$(Ph_4As)_2[W(mnt)_3]$	28	73	53	[7,8]

[a] Average of the values for θ/60 and $(90 - \varphi)/(90 - 55)$. [b] This work.

Interestingly, the coordination geometry of TP changes to an intermediate structure between TP and OCT upon replacing the Et_4N^+ cations of **1a** with the larger Ph_4P^+ cations in **1b** (θ = 23°, φ = 76°, and OCT/TP = 39%), despite the two metal centers having the same oxidation number. Similar geometrical changes were observed between $(Et_4N)_2[W(bdt)_3]$[11] (θ = 4°, φ = 87°, and OCT/TP = 2%)[7] and $(Ph_4As)_2[W(bdt)_3]$[10] (θ = 23°, φ = 76°, and OCT/

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

TP = 44%).[7] In both series of $bdtCl_2$ and bdt complexes the smaller counter-cation favors a near TP structure, whereas the larger counter-cation results in an intermediate structure between TP and OCT. Furthermore, when the tungsten(IV) is oxidized (see **1a** vs. **2a**) the coordination geometry changes considerably from an almost TP structure to an intermediate structure between TP and OCT (θ = 33°, φ = 70°, and OCT/TP = 56%). However, in complexes having the larger PPh_4^+ cation, oxidation from **1b** to **2b** (θ = 27°, φ = 73°, and OCT/TP = 45%) results in only slight changes in the coordination geometry.

The θ and φ values of **2c** (θ = 30°, φ = 72°, and OCT/TP = 50%) are similar to those for **2a** and **2b**, indicating that, in tungsten(V) $bdtCl_2$ complexes, geometrical changes rarely occur upon changing the counter-cations. Although $(Me_2Ph_2P)[W(bdt)_3]$[13] was found to adopt an intermediate structure between TP and OCT (θ = 30°, φ = 72°, and OCT/TP = 62%),[7] the structures of $(Me_2Ph_2P)_2[W(bdt)_3]$ and $[W(bdt)_3]^-$, which have different counter-cations from $Me_2Ph_2P^+$, have not been reported. The present results indicate that counter-cations significantly influence the coordination geometries in tungsten(IV) complexes, while little effect is observed in tungsten(V) complexes. Further, the geometries of complexes with small cations such as Et_4N^+ are sensitive to the oxidation state of the metal. The factors governing those geometrical changes have not been identified at this stage, but both packing forces in the crystals and matching of ligand orbitals and metal d orbitals in energies may be important for this series of tungsten $bdtCl_2$ complexes. The molybdenum center in **3a** takes an almost TP structure (θ = 2°, φ = 88°, and OCT/TP = 5%), suggesting that replacement of tungsten with molybdenum in $[M(bdtCl_2)_3]^{2-}$ complexes does not influence the coordination geometry around the metal centers.

Conclusions

A series of tungsten(IV) and -(V) tris(3,6-dichloro-1,2-benzenedithiolate) complexes with Et_4N^+, Ph_4P^+, and pyridinium cations as well as a molybdenum(IV) derivative with an Et_4N^+ cation have been presented. Solid-state crystallographic analysis reveals that the coordination geometries of the six-coordinate tungsten(IV) centers depend significantly on the sizes of the counter-cations, with a trigonal-prismatic geometry for the smaller Et_4N^+ (**1a**) and an intermediate structure between a trigonal prism and an octahedral geometry for the larger Ph_4P^+ (**1b**). On the other hand, tungsten(V) complexes including Et_4N^+, Ph_4P^+, and pyridinium cations (**2a**–**2c**) adopt almost the same intermediate structures. Furthermore, the coordination geometries around tungsten in Et_4N^+ complexes are dependent on the oxidation state of the metal (trigonal prism for W^{IV} and intermediate for W^{V}), except in the case of Ph_4P^+ complexes.

Experimental Section

$(Et_4N)_2[W(bdtCl_2)_3]$ (1a) and $(Et_4N)[W(bdtCl_2)_3]$ (2a): A CH_3CN solution (10 mL) containing H_2bdtCl_2 (0.50 g, 0.0025 mol) and Et_3N (0.75 mL, 0.0047 mol) was added slowly to a suspension of $[WOCl_3(THF)_2]$ (0.45 g, 0.001 mol) in CH_3CN (10 mL) at –40 °C. The solution was warmed to room temperature and stirred for 30 min. The obtained purple suspension was filtered and the filtrate was concentrated to about 6 mL. Addition of Et_4NI (0.38 g, 0.0015 mol) in CH_3OH (15 mL) to the solution gave a purple precipitate. The purple solid was dissolved in the minimum amount of acetone and purified by passing through an alumina column using acetone/CH_3OH as the eluent. A red component of $(Et_4N)_2[W(bdtCl_2)_3]$ was eluted first and then a purple component of $(Et_4N)[W(bdtCl_2)_3]$ was separated. Each solution was evaporated to dryness.

1a: Yield: 0.38 g (35%). $C_{34}H_{46}Cl_6N_2S_6W$ (1071.7): calcd. C 38.11, H 4.33, N 2.61. found C 37.76, H 4.08, N 2.56. UV/Vis (CH_3CN): λ_{max} (ε) = 470 nm (8300 $M^{-1}cm^{-1}$), 535 (4700).

2a: Yield 0.14 g (15%). $C_{26}H_{26}Cl_6NS_6W$ (941.46): calcd. C 33.17, H 2.78, N 1.49; found C 33.41, H 2.70, N 1.54. UV/Vis (CH_3CN): λ_{max} (ε) = 360 nm (9400 $M^{-1}cm^{-1}$), 540 (5200), 650 (sh). ESI-MS: m/z = 811.5 $[M]^-$. CV (V vs. SCE in CH_3CN): –0.19 (reversible), +0.47 (reversible).

$(Ph_4P)_2[W(bdtCl_2)_3]$ (1b): The complex was prepared in the same way as **1a** except that PPh_4Br was employed instead of Et_4NI. Yield: 0.58 g (39%). $C_{66}H_{46}Cl_6P_2S_6W$ (1490.0): calcd. C 53.20, H 3.11; found C 53.46, H 3.41.

$(Ph_4P)[W(bdtCl_2)_3]$ (2b): A methanolic solution (10 mL) of H_2bdtCl_2 (0.07 g, 0.0003 mol) was added to WO_2Cl_2 (0.03 g, 0.0001 mol) and a purple solution was obtained after 24 h. After filtration, Ph_4PBr (0.042 g, 0.0001 mol) was added to the obtained purple solution to give deep-purple microcrystals. The precipitate was collected by filtration and dried in air. Yield: 0.07 g (61%). $C_{42}H_{26}Cl_6PS_6W$ (1150.6): calcd. C 43.84, H 2.28; found C 43.98, H 2.51.

$(C_5NH_6)[W(bdtCl_2)_3]\cdot 2CH_3OH$ (2c)·$2CH_3OH$: This complex was prepared in the same way as **2b** except that pyridinium trifluoromethanesulfonate was used instead of Ph_4PBr. Yield: 0.05 g (54%). $C_{25}H_{20}Cl_6NO_2S_6W$ (955.37): calcd. C 31.43, H 2.11, N 1.47; found C 31.59, H 2.38, N 1.51.

$(Et_4N)_2[Mo(bdtCl_2)_3]$ (3): $[MoO_2Cl_2]$ (0.04 g, 0.2 mmol) was added to a THF solution (10 mL) of H_2bdtCl_2 (0.13 g, 0.6 mmol) and the solution was stirred for 3 h. The obtained green solution was concentrated to 5 mL and purified by passing through a neutral alumina column using acetone/CH_3OH (1:4) as an eluent. A blue band was collected and concentrated to 5 mL, and addition of Et_4NI (0.05 g, 0.19 mmol) gave a blue microcrystalline powder, which was collected by filtration and dried in vacuo. Yield: 0.004 g (21%). $C_{34}H_{46}Cl_6MoNS_6$ (983.80): calcd. C 41.51, H 4.71, N 2.85; found C 41.39, H 4.65, N 2.87. UV/Vis (CH_3CN): λ_{max} (ε) = 284 nm (46800 $M^{-1}cm^{-1}$), 352 (20500), 574 (11000). CV (V vs. SCE in CH_3CN): +0.03 (reversible), +0.62 (reversible).

Calculation of θ and φ Angles (°) in Crystal Structures: The θ angle was calculated as the torsion angle between the two S atoms of $bdtCl_2$ with respect to the aligned centers of gravity between the S1, S3, and S5, and S2, S4, and S6 atoms, respectively. The φ angle was calculated as the dihedral angle between the SMS groupings of the bound ligands (S1MS2, S3MS4, S5MS6; M = Mo and W) and the trigonal planes S1S3S5 and S2S4S6, according to ref.[7] S1–S6 are labeled in Scheme S1 (see Supporting Information). Averaged values are employed in this paper. The percentage (OCT/TP) used for the OCT and TP is the average of the values θ/60 and $(90 - \varphi)/(90 - 55)$, respectively.

Other Measurements: Cyclic voltammograms were recorded at 100 mV s^{-1} with a Hokuto HZ-3000. The working and counter electrodes were a glassy-carbon disk and a platinum wire, respectively. The sample solutions were deoxygenated with a stream of N_2. The reference electrode used was an SCE. Electronic spectra were recorded with a Shimazu-U2550 spectrometer at 20 °C.

X-ray Crystallographic Study: Single crystals of **1a**, **1b**, **2a**, **2b**, and **2c** were recrystallized from acetone, hexane, acetonitrile/diethyl ether, and methanol, respectively. Although a single crystal of **3** was not obtained by recrystallization, a single crystal of **3a** was obtained by adding Et_3NHBr to a solution of **3** in CH_3CN. Each single crystal obtained was mounted on top of a glass fiber. X-ray data of the complexes were collected with graphite-monochromated Mo-K_α radiation on a Rigaku/MSC Mercury CCD diffractometer. The structures were solved by direct methods (SIR-97)[16] and expanded using DIRDIF 99.[17] The structures were refined anisotropically by full-matrix least-squares on F^2. The non-hydrogen atoms in all structures were attached at idealized positions on the carbon atoms and not refined. All structures converted in the final stages of refinement showed no movement in the atom positions. All calculations were performed with Single Crystal Structure Analysis Software, Ver. 3.6.0.[18] Further crystal data and agreement factors are listed in Tables 2 and 3.

CCDC-261315–261320 (for **1a**, **1b**, **2a**, **2b**, **2c**, and **3a**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

Supporting Information: Description of the θ and φ angles (Scheme S1), and detailed bond lengths [Å] and angles [°] around the metal centers (Tables S1–S6).

Keywords: Adsorption / Cadmium / Ligand design / N ligands / Zinc

The compound *N*-(4-amino-1-methyl-5-nitroso-6-oxo-1,6-dihydropyrimidin-2-yl)-*N′*-[bis(2-aminoethyl)]ethylenediamine (HL) was synthesised and structurally characterised by analytical methods and ^{1}H, ^{13}C and ^{15}N NMR spectroscopy. The protonation of HL and its coordinating ability towards Zn^{2+} and Cd^{2+} ions in water solution were also studied by potentiometric methods and UV/Visible and ^{1}H-^{13}C NMR spectroscopy. The molecular structures of $[H_3L]^{2+}[CdI_4]^{2-}\cdot 2H_2O$ and $[(Cl_3Zn)(\mu\text{-}Cl)\{Zn(\mu_2\text{-}HL)\}]_2\cdot 2.5H_2O$ were solved by single-crystal X-ray diffraction methods. On the basis of these data, the performance of HL anchored to activated carbon (AC) was evaluated as a molecular receptor for Zn^{2+} and Cd^{2+} metal ions in aqueous solution. This was done by a comparative study of the adsorption capacity of the adsorbents AC alone and HL anchored on the AC (AC-HL) for these metal ions and by a structural study of the AC-HL, AC-HL-Zn^{2+} and AC-HL-Cd^{2+} solid phases by XPS and IR spectroscopy.

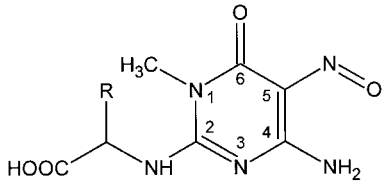
Introduction

Substitution reactions at the C(2) atom of the 4-amino-1-methyl-5-nitroso-6-oxo-1,6-dihydropyrimidin-2-yl moiety with an α-amino acid residue result in molecular compounds containing a rigid, flat pyrimidine moiety and a pendant amino-acidic residue[1] (Scheme 1).



Scheme 1.

These compounds have two Lewis base-type environments that control their coordinating behaviour: one is constituted by the neighbouring C(5)–NO and C(6)=O substituents in the pyrimidine ring, and the other by the characteristic basic functions existing at the amino acid residue linked to the C(2) position of the pyrimidine nucleus. Steric factors prevent co-operative binding of both pyrimidine and amino acid functions, to a single metal centre, and this favours the formation of 1D, 2D and 3D polynuclear solid complexes. In fact, the structures of some of the crystalline polynuclear complexes of these ligands with alkali and alkaline-earth metal ions have been solved[2] and show interesting features similar to those of metal–organic compounds with non-linear optical properties.[3]

The molecules depicted in Scheme 1 are characterised by a strong electronic polarisation at the pyrimidine nucleus as a result of the co-operative effect of the marked electron-withdrawing character of the C(5) nitroso function and the electron-donating character of the amino function at C(2). This fact is consistent with the non-basic character of the N(3) atom which, in our studies, has never been found to be a metal-binding centre of these ligands.[2] The strong polarisation of the pyrimidine π-electron cloud[1b] suggests the existence of low-energy LUMO orbitals that are able to interact with high-energy HOMO orbitals provided by electron-rich aromatic centres. Accordingly, in a recent work[4] we have explained the observed irreversible adsorption of two of these nitrosopyrimidine-amino acid conjugates onto an activated carbon (AC) as being due to π–π donor–acceptor interactions between the pyrimidine moiety of the ligands (acting as acceptor) and the arene centres of the AC[5] (acting as donor). These results suggest that, after adsorption of these molecules on the AC, their pyrimidine moieties remain attached to the carbon surface, coplanar with the graphene sheets, thus losing their ability to bind to metal ions. On the other hand, the amino acid residue linked to C(2) of the pyrimidine ring is projected outside of the carbon surface and becomes the only potential reactive centre for metal ions in the ligand–AC adducts. Hence, although the interactions between metal ions and free ligands

[a] Dpto. Química Inorgánica y Orgánica, Universidad de Jaén, 23071 Jaén, Spain
[b] Institute of Chemistry, University of Nêuchatel, 2007 Nêuchatel, Switzerland

are rather non-specific in aqueous solution, it is expected that the carbon-anchored ligands would behave as monofunctional ligands to metal ions by using only the basic function linked to C(2) of the pyrimidine ring as binding site.

Activated carbons have been extensively used to remove metals from industrial and municipal wastewater as they are cheap and accessible materials. Nevertheless, their efficiencies are strongly limited due to the non-specific nature of the basic functions which are usually added by the activation processes.[6] Moreover, the functionalisation by activation is limited to the edges of the graphene layers and to the entrance of the pores. For these reasons, although advantageous textural (e.g. adequate surface area and specific pore size distribution) and functional properties (both easily achievable by adequate activation processes) are important, the development of specific chemical properties at the carbon surface[7] to improve its metal-capturing properties, which is more difficult to attain, is also vital.

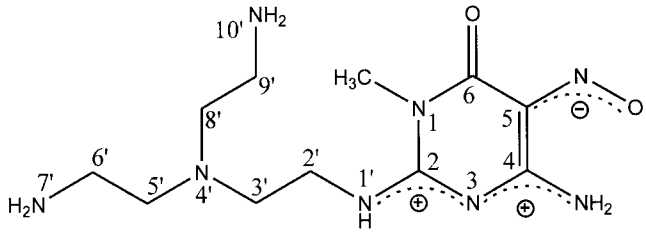
The adducts resulting from the irreversible adsorption of a monolayer of the C(2)-functionalised nitrosopyrimidines on the AC graphitic surface can be regarded as new selectively functionalised activated carbons whose mechanical and textural properties are provided by the carbon skeleton while the chemical functionalisation is provided by the functionality introduced as the C(2)-substituent at the nitrosopyrimidine derivative. Moreover, whenever the basic functions existing at the C(2) substituent of the pyrimidine moiety can be tailored, the adsorption of these compounds becomes an easy and suitable method to develop the desired functionality at the carbon surface. Of course, the efficacy of the proposed method is conditioned to maintaining the heteroaromatic moiety unaltered on changing the substituents at the C(2) position of the pyrimidine moiety.

As already commented, in a recent paper[4] we studied the adsorption of a new molecular receptor of this class, *N*-(4-amino-1-methyl-5-nitroso-6-oxo-1,6-dihydropyrimidin-2-yl)-*N′*-(bis-2-aminoethyl)ethylenediamine (HL), at several pHs, on a basic AC. We found that HL is irreversibly anchored at the arene centres of the carbon surface through the pyrimidine moiety, by strong π–π interactions,[4] thus providing functionalisation of the AC with a triamine grouping. The aim of this work was to gain insight into the performance of the proposed model by comparison of the capacity of an activated carbon and the above ligand previously adsorbed on it (AC-HL) to capture metal ions. For this, the adsorption data of $ZnCl_2$ and $CdCl_2$ in aqueous solution on an AC and AC-HL adsorbent were analysed in the light of the structural data of HL, which was characterised by X-ray diffraction methods, and also the coordination chemistry behaviour of Zn^{II}/HL and Cd^{II}/HL systems in aqueous solution.

Results and Discussion

Characterisation of the Ligand

HL was prepared by a procedure consisting of the nucleophilic attack of one of the amino primary groups of tris(2-aminoethyl)amine to the C(2) position of the pyrimidine precursor 4-amino-2-methoxy-1-methyl-5-nitroso-6-oxo-1,6-dihydropyrimidine (Scheme 2). For this, the pH of the reaction mixture was adjusted such that one of the three amino primary groups remained unprotonated.[8]



Scheme 2.

N projections in the ^{1}H-^{15}N HMBC spectrum of HL·2HCl exhibit the same signals as the pyrimidine precursor (see Experimental Section) along with another two signals attributable to the secondary and tertiary N atoms of the polyamine residue, with the former at lower field than the latter. The lack of signals for two of the primary amino groups means that they have been protonated and thus confirms the monosubstitution of the polyamine. The carbon atoms were assigned in the ^{1}H-^{13}C HSQC spectrum after the methylene protons of the polyamine moiety had been assigned in the ^{1}H-^{15}N HMBC spectrum.

The structure of compound $[H_3L]^{2+}[CdI_4]^{2-}\cdot 2H_2O$ was solved by single-crystal X-ray diffraction analysis. The molecular structure consists of protonated cations $[H_3L]^{2+}$, tetraiodocadmiate(II) anions and water solvent molecules (Figure 1). This allowed an analysis of the $[H_3L]^{2+}$ unit in which, as expected, the two protons attached to HL are at the primary amino groups of the polyamine.

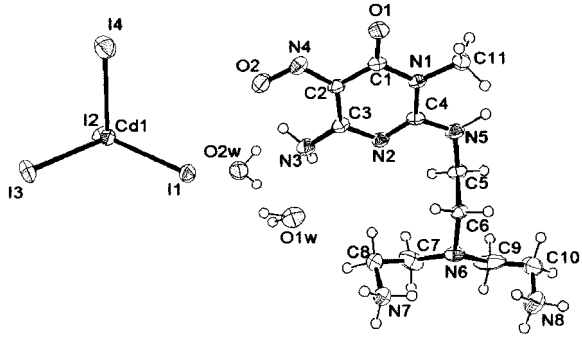


Figure 1. ORTEP drawing of $[H_3L]^{2+}[CdI_4]^{2-}\cdot 2H_2O$.

The structure of $[H_3L]^{2+}$ exhibits a planar conformation of the heterocyclic moiety [including the pyrimidine substituents labelled in Scheme 2 as C(6)O, C(5)NO, C(4)NH_2 and C(2)NH], whereas the C(2) substituent deviates from the aromatic plane. This suggests π electronic delocalisation in the pyrimidine and precludes the C(2)NH and C(4)NH_2 exocyclic substituents from acting as metal ion acceptors. The C(5)-nitroso group is oriented *trans* to C(6), which allows the formation of an intramolecular N–H···O hydrogen bond in an S(6) motif. An intramolecular hydrogen bond also exists between the N(7′) atom of a primary amino

group as donor and the N(4′) atom as acceptor. This description resembles the structure of analogous α-amino acid derivatives.[1,9]

The similarity between the C(5)–NO and N–O bond lengths, (1.320 Å and 1.302 Å, respectively), which are in the range of those observed in oximate anions [RR′C–N–O]$^-$, suggests the existence of a delocalised double bond in the C(5)NO grouping.[10,11] All of the C–N bonds lengths in the HN^2–C(2)–N(3)–C(4)–N^4H_2 fragment are rather similar [C(2)–N^2H = 1.33 Å; C(2)–N(3) = 1.30 Å; N(3)–C(4) = 1.353 Å and C(4)–N^4H_2 = 1.314 Å] and it is not possible to distinguish between single and double bonds. All of these parameters taken together suggest that the representation of Scheme 2 is the most appropriate for HL.

Ligand Protonation

The protonation constants of HL obtained by potentiometric methods in aqueous medium are reported in Table 1. The monoanion L$^-$, which exists at high pH values, binds four protons in the pH range investigated (2.5–10.5). The first three protonations are markedly grouped, and their log *K* values indicate a strongly basic character of the corresponding protonation positions, i.e. they take place at strongly basic atoms. On the contrary, the fourth protonation constant (log *K* = 2.12) indicates a far lower basicity for this position.

Table 1. Protonation constants (log *K*) of HL (0.1 M KCl, 298.1 K).

Reaction	log *K*
$L^- + H^+ \leftrightharpoons HL$	10.94
$HL + H^+ \leftrightharpoons [H_2L]^+$	9.70
$[H_2L]^+ + H^+ \leftrightharpoons [H_3L]^{2+}$	8.75
$[H_3L]^{2+} + H^+ \leftrightharpoons [H_4L]^{3+}$	2.12

The UV/Visible adsorption spectra of HL at various pH values is given in Figure 2. The spectrum at pH 5 is similar to that of the pyrimidine chromophore[2f] and consists of two UV bands due to π–π* transitions at λ_1 = 328 nm (ε_1 = 2.23×10^4 cm^{-1} mol^{-1} L) and λ_2 = 230 nm (ε_2 = 8.85×10^3 cm^{-1} mol^{-1} L). The visible band with a maximum at λ_3 = 524 nm (ε_3 = 76.50 cm^{-1} mol^{-1} L), is assigned to a forbidden n→π* transition of the non-bonding O electron pair of the C(5)NO group.[2f]

The spectra are unchanged in the pH range 4.1 to 10.0, thus indicating that the second and third protonations do not affect the pyrimidine chromophore, i.e. they take place on the primary amino groups of the polyamine. On the contrary, the small red-shift of the 328 nm band as the pH increases above about 10 indicates that the first protonation step takes place either at the -N$^-$-C(2) or NH$^-$-C(4) anions. To gain further insight into this protonation step we studied the ^{1}H and ^{13}C NMR spectroscopic data obtained from HL in D_2O at different pH values; the results are summarised in Figure 3. The significant upfield shifts of the methylene protons at pH values up to 10 suggest that the process

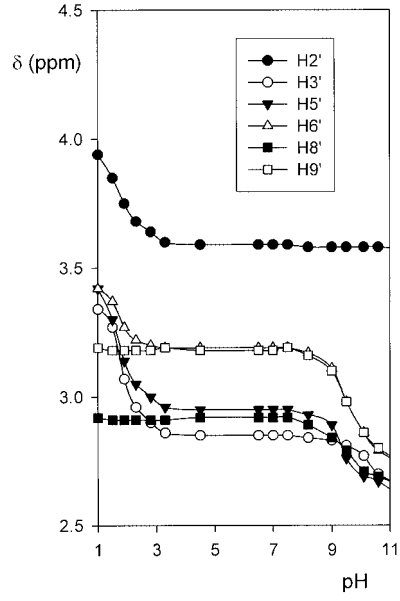

Figure 3. ^{1}H NMR chemical shifts of the HL signals as a function of pH.

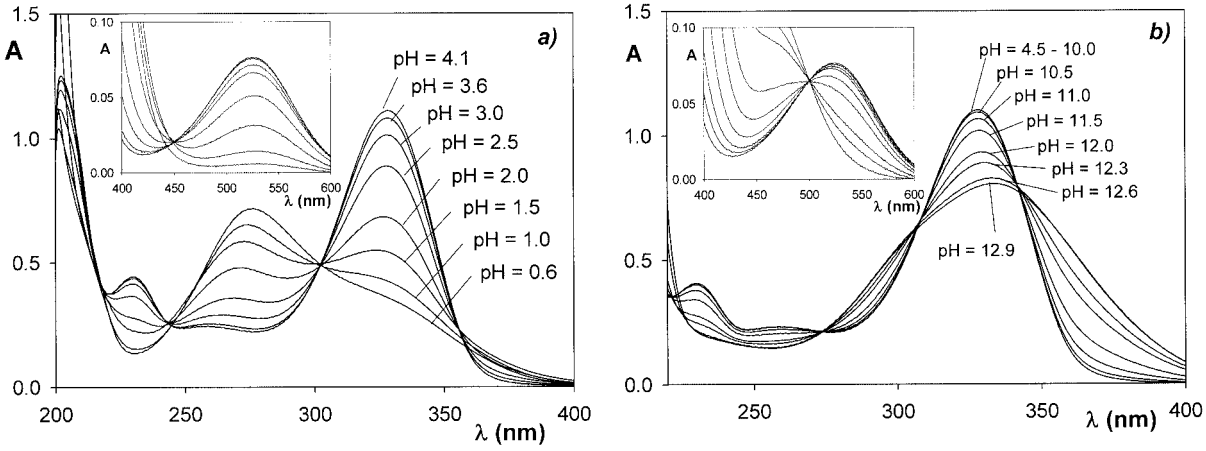

Figure 2. pH-Dependence of the absorption spectra of HL in the UV ([HL] = 5×10^{-5} M, 0.1 M KCl), and visible (inset, [HL] = 10^{-3} M, 0.1 M KCl) regions, a) in acidic media and b) in basic media.

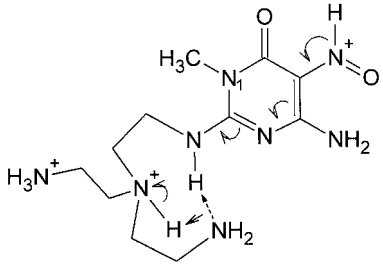
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

studied occurs at –N⁻-C(2). Moreover, the deshielding of such protons in the pH range 10–7 indicates the protonation of the two primary amino groups in this pH range.

In the pH range 1–4, where the fourth protonation step occurs (see Figure 2), a blue-shift of the 328 nm band and quenching of the absorption at 524 nm are observed with decreasing pH values. The latter indicates that the σ nonbonding pair on C(5)NO is used in binding this proton, thus hindering the n→π transition (band at 524 nm, see above). Protonation of the NO group instead of the $N(3)_{ring}$ atom is consistent with the above-described polar character of HL, according to which the electron density is higher at NO than at $N(3)_{ring}$.

In addition, in a ^{1}H NMR titration experiment of HL during this protonation (pH range 1–4) a deshielding of the protons at the 2′, 3′, 5′ and 6′ carbon atoms of the polyamine was observed (Figure 3). The non-chemical equivalence of the H5′ and H8′ and H6′ and H9′ signals in the polyamine residue indicates a conformational change accompanying this process, which is probably induced by the formation of an intramolecular hydrogen bond of the $H_2N\cdots HN$–C(2) type (Scheme 3).



Scheme 3.

Complex Formation in Aqueous Solution

Complex formation in the HL/Zn^{II} and HL/Cd^{II} systems in an aqueous medium was studied by a potentiometric method at [ligand]/[metal] = 1. The complex species formed, together with their stability constants, are listed in Table 2, and the species distribution plots are given in Figure 4.

Table 2. Stability constants of Zn^{II} and Cd^{II} complexes (log K) with HL (0.1 M KCl, 298.1 K).

Reaction	log K Zn^{II}	Cd^{II}
$M^{2+} + H_3L^{2+} \rightleftharpoons [MH_3L]^{4+}$	3.96	2.80
$M^{2+} + [MH_3L]^{4+} \rightleftharpoons [M_2H_2L]^{5+} + H^+$	6.33	
$M^{2+} + H_2L^+ \rightleftharpoons [MH_2L]^{3+}$		4.85
$M^{2+} + HL \rightleftharpoons [MHL]^{2+}$	9.56	7.45
$M^{2+} + 2HL \rightleftharpoons [M(HL)_2]^{2+}$	17.33	13.88
$M^{2+} + [MHL]^{2+} \rightleftharpoons [M_2HL]^{4+}$	3.84	2.94
$M^{2+} + L^- \rightleftharpoons [ML]^+$		9.82
$[ML]^+ + L^- \rightleftharpoons ML_2$		7.59
$M^{2+} + L^- + OH^- \rightleftharpoons MLOH$	3.00	
$M^{2+} + OH^- \rightleftharpoons [MOH]^+$		–8.35
$M^{2+} + 2OH^- \rightleftharpoons M(OH)_2$	–14.60	

Zn^{II} forms mono- and dinuclear complexes with HL in aqueous solution. At low pH values only the complex $[Zn(H_3L)]^{4+}$, with the metal bonded through the pyrimidine moiety, exists. The stability constant (log K = 3.96) is similar to the five-membered metal chelates formed by Zn^{II} with N,O donor ligands, such as the single amino acids glycine (log K = 5.16), methionine (log K = 4.38), ornithine (log K = 4.10) and valine (log K = 5.00) and the nucleoside guanosine (log K = 4.6).[8] This suggests that in the $[Zn(H_3L)]^{4+}$ complex the coordination to the metal ion takes place through the nitrogen atom of the C(5)NO group and the oxygen of C(6)O. This coordinating behaviour of the pyrimidine residue is the only one observed in the tetranuclear complex $[Zn_2(HL)_2][ZnCl_4]_2$ (see below) and also in the polynuclear complexes formed by Zn^{II} with pyrimidine analogues derived from L-valine and L-methionine.[12]

Figure 4 (a) shows that mono-deprotonation of $[Zn(H_3L)]^{4+}$ starts at a pH of around 3.5. The resulting $[Zn(H_2L)]^{3+}$ species is able to bind a second Zn^{II} through the two unprotonated amino groups of the polyamine residue to form the binuclear complex $[Zn_2(H_2L)]^{5+}$. The log K value calculated for the association of a Zn^{2+} ion to the

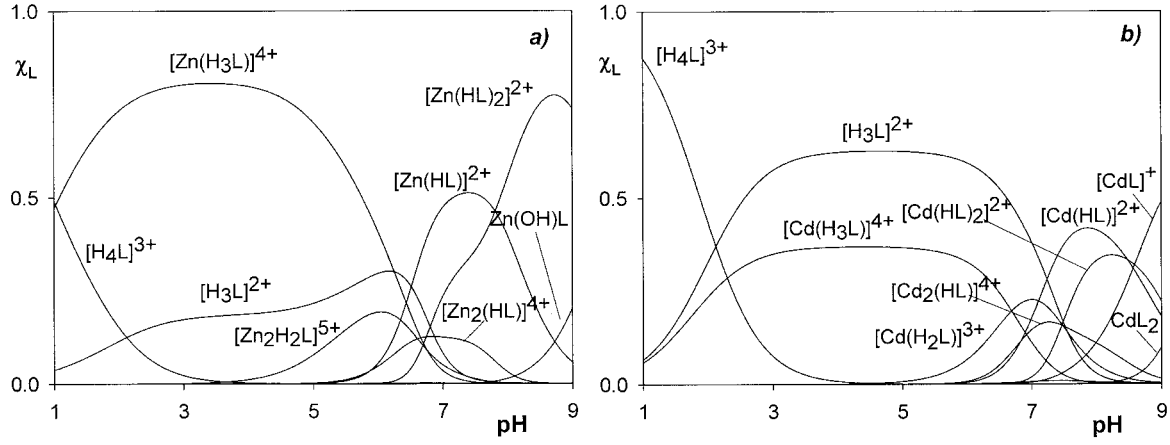


Figure 4. Species distribution plot for a) the HL/Zn^{II} system and b) the HL/Cd^{II} system in aqueous solution (1:1 molar ratio) as a function of pH ([HL] = [Zn^{II}] or [Cd^{II}] = 10^{-3} M, 0.1 M KCl, 298.1 K).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

polyamine moiety, $Zn^{2+} + [ZnH_3L]^{4+} \rightleftharpoons [Zn_2H_2L]^{5+} + H^+$, is 6.33. This suggests the coordination of Zn^{2+} by two of the nitrogen atoms of this moiety. The amount of $[Zn_2(H_2L)]^{5+}$ decreases sharply at slightly alkaline pH due to the formation of $Zn(OH)_2$ (not included in Figure 4 (a) for simplicity), but an additional increase of pH produces the complete deprotonation of the polyamine, and this favours the formation of $[Zn(HL)_2]^{2+}$ rather than the hydroxide species. The stability constant for $[Zn(HL)_2]^{2+}$ ($\log K = 17.33$) is consistent with that found for the 1:1 complex $[Zn(TrenH)]^{3+}$ ($\log K = 7.95$), where $TrenH^+$ is the N-tridentate ligand analogous to HL.[8,13] Finally, at a pH of about 8 deprotonation of the C(2)NH group is promoted by Zn^{II}, resulting in the formation of the complex [ZnL(OH)]. The calculated stability constant for the addition of a hydroxy plus an L anion to a Zn^{II} metal ion is $\log K = 16.70$. This value is similar to the Zn^{II} complex with the analogous *N*,*N*,*N*,*N* tetradentate ligand tris(2-aminoethyl)amine (Tren)[13] and suggests a similar coordinating behaviour.

With the aim of getting further information about the structures of the complexes formed in solution, the ^1H and ^{13}C NMR spectra were recorded of a 1:1 HL/Zn^{II} mixture and HL in aqueous solution at various pH values. Figure 5 displays the differences between the chemical shift values ($\Delta\delta$) of proton and carbon atoms vs. pH obtained from these experiments.

In the pH range 1–5, the $\Delta\delta$ values are significant for the C(5) and C(6) atoms of the pyrimidine and negligible for the remainder (see Figure 5, a1). This indicates that in the main species existing in this pH range, $[Zn(H_3L)]^{5+}$, the ligand is coordinated through the C(5)NO and C(6)O groups. This is also supported by the negligible $\Delta\delta$ values found for all of the methylene protons, which indicates that the polyamine unit is not involved in metal coordination.

In the pH range 4–6, non-zero $\Delta\delta$ values for the 5′, 6′, 8′ and 9′ methylene protons indicate that the formation of $[Zn_2(H_2L)]^{5+}$ by addition of a Zn^{II} ion to $[Zn(H_3L)]^{4+}$, which occurs at this pH, takes place at the monoprotonated

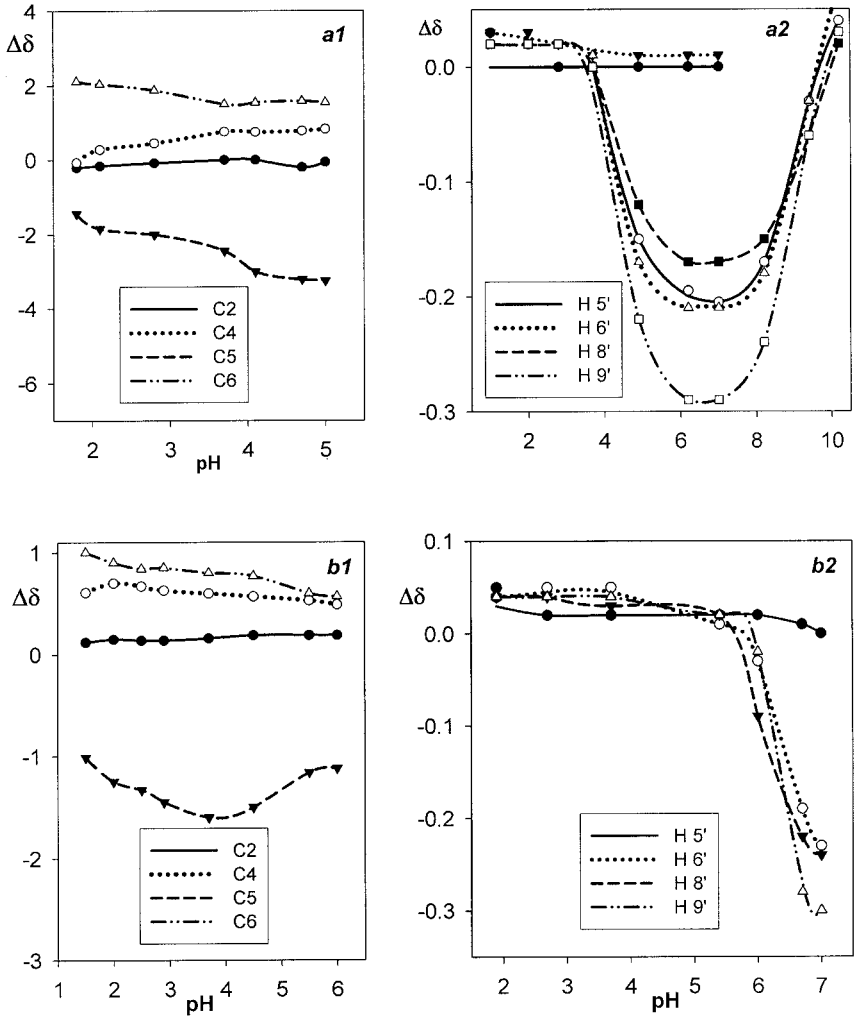

Figure 5. a1: Chemical shift differences between HL/Zn^{II} mixtures (1:1 molar ratio) and HL, at different pHs, for the ring-carbon signals. a2: Chemical shift differences for the polyamine methylenic protons. b1 and b2: Chemical shift differences for Cd^{II}.

polyamine. Figure 5 (a2) also shows the non-equivalence of the analogous methylene groups of each of the two terminal arms of the polyamine residue. This clearly indicates the involvement of only one of the two primary amine groups in the coordination.

The formation of [ZnLOH] species above pH 8 is accompanied by an increasing deshielding of all of the methylene protons (see Figure 5a2) except that of 2′ (not included in this figure for simplicity), which suffers a small opposite effect. This accounts for the involvement of the deprotonated C(2)-NH group of the polyamine in metal coordination and confirms that L acts as a tetradentate *N*,*N*,*N*,*N* ligand.

The complexation equilibria for HL/Cd^{II} system are given in Table 2, with the speciation plots in Figure 4 (b). These highlight that the coordination chemistry of Cd^{II} is similar to that of Zn^{II} as regards the stoichiometries of most of the complex species formed. The structures of the Cd^{II} complexes are also similar to the analogous Zn^{II} complexes described above. This was proved by an analysis of the data obtained from a NMR pH titration experiment of a 1:1 [Cd^{II}]/[HL] mixture (Figures 5, b1 and b2), which shows similar features to those discussed above for the Zn^{II}/HL system.

The stability constants of $[CdH_2L]^{3+}$ and $[CdHL]^{2+}$ complexes are similar to those of the analogous *N*,*N* bidentate 3-phenylpropane-1,2-diamine (log K = 4.1), pentane-1,2-diamine (log K = 5.5) and hexane-1,2-diamine (log K = 5.4)[14] and *N*,*N*,*N* tridentate, 1,4,7-triazaheptanediene (log K = 8.3)[15] ligands, respectively, thus indicating that the polyamine moiety acts either as a bidentate or tridentate chelating ligand, depending on the pH of the medium.

The main difference between the Zn^{II} and Cd^{II} complexes is that the Zn^{II} complexes are more stable than their Cd^{II} analogues. Hence, the speciation diagrams (Figures 4a and 4b) show that each of the Zn^{II} complexes is formed at significantly lower pHs than the analogous Cd^{II} ones. The higher affinity of Zn^{II} for nitrogen donors[15] than the softer acid Cd^{II} accounts for the lower stability constants of mononuclear complexes of Cd^{II} with the polyamine moiety compared to the analogous Zn^{II} complexes. This agrees with the structural differences observed between $[Zn_2(HL)_2]^{4+}$ and $[H_3L]^{2+}[CdI_4]^{2-}\cdot 2H_2O$ (see below), even when both of them are obtained at the same pH of 6 (Figures 1 and 6): whereas Zn^{II} is bonded to the polyamine in the former, in the latter the Cd^{II} is coordinated to the soft basic iodide ions and the tri-amine remains doubly protonated.

Crystal Structures of $[H_3L]^{2+}[CdI_4]^{2-}\cdot 2H_2O$ and $[(Cl_3Zn)(\mu\text{-}Cl)\{Zn(\mu_2\text{-}HL)\}]_2\cdot 2.5H_2O$

The crystal structures of $[H_3L]^{2+}[CdI_4]^{2-}\cdot 2H_2O$ and $[(Cl_3Zn)(\mu\text{-}Cl)\{Zn(\mu_2\text{-}HL)\}]_2\cdot 2.5H_2O$ were solved by single-crystal X-ray diffraction methods. The crystal and structure refinement data are summarised in Table 3. The molecular structure of $[H_3L]^{2+}[CdI_4]^{2-}\cdot 2H_2O$ consists of $[H_3L]^{2+}$ (whose structure was discussed above), tetraiodocadmiate(II) anions and water molecules (Figure 1). It is interesting to note that the Cd^{II} ion is not coordinated either to the pyrimidine or to the polyamine, but is bonded to four iodide ions. The structure of the CdI_4^{2-} anion corresponds to a deformed tetrahedron due to the involvement of two of the iodide anions in hydrogen bonding as hydrogen acceptors, with two amine primary groups of adjacent $[H_3L]^{2+}$ units acting as hydrogen donors.

The molecular structure of $[(Cl_3Zn)(\mu\text{-}Cl)\{Zn(\mu_2\text{-}HL)\}]_2\cdot 2.5H_2O$ consists of a neutral $[(Cl_3Zn)(\mu\text{-}Cl)\{Zn(\mu_2\text{-}HL)\}]_2$ complex and 2.5 water molecules. Figure 6 shows an ORTEP[16] drawing of the tetranuclear Zn^{II} complex, which contains two HL molecules and eight chloride ions as ligands. Each of the two HL molecules binds to the same

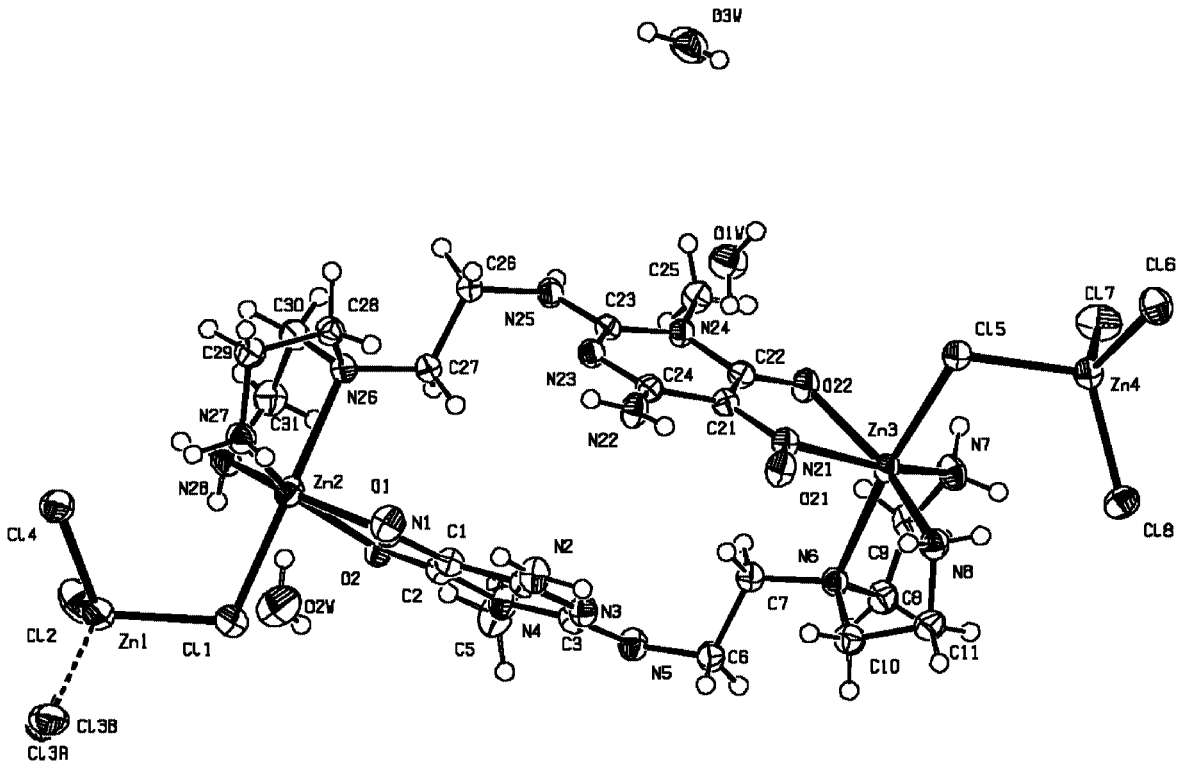

Figure 6. ORTEP drawing of $[(Cl_3Zn)(\mu\text{-}Cl)\{Zn(\mu_2\text{-}HL)\}]_2 \cdot 2.5H_2O$.

two Zn^{II} centres as a bridging ligand. The polyamine moiety acts as an *N*,*N*,*N* tridentate chelating ligand binding to a single Zn^{II} ion, whereas the pyrimidine acts as a didentate chelating ligand to a second Zn^{II} centre through the nitrogen of the NO group and the oxygen of C(6)O. Each of these Zn^{II} centres does is bound to a tetrachlorozincate(II) unit through a bridging chloride ligand. Therefore, the two zinc centres linked to HL have similar hexacoordinate environments consisting of the three nitrogen atoms of the polyamine from one HL molecule, the NO and C(6)O pyrimidine substituents from another HL unit and a chloride anion. The resulting coordination geometry can be described as tetragonal bipyramidal due to the fact that the bond lengths in the equatorial plane are notably shorter than those between the metal centre and the atoms in the apical positions.

The two remaining zinc atoms of the tetranuclear unit are placed in similar tetrahedral environments, with the Zn–μ-chloride bond significantly longer than the three terminal ones. It is noteworthy that none of the N_{cyclic} atoms of the HL units take part either in coordination to zinc or in hydrogen bonding, which points out the poor basicity character of this atom.

The main structural features highlighted for the pyrimidine moiety in $[H_3L]^{2+}$ $[CdI_4]^{2-} \cdot 2H_2O$ above are also exhibited by the HL molecules of the Zn^{II} complex. With this in mind, the opposed orientation of the pyrimidine planes of the two HL molecules in the $[(Cl_3Zn)(\mu\text{-}Cl)\{Zn(\mu_2\text{-}HL)\}]_2$ unit (Figure 6) is probably induced by the attractive dipole–dipole interactions between planes, which would stabilize the formed tetranuclear cyclic unit. This trend to the inverse orientation of the pyrimidine planes in the stacking of analogous pyrimidine compounds has been widely observed.[17]

Adsorption of $Zn^{2+}$and Cd^{2+}

As was mentioned above, a pH study of the adsorption/desorption of water-solved HL on a granular activated carbon (AC) showed the existence of π–π donor–acceptor interactions between the arene centres of the AC and the pyrimidine moiety of HL as the cause of the irreversible character of the adsorption process.[4] Further insight on this is obtained by comparison of the N_{1s} signals of the XPS spectra of the HL and AC-HL systems (Figure 7). This was done by assuming that the low nitrogen content of the AC (0.75%) implies negligible contribution (less than 1/10) to these signals compared to the HL nitrogen. Each of the N_{1s} signals is composed of two overlapping peaks corresponding to the five heterocyclic nitrogen atoms, i.e. the nuclear heterocyclic nitrogen atoms plus those directly bonded to the pyrimidine ring (at 400.02 eV for HL and 400.91 eV for AC-HL), and the three sp^3-type nitrogens of the tetraamine residue (at 398.40 eV for HL and 399.60 eV for AC-HL).

Both of these peaks are significantly shifted in the AC-HL spectrum relative to the HL spectrum. However, this fact is not relevant in the case of the peaks of the nitrogen atoms of the triamine due to the full involvement of these in the supramolecular assembling of solid HL by hydrogen bonds. On the contrary, the shifting of the peak of the heterocyclic nitrogens in AC-HL to higher energies relative to

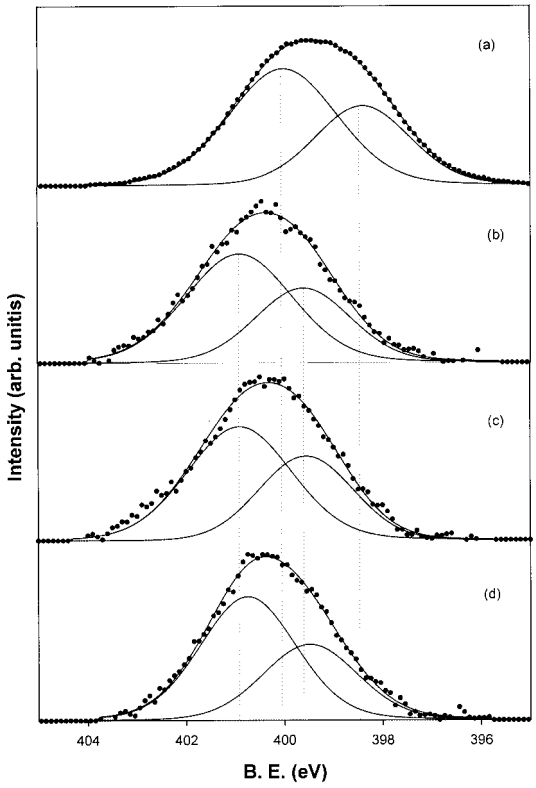

Figure 7. N_{1s} XPS spectra of (a) HL, (b) AC-HL, (c) AC-HL-Zn and (d) AC-HL-Cd.

HL is consistent with electron donation from the arene centres of the AC to the HL aromatic residue, which accompanies the adsorption process.

The anchorage of HL to the arene centres provides functionalisation of the AC with a potential tridentate *N,N,N* ligand that should enhance its capacity for the capture of metal ions. The shapes of the adsorption isotherms of $ZnCl_2$ and $CdCl_2$ on AC and AC-HL in aqueous solution, obtained at pH 5, show a significant improvement of the adsorption capacity relative to unfunctionalised AC, as shown in Figure 8. A pH of 5 was chosen as a compromise value to avoid the precipitation of metal hydroxides whilst ensuring the existence of a non-negligible amount of the partially or totally unprotonated polyamine function, which is available for metal ion–polyamine interaction, as deduced from the solution studies (see Figure 4).

Each of the final solutions obtained in the study of the adsorption of the metals on AC-HL was analysed by UV/visible spectroscopy to prove that no HL was desorbed. The XPS spectra of AC-HL-Zn^{II} and AC-HL-Cd samples, including the N_{1s} peaks, are similar to that of the non-metallated adsorbent, except for a new peak in the former due to the metals ($Zn_{2p3/2}$ at 1022 eV and $Cd_{3d5/2}$ at 406 eV). This indicates that the improvement in the adsorptivity on AC-HL relative to AC alone is due to the presence of HL on the carbon surface. Moreover, further evidence of interactions between the metal ions and HL was obtained by comparison of the IR spectra of the AC-HL adsorbent and AC-HL-metal solid phases, which show the appearance of new bands in the second cases at 488 cm^{-1} and 482 cm^{-1} for Zn^{II} and Cd^{II}, respectively, which are assignable to ν(M–N). In these spectra relatively strong bands assignable to ν(M–O) (at around 420 cm^{-1} in both cases) due to metal atoms bonded to the oxygen functional groups of the AC also appear.[18] These bands were assigned previously by comparing the IR spectrum of an AC sample with those of the AC-Zn and AC-Cd solid phases obtained from the adsorption experiments carried out to obtain the corresponding isotherms.

Both isotherms in Figure 8 fit the Langmuir equation. This allowed us to calculate the maximum adsorption capacity values of 0.042 and 0.097 mmol g^{-1} for AC and AC-HL adsorbents, respectively, in the case of Zn^{II}, and 0.040 and 0.143 mmol g^{-1} for AC and AC-HL in the case of Cd^{II}. These values show that binding of HL to AC enhances the adsorption capacity of AC by a factor of 2.5 in the case of Zn^{II} and 3.5 for Cd^{II}. Nevertheless, these results disagree with the relative values found for the association constants of HL with Zn^{II} and Cd^{II} (see above), which suggest a

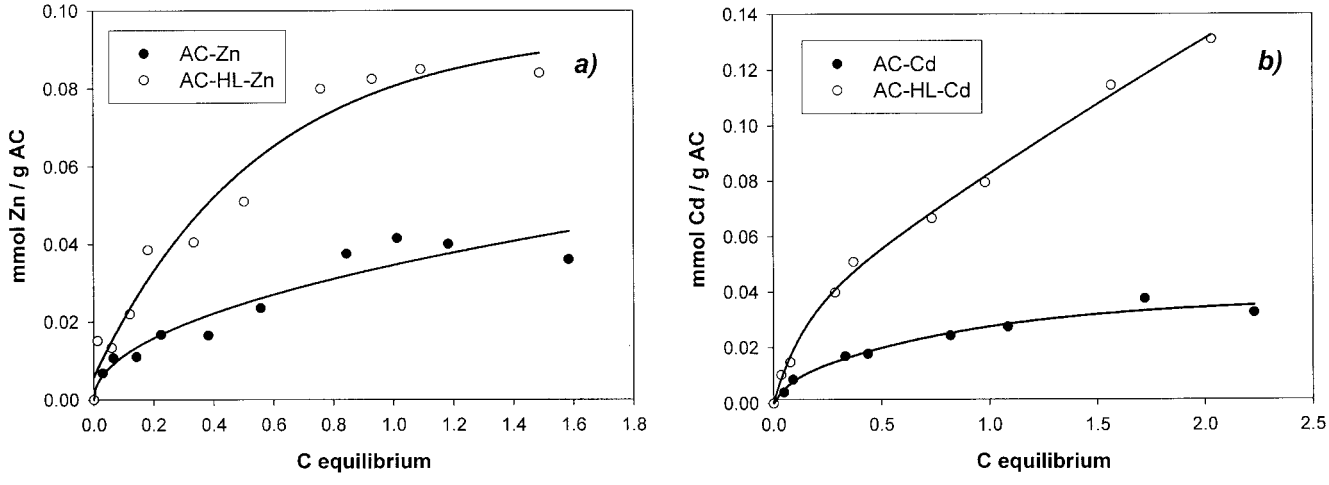

Figure 8. Adsorption isotherms of (a) Zn^{II} and (b) Cd^{II}.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

higher affinity of the triamine function for Zn^{II} than for Cd^{II}. This finding can be explained by assuming that the metals can be adsorbed either as single metal ions, when the triamine is unprotonated, or as MCl_4^{2-} when the triamine group is doubly protonated.

Considering these aspects, the two adsorption mechanisms in the case of Cd^{II} are plausible due to a non-negligible co-existence of $CdCl_4^{2-}$ and Cd^{2+} species in the medium, (log K = 6.63 for $CdCl_4^{2-}$) at the Cl^- concentrations used in the adsorption experiments. On the contrary, in the case of Zn^{2+} only the adsorption of the single metal ion on the unprotonated triamine is expected due to the lack of the more labile $ZnCl_4^{2-}$ species (log K = –0.18).[19] These findings agree with the isolation of the tetraiodocadmiate salt of the doubly protonated ligand from HL/Cd^{II} mixtures at pH 6, and the binuclear Zn^{II} complex of neutral HL from HL/Zn^{II} mixtures at the same pH. These are in accordance with the softer Lewis acid character of Cd^{II} than Zn^{II}.

Some of the chemical pollutants existing in the environment, such as arsenate, phosphate, sulfate, pertechnate, chromate, etc., are water-soluble tetrahedral anionic species. Thus, the above results suggest a possible interest in wastewater detoxification for this class of anions. In fact, the assembling of tetrahedral anions with polyamine receptors has been described in some recent monographs.[20] With this in mind, the observed affinity of the AC-HL adsorbent containing a triamine as available functional group to $CdCl_4^{2-}$ anion is not surprising and suggests the usefulness of the model compound described in this work as a host for tetrahedral anions. It has been suggested[21a] that the specificity of a polyamine receptor to a tetrahedral anion would be determined by the binding affinity, i.e. the nature of the ion-pair interaction. In the case of some macrocyclic polyamines, the strong binding of polyphosphates was found to be due to the existence of both electrostatic and hydrogen-bonding interactions.

The adsorption of a CrO_4^{2-} solution at pH 7 by the AC-HL receptor has been studied by us previously.[4] In that study, the IR spectra of a $[CrO_4]^{2-}[H_3L]^{2+}$ solid compound isolated from aqueous solution prove the existence of strong hydrogen-bonding interactions in the formation of the ion pair. These hydrogen-bonding interactions are likely responsible for the high maximum adsorption capacity of the adsorbent found (up to 0.14 mmol of CrO_4^{2-} per gram of carbon).

These results, together with other previous ones, highlight the versatile behaviour of HL-type receptors anchored on activated carbons, which makes them useful for the capture of both single metal ions and tetrahedral anions. They also encourage further studies with other single and tetrahedral ions for a better comprehension of the factors (topological, chemical, ...) that control the chemical affinity between the model receptor developed and the ions.

Conclusions

HL is characterised by a polarized aromatic moiety and a polyamine function linked by a soft bis-methylene spacer. The compound behaves as bifunctional ligand for Zn^{2+} and Cd^{2+} metal ions in aqueous solution. At low pH values it forms mononuclear complexes with these ions, which are coordinated through the C(5)NO-C(6)O grouping, and acts as a bidentate chelating ligand. The availability of the polyamine function for complex formation with metal ions occurs at slightly acidic pH values and depends on the polarizing character of the metal ion. This is reflected in the fact that the formation of bi- and mononuclear complexes with a metal ion linked through the polyamine moiety takes place at lower pH values with Zn^{2+} than with Cd^{2+} ion. In these complexes, the *N*,*N*,*N* coordinated triamine gives rise to stable metal–amine bonds.

HL is anchored on AC with the pyrimidine ring flat to the arene centres. This process, which is irreversible in water, seems to be due to π–π donor–acceptor interactions between the two aromatic moieties. Moreover, it is favoured by the electron-withdrawing character of the C(5)NO substituent of the pyrimidine moiety of HL. HL adsorption provides functionalisation of the arene centres with NH_2–$(CH_2)_2$–NH–$(CH_2)_2$ functions and this explains the improvement of the capacity of the AC for the adsorption of Zn^{2+} and Cd^{2+} metal ions. Moreover, in the case of Cd^{II}, the amphoteric character of the polyamine function allows it to adsorb Cd^{2+} and $[CdCl_4]^{2-}$ ions. All these results suggest the feasibility of the model proposed for specific functionalisation of the AC based on the topological and electronic properties of HL-type ligands. All these results have been discussed in the light of the coordination chemistry of the polyamine groups existing at the AC modified surface, which highlights the relevance of the solution and crystallographic data obtained in the coordination chemistry study of the ligand.

Experimental Section

Synthesis of 4-Amino-2-methoxy-1-methyl-5-nitroso-6-oxo-1,6-dihydropyrimidine (1): Compound **1**, which is a precursor of the ligand HL, was obtained by a previously reported method.[21]

***N*-(4-Amino-1-methyl-5-nitroso-6-oxo-1,6-dihydropyrimidin-2-yl)-*N*′-[bis(2-aminoethyl)]ethylenediamine Dihydrochloride (HL·2HCl; 2):** A solution of monohydrated **1** (5.5 g, 27.2 mmol) in CH_3CN (100 mL) was added slowly to a refluxing and stirred solution of tris(2-aminoethyl)amine dihydrochloride (6.5 g, 29.7 mmol). After the addition, the solution was refluxed for an additional 2 h, after which time a pink powdery solid appeared. The suspension was then filtered. The solid was washed with ethanol and diethyl ether and used without further purification. Yield: 9.5 g (90%). $C_{11}H_{24}Cl_2N_8O_2{\cdot}1/2H_2O$ (380.01): calcd. C 34.73, H 6.58, N 29.47; found C 34.68, H 6.46, N 29.43. ^{1}H-^{15}N HMBC ([D$_6$]DMSO): δ = 25, 68, 103, 137 ppm. ^{1}H NMR ([D$_6$]DMSO): δ = 2.67 (t, 2 H), 2.71 (t, 4 H), 2.91 (t, 4 H), 3.39 (s, 3 H), 3.53 (t, 2 H) ppm. ^{13}C NMR ([D$_6$]DMSO): δ = 27.8, 36.8, 40.2, 51.1, 52.5, 142.0, 149.8, 154.5, 161.6 ppm.

$[ZnCl_4]_2[Zn_2(HL)_2]{\cdot}2.5H_2O$ (3): A water solution (10 mL) of $ZnCl_2$ (90 mg, 0.66 mmol) was added, whilst stirring, to a solution of **2** (190 mg, 0.5 mmol) in water (10 mL). The pH of the resulting mix-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ture was adjusted to 6 by adding 2 N KOH. Orange crystals of **3** suitable for X-ray analysis were obtained by slow evaporation of this solution. $C_{11}H_{24.5}Cl_4N_8O_{3.25}Zn_2$ (593.08): calcd. C 22.25, H 4.13, N 18.88; found C 21.76, H 4.67, N 18.42.

$[H_3L][CdI_4]\cdot 2H_2O$ (4): An aqueous solution (10 mL) of $CdCl_2\cdot 2.5H_2O$ (0.15 g, 0.66 mmol) was added to a solution of **2** (0.19 g, 0.5 mmol) and NaI (0.15 g, 1 mmol) in water (30 mL). The pH was then adjusted at 6 by adding 2 N KOH. Orange crystals of **4** were obtained by slow evaporation of the solution. $C_{11}H_{28}CdI_4N_8O_4$ (956.01): calcd. C 13.81, H 2.93, N 11.72; found C 14.60, H 2.99, N 12.35.

Potentiometric Measurements: The potentiometric titrations were carried out at 298.1 ± 0.1 K in 0.1 M KCl with a 713 Metrohm pH-mV meter, equipped with a combined glass electrode and connected to a Metrohm 765 Dosimat autoburette (1 ± 0.001 mL). The experimental procedure used was the same as that described elsewhere.[22] The system was calibrated as a hydrogen concentration probe by titrating known amounts of HCl with CO_2-free KOH solutions and determining the equivalent point by Gran's method,[23] which allows the determination of the standard potential, E^0, and the ionic product of water (pK_w = 13.76 in 0.1 M KCl at 298.1 ± 0.1 K). Ligand concentrations of $1–1.5\times10^{-3}$ M and 1:1 ligand-to-metal molar ratios were employed in the potentiometric measurements. At least four titration experiments (about 150 data points for each one) were performed in the pH ranges 2.5–10. The computer program HYPERQUAD[24] was used to calculate equilibrium constants from emf data.

Spectrophotometric Measurements: Absorption spectra of HL solutions were recorded with a Perkin–Elmer Lambda 19 spectrophotometer. HCl and KOH were used to adjust the pH values, which were measured with a Crison 2002 micropH meter.

X-ray Crystallography: Suitable crystals of **3** and **4** were obtained as orange plates and orange rods, respectively. The intensity data were collected at 153 K (–120 °C) on a Stoe Mark II-Image Plate Diffraction System[25] equipped with a two-circle goniometer and using graphite-monochromated Mo-K_α radiation. The structures were solved by direct methods using the programme SHELXS-97.[26] The refinement and all further calculations were carried out using SHELXL-97.[27] In the case of compound **4** the H-atoms were either located from Fourier difference maps and refined isotropically or included in calculated positions and treated as riding atoms using the SHELXL default parameters. For compound **3**, the majority of the H-atoms were located from Fourier difference maps and refined isotropically. The water H-atoms were located from difference maps but then either refined isotropically or constrained to be 0.83(1) Å and U_{iso} = 1.5·U_{eq}(O-atom) Å^2. The non-H atoms were refined anisotropically by weighted full-matrix least-squares procedures on F^2.

CCDC-259715 (for **3**) and -259716 (for **4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

NMR Spectroscopy: ^{1}H (300.13 MHz), ^{13}C (75.48 MHz) and two dimensional spectra in [D_6]DMSO and in D_2O solutions at different pH values were recorded at 300 K with a Bruker DPX300 spectrometer. The pD values of HL and HL–metal ion solutions were adjusted by adding small amounts of NaOD and DCl solutions. The pH was calculated from the measured pD values using the relationship pH = pD – 0.40.[28]

XPS and IR Data: XPS measurements were performed with an Escalab 200R system (VG Scientific Co.) equipped with an Mg-K_α X-ray source ($h\nu$ = 1253.6 eV) and hemispherical electron analyzer. Prior to the analysis, the samples were pretreated in situ at 623 K for 6 h in He, dry air, or wet air. The IR spectra of AC, AC-metal, AC-HL and AC-HL-metal solid samples, were obtained from KBr pellets of the samples in the 650–400 cm^{-1} range with a Bruker Tensor 27 TGA-IR spectrometer

Adsorption of Zn^{2+} and Cd^{2+}: Adsorption experiments of Zn^{2+} and Cd^{2+} ions on an activated carbon (Merck K24504014; AC) and AC-HL as adsorbent materials, respectively, at pH 5, were carried out. Typically, amounts of 0.0500 g of the adsorbent were added to a 100-mL plastic flask containing 50 mL of the appropriate aqueous solution of the adsorbate ($ZnCl_2$ or $CdCl_2$ salts). For the adsorption experiments of the metals on AC-HL, the adsorbent was obtained from a previous experiment consisting of the adsorption of an HL solution on the AC, at pH 5, by fixing conditions at which the overall HL was irreversibly adsorbed (100 ppm of HL in 100 mL of water and 0.500 g AC[4]). The pH was adjusted in each of the experiments with KOH or HCl. The suspensions were shaken at 25 ± 0.1 °C for two days until equilibrium was reached. After the adsorption experiments, the adsorbents were carefully filtered and the residual metal concentration in the solutions was measured by ICP mass spectroscopy with an AGILENT 7500 Series (Shield Torch System).

Synthesis, Crystal Structure and Characterisation of a Novel Chiral Mixed-Valence Vanadium Oxide Hybrid, $[V_5O_{11}(dien)_3]$

Ming-Lai Fu,[a,b] Guo-Cong Guo,*[a] A-Qing Wu,[a] Bin Liu,[a] Li-Zhen Cai,[a] and Jin-Shun Huang[a]

Keywords: Chirality / dien ligand / Magnetism / Mixed-valence compounds / Vanadium

The novel chiral mixed-valence vanadium oxide hybrid $[V_5O_{11}(dien)_3]$ (**1**) (dien = $NH_2C_2H_4NHC_2H_4NH_2$) has been synthesised by a hydrothermal reaction of V_2O_5 and dien in aqueous solution and characterised by elemental analysis, IR spectroscopy, TG-DSC analysis, magnetism, EPR spectroscopy, single-crystal X-ray diffraction and powder XRD. The X-ray diffraction analysis revealed that the structure of **1** can be regarded as being constructed from two $[V^{V}O_4]^{3-}$ groups bicapping three $[V^{IV}O(dien)]^{2+}$ units to form a discrete asymmetric pentanuclear vanadium complex with the dien ligands coordinating directly to the vanadium(IV) centres. Compound **1** exhibits an interesting tube-like 3D supramolecular structure due to abundant hydrogen-bonding interactions between the oxygen atoms of the inorganic backbone and the hydrogen atoms of the dien ligands from adjacent molecules. The variable-temperature magnetic susceptibility data of **1** suggest a weak ferromagnetic interaction among V^{4+} ions in the cluster.

Introduction

Increasing attention has been paid to inorganic oxides due to their structural diversity and applications in the fields of catalysis, sorption, electrical conductivity, magnetism and photochemistry[1] and the synthesis of new materials possessing unique structures and properties based on inorganic oxides remains a challenge. The role of organic components on the structural modification of inorganic oxides has been well recognised in recent years.[2] Generally, the organic components act as structural directors to tune inorganic frameworks, compensate charges and fill space. On the other hand, they may also function as ligands coordinated directly to the oxide scaffolding or to the secondary metal centres.[3] Recently, the introduction of the hydrothermal technique and the use of organic structure-directing agents has led to the production of various vanadium oxide discrete clusters with 1D, 2D and 3D structures.[4] A large family of inorganic-organic hybrids based on the vanadium oxides has been investigated using organic amines as organic components in which the amines are usually protonated and intercalated between the anionic vanadium oxide layers.[5] However, the investigations of amines as ligands coordinated directly to vanadium centres has been limited.[6] We are interested in introducing transition metal–amine complexes into the inorganic framework and understanding the role of metal complexes on the modification of inorganic framework structures.[7] Herein, we report a novel chiral mixed-valence vanadium oxide, $[V_5O_{11}(dien)_3]$ (**1**), with the achiral tridentate dien ligands coordinated directly to the vanadium(IV) centres.

Results and Discussion

The title hybrid was prepared from V_2O_5 (0.182 g, 1 mmol), dien (4 mL) and H_2O (6 mL) under hydrothermal conditions in a 25-mL capacity Teflon-lined steel autoclave at 160 °C for 6 d. The dien in the reaction acts not only as an agent for reducing V^{5+} to V^{4+} but also as a ligand coordinated to V^{4+}. Furthermore, it is an organic base to adjust the pH value of the aqueous solution in order to maintain strongly basic conditions during the whole synthesis which plays a significant role in the formation of **1**. Detailed experiments suggest that excess dien is necessary to yield **1** using V_2O_5 as a starting material and it failed to form if the amount of dien was less than 3.5 mL or if NH_4VO_3 was used as a staring material instead (Table S1; see supporting information, for supporting information see also the footnote on the first page of this article).

A single-crystal X-ray analysis reveals that **1** consists of a chiral mixed-valence vanadium oxide hybrid $[V_5O_{11}(dien)_3]$ (Figure 1). The asymmetric pentanuclear vanadium cluster exhibits two types of vanadium coordination envi-

ronments in which the V(4) and V(5) atoms are in distorted VO_4 tetrahedra and the V(1), V(2) and V(3) atoms exhibit distorted VO_3N_3 octahedral geometries. In the VO_4 tetrahedron, the vanadium centre is coordinated by three bridging oxygen atoms (O_b) and one terminal oxygen atom (O_t). The V–O_b bond lengths are in the range of 1.708(1)–1.743(1) Å, the V–O_t bond lengths are 1.658(2) and 1.662(2) Å and the O–V–O bond angles range from 107.9(1) to 113.0(1)°. In the VO_3N_3 octahedron, each V atom is chelated by one dien ligand in a tridentate manner and in a facial configuration with the V–N bond lengths ranging from 2.137(2) to 2.339(2) Å and coordinated by one O_t atom and two O_b atoms from two VO_4 tetrahedra. The V–O_b bond lengths range from 1.925(1) to 1.966(1) Å and the V–O_t bond lengths are in the range of 1.611(2)–1.621(2) Å thereby form a distorted octahedron with a π configuration[8] in which the three dien ligands coordinated to V1, V2 and V3 exhibit *δδ*, *λλ* and *δδ* conformations, respectively. The significantly distorted V octahedra are evident from the axial angles which range from 158.3(1) to 164.5(1)°. Bond-valence sum (BVS) calculations[9] [V(1) = 4.066, V(2) = 4.057, V(3) = 3.999, V(4) = 5.179, V(5) = 5.160] show that the V octahedra are occupied by V^{4+} ions and the V tetrahedra by V^{5+} ions which is consistent with the overall charge balance of the compound. Magnetic measurements support the BVS calculations for the valence assignment of V atoms (see below). The five vanadium atoms in the pentanuclear cluster can be described as a giant trigonal bipyramid with three V^{4+} atoms lying on the equatorial plane and two V^{5+} atoms occupying the axial positions in which two $[VO_4]^{3-}$ groups are bicapping the $[VO(dien)]^{2+}$ unit through corner-sharing their polyhedra (Figure S1). The present mixed-valence pentanuclear vanadium hybrid has been found for the first time in the neutral form, although mixed-valence pentanuclear vanadium compounds have been previously characterised as anions in $[Et_4N]_2[V_5O_9X(O_2CR)_4]$ salts (X = Cl^-, Br^-; R = Ph, CH_3).[10]

An interesting feature is that the space group of **1** is $P6_3$ which results in its chiral nature. In recent years, much effort has been devoted to the controlled construction of inorganic coordination compounds with enantiopure topologies, stimulated by their potential impact on important areas of research such as enantioselective catalysis and molecular recognition. Achiral molecules[11] as well as chiral species[12] can be used to synthesise chiral coordination compounds. However, the achiral approach almost always leads to a racemic mixture[13] and it is not well understood how homochiral packing in crystals can be induced.[14] Although the inorganic V_5O_{11} backbone and the dien ligand in **1** are achiral, the homochiral structure of **1** is induced by the different twist of the organic ligand chelating to the vanadium(IV) centres. The powder XRD pattern of **1** and the pattern simulated on the basis of the single-crystal structure are presented in Figure 2. The diffraction peaks in both patterns correspond well in their positions, indicating the phase purity of the prepared sample. In the IR spectrum of **1** (Figure S2, supporting information), the strong bands at 967, 867, 832, 735 and 675 cm^{-1} are due to the terminal V=O stretch and the V–O–V stretch. Bands in the 1107–1619 cm^{-1} region can be attributed to characteristic peaks of the dien ligand.

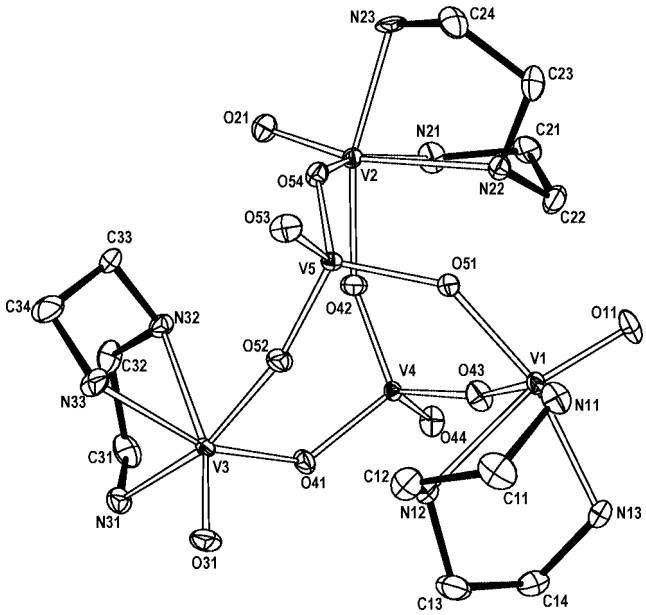

Figure 1. Molecular structure of **1** with 30% thermal ellipsoids. Hydrogen atoms are omitted for clarity.

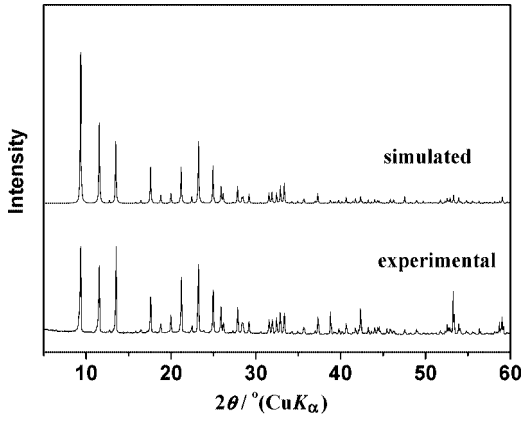

Figure 2. Experimental and simulated powder X-ray diffraction pattern of **1**.

As shown in Figure 3, the $[V_5O_{11}(dien)_3]$ molecules are stably packed together to exhibit an interesting tube-like 3D supramolecular array with 1D channels (about 2.4 Å in free diameter, Figure S3, supporting information) along the *c* direction by means of abundant hydrogen-bonding interactions between the oxygen atoms of vanadium oxides and the hydrogen atoms of dien ligands from adjacent molecules (Table 1; Figures S4 and S5, supporting information). It is of note that the hydrogen-bonding interactions play a significant role in the stabilisation of the structure of **1** which is consistent with the thermal analysis experiments. The TGA and DSC data, recorded from 30 to 1000 °C under flowing N_2, show that the weight of **1** is almost unchanged

from 30 to 260 °C (Figure S7). In the range of 260–400 °C the main weight loss occurs which is associated with two endothermic peaks and should be due to the loss of organic molecules. The endothermic peaks in this weight-loss stage imply that there exist strong coordination bonds between the V centre and the dien ligand and abundant hydrogen bonds in **1**. The observed weight loss (42.15%) is close to that which would result from losing three dien molecules per empirical formula unit (41.81%). The TGA chart shows that the next weight loss (7.99%) in the range of 400–800 °C may be due to the emission of oxygen to yield V_2O_3 as a residue (calcd. 7.57%).

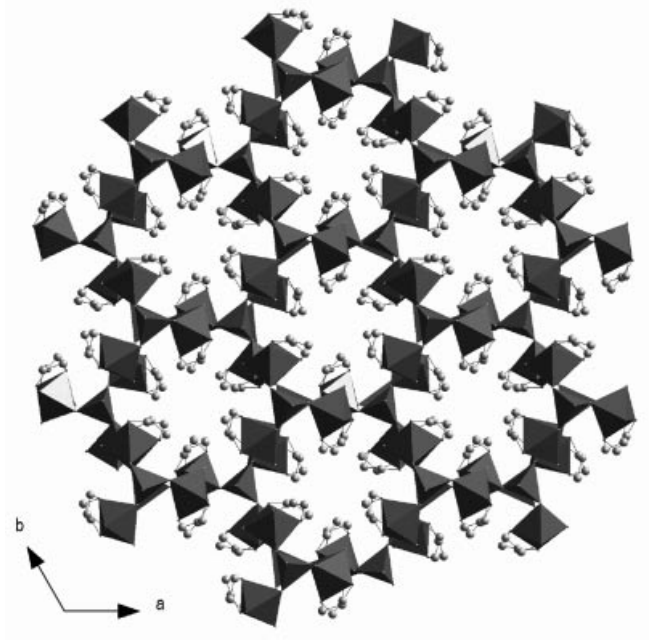

Figure 3. Polyhedral representation of **1** as a packed view along the *c* direction showing the tube-like structure.

The variable-temperature magnetic susceptibility data of **1** were recorded on a crystalline sample in a field of 1 T and in the 2–300 K temperature range as shown in Figure 4 in the χ_M and μ_{eff} vs. *T* plots. The data were fitted using the Curie-Weiss equation above 75 K: $\chi_M = C/(T - \theta) + \chi_0$, $\chi_0 = -3.6(1) \times 10^{-4}$ emu mol^{-1}, $C = 0.970(3)$ emuK mol^{-1} and $\theta = 1.6(2)$ K. The effective magnetic moment, calculated from the equation $\mu_{eff} = 2.828\ C^{1/2}$ is 2.8(2) μ_B which is close to the value of 3 μ_B for three independent unpaired electrons per formula unit. The slow increases in the μ_{eff} value with the decreasing temperature of **1** and a small positive θ clearly indicate the presence of weak ferromagnetic interactions among the V^{4+} ions in **1**. To simulate the experimental magnetic behaviour, we used the analytical experimental expression deduced for trinuclear magnetic metal atoms in compounds with classical spins.[15]

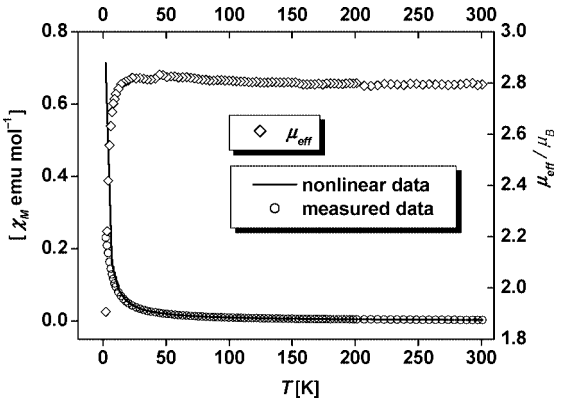

Figure 4. χ_M vs. *T* and μ_{eff} vs. *T* plots for **1**. The solid lines represent the nonlinear curve fit of the experimental data.

$$\chi_M = \frac{N\beta^2 g^2}{4kT} \frac{1 + 5\exp(3J/2kT)}{1 + \exp(3J/2kT)}$$

In this expression, *N* is Avogadro's number, β is Bohr's magneton and *k* is Boltzmann's constant. The best least-squares fit of the theoretical equation to experimental data leads to $g = 1.8570(6)$, $J/k = 3.3(1)$ K and the agreement factor $R = 1.02 \times 10^{-5}$ $\{R = \Sigma\ [(\chi_M T)_{obsd.} - (\chi_M T)_{calcd.}]^2 / \Sigma[(\chi_M T)_{obsd.}]^2\}$. The positive *J* value suggests that a weak ferromagnetic interaction exists in **1** which is in agreement with the result of the fit obtained from the Curie-Weiss law. Unlike the vast majority of known polynuclear vanadium(IV) or -(IV/V) compounds which exhibit antiferromagnetic coupling between V^{IV} magnetic ions,[16] the present chiral pentanuclear vanadium(IV/V) compound shows ferromagnetic behaviour. The EPR spectrum of **1** (Figure 5) at room temperature shows a V^{4+} signal with $g = 1.9543$ which is consistent with the value obtained from the fitting of the magnetic susceptibility data.

Conclusions

In conclusion, a novel chiral mixed-valence vanadium oxide hybrid, $[V_5O_{11}(dien)_3]$, in which the dien ligands are chelated to vanadium(IV) centres in a tridentate manner has been successfully synthesised by a hydrothermal process. This result shows that the chiral hybrid can be constructed from achiral starting materials which are induced by the different twist of the organic ligands chelating to the vanadium(IV) centres. The material exhibits an interesting tube-like channel structure resulting from abundant intermolecular hydrogen bonding interactions and shows weak ferromagnetic interactions.

Experimental Section

General Remarks: All reagents were purchased from commercial sources and used without further purification. Elemental analyses (C, H, N and O) were performed with an Elementar Vario EL III microanalyser. The infrared spectrum was recorded as a KBr pellet in the range of 4000–400 cm^{-1} with a Nicolet FTIR Magna 750 spectrophotometer. The powder X-ray diffraction pattern was collected with a Rigaku DMAX2500 diffractometer at 40 kV and 100 mA for Cu-K_α (λ = 1.5406 Å), with a scan speed of 5° min^{-1} at room temperature. The simulated pattern was produced using the Platon program and single-crystal reflection data. A Netzsch STA 449C thermogravimetric analyser was used to obtain TGA and DSC curves under N_2 with a temperature increment of 10 °C min^{-1} in the temperature range 30–1000 °C. An empty Al_2O_3 crucible was used as a reference.

$[V_5O_{11}(dien)_3]$ (1): Powdery V_2O_5 (0.182 g, 1 mmol) was added to a solution of dien (4 mL) in H_2O (6 mL). The mixture was stirred at room temperature for 1 h then transferred into a 25-mL teflon-lined stainless steel autoclave and heated at 160 °C under autogeneous pressure for 6 d. After cooling, the brown crystals obtained by filtration were washed with water and ethanol. Yield: 80% (based on V_2O_5). $C_{12}H_{39}N_9O_{11}V_5$ (740.2): calcd. C 19.47, H 5.31, N 17.03, O 23.78; found C 19.33, H 5.06, N 17.08, O 23.70.

X-ray Crystallographic Study: The single-crystal X-ray data for **1** were collected with a Rigaku Mercury CCD diffractometer with graphite-monochromated Mo-K_α radiation using the ω-scan technique at 293 K and CrystalClear[17] software was used for data reduction. The structure was solved by direct methods using the Siemens SHELXTL™ Version 5 crystallographic software package.[18] The difference Fourier maps based on these atomic positions yielded the other non-hydrogen atoms and the hydrogen atoms bound to nitrogen atoms. The structure was refined using a full-matrix least-squares refinement on F^2. All non-hydrogen atoms were refined anisotropically. The positions of hydrogen atoms bound to carbon atoms were generated symmetrically, allowed to ride on their respective parent atoms and included in the structure factor calculations with assigned isotropic thermal parameters but were not refined. Crystallographic data are summarised in Table 2 and selected bond lengths and angles are listed in Tables 3 and 4. CCDC-260926 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Supporting Information (see also footnote on the first page of this article): Details of the compositions of reactants for the preparation of **1**, DSC and TG curves, IR spectra and crystal structural diagrams indicating hydrogen bonds.

Novel Analogues of 5-Fluorouracil – Synthesis, X-ray Crystallography, and Cytotoxic Effects in Normal Human Peripheral Blood Lymphocytes and Colon Adenocarcinoma HT 29

Ksenia Matlawska,*[a] Urszula Kalinowska,[b] Andrea Erxleben,[c] Regina Osiecka,[a] and Justyn Ochocki[b]

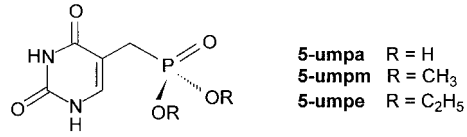
Keywords: Alkali metals / Phosphonate ligands / X-ray diffraction / Antitumor agents / Uracil derivatives

The aim of many studies is to discover new chemicals as potential antitumor agents. We have prepared novel analogues of 5-fluorouracil (5-Fu): 5-uracilmethylphosphonic acid (5-umpa), dimethyl 5-uracilmethylphosphonate (5-umpm), diethyl 5-uracilmethylphosphonate (5-umpe) and a K^+ (K^+/5-umpa, **1**) and Na^+ (Na^+/5-umpa, **2**) complex of 5-umpa. Complexes **1** and **2** have infinite chain structures built up by H-bonded pairs of 5-umpa$^-$ and $\{(H_2O)K(\mu\text{-}OH_2)_3K(OH_2)\}^{2+}$ and $\{(H_2O)_2Na(\mu\text{-}OH_2)_2Na(OH_2)_2\}^{2+}$ entities. The alkali metal ions bind directly to the exocyclic oxygen atoms O(2) and O(4) of the nucleobase moiety and indirectly, i.e. through hydrogen-bond interactions involving metal-coordinated water molecules, to the phosphonate group. The new derivatives were tested for their antiproliferative and cytotoxic effects on normal human peripheral blood lymphocytes and HT 29 cancer lines in vitro using the tetrazolium salt (MTT) assay. The IC_{50} values were evaluated (the drug concentration inhibiting 50 % of the cell growth after 72 h exposure of cells to the drug). The results indicate that 5-umpa, 5-umpm, 5-umpe, and the K^+ and Na^+ complexes of 5-umpa do not exert toxic effects on regular lymphocytes and on the colon adenocarcinoma HT 29 cell line ($IC_{50} > 1$ mM), in comparison with 5-Fu. However, an atypical course of survival curves was observed after treatment of HT 29 cells with 5-umpa, 5-umpm and the Na^+ complex of 5-umpa. These observations suggest that it is very important to continue the studies in different biological systems in vitro and in vivo using various experimental protocols.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

For many years 5-fluorouracil (5-Fu) has been widely used in cancer chemotherapy, especially in the treatment of colorectal, liver, ovarian, head and neck, and lung and breast carcinomas.[1–4] This fluorinated analogue of the natural pyrimidine base uracil can be used alone in monotherapy or in combination with other cytotoxic drugs (e.g. methotrexate, cisplatin) or with agents that are themselves not toxic but that modulate antitumor activity of 5-Fu (e.g. leucovorin).[3,5–10] Unfortunately, clinical application of this drug is limited by many undesirable effects, such as myelosuppresion (leucopenia, thrombocytopenia), gastrointestinal symptoms (nausea, vomiting, stomatitis, diarrhea), neurotoxicity (ataxia of trunk or extremities, unsteady gait, slurred speech, nystagmus), cardiotoxicity, and hyperpigmentation of skin.[1] Due to this scientists continually search for new less toxic and more effective compounds.

We have discovered novel phosphonate derivatives of uracil: 5-umpa (5-uracilmethylphosphonic acid), 5-umpm (dimethyl 5-uracilmethylphosphonate), 5-umpe (diethyl 5-uracilmethylphosphonate), and a K^+ and Na^+ complex of 5-umpa (Scheme 1).[11]



Scheme 1. Schematic structures of the uracil phosphonate derivatives.

Recently, the first three compounds 5-umpa, 5-umpm, and 5-umpe have been shown to prolong the survival time of mice with lymphoid leukemia 1210 when used in combination with cisplatin and as individual agents.[12] These findings prompted studies on the complexing properties with respect to platinum[13] and biologically relevant metal ions.[14,15]

The spectroscopic investigation and X-ray structure determination of 5-umpa, 5-umpm, and 5-umpe were described previously.[11,16] Solution studies on complex formation between the uracil derivative 5-umpa and alkaline earth metal ions have been reported recently and showed that Ca^{2+} and Mg^{2+} interacted directly with the phosphonate oxygen atom, while the neutral nucleobase residue did not participate in complex formation.[15] In the present study, two complexes of 5-umpa with Na^+ and K^+ ions are described. Coordination of alkali metal ions to nucleobase derivatives having negatively charged phosphonate groups also has some relevance to the interaction of alkali metal ions with nucleic acids in biological systems. Due to their function as counterions for the charge neutralization of the sugar-phosphate backbone of DNA and RNA, alkali metal ions are essential for the stability of nucleic acids. In principle, they can interact with nucleic acids through direct coordination or through hydrogen bonding through aqua ligands; the potential binding sites are the negatively charged phosphate groups and the nucleobase donor atoms, in particular, exocyclic carbonyl oxygen atoms. Recently, direct binding of Na^+ ions in the minor groove of DNA, e.g. to N(3) of adenine, O(2) of thymine or cytosine, has been proposed on the basis of high-resolution X-ray analyses of B-DNA fragments.[17] Furthermore, coordination of Na^+ and K^+ to the exocyclic oxygen atoms of nucleobases, such as O(6) of guanine and O(4) of thymine or uracil, has been found to be crucial for the formation of multistranded nucleic acid arrangements, e.g. guanine, uracil or thymine quartets.[18–22] Several studies have been devoted to the preparation of models for alkali-metal-ion–nucleic-acid interactions. These mostly involve the use of neutral model nucleobases that lack phosphate groups as alternative binding sites for the alkali metal ions.[14,15,23–25] Although 5-umpa differs from the natural uracil nucleotide, it can nevertheless give some further insight into the coordination mode in complexes of alkali metal ions and nucleic acids.

Here we report on the solid-state structures of $[\{K(H_2O)(\mu\text{-}OH_2)_{1.5}\}_2(5\text{-umpa}^-)_2]_n$ (**1**) and $[\{Na(H_2O)_2(\mu\text{-}OH_2)\}_2(5\text{-umpa}^-)_2]_n$ (**2**), where Na^+ and K^+ bind directly to the exocyclic oxygen atoms O(2) and O(4) of the nucleobase part and interact indirectly, i.e. through hydrogen-bond interactions involving metal-coordinated water molecules, with the phosphonate group.

The first step in estimating biological activity of new chemical compounds is to study their cytotoxicity in vitro. In view of this, we used the ability of viable cells to convert the yellow dye MTT [3-(4,5-dimethylthiazol-2-yl)-2,5-diphentyltetrazolium bromide] to purple crystals of formazan by mitochondrial dehydrogenases.[26]

Results and Discussion

X-ray suitable crystals of the potassium and sodium complexes of 5-umpa were obtained from aqueous solutions of 5-umpa upon adjusting the pH to 8.9 with KOH or NaOH. Single-crystal X-ray analysis (Table 5) of the potassium complex **1** reveals an infinite chain structure built up by H-bonded pairs of 5-umpa$^-$ and $\{(H_2O)K(\mu\text{-}OH_2)_3\text{-}K(OH_2)\}^{2+}$ entities, in which two K^+ ions are triply bridged by water molecules (Figure 1 and Table 1, Scheme 2).

The phosphonate group of the uracil derivative is monodeprotonated as expected on the basis of the pK_a value of 5-umpa (7.15 ± 0.01) and as evident from the P–O bond lengths.[15] Two P–O bonds [P(1)–O(5) and P(1)–O(6)] are of equal length within the standard deviations [1.499(2) and 1.506(2) Å], and these bond lengths are slightly longer than those found for P=O double bonds (1.449–1.489 Å).[30] The P(1)–O(7) bond of 1.576(2) Å is significantly longer and compares well with the average bond length of a P–O single bond, so that the proton can be assumed to be bound to

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

O(7).[30] This interpretation is also consistent with the H-bonding pattern described below. Direct binding of K^+ ions to the nucleobase moiety through the exocyclic carbonyl oxygen atoms O(2) and O(4), as well as hydrogen bonding between K^+-bound water and the phosphonate group is observed. Each K^+ is coordinated in a distorted octahedral manner to four water molecules, three of which form bridges to the neighboring K^+ ion, and two carbonyl oxygen atoms; the latter are *cis* to each other. The pairs of 5-umpa$^-$ ligands are connected through direct interaction with K^+ and through two H-bonds of normal length that involve N(3) and O(4) [O(4)···N(3) 2.864(4) Å, –1/2 – *x*, –1/2 – *y*, 1 – *z*]. The H-bonded umpa$^-$ ligands that are located around a twofold axis of symmetry are exactly coplanar. Bond lengths and angles in the uracil ring show no unusual features for this heterocyclic system. Additional H bonding occurs through the bridging water ligands O(2w) and O(3w) and the phosphonate oxygen atoms O(5) and O(6); the O(2w)···O(5) and O(3w)···O(6) distances are 2.707(3) and 2.931(3) Å, respectively. These intrastrand hydrogen-bond formations give rise to eight-membered macrochelates, as indicated in Figure 1. Besides the intrastrand interactions, interstrand H bonding, i.e. between neighboring chains, through the terminal and bridging aqua ligands is observed. This involves phosphonate groups as well as exocyclic carbonyl oxygen atoms [O(2)] (Table 2). Thus, extensive hydrogen bonding is realized in the crystal packing. The shortest H-bond [2.614(3) Å] is formed between two mono-deprotonated phosphonate groups of adjacent chains [O(5)···O(7), –*x*, –*y*, 1 – *z*].

Table 2. Hydrogen-bonding interactions [Å] in **1**.

O(2w)···O(5)[a]	2.707(3)	O(3w)···O(6)[a]	2.931(3)
O(4)···N(3)[b]	2.864(4)	O(1w)···O(2)[c]	2.819(3)
O(1w)···N(1)[d]	2.833(3)	O(2w)···O(6)[e]	2.826(3)
O(1w)···O(6)[f]	2.823(4)	O(5)···O(7)[f]	2.614(3)

[a] –1/2 + *x*, –1/2 – *y*, –1/2 + *z*. [b] –1/2 – *x*, –1/2 – *y*, 1 – *z*. [c] –1/2 – *x*, –1/2 + *y*, 1/2 – *z*. [d] *x*, –1 + *y*, *z*. [e] –1/2 + *x*, 1/2 – *y*, –1/2 + *z*. [f] –*x*, –*y*, 1 – *z*.

The basic structure of the sodium complex of 5-umpa **2** is identical to that of **1**. Figure 2 shows a section of the infinite chain formed by pairs of 5-umpa$^-$ ligands connected through two N(3)···O(4) H-bonds and $\{(H_2O)_2Na(\mu\text{-}OH_2)_2Na(OH_2)_2\}^{2+}$ moieties. For the P–O bond lengths, the same trend is observed as in the case for **1** [P(1)=O(7) 1.507(2) Å, P(1)=O(5) 1.524(2) Å and P(1)–O(6)H 1.559(2) Å]. Again, the alkali metal ions bind directly to the exocyclic carbonyl oxygen atoms O(2) and O(4) and interact indirectly through aqua ligands with the phosphonate oxygen atoms (Table 1 and Table 3) leading to eight-membered macrochelates as shown in Figure 2 and Scheme 3.

However, in contrast to **1**, only one intramolecular hydrogen bond is formed between a terminal water ligand and O(6) of the phosphonate group [2.931(3) Å]. Interestingly, this H-bond involves the phosphonate oxygen atom that is likely to be protonated, considering the P(1)–O(6) bond length of 1.559(2) Å. Compared with the conformation of the phosphonate group observed in **1**, the phosphonate

Scheme 3. Formula diagram of **2**. H-bonding interactions are omitted for clarity.

group seems to be pointed away from the $\{(H_2O)_2Na(\mu\text{-}OH_2)_2Na(OH_2)_2\}^{2+}$ entity. This allows a short interstrand H-bond between O(7) and O(1w) at *x*, –1 + *y*, *z*. The differences in the H-bonding details (i.e. intra- versus interstrand) in **1** and **2** may be connected to the fact that the average K–O bond length (2.78 Å) in **1** is 0.35 Å longer than the average length of a Na–O bond in **2** (2.43 Å). Furthermore, the different number of bridging and terminal water ligands, as well as the presence of further uncoordinated, interstitial water molecules in **2**, lead to major differences in the crystal packing of **1** and **2**. In particular, the uncoordinated water molecule O(4w) generates an extended network of H-bonding interactions, as depicted in Figure 3. Adjacent chains are stacked along the *x* axis, however, the distance of approximately 5 Å rules out any significant stacking interactions between the uracil rings. The stacks are stabilized by hydrogen bonding between the bridging water ligand O(2w) and the carbonyl oxygen atom O(2) at 1 – *x*, 1 – *y*, 1 – *z*. Neighboring stacks are connected through hydrogen-bonding interactions between terminal O(1w) and the phosphonate group [O(1w)···O(7) 2.701(3) Å, *x*, –1 + *y*, *z*]. In addition, strong H-bonds with a length of 2.551(3) Å

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

are formed between adjacent mono-deprotonated phosphonate groups, these are even shorter than the analogous ones in **1**.

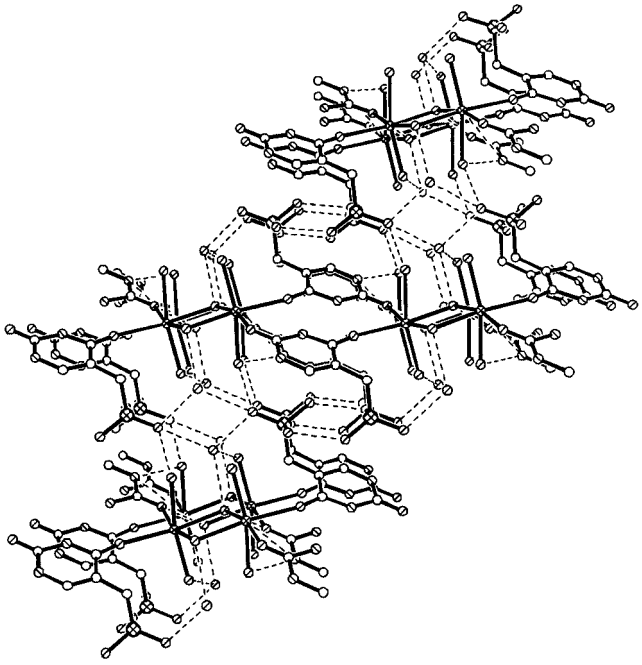

Figure 3. Hydrogen-bonding pattern in the crystal packing of **2**.

Recent solution studies have shown that the phosphonate oxygen atoms were the primary target for alkaline earth metal ions, while the uracil residue did not participate in complex formation when it was in its neutral form.[16] Likewise – although with some exceptions[31] – cocrystallization of Mg^{2+} with neutral nucleobases usually gives structures in which the $[Mg(H_2O)_6]^{2+}$ cation interacts indirectly through the aqua ligands with the nucleobase.[32] By contrast, the nucleobase residue seems to be the primary target of alkali metal ions as evident from the direct binding observed in **1** and **2**, and in other examples with neutral nucleobases.[25]

The observation of direct binding to the carbonyl oxygen atoms of uracil and indirect binding to the phosphonate oxygen atoms can be considered relevant to the interaction of alkali metal ions with natural nucleotides that contain nucleobase residues and negatively charged phosphate groups as alternative binding sites.

Survival curves for regular lymphocytes and HT 29 cells exposed to different concentrations of 5-Fu, 5-umpa, 5-umpm, 5-umpe, Na^+/5-umpa, K^+/5-umpa – and IC_{50} values calculated on grounds of the mathematical analysis of these curves– are presented in Figure 4A–4F (lymphocytes), Figure 5A–5F (HT 29), and in Table 4.

Data for 5-umpe and 5-umpm are not presented in Table 4 due to the fact that the concentrations used (1–10 mM) only caused the growth of the lymphocytes to slow down up to 85% (Figure 4C, Figure 4D). Likewise, in cells treated with Na^+/5-umpa, only the highest concentration caused an evident viability decrease to about 50%; however, this value was never exceeded (Figure 4E). Thus, it was impossible to establish IC_{50} from these survival curves.

The IC_{50} values for-5 Fu, 5-umpa, and K^+/5-umpa are 1.72 mM, 5 mM, and 4.15 mM, respectively, and their relation is as follows: 5-Fu < K^+/5-umpa < 5-umpa (Figure 4A, 4B, 4F).

The IC_{50} values are similar for K^+/5-umpa and 5-umpa, but they are nearly twice that obtained for 5-Fu. All IC_{50} values obtained after treatment of regular lymphocytes with 5-Fu and its novel analogues are higher than 1 mM, which suggests the almost lack of cytotoxic effects of these compounds – this is the most relevant and desired feature of every compound that is considered as a new tumor chemotherapeutic drug.[3,36]

However, the data given in Table 4 show that new analogues of 5-Fu also exhibited no activity in killing HT 29 tumor cells. Only model 5-Fu was very effective against HT 29 tumor cells; the IC_{50} factor was 2.9 μM.

In fact, we would like to point out that it is difficult to establish mutual relationships between the new 5-Fu analogues with respect to their effect on HT 29 tumor cells due to the atypical course of each survival curve. Therefore, it seems reasonable to separately analyze the effects exerted by each particular compound. As mentioned above, 5-Fu is very active against HT 29 tumor cells (Figure 5A). However, even small (0.5 μM) doses of 5-umpa and 5-umpm induced a rapid decrease in the viability of the HT 29 cells to 60–65%. A further increase in the dose slowly diminished the HT 29 cells viability, and finally IC_{50} was reached at 2.16 mM for 5-umpa and 1.58 mM for 5-umpm (Figure 5B, Figure 5C). It was impossible to establish IC_{50} for Na^+/5-umpa. The survival curve for this compound was very atypical. Low concentrations of Na^+/5-umpa, 0.2 μM and 1 μM, caused a rapid loss of the viability of the HT 29 tumor cells to 65% and 51%, respectively. A further dose increase did not affect the viability of the HT 29 cells, which was oscillating near 50% (Figure 5E). The survival curve for K^+/5-umpa was more typical, IC_{50} was 3.31 mM, whereas a dose of 1 μM diminished the viability to 75% (Figure 5F). Compound 5-umpe appeared to be ineffective against the HT 29 cells. Only at the highest concentration did the cell viability decrease to 55% (Figure 5D).

Anticancer chemotherapy usually involves the administration of various chemical compounds, which immediately kill, or take control of transformed cells. Unfortunately, the success of chemotherapy strongly depends on evoked, undesirable effects. The majority of currently used chemotherapeutics do not display particular anticancer specificity, and affect both tumor and nontumor tissues. Present in vitro and in vivo studies point out that many presently applied compounds exhibit mutagenic, teratogenic, and carcinogenic activity.[33]

Our study suggests that 5-Fu and its new analogues show insignificant cytotoxic effects on regular human peripheral blood lymphocytes. These findings might be of help in applying the drugs characterized below as potential anticancer compounds in chemotherapy. According to the cytotoxic and genotoxic studies of Tice et al.,[34] the compounds

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

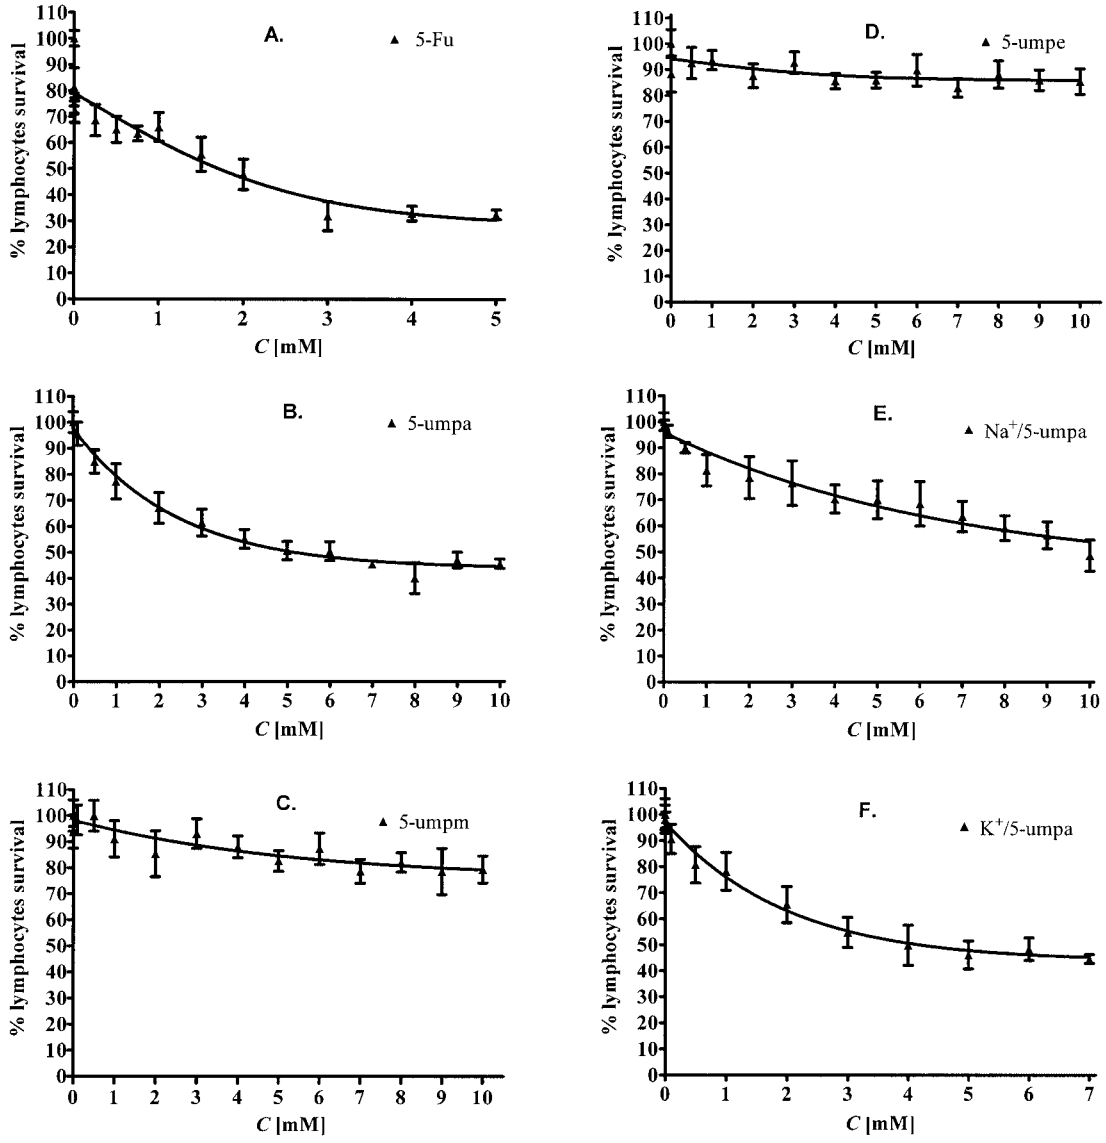

Figure 4. Dose-dependent growth inhibition curves for human peripheral blood lymphocytes after exposure to: 5-Fu **(A)**, 5-umpa **(B)**, 5-umpm **(C)**, 5-umpe **(D)**, Na^+/5-umpa **(E)**, K^+/5-umpa **(F)**. Lymphocytes were treated with various concentrations of the tested compounds for 72 h (37 °C, 5% CO_2). After incubation, the antiproliferative effects of these compounds were examined by MTT assay. These results represent the mean ± s.d. of three replicates from at least six separate experiments.

showing noticeable effects with a concentration of over 10 mM can be recognized as nontoxic; thus, we postulate that Na^+/5-umpa, 5-umpm and 5-umpe remain harmless for human lymphocytes.

The results obtained after exposure of HT 29 colorectal adenocarcinoma cell lines to new 5-Fu analogues seem to be interesting despite the fact that 5-Fu exerts the strongest aversive activity. These results are similar to those reported by Mader et al.[35] and Wiebke et al.[10]

IC_{50} was not assessed for each compound, however, we would like to point out that, in particular, after the treatment with 5-umpa, 5-umpm or Na^+/5-umpa, rapid loss of viability of the HT 29 cells was observed already after small doses of up to 1 μM. A further increase in the dose did not significantly affect the viability decrease. We cannot forget that DNA repair is an accomplice in cancer therapy resistance. It influences the chemosensitivity of tumor cells toward DNA-reactive cytotoxic drugs.[37] Probably, the effectiveness of the repair mechanisms in HT 29 cells strongly contributed to this phenomenon, and results in the limited tolerance to toxic activity of the applied compounds. However, these mechanisms were not fully successful, which may be in favor of the new 5-Fu analogues. It may be assumed that not only the dose but also the expose time should be taken into consideration in toxicity assessment of the new analogues of 5-Fu. Further studies are needed to confirm this hypothesis. In summary, the above results seem to be incredibly interesting because a question can be put forward: is the key element in searching for efficient chemotherapeutics the high toxicity of the compound examined

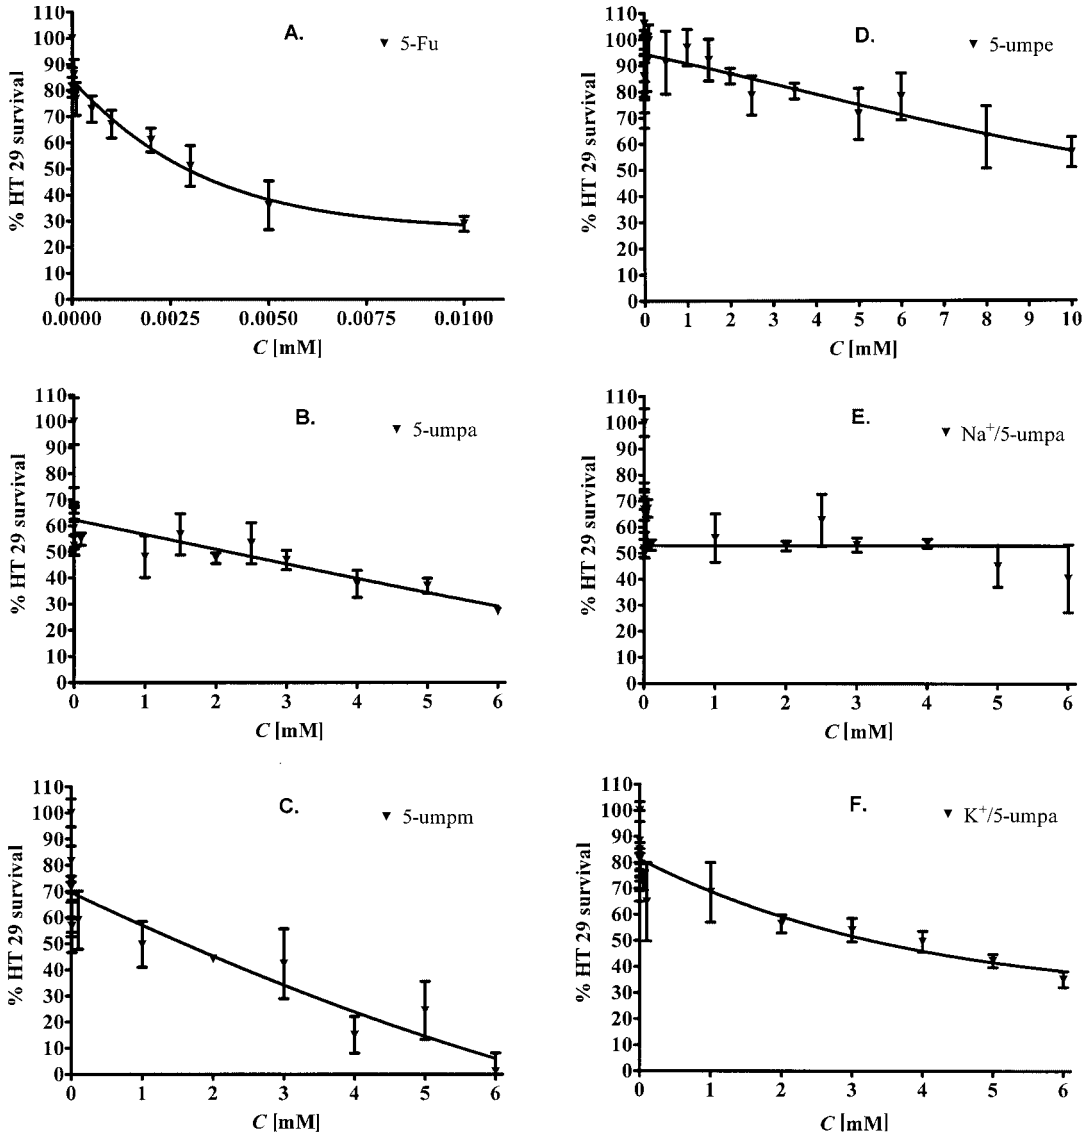

Figure 5. Dose-dependent growth inhibition curves for colon adenocarcinoma cell lines HT 29 after exposure to: 5-Fu **(A)**, 5-umpa **(B)**, 5-umpm **(C)**, 5-umpe **(D)**, Na^+/5-umpa **(E)**, K^+/5-umpa **(F)**. Treatment with various concentrations of the tested compounds for 72 h (37 °C, 5% CO_2). After incubation of HT 29 in 96-well plates, the antiproliferative effects of these compounds were examined by MTT assay. These results represent the mean ± s.d. of three replicates from at least six separate experiments.

Table 4. Cytotoxicity of 5-Fu and its new analogues in normal human peripheral blood lymphocytes and colon adenocarcinoma cells HT 29 in vitro after exposure for 72 h. IC_{50} values were established as drug concentrations that cause 50% inhibition of cell growth after 72 h incubation.

Drug	IC_{50}	
	Lymphocytes	HT 29
5-Fu	1.72 mM	0.0029 mM
5-umpa	5 mM	2.16 mM
5-umpm	–[a]	1.58 mM
5-umpe	–[a]	–[a]
Na^+/5-umpa	–[a]	–[b]

[a] Decrease in the viability of the cells to 80% for 5-umpm and 5-umpe, but to nearly 50% after exposure to the highest concentration of Na^+/5-umpa. [b] Rapid loss of cells viability at low concentrations (0.5–1 μM) to 50–65%, higher concentrations did not further decrease cell viability.

with respect to tumor cells, or the low toxicity towards healthy cells after application of small doses? We opt for the latter, especially, since it promotes searching for adjuvants that exhibit a synergistic effect in the efficient extermination of tumor cells.

Our results are of significance if the studies undertaken by Ochocki and Graczyk,[12] who investigated synergism of new analogues of 5-Fu and cisplatin in vivo in leukemia mouse 1210 (so-called "*platinum pyrimidine blues*"), are referred to. The authors demonstrated that 5-umpe did not exert any cytotoxic effect, whereas umpm, in conjunction with cisplatin, was very effective against L1210 leukemia cells. Our in vitro studies carried out recently confirmed the results of our antecedents with respect to 5-umpe; however, the same studies revealed a nontoxic character of 5-umpm and confirmed its efficiency in the elimination of tumor cells.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

5-umpa seems to deserve more attention. Its carcinotoxicity towards colorectal adenocarcinoma cells was observed already at low concentrations. In vivo studies demonstrated the lethal effect of this compound. It is strongly recommended that the synergism of 5-umpa with cisplatin is investigated, with the use of lower doses for more accurate cytotoxic and genotoxic assessment.

The lack of experimental data for Na^+/5-umpa and K^+/5-umpa results from the fact that these analogues have been prepared recently. Notwithstanding the fact that further studies have to be carried out, our first results demonstrate that these compounds, especially Na^+/5-umpa, display a certain ability to destroy HT 29 colorectal adenocarcinoma cells.

Conclusions

In conclusion, the results of our in vitro experiments conducted with the use of 5-umpa, Na^+/5-umpa, and 5-umpm are very interesting and provide evidence for their potential practical application as anticancer drugs. The results obtained are the basis for further studies to establish, for example, their mechanism of action, genotoxicity, and synergism with other drugs. The results will be useful for the selection of compounds that are the most effective chemotherapeutics whilst simultaneously exhibiting the lowest toxicity to healthy cells, and they can be used during the process of their registration as anticancer drugs. They may also indicate new approaches in searching for novel ways of synthesizing analogues for already existing drugs.

Experimental Section

General Remarks: The peripheral blood was obtained from the Blood Bank in Lodz, Poland, whereas the colon adenocarcinoma HT 29 cell line was purchased from the Centre of Oncology in Gliwice, Poland.

Compound 5-Fu was purchased from Sigma–Aldrich CO (St. Louis, MO, U.S.A). The new phosphonate derivatives: 5-umpa, 5-umpm, 5-umpe, or K^+/5-umpa and Na^+/5-umpa were obtained from the Department of Bioinorganic Chemistry, Medical University, Lodz, Poland.

5-uracilmethylphosphonic acid, dimethyl 5-uracilmethylphosphonate, and diethyl 5-uracilmethylphosphonate were prepared as described previously.[11] Infrared spectra of KBr pellets were measured with an ATI MATTSOM IFS FT spectrometer.

$K(C_5H_6N_2O_5P)(H_2O)_{2.5}$ (1): 5-umpa (103 mg, 0.5 mmol) was dissolved in water (20 mL) and adjusted to pH 8.9 with 1 N KOH. Slow evaporation of the solvent at room temperature gave colorless needles of **1** for X-ray analysis. Yield: 116 mg (90%). Drying of **1** in vacuo gave $K(C_5H_6N_2O_5P)\cdot(H_2O)_{0.75}$. Selected IR data: 3553 (br), 3070 (br), 2923 (br), 2847 (br), 1710 (vs), 1460 (br), (m), 1440 (m), 1327 (m), 1134 (m), 997 (m), 913 (s), 503 (s) cm^{-1}. $K(C_5H_6N_2O_5P)\cdot(H_2O)_{0.75}$: calcd. C 23.42, H 3.29, N 10.93; found C 23.31, H 2.93, N 10.87.

$Na(C_5H_6N_2O_5P)(H_2O)_4$ (2): 5-umpa (103 mg, 0.5 mmol) was dissolved in water (20 mL) and adjusted to pH 8.9 with 1 N NaOH. Slow evaporation of the solvent at room temperature gave colorless plates of 2. Yield: 108 mg (92%). Drying of **2** in vacuo gave $Na(C_5H_6N_2O_5P)\cdot(H_2O)_{0.33}$. Selected IR data: 3512 (br), 3060 (br), 2923 (br), 2852 (br), 1685 (vs), 1460 (br), (m), 1421 (m), 1245 (s), 1143 (m), 1022 (m), 908 (s), 517 (s) cm^{-1}. $Na(C_5H_6N_2O_5P)\cdot(H_2O)_{0.33}$: calcd. C 25.43, H 2.71, N 12.04; found C 25.66, H 2.87, N 11.97.

Fresh stock solutions of all compounds were prepared in water [Sigma–Aldrich CO (St. Louis, MO, U.S.A)] and were heated at 37 °C until the compounds dissolved. Before use, the stock solutions were cooled and diluted in a culture medium; they were then used to investigate the cytotoxicity effects in vitro.

PBS (phosphate buffered saline) MTT, SDS (lauryl sulfate), DMF (*N*,*N*-dimethylformamide), DMSO (dimethyl sulfoxide) were purchased from Sigma–Aldrich CO (St. Louis, MO, U.S.A). The culture medium for lymphocytes consisted of RPMI 1640 medium supplemented with 15% FBS (fetal bovine serum), 1% penicillin–streptomicin solution stabilized, 1% L-glutamine, and 1% PHA (phytohemagglutinin), whereas the culture medium for the HT 29 cell line contained of RPMI 1640 with Glutamax, 10% FBS, 1% penicillin–streptomicin solution stabilized, and 1% MEM non-essential amino acid solution. For trypsinization of adherent HT 29 cells, trypsin-EDTA was used. PHA, RPMI with Glutamax, FBS, and trypsin-EDTA were purchased from Gibco Laboratories Life Technologies, INC (Grand Island, New York, U.S.A.); the remaining reagents were purchased from Sigma–Aldrich CO (St. Louis, MO, U.S.A).

X-ray Crystallographic Study: Crystal data for compounds **1** and **2** were collected at room temperature with an Enraf–Nonius-KappaCCD diffractometer (KappaCCD package, Nonius, Delft, The Netherlands, 1997) using graphite-monochromated Mo-K_α radiation (λ = 0.71069 Å) (Table 5). For data reduction and cell refinement, the programs DENZO and SCALEPACK were used.[27] The structures were solved by direct methods and subsequent Fourier syntheses, and refined by full-matrix least-squares on F^2 with the SHELXTL PLUS and SHELXL-93 programs.[28] All non-hydrogen atoms were refined anisotropically. Carbon- and nitrogen-bound hydrogen atoms were placed at calculated positions and given isotropic thermal parameters equivalent to 1.2 times those of the atom to which they are attached. CCDC-251795 for **1** and CCDC-251794 for **2** contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.′

Cell Culture and MTT Assay: The peripheral blood was obtained from six healthy, nonsmoking donors of both sexes. Lymphocytes were isolated by centrifugation in gradient of density of Histopaque 1077 (Sigma–Aldrich CO, St. Louis, MO, U.S.A) (15 min, 100×*g*). Mitogen PHA was used for stimulation of proliferation of lymphocytes which exhibit a doubling time of approximately 30 h. Lymphocytes were counted and then seeded in 96-well microtitre plates (Nunc Brandt Products, U.S.A.) at a density of 10^5cells/well with a final volume of 100 μL. The monolayer of colon adenocarcinoma HT 29 cells in 25 cm^2 flasks was treated with trypsin-EDTA, and then the cells were seeded in 96-well microtitre plates at a density of 6×10^3 cells/well with a final volume 200 μL. The cultures of the HT 29 tumor cells show a doubling time of about 30–40 h.

After a 24-h incubation in a 5% humidified incubator at 37 °C, the cells were treated with different concentrations of 5-Fu and its new analogues. After a 72-h incubation, 20 μL of MTT solution (5 mg/mL in sterile PBS) was added to each well, and the plates were incubated for a further 2 h.

R_1, wR_2 (all data)	0.066, 0.151	0.079, 0.211

[a] $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$. [b] $wR_2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{1/2}$; $w^{-1} = \sigma^2(F_o^2) + (aP)^2 + bP$; $P = (F_o^2 + 2F_c^2)/3$ with $a = 0.0898$ for **1**, 0.1074 for **2**, $b = 0.0000$ for **1** and 0.0600 for **2**.

The purple formazan crystals produced were dissolved in a mixture of 20%SDS/50%DMF (120 µL/well, 24 h) in the case of the lymphocytes, and in DMSO in the case of the HT 29 cell line (100 µL/well, 5 min).

The plates were agitated on a plate shaker for 5 min, and the absorbance of each well was measured at 580 nm using a Stat Fax–2100 Awareness Technology Inc. microplate reader.[29]

The sensitivity of the cells to the tested compounds was shown as percentage of the survival of the cells (an untreated control value – 100% in relation to drugs concentration values). The cytotoxic effects were expressed as the IC_{50} value, which is the concentration of the drug required to reduce cell growth to 50% relative to the control. Those parameters were estimated on the basis of the analysis of the cell growth curves using the GraphPad Prism 4 computer program. All results were presented as mean ± s.d. of three replicates from six to twelve independent experiments.

Acknowledgments

The authors would like to thank Professor Bernhard Lippert from the University of Dortmund, Germany for his critical review of this manuscript, which is greatly appreciated. The authors also thank Prof. Stanislaw Szala from the Oncology Centre, Maria Curie-Sklodowska Institute in Gliwice, Poland, for providing the HT 29 colon adenocarcinoma cell line used in this investigation. This study was supported by the German–Polish programme grant No. 503-100-3 and by grant No. 502-13-849 of the Medical University of Łódź. J.O. gratefully acknowledges a fellowship from Deutscher Akademischer Austauschdienst (DAAD).

From Mono- and Dinuclear to Polynuclear Cobalt(II) and Cobalt(III) Coordination Compounds Based on *o*-Phthalic Acid and 2,2′-Bipyridine: Synthesis, Crystal Structures, and Properties

Svetlana G. Baca,*[a] Irina G. Filippova,[b] Christina Ambrus,[c] Maria Gdaniec,[d] Yurii A. Simonov,[b] Nicolae Gerbeleu,[a] Olesea A. Gherco,[b] and Silvio Decurtins[c]

Keywords: Carboxylate ligands / Cobalt / Magnetic properties / N ligands

The reaction of *o*-phthalic acid (H_2Pht) and 2,2′-bipyridine (bpy) with cobalt(II) carbonate at different temperatures results in the isolation of three types of new cobalt(II) and cobalt(III) compounds. The mononuclear cobalt(III) complex $[Co(CO_3)(bpy)_2]_2(Pht)\cdot16H_2O$ (**1**) is obtained when the reaction is run at 60 °C. Crystallographic analysis revealed that **1** contains two crystallographically independent $[Co(CO_3)(bpy)_2]^+$ cations, a Pht^{2-} anion, and sixteen solvate water molecules. The latter form a wall of channels with the oxygen atoms of the carboxylate groups of the Pht^{2-} anions, which are occupied by pairs of cations. Increasing the temperature of the reaction to 80 °C leads to the formation of the open dinuclear cobalt(II) complex $[(bpy)_2Co(Pht)H(Pht)Co(bpy)_2](HPht)(H_2Pht)\cdot2H_2O$ (**2**), which crystallizes in two polymorphic modifications **2a** and **2b**. Compound **2a** consists of a centrosymmetric dinuclear $[(bpy)_2Co(Pht)H(Pht)Co(bpy)_2]^+$ cation, an $HPht^-$ anion, an H_2Pht molecule, and two solvate H_2O molecules. In **2b**, a small alteration in the crystal structure leads to an increase of the unit-cell volume. The asymmetric unit of **2b** contains six crystallographically independent Co^{II} complexes, which combine into four $[(bpy)_2Co(Pht)H(Pht)Co(bpy)_2]^+$ units. The main structural unit of the cyclic dinuclear complex $[Co(Pht)(bpy)(H_2O)]_2\cdot2H_2O$ (**4**) is neutral and cenrosymmetric, with the two Co^{II} atoms linked by two phthalate ligands to form a 14-membered cycle. A further temperature increase results in the isolation of both the mononuclear complex $[Co(Pht)(bpy)(H_2O)_3]\cdot3H_2O$ (**3**) and the polynuclear helical coordination polymer $[Co(Pht)(bpy)(H_2O)]_n$ (**5**). Extended hydrogen bonding networks as well as aromatic π–π stacking interactions stabilize multidimensional supramolecular architectures in all compounds. Magnetic susceptibility measurements have been performed for complexes **1**, **2**, **3**, and **5**. Simulations gave the following parameter sets: for complex **2** $|D| = 70\ cm^{-1}$, $g = 2.55$ and $J = -0.1\ cm^{-1}$; for complex **3** $|D| = 80\ cm^{-1}$, $g = 2.6$, and for complex **5** $|D| = 65\ cm^{-1}$, $g = 2.45$. Complex **1** is diamagnetic.

Introduction

Carboxylate complexes have received a great deal of attention over the last few years due to their interesting coordination chemistry, unusual structural features, remarkable physical and chemical properties, and extensive practical applications as dyes, extractants, drugs, pesticides, magnetic devices, etc.[1] Metal carboxylates with a high stability are also efficient catalysts in a vast range of chemical and biochemical processes.[2] Although a great number of metal carboxylates have been obtained to date, the rational design and synthesis of novel metal carboxylates by employing new synthetic tools or by varying the nature of the reactants and synthetic conditions are currently under active investigation. In this context, *o*-phthalic acid (H_2Pht), which can exhibit a variety of coordination abilities[3] and has a tendency to form large metal cluster aggregates[4–9] or architectures with multi-dimensional frameworks, has been extensively explored. We have recently reported a series of nickel(II), copper(II), and zinc(II) phthalate compounds[3,10–16] that show a great structural diversity, ranging from monomeric to polymeric assemblies. Herein we extend these studies to investigate the interactions of this universal ligand with cobalt ions in the presence of aromatic amines. In this respect, several cobalt phthalate compounds that are already known should be mentioned here. A very interesting example of a three-dimensional cobalt(II) polymer, namely $[Co(Pht)_2(bipy)]_n$ (bipy = 4,4′-bipyridine), which consists of interlinked Co–Pht–Co and Co–bpy–Co linear chains, has been reported by Lightfoot et al.[17] Several dimers linked by *o*-phthalate $[Co_2(Pht)(L)(H_2O)](ClO_4)_2$ (L = 2,2′-bipyridine, 1,10-phenanthroline, and 5-ni-

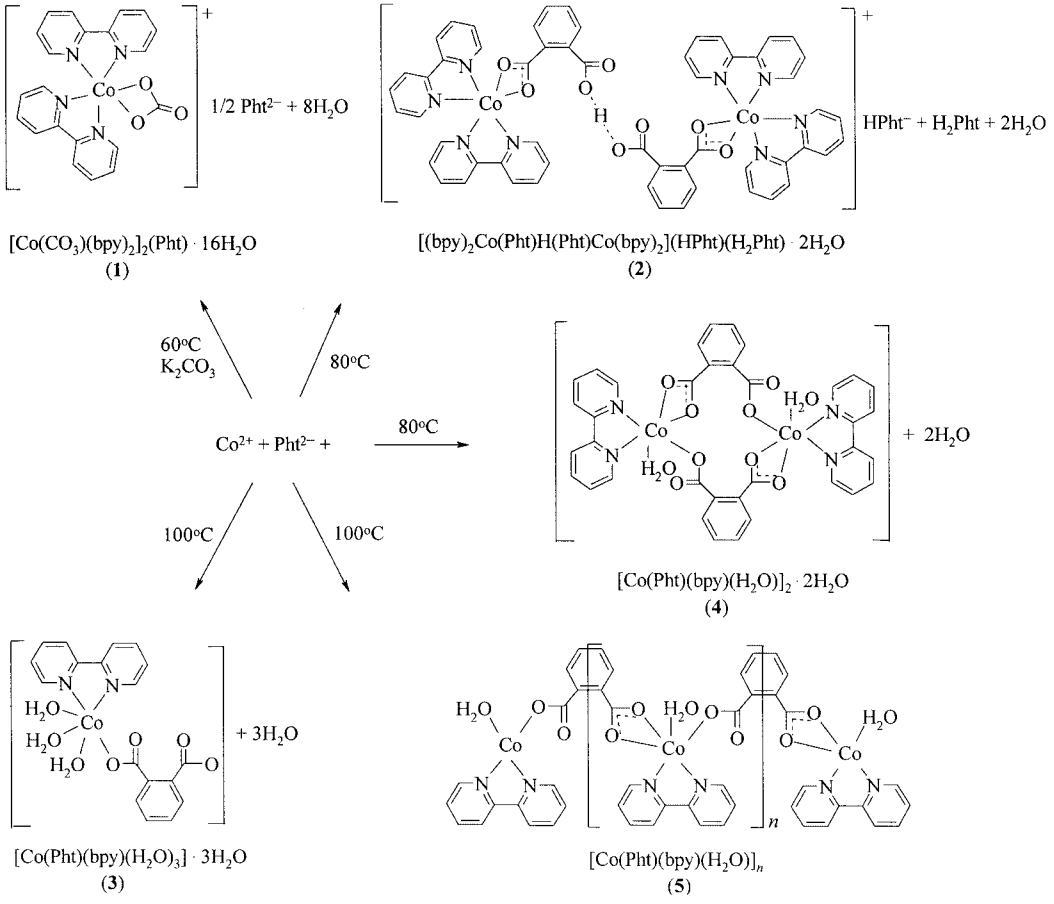
tro-1,10-phenanthroline) have also been isolated.[18] Finally, the monomeric complexes $[Co(Pht)(phen)(H_2O)_3]\cdot H_2O$ and [Co(Pht)(dipya)] (phen = 1,10-phenanthroline, dipya = 2,2′-dipyridylamine) have been synthesized.[19] Recently, we have also described the synthesis and structural characterization of cobalt(II) phthalate coordination polymers with derivatives of imidazole, for example 1-methylimidazole (1-MeIm),[3] 2-methylimidazole (2-MeIm),[12] and 4-methylimidazole (4-MeIm).[15] In this paper we report on the synthesis, characterization, and crystal structures of three types of new cobalt(II) and cobalt(III) compounds with *o*-phthalic acid and 2,2′-bipyridine (bpy), namely the mononuclear cobalt(III) and cobalt(II) complexes $[Co(CO_3)(bpy)_2]_2(Pht)\cdot 16H_2O$ (**1**) and $[Co(Pht)(bpy)(H_2O)_3]\cdot 3H_2O$ (**3**), respectively, the open dinuclear complex $[(bpy)_2Co(Pht)H(Pht)Co(bpy)_2](HPht)(H_2Pht)\cdot 2H_2O$ (**2**) and the cyclic dinuclear complex $[Co(Pht)(bpy)(H_2O)]_2\cdot 2H_2O$ (**4**), as well as the polynuclear helical coordination polymer $[Co(Pht)(bpy)(H_2O)]_n$ (**5**).

Results and Discussion

Synthesis

The reaction of *o*-phthalic acid with cobalt(II) carbonate in the presence of amine at different temperatures affords four new coordination compounds, as shown in Scheme 1. An oxidation of cobalt(II) ions to cobalt(III) was observed when the reaction was carried out at 60 °C in the presence of the base K_2CO_3, and the reaction mixture was left in contact with air. This resulted in the formation of crystals of the cobalt(III) complex $[Co(CO_3)(bpy)_2]_2(Pht)\cdot 16H_2O$ (**1**) in two weeks. To the best of our knowledge, **1** is the first example of a trivalent cobalt compound with *o*-phthalic acid, although in **1** the phthalate dianion is acting only as a counterion. It is interesting to note that similar bis(bipyridine)(carbonato)cobalt(III) nitrate and iodide complexes have also been obtained from the initial cobalt(II) salts but only under O_2 or CO_2.[20] It seems that the presence of aromatic amines such as bpy or phen facilitates the oxidation of the initial cobalt(II) species. Increasing the temperature of the reaction to 80 °C leads to the formation of the dimeric complex $[(bpy)_2Co(Pht)H(Pht)Co(bpy)_2](HPht)(H_2Pht)\cdot 2H_2O$ (**2**), the identity of which was confirmed by X-ray crystallography. The two $[Co(bpy)_2]^{2+}$ units in **2** are connected by a symmetric O···H···O hydrogen bond between the carboxylate groups of two different coordinated phthalate ligands. A similar Zn compound has recently been reported.[14] Compound **2** crystallizes from hot H_2O solution in two polymorphic modifications (**2a** and **2b**), which consist of similar structural units and differ in the crystal structure organization. Further increasing the reaction tempera-



Scheme 1.

ture resulted in the isolation of two new products, namely the coordination polymer $[Co(Pht)(bpy)(H_2O)]_n$ (**5**) and the mononuclear complex $[Co(Pht)(bpy)(H_2O)_3]\cdot 3H_2O$ (**3**), which were obtained in around 20% and 12% yields, respectively. One needs to mention here that the cyclic dimer **4** (Scheme 1) was obtained from the reaction of cobalt(II) acetate with H_2Pht and bpy in MeOH in a very low yield, therefore the sample was only suitable for X-ray studies. All attempts to optimize the yield of **4** were unsuccessful.

Spectroscopic Studies

The most relevant features of the IR spectra of compounds **1**–**3** and **5** are the absorptions due to the stretching of the dicarboxylate groups. The positions of these bands and the separations ($\Delta\nu$) between $\nu_{asym}(CO_2)$ and $\nu_{sym}(CO_2)$ indicate that the phthalate carboxylate groups function in different coordination modes. For complex **1**, in which the *o*-phthalic acid is fully deprotonated but acts only as a counterion, the characteristic bands of the uncoordinated carboxylate groups of Pht^{2-} appear at 1678 and 1564 cm^{-1} for asymmetric stretching, and at 1403 and 1382 cm^{-1} for symmetric stretching. In the IR spectrum of complex **2**, the medium-intensity peaks at 1717 and 1366 cm^{-1} also indicate the presence of uncoordinated *o*-phthalic acid [$\nu_{asym}(CO_2)$ for *o*-phthalic acid of 1690 and 1678 cm^{-1}].[21] The absorptions at lower frequencies (1579 and 1411 cm^{-1}) can be attributed to deformation vibrations of the chelating carboxylate groups ($\Delta\nu$ = 168 cm^{-1}).[22] The IR spectrum of **3** shows a broad $\nu_{asym}(CO_2)$ absorption with a maximum at 1568 cm^{-1} and a $\nu_{sym}(CO_2)$ absorption at 1404 cm^{-1}, which can be assigned to the chelating carboxylate group ($\Delta\nu$ = 164 cm^{-1}). For polymer **5**, the bands of the dicarboxylate groups appear at 1578 and 1543 cm^{-1} for the asymmetric stretching and at 1420 and 1385 cm^{-1} for the symmetric stretching. The $\Delta\nu$ values are 193 and 123 cm^{-1} and are attributed to the existence of both monodentate and chelating modes of the carboxylate groups, respectively. The infrared spectra of **1**–**3** and **5** also show broad bands in the 3634–3230 cm^{-1} region, which can be assigned to water molecules. Additionally, complex **1** has a strong band at 1638 cm^{-1} and a medium band at 1202 cm^{-1}, which are absent in the IR spectra of other complexes and are indicative of a chelating carbonate group.[23]

Thermogravimetric Studies

Compounds **1**–**3**, and **5** were heated in the temperature range 25–600 °C. The TGA data show that the first weight loss corresponds to the removal of water molecules in all compounds. Complex **1** loses eleven water molecules in two steps from 30 to 150 °C (the total weight loss is 15.40%, calculated 15.07%). On further heating, **1** loses 43.88% of its weight between 160 and 270 °C, which corresponds to the release of the five remaining water molecules, the uncoordinated phthalate dianion (Pht^{2-}), and two bpy molecules (calculated 43.08%). Complex **1** decomposes to the final product Co_2O_3, with a remaining percentage of 13.22% (calculated 12.61%), when heated from 270 to 360 °C. For dimer **2**, the first weight loss is observed from 70 to 150 °C and is due to the loss of two water molecules (observed 2.51%, calculated 2.50%). In the temperature range of 170–510 °C the decomposition of the organic ligands takes place in four unidentified steps with a total weight loss of 85.91% to the final product CoO (found 11.39%, calculated 10.41%). For complex **3**, the first weight loss corresponding to both three uncoordinated and three coordinated water molecules (found 21.91%, calculated 22.17%) is found in the temperature range 30–150 °C. The second weight loss is observed from 150 to 320 °C and corresponds to the dissociation of the bpy ligand (found 30.31%, calculated 32.05%). The third weight loss of 19.58%, from 320 to 450 °C, is due to the loss of phenyl radical.[24,25] A further weight loss of 11.49%, corresponding to the elimination of two molecules of CO[26] (calculated 12.15%), occurs between 450 and 540 °C. The final product is CoO, with a remaining percentage of 16.70% (calculated 15.37%). In contrast to **1**–**3**, the coordination polymer **5** is stable up to approximately 180 °C and then it loses 4.42% of its weight, which corresponds to the loss of a coordinated water molecule (calculated 4.53%). A further mass decrease is observed between 230 and 320 °C and corresponds to the loss of the bpy molecule (found 38.05%, calculated 39.32%). The decomposition of the Pht ligand is observed above 320 °C in two steps, with the weight loss of 18.65 and 14.10% each, by the removal of phenyl radical (calculated 20.28%) and two molecules of CO (calculated 15.93%), respectively, and is completed below 440 °C to give the expected oxide (found 20.15%, calculated 18.86%).

Description of the Crystal Structures

$[Co(bpy)_2(CO_3)]_2(Pht)\cdot 16H_2O$ (1)

X-ray analysis indicates that the asymmetric unit of **1** contains two crystallographically independent $[Co(CO_3)(bpy)_2]^+$ cations, a Pht^{2-} anion, and sixteen solvate water molecules (Figure 1). The structure of the cations is similar to that in the related compounds $[Co(CO_3)(bpy)_2]NO_3\cdot 5H_2O$[20] and $[Co(CO_3)(bpy)_2]Cl\cdot 3H_2O$.[27] Each Co^{III} atom in **1** is coordinated by four nitrogen atoms of two chelating bpy molecules and two oxygen atoms of the chelating CO_3^- group, and thus adopts a distorted octahedral N_4O_2 environment. The average Co–N distances are 1.930 for Co(1) and 1.932 Å for Co(2), while the Co(1)–O bonds are 1.901(2) and 1.893(2) Å, with 1.895(2) and 1.898(2) Å for the Co(2)–O bonds (Table 1). The observed distortion from an octahedral geometry could be caused by the small bite angle of the chelating carbonate group [the O–Co–O angles are 69.42(8)° and 69.31(8)° for Co(1) and Co(2), respectively]. The O–Co–O bite angle of the chelating carbonate ligand agrees well with other bis(bipyridine)(carbonato)cobalt(III) [69.9(2)°][20] and (carbonato)bis(phenanthroline)cobalt(III) complexes [varies from 68.4(5)° to

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

69.8(2)°].[20,28] The dihedral angles between the four-membered chelate ring of the carbonate group and two five-membered chelate rings of the bpy ligands are 94.6(1)° and 87.0(1)° for Co(1), and 87.0(1)° and 96.5(1)° for Co(2).

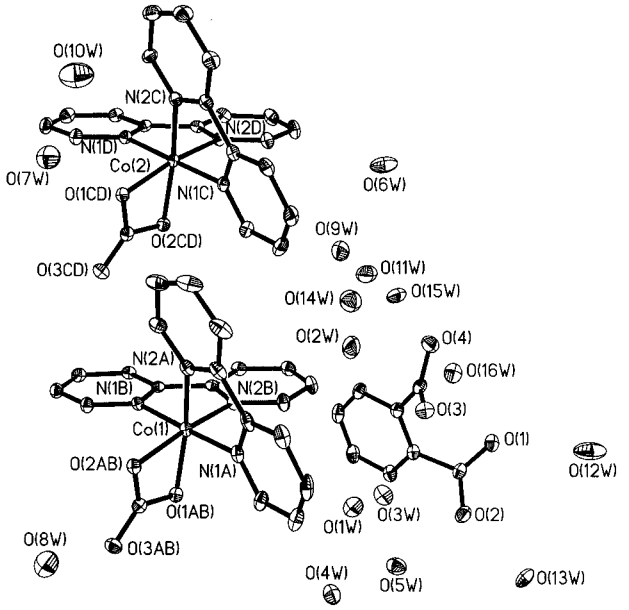

Figure 1. Crystallographically independent structure fragment with numbering scheme and displacement ellipsoids drawn at the 30% probability level in compound **1**. Two water molecules are disordered over two positions: O(13w) and O(13*), O(14w) and O(14*). Hydrogen atoms have been omitted for clarity.

Pht^{2-} acts as a fully deprotonated counterion. The average dihedral angle between the planes of its carboxylate groups is 60.6°, and the angles between the planes of the carboxylate groups and the aromatic ring are 48.8° and 52.1°. The sixteen solvent water molecules and the uncoordinated oxygen atoms of the carboxylate groups of the Pht^{2-} anion form a system of hydrogen bonds that generate a wall of channels. These channels are extended along the *b* axis (Figure 2) and are occupied by pairs of $[Co(CO_3)(bpy)_2]^+$ cations. The latter are attached to the channels' walls by hydrogen bonds [O(4w)–H···O(3CD) = 2.800(3), O(8w)–H···O(3AB) = 2.814(3), and O(7w)–H···O(1CD) = 2.811(3) Å], as well as by π–π interactions between the Pht ring and the pyridine ring from the Co(1) complex [the centroid–centroid distance is 3.562(2) Å].

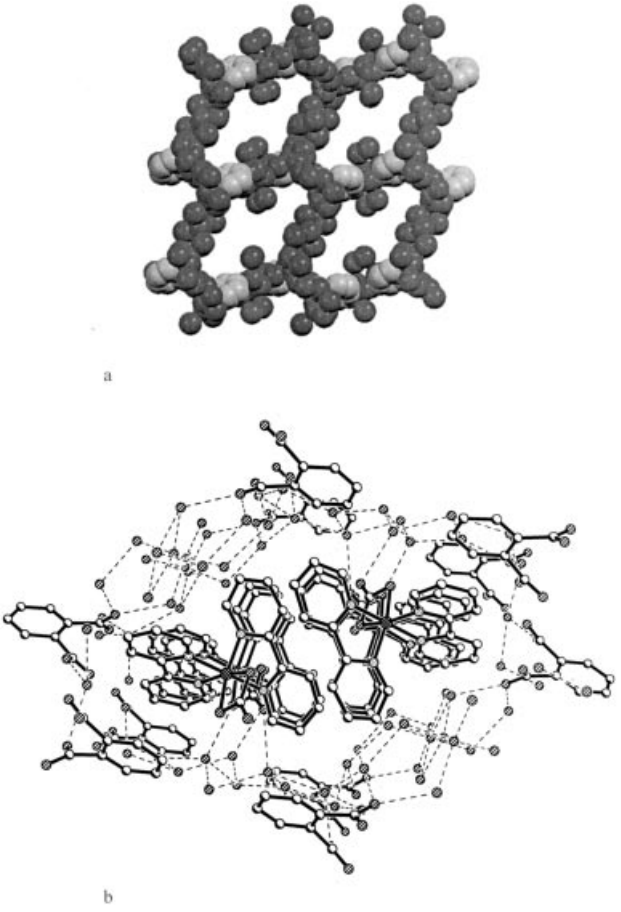

Figure 2. (a) Space-filling representation of channels in the structure of compound **1**. Cations $[Co(bpy)_2(CO_3)]^+$ have been omitted for clarity. (b) One channel with a pair of columns formed by $[Co(bpy)_2(CO_3)]^+$ cations in **1**. Hydrogen atoms have been omitted for clarity and hydrogen bonds are indicated by dotted lines.

The cations are arranged in pairs of columns due to π–π stacking interactions between the antiparallel aromatic rings belonging to two Co(1) complexes and related by a symmetrical center at the (1/2, 1/2, 0) site (Figure 2b). The average contact distance of the adjacent aromatic rings is about 3.52 Å and the centroid–centroid distance is 3.780(2) Å. The corresponding distances for analogous pyridine rings of two Co(2) complexes are about 3.77 and 3.987(1) Å, respectively, and are slightly longer than those for typical aromatic-aromatic π–stacking interactions.[29] Weak C–H···O hydrogen bonds between the CH groups of the pyridine rings and the uncoordinated oxygen atoms of the CO_3 ligands join Co(1) and Co(2) complexes within the column [C(11C)–H···O(3AB) = 3.226 Å, C(11A)–H···O(3CD) = 3.215 Å].

[(bpy)$_2$Co(Pht)H(Pht)Co(bpy)$_2$](HPht)(H$_2$Pht)·2H$_2$O (2a, 2b)

X-ray diffraction analysis revealed that compound **2** crystallizes in two polymorphic forms: **2a** and **2b** (Table 2). The unit-cell parameters of **2a** and **2b** are related as follows: $a_{2b} \approx -(a_{2a} + c_{2a})$; $b_{2b} \approx b_{2a} + c_{2a} - a_{2a}$; $c_{2b} \approx 2(a_{2a} + b_{2a})$.

The former (**2a**) is isostructural with the analogous Zn complex[14] and also consists of a centrosymmetric dinuclear $[(bpy)_2Co(Pht)H(Pht)Co(bpy)_2]^+$ cation, an $HPht^-$ anion, an H_2Pht molecule, as well as two solvate H_2O molecules (Figure 3). Each Co atom has a distorted octahedral geometry containing four nitrogen atoms of two bpy ligands (the average Co–N bond length is 2.107 Å) and two oxygen atoms from one chelating carboxylate group of the Pht ligand [Co–O 2.112(2) and 2.225(2) Å]. The angle of the chelating carboxylate group O(3)–Co(1)–O(4) is 60.85(6)°. This value is in good agreement with those of similar 3d-metal complexes with a 1,3-chelating bidentate function of the Pht ligand.[10–15] It should be noted that the coordinated carboxylate group of the Pht residue in **2a** is almost coplanar with the aromatic ring − the dihedral angle between them is 10.2(1)°; for the second carboxyl group this angle is equal to 74.1(1)°. The two mononuclear structural units consisting of one metal ion, two bpy molecules, and one residue of *o*-phthalic acid are linked by a very short symmetric O···H···O hydrogen bond of 2.447(3) Å between the carboxylate oxygen atoms O(1) and O(1A) into a dimer. Consequently, the metal-containing backbone can be considered as a $[(bpy)_2Co(Pht)H(Pht)Co(bpy)_2]^+$ unit.

The dinuclear aggregate forms a hydrogen-bonded network with water molecules and the uncoordinated molecule of *o*-phthalic acid. The position of the hydrogen atoms of the carboxylic groups in the uncoordinated phthalate molecules could not be located because of disorder of oxygen atoms over two orientations with 50% probability. Therefore, we propose a model in which the crystal of **2a** contains

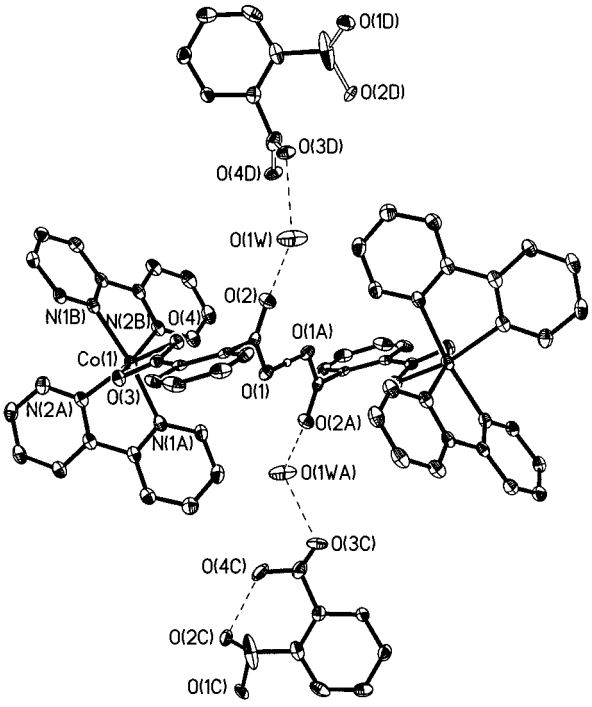

Figure 3. Dimeric aggregate in compound **2a**. Two configurations of the uncoordinated molecule of *o*-phthalic acid with C and D index are shown. All hydrogen atoms except a symmetric O(1)···H···O(1A) bond in the dimer have been omitted for clarity.

chains formed by an alternation of neutral H_2Pht molecules, water molecules, and monodeprotonated hydrogen phthalate anions ($HPht^-$), as shown in Figure 4. In this case, the inversion centers between two disordered carboxylic groups of the neighboring uncoordinated phthalate moieties in the chains have a statistical character (Figure 4). Variations of analogous chains have been observed in $\{[(\eta^6\text{-}C_6H_6)_2Cr]^+[HPht]^-[H_2Pht]\}$ as well as in $\{([(\eta^5\text{-}C_5H_5)_2$-

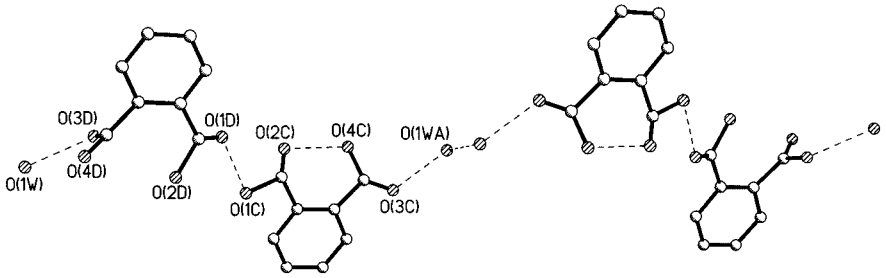

Figure 4. One version of a chain in **2a**. The molecule of Pht with D index is neutral and another one with C index is monodeprotonated.

$Co]^{+})_4([HPht]^{-})_2[Pht]^{2-}\}$.[30] The neutral molecule of *o*-phthalic acid forms two hydrogen bonds: O(1D)···O(1C) = 2.588(6) Å and O(3D)···O(1w) = 2.582(6) Å. Another conformer acts as a monoanion with only one short intramolecular hydrogen bond [O(4C)···O(2C) = 2.390(6) Å]. Two water molecules join pairs of H_2Pht–$HPht^-$ units into zigzag chains through O–H···O hydrogen bonds: O(1w)···O(1wA) ($-x + 1, -y + 2, -z$) = 2.690(4) Å, or O(1w)···O(3C) = 2.702(6) Å. The dinuclear aggregates are attached on both sides of the chains due to hydrogen bonds [O(1w)–H···O(2) = 2.795(3) Å].

Other noncovalent forces that contribute significantly to the 3D structural organization of **2a** should be mentioned, namely aromatic π–π interactions between the uncoordinated phthalate moieties and one of the coordinated bpy molecules (with A indexes), with a centroid–centroid distance of 3.754 Å. The angle between the overlapping aromatic system is 8.3(1)°. There are also π–π stacking interactions between the antiparallel bpy ligands from different dinuclear aggregates (the dihedral angle between the bpy planes being 0°, with a distance between the centroids of the bpy rings of 3.748 Å for the A molecules of bpy and 3.697 Å for B). The uncoordinated phthalate moieties also take part in a C–H···π interaction with the B bpy molecule [the distance between H(5C) and the centroid of the surrounding B ring is 2.646 Å]. Weak C–H···O hydrogen bonds involving the bpy carbon atoms and both the coordinated carboxylate oxygen atom (3.273 Å) and the oxygen atoms of the uncoordinated phthalate molecules (3.059 and 3.275 Å for two possible orientations) are also worthy of mention.

In compound **2b**, a small alteration in the crystal structure increases the unit cell's volume six times compared with that of **2a**. The asymmetric unit of **2b** contains six crystallographically independent Co^{II} complexes, which combine in the crystal structure into four $[(bpy)_2Co(Pht)H(Pht)Co(bpy)_2]^+$ units, as shown in Figure 5. Two of them, namely Co(5)–Co(5A) and Co(6)–Co(6A), are centrosymmetric, while the others [Co(1)–Co(2) and Co(3)–Co(4)] are noncentrosymmetric. A comparison of the main bond lengths and angles in all six Co complexes shows a close similarity between them. The average structural parameters of the coordination environment of the Co atoms are listed in Table 2. The maximum dispersion of distances in Co distorted octahedrons was observed for the Co–O(3) bond lengths, which are in the range 2.259(3)–2.213(2) Å. The Co–O(4) bond lengths vary from 2.099(2) to 2.132(3) Å. In the case of Co–N distances, their values are in the range 2.088(3)–2.144(3) Å, but the interval of bond lengths for each bpy molecule is not more than 0.037 Å.

The crystal structure of **2b** is organized in an analogous manner to **2a**. Every Co complex has satellite uncoordinated phthalate moieties connected to a bpy molecule by a π−π stacking interaction (the distance between the overlap-

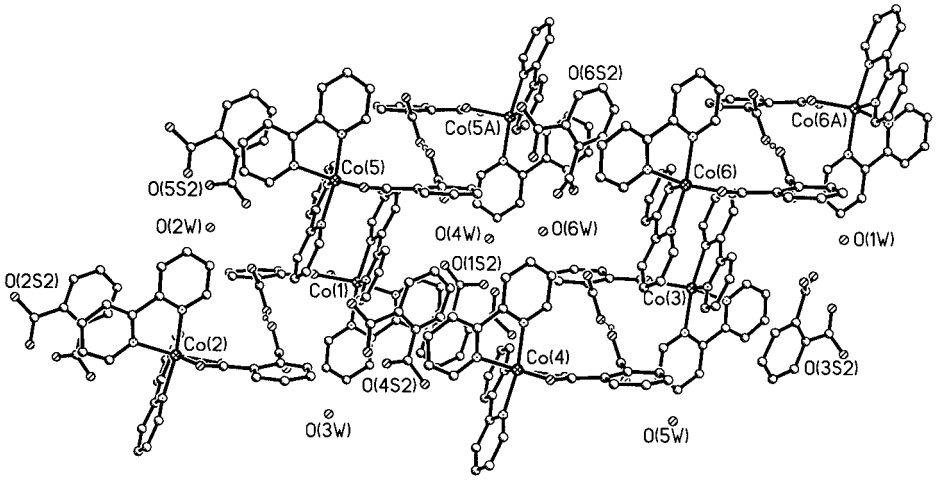

Figure 5. Six crystallographically independent Co complexes, which form four $[(bpy)_2Co(Pht)H(Pht)Co(bpy)_2]^+$ units in compound **2b**. Hydrogen atoms have been omitted for clarity.

ping aromatic rings is about 3.76 Å). Six Pht^{2-} anions compensate the charge of the dimeric units and take part in the formation of H-bonded chains that are similar to those in **2a** (Figure 4). There are four crystallographically independent chains in **2b**. The quality and volume of experimental data, as well as the disorder of some carboxylate groups of the Pht moieties and water molecules, did not permit the localization of all the hydrogen atoms in the structure. However, the possibility to distinguish both the neutral H_2Pht and monodeprotonated $HPht^-$ anion exists for the four molecules. Molecules with indexes 1S and 5S are neutral H_2Pht, while 3S and 6S molecules are $HPht^-$ anions, and the chains may be described as –O(1S)–H···O(4w){or O(4w′)}–H···O(6w){or O(6w′)}–H···O(6S)– and –O(5S)–H···O(2w){or O(2w′)}–H···O(1w){or O(1w′)}–H···O(3S)–. The distribution of the carboxylic H atom for the two remaining disordered phthalate moieties (2S and 4S) has statistical character as in **2a**. The dinuclear aggregates are attached on both sides of the chains due to O(w)–H···O_{carb} hydrogen bonds that are in the range 2.79(1)–2.98(1) Å. An additional π–π interaction occurs between the bpy molecules of adjacent Co complexes: Co(3) and Co(6), Co(1) and Co(5), Co(2) and Co(4).

An analysis of the charges on the four different supramolecular aggregates consisting of a $[(bpy)_2Co(Pht)H(Pht)Co(bpy)_2]^+$ unit and two satellite uncoordinated phthalate moieties (monodeprotonated or neutral) shows that the structure of **2b** has four types of supramolecular fragments. Two of them are formed around the centrosymmetric dimers Co(5)–Co(5A) and Co(6)–Co(6A) and have a positive charge $\{(H_2Pht)[(bpy)_2Co(5)(Pht)H(Pht)Co(5A)(bpy)_2](H_2Pht)\}^+$ and negative charge $\{(HPht)[(bpy)_2Co(6)(Pht)H(Pht)Co(6A)(bpy)_2](HPht)\}^-$, respectively. The supramolecular aggregate around Co(1)–Co(2) is statistically neutral or has charge +1, and the one around Co(3)–Co(4) has a 0 or –1 charge. This effect could explain the increase of the cell volume in **2b**.

[Co(Pht)(bpy)(H$_2$O)$_3$]·3H$_2$O (3)

Compound **3** (Figure 6) may be subsumed to the structural type $[M(Pht)(Amin)(H_2O)_3]\cdot nH_2O$ [M = Co, Ni; Amin = one bidentate ligand (bpy, dipya, phen)[19,31] or two monodentate ligands (Py, β-Pic, 1-MeIm);[32] n = 0, 1, 3]. In all these compounds, the *o*-phthalic acid residue is fully deprotonated and acts as a monodentate ligand. The Co atom in **3** is in a distorted octahedral environment, being coordinated by two nitrogen atoms from the bpy molecule, with a Co–N(1) distance of 2.126(1) Å and a Co–N(2) distance of 2.134(1) Å, the O(4) atom of the monocoordinated phthalate ligand [2.145(1) Å], and three oxygen atoms of water molecules [O(1w), O(2w), and O(3w) distances of 2.115(1), 2.112(1), and 2.056(1) Å, respectively] (Table 3). The water molecules O(1w) and O(2w) are *trans* to N(1) and N(2), respectively, whereas O(3w) lies *trans* to O(4). Thus, three coordinated water molecules make one edge of the octahedron, whereas the same coordinated water molecules lie in a meridian place in the related compounds.[19,30,31] However, the main features of the crystal packing in compound **3** are maintained. In all these compounds the coordinated and uncoordinated water molecules form both intramolecular and intermolecular hydrogen bonds leading to the organization of double-chains.[32] The arrangement of these chains mainly depends on the nature of the aromatic amine. The presence of supplementary out-of-sphere water molecules in compound **3** generates a 3D network held together by O–H···O hydrogen bonds. The water molecule O(2w) and the carboxylate oxygen atom O(3) are involved in intramolecular H-bonding [O(2w)–H···O(3) = 2.831(2) Å] forming a six-membered hydrogen-bonded Co(1)–O(2w)–H···O(3)–C(22)–O(4)–Co(1) ring (Figure 6). Individual molecules are joined into centrosymmetric dimers by the hydrogen bonds O(2w)–H···O(2) [2.678(2) Å] and O(3w)–H···O(1) [2.713(2) Å] (symmetry code for O(2) and O(3): $-x + 1, -y + 1, -z$). The Co···Co distance within the dimer is 7.368(1) Å. These dimeric units are further connected by O(w)–H···O(carb.) and O(w)–H···O(w) hydrogen bonds into double-chains running along the *a* axis of the unit cell of **3** (Figure 7). The distance between the metal centers of the adjacent dimers is 6.698(1) Å. The hydrogen bond O(4w)–H···O(6w) ($x, -y + 1/2, z - 1/2$) of 2.775(2) Å and possible π–π interactions between antiparallel molecules of bpy (the average distances

[Co(Pht)(bpy)(H$_2$O)]$_2$·2H$_2$O (4)

A neutral centrosymmetric dinuclear aggregate [Co(Pht)(bpy)(H$_2$O)]$_2$ is the main structural unit of compound **4**, in which two Co^{II} atoms are linked by two phthalate ligands to form a 14-membered cycle (Figure 9). The coordination modes of the two deprotonated carboxylate groups in the Pht residue are different. One carboxylate group is bidentate to a Co atom, while the other one is monocoordinated to the adjacent Co atom. The Co atoms are in a distorted octahedral environment. Deformation of the Co^{II} coordination polyhedron is observed both in bond lengths [range from 2.076(1) to 2.235(2) Å] and angles [O(3)–Co–O(4) = 60.15°; Table 4]. The Co atom is coordinated by three oxygen atoms [O(1*), O(3), O(4)] from two Pht residues [2.141(1), 2.235(2), and 2.076(1) Å], one water molecule [O(1w) 2.118(1) Å], and two nitrogen atoms [N(1), N(2)] of a bpy molecule [2.097(1) and 2.127(1) Å]. The Co···Co distance in this dimer is 5.034(1) Å. Similar dimers have been described recently in [Zn(Pht)(Im)(H$_2$O)]$_2$,[13] although in this latter complex the Pht ligands exhibit a 1,6-bridging function and the Zn atoms have a tetrahedral environment. A 14-membered cycle is formed in both compounds, but alteration of the structural function of the Pht residue leads to a shorter transannular distance in **4** [O(4)–O(4*) = 3.448(2) Å] compared to that in the Zn dimer [3.964(2) Å].[13]

Both the coordinated and solvate water molecules generate an extensive hydrogen-bonding network in **4**. The coordinated water molecule O(1w) is involved in intermolecular H-bonding [O(1w)–H···O(2) (–*x* + 1, –*y*, –*z* + 1) = 2.695(2) Å]. A pair of identical H_2O molecules [O(2w)], one above and the other below the plane of the 14-membered cycle, which additionally constrict the dimer, form hydrogen bonds as donors with the O(1) atoms of the monocoordinated carboxylate groups [O(2w)–H···O(1) = 2.871(2) Å] and as acceptors with the coordinated water molecules [O(1w)–H···O(2w) = 2.722(2) Å]. The second donor function of the O(2w) molecule reduces the organization of layers of dimers (Figure 10) parallel to the (101) plane. These layers are held together by π–π interactions between antiparallel bpy molecules with an average deviation of the bpy atoms from the adjacent ring of 3.41(3) Å.

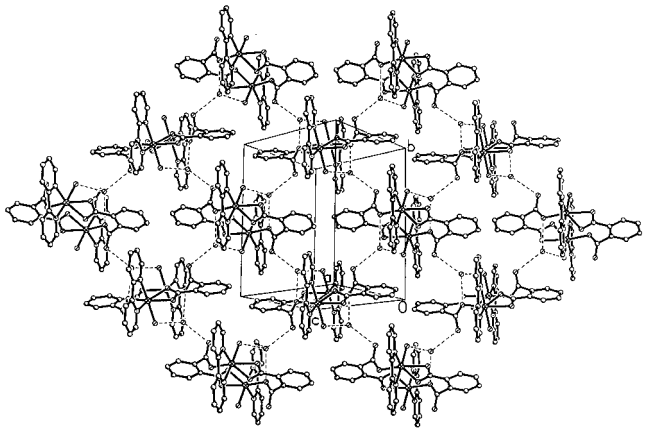

Figure 10. Packing diagram of compound **4**. Hydrogen atoms have been omitted for clarity and hydrogen bonds are indicated by dotted lines.

[Co(Pht)(bpy)(H$_2$O)]$_n$ (5)

The crystal structure of **5** consists of [Co(Pht)(bpy)(H_2O)] entities (Figure 11) as in **4,** but they are joined into a helical polymeric chain (Figure 12). It is necessary to note that **5** is isostructural with [Zn(Pht)(bpy)(H_2O)]$_n$.[33] The coordination polyhedron of the Co atom is composed of the same donor atoms as in **4** and is also distorted. The bond lengths range from 2.054(1) to 2.196(5) Å and the bond angles from 60.3(2)° to 117.8(2)° (Table 4). The Co–O(3) and Co–O(4) bond lengths for the bidentate carboxylate group are similar [2.196(5) and 2.181(5) Å], and that is a rather surprising result in light of the 1,3-chelating function of the Pht ligand.[11,14,15] There is a principal difference in the dihedral

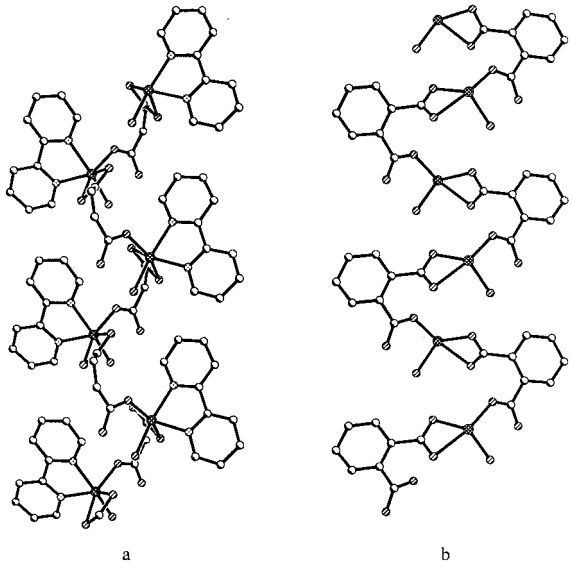

Figure 12. View along the *c*-axis of the single helical chain in compound **5** with bpy wings (a) and Pht wings (b).

angles between the planes of the coordinated carboxylate group and the aromatic ring in compounds **5** and **4**. In the former, this angle is equal to 61.5°, whereas in the latter the coordinated carboxylate group lies almost in the plane of the aromatic ring (the dihedral angle is 8°). The second carboxylate group of the phthalate dianion is monocoordinated to its adjacent Co atom [Co–O(1) = 2.054(6) Å]. The tridentate chelate-bridging function of the Pht ligand leads to the organization of the infinitive helical chain along the *c*-axis with a pitch of 8.432 Å (Figure 12). The neighboring Co···Co distance is 5.546(1) Å, slightly shorter than the Zn···Zn distance in $[Zn(Pht)(bpy)(H_2O)]_n$ (5.633 Å)[33] and much shorter than that in the helix of $[Co(Pht)(4\text{-MeIm})_2]_n$ [6.247(1) Å].[15] The adjacent complexes within the chain are joined additionally through two O–H···O hydrogen bonds between the coordinated water molecule and carboxylate oxygen atoms O(2) and O(4) of 2.570(8) and 2.760(8) Å, respectively. The chains are held together by van der Waals interactions (Figure 13).

Magnetic Studies

The temperature dependence of the molar magnetic susceptibility, χ_M, of complex **1** indicates a diamagnetic behavior. This corresponds to low-spin Co^{III} ($S = 0$) ions.

The thermal dependence of $\chi_M T$ ($\chi_M T$ being the product of the molar magnetic susceptibility and the temperature) and the simulated curve for a powdered sample of the dinuclear complex **2** are shown in Figure 14. The room-temperature $\chi_M T$ value of 6.0 emu K mol^{-1} agrees well with the calculated value of 6.0 emu K mol^{-1} for a high-spin Co^{II} compound ($S = 3/2$) with $g = 2.55$.[34] The gradual decrease of $\chi_M T$ upon lowering the temperature is typical for high-spin Co^{II}. This decrease of $\chi_M T$ is mainly due to zero-field splitting. Below 100 K, a possible weak antiferromagnetic interaction between neighboring Co^{II} ions provokes a further decrease of the $\chi_M T$ values. A simulation within the temperature range 5–300 K with a *g*-value of 2.55, an axial zero-field splitting parameter[34,35] of $|D| = 70$ cm^{-1}, and an exchange parameter, *J*, of –0.1 cm^{-1} gives the best agreement with the experimental data.

The room-temperature $\chi_M T$ value of 3.05 emu K mol^{-1} for compound **3** (Figure 15) agrees quite well with the calculated value of 3.17 emu K mol^{-1} for a high-spin Co^{II} compound ($S = 3/2$) with $g = 2.6$.[34] The gradual decrease of $\chi_M T$ upon lowering the temperature is typical for high-spin Co^{II}. This decrease of $\chi_M T$ is mainly due to zero-field splitting. A simulation within the temperature range 25–300 K with the parameters $|D| = 80$ cm^{-1} and $g = 2.6$ reproduces the experimental data quite well. At lower temperatures, the measured susceptibility shows a steeper decrease. This is probably due to weak antiferromagnetic intermolecular interactions between the Co^{II} complexes.

The thermal dependence of $\chi_M T$ of complex **5** is depicted in Figure 16. Attempts to obtain a satisfactory simulation for this linear-chain compound of Co^{II} ions were not successful. However, only to give an impression of the deviation from a single ion behavior, a simulation[36] within the temperature range of 100 K to 300 K, with a typical parameter set of $|D| = 65$ cm^{-1} and $g = 2.45$, is depicted in Figure 16. Obviously, intrachain magnetic-exchange interactions have a pronounced effect.

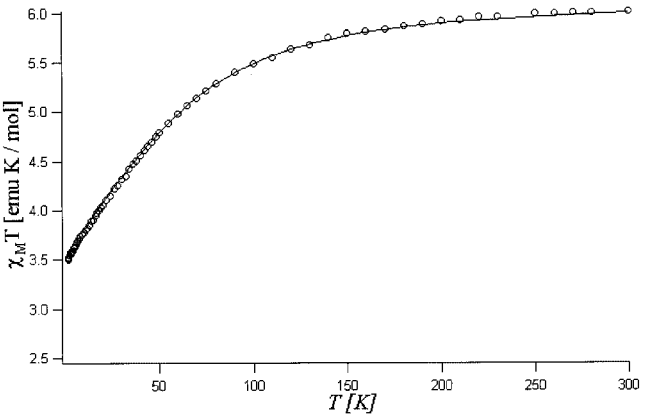

Figure 14. The circles correspond to the temperature dependence $\chi_M T$ for $[(bpy)_2Co(Pht)H(Pht)Co(bpy)_2](HPht)(H_2Pht)\cdot 2H_2O$ (**2**). A simulation from 5 to 300 K with the parameters[34–36] $|D| = 70$ cm^{-1}, $g = 2.55$, and $J = -0.1$ cm^{-1} is depicted as a line.

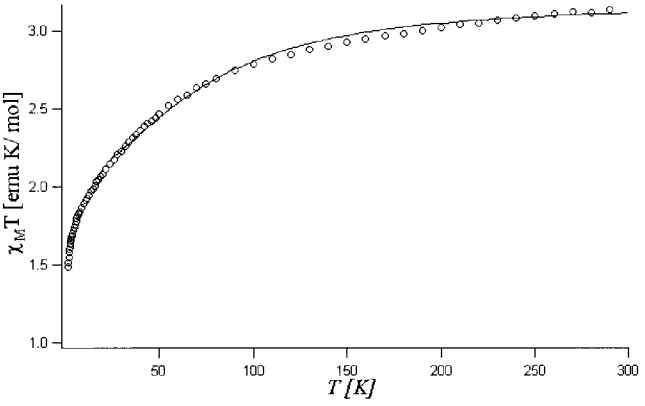

Figure 15. The temperature dependence, $\chi_M T$, for $[Co(Pht)(bpy)(H_2O)_3]\cdot 3H_2O$ (**3**) is depicted as circles. The line corresponds to a simulation from 25 to 300 K with the parameters $|D| = 80$ cm^{-1} and $g = 2.6$.

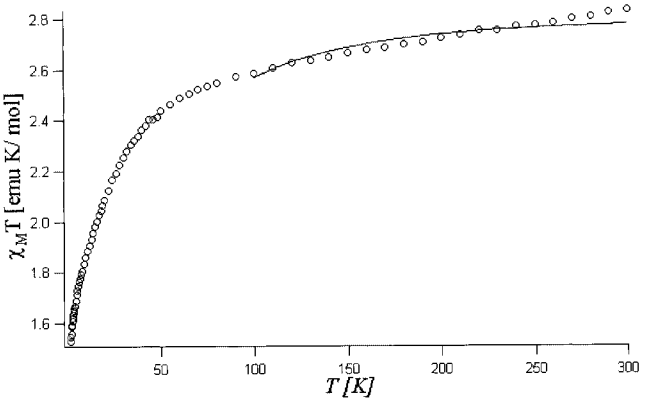

Figure 16. The temperature dependence, $\chi_M T$, for the chain complex $[Co(Pht)(bpy)(H_2O)]_n$ (**5**) is depicted as circles. A simulation for a single-ion behavior within the temperature range of 100 K to 300 K by using a typical parameter set of $|D| = 65$ cm^{-1} and $g = 2.45$ is shown as a line.

Conclusions

The reaction of cobalt(II) anions with *o*-phthalic acid and bidentate bipyridine ligands has produced some intriguing complexes. Complexes of different nuclearity are obtained depending on the temperature of the reaction: the mononuclear $[Co^{III}(CO_3)(bpy)_2]_2(Pht)\cdot 16H_2O$ (**1**) and $[Co(Pht)(bpy)(H_2O)_3]\cdot 3H_2O$ (**3**) complexes, the open $[(bpy)_2Co(Pht)H(Pht)Co(bpy)_2](HPht)(H_2Pht)\cdot 2H_2O$ (**2**) and cyclic dinuclear $[Co(Pht)(bpy)(H_2O)]_2\cdot 2H_2O$ (**4**), and polynuclear $[Co(Pht)(bpy)(H_2O)]_n$ (**5**). Moreover, in complex **1** the oxidation of cobalt(II) to cobalt(III) ions has occurred. The structural trends displayed in **1**–**5** illustrate the extraordinarily rich binding abilities of the carboxylate groups of the *o*-phthalate ligand and their ability to form extensive hydrogen-bonding interactions and build supramolecular architectures. The variable-temperature magnetic data indicate a weak antiferromagnetic interaction between neighboring Co^{II} centers in both the open dinuclear complex **2** and mononuclear complex **3**, whereas complex **1** is a rare example containing low-spin Co^{III} ($S = 0$) ions.

Experimental Section

General: All reagents were purchased from commercial sources and used as received. IR spectra were recorded with a Perkin–Elmer Spectrum One spectrometer in the region 4000–400 cm^{-1} using KBr pellets. TG analyses were carried out with a Mettler-Toledo TA 50 in dry dinitrogen (60 mL min^{-1}) at a heating rate of 5 °C min^{-1}. Magnetic susceptibility data of powdered samples were collected with an MPMS Quantum Design SQUID magnetometer (XL-5) in the temperature range 300–1.8 K and at a field of 1000 G. The samples were placed in a Saran foil bag and a straw was used as the sample holder. The output data were corrected for the experimentally determined diamagnetism of the sample holder and the diamagnetism of the sample calculated from Pascal's constants. The program MAGPACK[36] was used to model the experimental magnetic susceptibility data.

Synthesis of $[Co(CO_3)(bpy)_2]_2(Pht)\cdot 16H_2O$ (1): A warm solution of H_2Pht (1.66 g, 10 mmol) and bpy (1.56 g, 10 mmol) in water (20 mL) was added to a suspension of $CoCO_3\cdot Co(OH)_2\cdot nH_2O$ (1.18 g) and K_2CO_3 (1.38 g, 10 mmol) in water (30 mL). The resulting mixture was stirred at 60 °C for 30 min. The precipitated solid was removed immediately and the filtrate allowed to cool to room temp. Dark-red crystals of **1** suitable for X-ray diffraction studies were filtered off after two weeks, and washed with water, EtOH, and dried in air. Yield: 1.00 g (30.4% based on bpy). $C_{50}H_{68}Co_2N_8O_{26}$ (1315.0): calcd. C 45.67, H 5.21, N 8.52; found C 45.71, H 5.15, N 8.48. IR (KBr): $\tilde{\nu}$ = 3384 br, 3116 m, 3086 m, 3061 m, 3032 m, 1678 vs, 1639 s, 1606 s, 1563 s, 1501 m, 1472 s, 1449 s, 1403 s, 1382 s, 1318 m, 1282 w, 1247 m, 1202 s, 1157 m, 1123 w, 1109 w, 1075 w, 1037 w, 1025 w, 1004 w, 822 m, 773 vs, 751 sh, 729 s, 692 w, 676 w, 652 m, 509 m, 484 w cm^{-1}.

Synthesis of $[(bpy)_2Co(Pht)H(Pht)Co(bpy)_2](HPht)(H_2Pht)\cdot 2H_2O$ (2): H_2Pht (3.32 g, 20 mmol) and bpy (3.12 g, 20 mmol) were added to a suspension of $CoCO_3\cdot Co(OH)_2\cdot nH_2O$ (2.3 g) in water (50 mL). The resulting mixture was stirred at 80 °C for 10 min. The precipitated solid containing unreacted cobalt(II) carbonate was removed immediately and the filtrate allowed to cool to room temp. Large red crystals were filtered off after a week, washed with water, and dried in air. Yield: 4.52 g (62.87% based on bpy). $C_{72}H_{56}Co_2N_8O_{18}$ (1439.1): calcd. C 60.09, H 3.92, N 7.79; found C 59.90, H 3.86, N 7.59. IR (KBr): $\tilde{\nu}$ = 3428 br, 3073 m, 3035 sh, 1717 s, 1600 vs, 1579 vs, 1564 sh, 1538 s, 1493 sh, 1475 vs, 1444 vs, 1411 vs, 1366 s, 1315 m, 1293 m, 1251 m, 1177 m, 1159 m, 1075 m, 1059 m, 1022 s, 796 m, 773 vs, 736 s, 715 m, 683 w, 650 m, 576 m cm^{-1}. Single crystals suitable for diffraction studies were obtained by recrystallization of **2** from a hot aqueous solution.

Synthesis of $[Co(Pht)(bpy)(H_2O)_3]\cdot 3H_2O$ (3) and $[Co(Pht)(bpy)(H_2O)]_n$ (5). Method A: Cobalt(II) carbonate (1.18 g) was added to a hot solution of H_2Pht (1.69 g, 10 mmol) and bpy (1.56 g, 10 mmol) in water (50 mL). The resulting mixture was heated at reflux for 45 min. The precipitated solid was removed by filtration from the hot solution, and the filtrate allowed to cool to room temp. Cherry-colored crystalline **5** and large, rose-colored crystals of **3** suitable for X-ray investigation were collected by filtration after a week, washed with water and dried in air. The crystals of **3** and **5** were separated by hand. The yields of compounds **5** and **3** were 0.78 g (19.65%) and 0.3 g (12.1%), respectively. An additional batch of **3** was obtained by keeping the mother filtrate in air for 2 weeks. **3:** $C_{18}H_{24}CoN_2O_{10}$ (487.32): calcd. C 44.36, H 4.96, N 5.75; found C 44.28, H 4.68, N 5.67. IR (KBr): $\tilde{\nu}$ = 3230 br, 1652 sh, 1602 vs, 1568 vs, 1484 s, 1444 vs, 1404 vs, 1315 m, 1250 m, 1172 m, 1159 m, 1104 w, 1087 m, 1060 m, 1023 s, 840 s, 820 s, 764 vs, 736 vs, 701 s, 652 s, 632 m cm^{-1}. The identity of **5** was established by comparison of IR data with the crystallographically characterized precipitate from Method B, and by elemental analysis (found for compound **5**: C 54.11, H 3.45, N 6.84). **Method B:** A solution of KHPht (2.04 g, 10 mmol) in 20 mL of water was added to a hot solution of $Co(O_2CMe)_2\cdot 4H_2O$ (2.49 g, 10 mmol) and bpy (1.56 g, 10 mmol) in 20 mL of MeOH. The resulting cherry-colored solution was stirred and heated for 1 h. Crystals of compound **5** suitable for X-ray diffraction studies crystallized after several days, and they were then filtered off, washed with MeOH, and dried in air. Yield: 3.00 g (75.6%). $C_{18}H_{14}CoN_2O_5$ (397.24): calcd. C 54.43, H 3.55, N 7.05, Co 14.84; found C 54.43, H 3.61, N 6.99, Co 14.80. IR (KBr): $\tilde{\nu}$ = 3274 br, 3119 m, 3078 m, 1610 s, 1600 s, 1578 s, 1542 vs, 1492 s, 1474 s, 1446 vs, 1420 vs, 1384 s, 1314 m, 1262 w, 1252 m, 1175 m, 1152 m, 1085 m, 1057 m, 1041 w, 973 w, 921 w, 869 m, 824 m, 815 m, 763 vs, 737 s, 721 m, 692 s, 651 s, 631 m, 576 w, 456 m cm^{-1}. **Method C:** $Co(O_2CMe)_2\cdot 4H_2O$ (0.25 g, 1 mmol) in 10 mL of MeOH was added to a hot solution of H_2Pht (0.17 g, 1 mmol) and bpy (0.16 g, 1 mmol) in 15 mL of MeOH. The resulting cherry-colored solution was heated at reflux for 1 h. Water (1 mL) was then added to the solution and it was allowed to slowly evaporate at room temp. over 3 weeks to give a crystalline precipitate of **5** and several crystals of **4** suitable for diffraction studies. The yield of **5** was 0.25 g (62.5%). It was further identified by comparison of its IR spectrum with the crystallographically characterized precipitate from Method B, and by elemental analysis; found for the title compound **5**: C 54.30, H 3.48, Co 14.90, N 7.01.

X-ray Crystallographic Study: Experimental data for **2a** were collected with an Enraf–Nonius CAD4 single-crystal diffractometer with Cu-K_α radiation at 140 K and were processed using a locally written program.[37] Experimental data for all other crystals were obtained with a KUMA KM4CCD-κ-axis diffractometer with graphite-monochromated Mo-K_α radiation at 130 K for **1**, 293 K for **2b** and **4**, 130 K for **3**, and at 170 K for **5**. The data were processed using the KUMA diffraction (Wroclaw, Poland) program. Crystal data and details of data collection and refinement for **1**–**5** are given in Table 5. The structures were solved by direct methods (SHELXS-97)[38] and refined by the full-matrix least-squares method on F^2 (SHELXL-97)[39] with an anisotropic approach for

the non-hydrogen atoms for **1**, **2a**, **3**, **4**, and **5**. The crystals of **2b** have a substructure: $I_{exp.}$ for *hkl* reflections with $l = 2n >> I_{exp}$ for *hkl* with $l = 2n + 1$. The structure of **2b** was refined by using the Konnert–Hendrickson conjugate-gradient algorithm (CGLS) at the early stages, and then the blocked full-matrix refinement was performed. Hydrogen atoms were located from the difference syntheses of electronic density, except for H of disordered phthalate moieties and water molecules. Localized hydrogen atoms were included in the subsequent refinement in the riding-model approximation for **1**, **2a**, **2b**, and **5**. For **3** and **4**, H-atoms were refined in an isotropic approximation. CCDC-258617 (**1**), -258618 (**2a**), -258619 (**2b**), -258939 (**3**), -258620 (**4**), and -258621 (**5**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

Supporting Information (see footnote on the first page of this article): Figure S1 shows the correlation between the two unit cells of **2a** and **2b**. Hydrogen-bonding interactions in compound **1** (Table S1) and compound **3** (Table S2).

Silanes/Oxygen/(Water): Green High-Energy-Density Materials

Yi Hong Ding*[a] and Satoshi Inagaki*[b]

Keywords: Silanes / Green high-energy-density materials / Ab initio calculations / Bond energy

Design of green high-energy-density materials as powerful as the well-known H_2/O_2 and N_2H_4/O_2 systems is a never-ending goal. Here, we study the energetic properties of reactions of silanes with oxygen (and gaseous water) by the bond energy procedure and high-level quantum chemistry calculations. The silanes/oxygen/(water) reactions finally lead to the green products, namely silica and water or silicic acids that exist in nature. The energy densities of these systems with respect to silica and water are higher than those of the conventional H_2/O_2 and N_2H_4/O_2 systems. Their energy densities with respect to silicic acids are also higher than or comparable to that of the N_2H_4/O_2 system. We propose that silanes/oxygen/(water) could be powerful green high-energy-density materials.

Introduction

Recently, high-energy-density materials (HEDM) have received considerable attention as energetic carriers and fuels in various fields.[1] On the other hand, green chemistry is actively seeking ways to produce materials benign to human health and the environment.[2] We proposed[3] green high-energy-density materials (green HEDM), which should satisfy four conditions: (i) they should have high energy densities; (ii) they should have considerable kinetic stability; (iii) the predominant products of the reactions should be green compounds, i.e., species benign to human health and environment, especially ones, e.g., N_2, H_2O, silica, etc., which exist in nature; and (iv) the possibility to actually synthesize them for practical use should be high. We previously designed seven N_2H_2O isomers as potential "green HEDMs" that might produce the green exhausts N_2 and H_2O.[3] In fact, the greenness of energetic materials has received recent attention.[4,5]

The bimolecular H_2/O_2 and N_2H_4/O_2 systems are conventional HEDMs, which can produce green exhausts (H_2O and N_2) from the reactions $H_2 + ½\ O_2 \rightarrow H_2O$ and $N_2H_4 + O_2 \rightarrow N_2 + 2\ H_2O$. Here we report a new type of bi- or termolecular green HEDMs: silanes/oxygen/(water) systems. By means of the bond energy procedure and high-level theoretical computations, we find that the energy densities of all the systems are higher than or comparable to those of the conventional H_2/O_2 and N_2H_4/O_2 systems. To the best of our knowledge, this represents the first consideration of the silanes as "**green HEDMs**", although the self-ignition and explosiveness of monosilane (SiH_4) in air has long been known, and SiH_4 has been widely used in the semiconductor industries.[6,7]

Results and Discussion

In the present work, we investigate the energetic properties of the reactions (Scheme 1) of silanes (Si_nH_m) (Figure 1) including acyclic silanes (1 Si_nH_{2n+2}), cyclic silanes (2 Si_nH_{2n}), ladder silanes (3 $Si_{2n}H_{2n+4}$), and cage silanes (4 $Si_{2n}H_{2n}$).

The combustion of SiH_4 ($SiH_4 + 2\ O_2 \rightarrow SiO_2 + 2\ H_2O$) releases energy (190.31 kcal/mol at the CBS-QB3 level). The energy density (ED in cal/g) for a reaction system is defined as the released energy (ΔE in cal/mol) divided by the mollar mass (M in g/mol). The molar masses of the elements H, N, O and Si are taken as 1, 14, 16 and 28 g/mol, respectively. The energy density of the SiH_4/O_2 system was calculated to be 1982 cal/g with respect to the products SiO_2 and H_2O. This value is close to that (2191 cal/g) of the known N_2H_4/O_2 system with respect to N_2 and H_2O. Yet, it is still lower than that (3108 cal/g) of the H_2/O_2 system with respect to H_2O. The products SiO_2 and H_2O can further undergo a hydration reaction and increase the energy density of the SiH_4/O_2 system. Two H_2O molecules were found to undergo a stepwise, barrierless addition to the Si=O double bonds of SiO_2, producing monosilicic acid $Si(OH)_4$.[8] The heat of the hydration, $SiO_2 + 2\ H_2O \rightarrow Si(OH)_4$, is 135.73 kcal/mol. The total released energy for $SiH_4 + 2\ O_2 \rightarrow Si(OH)_4$ is thus 326.04 kcal/mol (190.31 + 135.73). The hydration increases the energy density by 1414 cal/g ($135.73 \times 1000/96$). The energy density of the SiH_4/O_2 system with respect to the product $Si(OH)_4$ was calculated to be surprisingly high (3396 cal/g), as high as that (3108 cal/g) of the H_2/O_2 system and much higher than that (2191 cal/g) of the N_2H_4/O_2 system.

Higher silanes need water to be fully converted to $Si(OH)_4$ (see Scheme 1, $n \geq 2$). As listed in Table 1, the energy densities of the seven acyclic silane $(Si_nH_{2n+2})/O_2/H_2O$ systems with respect to $Si(OH)_4$ lie between 3396 ($n = 1$) and 2904 cal/g ($n = 7$) at the CBS-QB3 level. For the four cyclic silane $(Si_nH_{2n})/O_2/H_2O$ systems, the energy densities are between 2944 ($n = 3$) and 2819 cal/g ($n = 6$). The two ladder silane $(Si_{2n}H_{2n+4})/O_2/H_2O$ systems have the energy densities 2760 ($n = 3$) and 2709 cal/g ($n = 4$). The three cage silanes $(Si_{2n}H_{2n})/O_2/H_2O$ have the energy densities 2826, 2672 and 2606 cal/g for $n = 2$–4, respectively. The silanes/oxygen/water examined here by the high-level CBS-QB3 calculations are as powerful HEDMs as the H_2/O_2 or N_2H_4/O_2 systems. The energy densities of SiH_4/O_2 and $Si_2H_6/O_2/H_2O$ are even higher than that of H_2/O_2.

The high-level CBS-QB3 calculations are rather expensive for much larger silanes/oxygen/(water) systems. We employed a semiquantitative bond energy procedure on the assumption of the locality of chemical bonds. The bond energy (BE) is usually defined as the energy required to break a covalent bond in a gaseous substance. Computationally, for a diatomic molecule AB, the A–B bond energy is defined as $BE(A–B) = E(AB) – E(A) – E(B)$, in which $E(X)$ means the total energy of an atom or a molecule X. Then, the bond energy differences between the reactants and products in a chemical reaction are used to estimate the reaction heat. In more detail, for a typical reaction between two diatomic molecules: A–A + B–B → 2 A–B, the reaction heat is described as $\Delta E = 2BE(A–B) – BE(A–A) – BE(B–B)$. At the CBS-QB3 level, the bond energies are calculated to be 109.87 (O–H), 118.71 (O=O), 76.43 (Si–H), 107.42 (Si–O), 146.98 (Si=O), and 45.49 (Si–Si) kcal/mol.[9] The reaction heats (ΔE in kcal/mol) and energy densities (ED in cal/g) of the $Si_nH_m/O_2/H_2O$ systems with respect to $Si(OH)_4$ can be expressed[10,11] by Equation (1)

$$\Delta E = 219.99n + 26.507m \quad (1)$$

and Equation (2)

$$ED = 2291.563 + 276.115/(n/m) \quad (2)$$

As shown in Table 1, the energy densities of the 16 silane $(Si_nH_m)/O_2/H_2O$ systems with respect to $Si(OH)_4$ estimated from the bond energies are very close to the values predicted by the fully geometry-optimized CBS-QB3 calculations. The relatively large errors (100, 258 and 104 cal/g for **1a**, **4a** and **4b**) are caused by the high strain of the three-membered rings. The generally good agreement of the energy densities between the bond energy procedure and high-

Table 1. The energy density (in cal/g) of silanes (Si_nH_m)/oxygen/(water) with respect to silic acid based on the CSB-QB3 (ED1//CBS-QB3) and bond energy (ED1//bond energy) calculations, and with respect to silica based on bond energy (ED2//bond energy) calculations.

Si_nH_m Species	ED1//CBS-QB3	ED1//Bond energy	ED2//Bond energy

level CBS-QB3 calculations suggests the reliability and usefulness of the bond energy procedure.

Gaseous silicon dioxide can also polymerize to silica $(SiO_2)_p$ to increase the energy density of the Si_nH_m/O_2 systems. Similar accurate evaluation of the reaction heats and energy densities with respect to silica is surely impossible because of the infinite structure of silica. We applied the bond energy procedure. The heat of the reaction: $SiO_2 \rightarrow 1/p(SiO_2)_p$ is calculated from the bond energies to be 135.72 kcal/mol ($107.42 \times 4 - 146.98 \times 2$).[12] This is the same value as that estimated for the hydration because the same numbers of each kind of bonds are broken or formed in the polymerization and the hydration. The reaction heats and energy densities of the $(Si_nH_m)/O_2$ systems with respect to silica and water can be generally expressed by Equation (3)[12,13]

$$\Delta E = 219.99n + 26.507m \quad (3)$$

and Equation (4)

$$ED = 3666.500 - 108.192/(n/m + 0.15) \quad (4)$$

The heat (326.02 kcal/mol) of the reaction $SiH_4 + 2\ O_2 \rightarrow$ silica$[1/p(SiO_2)_p] + 2\ H_2O$ estimated from the bond energy procedure is in excellent agreement with the experimental value of 325.2 ± 1.2 kcal/mol.[14] The estimated reaction heats for the transformation of other silanes (599.02 for Si_2H_6, 872.03 for Si_3H_8, and 1145.03 kcal/mol for Si_4H_{10}) in the gas phase to silica are a little larger than those (573.3, 835.1 ± 0.7 and 1092.4 kcal/mol, respectively[14]) observed for liquid Si_2H_6, Si_3H_8 and Si_4H_{10}; this discrepancy is due to the latent heat of vaporization. With respect to the products silica and water, all of the 16 silanes have energy densities equal to or higher than that (3396 cal/g) of SiH_4 (Table 1), which is higher than that of the H_2/O_2 system. When the increment caused by strain is taken into account, the energy densities of Si_3H_6, Si_4H_4, and $Si_6H_6/O_2/H_2O$ with respect to silica and water are expected to be as high as 3600, 3830, and 3676 cal/g, respectively.

The bond energy procedure shows that the energy densities of the $Si_nH_m/O_2/H_2O$ systems depend on the Si/H ratio (n/m). The energy density with respect to silicic acid increases as the Si/H ratio decreases: 2292 ($n/m \rightarrow \infty$) $<$ ED $\leq$ 3396 (n/m = ¼), while that with respect to silica and water increases with the Si/H ratio: 3396 (n/m = ¼) $\leq$ ED $\leq$ 3667 ($n/m \rightarrow \infty$). The upper limit (3396 cal/g) of the energy density with respect to silicic acid is identical to the lower limit with respect to silica and water. This clearly shows that the polymerization is preferable to the hydration because stable water is needed to complete the hydration. A high Si/H ratio is unfavorable for the energy density with respect to silicic acid, yet it is desirable for the energy density with respect to silica and water. The largest energy density (3667 cal/g) is expected for the combustion of the silane Si_nH_m ($n/m \rightarrow \infty$) followed by the polymerization to silica. The limit "$n/m \rightarrow \infty$" means pure silicon. The bond energy procedure also shows that the silanes with the same Si/H ratio (n/m) have the same energy densities. The cage silanes $(Si_{2n}H_{2n})/O_2/H_2O$ (n/m = 1) have higher energy densities than the cyclic silanes $(Si_nH_{2n})/O_2/H_2O$ (n/m = 0.5) with respect to silica and water, while the opposite is the case with the energy with respect to silicic acid.

The final products of the silane/oxygen/(water) systems, i.e., monosilicic acid $Si(OH)_4$, silica and water, all exist in nature and do no harm to the environment or humans. Monosilicic acid $Si(OH)_4$ is known to be "the dominant form of silicon in natural waters."[15] Silica is abundant[16] and "green"! Monosilane (**1a**) and disilane (**1b**) are now readily available commercially. The acyclic (**1c**,[17] **1d**[17] and **1e**[18]) and cyclic (**2c**[19] and **2d**[20]) silanes have already been synthesized in laboratory. The substituted species of cyclic (**2a**[21] and **2b**[22]), ladder (**3a**[23] and **3b**[24]), and cage (**4a**,[25] **4b**[26] and **4c**[27]) silanes have also been synthesized. Surely, here we only present a limited number of silanes (**1**–**4**) as examples. Given the molecular formula Si_mH_n, silanes could have various structural forms ranging from chainlike, cyclic, ladder, and even cage-type species. The green HEDMs with higher Si/H ratios have larger power. From a synthetic viewpoint, silyl (Si_pH_{2p+1}) derivatives of cyclic and cage silanes are also expected to be promising as green HEDMs.[28] Thus, silanes satisfy the green HEDM conditions (ii) considerable kinetic stability and (iv) high possibility of synthesis.

We are aware that the simplest SiH_4/O_2 system has already been utilized in a microengine for explosive combustion.[6] From the preceding discussions, we know that with respect to the green products $SiO_2 + H_2O$, the power of Si_nH_m/O_2 is between 3396 (n/m = 1/4) $\leq$ ED $\leq$ 3667 ($n/m \rightarrow \infty$). Surely, the power of SiH_4/O_2 is just the lower limit. So there is great hope to design various types of silane systems more powerful than the SiH_4/O_2 system. We optimistically hope that many kinds of interesting and powerful silanes could be synthesized in future as green HEDMs because only the Si/H ratio and strain determines the power. The systems are not only powerful but also "green". We also know that alkenyl silanes such as tetraallylsilane[29] and triallylsilane[30] and alkynyl silanes have been used as igniters. But such systems are surely much less powerful than our designed Si_nH_m systems because they have much lower Si/H ratios.

Conclusion

In summary, silanes/oxygen/(water) systems are green HEDMs. The energy densities of these systems are higher than or comparable to the conventional H_2/O_2 and N_2H_4/O_2 systems. The Si/H ratio together with ring strain is important for the HEDM power of silanes.

Computational Section

For the small and medium-sized silanes/oxygen/(water) systems producing silicic acid, ab initio calculations are performed to obtain the heat of reaction using the composite CBS-QB3 method that is incorporated in the Gaussian program package.[32] This method follows the complete basis set, CBS-Q, model chemistry

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

using B3LYP hybrid density functional geometries and frequencies, and has been demonstrated to have high accuracy on a variety of thermochemical properties.[33]

We apply the bond energy procedure for the larger reaction systems producing silicic acid and all the reaction systems producing silica. The bond energies are calculated by the CBS-QB3 method, which is known to give the atomic energies through inclusion of the atomic spin-orbit interactions (readily available from experiment) consistent with the experimental heats of formation of the atoms, although no relativistic corrections are made.[33]

The less computationally expensive B3LYP method underestimates the energy density of the silanes/oxygen/(water) systems. In fact, the energy densities of the SiH_4, Si_2H_6, Si_3H_8, and $Si_7H_{16}/O_2/(H_2O)$ reaction systems with respect to $Si(OH)_4$ are 2782, 2591, 2524, and 2446 cal/g,[31] which are significantly lower than the CBS-QB3 values (3396, 3120, 3020, and 2904 cal/g, respectively).

[8] All the intermediates and transition states involved in the addition reaction of two H_2O molecules to SiO_2 lie energetically lower than $SiO_2 + 2H_2O$.
[9] The following reactions: $H_2O \rightarrow 2H + {}^3O$, ${}^3O_2 \rightarrow 2\,{}^3O$, $SiH_4 \rightarrow {}^3Si + 4H$, $Si(OH)_4 \rightarrow {}^3Si + 4^3O + 4H$, $SiO_2 \rightarrow {}^3Si + 2^3O$ and $Si_2H_6 \rightarrow 2^3Si + 6H$ are used to calculate the bond energies of the O–H, O=O, Si–H, Si–O, Si=O, and Si–Si bonds that are involved in the reaction systems. Take the reaction $H_2O \rightarrow 2H + {}^3O$ as an example. The CBS-QB3 total energies of H_2O, H, and ${}^3O$ are –76.337462, –0.499818, and –74.987638 a. u., respectively. The energy required to break all the bonds of H_2O is $\Delta E = |2\times(-0.499818) + (-74.987638) - (-76.337462)|$ a. u. = 219.746 kcal/mol. Then the average O–H bond energy is BE(O–H) = 219.746/2 = 109.87 kcal/mol.
[10] In silanes, each Si atom is bonded to four Si or H atoms and each H atom to one Si atom. So there are $(4n - m)/2$ Si–Si and m Si–H bonds in one Si_nH_m.
[11] The calculation details of the reaction heats (ΔE) and energy densities (ED) of $Si_nH_m + (n + m/4)\,O_2 + (2n - m/2)H_2O \rightarrow n\mathrm{Si(OH)_4}$ are as follows: $\Delta E = [4n\times\mathrm{BE(Si–O)} + 4n\times\mathrm{BE(O–H)}] - [(4n - m)/2\times\mathrm{BE(Si–Si)} + \mathrm{m}\times\mathrm{BE(Si–H)} + (n + m/4)\times\mathrm{BE(O{=}O)} + (2n - m/2)\times 2\times\mathrm{BE(O–H)}] = [4\times\mathrm{BE(Si–O)} - 2\times\mathrm{BE(Si–Si)} - \mathrm{BE(O{=}O)}]n + [\tfrac{1}{2}\times\mathrm{BE(Si–Si)} - \mathrm{BE(Si–H)} - \tfrac{1}{4}\times\mathrm{BE(O{=}O)} + \mathrm{BE(O–H)}]m = 219.99n + 26.507m$ kcal/mol. The molar mass of $n\mathrm{Si(OH)_4}$ is $M = 96n$ g/mol. So $\mathrm{ED} = 1000\times\Delta E/M = 2291.563 + 276.115/(n/m)$.
[12] Suppose the polymerization: $SiO_2 \rightarrow 1/p(SiO_2)_p$. In silica [$1/p(SiO_2)_p$], each Si atom in the center of a tetrahedron is bonded to four O atoms. Each O-atom is bonded to two Si atoms. There are 2×2 Si–O bonds around the two O atoms. The total Si–O number is 8 (4 + 2×2). Because each bond is shared by two atoms, the exact number of the Si–O bonds in $1/p(SiO_2)_p$ is 8/2 = 4. As a result, in the polymerization process, two Si=O bonds in each SiO_2 molecule are transformed into four Si–O bonds in silica.
[13] For the $Si_nH_m + (n + m/4)\,O_2 \rightarrow n/p(SiO_2)_p + m/2H_2O$ process, the reaction heats are $\Delta E = 219.99\,n + 26.507m$ kcal/mol, the same as those for the $Si_nH_m + (n + m/4)O_2 + (2n - m/2)H_2O \rightarrow n\mathrm{Si(OH)_4}$ process. The molar mass of $n/p(SiO_2)_p + m/2H_2O$ is $M = 60n + 9m$ g/mol. So $\mathrm{ED} = 1000\times\Delta E/M = 3666.500 - 108.192/(n/m + 0.15)$ cal/g.

Ruthenium Complexes of the Scorpionate Ligand Bis(3,5-dimethylpyrazol-1-yl)-dithioacetate and the Effect of Nitric Oxide Coordination

Mayreli Ortiz,[a] Ariadna Penabad,[a] Alicia Díaz,[a] Roberto Cao,*[a] Antonio Otero,[b] Antonio Antiñolo,[b] and Agustín Lara[b]

Keywords: N ligands / Nitric oxide / Ruthenium / S ligands / Scorpionate ligands

Six new ruthenium(II) complexes with the scorpionate ligand bis(3,5-dimethylpyrazol-1-yl)dithio-κ^3N,N,S-acetate (bdmpzdta) were obtained by treatment of the ligand with $RuCl_3$ or $[RuCl_3(NO)]$ in 1:1 or 2:1 molar ratios in the presence or absence of ethylenediamine. In all six complexes the pyrazolic rings lie in the equatorial plane. The mononitrosyl complexes present a sharp ν(NO) band in the range 1864–1859 cm^{-1} for samples prepared either as KBr tablets or dichloromethane solutions. In the case of $[Ru(NO)(bdmpzdta)_2]Cl$ (**7**), the dithiocarboxylate group of one of the ligands is not coordinated (κ^2N,N). In the other five complexes, however, bdmpzdta behaves as a κ^3N,N,S scorpionate ligand. When the complexes obtained from $RuCl_3$ were dissolved in dichloromethane and NO was bubbled through the solution, a high degree of coordination of NO^+ was observed, according to IR, UV and voltammetric studies.

Introduction

The physiological functions of nitric oxide (NO) have been widely studied in the past decade as dysfunction in NO metabolism has been associated with a great number of diseases.[1,2] When a patient has a severe infection, as in so-called septic shock, the body generates such a large amount of nitric oxide that the patient's blood pressure practically collapses. A specific inhibitor for induced nitric oxide synthase, iNOS, has yet to be found. An alternative to save patients' lives in cases of septic shock involves finding NO scavengers that can be used when NO is produced in relatively large amounts.

Ru^{III} complexes are known to coordinate NO to form stable Ru^{II} mononitrosyl complexes and these can therefore act as efficient NO scavengers. A number of different Ru^{III} complexes with polyaminocarboxylic acids have been studied as NO scavengers.[3–5]

Recently, we reported different ruthenium(II) complexes with the bis(3,5-dimethylpyrazol-1-yl)methane derivatives bis(3,5-dimethylpyrazol-1-yl)methanesulfonate (bdmpzsa) and bis(3,5-dimethylpyrazol-1-yl)acetate (bdmpza).[6,7] Both ligands lie in the equatorial plane and coordinate as κ^3N,N,O scorpionates, but with a weak interaction through the oxyanionic moiety. Mononitrosyl complexes of Ru^{II} were also obtained from the same ligands with NO coordinated in the apical position.[7] NO was found to have a strong *trans* influence on the oxyanionic moiety. As a consequence, the mononitrosyl bis(bis-pyrazolic) complexes of Ru^{II} show an on/off switching process of the oxyanionic moiety *trans* to the coordinated NO.

We report here the main results obtained on Ru^{II} complexes with a similar ligand: bis(3,5-dimethylpyrazol-1-yl)-dithioacetate (bdmpzdta; **1**), which is depicted in Figure 1. This ligand is expected to behave as a κ^3N,N,S scorpionate, but with a softer anionic moiety. For this reason, a higher scorpionate affinity for Ru^{II} than the previously studied bdmpza and bdmpzsa ligands is to be expected.

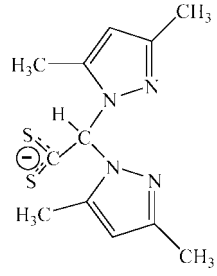

Figure 1. Schematic representation of ligand **1**.

Results and Discussion

In a previous paper,[6] we reported a kinetic study of the interaction of $RuCl_3$ with bis(3,5-dimethylpyrazol-1-yl)ace-

tate (bdmpza; $k = 1.1 \times 10^{-3}$ s^{-1}), and bis(3,5-dimethylpyrazol-1-yl)methanesulfonate (bdmpzsa; $k = 1.6 \times 10^{-3}$ s^{-1}), in a 1:1 molar ratio in methanol. Coordination of the ligand involves the reduction of Ru^{III} to Ru^{II}. We assumed that the reducing agent was methanol, but could not detect the corresponding oxidation product. After this study was published, a signal at δ = 9.2–9.4 ppm, corresponding to methanal, was detected in the ^{1}H NMR spectra when the reaction was carried out in an NMR tube.

The interaction of $RuCl_3$ with bis(3,5-dimethylpyrazol-1-yl)dithioacetate (bdmpzdta; **1**) was studied spectrophotometrically in methanol in an effort to confirm the reduction of Ru^{III}, as observed previously with similar ligands. A decrease in the absorbance of the bdmpzdta band at 350 nm and the appearance and increase in the absorbance of the MLCT band at approximately 300 nm were observed (see Figure 2).

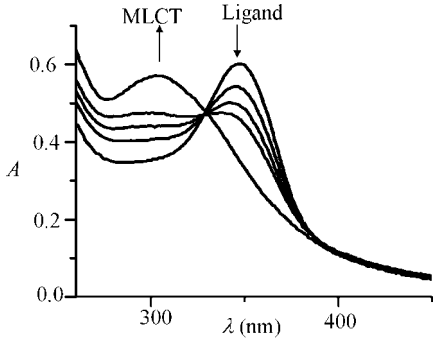

Figure 2. Variations in the UV/Visible spectra with time for the interaction of $RuCl_3$ with bdmpzdta (1:1 molar ratio) in methanol.

This MLCT band corresponds to the transition from Ru^{II} to **1**. A signal at δ = 9.35 ppm (due to methanal) was detected in the ^{1}H NMR spectra when the reaction was carried out in an NMR tube. From the variations observed in the MLCT band, pseudo first-order rate constants of $k = 1.2 \times 10^{-4}$ s^{-1} and 3.4×10^{-4} s^{-1} were obtained for 1:1 and 1:2 Ru^{III}:bdmpzdta molar ratios, respectively. Both values are ten times smaller than those reported previously for similar ligands (bdmpza and bdmpzsa).[6] Furthermore, with these latter ligands the rate constants for 1:2 molar ratios could not be detected using the same procedure.

The complete reduction of Ru^{III} was confirmed by EPR spectroscopy − all the complexes are silent. As one would expect, all NMR spectra contained sharp signals.

The interaction of ligand **1** with $RuCl_3$ gave the complexes $[\{Ru(H_2O)(bdmpzdta)(Cl)\}]_2$ (**2**), [Ru(bdmpzdta)(en)Cl] (**3**) and $[Ru(bdmpzdta)_2]$ (**4**) using procedures similar to those reported for bdmpza and bdmpzsa.[6] Similarly, $[RuNO(bdmpzdta)(Cl)_2]$ (**5**), $[RuNO(bdmpzdta)(en)]Cl_2$ (**6**) and $[RuNO(bdmpzdta)_2]Cl$ (**7**) were synthesised by the interaction of **1** with $[RuCl_3(NO)]$.

The ^{1}H and ^{13}C NMR spectra of **2**, **3**, **4**, **5** and **6** gave only one set of signals for the pyrazolic rings and ethylenediamine (**3**, **6**). In the case of compound **7** (Figure 3) this statement is not completely accurate since the signals of some of the atoms show a slight (or moderate) splitting. The observed equivalence in the NMR signals indicates that the pyrazolic rings of ligand **1** lie in the equatorial plane, as does the ethylenediamine unit in complexes **3** and **6** (Figure 3).

The composition and low solubility of complex **2** in polar organic solvents suggests a dimeric form in which the two chloride ions in the equatorial plane form bridges between the two Ru^{II} centres (Figure 3), similar to a previously reported structure.[8] Under such conditions, and with the water molecule (from $RuCl_3 \cdot xH_2O$) at the apical position *trans* to the coordinated dithiocarboxylate group, the two pyrazolic rings remain equivalent. Each of the two chloride anions in the equatorial plane of compound **5** is coordinated to one Ru^{II} (Figure 3) and the octahedral structure is achieved without the need for bridge formation.

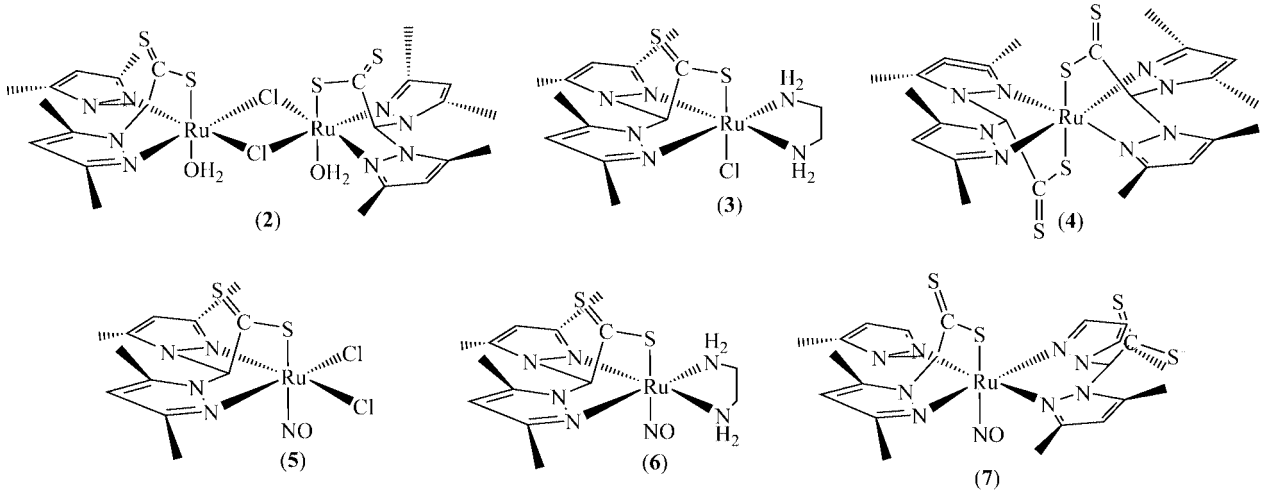

Figure 3. Schematic representation of the synthesised complexes **2**–**7**.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

As expected, the dithiocarboxylate group (a soft base) is very strongly coordinated at an apical position to Ru^{II} (soft acid) through a sulfur atom (Figure 3). Evidence for this structure is provided by the significant shift to higher field of the CS_2^- and aliphatic CH signals in the ^{13}C NMR spectra. Moreover, a significant shift in the $\nu_{C=S}$ and ν_{C-S} stretching bands is observed with respect to the IR spectrum of the free ligand. Coordination of the CS_2^- moiety to Ru^{II} is appreciably stronger than that observed for the CO_2^- moiety of bdmpza and the SO_3^- moiety of bdmpzsa, as reported previously.[6,7,9] Consequently, ligand **1** behaves as a κ^3N,N,S scorpionate ligand.

The strong coordination of the CS_2^- moiety should cause a slight distortion of the two pyrazolic rings in **1**. This distortion takes the rings out of the equatorial plane, although the effect is the same for both rings. This could be the reason why only one set of signals is observed even in the presence of this distortion. In this sense, it is interesting to point out that Otero et al. have investigated Ti^{IV}-bdmpzdta complexes and reported a distortion in the planarity of the pyrazolic rings.[10] In this latter case the soft CS_2^- moiety was coordinated to a hard acid (Ti^{IV}).

The interaction of ligand **1** with Ru^{II} should initially pass through the coordination mode κ^2N,N. The coordination of the CSS^- group should require additional energy and time in order to achieve the formation of the stable Ru^{II}–S bond. This process involves a distortion in the equatorial plane of the pyrazolic rings. Such a situation could explain the kinetically slow coordination of ligand **1** (ten times slower than for bdmpza and bdmpzsa).[6]

The coordination of NO in compounds **5**, **6** and **7** was fully characterised by IR spectroscopy. A sharp and intense band is observed at around 1860 cm^{-1} for all the mononitrosyl complexes, whether the samples were prepared as KBr tablets or CH_2Cl_2 solutions. This band was assigned to the ν(NO) stretching vibration and indicates that in these complexes NO is coordinated in a linear mode, as a $\{RuNO\}^6$ unit according to the Enemark–Feltham formalism.[11] As expected, these ν(NO) values are lower than that for the $[RuCl_3(NO)]$ starting material.

A single set of signals was observed for ligand **1** in the NMR spectra of compounds **5** and **6**, indicating that in the nitrosyl complexes NO is coordinated at the apical position *trans* to the bonded dithiocarboxylate moiety. It is worth pointing out that a single set of signals was also observed for ethylenediamine in compound **6**.

An interesting situation was found for $[Ru(bdmpzdta)_2NO]Cl$ (**7**) as the ^{13}C NMR spectrum (Figure 4) contains two signals for the CS_2^- group (δ = 211.0 and 243.2 ppm). The latter value corresponds to the free CS_2^- group that does not replace NO. In this complex one bdmpzdta is therefore coordinated as a bidentate ligand (κ^2N,N) and the other as a κ^3N,N,S scorpionate ligand. The difference between the two coordinated ligands in compound **7** is that the bidentate one is not distorted from the equatorial plane, while the scorpionate κ^3N,N,S ligand should be. This arrangement explains the observed splitting of the signals in the NMR spectra of **7**, an effect that is particularly significant for the aliphatic CH signal (Figure 4). The signal at δ = 70.3 ppm was assigned to the CH aliphatic group bound to the coordinated CS_2^-, while the signal at δ = 83.4 ppm corresponds to the free CS_2^-.

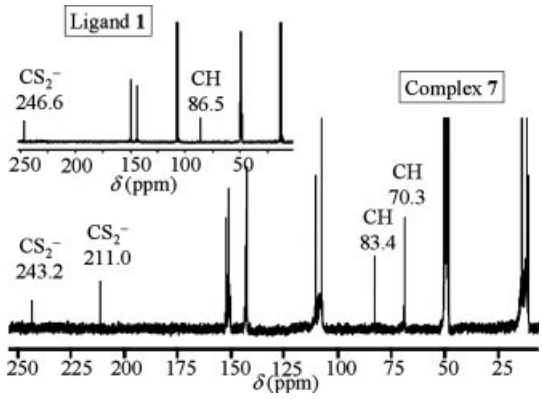

Figure 4. ^{13}C NMR spectra of ligand **1** (inset) and complex **7** in CD_3OD.

In the nitrosyl complexes $[Ru(NO)(L)_2]Cl$ (where L = bdmpza or bdmpzsa), a dynamic on/off switching exchange between the two oxyanionic groups was found to take place in the coordination to Ru^{II} at the only remaining vacant position (*trans* to NO).[7] This process is favoured by the powerful NO *trans* influence over the oxyanionic moiety. In contrast, such an exchange was not observed in complex **7** and the only Ru^{II}–S bond formed was not dissociated by NO in the *trans* position.

The *trans* influence of NO on the dithiocarboxylate group is evidenced by the marked shift observed (about 20 ppm) in the ^{13}C NMR signal relative to that in the corresponding NO-free complex. It appears that the ionic character of this bond is increased when coordinated NO weakens the Ru^{II}–S bond and increases the positive charge on the metal. In this way, the coordinated sulfur atom could increase its electron density with the consequent shielding of the CS_2 carbon atom. The coordination of NO appears to cause a strong electronic shift along the S–Ru^{II}–NO axis, which is also seen in the MLCT band as a hypsochromic shift (by about 10 nm). This change is observed in the UV/Vis spectra when comparing compounds **2**, **3** and **4** with the corresponding mononitrosyl complexes **5**, **6** and **7**, respectively. The mononitrosyl complexes (**5**, **6** and **7**) do not liberate NO under a strong vacuum and in compound **7** the second CS_2^- moiety does not substitute NO. These observations demonstrate the high stability of the Ru^{II}–NO bond. Taking this into consideration, we decided to study the possible interaction of compounds **2**, **3** and **4** with NO in an attempt to obtain the corresponding complexes with coordinated NO^+ ligand. In order to achieve this aim, NO was bubbled through dichloromethane solutions of these complexes under an oxygen-free inert atmosphere. The solutions, which were initially brown, became reddish after 15–20 min. These compounds were isolated and characterised by UV/Vis and IR spectroscopy. The UV/Vis spectra

Table 1. Spectroscopic properties of the compounds obtained after bubbling NO through CH_2Cl_2 solutions of **2**–**4**.

Compounds	IR ($\tilde{\nu}$, cm^{-1})			UV (λ, nm)
	ν(NO)	ν(C=S)	ν(C–S)	
[{Ru(bdmpzdta)(Cl)(H_2O)}]$_2$ (**2**) + NO(g)	1866	1028	784	286
[Ru(bdmpzdta)(Cl)(en)] (**3**) + NO(g)	1862	1032	782	290
[Ru(bdmpzdta)$_2$] (**4**) + NO(g)	1857	1034	786	292

are very similar (Table 1) to those of complexes obtained from [$RuCl_3$(NO)] (compounds **5**, **6** and **7**). A strong sharp band is observed in the IR spectra of these complexes at around 1860 cm^{-1} and this is assigned to ν(NO). This band was seen when the samples were prepared either as KBr tablets or CH_2Cl_2 solutions (Figure 5 for complex **3** with NO bubbled through). The positions of the ν(NO) bands are very similar to those in **5**, **6** and **7**, respectively, as depicted in Figure 5 for compound **3** (after NO bubbled through) and mononitrosyl complex **6**.

