer distance of 23.4 Å. By comparing the interlayer distance between $Mg_{3.0}Al\text{-}CO_3$ and $Mg_{2.8}Al(CoTPhsP)_{int}$ one observes that the porphyrin incorporation expands the LDH layers by 15.6 Å. Moreover, by subtracting the LDH layer thickness (4.8 Å) from the interlayer distance, the gallery height of $Mg_{2.8}Al(CoTPhsP)_{int}$ is found to be equal to 18.6 Å, which is similar to the dimensions of the metalloporphyrin molecular plane (ca. 18 × 18 Å).[23] These results indicate that CoTPhsP has been successfully intercalated in a perpendicular orientation to the LDH layers. Such a perpendicular arrangement has been observed for LDHs intercalated with anionic metalloporphyrins[19,20] and nonmetallated anionic porphyrins,[23–25] using different synthetic methods.

Characterization by infrared spectroscopy indicates that CoTPhsP has been intercalated intact into the LDH. The IR spectra (not shown) of both neat and intercalated porphyrin exhibit similar characteristic absorption bands: 854, 885, and 1003 cm^{-1} (C–H pyrrole bending); 1290, 1348, and 1392 cm^{-1} (C–N stretching); 1495 and 1563 cm^{-1} (C–C

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

phenyl and pyrrole stretching, respectively); 1038, 1126, and 1186 cm^{-1} (sulfonic groups).[27] In the IR spectra of $Mg_{2.8}Al(CoTPhsP)_{int}$, we noticed some changes in the relative band intensities at 1330–1400 cm^{-1}. In this region, the minor changes are attributed to the carbonate ions present in the LDH interlayer (ν_3 vibrational mode of CO_3^{2-}).[28] The hydroxide anion may also be present in the material, as it is formed in the LDH interlayer when using the reconstitution method[29] during the CoTPhsP intercalation procedure. Hence, it is possible that $Mg_{2.8}Al(CoTPhsP)_{int}$ contains, in addition to the porphyrin, hydroxide anions co-intercalated.

We have reported in a previous work that the intercalation of macrocyclic species in LDHs can lead to composites with an appreciable thermal stability.[30] Moreover, the guest localization in the LDH results in materials with distinct thermal behavior. Similar results were found with the LDH containing intercalated CoTPhsP, according to the thermogravimetric curves of the samples shown in Figure 3.

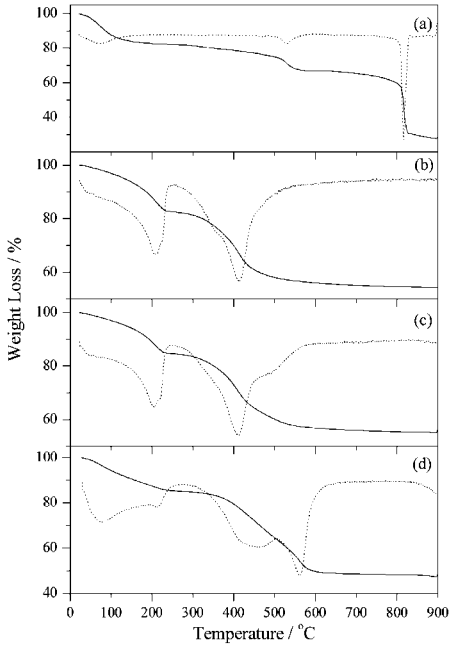

Figure 3. TGA (solid line) and DTG (dotted line) curves for CoTPhsP (sodium salt) (a), $Mg_{3.0}Al\text{-}CO_3$ (b), $Mg_{3.0}Al(CoTPhsP)_{ads}$ (c), and $Mg_{2.8}Al(CoTPhsP)_{int}$ (d).

The TG analysis of CoTPhsP shows a considerable thermal stability of the porphyrin (Figure 3a). A weight loss up to about 200 °C corresponds to the loss of hydration water. The porphyrin decomposition seems to occur in two steps. The first step is observed at about 490 °C and the second one starts at about 625 °C, with the main weight loss occurring at 815 °C. Figure 3b shows the TG curve for the LDH carbonate. The first step of weight loss (up to 210 °C) is ascribed to the water release and the second one (above 300 °C) to the LDH dehydroxylation and decarbonation, as discussed previously.[31]

The thermal behavior of $Mg_{3.0}Al(CoTPhsP)_{ads}$ up to around 600 °C can be interpreted as an overlap of TG curves for neat CoTPhsP and $Mg_{3.0}Al\text{-}CO_3$ (Figure 3c). Nevertheless, the weight loss observed for CoTPhsP above 625 °C is not present in the TG curve of the adsorbed CoTPhsP. The thermal behavior of $Mg_{2.8}Al(CoTPhsP)_{int}$ shows a higher stability towards decomposition of both the LDH matrix and CoTPhsP (Figure 3d). The dehydroxylation and decarbonation events seem to occur at about 330 °C, whereas the $Mg_{3.0}Al\text{-}CO_3$ LDH precursor decomposes at about 300 °C. The weight losses starting at 520 and 850 °C seem to be related to the decomposition of CoTPhsP, which suggests a higher stability than for neat CoTPhsP.

Textural characterization was performed by surface area and porosity measurements. $Mg_{3.0}Al\text{-}CO_3$ shows a surface area of 86 $m^2 g^{-1}$. For $Mg_{2.8}Al(CoTPhsP)_{int}$, the surface area of 34 $m^2 g^{-1}$ indicates that no micropores have been produced in the intercalation product as a substantial increase in the surface area compared to the LDH precursor would be expected if microporosity was present. This assumption was confirmed by N_2 adsorption-desorption isotherms of the sample. $Mg_{2.8}Al(CoTPhsP)_{int}$ exhibits type-IV isotherms (not shown) characteristic of nonmicroporous materials with a hysteresis loop indicating interparticle mesoporosity, according to the IUPAC classification.[32] We have previously observed similar results from the material isolated after intercalation of (phthalocyanine)Cu^{II} tetrasulfonate in the same LDH $Mg_{3.0}Al$ precursor.[30] $Mg_{3.0}Al(CoTPhsP)_{ads}$ shows a surface area of 106 $m^2 g^{-1}$. This increase in the surface area related to the $Mg_{3.0}Al\text{-}CO_3$ does not, however, indicate microporosity in the material. As described before, the interlayer space is occupied by the carbonate ions whereas CoTPhsP molecules are adsorbed on the external surface of the LDH.

Scanning electron micrographs obtained from the samples revealed a different morphology in the LDH after CoTPhsP intercalation by the reconstruction method (Figure 4). The SEM image of $Mg_{3.0}Al\text{-}CO_3$ presents a typical

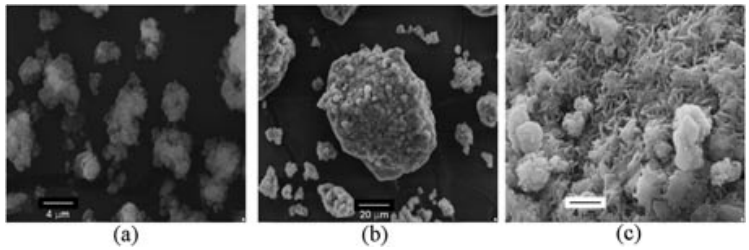

Figure 4. SEM images of $Mg_3Al\text{-}CO_3$ (10 000×) (a) and $Mg_{2.8}Al(CoTPhsP)_{int}$ with different magnifications: 2000× (b) and 10 000× (c).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

morphology expected for synthetic hydrotalcite-like compounds, with round particles of plate-like shapes (Figure 4a).

The adsorption of CoTPhsP on the external surface of the LDH layers results in a higher aggregation of the particles, which present the same morphology as observed for the LDH $Mg_{3.0}Al\text{-}CO_3$ (SEM image not shown). On the other hand, the intercalation of CoTPhsP into the LDH shows a distinct morphology (Figure 4b and Figure 4c). In the SEM images of $Mg_{2.8}Al(CoTPhsP)_{int}$ we observed a new phase with stick-like particles, and also particles with a plate-like shape.

Information about the electronic properties of free and immobilized CoTPhsP in the LDHs was obtained by recording the ESR and UV/Vis spectra of the samples. Figure 5 shows the UV/Vis spectra for CoTPhsP in different solutions.

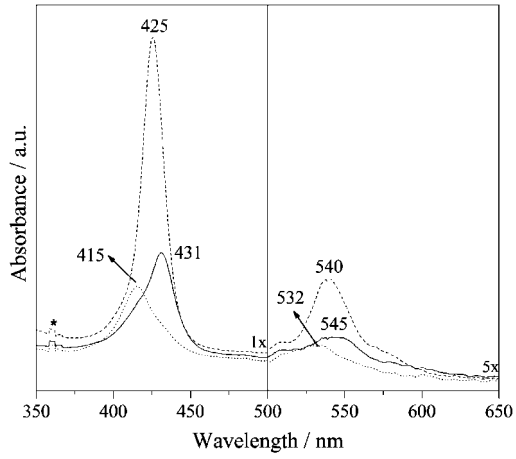

Figure 5. UV/Vis absorption spectra of 2 mmol L^{-1} CoTPhsP in aqueous solution (dashed line), in 90% DMF/10% water solution (solid line), and the latter solution after the addition of sodium dithionite (dotted line). Further details are provided in the text. The feature indicated by an asterisk is an instrument artifact.

The UV/Vis spectrum of CoTPhsP in aqueous solution shows the characteristic bands for metalloporphyrins, dominated by π-π* transitions, located at 425 nm (Soret band) and 540 and 580 nm (Q bands).[33] The presence of *N*,*N*-dimethylformamide (DMF), a coordinating solvent, results in a decrease in the intensity of both Soret and Q bands, accompanied by a small red shift (ca. 5 nm). The ESR spectra for 2 mmol L^{-1} CoTPhsP solutions were recorded for the assignment of the porphyrin species. An aqueous solution of this metalloporphyrin is ESR-silent, as previously reported in the literature.[34] The ESR spectrum of CoTPhsP in 90% DMF/10% water is shown in Figure 6a.

CoTPhsP is a low-spin Co^{II} complex with the single unpaired electron in the d_{z^2} orbital pointing out of the porphyrin plane.[35] This configuration makes the unpaired electron very sensitive to changes in the axial coordination of the metal ion, which makes the ESR technique useful for studying Co^{II}–porphyrins.[34–39] According to the literature,[34,36,39] CoTPhsP in water does not give an ESR signal

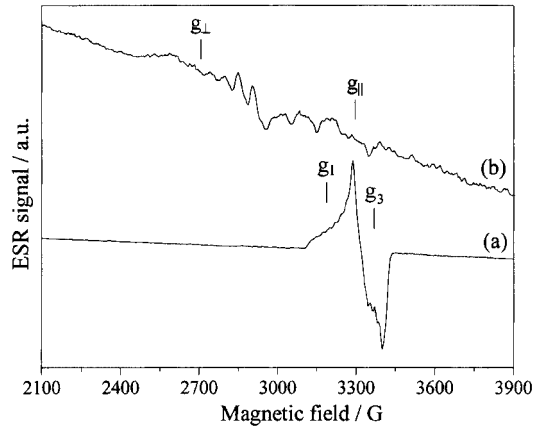

Figure 6. ESR spectra, recorded at 77 K, of 2 mmol L^{-1} CoTPhsP in 90% DMF/10% water solution (a) and after addition of sodium dithionite (b). Further details are provided in the text.

due to aggregation of the metalloporphyrin molecules and/or formation of a diamagnetic μ-peroxo complex with molecular oxygen (CoTPhsP–O_2–CoTPhsP). The addition of DMF causes deaggregation, resulting in a solution containing the monomeric species of the CoTPhsP. The resulting ESR spectra, as reported by de Bolfo et al.,[34] should present a characteristic signal with $g_{\|}$ = 2.040 ($A_{\|}$ = 95×10^{-4} cm^{-1}) and $g_{\perp}$ = 2.410 ($A_{\perp}$ = 43×10^{-4} cm^{-1}). In addition to the CoTPhsP monomeric species, a second ESR signal may be observed due to the complex formed by the metalloporphyrin with molecular oxygen (Co^{II}TPhsP–O_2) with g_1 = 2.088 (A_1 = 22×10^{-4} cm^{-1}), g_2 = 1.998 (A_2 = 8×10^{-4} cm^{-1}), and g_3 = 1.997 (A_3 = 16×10^{-4} cm^{-1}). The CoTPhsP–O_2 complex has also been detected for other cobalt–porphyrins.[35,39] The structure of this complex is also represented by Co^{III}TPhsP–O_2^- (superoxo complex) because the low values of hyperfine coupling in the ESR suggest that the unpaired electron resides primarily on the oxygen molecule.[37]

As shown in Figure 6a, the ESR spectrum for CoTPhsP in 90% DMF/10% water solution shows a signal at around 3300 G with g_1 = 2.090 (A_1 = 21.7×10^{-4} cm^{-1}) and g_3 = 1.997 (A_3 = 15.8×10^{-4} cm^{-1}) (g_2 factor and A_2 unresolved in the spectrum). This signal is attributed to the CoTPhsP–O_2 complex as the *g* factor and hyperfine-coupling values are in agreement with those reported by de Bolfo et al.[34] However, the monomeric ESR signal is not present in the spectrum of the CoTPhsP in solution. According to de Bolfo et al., a solid sample of CoTPhsP stored for a long time in air gives rise to an ESR spectrum showing only the CoTPhsP–O_2 signal, even when this stored sample was dissolved in aqueous solution containing different organic solvents.[34] Indeed, the CoTPhsP sample used in the present study was stored for more than six months without protection from atmospheric air. In an attempt to record the ESR spectra of the monomeric species, oxygen was removed from the 2 mmol L^{-1} CoTPhsP solution in 90% DMF/10% water solution by adding a small amount of sodium dithionite. Indeed, the ESR spectrum (Figure 6b) of this solution

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

did not show the CoTPhsP–O_2 signal and a new one appeared, which is related to the monomeric species, with $g_{\|}$ = 2.029 ($A_{\|}$ = 91.2×10^{-4} cm^{-1}) and $g_{\perp}$ = 2.455 ($A_{\perp}$ = 52×10^{-4} cm^{-1}). The UV/Vis spectrum of this deoxygenated CoTPhsP solution shows Soret and Q bands at 415 and 532 nm, respectively, with a blue shift in comparison to the spectrum for the solution containing the CoTPhsP–O_2 complex (Figure 5).

Based on the ESR spectra recorded for free CoTPhsP, we suggest that the UV/Vis absorption bands at 425 and 540 nm for the metalloporphyrin in aqueous solution can be assigned to the CoTPhsP–O_2–CoTPhsP complex, whereas in 90% DMF/10% water solution, the bands at 431 and 545 can be assigned to the CoTPhsP–O_2 complex. The bands observed at 415 and 532 nm, after addition of sodium dithionite to the latter solution, can be attributed to the CoTPhsP monomeric species. In light of these findings, $Mg_{3.0}Al(CoTPhsP)_{ads}$ and $Mg_{2.8}Al(CoTPhsP)_{int}$ were next examined by recording the UV/Vis (Figure 7) and ESR spectra (Figure 8) of these samples.

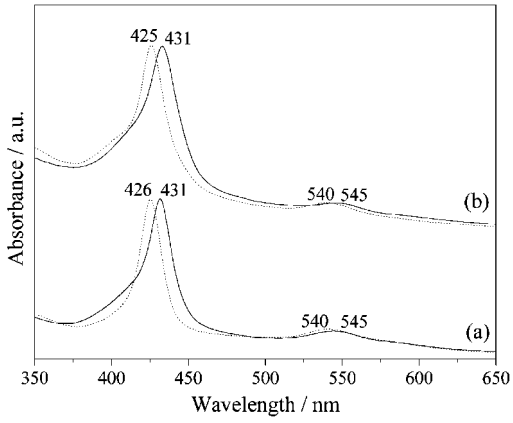

Figure 7. UV/Vis absorption spectra for $Mg_{2.8}Al(CoTPhsP)_{int}$ (a) and $Mg_{3.0}Al(CoTPhsP)_{ads}$ (b) solid samples dispersed in deionized water (dotted line) and 90% DMF/10% water solution (solid line).

The UV/Vis spectra for $Mg_{3.0}Al(CoTPhsP)_{ads}$ and $Mg_{2.8}Al(CoTPhsP)_{int}$ dispersed in deionized water and 90% DMF/10% water solution show a prominent broadening and a shoulder at around 410 nm in relation to neat CoTPhsP in the same solvents (Figure 5), although the Soret and Q band positions remain unchanged. Furthermore, the Soret band peak intensity decreases in relation to the Q band peak. Similar spectral profiles have also been observed in the electronic spectra of sulfonated metalloporphyrins[17,19–21] and nonmetallated sulfonated porphyrins intercalated in different LDHs,[23,24] which were ascribed to the aggregation of the porphyrin.[40,41] However, considering the ESR and UV/Vis spectra recorded for CoTPhsP in deionized water and in DMF/water solutions, we suggest that this broadening and the shoulder around 410 nm for the Soret band in $Mg_{3.0}Al(CoTPhsP)_{ads}$ and $Mg_{2.8}Al(CoTPhsP)_{int}$ are related to the different CoTPhsP species present in the LDHs. The main absorption bands are related to the CoTPhsP–O_2 complex (for dispersion in DMF/water) or the CoTPhsP–O_2–CoTPhsP species (for dispersion in water). The shoulder around 415 nm is due to the presence of monomeric species isolated in $Mg_{3.0}Al(CoTPhsP)_{ads}$ and $Mg_{2.8}Al(CoTPhsP)_{int}$. Indeed, these species were found in the powder ESR spectra for $Mg_{3.0}Al(CoTPhsP)_{ads}$ and $Mg_{2.8}Al(CoTPhsP)_{int}$ (Figure 8).

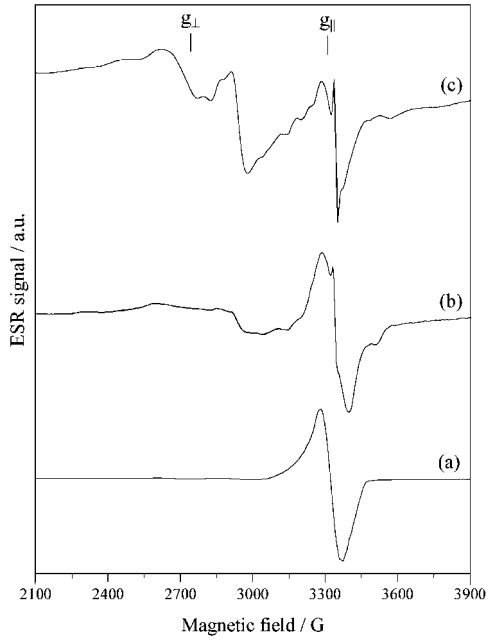

Figure 8. Powder ESR spectra, recorded at 77 K, of CoTPhsP (sodium salt) (a), $Mg_{3.0}Al(CoTPhsP)_{ads}$ (b), and $Mg_{2.8}Al(CoTPhsP)_{int}$ (c).

The ESR spectrum of CoTPhsP immobilized in the LDHs shows a resonance around 3300 G which is similar to that observed for neat CoTPhsP. As discussed before, this ESR signal is characteristic of the CoTPhsP–O_2 complex. Furthermore, a signal related to the monomeric species was also observed. The ESR spectrum of $Mg_{2.8}Al(CoTPhsP)_{int}$ shows a more resolved signal for this species with $g_{\|}$ = 2.043 ($A_{\|}$ = 90.5×10^{-4} cm^{-1}) and $g_{\perp}$ = 2.458 ($A_{\perp}$ = 52.6×10^{-4} cm^{-1}), in good agreement with the values found for CoTPhsP monomeric species in DMF/water solution, as reported by de Bolfo et al.[34] A narrow resonance at $g \approx 2.00$ has also been observed for other cobalt–porphyrins and attributed to a free-radical species[39] or impurities.[34,42] Comparing the relative intensities of the monomeric species and CoTPhsP–O_2 complex signals, $Mg_{2.8}Al(CoTPhsP)_{int}$ contains more CoTPhsP molecules in the monomeric form than the corresponding dioxygen complex. In contrast, the latter species is predominant in $Mg_3Al(CoTPhsP)_{ads}$.

The reactivity of the CoTPhsP complex in solution, intercalated, or adsorbed in the LDH was examined for the decomposition of hydrogen peroxide. Experimental curves of the oxygen released against time are given in Figure 9.

The curve of oxygen evolved obtained at 30 °C and pH = 9.60 (borate-buffered solution) shows a negligible reactivity for $Mg_{3.0}Al$-CO_3 (Figure 9a). The curve for CoTPhsP in homogeneous conditions reveals an oxygen release of 100 μL after 10 min, corresponding to 64% of the H_2O_2 used. Under heterogeneous conditions $Mg_{2.8}Al(CoTPhsP)_{int}$

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

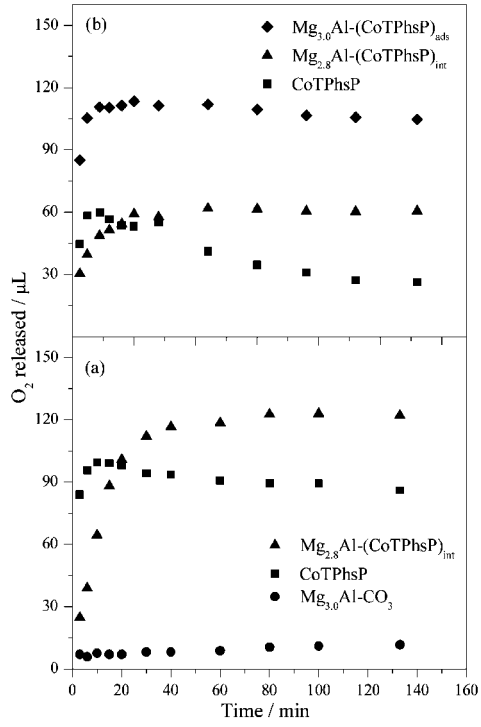

Figure 9. Experimental curves of oxygen released against time for hydrogen peroxide decomposition in the presence of CoTPhsP aqueous solution, $Mg_{3.0}Al$-CO_3, $Mg_{3.0}Al(CoTPhsP)_{ads}$, and $Mg_{2.8}Al(CoTPhsP)_{int}$ at 30 °C and pH = 9.60 (a) and 7.80 (b). Other conditions: 13.8 μmol of H_2O_2 and 3.62 μmol of CoTPhsP (a); 14.7 μmol of H_2O_2 and 7.50 μmol of CoTPhsP (b); final volume of 3.00 mL in borate-buffered solution.

was more active, converting 79% (123 μL) of the H_2O_2. In a second run, we obtained kinetic curves at pH = 7.80 (borate-buffered solution) and 30 °C (Figure 9b). Both CoTPhsP in homogeneous solution and $Mg_{2.8}Al(CoTPhsP)_{int}$ converted about 36% (ca. 60 μL) of the H_2O_2 used. The kinetic curve for $Mg_{3.0}Al(CoTPhsP)_{ads}$ is given in Figure 9b. As can be seen, this sample shows the best activity when compared to CoTPhsP in homogeneous conditions or intercalated into the LDH, converting about 69% (113 μL) of the H_2O_2.

In both pH = 9.60 and 7.80 buffered solution tests, the H_2O_2 decomposition reaction in the first minutes was faster in the presence of CoTPhsP in homogeneous conditions than $Mg_{2.8}Al(CoTPhsP)_{int}$. After this initial time, the CoTPhsP in solution was deactivated whereas the reaction for intercalated CoTPhsP proceeded. Furthermore, and different from $Mg_{2.8}Al(CoTPhsP)_{int}$ behavior, the H_2O_2 decomposition reaction in the presence of $Mg_{3.0}Al(CoTPhsP)_{ads}$ was faster than the CoTPhsP in solution even during the first few minutes of reaction. Finally, one expects a constant value of the released oxygen content after the maximum conversion, indicating the end of the reaction. However, we noticed a depletion of the oxygen evolved in the reaction with the CoTPhsP in homogeneous conditions.

It is well known that natural porphyrins undergo oxidative degradation by peroxides in the *meso* position.[43] The second generation of metalloporphyrin catalysts represented by *meso*-substituted porphyrins is considered less liable to oxidative degradation.[11] Nevertheless, our results indicate that CoTPhsP may be oxidized during the H_2O_2 decomposition reaction. This finding was corroborated by the UV/Vis spectra obtained from the homogeneous catalyst before and after the reaction. The spectrum (not shown) reveals a lower absorption intensity of the Soret band after the reaction. Another possibility for the oxygen depletion is the formation of an inactive μ-oxo complex (CoTPhsP–O–CoTPhsP) in the course of the H_2O_2 decomposition reaction.[11] Considering these paths for CoTPhsP deactivation in the presence of H_2O_2, it is evident that the metalloporphyrin stability is improved when immobilized in the LDHs. In consequence, the CoTPhsP reactivity is further enhanced.

In relation to the different reactivities observed between $Mg_{2.8}Al(CoTPhsP)_{int}$ and $Mg_{3.0}Al(CoTPhsP)_{ads}$, we consider that the CoTPhsP molecules intercalated in the LDH galleries cannot participate in the H_2O_2 decomposition because the intercalation compound is not microporous (N_2 adsorption-desorption isotherm). The active sites should therefore be the CoTPhsP molecules intercalated near the edge sites of the LDH galleries. However, the most important active sites are those located on the external surfaces of the LDH. The CoTPhsP molecules adsorbed on these sites are readily accessible for the H_2O_2 decomposition reaction. We have also observed this enhanced activity for (phthalocyanine)iron(III) tetrasulfonate adsorbed in Mg_xAl-CO_3 LDHs (x = 2, 3, and 4) in the oxidation of catechol.[44] This feature explains the better reactivity observed for $Mg_{3.0}Al(CoTPhsP)_{ads}$, which contains more available active sites than $Mg_{2.8}Al(CoTPhsP)_{int}$. Moreover, the adsorbed CoTPhsP shows a higher specific surface area (106 $m^2 g^{-1}$) than the intercalated material (34 $m^2 g^{-1}$), which further enhances the reactivity of CoTPhsP in the former.

These findings suggest the use of (tetrasulfonated porphyrin)cobalt immobilized in LDHs as heterogeneous catalysts for the conversion of organic substrates, using H_2O_2 as oxidant. This system is capable of decomposing H_2O_2 (catalase route), but oxidation reactions can be performed by stepwise addition of the oxidant to the system, which minimizes the H_2O_2 decomposition.[45] Additionally, peroxidation can be predominant or facilitated in the presence of an oxidizable substrate. The porphyrin immobilization in the LDH prevents rapid catalyst deactivation in the presence of the oxidant and provides easy catalyst recovery and re-use.

Conclusions

CoTPhsP has been successfully intercalated and adsorbed in $Mg_{3.0}Al$-CO_3 LDH. Infrared spectroscopy indicates that the metalloporphyrin structure is intact after its intercalation and adsorption in the LDHs. The intercalation of CoTPhsP into the LDH changes the crystallinity, thermal stability, and morphology of the resultant materials substantially in relation to the LDH-CO_3 precursor. The surface area and porosity analysis suggest that the material

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

containing the metalloporphyrin intercalated in LDH has no microporous structure. UV/Vis and electron spin resonance spectroscopy show that the metalloporphyrin immobilized in the LDHs is mainly present in two different forms: the complex formed with molecular oxygen (CoTPhsP–O_2) and the monomeric form (without the dioxygen coordinated).

CoTPhsP is more active and stable in the presence of hydrogen peroxide when the metalloporphyrin is intercalated or adsorbed in the LDHs. The metalloporphyrin adsorbed on the external surfaces of the LDH shows a higher reactivity than the intercalated LDH due to the greater number of active sites available in the former material. Studies involving these materials are underway to test their performance as catalysts for the oxidation of phenols.

Experimental Section

Materials: The reagents $Mg(NO_3)_2{\cdot}6H_2O$, $Al(NO_3)_3{\cdot}9H_2O$, and Na_2CO_3 were obtained from Aldrich. NaOH was obtained from Merck and 35% H_2O_2 (w/w) from Peroxidos do Brasil Ltda. (Tetrasulfonated porphyrin)Co^{II} was supplied by Mid Century. All reagents were used as received.

$Mg_{3.0}Al$-CO_3: The layered precursor containing carbonate ions with an Mg^{2+}/Al^{3+} molar ratio of 3 was prepared by co-precipitation of stoichiometric amounts of Mg^{2+} and Al^{3+} in the presence of CO_3^{2-} at pH = 10.0, as described elsewhere.[30] Chemical analysis confirmed the expected Mg^{2+}/Al^{3+} molar ratio of 3.0 and the water content, measured by TGA, of 3.2 H_2O molecules per Al^{3+} cation, which gives the following composition: $[Mg_{3.0}Al(OH)_{8.0}](CO_3)_{0.5}{\cdot}3.2H_2O$.

$Mg_{2.8}Al(CoTPhsP)_{int}$: The intercalation of CoTPhsP into the LDH was conducted as follows: $Mg_{3.0}Al$-CO_3 (1.0 g, 3.1 mmol) was calcined at 500 °C in air for 4 h; the mixed-metal oxide formed by the thermal decomposition of the LDH was suspended in CoTPhsP solution (130 mL, 4 mmol L^{-1}) using previously decarbonated deionized water, in a Teflon cup. The system was kept in a stainless-steel reactor at 80–85 °C under autogenous pressure for 8 d. The solid was isolated by centrifuging and then washed with decarbonated water until a colorless supernatant was observed. The solid was dried in a desiccator under vacuum with silica gel as drying agent. The following data were found from chemical analysis (C, H, N): C 15.3, H 4.47, N 1.22. Metal analysis indicated Mg^{2+}/Al^{3+} and Co^{2+}/Al^{3+} molar ratios of 2.80 and 0.09, respectively. The water content measured by TGA was equal to 3.2 H_2O molecules per Al^{3+} cation. The intercalated material contains 231 μmol of CoTPhsP per gram of material.

$Mg_{3.0}Al(CoTPhsP)_{ads}$: The CoTPhsP was adsorbed on the external surface of $Mg_{3.0}Al$-CO_3 by suspending it (1.0 g, 3.1 mmol) in CoTPhsP aqueous solution (150 mL, 4 mmol L^{-1}). The suspension was stirred at 80 °C for about 45 h. The sample was washed and dried as described for the intercalated material. Chemical analysis showed that the adsorbed material contains 107 μmol of CoTPhsP per gram of material.

Characterization Techniques: Powder XRD patterns of samples were recorded with a Rigaku diffractometer model Miniflex using Cu-K_α radiation (1.541 Å, 30 kV and 15 mA) and a step of 0.03°.

Specific area data (BET-N_2 method) were determined with a Quantachrome model Quantasorb sorption system after heating the samples at 200 °C under nitrogen gas flow for 2 h. Porosity analysis was determined from N_2 adsorption-desorption isotherms at liquid nitrogen temperature using a Micromeritics Asap 2010 instrument. Samples were heated at 200 °C under vacuum for 2 h before analysis. Scanning electron micrographs were recorded with an LEO 440i instrument using samples sputter-coated with carbon.

Elemental analysis (C, H, N) was performed with a Perkin–Elmer model 2400 analyzer. Magnesium, aluminum and cobalt contents in the LDH samples were determined with a Spectro Analytical Instruments ICP emission spectrometer. Thermogravimetric analysis (TGA) was carried out with a Shimadzu TGA-50 instrument under synthetic air (flow rate = 50 mL min^{-1}) at a heating rate of 10 °C min^{-1} up to 900 °C.

FT-IR spectra of samples in KBr matrix were recorded with a MIDAC model PRS-INT series 192 spectrometer or a Perkin–Elmer model 1750 spectrometer, in the range 4000–400 cm^{-1}. UV/Vis spectra were recorded with a Shimadzu model UV-2401PC spectrophotometer. For spectral acquisition of CoTPhsP solutions at high concentration (> 0.1 mmol L^{-1}), an aliquot of the solution (5 μL) was placed between two 1.25-mm-thick quartz rectangular windows (45 × 12.5 mm) and firmly fastened together in a holder for cells with detachable windows. Solid samples were dispersed in deionized water or water/DMF mixtures and the spectra recorded with the same spectrophotometer equipped with an integration sphere. ESR experiments were conducted with a Bruker ER 200D-SRC instrument, operating at X-band (ca. 9.5 GHz), and using DPPH (α,α-diphenyl-β-picrylhydrazyl) for calibration. Instrumental standard conditions for the measurements were: frequency = 9.48 GHz, microwave power = 20 mW, modulation frequency = 100 kHz, modulation amplitude = 15 G, at liquid nitrogen temperature (77 K).

Reactivity Tests with Hydrogen Peroxide: The reactivity and stability of the CoTPhsP in homogeneous conditions and immobilized in the LDHs towards hydrogen peroxide decomposition were evaluated by monitoring the released molecular dioxygen with a Warburg apparatus from B. Brown, model V-85, at a constant temperature (30 °C). The experiments were carried out at two different pHs in borate-buffered solutions (12.5 mmol L^{-1}). In the first run at pH = 9.60, CoTPhsP (0.30 mL of a 12.5 mmol L^{-1} solution), Mg_3Al-CO_3 (8.1 mg), and $Mg_{2.8}Al(CoTPhsP)_{int}$ (16.9 mg) were added to hydrogen peroxide (2.70 mL of a 5.12 mmol L^{-1} solution). In the second run at pH = 7.80, CoTPhsP (0.30 mL of a 25.0 mmol L^{-1} solution), $Mg_{2.8}Al(CoTPhsP)_{int}$ (34.7 mg) or $Mg_{3.0}Al(CoTPhsP)_{ads}$ (70.3 mg) were added to hydrogen peroxide (2.70 mL of a 5.44 mmol L^{-1} solution). Borate-buffered solution was used to complete the volume to 3.00 mL under the heterogeneous conditions. Each experiment was conducted in duplicate and the amounts of CoTPhsP were the same for both homogeneous and heterogeneous conditions. In order to certify that leaching of CoTPhsP was not taking place under the heterogeneous conditions, at the end of the tests, samples were taken and filtered through 0.22 μm disposable filters (Millipore). UV/Vis spectra of the filtered solutions were registered to check for the presence of free CoTPhsP, which was negative for all runs.

Acknowledgments

The authors are grateful to FAPESP and CNPq (Brazilian agencies) for financial support and fellowships. We also thank Dr. Antonio Carlos V. Coelho (EP-USP) for measuring the N_2 adsorption-desorption isotherms.

Intramolecular "CH···π(Metal Chelate Ring) Interactions" as Structural Evidence for Metalloaromaticity in Bis(pyridine-2,6-diimine)Ru^{II} Complexes

Yan-feng Jiang,[a] Chan-juan Xi,*[a] Yu-zhou Liu,[a] Juan Niclós-Gutiérrez,*[b] and Duane Choquesillo-Lazarte[b]

Keywords: Metalloaromaticity / Ruthenium / CH···π interaction / Chelates

The synthesis and structural characterization of two novel Ru^{II} complexes (**1** and **2)** with tridentate pyridine-2,6-diimine ligands are described. In both compounds, *ortho*-CH bonds from the phenyl or phenyl-like rings produce unexpected CH···π interactions with ruthenium-α,α′-diimine chelate rings. This insight is thought to provide new structural evidence for the metalloaromaticity of the chelate rings in the ruthenium complexes studied. The molecular geometry of complex **1** is remarkably similar to S_4 symmetrical geometry, which is also a consequence of the four CH···π(chelate ring) interactions working cooperatively. In contrast, there are only two pairs of these interactions working in complex **2** because of the steric effects and electronic influences caused by the methyl-group substitutions.

Introduction

CH···π interactions are the weakest hydrogen bonds that operate between a soft acid CH and a soft or intermediate base π system.[1] It has been recognized that this kind of weaker and softer interaction plays significant roles in various fields of chemistry such as crystal packing,[2] host–guest chemistry,[3] self-assembly,[4] and chiral recognition.[5] As it is nonpolar and effective in water, the CH···π interaction is also especially important in biological systems.[6] In this broad context, the soft base π system, which acts as a CH acceptor, is comprised not only of an organic moiety such as a double bond, a triple bond or a delocalized aromatic ring,[7] but also of a metal−chelate ring of suitable transition-metal complexes that has been reported recently.[8] Zarić and coworkers[8] have reported ample evidence of this phenomenon based on new data as well as on a broad view of structures available in the CSD database. This interesting work represents a remarkable effort towards the definition of structural parameters for the interaction between C–H polar bonds and the whole of a π(metal-chelate ring) system. The concept of "metalloaromaticity" was proposed a long time ago[9] and it is well known that a large variety of transition metal chelate rings feature this metalloaromaticity.[10] Now we report for the first time additional evidence for ruthenium(II) complexes in which the ruthenium−diimine chelate ring could act as a CH acceptor. In this paper we describe the synthesis and structural characterization of ruthenium(II) complexes bearing two 2,6-bis(phenylimine)-pyridine ligands. On the basis of the already known metalloaromaticity of ruthenium-α,α′-diimine chelate rings,[9] we report interesting and novel structural features concerning these 6N-coordinated complexes.

Results and Discussions

The tridentate 2,6-diimine-pyridine ligand, which was obtained by Schiff base condensation of 2 equiv. of aniline or 2,4-dimethyl-aniline with 2,6-diacetyl-pyridine,[11] reacted with $RuCl_3 \cdot 3H_2O$ in an ethanol/water (1:1) solution under reflux followed by anion exchange, to afford the 2:1 complex $[RuL^1{}_2][PF_6]_2$ (**1**) or $[RuL^2{}_2][PF_6]_2$ (**2**) (Scheme 1).

The asymmetric unit of compound **1** consists of a complex cation, two hexafluorophosphate anions, and one non-coordinated water molecule, as shown in Figure 1. The most noteworthy structural feature of complex **1** is that one *ortho*-H from each phenyl ring points towards the center of the corresponding ruthenium-α,α′-diimine chelate ring (Figure 2). Comprehensive analysis was carried out with the program PLATON,[13] and relevant structural parameters, defined as shown in Figure 3, are listed in Table 3. The H-ring centroid (H···Cg) and H···ring plane (H···⊥) distances are in the range of 2.79–3.00 Å and 2.79–2.95 Å, respectively, and the γ angles usually have values below 10°. These data are similar to those (H···Cg distance <3.0 Å and γ <12.5°) reported for CH···π interactions with chelate rings[8] and indicate that CH···π interactions occur between *ortho*-CH bonds and the whole of an electronically delocalized ruthenium chelate ring in complex **1**. The C–H···Cg angles, 125, 102, 103, and 108°, are still below the optimal value (180°) for the strongest CH···π interaction, which may be due to the steric constraints in the molecule. On the basis of the reported metalloaromaticity of benzoquinonediimine ruthenium complex,[10] this kind of CH···π(planar chelate ring) interaction in complex **1** is thought to be a new kind of structural evidence for the metalloaromaticity of such planar chelate rings.

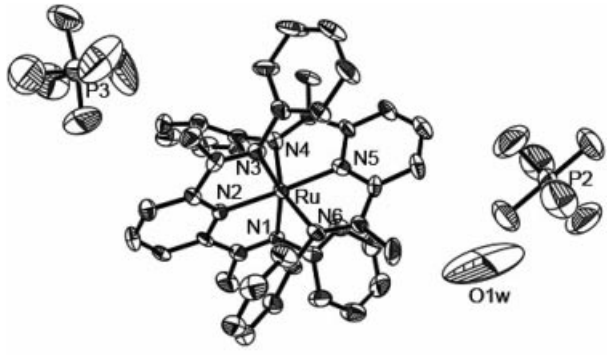

Figure 1. ORTEP drawing of compound **1** with thermal ellipsoids shown at the 30% level; hydrogen atoms were omitted for clarity.

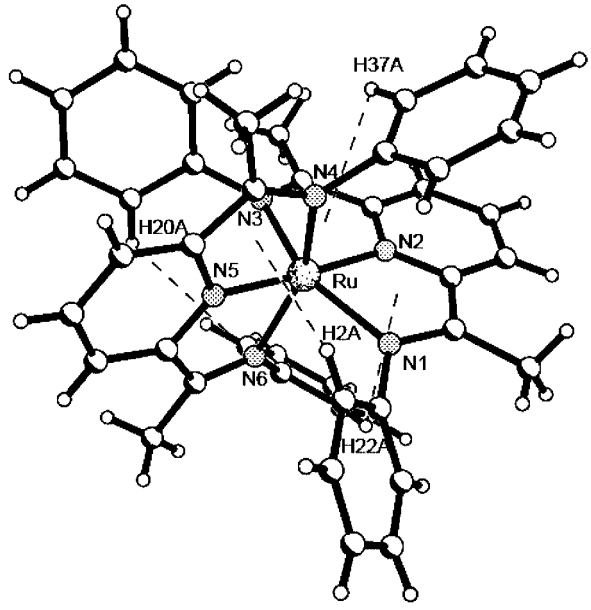

Figure 2. Four pairs of intramolecular "CH···(chelate ring)" interactions [C2H2A−(RuN4N5), C20H20A−(RuN5N6), C22H22A−(RuN1N2), and C37H37A−(RuN2N3)] work cooperatively in complex **1**.

Interestingly, it seemed that complex **1** belonged to a similar S_4 space group, but actually the complex ion $[RuL^1{}_2]^{2+}$ has a crystallographic C_1 symmetry, and the ruthenium atom has a slightly distorted octahedral geometry with *cis* angles at Ru^{II} of 77.2(3), 77.6(4), 92.5(3), 77.6(4), and

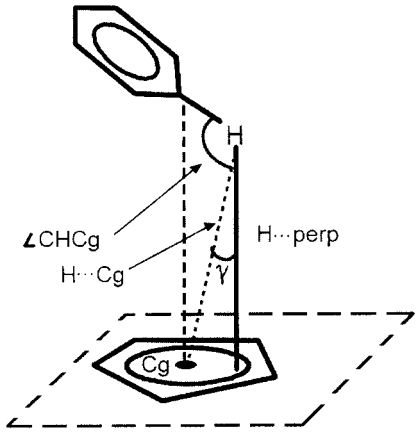

Figure 3. Cg is the centroid of the ruthenium chelate ring; γ is the angle defined by the H···Cg line and perpendicular H···(ring plane) line.

77.2(4)°. Geometry optimization calculations were carried out by the DFT method, and the result at the B3LYP/(LanL2DZ+3-21G*) level[14] proved that the optimized cation $[RuL^1_2]^{2+}$ indeed exhibited an S_4 space group, which may be a consequence of the four pairs of CH···(chelate ring) interactions working cooperatively.

It is also worth mentioning that the average distances of Ru–N(pyridine) bonds [1.961(8) Å] and Ru–N(imine) bonds [2.070(8) Å] in complex **1** are shorter than those reported [1.992(3) Å and 2.140(3) Å, respectively] for the ruthenium complex with a tridentate pyridine-2,6-diimine ligand.[15] It is strongly suggested that the compact and stable structure of **1** is achieved by a cooperation of intramolecular CH···π interactions.[8]

The crystal structure of complex **2** seems to be more complicated and asymmetrical because of the 2- and 4-substituted methyl groups in the phenyl-like rings, as shown in Figure 4. However, the existence of one *ortho*-H per phenyl-like ring in $\mathbf{L^2}$ could enable the formation of intramolecular CH···π interactions similar in nature to those found in complex **1**, but limited to two pairs of CH···(ruthenium-α,α′-diimine chelate ring) interactions, as shown in Figure 5. The difference between complexes **1** and **2** is attributed to the interligand steric repulsions and the electronic effects caused by the additional methyl groups.[1]

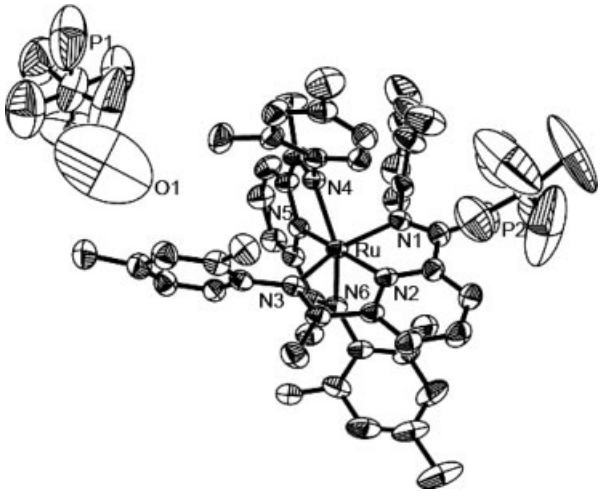

Figure 4. ORTEP drawing of complex **2** with thermal ellipsoids shown at the 30% level; hydrogen atoms were omitted for clarity.

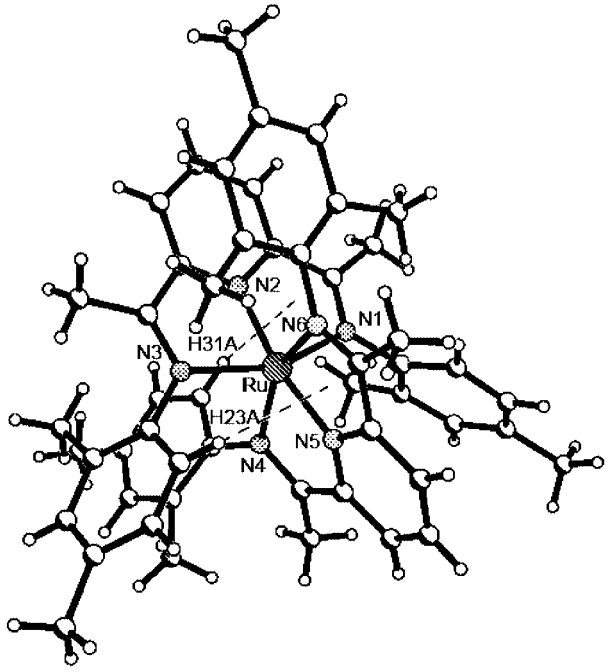

Figure 5. Only two pairs of intramolecular "CH···(chelate ring)" interactions [C23H23A−(RuN5N6) and C31H31A−(RuN1N2)] work cooperatively in complex **2**.

Conclusions

Intramolecular CH···π(chelate ring) interactions between ligand-aryl C–H bonds and ruthenium(II)-α,α′-diimine chelate rings are observed by X-ray crystal structural analysis of complexes **1** and **2**. To the best of our knowledge, this is the first time that these intramolecular CH···π(chelate ring)

Table 3. Intramolecular "CH···π(chelate ring)" interaction parameters for complexes **1** and **2**.

	CH-chelate ring	H···Cg [Å]	H···(ring plane) [Å]	C–H···Cg [°]	Γ [°]
C1	C2H2A−(RuN4N5)	2.79	2.79	125	2.67

interactions are used to feature the metalloaromaticity of such Ru^{II}-α,α′-diimine chelate rings.

Experimental Section

General: ^1H, ^{13}C NMR spectra were recorded with a JOEL JNM-ECA300 spectrometer. IR spectra were recorded with an AVATAR FTIR ESP spectrophotometer. ESI-MS spectra were obtained with a Bruker Esquire-LC/MSn spectrometer. Elemental analyses were carried out with a FlashEA1112 microanalyzer. The starting material $RuCl_3·3H_2O$ was purchased from Aldrich; the ligands 2,6-bis{1-(phenylimine)ethyl}pyridine (**L¹**) and 2,6-bis{1-[(2,4-dimethylphenyl)imine]ethyl}pyridine (**L²**) were prepared according to the literature method.[11]

Preparation of $[RuL^1_2][PF_6]_2$: A solution of **L¹** (156 mg, 0.498 mmol) and $RuCl_3·3H_2O$ (50 mg, 0.241 mmol) in ethanol/water (1:1) (20 mL) was refluxed under nitrogen for 24 h until the solution became red or purple. After cooling, the insoluble materials were removed by filtration, and the complex was precipitated by the addition of saturated KPF_6 aqueous solution (5 equiv.). The complex was purified by chromatography on silica gel. It was eluted with CH_3CN/H_2O (25:1). The second fraction afforded $[RuL^1_2][PF_6]_2$ as an orange solid (76 mg, 31%). ESI-MS: *m*/*z* (%) = 364 $\{M - 2PF_6\}^{2+}/2$. $C_{42}H_{38}F_{12}N_6P_2Ru·H_2O$ (M_r = 1035.81): calcd. C 48.70, H 3.89, N 8.11; found C 48.66, H 4.05, N 7.96. ^1H NMR ([D$_3$]acetonitrile): δ = 2.61 (s, 12 H, CH_3), 6.39 (d, ^3J(H,H) = 6.54 Hz, 8 H, aromatic protons), 7.20 (m, 12 H, aromatic protons), 7.92 (t, 2 H, py), 8.11 (d, ^3J(H,H) = 7.92 Hz, 4 H, py). ^{13}C NMR ([D$_3$]acetonitrile): δ = 18, 120, 128, 130, 134, 144, 154, 177. IR (KBr): $\tilde{\nu}$ = 3420 (O–H), 1697 (C=N), 846 cm^{-1} (P–F).

Preparation of $[RuL^2_2][PF_6]_2$: A solution of **L²** (146 mg, 0.395 mmol) and $RuCl_3·3H_2O$ (40 mg, 0.193 mmol) in ethanol/water (1:1) (20 mL) was refluxed under nitrogen for 48 h until the solution became red or purple. After cooling, the insoluble materials were removed by filtration, and the complex was precipitated by the addition of saturated KPF_6 aqueous solution (5 equiv.). The complex was purified by chromatography on silica gel. It was eluted with CH_3CN/H_2O (25:1). The second fraction afforded $[RuL^2_2][PF_6]_2$ as an orange−red solid (34 mg, 16%). ESI-MS: *m*/*z* (%) = 420 $\{M - 2PF_6\}^{2+}/2$. $C_{50}H_{56}F_{12}N_6O_{0.50}P_2Ru$ (M_r = 1140.02): calcd. C 52.68, H 4.95, N 7.37; found C 53.07, H 4.99, N 7.82. ^1H NMR ([D$_3$]acetonitrile): δ = 2.22–2.07 (m, 30 H), 2.65 (s, 6 H), 5.29–5.36 (m, 1 H), 5.77–6.11 (m, 3 H), 6.44 (m, 1 H), 6.57–6.85 (m, 7 H), 7.84–7.94 (m, 2 H), 7.95 (t, 2 H), 8.38–8.41 (m, 2 H). ^{13}C NMR ([D$_3$]acetonitrile): δ = 14, 16, 19, 29, 121, 123, 127, 128, 132, 134, 138, 145, 154, 174, 178. IR (KBr): $\tilde{\nu}$ = 3421 (O–H), 1635 (C=N), 841 cm^{-1} (P–F).

Acknowledgments

We thank the National Natural Science Foundation of China (20172032) (20372041) for supporting this work. We also thank Dr. Biao Wu (Institute of Chemistry, Chinese Academy of Sciences) for his help in the measurement of crystals. We are grateful to Prof. Guoshi Wu (Department of Chemistry, Tsinghua University) for his help in some of the calculations.

1,1′-Bis(oxazolin-2-yl)ferrocenes: An Investigation of Their Complexation Behavior toward $[Pd(\eta^3\text{-allyl})Cl]_2$

Christian G. Hartinger,*[a] Alexey A. Nazarov,*[a] Vladimir B. Arion,[a] Gerald Giester,[b] Maxim L. Kuznetsov,[c] Markus Galanski,[a] and Bernhard K. Keppler*[a]

Keywords: Asymmetric catalysis / Density functional calculations / Mass spectrometry / Metallocenes / Palladium

The coordination behavior of several aryl- and alkyl-bis(oxazolinyl)ferrocenes, which were prepared in high yields from ferrocene-1,1′-dicarbonyl dichloride and enantiomerically pure or racemic amino alcohols via the corresponding bis(β-hydroxyamide)s and dimesylates or ditosylates as intermediates, toward $[Pd(\eta^3\text{-allyl})Cl]_2$ was investigated by ESI mass spectrometry. The synthesized compounds were characterized by NMR spectroscopy and elemental analysis and the molecular structures of 1,1′-bis[(*R*)-4-isopropyloxazolin-2-yl]-ferrocene (**6b**), 1,1′-bis[(*S*)-4-isopropyloxazolin-2-yl]ferrocene (**7b**), 1,1′-bis[(*S*)-4-*sec*-butyloxazolin-2-yl]ferrocene (**11b**), 1,1′-bis[(*S*)-4-*tert*-butyloxazolin-2-yl]ferrocene (**12b**), 1,1′-bis[(*R*)-4-phenyloxazolin-2-yl]ferrocene (**13b**), and 1,1′-bis[(*S*)-4-phenyloxazolin-2-yl]ferrocene (**14b**) were determined by single-crystal X-ray diffraction analysis. The coordination behavior studies by ESI-MS show a strong preference for monodentate complex formation. This result is supported by theoretical studies carried out at the B3LYP level of theory. It was found that the latter coordination type of 1,1′-bis[(*S*)-4-methyloxazolin-2-yl]ferrocene (**1b**) to an allylpalladium moiety is kinetically favored over the bidentate one.

Introduction

Oxazolines are an intensively studied class of compounds. These five-membered heterocycles are found in natural metal chelators,[1–3] show interesting biological properties,[4,5] and also play an important role in synthesis[6–10] as well as have a remarkable range of applicability. Their uses vary widely from organic[6–8] and coordination chemistry,[9,10] via polymer chemistry,[11–13] to antiacaricide as well as antiinsecticidic purposes.[14] Oxazolines are used in a manifold variety of catalytic processes, for example hydrosilylation,[15] transfer hydrogenation,[16] allylic substitution,[17] allylic oxidation,[18] aziridination of olefins,[19] aziridination of imines,[20] cyclopropanation,[21–23] and the Diels–Alder reaction.[24] Furthermore, it should be noted that there is a great interest in oxazolines as they possess interesting properties in asymmetric synthesis when coordinated to transition metals.

Beside the natural occurrence of oxazolines, there are several methods that are useful for constructing the oxazoline or 4,5-dihydrooxazole moiety in the laboratory (for reviews see refs.[6,7,11]): the dehydration and ring formation of some carboxamides, for example hydroxy amides, the reaction between halo carboxamides and strong bases, as well as the addition of oxiranes to nitriles and of amino alcohols to carboxylic acids or imino esters offer a synthetic pathway to build up the required five-membered heterocycle. Lately, coordination-chemistry-driven approaches have moved into the focus of synthetic chemists' interest,[25,26] and the addition of haloalcohol/base or oxirane/chloride systems to Pt^{II}-bound nitrile,[27,28] and reactions between nitriles and amino alcohols catalyzed or mediated by a variety of metal ions, for example Zn^{II}, Cd^{II}, Ni^{II}, Al^{III}, Co^{II}, Cu^{II}, show high potential for the assembly of the oxazoline system.[29–32]

An impressive number of reports and essays show the applicability but also the popularity of ferrocene and its derivatives in many fields of organic, materials, synthetic, and also medicinal chemistry,[33–37] and the use of substituted ferrocenes in metal-catalyzed enantioselective synthesis has been a very important application for more than twenty years. Herein chiral ferrocene derivatives are involved which either bear the center of chirality on a substituent or contain an element of planar chirality.[38]

The combination of the coordinating oxazoline structure, which is easily obtainable (also in an enantiomerically pure form) from reactions involving nonracemic starting materials, such as α-amino alcohols, and ferrocene (with the possibility to introduce planar chirality) has led to the develop-

ment of compounds containing both moieties, i.e., ferrocene and an oxazolinyl moiety.[39–43] This method offers a straightforward way to synthesize chiral ferrocene derivatives which are, due to their distinct structural features, applicable in asymmetric synthesis. Surprisingly, Ahn et al. have reported a lack of catalytic activity for 1,1′-bis[(*S*)-4-*tert*-butyloxazolin-2-yl]ferrocene (**12b**) in the palladium-catalyzed allylic alkylation, while there are many examples of non-metallocene complexes with bisoxazoline ligands that give high enantiomeric excesses and turnover rates.[17,44–48]

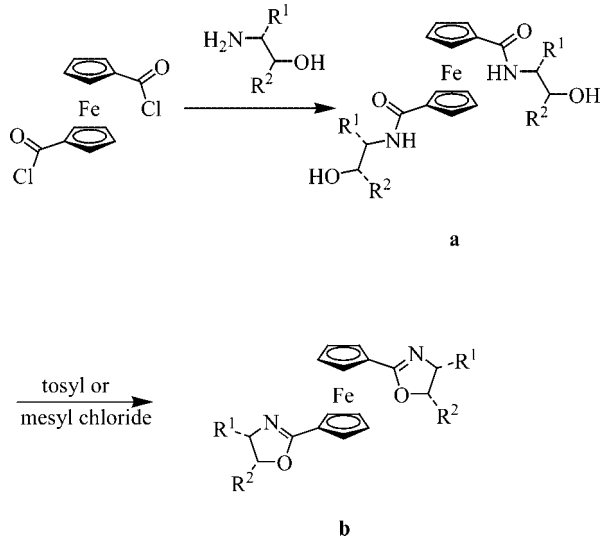
Electrospray ionization mass spectrometry (ESI-MS) is the softest desorption/ionization method, and its suitability to determine the coordination behavior of transition metal cations toward ligands has been studied extensively (for examples see refs.[49–52] and for a review see ref.[53]). The desolvation process mainly leads to the presence of ions in the gas phase that are also found in solution.[54] ESI-MS has a number of advantages over other techniques; in particular, it provides information on the characteristic isotopic patterns of compounds (especially metal compounds) and allows low sample consumption and use of many compatible solvents.[49]

In order to clarify the influence of the nature of the substituents on the catalytic potential of 1,1′-bis(oxazolin-2-yl)ferrocenes, several derivatives of the parent compound 1,1′-bis[(*S*)-4-*tert*-butyloxazolin-2-yl]ferrocene (**12b**) were synthesized and tested with respect to their catalytic potential in asymmetric allylic substitution, where the catalytic activity depends strongly on the formation of chelate structures between multidentate ligands and transition metals.[55,56] The coordination behavior of new 1,1′-bis(oxazolin-2-yl)ferrocenes bearing alkyl (**1b**, **7b**, and **12b**) or aryl substituents (**14b**) in the 4-position of the oxazoline ring toward $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$ was studied in detail by ESI-MS. In order to elucidate the energetic preference for the coordination of 1,1′-bis[(*S*)-4-methyloxazolin-2-yl]ferrocene (**1b**) to an allylpalladium moiety, DFT calculations at the B3LYP level of theory were also carried out.

Results and Discussion

Synthesis

The oxazolines bearing alkyl and aryl substituents at the 4- and/or 5-position of the oxazoline residue (see Scheme 1 and Table 1) were synthesized by a condensation reaction of 1,1′-ferrocenedicarbonyl dichloride with the corresponding α-amino alcohols at room temperature, followed by a ring-closing procedure with either methanesulfonyl chloride and triethylamine or *p*-toluenesulfonyl chloride, triethylamine and a catalytic amount of 4-(dimethylamino)pyridine at 0 °C.[41,57–62] The yield for the syntheses of the methyl- and aryl-substituted compounds was higher when using *p*-toluenesulfonyl chloride, and the methyl and diphenyl amides that precipitated during the synthesis were obtained in high purity by filtration. All oxazolines and other amides were isolated by flash column chromatography on silica gel using a mixture of ethyl acetate and *n*-hexane as eluent.



Scheme 1. General scheme for the synthesis of the 1,1′-bis-(oxazolin-2-yl)ferrocenes.

Table 1. List of the synthesized 1,1′-bis(oxazolin-2-yl)ferrocenes.

	Substituents		Tosyl/mesyl chloride	
	R^1	R^2	tosyl	mesyl

NMR spectroscopy was found to be a useful tool to follow the ring-closing process, i.e., the transformation from hydroxy amides to oxazolines. This process is marked in the ^{1}H NMR spectrum by the disappearance of the protons of the hydroxy and amide groups and in the ^{13}C NMR spectrum by a characteristic high-field shift from about δ = 170 to 166 ppm of the CO group, as well as by low-field shifts of the primary (for **2**, **15**, and **18**) or secondary amino alcohol carbon atoms from about δ = 64 ppm to about δ = 73 ppm [with the exception of **8** (from ca. δ = 52 to 73 ppm) and **18** (from ca. δ = 75 to 79 ppm] as well as of the amino alcohol carbon atoms next to the nitrogen from about δ = 50 to about 69 ppm (with the exception of **18**: from approximately δ = 60 to 89 ppm).

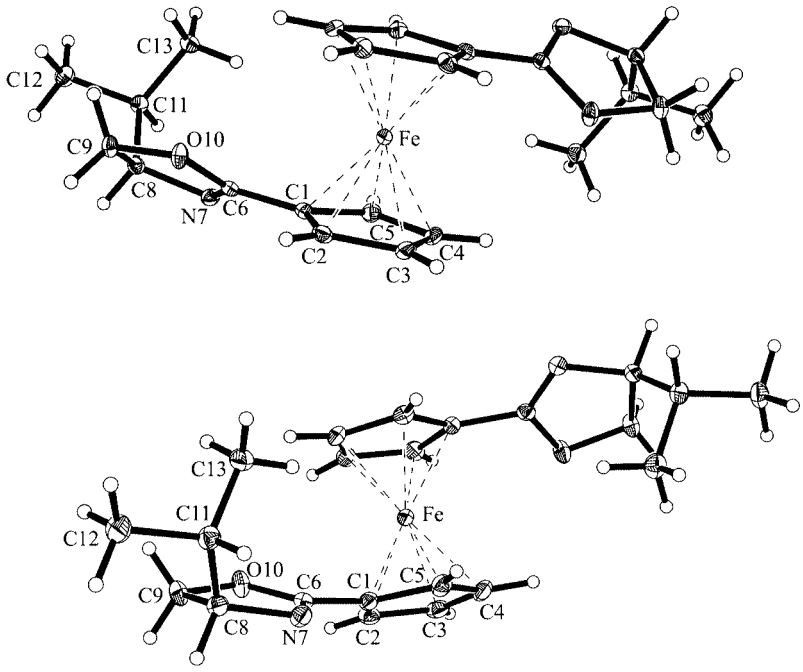

Figure 1. The molecular structure and labeling scheme of 1,1′-bis[(*R*)-4-isopropyloxazolin-2-yl]ferrocene (**6b**; top) and 1,1′-bis[(*S*)-4-isopropyloxazolin-2-yl]ferrocene (**7b**; bottom) with displacement ellipsoids drawn at the 50% probability level.

The syntheses of hydroxy amides as well as of the corresponding oxazolines with (*S*)-isopropyl, (*S*)-*tert*-butyl,[41] and (*S*)-phenyl moieties[39] in the 4-position of the oxazoline moiety have been reported earlier, but no crystal structure data were published. The synthesis of the 1,1′-ferrocenedicarboxamide **6a** has been reported, but no analytical data were presented.[42]

Crystal Structure Analysis

Crystal structure analysis has been performed to elucidate the influence of different substituents, viz., isopropyl, phenyl, *sec*- and *tert*-butyl, at oxazoline rings on the torsional twist angle of the Cp rings around the iron atom.

The results of the X-ray diffraction study of **6b** and **7b**, which crystallized as pure enantiomers in the noncentrosymmetric C_2 space group, are summarized in Figure 1. The asymmetric unit consists of one half of the molecule in **6b** and **7b**. The C8 atom in **6b** and **7b** possesses an (*R*) and (*S*) absolute configuration, respectively. The Cp rings in **6b** and **7b** approach an anticlinal eclipsed arrangement with a torsional twist angle Cp···Fe···Cp of 140.0° and 138.3°, respectively. The Cp rings are almost parallel to each other, the dihedral angles being 2.2° (**6b**) and 2.3° (**7b**). The orientation of the oxazoline ring with respect to the Cp ring can be characterized by the torsion angle C2–C1–C6–O10, which is 28.1° and –28.0° in **6b** and **7b**, respectively. The distribution of the electron density in the 4-isopropyloxazoline fragments in both **6b** and **7b** is very similar (see Table 2). The bond lengths and angles in the ferrocene moiety in both complexes are normal.[39]

Table 2. Selected bond lengths [Å] and angles [°] in **6b**, **7b**, **11b**, and **12b**.

	6b	7b	11b	12b
C1–C6	1.4685(18)	1.468(2)	1.479(8)	1.458(4)
C6–N7	1.2643(18)	1.264(2)	1.259(8)	1.265(3)
C6–O10	1.3641(17)	1.364(2)	1.345(8)	1.361(3)
N7–C8	1.4854(17)	1.487(2)	1.481(8)	1.474(4)
C8–C9	1.5397(19)	1.538(2)	1.520(9)	1.534(4)

C11–C12	1.5314(19)	1.534(2)	1.466(14)	1.511(4)
C11–C13	1.5312(17)	1.533(2)	1.586(12)	1.517(5)
N7–C8–C9	103.97(11)	103.95(13)	104.8(5)	104.1(2)
N7–C8–C11	110.08(11)	110.03(13)	110.8(6)	111.8(2)
C9–C8–C11	116.23(12)	116.36(15)	116.8(6)	115.5(2)

Like **6b** and **7b**, complex **11b** crystallizes as the (*S*)-enantiomer in the noncentrosymmetric $C222_1$ space group (see Figure 2 top) and the asymmetric unit consists of half the molecule. The Cp rings in **11b** adopt an antiperiplanar (staggered) arrangement with a torsional twist angle Cp···Fe···Cp of 176.5°. The Cp rings are almost parallel to each other, with a dihedral angle of 1.6°. The oxazoline ring is almost parallel to the Cp ring. The torsion angle C2–C1–C6–O10 is 3.2°. Like **11b**, complex **12b** crystallizes as the (*S*)-enantiomer in the noncentrosymmetric $C222_1$ space group (see Figure 2 bottom) and the asymmetric unit consists of half the molecule. The Cp rings in **12b** adopt an antiperiplanar (staggered) arrangement with a torsional twist angle Cp···Fe···Cp of 174.9°. The Cp rings are almost parallel to each other, with a dihedral angle of 0.4°. The oxazoline ring is almost parallel to the Cp ring. The torsion

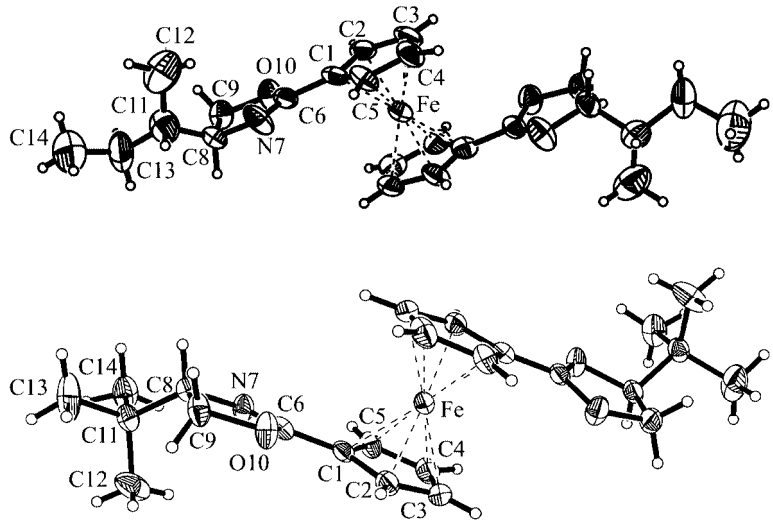

Figure 2. The molecular structure and labeling scheme of 1,1′-bis[(*S*)-4-*sec*-butyloxazolin-2-yl]ferrocene (**11b**; top) and 1,1′-bis[(*S*)-4-*tert*-butyloxazolin-2-yl]ferrocene (**12b**; bottom) with displacement ellipsoids drawn at the 50% probability level.

angle C2–C1–C6–O10 is 8.1°. Selected bond lengths and angles of **11b** and **12b** are given in Table 2.

Figure 3 shows one of the two independent molecules in the crystal structures of **13b** (*R*) and **14b** (*S*). Like in all previous compounds, the ferrocene moiety shows the expected geometry, with no unusual bond lengths or angles. The two Cp rings are almost parallel to each other, with dihedral angles of 4.5° and 2.0° in the two independent molecules of **13b** and 4.4° and 2.0° in **14b**. The Cp···Fe···Cp torsional twist angle is 54.2° and 52.9° for the independent molecules in **13b**, and –54.2° and –53.0° in **14b**, thus indicating a conformation between synclinal staggered (ideal twist angle of 36°) and synclinal eclipsed (ideal twist angle of 72°). As in **12b**, the oxazoline rings are almost parallel to the Cp rings, the torsional angles C2–C1–C6–O10, C18–C17–C22–O26 and C34–C33–C38–O42, C50–C49–C54–O58 being 6.1°, –11.5° and 4.7°, –3.6° in **13b** and –6.6°, 11.4°, –4.2°, 3.3° in **14b** (see Table 3 for selected bond lengths and angles).

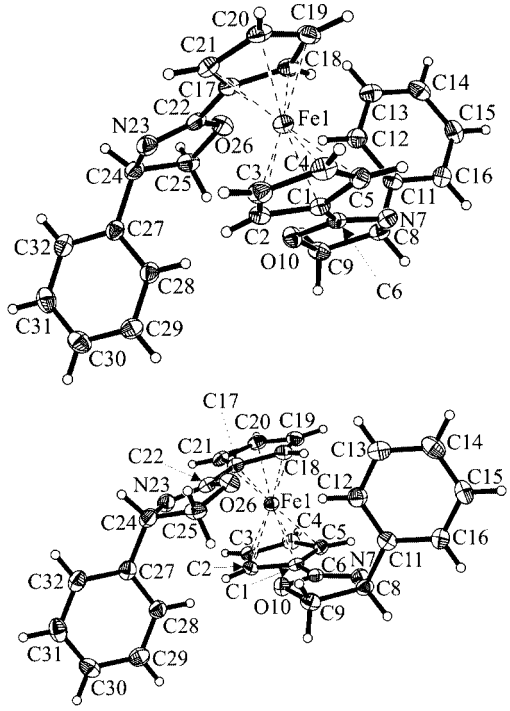

Figure 3. The molecular structure and labeling scheme of 1,1′-bis[(*R*)-4-phenyloxazolin-2-yl]ferrocene (**13b**; top) and 1,1′-bis[(*S*)-4-phenyloxazolin-2-yl]ferrocene (**14b**; bottom) with displacement ellipsoids drawn at the 50% probability level.

Investigation of the Coordination Properties

The application of bisoxazoline-based ligands in palladium-catalyzed allylic alkylation and in many other metal-catalyzed enantioselective reactions is well known.[9,17,44–48] Therefore the results of a study done by Ahn and co-workers, who found no catalytic activity for 1,1′-bis[(*S*)-4-*tert*-butyloxazolin-2-yl]ferrocene (**12b**), is rather surprising, although the ligand does bear a bulky *tert*-butyl group.

The catalytic potential of the ligands applied depends on several structural features, especially the bite angle and the bulkiness of the substituents. In order to study the influence of the substituents nature and of their bulkiness, a series of analogues was synthesized and their catalytic potential in the asymmetric allylic substitution investigated. The experiments were carried out with palladium complexes generated in situ by stirring the corresponding chiral ligand and $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$ under standard conditions, i.e., (*E*)-1,3-diphenylprop-2-enyl acetate as substrate and dimethyl malonate as nucleophile with the *N*,*O*-bis(trimethylsilyl)acetamide base system (BSA-KOAc; see Scheme 2).[63] In agreement with the results of Ahn and co-workers, we did not observe any catalytic activity for any of the synthesized compounds. The variation of the ligand/Pd ratio from 1:1 to a large excess of the Pd compound (up to 10 times excess) did not affect the catalytic activity, and all efforts to isolate a defined Pd complex were unsuccessful.

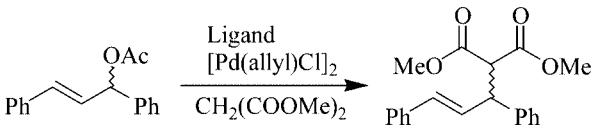

Scheme 2. General scheme for the palladium-catalyzed allylic alkylation.

In order to investigate the reasons for this lack of catalytic activity, the coordination of $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$ toward several 1,1′-bis(oxazolin-2-yl)ferrocenes was studied by ESI-MS in the positive-ion mode (for calculated *m*/*z* ratios of the parent compound and the expected adducts see Table 4). The incubation solution of the Pd complex and the oxazoline ligand was injected directly into the mass spectrometer and the MS measurement parameters were optimized in order to maximize signals corresponding to the mass-to-charge ratio of the ligands (see Table 5).

Table 4. List of the calculated *m*/*z* ratios for the ligands and for the complexes formed with $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$ (measured in positive-ion mode).

	Formula	*m*/*z* ratio
1b	$[C_{18}H_{20}FeN_2O_2 + H]^+$	353
1b + $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$	$[C_{18}H_{20}FeN_2O_2 + Pd(\eta^3\text{-}C_3H_5)]^+$	499
1b + $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$	$[C_{18}H_{20}FeN_2O_2 + PdCl]^+$	495
1b + $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$	$[C_{18}H_{20}FeN_2O_2 + Pd_2(\eta^3\text{-}C_3H_5)_2Cl]^+$	683
7b	$[C_{22}H_{28}FeN_2O_2 + H]^+$	409
7b + $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$	$[C_{22}H_{28}FeN_2O_2 + Pd(\eta^3\text{-}C_3H_5)]^+$	555
7b + $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$	$[C_{22}H_{28}FeN_2O_2 + PdCl]^+$	551
7b + $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$	$[C_{22}H_{28}FeN_2O_2 + Pd_2(\eta^3\text{-}C_3H_5)_2Cl]^+$	739
12b	$[C_{24}H_{32}FeN_2O_2 + H]^+$	437
12b + $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$	$[C_{24}H_{32}FeN_2O_2 + Pd(\eta^3\text{-}C_3H_5)]^+$	583
12b + $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$	$[C_{24}H_{32}FeN_2O_2 + PdCl]^+$	577
12b + $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$	$[C_{24}H_{32}FeN_2O_2 + Pd_2(\eta^3\text{-}C_3H_5)_2Cl]^+$	767
12b + $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$	$[C_{24}H_{32}FeN_2O_2 + Pd_2(\eta^3\text{-}C_3H_5)Cl_2]^+$	761
14b	$[C_{28}H_{24}FeN_2O_2 + H]^+$	477
14b + $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$	$[C_{28}H_{24}FeN_2O_2 + Pd(\eta^3\text{-}C_3H_5)]^+$	623
14b + $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$	$[C_{28}H_{24}FeN_2O_2 + PdCl]^+$	617
14b + $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$	$[C_{28}H_{24}FeN_2O_2 + Pd_2(\eta^3\text{-}C_3H_5)Cl_2]^+$	807

For 1,1′-bis[(*S*)-4-methyloxazolin-2-yl]ferrocene (**1b**), a signal at *m*/*z* = 353 was observed as the most intense peak $[C_{18}H_{20}FeN_2O_2 + H]^+$. Addition of $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$ in 1:1 ligand/Pd molar ratio resulted in the formation of a peak at *m*/*z* = 499 assignable to the mono-palladium complex $[C_{18}H_{20}FeN_2O_2 + Pd(\eta^3\text{-}C_3H_5)]^+$ and a relatively much less abundant one at *m*/*z* = 683 for the bis-palladium one $[C_{18}H_{20}FeN_2O_2 + Pd_2(\eta^3\text{-}C_3H_5)_2Cl]^+$. Increasing the amount of palladium (molar ratio 1:2) in the incubation mixture resulted only in a minor increase of the peak at *m*/*z* = 683; the signal assigned to $[C_{18}H_{20}FeN_2O_2 + Pd(\eta^3\text{-}C_3H_5)]^+$ remained the most intense.

Table 5. Operational MS parameters chosen for investigations on the complexation behavior of **1b**, **7b**, **12b**, and **14b**.

Parameters	Values
HV capillary [V]	4000
Dry gas flow [L min^{-1}]	5
Dry gas temperature [°C]	80
Nebulizer gas [psi]	10
Skimmer 1 [V]	35.7
Capillary exit offset [V]	73.6
Octopole [V]	2.50
Octopole Δ [V]	2.40
Trap drive	30.6
Injection rate [μL min^{-1}]	6
Polarity	positive
Scan range, *m*/*z*	50–1200

Similar investigations were performed for 1,1′-bis[(*S*)-4-isopropyloxazolin-2-yl]ferrocene (**7b**): at a molar ratio of 1:1 the most intense peak was again the ligand coordinated to one Pd^{II} center, which in this case also bears an allyl ligand. At the lower ligand/transition metal molar ratio (1:1) a remarkable amount of $[C_{22}H_{28}FeN_2O_2 + Pd_2(\eta^3\text{-}C_3H_5)_2Cl]^+$ is already detectable in this case. Addition of $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$ to obtain molar ratios of 1:2 and 1:10 influenced the mass spectra by increasing the signal with *m*/*z* = 739, and at a molar ratio of 1:10 there are already peaks with equal relative intensities for the mono-palladium (*m*/*z* = 555) and the bis-palladium conjugates (*m*/*z* = 739; see Figure 4). Additionally, MS/MS experiments of both adducts were done and it was found that the fragmentation of *m*/*z* = 739 leads to a peak for the mono adduct (*m*/*z* = 555).

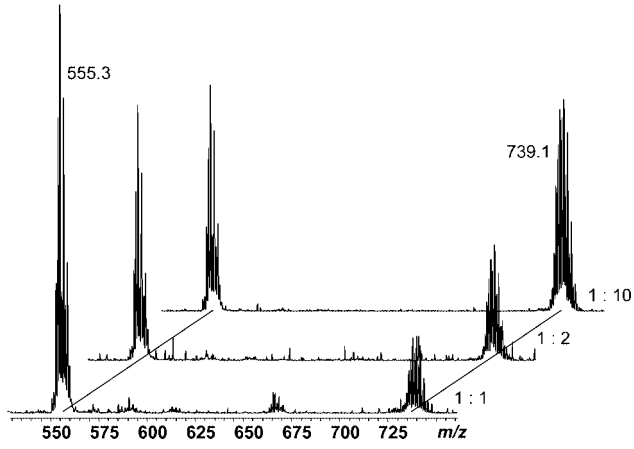

Figure 4. Mass spectrometric investigation of the coordination behavior of 1,1′-bis[(*S*)-4-isopropyloxazolin-2-yl]ferrocene (**7b**) toward $[Pd(allyl)Cl]_2$ at molar ratios of 1:1, 1:2, and 1:10 (ligand/palladium), with peaks found at *m*/*z* = 555 and 739 assignable to the mono- and bis-palladium complexes, respectively.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Further MS^3 experiments did not result in any assignable signals.

In the case of (*S*)-*tert*-butyloxazoline (**12b**) a major adduct with *m*/*z* = 767 is formed which was assigned to $[C_{24}H_{32}FeN_2O_2 + Pd_2(\eta^3\text{-}C_3H_5)_2Cl]^+$. Additionally, a coordination compound was detected which contains one allyl and two chloro ligands instead of two allyl and one chloro ligand. Note that due to the broad isotope distribution of palladium and chloro ligands an overlapping of the signals with *m*/*z* = 761 and 767 can not be avoided.

The (*S*)-phenyloxazoline **14b** was chosen as representative for the aryloxazolines for the MS experiments. At a molar ratio of 1:1 the monoadduct with $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$ is the most intense peak, while at a 1:2 ratio the dinuclear Pd species is formed. Extension of the reaction times for all the MS experiments did not influence the appearance of the mass spectra. The increase of the peak with two Pd atoms coordinated to the 1,1′-bis(oxazolin-2-yl)ferrocene ligands reveals that there is no stable chelate formed between the two oxazoline rings and the Pd^{II} cation. These results are in good agreement with a report published by Imai et al., who showed by NMR spectroscopy that 1,1′-bis[(*S*)-4-isopropyloxazolin-2-yl]ferrocene (**7b**) functions, independently of the Pd/oxazoline ratio, as a monodentate ligand.[64]

In order to study the experimentally found monodentate coordination of the ferrocene ligand to the allylpalladium moiety instead of the expected chelate formation, quantum-chemical calculations of equilibrium structures of the parent methyl-substituted ligand 1,1′-bis[(*S*)-4-methyloxazolin-2-yl]ferrocene (**1b**) and possible complexes with mono- and bidentate coordination of **1b** to Pd^{II} (**1c** and **1d**, respectively) were carried out at the B3LYP level of theory. The calculated structural parameters of **1b** are in perfect agreement with those found experimentally for **12b**, with a maximum deviation of 0.021 Å for the C8–C9 bond. For the other bonds, the difference between the calculated and experimental bond lengths often appears within the 3σ interval of the X-ray data.

The minima corresponding to both **1c** and **1d** were located (see Figure 5). A comparison of the total energies of these structures shows that the chelate complex **1d** is 19.07 kcal mol^{-1} more stable than complex **1c**. In terms of Gibbs free energy, when the entropic factor is taken into account, the stability of **1d** relative to **1c** decreases slightly but is still significant ($\Delta G = G_{1d} - G_{1c} = -15.83$ kcal mol^{-1}). Consideration of the solvent effects at the CPCM level (for CH_2Cl_2 as a solvent) results in a further, but only moderate, lowering of the energy difference between **1d** and **1c** (by 3.16 kcal mol^{-1}). Thus, the chelate complex displays a significantly higher stability than the monodentate structure despite the possible steric hindrances in the former; the exclusive formation of the monodentate-type complexes must therefore be determined by kinetic factors rather than by thermodynamic ones. Indeed, the formation of chelates is accompanied by the mutual rotation of two Cp cycles and by significant conformational changes in the ligand that should increase the activation energy compared to the formation of **1c** and similar structures.

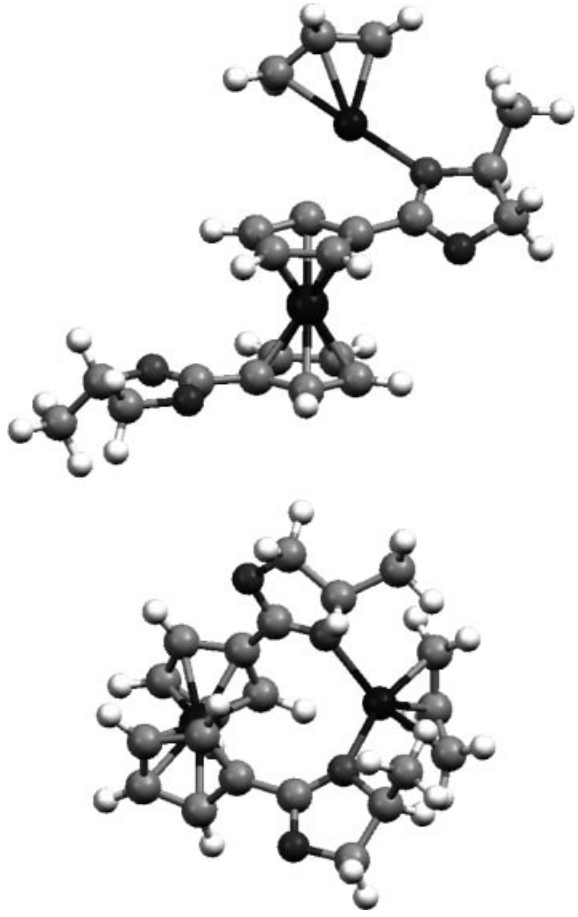

Figure 5. Equilibrium structures of complexes **1c** (top) and **1d** (bottom).

A possible explanation for the preferred monodenticity of the ligands might be the hindrance of rotation of the oxazoline moiety around the C–C axis. Taking into account the crystal structure analyses, the nitrogen atoms are not orientated toward each other and therefore the nitrogen lone-pairs in the solid state point in opposite directions.

Conclusions

Bisoxazolines are known to be excellent ligands in many enantioselective syntheses. A central factor in enantioselective synthesis is the formation of chelate structures by coordination of multidentate ligands to transition metals. The chelation process therefore has a great influence on the success of metal complexes in many catalytic processes.

We have described the synthesis and characterization of a wide variety of differently substituted 1,1′-bis(oxazolin-2-yl)ferrocenes with substituents located in either the 4- or 5-position of the oxazoline rings and being either alkyl or aryl groups. The synthesized compounds were characterized by standard analytical methods (NMR, elemental analysis). Additionally, for compounds **6b**, **7b**, **11b**, **12b**, **13b**, and **14b** the absolute configuration was determined by single-crystal X-ray diffraction analysis.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The catalytic activity of these compounds was tested in the palladium-catalyzed allylic alkylation. These experiments showed that this type of ligand possesses no activity in the test reaction and that a change of the substituent on the oxazoline ring does not influence this. We suppose that the lack of catalytic activity results from the insufficient coordination properties of the studied 1,1′-bis(oxazolin-2-yl)ferrocenes, i.e., chelate formation with the palladium center, a fact that was enlightened in mass spectrometric studies: the bisoxazolines are not capable of functioning as bidentate ligands. This feature was found to be independent of the type of substituents as well as their positions on the oxazoline ring. Comparing the presented results with the outcome of an NMR study reported by Imai and coworkers it can be assumed that the effect is also independent of the type of palladium complex.

In contrast, DFT calculations for this type of compounds revealed, as expected, that chelating structures are energetically more stable than the equivalent monodentate complexes. Therefore it is suggested that the chelate formation of the ferrocene ligands with an allylpalladium moiety instead of the bidentate one is kinetically controlled.

Experimental Section

General Remarks: All reactions were carried out in dry solvents under argon. The NMR spectra were recorded on a Bruker Avance DPX 400 instrument (Ultrashield™ Magnet) at 400.13 MHz (^{1}H) and 100.63 MHz (^{13}C) at 298 K in [D$_6$]DMSO or $CDCl_3$. Optical rotations were measured with a Perkin–Elmer 341 polarimeter using a 10 cm cell. Melting points were determined with a Büchi B-540 apparatus and are uncorrected. Electrospray ionization mass spectra were recorded on a Bruker esquire$_{3000}$ spectrometer in positive-ion mode (see Table 5 for measurement parameters). The elemental analyses were done by the Laboratory for Elemental Analysis of the Institute of Physical Chemistry, University of Vienna, with a Perkin–Elmer 2400 CHN Elemental Analyzer. Silica gel (Fluka-60 70–230 mesh) was used for column chromatography and silica gel (Polygram® SIL G/UV$_{254}$) for thin layer chromatography.

The full geometry optimization of all structures was carried out in Cartesian coordinates with the Gaussian 98[69] program package at the DFT level of theory. The calculations were performed using Becke's three-parameter hybrid exchange functional[70] in combination with the gradient-corrected correlation functional of Lee et al.[71] (B3LYP). A quasi-relativistic Stuttgart pseudopotential was used for the 28 core-electrons, the appropriate contracted basis set (8s7p6d)/[6s5p3d][72] for the palladium atom, and the 6-31G* basis set[73–76] for other atoms. For the Fe atom, the relativistic Stuttgart pseudopotential describing 10 core-electrons and the appropriate contracted basis set (8s7p6d1f)/[6s5p3d1f][77] was also used in some calculations. Symmetry operations were not applied for all structures. The Hessian matrix was calculated analytically for all equilibrium structures to prove the location of correct minima (no imaginary frequencies were found) and to estimate the thermodynamic functions calculated at 25 °C. Solvent effects were taken into account at the single-point calculations based on the gas-phase equilibrium geometries by using the polarizable continuum model[78] in the CPCM version[79] with CH_2Cl_2 as a solvent.

The *N*-substituted 1,1′-ferrocenedicarboxamides **7a**, **12a**, and **14a**, 1,1′-bis[(*S*)-4-isopropyloxazolin-2-yl]ferrocene (**7b**), 1,1′-bis[(*S*)-4-*tert*-butyloxazolin-2-yl]ferrocene (**12b**), and 1,1′-bis[(*S*)-4-phenyloxazolin-2-yl]ferrocene (**14b**) were prepared following a literature procedure.[39] The synthesized amides were stable for more than one year at room temperature while the oxazolines degraded over time. Therefore they should be stored under argon and in the refrigerator.

