We have presented here the syntheses, single-crystal structures and magnetic behaviors of two new azide complexes of nickel(II) (**1**) and copper(II) (**2**) using a Schiff base and 4,4′-bipyridyl disulfide, respectively, as coligands. Complex **1** is a 1D chain of nickel(II) with alternating single and double μ-(1,3-N_3) bridges. Complex **2** is a 2D grid of 4,4 topology comprising single μ-(1,3-N_3) and double bridging 4,4′-bipyridyl disulfide. Magnetic susceptibility data have been fitted using the Borrás–Almenar formula of alternating one-dimensional S = 1 system based on the Hamiltonian $H = -J\Sigma(S_{2i}S_{21-1} + \alpha S_{2i}S_{2i+1})$ for complex **1**. Whereas for complex **2**, susceptibility data were fitted by using the typical formula for a uniform antiferromagnetic S = 1/2 chain. The best-fit parameters for complex **1** indicate very strong antiferromagnetic coupling through the two kinds of azide bridging and for complex **2** reflect very small antiferromagnetic coupling through the μ-(1,3-azide). The magnetic interactions are compared to those of closely related complexes taking into account all the coordination angles involving azide bridging ligands as well as the coordination metal environment.

Experimental Section

Materials: High purity 4,4′-bipyridyl disulfide (Aldrithiol-4; 98%) and *N*,*N*,2,2-tetramethyl-1,3-propanediamine of Aldrich Chemical Co. Inc. were used and all other chemicals were of AR grade.

Physical Measurements: Elemental analyses (carbon, hydrogen and nitrogen) were performed using a Perkin–Elmer 240C elemental analyzer. IR spectra were measured from KBr pellets on a Nicolet 520 FTIR spectrometer. Magnetic measurements were carried out in the "Servei de Magnetoquímica (Universitat de Barcelona)" on polycrystalline samples (20 mg) with a Quantum Design SQUID MPMS-XL magnetometer working in the 2–300 K range. The magnetic field was 0.1 T. The diamagnetic corrections were evaluated from Pascal's constants. EPR spectra were recorded on powder samples at the X-band frequency with a BRUKER 300E automatic spectrometer, varying the temperature between 4–300 K.

Crystallographic Data Collection and Refinement: Data collections of the complexes reported were carried out at 293(2) K on a diffractometer equipped with a Mar-research image plate and Mo-K_α radiation (λ = 0.71073 Å). 95 frames were measured at 2° intervals with a counting time of 2 min, and the crystal positioned at 70 mm from the image plate. The crystallographic data, the condition for the intensity data collection and some features of the structure refinements are listed in Table 2. Data analysis was carried out with the XDS program[17] and the structures were solved by direct methods with the SHELX97 program.[18] An empirical absorption correction was applied using DIFABS.[19] The structures were anisotropically refined on F^2 using the SHELXL program[18] with the contribution of hydrogen atoms at calculated positions. The perchlorate anion of complex **2** was found to be disordered over two positions (refined occupancies of 0.78(2):0.28(2)). Three residuals on the ΔF map of complex **2** were interpreted as disordered water oxygens that account for a total of 1.25 molecules (2.50 per metal unit). All the calculations were performed using the Wingx System Ver. 1.64.5.[20]

Synthesis

Caution! Perchlorate as well as azide salts were used in small quantities and handled with care since explosion may occur.

$[Ni_2L_2(N_3)_3]_n(ClO_4)_n$ (1): The tridentate Schiff base (L) was prepared by refluxing pyridine-2-aldehyde (1 mmol; 0.107 g) and *N*,*N*,2,2-tetramethyl-1,3-propanediamine (1 mmol; 0.130 g) in methanol (10 mL) according to literature method.[21] A methanolic solution (10 mL) of nickel(II) perchlorate hexahydrate (1 mmol; 0.365 g) was added to the hot (ca. 40 °C) methanolic solution (10 mL) of tridentate Schiff-base ligand (1 mmol). The resulting solution was cooled to room temperature. An aqueous solution (5 mL) of sodium azide (1.5 mmol; 0.0975 g) was added dropwise to it with continuous stirring and the resulting reaction mixture was filtered and the filtrate was allowed to evaporate in a refrigerator. Suitable green single crystals for structure determination were obtained from the filtrate after a few days. Yield: 72%. $C_{26}H_{42}ClN_{15}Ni_2O_4$ (781.62): calcd. C 39.91, H, 5.37, N 26.86; found C 39.80, H 5.41, N 26.75. IR (cm^{-1}): 3443 (w), 3378 (w),

Synthetic Explorations Towards Sterically Crowded 1,2,3-Substituted Bis(indenyl)zirconium(IV) Dichlorides

Andreas C. Möller,[a,b] Richard Blom,[a] Richard H. Heyn,*[a] Ole Swang,[a] Carl-Henrik Görbitz,[c] and Tanja Seraidaris[d]

Keywords: Metallocenes / Ligand effects / Isomerization / Polymerization / Density functional calculations

The systematic synthesis of 1,3-dialkyl-substituted 2-silylindenes and their suitability as zirconocene ligands is discussed. Unexpected reactivities rendered a number of substitution patterns unfeasible, especially for alkyl groups other than methyl in 2-(trimethylsilyl)indene derivatives, and essentially for all derivatives of 2-(dimethylsilyl)indene. The syntheses of *rac*/*meso*-bis[1-methyl-2-(trimethylsilyl)indenyl]zirconium(IV) dichloride (**12**) and bis[1,3-dimethyl-2-(trimethylsilyl)indenyl]zirconium(IV) dichloride (**13b**) are described. The solid-state structure of the latter displays strong deformations within the ligand framework and an unusually large $Cp_{centroid}$-Zr–$Cp_{centroid}$ angle. Both, **12**/MAO and **13b**/MAO, displayed ethene and ethene-co-1-hexene polymerization activity. Curiously, **13b**/MAO shows an extraordinary monomer selectivity, which can be rationalized by means of DFT calculations on the active site.

Introduction

The field of metallocene-catalyzed olefin polymerization has achieved significant improvements on polymer properties. The ligand−tacticity relationship is well understood and, apart from tailor-made stereocontrol, co-monomer incorporation and block length have been emphasized as keys to innovative materials.[1] The detailed polymerization mechanism with all its variations is complicated and the choice of appropriate polymerization conditions to favor one monomer over the other still requires vast and tedious sets of experiments. An outline of the extensive efforts made within this area can be found in the various review articles.[2]

Previous work from our laboratory addressed unbridged zirconocene dichloride with silyl substituents in the 1 or 2 position.[3] Reports on trisubstituted indenyl ligands, i.e. substituents in the 1, 2, and 3 positions, are still quite uncommon. It may be expected that steric congestion in such complexes is significant and that overall polymerization activity may be negatively influenced. In this study, we wish to present our results on a systematic study of 1,3-dialkyl-2-silyl-trisubstituted indene ligands for the synthesis of zirconocene dichlorides.

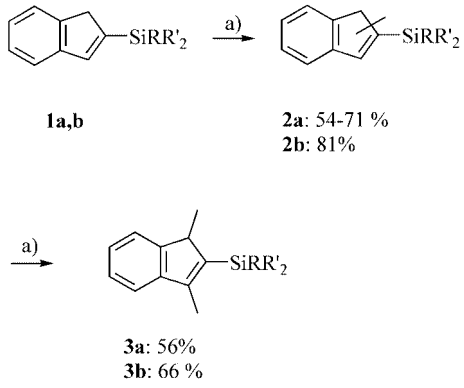
Results and Discussion

Ligand Syntheses

The introduction of alkyl groups in the 1 and 3 position of 2-silylindenes should be feasible in a straight forward manner by simple double alkylation of indenyllithium salts. Deprotonation of 2-(dimethylsilyl)indene (**1a**, 2-DMS-Ind) and 2-(trimethylsilyl)indene (**1b**, 2-TMS-Ind) was achieved by *n*-butyllithium in pentane at room temperature or –90 °C, respectively. In spite of the nonpolar solvent, deprotonation at lower temperatures provided hydride substitution products for **1a**, as observed by Kira et al.[4] Alternatively deprotonation can be achieved with potassium hydride at room temperature.

Methylation of the lithium salt of **1a** with methyl iodide at –40 °C in diethyl ether yielded exclusively 3-Me-2-DMS-Ind (**2a**), while 1-Me-2-TMS-Ind (**2b**) was obtained likewise from 2-TMS-Ind. Repetition of the deprotonation−methylation sequence afforded a 1:4 mixture of the 1,1-dimethyl and 1,3-dimethyl isomers for both, **3a** and **3b**. Deprotonation and washing with pentane provided pure lithium salts of the 1,3-dimethyl-2-silylindenes **3a** and **3b** (Scheme 1). **3a** exhibits diastereotopic methyl resonances of the silyl group in a 1:1 ratio due to the presence of the chiral C(1) atom.

In order to determine whether bulkier alkyl substituents could be placed in the 1,3 positions, studies on the introduction of the *i*Pr group were conducted on **1b**, as the TMS

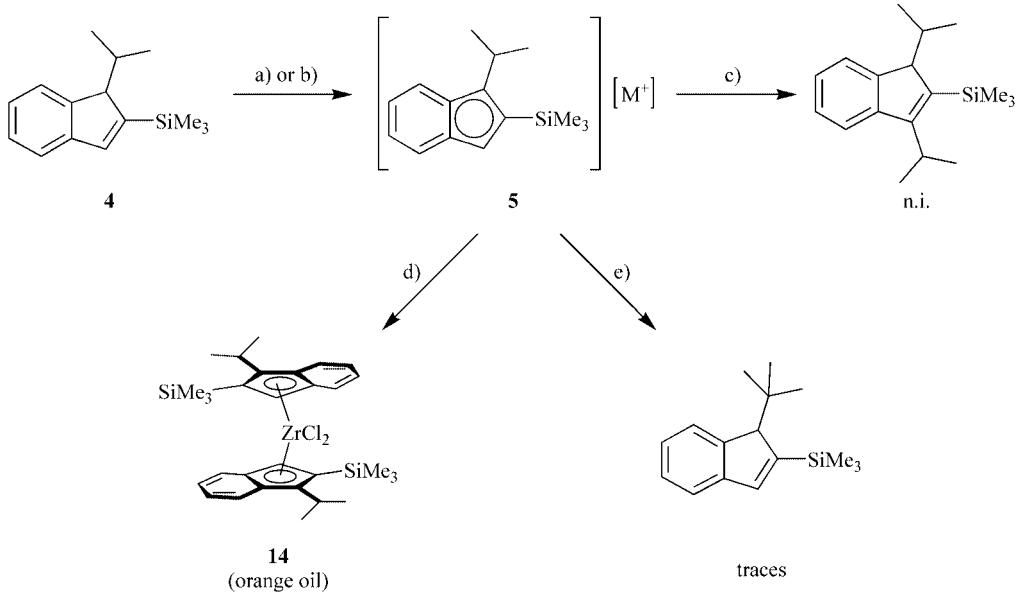


Scheme 1. General route towards 1,3-dialkyl-2-silylindenes. a) *n*BuLi, pentane, room temperature; MeI, diethyl ether, –40 °C. **a:** R = H, R′ = Me. **b:** R = R′ = Me. Yields are reported for the purified lithium salts of **3a** and **3b**, whereas spectroscopic data were obtained on the free ligands.

moiety is less prone to substitution reactions in the presence of lithium organyls. A brief summary of the results is given in Scheme 2. Following the procedure for methylation, exposure of the lithium salt of **1b** to isopropyl iodide sufficed to obtain the 1-*i*Pr isomer **4** in good yield. The proton and carbon NMR spectra of **4** reveal diastereotopic resonances for the *i*Pr methyl groups, and curiously the expected singlet for the trimethylsilyl (TMS) moiety displays two resonance maxima. We interpret these to arise from steric interaction of the *i*Pr and TMS groups. In addition, two different C(1) resonances are found. Deprotonation of **4** with *n*-butyllithium, however, leads to soluble lithium salts, which in a direct second alkylation with isopropyl iodide without prior isolation resulted in a mixture of four isomers, i.e. the mono-alkylated 1 and 3 isomers (3:1 parts) and the dialkylated 1,3 and 1,1 isomers (2:0.1 parts). The slight excess of *n*-butyllithium used in the reaction could be traced by detection of 2-methylhexane (0.3 parts). Deprotonation of **4** with potassium hydride in refluxing THF failed to provide a well-defined, insoluble potassium salt (K[**5**]). Due to the solubility of these salts, washing with pentane was accompanied by a loss of material.

A compelling explanation for these solubilities can be derived from a quenching experiment of Li[**5**] with methyl iodide in THF. GC/MS analysis of the reaction products revealed ten major products, of which one could be identified as 1-*t*Bu-2-TMS-Ind. Apparently Li[**5**] equilibrates between its indenyllithium and alkyllithium derivative, i.e. the lithium migrates from the Cp moiety of the indenyl through the *i*Pr group resulting in a covalent lithium carbon bond. Although satisfactory ^{1}H and ^{13}C NMR spectroscopic data were obtained, K[**5**] appears to be an inhomogeneous, poorly described compound, partially soluble in hydrocarbons. We suspect cation migration is still possible, despite the significantly bigger potassium cation.