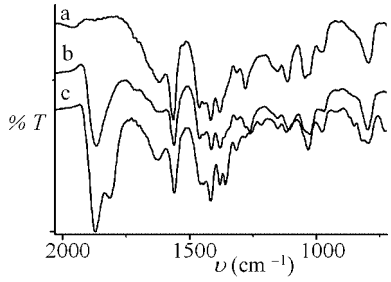

Figure 5. IR spectra of a) compound **3**, b) compound **3** with NO bubbled through and c) compound **6**.

The areas of the ν(NO) bands of the compounds after bubbling NO through were compared with those obtained from [$RuCl_3$(NO)], with the ν(C=S) and ν(C–S) stretching bands taken as references. The areas of the ν(NO) bands of the former compounds correspond to 75–90% of those of the latter. This indicates that a high percentage of Ru^{II} coordinates NO. Possible explanations for the incomplete coordination of NO include unavoidable partial oxidation of NO and its relatively low solubility in CH_2Cl_2. The fact that 100% NO coordination was not achieved in any of these compounds means that they are not pure. Purification of the nitrosyl compound by bubbling NO through solutions of the complexes was not successful.

The ^1H NMR spectra gave an overlap of signals that was not possible to interpret. The ^{13}C NMR spectra of the compounds obtained after bubbling NO through show a double set of signals that are not well resolved in most cases. A well-defined ^{13}C NMR spectrum was obtained only for the product of bubbling NO through a solution of complex **2** (Supporting Information, Figure S1). The differences between the chemical shifts of both set of signals, one of which is much more intense than the other, mainly lie in the range 0.1–1.1 ppm. For the CSS^- signal the observed difference was about 20 ppm. The set of signals with highest intensity is very similar to that of the spectra of the compounds obtained from [$RuCl_3$(NO)] (**5**–**7**), whereas the other set of signals is similar to that of the spectra of the corresponding NO-free complexes (**2**–**4**). Evidently, the compounds obtained by bubbling NO through solutions of complexes **2**–**4** show very similar characteristics (Table 1) to those found for compounds **5**–**7**, respectively, and should therefore be considered as equivalent. This fact should be attributed to the coordination of NO^+ by the bubbled complexes that is assumed to be present in this type of solution.[12]

DMSO solutions of the compounds obtained by bubbling NO through solutions of complexes **2**, **3** and **4** in dichloromethane were studied by voltammetry. The results of these experiments were also similar to those found for compounds **5**, **6** and **7**, respectively. The irreversible cathodic wave assigned to the Ru^{II}–$NO^+ + e^- \rightarrow Ru^{II}$–$NO^0$ reduction[13] is observed in the voltammograms of these six complexes between –700 and –720 mV, as depicted in Figure 6 for complexes **5** and (**2** + NO).

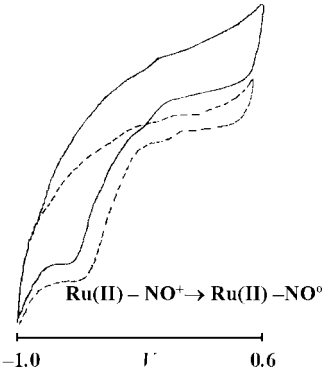

Figure 6. Cyclic voltammograms of complexes **5** (---) and (**2** + NO) (—).

Although the interaction of complexes **2**, **3** and **4** with NO was studied in dichloromethane, it is reasonable to consider the possibility that they could behave as NO scavengers in a biological system. This possibility is currently under investigation.

Conclusions

The interaction of $RuCl_3$ with bis(3,5-dimethylpyrazol-1-yl)dithioacetate (bdmpzdta; **1**) in methanol leads to the reduction of Ru^{III} to Ru^{II} with the stabilisation of the latter species. Reaction of compound **1** with [$RuCl_3$(NO)] gives new, stable nitrosyl complexes. In all six complexes the pyrazolic rings of ligand **1** lie in the equatorial plane with the CS_2^- group also coordinated. The ligand therefore behaves as a κ^3N,N,S scorpionate system. One exception to this trend was observed in complex **7**, where the second ligand

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

is coordinated in a κ^2N,N manner with its dithiocarboxylate moiety free.

When NO was bubbled through solutions of complexes **2**, **3** and **4** in dichloromethane, a high level of coordination of NO^+ took place to give compounds that are apparently equivalent to complexes **5**, **6** and **7**, respectively. For example, the ν(NO) band of the latter lies in the range 1864–1859 cm^{-1}, while for the former complex the band appears at 1866–1857 cm^{-1}. The irreversible voltammetric wave corresponding to the Ru^{II}–$NO^+ + e^- \rightarrow Ru^{II}$–NO° reduction is observed in the same range (–700 and –720 mV) for both sets of compounds.

Experimental Section

General Remarks: All chemicals used were of high quality and purchased from Aldrich. The solvents were dried and distilled before use.

Spectroscopy: The electronic spectra were recorded with an Ultrospec III spectrophotometer (Pharmacia-LKB) interfaced with a microcomputer for data acquisition. IR spectra were recorded with a Perkin–Elmer 883 FT-IR spectrometer, with samples prepared as KBr tablets or as CH_2Cl_2 solutions in CaF_2 cells. NMR spectra were obtained with a Bruker AC 250 (62.89 MHz for ^{13}C) spectrometer equipped with an ASPECT 3000 computer. All samples were dissolved in CD_3OD (30 mg/0.4 mL) and recorded at 300 K. The reported chemical shifts (δ) are expressed in ppm and referenced to tetramethylsilane (TMS). The nature of each carbon atom was determined using the DEPT technique with proton pulses at θ = 135°. X-band EPR spectra of nitrosylruthenium complexes at 120 K were obtained on a Bruker EMX-300 X-band spectrometer operating at a frequency of 9.5 GHz or aBruker ESP 300 spectrometer operating at 100 KHz field modulation for dichloromethane solutions and polycrystalline samples, respectively. The frequencies were measured with a Hewlett–Packard 5352B frequency counter. The temperature was regulated with an Oxford Instruments ESR 900 continuous flow helium cryostate (low temperature) and Bruker RS-232 continuous flow nitrogen thermostat (room temperature).

Techniques for Kinetic Determinations: The UV/Vis kinetic determinations were performed spectrophotometrically at 300 K with the appropriate software. Methanolic solutions containing 5.8×10^{-4} M $RuCl_3$ and corresponding amounts of **1** were studied in 1-cm quartz optical cells.

Electrochemical Measurements: Electrochemical measurements were carried out with a Yanaco P-900 cyclic polarograph coupled to a Graphted WX1000 X-Y recorder using a standard three-holder cell. Glassy carbon, Pt and Ag/AgCl (saturated) were used as working, counter and reference electrodes, respectively. The cyclic voltammograms of the complexes (0.01 M) in DMSO solution, which had been previously deoxygenized, were recorded with tetra-*n*-butylammonium tetrafluoroborate (0.2 M) as supporting electrolyte.

[{Li(bdmpzdta)(H_2O)}$_4$] (1): This ligand was prepared as reported previously.[10,14]

[{Ru(bdmpzdta)(Cl)(H_2O)}]$_2$ (2): $RuCl_3$ (0.050 g, 0.24 mmol) was dissolved in methanol (20 mL) and ligand **1** (0.069 g, 0.24 mmol) was added in two portions. The mixture was stirred for 4 h in an inert atmosphere. The solvent was removed from the resulting brownish suspension, the product was dissolved in dichloromethane, and the LiCl filtered off. The solvent was removed from the filtrate under vacuum to give a brown, hygroscopic solid. Yield: 0.166 g (80%). $C_{12}H_{17}ClN_4ORuS_2$ (433.7): calcd. C 33.21, H 3.92, N 12.92; found C 33.23, H 3.94, N 12.90. IR (KBr): $\tilde{\nu}$ = 1562 ν(C=N), 1027 ν_{as}(C=S), 791 cm^{-1} ν_s(C–S). UV/Vis: λ (log ε) = 295 nm (3.36, MLCT). ^1H NMR (250 MHz, CD_3OD, 298 K): δ = 2.12 (s, 6 H, Me^3), 2.40 (s, 6 H, Me^5), 5.95 (s, 2 H, H^4), 7.34 (s, 1 H, CH) ppm. $^{13}C\{^1H\}$ NMR/DEPT-135 (62.89 MHz, CD_3OD, 298 K): δ = 12.4 (+, Me^5), 13.8 (+, Me^3), 76.4 (+, CH), 105.1 (+, C^4), 143.2 (0, C^5), 152.5 (0, C^3), 240.5 (0, CS_2^-) ppm.

[Ru(bdmpzdta)(Cl)(en)] (3): A procedure similar to that described for **2** was used, but with the addition of ethylenediamine (16 μL, 0.24 mmol) before ligand **1**. A brown crystalline solid was obtained. Yield: 0.097 mg (84%). $C_{14}H_{23}ClN_6RuS_2$ (475.7): calcd. C 35.33, H 4.84, N 17.66; found C 35.36, H 4.87, N 17.64. IR (KBr): $\tilde{\nu}$ = 1562 ν(C=N), 1030 ν_{as}(C=S), 792 ν_s(C–S), 3233 $\nu_{as}(NH_2)$, 3127 cm^{-1} $\nu_s(NH_2)$. UV/Vis: λ (log ε) = 297 nm (3.53, MLCT). ^1H NMR (250 MHz, CD_3OD, 298 K): δ = 2.10 (s, 6 H, Me^3), 2.31 (s, 6 H, Me^5), 5.86 (s, 2 H, H^4), 7.12 (s, 1 H, CH), 2.24/2.33 [t, 4 H, CH_2(en)] ppm. $^{13}C\{^1H\}$ NMR/DEPT-135 (62.89 MHz, CD_3OD, 298 K): δ = 12.4 (+, Me^5), 13.8 (+, Me^3), 76.3 (+, CH), 105.1 (+, C^4), 143.2 (0, C^5), 152.5 (0, C^3), 239.6 (0, CS_2^-) ppm.

[Ru(bdmpzdta)$_2$] (4): A procedure similar to that described for **2** was used, but with the addition of a double quantity of ligand **1** (0.138 g, 0.48 mmol) in four portions. A brown crystalline solid was obtained. Yield: 0.141 g (90%). $C_{24}H_{30}N_8RuS_4$ (659.2): calcd. C 43.70, H 4.55, N 16.99; found C 43.73, H 4.58, N 16.97. IR (KBr): $\tilde{\nu}$ = 1562 ν(C=N), 1029 ν_{as}(C=S), 790 cm^{-1} ν_s(C–S). UV/Vis: λ (log ε) = 298 nm (3.14, MLCT). ^1H NMR (250 MHz, CD_3OD, 298 K): δ = 2.15 (s, 12 H, Me^3), 2.35 (s, 12 H, Me^5), 6.06 (s, 4 H, H^4), 7.05 (s, 2 H, CH) ppm. $^{13}C\{^1H\}$ NMR/DEPT-135 (62.89 MHz, CD_3OD, 298 K): δ = 13.4 (+, Me^5), 12.2 (+, Me^3), 75.7 (+, CH), 103.5 (+, C^4), 144.9 (0, C^5), 157.9 (0, C^3), 230.5 (0, CS_2^-) ppm.

[Ru(bdmpzdta)(Cl)$_2$(NO)] (5): [$RuCl_3$(NO)] (0.050 g, 0.21 mmol) was dissolved in methanol (20 mL) and ligand **1** (0.060 g, 0.21 mmol) was added in two portions. The reaction mixture was stirred for 4 h under an inert atmosphere. The solvent was removed from the resulting reddish suspension, the product was dissolved in dichloromethane, and the LiCl was filtered off. The solvent was removed from the filtrate under vacuum to give a brown hygroscopic solid. Yield: 0.071 mg (70%). $C_{12}H_{15}Cl_2N_5ORuS_2$ (481.2): calcd. C 29.93, H 3.12, N 14.55; found C 29.96, H 3.16, N 14.52. IR (KBr): $\tilde{\nu}$ = 1864 ν(NO), 1560 ν(C=N), 1031 ν_{as}(C=S), 785 cm^{-1} ν_s(C–S). IR (CH_2Cl_2): ν(NO) = 1860 cm^{-1}. UV/Vis: λ (log ε) = 284 nm (3.14, MLCT). ^1H NMR (250 MHz, CD_3OD, 298 K): δ = 2.11 (s, 6 H, Me^3), 2.42 (s, 6 H, Me^5), 5.93 (s, 2 H, H^4), 7.32 (s, 1 H, CH) ppm. $^{13}C\{^1H\}$ NMR/DEPT-135 (62.89 MHz, CD_3OD, 298 K): δ = 10.3 (+, Me^5), 13.0 (+, Me^3), 76.4 (+, CH), 105.2 (+, C^4), 140.4 (0, C^5), 146.8 (0, C^3), 218.1 (0, CS_2^-) ppm.

[Ru(bdmpzdta)(en)(NO)]Cl$_2$ (6): A procedure similar to that described for **5** was used, but with the addition of ethylenediamine (14 μL, 0.21 mmol) before ligand **1**. A brown crystalline solid was obtained. Yield: 0.085 g (75%). $C_{14}H_{23}Cl_2N_7ORuS_2$ (541.2): calcd. C 31.05, H 4.25, N 18.11; found C 31.08, H 4.29, N 18.13. IR (KBr): $\tilde{\nu}$ = 1860 ν(NO), 1562 ν(C=N), 1033 ν_{as}(C=S), 785 ν_s(C–S), 3232 $\nu_{as}(NH_2)$, 3130 cm^{-1} $\nu_s(NH_2)$. IR (CH_2Cl_2): ν(NO) = 1860 cm^{-1}. UV/Vis: λ (log ε) = 288 nm (3.34, MLCT). ^1H NMR (250 MHz, CD_3OD, 298 K): δ = 2.31 (s, 6 H, Me^3), 2.10 (s, 6 H, Me^5), 5.85 (s, 2 H, H^4), 7.15 (s, 1 H, CH), 2.20/2.40 [t, 4 H, CH_2(en)] ppm. $^{13}C\{^1H\}$ NMR/DEPT-135 (62.89 MHz, CD_3OD, 298 K): δ = 10.7 (+, Me^5), 13.5 (+, Me^3), 75.2 (+, CH), 106.0 (+, C^4), 140.3 (0, C^5), 147.7 (0, C^3), 220.3 (0, CS_2^-) ppm.

[Ru(bdmpzdta)$_2$(NO)]Cl (7): A procedure similar to that described for **5** was used, but with the addition of a double quantity of ligand **1** (0.120 g, 0.42 mmol) in four portions. A brown crystalline solid was obtained. Yield: 0.137 g (90%). $C_{24}H_{30}RuN_9OS_4Cl$ (724.7): calcd. C 39.75, H 4.14, N 17.39; found C 39.77, H 4.16, N 17.36. IR (KBr): $\tilde{\nu}$ = 1859 ν(NO), 1560 ν(C=N), 1033 ν_{as}(C=S), 786 cm^{-1} ν_s(C–S). IR (CH_2Cl_2): ν(NO) = 1862 cm^{-1}. UV/Vis: λ (log ε) = 289 nm (3.20, MLCT). ^{1}H NMR (250 MHz, CD_3OD, 298 K): δ = 2.15 (s, 12 H, Me^3), 2.30 (s, 12 H, Me^5), 6.08 (s, 4 H, H^4), 7.07 (s, 2 H, CH) ppm. $^{13}C\{^1H\}$ NMR/DEPT-135 (62.89 MHz, CD_3OD, 298 K): δ = 10.5 (+, Me^5), 13.2 (+, Me^3), 70.3 (+, aliphatic CH of CS_2^- coordinated moiety), 83.4 (+, aliphatic CH of CS_2^- uncoordinated moiety), 105.6/106.2 (+, C^4), 142.8 (0, C^5), 145.7 (0, C^3), 211.0 (0, coordinated CS_2^-), 243.2 (0, uncoordinated CS_2^-) ppm.

Interaction of 2, 3 or 4 with NO in Solution: Nitric oxide was obtained from the reaction between copper and nitric acid (5 M) under a nitrogen atmosphere using Schlenk techniques at 293 K. The gaseous product(s) of this reaction were passed through NaOH(conc) traps to remove nitrogen oxides other than nitric oxide. Compounds **2**, **3** and **4** (0.08–0.11 mmol) were each dissolved in 20 mL of dichloromethane in a Schlenk flask and deoxygenated with oxygen-free nitrogen. These 10^{-3} M solutions had nitric oxide bubbled through them for 20 min and were then stirred for 6 h whilst maintaining anaerobic conditions under nitrogen. The solutions, which were initially brown, became reddish. The corresponding products were isolated by evaporating the solvent under vacuum.

Study on the Binding of Base-Mismatched Oligonucleotide d(GCGAGC)$_2$ by Cobalt(III) Complexes

Huili Chen,[a] Pin Yang,*[a] Caixia Yuan,[a] and Xiaohua Pu[a]

Keywords: Mismatched DNA / Cobalt / Binding /Oligonucleotides

The binding of [Co(phen)$_2$(HPIP)]Cl$_3$ and [Co(phen)$_2$(DPQ)]Cl$_3$ to the oligonucleotide d(GCGAGC)$_2$ containing two sheared G:A mispairs has been studied by NMR spectroscopy for the first time. For both the complexes, a considerable number of intermolecular NOEs were observed in NOESY spectra of the cobalt-complex-bound hexanucleotide. The results suggest that [Co(phen)$_2$(HPIP)]Cl$_3$, with HPIP, intercalates between the G$_3$:A$_4$ base pairs from the minor groove and extends to the major groove, and [Co(phen)$_2$ (DPQ)]$^{3+}$ binds to the terminal G$_5$:C$_6$ region from two directions. ^{31}P NMR spectroscopy indicates that [Co(phen)$_2$(HPIP)]Cl$_3$ binding induces a change in the phosphate backbone in the region of the mismatched base pairs, while [Co(phen)$_2$ (DPQ)]$^{3+}$ does not cause obvious changes in the backbone. Melting experiments indicate that [Co(phen)$_2$(HPIP)]Cl$_3$ stabilizes the double-strand structure, while [Co(phen)$_2$(DPQ)]Cl$_3$ cause the duplex to untwist.

Introduction

Base mismatches arise naturally in the life cycle of a cell as a result of either polymerase error or DNA damage. Under most circumstances the cell corrects these mispairs by using a complex repair system to prevent mutations in the genetic code. Experimental systems for the recognition of mismatches are of particular interest in cases where this repair system is not functioning efficiently and allows errors in the DNA sequence to persist. However, the efficiency of mismatch error recognition and repair depends both on the nature of the mispair and on the flanking DNA sequence.[1–5] For example, the type of GA pairs depends entirely on the context, i.e. the proceeding base pair,[6] head-to-head GA pairing in a (NAGATN)$_2$ sequence switches to the more stable sheared side-by-side GA pairing when the context is changed to (NCGAGN)$_2$ or (NTGAAN)$_2$, while no duplex is formed (or only G:A bulges occur) in a (NGGACN)$_2$ context. Recognizing these "abnormal" structures at the atomic level presents new challenges. The sheared side-by-side G:A pairing has similar stabilities to the standard Watson–Crick base pairs.[7] Up to now, specific recognition of this mispair has not been reported. According to the reported paper,[8–12] the GpA phosphodiester link converts a B$_I$ conformation of normal B-form DNA into a B$_{II}$ conformation, which results in a downfield shift of the GpA ^{31}P resonance. Furthermore, the adenosine swings away from intrastrand stacking on the preceding guanine and participates in cross-strand stacking with the adenine of the opposite strand (Scheme 1). Molecular modeling shows the two stacking guanines lie in the major groove, and the two stacking adenines lie in the minor groove.

Metallocomplexes of the general form [M(phen)$_2$L]$^{n+}$ have contributed to our understanding of fundamental nucleic acid recognition. So far, most studies are limited to spectroscopic methods.[13–17] However, it is difficult to clarify the details of the interaction by the phenomenological information, such as red shift, blue shift, hyperchromicity and hypochromicity etc. Hence, more accurate methods, such as two-dimensional NMR spectroscopy, are needed to describe the interaction between DNA and the metallocomplex.

In this paper, we report on a NMR spectroscopic study of two Co complexes that bind to d(GCGAGC)$_2$ which contains two sheared G:A mispairs. The results indicate that [Co(phen)$_2$(HPIP)]$^{3+}$ indeed can selectively bind to the specific mispairs, and probably has the potential to repair the backbone in the region of the mispairs (Scheme 1 and Figure 1).

We tried to separate the racemic cobalt complex into the enantiomers using potassium antimonyl tartrate, but each isomer racemized in less than 24 hours; however, most of the important experiments could not be accomplished in such a short time. Further, it has been reported that the cobalt complex racemized rapidly in the presence of an oligonucleotide to generate a stable mixture of enantiomers

that is enriched in the isomer that interacts most favorably with the oligonucleotide.[18] In addition, molecular modeling suggests[19] that sheared G:A pairs cause a severe twisting of the DNA backbone, so that the right-hand duplex conformation close to the mispair is not very apparent, which weakens the enantiomer selectivity of the complex to DNA. Hence the use of the racemic complexes does not materially affect the conclusions reached from our experiments. We also present the results of the binding of $[Co(phen)_2(DPQ)]^{3+}$ to $d(GCGAGC)_2$ for comparison.

Results and Discussion

Assignment of the Proton Resonances of $d(GCGAGC)_2$

The ^1H NMR resonances of the free oligonucleotide were assigned with the use of both NOESY and TOCSY experiments, according to well-established methods.[21–23] The imino resonances in the NMR spectrum of the oligonucleotide dissolved in H_2O/D_2O (9:1) were examined to determine the extent of nucleotide base pairing. The spectrum indicates that only the terminal residue does not form a stable base pair, and two well-resolved imino resonances are observed. Hence, we believe that the oligonucleotide exists as double strands in our experiments. The imino proton at 10.36 ppm (Figure 2a) and the downfield ^{31}P resonance (Figure 2b) indicates that the sheared G:A base pairs exist in $d(GCGAGC)_2$.[8–12]

DNA Binding by $[Co(phen)_2(HPIP)]^{3+}$

The resonance signals of the free complex are assigned by using a combination of NMR experiments. The resonances from phen are easily distinguished from HPIP by the integral of each resonance. Within each ring system, the resonances are then assigned to particular protons with the use of the COSY spectrum. Because of the symmetrical structure of phen, on the NMR time scale, it is not possible to unambiguously distinguish the resonances of protons 5, 4, 3, 2 from 6, 7, 8, 9, respectively. We marked these protons

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

as H5/6, H4/7, H3/8, and H2/9. H2/9 is coupled with H3/8 by vicinal $^3J_{H,H}$, while it is coupled with H4/7 by long-range $^4J_{H,H}$, so the coupling constant of H2/9–H3/8 is bigger than that of H2/9–H4/7, and the cross-peak for H2/9–H3/8 is stronger than that for H2/9–H4/7. The resonance for H4/7 has been assigned by its downfield chemical shift,[24,25] hence, the resonance for H2/9 and H3/8 can also been confirmed from the COSY spectrum. The resonances for HPIP were assigned similarly.

The assignment of d(GCGAGC)$_2$-bound [Co(phen)$_2$(HPIP)]$^{3+}$ was also carried out with the help of COSY and NOESY spectra and previously reported hexanucleotide-bound [Ru(phen)$_2$(DPPZ)]$^{2+}$[24] and [Ru(phen)$_2$(DPQ)]$^{2+}$.[25] Further, the possible chemical shifts for intercalated metal-ligand protons are restricted to within 0–1.6 ppm upfield from the location of the resonances for the free metal-ligand.[26,27]

Addition of [Co(phen)$_2$(HPIP)]$^{3+}$ to d(GCGAGC)$_2$ induces large perturbations for the HPIP resonances (especially for H12, 13, 14, 15, 16), and much smaller perturbations for the ancillary phen ligand (Table 1 and Figure 3). This behavior is consistent with the fact that the ligand HPIP preferentially participates in binding with d(GCGAGC)$_2$. The magnitude and direction of the chemical shift change for the HPIP ligand protons are indicative of selective intercalation of this ligand.[28,29] The interaction between the complex and d(GCGAGC)$_2$ leads to two sets of resonances from the ligand phen and one set of resonances from HPIP, which might be caused by the different spatial surrounding of the two ancillary ligands after HPIP intercalates with the oligonucleotide. Molecular modeling shows that after the complex intercalates into the sheared G:A region, the protons H13, 14, 15, and 16 from HPIP are all located in the ring plane formed by the two stacking adenines, and H12 lies in the ring plane formed by the two stacking guanines. The strong shielding from the purine rings causes these resonances to shift upfield to a different extent, the H8 and H2 protons of A4 and H8 of G3 are located in the side face of the aromatic ring of HPIP. In previous work,[16] we observed that, after intercalation, the distance between the neighboring base pairs is doubled and the distances from the intercalating ligand plane to the two neighboring bases are similar to that between the neighboring base pairs before intercalation, so the ring current from HPIP has little effect on the resonances of these protons.

H11	7.95	7.88	–0.07
H10	7.57	7.65	+0.08
Phen			
H5/6	8.48	8.34–8.51	–0.14 to +0.03
H4/7	9.07	8.93–9.13	–0.14 to +0.06
H3/8	7.92	8.10–8.18	+0.18 to +0.26
		7.85–7.90	–0.07 to –0.02
H2/9	7.65,7.70	7.50–7.70	–

Addition of the metal complex to the hexanucleotide also induces significant broadening of the resonances of d(GCGAGC)$_2$ due to intermediate exchange on the NMR time scale (Figure 3B); this is, again, consistent with intercalation.[24,29] In one- and two-dimensional spectra of this complex bound to the oligonucleotide, two G_3H1' and G_1H1' protons are evident, which were assigned to be the free form in the lower field and the bound form in the higher field according to previously published results,[25] and the exchange between the two forms is slow on the NMR time scale.

The NOESY spectrum of d(GCGAGC)$_2$ with added [Co(phen)$_2$(HPIP)]$^{3+}$ (1:1) was recorded at 20 °C with a mixing time of 300 ms.[24,25] For the nucleotide helix, in addition to the expected intraduplex sequential NOEs, a number of intermolecular NOE cross peaks between [Co(phen)$_2$(HPIP)]$^{3+}$ and d(GCGAGC)$_2$ are observed (Table 2). Of note are the strong NOE cross peaks between the HPIP H14 and H16 protons and G_3H2', G_3H2'', and G_3H8, and the NOE cross peaks between H16 and G_3H3' (see Figure 4 and Figure S1). The medium-intensity NOEs between H10–A_4H2', H10–A_4H2'', H10–A_4H3' are also observed. Molecular modeling indicates that $G_3H2'/H2''$, G_3H8, G_3H3', $A_4H2'/H2''$, and A_4H3' are all located in the DNA major groove, and the distance between the protons from the intercalated ligand to the neighboring nucleotide may be less than 5 Å, therefore some additional NOEs also appear, such as H16–C_2H2'', between H15 and C_2H5, C_2H6, $C_2H2'/H2''$, $G_5H2'/H2''$, and between H13 and $C_2H2'/H2''$ and $G_5H2'/H2''$. In addition, the NOEs between phen and the protons located in the DNA minor groove are also clear, such as H3/8–A_4H4', H3/8–$A_4H5'/H5''$, and H2/9–G_3H1'. All of these data strongly suggest that the complex inserts into the sheared G_3A_4 region from the minor groove A_4 region, and the HPIP system spans the stacked base pairs and extends into the major groove G_3 region. As the metal complex binds by intercalation, a selective loss in intensity of the sequential NOEs might be expected because the distance between the stacked bases at the intercalation site will significantly increase. Obviously, the disappearance of the intrastrand sequential NOEs in the sheared G:A region was detected (Figure 4), such as A_4H8–$G_3H2'/H2''$, A_4H8–G_3H3', $G_3H2'/H2''$–$A_4H2'/H2''$, and simultaneously, the intensity of the sequential A_4H8–G_3H4' NOE apparently diminished. However, the binding of the complex might result in a change in the DNA backbone, and some unexpected NOEs also appeared, such as A_4H1'–G_3H4', A_4H1'–$G_3H2'/H2''$, G_3H1'–$A_4H2'/H2''$, and between A_4H2 and G_3H1', G_5H1', C_6H5, G_5H2', and $A_4H2'/H2''$.

The two imino resonances in the NMR spectrum recorded in H_2O/D_2O (9:1) indicate that the double-strand structure of the hexanucleotide is maintained after [Co(phen)$_2$(HPIP)]$^{3+}$ binding. Only small shifts (<0.05ppm)

[a] The NOE is very weak.

and a little broadening were observed upon the addition of the complex (Figure S2).

DNA Binding by $[Co(phen)_2(DPQ)]^{3+}$

The resonance assignment of the free- and bound $[Co(phen)_2(DPQ)]^{3+}$ was similar to that of $[Co(phen)_2(HPIP)]^{3+}$ (Figure 5A). The two resonances from the DPQ H12 proton indicate at least two binding orientations for the binding of the metal complex to the helix, and the exchange rate between the two forms is slow. It was not possible to assign unambiguously the H13 resonance because of the overlap with the H4/7 resonances. For the same reason as for $[Co(phen)_2(HPIP)]^{3+}$, we marked phen protons as H5/6, H4/7, H3/8, and H2/9.

Addition of $[Co(phen)_2(DPQ)]^{3+}$ to d(GCGAGC)$_2$ also induces a large upfield chemical shift of the resonance for the DPQ H12 proton. By contrast, resonances from phen exhibit only a small shift, suggesting that the DPQ preferentially binds.

Addition of the metal complex also induces a significant broadening and selective shifts of the hexanucleotide resonances (Figure 5). Especially, significant upfield shifts are observed for the protons located in the major groove in the terminal G_1C_2/G_5C_6 region, such as H8 of G_1 and G_5, H2′ of G_1, and H5 and H2′ of C_6. Similarly, H1′ protons of G_1 and G_5, which are located in the DNA minor groove, also show upfield shifts.

The NOESY spectrum of d(GCGAGC)$_2$ with added $[Co(phen)_2(HPIP)]^{3+}$ (1:1) was recorded at 20 °C with a mixing time of 300 ms. Figure 6 shows the aromatic to the sugar H1′, H3′region (a) and the sugar H2′/2′′region (b). In addition to the expected intraduplex sequential NOE cross peaks, a number of intermolecular NOE cross peaks between the metal complex and the duplex are also observed (Table 3). Of note are the NOE cross peaks between the complex and the terminal protons located in the major groove, such as H13–C_6/C_2H2′, H13–C_6H3′, H12–C_6/C_2H2′, H12–C_6H5, H11–G_5H2′/H2′′, H10–C_6/C_2H2′, and H10–C_6H5. Further, the NOE cross peaks between the phen H4/7 protons and the minor groove H1′ protons of C_6/C_2 are also observed. It was not possible to assign unambiguously the NOE cross peaks between the protons of the complex and the minor groove protons H4′/H5′/5′′ of C_6, C_2, G_1, and G_5 (a-g) because of the overlap of these resonances. These data strongly suggest that the cobalt complex binds to the DNA in the terminal G_1C_2/G_5C_6 region from two directions, one from the minor and the other from the major groove. The intensity of the sequential NOEs from C_6H6–G_5H3′ and G_1H8–C_2H3′ decrease with the binding of the metal complex. Additionally, the different degrees of broadening of the hexanucleotide resonances, induced by the addition of $[Co(phen)_2(DPQ)]^{3+}$, hinders the observation of a selective partial loss of the sequential NOE.

From the imino resonances, we confirm that the bound oligonucleotide still has a duplex conformation (Figure S2).

(A) aromatic region: (a) [Co(phen)$_2$(DPQ)]$^{3+}$, (b) [Co(phen)$_2$(DPQ)]$^{3+}$-d(GCGAGC)$_2$, (c) d(GCGAGC)$_2$; (B) sugar H1′ region: (a) [Co(phen)$_2$(DPQ)]$^{3+}$-d(GCGAGC)$_2$, (b) d(GCGAGC)$_2$.

^{31}P NMR Spectroscopy

^{31}P NMR spectroscopic studies of oligonucleotide bound by intercalators provide direct information on any backbone distortion which accompanies any interaction.[30] Unlike ^{1}H nuclei, for which upfield movement of the ligand resonances is caused by increases in shielding due to penetration into the ring currents of the base stack, the movement of ^{31}P nuclei in oligonucleotides is governed by changes in the torsion angles about the phosphate linkage.[31–33] As shown in Figure 7, the free oligonucleotide exhibits a sharp peak at 1.1 ppm, far away from the other resonances, which is typical for sheared G:A base pairs with a B_{II} conformation.[8–12] When the oligonucleotide is bound by [Co(phen)$_2$(HPIP)]$^{3+}$, the peak shifts upfield, and a new

H12	C_6/C_2H2′, C_6H5
H11	G_5H2′/H2′′
H10	C_2H2′/C_6H2′, C_6H5
H4/7	C_6H1′
H2/9	C_6H5, C_2H2′/C_6H2′

[a] C_2H2′ cannot be distinguished from C_6H2′.

little peak appears on the right of it. We speculate that it belongs to another resonance from 4P. The upfield shift indicates the change in the B_{II} conformation of the phosphate backbone in the G_3A_4 region. In combination with the ^{1}H NMR spectroscopy, we conclude that HPIP selectively inserts into the sheared G:A region. A few new peaks also appear in the upfield region; this occurs as a result of the intercalation of the complex into the G:A region, which causes the distortion of the neighborhood phosphate backbone. The addition of $[Co(phen)_2(dpq)]^{3+}$ shows no obvious change in the ^{31}P NMR resonances of the duplex.

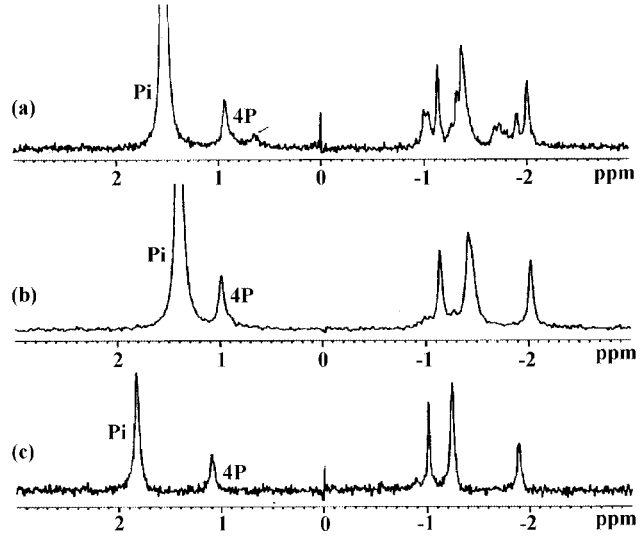

Figure 7. 121.8 MHz ^{31}P NMR spectra of (a) $[Co(phen)_2(HPIP)]^{3+}$-d(GCGAGC)$_2$, (b) $[Co(phen)_2(DPQ)]^{3+}$-d(GCGAGC)$_2$, and (c) free d(GCGAGC)$_2$.

Melting Experiments

Other strong evidence for the binding of the complexes to the duplex was obtained from DNA melting studies.[34] Intercalation of small molecules into the double helix is known to increase the helix melting temperature (T_m), the temperature at which the double helix is denatured into single-stranded DNA. For d(GCGAGC)$_2$, the transition tem-

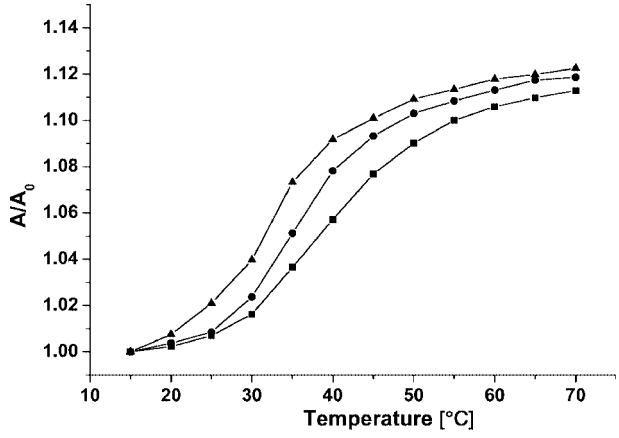

Figure 8. Effect of the Co complexes on the melting temperature of d(GCGAGC)$_2$ (15 μM) with a complex to duplex ratio of 2:1. d(GCGAGC)$_2$ (circle); $[Co(phen)_2(HPIP)]^{3+}$+ d(GCGAGC)$_2$ (square); $[Co(phen)_2(DPQ)]^{3+}$ + d(GCGAGC)$_2$ (triangle).

perature can be determined by monitoring the absorbance at 254 nm as a function of temperature. As shown in Figure 8, both the Co complexes have a significant effect on T_m. The melting temperature of d(GCGAGC)$_2$ increases from 35 °C to 40 °C with [Co(phen)$_2$(HPIP)]$^{3+}$, whereas it decreases to about 30 °C with [Co(phen)$_2$(DPQ)]$^{3+}$. The increase in T_m provides strong support for the intercalation of [Co(phen)$_2$(HPIP)]$^{3+}$ into the duplex, while [Co(phen)$_2$(DPQ)]$^{3+}$ binds to the duplex but does not intercalate.

Conclusion

The study on the site selective interaction between an octahedral metal complex and the mismatched oligonucleotide by NMR spectroscopy has not been reported up until now. Considering that the distortion of the backbone of DNA with sheared G:A mispairs weakens the selective binding of the enantiomer, we have attempted to study the interaction of an oligonucleotide d(GCGAGC)$_2$ with a racemic cobalt complex and have obtained some significant results.

In the NOESY experiments with d(GCGAGC)$_2$, many NOEs are observed between the metal complexes and the hexanucleotide. For [Co(phen)$_2$(HPIP)]$^{3+}$, as these NOEs are predominantly between HPIP and the major groove protons and between phen and the minor groove protons in the sheared G:A region, we conclude that the ligand HPIP inserts into the adenine base stacking from the minor groove, and extends to the guanine stacking in the major groove. The result of ^{31}P NMR spectroscopic study indicates that the binding of the complex induces a change in the B_{II} conformation of the phosphate backbone in the G_3A_4 region to a B_I conformation. In this sense, the complex has the potential to repair the phosphate backbone in the sheared G:A region. For [Co(phen)$_2$(DPQ)]$^{3+}$, as the NOEs are predominantly from the terminal G_1C_2/G_5C_6 sequence, it is concluded that the complex binds to the oligonucleotide by two modes, one is from the major and the other is from minor groove in the G:C region. The ^{31}P NMR spectroscopic study indicates that addition of the complex does not induce an obvious change in the conformation of the DNA. Melting experiments indicate that [Co(phen)$_2$(HPIP)]Cl$_3$ stabilizes the double-strand structure, while [Co(phen)$_2$(DPQ)]Cl$_3$ causes the duplex to untwist.

The difference in the binding properties between the two complexes could be because of the width of the ligand. The wider minor groove and the narrower major groove in the mispair region is exactly suitable for HPIP to insert between the sheared G:A base pairs.

Overall, the results of this study demonstrate that the octahedral metallointercalator [Co(phen)$_2$(HPIP)]$^{3+}$ can intercalate into the oligonucleotide d(GCGAGC)$_2$ in the sheared G:A region, which could have potential application in the design of mismatch-specific chemical agents.

Experimental Section

Materials: The oligonucleotide d(GCGAGC)$_2$ was purchased from AuGCT Biotechnology Co. Ltd, Beijing. The concentration was determined from the absorbance at 254 nm, and the single strand extinction coefficients were calculated from mononucleotide and dinucleotide data of a nearest-neighbor approximation.[20] The oligonucleotide was dissolved in phosphate buffer (pH 7.0, 0.50 ml of a 10 mM solution), containing NaCl (20 mM) and TMSP (0.05 mM). For the imino proton studies, the sample was dissolved into H_2O/D_2O (9:1). For the non-exchangeable proton studies, the sample was dissolved into the phosphate buffer and repeatedly lyophilized from 99.8% D_2O in a speed vacuum, and then dissolved in D_2O (0.50 ml of a 99.996% solution), with a concentration of 1 mM. The complexes were synthesized as previously reported.[17] Stock solutions of the metal complexes were prepared in D_2O (unbuffered) and added to the hexanucleotide in 10ul aliquots until a metal complex to hexanucleotide duplex ratio of 1 was achieved.

The absorbance spectra were recorded with a Hewlett Packard HP-843 chemstation spectrometer. The DNA melting experiments were carried out by controlling the temperature of the sample cell with a Shimadzu circulating bath while monitoring the absorbance at 254 nm.

NMR Spectroscopic Measurements: NMR measurements were made with Bruker DRX-500 and DRX-300 spectrometers and analyzed with a silicon graphics workstation running Xwin-nmr. Proton chemical shifts were referenced to an internal TMSP standard. Phosphate chemical shifts were referenced to an external 85% H_3PO_4 standard.

All NMR spectra were recorded at approximately 20 °C. Spectra recorded in H_2O/D_2O (9:1) were collected by using a binomial 1:3:3:1 pulse sequence for solvent suppression. Two-dimensional phase-sensitive NOESY spectra in 99.996% D_2O were recorded by the TPPI method, using 2048 data points in t_2 (over a spectral width of 5000 Hz) for 256 t_1 values with a pulse repetition delay 2 s. Suppression of the residual HDO resonance was achieved by low-power presaturation during the relaxation delay. Phase-sensitive TOCSY spectra were accumulated with 2048 data points in t_2 for 256 t_1 values with a pulse repetition delay 2 s.

Synthesis and Characterisation of Monodisperse Zirconia Particles

Johanna Widoniak,[a] Stefanie Eiden-Assmann,*[a] and Georg Maret[a]

Keywords: Zirconia / Monodisperse / Colloids / Particles / Sol–gel processes

Monodisperse spherical ZrO_2 particles were prepared by controlled hydrolysis of zirconium tetraalkoxide in alcoholic solution. Ageing the reaction solution at 60 °C for 4 h yields particles with sizes in the range between 200 and 2000 nm. The influence of various ions and surfactants on the final product was investigated. Stable suspensions of coated, monodisperse, zirconia particles were prepared by hydrolysis and subsequent polymerisation of tetraethoxysilane in an alkaline ethanol solution. Thermal analysis revealed that the weight loss of bound water occurred below 400 °C and is about 35 %. The phase transition from amorphous zirconia to the tetragonal phase proceeded at approximately 450 °C, the transition to the monoclinic phase began at about 600 °C and was completed at about 800 °C. The crystallinity of the powders was investigated by X-ray diffraction. Electrophoretic measurements were carried out to determine the charges on the particle surface. Elementary analyses were used for further investigations. On the basis of the results obtained, the mechanism of particle formation was discussed.

Introduction

Mesoscale spheres of metal oxides, like zirconia particles, are of particular interest for applications as ceramics. To advance the sintering kinetics, i.e. to obtain shorter sintering times and lower sintering temperatures, elimination of agglomerates and control of the particle size distribution is required. Controlled hydrolysis of metal alkoxides seems to be a promising method for obtaining particles with well-defined sintering properties during the powder synthesis. Zirconia particles are widely used as high-performance ceramics, catalysts or in cosmetics. New applications for zirconia powders are high-temperature fuel cells, lambda probes or bioceramics such as dental prostheses.[1]

The preparation of zirconia powders was described in a number of publications.[2–6] Sada et al.[3] reported the preparation of zirconia particles by hydrolysis of zirconium tetrabutoxide in 1-propanol. The average diameter of particles obtained range from 140 to 380 nm. A decrease in the particle size with increasing reaction ratio was observed. Kato et al.[2] prepared various sizes of particles by the seeded-growth method. Mizutani et al.[5] reported the influence of chain length and branching, and the molecular structure of the alcoholic solvent on the hydrolysis behaviour of zirconium tetrabutoxide. The goal of our research was to establish a controlled and reproducible synthesis of zirconia particles with a narrow size distribution and of various sizes. Additionally, we investigated the influence of ions and polymers and of different ratios of precursors on the synthesis of zirconia particles. In order to change the surface properties of the zirconia particles and to make the particles visible for confocal scanning laser microscopy (CSLM), the particles were coated with a silica shell into which dye molecules could be incorporated.

Results and Discussion

Zirconia particles with a narrow size distribution were obtained in a precipitation reaction from zirconium alkoxide and water in an alcoholic solution. Depending on the reaction conditions, particles in the range between 200 and 2000 nm were obtained (Figure 1). The scanning electron micrographs reveal the perfectly uniform shape and high monodispersity of our particles (Figure 2 and Figure 3). The synthesis proceeds in two steps. During the first step, the hydrolysis, zirconium hydroxide molecules and primary particles are generated. In the second step, the primary particles aggregate (see Figure 1).[5]

$$Zr(OR)_4 + H_2O \rightarrow Zr(OH)_4 + 4\ ROH$$

$$Zr(OH)_4 \rightarrow ZrO_2 + 2H_2O$$

The zirconia particles are formed by a stepwise hydrolysis of zirconium tetraalkoxides, as described above, and polymerisation of hydrolysed zirconium alkoxide.[3] In addition to hydrous zirconia, hydrated polymeric species with a number of Zr–O–Zr bridges are formed. A macromolecular oxide network is then obtained through hydrolysis and condensation.[2,10]

$$Zr(OR)_4 + H_2O \rightarrow (OR)_3Zr(OH) + ROH$$

$$(OR)_3Zr(OH) + (OR)_3Zr(OR) \rightarrow (OR)_3Zr–O–Zr(OR)_3 + ROH$$

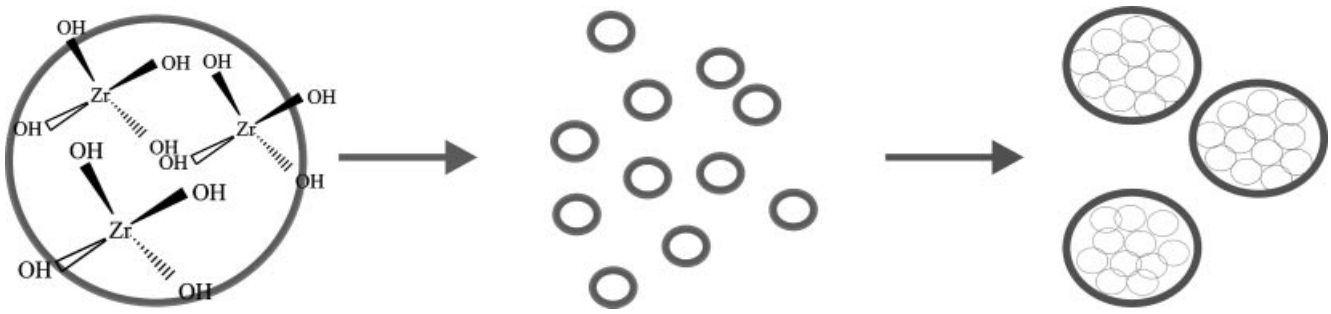

Figure 1. Primary particles formed by the hydrolysis of the metal alkoxide coalesce fast and grow into spheres. Residual primary particles do not form secondary particles but promote the growth of the spheres.

Variation of Precursors and Their Concentrations

To obtain spherical and monodisperse zirconia particles, various zirconium tetraalkoxides and alcohol solvents were tested. Among zirconium tetraethoxide, tetrapropoxide and tetrabutoxide, the best results were obtained with zirconium tetrabutoxide. When ethanol, 1-propanol and 1-butanol were tested as solvents, particularly uniform and monodisperse particles were obtained with ethanol for a wide range of precursor concentrations. 1-Propanol and 1-butanol provided only narrow ranges of concentration where spherical and monodispersed particles were obtained. In the case of ethanol, the induction time for the formation of particles optimally fell between 1 and 5 min. When the induction time was shorter than the optimum, hydrolysis occurred more quickly, and the nuclei formed polydisperse aggregates. In the case of a prolonged induction period, nucleus formation and particle growth proceeded simultaneously and polydisperse particles were formed.[5] An ethanol volume of 100 mL, mixed with 0.2–0.6 mL of Millipore water, aqueous salt or polymer solution, followed by the addition of 3.25–5.00 mL of zirconium tetrabutoxide was found to be the best condition for obtaining uniformly spherical and monodisperse zirconia particles.

The uniformity in size and spherical shape of the resulting particles decreased as the initial amount of water became higher than 0.6 mL or lower than 0.2 mL. The higher the water concentration in the reaction solution, the faster the hydrolysis, and the smaller the particles obtained (Figure 2). For zirconia particles synthesised with NaCl, the

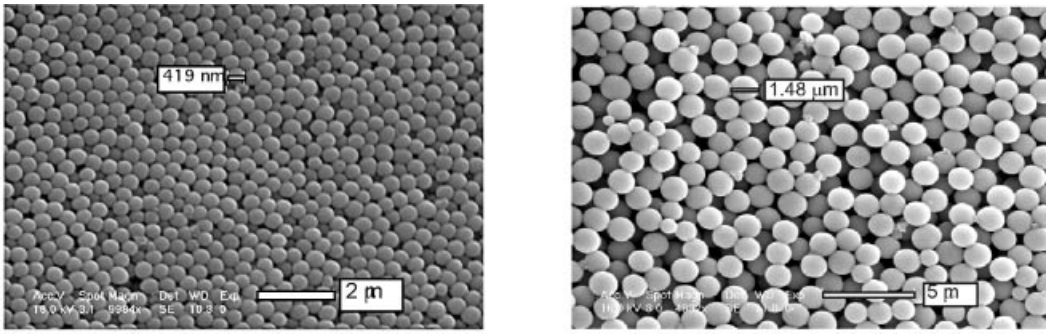

Figure 2. Zirconia particles synthesised with 0.40 mL (l) and 0.20 mL (r) of a 0.1 M NaCl solution, with addition of 3.25 mL $Zr(OBu)_4$ in 100 mL ethanol.

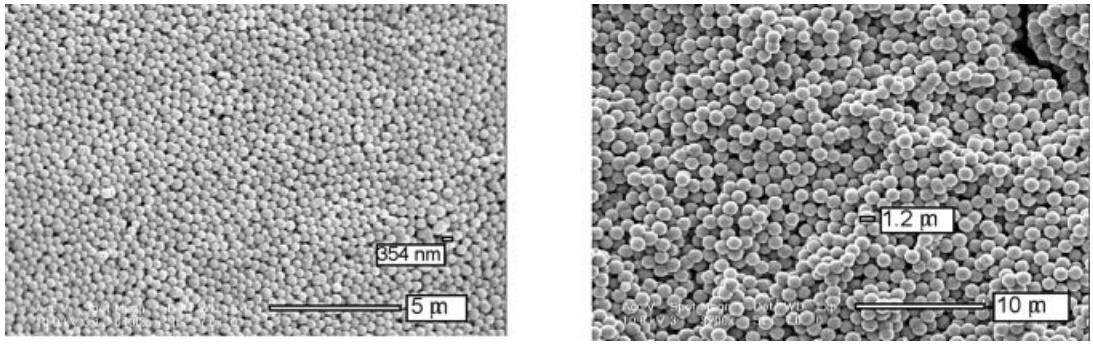

Figure 3. Zirconia particles synthesised with 3.25 mL (l) and 5.00 mL (r) of $Zr(OBu)_4$, with addition of 0.40 mL of a 0.1 M NaCl solution in 100 mL ethanol.

particle sizes decreased from 1500 to 400 nm when the amount of water in the solution increased from 0.2 to 0.4 mL per 100 mL ethanol. Analogous results were observed for particles synthesised with polymers such as Lutensol ON 50 (Table 1). With a large amount of water, the induction time of hydrolysis was very short; the hydrolysis was fast enough to generate a lot of primary particles. Because of the high density of primary particles, these particles agglomerated in an uncontrolled manner and became polydisperse. No precipitate was observed when the amount of water was below 0.1 mL. The average size increased depending on the initial concentration of $Zr(OBu)_4$. The sizes of the particles synthesised with Lutensol ON 50 increased from 300 to 1200 nm when the amount of zirconium tetrabutoxide increased from 1.25 to 5 mL per 100 mL ethanol (Figure 3, Table 2).

Table 1. Sizes of zirconia particles synthesised with various amounts of 0.1 M Lutensol ON 50 solution with addition of 5.00 mL zirconium butoxide in 100 mL ethanol.

Lutensol ON 50 (0.1 M solution in H_2O, mp) [mL]	Particle size [nm]
0.20	no precipitation
0.40	1200 ± 10%
0.50	1000 ± 10%
0.60	900 ± 10%
0.80	600–800
1.00	400–600

Table 2. Sizes of zirconia particles synthesised with various amounts of zirconium butoxide with addition of 0.40 mL of a 0.1 M NaCl solution in 100 mL ethanol.

$Zr(OBu)_4$ (80% solution in BuOH) [mL]	Particle size [nm]
1.25	300 ± 10%
2.50	450 ± 10%
3.25	550 ± 10%
2.75	700 ± 10%
4.25	1000 ± 10%
5.00	1200 ± 10%

Variation of Salts and Polymers

The stability of dispersion depends inter alia on the magnitude of the electric charge of the particles. Oxide surfaces in an aqueous medium are generally charged positively under acidic conditions and negatively under basic conditions. Similar to the measurements carried out by Kato et al.,[6] zeta potential values between 20 and 30 mV were detected in ethanol solution at pH 6 for our particles. For particles prepared with various salts, no significant differences were observed. In contrast, the zeta potential values obtained for titania particles synthesised with alkali halides increased from lithium chloride to caesium chloride, from 9 to 27 mV. The sizes and size distributions were very sensitive to the type of salt added.[8] The influence of alkali halides on the particles was not as strong as in the case of titania. The smallest particles were obtained, however, by addition of CsCl, the largest with LiCl (Table 3). Particles synthesised with pure Millipore water ranged between 300 and 1400 nm in size. We assume that interactions between the zirconium alkoxide, hydroxide and dioxide molecules and the salt ions are much weaker than those between the titanium compounds and salt ions.

Table 3. Sizes of zirconia particles synthesised with 0.40 mL of 0.1 M various salt or polymer solutions with addition of 3.25 mL zirconium butoxide in 100 mL ethanol.

Added salt or polymer	Particle size [nm]
CsCl	200 ± 10%
KCl	350 ± 10%
NaCl	550 ± 10%
LiCl	700 ± 10%
–	1000 ± 10%
Lutensol ON 50	600 ± 15%
Pluronic PE 6400	2000 ± 15%

The influence of polymers on the size and the size distribution of the colloidal particles was investigated in the next step. Two different types of polymers, diblock-copolymer Lutensol ON [$RO(CH_2CH_2O)_xH$] and triblock-copolymer Pluronic [PEO_n-PPO_m-PEO_n], were used for steric stabilisation. Depending on the amounts of water and zirconium tetrabutoxide, it was possible to obtain particles of up to 1200 nm with Lutensol ON 50 and of up to 2000 nm with Pluronic PE 6400. The hydrophilic part of Lutensol ON is likely to interact with the nanoparticle surface, while the hydrophobic part extends into the medium, thus providing additional steric stabilisation. In the case of Pluronic PE, the presence of two hydrophilic parts can be assumed to lead to a coating of the nanoparticle surfaces. The stabilisation by Pluronic polymers is not as effective and resulted in a broader size distribution of the titania particles. The same effect, but not as strongly pronounced, was observed for zirconia particles. The monodispersity of zirconia particles synthesised with Lutensol ON 50 was higher than that of particles prepared with Pluronic PE 6400.

In order to determine whether polymer molecules were built into the colloidal particles during the aggregation process, we carried out elementary analyses of as-synthesised zirconia powders. Elementary analyses showed carbon values of under 2%, which originated probably from untreated butoxide groups. Therefore, we assume that the polymer was not (or only in very small amounts) built into the final particles during the aggregation process. In the case of titania particles, higher amounts of carbon were observed. The interaction between polymer molecules and titanium alkoxide, hydroxide or dioxide was much stronger, so that polymer molecules were built into the particles. This resulted in porous titania particles with a specific surface area of a_s = 300 m^2/g in average, determined by the Brunauer–Emmett–Teller method. For zirconia particles, the values for the specific surface area were always below 10 m^2/g. Apparently, interactions between zirconium compounds and

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

polymer molecules are too weak to prevent a compact aggregation of the primary particles.

X-ray Diffraction and Thermal Analysis

X-ray diffraction patterns showed that the as-prepared ZrO_2 powders were amorphous. The DTA plot of ZrO_2 particles synthesised with salts showed a very broad exothermic peak from 30 to 360 °C due to dehydration (Figure 4). For samples synthesised with polymers, a sharp exothermic peak was observed, probably corresponding to the spontaneous thermal decomposition of untreated alkoxy groups. Bound water and untreated alkoxy groups, lost below 400 °C, make up 40% of the total weight. That means, the synthesised zirconia particles, after storing for 7 d in an oven at 100 °C, contain 4 mol water and hydroxide groups per mol of zirconium dioxide. The total formula can be specified as $ZrO_x(OH)_{2-x}n\ H_2O$ with $(x + n = 4)$. The amount of untreated alkoxy groups should be very low. Elementary analysis exhibited carbon values of under 2%.

For particles synthesised with polymers, the transformation into the tetragonal phase proceeded by heating to 450 °C, and for particles synthesised with addition of salts, to 510 °C. The transition to the monoclinic phase (Baddeleyte) occurred between 600 and 800 °C. A shift to higher transition temperatures was observed for zirconia particles prepared with addition of salt (Figure 4 and Figure 5). High-temperature X-ray diffraction patterns support these results.

X-ray diffraction provided evidence for the existence of small crystalline domains of approximately 5 to 10 nm, so that the particle growth seems to be controlled by the aggregation of primary nuclei (Figure 1). The sizes of crystalline domains were calculated with the Scherrer Formula. The TEM picture clearly showed the rough surface of a zirconia particle and supports the aggregation growth mechanism for the formation of our colloids (Figure 6). The same growth mechanism was found for the titanium dioxide particles synthesised by a hydrolysis process with titanium alkoxide in ethanol.[8] Bogush and Zukowski proposed nucleation followed by aggregation as a model that would confer monodispersity of precipitates.[9] The model is based on the premise that nucleation proceeds for a substantial fraction of the reaction period and that nuclei, as well as small clusters of nuclei, aggregate faster with large particles than they do with each other. Mizutani et al.[5] also described the aggregation model as the best suitable model for the growth of zirconia particles. They specified that the primary particles are formed by the hydrolysis of alkoxides during the induction time. In the second step, these particles aggregate to form larger particles. The growth can be followed by light scattering and hence reduction of light intensity transmitting trough the solution, according to the Tyndall phenomenon. Kato et al.[2,6] investigated the initial growth step of zirconia particles. They observed the growth of nuclei to primary particles of about 10–20 nm by electron microscopy. In the next step, the aggregation to larger particles proceeded because of excess surface energy because of a small radius. Furthermore, they assumed that residual primary particles do not form secondary particles but promote the growth of the spheres. The aggregation mechanism was also described by Sada et al.[3] to be best suitable for the growth of zirconia particles. These authors summarised, according to the reaction kinetics, that if the reaction is very slow, the particle growth takes place through polycondensation of nuclei on the particle surface. In fast reactions, an aggregation process of nuclei grown to primary particles takes place. The clarification of the formation mechanism of hydroxide particles is not trivial, inter alia due to the amorphous state of the precipitated solids. On the basis of

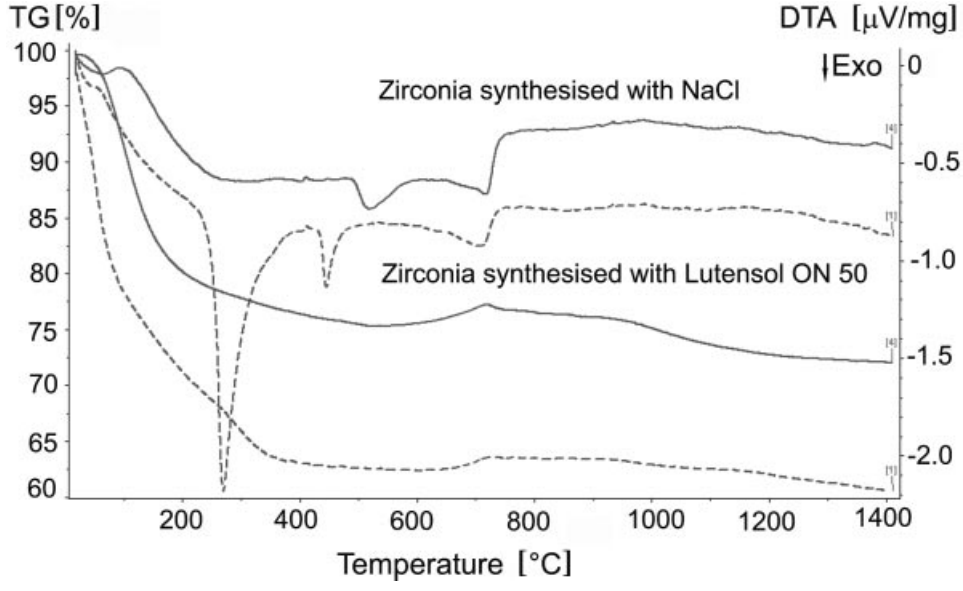

Figure 4. Thermal analysis of zirconia particles synthesised with addition of polymer molecules and with addition of salt ions.

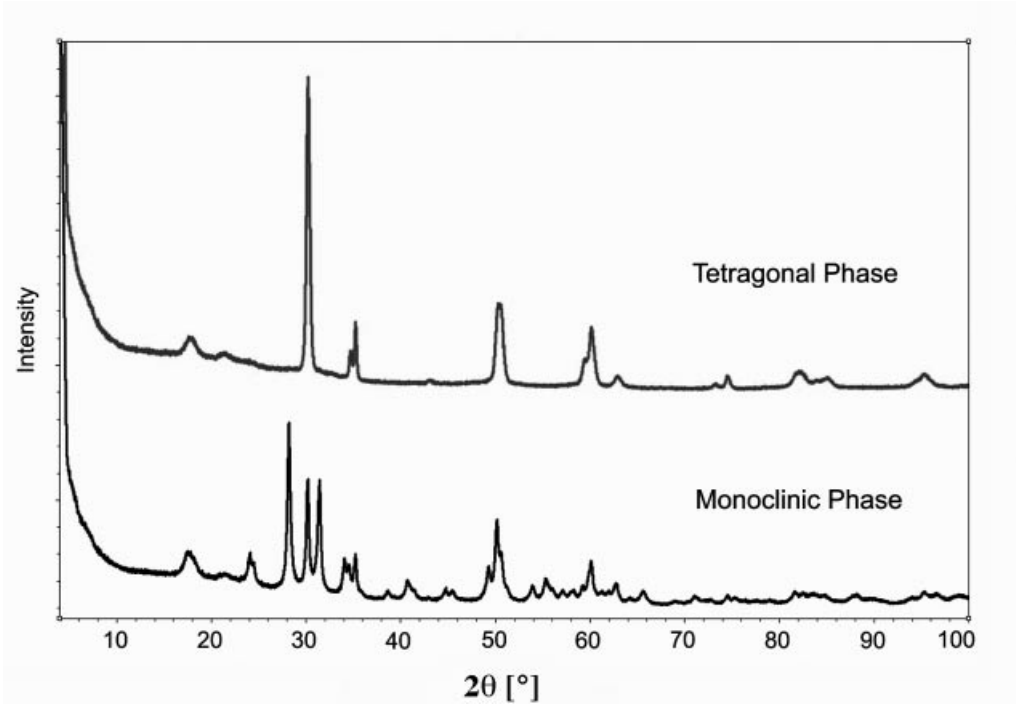

Figure 5. X-ray diffraction patterns of crystalline zirconia particles.

our results and on the literature, we assumed that the aggregation model describes the formation of our zirconia particles very well.

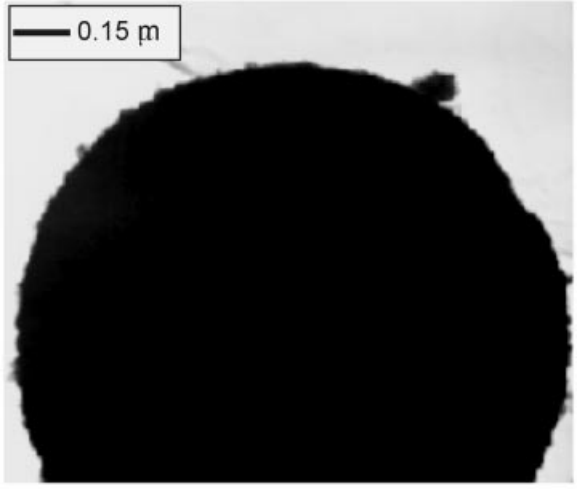

Figure 6. TEM picture illustrating the rough surface of a zirconia particle.

Silica-Coated Zirconia Particles

The surface properties of zirconia particles were controlled by coating with a silica layer. This was achieved by hydrolysis and condensation of TEOS in an ethanol/water/ammonia mixture. In the presence of ammonia as catalyst, the TEOS molecules were able to form bonds with the hydroxide groups of zirconia (Figure 7). The thermal and elementary analyses provided evidence for the existence of hydroxide groups and water at the particle surface. The total formula of zirconia particles was specified as ZrO_x-$(OH)_{2-x}$·nH_2O. The coat was formed according to the silica particle synthesis developed by Stöber et al.[11] Large zirconia spheres coated with fluorescent silica were visible in the CSLM. Therefore, fluorescein (APS-FITC) was added to the reaction solution. The dye molecules were incorporated into the shell. Figure 8 shows zirconia particles coated with a 50-nm thick shell of silica and APS-FITC in a one-step seeded growth process.

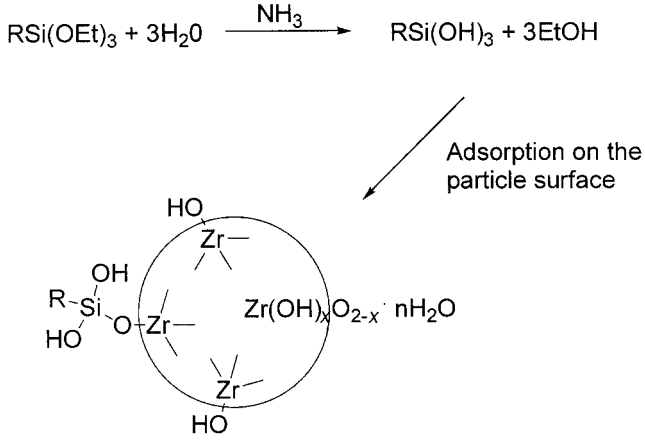

Figure 7. Coating of zirconia particles with TEOS.

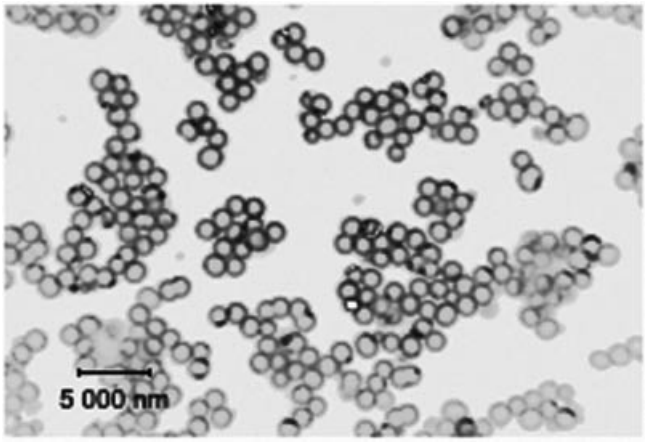

Figure 8. Confocal scanning laser micrograph of 1400 nm big zirconia particles coated with TEOS and fluorescein isothiocyanate acting as dye. The shell thickness is about 50 nm.

Conclusions

The controlled hydrolysis of alkoxides is a simple and powerful method to synthesise particles with well-defined sizes and narrow size distributions. Monodisperse, spherical ZrO_2 particles with sizes between 100 and 2000 nm were synthesised by hydrolysis. The size of the particles decreased with increasing reaction rate or with rising reaction temperature. Smaller particles were obtained with higher water concentration and larger particles with higher concentrations of zirconium butoxide. In contrast to the preparation of TiO_2 particles, in which salt ions and surfactant molecules were able to control the size of the particles and the porosity, the influence of such additives on the final zirconia particles is low. The surface properties of the zirconia particles were controlled by coating with a silica layer. The as-prepared powders were amorphous; a transition to crystalline forms was possible. The phase transition to the tetragonal phase occurred at about 450 °C, while the transition to the monoclinic phase began at 600 °C and was complete at about 800 °C.

Experimental Section

Materials: All reagents and solvents were used as received without further purification. Ethanol p.a., 1-propanol p.a., 1-butanol p.a. and alkali halide salts were purchased from Roth, zirconium alkoxides from Aldrich. Fluorescein isothiocyanate (FITC, isomer I) was purchased from Fluka, (3-aminopropyl)-triethoxysilane (APS) from Aldrich. Lutensol ON 50 and Pluronic PE 6400 were donated by BASF.

Synthesis of Zirconia Particles: In the synthesis of zirconia particles ethanol, 1-propanol and 1-butanol were used as solvents. Zirconium alkoxides like zirconium tetraethoxide, tetrapropoxide and tetrabutoxide were tested as precursors. Monodisperse spherical zirconia particles were synthesised by controlled hydrolysis of zirconium tetrabutoxide (80% solution in butanol) in ethanol. An ethanol volume of 100 mL was mixed with 0.2–0.6 mL of Millipore water, aqueous salt or polymer solution, followed by the addition of 3.25–5.00 mL zirconium tetrabutoxide at 60 °C under inert gas atmosphere, using a magnetic stirrer. Reagents had to be mixed completely, so that nucleation occurred uniformly throughout the solution. Depending on the concentration, visible particle formation started after several seconds or minutes and gave a uniform suspension of ZrO_2 beads. After 4 h, the reaction was finished, and the spheres were collected on a Millipore filter and washed with ethanol, or separated by centrifugation.

Coating of Zirconia Particles with Silica: A silica shell was formed around the zirconia particles by the following process: An aqueous ammonia solution (0.18 mL of a 25% solution) was added to a suspension of zirconia particles (100 mg) in ethanol (10 mL) whilst stirring. Subsequently, TEOS (0.2 mL) was added. To make the particles visible for CSLM, APS-FITC (0.01 mL) was added to the reaction solution. The reaction solution was stirred for 24 h, and the resulting particles were separated by filtration.

APS-FITC was synthesised in the following way: The dye FITC was covalently attached to the coupling agent APS by an addition reaction of the amine group with the thioisocyanate group. The reactants were slowly stirred for 12 h in ethanol, water was excluded to prevent hydrolysis and polymerisation of the APS molecules. 1 mL of ethanol p.a. was used per 0.1 g of APS.[7]

Characterisation of Zirconia Particles: The water content of the ZrO_2 beads was determined thermogravimetrically using a Netzsch-thermoanalyser STA 429 (under O_2, heating rate 10 K/min), combining thermogravimetry (TG), differential thermogravimetry (DTG) and differential thermal analysis (DTA). The crystallinity and phase-purity of the products were monitored by powder X-ray diffraction (XRD) using a Guinier-Huber camera 600 with Cu-$K_{\alpha 1}$ radiation. Scanning electron micrographs (SEM) were obtained with a Philips raster electron microscope (XL Series). Confocal scanning laser micrographs (CSLM) were obtained with a Zeiss Axiovert 200 with a Yokogawa confocal scanner. Electrophoretic mobility was measured with a Brookhaven Zetasizer. Particles were centrifuged out of suspension, and a small fraction of sedimented particles was resuspended in the supernatant again for use in mobility determinations. Nitrogen absorption isotherms were measured at 77 K with a Quantachrome Nova 3000 with samples which were degassed at 475 K and 1 mPa for 12 h.

Self-Assembly of 1D to 3D Cadmium Complexes: Structural Characterization and Properties

Xing Li,[a] Rong Cao,*[a] Wenhua Bi,[a] Daqiang Yuan,[a] and Daofeng Sun[a]

Keywords: Cadmiun / Hydrothermal synthesis / Layered compounds / O ligands / Self-assembly

Self-assembly reactions of 5-sulfoisophthalic monosodium salt (NaH_2sipa), $Cd(NO_3)_2 \cdot 4H_2O$ and 2,2′-bipyridine (or 4,4′-bipyridine) under hydrothermal condition give rise to four polymeric complexes, namely $\{[Cd_3(sipa)_2(2,2'\text{-bpy})_4(H_2O)_2] \cdot 6H_2O\}_n$ (**1**), $\{[Cd(sipa)(H\text{-}4,4'\text{-bpy})(H_2O)] \cdot 2H_2O\}_n$ (**2**); $\{[Cd_2(sipa)(4,4'\text{-bpy})_3(H_2O)_3] \cdot [Cd(sipa)(4,4'\text{-bpy})(H_2O)] \cdot 8H_2O\}_n$ (**3**), and $\{[Cd_3(sipa)_2(4,4'\text{-bpy})_4(H_2O)_2] \cdot 3H_2O\}_n$ (**4**), respectively. X-ray diffraction analyses reveal that complex **1** possesses a 1D rail-like chain structure, **2** is a 1D double chain, **3** has a 2D network consisting of an independent $[Cd_2(sipa)(4,4'\text{-bpy})_3(H_2O)_3]_n^{n+}$ cationic layer and a $[Cd(sipa)(4,4'\text{-bpy})(H_2O)]_n^{n-}$ anionic layer, and **4** is a novel 3D self-penetrating network constructed from two mixed bridging ligands. Thermogravimetric analyses (TGA) and fluorescent measurements of complexes **1**–**4** have also been performed.

Introduction

The rational design and synthesis of metal–organic coordination polymers with different dimensional topological structures is of great current interest because these complexes are potential candidates as new materials with uses in fluorescence, magnetism, catalysis, nonlinear optics, gas absorption, as semiconductors, and so on.[1] In recent decades, these studies have been developed rapidly and have produced delightful outcomes in which the structures or properties of a great number of reported compounds have been finely tuned by controlling the inorganic/organic component properties such as size, coordination geometries of the metal ions, flexibility, symmetry, and functionality of the organic ligands.[2] However, there are many seemingly insurmountable challenges regarding the preparation of polymeric complexes with directed dimensional networks containing inorganic or organic components exhibiting distinct physical and/or chemical properties. One of the key steps to assemble unusual architectures is to select appropriate organic ligands containing functional coordinating groups, and rigid multidentate ligands are a good choice.[3] The carboxylate groups have a strong ability to bond various metal ions and afford abundant coordination modes, thus rigid multi-carboxylate ligands have been widely used for the design and synthesis of a great variety of structures.[4] Introduction of a sulfonate group into rigid multi-carboxylate ligands may result in the formation of unexpected frameworks as the sulfonic group has a different shape and properties in terms of its coordination ability compared to the carboxylate group. Studies on the coordination chemistry of multi-carboxylate-sulfonic ligands are not very common. 5-Sulfoisophthalic acid (H_3sipa) has three distinct properties: (1) it has multiple coordination sites that may lead to high dimensional structures; (2) it possesses a symmetric geometry and rigidity that may yield novel topological structures; (3) it contains two kinds of coordinating functional groups that may form diverse supramolecular networks. However, only a few coordination polymers containing this ligand have been reported in the past few decades.[5] By employing 5-sulfoisophthalic acid as an organic ligand, we have successfully prepared two unusual planar tetracopper(II) SBUs that were further extended into an infinite metal–organic framework by the bridging carboxylates of the $sipa^{3-}$ ligand, as well as two new zeolite-like supramolecular compounds.[6] Our previous work spurred us on to systematically study metal–sipa coordination chemistry and to investigate the correlation between structures and properties. It has been well-documented that the introduction of terminal ligands into a reaction system can result in the formation of low-dimensional networks as the terminal ligands reduce the available metal binding sites and restrict the polymer's growth in this direction,[7] and that long bridging ligands can induce a single unit to grow into high dimensional frameworks.[8] Thus, the terminal ligand 2,2′-pyridine (2,2′-bpy) or the rigid bridging ligand 4,4′-bipyridine (4,4′-bpy) were introduced into a reaction system containing Cd^{II} ions and the $sipa^{3-}$ ligand with the hope of isolating polymeric complexes with different dimensional structures. Here we report the syntheses, structural

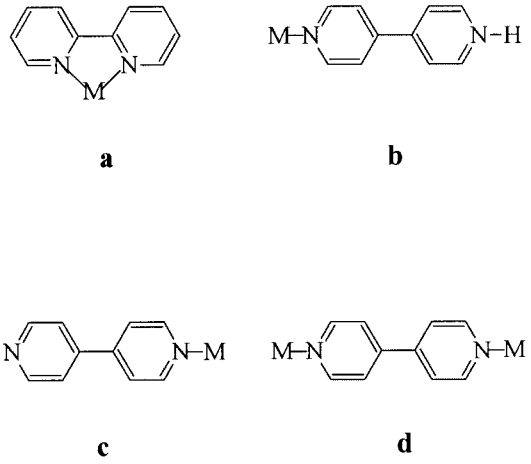
characterizations, and fluorescent properties of four novel cadmium complexes $\{[Cd_3(sipa)_2(2,2'\text{-bpy})_4(H_2O)_2]\cdot 6H_2O\}_n$ (**1**), $\{[Cd(sipa)(H\text{-}4,4'\text{-bpy})(H_2O)]\cdot 2H_2O\}_n$ (**2**), $\{[Cd_2(sipa)(4,4'\text{-bpy})_3(H_2O)_3]\cdot[Cd(sipa)(4,4'\text{-bpy})(H_2O)]\cdot 8H_2O\}_n$ (**3**), and $\{[Cd_3(sipa)_2(4,4'\text{-bpy})_4(H_2O)_2]\cdot 3H_2O\}_n$ (**4**). Complexes **1** and **2** possess one-dimensional structures, **3** contains a two-dimensional network consisting of independent cationic and anionic layers, and **4** assumes a novel self-penetrating three-dimension framework and has been briefly reported by us.[9]

Results and Discussion

Preparation of the Complexes

Coordination complexes of $sipa^{3-}$ with transition metals have been reported by our group and others recently,[5,6] but systematic studies on the coordination chemistry of $sipa^{3-}$ have been ignored. Our aim is to employ the hydrothermal method, which has been proven to be a very effective way for the synthesis of zeolite frameworks and high dimensional polymers, and to obtain novel structures by utilizing the $sipa^{3-}$ ligand's abundant coordination modes. It is well known that reaction parameters such as temperature, pH, and the ratio of reactants, as well as the addition of other ligands, can exert a profound influence on the final products under supercritical conditions. In this work, we focus on the influence of a second ligand and the molar ratio of the starting reactants. We started our work by using 2,2′-bpy as second ligand in the hydrothermal reaction of H_2sipa^-, Cd^{2+}, EtOH, and H_2O. Complex **1**, which possesses a 1D rail-like structure was prepared and no influence of the molar ratio of the reactants was observed. 2,2′-Bpy usually acts as a terminal ligand that chelates a metal ion to give low-dimensional structures, whereas 4,4′-bpy can assume different coordination modes (Scheme 1) and may generate 1D to 3D structures. Thus, 4,4′-bpy was employed instead of 2,2′-bpy with the hope of isolating different structures with varied coordination modes of 4,4′-bpy. When 4,4′-bpy replaces 2,2′-bpy in the hydrothermal reaction of H_2sipa^-, Cd^{2+}, and H_2O (H_2sipa^-/Cd^{2+}/4,4′-bpy = 1:1:1), complex **2**, with 1D double-chain, was isolated, which contains a protonated pyridine nitrogen atom with the 4,4′-bpy ligand acting as a monodentate ligand to a metal ion (Scheme 1b). When the molar ratio H_2sipa^-/Cd^{2+}/4,4′-bpy was changed to 2:3:5, the reaction yielded complex **3** with a 2D layer structure. In **3**, the 4,4′-bpy ligand displays two kinds of coordination modes: monodentate to coordinate a single metal ion and bidentate to bridge two metal ions (Scheme 1c and d). When the molar ratio H_2sipa^-/Cd^{2+}/4,4′-bpy was 4:3:4, complex **4**, which contains a 3D self-penetrating framework, was obtained, where the 4,4′-bpy acts as bidentate ligand to link two metal ions (Scheme 1, part d). Hence, by changing the molar ratio of reactants and utilizing a terminal or bridging secondary ligand, we have prepared 1D to 3D cadmium coordination complexes. In this reaction system the bpy ligands not only play the role of chelating or linking metal ions but also control the base/acid balance by protonating/deprotonating reactions between the pyridine nitrogen atoms and carboxylate groups.[5b] To confirm the purity, X-ray powder diffraction analyses (XRPD) were performed for all four complexes (see Supporting Information). These results show that the purity of the complexes is good enough to support our conclusions.



Scheme 1.

Description of Crystal Structures

$\{[Cd_3(sipa)_2(2,2'\text{-bpy})_4(H_2O)_2]\cdot 6H_2O\}_n$ (1)

Single crystal X-ray diffraction reveals that complex **1** possesses a one-dimensional structure constructed from Cd ions and $sipa^{3-}$ and 2,2′-bpy ligands, in which there are two types of coordination environments around the Cd ions. As shown in Figure 1, Cd1 is coordinated by two oxygen atoms from two SO_3 groups of $sipa^{3-}$ ligands and four nitrogen atoms from two 2,2′-bpy ligands. The two oxygen atoms occupy the axial positions, with an O1–Cd1–O1A bond angle of 180°, while the four nitrogen atoms are located in the equatorial plane, with the bond angles N1–Cd1–N1A and N2–Cd1–N2A being 180° and N1–Cd1–O1 and N2–Cd1–O1 being 87.6° and 89.7°, respectively, thus forming a slightly distorted octahedral geometry). The 2,2′-bpy ligand

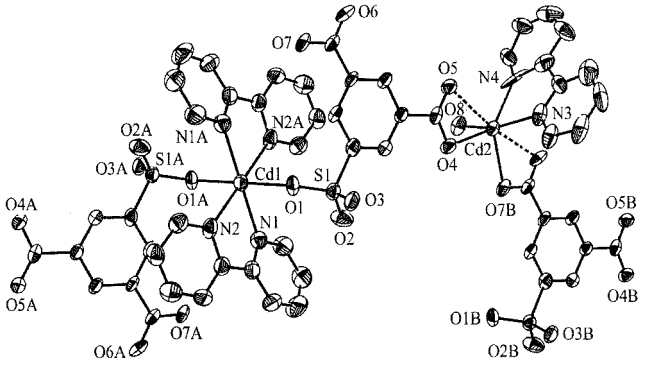


Figure 1. Ortep drawing of the coordination environments around the Cd ions in **1** with thermal ellipsoids at 30% probability. The isolated water molecules have been omitted for clarity.

binds in a chelate fashion to the metal ion and its two pyridine rings suffer from distortion, with a dihedral angle of 21°. Cd2 is in a distorted pentagonal-bipyramidal coordination environment and is coordinated by two nitrogen atoms (N3 and N4) from the bpy ligand, four oxygen atoms (O4–O7) from chelating carboxylates, and one oxygen atom (O8) (Table 1) from a water molecule, with the four carboxylate oxygen atoms and a nitrogen atom (N4) being located in the equatorial plane with Cd–O distances ranging from 2.292 to 2.616 Å and Cd2–N4 being 2.112 Å; O8 and N3 occupy the axial positions with bond lengths of 2.269 and 2.313 Å, respectively. Here, the long distances of Cd2···O6B (2.560 Å) and Cd2···O5 (2.616 Å) indicate a weak chelating interaction with the metal ions, which may be regarded as a semi-chelate coordination mode.[10] Therefore, Cd2 can also be described as having a pseudo pentagonal bipyramidal coordination geometry. The average bond lengths around Cd1 (2.317 Å) are somewhat shorter than those of Cd2 (2.354 Å), which is understandable due to the weak chelate interaction of the carboxylates in Cd2. The bond lengths S1–O1 (1.452 Å), S1–O2 (1.441 Å), and S1–O3 (1.449 Å) fall within the typical range of S–O bond lengths in a sulfonate ion (1.40–1.50 Å), and the distance C1–S1 (1.788 Å) is also as expected for a $sipa^{3-}$ ligand.[11] Due to the chelating carboxylate and the monodentate sulfonate, the $sipa^{3-}$ unit acts as three-armed connector that links a

Cd1 and two Cd2. Two Cd1 and four Cd2 centers form a grid unit $[Cd_6(sipa)_4]$ with the shortest Cd2–Cd2A and Cd1–Cd2 distances being 10.211 Å and 9.997 Å, respectively. Such units are extended into a 1D rail-like sheet by connection with a $sipa^{3-}$ ligand, with all metal ions located in the same plane. As expected, the presence of 2,2′-bipy and the coordinated water molecules around Cd2 prevents the one-dimensional chain from being further extended into a higher-dimensional network by covalent bonding (e.g. 2D or 3D), similar to those found in other metal/carboxylate/bpy reaction systems.[12] All pyridine rings of the 2,2′-bpy linking Cd2 orientate toward the outside of the one-dimensional sheet. The nearest distance of a pyridine ring to the adjacent sheet (3.383 Å) suggests a strongly offset face-to-face π···π stacking interaction and results in a 2D network (Figure 2). Complex **1** finally forms a 3D packing structure by hydrogen bonding and off-set face-to-face π···π stacking interactions.

{[Cd(sipa)(H-4,4′-bpy)(H$_2$O)]·2H$_2$O}$_n$ (2)

Compared with that in **1**, the $sipa^{3-}$ ligand in **2** shows different coordination modes: one carboxylate group chelates a Cd ion and the other bridges two Cd ions; the sulfonate group remains uncoordinated. In complex **2**, the 4,4′-bpy ligand is protonated at one end and acts as a monodentate ligand to coordinate to the metal ion; H_2sipa^- transfers its proton to a pyridine nitrogen atom for charge balance, which may be regarded as an acid-base reaction similar to those in previous reports.[5b,13] The Cd ion in **2** adopts a distorted octahedral geometry (Figure 3) and is coordinated in the equatorial plane by one monodentate carboxylate oxygen (O3A–Cd1 = 2.278 Å), one chelating carboxylate group (O1–Cd1 = 2.261 Å; O2···Cd1 = 2.535 Å), and one pyridine nitrogen (N1–Cd1 = 2.287 Å). The axial positions are occupied by one carboxylate oxygen (O4B–Cd1 = 2.389 Å) and one coordinated water molecule (O8–Cd1 = 2.324 Å; Table 2). Each two Cd ions are bridged by two carboxylate groups to form a binuclear cluster unit with a Cd–Cd distance of 3.877 Å. Each binuclear unit is interconnected by two $sipa^{3-}$ ligands to form a one-dimensional double chain along the diagonal of the *a*- and *b*-axes (Figure 4). Although 4,4′-bpy has replaced 2,2′-bpy, one of its nitrogen atoms is protonated and the sulfonate group remains uncoordinated, which results in the one-dimensional chain structure of **2**. The 1D double chain is extended into a 2D layer by hydrogen-bonding interactions, and a three dimensional framework is finally formed by hydrogen bonding and off-set face-to-face π···π stacking interactions between the benzene rings and the pyridine rings of adjacent 2D layers, with distance of about 3.40 Å.

{[Cd_2(sipa)(4,4′-bpy)$_3$(H_2O)$_3$]·[Cd(sipa)(4,4′-bpy)-(H_2O)]·8H_2O}$_n$ (3)

X-ray diffraction analysis shows that complex **3** has a two-dimensional structure that is different from those in a great number of 2D complexes previously reported[14] – it consists of independent cationic [Cd_2(sipa)(4,4′-bpy)$_3$-(H_2O)$_3$]$_n^{n+}$ and anionic [Cd(sipa)(4,4′-bpy)(H_2O)]$_n^{n-}$ layers. In the cationic layer, two crystallographically different coordinatio environments are observed around Cd1 and Cd2 (Figure 5). Cd1 is six-coordinate, with three carboxylate oxygen atoms and one nitrogen atom in the equatorial plane and one water molecule and one nitrogen atom occupying the axial positions to form a distorted octahedral coordination geometry. Cd2 also adopts a distorted octahedral coordination geometry and is coordinated in the equatorial plane by three nitrogen atoms from pyridine rings and one oxygen atom from a sulfonate group, with two coordinated water molecules located in the axial positions. However, Cd3 in the anionic layer has a slightly distorted pentagonal-bipyramidal coordination environment, with

one pyridine nitrogen and a water molecule in the axial positions and two chelating carboxylate groups and one nitrogen atom in the equatorial plane (Figure 5). The distances Cd3···O10A, Cd3···O8, and Cd1···O1 are 2.559, 2.584, and 2.504 Å, respectively, indicating a weak chelate interaction similar to that in **1**.[5,6] C55 and C56 of the 4,4′-bipyridine ring and O12, O13, and O14 of the SO_3 group of the sipa^{3-} ligand are disordered over two positions with bond length C55–C54 = 1.408 Å, C55′–C54 = 1.485 Å and C56–N8 = 1.372 Å, C56′–N8 = 1.430 Å (Table 3).

In the anionic layer each 4,4′-bpy ligand bridges two cadmium ions to yield a zigzag chain along the *c* axis. This chain forms a two dimensional step-like network by the linkage of the sipa^{3-} ligand through its two chelating carboxylate groups in the *ac* plane; the sulfonate groups do not engage in coordination and stand at the zygomorphic sides of the layer (Figure 6, part a). The layer contains two kinds of grids with different dimensions: side lengths 10.237 × 11.813 Å and diagonal distances 15.342 × 15.916 Å based on the metal–metal interval for **A**, and side 10.237 × 11.731 Å and diagonal 15.286 × 15.865 Å for **B**. The dihedral angle between **A** and **B** is 105.50°. On the other hand, the parallelogram 34-membered $Cd_4(sipa)_2(4,4'\text{-bpy})_2$ macro grid can be regarded as a basic building block for the whole 2D step-like structure. Each two $Cd_4(sipa)_2(4,4'\text{-bpy})_2$ units are linked together to form a ladder-like chain by sharing a Cd-bpy-Cd side, and the adjacent ladders are connected by 4,4′-bpy ligands to generate the final 2D step-like layer (Figure 6, part b).

In the cationic layer the sipa^{3-} acting as a three-armed ligand utilizes its monodentate and chelating carboxylate groups to link Cd1 to produce a one-dimensional cationic chain. Each two such chains are connected together by bridges formed by monodentate sulfonate, 4,4′-bpy, and Cd2 to yield a double chain along the *a* axis (Figure 7, part a). In fact, the double chain is an infinite brick-like sheet with a width of about 17.204 Å and height of about 3.710 Å from the closest pyridine ring center to the benzene ring center (the height is almost equal to the sum of the S–O and O–Cd distances). The uncoordinated end of 4,4′-bpy points outside of the brick-like sheet. On the other hand, the cadmium ions and the 4,4′-bpy ligands propagate into a zigzag chain along the *c* axis, and two such chains are fastened together by a sipa^{3-} ligand through its chelating carboxylates and monodentate sulfonate groups to yield a double zigzag cationic chain (Figure 7, part b). The infinite brick-like sheets (Figure 7, part a) and the double zigzag chains (Figure 7, part b) are connected by the sipa^{3-} ligands as linkers and the cadmium ions as nodes to form a two-dimensional cationic step-like network; the uncoordinated pyridine ends of 4,4′-bpy ligands fall on different sides of the step-like plane (Figure 7, part c).

The step-like cationic layer and the step-like anionic layer have an alternate arrangement, where the uncoordinated end of 4,4′-pyridine from the cationic layer penetrates into the cavities of the anionic layer to form a tightly stacked neutral structure through electrostatic forces as well as hydrogen-bonding interactions between carboxylate oxygen atoms, pyridine nitrogen atoms, and free water molecules that are present between the cationic and anionic layers (Figure 8).

It's interesting that the 4,4′-bpy ligands in **3** play different roles in the cationic layer: one acts as a bridging ligand results in the formation of the two dimensional structure,

whereas the other, in which one nitrogen remains free and does not engage in coordination to the metal ion, acts as a terminal ligand that prevents the formation of three dimensional networks, although the $sipa^{3-}$ ligands employ all their coordination functional groups. In the anionic layer, one 4,4′-bpy bridges two metal ions and two carboxylate groups of $sipa^{3-}$ chelate one metal ion, leading to the formation of a two-dimensional structure; the sulfonate group remains uncoordinated to prevent the formation of three-dimensional frameworks. To the best of our knowledge, **3** is the first example of independent cationic and anionic layers in the structural framework of cadmium sulfonate-carboxylate complexes, which have only rarely been reported in other metal–organic compounds.[15]

{[Cd_3(sipa)$_2$(4,4′-bpy)$_4$(H_2O)$_2$]·3H_2O}$_n$ (4)

The structure of **4** has already been described in our previous report[9] and a detailed discussion will not be made here. In **4**, four $sipa^{3-}$ ligands and four cadmium ions form a 32-membered-ring $Cd_4(sipa)_4$ unit, which then propagates into a one-dimensional ladder-like double chain by sharing the $sipa^{3-}$ ligands as sides. Four cadmium ions and four bpy ligands encircle a $Cd_4(bpy)_4$ unit[16,17] and the $Cd_4(bpy)_4$ units are further extended into a one-dimensional twisted 8-like chain by sharing vertex cadmium ions. The two types of one-dimensional chains are interlocked and interwoven into a two-dimensional framework by sharing cadmium ions in the *ab* plane (Figure 9 and Table 4). The most intriguing feature is that the two kinds of $Cd_4(sipa)_4$ and $Cd_4(bpy)_4$ units interlock and interconnect each other to produce a pseudocatenate structure. Each $Cd_4(bpy)_4$ unit interlocks two $Cd_4(sipa)_4$ units and each $Cd_4(sipa)_4$ interlocks two $Cd_4(bpy)_4$ through cadmium ion nodes to yield an interwoven structure that is further magnified in different directions into a new three-dimensional, self-penetrating topological network (Figure 10).[18]

Both $sipa^{3-}$ and 4,4′-bpy ligands in **4** take full advantage of their coordination functional groups to link metal ions and generate a new self-penetrating three-dimensional framework, whereas in **1** the presence of the 2,2′-bipy ligand prevents the one-dimensional chain from being further extended into a 2D or 3D network even though the $sipa^{3-}$ ligands employ all their functional groups in coordination. In **2** and **3**, although 4,4′-bpy replaces 2,2′-bpy, one nitrogen atom of the pyridine ligand does not engage in coordination or the sulfonate group remains uncoordinated, which results in preventing the formation of a 3D structure. Thus, the design and syntheses of coordination complexes with different dimensional structures may be carried out by the control or modification of the properties of e coordinating functional groups and/or introduction of a second organic ligand.

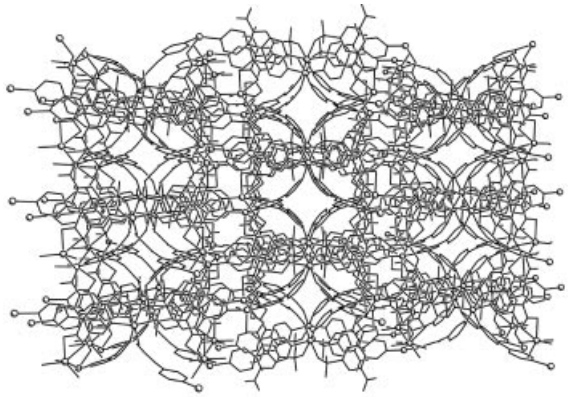

Figure 10. The three-dimensional self-penetrating structure along the *c* axis of **4**. Isolated water molecules are located in the channels.

Thermogravimetric Analysis (TGA)

Thermogravimetric analyses for complexes **1**–**4** were performed under a flow of nitrogen gas from room temperature to 1000 °C at a heating rate of 15 °C min^{-1}. Complex **1** begins to lose free water molecules at 184 °C and then loses further weight with increasing temperature. Differential thermal analysis (DTA) studies show two strongly endothermic reactions at 395 and 440 °C, respectively, which indicates that the framework collapses at 395 °C. For **2**, the first weight loss of 6.87% (calcd.: 6.36%) from 111 to 154 °C corresponds to the loss of two guest water molecules per formula unit ($2H_2O$/[Cd(sipa)(Hbpy)(H_2O)]·$2H_2O$ along with a strong absorption heat reaction; the coordination water molecules are slowly lost over the range 154–375 °C. DTA shows that one strong heat-absorption reaction takes place at 417 °C because of the collapse of the framework of **2**. Complex **3** starts losing weight at 50 °C and loses further weight with increasing temperature. DTA shows that a strongly endothermic reaction occurs at 436 °C, which indicates that the framework of **3** collapses. For **4**, the first weight loss of 5.75% (calcd. 5.86%) from 63 to 144 °C, which is accompanied by heat absorption, corresponds to the loss of three free waters and coordination water molecules per formula unit ($5H_2O$/{[Cd_3(sipa)$_2$-(bpy)$_4$(H_2O)$_2$]·$3H_2O$}). Strong heat absorption takes place in the range 340–420 °C, indicating the collapse of the structural framework at 340 °C.

Fluorescence Measurements

Previous studies have shown that polymeric compounds containing cadmium exhibit photoluminescent properties.[18] Hence, we also investigated the photoluminescent properties of complexes **1**–**4** (Figure 11). In the solid state, complex **1** displays two intense broadband fluorescent emissions at 335 and 351 nm, respectively, upon photoexcitation at 310 nm. Since NaH_2sipa exhibits photoluminescence emission at 355 nm, and free 2,2′-bipyridine exhibits emission at 362 nm, the emission bands at 351 and 335 nm of **1** can be attributed to the ligand donation. Strong photoluminescence emission bands at 510, 458, and 455 nm are observed for complexes **2**, **3**, and **4**, respectively, while free 4,4′-pyridine ligand presents weak photoluminescence emission at 486 nm. The photoluminescent emission of **2**–**4** may therefore be assigned to the nonradiative decay of the intraligand (π–π*) excited state and/or to ligand-to-metal charge transition, similar to previous reports.[5,19,20]

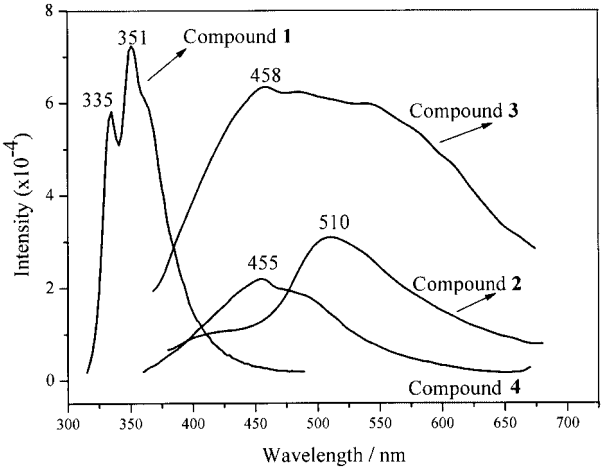

Figure 11. The photoluminescent spectra of **1**–**4** in the solid state at room temperature.

Conclusions

In conclusion, by selecting H_2sipa$^-$, 2,2′-bpy, and 4,4′-bpy as organic ligands, and the cadmium ion as knots, four polymeric complexes have been successfully isolated under hydrothermal conditions. Complex **1** possesses a 1D rail-like chain structure, **2** is a 1D double chain, **3** has a 2D network consisting of independent cationic [Cd_2(sipa)(4,4′-bpy)$_3$(H_2O)$_3$]$_n^{n+}$ and anionic [Cd(sipa)(4,4′-bpy) (H_2O)]$_n^{n-}$ layers, and **4** is a novel 3D self-penetrating network constructed from two mixed bridging ligands. The present work shows that a novel structure can be designed and assembled by combining the topology of organic ligands and the coordination geometry of metal ions.

Experimental Section

General: All chemicals were used as purchased without purification. The IR spectra were recorded as KBr pellets in the 4000–400 cm^{-1} region on a Magna 750 FT-IR spectrophotometer. The C, H, and N microanalyses were carried out with a Perkin–Elmer 240-element analyzer at this institute. Thermogravimetric analyses (TGA) were carried out on a Netzsch STA449C instrument. Fluorescent properties of **1**–**4** were measured on an Edinburgh Instruments analyzer model FL920.

{[Cd_3(sipa)$_2$(2,2′-bpy)$_4$(H_2O)$_2$]·$6H_2O$}$_n$ (1): A mixture of NaH_2sipa (0.053 g, 0.2 mmol), $Cd(NO_3)_2$·$4H_2O$ (0.092 g, 0.3 mmol), 2,2′-bipyridine (0.047 g, 0.3 mmol), EtOH (1.0 mL), and water (15 mL) was placed in a 25-mL Teflon-lined stainless autoclave and heated under autogenous pressure at 160 °C for 3 d. It was then cooled

{[Cd_2(sipa)(4,4′-bpy)$_3$(H_2O)$_3$]·[Cd(sipa)(4,4′-bpy)(H_2O)]·8H_2O}n (3): A mixture of NaH_2sipa (0.053 g, 0.2 mmol), $Cd(NO_3)_2$·4H_2O (0.092 g, 0.3 mmol), 4,4′-bipyridine dihydrate (0.096 g, 0.5 mmol), EtOH (1.0 mL), and water (15 mL) was placed in a 25-mL Teflon-lined stainless autoclave and heated under autogenous pressure at 160 °C for 5 d. It was then slowly cooled to room temperature over 24 h. Colorless sheet-like crystals of **3** were separated from the reaction mixture in about 54% yield (0.18 g). $C_{56}H_{62}Cd_3N_8O_{26}S_2$ (1664.5): calcd. C 40.41, H 3.75, N 6.73; found C 40.29, H 3.64, N 6.61. IR (KBr): $\tilde{\nu}$ = 3417 cm^{-1} m, 3088 m, 3051 m, 2565 w, 2141 w, 1942 w, 1603 vs, 1556 s, 1491 w, 1414 m, 1363 s, 1308 w, 1221 s, 1198 s, 1147 m, 1103 m, 1043 s, 874 w, 825 m, 806 s, 769 m, 731 m, 631 s, 580 w, 492 w, 447 w.

{[Cd_3(sipa)$_2$(4,4′-bpy)$_4$(H_2O)$_2$]·3H_2O}$_n$ (4): A mixture of NaH_2sipa (0.266 g, 1.0 mmol), $Cd(NO_3)_2$·4H_2O (0.231 g, 0.75 mmol), 4,4′-bipyridine dihydrate (0.192 g, 1.0 mmol), and water (10 mL) was placed in a 25-mL Teflon-lined stainless autoclave and heated under autogenous pressure at 160 °C for 3 d. It was then slowly cooled to room temperature over 24 h. The light-yellow block-like crystals of **4** were separated from the reaction mixture in about 23% yield (0.35 g). $C_{56}H_{48}Cd_3N_8O_{19}S_2$ (1538.3): calcd. C 43.72, H 3.14, N 7.28; found C 43.60, H 2.94, N 7.31. IR (KBr): $\tilde{\nu}$ = 3377 cm^{-1} w, 3211 w, 3055 w, 1942 w, 1605 vs, 1556 s, 1491 w, 1416 m, 1363 s, 1230 s, 1198 s, 1105 w, 1043 m, 1007 w, 922 w, 806 m, 783 w, 719 w, 629 m, 582 m, 492 w, 432 w.

X-ray Crystallography: Single crystals of complexes **1**–**4** with dimensions 0.24 × 0.18 × 0.12 (**1**), 0.36 × 0.24 × 0.10 (**2**), 0.24 × 0.18 × 0.06 (**3**), and 0.28 × 0.22 × 0.18 mm (**4**) were mounted on glass fibers for crystal structure analyses. For **1**, **2**, and **4** the data collections were performed on a Siemens Smart CCD diffractometer and for **3** on a Rigaku CCD diffractometer with graphite-monochromated Mo-K_a radiation (λ = 0.71073 Å) at 293 K. Empirical absorption corrections were applied using the SADABS program for **1**, **2**, and **4** and the CrystalClear program for **3**. All structures were solved by direct methods and the heavy atoms were located from the E-maps. Other non-hydrogen atoms were derived from the successive difference Fourier syntheses. The structures were refined by full-matrix, least-squares minimizations of $\Sigma(F_o - F_c)^2$ with anisotropic thermal parameters for all non-hydrogen atoms. All calculations were performed with the SHELXTL-97 program package.[21] The positions of hydrogen atoms were generated geometrically and treated isotropically. In complex **3**, C55 and C56 of the 4,4′-bipyridine ring and O12, O13, and O14 of the SO_3^- group from $sipa^{3-}$ ligand were disordered over two sets of positions and were refined with restraints. Table 5 summarizes the important crystal data for **1**–**4**.

CCDC-246223 (for **1**), -246224 (for **2**), -246225 (for **3**), and -221212 (for **4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Luminescence and Theoretical Studies of Cu(tripod)X [tripod = 1,1,1-Tris(diphenylphosphanylmethyl)ethane; X^- = Halide, Thiophenolate, Phenylacetylide]

Valeri Pawlowski,[a][‡] Günther Knör,[a] Christian Lennartz,*[b] and Arnd Vogler*[a]

Keywords: Electronic spectra / Luminescence / Copper complexes / Phosphane ligands / Quantumchemical calculations

Complexes of the type Cu^I(tripod)X [tripod = 1,1,1-tris(diphenylphosphanylmethyl)ethane; X^- = Br^-, I^-, PhS^-, $PhC{\equiv}C^-$] are phosphorescent in solution and in the solid state ($\lambda_{max} \approx$ 465 nm). Calculations show that the emissive triplet is of mixed MLCT/LLCT character. The emission is facilitated by the rigid tetrahedral structure, which is imposed by the tripod ligand. Accordingly, a distortion towards a square-planar geometry, which should occur upon MLCT excitation, is prevented. On the other hand, in the triplet state the phenyl substituents of the phosphane ligands undergo a rotation which favours radiationless deactivation. As a result, the emission efficiency is relatively small in solution, but much higher in the solid state owing to the rigidity of the lattice.

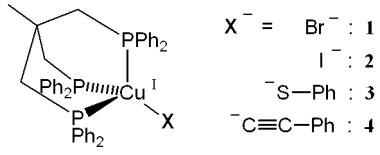
Introduction

The luminescence of transition metal complexes is a rapidly expanding research field.[1,2] Potential applications such as optical sensors or OLEDs (organic light-emitting diodes) have stimulated many studies in this area.[3,4] The appearance of a luminescence at room temperature is largely restricted to complexes of metals which belong to the second and third transition row, while complexes of first-row transition metals are frequently not emissive under ambient conditions. However, there is one notable exception. A variety of mononuclear and polynuclear Cu^I complexes are luminescent at room temperature in solution or in the solid state.[5–8] In particular, mononuclear complexes with polypyridine ligands have attracted much interest.[8,9] These compounds are characterized by emissive low-energy MLCT (metal-to-ligand charge transfer) states. (Phosphane)Cu^I complexes constitute another group of luminescent compounds[5] which, however, have not been investigated to the same extent as (polypyridine)Cu^I complexes. In particular, the nature of the emitting excited states of (phosphane)Cu^I complexes is not clear at all. The present study was undertaken to gain more insight into the excited-state properties of (phosphane)Cu^I complexes and to define structural requirements for potential applications. Complexes of the type Cu^I(tripod)X [tripod = 1,1,1-tris(diphenylphosphanylmethyl)ethane; X^- = Br^-, I^-, PhS^-, $PhC{\equiv}C^-$] were expected to serve this purpose (Scheme 1).



Scheme 1.

The rigid structure of these complexes,[10] which is imposed by the tripod ligand, should facilitate this work. These complexes are kinetically stable, soluble in a variety of organic solvents and volatile at higher temperatures without decomposition. Moreover, the rigidity of the compounds prevents extensive excited-state distortions. Accordingly, calculations of the frontier orbitals may be sufficient to characterize the lowest-energy excited state. In addition, the lack of flexibility could block radiationless deactivations and increase the luminescence efficiency. Finally, the rigidity should reduce the Stokes shift. As a result, the emission is expected to undergo a blue-shift. In this context, it should be mentioned that for certain applications such as OLEDs blue triplet emitters are requested, but are not yet available to the same extent as green and red molecular phosphors.

Results and Discussion

Experimental Results

The neutral compounds Cu(tripod)X [X^- = Br^-, I^-, PhS^-, $PhC{\equiv}C^-$] were readily obtained as white or slightly yellow-

ish solids by reaction of the corresponding copper(I) precursors CuX with the tridentate phosphane ligand tripod (Scheme 1). Their monomeric composition was confirmed by elemental analysis, and in the case of the halide derivatives **1** and **2** also by conductivity and molecular weight measurements.[11]

While the electronic spectrum of the tripod ligand in CH_2Cl_2 exhibits a featureless ultraviolet band at λ_{max} = 251 nm, the absorption spectra of the corresponding copper complexes display their maxima in the 300 nm spectral region (Figure 1). These bands are rather intense (ε = 13650 M^{-1} cm^{-1} at λ_{max} = 298 nm for **2** in CH_2Cl_2) and significantly red-shifted in the order of 4000–6500 cm^{-1} from the absorption of free tripod. In the case of the thiophenolate derivative **3**, an additional splitting of the main absorption band occurs with two well-resolved peaks at 270 and 290 nm.

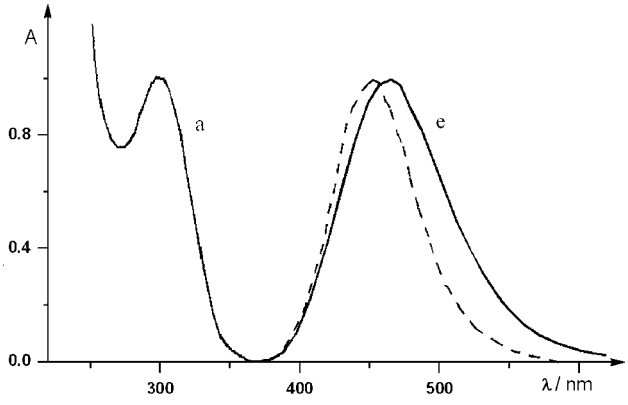

Figure 1. Electronic absorption (a) and emission (e) spectra of Cu(tripod)I (**2**) at room temperature and at 77 K (dashed curve). Absorption: 7.36×10^{-5} M in CH_2Cl_2, 1-cm cell. Emission: λ_{exc} = 300 nm, solid and in toluene matrix, intensity in arbitrary units.

All of the Cu(tripod)X complexes **1**–**4** exhibit an intense blue emission with peaks around 465 nm when excited with ultraviolet light in the solid state. This feature is shown in Figure 1 for Cu(tripod)I (**2**) with λ_{max} = 462 nm. At 77 K in a low-temperature toluene matrix, the luminescence maximum of **2** is blue-shifted to λ_{max} = 453 nm and the spectrum is slightly narrowed, while no significant structuring or larger change of shape of the emission band is observed (Figure 1). In argon-saturated dichloromethane solution, the luminescence of compound **2** shows a broad maximum with λ_{max} = 465 nm. A rather low quantum yield of $\varphi = 8 \times 10^{-4}$ is obtained in CH_2Cl_2 relative to quinine sulfate as a standard, and the luminescence in solution is found to be only moderately quenched by dioxygen. A quite similar behaviour is observed for the corresponding bromide derivative **1**.

The thiophenolate complex **3** also shows a blue emission at λ_{max} = 465 nm in the solid state, but in contrast to the halide derivatives **1** and **2**, a green luminescence with a significantly shifted, structureless band at λ_{max} = 508 nm is dominant in dichloromethane solution (Figure 2). As a solid compound, the luminescence spectrum of the phenylacetylide complex **4** displays a conspicuous structuring with a rather sharp maximum at 465 nm and a clearly resolved shoulder in the region of 510 nm. The peak separation of about 2000 cm^{-1} approximately matches the C≡C stretching frequency of the ligand X. In solution, however, a broad and nearly structureless band with λ_{max} = 475 nm is present in the organometallic derivative **4** as well. The spectroscopic data for all of the copper(I) complexes **1**–**4** in the solid state and in dichloromethane solution are summarized in Table 1.

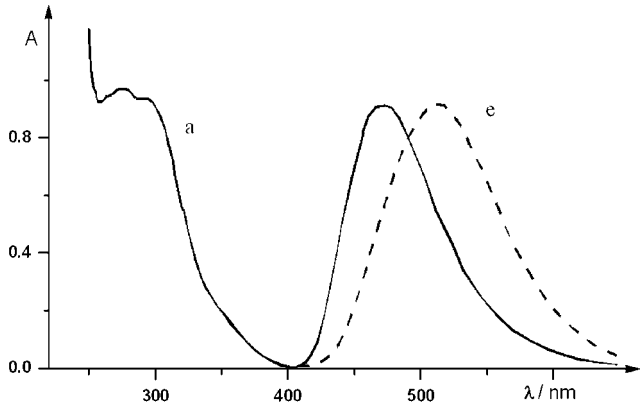

Figure 2. Electronic absorption (a) and emission (e) spectrum of Cu(tripod)SPh (**3**) at room temperature. Absorption: CH_2Cl_2, 1-cm cell. Emission: λ_{exc} = 300 nm, solid and in CH_2Cl_2 solution (dashed curve), intensity in arbitrary units.

Table 1. Absorption and emission maxima of Cu(tripod)X at room temperature.

X	λ_{max} [nm] (CH_2Cl_2)	λ_{em} [nm] (solid)	λ_{em} [nm] (CH_2Cl_2)
Br	296	462	462
I	298	461	465
SPh	270, 290	465	508
C≡CPh	297	465, 510	475

Discussion

The compounds Cu(tripod)X are monomeric and tetrahedral.[10,11] They are kinetically stable in distinction to other Cu^I complexes with monodentate or bidentate phosphane ligands, which undergo dissociation and dimerization in solution.[12,13] The electronic spectra of various (arylphosphane)Cu^I complexes have been reported.[5] However, assignments for the lowest-energy excited states seem to be controversial. In most cases it has been suggested that these states are of the phosphane IL (intraligand) type. This excitation involves the promotion of an electron from the Cu–P σ-bond into π*-orbitals, which are partially delocalized over the aryl substituents. Since the lone-pair of the free phosphane is stabilized by coordination, a blue-shift of this transition should take place. However, this has been frequently not observed. Generally, the lowest-energy transitions of such (arylphosphane)Cu^I complexes are very close to those of the free ligands, sometimes at somewhat higher

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and sometimes at slightly lower energies. The longest-wavelength absorptions of Cu(tripod)X (Table 1) are assigned to spin-allowed transitions in agreement with their high intensities.

Generally, the luminescence of Cu^{I} complexes is a phosphorescence, but occasionally a delayed fluorescence at shorter wavelengths has also been observed.[14–17] In the case of Cu(tripod)X complexes, the emission is certainly a phosphorescence, since it does not overlap with the absorption spectrum. Moreover, at low temperatures Cu(tripod)X complexes do not show a new long-wavelength emission, although the appearance of a phosphorescence should be favoured under these conditions.

Quantum chemical calculations were carried out for all complexes to determine the electronic character of the emission. TD-DFT calculations of the T_1-state at the T_1-geometry based on the singlet orbitals showed that the electronic character of the state is dominated by a one-electron transition from HOMO to LUMO (weight of the leading configurations > 0.95). Therefore the interpretation is based on HOMO and LUMO taken from the singlet wave function calculated at the T_1-state geometry (Figure 3).

The character of the HOMO is dominated by the d-p-π-antibonding interaction between Cu and X. Additionally, there is an antibonding interaction between the phosphane lone pair and the copper d-orbital. The LUMO is mainly localized on the phenyl rings and displays π* character (e_{2u} benzene-type). Accordingly, the electronic character of the transition is best described as MLCT(Cu^{I} → phosphane) + LLCT(X^{-} → phosphane). This is shown in Figure 4 for X = I, but is qualitatively very similar for the other Cu(tripod)-X complexes.

Comparison of the calculated geometries of the singlet ground state and triplet state (Table 2) shows that the main geometrical changes are due to rotations of the phenyl groups in the case of X = Br, I. The maximum rotation angles found among the phenyl groups amount to 50° and 35° for Br^{-} and I^{-}, respectively. The rms distances of all atoms add up to 68 pm and 49 pm, respectively. The Cu–Br/Cu–I bond length is slightly shortened (2.9/3.7 pm) in the triplet state due to the depopulation of the Cu–Br/Cu–I antibonding orbital. Distortions are substantially lower in the case of X = SPh. The maximum rotation is found on the thiophenyl group and amounts to 12° (rms *d* = 26 pm).

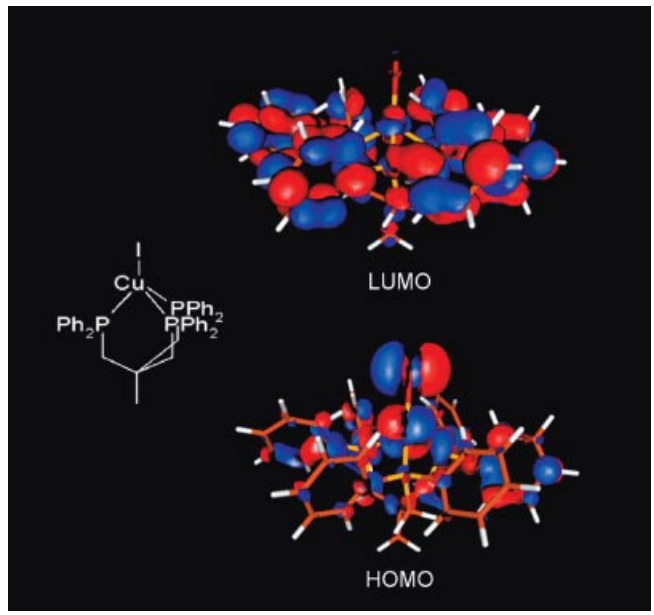

Figure 3. Frontier orbitals of Cu(tripod)I (**2**): HOMO (bottom) and LUMO (top).

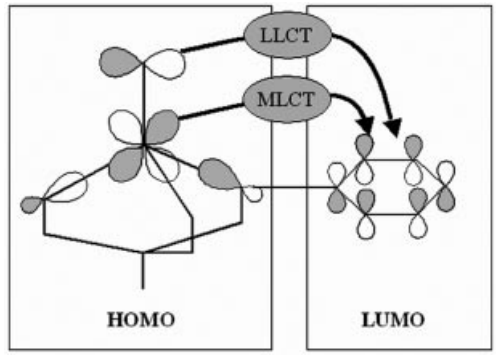

Figure 4. Schematic representation of the electronic transition. Only one of the six phenyl groups is shown.

The Cu–S bond is shortened by 4.7 pm in the triplet state. Nearly no distortions are found for X = C≡C–Ph (rms *d* = 11 pm; elongation of the Cu–C bond: 3.9 pm). In all cases

[a] TD-DFT/TZVP. [b] Energies shifted by 1.16 eV to fit the emission energy of X = Br, since this method is known to yield systematical red-shifts.

there is a slight increase of the P–Cu bond length in the triplet state.

The calculated emission energies of Cu(tripod)X with X = I, Br and SPh were found to be systematically red-shifted. Therefore, we added a constant shift of 1.16 eV to facilitate a comparison with the experimental values (Table 3). This shifting behaviour may be understood by the fact that standard approximate exchange-correlation functionals suffer from an artificial stabilization of CT states due to the wrong asymptotic behaviour of the corresponding exchange-correlation functionals.[18] We performed additional single-CI calculations (TZVP basis set) in order to determine the character of the lowest excited state for X = Br. Although this method only gives qualitative results for energies, it does not suffer from the artificial stabilization of charge-transfer states. We found that the CT state actually is the lowest-lying state in Cu(tripod)Br. Therefore, the relative TD-DFT energies should reflect the right trend. Indeed, the shifted TD-DFT energies nicely correlate with the observed phosphorescence energies of of Cu(tripod)X with X = I, Br and SPh (Table 3). The red-shift observed for the thiophenolate complex is caused by a greater destabilization of the HOMO which contains a rather large sulfur contribution.

For the phenylacetylide complex, there is a distinct discrepancy between the calculated and the observed phosphorescence energies. While in comparison to other Cu(tripod)-X complexes a blue-shift is calculated, a red-shift is indeed observed. Probably, here the TD-DFT calculation fails to describe the first excited state correctly due to the problems already mentioned above. For phenylacetylide complexes, such as $(PR_3)Au(C{\equiv}C–Ph)$,[19] an IL (phenylacetylide) phosphorescence occurs at energies which are comparable to the calculated transition energies (Table 3). It is conceivable that contrary to the calculation, the emission of Cu(tripod)(C≡C–Ph) now originates from the phenylacetylide IL triplet, which in reality is located below the MLCT/LLCT triplet. Therefore, the artificial stabilization of the CT states may result in a qualitatively wrong picture here.

The mixed MLCT/LLCT character of the lowest-energy excited state of Cu(tripod)I does not only follow from the present calculations; it is also supported by previous calculations on related systems.[20] Moreover, similar conclusions have been drawn for the assignment of the lowest-energy electronic transition in tetranuclear copper(I) clusters.[6,7] In this context it should be kept in mind that the structures of Cu^I complexes in their MLCT states are planar and not tetrahedral as in their ground states.[21–26] The rigidity of Cu(tripod)X is expected to facilitate the emission since radiationless transitions are hampered when the flexibility including excited-state distortions is restricted. Indeed, all four Cu(tripod)X complexes are luminescent in solution and at room temperature (Table 1). However, in solution at room temperature the efficiency is still rather low. We suggest that the rotations of the phenyl groups at the phosphane ligand, which take place in the lowest triplet state, favour radiationless deactivations. In the solid state the phosphorescence of Cu(tripod)X is much more intense and shifts to shorter wavelengths. This is certainly a consequence of a diminished flexibility in the lattice of the solid compound. However, since the extent of structural changes in the solid state is not well defined, the calculations should be better compared with the emission spectrum in solution. While the formal assignments of MLCT/LLCT transitions are certainly appropriate, the actual amount of charge redistribution seems to be rather small as indicated by the dipole moments (Table 3). Accordingly, a distinct solvent-dependent shift is neither expected nor observed.

In conclusion, the complexes Cu(tripod)X are characterized by a blue emission, which originates from a mixed MLCT ($Cu^I \rightarrow$ tripod)/LLCT ($X^- \rightarrow$ tripod) triplet. Owing to the rigid structure imposed by the tripod ligand, this phosphorescence appears not only in the solid state, but also at room temperature in solution.

Experimental Section

Materials: All solvents used for spectroscopic measurements were of spectrograde quality. CuBr, CuI, CuSPh, CuC≡CPh and the tripodal ligand 1,1,1-tris(diphenylphosphanylmethyl)ethane were commercially available (Aldrich and Strem) and used without further purification. The title compounds were obtained by the following synthetic routes.

Cu(tripod)Br (1): In a procedure different from the published route,[11,27] a solution of CuBr (0.16 g, 1.1 mmol) and tripod (0.71 g, 1.1 mmol) in 40 mL of acetonitrile was refluxed for 20 min, and then cooled to room temperature. The resulting white precipitate was collected by filtration, washed with acetonitrile and diethyl ether, and dried yielding 0.77 g (88%). $C_{41}H_{39}BrCuP_3$ (768.12): calcd. C 64.11, H 5.12, Br 10.40; found C 64.02, H 5.06, Br 9.61.

Cu(tripod)I (2): Similar to the bromide complex **1**, a solution of CuI (0.10 g, 0.5 mmol) and tripod (0.32 g, 0.5 mmol) in 20 mL of acetonitrile was refluxed for 20 min, and then cooled to room temperature. The resulting white precipitate was collected by filtration, washed with acetonitrile and diethyl ether, and dried yielding 0.32 g (73%). $C_{41}H_{39}CuIP_3$ (815.12): calcd. C 60.41, H 4.82, I 15.57; found C 60.23, H 4.57, I 15.23.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Cu(tripod)SPh (3): A suspension of CuSPh (0.26 g, 1.5 mmol) and tripod (0.96 g, 1.5 mmol) in 60 mL of acetonitrile was stirred at room temperature for 10 min and then kept under reflux for 90 min. After filtration of the hot, yellowish mixture, the solution was reduced to a small volume and cooled to room temperature. The resulting white precipitate was collected by filtration, washed with ethanol, and dried to yield 0.77 g (64%). $C_{47}H_{44}CuP_3S$ (797.39): calcd. C 70.79, H 5.56, S 4.02; found C 70.26, H 4.79, S 3.38.

Cu(tripod)C≡CPh (4): According to the published procedure,[28] a suspension of CuC≡CPh (0.25 g, 1.5 mmol) and tripod (0.96 g, 1.5 mmol) in 60 mL of benzene was stirred at ambient temperature for 24 h. After filtration from a dark green material, the pale yellow solution was concentrated to dryness. The residue was dissolved in toluene and petroleum ether was added. The resulting slightly yellowish precipitate was isolated by filtration, washed with petroleum ether and diethyl ether, and then dried to yield 0.96 g (81%). $C_{49}H_{44}CuP_3$ (789.34): calcd. C 74.56, H 5.62; found C 74.74, H 5.64.

Instrumentation: Absorption spectra were measured with a Shimadzu 2100 spectrophotometer. Emission spectra were recorded with a Hitachi 850 spectrofluorometer equipped with a Hamamatsu 928 photomultiplier for measurements up to 900 nm.

Calculations: Geometries and energies were calculated according to the density functional theory involving the BP86 functional[29] in combination with a split-valence basis set with polarisation functions on all heavy atoms [SV(P)[30]]. Triplet states were optimized according to the unrestricted KS approach. Time-dependent density functional calculations were performed with the same functional in combination with a valence triple zeta basis set (TZVP[31]). For iodine an effective core potential with relativistic corrections (ecp-46-mwb: derived from a multi-electron fit to the quasirelativistic Wood-Boring total valence energies) was employed[32]. Resolution of identity techniques[33] were used throughout. All calculations were carried out with the TURBOMOLE software package.[34]

NH···π Interactions Stabilize the Most-Hindered Rotamer of the (*S*)-Tyrosinato Side Group in Bis[(*S*)-tyrosinato](diamine)cobalt(III) Complexes: An NMR Spectroscopic and DFT Study[‡]

Djenana U. Miodragović,*[a] Željko J. Vitnik,[a] Slobodan M. Milosavljević,[a] Mijat J. Malinar,[a] and Ivan O. Juranić[a]

Keywords: Amino acids / Cobalt / Conformational analysis / Density functional calculations / NMR spectroscopy / Pi interactions

Conformational analysis based on an analysis of the vicinal α- and β-proton coupling constants of (*S*)-tyrosinato ligands in diastereomers of a bis[(*S*)-tyrosinato](1,3-diaminopropane)-cobalt(III) complex is used to calculate the mol fractions of the three most stable rotamers (***t***, ***g***, ***h***) of the (*S*)-tyrosinato ligand's side groups in D_2O solution. The results of this conformational analysis indicate a population increase in the sterically least favorable rotamer ***h*** in diastereomers of C_1-molecular symmetry (complexes **5** and **6**). The TOCSY spectrum of complex **6** in aqueous solution shows an exceptionally small chemical shift of one NH_2 proton from the coordinated diamine, which is explained by an interligand NH···π interaction. These findings demonstrate the persistence of this weak, noncovalent interaction in water solution. DFT calculations for complex **6**, whose diamine ring is in a chair conformation, indicate that the complex with an ***h*** conformation in both its (*S*)-tyrosinato ligand side-residues, which yields the most frequent NH···π interactions, represents an energy minimum. The fact that coordinated 1,3-diaminopropane in the examined complex **6** is in a chair conformation in aqueous solution is proved by the NMR analysis.

Introduction

The side-residues of aromatic amino acids participate in many in vivo molecular recognitions, such as antibody–antigen,[1–3] enzyme–substrate,[4–7] protein–nucleic acid bases[8,9] etc. Molecular recognition is brought about by various forms of noncovalent interactions in which the side-residues of aromatic amino acids take part, such as hydrogen bonding (Tyr, Trp), stacking interactions, hydrophobic interactions, cation–π interactions, and various forms of XH···π interactions (X = C, N, O). During the past decade the importance of NH···π interactions in molecular recognition in biochemical systems and in maintaining the native protein structure has emerged,[10–14] although such systems are very complex to study because of the multiple weak interactions which act in synergy. This gives rise to a need for simple model systems suitable for studying these interactions.

Although NH···π interactions in proteins have been known since 1984,[15] in complexes of transition metals they have been discovered only recently[16] as, because of their low interaction energy,[17,18] they are difficult to detect in solution. One of the best ways to identify the presence of NH···π interactions in aqueous solution is the anomalous chemical shift of the NH protons involved in the interaction.[19–25]

We recently reported that complexes of cobalt(III) with (*S*)-tyrosinato and (*S*)-phenylalaninato ligands can serve as simple model systems for studing NH···π and π···π interactions.[26,27] In our previous paper,[27] conformational analysis based on an analysis of the vicinal α- and β-proton coupling constants was used to calculate the mol fractions of the three most stable rotamers of (*S*)-tyrosinato and (*S*)-phenylalaninato side-groups in diastereomers of $[Co\{(S)\text{-tyr}\}_2en]^+$ and $[Co\{(S)\text{-phe}\}_2en]^+$ in D_2O solution. The results of this analysis indicated a population increase in the sterically least favorable rotamer ***h*** in C_1-molecular symmetry diastereomers, which for complex **5 tyr** is proved to be due to the intra- and interligand NH···π interactions.[27]

In this paper, on the basis of conformational analysis, our aim was to obtain the data on the rotamer population of the (*S*)-tyrosinato ligand side-groups in diastereomers of the previously synthesized $[Co\{(S)\text{-tyr}\}_2tn]^+$ complex[28] and to establish whether a population increase of rotamer ***h*** in C_1-molecular symmetry diastereomers of the complex exist, and if so, whether that is due to NH···π interactions as well. We also used ab initio DFT molecular orbital calculations in our study.

Results and Discussion

Rotamer Distribution − NMR Study

The complex bis[(*S*)-tyrosinato](1,3-diaminopropane)cobalt(III) chloride was synthesized by treatment of the alkali metal salt of (*S*)-tyrosine with bis(1,3-diaminopropane)(carbonato)cobalt(III) and then separated into its diastereomers (Figure 1) on an optically active Sephadex QAE column.[28]

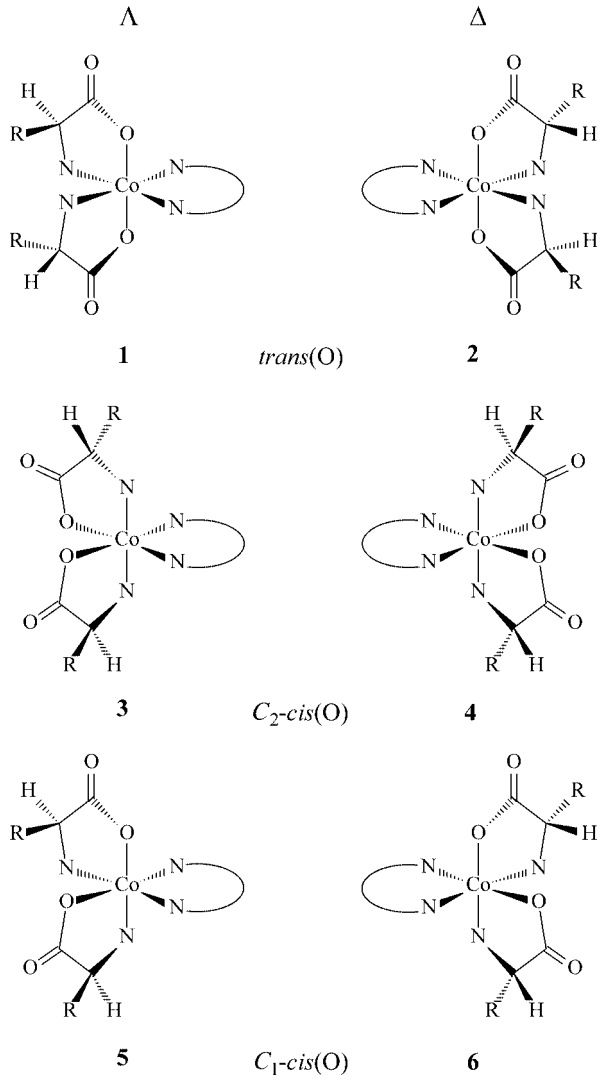

Figure 1. Theoretically possible diastereomers of $[Co\{(S)\text{-tyr}\}_2tn]$ (R = $CH_2C_6H_4OH$).

According to symmetry rules, the diastereomers can be divided into two groups: those having a C_2-molecular axis and higher degree of molecular symmetry [*trans*(O)- and *trans*(N) isomers, complexes **1**–**4**] and those having no symmetry elements [C_1-*cis*(O) isomers, complexes **5** and **6**].

Newman projections for the three most stable rotamers of the (*S*)-tyrosinato ligand side-group in the complex are shown in Figure 2. The mol fractions of the ***t***, ***g***, and ***h*** rotamers of the (*S*)-tyrosinato ligand side-groups in D_2O solution were calculated on the basis of the vicinal coupling constants of the α- and β-protons (J_{AX} and J_{BX})[29–31] as in our previous paper[27] (Table 1).

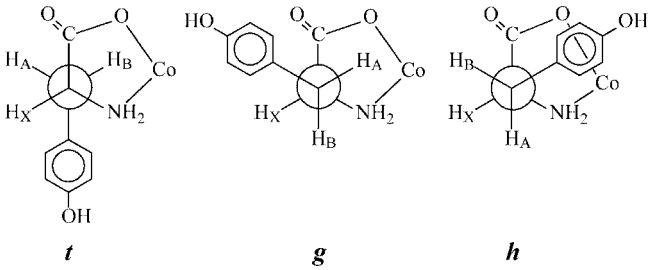

Figure 2. Newman projections of the three staggered rotamers of the (*S*)-tyrosinato side group in the cobalt(III) complex (the β carbon is in front and the α carbon is in the rear).

Table 1. Coupling constants and calculated rotamer mol fractions[31] of the (*S*)-tyrosinato side-groups in noncoordinated (*S*)-tyrosine, and in diastereomers of $[Co\{(S)\text{-tyr}\}_2tn]^+$ (bold), and $[Co\{(S)\text{-tyr}\}_2en]^+$[27] (*) in D_2O solution.

[a] These results have not been published to date.

With regard to the differences in symmetry, in diastereomers of C_2-molecular symmetry the two (*S*)-tyrosinato ligands have the same chemical environment in solution, and hence the α-and β-protons of both (*S*)-tyrosinato ligands show the same chemical shift as well as the same value for J_{AX} and J_{BX}. Therefore, the side-residues of the (*S*)-tyrosinato ligands have the same mol fractions of rotamers in solution (Table 1, complexes **3** and **4**). In the unsymmetrical complexes, the side-residues of the (*S*)-tyrosin-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ato ligands have different chemical environments and hence different mol fractions of rotamers ***t***, ***g***, and ***h*** in solution (Table 1, complexes **5** and **6**). As is well known, the α-proton of an aminocarboxylate ligand whose NH_2 group is *trans* to an NH_2 group resonates at lower field (in this paper **tyr I**) than the α-proton of an aminocarboxylate ligand whose NH_2 group is *trans* to oxygen (in this paper **tyr II**).[32,33]

The population analysis of the side-group rotamers of the (*S*)-tyrosinato ligands in diastereomers of $[Co\{(S)\text{-tyr}\}_2tn]^+$ in D_2O solution indicates that the (*S*)-tyrosinato coordination increases the population of the sterically most favorable rotamer ***t*** relative to the population of this rotamer in the noncoordinated amino acid (Table 1). On the other hand, rotamer ***g*** is the least favorable rotamer energy-wise (from the MO calculations) because the phenyl group is closest to the coordinated carboxylic group. Therefore, rotamer ***g*** is the least abundant rotamer. These results are analogous to the results obtained from an examination of the rotamer population of the side-group of (*S*)-phenylalaninato and (*S*)-tyrosinato ligands in diastereomers of $[Co\{(S)\text{-tyr}\}_2en]^+$ and $[Co\{(S)\text{-phe}\}_2en]^+$in D_2O solution.[27] At the same time, it has been noticed[27] that in diastereomers of these complexes with C_1-molecular symmetry, the population of rotamer ***h*** increases due to intra- and interligand NH···π interactions.

In this context, in this paper we intended to examine whether, in the diastereomers of C_1-molecular symmetry of $[Co\{(S)\text{-tyr}\}_2tn]^+$, the population of rotamer ***h*** also increases and whether this increase is caused by NH···π interactions. In order to allow this comparison, the results of the mol fraction abundance of the side-group rotamers of (*S*)-tyrosinato ligands in diastereomers of $[Co\{(S)\text{-tyr}\}_2tn]^+$ and $[Co\{(S)\text{-tyr}\}_2en]^+$[27] in D_2O solution are given in Table 1. A considerable increase can seen in the population of rotamer ***h*** in one residue of the (*S*)-tyrosinato ligand in complexes of C_1-molecular symmetry (**5 tyr II** and **6 tyr I**) relative to the population of this rotamer in noncoordinated (*S*)-tyrosine (mol fractions of rotamer ***h*** are 46 and 47% respectively). As the first result is in agreement with the result obtained in an analogous diastereomer with 1,2-diaminoethane, the population increase of rotamer ***h*** in the side-residue **tyr I** in complex **6** was investigated more closely.

If NH···π interactions lead to a population increase of rotamer ***h*** in complex **6** as well, then the NMR spectrum should show a small chemical shift of the NH proton that takes part in this interaction. A molecular model of the complex with the side-residues of the (*S*)-tyrosinato ligands in conformation ***h*** indicates the possibility of three different NH···π interactions in the molecule (Figure 3, a), namely an NH···π interaction within (*S*)-tyrosinato itself, an NH···π interaction between two coordinated (*S*)-tyrosinato ligands (one is a donor and the other an acceptor of the hydrogen atom), and an NH···π interaction between a partially positively charged hydrogen atom from the coordinated 1,3-diaminopropane and the aromatic ring of the (*S*)-tyrosinato ligand.

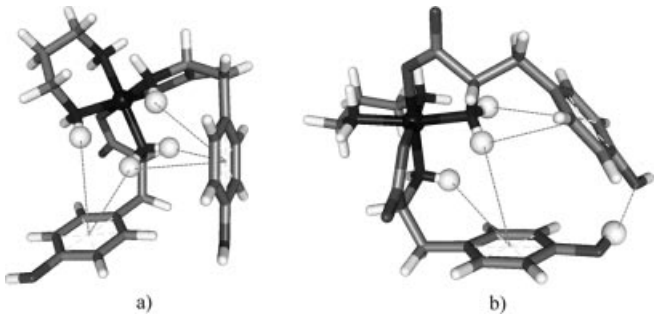

Figure 3. a) Calculated geometry of the Δ-C_1-*cis*(O)-$[Co\{(S)\text{-tyr}\}_2tn]^+$ complex (**6**) [both (*S*)-tyrosinato ligand side-groups adopt an ***h*** conformation and the diamine adopts a chair **A** conformation]. All possible NH···π interactions in the molecule are shown. b) Calculated geometry of complex **6** (**tyr I** adopts a ***t*** and **tyr II** an ***h*** conformation; the diamine adopts an $\mathbf{A}_{tw}$ conformation). Intramolecular NH···π interactions and H-bonds in the molecule are shown.

Since the mol fraction of rotamer ***h*** in the solution is small for the side-residue of **tyr II** (26%), the assumption of an NH···π interaction between two coordinated (*S*)-tyrosinato ligands can be rejected. In order to assign the NH protons, a TOCSY spectrum of complex **6** in H_2O solution was recorded (Figure 4). A small chemical shift of one NH proton at δ = 3.7 ppm (overlaps the signal of the α-proton), originating from coordinated 1,3-diaminopropane, can be seen in the spectrum. The chemical shift of this proton is indicative of strong shielding effects associated with the ring current of the aromatic ring.[23] In the 1,3-diaminopropane ligand, the difference in chemical shift between NH proton involved in the NH···π interaction and its geminal partner is –1.3 ppm. Thus we can conclude that the population increase of rotamer ***h*** of the side-residue **tyr I** in complex **6** is the result of an interligand NH···π interaction, i.e., an NH···π interaction between the partially positively charged hydrogen atom of the 1,3-diaminopropane ligand and the aromatic ring in the (*S*)-tyrosinato ligand.

A significant increase of the population of rotamer ***h*** is not found in analogous diastereomers of the (*S*)-phenylalanine complex. Williams and co-authors[23,34] have recently reported the existence of NH···π interactions in complexes of Co^{III} with (*S*)- and (*R*)-tryptophan and its derivatives. Our results, and those published by Williams,[23,34] are in accordance with the observation of Steiner and Koellner,[14] who noted that Trp and Tyr are the aromatic amino acids most frequently involved in NH···π interactions in proteins. The order efficacy of an aromatic acceptor for hydrogen bonding is Trp >> Tyr > Phe >> His.

DFT Study

DFT calculations were carried out for different conformations of the side-residues of (*S*)-tyrosinato ligands in complex **6** and for two different diamine chair conformations **A** and **B** because this isomer has no symmetry elements (Table 2). In the case of the diamine chair conformation in which the axial protons of the terminal methylene

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

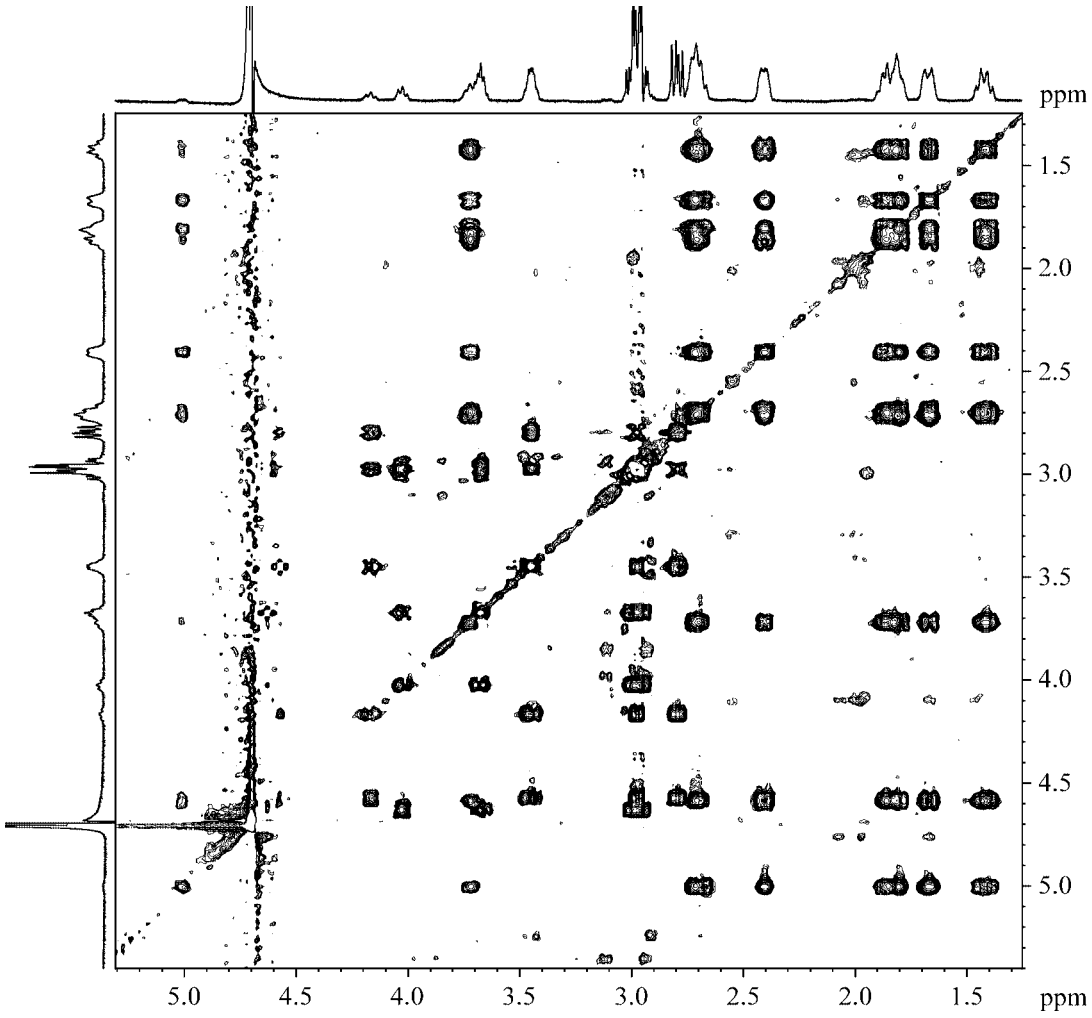

Figure 4. Partial TOCSY (500 MHz; mixing time 60 ms) spectrum of complex **6** in water solution.

groups are pointing toward the coordinated carboxylic group (conformation **A**, Table 2), the complex with two side-residues in conformation ***h*** represents an energy minimum. In this ***h*** conformation, the greatest number of NH···π interactions exist in the molecule (Figure 3, a), and it is followed, energy-wise, by the complexes in which one side-residue assumes an ***h*** and the second a ***t*** conformation. The least stable complex is that with both side-residues in conformation ***g*** (Figure 2). Here, the aromatic ring and the exocyclic oxygen of the coordinated carboxylic group are at the shortest distance, hence the repulsive forces are the greatest. The complexes in which only one side-residue takes conformation ***g*** are less stable energy-wise.

In the case of the diamine chair conformation, in which the axial protons of the terminal methylene groups point towards the α- and NH_2 protons of the coordinated (*S*)-tyrosinato ligand (conformation **B**, Table 2), the same order of stability of the conformers was obtained, but it is obvious that all complexes with the chair conformation **B** of the diamine are less stable than the corresponding complexes with conformation **A**. This is not surprising because in the chair conformation large steric hindrances are present between the axial protons of the terminal methylene groups of the diamine and the α- and NH_2 protons of the coordinated (*S*)-tyrosinato ligand.

Table 2. The relative energies of conformers[a] of complex **6**. The diamine adopts a chair (**A** and **B**) or twisted chair ($\mathbf{A}_{tw}$ and $\mathbf{B}_{tw}$) conformation.

	E_{rel}[b]			
tyr I, **tyr II**	Chair **A**	Chair **B**	$\mathbf{A}_{tw}$	$\mathbf{B}_{tw}$

t, ***h***	10.302	20.978	9.549	9.718
t, ***t***	30.766	44.833	49.982	57.887

[a] All energies [kJ mol^{-1}] are calculated relative to the energy of complex **6** (data obtained by a B3LYP/LANL2DZ//B3LYP/6-31G* calculation using an Onsager model) with chair conformation **A** and ***h*** conformations of the (*S*)-tyrosinato ligand side-chains, which represents an energy minimum. [b] In kJ mol^{-1}.

DFT calculations were also carried out for the case where the diamine adopts a twisted chair conformation ($\mathbf{A}_{tw}$ and $\mathbf{B}_{tw}$, Table 2). The most stable geometry of the complex is obtained when **tyr I** adopts a ***t*** and **tyr II** an ***h*** conformation. The molecular model of the complex (Fig-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ure 3, b) indicates the possibility of forming an intramolecular H-bond only for these conformations of the (*S*)-tyrosinato side-chains.

A full optimization was performed for the most stable conformers of complex **6** (Table 3). The Boltzmann distribution indicates that complex **6** with a chair **A** conformation of the diamine and with both (*S*)-tyrosinato ligands side-chains in the ***h*** conformation is present at about 90%.

Table 3. Relative energies of the fully optimized[a] conformers of complex **6** and Boltzman distribution of the conformers.

		E_{rel}[b]		Population[c]	
tyr I, **tyr II**	Diamine	Chair	$Chair_{tw}$	Chair	$Chair_{tw}$

[a] Obtained by a B3LYP/LANL2DZ calculation using an Onsager solvation model. [b] In kJ mol^{-1}. [c] Percentage at 298 K.

The results obtained on the basis of the NMR spectroscopic data for the rotamer population in complex **6** indicate that **tyr I** in D_2O solution prefers an ***h*** conformation and **tyr II** a ***t*** conformation. On the other hand, the DFT calculations have shown that both (*S*)-tyrosinato side-chains prefer an ***h*** conformation (this complex is energetically the most stable). Because of this discrepancy we included in our DFT calculations two water molecules that are bonded to the hydroxyl groups of the (*S*)-tyrosinato side-chains by hydrogen bonds. The calculation (Table 4) was performed for conformation **A** of the diamine, which in all cases investigated was more stable than conformation **B** (Table 2). One significant difference can be seen in comparison with the data in Table 2, namely that the complex in which **tyr I** adopts an ***h*** and **tyr II** a ***t*** conformation, which is in accordance with experimental results, is now more stable than the complex with the opposite conformation of the side-chains. As mentioned above, the only combination of (*S*)-tyrosinato side-chain rotamers that can form intramolecular H-bonds is when **tyr I** adopts a ***t*** and **tyr II** an ***h*** conformation (Figure 3, b). Incorporation of two water molecules disrupts the intramolecular H-bonds by forming solute–solvent H-bonds, and these intermolecular solute–solvent interactions could enhance or compete with the forces responsible for the stabilization of a particular rotamer in solution.[23,24] Complex solute–solvent interactions and bulk entropy effects cannot be modeled at the MO level, and this could be the reason for the slight difference between the theoretical and experimental results.

Table 4. Relative energies of the fully optimized[a] conformers of complex **6** (diamine adopts a more stable **A** conformation).

Conformation of the 1,3-Diaminopropane Chelate Ring in Solution

The data obtained from the analysis of the vicinal coupling constants of the methylene protons indicate that the 1,3-diaminopropane in complex **6** in D_2O (and H_2O) solution has a chair conformation. Thus, according to the Karplus equation,[35] which describes the dependence of vicinal coupling constant on the dihedral angle of the coupling protons, for the chair conformation the following values of the vicinal coupling constants are expected: $^3J_{aa}$ (10–16 Hz) and $^3J_{ae}$ and $^3J_{ee}$ (3–5 Hz).[36] By extracting the data from the NMR spectrum for complex **6** (at 500 MHz) in D_2O solution, the following data were obtained: the methylene protons bonded to the NH_2 group positioned *trans* to the nitrogen atom, resonate at δ = 2.7 (^3J = 10.6 and 2.7 Hz) and 2.4 ppm (^3J = 5.9 and 2.9 Hz), the methylene group protons bonded to the NH_2 group positioned *trans* to the oxygen atom resonate at δ = 1.9 (^3J = 10.3 and 2.7 Hz) and = 1.8 ppm (^3J = 5.8 and 3.0 Hz), while the protons of the central methylene group resonate at δ = 1.4 ppm. The existence of one vicinal coupling constant greater than 10 Hz indicates that the coordinated 1,3-diaminopropane adopts a chair conformation in D_2O (and H_2O) solution. It is worth mentioning that the relative chemical shifts of the axial and equatorial protons in terminal (bearing NH_2) methylene groups are opposite to the chemical shifts of these protons in a saturated cyclohexane ring, i.e. the axial protons resonate at higher δ values. The molecular model of complex **6** indicates that in the case of a chair conformation of the diamine ring the equatorial protons are found in the region of diamagnetic shielding of the aromatic ring in the tyrosinato ligand, which could explain the anomalous chemical shifts of the axial and equatorial protons of the terminal methylene groups.

Conclusions

The results of a conformational analysis indicate a population increase of the sterically least favorable ***h*** rotamer of the (*S*)-tyrosinato ligand side-group in diastereomers of C_1-molecular symmetry of $[Co\{(S)\text{-tyr}\}_2(diamine)]^+$-type complexes (diamine = 1,2-diaminoethane or 1,3-diaminopropane) in D_2O (and H_2O) solution that is caused by attractive intra- and/or interligand NH···π interactions.

DFT calculations for complex **6**, where the diamine adopts a chair conformation (as supported by NMR spectroscopic data), indicate that the complex with an ***h*** conformation of both the (*S*)-tyrosinato side-residues, which yields

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the most efficient NH···π interactions, represents an energy minimum.

The results obtained on the basis of ^{1}H NMR spectroscopy indicate that intramolecular NH···π interactions persist in aqueous solution, regardless of the energy-wise favored interactions with water molecules. This is in agreement with the results obtained by the investigation of amino–aromatic interactions in peptides.[21] Our results indicate the significance of noncovalent NH···π interactions involving (*S*)-tyrosinato side-chains and highlight the suitability of these simple cobalt(III) complexes to serve as models for studying these relatively poorly understood attractive forces.

Experimental Section

Synthesis: Diastereomers of the bis[(*S*)-tyrosinato](1,3-diaminopropane)cobalt(III) complex were synthesized by a previously described procedure.[28]

NMR Spectroscopy: ^{1}H NMR spectra were recorded on a GEMINI 2000 spectrometer at 200 MHz in D_2O solution (complexes **3**–**6**). The TOCSY spectrum of complex **6** in H_2O solution was recorded at 500 MHz on a Bruker ABX-500 spectrometer (mixing time 60 ms).

Computational Details: The optimized geometries and energies of conformers of Δ-C_1-*cis*(O)-[Co{(*S*)-tyr}$_2$tn]$^+$ (**6**) were obtained using the density functional theory (DFT) with the Becke three-parameter exchange functional (B3),[37] and the Lee–Yang–Parr (LYP) correlation functional.[38] The DFT method was used as it gives good results for all transition metal complexes of the first row.[39,40] These B3LYP calculations were carried out with the GAUSSIAN 98 program.[41] The geometries of all conformers of the complex were fully optimized using 6-31G* basis sets, and for these optimized geometries the energy was calculated with LANL2DZ basis set in the presence of a solvent (H_2O), using an Onsager model.[42–47] Full optimization for the most stable conformers was performed with the LANL2DZ basis set in the presence of a solvent, using an Onsager model and with explicit inclusion of two water molecules.

Acknowledgments

NMR spectra were recorded at the Mayo Clinic NMR Facility, Rochester, USA, by Prof. Nenad Juranić. The ab initio MO calculations were performed by Prof. Walter Knapp at the Free University in Berlin. The authors are grateful to the Ministry of Science and Environmental Protection of the Republic of Serbia (project nos. 1318, 1235, and 1755).

COVER PICTURE

The cover picture shows the first crystallographically characterized cationic triazacyclohexane complex of titanium. The hydrogen atoms of the ring-CH_2 groups engage in C−H···Cl interactions with the anion (only the shortest shown) and give rise to two characteristic doublets in the ^{1}H NMR spectrum with shifts that are highly dependent on the *N*-substituents, solvent and anion. The cationic complex is readily formed by the treatment of triazacyclohexanes with excess $TiCl_4$ which often results in large crystals containing the Ti_2Cl_9 anion. Details are discussed in the article by R. D. Köhn et al. on p. 3217 ff.

Recent Developments in the Chemistry of Beryllocenes

Rafael Fernández[a] and Ernesto Carmona*[a]

Keywords: Beryllium / Cyclopentadienyl ligands / Half-sandwich complexes / Metallocenes

Synthetic studies on substituted beryllocenes have provided new representatives of this family of compounds. Knowledge of their structures gives a better understanding of the long-standing problem of the structure of the parent beryllocene, $Be(C_5H_5)_2$. Theoretical calculations offer a clear picture of their bonding properties, while spectroscopic and reactivity investigations have clarified their dynamic behaviour. Beryllocenes of the type $BeCp'_2$ (Cp′ = methyl-substituted cyclopentadienyl group) and half-sandwich cyclopentadienylberyllium compounds are considered.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

The chemistry of metallocenes started in the early 1950s with the preparation of ferrocene and the recognition of its correct structural and bonding properties.[1] The first main-group metallocenes − the tin and lead compounds $M(C_5H_5)_2$ − were synthesised shortly afterwards.[2] In 1959, $[Be(C_5H_5)_2]$, the lightest member of the alkaline-earth metallocenes and of the general bis(metallocene) series of compounds MCp'_2, was obtained as a volatile, sublimable solid from the reaction of $BeCl_2$ and NaC_5H_5.[3] Over the years, introduction of the pentamethylcyclopentadienyl and other substituted cyclopentadienyl ligands (from now on generally represented by Cp′), including those with bulky substituents, has converted the metallocenes of the alkaline-earth elements into an attractive family of compounds that are characterised by a rich variety of structures.[4]

Beryllocene and some substituted beryllocenes possess a slipped-sandwich structure, whereas the magnesocenes feature parallel (i.e. ferrocene-like) sandwich arrangements.[4] Calcocene adopts an unexpected nonparallel polymeric structure but $[Ca(C_5Me_5)_2]$ is monomeric, although also with nonparallel rings, and this is the structure found in

Rafael Fernández was born in 1969 in Sevilla, Spain, where he received both his undergraduate and PhD (2000 under Prof. E. Carmona) degrees. He was awarded a Marie Curie postdoctoral fellowship at the University of Edinburgh, U.K., with Prof. Peter J. Sadler (2001–2003), where he started research in bioinorganic chemistry. At present, he enjoys a Ramón y Cajal fellowship and his current research interests include the design and synthesis of organometallic complexes as anticancer drugs.

Ernesto Carmona (PhD University of Sevilla, 1974 under the late Prof. F. González) is a Professor of Inorganic Chemistry at the University of Sevilla, Spain. He did postdoctoral work at Imperial College, London, with (the late) Prof. Sir G. Wilkinson (1974–77) where he started research in organometallic chemistry. His present research interests comprise C–H and C–C bond-activation reactions, transition metal alkyl and carbene complexes and metallocene chemistry of the main group and the transition elements. He has delivered the Seaborg Lectures (1994), the Pacific Northwest Inorganic Chemistry Lectures (2000), the Goldsmidt–Hermanos Elhúyar Lectures (2000–2001), the Arthur D. Little Lectures (2000–2001) and the Catalán–Sabatier Lecture (2005).

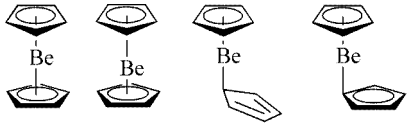
MICROREVIEWS: This feature introduces the readers to the authors′ research through a concise overview of the selected topic. Reference to important work from others in the field is included.

most MCp'_2 compounds of the heavier group 2 elements Ca, Sr and Ba.[4] Interestingly, this structural diversity appears to emerge from a simple, predominantly electrostatic, $M^{2+}\cdots 2Cp'^{-}$ bonding model. Theory predicts[5] that in the unsubstituted metallocenes of Mg to Ba [$M(C_5H_5)_2$] electrostatic forces account for approximately 70–85% of the total interaction energy. As expected, [$Be(C_5H_5)_2$] is more covalent,[5] and replacement of C_5H_5 by C_5Me_5 (viz. in [$Be(C_5Me_5)_2$]) results in further reduction of the ionicity by almost 10%. Numerous quantum chemical calculations on main-group metallocenes have been published in recent years, and the theoretical knowledge gained from these studies has been reviewed recently by Kwon and McKee, who concluded that "there is not enough data from high-level theoretical calculations to have a quantitative understanding of the factors involving covalent or ionic bonding between the Cp ligand and the main-group element".[6]

As already mentioned, the use of Cp′ ligands with different substituents and degrees of substitution has permitted the synthesis and characterisation of many MCp'_2 derivatives of the alkaline-earth elements. The chemistry of these complexes has been compiled in several review articles,[4] usually as part of larger overviews of main-group organometallic compounds. In this Microreview we concentrate on beryllocenes. We revise the longstanding problem of the structure of the parent [$Be(C_5H_5)_2$] and focus on the latest advances in this field. In particular, we discuss the structure and bonding properties of the recently reported beryllocenes with C_5Me_5 and C_5Me_4H rings. Chemical, spectroscopic (NMR) and theoretical studies have provided useful information on their dynamic behaviour. Both bis(cyclopentadienyl) and half-sandwich mono(cyclopentadienyl) beryllium derivatives are examined.

Bis(cyclopentadienyl)beryllium [$Be(C_5H_5)_2$] (1)

Since the preparation of beryllocene by Fisher and Hofmann in 1959,[3] its structure has provoked a long and controversial debate. Structures **I**–**IV** are some of the proposed models.



I **II** **III** **IV**

The symmetrical ferrocene-like structure **I** was ruled out because the complex has a permanent dipolar moment in solution[3] (2.24 D in cyclohexane at 25 °C). The first gas-phase electron diffraction study carried out in 1964[7] suggested a non-symmetrical structure **II**, with the Be atom unsymmetrically disposed between the two Cp rings,[8] while molecular orbital calculations[9] were in favour of a non-symmetrical structure of type **III**, in which there is an ionic η^5-Cp ring and a covalently bonded η^1-Cp ring.

Three X-ray studies were carried out between 1972 and 1984. The first, at –120 °C,[10] showed a slipped-sandwich structure **IV**, which was unprecedented at that time. The two Cp rings were found to be parallel and separated by 3.33 Å. The Be atom was disordered between two sites, being η^5-coordinated to one Cp ring ($Be–Cp_{centr}$ = 1.53 Å), and η^1-coordinated to the other, with a Be–C separation of 1.81(5) Å. This is longer than the Be–Me distance found in the complex [$Be(\eta^5\text{-}C_5H_5)Me$][11] (1.706 Å). The same authors carried out a second X-ray investigation, this time at room temperature, that showed similar results, but with the two Cp rings partially eclipsed.[12] A new electron diffraction study provided data compatible with the slipped-sandwich structure.[13]

The third X-ray diffraction determination was carried out in 1984 at –145 °C[14] and also showed a slipped-sandwich structure with disorder at the beryllium atom that alternates its position between two points separated by 1.303 Å. The Be–C–C angles between the metal and the η^1-ring were close to 90° and an important electronic delocalisation of the π-system of this ring was ascertained, with the negative charge being only partially localised on the carbon atom bonded to beryllium. Very recently, a new X-ray crystallographic analysis of [$Be(C_5H_5)_2$] was performed at 20 °C and at –100 °C. At the lower temperature the structure is of the reported η^5/η^1 type but at 20 °C it appears closer to η^5/η^2 coordination.[15]

The slipped-sandwich structure **IV** explains the microwave spectroscopic data of **1**.[16] Moreover, the IR spectrum of [$Be(C_5H_5)_2$] shows little variation between the solid, solution and vapour states.[17] Similarly, the Raman spectrum of solid beryllocene recorded between 160 and 25 °C, and of the liquid at 65 °C, shows no significant differences.[18] Hence, it is clear that the solid-state structure is maintained in all phases.

Adoption of a slipped-sandwich geometry by [$Be(C_5H_5)_2$] has been rationalised by Beattie and Nugent.[19] A variety of structures found for main-group metal cyclopentadienyls, ranging from the centrally bound ferrocene-type to peripherally bonded structures, were discussed. The energy of the $M–C_5H_5$ interaction can be considered as resulting from two effects, namely the strength of the M–C bond and the π-system delocalisation energy. The latter is a minimum for η^5-coordination whereas the η^1/σ binding mode provides the strongest M–C interaction. For an element like beryllium, which forms Be–C bonds of intermediate bond-heterolysis energy, neither of the two forces predominates and the compromise slipped-sandwich structure becomes the most favourable.[19]

Beryllocene is a highly fluxional molecule both in solution[20] and in the condensed phase,[15] according to ^1H, ^9Be and ^{13}C variable temperature NMR studies. The ^1H and the ^{13}C nuclei of the two C_5H_5 rings are magnetically equivalent down to –125 °C, which implies that their exchange is rapid even at these low temperatures. Molecular dynamics calculations[21] have identified two very facile rearrangements, namely a 1,5-sigmatropic shift of the Be(η^5-C_5H_5) unit around the periphery of the η^1-C_5H_5 ring and a "molecular inversion" process that interchanges the η^5 and η^1 ligands. The first is proposed to occur through an η^5/η^2

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

transition state, with an activation barrier of 5 kJ mol^{-1}, while for the second an activation energy of 8 kJ mol^{-1} associated with an η^3/η^3 transition state was calculated.[21] Very recently Hung, Macdonald and Schurko[15] have made an important contribution to our understanding of the solid-state structure and dynamics of different beryllocenes and have provided, among other relevant information, an experimentally determined value of 36.9 kJ mol^{-1} for the activation energy of the "molecular inversion" in $[Be(C_5H_5)_2]$ in the solid state.

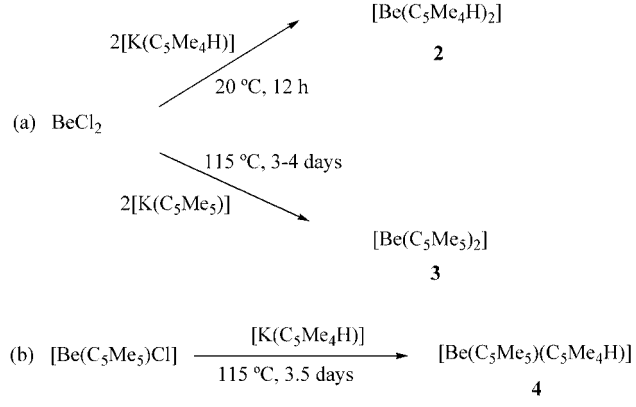
Numerous theoretical studies have attempted to explain the structure and other properties of $[Be(C_5H_5)_2]$.[21,22] Among the most recent ones, Rayón and Frenking found that at the BP86/6-31G(d) level the η^5/η^1 structure of C_s symmetry is a minimum on the potential energy surface, although with similar energy to the η^5/η^5 D_{5d} structure. The calculations indicate that the potential energy surface around the C_s/D_{5d} forms is very flat, in agreement with the fluxional structure of $[Be(C_5H_5)_2]$. Moreover, a significant covalent contribution (about 40%) to the bonding interaction was calculated. Similar structural conclusions were obtained by Budzelaar and co-workers, who found that the minimum energy structure for beryllocene has η^5 and η^1 rings[5c] that exchange via the η^3/η^3 structure with a barrier of around 7.5 kJ mol^{-1}.

Before closing the discussion on $[Be(C_5H_5)_2]$, two additional comments are appropriate. Firstly, dihydro-1*H*-azaboroyl (Ab) species of composition $[Be(Ab)_2]$ and $[Be(C_5H_5)(Ab)]$ have been prepared as possible models for **1**, as this heterocyclic ligand is isostructural and isoelectronic with C_5H_5.[23] X-ray studies at –150 °C show that $[Be(Ab)_2]$ has η^5 and η^1 ligands that are not parallel but instead form an angle of 14.5°. Secondly, following the report from our group on the synthesis and structure of $[Zn_2(\eta^5\text{-}C_5Me_5)_2]$, an unprecedented dimetallocene that features a metal–metal bonded dizinc unit unsupported by bridging ligands,[24] a theoretical study of the analogous model compounds $[M_2(C_5H_5)_2]$ (M = Be, Mg, Ca) has been reported. The calculations predict that in diberyllocene, $[Be_2(C_5H_5)_2]$, each metal forms a covalent bond with the other, with a Be–Be distance of 2.06 Å, and a predominantly ionic linkage to the adjacent cyclopentadienyl ring.[25]

The Substituted Beryllocenes $[Be(C_5Me_4H)_2]$ (2), $[Be(C_5Me_5)_2]$ (3) and $[Be(C_5Me_5)(C_5Me_4H)]$ (4)

As already mentioned, in the last few years a large number of MCp'_2 compounds of the alkaline-earth metals from Mg to Ba have been prepared using Cp′ ligands with different substituents and degrees of substitution, and their solid-state structures have been determined by X-ray methods.[4] It was therefore surprising to find that, prior to our work, $[Be(C_5H_5)_2]$ was the only structurally characterised beryllocene, although the mixed-ring compound $[Be(C_5Me_5)(C_5H_5)]$ had been obtained when $[Be(\eta^5\text{-}C_5H_5)Cl]$ and $[Li(C_5Me_5)]$ were heated together in a melted mixture (60 °C).[26] It is possible that attempts to make other $[BeCp'_2]$ compounds may have been deterred by the general belief that the small Be^{2+} ion (ionic radius of 0.27 Å in coordination number 4; 0.45 Å estimated value for six-coordination environments)[27] could not accommodate two bulky cyclopentadienyl ligands. This would explain the formation of only the half-sandwich complex $[Be(\eta^5\text{-}C_5Me_5)Cl]$ from the treatment of $BeCl_2$ with C_5Me_5 transfer agents.[28] Nevertheless, the successful isolation of $[Be(C_5Me_5)_2]$ when $BeCl_2$ and $[K(C_5Me_5)]$ react in a diethyl ether/toluene mixture at 115 °C over 3.5 days (vide infra)[29] has revealed that $[Be(C_5Me_5)_2]$ is a stable complex and that it had not been generated before only because coordination of the second C_5Me_5 ring is a slow process with a high kinetic barrier. Recent attempts to synthesise $[Be(Cp^{3Si})_2]$, containing the bulky cyclopentadienyl Cp^{3Si} [1,2,4-$C_5H_2(SiMe_3)_3$], under conditions similar to those used to prepare $[Be(C_5Me_5)_2]$, led only to decomposition products.[30] Since theory predicts an η^5/η^1 structure for the molecules of this compound, failure to generate it is probably due to kinetic difficulties and not to steric overcrowding.[30]

Octamethylberyllocene, $[Be(C_5Me_4H)_2]$ (**2**), and decamethylberyllocene, $[Be(C_5Me_5)_2]$ (**3**), have been synthesised by the reaction of $BeCl_2$ with $[K(C_5Me_4H)]$ and $[K(C_5Me_5)]$, respectively (Scheme 1, a). However, whereas compound **2** requires stirring at room temperature for about 12 h, the synthesis of **3** demands higher reaction temperatures (ca. 115 °C) and times (between 3 and 4 days) and even under these conditions the crude reaction mixture always contains small amounts of the half-sandwich complex $[Be(\eta^5\text{-}C_5Me_5)Cl]$.[29] Clearly, replacement of the chloride ligand by C_5Me_5 in the latter complex is difficult due to steric hindrance. In marked contrast, attempts to isolate the analogous $[Be(\eta^5\text{-}C_5Me_4H)Cl]$ derivative have proved fruitless – the use of stoichiometric amounts of $[K(C_5Me_4H)]$ leads only to $[Be(C_5Me_4H)_2]$ (**2**) and unreacted $BeCl_2$. In accordance with this, extended heating at high temperatures (Scheme 1, b) is also needed for the mixed-ring beryllocene $[Be(C_5Me_5)(C_5Me_4H)]$ (**4**), although the synthesis proceeds in high yield (isolated yields of crystalline **4** of around 70%). The three compounds are volatile, sublimable solids that are very soluble in common non-polar organic solvents. They are very reactive towards O_2 and H_2O and de-



Scheme 1. Synthesis of the beryllocenes **2**–**4**.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

compose immediately upon exposure to air. Compounds **2** and **3** enlarge the beryllocenes series of complexes significantly, while the mixed-ring compound **4** finds precedent only in the related $[Be(C_5Me_5)(C_5H_5)]$ derivative, formulated as $[Be(\eta^5\text{-}C_5Me_5)(\eta^1\text{-}C_5H_5)]$ on the basis of solution IR and NMR spectroscopic studies.[26] Solid-state characterisation of this species by X-ray methods has not been reported.

Compounds **2**–**4** were characterised by X-ray crystallography at low temperatures (100–300 K); the corresponding ORTEP diagrams are given in Figure 1. Recently the structures of **2** and **3** have also been re-determined at low temperature, with similar results.[15]

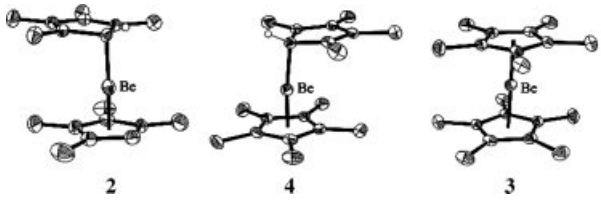


Figure 1. ORTEP perspectives of beryllocenes **2**, **3** and **4**.

Both $[Be(C_5Me_4H)_2]$ (**2**) and $[Be(C_5Me_5)(C_5Me_4H)]$ (**4**) exhibit η^5/η^1 geometries of the kind found for the parent beryllocene. Not unexpectedly, the structure of the mixed-ring beryllocene **4** consists of η^5-C_5Me_5 and η^1-C_5Me_4H binding. In the two compounds the η^1-C_5Me_4H ring bonds to the metal through the unique CH carbon, possibly to form a stronger Be–C bond.[29] The Be–CH bond lengths are identical within experimental error (1.77 Å) and compare well with the corresponding distance in $[Be(C_5H_5)_2]$ [1.826(6) Å].[10,12,14] These Be–CH distances are in the middle of the range of Be–C bonds (1.70–1.85 Å).[29]

The coordination of the η^5-Cp′ ring is highly symmetrical, and for either compound the five Be–C separations are almost identical and cluster around 1.90 Å. Considering that the Be–C(η^5) bond lengths in $[Be(C_5H_5)_2]$ have comparable values (average about 1.92 Å), it is evident that substitution of H by Me within the η^5-Cp′ ligand does not significantly alter the strength of the Be–C(η^5) bonds. The distances from beryllium to the η^5-C_5Me_5 ring centroids of **2** and **4** are also identical within experimental error (1.47 Å) and very similar to the corresponding separation in $[Be(C_5H_5)_2]$ (1.50 Å).[10,12,14]

The Be–C(η^1)–ring plane angle in the two complexes **2** and **4** is close to 100–102°, far from the 125° value which would be expected for η^1-bonding to a tetrahedral ring carbon atom.[31] Similarly, the Be–C(η^1)–C angles to the adjacent carbon atoms are smaller (ca. 99°) than the ideal 109.5° value that would correspond to a tetrahedral geometry. Additionally, the η^5- and η^1-rings are almost planar and nearly parallel, the angles between the rings being 6.6(1)° and 4.9(1)° for **2** and **4**, respectively. In the three compounds **1**, **2** and **4** there is an alternation in the bond lengths within the η^1 ring which is characteristic of the slipped-sandwich structural type. As shown in Figure 2, the difference in the lengths of the $C_{\alpha\beta}$ and $C_{\beta\beta}$ bonds (C_α is the carbon atom adjacent to the beryllium-bound carbon) is only 0.06–0.07 Å. This reveals some diene character for the η^1 rings. Nevertheless, partial delocalisation of the π-system exists, as the differences in the C–C bonds are significantly smaller than in cyclopentadiene (0.12 Å) and in cyclopentadienyl rings bonded in the common η^1/σ fashion. Thus, in $[B(\eta^5\text{-}C_5Me_5)(\eta^1\text{-}C_5Me_5)]^+$[32] and $[\{Hg(\eta^1\text{-}C_5Me_4SiMe_2tBu)Cl\}_4]$[33] the C–C bonds are dissimilar by about 0.14 Å.

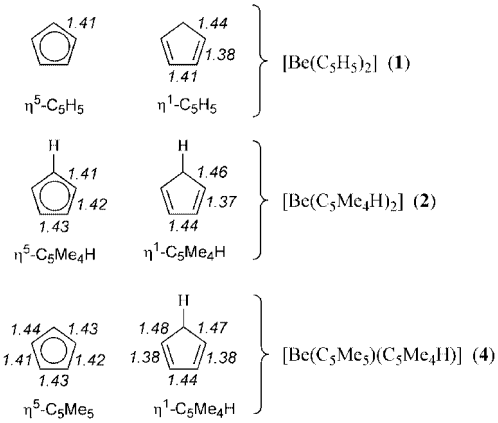

Figure 2. Lengths [Å] of the $C_{\beta\beta}$ and $C_{\alpha\beta}$ bonds in the Cp′ rings of **1**, **2** and **4**.

In contrast with beryllocenes **1**, **2** and **4**, $[Be(C_5Me_5)_2]$ (**3**) exhibits an almost regular, ferrocene-like, sandwich structure in the solid state (Figure 1). The two C_5Me_5 rings are perfectly parallel and planar (the average deviation from the mean plane is 0.01 Å) and are separated by 3.310(1) Å, a distance comparable to the 3.35 Å interlayer gap in graphite.[34] The Be–C_5Me_5 centroid distance of 1.655(1) Å is noticeably longer than the Be–Cp′ centroid separations in **2** and **4** (ca. 1.47 Å), thus revealing a significantly weaker Be–C_5Me_5 bonding interaction. This is not unexpected, however, in view of the existence of two π-C_5Me_5 rings in the molecules of **3** (formal coordination number of six) and of only four valence orbitals on beryllium. The relatively long Be–C_5Me_5 centroid and Be–C distances in **3** are not abnormal. As a matter of fact, they are comparable to those found in the known compounds $[Mg(C_5Me_5)_2]$[35] and $[Al(C_5Me_5)_2]^+$[36] if the differences in the ionic radii of the three metal ions are taken into account. Be^{2+}, when six coordinate, has an (estimated) effective ionic radius[27] of 0.45 Å, Al^{3+} of 0.535 Å and Mg^{2+} of 0.72 Å. Using an estimated value of 1.63 Å for the "ionic radius" of the ring carbon atoms[37] of the $C_5Me_5^-$ group in these compounds,[29] M–C(η^5) distances of 2.08 Å (Be), 2.16 Å (Al) and 2.35 Å (Mg) can be calculated that are in excellent agreement with the experimental values (2.05 Å in the Be, 2.16 Å in the Al and 2.34 Å in the Mg metallocenes).

Solid-state ^9Be and ^{13}C NMR studies have also been employed to elucidate the structure and dynamics of the methyl-substituted beryllocenes **2** and **3**, as well as the parent beryllocene.[15] Interestingly, within the relatively small

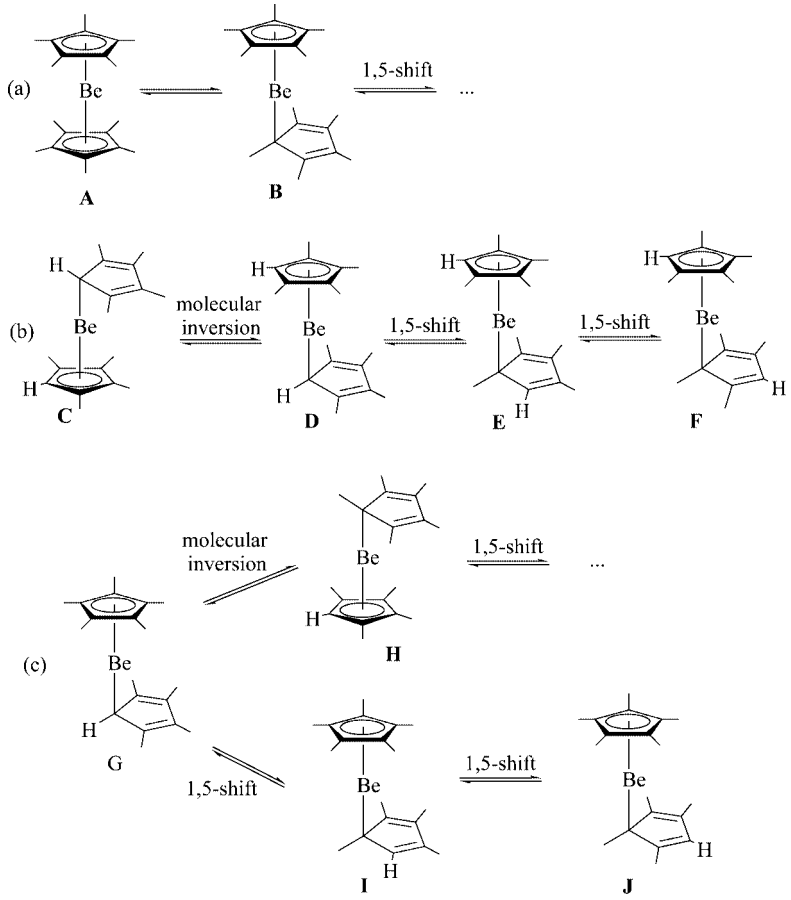
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

chemical-shift range of ^{9}Be (ca. +25 to –25 ppm) the isotropic chemical shift has been found to vary with the coordination of the Cp′ rings from, for instance, δ = –19.8 ppm in the η^5/η^1 beryllocene **2** to δ = –24.4 ppm in the η^5/η^5 compound **3**. It was also found that the Cp′ rings of **2** feature relatively little motion in the temperature interval from –100 to 80 °C, while in the case of **3** the rate of reorientation of the C_5Me_5 rings decreases substantially at low temperatures.[15]

The bonding in decamethylberyllocene (**3**) has been analysed at different levels of theory and the geometry of its molecules optimised enforcing the η^5/η^5 D_{5d} and the η^5/η^1 C_s symmetries. The B3LYP functional predicts the C_s structure to be the lower energy one by about 3 kcal mol^{-1}, whereas calculations with the PW91 functional lead to a difference of only 1 kcal mol^{-1}. This is consistent with the very fluxional structures of beryllocenes. The very low energy difference between the two geometries suggests that the compression implied by crystal packing may distort the molecules toward the observed η^5/η^5 geometry. The calculations also showed that the electrostatic contribution to the bonding ($Be^{2+}\cdots 2\ C_5Me_5^-$) for the D_{5d} structures of $[Be(C_5H_5)_2]$ and $[Be(C_5Me_5)_2]$ amounts to around 65 and 58%, respectively. Thus, it is clear that the bonding in **1** and **3** has a high covalent character and that the covalency is larger in $[Be(C_5Me_5)_2]$ than in $[Be(C_5H_5)_2]$.[29]

Variable temperature ^{1}H and ^{13}C NMR spectroscopy and reactivity studies are in agreement with the expected fluxionality for these molecules, consisting of two very low-energy processes: a 1,5-sigmatropic shift of the Be(η^5-Cp′) fragment around the periphery of the η^1 ring and the "molecular inversion" that results in the exchange of the two rings.[21] For the parent beryllocene the rates of molecular redistribution in solution[20] (300 K) and in the gas phase (400 K) are of the order of 10^{10}–10^{12} s^{-1} and therefore the processes cannot be detected by NMR methods.

In accordance with this, the two rings of $[Be(C_5Me_4H)_2]$ are equivalent (from –90 to +80 °C) and experience very little chemical-shift variation. Decamethylberyllocene shows a singlet in the ^{1}H NMR spectrum (δ = 1.9–2.0 ppm between –90 and +80 °C) and a unique ^{13}C resonance for the ring carbon nuclei (δ = 109.7 ppm at –90 °C). Naturally, this cannot be taken as being suggestive of fluxionality, but by similarity with the other beryllocenes it is reasonable to assume that the η^5/η^5 and η^5/η^1 structures exist in equilibrium in solution. For the mixed-ring beryllocene **4**, an important contribution of the η^5-C_5Me_5/η^1-C_5Me_4H solid-state structure to the solution structure has been proposed from the variable temperature ^{1}H and ^{13}C{^{1}H} chemical shifts and also from the observation of a well-resolved coupling (10 Hz) between the quadrupolar ^{9}Be and the ^{13}*C*H nuclei in the ^{13}C{^{1}H} NMR spectrum recorded at +95 °C.



Scheme 2. Rearrangements of substituted beryllocenes: a) $[Be(C_5Me_5)_2]$; b) $[Be(C_5Me_4H)_2]$; c) $[Be(C_5Me_5)(C_5Me_4H)]$.

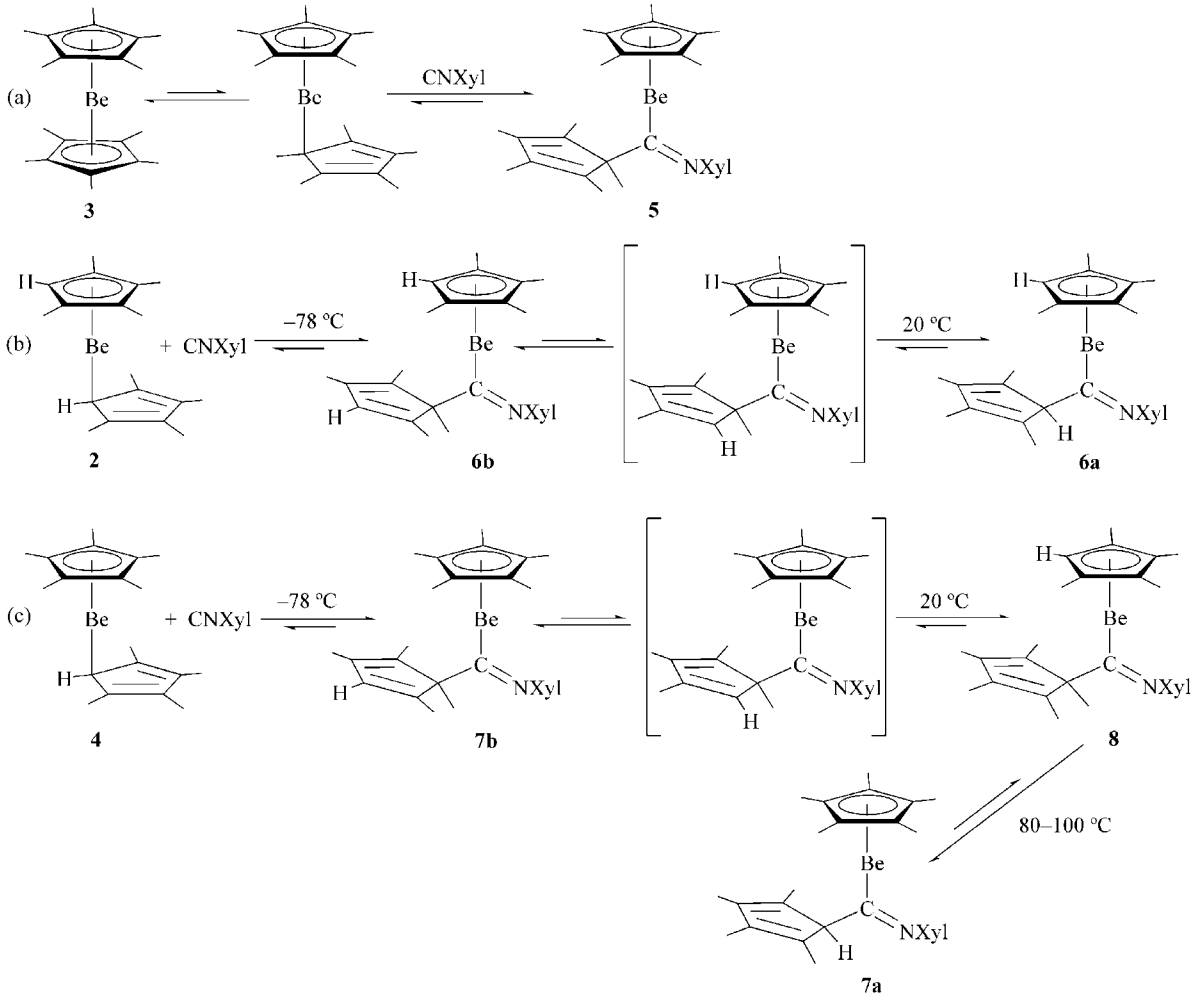
Reactions of $[Be(C_5Me_4H)_2]$, $[Be(C_5Me_5)_2]$ and $[Be(C_5Me_5)(C_5Me_4H)]$ with CNXyl: The Half-Sandwich Beryllocenes $[Be(\eta^5\text{-}Cp')\{C(NXyl)Cp''\}]$

The above-mentioned dynamic processes that account for the fluxionality of the beryllocenes should give rise to different isomeric structures (Scheme 2) in the solutions of **2**, **3** and **4**. Interestingly, the study of the reactions of these compounds with CNXyl (Xyl = C_6H_3-2,6-Me_2) could be taken to support the existence of most of these structures in solution and has therefore been employed as a chemical probe for both the sigmatropic shift and the molecular-inversion rearrangements that form them.[38] This relies on the assumption that formation of the iminoacyl complexes (see below) occurs by direct attack of CNXyl on a Be–η^1-Cp′ bond, without a change in the coordination of the η^5-Cp′ ring.

The permethylated beryllocene **3** and CNXyl react at room temperature to form the iminoacyl complex **5** (Scheme 3a). The reaction is reversible and the equilibrium is characterised by $\Delta H°$ and $\Delta S°$ values of 18(0.4) kcal mol^{-1} and 35(1) cal mol^{-1} K^{-1}, respectively. The reaction of $[Be(C_5Me_4H)_2]$ (**2**) and CNXyl is also reversible (Scheme 3b). However, due to the lower symmetry of the C_5Me_4H group, this system is somewhat more complex and three iminoacyl isomers are possible. Two of them, **6a** and **6b**, have been isolated and characterised. Even though variable temperature ^{1}H NMR monitoring of the reaction suggested the formation of another product, its characterisation was not possible. Mechanistically, CNXyl attack on a Be–η^1-Cp′ bond was suggested to explain iminoacyl formation rather than a migratory insertion reaction on the basis of steric crowding around the metal and the availability of only four valence orbitals. Regardless of this, since a Be–η^1-Cp′ bond participates in the C–C coupling, the formation of iminoacyls **5** and **6** (Scheme 3a and b) suggests the existence in solution of the η^5/η^1 structures **B** (in the case of **3**) and **D** and **F** (for **2**) resulting from the 1,5-sigmatropic shift (Scheme 2a and b).

Naturally, the identity of the two Cp′ rings of **2** and **3** does not permit detection of the "molecular inversion" rearrangement that interchanges the two rings. Nonamethylberyllocene (**4**) is therefore unique in this regard. As shown in Scheme 3c, four isomeric iminoacyl complexes are possible and, indeed, the treatment of **4** with CNXyl has allowed the isolation of three of them. As could be antici-



Scheme 3. Reaction of $[Be(C_5Me_5)_2]$ (**3**), $[Be(C_5Me_4H)_2]$ (**2**) and $[Be(C_5Me_5)(C_5Me_4H)]$ (**4**) with CNXyl.

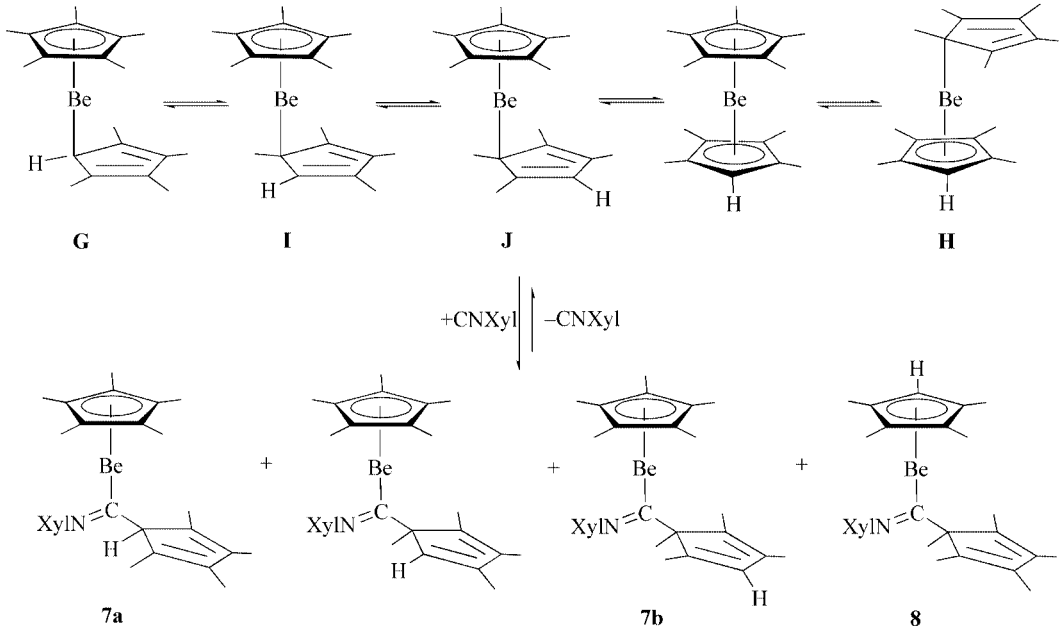
pated, the thermodynamic isomer **7a** contains an η^5-C_5Me_5 ligand and an iminoacyl fragment that results from C–C coupling between the CH unit of C_5Me_4H and CNXyl. Most interestingly, however, compound **8**, which is generated in the room temperature reaction, has an η^5-C_5Me_4H ring and a C(NXyl)C_5Me_5 iminoacyl ligand, thus indicating that the "inverted" beryllocene structure **H** of Scheme 2c is attainable in solution.

Summarizing the reactivity of beryllocenes represented in Schemes 2 and 3, the formation of iminoacyls **5**–**8** can be accounted for by assuming that iminoacyl formation is a reversible process, as has been convincingly demonstrated. The generation of the different isomers may be explained in relatively simple terms with the aid of Scheme 4 for the particular example of the reaction of **4** with CNXyl. It can be proposed that the different η^5/η^1 beryllocene isomers that may exist in solution (**G**, **H**, **I** and **J**) compete for the isocyanide, so that at a certain temperature the outcome of the reaction depends upon: i) the accessibility of the particular isomer, i.e. its population, and the activation barrier of its C–C coupling reaction, and ii) the thermodynamic stability of the resulting iminoacyl relative to that of the other isomers. For instance, the seemingly exclusive formation of **7b** at –78 °C suggests that its η^5/η^1 beryllocene precursor **J** is accessible at this temperature and, moreover, that it features the lowest barrier of all C–C couplings. Since the formation of **7b** is reversible, other less-facile C–C couplings may occur at higher temperature, for instance that leading to the "inverted" compound **8**. Finally, since the formation of **7a** requires heating at 80–100 °C, it appears that the strongest Be–CH bond of those possible for the Be–η^1-C_5Me_4H unit is the most reluctant to participate in the C–C coupling with CNXyl.

Other Half-Sandwich Cyclopentadienylberyllium Compounds

A large number of beryllium compounds containing only one cyclopentadienyl ligand have been described, mainly by the groups of Morgan, Coates and Gaines, and they have been considered in previous review articles.[4] Therefore, only a brief, non-comprehensive coverage is presented here. Most of these compounds have been prepared by the reaction between beryllocene and the corresponding disubstituted beryllium compound BeR_2, leading to the mixed products [BeCpR] with R = H,[39] Cl,[40] Br,[41] I,[42] CH_3,[11,39b] *t*Bu,[43] C_6F_5,[43] C_6H_5,[44] C≡CH,[45] and C≡C–CH_3.[45] Other half-sandwich beryllium complexes containing different borate ligands have been synthesised by other routes. For example, reaction of [BeCpCl] with $LiBH_4$ and KB_5H_8 leads to the complexes [BeCp(BH_4)][46] and [BeCp(B_5H_8)],[47] respectively. The synthesis of compounds [BeCp(B_3H_8)][48] and [BeCp(B_5H_{10})][49] has been achieved by the reaction of NaCp with [Be(B_3H_8)$_2$] and [BeBr(B_5H_{10})], respectively. The amide complexes [BeCp(NMe_2)], [BeCp(NEt_2)], [BeCp(NPh_2)] and [BeCp{N($SiMe_3$)$_2$}] have been prepared by mixing equimolar amounts of the corresponding Li or Na amide and [BeCpX] (X = Cl, Br). They can also be prepared by stirring an equimolar mixture of beryllocene and the corresponding beryllium bis(amide) complex.[50] Recently, the complex [BeCp($SiMe_3$)] has been synthesised[51] by the base-free reaction of [$LiSiMe_3$] with [BeCpCl]. It constitutes the first example of a compound with a direct Be–Si bond[51] and it is characterised by an Si–Be distance of 2.18 Å, which is significantly longer than the sum of the covalent radii (2.01 Å).



Scheme 4. Reaction of the possible isomers of **4** with CNXyl.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

All these cyclopentadienyl half-sandwich complexes are air-sensitive, colourless solids or liquids whose structural parameters are available mainly from X-ray structural data[47,51,52] and from electron diffraction and microwave studies.[39a,40–42,53] In nearly all cases the molecules are monomeric in the solid state, in solution, and in the gas phase, with pentahapto coordination of the cyclopentadienyl ligand. The beryllium to ring centroid distances (e.g. $[BeCpCl]_{(g)}$ 1.48 Å;[39a] $[BeCpCl]_{(s)}$ 1.45 Å;[52] $[BeCpBr]_{(g)}$ 1.53 Å;[40] $[BeCpMe]_{(g)}$ 1.50 Å;[11] $[BeCpCCH]_{(g)}$ 1.49 Å;[40] $[BeCpB_5H_8]_{(s)}$ 1.47 Å[46]) are all similar to that to the nearest ring in beryllocene[14] (1.505 Å). The Be–CH_3 bond length in [BeCpMe] is not significantly different from the Be–C bond length in dimethylberyllium [1.698(5) Å], but the Be–Cl bond length in [BeCpCl] is significantly longer in the gas phase [1.837(6) Å] and in the solid state [1.869(3) Å] than in monomeric beryllium dichloride (1.75 Å). It seems reasonable to assume that the dative Cl–Be π-bonding interaction is weaker in [BeCpCl] than in $BeCl_2$.

The most notable feature of the NMR spectrum of these compounds is that in the ^{13}C NMR spectrum of [BeCpBr], a ^{13}C–^{9}Be coupling of 1.1 Hz has been observed.[54] $[BeCpBH_4]$ is unique in exhibiting a very well-resolved ^{9}Be NMR multiplet spectrum and is the only known example of ^{9}Be–^{11}B coupling (3.6 Hz), as a 1:1:1:1 quartet and an unresolved ^{9}Be–^{10}B septet of equal intensity of 1.2 Hz are also observed.[57b] The ^{9}Be and ^{29}Si NMR spectra[51] of $[BeCp(SiMe_3)]$ exhibit a large J(Be–Si) coupling constant of 51 Hz, and the ^{9}Be chemical shift of $\delta = -27.70$ ppm is the highest-field value recorded to date, in accordance with the calculated bond-polarity pattern as well as a bond to Si.

Theoretical calculations at different levels have been performed for monocyclopentadienylberyllium compounds, especially for [BeCpH].[9c] It has been shown that [BeCpH] strongly prefers C_{5v} symmetry and pentahapto bonding with a high degree of covalent character. Bonding between beryllium and the monodentate ligand involves one sp hybrid orbital on the metal while the other sp hybrid interacts with the $a_1\pi$ orbital of the ring. The remaining 2p orbitals on beryllium overlap with filled $e_1\pi$ orbitals to form degenerate bonding orbitals. Beryllium is therefore surrounded by an octet of electrons and since these compounds are not electron deficient, there is relatively little tendency for association or complex formation.[11,39a,40,55]

In contrast to the many known organoberyllium compounds that contain a Be(η^5-C_5H_5) fragment,[4] there are only a few in which the cyclopentadienyl ligand is substituted. The half-sandwich species Be(η^5-C_5Me_5)Cl (**9a**) was first isolated by Burns and Andersen in 1987,[28] and later used by Pratten, Cooper and Aroney, to prepare the mixed-ring beryllocene $[Be(C_5Me_5)(C_5H_5)]$, which they characterised by solution IR and NMR studies.[26] The organometallic beryllium compounds Be(η^5-C_5Me_5)Me],[28] [Be(η^5-C_5Me_5)(P*t*Bu_2)][56a] and [Be(η^5-C_5Me_5)(As*t*Bu_2)][56b] were subsequently prepared from **9a**.

The complexes [Be(η^5-C_5Me_5)X] [X = Cl (**9a**), Br (**9b**)] are obtained in high yields when $[BeX_2(OEt_2)_2]$ (X = Cl, Br) are allowed to react with $[M(C_5Me_5)]$ salts (M = Na, K). The alkyl derivatives [Be(η^5-C_5Me_5)R] [R = Me (**10a**), CMe_3 (**10b**), CH_2CMe_3 (**10c**), CH_2Ph (**10d**)] can then be obtained by metathetical exchange with an alkyllithium reagent in Et_2O.[38] Compounds **9** and **10** are crystalline solids, which may be crystallised by cooling their concentrated pentane solutions.

The NMR spectroscopic data for compounds **9** and **10** (^1H, ^{13}C and ^{9}Be)[38] compare well with those reported for other Cp′–Be derivatives. The ^{13}C chemical shift of the Me group of [Be(η^5-C_5Me_5)Me] (**5a**) is $\delta = -25.4$ ppm and the signal appears as a well-resolved 1:1:1:1 pattern due to coupling to ^{9}Be ($I = 3/2$), with a ^1J(Be–C) coupling constant of 30 Hz. In all of the other alkyls this resonance was not observed, presumably due to quadrupolar relaxation by the beryllium nucleus. The ring carbon atoms are not affected by the quadrupolar nucleus since the singlet resonances are sharp and no coupling is detected. The chemical shift value of $\delta = 108$–109 ppm is almost the same as that found for structurally characterised Be(η^5-C_5Me_5) compounds.[28] The ^{9}Be chemical shifts also have normal values. The signals are relatively sharp (half-height width of 3.5 Hz for **9b** and 16 Hz for **10a**) and, due to paramagnetic ring-current effects,[41,57] they are located in the higher-field region of the ^{9}Be chemical shift range (from approximately $\delta = -25$ to +25 ppm).[20,41,57–59]

Both the halides **9** and the alkyls **10** are stable toward disproportionation. In an attempt to obtain the hydride [Be(η^5-C_5Me_5)H], which is isolobal with the alkyls **10**, Andersen et al. treated [Be(η^5-C_5Me_5)Br] with LiAlH. IR studies on the crude reaction product revealed the existence of absorptions at 1950–1985 cm^{-1} that could be due to a Be–H group.[38] However, no hydride resonance could be found by ^1H NMR spectroscopy. Instead, the ^1H, ^{9}Be and $^{13}C\{^1H\}$ NMR spectra of the mixture confirmed the existence of $[Be(C_5Me_5)_2]$ and [Be(C_5Me_5)Br]. Thus, it is possible that [Be(η^5-C_5Me_5)H] forms but it is not stable at room temperature and disproportionates to $[Be(C_5Me_5)_2]$ and BeH_2.

Summary and Outlook

Since 1959, and for a period of over forty years, beryllocene $[Be(C_5H_5)_2]$ (**1**) has been the only member of the beryllocene family of compounds. This singularity, and above all its unusual structure, has motivated an astonishingly large number of both experimental and theoretical investigations.

The preliminary studies reported by our group in 2000 constituted a major turn-about of this situation since synthetic and structural data for two new beryllocenes were provided.[29b] Like **1**, the new beryllocenes, viz. $[Be(C_5Me_4H)_2]$ (**2**) and $[Be(C_5Me_5)_2]$ (**3**), contain two Cp′ rings of the same kind. Shortly afterwards, preliminary information on the structure and chemical behaviour of the mixed-ring compound [Be(η^5-C_5Me_5)(η^1-C_5Me_4H)] (**4**) was also provided by our group.[38b]

The beryllocenes that possess one or two C_5Me_4H rings, i.e. **2** and **4**, feature η^5/η^1 geometries of the slipped-sand-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

wich type, with the η^1-C_5Me_4H ligand bonded to beryllium through the unique CH carbon atom.[29,38] At variance with the parent beryllocene **1**, the structures of **2** and **4** exhibit no positional or thermal disorder. The calculated geometries are in agreement with experimentally observed structures and the calculations reveal that the preference of beryllium for CH binding is due to larger charge localisation on this part of the η^1 ring.

In contrast with this situation, the long sought-after decamethylberyllocene [$Be(C_5Me_5)_2$] (**3**) has an almost regular sandwich structure in the solid state.[29] Possibly, crystal packing effects may originate steric repulsions between the methyl ring substituents that force the molecules of **3** to adopt the η^5/η^5 geometry in the condensed state. This distortion would be energetically facile as the calculated energy difference between the two geometries is very low.

The half-sandwich chloride derivative [$Be(\eta^5$-$C_5Me_5)Cl$] reported by Burns and Andersen[28] in 1987, and the bromide analogue,[38a] are key reagents for Be(η^5-C_5Me_5) chemistry. These compounds have been used as precursors for the synthesis of a number of Be(η^5-C_5Me_5) organometallics, including the alkyls [$Be(\eta^5$-$C_5Me_5)R$] and the beryllocenes [$Be(C_5Me_5)_2$], [$Be(C_5Me_5)(C_5Me_4H)$] and [$Be(C_5Me_5)(C_5H_5)$]. It is foreseeable that they will continue to play a major role in future Be(η^5-C_5Me_5) chemistry.

Synthesis and Electrochemical Characterization of Metallocene–PNA Oligomers

Andrea Maurer,[a] Heinz-Bernhard Kraatz,[b] and Nils Metzler-Nolte*[a]

Keywords: Electrochemical DNA detection / Ferrocene / Metallocenes / Peptide nucleic acids

The synthesis of ferrocene- and cobaltocenium–PNA conjugates with *C*-terminal cysteine residues by solid phase methods is described. Melting points with complementary DNA reveal that both metallocenes stabilize the duplex, although to a different extent. The effect is more pronounced when there is an overhang of the DNA at the PNA amino terminus. The conjugates were studied by electrochemical methods in solution. They were also immobilized on Au microelectrodes in self-assembled monolayers (SAMs) and further characterized electrochemically on the surface.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Peptide Nucleic Acid (PNA) oligomers are synthetic DNA analogues which have gained considerable attention because of their favourable properties, such as high stability in biological media and sequence-selective binding to RNA and DNA.[1–3] In addition to medicinal applications as a lead structure for antisense agents, analytical applications in molecular biology have been suggested for PNA.[4] In the sequence-specific detection of RNA or ss-DNA, PNA oligomers are superior to ss-DNA because of their higher binding affinity which allows for detection of shorter oligomer sequences.[5,6] At the same time, mismatch sensitivity is improved for PNA·DNA duplexes compared to homologous ds-DNA. In addition, the stability of PNA·DNA duplexes is far less dependent on factors such as salt concentration and impurities than a purely DNA-based detection system would be.[7,8]

Electrochemical systems for DNA detection are potentially cheaper and more reliable than the conventional fluorescence spectroscopy. Ferrocene and its derivatives are often used in such devices because of their favourable electrochemical properties.[9,10] The electrochemically active metal complex is covalently linked to a DNA oligomer which is readily immobilized on an electrode surface,[11,12] making this scheme also suitable for DNA arrays.[13,14] Because of the advantageous properties of PNA, it seems ideal to construct electrochemical DNA sensors using metal-PNA probes. Wang and coworkers have explored PNA-based DNA sensors.[15,16] These workers used freely diffusing metal complexes or so-called reagentless detection. No PNA oligomers with covalently bound electrochemically active metal complexes were known at the time. Our group has subsequently reported the first organometallic PNA monomers and oligomers,[17–19,10] followed by other groups.[20,21] No attempt has been made so far to exploit the favourable combination of properties in metallocene–PNA conjugates for electrochemical DNA detection. In fact, no metallocene conjugates with PNA oligomers were comprehensively characterized so far.

In this paper, we report the synthesis of metallocene–PNA oligomers with thiol groups for immobilization on Au microelectrodes. Ferrocene PNA oligomers are compared to the isostructural but positively charged cobaltocenium derivatives to avoid solubility problems associated with the lipophilic ferrocene group. The metallocene–PNA oligomers are characterized in their interaction with complementary DNA. They were deposited in self-assembled monolayers (SAMs) on Au microelectrodes. The two metallocenes are compared in terms of their suitability for an electrochemical DNA detection system.

Results and Discussion

For this study, a 10-mer PNA sequence was synthesized by standard solid phase techniques on TentaGel R PHB-Cys(Trt)-Fmoc resin. After synthesis of the PNA oligomer, the last Fmoc group was cleaved, and activated ferrocene carboxylic acid (**1**) or cobaltocenium carboxylic acid (**2**) was added. After cleavage from the resin by concentrated TFA, precipitation from cold ether and lyophilization, two PNA oligomers were obtained with sequences $CpFeC_5H_4$-

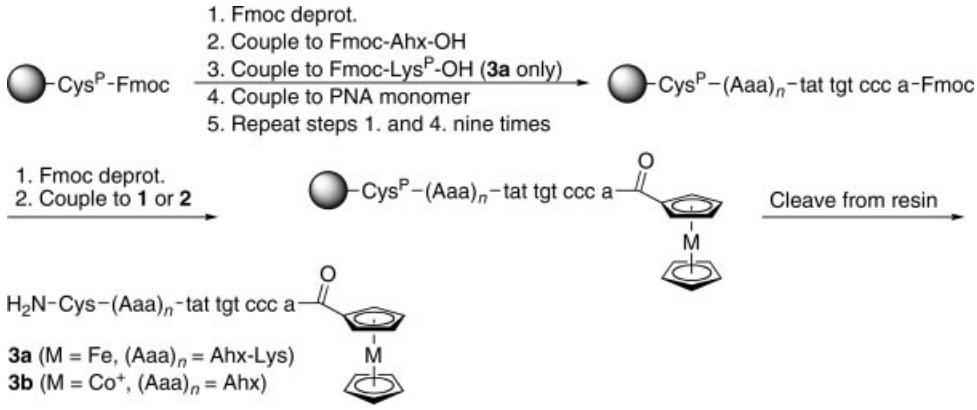

Scheme 1. Synthesis of metallocene–PNA oligomers **3**. See Supporting Information for details.

CO-a-ccc-tgt-tat-Lys-Ahx-Cys-NH_2 (**3a**) and [$CpCoC_5H_4$-CO-a-ccc-tgt-tat-Ahx-Cys-NH_2]$^+$ (**3b**, Ahx denotes ω-aminohexanoic acid). An *N*-acetylated oligomer Ac-a-ccc-tgt-tat-Lys-NH_2 (**3c**) was prepared for comparison (Scheme 1).

Purification and characterization of the PNAs was performed by RP-HPLC and MALDI-TOF mass spectrometry, respectively. The MS for **3a** shows a signal at *m*/*z* = 3233.8, which matches exactly the calculated value of 3233.3 for [M + H]$^+$. Spectra of similar quality were obtained for **3b** and **3c** (see Supporting Information). It should be noted that **3b** carries a positive charge already. The presence of the covalently attached metallocene group is also immediately apparent from the orange-brown or yellow colour of the resin for **3a** or **3b**, respectively, in comparison to white **3c**. A similar colour change was observed for a Mo organometallic complex attached to the pentapeptide enkephalin.[22] We recently found that attaching a cobaltocenium group to peptides significantly enhances the cellular uptake and nuclear localization of such conjugates.[23]

The metal–PNA conjugates were hybridized to complementary DNA in buffered aqueous solution in order to study the influence of the metal complexes on duplex stability. The melting curves for **3**·DNA were recorded in a temperature range of 20–80 °C (see Figure 1 and Table 1), using exactly matching DNA (**I**) and a complementary DNA strand which has three bases overhang at the metallocene PNA end (**II**). Several conclusions can be drawn from the melting temperature data: (1) the uncharged ferrocene influences duplex stability even if the PNA and DNA match exactly [Δ*T* (**3a·I**–**3c·I**) = 4.3 °C], (2) overhanging DNA stabilizes a PNA·DNA duplex [Δ*T* (**3a·II**–**3a·I**) = 1.5 °C], and (3) a positively charged metallocene further stabilizes the PNA·DNA duplex only if the DNA, which is formally a polyanion, overlaps the PNA to make an interaction with the metallocenium cation possible. In effect, the increase in melting temperatures is 5.1 °C in going from **3b·I** to **3b·II**, whereas it is only 1.5 °C in the ferrocene system. The second observation is in agreement with previous results.[5] The third observation has been suggested in work with coordination compounds but could not be proven independently of other factors.[24]

Table 1. PNA·DNA UV melting temperatures (°C). DNA sequences are 5′-ATA-ACA-GGG-T-3′ (**I**) and 5′-ATA-ACA-GGG-TAA-T-3′ (**II**). See Supporting Information for experimental details.

PNA/DNA	I	II
3a	42.8 ± 0.5	44.3 ± 0.5
3b	37.6 ± 0.5	42.6 ± 0.5
3c	38.5 ± 0.5	n. d.

Solution electrochemistry of the metallocene PNAs **3a** and **3b** alone shows a quasireversible wave at E^0 = 0.20 V (**3a**, see Figure 2) and E^0 = –1.51 V (**3b**) vs. Fc/Fc^+ in acetonitrile/H_2O (1:1) solution for the one-electron transitions of the metallocenes. Electron-transfer properties of a ferrocene–PNA monomer and dimer were studied by Baldoli, Maiorana and coworkers.[25] The metal-free conjugate **3c** does not show any signal at comparable concentration. En route to the design of a device for electrochemical DNA analysis, we investigated the electrochemistry of ferrocene–PNA conjugates immobilized on Au electrode surfaces.

Gold microelectrodes were prepared from Au wire (50 μm diameter) sealed into glass capillaries as described before.[26] After polishing on alumina and electrochemical preparation, the thiolated PNAs were immobilized on the Au microelectrodes as a duplex with DNA **II**. For those electrodes, an electrochemical signal can be recorded at *E* = 0.44 V for the ferrocene–PNA–DNA duplex (**3a·II**, see Figure 2) vs. Ag/AgCl in aqueous KCl (3 M) in cyclic vol-

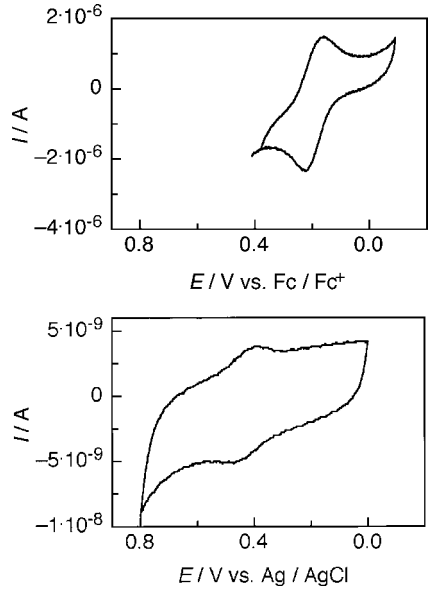

Figure 2. Cyclic voltammograms of **3a** in solution (top, CH_3CN/H_2O solution with 0.1 M $NaClO_4$, ca. 1 mM, platinum electrode with 2 mm diameter, vs. Fc/Fc^+, scan rate 0.5 Vs^{-1}) and of **3a·II** immobilized on the Au surface (bottom, aq. phosphate buffer at pH = 7, Au microelectrode, vs. Ag/AgCl, scan rate 2 Vs^{-1}). See Supporting Information for details.

tammetry (CV) as well as square wave voltammetry (SWV). Under identical conditions, no signal could be observed for the cobaltocenium–PNA conjugate **3b·II**. Ferrocene–DNA conjugates on Au electrodes are known to stand aligned at an angle around 45°. We suspected that the charged cobaltocenium–PNA conjugate might flip to the surface because of the flexible Ahx linker. Indeed, we were able to record a SWV for a cobaltocenium–PNA·DNA duplex that had no Ahx linker and was therefore more rigid (H_2N-Cys-tat-tgt-ccc-a-Cc·5′-ATA-ACA-GGG-T-3′; Cc: $CpCoC_5H_4$-CO-). In this case, a signal at $E = -0.92$ V was observed in the SWV.

From the electrochemical experiment, the surface concentration Γ_0* of **3a·I** was calculated from the oxidative peak current, the known scan rate and the surface area to be $\Gamma_0^* = 4\times10^{-11}$ mol cm^{-2}. This corresponds to roughly 7.3×10^8 molecules on an effective electrode surface of 2.8×10^{-5} cm^{-2}. For this calculation, the roughness factor for the surface area was experimentally determined by Cu-UPD to be 1.43. Under the assumption of complete electrode coverage by a self-assembled monolayer (SAM) this results in a footprint of 384 Å^2 per molecule, which is in agreement with previous measurements on Au-immobilized DNA and simple molecular geometry considerations.

Conclusions

In conclusion, we have presented the synthesis of metallocene PNA conjugates with thiol linkers for immobilization on Au microelectrodes. The synthesis of the first comprehensively characterized metallocene–PNA oligomers by solid phase peptide synthesis (SPPS) is described. Given the ubiquitous use of ferrocene in electrochemical sensors, the easy accessibility of the ferrocene–PNA system along with its favourable properties are worth mentioning. The use of a cobaltocenium–PNA conjugate is reported for the first time. Because ferrocene and cobaltocenium groups are almost isostructural but differ in charge as well as redox properties, subtle effects can be studied in detail as exemplified for the thermal stability of the metallocene bioconjugates in interaction with complementary DNA. The cobaltocenium–PNA conjugate shows excellent chemical stability upon storage and in solution. On the other hand, only the ferrocene–PNA shows clean electrochemical behaviour in the surface-immobilized duplex with complementary DNA. Taking together the ease of synthesis, chemical stability of the conjugates and favourable electrochemical properties, the metallocene–PNA system seems ideally suited for the development of electrochemical DNA arrays. Such devices are currently being developed in our groups.

Supporting Information is available online for this manuscript, including all experimental details as well as HPLC and MS data for PNA oligomers **3a**–**c**. Standard abbreviations are used for DNA bases (capital letters). The same small letters are used to denote PNA bases. Cys^P and Lys^P denotes protected cysteine (S-Trt) and lysine residue (N_ε-Boc-Lys).

Nonlinear Optical Activity and High Thermal Stability of a New 3D Open-Framework with Interconnected 24-, 16-, and 8-Atom Channels: $(NH_4)Zn[O_3PCH(OH)CO_2]$

Ruibiao Fu,[a] Huishuang Zhang,[a] Longsheng Wang,[a] Shengmin Hu,[a] Yaming Li,[a] Xihe Huang,[a] and Xintao Wu*[a]

Keywords: Zinc / Hydroxy(phosphonoato)acetate / Nonlinear optical activity / Hydrothermal synthesis / Open-framework

Hydrothermal reaction of hydroxy(phosphono)acetic acid, $H_2O_3PCH(OH)CO_2H$, with zinc(II) acetate resulted in a new ammonium zinc hydroxy(phosphonato)acetate, $(NH_4)Zn[O_3PCH(OH)CO_2]$ (**1**). The structure of **1** contains a 3D open-framework consisting of interconnected 24-, 16-, and 8-atom channels. TGA and XRD reveal that the framework is stable up to 350 °C in air. Its powder SHG intensity is about 0.8 times that of potassium dihydrogen phosphate KDP.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Noncentrosymmetric metal-organic coordination polymers have been extensively studied due to their intriguing second-order nonlinear optical (NLO) properties and high thermal stabilities. These properties make them particularly attractive candidates for NLO applications.[1–11] A general strategy to synthesise these nonlinear optically active materials is to use asymmetric ligands as bridging units as well as Zn^{2+} and Cd^{2+}. There are three reasons: (i) asymmetric ligands can serve as asymmetric building blocks to increase the probability of compounds crystallizing in a non-central space group; (ii) asymmetric ligands usually contain push-and-pull functional groups which results in a high efficiency of second harmonic generation (SHG); (iii) Zn^{2+} and Cd^{2+} have the advantage of optical transparency. In this communication, hydroxy(phosphono)acetic acid, containing a chiral carbon atom and three functional groups (OH, COOH and PO_3H_2), has been introduced as a bridging ligand and Zn^{2+} to synthesize a new 3D open-framework with intersected 24-, 16-, and 8-atom channels, $(NH_4)Zn[O_3PCH(OH)CO_2]$ (**1**), possessing nonlinear optical activity and high thermal stability.

Results and Discussion

X-ray single crystal diffraction reveals that 24-, 16-, and 8-atom rings exist in the 3D open-framework within compound **1** (Figure S-1, Supporting information). The Zn^{II} atom is in a slightly distorted $[ZnO_4]$ tetrahedral coordination geometry; it is surrounded by three phosphonate oxygen atoms (O1b, O2a, and O3) and one carboxylate oxygen donor (O5) from four equivalent hydroxy(phosphonato)-acetate groups. The values of the Zn–O bond lengths and O–Zn–O angles are in the range of 1.934(8)–1.967(7) Å and 107.1(3)–113.0(3)°, respectively. On the other hand, the hydroxy(phosphonato)acetate group is in a tetradentate mode. It connects four Zn^{II} atoms (Zn1b, Zn1c, Zn1d, and Zn1e) through three phosphonate oxygen atoms (O1c, O2c, and O3c) and one carboxylate oxygen donor (O5b).

There are three attractive structural features of the 3D open-framework: (i) One left- and one right-helical chain co-exist in an infinite ladder-like double chain (Figure 1). In the double chain, two $[ZnO_4]$ and two $[PCO_3]$ tetrahedrons form an 8-atom ring by sharing four corners (O1, O2, O1b, and O3b). The 8-atom rings interact with each other by sharing corners. (ii) As shown in Figure 2, the double chain connects 16- and 24-atom 1D channels along the crystallographic *a* and *c* axis, respectively. The 16-atom channel is occupied by NH_4^+ ions and assembled by 16-atom rings, which consist of three Zn^{II}, three P, four C and six O atoms with the sequences –Zn–O–P–C–C–O–Zn–O–P–O–Zn–O–C–C–P–O– (Figure S-1, Supporting information), while the 24-atom channel looks like the figure "8", constructed by 24-atom rings containing four hydroxy-(phosphonoato)acetate groups and four Zn^{II} atoms with the sequence –Zn–O–C–C–P–O–Zn–O–C–C–P–O–Zn–O–C–C–P–O–Zn–O–C–C–P–O– (Figure S-1, Supporting information). (iii) The 16-atom channels are parallel to the *c* axis.

Powder XRD patterns confirm that polycrystalline **1** is stable upon heating at 300 °C in air for 2 h (Figure 3). The

Ball representations exhibit the left- and right-helical chains (bottom); black spheres: Zn; gray spheres: P; white spheres: O. Unrelated atoms are omitted for clarity.