***N*,*N*′-Bis[(1*S*)-(2-hydroxy-1-methylethyl)]ferrocene-1,1′-dicarboxamide (1a):** A solution of 1,1′-ferrocenyldicarbonyl dichloride (0.78 g, 2.50 mmol) in CH_2Cl_2 (30 mL) was added slowly at 0 °C to a solution of (*R*)-(–)-2-amino-1-propanol (0.37 g, 5.00 mmol) and triethylamine (0.7 mL, 5.05 mmol) in CH_2Cl_2 (20 mL). The reaction mixture was stirred for 4 h, the formed precipitate was filtered off and washed five times with CH_2Cl_2 (30 mL). This procedure yielded 0.69 g (71%) of pure product after drying in vacuo. $[\alpha]_D^{20}$ = +18 (*c* = 0.25, DMSO); m.p. 200–201 °C decomp. ^{1}H NMR ([D$_6$]DMSO): δ = 7.52 (d, ^3J = 7.6 Hz, 2 H, N*H*), 4.75 (br. s, 4 H, Fc-*H*), 4.29 (br. s, 4 H, Fc-*H*), 3.97 (m, 2 H, NHC*H*), 3.45 (m, 2 H, HOCH_2), 3.38 (m, 2 H, HOCH_2), 1.12 (d, ^3J = 6.5 Hz, 6 H, CH_3) ppm. ^{13}C{^{1}H} NMR: δ = 169.24 (*C*O), 78.83 (Fc-*C*), 72.46 (Fc-*C*), 70.95 (Fc-*C*), 70.65 (Fc-*C*), 65.34 (HO*C*H$_2$), 47.78 (NH*C*H), 18.19 (*C*H$_3$) ppm. $C_{18}H_{24}FeN_2O_4$ (388.2): calcd. X-ray diffraction measurements were performed on a Nonius Kappa CCD diffractometer. Single crystals were positioned at 40 mm from the detector and 567 and 495 frames were measured, each for 60 and 40 s over a 1.5° scan for **13b** and **14b**, respectively. The data were processed using the Denzo-SMN software package. Crystal data, data collection parameters, and structure refinement details for **6b**, **7b**, **11b**–**14b** are given in Table 6. The structures were solved by direct methods and refined by full-matrix least-squares techniques. Non-hydrogen atoms were refined with anisotropic displacement parameters. H-atoms were located on difference Fourier

Reductive Isopropyl Radical Elimination from (dpp-bian)Mg-*i*Pr(Et_2O)

Igor L. Fedushkin*[a] Alexandra A. Skatova,[a] Markus Hummert,[b] and Herbert Schumann*[b]

Dedicated to Prof. Dr. Sergei F. Zhiltsov on the occasion of his 70th birthday

Keywords: Magnesium / N ligands / Alkyl complexes / Reductive elimination

The reaction of (dpp-bian)Na(Et_2O) with one equiv. of *i*PrMgCl in hexane affords (dpp-bian)Mg-*i*Pr(Et_2O) (**1**) whereas (dpp-bian)Mg$(Et_2O)_2$ (**2**) is formed when this reaction is carried out in Et_2O as a result of *isopropyl* radical elimination. Compound **1** which is stable in hexane and Et_2O also decomposes in THF with elimination of *isopropyl* radicals yielding (dpp-bian)Mg$(THF)_2$. The reaction of (dpp-bian)Na_2-$(Et_2O)_3$ with two equiv. of *i*PrMgCl in Et_2O produces **2** and iPr_2Mg, which then interact to give (dpp-bian)$(Mg\text{-}iPr)_2(Et_2O)$ (**3**) when treated with hexane or toluene. Compounds **1**–**3** were characterized by elemental analysis, UV/Vis and NMR spectroscopy, as well as by single-crystal X-ray diffraction.

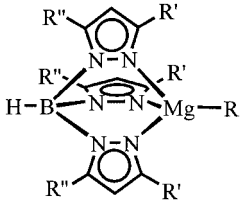
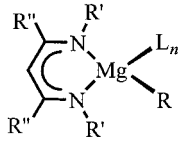
Introduction

Grignard compounds[1] are one of the most useful reagents in organic and organometallic chemistry.[2] Several decades after the discovery of these highly reactive species, it has turned out that the substitution of the halogen atom in alkyl- or arylmagnesium halides by other functional groups may strongly affect the reactivity, structure, and solution behavior of such organomagnesium compounds. The first alkylmagnesium amide, *i*PrMgN$Ph_2(Et_2O)_2$ was synthesized in 1967,[3a] and already two years later, X-ray diffraction data of e.g. {$[Me_2N(CH_2)_2MeN]MgMe\}_2$ were published.[3b] Recently, a series of heteroleptic alkyl- and alkynylmagnesium amides have been prepared.[3c] A new period in organomagnesium chemistry started with the use of tris(pyrazolyl)borato[4] and ketiminato ligands[5] which allowed the synthesis of monomeric, low-coordinate magnesiumalkyls.

We have reported on the successful synthesis of main group metal complexes with anionic or radical-anionic species of the 1,2-bis{(2,6-diisopropylphenyl)imino}acenaphthene (dpp-bian) ligand e.g. $\{[M]^+_n[(dpp\text{-}bian)]^{n-}(L)_x\}$ (M = Li, Na; n = 1–4; L = Et_2O, THF)[6a,6b] and $\{[M]^{2+}[(dpp\text{-}bian)]^{2-}(THF)_x\}$ (M = Mg, Ca, Ge).[6c,6d,6e] Up to this time the aryl-bian system was mainly used in transition metal chemistry,[7] but we have demonstrated that the magnesium complex (dpp-bian)Mg$(THF)_3$ is also a powerful reagent in organic synthesis.[6e,8a,8b] Thus, the electron transfer from this complex to Ph_2CO affords the pinacol coupling product, while its reaction with 9-(10H)-anthracenone yields the antryloxymagnesium derivative.[8a]





L = coordinating solvent; n = 0 or 1

R = alkyl or aryl; R' and R" = H or alkyl

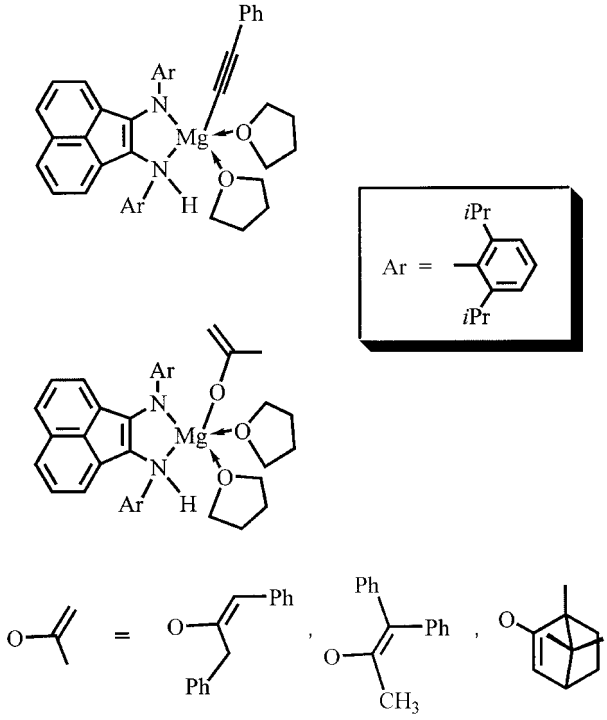
A further interesting type of reaction of (dpp-bian)-$Mg(THF)_3$ is the oxidative addition of acidic substances such as phenylacetylene[8b] or enolizable ketones.[8b]



In this paper we report on the solvent induced radical elimination of the *isopropyl* group from (dpp-bian)Mg-*i*Pr-(Et_2O) (**1**) – a process that is possible due to the ability of the dpp-bian radical anion to be further reduced to the dianion.

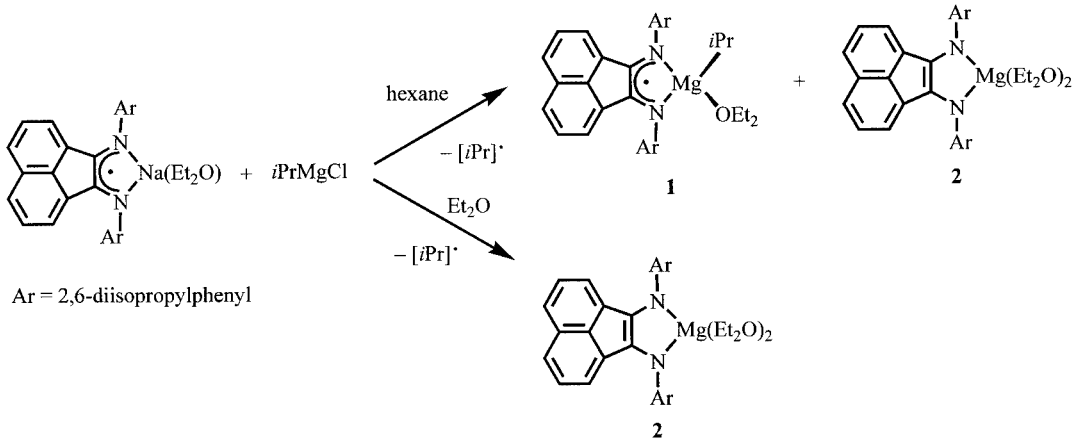
Results and Discussion

Reaction of *i*PrMgCl with (dpp-bian)$^-$Na$^+$ and (dpp-bian)$^{2-}$Na$^+_2$ in Et_2O and Hexane

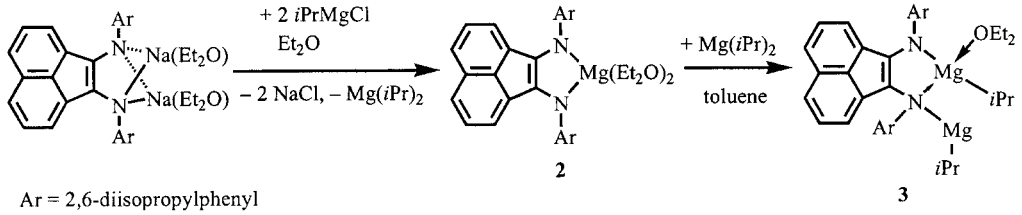
Exchange reactions of (dpp-bian)Na(Et_2O) with methyl- and ethylmagnesium bromide or trimethylsilylmethylmagnesium chloride in Et_2O produce cherry-red solutions from which the respective magnesiumalkyls, supported by the dpp-bian ligand, can be isolated as red crystalline substances in high yields.[8d] In contrast, the in situ reaction of (dpp-bian)Na(Et_2O) with one equiv. of *i*PrMgCl in Et_2O affords a green-brown solution from which yellowish-green crystals precipitate. As already indicated by the green color, which signals the presence of dpp-bian dianions, the expected (dpp-bian)Mg-*i*Pr(Et_2O) (**1**) containing (dpp-bian) radical anions is not formed. Accordingly, the isolated product (72% yield) proved to be (dpp-bian)Mg(Et_2O)$_2$ (**2**). The formation of **2** suggests that an intermediate formed in the course of the reaction obviously disproportionates with reduction of the dpp-bian radical anions to dianions and oxidation of the *isopropyl* carbanions to *isopropyl* radicals (Scheme 1). However, we succeeded in the synthesis of (dpp-bian)(Mg-*i*Pr)(Et_2O) (**1**), using hexane instead of Et_2O as the solvent in the reaction of (dpp-bian)Na with *i*PrMgCl. In this case, complex **1** can be isolated in yields up to 40% as blocklike, deep-red crystals along with 30 to 50% of **2** (Scheme 1).

In contrast to our expectations, **1** is stable in Et_2O, which means that an adduct of (dpp-bian)Na with *i*PrMgCl, formed initially in the reaction conducted in Et_2O, will disproportionate with elimination of *i*Pr radicals. But, according to ^{1}H NMR spectroscopic results, **1** disproportionates immediately with elimination of *i*Pr radicals when dissolved in THF.

The above suggested redox reaction and hence the elimination of *isopropyl* radicals should be excluded if the dpp-bian complex used in the reaction with *i*PrMgCl already contains the dpp-bian ligand in the dianionic form. Therefore, we reacted (dpp-bian)Na_2(Et_2O)$_2$ with two equiv. of *i*PrMgCl in Et_2O. The reaction results in an almost quantitative precipitation of **2** and, as a consequence, in the formation of Mg(*i*Pr)$_2$. Evaporation of the solvent from the entire reaction mixture followed by treatment of the remaining green solid components with toluene caused its dissolution at 70 °C yielding a deep-blue solution. Recrystallization of the solid remaining after removal of the toluene in vacuo, from hexane affords deep-blue crystals of (dpp-bian)(Mg-*i*Pr)$_2$(Et_2O) (**3**) with 60% yield (Scheme 2).



Scheme 1.



Scheme 2.

Since, according to X-ray crystal structure analysis, complex **3** consists of two *i*PrMg units, asymmetrically coordinated by the dpp-bian dianion, we have proved that the elimination of *i*Pr radicals is very much dependent on whether the coordinating ligand bound to magnesium can be reduced or not. At this point it should be noted, that magnesiumalkyls (alkyl = Me, *i*Pr, *t*Bu) supported by tris(pyrazolyl)borato[4] and ketiminato[5] ligands do not eliminate alkyl radicals because the monoanionic ketiminato and tris(pyrazolyl)borato ligands are not further to reduce.

Molecular Structures of 1, 2, and 3

The molecular structures of **1**, **2**, and **3** are depicted in Figure 1, Figure 2, and Figure 3, respectively. The crystal data collection and structure refinement data of **1**, **2**, and **3** are listed in Table 1, selected bond lengths and bond angles of the molecules are listed in Table 2. X-ray quality crystals were obtained from hexane (**1**) or toluene (**2**, **3**). The molecular structure of (dpp-bian)$Mg(Et_2O)_2$ (**2**) [Mg–N(1) 2.002, Mg–N(2) 2.003 Å] is very close to that of the analogous THF adduct (dpp-bian)$Mg(THF)_2$ [Mg–N(1) 1.994, Mg–N(2) 2.004 Å][6c] and will not be discussed in detail here.

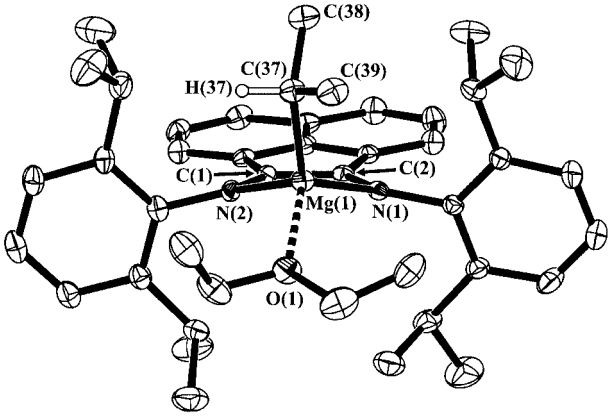


Figure 1. Molecular structure (ORTEP)[9] of **1**. The hydrogen atoms are omitted. Thermal ellipsoids are drawn at 30% probability level.

The unit cell of (dpp-bian)(Mg-*i*Pr)(Et_2O) (**1**) contains two independent molecules, the parameters of which are very much alike. Hence, the molecular structure of only one of them is depicted in Figure 1. Similar to (dpp-bian)$Mg(Et_2O)_2$ (**2**) the magnesium atom in **1** is four-coordinate. The radical anionic character of the dpp-bian ligand in **1** is indicated by the elongated Mg–N distances [Mg(1)–N(1) 2.120, Mg(1)–N(2) 2.103 Å] compared to those in **2** [Mg(1)–N(1) 2.002 and Mg(1)–N(2) 2.003 Å] containing the dianionic dpp-bian ligand. The Mg–O distance in **1** (2.051 Å) only slightly exceeds the Mg–O distances in **2** (2.009 and 2.049 Å). The Mg–C(37) bond length (2.145 Å) in **2** is comparable with the distance between Mg(2) and the methine

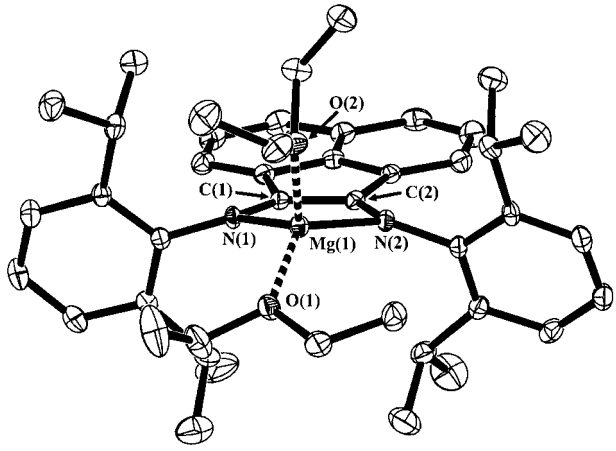

Figure 2. Molecular structure (ORTEP)[9] of **2**. The hydrogen atoms are omitted. Thermal ellipsoids are drawn at 30% probability level.

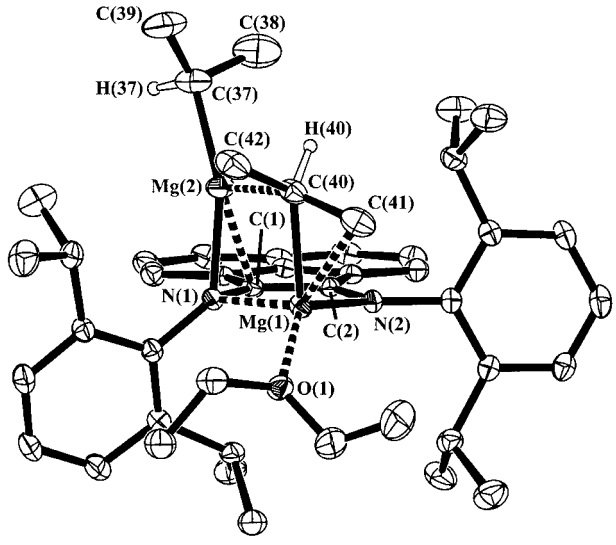

Figure 3. Molecular structure (ORTEP)[9] of **3**. The hydrogen atoms are omitted. Thermal ellipsoids are drawn at 30% probability level.

carbon atom C(37) of the terminal isopropyl group in **3** (2.129 Å).

In (dpp-bian)(Mg-*i*Pr)$_2$(Et$_2$O) (**3**), the coordinating sites of the two magnesium atoms relative to the dpp-bian ligand are quite different. The Mg(1) atom lies almost perfectly in the plane formed by the diimine fragment, whereas Mg(2) is positioned above this plane. At first sight, the molecular structure of **3** looks like that of a complex of (dpp-bian)-Mg(Et$_2$O)$_2$ (**2**) and *i*Pr$_2$Mg with the magnesium atom of the *i*Pr$_2$Mg unit (Mg(2)) being coordinated by the lone electron pair of N(1). However, the Mg(2)–C(37) bond length (2.129 Å) is much shorter than the Mg(2)–C(40) distance (2.282 Å), which in turn is somewhat longer than the Mg(1)–C(40) bond (2.266 Å). Further, taking into account, that the Mg(1)–N(1) and Mg(1)–N(2) bonds differ in their length (2.101 and 2.030 Å, respectively) and that the Mg(2)–N(1) distance (2.070 Å) is relatively short, it can be concluded that the Mg(1)–N(1) bond is a coordinative bond whereas the Mg(1)–N(2) bond is a covalent amido bond.

Table 2. Selected bond lengths [Å] and angles [°] for complexes **1**, **2**, and **3**.

UV/Vis and NMR Spectroscopic Studies on Solutions of 1 and 3

The solution behavior of **1** and **3** is quite remarkable. Both compounds are soluble in hexane and toluene and are stable in these solutions for several days. As already mentioned above, compound **1** is also stable in Et$_2$O, but disproportionates in THF while dissolution of **3** in Et$_2$O as well as in THF causes immediate decomposition into (dpp-bian) Mg(Et$_2$O)$_2$ and *i*Pr$_2$Mg.

The electron absorption spectra of solutions of **1** in Et$_2$O and of **3** in hexane and Et$_2$O are presented in Figure 4. The absorption maximum at 520 nm in the UV/Vis spectrum of **1** indicates the presence of dpp-bian radical anions. The absorption maximum at 598 nm in the spectrum of **3** in hexane corresponds to the dianion of dpp-bian, and the

absorption maximum at 737 nm in the spectrum of **3** in Et_2O indicates the formation of **2** by dismutation of **3** into (dpp-bian)Mg(Et_2O)$_2$ (**2**) and iPr_2Mg. The latter compound is colorless and invisible in the UV/Vis spectrum.

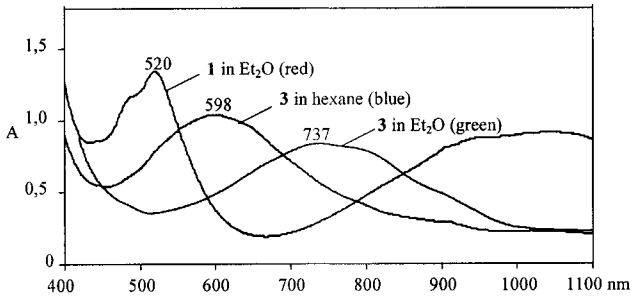

Figure 4. UV/Vis spectra of **1** and **3**.

The ^{1}H NMR spectrum of the blue solution of **3** in [D_8] toluene (Figure 5) reveals six septets, which are assigned to the methine protons of the *i*Pr substituents of the dpp-bian phenyl rings. The integrals of the two septets at δ = 3.69 and 3.54 ppm are five times higher than those of the other four very broad septets at 3.94, 3.80, 3.64 and 3.40 ppm and the overall integral of the six septets is twice as high as that of the multiplet at δ = 0.32 ppm, which is assigned to the methine protons of the isopropyl groups attached to the two magnesium atoms.

We conclude from these facts, that solutions of **3** in [D_8]-toluene contain two kinds of molecules differing in their structure. The major part consists of molecules in which Mg(2) is symmetrically positioned above the center of the metallocycle formed by the atoms C(1)–C(2)–N(1)–N(2)–Mg(1). Therefore, the signals of the two pairs of the *i*Pr methine protons substituting the phenyl rings and being situated above and below the diimine plane are different (3.69 and 3.54 ppm). A similar symmetrical structure has been found for (dpp-bian)(H)MgC≡CPh(THF)$_2$[8b] in THF solution, in which the cation H^+ is delocalized between the two nitrogen atoms. The minor part of the molecules, present in solution, possesses the structure established by crystal structure analysis, thus causing nonequivalence of all four phenyl ring substituting methine protons (3.94, 3.80, 3.64, and 3.40 ppm).

Going from toluene to THF as the solvent causes a dramatic change in the color of solution **3** (blue to green) as well as the appearance of the ^{1}H NMR spectrum (Figure 6).

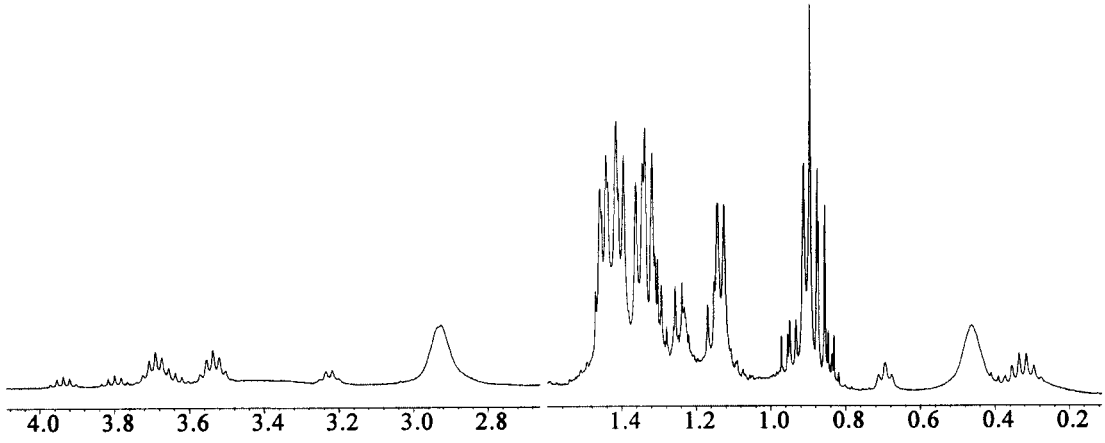

Figure 5. ^{1}H NMR spectrum of **3** in [D_8]toluene (400 MHz, 294 K). The aromatic region is omitted.

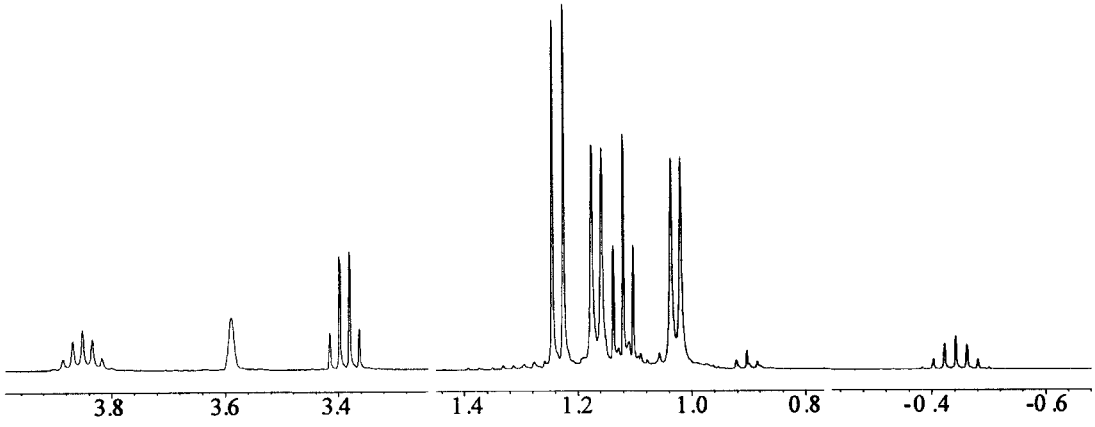

Figure 6. ^{1}H NMR spectrum of **3** in [D_8]THF (400 MHz, 294 K). The aromatic region is omitted.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

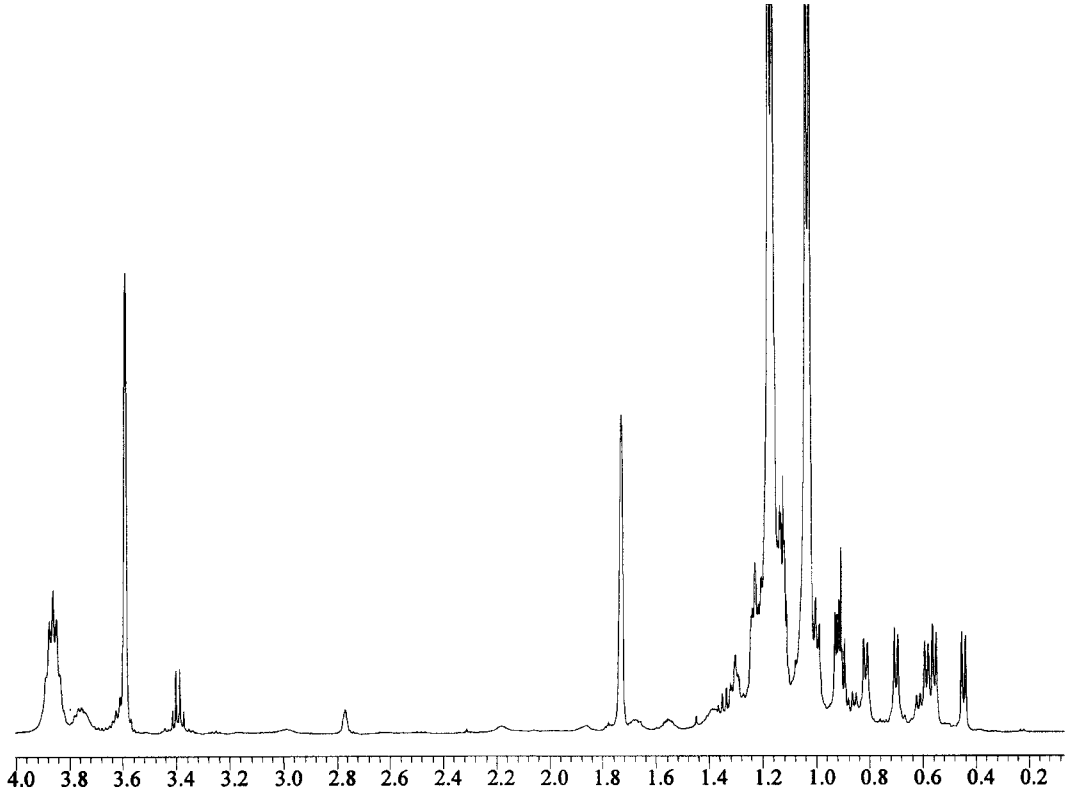

Figure 7. ^{1}H NMR spectrum of **1** in [D_8]THF (500 MHz, 294 K). The aromatic region is omitted.

The spectrum shows only one signal for the methine protons (δ = 3.86 ppm) and two doublets for the methyl protons of the isopropyl substituents of the phenyl rings (1.16 and 1.03 ppm). These signals are assigned to (dpp-bian)Mg(THF)$_3$.[6c] The high field septet at δ = –0.44 ppm and the doublet at δ = 1.23 ppm reflect the presence of *i*Pr$_2$Mg in the solution. Thus, complex **3** being dissolved in THF dissociates into *i*Pr$_2$Mg and (dpp-bian)Mg(THF)$_3$. The ^{1}H NMR spectrum of **1** in [D_{10}]Et_2O is not meaningful because of the paramagnetism of the complex, due to the presence of the dpp-bian radical anion. On dissolution of **1** in [D_8]THF the color of the solution changes within minutes from cherry-red to green and the ^{1}H NMR spectrum indicates the absence of paramagnetic species (Figure 7).

The septet at δ = 3.86 ppm and the doublets at δ = 1.17 and 1.03 ppm prove that diamagnetic (dpp-bian)Mg(THF)$_3$[6c] has been formed as a result of the elimination of *i*Pr radicals. As secondary products of the eliminated isopropyl radicals, the formation of propylene, propane, 2,3-dimethylbutane etc. is to be expected. Though certain amounts of these hydrocarbons are detected in the spectrum, the main reaction of the isopropyl radicals is the attack on THF molecules.

The ^{1}H-^{1}H COSY experiments revealed several cross peaks between pairs of doublets of low intensity (1.0–0.4 ppm) and broadened septets at relatively high fields (2.0–1.4 ppm). Thus, the doublets at 0.95 and 0.42, 0.81 and 0.59, and 0.70 and 0.55 ppm have cross peaks with septets at δ = 1.55, 1.67 and 1.39 ppm, respectively, and we assign these signals to *i*Pr substituted THF molecules. It is supposed that the coordinating strength of *i*Pr substituted THF molecules is somewhat higher than that of unsubstituted THF molecules and that the former will partly take the place of the THF ligands in (dpp-bian)Mg(THF)$_3$. The restricted rotation of the *i*Pr groups of magnesium coordinating *i*PrC_4H_7O ligands makes their methyl groups nonequivalent, thus giving rise to the doublets observed in the range 1.0–0.4 ppm.

Conclusions

The results of our investigations demonstrate that reductive elimination processes can be realized even with complexes of main group metals that are unable to change their oxidation state. This is accomplished when they are supported by the dpp-bian ligand, which may accept or deliver electrons.

Experimental Section

General Remarks: All manipulations were carried out in vacuo or under N_2 using Schlenk techniques. The solvents THF, Et_2O, hex-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ane and toluene were distilled from sodium/benzophenone prior to use. The deuterated solvents [D_8]THF, and [D_8]toluene (Aldrich) were dried at ambient temperature over sodium/benzophenone and, just prior to use, condensed under vacuum into NMR tubes containing the compounds. The ^1H and ^{13}C NMR spectra were recorded with a Bruker ARX-400 and Bruker ARX-500 spectrometer. The UV/Vis spectra were recorded with a Perkin–Elmer Lambda 25 spectrometer.

(dpp-bian)(Mg-*i*Pr)(Et_2O) (1): A solution of (dpp-bian)Na was prepared by stirring dpp-bian (1.0 g, 2 mmol) and sodium (0.05 g, 2.17 mmol) in Et_2O (50 mL). After the sodium had dissolved completely, the solvent was evaporated in vacuo. Hexane (40 mL) was added to the remaining salt and the suspension that formed was stirred vigorously for 30 min. A 1 M solution of *i*PrMgCl (2.4 mL) in Et_2O was then added with vigorous stirring. Within a few seconds, the powdery (dpp-bian)Na dissolved and a cherry-red solution was formed which was filtered from NaCl and **2** and was then concentrated to 10 mL. Cooling of this solution to 0 °C yielded 0.47 g (37%) of **1** as deep-red crystals. M. p. 136–140 °C (decomp.). $C_{43}H_{57}MgN_2O$ (624.24): calcd. C 80.42, H 8.95; found C 80.33, H 8.96.

(dpp-bian)Mg(Et_2O)$_2$ (2): A 2 M solution of *i*PrMgCl in Et_2O (1.2 mL) was added to a stirred solution of (dpp-bian)Na prepared in situ from dpp-bian (1.0 g, 2 mmol) and sodium (0.05 g, 2.17 mmol) in Et_2O (50 mL). Within a few minutes the solution turned brown-green. The solvent was removed in vacuo and the solid dissolved in hot toluene. Cooling the solution to room temperature caused precipitation of **2** as yellowish-green crystals. Yield 1.1 g (72%) of **2**·(toluene). M. p. > 140 °C (decomp.). ^1H NMR spectrum (400 MHz, [D_8]THF, 20 °C): δ = 6.96 (d, 4 H, CH aromatic, ^3J = 7.3 Hz), 6.84 (t, 2 H, CH aromatic, ^3J = 7.3 Hz), 6.46 (d, 2 H, CH aromatic, ^3J = 6.8 Hz), 6.39 (dd, 2 H, CH aromatic, ^3J = 6.8 Hz), 5.37 (d, 2 H, CH aromatic, ^3J = 6.0 Hz), 3.86 (spt, 4 H, ^3J = 6.6 Hz), 3.34 (q, 8 H, *Et*$_2$*O*), 1.17 (d, 12 H, CH(CH_3)$_2$, ^3J = 6.8 Hz), 1.12 (t, 12 H, *Et*$_2$*O*), 1.03 (d, 12 H, CH(CH_3)$_2$, ^3J = 6.4 Hz). $C_{44}H_{60}MgN_2O_2$·(C_7H_8) (765.4): C 80.03, H 8.95; found C 79.29, H 8.51.

(dpp-bian)(Mg-*i*Pr)$_2$(Et_2O) (3): A 2 M solution of *i*PrMgCl in Et_2O (2.4 mL) was added to a stirred solution of (dpp-bian)Na_2 prepared in situ from dpp-bian (1.0 g, 2 mmol) and sodium (0.1 g, 4.34 mmol) in Et_2O (50 mL). The color of the solution turned green and within seconds yellowish-green **2** precipitated. The solvent was removed in vacuo and the residual solid was treated with 40 mL of toluene. On heating to 70 °C the solid dissolved completely and the solution turned deep blue. The toluene was removed in vacuo and the residue was dissolved in hot hexane (80 mL). From the filtered solution, deep blue almost black crystals of **3** precipitated at 0 °C. Yield 0.85 g (60%). M. p. > 153 °C (decomp.). ^1H NMR spectrum (400 MHz, [D_8]THF, 20 °C): δ = 6.96 (d, 4 H, CH aromatic, ^3J = 7.5 Hz), 6.84 (t, 2 H, CH aromatic, ^3J = 7.5 Hz), 6.44 (d, 2 H, CH aromatic, ^3J = 8.1 Hz), 6.38 (dd, 2 H, CH aromatic, ^3J = 8.1 Hz), 5.36 (d, 2 H, CH aromatic, ^3J = 6.8 Hz), 3.86 (spt, 4 H, ^3J = 6.8 Hz), 3.39 (q, 8 H, *Et*$_2$*O*), 1.23 (d, 12 H, CH(CH_3)$_2$, ^3J = 7.8 Hz, *iPr*$_2$*Mg*), 1.17 (d, 12 H, CH(CH_3)$_2$, ^3J = 7.0 Hz), 1.12 (t, 12 H, *Et*$_2$*O*), 1.03 (d, 12 H, CH(CH_3)$_2$, ^3J = 6.8 Hz), –0.44 (spt, 2 H, ^3J = 7.8 Hz, *iPr*$_2$*Mg*). Anal calcd. (%) for $C_{46}H_{64}Mg_2N_2O$ (709.64): C 77.86, H 9.09; found C 77.25, H 8.97.

X-ray Crystallographic Study of 1–3: The crystal data and details of data collection are given in Table 1. The data for **1**–**3** were collected on a SMART CCD (graphite-monochromated Mo-K_α radiation, ω-scan technique, λ = 0.71073 Å). The structures were solved by direct methods using SHELXS-97[10] and were refined on F^2 using all reflections with SHELXL-97.[11] SADABS[12] was used to perform area-detector scaling and absorption corrections. The geometrical aspects of the structures were analyzed by using the PLATON program.[21] CCDC-250026 (for **1**), -250027 (for **2**) and -250028 (for **3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

EPR, ENDOR, and DFT Studies on (β-Octahalo-*meso*-tetraarylporphyrin)copper Complexes: Characterization of the Metal($d_{x^2-y^2}$)−Porphyrin(a_{2u}) Orbital Interaction

Junlong Shao,[a] Erik Steene,[b] Brian M. Hoffman,*[a] and Abhik Ghosh*[b]

Keywords: Copper / Porphyrins / Density functional calculations / ENDOR spectroscopy / EPR spectroscopy

A series of planar (porphyrin)copper(II) complexes and their β-octahalogenated saddled derivatives have been studied by Electron Paramagnetic Resonance (EPR) spectroscopy, Electron Nuclear DOuble Resonance (ENDOR) spectroscopy, and Density Functional Theoretical (DFT) calculations. Both EPR/ENDOR spectroscopy and DFT calculations indicate a decrease in spin density on the central copper(II) ion and on the nitrogen atoms in the saddled compounds relative to the planar complexes. The EPR/ENDOR measurements show that the hyperfine coupling decreases by 12% on the nitrogen atoms and 9% on the copper ion, in going from planar (5,10,15,20-tetraphenylporphyrin)copper (Cu[TPP]) to saddled (2,3,7,8,12,13,17,18-octabromo-5,10,15,20-tetraphenylporphyrin)copper (Cu[Br_8TPP]). Accordingly, saddling results in a decrease in the spin density on the copper ion and on the nitrogen atoms. DFT calculations on Cu[Br_8TPP] yield spin populations of 42.4% on the copper ion, 9.9% on each nitrogen atom and 4.9% on each *meso* carbon atom, relative to DFT spin populations of 62, 10.2 and 0.3% on the copper ion, each nitrogen and each *meso* carbon atom, respectively, for porphinecopper (Cu[P]). These calculations further indicate that the decrease in spin density on the copper ion in the saddled complexes results from a saddling-induced Cu($d_{x^2-y^2}$)−porphyrin(a_{2u}) orbital overlap whereby some of the Cu spin density is delocalized onto the porphyrin ring. The decrease in nitrogen spin population with saddling appears to be a more subtle effect caused by a superposition of two opposing factors. Saddling decreases the overlap between the nitrogen lone pairs and the Cu $d_{x^2-y^2}$ orbital on one hand and enhances the overlap between the copper $d_{x^2-y^2}$ orbital and the porphyrin a_{2u} HOMO on the other.

Introduction

Nonplanar conformations of porphyrins and related cofactors occur as conserved features of several metalloproteins, and it has been proposed that this nonplanarity is actually of biological importance.[1] Nonplanar deformations such as ruffling and saddling (Figure 1) exert a strong influence on the chemical properties of metalloporphyrins and related molecules; these properties include electrochemical half-wave potentials,[2,3] electronic absorption[4,5] and vibrational spectra,[6−8] energetics of different spin states and electron density distributions as reflected in NMR and EPR spectra,[9−17] DFT calculations,[18] and reactivity toward axial ligands, etc.[9,10,12,13,15,16,18] Many of these effects arise from specific metal(d)−porphyrin(π) orbital interactions that are symmetry-forbidden in planar metalloporphyrins, but which become allowed as a result of nonplanar deformations. For example, ruffling switches on the metal(d_{xy})−porphyrin(a_{2u}) orbital interaction, where the d_{xy} orbital is a "t_{2g}-type" d orbital (in the notation of the O_h point group). Electronic spin density distributions reflecting this orbital interaction have been extensively studied by NMR spectroscopy for ruffled iron(III) porphyrins.[9−12,14,15] Saddling switches on the metal($d_{x^2-y^2}$)−porphyrin(a_{2u}) orbital interaction (as shown

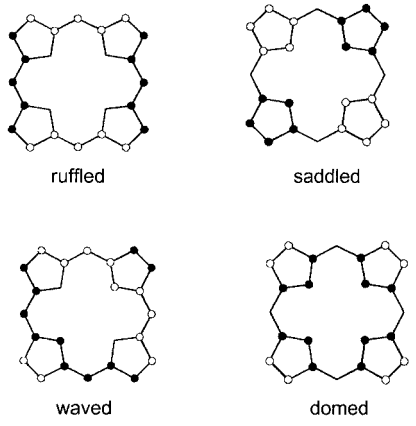

Figure 1. Nonplanar distortions of porphyrins; filled and open circles represent the displacement of the core atoms above and below the porphyrin mean plane

in Figure 2),[7,19] where the $d_{x^2-y^2}$ orbital is a "e_g-type" d orbital (in the notation of the O_h point group). NMR studies on saddled iron(III) porphyrins have also thrown light on this orbital interaction.[13,16] In this paper, we further[7,19] explore the consequences of the metal-$(d_{x^2-y^2})$−porphyrin(a_{2u}) orbital interaction by EPR and ENDOR spectroscopic studies and density functional theory (DFT) calculations on saddled Cu^{II} porphyrins. The results provide a clear picture of saddling-induced redistribution of unpaired electron density in (porphyrin)Cu^{II} compounds.

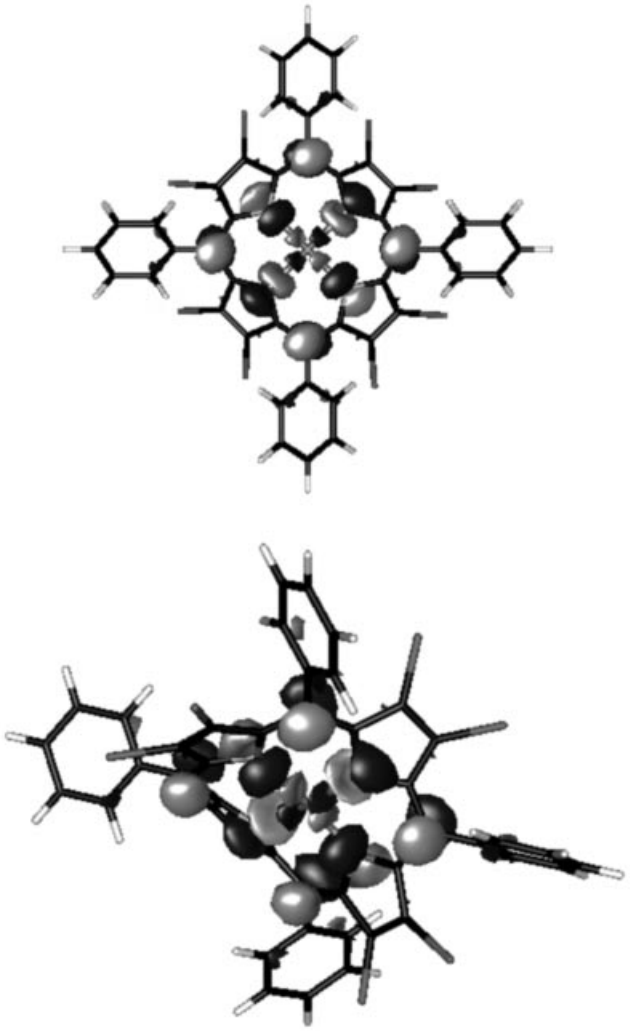

Figure 2. Two views of the singly occupied b_2 (a_{2u}-type) HOMO of Cu[Br_8TPP] (D_{2d})

Investigations of single crystal Cu[TPP] and Ag[TPP] with ^{14}N, ^{1}H, and metal ENDOR spectroscopy by Brown and Hoffman have yielded the complete hyperfine coupling and ^{14}N quadrupolar tensors of the two complexes.[20] Theoretical analyses of the spectra suggested metal spin populations of 0.62 for Cu[TPP] and 0.38 for Ag[TPP]. DFT(PW91/TZP) calculations on Cu^{II} porphine yielded a Cu spin population of 50.7%.[2] In this work, we present EPR and ^{14}N ENDOR measurements on the saddled Cu porphyrin derivatives Cu[Cl_8T(*p*-CF_3-P)P], Cu[Cl_8TPP], Cu[Br_8T(*p*-CF_3-P)P], and Cu[Br_8TPP] (Figure 3), and DFT(PW91/TZP) calculations on Cu[Br_8TPP], Cu[Br_8TPFPP], Cu[Cl_8TPP], and Cu[Cl_8TPFPP] (Figure 4).

Results

The EPR spectra of the (porphyrin)Cu complexes examined here are qualitatively similar to those of other tetragonal planar copper complexes. The $g_{\|}$ peaks partially overlap with the $g_{\perp}$ peaks. The $g_{\|}$, $g_{\perp}$ and $^{Cu}A_{\|}$ values were obtained by EPR simulations with WINEPR SimFornia (version 1.25, Bruker Analytische Messtechnik GmbH) and are listed in Table 1. In the EPR simulations, the nitrogen hyperfine tensors were taken from the ^{14}N ENDOR results. As can be seen from Table 1, the $g_{\|}$ (≈ 2.19) and $g_{\perp}$ (≈ 2.05) values of all the Cu porphyrin complexes examined are identical within experimental error. However, the absolute values of $^{Cu}A_{\|}$ differ significantly among the various compounds studied and decrease in the following order: Cu[T(*p*-CF_3-P)P] ≈ Cu[TPP] > Cu[Cl_8T(*p*-CF_3-P)P] ≈ Cu[Cl_8TPP] > Cu[Br_8T(*p*-CF_3-P)P] ≈ Cu[Br_8TPP]. These

[a] X and Y are functional groups marked in Figure 3. [b] Unit is in MHz. [c] Spin density on copper ion calculated with Equation (1).

Figure 5 displays the ^{14}N ENDOR spectra of Cu[TPP] and Cu[Br_8TPP] taken at $g_{\|}$ and $^{Cu}I_{-3/2}$, where only single-crystal-like spectra, derived from the molecules with their symmetry axis parallel to the static magnetic field, were collected for both samples. A significant hyperfine coupling shift (−5.4 MHz or −2.7 MHz peak-to-peak) between Cu[TPP] and Cu[Br_8TPP] was observed. Unlike the well-resolved double ENDOR spectra presented by Schweiger in his review on ENDOR studies of transition metal complexes,[22] the ^{14}N ENDOR spectra of Cu[T(*p*-CF_3-P)P] at both parallel and perpendicular field positions are unresolved, as shown in Figure 6. The well-matched simulation results (obtained with GENSIM, a locally developed software) are also presented in Figure 6. The sharp simulated peaks reveal the positions of the hyperfine couplings ($A_n/2$, $n = 1, 2, 3$), nuclear Zeeman splitting ($2\nu_N$, since $A_n/2 > \nu_N$) and quadrupole splitting ($3P_n$, $n = 1, 2, 3$). The quadrupole splitting was taken from previous work on Cu[TPP] and are assumed to differ only slightly in other complexes. Numerous hyperfine coupling values were attempted in the simulation to best match the simulated and experimental spectra. The $^{N}A_\perp$ at $g_{\|}$ (or $^{N}A_1$) values, unlike the others, were measured directly from the spectra. Unlike the single-crystal-like spectra taken at the parallel field position, there are two components, $^{N}A_2$ (or $^{N}A_\perp$) and $^{N}A_3$ (or $^{N}A_{\|}$), at the perpendicular field position. These originate from the Cu−N vectors perpendicular and parallel to the magnetic field, respectively. The full ^{14}N ENDOR spectra

of the various (porphyrin)copper complexes studied at parallel and perpendicular field positions, along with the simulated spectra, are shown in Figures 7 and 8, respectively. The arrows mark the hyperfine splitting peak positions in the spectra and the ^{14}N hyperfine couplings are listed in Table 1. The ^{14}N hyperfine couplings decrease in the same order as $^{Cu}A_{\|}$, namely Cu[T(*p*-CF_3-P)P] ≈ Cu[TPP] > Cu[Cl_8T(*p*-CF_3-P)P] ≈ Cu[Cl_8TPP] > Cu[Br_8T(*p*-CF_3-P)P] ≈ Cu[Br_8TPP]. This sequence is also depicted in the bar graph of Figure 9, which again shows that hyperfine couplings decrease on going from the β-unsubstituted to the β-octachloro and β-octabromo complexes.

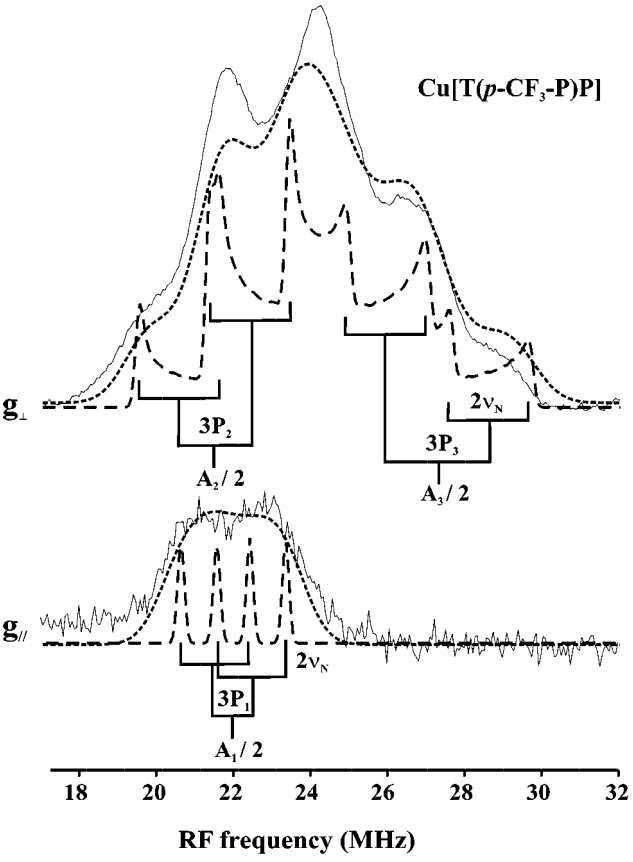

Figure 6. ^{14}N Davies ENDOR spectra of Cu[T(*p*-CF_3-P)P] at both parallel and perpendicular field positions; the solid lines are the experimental spectra, the dotted lines the simulated spectra, and the dashed lines the simulated lines with narrow line width to show the peak positions, which are marked in the graph; the experimental conditions are the same as in Figure 5

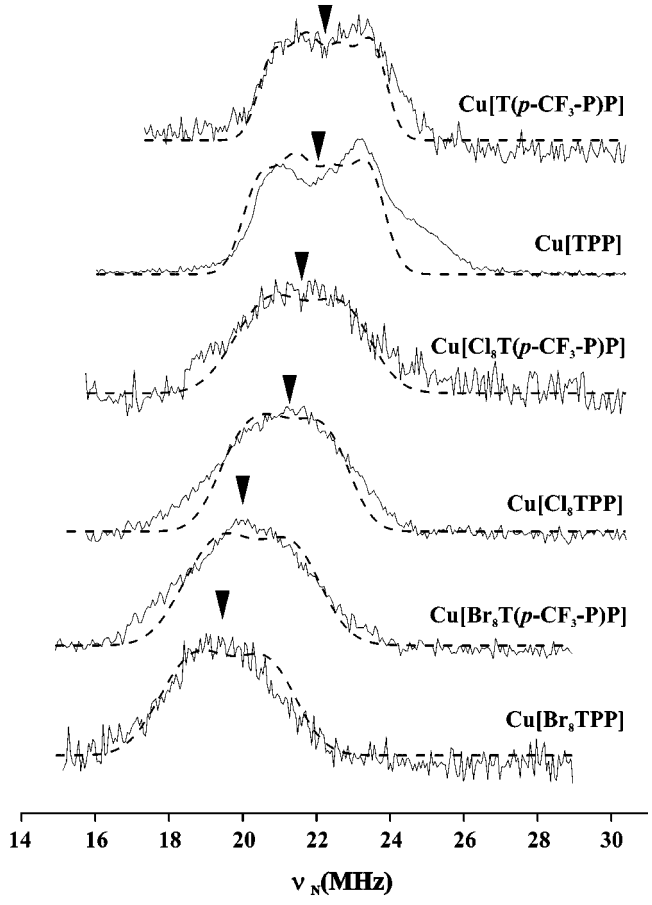

Figure 7. ^{14}N Davies ENDOR spectra of all the complexes at parallel field position; the arrows denote the centers of the hyperfine coupling peaks; the experimental conditions are the same as in Figure 5

Figure 10 shows the X-band (9 GHz, bottom) and K_a-band (35 GHz, top) proton and fluorine ENDOR spectra of Cu[Br_8T(*p*-CF_3-P)P]. With the X-band, the ^{19}F splittings, arising from the trifluoromethyl group, overlap at the low-frequency shoulder of the proton hyperfine coupling profile. With the K_a-band, the hyperfine couplings from the two components are completely separated. Since there are no β-protons on the pyrrole rings in this compound, the proton signals are assigned to phenyl ring protons. This indicates that proton hyperfine couplings originally assigned to pyrrole hydrogen atoms[20] are in fact associated with phenyl hydrogen atoms. Absent selective deuteration or chemical substitution, as done here, the distinction be-

tween these two types of proton at similar distances from Cu is very challenging.

Table 3, in conjunction with Figure 4, shows selected optimized geometry parameters for $Cu^{II}[Br_8TPP]$, $Cu^{II}[Br_8$-TPFPP], $Cu^{II}[Cl_8TPP]$, and $Cu^{II}[Cl_8TPFPP]$. As shown by the out-of-plane *z*-displacement of the β-carbon atoms (z_β), the β-octabrominated complexes are significantly more saddled than the corresponding β-octachlorinated analogues. However, analogous TPP and TPFPP derivatives are comparably saddled. The Cu−N bond lengths are approximately the same (2.01−2.03 Å) in all four molecules. Table 4 shows the calculated atomic spin populations for these four saddled porphyrins, and these data are discussed in the next section.

Table 4. Gross atomic spin populations

Discussion

Isotropic hyperfine coupling arises from the Fermi interaction and is proportional to the spin population on the observed nonmetal nucleus (nitrogen nuclei in this case) [Equation (1)],[23] where g_e is the electron *g* value, $g_{||}$ the par-

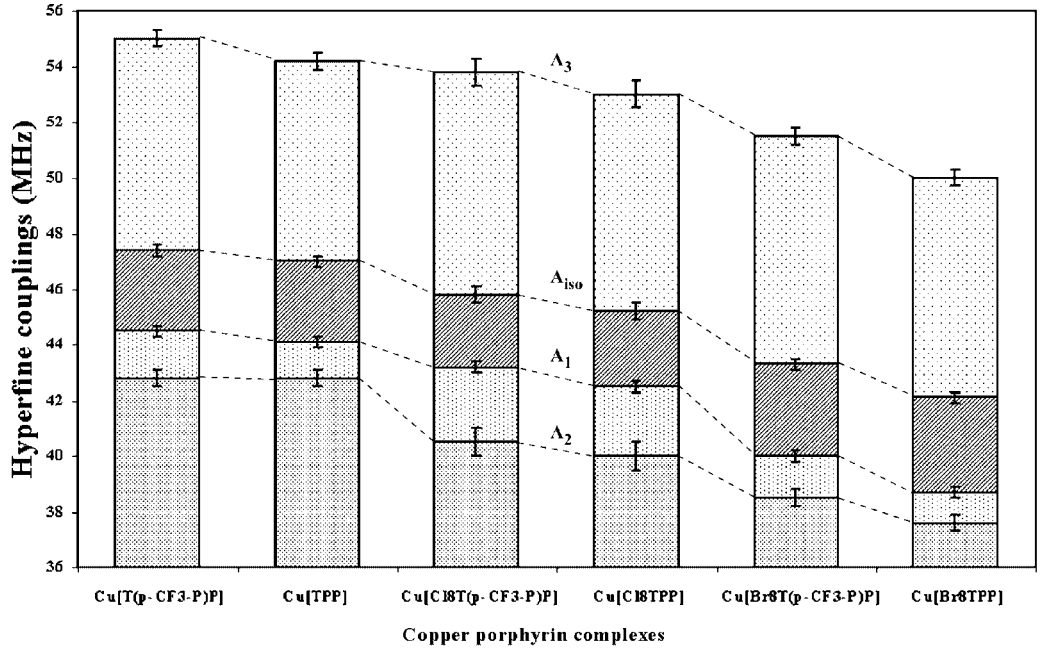

Figure 9. Bar graph of the hyperfine couplings of all (porphyrin)copper complexes

allel *g* value, $g_\perp$ the perpendicular *g* value, α_1^2 the odd electron populations on the copper ion, ignoring the interactions between copper $d_{x^2-y^2}$ and nitrogen 2s and 2p orbitals.

$$^{Cu}A_\parallel = {}^{Cu}A_1 = P[-\kappa - {}^4/_7\alpha_1{}^2 - {}^3/_7(g_e - g_\perp) - (g_e - g_\parallel)] \quad (1)$$

The parameter *P* is proportional to the radial expectation value of the square of the $d_{x^2-y^2}$ orbital amplitude of the metal, and κ is an empirical constant that describes the inner-shell polarization by the d-shell vacancy and quantifies the isotropic metal hyperfine coupling.[24] By taking $P = 0.037$ and[25] $\kappa = 0.406$ [adjusted value to obtain a spin density of 0.624[20] on the copper ion in Cu[TPP] with Equation (1)], we can empirically estimate the spin populations on all (porphyrin)copper complexes examined. Table 2 summarizes the EPR data for a wide range of (porphyrin)copper complexes, including the empirically estimated copper spin populations. The main conclusions based on Tables 1 and 2 are as follows.

As mentioned above, both the $^{Cu}A_\parallel$ and $^{14}N_{iso}$ hyperfine couplings decrease in the following order: Cu[T(*p*-CF_3-P)P] ≈ Cu[TPP] > Cu[Cl_8T(*p*-CF_3-P)P] ≈ Cu[Cl_8TPP] > Cu[Br_8T(*p*-CF_3-P)P] ≈ Cu[Br_8TPP] (Table 1). In other words, Table 1 indicates that the $^{Cu}A_\parallel$ hyperfine couplings of the saddled complexes are generally considerably lower than those of their planar counterparts and are comparable only to those observed for highly electron-deficient *meso*-tetrakis(pyridiniumyl)porphyrin derivatives, Cu[TMPyP][26] (Table 2). This indicates that the spin populations on the Cu and N atoms decrease with increasing saddling of the macrocycle. The decrease in the Cu spin population is understandable as a simple consequence of the saddling-induced Cu($d_{x^2-y^2}$)−porphyrin(a_{2u}) orbital overlap whereby some of the Cu spin density is delocalized onto the porphyrin ring. However, we believe that the decrease in nitrogen spin population with saddling reflects two opposing factors. On the one hand, saddling inhibits contact between the nitrogen lone-pairs and the Cu $d_{x^2-y^2}$ orbital. On the other hand, saddling encourages and enhances the overlap between the copper $d_{x^2-y^2}$ and the porphyrin a_{2u} HOMO. The combined result of these two factors is a certain decrease in spin population on the nitrogen atoms.

The decrease in spin density on going from the β-unsubstituted to the β-octahalogenated complexes, as measured by the $^{Cu}A_\parallel$ and $^{14}N_{iso}$ hyperfine couplings, is consistent with DFT calculations showing atomic spin populations for Cu^{II}[Br_8TPP]: Cu 42.4, N 9.9 and C_{meso} 4.9%. This can be compared with (porphine)Cu^{II}: Cu 50.7, N 10.8 and C_{meso} 0.2%. The DFT calculations indicate that the loss of spin density on the copper and nitrogen atoms in the saddled complexes is accompanied by an increase in the spin density on C_{meso}. This effect can potentially be explored by EPR and ENDOR analysis of $^{13}C_{meso}$ analogues of the relevant complexes, but such analyses have not yet been completed.

Conclusion

In summary, we have studied a number of (β-octahalo-*meso*-tetraarylporphyrins)copper(II) complexes by using EPR/ENDOR spectroscopy and DFT calculations to better understand the consequences of the saddling-induced metal($d_{x^2-y^2}$)−porphyrin(a_{2u}) orbital overlap on the electron distribution of (porphyrin)copper complexes. Both EPR/ENDOR spectroscopy and DFT calculations show that the spin populations on the central copper ion and on the nitrogen atoms are significantly decreased in these saddled complexes relative to their planar counterparts. The diminished spin density on the copper ion is directly attributable to the saddling-induced Cu($d_{x^2-y^2}$)−porphyrin(a_{2u}) orbital overlap whereby Cu spin density is delocalized onto the porphyrin ring. The decrease in nitrogen spin population with saddling appears to be a more subtle effect caused by a superposition of two opposing factors. Saddling decreases the overlap between the nitrogen lone pairs and the Cu $d_{x^2-y^2}$ orbital on one hand and enhances the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

overlap between the copper $d_{x^2-y^2}$ orbital and the porphyrin a_{2u} HOMO on the other.

Experimental Section

The β-octabrominated (porphyrin)copper complexes studied here have been described previously.[3] The β-octachlorinated (porphyrin)copper complexes were prepared using a slightly modified version of the procedure described by Dolphin and co-workers[27] for β-octachlorination of nickel porphyrins: [tetrakis(*para*-X-phenyl)-porphyrin]Cu^{II} (X = H or CF_3) (0.3 mmol) and *N*-chlorosuccinimide (3.6 mmol, 12 equiv.) were dissolved in *o*-dichlorobenzene and heated to 140 °C. The reaction was monitored by UV/Vis spectroscopy and more *N*-chlorosuccinimide was added during the course of the reaction to ensure complete conversion into the β-octachlorinated product (the Soret absorbance changes from ca. 415 to ca. 436 nm). The total reaction time was approximately 24 h. The resulting crude product was purified by flash chromatography on silica gel with dichloromethane/*n*-hexane (2:1) as eluent and further purified on preparative (20 × 20 cm) TLC plates (silica, 0.5 mm thick) with dichloromethane/*n*-hexane (2:1) as eluent. EPR and ENDOR samples were prepared by dissolving the complexes in a mixed solvent consisting of 40% chloroform (99.9%, Aldrich) and 60% toluene (99.8+%, Aldrich) by volume. The samples were frozen in liquid nitrogen. Powder samples of the complexes were prepared by mixing each complex with NiTPP (which is EPR-silent) in a 1:100 ratio in toluene solution with subsequent evaporation of the toluene. In the case of the rather insoluble Cu[Cl_8T(*p*-CF_3-P)P] complex, a solid sample of this complex was diluted with Ni[Cl_8T(*p*-CF_3-P)P] to generate a powder sample suitable for EPR measurements. In general, the powder samples yielded spectra that were identical to the frozen solution spectra, except that the former exhibited slightly higher resolution. EPR spectra were obtained on a Varian E-4 EPR spectrometer at 77 K. Two home-built X-band and Q-band pulsed ENDOR spectrometers, which have been described elsewhere,[28,29] were used to collect the ENDOR spectra at 4.2 K and 2 K, respectively. DFT calculations on selected saddled (porphyrin)copper complexes (Figure 4) were carried out using Slater-type valence triple-ζ with polarization basis sets, the VWN local functional, Perdew−Wang 1991 gradient corrections, a spin-unrestricted formalism, a fine mesh for numerical integration of matrix elements, full geometry optimizations, and the ADF program system.[30,31]

Catalytic Properties and the Role of Copper in Bovine and Lentil Seedling Copper/Quinone-Containing Amine Oxidases: Controversial Opinions

Enzo Agostinelli,*[a,b] Francesca Belli,[a] Laura Dalla Vedova,[a] Silvia Longu,[c] Anna Mura,[c] and Giovanni Floris[c]

Keywords: Cobalt / Cofactors / Copper / Hydrazines / 6-Hydroxydopa / Oxidoreductases

In this microreview, the differences in the catalytic cycle of two copper/quinone-containing amine oxidases, one from lentil seedlings, representative of plant enzymes, and the other from bovine serum, typical of mammalian enzymes, are discussed. Although both enzymes are involved in the control of the levels of mono-, di-, and polyamines, and contain the same organic cofactor, the quinone of 2,4,5-trihydroxyphenylalanine, known as TOPA or TPQ, lentil amine oxidase operates in a different way and with a much higher catalytic activity than the bovine serum enzyme. The role of copper in the two enzymes is also discussed.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Abbreviations: TPQ or TOPA: quinone of 2,4,5-trihydroxyphenylalanine (6-hydroxydopa quinone). Cu/TPQ-AO: copper/TPQ-containing amine oxidase. LSAO: Cu/TPQ-AO from lentil seedlings. BSAO: Cu/TPQ-AO from bovine serum.

Plant and mammalian plasma amine oxidases [amine:oxygen oxidoreductase (deaminating) (copper containing); EC 1.4.3.6] (Cu/TPQ-AOs) belong to the heterogeneous superfamily of enzymes catalyzing the oxidative deamination of primary amino groups of mono-, di-, and polyamines. Cu/TPQ-AOs share some fundamental structural properties: these enzymes are homodimers, with each subunit containing one tightly bound Cu^{II} ion and one quinone of 2,4,5-trihydroxyphenylalanine (TPQ) as cofactors.[1] These enzymes operate by abstracting two electrons from amines and transferring them to molecular oxygen to form the corresponding aldehyde, ammonia, and hydrogen peroxide. The ping-pong catalytic mechanism of Cu/TPQ-AOs can be divided into two half-reactions: (1) enzyme reduction by substrate at the quinone moiety (TPQ → $TPQH_2$) and (2) its reoxidation by molecular oxygen as shown below:

$$E_{ox} + R\text{-}CH_2\text{-}NH_3^+ \rightarrow E_{red}\text{-}NH_3^+ + R\text{-}CHO \quad (1)$$

$$E_{red}\text{-}NH_3^+ + O_2 + H_2O \rightarrow E_{ox} + NH_4^+ + H_2O_2 \quad (2)$$

Plant amine oxidases are intracellular enzymes, the best known and studied being those from seedlings of lentil (*Lens esculenta*)[2] and pea (*Pisum sativum*),[3] and from the latex of the shrub *Euphorbia characias*.[4] These enzymes prefer short aliphatic diamines, like putrescine (1,4-diaminobutane) and cadaverine (1,5-diaminopentane), as substrates. Plant AOs have an important role in cell growth by regulating the intracellular di- and polyamine levels, while the aldehyde products might have a key role in the biosynthesis of some alkaloids.

Mammalian plasma AOs are extracellular enzymes that are able to metabolize mono-, di-, and polyamines, even though in vitro they are preferentially active towards non-physiological amines like benzylamine. Plasma AOs are generally termed either plasma or serum AOs or benzylamine oxidases. The best known plasma AOs are those from bovine,[5,6] pig,[7] and equine plasma.[8]

In this microreview, a number of controversial questions about the structure and function of AOs are discussed, and

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

the characteristics of the enzyme from lentil seedlings (LSAO), as representative of plant AOs, are compared with the corresponding features of bovine serum enzyme (BSAO), typical of mammalian proteins.

1. The Organic Cofactor

The first controversial matter involving all Cu/TPQ AOs has been the identification of the organic carbonyl cofactor. For many years, the most likely candidate was considered an unusual covalently bound form of pyridoxal 5-phosphate, but confirmation of such a structure was not forthcoming. In 1984[9,10] two independent reports seemed to have solved this controversial problem by suggesting that pyrroloquinoline quinone might be the active organic cofactor of a variety of eukaryotic proteins, including copper AOs from bovine serum, pig kidney, and from plants. Finally, in 1990 Janes et al. demonstrated that the redox-active cofactor of eukaryotic amine oxidases is the 2,4,5-trihydroxyphenylalanine quinone (6-hydroxydopa; Figure 1).[1]

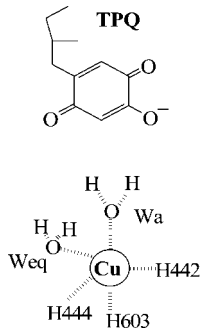

Figure 1. Structure of oxidized form of TPQ and the copper center.

TPQ is derived from the copper-catalyzed oxidation of a post-translationally modified tyrosine residue in the consensus sequence Asn-y-Asp/Glu of the polypeptide chain[11,12] common to plant and mammalian CuAOs analyzed so far.[13] Due to the presence of TPQ, the oxidized form of both LSAO and BSAO has a distinctive pink color and, in addition to the protein absorbance maximum at 278 nm, absorbs in the visible region: BSAO shows the electronic absorption band at 476 nm (ε_{476} = 3800 M^{-1} cm^{-1})[5] whereas

in LSAO the visible absorption band is centered at 498 nm (ε_{498} = 4100 $M^{-1}cm^{-1}$).[2]

2. The Number of Active Sites

Since all Cu/TPQAOs are homodimers of apparently identical subunits, although the molecular size of the BSAO subunit (85 KDa) is larger than that of LSAO (70 KDa), a problem arose concerning the number of active sites present in native proteins. Thus, a controversial matter on whether one[5,14] or two[15,16] TPQs per dimer are active in AOs from different sources is still debated. The conflicting results obtained on titrating AOs with carbonyl reagents, such as phenylhydrazine, have been rationalized for LSAO.[17] The titration of highly purified samples extrapolated to 1 mol of inhibitor per enzyme subunit indicated the presence of two active quinone moieties per dimer. With carbonyl reagents, such as phenylhydrazine, a stoichiometry of one organic cofactor per protein subunit/mol of inhibitor has been reported for highly purified samples of BSAO,[15] although other research groups, using similar methods, had previously determined a single carbonyl cofactor per dimer.[18,19] Taking into account the results obtained by Janes and Klinman,[15] a spectroscopic study was carefully undertaken on the reaction of BSAO with some inhibitors for determining the stoichiometry of binding.[5] The results showed that BSAO samples having a specific activity comparable to that used by Janes and Klinman react with a stoichiometry of one phenylhydrazine per BSAO dimer. The lower value for the phenylhydrazine/BSAO ratio was mainly attributed to the lower quality of phenylhydrazine being used in the titration, which is reflected by the different molar extinction coefficient of the adduct at 447 nm, corresponding to 41 500 $M^{-1}cm^{-1}$[5] vs. 32 400 $M^{-1}cm^{-1}$.[15] Moreover, reaction of the bovine serum enzyme with other inhibitors like hydrazines and hydrazides[20] led to the proposal of a so-called "half of the sites" reactivity mechanism.[5,21]

3. The Catalytic Cycle Of Cu/TPQ–AOs

Several differences are worth specific mention concerning the catalytic mechanism of LSAO and BSAO.

The Reductive Half-Reaction

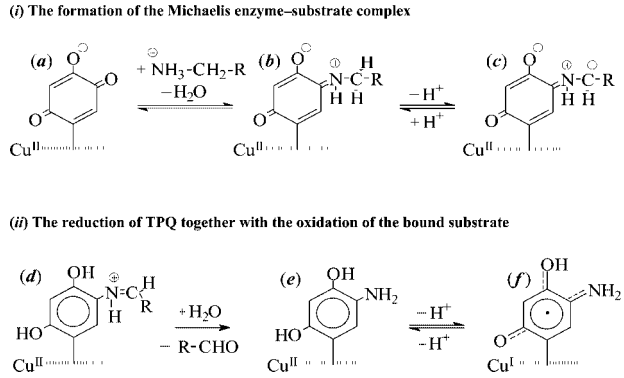
As shown in Scheme 1, at least three separate kinetic steps participate in the reductive half cycle: (*i*) the formation of the Michaelis enzyme–substrate complex, (*ii*) the reduction of TPQ together with the oxidation of the bound substrate to yield the enzyme–product complex; (*iii*) the hydrolysis of the enzyme–product complex with the release of the aldehyde and the formation of the aminoquinol derivative.

Formation of the Michaelis Enzyme–Substrate Complex

Step 1: The Substrate Schiff-Base Cu^{II}–Quinone Ketimine

The amine substrate binds to a carbonyl function of TPQ in the resting oxidized enzyme [Cu^{II}–TPQ, (see *a* in Scheme 1; Figure 2)] to form a substrate Schiff base [Cu^{II}–quinone ketimine; (see *b* in Scheme 1)]. Hartmann and coworkers[22] have demonstrated that the reaction of BSAO with benzylamine as substrate under anaerobic conditions generates a detectable relaxation at 340 nm, which was attributed to the quinone ketimine. Thus, the quinone and the quinone ketimine oxidized forms of the enzyme, which both absorb at 476 nm, are spectroscopically distinguishable since only *b* shows a shoulder at 340 nm.

In LSAO, as previously demonstrated,[23] the quinone ketimine intermediate has the same "pink" spectrum as that of the native enzyme



Scheme 1. Catalytic mechanism of Cu–AOs: the reductive half-reaction. (*a*) Resting oxidized enzyme; (*b*) Cu^{II}–quinone ketimine, the substrate Schiff base; (*c*) Cu^{II}–carbanion species; (*d*) Cu^{II}–quinolaldimine, the product Schiff base; (*e*) Cu^{II}–aminoquinol; (*f*) Cu^{I}–semiquinolamine radical.

Step 2: Cu^{II}–Carbanion Species

The oxidation of the amine substrate involves a base-catalyzed hydrogen abstraction from the C bound to nitrogen, leading to the formation of a Cu^{II}–carbanion species (see *c* in Scheme 1). The formation of the carbanion species has been demonstrated, in the case of BSAO, using *para*-substituted benzylamines,[24] and, in LSAO, through the reaction with the electrophilic reagent tetranitromethane to generate the nitroform anion.[25] The active-site base was identified as Asp_{300} in LSAO[26] and Asp_{381} in BSAO.[27]

The Reduction of TPQ Together With the Oxidation of the Bound Substrate

Step 3: The Product Schiff base Cu^{II}–Quinolaldimine

Transformation of the Cu^{II}–carbanion (*c*) into the product Schiff base Cu^{II}–quinolaldimine (see *d* in Scheme 1) involves the transfer of two electrons from the substrate amine to the oxidized form of TPQ, and is associated with the bleaching of the visible absorption band. In LSAO, after addition of the poor substrate *p*-(dimethylamino)benzylamine ($k_{cat} = 2.3 \times 10^{-4}$ s^{-1}) a new intense band centered at 400 nm appears.[2] This band is assigned to the protonated tautomeric form of the quinolaldimine (a "quino"-imine; Figure 3). The quino-imine form was also identified

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

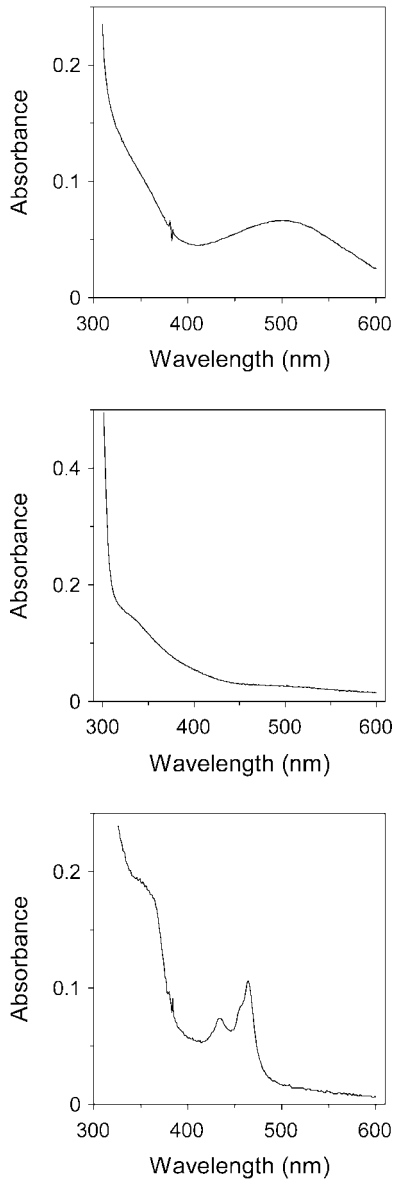


Figure 2. Visible absorption spectrum of LSAO. Top: resting oxidized enzyme; middle: the Cu^{II}–aminoquinol; bottom: Cu^{I}–semiquinolamine radical.

in BSAO[22] due to its broad absorption band at 460 nm. The reason why LSAO and the bovine serum enzyme give a different quino-imine spectrum is not clear.

Step 4: Cu^{II}–Aminoquinol

Oxidation of the bound substrate (followed by hydrolysis) releases the aldehyde product and gives the Cu^{II}–aminoquinol derivative (see *e* in Scheme 1). In both enzymes this species is colorless (Figure 2) and it was impossible to assign a defined difference spectrum attributed to the transformation of quinolaldimine into aminoquinol. In both enzymes the aldehyde is released after hydrolysis of the imine, and ^{15}N-isotope experiments have demonstrated that the amino group from the substrate is still bound to the TPQ ring structure.[28]

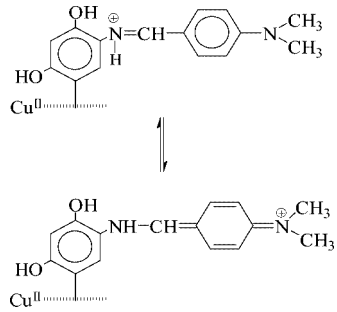

Figure 3. Oxidation of *p*-(dimethylamino)benzylamine by lentil enzyme. The quinolaldimine species is in equilibrium with its tautomeric form, the quino-imine.

Step 5: Cu^{I}–Semiquinolamine Cation Radical Species

This derivative is typical of plant AOs. In lentil enzyme, after the conversion of the TPQ cofactor to the substrate-reduced colorless Cu^{II}–aminoresorcinol, the solution turns yellow immediately as result of the formation of new absorption bands centered at 464, 434, and 360 nm, indicative of a second reduced derivative, the free radical Cu^{I}–semiquinolamine cation species (Scheme 1f; Figure 2).[29] It has been unequivocally demonstrated that copper ion reduction occurs.[2,23] The static spectrum of Cu^{I}–semiquinolamine has been shown to be pH-dependent.[23] The intensities of the absorbances of reduced LSAO observed at pH 7 decrease at both acidic and alkaline pH values, and disappear completely at extreme pH values (pH $<$ 5 or $>$ 10). The titration data have been fitted to an equilibrium between Cu^{I}–semiquinolamine and the bleached Cu^{II}–aminoquinol controlled by two independent ionizable groups with $pK_1 = 5.7$ and $pK_2 = 7.9$:

Cu^{I}–semiquinolamine (pH 7) $\rightleftharpoons$ Cu^{II}–aminoquinol (pH 5 or 10)

The radical species could not be detected below 258 K, and was observed in increasing amounts from 283 to 298 K, the highest temperature investigated.[30] Thus, in LSAO, as in other plant AOs, the Cu^{II}–aminoquinol derivative equilibrates rapidly with the Cu^{I}–semiquinolamine cation radical species by transferring one electron to copper, which in turn is reduced from the cupric to the cuprous state.[31] Even under the most favorable experimental conditions, the population of Cu^{I}–semiquinolamine radical does not exceed 30–40% of the total TPQ, as estimated by ESR spectroscopy.[32]

BSAO does not populate the Cu^{I}–semiquinolamine radical species, but the presence of about 1% of a radical derivative has been demonstrated by Su and Klinman[33] in the mechanism of dioxygen conversion into hydrogen peroxide without the conversion of Cu^{II} to Cu^{I} (see "the oxidative half-reaction" below).

In conclusion, in the reductive half-reaction four steps are quite similar in BSAO and LSAO and, in consideration of the spectroscopic changes described above, in both enzymes the Cu^{II}–quinone ketimine and Cu^{II}–carbanion species are believed to be pink, whereas Cu^{II}–quinolaldimine and Cu^{II}–aminoquinol species are colorless. As described as step five, the yellow Cu^{I}–semiquinolamine cation radical

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

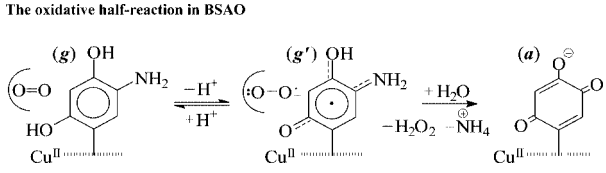
species is only present in plant enzymes and represents the biggest difference observed between LSAO and BSAO in the reductive catalytic mechanism.

The Oxidative Half-Reaction

The Oxidative Half-Reaction in BSAO is Very Different to That of LSAO

The Oxidative Half-Reaction in BSAO: Mechanism of Proton-Coupled Electron Transfer to Dioxygen

In an extensive study of the reoxidation of BSAO, an enzyme which does not normally populate the Cu^{I}–semiquinolamine radical, Su and Klinman[33] have reported a detailed analysis of a chemical and kinetic mechanism of dioxygen conversion into hydrogen peroxide that does not require the conversion of Cu^{II} into Cu^{I}. Oxygen initially binds to a non-metal site of the enzyme and the reduced TPQ starts the reaction by transferring one electron to dioxygen to form the superoxide anion. This superoxide may bind to Cu^{II}, thereby facilitating the transfer of a second electron and two protons from the semiquinolamine radical and the release of H_2O_2 (see *g* and *g′* Scheme 2). Thus, during its reoxidation, the reduced BSAO populates a single intermediate species, the reversible oxygen complex $E_{red}O_2$, which has the same absorbance spectrum as E_{red}. The subsequent release of ammonia regenerates the Cu^{II}–quinone species.



Scheme 2. Catalytic mechanism of BSAO: the oxidative half-reaction. *g, g′*: Cu^{II}–aminoresorcinol–oxygen complex. *a*: Resting oxidized enzyme.

The Oxidative Half-Reaction in LSAO

The Cu^{I}–semiquinolamine cation radical described in "the reductive half-cycle" is the species that reacts rapidly with oxygen.[23,30] This observation has allowed Floris and co-workers[23] to determine the oxidation rate constant of reduced LSAO as a function of the semiquinolamine radical population. Their study demonstrates that both reduced derivatives − the Cu^{I}–semiquinolamine and the Cu^{II}–aminoquinol − are capable of reacting with oxygen, although with widely different rate constants, and that at neutral pH the reaction path involving the semiquinolamine radical intermediate largely predominates. Moreover, under experimental conditions that inhibit the conversion to the radical species, the apparent second-order rate constant for oxidation of LSAO closely approaches that of BSAO, although the stability of the $E_{red}O_2$ complex is much lower in the former enzyme, perhaps because of its faster conversion to the oxidized derivative (E_{ox}). In the same way as BSAO, the subsequent release of ammonia regenerates the Cu^{II}–quinone species.

4. The Role of Copper

The discussion of the oxidative half-reaction implies another controversial matter: the role of copper in the catalytic mechanism of AOs. All Cu/TPQ AOs contain a copper atom in a 1:1 stoichiometric ratio with the organic cofactor. The ESR parameters of copper/TPQ AOs fall in the category of so-called type-2 Cu ESR spectra.[34] The copper ion is coordinated to three hystidine residues and two water molecules (Figure 1) and is located very close to the TPQ cofactor. Copper is essential for the reoxidation of the substrate-reduced enzyme in the presence of oxygen and appears to control the transfer of substrates from a hydrophobic binding site near the protein surface[35] to the deeply buried active site.[3,36]

A Structural Role for Copper

The role of the metal cofactor in the catalytic mechanism of BSAO has partially been solved by studies using both copper-free enzyme[18] and enzymes in which the copper has been replaced with other metals.[37] Copper can be removed from BSAO by treatment with sodium dithionite in the presence of potassium cyanide[18] or benzylamine under anaerobic conditions.[37] The two derivatives contained about 0.22 or 0.70 residual Cu^{II} centers per dimer (corresponding to 10 and 35% residual Cu^{II} per dimer, respectively)[37] depending on the reagent added (potassium cyanide or benzylamine) and were found to be almost totally inactive. The Cu-depleted protein does not react with hydrazine inhibitors and, when reduced by substrate, does not undergo the reoxidation process.[35] After complete removal of copper, the metal binding site of BSAO may accept other metal ions, like Co^{II}, Ni^{II}, and Zn^{II}.[31,38] The addition of cobalt to Cu^{II}-depleted BSAO partially restores the activity of the enzyme (up to 25–40%, corresponding to a k_{cat} value of 0.31–0.49)[18,39] (Table 1), thus confirming that the enzyme does not require the conversion of the cupric copper ion to the cuprous state in the mechanism of dioxygen conversion into H_2O_2. Thus, in BSAO, the metal, whether Cu^{II} or Co^{II}, is not directly involved in amine oxidation, but may have a structural function, as confirmed by the closely similar behavior of Cu^{II} and Co^{II} BSAO derivatives upon deconvolution of their thermal profiles in DSC studies.[38] In these studies, the deconvolution of thermal profiles in native BSAO showed five subpeaks, while the fully-Cu-depleted BSAO required at least six two-state transitions. The thermal profiles of Co^{II}-reconstituted enzyme closely resemble those of the native and Cu^{II}-reconstituted BSAO. The thermograms of both BSAO derivatives can be deconvoluted into five two-state transitions that characterize the native enzyme.[38]

Table 1. Differences and common features between amine oxidase from bovine serum (BSAO) and lentil seedlings (LSAO).

	BSAO	LSAO
Molecular size subunits (KDa)	85	70
Copper ions (content)	2	2
Number of active sites (TPQ dimer)	2,[15,16] 1[5,14]	2[17]
Absorbance maximum (TPQ oxidized)	476 nm, ε_{476} = 3800 $M^{-1}cm^{-1}$[5]	498 nm, ε_{498} = 4100 $M^{-1}cm^{-1}$[2]
Reduced TPQ aminoquinol	colorless	colorless
Reduced semiquinolamine radical	1% of the total TPQ[33]	30–40% of the total TPQ[29] 464, 434, and 360 nm
Percent activity of Co^{II}-reconstituted enzyme	25–40	7
k_{cat} of native (a) and Co^{II}-substituted (b) enzyme	(a) 1.23,[37,39] (b) 0.31–0.49[37,39]	(a) 155,[44] (b) 11[44]

Reactivity with hydrazine derivatives and assays of the enzymatic activity have shown that in the Co^{II} derivative the TPQ is reactive and the enzyme is catalytically competent. The substitution of copper with cobalt does not greatly impair the enzymatic activity. The Co^{II} derivative has the peculiar effect of decreasing both the k_{cat} and the K_M values.[37,39] Thus, substantially smaller K_M values were obtained for all examined amines than for native BSAO, thus confirming that the catalytic activity of Co^{II}–BSAO is not due to residual (10 or 35%) or spurious copper.[27,37]

Furthermore, the CD spectrum of Co^{II}-reconstituted BSAO shows a band at 540 nm which, like the band at 640 nm of the native protein, is assigned to the metal d–d electronic transition.[19,40] The band at 440 nm, which appears in both spectra, is assigned to a TPQ transition.[40]

Thus, we can conclude that, in BSAO, Cu^{II} does not appear to have the usual redox role.[18,35,41] Rather, it seems to affect the redox potential of TPQ and/or modulate the pK_a of the coordinated water molecule, through which it is bonded to organic cofactor-O_2, thus facilitating the proton transfer to O_2. This makes it possible to identify the bridging water, in the place of Asp385, with the catalytic base with a pK_a of about 8.0 controlling BSAO catalytic activity. Such a function could also, in principle, be carried out by a different metal ion.[27,39]

Involvement of Copper in the Catalytic Cycle

In LSAO, copper can be almost completely removed by treatment with *N*,*N*-diethyldithiocarbamate.[42] The residual copper in the LSAO apoenzyme, measured by atomic absorption spectroscopy, is about 0.2 ± 0.02 residual Cu^{II} atoms per dimer (10% residual Cu^{II} per dimer). Copper-free LSAO is still pink and shows a broad absorption peak in the visible region at 480 nm that is shifted towards shorter wavelengths with respect to the native enzyme, but with similar intensity; apo-LSAO is able to oxidize one equivalent of substrate, although copper removal prevents the formation of the semiquinolamine radical and reoxidation of the enzyme. The oxidation occurs under single turnover conditions and releases one equivalent of aldehyde per enzyme subunit under anaerobic as well as aerobic conditions.[43] Moreover, apo-LSAO reacts with phenylhydrazine in a stoichiometry of two mol of inhibitor per mol of apoenzyme dimer, i.e. in a similar manner as the native enzyme.[42] This suggests that in LSAO copper has not only a structural function, as supposed for BSAO. Through a detailed analysis of fully copper depleted, half reconstituted, or fully reconstituted, and of the Co^{II}-substituted LSAO, Padiglia et al.[44] have shown that copper ions are essential for the fast catalytic rate of lentil enzyme. Although the Co^{II}-substituted enzyme retains some activity, the k_{cat} value for the best substrate (putrescine) is much lower than that of the native enzyme (11 vs. 155), and the formation of the semiquinolamine radical is not proven. Thus, in LSAO, copper is certainly involved in the amine oxidation process, and the formation of the Cu^{I}–semiquinone species is an essential step of the catalytic pathway. Cu^{I}–semiquinolamine radical is the species that reacts preferentially with O_2[2,23,30] and the lower catalytic activity of Co^{II}–LSAO may be ascribed to its slow reoxidation.

5. Concluding Remarks

Amine oxidases, a widespread class of enzymes, are present in all living systems, where they control the level of very active compounds, i.e. mono-, di-, and polyamines. The oxidation of these compounds may generate other biologically active substances, such as aldehydes, ammonia, and hydrogen peroxide. Both copper ions and TPQ are essential for the enzyme function. The findings for the catalytic cycle of BSAO[45] offer an interesting comparison with those reported for plant amine oxidase.[23] The catalytic mechanism for LSAO may be referred to as a "protein–radical enzyme", operating through a free radical located on the cofactor and the reduction of copper from the cupric to the cuprous state. This is in contrast to BSAO, which forms the free radical intermediate only to a minor extent in the course of the reoxidative step without the reduction of copper. Thus, two steps of the catalytic mechanism are significantly slower in BSAO than in LSAO, namely the reoxidation and the proton abstraction occurring in the enzyme substrate complex. The former difference is rationalized as being due to the low to zero concentration of the semiquinolamine-radical intermediate, while the latter is less easily interpreted. Copper, like TPQ, is an essential cofactor and its removal inactivates the enzymes. Moreover, a change in the valence of copper is found only in lentil enzyme, which is much more active than bovine AO by almost two orders of magnitude (k_{cat} LSAO = 155 s^{-1}; k_{cat} BSAO = 1.23 s^{-1}). In conclusion, the presence of two active sites, the formation of the radical species, and the copper reduction might

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

be the reason for the higher catalytic activity of LSAO with respect to BSAO (Table 1).