Introduction of a *t*Bu group into 2-TMS-Ind may not be expected to be easy. Even in the case of indenyllithium, alkylation with *t*Bu bromide or iodide succeeds only in moderate yields.[5] Aiming for a possibly more demanding, but still more efficient route, we investigated a literature procedure for the synthesis of *t*Bu groups from 6,6-dimethyl(benzo)fulvenes.[6] 6,6-Dimethylbenzofulvene (**6**) is readily available in a one-pot reaction from indene, pyrrolidine and acetone in methanol,[7] and methyllithium is known to react smoothly in a 1,4-addition in diethyl ether to 1-*t*Bu-indenyllithium in a 80% yield. Acidic work-up and distillation afforded 3-*tert*-butylindene (**7**) in a 58% yield. Application of typical activators like TMEDA and $BF_3{\cdot}Et_2O$ does not improve the yield, but running the reaction in pentane in the presence of 10 wt.-% $AlCl_3$ offers the advantage of quantitative conversion, though acidic work-up is required prior to further reactions.



Scheme 2. Reactivity of 1-isopropyl-2-(trimethylsilyl)indene (**4**). a) *n*BuLi, pentane; b) potassium hydride, THF; c) 2-Iodopropane, diethyl ether/THF (n.i. = not isolated); d) $ZrCl_4$, THF, –40 °C; e) MeI, THF.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Introduction of a second *t*Bu group by the same means is more complicated (Scheme 3). Formation of the 1-*t*Bu-6,6-dimethylbenzofulvene (**8**) does not occur at room temperature, but with an excess of pyrrolidine and refluxing for several days, nearly quantitative conversion is achieved. Addition of methyllithium to **8**, provides 1,3-di-*t*Bu-indene (**9**), albeit in low yield. It may be reasoned that the *t*Bu group raises the energy of the *exo* double bond by its electron releasing character and thus inhibits nucleophilic attack by methyllithium. Disappointingly, we had to find that the synthesis of 2-TMS-6,6-dibenzofulvene starting from **1b** is not possible with the aforementioned procedure. Alternatively we investigated the reaction of the lithium salt of **1b** with acetone and subsequent dehydration with phosphoric acid or acid anhydrides. The first attempt, which employed phosphoric acid, provided the benzofulvene. Reproduction of this reaction was unsuccessful; we are not primarily interested in ill-defined polymers, but could, however, envision the obtained products to be useful for road building purposes.

Zirconocene Syntheses

To facilitate introduction to the coordination sphere of zirconium, **2b**, **3a**–**b** were all converted into their lithium salts **10**, **11a**–**b**, respectively, by exposure to stoichiometric amounts of a organyl lithium in pentane. The observed reactivities mirrored those of the starting material **1a–b**. The syntheses of the zirconium complexes were subsequently attempted by a salt metathesis reaction with zirconium tetrachloride, as illustrated in Scheme 4. For disubstituted ligands, *rac* and *meso* diastereomers may be obtained, whereas trisubstituted ligands exclusively provide enantiomers.

rac/*meso*-Bis[1-methyl-2-(trimethylsilyl)indenyl]zirconium(IV) dichloride (**12**) was obtained as a yellow powder in a respectable 55% yield. The *rac* and *meso* diastereomers were detected by ^1H NMR at a 1:1 ratio, and isolation or enrichment by crystallization at –40 °C failed. The *rac* and

meso diastereomers were assigned according to relative chemical shifts, as published elsewhere.[3]

Reaction of **11a** with zirconium tetrachloride in diethyl ether at 0 °C provided a yellow oil upon filtration through magnesium sulfate and subsequent solvent removal. Crystallization from diethyl ether was only limitedly successful, and we were not able to obtain an analytically pure sample due to the low yield. NMR spectroscopic data suggest, however, formation of bis[1,3-dimethyl-2-(dimethylsilyl)indenyl]zirconium(IV) dichloride (**13a**). Unreacted **11a** could easily be recovered in good yields. A change of solvent from diethyl ether to THF did not improve the reaction and only decomposition products could be obtained.

Metallation of **11b** in diethyl ether succeeded with formation of a yellow precipitate. The solubility of bis[1,3-dimethyl-2-(trimethylsilyl)indenyl]zirconium dichloride (**13b**) in diethyl ether was too limited to allow work-up in this solvent; toluene proved to be suitable. Orange or yellow powders were obtained in a 44% yield upon recrystallization from diethyl ether solution at –40 °C, depending on the crystallinity of the zirconocene. Single crystals grown from diethyl ether solution are bright orange in color.

As it may be anticipated from the observation of inhomegeneity of K[**5**], an orange oil was obtained as its reaction product with zirconium tetrachloride (Scheme 2). Crystallization was unsuccessful, though crystals would form after a few weeks in the drybox. The ductility of the crystals precluded further isolation.

Crystal Structure

An ORTEP[8] view of **13b** is given in Figure 1; selected bond lengths and angles are listed in Table 1. The coordination sphere of the zirconium atom can be described as a distorted tetrahedron. The two indenyl and chloride ligands are related by C_2 symmetry. The dihedral angle φ, which is defined as Si1–C3–C3*–Si1*, is measured to 165.7°, a nearly perfect *anti*-periplanar conformation of the indenyl li-

gands. As a consequence, the 1,3-methyl groups on the frontside (C11, C11*) almost ideally intersect the Cl1–Zr1–Cl1* angle, which spans 92.8°. The dihedral angle C11–C4–C4*–C11* is – with only 5.7° distortion – close to a perfect *syn*-periplanar orientation of these methyl groups. In contrast, the methyl groups on the backside (C10, C10*) span a dihedral angle (C10–C2–C2*–C10*) of –57.5° and minimize steric interaction by this strongly *syn*-clinal orientation.

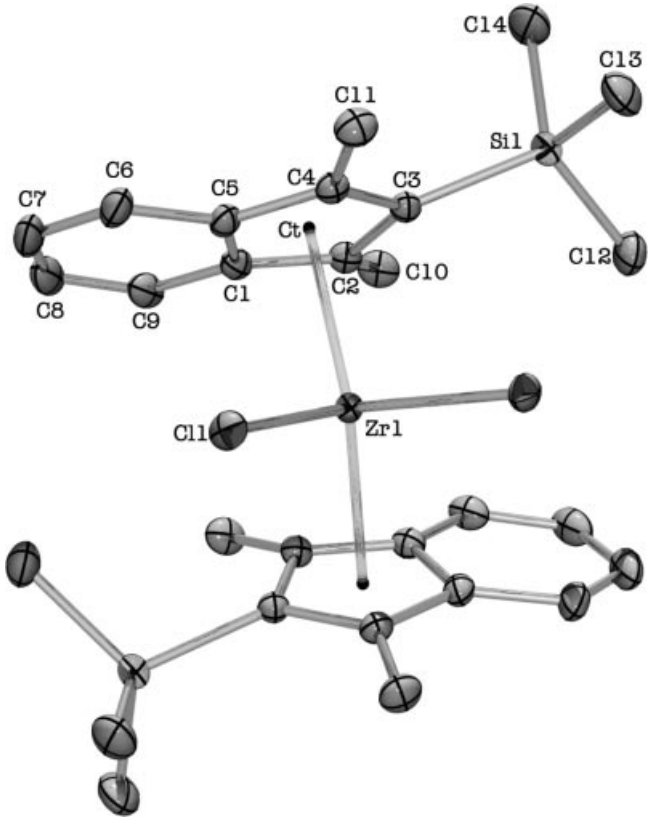

Figure 1. Refined crystallographic structure of bis[1,3-dimethyl-2-(trimethylsilyl)indenyl]zirconium dichloride (**13b**). Hydrogen atoms are omitted for clarity. Thermal ellipsoids are at the 50% probability level.

Table 1. Selected bond lengths [Å] and angles [°] for **13b**.

Bond length/angle [Å / °]	**13b**
Zr1–Cl1	2.4473(3)
Zr1–Ct	2.263
Zr1–C1	2.6188(10)
Zr1–C2	2.5385(10)
Zr1–C3	2.5370(10)
Zr1–C4	2.5320(10)
Zr1–C5	2.6252(9)
Si1–C3	1.8979(10)
Cl1–Zr1–Cl1*	92.843(13)
Ct–Zr1–Ct*	137.40
Ct–C3–Si1	168.84
Ct–C2–C10	167.76
Ct–C4–C11	175.43

The contribution of steric congestion is manifested in the out-of-plane bend angles of the indenyl ligands, which expose a convex surface to the zirconium center. In transversal direction, the frontside methyl groups are bent out of the linear arrangement by 4.6°, whereas the sterically more encumbered methyl groups on the backside are bent out by 12.2° – measured as C11–C4–Ct and C10–C2–Ct, respectively. In longitudinal direction, the curvature climbs from a modest 1.1° within the benzo moiety to 5.2° and 4.2° at the transition from benzo to Cp moiety and within the Cp ring, and finally reaches 19.3° for the transition Cp to silyl moiety. Consequently, the distortion of the tetrahedral symmetry around the zirconium is stronger than usual; the Ct-Zr1–Ct* angle ε measures 137.4°. To the best of our knowledge, this is the largest value ever reported for unbridged bis(indenyl)zirconium dichlorides. The largest values for ε have been reported for *rac*-ferrocenyl-bis(1-indenyl)zirconium dichloride, ferrocenyl-bis[2,3,4,5-tetramethyl-1-Cp]zirconium dichloride[9] and [(1,2,4-tri-(*t*Bu)Cp)(1,2,3,4-tetra-(*i*Pr)Cp)]zirconium dichloride[10] with 129.7, 138.5 and 138.8°, respectively.

Polymerization Characteristics and DF Calculations

In order to establish a rough estimate on the properties of **12** and **13b** as polymerization catalyst precursors in ethene homopolymerizations with MAO as cocatalyst, isobar and isothermal experiments were run at two different catalyst concentrations. Reference experiments were carried out with bis(indenyl)zirconium dichloride/MAO (**RefH**) and bis[2-(trimethylsilyl)indenyl]zirconium dichloride/MAO (**RefTMS**) at concentrations of $c(\mathrm{Zr}) = 1.0 \cdot 10^{-7}$ mol/L and $c(\mathrm{Zr}) = 1.0 \cdot 10^{-6}$ mol/L at Al/Zr ratios of 10000 and 1000, respectively. For **12**/MAO and **13b**/MAO, these conditions were not sufficient for detectable polymerization activity. Rather, **12**/MAO and **13b**/MAO required higher catalyst and MAO concentrations in order to show sufficient activity. A rough comparison of the catalyst's activities and the molecular weights obtained is given in Table 2.

The results for the homopolymerizations suggest a decrease in activity with increasing degree of substitution of the catalysts' ligand framework. We ascribe the significantly lower activities for high catalyst concentrations of **RefH**/MAO and **RefTMS**/MAO to diffusion control in the course of polymerization. The high amount of polymer produced increases the viscosity and hence reduces ethene up-take and agitation of the reaction mixture. Considering the polymer molecular masses, only **12**/MAO displays a notably different value compared to the other catalysts. The higher polydispersity index (PDI) obtained from **12**/MAO may be explained by the presence of the *rac* and *meso* isomer as active sites. The PDI's relative proximity to the value of 2 suggests their polymerization characteristics to be fairly alike.

The comonomer response of the different catalysts cannot be described by a simple consideration of steric congestion. Whereas the unsubstituted **RefH**/MAO displays a positive comonomer response, **RefTMS**/MAO and **12**/MAO suffer from strong deactivation by 80 to 90% relative to the

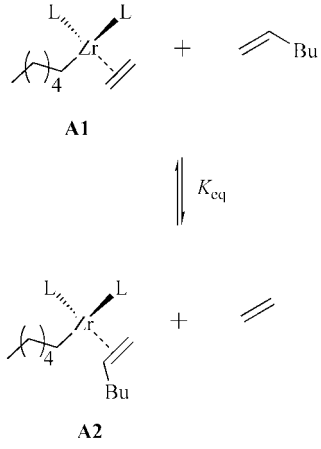
homopolymerization. In contrast, **13b**/MAO displays virtually no response to the comonomer and polymerises with roughly the same rate as before.

The fairly low activity of **13b**/MAO prompts the question of whether or not the catalyst precursor is sufficiently activated by the MAO available during the polymerization. To assess the dependence of **13b**/MAO on the Al/Zr ratio, a series of experiments was run at constant zirconium, ethene, and 1-hexene concentrations, while varying the Al/Zr ratio from approximately 1000 to 19000. The data obtained are listed in Table 3. We suggest that the catalyst activity does not strongly depend on the concentration of MAO or the Al/Zr ratio, though the data point to a slight increase in activity.

Table 3. Polymerization activities of **13b** in ethene-*co*-1-hexene polymerizations as a function of the Al/Zr ratio. $c(Zr) = 1.0\cdot10^{-6}$ mol·L^{-1}, $c(E) = 0.14$ mol·L^{-1}, $X_H = 0.5$ at 30 °C in toluene.