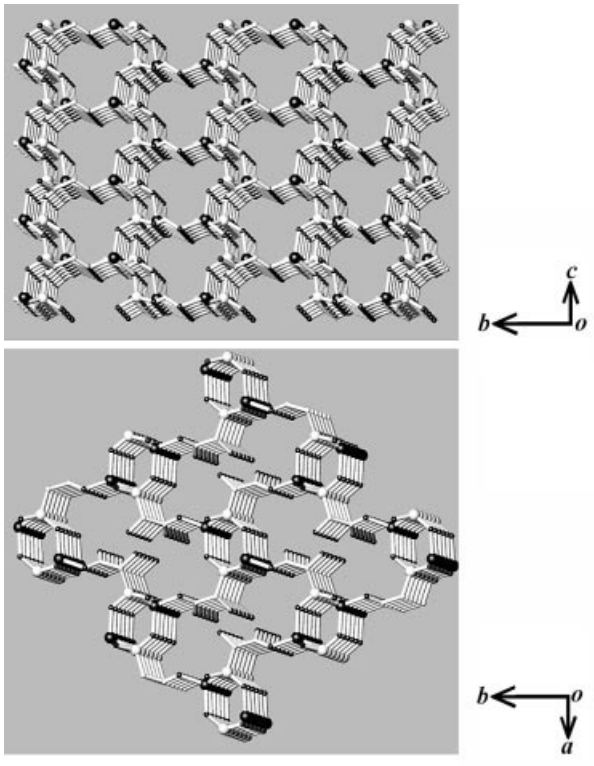

Figure 2. Packing views ofthe the 16- (top) and 24-atom (bottom) channels along the *a* and *c* axis, respectively; Large black spheres: Zn; large white sphere: P; small black spheres: O; small white spheres: C. Unrelated atoms are omitted for clarity.

main peaks of powder XRD still exist after a similar treatment at 350 °C, which indicates that the framework does not collapse. This is in agreement with the result of TGA measurements, which show that there is only little weight loss up to 350 °C (Figure 4). When a beam at λ = 1064 nm fundamental wavelength from a *Q*-switched Nd:YAG laser falls onto some powder of **1**, green light can be seen with naked eyes, confirming its acentricity. In order to evaluate its potential as second-order NLO material, powder second harmonic generation (SHG) measurements of **1** were performed according to a method previously reported by Kurtz.[12] The preliminary experimental result is that the powder SHG intensity of **1** is about 0.8 times that of potassium dihydrogen phosphate (KDP). Compound **1** is transparent in the visible region and insoluble in common solvents. Its remarkable thermal stability makes it an attractive candidate for NLO applications.

Conclusions

In conclusion, we have described a new 3D open-framework with interconnected 24-, 16-, and 8-atom channels, $(NH_4)Zn[O_3PCH(OH)CO_2]$, possessing nonlinear optical activity and high thermal stability. The compound was hydrothermally synthesized by using a bridging ligand with a chiral carbon atom and three functional groups. This result may provide a new way to synthesize attractive hybrid materials of high thermal stability for NLO applications.

Experimental Section

General Remarks: Reagents were obtained from commercial sources and used as received without further purification. C, H, N analyses were carried out with a Vario EL III element analyzer. Infrared spectra were obtained from KBr pellets in the range 4000–400 cm^{-1} with a Nicolet Magna 750 FT-IR spectrometer. Thermogravimetric analysis (TGA) was performed with a NETZSCH STA 449C under nitrogen at a heating rate of 10 °C·min^{-1} from room temperature to 1300 °C. Powder X-ray diffraction (XRD) patterns were acquired with a DMAX-2500 diffractometer using Cu-K_α radiation under ambient conditions.

Synthesis of $(NH_4)Zn[O_3PCH(OH)CO_2]$ (1): A mixture of $Zn(CH_3COO)_2{\cdot}2H_2O$ (1.0 mmol), NH_4Cl (25 mmol), NaF (4 mmol), hydroxy(phosphono)acetic acid (2 mmol), acetic acid (35 mmol) and water (444 mmol) was heated at 140 °C for 96 h. After the mixture was cooled slowly to room temperature, needle-shaped colorless crystals were obtained in about 10% yield (22.2 mg) based on $Zn(CH_3COO)_2{\cdot}2H_2O$. The pH value of the final mixture was 4.12. The purity of the product was checked by powder X-ray diffraction. $C_2H_6NO_6PZn$ (236.42): calcd. C 10.16, H 2.56, N 5.92; found C 10.06, H 2.62, N 5.96. IR (KBr pellet): $\tilde{\nu}$ = 3345 s (ν_{O-H}), 3215 vs (ν_{N-H}), 3072 s (ν_{N-H}), 2930 w (ν_{C-H}), 2856 m (ν_{C-H}), 2362 w, 1614 vs ($\nu_{C=O}$), 1433 vs (δ_{C-H}), 1279 m (ν_{C-O}), 1202 m (ν_{P-O}), 1126 s (ν_{P-O}), 1082 s (ν_{P-O}), 993 s (ν_{P-O}), 835 m, 766 m, 685 m, 600 m, 559 m, 521 m, 478 m cm^{-1}.

X-ray Crystallography Study: X-ray data on a suitable single crystal were collected at 293 ± 2 K with a Siemens SMART-CCD diffractometer using graphite-monochromated Mo-K_α radiation [λ(Mo-K_α) = 0.71073 Å]. Data were reduced and absorption-corrected with SMART and SADABS software, respectively. The structure was solved by direct methods and refined by full-matrix least-squares techniques on F^2 using SHELXTL-97.[13] All non-hydrogen atoms of **1** were treated anisotropically. Hydrogen atoms of OH and CH were generated geometrically. Idealized positions of H atoms of the NH_4^+ cation were fixed with N–H = 1.0 Å and H···H = 1.63 Å. Crystal data: orthorhombic, space group *Pna*2(1) (no. 33), a = 10.245(2), b = 12.447(3), c = 5.1538(11) Å, V = 657.2(2) $Å^3$, Z = 4, D_c = 2.389 g·cm^{-3}, μ = 3.963 mm^{-1}, F (000) = 472, T = 293(2) K, 1495 reflections were measured in the range of 5.14° ≤ 2θ ≤ 50.14°, 933 independent reflections (R_{int} = 0.0226), 863 observed reflections [$I > 2\sigma(I)$] with R_1 = 0.0518 and wR_2 = 0.1172; R_1 = 0.0562 and wR_2 = 0.1215 (all data) and GOOF on F^2 of 1.191. CCDC-234887 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Synthesis and Characterization of a 3D H-Bonded Supramolecular Complex with Chiral Channels Encapsulating 1D Left-Handed Helical Water Chains

Benyong Lou,[a] Feilong Jiang,[a] Daqiang Yuan,[a] Benlai Wu,[a] and Maochun Hong*[a]

Keywords: Chiral channels / Water chains / Amino acids

A chiral Cu^{II} dinuclear complex $[Cu_2(L\text{-shis})_2]\cdot 4H_2O$ (H_2shis = *N*-salicylidenylhistidine) has been synthesized. The dinuclear units are assembled into a 3D hydrogen-bonded supramolecular structure with 1D chiral channels through hydrogen bonds between imidazole N–H groups and carboxylate oxygen atoms. 1D left-handed helical water chains in an AABB fashion, anchored through weak hydrogen-bonding interactions with the host complex, are embodied in the chiral channels. X-ray powder diffraction shows the porous structure is destroyed when the lattice water molecules are removed thermally from the channels.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Metal-organic frameworks containing channels or pores with various sizes and shapes have attracted much attention because of their potential applications in catalysis, separation and gas sorption and storage.[1–3] Chiral porous materials have great advantages over achiral ones in enantioselective separation and catalysis.[4] A direct and effective method for such materials is to ultilize enantioselective ligands.[5–7] Therein, using natural amino acids as chiral precursors is a simple and practical alternative.[8–10] Moreover, amino acids can afford different kinds of hydrogen bonds, which has an important effect on the structures of metal-organic materials.[11–13] Our interest has been focused on the employment of natural amino acids for synthesizing chiral ligands to direct the assembly of chiral metal-organic porous materials.

One-dimensional (1D) chain arrangement of water molecules has attracted much interest due to its occurrence in many fundamental biological processes which depend on the unique properties of water chains.[14–16] Such water chains could model the biological systems for transport of water or ions across membrane proteins with aquapores, and several examples of 1D water chains anchored by organic compounds or complexes have been reported.[17–22] Chakravarty described an unprecedented 1D helical chain of water in a dicopper(II) complex with a helical porous supramolecular structure-[20] and Vittal reported a staircase-like helical coordination polymeric architecture of a nickel(II) complex that hosts a 1D helical chain of lattice water molecules in a helical pore.[21] In these two cases, the 1D helical water chains are anchored by helical host complexes through weak hydrogen-bonding interactions and exhibit an alternate arrangement of two water molecules in the chains. While trying to construct chiral porous materials using a simple Schiff-base ligand derived from L-histidine, we obtained complex $[Cu_2(L\text{-shis})_2]\cdot 4H_2O$ (**1**) (H_2shis = *N*-salicylidenylhistidine), in which lattice water molecules are well ordered and arrayed in an AABB fashion to form 1D left-handed helical water chains encapsulated in the channels of the H-bonded supramolecular complex.

Results and Discussion

Complex **1** was obtained by the reaction of $Cu(NO_3)_2\cdot 3H_2O$ and a mixture of L-histidine and salicylaldehyde in basic ethanol/aqueous solution. The single-crystal X-ray analysis reveals that complex **1** crystallizes in the chiral space group $C222_1$ and consists of the neutral dinuclear unit $[Cu_2(L\text{-shis})_2]$ and four lattice water molecules, as shown in Figure 1. Cu1 is in a four-coordinate environment in which the shis anion as a tridentate ligand chelates Cu1 through the phenolato oxygen atom O3, the nitrogen atom N1 and the carboxylate oxygen atom O1, and the remaining site is occupied by an imidazole nitrogen atom N3A (A: $x, -y, 1-z$) from another shis ligand. Two Cu^{II} centers are connected by imidazole "arms" from two shis ligands to form a boat-shaped dinuclear unit. There exist H-bond donors (imidazole N–H groups) and acceptors (carboxylate oxygen atoms) on the top and bottom rims of each dinuclear unit, respectively, and this makes it a good building block for a hydrogen-bonded network. In fact, four such dimers are linked through hydrogen bonds [N2···O2B =

2.699(5) Å, B: $x + 1/2, 1/2 - y, 1 - z$] to give a large cycle containing eight Cu^{II} centers. The eight-membered rings are further linked to each other through the same hydrogen bonds, generating a two-dimensional supramolecular grid layer.

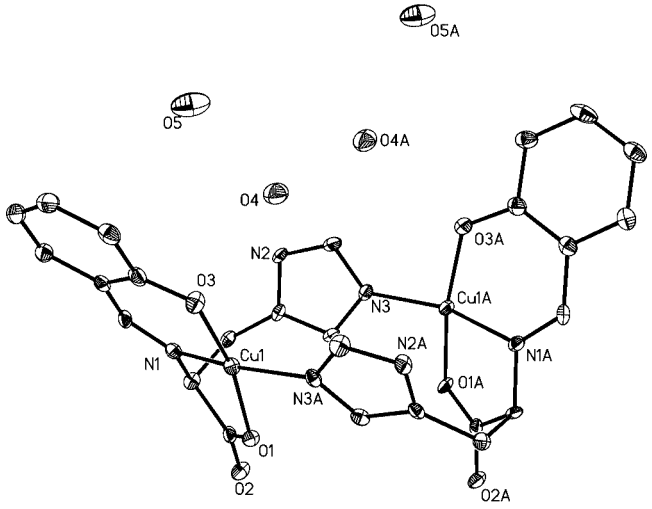

Figure 1. ORTEP view of the dinuclear complex. Selected bond lengths [Å] and angles [°]: Cu1–O1, 1.960(3); Cu1–N1, 1.922(4); Cu1–O3, 1.908(3); Cu1–N3A, 1.959(3); O3–Cu1–N1, 93.29(15); O3–Cu1–O1, 167.32(13); N1–Cu1–N3A, 162.34(13). Symmetry code: A: $x, -y, 1 - z$.

The asymmetric unit contains two water molecules which are bonded to each other through hydrogen bonding [O4···O5 = 2.813(5) Å]. The dinuclear unit anchors one water molecule through hydrogen bonding [O4···O3 = 2.983(5) Å] between coordinated phenolato oxygen atom O3 and atom O4 of water molecules. Atoms O4 and O4A (A: $x, -y, 1 - z$) of anchored water molecules are bonded to each other through hydrogen bonding [O4···O4A = 2.821(7) Å, A: $x, -y, 1 - z$]. Another water molecule is also anchored by a dinuclear unit of another asymmetric unit through hydrogen bonding [O5···O2H = 2.943(5) Å, H: $1 + x, y, z$] between uncoordinated carboxylate oxygen atom O2 and atom O5 of a water molecule. Thus, H-bonded O5–O4–O4A–O5A tetramers are filled with the grids of the 2D layer. Interestingly, the O5 atoms are also bonded to the same water molecules in symmetry through hydrogen bonds [O5···O5C = 2.869(8) Å, C: $3 - x, y, 3/2 - z$] which connect the 2D layers into a 3D structure with 1D chiral channels along the *c*-axis. Moreover, 1D helical water chains with a pitch of 16.9 Å along the *c*-axis are formed in the chiral channels, in which two water molecules are arranged by an AABB fashion (Figure 2). Such weak interactions upon the chiral host induce a homochiral left-handed helicity of water chains (Figure 3). In a sense, the formation of the helical water chain depends on the chemical information and structure of the dinuclear unit which anchors O4 and O4A within an H-bonded distance. Moreover, the H-bonded acceptors in **1** (phenolato and carboxylate oxygen atoms) are in favorable positions for anchoring different water molecules into an extended array.

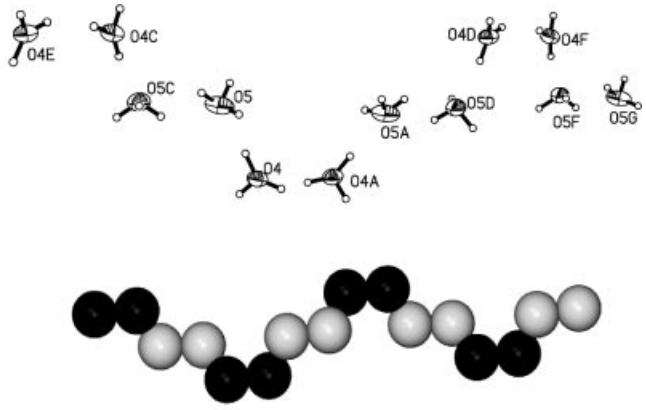

Figure 2. ORTEP view of the helical water chain along the *c*-axis (top) and view of the left-handed helix (bottom) containing water O4 (black) and water O5 (grey) in an AABB fashion. Symmetry codes: A: $x, -y, 1 - z$; C: $3 - x, y, 3/2 - z$; D: $3 - x, -y, z - 1/2$; E: $3 - x, -y, 1/2 + z$; F: $3 - x, y, 1/2 - z$; G: $x, y, z - 1$.

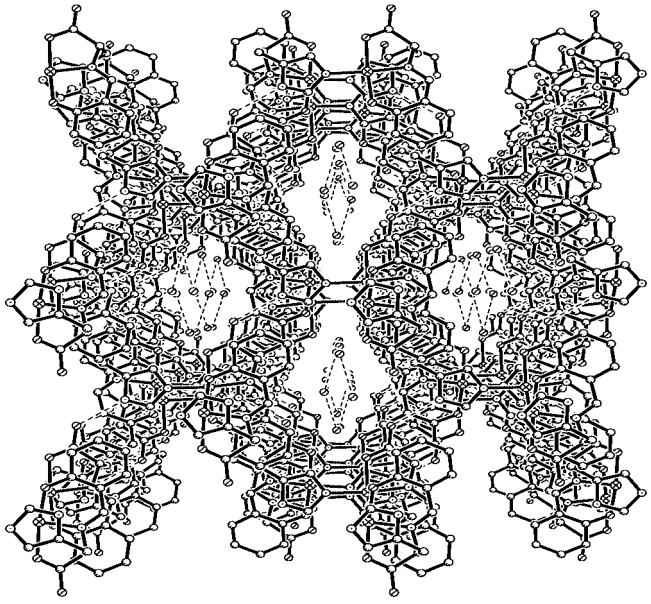

Figure 3. Helical water chains in the 1D channels of the host structure.

The thermogravimetric analysis (TGA) of **1** shows a weight loss of 10.4% in the temperature range 30–150 °C, which agrees with the calculated value (10.1%) for the loss of two water molecules per asymmetric unit. The DSC measurement at 20–150 °C at a rate of 5 °C·min^{-1} shows a single endothermal peak centered at 56.2 °C. The enthalpy per water molecule is ca. 16 kJ·mol^{-1}, which is similar to that observed in another infinite water chain.[19]

To investigate the influence of water molecules on the porous structure, we heated complex **1** at 150 °C for 2 h to remove water molecules (taking a cue from TGA). The elemental analysis of the dehydrated sample is consistent with the formula [Cu_2(L-shis)$_2$]. However, X-ray powder diffraction shows the porous structure of the host complex has been destroyed after the helical water chains being removed (Figure S3). It agrees well with interactions among the 2D

layers by weak hydrogen bonds between water molecules [O5···O5C = 2.869(8) Å, C: 3 – *x*, *y*, 3/2 – *z*]. When the water molecules are removed, the 2D layers are no longer as well ordered as in $[Cu_2(L\text{-shis})_2]\cdot 4H_2O$.

Conclusions

In conclusion, we have observed left-handed helical water chains in the chiral channels of the H-bonded chiral 3D supramolecular structure based on the dinuclear Cu^{II} complex of a Schiff base derived from L-histidine. The crystal structure of **1** exemplifies a synthetic host model anchoring the homochiral helical water chains in which water molecules are arranged in an AABB fashion.

Experimental Section

General Remarks: All reagents were analytical grade and used without further purification. The IR spectra as KBr disks were recorded with a Magna 750 FT-IR spectrophotometer. C, H, N elemental analyses were carried out with an Elementary Vario ELIII elemental analyzer. Thermogravimetric analysis was performed with a NETZSCH STA 449C instrument. The DSC curve was obtained with a NETZSCH DTA 404PC analyzer at a scan rate of 5 °C·min^{-1}. X-ray powder diffraction was performed with a Rigaku DMAX2500PC diffractometer.

Synthesis of Complex 1: To an aqueous solution (20 mL) of L-histidine (0.155 g, 1 mmol) and NaOH (0.040 g, 1 mmol), salicylaldehyde (0.122 g, 1 mmol) in ethanol (10 mL) was added slowly. The solution was stirred for 30 min and then $Cu(NO_3)_2\cdot 3H_2O$ (0.240 g, 1 mmol) in water (10 mL) was added. After stirring for 1 h, the filtered solution was allowed to stand in air for several days, and blue crystals were obtained in a yield of 60% (210 mg). $C_{26}H_{30}Cu_2N_6O_{10}$ (713.65): calcd. C 43.72, H 4.24, N 11.77; found C 43.47, H 4.38, N 11.55. IR (KBr): $\tilde{\nu}$ = 3416 br. [ν(OH)], 3151 m [ν(NH)], 1637 s [ν_{as}(COO)], 1603 s [ν(C=N)], 1369 m [ν_s(COO)] cm^{-1}.

X-ray Structure Determination: Single-crystal data were collected with a Rigaku Mercury-CCD diffractometer at 130 K, using graphite-monochromated Mo-K_α radiation (λ = 0.7107 Å). The structure was solved by direct methods and refined on F^2 by full-matrix least-squares procedures using the SHELXTL program package.[23] Crystal data: orthorhombic, space group $C222_1$ (no. 20), a = 11.8642(10), b = 14.6000(13), c = 16.9029(17) Å, V = 2927.9(5) Å^3, Z = 4, D_c = 1.619 g/cm^3, 9341 reflections collected, 2583 unique (R_{int} = 0.0468). Final *GooF* = 1.125, $R1$ = 0.0388, $wR2$ = 0.0860, R indices based on 2392 reflections with $I > 2\sigma(I)$ (refinement on F^2). Absolute structure parameter 0.038(19).[24] All non-hydrogen atoms were refined anisotropically and the organic hydrogen atoms were generated geometrically. The hydrogen atoms of water molecules are disordered. Full-occupancy hydrogen atoms H4B, H5B, and half-occupancy hydrogen atoms H4A, H4C, H5A, H5C were located by difference maps and constrained to ride on their parent O atoms in a trigonal arrangement. CCDC-268811 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Supporting Information (see footnote on the first page of this article): TGA and DSC curves of **1** (Figures S1 and S2); XRD patterns of **1** and the dehydrated product (Figure S3).

Reaction of 1,3,5-Triazacyclohexanes with $TiCl_4$: Formation of Cationic Complexes

Randolf D. Köhn,*[a] Philip Kampe,[a,b] and Gabriele Kociok-Köhn[a]

Dedicated to Professor Herbert Schumann on the occasion of his 70th birthday

Keywords: N ligands / Tridentate ligands / Titanium

N-substituted 1,3,5-triazacyclohexanes [R_3TAC; R = cyclohexyl, *p*-fluorobenzyl or Ph$(CH_2)_n$ (*n* = 1, 2, 3)] react with excess $TiCl_4$ to give the corresponding cationic κ^3 complexes $[(R_3TAC)TiCl_3][Ti_2Cl_9]$. Attempts to prepare complexes with titanium-free anions at lower Ti:R_3TAC ratio or with added Me_3SiOTf lead to the same cations with $[Ti_2Cl_{10}]^{2-}$ and $[Ti_2Cl_8(OTf)]^-$ anions. Five complexes as well as (*p*-fluorobenzyl)$_3$TAC have been characterised by X-ray crystallography. The ring C–H bonds engage in hydrogen bonding interactions in the crystals and strongly solvent and anion dependent ^{1}H NMR signals are detected in solution.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Many complexes containing triazacyclononane and larger macrocyclic amines are known.[1,2] They are used, for example, as bioinorganic model systems, reagents with high metal ion selectivity or as olefin polymerisation catalysts. The smaller *N*-substituted 1,3,5-triazacyclohexanes (R_3TAC) are much easier to prepare by the reaction of formaldehyde with primary amines allowing for a large variety of alkyl substituents. However, their coordination chemistry has mostly been explored only in the past ten years. A wide range of complexes with transition metals (like titanium complex **A**[3] in Scheme 1) and main group elements are well established. MAO activated chromium(III) complexes[4] (e.g. **B** in Scheme 1) are highly active homogeneous catalysts for the polymerisation and selective trimerisation of olefins.[5] Recently alternative catalysts for the selective trimerisation of ethylene based on aryl-substituted $CpTiCl_3$, **C**, have been discovered.[6] Since many features of the metal complexes containing R_3TAC, such as the ring centroid-metal distance, donor orbital orientation or positions of the ring substituents resemble those of analogous Cp rather than triazacyclononane complexes, we were interested in the preparation of analogous $[(R_3TAC)TiCl_3]^+$ complexes. The only previously described types of triazacyclohexane complexes of titanium are the neutral imido complexes **A** shown in Scheme 1.[3,7,8] In this paper we describe the synthesis of cationic 1,3,5-triazacyclohexane complexes by the reaction of the ligand with $TiCl_4$ (Scheme 2).

Results and Discussion

Treatment of $TiCl_4$ with one equivalent of *N*-substituted triazacyclohexanes **1** gave complex mixtures of products. However, a few yellow crystals of **2b** grew from this mixture as in the case of R = $Ph(CH_2)_2$ (**1b**). X-ray crystallography revealed a cationic complex $[(R_3TAC)TiCl_3]^+$ with $[Ti_2Cl_{10}]^{2-}$ anions. Apparently, excess $TiCl_4$ can abstract chloride ions to produce cationic R_3TAC complexes. Indeed, reaction of excess $TiCl_4$ with **1** gave high yields of often crystalline orange compounds. The optimal ratio of $TiCl_4$ to R_3TAC for a clean reaction was found to be 3:1. The crystal structures of **3a**, **3b** and **3d** contain the same cations as in **2b** but with the relatively more titanium rich anions $[Ti_2Cl_9]^-$. Similar ionisation of $TiCl_4$ has previously been observed in the reaction of hexaalkylbenzene with three equivalents of $TiCl_4$ giving $[(arene)TiCl_3][Ti_2Cl_9]$[9] Contrary to these arene complexes, the formation of **3** is irreversible on dilution. Thus, triazacyclohexanes are much stronger ligands than the arenes. The similarity of this reaction and the structures of the products show that the coordination chemistry of triazacyclohexanes share many characteristics with cyclic π ligands in the orientation of the donor orbitals, the position of the substituents near the plane of the donor atoms as well as the steric requirements.

The well-defined complexes **3** show only limited solubility in most inert organic solvents. The isolated crystalline solids are poorly soluble even in chlorinated solvents. The concentrations of saturated solutions of **3a** and **3d** in CH_2Cl_2 were found to be 2×10^{-4} and 2×10^{-3} mol cm^{-3}, respectively, by ^{1}H NMR spectroscopy. We generally find low solubility of triazacyclohexane complexes, probably due to hydrogen bonding interactions between ring–CH and Cl of the anion (or the complex itself) found in many solid-state structures. Thus, long-chain *N*-substituents or strong donor solvents are usually required for sufficient solubility. The concentration of **3e** was high enough to obtain ^{1}H and ^{19}F NMR spectra in pure $CDCl_3$ (about 4×10^{-3} mol cm^{-3} by NMR spectroscopy). All complexes **3** dissolved well in a mixture of $CDCl_3$ and $SOCl_2$ without apparent decomposition. Solutions in this mixture remained stable for many days even when exposed to air. Comparison of the NMR spectra of **3e** in neat $CDCl_3$ and those in 1:1 $CDCl_3/SOCl_2$ showed little differences except for the chemical shift of the two doublets for the ring CH_2 signals (4.89 and 4.74 ppm in $CDCl_3$ vs. 4.98 and 4.48 ppm in $CDCl_3/SOCl_2$). The observation of these two doublets for the equatorial and axial hydrogen atoms in the ring is also the best evidence for κ^3-R_3TAC coordination to a metal as observed previously.[10] The chemical shift and shift difference appears to be highly dependent on the environment (solvent, anion), probably due to C–H···X hydrogen bonding interactions. The shift difference varies from 0.1–0.9 ppm and is significantly smaller than the difference found in the neutral imido complexes of type **A** (1–2 ppm).[3,7,8]

In an attempt to obtain analogous cationic titanium complexes with titanium free anions we added Me_3SiOTf to the reaction mixture. Me_3SiCl was formed, however, a crystal structure of the product, **4d**, revealed the same cation not with an isolated triflate anion but with the titanium containing anion $[Ti_2Cl_6(\mu\text{-}Cl)_2(\mu\text{-}OTf)]^-$. Elemental analysis of the bulk product indicates that a mixture of **4d** and **3d** was obtained.

Addition of one equivalent of $LiB(C_6F_5)_4$ to a $CDCl_3/SOCl_2$ solution of **3d** leads to a significant change in the chemical shift of the pair of ring CH_2 signals of the ^{1}H NMR spectrum without changing the rest of the spectrum (4.96 and 4.62 ppm vs. 4.97 and 4.77 ppm in **3d**) indicating an anion exchange. Preparative scale metathesis of **3** or $TiCl_4$/**1** with $LiB(C_6F_5)_4$ allows the isolation of analogous salts **5** with largely $B(C_6F_5)_4$ anions, although no pure samples could be obtained due to anion contamination. **5d** had an NMR spectrum identical to the NMR tube experiment mentioned above and the spectra for **5b** (4.91 and 4.30 ppm vs. 5.03 and 4.81 ppm in **3b**) and for **5c** (3.60 and 3.45 ppm vs. coinciding peaks at 4.83 for **3c**) showed an increasing effect of the anion exchange (up-field shift and larger separation) for decreasing bulk of the *N*-substituents. A mixture of **5b** and **3b** leads to NMR signals at average positions indicating fast anion exchange on the NMR time-scale.

The strong dependence of the ring CH_2 ^{1}H NMR signals on the anion and the solvent indicates significant interactions of these C–H bonds with the environment.

X-ray Crystal Structures

All structures contain the $[(R_3TAC)TiCl_3]^+$ cation with titanium containing anions. Except for one feature, structural differences between cations with different anions (**2b**, **3b** and **3d**, **4d**) as well as anions with different cations (**3a**, **3b**, **3d**) are small and allow a separate discussion of the anions and cations.

Structural parameters of the coordination environment around titanium in the cations $[(R_3TAC)TiCl_3]^+$ shown in Figure 1 are summarised in Table 1. The structures are very similar to the neutral $[(R_3TAC)CrCl_3]$ where the analogous structure for R = $PhCH_2CH_2$ is known.[5] However, the Ti–N bond (2.23 Å) is much longer than in the chromium complex (2.10 Å) whereas the Ti–Cl bonds (2.20 Å) are shorter than in the chromium complex (2.28 Å), despite nearly identical ionic radii for Cr^{III} and Ti^{IV}.[11] Thus the higher charge on titanium favours the chloride bonding over the amine bonding. As in other triazacyclohexane complexes the nitrogen lone pair cannot be directed towards the metal and results in a bent-bonding situation. However, the Ti–N bonding is improved by bending the N-substituent towards the N_3 plane and therefore the lone pair towards the metal as shown in Scheme 3.

This bending can be expressed by the Ti–N–C angle or better the distance Δ of the α-C of the N-substituent above (or below) the N_3 plane. This can also be compared to the free ligand; the published structure[12] of **1a** has severe temperature dependent disorder between axial and equatorial benzyl groups making it difficult to obtain reliable Δ values. We crystallised the known ligand **1e** (R = *p*-fluorobenzyl)

and obtained a crystal structure without such disorder.[13] The structure of **1e** shows the most common conformation for free triazacyclohexanes with one axial and two equatorial N-substituents as shown in Figure 2. Δ for the two equatorial carbon atoms is +0.47 and +0.55 Å and close to the value of +0.49 Å expected for a ring with perfect tetrahedral angles and equal C–N bond lengths of 1.46 Å (average found in **1e**). The observed Δ values for the titanium complexes fall into three groups: +0.12 and +0.16 Å

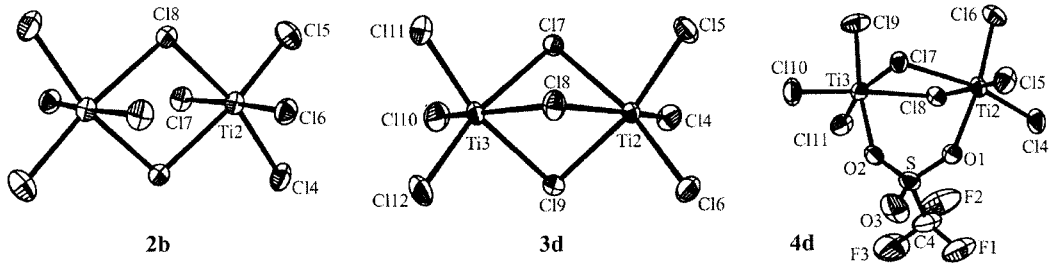

Figure 3. Structure of the anions in **2b**, **3d** and **4d**. The anions in **3a** and **3b** look nearly identical to that in **3d**.

for N-substituents in the *syn* conformation, –0.07 to +0.03 (av. –0.01) Å for the *anti* conformation and +0.03 to +0.08 (av. +0.05) Å for the cyclohexyl substituent (β-C in both *syn* and *anti* position). All values indicate a substantial bending of the N-substituent position towards the N_3 plane upon complexation in order to obtain better N-metal overlap. However, steric repulsion leads to less bending in the *syn* conformation (β-C···Cl) and increased bending in the *anti* conformation (β-C···axial ring C–H) with an intermediate case for cyclohexyl with repulsion at both β-C positions. The intermediate values for the cyclohexyl substituent show that both steric repulsions are important.

It is informative to compare the bonding parameters in these cationic $[(R_3TAC)TiCl_3]^+$ complexes with the neutral imido complexes **A**. The Ti–N bond lengths *trans* to Ti–Cl are nearly the same (2.23 Å) unless R is the bulky *t*Bu group (>2.30 Å) whereas the Ti–Cl bonds are substantially shorter in the cationic complexes (2.20 vs. 2.33–2.36 Å in **A**) but similar to those in the cationic arene complexes $[(arene)TiCl_3]^+$ (2.19 Å).[9] However, the Δ values for N-substituents *trans* to Cl in the imido complexes are much larger (+0.15 to 0.24 Å) than those found in the cationic complexes (–0.07 to +0.16 Å). Thus the tighter bonding of R_3TAC in cationic complexes is expressed as an improved nitrogen lone pair orientation (smaller Δ) rather than shorter Ti–N bonds.

All anions (Figure 3) contain two octahedrally coordinated titanium atoms. The two metals share one edge (two chloride bridges) in **2** or one face (three chloride bridges) in **3**. The anion in **4** contains a triflate bridge in addition to two chloride bridges and results in structural features intermediate between **2** and **3** as shown in Table 2. The anions in **2** and **3** have been observed before while the anion in **4** is new.[14]

The structures also allow us to look at the C–H···X interactions in the crystal and the effect of varying the N-substituents and anions. A CSD review of C–H···Cl interactions revealed H···Cl distances of 2.8–2.9 Å and C–H···Cl angles of 140–180° as the best parameters for this hydrogen bonding interaction when Cl is part of an anion.[15] The structures of all complexes in this work contain C–H···Cl contacts of this length or shorter and involve at least one ring C–H bond. Each anion has several contacts to neighbouring cations leading to an extended 3D network rationalising the poor solubility. However, there are noteworthy differences between the structures. The shortest contacts in **3** with the anion increase from **3b** (2.68 Å, R = $PhCH_2CH_2$) to **3a** (2.76 Å, R = $PhCH_2$) and **3d** (2.85 Å, R = cyclohexyl) as expected for increasing steric bulk exhibited by the substituent. In the latter case as well as in the similar **4d** (shortest C–H···Cl 2.78 Å + C–H···O(Tf) 2.51 Å) additional contacts of similar lengths with C–H groups of the substituents exist. The single short C–H···Cl contact in **3b** is replaced by two slightly longer contacts of 2.73 Å (ring CH) and 2.72 Å (α-CH_2 of R) reflecting the probably tighter binding of the Ti_2Cl_{10} dianion.

Table 2. Selected averaged distances [Å] and angles for the anions of **2**, **3** and **4**.

The above study demonstrates that cationic triazacyclohexane complexes of titanium can be obtained by the reaction of the ligand with excess $TiCl_4$. The N-substituents are more bent towards the metal than in neutral complexes with improved metal–N bonding. The ring C–H bonds of the triazacyclohexanes interact with the environment through significant hydrogen-bonding interactions leading to surprisingly poor solubility of these 3D networks in chlorinated solvents.

Experimental Section

General Details: All manipulations of air- and moisture-sensitive compounds were carried out under nitrogen or argon using standard Schlenk-line or glove box techniques. Solvents were dried according to standard methods and collected by distillation. R_3TAC except for **1c** are known and have been prepared analogous to the method described for **1c**. **1a**,**b**,**d**,**e** were crystallised from petroleum ether. ^1H and ^{13}C NMR spectra were recorded with a Varian Mercury-400 or Bruker Avance-300 or 400 at 20 °C and assignments were confirmed by COSY spectra. Mr Alan Carver (University of

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Bath) carried out the elemental analyses with an Exeter Analytical Instruments CE-440 Elemental Analyser.

Phenylpropyl$_3$TAC (1c): Phenylpropylamine (11.37 g, 84.22 mmol) and paraformaldehyde (2.53 g, 84.22 mmol) were dissolved in toluene (50 mL). The solution was heated to distil off the produced water as an azeotropic mixture with toluene. After 30 min the remaining solvent was removed by distillation under reduced pressure. The remaining pale yellow oil was dissolved in methanol (250 mL) and stored at 0 °C. The separated oil was washed with ethanol and dried under reduced pressure to give a colourless oil. ^{1}H NMR (300 MHz, $CDCl_3$): δ = 7.31–7.28 (6 H, C_6H_5–), 7.23 (9 H, C_6H_5–), 3.36 (br. s, 6 H, ring–CH_2), 2.69 (m, 6 H, –CH_2–Ph), 2.51 (m, 6 H, N–CH_2–), 1.83 (m, 6 H, Bz–CH_2–CH$_2$–N). ^{13}C{^{1}H} NMR (75 MHz, $CDCl_3$): δ = 142.1 (1-C_6H_5), 128.4 (3-C_6H_5), 128.2 (2-C_6H_5), 125.7 (4-C_6H_5), 74.5 (N–CH$_2$–N), 52.0 (PhEt–CH$_2$–N), 33.5 (Ph–CH$_2$–), 29.2 (Bz–CH$_2$–).

[(Benzyl$_3$TAC)TiCl$_3$]$^+$[Ti$_2$Cl$_9$]$^-$ (3a): I A solution of (PhCH$_2$)$_3$TAC (0.415 g, 1.16 mmol) in dichloromethane (25 mL) was added to a stirred solution of $TiCl_4$ (0.865 g, 4.56 mmol) in dichloromethane (25 mL) at room temperature under a stream of dinitrogen. After 5 h pale yellow platelets deposited. Washing with dichloromethane (10 mL) and drying in vacuo yielded clear yellow crystals. Yield: 0.56 g (52%). **II** A solution of (PhCH$_2$)$_3$TAC (1.24 g, 3.47 mmol) in toluene (25 mL) was added to a stirred solution of $TiCl_4$ (1.73 g, 9.12 mmol) in toluene (25 mL) at room temperature under a stream of dinitrogen. Dichloromethane (50 mL) was slowly added by condensation under reduced pressure. After 1 h of stirring, further $TiCl_4$ (1.73 g, 9.12 mmol) was added to give a dark orange solution. After another hour little orange crystals started to precipitate. These were dried under reduced pressure. Yield: 1.89 g (59%). ^{1}H NMR (300 MHz, $CDCl_3$/$SOCl_2$): δ = 7.48 m (9 H, C_6H_5–), 7.30 m (6 H, C_6H_5–), 5.06 and 4.14 (d, J = 9 Hz, 3 H, N–CH_2–N), 4.31 (s, 6 H, N–CH_2–Ph) ppm. ^{1}H NMR (400 MHz, saturated in CH_2Cl_2, 0.2 mM): δ = 7.5 (9 H, C_6H_5–), 7.3 (6 H, C_6H_5–), 4.75 and 4.25 (3 H, N–CH_2–N), 4.34 (s, 6 H, N–CH_2–Ph). ^{1}H NMR (400 MHz, saturated in CH_2Cl_2/$SOCl_2$, 1.0 mM): δ = 7.45 (9 H, C_6H_5–), 7.33 (6 H, C_6H_5–), 5.01 and 4.32 (d, 3 H, N–CH_2–N), 4.29 (s, 6 H, N–CH_2–Ph) ppm. ^{13}C{^{1}H} NMR (75 MHz, $CDCl_3$/$SOCl_2$): δ = 130.7 (1-C_6H_5), 130.6 (3-C_6H_5), 129.9 (2-C_6H_5), 127.6 (4-C_6H_5), 76.5 (N–CH$_2$–N), 60.9 (Ph–CH$_2$–N). $C_{24}H_{27}N_3Ti_3Cl_{12}$ (926.58): calcd. C 31.11, H 2.94, N 4.54; found C 30.9, H 2.99, N 4.52 ppm.

[(Phenylethyl$_3$TAC)TiCl$_3$]$^+$[Ti$_2$Cl$_9$]$^-$ (3b): A solution of (PhC$_2$H$_4$)$_3$-TAC (1 g, 2.5 mmol) in dichloromethane (25 mL) was added slowly to a solution of $TiCl_4$ (1.330 g, 7.01 mmol) in dichloromethane (25 mL) at room temperature under a stream of dinitrogen to give a clear brown solution. The product was cautiously precipitated by slow addition of hexane (20 mL). After 48 h a brownish yellow precipitate was separated and dried under reduced pressure to give a brownish yellow powder. Yield: 2.17 g (96%). ^{1}H NMR (300 MHz, $CDCl_3$/$SOCl_2$): δ = 7.41–7.34 (9 H, C_6H_5–), 7.26–7.23 (6 H, C_6H_5–), 5.03 and 4.81 (d, J = 9.2 Hz, 3 H, N–CH_2–N), 3.55 (t, 6 H, Ph–CH_2–), 2.98 (t, 6 H, Bz–CH_2–N) ppm. ^{13}C{^{1}H} NMR (75 MHz, $CDCl_3$/$SOCl_2$): δ = 135.3 (1-C_6H_5), 129.3 (3-C_6H_5), 128.5 (2-C_6H_5), 127.7 (4-C_6H_5), 77.9 (N–CH$_2$–N), 58.1 (Bz–CH$_2$–N), 30.5 (Ph–CH$_2$–) ppm. $C_{27}H_{33}N_3Ti_3Cl_{12}$ (968.66): calcd. C 33.48, H 3.43, N 4.34; found C 33.4, H 3.52, N 4.34.

[(Phenylpropyl$_3$TAC)TiCl$_3$]$^+$[Ti$_2$Cl$_9$]$^-$ (3c): A solution of (PhC$_3$H$_6$)$_3$-TAC (1 g, 2.26 mmol) in dichloromethane (25 mL) was added slowly to a solution of $TiCl_4$ (1.29 g, 6.80 mmol) in dichloromethane (25 mL) at room temperature under a stream of dinitrogen to give a clear dark brown solution. The product was cautiously precipitated by slow addition of hexane (20 mL). After 24 h a dark orange-brown precipitate was separated and dried under reduced pressure to give a brownish yellow crystal-like powder. Yield: 1.81 g (79%). ^{1}H NMR (300 MHz, $CDCl_3$/$SOCl_2$): δ = 7.34–7.27 (9 H, C_6H_5–), 7.24–7.18 (6 H, C_6H_5–), 4.85 and 4.81 (d, J = 9.6 Hz, 3 H, N–CH_2–N), 3.21 (m, 6 H, PhEt–CH_2–N) 2.68 (m, 6 H, Ph–CH_2), 1.98 (m, 6 H, PhCH$_2$–CH_2–) ppm. ^{13}C{^{1}H} NMR (75 MHz, $CDCl_3$/$SOCl_2$): δ = 139.1 (1-C_6H_5), 128.7 (3-C_6H_5), 128.3 (2-C_6H_5), 126.6 (4-C_6H_5), 77.5 (N–CH$_2$–N), 56.2 (PhEt–CH$_2$–N), 32.4 (Ph–CH$_2$–), 25.1 (PhCH$_2$–CH$_2$) ppm. $C_{30}H_{39}N_3Ti_3Cl_{12}$ (1010.74): calcd. C 35.65, H 3.89, N 4.16; found C 36.0, H 3.76, N 4.24.

[(Cyclohexyl$_3$TAC)TiCl$_3$]$^+$[Ti$_2$Cl$_9$]$^-$ (3d): A solution of Cy$_3$TAC (1 g, 3.00 mmol) in dichloromethane (25 mL) was added slowly to a solution of $TiCl_4$ (1.71 g, 9.01 mmol) in dichloromethane (25 mL) at room temperature under a stream of dinitrogen to give a clear brown solution. A bright yellow solid began to precipitate from the dark solution. After 48 h in the refrigerator the precipitate was isolated, washed with dichloromethane (20 mL) and dried under reduced pressure to give bright yellow crystals. Yield: 2.03 g (75%). ^{1}H NMR (300 MHz, $CDCl_3$/$SOCl_2$): δ = 4.97 and 4.77 (d, J = 8.8, 3 H, N–CH_2–N), 3.22 [3 H, CH–N], 2.20 [6 H, eq. –CH_2–CHN)], 2.00 [6 H, eq. –CH_2–CH$_2$CHN], 1.72 (3 H, eq. –CH_2–CH$_2$CH$_2$CHN), 1.38 [12 H, ax. –CH_2–CH_2–CHN] 1.2 (3 H, ax. –CH_2–CH$_2$CH$_2$CHN) ppm. ^{1}H NMR (400 MHz, saturated in CH_2Cl_2, 2.3 mM): δ = 4.927 and 4.85 (d, J = 8.5, 3 H, N–CH_2–N), 3.2 [3 H, CH–N], 2.18 [6 H, eq. –CH_2–CHN)], 1.94 [6 H, eq. –CH_2–CH$_2$CHN], 1.70 (3 H, eq. –CH_2–CH$_2$CH$_2$CHN), 1.34 [12 H, ax. –CH_2–CH_2–CHN] 1.12 (3 H, ax. –CH_2–CH$_2$CH$_2$CHN) ppm. ^{1}H NMR (400 MHz, saturated in CH_2Cl_2/$SOCl_2$ (3:1), 2.8 mM): δ = 4.93 and 4.88 (3 H, N–CH_2–N), 3.2 [3 H, CH–N], 2.2 [6 H, eq. –CH_2–CHN)], 1.94 [6 H, eq. –CH_2–CH$_2$CHN], 1.70 (3 H, eq. –CH_2–CH$_2$CH$_2$CHN), 1.34 [12 H, ax. –CH_2–CH_2–CHN] 1.12 (3 H, ax. –CH_2–CH$_2$CH$_2$CHN) ppm. ^{13}C{^{1}H} NMR (75 MHz, $CDCl_3$/$SOCl_2$): δ = 74.6 (N–CH$_2$–N), 66.6 (CH–N), 27.5 (CH$_2$–CHN), 25.2 (CH$_2$–CH$_2$CHN), 24.7 (CH$_2$–CH$_2$CH$_2$CHN) ppm. $C_{21}H_{39}N_3Ti_3Cl_{12}$ (902.64): calcd. C 27.94, H 4.36, N 4.66; found C 27.9, H 4.35, N 4.65.

[(Cyclohexyl$_3$TAC)TiCl$_3$]$^+$[[Ti$_2$Cl$_8$(OTf)]$^-$ (4d): Trimethylsilyl trifluoromethanesulfonate (0.67 mL, 3.7 mmol) was added to 5 mL of a 0.6 M solution of $TiCl_4$ in toluene (3 mmol) at 0 °C. The resulting deep red-brown solution was stirred for 30 min and then Cy$_3$TAC (1.0 g, 3.0 mmol) was added at 0 °C. After warming to ambient temperature and stirring for 1 h, hexane (30 mL) was added to give an orange precipitate. The solution was decanted and the residue dried under vacuum, washed with 50 mL of hexane and dried again under vacuum to give an orange-brown solid (2.6 g, 85%). Elemental analysis (CHN) of this product fits that of a mixture of complexes containing the cation with a 2:1 mixture of [Ti$_2$Cl$_8$(OTf)]$^-$ and [Ti$_2$Cl$_{10}$]$^{2-}$ anions. Crystals of **4d** were grown from a solution in $SOCl_2$/chloroform. ^{1}H NMR (300 MHz, $CDCl_3$/$SOCl_2$): δ = 4.92 and 4.87 (d, J = 9.4, 3 H, N–CH_2–N), 3.20 [3 H, CH–N], 2.19 [6 H, eq. –CH_2–CHN)], 1.98 [6 H, eq. –CH_2–CH$_2$CHN], 1.71 (3 H, eq. –CH_2–CH$_2$CH$_2$CHN), 1.4 [12 H, ax. –CH_2–CH_2–CHN] 1.2 (3 H, ax. –CH_2–CH$_2$CH$_2$CHN) ppm. ^{13}C{^{1}H} NMR (75 MHz, $CDCl_3$/$SOCl_2$): δ = 77.9 (N–CH$_2$–N), 67.0 (CH–N), 27.3 (CH$_2$–CHN), 25.0 (CH$_2$–CH$_2$CHN), 24.6 (CH$_2$–CH$_2$CH$_2$CHN) ppm. $C_{22}H_{39}N_3Ti_3Cl_{11}SO_3F_3$ (1016.26): calcd. C 26.00, H 3.87, N 4.14. Calcd for the mixture $C_{22}H_{39}N_3Ti_{2.5}Cl_{9.5}S_{0.5}O_{1.5}F_{1.5}$: C 30.35, H 4.52, N 4.83; found C 30.1, H 4.65, N 4.48.

[(Fluorobenzyl$_3$TAC)TiCl$_3$]$^+$[Ti$_2$Cl$_9$]$^-$ (3e): A solution of (*p*-F–PhCH$_2$)$_3$TAC (0.163 g, 0.40 mmol) in dichloromethane (10 mL) was added to a stirred solution of $TiCl_4$ (0.16 mL, 0.28 g,

Dinuclear Oxomolybdate(V) Species with Oxalato and Pyridine Ligands Revisited: *cis*/*trans* Isomerization of $[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(R\text{-}Py)_2]^{2-}$ (R-Py = Pyridine, Alkyl-Substituted Pyridine) in Water Evidenced by NMR Spectroscopy

Barbara Modec,*[a] Darko Dolenc,[a] Jurij V. Brenčič,[a] Jože Koller,[a] and Jon Zubieta[b]

Keywords: Isomerization / Molybdenum / N ligands / NMR spectroscopy / Polyoxometalates

The simple oxohalomolybdate(V) ions $[MoOCl_4(H_2O)]^-$ and $[MoOBr_4]^-$ were reacted with oxalic acid in mixtures containing an alcohol and a pyridine (R-Py) to form the dinuclear anions $[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(R\text{-}Py)_2]^{2-}$ based on the $\{Mo_2O_4\}^{2+}$ structural core. The dinuclear anion exists in two isomeric forms – as a *trans* and as a *cis* isomer. A *trans* arrangement of the pyridine ligands relative to the $Mo_2(\mu_2\text{-}O)_2$ bridge was observed for $(PyH)_2[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]$ (**1**), $(PyH)_2[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(3,5\text{-}Lut)_2]$ (**2**), $[MeNC_5H_3(Me)_2]_2[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(3,5\text{-}Lut)_2]\cdot H_2O$ (**3**), $(4\text{-}MePyH)_2[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(4\text{-}MePy)_2]\cdot 1/2(4\text{-}MePy)$ (**5**), and $[(C_6H_5)_4P]_2[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]\cdot H_2O$ (**7**) [Py = pyridine; 3,5-Lut = 3,5-lutidine; $MeNC_5H_3(Me)_2^+$ = *N*-methyl-3,5-lutidinium cation and 4-MePy = 4-methylpyridine], while a *cis* arrangement was found in only two compounds, namely $(4\text{-}EtPyH)_2[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(4\text{-}EtPy)_2]$ (**4**) (4-EtPy = 4-ethylpyridine) and $(4\text{-}MePyH)_3[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(4\text{-}MePy)_2]Br$ (**6**). The solution chemistry of the *trans*-$[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]^{2-}$ anion was monitored by ^1H and ^{13}C variable temperature NMR spectroscopy and showed evidence of two processes: the substitution of a pyridine ligand for water, coupled with *cis*/*trans* isomerization. Both reactions were exploited in the preparation of *trans*-$(PyH)_2[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(H_2O)_2]$ (**8**) from a water/methanol solution of *cis*-$(4\text{-}EtPyH)_2[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(4\text{-}EtPy)_2]$ (**4**). *trans*-$(PyH)_2[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(H_2O)_2]$ (**8**) was seen to react with methanol with the rupture of the molybdenum-to-oxalate bonds resulting in the cyclic octanuclear anion which crystallizes as a pyridinium salt, $(PyH)_2[Mo_8O_{16}(OCH_3)_8(\mu_8\text{-}C_2O_4)]\cdot 2CH_3OH$ (**9**). The compounds were fully characterized by X-ray structural analysis and IR spectroscopy. MO calculations were performed on the isomeric pair of $[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(4\text{-}MePy)_2]^{2-}$ in order to establish their relative energies.

Introduction

The MoO^{3+} structural unit pervades in the chemistry of molybdenum in the +5 oxidation state.[1] The metal displays a marked tendency to dimerize through one or two oxygen bridges with the formation of the $\{Mo_2O_3\}^{4+}$ and $\{Mo_2O_4\}^{2+}$ dinuclear fragments. In the case of the $\{Mo_2O_4\}^{2+}$ structural core a direct interaction between two molybdenum atoms, conveniently described as a single metal–metal bond, is formed. The X-ray structural analyses of numerous $\{Mo_2O_4\}^{2+}$ compounds have shown that the basic structural properties of the $\{Mo_2O_4\}^{2+}$ core are independent of the ligands which complete the five- or sixfold coordination environments of the metal.[1,2] In the absence of ligands, the metal centers attain coordinative saturation through further assembly of $\{Mo_2O_4\}^{2+}$ units which share their originally μ_2-bridging oxo groups to form discrete oligonuclear clusters.[3] For instance, the association of four $\{Mo_2O_4\}^{2+}$ units through the agency of methoxide ions has been shown to produce two different types of octanuclear metal oxide cores: (i) a ring-like $\{Mo_8O_8(\mu_2\text{-}O)_8(\mu_2\text{-}OCH_3)_8\}$,[4,5] and (ii) a more compact $\{Mo_8O_8(\mu_3\text{-}O)_4(\mu_2\text{-}O)_4(\mu_3\text{-}OCH_3)_2(\mu_2\text{-}OCH_3)_4\}^{2+}$ core.[6] In the presence of suitable ligands, their ligation to the $\{Mo_2O_4\}^{2+}$ core normally precedes the self-assembly of dinuclear subunits. Multidentate oxygen donor ligands, in particular oxalate, with its well-known ability to adopt different coordination modes, can theoretically connect the dinuclear $\{Mo_2O_4\}^{2+}$ units into polymeric materials. True polymeric $\{Mo_2O_4\}^{2+}$ species where multidentate oxygen donor ligands link the dinuclear building blocks into infinite structures are extremely rare. The only examples are $[Mo_2O_4(C_2O_4)Cl_2]_n^{2n-}$ and $[Mo_2O_4(C_2O_4)_2(H_2PO_4)]_n^{3n-}$, with infinite chain structures, and $[Mo_2O_4(PO_4)(HPO_4)]_n^{3n-}$, with an infinite layer structure.[7–9] The bridging ligand in $[Mo_2O_4(C_2O_4)Cl_2]_n^{2n-}$ is oxalate, while in the other two polymers the phosphate

serves to link the dinuclear subunits. The literature also reports on another type of polymeric compound where the repeating structural unit is a tetranuclear, cube-like metal oxide core with the formula $\{Mo_4O_4(\mu_3\text{-}O)_4\}^{4+}$ and the bridging ligands are the phosphates.[10] The cube-like core may be considered as the assembly of two $\{Mo_2O_4\}^{2+}$ units. Apparently, under the reaction conditions employed, the assembly of $\{Mo_2O_4\}^{2+}$ units took place first and was followed by phosphate coordination to the periphery of the $\{Mo_4O_4(\mu_3\text{-}O)_4\}^{4+}$ core.

We have demonstrated in our previous work that a series of complexes with the oxalate bonded in different ways can be obtained by tuning the oxalate-to-molybdenum ratio: $[Mo_8O_{16}(OCH_3)_8(\mu_8\text{-}C_2O_4)]^{2-}$ and $[Mo_2O_4(\mu_2\text{-}C_2O_4)Cl_2]_n^{2n-}$ when the oxalate amounts were small, and *trans*-$[Mo_2O_4(\eta^2\text{-}C_2O_4)Py_2]^{2-}$ and $[\{Mo_2O_4(\eta^2\text{-}C_2O_4)_2\}_2(\mu_4\text{-}C_2O_4)]^{6-}$ when the amounts of the ligand were large.[7,11] Furthermore, with an even larger amount of the oxalate, $\{Mo_2O_4\}^{2+}$ no longer formed, but rather the $\{Mo_2O_3\}^{4+}$ core with four coordination sites per metal center. The species obtained, $[Mo_2O_3(\eta^2\text{-}C_2O_4)_4]^{4-}$, thus contains two oxalato ligands per molybdenum. Although the X-ray structure analyses provided unambiguous characterization of the above-listed complexes, their solubility in water and their diamagnetic nature enabled NMR solution studies. The spectrum of the pyridine-coordinated complex *trans*-$[Mo_2O_4(\eta^2\text{-}C_2O_4)Py_2]^{2-}$ displays broadening of the pyridine resonances, which suggested substitution reactions in water solutions. Further studies were therefore initiated with the aim to provide an adequate explanation of these observations.

Results and Discussion

Structural Studies

Structures of Compounds with trans- and cis-$[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(R\text{-}Py)_2]^{2-}$ Anions

The *trans* and *cis* geometric isomers of the $[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(R\text{-}Py)_2]^{2-}$ ion are depicted in Figures 1 and 2, respectively. A central $\{Mo_2O_4\}^{2+}$ core, with a pyridine ligand and a bidentate oxalate completing the six-coordinate environment of each metal, may be recognized in both isomers. The position of the pair of pyridine ligands or oxalates can be either on the opposite sides of the plane defined by the Mo=O groups (*trans* isomer) or on the same side (*cis* isomer). The *trans* arrangement was observed for R-Py = pyridine (**1** and **7**), 3,5-lutidine (**2** and **3**), and 4-methylpyridine (**5**), while *cis* isomers were found for 4-ethylpyridine (**4**) and 4-methylpyridine (**6**). Both isomers were isolated only in the case of 4-methylpyridine. The two isomeric forms of the dinuclear anion differ in symmetry: neglecting the alkyl substituents on the pyridine rings, the *trans* isomer belongs to the C_2 point group, and the *cis* isomer to the C_s point group. However, the above-stated symmetry of the anions is rarely realized in solid-state structures. The exceptions are the *trans* anions in **1** and **2**, where the center of the $Mo(\mu_2\text{-}O)_2Mo$ group sits on a crystallographic twofold rotation axis and only half of the anion defines the asymmetric unit. The geometric parameters of the $\{Mo_2O_4\}^{2+}$ core in compounds **1**–**7** do not differ significantly and have similar values to those determined previously for many other $\{Mo_2O_4\}^{2+}$ compounds:[1,2] (i) a short Mo–Mo distance in the range 2.5430(3)–2.5559(5) Å for *trans* isomers and 2.5519(2)–2.5520(3) Å for *cis* isomers, signifying a single metal–metal bond, and (ii) a nonplanar $Mo(\mu_2\text{-}O)_2Mo$ moiety with fold angles in the ranges 149.5(2)–154.07(9)° and 152.17(5)–153.88(6)° for *trans* and *cis* isomers, respectively. The *trans* influence of the terminal oxo group is reflected in the nonequivalence of the two molybdenum-to-oxalate oxygen bond lengths. Relevant geometric parameters for the anions in **1**–**7** are summarized in Tables 1 and 2.

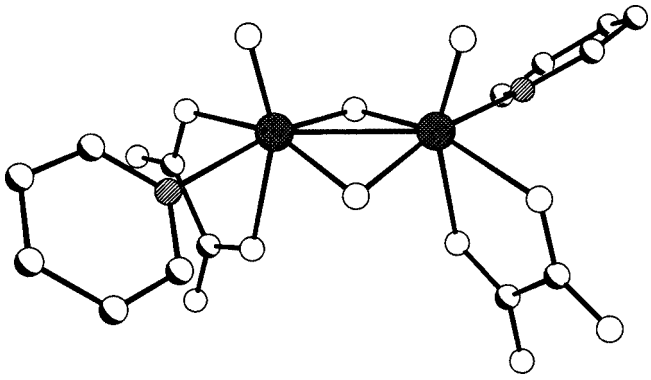

Figure 1. Ball-and-stick representation of the *trans*-$[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(Py)_2]^{2-}$ anion in **1**. Mo sites are cross-hatched, nitrogen atoms are lined bottom left to top right, and oxygen atoms are small, unshaded and carbon atoms small, shaded spheres. The same drawing scheme is used throughout.

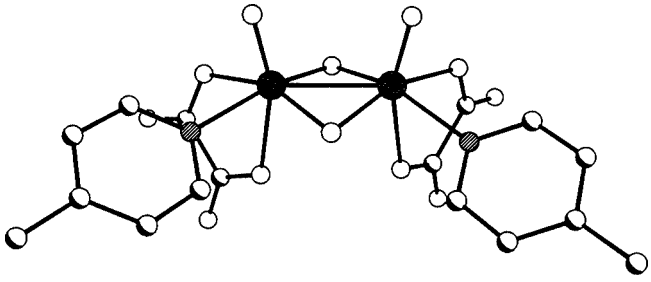

Figure 2. Ball-and-stick representation of the *cis*-$[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(4\text{-}MePy)_2]^{2-}$ anion in **6**.

Interesting patterns of hydrogen bonds are observed for compounds **1**–**7**. The oxalato ligands, which can act as acceptors of hydrogen bonds, are matched with protonated pyridine molecules, and these are seen to form either a hydrogen bonding interaction with one noncoordinated oxygen atom from the oxalate or a bifurcated interaction with both noncoordinated oxygen atoms of the oxalate (Figure 3). The former type is present in **1**, with relatively short N···O distances of 2.642(2) Å, while the latter occurs in **2** and **5**. In the case of bifurcated hydrogen bonds, one is shorter than the other, as illustrated by **2**, where the N···O distances are 2.700(2) and 2.984(2) Å. Another type of hy-

drogen-bonding interaction is observed for the *cis* isomers: the position of the protonated aromatic ring is such as to form two interactions to two closest coordinated oxygen atoms of two different oxalates (Figure 3). As exemplified by **4**, one of the two N···O distances is shorter than the other [2.728(2) vs. 2.977(2) Å]. In **3** and **7**, with no cations able to participate in hydrogen-bonding interactions, hydrogen bonds occur between the oxalato ligands and the water molecules of crystallization instead. For instance, in **3** each water molecule forms two hydrogen bonds to two noncoordinated oxalate oxygens from two different anions, with O···O distances of 2.904(3) and 2.986(3) Å. Infinite chains of alternating dinuclear anions and water molecules are thus formed (Figure 3). In **3** the chains propagate along the *b* axis.

Structure of trans-(PyH)$_2$[Mo$_2$O$_4$(η^2-C$_2$O$_4$)$_2$(H$_2$O)$_2$] (8)

The structure of **8** consists of dinuclear *trans*-$[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(H_2O)_2]^{2-}$ anions (shown in Figure 4) and protonated pyridine molecules as countercations. The asymmetric unit

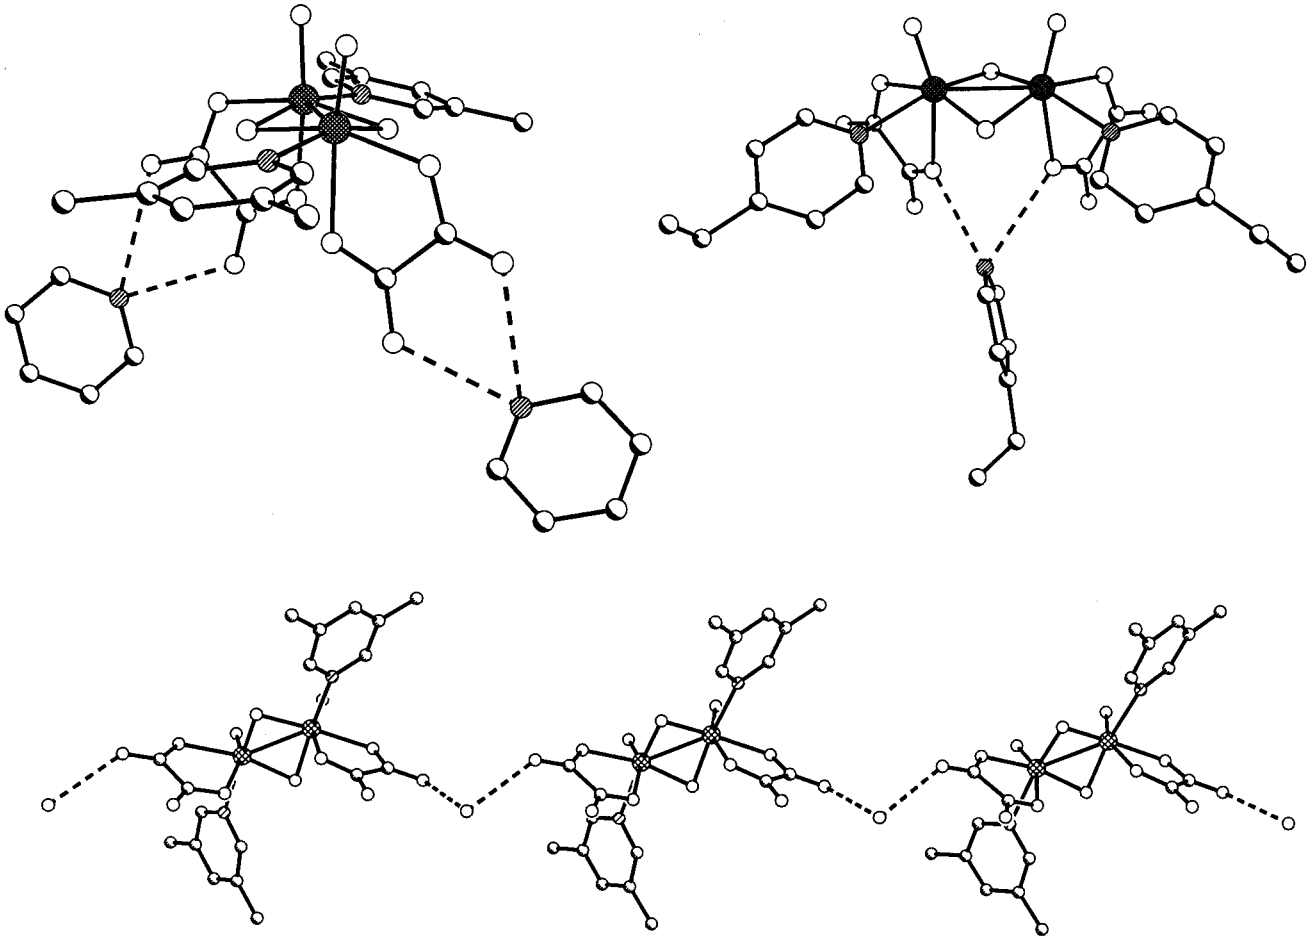

Figure 3. Types of hydrogen bonds in $[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(R\text{-}Py)_2]^{2-}$ compounds.

contains two dinuclear anions and four pyridinium cations. The bonding pattern within the two crystallographically independent *trans*-$[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(H_2O)_2]^{2-}$ anions is basically the same (see Table 3). Owing to the *trans* influence of the terminal oxo group, one of the two molybdenum-to-oxalate oxygen bond lengths is short and the other is long. The molybdenum-to-water bond lengths are comparable to those observed for $[Mo_4O_8(OH)_2(H_2O)_2(C_4O_4)_2]^{2-}$ [2.148(6) Å],[12] $Ba[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(H_2O)_2]\cdot 3H_2O$ [2.198(4) Å], and $Cs_2[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(H_2O)_2]\cdot H_2O$ [2.12(1) and 2.15(1) Å].[13,14]

[a] Two sets of parameters are listed, one for each anion in the asymmetric unit.

A complicated pattern of hydrogen bonds is formed in **8**. Each water ligand forms two hydrogen bonds, one to the doubly-bridging oxo group of the adjacent anion, with O···O distances in the range 2.675(3)–2.720(3) Å, and one to the noncoordinated oxygen of the oxalate, also from the adjacent anion, with O···O distances in the range 2.643(3)–2.662(3) Å. Each anion forms a total of eight hydrogen bonds to four neighboring anions, two to each neighbor. Infinite layers that are coplanar with the (110) unit-cell plane are thus formed. Pyridinium cations are attached to the oxalate oxygen atoms on both sides of these layers through the agency of hydrogen bonds with lengths in the range 2.744(4)–3.125(5) Å.

The structure of the $[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(H_2O)_2]^{2-}$ anion has been determined previously. It is of interest to note that the X-ray structure determination of *trans*-$Ba[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(H_2O)_2]\cdot 3H_2O$ was also the first on a compound containing the $\{Mo_2O_4\}^{2+}$ unit and, as such, unambiguously confirmed the existence of the previously assumed $\{Mo_2O_4\}^{2+}$ structural core.[13] In contrast to the uniform tendency of Mo=O bonds to weaken bonds *trans* to themselves, no significant *trans* influence was observed. This phenomenon was ascribed to a low *trans* susceptibility of the oxalato ligand.[15] However, later structural determinations on the *trans*-$[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(H_2O)_2]^{2-}$ anion clearly indicated the existence of a *trans* influence.[14] The pyridinium salt of this anion has also been reported, but with a different composition, $H(PyH)_3[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(H_2O)_2]_2\cdot 2H_2O$.[16] In the case of the thio-bridged derivative of the dinuclear aqua-ligated anion, i.e., $[Mo_2O_2(\mu_2\text{-}S)_2(\eta^2\text{-}C_2O_4)_2(H_2O)_2]^{2-}$, the *cis* geometric isomer has been isolated as well. A *cis* arrangement of the ligands was observed in two caesium salts, *cis*-$KCs_3[Mo_2O_2S_2(\eta^2\text{-}C_2O_4)_2(H_2O)_2]_2\cdot 4H_2O$,[14] and *cis*-$NaCs_3[Mo_2O_2S_2(\eta^2\text{-}C_2O_4)_2(H_2O)_2]_2\cdot 6H_2O$.[17] These were the only known *cis* isomers prior to this study.

Structure of $(PyH)_2[Mo_8O_{16}(OCH_3)_8(\mu_8\text{-}C_2O_4)]\cdot 2CH_3OH$ (9)

Compound **9** crystallizes in a triclinic unit cell with one octanuclear anion $[Mo_8O_{16}(OCH_3)_8(\mu_8\text{-}C_2O_4)]^{2-}$, two protonated pyridine molecules as countercations, and two methanol molecules. The asymmetric unit consists of one half of the anion, with the other half generated by the inversion center located at the center of the ring. Each cyclic anion consists of four $\{Mo_2O_4\}^{2+}$ units arranged around the μ_8-oxalate and linked together by pairs of μ_2-bridging methoxides (Figure 5). The bonding pattern in the anion is very similar to that determined previously for $(Bu_4N)_2[Mo_8O_{16}(OCH_3)_8(\mu_8\text{-}C_2O_4)]$[18] and $(MeNC_5H_5)_2[Mo_8O_{16}(OCH_3)_8(\mu_8\text{-}C_2O_4)]$:[11] the Mo–Mo bonds are 2.5767(4)–2.5876(4) Å, the nonbonding Mo···Mo contacts

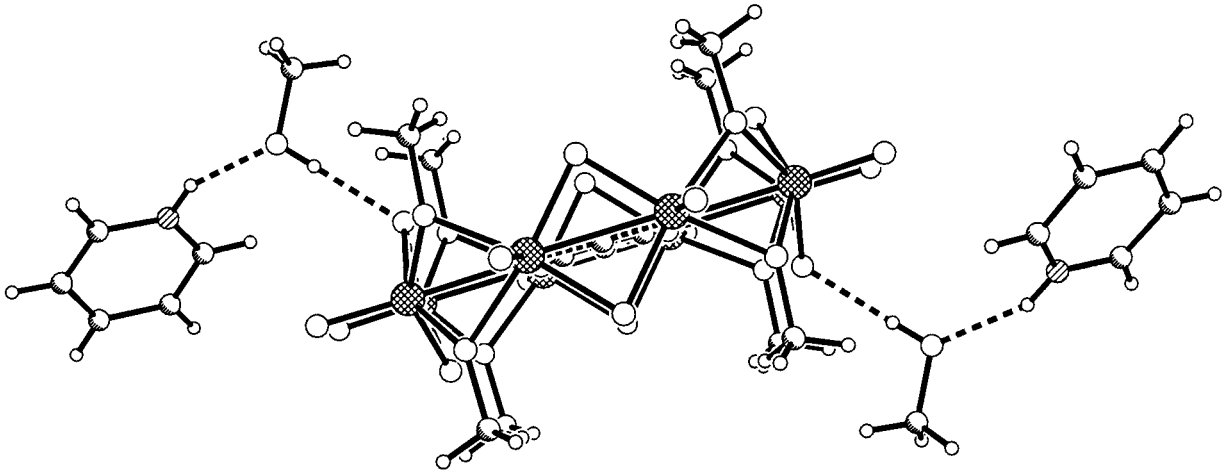

Figure 6. Octanuclear anion in **9** with a pair of hydrogen bonded methanol molecules and pyridinium cations.

spanning the methoxide bridges are 3.2489(4)–3.2548(4) Å, and the molybdenum-to-oxalate bond lengths are 2.357(3)–2.386(3) Å. Each octanuclear anion has a pair of methanol molecules linked by hydrogen bonds to the doubly-bridging oxo groups with lengths of 2.745(4) Å. Methanol participates in another hydrogen-bonding interaction with the protonated pyridine nitrogen, where it acts as the acceptor of the hydrogen bond (Figure 6). The corresponding O···N distance is 2.686(4) Å. Recently, a related octanuclear ring, $[Mo_8S_4O_{12}(OH)_8(C_2O_4)]^{2-}$, was reported. It is built of four $\{Mo_2O_2(\mu_2\text{-}O)(\mu_2\text{-}S)\}^{2+}$ subunits.[19] It supplements a series of octanuclear, cyclic anions built either of $\{Mo_2O_4\}^{2+}$ units or thio-bridged analogs, i.e., $\{Mo_2O_2(\mu_2\text{-}O)(\mu_2\text{-}S)\}^{2+}$ and $\{Mo_2O_2(\mu_2\text{-}S)_2\}^{2+}$.[17] This series confirms the ability of the structurally related, yet chemically markedly different, dinuclear cores to assemble in a similar manner with the formation of clusters with the same architectures. A structural similarity was observed with several other molybdenum(v) oxalato complexes, namely *trans*-$[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(H_2O)_2]^{2-}$ and its thio analog *trans*-$[Mo_2O_2S_2(\eta^2\text{-}C_2O_4)_2(H_2O)_2]^{2-}$,[15,20] and a series of tetranuclear anions, i.e., $[\{Mo_2O_4(\eta^2\text{-}C_2O_4)_2\}_2(\mu_4\text{-}C_2O_4)]^{6-}$,[11] $[\{Mo_2O_3S(\eta^2\text{-}C_2O_4)_2\}_2(\mu_4\text{-}C_2O_4)]^{6-}$,[20,21] and $[\{Mo_2O_2S_2(\eta^2\text{-}C_2O_4)_2\}_2(\mu_4\text{-}C_2O_4)]^{6-}$.[17] It is of interest to note that the recently reported hexanuclear species $[\{Mo_2O_2S_2\}_3(OH)_4(\eta^2\text{-}C_2O_4)_2(\mu_6\text{-}C_2O_4)]^{4-}$ has only been observed for the $\{Mo_2O_2(\mu_2\text{-}S)_2\}^{2+}$ series of compounds.[22]

Synthetic Considerations

The basic reaction system inspected was that with a pyridine, oxalic acid, acetonitrile, an alcohol, and $(PyH)_5[MoOCl_4(H_2O)]_3Cl_2$ or $(PyH)[MoOBr_4]$. Both molybdenum starting materials possess labile sites (aqua and halo ligands), which in the mixtures of pyridine and methanol undergo a facile substitution chemistry with the formation of the $\{Mo_2O_4\}^{2+}$ structural unit or discrete clusters, as demonstrated before.[3] With a sufficient amount of oxalate, i.e. a ligand to metal ratio greater than 1, the formation of *trans*-$[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]^{2-}$ takes place. The dinuclear anion was isolated in two salts, one with protonated pyridine molecules as countercations and the other as an *N*-methylpyridinium salt.[11] The two salts have different solubilities. While the pyridinium salt of *trans*-$[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]^{2-}$ is only soluble in water, the *N*-methylpyridinium salt is also soluble in methanol. Contrary to our expectations, the *N*-alkylation of pyridine which occurs in the latter case did not turn out to be a general reaction:[23] it was observed only in the case of methanol. When other alcohols were used, such as ethanol, 2-propanol and *tert*-butanol, the only solid isolated was *trans*-$(PyH)_2[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]$ (**1**). It is pertinent to note that the reaction mixture in the absence of alcohol also produced **1**. Although not required for the formation of dinuclear anions, the use of alcohols was justified by the fact that most oxalate salts, either with protonated or *N*-methylated pyridines, exhibit good alcohol solubility and the only product which crystallizes from the reaction mixture is that with the $[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(R\text{-}Py)_2]^{2-}$ anion.

By using 4-methylpyridine in place of pyridine we hoped to prepare analogous compounds of *trans*-$[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(4\text{-}MePy)_2]^{2-}$, which, provided they were also methanol soluble, would be a better choice for NMR solution studies as the anion $[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(4\text{-}MePy)_2]^{2-}$ would not only display a simpler pattern of aromatic resonances than pyridine, but also a methyl singlet in a different spectral region which could serve as a probe for monitoring the substitution reactions. However, the reaction mixture described for the preparation of **6** afforded two crystalline phases whose identities were revealed by X-ray structure analyses as *trans*-$(4\text{-}MePyH)_2[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(4\text{-}MePy)_2]\cdot 1/2(4\text{-}MePy)$ (**5**) and *cis*-$(4\text{-}MePyH)_3[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(4\text{-}MePy)_2]Br$ (**6**). The described reaction shows that the formation of both isomeric forms of the $[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(4\text{-}MePy)_2]^{2-}$ anion takes place simultaneously from the same reaction mixture, under the same conditions. MO calculations performed on the isomeric pair of $[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(4\text{-}MePy)_2]^{2-}$ anions revealed insignificant differences in their energy. According to the most reliable approach of the three used, the B3LYP density functional with a 6-31G*

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

basis set and pseudopotential, the *trans* isomer of $[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(4\text{-}MePy)_2]^{2-}$ has a lower energy than the corresponding *cis* isomer by only 7.24 kJ mol^{-1}. With so small an energy difference, the formation of either is equally probable unless the pair differs in solubility. The stereochemistry of the product thus depends to a larger extent upon its solubility rather than on the reaction conditions employed.

NMR Solution Studies

The ^{1}H NMR spectrum of an aqueous solution of *trans*-$(PyH)_2[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]$ (**1**) recorded at room temperature reveals six broad resonances in the aromatic spectral region, indicating that the pyridine ligands are involved in an exchange process. The temperature-dependent nature of these reactions was confirmed by recording the spectra at higher temperatures, at 10 K intervals up to 343 K, where the six resonances coalesce into three [δ = 8.25 (2 H, 3-H), 8.74 (1 H, 4-H), and 9.20 ppm (2 H, 2-H)] and the signals corresponding to pyridine, in coordinated and free form, and pyridinium cation became indistinguishable. The NMR spectra of aqueous solutions of *trans*-$(4\text{-}MePyH)_2[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(4\text{-}MePy)_2]\cdot 1/2(4\text{-}MePy)$ (**5**) and *cis*-$(4\text{-}MePyH)_3[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(4\text{-}MePy)_2]Br$ (**6**) gave evidence for another process. Apart from different values of integrals due to differences in the composition of **5** and **6**, their spectra are the same: a set of broad resonances in the aromatic spectral region and two, also broadened, methyl resonances. The isomerization of the *cis* into the *trans* isomer and vice versa was assumed to take place. The use of methanol-soluble *trans*-$(MeNC_5H_5)_2[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]$ enabled NMR experiments at temperatures below 273 K and a quantitative evaluation of this process. Since the *N*-methylpyridinium cation does not participate in the exchange process in the way the pyridinium cation does, its resonances (three in the aromatic part of the spectrum and the methyl singlet) are consequently sharp and their integrals remain constant. Upon lowering the temperature, the previously broad pyridine resonances become sharper and at 243 K are resolved into seven signals, shown by COSY to belong to three sets, denoted as A, B and C (Figure 7). The signals C2, C3, and C4 were unambiguously identified by the addition of a small amount of pyridine as belonging to free pyridine.[24] Its presence can be accounted for only if the complex is partially dissociated, but in that case, an additional set of signals belonging to the mono-substituted $[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py(H_2O)]^{2-}$ is expected. Two isomeric forms are also possible for the mono-substituted complex. Since the environments of pyridine ligands in both are very similar, we assume that the pair is indistinguishable in the ^{1}H NMR spectrum. Accordingly, the mono-substituted complex is considered throughout the text as one species only. The bis(aqua)-ligated $[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(H_2O)_2]^{2-}$ is also present; however this species is invisible in the ^{1}H NMR spectrum. The remaining four signals belong to sets A and B. Only the resonances of 2,6-H protons were clearly separated (A2 doublet centered at δ = 9.30 ppm and B2 doublet centered at δ = 9.16 ppm), while the resonances of the 4-H and 3,5-H protons were superimposed on each other (A4, B4 and A3, B3 signals). It is reasonable to expect that the immediate coordination environment is mostly experienced by the 2,6-H pair and to a significantly smaller extent by the 4-H proton or the 3,5-H pair. Set A was therefore assigned to belong to coordinated pyridine ligands in *cis*-$[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]^{2-}$ and set B to *trans*-$[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]^{2-}$ and the mono-substituted $[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py(H_2O)]^{2-}$ together. This assignment was based on the values of integrals of signals A2, B2, and C2[25] and the fact that the environment of the pyridine ligands in the *trans* isomer differs significantly from that in the *cis* isomer and that the environment of pyridine in the mono-substituted complex resembles that in the *trans* isomer very closely. On the basis of the chemical shifts of sets A and B, one can assume that the protons will resonate at lower field when the two pyridine rings are placed close to each other, as in the case of the *cis* isomer. In order to provide experimental support for the above-described assignment, two additional experiments were performed at 243 K. The solution of *trans*-$(MeNC_5H_5)_2[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]$ was divided into two aliquots, of which one was repeatedly diluted and the other was titrated with pyridine. An increase in the concentration of free pyridine upon dilution was paralleled with the gradual decrease of the amount of coordinated pyridine, as monitored by the sum of integrals of signals A2 and B2 relative to the integral of the cation (Figure S1). The relative heights of A2 and B2 changed as well: a gradual decrease in the integral of A2 was observed, while B2 remained virtually constant within this concentration range. The signal B2 became slightly deformed, indicating two overlapping resonances. The pyridine titration had the opposite effect: the signal A2 started to gain in intensity, while B2 remained constant (Figure S2). The total amount of coordinated pyridine increased upon pyridine titration. The sum of integrals of signals A2 and B2 gravitated towards the integral of the cation. It was also observed that even with large additions of pyridine, {0.254 mmol of pyridine per 0.0405 mmol of $[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]^{2-}$; Figure S2, spectrum f} the dissociation of pyridine was not entirely suppressed. Assuming that the extent of dissociation of the second pyridine ligand is very small and the amount of bis(aqua) complex negligible, approximate amounts of the mono-substituted complex and both major species, *cis*-$[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]^{2-}$ and *trans*-$[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]^{2-}$, could be calculated. Under these conditions, an excess of pyridine and a temperature of 243 K, around 8% of dinuclear complex exists in the mono-substituted form, while the *cis* isomer of $[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]^{2-}$ exceeds its *trans* isomer in concentration by a factor of 1.8.

With the expectation that the oxalate carbon resonances would provide extra information about the major species in the solution, the ^{13}C NMR spectra were recorded. Of the three coordination sites of each metal in the $\{Mo_2O_4\}^{2+}$ moiety, the two sites that are in the *cis* position to the Mo=O group may be denoted as the equatorial ones, and

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

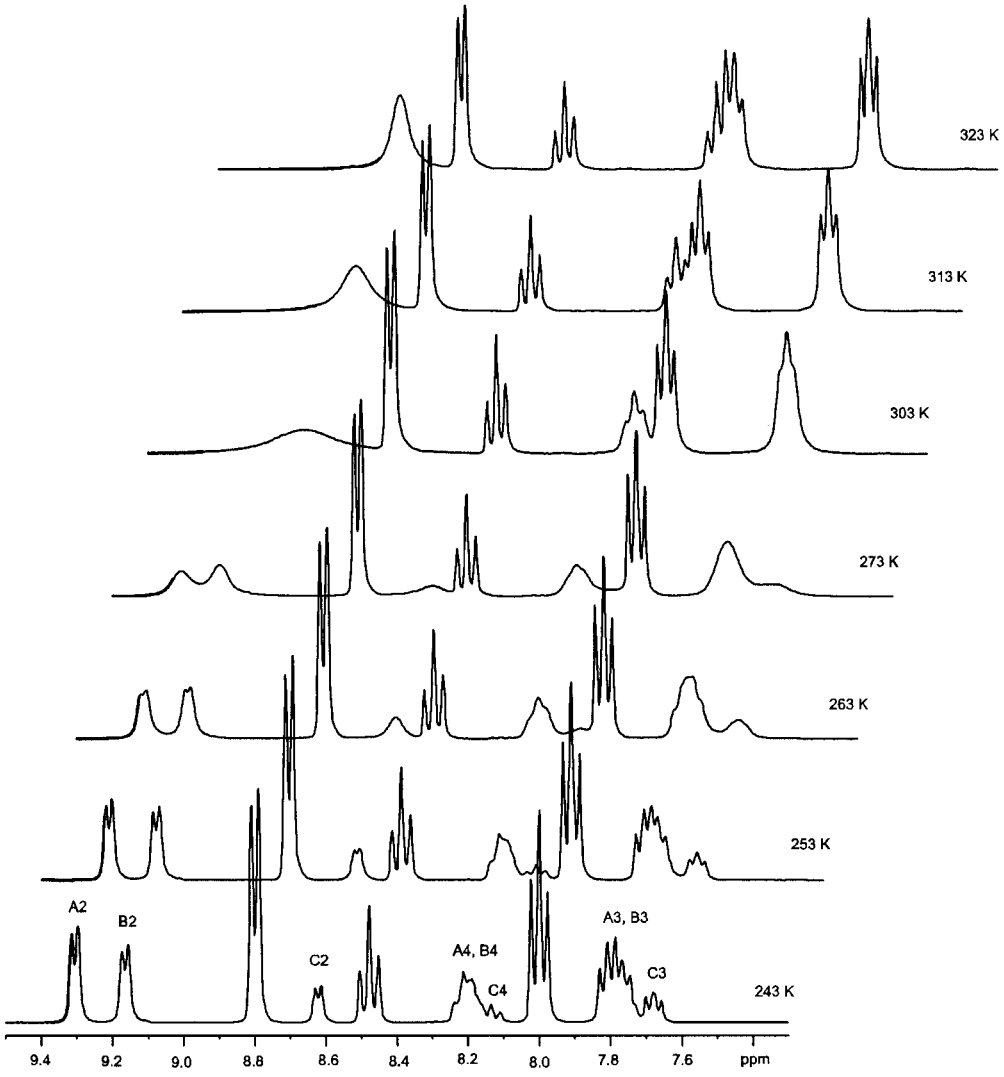

Figure 7. Variable temperature ^{1}H NMR spectra of *trans*-$(MeNC_5H_5)_2[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]$. Labels A, B, and C refer to different pyridine species, and 2, 3, and 4 to pyridine protons 2,6, 3,5, and 4, respectively.

the remaining site, i.e. the one *trans* to the terminal oxo group, as the apical one. With the oxalate bonded in the bidentate manner as in the title compounds **1**–**8**, where one coordinated oxygen occupies the equatorial position and the other the apical position, the two oxalate carbon atoms are not chemically equivalent. Furthermore, the coordination environment of the oxalato ligand in *cis*-$[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]^{2-}$ differs from that in *trans*-$[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]^{2-}$. The room temperature ^{13}C NMR spectrum of *trans*-$(MeNC_5H_5)_2[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]$ reveals two broad resonances at δ = 165.7 and 166.9 ppm, which resolved upon cooling to 243 K into three major ones at δ = 166.2, 166.5, and 167.7 ppm, and a minor one at δ = 167.5 ppm. However, no signal appeared at around δ = 173 ppm that would suggest the presence of free, noncoordinated oxalate.[26] In order to establish the dependence of the carbon oxalate frequencies upon the oxalate coordination mode, the ^{13}C NMR spectrum of $(MeNC_5H_5)_6[\{Mo_2O_4(\eta^2\text{-}C_2O_4)_2\}_2(\mu_4\text{-}C_2O_4)]$ was recorded. The oxalato ligands in the latter complex are bonded differently than in compounds **1**–**8** (Figure 8). Each of the four bidentate oxalates is bonded with both oxygen atoms in *cis* positions relative to the molybdenyl group, causing the chemical equivalence of the two carbon atoms. The carbon atoms of the tetraunidentate oxalate are equivalent as well. The ^{13}C NMR spectrum of $(MeNC_5H_5)_6[\{Mo_2O_4(\eta^2\text{-}C_2O_4)_2\}_2(\mu_4\text{-}C_2O_4)]$ reveals two resonances that could be associated with the oxalate moiety, an intense one at δ = 166.6 ppm and a weak one at δ = 173.0 ppm. The latter confirms the presence of free oxalate as a consequence of the rupture of the tetranuclear structure in solution. This result is not surprising in view of the results of the X-ray diffraction analysis, which showed that the bonds to μ_4-oxalate are weakened due to the labilizing *trans* influence of the four terminal oxo groups.[11] The cleavage of the tetranuclear anion produces two dinuclear $[Mo_2O_4(C_2O_4)_2]^{2-}$ fragments, each of which possesses two vacant coordination sites. Addition of one equivalent of pyridine per molybdenum results in a solution whose ^{1}H and ^{13}C NMR spectra are identical to the spectra of *trans*-$(MeNC_5H_5)_2[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]$, differing only in the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ratios between the *N*-methylpyridinium cation and pyridine. Since the bidentate oxalato ligands in *trans*-$[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]^{2-}$ and in $[\{Mo_2O_4(\eta^2\text{-}C_2O_4)_2\}_2(\mu_4\text{-}C_2O_4)]^{6-}$ do not occupy the same coordination sites of the $\{Mo_2O_4\}^{2+}$ unit, the equivalence of the NMR spectra indicates rearrangements on the sites occupied by the oxalates as well. The conversion of one isomer into another presumably proceeds via a five-coordinate intermediate state (Scheme 1). The intermediate species in which the bidentate oxalate is coordinated to the two equatorial sites and the free apical position remains to be occupied with a unidentate ligand, i.e. pyridine or water, is also probable. Its relative instability may be explained in terms of the *trans* influence of the terminal oxo group: it is more favorable if the apical position, which is subject to the *trans* influence, is occupied by one terminus of the bidentate ligand rather than by a unidentate ligand. Binding of pyridine to the apical position is therefore weaker and the ligand exchange at this position too fast, even at low temperatures, to be observed in the NMR spectrum. The dissociation of coordinated pyridine as the rate-determining step of the whole process was confirmed by measuring the rates of exchange in the 253–293 K temperature interval in the ^{1}H NMR spectra of $[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]^{2-}$ prepared in situ. The rate constants were measured on the basis of the line broadening of signal A2, which belongs to the pyridine ligands of *cis*-$[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]^{2-}$.[27] The shape of signal A2 at each temperature was compared with the corresponding signal in the simulated spectrum. The activation parameters for the dissociation of pyridine from *cis*-$[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]^{2-}$ were calculated from Eyring plot (Figure 9): $\Delta H^{\ddagger} = 82 \pm 4$ kJ mol^{-1} and $\Delta S^{\ddagger} = 79 \pm 14$ J mol^{-1} K^{-1}. The positive activation entropy is in agreement with the proposed dissociative mechanism. The determined value of the activation enthalpy could serve as a rough estimate of the molybdenum-to-pyridine bond strength.

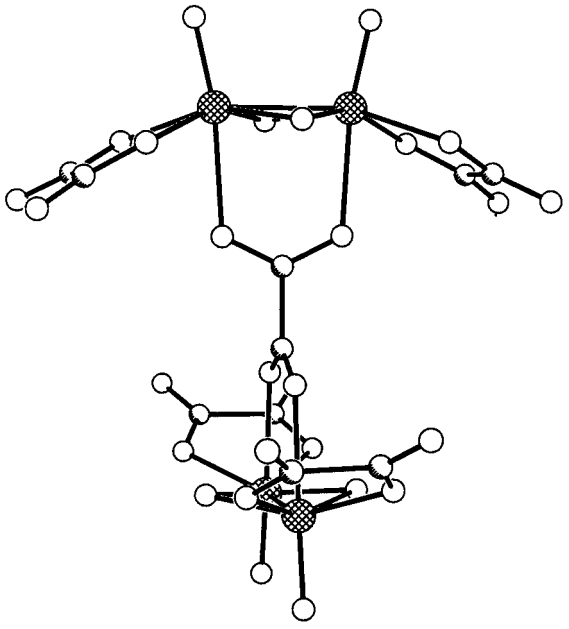

Figure 8. Oxalato ligands in $[\{Mo_2O_4(\eta^2\text{-}C_2O_4)_2\}_2(\mu_4\text{-}C_2O_4)]^{6-}$ adopt two binding modes: (i) the bidentate oxalates occupy the equatorial positions of the $\{Mo_2O_4\}^{2+}$ moiety, and (ii) the μ_4-oxalate occupies the apical positions of two $\{Mo_2O_4\}^{2+}$ moieties.[11]

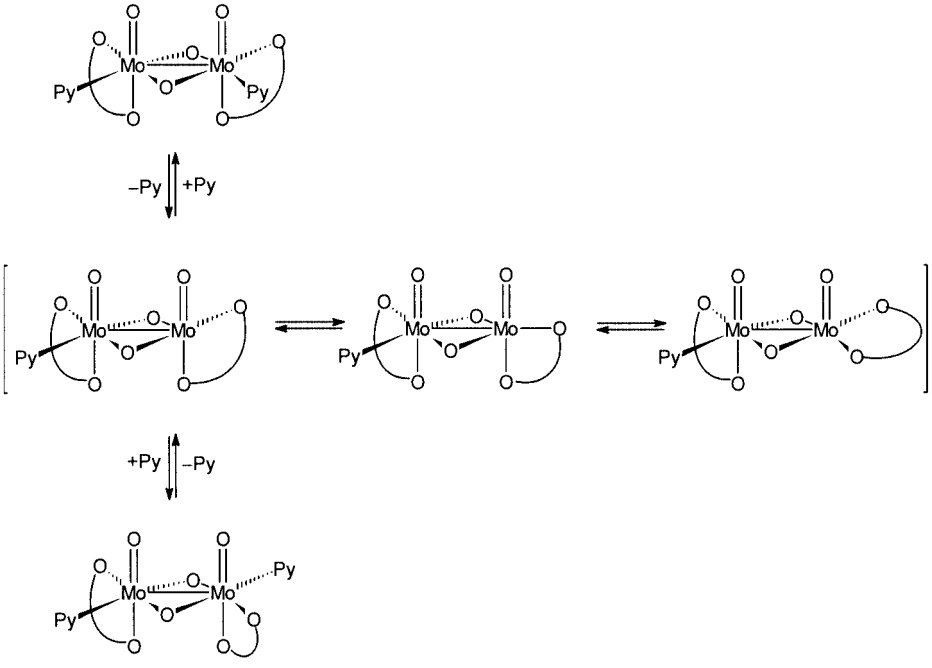

Scheme 1. Proposed *cis*/*trans* isomerization of $[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]^{2-}$ with intermediate states included in square brackets. For simplicity, only the rearrangements on one metal center of the dinuclear anion are shown.

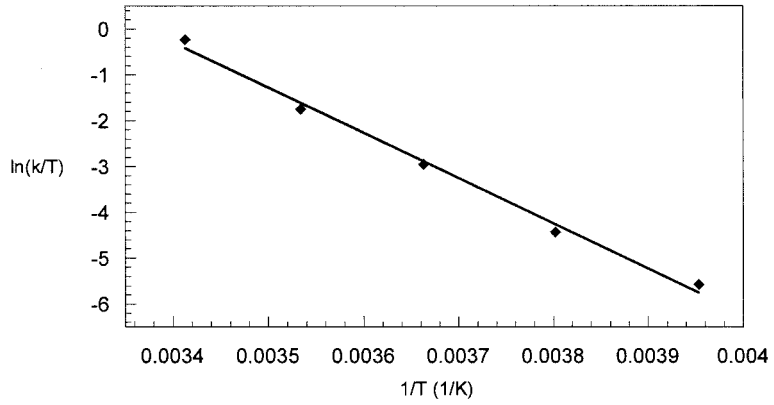

Figure 9. Eyring plot in the 253–293 K interval for the dissociation of pyridine from *cis*-$[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]^{2-}$ in D_2O/CD_3OD solution. The solid line represents the equation $y = -9876 \cdot x + 33.284$ ($r^2 = 0.9934$) from the linear regression analysis.

Speculations on the Solution Chemistry of *cis*- and *trans*-$[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(R\text{-}Py)_2]^{2-}$

Reports of oxalato complexes of molybdenum(v) date back almost a century, when the preparations of barium, potassium, and pyridinium salts of *trans*-$[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(H_2O)_2]^{2-}$ were reported.[28] In a later study, the substitution chemistry of *trans*-$[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(H_2O)_2]^{2-}$ with several ligands, including pyridine, was explored.[29] It was observed that the addition of pyridine to the sodium salt of *trans*-$[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(H_2O)_2]^{2-}$ did not result in the coordination of pyridine; rather, the coordination sphere remained intact and the product was the pyridinium salt of the same anion. The substitution of water for pyridine in *trans*-$[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(H_2O)_2]^{2-}$ was reported to be slow, with the equilibrium favoring the aqua complex. $(PyH)_2[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]$ could only be prepared from $(PyH)_2[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(H_2O)_2]$ upon prolonged refluxing in boiling pyridine. In reactions with some other ligands two other processes were suggested: a rupture of the doubly oxo-bridged structure to afford a singly oxo-bridged $\{Mo_2O_2(\mu_2\text{-}O)\}^{4+}$, and a substitution of the bidentate oxalate. Since the stereochemistry of the starting material was not known, no isomerization processes were proposed.

In line with the previous findings, we observed that both geometric isomers of $[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(R\text{-}Py)_2]^{2-}$ react in water with the substitution of coordinated pyridine for water molecules, which are present in huge excess. This substitution is, as evidenced by NMR spectroscopy, accompanied by another process, namely isomerization of the *trans* isomer into the *cis* and vice versa. The crystallization of *trans*-$(PyH)_2[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(H_2O)_2]$ (**8**) from a water/methanol solution of *cis*-$(4\text{-}EtPyH)_2[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(4\text{-}EtPy)_2]$ (**4**) after the addition of pyridinium sulfate adds firm support for both processes. Slow evaporation of a solution of *trans*-$(PyH)_2[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]$ (**1**) also afforded a dinuclear species with coordinated water – *trans*-$(PyH)_2[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(H_2O)_2]$ (**8**). On the other hand, when the pyridinium cations in the solution of *trans*-$(PyH)_2[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]$ (**1**) were neutralized with a strong base, followed by the addition of tetraphenylphosphonium bromide, no substitution occurred. The product was a water solvate – *trans*-$[(C_6H_5)_4P]_2[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]\cdot H_2O$ (**7**) – which retains the original, *trans*, configuration of the ligands. Although water solutions of $[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]^{2-}$ contain isomeric pairs of $[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]^{2-}$, partially substituted $[Mo_2O_4(\eta^2\text{-}C_2O_4)Py(H_2O)]^{2-}$ and fully substituted, aqua-ligated $[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(H_2O)_2]^{2-}$, we were not able either to isolate any of the two isomeric forms of $[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py(H_2O)]^{2-}$ or carry out the transformation of *trans*-$[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]^{2-}$ into the *cis* isomeric form on a preparative scale.

In the context of the above-discussed reactions of $[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]^{2-}$ anions in water, the reaction of *trans*-$(PyH)_2[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(H_2O)_2]$ (**8**) with methanol has to be briefly mentioned. Although **8** is sparingly soluble in methanol, it slowly reacts with it. Evaporation of a lightly colored, saturated methanol solution yields orange crystals of $(PyH)_2[Mo_8O_{16}(OCH_3)_8(\mu_8\text{-}C_2O_4)]\cdot 2CH_3OH$ (**9**). The formation of this octanuclear anion supports several other processes. The coordinated oxalate is shown to be labile under certain conditions and can be substituted with other ligands, methoxide being such a ligand. Due to the rupture of the molybdenum-to-oxalate bonds, the oxalate content in the resulting species is greatly reduced. Since the variable temperature NMR studies were carried out in a water/methanol mixture, the formation of **9** shows that the role of methanol is not restricted solely to that of a solvent.

Vibrational Spectroscopy

The most relevant feature of the IR spectra of the title compounds concerns the carbon-oxygen frequencies of the oxalato ligand because they are diagnostic of its coordination mode.[30] Several absorption bands observed for ν_{as}(OCO) in the range 1710–1633 cm^{-1}, two bands for ν_s(OCO) in the range 1418–1249 cm^{-1}, and a single band for δ(OCO) at 789–780 cm^{-1} (see Table 4) are typical for the bidentate coordination mode found in complexes **1**–**8**. The observed frequencies agree very well with the data observed for $Ba[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(H_2O)_2]\cdot 3H_2O$ {1710, 1680, 1653 [ν_{as}(OCO)], 1430, 1289 [ν_s(OCO)], 793 [δ(OCO)]}.[13] For

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the anion in **9** with all oxalate oxygen atoms engaged in coordination and metal–oxygen distances of approximately equal length, bands at 1661, 1650 [ν_{as}(OCO)], 1389, 1283 [ν_s(OCO)], and 814 [δ(OCO)] cm^{-1} were observed. Their frequencies do not differ from those reported for the *N*-methylpyridinium salt of this anion.[11]

Table 4. Characteristic oxalate absorptions [cm^{-1}] in $[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(R\text{-}Py)_2]^{2-}$ compounds and in *trans*-$(PyH)_2[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(H_2O)_2]$ (**8**).

Compound	ν_{as}(OCO)	ν_s(OCO)	δ(OCO)
1	1707, 1681, 1638	1418, 1279	789
2	1707, 1671	1415, 1275	780
3	1710, 1662	1376, 1294	785
4	1708, 1669, 1634	1417, 1272	785
5	1709, 1667	1414, 1275	784
6	1707, 1682, 1633	1417, 1277	789
7	1707, 1687, 1672	1376, 1249	784
8	1650[a]	1392, 1287	788

[a] A single, very broad band is displayed. The water bending mode absorbs in the same spectral region.

The antisymmetric and symmetric O–H stretching modes of the lattice water in **3** appear at 3533 and 3464 cm^{-1}, and in **7** at 3526 and 3396 cm^{-1}. Their frequencies fall in the usually observed region (3550–3200 cm^{-1}).[31] The absorptions assigned to coordinated water in the spectrum of **8** are seen as very broad bands. A broad band centered at about 2900 cm^{-1} may be attributed to both types of O–H stretching vibrations. The typical region for the water bending vibration (1630–1600 cm^{-1})[31] overlaps with the ν_{as}(OCO) vibration of the oxalate.

Conclusions

A series of compounds containing the *trans* or *cis* isomeric form of the $[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(R\text{-}Py)_2]^{2-}$ anion has been prepared. *trans*-$(4\text{-}MePyH)_2[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(4\text{-}MePy)_2]\cdot 1/2(4\text{-}MePy)$ (**5**) and *cis*-$(4\text{-}MePyH)_3[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(4\text{-}MePy)_2]Br$ (**6**) are the only examples where both isomers were isolated. The stepwise substitution of pyridine for water in solutions of $[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]^{2-}$ produces the mono-substituted $[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py(H_2O)]^{2-}$, whose presence was detected by NMR spectroscopy, and the bis-(aqua)-ligated $[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(H_2O)_2]^{2-}$. The isolation of *trans*-$(PyH)_2[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(H_2O)_2]$ (**8**) from a solution of *cis*-$(4\text{-}EtPyH)_2[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(4\text{-}EtPy)_2]$ (**4**) adds firm support for simultaneous *cis*/*trans* isomerization accompanying the substitution reactions. The latter result is in accordance with the MO calculations on the *trans* and *cis* isomer of $[Mo_2O_4(\eta^2\text{-}C_2O_4)_2(4\text{-}MePy)_2]^{2-}$, which revealed insignificant differences in their energy.

Experimental Section

General Remarks: Reagents were purchased from Aldrich and used without further purification. $(PyH)_5[MoOCl_4(H_2O)]_3Cl_2$ and $(PyH)[MoOBr_4]$ were prepared by published procedures.[32,33] Pyridinium sulfate was isolated as a white solid by neutralizing sulfuric acid with two equiv. of pyridine and drying in vacuo. The solvothermal reactions were carried out in sealed glass tubes under autogenous pressure. Several synthetic procedures are described for some compounds. The IR and far-IR spectra were measured on solid samples as Nujol or poly(chlorotrifluoroethylene) mulls using Perkin–Elmer 2000 series FT-IR spectrometer. ^1H and ^{13}C spectra were recorded on a Bruker Avance DPX 300 spectrometer referenced to the solvent. Elemental analyses were performed by the Chemistry Department service at the University of Ljubljana. The compounds **1**, **2**, **4**, and **6** were found to decompose on prolonged exposure to the air.

NMR Spectroscopy of *trans*-$(MeNC_5H_5)_2[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]$: *trans*-$(MeNC_5H_5)_2[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]$ (63 mg, 0.0809 mmol), prepared following the previously published procedure,[11] was dissolved in 0.6 mL of D_2O/CD_3OD mixture (1:1 volume ratio). The variable temperature ^1H NMR spectra (the aromatic region) are shown in Figure 7. The signals for the *N*-methylpyridinium cation in the spectrum recorded at 243 K are at δ = 4.36 (s, 3 H, $CH_3NC_5H_5$), 8.00 (m, 2 H, 3-H), 8.48 (t, J = 7.8 Hz, 1 H, 4-H), and 8.80 (d, J = 5.9 Hz, 2 H, 2-H) ppm. The assignments of other signals are described in the text.

NMR Spectroscopy of $(MeNC_5H_5)_6[\{Mo_2O_4(\eta^2\text{-}C_2O_4)_2\}_2(\mu_4\text{-}C_2O_4)]$: $(MeNC_5H_5)_6[\{Mo_2O_4(\eta^2\text{-}C_2O_4)_2\}_2(\mu_4\text{-}C_2O_4)]$ was prepared following the previously published procedure.[11] ^1H NMR (D_2O, 300 MHz): δ = 4.35 (s, 3 H, $CH_3NC_5H_5$), 8.00 (m, 2 H, 3-H), 8.48 (t, J = 7.9 Hz, 1 H, 4-H), 8.73 (d, J = 5.9 Hz, 2 H, 2-H) ppm. ^{13}C NMR (D_2O, 75 MHz): δ = 48.5 ($CH_3NC_5H_5$), 128.4 (C-3), 145.4 (C-2), 145.6 (C-4), 166.6 (coordinated oxalate), 173.0 (free oxalate) ppm.

NMR Determination of the Exchange Rates: $(MeNC_5H_5)_6[\{Mo_2O_4(\eta^2\text{-}C_2O_4)_2\}_2(\mu_4\text{-}C_2O_4)]$ (22 mg, 14.5 mmol) was dissolved in D_2O (0.3 mL), followed by the addition of CD_3OD (0.3 mL). An excess of pyridine (15.4 mg, 0.1927 mmol) was added to this solution. The relative amounts of *cis*-$[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]^{2-}$, *trans*-$[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]^{2-}$, and $[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py(H_2O)]^{2-}$ were calculated from the integrals of the corresponding signals. The spectra were measured at 10 K intervals in the temperature range 233–333 K.

***trans*-$(PyH)_2[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]$ (1):** A glass tube was charged with $(PyH)_5[MoOCl_4(H_2O)]_3Cl_2$ (50 mg, 0.117 mmol of Mo), $H_2C_2O_4\cdot 2H_2O$ (20 mg, 0.159 mmol), acetonitrile (0.5 mL), *tert*-butanol (1 mL), and pyridine (4 mL). The tube was sealed and heated for 90 h in an electric oven maintained at 115 °C. The tube was then allowed to cool slowly to room temperature. Orange, block-shaped crystals of **1** were collected by filtration and washed with dichloromethane. Yield: 73% (32 mg). *Note.* Other alcohols (ethanol, 2-propanol) can be used instead of *tert*-butanol. The yields are comparable (77% for the reaction mixture with ethanol and 80% for the reaction mixture with 2-propanol). IR: $\tilde{\nu}$ = 3130 cm^{-1} (w), 3089 (w), 3053 (w), 2168 (w), 2066 (w), 1707 (vvs), 1681 (vvs), 1638 (vvs), 1542 (vs), 1487 (vvs), 1418 (vvs), 1279 (vvs), 1224 (vs), 1203 (vs), 1171 (w), 1137 (w), 1078 (m), 1046 (m), 1016 (m), 997 (m), 955 (vvs), 935 (vs), 907 (s), 789 (vvs), 773 (vvs), 760 (vs), 742 (vvs), 691 (vvs), 641 (m), 603 (vs), 528 (s), 491 (vs), 477 (s), 441 (m), 400 (m), 361 (s), 341 (w), 318 (s), 291 (w), 279 (w), 269 (m), 247 (m), 228 (w) cm^{-1}. $C_{24}H_{22}Mo_2N_4O_{12}$ (750.3): calcd. ***trans*-(4-MePyH)$_2$[$Mo_2O_4(\eta^2\text{-}C_2O_4)_2$(4-MePy)$_2$]·1/2(4-MePy) (5):** A glass tube was charged with $(PyH)_5[MoOCl_4(H_2O)]_3Cl_2$ (50 mg, 0.117 mmol of Mo), $H_2C_2O_4\cdot 2H_2O$ (50 mg, 0.397 mmol), 4-methylpyridine (4 mL), 2-propanol (0.5 mL), and acetonitrile (0.5 mL). The tube was sealed and heated for 90 h in an electric oven maintained at 115 °C. The tube was then allowed to cool slowly to room temperature. Yellow, needle-shaped crystals of **5** were collected by filtration. Yield (based on the dried sample): 32% (15 mg). IR: $\tilde{\nu}$ = 3512 cm^{-1} (w), 3416 (w), 3062 (m), 1709 (vvs), 1667 (vvs), 1501 (vvs), 1462 (vvs), 1414 (vs), 1306 (w), 1275 (s), 1230 (m), 1212 (m), 1200 (m), 1097 (w), 1071 (m), 1032 (s), 1010 (m), 950 (vvs), 904 (m), 830 (m), 813 (vs), 784 (vvs), 742 (vvs), 668 (w), 522 (m), 491 (vs), 402 (w), 363 (m), 346 (w), 315 (s), 251 (m), 238 (w) cm^{-1}. *Note.* No elemental analysis was performed, since the crystals lost the 4-methylpyridine solvent of crystallization when removed from the solution.

***cis*-(4-MePyH)$_3$[$Mo_2O_4(\eta^2\text{-}C_2O_4)_2$(4-MePy)$_2$]Br (6). Procedure a:** A glass tube was charged with (PyH)[$MoOBr_4$] (120 mg, 0.235 mmol), $H_2C_2O_4\cdot 2H_2O$ (200 mg, 1.59 mmol), 4-methylpyridine (4 mL), 2-propanol (0.5 mL), and acetonitrile (0.5 mL). The tube was sealed and heated for 90 h in an electric oven maintained at 115 °C. After cooling to room temperature, the reaction mixture consisted of a clear, orange solution. Over a period of two weeks two types of crystals grew from the solution: yellow, needle-like crystals of **5** and orange, block-like crystals of **6**. The total amount of solid material was 62 mg. **Procedure b:** A glass tube was charged with (PyH)[$MoOBr_4$] (120 mg, 0.235 mmol), $H_2C_2O_4\cdot 2H_2O$ (100 mg, 0.794 mmol), and 4-methylpyridine (4 mL). The tube was sealed and heated for 90 h in an electric oven maintained at 115 °C. The reaction mixture was allowed to cool slowly to room temperature. Orange, block-shaped crystals of **6** were separated manually from the colorless, needle-like crystals of 4-methylpyridinium oxalate. Yield: 71% (82 mg). IR: $\tilde{\nu}$ = 2921 cm^{-1} (m), 2846 (m), 1707 (vvs), 1682 (vvs), 1633 (vvs), 1503 (vs), 1417 (vs), 1307 (s), 1277 (vs), 1232 (m), 1202 (m), 1098 (m), 1059 (m), 1032 (s), 1006 (m), 949 (vvs), 932 (vs), 904 (m), 813 (vs), 789 (vs), 748 (vs), 722 (vs), 666 (w), 651 (w), 553 (m), 519 (s), 503 (vs), 483 (vvs), 476 (vvs), 402 (m), 365 (s), 349 (m), 321 (vs), 294 (m), 273 (w), 247 (m), 218 (w) cm^{-1}. $C_{34}H_{38}BrMo_2N_5O_{12}$ (980.5): calcd. C 41.65, H 3.91, N 7.14, found C 41.58, H 3.64, N 6.98.

***trans*-[$(C_6H_5)_4P]_2[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]\cdot H_2O$ (7):** Compound **1** (250 mg, 0.333 mmol) was dissolved in water (10 mL). After the addition of potassium hydroxide (42 mg, 0.749 mmol), the clear, orange solution turned cloudy. The solution was then filtered and a solution of tetraphenylphosphonium bromide (315 mg, 0.754 mmol) in acetonitrile (7 mL) was added to the filtrate. The volume of the filtrate was reduced to one half by pumping on the vacuum line. The concentrated solution was kept in a closed flask at ambient conditions. Red crystals of **7** grew after two days and were collected by filtration and washed with dichloromethane. Yield: 41% (178 mg). IR: $\tilde{\nu}$ = 3526 cm^{-1} (w), 3396 (w), 1707 (m), 1687 (s), 1672 (vs), 1642 (s), 1603 (m), 1581 (m), 1481 (m), 1436 (s), 1376 (s), 1314 (w), 1249 (m), 1218 (m), 1160 (w), 1107 (vs), 1069 (w), 1042 (w), 1015 (w), 997 (m), 937 (vs), 919 (m), 898 (m), 845 (w), 784 (s), 755 (s), 743 (s), 721 (vs), 691 (vs), 634 (w), 528 (vs), 471 (m), 317 (m), 264 (w). $C_{62}H_{52}Mo_2N_2O_{13}P_2$ (1286.9): calcd. C 57.87, H 4.07, N 2.18, found C 57.68, H 4.28, N 2.09.

***trans*-(PyH)$_2$[$Mo_2O_4(\eta^2\text{-}C_2O_4)_2(H_2O)_2$] (8):** Compound **1** (250 mg, 0.333 mmol) was dissolved in water (10 mL). Methanol (10 mL) and pyridinium sulfate (256 mg, 1.00 mmol) were then added to the clear, orange solution. The solution was left in an open beaker under ambient conditions. Within a few hours orange crystals of **8** started to deposit from the solution. The crystals were collected by filtration and washed with dichloromethane. Yield: 67% (140 mg). IR: $\tilde{\nu}$ = 2900 cm^{-1} (br), 1650 (vvs), 1483 (s), 1418 (s), 1392 (s), 1287 (s), 1258 (s), 1197 (m), 1166 (m), 1058 (m), 1007 (m), 964 (vvs), 945 (vvs), 910 (vs), 856 (m), 788 (vs), 750 (vs), 722 (vs), 678 (vs), 609 (s), 588 (s), 534 (s), 490 (vvs), 447 (m), 393 (m), 350 (w), 311 (s), 260 (s), 180 (w) cm^{-1}. $C_{14}H_{16}Mo_2N_2O_{14}$ (628.2): calcd. C 26.77, H 2.57, N 4.46, found C 26.71, H 2.49, N 4.49.

Isomerization of *cis*-(4-EtPy)$_2$[$Mo_2O_4(\eta^2\text{-}C_2O_4)_2$(4-EtPy)$_2$] (4): Compound **4** (140 mg, 0.162 mmol) was dissolved in water (7.5 mL) and methanol (7.5 mL) and pyridinium sulfate (130 mg, 0.508 mmol) were added to the solution. The solution was allowed to stand in an open beaker under ambient conditions for three

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

days. Orange crystals of **8** were collected by filtration and washed with dichloromethane. Yield: 81% (82 mg).

$(PyH)_2[Mo_8O_{16}(OCH_3)_8(\mu_8\text{-}C_2O_4)]\cdot 2CH_3OH$ (9): Compound **8** (220 mg, 0.350 mmol) was added to methanol (15 mL) in an Erlenmeyer flask, which was stoppered and the reaction mixture stirred under ambient conditions for three days. The unreacted starting material (150 mg) was filtered off and the resulting filtrate was allowed to stand in an open beaker under ambient conditions overnight. Orange, needle-shaped crystals of **9** grew from the solution. Yield (based on the dried product and taking into the account only the reacted starting material): 84% (37 mg). IR: $\tilde{\nu}$ = 2925 cm^{-1} (s), 2851 (m), 2825 (m), 1661 (vs), 1650 (m), 1610 (w), 1528 (m), 1484 (m), 1444 (m), 1389 (s), 1283 (w), 1253 (w), 1200 (w), 1168 (m), 1027 (vs), 969 (vvs), 814 (vs), 750 (vvs), 721 (vvs), 676 (m), 539 (vvs), 462 (vvs), 380 (m), 339 (m), 275 (s), 221 (m) cm^{-1}. *Note.* No elemental analysis was performed since the crystals quickly lost the methanol solvent of crystallization when removed from the solution.

Computational Details: MO calculations on the *trans* and *cis* isomeric forms of $[Mo_2O_4(\eta^2\text{-}C_2O_4)(4\text{-}MePy)_2]^{2-}$ were performed in order to determine their relative stabilities using three different methods: (i) semi-empirical PM3, (ii) ab initio Hartree–Fock with the 3-21G basis set, and (iii) density functional B3LYP with the 6-31G* basis set and a pseudopotential. The SPARTAN′02 program was used.[34] The atomic coordinates of the anions in **5** and **6** were taken from the X-ray diffraction study. No geometric optimization was applied. The calculated energy differences are too small to have any significance. According to the first method, the energy of the *cis* isomer is 0.95 $kJ\,mol^{-1}$ lower than that of the *trans* isomer. The other two methods show the *trans* isomer as the more energetically favored, by 11.59 $kJ\,mol^{-1}$ using the second method and by 7.24 $kJ\,mol^{-1}$ using the third method.

X-ray Crystallographic Study: Crystals were mounted on the tip of a glass fiber with a small amount of silicon grease and transferred to the goniometer head. Data for **4** and **6** were collected on a Bruker P4 diffractometer equipped with a SMART CCD system.

Data processing was accomplished with the SAINT program.[35] Absorption corrections were made using SADABS.[36] Data for **1**, **2**, **3**, **5**, **7**, **8**, and **9** were collected on a Nonius Kappa CCD diffractometer. Data reduction and integration were performed with the software package DENZO-SMN.[37] Averaging of the symmetry-equivalent reflections largely compensated for the absorption effects. For all compounds, the coordinates of some or all of the non-hydrogen atoms were found by direct methods using the structure solution program SHELXS.[38] The positions of the remaining non-hydrogen atoms were located by use of a combination of least-squares refinement and difference Fourier maps in the SHELXL-97 program.[38] With the exception of **5** and **9**, all non-hydrogen atoms were refined anisotropically. The asymmetric unit of **5** contains two 4-methylpyridine molecules of crystallization, one of which is badly disordered, in addition to two dinuclear anions and four protonated 4-methylpyridine molecules. The disorder could not be modeled satisfactorily, resulting in relatively large *R* factors and residual density in the final difference Fourier map. The nitrogen and carbon atoms of both solvent molecules were refined isotropically. The oxalate ion in **9** is disordered over two positions. The carbon atoms C(6) and C(7) of the disordered oxalate ion were refined isotropically, each with an occupancy factor of 0.5. The hydrogen atoms were included in the structure factor calculations at idealized positions. Figures depicting the structures were prepared with SHELXTL.[39] Cell parameters and refinement results are summarized in Tables 5 and 6. CCDC-258550 (**1**), -258551 (**2**), -258552 (**3**), -258553 (**4**), -258554 (**5**), -258555 (**6**), -258556 (**7**) -258557 (**8**), and 258558 (**9**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Supporting Information (see also footnote on the first page of this article): Contains Figure S1 {^{1}H NMR spectra of the diluted D_2O/CD_3OD solutions of *trans*-$(MeNC_5H_5)_2[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]$, recorded at 243 K} and Figure S2 {^{1}H NMR spectra of D_2O/CD_3OD solutions of *trans*-$(MeNC_5H_5)_2[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]$ titrated with pyridine, recorded at 243 K}.

Acknowledgments

The work was supported by the Slovenian Ministry of Education, Science and Sport (grant P1-0134) and by the National Science Foundation (Grant CHE-0242153). We are grateful to Prof. Alojz Demšar for his help with the simulation of NMR spectra.

[23] We observed that pyridine *N*-methylation with methanol took place in the presence of oxalic acid at elevated temperature. The fact that *N*-methylpyridinium salts result from a nucleophilic attack of pyridine on methyl halide formed from methanol and hydrogen halide does not provide a valid explanation. The latter reaction requires strongly acidic conditions, while the reaction medium in our case contains mostly pyridine. Moreover, the halogenation of alcohols is known to proceed more readily with tertiary and secondary alcohols, but not with methanol. The exact nature of this process is currently under investigation.
[24] A downfield shift was observed for the signals of free pyridine [243 K spectrum: δ = 7.67 (C-3), 8.14 (C-4), 8.62 (C-2) ppm], suggesting that pyridine is not entirely free. The corresponding pyridine frequencies in water solution appear at δ = 7.24, 7.66, and 8.32 ppm.
[25] The integral of signal C2, which belongs to free pyridine, is smaller than the integrals of signals A2 and B2. This observation rules out an alternative explanation: an equilibrium between only one isomeric form of $[Mo_2O_4(\eta^2\text{-}C_2O_4)_2Py_2]^{2-}$ (set A), the mono-substituted complex (set B), and the bis(aqua)-ligated complex. In the latter situation the integral of C2 would be larger than the integral of B2 because the amount of free pyridine is twice the amount of the bis(aqua)-ligated complex plus the amount of the mono-substituted complex.
[26] For comparison, the carbonate carbon resonances in water solution of $[(Mo_2O_4)_3(\mu_6\text{-}CO_3)(\mu_2\text{-}CO_3)_3(\mu_2\text{-}OH)_3]^{5-}$ with two distinctly different carbonato ligands appear in the same spectral region: two major signals at δ = 160 and 165 ppm with a 1:3 intensity ratio and three minor ones at δ = 160.5, 164.5, and 165.5 ppm. [M. J. Manos, A. D. Keramidas, J. D. Woollins, A. M. Z. Slawin, T. A. Kabanos, *J. Chem. Soc., Dalton Trans.* **2001**, 3419–3420.] The ^{13}C NMR spectrum of an aqueous solution of ammonium oxalate reveals a resonance at δ = 173.9 ppm.

Keywords: Cadmium / Lead / Nonlinear optics / Organic–inorganic hybrid composites / Polymers

The zero-dimensional polymer $[Pb_6(\mu_2OOCCH{=}CHFc)_2(\mu_3\text{-}OOCCH{=}CHFc)_2(\mu_2\text{-}\eta^2\text{-}OOCCH{=}CHFc)_2(\eta^2\text{-}OOCCH{=}CHFc)_2(\mu_4\text{-}O)_2]$ (**1**), the one-dimensional chain polymers $[Pb(\eta^1\text{-}\mu_2\text{-}OOCCH{=}CHFc)_2(phen)]_n$ (phen = phenanthroline; (**2**), $\{[Cd(\mu_2\text{-}\eta^2\text{-}OOCCH{=}CHFc)(\eta^2\text{-}OOCCH{=}CHFc)(H_2O)_2](H_2O)_4\}_n$ (**3**), and the two-dimensional hybrid polymer $\{[Cd(\eta^2\text{-}OOCCH{=}CHFc)(bbbm)_{1.5}Cl]\cdot 1.5H_2O\}_n$ [bbbm = 1,1′-(1,4-butanediyl)bis-1*H*-benzimidazole; **4**] have been prepared by the reaction of sodium β-ferrocenylacrylate [FcCH=CHCOONa, Fc = $(\eta^5\text{-}C_5H_5)Fe(\eta^5\text{-}C_5H_4)$] with the appropriate metal salts. Solution-state differential pulse voltammetry for **1**–**4** indicated that the half-wave potentials of the ferrocenyl moieties in these polymers are all shifted to positive potential compared with that of sodium β-ferrocenylacrylate. The four polymers' third-order nonlinear optical (NLO) properties were determined by the Z-scan technique in DMF solutions. The results show that these polymers possess good nonlinear optical refraction effects. Their hyperpolarizability (γ) values are calculated to be 4.80×10^{-30}, 5.19×10^{-30}, 1.57×10^{-29}, and 2.04×10^{-29} esu for **1**–**4**, respectively. The γ values of the Cd^{II} polymers (**3** and **4**) are slightly larger than those of the Pb^{II} polymers (**1** and **2**), which indicates that the metal ions play an important role in the NLO properties of these polymers.

Introduction

Currently, the rational design and synthesis of metal–organic polymeric complexes containing multifunctional groups have received much attention because of their widespread potential applications in molecular sensor technology, peptide mimetic models, charge-transfer complexes, non-linear optical materials, organic synthesis, homogeneous catalysis, materials chemistry, and so on.[1–5] Due to the fascinating properties of the ferrocene moiety as well as the versatile coordination modes[6] and strong coordinating capability of the carboxylate groups, ferrocenecarboxylate compounds have been extensively used as functional ligands.[7–14] Furthermore, the introduction of ferrocenyl carboxylate groups into metal–organic frameworks provides an effective way to prepare new functional materials with unique features.

Ferrocenecarboxylate and ferrocenedicarboxylate were among the first to be prepared and studied in synthetic strategies, and lots of metal-based polymers containing them have been described.[12,13,15–20] However, relatively few reports have appeared on other ferrocenecarboxylate–metal polymers. In recent years, various groups and ourselves have put effort into the synthesis and property investigations of other ferrocenecarboxylate–metal polymers,[10,11] such as the structures and the redox properties of the polymers $[Pb(o\text{-}OOCC_6H_4COFc)(\eta^2\text{-}o\text{-}OOCC_6H_4COFc)(bpe)]_n$, $\{[Zn(o\text{-}OOCC_6H_4COFc)_2(4,4'\text{-}bpy)(H_2O)_2]\cdot 2MeOH\cdot 2H_2O\}_n$, $\{[Cd(o\text{-}OOCC_6H_4COFc)_2(bpe)(MeOH)_2]\cdot 2H_2O\}_n$, $\{[Pb\{\mu_2\text{-}\eta^2\text{-}OOCCH{=}(CH_3)CFc\}_2]\cdot MeOH\}_m$,[10] and $\{[Cd(\mu_2\text{-}OOCH_4C_6Fc)(\eta^2\text{-}OOCH_4C_6Fc)(bbp)](CH_3OH)\}_n$,[11] and the magnetic properties of $\{[Mn(OOCH_4C_6Fc)_2(\mu_2\text{-}OH_2)(H_2O)_2](H_2O)\}_n$ and $[Mn(\mu_2\text{-}OOCH_4C_6Fc)_2(phen)]_n$,[11] etc., but no reports have touched on the third-order NLO properties of ferrocenecarboxylate–metal polymers.

Following our earlier studies on ferrocenecarboxylate–metal polymers, we report here the syntheses and structures of a series of novel polymers constructed from FcCH=CHCOONa with Pb^{II} or Cd^{II} ions and subsidiary ligands. The third-order NLO studies in DMF solution show that all these polymers display self-focusing behaviors. This result is consistent with the previous conclusion that the NLO properties of coordination polymers are controlled by the valence shell structures of the central metal ions. Their thermal and electrochemical properties were also investigated.

Results and Discussion

Preparation of the Polymers

Polymers **1**–**4** were obtained by treatment of FcCH=CHCOONa with the appropriate metal salts and subsidiary

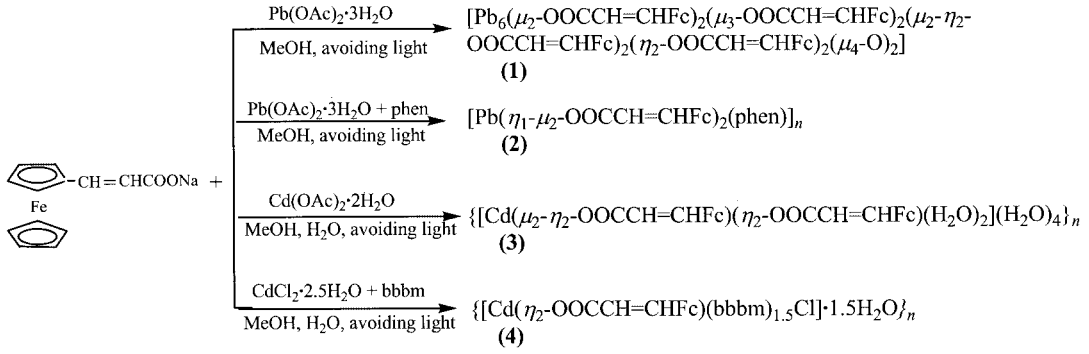

Scheme 1.

ligands in different solvents (Scheme 1). Crystals suitable for X-ray crystallography of polymers **1**–**4** were also obtained by slow evaporation of the solvents in the dark due to the reasons mentioned previously.[21] These crystals are only soluble in highly polar solvents such as DMSO and DMF, etc.

Under similar reaction conditions, the reactions of $Pb(OAc)_2$ with different ferrocenecarboxylates generate different structural geometries. For example, treatment of $Pb(OAc)_2$ with FcCOONa or $FcC(CH_3)$=CHCOONa gives the one-dimensional chain structural polymers $\{[Pb_2(OOCFc)(\eta^2\text{-}OOCFc)(\mu_2\text{-}\eta^2\text{-}OOCFc)(\mu_3\text{-}\eta^2\text{-}OOCFc)(MeOH)]\cdot 1.5MeOH\cdot H_2O\}_n$[6e] or $\{[Pb\{\mu_2\text{-}\eta^2\text{-}OOCCH=(CH_3)CFc\}_2]\cdot MeOH\}_n$,[10] while when FcCH=CHCOONa was treated with $Pb(OAc)_2$ a zero-dimensional polymer (**1**) was obtained whose structure displays significant difference from the former two polymers. The addition of phen to the reaction system of **1** led to the formation of the one-dimensional polymer **2**. Up to now, the synthesis of two-dimensional polymers containing ferrocenecarboxylate was still a great challenge. On the basis of self-assembly of coordination polymers, we successfully prepared a novel, two-dimensional hybrid polymer **4** with the organic bridging ligand bbbm.

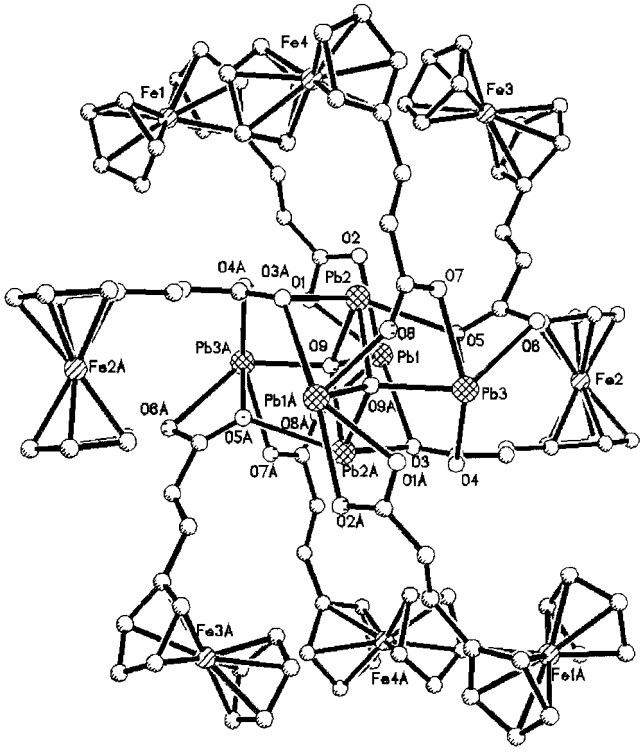

Figure 1. Crystal structure of $[Pb_6(\mu_2\text{-}OOCCH=CHFc)_2(\mu_3\text{-}OOCCH=CHFc)_2(\mu_2\text{-}\eta^2\text{-}OOCCH=CHFc)_2(\eta^2\text{-}OOCCH=CHFc)_2(\mu_4\text{-}O)_2]$ (**1**) with heteroatom labeling scheme.

Crystal Structure of $[Pb_6(\mu_2\text{-}OOCCH=CHFc)_2(\mu_3\text{-}OOCCH=CHFc)_2(\mu_2\text{-}\eta^2\text{-}OOCCH=CHFc)_2(\eta^2\text{-}OOCCH=CHFc)_2(\mu_4\text{-}O)_2]$ (1)

The molecule crystallizes in the space group $P\bar{1}$. X-ray diffraction analysis revealed that **1** is a zero-dimensional Pb^{II} polymer (Figure 1). The structure shows a giant, scroll-wheel-like arrangement of the eight ferrocene units in four kinds of coordination modes with a presumed Pb_6 octahedron core (the six Pb^{II} ions inhabit the six apexes of the presumed octahedron), and the six Pb^{II} ions are bridged by two $\mu_4\text{-}O^{2-}$ anions from the inner of the Pb_6 octahedron core, simultaneously. The molecule sits astride a center of inversion.

The eight $FcCH=CHCOO^-$ units surround the Pb_6 core and bridge the six Pb^{II} ions to form a stable Pb_6 octahedron. It is interesting that the eight $FcCH=CHCOO^-$ units display four kinds of coordination modes: bidentate (η^2-OOCCH=CHFc), bidentate (μ_2-OOCCH=CHFc), tridentate (μ_3-OOCCH=CHFc), and tridentate ($\mu_2\text{-}\eta^2$-OOCCH=CHFc). As for the Pb_6 octahedron, the mean deviation of the plane Pb2–Pb2A–Pb3–Pb3A (**A**), Pb1–Pb1A–Pb2–Pb2A (**B**), or Pb1–Pb1A–Pb3–Pb3A (**C**) is 0.000 Å. The dihedral angle between planes **A** and **B** is 68.8°, that between **A** and **C** is 85.5°, and that between **B** and **C** is 85.8°. The Pb1–Pb1A, Pb2–Pb2A, and Pb3–Pb3A distances are 6.621, 3.725, and 6.546 Å, respectively.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The six Pb^{II} ions lie in three kinds of coordination environments, considering an arbitrary length of approximately 2.8 Å to define maximum bonding interactions (this being the sum of the two ionic radii[22]). Pb1 and Pb3 are pentacoordinate. Each Pb1 binds to five oxygen atoms, two from a chelating η^2-OOCCH=CHFc$^-$ unit, one from bidentate μ_2-OOCCH=CHFc$^-$, one from tridentate μ_3-OOCCH=CHFc$^-$, and one from the μ_4-O^{2-} anion from the inner core of the Pb_6 octahedron. For Pb3, the five oxygen atoms are two from μ_2-η^2-OOCCH=CHFc$^-$, one from μ_3-OOCCH=CHFc$^-$, one from μ_2-OOCCH=CHFc$^-$, and one from the μ_4-O^{2-} anion. The coordination number of Pb2 is four, with four oxygen atoms from μ_2-η^2-OOCCH=CHFc$^-$, μ_3-OOCCH=CHFc$^-$, and two μ_4-O^{2-} anions. The Pb–O distances are in the range 2.264(8)–2.694 Å. This contrasts with the Pb atoms in the acetate, formate, and pentafluorobenozate complexes, where eightfold coordination is found;[23] coordination numbers of 7,[24] 9,[25] and 10[26] are also known in other Pb^{II} carboxylates.

The eight ferrocene fragments are located around the Pb_6 octahedron. Fe1, Fe4, Fe1A, and Fe4A are co-planar, as are Fe2, Fe3, Fe2A, and Fe3A, and the dihedral angle between the two planes is 89.8°, that is to say they are nearly perpendicular to each other.

It has previously been reported that bridging oxygen atoms are present at the center of a polyhedron formed by transition[27] and main- group[28] metals or hetero-polymetal containing Pb atoms,[29] for example the zero-dimensional Zn^{II} polymers $[(Zn_4O)(O_2CR)_6]$ (R = diethylamino, piperidino, or pyrrolidino),[30] and $[Zn_4(\mu_2\text{-}FcCOO)_6(\mu_4\text{-}O)]$.[6e] Reports on Pb^{II} carboxylate complexes containing an oxide ligand bridging the metal atoms in a homometallic polyhedron of Pb^{II} ions are very scare.[23]

Crystal Structure of $[Pb(\eta^1\text{-}\mu_2\text{-}OOCCH=CHFc)_2(phen)]_n$ (2)

The 1D chain structure of polymer **2** is formed by a double monatomic bridge connecting the adjacent Pb^{II} ions (Figure 2). Each Pb^{II} ion adopts a distorted octahedral PbN_2O_4 coordination environment. The repeated Pb_2O_2 rings construct the basic skeleton structure of the one-dimensional chain: the dimensions of the rhomboid are 2.549×2.734 Å^2, the dihedral angle between the two adjacent Pb_2O_2 rhomboid is 81.8°, and the Pb···Pb intrachain distance is 4.202 Å. The phen rings lie on alternate sides of each chain, parallel to the *c*-axis. The $Pb–N_{(phen)}$ distance [2.612(11) Å] is consistent with those in $\{[Pb(phen)_2(ox)]\cdot 5H_2O\}_n$ (ox = oxalate) [2.721(2) Å],[31] $[Pb(phen)(O_2CCH_3)(O_2NO)]_n$ [2.519(3) and 2.579(3) Å],[32] $[Pb(phen)_2(O_2CCH_3)(ClO_4)]$, and $[Pb(phen)_2(O_2CCH_3)(NCS)]_2$,[32] etc.

The Pb_2O_2 ring in **2** is different from those in dimeric $[Pb(phen)(O_2CCH_3)_2]_2$[33] and $[Pb(phen)(O_2CCH_3)(NCS)]_2$[34] and polymeric $[Pb(phen)(O_2CCH_3)(O_2ClO_2)]_n$[35] and $[Pb(phen)(O_2CCH_3)(O_2NO)]_n$,[36] where the Pb_2O_2 rings share edges with PbOCO quadrilaterals to form the dimer core. The long edge of the Pb_2O_2 ring in **2** (2.734 Å) is similar in length to those in $[Pb(phen)(O_2CCH_3)(O_2NO)]_n$ (2.80 Å) and $[Pb(phen)(O_2CCH_3)(O_2ClO_2)]_n$ (2.74 Å), but considerably shorter than those in $[Pb(phen)(O_2CCH_3)(NCS)]_2$ (3.19 Å) and $[Pb(phen)(O_2CCH_3)_2]_2$

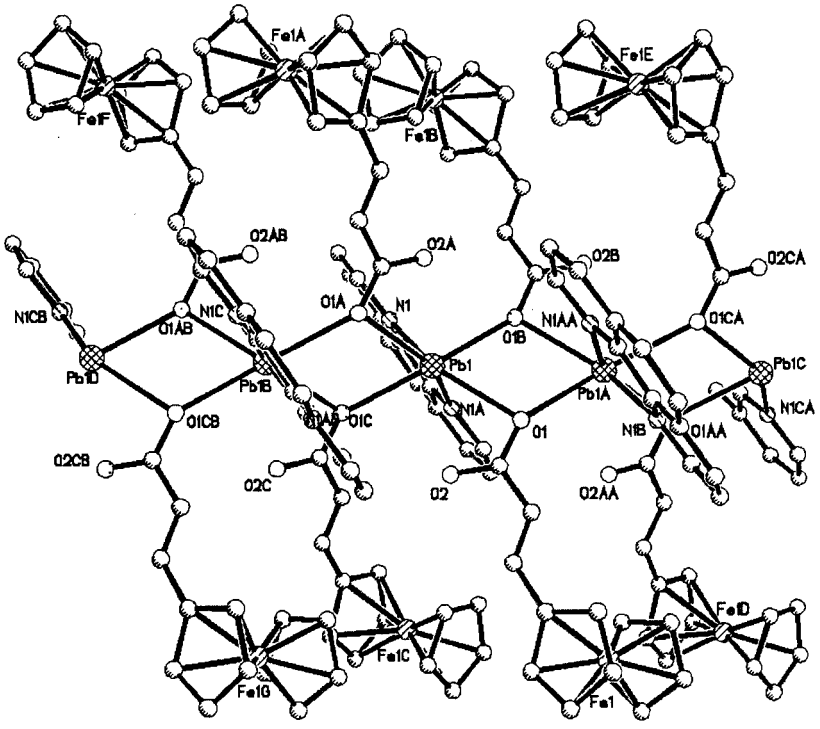

Figure 2. Perspective view of the 1D chain structure of $[Pb(\eta^1\text{-}\mu_2\text{-}OOCCH=CHFc)_2(phen)]_n$ (**2**) with only the heteroatoms labeled.

(3.37 Å). This indicates the strong coordinating ability of the FcCH=CHCOO$^-$ anion.

Since the distance between adjacent phen rings (8.270 Å) on one side of the 1D chain is out of the range of π–π stacking interactions there are no such interactions in the crystal structure, and it is the intermolecular interaction that is responsible for the packing in the solid-state structure.

Crystal Structure of {[Cd(μ$_2$-η^2-OOCCH=CHFc)-(η^2-OOCCH=CHFc)(H$_2$O)$_2$](H$_2$O)$_4$}$_n$ (3)

The X-ray diffraction analysis revealed that **3** crystallizes in the space group $P2_1/n$. As can be seen from Figure 3, each Cd^{II} ion is seven-coordinate and the adjacent [Cd(η^2-OOCCH=CHFc)(H$_2$O)$_2$] groups are linked by μ$_2$-η^2-OOCCH=CHFc$^-$ units into a one-dimensional chain polymer.

In the structural unit, each Cd^{II} ion binds to atoms O1 and O2 from a chelating η^2-OOCCH=CHFc$^-$, O3, O4, and O4A atoms from two μ$_2$-η^2-OOCCH=CHFc$^-$, groups and the O5 and O6 atoms from two coordinated H$_2$O molecules. The Cd–O$_{(OOCCH=CHFc^-)}$ distances are in the range 2.242(4)–2.580(5) Å. The Cd^{II} ions are not in a straight line: the adjacent Cd···Cd separation is 4.637 Å and the Cd–Cd–Cd angle is 105.5°. The one-dimensional [Cd(μ$_2$-η^2-OOCCH=CHFc)(η^2-OOCCH=CHFc)(H$_2$O)$_2$] chain extends along the *b*-direction. Viewed along the *b*-axis, two kinds of ferrocene fragments are located along both sides of the one-dimensional chain, and they alternate along this chain. The one-dimensional chains are connected by O–H···O hydrogen bonds and intermolecular interactions (Figure 4). The structure is similar to the reported 1-D infinite zigzag chain polymer [Cd{Fc(CO$_2$)$_2$}(DMF)$_2$(H$_2$O)]$_n$,[19] in which the Cd^{II} atoms are connected by the 1,1′-ferrocenedicarboxylate ligand in a 1,3′-disubstituted bridging mode.

Crystal Structure of {[Cd(η^2-OOCCH=CHFc)-(bbbm)$_{1.5}$Cl]·1.5H$_2$O}$_n$ (4)

The crystal structure analysis demonstrates that **4** crystallizes in the space group $P\bar{1}$. As shown in the structural unit (Figure 5), each Cd^{II} ion is six-coordinate in a slightly distorted octahedral environment with two oxygen atoms from a chelating η^2-OOCCH=CHFc$^-$ unit, three nitrogen atoms from three bridging bbbm ligands, and one Cl atom. The O1, O2, N3, Cl1, and Cd1 atoms are nearly co-planar (the mean deviation from the ideal CdCNO$_2$ plane is 0.0322 Å), and define the equatorial plane [Cd1–O1 = 2.273(12), Cd1–O2 = 2.476(12) Å, Cd1–N3 = 2.301(14) Å, and Cd1–Cl1 = 2.506(4) Å]. The N1 and N5 atoms of the other two bbbm units occupy the axial positions [Cd1–N1 = 2.520(13), Cd1–N5 = 2.347(12) Å], and the axial angle N1–Cd1–N5 is 166.3(4)°. All the Cd^{II} ions are bridged by the bbbm with ferrocene units in the side chain leading to an infinite two-dimensional network (Figure 6). The sheet extends along the [010] crystallographic plane.

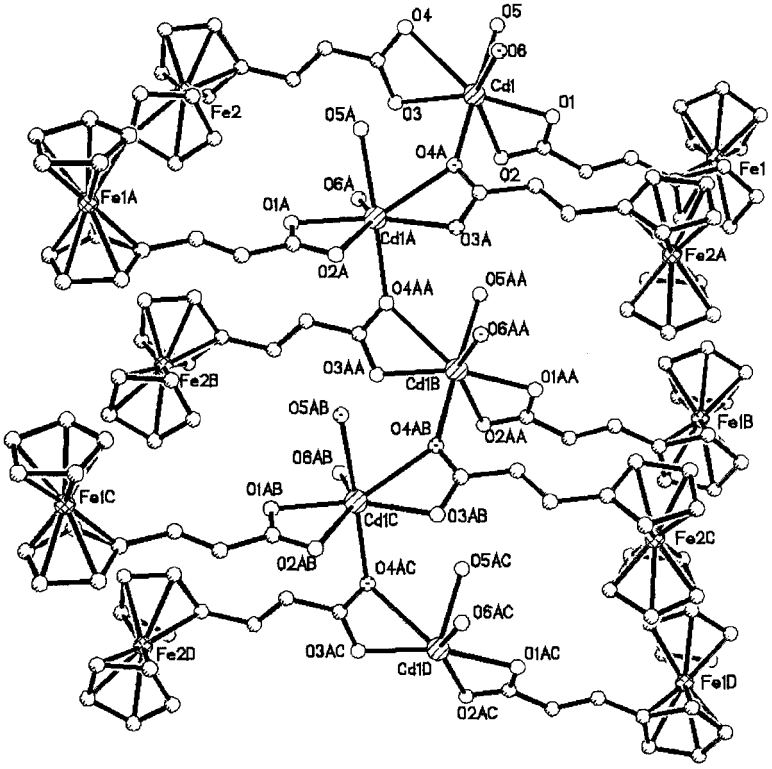

Figure 3. One-dimensional chain structure of {[Cd(μ$_2$-η^2-OOCCH=CHFc)(η^2-OOCCH=CHFc) (H$_2$O)$_2$](H$_2$O)$_4$}$_n$ (**3**) with only heteroatoms labeled.

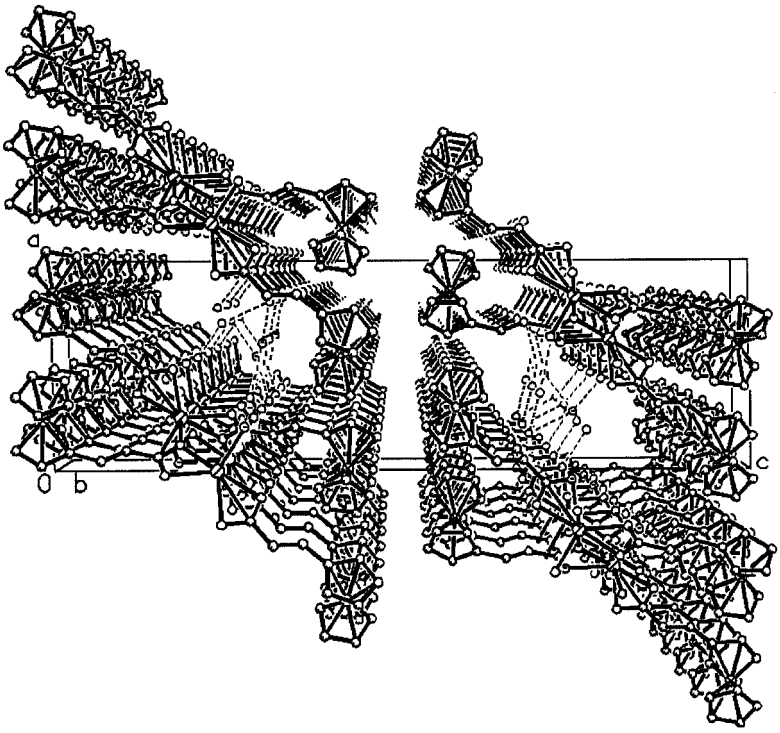

Figure 4. The solid-state structure of $\{[Cd(\mu_2\text{-}\eta^2\text{-}OOCCH{=}CHFc)(\eta^2\text{-}OOCCH{=}CHFc)(H_2O)_2](H_2O)_4\}_n$ (**3**).

Hybrid polymers with ferrocene units in the side chain have been published in our recent papers,[6e,10,11] such as the one-dimensional, ladder-like polymers $\{[Zn(OOCFc)_2(bpt)]\cdot 2.5H_2O\}_n$, $[Zn(OOCFc)(\eta^2\text{-}OOCFc)(bbp)]_n$, and $\{[Cd(\mu_2\text{-}OOCH_4C_6Fc)(\eta^2\text{-}OOCH_4C_6Fc)(bbp)](CH_3OH)\}_n$, the zigzag chain polymer $[Pb(FcCOO)(\mu_2\text{-}FcCOO)(bpe)]_n$, and the linear chain polymer $\{[Zn(o\text{-}OOCC_6H_4COFc)_2(4,4'\text{-}bpy)(H_2O)_2]\cdot 2MeOH\cdot 2H_2O\}_n$. However, two-dimensional ferrocenecarboxylate-containing hybrid polymers have not been reported up to now. Using the organic bridging ligand bbbm, we have successfully prepared the novel two-dimensional hybrid polymer **4** containing a ferrocenearboxylate component.

Thermogravimetric Analysis

The TG-DTA data of **1**–**4** were determined in the range 25–900 °C in air. It can be seen from the TG curve that **1** begins to lose weight at 212 °C, and the process of weight

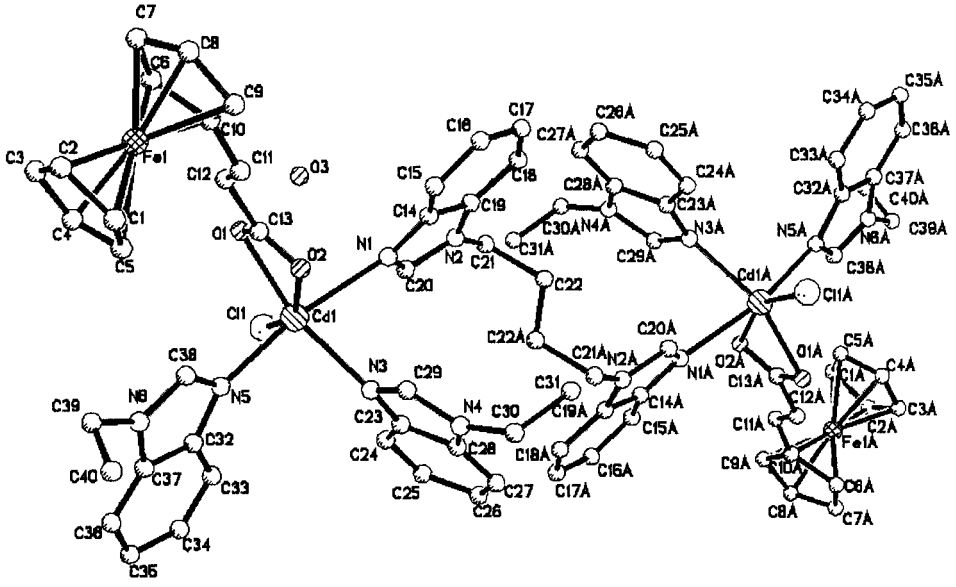

Figure 5. ORTEP diagram showing the structure unit of $\{[Cd(\eta^2\text{-}OOCCH{=}CHFc)(bbbm)_{1.5}Cl]\cdot 1.5H_2O\}_n$ (**4**). H atoms have been omitted for clarity.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

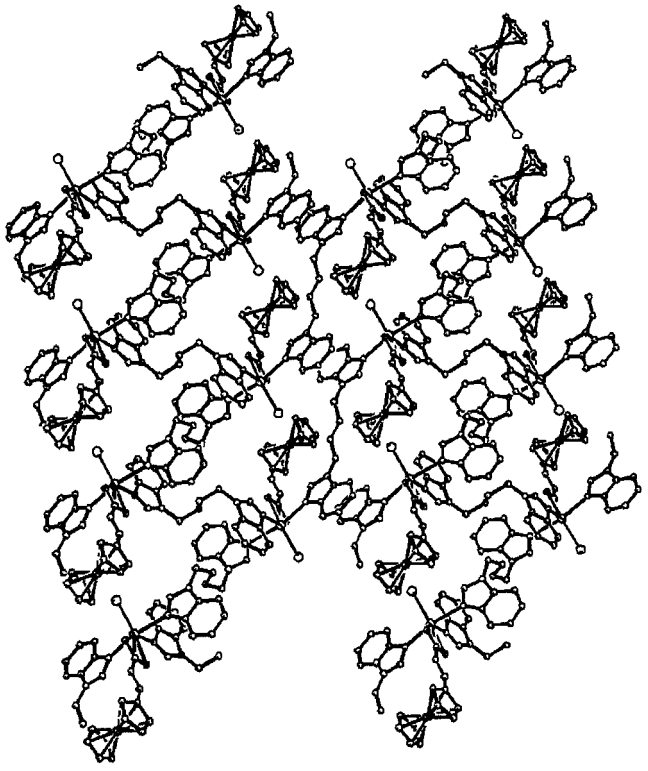

Figure 6. Two-dimensional sheet structure of $\{[Cd(\eta^2\text{-}OOCCH{=}CHFc)(bbbm)_{1.5}Cl]\cdot 1.5H_2O\}_n$ (**4**). H atoms have been omitted for clarity.

loss is sustained up to 381 °C; this corresponds to the decomposition of the FcCH=CHCOO⁻ anions. A plateau region is then observed from 381 to 900 °C. Finally, a brown amorphous residue was left, which can be assigned to 1.5PbO + 2FeO. There are two weak exothermic peaks at 258 and 304 °C, and a very strong exothermic peak at 399 °C on the DTA curve of **1**.

For polymer **2**, the weight-loss process begins at 183 °C and it goes through multiple weight loss steps, which can be assigned to the loss of the phen molecule and the decomposition of FcCH=CHCOO⁻ anions; this process is sustained up to 411 °C. A clear plateau region is then observed from 411 to 900 °C in the TGA plot. Finally, the brown amorphous residue is presumed to be PbO + 2FeO. There is one weak exothermic peak at 249 °C and one very strong exothermic peak at 390 °C on the DTA curve of **2**.

We find from the TG curve that **3** begins to lose weight at 35 °C, and this process is maintained up to 159 °C, corresponding to the loss of uncoordinated H_2O molecules. After a plateau region from 159 to 225 °C in the TG curve, it goes through complicated multiple weight-loss steps from 225 to 555 °C, corresponding to the loss of coordinated H_2O and the decomposition of the FcCH=CHCOO⁻ units. There is then a plateau region from 555 to 900 °C. The brown residue can be assigned to the residual CdO + 2FeO. There is one middle exothermic peak at 280 °C and one very strong exothermic peak at 414 °C on the DTA curve.

In the TG curve of **4**, the weight loss process from 164 to 232 °C can be assigned to the loss of H_2O molecules, then it goes through complicated multiple weight-loss steps in the temperature range of 232 to 600 °C, which can be assigned to the decomposition of bbbm and the FcCH=CHCOO⁻ anions. The final brown residue corresponds to CdO + FeO. The weight remains constant from 600 to 900 °C. In the DTA curve of **4**, there is a weak exothermic peak at 260 °C, a middle exothermic peak at 395 °C, and a very strong exothermic peak at 478 °C.

Redox Properties

The solution-state differential pulse voltammograms of **1**–**4** and FcCH=CHCOONa are shown in Figure 7. It can be seen from this figure that all these polymers show a single peak with a half-wave potential ($E_{1/2}$ vs. SCE) at 0.56 V for **1**, 0.54 V for **2**, 0.53 V for **3**, and 0.52 V for **4**, which can be assigned to the electron-transfer process of the ferrocenyl moiety. Relative to free FcCH=CHCOONa (0.51 V), the half-wave potentials of **1**–**4** are all shifted to slightly higher potential. It is apparent that these shifts can be attributed to the influence of the central metal ions, and this is consistent with the previous results of transition metal–ferrocenyl systems.[9,37] The reason for this is that the conjugated π-electron systems between the two metals allow communication,[38] and the electron-withdrawing nature of the coordinated metal centers makes the ferrocene unit harder to oxidize.[39]

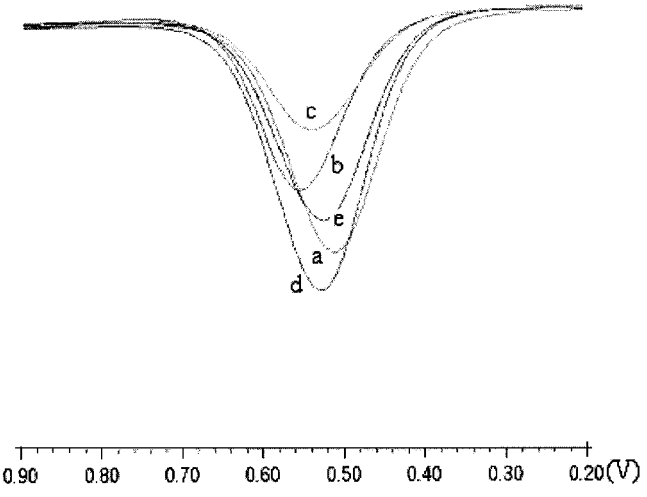

Figure 7. Differential pulse voltammogram of (a) NaOOCCH=CHFc (0.51 V), (b) **1** (0.56 V), (c) **2** (0.54 V), (d) **3** (0.53 V), (e) **4** (0.52 V) all at concentrations of approximately 1.0×10^{-3} M in DMF containing nBu$_4$NClO$_4$ (0.1 M) at a scanning rate of 20 mV s^{-1} (vs. SCE).

Nonlinear Optical Properties

The second-order NLO properties of ferrocenyl derivatives have been extensively studied,[40] but reports on the third-order NLO properties of ferrocenyl derivatives, especially ferrocenecarboxylate polymers, are very limited.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The UV/Vis spectra of **1**–**4** were determined in DMF solutions. From a previous study,[41,42] we know that ferrocene exhibits two characteristic absorptions in the UV/Vis spectra at 440 nm (assigned to the $^1E_{1g} \leftarrow {}^1A_{1g}$ transition) and 325 nm (assigned to the $^1E_{2g} \leftarrow {}^1A_{1g}$ transition). Similarly, the four polymers also show two characteristic bands at around 315 and 445 nm (Figure 8). All four polymers have a relatively low linear absorption ranging from 500 to 1000 nm, similar to other known organic–metal polymers.[42] This indicates low intensity loss and little temperature change caused by photon absorption when light propagates in the materials.

The NLO properties of **1**–**4** were investigated with a 532-nm laser pulse for 8 ns in a 1.21×10^{-4} M (**1**), 1.12×10^{-4} M (**2**), 1.37×10^{-4} M (**3**), or 1.16×10^{-4} M (**4**) DMF solution.

Figures 9a–d depict the Z-scan data for **1**–**4**, respectively. We find that all these polymers possess good nonlinear optical refraction effects. It is obvious that the theoretical curves (solid curves) reproduce well the general pattern of the observed experimental data (black dot). This fact suggests that the experimentally obtained NLO effects are effectively third-order in nature. The data show that these polymers have the same positive sign for the refractive nonlinearity, which gives rise to self-focusing behavior.

The NLO refractive effects were assessed by dividing the normalized Z-scan data obtained in the closed-aperture configuration by the normalized Z-scan data obtained in the open-aperture configuration.

The third-order NLO refractive index, n_2, can be derived from Equations (1), (2), and (3)[43]

$$T(Z,S)=\frac{\int_{-\infty}^{+\infty}\varepsilon_0 cn_0\pi\int_0^r|E_a(r,t,z)|^2 r\,dr\,dt}{S\int_{-\infty}^{+\infty}\frac{I_0\pi\omega_0^2}{2}e^{-(t/t_0)^2}dt} \quad (1)$$

$$E_a(r,t,z)=\frac{2\pi}{i\lambda(l-z)}e^{[i\pi r^2/\lambda(l-z)]}\int_0^\infty E(r',t,z)J_0\frac{2\pi r'r}{\lambda(l-z)}e^{[i\pi r'^2/\lambda(l-z)]}r'dr \quad (2)$$

$$E(r',t,z)=2\sqrt{\frac{I(r',t,z)}{\varepsilon_0 cn_0}}e^{\{(kn_2/\alpha_2)\ln[1+q(r',t,z)]\}} \quad (3)$$

where Z is the distance of the sample from the focal point, ε_0 and c are the permittivity and speed of light in vacuo, respectively, n_0 and n_2 are the linear and nonlinear refractive indices of the sample, respectively, r is the radial coordinate, t is the time, t_0 is the pulse width, I_0 is the peak irradiation intensity at focus, and $Z_0 = \pi\omega_0^2/\lambda$, with ω_0 being the spot radius of the laser beam at focus and λ being the wavelength of the laser; l is the distance between the aperture and focus, α_2 is the nonlinear absorption coefficient, and $S = 1 - \exp[-2(r_a/\omega_a)^2]$ is the linear aperture transmittance.

Based on Equation (1), the refractive index, n_2, was calculated to be 1.43×10^{-18} m^{2}W^{-1} for **1**, 1.43×10^{-18} m^{2}W^{-1} for **2**, 1.59×10^{-18} m^{2}W^{-1} for **3**, and 1.75×10^{-18} m^{2}W^{-1} for **4**. In accordance with the n_2 values, the effective third-order susceptibility $\chi^{(3)}$ can be calculated by $|\chi^{(3)}| = cn_o^2n_2/80\pi$; the $\chi^{(3)}$ values of **1**–**4** are 1.05×10^{-12}, 1.05×10^{-12}, 3.88×10^{-12}, and 4.27×10^{-12} esu, respectively.

The corresponding modulus of the hyperpolarizability, γ, was obtained from $|\gamma| = \chi^{(3)}/NF^4$, where N is the number density of the compound (concentration), F^4, the local field correction factor, is 3. The γ values (4.80×10^{-30} esu for **1**, 5.19×10^{-30} esu for **2**, 1.57×10^{-29} esu for **3**, and 2.04×10^{-29} esu for **4**) are larger than those observed in other ferrocenyl complexes, whose γ values range from 10^{-35} to 10^{-31} esu.[44] In general, nonlinear optical behavior governed by the nonlinear hyperpolarizability, γ, of the materials: the larger the γ value, the better the materials' NLO properties. On the other hand, from these data we can see that the γ values of the same metal ions are very close, and the γ values of **3** and **4** (Cd^{II} polymers) are a little larger than those of **1** and **2** (Pb^{II} polymers). This may be attributed to the influence of the central metal ions. The influence of these polymers' dimensionality on the third-order NLO properties is not very noticeable. Upon summarizing the limited literature relating to the third-order NLO properties of coordination polymers, we find that the coordina-

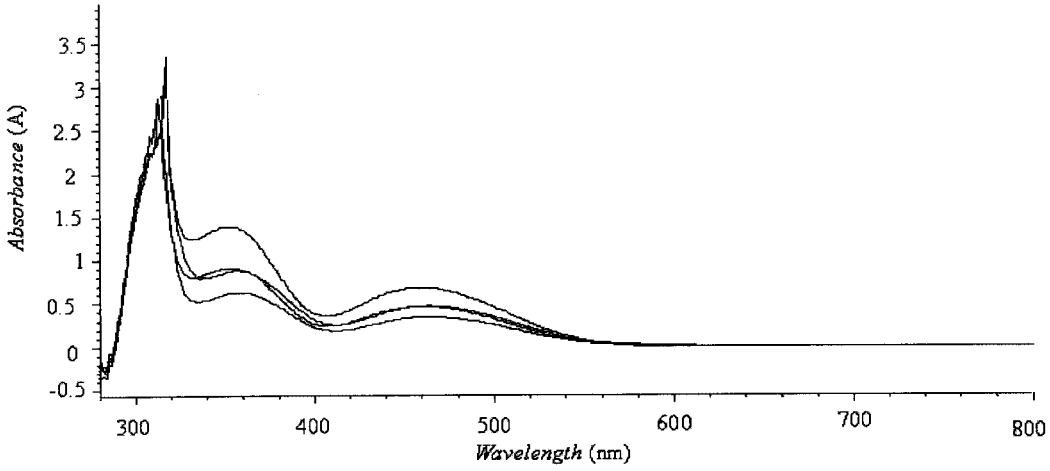

Figure 8. The UV/Vis spectra of polymers **1**–**4** in DMF solution.

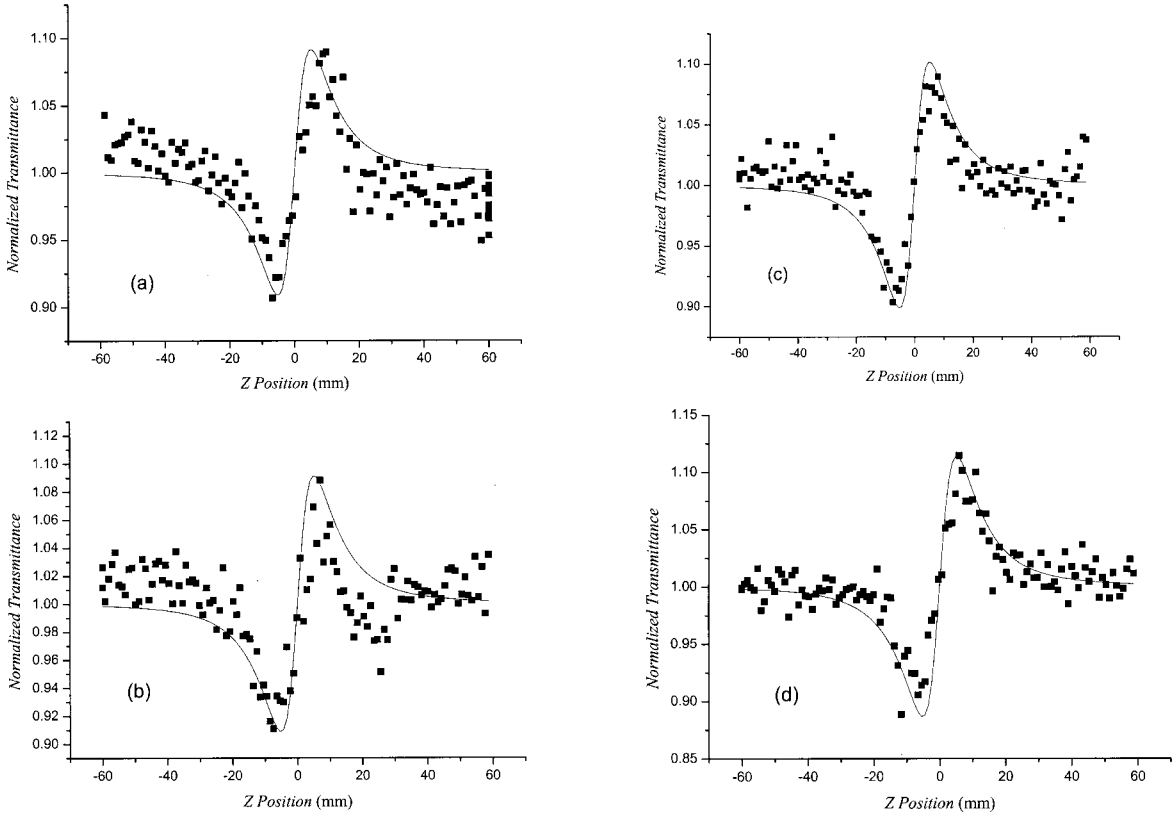

Figure 9. Z-scan data for **1**–**4**. The data were assessed by dividing the normalized Z-scan data obtained in the closed-aperture configuration by the normalized Z-scan data obtained in the open-aperture configuration. The black dots are the experimental data, and the solid curve is the theoretical fit. (a) The self-focusing effects of **1** in 1.21×10^{-4} M DMF solution at 532 nm. (b) The self-focusing effects of **2** in 1.12×10^{-4} M DMF solution at 532 nm. (c) The self-focusing effects of **3** in 1.37×10^{-4} M DMF solution at 532 nm. (d) The self-focusing effects of **4** in 1.16×10^{-4} M DMF solution at 532 nm.

tion polymers' large NLO properties may mainly be ascribed to the effect of metal ions, because the incorporation of transition metal ions into polymers can extend the π-conjugation length of the molecules, and the large π-conjugation system is favorable to increase the NLO susceptibility $\chi^{(3)}$ values.[45,46]

All the four polymers display self-focusing behavior, which is consistent with the previous conclusion[45] that the NLO properties of polymers are further controlled by the valence shell structures of the central metal ions. Nearly all the reported polymers with d^{10} valence shell metal ions give self-focusing behaviors, such as theorganic–metal polymers $[Zn(bbbt)(NCS)_2]_n$, $[Zn(pbbt)(NCS)_2]_n$,[45] $[HgI_2(4,4'\text{-azopyridine})]_n$, $[HgI_2(bpea)]_n$, $[Pb(NCS)_2(bpea)]_n$,[47] $[Cd(en)(NO_3)_2(4,4'\text{-bpy})]_n$,[48] and the ferrocenyl complexes $[Zn(4\text{-PFA})_2(NO_3)_2](H_2O)$, $[Hg_2(OAc)_4(4\text{-BPFA})_2](CH_3OH)$, $[Cd_2(OAc)_4(4\text{-BPFA})_2]$[4] etc. Other than the valence shell structures of the central metal ions, some other factors also have an effect on the intensity of the third-order optical nolinearity, such as the orbital overlap, orbital symmetry, degree of electron delocalization, linear polarizability etc. Further studies on the structure and third-order NLO properties relationship in these polymers are still underway. We believe that the study of third-order NLO properties of this kind of polymer may provide some promising candidates for the design of optical materials.

Conclusion

From the above discussion we can conclude that β-ferrocenylacrylate [FcCH=CHCOONa, Fc = $(\eta^5\text{-}C_5H_5)Fe(\eta^5\text{-}C_5H_4)$] is an excellent candidate to form extended structures whose versatile coordination modes can lead to the various and unpredictable structural geometries of different polymers. These metal–organic polymers possess good nonlinear optical refraction effects, and the metal ions play important roles in their NLO properties, because the incorporation of transition metal ions in polymers can extend the π-conjugation length of molecules, and the large π-conjugation system is favorable to increase the NLO susceptibility $\chi^{(3)}$ values.[45,46]

Experimental Section

General Details: All chemicals were of reagent grade from commercial sources and were used without further purification. β-Ferrocenylacrylic acid (FcCH=CHCOOH) was prepared according to the literature,[49] and its sodium salt was prepared by reaction with sodium methoxide. 1,1′-(1,4-Butanediyl)bis-1*H*-benzimidazole (bbbm) was prepared according to the literature.[50]

Preparation of $[Pb_6(\mu_2\text{-}OOCCH=CHFc)_2(\mu_3\text{-}OOCCH=CHFc)_2(\mu_2\text{-}\eta^2\text{-}OOCCH=CHFc)_2(\eta^2\text{-}OOCCH=CHFc)_2(\mu_4\text{-}O)_2]$ (1): FcCH=CHCOONa (27.8 mg, 0.10 mmol) in methanol (4 mL) was

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

added dropwise to a methanol solution (5 mL) of $Pb(OAc)_2 \cdot 3H_2O$ (38.0 mg, 0.1 mmol). The resultant pale-orange solution was allowed to stand at room temperature in the dark. Good quality red crystals were obtained several days later (yield: 6 mg, 58%). $C_{26}H_{22}Fe_2O_{4.5}Pb_{1.5}$ (828.92): calcd. C 37.67, H 2.68; found C 37.62, H 2.72. IR (KBr): $\tilde{\nu}$ = 3440 m, 3111 m, 2361 w, 1627 s, 1483 s, 1389 s, 1247 s, 818 m, 674 m, 489 m cm^{-1}.

Preparation of $[Pb(\eta^1\text{-}\mu_2\text{-}OOCCH{=}CHFc)_2(phen)]_n$ (2): Polymer **2** was prepared in a manner analogous to that used to prepare **1**, except that another kind of subsidiary ligand phen (phen = phenanthroline) (19.8 mg, 0.1 mmol) was added. The resultant red solution was allowed to stand at room temperature in the dark. Good quality red crystals were obtained after two weeks (yield: 28 mg, 62%). $C_{38}H_{30}Fe_2N_2O_4Pb$ (897.53): calcd. C 50.85, H 3.37, N 3.12; found C 50.39, H 3.56, N 3.38. IR (KBr): $\tilde{\nu}$ = 3445 m, 3094 s, 1637 s, 1540 s, 1372 s, 1244 m, 1101 m, 975 m, 846 m, 726 m, 670 m, 489 m cm^{-1}.

Preparation of $\{[Cd(\mu_2\text{-}\eta^2\text{-}OOCCH{=}CHFc)(\eta^2\text{-}OOCCH{=}CHFc)(H_2O)_2](H_2O)_4\}_n$ (3): FcCH=CHCOONa (55.6 mg, 0.2 mmol) in 3 mL of methanol was added dropwise to a 3 mL aqueous solution of $Cd(OAc)_2 \cdot 2H_2O$ (21.1 mg, 0.1 mmol). The resultant red solution was allowed to stand at room temperature in the dark. Good quality red crystals were obtained after a week (yield: 55 mg, 76%). $C_{26}H_{34}CdFe_2O_{10}$ (730.63): calcd. C 42.74, H 4.69; found C 42.68, H 4.73. IR (KBr): 3439 s, 3125 s, 2360 w, 1636 s, 1527 m, 1401 s, 1254 m, 1037 m, 815 m, 682 m, 488 m cm^{-1}.

Preparation of $\{[Cd(\eta^2\text{-}OOCCH{=}CHFc)(bbbm)_{1.5}Cl]\cdot 1.5H_2O\}_n$ (4): A methanol solution (5 mL) of bbbm (29 mg, 0.1 mmol) was added dropwise to an aqueous solution (2 mL) of $CdCl_2 \cdot 2.5H_2O$ (22.8 mg, 0.1 mmol) to give a clear solution. FcCH=CHCOONa (27.8 mg, 0.1 mmol) in 6 mL of methanol was then added dropwise to this mixture. Two weeks later good quality red crystals were obtained from the resultant red solution at room temperature in the dark (yield: 28 mg, 48%). $C_{40}H_{41}CdClFeN_6O_{3.5}$ (865.49): calcd. N 9.72, C 55.54, H 4.72; found C 55.49, H 4.72, N 9.70. IR (KBr): $\tilde{\nu}$ = 3432 s, 3114 s, 1633 s, 1541 s, 1398 s, 1252 m, 819 m, 750 m, 684 m, 491 m cm^{-1}.

X-ray Crystallography: Crystal data and experimental details for **1**–**4** are contained in Table 1. All the data were collected on a Rigaku RAXIS-IV imaging plate area detector diffractometer using graphite monochromated Mo-K_α radiation (λ = 0.71073 Å). Red, prismatic single crystals of **1**–**4** were selected and mounted on a glass fiber. The data were collected at a temperature of 291(2) K and corrected for Lorenz-polarization effects. A correction for secondary extinction was applied. The structures were solved by direct methods and expanded using Fourier techniques. The non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included but not refined. The final cycle of full-matrix least-squares refinement was based on observed reflections and variable parameters. All calculations were performed using the SHELXL-97 program.[51] Selected bond lengths and bond angles are given in Table 2.

CCDC-233289, -261304, -233290, and -233291 for **1**–**4**, respectively, contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

Physical Measurements: C, H, and N analyses were carried out on a MOD 1106 analyzer. IR data were recorded on a Bruker Tensor 27 spectrophotometer with KBr pellets in the 400–4000 cm^{-1} region. TGA-DTA measurements were performed by heating the sample from 25 °C to 900 °C at a rate of 10 °C min^{-1} in air in a Perkin–Elmer DTA-7 or TGA-7 differential thermal analyzer.

Differential pulse voltammetry studies were recorded with a CHI650 electrochemical analyzer utilizing the three-electrode configuration of a Pt working electrode, a Pt auxiliary electrode, and a commercially available saturated calomel electrode as the reference electrode with a pure N_2 gas inlet and outlet. The measurements were performed in DMF solution containing tetraethylammonium perchlorate (nBu_4NClO_4) (0.1 M) as supporting electrolyte, with a

50-ms pulse width and a 20-ms sample width. The potential was scanned from +0.2 to +0.9 V at a scan rate of 20 $mV\,s^{-1}$.

A DMF solution of **1**–**4** was placed in the 1-mm quartz cuvette for NLO measurements. The nonlinear refraction was measured with linearly polarized laser light (λ = 532 nm; pulse width: 8 ns) generated from a Q-switched and frequency-doubled Nd-YAG laser. The spatial profiles of the optical pulses were nearly Gaussian. The laser beam was focused with a 25-cm focal-length focusing mirror. The radius of the beam waist was measured to be 35 ± 5 μm (half-width at $1/e^2$ maximum). The interval between the laser pulses was chosen to be about 5 s for operational convenience. The incident and transmitted pulse energies were measured simultaneously by two Laser Precision detectors (RjP-735 energy probes), which were linked to a computer by an IEEE interface. The NLO properties of the samples were manifested by moving the samples along the axis of the incident beam (Z-direction) with respect to the focal point.[43] An aperture 0.5 mm in radius was placed in front of the detector to assist the measurement of the self-focusing effect.

Caution! Although no problems were encountered in this work, perchlorate salts are potentially explosive. They should therefore be prepared in small quantities and handled with care.

Formation of C–C Bonds in Diiron Complexes by Addition of Carbanions to Alkynyl(methoxy)carbene Ligands

Luigi Busetto,*[a] Fabio Marchetti,[a] Stefano Zacchini,[a] and Valerio Zanotti[a]

Keywords: Carbanions / Carbene ligands / C–C coupling / Iron

Addition of cyanide ions to the alkynyl(methoxy)carbene complexes $[Fe_2\{\mu\text{-}CN(Me)(R)\}(\mu\text{-}CO)(CO)\{C_\alpha(OMe)C_\beta{\equiv}C_\gamma R'\}(Cp)_2]^+$ (R = Xyl, R′ = Tol, **1a**; R = Xyl, R′ = Ph, **1b**; R = Xyl, R′ = Me_3Si, **1c**; R = Me, R′ = Tol, **1d**; R = Me, R′ = Ph, **1e**) occurs selectively at C_α to afford the 1,1-disubstituted σ-propargyl complexes $[Fe_2\{\mu\text{-}CN(Me)(R)\}(\mu\text{-}CO)(CO)\{C(OMe)(CN)(C{\equiv}CR')\}(Cp)_2]$ (R = Xyl, R′ = Tol, **2a**; R = Xyl, R′ = Ph, **2b**; R = Xyl, R′ = Me_3Si, **2c**; R = Me, R′ = Tol, **2d**; R = Me, R′ = Ph, **2e**). Conversely, the stabilised carbanaions $[CH(R)_2]^-$ (R = CN, CO_2Me) add at the C_γ position with subsequent hydrogen migration to C_β to give the 1-σ-buta-1,3-dienyl complexes $[Fe_2\{\mu\text{-}CN(Me)(Xyl)\}(\mu\text{-}CO)(CO)\{C_\alpha(OMe){=}C_\beta HC_\gamma(Tol){=}C_\delta(R)_2\}(Cp)_2]$ (R = CN, **3a**; CO_2Me, **3b**). No migration is possible in the absence of hydrogen atoms at C_δ, therefore addition of $[C(Me)(CO_2Me)_2]^-$ to **1a** results in the formation of the σ-allenyl complex $[Fe_2\{\mu\text{-}CN(Me)(Xyl)\}(\mu\text{-}CO)(CO)\{C_\alpha(OMe){=}C_\beta{=}C_\gamma(Tol)C_\delta(Me)(CO_2Me)_2\}(Cp)_2]$ (**4**). Protonation of the neutral complexes **3b** and **4** affords the vinyl(methoxy)carbene complexes $[Fe_2\{\mu\text{-}CN(Me)(Xyl)\}(\mu\text{-}CO)(CO)\{C_\alpha(OMe)C_\beta H{=}C_\gamma(Tol)C_\delta(R)(CO_2Me)_2\}]^+$ (R = H, **5**; Me, **6**), which exist in solution as mixtures of (*E*)- and (*Z*)-isomers in dynamic equilibrium, as shown by VT NMR studies. The cationic complex **6** shows electrophilic behaviour. Thus, addition of CN^- results in the σ-allyl complex $[Fe_2\{\mu\text{-}CN(Me)(Xyl)\}(\mu\text{-}CO)(CO)\{C_\alpha(OMe)(CN)[C_\beta H{=}C_\gamma(Tol)C_\delta(Me)(CO_2Me)_2]\}(Cp)_2]$ (**7**), whereas the reaction with Me_2NH affords the vinyl acyl complex $[Fe_2\{\mu\text{-}CN(Me)(Xyl)\}(\mu\text{-}CO)(CO)\{C_\alpha(O)C_\beta H{=}C_\gamma(Tol)C_\delta(Me)(CO_2Me)_2\}(Cp)_2]$ (**8**). The crystal structures of **2b** and **3a·CH_2Cl_2** have been determined.

Introduction

Alkynyl(alkoxy)carbenes represent a quite important class of organometallic complexes, since they are potentially useful reagents for the synthesis of organic compounds.[1] Most of the studies that have appeared to date concern mononuclear chromium and tungsten compounds of the type $(CO)_5M{=}C(OEt)C{\equiv}CR$. Their reactivity includes addition of protic nucleophiles (amines, imines, alcohols, thiols, phosphanes, carboxylic acids)[2–4] and carbon nucleophiles (alkynes, enamines, enaminones, enol ethers),[5–7] together with a large variety of cyclisation reactions.[8–10] We have recently reported the synthesis and the reactivity towards amines of the diiron alkynyl(methoxy)carbene complexes $[Fe_2\{\mu\text{-}CN(Me)(R)\}(\mu\text{-}CO)(CO)\{C_\alpha(OMe)C_\beta{\equiv}C_\gamma R'\}(Cp)_2]^+$ (R = Xyl, R′ = Tol, **1a**; R = Xyl, R′ = Ph, **1b**; R = Xyl, R′ = Me_3Si, **1c**; R = Me, R′ = Tol, **1d**; R = Me, R′ = Ph, **1e**).[11] The addition of amines to **1** was found to be completely regioselective at C_γ, whereas in the case of the mononuclear species $(CO)_5M{=}C(OEt)C{\equiv}CR$, addition at the carbene carbon C_α has also been observed.[1] The different regiochemistry observed could be due to either steric and/or electronic factors. In order to shed more light on this point, we decided to study the reactivity of **1** with other nucleophiles, and here we report some reactions involving **1** and different carbanions, such as CN^-, $[CH(R)_2]^-$ (R = CN, CO_2Me) and $[CMe(CO_2Me)_2]^-$. These reactions represent a direct way to form new C–C bonds in a diiron complex and, therefore, are potentially interesting in order to build new coordinated organic species.

Results and Discussion

The reaction of the alkynyl(methoxy)carbene complexes $[Fe_2\{\mu\text{-}CN(Me)(R)\}(\mu\text{-}CO)(CO)\{C_\alpha(OMe)C_\beta{\equiv}C_\gamma R'\}(Cp)_2]^+$ (R = Xyl, R′ = Tol, **1a**; R = Xyl, R′ = Ph, **1b**; R = Xyl, R′ = Me_3Si, **1c**; R = Me, R′ = Tol, **1d**; R = Me, R′ = Ph, **1e**) with $(nBu_4N)(CN)$ in CH_2Cl_2 solution (Scheme 1) results in the selective addition of the cyanide ion to the carbene carbon to give the 1,1-disubstituted σ-propargyl complexes $[Fe_2\{\mu\text{-}CN(Me)(R)\}(\mu\text{-}CO)(CO)\{C(OMe)(CN)(C{\equiv}CR')\}(Cp)_2]$ (R = Xyl, R′ = Tol, **2a**; R = Xyl, R′ = Ph, **2b**; R = Xyl, R′ = Me_3Si, **2c**; R = Me, R′ = Tol, **2d**; R = Me, R′ = Ph, **2e**) in good yields (70–80%). The reaction can be completely reversed by addition of CF_3SO_3Me.

The IR spectra of **2** show, as expected,[12] ν(CO) at around 1970 and 1790 cm^{-1} for the terminal and bridging carbonyls, respectively, and a weak ν(CN) absorption (at

2190 cm^{-1} for **2a**) that is shifted to 2142 cm^{-1} in [Fe_2{μ-CN(Me)(Xyl)}(μ-CO)(CO){C(OMe)(^{13}CN)(C≡CTol)}-$(Cp)_2$] (prepared from the reaction of **1a** with K^{13}CN) because of an isotope effect. The NMR spectra of **2** evidence the presence in solution of one single isomer. This is interesting, since complexes **1** are chiral and the addition of CN^- produces a second chiral centre, thus making possible the presence of diastereomeric species. The fact that only one form is present in solution indicates that the cyanide addition is regio- and stereoselective, occurring at one specific face of the plane containing the alkynyl(methoxy)carbene ligand; therefore, a racemic mixture of one single diastereomer is selectively formed.

Three low-field resonances in the ^{13}C NMR spectra are attributable to the bridging carbyne ($\delta \approx 335$ ppm), and to the bridging and the terminal carbonyls ($\delta \approx 270$ and 215 ppm, respectively). The CN carbon resonates at $\delta \approx 126$ ppm, whereas the C≡C group shows two distinct signals at $\delta = 94$–105 and 89–99 ppm. Finally, the sp^3 propargylic carbon resonates in the high-field region of the spectra, as expected for a metal-bound alkyl ($\delta \approx 50$ ppm).

The molecular structure of complex **2b** has been determined by single-crystal X-ray analysis (Figure 1 and Table 1). The molecule contains a terminal C(OMe)(CN)(C≡CPh) ligand bound to Fe_2{μ-CN(Me)(Xyl)}(μ-CO)(CO)$(Cp)_2$, which shows a *cis* geometry of the Cp ligands with the Xyl group placed in the opposite side of the

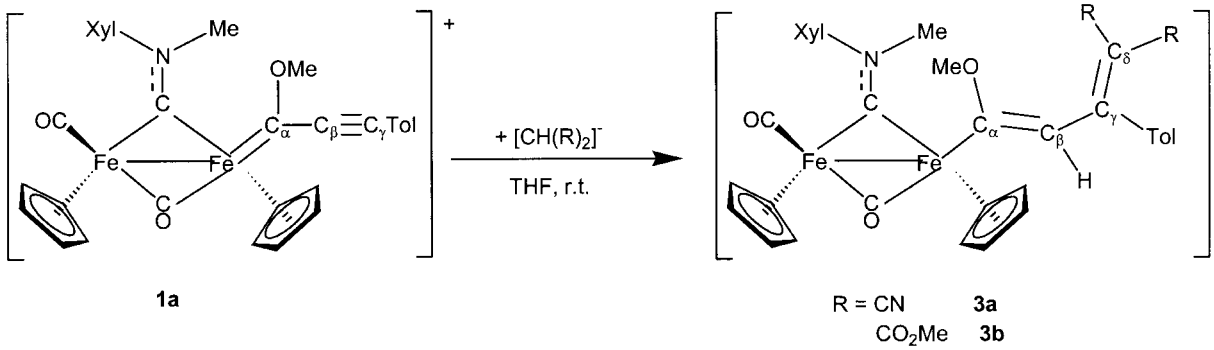

Scheme 2.

σ-propargyl, as previously found in analogous diiron and diruthenium complexes.[13,14] As in **1a**,[11] the C(13)–N(1) interaction [1.317(5) Å] suggests some double-bond character, and thus the aminocarbyne ligand can be alternatively described as a bridging iminium ion.

The bridging CO shows a marked asymmetry [Fe(1)–C(12) = 1.856(5) and Fe(2)–C(12) = 1.992(5) Å] as consequence of the different electronic properties of the terminal ligands [i.e. the σ-propargyl and CO]. Similarly, the bridging aminocarbyne is also asymmetric, although to a lesser extent [Fe(1)–C(13) = 1.839(4) and Fe(2)–C(13) = 1.897(4) Å]; an analogous behaviour has been observed previously in other diiron complexes containing bridging aminocarbyne and bridging carbonyl ligands.[12b,12c,13b,13c,15] The Fe(1)–C(23) distance [2.091(5) Å] is that of a pure Fe–C(sp^3) σ-bond and is similar to that found in the cyanomethyl complex [$Fe_2\{\mu$-$CN(Me)_2\}(\mu$-$CO)(CO)(CH_2CN)(Cp)_2$] [2.068(3) Å].[15] The propargylic nature of the ligand is indicated by the fact that the C(23)–C(26) interaction [1.470(7) Å] is a single bond whereas C(26)–C(27) [1.188(6) Å] is a triple bond; moreover, the C(23)–C(26)–C(27)–C(28) chain is almost linear [C(23)–C(26)–C(27) = 174.8(5)°; C(26)–C(27)–C(28) = 176.5(5)°]. The C(25)–N(2) interaction [1.144(6) Å] is typical for the triple bond in organic nitriles, and C(25) shows sp hybridisation [C(23)–C(25)–N(2) = 177.5(6)°].

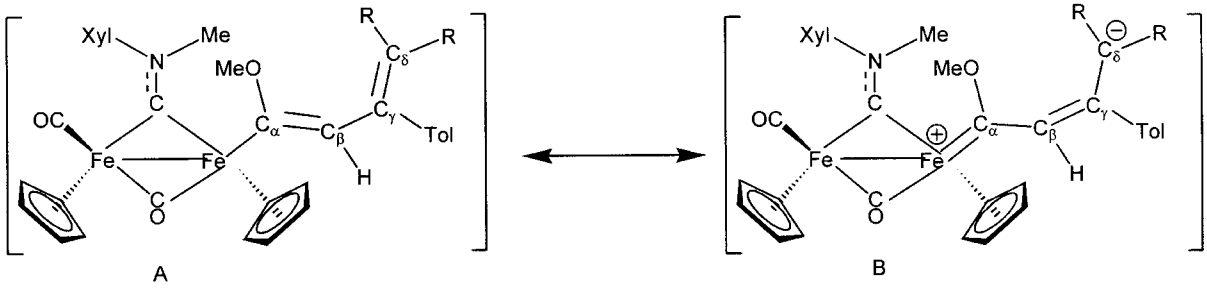

Scheme 3.

The molecular structure of **2b** indicates that cyanide addition has occurred stereoselectively from a single side of the plane containing the alkynyl(methoxy)carbene ligand, thus explaining the observed formation of a single isomer.

The addition of stabilised carbanions of the type $[CH(R)_2]^-$ (R = CN, CO_2Me) to **1a** occurs differently (Scheme 2) and results in the formation of the 1-σ-buta-1,3-dienyl complexes $[Fe_2\{\mu\text{-}CN(Me)(Xyl)\}(\mu\text{-}CO)(CO)\{C_\alpha(OMe)=C_\beta HC_\gamma(Tol)=C_\delta(R)_2\}(Cp)_2]$ (R = CN, **3a**; CO_2Me, **3b**) in good yields (60–70%). Compounds **3** have been fully characterised spectroscopically and, moreover, the crystal structure of **3a** has been determined by X-ray diffraction (Figure 2 and Table 2).

The molecule retains the $Fe_2\{\mu\text{-}CN(Me)(Xyl)\}(\mu\text{-}CO)(CO)(Cp)_2$ core present in the parent compound **1a**, to which the new terminal 1-σ-buta-1,3-dienyl ligand $C_\alpha(OMe)=C_\beta HC_\gamma(Tol)=C_\delta(CN)_2$ is bound. The almost equal C(23)–C(25) [1.413(5) Å], C(25)–C(26) [1.406(5) Å] and C(26)–C(27) [1.411(5) Å] distances indicate a strong delocalisation inside the butadienyl ligand, probably because of the presence of the strongly electron-withdrawing cyano groups. It is noteworthy that σ-butadienyl ligands usually show an alternating trend of the C–C bonds as, for example in $[Fe(Cp)(CO)_2(CH=CHCH=CHBr)]$ [1.341(4), 1.426(4) and 1.320(4) Å].[16] The delocalisation in the ligand causes some π-back-donation from the metal and, in fact, the Fe(1)–C(23) bond length [1.936(3) Å] is shorter than a pure Fe–C(sp^2) σ-interaction; for instance, 1.971(3) Å in $[Fe(Cp)(CO)_2(CH=CHCH=CHBr)]$[16] and 1.956(7) Å in the vinyl complex $[Fe_2\{\mu\text{-}CN(Me)(Xyl)\}(\mu\text{-}CO)(CO)\{C(OMe)=CHC(=NPh)(Tol)\}(Cp)_2]$.[11] For comparison, the Fe=C(carbene) distance in the parent compound **1a** is 1.849(7) Å.[11] These data suggest that the1-σ-buta-1,3-dienyl complex **3a** can be alternatively described as a zwitterionic vinyl carbene (resonance form B in Scheme 3), although the first form prevails.

From a stereochemical point of view, the C(23)=C(25) bond possesses an *E* configuration, whereas the ligand adopts an *s-cis* conformation about C(25)–C(26); the fact that the latter has a partial double-bond character also makes this conformation rigid in solution. This is fully confirmed by NOE experiments, which show a strong enhancement of the Tol protons after irradiation of H(25).

The NMR spectra of **3** show the presence of a single species in solution, therefore the reactions are completely regio- and stereoselective. The main feature of the ^1H NMR spectra is represented by the resonances at δ = 5.98 (**3a**) and 5.43 ppm (**3b**) attributable to C_β-H. The C_β and C_γ carbons of the 1-σ-buta-1,3-dienyl ligand appear at similar chemical shifts in both **3a** and **3b** [δ = 118.9 and 121.4 ppm (C_β) and 134.9 and 133–138 ppm (C_γ)], whereas the resonances of C_α and C_δ differ considerably [δ = 262.8 and 221.8 ppm (C_α) and 59.7 and 114.8 ppm (C_δ)]. The latter is directly influenced by the different substituents at C_δ, and this also has some important effects on the nature of the ligand. In fact, the low-field value of δ_{C_α} for **3a** (δ = 262.8 ppm) suggests the presence of some methoxy carbene character; for example, in the parent alkynyl(methoxy)carbene complex **1a**, we have δ_{C_α} = 281.4 ppm. Conversely, the value of δ_{C_α} for **3b** (δ = 221.8 ppm) is typical for an Fe–C(sp^2) single bond as found in σ-vinyl and σ-butadienyl complexes; for instance, the related complex $[Fe_2\{\mu\text{-}CN(Me)(Xyl)\}(\mu\text{-}CO)(CO)\{C_\alpha(OMe)=C_\beta HC_\gamma(Tol)=NPh\}(Cp)_2]$,[11] which contains a 1-σ-4-azabuta-1,3-dienyl ligand, has δ_{C_α} at δ = 204.0 ppm. This indicates that **3b** can be mainly described by the 1-σ-buta-1,3-dienyl form (A), whereas the zwitterionic form (B) becomes more important in the case of **3a**, as also indicated by its crystal structure.

The formation of **3** very likely proceeds by addition of $[CH(R)_2]^-$ to C_γ of **1a** to give a σ-allenyl intermediate, followed by hydrogen migration from C_δ to C_β (Scheme 4); an example of the latter process has been described for the formation of the zwitterionic η^3-allyl complex $[Pt\{\eta^3\text{-}CH_2C[C(CO_2Me)_2]CHPh\}(PPh_3)_2]$ from $[Pt(\eta^3\text{-}CH_2CCH)(PPh_3)_2]^+$ and $[CH(CO_2Me)_2]^-$.[17]

In order to confirm this, we studied the reaction between **1a** and $[C(Me)(CO_2Me)_2]^-$ (Scheme 5). As expected, no methyl migration is observed and, thus, the σ-allenyl complex $[Fe_2\{\mu\text{-}CN(Me)(Xyl)\}(\mu\text{-}CO)(CO)\{C_\alpha(OMe)=C_\beta=C_\gamma(Tol)C_\delta(Me)(CO_2Me)_2\}(Cp)_2]$ (**4**) can be isolated in good yield (78%).

The IR spectrum of **4** shows ν(CO) at 1963 and 1787 cm^{-1} for the terminal and bridging carbonyls, respectively, and $\nu(CO_2Me)$ at 1734 cm^{-1}. The NMR spectra indicate the presence in solution of two isomers in a 2:1 ratio, with similar but distinct resonances. This suggests that the addition of $[C(Me)(CO_2Me)_2]^-$ to **1a** is not stereoselective, but can occur on both sides of the plane containing the alkynyl(methoxy)carbene ligand (Scheme 6). Therefore, the two isomers differ only in the relative orientation of the Tol and $C_\delta(Me)(CO_2Me)_2$ substituents; in particular, in one isomer (A), the Tol group points towards the μ-

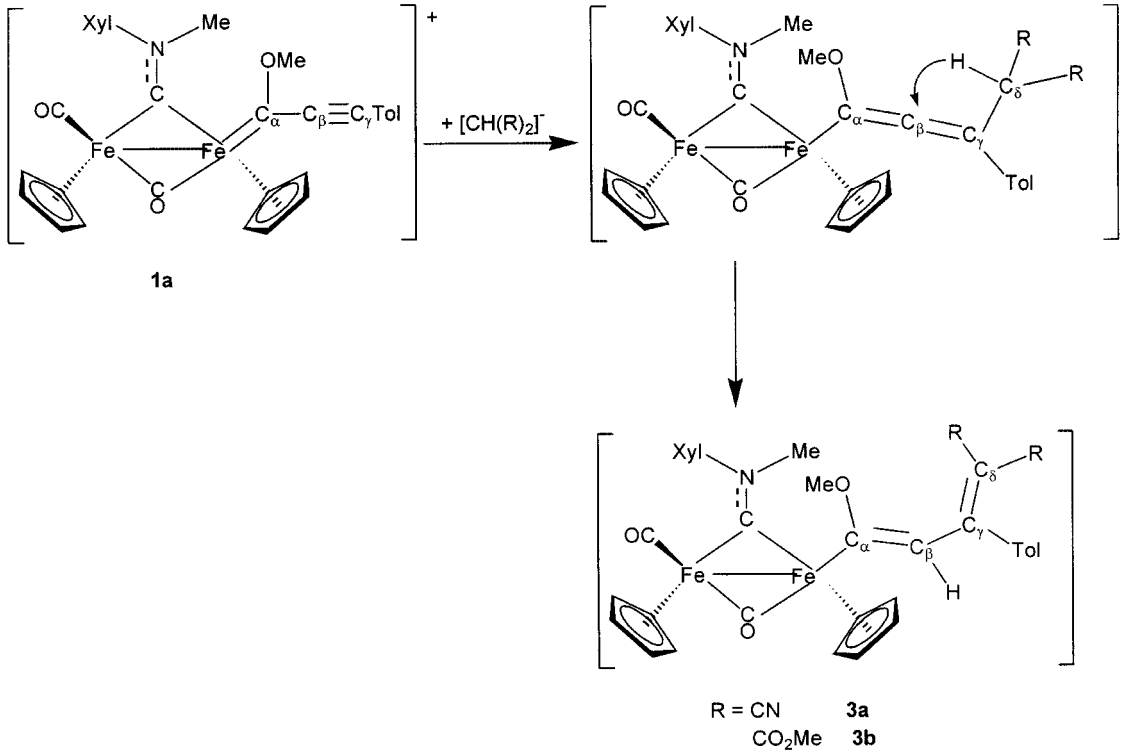
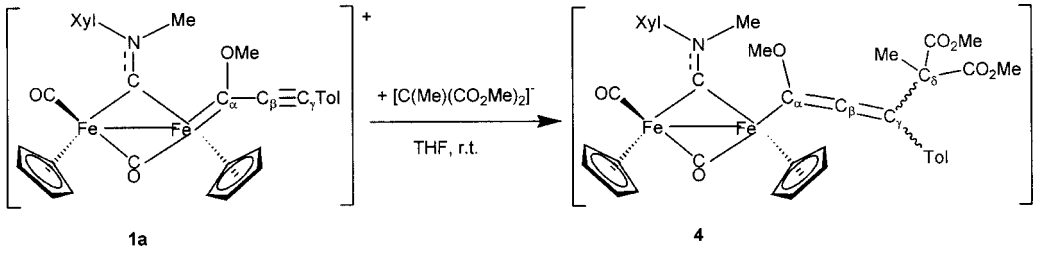
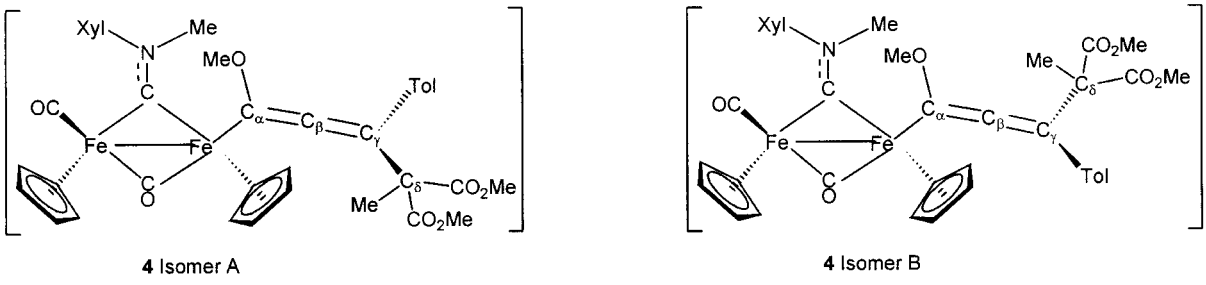


Scheme 4.



Scheme 5.

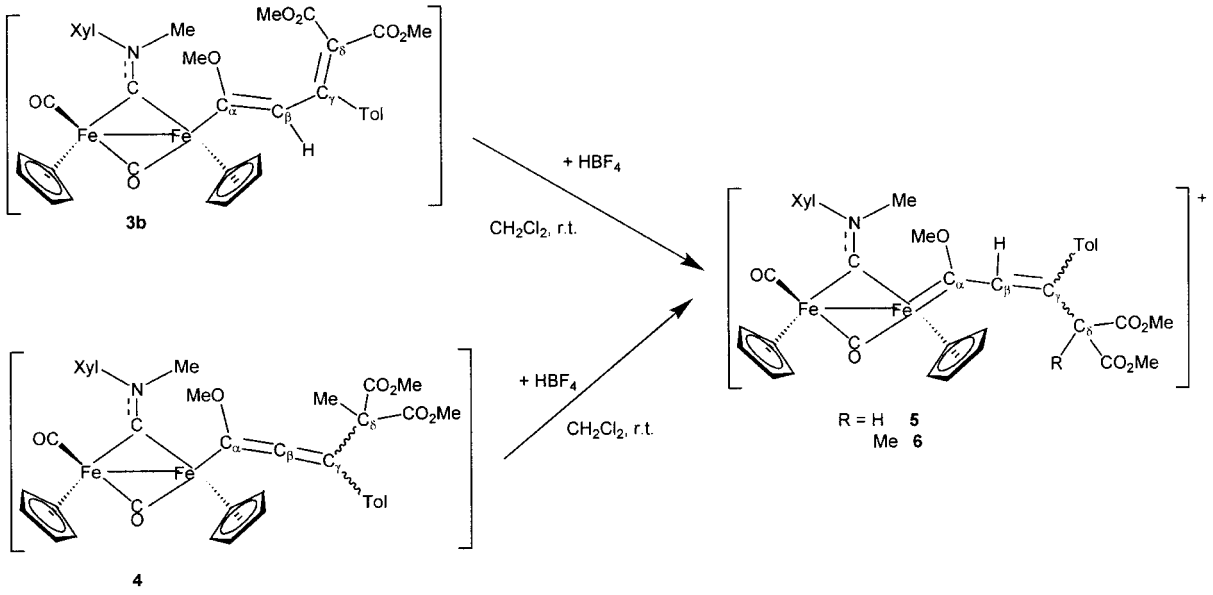


Scheme 6.

CN(Me)(Xyl) ligand, whereas in the other (B) it is directed to the same side as μ-CO.

It is quite interesting to compare this reaction with the addition of CN^- reported in Scheme 1. The latter is completely stereoselective, probably because it involves a site of the alkynyl(methoxy)carbene ligand (C_α) which is very close to the diiron core of the molecule and, thus, is sterically protected by the other ligands. Conversely, C_γ is sterically free and therefore very little control of the stereochemistry of the addition is possible. Some steric control is probably exerted also on the regiochemistry of these nucleophilic additions. In fact, the small CN^- ion can easily access C_α,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 7.

whereas the more cumbersome $[CH(R)_2]^-$ and $[C(Me)(CO_2Me)_2]^-$ add to C_γ.

The σ-allenyl ligand in **4** shows characteristic resonances in the ^{13}C NMR spectrum[18] at δ = 144–147, 195 and 104 ppm for C_α, C_β and C_γ, respectively. The aliphatic C_δ atoms resonate at $\delta \approx 59$ ppm, whereas its Me group resonates at $\delta \approx 22$ ppm.

Both complexes **3b** and **4** react quantitatively with strong acids to afford the cationic vinyl(methoxy)carbene complexes $[Fe_2\{\mu\text{-}CN(Me)(Xyl)\}(\mu\text{-}CO)(CO)\{C_\alpha(OMe)C_\beta H{=}C_\gamma(Tol)C_\delta(R)(CO_2Me)_2\}]^+$ (R = H, **5**; Me, **6**; Scheme 7). Conversely, the reaction of **3a** and **2a**–**e** with acids results in a complex mixture of decomposition products.

The regiochemistry of the protonation reactions is quite interesting as complex **3b** adds H^+ selectively at the C_δ carbon of the 1-σ-buta-1,3-dienyl ligand in order to favour the delocalisation of the positive charge along the entire ligand and the diiron frame. The same result is obtained in the case of the reaction of **4** by selective protonation of C_β.

The reactivity of σ-allenyl complexes towards nucleophiles has been widely studied, whereas data on reactions with electrophiles are quite scarce.[18] It is, however, been reported that electrophiles usually react at C_γ and not C_β. For instance, the protonation of $[Re(Cp)(NO)(PPh_3)(\sigma\text{-}CH{=}C{=}CH_2)]$ with HBF_4 results in the formation of $[Re(Cp)(NO)(PPh_3)(\eta^2\text{-}CH{\equiv}CCH_3)]^+$ by addition of H^+ to C_γ.[19] Thus, the reaction reported here represents a rare case of electrophilic attack at C_β of a σ-allenyl complex.

Complexes **5** and **6** were fully characterised spectroscopically. Their IR spectra show ν(CO) shifted by about 30 cm^{-1} towards higher frequencies with respect to the parent complexes **3b** and **4**, as expected for cationic compounds. The NMR spectra at room temperature indicate the presence of an exchange process, which can be frozen-out at 243 K. Under these conditions, two species can clearly be distinguished in solution in ratios of 1.3:1 for **5** and 1.5:1 for **6**. These were fully characterised by gs-HSQC and gs-HMBC experiments[20] at 243 K, and their stereochemistry assigned by NOE measurements conducted at 218 K to avoid saturation-transfer effects.[21] The two species are isomers which differ only in the configuration of the vinyl double bond $C_\beta{=}C_\gamma$ (Scheme 8). In both cases the major isomer is the one in which the C_β-H hydrogen is *cis* to the Tol group; because of the different nature of the substituents on C_δ, this possesses an (*E*)-configuration in **5** and a (*Z*)-configuration in **6**. Therefore, the minor isomers have the configuration (*Z*)-**5** and (*E*)-**6**. The two isomers can be easily distinguished from the ^1H chemical shift of C_β-H, which resonates at lower field in the major isomers [(*E*)-**5**: δ = 6.69 ppm; (*Z*)-**6**: δ = 6.53 ppm), than in the minor isomers [(*Z*)-**5**: δ = 6.49 ppm; (*E*)-**6**: δ = 6.24 ppm)], where it is *trans* to Tol. For example, NOE studies on **6** show that irradiation of the C_β-H resonance in the minor isomer (δ = 6.24 ppm) generates a strong enhancement of the C_δ-*Me* resonance, in agreement with the proposed (*E*)-configuration. The carbene nature of the ligand is supported by the typical ^{13}C chemical shift of C_α ($\delta \approx 315$ ppm); conversely, C_β and C_γ resonate at values characteristic of olefinic protons ($\delta \approx 140$ and 135 ppm, respectively).

The reaction of the vinyl(methoxy)carbene complex **6** with CN^- was then studied (Scheme 9). As in the case of the analogous reaction of **1**, the cyanide ion selectively adds to the carbene carbon to afford the σ-allyl complex $[Fe_2\{\mu\text{-}CN(Me)(Xyl)\}(\mu\text{-}CO)(CO)\{C_\alpha(OMe)(CN)[C_\beta H{=}C_\gamma(Tol)\text{-}C_\delta(Me)(CO_2Me)_2]\}(Cp)_2]$ (**7**) in good yield (68%). This reaction is also completely regio- and stereoselective, resulting in the formation of a single species whose spectroscopic and NOE data suggest a (*Z*)-configuration of the double bond.

Finally, the reactivity of **6** with a neutral nucleophile such as Me_2NH was considered (Scheme 10). This results in the formation of the neutral organometallic species $[Fe_2\{\mu\text{-}CN(Me)(Xyl)\}(\mu\text{-}CO)(CO)\{C_\alpha(O)C_\beta H{=}C_\gamma(Tol)C_\delta(Me)\text{-}$

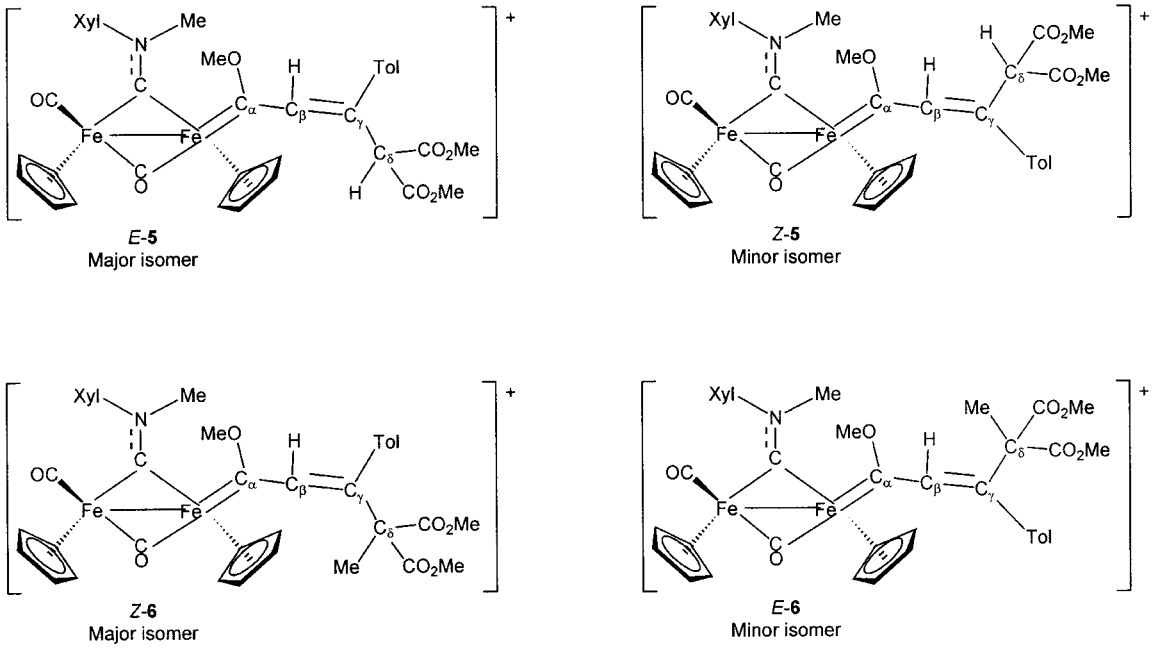
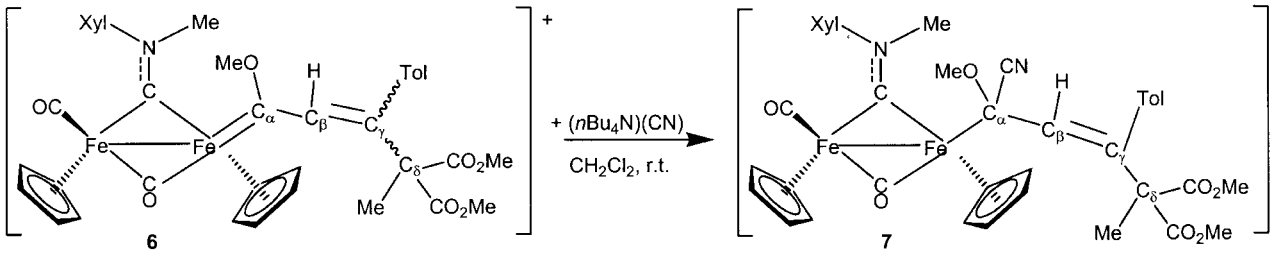
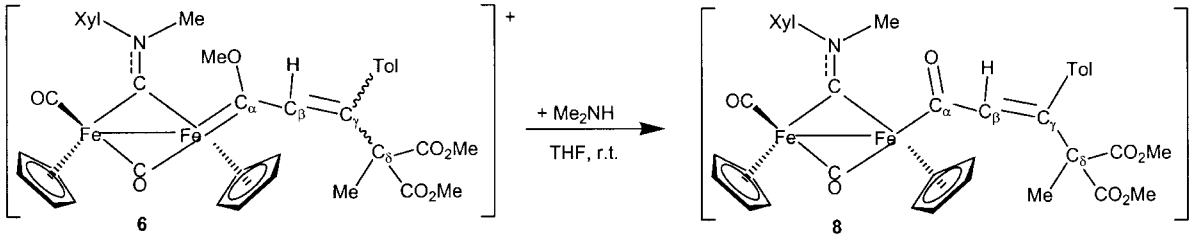


Scheme 8.



Scheme 9.



Scheme 10.

$(CO_2Me)_2\}(Cp)_2]$ (**8**), which can be recovered in good yield (76%) after column chromatography. The same species can also be obtained by direct chromatography of **6** through an Al_2O_3 column (previously treated with 4% water) with CH_2Cl_2/THF (1:1) as eluent. In the case of the reaction of **6** with Me_2NH, IR spectroscopy clearly indicates that **8** is already present in solution before chromatography. Complex **8** contains a vinylacyl ligand, as clearly indicated by its NMR spectra. In particular, the acyl carbon resonates at δ = 265.8 ppm, and the vinyl atoms show characteristic resonances (i.e. C_γ: δ = 125.6 ppm; C_β: δ = 143.3 ppm (^{13}C NMR) and C_β-H: δ = 6.45 ppm (^1H NMR). A single species is present in solution, for which, on the basis of its spectroscopic features, we can assume a (*Z*)-configuration for the double bond.

Conclusions

The results reported in this paper indicate that the alkynyl(methoxy)carbene ligand in **1** contains two different sites available for nucleophilic attack, i.e. C_α and C_γ. The regiochemistry of the reactions studied is mainly controlled by steric factors; thus, the small CN^- ion adds at C_α, whereas the bulkier $[CH(R)_2]^-$ and $[C(Me)(CO_2Me)_2]^-$ react selectively at C_γ. In the same way, it can be considered that the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

addition of amines to **1** is also mainly sterically controlled and therefore it occurs at C_γ, as observed previously.[11] Electronic factors must also be considered, and they point to the same conclusions. Thus, the hard CN^- nucleophile attacks in a 1,2 manner, accordingly to the HSAB theory, whereas the softer $[CH(R)_2]^-$ and $[C(Me)(CO_2Me)_2]^-$ anions react in a 1,4 manner.

The addition of carbanions to **1** results in the formation of new C–C bonds and, hence, different types of ligands are formed. In particular, addition at C_α generates 1,1-disubstituted σ-propargyl compounds, whereas σ-allenyl complexes are formed in the case of reaction at C_γ. The latter species can evolve further when a hydrogen is present on C_δ, resulting eventually in the formation of 1-σ-buta-1,3-dienyl complexes. All the ligands formed are terminally coordinated to the diiron frame, even though they are known to be able to act also as bridging ligands in different coordination modes.[18,22]

Finally, we have shown that the neutral complexes **3** and **4** can react with electrophiles and that the resultant cationic products can be further modified by nucleophilic additions. This represents an interesting step-by-step sequence for the building up of highly functionalised ligands in diiron species.

Experimental Section

All reactions were carried out routinely under nitrogen using standard Schlenk techniques. Solvents were distilled immediately before use under nitrogen from appropriate drying agents. Infrared spectra were recorded on a Perkin–Elmer Spectrum 2000 FT-IR spectrophotometer and elemental analyses were performed on a ThermoQuest Flash 1112 Series EA Instrument. All NMR measurements were performed on Varian Gemini 300 and Varian Mercury 400 instruments. The chemical shifts for ^1H and ^{13}C are referenced to internal TMS. The spectra were fully assigned by ^1H,^{13}C correlation measured using gs-HSQC and gs-HMBC experiments.[20] Monodimensional NOE measurements were recorded using the DPFGSE-NOE sequence.[23] All chemicals were used as received from Aldrich Co., except $[Fe_2\{\mu\text{-}CN(Me)(R)\}(\mu\text{-}CO)(CO)\{C_\alpha(OMe)C_\beta{\equiv}C_\gamma R'\}(Cp)_2][SO_3CF_3]$ (R = Xyl, R′ = Tol, **1a**; R = Xyl, R′ = Ph, **1b**; R = Xyl, R′ = Me_3Si, **1c**; R = Me, R′ = Tol, **1d**; R = Me, R′ = Ph, **1e**)[11] which were prepared by published methods. The anions $Na[CH(CN)_2]$, $Na[CH(CO_2Me)_2]$ and $Na[C(Me)(CO_2Me)_2]$ were prepared just before use by the reaction of Na with $CH_2(CN)_2$, $CH_2(CO_2Me)_2$ and $CH(Me)(CO_2Me)_2$, respectively, in THF.

Synthesis of $[Fe_2\{\mu\text{-}CN(Me)(R)\}(\mu\text{-}CO)(CO)\{C(OMe)(CN)(C{\equiv}CR'')\}(Cp)_2]$ (R = Xyl, R′ = Tol, 2a; R = Xyl, R′ = Ph, 2b; R = Xyl, R′ = Me_3Si, 2c; R = Me, R′ = Tol, 2d; R = Me, R′ = Ph, 2e): (n-Bu_4N)(CN) (110.0 mg, 0.417 mmol) was added to a solution of **1** (0.220 mmol) in CH_2Cl_2 (15 mL) and the mixture stirred at room temperature for 20 min; during this time, the solution changed from red to brown. The solvent was then removed under reduced pressure and the residue dissolved in CH_2Cl_2 (5 mL) and chromatographed through Al_2O_3. The final product was obtained as a brown fraction using CH_2Cl_2 as eluent.

IR (CH_2Cl_2, 293 K): $\tilde{\nu}$ = 1965(vs) (CO), 1774(s) (μ-CO), 1733(s) cm^{-1} (CO_2Me).

X-ray Crystallographic Study: Compounds **2b** and **3a**·CH_2Cl_2 were crystallised from CH_2Cl_2/pentane. Crystal data and collection details are reported in Table 3. The diffraction experiments were carried out on a Bruker SMART 2000 diffractometer equipped with a CCD detector using Mo-K_α radiation. Data were corrected for Lorentz polarisation and absorption effects (empirical absorption correction SADABS).[24] Structures were solved by direct methods and refined by full-matrix least-squares based on all data using F^2.[25] Hydrogen atoms were fixed at calculated positions and refined by a riding model. All non-hydrogen atoms were refined with anisotropic displacement parameters, unless otherwise stated. One Cp ligand in **2b** is disordered. Disordered atomic positions were split and refined isotropically using similar distance and similar U restraints and one occupancy parameter per disordered group. CCDC-261569 (for **2b**) and CCDC-261570 (for **3a**·CH_2Cl_2) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Acknowledgments

We thank the Ministero dell'Università e della Ricerca Scientifica e Tecnologica (MIUR) (project: "New strategies for the control of reactions: interactions of molecular fragments with metallic sites in unconventional species") and the University of Bologna ("Funds for Selected Research Topics") for financial support. We also thank one of the referees for useful suggestions.

Towards Molecular Conductors with a Spin-Crossover Phenomenon: Crystal Structures, Magnetic Properties and Mössbauer Spectra of [Fe(salten)Mepepy][M(dmit)$_2$] Complexes

Christophe Faulmann,*[a] Stéphane Dorbes,[a] Bénédicte Garreau de Bonneval,[a] Gábor Molnár,[a] Azzedine Bousseksou,[a] Carlos J. Gomez-Garcia,[b] Eugenio Coronado,[b] and Lydie Valade[a]

Keywords: Conducting materials / Magnetic properties / Moessbauer spectroscopy / Spin crossover / X-ray diffraction

Three new iron(III) compounds of formula [Fe(salten)-Mepepy][M(dmit)$_2$]·CH_3CN (M = Ni, Pd, Pt; H_2salten = 4-aza-heptamethylene-1,7-bis(salicylideneiminate); Mepepy = 1-(pyridin-4-yl)-2-(*N*-methylpyrrol-2-yl) ethane; dmit^{2-} = 1,3-dithiole-2-thione-4,5-dithiolato) have been synthesised and the crystal structure of each compound has been solved at different temperatures. The structures consist of alternating layers of [M(dmit)$_2$]$^-$ units and [Fe(salten)Mepepy] cations. In the Ni compound photo-isomerisation of the Mepepy ligand can be observed in dichloromethane solution. The temperature dependence of the magnetic susceptibility of the compounds reveals a gradual $S = 5/2 \rightleftharpoons S = 1/2$ spin crossover of the Fe^{III} ions. This phenomenon is confirmed by Mössbauer spectroscopy for the Ni compound, which also reveals a magnetic component at 4.5 K with a hyperfine magnetic field, H_i, of 442(3) Oe. Theoretical analysis of the thermal variation of the high-spin proportion allows us to calculate the thermodynamical parameters of the spin-crossover behaviour in this compound: energy-gap (Δ) = 1536 cm^{-1}, entropy change (ΔS) = 33 J K^{-1} mol^{-1} and a cooperative interaction, J, of 0 cm^{-1} (non-cooperative spin crossover). The fractional oxidation state complex [Fe(salten)Mepepy][Ni(dmit)$_2$]$_3$ has been obtained after electrooxidation of [Fe(salten)Mepepy]-[Ni(dmit)$_2$] in acetonitrile. It exhibits a gradual spin conversion coupled with antiferromagnetic interactions. Its room temperature electrical conductivity is 0.1 S cm^{-1}.