Preparation and Characterization of $Ag@TiO_2$ Core-Shell Nanoparticles in Water-in-Oil Emulsions

Dan Zhang,[a] Ximing Song,[b] Rongwei Zhang,[a] Ming Zhang,[a] and Fengqi Liu*[a]

Keywords: Silver / Titanium / Core-shell nanoparticles / Water-in-oil emulsion / Surface photovoltaic spectroscopy

We report a simple route for the effective synthesis of $Ag@TiO_2$ nanoparticles in water-in-oil (w/o) emulsions and provide detailed characterization of the materials with TEM, TG-DTA, IR, XRD, and SPS measurements. Such core-shell hybrid nanoparticles can be fabricated in two simple steps: the formation of the silver core by the reduction of a Tollens reagent with glucose in the water phase, and the hydrolysis of $Ti(OC_4H_9)_4$ at the water/oil interface for the formation of the amorphous TiO_2 shell. The procedure led to the formation of nanocomposites with a crystalline core in a size range from 5 to 15 nm in diameter and an amorphous shell of 6–10 nm thickness in a typical synthesis. The shell was converted to crystalline oxide upon thermal treatment. Surface photovoltaic spectroscopy (SPS) measurements indicate that the materials have potential for application in photoinduced electron storage and photocatalysis.

Introduction

Core-shell metal nanoparticles with oxide shells have attracted considerable attention owing to their stability under extreme conditions,[1] and their optical and catalytic properties.[2–3] The shells offer protection to the cores as well as introducing new properties to the hybrid structures.[4] An important shell-forming material is TiO_2, which offers wide-ranging properties.[5] A number of methods have been used to prepare the core-shell metal nanoparticles.[1,6–8] Among these methods are citrate reduction,[9] borohydride reduction,[10] sonochemical methods,[11] radiolytic reduction,[12] and metal evaporation-condensation.[13] It was shown that the size, composition, and structure of the resultant particles depended on the preparation conditions.

Water-in-oil (w/o) emulsions are thermodynamically stable with nanosized water droplets that are dispersed in a continuous oil phase and stabilized by surfactant molecules at the water/oil interface. The surfactant-stabilized water pools provide a microenvironment for the preparation of nanoparticles by preventing the excessive aggregation of particles. As a result, the particles obtained in such a medium are generally very fine and monodisperse. Many kinds of nanoparticles have been prepared in w/o emulsions including metals,[14] metal oxides,[15] and organic polymers.[16] However, within the limits of our knowledge, the preparation of core-shell metal nanoparticles with oxide shells in w/o emulsions has not been reported yet. In this paper, we describe an effective method for the preparation of $Ag@TiO_2$ nanoparticles in w/o emulsions and provide detailed characterization of the materials. We shall also touch upon one property we are pursuing currently, namely, surface photovoltaic spectroscopy.

Results and Discussion

$Ag@TiO_2$ nanoparticles were fabricated in two simple steps: the formation of the silver core by the reduction of a Tollens reagent with glucose in the water phase of the water-in-oil emulsions, and the hydrolysis of $Ti(OC_4H_9)_4$ (TOB) at the water/oil interface for the formation of the amorphous TiO_2 shell. The water and organic impurities in the as-obtained emulsions containing $Ag@TiO_2$ nanoparticles were removed by vacuum-drying followed by calcination. 0.559 g of $Ag@TiO_2$ nanoparticles were obtained after calcination at 800 °C for 4 h in a typical preparation, and the product yield was approximately 100%.

The transmission electron microscopy (TEM) images and the electron diffraction diagram in Figure 1 clearly illustrate the core-shell structure of $Ag@TiO_2$ nanoparticles with a crystalline core of size 5–15 nm and an amorphous shell of thickness 6–10 nm. The size of the nanoparticles is moderately uniform. There appears some nonuniformity in the shell thickness, but the coverage is complete. In Figure 1 (see B), no diffraction is seen from the amorphous shells at room temperature, but the core manifests bulk fcc patterns. (111), (200), (220), and (311) zone axes are observed.[17]

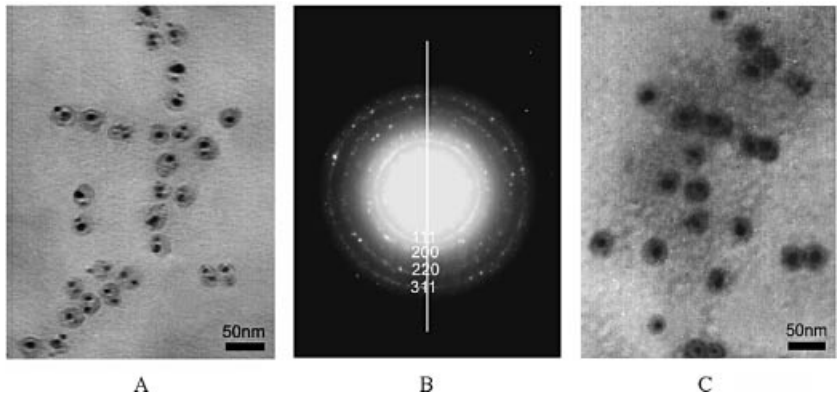

Figure 1. Transmission electron micrographs (A, C) and electron diffraction pattern (B) of $Ag@TiO_2$ nanoparticles. (A) Nanocomposites prepared from 0.59 mmol Ag^+ and 5.9 mmol TOB (wt.-% of Ag: 11.9). (C) Nanocomposites prepared from 0.59 mmol Ag^+ and 7.0 mmol TOB (wt.-% of Ag: 10.2).

The wt.-% of the core component has an influence on the properties of core-shell nanoparticles. In this work, the wt.-% of the Ag component in the nanocomposites could be adjusted by changing the molar ratio of TOB to Ag^+ in the Tollens reagent. From Figure 1 (see A and C), we can conclude that the size of the Ag core does not change and the shell thickness increases with increasing TOB at a fixed amount of Ag^+ in the Tollens reagent, i.e. with the decrease of the relative amount of Ag in the nanocomposites. The variation of the amount of Ag can lead to the formation of nanocomposites with various morphologies. The single-core nanocomposites with various shell thicknesses are the major morphology when the wt.-% of Ag is less than 11.9%, and the multicore nanocomposites are formed when the wt.-% of Ag equals 35.7%, as shown in Figure S2 in the Supporting Information.

The thermal analysis (TG-DTA) curves are shown in Figure 2. The TG curve could be divided into three main stages during the weight loss process of the $Ag@TiO_2$ sample. The first stage was in the range of 100–200 °C, corresponding to desorption or release of solvent and water in the sample. The second stage occurred in the range of 200–500 °C, which resulted mainly from the combustion and decomposition of organic matter, for example Span80, Op10, and butanol, produced from the hydrolysis of TOB. The third loss, less than 4%, was not very obvious in the range 500–700 °C, and was attributed to the dissociation of hydroxyl groups from the surface of TiO_2 nanoparticles. Hydroxyl groups were present in the infrared spectra until the samples were heated to 500 °C. It is well known that there are two types of surface OH groups, terminal Ti–OH and bridge Ti–(OH)–Ti. The dissociation temperatures of these

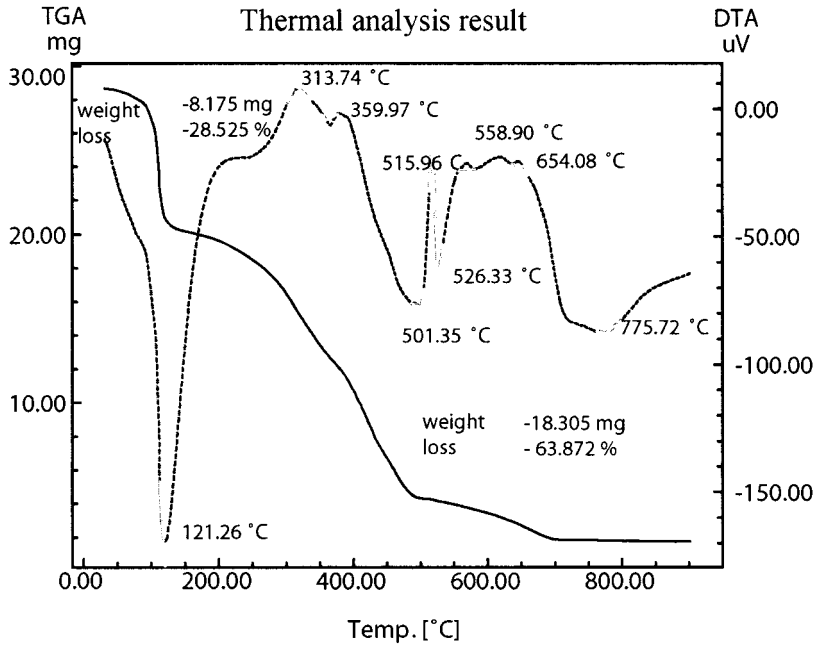

Figure 2. TG-DTA curves of $Ag@TiO_2$ nanoparticles in a typical synthesis.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

surface OH groups differ from each other, and each temperature could also be affected by the chemical surroundings. Thus the decrease in weight appears over a wide temperature range.[18] The DTA curve exhibits a decalescence peak at 121 °C, which corresponds to the desorption or release of solvent and water in the sample . Furthermore, two releasing thermal peaks can be observed at 314 and 360 °C, both corresponding to the combustion and decomposition of the organic matter, and some decalescence and releasing thermal peaks over the range 500–800 °C are also present; they result from the phase transition of TiO_2 from amorphous to anatase (around 500 °C), the dissociation of surface hydroxyl groups (500–700 °C) and the phase transition of TiO_2 from anatase to rutile (around 775 °C). As the oxide cover is solvated with unclear stoichiometry, we did not attempt to analyze the data further.

X-ray powder diffraction (XRD) analysis is usually used for the identification of core-shell structures and crystal phase as well as the estimation of crystallite size.[18] The XRD patterns of TiO_2 and Ag@TiO_2 nanoparticles calcined at 300–800 °C are shown in Figure 3. The peaks at 38°, 44°, 64°, 77° in Figure 3 (see B) are due to the (111), (200), (220), and (311) reflections of the Ag core.[1] Upon thermal treatment to 500 °C for 4 h, an obvious pattern resembling a mixture of anatase and Ag appears (note the peak at 25.3°[19]). The peaks remained almost the same even when the sample was calcined at 700 °C. However, an obvious pattern resembling a mixture of rutile and Ag appeared after calcination at 800 °C for 4 h (note the peak at 27.9°[20]). The phase transformations of the TiO_2 shell from amorphous to anatase and from anatase to rutile occurred with the increase of the calcination temperature, which was in good agreement with the results of TG-DTA. The phase transformation of TiO_2 from anatase, a crystal phase with catalytic activity, to rutile usually occurs at 500–600 °C.[18] However, in our experiments, both TiO_2 and Ag@TiO_2 nanoparticles prepared in the same system of inverse emulsion kept their anatase structure after calcination at 700 °C for 4 h (Figure 3). This observation opens up new possibilities for the application of photocatalysis over a wider temperature range. The effect of preparation methods on the phase-transformation temperature of TiO_2 from anatase to rutile needs further investigation.

The surface photovoltaic spectroscopy (SPS) technique provides a rapid, nondestructive monitor of the surface or interface properties of semiconductors such as TiO_2 and ZnO.[21] The particle size and the surface or interface properties of semiconductors are two important factors affecting the SPS response by influencing the separation efficiency of photoinduced electron–hole pairs.[22] Compared with the bulk or large particles of a semiconductor, the mechanism of SPS generation in a nanosized semiconductor is quite different, and causes the weak SPS signal of a semiconductor nanoparticle.[23] It was found that the smaller the size the weaker the SPS signal of TiO_2 or ZnO nanoparticles.[24] Moreover, the SPS signal of ZnO nanoparticles becomes much weaker when an appropriate amount of nanosized noble metal (Ag or Pd) is deposited on their surface. This

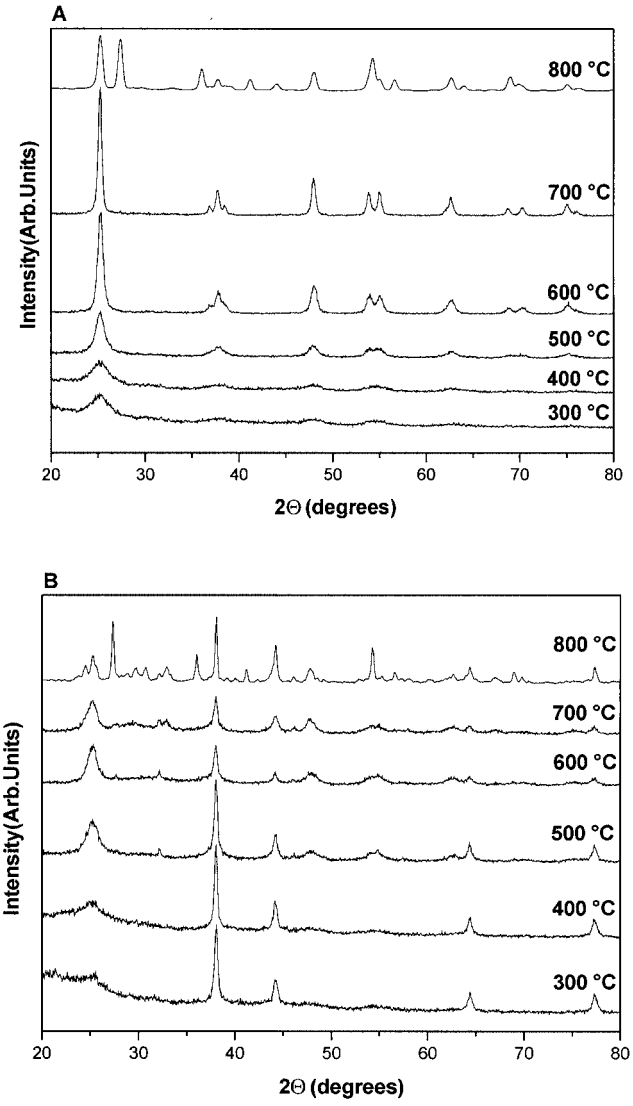

Figure 3. XRD patterns of TiO_2 (A) and Ag@TiO_2 (B) nanoparticles with 11.9% (wt.-%) Ag in a typical synthesis calcined at various temperatures.

may result from the fact that noble metal clusters effectively trap photoinduced electrons.[22]

SPS responses of Ag@TiO_2 and TiO_2 nanoparticles prepared in the same system of inverse emulsion after calcination from 500 °C to 800 °C are shown in Figure 4. The SPS response peaks at 300–400 nm can be attributed to the electron transition from the valence band to the conduction band of TiO_2 ($O_{2p}\rightarrow Ti_{3d}$).[22] The thresholds and surface photovoltages (SPV) obtained from Figure 4 as well as the sizes of the nanoparticles are summarized in Table 1. The red shift of SPS response peaks and the blue shift of thresholds with the increase of calcination temperature may be caused by the quantum size effect.[23] The threshold of Ag@TiO_2 is higher than that of TiO_2 at each calcination temperature (see Table 1) because the Ag core traps photoinduced electrons. The increase in the threshold after the formation of the core-shell structure results in the broadening

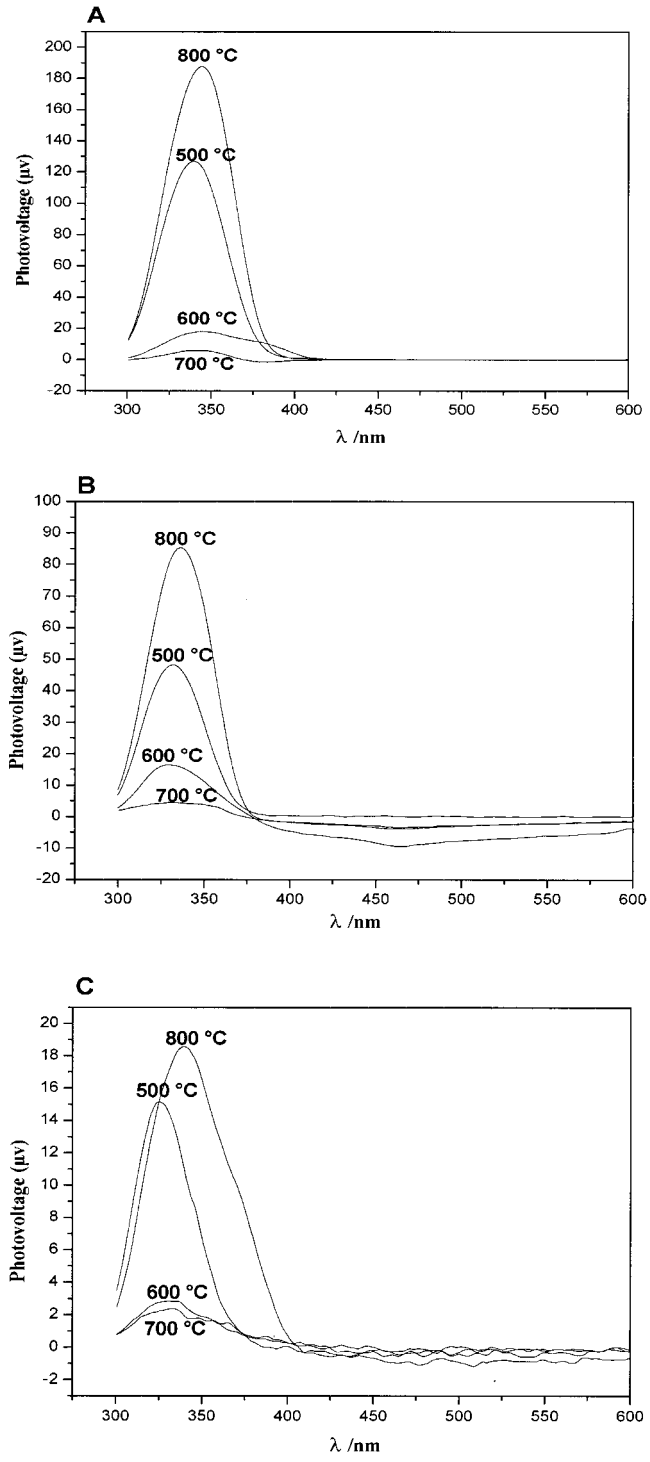

Figure 4. SPS responses of TiO_2 (A) and $Ag@TiO_2$ (B and C) nanoparticles calcined at various temperatures. (B) Nanocomposites prepared from 0.59 mmol Ag^+ and 7.0 mmol TOB (wt.-% of Ag: 10.2). (C) Nanocomposites prepared from 0.59 mmol Ag^+ and 5.9 mmol TOB (wt.-% of Ag: 11.9).

of the bandgap of TiO_2, which improves the separation efficiency of photoinduced carriers.

The SPS response signals of $Ag@TiO_2$ nanoparticles in Figure 4 (see B and C) are much weaker than those of TiO_2 nanoparticles in Figure 4 (see A) at the same calcination temperature, and the red shift of SPS response peaks of $Ag@TiO_2$ nanoparticles in Figure 4 (see C) is much clearer than that of TiO_2 nanoparticles in Figure 4 (see A), both of which are attributed to the effective trapping of photoinduced electrons by the Ag core. Additionally, no SPS signal of a mixture appeared in the SPS spectra when we mixed the same amount of Ag nanoparticles with TiO_2 nanoparticles prepared in the same system of inverse emulsion, because the amount of free Ag nanoparticles was too great.[22,25,26] All these results reveal that Ag nanoparticles were effectively coated with TiO_2 and the presence of the Ag core had an inarguable effect on the SPS signals. On the basis of the SPS responses of $Ag@TiO_2$ nanoparticles with 10.2 and 11.9 wt.-% of Ag, in Figure 4 (see B and C), it is concluded that the SPS response of $Ag@TiO_2$ nanoparticles becomes weaker with an increase in the amount of Ag, because this implies a decrease in the amount of TiO_2 on the surface of the Ag core. In fact, when the wt.-% of Ag in $Ag@TiO_2$ nanoparticles is more than 35.7%, there is no SPS response of $Ag@TiO_2$ nanoparticles at any calcination temperature.

The SPS response signals of $Ag@TiO_2$ and TiO_2 nanoparticles should become stronger with increasing calcination temperature if the size of the nanoparticles had been the only factor influencing SPS response. However, the SPS signals in the range of 500–700 °C for both $Ag@TiO_2$ and TiO_2 nanoparticles in Figure 4 weaken with increasing calcination temperature, which can obviously be attributed to the change of the surface properties of the nanoparticles in this temperature range. TG-DTA and FTIR spectra indicate that the dissociation of hydroxyl groups from the shell surface of $Ag@TiO_2$ nanoparticles takes place in the range of 500–700 °C. The surface hydroxyl groups can play an important role in the photocatalytic actions because the photoinduced holes can attack the surface hydroxyl group and yield a surface-bound OH radical, which efficiently hinders the recombination of electrons and holes.[27] The results of the SPS investigation are in good accordance with those of the TG-DTA and FTIR spectra.

The $Ag@TiO_2$ nanoparticles prepared in w/o emulsions are expected to have a higher photocatalytic activity on the basis of their special SPS responses according to an intrinsic relationship between the SPS response and the photocatalytic activity of TiO_2 or ZnO nanoparticles, i.e. the weaker the SPS signal, the higher the photocatalytic activity.[22] The photocatalytic activity of the $Ag@TiO_2$ nanoparticles is under study.

Conclusions

In summary, we have demonstrated that $Ag@TiO_2$ core-shell nanoparticles could be prepared in water-in-oil emulsions. Such a novel method should be adapted to the preparation of other core-shell metal nanoparticles with oxide shells. The SPS results indicate that $Ag@TiO_2$ nanoparticles

prepared in water-in-oil emulsions have potential applications in photoinduced electron storage and photocatalysis.

Experimental Section

Transmission electron microscopy (TEM) measurements were performed with a Hitachi H-8100 transmission electron microscope. The samples were prepared on carbon-coated copper grids. X-ray diffraction studies were carried out with a Rigaku wide-angle X-ray diffractometer (D/max γA using Cu-K_α radiation at λ = 1.541 Å). The detector was calibrated by using KCl powder as a standard [2θ = 28.345° (200) and 40.507° (220) under Cu-K_α radiation]. IR spectroscopic measurements were performed with a Nicolet Avatar 360 FTIR spectrometer. Surface photovoltaic spectroscopy (SPS) studies were carried out with a home-built apparatus which had a solid junction photovoltaic cell (ITO/sample/ITO) using the light source-monochromator lock-in detection technique. The measurements were performed at room temperature. Thermal analyses (TG-DTA) were carried out with a Rigaku DTG60H thermal analyzer working at a heating rate of 20 °C /min, with α-Al_2O_3 as the reference material.

Two nonionic surfactants, Span80 and Op10, were used for the preparation of w/o emulsions in this work. In a typical preparation procedure of Ag@TiO_2 nanoparticles, in order to obtain an inverse emulsion containing Ag nanoparticles, the water phase [8 mL of 2% (m/v) Tollens reagent (containing 0.59 mmol Ag^+) and 2 mL of an aqueous 10% (m/v) glucose solution] was added to the oil phase (70 mL of toluene containing 13.9 mmol of Span80 and 1.5 mmol of Op10). The mixture was stirred vigorously under nitrogen for 1 h at room temperature. Further stirring with a moderate agitation intensity at 60 °C for 3 h resulted in a brown-black dispersion, which indicated the formation of Ag-nanoparticle colloids. The coating of TiO_2 was carried out as follows: equimolar (5.9 mmol) amounts of $Ti(OC_4H_9)_4$ (TOB) and acetylacetone were mixed under sonication in a standard ultrasound bath for a few minutes and then added to the above dispersion. Acetylacetone was used as a chelating agent to control the hydrolysis and condensation of TOB.[4] The mixture was stirred under nitrogen at 60 °C for 9 h to give a solution containing Ag@TiO_2 nanoparticles, which was used for TEM measurements. The solution was vacuum dried at 60 °C for 72 h to give a viscous residue, which was analyzed by TG-DTA. The viscous residue was calcined at 300–800 °C for 4 h and then characterized by IR, XRD, and SPS measurements.

Novel Supramolecular Frameworks Self-Assembled from a Two-Dimensional Polymeric Network: Synthesis and Crystal Structure of a Macrocyclic Organotin(IV) Complex

Chunlin Ma,*[a,b] Yinfeng Han,[a] and Rufen Zhang,[a] and Daqi Wang[a]

Keywords: Polymers / Self-assembly / Supramolecular chemistry / Tin

The two-dimensional polymer $[n\mathrm{Bu_2Sn(O_2CC_6H_4)}]_4$ has been synthesized by the self-assembly of di-*n*-butyltin oxide and 4-carboxyphenylboronic acid. The X-ray crystal structure shows that the metal ions display a trigonal bipyramidal coordination geometry to bind the endocyclic oxygen atom. Intermolecular π–π stacking interactions between adjacent phenyl groups of the ligand cause the self-assembly into a 1D chain. In this chain one oxygen atom of the carboxylate group binds to one $[n\mathrm{Bu_2Sn(O_2CC_6H_4)}]_4$ unit to give rise to a 2D architecture.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Owing to the enormous variety of intriguing structural topologies and their unexpected properties for potential practical applications,[1–4] the chemistry of novel organotin(IV) polymers based on covalent interactions[5–9] or supramolecular contacts (such as hydrogen bonding and/or π–π stacking interactions)[10–13] has been actively investigated. The vast majority of reported work is based upon the use of polyfunctional organic ligands to bind to the tin ions through self-assembly processes, leading to the formation of compounds with fascinating topologies and physical properties. It has also been shown that the careful selection of appropriate multidentate bridging ligands is helpful not only to tailor effectively the polymer architectures but also to realize various applications. In this field, studies have been focused on benzenecarboxylate ligands, such as benzenetricarboxylic acid. However, much less work has been carried out to investigate organotin polymer boronic acid ligands. In this work, we select 4-carboxyphenylboronic acid as the ligand, on the basis of the following considerations: (i) 4-carboxyphenylboronic acid anions have two different groups, and they may act as linkers to connect metal ions into higher dimensional structures by varied coordination modes; (ii) 4-carboxyphenylboronic acid anions may have different effects in the construction of coordination polymers; (iii) the carboxyl and boronic acid occupy *trans* positions, and thus can act as a good bridging ligand and benefit the molecular self-assembly. Therefore, we selected this ligand with the hope of constructing novel organotin(IV) coordination polymers with fascinating structures and/or characteristic properties. To our surprise, we obtained an unprecedented tetranuclear macrocyclic organotin complex $[n\mathrm{Bu_2Sn(O_2CC_6H_4)}]_4$ by B–C cleavage and the new Sn–C bond formation. To the best of our knowledge, this is the first example where organic linkers are incorporated into one metal–organic polymer by B–C bond cleavage and new Sn–C bond formation. The complex has been characterized by elemental analysis and IR, ^{1}H, and ^{13}C NMR spectroscopy. Furthermore, we have also characterized the complex by X-ray crystallography.

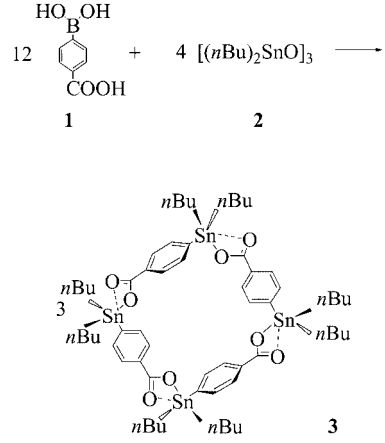
Result and Discussion

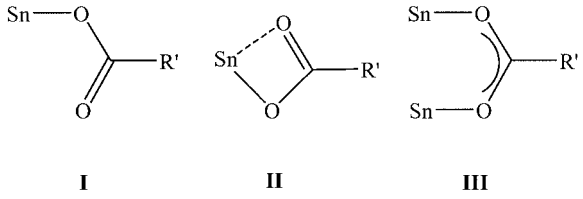
The synthetic procedure is shown in Scheme 1.



Scheme 1.

The main feature in the IR spectrum is the absence of a band in the region between 2800 and 3320 cm^{-1}, where the

ν(O–H) vibration in the free ligand appears, which indicates metal–ligand bond formation. In organotin carboxylate complexes, the IR spectra can provide useful information concerning the coordination mode of the carboxylate. When the carboxylate group coordinates to the atom in a monodentate manner, the difference between the wavenumbers of the (mode I) asymmetric and symmetric carboxylate stretching bonds, $\Delta\nu$ ($\nu_{asCOO^-} - \nu_{symCOO^-}$), is larger than that observed for ionic compounds. When the ligand chelates (mode II), $\Delta\nu$ is considerably smaller than that for ionic compounds, while for asymmetric bidentate coordination the value is in the range characteristic of monodentate coordination.[14] The characteristic wavenumber difference, $\Delta\nu$, for mode III is larger than that for chelated ions and nearly the same as that observed for ionic compounds (Scheme 2).



Scheme 2. Different coordination modes of the carboxylate group.

Based on the above results, it was possible to distinguish the coordination mode of the COO^- group. The magnitude of $\Delta\nu$ of about 273 cm^{-1}, compared with that for the corresponding sodium salt, reveals that the carboxylate ligands are monodentate under the conditions employed.[15,16]

The ^1H NMR spectrum of the complex shows that the signal for the OH proton in the spectrum of the ligand is absent in that of the complex, thus indicating the removal of the OH proton and the formation of Sn–O bonds. This consistent with the IR data. The ^{13}C NMR spectroscopic data for the complex are consistent with organotin carboxylate structures. Although at least four different types of carboxylate groups are present, only single resonance are observed for the COO group in the ^{13}C NMR spectrum. This is either due to accidental magnetic equivalence of the carbonyl carbon atoms or the separations between the four peaks of resonance are too small to be resolved.

The molecular structure and a fragment of the crystal lattice are illustrated in Figure 1 and Figure 2, respectively. A crystallographic study of complex **3** shows that the tetranuclear complex is characterized by a 28-membered $C_{20}O_4Sn_4$ macrocyclic ring system with all four oxygen atoms directed into the interior of the cavity and the eight *n*-butyl groups attached to the tin centers approximately perpendicular to the molecular plane (Figure 1). All the tin atoms possess the same ligand environments, with only minor differences in bond lengths and bond angles. For Sn(1), for example, the geometry of the tin atom is distorted tetrahedral and the tin atom forms four primary bonds: two to the butyl groups, one to phenyl, and one to an oxygen atom. Around the tin atom, the angles O(1)–Sn–C(29) [100.9(8)°], C(29)–Sn–C(33) [128.7(9)°], and C(26)–Sn–C(33) [116.4(8)°] are wider while O(1)–Sn–C(26) [93.8(5)°], C(29)–Sn–C(26) [109.1(9)°], and O(1)–Sn–C(33) [98.6(7)°] are narrower than the ideal tetrahedral angle. Also, the weak Sn···O bond [2.906 Å for Sn(1)···O(4′)] between tin and the exocyclic oxygen atoms of adjacent molecules is less than the sum of the van der Waal's radii of tin oxygen atoms (3.68 Å),[17] all of which are similar to those reported in the literature.[18] Therefore, if considering the Sn···O weak interaction, the structural distortion for the tin atom is best described as a trigonal bipyramidal geometry with O(1) and O(4′) atoms occupying the axial sites and an axial-Sn-axial [O(1)–Sn–O(4′)] angle of 175.36°. Sn(1), C(26), C(29), and C(33) are almost completely coplanar with the tin atom. The sum of angles between the tin atom and the equatorial atoms is 354.2°, consistent with the ideal value of 360°.

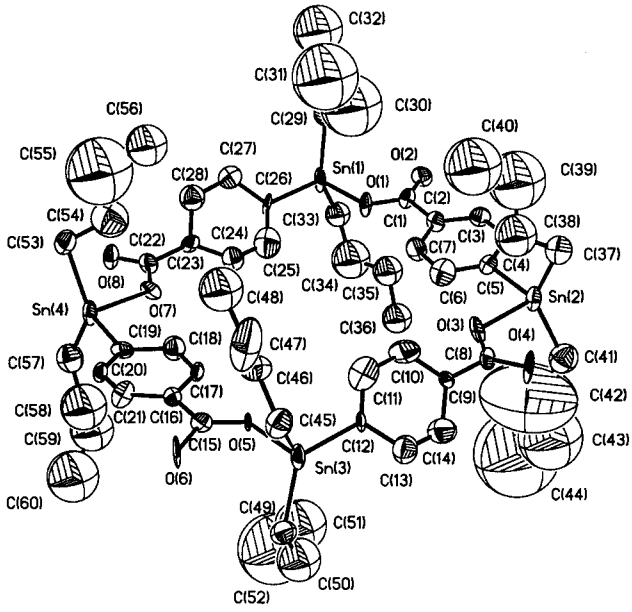


Figure 1. ORTEP plot of the molecular structure of [nBu$_2$Sn-($O_2CC_6H_4$)]$_4$ (**3**). Thermal ellipsoids are drawn with 30% probability. Selected bond lengths [Å] and angles [°]: Sn(1)–O(1) 2.072(10), Sn(1)–C(29) 2.08(2), Sn(1)–C(26) 2.091(15), Sn(1)–C(33) 2.15(2), Sn(1)···O(2) 3.191, Sn(1)···O(4A) 2.905, Sn(2)–O(3) 2.084(11), Sn(2)–C(37) 2.11(3), Sn(2)–C(41) 2.15(3),Sn(2)–C(5) 2.201(19), Sn(2)···O(4) 3.049, Sn(2)···O(6A) 2.769, Sn(3)–O(5) 2.065(10), Sn(3)–C(49) 2.12(2), Sn(3)–C(12) 2.137(15), Sn(3)–C(45) 2.18(2), Sn(3)···O(6) 3.209, Sn(3)···O(8A) 2.898, Sn(4)–O(7) 2.103(12), Sn(4)–C(57) 2.10(3), Sn(4)–C(19) 2.105(18), Sn(4)–C(53) 2.26(2), Sn(4)···O(8) 3.023, Sn(4)···O(2A) 2.751; C(29)–Sn(1)–C(26) 109.1(9), C(49)–Sn(3)–C(12) 116.1(8), C(26)–Sn(1)–C(33) 116.4(8), C(12)–Sn(3)–C(45) 112.9(8), O(1)–C(1)–O(2) 122.1(14), O(5)–C(15)–O(6) 123.1(14), C(37)–Sn(2)–C(41) 133.1(10), C(57)–Sn(4)–C(19) 109.8(9), C(37)–Sn(2)–C(5) 111.5(9), C(57)–Sn(4)–C(53) 135.9(9), C(41)–Sn(2)–C(5) 108.7(10), C(19)–Sn(4)–C(53) 110.0(8), O(3)–C(8)–O(4) 124.1(19), O(7)–C(22)–O(8) 119.8(17).

The size of cavity in this macrocycle can be evaluated from the Sn···Sn and transannular O···O distances, which are 9.181–9.214 Å and 7.219–7.341 Å, respectively, similar to those in di-*n*-butyltin(IV) isophthalate.[19] From the X-ray structure, we found that the tetranuclear macrocyclic rings are linked into a 1D chain through face-to-face π–π stacking and weak Sn···O interactions. In the case of the stacking

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

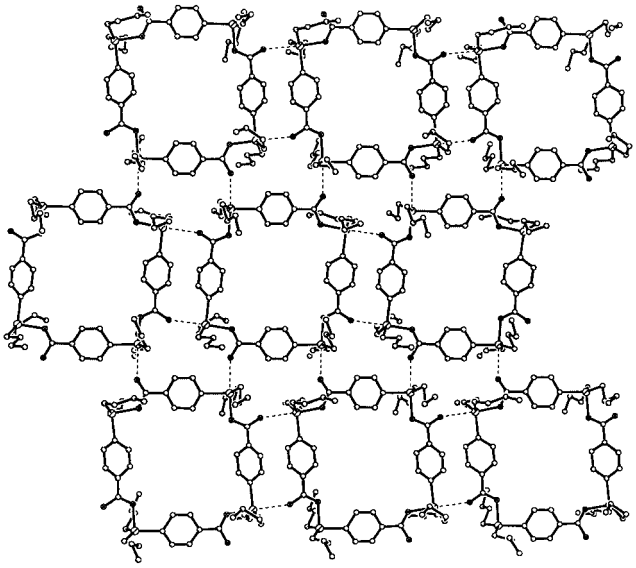

Figure 2. Polymeric network formed through intermolecular Sn···O′ and π–π stacking interactions.

phenyl rings, the centroid–centroid distance is 4.178 Å, which is much shorter than that of the optimized structure for parallel displaced stacking benzene dimer in the gas phase (4.50 Å)[20] and those of other reported stacking aryl groups (4.6 Å[21] and 4.83 Å[22]), thus indicating that the π–π stacking interactions are very strong and it is these interactions that stabilize the 1D chain in the crystal. Therefore, self-assembly occurs through weak Sn···O interactions and helps the molecules form a 2D architecture (Figure 2).

In summary, from the crystal structure described above we can conclude that the B–C cleavage and the new Sn–C bond formation are crucial for the formation of the macrocyclic structure. This discovery may cast light on the reactivity of alkyltin(IV) compounds. That is, we can intentionally design and synthesize alkyltin(IV) compounds to obtain valuable compounds with specific topologies.

Experimental Section

Materials and Measurements: Di-*n*-butyltin oxide and 4-carboxyphenylboronic acid are commercially available, and they were used without further purification. The melting points were obtained with a Kofler micro-melting point apparatus and were uncorrected. IR spectra were recorded on a Nicolet-460 spectrophotometer using KBr discs and sodium chloride optics. ^{1}H, ^{13}C, and ^{119}Sn NMR spectra were recorded on Varian Mercury Plus 400 spectrometer operating at 400, 100.6, and 149.2 MHz, respectively. The spectra were acquired at room temperature (298 K) unless otherwise specified; ^{13}C spectra are broadband proton decoupled. The chemical shifts are reported in ppm with respect to the references (external tetramethylsilane for ^{1}H and ^{13}C NMR, and neat tetramethyltin for ^{119}Sn NMR). Elemental analyses (C,H) were performed with a PE-2400II apparatus.

[*n*Bu$_2$Sn(O$_2$CC$_6$H$_4$)]$_4$ (3): The reaction was carried out under a nitrogen atmosphere. Di-*n*-butyltin oxide (0.497 g, 2 mmol) and 4-carboxyphenylboronic acid (0.332 g, 2 mmol) were added to a solution of dry toluene (50 mL) in a Schlenk flash. Refluxing was continued for 10 h. After filtration the solvent was evaporated in vacuo and the residue crystallized from dichloromethane to give complex **3** as white crystals. Yield: 81%. M.p. 110–112 °C. $C_{60}H_{88}O_8Sn_4$ (1412.18): calcd. C 51.04, H 6.28; found C 51.01, H 6.21. IR (KBr): $\tilde{\nu}$ = 3067, 2960, 2924, 2855, 1634, 1605, 1582, 1448, 1361, 1342, 561, 546, 471 cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 0.89 (t, CH_3), 1.34–1.72 (m, $^2J_{Sn,H}$ = 75.1 Hz, $CH_2CH_2CH_2$), 7.64 (d, C_6H_4), 8.13 (d, C_6H_4) ppm. ^{13}C NMR ($CDCl_3$): δ = 27.1 (α-CH_2, $^1J_{^{119}Sn,^{13}C}$ = 607 Hz), 28.5 (β-CH_2), 26.3 (γ-CH_2), 13.5 (CH_3), 172.1 (COO) ppm. ^{119}Sn NMR ($CDCl_3$): δ = –57.2 ppm.

X-ray Crystallography. Crystal Data for 3: Monoclinic, $P2_1/n$, a = 14.288(18), b = 28.66(3), c = 19.17(2) Å; β = 110.11(2)°, V = 7371 Å^3, T = 293 K, Z = 4, μ = 1.381 mm^{-1}, 34 071 reflections measured, 11 795 unique (R_{int} = 0.2467) which were used in all calculations. Final R indices were R_1 = 0.0978, wR_2 = 0.1692 [$I > 2\sigma(I)$], R_1 = 0.2967 wR_2 = 0.2391 (all data).

Self-Assembly of Protonated 1,12-Dodecanediamine Molecules and Strongly Undulated Uranyl Selenate Sheets in the Structure of Amine-Templated Uranyl Selenate: $(H_3O)_2[C_{12}H_{30}N_2]_3[(UO_2)_4(SeO_4)_8](H_2O)_5$

Keywords: Host-guest systems / Layered compounds / Selenium / Self-assembly / Uranium

The amine-templated uranyl selenate $(H_3O)_2[C_{12}H_{30}N_2]_3[(UO_2)_4(SeO_4)_8](H_2O)_5$ (**1**) has been prepared. Its structure [monoclinic, $P2_1/n$, a = 11.3437(7), b = 24.8042(12), c = 29.2496(19) Å, β = 96.701(5)°, V = 8173.8(8) Å^3, Z = 4, R_1 = 0.083] is based upon strongly undulating $[(UO_2)(SeO_4)_2]^{2-}$ sheets consisting of corner-sharing UO_7 bipyramids and SeO_4^{2-} tetrahedra. The undulations of the adjacent sheets have an *anti*-phase character that allows the formation of large eliptical channels that are occupied by rod micelles formed by self-assembly of protonated 1,12-dodecanediamine molecules.

Introduction

The preparation of new porous uranium-based materials is of interest because of their relevance to radioactive waste disposal, utilization of depleted uranium, catalysis, etc.[1] One of the pathways employed in the synthesis of new compounds is the use of amines as templates.[2] The role of amines as structure-directing agents has been under extensive discussion. There are strong indications that, in some systems, amine molecules may control the formation of new topologies that are not observed in purely inorganic structures, whereas in other systems the role of protonated amine molecules is simply to balance the negative charge of the inorganic part of a structure.[2] We note that in the preparation of uranium-based oxide compounds, short-chain and cyclic amines have mostly been employed, whereas the effect of long-chain amines, especially α,ω-alkyldiamines, is as yet unknown. We report here the synthesis and structure of $(H_3O)_2[C_{12}H_{30}N_2]_3[(UO_2)_4(SeO_4)_8](H_2O)_5$ (**1**), a new uranyl selenate templated by 1,12-dodecanediamine molecules.

Whereas the structural chemistry of uranyl selenites has been intensively investigated over the last few years,[2f,3] uranyl selenates have received much less attention[4] as their synthesis under low-temperature hydrothermal conditions (100–250 °C) rarely results in crystalline selenates, even if selenic acid, H_2SeO_4, is used as a source of selenium. This is caused by the instability of the selenate ion, SeO_4^{2-}, and its easy reduction to selenite, SeO_3^{2-}.[2f,5] To avoid the selenate/selenite reduction, yellow needles of **1** have been prepared by room-temperature evaporation of the solvent from an aqueous solution of uranyl nitrate, selenic acid, and 1,12-dodecanediamine. A semi-quantitative EDX analysis indicated a U/Se ratio of 1:2, and a single-crystal X-ray diffraction experiment allowed the crystal-structure characterization. The results of IR spectroscopic studies were found to be in good agreement with the results of the crystal-structure investigations.

Results and Discussion

The structure of **1** consists of well-defined organic and inorganic substructures (Figure 1). The inorganic substructure contains four symmetrically independent U^{VI} centers that form linear uranyl cations, UO_2^{2+} (U=O distances in the range of 1.732–1.766 Å). These uranyl cations are further coordinated equatorially by five oxygen atoms each to form pentagonal UO_7 bipyramids (U–O 2.326–2.500 Å). There are eight symmetrically independent Se^{VI} cations, each tetrahedrally coordinated by four oxygen atoms (Se–O 1.597–1.671 Å). The bond-valence sums for the U and Se atoms[6] are in the range of 5.89–6.35 valence units (v.u.). The UO_7 bipyramids and SeO_4^{2-} tetrahedra share corners to form the $[(UO_2)(SeO_4)_2]^{2-}$ sheets depicted in Figure 2 (see a). These sheets are parallel to (001) and are strongly undulated along the *c* axis. The undulation vector is parallel to [010] and is equal to *b* (24.804 Å). The undulation amplitude is about 25 Å. The undulations in the adjacent sheets

have an *anti*-phase character which means that large eliptical channels are created along the *a* axis.

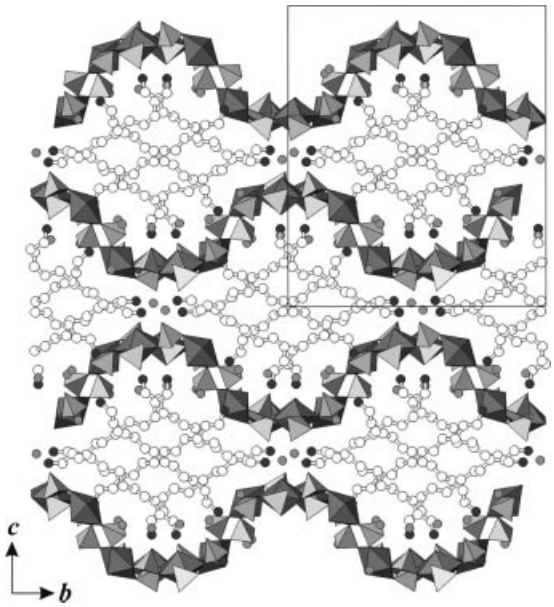

Figure 1. Crystal structure of **1** projected along the *a* axis. $[UO_7]^{8-}$ bipyramids are dark grey, and $[SeO_4]^{2-}$ tetrahedra are light grey. C and N atoms, and H_2O groups are shown as white, dark grey and light grey circles, respectively.

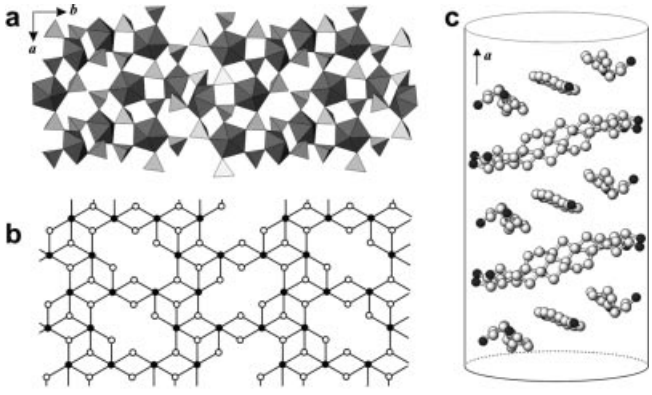

Figure 2. The $[(UO_2)(SeO_4)_2]^{2-}$ sheet in the structure of **1** (a), nodal representation (U and Se polyhedra are symbolized by black and white circles, respectively) (b), and organization of 1,12-dodecanediamine molecules into a rod micelle (c).

The topology of the $[(UO_2)(SeO_4)_2]^{2-}$ sheets is remarkable as it has not been observed previously in any uranium compound. It can be analyzed by means of a nodal representation, which is especially suitable for the description of structures based upon coordination polyhedra of two types.[7] Using this approach, the UO_7 bipyramids and SeO_4 tetrahedra are symbolized by black and white vertices, respectively. The vertices are linked by a line segment if two respective polyhedra share a common oxygen atom. The idealized black-and-white graph of the uranyl selenate sheet observed in **1** is shown in Figure 2 (see b). Although it is new for uranium chemistry, it can be obtained from a more regular (3.6.3.6) graph by eliminating some of its vertices and edges. This topological procedure is common for many sheet topologies observed in uranyl oxo salts.[2c,7]

The organic substructure consists of micelles of protonated 1,12-dodecanediamine molecules oriented parallel to the *a* axis. These micelles occupy the channels created by the packing of the $[(UO_2)(SeO_4)_2]^{2-}$ sheets. The assembly scheme of the 1,12-dodecanediamine chain molecules within the micelle is shown in Figure 2 (see c). The molecules are arranged into sublayers approximately parallel to (–102). The planes of these sublayers are not perpendicular to the micelle axis but form an angle of about 60°. In each layer, there are three parallel oriented $[C_{12}H_{30}N_2]^{2+}$ molecules. The molecules in the adjacent layers are at an angle of 30° relative to each other, which results in the elliptical form of the perpendicular section of the micelle. The lateral dimensions of the micelle are about 20 × 24 Å, i.e. are at the level of nanometers. The interactions between organic and inorganic substructures involve N···O hydrogen bonds to oxygen atoms of uranyl ions and terminal oxygen atoms of selenate tetrahedra. In addition, the structure contains two symmetrically independent H_3O^+ ions and five symmetrically independent H_2O molecules that contribute to the network of hydrogen bonds. The H_3O^+ ions correspond to the O(41) and O(42) sites, which can easily be identified as oxoniums by the analysis of their coordination environment. Both O(41) and O(42) are coordinated to three oxygen atoms located at O···O distances of 2.47–2.64 Å (Table 1). This coordination is a rather flat pyramid that can be inferred from the O···H_3O···O angles of 99.0–123.8°. This coordination geometry is typical for oxonium ions in oxo salt structures and has been observed in the structures of $(H_3O)(HSeO_4)$,[8] $(H_3O)(HSO_4)$,[9] $M(H_3O)(HSO_4)_2$ (M = Na,[10] K,[11] Ag[12]), $(H_3O)Sb_2(SO_4)_2$,[13] $Zr(H_3O)_2(SO_4)_3$,[14] $(H_3O)La(SO_4)_2(H_2O)$,[15] $(H_5O_2)(H_3O)_2Nd(SO_4)_3$,[16] $(H_3O)_2Nd(HSO_4)_3(SO_4)$,[16] etc. There are also several oxonium uranyl selenate hydrates known, although the coordination geometries of the oxonium ions in their structures are not as well-defined as in the structure of **1**. The presence of oxonium in **1** can also be confirmed by the presence of a strong band at 2853 cm^{-1} in the IR spectrum of **1**. This band can be assigned to strong hydrogen bonds corresponding to O···O distances of about 2.5–2.6 Å[17] (compare with the distances given in Table 1).

Protonated long-chain amine molecules are known to form cylindrical micelles in aqueous solutions by a self-assembly process that is governed by competing hydrophobic/hydrophilic interactions.[18] The flexible inorganic complexes present in the reaction mixture could then form around these cylindrical micelles to produce an inorganic structure that reflects the cylindrical form of the micelles. In the case of **1**, the inorganic structure has the form of a strongly undulated sheet, although structures with highly porous uranyl selenate nanotubules have also been observed.[19] This indicates the possibility of preparation of uranium oxo salt mesostructures if larger organic moieties (e.g., block copolymers) are involved in the synthesis procedure. This possibility is favored by the high flexibility of

the U–O–T links in uranyl compounds with tetrahedral TO_4^{2-} anions (T = S, Cr, Se, Mo).[20] The fabrication of meso- and nanostructures in uranium oxo-systems might be of great interest for the preparation of new functional nanomaterials and their subsequent use in nanotechnology. The latter perspective seems to be a promising direction for the utilization of depleted uranium, thousands tons of which are now stored in countries such as the USA and Russia.

Experimental Section

In a typical synthesis of **1**, 0.028 g of 1,12-dodecanediamine, 0.30 mL of 40% H_2SeO_4, and 0.081 g of $(UO_2)(NO_3)_2{\cdot}6H_2O$, were mixed with 2 mL of distilled H_2O. The mixture was poured into a watch glass and was kept in a fume hood at room temperature. Yellow needles of **1** were formed in approximately 10% yield (0.008 g) in about 3–4 days. The compound was characterized by semi-quantitative electron microprobe analysis. Far-IR and Raman spectra were recorded and the presence of uranyl ions and selenate groups was confirmed. Far-IR (nujol): $\tilde{\nu}$ = 3566 (m), 3486 (s), 3155 (m), 2927 (s), 2853 (s), 1613 (s), 1505 (m), 1470 (w), 1211 (w), 1191 (w), 1150 (w), 1016 (vw), 954 (s), 919 (m), 888 (s), 848 (s), 822 (s), 725 (m) cm^{-1}.

Crystallographic Data for $(H_3O)_2[C_{12}H_{30}N_2]_3[(UO_2)_4(SeO_4)_8](H_2O)_5$: Plate-like crystal ($0.02\times0.04\times0.22\ mm^3$), monoclinic, $P2_1/n$, a = 11.3437(7), b = 24.8042(12), c = 29.2496(19) Å, β = 96.701(5)°, V = 8173.8(8) $Å^3$, Z = 4, ρ_{calc} = 2.405 $g\,cm^{-3}$, $2\theta_{max}$ = 54.28°, λ(Mo-K_α) = 0.71073 Å, ω-scan (1° per image) at φ = 0° (STOE IPDS II), 293 K, 48 038 measured reflections, 17023 independent reflections, 11646 reflections with $|F_o| \geq 4\sigma_F$ (R_{int} = 0.084, R_σ = 0.089), numerical absorption correction (programs X-Shape and X-Red, STOE, Darmstadt, 1998), structure solution by direct methods, full-matrix least-square refinement (263 parameters) on $|F^2|$, no treatment of H atoms [programs SIR-97[21] and SHELXL-97 (G. M. Sheldrick, program for the refinement of crystal structures, Göttingen, **1997**)], R_1 = 0.083, wR_2 = 0.137 for observed reflections, max./min. electron density = 2.703/–1.672.

Synthesis and Characterisation of New Iridium Complexes with the (4*S*)-2-[2-(Diphenylphosphanyl)phenyl]-4-isopropyl-1,3-oxazoline Ligand That Catalyse Asymmetric Michael Reactions

Daniel Carmona,*[a] Joaquina Ferrer,[a] Mónica Lorenzo,[a] Fernando J. Lahoz,[a] Isabel T. Dobrinovitch,[a] and Luis A. Oro[a]

Keywords: Iridium / Phosphanyloxazolines / Metal enolates / Michael addition

The chiral iridium compounds [IrCl(COE){(*S*)-PN}] {COE = cyclooctene, PN = (4*S*)-2-[2-(diphenylphosphanyl)phenyl]-4-isopropyl-1,3-oxazoline, (**1**)}, [Ir(acac)ClH{(*S*)-PN}] {Hacac = acetylacetone, (**2**)} and [Ir{(*S*)-PN}$_2$]A {A = Cl (**3a**,**b**); BF_4 (**4a**,**b**); PF_6 (**5a**,**b**)} have been prepared, characterised and employed as catalysts for the asymmetric Michael addition of keto or cyano esters to α,β-unsaturated carbonyl compounds. The X-ray molecular structures of compounds **2** and **5b** are reported. The model catalytic intermediates [IrH(NCCHCO$_2$R){(*S*)-PN}$_2$]Cl {R = Me (**12**), Et (**13**)} have also been isolated and characterised.

Introduction

The catalytic asymmetric Michael reaction is a powerful and valuable method for the formation of C–C bonds β to a carbonyl group[1] that often allows construction of quaternary carbon centres.[2] Pioneering work was performed by Wynberg et al., who studied the use of chincona alkaloids as catalysts.[3] In 1984, Brunner and Hammer reported the first example of a transition-metal-catalysed asymmetric Michael addition, employing a complex derived from Co(acac) and (*S*,*S*)-1,2-diphenyl-1,2-ethylenediamine.[4] Since then, much attention has been paid to transition-metal-based systems for the asymmetric catalysis of the Michael reaction, and a variety of chiral transition-metal-based catalysts have been developed by several groups.[2b,5–11] Particularly important are the results achieved by Shibasaki et al. with their heterodimetallic catalysts in the Michael reaction of β-dicarbonyls or hydroxyketones with α,β-unsaturated carbonyls.[12] Related heterodimetallic catalysts have been subsequently developed by others.[13] However, although a few platinum-metal-based compounds have been employed as Michael reaction catalysts, the use of iridium derivatives for this reaction is very scarce.[14] On the other hand, most of the metallic catalytic systems are generated in situ by mixing the appropriate metallic precursor and the chiral ligand, and therefore the actual structure of the involved coordination compound(s) is usually unknown.

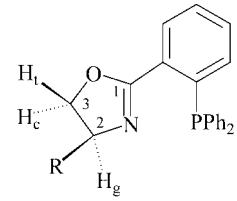
During our studies on phosphanyloxazoline iridium complexes,[15] we realised that the iridium(I) compound [IrCl(COE){(*S*)-PN}] {COE = cyclooctene, PN = (4*S*)-2-[2-(diphenylphosphanyl)phenyl]-4-isopropyl-1,3-oxazoline, (Scheme 1)} (**1**) activated the sp^3 CH methylene bonds of the acetylacetone (Hacac), affording the hydrido(enolato)-iridium(III) [Ir(acac)ClH{(*S*)-PN}] (**2**). The diastereoselective formation of **2** from **1** prompted us to test complex **1** as a catalyst for Michael addition reactions. In this context, Murahashi, Komiya, et al. have reported the formation of the hydrido(enolato)ruthenium(II) complexes, *mer*-[RuH(acac)(PPh$_3$)$_3$] and *mer*-[RuH(NCCHCO$_2$R)(NCCH$_2$CO$_2$R)(PPh$_3$)$_3$], by reacting either the dihydride [RuH$_2$(PPh$_3$)$_4$] or the orthometalated ethylene complex [RuH(PPh$_2$C$_6$H$_4$)(C$_2$H$_4$)(PPh$_3$)$_2$] with Hacac or alkylcyanoacetates, respectively.[16] Notably, it has been shown that a variety of transition-metal α-cyanocarbanion complexes, including the aforementioned, are intermediates in the catalytic Michael reactions of nitriles.[16,17] Furthermore, very recently, Ikayira et al. have isolated and characterised a chiral metal-carbon-bound ruthenium–malonato complex,



R = *i*Pr, (*S*)-PN;
*i*Bu, (*S*)-PN'

Scheme 1. Phosphanyloxazoline ligands.

which is the plausible intermediate in the asymmetric Michael reaction of α-substituted acetates with cyclic enones.[18]

Here we report on the synthesis and characterisation of the phosphanyloxazoline iridium complexes **1** and **2**, the related bis(*S*)-PN ligand cationic compounds [Ir{(*S*)-PN}$_2$]A {A = Cl (**3a,b**); BF_4 (**4a,b**); PF_6 (**5a,b**)}, as well as, on their use as catalysts for the Michael addition of cyano or keto esters **6** and **7** to α,β-unsaturated carbonyls **8**–**10** (Scheme 2). The X-ray molecular structures of compounds **2** and **5b** are also included. Furthermore, we also report the preparation and characterisation of the hydrido(enolate)-iridium(III) complexes [IrH(NCCHCO$_2$R){(*S*)-PN}$_2$]Cl {R = Me (**12**), Et (**13**)}, derived from **11a** and **11b**, as possible model intermediates in the catalytic Michael process.

Results and Discussion

Treatment of the dimer [Ir(μ-Cl)(COE)$_2$]$_2$[19] with two equivalents of (*S*)-PN, in pentane at –60 °C, afforded [IrCl(COE){(*S*)-PN}] (**1**). Since solutions of **1** in common organic solvents slowly decompose, attempts to obtain an analytically pure sample of this complex failed. However, the spectroscopic data for the generated species, collected at –60 °C, leave no doubt that the proposed formulation for **1** is correct (see Experimental Section).

Complex **1** reacted with acetylacetone, through activation of an sp^3 CH methylene bond, affording the hydrido(enolato)iridium(III) complex [Ir(acac)ClH{(*S*)-PN}] (**2**) stereoselectively. The spectroscopic data indicated the formation of a major isomer (95%) together with trace amounts of some other uncharacterised stereoisomers. The molecular structure of **2** has been determined by a single-crystal X-ray diffraction study (Figure 1). Selected bond parameters are reported in Table 1. Complex **2** has a distorted octahedral coordination environment. The metal centre is coordinated to the two oxygen atoms of an acetylacetonate anion and to the phosphorus and nitrogen atoms of the (*S*)-PN ligand. A chloride anion and a hydride ligand, mutually *trans* (Cl–Ir–H, 169.7°), complete the coordination sphere of the iridium atom. The metal atom is chiral, and the isomer present in the crystal is the *OC*-6–53-*A* diastereomer. The Ir–Cl bond length, 2.512(2) Å, is significantly longer than the mean value observed for terminal chlorides in octahedral Ir complexes, 2.426(7) Å;[20] most probably this fact is a consequence of the high *trans* influence of the hydride that elongates the Ir–Cl bond length to a mean value of 2.500(2) Å when both ligands are situated in a *trans* position relative to each other.[20]

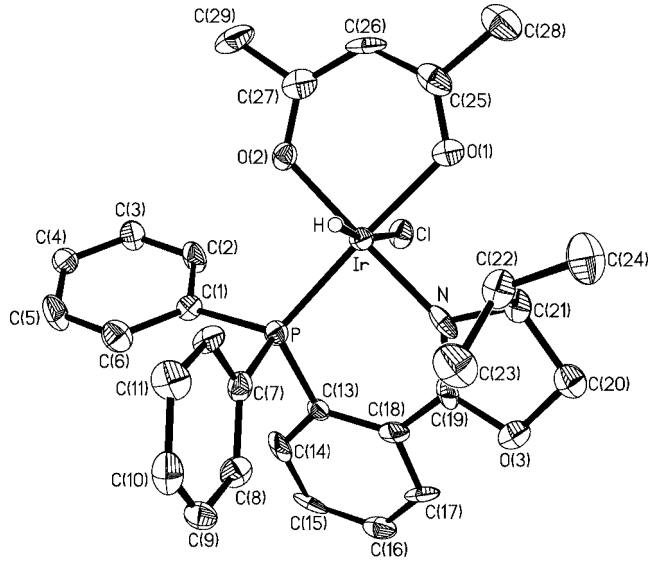

Figure 1. Molecular structure of **2** (organic hydrogen atoms are omitted for clarity).

The highly diastereoselective formation of **2** from **1** prompted us to test complex **1** as a catalyst for Michael addition reactions. A mixture of [Ir(μ-Cl)(COE)$_2$]$_2$ and two equivalents of (*S*)-PN catalysed the addition of the α-cyano propionate **6b** or the β-keto ester **7b** to methyl vinyl ketone with 23 and 26.5% *ee*, respectively. To improve the stereoselectivity, we tried to incorporate one additional (*S*)-PN group to the iridium coordination sphere. Thus, treatment of the dimer [Ir(μ-Cl)(COE)$_2$]$_2$ with 4.5 equivalents of (*S*)-PN, in acetone or dichloromethane, at room temperature, afforded cationic [Ir{(*S*)-PN}$_2$]Cl (**3**) in 75% yield. Complex **3** was isolated as a mixture of two isomers in relative amounts of about 60% (**3a)** and 40% (**3b**). Pure samples of both isomers could be obtained: pure **3b** was obtained when the reaction was carried out in toluene, and complex **3b** isomerised quantitatively to **3a** after refluxing two hours in acetone.

Furthermore, the chloride can be metathetically replaced by the reaction of **3** with $NaBF_4$ or KPF_6, affording the corresponding [Ir{(*S*)-PN}$_2$]A {A = BF_4 (**4a,b**); PF_6 (**5a,b**)} salts.

To obtain further structural information about these complexes, the molecular structure of compound **5b** was determined by X-ray diffractometric methods (Figure 2). Selected bond parameters are reported in Table 1. The cation presents a highly distorted square-planar geometry with relative *trans* arrangement of nitrogen and phosphorus atoms of both (*S*)-PN ligands. Both Ir–P–C–C–C–N six-membered metallacycles adopt an $^1S_2$ screw-boat conformation[21] with a relative *anti* disposition to each other (Figure 3). A similar arrangement has been previously found in

[a] When two values are given in the table, they represent analogous parameters from the two independent (*S*)-PN ligands of complex **5b**.

the related rhodium compound[22] $[Rh\{(S)\text{-}PN\}_2]BF_4$, as well as in the nickel(II) derivative[23] $[Ni\{(S)\text{-}PN'\}_2][O_3SCF_3]_2$, where (*S*)-PN′ represents the *iso*-butyl derivative shown in Scheme 1.

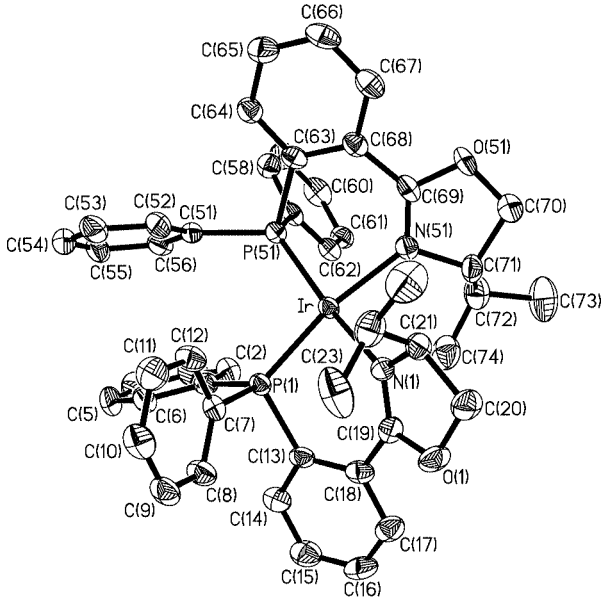

Figure 2. Molecular drawing of the cationic metal complex of **5b** (hydrogen atoms are omitted for clarity).

The NMR spectroscopic data of isomers only differing in the counter-anion are very similar, indicating that they

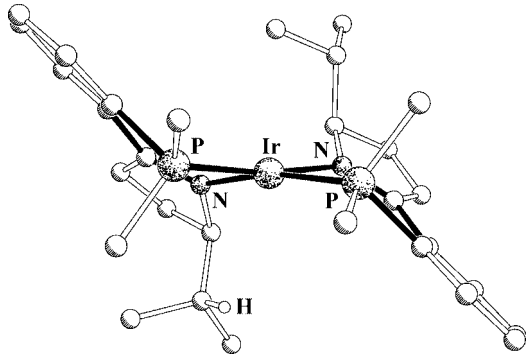

Figure 3. Relative *anti* conformation observed for the metallacycles Ir–P–C–C–C–N in the solid structure of **5b** (view along the pseudo C_2 axis).

should have similar structure. However, while the NMR spectra of **3b-5b** present only one set of signals for the (*S*)-PN ligand, those of **3a-5a** reveal that the two (*S*)-PN ligands are not equivalent. From the molecular structure of **5b**, we propose that, in compounds labelled **b**, the equivalence in solution of the two (*S*)-PN ligands arises from the existence of a C_2 axis, contained in the coordination plane, that bisects the P–Ir–P and N–Ir–N angles (Figure 3). The value of the PP′ coupling constant in **3a**–**5a** is about 15 Hz. Thus, in both types of isomers the phosphorus atoms adopt a *cis* geometry.

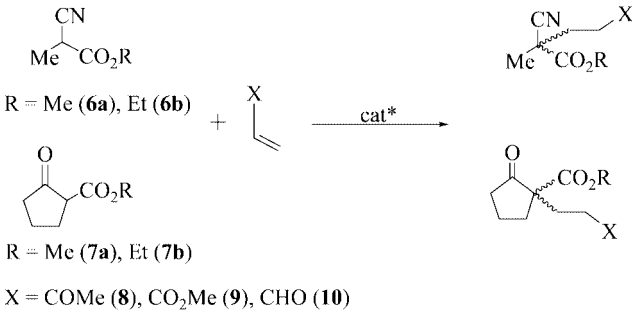
Concerning the **3a-5a** isomers, the most notable feature of their ^1H NMR spectra is the shielding of about 1.4 ppm

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of one of the CH isopropyl protons with respect to the other. Inspection of molecular models reveals that one of the CH isopropyl protons lies below the iridium coordination plane pointing to the metal (Figure 3). In fact, this proton is only 3.111(1) Å apart from the iridium in the solid structure of **5b**. From these data, we tentatively propose that the isomerization from **b** to **a** consists of the formation of a C–H···Ir agostic interaction[24] between the iridium atom and one of the CH isopropyl protons.

Preliminary results indicate that compounds **3**–**5** are active catalysts for the Michael addition of cyano or keto esters **6** and **7** to α,β-unsaturated carbonyls **8**–**10** (Scheme 3). Table 2 collects some selected results. Chloride **3b** is a very active catalyst for the Michael additions (entries 1–12), achieving quantitative conversion in most of the cases. However, the *ee* obtained are low. Unsymmetrical chloride **3a** (entries 13–15) is less active but more selective, affording *ee* of up to 39%. Surprisingly, changing the anion to BF_4 or PF_6 strongly decreases the activity (entries 16–22), rendering enantioselectivities ranging from 20 to 30% *ee*.

To obtain mechanistic information about the catalytic system, **3a** or **3b** were treated with excess of ethyl-2-cyanopropionate (**6b**) in catalytic conditions; no conclusive results were obtained, most of the starting substrates remained unaltered. However, when **3a** was reacted with the closely related α-cyanoacetates **11a** or **11b** (Scheme 2), the corresponding hydrido enolate iridium(III) complexes [IrH(NCCHCO$_2$R){(*S*)-PN}$_2$]Cl {R = Me (**12**), Et (**13**)} were diastereoselectively isolated in 85 and 88% yield, respectively. The IR spectra of compounds **12** and **13** show characteristic absorption bands at about 2175 and 2205 cm^{-1} assignable to ν(C≡N) and ν(Ir–H), respectively.



Scheme 3. Catalytic reactions.

An intense band due to ν(C=O) of the enolato ligand appears ca. 1667 cm^{-1}. The ^{1}H NMR spectra show a doublet of doublets at δ = –19.28 ppm (**12**) or –19.23 ppm (**13**) ($^2J_{PH}$ = 13.5, 26.6 Hz) attributed to a hydride ligand coupled to two nonequivalent phosphorus nuclei. Two singlets at δ = 3.57 and 3.18 ppm, assignable to the methyl and methine protons of the enolato ligand, are observed in the spectrum of **12**. For compound **13**, the methyl, methylene and methine protons of the enolato ligand resonate as a triplet at 1.21, a quartet at 4.08 and a singlet at 3.22 ppm, respectively. In both compounds the methine proton has no coupling with the phosphorus nuclei, suggesting that the enolate is N-bonded. The isolation of **12** and **13** from **3a** indicates that most probably, the oxidative addition of the sp^3 CH activated bond of the Michael donors to the iridium(I) complexes **3**–**5** would be the first step in the catalytic path. Interaction of the coordinated enolate with the Michael acceptor followed by adduct elimination would complete the catalytic cycle.

Table 2. Asymmetric Michael reactions using the new iridium compounds **3**–**5** as catalysts.[a]

Entry	Catalyst	Donor	Acceptor	Yield (%)[b]	*ee* (%)

In summary, we report the first chiral iridium(I) compounds that are active catalysts for the Michael addition of keto or cyano esters to α,β-unsaturated carbonyl compounds. The enantioselectivity obtained is modest. In fact, few examples of highly enantioselective catalytic Michael addition versions for the synthesis of quaternary stereocentres have been demonstrated to date.[2,11n] However, the catalytic efficiency in these clean quaternary-carbon-centre-forming reactions is promising. Further studies to extend the catalytic reaction to other related metallic systems and substrates are currently under progress in our laboratory.

Experimental Section

General Comments: The compounds described herein were handled with exclusion of air by using standard Schlenk techniques. All solvents were dried by known procedures and distilled under argon prior to use. NMR spectra were recorded with a Varian Gemini 2000 or a Bruker Avance 400 spectrometer. Chemical shifts are expressed in ppm upfield from $SiMe_4$ (^1H, ^{13}C) or 85% H_3PO_4 in D_2O (^{31}P). Coupling constants (*J*) are given in Hertz. For proton and carbon labelling, see Scheme 1. Infrared spectra were recorded with a Perkin–Elmer 783 spectrophotometer. Carbon, hydrogen, and nitrogen analyses were performed with a Perkin–Elmer 240B microanalyser. Molar conductivities were measured in approximately 5×10^{-4} mol dm^{-3} acetone solutions with a Philips PW 9509 digital conductivity meter. Gas chromatographic analyses were performed with a Hewlett–Packard 8590A gas chromatograph equipped with CP-Chirasil-CB or Lipodex-E columns. Optical rotations were measured with a Jasco P-1020 polarimeter. [Ir(μ-Cl)(COE)$_2$]$_2$[19] and (4*S*)-2-[2-(diphenylphosphanyl)phenyl]-4-isopropyl-1,3-oxazoline[25] were prepared according to published procedures. Acetylacetone and compounds **7a**, **7b**, **8**, **9**, **10**, **11a**, and **11b** were purchased from Aldrich Co. Ltd. The α-cyanopropionates **6a** and **6b** were prepared as previously reported.[11f]

Preparation of [IrCl(COE){(*S*)-PN}] (1): (*S*)-PN (83.0 mg, 0.22 mmol) was added to a suspension of [Ir(μ-Cl)(COE)$_2$]$_2$ (100.0 mg, 0.11 mmol) in pentane (10 mL) at –60 °C, under argon. The suspension was stirred for 1 h. During this time, a change of colour from orange to brown took place. The solid formed was filtered off, washed with pentane and vacuum-dried. Yield: 66.0 mg (65%). ^1H NMR (400.13 MHz, $CDCl_3$, –60 °C): δ = 8.8–6.6 (m, 14 H, Ph), 5.93 (m, 1 H, H_g), 4.50 (br., 2 H, CH=CH), 4.34 (m, 2 H, H_c and H_t), 2.81 (m, 1 H, CH *i*Pr), 2.6–0.7 (m, 14 H, COE), 0.83 (d, *J* = 6.0 Hz, 3 H, Me *i*Pr), 0.09 (d, *J* = 6.0 Hz, 3 H, *i*Pr) ppm. ^{13}C NMR (100.61 MHz, $CDCl_3$, –60 °C): δ = 161.88 (C_1), 134.4–123.6 (Ph), 69.06 (C_2), 68.29 (C_3), 64.44 (br., CH=CH), 31.14 (CH *i*Pr), 31.94, 29.97, 26.93, 25.80 (CH_2 COE), 19.36, 13.83 (Me *i*Pr) ppm. $^{31}P\{^1H\}$ NMR (161.97 MHz, $CDCl_3$, –60 °C): δ = 10.1 (s) ppm. IR (Nujol mulls): $\tilde{\nu}$ = 1616 ($\nu_{C=N}$) cm^{-1}.

Preparation of [Ir(acac)ClH{(*S*)-PN}] (2): (*S*)-PN (83.0 mg, 0.22 mmol) was added to a solution of [Ir(μ-Cl)(COE)$_2$]$_2$ (100.0 mg, 0.11 mmol) in acetone (10 mL), under argon. The solution was stirred for 30 min, and then Hacac (0.3 mL) was added. The resulting solution was heated under reflux for 6 h and then concentrated under vacuum. Addition of *n*-hexane led to the precipitation of **2** as a yellow solid, which was filtered off, washed with *n*-hexane, and air-dried. Yield: 134.8 mg (86%). ^1H NMR (300.1 MHz, $CDCl_3$, r.t.): δ = 8.2–6.9 (m, 14 H, Ph), 5.35 (s, 1 H, CH acac), 5.09 (ddd, *J* = 10.2, 5.7, 3.0 Hz, 1 H, H_g), 4.48 (dd, *J* = 10.2, 9.0 Hz, 1 H, H_c), 4.29 (dd, *J* = 9.0, 5.7 Hz, 1 H, H_t), 2.57 (m, 1 H,CH *i*Pr), 1.91 (s, 3 H, Me acac), 1.54 (s, 3 H, Me acac), 0.72 (d, *J* = 7.0 Hz, 3 H, Me *i*Pr), –0.09 (d, *J* = 7.0 Hz, 3 H, Me *i*Pr), –22.86 (d, *J* = 18.5 Hz, 1 H Ir–H) ppm. ^{13}C NMR (75.4 MHz, $CDCl_3$, r.t.): δ = 184.63 (CO acac), 183.81 (CO acac), 161.38 (C_1), 135.4–125.3 (Ph), 101.37 (CH acac), 69.02 (C_2), 66.52 (C_3), 30.93 (CH *i*Pr), 28.42 (Me acac), 26.82 (Me acac), 18.73 (Me *i*Pr), 11.93 (Me *i*Pr) ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, $CDCl_3$, r.t.): δ = –2.32 (s) ppm. IR (Nujol mulls): $\tilde{\nu}$ = 2216 (ν_{IrH}), 1617 ($\nu_{C=N}$) cm^{-1}. $C_{29}H_{32}ClIrNO_3P$ (701.223): calcd. C 49.74, H 4.61, N 2.00; found C 49.59, H 4.70, N 1.99.

Preparation of [Ir{(*S*)-PN}$_2$]Cl (3a, 3b): (*S*)-PN (187.7 mg, 0.50 mmol) was added to a solution of [Ir(μ-Cl)(COE)$_2$]$_2$ (100.0 mg, 0.11 mmol) in acetone (10 mL), under argon. The solution was refluxed for 2 h and then concentrated under vacuum. Addition of *n*-hexane led to the precipitation of **3a** as a red powder. Yield 185.1 mg (85%). Pure **3b** can also be obtained as a red powder by following the same procedure but using toluene as solvent. Yield 174.1 mg (80%). Compounds **3a** and **3b** had to be stored under argon. **3a:** ^1H NMR (300.1 MHz, CD_2Cl_2, r.t.): δ = 8.2–6.4 (m, 28 H, Ph), 5.25 (m, 1 H, H_g), 4.63 (m, 1 H, $H_{g'}$), 4.54 (m, 1 H, H_t), 4.36 (m, 2 H, $H_{t'}$, $H_{c'}$), 4.23 (m, 1 H, H_c), 2.78 (m, 1 H, CH *i*Pr), 1.42 (m, 1 H, CH *i*Pr′), 0.81 (d, *J* = 6.9 Hz, 3 H, Me *i*Pr′), 0.76 (d, *J* = 7.0 Hz, 3 H, Me *i*Pr), 0.22 (d, *J* = 6.6 Hz, 3 H, Me *i*Pr′), –0.09 (d, *J* = 6.9 Hz, 3 H, Me *i*Pr) ppm. ^{13}C NMR (75.4 MHz, CD_2Cl_2, r.t.): δ = 167.33 (d, *J* = 6.6 Hz), 164.39 (t, *J* = 4.8 Hz) (C_1, $C_{1'}$), 135.5–122.2 (Ph), 77.94, 70.16 (C_2, $C_{2'}$), 69.17, 69.09 (C_3, $C_{3'}$), 30.48, 29.40 (CH *i*Pr), 18.81, 18.34, 12.85, 12.78 (Me *i*Pr) ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, CD_2Cl_2, r.t.): δ = –11.83 (d, *J* = 14.7 Hz), –13.09 (d) ppm. Molar conductivity (acetone) = 71.9 ohm^{-1} cm^2 mol^{-1}. $C_{48}H_{48}ClIrN_2O_2P_2$ (974.54): calcd. C 59.16, H 4.96, N 2.87; found C 58.64, H 6.44, N 2.58. **3b:** ^1H NMR (300.1 MHz, CD_2Cl_2, r.t.): δ = 8.2–6.4 (m, 28 H, Ph), 4.88 (dd, *J* = 9.6, 9.3 Hz, 1 H, H_c), 4.44 (dd, *J* = 9.6, 3.6 Hz, 1 H, H_t), 4.24 (m, 1 H, H_g), 2.26 (m, 1 H, CH *i*Pr), 0.90 (d, *J* = 6.9 Hz, 3 H, Me *i*Pr), 0.31 (d, *J* = 6.6 Hz, 3 H, Me *i*Pr) ppm. ^{13}C NMR (75.4 MHz, CD_2Cl_2, r.t.): δ = 163.48 (C_1), 135.5–122.2 (Ph), 73.54 (C_2), 69.90 (C_3), 32.36 (CH *i*Pr), 19.90, 15.60 (Me *i*Pr) ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, CD_2Cl_2, r.t.): δ = 16.20 (s) ppm. $C_{48}H_{48}ClIrN_2O_2P_2$ (974.54): calcd. C 59.16, H 4.96, N 2.87; found C 58.54, H 6.35, N 2.96.

Preparation of [Ir{(*S*)-PN}$_2$]A {A = BF_4 (4a), PF_6 (5a)}: (*S*)-PN (187.7 mg, 0.50 mmol) and $NaBF_4$ or $NaPF_6$ (1 mmol) were added to a solution of [Ir(μ-Cl)(COE)$_2$]$_2$ (100.0 mg, 0.11 mmol) in acetone (10 mL), under argon. The resulting suspension was refluxed for 6 h, and the solvent was evaporated under vacuum. The residue was extracted with CH_2Cl_2 (10 mL) and filtered through a pad of Celite. The resulting solution was concentrated to ca. 1 mL, and the addition of diethyl ether led to the precipitation of a red solid, which was filtered off, washed with the precipitant and vacuum-dried. Yield 167.3 mg (73%) (**4a**) or 188.9 mg (78%) (**5a**). Complexes **4a** and **5a** had to be stored under argon. **4a:** ^1H NMR (300.1 MHz, CD_2Cl_2, r.t.): δ = 8.2–6.4 (m, 28 H, Ph), 5.32 (m, 1 H, H_g), 4.62 (m, 1 H, $H_{g'}$), 4.52 (m, 1 H, H_t), 4.34 (m, 2 H, $H_{t'}$, $H_{c'}$), 4.25 (m, 1 H, H_c), 2.83 (m, 1 H, CH *i*Pr), 1.50 (m, 1 H, CH *i*Pr′), 0.82 (d, *J* = 7.1 Hz, 3 H, Me *i*Pr′), 0.78 (d, *J* = 6.9 Hz, 3 H, Me *i*Pr), 0.23 (d, *J* = 6.4 Hz, 3 H, Me *i*Pr′), 0.07 (d, *J* = 6.9 Hz, 3 H, Me *i*Pr) ppm. ^{13}C NMR (75.4 MHz, CD_2Cl_2, r.t.): δ = 167.43 (d, *J* = 6.5 Hz), 164.49 (t, *J* = 4.8 Hz) (C_1, $C_{1'}$), 134.5–127.2 (Ph), 78.21, 70.25 (C_2, $C_{2'}$), 69.45, 69.26 (C_3, $C_{3'}$), 30.79, 29.74 (CH *i*Pr), 19.13, 18.55, 13.13, 13.13 (Me *i*Pr) ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, CD_2Cl_2, r.t.): δ = –10.91 (d, *J* = 15.1 Hz), –12.33 (d) ppm. $C_{48}H_{48}BF_4IrN_2O_2P_2$ (1025.89): calcd. C 56.19, H 4.71, N

Preparation of [IrH(NCCHCO$_2$R){(*S*)-PN}$_2$]Cl {R = Me (12), Et (13)}: A solution of (*S*)-PN (187.7 mg, 0.50 mmol) in acetone (2 mL) was added to a solution of $[Ir(\mu\text{-}Cl)(COE)_2]_2$ (100.0 mg, 0.11 mmol) in the same solvent (12 mL) at ambient temperature under argon. The solution was stirred for 6 h, and then methyl or ethyl α-cyanoacetate (0.3 mL) was added. The resulting solution was stirred for 22 h and then concentrated to ca. 1 mL. Addition of diethyl ether led to the precipitation of **12** or **13** as a yellow solid, which was filtered off, washed with diethyl ether and air-dried. Yield 197.2 mg (85%) (**12**) or 206.9 mg (88%) (**13**). **12:** ^{1}H NMR (300.1 MHz, $CDCl_3$, r.t.): δ = 8.3–6.6 (m), 5.65 (m, 28 H, Ph), 4.73 (m), 4.64 (m), 4.56 (m), 4.52 (m), 4.32 (m), 4.16 (m, 6 H, H_g, $H_{g'}$, H_c, $H_{c'}$, H_t, $H_{t'}$), 3.57 (s, 3 H, OCH_3), 3.18 (s, 1 H, NCCH), 2.78 (m, 1 H, CH *i*Pr), 2.30 (m, 1 H, CH *i*Pr′), 0.86 (d, J = 6.6 Hz, 3 H, Me *i*Pr′), 0.70 (d, J = 6.9 Hz, 3 H, Me *i*Pr), 0.02 (d, J = 6.6 Hz, 3 H, Me *i*Pr′), –0.40 (d, J = 6.9 Hz, 3 H, Me *i*Pr), –19.28 (dd, J = 26.6, 13.5 Hz, 1 H, Ir-H) ppm. ^{13}C NMR (75.4 MHz, $CDCl_3$, r.t.): δ = 184.77 (CO), 167.46, 164.85 (C_1, $C_{1'}$), 134.9–127.8 (Ph), 73.88, 71.97 (C_2, $C_{2'}$), 69.72, 68.22 (C_3, $C_{3'}$), 51.26 (OCH_3), 50.15 (NC-*C*H), 31.16, 28.99 (CH *i*Pr), 19.56, 18.25, 13.83, 12.70 (Me *i*Pr) ppm. ^{31}P{^{1}H} NMR (121.5 MHz, $CDCl_3$, r.t.): δ = 1.16 (d, J = 14.5 Hz), –13.30 (d) ppm. IR (Nujol): $\tilde{\nu}$ = 2207 sh. (ν_{IrH}), 2177 s (ν_{CN}) cm^{-1}. $C_{52}H_{53}ClIrN_3O_4P_2$ (1073.63): cacld. C 58.17, H 4.97, N 3.91; found C 58.64, H 5.47, N 4.25. **13:** ^{1}H NMR (300.1 MHz, $CDCl_3$, r.t.): δ = 8.3–6.6 (m), 5.68 (m, 28 H, Ph), 4.81 (m), 4.78 (m), 4.62 (m), 4.55 (m), 4.38 (m), 4.22 (m, 6 H, H_g, $H_{g'}$, H_c, $H_{c'}$, H_t, $H_{t'}$), 4.08 (q, J = 6.8 Hz, 2 H, OCH_2CH_3), 3.22 (s, 1 H, NCCH), 2.83 (m, 1 H, CH *i*Pr), 2.36 (m, 1 H, CH *i*Pr′), 1.21 (t, 3 H, OCH_2CH_3), 0.91 (d, J = 6.9 Hz, 3 H, Me *i*Pr′), 0.74 (d, J = 6.9 Hz, 3 H, Me *i*Pr), –0.03 (d, J = 6.9 Hz, 3 H, Me *i*Pr′), –0.36 (d, J = 6.9 Hz, 3 H, Me *i*Pr), –19.23 (dd, J = 26.6, 13.5 Hz, 1 H, Ir-H) ppm. ^{13}C NMR (75.4 MHz, $CDCl_3$, r.t.): δ = 182.92 (CO), 167.40, 164.75 (C_1, $C_{1'}$), 137.3–124.7 (Ph), 73.75, 71.81 (C_2, $C_{2'}$), 69.79, 68.51 (C_3, $C_{3'}$), 58.64 (OCH_2CH_3), 51.04 (NC*C*H), 31.14, 29.01 (CH *i*Pr), 19.51, 18.21 (Me *i*Pr), 14.90 (OCH_2CH_3), 13.90, 12.74 (Me *i*Pr) ppm. ^{31}P{^{1}H} NMR (121.5 MHz, $CDCl_3$, r.t.): δ = 1.18 (d, J = 14.5 Hz), –13.30 (d) ppm. IR(Nujol): $\tilde{\nu}$ = 2206 sh. (ν_{IrH}), 2176 s (ν_{CN}), 1666 s (ν_{CO}) cm^{-1}. $C_{53}H_{55}ClIrN_3O_4P_2$ (1087.65): calcd. C 58.53, H 5.09, N 3.86; found C 57.94, H 4.87, N 3.93.

Catalytic Michael Addition Procedure: The catalyst (0.01 mmol), donor **6** or **7** (1 mmol) and acceptor **8**–**10** (1.5 mmol) were dissolved in toluene (5 mL) under argon at room temperature, and the mixture was stirred for 22 h. After removal of all volatile materials, [D$_8$]toluene (500 μL) was added to the residue. The yield based on the donor was determined by ^{1}H NMR. The crude product was extracted with *n*-hexane, and the extract was purified by chromatography on silica gel. The products were identified by NMR spectroscopy.[7a,11l,26] Enantiomeric excesses were determined by GLC.

X-ray Structure Analyses of Complexes 2 and 5b: Single crystals of both complexes were glued to a glass fiber and mounted on a Bruker SMART APEX (equipped with a CCD area detector) (**2**) or Siemens-Stoe AED-2 diffractometer (**5b**) and examined using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Crystal data for **2** (from 4392 reflections, 2.2 < θ < 23.5°): $C_{29}H_{32}ClIrNO_3P{\cdot}0.5(C_4H_8O)$, tetragonal, space group $P4_12_12$; a = 11.2664(6), c = 46.726(4) Å, V = 5931.1(7) Å^3, Z = 8, D_c = 1.651 Mg m^{-3}, μ(Mo-K_α) = 4.680 mm^{-1}; crystal size 0.13 × 0.12 × 0.07 mm; T = 100.0(2) K, ω scans, max. 2θ = 55.1°; 38251 measured reflections, 6835 unique (R_{int} = 0.0835). Crystal data for **5b** (from 44 reflections, 12.5< θ < 15.0°): $C_{48}H_{48}F_6IrN_2O_2P_3$, M = 1083.99, orthorhombic, space group $P2_12_12_1$; a = 12.9657(10), b = 16.2713(17), c = 21.278(3) Å, V = 4489.1(8) Å^3, Z = 4, D_c = 1.604 Mg m^{-3}, μ(Mo-K_α) = 3.148 mm^{-1}; crystal size 0.23 × 0.20 × 0.19 mm; T = 200.0(2) K, $\theta/2\theta$ scans, max. 2θ = 50.0°; 9769 measured reflections, 7840 unique (R_{int} = 0.0213). Orange crystals of **5b** suitable for X-ray diffraction were grown by slow diffusion of diethyl ether into a solution of the complex in dichloromethane.