Activity [kg·mol$_{Zr}^{-1}$·mol$_E^{-1}$·h^{-1}]	Al/Zr
6000	950
18600	1900
26100	2800
45400	5700
44000	9500
33000	14200
79100	18900

Another issue of interest is the neutral to positive comonomer response of **13b**/MAO, which does not fit into the trend set by **RefTMS**/MAO and **12**/MAO. A ^{13}C NMR analysis of the copolymer obtained from **13b**/MAO was conducted according to the signal assignments published by Randall[11] and revealed a signal pattern typical for LLDPE polymers. The comonomer content was determined to 0.3 mol-% 1-hexene, which is essentially the detection limit. Assuming that the statistical distribution of the comonomer in the polymer chain is proportional to the equilibrium constant K_{eq} that would describe the population of the active site models **A1** and **A2**, as depicted in Scheme 5, it is possible to calculate the Gibbs energy [Equation (1)] for the enchainment of 1-hexene relative to ethene.



Scheme 5. Simplified representation of the active site with a polymer chain (*n*-hexyl) attached: **A1** with an ethene and **A2** with a 1-hexene ligand. For clarity, the 1,3-dimethyl-2-TMS-indenyl ligands are abbreviated as "L" and charges are omitted.

$$\Delta_r G = -RT\ln(K_{eq}) \quad (1)$$

$$K_{eq} = \frac{x_E x_H}{X_E X_H} \quad (2)$$

At 303.15 K with X_E and X_H = 0.5, and x_E = 0.997 and x_H = 0.003, we obtain $\Delta_r G$ = 11 kJ/mol and estimate the lower and upper limit to 10 and 14 kcal/mol, respectively. This value includes the reaction entropy, which could in general be obtained from an Arrhenius plot. A set of experiments was designed to investigate the dependence of the equilibrium constant K_{eq} on the temperature, as suggested by the van't Hoff equation. The results summarized in Table 4 indicate that there is no detectable relation between the polymerization temperature and catalyst activity or comonomer incorporation. The activity varies unsystematically, and the 1-hexene incorporation is constant. An experimental estimate of the reaction entropy is therefore not available.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Table 4. Polymerization activities of **13b** in ethene-*co*-1-hexene polymerizations as a function of the reaction temperature. The error indicates the experimental standard deviation; $c(Zr) = 1.0 \cdot 10^{-6}$ mol·L^{-1}, $c(E) = 0.14$ mol·L^{-1}, $X_H = 0.5$ at Al/Zr = 4000 in toluene.

T/°C	Activity [kg·mol$_{Zr}^{-1}$·mol$_E^{-1}$·h^{-1}]	M_w [Kg·mol^{-1}]	PDI	x_H
20	24400 ± 3100	494	11	0.003
30	18900 ± 1900	533	20	0.003
40	29600 ± 2200	391	15	0.003
48	44400 ± 1800	273	2.6	0.003
60	29800 ± 2000	172	6.9	0.003

In order to validate the quality of our estimate of the reaction Gibbs energy, we conducted DF calculations on an active site of **13b** which features a *n*-hexyl ligand and one ethene or 1-hexene unit. For the ethene complex, a pronounced α-agostic interaction of the polymer chain and the zirconium center was found, stretching the C–H bond length to 1.13 Å. The ethene ligand shows slight rehybridization through a HCH bond angle of 116.4° and is symmetrically coordinated at the typical Zr···C distances of 2.72 Å (C1) and 2.85 Å (C2). The 1-hexene complex displays evidence of steric strain already on visual inspection, as the *Z*-side of the 1-hexene ligand is tilted away from the zirconium center by a 16.5° deviation from the perfect orthogonal side-on coordination. This is due to intrusion of the butyl substituent into the space occupied by the methyl groups in the 1 and 3 positions of the indenyl ligands. Consequently, the Zr-olefin distance is increased to 2.78 Å (C1) and 3.32 Å (C2). An α-agostic interaction is not detectable, and there is an insignificant lengthening of the Zr−carbon bond to the polymer chain by 0.03 Å.

The relative energies of both olefin complexes, compared to the energies of the uncoordinated olefins, is a measure of their populations in the equilibrium during the polymerization process (Scheme 5). Since both olefins were present in equal amounts, stoichiometric corrections are not required. For the *rac*-like conformer of the active site the energy difference calculates to 8 kJ/mol, whereas the *meso*-like conformer is somewhat less stable with 13 kJ/mol. A meaningful comparison of product equilibria with stability of starting materials usually requires the knowledge of activation enthaplies. All attempts to calculate the activation enthalpies for the insertion process failed since the optimization of the transition state exclusively led to geometries where the olefin ligands would rotate along the zirconium−olefin bond and result in non-planar geometries. Although we have been able to calculate nonplanar transition states for other systems, the calculations would not converge in the case of **A1** or **A2**. The polydispersity index of 2.2 for the copolymerization suggests that only one active site needs to be considered.

Conclusions

The herein investigated syntheses of sterically demanding 1,2,3-substituted indenyl ligands on the basis of 2-silylindenes are unexpectedly difficult. Apart from hydride substitution problems, which may arise for the DMS moiety, substituents larger than a methyl group are surprisingly prone to hydrogen shift reactions of the deprotonated ligands. This side reaction affects the yield and applicability of the indenyl salts significantly. Introduction of an alkyl moiety without hydrogen shift capability like *t*Bu was precluded by steric strain in the synthesis of a suitable precursor. Further, the DMS-substituted ligand would not afford the desired zirconocene complex. As we have seen in earlier work, the presence of hydrogen on the silyl groups in 2 position does not seem to be favored for the zirconocene synthesis.[3]

In contrast, the syntheses of bis[1-methyl-2-TMS-indenyl]zirconium(IV) dichloride (**12**) and bis[1,3-dimethyl-2-TMS-indenyl]zirconium(IV) dichloride (**13b**) were achieved without undue difficulty, although the separation of the *rac* and *meso* diastereomers of **12** failed. The (basic) polymerization studies presented herein suggest that the activity in ethene polymerizations decreases with an increasing degree of substitution. In contrast to the very moderate activities, the molecular weights are less effected and this may be rationalized by the reduction in available space at the active site. Chain termination by chain transfer requires a β-agostic structure *and* the association of a monomer unit. Chain transfer to MAO requires an intimate interaction with the very same. Both processes are likely to be suppressed by a bulky ligand framework. This effect is even more pronounced for **13b**, which does not show the expected increase in activity with increasing Al/Zr ratio. Such an effect is often observed and poorly understood.

The virtual inertness of **13b** towards 1-hexene as a monomer is an interesting feature, which is to the best of our knowledge unprecedented. The unsuccessful attempts to find the transition state for this process support our idea that the selectivity is governed by steric factors. Nevertheless an interesting agreement between experiment and theory has been found: The calculated energy difference of 8 to 13 kJ/mol for the olefin complexes falls into the same range as the Gibbs energy of 11 kJ/mol, as derived from Boltzmann statistics on the 1-hexene incorporation into the polymer chain. This may indicate that the insertion of the monomer units may be controlled by a single activation barrier, despite our inability to calculate any suitable transition state. Systems like **13b**, employed in a catalyst mixture, are industrially desirable as they show a monomer selectivity which could be used to produce long chain branches in a copolymerization with 1-hexene. The catalyst activity is, however, traded for this selectivity.

Experimental Section

General: Unless otherwise indicated, all procedures were conducted using Schlenk techniques under argon. All solvents were dried from sodium with benzophenone or anthracene (diethyl ether, THF, and toluene) or lithium aluminium hydride (pentane) and distilled prior to use. Acetone (Merck) was dried with anhydrous magnesium sulfate for three days and distilled under argon. When used as a filter agent, magnesium sulfate (Merck) was dried at 140 °C for at least

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

two days prior to use. Iodomethane (Fluka) was dried with calcium hydride (Merck, used as received) and distilled under argon. 2-Iodo-propane (Fluka) and methanol p.a. (Merck) were used as received. Aluminum trichloride (resubl. grade, Aldrich Chemicals), pyrrolidine (Fluka), magnesium turnings (Merck and Aldrich Chemicals), *n*-butyllithium (Aldrich Chemicals or Merck), methyllithium (Aldrich Chemicals), *tert*-butyllithium (Aldrich Chemicals), boron trifluoride diethyl etherate (Aldrich Chemicals) and zirconium tetrachloride (Strem, 99.95%+, sublimed grade) were used as received. Column chromatography was conducted on silica gel 60 (0.040–0.063 mm) provided by Merck. Methylalumoxane (MAO) was purchased at Crompton Bergkamen, Germany, as a 10% toluene solution. Prior to use, the MAO solution was filtered through a D4-frit and volatiles removed in vacuo yielding a white solid. Polymerization grade ethene was provided by Borealis Stathelle, Norway. 1-Hexene (Aldrich) was purified before copolymerization by drying over potassium/benzophenone and subsequent distillation in an argon atmosphere. ^{1}H- and ^{13}C NMR spectra acquired with a Varian Gemini 300 MHz instrument were referenced to the residual solvent peaks. Low resolution MS was conducted with a Hewlett–Packard 5973 MSD, coupled with a Hewlett–Packard 6890 GC unit. GC columns used were HP-5, I.D. 0.32 mm, 0.250 µm, 30 m and DB-17, I.D. 0.25 mm, 0.250 µm, 30 m, both manufactured by J&W Scientific. GPC characterizations of the HDPE samples were conducted with a Waters 150CVplus instrument, operating with two HMW 6E and one HMW7, or three HT6E styragel columns (Waters) at 140 °C with trichlorobenzene as elution solvent and a dRI & viscosity detector. Alternatively, weight and number average molecular weights and polydispersity indices were measured at 140 °C with a Waters Alliance 2000 size exclusion chromatography (SEC) instrument equipped with Waters HT3, HT4, HT5 and HT6 columns. 1,2,4-Trichlorobenzene was used as solvent at a flow rate of 1.0 $cm^3 \cdot min^{-1}$. The columns were universally calibrated with narrow molecular weight polystyrene standards. Well-characterized lithium salts which resulted in isolable Zr complexes were not subjected to EA.

2-(Dimethylsilyl)indene (1a) and 2-(Trimethylsilyl)indene (1b): These compounds were prepared according to a published literature procedure.[3]

2-(Dimethylsilyl)-3-methylindene (2a). Potassium Hydride Route: Potassium hydride (432 mg, 10.8 mmol) was dissolved in THF (40 mL) and cooled to –90 °C. 2-(Dimethylsilyl)indene (1.88 g, 10.8 mmol) dissolved in THF (8 mL) was injected into the cold potassium hydride/THF suspension and the reaction mixture was warmed to room temperature while being stirred overnight. Substitution of THF by 20 mL diethyl ether and filtration through a cannula resulted in a clear, yellow-green solution of the 2-(dimethylsilyl)indenylpotassium complex. In a second Schlenk flask equipped with a pressurized addition funnel, methyl iodide (2.0 mL, 32.4 mmol) and diethyl ether (20 mL) were cooled to –40 °C before the potassium complex was added dropwise under isothermal conditions over a period of 30 minutes. The reaction was stirred overnight and warmed to room temperature, to yield a copious white precipitate. Filtration to remove insolubles and acidic quenching was followed by extraction with water (2 × 20 mL). Drying over magnesium sulfate and removal of solvent afforded the product (1.29 g, 6.9 mmol, 64%) at 85% purity. The isomer distribution was 4% 3 isomer, 81% 1 isomer, 8% un- and 7% disubstituted.

***n*-Butyllithium Route:** 2-(Dimethylsilyl)indene (2.04 g, 11.7 mmol) and pentane (50 mL) were placed in a Schlenk flask. *n*-Butyllithium (6.4 mL, 10.3 mmol) was slowly added via syringe. The solution was stirred overnight with waterbath cooling to yield a white precipitate. By filtration with a cannula, washing with pentane (2 × 20 mL) and drying under high vacuum a white powder (1.85 g, 10.3 mmol) was obtained. The 2-(dimethylsilyl)indenyllithium salt was dissolved in 30 mL diethyl ether and placed in an addition funnel mounted on a Schlenk flask charged with methyl iodide (2.9 mL, 46.8 mmol) in diethyl ether (30 mL). Drop-wise addition provided a yellow solution, which was stirred overnight prior to acidic work-up (20 mL 0.1 mol/L hydrochloric acid) in diethyl ether. Phase separation, washing of the organic layer with deionized water followed by drying over magnesium sulfate and removal of solvent at 70 mbar/40 °C afforded a pale yellow liquid (1.56 g, 8.3 mmol, 71%). Impurities were not detectable by GC/MS analysis. ^{1}H NMR (300 MHz, [D$_6$]benzene, 25 °C): δ = 0.19 [d, ^3J = 3.9 Hz, 6 H, SiH(CH_3)$_2$], 2.15 [t, ^5J = 2.1 Hz, 3 H, C(3)-Me], 3.14 [q, ^5J = 2.4 Hz, 2 H, C(1)-H], 4.69 [hept, ^3J = 3.9 Hz, 1 H, SiH(CH$_3$)$_2$], 7.17–7.25 [m, 1 H, C(5)-H], 7.25–7.27 [m, 2 H, C(6,7)-H], 7.32–7.37 [m, 1 H, C(4)-H] ppm. ^{13}C{^{1}H} NMR (75 MHz, [D$_6$]benzene, 25 °C): δ = –3.1 [2 C, SiH(CH_3)$_2$], 13.8 [1 C, C(3)-Me], 42.6 (1 C, C-1), 119.7 (1 C, C-4), 124.0 (1 C, C-7), 125.6 (1 C, C-6), 126.8 (1 C, C-5), 137.2 (1 C, C-3), 147.1 (1 C, C-2), 147.9 (1 C, C-7a), 150.4 (1 C, C-3a) ppm. GC/MS (70 eV): *m*/*z* (%) = 188 (100) [M$^+$], 173 (74) [M$^+$ – CH$_3$], 145 (41) [C$_9$H$_9$Si$^+$], 128 (75) [C$_{10}$H$_8^+$], 115 (15) [C$_9$H$_7^+$], 73 (10) [Si(CH$_3$)$_3^+$], 59 (78) [SiH(CH$_3$)$_2^+$].