Introduction

Since the discovery of the organic metal TTF–TCNQ (TTF = tetrathiafulvalene; TCNQ = tetracyanoethylene) much work has been devoted to the research of new conducting systems involving either donor–acceptor complexes or fractional oxidation-state compounds. These studies resulted in the discovery of several superconductors [derived, for example, from the BEDT-TTF molecule[1] (BEDT-TTF = bis(ethylenedithio)tetrathiafulvalene) or from the M(dmit)$_2$ complex[2] (dmit^{2-} = 1,3-dithiole-2-thione-4,5-dithiolato)]. In addition, these compounds are also now being used in a new area of research by a few groups, which consists in designing hybrid materials with a combination of different physical properties such as conductivity and magnetism,[3] conductivity and optical activity,[4] or magnetism and non-linear optics.[5] The possibilities offered by this hybrid approach in the field of the molecular conductors have been highlighted very recently.[6] In this kind of materials one might either just observe coexistence between these two properties, or an interplay due to a mutual interaction between the two effects. A good example of the coexistence of properties is found in the salt β′′-(BEDT-TTF)$_4$-[Fe(ox)$_3$](H_3O)·C_6H_5CN (ox = oxalate), reported by Day and co-workers,[7] which is the first example of a paramagnetic superconductor. An interplay between conductivity and magnetism has been observed, for example, in BETS-derived complexes [BETS = bis(ethylenedithio)tetraselenafulvalene].[8] Thus, λ-[(BETS)$_2$FeCl$_4$] undergoes a metal–insulator transition at 8 K and becomes metallic again below this temperature when a magnetic field of 10 T is applied.[9] Recently, Coronado et al.[10,11] succeeded in obtaining (BEDT-TTF)$_3$[MnCr(ox)$_3$](CH_2Cl_2) and (BETS)$_3$[MnCr(ox)$_3$]-(CH_2Cl_2), which exhibit the coexistence of conductivity and ferromagnetism.

In the above-discussed complexes, each property is carried by a distinct network: the organic part is at the origin of the conductivity, due to a charge transfer or a partial oxidation state of the organic donor, whereas the inorganic part is involved in the magnetic properties. In such compounds, observation of an interplay between the properties will depend on eventual interactions between the two networks. These electronic interactions can be favoured by short contacts and/or hydrogen bonding between the ade-

quate molecules, although the occurrence of the desired interplay is still not controllable. An attractive way of increasing the π–d interactions between the two networks consists of connecting them by covalent linkages. This has been attempted by Ouahab and co-workers in $[Cu(hfac)_2(TTF\text{-}py)_2](PF_6)\cdot 2CH_2Cl_2$[12] [hfac = hexafluoroacetylacetonate and TTF-py = 4-(2-tetrathiafulvalenylethenyl)pyridine], by connecting TTF to the Cu^{II} complex by unsaturated bonds and rings. So far, however, this approach has led to molecular compounds with very poor conducting properties and lack of magnetic properties of interest.

Some of us have also been interested in combining conductivity and magnetism by using metallocenium and $M(dmit)_2$ complexes.[13] Despite the interesting magnetic properties observed in $(Cp^*_2Mn)[Ni(dmit)_2]$, no fractional oxidation-state compound has been obtained with metallocenium and, consequently, the compound is an insulator. Another way of introducing a magnetic component into $M(dmit)_2$ complexes is to use spin-crossover cations. Spin crossover (abbreviated as SCO) in certain transition metal complexes has been known for a long time and has been well described and studied by several authors.[14] From the perspective of the present work, it should be noted that a slight modification in the ligand or in the nature of the solvent might result in a change of the value of the transition temperature, or even in the vanishing of the SCO phenomenon.

The ultimate goal of this work is to obtain a molecular conductor, and consequently a complex in a fractional oxidation state, that exhibits a spin crossover in such a way that the bistability of this magnetic switch may affect the conducting properties of the material. The choice of the starting SCO complex is crucial in the sense that it must not lose its magnetic properties when combined with the $M(dmit)_2$ complex. It must also not decompose or undergo any transformation during the oxidation process necessary to obtain the fractional oxidation state of the complex. In this context, Fe^{III} complexes seem promising as their oxidation state should not change during the synthesis of the fractional oxidation-state complex.

Several Fe^{III} complexes displaying SCO have already been described (see ref.[15] for a comprehensive review). In six-coordinate Fe^{III} systems an $S = 1/2 \leftrightharpoons S = 5/2$ conversion was observed in most cases. In these Fe^{III} SCO complexes, similar to the "benchmark" Fe^{II} complexes, the LS to HS spin-state change is accompanied by an increase of the metal–ligand distances ($\Delta r \approx 8$–15%). However, the average bond length change is significantly smaller in the case of Fe^{III} ions ($\Delta r \approx 5\%$) than for Fe^{II}. Due to this fact, the rate of interconversion of spin states is, in general, faster in Fe^{III} systems to such an extent that in many instances the ^{57}Fe Mössbauer spectra do not show separate HS and LS contributions. It is mainly for this reason that, in contrast to Fe^{II} compounds, a light-induced spin-state trapping (LIESST) effect is rarely observed in Fe^{III} complexes.[16–18] Furthermore, the majority of Fe^{III} SCO complexes display a gradual spin-state change as a function of temperature, while abrupt transitions with thermal hysteresis have been reported in only a few cases.[19–25] Although in a less straightforward way, this tendency may also be related to the smaller bond length changes in Fe^{III} complexes, given that the lattice expansion is a major ingredient for the cooperative interactions (elastic interactions) determining the gradual/abrupt nature of the spin-transition curves.[26]

For another attempt to obtain SCO properties in a molecular conductor (see ref.[19] for the first attempt), we chose the SCO complex [Fe(salten)Mepepy](BPh_4), previously reported by Sour et al.[27] [H_2salten = 4-azaheptamethylene-1,7-bis(salicylideneiminate); Mepepy = 1-(pyridin-4-yl)-2-(*N*-methylpyrrol-2-yl) ethane]. This Fe^{III} complex exhibits a gradual, thermally induced SCO.[27] Moreover, it also undergoes a partial photoinduced spin-state change in solution due to the photoisomerizable ligand Mepepy. Such a physical property might also play a role in the electrical properties of the final compound.

In this paper, we report the synthesis and X-ray characterisation of three new iron(III) compounds of formula [Fe(salten)Mepepy][$Ni(dmit)_2$] and [Fe(salten)Mepepy]-[$M(dmit)_2$]·CH_3CN (M = Pd, Pt), together with magnetic, spectroscopic and Mössbauer studies of the Ni derivative.

Results and Discussion

Description of the Structures

To the best of our knowledge this is the first time that the structure of complexes containing the Fe(salten)-(Mepepy) unit has been reported. The triclinic unit cell of each compound contains one $M(dmit)_2$ unit and one Fe(salten)(Mepepy) unit, with one acetonitrile molecule for the Pd and Pt complexes only (Figure 1).[28] Selected crystallographic data for every compound are reported in the Experimental Section (general crystallographic data can be found in the Supporting Information, Table S1).

Considering the cell parameters, the cell volume decreases upon lowering the temperature for every compound (see Table 1). For the Pd and Pt complexes, this decrease is accompanied by a decrease of the value for all parameters except the angles β and γ, whose values increase slightly. The Ni complex exhibits other features: only the β value increases when lowering the temperature, although the b and a values first decrease (from 295 to 240 K), and then increase again down to 100 K.

The intramolecular distances and angles within the $M(dmit)_2$ units are similar to those observed in other monoanionic $M(dmit)_2$ complexes.[29] In every complex, the Fe atom is in an octahedral environment, with the two oxygen atoms in a *trans* configuration. The two largest bond lengths around Fe are Fe–N21 and Fe–N32; the two shortest are Fe–O11 and Fe–O12. Thus, the [FeO_2N_4] octahedron can be regarded as axially elongated along the N32–Fe–N21 direction or axially compressed along the O11–Fe–O12 direction. The Mepepy fragment is not planar due to a slight distortion around the central C=C ethene bond:

the dihedral angle of C35–C38–C39–C40 ranges between 173.62(45)° (Ni, 100 K) and –179.90(41)° (Pd, 160 K; see Figure 2 and Table 2).

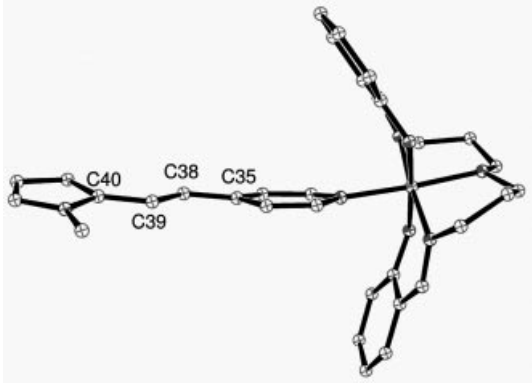

Figure 2. View of the [Fe(salten)Mepepy]$^+$ cation showing the non-planarity of the Mepepy part.

Table 2. Dihedral angle around C35–C38–C39–C40 and angle between the pyridine ring and the methylpyrrole ring in **1**, **2** and **3** at various temperatures.

		295 K	240 K	160 K	100 K

C35–C38–C39–C40	Pd	179.6(5)	179.7(4)	–179.9(4)	–179.4(4)
	Pt	178.8(6)	178.6(8)	179.1(6)	179.6(53)
Angle between the pyridine ring	Ni	10.7(7)	11.0(5)	12.0(5)	11.4(4)
and the methylpyrrole ring	Pd	14.0(4)	14.3(4)	14.3(4)	14.5(3)
	Pt	12.7(5)	12.9(6)	13.0(5)	13.4(4)

Three different temperature effects are observed for each complex: for the Ni complex, lowering the temperature induces a decrease of this torsion angle [from 176.0(8)° to 173.6(5)°], whereas it increases in the Pt complex [from 178.8(6)° to 179.6(5)°]. For the Pd complex, a rocking motion is observed from 179.6(5)° to –179.4(4)°. These variations in the dihedral angle around the central C=C bond also induce a non-planarity between the two rings of the Mepepy fragment. The angle between the pyridine ring and the methylpyrrole ring ranges between 10.7(7)° (Ni, 295 K) and 14.5(3)° (Pd, 100 K; see Table 2). Whatever the complex, this angle always increases when the temperature is lowered. In regard to the latter two parameters (dihedral angle and inter-planar angle), the largest deviations are observed for the Ni complex.

The bond lengths around Fe also decrease when lowering the temperature (see Table 3). The bonds Fe–N32 and Fe–N11 are the most sensitive to the temperature: they exhibit variations up to around –3.2% between 295 K and 100 K (for the Pt complex, bond Fe–N32). For every complex, a decrease of the temperature tends to reduce the gap between the different bond lengths: indeed, since the longest bond lengths are subject to the largest decrease, this induces a more regular distribution of the bond lengths around the Fe atom.

Depending on the temperature, the twelve angles subtended at the Fe atom do not vary similarly as some decrease whereas others increase. A noticeable point is the following: whatever the complex, the O11–Fe–N12 and N12–Fe–N32 angles decrease down to around –2.5% and the O11–Fe–N11 angle increases by up to about 2.0% when compared to their value at room temperature. The Pd complex is the one for which there are the smallest variations in the values of distances and angles around the Fe atom.

Deformations of the octahedron around Fe can be estimated from the angles between the three equatorial planes defined by the six Fe-coordinating atoms, together with the deviation of the central Fe atom from these planes. These planes are almost orthogonal to each other, as reflected by the values all larger than 88° (Table S2 in the Supporting Information), and the Fe atom always lies very close to these planes (max. deviation of 0.024 Å). The angles between the eight opposite faces of the octahedron around Fe also define its deformation: at room temperature, these values lie between 3.99° and 6.31°, thus indicating that the faces are not parallel (Table S2 in the Supporting Infor-

mation). In most cases a decrease of the temperature tends to reduce these angles (up to –3.23° for the Ni complex). These features, together with those discussed above, clearly show that the distorted octahedral environment around Fe tends to become more and more regular as well as more compact upon decreasing the temperature.

The structure can also be viewed as layers of iron complexes together with acetonitrile, separated from each other by layers of $M(dmit)_2$ units (Figure 3).

Each layer spreads out almost in the $(01\bar{1})$ plane. There are several short intermolecular contacts (around the sum of the van der Waals radii) within each layer. Within the $M(dmit)_2$ layers, short intermolecular contacts below 3.7 Å involve parallel $M(dmit)_2$ units connected through S–S interactions (Figure 3). Depending on M and the temperature, the units are connected through 1, 3, 5 or 7 contacts (≤3.7 Å) between S atoms. For a given M, the lower the temperature the larger the number of contacts (see Supporting Information, Table S3).

In addition, there are also some short intermolecular contacts (interatomic distances ≤ sum of the van der Waals radii[30]) between the sheets of $M(dmit)_2$ units and the layer of iron complexes and solvent (see Supporting Information, Table S4).

There is no contact between the acetonitrile and $M(dmit)_2$ units, whatever M is. Acetonitrile, if present, is connected through short contacts (see Supporting Information, Table S5) to the Fe units only.

The iron complexes are also connected to each other through several short contacts (see Supporting Information, Table S6), but no real hydrogen bonds exist. As for the interactions between the $M(dmit)_2$ units, the lower the temperature the larger the number of contacts between the various components of these compounds.

UV/Vis Spectroscopy and Light Irradiation Effects

The UV/Vis absorption spectrum of [Fe(salten)Mepepy](BPh$_4$) in CH_2Cl_2 is shown in Figure 4. It shows two strong and broad absorption bands (λ = 370 nm, ε = 17757 $M^{-1}cm^{-1}$; λ = 401 nm, ε = 16656 $M^{-1}cm^{-1}$) and a very weak band (λ = 486 nm, ε = 4803 $M^{-1}cm^{-1}$). This latter is due to a ligand-to-metal charge transfer (LMCT).[27] Whereas only one band (λ = 375 nm) is observed in CH_3CN,[27] the splitting and broadening of this transition in CH_2Cl_2 is probably due to solvent effects (smaller polarity of CH_2Cl_2 compared with CH_3CN), which change the energy of the electronic transitions and induce bathochromic and hypsochromic shifts. Nevertheless, the transitions at 370 and 401 nm can be assigned to a ligand-centred $\pi\rightarrow\pi^*$ transition similar to that observed in CH_3CN.[27] Upon irradiation, these transitions are slightly blue-shifted (from 371 to 364 nm, and from 401 to 397 nm), and their intensities are significantly decreased (from 17757 to 11667 $M^{-1}cm^{-1}$, and from 16656 to 11109 $M^{-1}cm^{-1}$). As in CH_3CN, the LMCT transition at 486 nm is not affected by light.[27] From this study on the starting [Fe(salten)Mepepy](BPh$_4$) salt, it can be concluded that this complex also undergoes a *trans* to *cis* isomerisation of the Mepepy ligand in CH_2Cl_2.

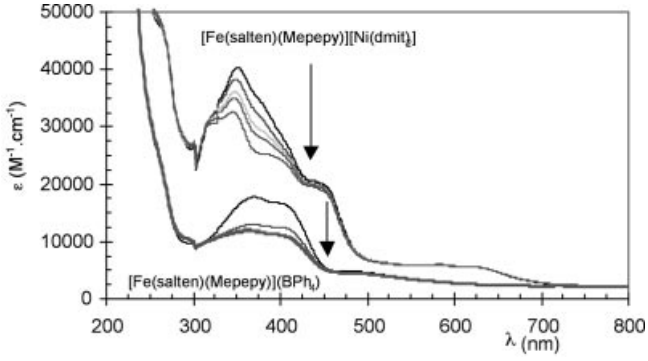

Figure 4. UV/Vis spectra and evolution upon irradiation of [Fe(salten)Mepepy](BPh$_4$) (lower curves) and [Fe(salten)Mepepy][Ni(dmit)$_2$ (upper curves) in CH_2Cl_2. Arrows indicate decrease of the intensity of the transitions upon irradiation.

The effect of light was then studied for the [Fe(salten)Mepepy][Ni(dmit)$_2$] complex in solution. The UV/Vis spectrum of this complex exhibits several absorption peaks. The main absorption band lies around 351 nm (ε = 40288 $M^{-1}cm^{-1}$) and contains several shoulders at shorter and longer wavelengths. This broad peak is the superposition of several transitions within the $[Ni(dmit)_2]^-$ unit ($\pi\rightarrow\pi^*$ and MLCT transitions[31]) and includes the transitions previously observed in the starting salt [Fe(salten)Mepepy](BPh$_4$). A satellite band is observed at 443 nm ($\pi\rightarrow\pi^*$, $\varepsilon \approx$ 20412 $M^{-1}cm^{-1}$) and two weaker bands at 582 nm ($n_S\rightarrow\pi^*$[31]) and 620 nm (with $\varepsilon \approx$ 6000 and 5600 $M^{-1}cm^{-1}$, respectively), attributed to MLCT transitions.[32] Irradiation results in a blue shift of the most important absorption (from 351 to 345 nm), accompanied by a decrease of ε = 32407 $M^{-1}cm^{-1}$. The shoulders also become more pronounced, and one is clearly visible at 385 nm (ε = 24992 $M^{-1}cm^{-1}$). The bands at 443, 582 and 620 nm are unaffected by irradiation. The absorption at 385 nm can be attributed to the ligand-centred $\pi\rightarrow\pi^*$ transition {initially at 370 nm in the starting salt [Fe(salten)Mepepy](BPh$_4$)}. Upon irradiation, this transition exhibits a decrease of around 25% of its intensity. The parallel evolution of the starting salt [Fe(salten)Mepepy](BPh$_4$) and [Fe(salten)Mepepy][Ni(dmit)$_2$] suggests that the $[Fe(salten)Mepepy]^+$ unit also undergoes an isomerisation in solution when associated with the $[Ni(dmit)_2]^-$ unit.

Raman Studies of the [Fe(salten)Mepepy]-Based Complexes

It is possible to evaluate the charge transfer in complexes containing $[Ni(dmit)_2]^{n-}$ units (in an entire or fractional oxidation state) by Raman spectroscopy.[33] The Raman spectrum of [Fe(salten)Mepepy][Ni(dmit)$_2$] is shown in Figure 5a. The lines at 599, 1435 and 1598 cm^{-1} were assigned to the Fe(salten) fragment in comparison with the spectra of [Fe(salten)]Cl (see Figure S2, Supporting Information). The lines at 134, 338, 357, 508, 1051 and 1395 cm^{-1} were assigned to the $[Ni(dmit)_2]^-$ unit by comparison with literature data,[33] and confirm that the charge transfer, ρ, is equal

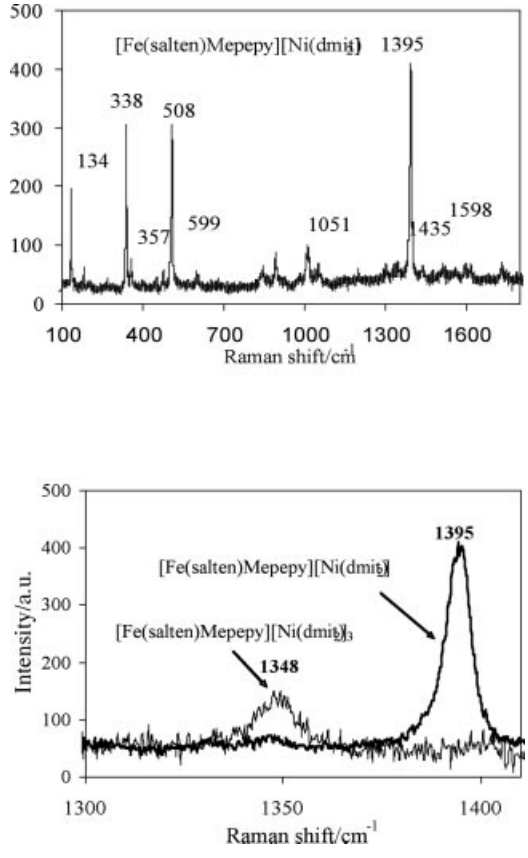

Figure 5. Raman spectra of a single crystal of [Fe(salten)Mepepy][Ni(dmit)$_2$] (top) and [Fe(salten)Mepepy][Ni(dmit)$_2$]$_3$ (bottom).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

to 1. In [Fe(salten)Mepepy][Ni(dmit)$_2$] the band at 1395 cm^{-1} is due to the C=C bond stretching mode. In [Fe(salten)Mepepy][Ni(dmit)$_2$]$_x$, this line (Figure 5b) is found at 1348 cm^{-1}. This band, whose position is very sensitive to the amount of charge transfer, allows us to determine a ρ value of around 0.3. The others lines of this spectrum are due to the Ni(dmit)$_2$ fragment and are in agreement with this ratio (Table S7, Supporting Information).

Magnetic Properties of Non-Fractional Oxidation State Complexes

For the Ni and Pt complexes (Figure 6), the temperature dependence of the $\chi_M T$ product shows a rapid but gradual decrease down to about 235 K, followed by a slightly descending plateau down to 2 K, with a slope about 10 times smaller than in the previous region and with a $\chi_M T$ product close to 0.9 cm^3 K mol^{-1} (χ_M = molar magnetic susceptibility).

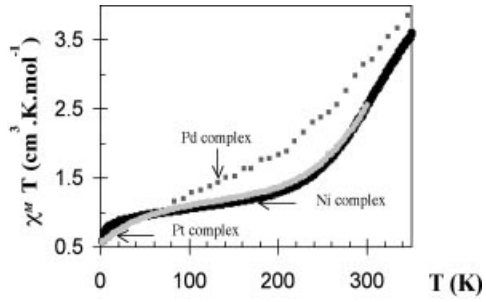

Figure 6. Variations of $\chi_M T$ as a function of the temperature for **1**, **2** and **3**.

For the Ni complex the magnetic properties are the same with or without acetonitrile in the complex (see Supporting Information, Figure S1). The Pd complex, which has been measured only between 80 and 350 K, exhibits almost similar behaviour, but with a smaller change in the slope at around 210 K. No plateau is observed down to 80 K. The behaviours of the Ni and Pt complexes are very close and similar to that observed for the starting iron salt [Fe(salten)-Mepepy](BPh$_4$).[27] For a given complex, the magnetic behaviour in the warming and cooling modes does not show any detectable thermal hysteresis loop. The 1:1 stoichiometry of the complexes [Fe(salten)Mepepy][M(dmit)$_2$] (M = Ni, Pd, Pt)} shows they are built on the association of an Fe^{III} complex with a formally M^{III} complex with S = 1/2.

Neglecting any magnetic interaction between Fe^{III} and M^{III}, as well as the orbital contributions, the expected "spin-only" value of $\chi_M T$ is equal to 4.38 cm^3 K mol^{-1} for Fe^{III} ions in the high-spin (HS) state (S = 5/2) and 0.37 cm^3 K mol^{-1} for both the M^{III} ions and the Fe^{III} ions in the low-spin (LS) state (S = 1/2). At the highest temperatures of the measurements, the experimental values are about 3.5 cm^3 K mol^{-1}, which are clearly below the expected values (ca. 4.8 cm^3 K mol^{-1}). In the low-temperature regime the experimental plateau is above the expected value (ca. 1.0 cm^3 K mol^{-1} compared to 0.74 cm^3 K mol^{-1}). These observations indicate that the spin transition is incomplete both at low and at high temperatures, i.e. at 350 K a fraction of Fe^{III} ions is still in the LS form, while there is a residual HS fraction even at the lowest temperatures, as confirmed by the Mössbauer data (see below).

Fitting the temperature dependence of the HS fraction (curve not shown) with the well-known Ising-like model[34–36] leads to the thermodynamic parameters of the spin crossover in this compound: an energy gap between the HS and LS levels, Δ, of 1536 cm^{-1} and a reasonable entropy change upon the spin crossover of ΔS = 33 J K^{-1} mol^{-1}. The fitting also leads to a very weak cooperative interaction ($J \approx 0$ cm^{-1}), in accordance with a non-cooperative system.

In summary, these results clearly show that the spin conversion is maintained in the Fe complex, even after the substitution of the BPh$_4^-$ anion by the [M(dmit)$_2$]$^-$ anion. This latter seems, therefore, to have a "neutral" effect on the magnetic properties of the [Fe(salten)Mepepy]$^+$ complex, whereas it has a "positive" effect when combined with [Fe(sal$_2$trien)]$^+$ (appearance of a strong cooperativity and a hysteresis loop, never observed before in this family of SCO complexes).[19]

Magnetic Properties of the Fractional Oxidation State Complex

A plot of the $\chi_M T$ product vs. temperature is shown in Figure S3 (Supporting Information). $\chi_M T$ is equal to 1.47 cm^3 K mol^{-1} at room temperature, and decreases almost linearly down to a value of 0.04 cm^3 K mol^{-1} at 2 K. Such a behaviour can be explained by a gradual spin conversion of the [Fe(salten)Mepepy]$^+$ unit from the HS state to the LS state, coupled to an antiferromagnetic interaction between the two components, which leads at low temperature to a non-magnetic ground spin state. This explanation is in agreement with a lack of magnetisation at 2 K (see Figure S4 in the Supporting Information).

Mössbauer studies were not possible in the present case because of the small amount of sample available (0.8 mg). For the same reason, room temperature electrical conductivity was only measured on the powder by the two-probes method. A value as large as 0.1 S cm^{-1} was obtained, which is indicative of the presence of a significant electron delocalisation in this compound.

Mössbauer Spectroscopy

The ^{57}Fe Mössbauer spectra of [Fe(salten)Mepepy]-[Ni(dmit)$_2$] were recorded between 4.5 K and 330 K. Figure 7 show selected spectra obtained in the cooling mode. The fitted Mössbauer parameters at each temperature are given in Table 4.

[a] δ = isomer shift; ΔE_Q = quadrupole splitting; $\Gamma/2$ = half-height width of the line; A_{HS}/A_{tot} = area ratio. [b] Error bars are given in parentheses; isomer-shift values refer to metallic iron at room temperature. Between 80 and 330 K both components were fitted with the same linewidth.

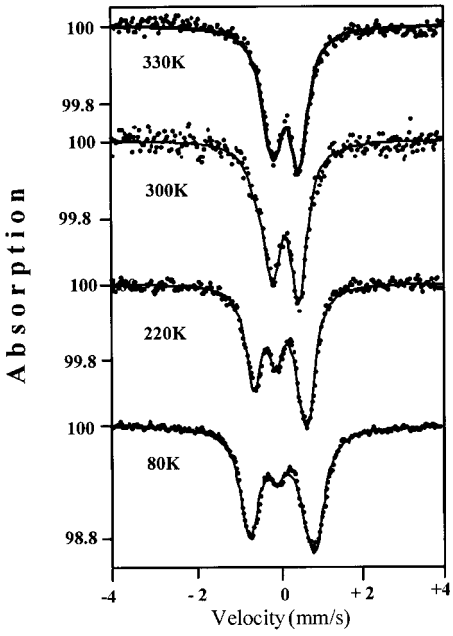

Figure 7. Selected Mössbauer spectra of [Fe(salten)Mepepy][Ni(dmit)$_2$] obtained in the cooling mode between 330 and 80 K. The solid lines represent fitted curves.

At 330 K, the spectrum for [Fe(salten)Mepepy][Ni(dmit)$_2$] consists chiefly (80%) of one component with isomer-shift and quadrupole-splitting values characteristic of HS Fe^{III}. The ratio of the LS component increases gradually with decreasing temperature. This component is characterised by somewhat larger isomer-shift and quadrupole-splitting values. It is important to note that, in contrast to the first doublet, this second spectrum exhibits almost no temperature dependence of the quadrupole splitting. Taking into account that in the ^{6}S configuration of Fe^{III} no low-lying excited levels are expected and its $^2T_{2g}$ configuration shows an appreciable thermal population of close-lying excited levels when slightly distorted, the low-temperature main doublet (76%) can be assigned unambiguously to a low-spin Fe^{III} species and the high-temperature main doublet (78%) corresponds to a high-spin Fe^{III} species. The distinct spectra obtained for the two spin-states indicate that the spin interconversion rates are slow compared to the hyperfine frequencies of Mössbauer spectroscopy (ca. 10^{-7}–10^{-8} s^{-1}]). The area ratio A_{HS}/A_{tot}, which is in a first approximation proportional to the HS fraction, decreases gradually from 330 K (≈78%) to 80 K (≈24%). It must be emphasised that the Mössbauer data were collected for the same sample that was studied with magnetic susceptibility. In spite of this, the HS fraction that can be deduced from the Mössbauer spectra (Table 4) and magnetic susceptibility data (Figures 6 and 7) are slightly different, especially in the high-temperature region (300 and 330 K). Among the reasons for this discrepancy one should note that the magnetic data are difficult to convert into HS fractions since the susceptibilities of the pure HS and LS species are not known. Furthermore, the high-temperature Mössbauer spectra are not sufficiently resolved (due to the close isomer-shift and quadrupole-splitting values of Fe^{III} in both states) and therefore there is a large uncertainty in the fits. On the whole, however, the Mössbauer data clearly confirm the gradual and incomplete $S = 1/2 \leftrightharpoons S = 5/2$ spin crossover of Fe^{III} species in [Fe(salten)Mepepy][Ni(dmit)$_2$].

Upon further cooling to 4.5 K a magnetic hyperfine splitting appears. The spectrum (Figure 8) shows that only the quadrupolar doublet corresponding to the residual HS fraction is converted into a magnetic hyperfine Mössbauer splitting.

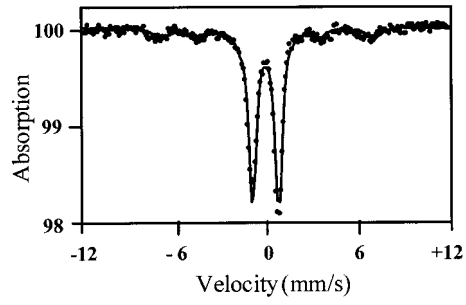

Figure 8. Mössbauer spectrum of [Fe(salten)Mepepy][Ni(dmit)$_2$] at 4.5 K. The solid line represents the fitted curve with both quadrupolar and magnetic components.

The spectrum was fitted by an axial hyperfine magnetic field parallel to the principal axis of the electric field gradient (EFG). The fit shows unambiguously that the principal EFG component is negative. In addition, the corresponding

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

hyperfine magnetic field, H_i, was evaluated to be 430 kOe. This value falls in the range expected for HS Fe^{III}.[37] The magnetic component of the spectrum was fitted with quite a large line-width [$\Gamma/2 = 0.51(8)$ mm s^{-1}], thus indicating the presence of some magnetic relaxation in the system. It should be noted, however, that the H_i value obtained here (430 kOe) is somewhat smaller than what can be expected from the $220<S_z>$ rule, which leads to a theoretical value of $H_i = 550$ kOe. This is due to the fact that the magnetic ordering at 4.5 K is not totally achieved and needs a lower temperature to be complete, in good agreement with the observation of the broadening of the linewidth at this temperature. One can attribute this magnetic splitting at 5 K either to a slow paramagnetic relaxation or to a long-range cooperative order. Considering the first possibility (slow paramagnetic relaxation), the dilute nature of the complex is evidenced by a shortest inter-complex Fe^{III}–Fe^{III} distance of about 6.9 Å, a magnitude which is large enough to result in long spin-spin relaxation times for high-spin iron(III). Considering the possibility of a long-range order, on the basis of the magnetic data we cannot exclude the possibility of the existence of magnetic couplings, even though it seems more reasonable to describe the low-temperature variation of magnetic properties in terms of zero-field splitting effects. We note that these limiting behaviours can be distinguished by Mössbauer spectroscopy by analysis of the temperature dependence of the spectra using the Mössbauer magnetic relaxation theory established by Blume and Tijon.[38] It can be also achieved experimentally using a weak external applied magnetic field, which may freeze the magnetic fluctuations.[39] These laborious approaches, however, are beyond the scope of this paper.

Conclusions

In attempt to combine conductivity and spin-crossover properties in the same material, we have synthesised three new compounds with the general formula [Fe(salten)Mepepy][M(dmit)$_2$]·CH_3CN (M = Ni, Pd, Pt). We have shown by magnetic susceptibility and Mössbauer measurements that the Fe^{III} ions preserve their spin-crossover properties in the new crystal lattice, although the spin crossover of the Ni complex is not complete at low temperature (80 K). Mössbauer spectroscopy has shown that the remaining high-spin state is magnetically ordered at 4.5 K, leading to a promising way to combine magnetic properties and bistability in inorganic molecular compounds. Preliminary attempts to synthesise fractional oxidation-state complexes have resulted in the synthesis of a conductive powder that exhibits a spin conversion with antiferromagnetic interactions. Although not structurally characterised, this compound is one of the first complexes to combine spin conversion and electrical properties. Work is currently in progress to combine such SCO compounds with metal-bisdithiolene complexes.[19]

Experimental Section

Synthesis: All reactions were performed under an inert atmosphere of argon, using Schlenk technique, and sheltered from daylight. Solvents were dried and distilled under argon prior to use.

[Fe(salten)Mepepy](BPh$_4$) and (NBu$_4$)[M(dmit)$_2$] (M = Ni, Pd, Pt) were synthesised following literature methods.[27,40]

Synthesis of [Fe(salten)Mepepy][M(dmit)$_2$]·CH_3CN (M = Ni, Pd, Pt): (NBu$_4$)[M(dmit)$_2$] (M = Ni, Pd, Pt; 0.24 mmol) was dissolved in a mixture of acetonitrile and acetone (30 and 20 mL, respectively) and a solution of [Fe(salten)Mepepy](BPh$_4$) (214 mg, 0.24 mmol) in acetonitrile (10 mL) was added dropwise. The resulting solution was stirred for 5 min and stored at 4 °C overnight. The precipitate obtained was filtered, washed with 5 × 5 mL of acetonitrile, 2 × 3 mL of diethyl ether, and dried under vacuum. Every compound was obtained as shiny, crystalline blocks, which were used for subsequent characterisations. Initially, the Ni complex was obtained with acetonitrile (its structure was solved at 160 K, see below). The same crystal, when analysed again a few weeks later on the diffractometer, did not contain acetonitrile.

1: [Fe(salten)Mepepy][Ni(dmit)$_2$]. $C_{38}H_{35}FeN_5NiO_2S_{10}$ (1028.9): calcd. C 44.36, H 3.43, N 6.81; found C 44.95, H 3.53, N 6.89.

2: [Fe(salten)Mepepy][Pd(dmit)$_2$]·CH_3CN. $C_{40}H_{38}FeN_6O_2PdS_{10}$ (1117.6): calcd. C 42.98, H 3.43, N 7.52; found C 42.95, H 3.58, N 7.10.

3: [Fe(salten)Mepepy][Pt(dmit)$_2$]·CH_3CN. $C_{40}H_{38}FeN_6O_2PtS_{10}$ (1206.3): calcd. C 39.82, H 3.18, N 6.97; found C 40.50, H 3.04, N 6.46.

Synthesis of [Fe(salten)Mepepy][Ni(dmit)$_2$]$_3$: This complex was obtained either by galvanostatic or potentiostatic oxidation of [Fe(salten)Mepepy][Ni(dmit)$_2$] in acetonitrile, using Pt electrodes.

UV/Vis Spectroscopy/Irradiation: Measurements were performed with [Fe(salten)Mepepy](BPh$_4$) and [Fe(salten)Mepepy][Ni(dmit)$_2$] at room temperature in CH_2Cl_2 solution with a Perkin–Elmer Lambda 5 equipment. Irradiation was performed with a 200 W (Hg) Oriel lamp (filter 400 nm).

X-ray Structure Analysis: X-ray data for each compound, were collected at 295, 240, 160 and 100 K on an IPDS diffractometer (Stoe) or on an Xcalibur (Oxford Diffraction) diffractometer, with monochromatic Mo-K_α radiation ($\lambda = 0.71073$ Å). Crystallographic data are given in Table 5. X-ray structure analysis was performed using the WinGX package.[41] H atoms were included at their calculated positions as riding on their adjacent atom. SIR97[42] or Shelxs97[43] were used for the structure solutions, Shelxl97[44] for the refinements, Platon[45] for structure analysis, and Ortep3[46] or Cameron[47] for the production of the crystallographic illustrations. CCDC-262730 to -262742 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Magnetic Measurements: Magnetic measurements were performed on powders (Pd and Pt complexes containing acetonitrile; Ni complex without acetonitrile) using either an MPMS SQUID magnetometer (Quantum Design) operating at 1 T or a Faraday-type magnetometer equipped with a DRUSH electromagnet (operating in the range 0.4–1.4 T), a Sartorius balance and a continuous-flow Oxford Instruments cryostat. The magnetic susceptibility values were calibrated against Hg[Co(SCN)$_4$]. Data were corrected for magnetisation of the sample holder and for diamagnetic contributions, which were estimated from Pascal's constants.

Raman Spectroscopy: Raman measurements were performed with a Dilor XY micro-Raman (source: 632.8 nm line of a He-Ne laser; laser power density: ≈10^5 W cm^{-2}). The spectra were recorded at VV polarisation.

Mössbauer Spectroscopy: The variable-temperature Mössbauer measurements were obtained on a constant-acceleration spectrometer with a 50 mCi source of ^{57}Co (Rh matrix). The isomer shift values (δ) are given with respect to metallic iron at room temperature. The absorber was a sample of microcrystalline powder enclosed in a 2-cm-diameter cylindrical plastic sample holder, the size of which was determined to optimise the absorption. The variable-temperature spectra were obtained in the range 4.5–330 K using a He bath cryostat (Air Liquid DTA). Fitting parameters for all spectra were obtained by using a least-squares computer program.[48] The standard deviations of statistical origin are given in parentheses.

Supporting Information (see footnote on the first page of this article) contains four figures {magnetic behaviour of **1** with or without solvent, magnetic behaviour and magnetisation of [Fe(salten)-Mepepy][Ni(dmit)$_2$]$_3$, and Raman spectra of [Fe(salten)]Cl, [Fe(salten)Mepepy](BPh$_4$) and [Fe(salten)Mepepy][Ni(dmit)$_2$]} and seven tables (crystallographic data, geometrical data, short intermolecular distances and assignments of the Raman spectra).

Supramolecular Cations of (*S*)-, (*R*)-, and (*RS*)-Indan-1-aminium(dibenzo[18]crown-6) in Magnetic $[Ni(dmit)_2]^-$ Salts

Tomoyuki Akutagawa,*[a–c] Kazumasa Matsuura,[b] Sadafumi Nishihara,[b] Shin-ichiro Noro,[a,b] and Takayoshi Nakamura*[a–c]

Keywords: Crown compounds / Magnetic properties / Supramolecular chemistry / Chirality / S ligands

Magnetic crystals were formed using supramolecular cation structures that consist of (*S*)-AIH^+(dibenzo[18]crown-6), (*R*)-AIH^+(dibenzo[18]crown-6), or (*RS*)-AIH^+(dibenzo[18]crown-6) (AIH^+ = indan-1-aminium) as the counter cation to $[Ni(dmit)_2]^-$ ions ($dmit^{2-}$ = 2-thioxo-1,3-dithiole-4,5-dithiolate), which bear one S = 1/2 spin. The resulting salts, (*S*)-AIH^+(dibenzo[18]crown-6)$[Ni(dmit)_2]$ (**1**), (*R*)-AIH^+(dibenzo[18]crown-6)$[Ni(dmit)_2]$ (**2**), and (*RS*)-AIH^+(dibenzo[18]crown-6)$[Ni(dmit)_2]$ (**3**), feature supramolecular cations that are formed through the inclusion of the ammonium moiety of AIH^+ into the cavity of dibenzo[18]crown-6 through N–H···O hydrogen bonds. Salts **1**, **2**, and **3** possess space groups of $P2_1$, $P2_1$, and $P2/m$, respectively, and possess similar molecular packings. Chiral cations (*S*)-AIH^+ (salt **1**) and (*R*)-AIH^+ (salt **2**) yielded chiral crystals, whereas racemic (*RS*)-AIH^+ (salt **3**) afforded a racemic crystal with a mirror plane. Within the crystals, alternating layers of $[Ni(dmit)_2]^-$ ions and (AIH^+)(dibenzo[18]crown-6) cations formed a layered structure along the *b* axis. Since the 2_1 axis of salts **1** and **2** were observed along the *b* axis, effective chiral magnetic interactions between the $[Ni(dmit)_2]^-$ ions were not observed. In the *ac* plane, weak interactions among the $[Ni(dmit)_2]^-$ ions formed a two-dimensional layer. Temperature-dependent magnetic susceptibilities of salts **1**, **2**, and **3** exhibited a Curie–Weiss-type behavior, which shows weak antiferromagnetic interactions between the $[Ni(dmit)_2]^-$ ions, with Weiss temperatures of –2.9, –2.9, and –4.2 K, respectively.

Introduction

Structures of organic ammonium RNH_3^+(crown ether) assemblies in the solid state depend on both the structure of the cation and on the size of the crown ether ring.[1] Various types of RNH_3^+ structures (R = H, CH_3, $C_6H_5CH_2$, NH_2, etc.) have been shown to form stable ammonium(crown ether) complexes in the solid state.[1] In these structures, the N–H^+···O hydrogen bonds and electrostatic interactions play important roles in binding the ammonium moiety into the cavity of the crown ethers.[2] Because it has been shown that the ionic radius of NH_4^+ matches the cavity size of [18]crown-6, it is reasonable to assume that N–H^+···O hydrogen bonds help form stable RNH_3^+([18]crown-6) complexes in the solid state. Although the cation-binding ability of dibenzo[18]crown-6 (1,4,7,10,13,16-hexaoxa-2,3:11,12-dibenzocyclooctadeca-2,11-diene) is similar to that of [18]crown-6,[3] the two benzene rings that are fused onto [18]crown-6 greatly affect the cationic structure of the RNH_3^+(dibenzo[18]crown-6) complexes and the molecular packing within the crystals. Comparatively, the O_6 plane of NH_4^+([18]crown-6) is nearly planar,[4] while the molecular structure of NH_4^+(dibenzo[18]crown-6) can be defined as a V-shaped conformation with the two benzene rings forming a bent structure in relation to the O_6 plane of the [18]crown-6 moiety.[5] The solid-state supramolecular cation structures of RNH_3^+ and dibenzo[18]crown-6, therefore, have the potential to yield a completely different type of cation assembly, as compared to those with [18]crown-6.

We have been involved in preparing supramolecular cationic structures and forming salts with $[Ni(dmit)_2]$ ($dmit^{2-}$ = 2-thioxo-1,3-dithiole-4,5-dithiolate).[6] Such an approach has allowed us to modify the assembled structures of the $[Ni(dmit)_2]^-$ ions, each bearing one S = 1/2 spin, and thus adjust the magnetic properties of the $[Ni(dmit)_2]^-$ salts. Among the salts, assembled structures between RNH_3^+ and [18]crown-6, such as anilinium([18]crown-6),[7] *p*-phenylenediammonium([18]crown-6)$_2$,[7] and *p*-xylylenediammonium([18]crown-6)$_2$ supramolecules,[8] yielded a variety of $[Ni(dmit)_2]^-$ ion assemblies that possess magnetic properties such as isolated spins, linear one-dimensional Heisenberg

chains, and spin-ladders, according to the shape of the cationic structures. Introduction of chirality into the RNH_3^+ cations can potentially enhance the $[Ni(dmit)_2]^-$ ion assemblies within the crystals. A slight chemical modification of the cationic structures, specifically from anilinium([18]-crown-6) to *p*-phenylenediammonium([18]crown-6)$_2$, was found to modulate the $[Ni(dmit)_2]^-$ ion assemblies,[7a] and to drastically change the magnetic properties, from that of spin-ladder to that of singlet dimers.[7b] In the present study, we examined the effects of relatively small structural perturbations of the hydrogen-bonded supramolecular cations of RNH_3^+(dibenzo[18]crown-6) structures by modifying the chirality of the RNH_3^+ units in the $[Ni(dmit)_2]^-$ salts. For this purpose, chiral cations (*S*)- and (*R*)-indan-1-aminium [(*R*)-AIH$^+$ and (*S*)-AIH$^+$, respectively] and racemic (*RS*)-indan-1-aminium [(*RS*)-AIH$^+$] were utilized to form the hydrogen-bonded (AIH$^+$)(dibenzo[18]crown-6) structures in the magnetic $[Ni(dmit)_2]$ salts (Scheme 1). Because the NH_3^+ moiety of AIH$^+$ has the capacity to hydrogen-bond to the six oxygen atoms of the dibenzo[18]crown-6 molecule, it can be suggested that the asymmetric carbon center of (*S*)- and (*R*)-AIH$^+$ may affect the chirality of the crystals.

Results and Discussion

Crystal Structures

As expected, salts of (*S*)-AIH$^+$(dibenzo[18]crown-6)-[Ni(dmit)$_2$] (**1**), (*R*)-AIH$^+$(dibenzo[18]crown-6)[Ni(dmit)$_2$] (**2**), and (*RS*)-AIH$^+$(dibenzo[18]crown-6)[Ni(dmit)$_2$] (**3**) have the same stoichiometry. The data for the X-ray structural analyses for salts **1**, **2**, and **3** were obtained at 297 K (Table 1). The crystal symmetry of salts **1** and **2** were chiral $P2_1$ due to the existence of an asymmetric center within the chiral (*S*)- and (*R*)-AIH$^+$ ions, while that of salt **3** was achiral $P2_1/m$ due to the racemic (*RS*)-AIH$^+$ ion. For all the salts, the ammonium moiety of AIH$^+$ lies above the cavity of dibenzo[18]crown-6, thus forming the AIH$^+$(dibenzo-[18]crown-6) cationic structure. Furthermore, the molecular arrangements of the $[Ni(dmit)_2]^-$ ions and the AIH$^+$(dibenzo[18]crown-6) cations are similar to each other. Because the LUMO of the $[Ni(dmit)_2]^-$ ion is occupied by a single electron, which bears one $S = 1/2$ spin, the salts can be described as magnetic crystals.

The structures of the supramolecular cations of salts **1**–**3** are shown in Figure 1. As shown in Figure 1a, the ammonium moiety of (*S*)-AIH$^+$ lies above the cavity of dibenzo[18]crown-6, which possesses a V-shaped conformation. As a note, X-ray structural analyses confirmed that the absolute chirality of (*S*)-AIH$^+$ (salt **1**) and (*R*)-AIH$^+$ (salt **2**) corresponded to that of the starting (*S*)- and (*R*)-AIH$^+$ ions (Figures 1b and 1c), respectively. For salt **3**, on the other hand, the N1 and C9–C16 atoms define a mirror plane, which allows the isomers (*S*)- and (*R*)-AIH$^+$ ions equal probability (50%) of occupation, thus reflecting the racemic nature of the cation (Figure 1d).

The structural parameters of the cationic structures for salts **1**–**3** are summarized in Table 2. In each case, effective N–H···O hydrogen bonding between the NH_3^+ group of AIH$^+$ and the six oxygen atoms of dibenzo[18]crown-6 was observed. The N–O hydrogen bonding distances range from 2.917(6) to 3.132(6) Å, in which the average N–O distance

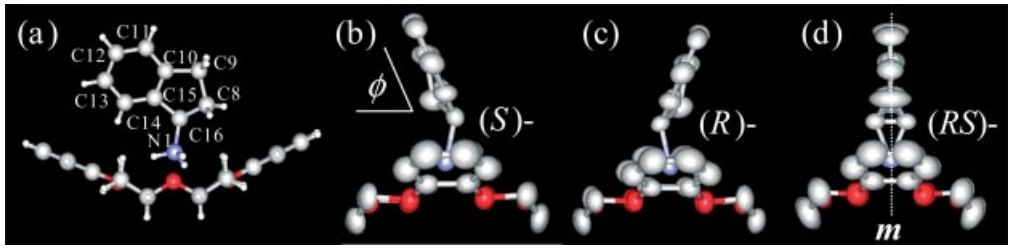

Figure 1. AIH^+(dibenzo[18]crown-6) structures of salts **1**–**3**. (a) Cation unit of salt **1** viewed parallel to the O_6 plane of dibenzo[18]crown-6. Configurations of (b) (*S*)-AIH^+, (c) (*R*)-AIH^+, and (d) (*RS*)-AIH^+ units viewed along the π plane of AIH^+. Hydrogen atoms are omitted for clarity.

for salts **1**, **2**, and **3** are 3.00, 3.02, and 3.02 Å, respectively. The greater average N–O distances, in comparison to the standard distance for the N–O hydrogen bond (2.87 Å),[9] indicate that the AIH^+(dibenzo[18]crown-6) structures involve six weak $NH_3^+\cdots O$ hydrogen-bond interactions. For salts **1** and **2**, the distance between N1 and the O_6 plane of dibenzo[18]crown-6 ($d_{N-O_{plane}}$) is 1.23 Å, while that of racemic salt **3** is slightly longer (1.27 Å). The dihedral angle (φ) between the O_6 plane of dibenzo[18]crown-6 and the C_6 plane of the AIH^+ benzene moiety for salts **1** and **2** is 66.04 and 66.24°, respectively. In contrast, the racemic nature of the (*RS*)-AIH^+ ion of salt **3** exhibits an average structure of 50% probability of each configuration. In this case, the static disorder of the (*R*)-AIH^+ and (*S*)-AIH^+ configuration yields a mirror plane as defined by the N1 and C9–C16 atoms resulting in φ = 90°. These structural differences in the cations, however, do not affect the $[Ni(dmit)_2]^-$ arrangements within the crystals.

Table 2. Structural parameters of the cations for salts **1**–**3**.[a]

	1	**2**	**3**
N1–O1, N1–O4	3.119(6), 3.002(5)	3.131(6), 2.952(5)	2.996(4)

N1–O3, N1–O6	2.955(5), 3.110(6)	3.010(5), 3.122(6)	3.119(5)
$N1–O_{AV}$	3.00	3.02	3.02
$d_{N-O_{plane}}$	1.23	1.23	1.27
φ	66.04	66.24	90

[a] The parameters $d_{N-O_{plane}}$ and φ are defined in the text.

The unit cell of salt **1** viewed along the *a* axis is shown in Figure 2. Although the space group of salt **3** is different from those of salts **1** and **2**, the overall molecular packing in crystal **3** is comparable to those of salts **1** and **2**. The AIH^+(dibenzo[18]crown-6) cations and $[Ni(dmit)_2]^-$ ions are independently arranged within the *ac* plane, whereas the cation and anion layers are alternately arranged along the *b* axis. Moreover, the cation layer disrupts the intermolecular interactions between the $[Ni(dmit)_2]^-$ layers along the *b* axis. Since the spiral 2_1 axis is parallel to the *b* axis, effective chiral intermolecular interactions between the $[Ni(dmit)_2]^-$ anions were not expected within the crystals.

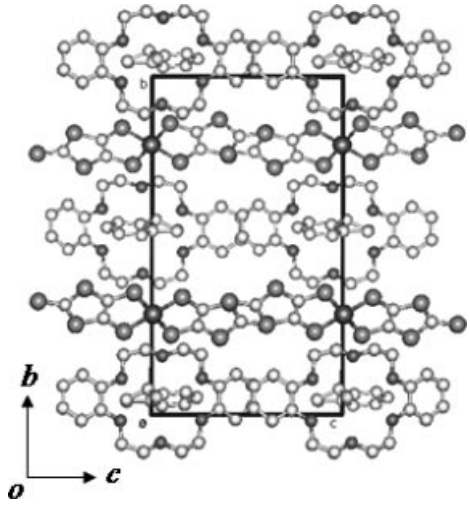

Figure 2. Unit cell of salt **1** viewed along the *a* axis. Hydrogen atoms are omitted.

The arrangements of the cations and anions within the *ac* plane are shown in Figure 3. The AIH^+(dibenzo[18]crown-6) units are stacked along the *a* axis, in which the V-shaped dibenzo[18]crown-6 units in the *ac* plane are arranged in the same direction along the *a* axis. Although a large dipole moment was expected in the *ac* plane, each cationic layer is arranged in a 2_1 symmetry, thus cancelling the dipole moment of the overall crystal. The $[Ni(dmit)_2]^-$ ions within the *ac* plane interact through weak lateral interatomic S···S contacts along the *c* and *a*+*c* axis. Despite the lack of significant π–π overlap between the $[Ni(dmit)_2]^-$ ions, a layered structure is formed by two-dimensional lateral S···S contacts in the *ac* plane. The magnitude of intermolecular interactions between the $[Ni(dmit)_2]^-$ ions was estimated from the calculated values of the transfer integrals (*t*) of LUMO based on extended Hückel molecular orbital calculations (Table 3). The transfer integrals of salts **1**, **2**, and **3** along the *a*+*c* axis (t_1) are 21.8, 21.5, and 26.9 meV, respectively, which are larger than those along the *c* axis (t_2 = 4.04, 4.15, and 4.98 meV for salts **1**, **2**, and **3**, respectively). Since the t_1 interactions are two- or threefold larger than the t_2 interactions, intermolecular interactions between $[Ni(dmit)_2]^-$ ions are dominated by those in the one-dimensional linear chain along the *a*+*c* axis. Each chain is ar-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ranged through weak interchain interactions (t_2) along the *c* axis. Because the magnitude of the intrachain interactions (t_1) for salt **3** is roughly 20% greater than those of salts **1** and **2**, slightly larger magnetic interactions should be present for salt **3** than for salts **1** and **2**.

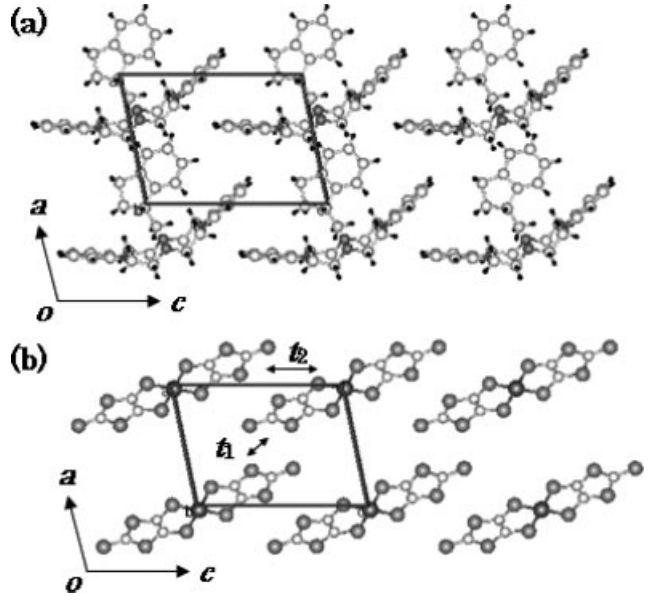

Figure 3. Crystal structures of salt **1**. (a) AIH^+(dibenzo[18]crown-6) cation and (b) $[Ni(dmit)_2]^-$ ion arrangements within the *ac* plane {intermolecular transfer integrals, t_1 and t_2, between the $[Ni(dmit)_2]^-$ ions are shown}.

Table 3. Transfer integral ($t \times 10^{-3}$ eV)[a] and magnetic parameters of salts **1**–**3**.

	1	**2**	**3**
t_1	21.8	21.5	26.9
t_2	4.04	4.15	4.98
C [emu K mol^{-1}]	0.367	0.374	0.372
θ [K]	-2.9	-2.9	-4.2

[a] The transfer integrals (t) were obtained by the LUMO of $[Ni(dmit)_2]^-$ based on the extended Hückel calculation ($t = -10S$ eV); S is the overlap integral.

Circular dichroism (CD) spectra of salts **1**–**3** with KBr pellets were measured to confirm the chiral intermolecular interactions between $[Ni(dmit)_2]^-$ ions. The intermolecular charge-transfer absorption between $[Ni(dmit)_2]^-$ ions has been observed at an energy around 8×10^3 cm^{-1}, while the intramolecular localized excitation bands of the $[Ni(dmit)_2]^-$ ion appear in the visible energy region with the absorption maxima around 12, 13, and 18×10^3 cm^{-1}.[10] Weak responses of CD spectra of salts **1** and **2** were observed at ca. 15 and ca. 20×10^3 cm^{-1} as a positive and negative rotation angle, respectively, while there was no meaningful response in the CD spectrum of racemic salt **3**. Therefore, the chiral arrangements of AIH^+ ions induced the circular dichroism in the intramolecular localized excitations of $[Ni(dmit)_2]^-$ ion along the *b* axis through intermolecular interactions between the $[Ni(dmit)_2]^-$ and AIH^+ ions.

Magnetic Properties

The magnetism of the crystals were determined by estimating the magnetic exchange energy (J), which is proportional to the square of t, i.e. magnitude of the intermolecular interaction.[11] Each $[Ni(dmit)_2]^-$ ion possesses one S = 1/2 spin, and therefore the molecular assemblies are directly related to the magnetism. Temperature-dependent magnetic susceptibilities (χ_{mol} vs. T) are similar among salts **1**–**3** (Figure 4 and Table 3); such similarity is also indicated by the comparable $[Ni(dmit)_2]^-$ arrangements among the crystals. The χ_{mol} vs. T of salts **1** and **2** exhibit Curie–Weiss behavior, in which the magnetic parameters C and θ are 0.367 emu K mol^{-1} and –2.9 K, respectively. Although salt **3** also exhibits Curie–Weiss behavior, the greater intrachain interactions (t_1 = 26.9 meV) of salt **3**, than those of salts **1** and **2**, provides a slightly larger Weiss constant of θ = –4.2 K (Figure 4b). In salt **3**, the magnitude of intermolecular t_1 and t_2 interactions between $[Ni(dmit)_2]^-$ anions are slightly larger than those of salts **1** and **2**, which increases the $|J|$ and $|\theta|$ values. The disordered arrangements of racemic AIH^+ ions in salt **3** affects the crystal lattice, which slightly changes the anionic arrangements to increase the intermolecular interactions between the $[Ni(dmit)_2]^-$ ions.

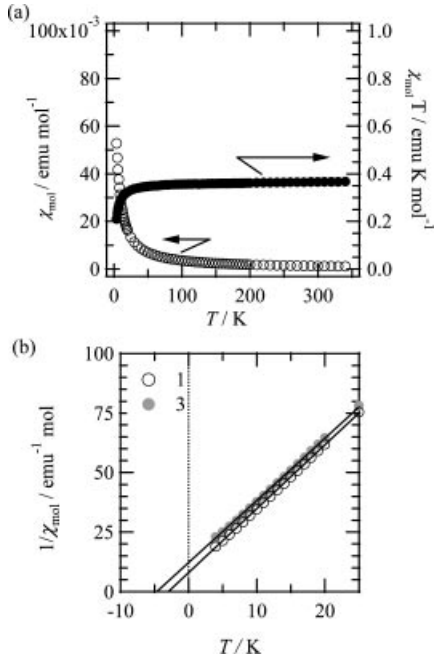

Figure 4. Temperature-dependent molar magnetic susceptibility (χ_{mol}) per one $[Ni(dmit)_2]^-$ ion for salts **1**–**3**. (a) χ_{mol} vs. T (left scale) and $\chi_{mol}T$ vs. T (right scale) plots for salt **1**. (b) χ_{mol}^{-1} vs. T plots for salts **1** and **3**.

Summary

Supramolecular cationic structures of (*S*)-AIH^+(dibenzo[18]crown-6), (*R*)-AIH^+(dibenzo[18]crown-6), and (*RS*)-AIH^+(dibenzo[18]crown-6) (AIH^+ = indan-1-aminium) were incorporated into $[Ni(dmit)_2]^-$ salts. Supra-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

molecular assemblies were formed through hydrogen-bond interactions between the NH_3^+ moieties of the AIH^+ ion and the oxygen atoms in the dibenzo[18]crown-6 molecule. Chiral (*S*)-AIH^+ and (*R*)-AIH^+ and racemic (*RS*)-AIH^+ yielded isomorphous crystals with a stoichiometry of AIH^+(dibenzo[18]crown-6)$[Ni(dmit)_2]$. The chiral salts possess a chiral space group of $P2_1$, while the latter salt possesses an achiral $P2_1/m$ space group. However, the molecular packing and temperature-dependent magnetic susceptibilities of the three salts are comparable to each other. The AIH^+(dibenzo[18]crown-6) cations are packed within the *ac* plane, whereas the $[Ni(dmit)_2]^-$ ions form a two-dimensional layer separated by a layer of cations. The transfer integrals in the $[Ni(dmit)_2]$ layer exhibit weak one-dimensional intermolecular interactions between the $[Ni(dmit)_2]$ molecules, which yield weak antiferromagnetic interactions between the $[Ni(dmit)_2]^-$ ions. Chiral cations (*S*)- and (*R*)-AIH^+ were successfully introduced into the supramolecular cationic structures in $[Ni(dmit)_2]$-based molecular magnets. Introduction of chirality into the crown ethers are currently underway in an attempt to achieve chiral intermolecular interaction between the $[Ni(dmit)_2]$ molecules.

Experimental Section

Preparation of $[Ni(dmit)_2]$ Salts: The precursor monovalent salt $n(Bu_4N)[Ni(dmit)_2]$ was prepared according to the literature.[12] The ammonium salts of (*S*)-, (*R*)-, and (*RS*)-$AIH^+BF_4^-$ were prepared by neutralization of commercially available chiral (*S*)-, (*R*)-, and racemic (*RS*)-AIH^+ using 42% aqueous HBF_4. Single crystals of salts **1**–**3** were grown by slow diffusion of $n(Bu_4N^+)[Ni(dmit)_2]^-$ and $AIH^+BF_4^-$ in vials charged with CH_3CN (ca. 20 mL). The compositions of crystals **1**–**3** were determined by X-ray structural analysis and by elemental analysis. Salt **1**: $C_{35}H_{36}NNiO_6S_{10}$ (946.01): calcd. C 44.44, H 3.84, N 1.48; found C 44.11, H 3.69, N 1.24. Salt **2**: $C_{35}H_{36}NNiO_6S_{10}$ (946.01): calcd. C 44.44, H 3.84, N 1.48; found C 44.64, H 3.91, N 1.67. Salt **3**: $C_{35}H_{36}NNiO_6S_{10}$ (946.01): calcd. C 44.44, H 3.84, N 1.48; found C 44.29, H 3.54, N 1.62.

Crystal Structure Determination: Crystallographic data (Table 1) were collected with a Rigaku Raxis-Rapid diffractometer with Mo-K_α (λ = 0.71073 Å) radiation from a graphite monochromator. Structure refinements were performed using the full-matrix least-squares method on F^2. Calculations were carried out using Crystal Structure software packages.[13] Parameters were refined using anisotropic temperature factors with the exception of those for the hydrogen atoms. CCDC-263460 (**1**), -263461 (**2**), and -263462 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Magnetic Susceptibility: Temperature-dependent magnetic susceptibilities were measured with a Quantum Design Model MPMS-XL SQUID magnetometer for polycrystalline samples. The applied magnetic field was 1 T for all measurements.

Calculation of Transfer Integrals: Transfer integrals (t) were calculated within the tight-binding approximation using the extended Hückel molecular orbital method. The LUMO of the $[Ni(dmit)_2]^-$ ion was used as the basis function.[14] Semi-empirical parameters for Slater-type atomic orbitals were obtained from the literature.[14] The t values between each pair of molecules were assumed to be proportional to the overlap integral (S) using the equation, $t = -10S$ eV.

Keywords: Thiocyanate / Azide / Cobalt / Manganese / 1,2-Bis(imidazol-1-yl)ethane / 1,2-Bis(1,2,4-triazol-1-yl)ethane / Magnetic properties

Four new metal-organic polymers with SCN^-/N_3^- anion bridges and flexible long spacers L {L = bim [1,2-bis(imidazol-1-yl)ethane] and bte [1,2-bis(1,2,4-triazol-1-yl)ethane]}, $[Co(SCN)_2(bim)]$ (**1-Co**), $[Co(SCN)_2(bte)]$ (**2-Co**), $[Mn(N_3)_2(bte)]$ (**3-Mn**), and $[Mn(N_3)_2(bim)]$ (**4-Mn**), were synthesized and characterized by single-crystal X-ray diffraction studies and their magnetic properties were investigated. Complex **1-Co** is a triple-bridging chain complex with double end-to-end SCN^- anions and single *gauche*-bim spacers as bridges. Complexes **2-Co** and **3-Mn** both contain 1D chains bridged by double end-to-end SCN^- or N_3^- anions and these chains are further extended to 2D (4,4) layers by the *anti*-bte spacers. Complex **4-Mn** has a topological 3D diamond structure constructed through 1D double end-on azide-bridged Mn^{II} chains and extended through the *anti*-bim spacers. Magnetic measurements reveal that **1-Co** and **3-Mn** remain paramagnetic; the dominant magnetic coupling between Co^{II} is weak ferromagnetic and that between Mn^{II} is strong antiferromagnetic. As for **2-Co** and **4-Mn**, they show metamagnetic behavior below T_N = 2.9 and 3.0 K, respectively. Our results show that a combination of the short anion bridges (SCN^-/N_3^-) and flexible bidentate long spacers can be used to construct coordination polymers with novel topologies and interesting magnetic properties.

Introduction

In the attractive field of supermolecular chemistry and crystal engineering, long bidentate spacers provide a useful approach to new functional materials with a variety of multi-dimensional arrays and networks.[1] Because of the large separation and the inefficiency to transmit magnetic interactions, these long spacers were seldomly used to construct molecule-based magnetic materials with high magnetic-ordering temperatures. However, their abilities to form new architectures with novel topologies and interesting magnetic properties still attracts intensive attention, such as compounds constructed by rigid *N*,*N*′-bidentate spacers like 4,4′-bipyridine (4,4′-bpy), (*E*)-1,2-bis(4-pyridinyl)ethene, pyrazine, and other related ligands.[2–4] Very recently, we reported a series of compounds $M(CHOO)_2(4,4'\text{-bpy})\cdot nH_2O$ (M = Mn, Co, n = 0; M = Co, Ni, n = 5) with all 3D structures and magnetically long-range ordering.[2d] As with its azide analog $M(N_3)_2(4,4'\text{-bpy})$ (M = Mn, Fe),[2a–2c] the bidentate long spacer 4,4′-bpy efficiently tuned the topologies of these compounds and led to weak ferromagnetism.

The design of coordination polymers is highly influenced by several factors such as the coordination geometry of the central atom, the structural characteristics of the ligand molecule, the solvent system and the counterion. When rigid bifunctional ligands are used as spacers to connect metal centers, the topology of the network is usually determined by the coordination geometry of the central metal preference. Contrary to rigid ligands, the flexible ligands with conformational flexibility induce a variety of structures and may lead to the formation of the supramolecular isomers.[3i,3j] Some coordination polymers with flexible ligands have been investigated.[3,4] For example two remarkable polyrotaxane-like polymers based on 1,4-bis(imidazol-1-ylmethyl)benzene (bix) were synthesized by Robson and coworkers.[3k,3l] The flexible ligands 1,2-bis(imidazol-1-yl)ethane (bim) and 1,2-bis(1,2,4-triazol-1-yl)ethane (bte) can adopt either *gauche* (angular) or *anti* (linear) conformations (Scheme 1).[4a] We previously reported several coordination polymers in which the ligands also exhibit either *gauche* or *anti* conformations.[4] Complex $[Mn(\textit{gauche}\text{-bte})_2(NCS)_2]_n\cdot[Mn(\textit{anti}\text{-bte})(H_2O)_2(NCS)_2]_n$ contains both a double-stranded chain and a single chain in the same crystal and both *gauche* and *anti* conformations of the bte spacer.[4c]

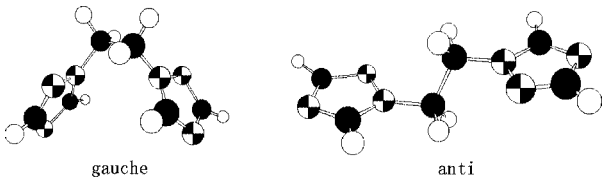

Scheme 1. The *gauche* and *anti* conformations of the bte and bim spacers (bte as example).

Of course, the main approach to constructing molecule-based magnetic materials is to employ short bridging ligands, which are efficient to mediate the magnetic coupling, to connect paramagnetic transition metal ions. Among the widely used anion ligands, the pseudohalide azide has been demonstrated to be the all-important one, if not the most, due to the versatility and the ability to mediate strong magnetic coupling, either ferro- or antiferromagnetic. Most commonly, the azide ion can adopt two possible bridging modes: end-to-end (*EE*) associated with antiferromagnetic (AF) coupling, and end-on (*EO*) related with ferromagnetic exchange.[5] In our previous reports,[2d,6] we explored another three-atom bridging ligand, the formate anion, which is a natural analog of azide, to construct new formate compounds with structures and magnetic properties similar to or different from those of azide. Furthermore, we investigated another pseudohalide anion: the thiocyanato ion (SCN^-). Like azide and formate, SCN^- can also mediate magnetic coupling between the metal ions, with the sign and the magnitude depending on the bridging modes and the localized structural details.[7–14] Owing to the two different donor groups (N and S) within it, the thiocyanate ion has less versatility and is less efficient as a magnetic coupler than the azide ligand. In contrast with the large number of azide-bridged compounds studied from a magnetic and structural point of view, there are fewer reports on the divalent first-row transition metal complexes bridged by SCN^-. Fully studied complexes are mainly compounds of Ni^{II}[8,9] and Cu^{II},[10–12] such as dimers,[8,10] 1D chains,[9,11] and 2D layers.[12] For Mn^{II} and Co^{II} compounds, the existing results are quite rare.[13,14] The 2D compounds $M(SCN)_2(ROH)_2$ (M = Mn, Co; R = CH_3, C_2H_5, C_3H_7)[13b,14] and the proposed 1D chain compounds $M(SCN)_2$(2,2-bipyridine) (M = Mn, Co) are rare examples that have been investigated thoroughly.[13a] New thiocyanate-bridged compounds, especially of Co^{II}, are needed to be explored further.

Taking into account the above-mentioned aspects, we report here the syntheses, structures and the magnetic properties of four new coordination polymers: $Co(L)(SCN)_2$ [L = bim (**1-Co**) and bte (**2-Co**)] and $Mn(L)(N_3)_2$ [L = bte (**3-Mn**) and bim (**4-Mn**)]. All four of these polymers assemble through both the flexible-bidentate long spacers (bim/bte) and the short anion ligands (SCN^-/N_3^-) as bridges. Among them, **1-Co** is a triple-bridging 1D compound bridged by double *EE*-SCN^- ligands and single *gauche*-bim spacers. **2-Co** is a 2D metamagnet with double *EE*-SCN^- ligands and *anti*-bte spacers as bridges. **3-Mn** has a very similar structure to that of **2-Co** and behaves as a magnetic AF chain. As for **4-Mn**, the double *EO*-azides and the *anti*-bim spacers lead to a metamagnet with a distorted 3D diamondoid structure.

Results and Discussion

Crystal Structures

Single-crystal X-ray diffraction of **1-Co** reveals that it crystallizes in the orthorhombic space group $Pna2_1$ and the structure is presented in Figure 1. In **1-Co**, each Co^{II} center is octahedrally coordinated by two nitrogen atoms from two bridging bim ligands in *trans* positions, two nitrogen and two sulfur atoms from four bridging *EE*-SCN^- groups. Lengthened along the S1–Co1–S2 axis, the octahedron is of an approximate D_{4h} point group. The bond lengths are as follows: Co1–N1 2.083(2), Co1–N3 2.076(2), Co1–N5 2.127(2), Co1–N6 2.122(2), Co1–S1 2.660(2), and Co1–S2 2.635(1) Å. The bond angles of D–Co1–D (D represents N or S atoms) are in the range of 88–92°. The angles of Co1–S2–C10 and Co1A–S1A–C9 are ca. 98°, which are close to a right angle, and the angles of Co1–N5–C9 and Co1A–N6A–C10 are 160° or so. So the geometry of the $Co_2(SCN)_2$ ring is close to that of a rectangle although with poor coplanarity. The geometrical feature of $Co_2(SCN)_2$ has already been observed in other thiocyanato-containing metal complexes and it is believed to have a very important influence on the magnetic coupling between the transition metal ions, especially Ni^{II}.[7a–7c,9c] It is well demonstrated that, because of the orthogonality of the orbitals, the more rectangular the geometry, the greater the possibility of ferromagnetic coupling will be.[7a–7c]

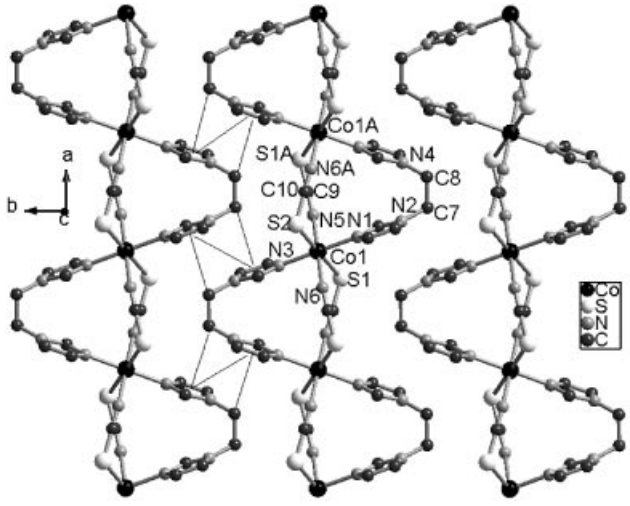

Figure 1. Toothed chain structures and the 2D layer of **1-Co**. Hydrogen atoms are omitted for clarity. The thin lines represent the π–π and C–H···π interactions between adjacent chains.

The SCN^- anion is almost linear [S1A–C9–N5 and S2–C10–N6A are 179.2(2) and 178.8(2)°, respectively] and the bim ligand is of the *gauche* conformation [torsion angle of N2–C7–C8–N4 is 59.2(3)°]. Both of these ligands act as bridges to connect adjacent Co^{II} ions to form a triple-bridg-

ing 1D toothed chain along the [100] crystallographic direction. Parallel chains stack in the [010] direction such that the convex bim bow of one chain extends into the concave section of the neighboring chain. There are obvious C–H···π interactions between the hydrogen atoms of alkanes and imidazole rings of adjacent chains (C–H···π angles 110.1 and 109.5°, and C···π distances 3.294 and 3.294 Å). Also, there are π–π interactions between the imidazole rings of the adjacent chains (perpendicular distance between centroids of the imidazole rings: 4.054 Å, dihedral angle: 0.6°). Thus, the 2D layer parallel with the *ab* plane is stabilized by these C–H···π and π–π interactions (Figure 1 and Table S1). The shortest intra- and interchain distances between Co^{II} ions are 5.625(2) and 9.095(2) Å, respectively. The layers stack together along the *c* direction in the sequence ···A–B–A–B··· with a slide of 4.55 Å (*b*/2) and the shortest Co–Co interlayer distance is about 8.170(2) Å.

Although **2-Co** has a similar composition to **1-Co** by replacing bim with bte, its structure and properties are different from **1-Co** (Figure 2). **2-Co** crystallizes in the triclinic space group $P\bar{1}$ and the Co^{II} atom is located in the symmetrical center. The cobalt atom in **2-Co** is also in the same elongated octahedron of an approximate D_{4h} point group formed by two *trans*-N atoms from bte, two *trans*-N and S atoms from four symmetry-related SCN^- anions of an *EE* mode. The bond lengths and the angles of D–Co–D are close to those of **1-Co** and the details can be found in the CIF file. Unlike **1-Co**, the ring of $Co_2(SCN)_2$ is almost coplanar and results in an approximate rectangle where the angles of Co–S–C and Co–N–C are ca. 165° and 100°, respectively, slightly larger than those in **1-Co**. Bridged by SCN^- only, **2-Co** forms 1D $[Co(SCN)_2]_n$ chains along the *a* axis; and the adjacent octahedra align parallel to one another. Different from the *gauche*-bim spacer in **1-Co**, the bte ligand in **2-Co** is of the *anti* conformation with the torsion angle N1–C3–C3A–N1A of 180.0 (2)°. Through this linear conformation, bte links adjacent cobalt chains to form a 2D neutral (4,4) network, which is very similar to that in $[Cd(NCS)_2(bte)]_n$.[4b] The 2D network in **2-Co** is completely different from the 1D toothed chain in **1-Co** only because bim in **1-Co** is replaced by bte in **2-Co**. This difference shows the subtle modulations of the bidentate spacers to construct novel topologies. The nearest Co–Co intrachain distance is 5.691(3) Å and that of the interchain is 12.014(56) Å. In the 2D network, there are no obvious π–π interactions between the adjacent triazole rings (shortest perpendicular distance between centroids of the triazole rings: 5.691 Å, dihedral angle: 0°). But, obvious π–π interactions between the 2D networks can be found (perpendicular distance between centroids of the triazole rings: 3.886 Å, dihedral angle: 0°), and there are C–H···π interactions between the hydrogen atoms of alkane and triazole rings of adjacent 2D networks (C3–H···π angles 124.5°, C···π distances 3.811 Å) (Table S2). All these weak interactions stack the 2D layers along the [011] direction in the sequence ···A–B–C–A–B–C··· to form the whole architecture (Figure S1).

The structure of **3-Mn** is very similar to that of **2-Co** (Figure 3), except that the bridging ligand is the *EE*-N_3^- anion instead of SCN^-. Also, this structure is very similar to that of $[Mn(N_3)_2(bpa)]_n$,[3m] except that the flexible bte spacer is present instead of the flexible bpa spacer. The 1D $[Mn(N_3)_2]_n$ chain is linked by bte to form a two-dimensional (4,4) layer and the layers stack along the [011] direction also in the ···A–B–C··· mode (Figure S2). There are no π–π interactions between the adjacent triazole rings in the 2D networks (shortest perpendicular distance between centroids of the triazole rings: 5.236 Å). Different from **2-Co**, the π–π interactions between adjacent 2D layers are negligibly weak (perpendicular distance between centroids of the triazole rings: 4.334 Å, dihedral angle: 0°). The coordination octahedron of Mn^{II} is more regular than that of **2-Co**; the bond lengths of Mn–N are in the range of 2.21–2.27 Å and the bond angles are from 87.0 to 93.0°. The metal–metal distance of 5.236(5) Å within the chain is shorter than that of 5.691(3) Å in **2-Co**, originating from the short length of the N_3^- ion as compared to SCN^- [2.348(8) and 2.799(10) Å for N_3^- and SCN^-, respectively]. The interchain M–M distance [11.948(56) Å] is similar to that of **2-Co** due to the same bridging ligand *anti*-bte.

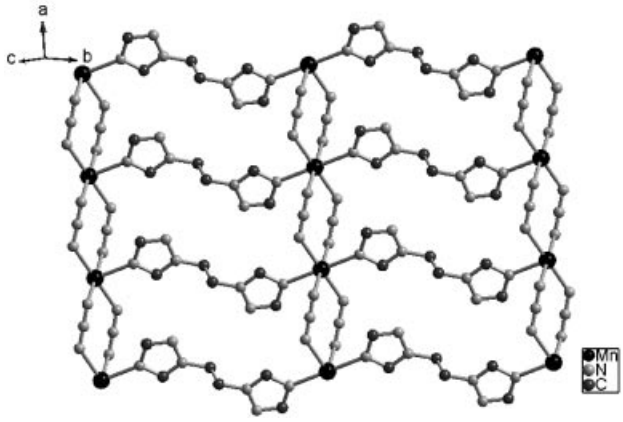

Figure 3. Two-dimensional (4,4) layer bridged by double end-to-end N_3^- and *anti*-bte ligands of **3-Mn**.

The crystal structure of **4-Mn** has some interesting characteristics. The change from the bte ligand in **3-Mn** to bim in **4-Mn** leads to very different crystal structures, which shows the importance that ancillary ligands play in tuning the crystal structure. As can be seen from Figure 4a, every Mn^{II} atom in **4-Mn** is also coordinated by six nitrogen atoms, two from the *cis*-imidazole rings of the bim ligand and the others from four *EO*-azide anions. The octahedron is largely distorted with the Mn–N bond lengths from 2.223(5) to 2.299(3) Å and N–Mn–N bond angles from 74.03(11) to 100.17(11)°. The Mn–N bond lengths do not vary much but the N–Mn–N angles deviate much from 90°, especially those of the N_{azide}–Mn–N_{azide} angles [e.g., N5–Mn1–N5a = 74.03(11)°, N8–Mn1–N8a = 77.44(11)°, and N5–Mn1–N8 = 100.17(11)°]. The detailed bond lengths and bond angles can be found in the CIF file. **4-Mn** is different from **3-Mn** in that there are two symmetrically independent azide anions (N5–N6–N7 and N8–N9–N10) and they both act as *EO* bridges, linking Mn^{II} ions to form a 1D zigzag $[Mn(N_3)_2]_n$ chain along the *a* direction (Figure 4b). The bond angles of Mn–N5–Mn and Mn–N8–Mn are 105.97(13) and 102.56(12)°, respectively, giving rise to two metal–metal intrachain distances, 3.614(5) and 3.535(5) Å, respectively. These kinds of double *EO*-azide-bridged Mn^{II} ions form a ferromagnetic chain in **4-Mn** as in two reported compounds.[2e,15]

The bim ligands in the *anti* conformation all act as bridges to expand the $[Mn(N_3)_2]_n$ chains into a 3D architecture. No obvious weak interactions can be found in **4-Mn** as the bim ligands are sufficiently separated from each other. Along the chain, the bim ligands of the Mn^{II} ions point in four different directions alternatively (Figure 4c), leading to an interesting shape of a "molecular windmill", with bim

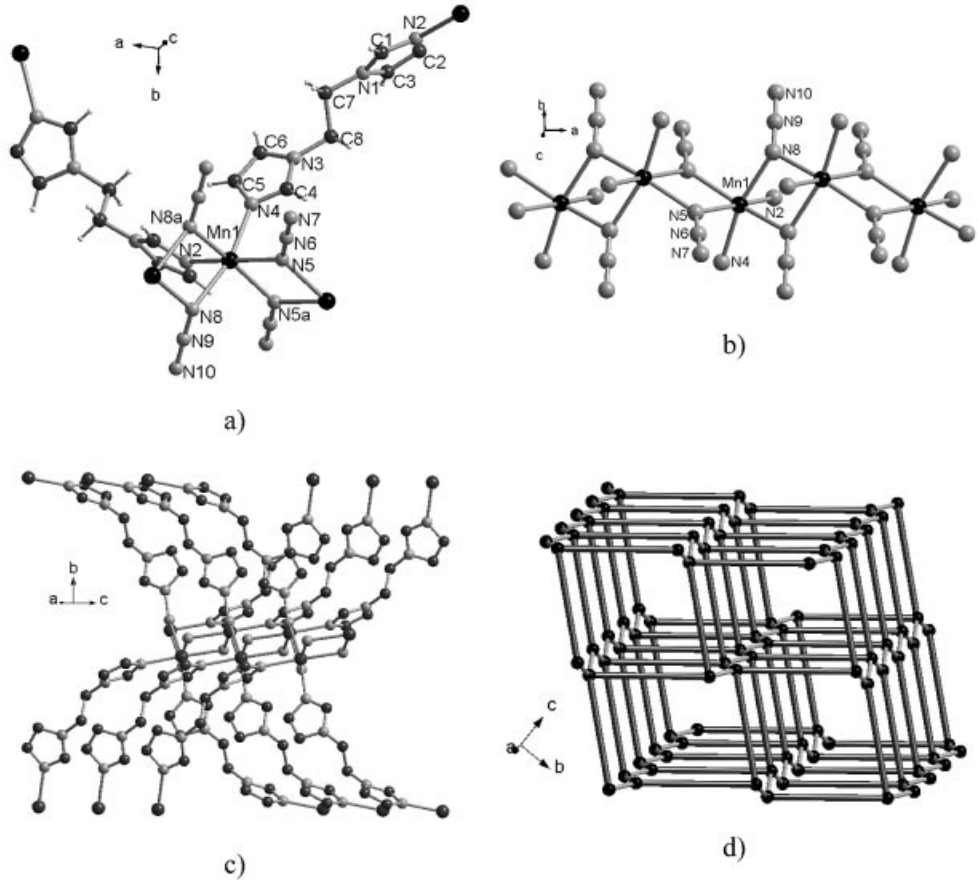

Figure 4. a) Coordination environment of Mn1 in **4-Mn**. b) Chain structure bridged by *EO*-azide anions along the *a* direction. c) Connections between adjacent chains. d) 3D distorted diamondoid topology of **4-Mn**.  © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ligands in four directions as four arms. As a result of this connection mode, every Mn^{II} atom is a four-connected node, and thus the topology of **4-Mn** is a distorted 3D diamond, as can be seen in Figure 4d. If a dimer Mn^{II} bridged by azide is considered as one node, the structure can also be viewed as a simple cubic topology. The distance between the Mn^{II} ions bridged by bim is 11.460(14) Å, and such a long distance leads to porous channels along the *a* direction.

Magnetic Properties

1-Co

The plots of $\chi_M T$ versus T and χ_M^{-1} versus T measured from 2 to 300 K in 1 kOe are displayed in Figure 5. At 300 K, the $\chi_M T$ value is 3.10 $cm^3 K mol^{-1}$ and decreases to a minimum of 1.71 $cm^3 K mol^{-1}$ at 8 K, then it increases abruptly to 5.78 $cm^3 K mol^{-1}$ at 2 K. Fitting the data above 30 K using the Curie–Weiss law, $\chi_M = C/(T - \theta)$, gives a Curie constant C = 3.31 $cm^3 K mol^{-1}$, significantly larger than the spin-only value of 1.875 $cm^3 K mol^{-1}$ for Co^{2+}, and a negative Weiss constant θ of –18.8 K. Commonly, this kind of behavior of $\chi_M T$ and the negative θ value may indicate the occurrence of a dominant antiferromagnetic coupling between the spin carriers. However, because the spin-orbit coupling itself can lead to a negative θ value and a decrease of $\chi_M T$ at high temperatures, caution must be paid concerning those spins with large spin-orbit coupling, such as the Co^{2+} ion in an octahedral ligand field. Actually, the increase of $\chi_M T$ below 8 K indicates the possibility of ferromagnetic coupling. Although difficult, some efforts have been made to calculate the spin-orbit coupling parameter λ (λ = –170 cm^{-1} for the free ion), the axial splitting parameter Δ (and then the axial zero-field splitting parameter D), and/or the exchange coupling parameter J for some mono- and dinuclear Co^{II} ions in the octahedral field.[16–18] In the case of **1-Co**, we fitted the susceptibility data by considering a mononuclear Co^{2+} ion with spin-orbit coupling parameter λ ($H = -\lambda LS$) in a molecular-field approximation. The χ_{mono} for a mononuclear Co^{2+} in an octahedral environment can be calculated from Equation (1)[16] with $x = \lambda/k_B T$.

The parameter A gives a measure of the crystal field strength relative to the interelectronic repulsions and is equal to 1.5 for a weak crystal field, 1.32 for a free ion, and 1.0 for a strong field. Considering the molecular-field theory with zJ as the total exchange parameter, we can fit our experimental data above 30 K with Equation (2).[19]

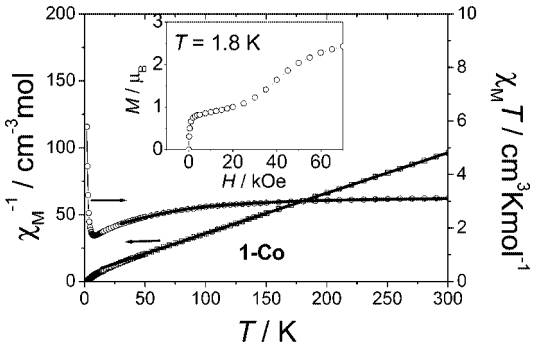

Figure 5. Plots of $\chi_M T$ versus T and χ_M^{-1} versus T from 2 to 300 K of **1-Co**. The line across χ_M^{-1} is the fit using the Curie–Weiss law and that along $\chi_M T$ represents the best fit using the model mentioned in the text. Inset: the field-dependent isothermal magnetization $M(T,H)$ for **1-Co** at 1.8 K.

$$\chi = \frac{\chi_{mono}}{1 - (2zJ/Ng^2\beta^2)\chi_{mono}} \quad (2)$$

In Equations (1) and (2), N, g, β, k_B, and T have their usual meanings. The best fit (Figure 5) gives λ = –117 cm^{-1} = –168 K, A = 1.24, and zJ = 0.42 cm^{-1} = 0.61 K with $R = 1.3 \times 10^{-5}$ [$R = \Sigma(\chi_{obsd.} - \chi_{calcd.})^2/\Sigma(\chi_{obsd.})^2$].

Although our results are semi-quantitative due to the impreciseness of the molecular-field theory, the evaluated positive zJ shows the possibility of the ferromagnetic interaction between Co^{II} neighbors. It is also evidenced by the isothermal magnetization measurement at 1.8 K (inset of Figure 5). The magnetization increases very fast from zero to about 0.7 μ_B at 2 kOe, which indicates the occurrence of ferromagnetic coupling and might suggest the occurrence of a phase transition. After a slow increase to about 1.0 μ_B at 20 kOe, the magnetization increases faster again to 2.43 μ_B at 70 kOe. To clarify the occurrence of a phase transition, the temperature dependence of the zero-field-cooled and field-cooled magnetization (ZFCM and FCM) at 20 Oe from 1.8 to 8 K, and the *ac* susceptibility under H_{dc} = 0 Oe and H_{ac} = 3 Oe from 1.8 to 4 K were measured, and the results are presented in Figure S3. All these results show no sign of long-range ordering at the lowest temperature limit of 1.8 K of our SQUID system.

2-Co

The temperature dependence of the susceptibility χ_M of **2-Co** was measured in a magnetic field of 5 kOe from 2 to 300 K and the result is plotted as $\chi_M T$ versus T and χ_M^{-1} versus T in Figure 6. After decreasing slowly upon cooling to a minimum of 3.49 $cm^3 K mol^{-1}$ at 40 K (inset of Figure 6), $\chi_M T$ increases abruptly to a peak at 4.5 K, and then

$$\chi_{mono} = \frac{1}{T} \times \frac{\frac{7(3-A)^2 x}{5} + \frac{12(2+A)^2}{25A} + \left\{\frac{2(11-2A)^2 x}{45} + \frac{176(2+A)^2}{675A}\right\} \times \exp\left(\frac{-5Ax}{2}\right) + \left\{\frac{(5+A)^2 x}{9} - \frac{20(2+A)^2}{27A}\right\} \exp(-4Ax)}{\frac{8x}{3}\left\{3 + 2\exp\left(\frac{-5Ax}{2}\right) + \exp(-4Ax)\right\}} \quad (1)$$

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

drops again until 2 K. The data in the range of 30–300 K obeys the Curie–Weiss law with $C = 3.79\ cm^3\,K\,mol^{-1}$ and a negative θ value of –3.50 K. As is discussed for **1-Co**, the small negative θ value does not necessarily come from the AF coupling through the *EE*-SCN^- ion but from the spin-orbit coupling. Similar to that of **1-Co**, the $\chi_M T$ data above 30 K can also be fitted by Equations (1) and (2) with a small temperature-independent paramagnetic constant $\chi_{TIP} = 0.0003\ cm^3\,mol^{-1}$. The best fit (Figure 6) gives $\lambda = -85.6\ cm^{-1} = -124$ K, $A = 1.45$ and $zJ = 2.43\ cm^{-1} = 3.51$ K with $R = 5\times10^{-6}$ [$R = \Sigma(\chi_{obsd.} - \chi_{calcd.})^2/\Sigma(\chi_{obsd.})^2$]. The A value shows the weak ligand field and the positive zJ clearly indicates the existence of the dominant ferromagnetic coupling between the adjacent Co^{II} ions, consistent with the result of **1-Co**.

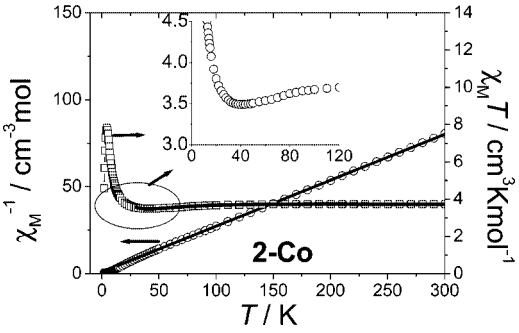

Figure 6. Plots of $\chi_M T$ versus T and χ_M^{-1} versus T from 2 to 300 K of **2-Co**.The line across χ_M^{-1} is the fit using the Curie–Weiss law and that along $\chi_M T$ represents the best fit using the model mentioned in the text. Inset: the expansion of the minimum of $\chi_M T$.

To prove the long-range ordering of **2-Co**, suggested by the peak of $\chi_M T$ at 4.5 K, we performed other measurements at low temperatures. The isothermal magnetization at 1.80 K with the field up to 50 kOe shows a pronounced sigmoid behavior of a metamagnet. The magnetization first increases slowly with increasing field strength, then shows a sharp transition to a ferromagnetic state (or a paramagnetic one) (Figure 7). At 50 kOe, the magnetization value is 2.80 μ_B, close to the expected saturated value of high-spin Co^{II}. The critical field is ca. 0.65 kOe at 1.8 K, estimated from the sharp peak of dM/dH, which is the field strength of the steepest point of the $M(H,T)$ curve. We also measured the *ac* isothermal magnetization at $H_{ac} = 3$ Oe with a dc field from –6 to + 6 kOe and a frequency of 666 Hz (Figure S4) and the FCM from 2 to 6 K at different fields (200, 400, 500, 600 and 800 Oe) (inset of Figure 7). The sharp peak of χ_M' is consistent with that of dM/dH; and the peak of χ_M in the FCM shifts to low temperatures with increasing external fields and finally disappears when the field is larger than the critical field. Also, the temperature-dependent ac susceptibility under $H_{dc} = 0$ Oe and $H_{ac} = 3$ Oe with frequencies of 277, 666, 1633, and 4111 Hz was measured from 2 to 6 K (Figure 8). The in-phase signal shows a sharp peak at ca. 2.9 K, and no detectable out-of-phase signal or frequency dependence was observed.

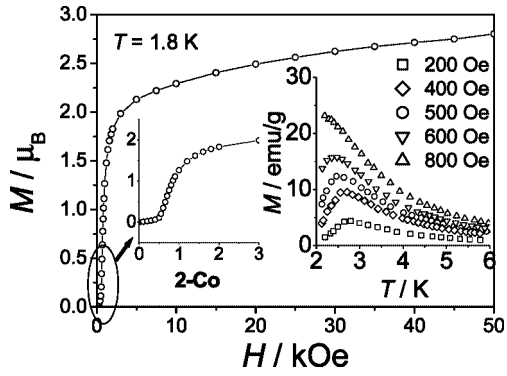

Figure 7. Field-dependent isothermal magnetization $M(T,H)$ for **2-Co** at 1.8 K. The low-field region is expanded for clarity. Inset: field-cooled magnetization from 2 to 6 K at different fields.

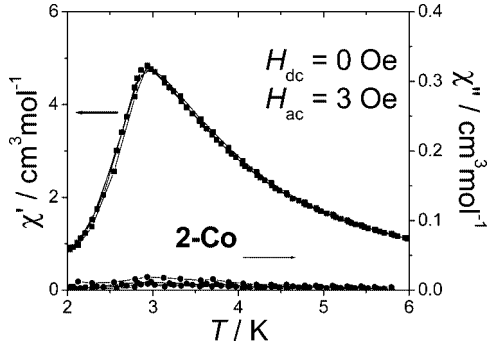

Figure 8. Ac susceptibilities from 2 to 6 K in zero applied dc field and an ac field of 3 Oe at different frequencies (277, 666, 1633, 4111 Hz) for **2-Co**.

All of the measured data indicates that **2-Co** is a metamagnet below the critical temperature 2.9 K, and the critical field for the metamagnetic transition is ca. 650 Oe at 1.8 K. Considering the structure, the metamagnetism of **2-Co** can be rationalized as a result of the competition between the weak antiferromagnetic coupling among the ferromagnetic $[Co(SCN)_2]_n$ chains and the external field. External fields larger than 650 Oe overcome the antiferromagnetic stacking of the chains and turn the AF ground state into a paramagnetic one.

3-Mn

The magnetic susceptibility χ_M of **3-Mn** measured at 10 kOe from 2 to 300 K shows a broad peak at about 50 K (Figure S5), which is typical for an AF-coupled system. As can be seen from Figure 9, the $\chi_M T$ value at 300 K is $3.61\ cm^3\,K\,mol^{-1}$, which is significantly lower than the spin-only value of $4.375\ cm^3\,K\,mol^{-1}$, and decreases continuously to $0.0387\ cm^3K\,mol^{-1}$ at 2 K. Fitting of the data above 130 K with the Curie–Weiss law gives $C = 4.94\ cm^3\,K\,mol^{-1}$ and $\theta = -108$ K, indicating a strong antiferromagnetic coupling between the Mn^{II} ions bridged by the *EE*-N_3^- anion. At 1.8 K, the isothermal magnetization $M(T,H)$ increases almost linearly from 0 to 50 kOe and reaches 0.2 μ_B per Mn^{II} atom at 50 kOe, far from the saturation value $M_S = 5\ \mu_B$ for a spin-only Mn^{II} ion, confirming the antiferromagnetic coupling between the Mn^{II} ions. Considering the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

low-dimensional structure of **3-Mn**, we can fit the susceptibility data χT above 30 K using Equation (3) based on the molecular-field theory;[19] χ_{chain} is the susceptibility of the Fisher model of a 1D equally spaced Hensenberg chain for a classical spin (S = 5/2) with the Hamiltonian $H = -2J\Sigma_{<i,j>}S_i \cdot S_j$ [Equation (4)][19a] with u represented by Equation (5).

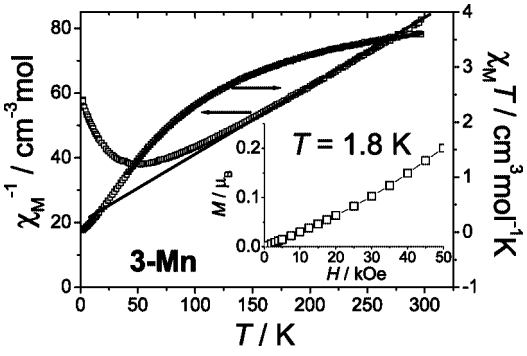

Figure 9. Plots of $\chi_M T$ versus T and χ_M^{-1} versus T from 2 to 300 K of **3-Mn**. The line across χ_M^{-1} is the fit using the Curie–Weiss law and that along $\chi_M T$ represents the best fit using the chain model mentioned in the text. Inset: field-dependent isothermal magnetization $M(T,H)$ for **3-Mn** at 1.8 K.

$$\chi = \frac{\chi_{chain}}{1 - (2zJ/Ng^2\beta^2)\chi_{chain}} \quad (3)$$

$$\chi_{chain} = \frac{Ng^2\beta^2S(S+1)}{3kT}\frac{1+u}{1-u} \quad (4)$$

$$u = \coth[\frac{JS(S+1)}{kT}] - [\frac{kT}{JS(S+1)}] \quad (5)$$

In Equations (3)–(5), S = 5/2; J and zJ represent the magnetic coupling constants of the intra- and interchains. The best fit (Figure 9) gives $J = -8.08(3)\ cm^{-1} = -11.7$ K, $zJ = -0.9(1)\ cm^{-1} = -1.3$ K, and $g = 2.057$ with $R = 4.7 \times 10^{-5}$ [$R = \Sigma(\chi_{obsd.}T - \chi_{calcd.}T)^2/\Sigma(\chi_{obsd.}T)^2$]. The negative J and zJ values show that an AF interaction exists both within and between the chains.

4-Mn

As can be seen from the plots of $\chi_M T$ versus T and χ_M^{-1} versus T measured from 2 to 300 K in 10 kOe displayed in Figure S6, the value of $\chi_M T$ increases gradually with decreasing temperature and shows a peak at 10 K. This behavior suggests intrachain ferromagnetic coupling; the decrease of $\chi_M T$ below 10 K may be due to interchain antiferromagnetic coupling or saturation effect of the field. Fitting of the data above 100 K with the Curie–Weiss law gives C = 4.16 $cm^3\,K\,mol^{-1}$ and a positive θ value of +23.5 K, also indicating the dominant ferromagnetic coupling between Mn^{II} ions transmitted by the *EO*-azide anion.

To further clarify the nature of the low-temperature phase, we have measured the FCM in different fields (200, 500, 1500 Oe) (inset of Figure 10) and the ac susceptibility under H_{dc} = 0 Oe and H_{ac} = 2 Oe from 2 to 15 K (Figure 10). The FCM at low fields of 200 and 500 Oe shows peaks at about 3.0 K but the peak disappears in the high-field region (1.5 kOe). This behavior is quite similar to that of **2-Co** and indicates a phase transition from an antiferromagnetic state to a ferromagnetic one above some critical field. Actually, the ac susceptibility under zero dc field is typical for an antiferromagnet; the in-phase signal shows a sharp peak at 3.0 K, and no detectable out-of-phase signal nor frequency dependence was observed. In order to investigate the phase transition with increasing field, the isothermal magnetization $M(T,H)$ with fields up to 70 kOe at 1.8 K (Figure 11) was measured. As a whole, the magnetization increases fast at low fields and almost reaches saturation at about 10 kOe. At the highest field of 70 kOe, the saturation value is 5.1 μ_B, very close to the saturated value of 5 μ_B for S = 5/2. Careful examination of the low-field range between 0 and 3 kOe reveals two obvious abrupt steps, with H_{c1} = 0.23 kOe and H_{c2} = 0.82 kOe, defined as the H values with the steepest slopes of the $M(H,T)$ curve (inset of Figure 11). The plateau region at 1.8 K is presumably associated with the familiar spin-flop state at the intermediate field values $H_{c1} < H < H_{c2}$. The ac isothermal magnetization under a field of H_{ac} = 2 Oe with H_{dc} from 0 to 3 kOe and a frequency of 666 Hz at 1.8 K (Figure S7) supports these two transitions. Two obvious peaks, χ'_M and χ''_M, are consistent with the peaks of dM/dH.

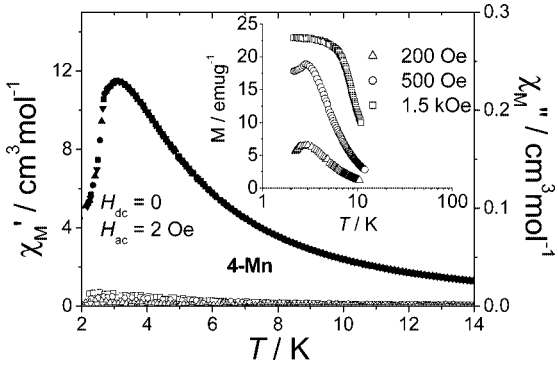

Figure 10. Ac susceptibilities from 2 to 6 K in the zero applied dc field and an ac field of 2 Oe at different frequencies (277, 666, 1633, 4111 Hz) for **4-Mn**. Inset: field-cooled magnetization at different fields.

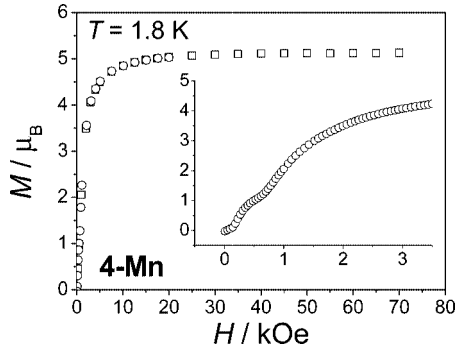

Figure 11. Field-dependent isothermal magnetization $M(T,H)$ for **4-Mn** at 1.8 K. Inset: expansion of the low-field region.

Based on the structure of **4-Mn** and the magnetic data, we rationalize that this phenomenon is a metamagnetic

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

transition coexisting with a spin-flop transition. The metamagnetic transition originates from competition between the external field and the AF coupling among ferro- or ferrimagnetic chains or layers. And the spin-flop transition is quite common for many antiferromagnets with weak anisotropy (for Mn^{II}, the ^6S ground state makes it one of the weakest anisotropic ions). The moment orientation switches from the easy axis to an orientation perpendicular to the applied field only when the fields are larger than a critical field H_{c1}.[19c] From the magnetic point of view, **4-Mn** can be considered as a 1D ferromagnetic chain because of the very large interchain Mn–Mn distances [11.460(14) Å] as compared to the short intrachain distances of 3.614(5) and 3.535(5) Å. The intrachain coupling transferred by the *EO*-N_3^- anion is ferromagnetic since the angles of Mn–N_{azide}–Mn are about 103° and 106°, and there are numerous reports concluding that this kind of bridging azide favors the ferromagnetic coupling between Mn^{II} ions.[2e,5a,15] With the weak AF coupling between the chains, these ferromagnetic chains are aligned in an *anti*-parallel fashion to each other at low external fields. As the field increases to a spin-flop field H_{c1} = 0.23 kOe, **4-Mn** transfers from the AF state to a spin-flop one and the antiparallel magnetizations of the two sub-lattices flop from the direction of the easy axis to that perpendicular to it. Further increase of the external field to a critical field H_{c2} = 0.82 kOe can totally overwhelm the interchain AF coupling and the state turns into a ferromagnetic one. Similar behavior was also observed in a compound where Mn^{II} and Ni^{II} ions were ferromagnetically bridged by NO_2^- anions to form a ferromagnetic chain.[20]

Conclusions

By using two flexible long ligands [1,2-bis(1,2,4-triazol-1-yl)ethane (bte) and 1,2-bis(imidazol-1-yl)ethane (bim)], and two short anion bridges SCN^- and N_3^-, we successfully synthesized four new coordination polymers formulated as $[Co(SCN)_2(bim)]$ (**1-Co**), $[Co(SCN)_2(bte)]$ (**2-Co**), $[Mn(N_3)_2(bte)]$ (**3-Mn**), and $[Mn(N_3)_2(bim)]$ **(4-Mn)**. **1-Co** crystallizes as a triple-bridging chain compound with double *EE*-SCN^- and single *gauche*-bim ligands as bridges. **2-Co** and **3-Mn** have very similar 2D (4,4) layer structures with an *anti*-bte ligand connecting $[Co(SCN)_2]_n$ or $[Mn(N_3)_2]_n$ chains bridged by double *EE*-SCN^-/N_3^- anions. **4-Mn** forms a distorted diamondoid structure through double *EO*-N_3^- and *anti*-bim bridging ligands. Magnetic measurement reveals that the dominant magnetic coupling between the Co^{II} ions in **1-Co** and **2-Co** is ferromagnetic. **1-Co** remains paramagnetic up to 1.8 K and **2-Co** is a metamagnet below T_N = 2.9 K with a critical field H_C = 650 Oe at 1.8 K. For **3-Mn**, the strong AF coupling leads to an AF chain compound without long-range ordering above 1.8 K. For **4-Mn**, the AF ground state exists below T_N = 3.0 K and a metamagnetic transition coexisting with a field-induced spin-flop transition was observed with the H_{c1} = 0.23 kOe and H_{c2} = 0.82 kOe. Our results show that a combination of short anion bridges (SCN^-/N_3^-) and flexible-bidentate long spacers can be used to construct coordination polymers with novel topologies and interesting magnetic properties.

Experimental Section

General Remarks: All starting materials were commercially available, reagent grade, and used as purchased without further purification. The ligands bim and bte were prepared according to a literature method.[21] Elemental analyses of C, H, N were carried out with a Perkin–Elmer 240C analyzer. FTIR spectra were obtained for KBr pellets with a Nicolet 170SX FTIR spectrophotometer in the 4000–400 cm^{-1} region. Variable-temperature magnetic susceptibility, zero-field ac magnetic susceptibility measurements, and field dependence of magnetization were performed with an Oxford Maglab 2000 System or a Quantum Design MPMS XL-5 SQUID system. The experimental susceptibilities were corrected for the diamagnetism of the constituent atoms (Pascal's tables).

Synthesis

$[Co(SCN)_2(bim)]$ (1-Co): $Co(NO_3)_2{\cdot}6H_2O$ (0.146 g, 0.5 mmol), KSCN (0.097 g, 1.0 mmol) and bim (0.081 g, 0.5 mmol) in 14 mL of water were heated in a Teflon-lined autoclave (20 mL) at 180 °C for 4 d. After slow cooling to room temperature, purple prism-shaped crystals suitable for single-crystal X-ray crystallographic analysis were obtained. The crystals were filtered from the mother liquor and washed with ethanol. Yield: 0.110 g (65%). $C_{10}H_{10}CoN_6S_2$ (337.29): calcd. C 35.61, H 2.99, N, 24.92; found C 35.54, H 2.96, N 24.86. IR: $\tilde{\nu}$ = 3129 (w), 2099 (vs), 1605 (w), 1520 (s), 1439 (w), 1373(w), 1285 (w), 1246 (w), 1107 (m), 1103 (m), 941 (w), 837 (w), 752 (m), 656 (m), 629 (m) and 471 (w) cm^{-1}.

$[Co(SCN)_2(bte)]$ (2-Co): $Co(NO_3)_2{\cdot}6H_2O$ (0.146 g, 0.5 mmol) and KSCN (0.097 g, 1.0 mmol) in a 20 mL solution of H_2O/EtOH (1:1, v/v) was added to one side of an H-shaped tube, and 20 mL of an H_2O/EtOH solution (1:1, v/v) of bte (0.082 g, 0.5 mmol) was added to the other side of the H-shaped tube. After approximately 3 months, purple crystals suitable for X-ray analysis were obtained. Yield: 0.090 g (53%). $C_8H_8CoN_8S_2$ (339.3): calcd. C 28.32, H 2.38, N 33.04; found C 28.24, H 2.29, N 32.86. IR: $\tilde{\nu}$ = 3121 (w), 2114 (vs), 1524 (m), 1451 (w), 1385 (m), 1319 (w), 1285 (m), 1208 (w), 1127(s), 1012 (m), 992 (m), 874 (w), 698 (w), 679 (m), 648 (m) and 463 (w) cm^{-1}.

$[Mn(N_3)_2(bte)]$ (3-Mn): A methanolic solution (20 mL) of bte (0.082 g, 0.5 mmol) was slowly added to an aqueous solution (20 mL) of $MnSO_4{\cdot}H_2O$ (0.085 g, 0.5 mmol) and excess NaN_3 (0.163 g, 2.5 mmol) while stirring. The mixtures were stirred at room temperature and the resultant solution was filtered. After the filtrate was allowed to stand in the air for 1 week, well-shaped pale yellow crystals were obtained. Yield: 0.126 g (83%). $C_6H_8MnN_{12}$ (303.1): calcd. C 23.77, H 2.66, N 55.45; found C 23.72, H 2.58, N 55.35. IR: $\tilde{\nu}$ = 3124 (w), 2076 (vs), 1780 (w), 1523 (s), 1461 (w), 1367 (w), 1281 (m), 1207 (m), 1154 (w), 1123 (m), 1010 (m), 985 (m), 893 (w), 700 (w), 679 (w), 654 (w) and 419 (w) cm^{-1}.

$[Mn(N_3)_2(bim)]$ (4-Mn): For this synthesis, $MnSO_4{\cdot}H_2O$ and bim were used in a 1:0.5 molar ratio with excess NaN_3 because the reaction of $MnSO_4{\cdot}H_2O$ and bim in a 1:1 molar ratio with excess NaN_3 will produce the complex $[Mn(N_3)_2(bim)_2]_n$.[4d] An aqueous solution (10 mL) of excess NaN_3 (0.163 g, 2.5 mmol) was mixed with 10 mL of an aqueous solution of $MnSO_4{\cdot}H_2O$ (0.170 g, 1.0 mmol) and stirred for 20 min. An ethanol solution (10 mL) of bim (0.081 g, 0.5 mmol) was then slowly added to the above solu-

Single-Crystal X-ray Crystallography: All data collections were performed at a temperature of 193.15 K except for the crystal data collection of **2-Co** which was performed at 298(2) K with a Rigaku Mercury CCD diffractometer with ω-scan technique. The structures were solved by direct methods and refined with full-matrix least-squares techniques based on F^2 using the SHELXS-97 and SHELXL-97 programs. Anisotropic thermal parameters were assigned to all non-hydrogen atoms. The hydrogen atoms of the bte and bim ligands were generated geometrically. Details of the crystallographic data are listed in Table 1. CCDC-221765 and -260333 to -260335 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: +44-1223/336-033; E-mail, deposit@ccdc.cam.ac.uk]. Also, CIF files of these four compounds can be found in the Supporting Information.

Supporting Information Available: Tables of the details of the π–π and C–H···π interactions of **1-Co** and **2-Co**, the stack of the layers of **2-Co** and **3-Mn**, ac susceptibility and ZFCM/FCM of **1-Co**, ac isothermal magnetization of **2-Co** and **4-Mn**, $\chi_M T$ versus T of **3-Mn**, $\chi_M T$ versus T, χ_M^{-1} versus T, and dM/dH of **4-Mn**.

Variability in the Structures of Luminescent [2-(Aminomethyl)pyridine]silver(I) Complexes: Effect of Ligand Ratio, Anion, Hydrogen Bonding, and π-Stacking

Rodney P. Feazell,[a] Cody E. Carson,[a] and Kevin K. Klausmeyer*[a]

Keywords: Silver / N ligands / X-ray diffraction / Coordination modes

The reaction of 2-(aminomethyl)pyridine (2-amp) with silver(I) salts of triflate (OTf^-), trifluoroacetate (tfa^-), and tetrafluoroborate (BF_4^-) produce monomeric, dimeric, bridged, and polymeric structural motifs. The structural characteristics are dependent upon the ratio of ligand/metal in the structure as well as the ability of the anion to coordinate to the metal centers and form hydrogen bonds to the bound ligands. The silver coordination environment takes on several geometries including near linear (**6**), trigonal (**4**), tetrahedral (**1**), and both trigonal-bipyramidal and square-based pyramidal in a single structure (**2**). Structures **2**, **3**, and **5** also display short Ag–Ag contacts ranging from 2.8958(3) to 3.0305(4) Å. The species with metal–metal interactions, which are connectively very similar to their metal-isolated counterparts of **1**, **4**, and **6**, are held together only by weak π-stacking interactions or hydrogen bonds to their respective anions. Low-temperature luminescence spectra were collected for all compounds and are compared.

Introduction

Progress in the field of crystal engineering has been greatly complemented by coordination studies of the coinage metals.[1–8] Studies of silver in particular have had much to offer. This is because of the flexibility in its coordination sphere and the ease with which it varies the coordination number.[9–13] Many silver coordination architectures are readily obtainable through slight variations in ligand and/or anion and include discrete, small molecules, supramolecular arrays, and 1-, 2-, and 3-dimensional coordination networks.[13–17] Several systematic studies of the structural dependence on anions have been nicely demonstrative of the diversity possible with small changes in counterion properties such as coordinating or hydrogen-bonding ability.[18–23] A related area of this research that has proved lacking, however, is that concerned with the ligand/metal ratio dependence of these structures.[24] To the best of our knowledge, no thorough report has been given that shows the effects of changing the ratio of ligand/metal in bidentate silver(I) systems of various anions. This led us to investigate the changes in the solid-state structures of [2-(aminomethyl)-pyridine]silver(I) complexes that are caused by altering the ratio of ligand/metal in the reaction mixtures. One resulting feature that is of particular interest in these and other silver complexes is the closed-shell metal–metal interaction that is very well known to occur in the monovalent group 11 elements.[25–31] While not as broadly represented or studied as the aurophilic attraction that holds the gold–gold interaction intact, a small surge of recent work has been dedicated to examining the properties of this argentophilic contact.[32–37] Included in this group are a handful of theoretical studies that put the strength of the interaction along the same intensity as that of a hydrogen bond with an idealized internuclear separation of 3.137–3.208 Å.[38–41]

Herein we demonstrate that not only can the molecular architecture of silver(I) coordination complexes be altered by changes in the counterion, but they can also be largely affected by the ratio of ligand/metal. The 2-(aminomethyl)-pyridine ligand, whose small bite angle imposes a predisposition for chelation, is seen to construct a range of coordination motifs, shown in Figure 1, from simple monomers to coordination polymers with various silver(I) salts simply by changing its ratio in solution. The resulting complexes contain a number of interesting structural features and physical properties including several short, sterically unfavored Ag–Ag interactions, bridging 2-amp ligands and a pronounced luminescence.

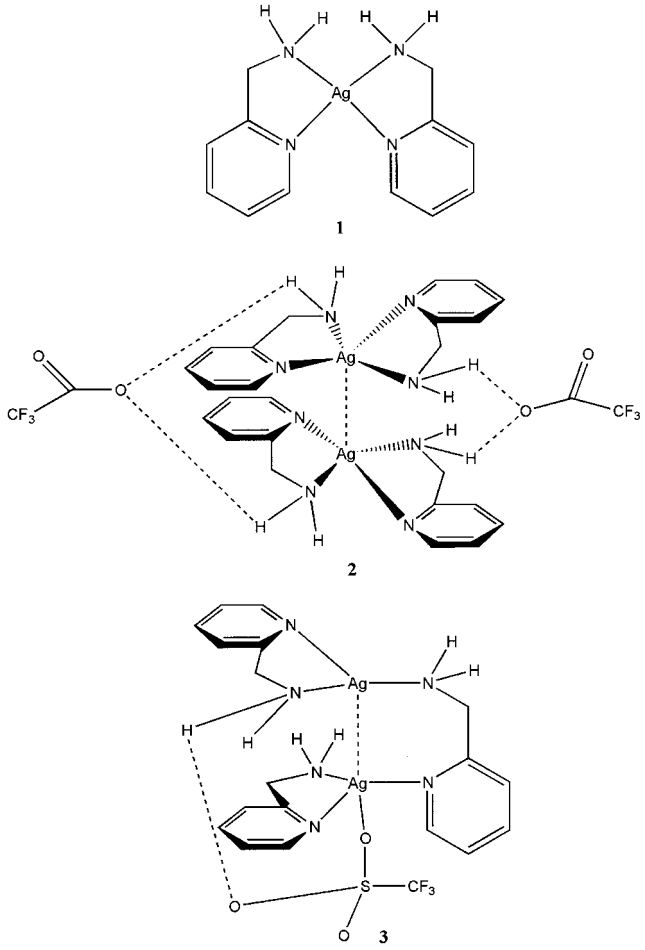
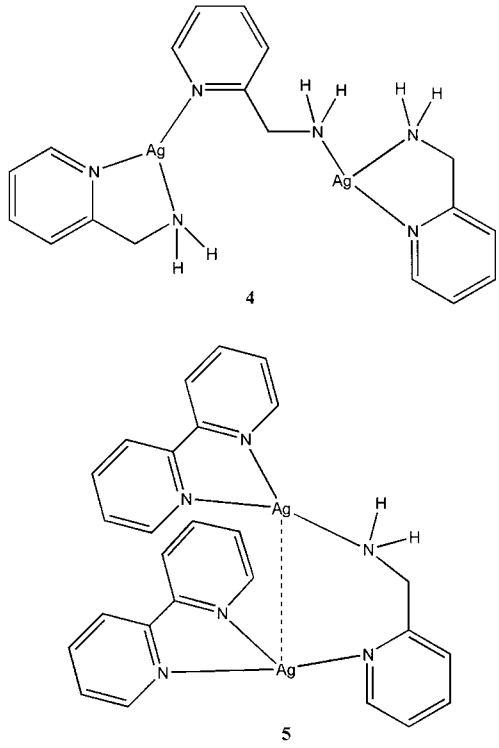
Results and Discussion

Preparation and NMR Spectroscopy

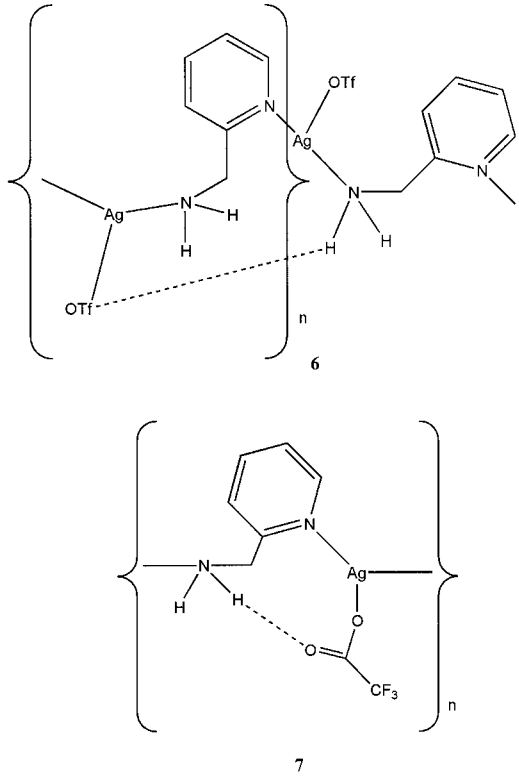
The 2-(aminomethyl)pyridine complexes **1**–**7** (Schemes 1, 2, and 3) were all prepared by the direct reaction of the ligand with silver(I) salts in varying ratios. The 1:1 $AgBF_4$ structure has already been discussed in a previous study.[23] The many intriguing structural features of the complexes presented here are seen to stem directly from the ratio of ligand/metal, with the ratio itself often being influenced by the properties of the anion present. An example of this is the silver triflate complex which we have been unable to force beyond a 3:2 ratio of ligand/metal, while that of the trifluoroacetate has not been isolable at 3:2 but proceeds directly to 2:1. Hydrogen bonding between the amine protons and the anions are a major determining factor in the structure, orientation, and 3-dimensional growth of the complexes.



Scheme 1.



Scheme 2.



Scheme 3.

The ^1H NMR spectra of all the compounds are, as expected, generally similar. Signal shifts of the amine protons as well as of the *ortho*-*N*-hydrogen atoms on the pyridine rings are demonstrative of the differences in coordinated silver environments caused by the different anions present. The greatest shifts are seen examining the $–NH_2–$ protons in the presence of silver, ranging from 1.3 to 2.0 ppm downfield of the δ = 1.67 ppm chemical shift of the free 2-amp ligand in solution (NMR spectroscopic data for the free

ligand is available in the Supporting information; for Supporting information see also the footnote on the first page of this article). These shifts are implicative of solution-state complexation.

X-ray Crystallography

Structural confirmation of all the complexes mentioned herein was provided by X-ray diffraction studies. Single crystals of all compounds were analyzed and structural diagrams are displayed in Figures 2–10. A summary of the X-ray data is presented in Tables 1 and 2. Collections of selected bond lengths, angles, interatomic distances and hydrogen bonds are given in Tables 3, 4, and 5.

Description of the Crystal Structures

The ratio of 2-amp ligand/Ag in the structures of both compounds **1** and **2** is 2:1. A significant change in both the metal geometries and the ligand–metal bond lengths are seen when going from **1** to **2**, and are the result of differences in interaction of the BF_4^- and tfa^- anions. The structure of **2** contains a rather short Ag–Ag interaction[38] that is obtained at the expense of the relaxed tetrahedral environment of the metal-separated structure of **1**.

The expansion of the silver coordination environment from linear in a two-coordinate polymeric setting[23] to near tetrahedral upon the addition of 2 equiv. of the chelating 2-(aminomethyl)pyridine ligand to produce compound **1** was as expected. In the former structure, the only way to achieve the two-coordinate environment necessary to accommodate a 1:1 ratio of 2-amp/$AgBF_4$ is with an outward twisting of the ligand. In this way the amino and pyridine donors of separate 2-amp ligands are utilized, linking the linearly coordinated silver ions into a one-dimensional coordination polymer. In the latter, the increased coordination number allows for the formation of a chelated complex which is easily achieved by the 2-amp ligand creating the distorted tetrahedron that is shown in Figure 2. The deformation of the tetrahedral bond angles in this compound is caused by the small bite angle of the coordinated 2-amp ligands which averages 73°. The interligand angles are thus made more obtuse, ranging from 125.9(2)° to 133.9(2)°. BF_4^- ions are held in place in the lattice by H-bonding with the amine protons. The crystal structure of compound **1** contains two independent molecules of $(2\text{-amp})_2AgBF_4$ caused by slight differences in conformation. Amine–Ag and pyridine–Ag bonds cannot be distinguished from one another in this structure by bond lengths alone. Considerable overlap is seen with the amine–Ag distances ranging from 2.293(6) to 2.371(5) Å and the pyridine–Ag distances ranging from 2.262(6) to 2.368(4) Å.

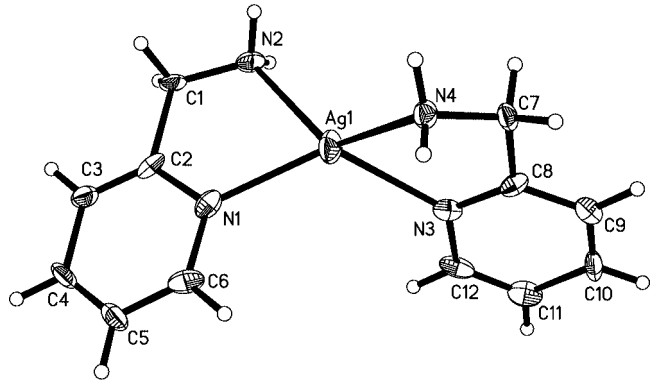

Figure 2. Molecular structure of one of the unique cationic monomers of **1**. Ellipsoids are drawn at the 50% probability level.

The crystal structure of complex **2** is shown in Figure 3 and is demonstrative of the strong effects that hydrogen bonding and the exchange of anion can have upon the structural characteristics of these compounds. Stoichiometrically identical to **1**, the use of the strong H-bond-accepting trifluoroacetate results in an unexpected sandwiching of two of the cationic units that are present in **1**. The increased propensity of the trifluoroacetate ion to hydrogen bonds enables it to act as a bridge pulling two amine groups of what would be separate units into close proximity of one another. This bridging activity is seen to occur on both sides of a now dimetallic cluster utilizing all four amine groups. The result is that the metal centers are pulled into such proximity to one another as to form a significant metal–metal interaction at 3.0077(4) Å. Similar distances are

normally found only in complexes where the interacting silver ions are being bridged directly by another donor or anion.[27] This is a noteworthy interaction seeing as how the tetrahedral environments of the individual metal centers have to undergo considerable distortions in order to achieve a geometry that allows for the contact to occur. The resulting metal–metal interaction hence seems not only to be lightly supported, but even unfavored. The reasoning behind the fact that the complex does not snap apart to become isostructural with **1** lies in the fact that the silver(I) ion is extremely flexible in its coordination sphere. In order to accommodate the silver–silver interaction the two metal centers must contort into two quite different conformations. The top silver ion adopts a distorted square-based pyramidal arrangement. For this to occur the N–Ag bond lengths are stretched to suit the new setting with the pyridine–silver bonds being stretched more, making it now possible to distinguish between the two types of donors on the basis of bond lengths. Amine–silver lengths range from 2.298(3) to 2.339(3) Å whereas the pyridine–silver lengths are stretched slightly longer to between 2.390(3) and 2.425(3) Å. The bottom silver ion suffers a similar contortion that leaves it in a trigonal-bipyramidal setting with both amine groups occupying the axial positions. Pyridine donors and the metal–metal interaction hold the equatorial spaces. This distinct difference in coordination sites assists in broadening the division between the lengths of the amine– and pyridine–silver separations; the axial amine–silver distances range from 2.265(3) to 2.292(3) Å while the equatorial pyridine–silver distances range from 2.459(3) to 2.558(3) Å. Looking outward from the initial interdimeric H-bonded bridge it is noticed that each oxygen atom of the trifluoroacetate ion is used to hold a separate set of these stacked complexes on top of each other such that the anion acts in an η^2,μ_4-fashion. This effectively constructs a linear chain of dimetallic clusters held together by hydrogen bonds.

The molecular structures of compounds **3** and **4** offer another example of the marked effect that changes in the H-bond-accepting ability of the anion has upon the conformation of the molecule. Ratios of ligand/metal in both complexes are 3:2 such that the structural differences again are being caused solely by the anion. The addition of a more strongly interacting anion has the effect of closing the 3:2 structure onto itself.

In **3**, the ratio of ligand/metal is controlled, or at least limited, by the anion. It is seen that even a fivefold excess of 2-amp does not force a ratio higher than 3:2 in the crystal structure shown in Figure 4. This is accredited to a bifunctional role of the triflate ion in the complex: its first function is to act as a coordinating anion to one of the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

metal ions, and its second is to concomitantly engage in an intramolecular H-bond through a separate oxygen atom. The addition of more than 1 equiv. of 2-amp disrupts the linear coordination environment that the silver ion has when the ligand is present in only 1 equiv. (as in compound **6**). The first 0.5 equiv. of ligand that is added past an initial 1:1 ratio forms a bridge joining two 2-amp-chelated silver(I) units. After this point, a triflate ion that binds to one of the metal centers through a single oxygen atom halts the addition of a full second equivalent of 2-amp ligand to the silver ions. In this orientation the triflate ion is then able to H-bond through a second oxygen atom to the amine protons of the ligand chelating the opposite silver ion. The effect is similar to that seen in compound **2**; H-bonding with the anion holds the silver ion bound only to nitrogen atoms sufficiently close to the anion-bound silver ion to create a strong metal–metal interaction. However, the geometry of the SO_3 portion of the triflate allows it to be involved in both coordination and H-bonding, thus forcing the structural difference with **2**. The bridging 2-amp ligand acts as a hinge as the H-bonded anion squeezes the silver ions to within 2.9137(3) Å of one another. In this structure there is a notable difference in bond lengths between the two types of ligands present. This should be expected as the stress of the five-membered ring is relieved in going from a chelating to a more relaxed bridging six-membered system. The chelated amine–silver distances are 2.277(1) and 2.236(1) Å and the chelated pyridine–silver distances are 2.396(1) and 2.403(1) Å. The same distances measured for the bridging ligand are noticeably shorter at 2.199(1) and 2.211(1) Å, respectively. The coordinating O1 atom has a bond length to Ag1 of 2.590(1) Å. In this structure, as in the last two, intermolecular H-bonding again plays a role in determining the packing of the complex with another 1-D "polymer" being constructed of the dimetallic units held together by H-bonds to the anions. H-bonds to O2 and O3 fashion a sort of dimer, while those to the non-coordinating anions assemble these dimers into a chain.

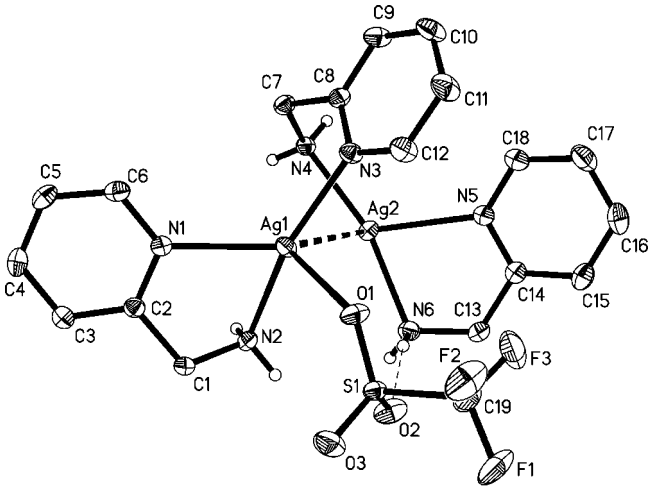

Figure 4. Molecular structure of the monopositive cation in **3**. Ellipsoids are drawn at the 50% probability level. All hydrogen atoms except for those on the amine nitrogen atoms have been removed for clarity.

In the absence of an anion capable of strongly receiving an H-bond the cationic closed structure of compound **3** opens to form the flat 3:2 complex **4**. The structure, as shown in Figure 5, is an intermediate one that bridges the gap between the polymer formed by 2-amp and $AgBF_4$ in the 1:1 ratio and the discrete structure of compound **1** with its 2:1 ratio, making $AgBF_4$ the only silver salt studied with which all three of these ratios were able to be achieved. Without the H-bonding of the anion to hold them together, the metal centers situate themselves widely separated by 5.794(2) Å on opposite sides of the bridging ligand. Each silver ion is then chelated by another 2-amp ligand creating a nearly planar dimetallic complex. Although twists and rotations about the center bridging ligand are likely to be occurring in solution, stacking of the molecules into sheets, as well as π–π interactions help keep them flat in the solid state. The distance between the planes of the aromatic rings averages around 3.2 Å from one layer to the next in the crystal structure. The BF_4^- anions can be seen to fit nicely into holes formed by this stacking of molecules and are held in place by weak H-bonds to the amine nitrogen atoms. The chelating amine–silver distances in **4** are 2.267(2) and 2.287(2) Å and the pyridine–silver distances are 2.313(2) and 2.355(2) Å. The bridging amine–silver and pyridine–silver distances are again seen to be quite shorter at 2.186(2) and 2.185(2) Å. Angles around the silver ions are distorted from the ideal 120° trigonal geometry due to the small bite angle of the chelating 2-amp ligand and have values ranging from 74.97(7) to 154.73(8)°. However, deviations of the silver ions from their respective three-nitrogen planes are small at 0.054(1) Å for Ag1 and 0.170(1) Å for Ag2, showing that they are still very much in a planar environment.

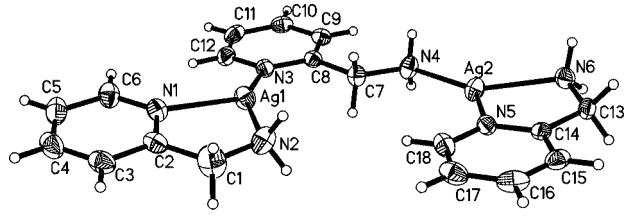

Figure 5. View of the cationic complex of **4**. Ellipsoids are drawn at the 50% probability level.

Compound **5** was prepared in an attempt to mimic the structural characteristics of **4** using 2,2′-bipyridine as the chelating ligand that caps the ends of the dimetallic structure. The addition of 2 equiv. of 2,2′-bipyridine to a solution that is 1:2 in 2-amp/$AgBF_4$ does indeed produce a compound that is stoichiometrically identical to **4** (when the bipyridine is substituted for the chelating 2-amp ligands). However, what resulted was the unexpected hybrid shown in Figure 6 that contains features of both **3** and **4**. The 2-amp ligand acts as expected in the presence of an excess of $AgBF_4$, bridging two separate metal centers. The addition of 2,2′-bipyridine results in two 2,2′-bipyridine-chelated silver ions separated by the bridging 2-amp ligand.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The connectivity of the structure formed is analogous to that seen in **4**. Otherwise, the similarities between this and **4** are few. Instead of opening up to make a flat structure, the amine-bound silver ion twists back around to form an interaction with the pyridine-bound silver ion. The resulting hairpin structure bears closer resemblance to the triflate salt in **3**. A major difference here is that there are no good H-bond donors on the bipyridine ligands and no strongly H-bond-accepting anion to link the chelating ligands, as in **2** and **3**. This leaves only the weaker π-stacking forces of the two bipyridine ligands to account for the conformation of this compound. The angle of the bipyridine planes from one another is a rather obtuse 28.4° and the ring centers are separated by an average of 4.546 Å. This lends itself to the observation that the argentophilic interaction in these compounds is a highly favored one and the 2-amp ligand bridging two interacting silver ions appears to be only slightly higher in energy than the conformation in which the silver ions are completely separated. There is also fairly prominent intermolecular π-stacking of the bipyridine rings both above and below each molecule with the parallel ring planes averaging only 3.316 Å from one another. The N–Ag distances here are quite short, second only to those seen in the polymer complex **6**. The Ag1–pyridine bond length is 2.150(2) Å and the Ag2–amine distance is 2.178(2) Å. The bipyridine-N–Ag distances are more along the lines of the lengths that have been displayed so far and range from 2.271(1) to 2.330(2) Å.

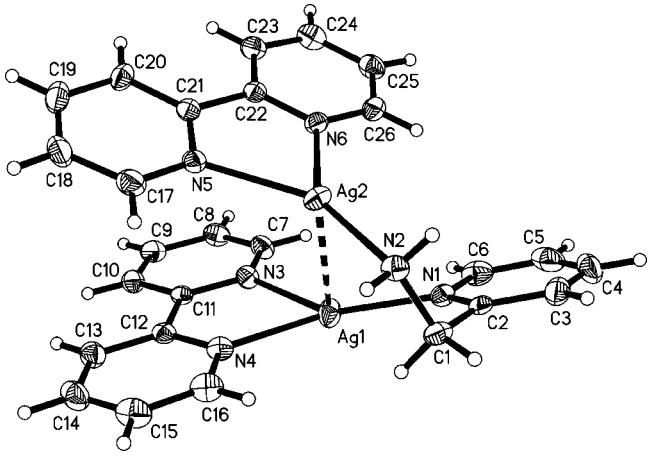

Figure 6. View of the cationic complex of **5**. Ellipsoids are drawn at the 50% probability level.

Compounds **6** and **7** show the result of the addition of the 2-amp ligand to silver triflate and trifluoroacetate salts in a 1:1 ratio. In the absence of a sufficient amount of strong donor sites to construct at least a three-coordinate environment around the metal center (in this case N-donors), each silver ion attempts to adopt its desired linear coordination environment. Since a maximum bite angle of around only 75° is obtainable with the chelating 2-amp ligand, donors from two separate ligands must be used in order to achieve this arrangement. The results are linear zigzag coordination polymers similar to those seen previously with noncoordinating anions.[23] In the case of **6** and **7**, the anions display an increasing coordination ability resulting in varying degrees of perturbation of the metal centers from their ideal linear geometry. They also allow for H-bonding within the polymer and to adjacent polymers, adding to the dimensionality of the structure.

2-(Aminomethyl)pyridine together with 1 equiv. of silver triflate assembles into a zigzagging 1-dimensional coordination polymer containing silver ions with a T-shape geometry, compound **6**. The unique portion of the polymer, shown in Figure 7, contains one silver ion bound in near-linear coordination by an amine nitrogen atom and its symmetry-equivalent pyridine nitrogen atom. The triflate anion is coordinated as well through a stretched bond to O1. When perpetuated, the 2-(aminomethyl)pyridine backbone of the polymer, shown in Figure 8, is seen to be nearly planar both perpendicular to and in the direction of its growth. This is similar to the conformation displayed in compound **4** and is likely the result of a combination of ring stacking and hydrogen bonding. The linear chains are stacked one on top of another with each row slightly offset from the previous as to accommodate the anions protruding into the next layer. The layers are held together throughout the length of the polymers by the interpolymeric hydrogen bonding of each triflate ion to an amine group both above and below the plane in which it is in. The triflate ions are held in the plane of the polymer by intrapolymeric H-bonding to an amine in the next unit. This also likely assists in keeping the planarity of the polymer. The triflate-O–Ag bond is a weak one at 2.644 Å, which is apparent from the only slight bending of the amine–Ag–pyridyl angle of

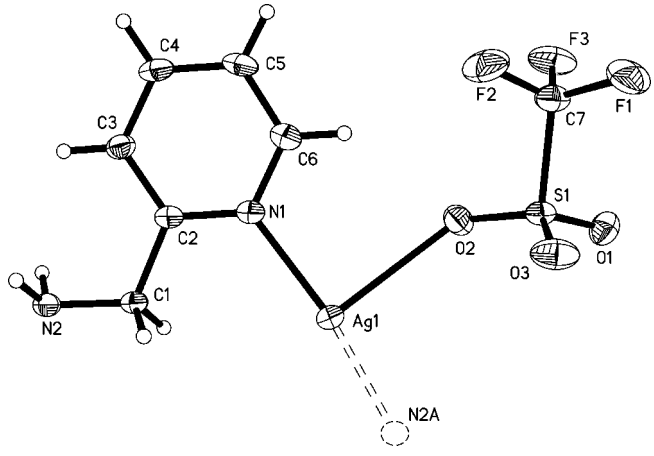

Figure 7. View of the unique portion of the polymer of **6** with the coordination environment about the silver ion shown complete. Ellipsoids are drawn at the 50% probability level.

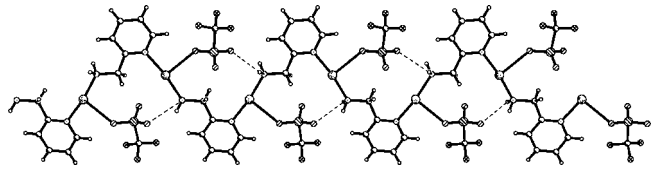

Figure 8. View of the 1-D polymer of **6** showing the intrapolymeric H-bonding.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

171.93(6)°. The N–Ag distances of this polymer are the shortest displayed herein at 2.145(2) Å for the pyridine–Ag length and 2.144(2) Å for the amine–silver distance.

The unique portion of compound **7**, shown in Figure 9, again contains a single silver ion, 2-amp ligand, and anion. It is made apparent here that trifluoroacetate acts as a stronger coordinating anion than triflate when there are insufficient N-donors to saturate the coordination sites of the silver ion. The 1-dimensional coordination polymer backbone of **7** that is seen in Figure 10 is connectively very similar to that of **6**. The more strongly interacting anion, while generally occupying the same spaces in the polymer as those held by triflate in the previous structure, imparts structural features not formerly seen. O1 coordinates strongly to Ag with a bond length of 2.498(2) Å, distorting the pyridine–Ag–amine angle to 152.96(9)°. This distortion causes the amino nitrogen atom to be pushed out of its planar position to give the linear polymer an overall helical appearance seen looking down the length of the polymer. With its remaining oxygen atom, the trifluoroacetate ion extends a bridge both above and, by symmetry equivalence, below the original polymer to link to silver ions of adjacent polymers. This stretched interaction at 2.715(2) Å crosslinks the helical polymers into a pseudo-2-dimensional pleated sheet structure. The intrapolymeric H-bonding here serves to help hold the 1-dimensional polymer into its spiraling conformation. The N–Ag bond lengths are quite short in this polymer as they were in compound **6**, though the presence of the more strongly donating anion causes them to lengthen slightly. The pyridine–Ag distance is 2.188(2) Å and the amine–Ag distance is 2.186(2) Å.

Luminescence Properties

Interest in hybrid inorganic–organic polymers for application as potential new "organic" light-emitting devices (OLEDs) has been on a steady rise over the past decade. Their versatility comes from the ability to tune their absorption and emission spectra by (typically) facile modifications to the metal environment. Such tuning is not an easy option for the strictly organic LEDs, which often require drastic synthesis and modifications to alter their photoluminescent properties.[42] All excitation and emission spectra were recorded at concentrations of 1×10^{-4} M in acetonitrile glasses at 77 K. The low-temperature solution luminescence was collected to give a general representation of what the solid-state excitation and emission would be, given that in the 77 K glasses there is substantial complex character (polymeric character in the case of compounds **6** and **7**).[18,43,44] Luminescence spectra of representative compounds are displayed in Figure 11. A more complete collection of spectra are available in the supporting information.

Discussion of Luminescence

The resemblance of the excitation spectra of compounds **1**–**7** with that of the free 2-(aminomethyl)pyridine ligand suggests that the luminescent behavior of these complexes is initiated by a ligand-based absorption, which then decays by means of ligand-to-metal charge transfer. Excitation maxima of all compounds are presented in

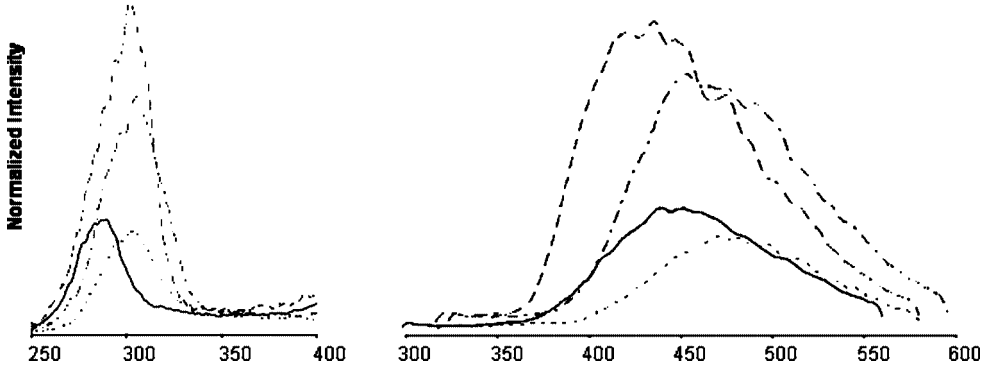

Figure 11. Normalized excitation and emission spectra of compounds **1**, **3**, **6**, and **7** taken in acetonitrile glasses at 1×10^{-4} M concentration at 77 K. —— = (2-amp)AgOTf, – – – = (2-amp)Ag(tfa), ····· = $(2\text{-amp})_2AgBF_4$, –·–·– = $Ag_2(2\text{-amp})_3(OTf)_2$.

Table 6 along with the local emission maxima. The emission spectra of the various compounds cover a modest range of the spectrum with local maxima spanning approximately 100 nm. The strongest emissions are seen to be produced by the compounds that have the most interacting anions, OTf and tfa, and of these the coordination polymer **7**, likely accredited to the extended networks of electronic interaction, shows a stronger emission. It is seen that the most intense luminescence, that of the 1:1 (2-amp)Ag(tfa) polymer, also occurs at the most energetic wavelengths with three strong transitions at 422, 436, and 448 nm. As a general trend, as the intensity of the luminescence drops off, so does the energy of the transitions. The next most intense emission comes from the 3:2 (2-amp)AgOTf cluster **3** with its strongest maxima at 453 nm, followed by the silver "sandwich" complex **2** at 460 nm. The triflate polymer **6** and the tetrafluoroborate monomers of **1** show similar intensity with maxima at 441 and 473 nm, respectively.

Table 6. Luminescent spectral data for compounds **1**–**7** at 77 K and 1×10^{-4} M in CH_3CN.

Compound	Excitation λ_{max} [nm]	Emission local λ_{min} [nm]

2	303	460, 470, 495
3	307	454, 468, 477, 492
4	300	446, 454, 462, 475
5	369	392, 435
6	290	440, 452, 462
7	302	422, 437, 449, 476

Conclusions

We have demonstrated here that a variety of silver(I) complexes can be formed with the bidentate nitrogen ligand 2-(aminomethyl)pyridine. The complexes, their structures and luminescent characteristics are seen to be highly dependent not only on the hydrogen-bonding and coordinating ability of the anion but also on the ratio of ligand/metal. The simplicity of the 2-amp ligand made it a desirable prospect for this concentration/counterion study that produced molecular structures ranging from simple monomers to folded dimetallic metal–metal interacting species to elaborate multidimensional polymers. This same type of behavior is currently being investigated in the 3- and 4-(aminomethyl)pyridines which have demonstrated great potential for the formation of coordination polymers and macromolecules by removing the ability to chelate that has been so prevalent in the 2-amp structures. Results of these studies will form the basis of further publications.

Experimental Section

General Remarks: All experiments were carried out under argon using a Schlenk line and standard Schlenk techniques. Glassware was dried at 120 °C for several hours prior to use. All reagents except 2,2′-bipyridine, which was stored in a bench top dessicator, were stored in a glovebox with an inert gas. Acetonitrile and diethyl ether were distilled from calcium hydride and sodium/benzophenone ketyl, respectively, immediately before use. 2-(Aminomethyl)-pyridine and 2,2′-bipyridine were purchased from Aldrich and used as received. Silver(I) trifluoroacetate, silver(I) trifluoromethanesulfonate, and silver(I) tetrafluoroborate were purchased from Strem Chemicals Inc. and used as received. ^{1}H NMR spectra were recorded at 300.13 MHz with a Bruker Spectrospin 300 MHz spectrometer. Elemental analyses were performed by Atlantic Microlabs Inc. in Norcross, Georgia. Excitation and emission spectra were recorded with an Instruments S. A. Inc. Fluoromax-2 model spectrometer using band pathways of 5 nm for both excitation and emission and are presented uncorrected.

General Synthesis: General procedures for the synthesis of compounds **1**–**4**, **6**, and **7** involved the addition of an acetonitrile solution (5 mL) of 2-(aminomethyl)pyridine to a stirred solution of the appropriate silver salt in acetonitrile (5 mL). The mixtures were stirred for 10 min then dried in vacuo to leave white to off-white powders. All flasks were shielded from light with aluminum foil to prevent the photodecomposition of the silver compounds. Crystals of compound **2** were grown by slow diffusion of hexanes into a dichloromethane solution at 5 °C. Crystals of compound **5** were grown by slow diffusion of diethyl ether into a dichloromethane solution at 5 °C. Crystals of all other compounds were obtained by slow diffusion of diethyl ether into acetonitrile solutions at 5 °C. The amount of reagents used, yields, and analytical data are presented in the following paragraphs as well as any modifications to the general synthetic procedure. Yields are based on the amount of silver salt used.

Synthesis of $Ag(2\text{-amp})_2BF_4$ (1): This reaction used 2 equiv. of 2-(aminomethyl)pyridine (0.111 g, 1.03 mmol) added to $AgBF_4$ (0.100 g, 0.51 mmol) to leave a white flaky solid in 92% (0.19 g, 0.47 mmol) yield upon solvent evaporation. Colorless block-shaped crystals were formed. ^{1}H NMR (298 K, CD_3CN): δ = 2.93 (br. s, 4 H, NH_2), 4.14 (s, 4 H, CH_2), 7.28 (m, 2 H), 7.739 (td, J_{H-Ho} = 7.5, J_{H-Hm} = 1.5 Hz, 4 H), 8.49 (d, J_{H-Ho} = 6.0 Hz, 2 H) ppm. $AgC_{12}H_{16}N_4BF_4$ (410.95): calcd. C 35.07, H 3.92, N 13.63; found C 35.03, H 3.78, N 13.33.

Synthesis of $Ag(2\text{-amp})_2(tfa)$ (2): This reaction used 2 equiv. of 2-(aminomethyl)pyridine (0.098 g, 0.91 mmol) added to Ag(tfa) (0.100 g, 0.45 mmol) to leave a light-brown fluffy solid in 82% (0.16 g, 0.37 mmol) yield upon evaporation of the solvent. Colorless block-shaped crystals were formed. ^{1}H NMR (298 K, CD_3CN): δ = 3.47 (br. s, 4 H, NH_2), 3.83 (s, 4 H, CH_2), 7.29 (m, 2 H), 7.77 (d, J_{H-Ho} = 6.0 Hz, 4 H), 8.48 (s, 2 H) ppm. $AgC_{14}H_{16}N_4O_2F_3$ (437.17): calcd. C 38.46, H 3.69, N 12.82; found C 38.24, H 3.57, N 12.54.

Synthesis of $Ag_2(2\text{-amp})_3(OTf)_2$ (3): This reaction used 3 equiv. of 2-(aminomethyl)pyridine (0.063 g, 0.58 mmol) added to 2 equiv. of AgOTf (0.100 g, 0.39 mmol). An oily yellow solid was left upon evaporation of the solvent in vacuo. This was then redissolved in a small amount of CH_3CN and precipitated with ether to leave a fluffy white solid in 76% (0.12 g, 0.15 mmol) yield upon drying. Colorless block-shaped crystals were formed. ^{1}H NMR (298 K, CD_3CN): δ = 3.32 (br. s, 6 H, NH_2), 4.11 (s, 6 H, CH_2), 7.28 (m, 3 H), 7.74 (td, J_{H-Ho} = 7.5, J_{H-Hm} = 1.5 Hz, 6 H), 8.49 (d, J_{H-Ho} = 6.0 Hz, 3 H) ppm. $Ag_2C_{20}H_{24}N_6O_6F_6S_2$ (838.31): calcd. C 28.86, H 2.89, N 10.02; found C 29.29, H 2.92, N 10.00.

Synthesis of $Ag_2(2\text{-amp})_3(BF_4)_2$ (4): This reaction used 3 equiv. of 2-(aminomethyl)pyridine (0.150 g, 1.39 mmol) added to 2 equiv. of $AgBF_4$ (0.180 g, 0.92 mmol). A white powder was left in 84% yield (0.278 g, 0.39 mmol) upon evaporation of the solvent in vacuo.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Colorless block-shaped crystals were formed. ^{1}H NMR (298 K, CD_3CN): δ = 3.12 (br. s, 6 H, NH_2), 4.15 (s, 6 H, CH_2), 7.29 (m, 3 H), 7.75 (td, $J_{H–Ho}$ = 7.4, $J_{H–Hm}$ = 1.5 Hz, 6 H), 8.50 (s, 3 H) ppm.

Synthesis of $Ag_2$2,2′-bpy$_2$(2-amp)$(BF_4)_2$ (5): This reaction used 2-(aminomethyl)pyridine (0.050 g, 0.46 mmol) added to 2 equiv. of $AgBF_4$ (0.180 g, 0.93 mmol). This solution was stirred for 10 min, then 2 equiv. of 2,2′-bipyridine (0.144 g, 0.92 mmol) in 5 mL of CH_3CN was added. This was stirred an additional 5 min, then dried in vacuo to leave an off-white powder in 90% (0.126 g, 0.22 mmol) yield. Colorless block-shaped crystals were formed. ^{1}H NMR (298 K, CD_3CN): δ = 3.19 (br. s, 2 H, NH_2), 4.05 (s, 2 H, CH_2), 7.43 (m, 8 H), 7.89 (m, 9 H), 7.98 (d, $J_{H–Ho}$ = 8.1 Hz, 2 H), 8.36 (d, $J_{H–Ho}$ = 4.8 Hz, 1 H) ppm.

Synthesis of Ag(2-amp)OTf (6): This reaction used 2-(aminomethyl)-pyridine (0.042 g, 0.39 mmol) added to AgOTf (0.100 g, 0.39 mmol) to leave an oily brown solid upon evaporation of the solvent. This solid was then redissolved in a small amount of CH_3CN and precipitated with diethyl ether to leave a brown solid in 85% (0.120 g, 0.33 mmol) yield. Colorless block-shaped crystals were formed. ^{1}H NMR (298 K, CD_3CN): δ = 3.42 (br. s, 2 H, NH_2), 4.16 (s, 2 H, CH_2), 7.25 (m, 1 H), 7.77 (td, $J_{H–Ho}$ = 6.9, $J_{H–Hm}$ = 1.0 Hz, 2 H), 8.52 (d, $J_{H–Ho}$ = 3.6 Hz, 1 H) ppm. $AgC_7H_8N_2O_3SF_3$ (365.08): calcd. C 25.80, H 2.47, N 8.56; found C 26.27, H 2.33, N 8.77.

Synthesis of Ag(2-amp)(tfa) (7): This reaction used 2-(aminomethyl)-pyridine (0.049 g, 0.45 mmol) added to Ag(tfa) (0.100 g, 0.45 mmol) to leave an off-white powder in 75% (0.11 g, 0.34 mmol) yield upon evaporation of the solvent. Colorless plates were formed. ^{1}H NMR (298 K, CD_3CN): δ = 3.68 (s, 2 H, NH_2), 4.11 (s, 2 H, CH_2), 7.28 (m, 1 H); 7.75 (td, $J_{H–Ho}$ = 7.5, $J_{H–Hm}$ = 1.5 Hz, 2 H), 8.53 (d, $J_{H–Ho}$ = 6.0 Hz, 1 H) ppm. $AgC_8H_8N_2O_2F_3$ (329.03): calcd. C 29.20, H 2.45, N 8.51; found C 29.38, H 2.39, N 8.40.

X-ray Crystallographic Study: Crystallographic data were collected on crystals with dimensions 0.181 × 0.150 × 0.100 mm for **1**, 0.210 × 0.150 × 0.090 mm for **2**, 0.279 × 0.216 × 0.202 mm for **3**, 0.310 × 0.270 × 0.250 mm for **4**, 0.245 × 0.231 × 0.199 mm for **5**, 0.167 × 0.143 × 0.094 mm for **6**, and 0.240 × 0.150 × 0.080 mm for **7**. Crystals of all compounds were immobilized on a cryoloop by encasing them in Paratone-N oil then cooling them in a nitrogen cold stream. Data were collected at 110 K with a Bruker X8 Apex. Graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) was used throughout. All structures were solved by direct methods after processing with SAINT-Plus and correction of the data using SADABS.[45] All of the data were processed with the Bruker AXS SHELXTL software, version 6.10.[43] All non-hydrogen atoms were refined anisotropically and hydrogen atoms were placed in calculated positions except for the amine hydrogen atoms of compound **3**, whose positions were allowed to refine. The crystal structures of compounds **1** and **2** each contain 2 unique monomers of their respective compounds. The structure of compound **4** contains a BF_4^- anion disordered over 2 positions. The anisotropic displacement parameters for the two orientations of the disorder are constrained to be equal and the site occupancies were refined as 0.825(3)/0.173(3) [for B(1/1a), F(1/1a), F(2/2a), F(3/3a), F(4/4a)]. CCDC-260748 (**1**), -260750 (**2**), -260753 (**3**), -262119 (**4**), -260752 (**5**), -260751 (**6**), and -260749 (**7**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Supporting Information (see footnote on the first page of this article): Additional figures showing extended H-bonding networks, stacking, and 3-D growth of compounds **2**, **6**, and **7** are available as well as full excitation and emission spectra for all compounds reported.

Synthesis and Crystal Structure of a Cocrystalline Compound of a Rare Earth Metalloporphyrin with Fullerene $\{[TPPYb(\mu\text{-}OH)_2Yb(THF)TPP]\cdot C_{60}\}_n$

Jie Zhang,*[a] Ruifang Cai,[a] Minqing Chen,[b] Linhong Weng,[a] and Xigeng Zhou*[a]

Keywords: Metalloporphyrin / Fullerenes / Cocrystal / Ytterbium

The reaction of $YbI_2(THF)_2$ with $TPPLi_2$ (TPP = 5,10,15,20-tetraphenylporphyrin) in THF, and then with 0.5 equiv. of C_{60}, which was solvated in toluene beforehand, gave the title compound $\{[TPPYb(\mu\text{-}OH)_2Yb(THF)TPP]\cdot C_{60}\}_n$, which is the first example of a rare earth metallofullerene cocrystal compound. X-ray structural analyses indicate that this compound displays a complicated supramolecular structure, which contains some unique noncovalent interactionsbetween C_{60} and the rare earth metalloporphyrin units.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

The fullerene (C_{60}) molecule has attracted much current attention due to its chemical properties, and uniform, spherical, and nanoscale physical structure, and its potential application in optical and electronic materials, superconductors, and sensors.[1] The organometallic chemistry of fullerene is becoming a flourishing subdiscipline of fullerene research.[2,3] However, research efforts are primarily focused on organotransition metal fullerene complexes in which the fullerene essentially behaves as a weak electron-deficient alkene ligand.[4] In the field of lanthanofullerene chemistry, only the chemistry of endohedral complexes with encapsulated metal atoms, $Ln@C_{2n}$ has been investigated.[5] These species are prepared by the arc vaporization of a mixture of graphite and lanthanoid oxide or carbide under helium.[6] Owing to the high electron-deficient character of lanthanide metal centers, the synthesis of exohedral lanthanide fullerene complexes poses a fundamental problem. The chemistry of exohedral lanthanide fullerene complexes has remained relatively unexplored.[2,7]

On the other hand, the weak noncovalent interactions of curved/flat or curved/curved molecular surfaces have recently attracted much attention in supramolecular chemistry and crystal engineering.[8] The curved π surface of C_{60} shows a tendency to interact with other molecules, making it an interesting candidate for engineering supramolecular arrays. It has been confirmed that the ball-shaped C_{60} molecule can cocrystallize with planar molecules such as porphyrins or metalloporphyrins through the interaction of the curved π surface of the fullerene with the planar π surface of the porphyrin, without the need to match convex surfaces with concave surfaces.[8] Many molecular complexes of fullerenes with transition metalloporphyrins have been obtained and structurally characterized.[9–11] However, no examples of cocrystals consisting of rare earth metalloporphyrins with fullerenes have been reported. In this contribution, we report the synthesis and structural characterization of a novel rare earth metalloporphyrin compound cocrystallized with C_{60} molecules, $\{[TPPYb(\mu\text{-}OH)_2Yb(THF)TPP]\cdot C_{60}\}_n$ (**1**). The X-ray structural analysis of **1** provides some insight into the supramolecular assembly between the fullerenes and metalloporphyrins, which incorporates some unique supramolecular interactions.

Results and Discussion

Bochkarev et al. synthesized the first fulleride complexes of low valence lanthanocene derivatives and confirmed the valence flexibility of Ln^{II} ions in these charge-transfer compounds by temperature-dependent ESR spectroscopy.[7] When considering the noncovalent interactions between the porphyrin rings and the fullerene molecules, we anticipate that strong interactions will be observed between the low valence ytterbium porphyrins and the C_{60} molecules. However, the reaction of $TPPYb^{II}$ with C_{60} leads only to an oxidation product. The reactions of $TPPLi_2$ with $YbI_2(THF)_2$ in THF, and the subsequent reaction with 0.5 equiv. of C_{60} which was solvated in toluene beforehand gave the ytterbium(III) porphyrinate complex cocrystallized with fullerene (**1**) [Equation (1)]. The oxidation of the Yb^{II} units may be caused by trace amounts of oxygen gas and moisture in the inert atmosphere, as similarly observed for another rare earth metalloporphyrin.[12] To obtain a crystal of complex **1** suitable for X-ray diffraction analysis, the selection of an appropriate solvent may be important. Owing to

C_{60} being almost insoluble in THF, and the ytterbium complex of tetraphenylporphyrin being hardly soluble in toluene, we chose for our experiments a solvent mixture of THF and toluene (THF/toluene, 11:1.5). In fact, the final product **1** is also poorly soluble in THF and toluene. It should be noted that we could not obtain the analogous Samarofullerene compound under the same conditions.

$$H_2TPP \xrightarrow[2)\ YbI_2(THF)_2\ \ 3)\ C_{60}/\ toluene]{1)\ nBuLi} \underset{\mathbf{1}}{[TPPYb(OH)_2Yb(THF)TPP]\cdot C_{60}}$$

TPP = 5,10,15,20-tetraphenylporphyrin

(1)

Unambiguous structure determination of complex **1** was completed by X-ray crystallographic analysis of a single crystal, which had been obtained by the slow diffusion of *n*-hexane into the THF and toluene solution of **1**. The molecular structure of **1** is shown in Figure 1. Selected bond lengths and short contact distances are given in Table 1 and Table 2, respectively. The asymmetric unit of **1** consists of one C_{60} molecule and one dinuclear ytterbium porphyrinate, in which the two ytterbium atoms are connected by two hydroxy-bridges. Compound **1** crystallizes in such a way that two dinuclear ytterboporphyrin units surround each fullerene. Within this unit the fullerene is positioned asymmetrically between the two [TPPYb(μ-OH)$_2$Yb(THF)-TPP] units. X-ray single crystal structure analysis reveals that supramolecular interactions between the curved/flat molecule interfaces exist. The most obvious noncovalent interaction is found between the planes of porphyrin rings and the curved surface of the fullerenes. The C_{60} molecule is centered over the porphyrins giving two different short contact modes. In the first mode, one porphyrin plane interacts with the 5:6 ring-junction C–C bonds of C_{60}, and in the other mode, the porphyrin plane interacts with the 5:6 and 6:6 ring-junction C–C bonds of another C_{60} molecule, as shown in Figure 2. This is significantly different form the results observed for most porphyrins or metalloporphyrins, which prefer to interact with the electron-rich 6:6 ring junction.[9,10] The mechanism of interaction of porphyrin with the 6:6 or 5:6 ring junctions of fullerene is unclear.[9g,10a] The N···C(C_{60}) distances in **1** are in the range of 3.08–3.09 Å and lie at the lower end of the range of van der Waals contacts, and well below the "standard" contact distance (3.2–3.3 Å), and are similar to the corresponding distances in metal-free porphyrin fullerene complexes.[13] However, these distances are significantly longer than the corresponding distances in transition metalloporphyrin fullerene cocrystals.[9–11] This may be attributed to the electron-deficient character of rare earth metal ions, and the electron-acceptor nature of fullerene, resulting in weaker interactions between the metalated porphyrin units and the fullerenes.

Table 1. Selected bond lengths [Å] for the ytterbium porphyrin unit in **1**.

As shown in Figure 3, the THF molecules may play a unique role in the crystal structure of **1**. This contrasts with other fullerene cocrystals of metalloporphyrins and metal-free porphyrins, in which the solvent molecules only exist in the crystal lattice.[9–11] Only one THF molecule in **1** is

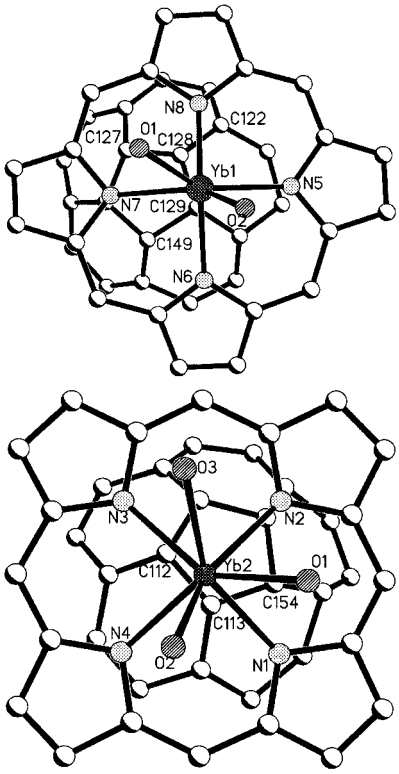

Figure 2. Orientation of C_{60} with respect to the ytterboporphyrin plane, as seen in **1**.

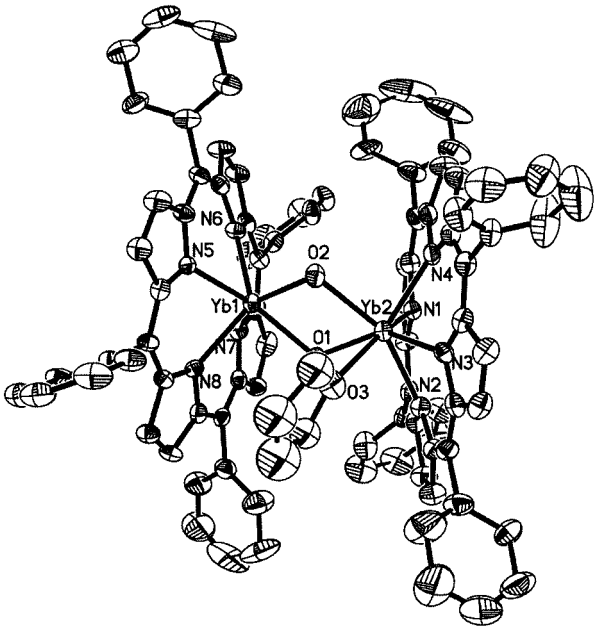

Figure 3. ORTEP diagram of the [TPPYb(μ-OH)$_2$Yb(THF)TPP] unit in **1** with the thermal ellipsoids drawn at the 30% probability level. Hydrogen atoms have been omitted for clarity.

coordinated to one Yb^{3+} ion, and this results in different coordination environments around the metal centers, in that one Yb^{3+} ion is seven-coordinate, while the other Yb^{3+} ion is six-coordinate. This causes the two porphyrin rings in the dinuclear ytterbium porphyrin units to lie unparallel, the dihedral angle between them is 31.91(1)°. This angle is comparable to the corresponding values found in the unique example of [{Yb^{III}(TTP)}$_2$(μ-OH)(μ-$OCH_2CH_2OCH_3$)] where the dihedral angle between the two porphyrin ring planes is 30.5°.[12] The difference in the metal coordination environments also means that the average distance of Yb(1) to the nitrogen atoms of one porphyrin ring [3.313(1) Å] is significantly shorter than the average distance of Yb(2) to the nitrogen atoms of another porphyrin ring [3.346(1) Å]. Also, the Yb(1)–O(1) and Yb(1)–O(2) distances [2.1819(9) Å, 2.1893(9) Å] are significantly shorter than the Yb(2)–O(1) and Yb(2)–O(2) distances [2.2451(9) Å, 2.2497(9) Å]. It should be noted that dinuclear rare earth metalloporphyrin complexes containing such an unsymmetrical coordination mode are rarely reported,[12] and the unparallel arrangement of the porphyrin planes in the metalloporphyrin units may cause the differences in the short contacts between the two porphyrin rings and the C_{60} molecule.

In **1**, the fullerene is too far from the ytterbium atoms for any covalent bond to form between them. The ytterbium atoms are displaced significantly out of the N4 planes of the porphyrins, in the direction opposite to that of the porphyrin-fullerene contacts, and as a result of this there is no possibility of a direct exohedral interaction forming between the ytterbium atoms and the fullerene molecules. This is significantly different from the results observed for the late transition metalloporphyrin fullerene cocrystals, in which strong noncovalent interactions exists between the metal centers and the fullerene molecules because of the electron-rich characters of these metal ions.[9,10] Interestingly, the fullerene is positioned so that the closest contact with the ytterbium atom involves 5:6 ring junctions, and it is significantly shorter than the van der Waals radii of the atoms involved. This may be attributed to the strong covalent interactions of the ytterbium atoms with the porphyrin rings through the hydroxyl bridges.

Within the cocrystal structures of metalloporphyrin with fullerene, there are two kinds of noncovalent interactions in the supramolecular assembly: one is the interaction of the planes of the porphyrin rings with the curved surfaces of the fullerenes, and the other is the porphyrin/porphyrin face-to-face contacts, which pair the porphyrin units. In the aryl-substituted metalloporphyrin fullerene cocrystalline complexes, the porphyrin/porphyrin contact is very weak due to the repulsive interactions of the terminal aryl substituents. Usually, in aryl-substituted porphyrin complexes only one metalloporphyrin unit interacts with two C_{60} molecules.[10c] In complex **1**, in addition to the fullerene/porphyrin interactions, there are covalent interactions between the Yb^{3+} ions and the two hydroxyl bridges between the two tetraphenyl-metalloporphyrins. This combination of covalent and noncovalent interactions produces helical ribbons that wind their way through the crystal (Figure 4).

Another feature of the structure of complex **1** is that there is a noncovalent interaction between the phenyl substituents of the porphyrin rings and the fullerene molecules. Although plenty of cocrystal complexes of fullerenes with

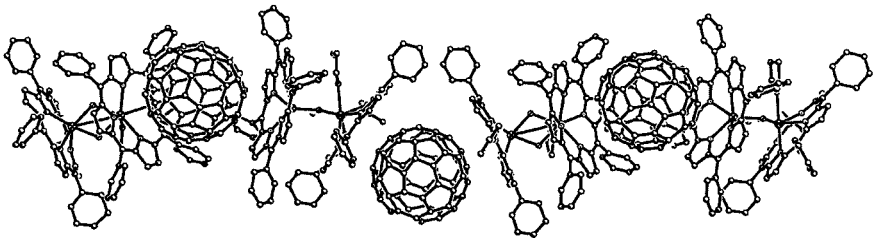

Figure 4. View of the helical chain in **1**.

transition metalloporphyrins have been obtained and structurally characterized, aryl-substituted metalloporphyrin fullerene cocrystalline complexes are very rare. Some researchers regard the modification of the structure of the terminal phenyl groups as very important in order to make the curved C_{60} surface match the planar surface of the porphyrin to enable cocrystal growth.[10b] In complex **1**, one of the phenyl substituents of the dinuclear ytterboporphyrin units forms a contact with a third C_{60} molecule, with the shortest C···C distance of 3.35 Å. To the best our knowledge, only one example of the phenyl substituents participating in noncovalent interactions has been reported, this previous example was of a metal-free porphyrin cocrystallized with C_{60} molecules.[10c] In **1**, this interaction may be attributed to the unparallel arrangement of the porphyrin plane which allows the phenyl substituent to move closer to the C_{60} molecules.

Conclusions

In summary, in this paper we have reported the successful synthesis of the first crystallographically confirmed cocrystalline compound of a rare earth metalloporphyrin with fullerene. This compound displays a complicated supramolecular structure containing unique noncovalent interactions between the fullerene molecules and the dinuclear rare earth metalloporphyrin units.

Experimental Section

General Procedure: All operations involving air- and moisture-sensitive compounds were carried out under purified argon or nitrogen using standard Schlenk techniques. The solvents THF, toluene, and *n*-hexane were refluxed and distilled over sodium benzophenone ketyl under nitrogen immediately prior to use. Tetraphenylporphyrin and *n*BuLi (2.0 M in cylcohexane) were purchased from Aldrich, and were used without further purification. Infrared spectra were obtained with a NICOLET FT-IR 360 spectrometer, with samples prepared as KBr pellets.

Synthesis of 1: *n*-Butyllithium (1.96 M, 120 μL in cyclohexane) was added dropwise to a solution of H_2TPP (76 mg, 0.118 mmol) in THF (20 mL) at ambient temperature. After stirring for 12 h a THF solution of $YbI_2(THF)_2$ (68 mg, 0.118 mmol, 15 mL) was slowly added to the reaction mixture, which was then stirred for a further 12 h. Then a toluene solution of C_{60} (42.6 mg, 0.59 mmol, 30 mL) was injected into the reaction solution. Towards the end of addition, brown solid precipitated from the dark purple solution. The reaction solution was stirred for 24 h at ambient temperature, and the precipitate was then filtered off. Crystallization by the slow diffusion of *n*-hexane into the pellucid dark purple solution yielded dark purple crystals of **1** after several months. IR (KBr): $\tilde{\nu}$ = 3436 (m), 1596 (m), 1477 (m), 1439 (s), 1330 (m), 1220 (m), 1182 (m), 1069 (s), 1006 (s), 990 (s), 798 (s), 751 (m), 722 (m), 700 (s), 656 (m), 632 (w), 577 (m), 527 (s) cm^{-1}.

Crystallographic Data for 1: Suitable single crystals of complex **1** for X-ray structural analysis were sealed under argon in Lindemann glass capillaries. Diffraction data were collected on a Bruker SMART Apex CCD diffractometer using graphite-monochromated Mo-K_α (λ = 0.71073 Å) radiation. During the collection of the intensity data, no significant decay was observed. Frames were integrated to the maximum 2θ angle of 50.02° with the Siemens SAINT program to yield a total 44738 reflections, of which 18883 were independent (R_{int} = 0.0795). The Laue symmetry indicated a monoclinic crystal system, and the final unit cell parameters were determined from the full-matrix least-squares refinement on F^2 employing the 18883 unique reflections. The intensities were corrected

for Lorentz-polarization effects and empirical absorption with the SADABS program.[14] The structure was solved by direct methods using the SHELXL-97 program.[15] All non-hydrogen atoms were found from the difference Fourier syntheses. The H atoms were included at calculated positions, with their isotropic thermal parameters related to those of the supporting carbon atoms, and were not included in the refinement. Further refinement led to the final R indices [$I > 2\sigma(I)$] $R_1 = 0.0732$. All calculations were performed using the SHELXL-97 program. A summary of the crystallographic data is given in Table 3. CCDC-250532 (**1**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Lanthanide(III)-Induced Conversion of 12-Metallacrown-4 to 5-Metallacrown-5 Complexes in Solution

Antoine Pacco,[a] Tatjana N. Parac-Vogt,[a] Els van Besien,[a] Kristine Pierloot,[a] Christiane Görller-Walrand,[a] and Koen Binnemans*[a]

Keywords: Lanthanides / Hydroxamic acids / Metallacrowns / N,O ligands / Rare earths

The conversion of 12-metallacrown-4 complexes with copper(II) in the central cavity to 15-metallacrown-5 complexes with lanthanide(III) ions in the central cavity upon addition of trivalent lanthanide ions was analysed in solution by electrospray ionisation mass spectrometry (ESI-MS), absorption spectrophotometry, circular dichroism and proton NMR spectroscopy. In all cases, copper(II) ions were the ring metals. The lanthanide-induced shifts of the proton resonances in the NMR spectra of different lanthanide(III)-containing 15-metallacrown-5 complexes with tyrosinehydroximate ligands were studied. The dynamics of ligand exchange of α-aminohydroximate-based lanthanide(III)-containing 15-metallacrown-5 complexes were studied in methanol solutions. The ring structure of the 12-metallacrown-4 complex that acts as starting compound for the formation of the 15-metallacrown-5 complexes was optimized by DFT methods using alaninehydroximate as a model ligand.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Metallacrowns, a class of macrocyclic compounds discovered by Pecoraro and coworkers in 1989, are inorganic analogues of crown ethers where heteroatoms and metals substitute for the ring carbons.[1,2] Several types of metallacrown complexes with different metals, ligands and ring sizes have been developed.[3] The stoichiometry of the metallacrown complexes depends on the type of ligand used. Aminohydroximate ligands, which are derivatives of hydroxamic acids with an additional amino group as a potential coordinating group, are suitable ligands for metallacrown formation because they can act as bridging ditopic ligands. These ligands form a metallamacrocycle ring with a metal-nitrogen-oxygen backbone in the presence of copper(II) ions. β-Aminohydroximate ligands can form connected six- and five-membered chelate rings giving rise to 12-metallacrown-4 complexes (12-MC-4) with four copper(II) ions in the macrocyclic ring. A fifth copper(II) ion is encapsulated by the four oxygen atoms of the ring leading to a pentanuclear copper(II) complex Cu^{II}[12-MC-4] whose crystal structure has been determined.[4]

On the other hand, α-aminohydroximate ligands form 15-metallacrown-5 (15-MC-5) compounds because these ligands chelate the metals by connected five-membered rings giving rise to a planar metallamacrocycle ring with five copper atoms in the ring. The cavity size of this ring is larger than the cavity size of the 12-metallacrown-4 complexes and affords the incorporation of lanthanide(III)[5–11] or uranyl ions.[11–13] 15-Metallacrown-5 complexes of lanthanide(III) ions with either chiral or nonchiral α-aminohydroximate ligands have been structurally characterized.[5–10] Careri and coworkers showed that α-aminohydroximate ligands form the 12-metallacrown-4 structural motif in aqueous solution in the absence of lanthanide(III) ions.[14] However, those Cu^{II}[12-MC-4] metallacrowns are less stable than those containing β-alaninehydroxamic acid as the ligand. No single crystal structure of 12-metallacrown-4 complexes containing α-aminohydroximate ligands has been determined yet, but solution studies have shown that Cu^{II}[12-MC-4] complexes are converted into (UO_2)[15-MC-5] complexes in aqueous solution upon addition of a uranyl salt.[13]

Although the lanthanide(III)-containing 15-metallacrown-5 complexes with α-aminohydroximate ligands have been thoroughly characterised in the solid state, their formation and self-assembly in solution still remain elusive. The formation of 12-metallacrown-4 complexes with salicylhydroximate ligands has been investigated in solution and data pointed out that some dimeric nickel(II) salicylhydroximate intermediates reorganize in basic solvents to form a 12-metallacrown macrocycle. It was also found that 12-metallacrown-4 copper(II) complexes with salicylhydroximate ligands maintain their structure in solution in the presence of excess ligand or metal ions.[3] In this study, we demonstrate that in the self-assembly of copper(II)-containing 15-metallacrown-5 complexes derived from α-aminohydroximate ligands, the final 15-metallacrown-5 is formed through the lanthanide(III)-templated reassembly of the 12-

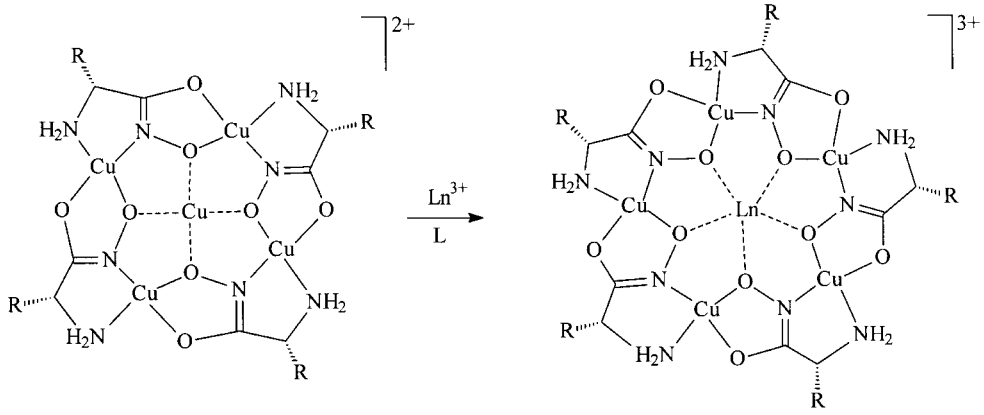

Scheme 1. Schematic representation of lanthanide-induced conversion of 12-metallacrown-4 (left) to 15-metallacrown-5 (right).

metallacrown-4 complex (Scheme 1). Since the structure of the 12-metallacrown-4 complex has not been determined yet, its ring structure with alaninehydroximate as a model ligand was optimized by DFT methods. The solution properties and ligand exchange of 15-metallacrown-5 complexes with α-aminohydroximate ligands and copper(II) ions were studied by a combination of several experimental techniques such as electron spray mass spectrometry (ESI-MS), paramagnetic nuclear magnetic resonance techniques, circular dichroism and UV/Vis spectrophotometry. The evaluation of the properties of metallacrown compounds in solution is important if one envisages solution-based applications of metallacrowns, for example, as sequestering agents for selective recognition of actinide or lanthanide ions and as contrast agents for magnetic resonance imaging applications.

Results and Discussion

Structure Optimization of Cu^{II}[12-MC-4] by DFT Methods

The structures of the ligands used in this study are presented in Scheme 2. The crystal structures of copper(II)-containing 12-metallacrown-4 complexes, Cu^{II}[12-MC-4], with β-aminohydroximate ligands were determined in the past,[4,8] but to the best of our knowledge no crystal structures of Cu^{II}[12-MC-4] with α-aminohydroximate ligands have been determined. The crystal structure of Cu^{II}[12-MC-4] with β-aminohydroximate ligands shows that the ligands form five- and six-membered chelate rings with the metal ions arranged in an almost planar ring. Dallavalle and coworkers have commented on the structure of Cu^{II}[12-MC-4] with the α-aminohydroximate ligands derived from phenylalanine-, tryptophan- and alaninehydroxamic acid. Because those ligands can form only five-membered chelate rings, this would give rise to a strained structure if planar, so they propose an arrangement of the rings in a cup-conformation with four sp^3-hybridised oxygen atoms bridging the peripheral and central copper(II) ions.[14–15]

In order to gain more insight into the structure of Cu^{II}[12-MC-4] with α-aminohydroximate ligands, we performed density functional theory (DFT) calculations (Figure 1). For comparison, we have also calculated the structure of Cu^{II}[12-MC-4] with β-aminohydroximate ligands by the same method. In both types of complexes (with α-alaninehydroxamic or β-alaninehydroxamic acid as the ligand), the four peripheral copper(II) ions form an almost planar structure. The central copper(II) ion is situated above this quasi-plane. For the complex formed with the α-aminohydroximate ligands, the deviation from planarity is larger than for the complex with β-aminohydroximate ligands. This can clearly be seen by comparing the dihedral angles between the four copper(II) ions: 1.4° in the β-form and 3.0° in the α-form. There is also a difference in the position of the central copper(II) ion above the quasi-plane: in the complex with α-aminohydroximate ligands the distance between the central copper(II) ion and a virtual line connecting two opposite copper(II) ions is 0.98 Å, whereas in the β-form it is only 0.50 Å. Another difference is the coordination of the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

copper(II) ions in the ring. In the complex with β-aminohydroximate ligands the copper(II) ions have a nearly planar coordination, whereas the deviation from planarity is more pronounced in the complex with α-aminohydroximate ligands. This can be related to the stability of these two structures in solution: the calculated complex-formation constant for Cu^{II}[12-MC-4] with α-Alaha ($\log\beta = 40$) is lower than that with β-Alaha ($\log\beta = 49$).[14] The difficulties of growing crystals of the α-form could lie in the subtle differences in the proposed structures.

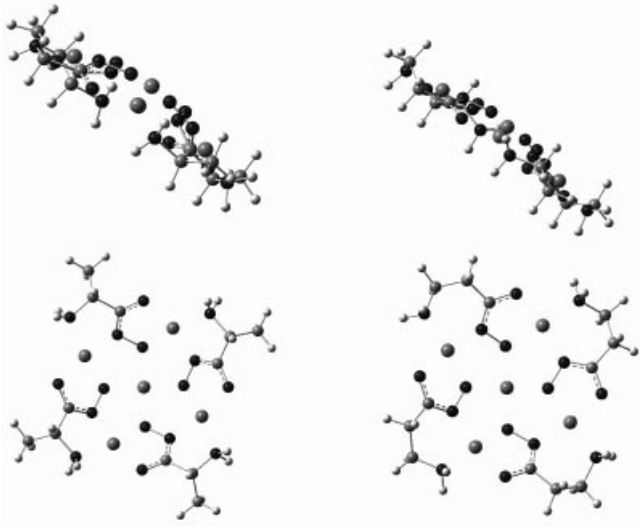

Figure 1. Structure of Cu^{II}[12-MC-4] with α-alaninehydroxamic acid (left) and β-alaninehydroxamic acid (right) resulting from the DFT calculation.

Titration of $[Cu_5L_4]^{2+}$ with Lanthanide(III) Ions Monitored by Optical Spectroscopy

Complex formation between α-aminohydroxamic acid and copper(II) ions can lead to several species depending on the pH of the solution. When copper(II) ions and α-Alaha are mixed in a 1:3 ratio, the distribution diagram shows that, in the pH range 4.5–5.5, the pentanuclear $[Cu_5(\alpha\text{-Alaha})_4]^{2+}$ complex is the most abundant species in solution.[14] When copper(II) ions and α-Leuha are mixed in a 1:1 ratio and the pH of the final solution is around 4.5, the only detectable complex in solution is also a pentanuclear $[Cu_5(\alpha\text{-Leuha})_4]^{2+}$ complex.[13] In the present study, the starting solutions for the titrations were also prepared by mixing the ligand and copper(II) acetate in a 1:1 ratio, so we can assume that under these conditions the pentanuclear complex is the most abundant species in solution. This was confirmed by ESI-MS results and will be discussed later.

The UV/Vis absorption spectrum of $[Cu_5(\alpha\text{-Leuha})_4]^{2+}$ at pH 4.5 is characterised by two prominent absorption bands with maxima at 650 nm and 343 nm. Similarly, the maximum absorbance for $[Cu_5(\alpha\text{-Tyrha})_4]^{2+}$ has been observed at 660 and 346 nm. The λ_{max} values in the visible region are in agreement with those calculated for $[Cu_5(\alpha\text{-Pheha})_4]^{2+}$ and $[Cu_5(\alpha\text{-Trpha})_4]^{2+}$ metallacrowns.[15] Bands at 352 and 336 nm have also been observed in these complexes and could be assigned to $N^-\text{–}O^-_{(nitrogen)} \rightarrow Cu^{II}$ and $N^-\text{–}O^-_{(oxygen)} \rightarrow Cu^{II}$ charge-transfer transitions.

Since the α-aminohydroxamic acids used in this study are chiral, their copper(II) complexes are expected to be optically active as well. The CD spectrum of $[Cu_5(\text{D-}\alpha\text{-Leuha})_4]^{2+}$ shows a positive Cotton effect at 350 nm and two negative peaks at 558 and 646 nm. The two latter peaks

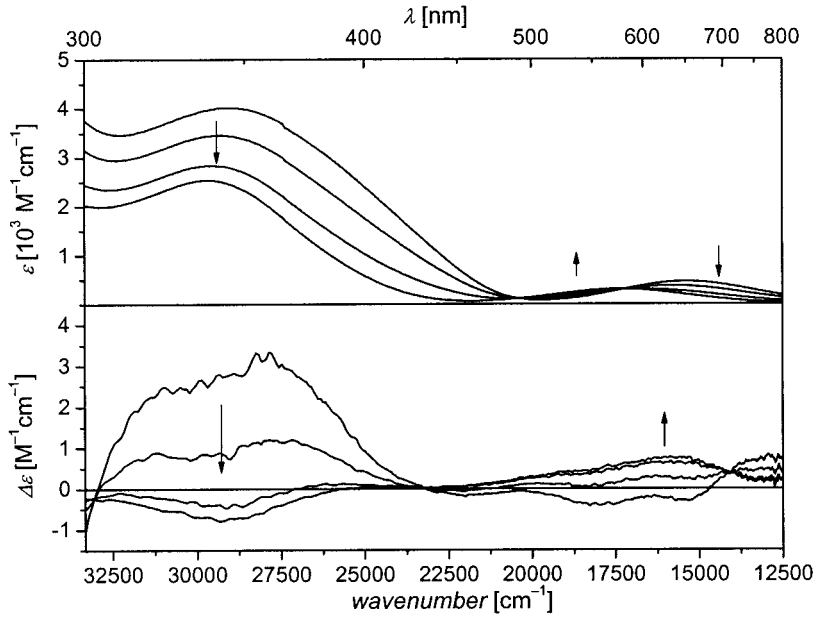

Figure 2. Changes in UV/Vis and CD absorption spectra of Cu^{2+}/D-α-Leuha solutions in water upon addition of Gd^{3+}. The Gd^{3+} ion was added in 0.33-equivalent increments relative to the 12-metallacrown-4 concentration.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

are either due to d-d transitions of the copper(II) ion or due to the presence of nonequivalent chromophores in the metallacrown. If L-α-Leuha was used as the ligand, the CD spectrum of the resulting $[Cu_5(L\text{-}\alpha\text{-Leuha})_4]^{2+}$ looked as a mirror image of the $[Cu_5(D\text{-}\alpha\text{-Leuha})_4]^{2+}$ spectrum, with two bands at 558 and 646 nm having positive Cotton effects and a band at a 350 nm having a negative Cotton effect. The CD spectrum of $[Cu_5(L\text{-}\alpha\text{-Tyrha})_4]^{2+}$ showed a weak positive Cotton effect at 350 nm and a weak negative Cotton effect at 672 nm. The stepwise addition of Gd^{3+} to the aqueous solution of $[Cu_5(D\text{-}\alpha\text{-Leuha})_4]^{2+}$ and $[Cu_5(L\text{-}\alpha\text{-Tyrha})_4]^{2+}$ caused significant changes both in the UV/Vis and in the CD spectra. As seen in Figure 2, the UV/Vis and CD spectra are characterised by isosbestic points, suggesting the presence of only two interconverting species in the solutions. At the end point of the titration of $[Cu_5(L\text{-}\alpha\text{-Tyrha})_4]^{2+}$ with Gd^{3+}, one band having a negative Cotton effect is observed at 557 nm. The ligand field analysis of lanthanide(III)-containing 15-metallacrown-5 copper(II) species was in accordance with this finding and suggested that three d-d transitions should be expected in the ligand field region, and the transition around ca. 556 nm should be the most intense.[5] After titration of $[Cu_5(L\text{-}\alpha\text{-Tyrha})_4]^{2+}$ with Gd^{3+}, the UV/Vis spectra are characterised by two prominent absorption bands with maxima at 581 nm and 340 nm. Similar absorption spectra have also been observed for the other lanthanide(III)-containing 15-metallacrown-5 complexes with L-α-Tyrha as ligand (Ln^{3+} = Y^{3+}, La^{3+}, Nd^{3+}, Sm^{3+}, Eu^{3+}, Tb^{3+}, Dy^{3+}, Ho^{3+}, Er^{3+}, Tm^{3+}). The absorption spectra of the different lanthanide-containing metallacrown complexes are virtually independent of the lanthanide(III) ions. The peak maxima in the spectra differ less than 2 nm from those of the gadolinium(III)-containing metallacrowns.

$[Cu_5L_4]^{2+}$ Titration with Lanthanide(III) Monitored by ESI-MS

Electrospray ionisation mass spectrometry (ESI-MS) is an effective method for studying the speciation of metal complexes in solution and was applied in studies of different metallacrown systems.[16] The method has been proven to be very useful in providing solution molecular weights of the formally neutral metallacrown complexes after the loss of bound anions. ESI-MS results indicate that solutions containing a copper(II) salt and α-Leuha in a 1:1 ratio form exclusively 12-MC-4 species in the solution, with peaks at 447 and 930 *m/e*, which could be assigned to the pentanuclear species $[Cu_5(\alpha\text{-Leuha})_5]^{2+}$ (447.2 calcd.) and $[Cu_5(\alpha\text{-Leuha})_5](Cl)^+$ (929.8 calcd.), respectively.

As seen in Figure 3, the addition of gadolinium(III) to the $[Cu_5(\alpha\text{-Leuha})_4]^{2+}$ solution caused disappearance of the peaks which were assigned to the 12-MC-4 species and the appearance of new peaks at 627 and 1319 *m/e*, which could be assigned to the 15-MC-5 species $[Gd(NO_3)Cu_5(\alpha\text{-Leuha})_5]^{2+}$ (628.9 calcd.) and $[Gd(NO_3)_2Cu_5(\alpha\text{-Leuha})_5]^+$ (1319.8 calcd.), respectively.

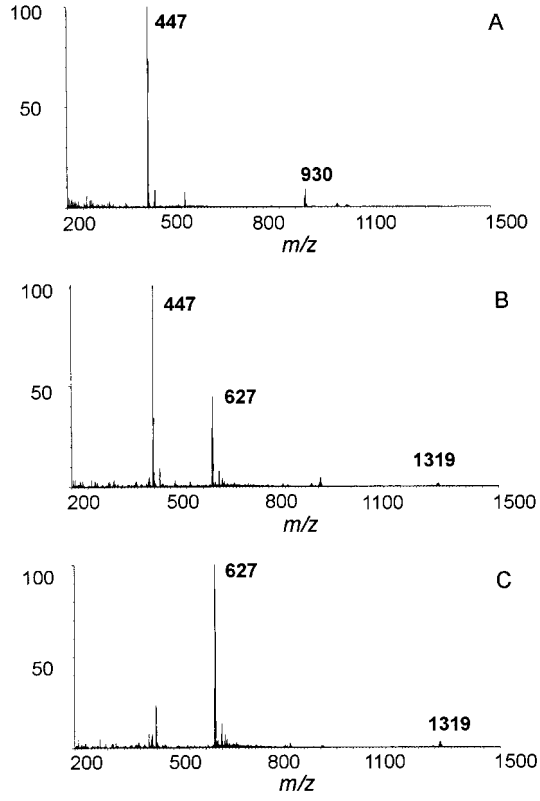

Figure 3. Positive-ion mode ESI-MS spectra of Cu^{2+}/Leuha solutions containing different amounts of Gd^{3+} relative to the 12-metallacrown-4 concentration: (a) 0.0 equiv., (b) 0.5 equiv., (c) 1.0 equiv.

A similar trend was observed upon addition of Gd^{3+} to the solution of $[Cu_5(\alpha\text{-Tyrha})_4]^{2+}$: the peaks corresponding to $[Cu_5(\alpha\text{-Tyrha})_4]^{2+}$ disappeared, and new positive-mode ESI-MS peaks appeared at *m/e* = 753 and 1570 corresponding to $[(Gd)Cu_5(\alpha\text{-Tyrha})_5](NO_3)^{2+}$ (753.9 calcd.) and $[(Gd)Cu_5(\alpha\text{-Tyrha})_5](NO_3)_2^+$ (1569.9 calcd.), respectively. In the ESI-MS spectra taken in the negative mode, only one peak at 1693 *m/e* appeared corresponding to $[(Gd)Cu_5(\alpha\text{-Tyrha})_5](NO_3)_4^-$ (1692.8 calcd.). These results indicate that after addition of 1 equiv. gadolinium relative to the 12-metallacrown-4, complete conversion of 12-metallacrown-4 to 15-metallacrown-5 occurs, and that the gadolinium(III)-containing 15-metallacrown-5 is the only species formed in solution.

$[Cu_5L_4]^{2+}$ Titration with Lanthanide(III) Monitored by NMR

In paramagnetic molecules, the NMR signals of protons close to the paramagnetic centres are broadened. Metallacrowns containing paramagnetic copper(II) ions and a paramagnetic lanthanide(III) ion in the cavity are therefore expected to give very broad signals with bad resolution. The extent of paramagnetic-induced line broadening depends on the electronic relaxation time of the paramagnetic metal centres. Broad lines are expected for complexes with copper(II) ions because of the relatively long electronic relax-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ation time of this ion (τ_s = 1–5 × 10^{-9} s).[17] However, a shortening of the electronic relaxation times of the metal ions involved can occur as a consequence of magnetic coupling.[18] The copper(II) ions in the 15-MC-5 ring are antiferromagnetically coupled so that the τ_s value is lower than it would be in the absence of magnetic coupling.[6,16] As a consequence, one could in principle observe signals in high resolution NMR experiments.

We studied the conversion of a 12-metallacrown-4 to a 15-metallacrown-5 in [D_4]MeOH by solution proton NMR spectroscopy. Spectra of solutions containing equimolar amounts of the copper(II)/aminohydroximate ligand (L-Leuha) and different amounts of lanthanide(III) ions were recorded after one day (Figure 4). The four different samples prepared contained 0.00, 0.33, 0.66 and 1.00 equiv. $Nd(NO_3)_3$ (relative to the amount of 12-metallacrown-4). The first spectrum, without any neodymium(III), shows only one broad peak at ca. 1 ppm. In the sample with 0.33 equiv. of neodymium(III), the signal at 1 ppm disappears and two new signals appear at approximately. 31 ppm and 16 ppm in addition to four other signals that appear between δ = 0 and 4 ppm (Figure 4). 2D-COSY experiments revealed that the peaks experiencing the largest paramagnetic shift, at 31 ppm and 16 ppm, belong to the α and γ protons of L-Leuha, respectively. The peaks of the methyl groups appear at δ = 0.5 and 1.5 ppm, indicating that these two groups are magnetically nonequivalent. The other two weak signals that appear between δ = 0 and 4 ppm are from the magnetically nonequivalent β-protons of the ligand. Addition of more neodymium(III) ions increased the intensity of all peaks, and only a slight shift to lower field was observed. We attempted a similar NMR titration experiment for the metallacrown system with L-Tyrha ligands. Unfortunately, solutions containing equimolar amounts of copper(II) and L-Tyrha *without* lanthanide(III) were turbid at those high concentrations and no NMR spectra of the starting solutions could be obtained. On the other hand, copper(II)/L-Tyrha solutions *with* lanthanide(III) ions were clear, and their NMR spectra are discussed later.

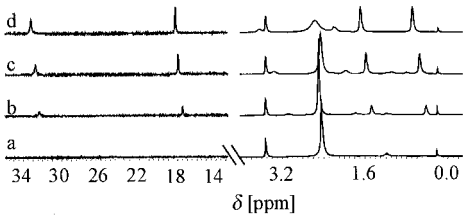

Figure 4. Proton NMR spectra of Cu^{2+}/Leuha solutions in [D_4]MeOH containing different amounts of Nd^{3+} relative to the 12-metallacrown-4 concentration: (a) 0.00 equiv., (b) 0.33 equiv., (c) 0.66 equiv., (d) 1.00 equiv.

It is interesting to note that in the case of 12-metallacrown-4, which is formed in the absence of any lanthanide(III) in solution, most of the NMR signals could not be detected. However, in the case of 15-metallacrown-5 complexes, which are formed upon addition of neodymium(III), the NMR signals of the ligand become observable. This difference points to the different electronic relaxation of the copper(II) ions in the 12-metallacrown-4 and 15-metallacrown-5. This difference is not surprising if one considers that the coordination around copper(II) ions is nearly square planar in 15-metallacrown-5,[12] but square pyramidal in 12-metallacrown-4, as shown by our DFT calculations.

NMR Analysis of $Ln(NO_3)_3$[15-$MC_{Cu^{II}N(L–Tyrha)}$-5]

Paramagnetic shift reagents, which are used to induce large NMR shifts in organic molecules to which they are coordinated, are available for most classes of compounds. One factor that has led to the widespread application of lanthanide-containing shift reagents (LSR) is that the shifts observed in the NMR spectrum are highly predictable.[19–22] This is a result of the magnetic properties of the lanthanide ions. In this study we do not focus on the effect that paramagnetic metallacrown compounds have on nuclei of a substrate molecule, but on the lanthanide induced shift (LIS) of the ligand protons of the metallacrown compounds. ^{1}H NMR spectra of $Ln(NO_3)_3$[15-$MC_{Cu^{II}N(L–Tyrha)}$-5] containing different lanthanide(III) ions in the central cavity were recorded in [D_4]MeOH solutions to examine the influence of lanthanide(III) ions on the chemical shift. The values of ^{1}H NMR resonances of the metallacrowns formed with Ln^{3+} (Ln = La, Ce, Pr, Nd, Sm, Eu, Tb, Dy, Ho, Er, Tm) and Y^{3+} are shown in Figure 5.

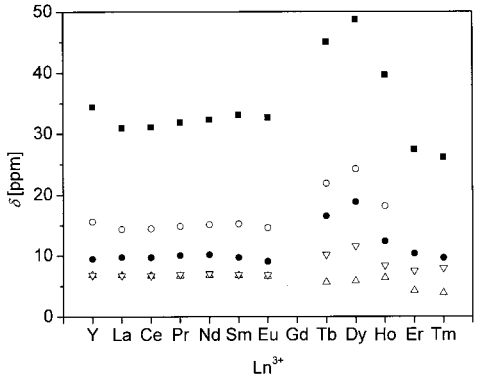

Figure 5. Proton NMR resonances for $Ln(NO_3)_3$[15-$MC_{Cu^{II}N(L–Tyrha)}$-5] with different Ln^{3+} ions and Y^{3+} [α-protons (squares), β-protons (empty and filled circles), aromatic protons (triangles pointing upwards and downwards)].

The assignment of the peaks was made with the help of 2D-COSY experiments with $Nd(NO_3)_3$[15-$MC_{Cu^{II}N(L–Tyrha)}$-5] (see below). The magnitude of the shift for the aromatic protons is less than that for the signals of the two β-protons and the α-proton. This is consistent with the fact that the proton in closest proximity to a paramagnetic centre is shifted farthest. $La(NO_3)_3$[15-$MC_{Cu^{II}N(L–Tyrha)}$-5] has four distinct proton resonances [at ≈ 31 ppm (1H), ≈ 14 ppm (1H), ≈ 10 ppm (1H) and at 6.7 ppm (4H)] that are paramagnetically shifted due to the copper(II) ions in the me-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tallacrown ring. The spectra of the 15-metallacrown-5 complexes with $Y^{3+}$and Ce^{3+} are similar to the spectrum of the complex with La^{3+}. For the $Ln(NO_3)_3$[15-$MC_{Cu^{II}N(L\text{–}Tyrha)}$-5] complexes with Ln^{3+} = Pr^{3+}, Nd^{3+}, Sm^{3+} and Eu^{3+} the signals of the aromatic protons appear as two separate resonances. 2D-COSY experiments with $Nd(NO_3)_3$[15-$MC_{Cu^{II}N(L\text{–}Tyrha)}$-5] showed a coupling between the resonances at ca. 15 ppm and ca. 10 ppm belonging to the two β-protons of the CH_2 group of the ligand. Interestingly, only one of these signals (the one at ca. 10 ppm) couples with the signal belonging to the α-proton (at ca. 32 ppm). From this, we infer that the β-protons of the CH_2 group are magnetically nonequivalent. The spectrum of $Gd(NO_3)_3$[15-$MC_{Cu^{II}N(L\text{–}Tyrha)}$-5] exhibits excessive line broadening of the signals due to the paramagnetic gadolinium(III) ion and is not discussed here. For the $Ln(NO_3)_3$[15-$MC_{Cu^{II}N(L\text{–}Tyrha)}$-5] complexes with Ln^{3+} = Tb^{3+}, Dy^{3+} and Ho^{3+} the paramagnetic shift is even larger. The signals belonging to the α- and the β-protons of the complex with Dy^{3+} experience the largest upfield shifts of the lanthanide series. One resonance signal of the aromatic protons of those three metallacrowns has shifted upfield, the other has shifted slightly downfield. 2D-COSY experiments with $Dy(NO_3)_3$[15-$MC_{Cu^{II}N(L\text{–}Tyrha)}$-5] showed only one coupling signal between the resonances belonging to the aromatic protons. The integration values of the peak belonging to the α-proton (1H), the two peaks belonging to the β-protons (1H each) and the two signals belonging to the aromatic protons (2H each) are consistent with this assignment. However if we consider the spectra of the $Ln(NO_3)_3$[15-$MC_{Cu^{II}N(L\text{–}Tyrha)}$-5] complexes with Ln = Er^{3+} and Tm^{3+} one proton resonance is missing. Again, 2D-COSY experiments with $Er(NO_3)_3$[15-$MC_{Cu^{II}N(L\text{–}Tyrha)}$-5] showed only one coupling signal between the resonances belonging to the aromatic protons. Presumably, the missing resonance must belong to one β-proton.

Lanthanide-induced shifts (LIS) for nuclei of a ligand upon coordination arise by two possible mechanisms. These two mechanisms are the pseudocontact and contact shift.[23] The contact shift of a nucleus directly bound to a lanthanide(III) ion is usually very large, but decreases rapidly as the number of bonds between the lanthanide(III) ion and the nucleus under study increases. Because there are at least four bonds between the central lanthanide(III) ion of the metallacrown and the ligand protons, the contribution of the contact shift is negligible, and the pseudocontact shift contribution can be considered as the most important one. In addition, shifts resulting from the pseudocontact mechanism are highly predictable.[19] If we look at the shifts belonging to the α-proton of the different $Ln(NO_3)_3$[15-$MC_{Cu^{II}N(L\text{–}Tyrha)}$-5] complexes, it can be seen that complexes with Ln = Pr, Nd, Sm, Eu, Tb, Dy and Ho have a similar effect as upfield shift reagents with a relative ordering of the shifts Dy > Tb > Ho > Sm > Eu > Nd > Pr, whereas complexes with erbium(III) and thulium(III) have a similar effect as downfield shift reagents. It is not surprising that the direction of the shifts and the relative ordering is nearly the same as the shifts of a substrate recorded in the presence of the shift reagent [Ln(dpm)$_3$], where the shifts also result mainly from the pseudocontact mechanism.[24]

Ligand Exchange in Ln^{III}[15-MC-5] Complexes

Previous ligand exchange studies for the copper(II) based metallacrowns Cu[12-$MC_{Cu^{II}N(shi)}$-4] and Cu[12-$MC_{Cu^{II}N(anha)}$-4] showed the kinetic inertness towards ligand exchange in methanol.[16] On the other hand, vanadyl-containing metallacrown complexes [9-$MC_{(VO)N(shi)}$-3] and [9-$MC_{(VO)N(nha)}$-3], unable to sequester metal ions in their cavities, were found to be kinetically labile in methanol.[25]

We tested the dynamics of ligand exchange of α-aminohydroximate-based 15-metallacrown-5 complexes with central lanthanide(III) cavity ions in methanol. ^{1}H NMR was used to monitor the ligand exchange for 15-metallacrown-5 complexes containing L-Tyrha and L-Pheha aminohydroximate ligands. The equimolar solutions of Nd[15-$MC_{Cu^{II}N(L\text{–}Tyrha)}$-5] (**1**) and Nd[15-$MC_{Cu^{II}N(L\text{–}Pheha)}$-5] (**2**) were mixed and after 1 h the ^{1}H NMR spectrum of the mixture shows two sets of peaks appearing at the same ppm values as for the separate solutions of **1** and **2** (Figure 6). After 1 d at room temperature, new peaks appeared in the spectra. When this mixture was kept for 2 d at 37 °C, some of those new peaks were resolved into multiplets. A similar spectrum was obtained in an experiment where the ligands L-Tyrha and L-Pheha were mixed in the presence of copper(II) and neodymium(III). We were wondering whether some metallacrowns containing both L-Tyrha and L-Pheha ligands (mixed-ligand metallacrowns) were forming in solution after a long period of time or initially at the time of their synthesis with both L-Tyrha and L-Pheha in the reaction mixture. If this takes place, the environment of the protons of one ligand will depend on the adjacent ligand in the metallacrown ring and they will not be magnetically equivalent anymore. This can be an explanation why the peaks are resolved into multiplets.

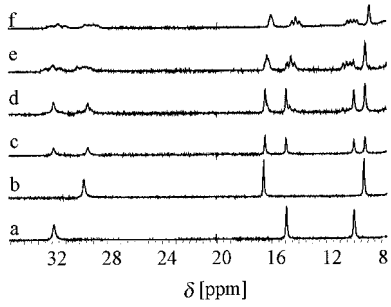

Figure 6. Proton NMR spectra of (a) Nd[15-$MC_{Cu^{II}N(L\text{–}Tyrha)}$-5] (**1**), (b) Nd[15-$MC_{Cu^{II}N(L\text{–}Pheha)}$-5] (**2**), (c) a 1:1 mixture of **1** and **2** after 1 h, (d) 1 d, (e) 2 d at 37 °C, (f) control experiment in which the metallacrown is synthesised from a [D_4]MeOH solution containing both L-Tyrha and L-Pheha, copper(II) and neodymium(III) in the reaction mixture.

In order to further understand the exchange process we used ESI-MS to probe the mass distribution of the complexes in solution. When initially both L-Tyrha and L-Pheha ligands (1:1) were allowed to react with the copper(II) and

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

lanthanide(III) ions, a uniform distribution of ESI-MS peaks with values corresponding to different Ln^{III}[15-$MC_{Cu^{II}N(L–Pheha)_x(L–Tyrha)_y}$-5] complexes with the *x*/*y* ratios 5:0, 4:1, 3:2, 2:3, 1:4 and 0:5 was observed. This distribution points to the formation of mixed-ligand metallacrowns and means that there is no preference for one of the two ligands.

The copper(II) and lanthanide(III) metal ions can be viewed as templates around which the macrocyclic ring in 15-metallacrown-5 complexes is formed. However the reactants, the α-aminohydroximate ligands, are forming a ring only through coordination with the copper(II) ions and not through inter- or intramolecular reaction of the ligands between themselves. This could allow easy rearrangement and mixing of the different ligands since they are only coupled together through coordination bonds to the copper(II) ions. This is not surprising, as it is known that copper(II) complexes are among the most labile complexes of the d-block metal(II) ions.[26]

Conclusions

The easy conversion of Cu^{II}[12-MC-4] to a Ln^{III}[15-MC-5] is accomplished by addition of Ln^{III} ions in solution. Evidence for the presence of only two metallacrown species in the conversion process was obtained by UV/Vis and CD spectrophotometry. Complete disappearance of Cu^{II}[12-MC-4] and formation of Ln^{III}[15-MC-5] was proved by ESI-MS spectrometry and NMR spectroscopy. Due to the labile copper(II)–ligand bond, easy mixing of the different α-aminohydroxamate ligands can take place in solution, leading to a mixture of different metallacrown complexes.

Experimental Section

Reagents: L-Leucine methyl ester hydrochloride, D-leucine methyl ester hydrochloride, L-tyrosine methyl ester hydrochoride and L-phenylalanine methyl ester hydrochoride were obtained as pure products from Acros Organics. All other chemicals and solvents were reagent grade. L-Leucine hydroxamic acid, D-leucine hydroxamic acid, L-tyrosine hydroxamic acid and L-phenylalanine hydroxamic acid were prepared via their respective methyl esters as reported in ref.[27].

Equipment and Techniques: Positive- and negative-mode electrospray mass spectra (ESI-MS) were obtained with a Q-tof 2 (Micromass, Manchester UK) instrument. The samples were injected into the apparatus after dissolution in acetonitrile or in methanol.

UV/Vis absorption spectra were recorded with a Shimadzu UV-1601PC spectrophotometer using quartz cells of 1 cm path length. Circular dichroism spectra were measured with a JASCO J-810 spectropolarimeter using quartz cells of 2 cm path length. The spectra were collected in the 200–900 nm range. The solutions for the measurements were always freshly prepared before measurement. The concentration of the copper(II) and α-aminohydroxamic acid solutions was 2 mM. The pH of the solution was determined before and after each measurement.

^1H NMR spectra were recorded in deuterated water (D_2O) or methanol ([D_4]MeOH) solutions with a Bruker Avance 300 spectrometer operating at 300 MHz. In the titration experiment, to four 500-μL solutions in [D_4]MeOH containing equimolar amounts of $Cu(OAc)_2$ and L-leucine hydroxamic acid (0.1 M) were added 0.00, 0.33, 0.66 and 1.00 equiv. $Nd(NO_3)_3$. This was achieved by adding respectively 0, 20, 40 and 60 μL of a neodymium(III) nitrate solution in [D_4]MeOH (0.166 M) and adjusting the total volume of the NMR samples to 600 μL. Solutions of $Ln(NO_3)_3$[15-$MC_{Cu^{II}N(L–Tyrha)}$-5] complexes with different lanthanide(III) ions and yttrium(III) were prepared by dissolving some crystals in [D_4]-MeOH. In the ligand-exchange experiments, two solutions containing metallacrown complexes (0.02 M in [D_4]MeOH) with different α-aminohydroxamic acids were mixed together. This NMR sample was also heated for 2 d at 37 °C in a water bath. In the control experiment, metallacrown was formed by adding neodymium(III) nitrate solution (240 μL, 0.166 M) in [D_4]MeOH to a solution of $Cu(OAc)_2$ (0.2 mmol) and both α-aminohydroxamic acids (0.1 mmol of each). Chemical shifts were referenced to sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) or to the solvent peak. Two-dimensional proton–proton correlation spectroscopy (2D COSY) was performed by applying the standard Bruker pulse sequence, and confirmed the assignment of the proton resonances.

Computational Details: The optimisation of the geometrical structures was accomplished by density-functional theory (DFT) as implemented in the Amsterdam Density Functional program package[28,29] ADF2002.03.[30] A triple zeta (TZP) basis set of Slater type orbitals was used. The frozen core approximation was employed, including all orbitals up to 2p for the copper atoms and 1s for the carbon, nitrogen and oxygen atoms. The local density functional of Vosko, Wilk and Nusair[31] was used, with the exchange and correlation corrections from Becke[32] and Perdew[33], respectively (BP86). The complexes were fully optimized without symmetry constraints.

Imino- and Oxazolino-Functionalised Pyrrolylphosphanes and Pyrrolylphosphinites: An Unexploited Class of Chiral *P,N*-Bidentate Ligands with Unusual Electronic Properties

Konstantin N. Gavrilov,[a] Vasily N. Tsarev,*[b] Stanislav I. Konkin,[a] Sergey E. Lyubimov,[b] Alexander A. Korlyukov,[b] Mikhail Yu. Antipin,[b] and Vadim A. Davankov[b]

Keywords: Allylic substitution / Asymmetric catalysis / Palladium / *P,N*-bidentate ligands / Rhodium

Enantiopure *P,N*-bidentate pyrrolylphosphanes and pyrrolylphosphinites have been prepared based upon chiral imino- and oxazolino-containing compounds. Complexation of the new ligands with $[Rh(CO)_2Cl]_2$ and $[Pd(allyl)Cl]_2$ has been found to give the chelate complexes $[Rh(CO)Cl(\eta^2\text{-}P,N)]$ and $[Pd(allyl)(\eta^2\text{-}P,N)]^+BF_4^-$, respectively. Imino- and oxazolino-functionalised pyrrolylphosphanes and pyrrolylphosphinites have been shown to be a novel class of *P,N*-bidentate ligands possessing exceptional π-acceptor and original σ-donor properties. With these ligands, up to 77 % *ee* has been achieved in the asymmetric Pd-catalyzed sulfonylation of 1,3-diphenyl-2-propenyl acetate with sodium *p*-toluenesulfinate. In the enantioselective alkylation of 1,3-diphenyl-2-propenyl acetate with dimethyl malonate, up to 93 % enantioselectivity has been achieved by using $[Pd(allyl)(\eta^2\text{-}P,N)]^+BF_4^-$ complexes as chiral catalysts.

Introduction

In the last decade, (1-pyrrolyl)phosphanes ($PPh_x(NC_4H_4)_{3-x}$, x = 0–2), phosphinites and phosphonites ($P(OPh)_x(NC_4H_4)_{3-x}$, x = 1–2) have been successfully applied in the synthesis of rhodium[1–7] and cobalt[8] complexes, as well as in Rh-catalyzed hydroformylation.[9,10] A set of spectroscopic, structural, and thermochemical measurements[1–7,10] showed that these substances are exceptional π-acceptor ligands. The rationale for this π-acceptor character is best demonstrated by the resonance forms **A**–**D**, Figure 1.

Aromatic delocalisation of the nitrogen lone pair into the five-membered ring places a partial positive charge adjacent to the phosphorus atom. This contribution in **B** and **C** would be expected to render the pyrrolyl substituent an effective electron-withdrawing group. Relative to phenyl, resonance form **D** would also be expected to contribute in an electron-withdrawing fashion, since a more electronegative nitrogen atom replaces carbon.[3] As a result, the substituent parameter χ_i for the 1-pyrrolyl functionality is approximately 12, and the π-acceptor character of these ligands is thus found to exceed that of arylphosphites (–OPh, χ_i = 9.7) and fluorinated aromatic phosphanes (–C_6F_5 χ_i = 11.2).[3]

The higher frequencies of the metal carbonyl stretch for rhodium complexes with pyrrolylphosphanes and pyrrolylphosphonites compared with rhodium complexes with phosphites (Table 1) are consistent with pyrrolyl-based ligands being a better π-acceptor than phosphites, as anticipated from the greater number of 1-pyrrolyl substituents, which reduces the back-donation to the metal carbonyl.

As for σ basicity, the $^1J_{P,Se}$ coupling constants in the ^{31}P NMR spectra of corresponding selenide derivatives indicate

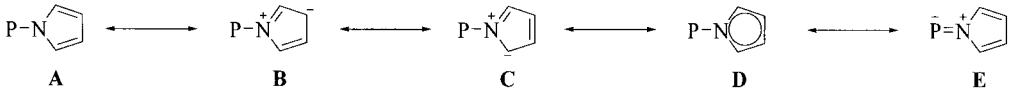

Figure 1. Resonance forms of pyrrolylphosphanes.

that $P(NC_4H_4)_3$ ($^1J_{P,Se}$ for $Se{=}P(NC_4H_4)_3$ = 970 Hz) is more basic than $P(OPh)_3$ and constrained phosphites ($^1J_{P,Se}$ for Se=L = 1099–1011 Hz) and less basic than $P(NR_2)_3$ ($^1J_{P,Se}$ for Se=L = 854–784 Hz).[6] For estimating the σ basicity of pyrrolylphosphanes, we suggest a well-known criterion that the values of $^1J_{P,Rh}$ coupling constants in the ^{31}P NMR spectra of corresponding chlorocarbonyl complexes

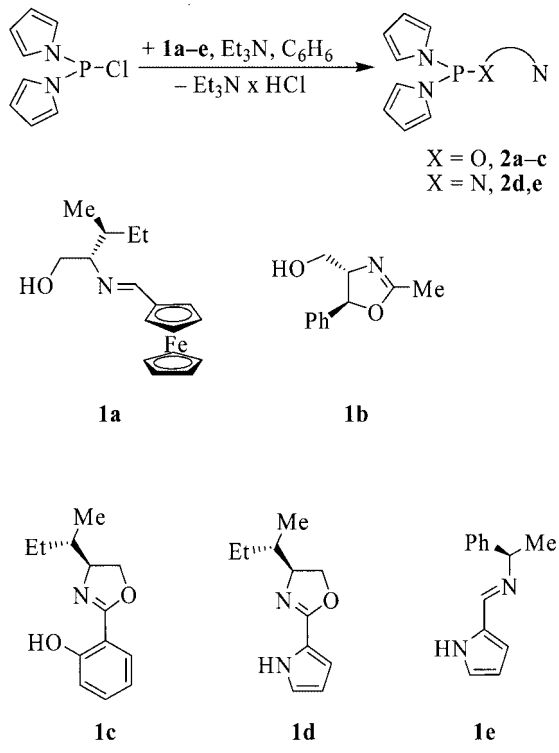
[Rh(acac)(CO){P(OEt)$_3$}][11]	1990	267
[Rh(CO){P(NC_4H_4)$_3$}$_2$Cl][1,2]	2024	180
[Rh(CO){P(NC_4H_4)$_2$(OPh)}$_2$Cl][10]	2018	190
[Rh(CO){P(OPh)$_3$}$_2$Cl][2]	2016	210

of rhodium(I) strongly correlate with the s character of the phosphorus lone pair.[11,12] According to this criterion, pyrrolylphosphanes are strong σ bases comparable not only with P(OPh)$_3$ and constrained phosphites, but also with alkyl phosphites (Table 1). A possible reason is a significant contribution of the resonance form with partial negative charge at the phosphorus atom, and easy polarization of the aromatic group.[13] Values of $^1J_{P,Se}$ and $^1J_{P,Rh}$ seem to be more correct criteria for σ basicity than the bond lengths Rh–P used by some authors.[14] On the basis of the X-ray data for the isostructural complexes [Rh(acac)(CO){P(OPh)$_3$}] (Rh–P 2.170 Å) and [Rh(acac)(CO){P(NC_4H_4)$_3$}] (Rh–P 2.166 Å), they made a conclusion about stronger σ-donor properties of P(OPh)$_3$ in comparison to P(NC_4H_4)$_3$. However, bond lengths M–P are dependent not only on σ basicity, but also on π acidity of the ligand.[6] Thus, in another pair of isostructural compounds [Rh(acac){P(OPh)$_3$}$_2$] (Rh–P 2.147, 2.156 Å) and [Rh(acac){P(NC_4H_4)$_3$}$_2$] (Rh–P 2.161, 2.176 Å), bonds Rh–P are longer in the complex with P(NC_4H_4)$_3$,[4] while $^1J_{P,Rh}$ is 291 and 261 Hz, respectively (compare also with the data in Table 1).