Data were integrated with the Bruker SAINT[27] (**2**) and Stoe REDU4 (**5b**) programs. Absorption correction was applied by using the SADABS program[28] (**2**) or the psi-scan approach[29] (**5b**). Structures were solved by direct methods[30] and completed by subsequent difference Fourier techniques. Refinement on F^2 was carried out for both structures by full-matrix least-squares (SHELXL-97).[30] In **2**, half a THF molecule was observed as crystallisation solvent in the structure. All non-hydrogen atoms, including those of the solvent molecule, were refined with anisotropic displacement parameters. The organic hydrogen atoms were included in calculated positions and refined with riding positional and thermal parameters. The hydride ligand was clearly observed in the last cycles of refinement, but it did not support a proper refinement as free isotropic atom. It was incorporated in the refinement with a restrained position and with a fixed displacement parameter. All non-hydrogen atoms in **5b**, except the F atoms in the PF_6^- anion, were refined with anisotropic displacement parameters. The PF_6^- anion was found to be disordered. A model for static disorder was established and the anion was refined with all atoms in two positions; occupancy factors were refined holding the sum of their occupancies equal to one. The hydrogen atoms were included accord-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ing to their geometry with restrained thermal and positional parameters.

The absolute configuration for both complexes were determined on the basis of the Flack parameter[31] [–0.008(11) for **2** and –0.018(6) for **5b**] and using as internal reference the previously known chirality of the asymmetric carbon atom in the phosphanyloxazoline ligand. Conventional final agreement factors[30] were: R_1 = 0.0506 [for 5588 reflections with $F^2>4\sigma(F^2)$], ωR_2 = 0.0937 and S = 0.968 for all independent reflections of **2**; R_1 = 0.0289 [for 7259 reflections with $F^2>4\sigma(F^2)$], ωR_2 = 0.0651 and S = 1.046 for all independent reflections of **5b**.

CCDC-240695 and CCDC-240696 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Highly Active Neutral Nickel(II) Complexes Bearing P,N-Chelate Ligands: Synthesis, Characterization and Their Application to Addition Polymerization of Norbornene

Hai-Yu Wang[a] and Guo-Xin Jin*[a]

Keywords: Nickel / P,N-chelate ligands / Homogeneous catalysts / Polymerization / Polynorbornene

Neutral nickel(II) complexes [[R–NP]NiPh(PPh_3)](**1**, R = H; **2**, R = CH_3) bearing P,N-chelate ligands ([H–NP] = (2-diphenylphosphanyl)benzenamine $\mathbf{L^1}$; [CH_3–NP] = (2-diphenylphosphanyl) *N*-methylbenzenamine $\mathbf{L^2}$) have been synthesized and characterized. The molecular structure of complex **1** has been confirmed by single-crystal X-ray analyses. After activation with methylaluminoxane (MAO), catalytic precursors **1** and **2** could polymerize norbornene to afford addition-type polynorbornene (PNB) with very high activities (4.43×10^7 g-PNB mol^{-1}-Ni h^{-1}), high molecular weight M_w (3.07×10^6 g mol^{-1}) and moderate molecular weight distribution M_w/M_n. Catalytic activities, polymer yield, M_w and M_w/M_n of PNB have been investigated under various reaction conditions.

Introduction

Various late transition metal complexes containing chelating ligands act as catalysts for the polymerization and oligomerization of olefins. Early work on the Shell Higher Olefin Process (SHOP)[1] utilized neutral Ni catalysts containing P–O chelates. Subsequent work has investigated, mainly, several classes of ligands: $[O\text{-}P]^-$,[2–6] $[O\text{-}N]^-$,[7–16] $[N\text{-}N]^-$.[17–23] P,N ligands have attracted increasing recent attention because of their bonding versatility with a metal center and the relative ease with which the electronic and steric properties of the donor atoms can be modified.[24–26] Braunstein et al.[27] reported a series of nickel complexes, containing P,N-chelate ligands, and their catalytic ethylene oligomerization behavior. Liang et al.[28] have synthesized several metal complexes supported by bidentate diarylamido phosphane ligands.

Homo-polymer addition of polynorbornenes is of considerable importance because the products have interesting and unique properties, including high chemical resistance, good solubility in organic solvents, good UV resistance, low dielectric constant, high glass-transition temperature, excellent optical transparency, large refractive index, and low birefringence. However, the addition polymerization of norbornene was much less developed than ROMP (ring-opening metathesis polymerization). In 1993, Deming and Novak introduced the first nickel complex for the addition polymerization of norbornene.[29] Several other catalyst systems have also been applied recently to this reaction.[30,31d]

Following our research on neutral nickel complexes,[16,31] we synthesized neutral nickel(II) complexes with a chelating P,N ligands and firstly investigated their catalytic norbornene addition polymerization behaviors. These neutral nickel(II) complexes have very high activities for cyclo-olefin polymerization. This article focuses on the syntheses of neutral nickel(II) complexes **1** and **2** bearing P,N-chelate ligands and the polymerization of norbornene upon activation with methylaluminoxane (MAO). The typical molecular structure of catalytic precursor **1** was characterized by an X-ray crystallographic study. To the best our knowledge, neutral nickel(II) complexes bearing P,N-chelate ligands for the addition polymerization of norbornene have been scarcely investigated.

Results and Discussion

Syntheses of Ligands and Complexes

Syntheses of complexes **1** and **2** are outlined in Scheme 1. (2-Diphenylphosphanyl)benzenamine (ligand $\mathbf{L^1}$) was prepared according to literature methods.[36] Ligand $\mathbf{L^2}$ [(2-diphenylphosphanyl)-*N*-methylbenzenamine] was synthesized by monolithiation of the NH_2 group of ligand $\mathbf{L^1}$ with *n*BuLi (1.0 equiv.), followed by the addition of CH_3I (1.0 equiv.). After workup, $\mathbf{L^2}$ was extracted with hot hexane and obtained after evaporation of solvent as a white solid.

Ligands $\mathbf{L^1}$ and $\mathbf{L^2}$ were treated with *n*BuLi in THF and then treated with *trans*-chloro(phenyl)bis(triphenylphosphane)nickel(II) to give complexes **1** and **2**, respectively. Both complexes were purified by recrystallization from tol-

uene. All compounds were well characterized by ^{1}H NMR, FT-IR as well as elemental analysis.

Single Crystal X-ray Structure Analyses of Complex 1

A single crystal of **1** suitable for X-ray diffraction study was grown from a concentrated CH_2Cl_2 solution at –30 °C. Table 1 summarizes the collection and refinement data of the analyses. Figure 1 shows the ORTEP diagram of **1**. Complex **1** contains a chelating [P,N] ligand, a triphenylphosphane group (PPh_3) and a phenyl group. The bulky diphenylphosphane moiety occupies the position trans to PPh_3, with a nearly linear P(1)–Ni(1)–P(2) angle of 173.97(3)°, and the phenyl group attached to Ni lies trans to N(1), with a C(19)–Ni(1)–N(1) angle of 172.80(10). The *cis* angles at nickel are in the range 84.44–95.83°. Thus, the nickel center lies perfectly on the square plane defined by the four donor atoms. In addition, the metal ion deviates from the [P(1), N(1), P(2) and C(19)] plane by ca. 0.0828 Å.

Addition Polymerization of Norbornene

Preliminary experiments indicated that complexes **1**and **2** can not catalyze ethylene polymerization with or without methylaluminoxane (MAO) as co-catalyst at 10 atm of ethylene. However, after activation with MAO, they could catalyze the polymerization of norbornene to afford addition-type polynorbornene (PNB) with high activities (10^7 g-PNB mol^{-1}-Ni h^{-1}), high molecular weight M_w (10^6 g mol^{-1}) and moderate molecular weight distributions M_w/M_n (2.65–3.93). Complexes **1** and **2** themselves and MAO did not

11[d]	**2**	–	trace	–		
12[e]	–	3000	trace	–		

[a] Polymerization conditions: solvent, chlorobenzene; total volume 10 mL; nickel complex (0.2 μmol), norbornene (1.88 g) [norbornene: nickel (molar) = 100 000]; reaction time 10 min; 30 °C. [b] 10^7 g-PNB mol^{-1}-Ni h^{-1}. [c] M_w (10^6 g mol^{-1}) and M_w/M_n determined by GPC. [d] Without co-catalyst MAO. [e] Without nickel complex.

produce polymers under the same conditions (entries 8, 11, 12 in Table 2). In general, the steric structure and bulky group in the nickel complexes slightly influence the catalytic activities. Moreover, the addition mechanism of norbornene, when using neutral nickel complexes, has been hypothesized as the insertion of norbornene into the Ni–C bond.[30i,30l] Thus, the N-methyl group of complex **2** makes the insertion of norbornene into the Ni–C bond more difficult than H of complex **1**, so complex **2** displays lower catalytic activity than complex **1**.

To investigate the reaction parameters affecting addition polymerization of norbornene, the catalytic precursor **1** was studied under different reaction conditions. MAO was essential for the polymerization of norbornene catalyzed by **1** and **2**. It initiates the polymerization of norbornene and probably creates an empty site for insertion of the norbornene monomer. Varying the MAO:complex **1** ratio (expressed here as Al:Ni ratio) had considerable effects on catalytic activity and M_w. The activity of **1** is almost zero for Al:Ni = 500 (entry 1, Table 2), but is up to 10^7 g-PNB mol^{-1}-Ni h^{-1} when Al:Ni > 1000. The catalytic activities of complex **1** increase first and then decrease with increasing Al:Ni ratio; the activity is highest at Al:Ni = 3000. The M_w of polymers also exhibits remarkable changes with Al:Ni, and is lowest at Al:Ni = 4000.

The reaction temperature also affects considerably the catalytic activities and M_w (Table 3). With increasing reaction temperature, the catalytic activities first increase and then decrease – the highest activity is at 30 °C (3.90×10^7 g-PNB mol^{-1}-Ni h^{-1}). In contrast, M_w decreased with increasing temperature while M_w/M_n varied irregularly.

Figure 2 reveals the effects of reaction time on catalytic activities and polymer yields. The yields of PNB gradually increase with increasing reaction time, but the catalytic activities of complex **1** always decrease. After 1 h, the yield is almost up to 90%, but the activity has reduced to 10^6 g-PNB mol^{-1}-Ni h^{-1}.

The concentration of norbornene also exerts a considerable influence on the polymerization reaction (Figure 3). The catalytic activity of complex **1** increases almost linearly with monomer concentration in the range 0.5–2.5 mol L^{-1}, and then remains nearly constant when the concentration exceeds 3.0 mol L^{-1}.

Table 3. Influence of the reaction temperature (T) on activities of complex **1**.

Entry	T[°C]	Polymer [g]	Activity[a]	M_w[b]	M_w/M_n
1	0	0.309	0.927	2.80	3.23
2	30	1.30	3.90	2.57	2.72
3	60	1.08	3.24	1.81	2.67
4	90	0.799	2.40	1.37	2.89

[a] 10^7 g-PNB mol^{-1}-Ni h^{-1}. [b] M_w (10^6 g mol^{-1}). Polymerization conditions: solvent, chlorobenzene; total volume 10 mL, nickel complex (0.2 μmol), norbornene (1.88 g) [norbornene:nickel(molar) = 100000]; MAO (0.35 mL,1.7 M) [Al:Ni = 3000]; reaction time 10 min.

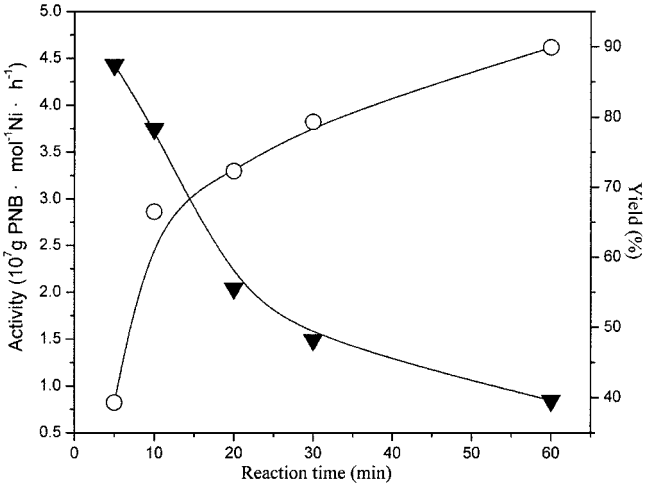

Figure 2. Activity (▲) and yield(○) vs. reaction time; 0.2 μmol complex **1**, norbornene:nickel(molar) = 100 000, Al:Ni = 3000, V_{total} = 10 mL, polymerization at 30 °C.

The crystallinity of the resultant polymers was investigated by XRD. Figure 4 shows the XRD diagram of the obtained PNB. Two broad halos at 2θ of 11 and 18° are present. This pattern is predominantly intrachain, probably corresponding to a short-range order, or to a pseudo-periodicity arrangement of the bicycle units along the chain.

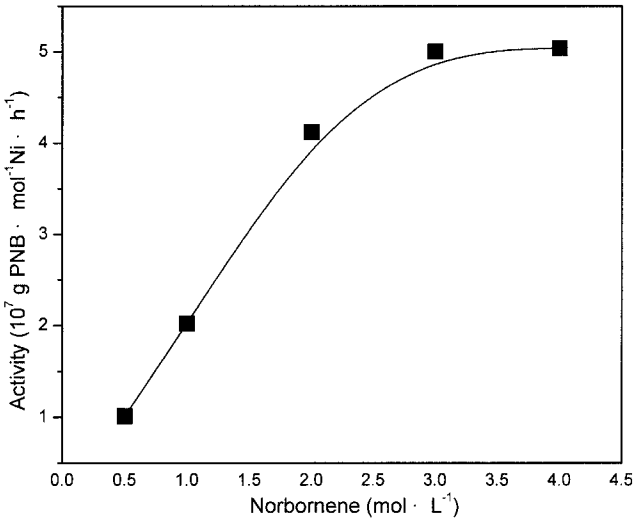

Figure 3. Activity vs. norbornene concentration; 0.2 μmol complex **1**, Al:Ni = 3000, V_{total} = 10 mL, polymerization at 30 °C for 10 min.

This is almost in agreement with reported results.[32,33] No traces of Bragg reflections, characteristic of crystalline regions, are revealed. The PNB is therefore, non-crystalline.

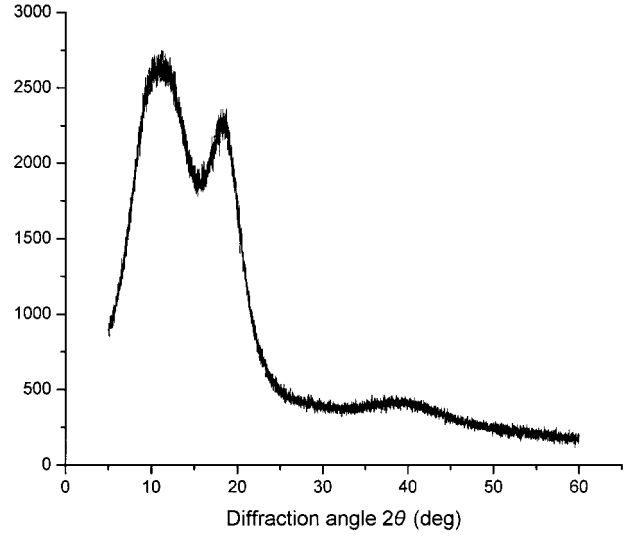

Figure 4. XRD diagram of PNB.

All polymers obtained showed very similar IR and ^{1}H NMR spectra. ^{1}H NMR spectra exhibited no trace of the double bond that is typical for ROMP polynorbornene.[34,30l] PNB resonances appear at 0.9–2.6 (m, maxima at 1.3, 1.5, 1.7, 2.4 ppm). A double bond, which is often seen at 1680–1620 cm^{-1}, was also absent from the IR spectra. The glass transition temperature (T_g) of addition-type homo-polynorbornene has proved difficult to obtain since it is, apparently, close to the temperature at which decomposition tends to set in.[35] Our attempts to determine the T_g of PNB also failed, and DSC studies did not give an endothermic signal upon heating to the decomposition temperature (above 450 °C).

Conclusions

(2-Diphenylphosphanyl)benzenamine (**L^1**) and (2-diphenylphosphanyl)-*N*-methylbenzenamine (**L^2**) were prepared in good yields for the syntheses of neutral nickel(II) complexes **1** and **2**. Complex **1** was characterized by single-crystal X-ray diffraction. Both complexes showed high catalytic activities for the addition polymerization of norbornene after activation with MAO. Catalytic activities of up to 4.43×10^7 g-PNB mol^{-1}-Ni h^{-1} and M_w up to 3.07×10^6 g·mol^{-1} were observed. Activities, polymer yield and M_w can be controlled by varying the reaction parameters. PNBs obtained here are amorphous and soluble in halogenated aromatic hydrocarbons. Therefore, neutral Ni^{ii} complexes with chelating P,N ligands are, perhaps, a promising system for the addition polymerization of norbornene. We are currently working to develop new P-N nickel complexes for the polymerization of norbornene.

Experimental Section

General Remarks: All manipulations of air- and/or water-sensitive compounds were performed under dry nitrogen using standard Schlenk and vacuum-line techniques. Solvents were dried by boiling under reflux with appropriate drying agents and distilled under nitrogen before use. (2-Diphenylphosphanyl)benzenamine[36] and *trans*-[Ni(PPh$_3$)$_2$(Ph)Cl][37] were prepared according to literature procedures. Norbornene (bicyclo[2.2.1]hept-2-ene, Acros) was purified by distillation over sodium and used as a chlorobenzene solution. Methylaluminoxane (MAO) was purchased from Aldrich as 10% weight of a toluene solution and used without further purification. Other commercially available reagents were purchased and used without purification.

^{1}H NMR spectra were recorded with a Varian Unity-400 spectrometer. Elemental analyses were performed on an Elementar vario EL III Analyzer. FT-IR spectra were recorded with a Niclolet-FT-IR-50X spectrometer. NMR spectroscopic data for PNB were obtained at ambient temperature with a Bruker AC 500 spectrometer instruments using [D$_4$]-*o*-chlorobenzene as solvent. Average molecular weight (M_w) and molecular weight distributions (M_w/M_n) of PNB products were determined using a PL GPC-220 gel permeation chromatograph at 150 °C, employing narrow standards calibration, and equipped with three PL gel columns (sets of PL gel 10 m MIXED-B LS). Trichlorobenzene was used as solvent at a flow rate of 1.00 mL min^{-1}. Differential scanning calorimetric (DSC) measurements were performed with a Perkin–Elmer Pyris 1 DSC. The X-ray diffraction (XRD) diagram of the polymer powder was obtained using a Bruker D4 Endeavor X-ray diffractometer with monochromatic radiation at a wavelength of 1.54 Å. Scanning was performed with 2θ ranging from 5 to 60°.

Synthesis of Ligand L^2: A solution of ligand **L^1** (0.555 g, 2.0 mmol) in THF (20 mL) was cooled to –78 °C and *n*BuLi was then added slowly (1.0 equiv., 0.87 mL, 2.3 M, 2.0 mmol). After the solution was stirred for 1 h at –78 °C, CH_3I (1.0 equiv., 0.125 mL, 2.0 mmol) was slowly added at –78 °C. The reaction mixture was then stirred for 2 h at –78 °C and warmed to room temperature overnight. The solution was hydrolyzed with degassed water (5 mL) and extracted with diethyl ether (3 × 3 mL). Finally, the organic phase was separated, dried over degassed $MgSO_4$, and filtered. After evaporation of the diethyl ether, the product was isolated as a white solid (yield 0.456 g, 1.56 mmol, 78%). ^{1}H NMR ($CDCl_3$): δ = 2.82 (s, 3 H, N–

CH_3), 6.65 (m, 2 H, *m*-H of P), 6.75 (m, 1 H, *p*-H of P), 7.34–7.23 (m, 11 H, Ar–H) ppm.

Synthesis of Complex 1: A solution of ligand $\mathbf{L^1}$ (0.277 g, 1.0 mmol) in THF (15 mL) was cooled to –78 °C, and *n*BuLi was added dropwise (1.0 equiv., 0.48 mL, 2.3 M, 1.0 mmol). This mixture was allowed to warm to room temperature and then stirred for 2 h to afford the lithium salt of $\mathbf{L^1}$. After evaporation of THF under vacuum, the lithium salt of $\mathbf{L^1}$ was dissolved in toluene (10 mL). The resultant solution was slowly channeled into a 50 mL flask with *trans*-[Ni(PPh$_3$)$_2$(Ph)Cl] (0.668 g, 0.96 mmol) in toluene (10 mL) and continuously stirred overnight at room temperature. The resultant reaction mixture was then separated by centrifugation to remove LiCl. After the upper clear dark red solution was concentrated to about 3 mL, hexane (20 mL) was added and complex **1** was obtained as a red-orange solid (yield 0.499 g, 77%). Red single crystals suitable for X-ray were recrystallized from CH_2Cl_2 at –30 °C. $C_{42}H_{35}NP_2Ni$ (674.39): calcd. C 74.80, H 5.23, N 2.08; found C 74.46, H 5.25, N 1.93. ^{1}H NMR ($CDCl_3$): δ = 7.93–7.27 (m, 34 H, Ar–H) ppm.

Synthesis of Complex 2: A dark red powder of complex **2** was obtained in a manner similar to that for complex **1** (yield of 68%, 0.449 g). $C_{43}H_{37}NP_2Ni$ (688.42): calcd. C 75.02, H 5.42, N, 2.03; found C 74.76, H 5.18, N 1.98. ^{1}H NMR ($CDCl_3$): δ = 2.79 (s, 3 H, N–CH_3), 7.91–7.26 (m, 34 H, Ar–H) ppm.

Structure Solution and Refinement for Complex 1: For **1**, a single crystal suitable for X-ray analysis was sealed in a glass capillary, and the intensity data of the single crystal were collected with a CCD-Bruker Smart APEX system. All determinations of the unit cell and intensity data were performed with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). All data were collected at room temperature using the ω scan technique. Structures were solved by direct methods, using Fourier techniques, and refined on F^2 by a full-matrix least-squares method. All non-hydrogen atoms were refined anisotropically, and all hydrogen atoms were included but not refined. Crystallographic data are summarized in Table 1.

CCDC-252436 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Polymerization of Norbornene: In a typical procedure (entry 4, Table 2), nickel complex **1** (0.2 μmol) in chlorobenzene (1.0 mL), norbornene (1.88 g) in chlorobenzene (3.0 mL) and another 3.0 mL of fresh chlorobenzene were added to a special polymerization bottle (20 mL) with strong stirrer under nitrogen. After keeping the mixture at 30 °C for 10 min, MAO (0.35 mL) was added to the polymerization system via syringe and the reaction was initiated. Ten minutes later, acidic ethanol ($V_{ethanol}$:$V_{concd.HCl}$ = 20:1) was added to terminate the reaction. The PNB produced was isolated by filtration, washed with ethanol and dried at 80 °C for 48 h under vacuum. For all polymerization procedures, the total reaction volume was 10.0 mL (achieved by varying the amount of chlorobenzene when necessary). IR (KBr): $\tilde{\nu}$ = 2950, 2865, 1475, 1453, 1294, 1257, 1220, 1189, 1142, 1105, 937, 890 cm^{-1}. ^{1}H NMR: δ = 0.9–2.6 (m, maxima at 1.3, 1.5, 1.7, 2.4 ppm).

[{Rh(Nbd)Cl}$_2$] (Nbd = norbornadiene) reacts with *o*-(diphenylphosphane)benzaldehyde in benzene solution to give the rhodium(III) complex [Rh(Cl)(C_7H_9){*o*-PPh_2(C_6H_4CO)}]$_n$ (**1**), where C_7H_9 is a nortricyclyl (Ntyl) group. Complex **1** reacts with various bidentate N-donors, such as biacetyldihydrazone, 2,2′-bipyridine, 8-aminoquinoline, 2-(aminomethyl)-pyridine, or pyridine, to afford nortricyclyl [Rh(Cl){*o*-PPh_2(C_6H_4CO)}(Ntyl)(NN)] complexes. The presence of the nortricyclyl group and the structure of the complexes have been confirmed by NMR spectroscopy and, in one case, by single-crystal X-ray diffraction. Nortricyclyl complexes containing bidentate N-donors are also formed by the reaction in benzene of PPh_2(*o*-C_6H_4CHO) with the corresponding [Rh(Cl)(Nbd)(NN)] compounds prepared "in situ". [Rh(Cl)-(Nbd)(bipy)] prepared "in situ" reacts with PPh_2(*o*-C_6H_4CHO) in methanol to give the complex [Rh(Cl){*o*-PPh_2(C_6H_4CO)}(C_7H_9)(bipy)], where C_7H_9 is a norbornenyl (Nbyl) group. This compound has been fully characterized by NMR spectroscopy. A proposal for the selective production of the norbornenyl and the nortricyclyl derivatives is presented.

Introduction

C–H bond cleavage in aldehydes, promoted by transition metal complexes, is an active area of research.[1] Rhodium and iridium compounds add, oxidatively, aldehyde C–H bonds to afford acylhydride derivatives;[2] such species are involved in catalytic processes such as aldehyde decarbonylation or alkene hydroacylation.[3] *o*-(Diphenylphosphanyl)-benzaldehyde [PPh_2(*o*-C_6H_4CHO)] promotes the chelate-assisted oxidative addition of aldehyde to rhodium(I)[4] iridium(I)[5] platinum(0)[6] or cobalt(I),[7] yielding *cis* acylhydride complexes that contain acylphosphane chelates PPh_2(*o*-C_6H_4CO). Ruthenium and osmium clusters also undergo oxidative addition to afford compounds with bridging acyl and hydride ligands.[8] PPh_2(*o*-C_6H_4CHO) is also a versatile ligand that can coordinate to transition metal atoms: (i) as a monodentate P-donor towards rhodium(I),[9] iridium(III),[10] palladium(II),[11] platinum(II),[12] ruthenium(II),[13] or tungsten(0);[14] (ii) as chelating phosphane-aldehyde ligand with the aldehyde portion bonded through oxygen (σ complex) as in [Ru(η^6-arene)Cl{κ^2-PPh_2(*o*-C_6H_4CHO)}][SbF_6][13] or [Re(Cl)$(CO)_3${κ^2-PPh_2(*o*-C_6H_4CHO)}][15] or through both oxygen and carbon (π complex) as in [Co(C_5Me_5){η^3-PPh_2(*o*-C_6H_4CHO)}][16] or [$W(CO)_2${η^3-PPh_2(*o*-C_6H_4-CHO)}].[14b]

1,5-Cyclooctadiene (Cod) rhodium or iridium complexes react with PPh_2(*o*-C_6H_4CHO) to undergo chelate-assisted oxidative addition, affording different types of complexes. [{Rh(Cod)Cl}$_2$] reacts through diolefin displacement to give a hydride, [Rh(Cl)(H){PPh_2(*o*-C_6H_4CO)}{κ^2-PPh_2(*o*-C_6H_4CHO)}],[17] while the cationic complex [Rh$(Cod)_2$]-ClO_4 affords cyclooctenyl derivative [Rh(η^3-C_8H_{13})-{PPh_2(*o*-C_6H_4CO)}{κ^2-PPh_2(*o*-C_6H_4CHO)}]ClO_4, due to hydride formation being followed by insertion of the diolefin into the Rh–H bond.[18] [{Ir(Cod)Cl}$_2$] gives the 1,5-cyclooctadiene complex [Ir(Cl)(H){PPh_2(*o*-C_6H_4CO)}-(Cod)] – a proposed model intermediate in the hydroacylation of olefins,[5] which reacts with PPh_2(*o*-C_6H_4CHO) to give hydridoirida-β-diketones, most likely via iridium(V) intermediates formed by oxidative addition of aldehyde to Ir^{III} species.[19] Recently, the reaction of [(η^5-C_5Me_5)-M(Cl)(μ-Cl)]$_2$ (M = Rh, Ir) with PPh_2(*o*-C_6H_4CHO) to afford [(η^5-C_5Me_5)M(Cl)(PPh_2(*o*-C_6H_4CO))] with HCl loss has been reported.[20]

We report here on the reactions of norbornadiene-containing rhodium(I) complexes with PPh_2(*o*-C_6H_4CHO).

Results and Discussion

[{Rh(Nbd)Cl}$_2$] (Nbd = norbornadiene) reacts with *o*-(diphenylphosphane)benzaldehyde in benzene solution to

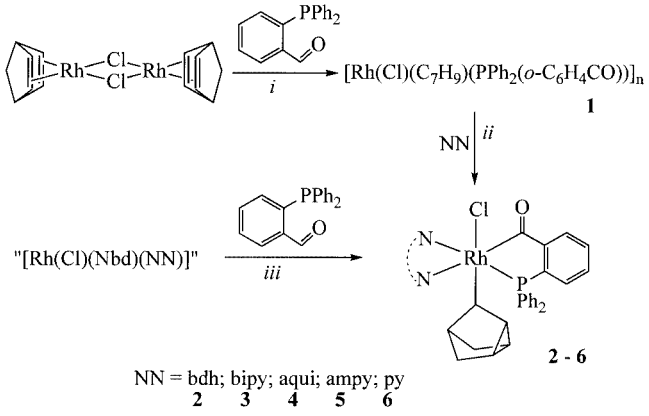
afford a yellow rhodium(III) complex, which according to its elemental analysis corresponds to $[Rh(Cl)(C_7H_9)\{o\text{-}PPh_2(C_6H_4CO)\}]_n$ **1** (see *i* in Scheme 1). Its IR spectrum shows a strong band at 1637 cm^{-1} due to bonded acyl groups. The FAB spectrum shows $[M-Cl]^+$ and $[M-Cl-(C_7H_9)]^+$ peaks for **1** ($n = 3$) at 1525 (47%) and 1432 (20%), respectively, suggesting a trinuclear structure. The four resonances in the 70–74 ppm region of the $^{31}P\{^1H\}$ NMR spectrum are of almost equal intensity as doublets, due to coupling with rhodium ($J_{Rh,P}$ = ca. 200 Hz). The ^1H NMR spectrum also shows four almost equal doublets in the 2.4–2.9 ppm region, complex multiplets in the 1.41–0.22 ppm region and no resonances in the olefinic region. On these spectroscopic grounds, we believe **1** contains a nortricyclyl group formed by the oxidative addition of aldehyde to rhodium to give an acylhydridenorbornadiene complex, followed by hydrogen transfer with a concurrent double bond shift to form the nortricyclyl group. This last type of step has been suggested in the rhodium-catalyzed amination of norbornadiene[21] and, recently, the formation of rhodium(III) complexes containing a nortricyclyl bonded group and using norbornadiene rhodium(I) compounds as starting material has been reported.[22]



Scheme 1. Formation of nortricyclyl derivatives in benzene.

The complexity of the NMR spectra indicates the presence of several isomers. On raising the temperature to +60 °C, the proton resonances at δ = 2.89, 2.71 and 2.46 ppm, and also three of the four resonances in the $^{31}P\{^1H\}$ NMR spectrum, decrease markedly, while the proton resonance at δ = 2.80 ppm and the doublet at $\delta^{31}P$ 71.52 ppm increase in intensity. These observations, along with the FAB data, suggest that **1** contains a mixture of two trinuclear isomers, one with equivalent phosphorus atoms and equivalent nortricyclyl groups and the other with three inequivalent phosphorus atoms and three inequivalent nortricyclyl groups. At higher temperatures, or longer periods in solution, the complex decomposes and, consequently, we could not obtain either a single isomer or single crystals for X-ray diffraction analysis. The reaction of **1** with several N-donor ligands confirmed the formation of the nortricyclyl (Ntyl) group.

Complex **1** reacts with bidentate N-donors, such as diimines or amino-imines, or with pyridine, to afford nortricyclyl $[Rh(Cl)\{o\text{-}PPh_2(C_6H_4CO)\}(Ntyl)(NN)]$ complexes [NN = biacetyldihydrazone (bdh), **2**; 2,2′-bipyridine (bipy), **3**; 8-aminoquinoline (aqui), **4**; 2-aminomethylpyridine (ampy), **5**; pyridine (py), **6**] (see *ii* in Scheme 1). In all cases, a single complex is obtained, as indicated by NMR spectroscopy. The $^{31}P\{^1H\}$ NMR spectra show only one doublet at low field (68–73 ppm), with $J_{Rh,P}$ of 170–183 Hz, which is consistent with phosphorus atoms trans to nitrogen.[4d] A doublet of doublets in the low-field region of the $^{13}C\{^1H\}$ NMR spectra (ca. 240 ppm) is due to the bonded acyl group, with $J_{Rh,C}$ around 37 Hz and $J_{P,C}$ of ca. 4 Hz. Nortricyclyl group assignments have been made using 2D NMR techniques (Experimental section). The ^1H NMR spectra show a doublet of doublets (1.4–2.4 ppm) for the Ntyl-CH bonded to rhodium, due to coupling with rhodium (ca. 10 Hz) and with a cis phosphorus ($J_{P,H}$ = ca. 2 Hz). Two doublets for each Ntyl-CH_2 group, three triplets due to the Ntyl-cyclopropyl fragment and a broad singlet due to another Ntyl-CH are also observed. $^{13}C\{^1H\}$ NMR spectra show, at ca. 40 ppm, the resonance due to the nortricyclyl carbon atom bonded to rhodium as either a doublet due to rhodium coupling ($J_{Rh,C}$ = ca. 25 Hz) or as a doublet of doublets if additional splitting by a cis phosphorus atom is observed ($J_{P,C}$ = ca. 6 Hz). Complex **2** contains a diimino-coordinated dihydrazone and shows two well-separated resonances for the pendant amino groups at δ = 5.65 and 7.78 ppm, respectively. The low-field resonance is most likely due to hydrogen bond formation. Complexes **4** and **5**, containing bonded amino groups, show the expected displacement of the corresponding amino resonance towards lower field on coordination. Only one isomer is formed, containing the amino group trans to the phosphane. Were the amino group cis to the phosphane, ring current effects originated by its aromatic rings would shift the signals towards higher field.[4d]

An X-ray diffraction study of **2** confirms the presence of the nortricyclyl group and the structure. There appears to be only two previous, recent, structural reports of a nortricyclyl unit bonded to rhodium.[22] The crystal consists of $[Rh(Cl)\{o\text{-}PPh_2(C_6H_4CO)\}(C_7H_9)(H_2NN{=}C(CH_3)C(CH_3){=}NNH_2)]$ neutral molecules and chloroform solvent molecules. Figure 1 shows an ORTEP view of the complex with the atomic numbering scheme, together with selected bond lengths and angles. The rhodium atom is coordinated in a slightly distorted octahedral fashion due to the presence of two bidentate ligands. The maxima deviations of 15.3 and 14.3° correspond to the angles N3–Rh–N2 and C8–Rh–P for the bidentate ligands. The nortricyclyl unit and the chlorine atom occupy axial positions. The equatorial plane, formed by the P, C8, N2 and N3 atoms of the two metallocycles, shows a maximum least-squares deviation of 0.09(1) Å for C8, with the rhodium atom 0.022(1) Å out of this plane. Rh–N2 [2.10(1) Å] trans to phosphorus is slightly shorter than Rh–N3 [2.16(1) Å] trans to acyl, reflecting the stronger trans influence of the acyl ligands. Rh–C1 [2.12(1) Å] is similar to those recently reported in nortricyclylrhodium compounds[22] and longer than Rh–C8 [2.00(1) Å], which is as expected.[4b] The difference between

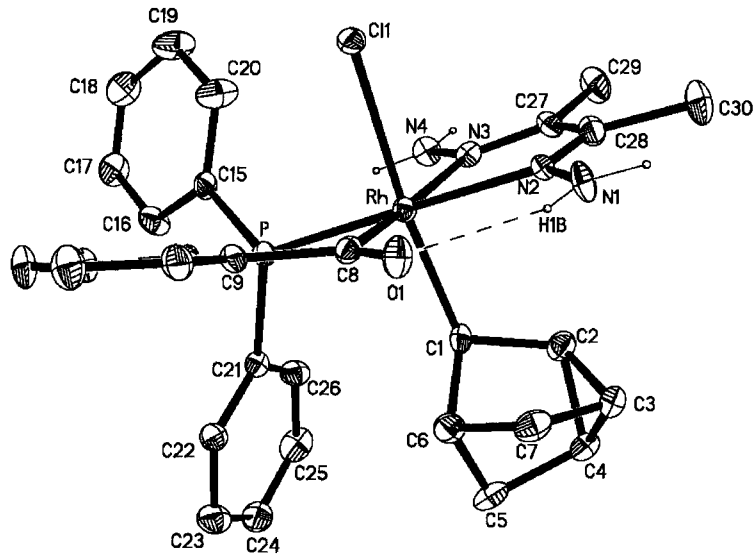

Figure 1. ORTEP view of complex **2**, showing the atomic numbering (30% probability ellipsoids); solvent molecules, some carbon atoms and all hydrogen atoms but four have been omitted for clarity; selected bond lengths [Å] and angles [°]: Rh–C(1) 2.12(2), Rh–C(8), 2.00(2), Rh–N(2) 2.10(1), Rh–N(3) 2.16(1), Rh–P 2.273(3), Rh–Cl(1) 2.525(3), O(1)–C(8) 1.21(1); C(8)–Rh–C(1) 97.8(5), C(8)–Rh–N(2) 97.9(4), C(1)–Rh–N(2) 89.2(4), C(8)–Rh–N(3) 170.7(4), C(1)–Rh–N(3) 87.8(4), N(2)–Rh–N(3) 74.7(4), C(8)–Rh–P(1) 83.2(3), C(1)–Rh–P(1) 90.1(3), N(2)–Rh–P 178.8(3), N(3)–Rh–P 104.3(3), C(8)–Rh–Cl(1) 85.2(3), C(1)–Rh–Cl(1) 174.2(4), N(2)–Rh–Cl(1) 85.5(3), N(3)–Rh–Cl(1) 88.6(3), P(1)–Rh–Cl(1) 95.2(1).

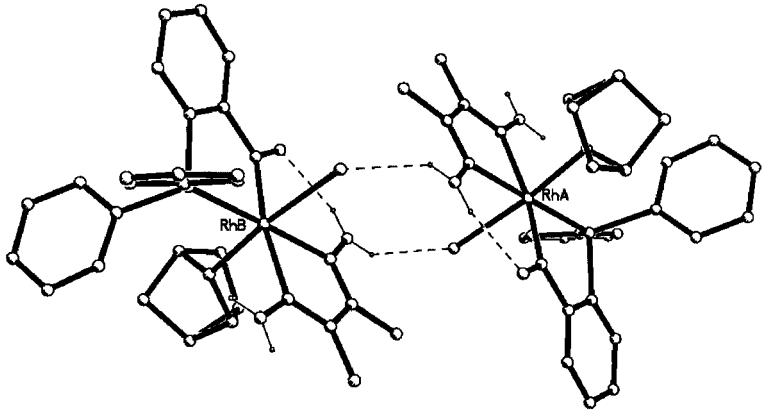

Figure 2. PLUTO view of the "dimer units" showing the hydrogen bonds for **2**.

the Rh–C distances may be viewed as a consequence of the different hybridization, i.e. sp^3 for C1 and sp^2 for C8,[4b,23] and also of C8 being part of a five-membered metallocycle. Complex **2** bears hydrogen bonds through both pendant amino groups of the bdh ligand. One NH_2 group (N1) binds the oxygen atom of the acyl group (O1) intramolecularly (Figure 1) and a solvent molecule through H1B in a bifurcated way. The H1A atom binds to the Cl1′ atom of the centrosymmetric molecule to give dimers (Figure 2). The other NH_2 group (N4) forms hydrogen bonds with two chlorine atoms of two other molecules of solvent. Table 1 lists the hydrogen bond geometry.

Complexes **2**–**5** are also formed, though impure (Experimental section), in the reaction of the corresponding complexes [Rh(Cl)(Nbd)(NN)][24] (NN = bdh, bipy, aqui, ampy), prepared "in situ", with stoichiometric 1:1 amounts of $PPh_2(o\text{-}C_6H_4CHO)$ in benzene (see *iii* in Scheme 1).

Table 1. Hydrogen bond geometry [Å] and angles [°] for [Rh(Cl)-{*o*-$PPh_2(C_6H_4CO)$}$(C_7H_9)(H_2NN{=}C(CH_3)C(CH_3){=}NNH_2)$]·$3\,CHCl_3$ (**2**).[a]

Coordinated norbornadiene in transition metal complexes is hydrogenated by both 1,2- and 1,4-addition to give norbornene and nortricyclene, respectively. The products obtained depend markedly on the starting materials and/or reaction conditions.[25]

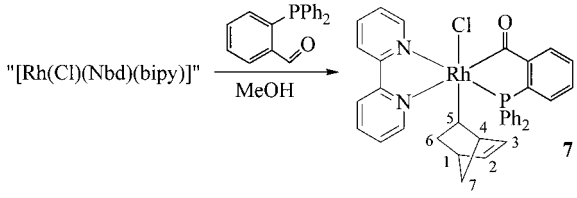
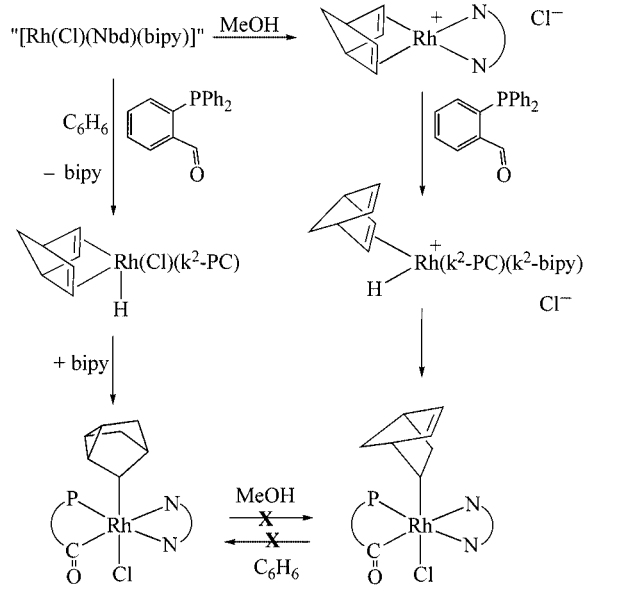
When [Rh(Cl)(Nbd)(bipy)], prepared "in situ", is treated with $PPh_2(o\text{-}C_6H_4CHO)$ in methanol, oxidative addition of aldehyde to rhodium followed by insertion of norbornadiene into the Rh–H bond also occurs, but in this case the norbornenyl (Nbyl) derivative [Rh(Cl){o-$PPh_2(C_6H_4CO)$}-Nbyl)(bipy)] (**7**), an isomer of **3**, is obtained [Equation (1)].



7 (1)

NMR spectroscopy, including 2D experiments, allows complete characterization of complex **7**. The presence of two doublets of doublets at δ = 5.06 and 4.89 ppm in the ^{1}H NMR spectrum, which correlate with two resonances at δ = 134.0 and 134.2 ppm, respectively, in the $^{13}C\{^1H\}$ NMR spectrum, is indicative of a non-coordinated olefin. The norbornenyl-CH group bonded to rhodium shows a multiplet at δ_H = 1.75 ppm and a doublet of doublets at δ^{13}C = 29.9 ppm due to coupling with rhodium and with a cis phosphorus atom. Other ^{1}H and $^{13}C\{^1H\}$ assignments are given in the Experimental section. The spectroscopic features of the acylphosphane chelate in **7** are similar to those in **3**: δ^{13}C=O = 238.5 (dd, $J_{Rh,C}$ = 32.4 Hz, $J_{P,C}$ = 6.0 Hz) ppm and δ^{31}P = 71.1 (d, $J_{Rh,P}$ = 171 Hz) ppm for **7**, and δ^{13}C=O = 235.8 (d, $J_{Rh,C}$ = 38.3 Hz) ppm and δ^{31}P = 72.8 (d, $J_{Rh,P}$ = 176 Hz) ppm for **3** in [D$_6$]DMSO. Therefore, **7** has the structural features shown in Equation (1), with the phosphorus atom and the acyl group trans to nitrogen, as in **3**.

These results show that the solvent plays an important role in the reaction of [Rh(Cl)(Nbd)(bipy)] with $PPh_2(o\text{-}C_6H_4CHO)$. Different paths lead to different isomers (**3** and **7**). Complex **3** remains unchanged in methanol and complex **7** is recovered unaltered from benzene. Scheme 2 presents a proposal for the selective production of the norbornenyl and nortricyclyl derivatives. The rhodium(I) starting material is a saturated species that requires ligand dissociation to undergo oxidative addition. In methanol, dissociation of chlorine to give an unsaturated cationic complex is feasible. Chelate-assisted oxidative addition can then occur with opening of the diolefinic chelate to give a hydride-monoolefin species that can afford the norbornenyl derivative. Related [Rh(Cl)(Cod)(bipy)] undergoes the chelate-assisted oxidative addition of $PPh_2(o\text{-}C_6H_4CHO)$ with diolefin displacement.[4c] Coordination of the norbornadiene as a diolefin is, most likely, a requirement for the hydrogen transfer with concurrent double bond shift to occur. In benzene, dissociation of 2,2′-bipyidine from the neutral pentacoordinate complex may allow the formation of a hydride-diolefin species that affords the nortricyclyl isomer.



Scheme 2. Proposal for the selective production of nortricyclyl and norbornenyl derivatives.

The reaction of other [Rh(Cl)(Nbd)(NN)] complexes prepared "in situ" (NN = bdh, aqui, ampy; N = py) with $PPh_2(o\text{-}C_6H_4CHO)$ in methanol gave complex mixtures of products. Decomposition products were formed in the reaction of [{Rh(Nbd)Cl}$_2$] with o-(diphenylphosphane)benzaldehyde in methanol.

Conclusions

Norbornadiene rhodium(I) complexes react with o-(diphenylphosphane)benzaldehyde to undergo chelate-assisted oxidative addition followed by hydrogen transfer to norbornadiene, giving acylalkylrhodium(III) derivatives. Nortricyclyl and the norbornenyl isomers have been obtained selectively by using the appropriate solvent. We propose that, in benzene, hydrogen transfer occurs with concurrent double bond shift to form a nortricyclyl group because the norbornadiene is bonded as a diolefin. In an ionising solvent such as methanol, hydrogen transfer to the norbornadiene coordinated as monoolefin can yield a norbornenyl group.

Experimental Section

General Procedures: The metal complexes were prepared at room temperature under nitrogen by standard Schlenk techniques. [{Rh(Nbd)Cl}$_2$][26] and o-(diphenylphosphane)benzaldehyde[27] were prepared according to reported procedures. Microanalyses were carried out with a Leco CHNS-932 microanalyser. IR spectra were recorded with a Nicolet FTIR 740 spectrophotometer in the range 4000–400 cm^{-1} using KBr pellets. NMR spectra were recorded with Bruker Avance DPX 300 or Bruker Avance 500 spectrometers, ^{1}H and $^{13}C\{^1H\}$ (TMS internal standard), $^{31}P\{^1H\}$ (H_3PO_4 external standard) and 2D spectra were measured as $CDCl_3$ or [D$_6$]DMSO solutions. Mass spectra were recorded on a VG Autospec, by liquid secondary ion (LSI) MS, using nitrobenzyl alcohol as matrix and a caesium gun (Universidad de Zaragoza).

Preparation of [Rh(Cl)(Nortricyclyl){PPh_2(*o*-C_6H_4CO)}]$_n$ (1): A stoichiometric amount of PPh_2(*o*-C_6H_4CHO) (0.12 mmol) was added to a benzene solution of [{Rh(Nbd)Cl}$_2$] (0.06 mmol). Subsequent stirring for 60 min at room temperature gave a yellow solid that was filtered off, washed with benzene and vacuum dried (yield 66%). IR: $\tilde{\nu}$(C=O) = 1637(s) cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 2.89 (d, $J_{Rh,H}$ = 11.5 Hz), 2.71 (d, $J_{Rh,H}$ = 11.1 Hz), 2.46 (d, $J_{Rh,H}$ = 9.1 Hz) and 2.80 (d, $J_{Rh,H}$ = 9.1 Hz) ppm, HC–Rh. ^{31}P{^{1}H} NMR ($CDCl_3$): δ = 73.1 (d, $J_{Rh,P}$ = 209 Hz), 72.9 (d, $J_{Rh,P}$ = 211 Hz), 71.8 (d, $J_{Rh,P}$ = 203 Hz) and 71.5 (d, $J_{Rh,P}$ = 208 Hz) ppm. FAB MS calcd. for [$C_{26}H_{23}ClOPRh]_3$: 1560; observed 1525 [M–Cl]$^+$, 1432 [M–Cl–(C_7H_9)]$^+$. $C_{26}H_{23}ClOPRh$: calcd. C 59.96, H 4.45; found C 59.66, H 4.29.

Preparation of [Rh(Cl)(Nortricyclyl)(PPh_2(*o*-C_6H_4CO))(NN)] (2–6): A stoichiometric amount of the corresponding bidentate N-ligand (0.06 mmol) or of pyridine (0.12 mmol) was added to a benzene suspension of **1** (0.06 mmol). Subsequent stirring for 60 min at room temperature afforded yellow solids that were filtered off, washed with benzene and vacuum-dried.

Data for 2: Yield 65%. Reaction of "[Rh(Cl)(Nbd)(bdh)]" with PPh_2(*o*-C_6H_4CHO) in Benzene: A stoichiometric amount of bdh (13.7 mg, 0.12 mmol) was added to a benzene solution of [{Rh(Nbd)Cl}$_2$] (27.6 mg, 0.06 mmol), affording a red suspension of [Rh(Cl)(Nbd)(bdh)]. Subsequent addition of PPh_2(*o*-C_6H_4CHO) (34.8 mg, 0.12 mmol) and stirring for 60 min at room temperature gave a yellow solid that was filtered off, washed with benzene and vacuum dried (yield: 62 mg). According to NMR spectra, the solid contains complex **2** as the main product (up to 87%). Small amounts of hydrides (up to 13%), products of diolefin displacement, were also observed.

Preparation of [Rh(Cl)(Norbornenyl)(PPh_2(*o*-C_6H_4CO))(bipy)] (7): A stoichiometric amount of 2,2′-bipyridine (0.12 mmol) and an excess of PPh_2(*o*-C_6H_4CHO) (0.24 mmol) were added to a MeOH suspension of [{Rh(Nbd)Cl}$_2$] (0.06 mmol). Subsequent stirring for 60 min at room temperature gave a yellow solid that was filtered off, washed with methanol and vacuum dried (yield: 46%). IR: $\tilde{\nu}$ = 1624 (s, C=O) cm^{-1}. ^{1}H NMR ([D_6]DMSO): δ = 5.06 (dd, $J_{H3,H2}$ = 5.36, $J_{H1,H2}$ = 2.89 Hz, 1 H, Nbyl-H2), 4.89 (dd, $J_{H4,H3}$ = 2.48 Hz, 1 H, Nbyl-H3), 2.40 (s, 1 H, Nbyl-H4), 1.83 (s, 1 H, Nbyl-H1), 1.75 (m, 1 H, Nbyl-H5), 0.61, 0.15 (d, J_{gem} = 7.23 Hz, 2 H, Nbyl-H7), –0.09, –0.57 (m, 2 H, Nbyl-H6) ppm. ^{13}C{^{1}H} NMR ([D_6]DMSO): δ = 238.5 (dd, $J_{Rh,C}$ = 32.4, $J_{P,C}$ = 6.0 Hz, 1C, C=O), 134.2 (1C, Nbyl-C3), 134.0 (1C, Nbyl-C2), 50.9 (1C, Nbyl-C7), 50.1 (1C, Nbyl-C4), 40.8 (1C, Nbyl-C1), 30.9 (1C, Nbyl-C6), 29.9 (dd, $J_{Rh,C}$ = 28.8, $J_{P,C}$ = 4.4 Hz, 1C, Nbyl-C5) ppm. ^{31}P{^{1}H} NMR ([D_6]DMSO): δ = 71.1 (d, $J_{Rh,P}$ 171 Hz) ppm. FAB MS: calcd. $C_{36}H_{31}ClN_2OPRh$ 676; *m*/*z* (%) = 676 [M]$^+$ (6), 641 [M–Cl]$^+$ (87). $C_{36}H_{31}ClN_2OPRh{\cdot}MeOH$: C 62.68, H 4.98, N 3.95; found C 62.60, H 4.90, N 3.84.

X-ray Crystal Structure Determination of 2: Single crystals of complex **2**, suitable for X-ray diffraction, were successfully grown by allowing slow diffusion of diethyl ether onto chloroform solutions.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

A yellow crystal was epoxy coated and mounted on a Bruker Smart CCD diffractometer using graphite monochromated Mo-K_α radiation (λ = 0.71073 Å) operating at 50 kV and 20 mA. Data were collected over a hemisphere of the reciprocal space by combination of three exposure sets. Each exposure of 10 s covered 0.3 in ω. The first 50 frames were recollected at the end of the data collection to monitor crystal decay after X-ray exposition. Several crystals were tried and the best data collection showed a decay of 18% in the intensities of standard reflections. Fundamental crystal data for the crystal given are summarized in Table 2. The structure was solved by Direct methods and conventional Fourier techniques. Refinement was done by full-matrix least-squares on F^2 (SHELX-97).[28] After three cycles of isotropic refinement of all atoms in the Rh complex, extra electron density was found and was attributed to three molecules of chloroform. All non-hydrogen atoms have been refined anisotropically, except the solvent molecules. All hydrogen atoms were calculated at geometrical positions. It was impossible to locate the hydrogen atoms of the NH_2 groups in a Fourier synthesis. The presence of three $CHCl_3$ molecules of crystallization is probably the source of the problems encountered during the data collection. All these atoms were refined only isotropically and with geometrical restraints and variable common carbon–chlorine distances. Despite these problems, the atoms of the rhodium complex refined well – as can be judged from the reasonable deviation in distances and angles, their thermal parameters and the quality-of-fit indicator. The high values of largest residual peak and hole in the final Fourier difference map and the largest shift/esd ratio were associated with the chlorine atoms of the solvent molecules.

Table 2. Crystal and refinement data for [Rh(Cl)(*o*-$PPh_2(C_6H_4CO)$)$(C_7H_9)(H_2NN{=}C(CH_3)C(CH_3){=}NNH_2)$]·3$CHCl_3$ (**2**).

Magnetic Anisotropy of New Layered Copper(II) Bromide Complexes of 1-Substituted Tetrazoles

Yurii Shvedenkov,*[a] Mark Bushuev,[a] Galina Romanenko,[b] Ludmila Lavrenova,[a] Vladimir Ikorskii,[b] Pavel Gaponik,[c] and Stanislav Larionov[a]

Keywords: Copper / Layered compounds / Nitrogen heterocycles / Magnetic properties / Phase transition

Two new isostructural complexes, dibromobis(1-ethyltetrazole)copper(II) (**1**) and dibromobis(1-hexyltetrazole)copper(II) (**2**), have been synthesised. Each bromine atom in the crystal structure of **1** and **2** is bonded to two copper atoms to give rise to a polymeric corrugated network. The polymeric layers are distinctly separated by tetrazole ligands. Both solids exhibit a phase transition to the ferromagnetic state with Curie temperatures of 8.5 K and 8.9 K for **1** and **2**, respectively, and a strong anisotropy of the magnetic susceptibility below the ordering temperature. The easy magnetisation axis lies along the monoclinic axis, and the hard magnetisation axis is orthogonal to the polymeric layers. Effective anisotropy fields were estimated as (720–3020 Oe).

Introduction

In the design of new molecular magnets capable of magnetic phase ordering it is necessary to satisfy at least two conditions: the crystal structures of such compounds should be polymeric (2D or 3D), and the formed exchange channels should have sufficient efficiency for the magnetic ordering at experimentally observable temperatures.[1] One of the strategies to obtain such coordination compounds is to use ligands that are potentially capable of realizing a bridging function. Halogen atoms and polynitrogen heterocycles are particularly useful in this respect. It is known that the combination of Cu^{II} salts with heterocyclic azole ligands leads to the formation of mononuclear,[2–5] polynuclear[6–9] and even polymeric[10–15] complexes. For the majority of polymeric complexes one or more of the bridges are *N*,*N*′-didentate divided.[12,16,17] As a result the Cu–Cu distances in these cases are considerably increased. The formation of coordination compounds with a square polymeric lattice of copper atoms and halide ions only is an occasional and specific case for complexes with polynitrogen heterocycle ligands.[18–25] Note that even the use of 1-substituted tetrazoles with furcated substitutes or disubstituted tetrazoles leads to the formation of chain or mononuclear complexes.[10,13,14] From this point of view, 1-substituted tetrazole derivatives with non-furcated substitutes are unique ligands for the design of molecular magnets with a two-dimensional crystal structure.

We have previously reported the formation of layered polymeric structures for a whole series of complexes of Cu^{II} and Co^{II} chlorides with 1-substituted tetrazoles (Rtz, R = ethyl, allyl, vinyl) with the general stoichiometry $[M(Rtz)_2Cl_2]$ (M = Cu^{II}, Co^{II}).[18–23,26] The $[Cu(Rtz)_2Cl_2]$ complexes undergo a ferromagnetic transition at temperatures lower than 10 K and $[Co(alltz)_2Cl_2]$[26] undergoes a phase transition to an antiferromagnetic state with a weak ferromagnetic behaviour at 99.6 K. Recently, complexes $[Cu(teec)_2A_2]$ [teec = 1-(2-chloroethyl)tetrazole; A = Cl^-, Br^-, NO_3^-] have been prepared and studied in detail.[4,25] It was found that $[Cu(teec)_2Cl_2]$ and $[Cu(teec)_2Br_2]$ are soft ferromagnets with T_c = 4.75 K and 8.01 K, respectively.[25] On the other hand, active studies of molecular magnets have stimulated the investigation of the anisotropy of magnetic properties with single crystalline samples. The first study of the magnetic anisotropy of a layered polymeric complex containing a tetrazole derivative was done with $[Co(alltz)_2Cl_2]$.[27]

This work continues our systematic investigation of the synthesis and characterisation of Cu^{II} halide complexes with tetrazoles. We report the preparation, structure and studies of the anisotropy of magnetic properties of a new layered polymer of Cu^{II} bromide with 1-ethyl- and 1-hexyltetrazoles.

Results and Discussion

Single crystals of complexes dibromobis(1-ethyltetrazole)-copper(II) (**1**) and dibromobis(1-hexyltetrazole)copper(II) (**2**)

for both a crystal structure determination and an investigation of the magnetic properties were grown from EtOH solutions under ambient conditions. Note that crystals obtained in a thermostat, while having a nice appearance, appeared to be twins or joints. This may be caused by vibrations originating from the thermostat's operation.

The values of bond lengths and angles of the complexes are listed in Table 1.

In these complexes the copper atom coordinates two tetrazole molecules in the equatorial plane (*trans* to each other) and two bromine atoms to form $[Cu(Rtz)_2Br_2]$ complex fragments (Figure 1).

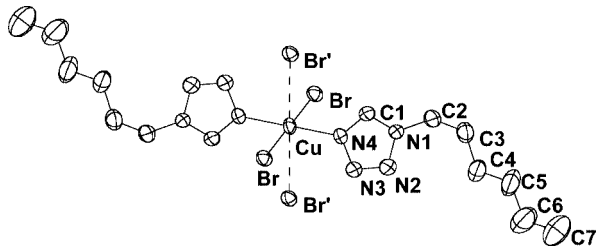

Figure 1. $[Cu(Rtz)_2Br_2]$ molecular structure exemplified by **2**. Hydrogen atoms have been omitted for clarity.

The structures of both complexes are very similar. The environment of the copper atom is a centrosymmetric square bipyramid due to additional bonds to the bromine atoms of neighbouring $\{Cu(Rtz)_2Br_2\}$ fragments. Thus, the bromine atoms form non-symmetric bridges (the Cu–Br–Cu angles are equal to 138.55° and 138.16° for **1** and **2**, respectively) and connect $\{Cu(Rtz)_2Br_2\}$ fragments into layers (Figure 2) parallel to the (100) plane. The tetrazole molecules separate the layers from each other. The tetrazole fragments are practically planar reflecting the π-conjugation in the heterocycle. A comparison of the bond lengths in the tetrazole ring allows us to distinguish between "single" and "double" bonds [N(1)–N(2), N(3)–N(4) and N(2)=N(3)]. The "double" C(1)=N(4) and "single" C(1)–N(1) bond lengths are practically identical in both compounds. The plane of the tetrazole fragment in both complexes does not coincide with the equatorial plane of the tetragonal bipyramid of the copper atom and makes angles of 55.8(1)° and 57.7° for **1** and **2**, respectively.

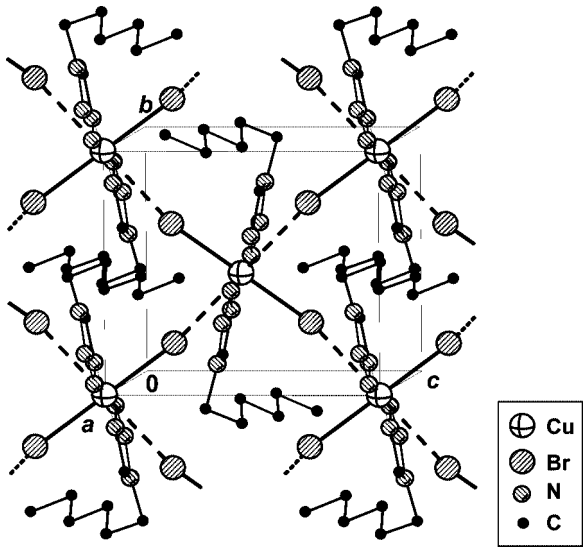

Figure 2. Fragment of $[Cu(Rtz)_2Br_2]$ polymeric layer structure exemplified by **2**. Hydrogen atoms have been omitted for clarity.

The N(1)–C(2) distance is typical for a single bond. The interlayer distance in **2** (19.750 Å) is much greater than in **1** (12.328 Å) because the alkyl groups protrude into the interlayer space. The distances between adjacent Br atoms are close to double the van der Waals radius [Br···Br′ = 3.8702(6) Å in **1** and 3.883(5) Å in **2**].

A comparison of the geometrical characteristics in **1**, **2** and previously reported $[Cu(Rtz)_2Cl_2]$ complexes[21,22,24,26] shows that the Cu–N(4) distances are practically identical for all compounds and are in the range of 1.98–1.99 Å. The lengths of the Cu–Br bonds in the equatorial plane are 2.43–2.45 Å, whereas the lengths of the axial Cu–Br′ bonds are equal to 3.08–3.09 Å. The axial Cu–Cl distances, as a rule, are also approximately 3 Å, and differ from the axial Cu–Br lengths only slightly. The Cu–A–Cu angles, where A = Cl^-, Br^-, are essentially independent of A (136–139°).

The dependencies $\mu_{eff}(T)$ and $1/\chi(T)$ above 10 K, as measured on polycrystalline samples, are presented in Figure 3 and Figure 4. At room temperature, μ_{eff} of complexes **1**, **2** are 1.869 μ_B and 1.884 μ_B, respectively, which correspond to the

magnetic moment for $S = 1/2$ with Cu^{II} g-factors equal to 2.158 and 2.175, respectively. At lower temperatures, μ_{eff} increases for compounds **1** and **2** (Figure 3), indicating that ferromagnetic exchange interactions dominate.

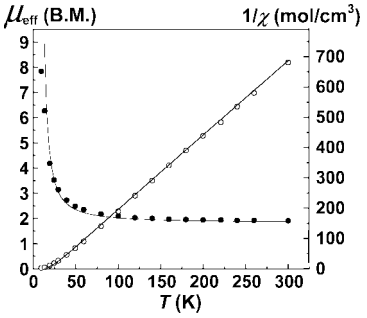

Figure 3. Dependencies $\mu_{eff}(T)$ (●) and $1/\chi(T)$ (○) in the paramagnetic region for **1**. Solid lines are the theoretical approximation.

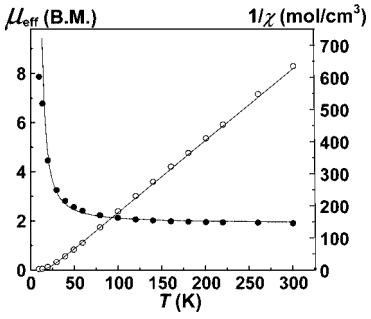

Figure 4. Dependencies $\mu_{eff}(T)$ (●) and $1/\chi(T)$ (○) in the paramagnetic region for **2**. Solid lines are the theoretical approximation.

The magnetic susceptibility follows the Curie–Weiss law [$\chi = C/(T - \theta)$] with the parameters given in Table 2. The values for the exchange parameter (J) between the Cu^{II} ions can be estimated from high-temperature data by series expansion for a two-dimensional Heisenberg model.[28]

Table 2. Magnetochemical parameters of **1** and **2**.

	C [cm^3 mol^{-1} K^{-1}]	θ [K]	J [K]	T_c [K]	H_x [Oe]	H_z [Oe]
1	0.414	19.9	8.77	8.5(3)	2550	720
2	0.409	24.2	9.11	8.9(5)	3020	860

For the high-temperature series expansion the J value is obtained by approximating the experimental dependencies from a known expression for the magnetic susceptibility: $\chi = Ng\beta^2S(S + 1)/3kT(1 + \sum_{n=1}^{10} a_nK^n)$, where $K = 2J/kT$ and a_n is a coefficient for a square-planar lattice. We applied the above formula to the description of $\mu_{eff}(T)$ dependencies of complexes in the temperature interval 10–300 K. The optimal J parameters (Table 2) were calculated this way. The relevant theoretical curves are presented in Figure 3 and 4 as solid lines.

Below 10 K the magnetic properties of **1** and **2** were investigated with single crystalline samples. Figure 5 and Figure 6 show the temperature dependence of the susceptibilities measured in a small magnetic field (1.2 ± 0.5 Oe) and the main curves of magnetisation $\sigma(H)$ at 4.5 K.

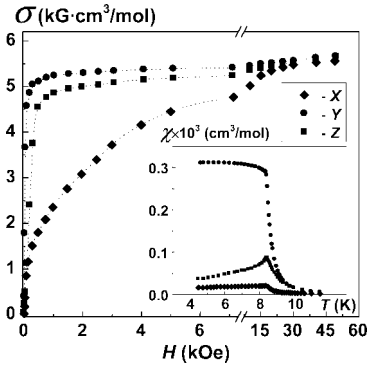

Figure 5. Magnetisation curves (4.5 K) and low field $\chi(T)$ curves in the transition area (insert) for single crystalline **1**.

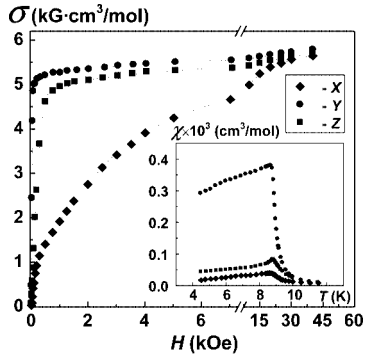

Figure 6. Magnetisation curves (4.5 K) and low field $\chi(T)$ curves in the transition area (insert) for single crystalline **2**.

Both solids exhibit a phase transition to the ferromagnetic state with T_c = 8.5 K and 8.9 K for **1** and **2**, respectively, and a strong anisotropy of the magnetic susceptibility below the ordering temperature (Figure 5 and 6).

By using the known expression $T_c = 4\pi J/\ln(J/J')$[29] (J' is the interlayer interaction) for layered Heisenberg magnets it is possible to estimate the ratio J'/J. For both compounds the ratio J'/J is close to 3×10^{-6} K, which is in good agreement with results for similar systems.

The maximal value of σ at T = 4.5 K is more than 5700 G cm^3 mol^{-1}, which is close to the saturation magnetisation ($Ng\beta S$ = 5585 G cm^3 mol^{-1}) for ferromagnetically coupled spins (S = 1/2) with g = 2. No hysteresis effects were detected for single crystals of **1** and **2** subjected to supermagnetisation. This fact indicates that complexes **1** and **2** behave as soft ferromagnets. The $\chi(T)$ and $\sigma(H)$ curves measured along different directions show essential anisotropy. In both cases, the easy magnetisation axis lies along the y axis, which is the only symmetry axis of the crystals. The hard magnetisation axis coincides with the X direction, which is orthogonal to the polymeric layers. The anisotropy of the magnetic properties

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

in the plane of the polymeric layers (*YZ*) is much less than in the perpendicular direction as a consequence of the quasi-two-dimensional magnetic nature of the investigated compounds. Thus, the observed anisotropy in **1** and **2** should be of the "easy plane" type. Anisotropic energies were estimated for the single crystals of **1** and **2**. The free energy of magnetic anisotropy may be represented as $F_i \approx -H_i\sigma_{sat}$, where $i = X, Z$, H_i is the effective anisotropy field and σ_{sat} is the saturation magnetisation.[30] The energy F_i was determined from the experimental magnetisation curves by numerical integration: $F_i = \int_0^{H_{max}} \sigma_y(H)dH - \int_0^{H_{max}} \sigma_i(H)dH$, where H_{max} is the maximum field during the measurements. The calculated effective anisotropy fields for the complexes are presented in Table 2. It is noteworthy that the calculated anisotropy fields of **1** and **2** are approximately three times larger than in layered polymeric CuL_2 complexes of 3-imidazoline nitroxides.[31] This is probably due to the fact that the organic radical is an isotropic paramagnetic centre, therefore in complexes CuL_2 the "effective concentration" of anisotropic magnetic centres is three times lower than in **1** and **2**. On the other hand, the estimated anisotropy fields of the ferrimagnetic compound [Mn(hfac)$_2$(NIT-*i*Pr)] (NIT-*i*Pr = derivative of 2-imidazoline nitroxide) are H_x = 1200 Oe and H_z = 7500 Oe.[32] Such large anisotropy fields for a complex of such a weakly anisotropic ion as Mn^{II} are probably caused by the low-dimensional polymeric chain structure of this compound. Thus, the anisotropy of solids increases not only for complexes with more anisotropic metal ions, but also for solids with lower dimensionality of the crystal structure. For coordination compounds the energy of the anisotropy combined with dipolar interactions contributes greatly to the value of the ordering temperature.[33] From this point of view the increase of anisotropy of a magnetic system can be considered as one of the ways to increase the transition temperature.

Conclusions

The magnetic properties of single crystalline samples of Cu^{II} bromide complexes of 1-substituted tetrazoles have been investigated. In the layered polymer complexes **1** and **2**, we have found a phase transition to the ferromagnetic state at T_c = 8.5 K (**1**) and 8.9 K (**2**) and a strong anisotropy of the magnetic susceptibility below the magnetic ordering temperature.

Experimental Section

General Remarks: All commercially available reagents were used as purchased. 1-Ethyltetrazole (ettz) and 1-hexyltetrazole (htz) were prepared by literature methods.[34] The copper content was determined by complexometric titration, with the samples being mineralized in a 1:1 mixture of concentrated H_2SO_4 and $HClO_4$. Elemental analysis was performed with a Carlo–Erba analyzer.

Dibromobis(1-ethyltetrazole)copper(II) (1) and Dibromobis(1-hexyltetrazole)copper(II) (2): A solution of ettz (0.40 g, 4 mmol) or htz (0.62 g, 4 mmol) in 16 mL of a 1:1 ethanol/hexane mixture was added to a solution of $CuBr_2$ (0.45 g, 2 mol) in 10 mL the same mixture. A brown precipitate formed, which was filtered off, washed with ethanol and dried in air. Yield of **1**: 0.84 g (80%); **2**: 0.62 g (75%).

1: $C_6H_{12}Br_2CuN_8$ (419.56): calcd. C 17.2, H 2.9, Cu 15.1, N 26.7; found C 16.7, H 2.9, Cu 15.4, N 27.1.

2: $C_{14}H_{28}N_8Br_2Cu$ (531.78): calcd. C 31.6, H 5.3, Cu 11.9, N 21.1; found C 31.5, H 5.2, N 20.3, Cu 12.1.

For growing large single crystals the initial solids were dissolved in EtOH at 43 °C. Then, as much solvent as possible was removed with a stream of air with the condition that crystallisation did not occur at room temperature. After that the flasks were stoppered and allowed to stand at ambient temperature. Dark-brown, parallelepiped-shaped single crystals of **1** and **2** with a maximal appearance of up to 3 × 3 × 0.1 mm grew after approximately one month.

X-ray Crystallographic Study: Single crystal data for **1** and **2** were collected on a SMART APEX Bruker AXS automatic diffractometer at ambient temperature using the standard procedure (Mo-K_α radiation). The structures were solved by direct methods. The full-matrix least-squares refinement was performed anisotropically for non-hydrogen atoms and isotropically for hydrogens. Some H-atoms were localised in difference electron density syntheses; the others were generated theoretically. All structure solution and refinement calculations were carried out with SHELXTL software.[35] The crystal data for the compounds and details of experiment, as well as selected bond lengths and angles are given in Table 1 and Table 3.

Magnetic Measurements: The magnetochemical experiments were performed with an MPMS-5S ("Quantum Design") SQUID magnetometer at temperatures from 4.5 K to 300 K in a homogeneous external magnetic field of up to 49.5 kOe. Magnetic measurements on single crystals were performed in three mutually orthogonal directions (X, Y, Z). The Y and Z directions were aligned with the crystallographic b and c axes. The molar magnetic susceptibility, χ, of the complexes was calculated by using Pascal's additive scheme including diamagnetic corrections and taking into account the temperature-independent paramagnetism of Cu^{II} ions, which was taken to be 60×10^{-6} cm^3 mol^{-1}. In the paramagnetic region the effective magnetic moment was calculated with the formula $\mu_{eff} = [(3k/N_A\beta^2)\chi T]^{1/2} \approx (8\chi T)^{1/2}$, where k is Boltzmann's constant, N_A is the Avogadro number and β is the Bohr magneton. The magnetic phase transition temperature was determined as the extremum of the derivative of the magnetic susceptibility with respect to temperature $\partial\chi/\partial T$. The magnetisation dependencies $\sigma(H)$ of the single crystals below the transi-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tion temperature were taken into account for the demagnetisation field of the sample. The real field in the crystal was calculated for each direction by the formula $H_i = H - N_i\sigma_i$, where $i = X, Y, Z$; N is the demagnetisation factor evaluated using the tables for the disk sample.[36]

CCDC-241146 (for **1**) and -241147 (for **2**) contain the supplementary crystallographic data for this paper data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Four New Lead(II) Thiolate Cluster Complexes – Unexpected Products of a Conventional Synthesis

Andreas Eichhöfer*[a]

Keywords: Cluster compounds / Lead / Sulfur / UV/Vis spectroscopy

The reaction of $Pb(OOCCH_3)_2 \cdot 3H_2O$ with 2.1 equiv. of HS-2,6-$(CH_3)_2C_6H_3$ in ethanol/water is expected to give [Pb{S-2,6-$(CH_3)_2C_6H_3$}$_2$]. However, we obtained an orange powder whose elemental analysis disagrees with that of the expected product and indicates small amounts of oxygen. Layering of concentrated solutions of this orange powder in dry THF with pentane under nitrogen results in the formation of a mixture of three identifiable crystalline compounds, namely [Pb_{10}{S-2,6-$(CH_3)_2C_6H_3$}$_{20}$], [Pb_6S{S-2,6-$(CH_3)_2C_6H_3$}$_{10}(C_4H_8O)_4$] and [Pb_8O_2{S-2,6-$(CH_3)_2C_6H_3$}$_{12}$]. In contrast, fractional crystallization from dilute solutions initially yielded only yellow crystals of [$Pb_{14}O_6${S-2,6-$(CH_3)_2C_6H_3$}$_{16}$]. Further concentration of the supernatant solution yielded, upon layering with pentane, [Pb_6S{S-2,6-$(CH_3)_2C_6H_3$}$_{10}(C_4H_8O)_4$] and [Pb_{10}{S-2,6-$(CH_3)_2C_6H_3$}$_{20}$], which are almost completely separable by controlling the duration of the crystallization step and the amount of condensed pentane. Recrystallization of the crude orange powder under aerobic conditions produces pure [$Pb_{14}O_6${S-2,6-$(CH_3)_2C_6H_3$}$_{16}$] with a yield five times higher than that under nitrogen. This shows that it is sensitive to oxidation by oxygen in solution. The structures of all four complexes have been determined by single-crystal X-ray analysis. The net formed by the six oxygen and twelve lead atoms in the center of [$Pb_{14}O_6${S-2,6-$(CH_3)_2C_6H_3$}$_{16}$] resembles a small piece of a layer of the solid-state structure of red PbO.

Introduction

Lead chalcogenide nanocrystals (PbS, PbSe, PbTe) have recently attracted interest due to their unique properties.[1–3] Size-quantization effects are strongly pronounced in these materials because of their relatively large exciton Bohr radii. Furthermore, the quantum size effect offers potential photonic applications. Theoretically, PbSe nanocrystals (NCs) are predicted to have absorptive and dispersive nonlinearities 1000 times larger than those of CdSe NCs of the same size.[4] However, in contrast to the recent, distinct growth in the chemistry of transition metal chalcogenide clusters,[5,6] related polynuclear molecules of the heavier main group elements seem to be rather unexplored to date.[7] It is known that the reaction of lead thiolates of the general formula $Pb(SR)_2$ (R = organic group) with stoichiometric amounts of sulfur or selenium yields the corresponding lead chalcogenides.[8] These findings suggest that nonstoichiometric reactions could probably lead to metastable lead chalcogenolato/chalcogenide cluster molecules. Therefore, we became interested in the synthesis of lead thiolate complexes as starting materials for the synthesis of such cluster molecules. In order to avoid known solubility problems of the mostly polymeric lead thiolates[8–10] we followed a recent recommendation of Briand[11] concerning the use of 2,6-dimethylthiophenol, which was reported to yield soluble [Pb{S-2,6-$(CH_3)_2C_6H_3$}$_2$]. However, the direct reaction of $Pb(OOCCH_3)_2 \cdot 3H_2O$ with 2.1 equiv. of HS-2,6-$(CH_3)_2C_6H_3$ at 60 °C obviously leads not only to the expected product [Pb{S-2,6-$(CH_3)_2C_6H_3$}$_2$] but also yields lead thiolate cluster complexes which have sulfur or oxygen atoms incorporated in the cluster framework, the structures of which are reported here.

Results and Discussion

In order to synthesize [Pb{S-2,6-$(CH_3)_2C_6H_3$}$_2$] we used the method of Shaw and Woods developed for the synthesis of [Pb(S-2-$CH_3C_6H_4$)$_2$].[8] The reaction of $Pb(OOCCH_3)_2 \cdot 3H_2O$ with 2.1 equiv. of HS-2,6-$(CH_3)_2C_6H_3$ in aqueous ethanol at 60 °C yielded an orange-red precipitate, which was filtered and dried. The elemental analysis disagrees with the expected product [Pb{S-2,6-$(CH_3)_2C_6H_3$}$_2$] especially with respect to the low amount of sulfur, a fact which has also been observed by Shaw et al. in the related synthesis of some other lead thiolate complexes. Additionally, the presence of small amounts of oxygen is indicated by the analysis. Layering of concentrated solutions of the crude product in dried THF with pentane results in the formation of a mixture of the crystalline compounds **1**–**3**, which could be identified by single-crystal X-ray analysis. In contrast to this, a solution 1/5 as concentrated in dried THF led to the crystallization of small amounts of **4** (12% calculated for

Pb) as the only product. Evaporation of the solvents of the clear supernatant yellow solution in vacuo produced a yellow-orange powder which was redissolved in 10 mL of THF. Layering of this concentrated solution with pentane yielded, firstly, crystals of **2**, followed by crystals of **1**, without any crystals of either **3** or **4**.

Obviously, the oxygen present in the crude orange powder was in this way completely bound by **4** and thus removed from the reaction solution. However, the crystallization of **1** and **2** proceeds in such a way that, initially, orange plate-like crystals of **2** appear, which tend to form solidified droplets of crystalline material after the layering process, while bundles of light-orange needles of **1** start to grow a few days later at higher concentrations of pentane. In this way, **1** and **2** can be nearly completely separated, as shown by powder diffraction patterns and elemental analysis (see below). The yield of **4** could be increased up to 56% by performing the recrystallization under aerobic conditions, which shows that the crude orange powder is sensitive to oxidation by oxygen in solution.

The light-orange, plate-like needles were found to display the desired composition $[Pb\{S\text{-}2,6\text{-}(CH_3)_2C_6H_3\}_2]$. Interestingly, the structure is neither polymeric, as in $[Pb(SC_6H_5)_2]_n$[9] or $[Pb(S\text{-}4\text{-}CH_3C_6H_4)_2]_n$,[10] nor trimeric, as in $[Pb_3(S\text{-}2,6\text{-}i C_3H_7C_6H_3)_6]$,[12] but is found to be oligomeric $[Pb_{10}\{S\text{-}2,6\text{-}(CH_3)_2C_6H_3\}_{20}]$ (**1**). Complex **1** crystallizes in the space group *Pbcn* with the molecule residing on an inversion center (Figure 1). The Pb–S contacts in the range of 255.8–317.5 pm have been assigned as bonds (solid lines), similar to those observed in the lead thiolates mentioned above, while longer contacts have been drawn for all molecules as dashed lines. Contacts to the next molecular unit are larger than 500 pm, which proves the oligomeric character of **1**. The lead atoms exhibit different coordination modes. Pb(2), and Pb(4) are in a distorted tetrahedral geometry comprising three sulfur atoms and the stereochemically active inert electron pair, whilst Pb(3) is bonded to six sulfur atoms in a highly distorted octahedral geometry caused by the additional inert electron pair. Pb(1) and Pb(5) possess complex coordination environments comprised of either five or four sulfur atoms. A comparison of the measured and calculated powder diffraction pattern of **1** (Figure 2) reveals the crystalline purity of the product isolated by fractional crystallization, as mentioned above.

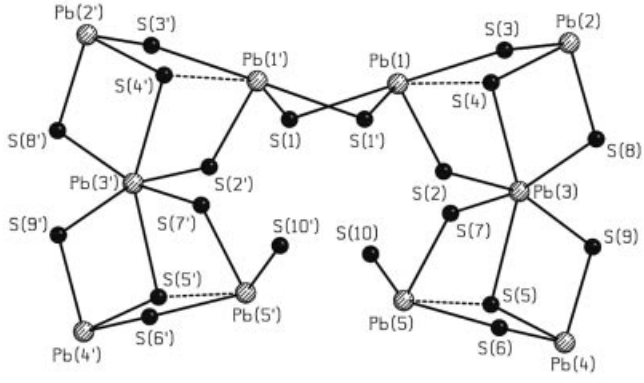

Figure 1. Molecular structure of $[Pb_{10}\{S\text{-}2,6\text{-}(CH_3)_2C_6H_3\}_{20}]$ (**1**). C and H atoms omitted for clarity. Selected bond lengths [pm] (solid lines): Pb(1)–S(2) 265.4(4), Pb(1)–S(1′) 269.1(4), Pb(1)–S(1) 298.1(4), Pb(1)–S(3) 305.9(5), Pb(2)–S(8) 265.8(4), Pb(2)–S(3) 267.9(5), Pb(2)–S(4) 275.4(3), Pb(3)–S(7) 2788(4), Pb(3)–S(2) 280.1(4), Pb(3)–S(4) 293.6(3), Pb(3)–S(5) 303.4(3), Pb(3)–S(8) 313.1(4), Pb(3)–S(9) 317.5(4), Pb(4)–S(9) 263.3(4), Pb(4)–S(5) 272.5(4), Pb(4)–S(6) 275.0(4), Pb(5)–S(10) 255.8(5), Pb(5)–S(7) 266.4(4), Pb(5)–S(6) 278.9(5). Weak contacts [pm] (dashed lines): Pb(5)–S(5) 355.5, Pb(1)–S(4) 362.7. Symmetry transformation for generation of equivalent atoms: $-x, y, -z + 0.5$.

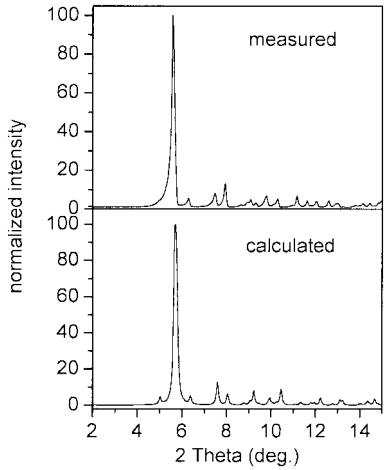

Figure 2. Measured (top) and calculated (bottom) powder diffraction pattern of $[Pb_{10}\{S\text{-}2,6\text{-}(CH_3)_2C_6H_3\}_{20}]$ (**1**).

The orange hexagonally shaped plates that form solidified droplets of crystalline material after the layering process were characterized to be $[Pb_6S\{S\text{-}2,6\text{-}(CH_3)_2C_6H_3\}_{10}(C_4H_8O)_4]$ (**2**). Obviously, part of the precursor thiol undergoes cleavage of the S–Aryl bond under the given experimental conditions. Complex **2** crystallizes in the $P\bar{1}$ space group with the central sulfur atom occupying an inversion center (Figure 3). The six lead atoms form an elongated octahedron whose eight trigonal faces are bridged by sulfur atoms, with Pb–S contacts mapped as bonds ranging from 262.7(2) to 311.3(3) pm. The two "axial" lead atoms [Pb(1) and Pb(1′)] are each additionally bonded to a thiolate ligand, while the equatorial lead atoms [Pb(2), Pb(2′), Pb(3), and Pb(3′)] are weakly coordinated by a THF solvent molecule (Pb–O: 300.2–304.2 pm). This leads to an octahedral coordination geometry for Pb(2), Pb(2′), Pb(3) and Pb(3′) which is distorted by the inert electron pair. Pb(1) and Pb(1′) are bonded to the five nearest sulfur atoms [S(2)–S(5) and symmetry-equivalent atoms] in a distorted square-pyramidal fashion with additional weak coordination by S(1) from the bottom face [Pb(1)–S(1): 350.6 pm]. Again, a comparison of the measured and calculated powder diffraction pattern of **2** (Figure 4) reveals the crystalline purity of the product that was isolated by fractional crystallization, as mentioned above.

Yellow, triclinic-shaped blocks were identified as the mixed lead oxide thiolate cluster complex $[Pb_8O_2\{SC_6H_3(CH_3)_2\}_{12}]$ (**3**). This is even observed when using freshly dried and distilled THF which suggests that Pb–O units are already present in the crude orange powder, a fact which was additionally supported by elemental analysis. The molecular structure of **3** ($\bar{1}$ symmetry), which crystallizes in the $P\bar{1}$ space group, consists of an octanuclear lead thiolate cluster which additionally incorporates two oxygen atoms (Figure 5). The two Pb_3O units are nearly planar [deviation of O(1) from the trigonal plane is 44 pm] with an average of 220.9(2) pm for the Pb–O distances. A similar structural unit is found in the pentanuclear, oxygen-centered lead thiolate cluster $[Pb_5O\{S\text{-}2,4,6\text{-}(CF_3)_3C_6H_2\}_8]\cdot 2C_7H_8$.[13] An additional "PbS-2,6-$(CH_3)_2C_6H_3$" unit is bonded to these two trigonal faces through three thiolate ligands [S(1), S(3), S(4), and equivalent atoms] forming two mixed oxide/thiolate-bridged Pb_4OS_5 cluster units which are linked at their Pb_3O faces by four additional μ_3-thiolate ligands [S(2), S(2′), S(5), and S(5′)]. The Pb–S distances are in the range of 256.2(3)/310.0(3) pm with eight additional weaker and longer contacts between 334.9 pm [Pb(2)–S(5)] and 361.4 pm [Pb(4)–S(4)].

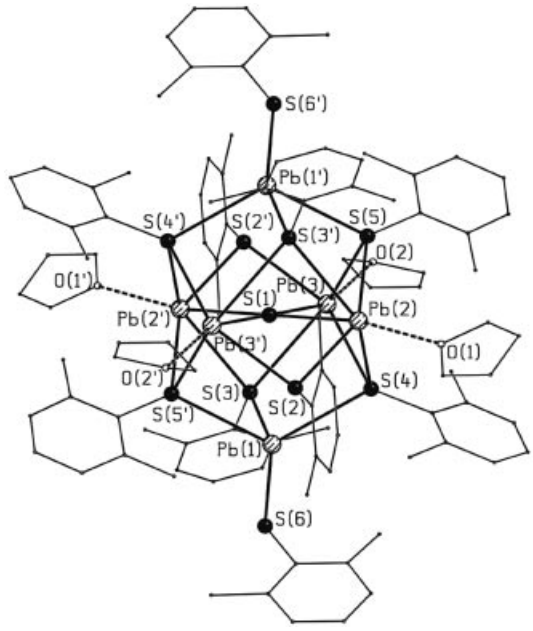

Figure 3. Molecular structure of $[Pb_6S\{S\text{-}2,6\text{-}(CH_3)_2C_6H_3\}_{10}(C_4H_8O)_4]$ (**2**). C and H atoms omitted for clarity. Selected bond lengths [pm] (solid lines): Pb(1)–S(6) 262.7(2), Pb(1)–S(3) 266.4(3), Pb(1)–S(4) 307.6(2), Pb(2)–S(4) 280.6(2), Pb(2)–S(2) 281.8(2), Pb(2)–S(1) 283.5(2), Pb(2)–S(3′) 309.3(2), Pb(2)–S(5) 312.1(2), Pb(3)–S(5) 276.0(2), Pb(3)–S(1) 283.36(8), Pb(3)–S(2′) 284.0(3), Pb(3)–S(4) 311.3(3). Weak contacts [pm] (dashed lines): Pb(1)–S(1) 350.6, Pb(1)–S(2) 353.6, Pb(2)–O(1) 304.1(3), Pb(3)–O(2) 300.2(3). Symmetry transformation for generation of equivalent atoms: $-x + 1, -y + 2, -z + 1$.