1-Methyl-2-(trimethylsilyl)indene (2b): The methylation of **1b** was conducted in a similar manner to **2a**. To a Schlenk flask charged with 2-(trimethylsilyl)indene (3.00 g, 15.0 mmol) dissolved in pentane (40 mL) at room temperature, *n*-butyllithium (19.0 mL, 49.0 mmol) was added through a septum and stirred vigorously. The reaction mixture was stirred overnight and warmed to room temperature to yield a clear, yellow solution. Upon addition of diethyl ether (2.0 mL) and stirring for another ten minutes, the formation of copious precipitate was observed. Solvent volume reduction to approximately 60% and subsequent filtration through a D4-frit provided a white solid, which was washed twice with pentane (10 mL) and dried under vacuum for 1 h. A second Schlenk flask equipped with an addition funnel and charged with methyl iodide (3.0 mL, 48.5 mmol) in diethyl ether (20 mL) was cooled to –40 °C. The lithium salt was dissolved in diethyl ether (30 mL), transferred to the addition funnel of the second Schlenk flask and dropwise added to the methyl iodide solution at –40 °C. After stirring overnight, the reaction was quenched with hydrochloric acid (20 mL, 0.1 mol/L). The organic layer was washed twice with water (20 mL) and dried with magnesium sulfate. Removal of solvent afforded the product (2.45 g, 12.1 mmol, 81%) with a purity of 99%, as determined by GC/MS. ^{1}H NMR (300 MHz, [D$_6$]benzene, 25 °C): δ = 0.24 [s, 9 H, Si(CH_3)$_3$], 1.30 [d, ^3J = 7.4 Hz, 3 H, C(1)-CH$_3$], 3.48 [dq, ^3J = 7.4, ^5J = 1.6 Hz, 1 H, C(1)-H], 6.90 [d, ^5J = 1.6 Hz, 1 H, C(3)-H], 7.28–7.35 [m, 2 H, C(5,6)-H], 7.37–7.43 [m, 2 H, C(4,7)-H] ppm. ^{13}C{^{1}H} NMR (75 MHz, [D$_6$]benzene, 25 °C): δ = –0.2 [3 C, Si(CH_3)$_3$], 17.4 [1 C, C(1)-Me], 49.7 (1 C, C-1), 121.6 (1 C, C-4), 123.2 (1 C, C-7), 125.8 (1 C, C-6), 127.1 (1 C, C-5), 140.9 (1 C, C-3), 145.0 (1 C, C-2), 153.1 (1 C, C-7a), 154.8 (1 C, C-3a) ppm. GC/MS (70 eV): *m*/*z* (%) = 202 (28) [M$^+$], 187 (11) [M$^+$ – CH$_3$], 159 (5) [M$^+$ – C$_3$H$_7$], 145 (6) [M$^+$ – C$_4$H$_9$], 128 (14) [M$^+$ – TMS], 115 (4) [C$_9$H$_7^+$], 73 (100) [TMS$^+$], 59 (7) [SiH(CH$_3$)$_2^+$].

1,3-Dimethyl-2-(dimethylsilyl)indene (3a): The synthesis was carried out in a fashion similar to **2a**. 2-(Dimethylsilyl)-1-methylindene (2.68 g, 14.3 mmol), *n*-butyllithium (8.8 mL, 14.1 mmol) and methyl iodide (3.5 mL, 57.2 mmol) were employed to obtain a yellow liquid (2.65 g). Column chromatography with pentane on silica provided a colorless liquid (1.61 g, 8.0 mmol, 57%), containing

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

both the product (70%) and its 1,1 isomer (30%). No further purification was attempted. ^{1}H NMR (300 MHz, [D$_6$]benzene, 25 °C): δ = 0.24 [d, ^3J = 3.9 Hz, 3 H, SiH(CH_3)$_2$], 0.25 [d, ^3J = 3.9 Hz, 3 H, SiH(CH_3)$_2$], 1.21 [d, ^3J = 7.5 Hz, 3 H, C(1)-CH$_3$], 2.12 [d, ^5J = 1.8 Hz, 3 H, C(3)-CH$_3$], 3.36 [dq, ^5J_d = 2.1, ^3J_q = 7.5 Hz, 1 H, C(1)-H], 4.68 [m, ^3J = 3.9 Hz, 1 H, SiH(CH$_3$)$_2$], 7.17–7.24 [m, 2 H, C(5,6)-H], 7.24–7.31 [m, 2 H, C(4,7)-H] ppm. ^{13}C{^{1}H} NMR (75 MHz, [D$_6$]benzene, 25 °C): δ = –2.4 [2 C, SiH(CH_3)$_3$], 17.6 [1 C, C(1)-Me], 25.8 [1 C, C(3)-Me], 49.3 (1 C, C-1), 119.7 (1 C, C-4), 122.9 (1 C, C-7), 126.0 (1 C, C-6), 127.0 (1 C, C-5), 143.5 (1 C, C-3), 146.5 (1 C, C-2), 149.4 (1 C, C-7a), 152.7 (1 C, C-3a) ppm. GC/MS (70 eV): *m/z* (%) = 202 (50) [M$^+$], 187 (33) [M$^+$ – CH$_3$], 159 (19) [C$_{10}$H$_{11}$Si$^+$], 142 (100) [C$_{11}$H$_{10}^+$], 128 (42) [C$_{10}$H$_8^+$], 115 (17) [C$_9$H$_7^+$], 73 (25) [Si(CH$_3$)$_3^+$], 59 (66) [SiH(CH$_3$)$_2^+$].

1,3-Dimethyl-2-(trimethylsilyl)indene (3b): Prior to the addition of *n*-butyllithium (15.0 mL, 37.5 mmol), **2b** (2.45 g, 12.1 mmol) in pentane (30 mL) was placed in a Schlenk flask and cooled to –90 °C. The solution was stirred overnight and warmed to room temperature, affording a suspension with a white precipitate after addition of diethyl ether (1 mL). Reduction of the solvent volume to approximately 60% was followed by a filtration through a D4-frit and washing of the precipitate with pentane (3 × 10 mL). While the white precipitate was dried in vacuo, a second Schlenk flask was equipped with an addition funnel and methyl iodide (2.25 mL, 36.3 mmol) in diethyl ether (20 mL) and cooled to –40 °C. The lithium salt was dissolved in diethyl ether (30 mL) and THF (10 mL), transferred to the addition funnel and dropwise added to the solution at –40 °C. Stirring overnight and acidic work-up provided a pale yellow crude product (2.21 g, 10.2 mmol). Its composition was determined to be ca. 20% of the 1,1 and 80% of the desired 1,3 isomer. No further separation of the isomers was attempted. The spectroscopic data was derived from the hydrolysis of the pure 1,3-dimethyl-2-(trimethylsilyl)indenyllithium. ^{1}H NMR (300 MHz, [D$_6$]benzene, 25 °C): δ = 0.24 [s, 9 H, Si(CH_3)$_3$], 1.20 [d, ^3J = 7.4 Hz, 3 H, C(1)-CH$_3$], 2.08 [d, ^5J = 2.0 Hz, 3 H, C(3)-CH$_3$], 3.48 [qq, ^5J = 2.0, ^3J = 7.4 Hz, 1 H, C(1)-H], 7.19–7.25 [m, 2 H, C(5,6)-H], 7.25–7.31 [m, 2 H, C(4,7)-H] ppm. ^{13}C{^{1}H} NMR (75 MHz, [D$_6$]benzene, 25 °C): δ = 0.9 [3 C, Si(CH_3)$_3$], 18.2 [1 C, C(1)-Me], 26.0 [1 C, C(3)-Me], 49.4 (1 C, C-1), 119.6 (1 C, C-4), 122.9 (1 C, C-7), 125.9 (1 C, C-6), 127.0 (1 C, C-5), 146.0 (1 C, C-3), 146.8 (1 C, C-2), 148.3 (1 C, C-7a), 152.8 (1 C, C-3a) ppm. GC/MS (70 eV): *m/z* (%) = 216 (29) [M$^+$], 201 (12) [M$^+$ – CH$_3$], 141 (11) [M$^+$ – TMS], 128 (11) [M$^+$ – Si(CH$_3$)$_4$], 115 (6) [C$_9$H$_7^+$], 73 (100) [TMS$^+$], 59 (6) [SiH(CH$_3$)$_2^+$].

1-Isopropyl-2-(trimethylsilyl)indene (4): The synthesis was carried out according to the procedure for **2b**. 2-(Trimethylsilyl)indenyllithium (870 mg, 4.5 mmol) and 2-iodopropane (0.5 mL, 5.0 mmol) were reacted to provide a yellow oil (770 mg, 3.3 mmol, 74%). ^{1}H NMR (300 MHz, [D$_6$]benzene, 25 °C): δ = 0.202 [s, 4.5 H, Si-(CH_3)$_3$], 0.204 [s, 4.5 H, Si(CH_3)$_3$], 0.48 [d, ^3J = 6.6 Hz, 3 H, C(1′)-H], 1.21 [d, ^3J = 7.4 Hz, 3 H, C(3′)-H], 2.40 [dqq, ^3J = 3.0, ^3J = 6.9 Hz, 1 H, C(2′)-H], 3.52 [dd, ^4J = 2.4, ^3J = 2.7 Hz, 1 H, C(1)-H], 6.99 [d, ^4J = 1.8 Hz, 1 H, C(3)-H], 7.11 [ddd, ^4J = 1.2, ^3J = 7.2, ^3J = 7.2 Hz, 1 H, C(5)-H], 7.22 [ddm, J = 0.6, ^3J = 7.2, ^3J = 7.2 Hz, 1 H, C(6)-H], 7.30 [dm, J = 0.6, ^3J = 7.5 Hz, 1 H, C(4)-H], 7.45 [d, ^3J = 7.5 Hz, 1 H, C(7)-H] ppm. ^{13}C{^{1}H} NMR (75 MHz, [D$_6$]benzene, 25 °C): δ = –0.2, –0.1 [3 C, Si(CH_3)$_3$], 16.4 (1 C, C-1′), 22.9 (1 C, C-2′), 30.3 (1 C, C-3′), 61.3, 61.4 (1 C, C-1), 121.7 (1 C, C-4), 124.9 (1 C, C-7), 125.4 (1 C, C-6), 127.3 (1 C, C-5), 142.3, 142.4 (1 C, C-3), 146.8 (1 C, C-2), 149.2 (1 C, C-7a), 152.9 (1 C, C-3a). GC/MS (70 eV): *m/z* (%) = 230 (23) [M$^+$], 215 (4) [M$^+$ – CH$_3$], 172 (6) [C$_{11}$H$_{12}$Si$^+$], 156 (16) [C$_{12}$H$_{12}^+$], 141 (7) [C$_{11}$H$_9^+$], 128 (6) [C$_{10}$H$_8^+$], 115 (5) [C$_9$H$_7^+$], 73 (100) [C$_3$H$_9$Si$^+$], 59 (7) [C$_2$H$_7$Si$^+$].