Therefore, pyrrolylphosphanes and pyrrolylphosphinites are characterised by rather paradoxical electronic properties, and are both more potent π acids and σ bases than phosphites, representing a novel and efficient group of optically active ligands.[15–17] It should be noted that the –P(NC_4H_4)$_2$ building block and the common chiral ligand –PPh$_2$ fragment are practically the same size, according to their Tolman's cone angle values.[1,4] One could expect that such unusual electronic and steric properties of ligands with –P(NC_4H_4)$_2$ fragments make these compounds promising for asymmetric catalysis, but to the best of our knowledge no examples of their catalytic application are known. In the present communication we report previously unknown chiral pyrrolylphosphanes and pyrrolylphosphinites and pioneering results of their application in the coordination chemistry of palladium and in asymmetric Pd-catalysed allylation.

Results and Discussion

The new *P,N*-bidentate pyrrolylphosphinites **2a**–**c** and pyrrolylphosphanes **2d**,**e** were obtained from chlorobis(1-pyrrolyl)phosphane in one step (Scheme 1).



Scheme 1.

Compounds **2a**–**e** are soluble in common nonprotic solvents and stable under dry conditions. Unlike P(NC_4H_4)$_3$, ligands **2d** and **2e** are moisture sensitive. A possible reason for this, as in the case of the keto-functionalised ligand P(NC_4H_4)$_2$(NC_4H_3C(O)Me-2),[7] is that a functionalised pyrrole ring represents a better leaving group than the unfunctionalised pyrrolyl groups and, additionally, is able to form hydrogen bonds with incoming protic nucleophiles.

Using the compounds **2a**–**e**, neutral and cationic *cis*-chelate metal complexes were obtained (Scheme 2).

Some important spectroscopic data of the complexes are summarised in Table 2.

The $^1J_{P,Rh}$ and ν(CO) data for complexes **3a**–**e** are in good agreement with the suggested structures.[18] IR and ^{13}C NMR spectroscopic characteristics of the carbonyl ligands in complexes **3a**–**e** (δ_C = 186.2 ppm, $^1J_{C,Rh}$ = 72 Hz, ^2J(C,P) = 16 Hz for **3a** and δ_C = 184.9 ppm, $^1J_{C,Rh}$ = 68 Hz, $^2J_{C,P}$ = 17 Hz for **3e**) indicate that **2a**–**e** represent a novel group of highly π-accepting *P,N*-bidentate ligands.[4,7,19] Notably, the ν(CO) values of **3d**,**e** prove that

ligands **2d**,**e** bearing three pyrrole rings, are the most π acidic in the group. A comparison of the $^1J_{P,Rh}$ and ν(CO) data for compounds **3a**–**c** (Table 2) and isostructural rhodium complexes previously described by us[18,20,21] (Table 3)

Table 3. Selected spectral parameters for [Rh(CO)Cl(η^2-*P,N*)] complexes with *P,N*-bidentate arylphosphite ligands.

Ligand	ν(CO), cm^{-1} ($CHCl_3$)	$^1J_{P,Rh}$, Hz ($CHCl_3$)
 [18]	2025	279
 [20]	2030	277
 [21]	2024	287

supports a general conclusion about higher σ-donor and π-acceptor properties of pyrrolylphosphanes and pyrrolylphosphinites with respect to phosphites.

It is rather difficult to determine the best σ donor among the ligands **2a**–**e**, since the $^1J_{P,Rh}$ values in chloro carbonyl rhodium chelate complexes depend largely on the nature of a nitrogen-containing fragment (see ref.[18] and references cited therein). But in the case of **3c** and **3d**, the ^{31}P NMR spectroscopic data (Table 2) indicate that pyrrolylphosphane **2d** is a stronger σ donor than pyrrolylphosphinite **2c**.

Complexes **3a**, **3c** and **3d** were characterised by X-ray diffraction. Their molecular structures are shown in Figure 2, Figure 3 and Figure 4, and selected bond lengths and angles are given in Table 4.

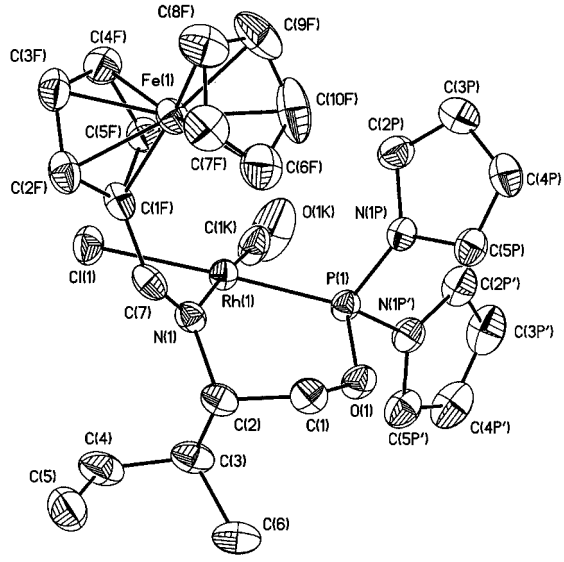

Figure 2. Molecular structure of complex **3a**. Atoms are given by thermal ellipsoids at 50% probability. Principal bonds and angles (Å and °): Rh(1)–C(1K) 1.837(3), Rh(1)–N(1) 2.141(2), Rh(1)–P(1) 2.1576(8), Rh(1)–Cl(1) 2.3742(9), P(1)–O(1) 1.598(2), P(1)–N(1P) 1.691(2), P(1)–N(1P′) 1.703(2), O(1)–C(1) 1.444(3), O(1K)–C(1K) 1.134(4); O(1)–P(1)–N(1P) 103.34(12), O(1)–P(1)–N(1P′) 96.27(12), N(1P)–P(1)–N(1P′) 100.49(11), O(1)–P(1)–Rh(1) 116.68(8), N(1P)–P(1)–Rh(1) 116.72(8), N(1P′)–P(1)–Rh(1) 119.95(9).

From X-ray studies it was found that in the crystal the molecules of **3a**,**c**,**d** are characteried by *S* configurations of C(2) and C(3) for **3a**, C(4) and C(5) for **3c**, and C(4) and C(5) for the **3d** asymmetric atoms, respectively.

The distorted sofa conformation (the deviation of the P(1) atom from the basal plane is 0.81 Å) of the six-membered metallacycle is observed in compound **3d**. In compound **3a,** where the fused five-membered cyclic fragments are absent, the six-membered metallacycle adopts the distorted chair conformation with deviations of the P(1) and C(2) atoms by 0.57 and 0.79 Å, respectively. The chair conformation of the six-membered metallacycle is also observed in previously studied complexes with the 1,3-diaza-2-phosphabicyclo[3.3.0]octane ligand.[22] So, it can be concluded that the distorted sofa conformation in **3d** is caused by the presence of five-membered cycles fused with the metallacycle.

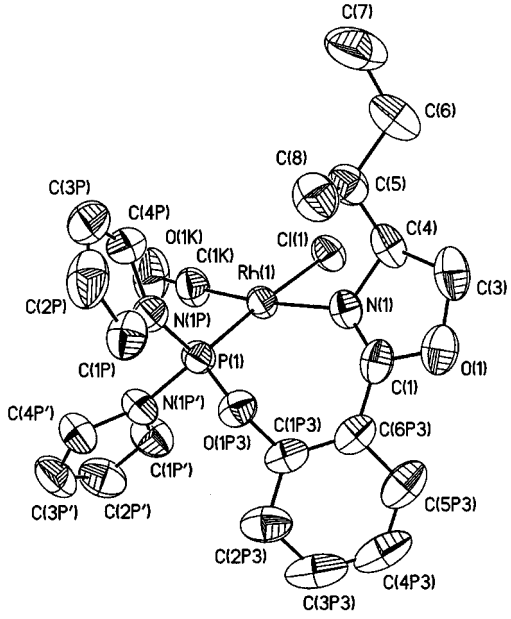

Figure 3. Molecular structure of complex **3c**. Atoms are given by thermal ellipsoids at 50% probability. Principal bonds and angles (Å and °): Rh(1)–C(1K) 1.828(3), Rh(1)–N(1) 2.1020(19), Rh(1)–P(1) 2.1553(9), Rh(1)–Cl(1) 2.3810(9), P(1)–O(1P3) 1.6166(17), P(1)–N(1P) 1.691(2), P(1)–N(1P′) 1.696(2), O(1K)–C(1K) 1.134(3); O(1P3)–P(1)–N(1P) 94.72(10), O(1P3)–P(1)–N(1P′) 103.95(10), N(1P)–P(1)–N(1P′) 102.73(10), O(1P3)–P(1)–Rh(1) 116.33(6), N(1P)–P(1)–Rh(1) 119.85(8), N(1P′)–P(1)–Rh(1) 116.05(8).

The seven-membered metallacycle in **3c** is fused with phenyl and oxazoline moieties and its conformation may be described as a distorted boat. Atoms C(1P3), C(6P3) and Rh(1) deviate from the plane P(1)O(1P3)N(1)C(1) by 0.93, 0.98 and 0.68 Å, respectively.

Table 4. Selected bond lengths [Å] and angles [°] for complexes **3a**, **3c** and **3d**.

	3a	**3c**	**3d**
Rh(1)–C(1K)	1.837(3)	1.828(3)	1.838(3)
Rh(1)–N(1)	2.141(2)	2.1019(19)	2.111(2)
Rh(1)–P(1)	2.158(1)	2.155(1)	2.145(1)
Rh(1)–Cl(1)	2.374(1)	2.381(1)	2.363(1)
O(1K)–C(1K)	1.134(4)	1.134(3)	1.129(4)
N(1)–Rh(1)–P(1)	88.36(7)	90.20(6)	86.54(6)
C(1K)–Rh(1)–P(1)	89.81(9)	91.13(9)	93.67(10)
C(1K)–Rh(1)–Cl(1)	89.00(9)	89.48(9)	89.35(10)
N(1)–Rh(1)–Cl(1)	92.67(7)	89.64(6)	90.64(6)
P(1)–Rh(1)–Cl(1)	177.35(3)	176.05(2)	174.45(3)
O(1K)–C(1K)–Rh(1)	178.0(3)	176.9(3)	178.1(3)

The oxazoline cycles in **3c** and **3d** have different conformations. In the former case this cycle is planar, while in the latter it adopts the envelope conformation with deviation of the C(4) atom by 0.15 Å. The ferrocenyl substituent in **3a** occupies a pseudoequatorial position.

The *endo*-cyclic rhodium atom has an almost ideal square-planar geometry, its deviation from the basal plane does not exceed 0.02 Å. On the other hand in **4** the deviation of the Rh^{I} atom from the basal plane is more pronounced (0.06 Å), which may be explained by steric overcrowding of the six-membered metallacycle. The P(1)–Rh(1) bonds in **3a**,**c**,**d** are somewhat shorter than those in the previously investigated 1,3-diaza-2-phosphabicyclo[3,3,0]octane ligand complex[22]. On the other hand, the shortening of the P(1)–Rh(1) bond did not lead to respective elongation of the Rh(1)–Cl(1) bond in comparison to the analogous bond in the previously described complex.[22] So, the *trans*-effect of a $P(C_4H_4N)_3$ moiety is almost the same as

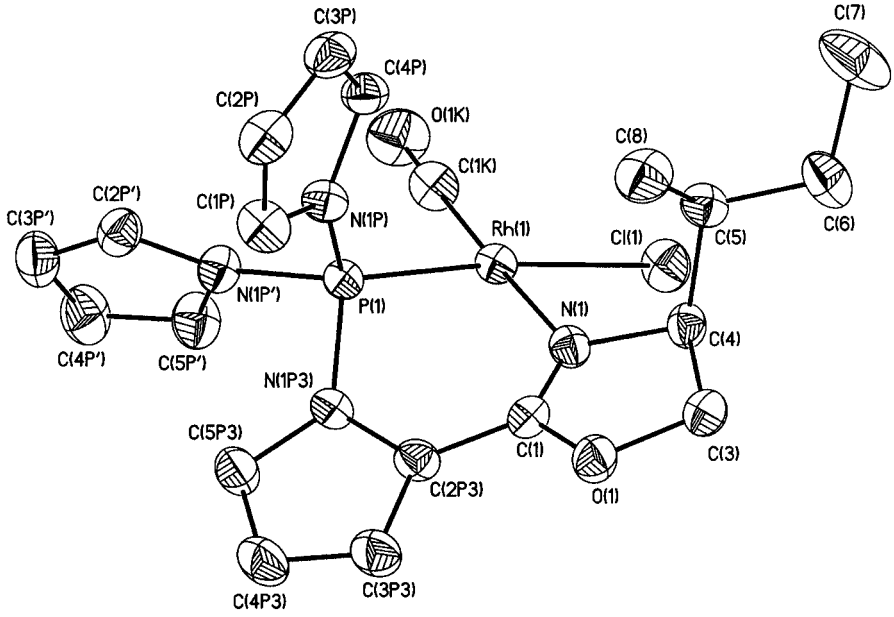

Figure 4. Molecular structure of complex **3d**. Atoms are given by thermal ellipsoids at 50% probability. Principal bonds and angles (Å and °): Rh(1)–C(1K) 1.838(3), Rh(1)–N(1) 2.111(2), Rh(1)–P(1) 2.1448(8), Rh(1)–Cl(1) 2.3631(9), P(1)–N(1P) 1.681(2), P(1)–N(1P′) 1.698(2), P(1)–N(1P3) 1.717(2), C(1K)–O(1K) 1.129(4); N(1P)–P(1)–N(1P′) 102.52(12), N(1P)–P(1)–N(1P3) 99.87(12), N(1P′)–P(1)–N(1P3) 100.44(11), N(1P)–P(1)–Rh(1) 118.26(8), N(1P′)–P(1)–Rh(1) 121.83(9), N(1P3)–P(1)–Rh(1) 110.46(8).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

in the case of the 1,3-diaza-2-phosphabicyclo[3.3.0]octane fragment.

The geometry of the P(1) atom in **3a** and **3c** is distorted tetrahedral, the bond angles at this atom vary in the range of 94–119°. It should be noted that endocyclic P–O bonds in **3a**,**c**,**d** have almost the same lengths as in previously studied compound.[22]

There is no correlation between $^1J_{P,Rh}$ values and Rh–P bond lengths, because, as mentioned above, the Rh–P bond length depends not only on σ basicity but also on the π acidity of the P ligand. Thus, the shortest Rh–P bonds were found in the complexes with the most π-acceptor pyrrolylphosphanes [Rh(CO)($P(NC_4H_4)_2(NC_4H_3C(O)Me$-2))Cl] [2.147 Å, $^1J_{P,Rh}$ = 237 Hz, $\tilde{\nu}$(CO) = 2017 cm^{-1} (KBr)],[7] [Rh(CO)($P(NC_4H_4)_2$(7-aza-1-indolyl))Cl] and **3d** (Table 5); **3d** has the shortest Rh–P bond among these complexes and related compounds like [Rh(acac)(CO){$P(NC_4H_4)_3$}]. The data in Table 5 clearly demonstrate that *ν*(CO) in the IR spectra of [Rh(CO)(L)Cl] complexes is strongly affected by changings in the π acidity of *P,N*-bidentate ligands. In particular, pyrrolylphosphane $P(NC_4H_4)_2$(7-aza-1-indolyl) is a much stronger π acceptor than $P(Ph)_2$(7-aza-1-indolyl), but weaker than **2d**,**e**. It is notable that whereas *ν*(CO) for the rhodium complexes varies significantly from 1986 to 2040 cm^{-1} ($\Delta\tilde{\nu}$(CO) = 54 cm^{-1}), $\Delta^1J_{C,Rh}$ does not exceed a mere 6 Hz (Table 5). Moreover, the $\tilde{\nu}$(CO) magnitudes of [Rh(CO)($P(Ph)_2$(7-aza-*N*-indolyl))Cl] and [Rh(CO)-($P(NC_4H_4)_2$(7-aza-*N*-indolyl)Cl] differ by 22 cm^{-1}, while their $^1J_{C,Rh}$ values are equal. These facts are in good agreement with a conclusion made earlier by us that $^1J_{C,Rh}$ for *cis-P,N*-chelate chlorocarbonyl complexes [Rh(CO)(L)Cl] lie within a narrow interval of 68–75 Hz and are practically indifferent to electronic characteristics of a phosphorus atom environment.[20] Duplication of peaks in the ^{31}P NMR spectra of compounds **4a**–**d** (Table 2) indicates the presence of their *exo*- and *endo*-isomers.[18,21] Sharp singlets in the ^{31}P NMR spectrum of **4e** can be rationalised either by fast interconversion of the isomers or by an absence of one of them.

Pyrrolylphosphanes and pyrrolylphosphinites **2a**–**e** and complexes **4c**,**d** were tested in asymmetric Pd-catalysed allylic substitution reactions (Scheme 3).

The results of allylic sulfonylation are summarised in Table 6. Good optical (up to 77% *ee*) and moderate chemi-

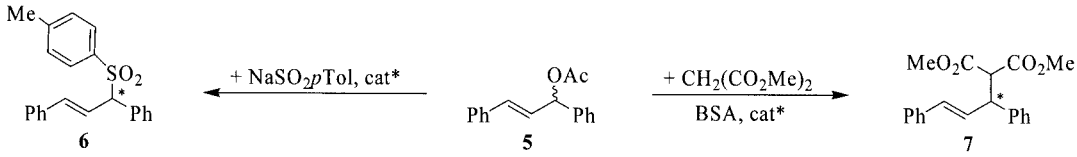

Scheme 3.

cal (up to 60%) yields of product **6** were achieved. **2b** (entry 5) was found to be the most stereoselective ligand, while **2a**, **2c** and **2e** showed basically the same enantioselectivity (54–64%), and no conversion was observed with **2d** (entries 10–12). An increased L*/Pd molar ratio in the processes catalysed by $[Pd(allyl)Cl]_2$ resulted in higher optical and chemical yields (entries 1,2; 4,5). Worth noting is that the most successful catalyst precursor for **2c** happened to be $[Pd_2(dba)_3]\times CHCl_3$ (entries 7–9).

Table 6. Enantioselective allylic sulfonylation of **5** with $NaSO_2pTol$ (in THF).

[a] *ee* measured by HPLC [(*R*,*R*)-Whelk-01, hexane/*i*PrOH = 4:1, 1 mL/min, 254 nm].

For the asymmetric allylic alkylation (Scheme 3, Table 7), ligands **2a** and **2c** provided the best results (entries 1,2,5). Thus, cationic complex **4c** afforded the product in 93% *ee* (93% conversion, entry 7).

Table 7. Enantioselective allylic alkylation of **5** with dimethyl malonate (in THF, L*/Pd = 1:1).

[a] Measured by HPLC. [b] Determined by HPLC (Daicel Chiralcel OD-H, hexane/*i*PrOH = 99:1; 0.5 mL/min, 254 nm).

Stereoinduction of pyrrolylphosphane **2e** is close to **2a** and **2c** (entry 11), but conversion is low. Ligands **2b** and **2d** demonstrated moderate enantioselectivity (up to 64% *ee*) with substantially low conversion in the case of **2d**. In contrast to allylic sulfonylation, $[Pd(allyl)Cl]_2$ was a superior catalyst precursor for all ligands.

Conclusions

Several chiral imino- and oxazolino-functionalised pyrrolylphosphanes and pyrrolylphosphinites were obtained for the first time by a simple one-step synthesis. These compounds have been shown to be a novel class of *P,N*-bidentate ligands possessing exceptional π-acceptor and original σ-donor properties. The new ligands were used in asymmetric Pd-catalyzed allylic substitution where up to 93% *ee* was achieved in the benchmark test with 1,3-diphenyl-2-propenyl acetate and dimethyl malonate. It should be pointed out, however, that the present work describes only five substances in this general class. A tremendous variety of similar substituents such as substituted pyrroles, indoles, imidazoles, pyrazoles, etc., are commercially available or obtainable by synthetic means.[1] The simple synthesis of pyrrolylphosphanes and pyrrolylphosphinites, their outstanding electronic properties, together with the wide variety of accessible pyrrolelike precursors make it an attractive area of research with great promise.

Experimental Section

General Remarks: All reactions were performed under argon in dehydrated solvents. IR spectra were recorded with a Specord M80 instrument. ^{31}P and ^{13}C NMR spectra were recorded with a Bruker AMX 400 instrument (162.0 MHz for ^{31}P, 100.6 MHz for ^{13}C). The assignments of the signals in the ^{13}C NMR spectra were made with the use of the DEPT technique and, for pyrrolyl substituents, using literature data.[10] Chemical shifts (ppm) are given relative to Me_4Si (^{13}C NMR) and 85% H_3PO_4 (^{31}P NMR). Mass spectra were recorded with a Kratos MS890 spectrometer (EI), an MSVKh TOF spectrometer with ionization by Cf-252 fission fragments (plasma desorption technique, PD) and AMD 402 spectrometer (FAB). Optical rotations were measured on a Perkin–Elmer 141 polarimeter. Elemental analyses were performed at the Laboratory of Microanalysis (Institute of Organoelement Compounds, Moscow).

$[Rh(CO)_2Cl]_2$,[25] $[Pd(allyl)Cl]_2$,[26] $[Pd_2(dba)_3]\times CHCl_3$,[27] chlorobis(1-pyrrolyl)phosphane,[10] compounds **1a**,[18] **1c**,[28] **1d**[29] and **1e**[30] were synthesised using literature procedures. 4-Hydroxymethyl-2-methyl-5-phenyl-2-oxazoline (**1b**) was purchased from Fluka. The syntheses of rhodium(I) complexes **3a**–**e** and palladium(II) complexes **4a**–**e** were performed by techniques similar to that reported.[18,31]

$NaSO_2pTol$, $CH_2(CO_2Me)_2$ and *N*,*O*-bis(trimethylsilyl)acetamide (BSA) were purchased from Acros Organics. Compound **5** was syn-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

thesised as published.[26] The catalytic experiments were carried out according to published procedures.[22]

Preparation of Ligands. General Technique: A solution of chlorobis(1-pyrrolyl)phosphane (4.2×10^{-3} mol) in benzene (15 mL) was added dropwise to a stirred solution of the appropriate compound **1a**–**e** (4.2×10^{-3} mol) and Et_3N (0.6 mL, 4.2×10^{-3} mol) in the same solvent (15 mL) at 0 °C. The reaction mixture was then heated to boiling point, allowed to cool down, stirred for 0.5 h at 50 °C, allowed to cool to room temperature and filtered. The solvent was removed in vacuo (40 Torr), and the residue was concentrated and dried in vacuo (1 Torr, 2 h).

{(2*S*)-2-(Ferrocenylmethylideneamino)-2-[(1*S*)-1-methylpropyl]-ethoxy}bis(1-pyrrolyl)phosphinite (2a): Yield: 1.85 g, 93%; dark red oil. $[a]_D^{21}$ = +151.4 (*c* = 0.5, $CHCl_3$). ^{13}C NMR ($CDCl_3$): δ_C = 161.7 (CH=N), 121.1 (d, ^2J = 14.9 H, CHNP), 120.9 (d, ^2J = 14.7 Hz, CHNP), 111.7 (d, ^3J = 6.5 Hz, *C*HCHNP), 111.6 (d, ^3J = 6.1 Hz, *C*HCHNP), 80.4 [$C_{Fc(ipso)}$], 76.3 (d, ^3J = 5.3 Hz, CHN), 70.1, 69.9, 69.1, 67.5 (all C_{Fc}), 69.2 (d, ^2J = 16.3 Hz, CH_2OP), 68.7 (C_{Cp}), 36.1 (*C*HCH$_3$), 25.2 (*C*H$_2$CH$_3$), 15.7 (CH*C*H$_3$), 10.8 (CH$_2$*C*H$_3$) ppm. ^{31}P NMR ($CDCl_3$): δ_P = 113.6 ppm. Catalytic Experiments

Palladium-Catalysed Allylic Sulfonylation of 1,3-Diphenylallyl Acetate with Sodium *p*-Toluenesulfinate: A solution of [Pd(allyl)Cl]$_2$ (0.0037 g, 0.01 mmol) or [$Pd_2(dba)_3$]×$CHCl_3$ (0.0103 g, 0.01 mmol) and the appropriate ligand (0.02–0.04 mmol) in THF (5 mL) was stirred for 40 min. 1,3-Diphenylallyl acetate **5** (0.1 mL, 0.5 mmol) was added to the solution and the reaction mixture was stirred for 15 min. Sodium *p*-toluenesulfinate (0.178 g, 1.00 mmol) was then added and the reaction mixture was stirred for 48 h, quenched with brine (10 mL) and extracted with THF (3×7 mL). The organic layer was washed with brine (2×7 mL) and dried over $MgSO_4$. The solvent was evaporated at reduced pressure (40 Torr). Crystallization of the residue from EtOH followed by desiccation in vacuo (10 Torr, 12 h) gave the product **6** as white crystals. All spectroscopic data of compound **6** were in good agreement with the literature.[32]

Palladium-Catalysed Allylic Alkylation of 1,3-Diphenylallyl Acetate with Dimethyl Malonate: A solution of [Pd(allyl)Cl]$_2$ (0.0037 g, 0.01 mmol) or [$Pd_2(dba)_3$]×$CHCl_3$ (0.0103 g, 0.01 mmol) and the appropriate ligand (0.02 mmol) in THF (5 mL) was stirred for 40 min [alternatively, the appropriate presynthesised complex (0.02 mmol) was dissolved in THF (5 mL)]. 1,3-Diphenylallyl acetate **5** (0.1 mL, 0.50 mmol) was added to the solution and the reaction mixture was stirred for 15 min. Dimethyl malonate (0.10 mL, 0.87 mmol), BSA (0.22 mL, 0.87 mmol), and sodium acetate (0.002 g) were also added. The reaction mixture was stirred for 48 h, diluted with THF (5 mL) and filtered through Celite. The filtrate was evaporated at reduced pressure (40 Torr) giving, after in vacuo desiccation (10 Torr, 12 h), product **7** as a colourless oil solidifying upon standing. All spectroscopic data of compound **7** were in good agreement with the literature.[33]

X-ray Crystallographic Study: Crystallographic data for **3a**, **3c** and **3d** are presented in Table 8. All X-ray diffraction measurements were carried out with a SMART 1000 CCD diffractometer at 100 K. The frames were corrected for absorption by the SADABS program.[34]

The principal experimental and crystallographic parameters are presented in Table 8. The structures of **3a**,**c**,**d** were solved by direct methods and refined by full-matrix techniques against F^2 in anisotropic approximations using the SHELXTL 5.1 program package.[35] The positions of hydrogen atoms were calculated geometrically and included in refinement in the rigid body approximation. The absolute configuration of **3a**,**c**,**d** was determined by using the Flack parameter. CCDC-261125 (for **3a**), -261126 (for **3c**) and -261124 (for **3d**) contain supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.acm.ac.uk/retrieving.html or from the Cambridge Crystallographic Data Centre 12, Union Road, Cambridge CB2 1EZ, UK [Fax: +44-1223-336033].

Acknowledgments

The authors thank Dr. P.V. Petrovskii (Institute of Organoelement Compounds, Moscow) for assistance in characterising the products and Dr. A.V. Korostylev (Leibniz-Institut für Organische Katalyse an der Universitat Rostock, Germany) for assistance in preparation of the manuscript. The authors gratefully acknowledge receiving the chiral HPLC columns (*R*,*R*) WHELK-01 from Regis Technologies (USA) and Chiralcel OD-H from Daicel Chemical Industries,

Tetranuclear Polypyridyl Complexes of Ru^{II} and Fe^{II}: Synthesis, Electrochemical, Photophysical and Photochemical Behaviour

Jean Lombard,[a] Sophie Romain,[a] Stéphane Dumas,[a] Jérôme Chauvin,[a] Marie-Noëlle Collomb,[a] Denis Daveloose,[b] Alain Deronzier,*[a] and Jean-Claude Leprêtre*[a]

Keywords: Bridging ligands / Electrochemistry / Iron / Photochemistry / Ruthenium

Three heterotetranuclear complexes $[\{Ru^{II}(bpy)_2(LL_n)\}_3Fe^{II}]^{8+}$ {bpy = 2,2′-bipyridine, n = 2, 4, 6; denoted $[\{Ru(LL_n)\}_3Fe]^{8+}$}, in which one iron centre is complexed by three Ru^{II}-tris-bipyridine-like moieties containing covalently bridging bis-bipyridine LL_n ligands, have been synthesised and characterised. The stability and the electrochemical, photophysical and photochemical properties of these complexes have been investigated in CH_3CN. The cyclic voltammograms of all complexes exhibit two successive reversible oxidation processes in the positive region, corresponding to the Fe^{II}/Fe^{III} and Ru^{II}/Ru^{III} redox couples. These systems are clearly separated ($\Delta E_{1/2}$ about 300 mV), which indicates the absence of an electronic connection between the two subunits. In the negative region, three successive reversible four-electron systems are observed, corresponding to the ligand-based reduction processes. The two oxidized forms of the complexes $[\{Ru^{II}(LL_n)\}_3Fe^{III}]^{9+}$ and $[\{Ru^{III}(LL_n)\}_3Fe^{III}]^{12+}$, which are obtained by two successive exhaustive electrolyses, are very stable. The $[\{Ru(LL_n)\}_3Fe]^{8+}$ complexes are luminescent, which shows that the covalent linkage between the Ru^{II}-tris-bipyridine and Fe^{II}-tris-bipyridine subunits leads to an only partial quenching of the Ru^{II*} excited states by energy transfer to the Fe^{II} centre. The luminescence lifetime and quantum yield are found to be independent of the complexes′ concentration, thus indicating that the energy-transfer process is only due to an intramolecular electron-exchange mechanism. Quantitative photoinduced oxidation of the tetranuclear complexes has been performed by continuous photolysis experiments in the presence of a large excess of a diazonium salt, which plays the role of a sacrificial oxidant. Two successive oxidation processes ($Fe^{II} \rightarrow Fe^{III}$ and $Ru^{II} \rightarrow Ru^{III}$) are observed.

Introduction

In recent years, important synthetic efforts have been made to mimic the function of the donor site of the photosystem II (PSII) by the development of superstructured heterometallic complexes.[1–3] The main strategy to elaborate models of PSII involves the covalent coupling of a photoactive $[Ru^{II}(bpy)_3]^{2+}$ (bpy = 2,2′-bipyridine) moiety, which plays the role of the P_{680} chlorophyll photosensitizer, to some monomanganese(II), binuclear (II,III) or (III,III) and trinuclear (II,II,II) complexes that model the catalytic centre that oxidizes water into oxygen.[4–7] It has been reported for the mononuclear manganese(II) complexes that an intramolecular electron transfer can occur from the Mn^{II} site to the photogenerated Ru^{III} species in the presence of an external electron acceptor like viologen in acetonitrile.[8] However, the rate constant for this process is fairly slow and the efficiency of the process depends on the distance between the two metallic centres. In addition, the system is complicated, since the Mn^{II}/Mn^{III} redox couple is only poorly reversible as the Mn^{III} species reacts with residual water to form binuclear Mn^{III}/Mn^{IV} oxo complexes.[9–11] Moreover, in most cases the Mn^{II} sites quench the excited state of the ruthenium(II) complex, presumably by an energy-transfer process.[8,12,13] With a view to studying this kind of intramolecular electron transfer, we have recently reported the photoredox behaviour of a series of heterobinuclear metallic complexes of Ru^{II} and Fe^{II}, namely $[Ru^{II}(bpy)_2(LL_n)\text{-}Fe^{II}(bpy)_2]^{4+}$ (denoted $[Ru(LL_n)Fe]^{4+}$), based on the use of bridging bis-bipyridine ligands LL_n (Scheme 1).[14] This system is simpler than the Ru^{II}/Mn^{II} one, since Fe^{II}/Fe^{III} is a perfectly reversible redox couple, with the oxidation of the $[Fe^{II}(bpy)_3]^{2+}$-like complex occurring at a potential close to that of $[Mn^{II}(bpy)_3]^{2+}$. In this previous study, we demonstrated that the ^{3}MLCT excited state of the Ru^{II}-tris-bipyridine centre is strongly quenched by the Fe^{II}-tris-bipyridine

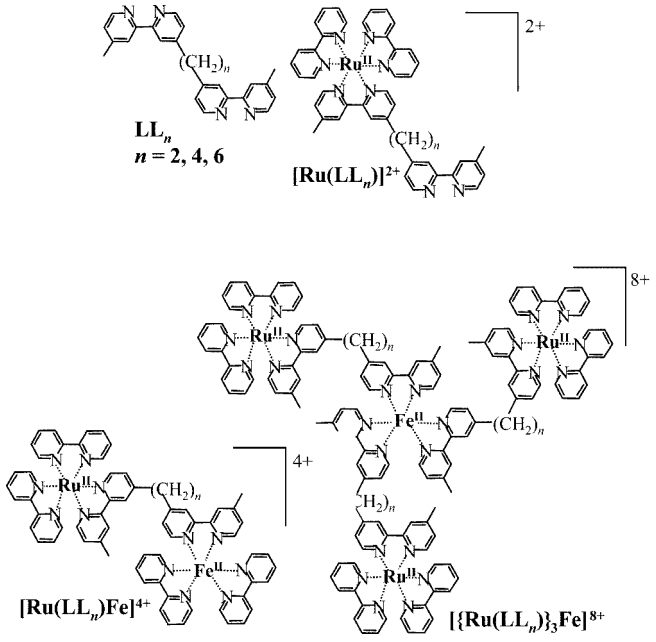
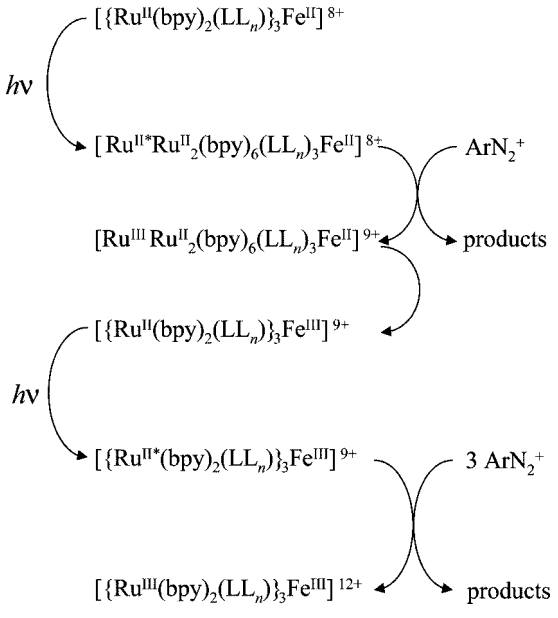
unit through an energy-transfer process that is mainly intermolecular. Nevertheless, this strong energy transfer can be easily short-circuited in the presence of an external irreversible electron acceptor like an aryldiazonium salt (ArN_2^+) by an electron transfer that leads finally to the photoinduced formation of $[Ru^{II}(LL_n)Fe^{III}]^{5+}$ species with high efficiency. It has been shown that the electron transfer between the ground state of the Ru^{III} and Fe^{II} species essentially occurs by an intermolecular process. In order to gain more information about these photoprocesses, we have synthesised a series of new heterobimetallic complexes of Ru^{II} and Fe^{II}: $[\{Ru^{II}(bpy)_2(LL_n)\}_3Fe^{II}]^{8+}$ {n = 2, 4, 6; denoted $[\{Ru(LL_n)\}_3Fe]^{8+}$} in which one iron centre is complexed by three Ru^{II}-tris-bipyridine moieties (Scheme 1). A previous publication reported some photophysical data of this kind of complex, but these compounds were only prepared in situ.[15] Under these conditions, the presence of some uncomplexed $[Ru^{II}(bpy)_2(LL_n)]^{2+}$ {denoted $[Ru^{II}(LL_n)]^{2+}$} species in the medium prevented the drawing of clear conclusions about the photophysical properties of the $[\{Ru(LL_n)\}_3Fe]^{8+}$ complexes. In the present study, we report the synthesis and characterisation of the three heterotetranuclear complexes $[\{Ru(LL_n)\}_3Fe]^{8+}$, their main redox and photophysical properties and the comparison of the latter properties with those of the heterobinuclear complexes $[Ru(LL_n)Fe]^{4+}$. Moreover, we have investigated the possibility to photoinduce the oxidation of the tetranuclear complexes in the presence of ArN_2^+. The expected multi-step oxidation process is summarised in Scheme 2.



Scheme 1. Chemical structure of the ligands LL_n and of the complexes $[Ru(LL_n)]^{2+}$, $[Ru(LL_n)Fe]^{4+}$ and $[\{Ru(LL_n)\}_3Fe]^{8+}$.



Scheme 2. Schematic presentation of the photooxidation mechanism of $[\{Ru(LL_n)\}_3Fe]^{8+}$ in the presence of an external electron acceptor (ArN_2^+).

Results and Discussion

Synthesis and Stability of the Complexes

Eliott and co-workers[15] have reported that the complexation of some $[Ru^{II}(bpy)_2(L\text{-}L)]^{2+}$ complexes (L-L = covalently linked bipyridines) with Fe^{2+} in situ in methanol/water (1:1) forms the tetranuclear complexes $[\{Ru^{II}(bpy)_2(L\text{-}L)\}_3Fe^{II}]^{8+}$. However, in this medium, it has been shown that such compounds undergo some dissociation (association constants between 10^{13} and 10^{15}). As a result, the presence of uncomplexed $[Ru^{II}(bpy)_2(L\text{-}L)]^{2+}$ species leads to the observance of a double exponential for the emission decay. The fast component of the decay corresponds to emission from ruthenium "ligands" complexed to iron, and the long one to the uncomplexed $[Ru^{II}(bpy)_2(L\text{-}L)]^{2+}$ centres. Moreover, isolation of tetranuclear complexes in a pure form by this group was unsuccessful. In this work, we have synthesised, isolated and purified three heterotetranuclear complexes $[\{Ru(LL_n)\}_3Fe]^{8+}$ (n = 2, 4 and 6) by the treatment of 0.4 equivalents of Fe^{2+}, as its perchlorate salt, with one equivalent of the corresponding $[Ru(bpy)_2(LL_n)]^{2+}$ complexes in ethanol/water (12:1). This synthetic method allows us to obtain the expected compounds with fairly good yields; their purity was checked by TLC and elemental analysis. In order to determine their photophysical properties in CH_3CN solution properly, we also verified their stability in this solvent by UV/Vis spectroscopy. The visible absorption spectra of $[\{Ru(LL_n)\}_3Fe]^{8+}$ in the concentration range 10^{-4}–10^{-7} M exhibit the expected regular bands at 356, 396 (shoulder), 430 (shoulder), 454 and 530 nm (shoulder) corresponding to the superimposition of the absorbance of the Ru^{II}- and Fe^{II}-tris-bipyridine subunits (Table 1).[15] For the three complexes $[\{Ru(LL_n)\}_3Fe]^{8+}$, there is no significant variation of the ratio of the absorbance values at 356, 454 and 530 nm with concentration (in the range 10^{-4} and 10^{-7} M), showing that no dissociation of the complexes occurs. The linearity of the absorbance vs.

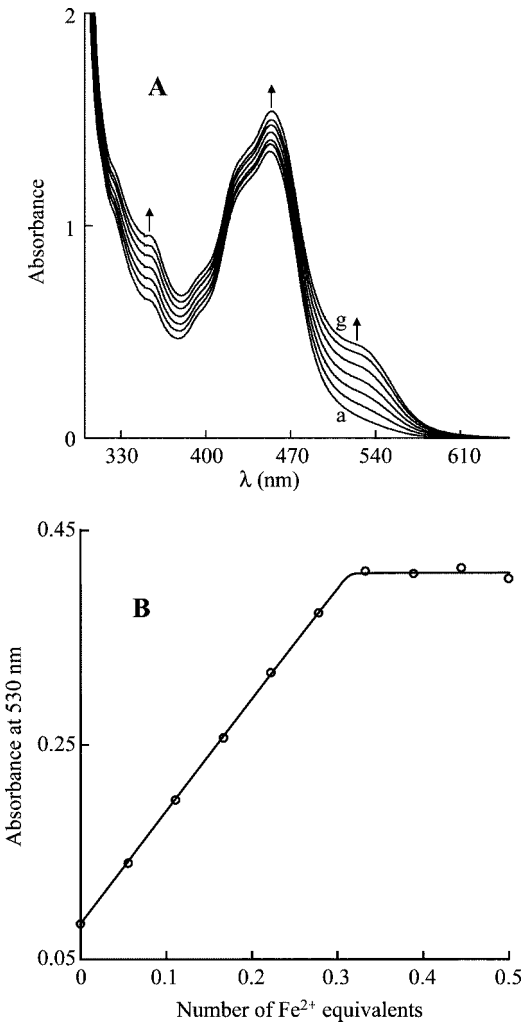

Figure 1. A) Evolution of the visible spectrum of a solution of $[Ru(LL_4)]^{2+}$ (0.105 mM) in CH_3CN + 0.1 M Bu_4NClO_4 during the addition of $Fe(ClO_4)_2 \cdot 8H_2O$: a) initial solution, b) after addition of 0.055 equiv. of Fe^{2+}, (c) 0.11, (d) 0.167, (e) 0.22, (f) 0.28, (g) 0.33 and 0.5. B) Evolution of the absorbance at 530 nm (l = 1 cm).

addition of Fe^{2+} allows the determination of the association constant as being greater than 10^{22}. This constant value is higher than those estimated in a methanol/water mixture (10^{13}–10^{15}),[15] presumably due to the more dissociative properties of this medium compared to the acetonitrile one. This high stability was also confirmed by following the absorbance at 530 nm of a $[Ru(LL_n)]^{2+}$ acetonitrile solution after progressive addition of $Fe(ClO_4)_2 \cdot 8H_2O$ (Figure 1). The absorbances at 356 and 530 nm increase linearly during the addition of Fe^{2+} until a maximum is reached for the expected ratio of one iron for every three $[Ru(LL_n)]^{2+}$ units. Addition of an excess of Fe^{2+} does not lead to any spectroscopic changes. The absence of free $[Ru(LL_n)]^{2+}$ is also confirmed by luminescence measurements in CH_3CN, since, for all synthesised complexes, the emission decay curves are clean single exponentials (see below).

Electrochemistry

In CH_3CN containing 0.1 M Bu_4NClO_4 the electrochemical behaviour of the three $[\{Ru(LL_n)\}_3Fe]^{8+}$ complexes is similar (see Table 2). The length of the aliphatic bridges has only a slight effect on the $E_{1/2}$ values of the oxidative and reductive processes. In the negative region, although the successive one-electron reductions of the bipyridine ligands in the $[Fe(dmbpy)_3]^{2+}$ (dmbpy = 4,4′-dimethyl-2,2′-bipyridine) and $[Ru(LL_n)]^{2+}$ complexes are clearly separated (by 115–140 mV, see Table 2), the reduction pattern of the $[\{Ru(LL_n)\}_3Fe]^{8+}$ complexes shows only three successive reduction waves {see Figure 2 for $[\{Ru(LL_4)\}_3Fe]^{8+}$}, as observed previously for the binuclear $[Ru(LL_n)Fe]^{4+}$ complexes.[14] Moreover, only the first reduction wave is clearly seen. A strong adsorption phenomenon coupled to the second reduction process leads to an important distortion of the third one. It should be mentioned that each reversible redox system corresponds to the overall exchange of four electrons corresponding to the one-electron reduction of one bipyridine unit per metallic centre. The exchange of

[a] $E_{1/2}$ (V) (ΔEp in mV) vs. Ag/Ag^+ (0.01 M $AgNO_3$ in CH_3CN + 0.1 M Bu_4NClO_4). [b] This value cannot be accurately measured since the waves are strongly distorted by adsorption phenomena (see text).

four electrons is confirmed by the fact that the height of the first reduction wave at a rotating disk electrode is equal to the sum of the heights of the two oxidation waves (see below and Figure 2).

In the positive region, the cyclic voltammograms of the three $[\{Ru(LL_n)\}_3Fe]^{8+}$ complexes exhibit two well-separated reversible redox systems (Figure 2). The potentials of these systems are closed to those of the mononuclear complexes $[Fe(dmbpy)_3]^{2+}$ and $[Ru(LL_n)]^{2+}$, thus allowing us to assign the first oxidative process to the Fe^{II}/Fe^{III} redox couple and the more anodic one to that of the Ru^{II}/Ru^{III} system (Table 2). Moreover, rotating disk electrode experiments confirmed that the complexes are obtained in pure form and that no dissociation occurs in CH_3CN, since the height of the Ru^{II}/Ru^{III} wave is three times that of Fe^{II}/Fe^{III}, in accordance with the 3:1 Ru/Fe stoichiometry in the tetranuclear complexes [Equations (1) and (2)].

$$[\{Ru^{II}(bpy)_2(LL_n)\}_3Fe^{II}]^{8+} \rightarrow [\{Ru^{II}(bpy)_2(LL_n)\}_3Fe^{III}]^{9+} + e^- \quad (1)$$

$$[\{Ru^{II}(bpy)_2(LL_n)\}_3Fe^{III}]^{9+} \rightarrow [\{Ru^{III}(bpy)_2(LL_n)\}_3Fe^{III}]^{12+} + 3e^- \quad (2)$$

As previously observed for the $[Ru(LL_n)Fe]^{4+}$ complexes,[14] the $E_{1/2}$ values of the Fe^{II}/Fe^{III} and Ru^{II}/Ru^{III} redox systems decrease slightly upon increasing the number of methylenes in the aliphatic bridge (Table 2). This $E_{1/2}$ variation is due to a slightly higher electron-donor effect of the LL_6 ligand compared to LL_4, and of the latter to LL_2.

Otherwise, the Ru^{II}/Ru^{III} redox system involves the simultaneous exchange of three electrons. In order to estimate the magnitude of the electronic connexion between the three ruthenium centres, computational fitting of the cyclic voltammetry curves of $[\{Ru(LL_n)\}_3Fe]^{8+}$ was performed, which led to the determination of the formal potentials E_f^1, E_f^2 and E_f^3 for the three ruthenium oxidation steps (Table 3) (see Figure 3 for $[\{Ru(LL_4)\}_3Fe]^{8+}$ and Experimental Section).[16,17] Since the difference between the extreme E_f values ($\Delta E_f^{3-1} = E_f^3 - E_f^1$) is close to the theoretical value (57 mV) for the three tetranuclear complexes,[16] the absence of an electronic connexion within the studied compounds is confirmed. One can see, as observed for the Fe^{II}/Fe^{III} system, that these E_f values are in accordance with the electron-donor character of the bridging ligand; the $E_{1/2}$ value of the Ru^{II}/Ru^{III} couple decreases slightly

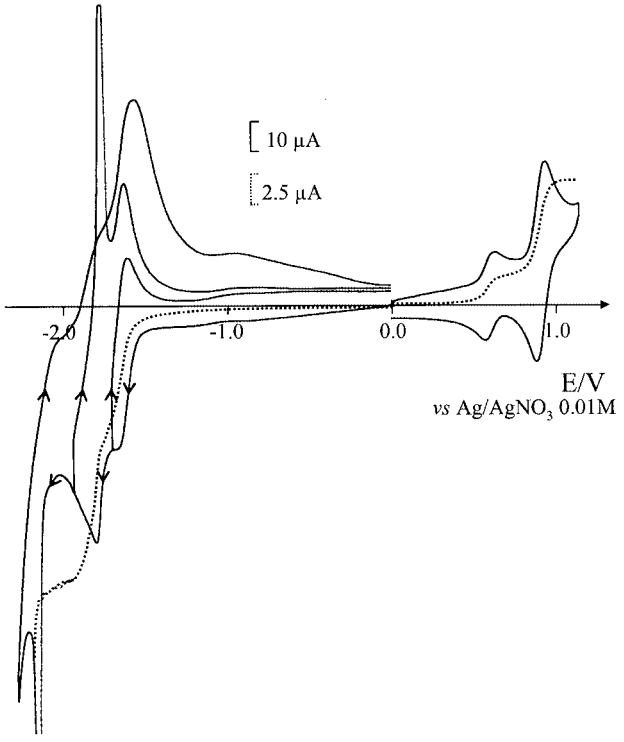

Figure 2. (–) Cyclic voltammograms of a 0.32 mM solution of $[\{Ru(LL_4)\}_3Fe]^{8+}$ in CH_3CN + 0.1 M Bu_4NClO_4 at a platinum electrode; scan rate: 100 mV s^{-1}. (---) Voltammograms at a platinum rotating disk electrode at ω = 600 r min^{-1}; scan rate: 10 mV s^{-1}.

(10 mV) in the order $LL_2 > LL_4 > LL_6$. Since the two oxidized forms of the complexes, $[\{Ru^{II}(LL_n)\}_3Fe^{III}]^{9+}$ and $[\{Ru^{III}(LL_n)\}_3Fe^{III}]^{12+}$ are expected to be produced during the photoinduced electron-transfer processes (Scheme 2), the stabilities of these species were evaluated by exhaustive electrolyses. Taking into account the large potential difference between the Fe^{II}/Fe^{III} and Ru^{II}/Ru^{III} redox systems ($\Delta E_{1/2}$ = 296 mV for LL_2, 315 for LL_4 and 317 for LL_6), the mixed-valent $[\{Ru^{II}(LL_n)\}_3Fe^{III}]^{9+}$ species are perfectly stable. Indeed, two successive exhaustive electrolyses carried out at 0.80 and 1.10 V consumed one and three electrons, respectively, per $[\{Ru(LL_n)\}_3Fe]^{8+}$, and allowed the bulk build-up of $[\{Ru^{II}(LL_n)\}_3Fe^{III}]^{9+}$ and $[\{Ru^{III}(LL_n)\}_3Fe^{III}]^{12+}$. This is illustrated by the evolution of the absorption spectra of the solutions after these sequential electrolyses

(see Figure 4 for LL_4). The typical initial bands of the Fe^{II}-tris-bipyridine unit (λ = 356 and 530 nm) disappear after one electron per complex has been passed (Table 1). After exchange of three other electrons, the bands of the Ru^{II}-tris-bipyridine units (λ = 356 and 454 nm) disappear and are replaced by those of the Ru^{III} ones (428 and 644 nm). Both oxidized forms are stable for several hours. Finally, we found that exhaustive reduction of all these oxidized species leads to the nearly quantitative recovery of the starting material, thus demonstrating the high reversibility of the process.

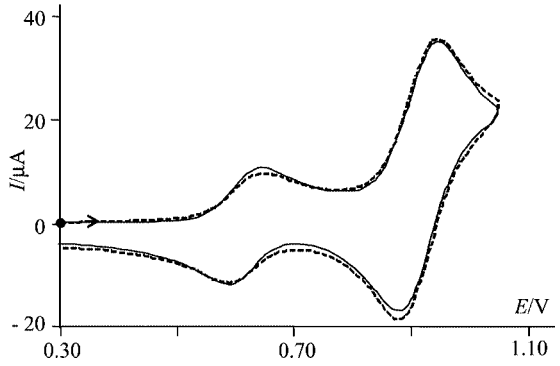

Figure 3. Cyclic voltammograms of a 0.14 mM solution of $[\{Ru(LL_4)\}_3Fe]^{8+}$ in CH_3CN + 0.1 M Bu_4NClO_4 at a platinum electrode; scan rate 200 mV s^{-1}: (---) experimental curve, (−) fitted curve.

Energy Transfer

The emission wavelength (λ_{emis}), luminescence lifetime (τ), and luminescence quantum yield (φ_L) of the $[\{Ru(LL_n)\}_3Fe]^{8+}$ complexes are reported in Table 4, along with those obtained for the corresponding $[Ru(LL_n)]^{2+}$ and $[Ru(LL_n)Fe]^{4+}$ parent complexes. On the nanosecond timescale, the luminescence decay of all $[\{Ru(LL_n)\}_3Fe]^{8+}$ complexes appears as a single exponential with a luminescence lifetime slightly lower than those of the monometallic $[Ru(LL_n)]^{2+}$ complexes. Further experiments were performed on a subnanosecond timescale using a picosecond Ti:Sapphire laser and single photon counting detection. No additive short component in the decay was observed. Nevertheless, if the luminescence is detected, it is largely quenched. Indeed, compared to the $[Ru(LL_n)]^{2+}$ complexes, the luminescence quantum yield is lowered from a factor of 6 for $[\{Ru(LL_6)\}_3Fe]^{8+}$ to almost 10 for $[\{Ru(LL_4)\}_3Fe]^{8+}$ (Table 4). These data indicate that, as observed for $[Ru(LL_n)Fe]^{4+}$, the Fe^{II}-tris-bipyridine unit quenches the ^3MLCT excited state in the $[\{Ru(LL_n)\}_3Fe]^{8+}$ complexes.

The luminescence lifetime and quantum yield of the $[\{Ru(LL_n)\}_3Fe]^{8+}$ complexes were found to be independent of the concentration of the samples (concentration range used from 10^{-6} to 2×10^{-5} M), which means that, in contrast to what we demonstrated for the binuclear $[Ru(LL_n)Fe]^{4+}$ complexes, the intermolecular quenching is not efficient in such tetranuclear systems. As a result, the partial inhibition of the luminescence of the Ru^{II} centre is only due to an intramolecular interaction with the central Fe^{II}-tris-bipyridine unit.

Electron transfer (ET) between Ru^{II}* and Fe^{II} centres has to be ruled out for this quenching pathway. Indeed, considering the potential values of the $Ru^{II}*/Ru^{I}$ [in the range 0.34–0.38 V for $[\{Ru(LL_n)\}_3Fe]^{8+}$ vs. Ag/Ag^+ in CH_3CN with 0.1 M Bu_4NClO_4][18] and Fe^{II}/Fe^{III} (in the range 0.58–0.60 V) redox couples, the electron-transfer quenching process is strongly endergonic (≥0.2 V). Likewise, the potential value of the $Ru^{II}*/Ru^{III}$ redox couple (between –1.12 and –1.14 V) compared to that of the first reduction potential of the iron unit (between –1.647 and –1.687) leads to a strongly endergonic process (≥0.52 V). Thus, a pure electronic energy transfer (EET) can be considered as the main quenching process.[14,19]

The quenching rate constant (k_q) was determined from Equation (3), where φ_L^{Ref} and φ_L^{S} are the luminescence quantum yields of the $[Ru(LL_n)]^{2+}$ and $[\{Ru(LL_n)\}_3Fe]^{8+}$ complexes, respectively, and τ^{Ref} the luminescence lifetime of $[Ru(LL_n)]^{2+}$.

$$k_q = \left(\frac{\phi_L^{Ref}}{\phi_L^{S}} - 1\right) \times \frac{1}{\tau^{Ref}} \quad (3)$$

The same order of magnitude of k_q ($5\times10^6 \leq k_q \leq 9\times10^6$ s^{-1}; Table 4) was obtained for all three compounds, which shows that the EET process is moderately efficient and clearly not connected to the length to the aliphatic chain of the bridging ligand. Eliott and co-workers[15] have obtained a similar magnitude of k_q ($8\times10^6 \leq k_q \leq 197\times10^6$ s^{-1}) in aqueous methanolic solution, but, in contrast to our results, these authors found a dependence of the k_q value with the distance beween Ru^{II} and Fe^{II}: the more important the Ru^{II}–Fe^{II} distance, the weaker the k_q value. One can suggest that the nature of the solvent might have an influence on the deactivation process. This influence of solvation conditions is confirmed by the lower τ values obtained in aqueous methanolic medium for the precursor ruthenium complexes {τ = 356 ns for $[Ru(LL_2)]^{2+}$}.[15]

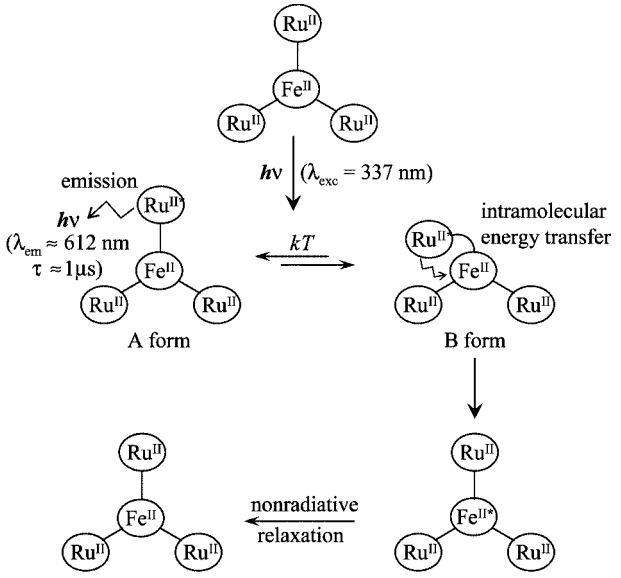
EET processes occur according to two mechanisms − Dexter (or electron exchange interaction)[20] and Förster (or coulombic interaction)[21] − both of which involve the spectral overlap of the luminescence of the donor with the absorption spectra of the acceptor. The Dexter mechanism requires contact between the donor and the acceptor, whereas the Förster one proceeds over a larger distance. For the Förster process, a critical transfer distance, R_0, can be calculated according to Equation (4)

$$R_0 = 1.25\times10^{17} \frac{\phi_D}{n^4} \int_0^\infty F_D(\bar{\nu})\varepsilon_A(\bar{\nu})\frac{d(\bar{\nu})}{\bar{\nu}^4} \quad (4)$$

where φ_D is the donor emission quantum yield {i.e. $[Ru(LL_n)]^{2+}$}, n the solvent refractive index and the integral term represents the spectral overlap of the normalised donor emission with the acceptor absorption. For the three $[\{Ru(LL_n)\}_3Fe]^{8+}$ complexes, an R_0 value of 20 ± 1 Å has been calculated, whereas the distance between the ruthenium and iron centres in theses structures is in the range from 10 to 12 Å according to space-filling molecular models.[15] When the estimated distance between both metallic centres is less than R_0, energy transfer is faster than radiative and non-radiative relaxation of the donor. Nevertheless, the fact that τ does not exhibit a systematic dependence on the Ru–Fe distance in the $[\{Ru(LL_n)\}_3Fe]^{8+}$ series suggests that the Förster mechanism should be considered as minor. Thus, the deactivation mainly proceeds by the Dexter mechanism. Therefore, since it involves the contact between the acceptor and the donor, the folding up of the molecule is required. Taking into account that the length of the alkyl chain does not lead to an important variation in τ, and that the deactivation process is mainly intramolecular, the experimental luminescence data can be understood if one considers that the tetranuclear complexes coexist in at least two forms in a thermodynamic equilibrium after irradiation in the MLCT band of the $[Ru(LL_n)]^{2+}$ subunit (Scheme 3). At the ground state level, the more stable geometry of the complexes is presumably the one which presents the four cationic metallic centres sufficiently distant to minimize the electrostatic repulsion. Quickly after the laser pulse irradiation, at the excited state level, the complexes undergo a sub-nanosecond (less than 30 ps) rearrangement, which cannot be detected by our setup, into two forms A and B (Scheme 3). In the A form, the relatively important Ru^{II}/Fe^{II} distance does not allow an efficient energy transfer (via a Dexter mechanism) and the luminescence of the ruthenium centre is detected with almost no perturbation due to the presence of the iron centre. It is well-known that, after irradiation in the MLCT band of the $[Ru(LL_n)]^{2+}$ moieties, an electron from the HOMO, which is localised around the metallic centre, is injected into the LUMO, which is delocalised over the bipyridine ligand, to form the transient $bpy^{\cdot-}$ radical anion.[22,23] In the B form, the two linked cationic metallic centres fold up in a way that confines the $bpy^{\cdot-}$ radical. Because two metallic centres are close, an efficient intramolecular EET is now feasible and contributes to the extinction of the luminescence of the complexes. From the luminescence quantum yield measurements, it appears that the B form is the more stable one at room temperature since φ_L decreases drastically from a factor of between 6 and 10 compared to that of $[Ru(LL_n)]^{2+}$ (Table 4). Moreover, if the A form and the B form are in rapid equilibrium, the excited state lifetime of the tetranuclear samples would be shorter than the corresponding

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$[Ru(LL_n)]^{2+}$ as the relaxation channel for the B form is much faster than for the A form.[24] This effect is weak for $[\{Ru(LL_2)\}_3Fe]^{8+}$ {τ = 1.07 μs compared to 1.11 μs for $[Ru(LL_2)]^{2+}$} and larger for complexes having a longer aliphatic bridge such as n = 4 and n = 6 (Table 4).



Scheme 3. Illustration of the photophysical behaviour of $[\{Ru(LL_n)\}_3Fe]^{8+}$ in CH_3CN + 0.1 M Bu_4NClO_4 after irradiation at 337 nm.

Although this phenomenon involves the proximity of cationic species, and therefore electrostatic repulsion, such an EET mechanism has already been suspected for other systems containing a $[Ru(bpy)_3]^{2+}$*-like donor with cationic iron[14,15] or manganese[12,25] complexes as acceptor. Nevertheless, the luminescence quantum yield of the $[\{Ru(LL_n)\}_3Fe]^{8+}$ complexes is much lower than that of $[Ru(LL_n)Fe]^{4+}$. To understand the reason for this difference, and to investigate the possibility of a self-quenching phenomenon of the Ru^{II}-tris-bipyridine units in the tetranuclear structure, we synthesised a similar tetranuclear complex in which Fe^{2+} is replaced by Zn^{2+}, namely $[\{Ru^{II}(bpy)_2(LL_2)\}_3Zn^{II}]^{8+}$ {denoted $[\{Ru(LL_2)\}_3Zn]^{8+}$}. The Zn^{II}-tris-bipyridine centre has no absorption in the visible region and, as expected, the absorption spectrum of the $[\{Ru(LL_2)\}_3Zn]^{8+}$ complex is close to that of $[Ru(LL_2)]^{2+}$. That excludes any possibility of an energy transfer between the Ru^{II}-tris-bipyridine units and the Zn^{II}-tris-bipyridine one after light irradiation. Moreover, since the Zn^{2+} site is not able to be oxidized, a quenching of the Ru^{II}* luminescence by an electron transfer is thermodynamically prohibited. The quantum yield and luminescence lifetime of $[\{Ru(LL_2)\}_3Zn]^{8+}$ were determined to be φ_L = 0.06 and τ = 1.07 μs, respectively. These values are similar to those obtained for $[Ru(LL_2)]^{2+}$ (φ_L = 0.06, τ = 1.11 μs), only the lifetime is weakly decreased as for $[\{Ru(LL_2)\}_3Fe]^{8+}$, indicating that the possible self-quenching of the similar $[Ru(LL_2)]^{2+}$ centre has to be considered as a minor process. Thus, the drastically lowered φ_L value for the $[\{Ru(LL_n)\}_3Fe]^{8+}$ complexes compared to $[Ru(LL_n)Fe]^{4+}$ can only be due to a higher probability of a dynamic quenching between Fe and Ru by folding up of the molecule in the tetranuclear structures than in the binuclear ones.

Photoinduced Electron Transfer

It has been established previously[14,26,27] that addition of an irreversible electron acceptor like 4-bromophenyldiazonium tetrafluoroborate ($ArN_2^+BF_4^-$) to a solution of the $[Ru^{II}(bpy)_3]^{2+}$ complex in CH_3CN + 0.1 M Bu_4NClO_4 allows the efficient production of $[Ru^{III}(bpy)_3]^{3+}$ under continuous irradiation (quantum yield 0.34). This permanent build up of $[Ru^{III}(bpy)_3]^{3+}$ arises because of the following electron transfer quenching reaction [Equations (5) and (6)]; the back-electron transfer reaction between $[Ru^{III}(bpy)_3]^{3+}$ and $ArN_2^{\cdot}$ radical is avoided by the rapid evolution of $ArN_2^{\cdot}$ into ArH and N_2.[25,26]

$$[Ru^{II}(bpy)_3]^{2+}* + ArN_2^+ \rightarrow [Ru^{III}(bpy)_3]^{3+} + ArN_2^{\cdot} \quad (5)$$

$$ArN_2^{\cdot} \xrightarrow{CH_3CN} ArH + N_2 \quad (6)$$

In the binuclear $[Ru(LL_n)Fe]^{4+}$ complexes, it has been demonstrated that ArN_2^+ can also react preferentially with the excited state of the $[Ru(LL_n)]^{2+}$ subunit to advantageously short-circuit the energy transfer.[14] For tetranuclear complexes, a similarly efficient photogeneration of the corresponding Ru^{III} species, i.e. $[Ru^{III}Ru^{II}_2(bpy)_6(LL_n)_3Fe^{II}]^{9+}$ is expected (Scheme 2). Indeed, the quenching of the Ru^{II}* centre in the $[\{Ru(LL_n)\}_3Fe]^{8+}$ complexes by EET is incomplete and the luminescence lifetime of the Ru^{II}* excited state is sufficiently long-lived (1 μs) to allow a bimolecular reaction using an external electron acceptor. In addition, the lifetime of the excited state of the Fe^{II} moiety is too short (<1 ns) to undergo an efficient bimolecular electron transfer with ArN_2^+.[19]

In order to photoinduce the oxidation of the $[\{Ru(LL_n)\}_3Fe]^{8+}$ complexes, ArN_2^+ was added to a solution of the complexes in deoxygenated CH_3CN + 0.1 M Bu_4NClO_4. Since the photogenerated Ru^{III} subunit plays the role of oxidant towards Fe^{II} (see electrochemical part), irradiation should lead, in a first step, to $[\{Ru^{II}(LL_n)\}_3Fe^{III}]^{9+}$ (Scheme 2). In a second step, the formation of the final $[\{Ru^{III}(LL_n)\}_3Fe^{III}]^{12+}$ species is expected as ArN_2^+ is added in excess. The rate constant of oxidant quenching (k_{ET}) of the excited state of the tetranuclear complexes by ArN_2^+ was determined from the Stern–Volmer plot, see Equation (7)

$$\tau/\tau_{Ar} = 1 + k_{ET}\cdot\tau\cdot[ArN_2^+] \quad (7)$$

where τ and τ_{Ar} are the luminescence lifetime of the complexes without and with a variable concentration of ArN_2^+, respectively, and k_{ET} is the rate constant of the electron transfer reaction according to Equation (8).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$$[Ru^{II}*Ru^{II}_2(bpy)_6(LL_n)_3Fe^{II}]^{8+} + ArN_2^+ \xrightarrow{k_{ET}} [Ru^{III}Ru^{II}_2(bpy)_6(LL_n)_3Fe^{II}]^{9+} + ArN_2^{\cdot} \quad (8)$$

The Stern–Volmer plots are linear for the three complexes (Figure 5). This indicates that the electron transfer is a simple bimolecular reaction, i.e. only one Ru^{II} centre reacts each time with ArN_2^+. The k_{ET} values obtained for the tetranuclear $[\{Ru(LL_n)\}_3Fe]^{8+}$ compounds ($>10^9$ $M^{-1}s^{-1}$) depend only slightly on the Ru–Fe distance in the complexes, and are around 10 times greater than the k_{ET} values determined for the binuclear $[Ru(LL_n)Fe]^{4+}$ complexes (Table 5). The markedly faster electronic quenching process in the case of tetranuclear complexes is presumably due to the lower efficiency of the competitive energy transfer by the Fe^{2+} centre (Table 4). Nevertheless, it is difficult to compare the energy-transfer constants of these two kinds of complexes since, for the tetranuclear complexes, the energy transfer occurs via an intramolecular process while for the binuclear ones it is intermolecular.

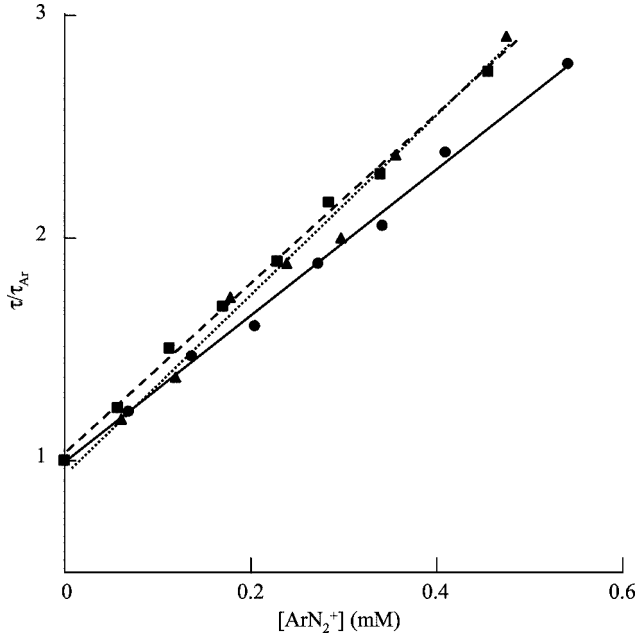


Figure 5. Stern–Volmer plots for the $[\{Ru(LL_n)\}_3Fe]^{8+}$ complexes in deoxygenated CH_3CN (0.01 mM) with ArN_2^+ (between 0 and 0.6 mM): $[\{Ru(LL_2)\}_3Fe]^{8+}$ (■), $[\{Ru(LL_4)\}_3Fe]^{8+}$ (●) and $[\{Ru(LL_6)\}_3Fe]^{8+}$ (▲).

Table 5. Electron transfer rate constant, k_{ET}, for $[Ru(LL_n)Fe]^{4+}$ and $[\{Ru(LL_n)\}_3Fe]^{8+}$ in the presence of a variable concentration of ArN_2^+ at room temperature in CH_3CN + 0.1 M Bu_4NClO_4.

Complexes	k_{ET} [$M^{-1}s^{-1}$]
$[Ru^{II}(LL_2)Fe^{II}]^{4+}$	3.7×10^8
$[Ru^{II}(LL_4)Fe^{II}]^{4+}$	5.3×10^8
$[Ru^{II}(LL_6)Fe^{II}]^{4+}$	6.4×10^8
$[\{Ru^{II}(LL_2)\}_3Fe^{II}]^{8+}$	3.6×10^9

$[\{Ru^{II}(LL_6)\}_3Fe^{II}]^{8+}$	4.0×10^9

Photooxidation by Continuous Irradiation

Successive photogeneration of the oxidized $[\{Ru^{II}(LL_n)\}_3Fe^{III}]^{9+}$ and $[\{Ru^{III}(LL_n)\}_3Fe^{III}]^{12+}$ species (Scheme 2) was followed by UV/Vis absorption spectroscopy. Solutions containing $[\{Ru(LL_n)\}_3Fe]^{8+}$ (0.03–0.04 mM) in the presence of an excess of ArN_2^+ (15 mM) in CH_3CN + 0.1 M Bu_4NClO_4 were irradiated with a mercury lamp (250 W). Two successive changes of the absorption spectrum were observed during the irradiation. In the first step, the band of the Fe^{II} unit at 530 nm decreases regularly until it disappears totally, in accordance with the formation of $[\{Ru^{II}(LL_n)\}_3Fe^{III}]^{9+}$ via the transient photogenerated Ru^{III} species (Figure 6). In a second step, irradiation induces the quantitative formation of $[\{Ru^{III}(LL_n)\}_3Fe^{III}]^{12+}$, as illustrated by the decrease of the MLCT band of the Ru^{II} unit at around 455 nm and the appearance of two new ones at 428 and 644 nm typical of the Ru^{III} species.

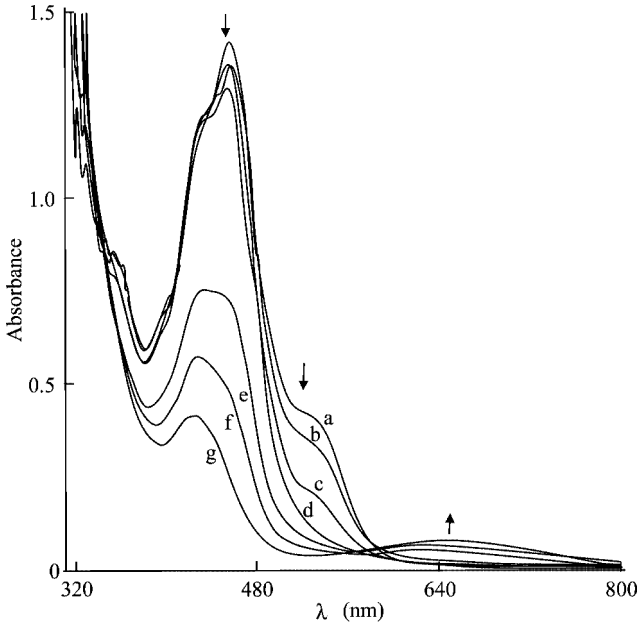

Figure 6. Spectral change of a mixture of $[\{Ru(LL_6)\}_3Fe]^{8+}$ (0.032 mM) and ArN_2^+ (15 mM), under visible irradiation: (a) initial solution, (b) 3 s, (c) 12 s, (d) 24 s, (e) 120 s, (f) 220 s, (g) 700 s, (l = 1 cm).

From a kinetic point of view, one can consider that, during the first step, there is a steady-state concentration of the Ru^{II} and Ru^{III} species since the sacrificial oxidant is present in large excess. Thus, the overall kinetic law for the oxidation of the Fe^{II}-tris-bipyridine unit can, as we previously proposed,[14] be approximated to a pseudo-first-order equation [Equation (9)], where $[Ru^{II}]$ and $[Fe^{II}]$ represent the concentration of the two subunits of the $[\{Ru(LL_n)\}_3Fe]^{8+}$ complexes in solution.

$$v = k[Ru^{II}][Fe^{II}][ArN_2^+] = K_{Fe}[Fe^{II}] = -d[Fe^{II}]/dt \quad (9)$$

In a similar fashion, during the second step involving the formation of $[\{Ru^{III}(LL_n)\}_3Fe^{III}]^{12+}$, a pseudo-first-order equation is also obtained, see Equation (10).

Table 6. Apparent oxidation rate constants for $[\{Ru(LL_n)\}_3Fe]^{8+}$ during irradiation in the presence of a large excess of ArN_2^+.

Complexes	K_{Fe} [s^{-1}]	K_{Ru} [s^{-1}]
$[\{Ru^{II}(LL_2)\}_3Fe^{II}]^{8+}$	$5.4\times10^{-2}\pm0.8\times10^{-2}$	$4.99\times10^{-3}\pm4\times10^{-5}$
$[\{Ru^{II}(LL_4)\}_3Fe^{II}]^{8+}$	$8.4\times10^{-2}\pm0.6\times10^{-2}$	$6.63\times10^{-3}\pm6\times10^{-5}$
$[\{Ru^{II}(LL_6)\}_3Fe^{II}]^{8+}$	$11.7\times10^{-2}\pm1\times10^{-2}$	$12.24\times10^{-3}\pm3\times10^{-5}$

$$v = k'[Ru^{II}][Fe^{III}][ArN_2^+] = K_{Ru}[Ru^{II}] = -d[Ru^{II}]/dt \quad (10)$$

These two oxidation steps were followed by the evolution of the absorbance at 530 and 454 nm, respectively, with the irradiation time. In all cases the absorbance variation was fitted by a monoexponential curve, as illustrated in Figure 7, in accordance with Equations (9) and (10), thus allowing the determination of K_{Fe} and K_{Ru} for the three heterotetranuclear complexes. These values are given in Table 6. It appears that both the Fe^{II} and Ru^{II} oxidation rate depend on the nature of the bridging ligand, and that the efficiency of the photoassisted process increases when the length of the alkyl chain increases, oxidation of $[\{Ru(LL_6)\}_3Fe]^{8+}$ being twice as fast as oxidation of $[\{Ru(LL_2)\}_3Fe]^{8+}$.

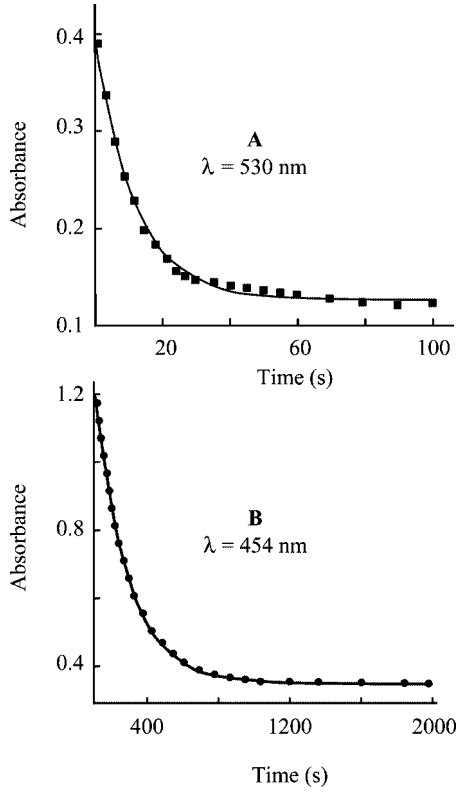

Figure 7. Evolution of the absorption intensity at 530 nm (A) and 454 nm (B) with irradiation time for the $[\{Ru(LL_6)\}_3Fe]^{8+}$ complexes (0.032 mM) in CH_3CN + 0.1 M Bu_4NClO_4, in the presence of ArN_2^+ (15 mM) (l = 1 cm). Bold lines correspond to the fit using a monoexponetial function. The fit parameters K_{Fe} and K_{Ru} are given in Table 6.

Two processes can control the overall efficiency of the oxidation steps and explain the influence of the aliphatic chain length on the photooxidation rate. The first one is the photogeneration of the Ru^{III} moieties. This process requires contact between two cationic species {i.e. ArN_2^+ and $[\{Ru(LL_n)\}_3Fe]^{8+}$} and involves an electrostatic repulsion phenomenon which should be important for the complex exhibiting the smaller Ru–Fe distance − $[\{Ru(LL_2)\}_3Fe]^{8+}$ − whereas it is less pronounced for $[\{Ru(LL_6)\}_3Fe]^{8+}$. The second process involves the oxidation of Fe^{II} into Fe^{III}. Since the electron transfer operates according to an intramolecular process, it requires the folding-up of the complex in order to allow the formation of Fe^{III} through the photogenerated Ru^{III} moieties. Taking into account that the flexibility of the aliphatic bridging ligand increases with the number of methylene units, the contact between Ru^{III} and Fe^{II} should be favoured in the case of $[\{Ru(LL_6)\}_3Fe]^{8+}$, whereas for $[\{Ru(LL_2)\}_3Fe]^{8+}$ the folding-up is more difficult and therefore the photooxidation rate is lowered.

Finally, the quantum yield of formation of $[\{Ru^{II}(LL_n)\}_3Fe^{III}]^{9+}$ (φ_F) was determined in CH_3CN (see Experimental Section) and was found to be equal to 0.22 for the most efficient system, i.e. $[\{Ru(LL_6)\}_3Fe]^{8+}$.

Conclusions

In this study we have demonstrated that for the tetranuclear $[\{Ru^{II}(LL_n)\}_3Fe^{II}]^{8+}$ complexes a partial energy transfer from the ^{3}MLCT excited state of the Ru^{II}-tris-bipyridine centres to the Fe^{II}-tris-bipyridine unit occurs by a pure intramolecular process, in contrast to what was observed for the corresponding binuclear complexes. This is a consequence of the structure of the tetranuclear complexes, in which the presence of the three Ru^{II} subunits prevents the close contact of the Fe^{II} centre with the Ru^{II} subunits of another tetranuclear complex and therefore an intermolecular energy transfer. The rate constant of the process is not clearly connected to the length of the aliphatic chain of the bridging ligand. This energy-transfer process can be easily short-circuited in the presence of an external irreversible electron acceptor by an electron-transfer process, leading, with a high quantum yield, to the photoinduced oxidation of the iron(II) subunit of the tetranuclear complexes (φ_F = 0.22) followed by that of the ruthenium(II) subunits.

An extension of this work is currently underway with similar tetranuclear polypyridyl complexes of Ru^{II} and Mn^{II}. An efficient photoinduced oxidation phenomenon is also expected for this kind of complex since the energy transfer between the two different metallic subunits is known to be less efficient than for the parent Fe^{II} compounds.

Experimental Section

General: Acetonitrile (Rathburn, HPLC grade) was used as received and stored under argon in a glovebox. Tetra-*n*-butylammonium perchlorate (Bu_4NClO_4, Fluka) was used as received. ^1H NMR spectra were recorded on a Bruker AC 250 spectrometer. The electrospray ionisation mass spectrometry (ESI-MS) experiments were performed on a triple quadrupole mass spectrometer Quattro II (micromass, Altrincham, UK). The ESI source was heated to 80 °C. The sampling cone voltage was set within the range 6–17 V according to the complex studied. Complexes in solution (1 mg mL^{-1} in CH_3CN) were injected using a syringe pump at a flow rate of 10 μL min^{-1}. The electrospray probe (capillary) voltage was optimised in the range 2–5 kV for positive ion electrospray. Elemental analyses were performed by the Service Central d'Analyse du CNRS at Vernaison (France). UV/Vis spectra were obtained using a Cary 1 and a Cary 100 absorption spectrophotometers on 1-mm path-length quartz cells for electrochemical experiments and 1-cm cells for irradiation experiments.

Electrochemistry: All electrochemical measurements were performed under argon in a glovebox at room temperature. Cyclic voltammetry and controlled potential electrolysis experiments were performed using an EG&G PAR model 173 potentiostat/galvanostat equipped with a PAR model universal programmer and a PAR model 179 digital coulometer. A CHI440 Electrochemical Analyzer (CH Instruments, Texas, USA) was used for the determination of formal potentials. A standard three-electrode electrochemical cell was used. Potentials were referenced to an Ag/10 mM $AgNO_3$ reference electrode in CH_3CN + 0.1 M Bu_4NClO_4. Potentials referred to that system can be converted into the ferrocene/ferrocenium couple by subtracting 87 mV and to SCE or NHE by adding 298 mV or 548 mV, respectively.[28] The working electrode was a platinum disk polished with 2-μm diamond paste (Mecaprex Presi) with a diameter of 5 mm for cyclic voltammetry [E_{pa}: anodic peak potential; E_{pc}: cathodic peak potential; $E_{1/2} = (E_{pa} + E_{pc})/2$; $\Delta E_p = E_{pa} - E_{pc}$] and 2 mm for rotating disk electrode experiments (RDE). Exhaustive electrolyses were carried out with a platinum plate. The auxiliary electrode was a Pt wire in CH_3CN + 0.1 M Bu_4NClO_4. For electrochemical experiments, electronic absorption spectra were recorded on a Hewlett–Packard 8452 A diode array spectrophotometer. Initial and electrolyzed solutions were transferred to a conventional 1-mm quartz cell in the glovebox.

Luminescence: The steady-state emission spectra were recorded on a Photon Technology International (PTI) SE-900M spectrofluorimeter. All the samples for luminescence and photooxidation experiments were prepared in a glovebox in deoxygenated CH_3CN + 0.1 M Bu_4NClO_4 and contained in a 1-cm quartz cell. The samples were maintained under aerobic conditions with a Teflon cap. The luminescence lifetime of the complexes was recorded after irradiation at λ = 337 nm with a 4-ns pulsed laser (spectra physics 337-201) and recorded at λ = 600 nm using a monochromator and a photomultiplicator tube (Hammamatsu R928) coupled with an ultra-fast oscilloscope (Tektronix TDS 520A). For subnanosecond decay experiments, sample excitation was performed at 400 nm, which was obtained by the second harmonic of a Titanium: Sapphire laser (picosecond Tsunami laser at an 80-MHz repetition rate). For decay acquisition, a GaAs microchannel plate photomultiplier (Hamamatsu model R 3809 U-51) followed by a homemade single-photon correlator were used. The ultimate time resolution of the entire chain was close to 30 ps. The emission quantum yield, φ_L, was determined at 25 °C in deoxygenated acetonitrile solutions with a CH_3CN solution of $[Ru^{II}(bpy)_3](PF_6)_2$ ($\varphi_L^{ref} = 0.062$)[29] according to Equation (11)

$$\phi_L^S = \frac{I_L^S}{I_L^{Ref}} \frac{(1-10^{-OD^{Ref}})}{(1-10^{-OD^S})} \phi_L^{Ref} \quad (11)$$

where the emission intensity, I_L, was calculated from the spectrum area $\int I(\lambda)d\lambda$, and OD represents the optical density at the excitation wavelength (450 nm). The superscripts "S" and "Ref" refer to the sample and to the standard, respectively.

Continuous Irradiation: The irradiation experiments were performed using a mercury lamp (Oriel 66901, 250 W) whose UV and IR radiations were filtered with a large band-pass filter centred around λ = 560 nm (irradiation range between 410 and 710 nm). The solutions contained a mixture of $[\{Ru(LL_n)\}_3Fe]^{8+}$ complex (0.03–0.04 mM) and ArN_2^+ (15 mM) in order to obtain an absorbance below 1.5 at 454 nm in CH_3CN + 0.1 M Bu_4NClO_4. Under these conditions the concentration of ArN_2^+ can be considered as constant during the experiments.

The quantum yields of formation of $[\{Ru^{II}(LL_n)\}_3Fe^{III}]^{9+}$, φ_F, measured after continuous irradiation at 436 nm, were performed with a 250-W Hg Lamp (Oriel 66901). The desired mercury emission line was isolated using a band-pass filter. The quantum yields were determined by actinometry at the wavelength of the maximum absorption of $[Fe(bpy)_3]^{2+}$ (526 nm) by comparing the absorption of the sample before and after irradiation and using the quantum yield formation of $[Ru(bpy)_3]^{3+}$ in the system $[Ru(bpy)_3]^{2+}/ArN_2^+$ as reference ($\varphi_F^{Ref} = 0.34$).[26] Samples were prepared with the same absorbance (Abs = 2) at 454 nm and the variation of absorbance during irradiation was checked to be less than 0.1. The quantum yield of formation, φ_F^S, of the sample was deduced from Equation (12).

$$\phi_F^S = \left[\frac{(\Delta OD)^S_{526\,nm}}{(\Delta OD)^{Ref}_{454\,nm}}\right]_{t,\lambda^{irr}=436\,nm} \times \phi_F^{Ref} \quad (12)$$

Synthesis of the Diazonium Salt: 4-bromophenyl diazonium tetrafluoroborate *p*-$BrC_6H_4N_2^+ \cdot BF_4^-$ ($ArN_2^+ \cdot BF_4^-$) was synthesised as described previously.[26]

Synthesis of Ligands LL_n and of $[Ru^{II}(bpy)_2(LL_n)](PF_6)_2$: The ligands 1,2-bis[4-(4′-methyl-2,2′-bipyridinyl)]ethane (LL_2), 1,2-bis[4-(4′-methyl-2,2′-bipyridinyl)]butane (LL_4), 1,2-bis[4-(4′-methyl-2,2′-bipyridinyl)]hexane (LL_6) and the $[Ru^{II}(bpy)_2(LL_2)](PF_6)_2$, $[Ru^{II}(bpy)_2(LL_4)](PF_6)_2$, $[Ru^{II}(bpy)_2(LL_6)](PF_6)_2$ complexes were synthesised as described previously.[14]

Synthesis of $[\{Ru^{II}(bpy)_2(LL_n)\}_3Fe^{II}](PF_6)_8$: An aqueous solution of 0.4 molar equivalents of $Fe(ClO_4)_2 \cdot 8H_2O$ was added to an orange solution of $[Ru^{II}(bpy)_2(LL_n)](PF_6)_2$ (100 mg) in ethanol (10 mL) at 60 °C, leading to the formation of the red-orange complex $[\{Ru^{II}(bpy)_2(LL_n)\}_3Fe^{II}]^{8+}$. After stirring the solution for one hour at 60 °C, the ethanol was removed under reduced pressure and the heterotetranuclear complex was extracted with CH_2Cl_2. The resulting solution was washed three times with an aqueous KPF_6 solution (0.1 M) in order to exchange the ClO_4^- anion with PF_6^-, and then twice with water. After drying over Na_2SO_4, CH_2Cl_2 was removed under reduced pressure. The red-orange product obtained corresponding to $[\{Ru^{II}(bpy)_2(LL_n)\}_3Fe^{II}](PF_6)_8$ was reprecipitated in CH_3CN/diethyl ether, washed with diethyl ether, and dried under vacuum. The purity of each complex was confirmed by elemental analysis, ^1H NMR spectroscopy and by the observation of a single spot by TLC [eluent H_2O/CH_3CN (10:90) containing KPF_6 (10 mM)].

$[\{Ru^{II}(bpy)_2(LL_2)\}_3Fe^{II}](PF_6)_8$ ($[\{Ru(LL_2)\}_3Fe]^{8+}$): 51 mg (45%). $C_{132}H_{114}F_{48}Fe_1N_{24}P_8Ru_3{\cdot}6H_2O$ (3663.3): calcd. C 43.28, H 3.46, N 9.18; found C 43.42, H 3.33, N 9.36. ESI-MS: *m/z* (%) = 3410.28 $[M - PF_6]^+$, 1632.70 (2) $[M - 2PF_6]^{2+}$, 1040.15 (6) $[M - 3PF_6]^{3+}$, 743.87 (10) $[M - 4PF_6]^{4+}$, 566.10 (42) $[M - 5PF_6]^{5+}$.

$[\{Ru^{II}(bpy)_2(LL_4)\}_3Fe^{II}](PF_6)_8$ ($[\{Ru(LL_4)\}_3Fe]^{8+}$): Yield: 46 mg (41%). $C_{138}H_{126}F_{48}Fe_1N_{24}P_8Ru_3{\cdot}6H_2O$ (3747.5): calcd. C 44.34, H 3.71, N 9.04; found C 44.82, H 3.72, N 9.03. ESI-MS: *m/z* (%): 3494.44 $[M - PF_6]^+$, 1674.75 (1) $[M - 2PF_6]^{2+}$, 1068.18 (8) $[M - 3PF_6]^{3+}$, 764.90 (17) $[M - 4PF_6]^{4+}$, 582.92 (53) $[M - 5PF_6]^{5+}$.

$[\{Ru^{II}(bpy)_2(LL_6)\}_3Fe^{II}](PF_6)_8$ ($[\{Ru(LL_6)\}_3Fe]^{8+}$): Yield: 24 mg (22%). $C_{144}H_{138}F_{48}Fe_1N_{24}P_8{\cdot}Ru_36H_2O$ (3831.65): calcd. C 45.14, H 3.94, N 8.78; found C 45.63, H 3.91, N 8.96. ESI-MS: *m/z* (%): 3578.60 $[M - PF_6]^+$, 1726.80 (1) $[M - 2PF_6]^{2+}$, 1096.22 (8) $[M - 3PF_6]^{3+}$, 785.92 (22) $[M - 4PF_6]^{4+}$, 599.74 (59) $[M - 5PF_6]^{5+}$.

Synthesis of $Zn(CF_3SO_3)_2$: Pure CF_3SO_3H (1 mL, 11.2 mmol) was added to a solution of CH_3CN (10 mL) containing Zn powder (7.13 g, 112 mmol). After stirring for one day, the excess of Zn was removed by filtration. Addition of diethyl ether to the filtrate yielded the formation of a white precipitate of $Zn(CF_3SO_3)_2$, which was filtered off, washed with diethyl ether and dried under vacuum (yield: 1.02 g, 50%).

Synthesis of $[\{Ru^{II}(bpy)_2(LL_2)\}_3Zn^{II}](PF_6)_8$: Solid $Zn(CF_3SO_3)_2$ (2.36 mg, 6.48 μmol) was added to a solution of $[Ru^{II}(bpy)_2(LL_2)](PF_6)_2$ (20.8 mg, 19.4 μmol) in ethanol (80 mL), leading to the formation of the $[\{Ru^{II}(bpy)_2(LL_2)\}_3Zn^{II}\}^{8+}$ complex. This solution was stirred for one hour at reflux. After cooling to room temperature, an aqueous solution (20 mL) of KPF_6 (15 mg, 64.8 μmol) was added and then the ethanol was removed under reduced pressure. The heterotetranuclear complex was extracted from the aqueous phase with CH_2Cl_2. The resulting CH_2Cl_2 solution was washed three times with an aqueous KPF_6 solution (0.1 M), and then twice with water. After drying over Na_2SO_4, CH_2Cl_2 was removed under reduced pressure. The orange product obtained corresponding to $[\{Ru^{II}(bpy)_2(LL_2)\}_3Zn^{II}](PF_6)_8$ was reprecipitated from CH_3CN/diethyl ether, washed with diethyl ether, and dried under vacuum (yield: 18.5 mg, 80%). $C_{132}H_{114}F_{48}N_{24}Ru_3P_8Zn_1$ (3564.8): calcd. C 44.47, H 3.22, N 9.43; found C 44.49, H 3.29, N 9.60.

Acknowledgments

We thank Dr. Jean-Claude Vial from the Laboratoire de Spectrométrie Physique (CNRS UMR 5588, Université Joseph Fourier, Grenoble I) for allowing us to use his picosecond emission decay setup. We also thank one referee for pointing out that the kinetics of two excited states in rapid equilibrium were worked out thoroughly by J. N. Demas.

Ab initio Study of Some Intramolecularly Donor-Stabilized Silenes

Dirk Wandschneider,[a] Manfred Michalik,[b] Hartmut Oehme,[c] and Andreas Heintz*[a]

Keywords: Silenes / Ab initio calculations / Donor-acceptor systems

Ab initio calculations were performed to predict geometric structures, stabilizing energies and rotational barriers of some intramolecularly donor-stabilized silenes. Calculations were performed using the HF, MP2, and B3LYP method with the 6-31G(d) and 6-31++G(d,p) basis set. Results were compared to experimentally available X-ray structures and energy barriers known from temperature dependent ^{1}H NMR measurements. Various approaches were applied to get an insight into the remarkable stability of these thermodynamically stabilized Si=C compounds. The results indicate a strong stabilizing effect of the intramolecular Si–N donor-acceptor bond.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

1. Introduction

Silenes, silicon derivatives with an Si=C double bond, are extremely labile compounds. In absence of scavenger reagents they undergo rapid dimerizations or oligomerizations, if they are not stabilized. A kinetic stabilization can be achieved by means of bulky substituents attached to the Si=C group. Some highly congested silenes could be isolated and structurally characterized.[1,2] Coordination of donor molecules like amines, THF or fluoride anions to the electrophilic silene silicon atom leads to an effective thermodynamic stabilization of the compounds.[3–6] A particularly effective stabilization is expected, when substituents with donor groups are introduced to the silenes and intramolecular donor–acceptor interaction between this donor group and the electrophilic silicon center is possible. Such intramolecular N→Si coordination was concluded from theoretical calculations of Gusel′nikov et al.[7] for a 1-methylene-5-methyl-2,8-dioxa-5-aza-1-silacyclooctane, and a stable dibenzosilafulvene with an 8-dimethylaminomethyl-1-naphthyl group at the silicon atom was isolated by Chernyshev et al.[8,9] However, no X-ray crystal structure analysis of the compound could be performed to validate their results.

Recently we were able to obtain the following silenes (Figure 1):[10–12]

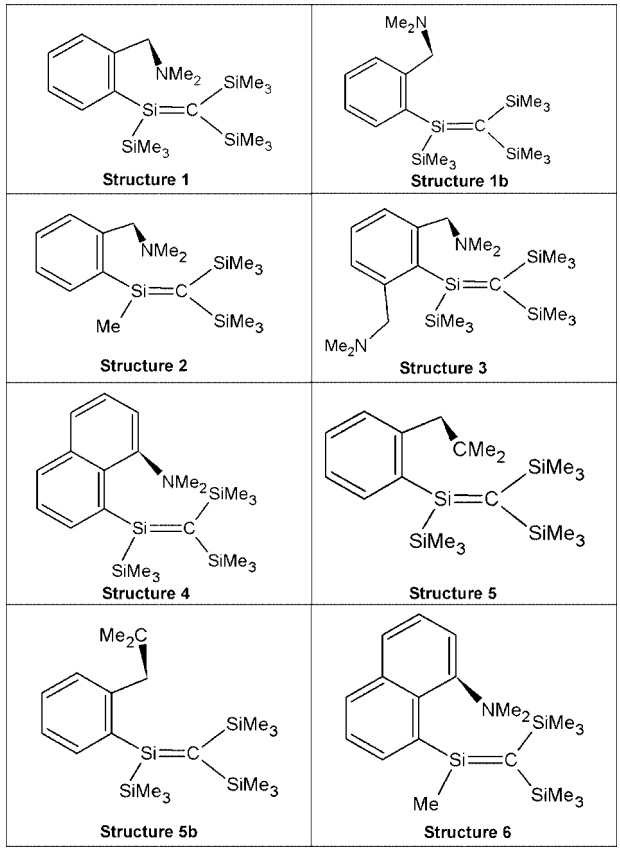

Figure 1. Selected structures of studied substances (schematically).

1-[2-(dimethylaminomethyl)phenyl]-1,2,2-tris(trimethylsilyl)silene (**1**),

1-[2-(dimethylaminomethyl)phenyl]-1-methyl-2,2-bis(trimethylsilyl)silene (**2**),

1-[2,6-bis(dimethylaminomethyl)phenyl]-1,2,2-tris(trimethylsilyl)silene (**3**), and

1-(8-dimethylamino-1-naphthyl)-1,2,2-tris(trimethylsilyl)-silene (**4**).

They were clearly characterized by X-ray structural analyses as intramolecularly donor-stabilized silenes. They proved to be thermally stable up to 140 °C and have a dramatically reduced reactivity compared with uncomplexed silenes.

In this paper we report some ab initio calculations of the geometric structures and energies of **1**, as well as some related compounds. The aim of these calculations was to estimate the impact of the intramolecular Si–N donor bond on the Si=C double bond. Additionally, the temperature dependent ^{1}H NMR spectra of **1**, **2** and **3** were interpreted in form of a hindered rotation about the Si=C bond and evaluated quantitatively by comparison of experimental data for the Gibbs activation energy $\Delta G^{\neq}$ with values calculated by ab initio methods.

2. Results and Discussions

The experimentally available X-ray structures of **1**, **2** and **3**[10–12] can be compared to the quantum mechanically fully optimized geometric structures of the isolated species. Obviously, some deviations between the isolated species and the species in the solid phase are to be expected, since packaging effects in the solid phase could not be accounted for in the ab initio calculations. Nevertheless, the geometric structure obtained by using the HF/6-31++G(d,p) method agrees favorably with the X-ray structure, as the results in Table 1 show for **1**. Worth mentioning is the short interatomic Si···N distance of about 2.0 Å, which is much shorter than the sum of the van der Waals radii (3.5 Å) and longer than a covalent Si–N bond (about 1.8 Å), supporting the idea of an Si···N donor–acceptor stabilized interaction. Therefore a distinct pyramidalization at the silene silicon center (sum of angles < 350°) is observed, whereas the configuration at the silene carbon atom is trignonal planar (sum of angles > 359°). The Si=C bond length is about 1.76 Å. This is distinctly longer than in the similarly substituted stable silene $Me_2Si=C(SiMe_3)(SiMe{t}Bu_2)_2$ (1.702 Å),[4] where no donor stabilization takes place. The Si=C distance is in good agreement with the corresponding distance in the intermolecular adduct of the silene $Me_2Si=C(SiMe_2Ph)_2$ with ethyldimethylamine (1.761 Å).[5] This supports the idea that the interaction of silenes with donor groups leads to an elongation of the Si=C bond[3–6] caused by a weakening of the Si–C π interaction. The Si=C distances of the kinetically stabilized silenes $(Me_3Si)_2Si=C(OSiMe_3)Ad$ (1.764 Å, Ad = 1-adamantyl)[13] and $(Me_3Si)({t}BuMe_2Si)=Ad'$ (1.741 Å, Ad′ = 2-adamantylidene)[14] are almost the same as those of the thermodynamically stabilized silenes, but these elongations were accounted for by the electronic effects of the substituents.[14,15]

For compound **3** the situation is quite comparable to compound **1**, as the results in Table 2 show. Only one of the two dimethylamino groups interacts with the tetra-coordinated silene silicon atom. This leads again to a pyramidalization at the silene silicon atom and one short interatomic Si···N distance. The configuration at the silene carbon atom is perfectly trigonal planar and the Si=C bond length is only slightly longer than in compound **1**.

There are several possibilities to calculate the stabilizing effect of the Si–N donor-acceptor interaction on the stability of the silenes and in particular of the Si=C double bond. For intermolecularly donor-stabilized silenes this energy can easily be calculated from the difference between the total energy of the complex and of the isolated molecules, using the so-called supermolecule approximation.

Table 1. Selected structural parameters of compound **1**.

	HF/6-31++G(d,p)	B3LYP/6-31++G(d,p)	X-ray results
Distance (Si=C) [Å]	1.755	1.761	1.748

Unfortunately, since donor and acceptor are subunits in the same molecule in **1**, **2** and **3**, this strategy does not work. There is no direct way to calculate this stabilizing contribution since it is superimposed by other effects like steric repulsion. Nevertheless, several approaches were undertaken and will be described in the following sections.

2.1. Calculations with the NBO Model

The stabilizing influence of the N→Si donor–acceptor interaction and the resulting elongation of the Si=C double bond in the intramolecularly donor-stabilized silenes can easily be rationalized by a mesomeric interpretation which predicts an ylide-like nature of the donor stabilized silenes (see Figure 2).

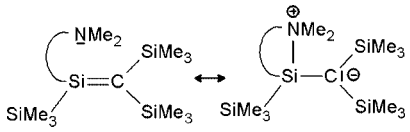

Figure 2. Mesomeric structures of compounds **1**, **3**, and **4**.

A similar conclusion is reached by using the Natural Bond Orbital (NBO) analysis.[16–18] This method transforms the delocalized Hartree–Fock orbitals into localized electron orbitals ("natural bond orbitals") that are closely tied to chemical bonding concepts and resembles the well known Lewis structure. Deviations from "normal" Lewis structures are represented as antibonding orbitals. The orbitals can interact very strongly. The energetic importance of the possible interaction between "filled" (donor) and "empty" (acceptor) NBO's can be estimated by using the NBODel keyword. In this method, the interactions between user defined orbitals are switched off to calculate their influence on the molecular stability. For compound **1** as well as for the conformer **1b**, where the CH_2–NMe_2 group is turned away from the electrophilic silicon atom, calculations were performed using the HF/6-31G(d) method. For compound **1**, the energy attributed to hyperconjugation between the lone pair at N and the empty orbital at the silene silicon atom is calculated as 277 kJ/mol and the Si–C π interaction is calculated as 87 kJ/mol. For compound **1b**, no N–Si interaction is possible, and the hyperconjugative Si–C π interaction is calculated as 168 kJ/mol. When the Si–N donor acceptor interaction takes place, the Si–C π interaction is strongly diminished and a reduction of the rotational barrier about the Si=C double bond in comparison to uncomplexed silenes in the order of 80 kJ/mol is conceivable. Since the occupation of the antibonding Si–C orbital is increased, an elongation of the Si=C bond has to be expected in comparison to silenes without a donor stabilization.

The very high value for the N–Si hyperconjugation interaction as predicted in the framework of the NBO model does not represent the net stabilization energy of the Si–N donor acceptor interaction. Other effects like Pauli exchange repulsion and to a lesser extent electrostatic interactions drastically diminish the stabilizing effect of the hyperconjugation, as was pointed out in the discussions concerning the internal rotational barrier of ethane.[19–22] This net stabilization energy has to be computed by other methods.

2.2. Influence of the Si–N Distance

If the CH_2–NMe_2 group is pointed towards the Si atom in the Si=C bond as in compound **1**, a Si–N donor-acceptor interaction is possible [d(Si–N) ≈ 2.0–2.1 Å]. If the direction of the CH_2–NMe_2 group is changed to point away from the Si atom as in conformer **1b**, no such interaction is possible [d(N–Si) ≈ 4.5 Å]. Both geometric structures were optimized using the HF/6-31++G(d,p) method. The structures show some distinctive deviations. In the conformer with the long Si–N distance, the Si=C double bond is shortened to 1.722 Å in comparison to 1.755 Å in the conformer with short Si–N distance. In the same way, the conformer **1b** shows no longer a pyramidalization at the silene silicon atom (sum of angles at the silene Si atom = 359.16°). Both results agree with our interpretation of the influence of the Si–N interaction on the Si=C double bond as a donor-acceptor interaction between the lone pair at N and the π* orbital of the silene double bond. This picture is also qualitatively supported by the contour plots of the HOMO and LUMO of conformer **1**, which are shown in Figures 3 and 4. A recognizable overlap between the n(N)- and the π(Si=C)-orbital is observed for the conformer with the short Si–N distance, whereas the HOMO and LUMO of the other conformer do not indicate any interaction between the N and Si atom.

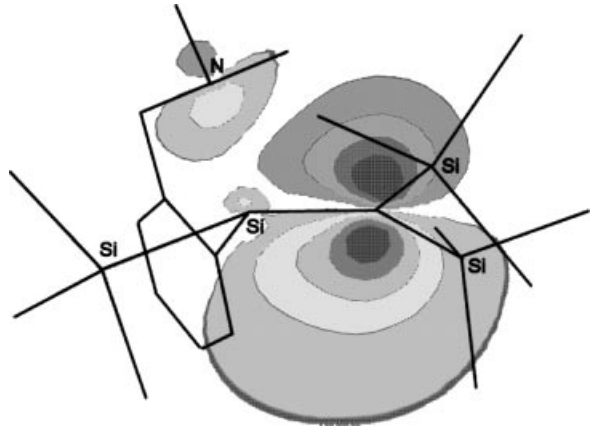

Figure 3. Contour plot of the HOMO orbital of compound **1**. The Figure shows the HOMO in the plane containing the N atom and the Si=C double bond.

Energy calculations of the conformers **1** and **1b** were performed using the MP2/6-31++G(d,p) method. These calculations showed that the structure with the short Si–N distance is energetically favored by 77 (37) kJ/mol at the MP2 (HF) level. This energy consists of the Si–N donor-acceptor stabilization energy and the steric repulsion effects in both conformers and is in reasonable accordance with the value of 82 (92) kJ/mol found by Gusel′nikov et al.[7] for the intramolecularly N-donor-stabilized 1-methylene-5-methyl-2,8-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

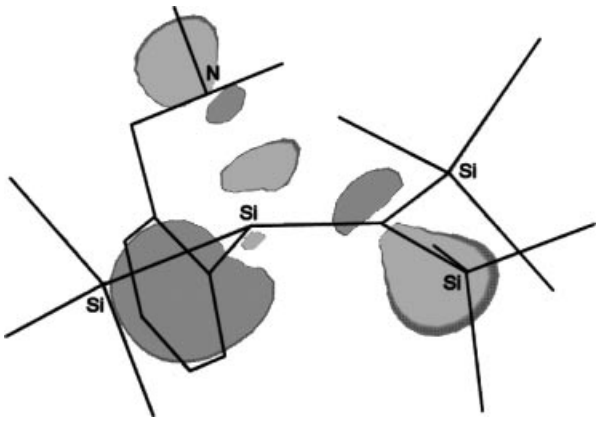

Figure 4. Contour plot of the LUMO orbital of compound **1**. The Figure shows the LUMO in the plane containing the N atom and the Si=C double bond.

dioxa-5-aza-1-silacyclooctane (MADS), calculated by the same method but using the smaller 6-31G(d) basis set. In contrast to the calculations of Gusel′nikov, a strong deviation between the results obtained with the MP2 and the HF method was observed for compound **1**, showing that electron correlation can not be neglected in this case.

The hypothetical intermolecular stabilization of dimethylsilene with NH_3 was calculated by Gusel′nikov et al.[7] as 31 kJ/mol using the MP2/6-31G(d) method in the supermolecular approximation. This value is smaller than the value obtained for silene **1**, showing that the electronic and steric effect of the different substituents can not be neglected.

To understand the influence of the steric repulsion on our results, some calculations were performed with model compound **5** (see Figure 1). In this compound, the dimethylamino group of **1** is replaced with the sterically similar isopropyl group. Again, configurations with a short (2.4 Å) and a long (4.7 Å) distance between this group and the silene silicon atom were calculated, representing the structures **5** and **5b**, respectively. In contrast to the NMe_2 group, no donor–acceptor interaction with the electrophilic silicon atom is expected for the isopropyl group. The energy difference between both conformers of **5** should thus be determined solely by steric repulsions. This leads to a strong stabilization of the configuration with the long isopropyl-silene silicon atom distance of 75 (122) kJ/mol calculated at the MP2/6-31++G(d,p) [HF/6-31++G(d,p)] level.

Under the assumptions made above, the Si···N interaction energy without steric repulsion effects can now be calculated as the difference between the two stabilization energies of the different conformers of compounds **1** and **5**. As a result, the Si···N interaction energy without the influence of steric repulsion is calculated as 152 (159) kJ/mol using the MP2/6-31++G(d,p) [HF/6-31++G(d,p)] method. This energy shows only a small dependence on electron correlation, since the errors in the HF calculations, which are mainly due to incorrect interorbital pair correlations, cancel out each other favorably.

2.3. Comparison of Stabilization Effect of NMe_2 Group on Silenes and Silanes

The results obtained above indicate a strong donor–acceptor interaction of the free electron pair of the N atom with the Si=C bond. Without the Si–C antibonding orbital of the Si=C bond, no strong donor-acceptor interaction should be possible. If the dimethylamino group is exchanged for an isopropyl group, again no strong donor–acceptor interaction is possible, regardless whether there exists a Si=C double bond or not. In the hydrogenation reactions of **1** and **5b** with H_2 leading to the saturated compounds **1c** and **5c** these effects determine the difference in the following two standard reaction energies:

1 + H_2 → **1c**; $\Delta E_{H(1)}$

5b + H_2 → **5c**; $\Delta E_{H(5)}$

The stabilizing effect of the NMe_2 group on the Si=C bond can be calculated from the difference between the hydrogenation reactions:

$\Delta E_{stab} = \Delta E_{H(1)} - \Delta E_{H(5)}$

As a result, a stabilizing effect ΔE_{stab} of 74 kJ/mol (41 kJ/mol) was obtained at the MP2/6-31++G(d,p) [HF/6-31++G(d,p)] level. These stabilization energies agree nearly quantitatively with the energies obtained from the investigation in section 2.2. A strong influence of electron correlation is also observed in these results.

Again it has to be assumed that other factors like higher steric repulsions in compound **1** in comparison to compound **5b** have a major impact on these stabilization energies. Using the results from the study of model compounds **5** and **5b** in section 2.2., a stabilization energy without the influence of steric repulsion of 149 (163) kJ/mol can be attributed to the Si···N interaction using the MP2/6-31++G(d,p) [HF/6-31++G(d,p)] method.

2.4. Rotational Barrier About the Si=C Double Bond

For compound **1**, **3** and the structurally quite similar compound **6**, temperature-dependent ^1H NMR studies were performed.[23] As expected, at room temperature two separate signals were found for the two nonequivalent trimethylsilyl groups at the carbon atom of the above-mentioned compounds. For compound **1** and **6** the dynamic ^1H NMR studies revealed that at elevated temperatures a coalescence of the signals of the $CSiMe_3$ groups occurred. For compound **3**, at temperatures of up to 80 °C no coalescence of these two signals could be observed. The data were used to determine the rotational barrier $\Delta G^{\neq}$ about the Si=C bond. The following approximate equation derived from the Eyring equation was used:[24]

$$\Delta G^{\neq} = T_c \cdot 19.13 \cdot (9.97 + \lg\frac{T_c}{\Delta \nu_c})$$

$\Delta G^{\neq}$ is the free energy barrier, T_c the coalescence temperature and $\Delta \nu_c$ is the signal separation of the $CSiMe_3$ groups extrapolated to the coalescence temperature.

These results can be compared to some data obtained from ab initio calculations. The rotational barrier of the Si=C bond was determined by performing a relaxed poten-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tial energy surface scan involving the dihedral angle Ph–Si=C–$SiMe_3$ of compounds **1**, **2**, and **3** using the HF/6-31G(d) method. The resulting energy vs. dihedral angle diagram is show in Figure 5. The geometries belonging to the maximal values of these curves were then recalculated using the higher 6-31++G(d,p) basis set at the HF and the MP2 level. The difference between these absolute energies corresponds approximately to the rotational barrier of the Si=C double bond. Since the rotational barrier is strictly speaking a difference of Gibbs energies, the following corrections were applied to the calculated energies $\Delta E^{\neq}_{elec}$ using the HF/6-31G(d) method:

$$\Delta G^{\neq} = \Delta E^{\neq}_{elec} + \Delta ZPE^{\neq} + \Delta E^{\neq}_{vib} + \Delta E^{\neq}_{rot} - T\Delta S^{\neq}$$

$\Delta ZPE^{\neq}$ is the correction due to zero point energy, $\Delta E^{\neq}_{vib}$ + $\Delta E^{\neq}_{rot}$ are the contributions due to vibration and rotation and $\Delta S^{\neq}$ is the entropy difference.

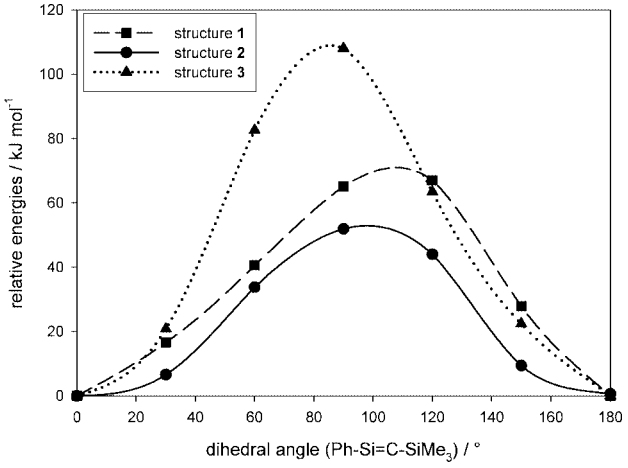

Figure 5. Rotational barrier of the Si=C double bond calculated at the HF/6-31G(d) level.

The resulting free energies as well as the energies obtained at the HF/6-31++G(d,p), the MP2/6-31++G(d,p) level and the experimental ^{1}H NMR results are shown in Table 3. Our best estimates for the rotational barrier in Table 3 (column 6) are obtained by using the results from the MP2 single point energy calculation (column 5) and applying the corrections according to the equation above by using the HF/6-31G(d) method (difference between column 3 and column 2). The rotational barriers determined by this quantum mechanical approach agree surprisingly well with the spectroscopically determined rotational barriers, supporting our interpretation of the experimental data.

These values are also very close to values found for intermolecular silene adducts

THF·Me_2Si=C($SiMe_3$)SiMe*t*Bu_2 and NMe_3·Me_2Si=C-($SiMe_3$)SiMe*t*Bu_2, where values of 50 kJ/mol and 65 kJ/mol, respectively, were reported.[25]

The calculated rotational barriers of isomer interconversion are smaller than in uncomplexed silenes, which were found to be about 160 kJ/mol.[1] This shows that the interaction of donor groups with the Si=C bond leads to a weakening of the Si–C π interaction in the order of 60–100 kJ/mol, in qualitative agreement with our results from the NBO calculation. The value for the cis/trans isomerization in alkenes, which amounts to approximately 250 kJ/mol,[26] is considerably higher than the value for the silenes, as expected.

3. Conclusions

The ab initio calculations on the silene compounds **1**, **2**, and **3** in the gas phase are in good agreement with data from X-ray structural analysis. Both methods show an Si–N distance that is shorter than in saturated counterparts. A strong interaction between the free N orbital and the antibonding orbital at the electrophilic silicon atom was observed. This is accompanied by a weakening of the Si=C double bond, which results in the elongation of the Si=C bond and the reduction of the rotational barrier about the Si=C bond. The stabilization energy gained of the donor-stabilized silenes in comparison to unstabilized silenes by coordination with the dimethylamino group is in the order of about 75 kJ/mol. This energy consists of a stabilizing donor-acceptor interaction (app. 150 kJ/mol) and a weakening steric repulsion effect (app. 75 kJ/mol).

The spectroscopically determined rotational barriers about the Si=C double bond of compounds **1**, **3** and **6** could be quantitatively reproduced by our ab initio calculations.

4. Computational Details

All calculations were performed for isolated species using the GAUSSIAN98 and GAUSSIAN03 program package.[27] At first, a full geometry optimization was performed using the 6-31G(d) basis set on the RHF level. All calculated structures represent minima on the potential energy surface; this means no negative frequencies were observed. The calculated frequencies were used to obtain the zero point energies and other thermodynamic properties of those structures. Some further geometry optimizations using the 6-

31++G(d,p) basis set on the HF and the B3LYP level were performed for the most important structures. All main structural elements from the X-ray structures could be reproduced qualitatively with both of the applied ab initio methods. The results from the B3LYP/6-31++G(d,p) geometry optimization show larger deviations from the X-ray structure (see Tables 1 and 2). This may be due to problems of B3LYP in describing steric interactions correctly. Therefore, we decided to use the geometric structures obtained from the HF calculations as the foundation for any further calculations like frequency calculations or single point energy calculations using the more sophisticated but also very time consuming MP2 method. Due to the high computational cost of the MP2 method for these large molecules, only single point energy calculations were performed using the MP2/6-31++G(d,p) method on the geometric structures obtained at the HF level. No geometry optimization was attempted at the MP2 theoretical level.

All NBO calculations were performed with NBO version 3.1[28] as incorporated in Gaussian03.

The calculation of the rotational barrier about the Si=C double bond was accomplished at the HF/6-31G(d) level by using the Opt = ModRedundant keyword of GAUSSIAN03. We changed the dihedral angle Ph–Si=C–$SiMe_3$ in 5 steps of 30°, starting with the value of approximately 0° corresponding to the fully optimized geometry.

Supporting Information: The supporting information (see also the footnote on the first page of this article) includes the coordinates and total energies of the above mentioned structures as well as the thermodynamic corrections.

Copper, Cobalt and Platinum Complexes with Dithiothiophene-Based Ligands

Dulce Belo,[a] Mauro J. Figueira,[a] Joana Mendonça,[a] Isabel C. Santos,[a] Manuel Almeida,*[a] Rui T. Henriques,[b] Maria Teresa Duarte,[c] Concepció Rovira,[d] and Jaume Veciana[d]

Keywords: S ligands / Coordination chemistry / Copper / Cobalt / Platinum

The preparation and characterisation of new thiophenedithiolate complexes of Cu, Co and Pt with the ligands α-tpdt and tpdt (α-tpdt = 2,3-thiophenedithiolate, tpdt = 3,4-thiophenedithiolate) is reported. The Co and Pt complexes present regular square-planar coordination geometry and low oxidation potentials when compared with complexes with simpler ligands, but their monoanionic state is found to be rather unstable. The $Co(tpdt)_2$ complex can be isolated both in the monoanionic and dianionic states as a stable compound but the $Co(\alpha\text{-tpdt})_2$ and the Pt complexes can be obtained only in the dianionic state, while their monoanionic state is unstable. The Co and Pt complexes can, however, be easily oxidised to the neutral state, giving a fine-powdered microcrystalline material without high electrical conductivity. With Cu only a less frequent geometry based on a tetrametallic Cu^I cluster and three ligands is observed as $[Cu_4(\alpha\text{-tpdt})_3]^{2-}$ and $[Cu_4(tpdt)_3]^{2-}$.

Introduction

Transition metal dithiolene complexes, $M(S_2X)_2$, because of a rich variety of coordination geometry and a vivid redox behaviour, have attracted continuing interest during the last 30 years.[1] Depending on the metal, M, coordination geometry and oxidation state, these complexes can be diamagnetic or carry different magnetic moments and therefore have been choice building blocks for the design of functional molecular materials.[2] Square-planar coordination geometries are favoured, with metals of Ni and Cu group in the anionic form $[M(S_2X)_2]^-$, and such complexes have been widely used as counterions in charge transfer solids with a variety of donors, often giving rise to new molecular materials displaying unconventional electrical and magnetic properties, including ferromagnetism,[3] metallic[4] and even superconducting properties.[5]

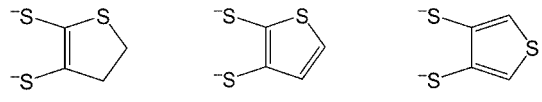
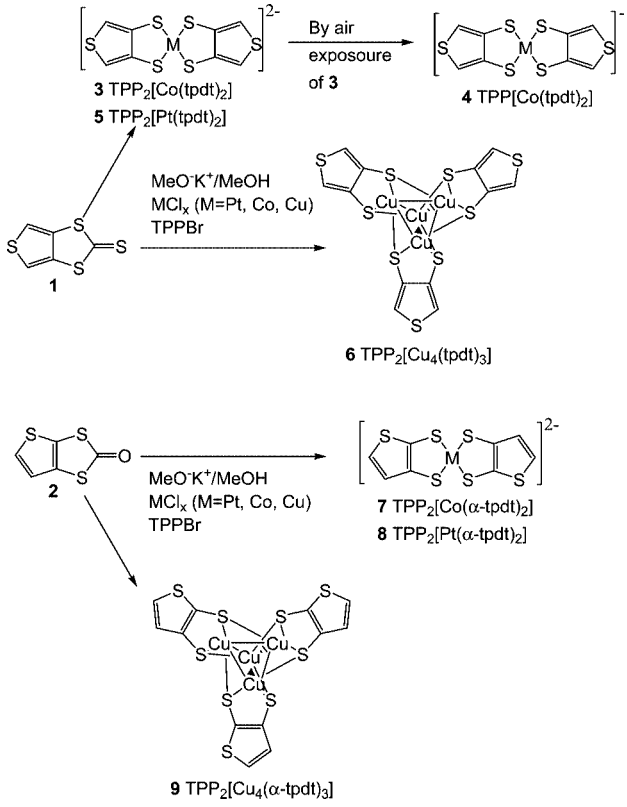
Another common coordination geometry in bisdithiolene complexes is the square pyramidal, 4+1, in dimerised arrangements, $[M(S_2X)_2]_2^{2-}$, favoured for M = Fe, Co and to a smaller extent occurring also for Ni.[6,7] Other geometries are known in metal bisdithiolene complexes and, for example, for Co, trimerised, $[Co(S_2X)_2]_3^{2-}$,[8] and even polymeric, $[Co(S_2X)_2]_n^{n-}$,[9] arrangements of square planar units also have been described.

The accessibility to different oxidation states in these complexes is greatly dependent on the type of ligand because their contribution to the HOMO and LUMO is often dominant. Extended π ligands favour both a lower oxidation potential and larger solid state interactions between neighbouring units in stacked structures of square-planar complexes. Sulfur-rich ligands with additional sulfur atoms in the periphery of the complex are expected to provide intermolecular S···S contacts that may enhance the magnitude and the dimensionality of the solid state intermolecular interactions.



In this context we recently focused our efforts on exploring complexes based on thiophenedithiolate ligands (α-tpdt = 2,3-thiophenedithiolate, dtpdt = 2,3-dihydro-5,6-thiophenedithiolate and tpdt = 3,4-thiophenedithiolate, Scheme 1). Previously we described the properties of the first Au[10] and Ni[11] complexes with thiophenedithiolate

ligands, which are generally characterised by rather low oxidation potentials. Many of these complexes can be obtained as a neutral species such as Au(α-tpdt)$_2$, one of the rare electrically conducting compounds based on a neutral molecule, and the first one showing metallic transport properties in spite of being characterised only as a polycrystalline sample.[10] The paramagnetic Ni^{III} complex was the key component of an interesting charge transfer salt displaying a metamagnetic transition.[11] More recently, other neutral Ni complexes based on more extended bisdithiolene ligands have been obtained as single crystals and were characterised as unimolecular metallic systems.[12]



Scheme 1. Preparation of the transition metal complexes **4**–**9**.

These results led us to prepare similar bisthiophenedithiolate complexes with different transition metals and to explore their possible use as building blocks for the preparation of magnetic or electrically conducting materials. In this paper we report on the preparation and properties of new thiophenedithiolate complexes of Cu, Co and Pt with the ligands α-tpdt and tpdt having diverse oxidation states and geometries.

Results and Discussion

The synthesis of TPP$_y$M(xtpdt)$_z$ followed a procedure (Scheme 1) similar to the one previously described for other transition metal complexes with dithiolatethiophene ligands, with minor modifications. The previous preparation of Au[10] and Ni[11] complexes with thiophenedithiolate ligands was made as tetrabutylammonium (TBA) salts. However, difficulties in crystallising the salts of these complexes with such cations led us to work with larger cations such as tetraphenylphosphonium (TPP), which favours the crystallisation process. The ligands were obtained in methanol solution from 5,6-thieno[2,3-*d*]-1,3-dithiol-2-one (**1**) for [M(α-tpdt)$_2$]$^{x-}$ salts, and from thieno[3,4-*d*]-1,3-dithiol-2-thione (**2**) in the case of [M(tpdt)$_2$]$^{x-}$ complexes, by cleavage with potassium methoxide. These ligands, without intermediate isolation, were immediately treated with the appropriate metal chloride to give the Co^{II}, Pt^{II} and Cu^{I} complexes, which precipitated as red (**5**), green (**3**), orange (**8**), dark brown (**7**) and golden brown (**6**, **9**) TPP salt, by treatment with TPPBr. These reactions were carried out in strictly anaerobic conditions inside a glovebox. The TPP[Co(tpdt)$_2$] complex (**4**) was obtained as a dark blue precipitate, just by stirring an acetonitrile solution of **3** under air. After recrystallisation, all compounds give air-stable crystals with yields ranging from 50 to 80%. The Pt complex **8** in acetonitrile solution, when exposed to air, changes colour to green, indicating that an oxidation process takes place, in agreement with the low oxidation potential observed in the cyclic voltammetry data (see below). However, possibly because of decomposition and instability of the Pt^{III} complexes, it was not possible to isolate the monoanionic species. Although with only a slightly larger oxidation potential the Pt(tpdt)$_2^{2-}$ complex **5** does not undergo any oxidation upon air exposure.

With the exception of the copper salts **6** and **9**, the abovementioned synthetic procedure leads to the dianionic species M^{II} with M = Co and Pt in a square-planar coordination geometry. Cu complexes are always obtained with a different stoichiometry, of four metals to three ligands. This stoichiometry, although unexpected, is not entirely new as it has been previously reported for a few [Cu$_4$(S$_2$X)$_3$]$^{2-}$ complexes.[13] However in most of these previous examples the stoichiometry of the complexes obtained is controlled by the metal–ligand proportion, the ligand excess favouring the formation of the square-planar Cu^{II} complex. In the present case we were not able to obtain the square-planar Cu coordination, even with a large excess of the ligands.

The crystal structures of complexes **4**–**9** were solved by single-crystal X-ray diffraction and their crystal and structure refining data are listed in Table 1 and Table 2. The Co and Pt complexes present identical, essentially planar, geometry (Figure 1 and Figure 2), with small nonplanar deviations observed only in the thiophenic sulfur atoms of complex **5**, which are displaced towards opposite directions giving rise to a very small chair-type distortion.

By contrast, this usual square-planar coordination geometry, found also in the previously described Au and Ni complexes with these ligands,[10,11] was not observed in the Cu complexes **6** and **9**, which present a different stoichiometry and structure: [Cu$_4$(xtpdt)$_3$]$^{2-}$. In these complexes the dianion is composed by four Cu^{I} atoms, each one coordinated to the other three Cu atoms. The Cu2, Cu3 and Cu4 atoms are chelated to two sulfurs from one dithiothiophene ligand and to another sulfur atom from a neighbouring ligand. Although Cu1 is also coordinated to three sulfur atoms,

each one belongs to different dithiothiophene ligands (Figure 3 and Figure 4). The Cu–Cu distances range from 2.740 to 2.640 Å and 2.729 to 2.655 Å, for complexes **6** and **9**, respectively, values which are comparable to the few similar complexes with other dithiolate ligands.[13] The Cu–S distances can be divided into two different ranges: one, Cu–S_L, involving sulfur atoms in the same ligand that range from 2.264 to 2.320 Å in salt **6** and 2.252 to 2.336 Å in salt **9**, and the other with slightly shorter bond lengths between

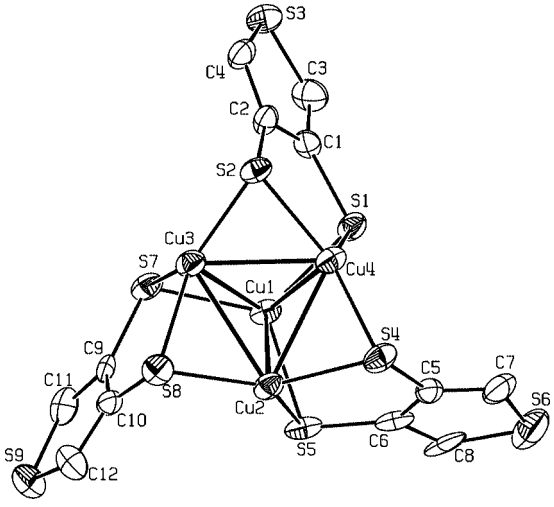

Figure 3. ORTEP views and atomic numbering scheme of $[Cu_4(tpdt)_3]^{2-}$ with thermal ellipsoids at 40% probability level.

the sulfur atom in the neighbouring ligand, Cu–S_N, that range from 2.216 to 2.231 and 2.212 to 2.240 for complexes **6** and **9**, respectively.

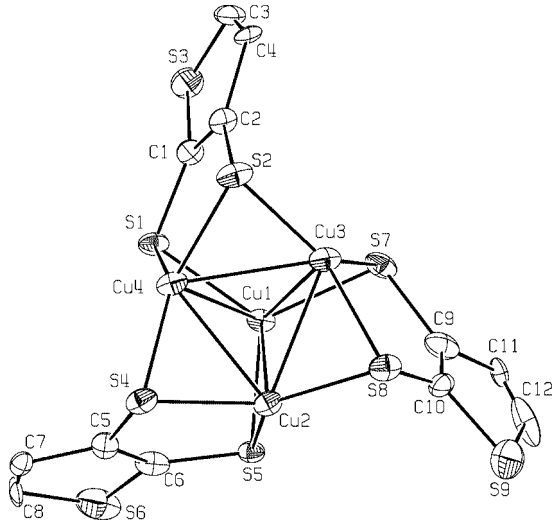

Figure 4. ORTEP views and atomic numbering scheme of $[Cu_4(\alpha\text{-}tpdt)_3]^{2-}$ with thermal ellipsoids at 40% probability level.

The angles between the average planes of each ligand are close to 70° (Figure 3 and Figure 4). In all cases, within the ligand, the bond lengths in the thiophenic ring are very close to those found in the corresponding Ni and Au analogues (Table 3 and Table 4).[10,11] The α-tpdt complexes of Co (**7**) and Pt (**8**) present a disorder in the orientation of the thiophenic sulfur of the ligands (Figure 2), making it impossible to distinguish between a *cis* or *trans* conformation of the complex, as both configurations with orientation disorder in the crystal could give the observed results. As the $Ni(\alpha\text{-}tpdt)_2$[11] and $Au(dtpdt)_2$[10] complexes previously studied were found to crystallise in the *trans* configuration, the observed disorder is most likely the result of orientational disorder of the complex in the *trans* configuration. In this respect it should be mentioned that in those cases one specific orientation of the complexes is favoured by several hydrogen bonds and strong S···S contacts involving the thiophenic ring, and therefore preventing possible orientational disorder of the complex in those structures. This is at variance with the structure of **7** and **8** where there are no strong thiophenic S···S contacts and the existing hydrogen bonds do not present any specific orientation.

Two different types of crystal packing were found on the studied salts. The first one consists of isolated anions, surrounded by the TPP cations and this type of crystal packing is shared for complexes **5**, **6**, **7**, **8** and **9** (Figure 5 and Figure 6). Although they are not isostructural, they present the same crystal packing pattern. The interactions between the anions and the cations are established through several hydrogen bonds. The interactions found are of the C–H···S type, involving both the thiophenic and the coordination sulfur atoms (Table 5). The effect on the crystal structure

of the sulfur atom position in the thiophenic ring (tpdt or α-tpdt) is negligible.

The crystal structure of **4** is composed by layers of dithiolate anions parallel to the *bc* plane, with TPP cations sitting in holes in these layers. The anionic layers are due to a network of short contacts. Anions of one type are connected between the terminal sulfur atoms by short S(3)···S(3)* [3.492(2) Å] contacts making regular chains along *b*. These chains are interconnected by another dithiolate anion, placed almost perpendicularly to the first ones, through short S6···C1 contacts [3.436(2) Å] (Figure 7). This last contact may denote a weak interaction between this S atom and the carbon π system. The TPP cations are sitting over the spaces left in this anionic layer.

Cyclic voltammetry of all $TPP_yM(xtpdt)_z$ was performed in acetonitrile versus Ag/AgCl and the redox potential values of the different processes observed are listed in Table 6. As in the case of the Au and Ni compounds previously described, these new transition metal complexes with dithiolatethiophene ligands present lower oxidation potentials than complexes with more simple bisdithiolene ligands such as maleonitrile dithiolate (mnt) or even benzodithiolate (bdt). With the exception of the copper complexes, which present a different stoichiometry and coordination environment, when going from tpdt to α-tpdt ligands the redox potentials decrease, showing an increasing facility of these complexes to be oxidised. The complexes with M = Co, Pt present at negative values a reversible process ascribed to

[a] $-x + 1, -y + 2, -z + 1$.

the $M(xtpdt)_2^{2-}/M(xtpdt)_2^{-}$ couple. These low values are in agreement with the fact that the $Co(tpdt)_2^{-}$ complex was obtained from the dianionic species upon air oxidation and with the previously mentioned fact that $Pt(\alpha\text{-}tpdt)_2^{2-}$ changes colour upon air exposure, indicative of oxidation. In spite of not so different oxidation potentials, $Co(\alpha\text{-}tpdt)_2^{2-}$ and $Pt(tpdt)_2^{2-}$ do not denote any air oxidation and the monoanionic species could not be isolated, probably because of instability associated with dismutation in the neutral and dianionic species. The Co and Pt complexes also show an irreversible process at more positive potentials, possibly associated with the formation of the insoluble neutral complexes, which could be obtained by chemical oxidation (see below). The Cu complexes also undergo two redox processes, a reversible wave for $Cu_4(tpdt)_3$ at –0.330 V, quasireversible for $Cu_4(\alpha\text{-}tpdt)_3$ at about –0.392 V (–0.506, –0.278) and an irreversible oxidation at higher potentials of about 0.18 V.

As suggested by the cyclic voltammetry data, in the case of Pt and Co complexes, the corresponding neutral metal(IV) complexes were easily obtained by chemical oxidation as fine and very insoluble precipitates. The same products, as judged by elemental analysis and IR, were also obtained by electrochemical oxidation from acetonitrile solutions containing the $TPP_y[M(xtpdt)_2]$ salts. Using standard electrocrystallisation galvanostatic conditions with a current density of 1 $\mu A/cm^2$ for about 7–12 days, in a two-compartment cell with platinum electrodes, only an equally fine and insoluble microcrystalline dark powder was obtained. The elemental analysis of these products is consistent with the neutral complex. Further characterisation of these products was hampered by the difficulty in the preparation of single crystals because of the large insolubility of these neutral complexes in most solvents. However, the measurements of the electrical conductivity by the four-probe method in compressed powder pellets indicated conductivity lower than 10^{-6} S/cm.

Summary

New thiophenedithiolate complexes of Cu, Co and Pt with the ligands α-tpdt and tpdt were prepared. The Cu complexes obtained, independently of the metal to ligand ratio, present a tetrametallic Cu^I cluster and three ligands: $[Cu_4(\alpha\text{-tpdt})_3]^{2-}$ and $[Cu_4(tpdt)_3]^{2-}$. The Co and Pt complexes, with square-planar coordination geometry, are obtained in the dianionic state. In spite of their low oxidation potential, only for Co(tpdt)$_2$ was it possible to isolate the monoanionic complex and in other cases this oxidation state is rather unstable. Further oxidation of these complexes to the neutral state gives an electrically insulating powder material.

Experimental Section

General Remarks: All manipulations were carried out with exclusion of air under dry nitrogen or argon unless otherwise stated. All solvents were purified following standard procedures. Thieno[3,4-*d*]-1,3-dithiol-2-thione (**1**) and 5,6-thieno[2,3-*d*]-1,3-dithiol-2-one (**2**) were synthesised as described previously. Other chemicals were commercially obtained and used without any further purification. Column chromatography was carried out using silica gel (0.063–0.2 mm) from S.D.S. UV/Vis spectra were recorded with a Cary 5G spectrophotometer (Varian). IR spectra were obtained with a Perkin–Elmer 577 spectrophotometer. MALDI mass spectra were obtained in time-of-flight negative linear mode with an apparatus Kratus Kompact Maldi 2 K probe (KRATOS Analytical) operated with pulsed extraction of the ions. Cyclic voltammetry data were obtained by using a BAS C3 Cell Stand. The measurements were performed at room temperature in acetonitrile solutions containing nBu$_4$PF$_6$ as supporting electrolyte, with a scan rate of 100 mV/s, platinum wire working and counter electrodes and using a Ag/AgCl as a reference electrode.

Tetraphenylphosphonium Salt of Cobalt(III) Bis(3,4-thiophenedithiolate), TPPCo(tpdt)$_2$ (4): Whilst stirring, thieno[3,4-*d*]-1,3-dithiol-2-thione (**1**) (100 mg, 5.25×10^{-4} mol) was added to a solution of potassium methoxide in methanol (10 mL, 2 M). The formed yellow solution was filtered and added to a solution (2 mL) of $CoCl_2\cdot6H_2O$ (63 mg, 2.6×10^{-4} mol) in methanol, turning to a green mixture. The inorganic precipitate was removed and the liquor added to 1 mL of a solution of tetraphenylphosphonium bromide (222 mg, 5.25×10^{-4} mol) in methanol giving a green precipitate, **3**. The green solid obtained was dissolved in acetonitrile and stirred under air. Just a few minutes later the solution turned from green to dark blue. After an hour this solution was filtered and evaporated, giving **4** as a blue precipitate. The stirring was maintained, in all steps, only until no visible modifications were observed. The best crystals of **4**, suitable for X-ray measurements, were obtained from crystallisation in acetonitrile/ethyl ether. Total

UV/Vis (CH_3CN) λ_{max} = 1915 nm; m.p. 67 °C dec. MS: *m*/*z* (%) = 352 (100) [M^-].

Bis(tetraphenylphosphonium) Salt of Platinum(II) Bis(3,4-thiophenedithiolate), $TPP_2Pt(tpdt)_2$ (5): The compound was prepared using the same method as for **4**, using $NaPtCl_4{\cdot}3H_2O$ instead of $CoCl_2{\cdot}6H_2O$. The product was obtained as dark red plate crystals, directly by synthesis, allowing the final solution to rest overnight. Yield: 50%, 152 mg; $C_{56}H_{44}P_2PtS_6$ (1166.36): calcd. C 57.67, H 3.80, S 16.49; found C 56.79, H 3.94, S 16.89; FTIR (KBr) $\tilde{\nu}$ = 3520 (m), 3440 (m) (C–H arom.), 1440 (s) (P-φ), 1300 (s), 1105 (s), 720 (s) (C–S), 690 (m) (C–S), 530 (s) cm^{-1}. UV/Vis (CH_3CN): λ_{max} = 871, 1915 nm; m.p. gradual decomposition 300 °C. MS: *m*/*z* (%) = 487.5 (100) [M^-].

Bis(tetraphenylphosphonium) Salt of Copper(I) Tris(3,4-thiophenedithiolate), $TPP_2Cu_4(tpdt)_3$ (6): The compound was prepared using the same method as for **4**, using $CuCl_2{\cdot}2H_2O$ instead of $CoCl_2{\cdot}6H_2O$. The product was obtained as a brown precipitate. The best crystals, suitable for X-ray measurements, were obtained by recrystallisation in acetonitrile/ethyl ether. Yield: 62%, 55 mg; $C_{60}H_{46}Cu_4P_2S_9$ (1371.69): calcd. C 52.54, H 3.38, S 21.03; found C 53.88, H 3.52, S 20.66; FTIR (KBr) $\tilde{\nu}$ = 1584 (m), 1482 (m), 1439 (m) (C-φ), 1277 (m), 1109 (s), 997 (m), 839 (m), 755 (s), 726 (s), 689 (s) (C–S), 531 (s) cm^{-1}. UV/Vis (CH_3CN): λ_{max} = 1912 nm; m.p. 120 °C dec. MS: *m*/*z* (%) = 325 (100) [$C_8H_4S_5Cu$], 209.7 [$C_4H_2S_3Cu$], 693.5 [M^-].

Tetraphenylphosphonium Salt of Cobalt(III) Bis(2,3-thiophenedithiolate), $TPP_2Co(\alpha\text{-}tpdt)_2$ (7): The compound was prepared using the same method as for **4**. The initial reactive was 5,6-thieno[2,3-*d*]-1,3-dithiol-2-one (**2**). The product was obtained as dark brown crystals after recrystallisation in acetonitrile/ethyl ether. Total yield: 80%, 214 mg; $C_{56}H_{44}CoP_2S_6$ (1030.20): calcd. C 65.29, H 4.30, S 18.67; found C 64.90, H 3.95, S 18.75; $\tilde{\nu}$ = 3440 (m), 3050 (m) (C–H arom.), 1650 (m), 1640 (m), 1590 (s), 1490 (s), 1445 (s) (P-φ), 1310 (m), 1240 (m), 1160 (m), 1110 (s), 1020 (m), 1000 (m), 755 (m), 730 (s), 700 (s), 630 (m), 54 (s) cm^{-1}. UV/Vis (CH_3CN): λ_{max} = 581, 795, 1912 nm; m.p. 117.8–119.5 °C. MS: *m*/*z* (%) = 144.7 (100) [S_3C_4] [M^-].

Bis(tetraphenylphosphonium) Salt of Platinum(II) Bis(2,3-thiophenedithiolate), $TPP_2Pt(\alpha\text{-}tpdt)_2$ (8): The compound was prepared from 5,6-thieno[2,3-*d*]-1,3-dithiol-2-one (II) following the same method as in **5**. After recrystallisation the compound was obtained as orange plate-shaped crystals. Yield: 53%, 161 mg; $C_{56}H_{44}P_2PtS_6$ (1166.36): calcd. C 57.67, H 3.80, S 16.49; found C 56.93, H 3.69, S 16.25; $\tilde{\nu}$ = 3054 (m) (C–H arom.), 1578 (m), 1429 (m) (P-φ), 1377 (s), 716 (s) (C–S), 682 (s) (C–S) cm^{-1}. UV/Vis (CH_3CN): λ_{max} = 990, 1912 nm. MS: *m*/*z* (%) = 487.5 (100) [M^-].

Bis(tetraphenylphosphonium) Salt of Copper(I) Tris(2,3-thiophenedithiolate), $TPP_2Cu_4(\alpha\text{-}tpdt)_3$ (9): Using as starting material **2** and following the same procedure used for **6**, the product was obtained as golden brown crystals. Yield: 59%, 53 mg; $C_{60}H_{46}Cu_4P_2S_9$ (1371.69): calcd. C 52.54, H 3.38, S 21.03; found C 53.27, H 3.47, S 20.35; $\tilde{\nu}$ = 1482 (m), 1439 (m) (P-φ), 1110 (m), 998 (m), 864 (m), 757 (m), 726 (s) (C–S), 692 (s) (C–S), 601 (m), 514 (s) cm^{-1}. UV/Vis (CH_3CN): λ_{max} = 432, 1418, 1908 nm; m.p. 213.3–214.4 °C dec. MS: *m*/*z* (%) = 144.9 [$C_4H_2S_3$], 324.8 [$C_8H_4S_5Cu$], 353 [$C_8H_4S_6Cu$].

Cobalt(IV) Bis(3,4-thiophenedithiolate), $Co(tpdt)_2$ (10): A solution of iodine in acetone was added to a solution of **4** in acetone (10 mL, 1.5×10^{-2} M), dropwise in stoichiometric amounts. The fine dark precipitate obtained was isolated by centrifugation, washed by Soxhlet extraction with acetone and dried in vacuo. Yield 32%, 17 mg; $C_8H_4CoS_6$ (351.41: calcd. C 27.34, H 1.15, S 54.74; found C 27.11, H 1.07, S 53.15.

Platinum(IV) Bis(3,4-thiophenedithiolate), $Pt(tpdt)_2$ (11): Using as starting material **5** and following the same procedure used for **10**, the neutral species was obtained as a fine-powdered dark solid. Yield 28%, 20 mg; $C_8H_4PtS_6$ (487.57): calcd. C 19.71, H 0.83, S 39.45; found C 19.03, H 0.95, S 37.14.

Cobalt(IV), Bis(2,3-thiophenedithiolate), $Co(\alpha\text{-}tpdt)_2$ (12): Using as starting material **7** and following the same procedure used for **10**, the neutral species was obtained as a fine-powdered dark solid. Yield 45%, 24 mg; $C_8H_4CoS_6$ (351.41): calcd. C 27.34, H 1.15, S 54.74; found C 26.94, H 1.14, S 53.04.

Platinum(IV), Bis(2,3-thiophenedithiolate), $Pt(\alpha\text{-}tpdt)_2$ (13): Using as starting material **8** and following the same procedure used for **10**, the neutral species was obtained as a fine-powdered dark solid. Yield 37%, 27 mg, $C_8H_4PtS_6$ (487.57): calcd. C 19.71, H 0.83, N 0.00, S 39.45; found C 19.94, H 1.14, N 0.00, S 35.83.

X-ray Crystallographic Study: The data collection was performed at room temperature for all compounds on an Enraf–Nonius CAD4 diffractometer equipped with a graphite monochromatised Mo-K_α radiation (λ = 0.71069 Å) in the ω-2θ-scan mode, except in the case of compound **5**, where data were collected at 120 K with a Nonius KAPPA CCD using a Mo rotating anode using φ- and ω-scans. Data collection and refinement details are presented in Table 1.

The structures were solved by direct methods using SIR97[14] and refined by full-matrix least-squares methods using the program SHELXL97[15] and the winGX software package.[16] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were placed in idealised positions and allowed to refine riding on the parent C atom. Molecular graphics were prepared using ORTEP 3[17] and SCHAKAL-97.[18] Crystal data and structure refinement are summarised in Tables 5 and 6. Experimental details, atomic coordinates, and bond lengths and angles have been deposited in the Cambridge Crystallographic Data Centre (CCDC). CCDC-263500–263505 for compounds **4**–**9** contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the CCDC via www.ccdc.cam.ac.uk/data_request/cif.

Self-Assembly by Ligand-Exchange Reactions

Dillip Kumar Chand,*[a] Ramalingam Manivannan,[a] Himansu S. Sahoo,[a] and Kandasamy Jeyakumar[a]

Dedicated to Prof. Makoto Fujita on his 47th birthday

Keywords: Cage compounds / NMR spectroscopy / Metallacycles / Palladium / Ligand exchange

An interesting phenomenon of ligand exchange is observed in the DMSO solution of certain self-assembled molecules generated from *cis*-protected Pd^{II} and organic ligands. Upon heating, assemblies such as $[\{Pd(en)\}_x(ligand)_y](NO_3)_{2x}$ change to $[Pd_m(ligand)_n](NO_3)_{2m}$ and $[Pd(en)_2](NO_3)_2$. The change is also possible at room temperature when 0.5 equiv. $Pd(en)(NO_3)_2$ is added in excess to the system. The transformation is incomplete when the ligand moiety is monodentate in nature, for example in the case of 4-phenylpyridine. However, multinuclear assemblies containing nonchelating, polydentate ligands used in this study entirely favor the transformation. This process is not possible with some related Pt^{II} compounds.

Introduction

Creation of discrete and definite molecular architectures using organic ligands and selected metal ions through self-assembly has received much attention in organic synthesis because of the inherent simplicity of the method.[1,2] Self-assembled structures that would result from the complexation of a metal ion with a designed ligand may be assumed to be fixed a priori.[2] However, the mode of arrangement of the participating components depends on the steric requirements, thermodynamic stability, and entropy cost of the final assembly, as well as on the guest molecule, if any, and on the solvent.[3] In the solution state, two or more isomers or structures may coexist in dynamic equilibrium depending upon the directionality/flexibility of the ligand, in particular when the metal–ligand bond of the system is labile in nature.[4] It has also been shown that it is possible in certain cases to shift such equilibria to favor one of the compounds as a single/major product by suitably controlling parameters like solvent, guest molecule, temperature, time etc.[5]

The construction of self-assembled structures under the influence of stereochemical details of the complex and the choice of pyridine-appended ligands have been studied well by Fujita[2e] and Stang[2c] in the coordination chemistry of palladium(II). Polynuclear complexes $(M_xL_y)^{n+}$ of different geometries and conformations have also been realized by the use of polydentate nonchelating ligands. Usually *cis*-protected Pd^{II}, e.g., $Pd(en)^{2+}$, has been employed,[2c,2e] and the area has been a subject of extensive study and review. Such systems require control over only two coordination sites of each metal center involved, because the other two positions are already protected. In contrast, there exist very few examples[6] of assemblies achieved from Pd^{II} where all four sites are available for coordination during the assembly process. The use of particular ligands for both *cis*-protected Pd^{II} and unprotected Pd^{II} is published as a comparative study.[6e]

Results and Discussion

We are interested in the dynamic nature of the Pd^{II}-driven self-assembly processes. The ligand **1** (Figure 1) and *cis*-protected $Pd(en)(NO_3)_2$ at a ratio of 1:1 form a binuclear M_2L_2 macrocycle, $[\{Pd(en)\}_2(\mathbf{1})_2](NO_3)_4$ (**5**), as a major product along with a tetranuclear macrocyclic compound, $[\{Pd(en)\}_4(\mathbf{1})_4](NO_3)_8$ (**6**) (Scheme 1), as reported earlier.[6e] The assembly process was performed in DMSO by stirring at 60 °C for 10 min. While taking another look at the dynamic equilibrium of the two self-assembled structures (**5** and **6**) resulting from ligand **1** and *cis*-protected Pd^{II}, we observed an interesting phenomenon. Our effort was to shift the equilibrium in favor of one of these two structures. When temperature was chosen as a parameter to vary, instead of the possible shift in equilibrium, we observed scrambling of the assemblies, giving rise to yet other

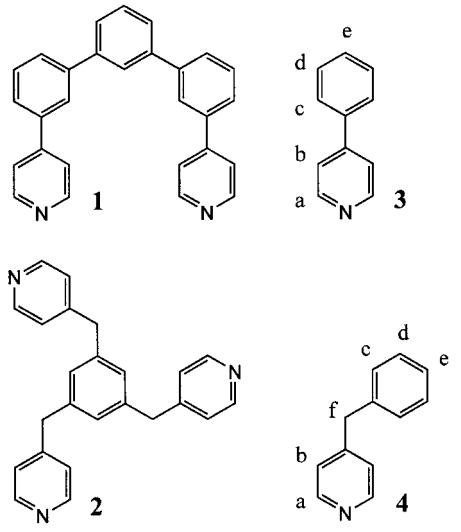

Figure 1. Structures of the ligands **1**, **2**, **3**, and **4**.

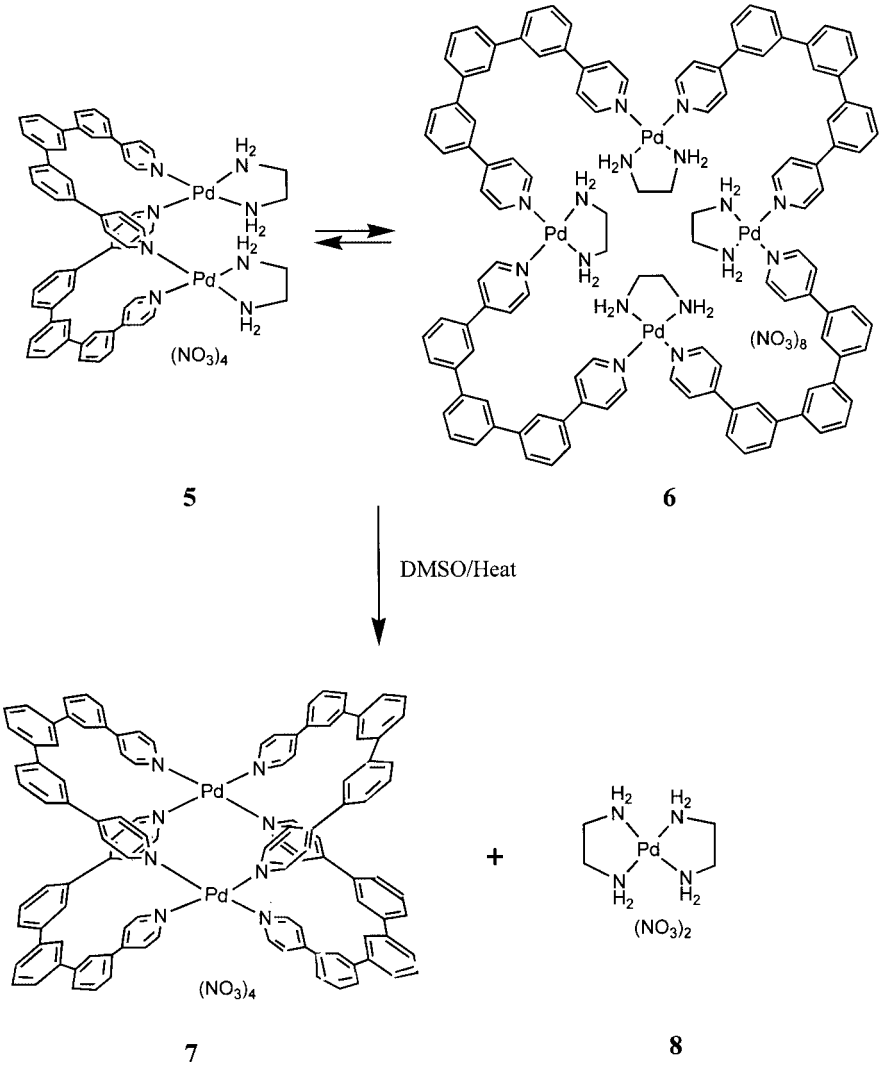
assemblies (Scheme 1). Scrambling is also observed in some other related systems and is discussed in this report.

It is observed here that for the complexation of **1** with *cis*-protected $Pd(en)(NO_3)_2$, heating or stirring is not required, and the system in DMSO gives rise to assemblies spontaneously at room temperature as a result of the simple combination of the components. The two compounds **5** and **6** are of course in dynamic equilibrium (Scheme 1), as is evident from the concentration-dependent nature of the equilibrium. Upon increasing the concentration, the bigger molecule **6** is favored, and with decreasing concentration, the smaller molecule **5** is favored. However, it was not possible to push the equilibrium of **5** and **6** exclusively in favor of one compound by varying the concentration.

In order to shift the equilibrium in favor of one of the assemblies we decided to vary other possible parameters. What is more interesting is the effect of heat on the dynamic equilibrium behavior. Experiments were performed at different temperatures; around 90 °C was found to be a good temperature for studying this process.[7] At a particular con-



Scheme 1. Transformation of a dynamic equilibrium of **5** and **6** to a mixture of **7** and **8** occurred by ligand exchange (see ref.[6b,6e] for the synthesis of **5**, **6**, and **7**).

centration, with the increase in temperature (heating) we could not observe a shift of equilibrium in [D_6]DMSO. Rather, new peaks were observed in the proton NMR at the expense of **5** and **6**. The assemblies were identified in due course as the M_2L_4 assembly $[(Pd)_2(\mathbf{2})_4](NO_3)_4$ (**7**)[6b] and $[Pd(en)_2](NO_3)_2$ (**8**).[8] The proportion of the complexes at any given time is calculated from the integration ratio of the corresponding py_α protons as observed in their ^1H NMR spectra (e.g., Figure 2). It is worthwhile to mention here that compound **7** can be prepared by combining the ligand **1** and $Pd(NO_3)_2$ at a ratio of 2:1 in DMSO and stirring at 90 °C for 10 min. Thus, a mixture of **5** and **6** changes, upon heating, to a mixture of **7** and **8**. At an intermediate stage all four compounds **5**, **6**, **7**, and **8** coexist, and finally only **7** and **8** are detected (Figure 2). We attribute such an observation to a ligand exchange around the metal centers promoted by the increase in temperature and the solvent.

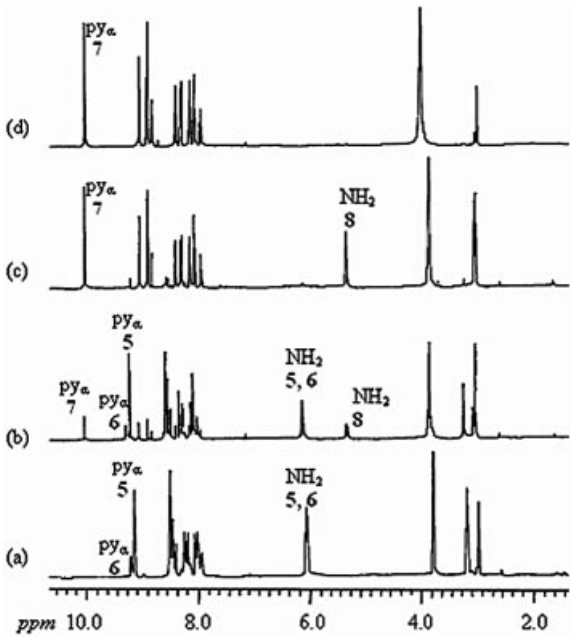

Figure 2. ^1H NMR spectra of a dynamic equilibrium mixture of $[\{Pd(en)\}_2(\mathbf{1})_2](NO_3)_4$ (**5**) and $[\{Pd(en)\}_4(\mathbf{2})_4](NO_3)_8$ (**6**), and the evolution, after this mixture was heated at 90 °C in [D_6]DMSO, of a mixture of $[(Pd)_2(\mathbf{2})_4](NO_3)_4$ (**7**) and $[Pd(en)_2](NO_3)_2$ (**8**) due to ligand exchange. NMR peaks are due to (a) **5** and **6** at t = 0 h (ref. [6e]); (b) **5**, **6**, **7**, and **8** at t = 6 h, an intermediate stage; (c) **7** and **8** at t = 48 h, completed scrambling; and (d) pure **7** (ref. [6e]) for comparison.

Another system considered was the assembly from ligand **2**. Ligand **2** and $Pd(en)(NO_3)_2$, at a ratio of 2:3, provide an M_3L_2 compositional assembly $[\{Pd(en)\}_3(\mathbf{2})_2](NO_3)_6$ (**9**) along with a mixture of other oligomeric compounds[9] in aqueous[5b] or DMSO solution.[6e] The assembly of ligand **2** with $Pd(NO_3)_2$ at a ratio of 8:6 gives a designed M_6L_8 molecular sphere, $[(Pd)_6(\mathbf{2})_8](NO_3)_{12}$ (**10**).[6d] As the scrambling of the ligand described (vide supra) for the ligand system **1** seemed interesting, the ligand system **2** was subjected to a similar set of experiments. A mixture of **9** and its oligomers, existing in dynamic equilibrium, was heated in [D_6]-DMSO, with the expectation of forming **10** and **8**. Once again, ligand exchange was observed around the Pd^{II} centers, and the dynamic equilibrium was transformed completely to a mixture of **10** and **8** (Scheme 2).

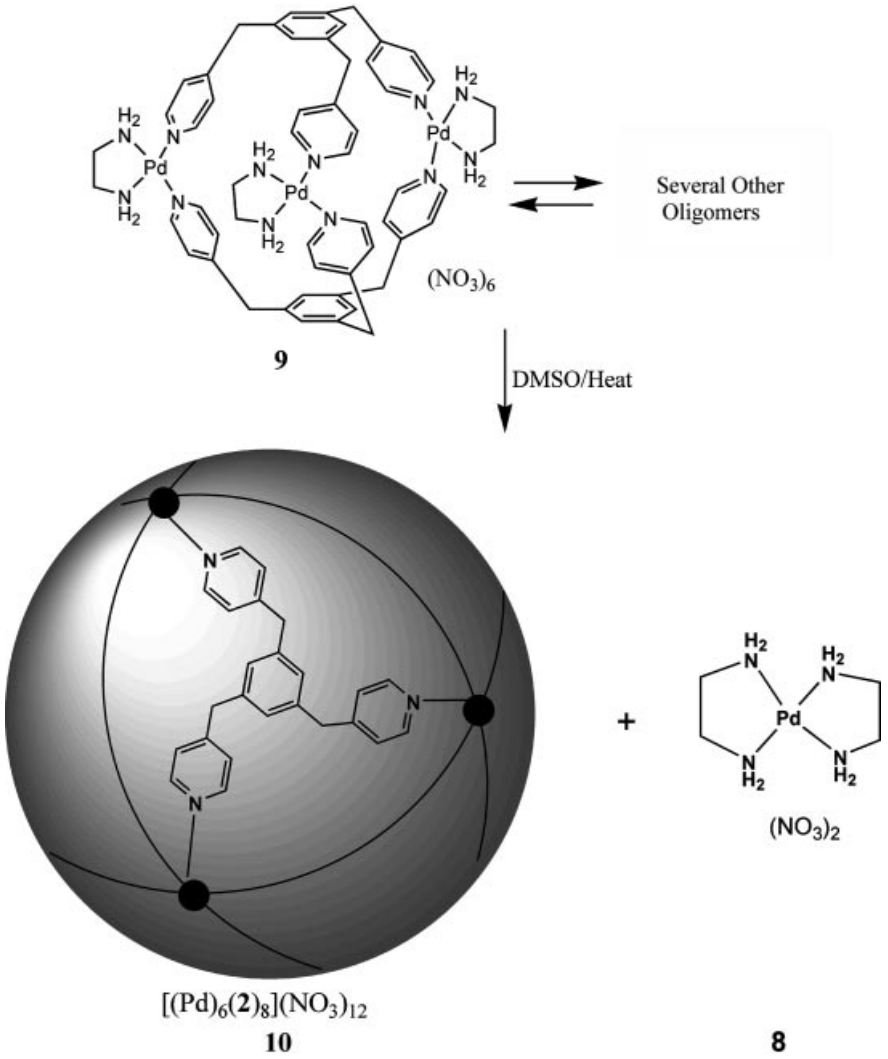
In the ligand-exchange process observed in this work, multinuclear assemblies containing *cis*-protected Pd^{II} centers, i.e. $[\{Pd(en)\}_x(ligand)_y](NO_3)_{2x}$, change to multinuclear assemblies containing simple Pd^{II} centers, i.e. $[Pd_m(ligand)_n](NO_3)_{2m}$, along with $[Pd(en)_2](NO_3)_2$. When the total number of Pd^{II} ions per molecule in the resulting assembly is "m" then it is associated with "m" numbers of $[Pd(en)_2](NO_3)_2$ molecules.

So far, we have discussed the findings with the polydentate nonchelating ligands **1** and **2**. An immediate comparison is necessary with a monodentate ligand reminiscent of these ligands. Thus 4-phenylpyridine (**3**) and 4-benzylpyridine (**4**) (Figure 1) were used for a similar study. The ligands **3** and **4** being monodentate, their complexes with *cis*-protected Pd^{II} and unprotected Pd^{II} are only mononuclear, and the synthesis of these new complexes (**11**–**14**) is described in this work. The complex $[Pd(en)(\mathbf{3})_2](NO_3)_2$ (**11**) was expected to give $[(Pd)(\mathbf{3})_4](NO_3)_2$ (**12**) and $[Pd(en)_2](NO_3)_2$ (**8**) as before upon heating (Scheme 3). This time the expected transformation proceeded, but not to completion (Figure 3, Figure 4). Structure **11** remained in a dynamic equilibrium with a mixture of **12** and **8**. A similar result was obtained with the ligand system **4**. Here $[Pd(en)(\mathbf{4})_2](NO_3)_2$ (**13**) remained in a dynamic equilibrium with a mixture of $[(Pd)(\mathbf{4})_4](NO_3)_2$ (**14**) and **8**.

Comparison of the scrambling process observed with the different ligand systems presented in this work reveals the following points. When $[\{Pd(en)\}_x(ligand)_y](NO_3)_{2x}$, having a Pd concentration of 10 mM is heated, the speed at which the scrambling proceeds to give the resulting assemblies depends upon the ligand of choice. Probably the process is also controlled by the composition and thermodynamic stability of the concerned self-assemblies. The ligand system **2** leads to the final stage of the process very quickly in 12 h, while **1** requires more than 2 days (Figure 4). The ligands **3** and **4** also form the expected new assemblies initially; however, after a certain amount is formed (about 18–20% of the ligand in the new assembly), a dynamic equilibrium is established, and the process is incomplete.

Some experiments were performed in [D_6]DMSO to understand the stability vs. lability of the complexes through proton NMR studies. When the required amount of ethylene diamine was added to any of the Pd^{II} complexes **5**–**7** or **9**–**14**, in each case the Pd^{II} ion was sequestered as $[Pd(en)_2](NO_3)_2$ (**8**) immediately, and the corresponding ligands were released. However, addition of any of the ligands **1**–**4** to **8** caused no changes. This indicates that the above-mentioned acyclic or nonchelated cyclic complexes are kinetically labile. However, the chelated complex **8** behaved in a kinetically nonlabile manner under the conditions employed. To throw some light on stability, the following experiments were performed. Complex **8** was added to a solution of assembly **7**. Compound **7** remained un-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 2. Transformation of a dynamic equilibrium of **9** and its oligomers to a mixture of **10** and **8** occurred due to ligand exchange (see ref. [5b] for the synthesis of **9** and ref. [6d] and [6e] for that of **10**).

changed as observed from the proton NMR of the mixture. A similar experiment was performed by the addition of **8** to **10**; the result was that **10** also remained unchanged. However, when **8** was combined with a solution of **12**, a considerable amount of **11** was generated immediately at room temperature, and once again, an equilibrium mixture of **11**, **12**, and **8** was observed. In line with the behavior of **12**, the complex **14**, upon being combined with **8**, also generated **13**. Thus, it is possible to suggest that **7** and **10** are, although kinetically labile, still comparatively stable enough to drive the ligand-exchange reaction for the ligand systems **1** and **2** and completely in favor of **7** and **10**, respectively. As for **12** and **14**, these two complexes are labile; however thermodynamically not stable enough to drive the equilibrium completely in the forward direction. In addition, the presence of **12** or **14** with **8** allows ligand exchange around the Pd^{II} center of relatively inert **8**. Hence, there exists a final equilibrium as a result of the interplay of all participating molecules.

Another control experiment was performed to find out whether the dissociation of $Pd(en)^{2+}$ and ligands from $[\{Pd(en)\}_x(ligand)_y](NO_3)_{2x}$ occurred and whether the dissociated $Pd(en)^{2+}$ was involved in promoting the ligand-exchange process observed. Thus we added a 0.5-equiv. excess of $Pd(en)(NO_3)_2$ to each one of the systems and found that the speed of scrambling was increased in the case of the ligand systems **1** and **2**. Interestingly, the ligand exchange could be observed in this situation even at room temperature. However, no detectable increase in speed was observed in the cases of **3** or **4** when 0.5 equiv. excess of $Pd(en)(NO_3)_2$ was added.

As the *trans*-effect is important in the chemistry of Pt^{II}, we checked the possibility of similar scrambling phenomena in Pt^{II}-driven self-assemblies. When $[\{Pt(en)\}_x(\mathbf{2})_y](NO_3)_{2x}$ assemblies were heated in $[D_6]$DMSO, we could not observe the formation of any trace of $[(Pt)_6(\mathbf{2})_8](NO_3)_{12}$; rather the system decomposed to unidentified products upon prolonged heating.[10] The kinetic inertness of the Pt–N bond compared to the lability of the Pd–N bond[11] suggests that self-correction is inefficient in the Pt^{II} system at the given reaction conditions in this work to give discrete products through a ligand-exchange pathway.

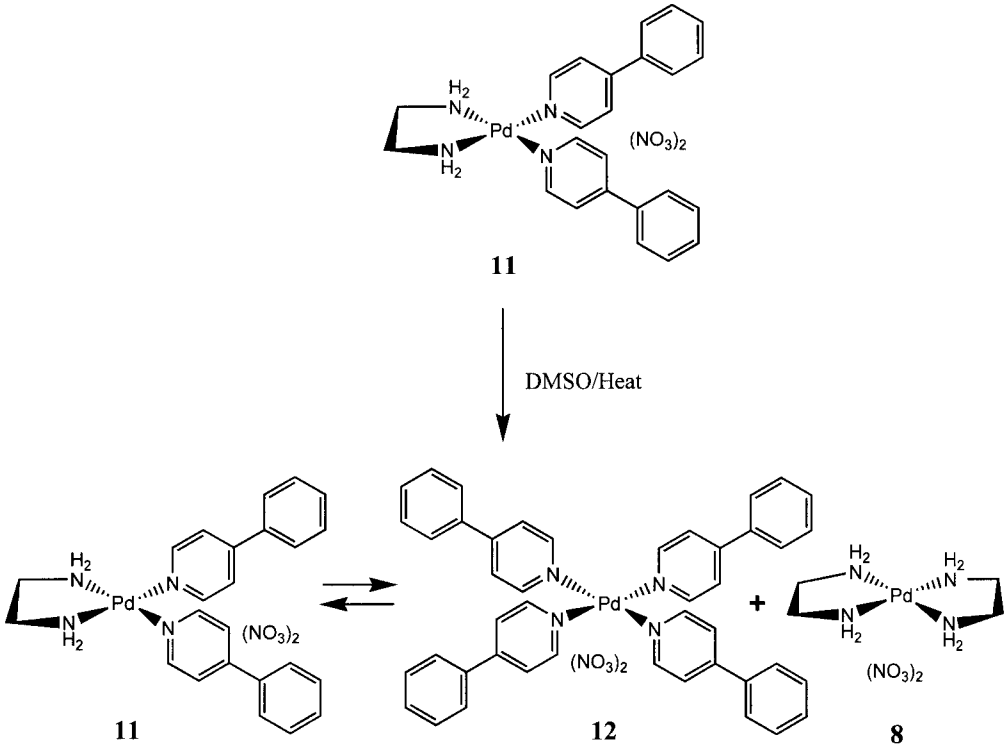

Scheme 3. Dynamic equilibrium of **11** and a mixture of **12** and **8** resulting from ligand exchange (approximately 18% of the ligand is present in **12** and 82% in **11**).

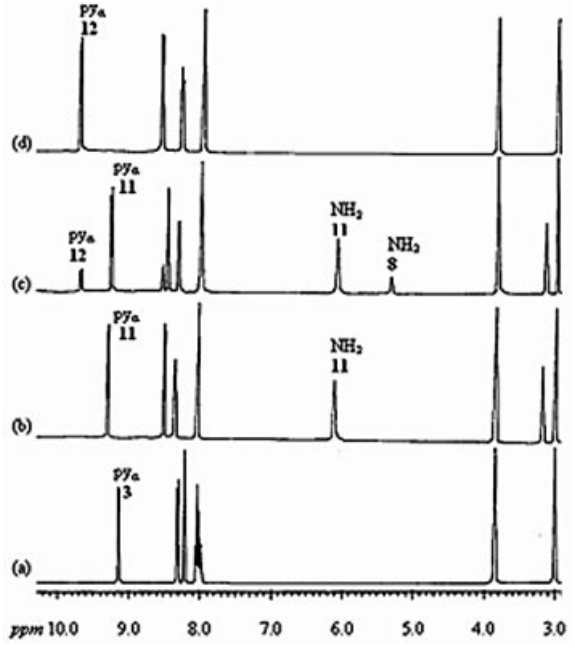

Figure 3. ^{1}H NMR spectra in [D$_6$]DMSO for (a) ligand **3**; (b) [Pd(en)(**3**)$_2$](NO$_3$)$_2$ (**11**); (c) the final equilibrium mixture of [Pd(en)(**3**)$_2$](NO$_3$)$_2$ (**11**), [Pd(**3**)$_4$](NO$_3$)$_2$ (**12**), and [Pd(en)$_2$](NO$_3$)$_2$ (**8**) obtained by heating a solution of **11** at 90 °C for 10 h; and (d) pure **12**.

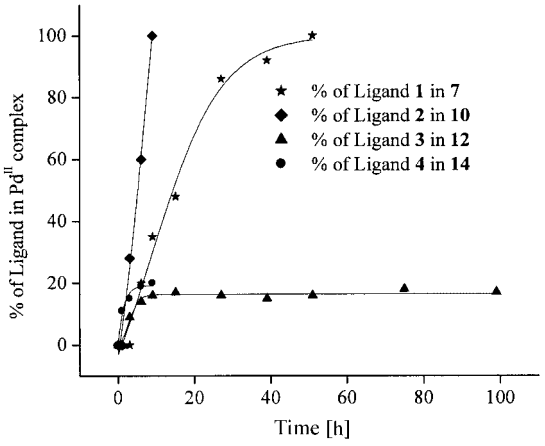

Figure 4. Percentage of ligand in the Pd^{II} complex, generated as a function of time, when [{Pd(en)}$_x$(ligand)$_y$](NO$_3$)$_{2x}$ is heated at 90 °C.

In conclusion, the result opens up a concern in Pd^{II} chemistry for further study to give more generalization on the ligand-exchange process. Consideration of other parameters like the solvent, the substituent on the ligand as well as that on the protecting group is certainly required to enrich the chemistry and explain the observations.

Experimental Section

The ligands **1** and **2** and complexes **5**–**10** have been synthesized by the methods reported earlier,[6e,8] while **3** and **4** are obtained from Lancaster. The complexes **11**–**14** are new and reported here. The downfield shift of the pyridine protons in **11**–**14** are attributed to complexation with Pd^{II}; the nature of the shift is in line with other related complexes. Deuterated solvent ([D$_6$]DMSO) was acquired from Aldrich and used as such for the complexation reactions for

NMR study. ^{1}H NMR spectroscopic data were obtained with a Bruker 400 MHz NMR spectrometer using external TMS in $CDCl_3$ as the reference. The assemblies of general formula $[\{Pd(en)\}_x(ligand)_y](NO_3)_{2x}$ prepared in [D$_6$]DMSO were heated at 90 °C in NMR tubes. The desired temperature was achieved by immersing the tubes in a constant-temperature bath. The sample tubes were taken out of the bath at chosen intervals of time, and ^{1}H NMR spectra are recorded at room temperature. Formation of $[Pd_m(ligand)_n](NO_3)_{2m}$ and $[Pd(en)_2](NO_3)_2$ in the reaction mixture was confirmed by comparing with the data of the corresponding pure samples. The proportion of the assemblies of interest was calculated from the integration ratio of the Py_α protons in question. Proton NMR spectroscopic data of the ligands **3** and **4** and of the complex $[Pd(en)_2](NO_3)_2$ (**8**) in [D$_6$]DMSO was required for this work and is reported here ^{1}H NMR (400 MHz, [D$_6$]DMSO, TMS): For **3**: δ = 9.136 (d, 2 H, a), 8.306 (d, 2 H, b), 8.212 (dd, 2 H, c), 8.049–7.960 (m, 3 H, d and e) ppm; for **4**: δ = 8.961 (broad, 2 H, a), 7.79–7.71(broad m, 7 H, b,c,d, and e), 4.440 (s, 2 H, f) ppm; for **8:** δ = 5.360 (s, 8 H, CH_2), 3.00 (s, 8 H, NH_2, merged with the residual solvent peaks) ppm.

Synthesis of 11–14

$[Pd(en)(3)_2](NO_3)_2$ (11): To a solution of $Pd(en)(NO_3)_2$, (14.5 mg, 0.05 mmol) in MeCN (5 mL) was added the ligand **3** (15.5 mg, 0.1 mmol). The mixture was stirred to get a clear solution. Subsequent addition of diethyl ether precipitated the complex **11** as a white solid (24 mg, 80%). ^{1}H NMR (400 MHz, [D$_6$]DMSO, TMS): δ = 9.333 (d, 4 H, a), 8.540 (d, 4 H, b), 8.388 (m, 4 H, c), 8.062 (m, 6 H, d and e), 6.130 (s, 4 H, NH_2), 3.189 (s, 4 H, CH_2) ppm. $C_{24}H_{26}N_6O_6Pd$: calcd. C 47.97, H 4.36, N 13.99; found C 48.08, H 4.46, N 13.78.

$[Pd(en)(4)_2](NO_3)_2$ (12): Following the synthesis of **11**, to a solution of $Pd(en)(NO_3)_2$, (14.5 mg, 0.05 mmol) in MeCN (5 mL) was added the ligand **4** (16.9 mg, 0.1 mmol). Subsequent addition of diethyl ether precipitated a white solid, the complex **12** (26 mg, 83%). ^{1}H NMR (400 MHz, [D$_6$]DMSO, TMS): δ = 9.097 (d, 4 H, a), 8.010 (d, 4 H, b), 7.810–7.744 (m, 10 H, c, d and e), 5.980 (s, 4 H, NH_2), 4.527 (s, 4 H, f), 3.103 (s, 4 H, CH_2) ppm. $C_{26}H_{30}N_6O_6Pd$: calcd. C 49.65, H 4.81, N 13.36; found C 49.74, H 4.99, N 13.58.

$[Pd(3)_4](NO_3)_2$ (13): To a solution of $Pd(NO_3)_2$, (11.7 mg, 0.05 mmol) in MeCN (5 mL) was added the ligand **3** (31.0 mg, 0.2 mmol), whereupon a white solid was precipitated out. The mixture was heated for a further period of 10 min at 90 °C, and the solid was separated (36 mg, 85%). ^{1}H NMR (400 MHz, [D$_6$] DMSO, TMS): δ = 9.758 (d, 8 H, a), 8.608 (d, 4 H, b), 8.345–8.322 (m, 8 H, c), 8.063–8.021 (m, 12 H, d and e) ppm. $C_{44}H_{36}N_6O_6Pd$: calcd. C 62.08, H 4.26, N 9.87; found C 62.26, H 4.30, N 9.71.

$[Pd(4)_4](NO_3)_2$ (14): To a solution of $Pd(NO_3)_2$, (11.7 mg, 0.05 mmol) in MeCN (5 mL) was added the ligand **4** (33.8 mg, 0.2 mmol), whereupon a white solid precipitated out. The mixture was heated for a further period of 10 min at 90 °C, and the solid was separated (35 mg, 78%). ^{1}H NMR (400 MHz, [D$_6$]DMSO, TMS): δ = 9.461 (d, 8 H, a), 7.956 (d, 8 H, b), 7.791–7.664 (m, 20 H, c, d and e), 4.462 (s, 8 H, f) ppm. $C_{48}H_{44}N_6O_6Pd$: calcd. C 63.54, H 4.89, N 9.26; found C 63.39, H 5.02, N 9.11.

Acknowledgments

This study was supported by a grant in aid for scientific research from the Department of Science and Technology (DST), New Delhi, India (No.SR/S1/IC-18/2003). We highly appreciate the NMR instrumentation facility provided by the DST under the FIST program to the Department of Chemistry, IIT Madras. Authors also acknowledge the help of Mr. Mohan in recording the ^{1}H NMR spectra.

[7] At higher temperatures, e.g., 120 °C, the process is faster and sometimes causes decomposition on prolonged heating. At lower temperatures, e.g., 60 °C, the process is slow, and hence more time is required for the study.

by using a suitable template, e.g., 4-methoxyphenyl acetate, as described in ref.[5b].

[10] When ligand **2** was treated with $Pt(NO_3)_2$ and heated at 90 °C for 10 min, it gave a complicated mixture, unlike the complexation of **2** with $Pd(NO_3)_2$. The suitable conditions for achieving $[(Pt)_6(\mathbf{2})_8](NO_3)_{12}$ from **2** and $Pt(NO_3)_2$ were found to be heating at 120 °C for 24 h.

[11] Substitution on Pd^{II} center shows 10^5-fold greater reactivity compared to Pt^{II}. Atom Transfer Radical Additions with the Cationic Half-Sandwich Complex $[Cp^*Ru(PPh_3)_2(CH_3CN)]OTf$

Laurent Quebatte,[a] Rosario Scopelliti,[a][‡] and Kay Severin*[a]

Keywords: ATRA reaction / Homogeneous catalysis / Radical reaction / Ruthenium

The cationic ruthenium half-sandwich complex $[Cp^*Ru(PPh_3)_2(CH_3CN)][OTf]$ (**2**) ($Cp^* = \eta^5$-C_5Me_5, OTf = SO_3CF_3) was synthesized by reduction of $[Cp^*RuCl_2]_2$ with zinc in the presence of NaOTf and subsequent reaction with PPh_3. When NaOTf was omitted, the corresponding tetrachlorozincate salts were obtained. Complex **2**, as well as the salts $[Cp^*Ru(CH_3CN)_3]_2[ZnCl_4]$ (**3**) and $[Cp^*Ru(PPh_3)_2(CH_3CN)]_2[ZnCl_4]$ (**4**), were characterized by single-crystal X-ray analysis. Complex **2** proved to be a potent catalyst for the atom transfer radical addition of CCl_4 and $CHCl_3$ to terminal olefins, displaying a performance superior to that of the previously described neutral catalyst $[Cp^*RuCl(PPh_3)_2]$. For the addition of $CHCl_3$ to styrene, a total turnover number of 890 was achieved.

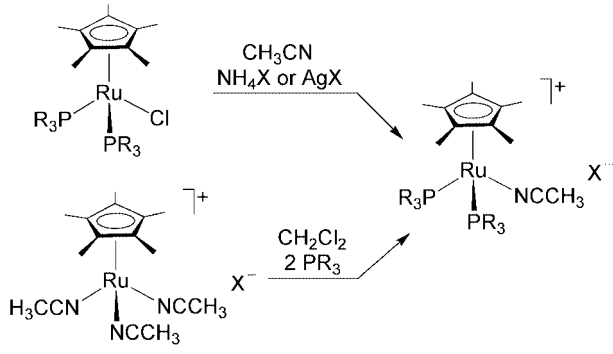
Introduction

The atom transfer radical addition (ATRA) of polyhalogenated compounds to olefins ("Kharasch reaction")[1] is a versatile method for C–C bond formation and has found several applications in organic synthesis.[2] In 1973, it was reported that the complex $[RuCl_2(PPh_3)_3]$ is able to efficiently catalyze this type of reaction and it was subsequently used as the catalyst of choice for more than 20 years.[3] Over the last 6 years, however, several new ruthenium-based catalysts with superior performance have been reported.[4] Among these, the complex $[Cp^*RuCl(PPh_3)_2]$ (**1**) is of special interest since it is one of the few catalysts, which allows to carry out the addition of CCl_4 and $CHCl_3$ to olefins at ambient temperatures.[5,6] Despite its high activity, complex **1** suffers from poor long term stability, a characteristic shared by many other highly active catalysts for the Kharasch reaction.[4]

Nagashima et al. have reported that the ATRA activity of the dinuclear complex $[Cp^*Ru\{\mu_2$-*i*PrN=C(Me)-N*i*Pr$\}RuClCp^*]$ could be increased by transforming it into a cationic species using $NaPF_6$ or $NaBPh_4$.[7] Similarly, the activity of ruthenium chloro catalysts for the closely related atom transfer radical polymerization (ATRP)[8] could be enhanced by chloride abstraction with silver salts.[9] For Ru vinylidene catalysts, on the other hand, it was reported that the abstraction of a chloro ligand lead to a decrease in ATRA activity.[10] In the following we show that the cationic complex $[Cp^*Ru(PPh_3)_2(CH_3CN)][OTf]$ (**2**) is a very potent catalyst for ATRA reactions. Its stability is significantly higher than that of the neutral counterpart **1**. Consequently, good turnover numbers (TONs) were observed, even for "difficult" reactions such as the addition of $CHCl_3$ to styrene.

Results and Discussion

Cationic complexes of the general formula $[Cp^*Ru(PR_3)_2(CH_3CN)]X$ (X^- = weakly coordinating anion) have been obtained by reaction of complex **1** with MX in acetonitrile ($M^+ = Ag^+$, NH_4^+)[11] or by reaction of $[Cp^*Ru(CH_3CN)_3]X$ with PR_3 in CH_2Cl_2 (Scheme 1).[12] For the synthesis of the complex $[Cp^*Ru(PPh_3)_2(CH_3CN)][OTf]$ (**2**), we decided to use the latter pathway since the trisacetonitrile complex $[Cp^*Ru(CH_3CN)_3]X$ is easily accessible by reduction of $[Cp^*RhCl_2]_n$ with zinc in acetonitrile in the presence of MX salts.[12]



Scheme 1. Synthesis of cationic complexes of the general formula $[Cp^*Ru(PR_3)_2(CH_3CN)]X$ (X^- = weakly coordinating anion).

Following this synthetic route it was possible to prepare the cationic complex **2** in 95% yield by reaction of

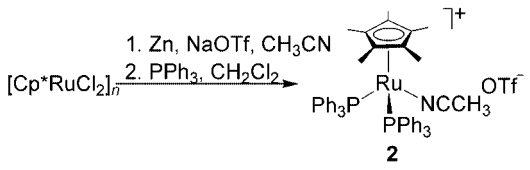
$[Cp^*RuCl_2]_2$ with zinc in acetonitrile in the presence of NaOTf and direct conversion of the product with two equivalents of PPh_3 (Scheme 2). Complex **2** displays a good solubility in polar organic solvents such as THF, dichloromethane and chloroform, and a moderate solubility in toluene. The identity of **2** was confirmed by NMR spectroscopy, elemental analysis and single-crystal X-ray analysis (Figure 1).



Scheme 2. Synthesis of complex **2**.

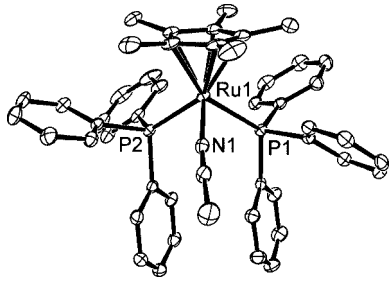


Figure 1. ORTEP[22] drawing of the molecular structure of **2** in the crystal. The OTf^- anion and the hydrogen atoms are omitted for clarity. Selected bond lengths [Å] and angles [°]: Ru1–N1 2.056(2), Ru1–P1 2.3709(6), Ru1–P2 2.3462(7); P2–Ru1–P1 99.41(2), N1–Ru1–P1 87.97(5), N1–Ru1–P2 87.95(6).

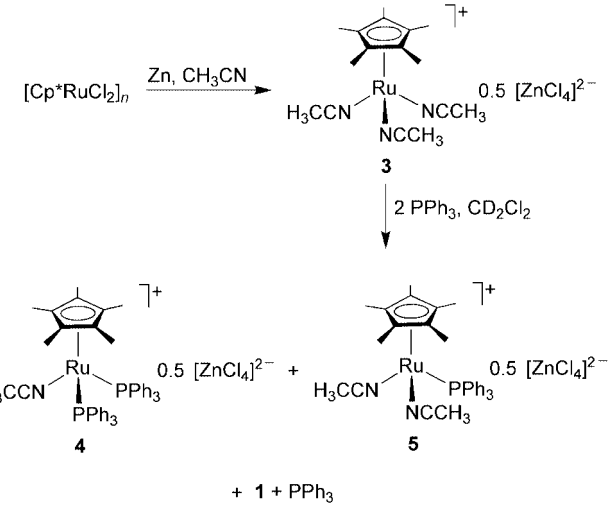
The cation of complex **2** displays the expected pianostool geometry. As a consequence of the steric demand of the triphenylphosphane ligands, the P–Ru–P angle [99.41(2)°] is larger than the N–Ru–P angles [N1–Ru1–P1 87.97(5)°; N1–Ru1–P2 87.95(6)°]. The Ru–P bond lengths [Ru1–P1 2.3709(6) Å, Ru1–P2 2.3462(7) Å] are similar to what has been found for the neutral complex **1**.[13]

In order to investigate the influence of the NaOTf salt during the synthesis of complex **2**, we have performed the reduction of $[Cp^*RuCl_2]_2$ with zinc in acetonitrile in the absence of this salt. The formation of a trisacetonitrile complex $[Cp^*Ru(CH_3CN)_3]^+$ (**3**) was observed but as the counterion, the tetrachlorozincate anion was formed as revealed by single-crystal X-ray analysis (Scheme 3, Figure 2). Complex **3** proved to be not suited for a clean synthesis of a bis(triphenylphosphane) adduct: when two equivalents of PPh_3 were added to a solution of **3** in CD_2Cl_2, the desired cationic bisadduct **4** was formed but along with the neutral complex **1**, the monoadduct **5**,[14,15] and free PPh_3 as evidenced by ^1H and ^{31}P NMR spectroscopy. From this mixture, it was possible to obtain single crystals of complex **4** by addition of pentane. A graphic representation of the structure of **4** is depicted in Figure 3.



Scheme 3. Synthesis of the tetrachlorozincate complex **3** and its reaction with PPh_3.

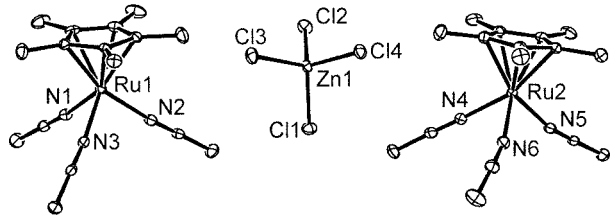


Figure 2. ORTEP[13] drawing of the molecular structure of **3** in the crystal. The hydrogen atoms are omitted for clarity. Selected bond lengths [Å] and angles [°]: Ru1–N1 2.095(2), Ru1–N2 2.108(2), Ru1–N3 2.103(2), Ru2–N4 2.110(2), Ru2–N5 2.102(2), Ru2–N6 2.109(2); N1–Ru1–N2 88.19(8), N1–Ru1–N3 84.67(8), N3–Ru1–N2 90.60(7), N5–Ru2–N4 90.84(8), N5–Ru2–N6 91.66(8), N–Ru2–N4 81.76(8).

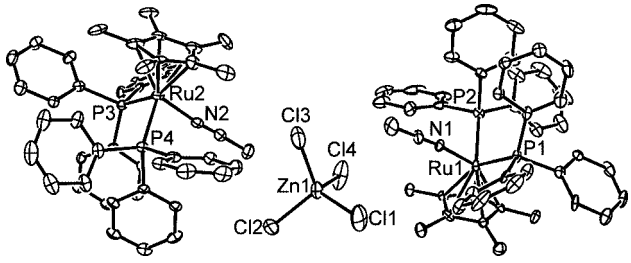

Figure 3. ORTEP[13] drawing of the molecular structure of **4** in the crystal. The hydrogen atoms and the solvent molecules ($3\times CH_2Cl_2$) are omitted for clarity. Selected bond lengths [Å] and angles [°]:Ru1–N1 2.037(6), Ru1–P1 2.3568(19), Ru1–P2 2.343(2), Ru2–N2 2.061(7), Ru2–P3 2.3556(19), Ru2–P4 2.346(2); N1–Ru1–P1 87.44(16), N1–Ru1–P2 88.12(18), P2–Ru1–P1 99.00(7), N2–Ru2–P4 89.28(18), N2–Ru2–P3 90.17(17), P4–Ru2–P3 97.19(7).

The bond lengths and angles found for the two crytallographically independent cations of complex **3** are very similar to those observed for other $[Cp^*Ru(CH_3CN)_3]^+$ complexes.[16] The N–Ru–N angles are close to 90°. The geometry of the cations can thus be described as pseudo-octahe-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

dral with the Cp* ligand occupying three facial coordination sites. As it was observed for complex **2**, the P–Ru–P angles of **4** [99.00(7) and 97.19(7)°] are larger than the P–Ru–N angles [P–Ru–N 87.44(16)–90.17(17)°].

To evaluate the ability of the cationic complex **2** to catalyze ATRA reactions, we first investigated the addition of CCl_4 to styrene at 60 °C using a molar ratio of **2**/styrene/CCl_4 = 1:300:432. The complete conversion of the olefin was observed within 2 h. For the neutral complex **1**, a conversion of 97% was reported after 5 h.[5] In order to obtain more information about differences in activity and stability of the catalysts **1** and **2**, we have investigated the time course of the reaction between styrene and CCl_4 at room temperature in chloroform with a molar ratio of Ru/styrene/CCl_4 = 1:300:600 (Figure 4). For reactions with the cationic catalyst **2**, a quantitative reaction was observed after ca. 4 h. For reactions catalyzed by the neutral complex **1**, on the other hand, a very fast product formation was found for the first 20 min, but then the rates dropped dramatically and the conversion reached a plateau at around 40%. When the solvent was changed to toluene and the CCl_4 concentration was reduced, an increased lifetime of the catalyst was observed but still the final conversion (60%) was lower than what was found for **2**. This data suggested that the neutral catalyst **1** shows a higher intrinsic activity than the cationic complex **2** but a significantly lower stability. This is in agreement with the observation of Simal et al. that complex **1** rapidly decomposed in presence of CCl_4: when 10 equivalents of CCl_4 were added to a solution of **1** in toluene at 20 °C, the complete conversion into a paramagnetic Ru^{III} compound occurred within 2 h.[5] When a similar experiment was performed with the cationic complex **2**, only 40% decomposition was observed after 2 h. For complex **1** it was suggested that PPh_3 dissociation is required to activate the catalyst.[5] This step is likely to be faster for the neutral complex **1** as compared to the cationic complex **2**, which may explain the higher initial activity of the former. The higher stability of the cationic complex **2**, on the other hand, may be due to a different activity of the Ru^{III} species formed by atom transfer but further investigations are needed to clarify this point.

The good performance of the cationic catalyst **2** was confirmed in other ATRA reactions (Table 1). As mentioned above, the reaction between styrene and CCl_4 could be completed within 5 h using 0.33 mol% of complex **2** at room temperature (entry 1). Using only 0.02 mol% catalyst, a total TON of 3050 was measured after 5 weeks.[17] A remarkably fast and clean reaction was observed with methyl methacrylate (MMA) and CCl_4 as the substrates (entry 2). After 2 h at room temperature, a yield of 93% was obtained. For the neutral catalyst **1**, for comparison, a yield of only 36% was found after 24 h.[5] The olefins *n*-butyl acrylate (entry 3) and 1-decene (entry 4) gave lower yields of 67 and 77%, respectively. For the former substrate, this was due to competing oligomerization reactions.

In order to perform ATRA reactions with the significantly less active substrate $CHCl_3$, the reaction temperature was increased to 40 °C and a catalyst concentration of 1 mol% was employed (entries 5–9). Under these conditions, catalyst **2** provided the chloroform adducts of the aromatic olefins styrene, *p*-chlorostyrene, and *p*-methoxystyrene with good yields (entries 5–7). A TON of 890 was obtained for the addition of $CHCl_3$ to styrene using 0.1 mol% of complex **2**. This is – to the best of our knowledge – the highest value ever reported for a ruthenium-based catalyst. For acrylate substrates, almost complete conversions were determined after 24 h. The yields of the desired addition products, however, were very modest due to competing polymerization reactions (entries 8 and 9).

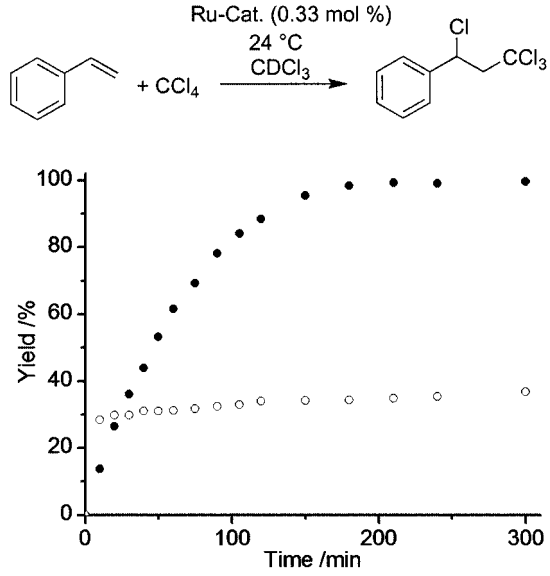

Figure 4. Time course of the reaction between styrene and CCl_4 catalyzed by complexes **1** (○) or **2** (●). Reaction conditions: Ru/styrene/CCl_4 = 1:300:600; solvent = $CDCl_3$; [Ru] = 4.6 mM; 24 °C. The yield is based on the formation of the product as determined by ^1H NMR spectroscopy.

Table 1. ATRA reactions catalyzed by complex **2**.[a]

Entry	Olefin	$CXCl_3$	*T* [°C]	*t* [h]	Conv. [%]	Yield [%]
1	styrene	CCl_4	24	5	100	97
2	methyl methacrylate	CCl_4	24	2	100	93
3	*n*-butyl acrylate	CCl_4	24	10	98	67
4	1-decene	CCl_4	40	24	80	77
5	styrene	$CHCl_3$	40	24	96	88
6	*p*-chlorostyrene	$CHCl_3$	40	48	95	92
7	*p*-methoxystyrene	$CHCl_3$	40	48	96	90
8	methyl methacrylate	$CHCl_3$	40	24	96	33
9	*n*-butyl acrylate	$CHCl_3$	40	24	99	15

[a] Reaction conditions: **2**/olefin/CCl_4 = 1:300:600, [**2**] = 4.6 mM, solvent: $CHCl_3$ or **2**/olefin/$CHCl_3$ = 1:100, [**2**] = 13.8 mM, solvent = $CHCl_3$. The conversion is based on the consumption of the olefin and the yield is based on the formation of the product as determined by GC or ^1H NMR spectroscopy after the time given.

Conclusions

Over the last few years, several highly active ruthenium-based catalysts for ATRA reactions have been described.[4]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

These catalysts allow to perform Kharasch reactions under very mild conditions with few side products. But still, there are some important challenges that need to be addressed by future research in this area. First of all, the mechanistic understanding of ruthenium-catalyzed ATRA reactions is rudimentary which hampers a more rational approach towards catalyst discovery (e.g. stereoselective catalysts) and optimization. Furthermore, catalyst stability is a problem for several of the newly developed complexes and apart from optimizing the reaction conditions (temperature, concentrations etc.), solutions to this dilemma are not evident. The results described above demonstrate that a simple modification such as the conversion of a chloro complex into a cationic acetonitrile complex may result in a significantly increased catalyst stability. Although it remains to be seen whether similar effects can be observed for other catalysts, it seems worthwhile to consider modifications of this type in future investigations.

Experimental Section

General: All reactions were performed under a dry dinitrogen atmosphere. The solvents and substrates were distilled from appropriate drying agents and stored under dinitrogen. Zn dust (< 10 micron; 98+%) was obtained from Aldrich, NaOTf (97+%) and PPh_3 (98.5+%) were obtained from Fluka. The complexes $[Cp^*RuCl_2]_2$[18] and $[Cp^*RuCl(PPh_3)_2]$[19] were prepared according to literature procedures. The ^1H, ^{13}C, and ^{31}P NMR spectra were recorded on a Bruker Advance DPX 400 spectrometer with the solvents as internal standards (^1H, ^{13}C) or a solution of H_3PO_4 in D_2O as external standard (^{31}P). All spectra were recorded at room temperature. GC-MS analyses were performed with a WCOT Fused Silica column (30 m) coupled to a Varian Saturn 2200 mass spectrometer.

Synthesis of Complex 2: Zn (0.2 g, 3.1 mmol) and NaOTf (84 mg, 488 μmol) were added to a solution of $[Cp^*RuCl_2]_2$ (100 mg, 162 μmol) in CH_3CN (5 mL) and the mixture was stirred for 2 h at room temperature. The yellow solution was filtered and the remaining Zn was washed with additional solvent (2 × 3 mL). After evaporation of the solvent, the resulting powder was dissolved in CH_2Cl_2 (5 mL), filtered, and the filtrate was washed with additional CH_2Cl_2 (2 × 3 mL). PPh_3 (256 mg, 976 μmol) was added to the combined solutions whilst stirring. After for 20 min, the mixture was concentrated to 2 mL and poured into a flask containing hexane (15 mL) to precipitate the product as a yellow powder, which was isolated by filtration, washed with hexane (2 × 3 mL), and dried under vacuum. Yield: 294 mg (95%). Single crystals were obtained by diffusion of pentane into a solution of **2** in CH_2Cl_2. ^1H NMR (400 MHz, CD_2Cl_2): δ = 1.13 (t, $^4J_{H,P}$ = 1.6 Hz, 15 H, Cp*), 2.65 (t, $^5J_{H,P}$ = 0.6 Hz, 3 H, CH_3CN), 7.13–7.46 (m, 30 H, Ph) ppm. ^{13}C NMR (101 MHz, CD_2Cl_2): δ = 5.9 (CH_3CN), 9.7 (CH_3, Cp*), 93.1 (C, Cp*), 128.2–134.2 (Ph), 129.3 (CH_3CN) ppm. ^{31}P NMR (162 MHz, CD_2Cl_2): δ = 42.20 ppm. Elemental analysis: calcd. (%) for $C_{49}H_{48}F_3NO_3P_2RuS \times H_2O$ (969.0): C 60.73, H 5.20, N 1.45; found C 60.84, H 5.17, N 1.56.

Synthesis of Complex 3: A solution of $[Cp^*RuCl_2]_2$ (736 mg, 1196 μmol) in CH_3CN (35 mL) was added Zn (5.0 g, 76.5 mmol) and stirred for 5 h at room temperature. The initial dark brown color changed to bright yellow. The solution was filtered and the remaining Zn was washed with additional solvent (15 mL). After evaporation of the solvent under vacuum, the resulting powder was suspended in Et_2O (15 mL), isolated by filtration, washed with additional Et_2O (15 mL) and dried under vacuum. Yield: 1030 mg (93%). Single crystals were obtained by slow diffusion of Et_2O into a solution of **3** in CH_3CN. ^1H NMR (400 MHz, CD_3CN): δ = 1.59 (s, 15 H, Cp*) ppm. ^{13}C NMR (101 MHz, CD_3CN): δ = 9.7 (CH_3, Cp*), 80.6 (C, Cp*) ppm. Elemental analysis: calcd. (%) for $C_{32}H_{48}Cl_4N_6Ru_2Zn \times 3/4\ CH_3CN$ (956.9): C 42.05, H 5.29, N 9.88; found: C 42.36, H 5.36, N 9.47.

Reaction of Complex 3 with PPh_3: PPh_3 (5.7 mg, 21.7 μmol) was added to a solution of complex **3** (5.0 mg, 5.4 μmol) in CD_2Cl_2 (500 μL). The resulting bright orange solution was analyzed by ^1H and ^{31}P NMR spectroscopy. Single crystals of **4** were obtained by slow diffusion of pentane into the reaction mixture. NMR [400 (^1H), 162 (^{31}P) MHz, aromatic protons, free CH_3CN and PPh_3 are omitted]: **4:** ^1H: δ = 1.13 (t, $^4J_{H,P}$ = 1.6 Hz, 15 H, Cp*), 2.87 (t, $^5J_{H,P}$ = 1.4 Hz, 3 H, CH_3CN) ppm. ^{31}P: δ = 43.0 ppm. **1:** ^1H: δ = 1.01 (t, $^4J_{H,P}$ = 1.4 Hz, 15 H, Cp*) ppm. ^{31}P: δ = 41.0 ppm. **5:** ^1H: δ = 1.42 (d, $^4J_{H,P}$ = 1.6 Hz, 15 H, Cp*), 2.22 (d, $^5J_{H,P}$ = 1.2 Hz, 6 H, CH_3CN) ppm. ^{31}P: δ = 48.9 ppm.

General Procedure for the ATRA of CCl_4 to Olefins: 1000 μL of a $CDCl_3$ stock solution of the olefin, CCl_4, and the internal standard mesitylene were added to a 1.5 mL vial containing the solid catalyst **2** (final conc.: [**2**] = 4.6 mM, [olefin] = 1.38 M, [CCl_4] = 2.76 M, [mesitylene] = 0.36 M). For 1-decene, the resulting solution was placed in an oil bath tempered at 40 °C. After the given time, a sample (20 μL) was removed from the reaction mixture, diluted with $CDCl_3$ (550 μL) and analyzed by ^1H NMR spectroscopy or gas chromatography. The kinetic experiments were performed in an analogous fashion by removing several samples at regular time intervals.

General Procedure for the ATRA of $CHCl_3$ to Olefins: 500 μL of a $CDCl_3$ stock solution of the olefin and the internal standard mesitylene were added to a 1.5 mL vial containing the solid catalyst **2** (final conc.: [**2**] = 13.8 mM, [olefin] = 1.38 M, [mesitylene] = 0.36 M). The resulting solution was placed in an oil bath tempered at 40 °C. After the given time, a sample (20 μL) was removed from the reaction mixture, diluted with $CDCl_3$ (550 μL) and analyzed by ^1H NMR spectroscopy or gas chromatography.

Decomposition Experiment: Complex **2** (2.8 mg, 2.9 μmol) and CCl_4 (2.9 μL, 30.1 μmol) were dissolved in CD_2Cl_2 (500 μL). The reaction followed by ^1H and ^{31}P NMR (400 and 162 MHz, respectively) for 10 h at 21 °C.

X-ray Crystallography: Details about the crystals and their structure refinement are listed in Table 2 and Table 3 whereas some relevant geometrical parameters are included into the picture captions. Data collection were performed at 140(2) K on a 4-circle goniometer having kappa geometry and equipped with an Oxford Diffraction KM4 Sapphire CCD. Data reduction was carried out with CrysAlis RED, release 1.7.0.[20] Absorption correction has been applied to all data sets. Structure solution and refinement were performed with the SHELXTL software package, release 5.1.[21] The structures were refined using the full-matrix least-squares on F^2 with all non-H atoms anisotropically defined. H atoms were placed in calculated positions using the "riding model". CCDC-268907–268909 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Synthesis, Crystal Structure, and Magnetic Properties of a Three-Dimensional Hydroxide Sulfate: $Mn_5(OH)_8SO_4$

Yong Fan,[a] Guang Hua Li,[a] Lei Yang,[a] Zhi Ming Zhang,[a] Yan Chen,[a] Tian You Song,*[a] and Shou Hua Feng*[a]

Keywords: Hydroxy sulfate / Hydrothermal synthesis / Magnetic properties / Thermodiffractometry / Structure elucidation

A 3D hydroxysulfate, $Mn_5(OH)_8SO_4$, formed from a mild hydrothermal reaction has been reported. The compound crystallizes in the triclinic system $P\bar{1}$ with cell parameters a = 7.5501(5) Å, b = 8.5558(6) Å, c = 8.6059(5) Å, α = 98.122(4)°, β = 102.370(4)°, γ = 99.646(4)°, V = 526.19(6) Å^3 and Z = 2. The crystal structure consists of a 3D framework with channels along the c-axis. In this structure, the manganese atoms in the distorted pentahedra and octahedra are interconnected by OH groups to form layers along the bc plane. These layers are further connected with MnO_5 distorted pentahedra, MnO_6 octahedra and $[SO4]^{2-}$ tetrahedra, resulting in a complicated network. The temperature dependence of the magnetic susceptibility shows a weak antiferromagnetic interaction in the compound.

Introduction

Recently, there has been growing interest in the study of structurally and chemically diverse microporous materials, especially those containing transition elements, because they have potential applications as ion exchangers, catalysts, and advanced materials with novel magnetic and electronic properties.[1–8] The discovery of structures with novel topologies and properties is dependent upon creative synthesis from combinations of tetrahedral anions and polyhedrally coordinated transition metal cations.[9–13] In these materials, anions such as phosphates, germanates, and arsenates are often involved as $[TO_4]$ units (T = tetrahedrally coordinated elements) of inorganic frameworks. Frameworks containing sulfate anions have been considerably less investigated, which is surprising since sulfates are known to promote a wide range of structural arrangements in inorganic solids.[14] From the synthetic chemistry point of view, transition-metal sulfates are very difficult to obtain as single crystals by hydrothermal techniques.

Since the pioneering works of Rao et al. some hybrid porous sulfates and inorganic sulfates containing transition elements have been reported. Wang et al. reported a double-chain copper sulfate.[15] Paul et al. recently reported several Kagomé lattices and other types of layered iron and cobalt sulfates.[16–20] S. Vilminot et al. reported a layered cobalt sulfate.[21] M. J. Rosseinsky et al. have also reported several layered cobalt sulfates.[22,23] M. I. Khan et al. reported a layered vanadium sulfate.[24] In most of the previous compounds prepared by hydrothermal techniques, the layers were like modified brucite, having some of the $[MO_6]$ (M = octahedrally coordinated metal element) octahedra replaced by $[TO_4]$ tetrahedra above and below the vacancies, whereas now a truly brucite-type magnetic layered compound has been reported by S. Vilminot et al.[25] There are much fewer 3D compounds reported. Wright et al. reported a 3D scandium sulfate.[26] C. N. R. Rao et al. have reported a 3D nickel sulfate.[27] S Vilminot et al. reported another nickel sulfate.[28] O. Hare et al. have synthesized several uranium sulfates, one of which has a 3D structure.[29–31] Metal sulfates without entrained organic cations also exhibit interesting catalytic, ion-exchange, and magnetic properties, and they have higher thermal stability relative to metal sulfate hybrids.

There is only one manganese sulfate compound, reported by S. Vilminot et al[32], which has a layered structure. Here we report the synthesis and structure of a 3D manganese sulfate, $Mn_5(OH)_8SO_4$, which has the highest metal/sulfur ratio yet reported. It is another member of the well-known basic transition-metal sulfate family.[33–37] The magnetic properties of this compound are also reported. A thermodiffractometric study reveals that the compound has a high thermal stability.

Results and Discussion

Characterization

The ICP analysis of the product shows the wt.-% of Mn and S to be 54.11 and 6.18, respectively, indicating a Mn/S

Supporting information for this article is available on the WWW under http://www.eurjic.org or from the author.

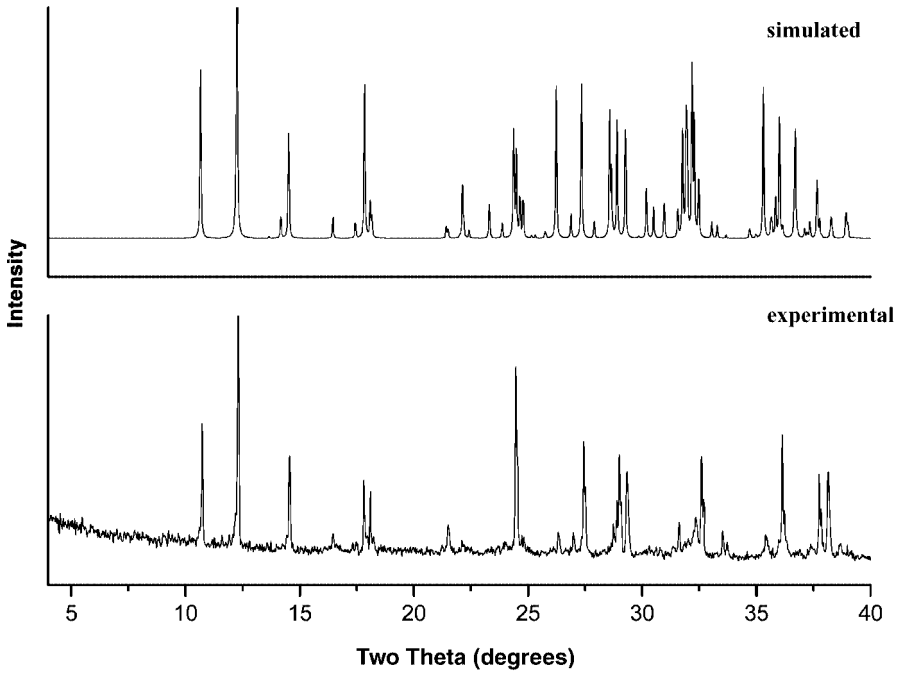

Figure 1. Experimental and simulated powder X-ray diffraction patterns for **1**.

ratio of 5:1, which is in agreement with the experimental wt.-% values of 54.26 and 6.36 based on the ideal formula given by single-crystal X-ray diffraction analysis.

The powder X-ray diffraction pattern was consistent with the simulated one as shown in Figure 1. The positions of the diffraction peaks in both patterns correspond well, which indicates the phase purity of the as-synthesized sample. The difference in reflection intensities between the simulated and experimental patterns was due to the variation in the crystal orientation of the powder sample.

An IR spectrum was recorded between 4000 and 400 cm^{-1} (Figure S2, Supporting Information; for Supporting Information see also the footnote on the first page of this article). The series of sharp bands in the 3635–3430-cm^{-1} and the 850–650-cm^{-1} regions are attributed to O–H. The typical vibrational bands of SO_4^{2-} are observed in the 1150–590-cm^{-1} range. The ν_3 and ν_4 vibrational bands of the sulfate group appear at 1150–1045 cm^{-1} and 650–590 cm^{-1}, respectively. The bands centered at 916 cm^{-1} are attributed to ν_1 vibrational bands of the sulfate group. The bands centered at 470 cm^{-1} and 425 cm^{-1} are attributed to O–Mn vibrations.

The combined thermogravimetric analysis-differential thermal analysis (TGA-DTA) of $Mn_5(OH)_8SO_4$ was carried out in air from room temperature to 900 °C by using a heating rate of 10 °C·min^{-1} and is shown in Figure 2. The results show three mass losses, two sharp and one broad. The first mass loss of about 10.9%, occurring in the region 198–362 °C, with a strong endotherm centered at 299 °C, corresponds to the loss of three H_2O groups (calcd. 10.7%) from six OH groups. The second mass loss of 3.9%, in the region 362–571 °C, corresponds to the loss of one H_2O from two OH groups (calcd. 3.6%). Two weak exotherms, centered at 336 °C and 381 °C, indicate structural changes. After that there is a slight weight gain starting at 571 °C, three weak exotherms centered at 542 °C, 597 °C, and 647 °C, indicating that some of the Mn^{II} ions have been oxidized. However, it is difficult to determine this weight gain accurately, as this process overlaps slightly with the weight loss due to the decomposition of the SO_4^{2-} fraction. Decomposition of

the SO_4^{2-} fraction starts to take place at 830 °C as a strong exothermic effect. The TG curve shows a continuous weight loss in this region. The final thermal decomposition product is Mn_2O_3 with its standard powder diffraction pattern (PDF database No: 41–1442).

A thermodiffractometric study of **1** (Figure 3) was undertaken to characterize the water loss. Compound **1** is only stable up to 280 °C; above this temperature water is lost.

Description of Structure

The asymmetric unit of **1** contains 29 non-hydrogen atoms (5 Mn, 1 S, and 23 O atoms) as shown in Figure 4. The Mn atoms adopt three different types of coordination: pentahedral, distorted pentahedral, and distorted octahedral, which is more complex than other basic sulfates.[33–37] In other metal sulfates, the metal atoms adopt only one octahedral or tetrahedral coordination, only $Zn(OH)_2$·$ZnSO_4$ adopts octahedral and tetrahedral coordination. Mn(1) is coordinated to five oxygen atoms [O(1), O(2), O(2A), O(3), and O(4)] from five different OH groups and shows as a slightly distorted pentahedron. O(2), O(2A), O(3), and O(4) form a plane with O(1) occupying the axial position. The Mn atom is slightly above or below the plane of the pyramid. The Mn(1)–O bond lengths range from 2.151(3) to 2.168(3) Å. Mn(2), Mn(3), and Mn(5) all adopt octahedral coordination: Mn(2) and Mn(3) are coordinated to six oxygen atoms from five different OH groups and a sulfate group, Mn(5) is coordinated to six oxygen atoms from four different OH groups and two different sulfate groups, with typical geometrical parameters {d_{av}[Mn(2)–O] = 2.211(3) Å, d_{av}[Mn(3)–O] = 2.217(3) Å, and d_{av}[Mn(5)–O] = 2.239(3) Å}. Mn(4) is coordinated by five oxygen atoms from five different OH groups; O(6A), O(8), and O(9A) form a distorted plane, whereas O(1) and O(9) occupy the axial positions, forming a distorted pentahedron. It is worth noting that the bond lengths of Mn(1)–Mn(3), Mn(1)–Mn(2), and Mn(2)–Mn(2)$^{\#2}$ are 3.1639(10) Å, 3.1729(9) Å, and 3.0933(14) Å, respectively.

The sulfate group in each asymmetric unit is tetrahedrally coordinated through its two oxygen atoms, O(10) and O(11A), and bonded to two different Mn atoms, Mn(2) and Mn(3), through the μ_3-O(7) bridge. O(12), the shortest of the S–O bonds, is a terminal oxygen with d_{av}(S–O) = 1.469(4) Å.

Formation of the 3D structure (Figure 5) can be explained by the linking of layers (Figure 6) through columns (Figure 7), which form empty channels. Each layer is obtained by linking chains of Mn atoms, bridged by O atoms. There is no similarity to the well-known structures of most basic hydroxide sulfates of divalent metals in which there are 1D chains or 2D layers linked by hydrogen bonding to form more complex networks. Mn(1)O(5), Mn(2)O(6), and Mn(3)O(6) form a chain (Chain 1), and Mn(1A)O(5), Mn(2A)O(6), and Mn(3A)O(6) form a neighboring chain (Chain 2). In Chain 1, Mn(1) is bridged to Mn(2) through 2 O atoms [O(1) and O(2)] on one side and to Mn(3) through 2 O atoms [O(3) and O(4)] on the other side. The fifth O atam [O(2A)] bridges Mn(2) to Mn(1A) and Mn(2A) of Chain 2. Mn(2) is further bridged to Mn(3) through two O atoms [O(6) and O(7)]. O(2) bridges Chain 1 to the Mn(1A) of Chain 2. O(5) and O(5A) bridge Mn(2) to Mn(2A) of Chain 2′, which faces the opposite direction to that of Chain 2. O(1) bridges Mn(1), Mn(2), and Mn(4)

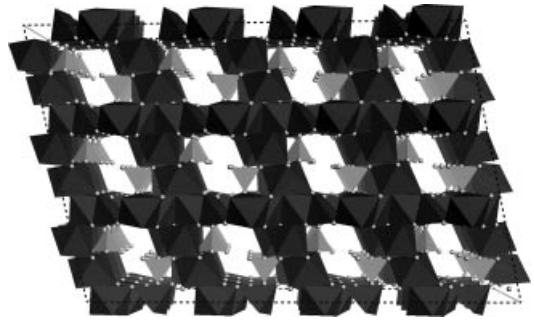

Figure 5. View of the crystal structure of the complex along the *c*-axis. SO_4^{2-} tetrahedra are gray and MnO_x polyhedra are black.

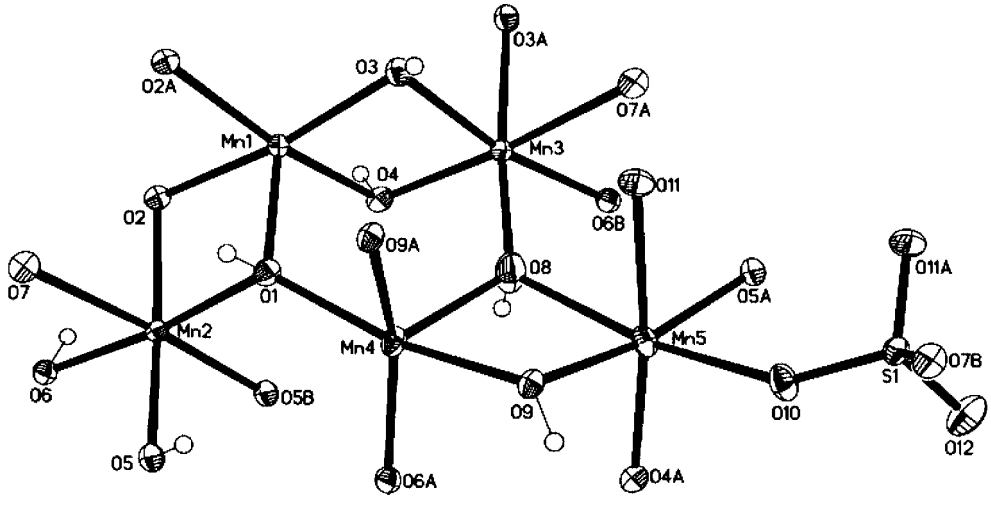

Figure 4. ORTEP drawing of the asymmetric unit of **1** showing the atom-labeling scheme (50% thermal ellipsoids).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of the column which lie perpendicular to the layer of the chains. Mn(3) is bridged to Mn(1) and Mn(2) in the same type of chain as explained earlier for Mn(1) and Mn(2) using four of its coordination sites. Its fifth coordinating oxygen, O(8), bridges it to Mn(4) and Mn(5) of the column, which runs out of the layer, and the sixth oxygen, O(3), bridges it to Mn(1A) and Mn(3A) of Chain 2. Thus the two neighboring chains run parallel but in opposite directions to each other. They are linked together through bridging O atoms to form a complex layer (Figure 6).

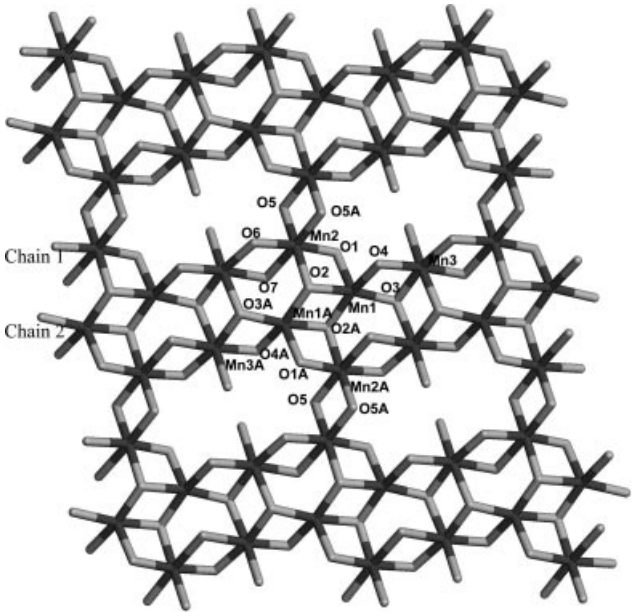

Figure 6. View of the structure perpendicular to the plane of the Mn/O/H layer orientated in the [100] plane.