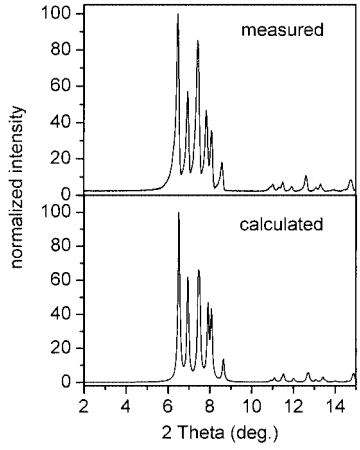

Figure 4. Measured (top) and calculated (bottom) powder diffraction pattern of $[Pb_6S\{S\text{-}2,6\text{-}(CH_3)_2C_6H_3\}_{10}(C_4H_8O)_4]$ (**2**).

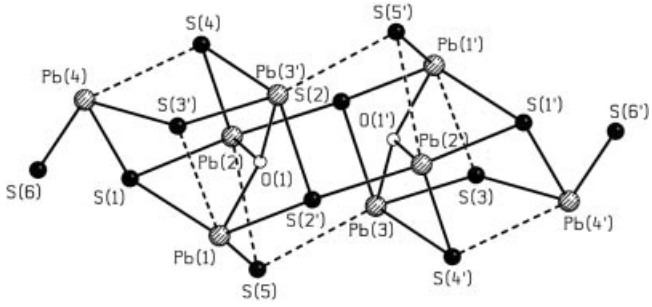

Figure 5. Molecular structure of $[Pb_8O_2\{S\text{-}2,6\text{-}(CH_3)_2C_6H_3\}_{12}]$ (**3**). C and H atoms omitted for clarity. Selected bond lengths [pm] (solid lines): Pb(1)–O(1) 220.5(6), Pb(2)–O(1) 222.4(6) Pb(3)–O(1′) 219.8(7), Pb(1)–S(5) 269.4(3), Pb(1)–S(1) 289.4(3), Pb(2)–S(4) 276.9(3), Pb(2)–S(2) 282.0(3), Pb(2)–S(1) 310.0(3), Pb(3)–S(3) 279.3(3), Pb(3)–S(2) 300.4(4), Pb(3)–S(4′) 302.6(4), Pb(4)–S(6) 256.2(3), Pb(4)–S(3′) 273.8(4), Pb(4)–S(1) 275.8(3). Weak contacts [pm] (dashed lines): Pb(1)–S(3′) 337.5, Pb(2)–S(5) 334.9, Pb(3)–S(5) 342.3, Pb(4)–S(4) 361.4. Symmetry transformation for generation of equivalent atoms: $-x$, $-y + 1$, $-z + 1$.

Small, yellow, needle-like plates of $[Pb_{14}O_6\{SC_6H_3\text{-}(CH_3)_2\}_{16}]$ (**4**) were found to be the only product crystallizing from dilute solutions of the crude orange-red powder in THF. Again, the use of freshly dried and distilled THF suggests that the oxygen can, in principle, only originate from compounds with Pb–O units that are already present in the crude powder. Interestingly, the yield of **4** is considerably increased upon dissolution of the crude powder in THF under aerobic conditions, which suggests that **4** can be seen as a stable oxidation product of the crude orange powder. This is in agreement with the investigations of Edelmann et al., who found $[Pb_5O\{S\text{-}2,4,6\text{-}(CF_3)_3C_6H_2\}_8]\cdot 2C_7H_8$ to be an oxidation product of the lead(II) thiolate $[Pb\{S\text{-}2,4,6\text{-}(CF_3)_3C_6H_2\}_2]$.[13] Complex **4** crystallizes in the $P\bar{1}$ space group and exhibits $\bar{1}$ symmetry (Figure 6). The net formed by the six oxygen [O(1), O(2), O(3), and symmetry-equivalent atoms] and twelve of the lead atoms [Pb(1)–Pb(6) and symmetry-equivalent atoms] resembles a small piece of a layer of the solid-state structure of red PbO, every layer of which is composed of a quadratic packing of oxygen atoms with the lead atoms occupying the quadratic cavities alternately above and below the oxygen planes. The Pb–O distances, with an average of 233.5 pm, are slightly longer in **4** than those in the red form of PbO (230 pm).[14] However, twenty of the contacts lie within a narrow range of 221.5–232.0(10) pm while four distances, namely Pb(2)–O(1′) [242.1(10) pm], Pb(2)–O(2) [269.6(10) pm], and distances to symmetry-equivalent atoms, show significantly larger values. The 16 thiolate ligands additionally bridge the lead atoms in different coordination modes, including the two remaining lead atoms Pb(7) and Pb(7′). The Pb–S bonds have been mapped in Figure 6 and range from 262.7(6) to 315.0(6) pm. A comparison of the measured X-ray powder patterns of a suspension of **4** in the mother liquor with the calculated pattern based on the data from single-crystal X-ray analysis (Figure 7) shows good agreement between the two and thus reveals the crystalline purity of this compound. Small deviations in intensity and reflection position might be due to the fact that the powder measurement was done at room temperature in contrast to 190 K for the single-crystal measurement, and that the needle-like crystals preferably align in the capillary vertical to the beam.

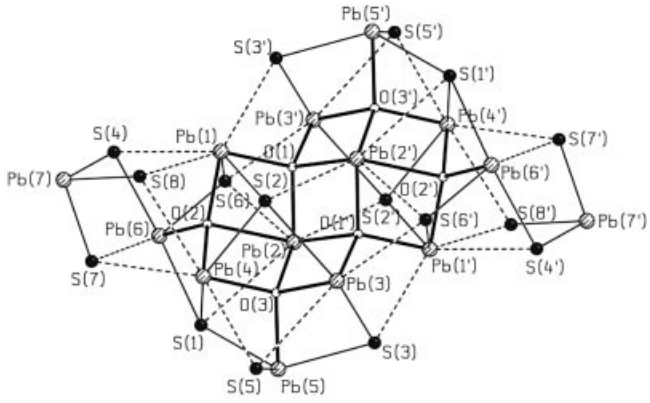

Figure 6. Molecular structure of $[Pb_{14}O_6\{S\text{-}2,6\text{-}(CH_3)_2C_6H_3\}_{16}]$ (**4**). C and H atoms omitted for clarity. Selected bond lengths [pm] (solid lines): Pb(1)–O(2) 225.0(10) Pb(1)–O(1) 231.9(9), Pb(2)–O(1) 227.2(9), Pb(2)–O(3) 238.6(9) Pb(2)–O(1′) 242.1(10) Pb(2)–O(2) 269.6(10), Pb(3)–O(1′) 229.8(8), Pb(3)–O(3) 232.0(10), Pb(1)–S(2) 285.0(4), Pb(4)–O(2) 226.8(9), Pb(4)–O(3) 228.2(9), Pb(5)–O(3) 229.5(9), Pb(6)–O(2) 221.5(10), Pb(3)–S(3) 285.9(5), Pb(4)–S(1) 302.4(5), Pb(4)–S(2) 305.5(4), Pb(5)–S(5) 264.6(5), Pb(5)–S(1) 289.8(6), Pb(5)–S(3) 289.9(6), Pb(6)–S(6) 274.4(5), Pb(6)–S(1) 293.5(5), Pb(6)–S(4) 299.8(5), Pb(7)–S(8) 262.7(6), Pb(7)–S(7) 263.1(6), Pb(7)–S(4) 270.4(6), Pb(7′)–S(8) 263.5(11), Pb(7′)–S(4) 264.1(9). Weak contacts [pm] (dashed lines): Pb(1)–S(4) 334.2, Pb(1)–S(6) 370.1, Pb(1)–S(8) 338.0, Pb(1)–S(3′) 323.2, Pb(2)–S(1) 361.1, Pb(2)–S(6) 333.6, Pb(2)–S(2′) 330.6, Pb(3)–S(5) 349.1, Pb(3)–S(6′) 325.0, Pb(4)–S(5) 331.2, Pb(4)–S(7) 338.6, Pb(4)–S(8) 370.0, Pb(6)–S(7) 322.8. Symmetry transformation for generation of equivalent atoms: $-x + 1$, $-y + 1$, $-z + 1$.

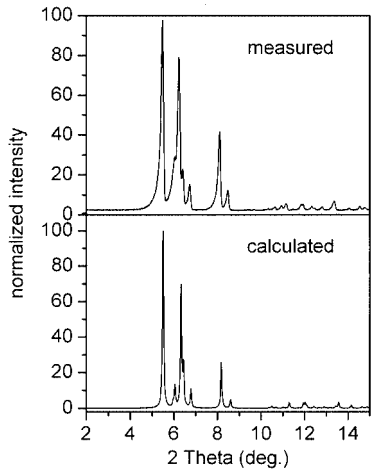

Figure 7. Measured (top) and calculated (bottom) powder diffraction pattern of $[Pb_{14}O_6\{S\text{-}2,6\text{-}(CH_3)_2C_6H_3\}_{16}]$ (**4**).

The UV/Vis spectra of **1**, **2**, and **4** in the solid state (Figure 8, bottom part) show a decrease in wavelength of the absorption onsets on going from **1** to **2** to **4**. Furthermore, the spectra display an almost featureless increase in absorbance down to 220 nm hardly indicating any maxima, of which the small shoulder at 430 nm (2.88 eV) in **4** is the most obvious. The solution spectrum of **4** is similar to that

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of the ground crystalline powders. Starting from higher wavelengths one observes the first absorption maximum in solution as a broad shoulder at around 420 nm (2.95 eV; the extinction coefficient for **4** in THF at 420 nm is 1.63×10^5 M^{-1}cm^{-1}). The following increase in absorbance in the region from 420 nm to 310 nm indicates one further weakly resolved shoulder and shows a last maxima at 256 nm (4.84 eV). The onset of the absorption of **4** in the solid state is thus slightly shifted to higher wavelength, in agreement with findings in other solid-state spectra.[15] In contrast, for **1** the onset of the solution spectrum is shifted by roughly 100 nm compared to the solid-state spectrum, a fact which cannot be simply explained by influences of the different measurement techniques alone. Rather, we assume that oligomeric **1** dissociates in solution into smaller units, probably [Pb{S-2,6-$(CH_3)_2C_6H_3$}$_2$], which displays two absorption maxima at 333 nm (3.72 eV) and 258 nm (4.8 eV) with an extinction coefficient of 5.95×10^5 M^{-1}cm^{-1} at 333 nm. Solutions of **2** in THF decompose immediately after dissolution, as indicated by the formation of a dark precipitate, while the clear supernatant solution displays the same UV/Vis spectrum as measured for **1**. The powder diffraction pattern of the dark precipitate displays weak and broad peaks for cubic PbS[16,17] and weak but sharper ones for cubic elemental lead.[18] This suggests that **2** decomposes in THF to form PbS/Pb and [Pb{S-2,6-$(CH_3)_2C_6H_3$}$_2$].

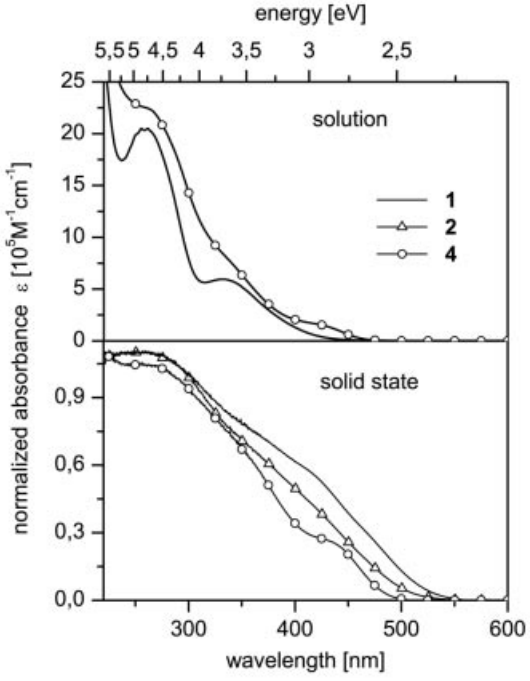

Figure 8. UV/Vis spectra of [Pb_{10}{S-2,6-$(CH_3)_2C_6H_3$}$_{20}$] (**1**), [Pb_6S{S-2,6-$(CH_3)_2C_6H_3$}$_{10}(C_4H_8O)_4$] (**2**), and [$Pb_{14}O_6${S-2,6-$(CH_3)_2C_6H_3$}$_{16}$] (**4**) in solution (THF) and the solid state (mull in nujol between two quartz plates).

These observations are currently part of further investigations where the effect of varying the reaction conditions (temperature, solvent, and stoichiometry) and the arenethiol are being studied. An additional focus will be the investigation of the reaction behavior of metal salts of the neighboring elements − tin, thallium and bismuth − with related thiols with a special focus on the formation of similar metal thiolate cluster complexes.

Experimental Section

General: Standard Schlenk techniques were employed throughout for the recrystallization of the preliminary reaction product using a double manifold vacuum line with high-purity dry nitrogen. All solvents were dried and distilled under nitrogen prior to use. Tetrahydrofuran and diethyl ether were dried with sodium/benzophenone, and pentane with $LiAlH_4$. $Pb(OOCCH_3)_2 \cdot 3H_2O$ (99+%) and 2,6-$(CH_3)_2C_6H_3$-SH (95%) were purchased from Aldrich. UV/Vis absorption spectra of cluster molecules in solution were measured with a Varian Cary 500 spectrophotometer in quartz cuvettes. Solid-state reflection spectra were measured for micron-sized crystalline powders between quartz plates with a Labsphere integrating sphere.

Synthesis: A hot solution (60 °C) of 2,6-$(CH_3)_2C_6H_3$SH (0.37 mL, 2.77 mmol) in 10 mL of ethanol was slowly added to a hot solution (60 °C) of $Pb(OOCCH_3)_2 \cdot 3H_2O$ (0.5 g, 1.32 mmol) in a mixture of 8 mL of C_2H_5OH and 2 mL of H_2O. A yellow precipitate was formed immediately which soon turned orange and finally became red. The reaction solution was heated at 60 °C for a further 30 min and then cooled to room temperature, filtered, washed with ethanol, and dried to give 0.49 g of an orange powder, which contained less sulfur than the expected product [Pb{S-2,6-$(CH_3)_2C_6H_3$}$_2$]. $C_{16}H_{18}PbS_2$ (481.64): calcd. C 39.9, H 3.8, S 13.31; found C 39.5, H 3.4, O 0.3, S 12.1.

1, 2, 3: For recrystallization the dried crude powder (0.49 g) was dissolved in 10 mL of THF and then layered with pentane by slow diffusion by evaporation from a connected flask to give a mixture of crystals of **1**, **2**, and **3**.

4: Pure crystals of **4** were obtained by dissolution of the crude powder (0.49 g) in 50 mL of THF and additional layering of this solution with pentane by slow diffusion by evaporation from a connected flask. (Yield: 0.063 g, 12.9% calculated for Pb). $C_{128}H_{144}O_6Pb_{14}S_{16}$ (5192.3): calcd. C 29.6, H 2.8, S 9.9; found C 29.9, H 2.6, S 10.2. Suitable crystals for X-ray analysis were obtained by careful layering of THF solutions of **4** with Et_2O in a Schlenk tube. The yield of **4** was increased by recrystallization of the crude powder (0.49 g) from 50 mL of THF in air without any layering with pentane. Yield: 0.29 g (56% calculated for Pb).

2: The solvents of the clear supernatant yellow solution from the crystallization of **4** were then removed in vacuo and the dry yellow-orange powder redissolved in 10 mL of THF. Layering of this solution with pentane by slow diffusion by evaporation from a connected flask yielded initially orange plate-like crystals of **2**, which tend to form solidified droplets of crystalline material during the layering process. After 2 d (ca. 6 mL of condensed pentane), the crystals were filtered and washed with pentane to yield 0.135 g (20.9% calculated for Pb) of **2**. $C_{96}H_{122}O_4Pb_6S_{11}$ (2935.9) (**2**·$4C_4H_8O$): calcd. C 39.3, H 4.2, S 12.1; found C 39.6, H 3.9, S 11.5.

1: The filtrate of **2** was again connected to the pentane flask and after 5 d yielded light-orange needles of **1**. Yield: 0.192 g (30.2% calculated for Pb). $C_{160}H_{180}Pb_{10}S_{20}$ (4816.3): calcd. C 39.9, H 3.8, S 13.3; found C 40.2, H 3.8, S 13.1. Continuation of the layering process resulted, at higher concentrations of condensed pentane, in the formation of a pale-yellow precipitate of unknown composition

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Crystallographic Data: Data collection was carried out with a STOE IPDS II diffractometer equipped with a Schneider rotating anode using graphite-monochromated Mo-K_α (λ = 0.71073 Å) radiation at 190 K. The structure solutions and full-matrix least-squares refinements based on F^2 were performed with the SHELX-97 program package.[19] Molecular diagrams were prepared with the program SCHAKAL 97.[20]

1: Light-orange needle-like plates, 0.5 × 0.08 × 0.06 mm, M_r = 4816.14, orthorhombic, space group *Pbcn* (no. 60), a = 31.217(6), b = 21.294(4), c = 30.898(6) Å, V = 20539(7) Å^3, Z = 4, D_c = 1.558 g cm^{-3}, μ(Mo-K_α) = 8.405 mm^{-1} giving a final R_1 value of 0.0672 for 856 parameters and 11 336 unique reflections with $I \geq 2\sigma(I)$ and wR_2 of 0.1830 for all 15 896 reflections (R_{int} = 0.0771).

2: Orange hexagonal plates, 0.24 × 0.18 × 0.02 mm, M_r = 2935.74, triclinic, space group $P\bar{1}$ (no. 2), a = 13.965(3), b = 14.819(3), c = 15.670(3) Å, α = 94.47(3), β = 114.44(3), γ = 115.45°, V = 2533.5(9) Å^3, Z = 1, D_c = 1.924 g cm^{-3}, μ(Mo-K_α) = 10.206 mm^{-1} giving a final R_1 value of 0.0486 for 479 parameters and 8632 unique reflections with $I \geq 2\sigma(I)$ and wR_2 of 0.1424 for all 10 378 reflections (R_{int} = 0.0598).

3: Yellow triclinic blocks, 0.2 × 0.127 × 0.08 mm, M_r = 3480.27, triclinic, space group $P\bar{1}$ (no. 2), a = 14.637(3), b = 15.278(3), c = 15.491(3) Å, α = 97.20(3), β = 108.18(3), γ = 118.38(3)°, V = 2736.0(9) Å^3, Z = 1, D_c = 2.112 g cm^{-3}, μ(Mo-K_α) = 12.536 mm^{-1} giving a final R_1 value of 0.0556 for 552 parameters and 8149 unique reflections with $I \geq 2\sigma(I)$ and wR_2 of 0.1584 for all 10 265 reflections (R_{int} = 0.0602).

4: Yellow plate-like needles, 0.4 × 0.07 × 0.04 mm, M_r = 5192.05, triclinic, space group $P\bar{1}$ (no. 2), a = 15.948(3), b = 17.919(4), c = 18.273(4) Å, α = 109.42(3), β = 100.93(3), γ = 112.51(3)°, V = 4238.1(15) Å^3, Z = 1, D_c = 2.034 g cm^{-3}, μ(Mo-K_α) = 14.083 mm^{-1} giving a final R_1 value of 0.0840 for 428 parameters and 12 414 unique reflections with $I \geq 2\sigma(I)$ and wR_2 of 0.2377 for all 16 723 reflections (R_{int} = 0.0872).

CCDC-246835 (**1**), -246836 (**2**), -246837 (**3**) and -246838 (**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif. X-ray powder diffraction patterns (XRD) were measured with a STOE STADI P diffractometer (Cu-K_α radiation, Germanium monochromator, Debye–Scherrer geometry) as a suspension of the crystals in sealed glass capillaries. Theoretical powder diffraction patterns were calculated on the basis of the atom coordinates obtained from single-crystal X-ray analysis by using the program package STOE WinXPOW.[21]

Acknowledgments

This work was supported by the Deutsch-Israelisches Programm (DIP) and the Deutsche Forschungsgemeinschaft (center for functional nanostructures CFN). The author is grateful to Prof. D. Fenske for helpful discussions and for providing excellent working conditions, E. Tröster for her invaluable assistance in the practical work, and Dr. Dale Cave for careful revision of the manuscript.

Keywords: Amide ligands / Cyclic voltammetry / N ligands / Titanium

The preparation of 1,4,7-{NH(2-C_6H_4F)$SiMe_2$}$_3$-1,4,7-triazacyclononane ($H_3N_{3\text{-}F}[9]N_3$) and 1,4,8-{N(H)Ph$SiMe_2$}$_3$-1,4,8-triazacycloundecane ($H_3N_3[11]N_3$), and their sodium derivatives $Na_3N_{3\text{-}F}[9]N_3(THF)_2$ and $Na_3N_3[11]N_3(THF)_2$, is described. The reaction of [$TiCl_3(THF)_3$] with $Na_3N_{3\text{-}F}[9]N_3(THF)_2$ and $Na_3N_3[11]N_3(THF)_2$ leads to [Ti{$N_{3\text{-}F}[9]N_3$}] and [Ti{$N_3[11]N_3$}]. The titanium complexes react readily with I_2 to give the Ti^{IV} derivatives [Ti{$N_{3\text{-}F}[9]N_3$}]I and [Ti{$N_3[11]N_3$}]I. All titanium compounds display distorted trigonal prismatic geometries where the metal is coordinated to the six nitrogen donors. Fluxional processes that convert the conformations of the five- and six-membered metallacycles and the Δ and Λ enantiomers of [Ti{$N_3[11]N_3$}]I have been identified in solution.

Introduction

The *N*-functionalization of azamacrocycles has been extensively explored as a method to design new ligand frameworks for metal cations. Several substituents and synthetic methodologies have been described and aspects such as structures, stabilities and physical properties have been broadly explored for many compounds. Despite the large number of transition-metal complexes of polyaza macrocyclic ligands bearing functionalized pendant arms reported in the literature,[1–3] the number of compounds displaying amide-tacn fragments as metal donors is much lower.[4–8] In this context we have reported the synthesis of a new six-donor triamidotriamine ligand precursor derived from tacn by introducing three $Si(Me)_2N(H)Ph$ pendant arms on the nitrogen atoms, and the preparation and characterisation of several triamide-tacn metal derivatives.[9,10] The ligand is hexacoordinate in all these complexes, irrespective of the size or oxidation state of the metals used (Ti, lanthanides, U). With the aim of modifying the donor properties of the original set and reduce the ligands' hapticity, with concomitant release of coordination positions at the metal centres, we introduced *ortho*-fluorine substituents in the phenyl rings and increased the macrocyclic framework and replaced tacn with triazacycloundecane (tacu). Although this goal has not been attained, we describe here the syntheses and characterisation of the new ligand precursors together with their sodium, Ti^{III} and Ti^{IV} derivatives. To the best of our knowledge, Ti-tacu complexes have not been reported before. Cyclic voltammetry results are also presented.

Results and Discussion

The reaction sequence used to synthesize 1,4,7-[{N(H)-2-C_6H_4F}$SiMe_2$]$_3$-triazacyclononane (**1**, $H_3N_{3\text{-}F}[9]N_3$), 1,4,8-{N(H)Ph$SiMe_2$}$_3$-triazacycloundecane (**2**, $H_3N_3[11]N_3$) and their sodium derivatives $Na_3N_{3\text{-}F}[9]N_3(THF)_2$ (**3**) and $Na_3N_3[11]N_3(THF)_2$ (**4**) is presented in Scheme 1. $H_3N_{3\text{-}F}[9]N_3$ (**1**) and $H_3N_3[11]N_3$ (**2**) were obtained in quantitative yields from the corresponding triazamacrocycle trihydrochloride derivatives.[11,12] $Na_3(THF)_2N_{3\text{-}F}[9]N_3$ (**3**) and $Na_3(THF)_2N_3[11]N_3$ (**4**) were also isolated in quantitative yields from THF from the reaction of **1** and **2** with NaH, respectively.

The characterization data of **1**–**4** are consistent with their formulation as trisubstituted macrocycle derivatives. The NMR spectra of $H_3N_{3\text{-}F}[9]N_3$ and $H_3N_3[11]N_3$ reveal C_{3v} and C_{2v} symmetry, respectively, compatible with fast nitrogen inversion of the macrocyclic amines. On the other hand, in the proton spectra of **3** and **4** the macrocyclic resonances are split into two groups that were identified by NOE difference experiments as the protons pointing towards the $SiMe_2$ pendant arm groups (H_{syn}) and opposite to them (H_{anti}). The differentiation between *syn* and *anti* protons is indicative of the coordination of the macrocyclic amines to the

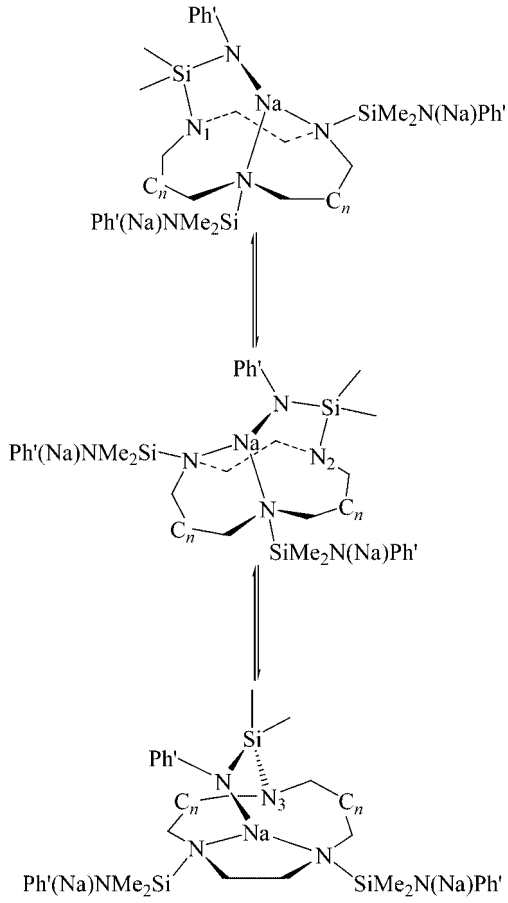
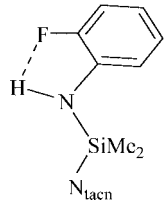


Scheme 2. Fluxional process responsible for the average C_3 and C_s symmetry of **3** and **4**, respectively. C_n = 0, 1; Ph′ = C_6H_5, *o*-C_6H_4F.



Scheme 3.

sodium cations and attests that, in these conditions, the macrocycle nitrogen inversion is slow on the NMR timescale. Although we have not been able to grow crystals of $Na_3(THF)_2N_{3\text{-}F}[9]N_3$ and $Na_3(THF)_2N_3[11]N_3$ suitable for X-ray structural determination, the similarity between the ^1H and ^{13}C NMR spectra of these compounds and those of $Li_3(THF)_2N_3[9]N_3$ suggests that, in solution, comparable fluxional processes take place.[9] As shown in Scheme 2, the fast exchange between the metals that occupy endocyclic and exocyclic positions creates average C_3 and C_s symmetries for **3** and **4**, respectively. In the case of the tacn derivative **3** this process makes all the pendant arms and macrocyclic carbons equivalent, but for **4**, two sets of resonances owing to the pendant arms (integrating 2:1) and four carbon macrocyclic resonances result. The ^{19}F NMR spectrum of **1** shows a doublet at δ = –57.5 ppm, with coupling constant of 3.9 Hz that results from the coupling with the NH groups through the intramolecular formation of five-membered rings, as represented in Scheme 3.

Treatment of $[TiCl_3(THF)_3]$ with one equivalent of $Na_3(THF)_2N_{3\text{-}F}[9]N_3$ or $Na_3(THF)_2N_3[11]N_3$ in toluene led to the synthesis of $[Ti\{N(2\text{-}FPh)SiMe_2\}_3(tacn)]$ (**5**, $[Ti\{N_{3\text{-}F}[9]N_3\}]$) and $[Ti\{N(Ph)SiMe_2\}_3(tacu)]$ (**6**, $[Ti\{N_3[11]N_3\}]$), respectively (Scheme 4). As expected for paramagnetic compounds, the ^1H NMR spectra of **5** and **6** show broad resonances for all the protons. Large paramagnetic shifts are observed for the macrocyclic protons adjacent to the nitrogens that appear at δ = 5.31 ppm in **5** and δ = 6.27 ppm in **6**. The EPR spectrum of a crystal of **5** at room temperature consists of a symmetrical single line. In solution, at 22 K, a more complex spectrum with g_{av} = 1.953 is obtained, whose hyperfine structure may arise from coupling with fluorine or with ^{47}Ti and ^{49}Ti. The spectral resolution does not allow us to estimate a coupling constant but it is likely that it results from electron coupling to ^{19}F given that coupling to titanium isotopes is rarely observed and has not been detected in the EPR spectrum of the non-fluorinated analogue $[Ti\{N_3[9]N_3\}]$.[9] The solution EPR spectrum of **6** at 298 K shows a symmetrical single line, with g_{av} = 1.944.

Orange crystals of **5** and **6** were grown from toluene solutions at 4 °C. ORTEP illustrations of their molecular structures, as determined by single-crystal X-ray diffraction, are represented in Figure 1 and Figure 2, respectively, and corresponding selected bond length and angles are listed in Table 1 and Table 2.

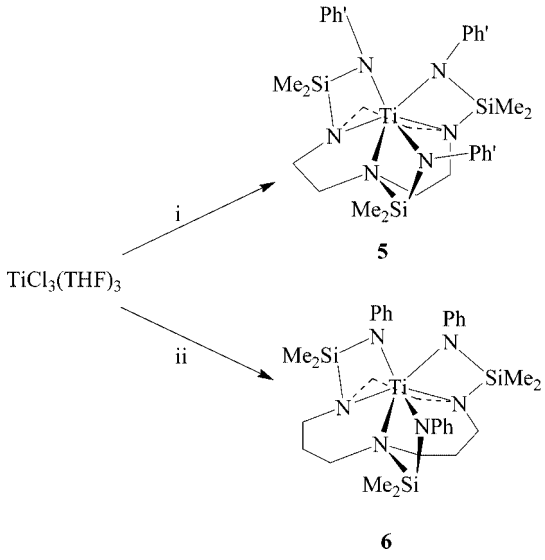

Scheme 4. i) $Na_3N_{3\text{-}F}[9]N_3$, Ph′ = *o*-C_6H_4F; ii) $Na_3N_3[11]N_3$.

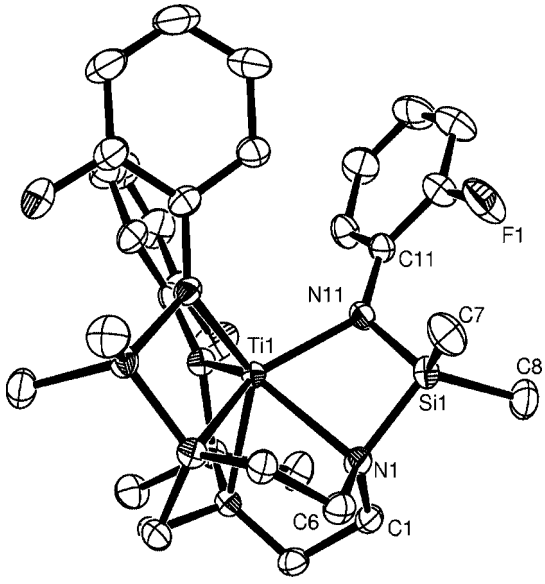

Figure 1. Molecular diagram of compound **5** showing the atomic labelling scheme (ellipsoids at 30% probability level).

In both compounds the metal coordination geometry is best described as distorted trigonal prismatic with three triazamacrocyclic amines and three pendant arm amides bonded to the titanium. Complex **5** crystallizes in the cubic space group $P2_13$ with twist angles between the amide and amine fragments, ϑ, defined by the dihedral angles N_{amino}–cent1–cent2–N_{amido} {N_{amine} and N_{amide} belong to the same pendant arm and cent1 and cent2 are the dummy centroid atoms defined respectively by the three N_{amine} [N(1), N(2), N(3)] and the three N_{amide} atoms [N(11), N(21), N(31)]}[11] of –8.4°, whereas **6** crystallizes in the triclinic space group $P\bar{1}$ with twist angles of –21.1°, –25.8° and –32.2°. The angle between the N(1)–N(2)–N(3) and N(11)–N(21)–N31 planes is 5.5° and the angle cent1–Ti–cent2 is 176.5° for **6** and, obviously, 0° and 180° for **5**. The higher asymmetry reflected by these angles when compared to tacn analogues is

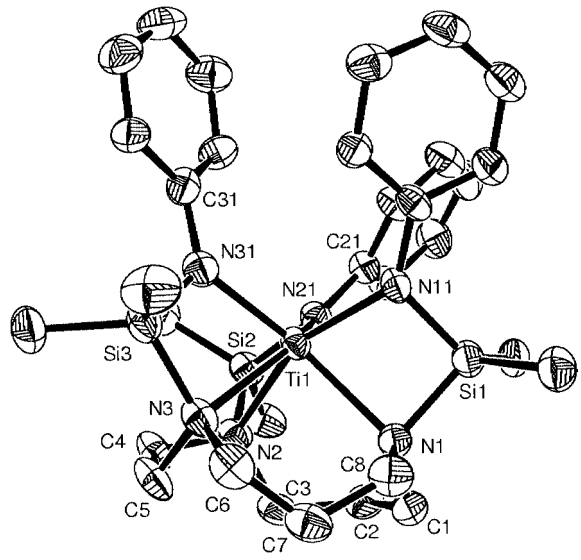

Figure 2. Molecular diagram of compound **6** showing the atomic labelling scheme (ellipsoids at 30% probability level).

a consequence of the different lengths of the tacu methylenic chains.

The distances between the metal and the N_{amine} and N_{amide} planes are 1.65 Å and 0.88 Å in **5** and 1.15 Å and 0.91 Å in **6**, respectively. The longer Ti–N_{tacn} distances compared to Ti–N_{tacu} show the ability of the larger macrocycle chains to adapt to the metal–nitrogen bonding requirements.[14] As it has a larger cavity, the triazacycloundecane ring accommodates the metal cation better than triazacyclononane and thus the metal–amine bonds become shorter. The cooperative effects between the two types of donor fragments is well expressed by the Ti–N_{amide} bond lengths, which follow the opposite trend; that is, the Ti–N_{amide} distances in **5** are shorter than those in **6**. The metal–nitrogen bond length variations are accompanied by different N(i)–Si(i)–N(ij) angles, which are slightly larger in **6** than in **5**. A comparison between the molecular structural parameters of [Ti{$N_{3\text{-}F}[9]N_3$}] and [Ti{$N_3[9]N_3$}] shows that the introduction of the fluorides do not alter the metal···ligand distances significantly, nor the overall coordination geometry. However, the close F···H contacts with the $Si(CH_3)_2$ hydrogens (2.30 Å and 2.73 Å) found in **5** might have induced a more constrained structure than that of [Ti{$N_3[9]N_3$}], thus inducing the crystallization in the cubic space group. Other differences between the two complexes refer to the stereochemical conformation of the TiN-$(CH_2)_2$N metallacycles and to the orientation of the shift between the N_{amido} and N_{amine} planes that is expressed by the twist angles defined above. The configuration of [Ti{$N_3[9]N_3$}] in the solid state was shown to be Δ(λλλ)/Λ(δδδ) whereas that of **5** is Λ(λλλ)/Δ(δδδ).

The two six-membered metallacycles defined by the titanium and the NC_3N chains in **6** display different conformations. The TiN(1)C(8)C(7)C(9)N(3) ring defines a chair conformation while Ti(N1)C(1)C(2)C(3)N(2) has a boat conformation. These arrangements have also been found in [Cu(tacu)Br_2] which is, according to a search performed in

[a] Centroid defined by the atoms in brackets.

CCDC, the only triazacycloundecane complex characterised by X-ray diffraction.[15]

Treatment of **5** and **6** with iodine gave the corresponding Ti^{IV} derivatives [Ti{$N_{3\text{-}F}$[9]N_3}]I (**7**) and [Ti{N_3[11]N_3}]I (**8**). The ^{1}H NMR spectrum of **7** is compatible with an average C_3 symmetry in solution where the macrocyclic protons appear as two sets of resonances attributable to H_{syn} and H_{anti}. The ^{19}F NMR spectrum shows a broad singlet at δ = –41.2 ppm.

The molecular structure of **7** is depicted in Figure 3 and selected bond lengths and angles are reported in Table 1.

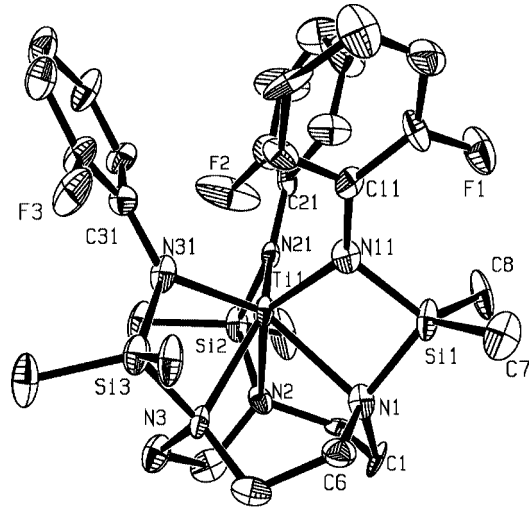

Figure 3. Molecular diagram of the cation of compound **7** showing the atomic labelling scheme (ellipsoids at 30% probability level).

In **7**, the titanium coordination geometry is best described as distorted trigonal prismatic with twist angles, ϑ, of 14.4°, 15.0° and 16.3°. The angle between the N(1)–N(2)–N(3) and N(11)–N(21)–N(31) planes is 1.6° and the angle cent1–Ti–cent2 is 178.1°. The amide nitrogen atoms are planar, with a sum of the angles around them of 359.6° for N(11), 359.8° for N(21) and 360.0° for N(31). The Ti–N_{amine} bond lengths range between 2.259 and 2.266 Å and the Ti–N_{amide} vary from 1.969 to 1.997 Å (see Table 1). Although slightly shorter than the values obtained for the Ti^{III}

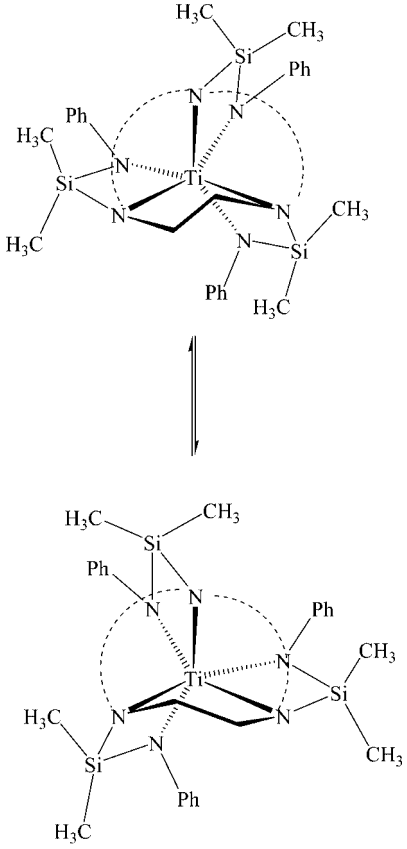
starting material, the metal···nitrogen distances in **7** are close to those found in cations $[Ti\{N_3[9]N_3\}]X$ (X = I, BPh_4), denoting that, once more, the *ortho*-fluorines have no significant influence on the ligand coordination. Similarly to **5**, short F···H distances (2.27–2.38 Å) between the fluoride and the $SiMe_2$ groups of each pendant arm are observed for **7**. The configuration of the five-membered $TiNC_2N$ metallacycles in **7** is the same as for **5** [Λ(λλλ)/Δ(δδδ)].

In CD_2Cl_2, at room temperature, the ^1H NMR spectrum of $[Ti\{N_3[11]N_3\}]I$ (**8**) is consistent with an average C_s symmetry, displaying two sets of aromatic resonances corresponding to the phenyl rings and three singlets for the six CH_3 groups of the bridging dimethylsilyl groups. The C_2-chain methylenic protons lead to different H_{syn} and H_{anti} resonances at δ = 3.39 and 3.68 ppm, respectively, and the C_3-chain protons give rise to four multiplets centred at δ = 2.37 and 2.05 ppm, corresponding to the H_{syn} and H_{anti} protons of the middle of the chain, and at δ = 3.47 and 3.30 ppm corresponding to the H_{syn} and H_{anti} protons adjacent to the nitrogen atoms. This pattern reveals that the three exchange processes available to the molecule at room temperature, namely the trigonal twist of the N_{amine} and N_{amide} planes, which corresponds to the equilibrium between the two possible enantiomers Δ and Λ, the δ/λ interconversion of the five-membered metallacycle and the chair/boat interconversion are fast processes on the NMR timescale (Scheme 5). At –40 °C, the dimethylsilyl protons split into five singlets and the three phenyl rings become non-equivalent, implying that the δ/λ isomerisation is blocked at that temperature. The C_2 macrocyclic protons pattern broadens as a consequence of the splitting into an ABCD system that partially overlaps the C_3 chain resonances. The two other fluxional processes are still operative, as revealed by the equivalence of the two methyl groups of the pendant arm bonded to the nitrogen between the two C_3 macrocyclic chains. At –70 °C these protons also become non-equivalent. Six different methyl resonances and the appearance of a series of interpenetrating multiplets due to non-equivalent macrocyclic protons are indicative that the equilibrium between the two enantiomers is blocked.



Scheme 5. Exchange processes responsible for the average C_s symmetry of $[Ti\{N_3[11]N_3\}]I$ (**8**).

To evaluate the donor ability of the $N_3[9]N_3$ and $N_{3\text{-}F}[9]N_3$ sets used we performed cyclic voltammetry measurements of complexes $[Ti\{N_{3\text{-}F}[9]N_3\}]$ (**5**), $[Ti\{N_{3\text{-}F}[9]N_3\}]I$ (**7**) and $[Ti\{N_3[9]N_3\}]X$ (X = I, **9**, BPh_4, **10**)[9] in acetonitrile at variable scan rates. The results are listed in Table 3.

Table 3. Electrochemical data for complexes **5**, **7**, **9** and **10**.

Compound[a]	$E^{red}_{1/2}$ [V]	$E^{ox}_{1/2}$ [V]	Solvent
$[Ti\{N_{3\text{-}F}[9]N_3\}]$		–1.59	CH_3CN
$[Ti\{N_{3\text{-}F}[9]N_3\}]I$	–1.58	–0.22	CH_3CN
$[Ti\{N_3[9]N_3\}]\ BPh_4$	–1.71		CH_3CN
	–1.78		CH_2Cl_2
$[Ti\{N_3[9]N_3\}]I$	–1.71	–0.20	CH_3CN

[a] At 25 °C, 6.5×10^{-2} M $(Bu_4N)BPh_4$, 10^{-3} M $FeCp_2$. All potentials were recorded at 200 mV s^{-1}.

The first remark concerns the stability of the different complexes in the medium. Triazacycloundecane derivatives are, in general, less stable than the triazacyclononane-based complexes and this characteristic prevents their study by cyclic voltammetry. The stability of the cations is higher than that of the reduced metal complexes and thus $[Ti\{N_3[9]N_3\}]$ and $[Ti\{N_3[11]N_3\}]$ are not suitable starting materials for CV measurements. Remarkably, $[Ti\{N_{3\text{-}F}[9]N_3\}]$ is much more stable than the other Ti^{III} compounds and, in acetonitrile, a reversible one-electron oxidation at $E^{ox}_{1/2}$ = –1.59 V was detected at a scan rate of 200 mV s^{-1}. Cationic tacn derivatives show reversible one-electron reduction peaks. Figure 4 shows the cyclic voltammogram of $[Ti\{N_3[9]N_3\}]BPh_4$ (**10**) as an example.

The values listed in Table 3 show that the redox potentials for the Ti^{IV}/Ti^{III} couple in complexes **9** and **10** are lower than the values reported for metallocene titanium dichlorides such as $[Cp_2TiCl_2]$, $[Cp^*_2TiCl_2]$ and $[(C_5H_4SiMe_3)_2TiCl_2]$, for which $E^{red}_{1/2}$ values range from –1.295 to –1.621 mV.[16–18] On the other hand, the value of –1.58 mV measured for $E^{red}_{1/2}$ of **7** reflects the additional stability of the LUMO when C_6H_5 is replaced by *o*-C_6H_4F. The similarity between the reduction potential of **7** and that of $[Ti\{O_3[9]N_3\}]PF_6$ ($H_3O_3[9]N_3$ = 1,4,7-tris(5-*tert*-butyl-2-hydroxybenzyl)-1,4,7-triazacyclononane; $E^{red}_{1/2}$ = –1.52 mV) shows that the donor ability of the amide moieties in **7** is comparable to that of the alkoxide fragments in $[Ti\{O_3[9]N_3\}]PF_6$.[17] The voltammograms of **7** and **9** display addition redox

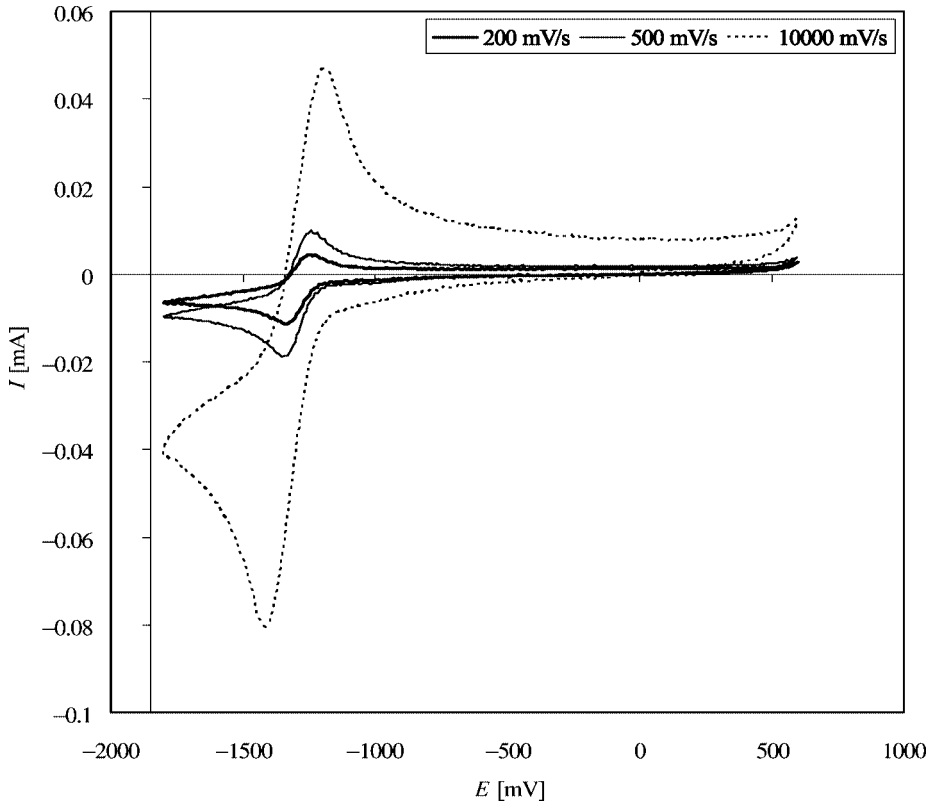

Figure 4. Cyclic voltammogram of [Ti{N_3[9]N_3}]BPh_4 (**10**) in [Bu_4N]BPh_4/CH_3CN, at scan rates of 200 mV s^{-1}, 500 mV s^{-1} and 1000 mV s^{-1}.

peaks at –0.22 V and –0.20 V, respectively, that are due to the I^- counterion.

Experimental Section

General Procedures and Starting Materials: All reactions were conducted under a nitrogen atmosphere. Solvents were pre-dried with 4 Å molecular sieves and refluxed over sodium-benzophenone (diethyl ether, tetrahydrofuran, *n*-hexane and toluene) or calcium hydride (dichloromethane) under an atmosphere of nitrogen, and collected by distillation. Deuterated solvents were dried with molecular sieves and freeze-pump-thaw degassed prior to use. Proton (300 MHz) and carbon (75.419 MHz) NMR spectra were recorded with a Varian Unity 300, at 298 K, unless stated otherwise. The spectra are referenced to internal residual protio-solvent (^1H) or solvent (^{13}C) resonances and reported relative to tetramethylsilane (δ = 0 ppm). Assignments were supported by NOE difference experiments and by ^{13}C-^1H hetero-correlations, as appropriate. EPR spectra were recorded at room temperature with a Bruker 300E spectrometer at X-band frequency ($\nu \approx 9.5$ GHz). Mass spectra were performed at the Laboratoire de Spectrométrie de Masse, Université de Rouen, France. Elemental analyses were obtained from the Laboratório de Análises do IST, Lisbon, Portugal.

Triethylamine, aniline, $SiMe_2Cl_2$, $TiCl_3$ and NaH (60% dispersion in mineral oil) were purchased from Aldrich. NEt_3 and NH_2Ph were pre-dried with molecular sieves, refluxed over calcium hydride, and collected by distillation. $SiMe_2Cl_2$ was purified by removal of residual HCl and then distilled trap-to-trap. NaH was washed with THF prior to use. [$TiCl_3(THF)_3$],[19] tacn·3HCl,[11] tacu·3HCl,[12] and 1,4,7-$(SiMe_2Cl)_3$-tacn[9] were prepared according to described procedures.

Cyclic voltammetric measurements were carried out with a Radiometer DEA 101 Digital Electrochemical Analyser interfaced with an IMT 102 Electrochemical Interface. [Bu_4N][BPh_4] (Fluka, electrochemical grade) was used as supporting electrolyte in CH_2Cl_2 or CH_3CN with a concentration of 6.5×10^{-2} M. All experiments were performed with concentrations of complexes in the range 2–4×10^{-3} M. All potentials are referenced to the ferrocene/ferrocenium couple as internal standard with $E_{1/2}$ = 0.50 V vs. S.C.E. A Pt disc (φ = 1 mm) was used as working electrode. The solvents were distilled immediately before use. All experiments were carried out at 25 °C in the absence of oxygen. Dry nitrogen was bubbled through the solution in the cell before measurements.

1,4,7-[{N(H)(2-C_6H_4F)}$SiMe_2$]$_3$-tacn (1): 2-Fluoraniline (2.1 mL, 21.9 mmol) was added to a suspension of NaH (0.95 g, 39.6 mmol) in THF. The mixture was heated to 60 °C and stirred for 12 h. The excess of NaH was filtered off and washed with 20 mL of THF, at room temperature. The filtrates were added dropwise to a solution of 1,4,7-$(SiMe_2Cl)_3$-tacn (2.74 g, 6.74 mmol) in toluene (80 mL), cooled to –40 °C. The mixture was warmed to room temperature and stirred for 12 h. The solvents were evaporated and the residue was extracted in hexane and filtered. Evaporation to dryness led to a very viscous yellow oil in quantitative yield (4.25 g). ^1H NMR (C_6D_6): δ = 6.94–6.90 (m, 3 H, H_{meta}), 6.88–6.87 (m, 3 H, H_{meta}), 6.85–6.82 (m, 3 H, H_{ortho}), 6.55–6.48 (m, 3 H, H_{para}), 3.77 (d, $J_{H,F}$ = 3.9 Hz, 3 H, N*H*), 2.89 (s, 12 H, NCH_2CH_2N), 0.09 (s, 18 H, CH_3) ppm. $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 153.1 (d, $^1J_{C,F}$ = 236.0 Hz, C_{ortho}), 135.8 (d, $^2J_{C,F}$ = 13.0 Hz, C_{ipso}), 124.8 (d, $^4J_{C,F}$ = 3.5 Hz, C_{meta}), 118.0 (d, $^3J_{C,F}$ = 7.0 Hz, C_{para}), 117.2 (d, $^3J_{C,F}$ = 3.5 Hz,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

C$_{ortho}$), 115.3 (d, $^2J_{C,F}$ = 20.0 Hz, *C*$_{meta}$), 50.5 (N*C*H$_2$*C*H$_2$N), –1.4 (*C*H$_3$) ppm. ^{19}F NMR (C$_6$D$_6$): δ = –57.47 ppm. $C_{30}H_{45}N_6F_3Si_3$ (630.98): calcd. C 57.08, H 7.19, N 13.33; found C 57.06, H 7.20, N 13.20. MS (EI): *m*/*z* = 630 [M]$^+$.

1,4,8-[SiMe$_2$Cl]$_3$-tacu: A suspension of tacu·3HCl (1.06 g, 3.97 mmol) in CH_2Cl_2 (50 mL), cooled to 0 °C, was treated with Et_3N (6,0 mL, 40 mmol). The mixture was stirred during 15 minutes and $SiMe_2Cl_2$ (3.0 mL, 24 mmol) was added. The reaction proceeded overnight at room temperature and a precipitate formed. The volatiles were then evaporated under vacuum and the residue was extracted with hexane and filtered. Evaporation of the hexane led to a white solid in quantitative yield (1.72 g). The reaction was scaled up to 20 mmol of tacu·3HCl. ^{1}H NMR (C$_6$D$_6$): δ = 2.90 (s, 4 H, NC*H*$_2$C*H*$_2$N), 2.83 [t, $^3J_{H,H}$ = 6.9 Hz, 4 H, N(CH$_2$)$_2$C*H*$_2$N(CH$_2$)$_2$N], 2.65 [t, $^3J_{H,H}$ = 6.9 Hz, 4 H, (CH$_2$)$_2$-C*H*$_2$NC*H*$_2$(CH$_2$)$_2$], 1.53 (quint., $^3J_{H,H}$ = 6.9 Hz, 4 H, NCH$_2$C*H*$_2$CH$_2$N), 0.29 (s, 12 H, SiC*H*$_3$), 0.27 (s, 6 H, SiC*H*$_3$) ppm. ^{13}C{^{1}H} NMR (C$_6$D$_6$): δ = 50.4 (N*C*H$_2$*C*H$_2$N), 46.2 [(CH$_2$)$_2$*C*H$_2$-N*C*H$_2$(CH$_2$)$_2$], 45.7 [N(CH$_2$)$_2$*C*H$_2$N(CH$_2$)$_2$N], 30.8 (NCH$_2$*C*H$_2$-CH$_2$N), 2.3 [(CH$_2$)$_3$N{Si(*C*H$_3$)$_2$}(CH$_2$)$_3$], 2.1 [(CH$_2$)$_3$N{Si(*C*H$_3$)$_2$}-(CH$_2$)$_2$] ppm. $C_{14}H_{34}N_3Cl_3Si_3$ (435.06): calcd. C 38.63, H 7.88, N 9.66; found C 38.55, H 7.96, N 9.55. MS (EI): *m*/*z* = 401 [M – Cl]$^+$.

1,4,8-[N(H)(C$_6$H$_5$)SiMe$_2$]$_3$-tacu (2): PhNH$_2$ (6.8 mL, 74 mmol) was added at 0 °C to a suspension of NaH (2.32 g, 93 mmol) in 100 mL of THF. The cooling bath was removed and, once the initial effervescence had stopped, the mixture was warmed at 60 °C for 12 h. The solution was filtered and the residue washed with THF (20 mL). The solution was transferred dropwise, at –40 °C, to a solution of 1,4,8-[ClSiMe$_2$]$_3$-tacu (10.24 g, 23.54 mmol) in 100 mL of toluene. The reaction took place at room temperature during 12 h and the volatiles were then evaporated. The residue was extracted with hexane and filtered off. Evaporation of the solvent led to 14.23 g of **2** (100%). ^{1}H NMR (C$_6$D$_6$): δ = 7.20–7.13 (m, 6 H, *H*$_{meta}$), 6.81–6.73 (m, 3 H, *H*$_{para}$), 6.67 (d, $^3J_{H,H}$ = 8.9 Hz, 4 H, *H*$_{ortho}$), 6.60 (d, $^3J_{H,H}$ = 8.9 Hz, 2 H, *H*$_{ortho}$), 3.15 (s, 2 H, N*H*), 3.12 (s, 1 H, N*H*), 3.02 (s, 4 H, NC*H*$_2$C*H*$_2$N), 2.73 [t, $^3J_{H,H}$ = 6.9 Hz, 4 H, (CH$_2$)$_2$C*H*$_2$NC*H*$_2$(CH$_2$)$_2$], 2.39 [t, $^3J_{H,H}$ = 6.9 Hz, 4 H, N(CH$_2$)$_2$C*H*$_2$N(CH$_2$)$_2$N], 1.63 (quint., $^3J_{H,H}$ = 6.9 Hz, 4 H, NCH$_2$C*H*$_2$CH$_2$N), 0.12 (s, 12 H, SiC*H*$_3$), 0.08 (s, 6 H, SiC*H*$_3$) ppm. ^{13}C{^{1}H} NMR (C$_6$D$_6$): δ = 147.4 (3 C, *C*$_{ipso}$), 129.5 (2 C, C$_{meta}$), 129.4 (4 C, C$_{meta}$), 118.3 (2 C, C$_{para}$), 118.2 (1 C, C$_{para}$), 116.9 (4 C, C$_{ortho}$), 116.8 (2 C, C$_{ortho}$), 50.2 (N*C*H$_2$*C*H$_2$N), 46.7 [(CH$_2$)$_2$*C*H$_2$N*C*H$_2$(CH$_2$)$_2$], 45.3 [N(CH$_2$)$_2$*C*H$_2$N(CH$_2$)$_2$N], 32.0 (NCH$_2$*C*H$_2$CH$_2$N), –1.05 [(CH$_2$)$_3$N{Si(*C*H$_3$)$_2$}(CH$_2$)$_3$], –1.08 [(CH$_2$)$_3$N{Si(*C*H$_3$)$_2$}(CH$_2$)$_2$] ppm. $C_{32}H_{52}N_6Si_3$ (605.06): calcd. C 63.50, H 8.67, N 13.90; found C 63.75, H 8.61, N 13.86. MS (EI): *m*/*z* = 604 [M]$^+$.

[1,4,7-{N(Na)(2-C$_6$H$_4$F)SiMe$_2$}$_3$-tacn]·2THF (3): A solution of 1,4,7-{[N(H)(2-C$_6$H$_4$F)]SiMe$_2$}$_3$-tacn (7.91 g, 12.54 mmol) in THF (25 mL) was added dropwise to a suspension of NaH (1.2 g, 50 mmol) in THF (100 mL). The mixture was then heated at 60 °C for 12 h. The solution was filtered off and the excess of NaH was washed with THF (30 mL). Evaporation of the THF led to a greenish solid in quantitative yield (10.54 g). ^{1}H NMR (C$_6$D$_6$): δ = 6.94 (m, 6 H, *H*$_{ortho}$, *H*$_{meta}$), 6.84 (t, $^3J_{H,H}$ = 6.6 Hz, 3 H, *H*$_{meta}$), 6.24 (m, 3 H, *H*$_{para}$), 3.41 (m, 8 H, OC*H*$_2$, THF), 3.07–2.95 (m, 6 H, C*H*$_2$, *syn*), 2.75–2.63 (m, 6 H, C*H*$_2$, *anti*), 1.30 (m, 8 H, C*H*$_2$, THF), 0.28 (s, 18 H, C*H*$_3$) ppm. ^{13}C{^{1}H} NMR (C$_6$D$_6$): δ = 158.1 (d, $^1J_{C,F}$ = 225.0 Hz, *C*$_{ortho}$), 149.5 (br., *C*$_{ipso}$), 125.1 (*C*$_{meta}$), 124.3 (*C*$_{ortho}$), 114.4 (d, $^2J_{C,F}$ = 24.0 Hz, *C*$_{meta}$), 110.3 (*C*$_{para}$), 67.9 (OCH$_2$, THF), 48.3 (NCH$_2$CH$_2$N), 25.6 (*C*H$_2$, THF), 0.1 (*C*H$_3$) ppm. ^{19}F NMR(C$_6$D$_6$): δ = –63.24 (m) ppm.

1,4,8-[{N(Na)(C$_6$H$_5$)SiMe$_2$}$_3$-tacu]·2THF (4): A solution of 1,4,8-[N(H)(C$_6$H$_5$)SiMe$_2$]$_3$-tacu (7.03 g, 11.62 mmol) in THF (ca. 25 mL) was added to a suspension of NaH (1.00 g, 42 mmol) in 100 mL of THF. The mixture was slowly warmed to 60 °C and stirred at this temperature for 12 h. After cooling to room temperature, the solution was filtered off and the NaH excess was washed with 30 mL of THF that was collected with the filtrate. The solvent was evaporated to dryness and a greenish powder was obtained by scratching the dried material under N_2, at liquid nitrogen temperature. Yield: 8.63 g, quantitative. ^{1}H NMR (C$_6$D$_6$): δ = 7.16 (t, $^3J_{H,H}$ = 7.2 Hz, 2 H, *H*$_{meta}$), 7.07 (t, $^3J_{H,H}$ = 6.9 Hz, 4 H, *H*$_{meta}$), 6.76 (t, $^3J_{H,H}$ = 7.2 Hz, 6 H, *H*$_{ortho}$), 6.58 (t, $^3J_{H,H}$ = 7.2 Hz, 1 H, *H*$_{para}$), 6.47 (t, $^3J_{H,H}$ = 6.9 Hz, 2 H, *H*$_{para}$), 3.27 (m, 8 H, OC*H*$_2$, THF), 2.86 [br. s, 6 H, NC*H*$_{syn}$H$_{anti}$CH$_2$C*H*$_{syn}$H$_{anti}$N(C*H*$_{syn}$H$_{anti}$)$_2$N], 2.56 [br. s, 2 H, N(CH$_{syn}$*H*$_{anti}$)$_2$N], 2.44 (br. s, 4 H, NCH$_{syn}$*H*$_{anti}$CH$_2$CH$_{syn}$-*H*$_{anti}$N), 1.67 (br. s, 2 H, NCH$_2$C*H*$_{syn}$H$_{anti}$CH$_2$N), 1.38 (br. s, 2 H, NCH$_2$CH$_{syn}$*H*$_{anti}$CH$_2$N), 1.24 (m, 8 H, C*H*$_2$, THF), 0.34 (s, 6 H, SiC*H*$_3$), 0.29 (s, 12 H, SiC*H*$_3$) ppm. ^{13}C{^{1}H} NMR (C$_6$D$_6$): δ = 161.1 (1 C, *C*$_{ipso}$), 160.4 (2 C, *C*$_{ipso}$), 130.7 (4 C, *C*$_{meta}$), 130.2 (2 C, *C*$_{meta}$), 122.9 (2 C, *C*$_{ortho}$), 121.8 (4 C, *C*$_{ortho}$), 113.3 (1 C, *C*$_{para}$), 113.2 (2 C, *C*$_{para}$), 67.8 (O*C*H$_2$, THF), 51.4 [(CH$_2$)$_2$*C*H$_2$-N*C*H$_2$(CH$_2$)$_2$], 50.7 [N(CH$_2$)$_2$*C*H$_2$N(CH$_2$)$_2$N], 49.0 [N(*C*H$_2$)$_2$N], 30.0 (NCH$_2$*C*H$_2$CH$_2$N), 25.5 (*C*H$_2$, THF), 1.2 [(CH$_2$)$_3$N{Si-(*C*H$_3$)$_2$}(CH$_2$)$_3$], 0.1 [(CH$_2$)$_3$N{Si(*C*H$_3$)$_2$}(CH$_2$)$_2$] ppm.

[Ti{N(2-C$_6$H$_4$F)SiMe$_2$}$_3$-tacn] (5): A solution of [1,4,7-{N(Na)(2-C$_6$H$_4$F)SiMe$_2$}$_3$-tacn]·2THF (2.30 g, 2.86 mmol) in toluene (10 mL) was rapidly added at –60 °C to a suspension of [TiCl$_3$(THF)$_3$] (1.11 g, 3.00 mmol) in toluene (40 mL). The mixture was allowed to warm to room temperature while being stirred for 12 h. The solution was filtered through a celite layer and the residue was washed with toluene and collected together with the filtrate. The solvents were evaporated under vacuum and the compound was washed at –30 °C with hexane (2 × 5 mL). Yield: 90% (1.69 g). ^{1}H NMR (C$_6$D$_6$): δ = 9.25, 7.98, 6.93 (br., 2-C$_6$*H*$_4$F), 5.30 (br., NC*H*$_2$C*H*$_2$N), 0.61 [br., Si(C*H*$_3$)$_2$] ppm. EPR (10^{-2} M in toluene, 22 K): *g* = 1.953. $C_{30}H_{42}F_3N_6Si_3Ti$ (675.82): calcd. C 53.29, H 6.27, N 12.44; found C 53.20, H 6.36, N 12.43. MS (EI): *m*/*z* = 583 [M$^+$ – C$_6$H$_2$F].

[Ti{N(Ph)SiMe$_2$}$_3$-tacu] (6): A suspension of [TiCl$_3$(THF)$_3$] (1.23 g, 3.31 mmol) in 50 mL of toluene was treated at –60 °C with a solution of 1,4,8-[{N(Na)(C$_6$H$_5$)SiMe$_2$}$_3$-tacu]·2THF (2.36 g, 3.18 mmol) in 10 mL of toluene. The mixture was allowed to reach room temperature and was stirred for a further 12 h. The solution was filtered through a celite layer and the solvent evaporated to dryness. The solid obtained was washed at –30 °C with hexane and dried. Crystals suitable for X-ray diffraction were obtained from toluene at 4 °C. Yield: 80% (1.65 g). EPR (10^{-2} M in toluene, 22 K): *g* = 1.944. $C_{32}H_{49}N_6Si_3Ti$ (649.90): calcd. C 59.11, H 7.60, N 12.94; found C 59.03, H 7.73, N 12.88. MS (EI): *m*/*z* = 649 [M]$^+$.

[Ti{N(2-C$_6$H$_4$F)SiMe$_2$}$_3$-tacn]I (7): A solution of [Ti{N(2-C$_6$H$_4$F)SiMe$_2$}$_3$-tacn] (0.80 g, 1.19 mmol) in 40 mL of toluene, cooled to –60 °C, was treated with I_2 (0.15 g, 0.60 mmol). The solution was allowed to warm to room temperature and was then stirred for 12 h. The solvent was evaporated to dryness and the residue was washed with hexane and dried in vacuo to give **7** as an orange solid in 98% yield (0.93 g). ^{1}H NMR (C$_6$D$_5$Br): δ = 7.37 (br. t, 3 H, *H*$_{meta\text{-}H3}$), 7.30–7.20 (m, 3 H, *H*$_{para}$), 6.95 (t, $^3J_{H,H}$ = 6.6 Hz, 3 H, *H*$_{meta\text{-}H5}$), 5.76 (t, $^3J_{H,H}$ = 7.2 Hz, 3 H, *H*$_{ortho}$), 4.65–4.40 (br. s, C*H*$_{anti}$H$_{syn}$), 3.95–3.75 (m, 6 H, CH$_{anti}$*H*$_{syn}$), 0.72 (s, 18 H, C*H*$_3$) ppm; (CD$_3$CN): δ = 7.09 (ddd, $^3J_{H,F}$ = 11.4, $^3J_{H,H}$ = 8.4, $^4J_{H,H}$ = 1.5 Hz, 3 H, *H*$_{meta\text{-}H3}$), 7.02–6.93 (m, 3 H, *H*$_{para}$), 6.52 (dt, $^3J_{H,H}$ = 7.8, $^5J_{H,F}$ = 1.5 Hz, 3 H, *H*$_{meta\text{-}H5}$), 5.43 (dt, $^3J_{H,H}$

(s, 3 H, CH_3), 0.38 (s, 3 H, CH_3), 0.21 (s, 3 H, CH_3), 0.09 (s, 3 H, CH_3) ppm. $^{13}C\{^1H\}$ NMR (CD_2Cl_2, room temp.): δ = 159.0, 152.8 (C_{ipso}), 129.6, 128.8, 124.1, 122.9, 119.7, 118.6 (C_{Ph}), 52.6, 50.7, 48.3 (NCH_2), 26.7 (NCH$_2$$CH_2$$CH_2$N), 1.8 ($CH_3$), 1.1 ($CH_3$), 0.0 ($CH_3$) ppm. $C_{32}H_{49}IN_6Si_3Ti$ (776.80): calcd. C 49.48, H 6.36, N 10.82; found C 49.18, H 6.27, N 10.39.

X-ray Experimental Details: X-ray data were collected on a MACH3 Nonius diffractometer equipped with Mo-K_α radiation (λ = 0.71069 Å) and a Turbo CAD4 with a rotating anode and Cu-$K_{\alpha1}$ radiation (in the case of compound **7**), at room temperature. Solution and refinement were performed with SIR97[20] and SHELXL[21] included in the WINGX Version 1.64.03b program package.[22] Compound **5** crystallized in the cubic space group $P2_13$, thus only 1/3 of the molecule is present in the asymmetric unit, as the Ti atom is on a 3-fold rotation axis. Compound **6** crystallized in the triclinic centrosymmetric space group $P\bar{1}$ with two similar molecules in the asymmetric unit. Geometrical data are discussed and presented only for one of the molecules. As for compound **7**, a large residual electron density is present near the iodide atom. Several refinements of a possible disorder of I^- (occupying three possible positions with different occupation factors) did not improve the refinement and several satellite residual peaks were kept. The possibility of a disordered I_3^- ion was also attempted but the I–I distances were not acceptable. All non-H atoms were refined anisotropically, and all hydrogen atoms were inserted in idealized positions riding on the parent C atom. All the details concerning data collection and refinement are presented in Table 4 and Table 5. Figures were drawn with ORTEP3.[23]

CCDC-250633 to -250635 (for **5**–**7**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Novel Methanol-Containing Oxomolybdate(v) Complexes: Synthesis and Structural Characterisation of Intermediates in the Formation of $\{Mo_2O_4\}^{2+}$ Clusters from $[MoOCl_4(H_2O)]^-$ and $[MoOBr_4]^-$ Precursors

Barbara Modec*[a] and Jurij V. Brenčič[a]

Keywords: Cluster compounds / Molybdenum / Polyoxometallates

A series of oxomolybdate(v) complexes with methanol was prepared by the reaction of $(PyH)_5[MoOCl_4(H_2O)]_3Cl_2$ (**1**) or $(PyH)[MoOBr_4]$ (PyH^+ = pyridinium cation, $C_5H_5NH^+$) in methanol. $(PyH)_2[MoOCl_4(MeOH)]Cl$ (**2**) is obtained upon substitution of coordinated water for methanol in **1**. Small amounts of weak bases such as pyridine or trifluoroacetate promote further substitution chemistry at the labile sites, followed by dimerisation to the well-known $\{Mo_2O_4\}^{2+}$ core. A dinuclear anion with coordinated methanol can be isolated as its pyridinium salt, $(PyH)_2[Mo_2O_4Cl_4(MeOH)_2]$, in two crystalline modifications, either as a triclinic (**3**) or as an orthorhombic polymorph (**4**). After prolonged reaction times further assembly of dinuclear fragments takes place and tetranuclear $[Mo_4O_8(OMe)_2(MeOH)_2Cl_4]^{2-}$ is formed. The products of the analogous reactions with $(PyH)[MoOBr_4]$ as the starting material depend largely upon the reaction temperature. Dinuclear $(PyH)_2[Mo_2O_4Br_4(MeOH)_2]$ (**5**), which crystallises in an orthorhombic unit cell and whose structure is isotypic to that of **4**, is obtained only if the reaction takes place at low temperature (5 °C); under ambient conditions $(PyH)_2[Mo_4O_8(OMe)_2(MeOH)_2Br_4]$ (**6**) is obtained instead. The tetranuclear anion of **6** consists of a commonly adopted assembly of two $\{Mo_2O_4\}^{2+}$ units. The identity of the products was determined by infrared spectroscopy and X-ray structure analyses.

Introduction

$\{Mo_2O_4\}^{2+}$ clusters with metal d electrons localised in single metal–metal bonds occupy a prominent position among the polyoxometallates, which continue to be a subject of great interest because of their potential applications ranging from catalysis to medicine.[1] Their basic building blocks, dinuclear $\{Mo_2O_4\}^{2+}$ moieties (Scheme 1) with a well-defined geometry,[2,3] can assemble in many different ways and lead to a variety of metal oxide cores, as illustrated by some recently prepared clusters, i.e., $[(Mo_2O_4)_4(OMe)_6(MeOH)_4Cl_2]$,[4] bimetallic alkoxides $[M_2(Mo_2O_4)_2(O\mathit{i}Pr)_{14}]$ (M = Ta, Nb),[5] $[(Mo_2O_4)_6(\mu_2\text{-}SO_3)_{12}(\mu_3\text{-}SO_3)_4]^{20-}$,[6] $[Na_4(H_2O)_6\{(Mo_2O_4)_{10}(P_2O_7)_{10}(CH_3COO)_8(H_2O)_4\}]^{24-}$,[7] $[(Mo_2O_4)_3(O_3PCH_2PO_3)_3(MoO_4)]^{8-}$,[8] $[Na(H_2O)_2\{(Mo_2O_4)_4(O_3PCH_2PO_3)_4(CO_3)_2\}]^{11-}$,[9] and a series of nano-sized, mixed-valence Mo^V/Mo^{VI} acetate complexes.[10] Theoretical calculations have been performed on some of these species in order to understand the bonding of such complex architectures.[11] Although the $\{Mo_2O_4\}^{2+}$ species were considered at first to be essentially products of inadvertent air oxidation, contemporary research in this field is aimed towards the development of more rational and high-yield synthetic procedures.

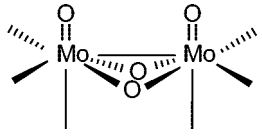

Scheme 1. A basic building unit: $\{Mo_2O_4\}^{2+}$ structural fragment.

We have demonstrated in our previous work that $(PyH)_2[MoOCl_5]$ reacts almost instantaneously in mixtures of methanol and pyridine to form discrete clusters built of two, three, four or six $\{Mo_2O_4\}^{2+}$ subunits.[12] A simple, high-yield preparation method, coupled with the relative stability and the fact that the coordinated chlorides are labile enough under appropriate conditions to allow a facile substitution chemistry, have made $(PyH)_2[MoOCl_5]$ an attractive starting material. Since the widely accepted notion, based on the analytical and spectroscopic data, was that its structure consists of octahedral $[MoOCl_5]^{2-}$ ions,[13] its X-ray structure analysis has not been undertaken until now. The general reaction route leading to $\{Mo_2O_4\}^{2+}$ clusters was proposed to begin with rapid substitution of the chlorides, followed by dimerisation through $Mo(\mu_2\text{-}O)_2Mo$ bridges with concomitant interaction between the two d^1 ions. There are three sites per metal in the $\{Mo_2O_4\}^{2+}$ moiety that are open for coordination of, preferably, oxygen-donor ligands. The multitude of known $\{Mo_2O_4\}^{2+}$ complexes with very diverse mono-, bi- or multidentate ligands suggests that many fulfil the metal's coordination demands.[14]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim **DOI: 10.1002/ejic.200400829**

In the absence of ligands in sufficient concentrations, the metal centres attain coordination saturation through the self-assembly of $\{Mo_2O_4\}^{2+}$ units by sharing the initially μ_2-bridging oxo groups. The surface of the clusters thus obtained still possesses sites available for coordination, but their number is greatly reduced compared to the $\{Mo_2O_4\}^{2+}$ subunit. A very important aspect in the process is the formation of methoxide ions and their subsequent incorporation into the cluster, which diminishes its negative charge. Because of the ability of alkoxides to participate in bridging interactions with two or three metal centres, the assembly of $\{Mo_2O_4\}^{2+}$ units in their presence results in a different core structure, as exemplified by the association of two $\{Mo_2O_4\}^{2+}$ units to form a tetranuclear core.[15] The alkoxide was shown to assist in the assembly and either a compact $\{Mo_4O_4(\mu_3\text{-}O)_2(\mu_2\text{-}O)_2(\mu_2\text{-}OR)_2\}^{2+}$ or more rarely $\{Mo_4O_4(\mu_2\text{-}O)_4(\mu_2\text{-}OR)_2\}^{2+}$ core with an open structure were formed. With no alkoxide present, a self-assembly into a cube-like $\{Mo_4O_4(\mu_3\text{-}O)_4\}^{4+}$ core was observed.

The ongoing research in our laboratory has been focused on the isolation and characterisation of the intermediate products in the formation of $\{Mo_2O_4\}^{2+}$ clusters. Knowing their identities would help to elucidate a multi-step reaction pathway from the starting oxohalomolybdate(v) to the final $\{Mo_2O_4\}^{2+}$ clusters. In this context, the reactions of $(PyH)_2[MoOCl_5]$ and $(PyH)[MoOBr_4]$ with pyridine or pyridinium trifluoroacetate in methanol were investigated. Prior to that, however, $(PyH)_2[MoOCl_5]$ was subjected to an X-ray structure analysis.

Results and Discussion

Structural Data

Structure of $(PyH)_5[MoOCl_4(H_2O)]_3Cl_2$ (1)

The X-ray structure analysis of $(PyH)_2[MoOCl_5]$ revealed its true identity as $(PyH)_5[MoOCl_4(H_2O)]_3Cl_2$, whose structure is isotypic with that of $(PyH)_5[MoOBr_4(H_2O)]_3Br_2$.[16] The orthorhombic unit cell contains six $[MoOCl_4(H_2O)]^-$ ions, four non-coordinated chloride ions and ten protonated pyridine molecules as countercations.. There are two crystallographically distinct $[MoOCl_4(H_2O)]^-$ ions (depicted in Figure 1). The one containing Mo(1) lies at the intersection of two mirror planes, with the chloro ligands in the planes and Mo(1), O(11) and O(12) on the twofold axis. Its symmetry is C_{2v}. The other anion has only one crystallographically imposed mirror plane. Mo(2), both oxygen atoms and the two chlorine atoms Cl(21) and Cl(23) lie in this plane. The distorted octahedral environments of Mo(1) and Mo(2) reveal the usual bonding pattern for $[MoOCl_4(H_2O)]^-$ anions:[17] (i) a short Mo=O bond [1.648(4) and 1.650(3) Å], consistent with a multiple bond character, (ii) a water ligand at 2.284(4) and 2.270(3) Å in a position *trans* to the terminal oxo group, and (iii) a displacement of molybdenum from the plane of the four chloro ligands towards the oxo group [0.334(1) Å for Mo(1) and 0.349(1) Å for Mo(2)]. An exhaustive list of structural parameters is given in Table 1.

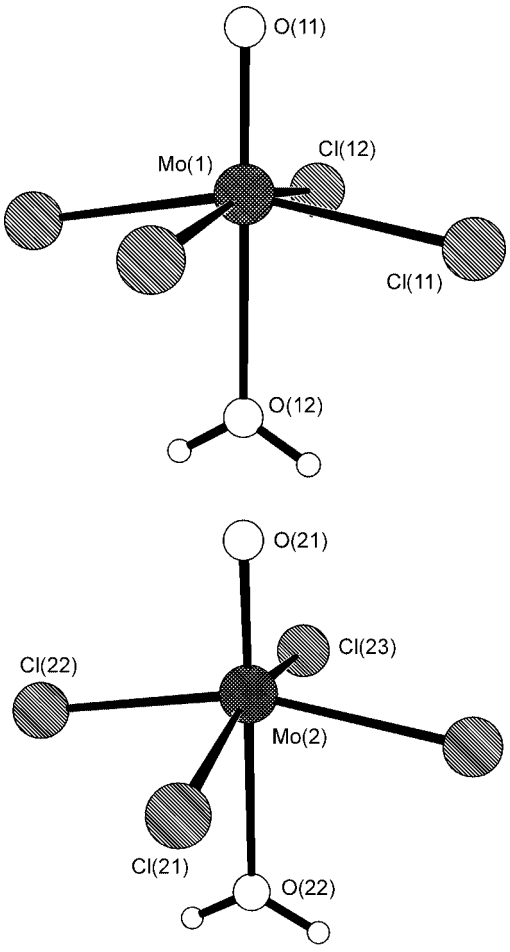

Figure 1. The two crystallographically independent $[MoOCl_4(H_2O)]^-$ ions found in compound **1**. The same drawing scheme pertains to all figures: molybdenum atoms are cross-hatched; chlorine or bromine atoms are lined bottom right to top left; nitrogen atoms are lined bottom left to top right; oxygen atoms are unshaded and carbon atoms shaded, medium-sized spheres and hydrogen atoms are unshaded small-sized spheres.

Table 1. Geometric parameters [Å; °] of the $[MoOCl_4(H_2O)]^-$ ions in **1**.

A complicated pattern of hydrogen bonds is formed in **1**. Six hydrogen bonds link three $[MoOCl_4(H_2O)]^-$ ions through water ligands to a pair of non-coordinated chloride ions (Figure 2a). Each water molecule is engaged in two

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

hydrogen bonds with two chlorides, with lengths of 3.164(3) and 3.129(2) Å. Three pyridinium cations are connected in a similar manner by bifurcated, rather long, hydrogen bonds with a pair of chloride counterions [N(1)···Cl = 3.3299(30) and N(2)···Cl = 3.3876(44) Å; Figure 2b]. Alternation of both types of trimeric assemblies through common chloride ions produces infinite chains which are parallel to the *b* axis (Figure 2c). The environment of each chloride ion in the chain is that of a distorted octahedron consisting of three water molecules and three pyridinium nitrogens.

The $[MoOCl_4(H_2O)]^-$ ion has been structurally characterised in several other compounds.[17] Due to the widespread participation of coordinated water molecules in O–H···Cl or O–H···O(terminal oxo group) hydrogen bonds, pairs of anions or infinite chains are observed in many solid-state structures. The water ligand is bonded in some $[MoOCl_4(H_2O)]^-$ compounds at longer distances. For in-

stance, a distance of 2.393(15) Å is observed in $[As(C_6H_5)_4][MoOCl_4(H_2O)]$.[17c] This lengthening is in agreement with the uniform tendency of Mo=O bonds to weaken bonds *trans* to themselves. Nevertheless, the bond lengths in **1** are still significantly longer than related bonds which are not subject to a *trans* influence, for example 2.148(6) Å determined for $[Mo_4O_8(OH)_2(H_2O)_2(C_4O_4)_2]^{2-}$.[18]

Structure of (PyH)$_2$[MoOCl$_4$(MeOH)]Cl (2)

The asymmetric unit of **2** contains a complex anion with the composition $[MoOCl_4(MeOH)]^-$, as shown in Figure 3, a chloride ion and two protonated pyridine molecules as countercations. The $[MoOCl_4(MeOH)]^-$ ions have pseudo-octahedral coordination spheres characterised by a short Mo=O bond, a methanol ligand in a position *trans* to it and four chloro ligands at 2.3715(6)–2.3817(6) Å. The molybdenum atom is, as expected, displaced away from the least-squares plane of the four chlorine atoms by 0.3212(4) Å towards the oxo group. This necessitates obtuse O=Mo–Cl angles in the range 96.80(6)–98.62(6)°. The molybdenum-to-methanol oxygen bond length is 2.2911(15) Å. Relevant structural parameters of the $[MoOCl_4(MeOH)]^-$ ion are summarised in Table 2. The methanol ligand is also engaged in a relatively short hydrogen-bonding interaction with a chloride counterion Cl(5) [O(2)···Cl(5) = 3.0235(16) Å]. The non-coordinated chloride Cl(5) participates in two more hydrogen bonds. Both are formed with pyridinium nitrogen atoms, the distance to N(1)a is 3.0508(21) Å [(*a*) *x*, *y*, 1 + *z*] and the distance to N(2)b is 3.1384(20) Å [(*b*) –0.5 + *x*, 0.5 – *y*, 0.5 + *z*].

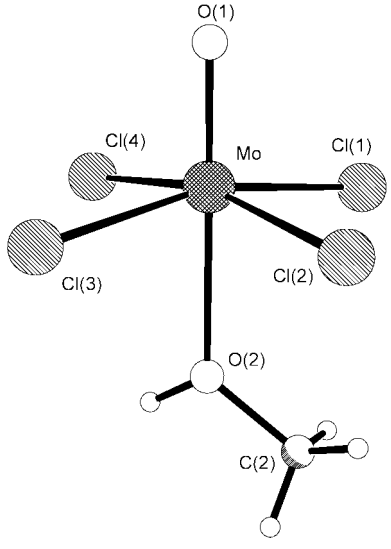

Figure 3. A drawing of the $[MoOCl_4(MeOH)]^-$ unit in **2** with the atom labelling scheme.

Although many $[MoOCl_4L]^-$ compounds with bases, L, such as tetrahydrofuran, dimethylphosphite, dimethylformamide and acetonitrile have been structurally characterised,[19] there were none where L is an alcohol until now. Nevertheless, the existence of the $[MoOCl_4(MeOH)]^-$ ion has been suggested previously in order to explain adequately the electronic spectrum of a methanol solution of $[N(C_4H_9)_4][MoOCl_4]$.[20]

Structure of the Triclinic Modification of (PyH)$_2$[Mo$_2$O$_4$Cl$_4$(MeOH)$_2$] (3)

A perspective view of the $[Mo_2O_4Cl_4(MeOH)_2]^{2-}$ anion is presented in Figure 4, which also shows the atom labelling scheme used. Each anion occupies a general position within the unit cell of a triclinic space group $P\bar{1}$. Associated with each dinuclear anion are two protonated pyridine molecules. A central $\{Mo_2O_4\}^{2+}$ structural core may be recognized with typical geometric parameters.[3] There are two pairs of terminal and bridging oxo ligands with Mo=O and Mo–O(μ_2) distances in the ranges 1.674(4)–1.679(4) and 1.938(8)–1.949(4) Å, respectively. The terminal oxo groups are bent away from each other. The Mo–Mo bond length of 2.5902(6) Å corresponds to a single metal–metal bond. The Mo(μ_2-O)$_2$Mo ring is not planar, but is folded by 146.01(10)° around the vector connecting the bridging oxygen atoms. The puckering of the Mo(μ_2-O)$_2$Mo ring is presumably a means of allowing a close approach of the metal atoms. A pair of chloro ligands and a methanol *trans* to the terminal oxo group complete a distorted octahedral geometry about each metal atom. The molybdenum-to-methanol oxygen bond lengths are, as expected for bonds in this position, relatively long [2.351(4) and 2.372(4) Å]. Pairs of coor-

dinated methanol molecules are oriented with their O–H termini pointing in the opposite directions. Although the entire anion belongs to the asymmetric unit, it comes very close to having C_2 symmetry.

Structures of the Orthorhombic Modifications of $(PyH)_2[Mo_2O_4Cl_4(MeOH)_2]$ (4) and $(PyH)_2[Mo_2O_4Br_4(MeOH)_2]$ (5)

The structures of the orthorhombic modifications of $(PyH)_2[Mo_2O_4X_4(MeOH)_2]$ (X = Cl, Br) are isotypic. Only one half of the anion belongs to the asymmetric unit, the other half being generated by a crystallographic twofold rotation axis, which passes along the Mo=O vectors through the centre of the Mo(μ_2-O)$_2$Mo rhombus. The relevant geometric parameters for the inner coordination spheres for **4** and **5** are given in Table 3. The dimensions of the anion in **4** compare very well with those in **3**.

Comparison of the Structures of Triclinic (3) and Orthorhombic Modification of $(PyH)_2[Mo_2O_4X_4(MeOH)_2]$ [X = Cl (4) and X = Br (5)]

The differences between the two modifications arise in the hydrogen-bonding pattern. The intermolecular hydrogen bonds are formed in both polymorphs between methanol and halo ligands. Two donors of hydrogen bonds in each anion, i.e., a pair of coordinated methanol molecules, are matched with two acceptors, two out of four halo ligands. Therefore each anion forms four hydrogen bonds, in the triclinic modification with two neighbouring anions, while in the orthorhombic modification with four. In the triclinic polymorph one chloro ligand, labelled Cl(11), and the methanol coordinated to the same molybdenum atom of the $\{Mo_2O_4\}^{2+}$ unit form two hydrogen bonds to the methanol and chloro ligand of the closest neighbouring anion (Figure 5), the corresponding O(5)···Cl(11)a distances are 3.176(4) Å [(*a*) 1 – *x*, –*y*, –*z*]. Similarly, Cl(22) and the methanol coordinated to the other molybdenum atom of the dinuclear anion also form two hydrogen bonds with their closest neighbour, the corresponding O(6)···Cl(22)b distances are 3.191(4) Å [(*b*) 2 – *x*, 1 – *y*, 1 – *z*]. A linkage of each anion with two neighbours produces infinite chains that propagate along the unit cell body diagonal. The engagement of two chloro ligands in hydrogen bonds accounts for the variations in the molybdenum-to-chlorine bond lengths: the chloro ligand involved in the hydrogen bond binds to molybdenum at a longer distance, i.e., Mo(1)–Cl(11) = 2.4839(12) Å and Mo(2)–Cl(22) = 2.4779(12) Å vs. Mo(1)–Cl(12) = 2.4419(13) Å and Mo(2)–Cl(21) = 2.4454(13) Å. In the orthorhombic polymorph each anion forms four hydrogen bonds, with lengths of 3.2925(18) Å, to four adjacent anions (Figure 6). Such a connectivity results in infinite layers parallel to the *ab* plane. The engagement of two out of four coordinated chloro ligands in hydrogen bonds is again reflected in the molybdenum-to-chlorine bond lengths, i.e., 2.4765(6) vs. 2.4462(6) Å. By analogy, **5** displays a non-equivalence of the molybdenum-to-bromine bond lengths, 2.6304(5) vs. 2.5995(5) Å.