1-Isopropyl-2-(trimethylsilyl)indenyllithium/potassium (5): The preparation of the lithium salt followed a literature procedure.[12] At –90 °C **4** (4.44 g, 19.3 mmol) was reacted with *n*-butyllithium (8.5 mL, 21.3 mmol) in pentane (30 mL). Stirring overnight and warming to room temperature provided an orange solution. A precipitate could be obtained neither by addition of diethyl ether (2 mL) nor by solvent removal. GC/MS analysis after quenching a sample of the reaction with methyl iodide in THF displayed 10 major products, of which 7 could be identified by the fragmentation pattern: **(i)** 1-Methyl-1-isopropyl-2-(trimethylsilyl)indene. GC/MS (70 eV): *m/z* (%) = 244 (32) [M$^+$], 229 (5) [M$^+$ – CH$_3$], 170 (40) [M$^+$ – TMS], 155 (17) [C$_{12}$H$_{11}^+$], 141 (12) [C$_{11}$H$_9^+$], 128 (7), 115 (6) [C$_9$H$_7^+$], 73 (100) [C$_3$H$_9$Si$^+$]; **(ii)** 1-isopropyl-2-(trimethylsilyl) indene (**4**); **(iii)** 3-methyl-1-isopropyl-2-(trimethylsilyl)indene. GC/MS (70 eV): *m/z* (%) = 244 (22) [M$^+$], 229 (6) [M$^+$ – CH$_3$], 201 (12) [M$^+$ – C$_3$H$_7$], 185 (6) [C$_{12}$H$_{14}$Si$^+$], 170 (25) [M$^+$ – C$_3$H$_9$Si], 155 (7) [C$_{12}$H$_{11}^+$], 141 (6) [C$_{11}$H$_9^+$], 128 (6), 73 (100) [C$_3$H$_9$Si$^+$], 59 (8) [C$_2$H$_7$Si$^+$]; **(iv)** 1,3-diisopropyl-2-(trimethylsilyl)indene; **(v)** 1-methyl-3-isopropyl-2-(trimethylsilyl)indene. GC/MS (70 eV): *m/z* (%) = 244 (36) [M$^+$], 229 (8) [M$^+$ – CH$_3$], 170 (54) [M$^+$ – TMS], 155 (14) [C$_{12}$H$_{11}^+$], 141 (9) [C$_{11}$H$_9^+$], 128 (7), 115 (5) [C$_9$H$_7^+$], 73 (100) [C$_3$H$_9$Si$^+$], 59 (7) [C$_2$H$_7$Si$^+$]; **(vi)** 1,1-diisopropyl-2-(trimethylsilyl)indene. GC/MS (70 eV): *m/z* (%) = 272 (19) [M$^+$], 257 (5) [M$^+$ – CH$_3$], 198 (55) [M$^+$ – TMS], 183 (18) [C$_{14}$H$_{15}^+$], 169 (5) [C$_{13}$H$_{13}^+$], 155 (5) [C$_{12}$H$_{11}^+$], 141 (5) [C$_{11}$H$_9^+$], 73 (100) [C$_3$H$_9$Si$^+$], 59 (7) [C$_2$H$_7$Si$^+$]; **(vii)** 3-*tert*-butyl-2-(trimethylsilyl)indene. GC/MS (70 eV): *m/z* (%) = 244 (25) [M$^+$], 229 (69) [M$^+$ – CH$_3$], 214 (100) [M$^+$ – C$_2$H$_6$], 199 (43) [M$^+$ – C$_3$H$_9$], 187 (5) [M$^+$ – C$_4$H$_9$], 169 (5) [C$_{13}$H$_{14}^+$], 155 (13) [C$_{12}$H$_{11}^+$], 141 (6) [C$_{11}$H$_9^+$], 128 (7), 115 (7) [C$_9$H$_7^+$], 73 (7) [C$_3$H$_9$Si$^+$]. Attempted preparation of the potassium salt: Potassium hydride (568 mg, 13.9 mmol) was added to a solution of **4** (2.9 g, 12.6 mmol) in THF (40 mL) at –90 °C. Quantitative reaction was not achieved before refluxing the suspension for several days. Filtration with a cannula, solvent removal, washing with pentane and drying in vacuo afforded a yellow-brown solid (1.8 g, 6.7 mmol, 53%). ^{1}H NMR (300 MHz, [D$_8$]THF, 25 °C): δ = 0.46 [s, 9 H, Si(CH_3)$_3$], 1.68 [d, ^3J = 9.0 Hz, 6 H, C(1′,3′)-H], 3.62 [hept, ^3J = 9.0 Hz, 1 H, C(2′)-H], 6.16 [s, 1 H, C(3)-H], 6.47–6.59 [m, 2 H, C(5,6)-H], 7.39 [m, 1 H, C(4)-H], 7.63–7.71 [m, 1 H, C(7)-H] ppm. ^{13}C{^{1}H} NMR (75 MHz, [D$_8$]THF, 25 °C): δ = 1.9 (3 C), 25.0 (2 C), 32.2, 99.8, 112.5, 112.8, 119.4, 119.8, 121.0, 123.1, 127.6, 132.0 (1 C) ppm.

Attempted Synthesis of 1,3-Diisopropyl-2-(trimethylsilyl)indene: The preparation was attempted by in situ derivatization of Li[**5**] without prior isolation. Following the procedure for the preparation of **3b**, 2-iodopropane (2.1 mL, 21 mmol) was used. After stirring for 6 h and incomplete conversion according to GC/MS analysis, another aliquot of iodopropane was added and reacted overnight. Acidic work-up and GC/MS analysis of the crude product revealed the presence of four components: 1- and 3-isopropyl-2-(trimethylsilyl)-indene, 1,1- and 1,3-diisopropyl-2-(trimethylsilyl)indene. To the crude product dissolved in THF at –40 °C, potassium hydride (791 mg, 19.3 mmol) was added. Stirring overnight afforded a green solution. Solvent removal and extraction with diethyl ether provided a light green precipitate and a dark green filtrate. Washing the light green precipitate with pentane led to partial dissolution of the precipitate. Drying in vacuo provided a light green, pyrophoric powder (3.3 g). We could not isolate a pure fraction of the desired product. GC/MS (70 eV): *m/z* (%) = 228 (24) [M$^+$], 257 (7) [M$^+$ – CH$_3$], 198 (66) [M$^+$ – TMS], 183 [C$_{14}$H$_{15}^+$], 169 (6) [C$_{13}$H$_{14}^+$], 155

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(6) [$C_{12}H_{11}^+$], 141 (6) [$C_{11}H_9^+$], 73 (100) [$C_3H_9Si^+$], 59 (7) [$C_2H_7Si^+$].

Attempted Synthesis of 1-Isopropylidene-2-(trimethylsilyl)indene: To a Schlenk flask charged with dry acetone (0.1 mL, 1.4 mmol) and $BF_3{\cdot}Et_2O$ (0.1 mL, 789 μmol) in diethyl ether (20 mL), 2-(trimethylsilyl)indenyllithium (100 mg, 824 μmol) was added. Formation of a colorless suspension was achieved within one hour. The solvent was replaced by a mixture of pentane and THF (20 mL, 3 mL), prior to addition of orthophosphoric acid (6 mL, 85%). The organic layer turned yellow while stirring overnight. Acidic work-up, washing with deionized water, drying over magnesium sulfate and drying in vacuo provided a yellow oil (100 mg, 284 μmol, 34%). Product: GC/MS (70 eV): *m*/*z* (%) = 228 (31) [M^+], 213 (6) [$M^+ - CH_3$], 197 (13) [$M^+ - C_2H_6$], 155 (6) [$C_{12}H_{11}^+$], 141 (7) [$C_{11}H_9^+$], 128 (5), 115 (6) [$C_9H_7^+$], 73 (100) [$C_3H_9Si^+$]. Hydrated intermediate: GC/MS (70 eV): *m*/*z* (%) = 228 (6) [$M^+ - H_2O$], 201 (14) [$C_{13}H_{17}Si^+$], 187 (43) [$C_{12}H_{14}Si^+$], 173 (12) [$C_{11}H_{12}Si^+$], 157 (6) [$C_{10}H_8Si^+$], 145 (21) [$C_9H_9Si^+$], 128 (11), 115 (12) [$C_9H_7^+$], 73 (100) [$C_3H_9Si^+$], 58 (15) [$C_3H_7O^+$].

6,6-Dimethylbenzofulvene (6): The synthesis followed a literature procedure and does not require Schlenk technique.[7] By stirring indene (5 mL, 42.9 mmol), acetone (3.8 mL, 51.8 mmol) and pyrrolidine (4.3 mL, 51.8 mmol) in methanol (50 mL) for two days and subsequent distillation (0.05Torr), a yellow oil (4.94 g, 31.7 mmol, 74%) was obtained. ^{1}H NMR (300 MHz, [D$_6$]benzene, 25 °C): δ = 1.84 [s, 3 H, C(1′)-CH_3], 1.97 [s, 3 H, C(3′)-CH_3], 6.72 [s, 2 H, C(2,3)-H], 7.17 [m$_c$, 2 H, C(5,6)-H], 7.28 [m$_c$, 1 H, C(4)-H], 7.64 [m$_c$, 1 H, C(7)-H] ppm. ^{13}C{^{1}H} NMR (75 MHz, [D$_6$]benzene, 25 °C): δ = 22.9 (1 C, C-1′), 24.8 (1 C, C-3′), 121.8 (1 C, C-4), 124.3 (1 C, C-7), 125.4 (1 C, C-6), 126.7 (1 C, C-5), 128.2 (1 C, C-3), 129.2 (1 C, C-2), 136.8 (1 C, C-2′), 137.8 (1 C, C-1), 142.7 (1 C, C-7a), 145.0 (1 C, C-3a) ppm. GC/MS (70 eV): *m*/*z* (%) = 156 (93) [M^+], 141 (100) [$M^+ - CH_3$], 128 (21) [$C_{10}H_9^+$], 115 (36) [$C_9H_7^+$].

3-*tert*-Butylindene (7): Following a literature procedure,[6] the product was obtained from reacting **6** (1.51 g, 9.7 mmol) with methyllithium (6.9 mL, 9.7 mmol) at 0 °C in diethyl ether (30 mL). Acidic work-up afforded a colorless liquid (740 mg, 4.3 mmol, 44%). As an alternative, the reaction may be run in pentane in the presence of 10 wt.-% freshly resublimated $AlCl_3$ at room temperature. Addition of methyllithium via syringe provided a white precipitate in quantitative yield within one hour. ^{1}H NMR (300 MHz, [D$_6$]benzene, 25 °C): δ = 1.33 (s, 9 H, *t*Bu), 3.02 [d, ^3J = 2.1 Hz, 2 H, C(1)-H], 5.99 [t, ^3J = 2.1 Hz, 1 H, C(2)-H], 7.12 [ddd, ^4J = 1.8, ^3J = 7.2, ^3J = 7.2 Hz, 1 H, C(5)-H], 7.23 [dd, ^3J = 7.8, ^3J = 7.8 Hz, 1 H, C(6)-H], 7.32 [d, ^3J = 7.5 Hz, 1 H, C(4)-H], 7.59 [d, ^3J = 7.8 Hz, 1 H, C(7)-H] ppm. ^{13}C{^{1}H} NMR (75 MHz, [D$_6$]benzene, 25 °C): δ = 29.9 (3 C, *t*Bu), 33.6 (1 C, *t*Bu), 37.7 (1 C, C-1), 122.8 (1 C, C-2), 124.67 (1 C, C-4), 124.72 (1 C, C-7), 126.35 (1 C, C-6), 126.40 (1 C, C-5), 144.6 (1 C, C-7a), 146.4 (1 C, C-7a), 154.0 (1 C, C-3) ppm. GC/MS (70 eV): *m*/*z* (%) = 172 (78) [M^+], 157 (77) [$M^+ - CH_3$], 142 (78) [$M^+ - C_2H_6$], 128 (29) [$C_{10}H_8^+$], 116 (82) [$C_9H_8^+$], 57 (100) [$C_4H_9^+$].

3-*tert*-Butyl-1-(isopropylidene)indene (8). A Schlenk flask equipped with a condenser was charged with **7** (1.54 g, 8.7 mmol), acetone (1.5 mL, 20.5 mmol), pyrrolidine (1.7 mL, 20.5 mmol), and methanol (30 mL) under air. Reflux of the reaction mixture for three days and removal of all volatiles in vacuo provided a red-brown oil. vacuum distillation provided a yellow liquid boiling at 80 °C$_{0.05\text{Torr}}$ which would solidify at room temperature (1.05 g, 5.0 mmol, 58%). ^{1}H NMR (300 MHz, [D$_6$]benzene, 25 °C): δ = 1.39 (s, 9 H, *t*Bu-H), 1.92 [s, 3 H, C(1′)-CH_3], 2.04 [s, 3 H, C(3′)-CH_3], 6.60 [s, 1 H, C(2)-H], 7.13–7.24 [m, 2 H, C(5,6)-H], 7.60 [m$_c$, 1 H, C(4)-H], 7.72 [m$_c$, 1 H, C(7)-H] ppm. ^{13}C{^{1}H} NMR (75 MHz, [D$_6$]benzene, 25 °C): δ = 23.0 (1 C, C-1′), 24.9 (1 C, C-3′), 30.2 (3 C, *t*Bu-C), 35.6 (1 C, *t*Bu-C), 122.2 (1 C, C-2′), 122.7 (1 C, C-4), 124.4 (1 C, C-7), 124.9 (1 C, C-6), 126.2 (1 C, C-5), 136.3 (1 C, C-2), 138.9 (1 C, C-7a), 139.9 (1 C, C-3a), 143.6 (1 C, C-1), 151.0 (1 C, C-3) ppm. GC/MS (70 eV): *m*/*z* (%) = 212 (29) [M^+], 197 (10) [$M^+ - CH_3$], 182 (5) [$M^+ - C_2H_6$], 165 (15), 156 (100) [$C_{12}H_{12}^+$], 141 (50) [$C_{11}H_9^+$], 128 (13) [$C_{10}H_9^+$], 115 (17) [$C_9H_7^+$], 57 (47) [$C_4H_8^+$].