Between the layers are complex columns formed by $Mn(5)O_6$ octahedra, $Mn(4)O_5$ distorted pentahedra and sulfate tetrahedra. In each column, two $Mn(5)O_6$ octahedra, two $Mn(4)O_5$ distorted pentahedra, and two sulfates are tetrahedrally linked together through edge or corner sharing to form a unit. These units are linked to form the infinite column (Figure 7).

The 3D structure is obtained by linking the layers in a unique pattern. The consecutive layers are linked to each other through complex columns which are perpendicular to them and thus form empty channels that can be viewed along the *c*-axis (Figure 5).

Magnetic Susceptibility

The temperature dependence of magnetic susceptibility at 5000 Oe was measured for **1** in the range 4–300 K (Figure 8). The experimental data were fitted by using the Curie–Weiss equation $\chi_m = C_m/(T - \Theta)$. The Curie constant is 21.72 emu·K·mol^{-1}. The Weiss constant, Θ, was determined to be –134.35 K in the temperature range of 25 K to 300 K, which suggests rather strong antiferromagnetic interactions between neighboring Mn atoms. This behavior is fully confirmed by the onset of a net maximum in the χ_m vs. T curve at 8.3 K; this maximum can be ascribed to the Neel temperature. The effective magnetic moment at 300 K, calculated from $\mu_{eff} = (8\chi_m T/5)^{1/2}$, is 5.64 μ_B per Mn, which is slightly lower than the theoretically expected value of 5.92 μ_B for Mn^{2+} in a high-spin d^5 system. This may be caused by the interaction of Mn atoms.

Conclusions

A 3D compound, $Mn_5(OH)_8SO_4$, has been synthesized hydrothermally from Mn^{II} ions and H_2SO_4. It has been structurally characterized by single-crystal X-ray diffraction analysis. The phase purity of the product has been confirmed by powder X-ray diffraction. The structure consists of alternately connected $\{MnO_x\}$ and $\{SO_4\}$ units which form a complex network. This compound is stable below 280 °C. The temperature dependence of the magnetic susceptibility shows a rather strong antiferromagnetic interaction in the compound.

Experimental Section

Characterization: The product was prepared by a hydrothermal method. In a typical synthesis, $MnCl_2{\cdot}4H_2O$ (0.199 g) was dissolved in water (10 mL) with stirring, and H_2SO_4 (0.1 mL) was added to form a solution. Cyclohexyl amine (2.4 mL) was added to this solution with continuous stirring until a homogeneous reaction mixture was formed. The final mixture with a molar ratio of $MnCl_2{\cdot}4H_2O/H_2SO_4$/cyclohexyl amine of 1:5:20 was crystallized in a 23-mL PTFE-lined acid digestion bomb at 170 °C for 5 d. The resultant product of pink sticks was filtered and washed thoroughly with distilled water. The yield was 25% based on Mn. Inductively coupled plasma (ICP) analysis was performed with a Perkin–Elmer Optima 3300DV ICP instrument. X-ray powder diffraction (XRD) data were collected with a Siemens D5005 diffractometer with Cu-K_α radiation (λ = 1.5418 Å). The step size was 0.02°, and the count time was 4 s. The infrared (IR) spectrum was recorded within the 400–4000 cm^{-1} region on a Nicolet Impact 410 FTIR spectrometer using KBr pellets. A Perkin–Elmer DTA 1700 was used to obtain the differential thermal analysis (DTA) and a Perkin–Elmer TGA 7 to obtain thermogravimetric analysis (TGA) curves in an air with a heating rate of 10 °C·min^{-1}. X-ray thermodiffractometry was performed in the furnace of a Siemens D-5000 diffractometer in the θ-θ mode in air. Magnetic susceptibility data were collected on the basis of a 0.0227 g sample over the temperature range of 4–300 K at a magnetic field of 5 kG with a Quantum Design MPMS-7 SQUID magnetometer.

X-ray Crystallographic Study: A suitable pink single crystal with dimensions $0.35\times0.32\times0.30$ mm^3 was glued to a thin glass fiber and mounted on a Siemens Smart CCD diffractometer equipped with a normal-focus, 2.4-kW sealed-tube X-ray source (graphite-monochromatic Mo-K_α radiation (λ = 0.71073 Å). Intensity data were collected at a temperature of 293 ± 2 K. Data processing was accomplished with the SAINT processing program.[38] The total number of measured reflections and observed unique reflections were 2885 and 1822, respectively. Intensity data of 1822 independent reflections ($-7 \le h \le 8$, $-10 \le k \le 7$, $-10 \le l \le 10$) were collected in the ω scan mode. An empirical absorption correction was applied using the SADABS program with T_{max} = 0.4000 and T_{min} = 0.3001). The structure was solved in the space group $P\bar{1}$ by direct methods and refined on F^2 by full-matrix least-squares using SHELXTL97.[39] The sulfur and manganese atoms were located first. Oxygen was then found in the difference Fourier map. The hydrogen atoms were placed geometrically. All non-hydrogen atoms were refined with anisotropic thermal parameters. The compound crystallizes in the triclinic system $P\bar{1}$ with cell parameters a = 7.5501(5) Å, b = 8.5558(6) Å, c = 8.6059(5) Å, α = 98.122(4)°, β = 102.370(4)°, γ = 99.646(4)°, V = 526.19(6) $Å^3$ and Z = 2. A summary of the crystallographic data is presented in Table 1. Further details of the crystal-structure investigation(s) may be obtained from the Fachinformationszentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany, on quoting the depository number CSD-391307 (Crysdata@FIZ-Karlsruhe.de).

Periodates of Tetravalent Titanium, Zirconium, Hafnium and Thorium: Synthesis, Characterisation and EXAFS Study

Andrew L. Hector*[a] and William Levason[a]

Keywords: Periodates / Polyoxometalates / EXAFS spectroscopy / Group 4 elements / Thorium

Reaction of $TiO(SO_4)\cdot xH_2O$ with periodic acid in aqueous solution at pH = 2 yields a precipitate of $Ti_2O_2HIO_6\cdot 5H_2O$, while reaction of zirconyl, hafnyl or thorium nitrate with periodic acid in hot aqueous nitric acid solutions yields $MHIO_6\cdot xH_2O$ (M = Zr, Hf, Th; x = 4 or 5). The thorium periodate is soluble in aqueous KOH and $KThIO_6\cdot 4H_2O$ can be precipitated from these solutions. The zirconium, hafnium and both thorium periodates are shown by EXAFS to consist of edge-sharing chains of MO_8 and IO_6 units, IR and Raman studies indicate protonation of periodate in the $MHIO_6$ modifications. The titanium periodate contains vertex-sharing IO_6 groups.

Introduction

Polyoxometalates of electropositive metals have a number of interesting properties. For example, zirconium phosphates can be produced with microporous or mesoporous structures and have potential uses in ion exchange, intercalation, ion conductivity, catalysis and molecular sorption.[1–3] Polymeric structures are found for many oxo anion compounds of Ti, Zr, Hf and Th. Periodate anions $[H_{5-n}IO_6]^{n-}$ function as strong O-donor ligands towards many metal ions of the p and later d blocks, often stabilising unusually high oxidation states, for example Pd^{IV}, Ni^{IV}, Ru^{VI}, Pb^{IV}, Tl^{III} or Cu^{III}.[4–8] In contrast, their compounds with early d-block metals are relatively little investigated.[4] In the case of the oxophilic M^{IV} ions of the group 4 metals (Ti, Zr, Hf) the brief mentions of periodate species in the literature are over 50 years old and contain only compositions derived from classical "wet" analyses, leading to rather unlikely formulations $7TiO_2\cdot I_2O_7$, and $(ZrO_2)_n\cdot I_2O_7\cdot xH_2O$ (x = 3, 4 or 6).[9,10] In the f-block tetravalent thorium is also reported to form periodate complexes.[9,11] The orange cerium(IV) compounds $CeHIO_6\cdot 4H_2O$ and $M'CeIO_6\cdot xH_2O$ (M′ = K, Rb or Cs) were described in the older literature[4,9] and have more recently[12] been characterised by IR and UV/Vis spectroscopy and possible structures proposed based upon extended X-ray absorption fine structure (EXAFS) data from these amorphous and insoluble solids. There are also reports of the stabilization of Tb^{IV} in periodate media.[14,15] Recently, open-framework uranyl periodate compounds have been described,[13] showing the potential to produce useful porous materials with electropositive metals. We report here an investigation of the periodate complexes of these early d-block metals in the oxidation state IV and some experiments on the f-block systems.

Results and Discussion

The products we obtained from the reaction of periodic acid or alkali metal periodates with various group 4 metal reagents proved to be insoluble in water except at very low and sometimes at high pH, amorphous by powder X-ray diffraction (PXD) and often of variable composition. In large part, this is a result of the complex and only partially understood solution chemistry of the group 4 M^{IV} ions in which oxo- or hydroxo-bridge oligomeric hydrolysis products are common features.[16,17] Often this results in rather intractable chemistry. Our general approach was to carry out a variety of exploratory syntheses, examine the products formed by energy dispersive X-ray analysis (EDX) to establish the elements present and their ratios, and use IR spectroscopy to examine the form ($[IO_4]^-$ or $[H_{5-n}IO_6]^{n-}$) of any periodate present.[4] Preparations which yielded species of reproducible composition and which were homogeneous by EDX (spectra collected on a series of points) were selected for detailed study.

Titanium

The addition of $TiCl_4$ to aqueous solutions of H_5IO_6, boiling freshly precipitated titanium dioxide with aqueous H_5IO_6, or reaction of $TiCl_4$ dissolved in glacial acetic acid with H_5IO_6 and KNO_3 in water (the last gave $KM''IO_6$ for M″ = Ge or Sn[7]), formed white precipitates which contained only small amounts of iodine (EDX evidence) and

 DOI: 10.1002/ejic.200500169 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

were mainly the hydrated dioxide. Similarly, heating freshly precipitated TiO_2 with H_5IO_6 or H_5IO_6/KIO_4 in water in hydrothermal bombs at ca. 150 °C for 3–4 d gave products containing very little iodine (the temperatures are limited by the stability of H_5IO_6 which decomposes above ca. 175 °C[18]). The addition of concentrated aqueous H_5IO_6 solution to one of $TiOSO_4{\cdot}xH_2O$ in hot aqueous H_2SO_4 or to a solution of freshly precipitated TiO_2 in hot aqueous nitric acid was more successful, producing white precipitates of constant composition. If carried out as described in the Exp. Sect. at pH = 2, after washing with water and prolonged drying in vacuo, the products have a reproducible heavy atom ratio of Ti/I = 2:1 and conventional analysis data are consistent with a composition $Ti_2O_2HIO_6{\cdot}5H_2O$. The thermogravimetric analysis (TGA) trace (Figure 1) is very simple, the first weight loss (< 200 °C) corresponding to $-5H_2O$, and the second to –"HIO_4", which is complete at ca. 700 °C leaving TiO_2 (identity confirmed by PXD).

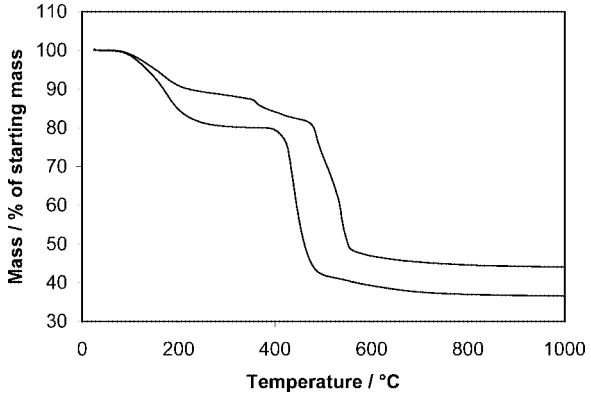

Figure 1. TGA traces of $ThHIO_6{\cdot}5H_2O$ (top) and $Ti_2O_2HIO_6{\cdot}5H_2O$ (bottom) recorded in oxygen.

If the reactions are carried out at higher pH, for example by adding KOH/KIO_4 solution to the acid solution of titanium, the white precipitates have variable composition and presumably are mixtures containing titanium dioxide. In the reactions carried out in the presence of KIO_4, or if the isolated product is treated with 2 M KOH solution no potassium is incorporated. The white powder $Ti_2O_2HIO_6{\cdot}5H_2O$ is insoluble and unaffected by water, dissolves in concentrated aqueous nitric or perchloric acids, and is decomposed by 10 M KOH on heating with precipitation of titanium dioxide.

The IR spectrum of this material shows vibrations due to H_2O, "IO_6" groups and a weak feature at 1135 cm^{-1} assigned to δ(IOH)[4] consistent with the protonation of the periodate required by charge balance. The spectral profile is similar to those found in other complexes containing HIO_6^{4-} species.[4,5] The low-frequency region is dominated by the strong broad absorptions of the coordinated periodate group and these probably obscure features due to Ti–O–Ti units. The compound fluoresces in the Raman spectrometer and this limits the spectral quality, but in addition to strong features at 791 (sh), 654 and 476 cm^{-1} associated with the periodate groups, there is a medium-intensity feature at 936 cm^{-1} which may be due to a Ti–O–Ti unit. The diffuse reflectance spectrum shows a broad feature in the near UV at ca. 36000 cm^{-1} which is tentatively assigned as overlapping internal absorptions of the coordinated periodate ligand and $O\rightarrow Ti^{IV}$ charge transfer (CT). The $Ti_2O_2HIO_6{\cdot}5H_2O$ is amorphous but some structural data were obtained by iodine-*K* edge EXAFS studies (see EXAFS section).

Zirconium and Hafnium

Reactions similar to those described for titanium, including attempted reactions of the freshly precipitated dioxides with H_5IO_6 in hydrothermal bombs or with refluxing aqueous H_5IO_6 failed to give periodato compounds. However, the addition of a concentrated aqueous periodic acid solution to a solution of zirconyl nitrate, $ZrO(NO_3)_2{\cdot}xH_2O$, in hot aqueous nitric acid, produced a white precipitate with a Zr/I = 1:1 composition. The hafnium analogue was obtained similarly using $HfO(NO_3)_2{\cdot}xH_2O$.[19] Provided the precipitation occurs at pH ≈ 2 and the products are washed thoroughly with hot water and dried in vacuo at room temperature to constant weight, they had a reproducible composition of $MHIO_6{\cdot}xH_2O$. These materials were found to be amorphous by PXD but homogeneous by EDX over a series of points. Both the conventional analyses and the TGA weight loss suggest that the thoroughly dried compounds have $x = 4$ for Zr and 5 for Hf. The differences between the two formulations are small but greater than the experimental uncertainty and are reproducible, although we cannot rule out that the water content may be slightly variable. As observed with titanium, working at a higher pH seems to lead to products containing appreciable amounts of the dioxides, and if preparations are carried out in the presence of KIO_4, or the freshly isolated $MHIO_6{\cdot}xH_2O$ is treated with 2 M KOH, no significant amount of potassium is incorporated. In contrast to the titanium periodate described above, the compounds $MHIO_6{\cdot}xH_2O$ dissolve in 10 M aqueous KOH to give a clear solution, but the white products precipitated from these solutions by addition of ethanol had a highly variable K/I/M ratio and have not been purified or identified. The compounds $MHIO_6{\cdot}xH_2O$ are amorphous, insoluble in water, but dissolve in concentrated HNO_3 or $HClO_4$. Their IR spectra show water, "IO_6" groups and a weak broad feature at 1150–1165 cm^{-1} assigned as δ(IOH). If the samples are treated with D_2O for 48 h, the IR spectra of the products show this band has diminished in intensity and a new feature at ca. 820 cm^{-1} is present assigned as δ(IOD). The Raman spectra of the two compounds (Figure 2) are very similar showing only small variations in relative band intensities and frequencies suggesting similar structural units present. The TGA data show decomposition to MO_2 at ca. 650 °C.

For many later transition metal ions, the periodate complexes have related tellurate analogues (containing $H_{6-n}TeO_6]^{n-}$ ligands[4]), but addition of telluric acid to solutions of Zr^{IV} or Hf^{IV} in nitric acid under the conditions

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

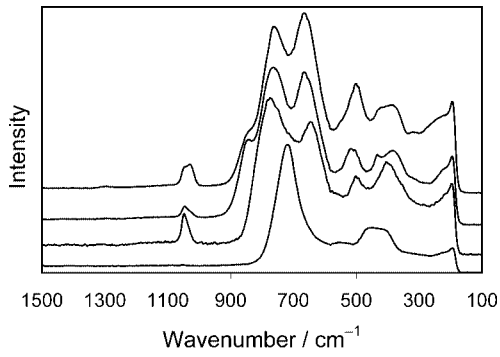

Figure 2. Raman spectra of (top to bottom) $ZrHIO_6{\cdot}4H_2O$, $HfHIO_6{\cdot}5H_2O$, $ThHIO_6{\cdot}5H_2O$ and $KThIO_6{\cdot}4H_2O$.

used to prepare the periodates gave no precipitation. It seems probable that the weaker telluric acid is fully protonated at these pH values and does not coordinate to the group 4 metal.

Thorium

Thorium(IV) is much less prone to hydrolysis and oligomerisation in aqueous solution than the group 4 metal ions, and treatment of aqueous thorium nitrate solution with an aqueous H_5IO_6 solution in the pH range 2–4 produces a white precipitate of composition $ThHIO_6{\cdot}5H_2O$. The IR and Raman spectra of this compound are very similar to those of the Zr and Hf compounds suggesting related structural units. The compound dissolves in concentrated mineral acids and in strong aqueous alkali solution. The TGA plot showing thermal decomposition to ThO_2 (Figure 1) is simple, showing water loss in two steps and then loss of "HIO_4" with no other intermediates formed.

When $ThHIO_6{\cdot}5H_2O$ is stirred with 5 M KOH solution, it slowly dissolves to give a colourless solution, from which slow addition of ethanol precipitates a white powder identified by analysis as $KThIO_6{\cdot}4H_2O$. The IR and Raman spectra of this product (Figure 2 and Exp. Sect.) are clearly different to that of $ThHIO_6{\cdot}5H_2O$, in particular the "IO_6" region is simpler and the weak features attributed in the latter to δ(IOH) modes are absent. The compound is amorphous and insoluble in water, except at very low pH. The behaviour of $ThHIO_6{\cdot}5H_2O$ in alkali is reminiscent of that of $CeHIO_6{\cdot}4H_2O$,[12] and contrasts with that of the Zr and Hf systems.

Cerium, Praseodymium and Terbium

Reaction of $[NH_4]_2Ce(NO_3)_6$ in aqueous HNO_3 with periodic acid precipitates deep yellow $CeHIO_6{\cdot}4H_2O$;[12] this can also be prepared from cerium(III) ions and periodic acid oxidised with ozonised oxygen[12] and (impure) from cerium(III) nitrate and aqueous periodic acid.[20] Since stable and soluble Pr^{IV} or Tb^{IV} precursors are unavailable, ozonisation of aqueous Pr^{III} and Tb^{III} nitrate solutions containing H_5IO_6 at pH = 2 was explored, but even after several hours there was no evidence for oxidation of the lanthanide (in situ UV/Vis spectra). There are several reports[14,15,21–24] that in alkaline solution at least partial conversion to the M^{IV} state is possible, either electrochemically or by using strong chemical oxidants such as peroxodisulfate or ozone. If $Pr(NO_3)_3$ solution is added dropwise to a 5 M KOH solution containing KIO_4, through which ozonised oxygen is passing, a brown colour appears and after several hours a deep yellow solution with a yellow-brown precipitate is formed. The UV/Vis spectra of the yellow solution is dominated by a strong broad band at ca. 34000 cm^{-1}, similar in energy to features reported for other Pr^{IV} species and assigned as $O \rightarrow Pr^{IV}$ CT.[21] The yellow solution decomposes slowly producing a white precipitate and a green solution of Pr^{III}. Filtration and addition of saturated KNO_3 solution to the filtrate produced a fawn-yellow precipitate which became darker on drying. EDX data on this precipitate showed it contained K, I and Pr but was inhomogeneous. The IR spectrum is similar to that of $KCeIO_6{\cdot}xH_2O$.[12] Once isolated, the material is insoluble in water or aqueous alkali and decomposes to green Pr^{III} instantly by acids. The solid decomposes to green Pr^{III} over a few hours/days. Similar ozonisation of a solution of $Tb(NO_3)_3$, KOH and KIO_4 produced a deep red brown solution and a brown precipitate. Filtration and addition of saturated aqueous KNO_3 to the filtrate gave a red-brown solid. EDX data on this solid showed K, Tb and I, although again the ratios differed from sample to sample. The IR spectrum showed water and "IO_6" and the UV spectrum, both of the original red-brown solution and the isolated solid, contained a strong broad feature at ca. 25500 cm^{-1} assigned as $O \rightarrow Tb^{IV}$ CT. Formation of Tb^{IV} in periodate media has been reported several times before[15,22] and Ying and Rudong[15] claimed the isolation and characterisation of $MTbIO_6{\cdot}xH_2O$ (M = Li, x = 14; M = Na, x = 7; M = K, x = 8) complexes by this route. Our spectroscopic data are in good agreement with those reported, but despite very many attempts we have been unable to obtain species which have a constant composition or are homogeneous.

We conclude that substances which probably contain $KMIO_6{\cdot}xH_2O$ (M = Pr or Tb) analogous to the cerium complex do form, but it is very doubtful if they can be obtained even approximately pure, and this precludes work to establish the structural units present.

EXAFS Studies

All the tetravalent periodate materials discussed herein are amorphous; all attempts to produce crystalline materials by varying the synthesis conditions and hydrothermal growth failed. The EXAFS study was undertaken with the aim of discovering some information about their local structures. EXAFS data were recorded at both the metal (Zr-K, Hf-L_{III}, Th-L_{III}) and iodine (K) edges for $MHIO_6{\cdot}xH_2O$ (M = Zr, Hf, Th) and $KThIO_6{\cdot}4H_2O$. For $Ti_2O_2HIO_6{\cdot}5H_2O$, only iodine-K edge data were recorded since the titanium-K edge lies in the iodine-L region.

The iodine edge spectra of $ZrHIO_6{\cdot}4H_2O$ were fitted readily with a first shell of 6 oxygen atoms at a distance

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of 1.88 Å. A second shell was clearly visible in the Fourier transform at 3.27 Å and this could be fitted, with very similar statistics, with one or two zirconium atoms. A larger number of zirconium atoms resulted in deterioration of the fit statistics. The zirconium EXAFS contained a strong first shell at 2.18 Å. This shell gave a poor fit with six oxygen atoms which improved markedly with eight-coordination. The fit with seven-coordinate Zr was indistinguishable from the eight-coordinate model. A second shell at 3.26 Å was modelled with two iodine atoms, similarly to the iodine data, a single iodine atom gave a reasonable fit but a larger number did not. The background-subtracted spectra and Fourier transforms are shown in Figure 3 and structural data are presented in Table 1.

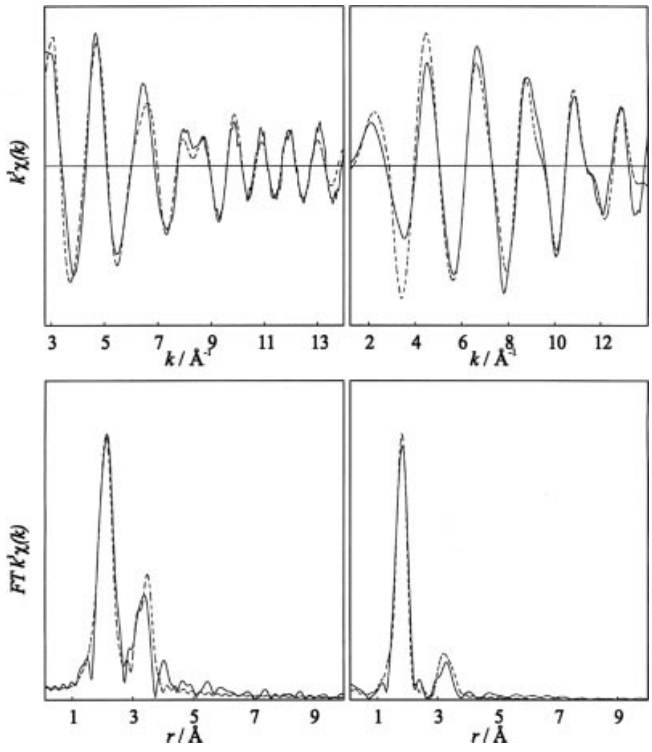

Figure 3. Fitted zirconium- (left) and iodine-*K* (right) edge EXAFS (top) and Fourier transformed EXAFS (bottom) spectra of $ZrHIO_6{\cdot}4H_2O$. Experimental data is shown as solid lines and calculated spectra as broken lines.

The Zr···I distances observed in both the Zr and I edge data are consistent with edge-sharing polyhedra, with a Zr–O–I bond angle of 108°. Based on this and the observed coordination numbers, two structural models for $ZrHIO_6{\cdot}4H_2O$ are plausible based on this EXAFS data. The first is that chains are formed with alternating IO_6 and ZrO_8 groups; this is the case if the second shell in both data sets is modelled with two atoms. The second model arises from the possibility of a single atom in the second shell and would give rise to dimeric species containing a periodate ion and one zirconium atom. This second model does not fit with the insolubility of the material, but more importantly is not plausible due to the composition. In the chain model the edge-sharing periodate ions fill four coordination sites on Zr, the remaining four can be occupied by water molecules (probably hydrogen-bonded to neighbouring chains). With dimers, six water molecules would be needed for ZrO_8. Seven-coordinate Zr is also consistent with the EXAFS data, but this would still require five water molecules. Thus, edge-sharing chains with alternating ZrO_8 and IO_6 groups (Figure 4) is considered the most likely structure of this material.

Table 1. EXAFS data for $MHIO_6{\cdot}xH_2O$ (M = Zr, Hf, Th) and $KThIO_6{\cdot}4H_2O$ (the calculated standard deviations are from the EXAFS fitting software and a 1% error in the distances should be considered more reasonable).

Metal edge EXAFS (Zr-*K*, Hf-L_{III}, Th-L_{III})[a]

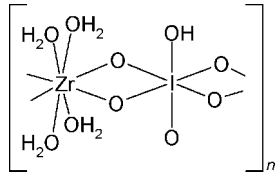

Figure 4. Proposed structural motif in $ZrHIO_6{\cdot}4H_2O$.

The EXAFS data quality for $HfHIO_6{\cdot}5H_2O$, $ThHIO_6{\cdot}5H_2O$ and $KThIO_6{\cdot}4H_2O$ was poorer than for the Zr system discussed above. The Hf-L_{III} edge data was noisy and had to be truncated; only 1.5–9 $Å^{-1}$ were used, but it was possible to obtain meaningful information from these data, albeit with slightly high *R* factors. The Th-L_{III} edge data suffered with two major monochromator glitches and the relevant data points were deleted. Similarly, a major glitch in the iodine edge EXAFS data, which was not observed in the other samples, became apparent in both Th samples and a section had to be cut from the data. This has resulted in high *R* factors for the Th data at both edges and unreliable second-shell information in the I-*K* edge fits.

Examination of the data in Table 1 shows that $HfHIO_6{\cdot}5H_2O$ is very similar to $ZrHIO_6{\cdot}4H_2O$ and the same structure appears to be adopted. The small reduction in the M–O distance is consistent with ionic radii[25] and the agreement between the Hf···I and I···Hf distances, though poorer than with Zr, is still within error. The M–O bond lengths for the Zr and Hf compounds are in excellent agreement with those in the $[M_4(OH)_8(H_2O)_{16}]^{8+}$ ions.[17] Interestingly, even accepting their lower reliability, the fits to the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

data collected on the protonated and potassium-exchanged thorium periodates are also compellingly similar to $ZrHIO_6{\cdot}4H_2O$. The first-shell distance increase for Th compared with Zr is slightly larger than the 0.21 Å suggested by ionic radii and this could be taken to imply nona-coordinate Th in $ThHIO_6{\cdot}5H_2O$, though the distance is the same in $KThIO_6{\cdot}4H_2O$ where the number of water molecules is insufficient for nona-coordinate Th. The EXAFS data of $ZrHIO_6{\cdot}4H_2O$ is also markedly similar to that of $CeHIO_6{\cdot}4H_2O$.[12] The chain structure which we consider likely here was also proposed in this earlier work, though it was only possible to fit one shell to the Ce EXAFS data and the chain structure was based on the iodine edge data only. Thus, we suggest that the same core structure is adopted throughout the series of tetravalent periodates with these electropositive metals containing $ZrHIO_6{\cdot}4H_2O$, $HfHIO_6{\cdot}5H_2O$, $CeHIO_6{\cdot}4H_2O$, $ThHIO_6{\cdot}5H_2O$ and $KThHIO_6{\cdot}4H_2O$. The fifth water molecule observed in some of these compounds is likely to be loosely associated. The potassium ion in $KThIO_6{\cdot}4H_2O$ does not appear to change the EXAFS data at either edge, but in all the metal edge spectra there are features in the Fourier transform beyond the second shell which have not been modelled. Vertex-sharing potassium would be in this region. The Raman spectra of the thorium compounds (Figure 2) show the change in the symmetry of the periodate ion on exchange of the proton in $ThHIO_6{\cdot}5H_2O$ with potassium to yield $KThIO_6{\cdot}4H_2O$ and are consistent with an increased symmetry on deprotonation but an otherwise similar environment.

The iodine-*K* edge data for $Ti_2O_2IO_6{\cdot}5H_2O$ were fitted (R = 20.92) with six oxygen atoms at 1.861(3) Å and two titanium atoms at 3.51(2) Å; Debye–Waller factors were 0.006(1) and 0.014(5) $Å^2$, respectively. Whilst the information which can be derived from one edge is clearly less, it is possible to see that this material is structurally different from those described above. Assuming a typical octahedral Ti^{IV}–O distance of 1.97 Å, the Ti–O–I bond angle would be around 133°; thus, it is likely that the structure of this material is based around vertex-sharing polyhedra. A second shell with more than two titanium atoms does not give a good fit, ruling out higher symmetry structures, and there are not enough oxide/hydroxide/water groups for a discrete molecular structure. Hence, a structure based on chains or sheets is likely.

Experimental Section

General: Physical measurements were made as described previously.[5] For analysis known weights of the compounds were boiled with 2 M H_2SO_4 and excess aqueous SO_2 which achieved dissolution and reduction to iodide. Iodine was determined gravimetrically as AgI and potassium gravimetrically as $KBPh_4$, and the group IV metals and Th as the dioxides by pyrolysis to constant weight in flowing O_2/N_2. Water contents were estimated from the TGA traces. All samples were examined by PXD and found to be fully amorphous. X-ray absorption data were collected at ambient temperature in transmission mode from powdered samples diluted with BN on station 9.3 of the SRS with an Si 220 monochromator. Background subtraction was performed with PAXAS[26] and EXAFS data were fitted using EXCURVE.[27] $ZrO(NO_3)_2{\cdot}xH_2O$, $TiO(SO_4){\cdot}xH_2O$, $Pr(NO_3)_3{\cdot}xH_2O$ and $Tb(NO_3)_3{\cdot}xH_2O$ (Aldrich), and $Th(NO_3)_4{\cdot}5H_2O$ (BDH), were used as received. $HfO(NO_3)_2{\cdot}xH_2O$ was prepared as described elsewhere.[19]

$Zr[HIO_6]{\cdot}4H_2O$: $ZrO(NO_3)_2{\cdot}xH_2O$ (0.26 g, ca. 1.0 mmol) was dissolved in hot aqueous nitric acid (5:1 v/v, H_2O/HNO_3, 200 mL) and the solution stirred vigorously, whilst a solution of H_5IO_6 (0.34 g, 1.5 mmol) in water (20 mL) was added dropwise. Immediately, a white precipitate formed, and after stirring for 30 min the hot solution was filtered, the solid washed with hot water (3 × 50 mL) and dried in vacuo for 24 h (0.35 g, 90%). $H_9IO_{10}Zr$ (387.19): calcd. I 32.8, Zr 23.6; found I 33.3, Zr 23.8. IR (Nujol): $\tilde{\nu}$ = 3380 (st, br), 1624 (m), 1153 (w), 780 (sh), 720 (vs), 494 (s), 379 (m) cm^{-1}. Raman: $\tilde{\nu}$ = 3300 (w, br) 1580 (w), 1038 (m), 825 (sh), 761 (vs), 662 (vs), 502 (m), 381 (m), 192 (m) cm^{-1}. UV/Vis (neat diffuse reflectance): $\tilde{\nu}$ = 45450, 35700, ca. 33000 (sh) cm^{-1}.

$Hf[HIO_6]{\cdot}5H_2O$: This compound was prepared similarly using $HfO(NO_3)_2{\cdot}xH_2O$. Yield 86%. $H_{11}HfIO_{11}$ (492.48): calcd. Hf 36.2, I 25.8; found Hf 35.8, I 24.9. IR (Nujol): $\tilde{\nu}$ = 3380 (st, br), 1615 (m), 1161 (w), 760 (sh), 720 (vs), 502 (s), 379 (m) cm^{-1}. Raman: $\tilde{\nu}$ = 3300 (w, br), 1580 (w), 1036 (m), 844 (sh), 765 (vs), 666 (vs), 514 (m), 434 (m), 381 (m), 194 (m) cm^{-1}. UV/Vis (neat diffuse reflectance): $\tilde{\nu}$ = 45450, 35700, ca. 34000 (sh) cm^{-1}.

$Th[HIO_6]{\cdot}5H_2O$: Thorium nitrate hydrate (0.24 g, 0.48 mmol) was dissolved in water (20 mL), concd. HNO_3 (1 mL) added and the mixture heated to ca. 80 °C. A solution of H_5IO_6 (0.15 g, 0.65 mmol) in water (10 mL) was added and the mixture stirred for 30 min. The white precipitate was filtered off, rinsed with hot water (3 × 20 mL) and dried in vacuo (0.22 g, 85%). $H_{11}IO_{11}Th$ (546.02): calcd. I 23.2, Th 42.5; found I 23.8, Th 42.4. IR (Nujol): $\tilde{\nu}$ = 3380 (st, br), 1620 (m), 1161 (w), 760 (sh), 725 (vs), 447 (s), 370 (m) cm^{-1}. Raman: $\tilde{\nu}$ = 3300 (w, br), 1580 (w), 1040 (m), 772 (vs), 640 (vs), 498 (m), 396 (m), 200 (m) cm^{-1}. UV/Vis (neat diffuse reflectance): $\tilde{\nu}$ = 44800, 36000 cm^{-1}.

$Ti_2O_2[HIO_6]{\cdot}5H_2O$: Powdered $TiO(SO_4){\cdot}xH_2O$ (1.6 g, 10 mmol) was suspended in hot water (300 mL) and the mixture vigorously stirred whilst aqueous ammonia (25% w/v, 10 mL) was added, producing a flocculent white precipitate. The mixture was boiled for 10 min, then filtered hot and the white solid washed with copious amounts of hot water to remove residual ammonia. The wet solid was added to a hot mixture of water and concd. nitric acid (4:1 v/v, 100 mL), where it dissolved slowly on stirring to give a clear solution. Periodic acid (2.3 g,10 mmol) in water (10 mL) was added to this solution resulting in a white precipitate. After 10 min, the precipitate was filtered off, washed with hot water (3 × 20 mL) and dried in vacuo. (1.8 g, 82%). $H_{11}IO_{13}Ti_2$ (441.72): calcd. I 28.7, Ti 21.7; found I 28.5, Ti 21.9. IR (Nujol): $\tilde{\nu}$ = 3300 (st, vbr), 1625 (m), 1135 (m), 890 (sh), 730 (s, br), 473 (s), 370 (m) cm^{-1}. Raman: $\tilde{\nu}$ = 936 (m, sh), 791 (s, sh), 654 (vs), 476 (s), 294 (s) cm^{-1}. UV/Vis (neat diffuse reflectance): $\tilde{\nu}$ = 44000, 35800 cm^{-1}.

$KThIO_6{\cdot}5H_2O$: $Th[HIO_6]{\cdot}5H_2O$ (0.2 g, 0.37 mmol) was suspended in 5 M KOH (10 mL) and stirred for 1 h, where it dissolved to give a clear solution. Ethanol (20 mL) was added dropwise to the rapidly stirred solution producing a white precipitate. This was filtered off, washed with ethanol/water (1:1 v/v, 20 mL) and dried in vacuo (0.18 g, 86%). $H_{10}IKO_{11}Th$ (584.11): calcd. I 22.3, K 6.7; found I 22.4, K 6.8. IR (Nujol): $\tilde{\nu}$ = 3350 (st, br), 1640 (m), 698 (vbr, s), 668 (sh), 440 (br, m) cm^{-1}. Raman: $\tilde{\nu}$ = 3300 (w, br), 1580 (w), 720 (vs), 540 (m), 466 (br, m), 200 (m) cm^{-1}.

COVER PICTURE

The cover picture shows the X-ray structures of some new half-sandwich (or piano-stool) Ru^{II}-[9]aneS_3 complexes ([9]aneS_3 = 1,3,7-trithiacyclononane) against a background of cells in culture. The complexes of the type $[RuCl_2(L)([9]aneS_3)]$, $[RuCl(L)_2([9]aneS_3)][CF_3SO_3]$, and $[Ru(dmsoS)(L)_2([9]aneS_3)][CF_3SO_3]_2$ (L = 1,3,5-triaza-7-phosphaadamantane, PTA; $(L)_2$ = 2 PTA or chelating N-ligand) were prepared from Ru-[9]aneS_3-dmso precursors and structurally characterized, both in solution and in the solid state. Some of them are analogues of known cytotoxic half-sandwich $Ru^{II}(\eta^6$-arene) organometallic compounds of the type $[RuCl(en)(\eta^6$-arene)$][PF_6]$ and $[RuCl_2(PTA)(\eta^6$-arene)], in which the aromatic fragment is replaced by the sulfur macrocycle [9]aneS_3 while the rest of the coordination sphere is left unchanged. Preliminary in vitro tests performed on some complexes against the mouse adenocarcinoma cancer cell line (TS/A) and the human mammary normal cell line (HBL-100) showed that, in general, the Ru-[9]aneS_3 compounds have a cytotoxicity comparable to that of the corresponding organometallic analogues. These results suggest that the aromatic fragment of the piano-stool Ru^{II} compounds is not an essential feature for the in vitro anticancer activity, and it might be effectively replaced by another face-capping ligand with a low steric demand, such as [9]aneS_3. Details are discussed in the article by E. Alessio et al. on p. 3423 ff. This work was performed within the framework of COST Action D20, a collaboration between WG 0001 and WG 0005.

γ-Alumina as a Support for Catalysts: A Review of Fundamental Aspects

Monica Trueba*[a] and Stefano P. Trasatti[a]

Keywords: Alumina / Materials science / Micro- and macrostructures / Supported catalysts

The present review discusses the most important aspects to take into consideration to improve the properties of γ-Al_2O_3 as a support for catalytic applications. We show that the synthetic route to γ-Al_2O_3 is the starting point that determines the micro- and macrostructure of the oxide and, consequently, allows control of the support characteristics. The relevance of the adequate structural characterization of the oxide as well as of its surface sorption behavior through the proton-affinity distributions, are considered. The usefulness of the latter during supported catalyst preparation, for catalytic active sites characterization, and for stability evaluation after calcination are discussed for the Co/γ-Al_2O_3 system in particular.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

0. Introduction

Among the different transition aluminas known, γ-alumina (γ-Al_2O_3) is perhaps the most important with direct application as a catalyst and catalyst support in the automotive and petroleum industries.[1,2] The usefulness of this oxide can be traced to a favorable combination of its textural properties, such as surface area, pore volume, and pore-size distribution and its acid/base characteristics, which are mainly related to surface chemical composition, local microstructure, and phase composition. Nevertheless, the chemical and hydrothermal stability of γ-Al_2O_3 are still a critical point for catalytic applications.

For example, the use of γ-Al_2O_3 as a support for Co-based catalysts in the Fischer–Tropsch (FT) process for the production of clean fuels[3,4] is not lacking in practical problems. The most common undesirable situations are: 1) alumina dissolution during supported catalyst preparation (usually in aqueous media), which affects the nature of the resulting Co species, 2) γ-Al_2O_3 rehydration during catalyst implementation because of the H_2O produced in the FT process, and 3) thermal degradation (sintering and phase transformation) in the catalyst regeneration step (hot-

E-mail: monica.trueba@unimi.it

Monica Trueba is a Ph.D. student in the Department of Physical Chemistry and Electrochemistry at the University of Milan (Italy). She is working on alumina supports for catalytic applications.

Stefano P. Trasatti is presently a researcher in the Physical Chemistry and Electrochemistry Department of the University of Milan. He received a PhD in Industrial Chemistry in 1995. In the same year he was awarded the Oronzio De Nora prize for the best work in the field of electrochemistry. He worked in a private company from 1996 to 2002 where he was responsible for surface treatments and material testing. He is the author of more than 20 papers and two patents in the field of metallic corrosion. His research interests include corrosion in refinery, corrosion monitoring and control, as well as the use of artificial intelligence systems in the study of corrosion.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

spots). It is clear that these side-reactions, which affect catalyst stability, activity, and selectivity, are principally related to support stability.

In the present work, the main aspects to be taken into account when trying to improve the properties of γ-Al_2O_3 as a support for catalysts are reviewed. First, the micro- and macroscopic nature of the support are described because without an adequate knowledge of them any applications will always be less than optimal. Next, the significance of the synthesis route is discussed, followed by the γ-Al_2O_3/H_2O interface and acid/base properties due to the effect of H_2O on support stability during both catalyst preparation and implementation. The importance of studying the oxide surface sorption behavior through the proton-affinity distributions is also considered. Finally, some practical implications for the Co/γ-Al_2O_3 system are presented.

1. γ-Alumina Structure

1.1. Microstructure

The principal features of the γ-Al_2O_3 microstructure are usually reported for the oxide obtained by the thermal dehydration (calcination) of aluminum hydroxides and oxyhydroxides. The transformation sequence during this process has been studied for many years, and it also gives other metastable phases of α-Al_2O_3 depending on the calcination temperature [Equation (1)].[2,5–10]

$$\text{Boehmite/amorphous } Al_2O_3 \rightarrow \gamma\text{-}Al_2O_3 \rightarrow \delta\text{-}Al_2O_3 \rightarrow \theta\text{-}Al_2O_3 \rightarrow \alpha\text{-}Al_2O_3 \quad (1)$$

γ-Al_2O_3 is reported to appear at temperatures between 350 and 1000 °C when it is formed from crystalline[11] or amorphous[12] precursors, and is stable at temperatures as high as 1200 °C when the latter is used as the starting material.

The structural characterization of γ-Al_2O_3 is commonly performed by techniques such as IR spectroscopy,[6,13–16] NMR spectroscopy,[10,14,15,17] X-ray diffraction (XRD),[10,14,17,18] transmission electron microscopy (TEM),[16,19] and BET adsorption.[16,17] Additional information from the use of relatively new methods such as neutron vibrational spectroscopy (NVS), prompt-gamma activation analysis (PGAA), and small-angle X-ray scattering (SAXS), is also available.[10,16] Nevertheless, despite the variety of experimental and computational[9,20,21] studies, there is still a considerable debate about the structure of γ-Al_2O_3 as well as many of the transitional Al_2O_3 phases.

The structure of γ-Al_2O_3 is traditionally considered as a cubic defect spinel type, whose experimental unit cell is illustrated in Figure 1<yigr1>. The defective nature derives from the presence of only trivalent Al cations in the spinel-like structure, i.e., the magnesium atoms in the ideal spinel $MgAl_2O_4$ are replaced by aluminum atoms. The oxygen lattice is built up by a cubic close-packed stacking of oxygen layers, with Al atoms occupying the octahedral and tetrahedral sites. To satisfy the γ-Al_2O_3 stoichiometry some of the

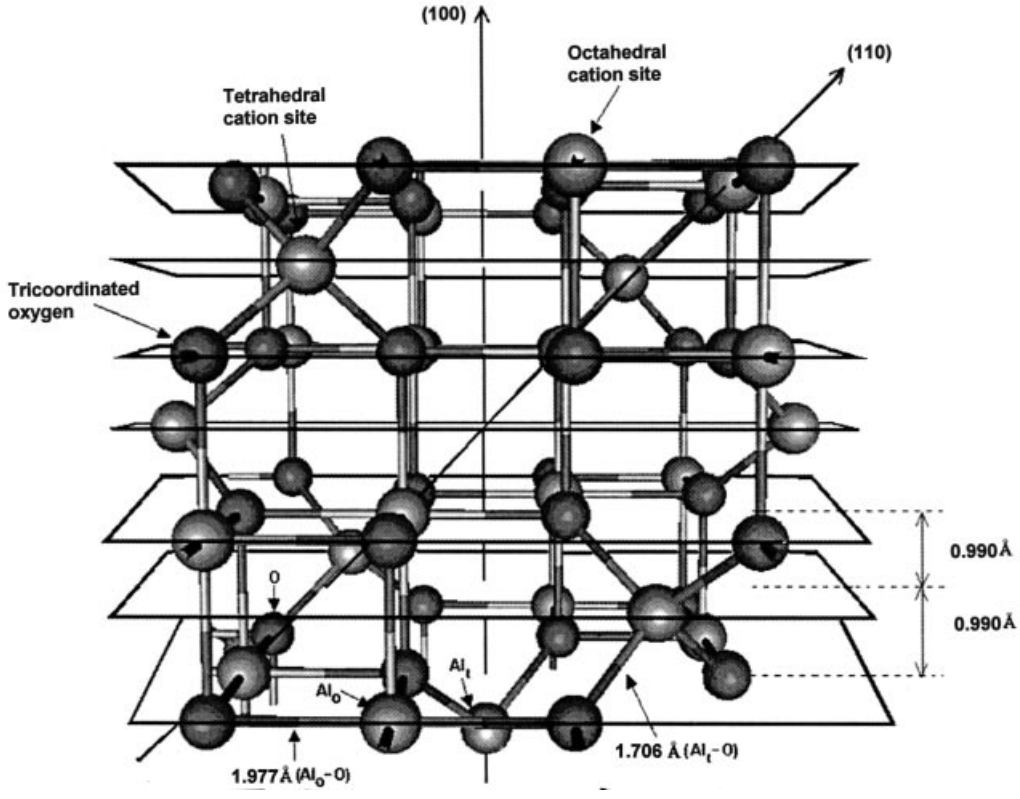

Figure 1. Experimental cubic γ-Al_2O_3 spinel-type unit cell.[21]

lattice positions remain empty (vacancies), although their precise location is still controversial.

When γ-Al_2O_3 is derived from amorphous aluminas it has always been reported to possess a cubic lattice.[12,22–25] Both a cubic lattice[26–28] and tetragonal distortion[29,30] are found for boehmite [AlO(OH)]- or gibbsite [$Al(OH)_3$]-derived γ-Al_2O_3. Other studies, however, have proposed the existence of only a tetragonal structure.[10,16,31] Recently, tetragonal γ-Al_2O_3 obtained from highly crystalline boehmite was reported to be present between 450–750 °C.[10] A reduction of the tetragonal distortion can be produced by increasing the temperature, but at no stage is cubic γ-Al_2O_3 obtained. A new phase has been identified with more obvious cation ordering above 750 °C, designated as γ′-Al_2O_3, which approaches the structure of δ-Al_2O_3 above 900 °C.

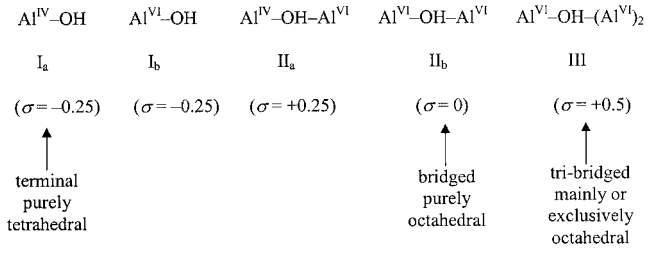
It should be pointed out that some discrepancies exist with respect to the δ-phase, which is usually an intermediate phase between γ- and θ-Al_2O_3 [Equation (1)]. Some studies have reported that there is no distinct difference between δ- and γ-Al_2O_3.[30,32] The main difference is considered to be in the arrangement of the Al atoms: the vacancies are distributed between octahedral and tetrahedral sites in γ-Al_2O_3, while they are only in octahedral sites in δ-Al_2O_3; the oxygen lattice is the same for both phases. Other works, however, report no occurrence of the δ-phase at all.[7,11]

Many studies of γ-Al_2O_3 by means of XRD, NMR spectroscopy, and TEM have demonstrated the preference for vacancies in octahedral sites with the Al cation in tetrahedral positions,[7,26,28] whereas other authors support the opposite conclusion, i.e., the vacancies tend to reside in tetrahedral positions.[15,29] On the other hand, it has also been suggested that the cationic vacancies should be more realistically imagined as being distributed randomly between tetrahedral and octahedral cavities.[30] Further, it has also been reported that γ-Al_2O_3 contains significant portions of cations occupying "non-spinel" sites, i.e., sites that are vacant in the ideal spinel structure.[27]

The role of hydrogen has also been stressed. Some works claim that a considerable amount of hydrogen is present in the bulk structure of γ-Al_2O_3,[7,13,33,34] although the possibility of the hydrogen spinel (HAl_5O_8) as a structural candidate instead of the OH species has been ruled out.[14,27,34] Computational studies show that this spinel structure is thermodynamically unstable.[9] A relatively well-ordered bulk crystalline γ-Al_2O_3 that contains no interstitial hydrogen has been reported in recent studies[16] where the H-containing species are localized at the surface and within amorphous regions.

The removal of OH groups during high temperature treatment creates coordinatively unsaturated surface (*cus*) cations where tetrahedral (Al^{IV}) and octahedral (Al^{VI}) aluminum coordinations are the most widely accepted.[10,14,35] However, variable amounts of pentahedrally coordinated aluminum (Al^{V}), concentrated principally at the surface, have also been found.[13,15,36,37] It has been reported that the Al^{V} content is strictly related to the pore-size distribution, crystallinity, and surface area such that a high Al^{V} amount implies low crystallinity and a high surface area.[13] Three-coordinate Al on the surface is unlikely, despite the fact that its presence would be expected based on the bulk structure.[14] The partly uncoordinated metal cations and oxide anions that lie at the surface of γ-Al_2O_3 can act as acids and bases, respectively, according to the Lewis definition.[35] The strongest acid sites are considered to be the Al^{IV} *cus* ions, which are mainly located in crystallographically defective configurations and are responsible for the high catalytic activity of highly dehydrated aluminas. Nevertheless, the defective configurations, which yield the reactive surface sites, tend to be annihilated during high-temperature dehydration. The tendency of the Al coordination number to be lowered on H_2O desorption produces a new kind of OH group. The last OH groups to be removed are not related to those which were present on the initial hydroxylated surface and whose structure determines the properties of the *cus* surface cations.

The most important surface features of γ-Al_2O_3 have been determined by means of IR[6,35,38] and NMR spectroscopy,[38–40] although the precise nature of the surface acid sites is still unknown. Up to now, the most accepted and frequently used empirical model to describe γ-Al_2O_3 surfaces was that developed by Knözinger and Ratnasamy:[6]



Accordingly, five different types of OH groups are present on the surface that exhibit a distinct "net electric charge" (σ), depending on the number of Al neighbors and on Al coordination. This model, however, has serious limitations due to its crude description of ideal γ-alumina surfaces that neglects surface hydroxylation/dehydroxylation process induced by temperature effects. Recently, using density functional (DFT) calculations, realistic models of the γ-Al_2O_3 surface have been proposed that account for the above process.[41] These models show that the behavior of various types of surface hydroxy groups depends strongly on the local chemical environment, morphology (exposed surfaces), and composition of the oxide, which are greatly influenced by the alumina precursors (starting materials) and synthetic methods used.

1.2. Macrostructure

Conventional γ-alumina is typically prepared by thermal dehydration of coarse particles of well-defined boehmite at a temperature above 400–450 °C.[2] The oxide obtained usually presents a surface area and pore volume below

250 $m^2 g^{-1}$ and 0.50 $cm^3 g^{-1}$, respectively. Also, its stability is greatly affected by steam, which accelerates the transformation of γ-Al_2O_3 into α-Al_2O_3, with a consequent marked drop of surface area as a result of sintering.

Besides thermal decomposition, several methods for γ-Al_2O_3 synthesis that use traditional techniques of preparative chemistry, such as precipitation and hydrolysis, have been developed to improve the oxide's textural properties and hydrothermal stability.[17,19,33,42–47] Moreover, the addition of thermal stabilizing modifiers (Zr^{4+}, Ca^{2+}, Th^{4+}, and La^{3+}) is quite popular. The latter inhibit the transformation of transition aluminas into the α-phase, opposite to the effect obtained with In^{3+}, Ga^{3+}, and Mg^{2+}. However, the acid-base behavior of the modified oxide can be very different with respect to the γ-Al_2O_3 itself (Table 1).[48,49] The Al_2O_3-SiO_2 system has also been widely studied.[50–53]

Since the transition of metastable phases into α-Al_2O_3 occurs predominantly at the contact between primary particles, the key for suppressing the rate of sintering (without additives) is to prepare active aluminas in a morphological state in which the area of contact between primary particles is minimized, such as those with a fibrillar crystalline structure.[33] It is well known that microcrystalline solids show slower decomposition kinetics (e.g. dissolution).[54] Furthermore, it is preferable to avoid high-temperature treatments during calcination/decomposition of hydroxide and/or oxide mixtures because the solid-state reactions could be affected.

The past few years have witnessed marked progress in the synthesis of γ-aluminas. Due to the recent advancements in mesostructured silicas and other oxides,[55,56] efforts have been devoted to the synthesis of mesostructured aluminas with a well-ordered arrangement of pores that is essentially preserved after calcination. Many attempts have been made to synthesize ordered mesoporous alumina by supramolecular templating methods, where nonionic, anionic or cationic surfactants, or nonsurfactant molecules have been used as structural directing agents for the synthesis.[17,57–61] However, most of the aluminas obtained in this way present mainly amorphous framework walls that limit their hydrothermal stability, which greatly compromises their usefulness in catalytic applications.

A novel three-step assembly pathway for the formation of a mesostructured alumina with framework pore-walls made of crystalline, lathlike γ-Al_2O_3 nanoparticles has been reported recently.[62–64] The textural properties, like surface area and pore volume (300–350 $m^2 g^{-1}$ and 0.45–0.75 $cm^3 g^{-1}$, respectively), are improved with respect to the conventional γ-alumina. Moreover, the morphological characteristics obtained, i.e., crystallinity and fibrillar-like structure, greatly improve the oxide's thermal and hydrolytic stability. These new mesostructures can be readily impregnated with transition metal precursors from aqueous solutions without loss of porosity, surface area, or pore volume, thus making them promising for applications in catalysis.

Sol-gel is the preferred method for the synthesis of aluminosilicates since it provides a low-temperature synthesis with excellent control over mixing.[50] In particular, slow simultaneous hydrolysis of the two alkoxides (precursors) is preferred to pre-hydrolysis since a higher yield of heterolinkages can be obtained. It has been shown that the nature of the precursor and the manner in which precursor hydrolysis is performed determine the properties of the resulting Al_2O_3-SiO_2 mixed oxide.[52,53] A decrease of the surface area (larger than the single oxides) with an increase of silica amount is obtained when aluminosilicates are prepared by slow simultaneous hydrolysis of Al and Si precursors.[53] A different tendency is reported for alumina-silica xerogels obtained by pre-hydrolysis.[52]

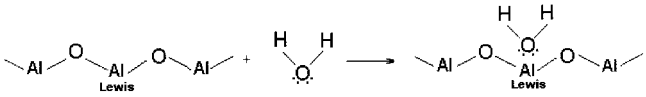
The wide experimental evidence indicates that the preparation history has an important effect on the type of γ-Al_2O_3 structure that is produced (phase composition, bulk and surface chemical composition, and local microstructure of the oxide) as well as on oxide stability and textural properties. The reaction sequence and kinetics depend on the properties of the precursor and this applies not only to its different forms, for example gelatinous or highly crystalline

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

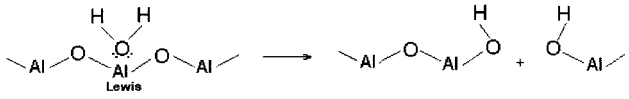
types, but also to the conditions under which the precursor is prepared.

2. γ-Al_2O_3/H_2O Interface

The existence of Lewis acid sites (*cus* cations) and basic sites (oxide anions) at the γ-Al_2O_3 surface allows its rehydroxylation (or rehydration) by interaction with H_2O, so that *cus* cations and anions can, in part, be converted into surface hydroxy groups.[6,13,21,35,37] This interaction has been represented as a two-step process for γ-Al_2O_3 under atmospheric conditions[21,37] that involves nondissociative adsorption of H_2O on Lewis sites (*cus* Al), which essentially consists in a transfer of electron density to a Lewis acid site



followed by dissociative chemisorption of H_2O and modification of surface Al coordination with the hydroxy group bonded to the Al atom, i.e., the two-coordinate oxygen atom adjacent to the Al site is protonated.



The rehydration of γ-alumina corresponds to the loss of tetrahedrally coordinated Al surface species and an increase of hydroxylated octahedral Al that can also involve some Al^{V}.[13] The reactivity towards water depends on the layers exposed at each surface.

When the oxide particles are dispersed in water, the surface oxo and hydroxo groups at the solid/solution interface can associate with protons to form positively charged surface complexes.[33,54,65] The term "surface complex" does not imply a particular bonding structure but is used simply to indicate that chemical and/or noncoulombic physical interactions between the ionized surface sites and the associating ion lead to a kind of surface complex. The proton binding by oxo or hydroxy groups produces –OH and $–OH_2$ species at the surface that will react according to their own proton affinity constant [Equations (2) and (3)]:[33]

$$[(M^{\nu})_n\text{-O}]^{\Sigma\nu-2} + H^+ \rightleftharpoons [(M^{\nu})_n\text{-OH}]^{\Sigma\nu-1},\ K_i^{\Sigma\nu-2} \quad (2)$$

$$[(M^{\nu})_n\text{-OH}]^{\Sigma\nu-1} + H^+ \rightleftharpoons [(M^{\nu})_n\text{-OH}_2]^{\Sigma\nu},\ K_i^{\Sigma\nu-1} \quad (3)$$

where $K_i^{\Sigma\nu-2}$ and $K_i^{\Sigma\nu-1}$ represent the intrinsic affinity constants that depend, for various types of surface groups, on the local configuration of the surface, especially the number (n) of surrounding metal (M) cations and their effective bond valence (ν). It follows that the oxide/solution interface may be very complex and consist of different surface species that can reside at the same time on the oxide surface.

As a result of γ-Al_2O_3 surface/H_2O interactions, the dissolution of the alumina oxide may be induced by adsorption of H^+ ions.[54,65] Earlier, the extent of dissolution was assumed to be controlled by thermodynamics. Presently, there is general agreement that this process is often controlled by slow chemical reactions occurring at the oxide/H_2O interface.[66–68] A dissolution reaction, more akin to etching, takes place preferentially along crystal defects induced by dislocations that may considerably accelerate kinetic processes while exerting only slight effects on the thermodynamic properties. The OH groups of the alumina surface determine not only its chemical and electrochemical properties but also the activity in the etching process. Thus, release of Al ions can be affected by any process that modifies the hydroxy group coverage of the oxide, such as temperature of calcination and cooling conditions, adsorption on surfaces, irreversible exchange of OH groups, etc.

Studies dedicated to clarifying the dissolution mechanism of anodic polycrystalline alumina membranes[67] have shown that the ratio of Al ion release into the solution depends on the alumina preparation, electrolyte conditions, such as ionic strength, and surface rehydroxylation. The authors considered that the different types of Al ions present on the surface are more active during the first treatment, since a decrease of the concentration of Al ions in solution is obtained upon repeated treatment with acid or base. They suggested that continuation of the etching is preceded by the rehydroxylation or hydrolysis of Al–O–Al bonds [Equation (4)]:

$$\text{Al–O–Al} + H_2O \rightarrow 2\,\text{AlO(OH)} \quad (4)$$

It is worth mentioning that the adsorption of small amounts of alumina on the surface of amorphous silica reduces the rate of silica dissolution in water even when much less than a monolayer of aluminum ions is present.[51] It has been postulated that negative aluminosilicate ion sites on the surface prevent hydroxy ions, which are required to catalyze the dissolution of silica, from approaching the interface.

3. Acid/Base Properties of γ-Al_2O_3

3.1. General Considerations

Most solid oxides develop pH-dependent surface charges when immersed in aqueous solution, according to the general equilibria given in Equations (5) and (6)]:[33,65,68,70]

$$\equiv\text{S–OH}_2^+ \rightleftharpoons \equiv\text{S}_{\text{basic}}\text{–OH} + H^+ \quad (5)$$

$$\equiv\text{S}_{\text{acid}}\text{–OH} + OH^- \rightleftharpoons \equiv\text{S–O}^- + H_2O \quad (6)$$

where $\equiv S_{basic}–OH$ and $\equiv S_{acid}–OH$ represent hydrated sites at the oxide surface with basic and acidic character and may have different local configurations. Depending on the concentration of either one or another type of sites, the oxides may show a dominant tendency to adsorb cations (SiO_2, SiO_2-Al_2O_3, zeolites), anions (MgO, La_2O_3, ZnO), or

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

both cations in basic solution and anions in acidic solution (Al_2O_3, TiO_2, Cr_2O_3).

Acid and basic sites behave exactly as acid and basic substances in solution. Therefore, they respond reversibly to a change in solution pH with the concomitant variation of the total surface charge, with the H^+ and OH^- ions usually being regarded as potential determining ions (absence of specific adsorption).

If Γ_{OH^-} is the surface concentration of negatively charged groups and Γ_{H^+} is the surface concentration of positively charged groups, the net surface charge of the oxide (σ_{ox}) is defined according to Equation (7),[71,72] where Γ is measured in mol cm^{-2} and σ_{ox} in C cm^{-2}.

$$\sigma_{ox} = F(\Gamma_{H^+} - \Gamma_{OH^-}) \quad (7)$$

The pH at which $\sigma_{ox} = 0$, that is where $\Gamma_{H^+} = \Gamma_{OH^-}$, is called the point of zero charge (*pzc*). This does not correspond to the situation of undissociated OH groups but more realistically to the condition of positive surface groups being at the same concentration as negative surface groups. Generally, the surface charge of solid oxide is positive at low pH and negative at high pH.

It should be pointed out that the terminology employed in the literature for "zero point" is plenty, and terms like isoelectric point of the solid (*ieps*),[69,70] point of zero salt effect (*pzse*),[73] point of zero net charge (*pznc*),[74] point of zero net proton charge (*pznpc*),[74–76] and pristine point of zero charge (*ppzc*)[77,78] can be found.

Besides *pzc*, another important quantity that characterizes oxide/solution interfaces is the isoelectric point (*iep*), which corresponds to the pH at which the so-called zeta (ζ) potential is zero.[70–72] This potential is related only to the presence of the free charges in the diffuse layer in solution and can be determined by means of electrokinetic experiments like electrophoresis.

According to the *pzc* and *iep* concepts, the difference between these characteristics is a substantial one. The *pzc* measures the condition of neutrality of the oxide surface while the *iep* is a measure of the condition of zero diffuse charge on the solution side. In the absence of specific adsorption the condition of neutrality corresponds to $\sigma_{ox} = 0$ on the solution side, hence *pzc* = *iep*. If specific adsorption is present, the net charge in the liquid phase of the interface may be different from zero, i.e., $\zeta \neq 0$ and *pzc* ≠ *iep*. Conversely, at the *iep*, the fact that the total charge is zero does not necessarily mean that $\Gamma_{H^+} = \Gamma_{OH^-}$ due to the possible presence of extra charge associated with specifically adsorbed non-potential-determining ions.

The *pzc* is commonly determined by potentiometric titration[52,53,73,76,77,79–81] as these results can be directly converted into proton-adsorption isotherms. The relative surface concentration of protons is frequently obtained by mass balance between the proton (or hydroxide) ions added to solution and the measured proton concentration in solution at equilibrium.[53,73,77–80] The titration procedure is usually performed for different concentrations of the inert electrolyte, i.e., at different solution ionic strengths. If the potential-determining ions are H^+ and OH^- for acid and base titration, respectively (absence of specific adsorption), the titration (charging) curves as well as adsorption isotherms should pass through a common intersection point (*cip*), identified as *pzc*. It should be pointed out that potentiometric titration is reliable only if the amount of protons exchanged by the oxide sample is larger than that involved in the autoprotolysis of water, which is pH dependent.[82] Accordingly, the pH window whereby useful information is obtained is from pH = 3 to 11 (outside this region the buffering effect of H_2O prevails).

3.2. Point of Zero Charge of γ-Al_2O_3

The surface sorption behavior of γ-Al_2O_3 has been widely studied, although the *pzc* for this oxide is not reported as a unique value or in a narrow range of pH values but between 6 and 9.[49,65,69,73,74,76,77,80–83] This is related mainly to the differences in material preparation that influence the micro- and macrostructure of the oxide, and to the experimental method used for *pzc* determination. General trends have been proposed, like the variation of the *pzc* with degree of sample hydration, impurities, structure defects, etc. Some of the available data are summarized in Table 1.

Recently, a discontinuous titration procedure that allows simultaneous measurement of protons and background electrolyte has shown that whereas proton adsorption/desorption gives rise to a positive/negative surface charge, Al dissolution does not.[74] This result supports previous studies which concluded that Al dissolution consumes H^+ ions without affecting the surface charge.[73,84,85] For example, increasing the amounts of soluble Al or CO_2 in solution lowers the phenolphthalein end-point (8.3) to 7.9 and 7–7.3, respectively.[85]

Two mechanisms of acid-base consumption have been proposed,[74] namely significant proton consumption at low values of pH as a result of either proton adsorption [Equation (8)] or Al dissolution [Equation (9)], and base consumption that reflects proton dissociation at higher pH (>6) [Equation (10)] and/or mineral dissolution [Equation (11)].

$$\equiv AlOH + H^+ \rightleftharpoons \equiv AlOH_2^+ \quad (8)$$

$$0.5\,Al_2O_{3(s)} + 3\,H^+ \rightleftharpoons Al^{3+} + 1.5\,H_2O \quad (9)$$

$$\equiv AlOH + OH^- \rightleftharpoons \equiv AlO^- + H_2O \quad (10)$$

$$0.5\,Al_2O_{3(s)} + 1.5\,H_2O + OH^- \rightleftharpoons Al(OH)_4^- \quad (11)$$

These two mechanisms cannot be distinguished on the basis of titration data alone, and independent measurement of the background ion adsorption and Al dissolution are required, as was stressed in other research papers.[76]

Traditional titration methods do not properly consider the solubility of γ-Al_2O_3, which is pH dependent, since various concentrations of Al in solution exert different effects on the shape of the colloidal titration curve. For a correct estimation of the adsorbed proton concentration only,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Schulthess and Parks[73] have developed a back-titration technique that allows the consideration of all sources that consume hydrogen ions and properly adjusts the titration curve for the changes in solubility as the pH changes. This method more accurately reveals the adsorption behavior of H^+ on the surface of γ-Al_2O_3. In fact, the obtained *pzc* values differ by more than one pH unit as forwards (8.60) and back (7.50) titration is performed.

Several studies have demonstrated that polyvalent cations in electrolyte solution compete successfully with protons for adsorption on the active sites of the alumina surface by means of a cation–proton exchange reaction.[54,69,74,75,79,86,87] It has been shown that this process constitutes an alternative method for the estimation of dissolution active sites, since it inhibits oxide dissolution (blocking effect).[53]

For γ-Al_2O_3, specific cationic adsorption is proposed because the *cip* is localized in the alkaline pH region and the H^+ adsorption is different from zero.[49,73,79,86] The common intersection point (*cip*), however, cannot be considered as the *pzc*, according to the previous definition. The competitive adsorption has been interpreted as follows.[73] If electrolyte cations/anions are specifically adsorbed over H^+/OH^- ions, an increase in apparent proton desorption/adsorption is produced. Each H^+/OH^- ion removed from the surface by cation/anion exchange would neutralize a OH^-/H^+ species in solution and this would not be readily distinguished from H^+ ion removal by adsorption. At the *cip*, the amounts of H^+ and OH^- displaced from the surface site are equal and no apparent change in pH is detected with changes in salt concentration (ionic strength). The fact that the *cip* is not coincident with the *pzc* indicates that the surface charge is not equivalent to the proton isotherms, and at high ionic strengths only apparent proton isotherms are obtained due to electrolyte cation/anion competition. The asymmetry (*cip* shift) of the charging curves also depends on the nature of the electrolyte ions and/or on the presence of differently reacting crystal planes.

The effect of the amount of γ-Al_2O_3 in solution on its surface behavior has also been investigated. It has been reported that the *pzc* decreases with concentration from about 9.5 at 1.0 wt.-% to 8.6 at 10 wt.-%,[76] thus indicating that the proton surface data obtained for dilute suspensions do not directly reflect the surface charge characteristics of concentrated suspensions. In a previous work it was found that the amount of oxide present in suspension does not influence the amount of protons consumed/released upon dissolution of γ-Al_2O_3; however, the concentration of the solid in solution was considerably lower (1–3 wt.-%).[77]

The acid-base properties of aluminosilicates have also been studied[33,50–53,88,89] due to the usefulness of these materials in catalytic applications. It has been reported that the surface charge and *pzc* of the mixed oxide increase with Al content,[53] although Lewis acid sites of similar strength are present on the surface independently of the Al/Si atomic ratio. Brønsted acidity also exists, especially in the samples with a higher percentage of silica, which arises from silanol groups (terminal silanol and bridging OH groups). The *pzc* of γ-Al_2O_3-SiO_2 also depends on the way γ-Al_2O_3 silanization is performed as well as on the silanization agent. For example, the use of ethyltriethoxysilane instead of dimethyldimethoxysilane lowers the *pzc* value from 7.1 to 6.25.[49]

3.3. γ-Al_2O_3 Surface Heterogeneity

Heterogeneity effects in the adsorption of oxide/electrolyte solutions were first considered by Leckie et al. in 1978.[90] Since then, many models[65,78,81,87,91,92] as well as a great variety of materials such as inorganic metal oxides,[82,86,87,93] mixed oxides,[94] clays,[95–97] carbons,[98,99] and humic substances[100,101] have been used to describe proton-binding behavior at oxide/solution interfaces. Most site-binding models are a combination of surface reactions and an electrostatic approach, and these models can often describe proton adsorption data quite satisfactorily, although their physical chemistry picture is very different. As a result, an objective picture of the intrinsic properties of the oxide/solution interface is difficult to obtain due to the dependence of the calculated parameters on the specific model applied.

An important result derived from γ-Al_2O_3 surface heterogeneity experimental studies[33,77,80] is the resolution of three or four categories of surface sites, making use of proton-binding isotherms from potentiometric titration and proton-affinity distributions. These sites contribute to proton binding and surface-charge development between pH = 3 and 11 and will react specifically with solution protons, depending on their log K_i and solution pH, as follows:

$$[Al^{VI}\text{–}O\text{–}Al^{IV}]^{-0.75} + H^+ \rightleftharpoons [Al^{VI}\text{–}OH\text{–}Al^{IV}]^{+0.25} \qquad \log K_{IIa} \approx 4.1$$

$$[Al^{IV}\text{–}OH]^{-0.25} + H^+ \rightleftharpoons [Al^{IV}\text{–}OH_2]^{+0.75} \qquad \log K_{Ia} \approx 6.8$$

$$[Al^{VI}\text{–}OH]^{-0.5} + H^+ \rightleftharpoons [Al^{VI}\text{–}OH_2]^{+0.5} \qquad \log K_{Ib} \approx 9.8$$

$$[(Al^{VI})_3\text{–}O]^{-0.5} + H^+ \rightleftharpoons [(Al^{VI})_3\text{–}OH]^{+0.5} \qquad \log K_{III} \approx 2.5$$

Nonactive surface sites over the mentioned pH range have also been proposed:

$$[Al^{VI}\text{–}OH\text{–}Al^{VI}]^0 + H^+ \rightleftharpoons [Al^{VI}\text{–}OH_2\text{–}Al^{VI}]^{+1} \qquad \log K_{IIb1} \approx -2$$

$$[Al^{VI}\text{–}O\text{–}Al^{VI}]^{-1} + H^+ \rightleftharpoons [Al^{VI}\text{–}OH\text{–}Al^{VI}]^0 \qquad \log K_{IIb2} \approx 12.5$$

Protonation of hydroxy groups is more difficult because of the proton–proton repulsion in the $–OH_2$ species. Only surface hydroxy groups with negative uncompensated charge (types I_a and I_b, according to Knözinger and Ratnasamy[6]) can be protonated in the pH interval used.

A direct consequence of this is that at any pH the oxide surface exhibits sites which carry positive charges (log $K_i >$ pH) and sites with negative charges (log $K_i <$ pH), which are disposed in regular arrays on different crystal planes at the surface. Another consequence is that, even at the pH

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

corresponding to *pzc*, some of the above sites can still be charged.

A knowledge of the proton distribution and proton-binding properties for various surface sites (strength and number), synonymous of surface heterogeneity, is needed to predict the pH dependence of the surface charge. It has been shown that the occurrence of the *cip* in charging curves depends on the actual distribution of the surface sites.[49,73,77,93,102] This applies not only to γ-Al_2O_3 modified with anionic and/or cationic species but also when its phase composition changes. As illustrated in Table 1, no definite *cip* is obtained for γ-Al_2O_3 samples containing 56% of the δ-phase[49] as a result of the increase of surface and bulk heterogeneity. Success in obtaining a meaningful and accurate proton adsorption distribution generally depends on the method of its evaluation, the quality of the experimental data, and the appropriate choice of adsorption model.[103] Among the variety of methods for the quantitative estimation of the surface heterogeneity of metal oxides,[103–106] a new method based on the determination of proton-affinity distribution by plotting titration data as derivatives of the proton/hydroxy ion adsorption as a function of pH has been proposed.[107] This approach is considered more realistic from a physical point of view.

Additional necessary information is the temperature dependence of the equilibrium constant and the influence of the temperature on the proton-affinity distribution at the oxide/electrolyte interface, both of which are also vital for any attempt at understanding proton-induced surface dissolution. Studies of the effect of temperature on the proton-affinity distribution at the γ-Al_2O_3/electrolyte interface have shown that temperature variations can affect proton binding in a different way on various groups of surface sites, depending on their enthalpy and entropy changes for specific proton adsorption.[80] The effect of temperature and electrolyte is twofold: proton-affinity constants depend on temperature like all free-energy functions, but the development of the surface charge is also perturbed by electrostatic repulsion in the double layer, which is dependent on the electrolyte concentration.

It is worth mentioning that the use of proton-affinity distributions allows us to obtain reliable quantitative information on the Brønsted acidity of mixed oxide systems such as aluminosilicates.[33,52] Methods like IR[50] or titration with Hammett color indicators[108] often meet with the difficulty of separating the contributions of Brønsted and Lewis acidity.

The adsorption properties of oxides as a function of solution pH may be predicted, at least in principle, by the knowledge of their *pzc*. However, the heterogeneity of acid/base sites on their surface raises some questions about the significance of a global *pzc*. For every heterogeneous surface the concept of *pzc* must be more carefully considered, although, in reality, *pzc* is an overall surface property rather than a thermodynamically meaningful constant. The proton-binding properties for various surface sites allow us to predict the γ-Al_2O_3 adsorption capacity as a function of pH more accurately.

4. γ-AL_2O_3 as a Support

4.1. General Aspects

Transition aluminas are frequently used as pre-shaped supports for preparing multiphase catalysts that consist of an active phase dispersed on a carrier or support.[33] The properties of the active phase depend mainly on the manner in which the active component of the catalyst (precursor) is introduced onto the support and the nature and strength of precursor–support interactions.

The major route for supported catalyst preparation makes use of aqueous media by simple impregnation (wet impregnation or incipient wetness) or by homogeneous deposition-precipitation, ion exchange, and specific adsorption. The choice of one or the other route is usually made by considering the nature and strength of the support–precursor interactions. Common subsequent steps are washing and drying, accompanied by irreversible transformation of the catalyst (its activation).

Different kinds of precursor–support interactions have been considered. Surface interactions for small ions are generally accepted to be predominantly electrostatic, which is supported by experimental results where the extent of adsorption of positive/negative ions increases with a pH rise/decrease. Nevertheless, some experimental evidence reflects exceptions from the simple rule of electrostatic adsorption with the existence of "specific" or "chemical" surface–adsorbate interactions that may compete with coulombic repulsion, as in the adsorption of cations such as Ni^{2+}, Co^{2+}, and Pb^{2+} onto a positively charged alumina surface.[109,110] These results support the existence of specific sites on the hydroxylated surface that act in adsorption of the catalyst precursor and are related to the intrinsic acid/base properties of the surface. Moreover, the adsorption by ligand substitution, i.e., surface hydroxyls "become members" of the coordination sphere of the adsorbate, has been suggested for halide complexes of Pt, Pd, Rh, Ir, Au, and Ru on alumina[111] and for amine complexes of Co^{2+}, Ni^{2+}, and Cu^{2+} on titania.[112]

The surface density of adsorption sites is usually low, which gives a high metal dispersion but insufficient loading. Regulation of the adsorption capacity of amphoteric supports like γ-Al_2O_3 can be done by doping solid oxides with electropositive (Na^+, Li^+) or electronegative (F^-, Cl^-) ions, which results in an increase/decrease of the apparent *pzc* values of supports. However, the introduction of basic or acidic modifiers may also change important properties of the catalysts (Table 1). Another possibility for increasing metal concentration is variation of the temperature of the impregnation solution.

In spite of the advantages of precursor impregnation from an aqueous phase, such as easy scale up at relatively low cost, the use of the metal is inefficient because of its incomplete loading and reduction and uncontrolled sintering during high-temperature salt decomposition. This has motivated researchers to study other ways to prepare supported catalysts, directed mainly at avoiding the use of H_2O

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

as the impregnation phase.[33] Organic media, vapour, and solid phases have been investigated. The most straightforward way for preparing dispersed metal catalysts consists in mounting metallic atoms or small clusters of metal atoms in their zero-valent state onto an appropriate support, which eliminates the need for any subsequent activation and the catalyst can be obtained in a single preparation step. For example, metallic Pt particles mounted on TiO_2 by means of a microemulsion method have been reported recently.[47] Metal–support interactions are not observed and the Pt/TiO_2 catalysts show higher catalytic activity than the same material prepared by the impregnation technique.

4.2. Co/γ-Al_2O_3 Catalysts

It is well known that supported catalysts containing metallic cobalt or as an oxide or sulfide are very important in heterogeneous catalysis. The actual interest is focused on the Co deposition mechanism and its dependence on the support surface features. It is not easy to explain why the maximum rate of deposition is obtained in the first stages of impregnation where a negligible amount of Al^{3+} ions have been released, especially considering that γ-Al_2O_3 surface dissolution is a slow process. A systematic kinetic study of Co^{2+} deposition together with γ-Al_2O_3 surface dissolution is thought to be the best way to clarify this mechanistic aspect.

Another important challenge is the elucidation of the local structure of the deposited Co^{2+} species. The first direct evidence for the formation of inner sphere Co^{2+} complexes on a γ-Al_2O_3 surface was obtained in the 1990s by means of extended X-ray absorption fine-structure (EXAFS). At present, it is not clear why an Al-Co precipitate with a hydrotalcite structure predominates in the cases where the deposition of Co^{2+} on γ-Al_2O_3 takes place through the $Co(H_2O)_6^{2+}$ species.

Studies to elucidate the mechanism of Co^{2+} adsorption on γ-Al_2O_3 have been developed since the early 1970s and were reviewed recently.[114] Most of the work reported uses Co^{II} aqua complexes as precursors. In general, Co^{2+} adsorption on γ-Al_2O_3 increases considerably with solution pH in the range from 5 to 8, although the process becomes increasingly masked by precipitation of $Co(OH)_2$ at higher pH values. Restoring the initial pH value by addition of acid or base has been proposed since the decrease of impregnation solution pH during Co^{2+} adsorption on γ-Al_2O_3 decreases the extent of the deposition process markedly. In this way, Co^{2+} precipitation inside the pores is avoided and Co/γ-Al_2O_3 catalysts with very highly active surfaces can be obtained. The extent of adsorption can also be increased by increasing the temperature during impregnation, thus influencing the resulting structure of the adsorbate. For example, $Co(OH)_2$ predominates under ambient conditions while $CoAl_2O_4$ becomes important at higher temperatures. Co^{2+} adsorption has also been studied on γ-Al_2O_3 modified with F^- ions − the adsorption increases with higher F^- content.

Studies of adsorption of Co^{2+} and Ni^{2+} amino complexes on γ-Al_2O_3 have demonstrated that alumina should not be considered inert during impregnation, even under mild conditions such as at ambient temperature, with a pH close to the *pzc* of the support, and with reasonable contact times.[83,115] Alumina dissolution is promoted not only by protons or hydroxy ions but also by the presence of Co and Ni ions in solution. The authors suggest that the following phenomena take place at the same time at the γ-Al_2O_3/solution interface during impregnation:
– adsorption of ions which, in certain cases, may even accelerate the rate of support dissolution;
– dissolution of alumina, which depends on the characteristics of the alumina surface;
– precipitation of cations released from the support with metal ions in solution;
– alumina rehydration.

The use of proton-affinity distributions for characterization of the active sites of γ-Al_2O_3/Co and γ-Al_2O_3/Co-Mo catalysts has been reported.[113] Potentiometric titration in combination with proton-affinity distributions has been proposed as a powerful method for the characterization of a supported catalyst surface.

The picture that emerges from the recent literature emphasizes the importance of the intrinsic heterogeneity of adsorption sites on the support for catalyst preparation. The proton-binding properties of various surface sites, i.e. the pH-dependent surface development, are also needed when the precursor salt is present in solution. Another important issue is the stability of the Co^{2+} complexes on γ-Al_2O_3 and the evolution of the system during subsequent preparation steps such as drying and calcination for the evaluation of the properties of the supported catalyst (activity and selectivity).

5. Conclusions

There is no doubt that the preparation history of γ-Al_2O_3 strongly determines its properties. Consequently, the phase composition, bulk and surface chemical composition, local microstructure, as well as stability and textural properties of the oxide can be controlled by varying the synthetic route for the application of γ-Al_2O_3 as a catalyst support. The frequent use of aqueous media for supported catalyst preparation implies that rigorous γ-Al_2O_3 characterization is important not only from a structural point of view. The oxide acid/base properties and adsorption capacity as a function of solution pH (and temperature) should be taken into consideration for both γ-Al_2O_3/electrolyte and γ-Al_2O_3/Co^{2+} salt solution systems as only the *pzc* value is not enough. Information from surface heterogeneity can help to understand and to regulate the adsorption mechanism as well as the occurrence of secondary reactions such as γ-Al_2O_3 dissolution. Further, the nature of the active sites of the supported catalyst and its stability should be evaluated prior to testing catalyst activity and selectivity.

A Chiral Copper Complex Forms Supramolecular Homochiral Helices via O–H···Cl–Cu Interactions

Chullikkattil P. Pradeep,[a] Panthapally S. Zacharias,*[a] and Samar K. Das*[a]

Keywords: Copper / Helical structures / Hydrogen bonds / Schiff bases / Self-assembly / Supramolecular chemistry

An enantiopure ligand H_2L [Schiff base prepared from (*S*)-(+)-2-phenylglycinol and 2-hydroxy-5-nitrobenzaldehyde] reacts with $CuCl_2{\cdot}2H_2O$ to yield a chiral copper complex [Cu(HL)Cl] (**1**) that forms right-handed supramolecular helices via O–H···Cl–Cu hydrogen bonds.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

The influence of metal centers on hydrogen bonding has become a topic of intense research recently since metal-directed hydrogen bonding has far-reaching importance in inorganic supramolecular chemistry, materials chemistry, and bioinorganic chemistry. Metal-directed hydrogen bonding can show considerable strength and directionality and thereby is able to control the self-assembly of the building blocks, thus resulting in a variety of interesting supramolecular architectures.[1] Among these, hydrogen-bonded systems involving metal halides (M–X) have been well studied in materials chemistry and organometallic chemistry.[2] Halogens act as strong hydrogen-bond acceptors when bound to transition metals, in contrast to their limited ability to serve as weak hydrogen-bond acceptors when bound to carbon. The directional properties of metal halides in the formation of hydrogen bonds have been shown independently by the groups of Brammer and Orpen.[3]

Among the various metallo-supramolecular architectures, helical structures are of considerable interest because of their intrinsic chirality and their potential for yielding materials with novel chemical, electronic, biological, and optical properties.[4] Of particular interest are chiral helices prepared by the self-assembly of chiral building blocks.[5] We have recently reported a supramolecular homochiral helical architecture assembled by C–H···Cl–M hydrogen-bonding interactions.[6] However, to the best of our knowledge, there is no report on homochiral helices based on O–H···Cl–M interactions. In the present communication we wish to report a chiral, mononuclear, square-planar copper complex that self-assembles through O–H···Cl–Cu interactions to form homochiral helices in the crystal packing.

The reaction of a 1:1 mixture of (*S*)-(+)-2-phenylglycinol and 2-hydroxy-5-nitrobenzaldehyde in methanol yielded the tridentate chiral ligand H_2L in moderate yield. Reaction of H_2L with $CuCl_2{\cdot}2H_2O$ in methanol at room temperature gave a green solid of [Cu(HL)Cl] (**1**), which on recrystallization from methanol gave X-ray quality crystals. The molecular structure of the complex is shown in Figure 1. The structure consists of a neutral, mononuclear, four-coordinate copper(II) complex with the chiral tridentate Schiff-base ligand providing the ONO donor atom set. The fourth position is occupied by a chloride ion. The overall coordination geometry of the compound is distorted square-planar, with the copper ion lying approximately at the center of the plane consisting of the ligand donor atoms Cl(1), O(1), N(1), and O(2).

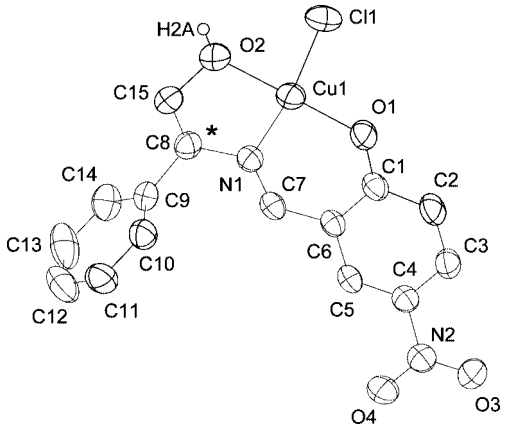

Figure 1. Thermal ellipsoidal plot (50%) of **1**. Hydrogen atoms are omitted for clarity. The asterisk mark indicates the chiral center. Selected bond lengths [Å] and angles [°]: Cu(1)–O(1) 1.880(2), Cu(1)–O(2) 1.968(2), Cu(1)–N(1) 1.954(2), Cu(1)–Cl(1) 2.2482(8), O(1)–C(1) 1.289(3), N(1)–C(7) 1.265(4); O(1)–Cu(1)–N(1) 94.04(9), O(1)–Cu(1)–O(2) 172.12(11), N(1)–Cu(1)–O(2) 81.37(10), O(1)–Cu(1)–Cl(1) 94.99(6), N(1)–Cu(1)–Cl(1) 170.74(7), O(2)–Cu(1)–Cl(1) 89.88(8).

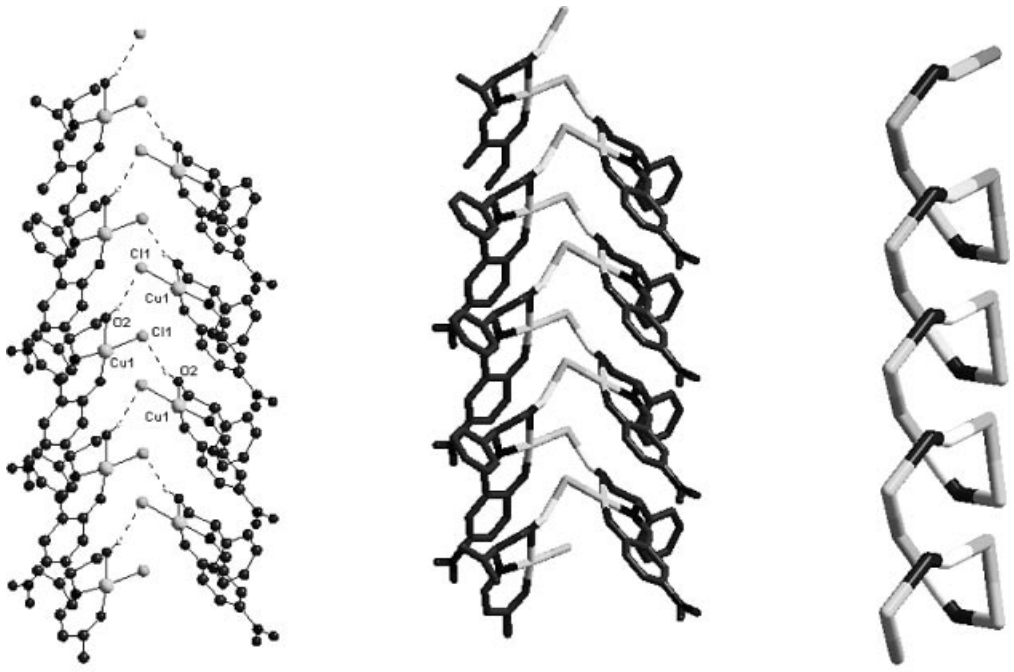

Figure 2. Intermolecular O–H···Cl–Cu hydrogen-bonding interactions between adjacent molecules that lead to the formation of homochiral helices. Ball-and-stick (left) and wire-frame (center) representations; helical backbone (right) (wire-frame representation).

The molecular packing in the crystal structure of **1** reveals strong O–H···Cl–Cu intermolecular hydrogen-bonding interactions involving the hydrogen atom on O(2) and the Cl(1) anion coordinated to the copper center (Figures 1 and 2). This results in the formation of supramolecular hydrogen-bonded helices that extend indefinitely throughout the crystal lattice (Figure 2) [selected hydrogen bonding parameters: H–O = 0.80(4) Å, H···Cl = 2.26(4) Å, O···Cl = 3.024(3) Å, and O–H···Cl = 159(4)°].

The O–H···Cl distance observed in this study [2.26(4) Å] is appreciably shorter than the sum of the van der Waals radii for the H and the neutral Cl atoms (2.95 Å). This can be classified as a strong interaction (those less than 2.52 Å are termed strong).[7a] Similar strong M–X···H–O bonds are known in the literature but they do not result in helical structures. Representative examples include a Cu–Cl···H–O hydrogen bond (H–O = 0.84 Å, H···Cl = 2.25 Å, O···Cl = 3.08 Å, and O–H···Cl = 173.3°) in the crystal structure of $[CuCl(C_{19}H_{19}N_3O)]$[7b] and a Cu–Cl···H–O hydrogen bond (H–O = 0.98 Å, H···Cl = 2.26 Å, O···Cl = 3.228 Å, and O–H···Cl = 171°) in the compound $[CuCl(C_5H_9N_3)(C_{12}H_8N_2)]Cl{\cdot}H_2O$.[7c] The strength of the interaction can be attributed to the strong hydrogen-bond donor ability of the O–H group due to its greater acidity and to the strong H-bonding acceptor property of the metal-bound chloride.

The path of the helix can easily be traced by following the hydrogen bonds clockwise around the twofold screw axis of the helix. Three copper complex fragments form one helix turn in **1** with a pitch of 5.831 Å (Figure 2). We believe that the turn required to generate a perfect periodic self-assembly of [Cu(HL)Cl] (**1**) in a helical fashion is induced by the chirality of the building block coupled with the strong O–H···Cl–Cu hydrogen-bonding interactions. The rigidity of the Schiff-base ligand, which occupies three binding sites of the Cu atom, may also have some role in dictating such a helical arrangement in this self-assembly process. The absolute configuration of complex **1** was successfully determined by refining the Flack parameter [0.029(13)].[8]

Since we have described (above) a supramolecular helical feature of the copper complex [Cu(HL)Cl] (**1**) in the solid state, we decided to perform spectral studies in the solid state. The solid-state circular dichroism (CD) and electronic reflectance spectra of [Cu(HL)Cl] (**1**) are presented in Figure 3. The CD spectrum shows both positive and negative bands. The overall feature of the solid-state reflectance electronic spectrum is not identical to its solution spectrum (see Supporting Information). This can be correlated to the intermolecular interactions in the solid state of complex **1**, as shown in Figure 2. The bands observed in the electronic and CD spectra of complex **1** at around 700 nm are assigned to d–d transitions. The EPR spectrum (Figure 4) of a powdered sample of complex **1** at liquid nitrogen temperature exhibits a typical axial feature with $g_{\|} = 2.22$ and $g_{\perp} = 2.08$ for a Cu^{II} (d^9) system. The feature remains the same even at room temperature. The solution EPR spectrum (see Supporting Information) of complex **1** in frozen methanol shows an axial feature too, but with copper hyperfine coupling for a typical monomeric tetragonal Cu^{II} complex with a $d_{x^2-y^2}$ ground-state doublet.

To summarize, we have synthesized and characterized a chiral, mononuclear, square-planar Cu^{II} complex [Cu(HL)Cl] (**1**), which self-assembles through strong O–H···Cl–Cu intermolecular hydrogen-bonding interactions to form a homochiral helical arrangement. The advantages of this

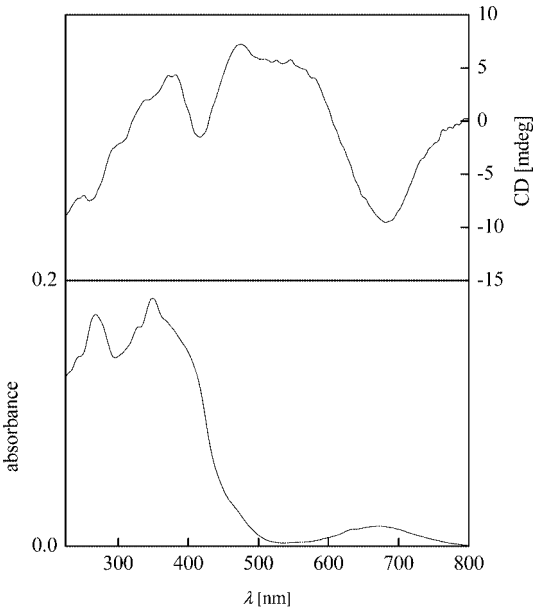

Figure 3. Circular dichroism and diffuse electronic reflectance spectra of **1** in the solid state (compound **1** was mixed with KBr to prepare a pellet).

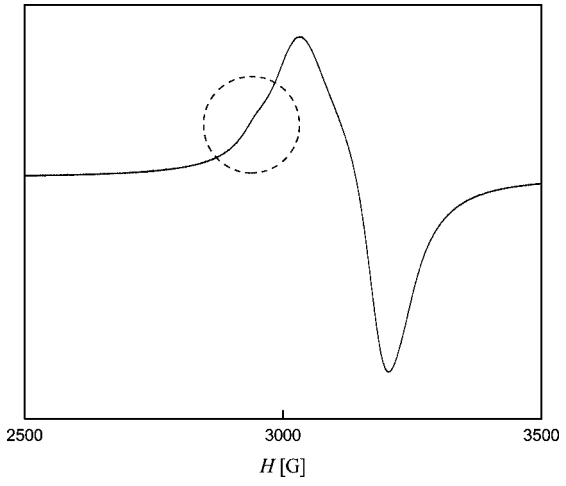

Figure 4. EPR spectrum of a powdered sample of **1** at liquid nitrogen temperature (the circle highlights the $g_{\|}$ feature).

system are that it is simple, easy to prepare, and provides potential for further explorations. The CD and electronic reflectance spectral studies (solid state vs. solution) of **1** support the intermolecular interactions in the solid state, which is consistent with the formation of supramolecular homochiral helices in the crystal. These intermolecular interactions may be lost in solution phase, as evidenced by EPR spectral studies.

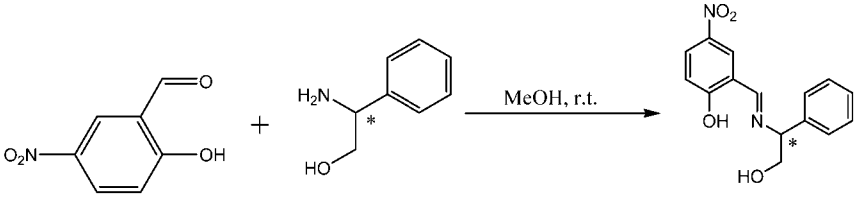
Experimental Section

General: Microanalytical (C, H, N) data were obtained with a Flash EA 1112 Series CHNS Analyzer. A Shimadzu 3101 PC UV/Vis/NIR spectrophotometer was used to record the electronic spectra. Infrared spectra were recorded on KBr pellets with a JASCO-5300 FT-IR spectrophotometer. ^{1}H NMR spectra of the ligand in $CDCl_3$ solution were recorded with a Bruker 400 MHz spectrometer using $Si(CH_3)_4$ as an internal standard. The CD spectra were measured with a JASCO J-810 spectropolarimeter. The EPR spectrum was recorded with a JEOL JES-FA200 spectrometer.

Synthesis of Enantiopure Ligand H_2L: (*S*)-(+)-2-Phenylglycinol (0.137 g, 1 mmol) and 2-hydroxy-5-nitrobenzaldehyde (0.167 g, 1 mmol) were stirred together in methanol (15 mL) at room temperature for 3 h. The resulting yellow solution was filtered and the filtrate was allowed to slowly concentrate. The resulting yellow solid was collected by filtration, washed with hexane, and dried at room temperature (0.25 g, 87%). $C_{15}H_{14}N_2O_4$ (286.28): calcd. C 62.93, H 4.93, N 9.79; found C 63.11, H 4.76, N 9.87. ^{1}H NMR ($CDCl_3$): δ = 4.00 (d, J = 7.2 Hz, 2 H, CH_2), 4.61 (t, J = 6.4 Hz, 1 H, CH), 7.00–7.45 (m, 6 H, Ar), 8.20–8.27 (m, 2 H, Ar), 8.52 (s, 1 H, H–C=N). IR (KBr): $\tilde{\nu}$ = 3272, 1649, 1615, 1545, 1350, 1225, 1070, 901, 835, 696 cm^{-1}. UV/Vis (CH_3OH): λ_{max} (ε) = 390 nm (6141 M^{-1}cm^{-1}), 324 (9655), 259 (18238), 240 (16123).

Synthesis of the Chiral Copper Complex [Cu(HL)Cl] (1): $CuCl_2{\cdot}2H_2O$ (0.17 g, 1 mmol) was added to a methanolic solution of the ligand H_2L (0.286 g, 1 mmol). The mixture was stirred at room temperature in air overnight. The resultant green solution gave a green, needle-shaped crystalline product on slow concentration, which was collected by filtration and recrystallized from methanol (0.265 g, 69%). $C_{15}H_{13}ClCuN_2O_4$ (384.27): calcd. C 46.88, H 3.41, N, 7.29; found C 47.02, H 3.49, N 7.18. IR (KBr): $\tilde{\nu}$ = 1634, 1600, 1549, 1468, 1387, 1308, 1094 cm^{-1}. Diffuse electronic reflectance (KBr pellet): λ_{max} = 270, 375, 700 nm. UV/Vis (CH_3CN): λ_{max} (ε) = 252 nm (20271 M^{-1}cm^{-1}), 235 (20105), 355 (18137), 690 (104).

X-ray Crystallographic Study: $C_{15}H_{13}ClCuN_2O_4$, M = 384.26 g mol^{-1}, monoclinic, space group $P2_1$, a = 11.3232(8), b = 5.8314(4), c = 12.3108(9) Å, β = 112.3110(10)°, V = 752.03(9) Å^3, Z = 2, $D_{calcd.}$ = 1.697 g cm^{-3}, μ = 1.651 mm^{-1}, F(000) = 390, crystal size 0.31 × 0.08 × 0.08 mm. A total of 8757 reflections were collected of which 3368 unique reflections (R_{int} = 0.0262) were used. R = 0.0338 for 3056 reflections with $I > 2\sigma(I)$. Data were collected at 298(2) K with a Bruker SMART APEX CCD area detector system



H_2L

[λ(Mo-K_α) = 0.71073 Å] fitted with a graphite monochromator; 2400 frames were recorded with an ω-scan width of 0.3°, each for 15 s; crystal–detector distance: 60 mm; collimator: 0.5 mm. Data reduction with SAINTPLUS,[9] structure solution with SHELXS-97,[10] and refined with SHELXL-97.[11] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were introduced in calculated positions and included in the refinement as riding on their respective parent atoms. The final Fourier difference synthesis showed minimum and maximum peaks of 0.566 and –0.223 e Å^{-3}. CCDC-265514 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Unexpected Behaviour of Pyridine-2-carbaldehyde Thiosemicarbazonatocopper(II) Entities in Aqueous Basic Medium – Partial Transformation of Thioamide into Nitrile

Patricia Gómez-Saiz,[a] Rubén Gil-García,[a] Miguel A. Maestro,[b] José Luis Pizarro,[c] María Isabel Arriortua,[c] Luis Lezama,[d] Teófilo Rojo,[d] and Javier García-Tojal*[a]

Keywords: Copper complexes / Desulfurization / Structure elucidation / Thiosemicarbazone complexes

Unusual species are obtained from the HL/Cu^{II}/NO_3^- system (HL = pyridine-2-carbaldehyde thiosemicarbazone) in basic aqueous solutions. A partial desulfurization process occurs for 1:1 Cu/HL molar ratio which gives rise to the precipitation of the mixed ligand [Cu(L)(L^{CN})] (**1**) complex [HL^{CN} = $C_7H_6N_4$, (pyridin-2-ylmethylene)hydrazinecarbonitrile]. This compound contains Cu^{II} ions in a square-pyramidal environment. On the other hand, distorted octahedral [$Cu(L)_2$] (**2**) entities are isolated in excess of the thiosemicarbazone ligand. Desulfurization of the thiosemicarbazone is detected even at physiological pH values. However, this reaction does not take place in absence of Cu^{II} ions, and HL·2.25H_2O (**3**) or HL·H_2O are obtained in these conditions.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

The copper(II) derivatives of pyridine-2-carbaldehyde thiosemicarbazone (HL = $C_7H_8N_4S$) exhibit relevant biological properties, in particular related to the cytotoxic effects against tumoral cells.[1] Spectroscopic studies in aqueous solution led to propose the existence of the $[Cu(HL)]^{2+}$, $[Cu(L)]^+$ and [Cu(L)(OH)] species, corresponding to two acid–base equilibria with proton dissociation constants pK_{a1} = 2.40 (deprotonation of the $N_{hydrazinic}$ atom in the ligand) and pK_{a2} = 8.30, respectively.[2] In fact, the high stability of the metal–ligand system has allowed the attainment and structural characterization of several compounds containing $[Cu(HL)]^{2+}$ and $[Cu(L)]^+$ entities.[3] They show a 1:1 metal–thiosemicarbazone stoichiometry, with the thiosemicarbazone acting as an NNS terdentate ligand. However, as far as we are aware, attempts to isolate either the basic [Cu(L)(OH)] species or its derivatives have not been carried out.

The present work deals with the structural studies developed on solids obtained from the pyridine-2-carbaldehyde thiosemicarbazone–nitrate–copper(II) system in aqueous solutions at high pH values. In this way, unexpected [Cu(L)(L^{CN})] (**1**) and [$Cu(L)_2$] (**2**) compounds have been obtained [HL^{CN} = $C_7H_6N_4$, (pyridin-2-ylmethylene)hydrazinecarbonitrile] together with the thiosemicarbazone ligand in a new structural arrangement, HL·2.25H_2O (**3**). Surprisingly, we have not found any evidence of the existence of [Cu(L)(OH)] derivatives in the solids isolated.

Results and Discussion

The addition of sodium hydroxide to an aqueous solution of the Cu(L)(NO_3) complex at pH = 9–11 yields complex **1** as a major component of a dark brown powdery solid. Unfortunately, attempts to purify this compound have been unsuccessful. In spite of this, it has been possible to obtain some small crystals and to solve the molecular structure[4,5] of the monomeric species, which is shown in Figure 1. As can be seen, one of the thiosemicarbazone ligands in compound **1** is converted into a new carbonitrile derivative which acts as a bidentate ligand. The geometry around the Cu^{II} ions is square-pyramidal (τ = 0.25).[6] Distances in the NCN terminal moiety are 1.312(8) and 1.129(9) Å for C14–N7 and C14–N8, respectively. The latter is closer to a C≡N link, but the first one exhibits some double bond character. Therefore, cyanamide (N–C≡N) and carbodiimide (N=C=N) contributions must be considered. Furthermore, it must be taken into account the conjugation along all the system. On the other hand, this car-

bonitrile ligand is unusual from a structural point of view, being the closest related C=N–N–C≡N structure found that corresponding to the C-biphenylene–N(1)-(4-iodophenyl)–N(2)-cyano–azomethinimine compound.[7]

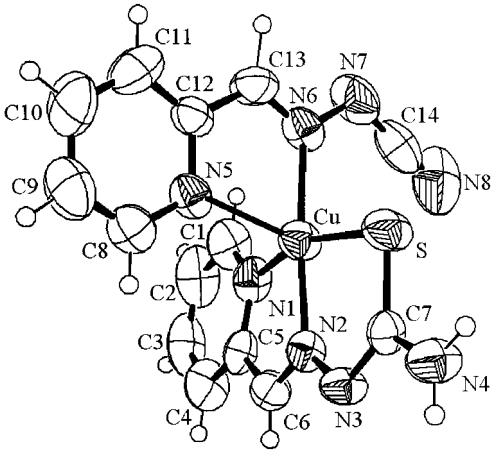

Figure 1. Crystal structure of compound **1**. Selected bond lengths [Å] and angles [°]: Cu–N1 2.025(4), Cu–N2 1.961(4), Cu–S 2.263(2), Cu–N5 2.222(5), Cu–N6 2.039(5), N2–C6 1.288(6), N2–N3 1.351(5), N3–C7 1.330(5), S–C7 1.720(6), N4–C7 1.334(5), N6–C13 1.279(6), N6–N7 1.360(6), N7–C14 1.312(8), N8–C14 1.129(9), N1–Cu–S 159.5(1), N1–Cu–N2 80.7(2), N1–Cu–N6 99.7(2), N5–Cu–N6 78.1(2), N1–Cu–N5 96.0(2), N2–Cu–N6 174.8(2), closest intermolecular Cu···Cu distance 6.528(2)[ii] ([ii] = $-x + 1, -y, -z + 1$).

The structure of compound **1** resembles that of complex **2** (see Figure 2) which was prepared with high purity following a 1:2 metal-to-ligand molar ratio in a basic medium.[8] The crystal building of **2** contains isolated distorted octahedral entities where each Cu^{II} ion is bonded to two NNS terdentate thiosemicarbazone ligands. The N1 atom can be considered as pseudocoordinated to the metal centre due to the long Cu–N1 bond length being the topology better described as a [5+1] coordination. Because of the Jahn–Teller effect in the Cu^{II} ion, there are few bis-chelate copper(II) complexes containing terdentate thiosemicarbazone ligands (to the best of our knowledge, less than 5% of the structures reported in the literature).[9]

The desulfurization of the thiosemicarbazone ligand to give the compound **1** is a complex process very sensitive to temperature, pH, time of reaction and stoichiometry. Variations in the experimental conditions at pH values above 7.0 give rise to differences in the composition of the solids. Most of the products obtained in our experiments exhibit very low crystallinity and dark colours. Because of this, it is very difficult to identify the components of the powders. Besides this, the amorphous precipitates show very low solubility in water and other solvents. This fact prevents purification of the samples without inducing important changes in the experimental conditions. All these problems make it necessary to find characteristic parameters to follow the process. In this sense, the strong infrared band at 2108 cm^{-1} corresponding to ν(CN) in compound **1** has allowed us to check the presence of desulfurized species in solid powdered samples obtained at different pH values. EPR measurements have also been used to identify the presence of **1** and

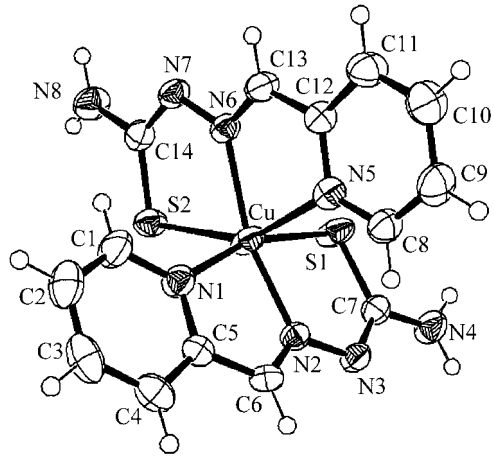

Figure 2. Crystal structure of compound **2**. Selected bond lengths [Å] and angles [°]: Cu–N1 2.515(3), Cu–N2 2.144(3), Cu–S1 2.505(1), Cu–N5 2.059(3), Cu–N6 2.002(3), Cu–S2 2.309(1), N2–C6 1.283(4), N2–N3 1.377(4), N3–C7 1.319(4), S1–C7 1.729(3), N4–C7 1.359(4), N6–C13 1.290(4), N6–N7 1.356(4), N7–C14 1.333(4), S2–C14 1.729(3), N8–C14 1.340(4), N1–Cu–S1 149.61(9), N1–Cu–N2 71.5(1), N1–Cu–N6 84.3(1), N5–Cu–S2 161.83(8), N5–Cu–N6 79.5(1), N1–Cu–N5 85.8(1), N2–Cu–N6 155.7(1), S1–Cu–S2 97.37(4), closest intermolecular Cu···Cu distance 5.9909(7)[i] ([i] = $-x + 1, -y + 2, -z + 1$).

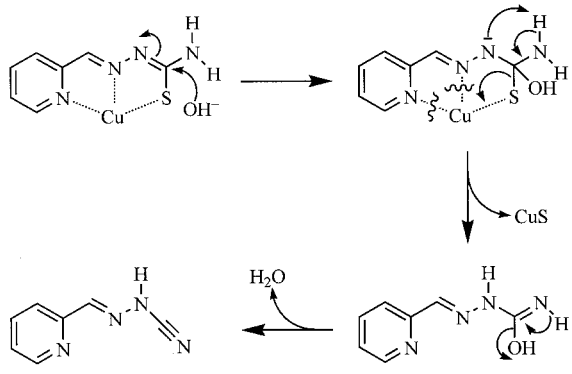
2 in the precipitates. Thus, a degree of desulfurization process has been detected even at physiological pH = 7.4 values in aqueous solutions of $Cu(L)(NO_3)$ at 40 °C. On the other hand, organic fragments are absent in the black solids collected when the reactions are maintained for more than 1 h at pH = 13 and temperatures higher than 40 °C (IR bands in the 4000–400 cm^{-1} region practically disappear if the products are washed with water after filtering off).

A three-step mechanism can be proposed for this reaction (Scheme 1). The resulting HL^{CN} ligand would link to a $[Cu(L)]^+$ entity and deprotonate in basic media. Note that CuS is only a nominal formula to refer the unidentified inorganic species present in the mixture. Nevertheless, qualitative evidences of the presence of sulfide and sulfate have been achieved for some of the samples analysed.[10]



Scheme 1.

Assays using KOH, NEt_3, or 0.5 M $Na_2CO_3/NaHCO_3$ buffer instead of NaOH lead to similar results. The nitrile derivative is also obtained when $Cu(L)(NO_3)$ is replaced by $[\{Cu(L)Cl\}_2]$[3b,3c,3i] as starting material.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

No evidence of nitrile formation has been found in the absence of Cu^{II} ions, even not when the aqueous solutions were evaporated to dryness. Instead, the yellow $HL{\cdot}2.25H_2O$ (**3**) compound was obtained at pH ≈ 13. The molecular structure of **3**[11] (Figure 3) shows bond lengths and angles very similar to those reported in the literature for $HL{\cdot}H_2O$[12] but, surprinsingly, the *syn* conformation of the N(1) and N(2) atoms with respect to the C(5)–C(6) bond resembles the crystal features of the pyridinium H_2L^+ derivatives obtained at very low pH values.[13] On the other hand, evaporation of aqueous solutions of the free ligand at pH ≈ 11 to dryness yields red crystals with the same structure reported by Byushkin et al. for $HL{\cdot}H_2O$ (see Supporting Information).

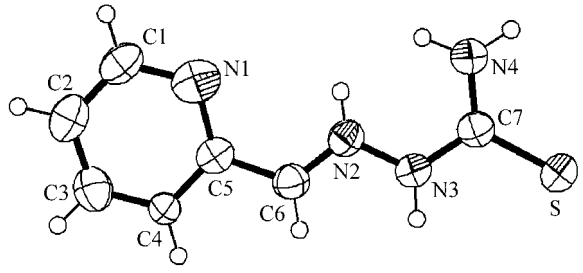


Figure 3. Crystal structure of compound **3**. Selected bond lengths [Å]: N2–C6 1.277(4), N2–N3 1.363(3), N3–C7 1.351(4), S–C7 1.695(3), N4–C7 1.314(4).

Taking into account the extensive literature dealing with the conversion of thioamides and thioureas into carbonitriles, cyanamides and carbodiimides,[14] one could expect that the reaction reported here is also quite common for thiosemicarbazone compounds. However, as far as we are aware, transformation of thiosemicarbazones into carbonitrile derivatives induced by basic media is an unprecedent process. In fact, we have tried the attainment of HL^{CN} by reaction of HL with HgO, but the $[Hg(L)_2]$ compound was obtained.[15] In the same way, previous attempts of desulfurization of HL using $HgCl_2$ + Na in methanol and $Pb(CH_3COO)_2{\cdot}3H_2O$ + KOH in water were unsuccessful.[1j] These results are probably due to the stability that the conjugation induces in this thiosemicarbazone system.

Recently, desulfurization of dithiocarbamatocadmium(II) complexes in the presence of amines has been reported.[16] In addition, there are indirect evidences of desulfurization of an analogous thiosemicarbazonecopper(II) system in aqueous basic medium.[17] However, the reactions described in these papers do not yield carbonitrile derivatives.

The presence of such a process in physiological conditions could lead to a re-interpretation of the biological properties of some thiosemicarbazone systems, mainly those aspects related to the possible therapeutic uses. Furthermore, this reaction opens an inexpensive way to achieve the synthesis of new ligands. In a more general scope, the transformation of thioamides into carbonitriles in the presence of Cu^{II} ions suggests possible pathways for the syntheses of biomolecules in sulfur-rich environments, e.g. prebiotic conditions.[18]

Supporting Information Available: IR and EPR spectra, powder diffractograms of samples at different pH values and a summary of the cif output for the $HL{\cdot}H_2O$ compound.

Acknowledgments

We thank Drs. J. J. Delgado and V. Diez-Gómez (SCAI, Universidad de Burgos, Spain), and Jon P. Chapman (Servicio General de Rayos X, Universidad del País Vasco, Spain) for the elemental analyses and some of the X-ray measurements. This work has been carried out with the financial support of the Dirección General de Investigación del Ministerio de Ciencia y Tecnología. BQU2002–00435 and the Junta de Castilla y León BU15/03. P. G.-S. thanks to the Universidad de Burgos for her Doctoral Fellowship.

[4] Synthesis of **1**: published methods with small modifications were used to synthesize HL[5] and Cu(L)(NO_3).[3b] The best way that we have found to obtain **1** with a less amount of impurities consists on the dropwise addition of a solution of HL (0.180 g, 1.0 mmol) in water (30 mL) previously basified with 5 M NaOH just to solution of the ligand (pH ≈ 11), to another aqueous solution of $Cu(NO_3)_2{\cdot}3H_2O$ (0.100 g, 0.5 mmol) with heating (70 °C). Once the addition was completed, the heating was stopped and the reaction was maintained for 1.5 h. The brown precipitate was filtered off, washed with water at pH ≈ 11 (2 × 20 mL) and dried over vacuum. Good results were also obtained starting from Cu(L)(NO_3) (0.152 g, 0.5 mmol) in water (30 mL) at 80 °C by addition of NaOH 0.1 M to reach pH = 9.0 and further reaction for 1 h maintaining the temperature and pH. Other trials were carried out at different pH values (7.4, 9.0, 11.0, and 13.0), temperatures (40, 50, and 80 °C) and reaction times (1 and 5 h) yielding compounds with varied compositions. **1** is present in some of these solids, except for those obtained in extreme conditions (e. g. reactions for 5 h at 80 °C and any pH value yielded black unidentified amorphous inorganic solids). Brown crystals of **1** suitable for X-ray analysis were separated from the mother liquours of the reaction of $Cu(NO_3)_2{\cdot}3H_2O$ and HL (stoichimetries 2:3) by slow evaporation at room temperature. $C_{14}H_{12}CuN_8S$ (387.92): calcd. C 43.3, H 3.1, N 28.9, S 8.3; found C 40.6, H 3.0, N 26.9, S 7.5. Selected IR bands (cm^{-1}, KBr): 3426 w, br., 3290 m, br., 3070 m, br., 3018 w, 2966 w, 2194 vw, 2108 vs, 1646 m, 1596 s, 1526 s, 1483 w, 1468 m, 1446 s, 1427 vs, sh, 1383 s, 1346 m, 1320 m, 1296 w, 1226 s, 1166 vs, 1155 vs, 1016 vw, 897 vw, 880 vw, 766 w, 738 w, 627 w. [10] Qualitative tests used to detect the presence of (a) sulfide and (b) sulfate: (a) HCl(c) (0.5 mL) was added to 0.030 g of each sample in a test tube, being the top of the tube covered with a paper wet with a solution of $Pb(NO_3)_2$ 0.5 M. H_2S evolution leads to the PbS formation; (b) addition of HCl(c) (1.0 mL) to 0.030 g of the solid, filtration, and addition of $Ba(NO_3)_2$ 0.04 M (0.5 mL) to the acid solution. White $BaSO_4$ precipitates if sulfate ions are present.

[11] Synthesis of **3**: several drops of 5 M NaOH were added to a suspension of HL (0.180 g, 1 mmol) in water (20 mL) to reach a pH ≈ 13 with heating. Some minutes later, the solid disappeared leading to a pale yellow solution. The reaction mixture was allowed to react 1 h after which a white crystalline compound was filtered off, washed with water at basic pH (2 × 20 mL) and dried (0.132 g, 60%). Pale yellow crystals suitable for X-ray studies were separated from a solution of HL in water at pH ≈ 13. $C_7H_{12.5}N_4O_{2.25}S$ (220.77): calcd. [15] Drops of 5 M NaOH were added over a solution of $HgCl_2$ (0.070 g, 2.5 mmol) in water (30 mL) just to complete precipitation of yellow HgO, which was filtered off and washed with water (2 × 20 mL) and acetone (20 mL). The freshly prepared oxide was put into a flask with a small amount of acetone and HL (0.180 g, 1 mmol) was added dropwise. The reaction was kept with reflux for 5 h. A yellow solid was collected and

washed with acetone (20 mL). This compound is a mixture of $[Hg(L)_2]$ + HgO. For a complete characterization of $[Hg(L)_2]$, see ref.[1j]

Unprecedented Coordination Mode Variation of Group 13 Metal–Alkyl Compounds Derived from Methyl Thiosalicylate

Janusz Lewiński,*[a] Wojciech Bury,[a] Tomasz Kopeć,[a] Ewa Tratkiewicz,[a] Iwona Justyniak,[b] and Janusz Lipkowski[b]

Keywords: Aluminum / Indium / Noncovalent interactions / Thiolates

The X-ray structure analysis of the alkylaluminum and -indium compounds derived from methyl thiosalicylate, $Me_2Al(SC_6H_4\text{-}2\text{-}CO_2Me)$ and $[Me_2In(\mu\text{-}SC_6H_4\text{-}2\text{-}CO_2Me)]_2$, revealed that the intermolecular S···C(π) interaction between the Al–S thiolate units and the ester π-surface can effectively compete with the hypercoordinate sulfur–metal dative bond. The former compound exists as the noncovalently bonded dimer involving the thiolate sulfur atom and the electrophilic carbon atom of the ester functionality, whereas the indium complex is a five-coordinate dimer with the $In_2(\mu\text{-}S)_2$ central core.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

The chemistry of five-coordinate aluminum complexes has an extensive literature[1] and the significance of the fifth coordinate site for aluminum-based reagent/catalyst function and/or selectivity is gradually emerging.[2] In spite of many contributions in this area, less direct information has been gleaned about the nature of bonding, stability, and reactivity of this class of compounds, and the identity of both active centers and transition-state structures remains elusive.[3] Therefore, detailed structural information concerning the extent of coordination and association in alkylaluminum complexes as well as the magnitude of the donor–aluminum interaction in five-coordinate species are crucial in understanding their physical behavior and chemical reactivity. In this regard, investigations based on the dialkylaluminum chelate complexes derived from donor-functionalized alcohols or unsaturated bifunctional O,X-H proligands, i.e., $[R_2Al(O,X)]_n$-type complexes, have appeared particularly fruitful.[4] Recently, our group has reported the results concerning the relationship between intra- and intermolecular forces resulting from donor–acceptor and hydrogen-bonding interactions using group 13 chelate complexes.[5] For instance, we have demonstrated that in the solid state dialkylaluminum chelate complexes have a tendency to form $[R_2Al(\mu\text{-}O,O')]_2$-type adducts with five-coordinate metal centers (Scheme 1, structure **I**) with the intermolecular Al–O distance varying from ca. 2.05 Å to the van der Waals surface (i.e., over 3.5 Å).[4f] Conversely, the structure investigations of the group 13 chelate complexes with salicylideneiminate anion (saldR′) revealed that the crystal structure of $R_2M(saldR')$ (M = Al or Ga) complexes is determined by distinct intermolecular hydrogen-bond motifs (structure **II**), while the indium analogue formed a five-coordinate dimer with $In_2(\mu\text{-}O)_2$ bridges in the solid state.[5a,5b] As an extension of this work, we report herein on structure investigations of alkylaluminum and -indium compounds derived from methyl thiosalicylate, which revealed that the intermolecular S···C(π) interaction between the Al–S thiolate units and the π-surface of the ester functionality (structure **IV**) can compete with the putative sulfur–aluminum hypercoordinate bond (structure **III**).

Results and Discussion

The reaction of Me_3Al with methyl thiosalicylate in an equimolar ratio results in the quantitative formation of $Me_2Al(SC_6H_4\text{-}2\text{-}CO_2Me)$ (**1**). The resulting complex has been characterized in solution by NMR spectroscopy and molecular weight measurements (see Exp. Sect.), and in the solid state its structure has been determined by X-ray crystallography. Compound **1** exists as a monomer in solution and crystallizes as a noncovalently bonded dimer (Figure 1). The monomeric units of **1** consist of the tetrahedral aluminum center. The salient structural feature of **1** is the conformation of the chelate-ring system S(1)–C(3)–C(8)–C(9)–O(1)–Al(1), which highly deviates from planarity with a puckering amplitude Q = 0.579(2) Å.[6] This deformation is realized by the bending on the sulfur atom, while the metal–ester linkage remains essentially planar; the torsion angles Al(1)–S(1)–C(3)–C(8) and Al(1)–O(1)–C(9)–C(8) are equal to 30.3(3)° and 1.2(4)°, respectively. The ester group is rotated relative to the phenyl ring with an O(1)–C(9)–C(8)–C(3) torsion angle of 23.9(4)°. Most strikingly, the analysis of the crystal-packing patterns of **1** shows notably short intermolecular S···C(π) [3.379(3) Å] distances between a pair of adjacent molecules that represents a type of weak attractive interaction of the sulfur atom to the π-system of the ester group. The observed S···C(π) distance remains significantly below the sum of the van der Waals radii,[7,8] and should be considered as denoting a bonding interaction. This assumption is further supported by the relative orientation of the thiolate and ester groups: the S···C=O angle is 88.7°, and both the Al–S···C(π) and the C–S···C(π) angles are close to the tetrahedral values indicating that the sulfur sp^3 lone pair is oriented approximately perpendicular to the ester group.

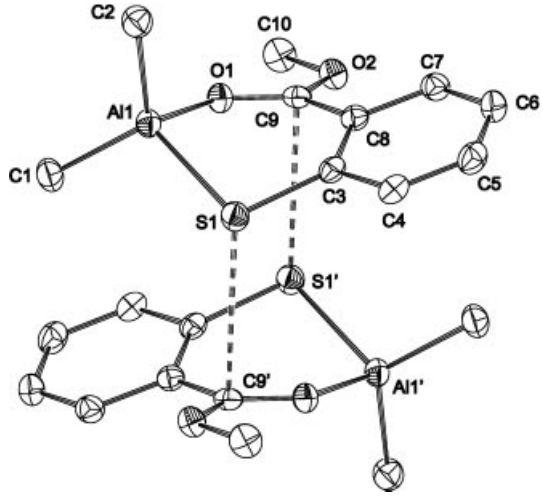

Figure 1. Molecular structure of **1** with thermal ellipsoids drawn at the 40% probability; hydrogen atoms are omitted for clarity.

The structural motif for **1** is surprising as both the participation of thiolate ligands in the formation of the $R_2Al(\mu\text{-}SR')_2AlR_2$ bridges and the Lewis acid properties of the metal center in tetrahedral dialkylaluminum chelate complexes are well recognized.[1] We have previously determined the following order for the Lewis acidity of the group 13 metal centers in the four-coordinate $R_2M(O,O')$ complexes: In ≥ Al > Ga,[4c] and it was of interest to see which type of coordination mode would be adopted by the alkylindium derivative of methyl thiosalicylate. The reaction of Me_3In with the pro-ligand results in the formation of $[Me_2In(\mu\text{-}SC_6H_4\text{-}2\text{-}CO_2Me)]_2$ (**2**) which is found to exist as a monomer/dimer equilibrium based on solution molecular weight studies (calcd. for dimeric **2** 623.72, found 530). A similar equilibrium was observed for dimethylindium acetylacetonate complex,[9] while the related dimethylindium complexes supported by methyl salicylate[4c] or *N*-phenylsalicylideneimine[5a] occurred exclusively in the dimeric form in benzene solution.

The X-ray crystallographic analysis revealed that in contrast to the aluminum complex **1**, the indium derivative **2** adopts the five-coordinate motif with the $In_2(\mu\text{-}S)_2$ central core (see Figure 2). The conformation of the chelate-ring system S(1)–C(3)–C(8)–C(9)–O(1)–In(1) is even more pleated than the related heterocyclic ring in **1** [with a puckering amplitude Q = 0.922(3) Å]. The In–S distances are dissimilar [2.561(5) and 2.853(2) Å], with that in the equatorial position being 0.292 Å shorter. The In(1)–O(1) distance of 2.452(4) Å is longer than the corresponding linkage in the related five-coordinate dimer derived from methyl salicylate, $[Me_2In(\mu\text{-}OC_6H_4\text{-}2\text{-}CO_2Me)]_2$ [2.165(4) Å].[4c] Thus, the five-coordinate dimeric motif observed for **2** demonstrates that group 13 metal–alkyl compounds supported by the monoanionic methyl thiosalicylate ligand are capable of aggregating through dative bridging bonds between the metal center and the thiolate group.

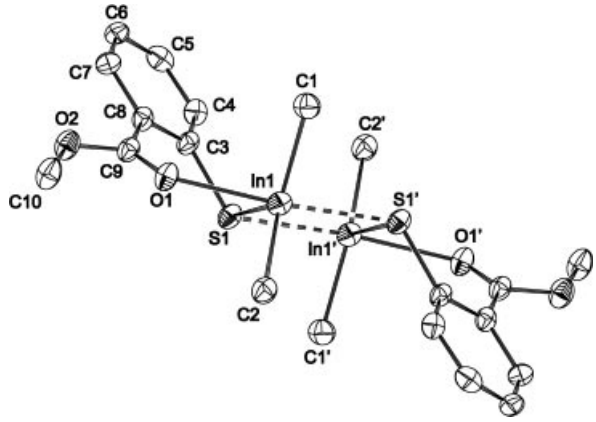

Figure 2. Molecular structure of **2** with thermal ellipsoids drawn at the 40% probability; hydrogen atoms are omitted for clarity.

Conclusions

In conclusion, the reported results clearly indicate that for the methylaluminum complex supported by the methyl thiosalicylate ligand the structure of type **IV** is preferred over the adduct of type **III** with the dative bond between the thiolate sulfur atom and the aluminum five-coordinate site. To the best of our knowledge, this is the first report

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

on the competition of the intermolecular n→π* interaction, involving the thiolate sulfur atom and the electrophilic carbon atom of the ester functionality, with the hypercoordinate bond in metal complexes and opens up an interesting area for further studies. Studies of both the relationship between the hypercoordinate bonds in the group 13 metal–alkyl complexes and noncovalent interactions, and the significance of the intermolecular S···C(π) interaction between M–S thiolate units and the π-surface of the carbonyl functionality in various systems are in progress.

Experimental Section

General Remarks: All reactions were carried out under dry nitrogen using standard Schlenk techniques. Solvents were dried and distilled prior to use. NMR spectra were recorded with a Varian Mercury 400 spectrometer.

$Me_2Al(SC_6H_4$-2-$CO_2Me)$ (1): $AlMe_3$ (0.312 g, 4.32 mmol) was added to a solution of methyl thiosalicylate (0.727 g, 4.32 mmol) in hexane (7 mL) at –78 °C. After the addition was completed, the reaction mixture was allowed to warm to room temperature and a pale yellow solid precipitated. The product was dissolved under heating to 40 °C and yellow block-shaped crystals were obtained at 0 °C. Yield: 0.934 g (96%). $C_{10}H_{13}AlO_2S$ (224.24): calcd. C 53.32, H 6.26, S 14.23; found C 53.07, H 6.32, S 14.11; molecular weight studies: calcd. 224.24, found 238. ^{1}H NMR (200 MHz, C_6D_6): δ = –0.17 (s, 6 H, $AlCH_3$), 2.88 (s, 3 H, OCH_3), 6.51–7.68 (m, 4 H, Ar) ppm. ^{13}C NMR (50 MHz, C_6D_6): δ = –8.3, 55.0, 123.2, 123.8, 132.7, 134.8, 137.3, 152.1, 175.9 (C=O) ppm. ^{27}Al NMR (104 MHz, C_6D_6): δ = 158 ppm.

$Me_2In(\mu$-SC_6H_4-2-$CO_2Me)$ (2): The reaction was carried out according to the same procedure as described for **1**, using $InMe_3$ (0.141 g, 0.89 mmol) and methyl thiosalicylate (0.152 g, 0.89 mmol) in toluene (7 mL). Colorless block-shaped crystals were obtained from a toluene/hexane solution at –20 °C after 24 h. Yield 0.27 g (98%). $C_{20}H_{26}In_2O_4S_2$ (624.19): calcd. C 38.49, H 4.20, S 10.27; found C 38.12, H 4.11, S 9.98. ^{1}H NMR (200 MHz, C_6D_6): δ = 0.42 (s, 6 H, $InCH_3$), 3.17 (s, 3 H, OCH_3), 6.67–7.64 (m, 4 H, Ar) ppm. ^{13}C NMR (50 MHz, C_6D_6): δ = –2.9, 52.5, 124.4, 129.6, 131.8, 132.2, 136.7, 143.7, 172.0 (C=O) ppm.

X-ray Crystallographic Study: A single crystal of **1** and **2** suitable for X-ray diffraction studies was placed in a thin-walled capillary tube (Lindemann glass 0.5 mm) under an inert gas. The tube was plugged with grease, then flame-sealed and mounted on a goniometer head. **1:** Triclinic, space group $P\bar{1}$ (no. 2), a = 8.4030(4), b = 8.6340(6), c = 9.9590(5) Å, α = 88.776(4), β = 66.253(3), γ = 62.170(3)°, V = 572.34(6) Å^3, Z = 2, F(000) = 236, $D_{calcd.}$ = 1.301 g m^3, T = 150(2) K. **2:** Monoclinic, space group $P2_1/c$ (no. 14), a = 8.1080(17), b = 13.151(3), c = 11.423(2) Å, β = 108.0.94(15)°, V = 1157.8(4) Å^3, Z = 4, F(000) = 759, $D_{calcd.}$ = 2.198 g m^3, T = 150(2) K. Nonius Kappa-CCD diffractometer, μ(Mo-K_a) = 4.19 mm^{-1}. The structures of **1** and **2** were solved by direct methods using the SHELXS-97[10] program and were refined by full-matrix least squares on F^2 using the program SHELXL-97.[11] Refinement converged at R_1 = 0.0514, wR_2 = 0.1185 for all data and 130 parameters [R_1 = 0.0443, wR_2 = 0.1145 for 1600 reflections with $I_o > 2\sigma(I_o)$], GOF = 1.07 for **1**; R_1 = 0.0514, wR_2 = 0.1185 for all data and 130 parameters [R_1 = 0.0443, wR_2 = 0.1145 for 1600 reflections with $I_o > 2\sigma(I_o)$], GOF = 1.053 for **2**. CCDC-240417 (**1**) and -240418 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Supporting Information: Selected bond lengths and angles in **1** and **2** (see footnote on the first page of this article).

An Unusual 3D Interdigitated Architecture Self-Assembled from Sidearm-Containing 2D Bilayer Motifs with a Cuboidal Framework

Xin-Long Wang,[a] Chao Qin,[a] En-Bo Wang,*[a] and Lin Xu[a]

Keywords: Bilayers / Interdigitation / Luminescence / Supramolecular chemistry / Zinc

The new complex [Zn(H_2bptc)(bpy)]·0.5bpdo (**1**) [H_4bptc = 3,3′,4,4′-biphenyltetracarboxylic acid, bpy = 4,4′-bipyridine, and bpdo = 4,4′-bipyridine *N*,*N*′-dioxide] has been synthesized and characterized. It exhibits a novel (2D→3D) interdigitated architecture that is obtained for the first time from the self-assembly of sidearm-containing bilayer motifs with a cuboidal framework, in which each cuboidal box of one bilayer is interdigitated by two arms that belong to two adjacent bilayers. The luminescent properties of **1** are discussed.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

The interest in entangled systems is rapidly increasing not only for their potential applications as functional materials[1] but also their aesthetic and often complicated architectures and topologies.[2] Interpenetrating networks are the most popular among the entangled polymeric systems, and many appealing interpenetrated frameworks have been constructed, aided by the rapid growth of network-based crystal engineering, and have been well discussed in two comprehensive reviews by Robson and Batten.[3] More recently, a complete analysis of all 3D interpenetrated metal-organic framework structures contained in the CSD database has been proposed with a rationalization and classification of the topology of interpenetration.[4] A characteristic feature of interpenetration is that it is necessary to break internal connections in order to separate the individual nets. In contrast, other types of polymeric supramolecular architectures can, in principle, be disentangled without the need for breaking links (hereafter referred to as "extricable entanglement"), and their resulting overall architectures are more flexible than the usual networks entirely based on coordination bonds − a functional property that has potential applications ranging from drug-delivery vehicles to sensor devices.[5] Unfortunately, these species are much less known, as evidenced by a recent review by Ciani and co-workers.[6] At present, limited examples include infinite multiple helices,[7] cloth-like warp-and-weft sheet structures,[8] interdigitation,[9] and polypseudo-rotaxane structures.[10] Up to now, of the previously reported interdigitated examples, almost all are related to highly undulating *single* layers containing small and cramped windows,[9a,9b] including two exceptional cases in which interdigitation occurs between two different structural motifs (a 1D chain and a 2D puckered layer).[9c,9d] A molecular bilayer as a new structural motif was not reported until recently,[11] although since then several types of bilayer architectures have been fabricated by the assembly of T-shaped,[12] non-T-shaped,[13] or rectangular segments.[14] To the best of our knowledge, the only known interdigitated species containing *double* layer motifs is [Ag(bpe)($L_{0.5}$)]·H_2O [bpe = 1,2-bis(4-pyridyl)ethane; L = 4,4′-biphenyldicarboxylate,[9e] which is comprised of two sets of polycatenated T-shaped bilayers and where, quite surprisingly, the closest bilayers belonging to the different sets are interdigitated in pairs in a tongue-and-groove fashion.[15] An interesting question that arises from this is whether interdigitated structures can also be generated by the aggregation of other types of bilayers, and, if so, what would they be like.

Fortunately, by trial and error we have isolated such a complex, namely [Zn(H_2bptc)(bpy)]·0.5bpdo (**1**) [H_4bptc = 3,3′,4,4′-biphenyltetracarboxylic acid, bpy = 4,4′-bipyridine, and bpdo = 4,4′-bipyridine *N*,*N*′-dioxide], which, for the first time, defines a 3D interdigitated architecture assembled by sidearm-containing bilayer motifs with a cuboidal framework.

Results and Discussion

Single-crystal X-ray diffraction reveals that **1** (see Exp. Sect. for synthesis) is an extended 3D interdigitated network involving 2D bilayers with dangling arms. Each Zn^{II} atom is coordinated by three carboxylate oxygen atoms from three different bptc ligands and two nitrogen atoms from two bpy ligands to give a distorted trigonal-bipyrami-

dal geometry (Figure 1). Two crystallographically equivalent zinc atoms are bridged by a pair of bptc carboxylate ends into a dinuclear zinc unit with a Zn···Zn distance of 3.82(7) Å. The dizinc carboxylate moieties are linked by four *exo*-tridentate bptc ligands (two of the four carboxylate groups do not take part in coordination but are pendent) to two adjacent dinuclear zinc units, thus generating a 1D $[Zn_2(Hbptc)_2]_n$ double chain (Figure S1). The zinc ions have an affinity for a five-coordinate environment, as discussed above, three of which have been used in the construction of the double chain, therefore the remaining two provide additional binding sites, i.e. two bpy ligands coordinate *trans* to each metal center in an axial position, thereby further connecting adjacent double chains into a unique 2D bilayer containing cuboidal boxes of approximate dimensions 11.4×13.0×3.8 Å, as illustrated in Figure 2. The 2D bilayer framework can also be considered as being constructed by two (4,4) grid sheets of composition $[Zn(H_2bptc)(bpy)]$ linked by μ_2-carboxylato groups of bptc.

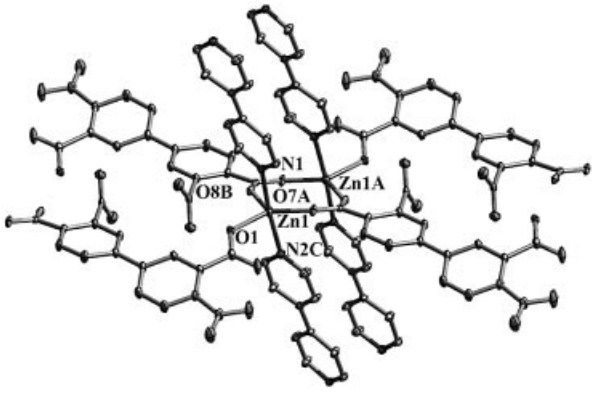

Figure 1. ORTEP view of the Zn^{II} coordination environments. Selected bond lengths [Å]: Zn(1)–O(1) 1.9935(15), Zn(1)–O(7A) 2.0007(14), Zn(1)–O(8B) 2.0189(14), Zn(1)–N(1) 2.1642(16), Zn(1)–N(2C) 2.1665(17). Symmetry codes: A: *x*, *y*, *z* + 1; B: –*x* + 1, –*y* + 1, –*z* + 1; C: *x*, *y* – 1, *z*.

It should be noted that, different from the previously reported bilayers assembled from rectangular building blocks, the unusual bilayer structure reported here has lateral arms pointing out from both sides of the bilayer (Figure 2, bottom). This remarkable feature is a necessary condition for the formation of interdigitation. To sum up, three factors can be envisaged to play roles in the generation of mutual interdigitation in **1**: (i) the presence within the 2D bilayer motifs of very large cuboidal boxes (with dimensions 11.4×13.0×3.8 Å) built up by four pairs of dizinc units, four bptc, and four bipy ligands, (ii) the existence of dangling bptc groups that are disposed in a mutual *anti* orientation with respect to the bilayer plane, and (iii) the fact that all the bilayers are stacked parallel at a distance of about 5.72 Å, while the effective length of each dangling arm is around 8.64 Å (from the baricenter of the dizinc unit to the uncoordinated carboxyl oxygen atom end), thus providing, obviously, the possibility for the ultimate realization of mutual interdigitation. Under these premises, the lateral arms of each bilayer point into the cuboidal voids of the adjacent

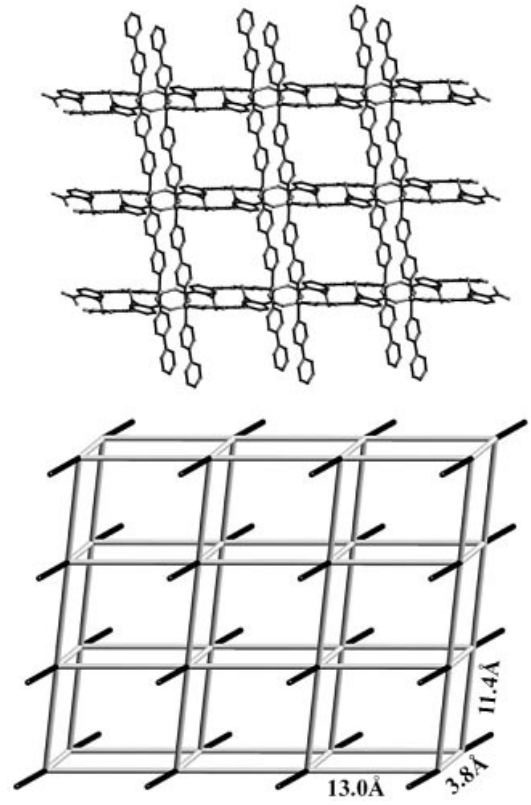

Figure 2. View of the 2D bilayer (top) and a schematic representation of the sidearm-containing 2D bilayer with large cuboidal boxes (bottom).

bilayers, in a mutual relationship. Each cuboidal box is therefore interdigitated by two arms that belong to two different bilayers, one entering from one side and the other from the opposite one, as shown in Figure 3. Finally, this unique fashion originated by the entanglement of three adjacent polymeric motifs at a time gives the novel (2D→3D) interdigitated array of compound **1** (see Figure 4). The aromatic rings of bptc pointing into the cuboidal box are parallel to those of edges bridged by bptc ligands, thus generating the π–π stacking interactions with a face-to-face separation of 3.61 Å that stabilize the whole entanglement. The schematic representation of the "mutual interdigitation" in this species shows that two adjacent bilayers are displaced by about one third of the polymer period along the direction of extension. The sequence of the bilayers in the 3D network is therefore of the ABCABC type (Figure 4).

A potential driving force for interdigitation is the need to fill the void space of a single network. However, in spite of this feature, the resulting 3D network still contains one-dimensional channels running along the *a*-axis and the effective free volume is 20.2%, as calculated by PLATON (Figure S2). Guest bpdo molecules reside in the channels and are hydrogen-bonded to the uncoordinated carbonyl oxygen atom of the bptc [O(6)···O(9) 2.577(3) Å]. Moreover, they form significant π–π stacking interactions with the arm moieties [interplanar distance of 3.55(6) Å], thereby stabilizing the whole 3D host-guest network.

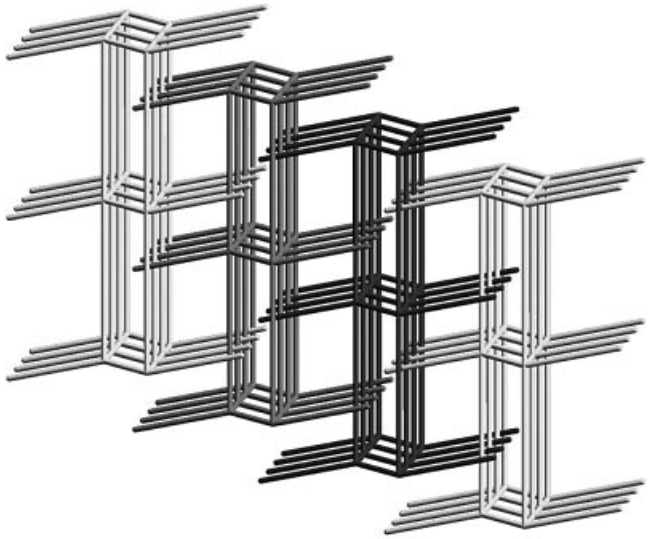

Figure 4. Schematic view of the (2D→3D) interdigitated array showing the relative displacement of the adjacent bilayers.

Compound **1** shows a strong photoluminescence in the solid state at room temperature, with a maximum emission band at 456 nm upon excitation at 338 nm (Figure 5). As there are no obvious emissions observed for the organic components under the same experimental conditions, the intense luminescence in compound **1** may be attributable to ligand-to-metal charge transfer.[16]

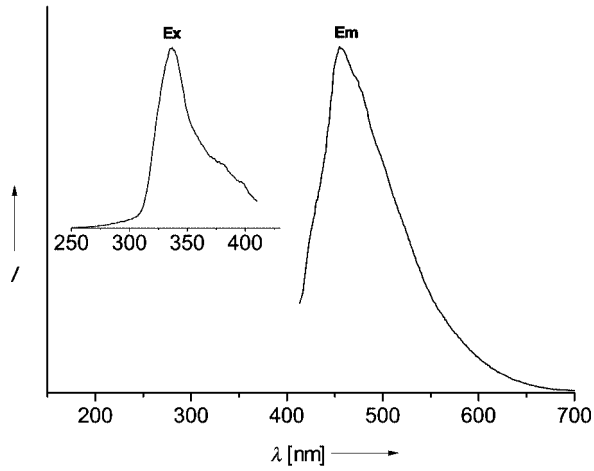

Figure 5. Photoluminescent spectra of **1** in the solid state at room temperature. Ex = excitation, Em = emission.

Conclusions

In summary, this work has, for the first time, demonstrated that an interdigitated structure can be produced by the assembly of bilayer motifs with a cuboidal framework. Compound **1**, besides adding a new member to the class of extricable entanglement, provides a remarkable new structural motif for the entangled system. Based on this new motif, one can envisage using it to construct another unknown entangled type − polythreading of bilayers − when the lateral arms are long enough to ensure complete threading through the cuboidal box. Further development and study of this interesting molecular module are in progress in our laboratories.

Experimental Section

Synthesis of 1: A mixture of $Zn(NO_3)_2 \cdot 6H_2O$ (149 mg, 0.5 mmol), H_4bptc (165 mg, 0.5 mmol), bpy (78 mg, 0.5 mmol), bpdo (47 mg, 0.25 mmol), triethylamine (0.05 mL, 0.35 mmol), and water (10 mL) in a 23-mL Teflon-lined reactor were heated at 160 °C under autogenous pressure for 5 d and then cooled to room temperature at a rate of 10 °C h^{-1} to give colorless crystals of **1** (yield: 135 mg, 42% based on Zn). $C_{31}H_{20}N_3O_9Zn$ (643.87): calcd. C 58.72, H 3.13, N 6.53; found C 58.35, H 3.47, N, 6.46. FT-IR (KBr): $\tilde{\nu}$ = 1715 (s), 1604 (vs), 1519 (s), 1491 (s), 1410 (s), 1380 (vs), 1210 (m), 1170 (m), 1150 (m), 805 (m), 782 (m) cm^{-1}.

X-ray Crystallographic Study: The data were collected with a Rigaku R-AXIS RAPID IP diffractometer with Mo-K_α monochromated radiation (λ = 0.71073 Å) at 173(2) K. An empirical absorption correction was applied. The structures were solved by direct methods and refined by the full-matrix least-squares method on F^2 using the SHELXTL crystallographic software package.[17] Anisotropic thermal parameters were used to refine all non-hydrogen atoms. The hydrogen atoms were included at idealized positions. Crystal data for **1**: $C_{31}H_{20}N_3O_9Zn$, M = 643.87, triclinic, space group $P\bar{1}$, a = 9.6477(19), b = 11.410(2), c = 12.980(3) Å, α =

Is the Aromatic Fragment of Piano-Stool Ruthenium Compounds an Essential Feature for Anticancer Activity? The Development of New Ru^{II}-[9]aneS_3 Analogues

Barbara Serli,[a] Ennio Zangrando,[a] Teresa Gianferrara,[b] Claudine Scolaro,[c] Paul J. Dyson,[c] Alberta Bergamo,[d] and Enzo Alessio*[a]

Keywords: Antitumor agents / Facial coordination / Half-sandwich complexes / Ruthenium / S ligands

New half-sandwich Ru^{II}-[9]aneS_3 complexes ([9]aneS_3 = 1,4,7-trithiacyclononane), namely [$RuCl_2$(PTA)([9]aneS_3)] (**4**), [RuCl(PTA)$_2$([9]aneS_3)][OTf] (**5**), [RuCl(en)([9]aneS_3)][OTf] (**6**), [RuCl(enac)([9]aneS_3)][OTf] (**7**), [RuCl(bipy)([9]aneS_3)][OTf] (**8**), and [Ru(dmso-S)(bipy)([9]aneS_3)][OTf]$_2$ (**9**) [PTA = 1,3,5-triaza-7-phosphaadamantane; enac = 1,2-bis-(isopropyleneimino)ethane; OTf = $CF_3SO_3^-$] were prepared from Ru-[9]aneS_3–dmso precursors and structurally characterized, both in solution and in the solid state by X-ray crystallography. Some of them are analogs of known cytotoxic organometallic Ru^{II}-(η^6-arene) and Ru^{II}-(η^5-cyclopentadienyl) compounds, in which the aromatic fragment is replaced by the sulfur macrocycle 1,4,7-trithiacyclononane, while the rest of the coordination sphere is left unchanged. Similarly to the aromatic analogs for which data are available, in aqueous solution the Ru-[9]aneS_3 complexes (with the exception of **5**) hydrolyze a chloride (or a dmso in the case of **9**) to give the corresponding aquo species. This process is rapidly reversed in the presence of free chloride, and coordination of phosphate is likely to occur to the aquo species in phosphate buffered solutions at physiological pH. Preliminary in vitro tests performed on complexes **4**–**6** against the mouse adenocarcinoma cancer cell line (TS/A) and the human mammary normal cell line (HBL-100) showed that, in general, the Ru-[9]aneS_3 compounds have a cytotoxicity comparable to that of the corresponding organometallic analogs. These results suggest that the aromatic fragment of the piano-stool Ru^{II} compounds is not an essential feature for the in vitro anticancer activity, and it might be effectively replaced by another face-capping ligand with a low steric demand, such as [9]aneS_3.

Introduction

The field of anticancer ruthenium drugs is attracting growing interest because some compounds have proved to have very encouraging pharmacological profiles;[1] in particular, they show in vivo activity against tumors that are resistant to cisplatin and carboplatin and a generally lower toxicity (and hence side-effects) than platinum drugs. The most advanced representatives of this new class of anticancer agents are the two Ru^{III} coordination compounds KP1019 {[indH][*trans*-$RuCl_4$(ind)$_2$]; ind = indazole}, developed in the Eighties by Keppler and co-workers,[2] and NAMI-A {[imH][*trans*-$RuCl_4$(dmso-S)(im)]; im = imidazole}, developed in the Nineties by some of us.[3] NAMI-A is selectively active against metastases of solid tumors,[4] while KP1019 is active against colorectal tumors.[5] Both compounds were recently tested on humans because of their promising activities against platinum-resistant malignancies; NAMI-A has completed a phase-I trial and is scheduled to begin phase-II trials soon,[6] while KP1019 is currently in phase-I trials.[7] Contrary to platinum anticancer compounds, the activity of NAMI-A seems to be unrelated to direct cytotoxicity.

More recently, an entirely different class of Ru^{II} compounds developed by Sadler and co-workers has shown very promising anticancer activity both in vitro and in vivo.[8] This class comprises organometallic half-sandwich Ru^{II}–arene complexes of the type [RuCl(en)(η^6-arene)][PF_6] (arene = benzene, *p*-cymene, tetrahydroanthracene, dihydroanthracene, biphenyl), also called "piano-stool" complexes because of their geometry (Figure 1). Such complexes exhibit IC_{50} values (IC_{50} = concentration of compound that kills 50% of cell population) in vitro in the range 6–200 μM against a human ovarian cancer cell line, compared with values of 0.5 μM for cisplatin and 6 μM for carboplatin.[8] The initial in vitro and in vivo studies sug-

gested that the most active complexes contain the most hydrophobic η^6-arene ligands. For example, [RuCl(en)(η^6-biphenyl)][PF_6] is active in the A2780 human ovarian cancer xenograft and is not cross-resistant in the A2780cis xenograft.[9] The target for these Ru^{II}–arene complexes might be DNA.[10] Investigations with natural DNA in a cell-free medium indicated that they bind preferentially to guanine residues; binding involves mono-functional coordination to G N7 (after chloride release) and noncovalent, hydrophobic interactions between the arene ligand and DNA, which may include arene intercalation and minor groove binding.[11]

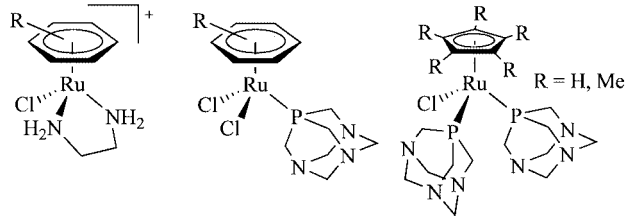

Figure 1. Schematic drawings of the cytotoxic organometallic piano-stool compounds. [RuCl(en)(η^6-arene)]$^+$, [$RuCl_2$(PTA)(η^6-arene)], and [RuCl(PTA)$_2$(η^5-C_5R_5)].

The biological activities of other piano-stool organometallic Ru^{II} complexes have been investigated at different levels. The 1,3,5-triaza-7-phosphaadamantane (PTA) complex [$RuCl_2$(PTA)(η^6-*p*-cymene)] (Figure 1) has proved to have in vitro pH-dependent DNA binding properties and to induce apoptosis in neuroblastoma cells at nanomolar concentrations.[12] It was observed that for the Ru^{II}–arene PTA complexes loss of the arene can occur on binding to an oligonucleotide.[13] In vivo, [$RuCl_2$(PTA)(η^6-*p*-cymene)] has been found to be capable of inhibiting lung metastases in CBA mice bearing the MCa mammary carcinoma, reducing both their number and weight.[14] Related compounds have also been shown to exhibit antimicrobial properties.[15] In vitro anticancer properties have been demonstrated for the compounds [RuCl(BESE)(η^6-*p*-cymene)]$^+$ [BESE = $EtS(O)(CH_2)_2S(O)Et$][16] and [RuCl(PTA)$_2$(η^5-C_5Me_5)] (interestingly, the corresponding η^5-C_5H_5 complex is not cytotoxic, perhaps due to its lower lipophilicity).[17] In addition, [$RuCl_2$(Y)(η^6-C_6H_6)] compounds (Y = dmso, 3-aminopyridine, aminoguanidine, *p*-aminobenzoic acid) have been shown to have topoisomerase II poisoning and in vitro anticancer activity (at 100–300 μM concentrations); interaction of these compounds with DNA in vitro and formation of ternary cleavage complexes of topo II-drug-DNA has been demonstrated.[18] Coordination of the known anticancer agent 1-β-hydroxyethyl-2-methyl-5-nitroimidazole (metronidazole) to the Ru^{II}–benzene fragment affords [$RuCl_2$(metronidazole)(η^6-C_6H_6)], which has superior selective cytotoxicity to metronidazole itself and topoisomerase II activity.[19] Sheldrick and co-workers have published some ruthenium(II)–arene compounds with alanine- and guanine-derived co-ligands,[20] and while their anticancer activity was not included in the report, they were found to be cytotoxic towards P388 leukaemia cells.[21]

All these organometallic compounds are characterized by the presence of a face-capping aromatic ligand, either neutral (η^6-arene) or negatively charged (η^5-cyclopentadienyl), firmly bound to ruthenium. We were interested to establish whether the aromatic fragment is an essential feature for the biological activity of these piano-stool Ru^{II} complexes or if another face-capping ligand with a low steric demand would play the same role. For this reason we synthesized a new series of half-sandwich Ru^{II} complexes similar to the organometallic compounds described above, in which the aromatic fragment is replaced by the sulfur macrocycle 1,4,7-trithiacyclononane ([9]aneS_3), while the rest of the coordination sphere is left unchanged. The capability of [9]aneS_3 to coordinate to transition metal centers (and to ruthenium in particular) as a robust, face-capping, six-electron donor ligand, in analogy to the η^6-arene and η^5-cyclopentadienyl fragments (Figure 2), is well known.[22–27]

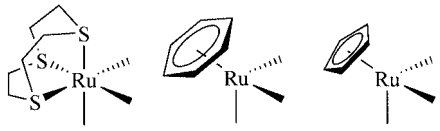

Figure 2. Schematic structural comparison of three half-sandwich Ru^{II} fragments with different face-capping ligands.

We report here the synthesis and structural characterization, both in solution and in the solid state, of the following complexes: [$RuCl_2$(PTA)([9]aneS_3)] (**4**), [RuCl(PTA)$_2$([9]aneS_3)][OTf] (OTf = triflate, $CF_3SO_3^-$) (**5**), and [RuCl(en)([9]aneS_3)][OTf] (**6**), which are analogs of some of the organometallic compounds described above; in addition, we have also prepared and characterized [RuCl(enac)([9]aneS_3)][OTf] [enac = 1,2-bis(isopropyleneimino)ethane] (**7**), [RuCl(bipy)([9]aneS_3)][OTf] (**8**), and [Ru(dmso-S)(bipy)([9]aneS_3)][OTf]$_2$ (**9**). The chemical behavior of these complexes in aqueous solution and at physiological pH have been investigated, and the in vitro tumor cell growth inhibition effects of **4**–**6** assessed.

Results and Discussion

The Precursors

Precursors for the new piano-stool compounds described below were the Ru-[9]aneS_3-dmso complexes [$RuCl_2$(dmso-S)([9]aneS_3)] (**1**), [RuCl(dmso-S)$_2$([9]aneS_3)][OTf] (**2**), and [Ru(dmso)$_3$([9]anoS_3)][OTf]$_2$ (**3**; Figure 3), in which the sulfoxides are quite easily replaced by stronger ligands. Compound **1** was first described by Landgrafe and Sheldrick in 1994,[24a] while **2** and **3** were more recently prepared by us by treatment of **1** with one or two equivalents of AgOTf, respectively.[28] Complex **3** crystallizes as [Ru(dmso-O)(dmso-S)$_2$([9]anoS_3)][OTf]$_2$ but in noncoordinating solvents it rapidly equilibrates with its linkage isomer [Ru(dmso-O)$_2$(dmso-S)([9]aneS_3)][OTf]$_2$, which is slightly more stable. Incidentally, complex **2** closely resembles the disulfoxide complex [RuCl(BESE)(η^6-*p*-cymene)][PF_6], for which James and co-workers had reported in vitro anti-cancer activity,[16] with [9]aneS_3 in place of *p*-cymene and two

S-bonded dmso's in place of the doubly S-bonded disulfoxide $EtS(O)(CH_2)_2S(O)Et$ (BESE).

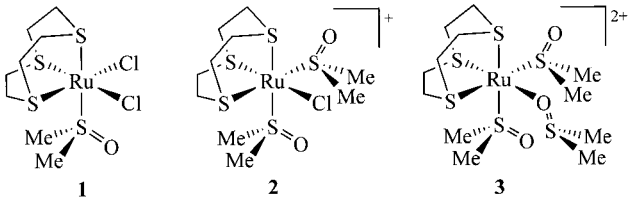

Figure 3. Schematic drawings of the precursors **1**–**3**.

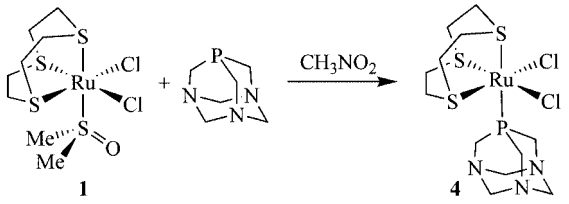
All the products described below were characterized by elemental analysis, spectroscopic techniques in solution (NMR and UV/Vis spectroscopy), and in the solid state by IR spectroscopy and by X-ray diffraction analysis.

PTA Compounds

The reaction of **1** with one equivalent of 1,3,5-triaza-7-phosphaadamantane (PTA) in refluxing nitromethane led, upon selective replacement of dmso, to the isolation of the neutral compound $[RuCl_2(PTA)([9]aneS_3)]$ (**4**) in high yield (Scheme 1).



Scheme 1.

The ^1H NMR spectrum of **4** in D_2O (the only solvent in which the complex is highly soluble), recorded immediately after dissolution, shows a manifold of partially overlapping multiplets (δ = 2.6–3.0 ppm) attributed to the CH_2 protons of the [9]aneS_3 ligand,[29] and two equally intense signals (narrow unresolved multiplets) for the PTA ligand (δ = 4.22 and 4.55 ppm). By comparison with the spectrum of $[RuCl_2(PTA)(\eta^6\text{-}p\text{-cymene})]$,[12a] the downfield singlet was assigned to the CH_2 protons in the nitrogen heterocycle of PTA and the other to the CH_2 protons in the phosphorus-nitrogen heterocycle of PTA. The ^{31}P NMR spectrum shows a singlet at δ = –33.41 ppm {cf. δ = –36.63 ppm for $[RuCl_2(PTA)(\eta^6\text{-}p\text{-cymene})]$ in $CDCl_3$}.

In the solid state, the metal exhibits the expected distorted octahedral geometry (Figure 4). The Ru–ligand bond lengths are slightly different in the two independent molecules (A and B) identified in the asymmetric unit. The Ru–P bond lengths [2.290(3) Å and 2.279(2) Å] are similar to those observed in $[RuCl_2(PTA)(\eta^6\text{-}p\text{-cymene})]$.[12a] The Ru–Cl distances fall in a range from 2.429(3) to 2.459(3) Å and are similar to those in the precursor **1**.[24a] The three Ru–S bond lengths are remarkably different: those *trans* to Cl are significantly shorter [2.233(3)–2.275(3) Å, similar to those in precursors **1**] than that *trans* to the PTA phosphorus donor [2.365(3) and 2.349(3) Å in A and B, respectively]. The latter are comparable to the Ru–S bond length *trans* to phosphorus found in $[RuCl_2(PPh_3)([9]aneS_3)]$ [2.356(2) Å].[30] Water molecules (two for each complex unit) occupy voids in the crystal lattice and interact through H-bonds with the chloride ligands and with the PTA nitrogens.

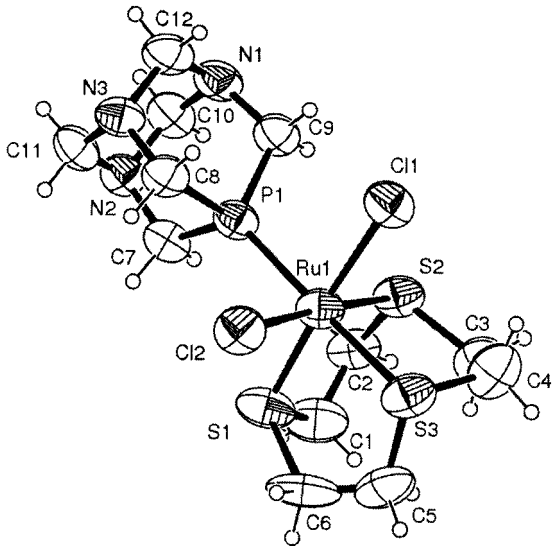


Figure 4. X-ray molecular structure of one of the two independent complexes of $[RuCl_2(PTA)([9]aneS_3)]\cdot 2(H_2O)$ (**4**). Selected bond lengths [Å] and angles [°], with data in parentheses referring to the second unit: Ru(1)–S(1) 2.248(3) [2.233(3)], Ru(1)–S(2) 2.275(3) [2.261(3)], Ru(1)–S(3) 2.365(3) [2.349(3)], Ru(1)–Cl(1) 2.429(3) [2.445(3)], Ru(1)–Cl(2) 2.429(3) [2.459(3)], Ru(1)–P(1) 2.290(3) [2.279(2)]; P(1)–Ru(1)–S(3) 175.2(1) [175.4(1)], S(1)–Ru(1)–Cl(1) 175.7(1) [174.5(1)], S(2)–Ru(1)–Cl(2) 175.5(1) [177.1(1)].

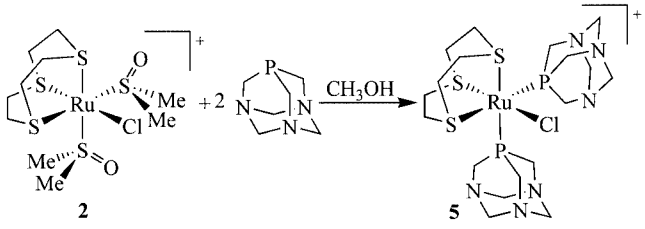
Treatment of $[RuCl(dmso)_2([9]aneS_3)][OTf]$ (**2**) with two equivalents of PTA in refluxing methanol yielded the cationic compound $[RuCl(PTA)_2([9]aneS_3)][OTf]$ (**5**) (Scheme 2).



Scheme 2.

The ^1H NMR spectrum of **5** in D_2O is similar to that of **4**: the two equivalent PTA ligands give two resonances, integrating for 12 protons each, at δ = 4.25 and 4.59 ppm. The ^{31}P NMR spectrum shows a single resonance at δ = –33.45 ppm for the two equivalent phosphorus atoms. In the solid state (Figure 5), the two Ru–P bond lengths [2.317(2) and 2.315(2) Å] and the Ru–Cl distance [2.442(2) Å] present a trend similar to that found in the crystal of **4**, with values comparable to those found in

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$[RuCl(PTA)_2(\eta^5\text{-}C_5Me_5)]$.[17] As previously observed (complex **4**), the Ru–S bond length *trans* to Cl [2.295(2) Å] is shorter than those *trans* to the PTA ligands [2.395(2) and 2.372(2) Å].

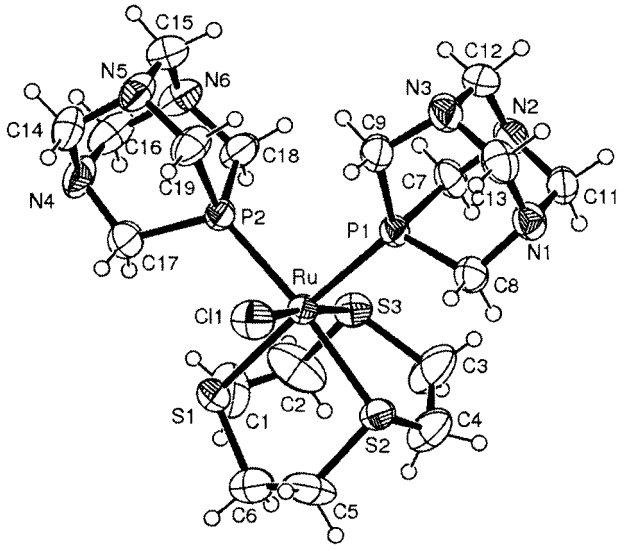


Figure 5. X-ray molecular structure of the complex cation of $[RuCl(PTA)_2([9]aneS_3)][OTf]\cdot(CH_3OH)$ (**5**). Selected bond lengths [Å] and angles [°]: Ru–S(1) 2.395(2), Ru–S(2) 2.372(2), Ru–S(3) 2.295(2), Ru–Cl(1) 2.442(2), Ru–P(1) 2.317(2), Ru–P(2) 2.315(2); P(1)–Ru–S(1) 176.66(7), P(2)–Ru–S(2) 174.17(7), S(3)–Ru–Cl(1) 174.68(7).

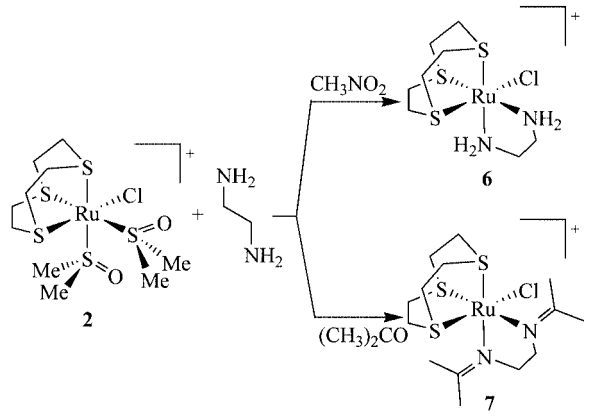
Ethylenediamine Compounds

The reaction of $[RuCl(dmso\text{-}S)_2([9]aneS_3)][OTf]$ (**2**) with one equivalent of ethylenediamine in refluxing nitromethane yielded, upon replacement of the two dmso ligands, the cationic compound $[RuCl(en)([9]aneS_3)][OTf]$ (**6**) (Scheme 3).



Scheme 3.

According to the X-ray structural analysis (Figure 6), the Ru–N and Ru–Cl bond lengths, as well as the chelating N–Ru–N angle, are comparable with the values found by Sadler and co-workers for the $[RuCl(en)(\eta^6\text{-arene})][PF_6]$ compounds.[10] The Ru–S distance *trans* to Cl [2.256(1) Å] is similar to the shortest one in **4**, and those *trans* to the N atoms agree with values documented for [9]aneS$_3$ *trans* to nitrogen ligands.[24a,25,28]

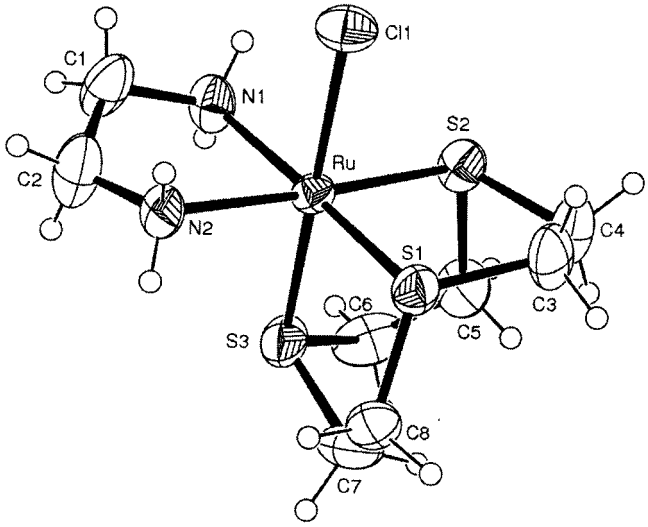


Figure 6. X-ray molecular structure of the complex cation of $[RuCl(en)([9]aneS_3)][OTf]$ (**6**). Selected bond lengths [Å] and angles [°]: Ru–S(1) 2.268(3), Ru–S(2) 2.290(3), Ru–S(3) 2.256(1), Ru–Cl(1) 2.443(1), Ru–N(1) 2.119(9), Ru–N(2) 2.180(7); N(1)–Ru–N(2) 80.7(1), N(1)–Ru–S(1) 175.4(2), N(2)–Ru–S(2) 176.3(3), S(3)–Ru–Cl(1) 179.7(1).

The $^{13}C\{^1H\}$ NMR spectrum of **6** in CD_3NO_2 (three resonances for the six CH_2 groups of [9]aneS$_3$ and a single resonance for the two CH_2 groups of the en ring) shows that the symmetry of the complex in solution (C_s) is higher than that observed in the solid state. Owing to rapid conformational equilibration of the [9]aneS$_3$ and en ligands, the complex has a plane of symmetry in solution that contains the S–Ru–Cl axis and bisects the [9]aneS$_3$ and the opposite en ligand. The ^1H NMR spectrum of **6** in CD_3NO_2 shows, besides the multiplets for [9]aneS$_3$, four equally intense, well-resolved signals for the coordinated ethylenediamine (Supporting Information). In accordance with the C_s symmetry {and by comparison with the assignements of $[RuCl(en)(\eta^6\text{-arene})]^+$ compounds}, the relatively broad resonances at δ = 3.35 and 3.91 ppm (coupled in the H-H COSY spectrum) were assigned to the two pairs of diastereotopic protons on the equivalent NH_2 groups, while the multiplets at δ = 2.83 and 2.94 ppm (coupled in the H-H COSY spectrum) were assigned to the two pairs of diastereotopic protons on the CH_2 groups. These latter resonances are coupled to the CH_2 signal of en at δ = 45.9 ppm in the H-C COSY spectrum. The ^1H NMR spectrum in D_2O is similar, but the two CH_2 resonances overlap with the multiplets of [9]aneS$_3$ (see below).

When the reaction between **2** and ethylenediamine was performed in refluxing acetone, condensation between the ligand and the solvent occurred to give 1,2-bis(isopropyleneimino)ethane (enac), which binds to ruthenium as a chelate. The cationic species $[RuCl(enac)([9]aneS_3)][OTf]$ (**7**) was thus obtained in good yield as a yellow solid and the structure was confirmed by X-ray analysis (Figure 7).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

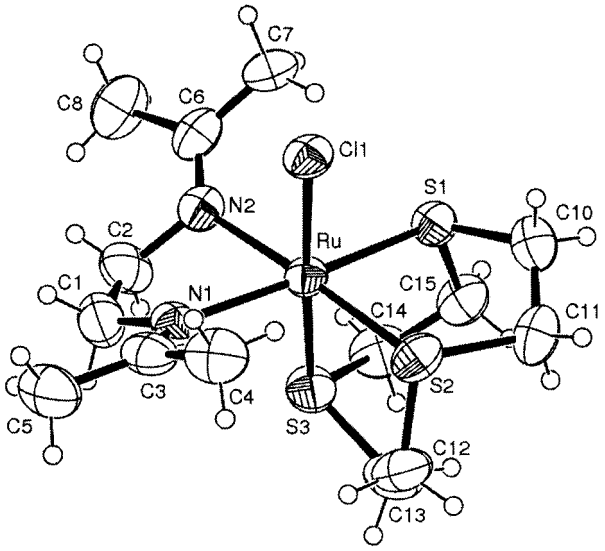

Figure 7. X-ray molecular structure of the complex cation of [RuCl(enac)([9]aneS_3)][OTf]·0.75H_2O (**7**). Selected bond lengths [Å] and angles [°]: Ru–S(1) 2.378(2), Ru–S(2) 2.414(2), Ru–S(3) 2.132(2), Ru–Cl(1) 2.296(2), Ru–N(1) 2.220(6), Ru–N(2) 2.239(5); N(1)–Ru–N(2) 74.3(2), N(1)–Ru–S(1) 173.4(1), N(2)–Ru–S(2) 177.4(1), S(3)–Ru–Cl(1) 176.26(7).

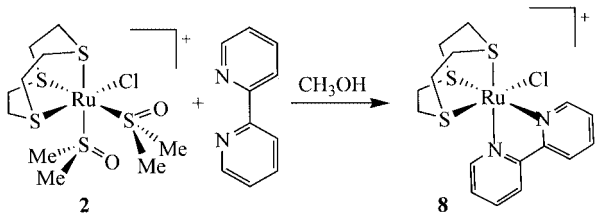
Complex **7** exhibits geometrical features that are remarkably different to the other structures reported and to those expected for similar Ru species. In fact, the Ru–N bond lengths are significantly longer than those found in compound **6** with the en ligand [2.220(6) and 2.239(5) Å vs. 2.119(9) and 2.180(7) Å]. In addition, the two Ru–S bond lengths *trans* to N [2.3776(18), 2.4139(18) Å] are extremely long if compared with those in **6**. Conversely, the Ru–Cl and the *trans* Ru–S bonds are exceptionally short: 2.296(2) and 2.132(2) Å, respectively [the Ru–Cl distance has to be compared with the value of 2.443(1) Å found in **6**]. These features can be ascribed to the steric requirements of the chelating N ligand that presents a bowed arrangement with coplanar N=C$(Me)_2$ groups that make an angle of 43.8(3)°. Methyls C(4) and C(7) point towards the chloride at a distance of around 3.54 Å.

The ^{1}H NMR spectrum of **7** in CD_3NO_2 shows, besides the [9]aneS_3 resonances, an unresolved multiplet at δ = 3.90 ppm for the four CH_2 protons and two singlets (6 H each) at δ = 2.23 and 2.57 ppm for the two pairs of diastereotopic methyl groups of the 1,2-bis(isopropyleneimino)-ethane ligand.

2,2′-Bipyridine Compounds

The reaction between [RuCl(dmso-S)$_2$([9]aneS_3)][OTf] and one equivalent of 2,2′-bipyridine (bipy) in refluxing methanol led again to the selective replacement of the two sulfoxides and formation of the cationic compound [RuCl(bipy)([9]aneS_3)][OTf] (**8**) (Scheme 4). The analogous complex [RuCl(bipy)([9]aneS_3)]Cl, as the chloride salt, has been prepared (and structurally characterized) by Goodfellow and co-workers upon reaction of **1** with a slight excess of bipy in refluxing ethanol.[26a]



Scheme 4.

The geometry of the product was confirmed by X-ray crystallography (Figure 8). The Ru–N [2.094(4) and 2.102(4) Å], Ru–Cl [2.426(1) Å], and Ru–S [2.280(1) Å *trans* to Cl; 2.298(1) (Å) *trans* to N] bond lengths are consistent with those previously reported for the chloride derivative.[26a]

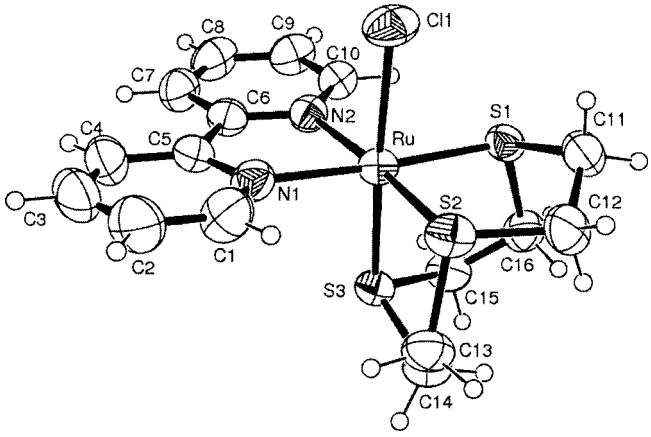


Figure 8. X-ray molecular structure of the complex cation of [RuCl(bipy)([9]aneS_3)][OTf] (**8**). Selected bond lengths [Å] and angles [°]: Ru–S(1) 2.298(1), Ru–S(2) 2.299(1), Ru–S(3) 2.280(1), Ru–Cl(1) 2.426(1), Ru–N(1) 2.102(4), Ru–N(2) 2.094(4); N(2)–Ru–N(1) 77.9(2), N(1)–Ru–S(1) 175.6(1), N(2)–Ru–S(2) 174.5(1), S(3)–Ru–Cl(1) 176.12(5).

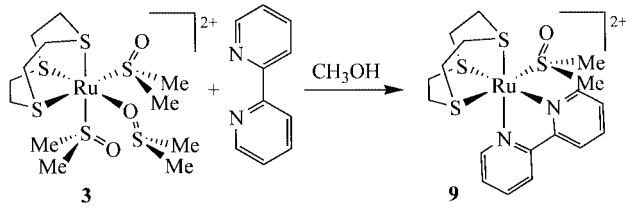
The ^{1}H NMR spectrum of **8** in CD_3NO_2 shows four equally intense signals in the aromatic region for the coordinated bipy, indicating that the two halves of the chelate are equivalent.

Similarly, [Ru(dmso-S)(bipy)([9]aneS_3)][OTf]$_2$ (**9**), in which the chloride of **8** is formally replaced by a dmso-S ligand, was obtained by treatment of the dicationic precursor [Ru(dmso)$_3$([9]aneS_3)][OTf]$_2$ (**3**) with one equivalent of 2,2′-bipyridine in refluxing methanol (Scheme 5). The X-ray structure of **9** is shown in Figure 9. The coordination bond lengths and angles are in agreement with the parameters found in **8**, but the Ru–S(3) bond length *trans* to dmso is slightly longer than the corresponding value *trans* to Cl in **8** [2.339(3) vs. 2.280(1) Å], thus indicating a different *trans* influence for dmso and chlorine, as previously observed.[24a] The Ru–S(dmso) bond length of 2.285(3) Å is very similar to that in the precursor **1** [2.287(2) Å]. The plane of bipy forms a dihedral angle of about 12° with the N(1), N(2), S(1), and S(2) donors, away from the axial dmso ligand.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 5.

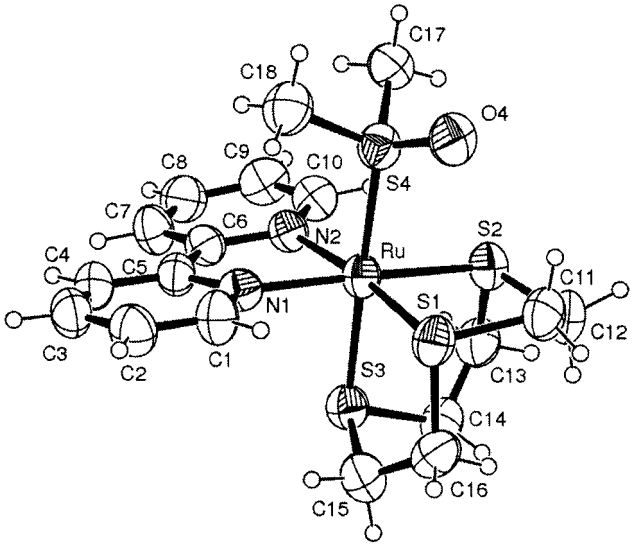


Figure 9. X-ray molecular structure of the complex cation of $[Ru(dmso\text{-}S)(bipy)([9]aneS_3)][OTf]_2{\cdot}2(H_2O)$ (**9**). Selected bond lengths [Å] and angles [°]: Ru–S(1) 2.322(3), Ru–S(2) 2.311(2), Ru–S(3) 2.339(3), Ru–S(4) 2.285(3), Ru–N(1) 2.071(7), Ru–N(2) 2.100(7); N(1)–Ru–N(2) 77.8(3), N(1)–Ru–S(2) 174.0(2), N(2)–Ru–S(1) 173.1(2), S(4)–Ru–S(3) 178.48(9).

The ^{1}H NMR spectrum of **9** in D_2O is similar to that of **8**, with an additional singlet at δ = 2.83 for the equivalent methyl groups of the dmso-S ligand. This resonance is remarkably upfield-shifted for a dmso coordinated through S, and actually falls in the region typical for dmso-O, because of the shielding cone of the adjacent bipy, as becomes apparent from the X-ray structure (Figure 9). The S=O stretching vibration in the solid state falls at an unusually high energy (1160 cm^{-1}), suggesting that in this dicationic complex dmso-S acts mainly as a σ-donor.

Llobet et al. have stated that $[9]aneS_3$ exerts a strong steric interaction on the *cis* ligands on the basis that in $[Ru(H_2O)(phen)([9]aneS_3)][ClO_4]_2$ the *cis* X–Ru–S angles are larger than 90°.[27b] However, in all structures reported the S–Ru–S angles involving the $[9]aneS_3$ are in a range from 82.68(7) to 89.6(1)°, and these values are likely to be dependent on the nature of the macrocycle. A careful inspection of the *cis* X–Ru–S bond angles reveals that these are larger than 90° in **4** and **5** (X = P), due to the bulk of the PTA ligand, and in **6**–**9** (X = N) because of the small bite angle of the chelating nitrogen ligand. Thus, these slight deformations are not ascribable to the bulk of the $[9]aneS_3$ ligand but, rather, to the geometrical requirements of the other ligands, as confirmed by the fact that the *cis* Cl–Ru–S bond angles are close to, or slightly less than, 90°.

As a conclusion it is worthwhile to note that X-ray diffraction studies indicate close geometrical similarities between the present complexes and the piano-stool Ru^{II} compounds bearing an η^6-arene ligand instead of the $[9]aneS_3$ tripodal group.

Chemical Behavior in Aqueous Solution

These new piano-stool ruthenium complexes were prepared with the aim of comparing their biological activities with those of the corresponding organometallic compounds bearing an aromatic fragment in place of the $[9]aneS_3$ ligand. Thus, as a first step, the chemical behavior of compounds **4**–**9** was investigated in water, in the presence of 100 mM NaCl (that mimics the extracellular chloride concentration), and in PBS buffer solution at physiological pH (0.01 M phosphate buffer, pH 7.4, 0.9% NaCl) by ^{1}H NMR and UV/Vis spectroscopy.

Both the ^{1}H NMR and UV/Vis spectra of the neutral PTA complex $[RuCl_2(PTA)([9]aneS_3)]$ (**4**) changed quite rapidly during the first 30 min after dissolution in water due to dissociation of one chloride to give $[RuCl(H_2O)(PTA)([9]aneS_3)]^+$ (**4a**). The evolution of the absorption spectrum is characterized by two isosbestic points at 330 and 408 nm (Supporting Information). In the ^{1}H NMR spectrum the two PTA resonances of **4** (δ = 4.22, 4.55 ppm) are gradually replaced by those of **4a** (δ = 4.23, 4.57 ppm), which are only slightly shifted downfield; no signals for the free ligands were observed.[31] The spectra remained unchanged afterwards, even after prolonged periods (weeks), indicating that **4a** is stable. Addition of 100 mM NaCl to a D_2O solution of **4a** reversed the hydrolytic process completely, and the original NMR spectrum of **4** was immediately re-obtained (Supporting Information). A pK_a value of 3.3 for coordinated PTA in **4a** was obtained from a ^{31}P NMR pH titration curve in D_2O (Supporting Information). For comparison, a pK_a value of 3.13 has been estimated from a ^{31}P NMR titration for coordinated PTA in the $[RuCl_2(PTA)(\eta^6\text{-}p\text{-cymene})]$ complex,[14] while a pK_a value of 10.1 was similarly obtained for the coordinated water molecule in $[Ru(H_2O)(phen)([9]aneS_3)]^{2+}$.[27b] Conversely, the p$K_a$ values of the coordinated water in $[Ru(H_2O)(en)(\eta^6\text{-arene})]^{2+}$ adducts, as determined by ^{1}H NMR spectroscopy, are in the range 7.71–8.25.[32]

In phosphate buffered saline (pH 7.4) the hydrolysis of **4** to **4a** occurs as in water, but is followed by a further slow reaction leading to a new species **4b**. In the ^{1}H NMR spectrum this process is accompanied by the gradual decrease of the two PTA resonances of **4a** and simultaneous growth of two new signals (δ = 4.28 and 4.60 ppm) for **4b**. After 15 days at ambient temperature **4a** and **4b** are present in solution in approximately equal amounts. This slow process is perhaps due to partial dissociation of the chloride of **4a** to yield $[Ru(H_2O)_2(PTA)([9]aneS_3)]^{2+}$ (**4b**); however, coordination of phosphate, as observed in the $[Ru(H_2O)(en)(\eta^6\text{-ar-}$

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

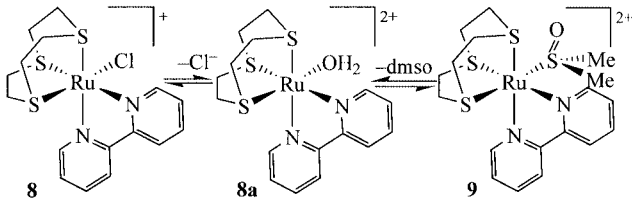
ene)]$^{2+}$ and [Ru(H_2O)Cl(PTA)(η^6-arene)]$^+$ species,[14,32] cannot be excluded (see below).

The cationic PTA complex [RuCl(PTA)$_2$([9]$aneS_3$)][OTf] (**5**) was found to be remarkably inert both in water and at physiological pH. No significant spectral changes were observed over a period of two weeks. Addition of 100 mM Cl induced no spectral changes (Supporting Information). A pK_a value of 2.4 for coordinated PTA in **5** was obtained from a ^{31}P NMR pH titration curve in D_2O (Supporting Information).

Investigation of the behavior of [RuCl(en)([9]$aneS_3$)][OTf] (**6**) in aqueous solution by ^{1}H NMR spectroscopy is difficult due to overlap of the signals of the CH_2 protons of en and [9]$aneS_3$. In the ^{1}H NMR spectrum of **6** in D_2O immediately after dissolution two sets of NH_2 signals, belonging to two species in an approximate 3:1 ratio, are observed (Supporting Information). The spectrum remained basically unchanged for days. Addition of 100 mM NaCl reversed the initial ratio between the two sets of NH_2 resonances immediately, suggesting the presence of an equilibrium between the two species (Supporting Information). Thus, the resonances of the most intense set (δ = 3.87, 4.70 ppm) were assigned to the aquated species [Ru(H_2O)(en)([9]$aneS_3$)]$^{2+}$ (**6a**), while those of the minor set (δ = 3.65, 4.54 ppm) were attributed to the parent compound **6**, which becomes predominant in the presence of excess chloride. The ^{1}H NMR spectrum in buffer solution, besides the NH_2 signals of **6** and **6a**, shows two other less-intense broad resonances at δ = 4.35 and 4.45 ppm, assigned to the NH_2 of coordinated en in a new species **6b**. The signals of **6** decrease slowly with time while those of **6a** and **6b** correspondingly increase, and after one week **6b** was the main species in solution. Tentatively, **6b** might form from **6a** upon phosphate coordination (no signals for free ethylendiamine or [9]$aneS_3$ were observed to grow with time).

The ^{1}H NMR spectrum of [RuCl(enac)([9]$aneS_3$)][OTf] (**7**) in D_2O recorded immediately after dissolution is similar to that in CD_3NO_2 (see above) and remains unchanged with time. However, upon addition of NaCl the resonances of a new species, of almost equal intensity, appear immediately beside those of the original species (Supporting Information). Thus, the resonances of the original set were assigned to the aquated species [Ru(H_2O)(enac)([9]$aneS_3$)]$^{2+}$ (**7a**; for example, the singlets of the methyl groups appear at δ = 2.23 and 2.57 ppm), while those of the new set (methyl groups at δ = 2.22 and 2.61 ppm) were attributed to the parent compound **7**, which is in equilibrium with **7a**. In the absence of free chloride, this equilibrium is completely shifted towards **7a** at NMR concentrations. The ^{1}H NMR spectrum in phosphate-buffered saline solution shows, besides the signals of **7** and **7a**, the resonances of yet another species with coordinated enac, **7b**, which were found to grow slowly with time (days). No signals for the free ligands were observed during these processes. Most likely, also in this case **7b** is derived from **7a** upon coordination of phosphate.

[RuCl(bipy)([9]$aneS_3$)][OTf] (**8**) is relatively labile in aqueous solution. The ^{1}H NMR spectrum recorded immediately after dissolution of the complex in D_2O shows two sets of signals for the coordinated bipy in an approximate 3:2 ratio (Supporting Information). The most abundant set was assigned to **8** and the other, which grows with time, to the dicationic aquated species [Ru(H_2O)(bipy)([9]$aneS_3$)]$^{2+}$ (**8a**).[33] After 30 min the ratio between **8** and **8a** was about 1:2 (Supporting Information), and the equilibrium could be reversed by the addition of chloride. During the hydrolytic process, no signals for free bipy or [9]$aneS_3$ were observed. The same aquo species **8a** was obtained, but much more slowly (days), from [Ru(dmso-S)(bipy)([9]$aneS_3$)][OTf]$_2$ (**9**) upon dissociation of the dmso ligand (Scheme 6). In this case the process could also be followed by monitoring the growth of the resonance of free dmso at δ = 2.72 ppm.



Scheme 6.

The behavior of **8** and **9** at pH 7.4 is similar to that found in water and is mainly influenced by the presence of free chloride in the buffer. Thus, for both complexes the equilibrium amount of **8a** is lower than in pure water and compound **9** slowly equilibrates also with **8** (Scheme 6). In addition, for both complexes the signals of a new species with coordinated bipy, presumably with phosphate bound in the place of water, were observed to grow slowly with time.

Cell Growth Inhibition Effects on TS/A Adenocarcinoma Cells and on HBL-100 Mammary Cells

The MTT test, which measures mitochondrial dehydrogenase activity as an indication of cell viability, was carried out with the water-soluble compounds [$RuCl_2$(PTA)([9]$aneS_3$)] (**4**), [RuCl(PTA)$_2$([9]$aneS_3$)][OTf] (**5**), and [RuCl(en)([9]$aneS_3$)][OTf] (**6**) using two different cell lines − tumour mouse TS/A cells and normal human HBL-100 cells. The effects of compounds **4**–**6** on the cell growth were evaluated after treatment for 24, 48, and 72 h. The cell viability after these times was determined by the MTT assay and the results from these studies are summarized in Figure 10. The experiments were performed in quadruplicate and repeated twice for all three compounds; the IC_{50} values resulting from an average over the two experiments are listed in Table 1.

Compounds **4**–**6** show different in vitro behaviors against the mouse adenocarcinoma cancer cell line (TS/A) and against the human mammary nontumor cell line (HBL-100). Complex **4** is scarcely cytotoxic and shows IC_{50} values that are high and very similar in both cell lines. It is worth comparing these data with the aromatic [$RuCl_2$(PTA)(η^6-arene)] analogs of complex **4**, values for which are also given in Table 1.

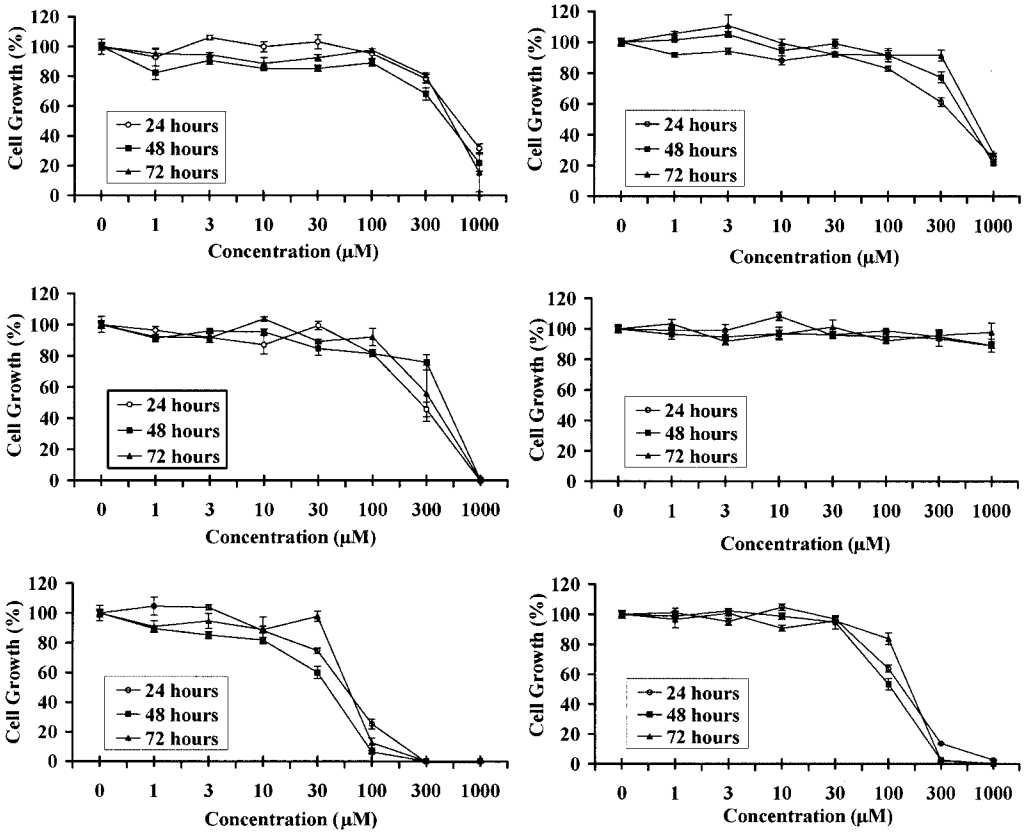

Figure 10. Effects of [$RuCl_2$(PTA)([9]$aneS_3$)] (**4**) (top), [RuCl(PTA)$_2$([9]$aneS_3$)][OTf] (**5**) (middle), and [RuCl(en)([9]$aneS_3$)][OTf] (**6**) (bottom) on TS/A (left) and HBL-100 (right) cell proliferation. The cells were sown on day 0 and treated on day 1 with a range of concentrations between 1–1000 μM of compounds **4**–**6** for 24, 48, and 72 hours. Cell growth was evaluated using the MTT test at the end of the treatment.

Table 1. IC_{50} values of [$RuCl_2$(PTA)([9]$aneS_3$)] (**4**), [RuCl(PTA)$_2$([9]$aneS_3$)][OTf], (**5**) and [RuCl(en)([9]$aneS_3$)][OTf], (**6**) on the TS/A and HBL-100 cell lines after incubation for 72 h.

Compound	IC_{50} (TS/A) [μM]	IC_{50} (HBL-100) [μM]
[$RuCl_2$(PTA)([9]$aneS_3$)] (**4**)	650	738
[RuCl(PTA)$_2$([9]$aneS_3$)][OTf] (**5**)	388	>1000
[RuCl(en)([9]$aneS_3$)][OTf] (**6**)	65	175
[$RuCl_2$(PTA)(η^6-*p*-cymene)][a]	507	>1000
[$RuCl_2$(PTA)(η^6-benzene)][a]	231	>1000

[a] IC_{50} values taken from ref. 14.

A larger difference in cytotoxicity between the two cell lines is observed for complex **5**, which is mildly active against the TS/A adenocarcinoma cells with an IC_{50} value of 388 μM after 72 h of incubation, but is essentially nontoxic to the HBL-100 normal cells under analogous conditions, even at very high concentrations (IC_{50} > 1000 μM). It thus appears that the presence of two PTA ligands is important to have a selectivity of the compounds towards the cancer cells.

Complex **6** is the most cytotoxic among those tested and it is also somewhat selective towards cancer cells (Table 1). The aromatic analogs of complex **6**, developed by Sadler and co-workers,[8,9] also show greater cytotoxicity than Ru^{II}–arene PTA complexes (aromatic analogs of complex **4**).[14] A direct comparison between **6** and the corresponding [RuCl(en)(η^6-arene)][PF_6] complexes is difficult as cytotoxicity tests were performed against different cell lines; for example, [RuCl(en)(η^6-*p*-cymene)][PF_6] has an IC_{50} value of 10 μM against A2780 cells. Nevertheless, from these data it appears that the aromatic fragment is not essential for cytotoxicity and that the [9]$aneS_3$ ligand can be used in its place.

Conclusions

In summary, some new half-sandwich Ru^{II}-[9]$aneS_3$ complexes, namely [$RuCl_2$(PTA)([9]$aneS_3$)] (**4**), [RuCl(PTA)$_2$([9]$aneS_3$)][OTf] (**5**), [RuCl(en)([9]$aneS_3$)][OTf] (**6**), [RuCl(enac)([9]$aneS_3$)][OTf] (**7**), [RuCl(bipy)([9]$aneS_3$)][OTf] (**8**), and [Ru(dmso-S)(bipy)([9]$aneS_3$)][OTf]$_2$ (**9**) have been prepared from Ru-[9]$aneS_3$-dmso precursors and structurally characterized. Some of them are analogs of known cytotoxic organometallic Ru^{II}-(η^6-arene) and Ru^{II}-(η^5-cyclopentadienyl) compounds, in which the aromatic fragment is replaced by the sulfur macrocycle 1,4,7-trithiacyclononane while the rest of the coordination sphere is left unchanged.

For all new complexes, the results from the X-ray studies are consistent with the NMR spectroscopic data, thus indi-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

cating that the structures observed in the solid state are maintained in solution. Owing to rapid conformational equilibration of the [9]aneS_3 (and en ligand in **6**), the symmetry of each complex in solution (C_s) is higher than in the solid state. In solution they have a plane of symmetry that contains the S–Ru–X axis (X = P in **4**; X = Cl in **5**–**8**; X = S in **9**) and bisects the [9]aneS_3 and the opposite ligands (either two equal monodentate ligands as in **4** and **5**, or a chelate as in **6**–**9**). Similarly to the aromatic analogs for which data are available, in aqueous solution the Ru-[9]-aneS_3 complexes (with the exception of **5**) hydrolyze a chloride (or a dmso in the case of **9**) to give the corresponding aquo species. This process is rapidly reversed in the presence of free chloride, and coordination of phosphate to the aquo species is likely to occur in phosphate-buffered solutions at physiological pH. No dissociation of [9]aneS_3 or of the other ligands was observed.

Preliminary in vitro tests were performed on three complexes (**4**–**6**) against the mouse adenocarcinoma cancer cell line (TS/A) and the human mammary normal cell line (HBL-100). In general, the Ru-[9]aneS_3 compounds have a cytotoxicity comparable to that of the corresponding organometallic analogs. The most cytotoxic complex among those tested was [RuCl(en)([9]aneS_3)][OTf] (**6**), with IC_{50} values of 65 μM (TS/A) and 175 μM (HBL-100). Most interestingly, compounds **5** and **6** are more cytotoxic against the cancer cell line (TS/A) than against the human mammary normal cell line (HBL-100); thus, they might lead to anticancer activity with low general toxicity and hence low side-effects.

In conclusion, the results of the in vitro studies suggest that the aromatic fragment of the piano-stool Ru^{II} compounds is not an essential feature for the in vitro anticancer activity, and it might be effectively replaced by another face-capping ligand with a low steric demand such as [9]-aneS_3. As Sadler and co-workers have shown that there is a direct correlation between cytotoxicity and the size (and therefore the lipophilicity) of the arene, it is possible that in the future the cytotoxicity of the Ru-[9]aneS_3 complexes might similarly be increased by using more lipophilic ligands.

Experimental Section

UV/Vis spectra were obtained on a Jasco V-550 spectrometer in quartz cells. ^1H and ^{13}C NMR spectra were recorded at room temperature at 400 and 100.5 MHz, respectively, on a JEOL Eclipse 400 FT instrument. All spectra were recorded at room temperature. Proton peak positions were referenced to 2,2-dimethyl-2,2-silapentane-5-sulfonate (DSS, set at δ = 0.00 ppm) in D_2O, or to the peak of residual non-deuterated solvent set at δ = 4.33 ppm in CD_3NO_2. Carbon peak positions were referenced to DSS (set at δ = 0.0 ppm) in D_2O, or to the central peak of the solvent set at δ = 62.8 ppm in CD_3NO_2. ^{31}P NMR spectra were recorded on a Bruker Avance DPX 400 MHz spectrometer at 161.9 MHz. Infrared spectra (KBr) were recorded on a Perkin–Elmer 983G spectrometer or on a Perkin–Elmer 2000 NIR FT-Raman spectrometer. ESI mass spectra of the complexes were obtained on a Thermofinigan LCQ Deca XP Plus quadrupole ion trap instrument set in positive mode (solvent: methanol; flow rate: 5 μL min^{-1}; spray voltage: 5 kV; capillary temperature: 100 °C; capillary voltage: 20 V), as described previously.[34] Elemental analysis (C, H, N) was performed at the Dipartimento di Scienze Chimiche, Università di Trieste. [$RuCl_2$(dmso-S)([9]aneS_3)] (**1**),[24] [RuCl(dmso-S)$_2$([9]aneS_3)][OTf] (**2**),[28] [Ru(dmso)$_3$([9]anoS_3)][OTf]$_2$ (**3**),[28] and PTA[35] were prepared according to literature procedures. Trithiacyclononane was purchased from Aldrich.

The pH titration curves, reporting the chemical shift of the ^{31}P NMR spectra vs. the pD values, were fitted to the Henderson–Hasselbalch equation using the program Micromath® Scientist® with the assumption that the observed chemical shifts are weighted averages according to the populations of the protonated and deprotonated species. The resonance frequencies change smoothly with pH between the chemical shifts of the charged form HA^+, and those of the neutral, deprotonated form A, which is present at high pH. At any pH, the observed chemical shift is a weighted average of the two extreme values $\delta(HA^+)$ and $\delta(A)$:

$$\delta_{av} = \frac{\delta(HA^+)[HA^+]+\delta(A)[A]}{[HA^+]+[A]}$$

The midpoint of the titration curve occurs when the concentrations of the acid and its conjugate base are equal: $[HA^+] = [A]$, i.e. when the pH equals the pK_a of the compound.

[$RuCl_2$(PTA)([9]aneS_3)] (4): PTA (37 mg, 0.16 mmol) was added to [$RuCl_2$(dmso-S)([9]aneS_3)] (**1**; 100 mg, 0.16 mmol) partially dissolved in nitromethane (15 mL). The mixture was then heated to reflux to yield a yellow solution after 2–3 min, and a yellow-orange solid after about 10 min. After 2 h reflux, the precipitate was removed by filtration, washed with cold nitromethane and diethyl ether, and vacuum dried. Yield: 51 mg (62%). $C_{12}H_{24}Cl_2N_3PRuS_3$ (509.47): calcd. C 28.3, H 4.75, N 8.25; found C 28.2, H 5.11, N 8.13. ^1H NMR (400 MHz, D_2O, 25 °C): δ = 3.00–2.60 (m, 12 H, [9]aneS_3), 4.23 (s, 6 H, PTA), 4.55 (s, 6 H, PTA) ppm. $^{31}P\{^1H\}$ NMR (161.9 MHz, D_2O, 25 °C): δ = –33.41 (s) ppm. UV/Vis (H_2O, 25 °C): λ_{max} (ε) = 317 nm (632 $M^{-1}cm^{-1}$), 362 (542), 423 (390). ES-MS (MeOH): *m*/*z* = 512 (calcd. 511) [$RuCl_2$(PTA)([9]aneS_3) + $H]^+$, 492 (calcd. 492) [RuCl(H_2O)(PTA)([9]aneS_3)]$^+$, 474 (calcd. 474) [RuCl(PTA)([9]aneS_3)]$^+$.

[$RuCl(PTA)_2$([9]aneS_3)][OTf] (5): PTA (45 mg, 0.29 mmol) was added to [RuCl(dmso-S)$_2$([9]aneS_3)][OTf] (**2**; 90 mg, 0.144 mmol) partially dissolved in methanol (15 mL) and the mixture was refluxed for 2 h. The yellow solution was then concentrated in vacuo to ca. 3 mL, and a few drops of diethyl ether were added. A yellow solid formed upon standing, which was removed by filtration, washed with cold methanol and diethyl ether, and vacuum dried. Yield: 75 mg (60%). $C_{19}H_{36}ClF_3N_6O_3P_2RuS_4$ (780.24): calcd. C 29.2, H 4.65, N 10.77; found C 29.1, H 4.29, N 10.50. ^1H NMR (400 MHz, D_2O, 25 °C): δ = 2.62 (m, 2 H, [9]aneS_3), 2.92 (m, 10 H, [9]aneS_3), 4.25 (s, 12 H, PTA), 4.59 (s, 12 H, PTA) ppm. ^1H NMR (400 MHz, CD_3CN, 25 °C): δ = 2.38 (m, 2 H, [9]aneS_3), 2.78 (m, 8 H, [9]aneS_3), 2.99 (m, 2 H, [9]aneS_3), 4.20 (s, 12 H, PTA), 4.50 (s, 12 H, PTA) ppm. $^{13}C\{^1H\}$ NMR (100.5 MHz, CD_3CN, 25 °C): δ = 32.1, 34.2, 41.2 (CH_2, [9]aneS_3), 54.2, 73.2 (CH_2, PTA), 123.7, 125.5 (CF_3, OTf) ppm. $^{31}P\{^1H\}$ NMR (161.9 MHz, D_2O, 25 °C): δ = –33.45 (s) ppm. UV/Vis (H_2O, 25 °C): λ_{max} (ε) = 357 nm (480 $M^{-1}cm^{-1}$), 296 (1000). ES-MS (MeOH): *m*/*z* = 631 (calcd. 631) [$RuCl(PTA)_2$([9]aneS_3)]$^+$.

[RuCl(en)([9]aneS_3)][OTf] (6): Ethylenediamine (10.7 μL, 0.16 mmol) was added to [RuCl(dmso-S)$_2$([9]aneS_3)][OTf] (**2**; 150 mg, 0.16 mmol) dissolved in nitromethane (10 mL) and the mixture was refluxed for 2 h. The yellow solution was concentrated

in vacuo to ca. 5 mL, filtered through paper, and a few drops of diethyl ether were added. A yellow-brown microcrystalline solid formed upon standing, which was removed by filtration, washed with cold nitromethane and diethyl ether, and vacuum dried. Yield: 110 mg (87%). $C_9H_{20}ClF_3N_2O_3RuS_4$ (526.03): calcd. C 20.5, H 3.83, N 5.32; found C 20.4, H 3.52, N 4.95. ^{1}H NMR (400 MHz, CD_3NO_2, 25 °C): δ = 2.8–2.3 (m, 12 H, [9]aneS$_3$), 2.83 (br., 2 H, en), 2.94 (br., 2 H, en), 3.35 (br., 2 H, NH), 3.91 (br., 2 H, NH) ppm. ^{13}C{^{1}H} NMR (100.5 MHz, CD_3NO_2, 25 °C): δ = 32.7, 33.1, 35.9 (CH_2, [9]aneS$_3$), 45.9 (CH_2, en), 120.8, 124.0 (CF_3, OTf) ppm. UV/Vis (H_2O, 25 °C): λ_{max} (ε) = 370 nm (490 M^{-1}cm^{-1}). Selected IR (KBr): $\tilde{\nu}$ = 3295 cm^{-1} (w, νNH$_2$), 3250 (w, νNH$_2$), 1577 (m, δNH$_2$), 1257, 1140, 1026 cm^{-1} (s, νOTf). ES-MS (MeOH): *m*/*z* = 377 (calcd. 377) [RuCl(en)([9]aneS$_3$)]$^+$.

[RuCl(enac)([9]aneS$_3$)][OTf] (7): Ethylenediamine (15 μL, 0.225 mmol) was added to [RuCl(dmso-S)$_2$([9]aneS$_3$)][OTf] (**2**; 140 mg, 0.1125 mmol) dissolved in acetone (20 mL) and the mixture was refluxed for 2 h. The yellow solution was concentrated in vacuo to ca. 5 mL and a few drops of diethyl ether were added. A yellow microcrystalline solid formed on standing, which was removed by filtration, washed with cold acetone and diethyl ether, and vacuum dried. Yield: 40 mg (59%). $C_{15}H_{28}ClF_3N_2O_3RuS_4$ (606.15): calcd. C 29.7, H 4.65, N 4.62; found C 30.4, H 4.34, N 4.47. ^{1}H NMR (400 MHz, D_2O, 25 °C): δ = 2.23 (s, 6 H, CH_3), 2.8–2.4 (m, 12 H, [9]aneS$_3$), 2.57 (s, 6 H, CH_3), 3.93 (m, 4 H, CH_2 enac) ppm. ^{1}H NMR (400 MHz, CD_3NO_2, 25 °C): δ = 2.24 (s, 6 H, CH_3), 2.8–2.4 (m, 12 H, [9]aneS$_3$), 2.69 (s, 6 H, CH_3), 3.90 (m, 4 H, CH_2 enac) ppm. UV/Vis (H_2O, 25 °C): λ_{max} (ε) = 275 nm (4300 M^{-1}cm^{-1}), 376 (580). Selected IR (KBr): $\tilde{\nu}$ = 1625 cm^{-1} (m, νC=N), 1267, 1148, 1031 (s, νOTf) cm^{-1}.

[RuCl(bipy)([9]aneS$_3$)][OTf] (8): 2,2′-Bipyridine (25 mg, 0.16 mmol) was added to [RuCl(dmso-S)$_2$([9]aneS$_3$)][OTf] (**2**; 100 mg, 0.16 mmol) partially dissolved in methanol (10 mL) and the mixture was refluxed for 1 h. After about 10 min the solution turned orange. Upon concentration in vacuo to ca. 3 mL an orange solid formed, which was removed by filtration, washed with cold methanol and diethyl ether, and vacuum dried. Yield: 65 mg (65%). $C_{17}H_{20}ClF_3N_2O_3RuS_4$ (622.11): calcd. C 32.8, H 3.24, N 4.50; found C 32.1, H 3.34, N 4.30. ^{1}H NMR (400 MHz, CD_3NO_2, 25 °C): δ = 3.1–2.5 (m, 12 H, [9]aneS$_3$), 7.63 (t, 2 H, H5,5′), 8.14 (t, 2 H, H4,4′), 8.48 (d, 2 H, H3,3′), 9.08 (d, 2 H, H6,6′) ppm. UV/Vis (H_2O, 25 °C): λ_{max} (ε) = 286 nm (13800 M^{-1}cm^{-1}), 420 (2350).

[Ru(dmso-S)(bipy)([9]aneS$_3$)][OTf]$_2$ (9): 2,2′-Bipyridine (11.4 mg, 0.073 mmol) was added to [Ru(dmso)$_3$([9]aneS$_3$)][OTf]$_2$ (**3**; 60 mg, 0.073 mmol) dissolved in methanol (15 mL) and the mixture was refluxed for 1 h. Upon concentration in vacuo to ca. 3 mL a yellow solid formed, which was removed by filtration, washed with cold methanol and diethyl ether, and vacuum dried. Yield: 50 mg (84%). $C_{20}H_{26}N_2F_6O_7S_4Ru$ (813.85): calcd. C 29.5, H 3.22, N 3.44; found C 29.2, H 3.14, N 3.30. ^{1}H NMR (400 MHz, D_2O, 25 °C): δ = 3.3–2.7 (m, 12 H, [9]aneS$_3$), 2.83 (s, 6 H dmso-S), 7.81 (t, 2 H, H5,5′), 8.31 (t, 2 H, H4,4′), 8.60 (d, 2 H, H3,3′), 9.05 (d, 2 H, H6,6′) ppm. Selected IR (KBr): $\tilde{\nu}$ = 163 cm^{-1} (s, νSO, dmso-S), 517 (m, νRuS, dmso-S), 1267, 1258, 1150, 1030 (s, νOTf) cm^{-1}. UV/Vis (H_2O, 25 °C): λ_{max} (ε) = 268 nm (16000 M^{-1}cm^{-1}), 306 (9800), 316 (13000), 344 (3220).

X-ray Crystallography: Diffraction data for all compounds were collected at room temperature on a Nonius DIP-1030H system with graphite-monochromated Mo-K_α radiation, with the exception of the data set of compound **4**, which was collected at 220(2) K with a Bruker–Nonius FR591 rotating anode (Cu-K_α) equipped with a KappaCCD detector. Cell refinement, indexing, and scaling of the data sets were performed with the programs Denzo and Scalepack.[36] The structures were solved by Patterson and Fourier analyses and refined by the full-matrix least-squares method based on F^2 with all observed reflections.[37] A Flack parameter of 0.55(7) for space group $P2_1$ in **6** indicates racemic twinning of the crystal. The ΔF maps revealed water molecules in **4** and **9** (two molecules per complex unit) and in **7** (residuals accounting for 0.75 water oxygen), and methanol (one molecule) in **5**. The hydrogen atoms were located at geometrically calculated positions except those of disordered water. The structural figures were drawn with ORTEP3 for Windows (ellipsoids at 40% probability level),[38] and all the calculations performed with the WinGX System, Ver 1.64.05.[39] Crystal data and details of structure refinements for compounds **4**–**9** are reported in Tables 2 and 3.

CCDC-265997–266002 (for **4**–**9**) contain the supplementary crystallographic data for this paper. These data can be obtained free

In vitro Tests: TS/A murine adenocarcinoma cell line, initially obtained from Dr. G. Forni (CNR, Centro di Immunogenetica ed Oncologia Sperimentale, Torino, Italy) belongs to the tumor cell panel of the Callerio Foundation (Trieste) and is stored in liquid nitrogen. Cells were cultured according to a standard procedure,[40] and maintained in RPMI-1640 medium (EuroClone, Wetherby, U.K.) supplemented with 10% Fetal Bovine Serum (FBS, Invitrogen, Milano, Italy), 2 mM L-glutamine (EuroClone) and 50 μg mL^{-1} gentamycin sulfate solution (EuroClone). The cell line was kept in a CO_2 incubator with 5% CO_2 and 100% relative humidity at 37 °C. Cells from a confluent monolayer were removed from flasks by a trypsin-EDTA solution (EuroClone). HBL-100 nontumorigenic epithelial cells were maintained in McCoy's 5A medium (SIGMA, St. Louis, MO, USA) supplemented with 10% FBS, 2 mM L-glutamine, 100 UI mL^{-1} penicillin, and 100 μg mL^{-1} streptomycin (EuroClone) in a humidified atmosphere with 5% CO_2 at 37 °C.

Cell viability was determined by the trypan blue dye exclusion test. For experimental purposes, the cells were sown in multi-well cell culture plastic plates (Corning Costar Italia, Milano, Italy). Cell growth was determined by the MTT viability test.[41] Cells were sown on 96-well plates and 24 h after showing were incubated with the appropriate compound at concentrations of 1–1000 μM, prepared by dissolving in a medium containing 5% of serum for 24, 48, and 72 h. Analysis was performed at the end of the incubation time. Briefly, MTT [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide] dissolved in PBS (5 mg mL^{-1}) was added to all wells (10 μL per 100 μL of medium) and the plates were then incubated at 37 °C with 5% CO_2 and 100% relative humidity for 4 h. After this time, the medium was discarded and 100 μL of dmso (SIGMA) was added to each well according to the method of Alley and co-workers.[42] The optical density was measured at 570 nm on a SpectraCount Packard (Meriden, CT) instrument.

Keywords: Tellurium / Conducting materials / Magnetic properties / Band structure

Molecular conductors based on *peri*-ditellurium-bridged polyacene donor molecules 3,4-dimethylanthra[1,9-*cd*:4,10-*c′d′*]bis[1,2]ditellurole (2,3-DMTTeA) and 2,3,6,7-tetramethylnaphtho[1,8-*cd*:4,5-*c′d′*]bis[1,2]ditellurole (TMTTeN) were prepared. The crystal structure analyses of neutral 2,3-DMTTeA molecule and its cation radical salts revealed that these crystals involve an orientational disorder of the asymmetrical molecule, 2,3-DMTTeA, and that the intermolecular network through tellurium atoms is very strong and dominant in terms of the construction of the crystal frameworks. In the crystal of $(TMTTeN)_2M(CN)_2$ (M = Ag and Au), the crystal structure analyses and the extended Hückel tight-binding band calculations indicated that these salts are quasi three-dimensional conductors. These salts are highly conductive (720–760 $S\,cm^{-1}$) and maintain metallic states down to about 50 K. Furthermore, the $Ag(CN)_2^-$ salt exhibited a Pauli paramagnetic behavior down to 2 K [χ(para) ≈ 2.0–2.5×10^{-4} $emu\,mol^{-1}$]. In the crystal of $(TMTTeN)(SCN)_{0.88}$, the donor molecules are stacked to form one-dimensional columns and construct a three-dimensional network between the columns through the intermolecular Te···Te contacts. The SCN^- salt is also highly conductive (590 $S\,cm^{-1}$) and maintains a metallic behavior down to 4.2 K. Almost temperature-independent paramagnetic susceptibility of $(TMTTeN)(SCN)_{0.88}$ indicates Pauli paramagnetism of this salt [χ(para) ≈ $1.6–1.9 \times 10^{-4}$ $emu\,mol^{-1}$]. A tight-binding band structure calculation indicates that the Fermi surface of the SCN^- salt is open along the b^* and c^* directions, but the intermolecular interactions between the donor columns are not so weak because of the three-dimensional network mediated by the protruded tellurium atoms.

Introduction

Over the past few decades, a considerable number of studies have been performed on the chemistry and physics of organic conductors.[1] The main principle of the molecular design of conductors with stable metallic states has been considered to be an achievement of the two-dimensional electronic state of molecular crystals that is realized by an introduction of sulfur and selenium atoms into π electron systems. These heavy chalcogen atoms included in π donor molecules are expected to increase the intermolecular interactions in the solid state and to yield wide conduction bands. In this sense, tellurium-containing molecular conductors are of special interest. However, very few attempts have been made on the tellurium-containing donor molecules,[2] such as tetratellurafulvalene (TTeF)[3] and hexamethylene-TTeF (HMTTeF),[4] because of difficulties of synthesis and poor solubilities to common organic solvents. Among them, crystal structures of $(HMTTeF)_4(PF_6)_2$ and $(HMTTeF)_2[Pt(dmit)_2]$,[5] where dmit is dimercaptoisotrithione, have been reported and revealed their unique donor arrangements. In addition, several years ago $(HMTTeF)(Et_2TCNQ)(THF)_x$ was reported to be metallic around room temperature, where Et_2TCNQ is 2,5-diethyl-7,7,8,8-tetracyano-*p*-quinodimethane.[6] However, no HMTTeF salt has been known to show a metallic behavior down to low temperatures. Therefore, no systematic research has been carried out thoroughly in terms of both the electrical conductivities and structure analyses of the HMTTeF salts. On the other hand, the TCNQ complex of TTeF showed a metallic behavior down to 2 K with a very high room temperature conductivity of 2200 $S\,cm^{-1}$ in comparison with those of its sulfur and selenium analogs.[7] This result indicates

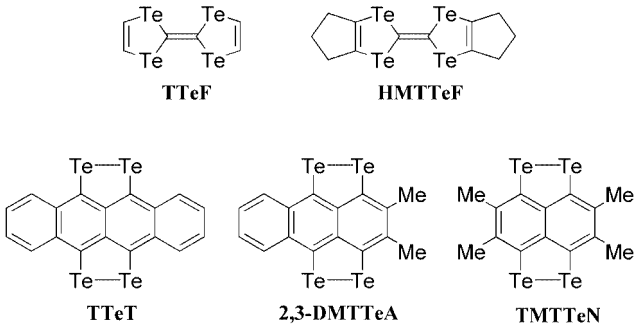
that organic metals possessing high conductivities and wide bandwidths can be realized by the substitution for tellurium atoms.