It can also be observed that the molybdenum-to-chlorine bond lengths in **3** and **4** are similar to those determined for the aqua-ligated ion $[Mo_2O_4Cl_4(H_2O)_2]^{2-}$ [2.453(2) and 2.475(2) Å][21] or the very similar $[Mo_2O_4Cl_3(H_2O)_3]^-$ [2.434(2)–2.450(2) Å],[22] and are longer than in their base-free analogue, $[Mo_2O_4Cl_4]^{2-}$, where the distances are 2.392(6)–2.407(6) Å for the $[As(C_6H_5)_4]^+$ salt[23] or 2.352(4)–2.391(3) Å for $(Ph_3P{=}N{=}PPh_3)(Et_3NH)$-$[Mo_2O_4Cl_4]$.[24] The decrease in the bond lengths in the $[Mo_2O_4Cl_4]^{2-}$ ions with five-coordinate metal atoms is fully in agreement with the reasonable expectation of the increased bond strengths to other ligands when the sixth ligand is absent. The molybdenum-to-bromine bonds in **5** are longer than those determined for $[Mo_4O_8(OEt)_2Br_2Py_4]$ [2.5355(11)–2.5747(10) Å][12a] or mononuclear $(PyH)_5$-$[MoOBr_4(H_2O)]_3Br_2$ [2.498(4)–2.563(4) Å].[16]

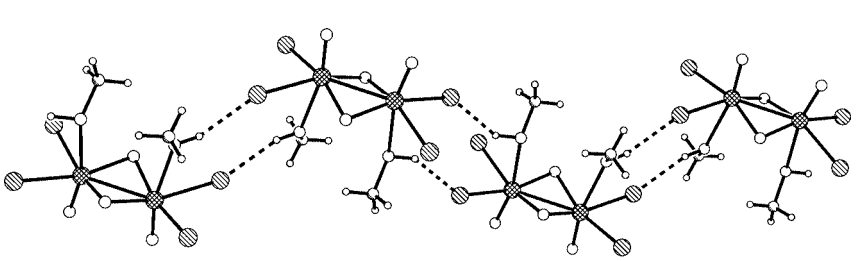

Figure 5. Hydrogen bonds in **3**: pairs of O(methanol)···Cl interactions link dinuclear anions into infinite chains.

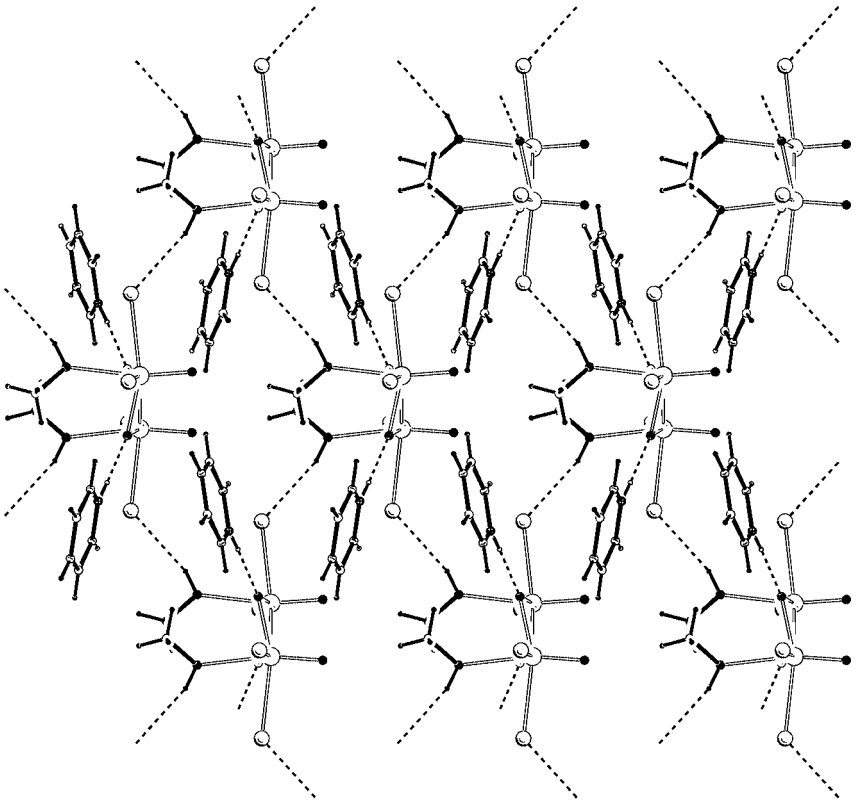

Figure 6. Hydrogen bonds in **4** and **5**: four O(methanol)···X interactions link each anion to four adjacent anions to form infinite layers perpendicular to the *c* axis.

The pyridinium cations are hydrogen bonded to the doubly-bridging oxygen atoms from the anions in both modifications (Figure 7). The corresponding N···O distances are 2.7001(60)–2.7031(62) Å for **3**, 2.6799(27) Å for **4** and 2.7329(45) Å for **5**.

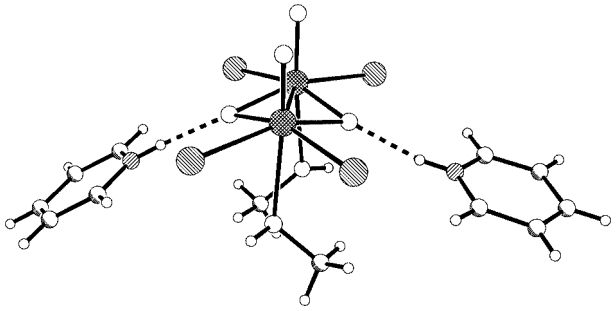

Figure 7. A dinuclear anion in **5** with a pair of hydrogen-bonded pyridinium cations.

Structure of $(PyH)_2[Mo_4O_8(OMe)_2(MeOH)_2Br_4]$ (6)

The structure of compound **6** is similar to its three, already described, analogues $(PyH)_2[Mo_4O_8(OMe)_2(MeOH)_2Cl_4]$ and $(PyH)_2[Mo_4O_8(OEt)_2(EtOH)_2X_4]$ (X = Cl and Br).[12a] It consists of pyridinium cations and tetranuclear anions (Figure 8). Selected geometric parameters are given in Table 4. The centrosymmetric tetranuclear core may be envisioned as two $\{Mo_2O_4\}^{2+}$ units sharing a pair of bridging oxo groups and being linked, in addition, by two methoxide ions (Scheme 2). The six peripheral positions of the $\{Mo_4O_4(\mu_3\text{-}O)_2(\mu_2\text{-}O)_2(\mu_2\text{-}OMe)_2\}^{2+}$ core are occupied by two methanol molecules at 2.2046(28) Å and four bromo ligands, two at shorter distances [2.5709(5) Å] and two at longer distances [2.5923(5) Å]. Methanol is engaged in a hydrogen-bonding interaction with the neighbouring bromo ligand at a distance of 3.2050(30) Å. This hydrogen bond contributes substantially to the stability of **6**. The hydrogen bond accounts for the variations in the molybdenum-to-bromine bond lengths. The pyridinium cations and the anionic clusters are linked, as observed before, through the agency of hydrogen bonds of moderate

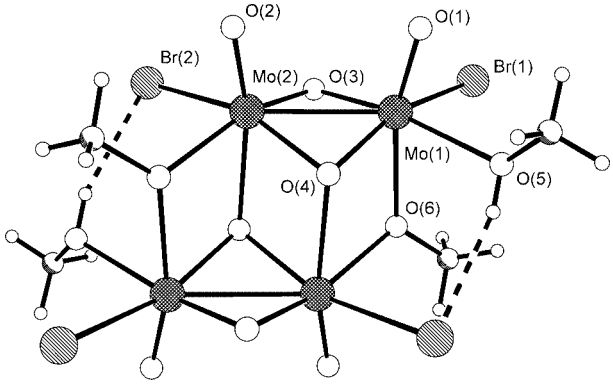

Figure 8. A drawing of the tetranuclear $[Mo_4O_8(OMe)_2(MeOH)_2Br_4]^{2-}$ unit in **6**. Hydrogen bonds between methanol and bromo ligands are drawn as dashed lines.

Comments on the Methanol Ligation

Structurally characterised alcohol complexes of molybdenum(V) are relatively rare. Invariably, these are all rather unstable species, in spite of the fact that in most cases the coordinated alcohol is involved in intra- or intermolecular hydrogen-bonding interactions through which some stability is gained. The only structurally characterised mononuclear complex is a very unstable $[MoOCl_3(EtOH)]$ with a square-pyramidal geometry and ethanol *cis* to the strongly bound terminal oxo group.[25] Likewise, the alcohol adopts *cis* positions with respect to the molybdenyl group in a series of dinuclear complexes with the composition $[Mo_2O_4L_2(ROH)_2]$ (L = β′-hydroxy-β-enaminone; R = Me, Et, *i*Pr),[26] tetranuclear $[(Mo_2O_4)_2(OMe)_2(MeOH)_2[HB(pz)_3]_2]$ [$HB(pz)_3^-$ = hydrotris(pyrazolyl)borate],[27] and octanuclear $[(Mo_2O_4)_4(OMe)_6(MeOH)_4Cl_2]$.[4] However, the position of ethanol in $[Mo_2O_2Cl_4(\mu_2\text{-}OEt)_2(\mu_2\text{-}EtOH)]$, where it also serves as a third bridge between metal atoms, is *trans* to both Mo=O groups.[28] The extreme reactivity of the latter complex was further exploited in the preparation of $[Mo_4O_6(OEt)_4(EtOH)_2Cl_4]$[24] and $[Mo_8O_{12}(OH)_6(OEt)_4(EtOH)_4Cl_6]$,[29] which both retain ethanol ligands on their periphery. The methanol ligands in the anions of $(PyH)_2[MoOCl_4(MeOH)]Cl$ (**2**), $(PyH)_2[Mo_2O_4Cl_4(MeOH)_2]$ (**3** and **4**) and $(PyH)_2[Mo_2O_4Br_4(MeOH)_2]$ (**5**) are *trans* to the terminal oxo groups. Owing to the *trans* influence of the latter, the methanol ligand binds at a longer distance. The corresponding bond in **2** is somewhat short taking into account its position. Comparison of the molybdenum-to-alcohol bond lengths in various molybdenum(V) compounds (Table 5) reveals that these can be as long as 2.49 Å or as short as 2.10 Å. The former describes a situation with the alcohol ligand in *trans*, and the latter with the alcohol ligand in the *cis* position with respect to the Mo=O group.

Table 5. Molybdenum-to-alcohol bond lengths [Å] in a series of molybdenum(V) compounds.[a]

Vibrational Spectroscopy

The presence of a terminal metal–oxygen double bond can be correlated with a stretching frequency in the range 1020–940 cm^{-1}.[3,31] The spectrum of $(PyH)_5[MoOCl_4(H_2O)]_3Cl_2$ (**1**) reveals a strong absorption at 982 cm^{-1}. A related compound, the bis(ethylenedithio)tetrathiafulvalene salt of $[MoOCl_4(H_2O)]^-$, displays the Mo=O stretch at 974 cm^{-1}.[17b] The spectra of compounds **2**, **3**, **5** and **6** display several strong bands in the region of 990–950 cm^{-1} which are associated with the Mo=O stretching frequencies.

The alcohol O–H stretching vibration is known to be sensitive to the involvement of the alcohol in hydrogen bonds. As a result, the band is shifted into a lower frequency region, to about 3300 cm^{-1}.[32] The spectrum of $(PyH)_2[Mo_4O_8(OMe)_2(MeOH)_2Br_4]$ (**6**) reveals a weak absorption at 3259 cm^{-1}, which may be attributed to the O–H stretching vibration. A band of medium intensity in a higher frequency region, at 3443 and 3431 cm^{-1}, is displayed in the spectra of $(PyH)_2[Mo_2O_4Cl_4(MeOH)_2]$ (**3**) and $(PyH)_2[Mo_2O_4Br_4(MeOH)_2]$ (**5**), respectively. Similarly, the O–H stretching mode in the spectrum of $[MoOCl_3(EtOH)]$ is also found at 3413 cm^{-1}.[25] Since considerable difficulties were experienced in recording the spectrum of $(PyH)_2[MoOCl_4(MeOH)]Cl$ (**2**), due to its decomposition, no conclusive assignments can be based upon it. Absorptions at 1002 cm^{-1} for **3**, 1003 cm^{-1} for **5** and 1026 cm^{-1} for **6** may be assigned to the C–O stretching vibrations. Their frequencies are consistent with the normally observed range (1075–1000 cm^{-1}).[32] The spectra of all methanol complexes, with **2** included, display a band of medium intensity in a narrow frequency range of 878–851 cm^{-1}. This absorp-

tion was tentatively ascribed to the methyl rocking vibration.

The Starting Oxohalomolybdates(V)

Although the simple oxohalomolybdates(v), i.e., the six-coordinate, octahedral $[MoOX_5]^{2-}$, $[MoOX_4L]^-$ and five-coordinate, square-pyramidal $[MoOX_4]^-$ (X = F, Cl, Br, I and L = H_2O, THF etc.) have been extensively studied for more than a century,[33] as far as our starting materials, $(PyH)_2[MoOCl_5]$ and $(PyH)[MoOBr_4]$, are concerned, neither their true identities nor their structures were known. The formulation of the former as $(PyH)_2[MoOCl_5]$ was clearly erroneous, as shown by the X-ray structure analysis of **1** which has disclosed that it consists of $[MoOCl_4(H_2O)]^-$ and not $[MoOCl_5]^{2-}$ ions. Since $(PyH)_5[MoOCl_4(H_2O)]_3Cl_2$ (**1**) was isolated from hydrochloric acid, this result is not surprising in view of the previous finding that the species formed on dissolving $(Et_4N)_2[MoOCl_5]$ or $[MoOCl_3]$ in concentrated aqueous hydrochloric acid is $[MoOCl_4(H_2O)]^-$ and not $[MoOCl_5]^{2-}$,[34] as generally supposed.

Contrary to the well-defined geometry of $[MoOX_4L]^-$ ions, there has been considerable ambiguity concerning the structures of the base-free $[MoOX_4]^-$ ions. The metal displays a marked tendency to extend its coordination number to six, for instance by coordinating to water, so the square-pyramidal $[MoOX_4]^-$ ions are unstable in the presence of moisture, unless protected by bulky cations.[35] The sixfold coordination can also be achieved through straight Mo=O···Mo or bent Mo–X···Mo interactions, which result in pair-wise associations or infinite chains. Isopropylideneiminium[36] and trifluoroacetamidinium[37] salts of $[MoOCl_4]^-$ actually exist in the solid state as dimeric $[MoOCl_4]_2^{2-}$ anions where two asymmetric chloro bridges link a pair of molybdenum atoms. In the infinite anionic chains of $[Te_{15}X_4]_n[MoOX_4]_{2n}$ (X = Cl, Br), short, formally Mo=O double bonds with lengths of about 1.63 Å alternate with weaker, longer Mo–O bonds with lengths of around 2.41 Å.[38] On the other hand, the linkage of square-pyramids via asymmetric chloro bridges in $K[MoOCl_4]$ produces infinite zig-zag chains.[39] The presence of the sixth ligand, for instance base L in $[MoOX_4L]^-$, has the effect of altering the strength of the Mo=O bond, and this is reflected in the position of the Mo=O stretching frequency.[40] Consequently, the shift in the Mo=O stretching frequency due to the Mo=O···Mo interaction is even more pronounced. The absorption at 883 cm^{-1} in the infrared spectrum of $(PyH)[MoOBr_4]$ strongly indicates a polymeric chain structure via Mo=O···Mo interactions.[13,41] Support for this also comes from the infrared spectrum of $(PyH)_2[Mo_2O_4Cl_4]\cdot 3H_2O$ whose X-ray structure reveals chains of dinuclear $[Mo_2O_4Cl_4]^{2-}$ ions linked via Mo=O···Mo interactions.[42] The Mo–O stretching band for $(PyH)_2[Mo_2O_4Cl_4]\cdot 3H_2O$ is observed at 888 cm^{-1}.

Synthetic Considerations

The green colour of the solution obtained upon dissolving $(PyH)_5[MoOCl_4(H_2O)]_3Cl_2$ (**1**) in methanol does not suggest a substantial extent of dimerisation. Undisputedly, the first reaction upon dissolving the $[MoOCl_4(H_2O)]^-$ ion in methanol is the substitution of the coordinated water for methanol, which is present in huge excess. The product of this reaction, $[MoOCl_4(MeOH)]^-$, is a labile species, which reacts with atmospheric moisture almost instantaneously. If the solution whose preparation is described in the synthetic procedure for **2** is exposed to air after the addition of diethyl ether, it undergoes a rapid colour change from green to orange. The evaporation of solvents in air produces a substantial amount of orange crystals, which were identified by X-ray diffraction as a triclinic modification of $(PyH)_2[Mo_2O_4Cl_4(MeOH)_2]$ (**3**), within a couple of hours. Overnight evaporation leaves behind a solid residue which consists mainly of large, needle-like crystals of the starting material $(PyH)_5[MoOCl_4(H_2O)]_3Cl_2$ (**1**), and an unidentified, dark blue, amorphous phase. The taking-up of water from the atmosphere by $[MoOCl_4(MeOH)]^-$ and the subsequent deposition of $(PyH)_5[MoOCl_4(H_2O)]_3Cl_2$ (**1**) as the final product, is not surprising. As far as the formation and the fate of the intermediate product, $(PyH)_2[Mo_2O_4Cl_4(MeOH)_2]$ (**3**), are concerned, both are unclear. Bearing in mind that no substantial dimerisation takes place in methanol, it is likely that water from the atmosphere triggers the dimerisation. Since $[Mo_2O_4Cl_4(MeOH)_2]^{2-}$ still possesses labile sites, four chloro and two methanol ligands, further substitution reactions are initiated and accompanied by partial oxidation to the +6 oxidation state, which results in a blue material. Addition of a stoichiometric amount of pyridine or trifluoroacetate to a methanol solution of $[MoOCl_4(H_2O)]^-$ was shown to promote the dimerisation and $(PyH)_2[Mo_2O_4Cl_4(MeOH)_2]$ (**3** and **4**) was isolated. On prolonged reaction times further assembly of $\{Mo_2O_4\}^{2+}$ units into $\{Mo_4O_4(\mu_3\text{-}O)_2(\mu_2\text{-}O)_2(\mu_2\text{-}OMe)_2\}^{2+}$ core (Scheme 2), found in the final product $(PyH)_2[Mo_4O_8(OMe)_2(MeOH)_2Cl_4]$, was observed. The latter process can be avoided by keeping the reaction temperature at 5 °C. Addition of a larger amount of pyridine yields $[Mo_4O_8(OMe)_2Cl_2Py_4]$. Pyridine advances the assembly of dinuclear units and once its concentration is high enough, it coordinates to four out of six terminal positions of the $\{Mo_4O_4(\mu_3\text{-}O)_2(\mu_2\text{-}O)_2(\mu_2\text{-}OMe)_2\}^{2+}$ core.

With the greater lability of the coordinated bromo ligands, the chances of isolating one of the more reactive intermediates are significantly smaller. Rather, the substitution tends to proceed further than in the case of the chloro starting material. Accordingly, the mononuclear $[MoOBr_4(MeOH)]^-$ could not be isolated under analogous conditions to those employed for $[MoOCl_4(MeOH)]^-$. $(PyH)_2[Mo_2O_4Br_4(MeOH)_2]$ (**5**) can only be isolated at 5 °C after the addition of trifluoroacetate to the methanol solution. At room temperature, further assembly of dinuclear subunits takes place with the formation of $(PyH)_2[Mo_4O_8(OMe)_2(MeOH)_2Br_4]$ (**6**) as the final product. The greater reactivity of the bromo-coordinated species is also demonstrated by the reaction where a small amount of pyridine was added to a methanol solution of $(PyH)[MoOBr_4]$, which produced $(PyH)_2[Mo_4O_8(OMe)_2(MeOH)_2Br_4]$ (**6**)

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

even at low temperature. $(PyH)_2[Mo_4O_8(OMe)_2(MeOH)_2Br_4]$ (**6**) is the first relatively stable bromo-coordinated species.

Similar compounds to ours have been obtained under strictly anhydrous conditions and temperatures as low as –78 °C from reactions of molybdenum(v) chloride in methanol.[43] The methanolysis of the Mo–Cl bonds was proposed to take place in step with successive formation of Mo=O bonds.[44] The formulae of the products, inferred from the elemental analysis data, are highly reminiscent of our methanol complexes. In particular, this applies to the green product of the reaction of $MoOCl_3$·2MeOH with pyridinium chloride in methanol at –78 °C, formulated as (PyH)[$MoOCl_4$]·MeOH, and the red, crystalline (PyH)[MoO_2Cl_2]·MeOH obtained from the reaction of $MoCl_5$ with pyridine in methanol.[43] The composition of the former resembles that of $(PyH)_2[MoOCl_4(MeOH)]Cl$ (**2**), while the composition of the latter is the same as for $(PyH)_2[Mo_2O_4Cl_4(MeOH)_2]$ (**3**). The lack of spectroscopic data precludes unambiguous conclusions about their true identity, although it can be reasonably expected that both molybdenum(v) chloride and $(PyH)_5[MoOCl_4(H_2O)]_3Cl_2$ (**1**) would react in methanol with the formation of species with, if not exact, at least similar compositions. Irrespective of the starting material, the reactive fragments released in the first stages of the reaction reassemble with the formation of the most stable and least soluble species under the given conditions. In a more recent study of the molybdenum(v) chloride reactions in rigorously dried ethanol, $[MoOCl_3(EtOH)]$, H[$MoOCl_4$]·2EtOH,[25] and $[Mo_2O_2Cl_4(\mu_2\text{-}OEt)_2(\mu_2\text{-}EtOH)]$,[28] were isolated as the very first products, as confirmed by X-ray diffraction analyses. $[Mo_2O_2Cl_4(\mu_2\text{-}OEt)_2(\mu_2\text{-}EtOH)]$, which possesses several good leaving groups, reacts readily to form $[Mo_2O_4Cl_4]^{2-}$ and a series of $\{Mo_2O_2(\mu_2\text{-}O)(\mu_2\text{-}OEt)\}^{3+}$-containing clusters.[24,29] Interestingly, the same structural types are encountered within the $\{Mo_2O_2(\mu_2\text{-}O)(\mu_2\text{-}OEt)\}^{3+}$ clusters as in the larger group of $\{Mo_2O_4\}^{2+}$ clusters. Moreover, hydrogen chloride and chloroethane were found to be side products in the ethanolysis of Mo–Cl bonds. The proposed mechanisms of the formation of Mo–O and Mo–OR bonds cannot be applied to our reaction system as no attempts were made to avoid traces of water. In view of the high susceptibility of $[MoOX_4]^-$ and $[MoOX_4L]^-$ species towards hydrolysis, the role of water inherently present in the used solvents has to be acknowledged. The comparison with the two above-mentioned systems is therefore limited to the nature of the obtained products only.

Conclusions

Facile substitution chemistry of mononuclear $[MoOCl_4(H_2O)]^-$ or polymeric $[MoOBr_4]_n^{n-}$ in methanol solutions has afforded a series of novel molybdenum(v) complexes with coordinated methanol: a mononuclear anion in $(PyH)_2[MoOCl_4(MeOH)]Cl$ (**2**), a dinuclear $\{Mo_2O_4\}^{2+}$-based anion in $(PyH)_2[Mo_2O_4Cl_4(MeOH)_2]$, which crystallises in a triclinic (**3**) and in an orthorhombic (**4**) unit cell, an analogous bromo-coordinated dinuclear anion in $(PyH)_2[Mo_2O_4Br_4(MeOH)_2]$ (**5**) and a tetranuclear anion built of two $\{Mo_2O_4\}^{2+}$ subunits in $(PyH)_2[Mo_4O_8(OMe)_2(MeOH)_2Br_4]$ (**6**). The coordinated methanol molecule invites further investigations as a potentially functional and highly labile group. Such studies are underway.

Experimental Section

General Remarks: Reagents were purchased from Aldrich. No precaution was taken to eliminate traces of moisture present in solvents. The IR spectra were measured on solid samples as Nujol or poly(chlorotrifluoroethylene) mulls using a Perkin–Elmer 2000 series FT-IR spectrometer. Elemental analyses were performed by the Chemistry Department service at the University of Ljubljana. Molybdenum was determined as $PbMoO_4$ and halide by potentiometric titration with a 0.100 M solution of $AgNO_3$.

(PyH)[$MoOBr_4$]: Finely powdered $(NH_4)_2[MoBr_5(H_2O)]$[45] (2.75 g, 5.0 mmol) was added to a mixture of pyridine (0.8 mL) and conc. hydrobromic acid (25 mL). The solution was gently heated at about 80 °C until all solid material had been consumed. Hydrazinum dichloride (0.50 g, 4.76 mmol) was added and the reaction mixture was heated for another five minutes. Meanwhile its colour changed from brown to yellow-red. The obtained solution was left to stand at ambient conditions. The red, block-shaped, crystals that formed overnight were filtered off and washed with hexanes. Yield: 32% (820 mg, 1.6 mmol). IR: $\tilde{\nu}$ = 1627 cm^{-1} (s), 1597 (vs), 1530 (vvs), 1321 (s), 1229 (w), 1195(m), 1164 (m), 1047 (m), 974 (w), 883 (vvs), 747 (m), 731 (vvs), 664 (vvs). $C_5H_6Br_4MoNO$ (511.65): calcd. C 11.74, H 1.18, Br 62.47, Mo 18.75, N 2.74; found C 11.51, H 1.30, Br 62.3, Mo 18.6, N 2.69.

$(PyH)_5[MoOCl_4(H_2O)]_3Cl_2$ (1): This synthetic procedure combines two literature approaches to related compounds.[46] A mixture of conc. hydrochloric acid (12.5 mL) and hydriodic acid (3.5 mL) was added to a 1.0 M solution of molybdenum(VI) oxide in conc. hydrochloric acid (25 mL). The reaction mixture was heated in an open flask until all iodine had been driven off. A mixture of pyridine (6.3 mL) and conc. hydrochloric acid (35 mL) was added, the flask was stoppered and left in an ice bath for two hours. Emerald-green, needle-shaped crystals of **1** were filtered off and washed with hexanes. Yield: 82% (8.80 g, 6.84 mmol). IR: $\tilde{\nu}$ = 3195 cm^{-1} (w), 3146 (w), 3126 (w), 3088 (w), 1631 (m), 1598 (vs), 1525 (vs), 1237 (m), 1196 (m), 1164 (m), 1078 (w), 1047 (m), 1027 (w), 982 (vvs), 905 (m), 749 (vvs), 722 (m), 677 (vvs). $C_{25}H_{36}Cl_{14}Mo_3N_5O_6$ (1286.7): calcd. C 23.34, H 2.82, Cl 38.57, Mo 22.37, N 5.44; found C 23.45, H 2.74, Cl 38.4, Mo 22.3, N 5.37.

$(PyH)_2[MoOCl_4(MeOH)]Cl$ (2): $(PyH)_5[MoOCl_4(H_2O)]_3Cl_2$ (**1**; 400 mg, 0.311 mmol) was dissolved in methanol (4.0 mL). The solution was kept in a stoppered Erlenmeyer flask at ambient conditions overnight. Diethyl ether (8.5 mL) was added dropwise with constant stirring. After the addition of diethyl ether, the colour of the solution changed from yellow-green to light-green. Within one hour large, plate-like crystals of **2** started to grow from the solution. *Note.* The crystals of **2** decompose almost instantaneously when taken out from the mother liquor. IR: $\tilde{\nu}$ = 3207 cm^{-1} (w), 3145 (w), 1632 (m), 1599 (s), 1526 (s), 1322 (m), 1237 (m), 1190 (m), 1164 (m), 1079 (w), 1050 (m), 1056 (m), 1030 (m), 982 (s), 962 (vs), 851 (m), 748 (vs), 729 (vs), 669 (vs), 608 (s).

Triclinic (3) and Orthorhombic (4) Modifications of $(PyH)_2[Mo_2O_4Cl_4(MeOH)_2]$. Procedure a: $(PyH)_5[MoOCl_4(H_2O)]_3Cl_2$ (**1**; 400 mg, 0.311 mmol) was dissolved in methanol (4.0 mL). Pyridine (1.20 mmol; 2.4 mL of a 0.50 M pyridine solution in methanol) was added to the solution. The colour changed immediately from yellow-green to brown-orange. The Erlenmeyer flask was stoppered and left at ambient conditions for three hours. Orange crystals of **3** could then be filtered off. Yield: 40% (116 mg, 0.187 mmol). IR: $\tilde{\nu}$ = 3611 cm^{-1} (w), 3552 (w), 3443 (m), 3411 (w), 3129 (w), 3107 (w), 3082(w), 3059 (w), 1634 (m), 1615 (m), 1592 (m), 1541 (m), 1484 (vvs), 1253 (m), 1200 (s), 1167 (m), 1103 (m), 1095 (w), 1061 (w), 1051 (w), 1002 (vvs), 986 (vvs), 964 (vvs), 950 (m), 878 (m), 760 (vs), 750 (vvs), 743 (vvs), 735(vvs), 728 (vvs), 681 (vs), 607 (s), 503 (s). *Note.* If the reaction mixture was left at ambient conditions overnight, red, block-like crystals formed. The product revealed an infrared spectrum identical to that described for $(PyH)_2[Mo_4O_8(OMe)_2(MeOH)_2Cl_4]$.[12a] Yield: 41% (91 mg, 0.097 mmol). IR: $\tilde{\nu}$ = 3232 cm^{-1} (m), 3159 (w), 3129 (w), 3105 (w), 3085 (w), 3062 (w), 1635 (vs), 1610 (vvs), 1537 (vvs), 1251 (m), 1201 (s), 1164 (s), 1113 (m), 1032 (vvs), 1002 (vvs), 966 (vvs), 946 (vvs), 878 (w), 755 (vvs), 725 (vvs).

Procedure b: Pyridinium trifluoroacetate (1.20 mmol; 1.0 mL of a 1.20 M solution in acetonitrile) was added to methanol (4.0 mL). $(PyH)_5[MoOCl_4(H_2O)]_3Cl_2$ (**1**; 400 mg, 0.311 mmol) was dissolved in this solution. The orange-brown reaction mixture was left in a closed flask at ambient conditions overnight. A vial containing diethyl ether (2.5 mL) was carefully placed into the flask on the following day. The flask was stoppered and placed in the refrigerator. Orange, rhombic crystals of $(PyH)_2[Mo_2O_4Cl_4(MeOH)_2]$ (triclinic modification **3**) and red, block-shaped crystals of $(PyH)_2[Mo_2O_4Cl_4(MeOH)_2]$ (orthorhombic modification **4**) grew from the solution within 24 hours.

Addition of a Larger Amount of Pyridine to a Methanol Solution of $(PyH)_5[MoOCl_4(H_2O)]_3Cl_2$ (1): $(PyH)_5[MoOCl_4(H_2O)]_3Cl_2$ (**1**; 400 mg, 0.311 mmol) was dissolved in methanol (4.0 mL). After the addition of 12.3 mmol of pyridine (1.0 mL) to the yellow-green solution, its colour changed to brown-orange. The Erlenmeyer flask was stoppered and left at ambient conditions for five hours. A red, crystalline product was filtered off and washed with hexanes. The product revealed an infrared spectrum identical to that described for $[Mo_4O_8(OMe)_2Cl_2Py_4]$.[12f] Yield: 91% (205 mg, 0.213 mmol). IR: $\tilde{\nu}$ = 3391 cm^{-1} (m), 3067 (w), 2788 (m), 1636 (w), 1607 (vvs), 1571 (w), 1540 (w), 1362 (w), 1303 (w), 1246 (w), 1222 (vs), 1164 (m), 1154 (m), 1076 (vvs), 1044 (vvs), 1024 (vvs), 954 (vvs), 933 (vvs), 921 (vvs), 875 (w), 757 (vvs), 744 (vvs).

$(PyH)_2[Mo_2O_4Br_4(MeOH)_2]$ (5): Pyridinium trifluoroacetate (1.20 mmol; 1.0 mL of a 1.20 M solution in acetonitrile) was added to methanol (4.0 mL) in an Erlenmeyer flask. $(PyH)[MoOBr_4]$ (480 mg, 0.94 mmol) was dissolved in this solution. The orange-red solution was immediately placed in the refrigerator (5 °C). Diethyl ether (2.5 mL) was carefully added to the solution on the following day. The reaction mixture was placed back in the refrigerator and after two days a second portion of diethyl ether (4.5 mL) was added. Red, block-shaped crystals of **5** appeared within six hours. *Note.* The crystals are not stable outside the mother liquor. IR: $\tilde{\nu}$ = 3611 cm^{-1} (w), 3563 (w), 3431 (m), 3127 (w), 3101 (w), 3083 (w), 3062 (m), 3059 (w), 2924 (m), 2856 (m), 1625 (vs), 1613 (vs), 1592 (s), 1537 (s), 1483 (vs), 1253 (w), 1200 (m), 1194 (m), 1164 (m), 1093 (w), 1060(m), 1051 (m), 1003 (s), 971 (vvs), 953 (vs), 876 (w), 755 (vs), 718 (vvs), 679 (vs), 606 (s), 490 (s).

$(PyH)_2[Mo_4O_8(OMe)_2(MeOH)_2Br_4]$ (6). Procedure a: The same procedure was used as for the preparation of compound **5**, only the reaction mixture was left to stand at ambient conditions. Pyridinium trifluoroacetate (1.20 mmol; 1.0 mL of a 1.20 M solution in acetonitrile) was added to methanol (4.0 mL) in an Erlenmeyer flask. $(PyH)[MoOBr_4]$ (480 mg, 0.94 mmol) was dissolved in this solution. The flask was stoppered and the orange-red reaction mixture was left to stand at ambient conditions for two days. A vial containing diethyl ether (5.0 mL) was carefully inserted into the flask. The flask was tightly stoppered and left at ambient conditions for two more days. Red, block-shaped crystals of **6** were filtered off and washed with hexanes. Yield: 53% (140 mg, 0.125 mmol).

Procedure b: $(PyH)[MoOBr_4]$ (480 mg, 0.94 mmol) was dissolved in methanol (4.0 mL) and pyridine (1.20 mmol; 2.4 mL of a 0.50 M solution in methanol) was then added. The orange-red solution was left at ambient conditions. A vial with diethyl ether (5.0 mL) was carefully inserted into the Erlenmeyer flask on the following day. Red, block-shaped crystals formed within two days. The product was filtered off and washed with hexanes. Yield: 39% (103 mg, 0.0921 mmol). *Note.* The same product, $(PyH)_2[Mo_4O_8(OMe)_2(MeOH)_2Br_4]$ (**6**), was obtained if the reaction mixture was kept at 5 °C the whole time. IR: $\tilde{\nu}$ = 3259 cm^{-1} (m), 3135 (w), 3132 (w),

C 15.04, H 2.34, Br 28.60, Mo 34.33, N 2.51; found C 15.12, H 2.42, Br 28.75, Mo 34.2, N 2.45.

X-ray Crystallographic Study: The crystals were mounted on the tip of a glass fibre with a small amount of silicon grease and transferred to a goniometer head. Data were collected with a Nonius Kappa CCD diffractometer. For all compounds, data reduction and integration were performed with the software package DENZO-SMN.[47] Averaging of the symmetry-equivalent reflections largely compensated for the absorption effects. The coordinates of some or all of the non-hydrogen atoms were found by direct methods using the structure solution program SHELXS.[48] The positions of the remaining non-hydrogen atoms were located by use of a combination of least-squares refinement and difference Fourier maps with the SHELXL-97 program.[48] Non-hydrogen atoms were refined with anisotropic displacement parameters. The water hydrogen atoms in **1**, hydroxyl methanol hydrogen atoms in **2**, **3**, **4** and **5** located in the final stages of the refinement from the difference Fourier maps were refined with isotropic displacement parameters. The remaining hydrogen atoms were included in the structure-factor calculations at idealised positions. Cell parameters and refinement results for compounds **1**–**6** are summarised in Table 6. Figures depicting the structures were prepared using SHELXTL[49] and PLATON.[50] CCDC-248502 (for **1**), -248503 (for **2**), -248504 (for **3**), -248505 (for **4**), -248506 (for **5**) and -248507 (for **6**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Acknowledgments

We are grateful to the Slovenian Ministry of Education, Science and Sport for supporting this work through research grant P1-0134. We also thank the same agency for funds to purchase the Nonius Kappa CCD diffractometer.

[41] (PyH)[$MoOBr_4$] crystallises in the shape of relatively large and well-formed, block-like crystals, yet these do not diffract well enough to allow a successful structure solution. Although the infrared spectrum reveals typical absorptions of pyridinium cations, apart from the clearly visible pattern of infinite $[MoOBr_4]_n^{n-}$ chains in the partial structure solution, the remaining residual electron density cannot be associated with pyridinium cations. Cell dimensions for (PyH)[$MoOBr_4$]: $a = b = 8.40$ Å, $c = 4.00$ Å, $\alpha = \beta = \gamma = 90°$, tetragonal (J. V. Brenčič, I. Leban, unpublished results).
[42] R. Mattes, D. Altmeppen, M. Fetzer, *Z. Naturforsch., Teil B* **1976**, *31*, 1356–1359. Similar problems were encountered during the X-ray structure solution as for (PyH)[$MoOBr_4$]: a clearly-visible pattern of anionic $[Mo_2O_4Cl_4]_n^{2n-}$ chains and no pyridinium cations.

Platinum Complexes with the Novel Ligand Diethyl [(Methylsulfinyl)-methyl]phosphonate (SMP): Solid-State Characterization of Potassium Trichloro(SMP)platinum(II) which, in Solution, Gives Dichloro(SMP)-platinum(II) and Potassium Chloride

Mariarita Laforgia,[a,b] Nicola Margiotta,[a] Francesco Capitelli,[c] Valerio Bertolasi,[d] and Giovanni Natile*[a,b]

Keywords: Bone tumors / NMR spectroscopy / Phosphonate / Platinum / X-ray crystallography

Phosphonate ligands have been employed in the synthesis of platinum complexes, which are active against bone tumors. The stability of a new compound of this family, $[PtCl_2(SMP)]$ {**1**; SMP = diethyl[(methylsulfinyl)methyl]phosphonate}, has been investigated in water and acetone. The compound is stable in aqueous solution where it undergoes only partial solvolysis that is completely repressed by addition of free chloride ions. However, crystallization of **1** from water/acetone/chloroform (0.2:1:1, v/v/v) containing an equimolar amount of KCl affords a new compound containing monodentate SMP {$K[PtCl_3(SMP\text{-}S)]$, **2**}. Dissolution of **2** in water or acetone restores **1**. The driving force in the formation of **2** appears to be the network of electrostatic interactions between cations and complex anions in the solid state. It is not only the detached P=O oxygen atom, but also the oxygen atom bound to the sulfur atom and a coordinated chloride ligand of the same platinum unit that interact rather strongly with the cation. It is expected that the same reaction (partial detachment of the phosphonate and anchoring of the cation) can take place in hypercalcaemic districts associated to bone tumors.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Platinum(II) complexes are excellent antitumor agents for the treatment of solid tumors, such as testicular, ovarian, and bladder carcinomas; but are much less effective towards other forms of cancer.[1]

We have recently reported on a new class of platinum(II) compounds, which have been designed for the treatment of bone tumors and the hypercalcaemia frequently associated with many cancer diseases.[2] These compounds contain the novel ligand diethyl [(methylsulfinyl)methyl]phosphonate (SMP); the sulfur atom of the sulfoxide and the oxygen atom doubly bonded to the phosphorus atom are the effective donor atoms for the metal ion. Multinuclear NMR spectroscopic data showed that the puckering of the five-membered chelate ring depends upon the configuration at the sulfur atom: δ puckering for the (*S*) configuration of the free ligand.

The use of phosphonate ligands for platinum is not new in the literature. The most representative examples are Keppler's aminobis(phosphonates), which coordinate to the metal ion through a tertiary nitrogen atom and one of the ionized hydroxy groups of the phosphonic acid.[3–6]

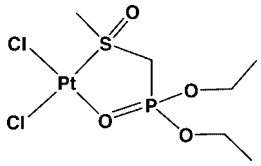
Our ligand was designed with the objective of increasing the chemical stability of the platinum compounds while retaining the selective tropism for bone tissue. The chemical stability could be increased by introducing a sulfoxide group with high coordination ability towards platinum ion in the phosphonate molecule. Moreover, in order to increase the lipophilicity of our compounds (a critical parameter for the crossing of the cell membrane), the free acid was converted into the diethyl ester derivative. The use of a phosphonic ester should not preclude the reaction between phosphonate groups and calcium ions of bone tissues, since it is known that phosphonic esters are partially hydrolyzed in vivo by several esterase enzymes present in the biological medium.[7]

Since the newly reported platinum complexes of formula $[PtL_2(SMP\text{-}O,S)]$ (where $L_2 = Cl_2$, dimethyl malonate, ethylenediamine, or 1,2-diaminocyclohexane) were the first in which a phosphonate group was coordinated to a platinum center through the oxygen atom doubly bonded to the phosphorus atom, we wanted to investigate the chemical stability of the Pt–O=P linkage under different experimen-

 DOI: 10.1002/ejic.200400842

tal conditions. Also, the possible hydrolysis of the P–O–Et bonds was considered.

The stability of $[PtCl_2(SMP)]$ (see Scheme 1) in pure water or in water containing 0.1 M chloride ions (a concentration comparable to that of a physiological extracellular medium) was monitored by ^1H, ^{31}P, and ^{195}Pt NMR spectroscopy.



Scheme 1. Shorthand drawing of the complex $[PtCl_2(SMP)]$ (**1**).

The X-ray structure of a crystallized species ($K[PtCl_3(SMP)]$) that is different from that present in solution is also reported.

Results and Discussion

Stability of $[PtCl_2(SMP)]$

Similarly to cisplatin,[8–10] the complex $[PtCl_2(SMP)]$ (**1**) undergoes solvation in aqueous solution. In the starting dichloro complex the methyl group linked to the sulfur atom gives rise to a doublet centered at δ = 3.67 ppm ($^4J_{H,P}$ = 2 Hz) with platinum satellites ($^3J_{H,Pt}$ = 18 Hz).[2] Soon after dissolution, another doublet, slightly shifted to lower field (δ = 3.73 ppm), appears and its intensity increases with time (see Figure 1). This is in agreement with the immediate formation of a monosolvated species obtained by release of the chloride ligand *trans* to the sulfoxide.[11] A second doublet (centered at δ = 3.70 ppm), of very low intensity and overlapping with one ^{195}Pt satellite of the dichloro species can be interpreted as evidence for a second solvato species. Detachment of the second chloride ligand and entering of another water molecule into the coordination sphere of the platinum ion is a possibility; however, because of the asymmetry of the SMP ligand, a second monoaqua species, in which the solvent molecule is *trans* to the phosphonate oxygen atom rather than to the sulfur atom, can be formed. Addition of potassium chloride to the NMR sample leads to regression of the hydrolysis products, as demonstrated by the immediate disappearance of the doublet at lower field.

A parallel investigation by ^{31}P NMR gave similar results. A new phosphorus signal (δ = 15.3 ppm), which appears close to the dominant signal of the starting dichloro species (δ = 15.8 ppm), indicates the formation of an aqua species.

The long-term stability of complex **1** in an aqueous solution containing a 0.1 M chloride concentration was also investigated. No changes in the ^1H, ^{31}P or ^{195}Pt NMR spectra were observed over a period of weeks, except for very weak ^1H and ^{31}P NMR signals belonging to free SMP appearing after three weeks. No intermediate species with monocoordinated SMP or products of the hydrolysis of the ester functions were detected.

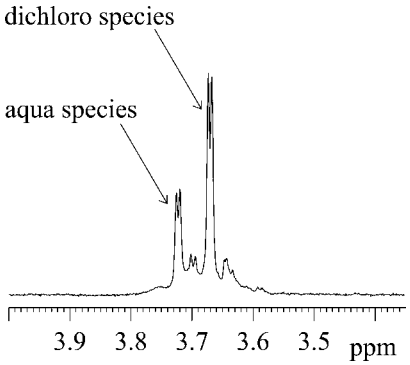


Figure 1. ^1H NMR signals in the region of methyl sulfoxide for complex **1** in aqueous solution, 24 h after dissolution. The signals at δ = 3.70 and 3.64 ppm are essentially ^{195}Pt-coupling satellites ($^3J_{H,Pt}$ = 18 Hz). One ^{195}Pt satellite is also visible for the monoaqua species at δ = 3.76 ppm.

In order to further check the stability of the Pt–O=P bond, we carried out an experiment in which an equimolar amount of potassium chloride was added to a sample of complex **1** in $[D_6]$acetone/D_2O (10:1, v/v; 5 mM concentration). Chloride ions are expected to be more nucleophilic in acetone since they are deprived of their hydration shell. However, no products of partial or complete detachment of the SMP ligand were detected in solution and the ^{31}P and ^{195}Pt NMR spectra still showed the pseudo-triplet (^{31}P) and doublet (^{195}Pt) characteristic of chelated SMP ($^2J_{P,Pt}$ = 90 Hz;[12] see Figure 2). Furthermore the ^1H NMR spectrum remained unchanged.

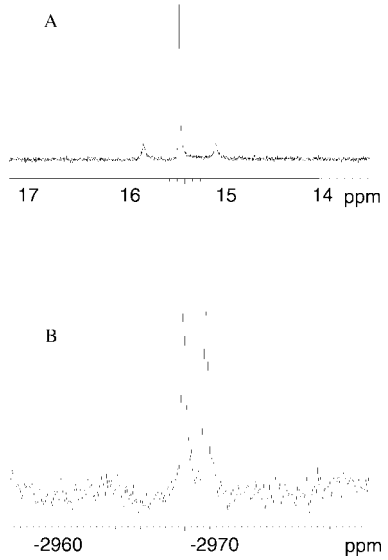

Figure 2. ^{31}P (121.5 MHz; A) and ^{195}Pt (64.3 MHz; B) NMR spectra of complex **1** in $[D_6]$acetone/D_2O solution (10:1, v/v) containing an equimolar amount of KCl.

However, rather unexpectedly, a crystalline orange product, **2**, was obtained by solvent evaporation from a solution of complex **1** and equimolar KCl in water/acetone/chloroform (0.2:1:1, v/v/v). The elemental analysis proved that the composition of the orange crystals corresponds to **1** + KCl. Moreover, the crystals of **2**, redissolved in acetone as well as in water, gave ^1H and ^{31}P NMR spectra perfectly

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

overlapping with those of complex **1** containing dicoordinated SMP. Therefore, both the elemental analyses and the NMR experiments confirmed that compound **2** is a product of the co-crystallization of **1** and KCl, and this was in complete agreement with previous observations indicating that complex **1** was perfectly stable in solutions containing free chloride ions. However, the crystal structure revealed that compound **2** is a new species with the formula K[$PtCl_3$(SMP-*S*)]. The details of the anion structure and of the cation/anion crystal packing will be described in a following section.

The [$PtCl_3$(SMP-*S*)]$^-$ anion can be formed from **1** by displacement of the oxygen atom doubly bonded to the phosphorus atom and coordination of a chloride ion. The greater lability of the Pt–O bond with respect to the Pt–S bond, as well as the greater thermodynamic stability of the Cl_3S set of donor atoms with respect to the Cl_2OS set, could both be leading factors in the formation of the [$PtCl_3$(SMP-*S*)]$^-$ anion. However, rather surprisingly, in solution a rapid ring-closure process restores the five-membered chelate and converts **2** back to **1** + KCl.

How can we explain the stability of the form with chelated SMP in a solution containing KCl and the stability of the form with semidetached SMP and coordinated chloride in the solid state? Certainly a key role must be played by the electrostatic interactions between cations and anions in the solid state and these were also elucidated from the X-ray data.

X-ray Structure of K[$PtCl_3$(SMP)]

A view of the molecular structure, together with the atomic numbering scheme, is given in Figure 3. Bond lengths and angles are reported in Table 1.

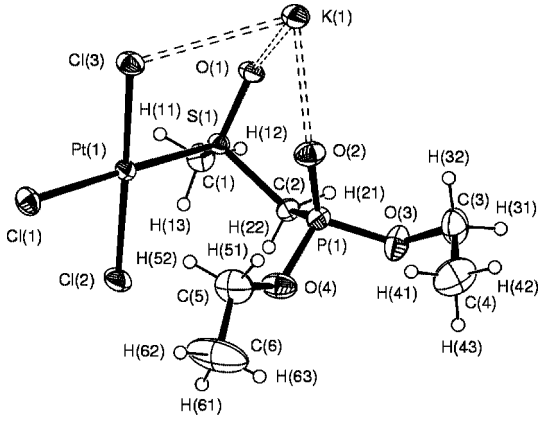

Figure 3. View of the asymmetric unit with the atomic numbering scheme for K[$PtCl_3$(SMP)] (**2**). Thermal ellipsoids enclose 30% probability.

There are no atoms in special positions. The platinum coordination geometry is square planar, with three chlorine atoms and one sulfur atom acting as donors. The four donors are coplanar within 0.06 Å and the platinum atom is displaced by only 0.017 Å from this plane.

C(5)–H5(1)	0.97		
C(5)–H5(2)	0.97		
C(6)–H(61)	0.96		
C(6)–H(62)	0.96		
C(6)–H(63)	0.96		

The three Pt–Cl bond lengths are very similar notwithstanding the greater *trans* effect expected for the sulfoxide ligand [2.310(1), 2.307(1), and 2.310(1) Å for Pt(1)–Cl(1), Pt(1)–Cl(2), and Pt(1)–Cl(3), respectively] and are in agreement with previously reported values for anionic [$PtCl_3$(sulfoxide)] complexes.[13–15]

Concerning the bond angles between *cis* ligands, the two Cl–Pt–Cl angles and one of the Cl–Pt–S angles are very close to 90° [Cl(1)–Pt(1)–Cl(2) = 88.98(4)°, Cl(1)–Pt(1)–Cl(3) = 88.01(4)°, Cl(2)–Pt(1)–S(1) = 89.35(4)°], while the second Cl–Pt–S angle is noticeably larger than 90° [Cl(3)–Pt(1)–S(1) = 93.65(4)°]. This is probably due to the steric interaction between Cl(3) and the sulfur-bound O(1). The O(1) atom practically lies on the platinum coordination plane [Cl(2)–Pt(1)–S(1)–O(1) and Cl(3)–Pt(1)–S(1)–O(1) torsion angles of 176.92(14)° and –4.71(15)°, respectively; see Figure 3] and, as a consequence, a repulsive interaction between the oxygen and Cl(3) atoms is expected. The same trend has been observed in analogous compounds with platinum-coordinated sulfoxides.[16–18]

The sulfur center is approximately tetrahedral; the greatest deviation from the ideal value is observed for the Pt(1)–S(1)–O(1) and C(1)–S(1)–C(2) angles [118.65(12)° and 98.79(21)°, respectively].

The phosphorus atom is also approximately tetrahedral with the greatest deviation for the O(3)–P(1)–C(2) angle [99.44(20)°]. The double bond character of P=O is confirmed by the short P(1)–O(2) distance [1.464(3) Å], which should be compared with the distances of the other two P–

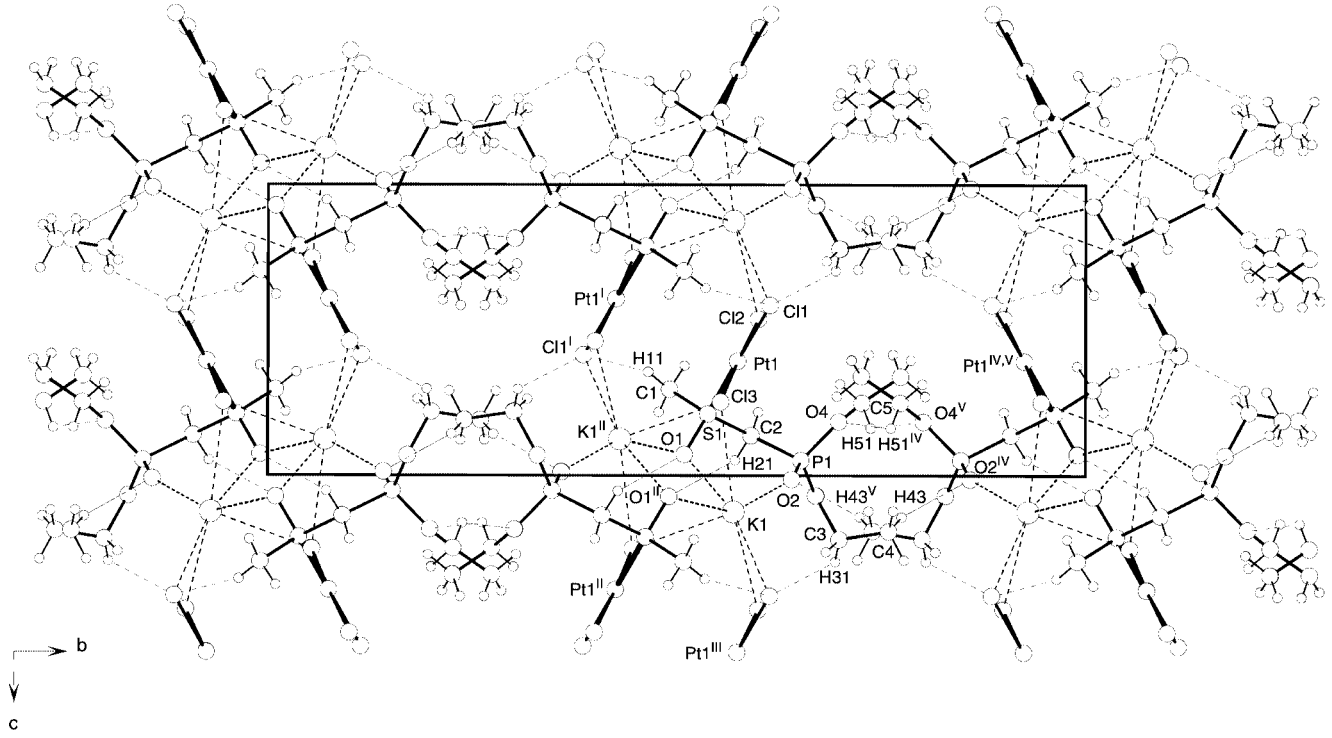

Figure 4. Crystal packing of K[$PtCl_3$(SMP)] (**2**). The numbering of atoms is given only for the fundamental asymmetric unit. The symmetry operations leading to the adjacent asymmetric units (I, II, III, IV, V) are indicated close to the platinum centers. The symmetry operations I, II, III, IV and V are defined as: I = –*x*, –*y*, 1 – *z*; II = 1 – *x*, –*y*, 2 – *z*; III = *x*, *y*, 1 + *z*; IV = 0.5 + *x*, –0.5 – *y*, *z*; V = –0.5 + *x*, –0.5 – *y*, *z*.

O bonds [1.560(4) and 1.556(3) Å for P(1)–O(3) and P(1)–O(4), respectively]. Finally, the S=O bond length of 1.477(3) Å is in good agreement with other reported crystallographic data.[19–21]

Crystal Packing

The three-dimensional network is constructed by pairs of quasi parallel $PtCl_3S$ moieties at a distance of ca. 4.05 Å (Pt1 and Pt1^{I} units in Figure 4). Only the methyl groups of the coordinated sulfoxides protrude in the space between the two coordination planes and the S–Me of each subunit creates an H-bond type interaction with a chlorine atom of the other subunit [C(1)···Cl(1)^{I} = 3.57(1) Å, H(11)···Cl(1)^{I} = 2.73(6) Å, C(1)–H(11)–Cl(1)^{I} = 155(5)°]. Within a pair, the two subunits are also held together by two potassium cations, which interact with Cl(3) and O(1) of one platinum subunit (Pt1) and with Cl(1) and Cl(2) of the second platinum subunit (Pt1^{I}). The same potassium cation also interacts with the Cl(3), O(1) and O(2) atoms of a platinum anion of an adjacent pair (see Pt1^{II} in Figure 4). In this way each potassium cation results trapped in an irregular 7-donor cage formed by four chlorine and three oxygen atoms (the K···Cl and K···O distances are given in the caption to Figure 5).

Adjacent pairs are linked by two K cations (for instance K1 and K1^{II} in Figure 4) and four H-bond type interactions between Cl(1)^{I}, O(1), C(2), and C(3) atoms of one pair and the C(3)^{II}, C(2)^{II}, O(1)^{II}, and Cl(1)^{III} atoms of the adjacent pair, respectively [Cl(1)^{I}···C(3)^{II} = 3.60(1) Å, Cl(1)^{I}···H(31)^{II} = 2.78(0) Å, Cl(1)^{I}–H(31)^{II}–C(3)^{II} = 142(0)°; O(1)···C(2)^{II} = 3.48(1) Å, O(1)···H(21)^{II} = 2.54(4) Å, O(1)–H(21)^{II}–C(2)^{II} = 156(3)°; C(2)···O(1)^{II} = 3.48(1) Å, H(21)···O(1)^{II} = 2.54(4) Å, C(2)–H(21)–O(1)^{II} = 156(3)°; C(3)···Cl(1)^{III} = 3.60(1) Å, H(31)···Cl(1)^{III} = 2.78(0) Å, C(3)–H(31)–Cl(1)^{III} = 142(0)°].

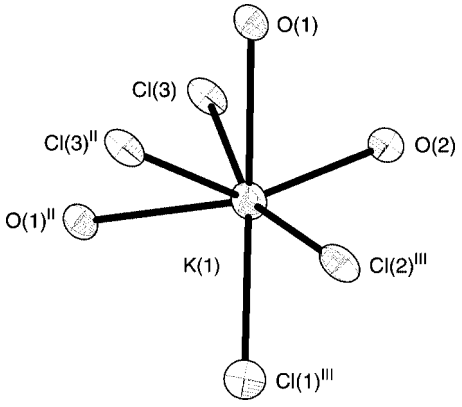

Figure 5. Potassium coordination sphere for K[$PtCl_3$(SMP)]; K···Cl and K···O distances are: K(1)–O(1) 3.048(3), K(1)–O(2) 2.580(3), K(1)–Cl(3) 3.244(2), K(1)–O(1)^{II} 2.980(3), K(1)–Cl(3)^{II} 3.136(2), K(1)–Cl(1)^{III} 3.132(2), K(1)–Cl(2)^{III} 3.280(2) Å. Symmetry: II = 1 – *x*, –*y*, 2 – *z*; III = *x*, *y*, 1 + *z*.

The infinite chains of anion pairs extend along the *c* direction; all the coordination planes of the platinum anions are quasi perpendicular to the *bc* plane (the angle between the mean square platinum plane and the *bc* plane is 82.17°).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Adjacent chains are held together by hydrophobic interactions between ethyl radicals and H-bond type interactions involving C(5), O(4), O(2), and C(4) atoms of one asymmetric unit and $O(4)^{V}$, $C(5)^{IV}$, $C(4)^{V}$, and $O(2)^{IV}$ atoms of two adjacent units, thus forming a three-dimensional network [C(5)···$O(4)^{V}$ = 3.38(1) Å, H(51)···$O(4)^{V}$ = 2.71(0) Å, C(5)–H(51)–$O(4)^{V}$ = 127(0)°; O(4)···$C(5)^{IV}$ = 3.38(1) Å, O(4)···$H(51)^{IV}$ = 2.71 Å, O(4)– $H(51)^{IV}$–$C(5)^{IV}$ = 127(0)°; O(2)···$C(4)^{V}$ = 3.49(1) Å, O(2)···$H(43)^{V}$ = 2.61(0) Å, O(2)–$H(43)^{V}$–$C(4)^{V}$ = 153(5)°; C(4)···$O(2)^{IV}$ = 3.49(1) Å, H(43)···$O(2)^{IV}$ = 2.61(0) Å, C(4)–H(43)–$O(2)^{IV}$ = 127(0)°].

Conclusions

It has been shown that compound **1** is fairly stable in a water solution containing a chloride ion concentration comparable to that of a physiological medium. Moreover, in the absence of free chloride, only partial solvolysis with release of a chloride ion is observed. However, in the presence of a cation such as K^+ (but the same should apply to any positively charged ion comprising the biologically relevant Ca^{++}), the solution stability of the SMP chelate does not prevent the phosphonate group from leaving the platinum center in order to interact with the cation.

The electrostatic interaction between cations and complex anions in the solid state appears to be the driving force for the formation of **2**. The potassium ion fits perfectly in a cage of seven donors (three oxygen and four chlorine atoms) from three different platinum units.

These findings can be highly relevant to the behavior of this compound in a biological environment. We used the SMP diethyl ester on the ground that in physiological conditions it can undergo enzymatic hydrolysis with the formation of phosphonic acids, which can then interact with calcium cations. However, it has been found that the SMP ligand itself can interact with cations. Not only can the P=O oxygen atom be detached from the platinum atom but the oxygen atom bound to the sulfur atom and even a platinum-bound chlorine ligand are willing to embrace a metal cation. It is expected that the reaction observed in the crystallization of **1** in the presence of KCl can take place in the hypercalcaemic districts associated with bone tumors. In the design of the SMP ligand the sulfoxide functionality was introduced in order to have a good donor atom for platinum, the ability of the sulfur-bound oxygen atom to interact with a cation had not been anticipated and therefore it represents an unexpected fortunate circumstance.

Finally, the very likely hydrolysis of the phosphodiester moiety promoted by esterase enzymes present in the biological medium could further increase the ability of this drug to be captured in calcium-rich districts. It cannot be excluded, however, that the platinum atom can interact with sulfur and nitrogen atoms belonging to the amino acids of such enzymes (methionines and histidines are particularly abundant in these proteins), thereby inhibiting their hydrolytic activity. Biological studies are currently underway.

Experimental Section

General Methods: NMR spectra were recorded with a Bruker AVANCE DPX-WB 300 MHz instrument. ^{1}H chemical shifts were referenced to TMS by using the residual protic peak of the solvent as internal reference (δ = 2.04 ppm for [D_6]acetone and δ = 4.80 ppm for deuterium oxide). ^{31}P chemical shifts were referenced to 85% H_3PO_4. IR spectra were obtained with a Perkin–Elmer Spectrum One Infrared Spectrophotometer using KBr as solid support for pellets. Elemental analyses were performed with a Carlo Erba Elemental Analyzer model 1106 instrument.

Preparation of Complexes: The complex [$PtCl_2$(SMP)] (**1**) was prepared according to the reported procedure.[2]

Preparation of Samples for NMR Experiments: [$PtCl_2$(SMP)] (**1**) (2.5 mg, ca. 0.005 mmol) was dissolved in 1 mL of D_2O or [D_6]acetone and placed in an NMR tube. ^{1}H and ^{31}P NMR experiments were recorded every 3 h for 1 d and every 6 h for the following days.

Crystallization of K[$PtCl_3$(SMP)] (2): [$PtCl_2$(SMP)] (10 mg, 0.02 mmol) and KCl (1.50 mg, 0.02 mmol) were dissolved in a mixture of H_2O/acetone/$CHCl_3$ (0.2:1:1, v/v/v; 2 mL). By spontaneous evaporation of the solvent, orange crystals, which were characterized by elemental analysis, IR spectroscopy, and X-ray crystallography were obtained. $C_6H_{15}Cl_3KO_4PPtS$ (554.75): calcd. C 13.0, H 2.7; found C 13.3, H 2.8. IR: $\tilde{\nu}$ = 2913 ν(C–H), 1253 ν(P=O), 1049 ν(S=O), 1013 ν(P–O–R), 341 ν(Pt–Cl) cm^{-1}.

Crystal Data: $PtC_6H_{15}Cl_3KO_4PS$, monoclinic, space group $P2_1/a$, a = 7.9610(1), b = 23.5720(3), c = 8.6040(1) Å, β = 101.649(1), V = 1581.34(3) $Å^3$, λ = 0.71073 Å, Z = 4, F(000) = 1048, D_c = 2.330 g cm^{-3}, μ(Mo-K_α) = 9.874 mm^{-1}. Yellow/orange prism 0.10 × 0.14 × 0.54 mm. CCDC-252376 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Data Collection and Processing: 19235 reflections (4600 unique) were collected in the range $3.46° \leq 2\theta \leq 30.02°$, with a Nonius Kappa CCD diffractometer equipped with a fine-focus sealed-tube graphite-monochromated Mo-K_α radiation. Data were corrected for Lorentz and polarisation effects, and for absorption according to Blessing.[22] Omission of intensities with $I \leq 2\sigma(I_{obs})$ gave 4097 observed reflections, which were employed for the analysis.

Structure Analysis and Refinement: The structure was solved by Direct Methods application (SIR97)[23] and refined by a full-matrix least-squares technique (SHELX-L).[24] Each asymmetric unit contains one independent molecule. All non-hydrogen atoms were refined anisotropically, while hydrogen atoms were localized through Fourier map application, with the exception of H(31), H(32), H(41), H(42), H(43), H(51), H(52), H(61), H(62) and H(63) atoms, which, because of refinement instability, were placed in idealized positions and had a common isotropic thermal parameter [$U_{iso}(H) = 1.2U_{iso}(C)$] assigned. The final cycle of least-squares refinement included 176 parameters {weighting scheme applied: $w^{-1} = [\sigma^2(F_o^2) + (0.0290P)^2 + 3.1142P]$, with $P = [(F_o^2 + 2F_c^2)/3]$}. Final residuals were $R = 0.030$ and $wR = 0.069$, $GoF = 1.045$. Crystal data and structure refinement features are reported in Table 2.

Kinetics of Cyclooctene Epoxidation with *tert*-Butyl Hydroperoxide in the Presence of [MoO_2X_2L]-Type Catalysts (L = Bidentate Lewis Base)

Ahmad Al-Ajlouni,[a] Anabela A. Valente,[b] Carla D. Nunes,[b] Martyn Pillinger,[b] Ana M. Santos,[c,d] Jin Zhao,[c] Carlos C. Romão,[d] Isabel S. Gonçalves,*[b] and Fritz E. Kühn*[c]

Keywords: Epoxidation / Homogeneous catalysis / Kinetics / Molybdenum

Mo^{VI} complexes with the general formula [MoO_2X_2L] [X = Cl, Br; L = 4,4′-dimethyl-2,2′-bipyridine (dmbp) or 4-hexyl-4′-methyl-2,2′-bipyridine (hmbp)] have been prepared and characterized by IR and solution NMR (^1H, ^{13}C, ^{17}O and ^{95}Mo) spectroscopy. The complexes were applied as catalysts in the homogeneous phase for the epoxidation of cyclooctene, with *tert*-butyl hydroperoxide (TBHP) as the oxygen source. The desired epoxide was the only product and turnover frequencies of up to about 9000 h^{-1} could be reached. The catalytic activities increased in the order [MoO_2Br_2(dmbp)] < [MoO_2Br_2(hmbp)] < [MoO_2Cl_2(dmbp)] < [MoO_2Cl_2(hmbp)]. A kinetic model was built up for a homogeneous batch reactor based on a simplified mechanism involving three steps: (i) reversible coordination of TBHP to the starting Mo^{VI} complex to give a Mo^{VI} alkylperoxide; (ii) irreversible oxidation of cyclooctene to cyclooctene oxide by the species formed in step 1, with formation of the starting complex and *tert*-butyl alcohol; (iii) reversible coordination of *tert*-butyl alcohol to the starting complex. This model is consistent with the observed kinetics. The first step in this reaction mechanism was characterized in more detail by studying the kinetics of the reaction of the starting complexes with TBHP in the absence of any reductant by UV/Vis spectroscopy. Rate constants, equilibrium constants, and activation parameters were determined. All $\Delta S^{\ddagger}$ values were negative and therefore support an associative mechanism in which a seven-coordinate intermediate is formed. The results also suggest that the first step is not always the rate-limiting step of cyclooctene epoxidation with these complexes.

Introduction

Dioxomolybdenum(VI) complexes are important catalysts or catalyst precursors for oxygen-atom transfer reactions in industrial and biological systems.[1] Polymeric compounds of the composition MoO_2X_2 and WO_2X_2 have been known for many years.[2a] With Lewis bases, such as 2,2′-bipyridine, and with donor solvents, such as THF, adducts of the composition [MO_2X_2L] (M = Mo, W) are formed.[2b,2c] A particular interest in complexes of this type arose in the late 1960s when ARCO and Halcon were granted patents on olefin epoxidation catalyzed by Mo^{VI} compounds in the homogeneous phase.[2d,2e] In the following years different mechanisms were suggested to explain the reactivity of these complexes, most notably those by Mimoun et al.[2f] and by Sharpless et al.[2g] The debate has not been settled to date, despite the fact that a lot of information has been derived from NMR studies and catalytic reactivity patterns;[2h] several theoretical and mechanistic studies have also been presented.[2i–2l] It is generally agreed, however, that formation of a Mo^{VI} alkyl peroxide occurs followed by transfer of the distal oxygen atom of the alkyl peroxide rather than an oxo ligand.[2m] It is also becoming clear from the results published during the last decades on Mo^{VI} and W^{VI} complexes that the different catalyst types do not all follow the same mechanism,[2n–2p] as some authors assumed in the early days of this chemistry.[2q,2r]

We have recently published a series of papers focusing on complexes of the type [MO_2X_2L], which are excellent catalyst precursors for olefin epoxidation in the presence of *tert*-butyl hydroperoxide (TBHP).[3] Already in the early 1980s Mimoun et al. assumed that the [MO_2X_2L] complexes are transformed into [$Mo(O_2)_2OL_2$] in the presence of excess H_2O_2,[4] while the reaction of [MoO_2X_2L] with excess TBHP remained unclear. It has to be noted, however, that the industrially applied oxidation agent in the ARCO/Halcon process is TBHP. It is therefore of significant interest to

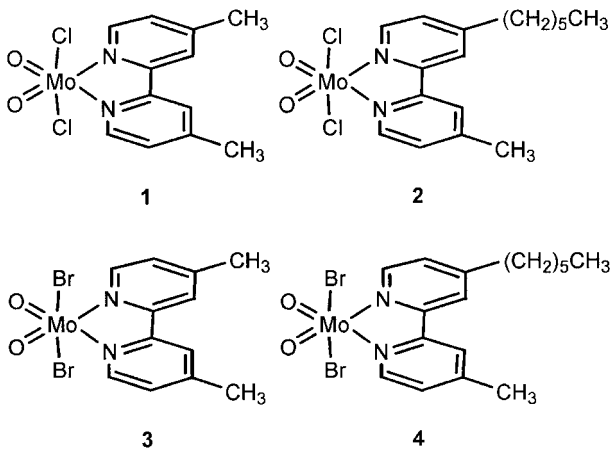
gain a deeper insight into the mechanism of the epoxidation catalysis with $[MoO_2X_2L]$ as the catalyst precursor and TBHP as oxidizing agent. In this paper we present a kinetic model of the epoxidation reaction supported by NMR and UV/Vis spectroscopy, GC/MS, and calculations using the program Kinsim.[5]

Results and Discussion

Preparation and Characterization of the Dioxomolybdenum(VI) Complexes

The dioxomolybdenum(VI) complexes **1**–**4** (Scheme 1) were obtained as pale-yellow, microcrystalline powders in good yields by previously described routes.[3b] In general, the spectroscopic data for these four complexes present no surprises compared with other Lewis-base adducts of bis(halogeno)dioxomolybdenum(VI) prepared using the same method.[3b] Thus, the complexes display their symmetric and asymmetric IR stretching vibrations for the *cis*-dioxo unit in the expected range (905–940 cm^{-1}).[3] ^{17}O NMR solution spectra were obtained for ^{17}O labeled complexes **5**–**8**. The chemical shifts for the dichloro derivatives **5** and **6** are $\delta(^{17}O)$ = 1005 and 993 ppm, respectively, and these are identical within the error range to those of the corresponding dibromo complexes [$\delta(^{17}O)$ = 1003 and 994 ppm]. The related 2,2′-bipyrimidine adducts $[MoO_2X_2(bpym)]$ were also found to exhibit a minimal ^{17}O shift difference between the chloro and bromo derivatives [$\delta(^{17}O)$ = 997 (Cl) and 996 ppm (Br)].[5] For complexes **5** and **6**, and **7** and **8**, the 9–12 ppm ^{17}O NMR shift difference reflects a slightly higher electron density in the complexes containing the unsymmetrical 4-hexyl-4′-methyl-2,2′-bipyridine ligand. ^{95}Mo NMR solution spectra were also recorded for complexes **5**–**8**. The differences in the ^{95}Mo shift between the symmetrical and the unsymmetrical bipyridine ligand is comparatively small, only a few ppm in each case. The chemical shift difference between Cl and Br is about 50 ppm. These results parallel those observed for adducts of the type $[MoO_2X_2L]$ (X = Cl, Br; L = 2,2′-bipyridine, 2,2′-bipyrimidine).[6]



Scheme 1.

Kinetics of Catalytic Olefin Epoxidation With Complexes 1–4

Certain dioxomolybdenum(VI) complexes are able to catalyze the epoxidation of olefins with molecular oxygen as an oxygen source at atmospheric pressure.[7–9] However, preliminary experiments showed that the complexes $[MoO_2Cl_2$(4,4′-dimethyl-2,2′-bipyridine)] (**1**) and $[MoO_2Cl_2$(4-hexyl-4′-methyl-2,2′-bipyridine)] (**2**) are not active for the epoxidation of cyclooctene with molecular oxygen at atmospheric pressure under any of the conditions applied previously in the literature.

The dioxomolybdenum(VI) complexes **1**–**4** are active in the epoxidation of cyclooctene with TBHP as oxidant, at 55 °C, yielding cyclooctene oxide as the only product. The catalytic activity of the complexes depends strongly on the substituent pattern of the donor ligand, in agreement with previous studies on oxomolybdenum complexes.[2p,3d,3e,6,9–11] Cyclooctene conversion is higher in the presence of **2** than **1** (initial activities at a catalyst:substrate ratio of 1:100 are 248 $mol\,mol_{Mo}^{-1}\,h^{-1}$ and 25 $mol\,mol_{Mo}^{-1}\,h^{-1}$, respectively), and the yield of cyclooctene oxide reaches about 97% after 24 h in the case of **2** compared to about 76% for **1** (Figure 1). A similar trend is observed for complexes **3** and **4**. As discussed below, it is possible that the presence of a large organic group on the bipyridine ligand leads to the formation of a more hindered (reactive) oxidizing Mo^{VI} intermediate. The Br catalysts possess lower activity towards cyclooctene epoxidation than the corresponding Cl analogs, in agreement with the results reported in the literature for complexes of this type.[6]

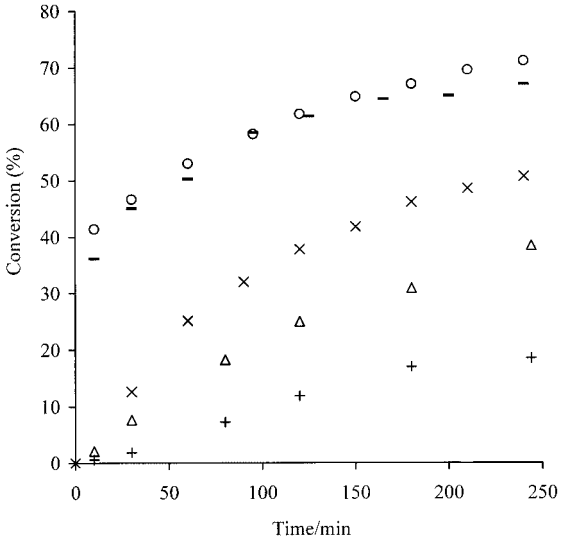


Figure 1. Conversion vs. time profiles for cyclooctene epoxidation using TBHP at 55 °C in the presence of $[MoO_2Cl_2$(4,4′-dimethyl-2,2′-bipyridine)] (**1**; ×), $[MoO_2Cl_2$(4-hexyl-4′-methyl-2,2′-bipyridine)] (**2**; ○), $[MoO_2Br_2$(4,4′-dimethyl-2,2′-bipyridine)] (**3**; +), $[MoO_2Br_2$(4-hexyl-4′-methyl-2,2′-bipyridine)] (**4**; Δ), and a radical scavenger plus **2** (–).

As has already been confirmed with related compounds, such as $[CpMoO_2Cl]$ and derivatives,[12] a catalyst-to-sub-

strate ratio of 1:100 is far from being optimal. Reducing the catalyst-to-substrate ratio to 1:10 000 leads to the highest turnover frequencies (TOFs). The highest activities have been observed with [MoO_2X_2(4,4′-bis(*tert*-butyl)-2,2′-bipyridine)] and cyclooctene as substrate. The TOF of that system with a 1:10 000:15 000 catalyst:substrate:oxidant ratio is 9360 h^{-1} after five minutes. With compound **2** a TOF of about 8800 h^{-1} is reached under the same reaction conditions. With [$CpMoO_2Cl$] systems TOFs as high as 20 000 h^{-1} can be obtained,[12] while with the very active catalyst methyltrioxorhenium[13] (utilizing H_2O_2 instead of TBHP) TOFs of up to 14 000 have been reported.[13c] Nevertheless, the TOFs reached with some of the [MoO_2X_2L] systems reported here are still impressive and show the potential of these compounds as oxidation catalysts.

In this section a mechanism is proposed based on our experimental results and other studies for similar systems,[14] and a kinetic model is developed for a homogeneous batch reactor. In order to exclude solvent effects on the reaction no additional solvent was used. The fact that complexes **1**–**4** do not oxidize cyclooctene with O_2 at atmospheric pressure makes it unlikely that noncatalytic "olefin autoxidation" operates when the epoxidation is carried out with TBHP, at 55 °C, in air. Furthermore, no induction periods were detected (Figure 1) and without catalyst no conversion was observed (under otherwise identical reaction conditions).

Herrmann et al. have reported that for complexes of the type [MoO_2L_2] (L = pyridyl alcohol) a radical-type mechanism could be involved in olefin epoxidation with elemental oxygen (atmospheric pressure).[9] In the present work, the existence or otherwise of a mechanism involving radical pathways was investigated by carrying out an experiment with complex **2** in the presence of a radical scavenger added at the beginning of the reaction (equimolar amounts of cyclooctene and 2,6-di-*tert*-butyl-4-methylphenol, under identical reaction conditions to those described in the Experimental Section). As shown in Figure 1 the reaction rate was not significantly affected, which suggests that a nonradical reaction mechanism is involved.

According to some authors, the mechanism of molybdenum(VI)-catalyzed epoxidation may be similar to those involving titanium(IV) and vanadium(V).[10,15] The reaction mechanisms suggest that the first step in the epoxidation of an alkene is the coordination of the Lewis basic hydroperoxide to the Lewis acidic metal center by the terminal oxygen, thereby activating the peroxide for oxygen transfer.[2p,6,11,15,16] As expected, in the absence of oxidant no reaction took place. There is a consensus that the nature of the reactive intermediate formed by coordination of TBHP to molybdenum complexes is of the alkylperoxidic type.[4,6,11] We have generalized this to the case of complexes **1**–**4** ([MoL^x], L^x = ligand set) for cyclooctene epoxidation (under the reaction conditions used), in which the oxidizing agent is [$MoL^y(O_2R)$] (R = *tert*-butyl), formed in Equation (1). The incoming TBHP molecule can affect the ligands such that L^x becomes L^y. In a previous study with the complexes [MoO_2X_2(4,4′-dihexyl-2,2′-bipyridine)] (X = Cl, Me) and TBHP we were able to re-isolate the unchanged starting complexes, in quantitative yield, after the catalytic reactions.[6,17] There is no indication that η^2-bisperoxo species of the type [$MoO(O_2)_2L$] are formed and then "recycled" to the starting materials. We can therefore conclude that the Mo–X bonds are not cleaved during the reaction with TBHP and that the catalytically active species exists in an equilibrium with the starting complex in solution.

$$\text{TBHP} + [MoL^x] \underset{k_2}{\overset{k_1}{\rightleftharpoons}} [MoL^y(O_2R)] \quad (1)$$

Many studies have reported that molybdenum(VI) centers favor heterolytic peroxometal pathways (Mo^{VI} alkyl peroxide intermediate), leading to electrophilic attack on the olefinic double bond.[11,18] It has been reported for molybdenum peroxo complexes that oxygen transfer to the olefin takes place irreversibly.[15,16] We will therefore assume that cyclooctene is irreversibly oxidized to cyclooctene oxide (CyO) by [$MoL^y(O_2R)$], with formation of the starting complex [MoL^x] and *tert*-butyl alcohol [TBOH, Equation (2)]. It is known that molybdenum catalysts are active for the conversion of TBHP to TBOH.[10,11,16,19]

$$[MoL^y(O_2R)] + \text{Cy} \xrightarrow{k_3} [MoL^x] + \text{CyO} + \text{TBOH} \quad (2)$$

Molybdenum-catalyzed epoxidations with TBHP can be prone to autoretardation by the co-product TBOH, the extent of which would be related to the equilibrium constants for the formation of catalyst–alkylperoxide and catalyst–alkoxide complexes.[3f,3h,20] Such autoretardation effects would explain the decrease of the observed reaction rate, which is more rapid in the case of the more active complex **2** (Figure 1). When TBOH was added at the beginning of the reaction (equimolar amounts of cyclooctene and TBOH, under identical reaction conditions to those described in the Experimental Section), the initial activity of **2** for cyclooctene epoxidation decreased by about 44%. On the other hand, TBHP efficiency for cyclooctene conversion (determined by iodometric titration at 240 min) was around 95% (TBHP consumed in cyclooctene epoxidation/total conversion of TBHP). It is assumed that TBOH can react reversibly with [MoL^x] to give a complex designated as [$MoL^z(OR)$] [Equation (3)].

$$[MoL^x] + \text{TBOH} \underset{k_5}{\overset{k_4}{\rightleftharpoons}} [MoL^z(OR)] \quad (3)$$

The overall rates of formation of cyclooctene, cyclooctene oxide, TBHP, TBOH, and molybdenum species can be written for the above elementary reactions as follows [Equations (4), (5), (6), (7), (8), (9) and (10)].

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$$r_{Cy} = -k_3[MoL^y(O_2R)][Cy] \quad (4)$$

$$r_{CyO} = k_3[MoL^y(O_2R)][Cy] \quad (5)$$

$$r_{TBHP} = -k_1[TBHP][MoL^x] + k_2[MoL^y(O_2R)] \quad (6)$$

$$r_{TBOH} = k_3[MoL^y(O_2R)][Cy] - k_4[MoL^x][TBOH] + k_5[MoL^z(OR)] \quad (7)$$

$$r_{[MoL^x]} = -k_1[TBHP][MoL^x] + k_2[MoL^y(O_2R)] + k_3[MoL^y(O_2R)][Cy] - k_4[MoL^x][TBOH] + k_5[MoL^z(OR)] \quad (8)$$

$$r_{[MoL^y(O_2R)]} = k_1[TBHP][MoL^x] - k_2[MoL^y(O_2R)] - k_3[MoL^y(O_2R)][Cy] \quad (9)$$

$$r_{[MoL^z(OR)]} = k_4[MoL^x][TBOH] - k_5[MoL^z(OR)] \quad (10)$$

Assuming that $[MoL^x]$, $[MoL^y(O_2R)]$, and $[MoL^z(OR)]$ are the only metal species formed, and that their total concentration at any instant is equal to the initial concentration of complex $[MoLx]_0$, we get [Equation (11)]

$$[MoL^x]_0 = [MoL^x] + [MoL^y(O_2R)] + [MoL^z(OR)] \quad (11)$$

Applying a mole balance to a homogeneous liquid-phase batch reactor (constant-volume reaction process under isothermal operation) the following differential equation can be written with respect to each chemical species [Equation (12)]

$$\frac{d[P]}{dt} = r_p \quad (12)$$

where P is cyclooctene, cyclooctene oxide, TBHP, TBOH, or a molybdenum species. Figure 2 shows the model fitting to data points for the experiments of cyclooctene epoxidation with TBHP in the presence of **1**–**4**. In all cases the predicted kinetic curves fit the experimental data points. The fairly good fitting achieved indicates that the above mechanism of cyclooctene oxidation is consistent with the experimental data and that the assumptions made are valid and reasonable.

UV/Vis Studies of Catalyst Formation

The kinetics of the reaction of $[MoL^x]$ with TBHP in the absence of any reductant was studied by UV/Vis spectroscopy, thereby allowing equilibrium constants and rate constants to be determined for this step.

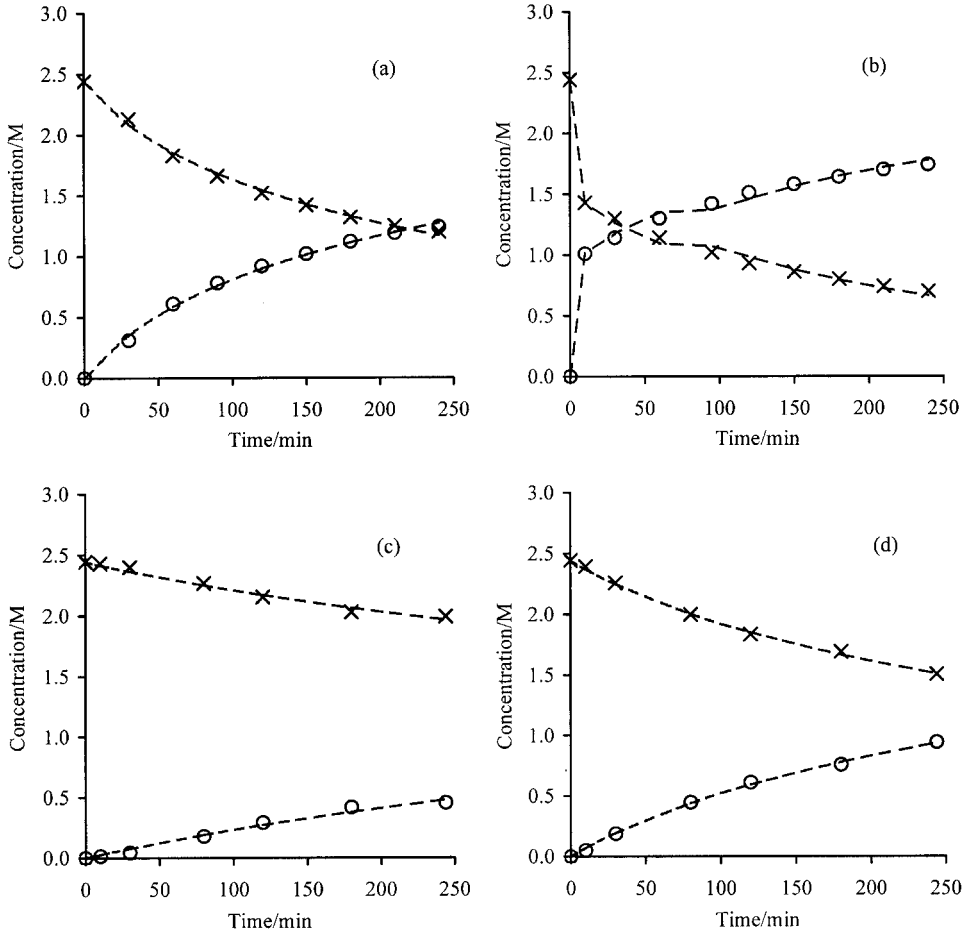

Figure 2. Concentration vs. time profiles of cyclooctene and cyclooctene oxide for (a) **1**, (b) **2**, (c) **3** and (d) **4** determined experimentally (points) and calculated for the proposed model (dashed lines).

The Equilibrium Constants of Catalyst Formation

The absorbance vs. concentration diagram of solutions of complex **3** and **4** with TBHP is not like a titration curve (see Figure 3 for complex **3**). It continues, however, to build up as more TBHP is added, until finally a plateau is reached. This reaction was assumed to form a 1:1 adduct, $[MoL^y(O_2R)]$, in equilibrium with the original $[MoL^x]$ and TBHP [Equation (1)]. The changes in absorbance (at 300 nm) due to the loss of $[MoL^x]$ and formation of $[MoL^y(O_2R)]$ can be expressed by Equation (13) (assuming a 1.0-cm path-length)

$$Abs = \varepsilon_1[MoL^x] + \varepsilon_2[MoL^y(O_2R)] \quad (13)$$

where ε_1 and ε_2 are the molar absortivities for $[MoL^x]$ and $[MoL^y(O_2R)]$ adducts, respectively. Substituting the equilibrium constant (K_{eq}) for the formation of the $[MoL^y(O_2R)]$ adduct in Equation (13), and using the molar balance $[Mo]_T = [MoL^x] + [MoL^y(O_2R)]$, we obtain Equation (14):

$$\frac{Abs}{[Mo]_T} = \frac{\varepsilon_1 + \varepsilon_2 K_{eq}[TBHP]}{1 + K_{eq}[TBHP]} \quad (14)$$

The data were obtained with a constant initial concentration of MoL^x and over a range of concentrations of TBHP of 5.0–50 mM. The fitting of Equation (14) to the experimental data of absorbance (at equilibrium) as a function of TBHP allowed values for the equilibrium constants to be calculated (Figure 3, Table 1).

The thermodynamic parameters for the reaction of **3** with TBHP to form the catalyst were estimated from the equilibrium constants at 25 °C and 55 °C, determined as 123 ± 19 and 482 ± 34 M^{-1}, respectively (Table 1). The values of ΔG (at 25 °C), ΔH, and ΔS are -12 kJ mol^{-1}, $+28.6$ kJ mol^{-1} and $+136$ J mol^{-1} K^{-1}, respectively, indicating that the formation of the catalyst is an endothermic and spontaneous process. The positive enthalpy value may also indicate that the Mo–OOR bond is weaker than the Mo–X bond. The equilibrium constant for the reaction of **3** with TBHP is seven to eight times greater than that for the reaction of **4** with TBHP. It seems therefore that the presence of the large hexyl substituent (compared with the methyl for **3**) reduces the stability of the catalyst relative to the starting complex. This would explain the observed higher reactivity (lower stability) of the Mo^{VI} oxidizing species bearing a hexyl group towards cyclooctene epoxidation.