1,3-Di-(*tert*-butyl)indene (9): The synthesis followed essentially the synthesis of **7**. To an agitated solution of 3-*tert*-butyl-1-(isopropylidene)indene (4.89g, 23.1 mmol) in diethyl ether (30 mL), methyllithium (16.5 mL, 26.4 mmol) was added dropwise at 0 °C. After stirring for 2 h with warming to room temperature, GC/MS analysis of the reaction mixture showed only traces of the product. Addition of more methyllithium (15.0 mL, 24 mmol) and refluxing the reaction for 10 h provided a conversion of 25% (GC/MS). The reaction was poured over a mixture of diluted hydrochloric acid, diethyl ether and crushed ice (300 mL). Adjustment to pH 4 was followed by stirring for 10 minutes and phase separation. The organic layer was washed with deionized water (2 × 100 mL) and dried with magnesium sulfate prior to solvent evaporation. Column chromatography at silica gel (420 g) afforded a colorless liquid (0.652 g, 2.9 mmol, 12%). ^{1}H NMR (300 MHz, [D$_6$]benzene, 25 °C): δ = 0.94 [s, 9 H, C(1)-*t*Bu], 1.34 [s, 9 H, C(3)-*t*Bu], 3.08 [d, ^3J = 2.4 Hz, 1 H, C(1)-H], 6.16 [d, ^3J = 2.1 Hz, 1 H, C(2)-H], 7.10 [ddd, ^4J = 1.8, ^3J = 7.5, ^3J = 7.5 Hz, 1 H, C(5)-H], 7.21 [ddd, ^4J = 1.2, ^3J = 7.8, ^3J = 7.8 Hz, 1 H, C(6)-H], 7.50 [d, ^3J = 7.2 Hz, 1 H, C(4)-H], 7.54 [d, ^3J = 7.5 Hz, 1 H, C(7)-H] ppm. ^{13}C{^{1}H} NMR (75 MHz, [D$_6$]benzene, 25 °C): δ = 23.5 [1 C, C(1)-*C*$(CH_3)_3$], 29.0 [3 C, C(1)-C(*C*$H_3)_3$], 30.0 [3 C, C(3)-C(*C*$H_3)_3$], 32.6 [1 C, C(3)-*C*$(CH_3)_3$], 59.2 (1 C, C-1), 122.8 (1 C, C-4), 124.4 (1 C, C-7), 125.7 (1 C, C-6), 126.6 (1 C, C-5), 130.4 (1 C, C-2), 145.1 (1 C, C-7a), 148.4 (1 C, C-3a), 153.4 (1 C, C-3) ppm. GC/MS (70 eV): *m*/*z* (%) = 228 (41) [M^+], 172 (43) [$M^+ - C_4H_8$], 157 (59) [$C_{12}H_{13}^+$], 141 (31) [$C_{11}H_9^+$], 128 (11) [$C_{10}H_8^+$], 116 (37) [$C_9H_8^+$], 57 (100) [$C_4H_9^+$].

1-Methyl-2-(trimethylsilyl)indenyllithium (10): The deprotonation was carried out in a similar fashion to **2b**. The lithium salt could be isolated as a white powder in quantitative yield.

1,3-Dimethyl-2-(dimethylsilyl)indenyllithium (11a): The deprotonation of the ligand precursors followed a literature procedure.[12] The indene derivative (1.0 equiv.) and *n*-butyllithium (1.0 equiv.) were placed in a Schlenk flask charged with pentane (30 mL). Stirring at room temperature overnight provided little precipitate. Addition of 1 mL diethyl ether lead to the formation of appreciable amounts of precipitate, but filtration via cannula turned out to be difficult due to the formation of a viscous gel. Washing with pentane (2 × 30 mL) and subsequent solvent removal under high-vacuum yielded a light yellow powder (1.07 g, 5.1 mmol, 64%). $C_{13}H_{17}LiSi$ (208.30): calcd. C 74.96, H 8.23; found C 74.40, H 8.16. ^{1}H NMR (300 MHz, [D$_8$]THF, 25 °C): δ = 0.51 [d, ^3J = 3.9 Hz, 6 H, SiH(C$H_3)_2$], 2.65 [s, 6 H, C(1,3)-Me], 4.94 [hept, ^3J = 3.9 Hz, 1 H, SiH(C$H_3)_2$], 6.58 [m$_{AA'XX'}$, 2 H, C(5,6)-H], 7.38 [m$_{AA'XX'}$, 2 H, C(4,7)-H] ppm.

1,3-Dimethyl-2-(trimethylsilyl)indenyllithium (11b): The deprotonation was carried out in a similar fashion to **2b**, but started at –90 °C. Using an isomer mixture of **3b** (2.21 g, 10.2 mmol, 78% purity) and *n*-butyllithium (12.2 mL, 30.6 mmol) in pentane (30 mL) provided a light green powder (1.58 g, 7.1 mmol, 89%) after filtration through a D4-frit, washing with pentane (2 × 10 mL) and solvent removal under high vacuum.

***rac/meso*-Bis[1-methyl-2-(trimethylsilyl)indenyl]zirconium(IV) Dichloride (12):** To a Schlenk flask equipped with a septum, charged with **10** (714 mg, 3.4 mmol) and zirconium tetrachloride (396 mg, 1.7 mmol) and cooled to 0 °C, diethyl ether (30 mL) was added via syringe. Stirring overnight afforded a suspension of a yellow precipitate. Filtration trough a D4 frit with a layer of magnesium sulfate (3 cm) and washing with diethyl ether until all yellow residue in the Schlenk flask was dissolved, provided a clear, yellow solution. Volume reduction to the formation of precipitate was followed by crystallization at –40 °C. Subsequent crystallizations failed to separate the *rac* and *meso* isomer, which were obtained in a 1:1 ratio (528 mg, 941 μmol, 55%). $C_{26}H_{34}Cl_2Si_2Zr$ (564.86): calcd. C 55.29, H 6.07; found C 55.55, H 6.15. ***rac* Isomer:** ^{1}H NMR (300 MHz, [D$_6$]benzene, 25 °C): δ = 0.32 [s, 18 H, Si(C*H*$_3$)$_3$], 2.29 [s, 6 H, C(1)-CH$_3$], 5.62 [s, 2 H, C(3)-H], 6.84–6.94 [m, 4 H, C(5,6)-H], 7.48–7.56 [m, 2 H, C(4,7)-H] ppm. ***meso* Isomer:** ^{1}H NMR (300 MHz, [D$_6$]benzene, 25 °C): δ = 0.14 [s, 18 H, Si(C*H*$_3$)$_3$], 2.52 [s, 6 H, C(1)-CH$_3$], 5.07 [s, 2 H, C(3)-H], 6.94–7.00 [m, 4 H, C(5,6)-H], 7.10–7.15 [m, 2 H, C(4)-H], 7.25–7.30 [m, 2 H, C(7)-H] ppm. ***rac* and *meso* Isomer:** ^{13}C{^{1}H} NMR (75 MHz, [D$_6$] benzene, 25 °C): δ = 0.7 [6 C, Si(*C*H$_3$)$_3$], 1.1 [6 C, Si(*C*H$_3$)$_3$], 14.1 [2 C, C(1)-CH$_3$], 14.4 [2 C, C(1)-CH$_3$], 106.8 (2 C, C-3), 109.8 (2 C, C-3), 124.7, 124.8, 125.0, 125.1, 125.2, 125.4, 125.6, 125.9, 126.3, 126.6, 127.6, 128.5, 132.3, 133.0, 135.3, 138.8 ppm.

Attempted Synthesis of Bis[1,3-dimethyl-2-(dimethylsilyl)indenyl]zirconium(IV) Dichloride (13a): In a Schlenk flask, **11a** (185 mg, 889 μmol) and zirconium tetrachloride (104 mg, 446 μmol) were reacted in diethyl ether (30 mL) at 0 °C. The initially brown-yellow suspension turned green-yellow while stirring overnight. A clear yellow solution was obtained by filtration through a layer of magnesium sulfate on a D4 frit and washing of the reaction residue with diethyl ether. Volume reduction to 10 mL and refrigeration to –40 °C provided traces of precipitate. The obtained NMR spectroscopic data suggests the formation of the desired product, but reliable analysis including elemental analysis was precluded by the small amount of precipitate obtained. ^{1}H NMR (300 MHz, [D$_6$]benzene, 25 °C): δ = 0.24 [d, ^3J = 3.9 Hz, 12 H, SiH(C*H*$_3$)$_2$], 2.15 [s, 12 H, C(1,3)-CH$_3$], 4.76 [hept, ^3J = 4.2 Hz, 2 H, Si*H*-(CH$_3$)$_2$], 6.80–7.00 [m, 4 H, C(5,6)-H], 7.15–25 [m, 4 H, C(4,7)-H] ppm.

Bis[1,3-dimethyl-2-(trimethylsilyl)indenyl]zirconium(IV) Dichloride (13b): A Schlenk flask with **11b** (1.00 g, 3.4 mmol) and zirconium tetrachloride (0.52 g, 1.69 mmol) was cooled to 0 °C before diethyl ether (30 mL) was added dropwise. The suspension turned dark yellow and formed a yellow precipitate while stirring overnight. Filtration with a cannula and a D4-frit loaded with magnesium sulfate (3 cm) afforded a dark yellow solution. Extraction of the reaction residue and filter cake with diethyl ether and toluene, followed by recrystallization from the respective solvent afforded four crops of a yellow or orange solid (393 mg, 665 μmol, 44%). Single crystals of X-ray quality were grown from a cold saturated diethyl ether solution at –40 °C. $C_{28}H_{38}Cl_2Si_2Zr$ (592.91): calcd. C 56.72, H 6.46; found C 56.75, H 6.48. ^{1}H NMR (300 MHz, [D$_6$]benzene, 25 °C): δ = 0.31 [s, 18 H, Si(C*H*$_3$)$_3$], 2.13 [s, 12 H, C(1,3)-C*H*$_3$], 6.86 [m$_{AA'XX'}$, J_A = 6.5, J_X = 0.8, J = 8.7, J' = 1.0 Hz, 4 H, C(5,6)-H], 7.15–7.19 [m, 4 H, C(4,7)-H] ppm. ^{13}C{^{1}H} NMR (75 MHz, [D$_6$]benzene, 25 °C): δ = 2.0 [6 C, Si(*C*H$_3$)$_3$], 13.8 (4 C, 1,3-*C*H$_3$), 121.0 (4 C, C-1,3), 124.0 (4 C, C-4,7), 124.8 (4 C, C-5,6), 127.7 (4 C, C-3a,7a), 139.9 (2 C, C-2) ppm.

Attempted Synthesis of *rac/meso*-Bis[1-isopropyl-2-(trimethylsilyl)indenyl]zirconium(IV) Dichloride (14): To a Schlenk flask charged with 1-isopropyl-2-(trimethylsilyl)indenylpotassium (**5**) (1.00 g, 3.7 mmol) and zirconium tetrachloride (429 mg, 1.86 mmol), THF (40 mL) was added at –40 °C. Stirring overnight afforded a yellow solution. Solvent change from THF to diethyl ether led to the formation of precipitate. Filtration via cannula and through magnesium sulfate on a D4 frit yielded a brown-yellow oil upon solvent removal. Crystallization occurred after two months of storage in the drybox, though the crystals were too ductile to be isolated. No conclusive NMR spectroscopic data could be obtained for this complex.

Crystal Structure Determination: A yellow platelet with dimensions 0.85 × 0.33 × 0.10 mm was mounted on a glass fiber. Pertinent data for the crystal and solution are collected in Table 5. Reflections were measured with a Siemens SMART 1000 CCD-diffractometer using Mo-K_α radiation. The data collections with SMART[13a] included three sets of exposures with the detector set at 2θ = 26 and crystal-to-detector distance 50 mm. Data integration and cell refinement was carried out by SAINT,[13b] while absorption correction was carried out by SADABS.[13c] SHELXTL[13d] was used for structure solution by direct methods as well as for subsequent full-matrix least-squares refinement on F^2. All atoms except protons were refined anisotropically.

CCDC-253467 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

$R(F_0)$	1.91[a]
$R_w(F_O^2)$	4.75[b]
GOF	1.050

[a] Calculated on 5395 reflecions with $I > 2\sigma(I)$. [b] Calculated on all 5687 reflections.

General Polymerization Procedure: Polymerizations were carried out in 100-mL glass reactors equipped with a cooling/heating mantle, an argon/vacuum connection, magnetic stirrer and a septum. Prior to use, the reactors were evacuated at 90 °C for two hours and flushed three times with argon. At 30 °C, the reactors were charged with 50 mL aliquots of freshly distilled toluene, the appropriate amount of solid MAO and subsequently pressurized to a preset pressure of ethene until no further ethene consumption could be registered by the massflow controllers. Polymerization was initiated by injection of the appropriate volume of a toluene solution of the catalyst precursor. Typically, the catalyst precursor solutions had concentrations of $1.0 \cdot 10^{-3}$ mol/L. The reaction was stopped by addition of methanol (5 mL). Work-up of the polymers included extraction of the toluene suspension with methanol/hydrochloric acid (9:1) to remove inorganic residues. Products were fil-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tered, washed with methanol and dried under high vacuum for two days.