From the viewpoint of the crystal structures, furthermore, conducting salts based on tellurium-containing donors are interesting because the formation of a tellurium network seems to be dominant in terms of the construction of crystal structures. Polyacene donor molecules containing *peri*-ditellurium bridges are considered to utilize the atomic character of their protruded tellurium atoms more directly than the TTeF donors such as TTeF and HMTTeF. Needless to say, the tellurium crystal that has a three-dimensional Te···Te network shows a semimetallic behavior under ambient pressure and brings a superconducting transition at 3.3 K under pressure of 4.5 GPa,[8] which is extremely lower than the pressures required for a sulfur crystal (10.1 K under 93 GPa and 14 K under 157 GPa)[9] and a selenium crystal (6.8 K under 13 GPa).[10,11] Therefore, the tellurium-containing molecular conductors deserve much attention if such a nature of the tellurium crystal is reflected in their physical properties.

Tetratellurotetracene (TTeT)[12,13] is a well-known donor molecule containing *peri*-ditellurium bridges. However, few cation radical salts and charge transfer complexes of TTeT have been reported owing to its extremely poor solubility and their crystal structures have not been made clear so far.[14] Therefore, we focused on the other donors containing *peri*-ditellurium bridges such as 3,4-dimethylanthra-[1,9-*cd*:4,10-*c′d′*]bis[1,2]ditellurole (2,3-DMTTeA)[15] and 2,3,6,7-tetramethylnaphtho[1,8-*cd*:4,5-*c′d′*]bis[1,2]ditellurole (TMTTeN),[16] because their solubilities to organic solvents are considerably improved in comparison to other reported tellurium-containing donors because of the existence of methyl groups. We report here the structures of the neutral 2,3-DMTTeA and TMTTeN molecules, and the structures and physical properties of their cation radical salts.[17–19]



Results and Discussion

Molecular Structures and the Highest Occupied Molecular Orbital (HOMO)

In the early 1980s, we proposed to estimate the "dimensionality" of molecular conductors from their Fermi surfaces calculated by an extended Hückel tight-binding band approximation.[20] By virtue of the successful studies on low-temperature magnetotransport experiments of two-dimensional conductors around 1990,[21] the extended Hückel tight-binding band calculation was accepted as a conventional method to evaluate the dimensionality of electronic structures of organic conductors. Although sufficiently reliable empirical parameters of atomic orbitals that are used in the extended Hückel band calculations are hardly obtained even for selenium atoms, the accumulated information on the band structures of the organic conductors composed of selenium-containing tetrathiafulvalene (TTF)-like donors, such as tetramethyltetraselenafulvalene (TMTSF) and bis(ethylenedithio)tetraselenafulvalene (BETS), permits us fairly good band structure calculations. However, it is still not so clear whether a similar calculation could be applied to the tellurium-containing systems, especially to the conductors composed of non-TTF-type donors.

An ab initio molecular orbital (MO) calculation has been made on the TMTTeN molecule. The calculated HOMO has a π character as shown in Figure 1. Because the HOMO has an *anti*-bonding character at the Te–Te bond, the Te–Te bond length is expected to be shortened in its cationic state. As described later, the X-ray crystal structure analyses of TMTTeN systems with various formal charges of the molecules (δ) have been made. In Table 1, the formal charge (δ) dependence of the average bond lengths of $TMTTeN^{+\delta}$ molecules {δ = 0 (neutral crystal), 0.5 [the $Ag(CN)_2^-$ and $Au(CN)_2^-$ salts], 0.7 (the AsF_6^- salt) and 0.9 (the ClO_4^- and SCN^- salts)} is summarized (see also Figure 2).

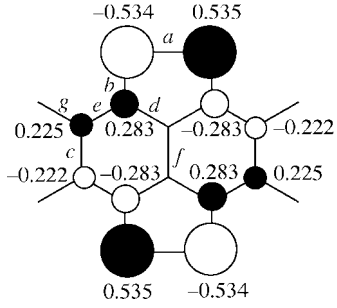


Figure 1. Schematic drawing of the HOMO of TMTTeN. Atomic orbital coefficients are also shown.

As shown in Figure 2, there seems to be a good correlation between δ and bond lengths in terms of the bonds *a* and *c* (see Figure 1, a). The shortening of the Te–Te (*a*) and C–C (*c*) bonds in the cationic state indicates the antibonding nature of the HOMO at these bonds, which is consistent with the result of the MO calculation. Thus, the HOMO will have an a_u symmetry with a node at the Te–Te bond. It is easily imagined that the node at the Te–Te bond is not favorable for the construction of molecular conductors with two- (or three-) dimensional electronic bands, despite the introduction of tellurium atoms. In contrast to the conductors based on TTF-like donors, whose HOMO has the same sign at every chalcogen atom, the transverse intermolecular interaction between TMTTeN molecules may be cancelled

out as a result of the sum of the positive and negative Te···Te overlap integrals.

Crystal Structure Analyses

Neutral 2,3-DMTTeA Molecule

Figure 3 shows the crystal structure of the neutral 2,3-DMTTeA molecule recrystallized from carbon disulfide. There is one crystallographically independent donor molecule in the crystal. The 2,3-DMTTeA molecule has a planar structure. The molecular structure of 2,3-DMTTeA is subject to an orientational disorder that is caused by the unsymmetry of the molecule, which makes 2,3-DMTTeA appear as if it has a tetracene framework instead of the actual anthracene framework. Such an orientational disorder was not observed in the sulfur and selenium analogs of 2,3-DMTTeA.[15b] These facts indicate that the network formed by the tellurium atoms is very strong and dominant in terms of the construction of the crystal structures in comparison to the interaction between the anthracene moieties. As Figure 3 (parts a and b) indicate, the donor molecules form columns with a short interplanar distance of 3.78 Å along the *b*-axis, whereas a slip distance (5.41 Å) is very large along the donor short axis. Consequently, there is no intermolecular Te···Te contact that is less than the sum of the van der Waals radii (4.2 Å) in the donor columns. On the other hand, there are several short intercolumnar contacts, as shown in part b of Figure 3. To put it briefly, the molecules form side-by-side arrays along the *c*-axis through the short Te···Te contacts.

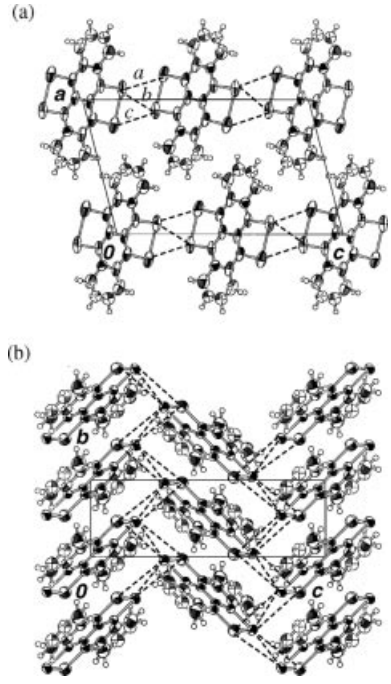

Figure 3. Crystal structures of the neutral 2,3-DMTTeA molecule projected on (a) the *ac*-plane and (b) the *bc*-plane. Owing to the orientational disorder, the occupation probability of two terminal CH_2 groups is 50%, and 2,3-DMTTeA molecule is drawn as if it has a tetracene framework. Intermolecular contacts [Å]: Te(1)···Te(2), a = 4.052(1); Te(1)···Te(2), b = 3.838(1); and Te(1)···Te(1), c = 4.100(1).

Neutral TMTTeN Molecule

An X-ray crystal structure analysis was performed on the neutral crystal of TMTTeN recrystallized from carbon disulfide. As shown in Figure 4 (part a and b), the crystal

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

includes carbon disulfide as an interstitial solvent. TMTTeN has no orientational disorder as in the molecular structure of 2,3-DMTTeA, because of the symmetrical shape of TMTTeN. Two kinds of crystallographically independent donor molecules (A and B) exist in the crystal (see Figure 4 (part a and b). Among them, molecule B is located on the inversion center. As Figure 4 (b) indicates, each of the donor molecules A and B form independent stacking columns along the *c*-axis. However, there is no intermolecular short Te···Te contact in both the donor columns of molecules A and B. On the other hand, there are several short intercolumnar intermolecular Te···Te contacts between the donor columns of molecules A and B, and the three-dimensional network formed by the protruded tellurium atoms of the donor molecules is developed in the crystal.

Cation Radical Salts of 2,3-DMTTeA

X-ray crystal structure analyses were performed on the cation radical salts of 2,3-DMTTeA with BF_4^-, ClO_4^-, ReO_4^-, PF_6^-, AsF_6^-, and Br^- anions. The BF_4^- and ReO_4^- salts are isostructural to the ClO_4^- salt and the PF_6^- salt is isostructural to the AsF_6^- salt. For this reason, only the crystal structures of the ClO_4^- and AsF_6^- salts are discussed among the tetrahedral and octahedral anion salts, respectively.

Crystal Structure of (2,3-DMTTeA)$_3$(ClO$_4$)$_2$

Overlap mode and crystal structure of the ClO_4^- salt of 2,3-DMTTeA are shown in Figure 5. The compositions of

the BF_4^-, ClO_4^-, and ReO_4^- salts were determined to be $(2,3\text{-DMTTeA})_3(\text{anion})_2$. There are two crystallographically independent fragments of the donor [a quarter (A) and a half (B) of the donor molecule] and a half of the ClO_4^- anion, resulting in an average oxidation state of the donor molecule of +2/3. The anion molecules are located in the channel surrounded by 2,3-DMTTeA molecules (see Figure 5, c). As shown in Figure 5 (a and b), molecule A has an orientational disorder of the anthracene moiety that is similar to the case of the neutral 2,3-DMTTeA molecule, whereas molecule B has no orientational disorder. Molecules A and B form A–B–B′-type stacking columns along the *c*-axis in which their long axes are rotated by 90° at the A–B overlap (see Figures 5, a and d). On the other hand, the overlap mode of molecules B and B′ is so-called "head-to-tail overlap" as shown in part b of Figure 5. As Figure 5 indicates (c and d), a three-dimensional Te···Te network is formed through several intermolecular short Te···Te contacts. The interplanar distance between molecules A and B (3.81 Å) is almost the same as that between molecules B and B′ (3.83 Å). On the contrary, the intracolumnar overlap integral between molecules A and B ($c2 = 0.85\times10^{-3}$) is much smaller than that between molecules B and B′ ($c1 = -24.75\times10^{-3}$) and is rather similar to those along the side-by-side directions ($p1 = -0.96\times10^{-3}$, $p2 = 0.97\times10^{-3}$, $p3 = 0.53\times10^{-3}$, $q1 = 0.14\times10^{-3}$, and $q2 = 0.06\times10^{-3}$), because the overlap mode between molecules A and B is not preferable and there is no short Te···Te contact between molecules A and B, where these intermolecular overlap integrals were calculated using the extended Hückel approximation. From the viewpoint of the intermolecular interaction, these results suggest the isolation of the dimers (molecules B and B′) in the donor column, giving rise to very low electrical conductivities of the tetrahedral anion salts ($\sigma_{rt} \approx 10^{-2}$ to 10^{-3} S cm^{-1}) as discussed later.

Crystal Structure of (2,3-DMTTeA)(AsF$_6$)$_{0.2}$

Figure 6 shows the overlap mode and crystal structure of the AsF_6^- salt of 2,3-DMTTeA. The orientational disorder of the 2,3-DMTTeA molecule is also observed in this salt. The compositions of the PF_6^- and AsF_6^- salts could not be determined by population refinement because of a heavy positional disorder of the anion molecules. Consequently, the compositions of $2,3\text{-DMTTeA}(\text{anion})_{0.2}$ were determined by electron probe microanalyses (EPMA). The anion molecules are located in the channels surrounded by the donor molecules, which is similar to the case of the tetrahedral anion salts. The anions are disordered along the donor stacking axis, and there are two kinds of possible positions of the AsF_6^- anion in a channel. Diffuse X-ray diffraction patterns are observed by an oscillation photograph and revealed that the AsF_6^- salt has a fivefold structure along the *a*-axis, suggesting that one AsF_6^- anion molecule exists per five unit cells. This result is consistent with the composition of the salt (5:1) determined by EPMA. As shown in Figure 6 (a and c), the donor molecules form uniform stacks along the *a*-axis. The dihedral angle of two donor molecules is 32.34° between the adjacent columns along the *b*-axis. An intermolecular interplanar distance is 3.81 Å and slip distances are 1.13 Å (*I*) and 1.21 Å (*II*) along the molecular long and short axes, respectively, indicating the relatively good overlap mode of the donors in the stack. As Figure 6 (b and c) indicates, there are several interstack Te···Te contacts [Te(1)···Te(1); a = 3.828(3) Å and Te(2)···Te(2); b = 3.882(3) Å] that are shorter than the intrastack one [Te(1)···Te(2); c = 4.155(2) Å]. The intermolecular interaction along the donor stacking direction shows a large overlap integral ($a1 = -20.96\times10^{-3}$) in comparison with the other ones ($c1 = -0.19\times10^{-3}$, $p1 = -2.22\times10^{-3}$, and $q1 = -0.46\times10^{-3}$). Hence, the intracolumnar conduction path of the AsF_6^- and PF_6^- salts is considered to be much better than those of the above-mentioned tetrahedral anion salts of 2,3-DMTTeA, but this salt showed a semiconducting behavior probably because of the strong one-dimensionality of the intermolecular interaction along the *a*-axis.

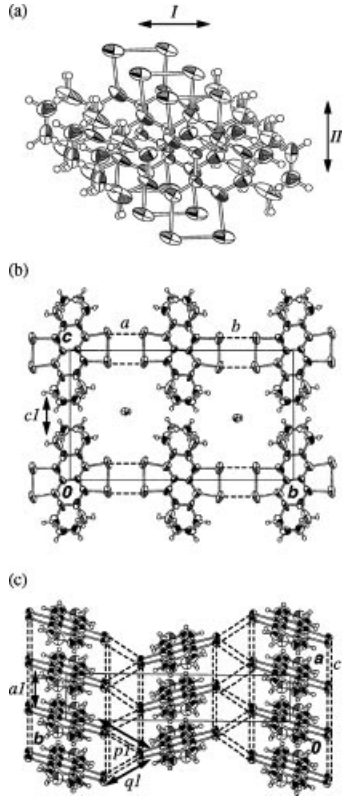

Figure 6. (a) Overlap mode of the donor molecules in $(2,3\text{-DMTTeA})(AsF_6)_{0.2}$ projected on the molecular planes. Interplanar distance [Å]: 3.81. Slip distances [Å]: I = 1.13 and II = 1.21. (b) Crystal structure of $(2,3\text{-DMTTeA})(AsF_6)_{0.2}$ projected on the *bc*-plane. (c) Donor arrangement in $(2,3\text{-DMTTeA})(AsF_6)_{0.2}$ viewed along the *c*-axis. Intermolecular contacts [Å]: Te(1)···Te(1), a = 3.828(3); Te(2)···Te(2), b = 3.882(3); and Te(1)···Te(1), c = 4.155(2). Overlap integrals ($\times10^{-3}$): $a1$ = –20.96, $c1$ = –0.19, $p1$ = –2.22, and $q1$ = –0.46. Dihedral angle between the adjacent donor molecules along the *b*-axis [°]: 32.34.

Crystal Structure of (2,3-DMTTeA)$_2$Br

The overlap mode and crystal structure of the Br^- salt of 2,3-DMTTeA are shown in Figure 7. In spite of use of the tetra-*n*-butylammonium salt of the $GaBr_4^-$ anion as a sup-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

porting electrolyte, an EPMA measurement revealed that the gallium atom is not contained in the obtained crystal. The orientational disorder of the donor molecule is also observed in this salt. The composition was determined to be $(2,3\text{-DMTTeA})_2Br$ by EPMA. The anion molecules are disordered along the *c*-axis and occupy only one of two kinds of channels, which is surrounded by tellurium atoms of the donor molecule as if the anion avoids the steric hindrance of the outer benzene-ring of 2,3-DMTTeA molecules. As Figure 7 indicates, the donor arrangement of the Br^- salt is isostructural to that of a quasi one-dimensional metal $(TSeT)_2Cl$ with a tetragonal lattice, where TSeT is tetraselenotetracene, reported by Shibaeva et al. in 1978.[22,23] The donor molecules form uniform columns along the *c*-axis with a very short interplanar distance of 3.31 Å and a large slip distance along the molecular long axis (4.31 Å) (see Figure 7, a and c). The donor molecules are inclined with a dihedral angle of 53.99° between the adjacent donor columns. As shown in Figure 7 (b and c), no intermolecular Te···Te contact appears between the donor columns, whereas short contacts [Te(1)···Te(1); *a* = 3.699(4) Å] are developed in the column, suggesting a tight one-dimensional nature along the *c*-axis. The overlap integral between the donor molecules along the *c*-axis (*c1* = 53.81×10^{-3}) is very much larger than those of interstack ones (*p1* = -2.62×10^{-3}, *p2* = -1.22×10^{-3}, *q1* = -0.13×10^{-3}, and *q2* = -1.22×10^{-3}). These results also suggest its strong one-dimensional character along the stacking direction, which results in a quite high conductivity ($\sigma_{rt} \approx 1500\ S\,cm^{-1}$) and a semiconducting behavior.

Cation Radical Salts of TMTTeN

X-ray crystallographic analyses were performed on the cation radical salts of TMTTeN with $Ag(CN)_2^-$, $Au(CN)_2^-$, SCN^-, ClO_4^-, and AsF_6^- anions. Because the crystal structures of the $Ag(CN)_2^-$ and $Au(CN)_2^-$ salts are similar to each other, only the crystal structure of the $Ag(CN)_2^-$ salt is discussed here in respect of these two salts.

Crystal Structure of $(TMTTeN)_2Ag(CN)_2$

Figure 8 shows the overlap mode and crystal structure of the $Ag(CN)_2^-$ salt. The composition of the $Ag(CN)_2^-$ and $Au(CN)_2^-$ salts was determined to be $(TMTTeN)_2$(anion)

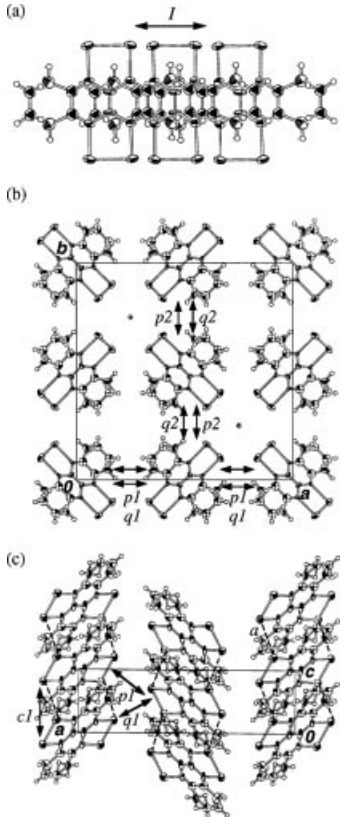

Figure 7. (a) Overlap mode of the donor molecules in $(2,3\text{-DMTTeA})_2Br$ projected on the molecular planes. Interplanar distance [Å]: 3.31. Slip distances [Å]: *I* = 4.31. by a population refinement. The projections of the crystal structure of the $Ag(CN)_2^-$ salt on the *ab*- and *bc*-planes are shown in Figure 8 (b and c, respectively). The donor molecules are stacked along the *c*-axis and take the same orientation with a short interplanar distance of 3.41 Å and a large slip distance of 4.13 Å. The dihedral angle of the donor molecules is 71.4° between the adjacent donor columns. The $Ag(CN)_2^-$ anions are located on the 4_2-axes and are heavily disordered along the *c*-axis. However, the structure was refined to an R-factor of 3%. The crystal structure of this salt is quite similar to those of $(2,3\text{-DMTTeA})_2Br$ and $(TSeT)_2Cl$[23] with tetragonal lattices, but the positions of the anion molecules are different from the other salts. That is, the $Ag(CN)_2^-$ anions occupy all four channels in the unit cell that is surrounded by the donor molecule, because the methyl groups of TMTTeN are considerably smaller than the disordered large benzene ring of 2,3-DMTTeA and, as a result, there is enough space for the anions compared to $(2,3\text{-DMTTeA})_2Br$ (see Figure 8, b). As shown in Figure 8 (b and c), there are several intermolecular Te···Te contacts, and a three-dimensional network through tellurium atoms is developed between the intracolumns and intercolumns in contrast to the one-dimensional character of $(2,3\text{-DMTTeA})_2Br$. The one-dimensionality of the intermolecular interaction is weaker than that of $(2,3\text{-DMTTeA})_2Br$: $c1/p1 \approx 13$ in $(TMTTeN)_2Ag(CN)_2$, where $c1$ (90.96×10^{-3}) and $p1$ (-6.99×10^{-3}) are the overlap integrals parallel and perpendicular to the *c*-axis (the donor stacking axis), respectively, while $c1/p1 \approx 20$ in $(2,3\text{-DMTTeA})_2Br$, resulting in a stable metallic behavior of $(TMTTeN)_2Ag(CN)_2$ as discussed later.

Crystal Structure of (TMTTeN)(SCN)$_{0.88}$

The overlap mode and crystal structure of the SCN^- salt are shown in Figure 9. In spite of preparation from the solution containing both the SCN^- and ClO_4^- anions, the composition of the obtained salt was determined to be $(TMTTeN)(SCN)_{0.88}$ by a population refinement and no ClO_4^- anion was discovered, which is consistent with the result of the EPMA measurement that shows no trace of chlorine atom. Although the crystals of the SCN^- salt with the same shape were also prepared from the solution that contains only the SCN^- anion by an electrocrystallization, the obtained crystals were very small. The projections of the crystal structure of the SCN^- salt on the *bc*-, *ab*- and *ac*-planes are shown in parts b–d in Figure 9. The donor molecules are stacked to form columns along the *a*-axis with a short intermolecular interplanar distance of 3.62 Å and a large slip distance of 4.03 Å. The anions are located in the channels that are formed by TMTTeN molecules. The donor molecules are inclined with a dihedral angle of 72.2° between the two adjacent donor columns along the *b*-axis. The donor arrangement of $(TMTTeN)(SCN)_{0.88}$ is almost

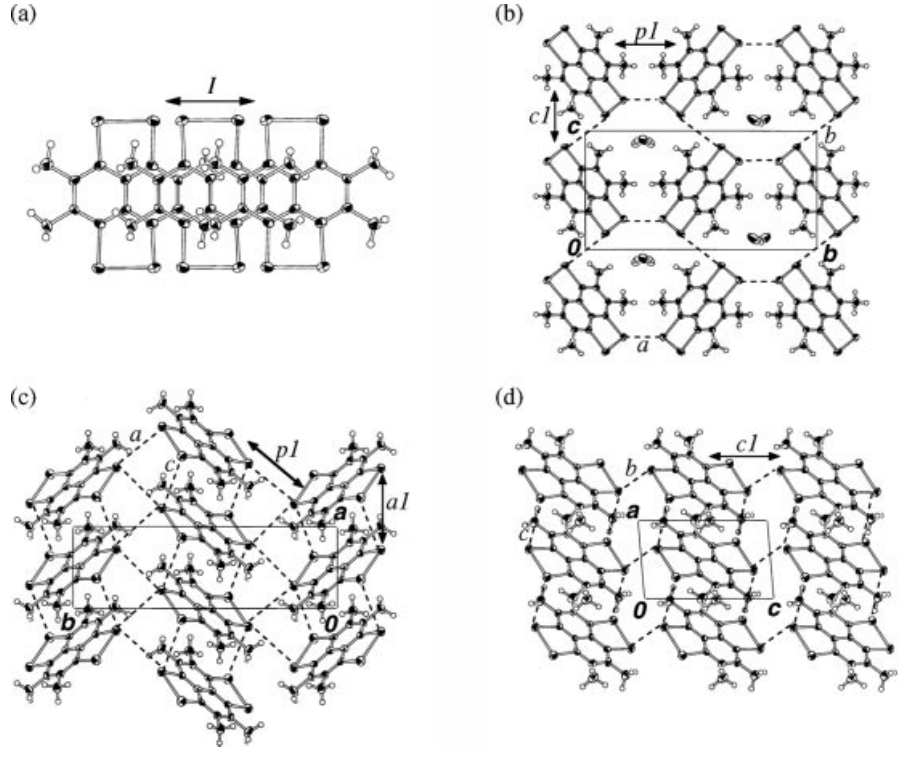

Figure 9. (a) Overlap mode of donor molecules in $(TMTTeN)(SCN)_{0.88}$. Interplanar distance [Å]: 3.62. Slip distance [Å]: I = 4.03. (b) Crystal structure of $(TMTTeN)(SCN)_{0.88}$ projected on the *bc*-plane. Donor stacking columns of $(TMTTeN)(SCN)_{0.88}$ viewed (c) along the *c*-axis and (d) along the *b*-axis. Intermolecular contacts [Å]: Te(1)···Te(1), a = 4.048(1); Te(2)···Te(2), b = 4.123(1); and Te(1)···Te(2), c = 3.788(2). Overlap integrals ($\times10^{-3}$): $a1$ = 82.83, $c1$ = –24.36, and $p1$ = –7.23. Dihedral angle between the adjacent donor molecules along the *b*-axis [°]: 72.2.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the same as that of previously reported $(TSeT)_2SCN$.[23,24] This crystal structure belongs to a monoclinic lattice and is not isostructural to those of the $Ag(CN)_2^-$ and $Au(CN)_2^-$ salts with tetragonal lattices. That is, the penetration of the SCN^- anion into the TMTTeN lattice results in a modification of the packing pattern of TMTTeN molecules along the *c*-axis of the crystals, but the arrangements of TMTTeN molecules along the other two axes are almost the same as those of the $Ag(CN)_2^-$ and $Au(CN)_2^-$ salts. On the other hand, the atomic positions of the SCN^- anions are disordered along the donor stacking axis. As shown in Figure 9 (b–d), there are many intermolecular Te···Te contacts and a three-dimensional network is developed through tellurium atoms in the crystal. The overlap integral along the stack is fairly large ($a1 = 82.83 \times 10^{-3}$) compared to the others ($c1 = -24.36 \times 10^{-3}$ and $p1 = -7.23 \times 10^{-3}$) because of the tight stacking structure of TMTTeN molecules. On the other hand, the interstack overlap integral *c1* is about three times larger than *p1* because of a parallel arrangement of two TMTTeN molecules in the interaction *c1* in contrast to an almost orthogonal arrangement in the interaction *p1*. The large interaction *c1* also originates from the structural situation where two intermolecular Te···Te overlaps between each tellurium pair with longer Te···Te distance and shorter Te···Te distance cannot cancel each other out in spite of the nodal plane at the Te–Te bond. Thus, the overlap integral along the stacking axis (*a1*) is only three times larger than that of the side-by-side direction (*c1*), suggesting relatively strong quasi two-dimensionality in the *ac*-plane, which results in a stable metallic behavior down to 4.2 K.

Crystal Structure of (TMTTeN)$(ClO_4)_{0.88}$

The overlap mode and crystal structure of the ClO_4^- salt are shown in Figure 10. The composition of the ClO_4^- salt was determined to be $(TMTTeN)(ClO_4)_{0.88}$ by a population refinement. The donor arrangement of the ClO_4^- salt is a little different from those of the $Ag(CN)_2^-$ and $Au(CN)_2^-$ salts. Namely, the donor molecules form the columns with uniform stackings along the *c*-axis and the anion molecules are disordered along the donor stacking axis on the special position of the 4_2-axes in a similar manner to the $Ag(CN)_2^-$ and $Au(CN)_2^-$ salts. However, the gradient between the donor molecules is very gentle, with a dihedral angle of 26.9° between the two adjacent donor columns, compared to that of the $Ag(CN)_2^-$ salt (71.4°). As it turned out, the lattice constants of the *a*- and *b*-axes of the ClO_4^- salts are longer by about 2.4 Å, and the *c*-axis of the ClO_4^- salt is shorter by about 1.3 Å than those of the $Ag(CN)_2^-$ and $Au(CN)_2^-$ salts. Furthermore, the donor molecule has a small slip distance (1.08 Å), but the interplanar distance (3.87 Å) is larger than that of the $Ag(CN)_2^-$ salt (3.41 Å) (see parts a in Figure 8 and Figure 10). This large interplanar distance might be related to a larger positive charge on the TMTTeN molecule (+0.88) than the case of the $Ag(CN)_2^-$ salt (+0.5). As shown in Figure 10 (b and c), a three-dimensional network mediated by tellurium atoms that is similar to the other TMTTeN salts is developed in the crystal. Consequently, not only a strong intermolecular interaction is observed in the donor stacking direction (*c1* $= -80.61 \times 10^{-3}$), but a comparatively strong interaction also exists between stacking columns ($p1 = -5.45 \times 10^{-3}$). However, this salt showed a semiconducting behavior with a relatively low conductivity of $\sigma_{rt} \approx 0.8\ S\,cm^{-1}$, probably because of the difference of the stacking mode of the donors.

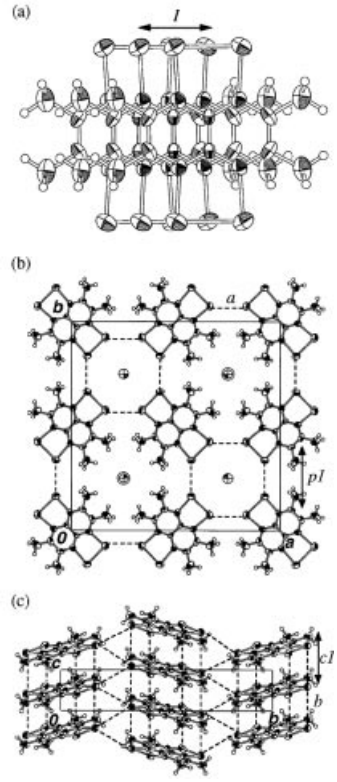

Figure 10. (a) Overlap mode of the donor molecules in (TMTTeN)$(ClO_4)_{0.88}$. Interplanar distance [Å]: 3.87. Slip distance [Å]: $I = 1.08$. (b) Crystal structure of $(TMTTeN)(ClO_4)_{0.88}$ projected on the *ab*-plane. (c) Donor stacking columns of $(TMTTeN)(ClO_4)_{0.88}$ viewed along the *a*-axis. Intermolecular contacts [Å]: Te(1)···Te(1), $a = 4.112(2)$; and Te(1)···Te(1), $b = 4.020(2)$. Overlap integrals ($\times 10^{-3}$): $c1 = -80.61$ and $p1 = -5.45$. Dihedral angle between the adjacent donor molecules [°]: 26.9.

Crystal Structure of (TMTTeN)$(AsF_6)_{0.7}$

Figure 11 shows the overlap mode and crystal structure of the AsF_6^- salt. The space group of this salt ($P42_1m$) is different from the other tetragonal salts ($P4_2/ncm$), and a half of the donor molecule is a crystallographically independent unit. The composition of the AsF_6^- salts is determined to be $(TMTTeN)(AsF_6)_{0.7}$ by a population refinement. The donor arrangement, interplanar distance of 3.44 Å and slip distance of 4.06 Å in the AsF_6^- salt is almost the same as those of the $Ag(CN)_2^-$ salt, suggesting that the donor molecules of these salts possess almost the same degree of positive charge. Although the anion molecules are located on all four channels that are formed by the donor molecules, only the anions in the two channels that are surrounded by tellurium atoms of the donor molecules are disordered along the *c*-axis. As shown in Figure 11 (b and c), a three-dimensional network through tellurium atoms is also devel-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

oped and is similar to the linear anion salts like the $Ag(CN)_2^-$ and $Au(CN)_2^-$ salts. Intermolecular overlap integrals are comparatively large ($c1 = 89.01\times10^{-3}$, $p1 = -8.60\times10^{-3}$, $p2 = -8.63\times10^{-3}$, $q1 = -7.08\times10^{-3}$, and $q2 = -6.80\times10^{-3}$).

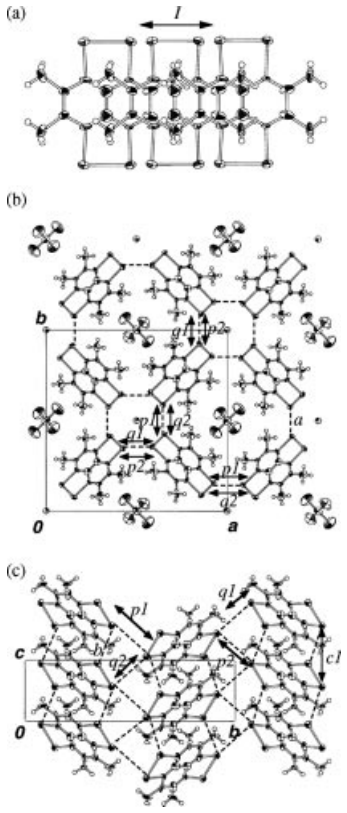

Figure 11. (a) Overlap mode of the donor molecules in $(TMTTeN)(AsF_6)_{0.7}$. Interplanar distance [Å]: 3.44. Slip distance [Å]: $I = 4.06$. (b) The crystal structure of $(TMTTeN)(AsF_6)_{0.7}$ projected on the *ab*-plane. (c) Donor stacking columns of $(TMTTeN)(AsF_6)_{0.7}$ along the *a*-axis. Intermolecular contacts [Å]: Te(1)···Te(2), $a = 4.054(3)$; and Te(1)···Te(2), $b = 3.716(2)$. Overlap integrals ($\times10^{-3}$): $c1 = 89.01$, $p1 = -8.60$, $p2 = -8.63$, $q1 = -7.08$ and $q2 = -6.80$. Dihedral angle between the adjacent donor molecules [°]: 65.24.

Physical Properties

Conducting Properties of the 2,3-DMTTeA Salts

Room temperature conductivities and activation energies of the obtained 2,3-DMTTeA salts are summarized in Table 2. The resistivities of the BF_4^-, ClO_4^-, ReO_4^-, PF_6^-, AsF_6^-, and SbF_6^- salts were measured down to about 80 K along the donor stacking axes. The BF_4^-, ClO_4^-, and ReO_4^- salts showed semiconducting behaviors with low conductivities of $\sigma_{rt} \approx 10^{-2}$ to 10^{-3} S cm^{-1} owing to their inadequate conduction paths along the donor stacking axes that originate from the crossed overlap mode of molecules A and B (Figure 5) and the strong dimerization of molecules B and B′. The temperature dependence of electrical resistivities of the PF_6^-, AsF_6^-, and SbF_6^- salts are also semiconducting with relatively high room temperature conductivities of 1.0–20 S cm^{-1} and low activation energies of 0.02–0.09 eV because of their quasi one-dimensional structures that indicate a strong one-dimensional nature along the donor stacking axis. On the other hand, the Br^- and SCN^- salts showed quite high conductivities of σ_{rt} = 1300 and 890 S cm^{-1} and semiconducting behaviors with very low activation energies of 0.01 and 0.004 eV, respectively, owing to the tight one-dimensional character along the donor stacking direction and the disorders of the donor and anion molecules. The CuI_2^- salt showed a semiconducting behavior with a low room temperature conductivity of 10^{-3} S cm^{-1} and a large activation energy of 0.17 eV. The NO_3^- salt indicates a semiconducting behavior with a relatively large room temperature conductivity of 4.7 S cm^{-1} and a large activation energy of 0.031 eV. As a result, no metallic salt has been discovered in the 2,3-DMTTeA salts, probably because of the strong one-dimensionality of their electronic structures and the disorder effect of 2,3-DMTTeA molecules in the crystal.

Conducting Properties of the TMTTeN Salts

Room temperature conductivities and activation energies of the TMTTeN salts are listed in Table 3. All the salts except for the $Ag(CN)_2^-$, $Au(CN)_2^-$, and SCN^- salts are semiconductors or insulators. Among them, the $Cu(SCN)_2^-$ and

[a] All preparations were carried out at 40 °C under nitrogen. [b] All the supporting electrolytes were tetra-*n*-butylammonium salts except for the $Cu(SCN)_2^-$, $N(CN)_2^-$, BF_4^-, and SbF_6^- salts. Tetraethylammonium salt was used in the BF_4^- salt and tetraphenylphosphonium salt was used in the $N(CN)_2^-$ salt. In the $Cu(SCN)_2^-$ and SbF_6^- salts, bis(triphenylphosphoranylidene)ammonium salts were used. [c] EtOH = ethanol, TCE = 1,1,2-trichloroethane, THF = tetrahydrofuran, PhCN = benzonitrile and PhCl = chlorobenzene. [d] This salt was prepared under existence of two kinds of anion complexes, tetra-*n*-butylammonium salts of SCN^- and ClO_4^- anions.

$GaBr_4^-$ salts showed very high room temperature conductivities of 840 and 360 S cm^{-1} with low activation energies of 0.02–0.04 eV, respectively. On the other hand, the ClO_4^- salt showed a low room temperature conductivity of 10^{-1} S cm^{-1}. The linear $Ag(CN)_2^-$, $Au(CN)_2^-$, and SCN^- anion salts showed very high room temperature conductivities (590–760 S cm^{-1}). As shown in Figure 12, the temperature dependences of the resistivities of the $Ag(CN)_2^-$ and $Ag(CN)_2^-$ salts are metallic down to about 50 K, below which the resistivities increase very slowly down to 4.2 K with decreasing temperature. On the other hand, Figure 12 also shows that the temperature dependence of electrical resistivities of the SCN^- salt is metallic down to 4.2 K without any increase of resistivities, in contrast to the $Ag(CN)_2^-$ and $Ag(CN)_2^-$ salts. Although the temperature dependence of its resistivity is very small, like those of the $Ag(CN)_2^-$ and $Au(CN)_2^-$ salts, this SCN^- salt displays no increase in resistivity. Therefore, the SCN^- salt is revealed to be a genuine stable metal down to low temperatures. As mentioned before, this system has a strong transverse intermolecular interaction (see *c1* in Figure 9), which is the origin of its stable metallic state. On the other hand, the AsF_6^- salt also has a relatively high conductivity of 13 S cm^{-1}, but showed a semiconducting behavior at room temperature. Considering it has almost the same donor arrangement as the metallic $Ag(CN)_2^-$ and $Au(CN)_2^-$ salts, this semiconducting behavior may suggest that the large disorder effect of the octahedral AsF_6^- anion prevents a metallic conducting behavior.

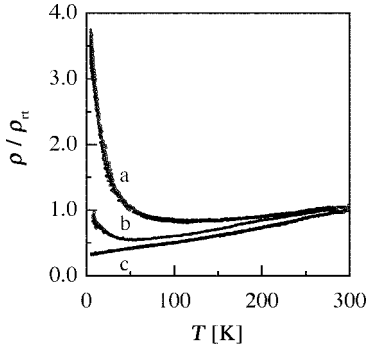

Figure 12. Temperature dependence of the electrical resistivities of the metallic TMTTeN salts. a, $(TMTTeN)_2Au(CN)_2$; b, $(TMTTeN)_2Ag(CN)_2$; and c, $(TMTTeN)(SCN)_{0.88}$.

Magnetic Properties of the TMTTeN Salts

The magnetic susceptibilities of $(TMTTeN)_2Ag(CN)_2$ and $(TMTTeN)(SCN)_{0.88}$ were measured using SQUID magnetometer down to 2 K at 30 kOe. The susceptibility of the neutral TMTTeN crystal was also measured in order to estimate the diamagnetic contribution of the TMTTeN molecule, which was performed by subtracting that of carbon disulfide included in the crystal of the neutral TMTTeN molecule. Figure 13 shows the temperature dependence of paramagnetic susceptibilities of $(TMTTeN)_2Ag(CN)_2$ and $(TMTTeN)(SCN)_{0.88}$. The paramagnetic susceptibility of $(TMTTeN)_2Ag(CN)_2$, which is corrected by subtracting a diamagnetic contribution and a small low-temperature Curie component due to paramagnetic impurities and/or lattice defects, was almost constant throughout the temperature range, indicating a Pauli paramagnetism based on metal electrons ($2.0–2.5\times10^{-4}$ emu mol^{-1}). No anomaly that corresponds to the gradual resistivity increase around 50 K was observed, suggesting the stable metallic nature of this salt. On the other hand, the paramagnetic susceptibilities of $(TMTTeN)(SCN)_{0.88}$ are also almost constant throughout the temperature range, indicating the Pauli paramagnetism of the system ($1.6–1.9\times10^{-4}$ emu mol^{-1}). Therefore, as revealed by the low-temperature resistivity behaviors, these salts are the first systems that possess metallic ground state among the *peri*-ditellurium-bridged donors. Because these TMTTeN conductors have an approximately one-dimensional cosine band along the molecular stacking direction, the smaller susceptibility of $(TMTTeN)(SCN)_{0.88}$ and larger susceptibility of $(TMTTeN)_2Ag(CN)_2$ seem to be related to the difference in not only their bandwidths but also their band-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

fillings; namely, the ratio $\sin(\pi \times 0.5/2)/\sin(\pi \times 0.88/2) \approx 0.72$, is nearly equal to the ratio of the susceptibilities of these salts. In addition, the magnitude of these susceptibilities is about half that of the well-known κ-type BEDT-TTF superconductors ($\approx 5 \times 10^{-4}$ emu mol^{-1}),[25] where BEDT-TTF is bis(ethylenedithio)-TTF. Their small susceptibilities suggest large bandwidths of $(TMTTeN)_2Ag(CN)_2$ and $(TMTTeN)(SCN)_{0.88}$, which are brought about by the strong intermolecular interaction, and are consistent with the organic metals based on tellurium-containing donors such as (TTeF)(TCNQ).[26]

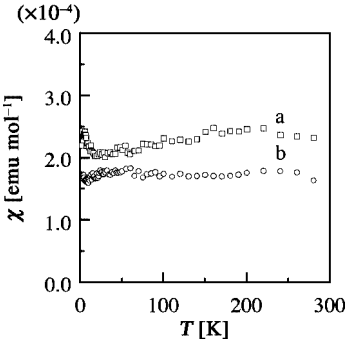

Figure 13. Temperature dependence of the paramagnetic susceptibilities of the TMTTeN salts. a, $(TMTTeN)_2Ag(CN)_2$; and b, $(TMTTeN)(SCN)_{0.88}$.

Band Structure Calculations

We have previously reported the results of the extended Hückel tight-binding band calculation on $(TMTTeN)_2Ag(CN)_2$.[18] However, the extended Hückel tight-binding band is calculated anew, because the empirical parameters used here are redetermined on the basis of the results of the ab initio MO calculations. As the first step of the band structure calculation, an extended Hückel MO was obtained as approximately the same as the ab initio MO. The calculated intermolecular overlap integrals of the individual salts have already been presented, together with their crystal structures. Generally speaking, the transverse interactions became much smaller than the interaction along the direction of the molecular stacking, because of the nodal plane at the Te–Te bond. The energy dispersion curves of conduction bands and the Fermi surfaces of $(TMTTeN)_2Ag(CN)_2$ and $(TMTTeN)(SCN)_{0.88}$ are shown in Figures 14 and 15, respectively.

Energy Dispersion Curves and Fermi Surface of $(TMTTeN)_2Ag(CN)_2$

Owing to the tetragonal lattice symmetry, the obtained band dispersions are doubly degenerated on the XM line (see Figure 14), which makes the Fermi surfaces that are composed of two corrugated one-dimensional Fermi surfaces quasi three-dimensional. A large bandwidth (≈4.0 eV) is consistent with the observed small Pauli susceptibility. The Fermi surfaces are closed in the a^*c^*- and b^*c^*-planes and also in the plane perpendicular to the c^*-axis [an example of the cross section of the Fermi surface at the plane (Γ′X′Y′) perpendicular to the c^*-axis is presented], as shown in Figure 14. As mentioned before, the analogous selenium-donor system $(TSeT)_2Cl$ showed a metal–semi-

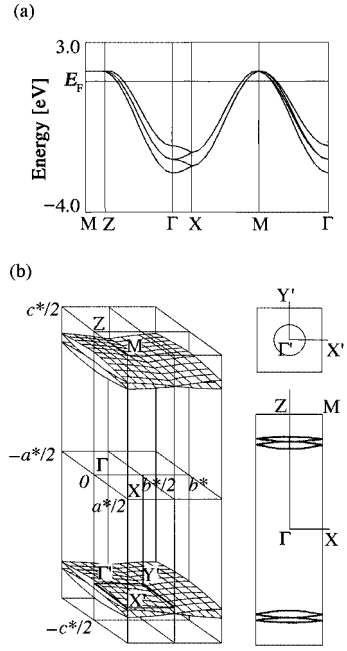

Figure 14. Energy band structures and three-dimensional Fermi surfaces of $(TMTTeN)_2Ag(CN)_2$ obtained by the extended Hückel tight-binding band calculation and their cross sections at the plane through ΓXZ and Γ′X′Z′, where Γ = (0, 0, 0), X = (a^*/2, 0, 0), Z = (0, 0, c^*/2), Γ′ = (0, 0, –0.35c^*), X′ = (a^*/2, 0, –0.35c^*), and Y′ = (0, b^*/2, –0.35c^*).

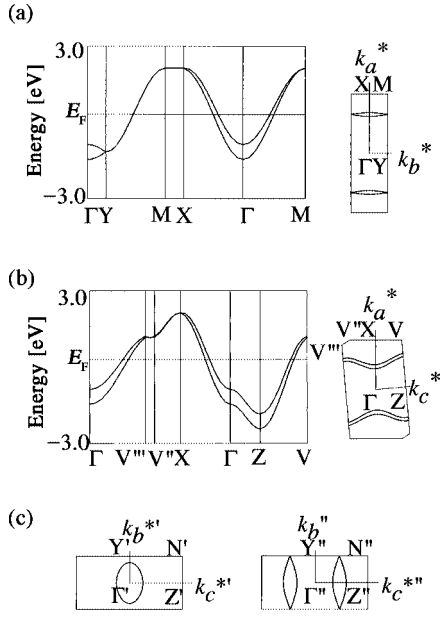

Figure 15. Energy band structures and cross sections of Fermi surfaces of $(TMTTeN)(SCN)_{0.88}$ obtained by the extended Hückel tight-binding band calculation. Γ = (0, 0, 0), X = (a^*/2, 0, 0), Y = (0, b^*/2, 0), Z = (0, 0, c^*/2), Γ′ = (0.23a^*, 0, 0), Y′ = (0.23a^*, b^*/2, 0), Z′ = (0.23a^*, 0, c^*/2), Γ″ = (0.28a^*, 0, 0), Y″ = (0.28a^*, b^*/2, 0), and Z″ = (0.28a^*, 0, c^*/2).

metal transition around 20 K, where a susceptibility drop that indicates a partial disappearance of the Fermi surfaces was observed. The stable metallic state of $(TMTTeN)_2Ag(CN)_2$ is attributable to the stronger three-dimensionality of the band structure. Therefore, $(TMTTeN)_2Ag(CN)_2$ is the first organic conductor that has a stable metallic state and "quasi three-dimensional Fermi surfaces" at ambient pressure on the basis of the tellurium-containing π donors.

Energy Dispersion Curves and Fermi Surface of (TMTTeN)(SCN)$_{0.88}$

As Figure 15a indicates, the band dispersions are doubly degenerated on the YM line. A large bandwidth (≈4.5 eV) is consistent with the observed small Pauli susceptibility. The Fermi surface of the SCN^- salt is open along the *b**- and *c**-directions, but the intermolecular interactions between the donor columns are fairly strong, as mentioned before. As shown in part c of Figure 15, cross sections of the Fermi surface perpendicular to the *a**-axis indicate a two- or quasi two-dimensional metallic state. Consequently, the Fermi surfaces are considered to be stable against the nesting of the Fermi surfaces. This may be an origin of the stable metallic state of the SCN^- salt.

Conclusions

Crystal structures and physical properties of various cation radical salts based on the *peri*-ditellurium-bridged polyacene donor molecules 2,3-DMTTeA and TMTTeN were examined. We have obtained the stable metallic cation radical salts of the TMTTeN molecule. Compared with usual organic conductors, the molecular conductors based on these tellurium-containing π donors show a very strong tendency to form a three-dimensional network mediated by tellurium atoms. Owing to the strong Te···Te network, the anions have very small contributions to the architecture of the crystal structures and are located fairly randomly in the channels that are formed by the donor molecules in most cases. New conducting systems with ordered crystal structures will be obtained by suitable selection of counteranions, which will afford a new class of three-dimensional organic metals with bandwidths much wider than the hitherto-obtained organic metals.

Experimental Section

General Remarks: 2,3-DMTTeA and TMTTeN were synthesized according to the reported methods.[15,16] Tetrahydrofuran (THF) was freshly distilled from sodium and benzophenone under nitrogen prior to use. Chlorobenzene (PhCl) was washed three times with concd. sulfuric acid, then with aqueous sodium hydrogen carbonate solution and water, followed by drying with calcium chloride and distilled from diphosphorus pentaoxide. Ethanol (EtOH) was distilled from magnesium ethoxide under nitrogen. Benzonitrile (PhCN) was dried with calcium chloride and distilled from diphosphorus pentaoxide under reduced pressure. 1,1,2-Trichloroethane (TCE) was washed three times with concd. sulfuric acid, then with aqueous sodium hydrogen carbonate solution and water, followed by drying with calcium chloride and was distilled under nitrogen. All the supporting electrolytes were recrystallized several times with organic solvents.

Electrocrystallization: The crystals of cation radical salts were grown by an electrochemical oxidation in the solvent shown in Table 2 for the 2,3-DMTTeA salts and Table 3 for the TMTTeN salts in the presence of the donor and the tetraalkylammonium, tetraphenylphosphonium, or bis(triphenylphosphoranylidene)ammonium salts of the corresponding anions under a constant current of 0.05–0.7 μA at room temperature in the case of the 2,3-DMTTeA salts and at 40 °C in the case of the TMTTeN salts.

Crystal Structure Determination: X-ray crystal structure analyses were performed on the neutral 2,3-DMTTeA and TMTTeN molecules recrystallized from carbon disulfide and their cation radical salts. Intensity data were measured with Rigaku AFC5R or AFC7R automated four-circle diffractometers or R-AXIS IV imaging plate area detector [only for $TMTTeN(AsF_6)_{0.7}$] by using graphite-monochromated Mo-K_α radiation at room temperature. Experimental details and crystal data are listed in Table 4, Table 5, and Table 6. Anisotropic temperature factors were applied for the non-hydrogen atoms. The calculated positions of hydrogen atoms were not refined but included in the final calculation. All calculations were performed using the teXsan[27] crystallographic software package of the Molecular Structure Corporation. CCDC-118377–118378, 121877–121880, 142670, and 264456–264461 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Ltd.). Data were accumulated for 100 s with time constants of 12 μs. Data collections and analyses were controlled by the Delta Class Analyzer (Kevex).

Magnetic Susceptibility Measurement: The magnetic susceptibilities were measured at a field of 30 kOe in the temperature range from 300 to 2 K using a Quantum Design MPMS-7 SQUID magnetometer. The samples were wrapped with clean aluminum foil whose magnetic susceptibility was separately measured and subtracted. The data were corrected for the diamagnetic contribution estimated from Pascal's constants, and the actual measurement of the neutral TMTTeN molecule [$\chi^{dia} = 7.47 \times 10^{-4}$ emu mol^{-1} for the $Ag(CN)_2^-$ salt and $\chi^{dia} = 3.63 \times 10^{-4}$ emu mol^{-1} for the SCN^- salt] and Curie impurities [0.05 mol-% for the $Ag(CN)_2^-$ salt and no subtraction of Curie impurities for the SCN^- salt].

Electrical Resistivity Measurement: The electrical resistivities were measured by a four-probe method along the donor stacking axis of the single crystals using Huso Electro Chemical System HECS 944C1 and/or HECS 944C Multi-channel 4-terminal conductometer. Electrical contacts were achieved with gold wires (Ø 0.015 mm) and gold paste.

Molecular Orbital (MO) and Band Structure Calculations: In order to use the simple extended Hückel type tight-binding band calculation for the molecular conductors based on *peri*-ditellurium-bridged polyacene donor molecules, reliable determination of the highest occupied molecular orbital (HOMO), from which a conduction band is formed, had to be made beforehand. The ab initio MO calculations of TMTTeN were performed by replacing the methyl groups with hydrogen atoms using Gaussian 94[28] on a Hewlett–Packard workstation (Apollo 9000 series model 735) at the Research Centre for Spectrochemistry of the University of Tokyo. The Huzinaga-Dunning double zeta basis set was used.[29] The Los Alamos effective core potential plus double zeta basis set (LanL2DZ) was used for tellurium atoms.[30]

The overlap integrals, band structures, and Fermi surfaces were calculated by a tight-binding method based on the extend Hückel approximation. Slater-type atomic orbitals were used for the calculation of MOs. The parameters for tellurium atoms were determined on the basis of the ab initio MO calculations and crystallographic analyses discussed before in this paper. The exponent ζ and the ionization potential (eV) were: Te 5s, 2.33, –17.41; Te 5p, 2.01, –8.98; Te 5d, 1.64, –4.76; C 2s, 1.625, –21.4; C 2p, 1.625, –11.4; H 1s, 1.0, –13.6. In the case of 2,3-DMTTeA salts, overlap integrals were calculated by using the coordinates of only one side of two conformations of the disordered molecule.

Conformational Analysis of Chiral Ferrocene–Peptides

Katja Heinze,*[a] and Manuela Beckmann[a]

Dedicated to Professor Gottfried Huttner on the occasion of his 68th birthday

Keywords: Conformational analysis / Hydrogen bonds / Metallocenes / Modelling / Peptides

Ferrocene-containing dipeptides Ac-Fca-AA-OMe (AA = L-Val, L-Ile) with the artificial amino acid 1′-aminoferrocene-1-carboxylic acid (Fca) and chiral α-amino acid building blocks display hydrogen-bonded structures that result in organised helical ferrocene units in solution, as evidenced by spectroscopic and theoretical investigations.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Short peptides usually exist as an ensemble of rapidly interconverting conformers in solution. However, intramolecular forces (hydrogen bonds, salt bridges, π-interactions) may stabilise a few preferred conformations even in small molecules.[1] In recent years, bioorganometallic chemistry has developed as a rapidly growing field, and this holds especially true for ferrocene as the organometallic ingredient.[2] The favourable electrochemical properties of ferrocenes have been exploited for use as redox probes in ferrocene-containing biomolecules. The almost unhindered rotational freedom of the ferrocene cyclopentadienyl rings might give rise to new structural and dynamic aspects in 1,1′-disubstituted ferrocene bioconjugates.[3]

We recently investigated the solid-state and solution structure of the *N*-protected active ester of 1′-aminoferrocene-1-carboxylic acid (Fca), benzotriazol-1-yl 1′-(acetylamino)ferrocene-1-carboxylate (Ac-Fca-OBt; Ac = acetyl, Bt = benzotriazol-1-yl) and found an intramolecular hydrogen bond both in the solid state and in solution with an activation barrier for the interconversion between enantiomeric conformations of 43 kJ mol^{-1}.[3] Kraatz et al. have reported the Boc-protected analogue and proposed a similar solution structure.[4]

Recently, Rapić and Metzler-Nolte reported the solid-state structure of the tetrapeptide Boc-Ala-Fca-Ala-Ala-OMe, which possesses two intramolecular hydrogen bonds that result in a (*P*)-helical arrangement of the Cp rings.[5] Similar observations on disubstituted ferrocene–peptide conjugates of ferrocenedicarboxylic acid have been reported by Hirao,[6,7] Kraatz[8] and Metzler-Nolte,[9] while the monosubstituted ferrocene–peptide conjugates of ferrocenecarboxylic acid frequently employed for labelling purposes do not exhibit a preferred helical arrangement at the ferrocene moiety.[6,7,9]

Simple chiral dipeptides of Fca, such as Ac-Fca-AA-OMe (AA = α-amino acid), possess just one chiral carbon atom in the vicinity of the ferrocene unit but should be able to display an intramolecular hydrogen bond which could result in a preferred conformation of the dipeptides in solution. Here we describe our results of a conformational analysis of Ac-Fca-AA-OMe (AA = L-Val, L-Ile) dipeptides in solution using spectroscopic and theoretical methods.

Results and Discussion

The dipeptides **1** and **2** were synthesised starting from the activated ester Ac-Fca-OBt[3] and H-Val-OMe·HCl and H-Ile-OMe·HCl, respectively (Scheme 1). The conjugates were fully characterised by mass spectrometry, showing the expected [M$^+$] peaks at m/z = 400 and 414, respectively, elemental analyses, IR spectroscopy (see Exp. Sect.) and cyclic voltammetry (oxidation waves at 535 and 565 mV vs. SCE, respectively).

In order to investigate the possible conformations of **1** and **2** in CH_2Cl_2 solution we performed NMR, IR and CD spectroscopic experiments with **1** and **2** in solution together with a theoretical analysis. The following discussion will at first focus on the conformations of **1** and subsequently a generalised conclusion will be attempted.

The ^{1}H NMR spectra of analytically pure samples of **1** in CD_2Cl_2 (Figure 1, Table 1) show two distinct species groups in the amide proton region and for the methyl group CH_3(A) in an approximate ratio of 10:1, which do not interconvert on the NMR timescale at 303 K {major con-

CH_2	–	–	1.26 (m), 1.50 (m)	

[a] Not observed due to overlap with H^β signal.

formers: $\delta(H^1)$ = 7.57 ppm, $\delta(H^6)$ = 6.30 ppm, $\delta[CH_3(A)]$ = 1.99 ppm; minor conformers: $\delta(H^1)$ = 7.78 ppm, $\delta(H^6)$ = 5.84 ppm, $\delta[CH_3(A)]$ = 2.02 ppm at 303 K}.

The cyclopentadienyl proton signals of the major conformers were assigned by 2D NMR experiments and a literature comparison[3,5,10] (Figure 1, Table 1). The expected NOE cross-peaks (intra-Cp, amide-Cp and within the L-valine unit) are observed in the NOESY spectra, while no cross-peaks are observed between the substituents. For the major species in CD_2Cl_2 solution all Cp protons are magnetically non-equivalent as the chiral carbon centre C^α of the L-amino acid part generates diastereotopic sides of the ferrocene both in the "lower" Cp ring (H^7/H^{10}: δ = 4.51/4.69 ppm; H^8/H^9: δ = 4.36/4.40 ppm) *and* in the "upper" Cp ring (H^2/H^5: δ = 4.42/4.57 ppm; H^3/H^4: δ = 4.04/4.07 ppm) which demonstrates that the chiral information is effectively transferred from the α-amino ester to the "lower" Cp *and* to the "upper" Cp ring. An analogous stereodiscrimination is found for the cyclopentadienyl carbon atoms (C^7/C^{10}: δ = 69.1/69.3 ppm; C^8/C^9: δ = 71.0/71.3 ppm; C^2/C^5: δ = 63.7/64.3 ppm; C^3/C^4: δ = 65.8/65.9 ppm).

Variable-temperature ^{1}H NMR spectra between 193 and 303 K allowed us to investigate the hydrogen-bonding situation of both conformer groups of **1** by monitoring the tem-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

perature dependence of all amide proton signals. For the major conformers $\Delta\delta(H^1)$ = –6.8 ppb K^{-1} and $\Delta\delta(H^6)$ = –3.3 ppb K^{-1} (determined by a regression analysis between 243 and 303 K), thus showing that only H^1 is involved in a dynamic hydrogen bond, whereas for the minor conformers $\Delta\delta(H^1)$ = –5.9 ppb K^{-1} and $\Delta\delta(H^6)$ = –11.1 ppb K^{-1}, which suggests that *both* H^1 and H^6 are dynamically hydrogen-bonded [cf. non-hydrogen bonded Fc-NH-C(=O)-CH_3: $\Delta\delta(H^1)$ = –2.9 ppb K^{-1} and hydrogen-bonded Fc-NH-C(=O)-Fc-NH-C(=O)CH_3: $\Delta\delta(H^1)$ = –6.6 ppb K^{-1} and $\Delta\delta(H^6)$ = –11.0 ppb K^{-1}[3]].

The solution IR spectra of **1** (Figure 2) display signals due to hydrogen-bonded NH groups (3357 and 3325 cm^{-1}) together with free NH groups (3433 cm^{-1}), as well as absorption bands corresponding to hydrogen-bonded ester carbonyl groups (1728 cm^{-1}) and free ester groups (1739 cm^{-1}) in addition to several amide I (1664–1653 cm^{-1}) and amide II bands (1546–1512 cm^{-1}).

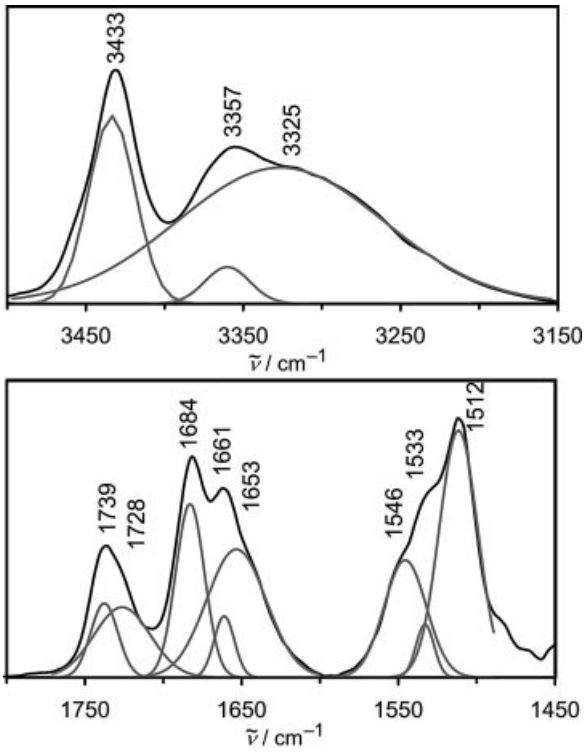

Figure 2. IR spectra of **1** in CH_2Cl_2 (left: amide A region; right: amide I+II region).

In the UV/Vis spectra the typical ferrocene absorption is observed at around 440 nm (see Exp. Sect.). The CD spectra of **1** and **2** in CH_2Cl_2 (Figure 3) display a positive Cotton effect at the ferrocene absorption (M_θ = 7440 and 6490 mdeg M^{-1} cm^{-1} at 450 nm for **1** and **2**, respectively) which is usually interpreted as a (*P*)-helical conformation of the ferrocene.[5,6,9] The CD signal intensity is diminished (M_θ = 3570 and 3210 mdeg M^{-1} cm^{-1} for **1** and **2**, respectively) by the addition of 20% (v/v) methanol, which might compete for hydrogen-bonding sites and result in a reduction of the helicity at the ferrocene. The negative CD at 500 nm might arise from minor conformations of **1** and **2** with (*M*)-helical ferrocene units or freely rotating Cp rings.[11]

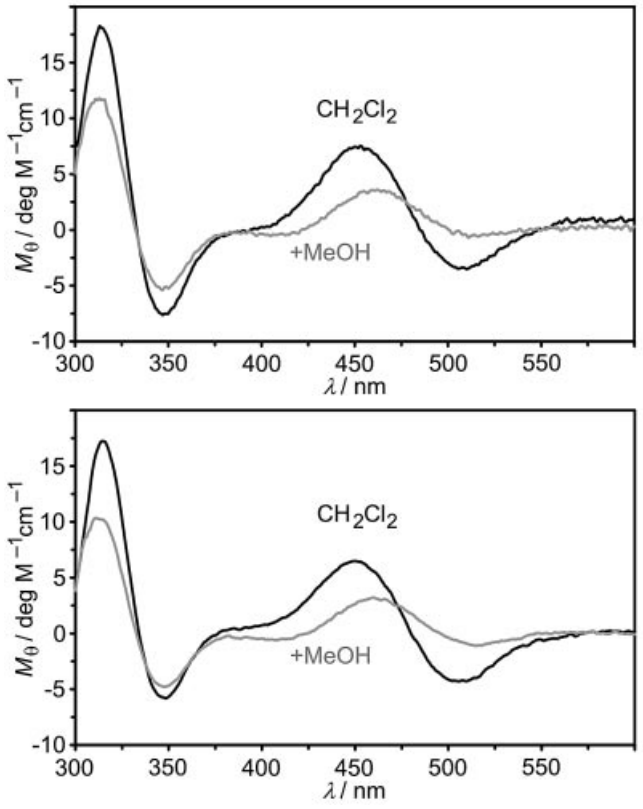

Figure 3. CD spectra of **1** (left) and **2** (right) (1 mM) in CH_2Cl_2 (dark line) and CH_2Cl_2/MeOH 20% (v/v) (light line).

Thus, ferrocene conjugates **1** and **2** appear to have similar helical conformations in CH_2Cl_2 solution that are destroyed in coordinating solvents. Additionally, NMR spectra in CD_2Cl_2/D_2O and CD_2Cl_2/DMSO/D_2O solvent mixtures reveal a different pattern in the Cp-H region between δ = 3.9 and 4.8 ppm, thus indicating different conformations in these solvent mixtures. In addition to the different pattern in the Cp-H region, the amide protons are exchanged against deuterium, with amide proton H^6 having a larger half-life than H^1, probably due the higher steric shielding of H^6 by the ester and alkyl groups of the α-amino acid part than for H^1.

A modelling study was performed in order to obtain more insight into the possible conformational space of the ferrocene–dipeptides. As force fields used in molecular mechanics calculations and dynamics simulations are currently not available for ferrocene derivatives, we employed the DFT method. DFT calculations (B3LYP, LanL2DZ) on **1** in the gas phase with varying starting geometries resulted in an ensemble of ten stable hydrogen-bonded conformations (Figure 4, Table 2), which fall into four categories (**RL**, **LR**, **LL** and **RR**) that differ in the relative orientation of the NH vectors (R and L denote a clockwise and anticlockwise rotation, respectively, of the N^1H^1 and N^2H^6 vectors when looking along the [centroid C^1–C^5]–[centroid C^6–C^{10}] axis). Different types of intramolecular hydrogen bonds (**a**:

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$H^1\cdots O^3$; **b**: $H^1\cdots O^2$; **c**: $H^6\cdots O^1$) are observed within these groups. No minimum structure could be found for conformers **RL-c** and **LR-c** with the NH vectors directed towards each other and with a hydrogen bond between H^6 and O^1 as the geometry optimisations always converge to structures **RL-b** and **LR-b**, respectively. In fact, **RL-c** rather corresponds to the transition state of the isomerisation **RL-a** → **LL-c** (Table 2). Likewise, the non-hydrogen-bonded geometries **RL-d**, **LL-d** and **RR-d** represent transition states with one imaginary frequency for the Cp ring rotation rather than minimum structures, while **LR-d** again represents a local minimum (Figure 5, Table 2).

The relative energies of the different conformations fall into a narrow region of 0–30 kJ mol^{-1} as expected for a small peptide (Table 2). In spite of these small energy differences, an attempt to explain the experimental data on the basis of the calculated geometries and energies was undertaken. From the conformer population data it is reasonable to include only conformers **RL-a**, **RL-b**, **LR-b**, **LL-a**, **LL-b** and **LL-c** in the following interpretation of the experimental data (Figure 4, highlighted structures; see also Table 2 and Scheme 2).

The observation of hydrogen-bonded ester carbonyl groups (type **a** hydrogen bond: **RL-a** and **LL-a**) together

RL-a → LL-c	24.6[g]	–	+38.5	$H^6\cdots O^1$ = 2.25 ($H^1\cdots O^3$ = 3.43)
LL-a → LL-b	16.2[h] (7.9[i])	–	–42.1	($H^1\cdots O^3$ = 3.04) $H^1\cdots O^2$ = 2.39

[a] Conformer populations were calculated by using a Boltzmann distribution at 298 K. [b] The torsion angle, α, is defined as C^1–[centroid C^1–C^5]–[centroid C^6–C^{10}]–C^6. [c] This geometry corresponds to a transition state with N_{imag} = 1 (16.7i cm^{-1}; Cp ring rotation). [d] This geometry corresponds to a minimum (N_{imag} = 0). [e] This geometry corresponds to a transition state with N_{imag} = 1 (5.5i cm^{-1}; Cp ring rotation). [f] This geometry corresponds to a transition state with N_{imag} = 1 (11.0i cm^{-1}; Cp ring rotation). [g] This geometry corresponds to a transition state with N_{imag} = 1 (45.7i cm^{-1}; combined Cp ring rotation, *N*-acetyl rotation and hydrogen-bond breaking). [h] This geometry corresponds to a transition state with N_{imag} = 1 (32.6i cm^{-1}; combined Cp ring rotation and hydrogen-bond breaking). [i] Energy relative to **LL-a**.

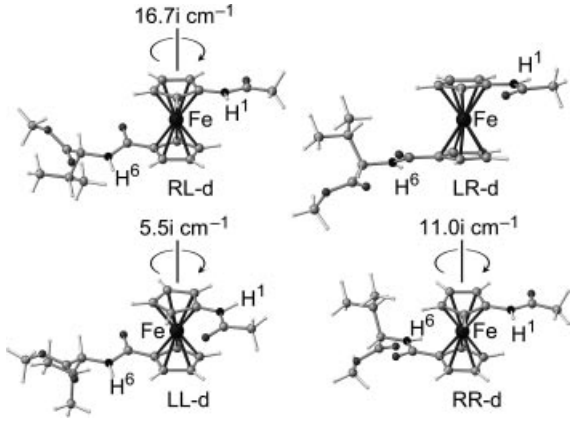

Figure 5. Non-hydrogen bonded structures of **1**.

with free ester carbonyl groups, as well as hydrogen-bonded amide carbonyl groups (type **b** and **c** hydrogen bonds: **RL-b**, **LR-b**, **LL-b**, **LL-c**) together with free amide carbonyl groups, in the calculated conformers is in agreement with the experimental IR spectroscopic data (Figures 2 and 4).

On the basis of their relative abundance, the two signal sets with relative intensity of 91% and 9% observed in the ^{1}H NMR spectra are assigned to groups **RL** (calculated conformer population 88%) and **LL** (calculated conformer population 10%), respectively, while populations of group **LR** and group **RR** fall below the detection limit of NMR spectroscopy.

Interconversion within the NMR-observable conformer groups **RL** and **LL** is fast on the NMR timescale as only time-averaged NMR signals are observed for each group (Scheme 2). Thus, the activation barrier for the involved processes hydrogen-bond breaking and Cp-ring rotation should be rather small. The activation barriers for these elementary steps can be estimated to be 8 kJ mol^{-1} for hydrogen-bond breaking and 5–10 kJ mol^{-1} for Cp-ring rotation[12] (13–18 kJ mol^{-1} for both steps; cf. energies of non-hydrogen-bonded species **d** in Table 2). In fact, a transition state for the conformational rearrangement **LL-a** → **LL-b** could be located only 7.9 kJ mol^{-1} above **LL-a**.

However, for the transformation **RL** → **LL**, in addition to hydrogen-bond breaking and Cp-ring rotation, the *N*-acetyl group has to flip relative to the Cp plane, which results in an additional activation barrier of 17–25 kJ mol^{-1} [rotational barrier estimated for the model compound (acetylamino)ferrocene Ac–NH–Fc; Figure 6[13]]. Thus, in total the energy required for this stepwise pathway **RL-a** → **RL-d** → *N*-acetyl rotation → **LL-d** → **LL-a**/**LL-b**/**LL-c** can be estimated to lie in the range 30–43 kJ mol^{-1}. For **RL-a** → **LL-c** a direct low-energy hydrogen-bond-assisted pathway combining *N*-acetyl rotation and Cp-ring rotation could be found with a transition state 24.6 kJ mol^{-1} higher in energy than **RL-a** (Figure 7, Scheme 2). Even the energy for this direct pathway is substantially higher than that estimated for the easy transformation between **a**, **b** and **c** conformers. Thus, the DFT calculations provide a qualitative rationale for the observation of two slowly interconverting species groups (Scheme 2).

The assignment of the major conformers to group **RL** and the minor conformers to group **LL** was further supported by the variable-temperature ^{1}H NMR spectra as the major conformers only possess $H^1\cdots$O hydrogen bonds (**RL-a**, **RL-b**) while the minor conformers have $H^1\cdots$O *and* $H^6\cdots$O hydrogen bonds (**LL-a**, **LL-b** and **LL-c**, Figure 4, Scheme 2) in agreement with the observed large temperature dependence of the signal for proton H^6 in the minor species group.

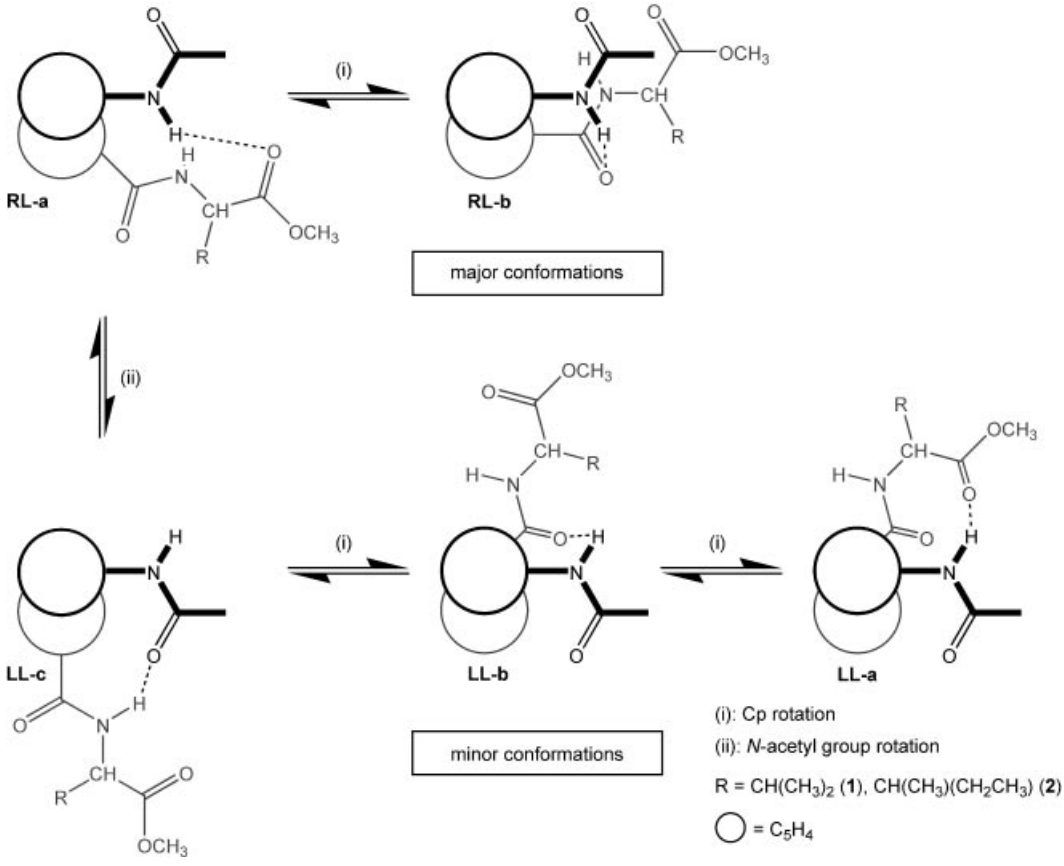

Scheme 2.

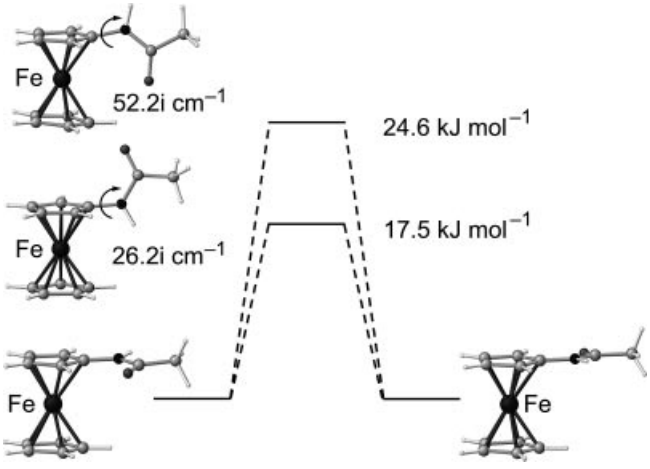

Figure 6. Energy profile for the *N*-acetyl group rotation in the model complex Ac-NH-Fc.

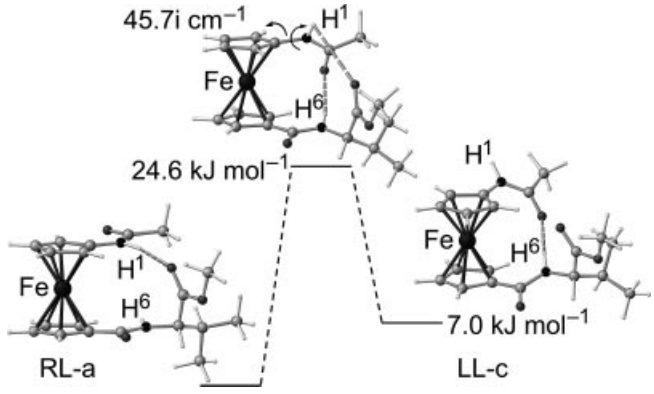

Figure 7. Energy profile for the hydrogen-bond-assisted direct conversion **RL-a** → **LL-c**.

Due to the restrained relative orientation of the ferrocene chromophore and the chiral centre due to the hydrogen bonding the ferrocene itself gains helical chirality, which results in fairly large Cotton effects compared to those of monosubstituted ferrocenes with a chiral centre in the substituent.[11] The dominant (*P*)-helical conformation of the ferrocene unit suggested by the CD spectra (Figure 3) can be explained by conformers **RL-a**, **LR-b** and **LL-c** with positive torsion angles *a*, which together amount to 91% of the species according to the calculations (Table 2). Thus, the DFT modelling of the conformational space of **1**, albeit not in a strictly quantitative sense, can explain all the experimental findings (IR, NMR and CD data).

For the isoleucine derivative **2** the experimental data are almost identical to those of **1** (see Exp. Sect. and Supporting Information), thereby suggesting a similar conformation of **2** in solution. Figure 8 depicts the calculated minimum structure of **2** (analogous to **RL-a** with a population of 62%; see Supporting Information), which has a Cp torsion angle, *a*, of +47.3°. This observation points to the fact

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

that a second chiral carbon centre (C^{β}) in the side-chain of the isoleucine moiety has only a marginal influence on the ferrocene conformation and that the preferred ferrocene helicity in these dipeptides is determined by the configuration of the C^{α} atom of the α-amino acid.

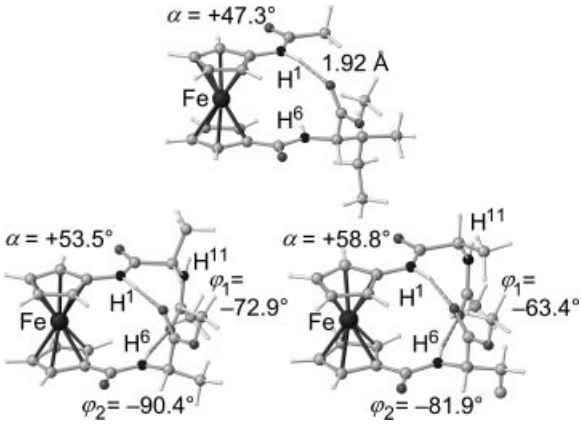

Figure 8. DFT calculated minimum structure of **2** (top), Ac-Ala-Fca-Ala-OMe (bottom left) and Ac-D-Ala-Fca-Ala-OMe (bottom right) [φ_1 and φ_2 are the C(=O)–C^{α}–N–C(=O) torsion angles].

To further corroborate the above interpretations the tripeptides Ac-Ala-Fca-Ala-OMe and Ac-D-Ala-Fca-Ala-OMe, which possess two intramolecular hydrogen bonds, were modelled (Figure 8) and the ferrocene helicity and amide backbone torsion angles φ [C(=O)-N–C^{α}-C(=O)] compared to those of the structurally characterised tetrapeptide Boc-Ala-Fca-Ala-Ala-OMe.[5] For the tetrapeptide, values of $\alpha = +60.7°$, $\varphi_1 = -81.3°$ and $\varphi_2 = -90.1°$ have been determined in the solid state, and these compare well with the calculated values for the tripeptide Ac-Ala-Fca-Ala-OMe ($\alpha = +53.5°$, $\varphi_1 = -72.9°$ and $\varphi_2 = -90.4°$), further supporting the above interpretations. This finding suggests that the ferrocene helicity is determined by the configuration of the first C-terminal amino acid rather than the configuration of the N-terminal amino acid. In fact, replacing the N-terminal L-Ala by D-Ala results in a very similar conformation (Ac-D-Ala-Fca-Ala-OMe: $\alpha = +58.8°$, $\varphi_1 = -63.4°$ and $\varphi_2 = -81.9°$; Figure 8).

Conclusions

One chiral carbon atom within the C-terminal substituent at the organometallic amino acid Fca is sufficient to induce helical chirality at the ferrocene provided that an efficient hydrogen-bonding pathway exists between the two cyclopentadienyl rings. The conformer **RL-a**, which accounts for the major conformation of **1** and **2** in solution, possesses a (*P*)-helical ferrocene unit. The helicity is induced by a single intramolecular amide-to-ester hydrogen bond as the chirality-transfer pathway. The organised chiral secondary structures of small Fca-containing peptides open up an opportunity to design selective receptors[14–17] and homodisperse oligomers[13a,18] with well-defined secondary structures containing neutral or cationic ferrocene units in the backbone. Further work in these directions is currently in progress.

Experimental Section

General: Unless noted otherwise, all manipulations were carried out under argon by means of standard Schlenk techniques. All solvents were dried by standard methods and distilled under argon prior to use. All other reagents were used as received from commercial sources. NMR: Bruker Avance DPX 200 at 200.15 MHz and Varian Unity Plus 400 at 399.89 MHz (^{1}H); chemical shifts (δ) in ppm with respect to residual solvent peaks as internal standard: CD_2Cl_2 (^{1}H: δ = 5.32 ppm). IR spectra were recorded with a BioRad Excalibur FTS 3000 spectrometer using CaF_2 cells in CH_2Cl_2. Cyclic voltammetry was performed using an EG&G model 273 potentiostat, a glassy carbon electrode, a platinum electrode and an SCE electrode, 10^{-3} M in 0.1 M nBu$_4$NBF$_4$/CH_2Cl_2; potentials are given relative to that of SCE; $E_{1/2}$ of the Fc/Fc$^+$ couple under the experimental conditions is 420(10) mV vs. SCE. Circular dichroism spectra were recorded with a JASCO J-810 spectropolarimeter in 1-cm Suprasil cells thermostatted at 20 °C under argon. Mass spectra were recorded with a Finnigan MAT 8400 spectrometer with 4-nitrobenzyl alcohol as the matrix (FAB). Elemental analyses were performed by the microanalytical laboratory of the Organic Chemistry Department, University of Heidelberg. Melting points were determined with a Gallenkamp capillary melting point apparatus MFB 595 010 and are uncorrected.

Computational Methods: Density functional calculations were carried out with the Gaussian03/DFT[19] series of programs. The B3LYP formulation of density functional theory was used with the LanL2DZ basis set.[19] Geometry optimisations were performed using the Berny algorithm as implemented in Gaussian03. Convergence criteria were as follows: maximum force 0.00045; root-mean-square of forces 0.0003; maximum displacement 0.0018; root-mean-square displacements 0.0012. All points were characterised as minima ($N_{imag} = 0$) or first-order saddle points ($N_{imag} = 1$) by frequency analysis.

Synthesis of 1 and 2: A solution of the activated ester Ac-Fca-OBt in THF was treated with 1 equiv. of H-Val-OMe·HCl (for **1**) or H-Ile-OMe·HCl (for **2**) and 1 equiv. of NEt_3 and stirred at ambient temperature for 3 h. The solvent was then removed under reduced pressure and the residue was dissolved in dichloromethane. The solution was washed with water, aqueous $NaHCO_3$, saturated NaCl and 2% citric acid. The organic layer was dried with $MgSO_4$ and the solvent was removed under reduced pressure to give an orange powder. **1:** Yield: 160 mg, 0.40 mmol (82%). $C_{19}H_{24}FeN_2O_4$ (400.26): calcd. Novel Structure Evolution of Lanthanide–SIP Coordination Polymers (NaH_2SIP = 5-Sulfoisophthalic Acid Monosodium Salt) from a 1D Chain to a 3D Network as a Consequence of the Lanthanide Contraction Effect

Qing-Yan Liu[a,b] and Li Xu*[a]

Keywords: Crystal structures / Hydrothermal synthesis / Lanthanides / Lanthanide contraction

The new series of lanthanide–SIP coordination polymers $[\{Ln(SIP)(H_2O)_5\}(H_2O)_3]_n$ (Ln = Lu (**1**), Yb (**2**), Tm (**3**), and Er (**4**)], $[\{Ln(SIP)(H_2O)_4\}]_n$ (Ln = Ho (**5**), Dy (**6**), Tb (**7**), Sm (**8**), Pr (**9**), and Nd (**10**)], and $[\{La(SIP)(H_2O)_3\}(H_2O)]_n$ (**11**), have been synthesized by hydrothermal reactions of Ln_2O_3 and 5-sulfoisophthalic acid monosodium salt (NaH_2SIP) at 160 °C and characterized by single-crystal X-ray diffraction. The unprecedented three structure types ongoing from Lu^{III} to La^{III} have been established: type I for the small ions, Lu, Yb, Tm, and Er; type II for the medium ions including Ho, Dy, Tb, Sm, Pr, and Nd; and type III for the largest La ion. Type I adopts a one-dimensional zigzag chain-like structure, type II exhibits a two-dimensional undulate layer structure, and type III features a two-dimensional double-layer pillared by sulfonate groups to form a three-dimensional open framework. The progressive structural changes from type I to type II and to type III with increasing atomic number were rationalized by the effect of the lanthanide contraction. Their spectroscopic properties and thermal stability were also investigated.

Introduction

The design and construction of coordination polymers is one of the most active areas of materials research. The intense interest in these materials is driven by both their interesting network topologies and their potential applications in catalysis, molecular magnets, sensors, ion exchange, adsorption, and phase separation.[1–6] Numerous coordination polymers with varied dimensions and topologies have been obtained through a judicious choice of organic linkers and metal ions.[7–14] Many of the efforts have so far been devoted to the study of transition-metal-based coordination polymers.[15–19] The chemistry of lanthanide coordination polymers has been less-well investigated despite their useful luminescent, catalytic, and magnetic properties.[20–25] For example, our knowledge about how the lanthanide contraction works in crystal-structure formation is limited because of few systematic investigations across the lanthanide series with a single ligand.[26–28] This contribution deals with the self-assembly of the lanthanide series with the single SIP ligand. SIP was selected for several reasons: (1) it contains a soft sulfonate group that may serve as a more sensitive probe in the exploration of the effect of the lanthanide contraction; (2) it has three functional groups that allow the formation of structures of higher dimensions; (3) π–π stacking interactions between the aromatic rings may facilitate ordered, noninterpenetrated open frameworks; (4) it has an asymmetric geometry that may lead to acentric crystal structures that are needed for the development of non-linear optical materials. This new series of lanthanide–SIP coordination polymers prepared by hydrothermal reactions displays three types of polymeric structures, ranging from one-dimensional chains to a three-dimensional framework on going from Lu to La.

Results and Discussion

Preparation of the Complexes

We prepared the series of Ln^{III}–SIP compounds **1**–**11** with the structures $[\{Ln(SIP)(H_2O)_5\}(H_2O)_3]_n$ [Ln = Lu (**1**), Yb (**2**), Tm (**3**), and Er (**4**)], $[\{Ln(SIP)(H_2O)_4\}]_n$ [Ln = Ho (**5**), Dy (**6**), Tb (**7**), Sm (**8**), Pr (**9**), and Nd (**10**)], and $[\{La(SIP)(H_2O)_3\}(H_2O)]_n$ (**11**) (excluding the rare and radioactive Pm as well as Eu^{III} and Gd^{III} reported previously[29]) by a hydrothermal reaction of Ln_2O_3 and NaH_2-SIP in aqueous solution. The preparative reactions were carried out at different temperatures (140 °C, 160 °C, and 180 °C) to investigate the temperature dependence of their solid structures. X-ray diffraction analyses of the products

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim DOI: 10.1002/ejic.200500271

indicated that the same results were obtained at these reaction temperatures although the purity and yields were slightly different, indicative of the thermodynamic nature of the hydrothermal reactions. Attempts to get single crystals of the Ce–SIP compound by reacting CeO_2 with NaH_2SIP were unsuccessful. This compound has been reported previously but the crystal structure was not determined. The crystalline compounds **1**–**11** could not be isolated from the conventional reaction of Ln_2O_3 with NaH_2SIP in aqueous solution at room temperature, indicating the kinetic nature of the reactions. The different results between the conventional solutions and hydrothermal reactions may be caused by a different reaction mechanism: the hydrothermal reaction mechanism is shifted from the kinetic to the thermodynamic domain when compared to a conventional solution reaction.[30–32]

Crystal Structures

The X-ray diffraction analyses of compounds **1**–**11** revealed three types of solid structures on going from Lu to La: a 1D chain (**1**–**4**, Lu–Er), a 2D sheet (**5**–**10**, Ho–Pr), and a 3D network (**11**, La). These structure types result from the different coordination modes of SIP, as illustrated in Scheme 1, presumably as a consequence of the lanthanide contraction, as will be detailed below.

Type I: Structure of $[\{Ln(SIP)(H_2O)_5\}(H_2O)_3]_n$ [Ln = Lu (1), Yb (2), Tm (3), and Er (4)]

The type I structure features a one-dimensional ribbon, as exemplified in Figure 1 for **4** (Ln = Er). Each Er^{III} ion is coordinated to nine oxygen atoms, four from the carboxylate groups and five from water molecules (Figure 1a). SIP uses the two carboxylate arms to chelate to the Er^{III} ions, as illustrated in Scheme 1(a), to form an infinite zigzag chain (Figure 1b). The Er–O distances given in Table 1 range from 2.310(3) to 2.463(3) Å (average value 2.397 Å). The phenyl rings in the chain are not parallel but are twisted relative to each other with a dihedral angle of around 48.4°. The uncoordinated sulfonate group forms hydrogen bonds with coordinated and lattice water molecules.

The extensive interchain hydrogen bonds link the zigzag chains into a three-dimensional supramolecular layer structure, as illustrated in Figure 2. Two types of hydrogen bonds are observed between the chains: hydrogen bonds between the coordinated water molecules and carboxylate oxygen atoms (O···O = 2.723–2.900 Å), and hydrogen bonds between the coordinated water molecules and sulfonate oxygen atoms (O···O = 2.675, 2.814, and 2.929 Å). The supramolecular layer structures are further stabilized by π–π interactions between the parallel aromatic rings in an off-set fashion, with a face-to-face distance of about 3.687 Å. Similar hydrogen bonds and π–π interactions between aromatic rings have also been reported in the cadmium complexes recently reported.[33,34] The lattice water molecules located in the cavities of the supramolecular open framework are hydrogen bonded to each other and the chain, with O···O distances ranging from 2.703 to 3.081 Å.

The Lu (**1**), Yb (**2**), and Tm (**3**) complexes possess a similar structure. Selected bond lengths, hydrogen bonds, and π–π stacking distances between aromatic rings are listed in Table 1. The results indicate that the Ln–O bond lengths increase from Lu (**1**) to Er (**4**), as expected for the lanthanide contraction.

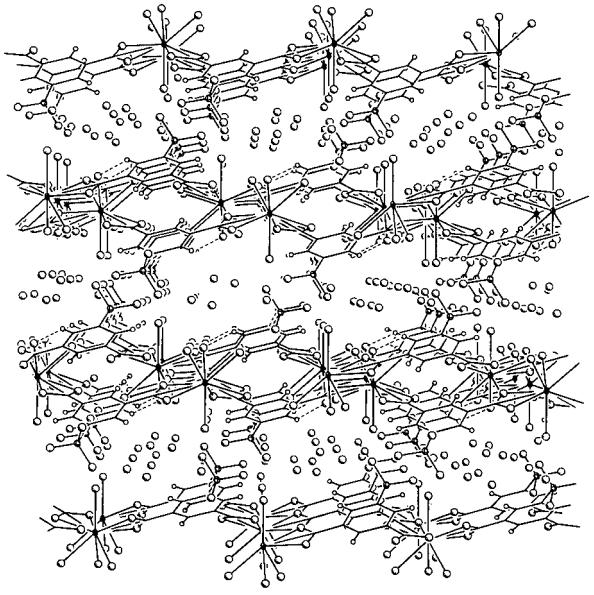

Figure 2. Three-dimensional supramolecular framework of **1**–**4**. The lattice water molecules occupy the interlayer space. The interlamellar interactions between the neighboring layers are hydrogen bonds (not shown).

Type II: Structure of [{Ln(SIP)(H$_2$O)$_4$}]$_n$ [Ln = Ho (5), Dy (6), Tb (7), Sm (8), Pr (9), and Nd (10)]

The lanthanide ions Ho (**5**), Dy (**6**), Tb (**7**), Sm (**8**), Pr (**9**), and Nd (**10**) form type II structures with the acentric crystal system, space group $Pna2_1$. They have similar crystal structures, as displayed in Figure 3a for Ln = Pr. Their selected bond lengths, hydrogen bonds, and π–π stacking distances are listed in Table 2. The type II structure can be described as an undulating, two-dimensional, sheet-like structure constructed from fused $[Pr(SIP)_3(H_2O)_4]$ pseudo-hexagonal grids (Figure 3b). The tridentate SIP ligand links the three surrounding Pr^{III} atoms through two chelating carboxylate groups and one sulfonate oxygen atom, as illustrated in Scheme 1(b). The presence of intermolecular hydrogen bonds and π–π interactions finally results in a three-dimensional supramolecular structure, as depicted in Figure 4. Compounds **5**–**10** are isomorphous with the previously reported Eu^{III} and Gd^{III} complexes.[29] A structural comparison with type I compounds may give an insight into the formation of type II species. Both types of compounds have nine-coordinate lanthanide ions in a similar coordination geometry. The type II structure may best be understood as resulting from interchain replacement of one of the coordinated waters by one sulfonate oxygen atom in a type I structure. The resultant Ln–O_3S bonding links the

zigzag chains into a 2D sheet. Such structure evolution suggests a stronger trend for the type II lanthanide ions to bind to anionic sulfonate groups, as will be detailed later.

Type III: 3D Open Framework Structure of [{La(SIP)-$(H_2O)_3$}(H_2O)]$_n$ (11)

Only lanthanum, which has the largest ionic radius in the lanthanide series, was found to form a 3D coordination polymer, namely [{La(SIP)$(H_2O)_3$}(H_2O)]$_n$ (**11**). As shown in Figure 5a, each La^{III} ion is coordinated by nine oxygen atoms, six from five SIP ligands and three from water molecules. The five SIP ligands are coordinated to the La^{III} center in three distinct modes, two by one carboxylate oxygen, two through one sulfonate oxygen, and one by a chelating carboxylate group. The La–O distances (Table 3) range from 2.451(5) to 2.596(5) Å (av. 2.544 Å), with the longest La–O distance associated with the sulfonate oxygen atoms. The S–O bond lengths are normal[35] [1.439(5), 1.443(5) and 1.446(5) Å] and similar to each other, as expected for the strong conjugation of sulfonate. As shown in Scheme 1 (c), SIP functions as an unprecedented hexadentate ligand with only one sulfonate oxygen atom uncoordinated. Of the three functional groups of SIP, one chelating carboxylate group and one unidentate oxygen atom of sulfonate group, together with the similar ones from a neighboring SIP, connect the two neighboring La^{III} ions to form the sixteen-

membered ring depicted in Figure 5b. Of interest is the other carboxylate group, which, together with the similar one from neighboring SIP, bridges a pair of La^{III} ions to form an $[La_2O_4C_2]$ eight-membered ring with an La···La separation of 4.982 Å, as shown in Figure 5a. Two types of rings connected by SIP propagate along the crystallographic *bc* plane to yield a two-dimensional sheet-like structure (Figure 5a). As described above, SIP uses five of its six donor atoms to form a 2D sheet. The sixth donor atom from the sulfonate group functions as a linker between the layers to form a 3D open framework, as depicted in Figure 6, with an approximate interlamellar separation of 3.884 Å. The free oxygen atom of the sulfonate group is involved in hydrogen bonding with the coordinated water molecules at a distance of 2.687–2.968 Å. The lattice water molecules are located in the cavities of the structure, forming a number of hydrogen bonds with carboxylate oxygen atoms, sulfonate oxygen atoms, and coordinated water molecules (O···O = 2.596–2.991 Å). The coordination polymer is further stabilized by π–π stacking interactions between the parallel aromatic rings in an off-set fashion, with a face-to-face distance of about 3.517 and 3.642 Å.

Discussion of Structure Evolution

The self-assembly of the lanthanide series with a single ligand was found to form three unprecedented types of structures, ranging from a 1D chain to a 2D sheet and a 3D framework, wherein all lanthanide ions are nine-coordinate and trivalent. This intriguing structure evolution across the lanthanide series may be attributable to the effect of the lanthanide contraction. The structure evolution (from Lu to La) results from the extent to which the coordinated water molecules are replaced by the sulfonate oxygen atoms of the SIP ligand. Thus, the effect of the lanthanide contraction should be responsible for the water substitution with the sulfonate anions during the structure evolution. The preference to bond to anionic ligands can be measured as follows:

$$\Phi = Z/r$$

where Φ is the basicity, Z is the oxidation state, and r is the ionic radius.[36]

La^{III} has the largest ionic radius and thus the smallest basicity in the lanthanide(III) series. In other words, La^{III} has the greatest tendency to form La^{III}–O_3S bonds, thus accounting for the replacement of water by one sulfonate oxygen during the 2D → 3D structure evolution. Moreover, the large ionic radius allows the presence of five surrounding SIP ligands. The lighter lanthanide ions from Ho^{III} to Pr^{III} adopt a 2D sheet-like structure as a consequence of both their slightly higher basicity and smaller ionic radii. The lightest four lanthanide ions (Lu^{III}–Er^{III}) show no substantial interactions with the sulfonate oxygen donor atoms in their chain-like structures, consistent with their larger basicity and smallest radii. In summary, the sulfonate group of SIP is a comparatively soft oxygen donor ligand and is thus able to serve as a more sensitive probe for investigating the effect of the lanthanide contraction in crystal-structure formation of the lanthanide series, thereby accounting for the unprecedented three structure types observed in this lanthanide–SIP system.

FT-IR Spectra and Thermogravimetric Analyses

The FT-IR spectra of these complexes exhibit broad absorption bands in the range 3500–3200 cm^{-1} due to the presence of water molecules in the structures. The strong bands at 1360–1670 cm^{-1} for all complexes are characteristic of the carboxylate group. The absorptions in the region 1000–1230 cm^{-1} for all complexes are typical of the sulfonate group.[37] Interestingly, the characteristic bands of the carboxylate group show some changes from type I to type II, even though the coordination mode of the carboxylate groups in the two structure types is identical. In the type I structure these peaks are observed in the range 1668–1397 cm^{-1}, while in the type II structure these absorptions are in the range 1605–1381 cm^{-1} with two weak shoulders in the range 1665–1630 cm^{-1}. The IR spectrum of the La–SIP compound (type III) is nearly identical to that of the type II structure. However, the characteristic bands of the sulfonate group do not show any obvious change from type I to type III.

To assess the thermal stability of these compounds and their structural variation as a function of the temperature,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

thermogravimetric analyses (TGA) were performed on single-phase polycrystalline samples of these materials (Figure S1). Since compounds of the same structure type show similar thermal behavior, the results of only three representative compounds − Yb (**2**) of type I, Tb (**7**) of type II, and La (**11**) of type III − are discussed. The TGA measurements for Yb (**2**) exhibit three distinct weight-loss steps. The first weight loss occurs between 60 and 110 °C due to the release of three lattice water molecules (weight loss: measured 9.55%; calculated 9.64%). The second weight loss in the temperature range 110–240 °C corresponds to the removal of the coordinated water molecules (observed 14.65%; calculated 16.07%). A further increase of the temperature leads to the decomposition of the compound at 540 °C. The thermogravimetric analysis of Tb (**7**) shows that the initial weight loss occurs in the temperature range 120–200 °C, attributable to the release of all coordinated water molecules (observed 14.67%; calculated 15.19%). The thermogravimetric analysis of La (**11**) indicates that the loss of the water (14.95%) takes place between 100 °C and 160 °C, corresponding to the release of all water molecules (calculated: 15.85%).

Conclusions

In conclusion, the self-assembly of the lanthanide series with a single (SIP) ligand with soft sulfonate probes leads to the formation of the unprecedented three structural types I (1D), II (2D), and III (3D). The compounds of the heaviest lanthanides (Lu, Yb, Tm, and Er) adopt a type I structure without Ln–sulfonate bonds, the Ho, Dy, Tb, Sm, Pr, and Nd compounds belong to type II, with one Ln–sulfonate bond, and the largest, La, forms a type III structure with two La–sulfonate bonds. The progressive structural changes resulting from the distinct preference for the lanthanide series to bind to anionic sulfonate groups are believed to due to their different basicity as a consequence of the effects of the lanthanide contraction. In addition, the SIP ligand displays diverse coordination modes, which together with the versatile coordination ability of the bridging ligand makes it adaptable to lanthanide ions of different sizes and leads to the various topologies of the coordination networks.

Experimental Section

General Remarks: All chemicals were purchased commercially and used without further purication, including 5-sulfoisophthalic acid monosodium salt (Alfa). Elemental analyses were carried out with an Elementar Vario EL III analyzer and IR spectra (KBr pellets) were recorded with a Perkin–Elmer Spectrum One. The thermogravimetric measurements were performed with a Netzsch STA449C apparatus under nitrogen with a heating rate of 10 °C min^{-1} from 25 to 800 °C. All complexes were synthesized by a hydrothermal method under autogenous pressure.

$[\{Lu(SIP)(H_2O)_5\}(H_2O)_3]_n$ (1): In a typical synthesis, solid Lu_2O_3 (0.04 g, 0.1 mmol) was dispersed in an aqueous solution (15 mL) of 5-sulfoisophthalic acid monosodium salt (0.03 g, 0.12 mmol) with a pH value of ca. 3–4. The mixture was placed in a Teflon-lined stainless-steel autoclave (30 mL), and the autoclave was sealed, heated to 160 °C under autogenous pressure for 5 d, and then cooled to room temperature at a rate of 6 °C h^{-1}. The resulting colorless, crystalline product was filtered, washed with distilled water, and dried at ambient temperature (0.035 g, yield 62% based on Lu). $C_8H_{19}LuO_{15}S$ (562.26): calcd. C 17.08, H 3.38; found C 17.01, H 3.33. IR (KBr pellet): $\tilde{\nu}$ = 3388(vs), 1664(s), 1612(vs), 1542(vs), 1460(s), 1396(vs), 1211(s), 1175(s), 1119(m), 1043(vs), 746(m), 628(s) cm^{-1}.

$[\{Yb(SIP)(H_2O)_5\}(H_2O)_3]_n$ (2): The synthetic procedure for **2** was similar to that for **1** but replacing Lu_2O_3 with Yb_2O_3. A colorless, crystalline product was obtained (0.042 g, yield 75% based on Yb). $C_8H_{19}O_{15}SYb$ (560.33): calcd. C 17.14, H 3.39; found C 17.00, H 3.36. IR (KBr pellet): $\tilde{\nu}$ = 3391(vs), 1667(s), 1614(vs), 1538(vs), 1462(s), 1397(vs), 1208(s), 1175(s), 1120(m), 1042(vs), 746(m), 628(s) cm^{-1}.

$[\{Tm(SIP)(H_2O)_5\}(H_2O)_3]_n$ (3): The synthetic procedure for **3** was similar to that for **1** but replacing Lu_2O_3 with Tm_2O_3. A pale-orange, crystalline product was obtained (0.037 g, yield 66% based on Tm). $C_8H_{19}O_{15}STm$ (556.22): calcd. C17.27, H 3.42; found C 17.19, H 3.41. IR (KBr pellet): $\tilde{\nu}$ = 3389(vs), 1667(s), 1614(vs), 1540(vs), 1460(s), 1395(vs), 1210(s), 1176(s), 1119(m), 1042(vs), 745(m), 628(s) cm^{-1}.

$[\{Er(SIP)(H_2O)_5\}(H_2O)_3]_n$ (4): The synthetic procedure for **4** was similar to that for **1** but replacing Lu_2O_3 with Er_2O_3. A pale-red, crystalline product was obtained (0.043 g, yield 78% based on Er). $C_8H_{19}ErO_{15}S$ (554.55): calcd. C17.31, H 3.43; found C 17.30, H 3.41. IR (KBr pellet): $\tilde{\nu}$ = 3391(vs), 1668(s), 1614(vs), 1538(vs), 1460(s), 1396(vs), 1210(s), 1176(s), 1120(m), 1042(vs), 745(m), 630(s) cm^{-1}.

$[\{Ho(SIP)(H_2O)_4\}]_n$ (5): The synthetic procedure for **5** was similar to that for **1** but replacing Lu_2O_3 with Ho_2O_3. A colorless, crystalline product was obtained (0.028 g, yield 59% based on Ho). $C_8H_{11}HoO_{11}S$ (480.16): calcd. C 20.04, H 2.29; found C 19.86, H 2.21. IR (KBr pellet): $\tilde{\nu}$ = 3390(vs), 3232(vs), 1658(w), 1642(w), 1605(vs), 1559(vs), 1458 vs), 1391(vs), 1208(m), 1180(s), 1115(w), 1042(s), 744(w), 628(m) cm^{-1}.

$[\{Dy(SIP)(H_2O)_4\}]_n$ (6): The synthetic procedure for **6** was similar to that for **1** but replacing Lu_2O_3 with Dy_2O_3. A colorless, crystalline product was obtained (0.030 g, yield 63% based on Dy). $C_8H_{11}DyO_{11}S$ (477.73): calcd. C 20.15, H 2.31; found C 20.14, H 2.25. IR (KBr pellet): $\tilde{\nu}$ = 3405(vs), 3232(vs), 1658(w), 1641(w), 1601(vs), 1538(vs), 1451(vs), 1382(s), 1223(m), 1206(m), 1180(s), 1116(w), 1043(s), 738(w), 620(m) cm^{-1}.

$[\{Tb(SIP)(H_2O)_4\}]_n$ (7): The synthetic procedure for **7** was similar to that for **1** but replacing Lu_2O_3 with Tb_4O_7. A colorless, crystalline product was obtained (0.031 g, yield 66% based on Tb). $C_8H_{11}O_{11}STb$ (474.15): calcd. C 20.25, H 2.32; found C 20.22, H 2.28. IR (KBr pellet): $\tilde{\nu}$ = 3391(vs), 3210(vs), 1664(w), 1639(w), 1602(vs), 1536(vs), 1458(vs), 1392(vs), 1208(m), 1177(m), 1116(m), 1042(s), 777(m), 742(m), 625(m) cm^{-1}.

$[\{Sm(SIP)(H_2O)_4\}]_n$ (8): The synthetic procedure for **8** was similar to that for **1** but replacing Lu_2O_3 with Sm_2O_3. A colorless, crystalline product was obtained (0.028 g, yield 61% based on Sm). $C_8H_{11}O_{11}SSm$ (465.58): calcd. C 20.65, H 2.36; found C 20.60, H 2.32. IR (KBr pellet): $\tilde{\nu}$ = 3408(vs), 3201(vs), 1653(w), 1634(w),

$C_8H_{11}NdO_{11}S$ (459.47): calcd. C 20.92, H 2.40; found C 20.88, H 2.36. IR (KBr pellet): $\tilde{\nu}$ = 3410(vs), 3251(vs), 1650(w), 1636(w), 1601(vs), 1534(vs), 1448(vs), 1382(vs), 1223(vs), 1204(m), 1167(m), 1109(m), 1049(s), 773(m), 737(m), 626(m), 583(m) cm^{-1}.

$[\{La(SIP)(H_2O)_3\}(H_2O)]_n$ (11): The synthetic procedure for **11** was similar to that for **1** but replacing Lu_2O_3 with La_2O_3. A colorless, crystalline product was obtained (0.035 g, yield 76% based on La). $C_8H_{11}LaO_{11}S$ (454.14): calcd. C 20.25, H 2.32; found C 20.24, H 2.30. IR (KBr pellet): $\tilde{\nu}$ = 3446(vs), 3218(vs), 1644(m), 1599(s), 1564(s), 1538(vs), 1451(s), 1436(s), 1378(vs), 1217(s), 1179(m), 1112(m), 1051(s), 775(m), 726(m), 619(m) cm^{-1}.

X-ray Crystallographic Study: X-ray diffraction data for complexes **2–5**, **7**, **9**, and **10** were collected with a Rigaku Mercury CCD diffractometer equipped with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The CrystalClear software package was used for data reduction and empirical absorption correction.[38] Data collection for complexes **1**, **6**, **8**, and **11** was performed with a Siemens Smart CCD diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Empirical absorption corrections were applied using the SADABS program.[39] All structures were solved by direct methods and successive Fourier difference syntheses, and refined by the full-matrix least-squares method on F^2 (SHELXTL Version 5.1[40]). All non-hydrogen atoms were refined with anisotropic thermal parameters for all structures except **1**, **6**, and **8**. In the structures of **1**, **6**, and **8** all non-hydrogen atoms were refined anisotropically except several carbon and oxygen atoms, which were refined isotropically in order to prevent some of them being "non-positive-definite". Aromatic hydrogen atoms were assigned to calculated positions with isotropic thermal parameters fixed at 1.2-times that of the attached carbon atom. Some water hydrogen atoms were placed in calculated positions with isotropic thermal parameters fixed at 1.5-times that of the attached oxygen atom. Other water hydrogen atoms were located from difference maps and refined with O–H distances restrained to 0.95 Å, and isotropic thermal parameters fixed at 1.5-times that of the respective oxygen atom. The R_1 values are defined as $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$. The crystallographic data for **1–11** (except **10**) are listed in Tables 4 and 5. Selected bond lengths together with some nonbonding interactions for **1–4**, **5–9**, and **11** are listed in Tables 1, 2, and 3, respectively. CCDC-267294 to -267303 (for **1–9** and **11**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Microwave-Assisted and Pd^{II}-Mediated Nitrile–Oxime Coupling

Dmitrii A. Garnovskii,[a] Nadezhda A. Bokach,[b] Armando J. L. Pombeiro,*[a] Matti Haukka,[c] João J. R. Fraústo da Silva,[a] and Vadim Yu. Kukushkin*[b]

Keywords: Microwave synthesis / Metal-mediated synthesis / Nitriles / Oximes / Nitrile–oxime coupling / Palladium complexes

Refluxing $PdCl_2$ with the ketoximes $R^1R^2C{=}NOH$ (R^1R^2 = MeMe, MeEt, C_5H_{10}) in RCN (R = Me, Et, *n*Pr, Ph) for 2–3 h results in precipitation of the oxime complexes $[PdCl_2(R^1R^2C{=}NOH)_2]$, whereas further reflux of the reaction mixture for an additional 6–12 h leads to formation of the chelated species $[PdCl_2\{NH{=}C(R)ON{=}CR^1R^2\text{-}\kappa^2N\}]$ (R/R^1R^2 = Me/MeMe **1**; Et/MeMe **2**; *n*Pr/MeMe **3**; Me/MeEt **4**; Me/C_5H_{10} **5**; Ph/MeMe **6**) by a Pd^{II}-mediated coupling between the oximes and the nitriles; complexes **1**–**6** were isolated in the solid state in 60–75 % yields. The reaction time could be drastically reduced, to 15–30 min, when the system was additionally irradiated with microwaves (100 W, about 60 °C). Compounds **1**–**6** can also be obtained without isolation of the intermediate oxime complexes either by refluxing for 8–15 h or by microwave irradiation (100 W, about 60 °C) for 15–30 min. The formulation of **1**–**6** is based upon satisfactory C, H, and N elemental analyses, FAB mass spectrometry, and IR, ^1H and $^{13}C\{^1H\}$ NMR spectroscopy, while the structures of **1**·(Me_2CO), **1**·($CHCl_3$), **2**·(H_2O), and **6**·½(H_2O) were determined by X-ray single-crystal diffraction.

Introduction

In the past five years, microwave irradiation (MWI) has become an increasingly useful tool in synthetic chemistry.[1–12] The major advantages of microwave-assisted syntheses are associated with a substantial decrease of reaction times, an increase of the selectivities of the processes, and, consequently, better purity of the products formed.[2,4,6–8,10–12] In the overwhelming majority of cases, MWI has been applied in organic synthesis. However, some reports on the application of MWI in the synthesis of coordination compounds are also present in the literature.[13–25] In particular, microwave syntheses have been used for the preparation of nanophases and nanocrystalline materials starting from metal complexes,[16,19,20] for preparations by substitution,[17,18,21] and for phthalocyanine syntheses.[13–15,22,23] Recently, some of us have demonstrated that MWI also efficiently promotes reactions of coordinated ligands, such as in the [2+3]-cycloaddition[24] and the addition of hydroxamic acids to metal-bound nitriles.[25]

In the current work, we have extended our previous results on microwave-assisted reactions of ligated nitriles to another system by applying MWI for the nitrile–oxime coupling to form the imino species $HN{=}C(R)ON{=}CR'R''$. In a series of previous papers,[26] we have found that these processes are especially efficient when metal centers are in high oxidation states, for example Pt^{IV},[27] Re^{IV},[28] or Rh^{III},[29] whereas low-oxidation-state metal centers, such as Pt^{II},[30] are insufficiently strong activators to provide the coupling under conventional conditions. Hence, we believed that MWI could provide an additional activation for the addition of oximes to nitriles complexed by low-oxidation-state metal centers and to expand, in this way, the number of this type of compounds with their potential application in organic[31] and phthalocyanine syntheses.[32]

Results and Discussion

In organic chemistry, oximes are known as ambidentate nucleophiles and their reactions with electrophilic reagents, such as acylation, have been extensively studied and reviewed.[33] Metal-mediated oxime–nitrile coupling (or, in other words, iminoacylation by complexed nitriles), is a little-explored area and only recently have publications on this subject started to appear in the literature. The largest fraction of these reports is devoted to the coupling induced by high-oxidation-state metal centers, while reactions at low-oxidation-state metal centers, such as Pd^{II}, are scarce. It is important to note that the first data on metal-mediated iminoacylation, reported at a conference,[34] deal with the reaction between 3,3-dimethyl-2-butanone oxime and $[PdCl_2(PhCN)_2]$ to yield, among other products, the imino

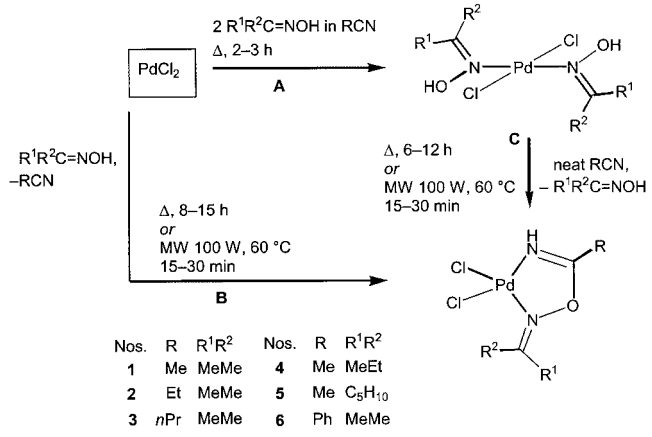
complex $[PdCl_2\{NH=C(Ph)ON=CMetBu\}_2]$. The latter observation, which was not developed further, prompted us to investigate the coupling at a Pd^{II} center under both microwave and conventional thermal conditions. For this work we used $PdCl_2$ in neat RCN (R = Me, Et, *n*Pr, Ph) and the ketoximes $R^1R^2C=NOH$ (R^1R^2 = MeMe, MeEt, C_5H_{10}).

Refluxing $PdCl_2$ with the ketoximes $R^1R^2C=NOH$ in RCN for 2–3 h results in precipitation of the known[35] oxime complexes $[PdCl_2(R^1R^2C=NOH)_2]$ (Scheme 1, route **A**). However, further reflux of the reaction mixture for an additional 6–12 h leads to formation of the chelated species $[PdCl_2\{NH=C(R)ON=CR^1R^2\text{-}\kappa^2N\}]$ (**1**–**6**) (route **C**); these complexes were isolated in the solid state in 60–75% yields.



Scheme 1.

The reaction time could be drastically reduced, to 15–30 min, when the system was additionally irradiated with microwaves (100 W, about 60 °C). The yields of the complexes for both conventional and microwave methods were almost identical. Compounds **1**–**6** can also be obtained by route **B** without isolation of the intermediate oxime complexes.

We believe that a plausible mechanism for the oxime–nitrile coupling at the Pd^{II} center involves the formation of the bis(oxime) complexes $[PdCl_2(R^1R^2C=NOH)_2]$, which, in neat RCN, can form an equilibrium concentration of $[PdCl_2(R^1R^2C=NOH)(RCN)]$ by displacement of one oxime ligand. In the latter intermediate, the ligated nitrile is subject to intramolecular attack by the adjacent oxime (or oximato ligand formed upon deprotonation). In general, the coupling between electrophilically activated species and nucleophiles is highly probable when the two species are bound to a common metal center,[36] and, moreover, the chelate effect also drives the reaction.

All isolated compounds (**1**–**6**) gave satisfactory C, H, and N elemental analyses and the expected molecular ion and fragmentation patterns in the FAB^+ mass spectra. The IR spectrum of each product displays two strong ν(C=N) bands in the range between 1672 and 1613 cm^{-1} and a strong band in the high frequency region between 3265 and 3217 cm^{-1} that can be attributed to the ν(N–H) stretching vibration. The ^1H NMR spectra of **1**–**6** in $[D_6]$acetone show a broad peak for the =N*H* group at δ = 9.01–9.44 ppm. This range is specific for imino hydrogens involved in hydrogen bonding.[27] The latter was unambiguously determined in the solid state for the solvates **1**·(Me_2CO), **2**·(H_2O), and **6**·½(H_2O) (see below). We anticipate that complexes **1**–**6** should also exhibit a similar type of H-bond with either $[D_6]$acetone or with traces of water in the commercially available solvent. In the ^1H NMR spectrum, complex **4** displays two set of signals for the alkyl groups (two Me's and Et) of the chelated ligand [the latter derived from the coupling with a mixture of *syn*/*anti*-MeC(=NOH)Et] due to *syn*/*anti*-isomers of the ligand.

The structures of **1**·(Me_2CO), **1**·($CHCl_3$), **2**·(H_2O), and **6**·½(H_2O) were determined by single-crystal X-ray diffraction; the molecular structure of **1**·(Me_2CO) is depicted in Figure 1. The atoms in the other similar structures are numbered correspondingly and bond lengths and angles are given in Table 1.

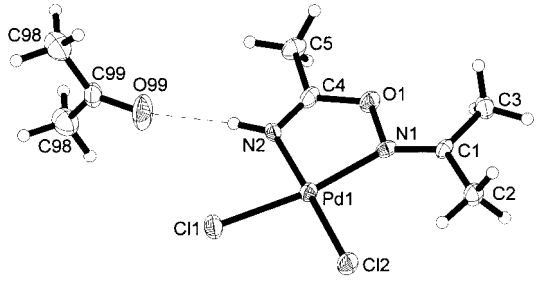


Figure 1. Thermal ellipsoid view of $[PdCl_2\{NH=C(Me)ON=CMe_2\text{-}\kappa^2N\}]$·($Me_2CO$) (**1**·$Me_2CO$) with the atomic numbering scheme. Thermal ellipsoids are drawn with 50% probability. N(2)···O(99) = 2.954(6) Å.

Table 1. Selected bond lengths [Å] and angles [°] **1**·(Me_2CO), **1**·($CHCl_3$), **2**·(H_2O), and **6**·½(H_2O).

	1·(Me_2CO)	**1**·($CHCl_3$)	**2**·(H_2O)	**6**·½(H_2O)

Pd(1)–N(2)–C(4)	117.0(4)	117.05(13)	117.6(3)	117.6(3)
C(4)–O(1)–N(2)	113.0(4)	113.57(13)	113.3(3)	114.4(3)

Inspection of Table 1 shows that the relevant bond lengths and angles of the four complexes agree with each other within 3σ and they are also well-coherent with the normal bond lengths and angles.[37]

In conclusion, one should note that (*i*) the observed oxime coupling is metal-mediated (as we have shown previously,[1] the addition of oximes to nonactivated organonitriles RCN, i.e. those with a donor group R, does not proceed in the absence of any metal complex even under rather harsh reaction conditions) and (*ii*) the reaction is dramatically accelerated by microwave irradiation, thus al-

lowing the formation of (imino)Pd^{II} complexes in a short time.

Experimental Section

Materials and Instrumentation: All reagents and solvents were obtained from commercial sources and used as received. C, H, and N elemental analyses were carried out by the Microanalytical Service of the Instituto Superior Técnico. Melting points were determined on a Kofler Table. For TLC, Merck UV 254 SiO_2 plates were used. Positive-ion FAB mass spectra were obtained on a Trio 2000 instrument by bombarding 3-nitrobenzyl alcohol (NBA) matrices of the samples with 8 keV (ca. 1.28×10^{15} J) Xe atoms. Mass calibration for the data system acquisition was achieved with CsI. IR spectra (4000–400 cm^{-1}) were recorded on a JASCO FT/IR-430 instrument in KBr pellets. ^1H NMR spectra were measured on a Varian UNITY 300 spectrometer at ambient temperature. The microwave irradiation experiments were undertaken in a focused microwave CEM Discover®LabMate™ reactor (100 W, 2.45 Hz) fitted with a rotational system and an IR temperature detector; reactions were performed in 10-mL pressure-rated reaction tubes, volumes of reaction mixtures were about 3 mL. Detailed information on the reactor is given at http://www.combichemlab.com/website/files/Combichem/Microwave/cem.htm.

[$PdCl_2${NH=C(R)ON=CMe_2-κ²*N*}] (R = Me 1, Et 2, *n*Pr 3, Ph 6): $PdCl_2$ (20.0 mg, 0.11 mmol) and 2-propanone oxime (17.0 mg, 0.23 mmol) were suspended in the corresponding RCN (1 mL) and the reaction mixture was heated under reflux conditions for 2–3 h until the yellow solid complex [$PdCl_2$(HON=CMe_2-κ*N*)$_2$] had formed. However, if the reaction mixture was refluxed for an additional 6 (**1**), 8 (**2**), or 9 h (**3**), it leads to (*i*) R = Me: the release of orange complex **1**, which was filtered off, washed three times with a small amount of acetonitrile and dried in vacuo. Yield: 25 mg (76%). The latter reaction was also performed under MW irradiation (100 W, about 60 °C) and was complete in 15 min (yield: 24 mg, 73%). (*ii*) R = Et and *n*Pr: formation of an orange solution. The solvent was removed under a gentle stream of nitrogen and the orange solid was washed with diethyl ether and dried in vacuo. Yields: 23 mg (67%; **2**) and 25 mg (69%; **3**). The latter reaction was also performed under MW irradiation (100 W, about 60 °C) and was complete in 30 min. Yields: 22 mg (64%; **2**) and 27 mg (74%; **3**). (*iii*) After refluxing for more than 10 h (R = Ph), the dissolution of the oxime complex was complete and the solution turned orange. The solvent was removed under a gentle stream of nitrogen and the orange crystalline residue was washed three times with diethyl ether and dried in vacuo. Yield: 23.5 mg (59%; **6**). The use of MW irradiation (100 W, about 60 °C) allowed the completion of this reaction in 30 min.

1: $C_5H_{10}Cl_2N_2OPd$ (291.5): calcd. C 20.60, H 3.46, N 9.61; found C 20.80, H 3.42, N 9.31. FAB$^+$-MS: *m*/*z* = 313 [M – H + Na]$^+$, 289 [M – 2H]$^+$, 255 [M – HCl]$^+$. M.p. 187–188 °C. IR (KBr): $\tilde{\nu}$ = 3239 s cm^{-1} ν(N–H), 1672 s and 1625 s ν(C=N). ^1H NMR ([D_6]-acetone): δ = 2.36 (s, 3 H, Me), 2.44 (s, 3 H, Me), 2.68 (s, 3 H, Me), 9.01 (br. s, 1 H, NH) ppm.

2: $C_6H_{12}Cl_2N_2OPd$ (305.5): calcd. C 23.60, H 3.93, N 9.18; found C 23.82, H 3.69, N 9.19. FAB$^+$-MS: *m*/*z* = 306 [M + H]$^+$, 271 [M + H – Cl]$^+$, 235 [M + H – 2Cl]$^+$. M.p. 194–195 °C. IR (KBr): $\tilde{\nu}$ = 3217 s cm^{-1} ν(N–H), 1665 s and 1621 s ν(C=N). ^1H NMR ([D_6]-acetone): δ = 1.27 (t, $^3J_{H,H}$ = 6.8 Hz, 3 H, Me from Et), 2.38 (s, 3 H, Me), 2.69 (s, 3 H, Me), 2.95 (q, $^3J_{H,H}$ = 6.8 Hz, 2 H, CH_2 from Et), 9.13 (br. s, 1 H, NH) ppm.

3: $C_7H_{14}Cl_2N_2OPd$ (319.5): calcd. C 26.33, H 4.38, N 8.77; found C 25.98, H 4.06, N 8.81. FAB$^+$-MS: *m*/*z* = 320 [M + H]$^+$, 285 [M + H – Cl]$^+$. M.p. 174–175 °C. IR (KBr): $\tilde{\nu}$ = 3222 s cm^{-1} ν(N–H), 1667 s and 1620 s ν(C=N). ^1H NMR ([D_6]acetone): δ = 0.98 (t, $^3J_{H,H}$ = 6.6 Hz, 3 H, CH_3), 1.76 (q, $^3J_{H,H}$ = 6.6 Hz, 2 H, CH_2), 2.37 (s, 3 H, Me), 2.69 (s, 3 H, Me), 2.77 (t, $^3J_{H,H}$ = 6.6 Hz, 2 H, CH_2), 9.11 (br. s, 1 H, NH) ppm.

6: $C_{10}H_{12}Cl_2N_2OPd$ (353.5): calcd. C 34.09, H 3.44, N 7.96; found C 34.17, H 3.23, N 8.25. FAB$^+$-MS: *m*/*z* = 319 [M – Cl + 3H]$^+$, 317 [M – Cl + H]$^+$, 316 [M – Cl]$^+$. M.p. 169–170 °C. IR (KBr): $\tilde{\nu}$ = 3218 s cm^{-1} ν(N–H), 1649 s and 1617 s ν(C=N), 1579 s ν(C=C). ^1H NMR ([D_6]acetone): δ = 2.55 (s, 3 H, CH_3), 2.76 (s, 3 H, CH_3), 7.61–8.13 (m, 5 H, Ph), 9.44 (br. s, 1 H, NH) ppm.

[$PdCl_2${NH=C(Me)ON=CMeEt-κ²*N*}] (4): $PdCl_2$ (20.0 mg, 0.11 mmol) and 2-butanone oxime (20.0 mg, 0.23 mmol; a mixture of *syn* and *anti* isomers) were suspended in acetonitrile (1 mL). The reaction mixture was refluxed for 9 h until the complete dissolution of $PdCl_2$ to give an orange solution, whereupon acetonitrile was evaporated with a flow of nitrogen and the yellow oily residue was crystallized under a layer of diethyl ether to give an orange yellow solid that was filtered off and dried in air at room temperature. Yield: 23 mg (67%). The latter reaction was also performed under MW irradiation (100 W, about 60 °C) and was complete in 15 min. Yield: 22 mg (63%). $C_6H_{12}Cl_2N_2OPd$ (305.5): calcd. C 23.60, H 3.93, N 9.18; found C 22.97, H 3.91, N 9.13. FAB$^+$-MS: *m*/*z* = 305 [M]$^+$, 269 [M – HCl]$^+$. IR (KBr): $\tilde{\nu}$ = 3237 s cm^{-1} ν(N–H), 1670 s and 1617 s ν(C=N). ^1H NMR ([D_6]acetone): two *syn*-*anti* isomers in ca. 3:2 ratio. Major isomer: δ = 1.16 (t, $^3J_{H,H}$ = 7.2 Hz, 3 H) and 3.16 (q, $^3J_{H,H}$ = 7.2 Hz, 2 H) (C_2H_5), 2.37 (s, 3 H, CH_3), 2.44 (s, 3 H, CH_3 from oxime), 9.05 (br. s, 1 H, NH); minor isomer: δ = 1.22 (t, $^3J_{H,H}$ = 7.2 Hz, 3 H) and 2.75 (q, $^3J_{H,H}$ = 7.2 Hz, 2 H) (C_2H_5), 2.68 (s, 3 H, CH_3 from oxime), 2.45 (s, 3 H, CH_3), 9.05 (br. s, 1 H, NH) ppm.

[$PdCl_2${NH=C(Me)ON=C(C_5H_{10})-κ²*N*}] (5): $PdCl_2$ (20.0 mg, 0.11 mmol) and cyclohexanone oxime (26.0 mg, 0.23 mmol) were suspended in acetonitrile (1 mL) and refluxed for 4 h, whereupon a yellow, crystalline precipitate of [Pd{HON=C(C_5H_{10})}$_2$] formed. If this suspension was refluxed for an additional 11 h, the oxime complex gradually dissolved to give an orange solution. The solvent was removed under a stream of nitrogen and the orange solid was washed with diethyl ether and dried in vacuo. Yield: 26 mg (69%). The latter reaction was also performed under MW irradiation (100 W, 60 °C) for 30 min. Yield: 25 mg (68%). $C_8H_{14}Cl_2N_2OPd$ (331.5): calcd. C 29.00, H 4.22, N 8.45; found C 28.72, H 3.71, N 8.69. FAB$^+$-MS: *m*/*z* = 331 [M]$^+$, 330 [M – H]$^+$, 260 [M – 2Cl]$^+$. M.p. 191–193 °C. IR (KBr): $\tilde{\nu}$ = 3265 s cm^{-1} ν(N–H), 1658 s and 1613 s ν(C=N). ^1H NMR ([D_6]acetone): δ = 1.65 (m, 2 H, C_5H_{10}), 1.85 (m, 4 H, C_5H_{10}), 2.46 (s, 3 H, CH_3), 2.50 (m, 2 H, C_5H_{10}), 2.60 (m, 2 H, C_5H_{10}), 9.20 (br. s, 1 H, NH) ppm.

X-ray Structure Determinations. Crystals were immersed in cryo-oil, mounted in a Nylon loop, and measured at a temperature of 100 K or 110 K. The X-ray diffraction data were collected with a Nonius KappaCCD diffractometer using Mo-K_α radiation (λ = 0.71073 Å). The Denzo-Scalepack[38] or EvalCCD[39] program packages were used for cell refinements and data reduction. The structures were solved by direct methods using SIR2000[40] or by the Patterson method with DIRDIF-99.[41] A multiscan absorption correction based on equivalent reflections (XPREP in SHELXTL v. 6.14)[42] was applied to all of the data (the T_{min}/T_{max} values were 0.7411/0.8986, 0.5614/0.8510, 0.5097/0.8461, and 0.4884/0.8636 for **1**·(Me_2CO), **1**·($CHCl_3$), **2**·(H_2O), and **6**·½(H_2O), respectively). Structural refinements were carried out with SHELXL-97 with the WinGX graphical user interface.[43,44] NH and H_2O were located from the difference Fourier map but not refined in **6**·½(H_2O) [N(2)

4f-*ansa*-Metallocenes−Dinuclear Complexes where the *ansa*-Dicyclopentadienyl Ligands Simultaneously Act in a Chelating and Bridging Mode − Crystal Structure of $(LY)_2(\mu\text{-}L)$ [L = 2,6-Pyridinediylbis(methylcyclopentadienyl)]

G. Paolucci,*[a] M. Vignola,[a] S. Formenti,[a] and W. Massa[b]

Keywords: Yttrium / Praseodymium / Dinuclear *ansa*-lanthanocenes / Metallocenes

The reaction between $[L^NYX]_2$ [X = Cl, OTf; L^N = 2,6-pyridinediylbis(methylcyclopentadienyl] and $L'Na_2$ [L′ = L^N = 2,6-pyridinediylbis(methylcyclopentadienyl; L^{Si} = dimethylsilanediylbis(cylopentadienyl); L^O = 2,5-furanediylbis(methylcyclopentadienyl)] in a 2:1 molar ratio affords dinuclear complexes of formula $(LY)_2(\mu\text{-}L')$, in which the *ansa*-bis(cyclopentadienyl) ligands simultaneously act both in a chelating and bridging mode. The X-ray crystal structure of $(L^NY)_2(\mu\text{-}L^N)$, determined at 193 K shows an arrangement close to trigonal planar of the centroids C_g of the three Cp ligands around the Y atoms. The reactivity of the $(L^NLn)_2(\mu\text{-}L')$ species containing different bridging *ansa*-bis(cyclopentadienyl) groups with an additional free donor atom was tested to verify the possibility of coordination of a third lanthanide ion. The rearrangement reactions that occur, finally leading to the formation of the only $[L^NLnX]_2$ species, are likely to depend on the presence of the further coordinating atom in the ligand bridging the two metal ions.

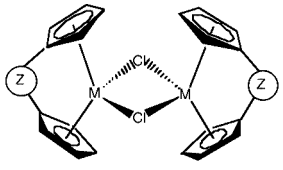
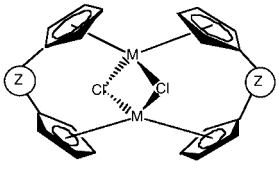
Introduction

ansa-Bis(cyclopentadienyl) ligands usually bind to early d-transition,[1] lanthanoid,[2] and actinide[3] metal ions exclusively as metal-chelating ligands (isomeric species **I**). However, the *ansa*-bis(cyclopentadienyl) ligands in dimeric *ansa*-lanthanocene complexes can, in principle, behave both in a chelating and bridging mode with formation of the isomeric species **I** and **II**, respectively. Some examples of dimeric complexes in which each *ansa*-bis(cyclopentadienyl) ligand bridges the two metal ions (**II**) are known both in complexes of d-[4,5] and f-elements.[6–10] To date, no example of completely characterized dinuclear complexes containing the *ansa*-bis(cyclopentadienyl) ligands simultaneously acting in the two binding modes have been reported.



Isomer I



Isomer II

Recently, we have observed that the disodium salt of 2,6-bis(cyclopentadienylmethyl)pyridine (L^NNa_2) affords Pr^{III} or U^{IV} complexes of the type $[(L^NPr)_2(\mu\text{-}L^N)]$[11] and $[(L^NUCl)_2(\mu\text{-}L^N)]$,[12] respectively, where the ligand simultaneously acts both in a chelating and bridging mode. The $[(L^NPr)_2(\mu\text{-}L^N)]$ complex firstly obtained[11] as a by-product in the synthesis of the complex $[L^NPrCl]_2$ was successively prepared in moderate yield (60–70%) by reaction of L^NNa_2 and $PrCl_3$ in a 3:2 molar ratio. Here we report an improved synthesis of $[(L^NPr)_2(\mu\text{-}L^N)]$ together with the synthesis and characterization of some $(L^NY)_2(\mu\text{-}L^N)$, $(L^NY)_2(\mu\text{-}L^{Si})$, and $(L^NY)_2(\mu\text{-}L^O)$ dinuclear complexes [L^N = 2,6-$(C_5H_4CH_2)_2$-C_5H_3N; L^{Si} = $Me_2Si(C_5H_4)_2$; L^O = 2,5-$(C_5H_4CH_2)_2$-C_4H_2O]. The presence of the additional free donor atom in the bridging ligand in the complexes $(L^NY)_2(\mu\text{-}L^N)$ and $(L^NY)_2(\mu\text{-}L^O)$, prompted us to investigate the possibility of coordinating a third metal ion, thus obtaining homo- and heterotrinuclear species.

Results and Discussion

Synthesis and Characterization of $[(L^NLn)_2(\mu\text{-}L^N)]$ (Ln = Y, Pr) and $[(L^NY)_2(\mu\text{-}L')]$ (L′ = L^{Si}, L^O)

In a previous work dealing with the synthesis of the complex $[L^NPrCl]_2$, we observed[11] the presence of an impurity which, on the basis of analytical and ^1H NMR spectroscopic data, was defined as $[L^NPr]_2[\mu\text{-}L^N]$. As a confirmation, the same compound was obtained by reaction of L^NNa_2 and $PrCl_3$ in a 3:2 molar ratio. This complex was also prepared by reaction of $[L^NPrCl]_2$ and L^NNa_2 in a 2:1 molar ratio. However, the workup of the reaction mixture was difficult and any attempt to purify the complex to obtain crystals suitable for X-ray analysis was unsuccessful, mainly due to the very similar solubilities of the reagents

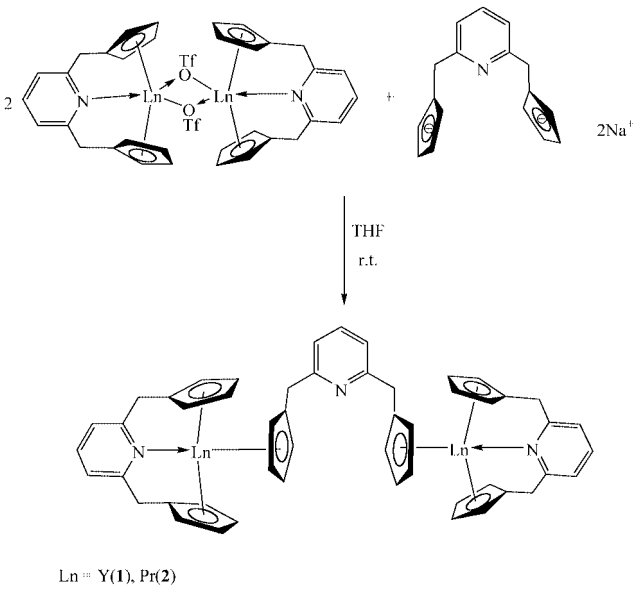
and the product. By using as starting materials the *ansa*-lanthanocene triflates, $[L^NLnOSO_2CF_3]_2$ (Ln = Y, Pr), more soluble and reactive species than the analogous chlorides $[L^NLnCl]_2$, the yields of the resulting $[L^NLn]_2[\mu\text{-}L^N]$ complexes are very high, thus making the workup and purification of the reaction products easier (Scheme 1).



Scheme 1.

The NMR (^1H and ^{13}C) characterization of the diamagnetic complex $[L^NY]_2[\mu\text{-}L^N]$ (**1**) was simple and clearly indicative of its structure in solution (Figure 1).

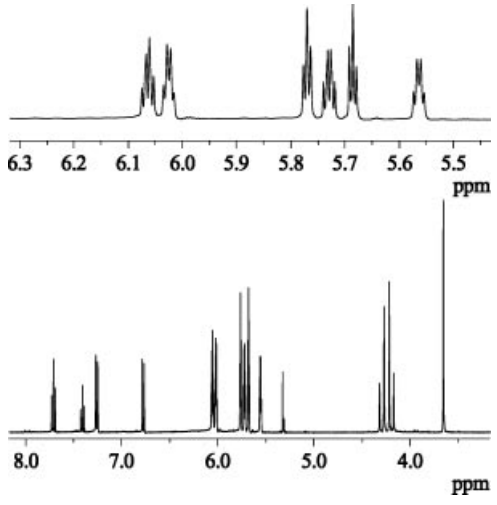


Figure 1. ^1H NMR of $[L^NY]_2[\mu\text{-}L^N]$ (**1**) ([D$_2$]dichloromethane, 400 MHz) (bottom) and its expanded part in the range δ = 6.3–5.5 ppm (top).

As reported in Figure 1, the ^1H NMR spectrum of **1** shows, in addition to a signal pattern similar to that observed in the ^1H NMR spectrum of the complex $[L^NYOSO_2CF_3]_2$ where the ligands act exclusively in a chelating mode,[2c] an additional rather simple pattern of signals readily assignable to the ligand acting in the bridging mode, with an intensity halved with respect to the signals of the two chelating ligands. In fact, the AB systems at δ = 6.06, 6.03, 5.73, 5.56 ppm correspond to the C_5H_4 protons of the chelating ligands, as the rigidity due to the additional coordination of the pyridine nitrogen atoms typical of these chelate systems makes the four C_5H_4 protons non-equivalent. On the contrary, in the case of the ligand bridging the two yttrium ions, the absence of evidence of substantial N→Y coordination makes the two pyridine-bonded C_5H_4 units virtually equivalent so that the two α-C_5H_4 and the two β-C_5H_4 protons give rise to two pseudo-triplets at δ = 5.77 and 5.69 ppm (A_2B_2 system), respectively. More diagnostic of the different rigidity of the two types of ligand L^N of **1** (i.e. in the chelating and bridging modes) are the resonances of the relative methylene groups. In fact in the case of the chelating ligands the two methylene protons are diastereotopic and give rise to an AB system centered at δ = 4.25 ppm, while in the ligand bridging the two yttrium ions free rotation makes all the methylene protons equivalent (singlet at δ = 3.66 ppm).

In the case of the paramagnetic complex $[L^NPr]_2[\mu\text{-}L^N]$ (Ln = Pr: **2**) the previously proposed structure[11] similar to that of the yttrium complex **1** could again be deduced from its ^1H NMR spectrum.

Crystal Structure of 1·CH_2Cl_2

The results of a single-crystal X-ray analysis of **1** (Figure 2) confirms the presence of discrete $[Y_2L^N{}_3]$ molecules, involving two chelating and one bridging ligand L^N. Somewhat surprisingly, the μ-L^N ligand displays a conformation with *anti*-oriented C_5H_4 rings rendering the two (*chel*-L^N)Y fragments non-equivalent. Interestingly, the N2–Y2–N3 angle is not far from 180°, suggesting some weak N2→Y2 interaction, in spite of a rather long N2–Y2 distance of 3.39 Å. Another reason for the unsymmetrical conformation of μ-L^N could be the formation of more favorable crystal packing. Within both (*chel*- L^N)Y fragments N–Y distances of 2.528(3) Å (N1–Y1) and 2.571(3) Å (N3–Y2), respectively, were found, which are in excellent agreement with data reported for $[YL^N(\mu\text{-OTf})]_2$ [2.506(4) Å[2i]], $[YL^N(\mu\text{-OH})]_2$ [2.621(3) Å[2j]], and $[YL^{ind}N(SiHMe_2)_2]$ [2.511(2) Å; L^{ind} carries two indenyl units instead of two C_5H_4 rings[20]]. Thus, substantial N→Y interaction must be assumed to take place within each (*chel*-L^N)Y fragment of **1**, as confirmed by the NMR spectrum of dissolved **1** (vide supra).

Each Y ion formally adopts a coordination number of 10, owing to three η^5-C_5H_4 rings and one N atom. The arrangement of the centers C_g of the three C_5H_4 ligands around the Y atoms is close to trigonal-planar symmetry (Table 1). There is no significant difference in the distances Y–C_g between the chelating and the bridging C_5H_4 ligands. The N-atoms are on the top of the pyramids with the $Y(C_5H_4)_3$ base plane. A packing diagram is shown in Figure 3. The dichloromethane molecules are positioned in gaps between five complex molecules. According to the criteria of Takahashi et al.,[22] a CH–π interaction can be dis-

To verify if there is a possibility that one additional *ansa*-bis(cyclopentadienyl) unit bridging two chelated $[L^NLnOSO_2CF_3]_2$ units could be extended to other *ansa*-bis(cyclopentadienyl) ligands, containing an, in principle additional, coordinating atom in the side chain, the two new yttrium species $[L^NY]_2[\mu\text{-}L^{Si}]$ (**3**) and $[L^NY]_2[\mu\text{-}L^O]$ (**4**) were prepared [L^{Si} = dimethylsilanediylbis(cyclopentadienyl), L^O =

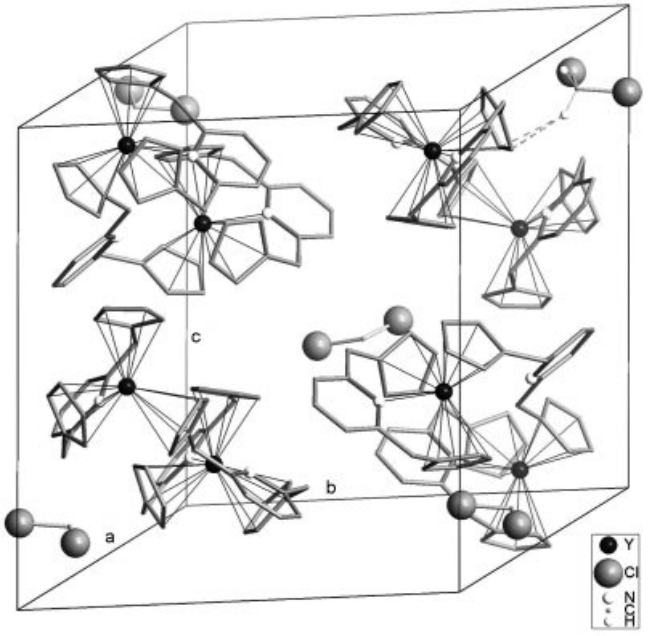

Figure 3. Packing diagram of **1**·CH_2Cl_2. Hydrogen atoms omitted. Possible CH–π interaction marked with dashed lines (H60A···C48, C49) for the upper right CH_2Cl_2 molecule only.

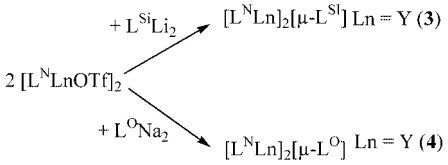
2,5-furanediylbis(methylcyclopentadienyl)] by reaction of $[L^NYOSO_2CF_3]_2$ with $L^{Si}Li_2$ and L^ONa_2 in a 1:1 molar ratio (Scheme 2).



Scheme 2.

The ^{1}H NMR spectrum of **3** suggests a greater flexibility of the two L^NY systems derived from the presence of a

broad singlet at δ = 4.23 ppm instead of the AB system (due to the diastereotopic methylene protons) observed in the case of **1**. The cyclopentadienyl protons of the L^N unities are still non-equivalent giving rise to four pseudoquadruplets centered at δ = 6.23, 6.18, 6.07, and 5.83 ppm, while the signals of the α- and β-cyclopentadienyl protons of the bridging ligand L^{Si} appear at δ = 6.17 and 6.05 ppm, respectively.

The ^{1}H NMR spectrum of species **4** suggests either a higher or lower rigidity with respect to species **3** and **1**, as shown by the AB pattern at δ = 4.26 ppm for the diastereotopic methylene protons of the two L^N units, while the methylene protons of the L^O unit give rise to a singlet at δ = 3.40 ppm. The cyclopentadienyl protons of the chelated L^N units originate four pseudoquadruplets at δ = 6.00–5.85 (m), 5.67 (q), 5.64–5.58 (m), and 5.43 (q) ppm, partially superimposed with the triplets of the α- and β-cyclopentadienyl protons of the bridging L^O unity.

Reactivity Tests of $[LY]_2[M\text{-}L]$ Complexes

By considering the presence of an uncoordinated pyridine nitrogen atom in the bridging ligand of **1**, and with the aim to verify the possibility of access to homo- and heterotrinuclear complexes by coordination of a third metal ion into the bridging unity, the dinuclear yttrium complex **1** was treated with an equimolar amount of $Y(OTf)_3$. Not quite unexpectedly, the only isolated product was the complex $[L^NYOTf]_2$.

$$[L^NY]_2[\mu\text{-}L^N] + Y(OTf)_3 \rightarrow 3/2\ [L^NYOTf]_2$$

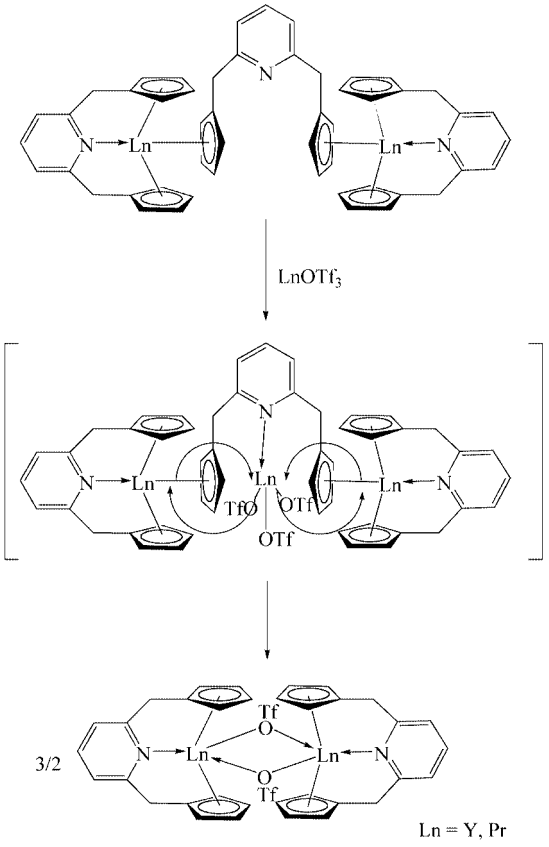
The same behavior was observed by treating the complex $[L^NPr]_2[\mu\text{-}L^N]$ with $Pr(OTf)_3$ in a 1:1 molar ratio and under the same experimental conditions. Also in this case, the ^{1}H NMR spectrum of the final product is consistent with the formulation of $[L^NPrOTf]_2$.

One possible explanation could imply a preliminary coordination of the third lanthanide ion by the free pyridine nitrogen atom, followed by a rapid intramolecular rearrangement through redistribution of the ligands as shown in Scheme 3.

On the basis of the proposed reaction pathway, the driving force could be the presence of the coordinating pyridine nitrogen atom of the bridging ligand unity. As a consequence, this type of intramolecular rearrangement must be absent in complexes of the type $[L^NLn]_2[\mu\text{-}L']$ where the bridging unit does not contain further coordinating atoms.

Accordingly, by treating $[L^NY]_2[\mu\text{-}L^{Si}]$ (**3**) with $Y(OTf)_3$ under the same experimental conditions as for complex **1**, no change of the initial ^{1}H NMR spectrum was observed even after 36 h of reaction at room temperature.

To confirm that the coordination step of the third metal ion by the coordinating atom of the bridging ligand into the molecule plays a fundamental role in allowing the intramolecular rearrangement, the same reaction was carried out with the complex $[L^NY]_2[\mu\text{-}L^O]$ (**4**) and, as expected, the rearrangement took place and dinuclear $[L^NYOTf]_2$ was isolated (Figure 4). From the mother liquor a mixture of other hardly separable complexes, probably containing the species $[L^OYOTf]_2$ and $[L^NY(\mu\text{-}OTf)(\mu\text{-}OTf)YL^O]$ was recovered.



Scheme 3.

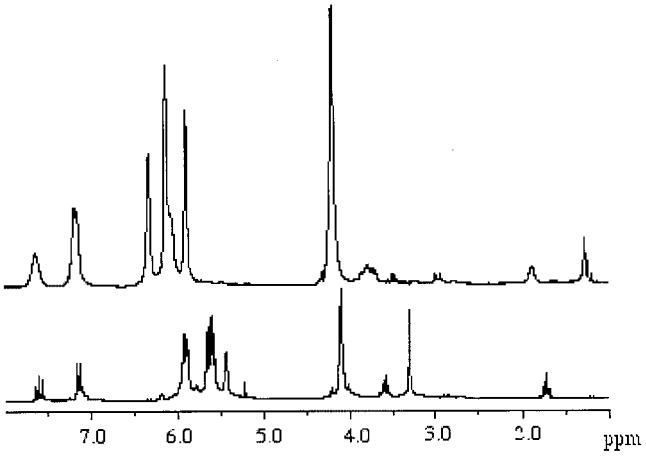


Figure 4. ^{1}H NMR spectra of $[L^NY]_2[\mu\text{-}L^O]$ (bottom) and of the reaction mixture $[L^NY]_2[\mu\text{-}L^O]$ + $Y(OTf)_3$ (top).

Conclusions

ansa-Lanthanocene complexes of the type L^NLnX (X = OTf, Cl) react in a 2:1 molar ratio with *ansa*-bis(cyclopentadienyl) ligands with, or devoid of, an additional coordinat-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ing atom in the chain bridging the two cyclopentadienyl rings to give dinuclear species containing the *ansa*-bis(cyclopentadienyl) ligands simultaneously acting in a chelating and bridging mode. In the case of the species $[L^NLn]_2[\mu\text{-}L']$ (Ln = Y, Pr), where the bridging ligand L′ contains an additional coordinating atom, any attempt to introduce a third Ln^{III} ion to form homo- or heterotrinuclear complexes failed due to an intramolecular ligand redistribution reaction affording L^NLnX species.

Experimental Section

General Procedures: All manipulations were carried out under purified nitrogen in a glove-box apparatus (MBraun G200). The commercially available solvents, tetrahydrofuran, toluene, *n*-hexane, and diethyl ether, were firstly distilled from $LiAlH_4$ and then from sodium benzophenone ketyl under nitrogen. Dichloromethane was distilled from CaH_2. Deuterated [D_8]toluene was dried with Na/K alloy and collected by thaw cycles. CD_2Cl_2 and $CDCl_3$ were dried with CaD_2 and collected by taw cycles. Yttrium and praseodymium trifluoromethanesulfonates were prepared according to literature methods.[13] *n*BuLi (Aldrich) in THF and pentane or *n*-hexane solutions were titrated before use. The disodium salt of the ligands (L^NNa_2,[14] $L^{Si}Na_2$,[15] L^ONa_2[16]) and the complexes $[L^NLnOTf]_2$[17] were prepared as reported in the literature. NMR spectra were recorded with a Bruker AC 200 or a Varian Unity 400 spectrometer. Chemical shifts (ppm) for ^1H and ^{13}C spectra were internally referenced to the residual undeuterated solvent resonances and related to tetramethylsilane (δ = 0 ppm).

$[(L^NY)_2(\mu\text{-}L^N)]$ (1): To a solution of $[L^NYOTf]_2$ (0.942 g, 1.0 mmol) in THF (20 mL) a solution of L^NNa_2 (0.139 g, 0.5 mmol) in THF (20 mL) was slowly added at room temperature under magnetic stirring, and the mixture reacted at room temperature overnight. After removal of the solvent and volatiles under vacuum, the solid residue was added to dichloromethane (50 mL) and the insoluble sodium triflate filtered off. The volume of the resulting yellow solution was then reduced to 20 mL under vacuum and the solution left to crystallize at –20 °C to give pale yellow crystals (0.799 g, 91.1% yield). $C_{51}H_{45}N_3Y_2$ (877.75): calcd. C 69.79, H 5.17, N 4.79; found C 69.65, H 5.25, N 4.65. ^1H NMR (400 MHz, CD_2Cl_2, 25 °C): δ = 7.72 (t, $^3J_{H,H}$ = 7.7 Hz, 2 H, Py^a-4), 7.41(t, $^3J_{H,H}$ = 7.6 Hz, 1 H, Py^b-4), 7.26 (d, $^3J_{H,H}$ = 7.7 Hz, 4 H, Py^a-3,5), 6.70 (d, $^3J_{H,H}$ = 7.6 Hz, 2 H, Py^b-3,5), 6.06 (AB system, δ_A = 6.07, δ_B = 6.06, J_{AB} = 3.0 Hz, 4 H, Cp^a), 6.03 (AB system, δ_A = 6.03, δ_B = 6.02, J_{AB} = 2.4 Hz, 4 H, Cp^a), 5.77 (A_2B_2 system, J_{AB} = 2.6 Hz, 4 H, Cp^b), 5.73 (AB system, δ_A = 5.74, δ_B = 5.72, J_{AB} = 3.0 Hz, 4 H, Cp^a), 5.69 (A_2B_2 system, J_{AB} = 2.6 Hz, 4 H, Cp^b), 5.56 (AB system, δ_A = 5.57, δ_B = 5.56, J_{AB} = 2.4 Hz, 4 H, Cp^a), 4.25 (AB system, δ_A = 4.29, δ_B = 4.21, J_{AB} = 18.5 Hz, 8 H, CH_2^a), 3.66 (s, 4 H, CH_2^b) ppm. ^{13}C NMR (100 MHz, CD_2Cl_2, 25 °C): δ = 166.33, 162.12, 136.66 (C9), 136.99 (C26), 123.29, 122.35 (C8), 121.40, 120.10 (C25), 119.34 (C4), 114.11 (C2), 112.63 (C18), 109.23 (C19), 108.03 (C1), 103.27 (C3), 38.90 (C23), 37.65 (C6) ppm.

$[(L^NPr)_2(\mu\text{-}L^N)]$ (2): The compound was prepared in a manner analogous to that for **1** from $[L^NPrOTf]_2$ (1.047 g, 2 mmol) and L^NNa_2 (0.279, 1 mmol) in a 2:1 molar ratio. Dark green crystals of **2** were obtained (0.863 g, 88% yield). $C_{51}H_{45}N_3Pr_2$ (981.76): calcd. C 62.39, H 4.62, N 4.28; found C 62.50, H 4.55, N 4.50.

$[(L^NY)_2(\mu\text{-}L^{Si})]$ (3): To a solution of $[L^NYOTf]_2$ (0.942 g, 1.0 mmol) in THF (20 mL) a solution of $L^{Si}Li_2$ (0.100 g, 0.5 mmol) in THF (20 mL) was slowly added at room temperature under magnetic stirring, and the mixture reacted at room temperature overnight. After removal of the solvent and volatiles under vacuum, the solid residue was added to dichloromethane (50 mL) and the insoluble lithium triflate filtered off. The volume of the resulting yellow solution was reduced to 20 mL under vacuum and the solution left to crystallize at –20 °C to give pale yellow crystals (0.706 g, 85% yield). $C_{46}H_{44}N_2SiY_2$ (830.77): calcd. C 66.50, H 5.34, N 3.37; found C 66.60, H 5.40, N 3.50. ^1H NMR (200 MHz, $CDCl_3$, 25 °C): δ = 7.69 (t, $^3J_{H,H}$ = 7.7 Hz, 2 H, Py-4), 7.21 (d, $^3J_{H,H}$ = 7.7 Hz, 4 H, Py-3,5), 6.23 (AB system, J_{AB} = 3.0 Hz, 4 H, Cp^a), 6.18 (m, 8 H, Cp^a + Cp^b), 6.07 (AB system, J_{AB} = 3.0 Hz, 4 H, Cp), 6.05 (A_2B_2 system, J_{AB} = 2.6 Hz, 4 H, Cp^b), 5.83 (AB system, J_{AB} = 3.0 Hz, 4 H, Cp^a), 4.23 (br. s, 4 H, CH_2^a), –0.18 (s, 6 H, CH_3) ppm.

$[(L^NY)_2(\mu\text{-}L^O)]$ (4): To a solution of $[L^NYOTf]_2$ (0.942 g, 1.0 mmol) in THF (20 mL) a solution of L^ONa_2 (0.134 g, 0.5 mmol) in THF (20 mL) was slowly added at room temperature under magnetic stirring, and the mixture reacted at room temperature overnight. After removal of the solvent and volatiles under vacuum, the solid residue was added to dichloromethane (30 mL) and the sodium triflate filtered off. The volume was reduced to 20 mL under vacuum and the yellow solution left to crystallize at –20 °C giving yellow-orange crystals (0.719 g, 83% yield). $C_{50}H_{44}N_2OY_2$ (866.72): calcd. C 69.29, H 5.12, N 3.23; found C 69.35, H 5.20, N 3.30. ^1H NMR (200 MHz, $CDCl_3$, 25 °C): δ = 7.68 (t, $^3J_{H,H}$ = 7.6 Hz, 2 H, Py-4), 7.24 (d, $^3J_{H,H}$ = 7.6 Hz, 4 H, Py-3,5), 6.12–5.92(m, 8 H, Cp^b), 5.75 (AB system, J_{AB} = 2.6 Hz, 4 H, Cp^a), 5.72–5.69 (m, 8 H, Cp^a + Fur), 5.68 (AB system, J_{AB} = 3.0 Hz, 4 H, Cp^a), 5.55 (AB system, J_{AB} = 2.6 Hz, 4 H, Cp^a), 4.21 (A_2B_2, J_{AB} = 18.5 Hz, 8 H, CH_2^a), 3.40 (s, CH_2^b) ppm.

X-ray Crystal Structure Determination: A single crystal was mounted under inert oil in a glass capillary and investigated at 193 K with an IPDS image plate system. The data were corrected for Lorentz and polarization effects, and a numerical absorption correction based on indexed faces was applied. The structure was solved by direct methods (SHELXS-97)[18] and difference Fourier syntheses in space group $P2_1/c$ and refined against all F^2 data using the SHELXL-97 program.[19] All hydrogen atoms were kept riding on calculated positions (C–H 0.95 Å) with isotropic displacement factors taken as 1.2 times the U_{eq} value of the corresponding C atom. All heavier atoms were refined with anisotropic displacement parameters. No disorder was observed for the CH_2Cl_2 solvent molecule. Details of the experimental and crystal data are summarized in Table 2. CCDC-261469 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Reactivity Test of $[(L^NY)_2(\mu\text{-}L^N)]$ (1) with $Y(OTf)_3$: To a solution of $[(L^NY)_2(\mu\text{-}L^N)]$ (**1**) (0.439 g, 0.5 mmol) in THF (20 mL) a solution of $Y(OTf)_3$ (0.268 g, 0.5 mmol) in the same solvent (15 mL) was added at room temperature under vigorous magnetic stirring, and the mixture reacted overnight at room temperature. After solvent removal under vacuum, the solid residue was completely dissolved in dichloromethane (20 mL). By slow evaporation of the solvent, pale yellow microcrystals of $[L^NYOTf]_2$ were obtained (0.629 g, 89% yield) as confirmed by elemental analysis, NMR spectroscopic data, and comparison with an authentic sample.

Reactivity Test of $[(L^NPr)_2(\mu\text{-}L^N)]$ (2) with $Pr(OTf)_3$: To a deep green solution of $[(L^NPr)_2(\mu\text{-}L^N)]$ (**2**) (0.491 g, 0.5 mmol) in THF (20 mL) a solution of $Pr(OTf)_3$ (0.294 g, 0.5 mmol) in the same solvent (15 mL) was added at room temperature under vigorous magnetic stirring, and the resulting green reaction mixture reacted

overnight at room temperature. The solvent was removed under vacuum and the solid residue completely dissolved in dichloromethane (20 mL). By slow evaporation of the solvent, green microcrystals of $[L^NPrOTf]_2$ were separated (0.465 g, 89% yield) as confirmed by elemental analysis, NMR spectroscopic data, and comparison with an authentic sample.

Reactivity Test of $[(L^NY)_2(\mu\text{-}L^{Si})]$ (3) with $Y(OTf)_3$: To a solution of $[(L^NY)_2(\mu\text{-}L^{Si})]$ (**3**) (0.415 g, 0.5 mmol) in THF (20 mL) a solution of $Y(OTf)_3$ (0.268 g, 0.5 mmol) in the same solvent (15 mL) was added at room temperature under magnetic stirring, and the mixture reacted overnight at room temperature. The solvent was removed under vacuum and the solid residue was added to dichloromethane (20 mL) where it was partially soluble. The solid residue was filtered off and characterized by elemental analysis as unreacted $Y(OTf)_3$. By addition of *n*-hexane to the solution, pale yellow microcrystals of $[(L^NY)_2(\mu\text{-}L^{Si})]$ separated.

Reactivity Test of $[(L^NLn)_2(\mu\text{-}L^O)]$ (4) with $Ln(OTf)_3$: To a solution of $[(L^NY)_2(\mu\text{-}L^O)]$ (**4**) (0.433 g, 0.5 mmol) in THF (20 mL) a solution of $Y(OTf)_3$ (0.268 g, 0.5 mmol) in the same solvent (15 mL) was added at room temperature under vigorous magnetic stirring, and the mixture reacted overnight at room temperature. The solvent was removed under vacuum and the solid residue was dissolved in dichloromethane (20 mL). The solvent was then removed under vacuum at room temperature to give, as the main product, pale yellow microcrystals of $[L^NYOTf]_2$ (0.193 g, 41% yield), as confirmed by elemental analysis and NMR spectroscopic data. From the mother liquor a mixture of compounds hardly separable was recovered.

Acknowledgments

The work was supported by a grant from the Italian Ministry of the University and of Scientific and Technologic Research (MURST, PRIN-2004). G. P. is grateful to Dr. Luca Coletto and Dr. Jacopo Zanon for their contribution to the syntheses of the complexes and for useful discussions.

Non-Covalent Aggregation of Discrete Metallo-Supramolecular Helicates into Higher Assemblies by Aromatic Pathways: Structural and Chemical Studies of New Aniline-Based Neutral Metal(II) Dihelicates

Miguel Vázquez,[a][‡] Manuel R. Bermejo,*[b] Maurizio Licchelli,[a] Ana M. González-Noya,[b] Rosa M. Pedrido,[b] Claudio Sangregorio,[c] Lorenzo Sorace,[c] Ana M. García-Deibe,[b] and J. Sanmartín[b]

Keywords: Fluorescence / Helical structures / Pi interactions / Self-assembly / Supramolecular chemistry

Neutral manganese(II), iron(II), cobalt(II), nickel(II), zinc(II) and cadmium(II) complexes with an *N*-tosyl-substituted N_4-donor Schiff base containing a 4,4′-methylenedianiline residue as spacer [H_2L^a: *N*,*N*′-bis(2-tosylaminobenzylidene)-4,4′-methylenedianiline], and the zinc(II) complex with an analogous ligand [H_2L^b: *N*,*N*′-bis(2-tosylaminobenzylidene)-4,4′-oxodianiline] have been prepared by an electrochemical procedure. FAB and ESI mass spectra of the complexes show peaks due to species corresponding to a general formula $[M_2(L^{a,b})_2 + H]^+$, thereby suggesting their dinuclear nature. A detailed study of the crystal packing in the unit cell of the zinc(II) complex with H_2L^a shows that the helicates aggregate to form discrete prismatic moieties containing three molecules held together by π–π and σ–π interactions. Moreover, the Zn^{II} neutral dihelicate with H_2L^b forms a 3D network in the solid state due to intermolecular π-stacking interactions. ^1H NMR studies of the diamagnetic compounds reported herein have been performed. Finally, the ligand H_2L^a and its Zn^{II} and Cd^{II} complexes have been studied by spectrophotometric and spectrofluorimetric techniques in order to get a better understanding of the formation mechanisms of the complexes and of the nature of their fluorescence emission. Emission studies show that the Zn^{II} and Cd^{II} dihelicates with H_2L^a display a green fluorescence in acetonitrile solution (λ = 473 nm, Φ = 0.03 and λ = 476 nm, Φ = 0.01, respectively).

Introduction

Metallo-helicates are a dynamic research field in supramolecular chemistry.[1–3] However, predicting the result of a self-assembly process is still not easy as it depends on numerous factors, such as the coordination and stereochemical preferences of the metal centres, the structure of the ligand strands or the existence of weak inter- or intramolecular non-covalent connections, such as hydrogen bonds[4] or interactions between aromatic groups.[5]

Aromatic interactions are a very important class of non-covalent intermolecular forces in biology, chemistry and materials science.[6] It has been demonstrated that, in the absence of strong hydrogen-bond donors and acceptors, aromatic groups tend to aggregate via π–π interactions, σ–π (C–H···π) connections, or both, and this trend is magnified when the aromatic groups are electron-poor ring systems.[7] These weak non-covalent bonds can sustain supramolecular architectures,[8] such as the vertical base–base interaction in DNA,[9] the tertiary and quaternary structures of peptides and proteins,[11] the packing of aromatic molecules in crystals,[10] or supramolecular host–guest bonding.[12] Furthermore, Hannon et al. have recently illustrated how metal–ligand and π–π interactions can be used in concert to force the aggregation of helicates into larger nanoscale arrays, such as chiral balls[13] or metallo-supramolecular cylinders.[14] The synthetic method employed to build these assemblies, the so-called "second supramolecular event approach", consists of using an initial supramolecular event to construct small supramolecular units, which are then used as building blocks in a second supramolecular event to give a higher order aggregate.

We have recently embarked upon a program to exploit the helical structural motif as a means of producing larger supramolecular architectures through non-covalent aggregation. In a first approach, we have reported how the introduction of an OH group into an alkyl spacer can provoke the aggregation of neighbouring fluorescent helicates through hydrogen bonding.[15] After that, we decided to ex-

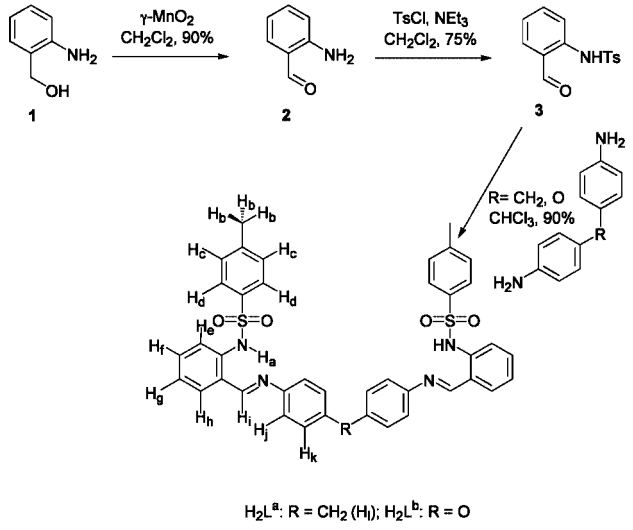
plore new routes to employ other non-covalent interactions in the aggregation processes. For this reason we have designed the Schiff-base ligand H_2L^a (Scheme 1), which contains four aniline groups that are potentially electron-deficient ring moieties when coordinating to a metal centre, with the hope that they should induce the aggregation of neighbouring helicate units through aromatic interactions.[16] H_2L^a is also equipped with a long and flexible spacer unit that effectively drives the self-assembly of dihelicates.[17] We have succeeded in synthesising the dinuclear complex of Cu^{II} of this ligand,[18] and herein we describe the synthesis, structural characterisation and absorption, emission and magnetic properties of the manganese(II), iron(II), cobalt(II), nickel(II), zinc(II) and cadmium(II) derivatives of this ligand. Moreover, in order to shed more light on the impact that a change in the flexibility of the spacer could have on the aggregation properties of these complexes, the zinc(II) derivative with an analogous ligand H_2L^b (Scheme 1) has been synthesised and structurally characterised.



Scheme 1. Synthesis of the ligands H_2L^a and H_2L^b.

Results and Discussion

Synthesis of *N*,*N*′-Bis(2-tosylaminobenzylidene)-4,4′-methylenedianiline (H_2L^a) and *N*,*N*′-Bis(2-tosylaminobenzylidene)-4,4′-oxodianiline (H_2L^b)

Ligands H_2L^a and H_2L^b were synthesised with an overall yield of 60% according to a three-step procedure (Scheme 1).[19] The first step involves the oxidation of 2-aminobenzyl alcohol (**1**) with γ-MnO_2 in dry dichloromethane for 24 h at room temperature, under argon to give 2-aminobenzaldehyde (**2**).[20] Subsequently, the *N*-tosylation of **2** with tosyl chloride and triethylamine to give 2-tosylaminobenzaldehyde (**3**) was performed. Compound **3** has also been prepared and structurally characterised by us by another method.[21] Finally, Schiff-base condensation of **3** and 4,4′-methylenedianiline or 4,4′-oxodianiline in chloroform at reflux temperature afforded ligands H_2L^a and H_2L^b, respectively. These ligands were satisfactorily characterised (see Exp. Sect.).

Electrochemical Synthesis of the Complexes

A series of metal neutral complexes was obtained by electrochemical oxidation[22] of the corresponding metal anode in an acetonitrile solution of the corresponding ligand in the presence of a small quantity of tetraethylammonium perchlorate as supporting electrolyte. The electrochemical efficiencies of the cells were close to 0.5 mol F^{-1}, which are compatible with the following reaction scheme:

Cathode: $2\ H_2L^{a,b} + 4e^- \rightarrow 2\ H_2\ (g) + 2\ (L^{a,b})^{2-}$

Anode: $2\ (L^{a,b})^{2-} + 2M \rightarrow [M(L^{a,b})]_2 + 4\ e^-$

This synthetic procedure allowed us to obtain neutral metal complexes of the type $[M(L^{a,b})]_2{\cdot}(CH_3CN)_n$ (n = 0–2) with high purity and in very good yield. The empirical formulae found, namely $[M(L^a)]{\cdot}(CH_3CN)_n$ (M = Mn, Fe, Co, Ni, Zn, Cd; n = 0–2) and $[Zn(L^b)]{\cdot}(H_2O)_4$, suggest that the metals react with the ligands in a 1:1 molar ratio. All of them seem to be stable in the solid state and, with the exception of the manganese(II) and iron(II) complexes with H_2L^a, also in solution. They are fairly soluble in the most common polar aprotic organic solvents, but totally insoluble in both apolar or protic media.

The complexes with H_2L^a show a shift of the ν(C=N) absorption to lower wavenumbers (7–25 cm^{-1}; cf. 1621 cm^{-1} in the free ligand). In addition, a shift of the ν(C–N) absorption to lower wavenumbers is also observed (34–48 cm^{-1}; cf. 1337 cm^{-1} in the free ligand). Moreover, the zinc(II) complex with H_2L^b shows a slight shift of 7 cm^{-1} for ν(C=N) (1617 cm^{-1} in the free ligand) and a shift of 40 cm^{-1} for ν(C–N) (1340 cm^{-1} in the free ligand), both to lower wavenumbers. These IR data suggest that both imine and amide nitrogen atoms are involved in coordination to the metal centres in all the complexes.

The FAB mass spectra of the complexes show peaks due to fragments $[M_2(L^{a,b})_2 + H]^+$. Such results imply a successful coordination of the ligands to the metals and suggest the dinuclear nature of the complexes. Fragments containing solvent molecules were not observed, which points to the solvate nature rather than to a coordination behaviour of the solvent molecules. Higher molecular weight peaks, which could suggest the presence of supramolecular aggregates, were not observed in any spectra. In order to assess the identity of the complex species formed in solution by the ligands H_2L^a and H_2L^b more clearly, further investigations were performed by electrospray ionisation mass spectroscopy (ESI-MS). All the spectra exhibit base peaks (ca. 100%) corresponding to $[M_2(L^{a,b})_2 + H]^+$ fragments. These data suggest that the [2+2] complexes are the main species in solution.

Crystal Structure of $[Zn(L^a)]_2 \cdot CH_3CN$ (5)

Recrystallisation of **5** from acetonitrile by slow concentration afforded yellow crystals for which we determined the molecular structure by X-ray crystallography.[23]

The asymmetric unit of the zinc(II) dihelicate **5** (Figure 1) contains two Zn atoms, two ligands and one acetonitrile molecule. The Zn–Zn distance is 11.83 Å and the ligands wrap around the two zinc centres to form a double helix with helical twists of 140.0° ([Zn1–N3–N2–Zn2) and 143.5° (Zn1–N7–N6–Zn2). The distortion from an ideal tetrahedral geometry is shown by the angles between the nitrogen and zinc atoms, which range from 93.0° to 126.8° for Zn1, and from 93.6° to 126.9° for Zn2.

Each ligand forms two six-membered chelate rings, which are nearly planar, one around each zinc atom. The angle between these chelate rings at both metal centres are 96.03(1)° for Zn1 and 103.94(1)° for Zn2. Two oxygen atoms from the tosyl groups interact weakly with each metal centre (Zn–O distances range from 2.65 to 2.87 Å). All other bond lengths are similar to those found in other tetrahedral zinc(II) complexes with related Schiff-base ligands.[15,19,24] The phenyl rings of the diarylmethane spacer are face-to-face π-stacked with those on the adjacent ligand strand [centroid–centroid distances: rings C22 to C27 and C63 to C68 = 4.19 Å; rings C15 to C20 and C55 to C60 = 4.01 Å; angles between ring planes: rings C22 to C27 and C63 to C68 = 27.11(2)°, rings C15 to C20 and C55 to C60 = 18.02(2)°]. All these distances and angles reveal the non-equivalence of the environment of the two zinc atoms and of both ligand units, which gives rise to a certain degree of asymmetry.[5a,19] This coordinative asymmetry leads to the formation of two grooves of different size in the main body of the metallo-organic double helix, reminiscent of the structure of DNA.[25] A good approximation to the wrapping angle of the helicate could be the torsion angle formed by the two metal ions, that define the helical axis of the helicate, and the outer donor atoms of the same ligand strand that coordinate these two metal centres. In our case these torsion angles are 279.5° for N8–Zn1–Z2–N5 and 280.4° for N4–Zn1–Zn2–N1.

A great number of intermolecular face-to-face and edge-to-face aromatic interactions between neighbouring helicates are present in the crystal cell. A detailed study of the

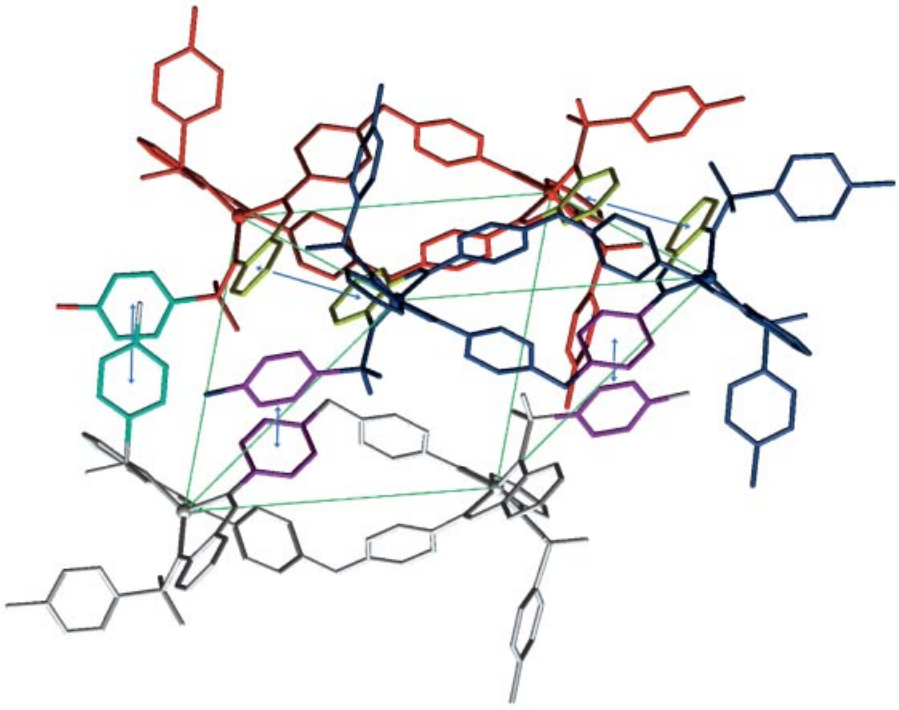

Figure 2. Part of the unit cell of **5** exhibiting the three different types of intermolecular aromatic interactions (cyan, yellow and pink) between three adjacent dihelicates (blue, grey and red). The dinuclear helicates aggregate to form discrete supramolecular prismatic assemblies of three molecules.

crystal packing reveals that the Zn^{II} dihelicates aggregate to form discrete prismatic moieties of three metallo-supramolecular members held together by π–π and σ–π connections.

There are three aromatic supramolecular interactions of different nature in each "triangular prism"; they are coloured cyan, yellow and pink in Figure 2. Both the yellow and cyan interactions are offset π–π interactions, while the pink ones are σ–π. The red dihelicate is connected to the blue one through two identical offset π–π interactions (yellow) between the aromatic rings of their benzylidene binding moieties ($centroid_{red}$–$centroid_{blue}$ distance = 3.89 Å). Moreover, the red dihelicate is connected to the grey one through a unique offset π–π interaction (cyan) between the aromatic rings of their terminal tosyl groups ($centroid_{red}$–$centroid_{white}$ distance = 4.07 Å). Finally, the white dihelicate is connected to the blue one through two identical edge-to-face interactions (pink) using one aromatic ring from the spacer and another from the terminal tosyl group, in a double contact (H_{blue}–$centroid_{white}$ distance = 3.18 Å). These distances are similar to those reported in the literature by us[18] and others[26] for analogous helicates, but shorter than that found for $[Zn(L^b)]_2$ (see below).

Figure 3 shows two different views of two adjacent triangular prisms, painted red and green. There are no π–π or σ–π aromatic interactions between neighbouring prismatic aggregates − they are discrete moieties. Each prism contains both types of helical enantiomer (left-handed and right-handed). The red prism (Figure 3b, left) contains one left-handed and two right-handed helicates, while the green prism (Figure 3b, right) contains one right-handed and two left-handed helicates. The unit cell encloses both isomers in 50% yield.

In summary, the discrete dinuclear dihelicates aggregate in the solid state into groups of three molecules that form an unprecedented assembly of six Zn^{II} ions and six ligands. The volume of the triangular prism defined by the six Zn^{II} ions is 598 $Å^3$ (Figure 4).

Crystal Structure of $[Zn(L^b)]_2 \cdot CH_3CN$

Yellow crystals of $[Zn(L^b)]_2 \cdot CH_3CN$ suitable for X-ray studies[27] were obtained by slow concentration of a saturated acetonitrile solution of $[Zn(L^b)]_2 \cdot (H_2O)_4$ (**7**). The structure of this complex (Figure 5) reveals the formation of a binuclear zinc(II) complex, with the ligands spanning both metal centres and intertwined to give a perfectly symmetrical double helix (symmetry space group of the unit cell = *Fddd*). A racemic mixture of both enantiomers (left- and right-handed) is observed in the crystal cell.

Each zinc(II) centre occupies a four-coordinate distorted tetrahedral environment, being bound by two aminobenzylidenimine units, one from each ligand. Thus, both ligands act as bisbidentate N_4 donors. The distortion from an ideal tetrahedral geometry is shown by the angles between the nitrogen and zinc atoms, which range from 92.2° to 128.0°. Each ligand forms two six-membered chelate rings, which are nearly planar, one around each metal atom. The angle between the chelate rings in both metal centres is 112.9°. Two oxygen atoms from the tosyl groups interact

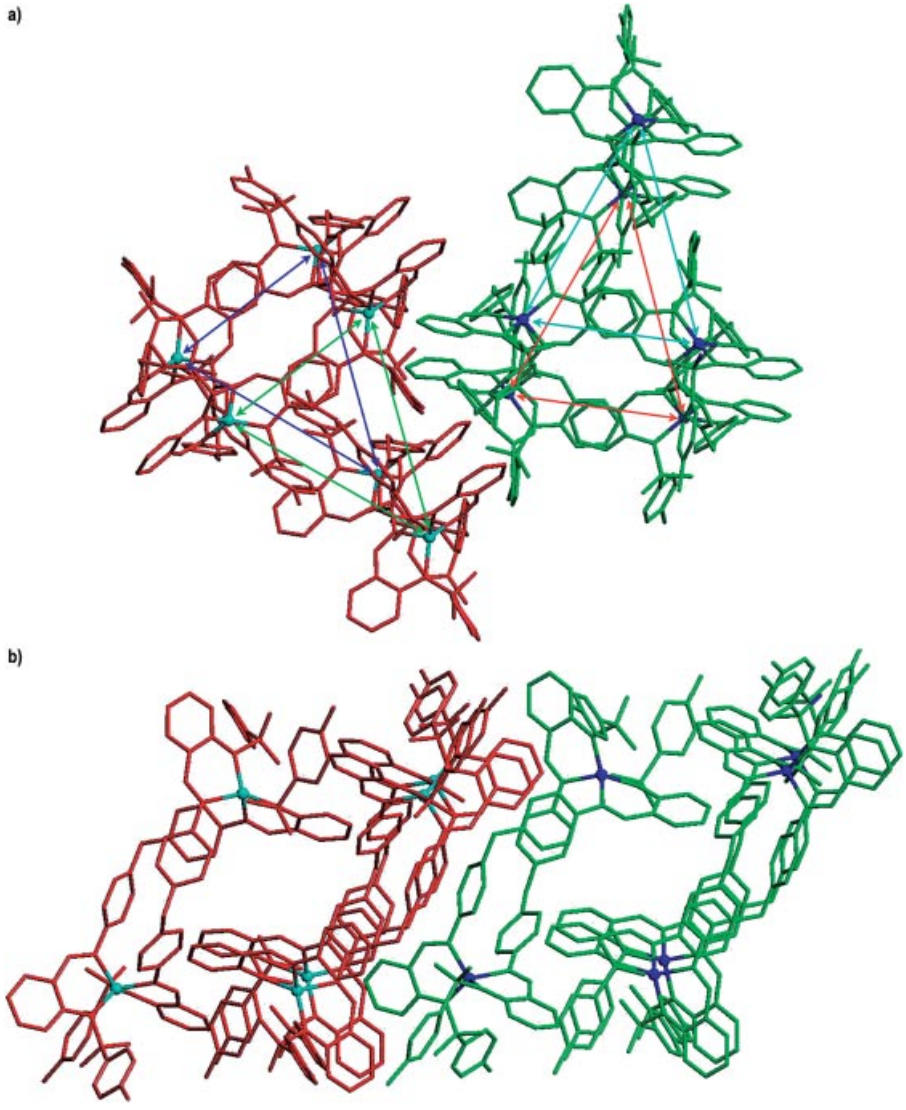

Figure 3. Two different views of two neighbouring prisms (red and green) in the unit cell of **5**. There are no aromatic interactions (π–π or σ–π) between adjacent prismatic aggregates.

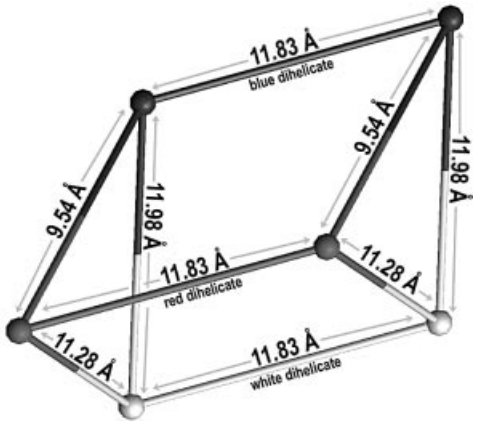

Figure 4. Schematic representation of the supramolecular triangular prism of zinc(II) dihelicates in **5** showing the inter- and intramolecular Zn–Zn distances. The spheres represent the zinc(II) ions, and their colour indicates their original dihelicate, as shown in Figure 2. The volume of the geometrical solid defined by the six Zn^{II} ions is 598 $Å^3$.

weakly with each metal centre (Zn–O distance = 2.69 Å). All the other bond lengths are similar to those found in other tetrahedral zinc(II) complexes with similar N_4 Schiff bases.[15,19,24]

The phenyl rings of the oxodianiline spacer are face-to-face π-stacked with those on the adjacent ligand strand (centroid–centroid distance = 3.99 Å; angle between ring planes = 12.9°). To achieve this, the two ligand units are pulled symmetrically along the helical axis. The helical twist of the ligand strands around the helical axis, defined by the N(1)–Zn(1)–Zn(1_3)–N(1_4) dihedral angle, is 268.8°.

The intermolecular π-stacking interactions present in this crystal structure, which are responsible for the aggregation of the discrete zinc(II) helicate units into a polymeric 3D network of helicates, are very similar to those described in our previous communication.[18] Each Zn^{II} dihelicate uses two aromatic rings to connect to another helical unit, one from the oxodianiline spacer and the other from the benzylidene binding moiety, in a double interaction. Overall, each

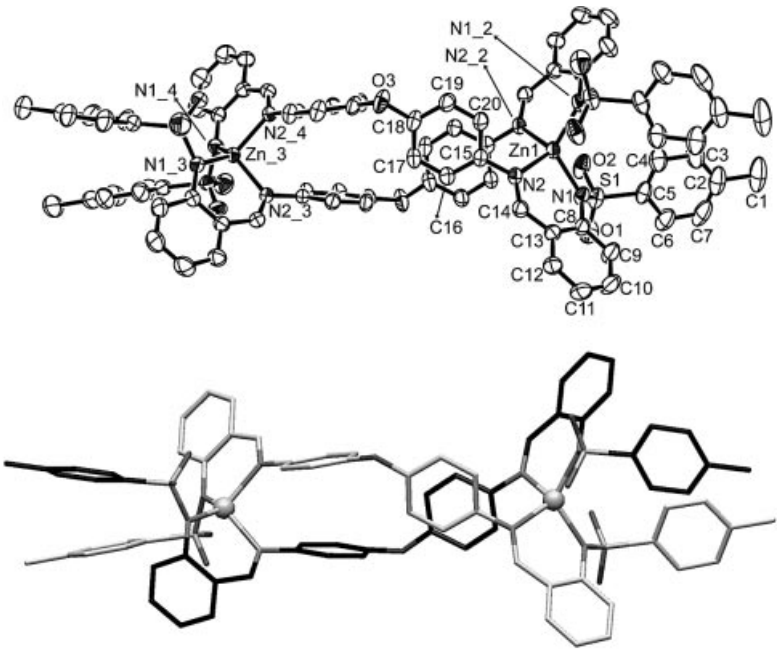

Figure 5. Top: ORTEP representation of the molecular structure of $[Zn(L^b)]_2{\cdot}CH_3CN$ Thermal ellipsoids are shown at the 50% probability level. Bottom: Stick representation of the X-ray crystal structure of $[Zn(L^b)]_2{\cdot}CH_3CN$. Hydrogen atoms and the solvent molecule have been omitted for clarity.

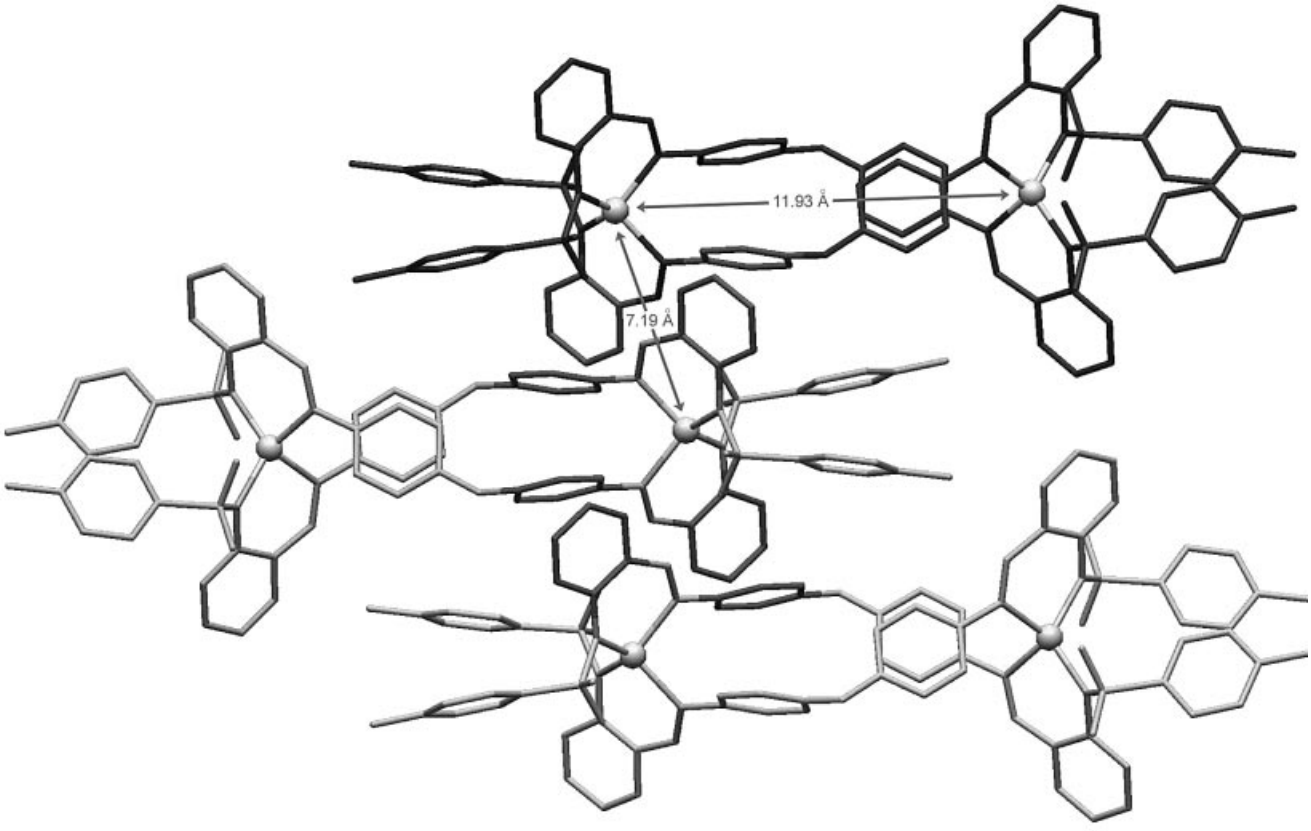

Figure 6. A representation of part of the unit cell of $[Zn(L^b)]_2{\cdot}CH_3CN$, showing the double π-stacking connections established between adjacent dihelicates. This is a 2D view of the crystal cell; π–π connections on the left side of the central dihelicate that grow normal to the plane of the paper must be considered equivalent. Interestingly, the intermolecular Zn–Zn distance (7.19 Å) is shorter than the intramolecular one (11.93 Å).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

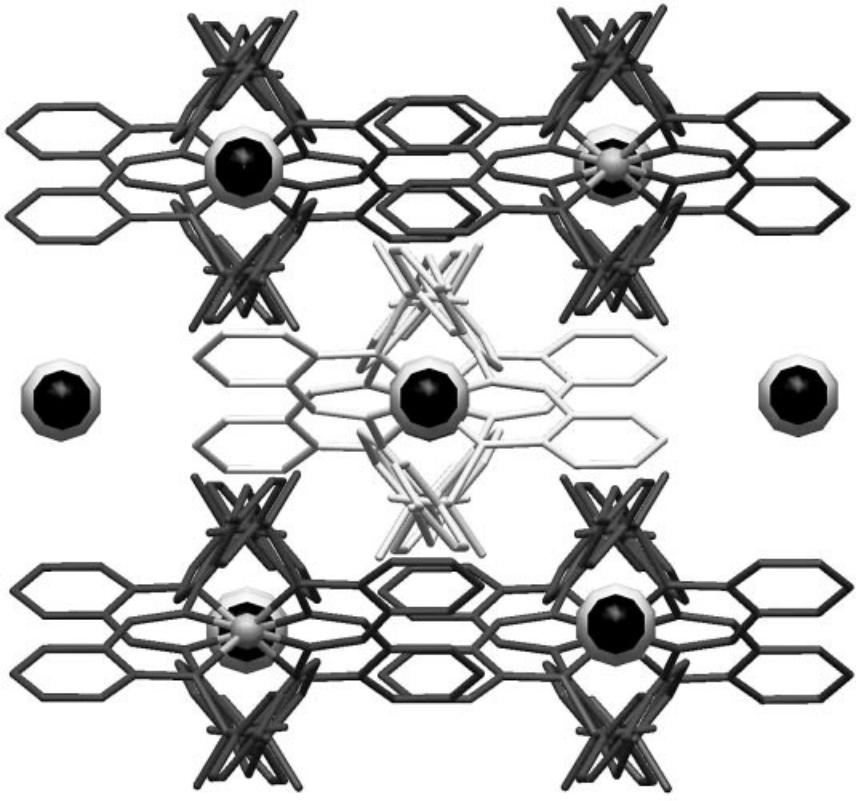

Figure 7. A perspective of the unit cell of $[Zn(L^b)]_2 \cdot CH_3CN$. It can be considered as a 3D supramolecular solid into which acetonitrile guest molecules (white-black spheres) are absorbed.

helicate is connected to another four molecules, through eight identical offset π–π interactions, forming a 3D network of helicates (Figure 6). The distance between the centroids of the intermolecular stacked aromatic rings is 4.80 Å. The "displacement angle" between these stacked rings, defined as the angle between the centroids vector and the normal to the benzylidene ring plane, is 21.7°. Moreover, the distance between the two closest zinc(II) centres of connected dihelicates is shorter (7.19 Å) than the intramolecular Zn–Zn distance (11.93 Å).

Another interesting structural feature of this complex is the presence of two, totally unbound acetonitrile molecules per formula unit that fill the 3D body of the network (Figure 7). This fact shows the capability of the array to include a large number of small, neutral guest molecules.[28] It must be noted that while a number of open frameworks have been assembled by the reactions of metal ions with a large variety of organic molecules, such as di-, tri-, and polytopic N-bound organic linkers or carboxylate linkers (i.e. 4,4-bipyridine[29] and benzene-1,3,5-tricarboxylate[30]), those sustained by π–π interactions are still rare or lacking.[31] Moreover, the use of helical metal-organic architectures as building blocks for the formation of 3D networks has been explored only recently.[26]

This supramolecular situation is quite different to that described above for the other Zn^{II} helicate **5**, where the π–π and σ–π interactions between the aromatic rings of different complexes allow the formation of discrete prismatic aggregates of three helicates. However, it is very similar to that found for the recently reported Cu^{II} derivative with H_2L^a,[18] the difference being that the metal centres in the copper(II) dihelicate occupy very distorted (near square-planar) tetrahedral environments.

The ligand H_2L^b is more rigid than H_2L^a due to the substitution of the CH_2 group in the spacer by an oxygen atom. In addition, the Zn^{II} ion is coordinatively more flexible than Cu^{II}. Taking all this into account, we reasoned that the introduction of more rigidity into any of the building blocks that form a helicate (the ligands or the metal centres) leads to the formation of more-symmetric dihelicates. Moreover, this high symmetry seems to support the self-aggregation of the helicates into polymeric arrays rather than discrete assemblies. Therefore, we suggest that more-rigid building blocks facilitate the self-aggregation of the dihelicates into 3D frameworks.

Magnetic Studies

The occurrence of a coupling between metal centres reported for the Cu^{II} derivative of the ligand H_2L^a[18] could not be confirmed by measurements on the other paramagnetic complexes. The magnetic moments of all the paramagnetic complexes reported herein were recorded in the solid state between 2 and 300 K. The values of the magnetic moments, obtained by the Curie–Weiss fit of susceptibility

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

data, are in the range expected for magnetically diluted tetrahedral metal(II) ions.[32] The temperature dependence of the magnetic susceptibilities for all the complexes shows deviation from Curie behaviour at low temperature ($T < 30$ K).

The occurrence of a coupling between metal centres could not be confirmed by measurements of the magnetic susceptibilities on these paramagnetic complexes. Indeed, even if present, the coupling is so weak that its presence would be masked in all the other complexes by zero-field splitting effects, whose energies are comparable to, or even larger in magnitude than, those involved in exchange-coupling. In particular, it should be noted that the electronic ground state in tetrahedral coordination for Ni^{II} ($^3T_1$) and Fe^{II} ($^5T_2$) is orbitally degenerate (although this degeneracy can be removed by low-symmetry effects) and that the magnetic behaviour of tetrahedral Co^{II} is largely affected by spin-orbit coupling of the low-lying excited $^4T_2$ state and the ground $^4A_1$ one. In this framework the observed deviation from Curie–Weiss behaviour observed at low temperature for these systems should be more likely attributed to single-ion effects than to exchange interactions.[33]

NMR Studies

All the NMR experiments carried out with the ligand H_2L^a and the Zn^{II} and Cd^{II} complexes **5** and **6** were recorded with $CDCl_3$ as solvent. The NMR studies with the ligand H_2L^b and the Zn^{II} complex **7** were recorded in [D_6]-DMSO. Assignment of the signals was based on previous results[15,19,24] and on the available literature.[17,34] A comparison between the spectra of the free ligand and those of their respective complexes highlights some interesting features. The NH protons (H_a in Scheme 1) present in the free ligands disappear in the spectra of the complexes, in agreement with the deprotonation of the sulfonamide groups, and the imine hydrogen atoms (H_i) show a shift to higher field for the three complexes (ca. 0.15 ppm), thus demonstrating the coordination of the imine groups to the metal centre. Moreover, the imine protons of the cadmium complex **6** are flanked by satellites arising from spin-spin coupling to $^{111/113}Cd$, suggesting that the complex is kinetically inert on the NMR timescale. The FAB and ESI mass spectra of **5** and **6** suggest the existence of dinuclear $[M(L^a) + H]_2$ species in solution. In addition, their room temperature ^1H NMR spectra in chloroform reveal single sharp sets of proton resonances, indicating the existence of just one species in solution for both complexes. The non-diastereotopic CH_2 protons of the spacer (H_l) of the ligand H_2L^a permitted us to identify their nature. In a dihelical structure, these two protons will be equivalent and a singlet must therefore be observed: in both spectra, a single set of resonance signals are detected, and there is no evidence of the pair of doublets which is characteristic of the CH_2 group in the non-helical box architecture. Thus, the NMR spectroscopic data lead us to conclude that these solution species must also be neutral dimeric helicates of $[M(L^a)]_2$ stoichiometry. The substitution of the non-diastereotopic CH_2 protons by an oxygen in H_2L^b makes it impossible to prove whether the dihelical nature of the [2+2] species of **7** is present in solution.

UV/Vis Absorption and Fluorescence Emission Studies

Absorption and fluorescence data recorded for the ligand and its metal complexes are reported in Table 1. The UV/Vis absorption spectrum of H_2L^a, in acetonitrile solution, exhibits three strong bands (244, 328 and 342 nm). Coordination to M^{II} ions leads to a substantial variation of the absorption spectra. In particular, a new band appears with a maximum in the 370–390 nm range. Unfortunately, all attempts to record the UV/Vis absorption spectra of the manganese(II) and iron(II) derivatives with H_2L^a were unsuccessful because of their poor stability in solution.

Table 1. Absorption and fluorescence data recorded in CH_3CN.

Compound	λ [nm]	ε [$M^{-1}\,cm^{-1}$]	λ_{em} [nm]	Φ
H_2L[a]	244 328 342	49200 26400 26100	475	$<10^{-3}$
3	244 302 384	84800 47300 28700	–	–
4	246 292 388	154900 63500 41400	–	–

[a] UV/Vis spectra recorded in DMSO.

Fluorescence emission studies in acetonitrile solution show that H_2L^a has a residual luminescence at about 475 nm ($\Phi < 0.001$). The chelation of metal ions to $(L^a)^{2-}$ induces an enhancement of the fluorescence emission (CHEF effect), which is significantly more pronounced for zinc(II), as indicated by the quantum yields values determined for both complexes in acetonitrile ($\Phi = 0.03$ and 0.01 for Zn^{II} and Cd^{II}, respectively). Complex **5** displays a single exponential fluorescence decay at 473 nm, with a lifetime of $\tau = 1.75 \pm 0.03$ ns. The fluorescence lifetime of **6** could not be measured because it is shorter than the response time of our equipment ($\tau < 1$ ns). Moreover, the excitation spectrum of **5** ($\lambda_{em} = 473$ nm) is coincident with the absorption spectrum. Finally, it must be noted that complex **5** does not exhibit triplet emission at low temperature.

Although the origin of the luminescence[15,19] displayed by these compounds remains unknown we have recently proposed that the fluorescence active unit of similar tosylimine derivatives is located on the 2-tosylaminobenzaldehyde residue, since this exhibits an intense luminescence at

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

about 498 nm in CH_3CN solution. These new data confirm the important role that the spacer group of this family of tosylimine ligands plays on their fluorescence properties: 4,4′-methylenedianiline, (1*R*,2*R*)-diaminocyclohexane and 1,3-diamino-2-propanol spacers quench the luminescence of the 2-tosylaminobenzaldehyde residue effectively, whereas other spacers such as 1,2-diaminoethane or 1,3-diaminopropane do not prevent the fluorescence emission of their corresponding free ligands.

The relative stability of **5** and **6** was studied by spectrophotometric and spectrofluorimetric experiments. Trifluoroacetic acid (TFA) was added to an acetonitrile solution of these complexes in order to test their behaviour in acidic media. No aqueous solvents were used due to the low solubility of **5** and **6** in these media. For both complexes, the addition of an excess of TFA makes the absorption spectra to become superimposable on that of the free ligand. Such evidence suggests that a demetallation reaction takes place with a protonation of the $(L^a)^{2-}$ species. The titration profiles indicate that the demetallation is complete after addition of about 5 equiv. of TFA for the Zn^{II} complex and about 1 equiv. for the Cd^{II} complex. Therefore, the zinc complex appears to show a higher stability towards acidis. In addition, the formation of only one isosbestic point in the UV/Vis spectra of **5** and **6** during the addition of TFA suggests the existence of only two species in solution: the corresponding complex and the free ligand. Figure 8 shows the variation of the UV/Vis absorption spectra of **5** upon the addition of a standard acetonitrile solution of TFA.

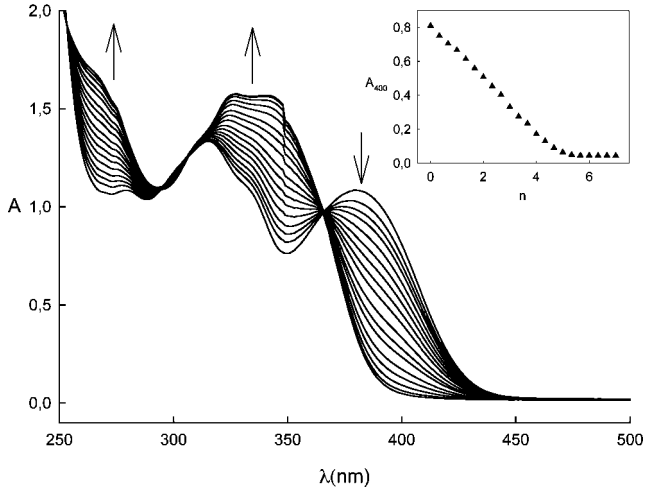

Figure 8. Spectrophotometric titration of an acetonitrile solution of **5** (3×10^{-5} M) with a standard solution of TFA. Inset: absorption intensity at 400 nm (A_{400}) vs. equiv. of TFA (n).

Similar results were obtained by fluorescence measurements. Figure 9 shows the variation of the emission spectra of **5** upon the addition of a standard acetonitrile solution of TFA. The successive addition of acid leads to a progressive decrease of the fluorescence intensity at 473 nm, which, at the end of the titration (after approx. 5 equiv. of TFA), results in a residual emission ($\Phi < 10^{-3}$) characteristic of the free ligand. In the case of the cadmium(II) complex the fluorescence at 476 nm ($\Phi = 0.01$) is completely quenched after the addition of about 1 equiv. of TFA. These data are consistent with the demetallation reaction mentioned above.

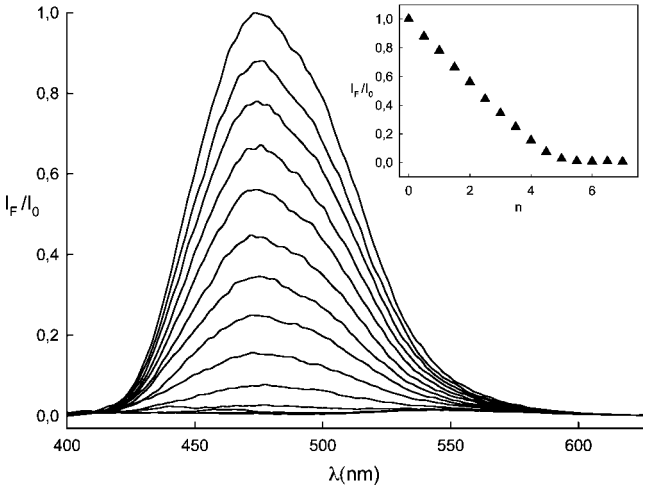

Figure 9. Spectrofluorimetric titration (λ_{exc} = 366 nm) of an acetonitrile solution of **5** (3×10^{-5} M) with a standard solution of TFA. On acid addition, the emission band at 473 nm decreases and the green fluorescence is quenched. Inset: fluorescence intensity at 473 nm (I_F/I_0) vs. equiv. of TFA (n).

Conclusions

In this work we have confirmed the capability of the N_4 Schiff-base ligands *N*,*N*′-bis(2-tosylaminobenzylidene)-4,4′-methylenedianiline (H_2L^a) and *N*,*N*′-bis(2-tosylaminobenzylidene)-4,4′-oxodianiline (H_2L^b) to support the aggregation of discrete helicates into higher supramolecular assemblies through intermolecular non-covalent aromatic interactions. The ligand H_2L^b is more rigid than H_2L^a due to the substitution of the CH_2 group in the spacer by an oxygen atom. The molecular structure of the zinc(II) dihelicate with H_2L^a shows that the discrete complexes aggregate to form discrete prismatic moieties of three molecules held together by π–π and σ–π interactions. The resulting nanoscale structure is a supramolecular assembly of six Zn^{II} ions and six ligands. The volume of the nanoscale triangular prism defined by the six Zn^{II} ions is 598 Å^3. The Zn^{II} complex with H_2L^b forms a polymeric 3D framework in the solid state due to π-stacking interactions between the aniline moieties of discrete dihelicates. Taking into consideration these two structures and those of the previously reported Cu^{II} dihelicate with the ligand H_2L^a,[18] we suggest that an increment of the "rigidity" in any of the building blocks that form this class of neutral dihelicates (aniline ligands and metal centres) definitively favours the self-aggregation of the complexes into 3D polymeric frameworks rather than discrete assemblies.

In addition, the ligand H_2L^a and its diamagnetic Zn^{II} and Cd^{II} complexes have been studied by NMR, spectrophotometric and spectrofluorimetric techniques, leading to

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

an understanding of their formation mechanism as well as their structure in solution. Fluorescence studies also confirmed the emissive properties of the tosylaminobenzylidene moiety and the important role that the spacer group of this family of tosylimine ligands plays in this sense. The 4,4′-methylenedianiline spacer avoids luminescence of the 2-tosylaminobenzylidene residue, and only the chelation of Zn^{II} to $(L^a)^{2-}$ involves a significant enhancement of the fluorescence emission (λ_{em} = 473 nm, Φ = 0.03). On the other hand, the Cd^{II} dihelicate displays a low green fluorescence in acetonitrile solution (λ = 476 nm, Φ = 0.01). Finally, it must be noted that the Zn^{II} dihelicate displays a single exponential fluorescence decay at 473 nm, with a lifetime, τ, of 1.75 ± 0.03 ns.

We are currently exploring how to integrate further supramolecular interactions to design more-sophisticated assembly pathways based on multiple recognition events.

Experimental Section

Materials: All the starting materials were purchased from Aldrich and used without further purification. All metals were used as plates, except manganese metal, which was used as pellets. All of them were washed with a dilute solution of hydrochloric acid prior to the electrolysis.

Physical Measurements: Elemental analyses were performed with a Carlo Erba EA 1108 analyzer. The infrared spectra were recorded as KBr pellets with a Bio-Rad FTS 175 spectrophotometer in the range 4000–600 cm^{-1}. Fast atom bombardment (FAB) mass spectra were recorded with a Kratos MS-50 mass spectrometer, employing Xe atoms at 70 keV with *m*-nitrobenzyl alcohol as the matrix. ESI spectra were obtained with an LCQDECA ion-trap mass spectrometer equipped with an electrospray ionisation ion source and controlled by Xcalibur software 1.1 (Thermo-Finnigan). Magnetic susceptibilities of paramagnetic complexes were measured between 2 and 300 K with applied magnetic fields of 0.1 and 1 Tesla using a Cryogenic S600 SQUID magnetometer. Given the expected large anisotropy of Fe^{II}, Co^{II} and Ni^{II} derivatives, they were pressed into pellets to avoid the orientation of polycrystalline powders. Data were corrected for the magnetism of the sample holder, which was determined separately in the same temperature range and field, and the underlying diamagnetism of each sample was estimated from Pascal's constants.[35] The NMR spectra were recorded with a Bruker DPX-250 spectrometer, with $CDCl_3$ and $[D_6]$DMSO as solvents. UV/Vis spectra were recorded with a Varian Cary 100 spectrophotometer; emission and excitation spectra were recorded with a Perkin–Elmer LS-50B luminescence spectrometer. Spectrophotometric and spectrofluorimetric titrations were performed on 10-mL samples of solutions of the complexes (3×10^{-5} M) in CH_3CN, by microaddition of CH_3CN stock solutions of TFA. In each experiment, the overall addition was limited to about 200 μL, so that the volume increment was not significant. The fluorescence decay curves were recorded with an Edinburgh Instruments Model FL 900 time-correlated single-proton counting spectrometer, at the Centro Grandi Strumenti (Università di Pavia). The instrument was operated with a flash lamp filled with H_2 at a pressure of 0.4 atm, with a frequency of 40 kHz and a pulse width of 1.0 ns. The relative fluorescence quantum yields were obtained by the optically diluted method,[36] with dansyl amide (Φ = 0.37 in CH_3CN) as reference.[37]

2-Aminobenzaldehyde (2): 2-Aminobenzyl alcohol (1 g, 8.0 mmol) was dissolved in dry dichloromethane (50 mL) and γ-MnO_2 (0.70 g, 8.0 mmol) was added under argon. The reaction mixture was stirred at room temperature for 24 h. After this, the resulting mixture was filtered through a silica gel bed. The filtrate was concentrated under reduced pressure to leave an oily residue. The residue was then passed through a short silica gel column (silica gel, hexane/ethyl acetate, 5:1) to afford the pure aldehyde **2**.[20] Yield: 0.861 g (90%). FAB MS: *m*/*z* = 122.1 [M^+ + H]. C_7H_7NO: calcd. C 69.4, H 5.8, N 11.6; found C 69.3, H 5.9, N 11.6.

2-Tosylaminobenzaldehyde (3): Aldehyde **2** (0.86 g, 7.10 mmol) was dissolved in dry dichloromethane (50 mL) and tosyl chloride (1.36 g, 7.10 mmol) and triethylamine (5.0 mL, 35.5 mmol) were added under argon. The reaction mixture was heated at reflux temperature for 8 h. After this, the resulting mixture was filtered through a thin Celite bed. The solution was then treated with acid water (pH = 4–5, 3 × 100 mL) and the organic solution dried with Na_2SO_4. The solvent and the excess of triethylamine were removed in vacuo and the residue was recrystallised from chloroform.[19,21] Yield: 1.487 g (75%). FAB MS: *m*/*z* = 276.1 [M^+ + H]. $C_{14}H_{13}NO_3S$: calcd. C 61.1, H 4.7, N 5.1, S 11.6; found C 69.3, H 4.6, N 5.1, S 11.7.

***N*,*N*′-Bis(2-tosylaminobenzylidene)-4,4′-methylenedianiline (H_2L^a):** 4,4′-Methylenedianiline (0.50 g, 2.54 mmol) was added to a chloroform solution (150 mL) of **3** (1.40 g, 5.08 mmol). This mixture was heated (70 °C) and the volume of the solution was reduced to about 30 mL over period of 3 h in a Dean–Stark trap. The resulting solution was filtered and then concentrated. The orange powdery solid was collected by filtration, washed with diethyl ether (25 mL), and dried in vacuo. Yield: 1.501 g (80%). FAB MS: *m*/*z* = 713.1 [M^+ + H]. $C_{41}H_{36}N_4O_4S_2$: calcd. C 69.1, H 5.1, N 7.8, S 9.0; found C 69.1, H 5.2, N 7.9, S 8.9. IR (KBr): $\tilde{\nu}$ = 1621 $\nu_{C=N}$, 1337 ν_{C-N}, 1287 ν_{asSO_2}, 1156 ν_{sSO_2} cm^{-1}. ^1H NMR (250 MHz, $CDCl_3$, 25 °C): δ = 12.98 (s, 2 H, H_a), 8.48 (s, 2 H, H_i), 7.73 (d, ^3J = 8.1 Hz, 4 H, H_d), 7.66 (d, ^3J = 7.8 Hz, 2 H, H_e), 7.37–7.15 (m, 16 H, $H_{c,f,h,j,k}$), 7.05 (t, ^3J = 7.8 Hz, 2 H, H_g), 4.04 (s, 2 H, H_l), 2.32 (s, 6 H, H_b) ppm. UV/Vis (CH_3CN): λ_{max} (ε) = 244 (49200 $M^{-1}cm^{-1}$), 328 (26400), 342 (26100) nm. Fluorescence (CH_3CN): λ = 475 ($\Phi < 10^{-3}$) nm.

***N*,*N*′-Bis(2-tosylaminobenzylidene)-4,4′-oxodianiline (H_2L^b):** 4,4′-Oxodianiline (0.30 g, 1.50 mmol) was added to a chloroform solution (150 mL) of **3** (0.82 g, 3.00 mmol). This mixture was heated (70 °C) and the volume of the solution was reduced to about 30 mL over period of 6 h in a Dean–Stark trap. The resulting solution was filtered and then concentrated. The obtained powdery solid was collected by filtration, washed with diethyl ether (30 mL), and dried in vacuo. Yield: 1.02 g (95%). FAB MS: *m*/*z* = 715.1 [M^+ + H]. $C_{40}H_{34}N_4O_5S_2$: calcd. C 67.14, H 4.76, N 7.83, S 8.95; found C 66.37, H 4.80, N 7.92, S 8.63. IR (KBr): $\tilde{\nu}$ = 3439 ν_{N-H}, 1617 $\nu_{C=N}$, 1340 ν_{C-N}, 1289 ν_{asSO_2}, 1157 ν_{sSO_2} cm^{-1}. ^1H NMR (250 MHz, $[D_6]$-DMSO, 25 °C): δ = 12.62 (s, 2 H, H_a), 8.80 (s, 2 H, H_i), 7.76 (d, ^3J = 8.2 Hz, 2 H, H_e), 7.70 (d, ^3J = 8.2 Hz, 4 H, H_d), 7.44 (m, 8 H, $H_{h,f,k}$), 7.33 (d, ^3J = 8.2 Hz, 4 H, H_c), 7.20 (m, 6 H, $H_{f,j}$), 2.31(s, 6 H, H_b) ppm.

Metal Complexes: The neutral metal complexes $[Mn(L^a)]_2 \cdot CH_3CN$ (**1**), $[Fe(L^a)]_2 \cdot (CH_3CN)_2$ (**2**), $[Co(L^a)]_2 \cdot CH_3CN$ (**3**), $[Ni(L^a)]_2$ (**4**), $[Zn(L^a)]_2 \cdot CH_3CN$ (**5**), $[Cd(L^a)]_2$ (**6**) and $[Zn(L^b)]_2 \cdot (H_2O)_4$ (**7**) were obtained using an electrochemical procedure.[19] An acetonitrile solution of the corresponding ligand (H_2L^a or H_2L^b) containing tetraethylammonium perchlorate as supporting electrolyte was electrolyzed using a platinum wire as the cathode and a metal plate as the anode. The cell can be summarised as Pt(–)$|H_2L^{a,b}$ + MeCN|M(+), where M stands for the metal. The synthesis method is similar for all the metals except in the cases of manganese(II) and

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

iron(II) complexes. These two compounds were prepared in a closed cell under argon. The synthesis is typified by the preparation of **5**: A suspension (0.1 g, 0.14 mmol) of H_2L^a in acetonitrile (80 mL), containing 10 mg of tetraethylammonium perchlorate, was electrolysed for 1.5 h, using a zinc plate as anode, with a current of 10 mA. (***Caution:*** Although no problem was encountered in this work, all perchlorate salts are potentially explosive and should therefore be handled with the appropriate care!) Concentration of the resulting yellow solution to a third of its initial volume yielded a yellow solid that was washed with diethyl ether and dried under vacuum. All metal complexes were obtained with high purity and yield. Crystallisation from acetonitrile produced crystals of **5**. Unfortunately, all attempts to crystallise the other complexes were unsuccessful.

$[Mn(L^a)]_2\cdot CH_3CN$ (1): Yield: 0.081 g (84%). MS FAB: *m*/*z* = 1532.4 $[Mn_2(L^a)_2 + H]^+$. ESI MS: *m*/*z* = 1531.6 $[Mn_2(L^a)_2 + H]^+$. $C_{84}H_{71}Mn_2N_9O_8S_4$: calcd. Crystallographic Measurements: The structure determinations of **5** and $[Zn(L^b)]_2\cdot CH_3CN$ were performed at room temperature with a Siemens CCD diffractometer, using graphite-monochromated Mo-K_α radiation from a fine focus sealed tube source. Intensities were corrected for absorption (SADABS). The structures were successfully solved by direct methods (SIR97),[38b] which gave the positions of most of the non-hydrogen atoms. Remaining atoms were identified by successive Fourier difference syntheses. Refinements were carried out on F^2 by full-matrix least-square techniques using SHELXL-97.[38a] Hydrogen atoms were added in calculated positions assuming idealised bond geometries.