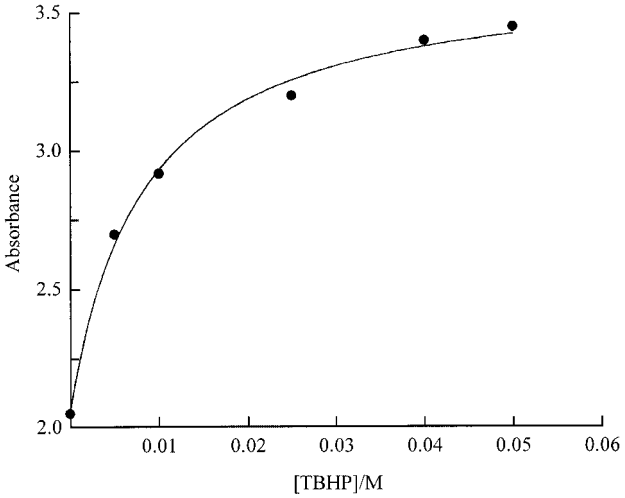

Figure 3. A plot of the absorbance at 300 nm of equilibrium mixtures of TBHP and **3** as a function of [TBHP] at $[Mo]_T = 0.5$ mM in acetonitrile at 25 °C. The solid line is the absorbance calculated from Equation (14) with the values of $K_{eq} = 123$ M^{-1}, $\varepsilon_1 = 4.0 \times 10^3$ M^{-1} cm^{-1} and $\varepsilon_2 = 7.3 \times 10^3$ M^{-1} cm^{-1}.

Kinetic Studies of Catalyst Formation

The rate constants for the reactions of complexes **2**, **3** and **4** with TBHP were determined by initial rate (method I) and pseudo-first-order (method II) methods. In both cases, the complexes were in limiting amount (0.5 mM) and TBHP in large excess (at least 10-fold).

Initial Rate (Method I)

The initial rates (v_i) were calculated from the initial absorbance change (2–5%) of the absorbance-time curves based on Equation (15),

Table 1. The equilibrium constants and the rate constants for the reactions of the Mo^{VI} complexes **2**, **3** and **4** with TBHP.

Complex	K_{eq}	k_1 [L mol^{-1} s^{-1}]	k_2 [10^{-3} s^{-1}]	$\Delta H^{\ddagger}$ [kJ mol^{-1}]	$\Delta S^{\ddagger}$ [J (mol K)$^{-1}$]

$$v_i = \frac{\Delta Abs_i}{\Delta t \cdot b \cdot \Delta \varepsilon} \quad (15)$$

where ΔAbs_i is the initial absorbance change observed for the reaction of complex **i** (i = **2**, **3**, **4**) with TBHP in the time interval Δt, $\Delta\varepsilon$ is the difference in the molar absortivities of the starting complex [MoL^x] and the catalyst [$MoL^y(O_2R)$], and b is the light path length. Variation of the initial rate with the initial concentration of TBHP is shown in Figure 4 for complex **3** at 55 °C. The second-order rate constants (k_1, Table 1) were calculated from the slopes based on the rate-law equation $v_i = k_1[MoL^x][TBHP]$, where slope = $k_1[MoL^x]$.

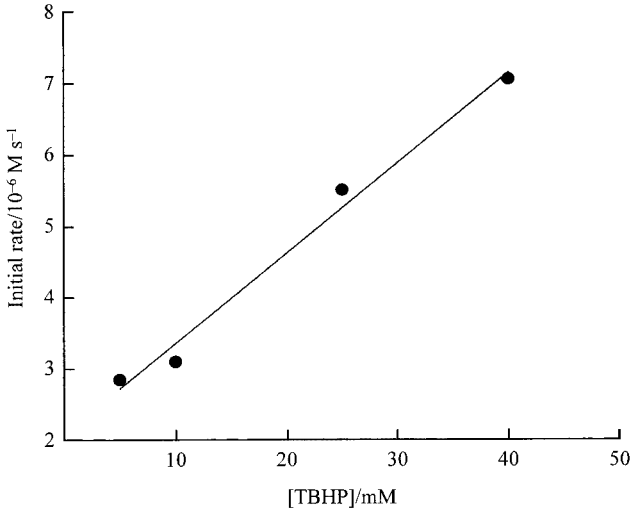

Figure 4. Variation of the initial rate with [TBHP] for the reaction of **3** (0.5 mM) and TBHP in acetonitrile at 55 °C. The solid line represents the calculated data based on a linear fit of the experimental data with slope = $k_1[\mathbf{3}] = 1.25 \times 10^{-4}$ s^{-1}.

Pseudo-First-Order (Method II)

In this method, the pseudo-first-order rate constants (k_ψ) were determined by fitting the last 20–50% of the absorbance vs. time curves to a first-order exponential equation, in a similar fashion to that reported previously.[21] The values of k_ψ vary linearly with [TBHP] in the range 5–25 mM and the slopes give the second-order rate constants (k_1), as shown in Figure 5 for complex **4** at 25 °C. The values of the reverse rate constants k_2 [Equation (1)] were calculated from the values of the second-order rate constants k_1 for the reaction of complexes **2**, **3**, and **4** with TBHP and the equilibrium constants, $k_2 = k_1/K_{eq}$. Methods I and II give similar values of k_1 and k_2 within the range of experimental error (Table 1).

The kinetic results show that the rate of formation of the catalyst, [MoLy(O_2R)], is much faster for the Br complexes than for the Cl ones (Table 1). For example, the rate constant for the formation of the catalysts from the reaction of [MoO_2Br_2(4-hexyl-4′-methyl-2,2′-bipyridine)] (**4**) with

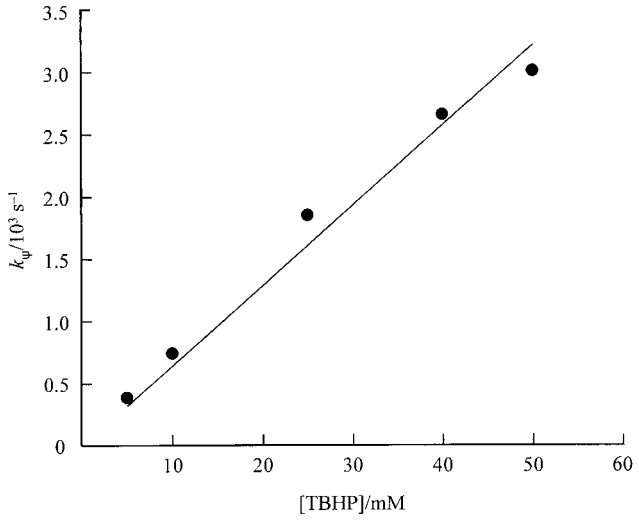

Figure 5. A plot of the pseudo-first-order rate constants as a function of [TBHP] for the reaction of **4** (0.5 mM) with TBHP in acetonitrile at 25 °C.

TBHP is 2–3 orders of magnitude higher than that for the reaction of [MoO_2Cl_2(4-hexyl-4′-methyl-2,2′-bipyridine)] (**2**) with TBHP. These results, taken together with the fact that Br catalysts of this type generally possess lower activity towards epoxidation of an olefin,[6] suggest that the first step (the catalyst formation) is not always the rate-limiting step of cyclooctene epoxidation with these complexes.

Experimental results on the effect of temperature variation in the range 20–60 °C on the catalyst formation from the reaction of complexes **1**–**4** with TBHP showed that the rate increases significantly with increasing temperature. Plots of $\ln(k_1/T)$ vs. $1/T$, where k_1 is the second-order rate constant for the reaction of the Mo complex with TBHP, led to the activation parameters $\Delta H^\ddagger$ and $\Delta S^\ddagger$ (Figure 6,

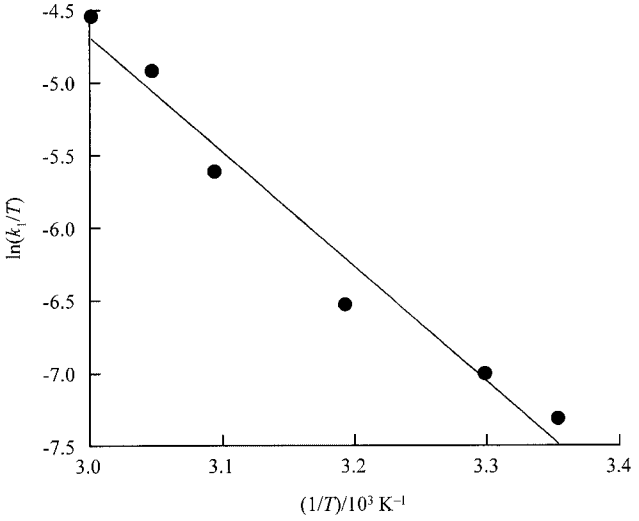

Figure 6. A plot of $\ln(k_1/T)$ vs. $1/T$ for the catalyst formation from the reaction of TBHP with **3** in acetonitrile. The activation parameters were calculated from the slope (–7.9) and the intercept (19.0) based on the equation $\ln(k_1/T) = 23.76 + \Delta S^\ddagger/R - \Delta H^\ddagger/R(1/T)$.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Table 1). All the $\Delta S^{\ddagger}$ values obtained for the catalyst formation in this study have negative values, thus indicating that the catalyst formation is associated with an entropy decrease. These results support an associative mechanism in which a seven-coordinate intermediate is formed. The trend in the $\Delta H^{\ddagger}$ values confirms the trend in the rate constants for the catalyst formation (k_1 decreases in the order **4** > **3** > **2**). Also, the values of $\Delta H^{\ddagger}$ are of the same order of magnitude as those obtained for similar W complexes.[21] However, in the case of the Mo complexes the values of $\Delta H^{\ddagger}$ are generally lower, which explains the higher activity of Mo catalysts in comparison with the W ones.

Concluding Remarks

Several complexes with the general formula $[MoO_2X_2L]$ (X = Cl, Br) have been synthesized and examined as catalysts for the epoxidation of cyclooctene using TBHP as the oxidant. The kinetics studies support the theory that the first step in the reaction mechanism is associative and involves the reaction of TBHP with the starting complex. It is assumed that the peroxide transfers a hydrogen to one of the Mo=O oxygens and the remaining ROO^- anion binds as a seventh ligand. In contrast to recent findings on tungsten complexes[21] and with theoretical investigations on Mo complexes, the present work indicates that the first step is not always the rate-limiting step. DFT calculations are being carried out in order to probe in more detail various aspects of the reaction mechanism.

Experimental Section

All preparations and manipulations were carried out using standard Schlenk techniques under nitrogen. Solvents were dried by standard procedures (THF, hexane, and diethyl ether over Na/benzophenone ketyl; CH_2Cl_2 and CH_3CN over CaH_2), distilled, and kept under nitrogen over molecular sieves. Microanalyses were performed at the ITQB and the Mikroanalytische Labor of the Technical University of Munich (M. Barth). IR spectra were measured on Mattson Mod 7000 and Perkin–Elmer FTIR spectrometers using KBr pellets. Solution NMR spectra were measured on Bruker CXP 300 (^{1}H, 300 MHz), Bruker Avance DPX-400 (^{1}H: 400 MHz; ^{13}C: 100.28 MHz; ^{95}Mo: 26.07 MHz) and JEOL JNM GX-400 (^{13}C: 100.28 MHz; ^{17}O: 54.14 MHz) spectrometers. 4,4′-Dimethyl-2,2′-bipyridine was purchased from Aldrich and used as received. The compounds 4-hexyl-4′-methyl-2,2′-bipyridine,[22] $[MoO_2X_2]$ (X = Cl, Br)[23] and $[MoO_2X_2(THF)_2]$ (X = Cl, Br)[2b] were prepared according to published procedures with only minor changes.

Synthesis of Complexes 1–4: The complexes $[MoO_2Cl_2(THF)_2]$ (1.37 g, 4.00 mmol) and $[MoO_2Br_2(THF)_2]$ (1.73 g, 4.00 mmol) were each dissolved in CH_2Cl_2 (20 mL) and treated with 1 equiv. of 4,4′-dimethyl-2,2′-bipyridine or 4-hexyl-4′-methyl-2,2′-bipyridine. The resulting turbid solutions were each stirred for a further 1 h. The solvent was removed under vacuum, and the product washed with diethyl ether and dried under vacuum.

$[MoO_2Br_2$(4-hexyl-4′-methyl-2,2′-bipyridine)] (4): Yield: 1.54 g (71%). Selected IR (KBr): $\tilde{\nu}$ = 2925 cm^{-1} (s), 1611 (vs), 1417 (s), 1026 (s), 935 (vs) ($Mo{=}O_{asym}$), 906 (vs) ($Mo{=}O_{sym}$) cm^{-1}. ^{1}H NMR (400 MHz, CD_2Cl_2, 20 °C): δ = 0.83 (t, 3 H, CH_3CH$_2$-), 1.28 [m, 6 H, $(CH_2)_3$], 1.70 (m, 2 H, CH_2), 2.54 (s, 3 H, CH_3), 2.78 (m, 2 H, CH_2), 7.48 (d, 2 H, py-H), 8.02 (d, 2 H, py-H), 9.32 (t, 2 H, py-H) ppm. ^{13}C NMR (CD_3Cl, 20 °C): δ = 14.0, 21.8, 22.5, 29.0, 30.1, 31.5, 35.9, 122.4 (py-C), 123.2 (py-C), 127.0 (py-C), 127.8 (py-C), 149.6 (py-C), 151.9 (py-C), 153.2, 157.9 (py-C) ppm. ^{95}Mo NMR (CD_2Cl_2, 20 °C): δ = 251 ppm. $C_{17}H_{22}Br_2MoN_2O_2$ (542.12): calcd. C 37.66, H 4.09, N 5.17; found C 37.49, H 3.88, N 5.09.

Synthesis of ^{17}O-Labeled Complexes 5–8: The labeled complexes $[Mo^{17}O_2Cl_2(DMF)_2]$ and $[Mo^{17}O_2Br_2(DMF)_2]$ were prepared according to the published procedure using $H_2{}^{17}O$.[4] IR (KBr): $\tilde{\nu}$ = 941 cm^{-1} (s), 928 (vs), 904 (vs), 891 (s), 870 (vs), 860 (s) (Mo=O) cm^{-1}. Recrystallization of $[Mo^{17}O_2X_2(DMF)_2]$ (X = Cl, Br) from THF gave the labeled starting materials $[Mo^{17}O_2Cl_2(THF)_2]$ and $[Mo^{17}O_2Br_2(THF)_2]$, which were subsequently used to prepare the labeled Lewis-base adducts **5**–**8**.

$[Mo^{17}O_2Cl_2$(4,4′-dimethyl-2,2′-bipyridine)] (5): IR (KBr): $\tilde{\nu}$ = 938 cm^{-1} (vs), 924 (s), 908 (vs), 897 (s), 874 (s) (Mo=O) cm^{-1}. ^{17}O NMR (DMSO, 20 °C): δ = 1005 ppm.

$[Mo^{17}O_2Cl_2$(4-hexyl-4′-methyl-2,2′-bipyridine)] (6): IR (KBr): $\tilde{\nu}$ = 937 cm^{-1} (vs), 928 (s), 913 (vs), 903 (s), 889 (m), 871 (s) (Mo=O) cm^{-1}. ^{17}O NMR (CD_2Cl_2, 20 °C): δ = 993 ppm.

$[Mo^{17}O_2Br_2$(4,4′-dimethyl-2,2′-bipyridine)] (7): IR (KBr): $\tilde{\nu}$ = 934 cm^{-1} (s), 922 (s), 904 (vs), 895 (s), 869 (s) (Mo=O) cm^{-1}. ^{17}O NMR (DMSO, 20 °C): δ = 1003 ppm.

$[Mo^{17}O_2Br_2$(4-hexyl-4′-methyl-2,2′-bipyridine)] (8): IR (KBr): $\tilde{\nu}$ = 934 cm^{-1} (vs), 927 (s), 903 (vs), 871 (m) (Mo=O) cm^{-1}. ^{17}O NMR (CD_2Cl_2, 20 °C): δ = 994 ppm.

Catalytic Reactions with Compounds 1–4 as Catalysts: The epoxidation of cyclooctene was carried out at 55 °C, in air, in a batch reactor equipped with a magnetic stirrer. The reactor was loaded with 73 μmol of complex, 7.3 mmol of cyclooctene (1% molar ratio of catalyst/substrate) and 11 mmol of *tert*-butyl hydroperoxide (5.5 M in decane), which was used as oxidant. Samples were with-

drawn periodically and analyzed with a gas chromatograph (Varian 3800) equipped with a capillary column (SPB-5, 20 m × 0.25 mm × 0.25 μm) and a flame ionization detector. The products were identified by gas chromatography-mass spectrometry (HP, 5890 Series II GC; HP 5970 Series Mass Selective Detector) using He as carrier gas.

UV/Vis Experiments: All kinetic experiments were carried out under pseudo-first-order conditions with excess TBHP in CH_3CN at 25 and 55 °C. The reactions were carried out in quartz cuvettes with a path length of 1 cm. In a typical experiment, TBHP was added to a thermostatted UV cell containing a solution of the catalyst. The catalyst concentration was held constant at 0.5 mM and TBHP concentration was varied in the range 5.0–50 mM. The absorbance changes at 300 nm were recorded with time using a Jasco V-560 spectrophotometer equipped with a Jasco EHC-477S Peltier thermostatted single cell holder. All data analysis was carried out with the KaleidaGraph program.

Acknowledgments

This work was partly funded by the FCT, POCTI, and FEDER (Project POCTI/QUI/37990/2001). The authors are also grateful to DAAD and CRUP (INIDA and Acções Integradas Programme) for financial support. ISG thanks the FCT for a grant (BSAB/372/2003) and AMS is grateful to the Alexander von Humboldt Foundation for a postdoctoral research fellowship. CDN acknowledges grants from the University of Aveiro and the FCT.

Synthesis, Structure, Reactivity, and Catalytic Activity of *C,N*- and *C,N,N*-Orthopalladated Iminophosphoranes

Raquel Bielsa,[a] Angel Larrea,[b] Rafael Navarro,*[a] Tatiana Soler,[a] and Esteban P. Urriolabeitia*[a]

Keywords: C–C Coupling / C–H Activation / Homogeneous catalysis / N ligands / Palladium

The orthopalladated complexes $[Pd(\mu\text{-}Cl)(C_6H_4\text{-}2\text{-}PPh_2{=}NPh\text{-}\kappa\text{-}C,N)]_2$ (**1**) and $[Pd(C_6H_4\text{-}2\text{-}PPh_2{=}N\text{-}C(O)\text{-}2\text{-}NC_5H_4\text{-}\kappa\text{-}C,N,N)Cl]$ (**11**) have been obtained by reaction of $Pd(OAc)_2$ (OAc = acetate) with the iminophosphoranes $Ph_3P{=}NPh$ and $Ph_3P{=}N\text{-}C(O)\text{-}2\text{-}NC_5H_4$, respectively, in the presence of excess LiCl. Complex **11** has been characterised by X-ray diffraction methods. The orthoplatinated derivative $[Pt(C_6H_4\text{-}2\text{-}PPh_2{=}N\text{-}C(O)\text{-}2\text{-}NC_5H_4\text{-}\kappa\text{-}C,N,N)Cl]$ (**12**) can be obtained by reaction of $[PtCl_2(NCPh)_2]$ with $Ph_3P{=}N\text{-}C(O)\text{-}2\text{-}NC_5H_4$ in refluxing 2-methoxyethanol. Complex **1** shows the typical reactivity of *C,N*-orthopalladated complexes, while complex **11** shows that the *C,N,N*-orthometallated ligand is strongly bonded to the Pd atom and cannot be easily displaced. The catalytic activity of the complexes $[Pd(\mu\text{-}Cl)(C_6H_4\text{-}2\text{-}PPh_2{=}NPh\text{-}\kappa\text{-}C,N)]_2$ (**1**), $[Pd(C_6H_4\text{-}2\text{-}PPh_2{=}NPh\text{-}\kappa\text{-}C,N)(Cl)(py)]$ (**4**), $[Pd(C_6H_4\text{-}2\text{-}PPh_2{=}N\text{-}C(O)\text{-}2\text{-}NC_5H_4\text{-}\kappa\text{-}C,N,N)Cl]$ (**11**) and $[Pd(C_6H_4\text{-}2\text{-}PPh_2{=}N\text{-}C(O)\text{-}2\text{-}NC_5H_4\text{-}\kappa\text{-}C,N,N)(NCMe)]ClO_4$ (**13**) in the Mizoroki–Heck (MH) reaction between methyl acrylate and different haloarenes has been examined. All complexes behave as moderate to good catalysts, yielding turnover numbers (TON) up to 526000. Their role as catalysts or precatalysts and the formation of nanoparticles is also discussed.

Introduction

Iminophosphoranes (phosphane imines) are compounds of general structure $R_3P{=}NR'$ (R, R′ = alkyl, aryl, acyl, etc). They show notable analogies with the phosphorus ylides $R_3P{=}CR'(R'')$,[1] and also have numerous applications in organic chemistry (e.g. the aza-Wittig reaction), either as neutral or as anionic reagents.[1–3] In addition, the bonding properties of these compounds as ligands towards transition metals are still attracting the interest of chemists,[4–28] for several reasons: their ability to form and to stabilize carbene complexes,[5,8] the easy modulation of the electronic and steric properties of different types of catalysts (for instance, in oligo- and polymerisation of ethylene,[4,6,23] hydrogen-transfer processes,[9,10] etc.), their applications in enantioselective synthesis and catalysis (allylic substitution),[25,26] the synthesis of alkaline earth organometallic complexes,[7] and, in general, due to their versatility. In this context, we have recently reported some aspects of the chemistry of the α-stabilized iminophosphoranes $Ph_3P{=}NCN$, $Ph_3P{=}NC(O)CH_2Cl$ and $Ph_3P{=}NC(O)\text{-}2\text{-}NC_5H_4$, which can behave as monodentate, bridging bidentate or chelate bidentate ligands towards Pd^{II} and Pt^{II} complexes using different donor atoms.[29,30]

However, the synthesis of orthometallated aryl complexes derived from iminophosphoranes is still scarcely represented, as well as the properties of the resulting complexes (reactivity, catalytic performance),[31–36] although very recently relevant contributions have appeared in the literature.[37,38]

With the aim of expanding the scope of this type of orthometallated derivatives, and also to gain more insight into their chemical behaviour, we have studied the reactivity of several iminophosphoranes towards Pd^{II} and Pt^{II} metallating reagents. In addition, we have also studied the reactivity of the resulting orthopalladated complexes towards different neutral and anionic ligands. We also report their behaviour as catalysts in specific C–C couplings such as the MH reaction, a field in which the application of orthopalladated complexes is in continuous growth.[39–44]

Results and Discussion

Synthesis of Orthometallated Iminophosphorane Complexes

The reactivity of different iminophosphoranes, such as $Ph_3P{=}NPh$, $Ph_3P{=}NCN$,[45] $Ph_3P{=}NC(O)CH_2Cl$, $Ph_3P{=}NC(O)\text{-}2\text{-}NC_5H_4$[46] and $Ph_3P{=}N{-}N{\equiv}C$[47] towards some standard metallating Pd^{II} and Pt^{II} reagents has been studied. The reaction of $Pd(OAc)_2$ (OAc = acetate) with

[a] Departamento de Química Inorgánica, Instituto de Ciencia de Materiales de Aragón, Universidad de Zaragoza-CSIC, 50009 Zaragoza, Spain

Ph_3P=NPh (1:1 molar ratio) in refluxing CH_2Cl_2, followed by evaporation to dryness and treatment of the residue with excess LiCl in MeOH, gives the orthometallated dimer $[Pd(C_6H_4\text{-}2\text{-}PPh_2{=}NPh\text{-}\kappa\text{-}C,N)(\mu\text{-}Cl)]_2$ (**1**) in very good yield (see Scheme 1). It has been previously reported that complexes related to **1**, but with different aryl substituents, can be obtained from the reaction of $Na_2[PdCl_4]$[36] or $Pd(OAc)_2$[37] and the corresponding iminophosphoranes in moderate to good yields (56–97%). The synthesis of **1** has been reported very recently[38] from the reaction of $[o\text{-}C_6H_4\text{-}PPh_2NPh)Li]_2{\cdot}OEt_2$ with $[PdCl_2(COD)]$ (COD = 1,5-cyclooctadiene). However, this process gives a mixture of **1** and the bis-aryl derivative, from which **1** is isolated in very poor yield (14%). As expected, **1** can also be obtained from the reaction of $Li_2[PdCl_4]$ and Ph_3P=NPh, but this reaction gives a mixture of **1** and the N-bonded derivative $[Cl_2Pd\{N(=PPh_3)Ph\}_2]$ from which **1** could not be separated in pure form. Thus, the preparation described here seems to be the most convenient method for the synthesis of **1**. In order to obtain the corresponding Pt^{II} derivative, two different procedures were checked. The first one involves the direct orthometallation of the substrate by reaction with $[PtCl_2(NCPh)_2]$ in refluxing 2-methoxyethanol, a method successfully applied in the synthesis of cycloplatinated complexes derived from phosphonium salts.[48,49] The second one is the reaction of the substrate with the dimer $[Pt(\mu\text{-}Cl)(\eta^3\text{-}2\text{-}MeC_3H_4)]_2$ in refluxing chloroform.[50] However, neither of the two methods gives the expected orthoplatinated dimer: in the first case, complete reduction to black Pt^0 was observed, while in the second case a complex mixture of unidentified products was obtained.

We attempted a similar reaction with the other α-stabilized iminophosphoranes. The reaction of $Pd(OAc)_2$ with Ph_3P=N-C(O)-2-NC_5H_4 and with LiCl, performed under the same experimental conditions as those reported for **1**, gives the orthometallated monomer $[Pd(C_6H_4\text{-}2\text{-}PPh_2{=}N\text{-}C(O)\text{-}2\text{-}NC_5H_4\text{-}\kappa\text{-}C,N,N)(Cl)]$ (**11**) in good yield (see Scheme 2). As described for **1**, the reaction of $Li_2[PdCl_4]$ with Ph_3P=N-C(O)-2-NC_5H_4 gives a mixture of **11** and the coordination product $[Cl_2Pd\{N(=PPh_3)C(O)\text{-}2\text{-}NC_5H_4\}]$, already described by us,[30] and from which **11** could not be cleanly separated. On the other hand, the analogous Pt^{II} complex $[Pt(C_6H_4\text{-}2\text{-}PPh_2{=}N\text{-}C(O)\text{-}2\text{-}NC_5H_4\text{-}\kappa\text{-}C,N,N)(Cl)]$ (**12**) can be easily obtained in moderate yield by reaction of $[PtCl_2(NCPh)_2]$ with Ph_3P=N-C(O)-2-NC_5H_4 (1:1 molar ratio) in refluxing 2-methoxyethanol for 8 h. It is worthwhile to note that the previous reactivity of the iminophosphorane Ph_3P=N-C(O)-2-NC_5H_4 towards different Pd^{II} and Pt^{II} precursors[30] never resulted in a metallated compound. The obvious difference in reactivity with that reported here comes from the reaction conditions: the processes performed at room temperature or at a low reflux temperature (CH_2Cl_2/acetone) give coordination compounds,[30] while those performed in harsh conditions (refluxing 2-methoxyethanol) give the metallated derivatives.

Attempted orthometallation reactions involving the iminophosphoranes $Ph_3P{=}NC{\equiv}N$, $Ph_3P{=}NC(O)CH_2Cl$ and $Ph_3P{=}NN{\equiv}C$ using the methods described above were not successful. In the case of Pd, mixtures of the corresponding *cis*- and *trans*-$[Cl_2Pd(N\text{-ligand})_2]$ derivatives were obtained;[29,30] in the case of platinum only decomposition to black Pt^0 was observed. Due to the lack of reactivity of these iminophosphoranes, they were not further investigated.

Complex **1** has been characterised previously and its structure is shown in Scheme 1.[38] Complexes **11** and **12**

give satisfactory elemental analyses, and their mass spectra show the expected molecular peaks with the correct isotopic distribution. The IR spectra of **11** and **12** show sharp absorptions due to the ν_{CO} stretch at 1644 (**11**) and 1646 (**12**) cm^{-1}, shifted to higher frequencies with respect to the corresponding absorption in the free ligand, and also show two strong bands due to the ν_{PN} stretch at 1332 (**11**) and 1330 (**12**) cm^{-1}, while in the free ligand this absorption appears at 1366 cm^{-1}.[46] These two facts indicate that the iminic N-atom is coordinated to the metal centre.[30] The ^1H NMR spectra of **11** and **12** show similar patterns, and unambiguously reveal the presence of the cyclometallated $[M(C_6H_4\text{-}2\text{-}PPh_2{=}N\text{-})]$ unit. Thus, four different signals assigned to the protons of the C_6H_4 unit can be observed at δ = 7.00, 7.13, 7.28 and 8.10 ppm in complex **11** and at δ = 6.95, 7.05, 7.23 and 8.02 ppm in **12**, with the signal at δ = 8.02 ppm showing ^{195}Pt satellites, as well as signals corresponding to the pyridine group. Moreover, the N-bonding of the pyridine ring can be inferred from the shift to low field of the resonance attributed to the H_α proton (δ = 8.97 ppm in **11**; δ = 9.17 ppm in **12**) with respect to its position in the free ligand (δ = 8.69 ppm),[46] and from the presence, in **12**, of ^{195}Pt satellites for the multiplet at δ = 9.17 ppm ($^3J_{Pt,H} \approx 20$ Hz). These IR and ^1H NMR spectroscopic data are in good agreement with the structure proposed in Scheme 2 for **11** and **12**, in which the orthometallated iminophosphorane acts as a *C*,*N*,*N*-terdentate ligand. The $^{31}P\{^1H\}$ NMR spectra of **11** and **12** show singlet signals at δ = 51.88 ppm in both cases (the signal of **12** shows the expected ^{195}Pt satellites), and these signals are strongly deshielded with respect to their position, not only in the free ligand (δ = 23.89 ppm) but also in the *N*,*N*-bonded complexes ($\delta \approx$ 34 ppm).[30] The position of this resonance is similar to that found in other recently described cyclopalladated derivatives in which the metallated iminophosphorane behaves as a *C*,*N*-chelating group.[37] Finally, the $^{13}C\{^1H\}$ NMR spectrum of **11** shows signals corresponding to the presence of all the expected functional groups, and confirms the structure proposed in Scheme 2. The orthometallated carbon atom C_1-Pd appears at δ = 153.19 ppm.

In summary, the standard methods of C–H bond activation to give orthometallated complexes of Pd^{II} and Pt^{II} can be applied successfully to iminophosphorane ligands to afford cyclopalladated and cycloplatinated complexes. The crystal structure of **11** has been determined by X-ray diffraction methods and provides additional structural information.

X-ray Structure of Complex 11

Crystals of **11** of adequate quality for X-ray purposes were grown by slow vapour diffusion of Et_2O into a CH_2Cl_2 solution of the crude complex at room temperature. A drawing of the organometallic complex is shown in Figure 1. The parameters concerning the data collection and refinement are collected in Table 1, and selected bond lengths and angles are given in Table 2.

The Pd atom is located in a slightly distorted square-planar environment and is surrounded by the metallated carbon atom C(7), the chlorine atom Cl(1) and the two N atoms of the iminophosphorane ligand, the iminic N atom, N(1), and the pyridinic N atom, N(2). Thus, the metallated iminophosphorane behaves as a *C*,*N*,*N*-terdentate ligand, in good agreement with the NMR spectroscopic data, forming two fused, five membered rings. The bite angles of the two chelating moieties are 87.24(9)° [C(7)–Pd(1)–N(1)] and 79.40(8)° [N(1)–Pd(1)–N(2)], and the sum of the bond

angles around the Pd(1) atom is 360.05(9)°. The molecule deviates only slightly from planarity: for instance, the maximum deviations found in the best least-square planes defined by [C(7)–C(12)–P(1)–N(1)–Pd(1)] and [Pd(1)–N(1)–C(1)–C(2)–N(2)] are only 0.09 Å and 0.02 Å, respectively. The dihedral angle between these two planes is 4.5°. The Pd(1)–C(7) bond length [1.976(3) Å] is statistically identical or slightly longer than those found in the related complex [Pd{κ^2-*C*,*N*-C_6H_4(PPh_2=NC_6H_4Me-4′)-2}(μ-OAc)]$_2$ [1.964(3) Å and 1.959(3) Å], and is shorter than that found in [Pd{κ^2-*C*,*N*-C_6H_4(PPh_2=NC_6H_4Me-4′)-2}(tmeda)]ClO_4 [2.019(3) Å] (tmeda = *N*,*N*,*N*′,*N*′-tetramethylethylenediamine).[37] The Pd–N(iminic) bond length [Pd(1)–N(1) = 1.997(2) Å] is shorter than those found in the aforementioned related complexes [2.050(2), 2.051(2) and 2.055(2) Å], probably reflecting the low *trans* influence of the chlorine ligand. The Pd–N(pyridine) bond length [Pd–N(2) = 2.120(2) Å] is similar to those found in related arrangements (pyridine *trans* to aryl carbon).[51,52] This distance is longer than those found in related Pd^{II} complexes in which the pyridine fragment is *trans* to an atom with a smaller *trans* influence; for instance, the Pd–N(py) bond length in [Pd($C_6H_4CH_2NMe_2$)(Ph_3PNC(O)-2-NC_5H_4)]ClO_4 is 2.056(3) Å, and in this complex the pyridine is *trans* to the aminic N atom of the NMe_2 group.[30]

The P(1)–N(1) bond length [1.649(2) Å] is longer than those reported in all related complexes. The complex [Pd{κ^2-*C*,*N*-C_6H_4(PPh_2=NC_6H_4Me-4′)-2}(μ-OAc)]$_2$ shows P–N bond length values of 1.605(2) Å and 1.610(2) Å, while that found in [Pd{κ^2-*C*,*N*-C_6H_4(PPh_2=NC_6H_4Me-4′)-2}(tmeda)]ClO_4 is 1.607(3) Å.[37] This clear elongation of the P–N bond in **11** is due to two main facts: the coordination of the N atom and the presence of the carbonyl group, which delocalizes the charge density through the P-N-C-O system. As a comparison, the P–N bond length in [Pd($C_6H_4CH_2NMe_2$)(Ph_3PNC(O)-2-NC_5H_4)]ClO_4 is 1.624(4) Å,[30] and in this complex the iminophosphorane bonds to the palladium through the pyridine N-atom and the carbonyl oxygen, leaving the -N=P fragment uncoordinated. The delocalisation of the charge density is also reflected in the short value of the N(1)–C(1) bond length [1.362(3) Å], which is similar, within experimental error, to that found in Ph_3P=NC(O)Ph [1.353(5) Å].[53,54] Finally, the environment around the P atom is tetrahedral, with P–C bond lengths similar to those found in related complexes.[30,37]

Reactivity of Orthometallated Iminophosphorane Complexes

The reactivity of complexes **1** and **11** was examined in order to check the stability of the metallated chelating (**1**) or pincer (**11**) ligands. The main results are resumed in Scheme 1 and 2, respectively. Thus, the dinuclear complex **1** reacts with neutral monodentate ligands L (L = PPh_3, $PPhMe_2$ or pyridine) to give the corresponding mononuclear derivatives **2**, **3** and **4**, respectively, as a result of the cleavage of the chloride bridging system. The NMR spectra

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of **2** and **3** display a single set of signals in each case, which shows that these complexes are obtained as a single isomer. The $^{31}P\{^1H\}$ NMR spectrum of **2** shows the presence of two doublet signals ($^3J_{P,P}$ = 4.7 Hz), which suggests the *trans* location of the iminic nitrogen and the PPh_3 ligand. The *cis* arrangement of the metallated carbon and the phosphane ligand is in good agreement with the *transphobia* between these ligands.[37,55–57] However, the NMR spectra of complex **4** show the presence of a mixture of isomers **a** and **b** (see Scheme 1) in a molar ratio **4a:4b** of 4.1:1. This fact is worthy of note, since the typical reactivity of *C*,*N*-cyclopalladated halide-bridged dimers towards neutral ligands L (L = phosphanes, pyridines, etc.) always gives a single isomer in which the incoming ligand is coordinated *trans* to the nitrogen atom.[58–60] Moreover, the major isomer **4a** has been characterised as that containing the pyridine ligand *cis* with respect to the iminic nitrogen, that is, to the NPh group. This assignment of structures **4a** and **4b** has been carried out by comparison of the chemical shifts of the H_6 proton of the C_6H_4 group (*ortho* to the metallated position) in the two isomers. Thus, the major isomer **4a** shows the signal corresponding to H_6 at δ = 8.30 ppm, while the minor isomer **4b** shows the corresponding signal at δ = 6.30 ppm. This clear upfield shift can be due to the anisotropic shielding undergone by H_6, which is promoted by the *cis* pyridine ligand in **4b**.[58] In line with this, a mutual anisotropic shielding between the phenyl and pyridine rings in complex **4a** should be possible and, in fact, the chemical shifts of the *ortho* protons of both rings in **4a** are found at higher field than the corresponding ones in **4b** [NPh: δ = 6.79 ppm (**4a**) and δ = 7.13 ppm (**4b**), $\Delta\delta$ = 0.34 ppm; py: δ = 8.52 ppm (**4a**) and δ = 8.90 ppm (**4b**), $\Delta\delta$ = 0.38 ppm]. Obviously, the free rotation of both rings − the pyridine around the Pd–N bond and the phenyl around the N–C bond − gives less-effective shielding (about 0.3–0.4 ppm) than in the case of the fixed orthometallated ring (2 ppm). A similar behaviour is observed in the $^{13}C\{^1H\}$ NMR spectrum of the mixture **4a/4b** (see Experimental Section).

The treatment of **1** with Tl(acac) (acac = acetylacetonate; CH_2Cl_2, 1:2 molar ratio) gives the *O*,*O*′-acac derivative [Pd(C_6H_4-2-PPh_2=NPh)(acac-O,O′)] (**5**), while the reaction of **1** with $AgClO_4$ (1:2 molar ratio) in acetonitrile gives the bis-solvate [Pd(C_6H_4-2-PPh_2=NPh)$(NCMe)_2$]ClO_4 (**6**). The two complexes show correct elemental analyses and mass spectra. Key spectroscopic parameters for **5** are the presence of two strong absorptions attributed to the *O*,*O*′-bonded acac ligand in the IR spectrum (1582, 1515 cm^{-1}) and the presence of the typical signals in the ^1H [δ = 1.74 and 2.06 ppm (CH_3); δ = 5.35 ppm (CH)] and $^{13}C\{^1H\}$ NMR spectra [δ = 27.14 and 27.31 ppm (CH_3); δ = 99.75 ppm (CH); δ = 185.42 and 187.92 ppm (CO)].[61] In the same way, the observation of two absorptions at 2321 and 2291 cm^{-1} in the IR spectrum, and two signals at δ = 2.26 and 2.50 ppm in the ^1H NMR spectrum of **6** suggest the presence of bonded acetonitrile. In these two cases, the presence of the cyclopalladated unit is confirmed through the observation of its characteristic absorptions (IR, ν_{PN}) and resonances in the NMR spectra.

Complex **1** reacts with $AgClO_4$ (1:2 molar ratio) in acetone to give, after filtration of the AgCl, solutions containing the solvated species [Pd(C_6H_4-2-PPh_2=NPh)$(S)_x$]ClO_4 (S = solvent; x = 2). The treatment of these freshly prepared solutions with bidentate ligands L_2 (1:1 molar ratio) gives the cationic complexes [Pd(C_6H_4-2-PPh_2=NPh)(L_2)]ClO_4 [L_2 = $Ph_2PCH_2PPh_2$ (**7**), $Ph_2PCH_2CH_2PPh_2$ (**8**), 1,10-phenanthroline (**9**), 2,2′-bipyridine (**10**)]. We have not observed the displacement of the metallated unit, nor the decoordination of the iminic nitrogen, even if the reactions are performed in presence of an excess of incoming ligand L_2. Compounds **7**–**10** show correct elemental analyses and mass spectra, and their IR spectra show in all cases the presence of a strong absorption in the range 1260–1290 cm^{-1}, assigned to the ν_{PN} stretch, which suggest that the iminic N-atom is bonded to the metal centre. The chelate coordination of the L_2 ligands is clearly inferred from their NMR spectra. The $^{31}P\{^1H\}$ NMR spectrum of **7** shows three signals, one at low field (δ = 48.38 ppm) attributed to the P atom in the metallated ring, and two at high field (δ = –10.60 and –34.16 ppm) characteristic of the *P*,*P*′-chelating dppm.[62] From the analysis of the $^{31}P\{^1H\}$ NMR spectrum of **8** the *P*,*P*′-bonding mode of the dppe is also evident since it shows three low-field signals, one corresponding to the iminophosphorane (δ = 45.31 ppm) and the other two to the dppe ligand (δ = 43.81 and 58.85 ppm).[63] In the case of complex **9** the ^1H NMR spectrum shows, in addition to the signals assigned to the NPh, PPh_2 and C_6H_4 protons, eight sharp peaks attributed to the phen ligand, and this fact clearly reveals the inequivalence of the two halves of the phen ligand due to its *N*,*N*′-bonding to the metal centre. Moreover, the complete attribution of all resonances of the phen ligand can be done unambiguously since one of the *ortho* protons is shifted to high field (δ = 8.00 ppm) with respect to the other (δ = 9.22 ppm) due to the anisotropic shielding exerted by the NPh ring.

In summary, the reactivity of **1** in cleavage reactions with neutral ligands (**2**–**4**) or substitution reactions of the halide bridging system by anionic (**5**) or neutral ligands (**6**–**10**) shows that the five-membered orthometallated iminophosphorane is quite stable, and behaves similarly to other *C*,*N*-orthometallated complexes derived from different amines. However, the reactivity of complex **11**, which contains a *C*,*N*,*N*-terdentate ligand reveals some noteworthy differences.

The reaction of **11** with $AgClO_4$ (1:1 molar ratio) in NCMe gives the solvate derivative [Pd(C_6H_4-2-PPh_2=N-C(O)-2-NC_5H_4-κ-C,N,N)(NCMe)]ClO_4 (**13**). The presence of bonded NCMe is inferred from the observation of an absorption in the IR spectrum at 2328 cm^{-1} (ν_{CN}) and a signal at δ = 2.79 ppm in the ^1H NMR spectrum. A comparison of the spectral parameters of **13** with those of **11** suggests that the metallated iminophosphorane still behaves as a *C*,*N*,*N*-terdentate ligand. The complex [Pd(C_6H_4-2-PPh_2=N-C(O)-2-NC_5H_4-κ-C,N,N)(PPh_3)]ClO_4 (**14**) can be obtained in the same way by treatment of **11** with $AgClO_4$ and PPh_3 (1:1:1 molar ratio) in acetone. The characterisation of **14** is straightforward from its $^{31}P\{^1H\}$ NMR spec-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

trum, which shows the presence of coordinated PPh_3 (δ = 39.34 ppm), and from its ^1H NMR spectrum, which shows all expected signals for the proposed stoichiometry. It is noteworthy that complex **14** is also obtained when the reaction is performed in the presence of an excess of PPh_3 (1:1:2 molar ratio), thus showing that the displacement of the N-bonded pyridine group does not take place under these conditions.

In order to check the strength of the pyridine fragment (usually a ligand easily removable from the metal coordination sphere) and the stability of the terdentate bonding mode κ-C,N,N of the metallated iminophosphorane, we investigated the reactivity of **11** towards several bidentate ligands, which usually act as chelating ligands. Complex **11** does not react with Tl(acac) under the usual experimental conditions (room temperature, 1:1 molar ratio), and unchanged **11** can be recovered at the end of the reaction. However, the reaction of **11** with $AgClO_4$ and $Ph_2PCH_2PPh_2$ (dppm), $Ph_2PCH_2CH_2PPh_2$ (dppe), 1,10-phenanthroline (phen) or 2,2′-bipyridine (bipy) (1:1:1 molar ratio) in acetone gives complexes of stoichiometry $[Pd(C_6H_4\text{-}2\text{-}PPh_2{=}N\text{-}C(O)\text{-}2\text{-}NC_5H_4)(L\text{-}L)]ClO_4$ [L-L = dppm (**15**), dppe (**16**), bipy (**17**), phen (**18**)], in keeping with their elemental analyses and mass spectra. The IR spectra of **15**–**18** show the absorption due to the ν_{PN} stretch in the range 1330–1340 cm^{-1}, thereby suggesting that the Pd–N(imine) bond is still present. The NMR spectra of **15** are temperature independent and show clearly that the metallating ligand is terdentate κ-C,N,N: the $^{31}P\{^1H\}$ NMR spectrum shows three well-defined signals at δ = 49.14 ($N{=}PPh_2$), 27.05 (dppm, $Pd\text{-}PPh_2$) and –24.75 ppm (dppm, free PPh_2). The observation of only one signal at high field (δ = –24.75 ppm) is diagnostic for the presence of monodentate P-dppm.[62] The formation of a four-membered metallacycle (*P*,*P*′-dppm) at the expense of the loss of the more stable five-membered ring by cleavage of the Pd–N(py) bond is probably not an energetically favourable process. In contrast to this, the NMR spectra of **16** are temperature dependent. At room temperature, the $^{31}P\{^1H\}$ NMR spectrum shows only a sharp singlet peak at δ = 47.28 ppm, assigned to the metallated $C_6H_4\text{-}2\text{-}PPh_2{=}N$ unit. On cooling ($CDCl_3$, 233 K) two new signals appear and an AMX spin system is observed. At this temperature, the chemical shift of the iminophosphorane appears at virtually the same position (δ = 47.84 ppm), as a doublet of doublets, and the signals attributed to the dppe ligand appear at δ = 41.38 (dd) and 58.21 ppm (d), clearly showing its *P*,*P*′-chelating mode.[50,63] The cleavage of the Pd–N(py) bond at low temperature is also inferred from the position of the *ortho* proton of the pyridine group, which appears in the ^1H NMR spectrum at δ = 8.72 ppm, that is, shifted to high field with respect to its position in **11**. All these facts suggest that the metallated $C_6H_4\text{-}2\text{-}PPh_2{=}N$ unit behaves statically on the NMR timescale in the range of temperatures measured, while the pyridine and dppe groups are involved into a series of dynamic process of coordination–decoordination, with the two processes being more or less equally favourable at room temperature. This process is stopped at low temperature, with *P*,*P*′-chelation of the dppe ligand.

The ^1H NMR spectra of **17** and **18** are temperature independent from 298 to 213 K (CD_2Cl_2) and show some noteworthy features. The first is the equivalence of the two rings of the bipy or phen ligands, inferred from the presence of a set of only four resonances (see Experimental Section), which do not split on cooling. This equivalence can be explained by assuming that they are bonded to the metal centre through only one nitrogen atom and that there is a rapid exchange of the N-bonded atoms, which can not be stopped at low temperature. This fast exchange can be easily rationalised through either a dissociative mechanism of the Pd–N bond or through a fluxional process, which could be a "single oscillatory motion of the potentially bidentate ligand via a trigonal-bipyramidal transition state". Similar proposals have been reported for related systems.[50,63] Whatever the mechanism, the coordination of the N-N ligands seems to occur in a plane normal to the molecular plane. This fact is clearly reflected in the anisotropic shielding undergone not only by the H_6 proton of the metallated C_6H_4 group (*ortho* to the palladated position), but also by the *ortho* proton of the pyridine fragment (H_α). These two protons appear strongly shifted to high field with respect to their positions in any other derivative. For instance, H_6 (C_6H_4) appears at δ = 6.33 (**17**) or 5.85 ppm (**18**) while in **11** its chemical shift is δ = 8.10 ppm; H_α (py) appears at δ = 7.95 (**17**) or 7.29 ppm (**18**) and at δ = 8.97 ppm in **11**.

In summary, the reactivity of **11** shows that the bonding of the terdentate ligand $[C_6H_4\text{-}2\text{-}PPh_2{=}N\text{-}C(O)\text{-}2\text{-}NC_5H_4\text{-}\kappa\text{-}C,N,N]$ to the Pd atom is remarkably stable. The decoordination of the pyridine fragment is not achieved upon treatment with classical chelating ligands (dppm, phen, bipy) and even in the presence of strongly chelating groups (dppe) only a competitive dynamic process is observed. These facts, together with the stability shown by the *C*,*N*-metallated complexes **1**–**10**, prompted us to study the plausible applications of this type of complex in catalytic processes.

Catalityc Activity of Orthometallated Complexes: Their Role as Precatalysts and the Formation of Nanoparticles in Mizoroki–Heck Processes

Four different complexes were selected in order to check the catalytic activity of orthopalladated iminophosphoranes. Complexes **1** and **4** are representative of complexes with the metallated $Ph_3P{=}NPh$ ligand, one neutral and one cationic, and both of them with available coordination sites. In the same way, **11** and **13** are representative examples of complexes with the metallated $Ph_3P{=}NC(O)$-2-py ligand, and with the same characteristics. The selected catalytic process is the C–C Mizoroki–Heck (MH) coupling between aryl halides and methyl acrylate, due to the exceptional activity shown by C,X-cyclopalladated complexes in this type of reaction (not limited to the MH reaction, but also applied to Suzuki, Stille, etc.),[39–44,50,64–69] and the wide interest in C–C Heck or Heck-type couplings.[70–77]

All selected complexes behave as moderate to good catalysts (see Experimental Section and Table 3) in the arylation of methyl acrylate to give methyl (*E*)-cinnamate in refluxing DMF (entries 1–14) when phenyl iodide is employed. The best yields are obtained when the amount of catalyst is 10^{-2} (mmol catalyst per mmol aryl halide; entries 1, 5, 9 and 12) but this amount can be as low as 10^{-6} (entries 4, 8, 11 and 14) and still give reasonable yields of isolated products and very high turnover numbers. However, as is evident from Table 3, the yield of isolated cinnamates drops when the concentration of catalyst decreases. The best reaction solvent for this type of process was found to be DMF. In spite of its similarity, very poor yields were obtained when *N*,*N*-dimethylacetamide (DMA) was used (entries 1–4 vs. entries 15–18), and the reaction was completely inhibited in NMP (*N*-methylpyrrolidinone). A comparison of the different catalysts shows that complexes **1** and **4** give better conversions than complexes **11** or **13**, and this fact could be related to the presence of the highly stable terdentate ligand [C_6H_4-2-PPh_2=N-C(O)-2-NC_5H_4-κ-C,N,N] in **11** and **13** (see below). The presence of weakly bonded ligands in **4** or **13** seems also to improve the yields, with respect to **1** or **11**, at low concentrations of catalyst. On the other hand, a comparison of the different substrates shows that the reactivity of deactivated bromoarenes (*p*-BrC_6H_4CN or *p*-BrC_6H_4CHO) is substantially lower for all catalysts than that described for PhI (entries 19–26). Due to these low conversions, no reactions were attempted with activated bromoarenes or with chloroarenes.

As general trends, we have observed that all reactions start after an induction period of approx. 30 min. During this time, the initial yellow or pale-yellow solution becomes dark red but without evidence of formation of palladium black. After the reaction, we attempted the recovery of the catalyst during the workup, but all these attempts were unsuccessful. Moreover, the analysis of the crude of the catalytic reaction, after removal of solvent (DMF) by distillation, by $^{31}P\{^1H\}$ NMR spectroscopy shows only peaks due to O=PPh_3 and other unidentified species; signals due to the initial catalyst were not observed. That is, the orthometallated unit is lost during the catalytic cycle. Interestingly, the resulting dark red solutions obtained at the end of the catalysis are still catalytically active and, after the addition of a second batch of reagents, the catalysis can be reassumed without an induction period. However, the yields drop from the first to the second and following runs, showing the deactivation of the catalytically active species. For instance, in a series of test experiments of four consecutive runs under the conditions described in entry 1 (1% catalyst **1**, PhI, DMF, reflux 24 h for each run) the obtained yields of methyl (*E*)-cinnamate were 90% (1st run), 60% (2nd run), 20% (3rd run) and 0% in the last run.

The observation of an induction period in all catalytic experiments, the evidence of the decomposition of the catalyst by NMR spectroscopy, the obvious impossibility to recover the catalyst after the end of the first run, and the confirmation that the catalysis can be reassumed after the first run strongly suggest that the organometallic derivatives **1**, **4**, **11** or **13** are not the true catalysts, but only the precatalysts. What, therefore, is the nature of the true catalytic species? Recent studies in this area show that, in many cases, the orthopalladated derivatives behave only as palladium reservoirs which, depending on the nature of the metallated unit, produces either low-coordinate Pd^0 species (cyclometallated phosphanes) or palladium nanoparticles (for instance, *C*,*N*-cyclopalladated complexes),[39–41,50,69,78] which are the true catalysts. Since our orthometallated iminophosphoranes can be considered to be closely related to a *C*,*N*-cyclometallated complex, we investigated the plausible formation of nanoparticles of Pd^0 from our catalysts. With this

purpose, we checked the stability of the complexes under the reaction conditions (DMF, refluxing for 24 h). Thus, complexes **1**, **4**, **11** and **13** were refluxed in DMF for 24 h, and the resulting solutions were analysed by TEM, since this method is one of the best for detecting nanoparticles.[79–81] In all studied cases, the presence of nanoparticles (averaged diameter 10 nm) was evident. Figure 2 shows a TEM image obtained from a solution of complex **4** after thermal treatment. It is worthy of mention that the amount of nanoparticles detected is not the same in all cases. For complexes **1** and **4**, the amount of nanoparticles is substantially higher than that found in solutions of complexes **11** and **13**, after the same thermal treatment. Thus, the simple heating of the complexes in the reaction solvent produces their decomposition and the formation of the nanoparticles, and it is known that nanoparticles of Pd catalyze the MH reaction.[79–81]

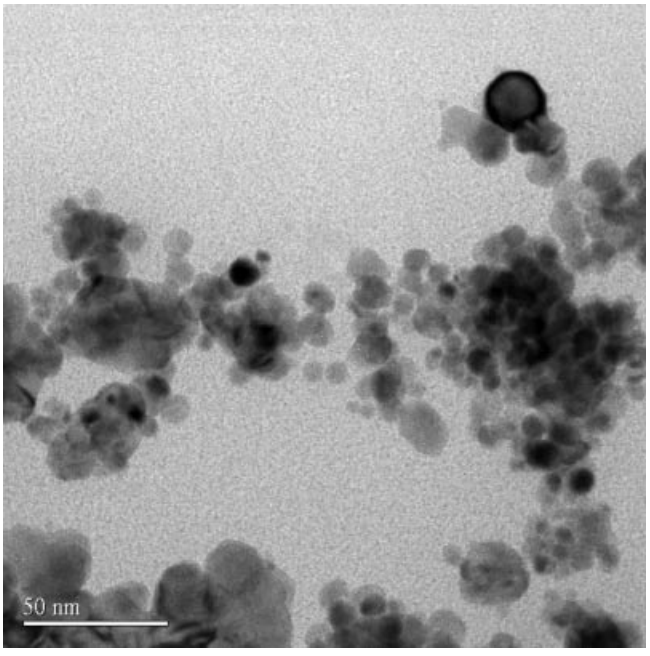

Figure 2. TEM image taken from a solution of complex **4** after 24 h in refluxing DMF.

We then compared the catalytic process described in entry 1 with that performed under the same experimental conditions but using nanoparticles. Monitoring by ^{1}H NMR spectroscopy showed that in the reaction carried out with nanoparticles, generated from **1** as described above, the presence of the reaction product can be detected only 10 min after the start of the reaction (time required to reach reflux temperature), that is, without an induction period, while in the process performed with catalyst **1** (entry 1) the presence of the products of the reaction is not detected until 30 min of additional refluxing. This additional time matches very well with the induction period (change of colour of the solution) observed in all catalytic reactions performed with complexes **1**, **4**, **11** and **13**. The yields obtained in these two processes are very similar (92% with catalyst **1** vs. 98% with nanoparticles). A second test to check the role of the nanoparticles as the catalytically active species is the mercury drop test (poisoning experiments).[78,82–84] The addition of an excess of Hg (with respect to the catalyst) to the process described in entry 1 completely inhibits the reaction and no product, even at trace levels, was detected at the end of the reaction.

In summary, the complexes with orthopalladated iminophosphoranes are precatalysts for the MH arylation of methyl acrylate to give the corresponding (*E*)-cinnamates in moderate to good yields. The true catalytic species are nanoparticles of elemental palladium, whose presence was confirmed by TEM, generated by decomposition of the catalyst.

Conclusions

The orthopalladated complexes [Pd(μ-Cl)(C_6H_4-2-PPh_2=NPh-κ-C,N)]$_2$ (**1**) and [Pd(C_6H_4-2-PPh_2=N-C(O)-2-NC_5H_4-κ-C,N,N)Cl] (**11**) have been obtained by reaction of Pd(OAc)$_2$ with the iminophosphoranes Ph_3P=NPh and Ph_3P=N-C(O)-2-NC_5H_4, respectively, in the presence of excess LiCl. The orthoplatinated derivative [Pt(C_6H_4-2-PPh_2=N-C(O)-2-NC_5H_4-κ-C,N,N)Cl] (**12**) can be obtained by reaction of [$PtCl_2(NCPh)_2$] with Ph_3P=N-C(O)-2-NC_5H_4 in refluxing 2-methoxyethanol. The reactivity of **1** in cleavage reactions with neutral ligands (**2**–**4**) or substitution reactions of the halide-bridging system by anionic (**5**) or neutral ligands (**6**–**10**) shows that the five-membered orthometallated iminophosphorane is quite stable, and behaves similarly to other *C*,*N*-orthometallated complexes derived from different amines. The reactivity of **11** shows that the bonding of the terdentate ligand [C_6H_4-2-PPh_2=N-C(O)-2-NC_5H_4-κ-C,N,N] to the Pd atom is remarkably stable. The decoordination of the pyridine fragment is not achieved with classical chelating ligands (dppm, phen, bipy) and even in the presence of strongly chelating groups (dppe) only a competitive dynamic process is observed. The complexes **1**, **4**, **11** and **13** are precatalysts for the MH arylation of methyl acrylate to give the corresponding (*E*)-cinnamates in moderate to good yields. The true catalytic species are nanoparticles of elemental palladium, whose presence is confirmed by TEM, generated by decomposition of the catalyst.

Experimental Section

CAUTION: *Perchlorate salts of metal complexes with organic ligands are potentially explosive. Only small amounts of these materials should be prepared and handled with great care.*[85]

General Methods: Solvents were dried and distilled under argon using standard procedures. Elemental analyses were performed on a Perkin–Elmer 2400-B microanalyser. Infrared spectra (4000–400 cm^{-1}) were recorded on a Perkin–Elmer Spectrum One FT-IR spectrophotometer from nujol mulls between polyethylene sheets. Mass spectra (positive ion FAB) were recorded from CH_2Cl_2 solutions on a V. G. Autospec spectrometer. ^{1}H, ^{13}C{^{1}H} and ^{31}P{^{1}H} NMR spectra were recorded in $CDCl_3$ or CD_2Cl_2 solutions at room temperature (other temperatures are specified) on Bruker

ARX-300 or Avance400 spectrometers operating, respectively, at 300.13 MHz (ARX300) and 400.13 MHz (Avance400). The ^1H and $^{13}C\{^1H\}$ NMR spectra were referenced to the residual solvent signal as internal standard and the $^{31}P\{^1H\}$ NMR spectra to external H_3PO_4 (85%). The starting material Ph_3P=NPh is commercially available (Aldrich) and Ph_3P=N-C(O)-2-NC_5H_4 was prepared following published methods.[46]

Complex 1: $Pd(OAc)_2$ (1.000 g, 4.45 mmol) was added to a solution of Ph_3P=NPh (1.572 g, 4.45 mmol) in dry CH_2Cl_2 (20 mL) under argon, and this mixture was refluxed for 1.5 h. The initial orange-brown solution evolved slowly during the reaction time to give a deep orange solution. After cooling, the solvent was removed to dryness, the residue was dissolved in MeOH (20 mL), treated with an excess of anhydrous LiCl (0.755 g, 17.8 mmol) and then stirred at room temperature. After a few seconds complex **1** precipitated as a deep-yellow solid, although stirring was continued for an additional 30 min. After this time **1** was filtered off, washed with MeOH (20 mL) and Et_2O (50 mL) and air dried. Yield: 2.108 g (95.9%). $C_{48}H_{38}Cl_2N_2P_2Pd_2$ (988.50): calcd. C 58.32, H 3.87, N 2.83; found C 58.58, H 3.93, N 2.91. IR: $\tilde{\nu}$ = 1292, 1263 (ν_{PN}) cm^{-1}. NMR spectroscopic data have been reported previously.[38]

Complex 2: PPh_3 (0.041 g, 0.158 mmol) was added to a suspension of **1** (0.078 g, 0.079 mmol) in 5 mL of CH_2Cl_2. The initial orange suspension gradually dissolved and, after 5 min stirring at room temperature, a pale-yellow solution was obtained. The evaporation of this solution and treatment of the oily residue with 20 mL of Et_2O gave **2** as a white solid, which was filtered off, washed with additional Et_2O (10 mL) and air dried. Yield: 0.092 g (77%). $C_{42}H_{34}ClNP_2Pd$ (756.54): calcd. C 66.68, H 4.53, N 1.85; found C 66.51, H 4.47, N 1.85. IR: $\tilde{\nu}$ = 1289 (ν_{PN}) cm^{-1}. MS (FAB+): *m*/*z* (%) = 720 (25) $[M - Cl]^+$. ^1H NMR ($CDCl_3$): δ = 6.46 (tt, $^3J_{H,H}$ = 7.8, $^4J_{H,H}$ = 1.2 Hz, 1 H, C_6H_4), 6.59–6.75 (m, 3 H, C_6H_4), 6.83–6.98 (br. m, 5 H, NPh), 7.18–7.24 (m, 6 H, H^m, PPh_3), 7.27–7.33 (m, 3 H, H^p, PPh_3), 7.48–7.62 [m, 12 H, PPh_3 (6 H^o) + PPh_2 (4 H^m + 2 H^p)], 7.89–7.96 (m, 4 H, H^o, PPh_2) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 33.46 (d, $^3J_{P,P}$ = 4.7 Hz, 1 P, Pd–PPh_3), 38.69 (d, $^3J_{P,P}$ = 4.7 Hz, 1 P, P=N) ppm.

Complex 3: Complex **3** was prepared following a synthetic procedure similar to that reported for **2**. Thus, **1** (0.200 g, 0.202 mmol) in CH_2Cl_2 (5 mL) was treated with $PPhMe_2$ (57.6 μL, 0.404 mmol) to give **3** as a cream solid. Yield: 0.232 g (90.7%). $C_{32}H_{30}ClNP_2Pd$ (632.4): calcd. C 60.78, H 4.78, N 2.21; found C 60.61, H 4.74, N 1.91. IR: $\tilde{\nu}$ = 1291, 1260 (ν_{PN}) cm^{-1}. MS (FAB+): *m*/*z* (%) = 631 (20) $[M]^+$, 596 (100) $[M - Cl]^+$. ^1H NMR ($CDCl_3$): δ = 1.68 (d, $^2J_{P,H}$ = 10.5 Hz, 6 H, PMe_2), 6.69–6.74 (m, 1 H, C_6H_4), 6.78–6.95 [m, 8 H, C_6H_4 (3 H) + NPh], 7.30–7.38 (m, 3 H, H^m + H^p, PPh), 7.45–7.51 (m, 4 H, H^m, PPh_2), 7.54–7.60 (m, 2 H, H^p, PPh_2), 7.69–7.76 (m, 2 H, H^o, PPh), 7.83–7.89 (m, 4 H, H^o, PPh_2) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 8.75 (s, 1 P, Pd-$PPhMe_2$), 34.12 (s, 1 P, P=N) ppm.

Complex 4: Complex **4** was prepared following a synthetic procedure similar to that reported for **2**. Thus, **1** (0.200 g, 0.202 mmol) in CH_2Cl_2 (10 mL) was treated with pyridine (65.1 μL, 0.808 mmol) to give **4** as a yellow solid. Yield: 0.198 g (85.3%). Complex **4** was characterised spectroscopically (NMR) as a mixture of the isomers **4a/4b** in a molar ratio of 4.1:1. $C_{29}H_{24}ClN_2PPd$ (573.35): calcd. C 60.75, H 4.22, N 4.89; found C 60.80, H 4.10, N 5.06. IR: $\tilde{\nu}$ = 1589 (py), 1285 (ν_{PN}) cm^{-1}. ^1H NMR ($CDCl_3$) (not all signals for the minor isomer **4b** could be detected due to overlap): δ = 6.30 (dd, $^3J_{H,H}$ = 5.6, $^4J_{H,H}$ = 1.6 Hz, H^6, **4b**), 6.56 (tm, $^3J_{H,H}$ = 7.2, $^4J_{H,H}$ = 1.2 Hz, H^p, NPh, **4a**), 6.65 (t, $^3J_{H,H}$ = 7.2 Hz, H^m, NPh, **4a**), 6.79 (dm, $^3J_{H,H}$ = 7.2, $^4J_{H,H}$ = 1.2 Hz, H^o, NPh, **4a**), 6.86 (ddd, $^3J_{P,H}$ = 10.4, $^3J_{H,H}$ = 7.6, $^4J_{H,H}$ = 1.6 Hz, H^3, C_6H_4, **4a**), 6.94–6.99 (m, H^m, py, **4a**), 7.00–7.04 (m, H^4, C_6H_4, **4a**), 7.13 (dm, $^3J_{H,H}$ = 8.4, $^4J_{H,H}$ = 1.2 Hz, H^o, NPh, **4b**), 7.22 (tt, $^3J_{H,H}$ = 7.2, $^4J_{H,H} \approx {}^5J_{P,H}$ = 1.6 Hz, H^5, C_6H_4, **4a**), 7.31–7.35 (m, H^m, py, **4b**), 7.43 (tt, $^3J_{H,H}$ = 7.6, $^4J_{H,H}$ = 1.6 Hz, H^p, py, **4a**), 7.48–7.55 (m, H^m, PPh_2, **4a** + **4b**), 7.59–7.63 (m, H^p, PPh_2, **4a** + **4b**), 7.74–7.79 (m, H^o, PPh_2, **4a**), 7.88–7.93 (m, H^o, PPh_2, **4b**), 8.30 (ddd, $^3J_{H,H}$ = 7.2, $^4J_{P,H}$ = 1.6, $^4J_{H,H}$ = 1.2 Hz, H^6, C_6H_4, **4a**), 8.52 (dd, $^3J_{H,H}$ = 6.4, $^4J_{H,H}$ = 1.6 Hz, H^o, py, **4a**), 8.90 (dd, $^3J_{H,H}$ = 5.2, $^4J_{H,H}$ = 1.6 Hz, H^o, py, **4b**) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$) (not all signals for the minor isomer **4b** could be detected due to overlap): δ = 121.74 (d, $^5J_{P,C}$ = 2.0 Hz, C^p, NPh, **4a**), 123.83 (s, C^m, py, **4a**), 124.04 (d, $^3J_{P,C}$ = 14.1 Hz, C^4, C_6H_4, **4a**), 125.02 (s, C^m, py, **4b**), 127.43 (d, $^3J_{P,C}$ = 9.1 Hz, C^o, NPh, **4a**), 127.72 (s, C^m, NPh, **4a**), 128.24 (d, $^2J_{P,C}$ = 21.1 Hz, C^3, C_6H_4, **4a**), 128.61 (d, $^1J_{P,C}$ = 86.5 Hz, C^{ipso}, PPh_2, **4a**), 128.86 (d, $^3J_{P,C}$ = 11.1 Hz, C^m, PPh_2, **4a**), 128.90 (d, $^3J_{P,C}$ = 11.1 Hz, C^m, PPh_2, **4b**), 130.29 (d, $^4J_{P,C}$ = 3.0 Hz, C^5, C_6H_4, **4b**), 130.38 (d, $^4J_{P,C}$ = 3.1 Hz, C^5, C_6H_4, **4a**), 132.75 (d, $^4J_{P,C}$ = 2.0 Hz, C^p, PPh_2, **4a**), 133.23 (d, $^2J_{P,C}$ = 9.1 Hz, C^o, PPh_2, **4a**), 133.50 (d, $^2J_{P,C}$ = 10.1 Hz, C^o, PPh_2, **4b**), 134.43 (d, $^3J_{P,C}$ = 15.1 Hz, C^6, C_6H_4, **4b**), 136.48 (s, C^p, py, **4a**), 137.35 (s, C^p, py, **4b**), 138.53 (d, $^3J_{P,C}$ = 15.1 Hz, C^6, C_6H_4, **4a**), 140.55 (d, $^1J_{P,C}$ = 139 Hz, C^2, C_6H_4, **4a**), 147.12 (d, $^2J_{P,C}$ = 3.0 Hz, C^{ipso}, NPh, **4a**), 147.19 (d, $^2J_{P,C}$ = 3.0 Hz, C^{ipso}, NPh, **4b**), 151.04 (s, C^o, py, **4a**), 152.27 (d, $^2J_{P,C}$ = 20.1 Hz, C^1, C_6H_4, **4a**), 153.73 (s, C^o, py, **4b**), 156.39 (d, $^2J_{P,C}$ = 20.1 Hz, C^1, C_6H_4, **4b**) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 44.31 (**4b**), 48.21 (**4a**) ppm.

Complex 5: Tl(acac) (0.123 g, 0.404 mmol) was added to a suspension of **1** (0.200 g, 0.202 mmol) in CH_2Cl_2 (10 mL). The resulting mixture was stirred at room temperature for 1 h, then filtered through Celite. The clear yellow solution was evaporated to dryness and the oily residue treated with cold *n*-hexane (10 mL) to give **5** as a yellow solid. This solid was filtered off and dried in vacuo. Yield: 0.184 g (81.5%). $C_{29}H_{26}NO_2PPd$ (557.91): calcd. C 62.43, H 4.69, N 2.51; found C 62.49, H 4.60, N 2.35. IR: $\tilde{\nu}$ = 1582, 1515 (ν_{CO}), 1287, 1262 (ν_{PN}) cm^{-1}. MS (FAB+): *m*/*z* (%) = 557 (30) $[M]^+$. ^1H NMR (CD_2Cl_2): δ = 1.74 (s, 3 H, Me, acac), 2.06 (s, 3 H, Me, acac), 5.35 (s, 1 H, CH, acac), 6.83 (td, $^3J_{H,H}$ = 7.8, $^4J_{H,H}$ = 1.2 Hz, 1 H, H^p, NPh), 6.95 (dd, $^3J_{H,H}$ = 7.6, $^4J_{H,H}$ = 1.2 Hz, 1 H, H^3, C_6H_4), 6.99 (t, $^3J_{H,H}$ = 7.2 Hz, 2 H, H^m, NPh), 7.05–7.10 [m, 3 H, NPh (H^o) + C_6H_4 (H^4)], 7.27 (tt, $^3J_{H,H}$ = 7.6, $^4J_{H,H} \approx {}^5J_{P,H}$ = 1.6 Hz, 1 H, H^5, C_6H_4), 7.53–7.57 (m, 4 H, H^m, PPh_2), 7.64–7.68 (m, 2 H, H^p, PPh_2), 7.71 (dm, $^3J_{H,H}$ = 8.0 Hz, 1 H, H^6, C_6H_4), 7.82–7.87 (m, 4 H, H^o, PPh_2) ppm. $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 27.14 (s, Me, acac), 27.31 (s, Me, acac), 99.75 (s, CH, acac), 121.39 (s, C^p, NPh), 124.17 (d, $^3J_{P,C}$ = 14 Hz, C^4, C_6H_4), 126.99 (d, $^3J_{P,C}$ = 10 Hz, C^o, NPh), 127.47 (s, C^m, NPh), 127.73 (d, $^2J_{P,C}$ = 22 Hz, C^3, C_6H_4), 128.21 (d, $^1J_{P,C}$ = 85 Hz, C^{ipso}, PPh_2), 128.91 (d, $^3J_{P,C}$ = 11 Hz, C^m, PPh_2), 129.64 (d, $^4J_{P,C}$ = 3 Hz, C^5, C_6H_4), 132.40 (d, $^3J_{P,C}$ = 14 Hz, C^6, C_6H_4), 132.79 (d, $^4J_{P,C}$ = 2 Hz, C^p, PPh_2), 133.22 (d, $^2J_{P,C}$ = 10 Hz, C^o, PPh_2), 140.75 (d, $^1J_{P,C}$ = 139 Hz, C^2, C_6H_4), 146.49 (d, $^2J_{P,C}$ = 3 Hz, C^{ipso}, NPh), 152.99 (d, $^2J_{P,C}$ = 20 Hz, C^1, C_6H_4), 185.42 (s, CO, acac), 187.92 (s, CO, acac) ppm. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 46.04 ppm.

Complex 6: $AgClO_4$ (0.084 g, 0.405 mmol) was added to a suspension of **1** (0.200 g, 0.202 mmol) in NCMe (15 mL) and the resulting mixture was stirred at room temperature for 30 min with exclusion of light. After this time the grey suspension was filtered through Celite and the resulting pale-yellow solution was evaporated to small volume (approx. 1 mL). Addition of *n*-pentane (10 mL) and continuous stirring gave **6** as a pale-yellow solid, which was filtered off and dried in vacuo. Yield: 0.226 g (87.5%). $C_{28}H_{25}ClN_3O_4PPd$ (640.35): calcd. C 52.52, H 3.93, N 6.56; found C 52.60, H 3.93, N

133.79 (d, $^2J_{P,C}$ = 11.2 Hz, C^o, PPh_2), 134.52 (d, $^4J_{P,C}$ = 2.5 Hz, C^p, PPh_2), 138.48 (d, $^1J_{P,C}$ = 130 Hz, C^2, C_6H_4), 139.11 (d, $^3J_{P,C}$ = 14.5 Hz, C^6, C_6H_4), 139.51 (s, C^4, py), 149.18 (s, C^6, py), 152.98 (s, C^2, py), 153.19 (d, $^2J_{P,C}$ = 8.6 Hz, C^1, C_6H_4), 172.25 (d, $^2J_{P,C}$ = 4.6 Hz, C=O) ppm. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 51.88 ppm.

Complex 12: A suspension of $[PtCl_2(NCPh)_2]$ (0.200 g, 0.424 mmol) and Ph_3P=NC(O)-2-NC_5H_4 (0.162 g, 0.424 mmol) in 15 mL of 2-methoxyethanol was refluxed for 8 h. During this time the initial suspension dissolved, and a greenish solution (presence of Pt^0) was obtained. After cooling, complex **12** precipitated from the alcoholic medium as a green solid. This solid was filtered and washed with Et_2O (20 mL). The crude solid of **12** was further dissolved in CH_2Cl_2 (40 mL), treated with charcoal and filtered through Celite to give a yellow solution. The evaporation of the solvent to dryness and treatment of the residue with Et_2O (30 mL) gave **12** as a yellow solid. Yield: 0.118 g (45.7%). Complex **12** was recrystallised from CH_2Cl_2/OEt_2 to give yellow needles of **12**·CH_2Cl_2, which were used for analytical and spectroscopic measurements. $C_{24}H_{18}ClN_2OPPt{\cdot}CH_2Cl_2$ (696.87): calcd. C 43.09, H 2.89, N 4.02; found C 42.98, H 2.84, N 4.24. IR: $\tilde{\nu}$ = 1646 (ν_{CO}), 1330 (ν_{PN}) cm^{-1}. MS (FAB+): *m*/*z* (%) = 612 (95) $[M]^+$, 576 (100) $[M - Cl]^+$. ^1H NMR (CD_2Cl_2): δ = 6.95 (ddd, $^3J_{P,H}$ = 11.6, $^3J_{H,H}$ = 6.0, $^4J_{H,H}$ = 1.2 Hz, 1 H, H^3, C_6H_4), 7.05 (tdd, $^3J_{H,H}$ = 7.6, $^4J_{P,H}$ = 5.2, $^4J_{H,H}$ = 1.2 Hz, 1 H, H^4, C_6H_4), 7.23 (tt, $^3J_{H,H}$ = 7.6, $^4J_{H,H} \approx {}^5J_{P,H}$ = 1.6 Hz, 1 H, H^5, C_6H_4), 7.48–7.53 (m, 4 H, H^m, PPh_2), 7.60 (ddd, $^3J_{H,H}$ = 7.2, $^3J_{H,H}$ = 5.2, $^4J_{H,H}$ = 1.2 Hz, 1 H, H$^\beta$, py), 7.62–7.67 (m, 2 H, H^p, PPh_2), 7.78 (dm, $^3J_{H,H}$ = 7.6 Hz, 1 H, H$^\delta$, py), 7.80–7.86 (m, 4 H, H^o, PPh_2), 7.98 (td, $^3J_{H,H}$ = 7.6, $^4J_{H,H}$ = 1.6 Hz, 1 H, H$^\gamma$, py), 8.02 (ddd, $^3J_{H,H}$ = 7.6, $^4J_{P,H}$ = 3.2, $^4J_{H,H}$ = 1.2, $^3J_{Pt,H}$ = 30.4 Hz, 1 H, H^6, C_6H_4), 9.17 (ddd, $^3J_{H,H}$ = 5.2, $^4J_{H,H}$ = 1.6, $^5J_{H,H}$ = 0.4, $^3J_{Pt,H} \approx$ 20 Hz, 1 H, H$^\alpha$, py) ppm. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 51.88 ($^2J_{Pt,P}$ = 452 Hz) ppm.

Complex 13: $AgClO_4$ (0.040 g, 0.191 mmol) was added to a suspension of **11** (0.100 g, 0.191 mmol) in NCMe (20 mL). The resulting white suspension was stirred at room temperature with exclusion of light for 30 min, then filtered through Celite. The resulting pale-yellow solution was evaporated to small volume (approx. 1 mL). Addition of Et_2O (20 mL) and continuous stirring gave **13** as an off-white solid, which was filtered, washed with additional Et_2O (10 mL) and air dried. Yield: 0.081 g (67.5%). Complex **13** was recrystallised from CH_2Cl_2/OEt_2 to give colourless microcrystals of **13**·2CH_2Cl_2, which were used for analytical and spectroscopic measurements. $C_{26}H_{21}ClN_3O_5PPd{\cdot}2CH_2Cl_2$ (798.17): calcd. C 42.14, H 3.16, N 5.26; found C 41.56, H 3.27, N 5.10. IR: $\tilde{\nu}$ = 2328 (ν_{CN}), 1669 (ν_{CO}), 1323, 1296 (ν_{PN}) cm^{-1}. MS (FAB+): *m*/*z* (%) = 487 (100) $[M - NCMe - ClO_4]^+$. ^1H NMR ($CDCl_3$): δ = 2.79 (s, 3 H, NCMe), 7.04 (ddd, $^3J_{P,H}$ = 10.6, $^3J_{H,H}$ = 7.6, $^4J_{H,H}$ = 1.1 Hz, 1 H, H^3, C_6H_4), 7.23 (tdd, $^3J_{H,H}$ = 7.5, $^4J_{P,H}$ = 5.1, $^4J_{H,H}$ = 1.2 Hz, 1 H, H^4, C_6H_4), 7.37 (tt, $^3J_{H,H}$ = 7.3, $^4J_{H,H} \approx {}^5J_{P,H}$ = 1.7 Hz, 1 H, H^5, C_6H_4), 7.45 (ddd, $^3J_{H,H}$ = 7.6, $^4J_{P,H}$ = 2.2, $^4J_{H,H}$ = 0.8 Hz, 1 H, H^6, C_6H_4), 7.56–7.63 (m, 4 H, H^m, PPh_2), 7.70–7.75 (m, 2 H, H^p, PPh_2), 7.84–7.91 [m, 5 H, PPh_2 (4 H^o) + py (H$^\beta$)], 7.95 (d, $^3J_{H,H}$ = 7.5 Hz, 1 H, H$^\delta$, py), 8.09 (td, $^3J_{H,H}$ = 7.5, $^4J_{H,H}$ = 1.8 Hz, 1 H, H$^\gamma$, py), 8.97 (dd, $^3J_{H,H}$ = 5.4, $^4J_{H,H}$ = 2.2 Hz, 1 H, H$^\alpha$, py) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 56.71 ppm.

Complex 14: $AgClO_4$ (0.103 g, 0.497 mmol) was added to a suspension of **11** (0.260 g, 0.497 mmol) in acetone (20 mL). The resulting suspension was stirred at room temperature with exclusion of light for 20 min, then filtered through Celite. PPh_3 (0.130 g, 0.497 mmol) was added to this freshly prepared solution and stirring was continued for an additional 30 min. The pale-yellow solution was evaporated to dryness and the oily residue was treated with Et_2O (20 mL). Continuous stirring gave **14** as a white solid, which was filtered, washed with Et_2O (10 mL) and air dried. Yield: 0.321 g (76.0%). Complex **14** was recrystallised from CH_2Cl_2/*n*-hexane to give pale-yellow crystals of **14**·2.5CH_2Cl_2, which were used for analytical and spectroscopic measurements. $C_{42}H_{33}ClN_2O_5P_2Pd{\cdot}2.5CH_2Cl_2$ (1061.9): calcd. C 50.33, H 3.61, N 2.64; found C 49.76, H 3.42, N 2.48. IR: $\tilde{\nu}$ = 1651 (ν_{CO}), 1339 (ν_{PN}) cm^{-1}. MS (FAB+): *m*/*z* (%) = 749 (55%) $[M - ClO_4]^+$. ^1H NMR (CD_2Cl_2): δ = 6.78 (dd, $^3J_{H,H}$ = 5.2, $^4J_{H,H}$ = 0.4 Hz, 1 H, py), 6.85–6.87 (m, 2 H, C_6H_4), 7.13–7.17 [m, 3 H, C_6H_4 (2 H) + py (1 H)], 7.52–7.57 (m, 6 H, H^m, PPh_3), 7.63–7.68 (m, 3 H, H^p, PPh_3), 7.71–7.76 (m, 4 H, H^m, PPh_2), 7.84–7.91 [m, 8 H, PPh_3 (6 H^o) + PPh_2 (2 H^p)], 7.96–8.04 [m, 5 H, PPh_2 (4 H^o) + py (1 H)], 8.07 (dm, $^3J_{H,H}$ = 8.0 Hz, 1 H, py) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 39.34 (s, 1 P, Pd–PPh_3), 49.18 (s, 1 P, P=N) ppm.

Complex 15: Complex **15** was prepared following a procedure similar to that reported for **14**. A solution of **11** (0.100 g, 0.191 mmol) in acetone (20 mL) was treated with $AgClO_4$ (0.040 g, 0.191 mmol) and dppm (0.073 g, 0.191 mmol) to give **15** as an orange solid. Yield: 0.163 g (87.8%). Complex **15** was crystallised from CH_2Cl_2/OEt_2 to give orange crystals of **15**·CH_2Cl_2, which were used for analytical and spectroscopic measurements. $C_{49}H_{40}ClN_2O_5P_3Pd{\cdot}CH_2Cl_2$ (1056.6): calcd. C 56.84, H 4.00, N 2.65; found C 56.93, H 3.75, N 2.79. IR: $\tilde{\nu}$ = 1650 (ν_{CO}), 1338 (ν_{PN}) cm^{-1}. MS (FAB+): *m*/*z* (%) = 871 (100) $[M - ClO_4]^+$. ^1H NMR ($CDCl_3$): δ = 3.47 (d, $^2J_{P,H}$ = 11.1 Hz, 2 H, CH_2, dppm), 6.84–7.97 (m, 38 H, Ph; extensive overlap of the signals) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = –24.75 (d, $^2J_{P,P}$ = 100 Hz, 1 P, free PPh_2), 27.05 (d, $^2J_{P,P}$ = 100Hz, 1 P, Pd–PPh_2), 49.14 (s, 1 P, P=N) ppm.

Complex 16: Complex **16** was prepared following a procedure similar to that reported for **14**. A solution of **11** (0.100 g, 0.191 mmol) in acetone (20 mL) was treated with $AgClO_4$ (0.040 g, 0.191 mmol) and dppe (0.076 g, 0.191 mmol) to give **16** as a cream solid. Yield: 0.157 g (83.3%). Complex **16** was recrystallised from CH_2Cl_2/*n*-hexane to give pale yellow crystals of **16**·CH_2Cl_2, which were used for analytical and spectroscopic measurements. $C_{50}H_{42}ClN_2O_5P_3Pd{\cdot}CH_2Cl_2$ (1070.6): calcd. C 57.22, H 4.14, N 2.62; found C 57.53, H 4.02, N 2.64. IR: $\tilde{\nu}$ = 1622 (ν_{CO}), 1329 (ν_{PN}) cm^{-1}. MS (FAB+): *m*/*z* (%) = 885 (70) $[M - ClO_4]^+$. Room temperature NMR spectroscopic data: ^1H NMR ($CDCl_3$): δ = 2.22–2.29 (br. s, 4 H, CH_2, dppe), 6.83–7.92 (m, 38 H, aromatics) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 47.28 (s, P=N) ppm. Low temperature NMR spectroscopic data (233 K): ^1H NMR ($CDCl_3$): δ = 2.31, 2.42, 2.88, 3.01 (4m, 4 H, CH_2, dppe), 6.60 (m, 1 H, C_6H_4), 6.92–7.11 (3m, 3 H, C_6H_4), 7.17–8.12 (m, 33 H, aromatics), 8.72 (dd, $^3J_{H,H}$ = 5.6, $^4J_{H,H}$ = 1.8 Hz, 1 H, H$^\alpha$, py) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 41.38 (dd, $^3J_{P,P}$ = 27.5, $^3J_{P,P}$ = 13.0 Hz, 1 P, P *trans* to N), 47.84 (dd, $^3J_{P,P}$ = 13.0, $^3J_{P,P}$ = 3.2 Hz, 1 P, P=N), 58.21 (d, $^3J_{P,P}$ = 27.5 Hz, 1 P, P *trans* to C) ppm.

Complex 17: Complex **17** was prepared following a procedure similar to that reported for **14**. A solution of **11** (0.100 g, 0.191 mmol) in acetone (20 mL) was treated with $AgClO_4$ (0.040 g, 0.191 mmol) and 2,2′-bipyridine (0.030 g, 0.191 mmol) to give **17** as a yellow solid. Yield: 0.110 g (77.5%). Complex **17** was crystallised from CH_2Cl_2/*n*-hexane to give yellow crystals of **17**·CH_2Cl_2, which were used for analytical and spectroscopic measurements. $C_{34}H_{26}ClN_4O_5PPd{\cdot}CH_2Cl_2$ (807.13): calcd. C 51.71, H 3.43, N 6.94; found C 51.79, H 2.87, N 7.18. IR: $\tilde{\nu}$ = 1652 (ν_{CO}), 1332 (ν_{PN}) cm^{-1}. MS (FAB+): *m*/*z* (%) = 643 (25) $[M - ClO_4]^+$. ^1H NMR ($CDCl_3$): δ = 6.33 (ddd, $^3J_{H,H}$ = 7.1, $^4J_{P,H}$ = 4.7, $^4J_{H,H}$ = 2.6 Hz, 1 H, H^6, C_6H_4), 6.92–6.99 (m, 1 H, C_6H_4), 7.08–7.12 (m, 2 H, C_6H_4), 7.55 (ddd, $^3J_{H,H}$ = 7.6, $^3J_{H,H}$ = 5.2, $^4J_{H,H}$ = 1.2 Hz, 2 H, H$^\beta$, bipy),

7.58–7.67 [m, 5 H, PPh_2 (4 H^m) + py (H^β)], 7.71–7.74 (m, 2 H, H^p, PPh_2), 7.76–7.85 (m, 4 H, H^o, PPh_2), 7.87–7.92 (m, 2 H, H^δ + H^γ, py), 7.95 (dd, $^3J_{H,H}$ = 4.0, $^4J_{H,H}$ = 1.5 Hz, 1 H, H^α, py), 8.02 (td, $^3J_{H,H}$ = 7.7, $^4J_{H,H}$ = 1.6 Hz, 2 H, H^γ, bipy), 8.30 (dt, $^3J_{H,H}$ = 7.7, $^4J_{H,H} \approx {}^5J_{H,H}$ = 1 Hz, 2 H, H^δ, bipy), 8.91 (ddd, $^3J_{H,H}$ = 5.2, $^4J_{H,H}$ = 1.6 Hz, 2 H, H^α, bipy) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 53.96 ppm.

Complex 18: Complex **18** was prepared following a synthetic procedure similar to that reported for **14**. A solution of **11** (0.100 g, 0.191 mmol) in acetone (20 mL) was treated with $AgClO_4$ (0.040 g, 0.191 mmol) and 1,10-phenanthroline (0.034 g, 0.191 mmol) to give **18** as a yellow solid. Yield: 0.100 g (68.2%). $C_{36}H_{26}ClN_4O_5PPd$ (767.45): calcd. C 56.34, H 3.41, N 7.30; found C 56.15, H 3.08, N 7.09. IR: $\tilde{\nu}$ = 1645 (ν_{CO}), 1338 (ν_{PN}) cm^{-1}. MS (FAB+): *m*/*z* (%) = 667 (30) $[M - ClO_4]^+$. ^1H NMR ($CDCl_3$): δ = 5.85 (dd, $^3J_{H,H}$ = 7.8, $^4J_{H,H}$ = 2.4 Hz, 1 H, H^6, C_6H_4), 6.83–6.88 (m, 1 H, C_6H_4), 6.97–7.02 (m, 2 H, C_6H_4), 7.29 (dm, $^3J_{H,H}$ = 4.2, $^4J_{H,H}$ = 0.6 Hz, 1 H, H^α, py), 7.36 (ddd, $^3J_{H,H}$ = 7.5, $^3J_{H,H}$ = 5.1, $^4J_{H,H}$ = 1.5 Hz, 1 H, H^β, py), 7.53–7.58 (m, 1 H, py), 7.63–7.69 (m, 4 H, H^m, PPh_2), 7.75–7.80 (m, 2 H, H^p, PPh_2), 7.88 (dd, $^3J_{H,H}$ = 8.1, $^3J_{H,H}$ = 4.8 Hz, 2 H, H^β, phen), 7.94–8.01 [m, 5 H, PPh_2 (4 H^o) + py (1 H)], 8.10 (s, 2 H, H^δ, phen), 8.61 (dd, $^3J_{H,H}$ = 8.1, $^4J_{H,H}$ = 1.5 Hz, 2 H, H^γ, phen), 9.36 (dd, $^3J_{H,H}$ = 4.8, $^4J_{H,H}$ = 1.8 Hz, 2 H, H^α, phen) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 53.96 ppm.