Computational Details: Hybrid DFT calculations were performed with the Gaussian98 package.[14] The B3LYP functional with the 6-31G* basis set was employed for our purposes and proved to be suitable.[15] For Zr, a modified version of the LANL2DZ ECP basis was used.[16] In the original basis set, the 4d shell is described by two contracted functions consisting of three and one primitive Gaussians denoted (31), respectively. To increase flexibility in the d shell we decontracted the set to three functions, consisting of 2, 1, and 1 primitive functions, respectively. For integration, ultrafine grid was employed. All other settings remained default. Due to the high demand for computation time of transition state searches, these were conducted with the Gaussian03 package using the density fitting approximation with auxiliary basis sets as implemented with a pure BP86 functional and a 6-31G* basis set.[17] All calculations were conducted with ultrafine integration grid, while all other parameters remained default.

Acknowledgments

We would like to thank Aud M. Bouzga for assistance with the multi-nuclear NMR experiments. This research was generously supported by the Research Council of Norway through a Dr.-Ing. scholarship (to A. C. M., grant no. 145544/431). Heidi N. Bryntesen's (Borealis Stathelle) generous effort of conducting GPC measurements is very much appreciated.

Structural and Electrochemical Studies of Dimerization and Rotational Isomerization in Multi-Iron Silicotungstates

Travis M. Anderson,[a] Rui Cao,[a] Wade A. Neiwert,[a,c] Kenneth I. Hardcastle,[a] Craig L. Hill,*[a] Malika Ammam,[b] Bineta Keita,[b] and Louis Nadjo*[b]

Keywords: Polyoxometalates / Cyclic voltammetry / Iron / Tungsten

A structural and electrochemical investigation of dimerization and Baker–Figgis (rotational) isomerization in the tri-ferric-substituted silicotungstates has been undertaken because these phenomena are important in a large number of polyoxometalates. A single-crystal X-ray diffraction analysis of $K_4Na_7[(\beta\text{-}SiFe_3W_9(OH)_3O_{34})_2(OH)_3]$ (**β1**) has been carried out [a = 12.9709(7) Å, b = 38.720(2) Å, c = 21.4221(12) Å, orthorhombic, *Pbcm*, R_1 = 8.48 %, based on 13809 independent reflections]. The complex is isostructural with $[(\alpha\text{-}SiFe_3W_9(OH)_3O_{34})_2(OH)_3]^{11-}$ (**α1**) except that the edge-shared W_3O_{13} caps in each $[SiFe_3W_9(OH)_3O_{34}]^{4-}$ unit are rotated by 60°. Electrochemical measurements, performed in a pH 5 acetate buffer, indicate a positive shift in the Fe^{III}-based peak potential (and no change for the W^{VI}-based potential) upon going from **α1** to its monomeric derivative $[(\alpha\text{-}Si(FeOH_2)_3W_9(OH)_3O_{34})]^{4-}$ (**α2**) (–0.484 ± 0.005 V and –0.474 ± 0.005 V, respectively). In contrast, the peak potentials of the Fe^{III}- and W^{VI}-based redox processes of **β1** are both found at more negative values than its rotational isomer **α1**. The absolute values of the reduction peak potential differences are 0.022 V for Fe^{III} and 0.162 V for W^{VI}.

Introduction

The use of polyoxometalates (POMs) as catalysts constitutes a substantial and rapidly growing literature.[1,2] In particular, d-electron-transition-metal-substituted POMs have attracted much attention as oxidation catalysts because they are thermodynamically stable to oxidative degradation; yet many of the fundamental properties of POMs that impact catalysis and other applications as well, including elemental composition, solubility, redox potentials, charge density, size, and shape, can be systematically altered to a considerable degree. As a result, these compounds combine the stability advantages of heterogeneous catalysts with the selectivity advantages of homogeneous catalysts.

Recently we began a program aimed at the synthesis and characterization of a series of multi-iron heteropolytungstates with the goal of exploring their redox chemistry and catalytic (and electrocatalytic) properties.[3] In general, parameters (such as pH and heteroatom effects) that favor multi-electron-transfer reactions in POMs continue to be a focus on ongoing efforts.[4,5] Previously it was shown in a comparison of the cyclic voltammograms of α_1- and α_2-$[P_2(FeOH_2)W_{17}O_{61}]^{7-}$ that the location of Fe^{III} (cap or belt site) within the heteropolytungstate framework influences the electrochemical properties of the molecules.[6] More recently, we have also shown that the accumulation of multiple edge-sharing Fe^{III} centers in Wells–Dawson-derived sandwich-type complexes leads to more favorable electrocatalytic properties than those observed in monosubstituted complexes such as α_2-$[As(FeOH_2)W_{17}O_{61}]^{7-}$.[7]

This paper focuses on how two different types of common POM structural perturbations influence the electrochemical properties of Fe^{III} redox centers in a series of multi-iron silicotungstates (Figure 1). In one study, two complexes differing only in the rotational arrangement (i.e. Baker–Figgis isomerism)[8] of their edge-shared W_3O_{13} caps, $[(\alpha\text{-}SiFe_3W_9(OH)_3O_{34})_2(OH)_3]^{11-}$ (**α1**) and $[(\beta\text{-}SiFe_3W_9(OH)_3O_{34})_2(OH)_3]^{11-}$ (**β1**), are compared. In the other study, the dimer, **α1**, is compared with its monomeric analogue, $[(\alpha\text{-}Si(FeOH_2)_3W_9(OH)_3O_{34})]^{4-}$ (**α2**).[9] Unlike **α1** and **β1**, complexes **α1** and **α2** have different coordination environments around their Fe^{III} centers. The replacement of a hydroxo ligand in **α1** with an aqua ligand in **α2** results in a 20-nm red shift (from 436 nm to 456 nm) for the Fe^{III}-centered d-d transitions in the electronic spectra of the two complexes.

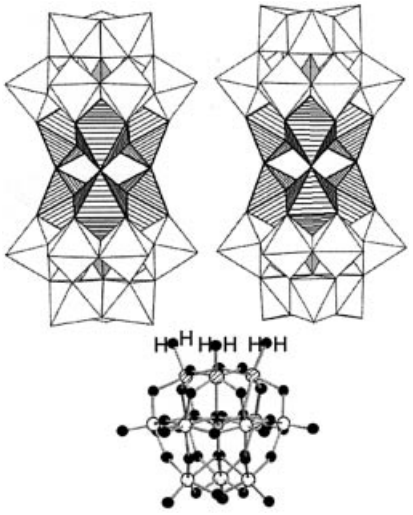

Figure 1. Polyhedral representations of $[(\alpha\text{-}SiFe_3W_9(OH)_3O_{34})_2(OH)_3]^{11-}$ (**α1**, top left) and $[(\beta\text{-}SiFe_3W_9(OH)_3O_{34})_2(OH)_3]^{11-}$ (**β1**, top right), and a ball-and-stick representation of $[(\alpha\text{-}Si(FeOH_2)_3W_9(OH)_3O_{34})]^{4-}$ (**α2**, bottom). White, gray, and striped polyhedra represent WO_6, SiO_4, and FeO_6, respectively (**α1** and **β1**). In **α2**, the W, Fe, Si, and O atoms are shown as white, striped, gray, and black spheres, respectively.

Results and Discussion

Syntheses: The syntheses of $[\alpha\text{-}SiFe_3W_9(OH)_3O_{34}]^{4-}$ (**α2**) and $[\beta\text{-}SiFe_3W_9(OH)_3O_{34}]^{4-}$ (**β2**) were originally reported by Pope.[10] However, mass spectrometry data suggested these complexes contained small to modest amounts of the dimeric species ($[(\alpha\text{-}SiFe_3W_9(OH)_3O_{34})_2(OH)_3]^{11-}$ (**α1**) and $[(\beta\text{-}SiFe_3W_9(OH)_3O_{34})_2(OH)_3]^{11-}$ (**β1**), respectively) as impurities.[10] Recently, we reported a modified procedure that utilizes differences in the acid sensitivities of $Na_7H_3[\alpha\text{-}SiW_9O_{34}]$ and $K_{10}[\alpha\text{-}SiW_9O_{34}]$ to obtain **α1** and **α2**, respectively, in high purity (with 40–70% yield).[9] In this report, an analogous procedure is used to obtain **β1** (i.e. reaction of $Na_9H[\beta\text{-}SiW_9O_{34}]$ with 3 equivalents of Fe^{III} in 0.5 M sodium acetate (pH = 6) yields **β1** in 20% yield).

Solid State Characterization of β1: The X-ray crystallographic studies of **β1** show that two A-type $[\beta\text{-}SiFe_3W_9(OH)_3O_{34}]^{4-}$ units are linked by three Fe-μ-OH–Fe bridges such that the complex has overall ca. D_{3h} symmetry (Figure 1). The complex is isostructural with **α1** except that the edge-shared W_3O_{13} caps in each $[SiFe_3W_9(OH)_3O_{34}]^{4-}$ unit are rotated by 60°. Table 1 gives average bond lengths and angles for the two complexes. Bond valence sum (BVS) calculations for Fe1, Fe2, Fe3, and Fe4 (see Figure S1 in the Supporting Information for the numbering scheme; for supporting information see also the footnote on the first page of this article) give average oxidation states of 2.96, 2.99, 3.06, and 2.99, respectively.[11] BVS calculations (average value = 1.2) also establish that hydroxo bridges are present between the adjacent Fe^{III} centers in each $[SiFe_3W_9(OH)_3O_{34}]^{4-}$ unit.

[a] Data from reference[9].

The differential scanning calorimetry curve for **β1** shows one endothermic and two exothermic processes in the region from 20 °C to 600 °C (Figure 2). The endothermic process from 100 °C to 160 °C is attributed to desorption of water molecules of crystallization from the lattice structure. This conclusion is corroborated by thermogravimetric analysis and infrared spectroscopy. The first exothermic process (from 200 °C to 275 °C, indicated by arrows and verified by infrared data) is attributed to the solid-state isomerization (from **β1** to **α1**) of the POM. Infrared spectroscopy shows that there is an 18 cm^{-1} shift in the combination W=O stretching/W–O–W bending mode centered at 883 cm^{-1} in **β1** upon heating the sample to 275 °C. The 18 cm^{-1} shift places this band at 901 cm^{-1}, which is identical to that reported for an authentic sample of **α1** (Figure 3).[9] Finally, there is an exothermic process observed from 550 °C to 600 °C that is attributable to the collapse of the tungsten framework of the POM. This is also corroborated by infrared spectroscopy data, which shows significant changes in the W=O (W–O) stretching and W–O–W bending modes after heating to 550 °C.

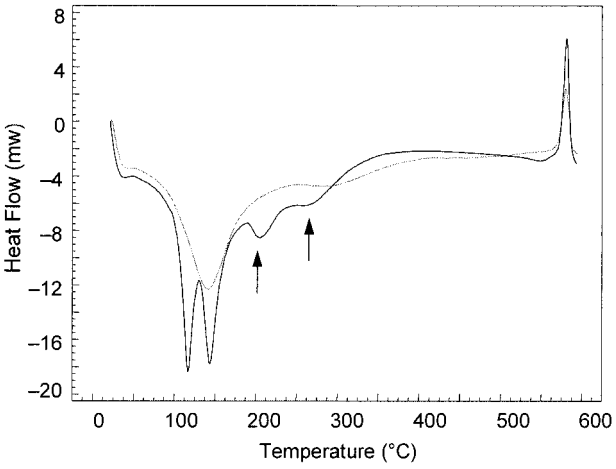

Figure 2. Differential scanning calorimetry data for $K_4Na_7[(\beta\text{-}SiFe_3W_9(OH)_3O_{34})_2(OH)_3]$ (**β1**) (black line) and $K_4Na_7[(\alpha\text{-}SiFe_3W_9(OH)_3O_{34})_2(OH)_3]$ (**α1**) (gray line). The endothermic desorption of solvent water molecules of crystallization from 100 °C to 160 °C in **β1** is nearly resolved into two peaks, whereas the same process in **α1** appears as only one broad peak. The arrows are used to indicate the temperature range of the first exothermic feature based on infrared data. This corresponds to where the solid state rotational isomerization of the W_3O_{13} caps takes place.

Electrochemical Studies: Recently, we reported the detailed electrochemical behavior of the Fe^{III} centers within a

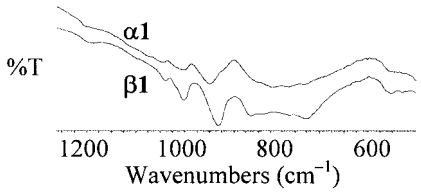

Figure 3. Infrared spectra of **α1** (top) and **β1** (bottom). The spectra are shown in percent transmittance (and labeled as %T on the *y* axis). The band at 883 cm^{-1} in the spectrum of **β1** is shifted by 18 cm^{-1} (to 901 cm^{-1}) in **α1**.

large family of related sandwich-type complexes, including αββα-$[(Fe^{III}OH_2)_2(Fe^{III})_2(X_2W_{15}O_{56})_2]^{12-}$ (X = P^V or As^V).[3a,4,7] In a pH 5 acetate buffer, these compounds show a stepwise reduction of the four edge-sharing Fe^{III} centers. In contrast, the corner-sharing Fe^{III} centers in **α1**, **α2**, and **β1** have a single Fe^{III}-based voltammetric wave in the same pH 5 acetate buffer. In addition, unlike the sandwich-type complexes, **α1**, **α2**, and **β1** also adsorb to different extents onto the surface of the glassy carbon electrode. This behavior was discovered by the observation that there is a steady negative shift in the potentials of the complexes in every other run. This phenomenon is slight for complexes **α1** and **α2**, but it is more pronounced for **β1**. All of the electrochemical data presented in the following paragraphs were obtained with freshly polished glassy carbon electrodes except where noted.