Synthesis, Structural Characterization, and Density Functional Study of Homo- and Heteropolyhalide Complexes of Cu^{II} with Dien and Dpta Ligands: Crystal Structure of [Bis(3-aminopropyl)amine](bromo)(diiodobromo)copper(II)

Aikaterini T. Chaviara,[a] Athanasios C. Tsipis,*[b] Philip J. Cox,[c] and Christos A. Bolos*[a]

Keywords: Copper / Density functional calculations / Halides / N ligands

Polyhalide mononuclear $[CuX(L)(XY_2)]$ and dinuclear $[\{CuX(L)\}_2(\mu\text{-}XY_2X)]$ Cu^{II} complexes [L = diethylenetriamine (dien) or dipropylenetriamine (dpta); X = Cl, Br and Y = Br, I] have been obtained by treating the precursor $[CuX_2(L)]$ complexes with Br_2 or I_2 in 1:1 and 2:1 molar ratios. The new homo- and heteropolyhalide Cu^{II} complexes, either mononuclear or dinuclear, were predicted to be five-coordinate Cu^{II} complexes exhibiting a distorted square-pyramidal configuration. DFT calculations at the B3LYP level of theory provided a satisfactory description of the structures of all complexes, while the distorted square-pyramidal structure of a representative complex, namely $[CuBr(dpta)(BrI_2)]$, was further substantiated by a single-crystal X-ray diffraction study. In the square-pyramidal structure of $[CuBr(dpta)(BrI_2)]$, the basal plane of the pyramid involves three Cu–N contacts [1.990(7), 2.065(7), and 1.989(7) Å] from dpta and the Br(1) atom, while Br(2), which participates in the formation of the terminal $[BrI_2]^-$ ligand, occupies the apical position. The Cu–Br(1) and Cu–Br(2) bond lengths were found to be 2.5797(14) Å (terminal) and 2.735(14) Å (bridging), respectively, while the Br1–Cu–Br2 bond angle is 98.83(5)°. The terminal $[BrI_2]^-$ ligand is almost linear [Br–I–I bond angle of 174.48(3)°]. DFT calculations, spectroscopic measurements, including far-IR and EPR studies, and magnetic measurements of the dinuclear complexes predict that the bridging tetrahalide XY_2X moiety adopts a linear configuration as well. The bonding, electronic, and related properties of the complexes are also discussed in the framework of density functional theory.

Introduction

Polyhalides are an interesting class of complex materials, which have drawn the attention of synthetic, theoretical, and applied scientists for many years. The tendency of the heavier halogens, particularly iodine, to form stable polyhalide anions $[X_mY_nZ_p]^-$, (X, Y and Z are identical or different halogen atoms; $m + n + p$ is an odd number that can be 3, 5, 7 or 9) or $[X_4]^{2-}$ dianions of variable stoichiometry has been studied thoroughly.[1–3] The formation of a particular polyhalide species depends not only on the specific halogen (X = I, Br, Cl) but also on the bulkiness and polarizability of the cation, the relative concentrations of the components, and, in some cases, on the synthetic route used.[4] The homo- and heterotrihalide anions $[X_3]^-$ and $[X_2Y]^-$ may be considered as donor–acceptor adducts resulting from the addition of a halide anion (Lewis base) to a halogen or interhalogen molecule (Lewis acids).[5] The bonding in the $[X_3]^-$ species can be described by delocalized three-center four-electron (3c-4e) interactions or, alternatively, by a σ-dative $X \rightarrow X_2$ donor–acceptor interaction.[6] The polyhalide species have found a wealth of applications as useful optical materials,[7] superconducting polymers,[8] electric and magnetic materials,[9] oxidizing[10] or halogenating reagents,[11] recyclable oxidizing reagents,[12] or recyclable reagents for the selective iodination of amines and phenols.[13] The halide ions can be used for the halogenation of organic substrates, thus giving products that are important as potent antitumor, antifungal, antibacterial, antineoplastic, anti-inflammatory, and antiviral agents.[14] Polyhalides are generally prepared[5] by the reaction of an ionic halide with the appropriate halogen under conditions specified by the relevant reactivity of the reactants and products through an ion–dipole interaction. The two reacting species can be combined by direct exposure of the halide to the gaseous halogen, by mixing in an appropriate solvent, by in situ reaction following the production of the interhalogen compound, and finally by the exchange reaction of halogens of different atomic number. The product's stability is governed by the size and the polarizability of the specific halogen atoms.

Although a vast number of polyiodide compounds of univalent cations (Cs^+, K^+, Na^+, NR_4^+) have been pre-

pared, the synthetic attempts to synthesize polyhalide coordination compounds of transition metals are limited. In this work we report on the synthesis, structural characterization, electronic structure, and bonding of novel Cu^{II} polyhalide complexes obtained by the reaction of the $[Cu(dien)X_2]$ and $[Cu(dpta)X_2]$ complexes with iodine and bromine. The study of the new halometalate derivatives provides further structural information about different linking motifs of halogen-rich compounds.

Results and Discussion

Synthesis

Mononuclear copper(II) trihalide complexes of the general formula $[CuX(L)(XY_2)]$ and the tetrahalide-bridged dicopper(II) loose associations formulated as $[\{CuX(L)\}_2(\mu\text{-}XY_2X)]$ (L = dien, dpta; X = Cl, Br; Y = Br, I) were prepared by treating the precursor $[CuX_2(L)]$ (L = dien, dpta; X = Cl, Br) complexes with Br_2 or I_2 in 1:1 or 2:1 molar ratios, respectively. The precursor $[CuX_2(L)]$ (X = Br, L = dien, **1**;X = Cl, L = dien, **2**; X = Br, L = dpta, **3**; X = Cl, L = dpta, **4**) complexes undergo ligand dissociation in methanol solution to afford the cation $[CuX(L)]^+$ (L = dien, dpta) and X^- anions. The halide anions formed serve as the nucleophilic active center, thus fulfilling one of the highly desirable criteria of such specific addition reactions. The Cu^{II} polyhalide complexes isolated are deeply colored brown or green, crystalline or amorphous powders that are stable at low temperatures.

Structural Characterization

The new compounds were characterized by elemental analysis (C, H, N, Cu) and spectroscopic (IR, UV/Vis), magnetic, and molar conductivity measurements. Moreover, equilibrium structures of all the complexes studied were determined by electronic structure calculation methods at the B3LYP/LANL2DZ level of theory. Furthermore, the crystal structure of the representative mononuclear complex $[CuBr(dpta)(BrI_2)]$ (**5**) was determined by X-ray crystallography.

Vibrational Spectra

The infrared and far-infrared spectra of the compounds, recorded in the ranges 4000–250 cm^{-1} and 400–100 cm^{-1}, respectively, show all the expected strong bands of the coordinated dien and dpta ligands, which confirms the tridentate[15,16] bonding mode of their coordination to the Cu^{II} centers. The peaks at 255–311 cm^{-1} and 223–311 cm^{-1} are typical of copper halides and are attributed to the ν(Cu–Cl) and ν(Cu–Br) stretching vibrations, respectively, of the terminal halide ligands.[17] The computed unscaled harmonic vibrational frequencies of $[CuX(L)(XY_2)]$ (X = Br, Y = I, L = dien, **5**; X = Cl, Y = Br, L = dpta, **6**; X = Br, Y = Br, L = dien, **7**) and $[\{CuX(L)\}_2(\mu\text{-}XY_2X)]$ (X = Cl, Y = Br, L = dien, **8**; X = Cl, I; L = dpta; **9**, X = Br Y = Br, L = dpta, **10**; X = Br, Y = I, L = dien, **11**), due to ν(Cu–Cl) and ν(Cu–Br) stretching vibrations are found in the regions 220–245 and 170–190 cm^{-1}, respectively. The normal vibrational modes of the polyhalide moieties in **5**–**11** appear in the far-IR region of the spectra as two strong bands located at around 158 and 188 cm^{-1} for the mononuclear complexes and as a weak and very broad band at 123–182 cm^{-1} for the dinuclear ones. The weak, broad band due to the bridging $[X–Y–Y–X]^{2-}$ polyhalide unit, which corresponds to an IR-inactive normal mode, is indicative of the linearity of the tetrahalide bridge; this was further corroborated by the DFT calculations of the equilibrium geometries of the respective compounds. The computed far-infrared harmonic vibrational frequencies due to the stretching and bending vibrational normal modes of the polyhalide moieties, along with their assignments, are compiled in Table 1. Notice that the computed bending modes of the polyhalide moieties in **5**–**11** occur in the same region as $\delta(IBr_2)$ and $\delta(I_3Br)$ of the $[I_3Br_4]^-$ anion in the $[PPh_4][I_3Br_4]$ molecule (72–97 cm^{-1}).[18]

Electronic Spectra

The electronic absorption spectra of the complexes in DMF solution and in the solid state (Nujol mulls) exhibit

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

two or three absorption bands in the ultraviolet and in the visible region of the spectra. To help assignment of the bands and evaluate the properties of the excited states of the Cu^{II} polyhalide complexes, TD-DFT calculations were employed for the precursor complexes **1**–**4** and the mononuclear complexes **5**–**7** in their doublet ground states. Because of the large size of the dinuclear complexes in their triplet ground states, all attempts to compute their principal singlet–singlet electronic transitions were unsuccessful with the computational resources available. The TD-DFT principal singlet–singlet electronic transitions, excitation energies, and oscillator strengths of the mononuclear polyhalide complexes and their precursors are compiled in Table 2.

The computed electronic transitions of the polyhalide Cu^{II} complexes are in excellent agreement with the experimental ones. Thus, all polyhalide complexes exhibit an intense band in the UV region of the spectra at about 360 nm and a broad band in the visible region at 588–645 nm. According to the TD-DFT calculations the high mixing of excited configurations due to the low symmetry of the complexes does not allow us to classify the calculated transitions into the well-known intraligand (LL) or interligand (LL′), ligand-to-metal (LMCT) or metal-to-ligand (MLCT), and ligand field (LF) transitions. The absorption bands arise from electronic transitions between highly delocalized MOs resulting from the mixing of excited configurations having large coefficients in the CI wavefunctions. To intuitively understand the absorption processes, representative density diagrams of the participating MOs for the mononuclear complex **5** are depicted in Figure 1.

For the mononuclear precursor dihalide complexes **1**–**4** the absorption bands in the region of 200–300 nm could be classified as LMCT bands resulting from a combination of dipole-allowed X→Cu and L→Cu (X = Cl, Br; L = dien, dpta) excitations. On the other hand, the absorption bands in the region 300–600 nm correspond to a combination of ligand-field *d*→*d* and X→Cu LMCT transitions. The interligand nature of the LLCT transitions occurring between different ligands of the complexes is worthy of note (Figure 1).

Table 2. Principal electronic transitions, wavelengths (λ), and oscillator strengths (f) for the mononuclear [Cu(L)(X_2)] and [CuX(L)(XY_2)] (L = dien, dpta; X = Cl, Br and Y = Br, I) complexes computed at the B3LYP/LANL2DZ level of theory.

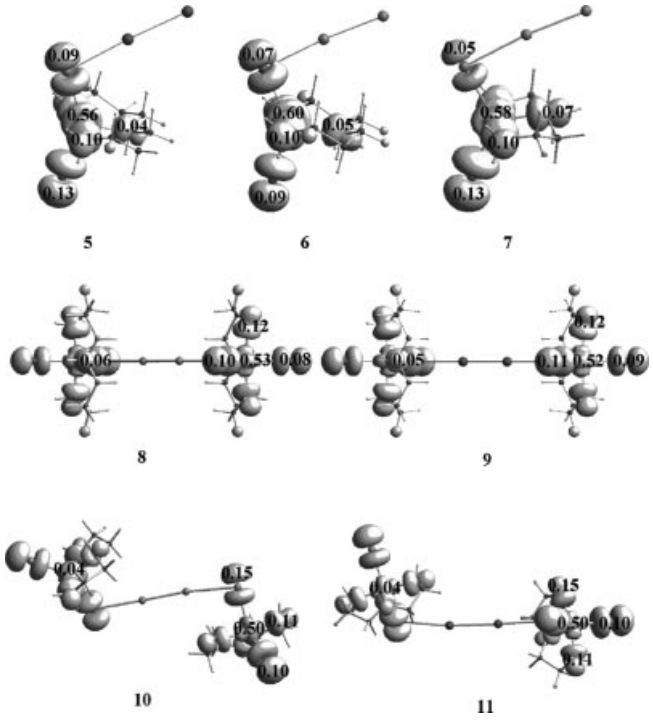
Magnetic Moments, Spin Densities, and Conductivity Measurements

The mononuclear and dinuclear structures of the polyhalide complexes exhibit normal μ_{eff} values per Cu^{II} in the range 1.65–2.19 BM. The room temperature μ_{eff} values of the dinuclear complexes are indicative of a triplet ground state, which was further corroborated by the DFT calculations, as will be discussed later on. In effect, the μ_{eff} values of the complexes are consistent with the computed spin-density distribution. The total spin-density surfaces (SDS) of the polyhalide complexes, along with the numerical values of the spin density at each atom, are displayed in Scheme 1.



Scheme 1.

It can be seen that the spin density is mainly localized on the central Cu^{II} atoms and the N donor atoms of the dien or dpta ligands. In the dinuclear complexes the spin density distribution follows a similar pattern, but with the spin density localized on the Cu^{II} central atoms being slightly lower, in line with the lower μ_{eff} values of the dinuclear complexes. It is important to note that no spin density is delocalized onto the incoming halogen to form the terminal trihalide or the bridging tetrahalide ligands. Moreover, the computed $<S^2>$ values of 0.754 and 2.005 for the mononuclear and dinuclear complexes, respectively, indicate minimal artificial spin contamination in the calculations.

The molar conductivity measurements of the mononuclear complexes in DMF solution illustrate their essentially 1:1 electrolytic character.[19] As far as the dinuclear complexes are concerned, their $\Lambda\mu$ values are generally slightly higher than those of the mononuclear species, but within the 1:1 range, the only exception being complex **10**, the $\Lambda\mu$ value of which (147 $\mu S\,cm^{-1}$) indicates 2:1 dissociation. The easy dissociation of the dinuclear complexes to mononuclear [$CuX(L)(XY_2)$] ones and the [$CuX_2(L)$] precursors did not allow us, despite many attempts, to isolate crystals suitable for an X-ray diffraction study of their molecular structures. In light of this, the dinuclear complexes can be considered as loose associations between the mononuclear

N(3A)–Cu(1A)–Br(2A)	103.4(2)	Br(1A)–Cu(1A)-Br(2A)	98.83(5)

The gross geometry of complex **5** appears to be that of a distorted square pyramid and is characterized by *trans*-N–Cu–N (162.9°) and N–Cu–Br (170.4°) bond angles that deviate slightly from the ideal value of 180°. In this distorted CuN_3Br_2 square-pyramidal environment, three nitrogen atoms [N(1A), N(2A) and N(3A)] of the dien or dpta ligands and one bromine atom [Br(1A)] lie in the equatorial plane, whereas the axial position is occupied by the bromine atom [Br(2A)] of the trihalide $[BrI_2]^-$ ligand. The copper atoms Cu(1A) and Cu(1B) are displaced by 0.226(4) and 0.210(4) Å from the plane towards the apical Br(2A) and Br(2B), respectively. The N3–Cu–N2, N2–Cu–N1, N3–Cu–Br1, and Br1–Cu–N1 bond angles in the equatorial plane have values of 92.5(3)°, 94.3(3)°, 86.6(2)°, and 84.2(2)°, respectively, which deviate from the ideal value of 90° for a perfect square plane. The three Cu–N bond lengths span the range of 1.989(7) to 2.065(7) Å, and are consistent with those found in square-pyramidal Cu^{II} complexes with nitrogen donor ligands. The Cu–Br(1) bond length [2.5797(14) Å] in the basal plane is, as expected, shorter than that of the axial Cu–Br(2) bond length [2.7351(14) Å]. Note that the axially coordinated Br(2) atom involved in the formation of the trihalide $[BrI_2]^-$ ligand is not perpendicular to the equatorial plane, the relevant N3–Cu–Br2 and Br1–Cu–Br2 bond angles being 103.4° and 98.83°, respectively. The chair conformation adopted by the six-membered chelate ring formed upon coordination of the dpta ligand to the copper(II) central atom is noteworthy. The trihalide $[BrI_2]^-$ ligand coordinated through the bromine donor atom is almost linear; the Br–I–I bond angle (174.48°) compares well with the respective bond angles of the isostructural CsI_3 (176.3°) and CsI_2Br (178.0°) species. The Br–I bond length of 2.9484 Å is slightly longer than the I–I bond length of 2.7619 Å. These data are in line with the relevant structural features of the $[BrI_2]^-$ moiety in CsI_2Br,[20] which exhibits Br–I and I–I bond lengths of 2.906 and 2.777 Å, respectively.

The equilibrium structures of the whole series of mononuclear and dinuclear polyhalide complexes of Cu^{II} were also determined using computational techniques at the DFT level of theory.

EPR Spectra

The EPR spectrum for powdered $[\{CuBr(dien)\}_2(\mu\text{-}Br_4)]$ and $[\{CuBr(dien)\}_2(\mu\text{-}Br_2I_2)]$ samples (Figure 3) are dominated by a broad derivative centered at $g \approx 2$ plus a weaker feature at $g \approx 4$. Linewidth limitations did not allow us to resolve the hyperfine couplings. The feature at $g \approx 4$ is a semi-forbidden $|\Delta m_s| = 2$ transition[21] that is indicative of pairs of interacting Cu^{II} paramagnetic centers. Similar spec-

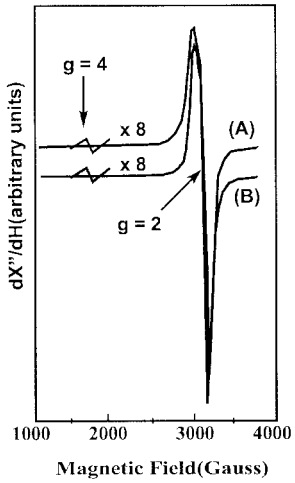

Figure 3. Powder EPR spectrum of powderered [{CuBr(dien)}$_2$(μ-Br_4)] (A) and [{CuBr(dien)}$_2$(μ-Br_2I_2)] (B). Experimental conditions: Temperature: 10.1 K; microwave frequency: 9.42 GHz; modulation amplitude: 10 G peak to peak; microwave power: 32 mW; modulation frequency: 100 kHz. The inset g = 4 signals were recorded using an eightfold larger gain and at 64 mW.

tra have been previously reported for other dinuclear Cu^{II} complexes.[22–24] Accordingly, the present EPR data show that both [{CuBr(dien)}$_2$(μ-Br_4)] and [{CuBr(dien)}$_2$(μ-Br_2I_2)] consist of dinuclear Cu^{II} centers. The details of the lineshape of coupled spin systems depend critically on the relative size of the dipolar and exchange interaction terms, i.e. D and J.[21]

Computational Studies by DFT – Equilibrium Geometry, Electronic Structure, and Bonding Mechanism in Mononuclear Cu^{II} Polyhalide Complexes

The next goal of this work was to determine the details of the electronic structure and, in particular, the nature of the bonding of the polyhalide $[XY_2]^-$ ligand in a series of mononuclear [CuX(L)(XY_2)] (L = dien or dpta; X = Cl, Br and Y = Br, I) compounds and explore the effect of the nature of the halogens on the formation and stability of the polyhalide ligands. Selected geometric, energetic, and electronic parameters for the mononuclear complexes com-

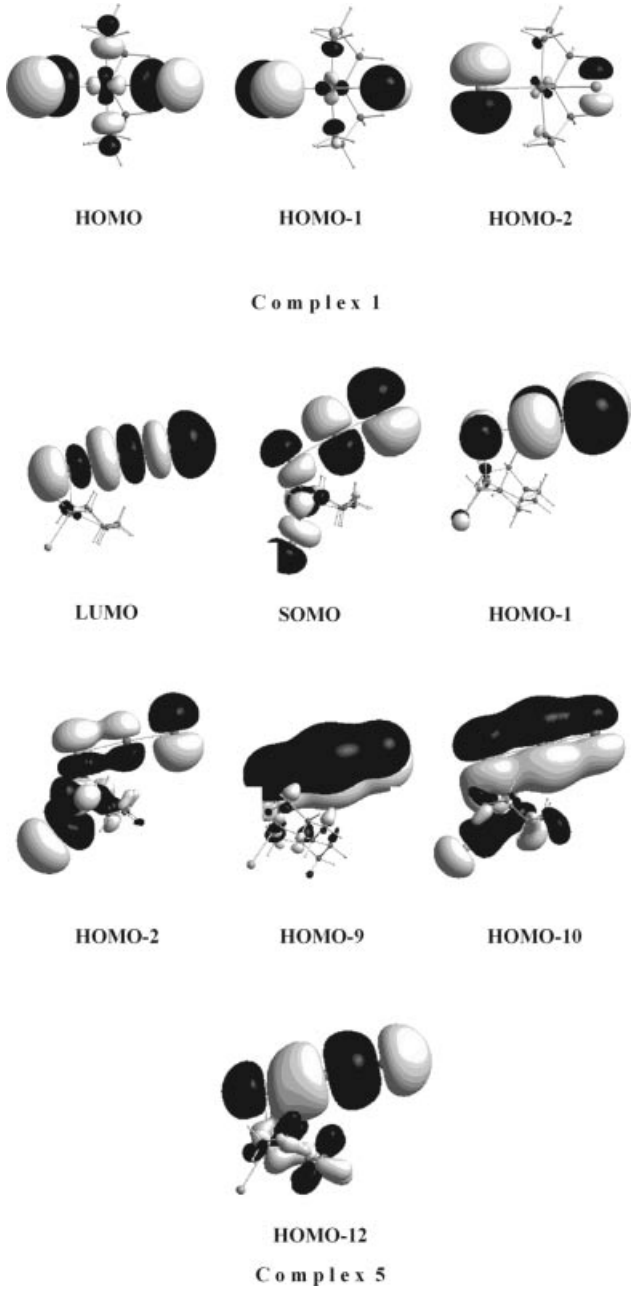
puted at the B3LYP/LANL2DZ level of theory are compiled in Table 5.

It can be seen that the B3LYP/LANL2DZ calculations reproduce well the molecular structure of complex **5** determined by X-ray crystallography. In all mononuclear complexes the trihalide $[XY_2]^-$ ligand adopts an almost linear configuration with the X–Y–Y bond angle ranging from 173.8° up to 176.8°. The $[XY_2]^-$ ligand occupying the axial position in the distorted square pyramidal geometry of the complexes is coordinated to the Cu^{II} central atom in a bent fashion. The computed Cu–X–Y bond angles found in the range of 84.4–107.2° depend on the nature of the halides involved in the formation of the $[XY_2]^-$ ligands. In general terms, the Cu–X–Y bond angles are smaller in the dpta than in the dien complexes.

The association of the incoming Y_2 molecule with the halide X^- ligand to afford the coordinated trihalide $[XY_2]^-$ ligand corresponds to a relatively weak interaction. The association energies, ΔE_1, computed at the B3LYP/LANL2DZ level of theory amount to only 10.6–15.8 kcal mol^{-1} and are comparable to those of hydrogen bonds. However, the trihalide $[XY_2]^-$ ligands interact strongly with the Cu^{II} central atom, the computed Cu–XY_2 bond-dissociation energy, ΔE_2, being 80.5–88.7 kcal mol^{-1}.

Generally, the trihalide $[XY_2]^-$ ligands form slightly stronger coordination bonds in the dien than in the dpta complexes. In both series of complexes the ΔE_2 values follow the trend $[ClBr_2]^- > [ClI_2]^- > [Br_3]^- > [BrI_2]^-$.

Upon association of the Y_2 molecule with the halide X^- ligand there is a charge transfer from the X^- ligand towards the Y_2 molecule, with the transferred electron density mainly localized on the terminal Y atom, which acquires a negative net atomic charge of about –0.20 to –0.24 charge units. The internal Y atom acquires only –0.02 to –0.09 charge units. Moreover, the X atom of the coordinated $[XY_2]^-$ ligands acquires a negative net atomic charge amounting to about –0.27 to –0.45 charge units. Obviously, repulsive electrostatic interactions of the negatively charged X and Y_{int} atoms in the $[XY_2]^-$ ligands do exist, therefore the weak X···Y_{int} interactions could be attributed to covalent interactions. In effect, the X···Y_{int} bonding mechanism could be described as donor–acceptor interactions with the incoming Y–Y molecule acting as acceptor through its σ* LUMO, and the coordinated halide ligand X of the $[CuX(L)(XY_2)]$ mononuclear complex acting as the donor through the HOMO, which is mainly localized on that ligand (Scheme 2). These donor–acceptor interactions give rise to both charge transfer from the donor to the acceptor and weakening of the bonding within the acceptor through partial accumulation of electron density on the antibonding σ* LUMO of the acceptor, which is reflected in the elongation of the Y–Y bond length by 0.099 to 0.148 Å. A thorough search of the molecular orbitals of the trihalide complexes reveals that there are bonding MOs describing the X···Y_{int} interactions. Such MOs, along with the doubly degenerate singly occupied (SOMO) and the lowest unoccupied (LUMO) MOs for a representative complex **5** and its precursor complex **1** are also displayed in Scheme 2.



Scheme 2.

The multicenter bonding interactions in HOMO-9 and HOMO-10 and the antibonding ones in SOMO and HOMO-1 should be noted. The HOMO-9 and HOMO-10 correspond to π MOs constructed from the p_π orbitals of the halogen atoms of the X–Y–Y moiety, while the HOMO-12 is a σ-type MO constructed from the p_σ orbitals of the halogen atoms of the X–Y–Y moiety. The SOMO and HOMO-1 correspond to the antibonding π* counterparts of the π_{XYY} MOs. On the other hand, the LUMO corresponds to a σ* MO resulting from the antibonding interaction of p_σ orbitals of the halogen atoms of the X–Y–Y moiety. The computed bond overlap population (bop) values of the X···Y_{int} bonds (Table 5) illustrate the weak nature of the X···Y_{int} interactions. In general terms, these interactions

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

follow the trend $Br\cdots Br_{int} > Cl\cdots Br_{int} > Br\cdots I_{int} > Cl\cdots I_{int}$, thus suggesting that the strength of the $X\cdots Y_{int}$ interactions increases as the difference of electronegativity of the constituent halogen atoms decreases. Finally, the hardness, η, given by $(\varepsilon_{LUMO} - \varepsilon_{HOMO})/2$, was found to be in the range of 1.41–1.62 eV; it reflects the relative stability of the complexes (Table 5).

Equilibrium Geometry, Electronic Structure, and Bonding Mechanism in Dinuclear Cu^{II} Polyhalide-Bridged Complexes

The dinuclear [{CuX(L)}$_2$(μ-XY$_2$X)] (L = dien, dpta; X = Cl, Br and Y = Br, I) complexes adopt the triplet ground state. The singlet states correspond to local minima in the PES and are 33–37 kcal mol^{-1} higher in energy than the triplet ground states. Selected geometric, energetic, and electronic parameters for the dinuclear complexes computed at the B3LYP/LANL2DZ level of theory are compiled in Table 6.

The two metal centers in the dinuclear complexes exhibit the same stereochemistry, being five coordinate with a distorted square-pyramidal geometry resembling that of the respective precursor [CuX$_2$(L)] complexes. This is indicative of the loose association of the Y$_2$ molecule with the two [CuX$_2$(L)] moieties. The computed dissociation energy of the Y$_2$ molecule from the dinuclear complexes amounts to 15.1–18.3 kcal mol^{-1} at the B3LYP/LANL2DZ level. On the other hand, the dissociation energy of the dinuclear complexes to the [CuX$_2$(L)] and [CuX(L)(XY$_2$)] species was predicted to be only 2.5–4.6 kcal mol^{-1}, thus illustrating that the dinuclear complexes are easily dissociated into the more stable mononuclear [CuX(L)(XY$_2$)] species. The weak X···Y interaction is mirrored by the relatively long X···Y distances (Table 6).

The trihalide [XY$_2$] moiety in all dinuclear complexes is almost linear, with the X–Y–Y bond angle ranging from 174.3° up to 176.8°. However, the Cl–Br–Br–Cl (complex **8**) and Cl–I–I–Cl (complex **9**) bridging units are almost linear, with the torsion angles being about 177°, while the Br–Br–Br–Br (complex **10**) and Br–I–I–Br (complex **11**) bridging units form dihedral angles of 144.9 and –86.5°, respectively. These configuration preferences of the X–Y–Y–X bridging units could be due to electronegativity effects.

The bonding mechanism of the Y$_2$ molecule from each side with the halide X$^-$ ligands of the two mononuclear [CuX$_2$(L)] species corresponds to donor–acceptor interactions giving rise to both a charge transfer from the X$^-$ donor ligands to Y acceptor atoms while the orbital interactions result in the weakening of the Y–Y bond. Both Y atoms acquire a negative net atomic charge of about –0.15 charge units. On the other hand, the elongation of the Y–Y bond length by 0.123 to 0.165 Å is, as expected, higher in the dinuclear than in the mononuclear complexes. A search of the molecular orbitals of the dinuclear complexes reveals that the presence of bonding MOs that describe the X···Y···Y···X interactions. The relevant MOs, along with the doubly degenerate SOMOs and the LUMO for a representative complex (**9**), are displayed in Scheme 3.

Conclusions

In this paper we have reported the synthesis, structural characterization, and DFT study of novel mono- and dinuclear polyhalide Cu^{II} complexes with general formulae [CuX(L)(XY$_2$)] and [{CuX(L)}$_2$(μ-XY$_2$X)] (L = dien or dpta; X = Cl, Br and Y = Br, I). The vibrational spectra confirm the tridentate bonding mode of the dien or dpta ligands to the central Cu^{II} atom and show the characteristic bands related to polyhalide moieties, thus indicating the lin-

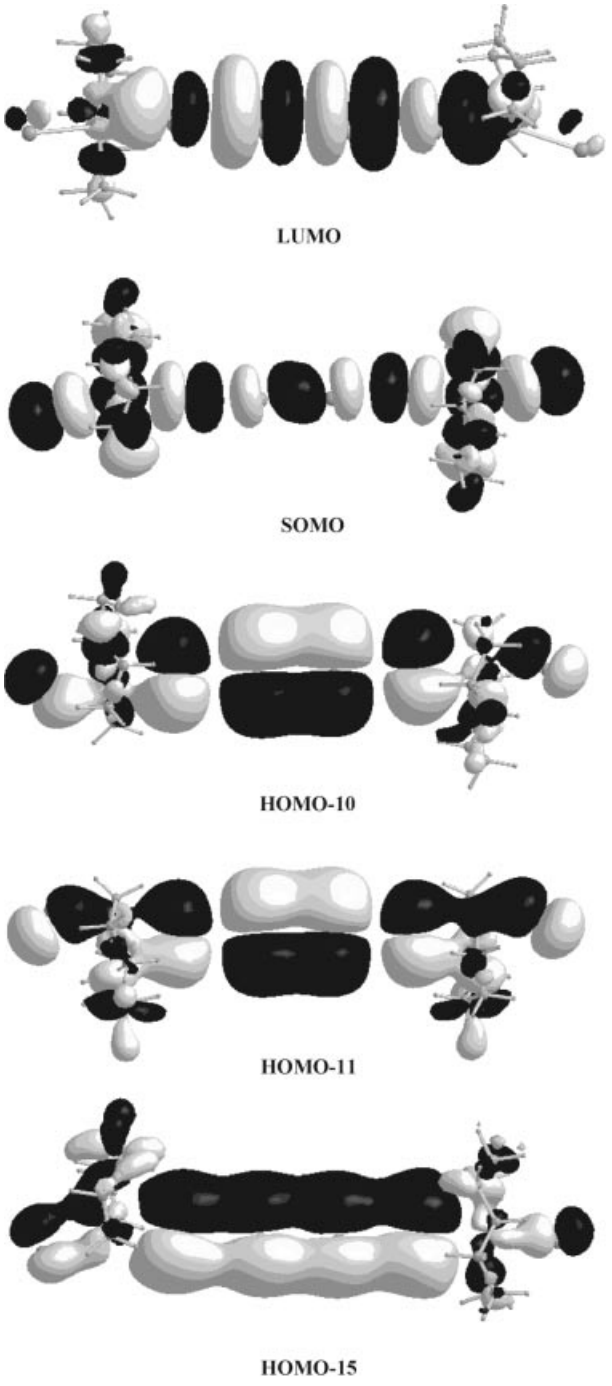

Scheme 3.

earity of the $[X–Y–Y–X]^{2–}$ tetrahalide bridges. According to X-ray data the mononuclear $[CuBr(dpta)(BrI_2)]$ complex adopts a distorted square-pyramidal structure with the apical position occupied by a Br atom that participates in the linear terminal $[BrI_2]^–$ ligand. On the other hand, DFT calculations support a distorted square-pyramidal structure for the $[CuX(L)(XY_2)]$ complexes, in agreement with the experimental findings. The Y_2 molecule in these complexes is weakly bound to the $X^–$ anion, with association energies estimated to be 10.6–15.8 kcal mol$^{–1}$ at the B3LYP/LANL2DZ level. In contrast, the Cu–XY_2 bond-dissociation energies are much larger (80.5–88.7 kcal mol$^{–1}$). The Cu–XY_2 BDEs, which are higher in the dpta than the dien complexes, follow the trend $[ClBr_2]^– > [ClI_2]^– > [Br_3]^– > [BrI_2]^–$.

Both X and Y_{int} atoms in the $[XY_2]^–$ ligand acquire negative charges that give rise to a weak electrostatic interaction. The quite long X···Y_{int} separation distance could be ascribed as a donor–acceptor interaction, with the incoming Y_2 molecule acting as the acceptor through its σ* LUMO and the coordinated $X^–$ ligand being the donor through the HOMO of the $[CuX(L)(XY_2)]$ complex, which is mainly localized on the halide ligands.

The dinuclear $[\{CuX(L)\}_2(\mu\text{-}XY_2X)]$ complexes adopt a triplet ground state while the singlet state corresponds to a local minimum that is about 33–37 kcal mol$^{–1}$ higher in energy. This is corroborated by the μ_{eff} values of the dinuclear complexes, which point to a triplet ground state without any appreciable magnetic interaction. The two metal centers exhibit a distorted square-pyramidal geometry resembling that of the mononuclear $[CuX(L)(XY_2)]$ complexes. The dinuclear $[\{CuX(L)\}_2(\mu\text{-}XY_2X)]$ complexes can easily dissociate into $[CuX(L)(XY_2)]$ and $[CuX_2(L)]$ species due to the very weak X–Y_2 interactions (BDEs are only 2.5–4.6 kcal mol$^{–1}$). The $[XY_2]$ moiety in all dinuclear complexes is almost linear. Finally, the bonding mechanism in the dinuclear $[\{CuX(L)\}_2(\mu\text{-}XY_2X)]$ complexes is described by donor–acceptor interactions which give rise to both charge transfer from the coordinated $X^–$ ligands to the Y_2 moiety at each side and orbital interactions resulting in the elongation of the Y–Y bond, which is greater in the dinuclear than in mononuclear complexes.

Experimental Section

Materials and Instruments: All chemicals were purchased from Aldrich, EDH Chemicals, or Merck and were reagent grade. Carbon, hydrogen, and nitrogen were determined by microanalysis using a Perkin–Elmer 2400 elemental analyser. Copper was determined with a Perkin–Elmer model 403 Atomic Absorption Spectrometer equipped with the appropriate hollow cathode lamps. Molar conductivities were measured with a WTW conductivity bridge employing a calibrated dip-type cell and $10^{–3}$ M solutions in DMF. Magnetic susceptibility measurements on powder samples were performed at room temperature (25 °C) employing the Faraday method with a home-built balance calibrated against $Hg[Co(NCS)_4]$. Diamagnetic corrections were estimated from Pascal's constants. Infrared spectra were obtained by the KBr disc technique and were recorded with a Perkin–Elmer FT-IR Spectrum One spectrometer. Far-infrared spectra (400–100 cm$^{–1}$) were recorded for polyethylene disks with a Bruker 113V Spectrum spectrometer. A 6.25-μm thickness Mylar beam splitter was used for these studies. Electronic spectra in DMF solutions (range 200–1100 nm) and in solid state (Nujol mull, range 400–1100 nm) were measured with a Shimadzu 160A instrument in the range 200–1100 nm. Continuous-wave EPR spectra were recorded at liquid helium temperatures with a Bruker ER 200D X-band spectrometer equipped with an Oxford Instruments cryostat. The microwave frequency and the magnetic field were measured with a microwave frequency counter HP 5350B and a Bruker ER035 M NMR-gaussmeter, respectively.

Computational Details: The structural, electronic, and energetic properties of all compounds were computed with the Becke three-parameter hybrid functional[25,26] combined with the Lee–Yang–Parr correlation functional,[27] abbreviated as B3LYP, using the LANL2DZ basis set[28] that includes Dunning–Huzinaga full double-ζ on the first row and Los Alamos ECPs plus DZ on the copper and halogen atoms. This hybrid B3LYP functional was used since it gives acceptable results for molecular energies and geometries, as well as proton donation, and weak and strong H-bonds.[29–35] No constraints were imposed on the geometry in any of the computations. Full geometry optimization was performed for each structure using Schlegel's analytical gradient method,[36] and the attainment of the energy minimum was verified by calculating the vibrational energy that results in the absence of imaginary eigenvalues. All the stationary points were identified for minimum (number of imaginary frequencies NIMAG = 0) or transition states (NIMAG = 1). Time-dependent density functional theory (TD-DFT)[37–39] calculations were performed on the equilibrium ground state geometries employing the same density functionals and basis sets as used in the geometry optimization. The Davidson algorithm was used, in which the error tolerance in the square of the excitation energies and trial-vector orthonormality criterion were set to 10^{-8} and 10^{-10}, respectively. The success of the TD-DFT method in calculating excitation energies of transition metal complexes has been demonstrated in several recent studies.[40–42] All calculations were performed using the GAUSSIAN03 series of programs.[43] The qualitative concepts and the graphs derived from the Chem3D program suite[44] highlight the basic interactions resulting from the DFT calculations.

Synthesis of the Complexes: The precursors [$CuBr_2$(dien)] (**1**) and [$CuCl_2$(dien)] (**2**) were prepared by literature methods,[45] while the analogous complexes [$CuBr_2$(dpta)] (**3**) and [$CuCl_2$(dpta)] (**4**) were prepared as described below.

[$CuBr_2$(dpta)] (3): dpta (1.41 mL) was added dropwise to a methanolic suspension (ca. 30 mL) containing 2.23 g (10^{-2} mol) of $CuBr_2$. After vigorous stirring for 20 min, a blue precipitate was formed, which was then separated by filtration, washed several times with diethyl ether, and dried in vacuo. Yield: 2.16 g (61%).

[$CuCl_2$(dpta)] (4): The [$CuCl_2$(dpta)] complex, due to its high solubility in methanol, cannot be isolated, therefore the trihalide [CuCl(dpta)($ClBr_2$)] and the tetrahalide [{Cu(dpta)Cl}$_2$(μ-Cl_2I_2)] complexes were prepared in situ.

[CuBr(dpta)(BrI_2)] (5): A methanolic solution (20 mL) of I_2 (1.27 g, 5 mmol) was added dropwise to a methanolic suspension (30 mL) of [$CuBr_2$(dpta)] (1.775 g, 5 mmol). Diethyl ether (10 mL) was added to the resulting dark-green solution, which was further left at low temperature (4 °C) for 24 h, after which the formation of high-quality, dark-green crystals suitable for X-ray diffraction analysis was observed. The crystals formed were isolated by filtration and dried in air. Yield: 1.61 g (53%). $C_6H_{17}Br_2CuI_2N_3$ (608.38): calcd. C 11.84, H 2.82, Cu 10.44, N 6.91; found C 12.00, H 2.83, Cu 10.25, N 6.96. IR: ṽ = 3277 s, 3203 ws, 3126 vs, 504 m, 252 w, 223 cm^{-1} w. Λ_μ (DMF) = 68 μS cm^{-1}. UV/Vis (DMF): λ_{max} (log ε) = 680 nm (2.42); (Nujol): λ_{max} = 740, 451, 410 nm. μ_{eff} = 1.85 μ_B.

[CuCl(dpta)($ClBr_2$)] (6): A methanolic solution containing 1.41 mL of dpta was added to a solution of $CuCl_2 \cdot 2H_2O$ (1.71 g, 10 mmol) in the same solvent. Br_2 (0.55 mL in 10 mL of methanol) was added to the resulting blue solution. After 1 h, the solution was filtered to remove any impurities, ethanol (10 mL) was added to the filtrate, and the brown precipitate was isolated by filtration, washed several times with ethanol and diethyl ether, and dried in vacuo to give red brown microcrystals of **6** (1.19 g, 28%). $C_6H_{17}Br_2Cl_2CuN_3$ (425.38): calcd. C 16.94, H 4.03, Cu 14.93, N 9.88; found C 17.10, H 4.11, Cu 14.80, N 9.85. IR: ṽ = 3260 vs, 3205 vs, 3113 vs, 511 w, 383 w, 326 cm^{-1} w. Λ_μ (DMF) = 75 μS cm^{-1}. UV/Vis (DMF): λ_{max} (log ε) = 720 (1.97), 921 sh, 434 nm sh; (Nujol): λ_{max} = 792, 530 sh, 461 nm sh. μ_{eff} = 1.65 μ_B.

[CuBr(dien)(Br_3)] (7): A methanolic solution (ca. 5 mL) of 0.1 mL of Br_2 was added to another methanolic solution (ca. 20 mL) of [$CuBr_2$(dien)] (0.650 g, 2 mmol). Upon addition, the blue solid turned green. After stirring for 30 min, the solid formed was separated by filtration, washed several times with diethyl ether, and dried in vacuo to give green microcrystals of **7** (0.272 g, 28%). $C_4H_{13}Br_4CuN_3$ (486.33): calcd. C 9.88, H 2.68, Cu 13.06, N 8.64; found C 9.78, H 2.56, Cu 13.20, N 8.57. IR: ṽ = 3290 vs, 3230 vs, 3157 vs, 523 w, 336 w, 315 cm^{-1} w. Λ_μ (DMF) = 82 μS cm^{-1}. UV/Vis (DMF): λ_{max} (log ε) = 618 nm (2.21); (Nujol): λ_{max} = 651, 444, 403 nm sh. μ_{eff} = 2.19 μ_B.

[{CuCl(dien)}$_2$(μ-Cl_2Br_2)] (8): [$CuCl_2$(dien)] (4.75 g, 20 mmol) was dissolved in ca. 30 mL of methanol. After 30 min of vigorous stirring, 0.55 mL of Br_2 in 10 mL of methanol was added and the color of the solution turned from blue to green. The green solid formed was then separated by filtration, washed several times with diethyl ether, and dried in vacuo to give green microcrystals of **8** (4.51 g, 71%). $C_8H_{26}Br_2Cl_4Cu_2N_6$ (635.04): calcd. C 15.13, H 4.13, Cu 20.01, N 13.23; found C 15.23, H 4.20, Cu 19.85, N 13.36. IR: ṽ = 3300 vs, 3244 vs, 3169 vs, 516 w, 383 w, 311 cm^{-1} w. Λ_μ (DMF) = 106 μS cm^{-1}. UV/Vis (DMF): λ_{max} (log ε) = 683 (2.01), 902 nm (1.92); (Nujol): λ_{max} = 684, 449, 404 nm sh. μ_{eff} = 1.89 μ_B.

[{CuCl(dpta)}$_2$(μ-Cl_2I_2)] (9): A methanolic solution of 1.41 mL of dpta was added to a solution of $CuCl_2 \cdot 2H_2O$ (1.71 g, 10 mmol) in 20 mL of methanol. A solution of iodine (1.27 g, 5 mmol) in 20 mL of methanol was added to the resulting blue solution. After 1 h of stirring, the green solution was left to stand and then 10 mL of diethyl ether was added. After 1 h, a microcrystalline dark-green product had formed, which was isolated by filtration, washed twice with 5 mL of diethyl ether and dried in vacuo to give green microcrystals of **9** (2.24 g, 57%). $C_{12}H_{34}Cl_4Cu_2I_2N_6$ (785.15): calcd. C 18.36, H 4.36, Cu 16.19, N 10.70; found C 18.69, H 4.40, Cu 16.01, N 10.56. IR: ṽ = 3250 vs, 3207 vs, 3130 vs, 506 m, 338 w, 255 cm^{-1} w. Λ_μ (DMF) = 88 μS cm^{-1}. UV/Vis (DMF): λ_{max} (log ε) = 647 nm sh; (Nujol): λ_{max} = 783, 460 nm sh. μ_{eff} = 1.76 μ_B.

[{CuBr(dien)}$_2$(μ-Br_4)] (10): A methanolic solution (ca. 5 mL) of 0.15 mL of Br_2 was added to another methanolic solution (ca. 20 mL) of [$CuBr_2$(dien)] (1.63 g, 5 mmol). Upon addition, the blue solid turned dark blue. After stirring for 30 min, the solid formed was separated by filtration, washed several times with diethyl ether, and dried in vacuo to give dark-green microcrystals of **10** (1.04 g, 51%). $C_8H_{26}Br_6Cu_2N_6$ (812.85): calcd. C 11.82, H 3.22, Cu 15.63, N 10.34; found C 11.76, H 3.32, Cu 15.49, N 10.29. IR: ṽ = 3300 vs, 3235 vs, 3125 vs, 518 w, 253 w, 246 cm^{-1} w. Λ_μ (DMF) = 142 μS cm^{-1}. UV/Vis (DMF): λ_{max} (log ε) = 598 (2.55), 941 nm (2.12); (Nujol): λ_{max} = 633 sh, 526, 425 nm sh. μ_{eff} = 2.16 μ_B.

[{CuBr(dien)}$_2$(μ-Br_2I_2)] (11): A methanolic solution (ca. 20 mL) of I_2 (0.254 g, 1 mmol) was added to another methanolic solution (20 mL) of [$CuBr_2$(dien)] (0.65 g, 2 mmol). Upon addition, the blue solid turned brown. After stirring for 30 min, the solid formed was separated by filtration, washed several times with diethyl ether, and dried in vacuo to give black microcrystals of **11** (0.79 g, 88%). $C_8H_{26}Br_4Cu_2I_2N_6$ (906.85): calcd. C 10.60, H 2.89, Cu 14.01, N 9.27; found C 10.686, H 2.97, Cu 14.10, N 9.33. IR: ṽ = 3286 s, 3233 vs, 3161 vs, 516 w, 238 cm^{-1} w. Λ_μ (DMF) = 110 μS cm^{-1}. UV/

Vis (DMF): λ_{max} (log ε) = 617 nm (2.46); (Nujol): λ_{max} = 742, 572, 463, 399 nm. μ_{eff} = 1.99 μ_B.

X-ray Crystallographic Study: X-ray diffraction data were collected with an Enraf–Nonius Kappa CCD area-detector diffractometer. The programs DENZO[46] and COLLECT[47] were used in data collection and cell refinement. Details of data collection and structure refinement are given in Table 7. All crystals produced were twinned such that the data set obtained for a single crystal contained overlapping reflections. After removal of the affected reflections, 51.9% of the data set remained. The structure was solved with the program SIR97[48] and refined with SHELX-97.[49] Molecular plots were obtained with the program ORTEP-3.[50] CCDC-260389 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Table 7. Crystal data and structure refinements for [CuBr(dpta)-(BrI_2)] (**5**).

Empirical formula	$C_6H_{17}Br_2CuI_2N_3$
Formula mass	608.39
Temperature	120(2) K
Wavelength	0.71073 Å
Crystal system	monoclinic
Space group	*C*2/*c*
Unit cell dimensions	a = 26.7159(13) Å, α = 90°
	b = 9.01969(10) Å, β = 96.097(3)°
	c = 25.4078(7) Å, γ = 90°
Volume	6087.9(3) $Å^3$
Z	16
Density (calculated)	2.655 $Mg\,m^{-3}$
Absorption coefficient	10.717 mm^{-1}
F(000)	4464
Crystal size	0.32 × 0.18 × 0.08 mm
θ range for data collection	5.04–27.50°
Index ranges	$-34 \le h \le 34$
	$-11 \le k \le 11$
	$-31 \le l \le 31$
Reflections collected	15827
Independent reflections	3633 [R(int) = 0.0403]
Refinement method	Full-matrix least squares on F^2
Data/restraints/parameters	3633/0/254
Goodness-of-fit on F^2	1.082
Final R indices [$I > 2\sigma(I)$]	R_1 = 0.0350, wR_2 = 0.0802
R indices (all data)	R_1 = 0.0521, wR_2 = 0.0846
Largest difference peak/hole	0.838/–0.955 e $Å^{-3}$

Acknowledgments

The financial support of this work by the Greek General Secretariat for Research and Technology and the European Commission within the framework of the PENED01 projects is gratefully acknowledged (grant no. 01EΔ367). We would like to thank Assistant Professor J. Deligiannakis for providing the EPR data and also the EPSRC X-ray crystallography service at the University of Southampton for collecting the X-ray data.

First Observation of NIR 4f–4f Luminescence through the Energy Transfer from the SOMO π* Doublet in Nitronyl Nitroxide Radical Lanthanide(III) Complexes

Sumio Kaizaki,*[a] Dai Shirotani,[a] Yasunori Tsukahara,[a] and Hiroyasu Nakata[b]

Keywords: Near infrared 4f–4f luminescence / Lanthanide(III) complexes / Nitronyl nitroxide radical / Energy transfer / Antenna effect

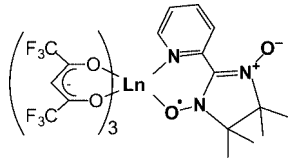
This study demonstrates the first observation of energy transfer from the doublet state of the nitronyl nitroxide radical ligand in Ln^{III} complexes, exerting the light-harvesting antenna effect on the NIR luminescence for the first time.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

With the aim of obtaining low-cost near-infrared (NIR) light sources for communications or sensing and biological applications, there have been a number of investigations concerning lanthanide(III) complexes with aromatic imines or organic dyes where the triplet states and/or ligand-to-metal charge transfer (LMCT) play crucial roles in the energy transfer as photosensitizers exerting antenna effects.[1–3] Lanthanide complexes having nitroxide radical(s) could have intriguing emitting properties with regards to the differences in the spin multiplicity of ligand excited states on going from triplet (organic compounds) to doublet (radicals) states. From magnetic studies on nitroxide radical complexes,[4] Luneau and Reber et al. reported the luminescence spectra of uncoordinated[5] and coordinated nitroxides,[6] where attempts were made to understand the electronic states[5] or to seek qualitative trends between the luminescence and the magnetic interaction.[6] During our endeavor to reveal the magneto-optical properties of metal complexes with nitronyl or imino nitroxide radicals such as NIT2py [4,4,5,5-tetramethyl-2-(2′-pyridyl)-4,5-dihydro-1*H*-imidazol-1-oxyl 3-oxide] or IM2py [4,4,5,5-tetramethyl-2-(2′-pyridyl)-4,5-dihydro-1*H*-imidazol-1-oxyl][7–9] as well as of the Ln^{III}–Cr^{III} dinuclear complexes,[10–11] the emission spectra afforded information on the energy transfer from the nitroxide SOMO π* or the Cr^{III} ^2E state to the 4f state. Therefore, the SOMO π* of the nitroxide radical in lanthanide complexes could be expected to become a potential light harvesting antenna. However, there has been no report on Ln^{III} complexes exhibiting NIR 4f–4f luminescence associated with the SOMO π* of the NIT2py radical ligand to 4f energy transfer.

In this article the NIR luminescence is examined for the $[Ln^{III}(hfac)_3(NIT2py)]$ complex in the solid state (Scheme 1) with regards to energy transfer or the antenna effect.



Scheme 1. Schematic molecular structure of $[Ln(hfac)_3(NIT2py)]$.

Results and Discussion

The employed lanthanide(III) complexes are classified into three groups: (i) non-emissive (Lu^{III}: **1**), (ii) Vis-emissive (Eu^{III}: **2**; Sm^{III}: **3**), (iii) NIR-emissive (Nd^{III}: **4**; Tm^{III}: **5**; Yb^{III}: **6**).

The lanthanide complexes **1–6** show similar UV/Vis band patterns with peaks or shoulders near 550 nm and molar absorption coefficients of $\varepsilon_{max} \approx 350–380$ $mol^{-1}\,dm^3$ and $\varepsilon_{514} \approx 250$ $mol^{-1}\,dm^3$, which are assigned to the intraligand n–π* transition of the NIT2py ligand. Therefore, the photoexcitation conditions are not very different from one another at 541 nm.

The absorption and luminescence spectra of the non-emissive 4f–4f complex (**1**) exhibits a vibronic structure (Figure 1). Since the band contours of the two spectra show a mirror image relationship, the luminescence at 9–15×10^3 cm^{-1} is the intraligand doublet-doublet (D-D) luminescence from only one SOMO π* excited state, in con-

trast to the (NITBzIm)Ln^{III} complexes which were claimed to have two SOMO π* states from the emission spectra.[8]

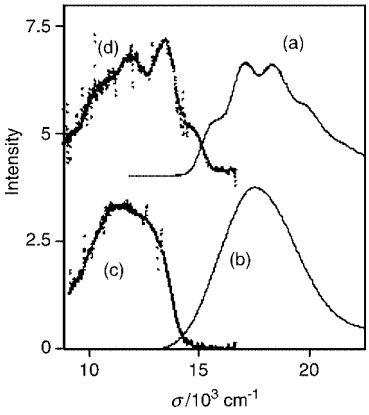

Figure 1. UV/Vis spectra (dotted lines) in CH_2Cl_2 at 180 K and luminescence spectra (solid lines) in the solid state at 180 K of **1** (a) and (d) and NIT2py ligand (b) and (c), respectively.

The Vis-emissive complexes **2** and **3** only demonstrated the intraligand D-D luminescence at 15 K. This results from the energy transfer from the 4f levels to the SOMO π* level, as compared with the cases of [Eu^{III}(hfac)$_3$(IM2py)][7a] and [Eu^{III}(hfac)$_3$(NITBzim or IMBzim)] [hfac = hexafluoroacetylacetonate; NITBzim = 2-(2-benzimidazolyl)-4,4,5,5-tetramethylimidazolin-1-oxyl 3-oxide; IMBzim = 2-(2-benzimidazolyl)-4,4,5,5-tetramethylimidazoline 1-oxide].[6] For [Eu^{III}(hfac)$_3$(IM2py)], the visible 4f–4f luminescence was observed by excitation at 222 nm corresponding to the intraligand hfac transition, but not by excitation at 465 nm corresponding to the intraligand IM2py transition at room temperature; exhibiting the energy transfer from the triplet state of the ancillary hfac ligand.[8a] However, at 5 K the 4f–4f luminescence of the (IM2py)Eu complex was observed by Ar^+ laser excitation.[6b–6d] The present (NIT2py)Eu^{III} complex only gives the intraligand (NIT2py) luminescence, probably due to the lower lying SOMO π* in NIT2py compared with the SOMO π* in IM2py[8a], as shown in Figure 2. On the other hand, the luminescence behavior of [Eu(NITBzim)$_2$(NO$_3$)$_3$] is similar to that of the present NIT2py complex, whereas [Eu(hfac)$_3$(NITBzim or IMBzim)] demonstrates both the intraligand and visible 4f–4f luminescence.[6b–6d] This difference results from the relative location between the SOMO π* band envelope of nitroxide radicals and the emissive 4f energy levels as can be seen in Figure 2.

As shown in Figure 3, the NIR 4f–4f emissive complexes gave typical 4f–4f luminescence at 7490 cm^{-1} ($^4F_{3/2}\rightarrow{}^4I_{13/2}$), 9400 cm^{-1} ($^4F_{3/2}\rightarrow{}^4I_{11/2}$), 11100 cm^{-1} ($^2F_{3/2}\rightarrow{}^4I_{9/2}$) for **4** and 10000 cm^{-1} ($^3H_4\rightarrow{}^3H_6$), 12500 cm^{-1} ($^3F_3\rightarrow{}^3H_6$) for **5** and ca. 10000 cm^{-1} ($^2F_{5/2}\rightarrow{}^2F_{7/2}$) for **6**. These facts indicate that the energy transfers occur from the SOMO π* to the 4f excited levels. The 4f–4f transitions of these complexes are located below the NIT2py SOMO π* state. This behavior is analogous to the case of the energy transfer from the $^2E(Cr^{III})$ to the 4f levels for the Cr–Nd and Cr–Yb dinuclear complexes, [(acac)$_2$Cr(bpypz)Ln(hfac)$_3$],[10d,11] but

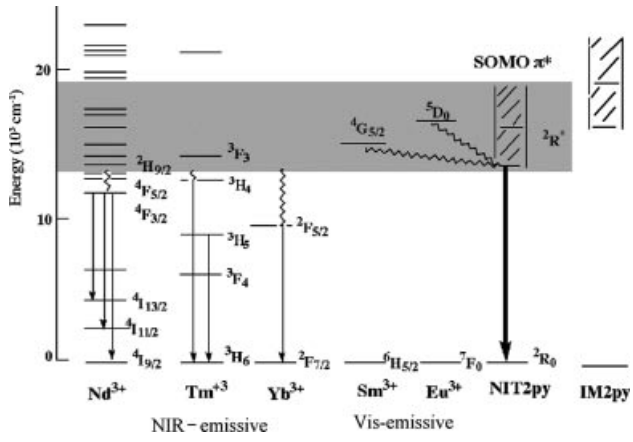

Figure 2. Energy levels for the Ln complexes and nitroxide radicals.

different from that for the corresponding complexes, [(acac)$_2$Cr(ox)Ln(HBpz$_3$)$_2$], which exhibit the simultaneous 3d–3d and 4f–4f luminescence at low temperature.[11] In our recent luminescence study of (NIT2py)- and (IM2py)Cr^{III} complexes, it is found that the NIT2py and IM2py radicals exert the antenna effect, showing a fast energy transfer from the SOMO π* to the $^2E/^2T_1(Cr^{III})$ state.[9] These findings suggest that the SOMO π* doublet state of the nitroxide radical could be of potential for visible-light sensitization of NIR luminescence as a light-harvesting antenna. This could be required for possible candidates of NIR light sources or multiplex assays to simultaneously detect a mixture of lanthanide ions with narrow luminescence peaks by visible-light excitation. This is because of the lower lying NIT2py SOMO π* band range existing within the emissive 4f levels compared with that of IM2py and NITBzim or IMBzim.

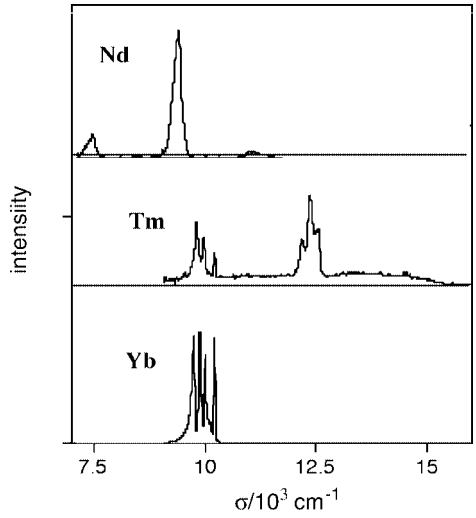

Figure 3. Luminescence spectra in the solid state at 15 K of [Ln(hfac)$_3$(NIT2py)] (top to bottom: **4**, **5**, **6**).

Conclusion

In summary, we observed the 4f–4f NIR luminescence of the (NIT2py)Ln^{III} complexes at 15 K through the direct

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

energy transfer from the SOMO π* doublet state to the 4f levels for the first time. Since there was no observation of the simultaneous luminescence for the NIR-emissive Ln^{III} complexes, it appears that the NIT2py radical exerts an antenna effect as a light-harvesting ligand. It is invaluable to clarify the difference between the doublet (SOMO π*)-to-4f direct energy transfer in nitroxide complexes and the triplet-to-4f indirect energy transfer through intersystem crossing from the singlet to triplet state in nonradical organic ligands,[2,3] e.g., in relation with the LMCT for Eu^{III}[12] or Yb^{III} complexes.[13]

Further photophysical and photochemical studies will be needed for the development of new photosensitizers for NIR light sources. This would be made feasible by tuning the emissive states with a variation of the substitution of NIT radicals such as benzimidazole in the nitroxide radical Ln^{III} complexes.

Experimental Section

Measurements: The NIR absorption spectra were recored with a Perkin–Elmer Lambda 19 spectrophotometer at room temperature in chloroform solution. The luminescence spectra were measured with a SPEX 1269 spectrometer with excitation by an Ar^+ laser (514.5 nm). The focus distances for the excitation and emission were 25 cm and 1.3 m, respectively. The excitation and emission slit widths were 4 mm and 2 mm, respectively. The dispersed signal was detected by a Ge-pin photodiode (North Coast EO-817L) cooled by liquid nitrogen.

Preparation of Complexes: The (NIT2py)Ln^{III} complexes were prepared by a modified literature method.[2a] NIT2py (1 mmol) was added to a solution of $[Ln(hfac)_3(H_2O)_2]$ (1 mmol) in $CHCl_3$/EtOH (1:1) (20 mL). The resulting violet solution was stirred at room temperature. After 1 d, violet elongated crystals with no crystallization solvent were obtained. The Eu^{III}, Lu^{III} and Yb^{III} complexes were stable at –5 °C, while the other Ln^{III} complexes were stable at room temperature. $C_{27}H_{19}F_{18}LuN_3O_8$ (1030.40): calcd. C 31.47, H 1.86, N 4.08; found C 31.92, H 1.92, N 4.15. $C_{27}H_{19}F_{18}N_3O_8Yb$ (1028.47): calcd. C 31.53, H 1.86, N 4.09; found C 32.04, H 1.93, N 4.09. $C_{27}H_{19}F_{18}N_3NdO_8$ (999.67): calcd. C 32.44, H 1.92, N 4.20; found C 34.19, H 2.38, N 4.21. $C_{27}H_{19}F_{18}N_3O_8Tm$ (1024.37): calcd. C 31.66, H 1.87, N 4.10; found C 31.43, H 1.80, N 4.11.

A Tetraphosphane Imine Ligand Which Enforces Square-Pyramidal Coordination

Christopher Zimmermann,[a] Frank W. Heinemann,[b] and Andreas Grohmann*[a]

Dedicated to Professor Herbert Schumann on the occasion of his 70th birthday

Keywords: Tetrapodal pentadentate ligand / Phosphane ligands / Chelates / Cobalt / Nickel

The tetrapodal pentadentate NP_4 ligand 2,6-$C_5H_3N[CMe(CH_2PPh_2)_2]_2$, which is readily prepared from the reaction of the corresponding tetrabromide with $KPPh_2$, forms mononuclear complexes with nickel(II) and cobalt(II). In the case of nickel(II), the coordination mode adopted by the ligand is sensitive to the nature of the counterion: Use of $NiCl_2$ gives a chloro complex as one of the products, which, as determined by X-ray crystallography, has a central ion coordinated by three phosphane and one chloro substituent in a distorted square planar fashion; by contrast, the reaction with $Ni(BF_4)_2$ gives a complex of approximate square-pyramidal geometry as the only product, in which all five atoms of the NP_4 set are coordinated to the nickel ion, despite the steric bulk of the eight phenyl substituents. The same type of complex is obtained with $Co(BF_4)_2$ and $Co(ClO_4)_2$. Attempts to increase the coordination number of either complex beyond 5 have been unsuccessful. In particular, the cobalt(II) complex (17 valence electrons) is practically inert to reagents such as O_2, NO, NO^+, I_2, Cl_2 or H_2. Full spectroscopic details for the complexes, as well as X-ray structure analyses, are reported.

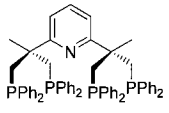
Introduction

Chelating phosphane ligands are widely employed in catalysis and organic synthesis.[1,2] The vast majority of applications in homogeneous catalysis requires bidentate ligands (e.g., in asymmetric hydrogenation).[3] Owing to the necessity for "labile" donors and/or vacant coordination sites in molecular catalysts, ligands of higher denticity such as tridentate $H_3CC(CH_2PPh_2)_3$, "triphos", or tetradentate $P(CH_2CH_2PPh_2)_3$, "pp3", are less prone to give catalytically active species, although specialised applications in the "heterogenisation" of homogeneous catalysts do make use of the increased thermal and kinetic complex stability that such ligands impart.[4] Complexes of polypodal phosphane ligands show a rich coordination and reaction chemistry in their own right, however. This is because of the increasing electron-richness of the metal centre, which is a direct consequence of the increasing number of aryl-, or, better still, alkylphosphane donors. It is in this context that we have begun to extend our study of tetrapodal pentadentate ligands[5] to include tetraphosphane imine ligands. We recently described the C_{2v}-symmetrical NP_4 ligand 2,6-bis{2-(diphenylphosphanyl)-1-[(diphenylphosphanyl)methyl]-1-methylethyl}pyridine ("py{PPh_2}$_4$", **1**).[6] The present contribution summarises coordination chemistry aspects of this ligand with respect to nickel(II) and cobalt(II).



1

Results and Discussion

Coordination Behaviour of py{PPh_2}$_4$ Towards Nickel(II)

A red-brown solid was obtained from the reaction of equimolar amounts of py{PPh_2}$_4$ and $NiCl_2 \cdot 6H_2O$ in refluxing acetonitrile (cf. Experimental Section). Recrystallisation from methanol in the presence of $NaPF_6$ produced a microcrystalline purple material. Structural analysis using a single crystal from this batch revealed a chiral (*) 16 valence electron chloro complex (**2**) with a tetracoordinate nickel(II) centre. The tetraphosphane acts as a tridentate chelator, one diphenylphosphanyl unit and the pyridine nitrogen atom remaining uncoordinated [Equation (1)]. The

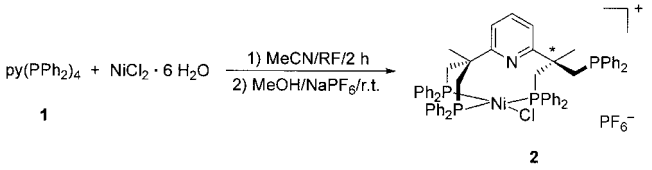
 DOI: 10.1002/ejic.200500281

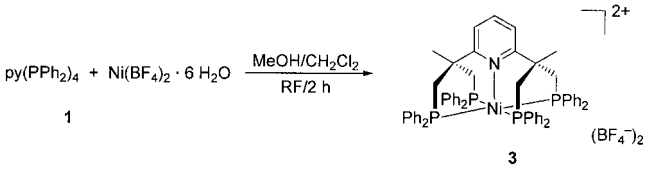
complex is also detected in the mass spectrum of the purple material, where it gives rise to a peak at *m*/*z* = 1022 ({[(py{PPh_2}$_4$)NiCl]}$^+$, 20%).



(1)

It should be noted, however, that the percentage of carbon in the solid analyses is consistently too low to be acceptable for pure compound **2**, $C_{61}H_{57}ClF_6NNiP_5$ (1167.14), which requires C 62.78, H 4.92, N 1.20%; a typical analysis is C 56.12, H 4.72, N 1.31%. This indicates that a mixture of products (of different solubilities) is formed, and that the major part of the material may in fact be the bis(hexafluorophosphate) salt, which requires C 57.39, H 4.50, N 1.10%. The ^{1}H, ^{13}C, and ^{31}P NMR spectroscopic data do suggest a highly symmetrical species and are virtually identical to the spectra obtained for the bis(tetrafluoroborate) salt **3** (below).

Apparently, the coordination mode adopted by the ligand is determined by the reaction conditions (solvent, coordinating ability of the counterion); this is evident from the outcome of an overall similar reaction, between stoichiometric amounts of py{PPh_2}$_4$ and $Ni(BF_4)_2 \cdot 6H_2O$ in a methanol/dichloromethane mixed solvent (1:1). In this case, there is only one product, which contains the tetraphosphane as a pentadentate capping ligand. The 18 valence electron complex [(py{PPh_2}$_4$)Ni]$(BF_4)_2$ (**3**), which forms as purple-brown microcrystals in 50% yield [Equation (2)], has the nickel(II) ion in a distorted square-pyramidal coordination environment. In the mass spectrum, the cation appears at *m*/*z* = 987 ({[(py{PPh_2}4)Ni]}$^+$, 75%).



(2)

Compound **3** is readily soluble in acetonitrile and chloroform, and sparingly soluble in methanol. In the IR spectrum (KBr), the band at 1435 cm^{-1} attributed to the P–Ph stretching vibration is second in intensity only to the band diagnostic of BF_4^- (1060 cm^{-1}). Compared to the IR spectroscopic data for uncoordinated py{PPh_2}$_4$, ν_{P-Ph} (str) does not shift upon coordination.[6] Complex **3** is diamagnetic and gives well-resolved NMR spectra at room temperature. The ^{19}F spectrum has a singlet at δ = –149.5 ppm (in CD_2Cl_2), which is due to tetrafluoroborate. In the ^{31}P spectrum, there are two triplets for the diphenylphosphanyl groups at δ = 18.7 ppm and –10.9 ppm (A_2B_2 system). This spin system indicates similar geometries of the cation both in solution and in the solid state, with distortion of diametrically opposed Ni–P bonds from a square-planar towards a tetrahedral arrangement (cf. discussion of the X-ray structure, below). High symmetry in solution is also evident from the ^{1}H and ^{13}C NMR spectra. The pyridine protons give rise to a triplet (δ = 8.74 ppm) and a doublet (δ = 8.39 ppm) in a 1:2 intensity ratio (AB_2 system). Several multiplets between 7.6 ppm and 4.8 ppm are assigned to the diphenylphosphanyl protons. The methylene groups appear as three doublets between 3.3 ppm and 2.3 ppm (equivalent to 2, 2, and 4 protons, respectively), and a singlet at ca. 2.3 ppm accounts for the six methyl protons. In the ^{13}C spectra, there are 12 signals between 169.0 and 123.0 ppm for the aromatic C atoms. One signal each arises from the quaternary (δ = 42.3 ppm) and methyl carbon atoms (δ = 29.2 ppm), whereas the methylene carbon atoms produce two signals at δ = 38.9 ppm and 34.5 ppm, in accordance with the anisochrony observed for the phosphorus atoms.

Molecular Structures of [(py{PPh_2}$_4$)Ni(Cl)](PF$_6$) and [(py{PPh_2}$_4$)Ni](BF$_4$)$_2$

Single crystals suitable for X-ray structure determination had the compositions [(py{PPh_2}$_4$)Ni(Cl)](PF_6)·MeOH (**2**·MeOH) and [(py{PPh_2}$_4$)Ni]$(BF_4)_2$·CH_2Cl_2 (**3**·CH_2Cl_2). Compound **2** is a chiral chloro complex with tridentate coordination of the phosphane ligand (Figure 1); it crystallises as the racemate in the space group $P\bar{1}$. One phosphorus donor and the pyridine nitrogen atom remain uncoordinated [*d*(Ni1···N11) = 301.6(2) pm]. Selected bond lengths and angles are given in Table 1. The chloro ligand is displaced by 122.1(2) pm from the best plane defined by the nickel ion and the three coordinated P atoms, resulting in a coordination geometry around Ni^{II} which is intermediate between square planar and tetrahedral. The Ni–P and Ni–Cl bond lengths are within the range found for other chloro nickel(II) complexes with polyphosphane ligands.[7]

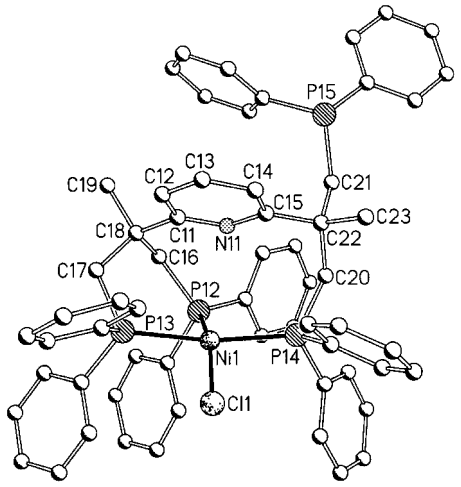


Figure 1. Molecular structure of the cation in the chloro nickel(II) complex **2** (H atoms not shown).

Table 1. Selected bond lengths [pm] and angles [°] in **2**·MeOH (standard deviations in parentheses).

Ni1–P12	220.0(1)
Ni1–P13	226.2(2)
Ni1–P14	223.6(1)
Ni1–Cl1	218.3(1)
P12–Ni1–P13	88.86(4)
P12–Ni1–P14	97.90(4)
P13–Ni1–Cl1	89.33(4)
P14–Ni1–Cl1	89.85(4)
P12–Ni1–Cl1	155.29(4)
P13–Ni1–P14	165.30(4)

Compound **3** crystallises in the space group *Pccn* and contains distorted square-pyramidal coordinated nickel(II). The structure of the complex cation is shown in Figure 2.

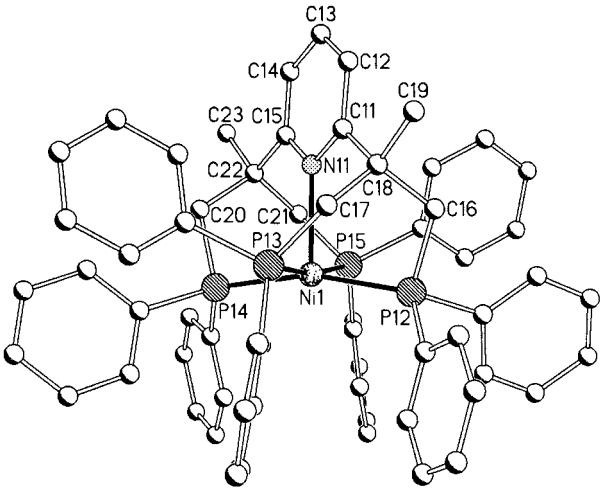

Figure 2. Molecular structure of the cation in the nickel(II) complex **3** (H atoms not shown).

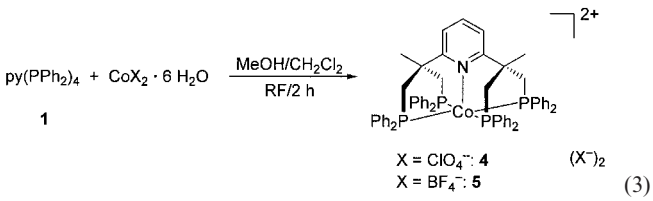
The distortion consists in the pairwise displacement of diametrically opposite phosphane donors below (P12–Ni1–P14) and above (P13–Ni1–P15) the best plane defined by the NiP_4 unit. All phenyl substituents on P12 and P14 are below this plane, whereas donor atoms P13 and P15 have one phenyl ring above and one below. As a consequence, there are two types of Ni–P bond environments in the solid state, which persist in solution and give rise to an A_2B_2 spin system in the ^{31}P NMR spectra of **3**. Selected bond lengths and angles of **3** are listed in Table 3. There are no significant differences between the Ni^{II}–P distances in **3** and **2**.

Coordination Behaviour of py{PPh_2}$_4$ Towards Cobalt(II)

In view of the results obtained for nickel(II), only cobalt(II) salts with weakly coordinating anions were used. Equimolar amounts of py{PPh_2}$_4$ und $Co(ClO_4)_2$·$6H_2O$ in a methanol/dichloromethane solvent mixture (1:1) produce a red-brown solution from which, upon N_2-induced evaporation, [(py{PPh_2}$_4$)Co]$(ClO_4)_2$ (**4**) may be obtained as red-brown microcrystals in moderate yield [25%, Equation (3)]. When $Co(BF_4)_2$·$6H_2O$ is used, the corresponding tetrafluoroborate salt **5** is formed (52%).



(3)

Both compounds are soluble in CH_2Cl_2 and sparingly soluble in methanol and THF. They are paramagnetic 17-valence-electron complexes of square-pyramidal coordinated cobalt(II), with the parent ion as the base peak in the mass spectra (m/z = 986, [(py{PPh_2}$_4$)Co]$^+$, 100%). The IR (KBr) spectra of **5** and the corresponding nickel(II) complex **3** are virtually identical, as expected. The magnetic moment determined for **4** (μ_{eff} = 1.60(3) BM; Gouy balance) corresponds to one unpaired electron, suggesting a low-spin configuration. (This configuration is assumed for the following discussion; given the possibility of experimental error with this technique, however, a reliable assignment of the spin state will require an ESR spectroscopic investigation). The properties of a number of low-spin cobalt(II) complexes of the type $[CoL_2X]Y$ (L = bidentate neutral ligand with variable donor set, X = coordinating anion; Y = noncoordinating anion) have been published.[8–10] Meek and coworkers reported the series of complexes $[(dppe)_2Co^{II}X](SnX_3)$ [X = Cl, Br, I; dppe = 1,2-bis(diphenylphosphanyl)ethane] and also investigated their magnetic behaviour.[11] Depending on the conditions employed (solvent, temperature, mode of crystallisation), the products have either square-pyramidal or trigonal-bipyramidal coordination geometry, but all complexes are low-spin. Magnetic moments vary slightly and are greater under square-pyramidal coordination geometry (μ_{eff} = 2.03–2.14 BM) than under trigonal-bipyramidal geometry (μ_{eff} = 1.89–1.97 BM). For the series of structurally uncharacterised complexes $[Co(P_4)X](BPh_4)$ (P_4 = hexaphenyl-1,4,7,10-tetraphosphadecane, X = Cl, Br, I, NCS), Sacconi and coworkers reported magnetic moments of μ_{eff} = 1.98–2.13 BM.[12] In spite of their different symmetries, both series of complexes have magnetic moments

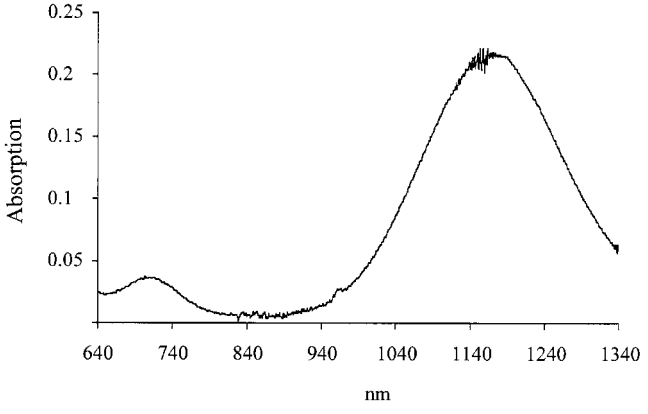


Figure 3. Vis/NIR part of the electronic spectrum of [(py{PPh_2}$_4$)Co]$(ClO_4)_2$ in CH_2Cl_2 (10^{-3} M) at room temperature.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

comparable to a low-spin cobalt(II) complex in an octahedral ligand field ($\mu_{eff} \geq \mu^{s.o.} = 1.73$ BM).[13] By way of comparison, the magnetic moment determined for **4** is smaller by 0.3 to 0.5 BM. The UV/Vis/NIR spectrum of **4** shows two *d-d* transitions at 703 nm (14225 cm^{-1}) and 1166 nm (8576 cm^{-1})(Figure 3).

The ligand field splitting varies with the ligand's position in the spectrochemical series. More weakly coordinating ligands should produce a red shift in the corresponding absorption bands, as has been verified for Sacconi's series, $[Co(P_4)X](BPh_4)$ (P_4 = hexaphenyl-1,4,7,10-tetraphosphadecane, X = Cl, Br, I): Upon going from Cl to I, the two lowest-energy bands shift to lower wavenumbers as shown in Table 2.[12] Assuming square-pyramidal geometry for these complexes in solution, the data obtained for square-pyramidal **4** (Table 2) fit in well, as pyridine is above the halide ions in the spectrochemical series: py > … > Cl > … > Br > I.[13,14]

Table 2. Comparison of the absorption maxima of the two lowest-energy transitions in the solution UV/Vis/NIR spectra of cobalt(II) polyphosphane complexes (see text).

Ionic species	Absorption maximum [cm^{-1}]	Absorption maximum [cm^{-1}]
$[(py\{PPh_2\}_4)Co]^{2+}$[a]	8576	14225
$[Co(P_4)Cl]^{+}$[b]	8270	10520
$[Co(P_4)Br]^{+}$[b]	8000	10000
$[Co(P_4)I]^{+}$[b]	7940	9700

[a] In CH_2Cl_2. [b] In 1,2-dichloroethane.

Preliminary cyclovoltammetric measurements of **4** in CH_2Cl_2 solution at room temperature (internal standard: ferrocene) show one irreversible wave in the cathodic and one in the anodic region. The cathodic wave (–507 mV) may be assigned to the formation of an 18 valence electron cobalt(I) complex ($[(py\{PPh_2\}_4)Co]^+$); the anodic wave, after normalisation on ferrocene, falls outside the voltage range acceptable for CH_2Cl_2 as a CV solvent (–1800 mV to +1500 mV) and thus has no diagnostic value. Renewed measurements, employing both the perchlorate and the tetrafluoroborate salts, in a range of solvents and at different temperatures are expected to clarify whether a cobalt(III) complex is in fact accessible.

Molecular Structure of $[(py\{PPh_2\}_4)Co](ClO_4)_2$

The single crystals used for structure determination had the composition $[(py\{PPh_2\}_4)Co](ClO_4)_2 \cdot 0.75CH_2Cl_2$ (**4**·$0.75CH_2Cl_2$). For $[(py\{PPh_2\}_4)Co](BF_4)_2 \cdot MeOH$, preliminary data confirm the identical structure of the molecular cation. Compound **4** crystallises in the space group $P2_1/c$; the structure of its cation is shown in Figure 4. The metal–nitrogen bond in **4** is ca. 8 pm shorter than in the nickel(II) complex **3**, whereas the metal–phosphorus bonds in **4** are 2–5 pm longer than in **3**. Otherwise, there are no significant structural differences between the cations in both complexes. Table 3 lists a comparison of parameters.

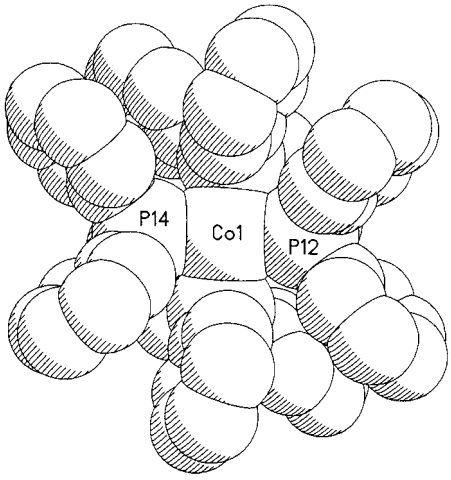

Figure 5. Space-filling model of the cobalt(II) complex **4**, viewed along the Co–N axis.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The Co–P bond lengths in **4** are within the range observed for other low-spin cobalt(II) complexes with polyphosphane ligands.[11] For example, the average Co–P bond length in $[(dppe)_2CoCl]SnCl_3$ is, under square-pyramidal coordination geometry, 227.6(2) pm, and 225.8(5) pm in the case of trigonal-bipyramidal coordination. The space-filling representation in Figure 5 shows a vacant potential coordination site, which is surrounded by six phenyl rings of the tetraphosphane ligand in a fencelike manner.

The Cobalt(II) Complexes [(py{PPh$_2$}$_4$)Co](X)$_2$ [X = ClO$_4$, BF$_4$] and Their Reactivity Towards CO, NO, NO$^+$, I$_2$, Cl$_2$ and H$_2$

The square-pyramidal cobalt(II) complexes of the new tetraphosphane ligand are remarkably stable towards oxidation, and can be kept in air for extended periods of time without noticeable decomposition. Attempts to increase the coordination number of the cobalt ion beyond 5 in a directed manner, either by simple coordination or by oxidative addition of a small monodentate ligand, have so far met with no success. In keeping with the electrochemical results, a square-pyramidal coordinated, 16-valence-electron cobalt(III) species does not seem accessible. Treatment with I_2 (0.5 equiv., room temperature, 48 h, in THF) reproduces the starting material, whereas the reaction with Cl_2 (0.5 equiv., –50 °C, 2 h, CH_2Cl_2) gives a mixture of products, consisting for the main part of the starting material. Mass spectral features consistent with the formation of the desired chloro complex have a marginal character at best. Whereas the expected steric demand of an iodide or a chloride ligand may preclude its coordination, there is also no indication for the formation of a hydride complex, by oxidative addition of H_2 (**4** in CH_2Cl_2 solution, 40 bar H_2 pressure; mixture monitored by ^{1}H NMR after 1, 4 and 10 d; cf. the synthesis of hydridopentacyanocobaltate(III) from pentacyanocobaltate(II) and H_2[15,16]). Likewise, treatment of solutions of **4** with CO (1 bar, CH_2Cl_2, room temperature, 2 h or MeOH, 50 °C, 1 h) or of **5** with $NOBF_4$ (CH_2Cl_2, room temperature, 48 h) produced no reaction. Only in those cases where solutions of **4** or **5** in CH_2Cl_2 were treated with equimolar amounts of gaseous NO, IR monitoring of solution samples indicated a significant reaction: two bands, one of intermediate intensity at 1856 cm^{-1} and one strong band at 1802 cm^{-1} appear within 1 h; there are no further spectral changes after extended reaction times (16 h). Whether or not this observation indicates the formation of two distinct NO complexes, or a dinitrosyl complex, is as yet unclear. The formation of N_2O [ν_{NN} (str) = 2222 cm^{-1}] with concomitant oxidation of potentially decoordinated phosphane functionalities (a reaction reported to proceed smoothly and quantitatively for free py{PPh$_2$}$_4$ under suitable conditions[6]) is not observed. Both bands (at 1853 and 1797 cm^{-1}) persist with comparable intensity in IR spectra (KBr disc) obtained from the brown solid which remains after evaporation of the solvent. While attempts to obtain single crystals from this material, which would allow structural characterisation, have been unsuccessful, mass spectroscopic data do not rule out the formation of a singly substituted NO complex: the complex ion, $[(py\{PPh_2\}_4)Co]\}^+$, is recorded at m/z = 986 (100%), with a relatively prominent signal at m/z = 1017 (19%); $\Delta(m/z)$ = 31 (fast atom bombardment, matrix: *p*-nitrobenzyl alcohol). Treatment of **4** with NO at 0 °C, however, produced no reaction.

The preparation of ruthenium(II) complexes of the new tetraphosphane ligand will be reported elsewhere. Whereas the phenyl-substituted tetraphosphane ligand **1** may be too sterically encumbered to give complexes with iron(II), such complexes are in fact accessible with the methyl analogue, py(PMe$_2$)$_4$, which we have recently prepared. A study of its coordination behaviour and reactivity is under way.

Conclusions

The new highly symmetrical NP_4 ligand 2,6-$C_5H_3N[CMe(CH_2PPh_2)_2]_2$ forms mononuclear complexes with nickel(II) and cobalt(II), despite the steric bulk of eight phenyl rings on its four phosphorus-substituted "tentacles". The adopted mode of coordination depends on the nature of the counterion: In the case of strongly coordinating chloride, the ligand may in effect be tridentate (P_3) whereas, for weakly coordinating anions (BF_4^-, ClO_4^-), all five donor atoms coordinate to the central ion, to give complexes of approximate square-pyramidal geometry. The cobalt complex is virtually inert with respect to coordination of a sixth monodentate ligand (including dioxygen), owing to a "fence" of phenyl groups shielding the sixth coordination site. The reactivity of these complexes is expected to increase considerably upon the introduction of sterically less demanding and more basic P donors, such as the dimethylphospanyl residue.

Experimental Section

Unless noted otherwise, all reactions were carried out at room temperature in dried solvents under dry dinitrogen, using standard Schlenk techniques. The tetraphosphane ligand py{PPh$_2$}$_4$ was prepared by literature methods;[6] $NiCl_2{\cdot}6H_2O$, $Ni(BF_4)_2{\cdot}6H_2O$, $Co(ClO_4)_2{\cdot}6H_2O$ and $Co(BF_4)_2{\cdot}6H_2O$ were purchased from Fluka or Aldrich and used without further purification. IR spectra of solids were measured using KBr disks; solution IR spectra were recorded in CaF_2 cuvets, with compensation of solvent absorptions. IR spectra were assigned on the basis of literature data.[17] Magnetic moments of polycrystalline samples were determined on a Gouy balance (Johnson-Matthey) at room temperature, with diamagnetic corrections calculated from Pascal's constants.[18] Spectroscopic data were obtained using the following instruments: IR spectroscopy: Perkin–Elmer 1600 FT IR and 16PC FT IR; mass spectrometry: Varian MAT 212 and Jeol JMS 700; NMR spectroscopy: Jeol FT-NMR JNM-EX 270, Lambda LA 400 und ALPHA 500. Signs of coupling constants in the ^{1}H, ^{13}C, and ^{31}P NMR spectra were not determined. Elemental analyses were carried out with Carlo Erba EA 1106 and 1108 analysers. Cyclic voltammograms were recorded with a PAR 264A potentiostat and a three-electrode cell with a glassy carbon ROTEL working electrode and Pt reference and counter electrode (nBu$_4$NPF$_6$, 10^{-1} mol L^{-1}; internal standard $(Cp)_2Fe/(Cp)_2Fe^+$; $E_{1/2}$ = +0.4 V vs. NHE[19]).

[(py{PPh_2}$_4$)NiCl]PF_6 (2): To a solution of py{PPh_2}$_4$ (375 mg, 0.400 mmol) in acetonitrile (20 mL) was added solid $NiCl_2 \cdot 6H_2O$ (10 mg, 0.40 mmol) in one portion. The resulting reddish-brown suspension was heated to reflux for 30 min, to give a clear solution of the same colour. Stripping of the solvent and drying in vacuo left a red-brown solid, which was dissolved in methanol. Addition of $NaPF_6$ (70 mg, 0.40 mmol) to the warm deep purple solution produced a purple microcrystalline precipitate after 12 h (182 mg). Elemental analysis (CHN) data are consistently too low in carbon. This observation, as well as the fact that the chloroform-soluble fraction gives ^{1}H, {^{1}H}^{13}C, and {^{1}H}^{31}P NMR spectra virtually identical to those of **3**, indicate that a mixture of complexes (with and without coordinated chloride) may have formed (see text). MS (FAB, *p*-NBA): *m*/*z* (%) = 1022 [(py{PPh_2}$_4$)NiCl]$^+$ (20).

[(py{PPh_2}$_4$)Ni]$(BF_4)_2$ (3): The addition of a solution of $Ni(BF_4)_2 \cdot 6H_2O$ (267 mg, 0.780 mmol) in methanol (20 mL) in one portion to a solution of py{PPh_2}$_4$ (724 mg, 0.780 mmol) in dichloromethane (20 mL) instantaneously produced a brown solution, which was heated to reflux for 30 min and subsequently taken to dryness. The obtained purple-brown powder was triturated with n-hexane, separated by filtration, and dried in vacuo. Yield: 465 mg **3**·MeOH (50%). **3**·MeOH: $C_{62}H_{61}B_2F_8NNiOP_4$ (1192.37): calcd. MS (FD$^+$, CH_2Cl_2): *m*/*z* (%) = 987 (75) [(py{PPh_2}$_4$)Ni]$^+$, 1073 (15) {[(py{PPh_2}$_4$)Ni]BF_4}$^+$. ^{1}H NMR (400 MHz, CD_2Cl_2, room temp.): δ = 8.74 (t, $^2J_{H,H}$ = 8.0 Hz, 1 H, py-H^4), 8.39 (d, $^2J_{H,H}$ = 8.0 Hz, 2 H, py-H^{3,5}), 7.6–4.8 (m, 40 H, overlaid from low to high field: py-H^{3,5}; C_{ortho}-H, C_{ortho}′-H, C_{meta}-H, C_{meta}′-H, C_{para}-H, C_{para}′-H), 3.24 (d, $^2J_{H,H}$ = 7.8 Hz, 2 H, -C*H*$_2$-), 3.05 (d, $^2J_{H,H}$ = 7.8 Hz, 2 H, -C*H*$_2$-), 2.42 (d, $^2J_{H,H}$ = 7.4 Hz, 4 H, -C*H*$_2$-), 2.29 (s, 6 H, -C*H*$_3$) ppm. {^{1}H}^{13}C NMR (400 MHz, CD_2Cl_2, room temp.): δ = 168.3–123.8 (12 signals, 53 C, py-C^4, py-C^{2,6}, py-C^{3,5}, C_{ipso}, C_{ipso}′, C_{ortho}, C_{ortho}′, C_{meta}, C_{meta}′, C_{para}, C_{para}′), 42.3 (2 C, >C<), 38.8 (2 C, -*C*H$_2$-), 34.5 (2 C, -*C*H$_2$-), 29.3 (2 C, -*C*H$_3$) ppm. {^{1}H}^{19}F NMR (400 MHz, CD_2Cl_2, room temp.): δ = –149.5 (s, 4 F, B*F*$_4$) ppm. {^{1}H}^{31}P NMR (400 MHz, $CDCl_3$, room temp.): δ = 18.7 (t, $^2J_{P,P}$ = 151 Hz, 2 P, -*P*Ph$_2$), –10.9 (t, $^2J_{P,P}$ = 149.5 Hz, 2 P, -*P*Ph$_2$) ppm.

[(py{PPh_2}$_4$)Co]$(ClO_4)_2$ (4): A solution of py{PPh_2}$_4$ (1.10 g, 1.18 mmol) in dichloromethane (20 mL) was slowly added to a stirred solution of $Co(ClO_4)_2 \cdot 6H_2O$ (430 mg, 1.18 mmol) in methanol (30 mL). In the course of the addition, the colour of the resultant solution changed from pink to brown. After heating to reflux for 30 min, the solution was allowed to cool to room temperature, and its volume reduced in a slow stream of dinitrogen. After 72 h, a red-brown microcrystalline precipitate had formed, which was separated by filtration (G4 frit), washed with Et_2O (2 × 10 mL), and dried in a stream of dinitrogen. Yield: 369 mg **4**·2 MeOH (25%). More product was obtained from the mother liquor after evaporation of the solvent mixture in air. **4**·2MeOH: $C_{63}H_{65}Cl_2CoNO_{10}P_4$ (1249.95): calcd. C 60.54, H 5.24, N 1.12; found C 60.31, H 5.37, N 0.94. IR (KBr): $\tilde{\nu}$ = 3427 (br), 3054 (H–C_{aryl}), 2962 (-CH_3), 1573, 1483, 1454, 1435 (str, P–Ph), 1262, 1096 (str, br, ClO_4^-), 803, 742, 694, 623 (ClO_4^-), 516 cm^{-1}. MS (FAB, *p*-NBA): *m*/*z* (%) = 986 (100) [{py{PPh_2}$_4$}Co]$^+$, 1085 (60) {[py{PPh_2}$_4$Co]ClO_4}$^+$. μ_{eff} (spin only) = 1.60(3) BM. UV/Vis (10^{-3} mol L^{-1} in CH_2Cl_2, room temp.): λ (ε) = 1166 nm (218 dm^3 mol^{-1} cm^{-1}), 703 nm (37 dm^3 mol^{-1} cm^{-1}).

[(py{PPh_2}$_4$Co]$(BF_4)_2$ (5): A mixture of solid $Co(BF_4)_2 \cdot 6H_2O$ (347 mg, 1.02 mmol) and solid py{PPh_2}$_4$ (950 mg, 1.02 mmol) was taken up in a methanol/dichloromethane mixture (1:1; 40 mL). The initial pink colour of the solution changed to brown after ca. 5 min. The solution was heated to reflux overnight, allowed to cool to room temperature during several h, taken to dryness in an oil pump vacuum, and the remaining solid triturated with n-hexane, to produce a reddish-tan precipitate, which was filtered (G4 frit), and dried in vacuo. Yield: 751 mg **5** (52%). **5**·4 MeOH: $C_{65}H_{73}B_2CoF_8NO_{12}P_4$ (1416.73): calcd. C 60.58, H 5.71, N 1.09; found C 60.40, H 5.19, N 0.99. Ph), 1060 (BF_4), 742, 694 cm^{-1}. MS (FD^+, CH_2Cl_2): *m*/*z* (%) = 986 (100) $[(py\{PPh_2\}_4)Co]^+$.

X-ray Crystallography of Compounds 2, 3, and 4: Purple single crystals of $[(py\{PPh_2\}_4)Ni(Cl)]PF_6 \cdot MeOH$ (**2**·MeOH) were obtained within 3 d by isothermal diffusion of Et_2O into a saturated solution of the reaction product in methanol. Dark red crystalline blocks of $[(py\{PPh_2\}_4)Ni](BF_4)_2 \cdot CH_2Cl_2$ (**3**·CH_2Cl_2) were similarly obtained from CH_2Cl_2/Et_2O within 2 d. Red crystals of $[(py\{PPh_2\}_4)Co](ClO_4)_2 \cdot 0.75\ CH_2Cl_2$ (**4**·0.75 CH_2Cl_2) formed within 2 d from a dichloromethane solution whose volume was reduced in a slow stream of dry dinitrogen. Suitable crystals were mounted in glass capillaries. Data sets were obtained on a Siemens P4 diffractometer, using Mo-K_α radiation (λ = 71.073 pm) and the ω-scan technique. The structures of all complexes were solved by direct methods and refined using full-matrix least-squares procedures on F^2 (SHELXTL NT 6.12).[20] All non-hydrogen atoms of all complexes were anisotropically refined. Compound **2** crystallises with one molecule of MeOH per formula unit, which is disordered. Two preferential orientations for the C–O unit were refined, with an occupancy of 0.53(2) (O1, C1) and 0.47(2) (O2, C2), respectively. Compound **3** crystallises with one molecule of CH_2Cl_2 and compound **4** with ca. 0.75 CH_2Cl_2 per formula unit. The dichloromethane molecule in **4** is disordered; two preferential positions were determined for one of the chloride atoms, with occupancies refined to 0.53(2) for Cl12 and 0.22(2) for Cl13. Cl13 was only isotropically refined. Treatment of hydrogen atoms: All hydrogen atoms were geometrically positioned and allowed to ride on their carrier atoms during the refinement; their isotropic displacement parameters were tied to those of the adjacent C and O atoms by a factor of 1.2 or 1.5. Crystallographic data are listed in Table 4. CCDC-266966 (**2**·MeOH), CCDC-266967 (**3**·CH_2Cl_2), and CCDC-266968 (**4**·0.75CH_2Cl_2) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Acknowledgments

Financial support of this work by the Deutsche Forschungsgemeinschaft is gratefully acknowledged. We appreciate the diligence and helpful suggestions of two referees concerning the products of the complexation reactions with nickel.

Series of Mn Complexes Based on *N*-Centered Ligands and Superoxide – Reactivity in an Anhydrous Medium and SOD-Like Activity in an Aqueous Medium Correlated to Mn^{II}/Mn^{III} Redox Potentials[‡][‡‡]

Stéphanie Durot,[a][‡‡‡] Clotilde Policar,*[a][‡‡‡] Federico Cisnetti,[a] François Lambert,[a] Jean-Philippe Renault,[c] Giorgio Pelosi,[b] Guillaume Blain,[d] Hafsa Korri-Youssoufi,[a] and Jean-Pierre Mahy[a]

Keywords: N,O ligands / Manganese / Superoxide / SOD mimics / Imidazole / Phenolate

Two crystal structures are described in this article: (a) the structure of a monomeric Mn^{II} complex with the tridentate *N*-centered N_3 ligand tris[(1-methyl-2-imidazolyl)methyl]amine (TMIMA) ($[Mn^{II}(TMIMA)_2]^{2+}$); and (b) the structure of a monomeric Mn^{III} complex with the tridentate *N*-centered N_2O ligand 2-{[(1-methyl-2-imidazolyl)methyl]amino}phenolate (PI^-)[2] ($[Mn^{III}(PI)_2]^+$) (**5**). The latter was isolated both in the Mn^{II} and in the Mn^{III} state, although only Mn^{III} crystals were successfully grown. They are part of a series of Mn complexes prepared as SOD mimics, namely $[Mn(BMPG)(H_2O)]^+$ (**2**) {BMPG = *N*,*N*-bis[(6-methyl-2-pyridyl)methyl]glycinate}, $[Mn(IPG)(MeOH)]^+$ (**3**) {IPG = *N*-[(1-methyl-2-imidazolyl)methyl]-*N*-(2-pyridylmethyl)glycinate}, $[Mn(BIG)(H_2O)_2]^+$ (**4**) {BIG = *N*,*N*-bis[(1-methyl-2-imidazolyl)methyl]glycinate}. The reactivity of Mn^{II} complexes **1** and **2** in an anhydrous medium is described and compared to that of complexes **3** and **4**, the data for which was previously published. The cyclic voltammograms of the whole complex series were recorded in an aqueous medium (collidine buffer). Their SOD-like activities were estimated by the McCord–Fridovich test (*IC*50 with 22 μM cytc Fe^{III}: 1.6 ± 0.1 μmol L^{-1} for **1**, 1.2 ± 0.5 μmol L^{-1} for **2**, 3.0 ± 0.2 μmol L^{-1} for **3**, 3.7 ± 0.6 μmol L^{-1} for **4**, 0.8 ± 0.1 μmol L^{-1} for **5**). *IC*50 values were converted into the corresponding kinetic constant k_{McCF} values. A linear correlation between E_a and $\log(k_{McCF})$ was obtained, indicating that in this series the conversion to Mn^{III} is probably the rate-limiting step. This is of substantial importance for further Mn–SOD mimic design in this series.

Introduction

Superoxide ($O_2^{\cdot-}$), as the first species in the dioxygen reduction cascade, is a toxic species involved in oxidative stress.[3–5] Its concentration is controlled in vivo by superoxide dismutases, metalloenzymes that catalyze its dismutation. Superoxide is considered to be responsible for several pathological situations. There is a pharmaceutical requirement for molecules that could scavenge or, even better, catalytically dismutate superoxide.[6–8] The design of low molecular weight complex SOD mimics requires greater understanding of the effect of the metal environment on the SOD-like activity. In the field of superoxide dismutase mimics, copper, iron, manganese and cobalt complexes have been described.[7–12] Mn is the least toxic of these metal ions.[8] In our laboratory, we design Mn complexes and test them as SOD mimics. In this article, the crystal structure of a monomeric Mn^{II} complex (**1**) derived from $\mathbf{L^1}$ {tris[(1-methyl-2-imidazolyl)methyl]amine or TMIMA} is presented $\{[Mn^{II}(TMIMA)_2](PF_6)_2\}$. The crystal structure of a monomeric Mn^{III} complex derived from $\mathbf{L^2}$ (2-{[(1-methyl-2-imidazolyl)methyl]amino}phenolate or PI^-) is also described $\{[Mn^{III}(PI)_2](PF_6)\}$. In the latter case, both Mn^{II} (**5′**) and Mn^{III} states (**5**) could be isolated, although only Mn^{III} crystals were successfully obtained. Complexes **1** and **5** are part of a series of Mn complexes prepared as SOD mimics, previously published, namely $[Mn(BMPG)(H_2O)]^+$ (**2**) {BMPG = *N*,*N*-bis[(6-methyl-2-pyridyl)methyl]-glycinate},[13] $[Mn(IPG)(MeOH)]^+$ (**3**) {IPG = *N*-[(1-methyl-2-imidazolyl)methyl]-*N*-(2-pyridylmethyl)glycinate}, $[Mn(BIG)(H_2O)_2]^+$ (**4**) {BIG = *N*,*N*-bis[(1-methyl-2-imidazolyl)methyl]glycinate}.[1] A general approach to reaction with superoxide has already been published.[1] Firstly, this

Supporting information for this article is available on the WWW under http://www.eurjic.org or from the author.

article consists of a study of the reactivity of Mn^{II} complexes with superoxide in an anhydrous medium (DMSO). Secondly, the reactivity in an aqueous solution is evaluated with the conventional McCord–Fridovich assay and/or pulse radiolysis. Presented is a brief study of the Mn^{II} complexes (**1** and **2**) in the anhydrous medium and an evaluation of the SOD activity of complexes **1**, **2**, and **5** with the McCord–Fridovich assay. These activities are presented here in terms of a recalculated kinetic constant, k_{McCF}. For two of the complexes, namely, **3** and **4**, k_{McCF} values are compared with the kinetic constants measured by pulse radiolysis. For the whole series the relationship between redox potential and k_{McCF} has been investigated.

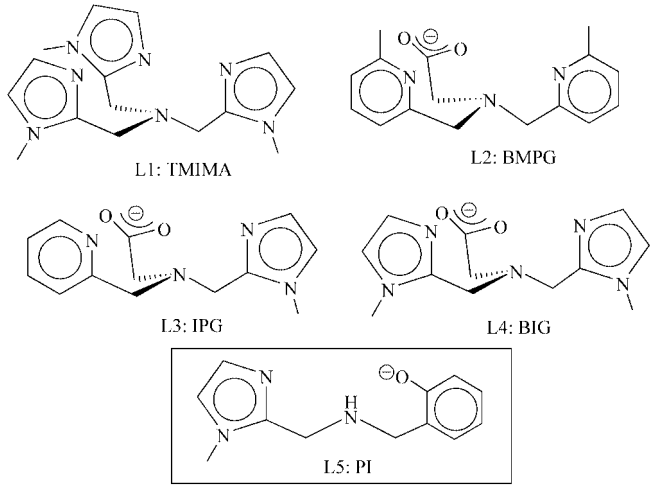

Figure 1. Structure of the ligands.

Results

Syntheses

Ligand Synthesis

The synthesis of the $\mathbf{L^1}$ ligand is already known.[14,15] A new synthetic pathway is presented in the Exp. Sect., involving an amine tertiarization by reductive amination instead of a nucleophilic substitution. The new method displayed a higher yield (90% vs. 62% from bis[2-(1-methyl-2-imidazolyl)methyl]amine.

Ligand $\mathbf{L^5}$ was synthesized as shown in Scheme 1 by a two-step synthesis. The yield was moderate but the procedure was very easy. 2-(Methylamino)phenol was obtained by catalytic hydrogenation (Ni) of 2-cyanophenol. It was reductively coupled to *N*-methyl-2-imidazolcarboxaldehyde obtained according to a published procedure.[16]

Preparation of the Complexes

Mn^{II} complex **1** was obtained from $\mathbf{L^1}$ (see Figure 1) with PF_6^- as the counter-anion in MeOH/H_2O (1:1). X-ray suitable crystals were successfully grown providing the monomeric $[Mn^{II}(TMIMA)_2](PF_6)_2$ compound **1**. Experimental details are described in the Exp. Sect.

Mn^{II} complex **5′** was obtained from $\mathbf{L^5}$ (see Figure 1) under strictly controlled anaerobic conditions. A white precipitate was obtained, but no crystal has been successfully grown so far. The powder could be recrystallized from CH_3CN by diffusion of *t*BuOMe as $[Mn^{III}(PI)_2](PF_6)(CH_3CN)$. When the synthesis was carried out in the presence of dioxygen, a dark violet precipitate of an Mn^{III} complex (**5**) was directly obtained.

Description of the Structure of $[Mn(TMIMA)_2](PF_6)_2$ (1)

An X-ray diffraction study was carried out on the $[Mn(TMIMA)_2](PF_6)_2$ complex **1** and the experimental details are reported in Table 6 (Exp. Sect.). The asymmetric unit consists of a cationic moiety, formed by two neutral tridentate ligands coordinated to a central Mn^{II} ion, lying on a center of symmetry, and two hexafluorophosphate anions (see Figure 2). Selected distances and angles are reported in Table 1.

The hexafluorophosphate anions are found in two positions with an occupancy of 0.5. The manganese(II) ion is coordinated to six imidazole nitrogen atoms with distances of 2.364(2), 2.366(3), and 2.307(2) Å (by symmetry, the other Mn–N distances are identical). These distances are larger than the average value found using the Cambridge Crystallographic Database (CCDC)[17] for manganese complexes with ligands containing the imidazole ring [av. 2.226(12) Å on the basis of 42 fragments; see the list in the Supporting information].

The $Mn–N_{tripod}$ distance is 2.916(2) Å, which is longer than the sum of their van der Waals radii (2.82 Å). This is due both to the complete metal coordination sphere and to

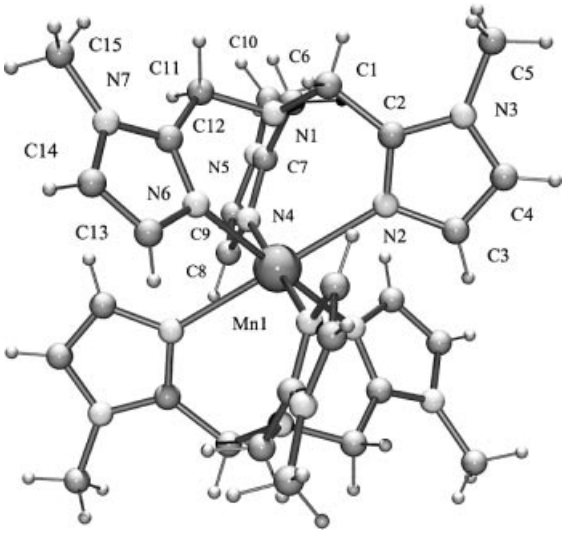

Figure 2. Representation of cationic complex **1**.

Table 1. Selected bonds and angles (symmetry operator A: $1 - x$, $-y$, $1 - z$).

Bonds	[Å]	Angles	[°]
Mn1–N2	2.364(2)	N2–Mn1–N4	98.73(7)
Mn1–N4	2.307(2)	N2–Mn1–N6	99.91(8)
Mn1–N6	2.366(3)	N4–Mn1–N6	100.48(7)
Mn1–N2A	2.364(2)	N2–Mn1–N4A	81.28(7)
Mn1–N4A	2.307(2)	N2–Mn1–N6A	80.09(7)
Mn1–N6A	2.366(3)	N4–Mn1–N6A	79.52(7)

the steric constraints imposed by the presence of two bulky ligands. In comparable structures, with a single tripodal ligand and a monodentate donor that completes the octahedron, the tripodal nitrogen atom is much closer to the central ion and forms a coordination bond: the average distance in these cases is 2.53(4) Å (on the basis of the same 42 fragments listed in the Supporting information). Deviation from the octahedral structure is also noticeable in the angle values (see Table 1).

Sheets of complex molecules, interacting through van der Waals contacts, pile up running parallel to the *xz* plane and are held together by a complex system of hydrogen bonds formed by the fluorine atoms of the hexafluorophosphate anions with the methyl and methylene groups of the ligand. The shortest distance between manganese ions is Mn···Mn (x, $-y - 1/2$, $+z - 1/2$) and is 9.413(1) Å. The magnetic properties of complex **1** are that of a Curie-law Mn^{II} ion, with a $\chi_{mol}T$ value of 4.4 $cm^3 mol^{-1} K$ from ambient temperature down to 2 K (results not shown), with no efficient Mn^{II}–Mn^{II} intermolecular through-space interaction at such distances.[13]

Description of the Structure of $[Mn(PI)_2](PF_6)(CH_3CN)$ (5)

An X-ray diffraction study has been carried out on the complex $[Mn(PI)_2](PF_6)(CH_3CN)$ (**5**). An ORTEP view of the manganese complex is shown in Figure 3 and the experimental details regarding data collection are reported in Table 6 (Exp. Sect.). The structure consists of two cationic moieties made up of manganese atoms lying on centers of symmetry surrounded by two tridentate monoanionic ligands. Manganese(III) ions present a slightly distorted octahedral coordination geometry as can be seen from the coordination distances and angles (Table 2), with a compression along the $O_{phenolato}$–Mn–$O_{phenolato}$.

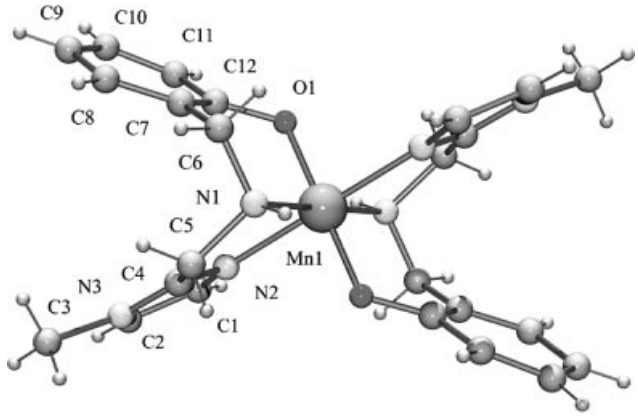

Figure 3. Representation of cationic complex **5**.

Table 2. Selected distances and angles for **5**.

Distances	[Å]	Angles	[°]
Mn1–O1	1.82(1)	O1–Mn1–N1	91.6(7)
Mn1–N1	2.20(2)	O1–Mn1–N2	92.3(7)
Mn1–N2	2.17(2)	N1–Mn1–N2	78.9(8)
Mn2–O2	1.85(1)	O2–Mn2–N4	91.7(6)
Mn2–N4	2.19(2)	O2–Mn2–N5	93.3(6)
Mn2–N5	2.18(2)	N4–Mn2–N5	79.0(7)

It is noteworthy that a hydrogen bond exists in the two independent molecules between the amino NH group and the phenol oxygen atom of the centrosymmetrically related ligand molecule [N1···O1 2.81(2) Å and N4···O2 2.83(2) Å]. A hexafluorophosphate anion compensates the charge of the cationic complex. Hydrogen bonds between fluorine atoms of PF_6^- and N1 and N4 are responsible for the overall packing. The structure also contains an acetonitrile crystallization molecule that occupies the remaining interstices.

Reactivity of the Mn^{II} Complexes with Superoxide in an Anhydrous Medium

In the series **1**, **2**, **3**, and **4**, Mn^{II} ions bear 0, 1 or 2 H_2O molecules, and show different bulkiness around Mn. The reactivity of both $[Mn^{II}(BMPG)(H_2O)]^+$ (**2**) and $[Mn^{II}(TMIMA)_2]^{2+}$ (**1**) was studied as described previously in the case of both **3** and **4**.[1]

Successive amounts of superoxide were added to a 10^{-3} mol L^{-1} solution of the complex in anhydrous DMSO. EPR spectra were recorded at 10 K. For **2**, the initial Mn^{II} signal[18] decreased from 0 to 1.5 equiv. superoxide. From 1.5 to 3 equiv., the solution was EPR-silent; and above

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Table 3. Reactivity of superoxide in anhydrous DMSO with Mn^{II} complexes from the N-tripodal series: amount of superoxide consumed deduced from the EPR spectrum.

	$Mn^{II}(TMIMA)_2^{2+}$	$Mn^{II}(IPG)(MeOH)^+$	$Mn^{II}(BMPG)(H_2O)^+$	$Mn^{II}(BIG)(H_2O)_2^+$
Number of water bound to Mn	0	0	1	2
$O_2^{\cdot-}$ consumed (equiv./Mn^{II})	1 equiv.	1 equiv.	3 equiv.	>5 equiv.

4 equiv., a signal from superoxide was finally obtained and quantified (data not shown, see Exp. Sect. and Table 3). For **1**, the 6-line hyperfine signal from Mn^{II} decreased upon superoxide addition; and at 2 equiv., the superoxide EPR signal was recovered and quantified (see Exp. Sect., Table 3 and Figure 4).

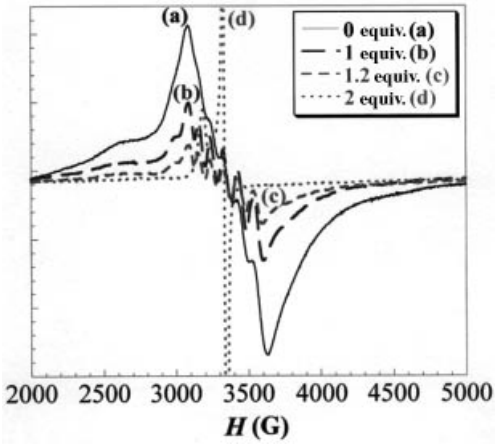

Figure 4. Reactivity of $[Mn(TMIMA)_2]^{2+}$ (**1**) with superoxide in anhydrous DMSO. $[Mn(TMIMA)_2](PF_6)_2$ (10^{-3} mol L^{-1}), 100 K, ν = 9.38 GHz, att. 20 dB, mod. amp. 5 G, t_c = 41 ms.

These results show that both **1** and **2** react with superoxide. No multiline signal was observed, showing that the formation of $Mn^{III}Mn^{IV}$ di-μ-oxo dimers, previously observed with **3** and **4**,[1,19] was not obtained in the case of **1** and **2**. This can be tentatively assigned to the steric crowding due the methyl groups in **2** and to the complete coordination sphere in **1**.

The superoxide signal was recovered at a different $O_2^{\cdot-}$/Mn stoichiometry for these complexes and quantified. The amount of $O_2^{\cdot-}$ consumed was determined (see Table 3). It appears that the more water molecules are coordinated to the Mn^{II}, the more equivalents of superoxide are consumed. The presence of the Mn ion is necessary since water alone, at the same concentration and under the same experimental conditions, did not switch off the superoxide signal.

Tuning Redox Potentials to Tune the SOD-Like Activity

Redox Potential and SOD Activity

The catalysis of the superoxide dismutation is a redox process, involving both Mn^{II} and Mn^{III} oxidation states. To make this redox catalysis efficient, the redox potential of the Mn^{III}/Mn^{II} couple should be, as encountered in SODs,[20] between the potential of the two couples $O_2/O_2^{\cdot-}$ and $O_2^{\cdot-}/H_2O_2$−that is, at pH = 7, –0.40 V and +0.65 V/SCE, respectively (see Figure 5).[9,21–24] Theoretically, the closer the potential of the two couples, the faster the reaction between them. Hitherto, the value optimizing the kinetics of both oxidation and reduction is the midway potential, i.e. 0.12 V/SCE.[9,20]

The Mn^{III}/Mn^{II} redox potential is controlled by the coordination sphere around the metal center, either through the nature of the Lewis bases coordinated to the Mn center, by electronic effect on the Lewis bases,[25] or by the geometry around the Mn center. Increasing the number of the O^- donor will lower the potential by increasing the electron density onto the metal center. Mn^{III}, as a d^4 ion, will prefer a geometric distortion from the octahedric structure. The redox potential of the Mn^{III}/Mn^{II} couple can be lowered by

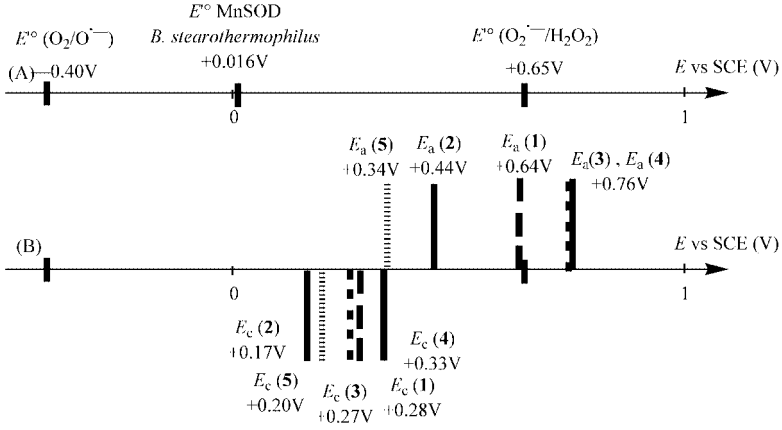

Figure 5. (A) Apparent standard redox potential for superoxide couples at pH = 7. (B) Anodic and cathodic half-wave potentials for the complexes in collidine pH 7.5 buffer.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

controlling the geometry around the metal center, that is by imposing some deformation with regards to the octahedral environment.[26]

No electrochemical wave was observed for the Mn^{II} complexes of this series in dimethyl sulfoxide, acetonitrile or phosphate buffer. This is not uncommon for Mn^{II} complexes.[27–29] In collidine buffer (pH = 7.5)[30] however, irreversible waves were recorded (see Figure 6 in the case of **4**). Anodic and cathodic potentials (Table 4 and Figure 5) are within (**2**, **5**, and **1**) or at the limit (**3** and **4**) of the required region for effective superoxide dismutation. Potentials for **3** and **4** are close, which is consistent with the similar environment around the metal cations. They are close to the potential previously reported for a Mn^{II} coordinated with *N*,*N*-bis(2-pyridylmethyl)-(*S*)-histidine, which shows a similar coordination sphere (2 imidazoles, 1 pyridine, 1 carboxylate).[30] For **1** and **2**, the anodic wave potentials are less positive. The conversion of Mn^{II} into Mn^{III} is thus easier. This can be assigned to the steric crowding encountered in **1** and **2**, which may favor a distorted environment around the metal center. In **5**, the N_4O_2 environment favors the Mn^{III} by comparison with the nitrogen-richer environment for the other complexes.

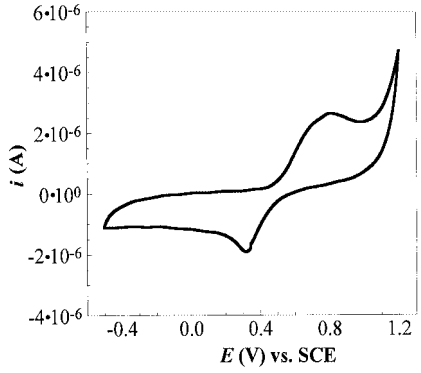

Figure 6. Voltammogram of **4** [2×10^{-3} mol L^{-1} (on the basis of Mn content)], collidine buffer (50 mM), pH = 7.5, 100 mV s^{-1}. Working electrode: vitrous carbon disk.

Evaluation of the SOD-Like Activity: McCord–Fridovich Assay

Reactivity towards the superoxide was investigated in an aqueous phosphate buffer (pH = 7.8) with the McCord–Fridovich assay, using the xanthine-xanthine oxidase system to produce the superoxide. The test is based on a kinetic competition for superoxide reduction between the putative superoxide scavenger and ferricytochrome c.[31] The reduction of ferricytochrome c was monitored spectrophotometrically at 550 nm. This test requires several preliminary checks in order to ensure its reliability (see Exp. Sect.).[1,8,32,33]

Complexes **1**–**5** inhibited the reduction of ferricytochrome c. The inhibition percentage was measured for several complex concentrations and the *IC*50 value was then deduced by two graphical methods (see Figure 7 and Exp. Sect. for details).[1,31,32,34,35] They are reported in Table 5.

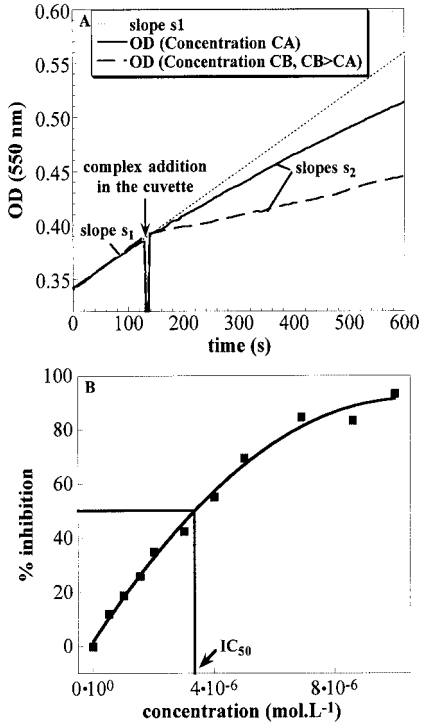

Figure 7. A. Kinetics of the reduction of ferricytochrome c (550 nm) without and with the putative SOD mimic **4**. B. Inhibition percentage as a function of **4**: *IC*50 determination.

It should be noted that reported *IC*50 values are dependent both on the detector used [usually cytochrome c Fe^{III} or nitroblue tetrazolium (NBT)] and on its concentration. For a given putative SOD mimic, the smaller the detector concentration, the smaller the *IC*50 value. Therefore, *IC*50 values are not appropriate for comparisons with the literature. From the measured *IC*50 values, it is possible to calculate a kinetic constant value (k_{McCF}), which is independent of both detector concentration and nature. At the *IC*50 concentration, superoxide reacts at the same speed with the detector and the putative SOD mimic. Then, $k_{McCF} = k_{detector}\cdot[detector]/IC50$.[36] In the case of cytochrome c Fe^{III} as the detector, $k_{Cyt\ c}$ (pH = 7.8; 21 °C) = 2.6×10^5 mol^{-1} Ls^{-1}.[37] In the case of NBT, k_{NBT} (pH = 7.8) = 5.94×10^4 mol^{-1} Ls^{-1}.[38]

Table 5 reports some values from the literature. The tested compounds **1**–**4** are within the range of the activities

[a] 50% inhibition concentration. Indices specify the UV/Vis probe (cytc Fe^{III} or NBT) concentration used for the test. k_{cat} is the catalytic constant directly measured by pulsed radiolysis or stopped-flow techniques and k_{McCF} are recalculated kinetic constants from the *IC*50 value. [b] Measured with XTT as UV/Vis probe. [51] k_{cat} was directly provided in the article, by comparison with SOD.[52] [c] IT: indirect test; SF: stopped flow; PR: pulsed radiolysis. DFB: desferrioxamine B; TBAP: 5,10,15,20-tetrakis(4-benzoic acid)porphyrin; PA: picolinate; TPAC: *cis*,*cis*-1,3,5-tri{(5-trimethylammonium)-2-hydroxypicolyl)amino}cyclohexane; salen: *N*,*N*′-bis(salicylideneamino)ethane; TPAA: tris{2-[*N*-(2-pyridylmethyl)amino]ethyl}amine; NTB: tris(2-benzimidazolylmethyl)amine; XTT: 3′-{1-[(phenylamino)carbonyl]-3,4-tetrazolium}bis(4-methoxy-6-nitrobenzenesulfonic acid) hydrate; Obz: benzoate; $HB(3,5\text{-}iPr_2pz)_3$: hydrotris(3,5-diisopropyl-1-pyrazolyl)borate; EDTB: *N*,*N*,*N*′,*N*′-tetrakis(2′-benzimidazolylmethyl)-1,2-ethanediamine; M40403 and *S*,*S*-dimethyl-M40403: Mn^{II} complexes from modified 1,4,7,10,13-pentaazacyclopentadecane ligands; BVDME: biliverdine IX dimethyl ester; TE-2-PyP: 5,10,15,20-tetrakis(*N*-ethylpyridinium-2-yl)porphyrin.

reported for Mn^{II} complexes. Compound **5** is the best within this series. *IC*50 values for Mn^{II} complexes **3** and **4** are far better than those reported for the corresponding Fe^{III} complexes. Mn seems to be a most suitable ion for SOD mimics, as it is the least toxic of the Fe, Co, Ni, Cu, Mn series. Moreover, the best SOD mimic reported so far is a Mn^{II} complex (see Table 5).

Pulse Radiolysis (for 3 and 4)

This McCord–Fridovich assay, as a determination of catalytic SOD-like activity is controversial. It has been shown, using stopped-flow techniques,[8,33] or pulse radiolysis,[28] that such an indirect test can be positive in the case of both a catalytic and a stoichiometric superoxide scavenger. As a matter of fact, in the McCord–Fridovich assay, superoxide is produced in low amounts. For compounds displaying high *IC*50 values (over 1 μmol L^{-1}), the conditions required to probe a catalytic behavior may not be fulfilled if $n_{complex} >> n_{superoxide}$ in the experiment. However, this test remains relevant as the X/XO system provides a stationary state of superoxide of low concentration, which is closer to what is usually encountered in vivo.[11,24] Moreover, in the case of a small *IC*50 value indicative of a catalytic activity, the k_{McCF} value derived from the *IC*50 value (see above) corresponds to the k_{cat}.

To test the catalytic behavior within the series, we studied the reactivity of **3** and **4** by pulse radiolysis. They were chosen because they have the highest *IC*50 values of the series, i.e. they were the slowest of the series.

Pulse radiolysis was used to produce the superoxide radical by irradiation of oxygenated aqueous solutions with high energy ionizing radiation.[53] Primary radicals ($H^{\cdot}$, e^{-}_{aq}, $HO^{\cdot}$) are rapidly and quantitatively converted into either superoxide $O_2^{\cdot-}$ or its protonated form hydroperoxyl $HO_2^{\cdot}$, in the presence of either formate or alcohols.[54,55] Propan-2-ol was chosen as formate might coordinate to Mn. The aqueous solution, driven at a constant rate through the UV/Vis microcell, was irradiated for a short time period with an irradiation frequency (1 Hz) chosen so that between two pulses the solution was totally renewed. Absorbances were averaged over 100 pulses. This setup provides an improvement of the signal to noise ratio, by comparison with generally used single-pulse experiments.[56–59]

Superoxide decay was directly monitored at 270 nm, in aqueous phosphate buffer solutions (5 mmol L^{-1}, pH = 7.8). Spontaneous decay of $O_2^{\cdot-}$ followed a second order rate law, as expected for autodismutation of superoxide. The ob-

served rate constant had a value of $1.3\times10^5\,mol^{-1}\,L\,s^{-1}$, consistent with that reported in the literature[54] at pH = 7.8 ($1.0\times10^5\,mol^{-1}\,L\,s^{-1}$). The effect of either **3** or **4** on the superoxide decay was tested for different concentrations of complex (2×10^{-7}, $10^{-5}\,mol\,L^{-1}$ for **3** and 2.14×10^{-7}, 2.14×10^{-6}, and $2.14\times10^{-5}\,mol\,L^{-1}$ for **4**, with an initial superoxide concentration $[O_2^{\cdot-}]_0 = 7.3\times10^{-5}\,mol\,L^{-1}$). From the absorbance decay at 270 nm, kinetic constants were deduced (see Exp. Sect.). The catalytic rate constants k_{cat} were obtained (see Exp. Sect.). They are reported in Table 5.

The apparent first-order kinetics observed for the superoxide decay in the presence of either complex, under conditions where $n_{complex} < n_{superoxide}$, showed that both **3** and **4** act as true catalysts for superoxide dismutation. The derived catalytic rate constant for **3** is of the same order of magnitude than that calculated from the *IC*50 values obtained by the McCord–Fridovich assay. For **4**, rate constants obtained from both methods are in good agreement.[60]

This pulse radiolysis experiment is strong evidence for the catalytic behavior of **3** and **4**. This conclusion concerning **3** is reinforced by further pulse radiolysis experiments that is described elsewhere.[61]

Correlation between SOD Activity and Potentials

As shown above, all redox potentials of the complexes of this series are in the expected range for the catalysis of superoxide dismutation. A linear correlation can be found between anodic half-wave potentials for the Mn^{III}/Mn^{II} couple and $\log(k_{McCF})$ with a negative slope, as shown in Figure 8. Within this series, the activity can be improved by a stabilization of the +III oxidation state: the rate-limiting step is the oxidation into Mn^{III}. Similar correlations have been described previously: (a) in the case of different series of Mn^{III}–porphyrins,[9,23,49] with a positive slope, indicating that the reduction to Mn^{II} was the rate-limiting step and; (b) in the case of Fe^{II} complexes with a negative slope, indicating that the oxidation to iron(III) was the rate-limiting step.[62]

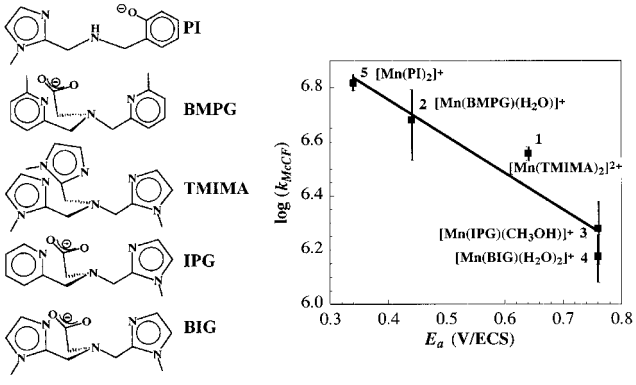

Figure 8. Correlation between E_a and $\log(k_{McCF})$.

Conclusions

The new Mn complexes **1** and **5**, whose structures are presented here, are part of a series of Mn complexes that were studied as SOD mimics. Reactivity in an anhydrous medium was described for **1** and **2** and compared with that of **3** and **4**, previously published.[1] The SOD activity was evaluated through the McCord–Fridovich assay and pulse radiolysis. *IC*50 values directly obtained from the McCord–Fridovich assay, are dependent on the experimental conditions used−that is on the concentration of the detector and its concentration. The results are thus provided and discussed here as derived values, k_{McCF}. We suggest that k_{McCF} should be more commonly used, as *IC*50 values are not comparable from one experiment to the other if different detectors or different concentrations of the same detector were used. The SOD activity in this series is found to be within the reported range for Mn^{II} compounds (see Table 5). The redox properties of the complexes from this series were studied by cyclic voltammetry in a collidine buffer. The potentials of the complexes of the series were tuned both by inducing steric constraints and by increasing the Lewis donor character of the ligands. The present article shows a linear trend between the anodic half-wave potential and $\log(k_{McCF})$ with a negative slope, indicating that the SOD activity in such a series can be improved by lowering the redox potential. Some new compounds are now under investigation to improve SOD activity.

Experimental Section

General: IR spectra (KBr) were recorded with a Bruker IFS 66 FT-IR spectrometer. ^1H NMR spectra were recorded with a Bruker AM 250 spectrometer (^1H, 250 MHz) or a Bruker AC 360 (^1H, 360 MHz). Cyclic voltammetry experiments were performed with an AUTOLAB potentiostat. Electronic absorption spectra were recorded with a Safas 190 DES double-mode spectrophotometer. Chemical reagents were purchased either from Aldrich or Acros and used without further purification. Xanthine oxidase and ferricytochrome c were purchased from Sigma.

Syntheses and Characterization

***N*,*N*,*N*-Tris[(1-methyl-2-imidazolyl)methyl]amine (TMIMA):** A solution of *N*,*N*-bis[(1-methyl-2-imidazolyl)methyl]amine[40] (see also refs.[14,63,64]) (4.1 g, 0.02 mol) with 1-methyl-2-imidazolcarbaldehyde (2.5 g, 0.02 mol)[16] in non-anhydrous MeOH (150 mL) was hydrogenated in the presence of Pd/C (10%) for 3 d. Pd/C was removed by filtration and the supernatant was concentrated to dryness. The white solid was purified by precipitation in CH_3Cl/Et_2O. Yield: 90%. M.p. 200 °C. ^1H NMR (250 MHz, CD_3OD): δ = 3.0 (s, 9 H, CH_3N), 3.8 (s, 6 H, 3 im-CH_2N), 6.7 (d, J = 2.3 Hz, 3 H, H_{im}), 6.9 (d, J = 2.3 Hz, 3 H, H_{im}) ppm. ^{13}C NMR (62 MHz, CD_3OD): δ = 31.7 (CH_3N), 48.7 (NCH_2-im), 121.3 (C_{4im}), 127.3 (C_{5im}), 145.4 (C_{2im}) ppm. IR (KBr; strong bands only): $\tilde{\nu}$ = 1495.8 (ν_{im}), 749.3 (δ_{im}) cm^{-1}. ESI-MS: *m*/*z* (%) = 300.2 (30) [M + H], 322.2,(10) [M + Na].

[2-(Methylamino)phenol]: This protocol was inspired from a published aliphatic nitrile reduction procedure.[65] 2-Cyanophenol (4 g, 33.6 mmol) was dissolved in EtOH (120 mL). An aqueous solution (20 mL) of NaOH (5 g, 125 mmol) and Raney nickel (about 3 g) were then added. The resulting suspension was stirred under H_2 (40 bars) for 4 h. After decantation of the nickel, the solution was filtered and EtOH was evaporated. CH_2Cl_2 (30 mL) was added and the pH of the aqueous phase was brought to 9.3 by addition of 2 N

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

HCl. The organic phase was decanted and the aqueous phase was further extracted 3 times with small portions of CH_2Cl_2. The organic phase was dried (Na_2SO_4) and the solvents were evaporated. 2-(Methylamino)phenol (2.42 g, yield 59%) was obtained as a white solid. The nonquantitative yield is probably due to the formation of the Ni^{II} complex which gives a blue-green coloration to the aqueous phase. ^1H NMR (250 MHz, $CDCl_3$): δ = 1.25 (br. s, NH_2), 4.14 (s, 2 H, CH_2), 6.81 (m, 2 H, Ar), 6.98 (d, J = 5 Hz, 1 H, Ar), 7.18 (t, J = 7.5 Hz, 1 H, Ar) ppm.

2-({[(1-Methyl-2-imidazolyl)methyl]amino}methyl)phenol (PIH): 2-(Methylamino)phenol (1 g, 8.1 mmol) and 1-methyl-2-imidazolecarbaldehyde (0.89 g, 8.1 mmol), synthesized according to a published procedure[16] were dissolved in anhydrous EtOH (80 mL). This solution was heated to reflux over 3 h and thencooled to ambient temperature. $NaBH_4$ (0.384 g, 10.2 mmol) was then added in small portions over 15 min and the resulting solution was refluxed for 5 min. 2 N aqueous HCl was then added until the end of gaseous release. EtOH was evaporated and CH_2Cl_2 (30 mL) was added. The pH of the aqueous phase was brought to 9.5 by addition of a 2 N aqueous NaOH solution. The organic phase was decanted and the aqueous phase was further extracted 3 times with small portions of CH_2Cl_2. The joint organic phases were dried (Na_2SO_4) and the solvents evaporated. PIH (1.2 g, yield 68%) was obtained as an orange oil. ^1H NMR (360 MHz, $CDCl_3$): δ = 3.45 (s, 3 H, NCH_3), 3.72 (s, 2 H, CH_2), 3.87 (s, 2 H, CH_2), 7.01 (t, J = 8 Hz, 1 H, Ar), 6.94 (d, J = 7.3 Hz, 1 H, Ar), 6.87 (br s, 1 H, Ar), 6.74 (br. m, 3 H, Ar) ppm. ^{13}C NMR (90 MHz, $CDCl_3$): δ = 32.3 ($N_{im}CH_3$), 43.3 and 51.0 ($N_{im}CH_2$ and $N_{Ar}CH_2$), 116.0, 118.9, 121.1, 122.8, 126.7, 128.5, 128.9, 145.2 (phenol and imidazole), 157.5 ($C_{phenol}OH$) ppm. IR (KBr; strong bands only): $\tilde{\nu}$ = 1456 and 1489 (ν_{im}), 1255 (ν_{phenol}), 756 (δ_{im}) cm^{-1}. ESI-MS: m/z (%) = 218.1 (100) [M + H].

$Mn(TMIMA)_2(PF_6)_2$ (1): An $MnBr_2$ solution in distilled water (125 mg in 7 mL) was added after deoxygenation (argon) to a hot (40 °C) deoxygenated methanolic solution of TMIMA (150 mg in 7 mL). After 1.5 h at 40 °C, it was allowed to cool to room temp. A deoxygenated solution of ammonium hexafluorophosphate (288 mg) in MeOH/H_2O (5 mL, 1:1) was then added. Crystals suitable for X-ray diffraction were grown by slow concentration over 24 h. Yield: 50%. $C_{30}H_{42}F_{12}MnN_{14}P_2$ (943.6): calcd. C 38.19, H 4.49, F 24.16, Mn 5.82, N 20.78, P 6.56; found C 38.00, H 4.39, F 24.60, Mn 5.83, N 20.70, P 6.48. IR (KBr): $\tilde{\nu}$ = 1503 (ν_{im}), 839 (PF_6^-), 741 (δ_{im}), 556 (PF_6^-) cm^{-1}. Crystals of $[Mn(TMIMA)_2](PF_6)_2$ (**1**) were obtained from a water/methanol solution as prismatic crystals. One of these, the size of which was 0.3 × 0.6 × 0.6 mm, was mounted on a SMART 1000 Bruker AXS diffractometer with Mo-K_α radiation (λ = 0.7107 Å). Atomic scattering factors were taken from ref.[66] The structure was solved by direct methods using SIR97[67] and refined using SHELXL-97[68] on F^2 by full-matrix least squares with anisotropic displacement parameters for all non-hydrogen atoms. All hydrogen atoms were calculated in ideal geometrical positions. Final refinement gave R_1 = 0.0348 and wR_2 = 0.0984. Experimental details for the X-ray data collection are reported in Table 6. The refinement procedure was carried out using the WinGX package[69] with the program PARST[70] for the geometrical description of the structures and ORTEP[71] and PLUTO[72] for the structure drawings.

$[Mn(PI)_2](CH_3CN)(PF_6)$ (5): A deoxygenated aqueous solution (8 mL) of $MnBr_2$ (124 mg, 0.58 mmol) was added to a deoxygenated methanolic solution (8 mL) of PIH (0.70 mmol). Et_3N (0.025 g, 0.25 mmol) was added. The resulting solution was allowed to stand for 1.5 h at ambient temperature under positive argon pressure. A deoxygenated solution (2.5 mL H_2O/2.5 mL MeOH) of NH_4PF_6 (0.25 g, 1.53 mmol, 2.6 equiv.) was then added. A white powder was then precipitated. The solid was filtered off and redissolved in CH_3CN. The solution turned violet and crystals of $[Mn(PI)_2](PF_6)\cdot CH_3CN$ suitable for X ray diffraction were obtained in low yield (50% from the powder) from acetonitrile by diffusion of tBuOMe as tiny dark crystals (see below). When the preparation was carried out at a higher temperature (50 °C) and under dioxygen, a purple black solution was obtained and a purple black powder was precipitated upon NH_4PF_6 addition. $C_{24}H_{28}F_6N_6O_2MnP(CH_3CN)_{0.5}(H_2O)_{1.5}$ (679.66): calcd. C 44.14, H 4.82, Mn 8.08, N 13.39, P 4.56; found C 44.30, H 4.51, Mn 7.99, N 13.37, P 4.66. IR (KBr; strong bands only): $\tilde{\nu}$ = 3438 and 3339 (ν_{NH}), 1595, 1507, 1477, 1268 ($\nu_{COphenol}$), 841 (PF_6), 779, 767 (δ_{im}), 557 (PF_6) cm^{-1}. Among the crystals obtained a few specimens were chosen and tested for diffraction. All of them were very small and badly twinned. The best crystal found (0.1 × 0.1 × 0.3 mm) was mounted on a Philips diffractometer with Mo-K_α radiation (λ = 0.7107 Å). Tabulated atomic scattering factors were taken from ref.[66] The structure was solved by direct methods using SIR97[67] and refined using SHELXL-97[68] on F^2 by full-matrix least squares with anisotropic displacement parameters for all atoms but the acetonitrile molecule and the hydrogen atoms. All hydrogen atoms were calculated in ideal geometrical positions. Because of its very small size the crystal used for structure characterization gave extremely weak diffraction. The final refinement suffers therefore from a very low ratio between the parameters to refine and the number of observed reflections. Final refinement gave R_1 = 0.117 and wR_2 = 0.36. Experimental details for the X-ray data collection are reported in Table 6. The refinement procedure was carried out using the WinGX package[69] with the program PARST[70] for the geometrical description of the structures and ORTEP[71] and PLUTO[72] for the structure drawings.

CCDC-245983 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Reactivity in Anhydrous DMSO with Superoxide: The protocol for studying the reactivity with Mn^{II} complexes was the same as that previously published (preparation of superoxide solutions, spectrophotometric titration).[1] Several aliquots were prepared with a final volume of 1 mL, containing the complex and n equiv. of superoxide. After the superoxide was added, the aliquot was manually stirred. 100 μL was introduced in an EPR tube which was immediately frozen in an EtOH/N_2(liq) bath and then kept in N_2(liq). EPR spectra were then recorded. For each experiment, the superoxide was quantified by EPR from the intensity of the g_{xy} = 2.00 peak and a linear correlation with concentration was found (see Supporting information). This was used to quantify the remaining superoxide within each EPR tube.

Cyclic Voltammetry Experiments: Cyclic voltammetry experiments were performed at room temperature with an argon stream in a collidine buffer (pH = 7.5; 50 mmol L^{-1}). The working electrode was a vitreous carbon disk. The reference electrode was an SCE, saturated with KCl. Concentrations of the complexes were 2×10^{-3} mol L^{-1} and 6×10^{-4} mol L^{-1} on the basis of Mn^{II} content.

McCord–Fridovich Assay or Xanthine-Xanthine Oxidase-Cytochrome c Assay: The superoxide anion was supplied to the system from the xanthine-xanthine oxidase reaction.

Reliability of the McCord–Fridovich Assay: To check that the tested compounds do not inhibit the production of superoxide by xanthine oxidase, the rate of conversion of xanthine to urate (see be-

low) was determined by measuring the increase in absorbance at 290 nm over a 2-min period with and without the tested compounds. At concentrations higher than the *IC*50 value, no inhibition of this conversion was recorded. We also checked that ferricytochrome c was stable in the presence of the putative SOD mimics.

Xanthine to Urate Assay: To measure the rate of conversion of xanthine to urate, xanthine oxidase (30 μL of 0.77 U mL^{-1} XO) was added to a solution of potassium phosphate buffer (pH = 7.8; 50 mmol L^{-1}) containing xanthine (150 μmol L^{-1}) at a final volume of 1.0 mL at 25 °C. Urate production was monitored at 290 nm. No difference in the slope was recorded with or without the putative SOD mimics.

Reduction of Ferricytochrome c: Activities were measured using ferricytochrome c reduction.[1,31,33,73] The assay was performed at 25 °C in 3 mL of reaction buffer (50 mmol L^{-1} potassium phosphate buffer, pH = 7.8) containing ferricytochrome c (22 μmol L^{-1}), xanthine (200 μM), and an amount of xanthine oxidase such as to give a rate of ΔOD_{550nm} = 0.025 min^{-1} (about 0.01 U mL^{-1}) in the absence of a putative SOD mimic. A reduction of ferricytochrome c was monitored at 550 nm. After 2 min, different amounts of the putative SOD mimic were added. Rates were linear for at least 8 min. Both rates in the absence and in the presence of the complex were determined for each concentration of complex added. The *IC*50 value represents the concentration of putative-SOD mimic that induces a 50% inhibition of the reduction of cytochrome c. If *s1* is the slope before addition of the putative SOD mimic and *s2* is the slope after addition of the putative SOD mimic, the inhibition percentage is given by I (%) = (*s1* – *s2*)/*s1*×100. For an *IC*50 value determination, I is measured for several concentrations in the range of the *IC*50. *IC*50 is obtained for I = 50%; (*s1* – *s2*)/*s2* was also plotted against the complex concentration, providing a linear correlation. *IC*50 is then obtained for (*s1* – *s2*)/*s2* = 1.[34]

Pulse Radiolysis Experiments: The pulse radiolysis experiment was carried out using a 10 MeV Titan β linear accelerator at the Laboratory of Radiolysis, CEA Saclay. Pulses can last between 5 ns and 1 μs, and the frequency between two pulses is adjustable. A 10 ns pulse corresponds to a 20 Gray dose. Solutions saturated with oxygen are driven in a quartz circulating microcell (spectral path length 1 cm, volume 400 μL) at a constant flux (1 mL min^{-1}). The spectroscopic and temporal analysis is mediated by an optical fiber, linked to a monochromator, then to a photomultiplier and lastly to a Tektronix numerical oscilloscope allowing the observation of the temporal evolution of absorbance. Absorbance was averaged over 100 pulses. It provides an improvement of the signal/noise ratio, by comparison with generally used single-pulse experiments. The amount of superoxide generated during pulse radiolysis was established by the absorbance value at 260 nm, assuming that ε_{260} = 1940 mol L^{-1} cm^{-1}[54] All measurements were carried out in propan-2-ol (100 mmol L^{-1}) in phosphate buffer (5 mmol L^{-1}) at pH = 7.8 and 25 °C. Various amounts of complexes MnIPG or MnBIG were dissolved in that buffer. Solutions were oxygen-saturated by bubbling O_2 for at least 60 min. The electron pulse lasted 1 μs, generating a 7.3×10^{-5} mol L^{-1} superoxide solution. The irradiation frequency was 1 Hz, so that the cell content was totally renewed between two pulses. The disappearance of superoxide was monitored at 270 nm (ε_{270} = 1479 mol L^{-1} cm^{-1} at pH = 7.8 and 23 °C[53]). Rates were derived assuming, either second-order kinetics corresponding to the auto-dismutation of superoxide [$OD = OD_0/(1 + k_{obs}\ OD_0 t)$], or a pseudo-first order kinetics in the presence of complexes {$OD = OD_0[\exp(-k_{obs}t)] + B$, $k_{obs} = k_{cat}$[complex] + A}. Simulations of kinetic traces are performed using Gepasi3 (auto-dismutation) or Kaleidagraph (complex catalyzed dismutation).

[18] The six hyperfine lines are broadened because of intermolecular interactions.
[19] In the case of **3**, the formation of a di-μ-oxo–$Mn^{III}Mn^{IV}$ species was observed after addition 0.5 equiv. of superoxide. The di-μ-oxo–$Mn^{III}Mn^{IV}$ species has been shown to be further reduced to a di-μ-oxo–$Mn^{III}Mn^{III}$ species (1 equiv. of superoxide). In the case of **4**, a similar behaviour was recorded upon addition of superoxide, but with a different stoichiometry. The $Mn^{III}Mn^{IV}$–di-μ-oxo complex was obtained after addition of 1.5 equiv. of superoxide and the EPR-silent $Mn^{III}Mn^{III}$–di-μ-oxo species was obtained after addition of 2 equiv. of superoxide. A mechanism involving the oxidation of the starting Mn^{II} complex to an $Mn^{III}Mn^{IV}$–di-μ-oxo and then a reduction to the $Mn^{III}Mn^{III}$–di-μ-oxo species has been proposed.

[60] In ref. 1[1], two *IC*50 values are reported for each complex. One value corresponds to that reported here. The other one, labeled specific *IC*50 or $IC50_{spe}$, was measured in the presence of an excess of ligand. This was done to estimate the effect of decoordination which could occur at a low concentration. For **3**, $IC50_{spe} = 2.0 \pm 0.2\ \mu mol\,L^{-1}$ ($k_{catspe} = 2.9 \pm 0.5\ 10^6\,mol^{-1}\,Ls^{-1}$) and for **4**, $IC50_{spe} = 1.7 \pm 0.2\ \mu mol\,L^{-1}$ ($k_{catspe} = 3.4 \pm 0.4\ 10^6\,mol^{-1}\,Ls^{-1}$). These values are closer to the pulse radiolysis values.

The *N*-Lithiation of 2,4,6-Triphenylborazine[‡]

Heinrich Nöth,*[a] and Alexander Troll[a]

Dedicated to Prof. Dr. Dr. h. c. mult. Rolf Huisgen on the occasion of his 85th birthday

Keywords: Lithium / Boron / Deprotonation reactions / Tetraphenylborazinates

The reaction of the borazine $Ph_3B_3N_3H_3$, **1**, with a diethyl ether solution of LiMe/LiI/TMEDA yields [$(Ph_4B_3N_3H_3)$Li(tmeda)LiI(tmeda)], **2**. However, when halide free LiMe is used in the presence of TMTA, then $(Ph_4B_3N_3H_3)$Li(tmta), **3**, is formed which shows that a Me/Ph exchange occurs with the formation of LiPh which adds to **1** to form the borazinate **3**. A Bu/Ph exchange is also observed in the reaction of **1** with Li*t*Bu/tmta. The product isolated from THF is compound [$(Ph_4B_3N_3H_2Li$–Li$(thf)_3$], **6c**, which results from deprotonation of and LiPh addition to **1**. A straightforward 1:1 LiPh addition reaction is observed on treatment of the borazine $Ph_3B_3N_3Me_3$, **4**, with LiPh in diethyl ether solution to give the borazinate $(Ph_4B_3N_3Me_3)$Li(OEt_2), **5**. Reaction of **1** with LiPh (ratio 1:1) in diethylether produces $(Ph_4B_3N_3H_2Li)$-[$Ph_3B_3N_3H_2$Li$(OEt_2)_2$], **7**, while an excess of LiPh leads to triple deprotonation and LiPh addition to the N atoms of compound $(Ph_3B_3N_3Li_3)$ to give the adduct [$Ph_3B_3N_3Li_3(OEt_2)_3$]-[LiPh(OEt_2)], **8**. All new compounds have been characterized by spectroscopic methods and X-ray structure determinations.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Borazines of type $R_3B_3N_3H_3$ can be deprotonated at the NH groups by organyllithium compounds. The resulting *N*-lithioborazine derivatives have been used to synthesize new organylborazines by treating them with organyl halides.[2,3] So far, only *N*-monolithio-borazines, $R_3B_3N_3H_2Li$ (R = Me, *t*Bu, NMe_2) have been characterized structurally as complexes with ligands such as diethyl ether (OEt_2), tetrahydrofuran (THF), tetramethyl diethylene diamine (TMEDA) or 1,3,5-trimethyl-1,3,5-hexahydrotriazine (TMTA).[1] Deprotonation proceeds by an addition-elimination process as demonstrated for the reaction of $tBu_3B_3N_3H_3$ with *t*BuLi.[1] Solvates of *N*-lithioborazines $R_3B_3N_3H_2Li$ (R = Me, *t*Bu, Me_2N) are usually present in the solid state in the form of dimers. Monomers are obtained with bulky ligands such as TMTA and/or large substituents (*t*Bu) located at the boron atoms.[1]

In 2,4,6-triphenylborazine, **1**, the phenyl groups are twisted against the borazine plane by about 29°[4] leaving a cleft between the phenyl groups. Due to this geometry, it was expected that **1** might behave differently towards LiR compounds compared with 2,4,6-trimethylborazine. And this is indeed the case as we will show here.

Reaction of $Ph_3B_3N_3H_3$, 1, with MeLi and LiBu

Because of the fact that **1**[5] is much more soluble in diethyl ether or tetrahydrofuran than in hydrocarbons its behaviour towards organyllithium compounds was studied mostly in ether solvents. Scheme 1 gives an overview of the results.

LiMe was first used as a solution in diethyl ether which contained an equivalent amount of LiI. The 1:1 reaction in the presence of TMEDA led to the monodeprotonated triphenylborazine $Ph_3B_3N_3H_2$Li(tmeda) cocrystallizing with LiI(tmeda) to give the product **2** (see Scheme 1). On the other hand, when halide free LiMe, prepared from Li metal and MeCl in diethyl ether, was activated by TMTA then the isolated compound **3** proved to be the Li complex of the 2,4,4,6-tetraphenylborazinate anion. This demonstrates that a LiMe/LiPh exchange has taken place, and that the generated LiPh has added to **1**. Compound **3** was isolated in 78% yield which fits well with Equations (1) and (2).

An organyl group exchange was also observed when **1** was treated with a solution of LiBu and TMTA in diethyl ether. The tmta complex **6b** could not be characterized, but crystallization of the reaction product from THF gave crystals of **6c** which proved to be a lithium (*N*-lithio-tetraphenylborazinate) isolated as its THF solvate [$(Ph_4B_3N_3H_2Li)$-Li$(thf)_3$]. Its formation is shown in Equations (3) and (4). A different solvate of this lithium *N*-lithio-tetraphenylborazinate could be isolated from a 1:1 reaction of LiPh in

[‡] Contributions to the Chemistry of Boron, 257. Part 256: Ref.[1]

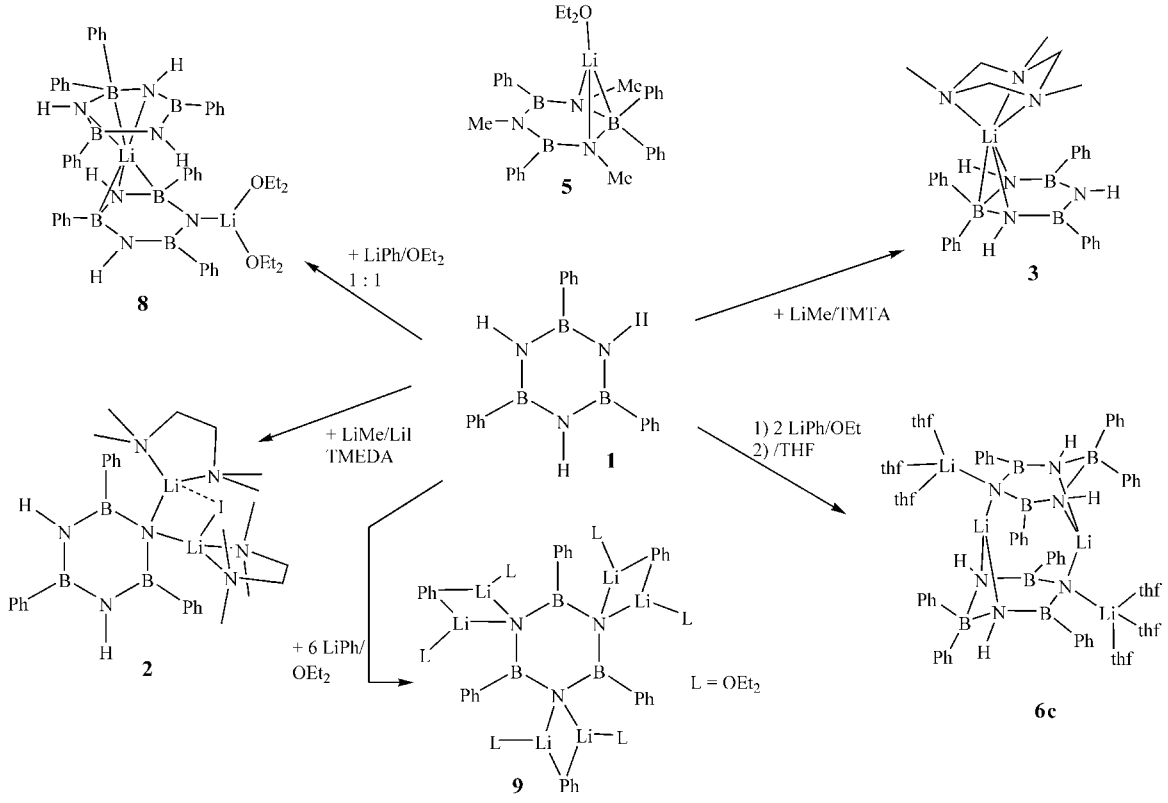
 DOI: 10.1002/ejic.200500135



Scheme 1. Reactions of **1** with LiMe/LiI, LiMe and LiPh.

$$Ph_3B_3N_3H_3 + 3\ LiMe + 3\ TMTA \rightarrow Me_3B_3N_3H_3 + 3\ LiPh(tmta) \quad (1)$$

$$\underset{\mathbf{1}}{3\ Ph_3B_3N_3H_3} + 3\ LiPh(tmta) \rightarrow \underset{\mathbf{3}}{3\ (Ph_4B_3N_3H_3)Li(tmta)} \quad (2)$$

diethyl ether with **1**. It was isolated as its bis(diethyl ether) adduct $[Ph_4B_3N_3H_2Li]Li(OEt_2)_2$, **6a**, which on treatment with THF converted to **6c**. These results suggest that **1** adds LiPh preferentially to give a stable tetraphenylborazinate. In order to test this assumption LiPh was allowed to react with $Ph_3B_3N_3Me_3$, **4**, where no deprotonation at the N atoms is expected. Indeed, LiPh adds readily to **4** producing a lithiumborazinate as shown in Equation (5) which was isolated as its mono diethyl ether adduct **5**.

$$5\ Ph_3B_3N_3H_3 + 6\ LiBu(tmta) \rightarrow$$
$$2\ Bu_3B_3N_3H_3 + 3\ Ph_4B_3N_3H_2Li_2(tmta)_n + 3\ PhH + 6 - n\ TMTA$$
$$\mathbf{6b} \quad (3)$$

$$Ph_4B_3N_3H_2Li_2(tmta)_n + 3\ THF \rightarrow \underset{\mathbf{6c}}{Ph_4B_3N_3H_2Li_2(thf)_3} + n\ TMTA \quad (4)$$

$$\underset{\mathbf{4}}{Ph_3B_3N_3Me_3} + LiPh + OEt_2 \rightarrow \underset{\mathbf{5}}{Ph_4B_3N_3Me_3Li(OEt_2)} \quad (5)$$

It was, therefore, of interest to test how LiPh in diethyl ether solution would react with **1**. As depicted in Scheme 1 and Equations (6) and (7), reactions indeed occur but are always accompanied by the deprotonation of **1**. In the case of the 1:1 reaction [Equation (6)] the isolated crystals proved to be composed of the components $Ph_3B_3N_3H_2Li$ and $Ph_4B_3N_3H_3Li(OEt_2)_2$, **7**, which are linked by Li–N and Li–B bonds as shown by its molecular structure determined by X-ray crystallography (see Figure 2a).

$$2\ Ph_3B_3N_3H_3 + 2\ LiPh + 2\ OEt_2 \rightarrow$$
$$\underset{\mathbf{7}}{[(Ph_4B_3N_3H_3Li(OEt_2)_2][Ph_3B_3N_3H_2Li]} + 2\ PhH \quad (6)$$

$$Ph_3B_3N_3H_3 + 2\ LiPh + 2\ OEt_2 \rightarrow \underset{\mathbf{6a}}{Ph_4B_3N_3H_2Li_2(OEt_2)_2} + PhH \quad (7)$$

When **1** was allowed to react with LiPh in a 1:2 ratio in diethyl ether, both addition and deprotonation of **1** occurred within a single molecule of **1** to give $[Ph_4B_3N_3H_2Li]$-Li. The compound was isolated as its bis(diethyl ether) solvate, $Ph_4B_3N_3H_2Li_2(OEt_2)_2$, **6a**, which readily looses most of its diethyl ether in vacuo. This compound can be transferred like **6b** into its tris(THF) complex **6c**, but single crystals of good quality were obtained only by its preparation according to Equations (3) and (4). This compound is also formed when the ratio of **1**/LiPh was increased up to 1:4 (as shown by ^1H and ^{11}B NMR spectroscopy). However, when this ratio was increased to 1:6 then a new compound **8** (see Scheme 1) could be isolated. This compound proved

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

to be the triply deprotonated borazine **1**, $Ph_3B_3N_3(Li{\cdot}OEt_2)_3$, stabilized by 3 equiv. of $LiPh(OEt_2)$ [Equation (8)].

$$Ph_3B_3N_3H_3 + 6\ LiPh + 6\ OEt_2 \rightarrow \underset{\mathbf{8}}{Ph_3B_3N_3Li_3(OEt_2)_3{\cdot}(LiPh{\cdot}OEt_2)_3} \quad (8)$$

The conclusion that we can draw is that a detailed study of the behaviour of borazines $R_3B_3N_3H_3$ with active organylmetal compounds offers an interesting new area of research akin to metal aryls.

Molecular Structures

Although single crystals were obtained of the new compounds [with the exception of **6a** and **6b** most of them showed only weak diffracting power even at low temperature (–80 °C)]. The molecular structures of compounds **2** to **8** are depicted in Figures 1–6, and relevant bonding parameters of B_3N_3 rings are presented in Tables 1 and 2. Two types of B_3N_3 rings can be compared: (a) *N*-lithioborazines in compounds **2** and **7**, with **6c** as a special case; and (b) lithioborazinates containing a tetracoordinated boron atom as found in compounds **3**, **5**, **6c** and **7**. For all cases the numbering in the figures starts with N1 (or the analogous atom N4 in combined borazines/borazinates or if two independent molecules are present in the unit cell) carrying one or two Li atoms. Atoms B2 (and/or B5) stand in *para* position to N1 (N4). In the case of the borazinates, B2 (and/or B5) are tetracoordinate B atoms. For centrosymmetric dimers only the asymmetric unit will be discussed in addition to the bonds from the Li atom that bridges the two rings. However, when there are two independent molecules in the unit cell, then the data of only one of them will be described provided that there are no strong deviations in the bonding parameters. This is, for instance, the case for **6c**. A selection of additional parameters is listed in the captions to the figures. While most of the observed Li–N distances were found in the range of 2.0 to 2.3 Å there are also short Li–B distances (2.2–2.4 Å) that we take as Li–B bonds. Li–B distances that are larger than 2.5 Å were considered to be nonbonded distances.

Compound **2** (see Figure 1) is a molecular complex of LiI with the *N*-lithioborazine $Ph_3B_3N_3H_2Li$. Each of the Li atoms is coordinated to one molecule of TMEDA, respectively. The LiN_2 planes of the tmeda ligands at Li1 and Li2 stand almost perpendicular to one another. The four N–Li–N bond angles at atom Li2 range from 84.2(2) to 116.3(2) indicating a distorted tetrahedral array. The Li2–I1 distance is 2.769(5) Å, similar to that found for $LiI(thf)_3$ [2.741(7) Å] [6] or LiI(pmdta) [2.75(3), 2.67(3) Å][7] while compound $[(tmeda)_2Li]I$ has an ionic structure.[8] Atom Li1 of **2** is

Table 1. Bond lengths [Å] and bond angles [°] of compounds **2** and **7** containing a $Ph_3B_3N_3H_2Li$ unit. Values for **7a/7b** refer to the two independent molecules in the unit cell. Numbering scheme for **7b** refers to the equivalent atoms in **7a**.

tricoordinate and is located in a planar environment of three N atoms (sum of bond angles = 359.8°). Quite unusual is the very open N1–Li1–N4 bond angle of 166.5(3)°. This arrangement seems to be due to a weak dipolar interaction of Li1 with I1. The Li1···I1 distance is 3.78 Å. A comparatively sharp bond angle is observed for Li1–N1–Li2 with 104.9(2)°.

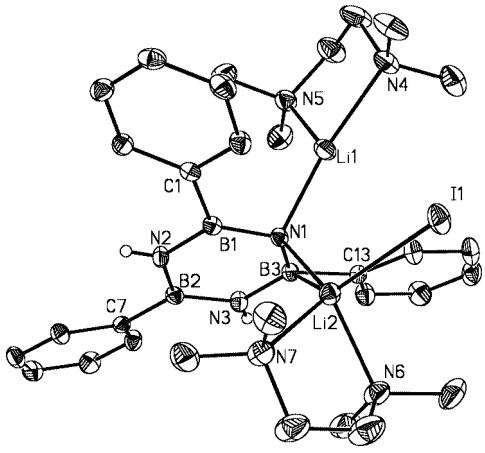

Figure 1. ORTEP plot of the molecular structure of **2**. Thermal ellipsoids are represented at a 25% probability scale. Selected bond lengths [Å] and angles [°]: B1–C1 1.595(4), B3–C13 1.598(4), B2–C7 1.582 (4), Li1–N1 1.999(5), Li1–N4 2.148(5), Li1–N5 2.140(6), Li2–N1 2.094(5), Li2–N6 2.152 (5), Li2–N7 2.223(5), Li2–I1 2.769(5), Li1···Li2 3.245(7). Li1–N1–Li2 104.9(2), B1–N1–Li1 107.3(2), B3–N1–Li1 111.6(2), B1–N1–Li2 109.5(2), B3–N1–Li2 105.3(2), N5–Li1–N4 85.3(2), N1–Li1–N5 108.2(2), N1–Li1–N4 166.5(3), N1–Li2–N6 126.2(2), N1–Li2–N7 116.3(2), N6–Li2–N7 84.2(2), B1–C1–C2 120.9(2), B2–C7–C8 121.7(2), C8–C7–C12 116.4(2), B3–C13–C14 122.6(2), C18–C13–C14 115.9(2). Torsion angles [°]: B2–N2–B1–C1 173.4, B2–N3–B3–C13 171.2, C8–C7–B2–N2 –20.7.

The geometry of the $Ph_3B_3N_3H_2Li$ unit is close to that found for $Me_3B_3N_3H_2Li$.[1] The borazine ring is not planar as shown by an interplanar angle of 7.4° for B1N1B3/B1N2N3B3. Angles B1–N1–B3 and N2–B2–N3 are smaller than 120° with 117.4(2)° and 115.4(2)° while all other endocyclic bond angles are 120° or a few degrees larger (see Table 1). Thus, the borazine unit is elongated along the N1···B2 vector. Typical are the B1–N2 and N3–B3 bonds which are elongated with respect to all the other B–N bonds. The phenyl groups are arranged in a propeller-like fashion and form torsion angles with the borazine ring of 14.7, 18.3, and 19.3° at atoms B3, B1 and B2 respectively, i.e. they are less twisted than in the parent compound **1**.

An *N*-lithioborazine unit is also present in compound **7** which is a borazine borazinate (see Figure 2a). Its two B_3N_3 rings are joined by atom Li2 coordinated to three N and two B atoms of the two rings while the second lithium atom (Li1) is coordinated to the N1 atom and two diethyl ether molecules.[9] The *N*-lithioborazine part (N1 to B3, N1A to B3A) is planar and stands almost parallel to the N4B4N5N6 plane of the borazinate unit (interplanar angle = 5.2°). Quite open are the Li1–N1–Li2 and N1–Li2–N6 bond angles with 126.2(3)° and 136.4(3)°, respectively. As shown in Table 1, the molecular parameters of the borazine ring are similar to those of compound **2**. The bonding, however, is drastically different in the borazinate unit due to the presence of the tetracoordinate B5 atom. This has the consequence that the B_3N_3 ring deviates strongly from planarity and adopts a tub shape with the B5 and N4 atoms pushed outside of the ring plane B4N5N6B6. Interplanar angles are N6B5N5/N6B6N5B4 = 31.3° and B6N4B4/B6N6B4N5 = 6.1°. This distortion of the borazine ring into a tub shape is obviously not only the consequence of the presence of the tetracoordinate B5 atom but also a consequence of the fact that the Li2 atom coordinates to N5 and N6 of the borazinate ring and to N1 of the borazine unit with Li2–N5, Li2–N6 and Li2–N1 distances of 2.157(7), 2.187(7) and 2.250 (6) Å, respectively. The sum of the bond angles at atom Li1 is 353.6° while it is 334.7° for atom Li2 (to atoms N1, N5, and N6) which joins the two B_3N_3 rings. There are two independent molecules in the unit cell. Figure 2b) depicts the core structures of the two independent molecules of **7** which are rather similar. There are no Li–Li bonding interactions.

Compound **3** crystallizes in two isomeric forms as a lithium tetraphenylborazinate (see Figure 3a,b). Its essential bonding parameters are listed in Table 2. As found for the borazinate part in compound **7** the Li atom coordinates with N atoms of the ring adjacent to the tetracoordinate B atom. In this case the atom Li1 is pentacoordinate by five N atoms, e.g. there are three Li–N bonds to the tmta molecule which range from 2.170 to 2.202(6) Å, while those to the borazinate atoms N2 and N3 are 2.222(6) and 2.184(7) Å, respectively. In addition Li1 coordinates also to atom C7. Figure 3b shows the core structure of compound **3** demonstrating that its Li atom is in an interesting coordinative situation as four N atoms and the Li atom form a plane while atoms N5 and C7 lie outside of this plane. This results in a strongly distorted octahedral coordination of the Li1 atom [bond angles: B2–Li1–C13 178.3(4), N3–Li1–N6 174.9(3), C7–Li1–N5 169.8(3), N2–Li1–N4 172.5(3), C7–Li1–N4 107.3(3), C7–Li1–N6 106.6(3)].

The sum of bond angles at atoms B1 and B3 is 360°. Nevertheless, the B_3N_3 ring in **3** is no longer planar and adopts like the corresponding ring in **5** a tub conformation with interplanar angles B2B3N3/N2B2B1N3 of 27.1°, and B1N1N2/N2B2B1N3 of 11.9°. All endocyclic bond angles at the B atoms are smaller than 120° while those at the N atoms are larger. B–N and B–C bonds to the tetracoordinate atom B2 are longer than those to the tricoordinate atoms. A new feature is that the B–N bonds next to the B2–N bonds are shorter than those to atom N1. This distinguishes the borazinates from the *N*-lithioborazines, and this has also been observed for the borazinates **3**, **5**, and **6c**, although the latter is a special case.

The borazinate **5** shows almost the same features as compound **3**. Once again there are two independent molecules in the unit cell which differ by the coordination of the Li atoms. These two molecules are shown in Figure 4a,b. In molecule **5a** the Li1 atom coordinates to the O atom of

Interplanar angles [°]: B1N2B3N3/B1N1B3 4.5, B1N2B3N3/N2B2N3 5.2, B1N2B3N3/C18C13C14 19.3, B1N2B3N3/C7C8C12 19.9, B1N2B3N3/C C16C 26.3; B4N5N6B6/B4N4B6 33.2, B4N5N6B6/N5B5N6 26,7, B4N5N6B6/C20C19C24 69.5, B4N5N6B6/ C38C37C42 16.7, N5B5N6/C44C43C48 90.5, N5B5N6/ C50C49C54 52.5. Second molecule: B11N12N13B13/B1111B13 2.7, B11N12N13B13/N12B23N13 4.7, B11N12N13B13/C102C101C106 150.2, B11N12N13B13/C108C107C112 14.8, B11N12N13B13/C114C113C118 6.9. (b) The core structure of the two independent molecules of **7**.

the diethyl ether molecule and to two N atoms next to the tetracoordinate B atom of the borazinate ring. In addition there is a weak Li–C interaction. While the Li2 atom of the second isomer shows less symmetry because the Li–N bonds involve not only one N atom next to the tetracoordinate atom B5 but also one to atom N4.

Compound **6c** (see Figure 5) is a special case because it combines both a borazinate and a deprotonated N atom within a single borazine ring. It crystallizes from THF as $Ph_4B_3N_3H_2Li_2(thf)_3$. This molecule is present in the solid state as a dimer where the Li atom of the two borazinate units binds the two rings together each forming three Li–N bonds. Therefore, all ring nitrogen atoms are involved in bonding. Both independent Li atoms (Li1 and Li2) show tetracoordination. The Li atom of the *N*-lithioborazine part is coordinated to the N1 atom of its ring and three O atoms of the THF molecules. Figure 5a shows the dimeric molecule (for clarity two phenyl groups are depicted only by their *ipso*-C atoms) while Figure 5b depicts the disorder of two of the three THF molecules.

In all compounds with a borazinate unit there are Li···B interactions. In **5** the shortest Li–B contact is Li1–B2 with

B1N23N3B3/C1C2C6 120.0, B1N2N3B3/C10C11C15 107.4, B1N23N3B3/C16C17C21 91.5, B1N2N3B3/C22C23C27 117.4. (b) The structure of the second isomer of compound **5b**. Selected bond lengths [Å] and angles [°]: Li2–N4 2.143(6), Li2–N5 2.426(3), Li2–B4 2.485(6), Li2–B5 2.400(5), Li2–C53 2.414(6), Li2–C58 2.399(6), B4–C43 1.587(4), B5–C53 1.662(4), B5–C59 1.628(4), B6–C65 1.569(4). O2–Li2–N4 114.6(2), O2–Li2–N5 136.5(3), N4–Li2–N5 64.4(2), N4–B4–Li2 73.4(2), N5–B4–Li2 62.2(2), B4–N4–Li2 71.5(2), B4–N5–Li2 82.2(2). Interplanar angles [°]: B4N4N6B6/B4N4B6 10.7, B4N5N6B6/N5B5N6 2.8.

2.314(8) Å, in **6c** the Li–B distances are 2.342(8) Å for Li1–B2, 2.213(3) for Li1–B3, 2.400(5) for Li2–B4, and 2.485(6) Å for Li2–B5, while the distance Li2–B3a is 2.701(6) Å. Moreover, in compound **3** the shortest Li–B distances are Li2–B5 with 2.298(8) and Li4–B15 2.277(8) Å; all other Li–B distances are larger ranging from 2.583 to 2.694(4) Å. Taking these distances into account there are obviously η-(BN)Li interactions in these compounds similar to the Li–C interactions of aryllithium compounds.[10] However, in contrast to $(Et_3B_3N_3Me_3)Cr(CO)_6$[11] with its puckered borazine ring, the B_3N_3 rings deviate either only slightly from planarity or adopt a tub or a twist conformation for borazinates. Thus, the *N*-lithioborazines and borazinates are structurally quite different compared to aryllithium compounds.

Interplanar angles [°]: B1N1N3B3/B1N1B3 2.6, B1N1N3B3/N2B2N3 27.8, B1N1N3B3/C19C20C24 12.9, B1N1N3B3/C2C1C6 7.6, N2B2N3/C14C13C18 50.5, N2B2N3/C8C7C12 125, C13C14C18/C8C7C12 75.5. (b) Plot of the disordered THF molecules in compound **6c**.

Finally, Figure 6 represents the molecular structure of compound **8**. Several crystals were subjected to data collection, but all of them diffracted very weakly even when fairly large crystals were used. Therefore, we will not discuss any bonding parameters, but use the result of the "best" crystal structure solution (R_1 = 16.2%) to show its rather unusual structure which can be looked at as a triply *N*-lithiated 2,4,6-triphenylborazine stabilized by three molecules of phenyllithium. Each Li atom binds to one diethyl ether molecule.

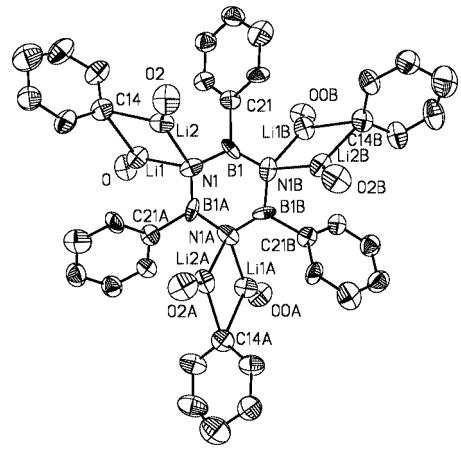

Figure 6. ORTEP plot of the molecular structure of compound **8**. Thermal ellipsoids represent a 25% probability. NMR and IR Spectra

^{11}B NMR spectroscopic data allow a clear distinction between *N*-lithioborazines and lithium borazinates (see Tables 3 and 4). For the former, the ^{11}B resonance is practically the same as for **1** with somewhat broader line widths. For **2** a slightly better shielded ^{11}B nucleus is observed although two kinds of tricoordinate B atoms might have been detected. This suggests that either this molecule is fluxional in solution or that the shift difference between the boron atoms B1 and B3 that are adjacent to the deprotonated nitrogen atom N1 and to the boron atom B2 is marginal. We prefer this latter alternative as two kinds of phenyl groups are observed both in the ^{13}C and ^{1}H NMR spectra. The borazinates, however, show two ^{11}B NMR signals in a 1:2 ratio for the tetracoordinate B2 atoms and the tricoordinate B1 and B3 atoms. The latter are in general slightly better shielded – by about 1 ppm – than those of the parent compound **1**. As expected, the ^{11}B NMR signal of the tetracoordinate B2 atoms are observed at lower frequencies with δ^{11}B at about –5 ppm. They also show much sharper signals compared to the tricoordinate B atoms (Table 3 and Table 4).

The ^{7}Li resonances indicate that the structures found for the solid state are retained in solution as compounds **2**, **6**, and **7** show two different ^{7}Li NMR signals. We assign the signals in the higher field (in the range of 0.9 to –0.39 ppm) to the "terminal" Li atoms while those in the range from 1.58 to 2.4 ppm are assigned to those of the borazinates where the Li atom binds to the borazinate nitrogen atoms.

There are two sets of signals for the C atoms of the phenyl groups bound to B1/B3 and B2 atoms in compounds

having an *N*-lithioborazine skeleton while for the borazinates the two phenyl groups at the tetracoordinate boron atom B2 are chemically and magnetically different (see data in Table 3). ^{13}C NMR signals for the boron bonded *ipso*-C atoms could not be observed. This is a well-known phenomenon. The ^{1}H NMR signals of the phenyl groups show the expected ^3J(H,H) coupling with a value of 7 Hz. All NH proton signals are slightly deshielded compared with those of **1**. In the case of the borazinates two broad signals are observed in contrast to a single resonance for the *N*-lithioborazines.

B–N stretching bands of the BN ring modes are found in a range from 1475 to 1370 cm^{-1}. In most cases the band at 1472 cm^{-1} of **1** is shifted to smaller wave numbers indicating a weakening of the B–N bonding.

Discussion and Conclusion

The question of bonding in borazines in comparison to benzene is still not definitely settled[12] and whether borazines are supposed to be antiaromatic or aromatic depends on whether one discusses magnetic properties or bond energies. However, there is consent that borazines are much more reactive than benzene and its derivatives due to the B–N bond polarity. This not only relates to the ready addition of electrophiles to its N atoms but also of nucleophiles to the B atoms, and borazinate formation is a typical example of the latter. In addition, borazines of type $R_3B_3N_3H_3$ are also weak protic acids as was first shown by Wagner and Bradford[2,3] and delineated also in this and the previous study.[1] In the resulting *N*-lithioborazines and lithium borazinates the Li atoms coordinate in most cases to two N atoms of a B_3N_3 ring, but also all three atoms may be used for this purpose (**6c**). The resulting lithium tetraphenylborazinates add LiI or $Ph_3B_3N_3H_2Li$ in a 1:1 ratio (compounds **2** and **7**) or the borazinates may even dimerize (compounds **6** and **7**). Quite unusual is the 1:1 deprotonation and borazinate formation at a single borazine

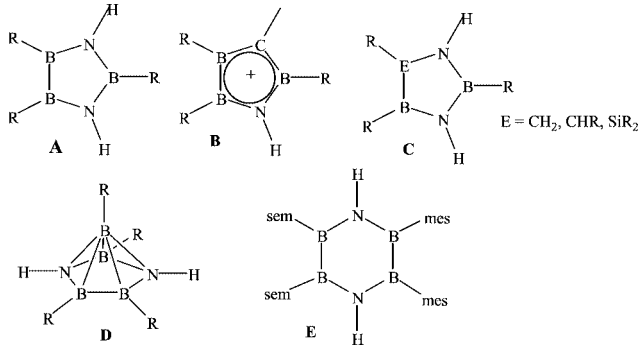
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ring as found for the 1:2 reaction of LiPh with **1** to give compound **7**. And in the case of the 1:6 ratio of **1** with LiPh even a triple deprotonation was observed, the compound $Ph_3B_3N_3Li_3$, being stabilized by the addition of three molecules of LiPh, **8**. These are reactions unprecedented compared with the behaviour of benzene derivatives.

The ring planarity of the B_3N_3 ring is lost by the formation of the borazinate anion which adopts a tub shape conformation or contains twisted B_3N_3 rings. In these cases, the Li cation coordinates to two or even three ring N atoms. In the latter case, one observes dimerization via two Li bridges between two B_3N_3 rings (**6c** and **7**). Borazinate formation is accompanied with a strengthening of the two B–N bonds adjacent to the tetracoordinate boron atoms, while these bonds are weaker (longer) in the *N*-lithioborazines. This indicates that the electron distribution in these two ring systems is different. Although the monolithioborazines may be looked at as isoelectronic counterparts to aryllithium compounds[9,10] this statement may be far too shortfetched. Observed Li–N and Li–B interactions are not necessarily an indication of η-(NB)Li bonding. In the case of $(Et_3B_3N_3Et_3)Cr(CO)_3$, this type of interaction has been disputed because the borazine ring is puckered and the CO bonds are close to linearity with the Cr–C bonds.[13] However, a more recent theoretical treatment of the bonding in borazine tricarbonylchromium compounds is in favour of π-bonding.[14] One argument given is that the puckering of the ring is only weak and not comparable with a hexahydrotriazine.

The *N*-lithioborazines are also structurally not close to the $Cr(CO)_3$ complexes of borazines.[11] None of the compounds contain a Li atom that sits symmetrically above the B_3N_3 ring plane. An approximation is, however, found in one of the two isomers of **5** but two of its three Li–B distances are >2.5 Å. Thus, the structural chemistry of *N*-lithioborazine and lithium borazinates is unique which is, of course, due to the B–N bond polarity of the borazine ring system. One may try, however, to find similarities between the structures of *N*-lithioborazines and lithium carboranates.[15,16] In the latter class of compounds the solvated Li cation may be coordinated to a B–B, B–C or a C–C bond or to an open face of the carborane as found for *closo-exo*-5,6-[μ-H_2Li(thf)$_2$][1-Li(thf)$_2$-2-(Me_3Si)-3-(R)-2,4-(Me_3Si)-2,4-$C_2B_4H_4$] (R = $SiMe_3$, Me).[17] In this complex, one Li cation sits on top of an open C_2B_3 face while the second is bonded sidewise to a B–B bond. This lithium carboranate on reaction with YCl_3 produces the complex [Li(thf)$_4$]{(1-Cl-1-H_6)-2,2′,3,3′(Me_3Si)$_4$-4,4′,5,5′-Li(thf)[1,1′-*commo*-Y(2,3-$C_2B_4H_4$)$_2$]}[18] where the Li cation of the yttriate coordinates to four B atoms (2 each per carborane unit) with Li–B distances of 2.31(4), 2.27(4), and 2.49(4) Å. In the starting material the Li–B distances are Li1–B3 2.291(9), Li1–B4 2.371(9), and Li1–B5 2.237(10) Å.[17] A totally different situation results for the lithium salt of the triboracyclobutane dianion {[Me_3Si(CH_2SiMe_3)B][B(duryl)]$_2$}$^{2-}$ where both THF-solvated Li cations coordinate to two boron atoms of the BBB triangle with Li–B distances of 2.309(5), 2.325(5) for the Li(thf) group and 2.323(5) and 2.529(5) Å for the Li(thf)$_2$ unit. The Li atom lies almost in the B_3 plane.[19] Reduction of the six-membered [MeB(CHMe)]$_3$ by Li metal in diethyl ether or THF occurs in several steps leading finally to an *arachno*-borane structure for [MeBCH(Me)-Li]$_3$.[20] In this molecule the Li atoms bridge to basal adjacent C atoms but binds also to B atoms with distances ranging from 2.239(6) and 3.251(6) Å. Li–C bond lengths are somewhat longer at 2.247–2.456(6) Å.

Obviously, there are no close similarities between *N*-lithioborazines and lithium carboranates, the closest ones are those in which a Li atom coordinates to two borazine rings or to two open faces of two carborane anions. η^6-Coordination of an *N*-lithioborazine results in one of the isomers of compound **5**, but only when relatively long Li–N and Li–B distances are included. Carborane anions usually offer a pentagonal face as the most basic site for Li coordination while in *N*-lithioborazines Li–N coordination prevails. This situation may change for the following five-membered rings (Scheme 2) which on deprotonation may behave more like the carboranes.



Scheme 2.

Moreover, the deprotonation of the *arachno*-diazahexaborane and/or its classical isomer, 1,4-diazatetraborinane should provide interesting examples for studying the relationships between carboranes offering a B_3C_2 open face and its isoelectronic BN analogue.

Experimental Section

General Remarks: All experiments were carried out using standard Schlenk techniques under argon. Organyllithium compounds were obtained as diethyl ether or hexane solutions from Chemetall AG. Solvents were dried and distilled under nitrogen. NMR spectra were recorded with a Jeol EX00 for ^{1}H, ^{7}Li, ^{11}B, ^{13}C NMR (399.782, 157.48, 128.262, 100.531 MHz, respectively) spectra using $SiMe_4$ and C_6D_6 as internal standards with a 1 M aqueous LiCl solution, or BF_3·OEt_2 as the external standard. A Siemens P4 diffractometer equipped with the low-temperature device LT2 was used for intensity data collection with Mo-K_α radiation and a CCD area detector. Data were recorded at –80 °C.

2,4,6-Triphenylborazine (1):[4,13] Freshly distilled ($Me_3Si)_2NH$ (93.8 mL, 72.6 g, 450 mmol) was dissolved in dichloromethane (250 mL) and the solution cooled to –78 °C. Then $PhBCl_2$ (75.0 g, 472 mmol) was added with stirring. The mixture was then kept at 55 °C for 10 d. Within this period the ^{11}B NMR signal for the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

PhB(Cl)NHSiMee$_3$ (δ^{11} B = 37.6 ppm) vanished and only the signal for **1** was observed (δ^{11}B = 34.8 ppm). All volatiles (CH_2Cl_2, Me_3SiCl) were then removed in vacuo and the residue crystallized from diethyl ether. Yield: 45.4 g, 98%. M.p. 180–185 °C. ^{13}C NMR (C_6D_6): δ = 128.4, 130.1, 132.4 ppm. ^{11}B NMR: δ = 34.8 ppm.

(Tetramethylethylenediamine)lithium–2,4,6-triphenylborazine–(tetramethylethylenediamine)lithium Iodide (2): 1 (1.03 g, 3.34 mmol) was dissolved in diethyl ether (60 mL) at 0 °C. With stirring, a solution of commercial LiMe (containing LiI) in diethyl ether (2.20 mL, 3.52 mmol) and TMEDA (1.0 mL) was added drop wise to the borazine solution. After warming to ambient temperature, the clear solution was stirred for 2 d and then reduced in volume to about 20 mL. At –5 °C colorless prisms separated from the slightly brown solution. Yield: 2.10 g, 92%. M.p. 173–175 °C. ^{1}H NMR (C_6D_6): δ = 2.00 (s, 24 H, NCH_3), 2.14 (s, 8 H, NCH_2) ppm. ^{13}C NMR: δ = 46.0, 58.2 ppm. ^{11}B NMR: δ = 34.1 ($h_{1/2}$ = 350 Hz) ppm. $C_{30}H_{49}B_3IN_7Li_2$ (680.98): calcd. C 52.91, H 7.25, I 18.63, N 14.40; found C 52.86, H 7.13, I 18.51, N 14.22.

(1,3,5-Trimethylhexahydrotriazine)lithium 2,4,4,6-Tetraphenylborazinate (3): 1 (1.17 g, 3.79 mmol) was placed into a flask containing diethyl ether (60 mL). The suspension was cooled to 0 °C. To a solution of LiMe (prepared from Li grains and MeCl in diethyl ether, 4.0 mmol, 2 5 mL, 1.6 M) diluted with diethyl ether (10 mL) was added trimethylhexahydrotriazine (1.1 mL, 7.8 mmol). This LiMe reagent was slowly added dropwise into the diethyl ether solution of **1** at 0 °C. A clear solution resulted which was stirred for 2 d and then reduced in volume in vacuo. On keeping the solution at –5 °C, colorless prisms of **3** separated (1.90 g, 3.63 mmol, 95%). M.p. 91–95 °C. ^{1}H NMR (C_6D_6): δ = 1.95 (s, 9 H, NCH_3), 3.01 (s, 6 H, NCH_2) ppm. ^{13}C NMR: δ = 38.4, 76.6 ppm (azin). ^{11}B NMR: δ = –5.2 ($h_{1/2}$ = 150 Hz), 33.1 ($h_{1/2}$ = 400 Hz) ppm (ratio 1:2). ^{7}Li NMR: δ = 2.1 ($h_{1/2}$ = 40 Hz) ppm. IR (Nujol/Hostaflon; only medium to strong signals): $\tilde{\nu}$ = 3411 m, 3077 m, 3053 m, 3030 m, 3013 m, 2992 m, 2050 m, 2870 m, 2795 m, 2734 m, 2720 m, 2711 m, 1600 m, 1502 st, 1474 st, 1441 vst, 1422 vst, 1408 vst, 1347 m, 1314 m, 1272 st, 1502 st, 1474 st, 1441 vst, 1408 vst, 1347 m, 1314 m, 1272 st, 1195 m, 1157 m, 1118 vst, 1029 m, 1016 st, 939 st, 930 m, 866 m, 762 m, 756 m, 732 st, 704 vst, 671 st, 6521 m, 581 m, 557 m cm^{-1}. $C_{30}H_{38}B_3LiN_6$ (522.06): calcd. C 69.02, H 7.34, N 16.10; found C 68.08, H 7.42, N 15.71.

(Diethyl ether)lithium 1,3,5-Trimethyl-2,4,6,6-tetraphenylborazinate (5): To a stirred solution of $(PhBNMe)_3$, **4**,[13] in diethyl ether (0.304 g, 0.86 mmol, 40 mL) was added at 0 °C a solution of LiPh (0.45 mL, 0.9 mmol) in diethyl ether/cyclohexane (1:1). The resulting clear yellow solution was stirred for 2 d at ambient temperature and then reduced to a volume of ca. 20 mL in vacuo. On storing the solution at –5 °C crystals separated within a few days. Yield: 0.42 g of **5**, 95%. M.p. 165 °C (dec.). ^{1}H NMR (C_6D_6): δ = 0.68 (t, 6 H, CH_2CH_3), 2.49 (s, 6 H, 1,5-NCH_3), 2.71 (s, 3 H, 3-NCH_3), 2.90 (q, 4 H, OCH_2), 7.13 (t, 4 H, *m*-PhB-2,6, $^3J_{H,H}$ = 7.0 Hz), 7.17 (t, 2 H, *m*-PhB-4, $^3J_{H,H}$ = 7.0 Hz), 7.19 (t, 2 H, *m*-PhB, $^3J_{H,H}$ = 7.0 Hz), 7.25 (t, 1 H, *p*-PhB-4, $^3J_{H,H}$ = 7.0 Hz), 7.26 (t, 1 H, *p*-PhB-4′, $^3J_{H,H}$ = 7.0 Hz), 7.30 (t, 2 H, *m*-PhB-2,6, $^3J_{H,H}$ = 7.0 Hz), 7.35 (dd, 4 H, *o*-PhB-2,6, $^3J_{H,H}$ = 7.0, $^4J_{H,H}$ = 1.0 Hz), 7.59 (d, 4 H, *o*-PhB-2,2′, $^3J_{H,H}$ 7.0 Hz) ppm. ^{13}C NMR (C_6D_6): δ = 14.9 (CH_2CH_3), 36.6 (NCH_3), 37.2 (NCH_3), 64.6 (OCH_2) ppm. ^{11}B NMR: δ = 1.9 ($h_{1/2}$ = 130 Hz), 37.2 ($h_{1/2}$ = 400 Hz) ppm. ^{7}Li NMR: δ = 2.1 ($h_{1/2}$ = 40 Hz) ppm. IR (Nujol/Hostaflon; only medium to very strong signals): $\tilde{\nu}$ = 3067 st, 3044 st, 3006 st, 2997 st, 2982 st, 2945 st, 2894 st, 2852 m, 2819 m, 1595 st, 1567 m, 1497 st, 1481 st, 1466 st, 1431 st, 1397 vst, 1368 st, 1355 vst, 1298 vst, 1265 st, 1258 st, 1194 m, 1160 m, 1146 st, 1111 m, 1064 st, 1044 m, 1019 st, 999 m, 912 m, 900 m, 854 m, 845 m, 756 wt, 721 st, 716 st, 704 vst, 621 m, 617 m, 486 m cm^{-1}. $C_{31}H_{39}B_3LiN_3O$ (509.05): calcd. C 73.15, H 7.72, N 8.25; found C 71.88, H 7.73, N 8.16.

Bis(diethyl ether)lithium 2,4,6,6-Tetraphenylborazinate–lithium–2,4,6-triphenylborazine (7): To a stirred solution of **1** (0.858 g, 2.7 mmol) in diethyl ether (50 mL) was slowly added a 2 M solution of LiPh (1.39 mL, 2.78 mmol) in diethyl ether/cyclohexane. The brownish solution was then stirred for 5 d at ambient temperature followed by reduction of its volume to 20 mL in vacuo. The solution was kept at –5 °C. Colorless crystals separated from the slightly brown solution. Yield: 1.05 g of **7**, 91%. M.p. 130–132 °C (dec.). ^{1}H NMR (C_6D_6): δ = 1.07 (t, 12 H, CH_2CH_3, $^3J_{H,H}$ = 7 Hz), 3.20 (q, 8 H, OCH_2, $^3J_{H,H}$ = 7 Hz), 4.64 (br. s, 2 H, N-1′,5′-H), 5.57 (br. s, 2 H, N-3,5-H) 6.94–7.58 (m, 35 H, PhB) ppm. ^{13}C NMR: δ = 15.2 (CH_2CH_3), 65.8 (OCH_2) ppm. ^{11}B NMR: δ = –4.6 ($h_{1/2}$ = 170 Hz), 33.5 ($h_{1/2}$ = 360 Hz) ppm. ^{7}Li NMR: δ = 0.9 ($h_{1/2}$ = 80 Hz), 2.4 ($h_{1/2}$ = 120 Hz) ppm. IR (Nujol, Hostaflon; only medium to very strong bands quoted): $\tilde{\nu}$ = 3446 m, 3430 m, 3074 m, 3049 st, 3009 st, 2997 st, 2977 st, 2931 st, 2898 m, 2862 m, 1599 vst, 1571 m, 1501 vst, 1479 st, 1424 vst, 1399 vst, 1359 m, 1339 m, 1312 st, 1300 m, 1264 m, 874 m, 752 st, 743 m, 705 vst, 663 m, 652 m, 682 m, 515 m cm^{-1}. $C_{50}H_{60}B_6Li_2N_6O_2$ (855.82): calcd. C 70.17, H 7.07, N 9.82; found C 70.95, H 7.89, N 9.43.

Bis(diethyl ether)lithium *N*-Lithio-tetraphenylborazinate (6a): To a stirred solution of **1** (0.640 g, 2.07 mmol) in diethyl ether (60 mL) a solution of LiPh in diethyl ether/cyclohexane (2 M, 2.15 mL, 4.3 mmol) was added dropwise at 0 °C. The mixture was stirred 4 d at ambient temperature. Then its volume was reduced to about 20 mL in vacuo. The brown solution was stored at –5 °C. After a few days, colorless crystals were isolated. Yield: 0.962 g of **6a**, 85%. The same compound was also obtained by treating **1** with 3 or 4 equiv. of LiPh (only tested by ^{11}B NMR). When compound **6a** was kept in vacuo, 1.5 equiv. of diethyl ether was lost. M.p. 140–142 °C. ^{1}H NMR: δ = 1.07 (t, CH_2CH_3, $^3J_{H,H}$ = 7 Hz), 3.20 (q, $^3J_{H,H}$ = 7 Hz, 8 H, OCH_2), 5.78 (br. s, 4 H, HN-1,1′,5,5′) ppm. ^{13}C NMR: δ = 15.3 (CH_2CH_3), 65.7 (OCH_2) ppm. ^{11}B NMR: δ = –5.9 ($h_{1/2}$ = 130 Hz), 36.8 ($h_{1/2}$ = 800 Hz) ppm. ^{7}Li NMR: δ = –0.39 ($h_{1/2}$ = 150 Hz), 3.0 ($h_{1/2}$ = 150 Hz) ppm. IR (Nujol, Hostaflon; only medium to very strong bands quoted): $\tilde{\nu}$ = 3096 m, 3047 m, 2926 m, 1596 m, 1499 m. 1483 m, 1434 st, 1343 vst, br, 1278 st, 1245 m, 1188 m, 1070 m, 1027 m, 851 st, 805 m, 755 m, 737 st, 703 vst, 683 st, 585 m, 491 m cm^{-1}. $C_{52}H_{54}B_6Li_4N_6O$ (891.67) [dimeric mono(diethyl ether) adduct]: calcd. C 71.65, H 6.24, N 9.64; found C 71.39, H 6.27, N 9.03.

Tris(tetrahydrofuran)lithium *N*-Lithio-2,2,4,6-tetraphenylborazinate (6c): *N*,*N*′,*N*′′-trimethylhexahydrotriazine (1.83 g, 14.2 mol) was added to a hexane solution of *n*BuLi (5.0 mL. 1.6 M, 8.0 mmol). This slightly yellow solution was then added to a stirred solution of **1** (2.34 g, 7.76 mmol) in hexane (40 mL). Gas evolution was noted after a few drops had been added. After addition, the mixture was kept at reflux for 14 h. The solid (1.65 g, most likely **6b**) was isolated by filtration and was then dissolved in THF (25 mL). After removal of the solvent, a brown oil remained. Most of the oil solidified on storing for several days. The resulting colorless crystals were isolated and washed with a small amount of pentane. Yield: 1.62 g of **6c**, 56%. M.p. 148–151 °C. Several of the crystals had single-crystal quality. By dissolving **6a** in THF the same compound separated from a concentrated solution kept at –25 °C. ^{1}H NMR: δ = 1.37 (t, $^3J_{H,H}$ = 7 Hz, 24 H, OCH_2CH), 3.54 (q, $^3J_{H,H}$ = 7 Hz, 24 H, OCH_2), 5.78 (br. s, 4 H, N-1,1′,5,5′) ppm. ^{13}C NMR: δ = 26.2 (OCH_2CH_2), 68.3 (OCH_2) ppm. ^{11}B NMR: δ = –3.5, 34.2 ppm. ^{7}Li NMR: δ = –0.39 ($h_{1/2}$ = 40 Hz), 1.58 ($h_{1/2}$ = 10 Hz) ppm.

IR (Nujol, Hostaflon; only medium to very strong bands quoted): $\tilde{\nu}$ = 3011 m, 2982 m, 1950 m, 2799 m, 1599 m, 1502 st, 1449 st, 1425 st, 1399 st, 1339 cm^{-1}. $C_{36}H_{46}B_3Li_2N_3O_3$ (615.13): calcd. C 70.30, H 7.54, N 6.83; found C 69.41, H 7.34, N 6.67.

1,3,5-Tris[(diethyl ether)lithio]-2,4,6-triphenylborazine–Tris(phenyllithium–diethyl ether) (8): To a stirred solution of **1** (450 mg, 1.47 mmol) in diethyl ether (40 mL), a solution of PhLi in diethyl ether/cyclohexane (1:1, 4.5 mL, 9.0 mmol) was slowly added at 0 °C. The brown solution was stirred for 3 d. Then its volume was reduced to ca. 20 mL. Moisture-sensitive crystals separated from the solution within a few days at –5 °C. Some of them had single-crystal quality but showed low diffracting power. Yield: 1.37 g of **8**, 1.34 mmol, 92%. M.p. 166–168 °C. ^{1}H NMR (C_6D_6): δ = 0.75 (t, $^3J_{H,H}$ = 6 Hz, 36 H, CH_2CH_3), 2.90 (q, $^3J_{H,H}$ = 6 Hz, 24 H, OCH_2), 6.87 (t, $^3J_{H,H}$ = 7 Hz, 6 H, *m*-PhB), 7.15 (t, $^3J_{H,H}$ = 7 Hz, 6 H, *m*-PhLi), 7.21 (t, $^3J_{H,H}$ = 7 Hz, 3 H, *p*-PhLi), 7.35 (t, $^3J_{H,H}$ = 7 Hz, 3 H, *p*-PhB), 7.70 (d, $^3J_{H,H}$ = 7 Hz, 6 H, *o*-PhB), 8.01 (d, $^3J_{H,H}$ = 7 Hz, 6 H, *o*-PhLi) ppm. ^{13}C NMR: δ = 14.6 (CH_2CH_3), 65.1 (OCH_2), 121.8 (*i*-PhLi), 127.4 (*p*-PhLi), 128.5 (*m*-PhLi), 129.0 (*p*-PhB), 133.5 (*m*-PhB), 143.6 (*o*-PhB), 145.4 (*o*-PhB) ppm. ^{11}B NMR: δ = 39.6 ($h_{1/2}$ = 800 Hz). ^{7}Li NMR: δ = 2.9 ($h_{1/2}$ = 190 Hz). IR (Nujol, Hostaflon; only medium to very strong bands quoted): $\tilde{\nu}$ = 3063 m,3048 m, 2979 m, 2936 m, 2889 m, 1594 m, 1483 m, 1467 m, 1457 m, 1447 m, 1430 st, 1408 m, 1387 m, 1330 vst, 1316 vst, 1261 st, 1210 m, 1189 st, 1153 m, 1095 m, 1064 st, 1044 m, 1023 m, 1005 m, 978 m, 836 m, 789 m, 764 m, 740 st, 726 st, 675 m, 622 m, 616 st, 593 m, 445 m, 434 st cm^{-1}. $C_{60}H_{90}B_3Li_6N_3O_6$ (1023.47): calcd. C 70.41, H 8.86, N 4.11; found C 68.78, H 8.49, N 4.79.

X-ray Crystal Structure Analyses: Crystals were placed under a blanket of a cold stream of N_2 in perfluoroether oil (stock point –40 °C). The selected single crystal was mounted on the tip of a glass fiber and placed on a supporting copper rod which was transferred onto the goniometer head cooled to –80 °C with a Bruker LT2 device. After centering the crystal, data on 5 different sets of 15 frames each were recorded using a Siemens P4 diffractometer equipped with a CCD detector. These data were used to determine the unit cell with the program SMART.[21] Data collection was performed using the hemisphere mode of the program SMART. Data on 1200 frames were collected which were reduced with the program SAINT.[22] The normalized data set was then used to obtain a model structure.[23] As most data sets showed only weak reflection beyond $2\theta > 30°$, several cycles of isotropic refinements of found non-hydrogen positions were necessary to complete the non-hydrogen framework. After refinement with anisotropic thermal parameters, most hydrogen positions were observed after several cycles. Only the found positions for NH hydrogen atoms were isotropically refined. The CH hydrogen atoms were placed in calculated positions and refined with a riding model in the final cycles of refinement (not so for compound **5** where several hydrogen positions at the phenyl groups were freely refined but in the final cycles with fixed U_i values). The U_{ij} values of the carbon atoms of the diethyl ether molecule showed too long C–O bonds and too short C–C distances, suggesting site disorder. However, a split-model calculation did not significantly improve the *R* value. Therefore, the data of the unsplit situation is quoted. On the other hand, two of the three THF molecules of **6c** were site-disordered. The refinement showed about equal occupancy of the two positions. Therefore, in the final cycles SOF was fixed to 0.5. In case of compound **8** data

Complexes of the Bicyclic Multifunctional Sulfur-Nitrogen Ligand $F_3CCN_5S_3$ with Co^{2+}, Zn^{2+}, Cu^{2+}, and Cd[‡]

Carsten Knapp[a] and Rüdiger Mews*[a]

Keywords: Bridging ligands / Heterocycles / N ligands / S ligands / Transition metals

The ability of the sulfur-nitrogen-carbon bicycle $F_3CCN_5S_3$ to act as a donor towards transition metal cations has been investigated. $F_3CCN_5S_3$ forms complexes with $[M(SO_2)_2](AsF_6)_2$ [M = Co, Cu, Zn, Cd] in the ratio 2:1 of the composition $[M(F_3CCN_5S_3)_2(OSO)_2(FAsF_5)_2]$ [M = Co (**1**), Zn (**3**)], $[Cu(F_3CCN_5S_3)_2(\mu\text{-}F)(\mu\text{-}F_2AsF_4)]_2$ (**4**), and $[Cd(F_3CCN_5S_3)(\mu\text{-}F_3CCN_5S_3)(\eta^2\text{-}F_2AsF_4)_2]_2$ (**5**) in liquid sulfur dioxide. In the octahedral Co and Zn complexes $F_3CCN_5S_3$ coordinates as a monodentate ligand through the bridging nitrogen atom N5, which carries the highest negative charge according to theoretical calculations. With Cu^{2+} a dinuclear structure with a central planar, four-membered Cu_2F_2 ring is formed, which has the shortest Cu···Cu distance of all structurally characterized Cu_2F_2 units. Similar to the Co and Zn complexes, $F_3CCN_5S_3$ acts as a terminal monodentate ligand in the Cu compound. The reaction with the larger and softer Cd^{2+} cation results in a dinuclear complex that contains terminal and bridging $F_3CCN_5S_3$ ligands. The bridging ligands coordinate through N5 and a nitrogen atom neighboring the carbon atom. In addition, a third weak bonding interaction between one fluorine atom of the trifluoromethyl substituent and the Cd^{2+} center is observed. The formation of the different structures and the versatile coordination modes of the $F_3CCN_5S_3$ ligand are discussed.

Introduction

Recently, we reported the syntheses, crystal structures, and solid-state packing of $1\lambda^4,3\lambda^4,5\lambda^4$-trithia-2,4,6,8,9-pentaazabicyclo[3.3.1]nona-1(9),2,3,5,7-pentaenes (RCN_5S_3) with different alkyl and aryl substituents.[1] Based on quantum chemical calculations,[1a,2] these bicyclic sulfur-nitrogen heterocycles were proposed to act as versatile multifunctional ligands in coordination chemistry. The presence of several lone pairs and energetically low-lying orbitals of different symmetries should allow different coordination modes and a versatile chemistry. The calculations showed that the nitrogen atoms carry a high negative partial charge and the sulfur atoms a high positive one. The highest negative charge was found to be at the bridging nitrogen atom N5, independent of the substituent R.[1a] Thus, RCN_5S_3 might act as either a donor or an acceptor. Electrophiles exclusively attack the heterobicycle at the sulfur atom of the sulfurdiimide bridge, as was shown in reactions with EPh_3 (E = P, As)[3,4a] and in the structure determination of $[(Me_2N)_3S]^+[F_3CCN_5S_3NC(NH_2)CF_3]^-$.[4a] Reactions with Lewis acids, however, are more versatile. The Lewis acid AsF_5 attacks, as expected, at the bridging nitrogen atom N5 of $F_3CCN_5S_3$, while the proton, the simplest Lewis acid, interacts with a nitrogen atom neighboring the ring carbon atom.[4]

In this report we will focus on reactions of $F_3CCN_5S_3$ with $[M(SO_2)_x](AsF_6)_2$. The trifluoromethyl-substituted derivative $F_3CCN_5S_3$ is a representative example of this class of compounds. In addition, the sulfur-nitrogen heterocycle is stabilized by the F_3C group.[1a,5] Transition metal sulfur dioxide hexafluoroarsenates in liquid sulfur dioxide are an excellent system to introduce even very weak donor ligands into coordination chemistry.[6,7] Due to the weakly coordinating SO_2 ligands and AsF_6^- counteranions, the metal centers are almost "naked". Thus, even very weak donors can be attached to the metal centers. Until now only two metal complexes of $F_3CCN_5S_3$ were known,[2] namely $[Ni(F_3CCN_5S_3)_2(SO_2)_2(AsF_6)_2]$, formed from $[Ni(SO_2)_6](AsF_6)_2$, where, similar to the AsF_5 adduct, the $F_3CCN_5S_3$ acts as an N-ligand and coordinates through the bridging nitrogen atom N5 to the metal center, and the silver complex $[Ag(F_3CCN_5S_3)(\mu\text{-}F_3CCN_5S_3)]_2(AsF_6)_2$, which contains two differently coordinating $F_3CCN_5S_3$ molecules as terminal and bridging ligands, respectively. These two examples show that the coordination modes of the ligand depend on the metal center. Therefore it seemed worthwhile to extend our investigations to other metals.

In this paper reactions of the metal sulfur dioxide hexafluoroarsenates $[M(SO_2)_2](AsF_6)_2$ (M = Co, Cu, Zn, Cd) with $F_3CCN_5S_3$ are reported. The X-ray structures of the

resulting complexes and the different coordination modes of the ligand $F_3CCN_5S_3$ are discussed.

Results and Discussion

The reaction of $F_3CCN_5S_3$ with the transition metal cations $Co^{2+}$and Zn^{2+} in liquid sulfur dioxide yielded orange crystals of $[M(F_3CCN_5S_3)_2(OSO)_2(FAsF_5)_2]$ [M = Co (**1**), Zn (**3**)], which are isostructural with the known Ni^{2+} complex **2**.[2] The presence of O-coordinated SO_2 in these complexes can be concluded from the S–O stretching mode in the IR spectra; O-coordination is preferred by hard metal centers.[6,8] The As–F stretching vibrations for the AsF_6^- counteranions are split and partly shifted to higher wavenumbers, in agreement with a distorted coordinated AsF_6^- (Scheme 1).

A different result is expected for the reaction with Cu^{2+}, because Cu^{2+} compounds (d^9) are strongly affected by the Jahn–Teller distortion. Very air-sensitive blue crystals were obtained from the reaction of $F_3CCN_5S_3$ with $[Cu(SO_2)_x](AsF_6)_2$ in liquid sulfur dioxide. The IR spectrum shows no absorptions in the region of S–O stretching vibrations, in agreement with the results of the X-ray structure determination (see below). The isolated dinuclear complex of the formula $[Cu(F_3CCN_5S_3)_2(\mu\text{-}F)(\mu\text{-}F_2AsF_4)]_2$ (**4**) contains a central four-membered Cu_2F_2 ring with two Cu^{2+} cations bridged by two fluoride and two AsF_6^- anions. In addition, each Cu^{2+} ion coordinates two $F_3CCN_5S_3$ ligands. The bridging fluoride ions result from the decomposition of AsF_6^- anions. It has been known for a long time that $[Cu(AsF_6)_2]$ readily loses AsF_5 with formation of $[CuF_n(AsF_6)_{2-n}]$ of ill-defined composition.[9] Recently, $[CuF(AsF_6)]$[10] has been structurally characterized[11] and might allow the straightforward preparation of **4** in the future (Scheme 2).

Cd^{2+} is a "softer" metal cation, due to its larger ionic radius than the cations of the first row transition metals discussed above, therefore a different behavior is observed: the reaction of $[Cd(SO_2)_x](AsF_6)_2$ with $F_3CCN_5S_3$ in liquid sulfur dioxide yields the dinuclear complex $[Cd(F_3CCN_5S_3)(\mu\text{-}F_3CCN_5S_3)(\eta^2\text{-}F_2AsF_4)_2]_2$ (**5**), similar to the silver complex we described earlier (Scheme 3).[2]

Structural Investigations

Structures of $[M(F_3CCN_5S_3)_2(OSO)_2(FAsF_5)_2]$ [M = Co (1), Zn (3)]

Single crystals of all compounds suitable for X-ray diffraction were obtained by slow evaporation of the solvent (liquid sulfur dioxide) at room temperature. Complexes **1** and **3** are isostructural and crystallize in the monoclinic space group $P2_1/n$ (Figure 1). The metal cation lies on an inversion center and is surrounded by two $F_3CCN_5S_3$ ligands. In addition, the two AsF_6^- counteranions are linked to the cation by bridging fluoride ions, with the remaining two free coordination sites being filled by sulfur dioxide solvent molecules to complete the octahedral coordination sphere (Figure 1). For comparison, selected average bond lengths are included in Table 1 together with the data for $F_3CCN_5S_3$ and $F_3CCN_5S_3{\cdot}AsF_5$.

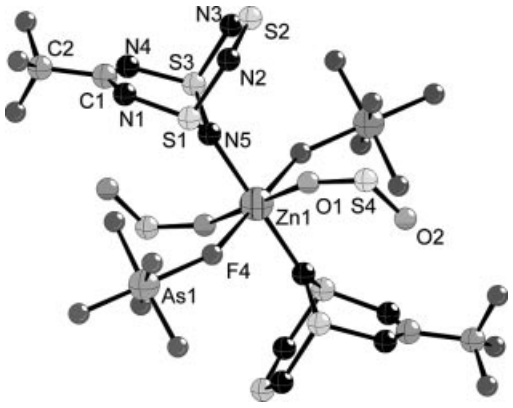

Figure 1. Structure of $[Co(F_3CCN_5S_3)_2(SO_2)_2(FAsF_5)_2]$ (**1**), which is isostructural to $[Zn(F_3CCN_5S_3)_2(SO_2)_2(FAsF_5)_2]$ (**3**). Selected bond lengths [pm] for **1**: Co(1)–N(5) 205.8(2), Co(1)–F(4) 209.53(16), Co(1)–O(1) 214.0(2), C(1)–N(1) 131.3(4), C(1)–N(4) 132.0(4), C(1)–C(2) 153.7(4), N(1)–S(1) 162.7(2), S(1)–N(5) 164.7(2), S(1)–N(2) 170.9(3), N(2)–S(2) 154.4(3), S(2)–N(3) 154.8(3), N(3)–S(3) 171.4(3), S(3)–N(4) 162.6(3), S(3)–N(5) 165.1(2), O(1)–S(4) 144.4(2), S(4)–O(2) 141.1(3), As(1)–F(4) 179.13(17), average As–F 169.9. Selected bond lengths [pm] for **3**: Zn(1)–N(5) 203.42(19), Zn(1)–F(4) 210.44(15), Zn(1)–O(1) 218.14(18), C(1)–N(1) 131.5(3), C(1)–N(4) 132.1(3), C(1)–C(2) 153.0(3), N(1)–S(1) 162.3(2), S(1)–N(5) 164.9(2), S(1)–N(2) 170.9(2), N(2)–S(2) 154.4(3), S(2)–N(3) 155.1(3), N(3)–S(3) 171.1(3), S(3)–N(4) 162.4(2), S(3)–N(5) 165.1(2), O(1)–S(5) 144.08(19), S(5)–O(2) 141.2(2), As(1)–F(4) 178.65(15), average As–F 169.8.

The $F_3CCN_5S_3$ ligand coordinates to the metal center through the bridging nitrogen atom N5, which carries the highest negative charge according to theoretical calculations.[4a] The M–N distance of about 205 pm in **1**, **2**, and **3** [203.42(19) pm in **1** and 206.3(4) in **2**] is in agreement with the similar ionic radii of the cations. The changes of the bond length within the sulfur-nitrogen heterocycle on coordination to a transition metal cation and on adduct formation with AsF_5 compared with the free ligand follow the same pattern as discussed previously.[4a]

The M···O distance increases from M = Zn to M = Ni by about 8 pm and is approximately 7 pm longer than in complexes containing only SO_2, such as $[Ni(OSO)_6](AsF_6)_2$ [203.3(3)–204.3(3) pm][13] and $[Co(OSO)_4(FAsF_5)_2]$ [205.9(4)–207.5(4) pm].[7]

In agreement with accepted bonding models,[14] the end-on coordination of the SO_2 ligand to the cation results in two different S–O bond lengths. Compared to the free SO_2 molecule (143 pm),[15] the M···O–S bond is slightly stretched (144 pm), whereas the terminal S–O bond is slightly shortened (140–141 pm). This distortion is a function of the Lewis acidity of the acceptor and decreases with the weakening of the M···O interaction from M = Zn to M = Ni.[2]

Similar to the M···O distances, the M···F distances [209.53(16) pm in **1**] are longer than in the complexes containing only SO_2 as additional ligands {e.g. $[Co(OSO)_4(FAsF_5)_2]$: 201.8(3)–202.6(3) pm}.[7] The counteranion acts as a monodentate ligand resulting in a distortion of the AsF_6^- octahedron. The As–F bond of the bridging fluoride F4 in **3** is about 10 pm longer than the average of the other As–F bond lengths.

Structure of $[Cu(F_3CCN_5S_3)_2(\mu\text{-}F)(\mu\text{-}F_2AsF_4)]_2$ (4)

Blue crystals suitable for X-ray diffraction were also obtained by slow evaporation of the liquid sulfur dioxide. Structure solution and refinement were realized in the triclinic space group $P\bar{1}$. The dinuclear complex contains a central planar, four-membered Cu_2F_2 ring (Figure 2). Two $F_3CCN_5S_3$ ligands coordinate through the bridging nitrogen atom N5 to each copper, completing a square-planar environment around the Cu^{2+} ion. In addition, the two metal centers are bridged by the AsF_6^- counteranions above and below the Cu_2F_2 unit. The contacts within the plane are much stronger than the Cu–F contacts perpendicular to the plane due to the Jahn–Teller effect. This view is supported by applying Brown's bond valence approach,[16] which assigns 0.28 v.u. (valency units) for the Cu–N contacts and 0.42 v.u. for the Cu–F bonds within the Cu_2F_2 ring, but only 0.13 v.u. for the Cu–F contacts to the bridging hexafluoroarsenate ions. Only a few compounds containing a Cu_2F_2 ring have been structurally characterized, and the Cu···Cu distance is normally in the range of 290–340 pm.[17] The title compound contains the shortest Cu···Cu distance of all Cu_2F_2 four-membered rings [287.5(2) pm], which might be a result of the AsF_6^- bridges. Since the Cu···F–AsF_4–F···Cu interactions are weak, the hexafluoroarsenate ions are less distorted than in the com-

plexes discussed above. The influence of the metal center on the average bond lengths of the $F_3CCN_5S_3$ ligands is small: the changes within the heterocycle are in the expected range for $F_3CCN_5S_3$ coordinated to an acceptor.[4a]

Magnetic measurements on **4** were not carried out but might be interesting as structural[17] and theoretical investigations[18] on Cu_2F_2 rings of similar geometry have shown antiferromagnetic coupling between the Cu^{2+} centers.

Structure of $[Cd(F_3CCN_5S_3)(\mu\text{-}F_3CCN_5S_3)(\eta^2\text{-}F_2AsF_4)_2]$ (5)

Orange crystals suitable for X-ray diffraction were also obtained by slow evaporation of the liquid sulfur dioxide solvent. The structure solution and refinement were realized in the monoclinic space group $P2_1/n$. The complex has a structure similar to that of the corresponding silver compound $[Ag(F_3CCN_5S_3)(\mu\text{-}F_3CCN_5S_3)]_2(AsF_6)_2$.[2] The dinuclear structure contains two different kinds of $F_3CCN_5S_3$ ligands − bridging and terminal (Figure 3). As usual, the terminal $F_3CCN_5S_3$ coordinates through the bridging nitrogen atom N5. The second $F_3CCN_5S_3$ acts as a bidentate ligand through the bridging nitrogen atom (here N10) and the nitrogen atom (N6) next to the trifluoromethyl substituent, and bridges the two metal cations to form an eight-membered $Cd_2N_4S_2$ metallacycle. The Cd–N6 distance [232.25(18) pm (M = Cd), 249.7(4) pm (M = Ag)] is much shorter, and the Cd–N10 distance [240.54(19) pm (M = Cd), 228.1(4) pm (M = Ag)] much longer, than in the corresponding silver compound, while the Cd–N5 distance to the terminal ligand is not influenced by the metal [225.79(19) pm (M = Cd), 222.3(5) pm (M = Ag)]. This is the result of an additional weak bonding interaction between one fluorine atom of the trifluoromethyl substituent and the cadmium center. Bidentate hexafluoroarsenate ions complete the coordination sphere around the metal center, to give a coordination number of eight. Bidentate hexafluoroarsenate ions are less common, but have been observed before in Ag^+ and Cd^{2+} complexes.[19] By applying the bond valence approach,[16] the relative strengths of the different contacts become obvious (Figure 4). The Cd–N contacts are the dominating interactions (0.30–0–45 v.u.), while the Cd–F contacts to the bidentate hexafluoroarsenate ions are weaker (0.13–0.20 v.u.). The additional bonding between

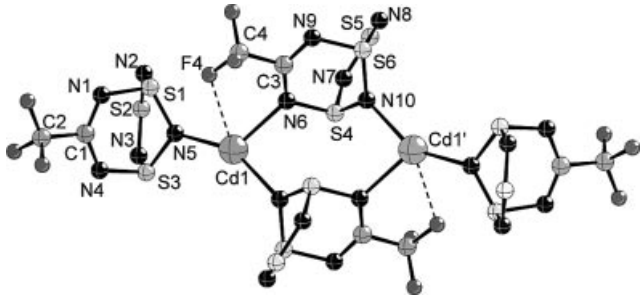

Figure 3. Structure of $[Cd(F_3CCN_5S_3)(\mu\text{-}F_3CCN_5S_3)]_2^{4+}$. Anions have been omitted for clarity.