Catalytic Mizoroki–Heck Arylations of Methyl Acrylate. General Procedure: Methyl acrylate (1.35 mmol), NEt_3 (1.13 mmol) and the corresponding catalyst (complexes **1**, **4**, **11** or **13**, see amounts in Table 3) were added to a solution of the corresponding aryl halide (1.13 mmol) in dimethylformamide or dimethylacetamide (15 mL). This mixture was refluxed under argon for 24 h. After cooling, water (10 mL) was added. The organic phase was extracted several times with CH_2Cl_2 (3 × 10 mL) and the combined extracts were dried with anhydrous $MgSO_4$. The solvents were distilled off and the residue was extracted with *n*-pentane. Evaporation of the pentane solution to dryness gave the arylation products as white waxy solids or colourless oils (yields are collected in Table 3).

Transmission Electron Microscopy: For the TEM experiments a few drops of a solution of the samples in dichloromethane was deposited onto carbon-coated copper grids. In this way the organic ligands were dissolved whereas the metallic particles remained undissolved and dispersed, thus allowing their observation in the TEM. The observations were carried out with a Jeol 2000FXII microscope (point to point resolution: 2.8 Å) equipped with an Oxford Instruments INCA 200 Energy Dispersive Spectroscopy analyzer and a Gatan MSC-794 CCD camera for recording the images.

Crystallography. Data Collection: Crystals of complex [Pd(C_6H_4-2-PPh_2=N-C(O)-2-NC_5H_4-κ-C,N,N)Cl] (**11**) were grown by slow vapour diffusion of Et_2O into a CH_2Cl_2 solution of the crude complex at room temperature. A crystal of dimensions 0.20 × 0.10 × 0.043 mm was mounted on a quartz fibre in a random orientation and covered with epoxy. Data collection was performed at 100 K on a Bruker Smart Apex CCD diffractometer using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). A hemisphere of data was collected based on three ω-scan runs. For each of these runs, frames (606, 435, and 230, respectively) were collected at 0.3° intervals and 10 s per frame. The diffraction frames were integrated using the program SAINT[86] and the integrated intensities were corrected for systematic errors with SADABS.[87]

Structure Solution and Refinement: The structure was solved by Patterson and Fourier methods.[88] All non-hydrogen atoms were refined with anisotropic displacement parameters. The hydrogen atoms were placed at idealised positions and treated as riding atoms. Each hydrogen atom was assigned an isotropic displacement parameter equal to 1.2-times the equivalent isotropic displacement parameter of its parent atom. The structure was refined to F_o^2, and all reflections were used in the least-squares calculations.[89]

CCDC-253369 (for **11**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Acknowledgments

Funding by the Diputación General de Aragón (Spain, Project P061/2001) and Dirección General de Investigación Científica y Técnica (DGICYT) (Spain, Projects BQU2002-0510, BQU2002-00554 and MAT2003-1182) is gratefully acknowledged. R. B. thanks the MECD (Spain) for a predoctoral fellowship and T. S. thanks the MECD (Spain) for a postdoctoral fellowship.

Reactions of the *B*-Phenylborole Complex [CpRh(η^5-C_4H_4BPh)] with Metalloelectrophiles [(ring)M]$^{2+}$

Dmitry A. Loginov,[a] Dmitry V. Muratov,[a] Pavel V. Petrovskii,[a] Zoya A. Starikova,[a] Maddalena Corsini,[b] Franco Laschi,[b] Fabrizia de Biani Fabrizi,[b] Piero Zanello,[b] and Alexander R. Kudinov*[a]

Keywords: Boron / Electrochemistry / Heterocycles / Rhodium / Sandwich compounds

Thirty-valence-electron dicationic triple-decker complexes with a bridging borole ligand [CpRh(μ-η^5:η^5-C_4H_4BPh)M(ring)]$^{2+}$ [M(ring) = CoCp* (**3**), IrCp* (**6**), Ru(η-$C_6H_3Me_3$-1,3,5) (**8a**), Ru(η-C_6Me_6) (**8b**)] were obtained by stacking reactions of [CpRh(η^5-C_4H_4BPh)] (**2**) with the corresponding half-sandwich fragments [M(ring)]$^{2+}$. Minor formation of arene-type complexes [CpRh(μ-η^5:η^6-C_4H_4BPh)M(ring)]$^{2+}$ was observed for M(ring) = IrCp* and Ru(arene). On the contrary, the arene-type complex [CpRh(μ-η^5:η^6-C_4H_4BPh)RhCp*]$^{2+}$ (**5**) was isolated as the sole product from the reaction of **2** with the fragment [RhCp*]$^{2+}$; an intermediate formation of the triple-decker complex [CpRh(μ-η^5:η^5-C_4H_4BPh)RhCp*]$^{2+}$ (**4**) in this reaction was detected by ^{1}H NMR spectroscopy. Heating **6** in nitromethane gives the symmetrical triple-decker complex [Cp*Ir(μ-η^5:η^5-C_4H_4BPh)IrCp*]$^{2+}$ (**10**). The cations were isolated as salts with the BF_4^- anion. The structures of **2**, **5**$(BF_4)_2$, **6**$(BF_4)_2$ and **8a**$(BF_4)_2$ were determined by X-ray diffraction. The electrochemical properties of the complexes were also investigated.

Introduction

The interaction of arenes with 12-valence-electron (VE) metal complex fragments affords arene complexes. For instance, by using dicationic fragments [(ring)M]$^{2+}$ [(ring)M = Cp*Rh, Cp*Ir, (arene)Ru] in the form of their labile solvates with acetone, a great number of arene complexes [(ring)M(arene)]$^{2+}$ has been prepared.[1] A closely related reaction − the electrophilic stacking of sandwich compounds with [(ring)M]$^{n+}$ (n = 1, 2) fragments − has proved to be an effective method for the synthesis of cationic triple-decker complexes.[2] In particular, using this method, complexes with bridging five-electron ligands (cyclopentadienyl[3] and boratabenzene[4]) have been obtained. Herberich et al.[5] have prepared 30 VE triple-decker complexes [(ring)M(μ-η^5:η^5-C_4H_4BPh)CoCp]$^{2+}$ [(ring)M = Cp*Ir and (C_6Me_6)Ru] with a central four-electron borole ligand by reaction of the fragments [(ring)M]$^{2+}$ with the (*B*-phenylborole)cobalt complex [CpCo(η^5-C_4H_4BPh)] (**1**). In a similar reaction with the cyclohexyl-substituted analogue [CpCo(η^5-C_4H_4BCy)] we have synthesized the complexes [(ring)M(μ-η^5:η^5-C_4H_4BCy)CoCp]$^{2+}$ [(ring)M = Cp*Rh, (C_6H_6)Ru, (1,3,5-$C_6H_3Me_3$)Ru; Cy = cyclohexyl].[6]

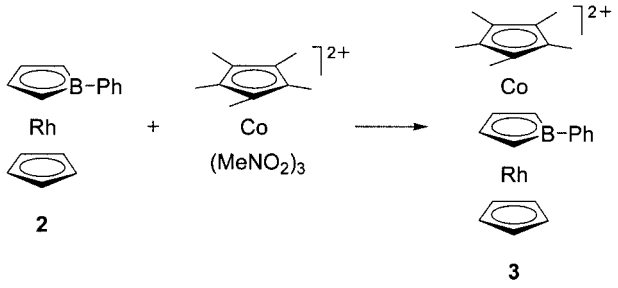
It is noteworthy that in the case of the phenyl-substituted complexes **1** and [CpRh(η^5-C_4H_4BPh)] (**2**) there are two possible places for attack by the metalloelectrophile: the borole ring or the phenyl substituent. However, for the cobalt complex **1** only electrophilic attack at the borole ligand has been described.[5] Herein we report the reactions of the analogous rhodium complex **2** with dicationic fragments [(ring)M]$^{2+}$ as well as the results of structural and electrochemical study of the products.

Results and Discussion

Stacking Reactions

The electrophilic stacking reaction of **2** with the dicationic fragment [Cp*Co]$^{2+}$ (in the form of its nitromethane solvate)[7] yields the 30 VE triple-decker complex **3** as the sole product, which suggests that the electrophilic attack proceeds exclusively at the borole ring (Scheme 1).[8] The absence of a product formed by attack at the phenyl substituent is in accordance with the known fact that the fragment [Cp*Co]$^{2+}$ does not react with benzene under such conditions.[9]

On the contrary, in the case of a similar reaction with the [Cp*Rh]$^{2+}$ fragment (in the form of its nitromethane or acetone solvate) only the arene-type complex **5** was isolated (Scheme 2). However, it was shown by means of ^{1}H NMR spectroscopy that the starting materials disappear within 5 min in [D_3]nitromethane and the mixture formed contains



Scheme 1. Formation of the triple-decker complex **3**.

both complex **5** and the triple-decker complex **4** in a ratio of about 1:9. After 4 h the signals of **4** disappear and the intensities of the signals of **5** increase, thus suggesting that **4** is unstable at room temperature and transforms into the arene-type complex **5**. It may be concluded that the initial attack of $[Cp^*Rh]^{2+}$ proceeds at the borole ring with its subsequent transfer to the benzene ring.

The stacking reaction of **2** with the iridium-containing fragment $[Cp^*Ir]^{2+}$, as its $MeNO_2$ solvate, affords the RhIr triple-decker complex **6** which, according to ^1H NMR spectroscopy, contains an admixture of the arene-type complex **7** (ca. 6%) (Scheme 3). In contrast to **4**, both **6** and **7** are stable at room temperature and do not interconvert. Unfortunately, we were unable to purify **6** either by recrystallization or by chromatography. Nevertheless, the content of **7** in the product can be decreased to about 4% by lowing the reaction temperature to –15 °C; this suggests that the electrophilic attack is kinetically controlled. The use of acetone instead of $MeNO_2$ leads to a further decrease of the admixture content (0.8%), apparently due to a slowing of the process caused by the lower reactivity of the acetone solvate. The best purity achieved for the triple-decker **6** was more than 99%. In a similar manner, the reaction of **2** with $[(arene)Ru]^{2+}$ fragments (arene = 1,3,5-$C_6H_3Me_3$, C_6Me_6) yields the RhRu triple-decker complexes **8a**,**b** contaminated with the arene-type complexes **9a**,**b**. The best purity of **8a**,**b** (achieved using acetone as a solvent at –15 °C) was about 97%.

We studied the thermal transformation of the triple-decker complexes **6** and **8a**,**b**, and found that the RhIr complex **6** transforms into the diiridium analogue **10** in refluxing nitromethane, apparently as a result of a symmetrization reaction (Scheme 4);[10] the absence of the corresponding dirhodium complex $[CpRh(\mu\text{-}\eta^5\text{:}\eta^5\text{-}C_4H_4BPh)RhCp]^{2+}$ may be explained by its low stability. However, the reaction is rather slow (according to ^1H NMR spectroscopy the degree of conversion is about 30% after 12 h) and we were unable to obtain complex **10** in pure form. Obviously,

the nucleophilic degradation[3d,11] by solvent molecules is the first stage of this process. In contrast to **6**, the RhRu complexes **8a**,**b** are stable in refluxing nitromethane.

NMR Spectroscopy

The ^1H and ^{11}B NMR spectroscopic data for complexes **3**–**10** are given in Table 1. For the triple-decker complexes **3**, **4**, **6** and **8** the signals of the borole ring protons are strongly shifted downfield ($\Delta\delta$ = 0.7–1.3 ppm) from the corresponding signals for the sandwich compound **2**. For the arene-type complexes **5**, **7** and **9** these signals are shifted in the same direction but to a lesser extent ($\Delta\delta$ = 0.3–0.4 ppm), thus making ^1H NMR spectroscopy sufficiently informative to distinguish between triple-decker and arene-type structures.

In the ^{11}B NMR spectra of the triple-decker complexes **3**, **6** and **8** the signals of the boron atoms of the borole ligand are shifted upfield ($\Delta\delta$ = 2.8–6.6 ppm) from the corresponding signal for **2**. An analogous shift ($\Delta\delta$ = 2.7–5.0 ppm) was observed earlier for the related cobalt-containing triple-decker complexes [(ring)M(μ-η⁵:η⁵-C_4H_4BR)-CoCp]²⁺ (R = Ph, Cy).[5a,6] For the arene-type complex **5** the signal of the borole ring boron atom is also shifted upfield ($\Delta\delta$ = 6.6 ppm), thus suggesting that ^{11}B NMR spectroscopy is not useful for distinguishing between triple-decker and arene-type structure.

X-ray Diffraction Study

Structure of the Sandwich Complex 2

Complex **2** has the expected sandwich structure (Figure 1). Selected bond lengths and angles are given in Table 2. The planes of the Cp and C_4H_4B cycles are approximately parallel; the dihedral angle Cp/C_4H_4B is equal to 2.42°. The Rh–B [2.304(4) Å] and Rh–C(C_4H_4B) [Rh–C 2.122(4)–2.198(4) Å, av. 2.16 Å] bonds are somewhat shorter than the corresponding bonds in [(η⁵-C_4H_4BPh)-$Rh(PPh_3)_2Cl$] [Rh–B 2.400(5) Å; Rh–C 2.137(4)–2.236(4) Å, av. 2.19 Å].[12] This fact is probably connected to stronger back-donation in the case of **2** as a consequence of the strong electron-donor effect of Cp. An analogous shortening of the Rh–B and Rh–C bonds in [(9-SMe_2-7,8-$C_2B_9H_{10}$)RhCp*]⁺ compared with [(9-SMe_2-7,8-$C_2B_9H_{10}$)Rh(dppe)Cl]⁺ (dppe = $Ph_2PCH_2CH_2PPh_2$) has been reported.[13]

Structures of the Triple-Decker Complexes 6(BF₄)₂ and 8a(BF₄)₂

The structures of complexes **6**$(BF_4)_2$ and **8a**$(BF_4)_2$ contain separated **6** or **8a** cations and BF_4^- anions. The cations

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

have triple-decker structures formed by three cyclic frameworks, between which two metal atoms are located (Figure 2). Selected bond lengths and angles are given in Tables 3 and 4. In both cases the planes of the cyclic ligands are almost coplanar (dihedral angles Cp*/C_4H_4B = 0.08° and C_4H_4B/Cp = 1.32° for **6**; $C_6H_3Me_3/C_4H_4B$ = 2.39° and C_4H_4B/Cp = 1.36° for **8a**). It was shown earlier that in the case of triple-decker complexes with bridging boratabenzene and pentaphospholyl ligands all bonds in the triple-decker fragment M(ring)M′ are longer than analogous bonds in related mononuclear sandwich compounds.[4b,11] The same pattern, viz. elongation of all bonds in the fragment M(μ-η^5:η^5-C_4H_4BPh)Rh in comparison with the corresponding bonds in **2**, is observed for **6** and **8a**. For example, the B–C [1.593(11) and 1.617(10) Å, av. 1.605 Å] and C–C [1.478(10), 1.506(10), and 1.488(10) Å, av. 1.491 Å)] bonds in the borole ring of **6** are considerably longer than the corresponding bonds in **2** [B–C 1.543(6) and 1.547(6) Å, av. 1.545 Å; C–C 1.425(5), 1.445(7), and 1.418(6) Å, av. 1.429 Å]. Furthermore, the Rh–C(C_4H_4BPh) bonds in **6** [2.174(7)–2.203(8) Å, av. 2.19 Å] and in **8a** [2.182(4)–2.216(4) Å, av. 2.20 Å] are longer than the corresponding bonds in **2** (av. 2.16 Å). This elongation is apparently connected with a loosening of the bonds upon bifacial coordination of the C_4H_4BPh ligand with two metal atoms as compared with its monofacial coordination with only one metal atom. The elongation of the metal-to-ring distances (Δ) in **6** and **8a** in comparison with **2** could be also expected. However, Δ(Rh···C_4H_4BPh) in **6** (1.778 Å) and **8a** (1.795 Å) is not longer, and is even somewhat shorter, than the corresponding distance in **2** (1.792 Å), which may be connected with a compensation of the expected elongation of Δ by shortening of the metal-to-ring distance as a result of the increase of the ring size.

Structure of the Arene-Type Complex 5(BF$_4$)$_2$

The structure of complex **5**$(BF_4)_2$ contains separated cation **5** and BF_4^- anions. The cation **5** consists of two sandwich moieties [CpRh(η^5-C_4H_4B)] and [Cp*Rh(η^6-C_6H_5)] connected to each other by a C–B σ-bond (Figure 3). Selected bond lengths and angles are given in Table 5. The planes of the cyclic ligands in each sandwich moiety are almost coplanar (the dihedral angles Cp/C_4H_4B and Cp*/C_6H_5 are equal to 3.52° and 0.47°, respectively). All bonds in the [CpRh(η^5-C_4H_4B)] moiety are very similar in length to the corresponding bonds in **2**, thus indicating that coor-

Electrochemistry

In principle, the sandwich unit **2** constitutes a poor redox-active component for polynuclear species planned to display intramolecular electronic communication. In fact, in CH_2Cl_2 solution it undergoes an irreversible oxidation at high potential values (controlled potential coulometry consumed 1.5 electrons per molecule, thus indicating that the probable degradation of [**2**]$^+$ leads to redox active by-products). In reality, as we will show, its linking to half-sandwich transition metal units modifies the overall electronic situation such as to improve significantly the electron-transfer ability of the resulting dinuclear species.

As the most representative example, Figure 4 (a) shows the voltammetric picture exhibited by the 30 VE triple-decker CoRh dication [**3**]$^{2+}$.

Two sequential, coulometrically measured one-electron reductions with features of chemical reversibility are displayed, which are interposed by a spurious peak-system, which is assigned to strong adsorption of the reagent.[14] In

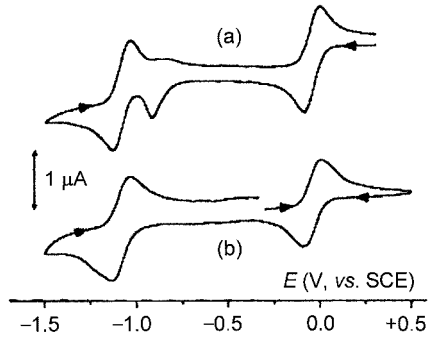

Figure 4. Cyclic voltammetric responses recorded at a platinum electrode in CH_2Cl_2 solution of [**3**]$^{2+}$ (1.0×10^{-3} M): (a) original solution; (b) after exhaustive electrolysis in correspondence of the first reduction. [NBu_4][PF_6] (0.2 M) supporting electrolyte. Scan rate 0.2 V s^{-1}.

fact, as shown in Figure 4 (b), the cyclic voltammetric profile obtained on the exhaustively one-electron-reduced solution (E_w = –0.5 V) no longer exhibits such an anomalous process. More importantly, it can be seen that the response after exhaustive electrolysis is quite complementary to the original one, thus confirming the stability of the corresponding monocation [**3**]$^+$ not only over the short timescale of cyclic voltammetry, but also over the longer time of macroelectrolysis. No traces of oxidation of the parent subunit **2** were detected.

As a matter of fact, analysis of the cyclic voltammograms relevant to the first reduction (due to the above-cited absorption phenomena, mechanical cleaning of the electrode was needed after each scan) with a scan rate varying from 0.02 V s^{-1} to 1.00 V s^{-1} agrees with the occurrence of a simple, chemically and electrochemically reversible, one-electron reduction. In fact: (i) the current ratio i_{pa}/i_{pc} is constantly equal to unity; (ii) the current function $i_{pc} \cdot v^{-1/2}$ is substantially constant; and (iii) the peak-to-peak separation approaches the theoretical value of 59 mV. It should be noted that the electrochemical reversibility indicates that the monocation substantially maintains the geometry of the dication precursor.[14]

In reality, among the dinuclear complexes studied here, the appearance of two consecutive one-electron reductions is essentially limited to [**3**]$^{2+}$, as the other dications (except for [**8a**]$^{2+}$) only display a one-electron reduction, the extent of chemical reversibility of which varies with the nature of the different half-sandwich subunit. As a matter of fact, the i_{pa}/i_{pc} current ratio for the pertinent reduction process is lower than unity in all cases at low scan rate and progressively tends to unity at high scan rates.

Table 6 compiles the formal electrode potentials of the above-cited redox changes, together with the lifetime ($t_{1/2}$) of the different monocations, which, because of the substantial invariance of the responses with concentration, have been assumed to be coupled to a first-order chemical complication.[14]

Apart from the expected roles of the inductive effects of the half-sandwich units added to **2** upon the electrode potentials, the higher stability of the triple-decker mono-

cations with respect to the extreme lability of the arene-type monocation $[\mathbf{5}]^+$ deserves attention.

Spectroelectrochemistry of the $[3]^{2+}/[3]^+$ Redox Change

UV/Vis spectroelectrochemical measurements on the one-electron reduction of the dication $[\mathbf{3}]^{2+}$ were performed in CH_2Cl_2 solution at 298 K using an OTTLE cell. As Figure 5 shows, the original red dication displays a prominent band at λ_{max} = 320 nm together with a few less-intense transitions at 265, 449 and 520 nm. Upon reduction, the intensity of such bands progressively decreases, except for the transition at 265 nm, which progressively increases with a concomitant blue-shift to 244 nm.

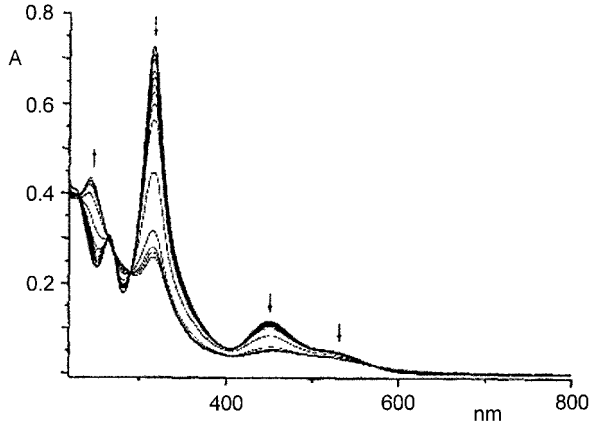

Figure 5. UV/Vis spectra recorded in CH_2Cl_2 solution of $[\mathbf{3}]^{2+}$ (1.0×10^{-3} M) upon one-electron reduction in an OTTLE cell. $[NBu_4][PF_6]$ (0.2 M) supporting electrolyte. E_w = –0.1 V vs. Ag pseudoreference electrode.

The appearance of four isosbestic points, which are due to the mixture of $[\mathbf{3}]^{2+}/[\mathbf{3}]^+$, further supports the chemical reversibility of the electron transfer.

In order to test for a possible assignment of the two lowest energy bands of $[\mathbf{3}]^{2+}$ as metal-to-metal charge transfer (MMCT) absorptions, their solvent dependence concerned with both position and band width was checked. Figure 6 shows the pertinent spectra in tetrahydrofuran, dichloromethane and acetonitrile. In spite of the small blue-shift observed on going from CH_2Cl_2 to the better donor solvents THF and MeCN, the measured half-height band width, $\Delta\nu_{1/2(exp)}$, is too small with respect to the theoretical one, which for a Class II mixed-valent complex is expected to be: $\Delta\nu_{1/2} = [2310(\nu_{max} - \Delta E°)]^{1/2}$, where $\Delta E°$ is the separation of potentials (in cm^{-1}) for the formal redox couples in non-interacting $[CpRh(\eta^5\text{-}C_4H_4BPh)]$ (complex **2**) and $[Cp^*Co(\eta^5\text{-}C_4H_4BPh)]$.[15] In fact, assuming that a MMCT for $[\mathbf{3}]^{2+}$ would involve a Co^{III}-Rh^{III} to Co^{II}-Rh^{IV} transition, a value of $\Delta E°$ = 1.15 V (= 9275 cm^{-1}) may be used, taking into account the $E°'$ measured for the Rh^{III}/Rh^{IV} redox change in $[\mathbf{2}]^+$ (+1.12 V) and approximating the $E°$ of the Co^{II}/Co^{III} redox change in $[Cp^*Co(\eta^5\text{-}C_4H_4BPh)]$ to the formal electrode potential of the first reduction of $[\mathbf{3}]^{2+}$ ($E°'$ = –0.03 V). Accordingly, we obtain $\Delta\nu_{1/2(calc)}$ = 4860 cm^{-1} and $\Delta\nu_{1/2(calc)}$ = 5492 cm^{-1} for the two lowest energy bands in dichloromethane, which is almost two times

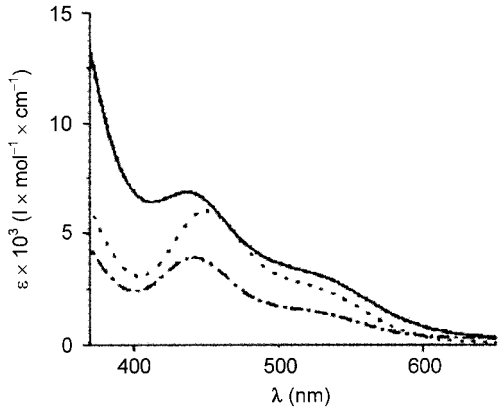

Figure 6. Comparison of the optical spectra of $[\mathbf{3}]^{2+}$ in: MeCN (–), CH_2Cl_2 (·····), THF (·–·–·).

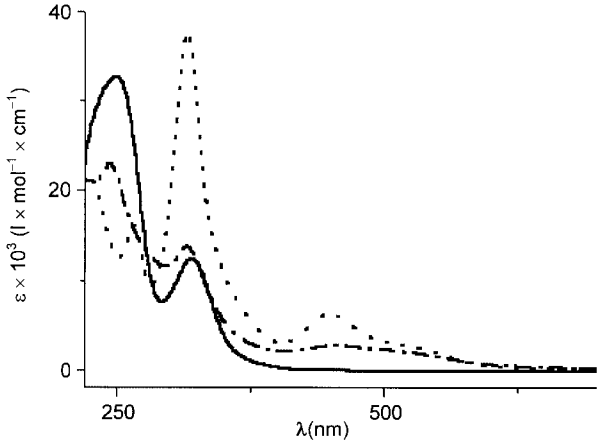

Figure 7. Comparative optical spectra of: (a) **2** (1.4×10^{-3} M)(); (b) $[\mathbf{3}]^{2+}$ (1.0×10^{-3} M) (·····); (c) $[\mathbf{3}]^+$ (1.0×10^{-3} M) (·–·–·). CH_2Cl_2 solution.

greater than the experimental values $\Delta\nu_{1/2(exp)}$ = 2862 cm^{-1} and $\Delta\nu_{1/2(exp)}$ = 2852 cm^{-1}, respectively. This result therefore rules out the MMCT assignment.

Comparison of the UV/Vis spectra of the triple-deckers [**3**]$^{2+}$ and [**3**]$^{+}$ with the subunit **2** (Figure 7) suggests that the MLCT absorptions at 320 and 244 nm are substantially contributed by the rhodium subunit, whereas the d-d transitions of the Co^{III}/Co^{II} centres in [**3**]$^{2+/+}$ could be responsible for the absorptions at wavelengths higher than 400 nm.

EPR Measurements of the Electrogenerated Monocation [3]$^{+}$

Figure 8 shows the low-temperature X-band EPR spectrum of the electrogenerated 31 VE triple-decker monocation [**3**]$^{+}$ in CH_2Cl_2 solution.

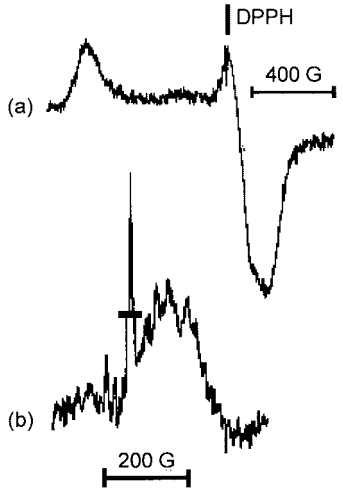

Figure 8. X-band EPR spectrum of [**3**]$^{+}$ in CH_2Cl_2 solution. T = 100 K: (a) first derivative; (b) second derivative.

The broad spectrum shown in Figure 8 (see part a; peak-to-peak separation ca. 1050(5) G) exhibits three rhombic signals with g_i values [g_l = 2.497(8); g_m = 1.971(8); g_h = 1.899(8); $<g>$ = 1/3(g_l + g_m + g_h) = 2.122(8), with l, m and h standing for low-, medium- and high-field, respectively] that are very different from that of a single unpaired electron ($g_{electron}$ = 2.0023). In the second derivative mode, the two partially overlapped high-field signals display resolution of the underlying hpf signals.

A lineshape analysis can be carried out taking into account the anisotropic S = 1/2 Electron Spin Hamiltonian (Zeeman interaction) with resolution of the metallic hyperfine (hpf) signals (IAS interaction).[16]

The second derivative mode is crucial for the understanding of the nature of the metal ion directly involved in the anisotropic IAS interaction. In fact, as shown in Figure 8(see part b), in the high-field region it displays a structured hpf multiplet constituted by almost six well-separated signals of equal intensity [1:1:1:1:1:1; $a_{m,l}$ = 48(8) G], which testifies to the direct coupling of the S = 1/2 unpaired electron with the magnetically active ^{59}Co nucleus [I(^{59}Co) = 7/2; natural abundance = 100%]. The theoretically expected octuplet typical of low-spin Co^{II} centres is not completely resolved as a consequence of both the actual anisotropic linewidth, which affects the overall signals, and the active A-strain effects, which narrow the eight hpf signals to different degrees.[16] The lineshape analysis rules out the assignment of the present high field multiplet to the Rh^{II} subunit in that the expected anisotropic signals should exhibit poorly resolved doublets [I(^{103}Rh) = 1/2; natural abundance = 100%] and the corresponding g_i signals would resonate at different field values.[17]

Moreover, no attribution of the detected multiplet to magnetically coupled ligand ^{1}H nuclei can be proposed as the actual number and the relative intensities of such signals are totally in contrast with the present spectral resolution.

The simulated geometry and the pertinent MO diagram distribution displayed in Figure 9 below confirm the above analysis. In fact, the SOMO of the electrogenerated monocation is mainly constituted by the 3d Co^{II} AOs, with a very minor contribution arising from the Rh^{III} centre and the H and C of the aromatic ligands. On this basis, the intense and narrow signal overlapping the second derivative multiplet is probably due to an organic radical by-product.

Raising the temperature to the glassy-fluid transition (T = 178 K) the large axial spectrum collapses into a broad and unresolved isotropic signal. The lack of Co^{II} hpf resolution in fluid solution is not surprising considering the large Co^{II} λ spin-orbit coupling constant and possible structural anisotropies which fasten the electron spin relaxation rates.[16,18]

At room temperature the spectrum exhibits features compatible with those recorded under glassy conditions [g_{iso} = 2.02(8) and ΔH_{iso} = 470(8) G], although no hpf splittings are detected [likely due to the actual linewidth, (ΔH_{iso}/7 = 67(8) G) $\geq$ a_{iso}(Co)]. These findings suggest that the primary geometry of the monocation is maintained under different experimental conditions. Upon fast refreezing, the previous rhombic signal is partially recovered as a consequence of some chemical lability under not perfectly inert atmosphere.

Molecular Orbital Calculations for [3]$^{2+}$

In order to support the interpretation of the EPR spectrum of the 31 VE triple-decker cation [**3**]$^{+}$, an extended Hückel analysis was carried out. Fragment analyses were performed for a model built by using bond distances and angles taken as the average of the experimental values in analogous complexes.[19] It has been shown previously that the extended Hückel method combined with INDO calculations gives reliable results for μ-borole triple-decker complexes.[20]

This model, and fragments thereof, together with the reference system, are shown at the bottom of Figure 9, which depicts the interaction between the orbitals of the [Cp*Co]$^{2+}$ (shown on the right) and [CpRh(η^5-C_4H_4BPh)] (shown on the left) fragments that generate the [CpRh(μ-η^5:η^5-C_4H_4BPh)CoCp*]$^{2+}$ triple-decker.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

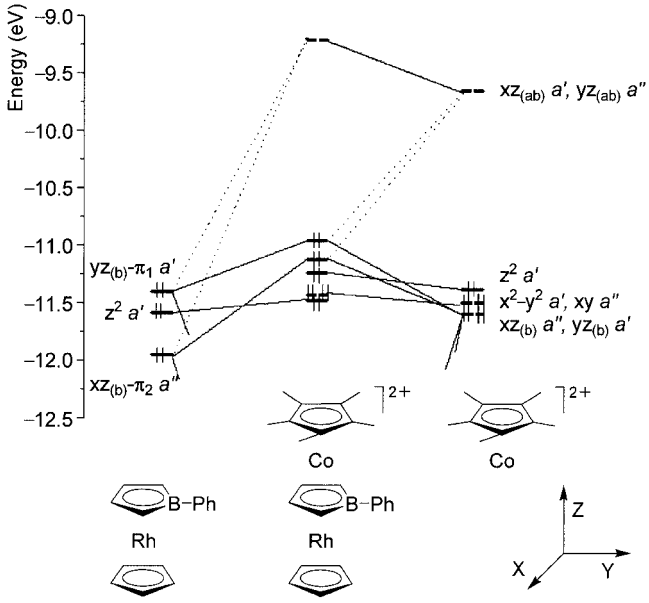

Figure 9. FMO interaction between the frontier orbitals of the $[Cp^*Co]^{2+}$ and $[CpRh(\eta^5\text{-}C_4H_4BPh)]$ fragments to give the $[CpRh(\mu\text{-}\eta^5\text{:}\eta^5\text{-}C_4H_4BPh)CoCp^*]^{2+}$ triple-decker.

The symmetry labels used are those of the C_s point group, which is the lowest symmetry exhibited by the triple-decker model or fragments discussed here, and is imposed by $[CpRh(\mu\text{-}\eta^5\text{:}\eta^5\text{-}C_4H_4BPh)CoCp^*]^{2+}$. The frontier orbital region is characterized by two orthogonal three-orbital-four-electron systems. Indeed, the bonding and antibonding combinations Cp*(π)-Co(d_{xz}) and Cp*(π)-Co(d_{yz}) spawn two degenerate couples of orbitals both having the right a′ and a″ symmetry and the appropriate fit in energy to interact with the bonding set of orbitals Cp(π)-Rh(d_{xz})-C_4H_4BPh(π) and Cp(π)-Rh(d_{yz})-C_4H_4BPh(π). The repulsive interaction between two filled sets of orbitals, which gives rise to the antibonding HOMO and HOMO–1, is therefore stabilised by the interaction with the empty antibonding Cp*(π)-Co(d_{xz}) and Cp*(π)-Co(d_{yz}) orbitals. As a consequence of this interaction, two almost degenerate LUMOs are present, which are antibonding combinations of the fragments $[CpRh(\eta^5\text{-}C_4H_4BPh)]$ and CoCp*, with 33% contribution of Co(d_{xz}) or Co(d_{yz}) and only 4% of Rh(d_{xz}) or Rh(d_{yz}). One of these orbitals is shown in Figure 9, where the major contribution of the cobalt-containing half is evident.

According to these findings, both reduction processes of the 30 VE cation $[\mathbf{3}]^{2+}$ involve mainly the cobalt atom. This is in agreement with the EPR analysis, which also supports a predominant contribution of cobalt in the SOMO of the 31 VE cation $[\mathbf{3}]^{+}$. The absence of oxidation processes for $[\mathbf{3}]^{2+}$ in the experimental window, which is in contrast with the higher energy of its HOMO with respect to **2**, may be explained by the positive charge of this complex, which, on an electrostatic basis, would inhibit any further electron removal.

Conclusions

The electrophilic attack of dicationic fragments $[(ring)M]^{2+}$ has been shown to proceed mainly at the borole ring of the *B*-phenylborole complex **2** to give 30 VE triple-decker complexes $[CpRh(\mu\text{-}\eta^5\text{:}\eta^5\text{-}C_4H_4BPh)M(ring)]^{2+}$. These complexes are stable when (ring)M is Cp*Co, Cp*Ir and (arene)Ru. However, the Cp*Rh analogue **4** transforms into the arene-type complex **5** at room temperature. Comparison of X-ray structural data for complexes **2**, **5**, **6** and **8a** reveals that the coordination of $[(ring)M]^{2+}$ species to the borole ring of **2** leads to elongation of the bonds within this ring, whereas the coordination to the benzene ring does not cause significant changes in the bonds within the borole ring.

The electrochemical data demonstrate the much higher stability of the 31 VE triple-decker monocations $[\mathbf{3}]^{+}$, $[\mathbf{6}]^{+}$ and $[\mathbf{8a}]^{+}$ (formed by one-electron reduction of the corresponding dications) compared with the 31 VE arene-type monocation $[\mathbf{5}]^{+}$. For instance, $[\mathbf{3}]^{+}$ is stable not only over the short times of cyclic voltammetry, but also over the long times of macroelectrolysis. UV/Vis and EPR spectral measurements as well as MO calculations suggest that the reduction process $[\mathbf{3}]^{2+}/[\mathbf{3}]^{+}$ involves mainly the cobalt atom.

Experimental Section

General: The reactions were carried out under an inert atmosphere in dry solvents. The isolation of products was conducted in air. Starting materials **2**,[21] $[Cp^*CoCl_2]_2$,[22] $[Cp^*RhCl_2]_2$,[23] $[Cp^*IrCl_2]_2$,[23] $[(\eta^6\text{-}C_6H_3Me_3\text{-}1,3,5)RuCl_2]_2$[24] and $[(\eta^6\text{-}C_6Me_6)RuCl_2]_2$[25] were prepared as described in the literature. ^1H and $^{11}B\{^1H\}$ NMR spectra were recorded on a Bruker AMX-400 spectrometer (^1H: 400.13; ^{11}B: 128.38 MHz) relative to the residual protons of the solvents (^1H) or $BF_3{\cdot}Et_2O$ (^{11}B, external standard). Materials and apparatus for electrochemistry and joint EPR spectroscopy have been described elsewhere.[26] Unless otherwise specified, potential values are referred to the Saturated Calomel Electrode (SCE). Under the present experimental conditions, the one-electron oxidation of ferrocene occurs at $E^{\circ\prime}$ = +0.39 V. The UV/Vis spectroelectrochemical measurements were carried out using a Perkin–Elmer Lambda 900 UV/Vis spectrophotometer and an OTTLE (optically transparent thin-layer electrode) cell[27] equipped with a Pt minigrid working electrode (32 wires/cm), a Pt minigrid auxiliary electrode, an Ag wire pseudoreference and CaF_2 windows. The electrode potential was controlled during electrolysis by an Amel potentiostat 2059 equipped with an Amel function generator 568. Nitrogen-saturated solutions of the compound under study were used with $[NBu_4][PF_6]$ (0.2 M) as supporting electrolyte. The working potential was fixed at the peak potential of the process under study and the spectra were collected stepwise after each 2 min electrolysis. Extended Hückel calculations were performed using the CACAO98 for Windows programs package.[28] Bond distances and angles of the model molecule were taken as the average of the experimental values. Slater orbital ionization energies were corrected from the default ones by taking H_{ii} from a set of values calculated by DFT theory.[29] The exponentials of the Slater orbitals were taken from the program library.

Synthesis of $3(BF_4)_2$: A mixture of $[Cp^*CoCl_2]_2$ (43 mg, 0.08 mmol) and $AgBF_4{\cdot}3$ dioxane (150 mg, 0.33 mmol) in $MeNO_2$ (1 mL) was

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

stirred for 0.5 h at room temperature. The precipitate of AgCl was centrifuged off and the solution obtained was added to **2** (50 mg, 0.16 mmol). The reaction mixture was stirred for 2 h. Diethyl ether (ca. 10 mL) was then added to precipitate **3**$(BF_4)_2$ as a red solid, which was reprecipitated twice from nitromethane by addition of diethyl ether. Yield 50 mg (46%). $C_{25}H_{29}B_3CoF_8Rh$ (675.76): calcd. C 44.44, H 4.33; found C 44.37, H 4.25.

Synthesis of 5$(BF_4)_2$: A mixture of $[Cp^*RhCl_2]_2$ (40 mg, 0.06 mmol) and $AgBF_4$·3 dioxane (120 mg, 0.26 mmol) in $MeNO_2$ or Me_2CO (1 mL) was stirred for 0.5 h at room temperature. The precipitate of AgCl was centrifuged off and the solution obtained was added to **2** (40 mg, 0.13 mmol). The reaction mixture was stirred for 2 h. Diethyl ether (ca. 10 mL) was then added to precipitate **5**$(BF_4)_2$ as a yellow solid, which was reprecipitated twice from acetone by addition of diethyl ether. Yield 65 mg (70%). $C_{25}H_{29}B_3F_8Rh_2$ (719.72): calcd. C 41.72, H 4.06; found C 41.44, H 4.09.

Synthesis of 6$(BF_4)_2$ and 8a,b$(BF_4)_2$: Me_2CO (1 mL) was added to a mixture of $[(ring)MCl_2]_2$ [(ring)M = Cp*Ir, (η^6-$C_6H_3Me_3$-1,3,5)Ru, and (η^6-C_6Me_6)Ru] (0.08 mmol) and $AgBF_4$·3 dioxane (150 mg, 0.33 mmol). The reaction mixture was stirred for ca. 0.5 h and the precipitate of AgCl was centrifuged off. The solution obtained was added to **2** (50 mg, 0.16 mmol) and stirred for 2 h at –15 °C. After warming to room temperature, diethyl ether (ca. 10 mL) was added to precipitate a bright-coloured solid, which was reprecipitated twice from acetone by addition of diethyl ether.

6$(BF_4)_2$: Yellow, yield 84 mg (64%). $C_{25}H_{29}B_3F_8IrRh$ (809.05): calcd. C 37.11, H 3.61; found C 37.05, H 3.67.

8a$(BF_4)_2$: Orange, yield 84 mg (74%). $C_{24}H_{26}B_3F_8RhRu$ (702.86): calcd. C 41.01, H 3.73; found C 40.46, H 3.61.

8b$(BF_4)_2$: Orange, yield 80 mg (67%). $C_{27}H_{32}B_3F_8RhRu$ (744.94): calcd. C 43.53, H 4.33; found C 43.17, H 4.65.

X-ray Crystallographic Study: Crystals of **2** were grown by slow evaporation of its petroleum ether solution. Crystals of **5**$(BF_4)_2$, **6**$(BF_4)_2$ and **8a**$(BF_4)_2$ were obtained by slow interdiffusion of a two-phase system containing diethyl ether and an acetone solution of the complex. The principal crystallographic data, procedures for collecting experimental data, and characteristics of structure refinement are listed in Table 7. Single-crystal X-ray diffraction experiment for **2** was carried out with a Syntex $P2_1$ diffractometer (graphite monochromated Mo-K_α radiation, $\theta/2\theta$ scans technique) at 153 K. Analogous experiments for **5**$(BF_4)_2$, **6**$(BF_4)_2$ and **8a**$(BF_4)_2$ were carried out with a Bruker SMART 1000 CCD area detector, with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å, ω-

scans with 0.3° steps in ω and 10 s per frame exposure) at 110–140 K. The low temperature of the crystals was maintained with a Cryostream (Oxford Cryosystems) open-flow N_2 gas cryostat. Reflection intensities were integrated by using the SAINT software[30] and the semi-empirical method SADABS.[31] The structures were solved by direct methods and refined by full-matrix least-squares against F^2_{hkl} in an anisotropic (for non-hydrogen atoms) approximation. All hydrogen atoms in the structures were placed in geometrically calculated positions and included in the final refinement using the "riding" model with $U_{iso}(H)$ parameters equal to 1.2 $U_{eq}(C_i)$ or 1.5 $U_{eq}(C_{ii})$, where $U(C_i)$ and $U(C_{ii})$ are the equivalent thermal parameters of the methyne and methyl carbon atoms, respectively, to which the corresponding H atoms are bonded. All calculations were performed on an IBM PC/AT using the SHELXTL software.[32]

Acidities of Nitrous and Nitric Acids

Otto Exner[a] and Stanislav Böhm*[b]

Keywords: Ab initio calculations / Isodesmic reaction / Resonance / Acidity

The energies of nitrous and nitric acid and their anions were calculated at the MP2(FC)/6-311++G(2d,2p) level. Their acidity was related to the acidity of hydroxylamine derivatives using isodesmic reactions. This procedure reveals that the molecules of HNO_2 and HNO_3 are strongly stabilized (by 119 or 206 kJ·mol^{-1}, respectively) but their anions are stabilized even more (by 282 or 428 kJ·mol^{-1}). The acidity of these acids is thus caused by the low energy of their anions and not by the high energy of the acid molecules, similarly to the case of carboxylic acids. This stability may be partly due to resonance but the contribution of this effect can only be estimated. Correlation of the acidities of various acids with the inductive and polarization parameters led to the following estimate: in the case of nitrous acid 46 % of the acidity enhancement is due to resonance while in the case of nitric acid it is 25 %.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

The strong acidity of nitric and nitrous acids – both in the gas phase and in aqueous solution – has been attributed, within the framework of the classic theory of resonance, to resonance in their anions.[1] Description of their structure by resonance formulae is still considered as convenient[2] and used in textbooks; it is a completely analogous explanation to the case of the relatively strong acidity of carboxylic acids. An alternative theory was suggested first for carboxylic acids[3] and then extended to nitrous and nitric acids:[4,5] the origin of the acidity is seen in the charge distribution and in the electrostatic potential of the uncharged molecules of the acids. In the case of carboxylic acids, the problem raised a vivid discussion[6–11] and complete agreement has not yet been reached. In our opinion, the problem can be rationalized (and for the greater part solved) if it is divided into two independent questions:[7,10]
a) Is the acidity of the isolated molecules caused by the low energy of their anions or by the high energy of the acid molecules?
b) Is the acidity dependent on the resonance in the anions (or also in the acid molecules)?

In the case of carboxylic acids, in our opinion the first problem has been solved[10] using the framework of isodesmic reactions.[12,13] Concerning the second problem, several models were advanced estimating the contribution of resonance with a fair agreement to approximately one third of the acidity enhancement.[8–10]

[a] Institute of Organic Chemistry and Biochemistry, Academy of Sciences of the Czech Republic,

[b] Department of Organic Chemistry, Prague Institute of Chemical Technology,
16628 Praha 6, Czech Republic

In the present article, the above-mentioned approach is applied to the acidity of nitrous and nitric acid. The procedure is not always self-evident since the choice of reference compounds is not as straightforward as for carboxylic acids but, in our opinion, it is just the application of the methods of organic chemistry that may shed light on the problem from a new standpoint. The article will be divided into two sections corresponding to the two questions a) and b). The first part is much more important since the question sub a) can be answered unambiguously. The solution makes use of isodesmic reactions and of the energies calculated by ab initio MO methods.[14] In the second part, only one possible model will be mentioned for estimating the resonance contribution, which is supported by experimental gas-phase acidities. Let us stress that our approach is based either on the experimental energies (mainly the gas-phase acidities) or on the calculated energies that can be related to some experimental values; any reference to fictive or theoretical structures is avoided.

Results and Discussion

Energy of the Anions and of the Acid Molecules

The relatively strong acidity of carboxylic acids has always been evaluated with alcohols as a natural reference.[3,6–11] By the same token, a reference compound for nitrous acid is a hydroxylamine derivative. In the isodesmic and homodesmotic[15] reaction, see Equation (1), the molecule of nitrous acid is constructed from nitrosomethane and *N*,*N*-dimethylhydroxylamine. The reaction energy Δ_1E is a measure of the interaction of the groups N=O and OH in the molecule of nitrous acid. Of course, Equation (1) represents only one possible solution but its merit is that it oper-

 DOI: 10.1002/ejic.200400925 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ates exclusively with stable and well-characterized molecules, even when their enthalpies of formation have not been experimentally determined. Introducing the methyl groupsw into Equation (1) has another advantage, that is, molecules of similar polarizability[3,7] are compared. If in Equation (1) hydroxylamine were used instead of *N*,*N*-dimethylhydroxylamine, the results would not be significantly altered.

$$O{=}N{-}CH_3 + (CH_3)_2N{-}OH = O{=}N{-}OH + (CH_3)_2N{-}CH_3 \quad (1)$$

Similarly, the interaction of the two oxygen atoms in the nitrite anion is measured by the reaction energy Δ_2E of the reaction of Equation (2); by this interaction the two oxygen atoms become equivalent.

$$O{=}N{-}CH_3 + (CH_3)_2N{-}O^- = O{=}N{-}O^- + (CH_3)_2N{-}CH_3 \quad (2)$$

An isodesmic reaction generating nitric acid from its component functions would be somewhat complex. On the other hand, one can relate nitric acid to nitrous acid in a simple way by Equation (3).

$$O{=}N{-}OH + (CH_3)_3N{-}O = O{=}N(O){-}OH + (CH_3)_3N \quad (3)$$

The reaction energy Δ_3E represents the difference between the interactions in nitric and nitrous acid; the total interaction in nitric acid is given by $\Delta_1E + \Delta_3E$. Similarly the relation of nitrate and nitrite anions is represented by Equation (4); the total interaction within the nitrate anion is given by $\Delta_2E + \Delta_4E$.

$$O{=}N{-}O^- + (CH_3)_3N{-}O = O{=}N(O){-}O^- + (CH_3)_3N \quad (4)$$

Ab initio calculated energies of the compounds involved in Equations (1) to (4) are listed in Table 1. Few compounds can exist in equilibrium of two conformers, as given in the footnotes to Table 1, but the pertinent energy differences are negligible. Nevertheless, the energies of the isodesmic reactions, Δ_1E to Δ_4E, were always calculated for the equilibrium mixtures of conformers at 298 K (Table 2).

In the qualitative sense, the results are the same for nitrous and nitric acid. The molecule of HNO_2 is strongly stabilized (by more than 100 kJ·mol^{-1}) but the anion NO_2^- is stabilized much more (almost by 300 kJ·mol^{-1}); the difference determines the acidity. For HNO_3 and NO_3^- the values are almost two times greater (200 and 400 kJ·mol^{-1}, respectively). In relation to these figures, any arbitrariness in the isodesmic reactions and imperfections of the theoretical model are of no consequence. Even the conformations of some of the compounds involved are irrelevant from this point of view. Therefore, our results are in contrast to the claim[4,5] that the acidity is due to the initial-state charge distribution.

$(CH_3)_2NO^-$	–209.2526309		1.408
$(CH_3)_3N{-}O$	–249.0418991		1.368
$(CH_3)_3N$	–174.0148768		

[a] These figures agree with the experimental values[16] with the greatest deviation of 0.008 Å, this is a better agreement than that obtained at the level CCSD(T)/cc-PVQZ(spdf,spd)[17] and much better than at the levels B3LYP/6-311G(d,p)[18] or BH&HLYP/6-311G(d,p)[19]. [b] Agreement with the experimental values[16] within 0.007 Å. [c] Experimental value[20] 1.253(6) Å. [d] The O–H bond eclipsed with the electron lone pair on N.

Correlating our results to experimental values is of vital importance to our approach. For the two conformers of HNO_2, antiperiplanar *ap* and synperiplanar *sp*, we calculated the energy difference of 2.6 kJ·mol^{-1} (the *ap* conformer is more stable); the experimental value[21] is 2.1 kJ·mol^{-1}. The low-level calculations[3] (RHF/3-21+G) gave 3.8 kJ·mol^{-1}. Recent calculations[18] produced satisfactory results only at the MP2/6-311G(3df,2p) or G2M(RCC,MP2) levels while at the QCISD(T)/6-311G(d,p) and lower levels even the order of stability was reversed. The conformational energy is evidently too small and its calculations are sensitive to the level employed. A better idea about the reliability of the calculations can be obtained from the relative acidities of HNO_3 and HNO_2, that is, from Equation (5).

$$HNO_3 + NO_2^- = NO_3^- + HNO_2 \quad (5)$$

Our calculated reaction energy Δ_5E is –57.8 kJ·mol^{-1} (see Table 2) while the experimental Gibbs energy[9] $\Delta_5G°$ is –54.4 kJ·mol^{-1} and the enthalpy[22] $\Delta_5G°$ is –66.6 kJ·mol^{-1}.[23] Calculations at the RHF/3-21+G level yielded[4] –107 kJ·mol^{-1}. This theoretical model was obviously insufficient and further results of this paper[4] can be questioned.[23]

Table 2. Calculated acidities and energies of the isodesmic reactions (kJ·mol^{-1}).

	Formation of the acid	Formation of the anion	Acidity
HNO_2 *ap* [Equations (1) or (2)]	–116.3	–281.7	–165.4
HNO_2 *sp* [Equations (1) or (2)]	–118.9	–281.7	–162.8
HNO_2 equil. mixture	–118.2	–281.7	–163.5

Effect of Resonance

When we accept that the strong acidity of both HNO_2 and HNO_3 is due to the low energy of their anions, it does not follow that this low energy is a consequence of resonance. However, resonance may be defined differently and its effect cannot be calculated unambiguously. It is necessary to design a molecule, more or less fictive, without resonance but otherwise similar to the molecule under investigation. In the case of carboxylic acids, several different models were designed and it may be considered as a remarkable agreement that some of them evaluated the effect of resonance to 30–40% of the increased acidity.[8–10] Let us mention here only one model,[10] originated from the fundamental idea of Taft,[9] that relates to stable molecules and is based exclusively on the experimental data. The relative gas-phase acidities of common oxygen acids ROH are defined by Equation (6).

$$R–OH + OH^- = R–O^- + H_2O \quad (6)$$

In the absence of resonance effects, the relative acidity $\Delta_6G°(298)$ can be empirically approximated[9] as a linear function of the inductive constants σ_I and polarizability constants σ_α. For 15 selected R substituents (H, seven alkyl groups, $CH_2C_6H_5$, CH_2OCH_3 and five fluorinated alkyls – mostly organic compounds since derivatives of hydroxylamine are not at our disposal) we obtained Equation (7).

$$\Delta_6G°(298) = 1603(4) – 299.8(73)\sigma_I + 97.9(73)\sigma_\alpha \ (kJ·mol^{-1}) \quad (7)$$

Figure 1 is a graphical representation of this relationship, where experimental[9] $\Delta_6G°(298)$ values were plotted against the right-hand side of Equation (7). The points for HNO_2 and HNO_3 in this graph deviate by the assumed contribution of resonance, 75 or 56 kJ·mol^{-1}, respectively. It follows that resonance should be responsible for 46% or 25%, respectively, of the enhanced acidity. (In the case of HNO_3 this estimate is biased since it starts from the group NO_2 and hence does not include the resonance already involved in this group.) Taking into consideration all the approximations, it seems safe to conclude that resonance is a very important factor in the case of HNO_2 and less important in the case of HNO_3. The explanation of this difference may be found in the so-called crossed conjugation in the anion NO_3^-.

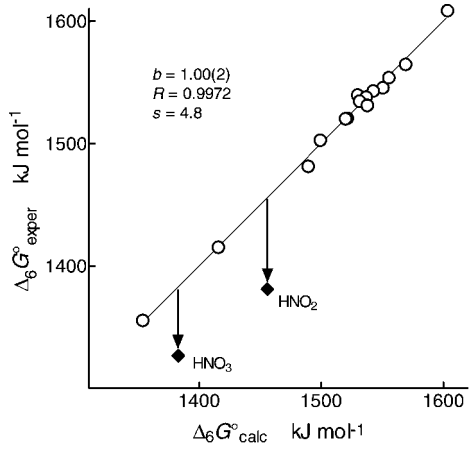

Figure 1. Plot of the experimental gas-phase acidities of the oxygen acids without resonance, Equation (6), vs. their values calculated according to the empirical Equation (7); the points for HNO_2 and HNO_3 deviate due to resonance as shown by the arrows.

In the case of carboxylic acids, a further attempt was made to evaluate separately the effect of resonance in the anion and in the acid molecule.[10] Application of this process to nitrous or nitric acid would require the construction of complex isodesmic reactions involving unstable or nonexisting molecules; their enthalpies of formation should be calculated using high-level models. We have rejected this approach as it is too sophisticated.[25]

In addition to energies, the theory of resonance predicts qualitatively changes of other observable quantities. For our compounds, the effect on the bond lengths should be the most conspicuous: N=O double bonds in HNO_2 and HNO_3 should be lengthened, N–O single bonds shortened. In the anions NO_2^- and NO_3^- the N–O bonds are equal and should be intermediate between single and double bonds. The latter prediction is fulfilled (see Table 1) but the former is not, particularly as the N=O bonds in HNO_2 are not longer than in $CH_3N=O$. Similar results were obtained when testing the resonance theory on amides and carboxylic acids: the single bonds were shortened but the C=O bond was lengthened insignificantly.[27] One must conclude that the resonance formulae are a fairly approximate picture. They can describe some observable quantities surprisingly well but can fail in other cases.

Conclusions

The framework of isodesmic reactions enables us to conclude that the strong acidity of HNO_2 and HNO_3 is caused by the low energy of their anions. The energy of the acid molecules is not particularly high; on the contrary it is also lowered and causes an opposite effect (acid weakening). The energies of the isodesmic reactions are so great that any defect of the model, either in the choice of reference compounds or in the computational procedure, is insignificant. On the other hand, the question of whether the acidity is due to resonance is inexact and can be answered only approximately. Resonance is operating but is less significant than the inductive effect, with HNO_3 maybe less than with HNO_2. In our opinion, this problem is not of particular importance since resonance means always a difference between a real molecule and an artificial formalism. In our opinion it has been merely a tool for identifying the difference between real structures and primitive traditional formulae.

Computational Details

Energies of nitrous and nitric acids, of their anions and of reference compounds were calculated at the levels MP2(FC)6-311++G(2d,2p)//MP2(FC)6-311++G(2d,2p) (Table 1) and B3LYP/6-311++G(2d,2p)//B3LYP/6-311++G(2d,2p)[23] with the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

GAUSSIAN 03 program.[14] All reasonable conformations were taken into consideration and calculations were started from the pertinent near structures. Planarity or any symmetry was never anticipated. All structures were checked by vibrational analysis and behaved as energy minima.

Population of conformers was calculated with the standard approximation that $\Delta G°(298) \approx \Delta E$; with this population the effective ΔE for the equilibrium mixture of conformers for each compound was obtained. The energies of isodesmic reactions, $\Delta_1 E$ to $\Delta_4 E$, were calculated with these effective ΔE values.

[23] In previous work, for instance see ref. [24], we usually got a better fit with the Gibbs energies than with the enthalpies due to less dependability of the latter. In order to test the dependence of our results on the theoretical model we calculated the reaction energy $\Delta_5 E$ still at the level B3LYP/6-311++G(2d,2p)//B3LYP/6-311++G(2d,2p) and obtained –65.4 kJ·mol^{-1}. This theoretical model seems to be somewhat better but note that even the inaccuracy of 10 kJ·mol^{-1} would not change our final results.
[24] J. Roithová, O. Exner, *J. Phys. Org. Chem.* **2001**, *14*, 752–758.
[25] Another approach could be taken by considering the valence bond theory. In the case of carboxylic acids, a reasonable estimate of resonance was obtained, ref. [26], but several possible localized structures were designed with some arbitrariness, even for structures without resonance (ethanol); moreover, the agreement with experimental acidities was very bad. Nevertheless, we agree with a referee that this would be the most important alternative to our approach.

Two New μ-(1,3-Azido)-Bridged Polymers: Alternating Single and Double Bridges in a 1D Nickel(II) Complex and Uniform Bridge in a 2D Copper(II) Complex: Syntheses, Single-Crystal Structures and Magnetic Studies

Subal Chandra Manna,[a] Sanjit Konar,[a] Ennio Zangrando,[b] Michael G. B. Drew,[c] Joan Ribas*[d] and Nirmalendu Ray Chaudhuri*[a]

Keywords: Nickel(II) / Copper(II) / Azide bridges / Crystal structures / Magnetic properties

Two polymeric azido bridged complexes $[Ni_2L_2(N_3)_3]_n(ClO_4)_n$ (**1**) and $[Cu(bpds)_2(N_3)]_n(ClO_4)_n(H_2O)_{2.5n}$ (**2**) [L = Schiff base, obtained from the condensation of pyridine-2-aldehyde with *N*,*N*,2,2-tetramethyl-1,3-propanediamine; bpds = 4,4′-bipyridyl disulfide] have been synthesized and their crystal structures have been determined. Complex **1**, $C_{26}H_{42}ClN_{15}Ni_2O_4$, crystallizes in a triclinic system, space group $P\bar{1}$ with a = 8.089(13), b = 9.392(14), c = 12.267(18) Å, α = 107.28(1), β = 95.95(1), γ = 96.92(1)° and Z = 2; complex **2**, $C_{20}H_{21}ClCuN_7O_{6.5}S_4$, crystallizes in an orthorhombic system, space group *Pnna* with a = 10.839(14), b = 13.208(17), c = 19.75(2) Å and Z = 4. The crystal structure of **1** consists of 1D polymers of nickel(L) units, alternatively connected by single and double bridging μ-(1,3-N_3) ligand with isolated perchlorate anions. Variable temperature magnetic susceptibility data of the complex have been measured and the fitting of magnetic data was carried out applying the Borrás-Almenar formula for such types of alternating one-dimensional S = 1 systems, based on the Hamiltonian $H = -J\Sigma(S_{2i}S_{2i-1} + \alpha S_{2i}S_{2i+1})$. The best-fit parameters obtained are J = –106.7 ±2 cm^{-1}; α = 0.82 ± 0.02; g = 2.21 ± 0.02. Complex **2** is a 2D network of 4,4 topology with the nodes occupied by the Cu^{II} ions, and the edges formed by single azide and double bpds connectors. The perchlorate anions are located between pairs of bpds. The magnetic data have been fitted considering the complex as a pseudo-one-dimensional system, with all copper(II) atoms linked by μ(1,3-azido) bridging ligands at axial positions (long Cu···N_3 distances) since the coupling through long bpds is almost nil. The best-fit parameters obtained with this model are J = –1.21 ± 0.2 cm^{-1}, g = 2.14 ± 0.02.

Introduction

Azide represents an efficient superexchange pathway for propagating magnetic interaction between paramagnetic centers and along with its versatile coordination modes,[1] it is widely used for preparing magnetic materials of various dimensionality.[2,3] In general, the μ-(1,3-N_3) azide bridge creates an antiferromagnetic interaction while the μ-(1,1-N_3) connection mode shows a ferromagnetic interaction.[4] The M–N–M angle in μ-(1,1-N_3), and the M–N–N angle and the M–N_3–M dihedral angle in μ-(1,3-N_3) are the key factors in tuning the magnetic interaction.[5] It is well-established that the type and the connectivity of the coligand, i.e. monodentate, chelate, chelate-bridge, bridge, etc. (either neutral or ionic), dictate the binding modes of the azide ligand. It is also observed that different coligands of similar denticity with azide, in a particular bridging mode, i.e. μ-(1,1-N_3), μ-(1,3-N_3), etc. can affect the magnetic properties even in a same paramagnetic metal system. In fact the shape and size of coligands control the M–N–M angle in μ-(1,1-N_3), and the M–N–N angle and M–N_3–M dihedral angle in μ-(1,3-N_3).[6] In many cases spacers i.e. 4,4′-bipyridine, pyrazine, 1,2-bis(4-pyridyl)ethane, etc., are used in combination with azide to augment the ease of synthesizing multidimensional coordination polymers, leading to magnetic materials. Recently, the 4,4′-bipyridyl disulfide (bpds) ligand, characterized by the twisted –S–S– bridge, has been employed for the construction of coordination polymers showing topologically interesting assemblies.[7] It is worth noting that in most of the cases the bpds ligand coordinates metals in a double bridged fashion and, thanks to the flexible heterocyclic rings, sometimes stabilizes the structure through strong π–π interactions.[8] A literature survey revealed that molecular architecture obtained from the combination of bpds and azide is scarce.

Moreover, reports of alternate double and single μ-(1,3-N_3) bridges in transition metals is also rarely documented,

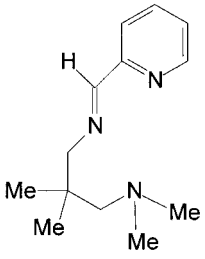
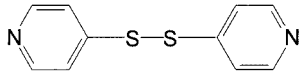
especially with nickel(II), and up to date only one system, with a triamine as coligand, has been reported.[9] The magnetism in such types of alternate bridging systems appears intriguing owing to the number of variable factors in these compounds.[6] The above facts prompted us to synthesize azide species using bpds as well as the tridentate ligand as a coligand. A Schiff base (L), derived from the condensation of pyridine-2-aldehyde with *N*,*N*,2,2-tetramethyl-1,3-propanediamine, has been chosen in the present work as the tridentate ligand. Previous attempts from our group to synthesize alternate single and double μ-(1,3-N_3) 1D chains of nickel using the mentioned Schiff base afforded 1D polymers comprising only single μ-(1,3-N_3) bridges which exhibited novel metamagnetic behavior.[10] In order to achieve alternating single and double azide bridges we have varied the relative molecular amount of the reagents.



L



bpds

The present contribution reports the syntheses, crystal structures and variable temperature magnetic behavior of two azido-bridged coordination polymeric networks, namely $[Ni_2L_2(N_3)_3]_n(ClO_4)_n$ (**1**) and $[Cu(bpds)_2(N_3)]_n(ClO_4)_n$-$(H_2O)_{2.5n}$ (**2**). To the best of our knowledge complex **1** is the second example of a μ-(1,3-N_3) alternate single and double bridging Ni^{II} system. Complex **2** is a 2D grid of 4,4 topology with Cu^{II} ions occupying the nodes, where single azide and double bpds connectors take part in the formation of edges. Magnetic properties of complexes **1** and **2** have been interpreted indicating a very strong antiferromagnetic coupling and a weak antiferromagnetic one, respectively.

Results and Discussion

Description of the Structures

Complex 1

Crystal structure determination reveals that complex **1** consists of positively charged 1D polymers, $[Ni_2L_2(N_3)_3]_n^+$ counterbalanced by lattice perchlorate anions. The ORTEP drawing of the metal center with the atom numbering scheme is shown in Figure 1 while selected geometrical parameters are given in Table 1. The nickel(II) center, *meridionally* coordinated by the tridentate Schiff base, completes the distorted octahedral coordination sphere with three end-to-end bridging azide nitrogen atoms, resulting in a

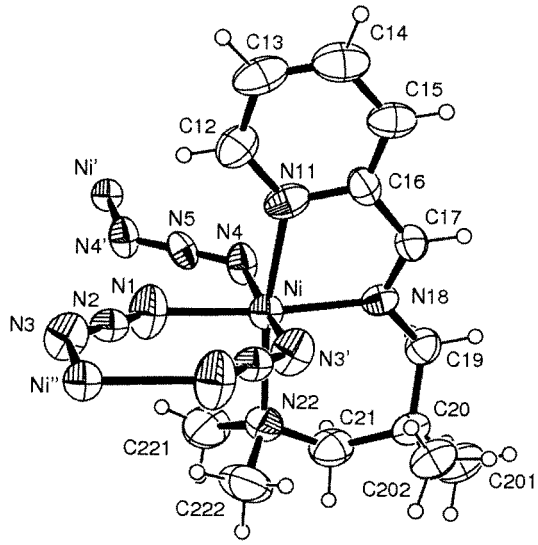


Figure 1. ORTEP plot of complex **1** with atom numbering scheme showing the alternating single and double connecting azide ligands.

NiN_6 chromophore. The Schiff base N donors [N(11), N(18), N(22)] and the azide nitrogen atom N(1) define the equatorial plane around each pseudo octahedral nickel ion [Ni–N(1) 2.096(7), Ni–N(11) 2.107(7), Ni–N(18) 2.062(6), Ni–N(22) 2.175(7) Å]. The *trans* axial positions are occupied by the nitrogen atoms from the two different azides (Ni–N(3′) and Ni–N(4) of 2.164 and 2.127(6) Å, respectively) with a N(3′)–Ni–N(4) bond angle of 173.3(2)°. The slight distortion of each Ni^{II} is reflected on the *cisoid* angles [78.6(2)–95.0(8)°]. The equatorial mean plane is slightly tetrahedrally distorted (max deviation of ± 0.02 Å) with the metal displaced by 0.03 Å towards N(4).

The 1D chain developing along axis *b*, is formed by Ni(L) units connected alternatively by single and double bridging μ-(1,3-azide) ligands (Figure 2). The intermetallic separations between the single and double azide bridge are 5.875(3) and 5.304(3) Å, respectively. These values are comparable with those of 5.799 and 5.249 Å found in the closely related alternating system $[Ni_2(\mu\text{-}N_3)_3(dpt)_2](ClO_4)$,[9] where the tridentate amine ligand, dpt is bis(3-aminopropyl)-amine. In contrast, the neutral polymer $[Ni(L)(N_3)_2]_n$[10] with single end-to-end azide junctions, the other N_3 being monocoordinated and pendant from the chain, shows an intermetallic distance of 5.662(1) Å, representing a mean value of the Ni···Ni distances for the present case. The N(2)–N(1)–Ni and N(2)–N(3)–Ni angles exhibited by the coordinated azide nitrogens are comparable, being 132.9(5) and 133.2(5)°, respectively, but somewhat larger than the N(5)–N(4)–Ni of 122.5(3)°. Correspondingly, the azide N(1)–N(2)–N(3) displays an angle of 176.1(7)° and the other [N(4)–N(5)–N(4′)] has a linear arrangement being located on a symmetry center. The pseudo torsion angles Ni–N(1)–N(3)–Ni′′ and Ni–N(4)–N(4′)–Ni′ are 180.0 and 5.3°, respectively.

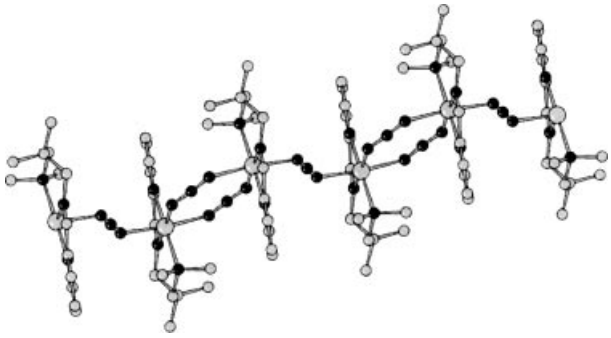

Figure 2. Polymeric structure of complex **1** (inversion centers are located at central nitrogen of the single bridging azide and in the midpoint of the double bridging azide).

Complex 2

The structure determination of **2** reveals that it is comprised of 2D undulated layers of $[Cu(N_3)(bpds)_2]^+_n$, where the charge is counterbalanced by perchlorate (ClO_4^-) anions with disordered water molecules in the crystal lattice. The ORTEP view of the coordination environment with the atom labeling scheme is shown in Figure 3 and a selection of bond lengths and angles is given in Table 1. The copper ion, located on a twofold axis, presents a hexacoordination geometry with four bpds nitrogen donors in the equatorial plane [Cu–N(11) 2.055(6), Cu–N(22) 2.044(6) Å, mean deviations of N donors ± 0.061(4) Å] and two azide nitrogens axially located at significantly longer distances [Cu–N(2), 2.447(7) Å]. The Cu–N(2)–N(1) bond angle presents a rather large value of 140.2(5)°. Taking into account the coordination linkages, the crystal structure can be envisaged as being formed by –Cu–$(bpds)_2$–Cu– polymers of colinear Cu^{II} ions connected by μ-(1,3-N_3) ligands to build a 2D grid of 4,4 topology, with the nodes occupied by the copper ions, and the edges by the single μ-(1,3-N_3) and the double bpds connectors. Figure 4 shows a packing view down axis *c* indicating the perchlorate anions located inside the grid in between the double bpds connectors. The intermetallic distance along the azide is 6.703 Å and through the bpds ligands 10.839 Å (axis *a*). The zigzag arrangement of copper ions, in the –Cu–(N_3)–Cu– array, displays a Cu–Cu–Cu angle of 160.31° and an ideal torsion angle Cu–N–N–Cu of 128.9°.

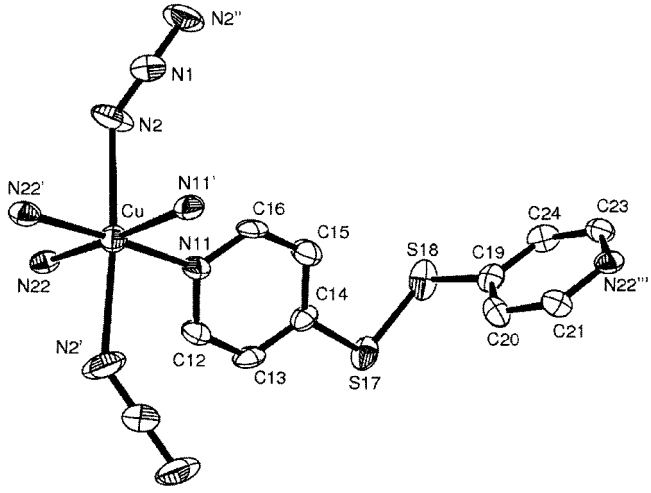

Figure 3. ORTEP plot of complex **2** with atom numbering scheme (symmetry operations: (′) *x*, –*y* + 3/2, –*z* + 3/2; (′′) *x* – 1, –*y* + 3/2, –*z* + 3/2; (′′′) 1 + *x*, *y*, *z*).

The crystal structure evidences a *gauche* conformation for the bpds spacer with a C–S–S–C torsion angle of 92.2(3)°, which is well in the range of 83.8(6)–95.5(8)°, found in a series of coordination polymers containing bpds ligands, in spite of the different coordination metal environment.[7e] However, it is interesting to note that the centrosymmetric space group furnishes both the possible enantiomeric conformers [± 92.2(3)°] for the acyclic disulfide[7c] and each 2D layer, piled parallel to the *ab* plane (Figure 5), contains only one of these.

Magnetic Properties

Complex 1

The magnetic properties of complex **1** in the form of χ_m and $\chi_m T$ (inset) vs. T plots (χ_m is the molar magnetic susceptibility for one Ni^{II} ion) are shown in Figure 6. The

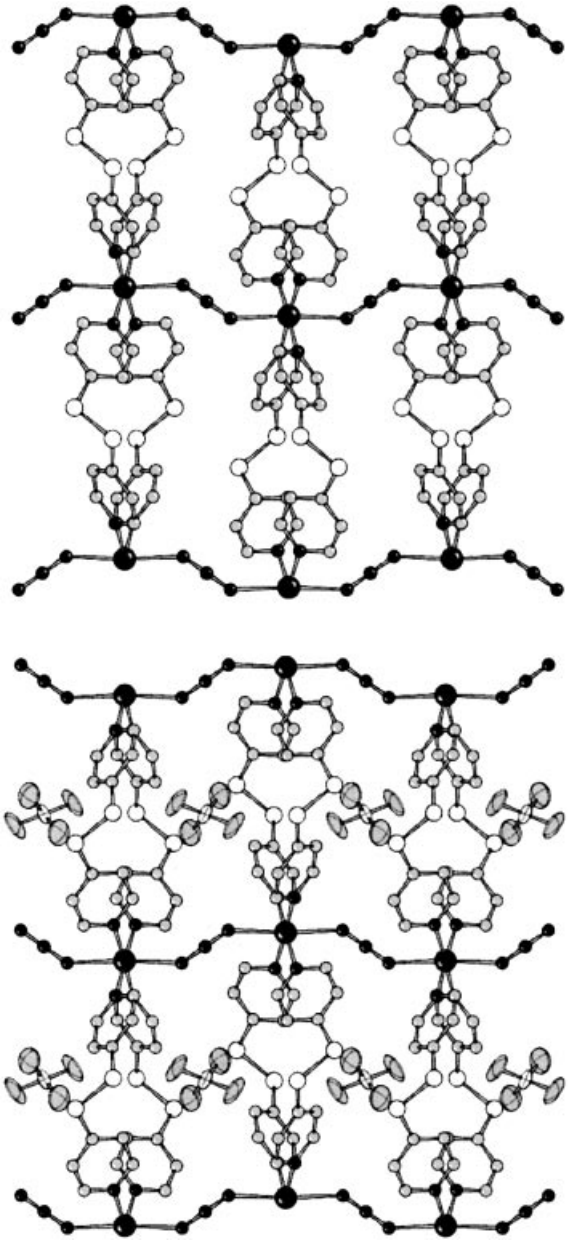

Figure 4. The 2D grid of complex **2** viewed down axis *c* indicating the location of perchlorate anions.

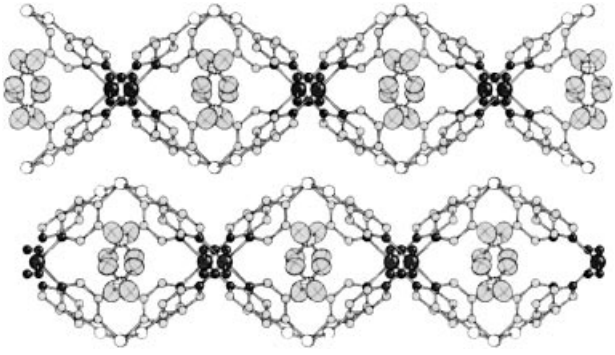

Figure 5. Side view (down axis *b*) of the 2D layers of complex **2** with perchlorate anions indicated as ellipsoids (disordered water molecules not shown).

value of $\chi_m T$ = 0.61 $cm^3 mol^{-1} K$ at 300 K is smaller than the expected value for an isolated Ni^{II} ion with g > 2.00 ($\chi_m T$ close to 1.0 $cm^3 mol^{-1} K$). Starting from room temperature $\chi_m T$ values smoothly decrease down to 0.0 $cm^3 mol^{-1} K$ at 2 K. At room temperature the χ_m value starts at 0.0022 $cm^3 mol^{-1}$ and increases in a uniform manner to a maximum of 0.0023 $cm^3 mol^{-1}$ around 190 K. Then χ_m values decrease to 0.0012 $cm^3 mol^{-1}$ at 25 K and again increase at lower temperature (0.0014 $cm^3 mol^{-1}$ at 2 K). The global feature is characteristic of very strong antiferromagnetic interactions, compensated at low temperature by the presence of small amounts of paramagnetic impurities (usually mononuclear ones following the Curie law) that originate from the increasing of χ_m at low temperatures.

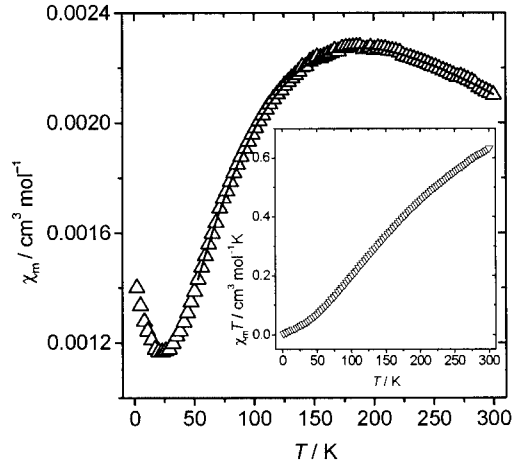

Figure 6. Plot of the χ_m vs. *T* for complex **1** (solid line represents the best-fit calculation; inset: plot of the $\chi_m T$ vs. *T*).

Complex **1** is actually an alternating 1D nickel(II) system with two kinds of alternate azide bridges: single and double end-to-end μ-(1,3-N_3). The fit of the magnetic data has been carried out applying the Borrás–Almenar formula for such types of alternating one-dimensional *S* = 1 systems,[11] based on the Hamiltonian $H = -J\Sigma(S_{2i}S_{21-1} + \alpha S_{2i}S_{2i+1})$. In this Hamiltonian the single-ion anisotropy of Ni^{II} is not included. The work of Borrás–Almenar allows for the employment of two different formulae according to the alternation parameter (α between 0 and 0.5 or between 0.5 and 1). After some preliminary attempts, the best results corresponded to $\alpha > 0.5$. Thus, the formula used in the fit was the following:

$$\chi_m = 0.25g^2/T \cdot (A + Bx + Cx^2):(1 + Dx + Ex^2 + Fx^3)$$

with $A = 1$; $B = 0.5$; $C = 0.1$; $D = 1.13693 + 0.748419\alpha$; $E = 1.650652 - 1.4622193\alpha + 1.668971\alpha^2$; $F = 0.4447955 + 1.162769\alpha$; $x = |J| / kT$.

Considering the shape of the experimental curve at low temperatures (Curie-law impurities) and that the Borrás–Almenar formula is not valid at low temperatures, mainly with a noticeable *J* value, we have removed all the experimental points from 50 to 2 K for the fit. With this condition, the best-fit parameters obtained are $J = -106.7 \pm 2\ cm^{-1}$; $\alpha = 0.82 \pm 0.02$; $g = 2.21 \pm 0.02$ and $R = 1.33 \times 10^{-5}$ (*R* is the agreement factor defined as

$\Sigma_i[(\chi_m T)_{obs} - (\chi_m T)_{calc}]^2 / \Sigma_i[(\chi_m T)_{obs}]^2$). These results indicate very strong antiferromagnetic coupling through the two kinds of azide bridging ligands. At this point, a question arises: which is which?

To the best of our knowledge only one similar complex has been reported by one of the authors.[9] The calculated J values were $J = -84.6\ cm^{-1}$ (for the double azido bridge) and $J' = -41.4\ cm^{-1}$ (for the single azido bridge). According to reported magneto-structural correlations,[6,9,12] the antiferromagnetic component of J is strongly dependent on the Ni–N–N and the Ni–N–N–N–Ni torsion angles, whereas only slightly from the Ni–N bond, with distances typically in the range, 2.12–2.17 Å.[6,9,12] For the mono-bridged fragment, the maximum coupling is expected for Ni–N–N angles close to 108°, while for greater values, the antiferromagnetic interactions must decrease. An accidentally orthogonal valley, centered at 164°, is found.[6] The values reported in the literature for similar systems range from $J = -100\ cm^{-1}$ (Ni–N–N angle of 120.9°) to $-49\ cm^{-1}$ (Ni–N–N angle of 137.2°). Thus, it seems that the sensitivity to this angle is very important. In complex **1**, the Ni–N–N of 122.52° implies strong antiferromagnetic coupling. Moreover, the Ni–N–N–N–Ni torsion angle is 180°, which allows the maximum AF coupling.[6]

The Ni-$(N_3)_2$-Ni fragment in complex **1** is not comparable to that previously reported.[9,12] In that case, a strong torsion between the two azide bridging ligands was detected, in contrast to parallel azide ligands in complex **1**. Thus, in the present case, the most important factor is only the δ angle, that represents the dihedral angle formed by the $(N_3)_2$ plane and the N–Ni–N plane.[6] For $\delta = 180°$ (0°) the AF coupling is at a maximum, whereas it is strongly reduced as this angle increases. The Ni–N–N is also important in this case. According to literature data, J values occur from $-114.5\ cm^{-1}$ for $\delta = 3.0$ to $-4.6\ cm^{-1}$ for $\delta = 45.0°$.[6] Thus, the small δ angle of 2.66° detected in **1** allows strong AF coupling. It seems to be logical that with the most favorable conditions of the double azide bridges, the J value is greater than that associated with a single azide bridging ligand.[6,9,12] Here these conditions are very favorable: thus the greatest J value may be assigned to the double azide bridging system while the smallest J to the single azide bridging ligand.

Complex 2

Magnetic properties of complex **2** are shown in Figure 7 as $\chi_m T$ vs. T plots (χ_m is the molar magnetic susceptibility for one Cu^{II} ion). The value of $\chi_m T$ at 300 K ($0.43\ cm^3 mol^{-1} K$) is as expected for one magnetically quasi-isolated spin doublet ($g > 2.00$). Starting from room temperature the $\chi_m T$ values smoothly decrease down to 50 K, then quickly to $0.25\ cm^3 mol^{-1} K$ at 2 K. The global feature is characteristic of very weak antiferromagnetic interactions. The reduced molar magnetization at 2 K (Figure 7, inset) also indicates that the antiferromagnetic coupling is very small. The $M/N\beta$ value at 5 T is close to one electron and the experimental curve lies slightly below the Brillouin function, assuming $g = 2.14$ (according to magnetic data and EPR measurements, see below).

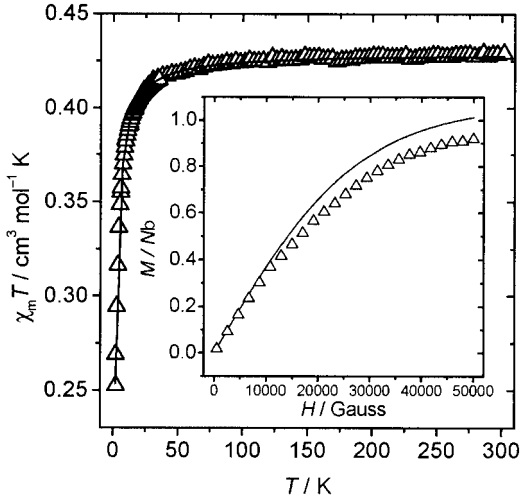

Figure 7. Temperature dependence of $\chi_m T$ vs. T for complex **2** (solid line indicates the best fit); inset: plot of the reduced magnetization ($M/N\beta$) at 2 K (solid line represents the Brillouin formula for the g value calculated from EPR spectra).

Actually complex **2** is a complicated two-dimensional copper(II) network with two kinds of bridging ligands: bpds and μ-(1,3-azide). Taking into consideration the long distances and the number of carbon atoms between adjacent copper(II) ions separated by the bpds, we may consider, from a magnetic point of view, a pseudo-one-dimensional structure. All copper(II) atoms are linked by μ-(1,3-N_3) bridging ligands in apical-apical positions (long-long distances). This gives a uniform $S = 1/2$ system. The fit of the magnetic data has been carried out using the formula given by Bonner and Fisher for this kind of uniform antiferromagnetic $S = 1/2$ chains.[13] The best-fit parameters obtained with this model are $J = -1.21 \pm 0.2\ cm^{-1}$, $g = 2.14 \pm 0.02$ and $R = 2.1 \times 10^{-6}$ (R is the agreement factor defined as $\Sigma_i[(\chi_m T)_{obs} - (\chi_m T)_{calc}]^2 / \Sigma_i[(\chi_m T)_{obs}]^2$. This result indicates very small antiferromagnetic coupling through the μ-(1,3-azide) bridging ligands. The small J value can be interpreted as a consequence of the almost nil overlap between the copper(II) ions through the μ-(1,3-N_3) bridging ligands in the apical(long)-apical(long) coordination mode. Similar features have already been reported for other apical-apical polynuclear azide complexes, such as the dinuclear one reported by Drew et al., where the authors indicated "relatively weak antiferromagnetic interaction" without giving any value of J.[14] Taylor et al.,[15] reported an analogous complex where the lack of significant coupling between copper centers mediated by azide has been rationalized on the basis of the overlap. The major σ pathway for the interaction of two copper ions is via their d_{z^2} orbitals through the azide. The nearly square-pyramidal geometry of the d^9 copper atoms suggests that they have $d_{x^2-y^2}$ ground states:[13] therefore the unpaired electrons are localized in the basal plane and cannot effectively undergo coupling. Finally, one of us reported a similar complex with this kind of azide bridging in combination of bridging oxalate where

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the authors stated that "the coupling parameter corresponding to the apical bridge can reasonably be expected to be very small".[5f] On the other hand, the presence of the bpds bridging ligand which connects the one-dimensional –[μ-(1,3-N_3)Cu]$_n$– polymers can also contribute to the final J value. Thus, although the R value is very good, it must be considered carefully, owing to other possible magnetic interactions.

Let us remember that when the coordination mode is not apical(long)-apical(long) but equatorial(short)-equatorial(short) the coupling is normally strongly antiferromagnetic.[16] However, the most usual coordination mode is neither equatorial(short)-equatorial(short) nor apical(long)-apical(long) but equatorial(short)-apical(long) for the most current five-coordination mode. In this case both weak ferro- or antiferromagnetic coupling can be found, depending mainly on the distortion of the copper(II) ions.

The EPR spectra show the same shape at different temperatures (Figure 8), which is the typical pattern corresponding to an elongated octahedral copper(II) center with $g_{||}$ = 2.28 and $g_{\perp}$ = 2.07 (g_{av} = 2.14), in perfect agreement with the value obtained by magnetic measurements.

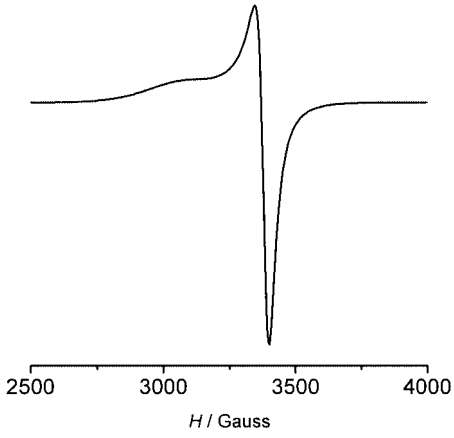

Figure 8. The EPR spectrum of complex **2** at room temperature (same shape was obtained at different temperatures).

Conclusion