Figure 4 (A) shows the cyclic voltammogram of **α1** in the pH 5 acetate buffer with a scan rate of 10 mV·s^{-1}. The pattern has been restricted to the reduction of the Fe^{III} centers and the first W^{VI} reduction process. The W^{VI}-based wave is electrochemically quasi-reversible and chemically reversible upon reversal of the potential. The Fe^{III}-based wave in this system is observed at E_{pc} = –0.484 ± 0.005 V (vs. SCE). Controlled potential coulometry experiments (with the potential set at –0.550 V vs. SCE) indicate that **α1** consumes 6.08 ± 0.05 electrons per molecule. This is consistent with the simultaneous one-electron reduction of the six Fe^{III} centers. The characteristic blue color of a reduced tungsten-oxygen framework was not observed during this experiment, consistent with the observation that there is a large separation between the Fe^{III}- and the W^{VI}-based redox processes. Finally, it was possible to completely re-oxidize **α1** back to the Fe^{III} state, which confirms and also extends the time dependence of the chemical reversibility and stability of the complex previously observed by cyclic voltammetry.

Figure 4 (B) compares the cyclic voltammograms of **α1** and **α2** under identical conditions (0.2 mM POM in 0.5 M acetate buffer, pH 5; scan rate 10 mV·s^{-1}). The Fe^{III}-based waves of the two complexes have slightly different shapes, with **α2** showing a larger half peak width than **α1** (0.118 vs. 0.080 V for **α2** and **α1**, respectively). The peak potential of **α2** is also at a more positive value than **α1** (–0.474 ± 0.005 V vs. –0.484 ± 0.005 V, respectively). In contrast, the W^{VI}-based waves are superimposable in shape and intensity. Given that the experimental errors for the peak potential

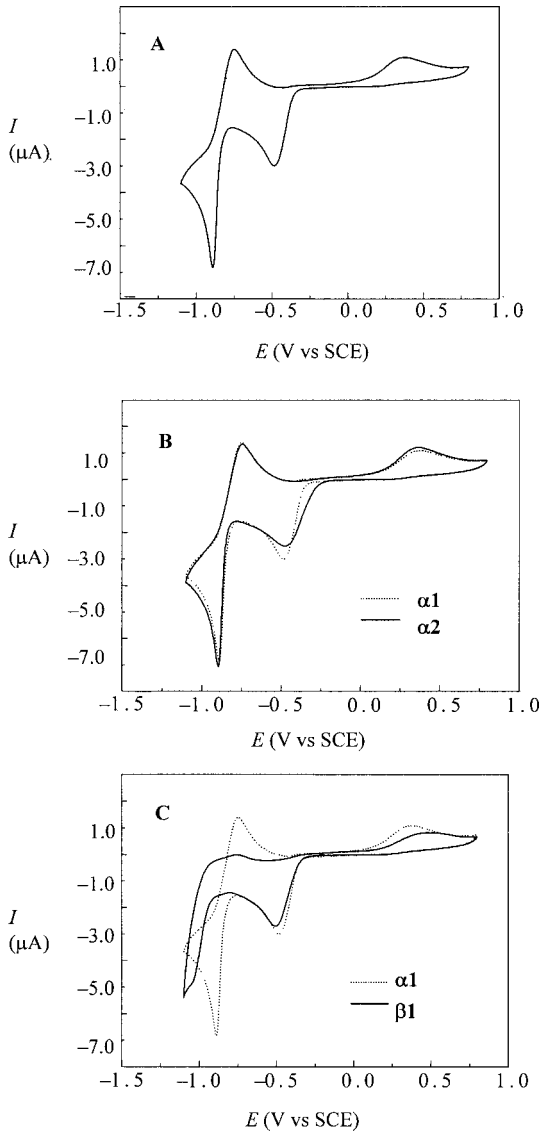

Figure 4. Cyclic voltammograms of **α1**, **α2**, and **β1** in a pH 5 acetate buffer (0.5 M CH_3COONa + CH_3COOH). The pattern has been restricted to the reduction of the Fe^{III} centers and the first W^{VI} reduction process. POM concentration: 0.2 mM; scan rate: 10 mV·s^{-1}; working electrode: glassy carbon; reference electrode: SCE **A:** Cyclic voltammogram of **α1** alone **B:** Cyclic voltammogram of **α1** and **α2** **C:** Cyclic voltammogram of **α1** and **β1**.

measurements of **α2** and **α1** are both ±0.005 V, the difference in the E_{pc} values for the two complexes is quite small. However, the perfect reproducibility of the measurements confirms the order of the peak potentials and suggests their differences are statistically significant. The difference in the peak potentials of **α1** and **α2** could be attributed to the fact that a hydroxo ligand on each Fe^{III} center in **α1** is replaced by an aqua ligand in **α2**. In addition, **α1** has a higher overall negative charge (and slightly higher charge density) than **α2**. Finally, interconversion of the two complexes through protonation equilibria and their co-existence in the same protonation state seems unlikely given the fact that protonation is known to cause the dimer to convert to the monomer.[9]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Figure 4 (C) compares the cyclic voltammograms of **α1** and its Baker–Figgis rotational isomer, **β1** (0.2 mM POM in 0.5 M acetate buffer, pH 5; scan rate 10 $mV \cdot s^{-1}$). Complex **β1** has a negative shift in its peak potentials for both the Fe^{III} and the W^{VI} redox processes. The absolute values of the reduction peak potential differences are 0.022 V and 0.162 V for Fe^{III} and W^{VI}, respectively. To the best of our knowledge, these observations are unprecedented as all previously characterized β-isomers of the unsubstituted Keggin and Wells–Dawson heteropolytungstates are reduced at potentials that are slightly more positive than their corresponding α-isomers.[12] The Fe^{III}-based waves are chemically reversible for both **α1** and **β1**, but **β1** has more pronounced electrochemical irreversibility than **α1**. In addition, the chemical reversibility of the W^{VI}-based wave of **α1** vanishes completely in **β1**. Finally, a small, reversible process observed between the Fe^{III} and W^{VI} waves of **β1** is tentatively attributed to the formation of a small amount of **α1**.

Differences in the electrochemical properties of **α1** and **β1** must be at least partly attributable to the fact that crystallographic studies show these complexes are truly Baker–Figgis rotational isomers. A correlative reason might be traced to differences in the pK_a values of the various protonateable centers in **α1** and **β1**, the latter complex being the more acidic of the two. To probe this further, exhaustive controlled potential electrolysis of the Fe^{III} centers in **β1** was performed using a glassy carbon plate in pH 5 acetate buffer with the potential set at –0.550 V. The current became negligibly small after the consumption of 5.3 electrons per molecule. Cyclic voltammograms (restricted to the Fe^{III}-based redox process) were run before and after electrolysis. When the same glassy carbon plate was used for the initial voltammogram, electrolysis, and the final voltammogram (for a total of three runs), a desorptive oxidation peak and a composite Fe reduction wave appear. This suggests that adsorption and transformation of **β1** has taken place on the surface of the electrode (see Figure S2 in the Supporting Information). Quantitative re-oxidation of the solution to the Fe^{III} state was not possible, as indicated by controlled potential coulometry data (consumption of 2.5 ± 0.1 electrons per molecule). Figure 5 shows the cyclic voltammogram of **β1** before and after the forward and backward electrolysis using a clean carbon plate electrode. The results show that the Fe-wave has become composite and is now located at a more positive potential. Given the fact that this transformation is not observed for **α1**, these observations collectively suggest that **β1** is less stable than **α1** upon the reduction of the Fe^{III} centers.

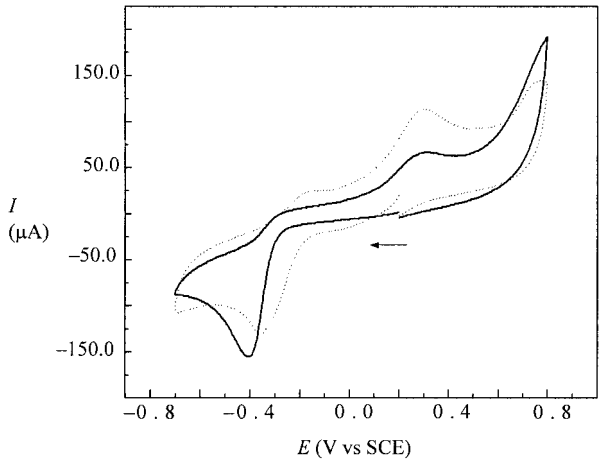

Figure 5. Cyclic voltammograms of **β1** in a pH 5 acetate buffer (0.5 M CH_3COONa + CH_3COOH) before electrolysis of the Fe^{III} centers (solid line) and after exhaustive reduction of the Fe^{III} centers and complete re-oxidation of the resulting solution (dotted line). The pattern has been restricted to the reduction and reoxidation of the Fe^{III} centers only. POM concentration: 0.2 mM; scan rate: 10 $mV \cdot s^{-1}$; working electrode: glassy carbon plate; reference electrode: SCE.

Conclusions

The redox chemistry of three closely related multi-iron silicotungstates have been investigated in order to determine how dimerization and rotational isomerization affects the electrochemical properties of these complexes. In a pH 5 acetate buffer, there is a positive shift in the Fe^{III}-based peak potential upon going from the dimer, $[(\alpha\text{-}Si\text{-}Fe_3W_9(OH)_3O_{34})_2(OH)_3]^{11-}$ (**α1**), to its monomeric derivative $[(\alpha\text{-}Si(FeOH_2)_3W_9(OH)_3O_{34})]^{4-}$ (**α2**). This is due in part to the higher overall charge of the dimer, and it is also partly attributable to differences in the coordination environments of Fe^{III} in the two complexes (i.e. a hydroxo ligand on each Fe^{III} center in **α1** is replaced with an aqua ligand in **α2**, based on BVS calculations on the X-ray crystal structure data). The peak potentials of the Fe^{III}- and W^{VI}-based redox processes of **β1** are both found at more negative values than its rotational isomer **α1**. Exhaustive controlled potential electrolysis studies of the Fe^{III} centers in **β1** collectively suggest that **β1** is less stable than **α1** upon the reduction of the Fe^{III} centers.

Experimental Section

General Methods and Materials: $KNa_3[(\alpha\text{-}Si(FeOH_2)_3W_9(OH)_3O_{34})]$, $K_4Na_7[(\alpha\text{-}SiFe_3W_9(OH)_3O_{34})_2(OH)_3]$, and $Na_9H[\beta\text{-}SiW_9O_{34}]$ were obtained by published procedures[9,13] and purity was confirmed by infrared and UV/Vis spectroscopy and elemental analyses. Elemental analyses of Fe, K, Na, Si, and W were performed by Desert Analytics (Tucson, Arizona). Infrared spectra (2% sample in KBr) were recorded with a Nicolet 510 instrument. The electronic absorption spectra were taken with a Perkin–Elmer Lambda 19 UV/Vis spectrophotometer. Average magnetic susceptibilities were measured with a Johnson-Matthey Model MSB-1 magnetic susceptibility balance as neat powders at 24 °C; the balance was calibrated using $Hg[Co(SCN)_4]$ as a standard. Pascal's constants were used to obtain the final diamagnetic corrections. Differential scanning calorimetric and thermogravimetric data were collected with ISI DSC 550 and TGA 1000 instruments, respectively.

Synthesis of $K_4Na_7[(\beta\text{-}SiFe_3W_9(OH)_3O_{34})_2(OH)_3]\cdot 40H_2O$ (β1): A 0.87 g (2.2 mmol) sample of $Fe(NO_3)_3\cdot 9H_2O$ was dissolved in 30 mL of 0.5 M sodium acetate in an 150 mL beaker. A 2.0 g (0.72 mmol) sample of $Na_9H[\beta\text{-}SiW_9O_{34}]\cdot 18H_2O$[13] was slowly added to the Fe^{III} solution with vigorous stirring. The final pH of

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the solution is ca. 6. Any insoluble material that was present was removed by filtration with Celite, and a solution of 0.5 g of KCl dissolved in 5 mL of H_2O was added to the resulting filtrate. Light green, diffraction quality crystals formed at 10 °C in the resulting filtrate after approximately five days (0.43 g, yield 20%). IR (2% KBr pellet, 1200–500 cm^{-1}): $\tilde{\nu}$ = 1129 (w), 991 (w), 960 (m), 883 (s), 811 (w), 770 (w), 724 (m), and 523 (w). Electronic spectroscopic data (400–700 nm, in H_2O): λ (ε, M^{-1} cm^{-1}) = 436 nm (200). Magnetic susceptibility: μ_{eff} = 7.7 μ_B/mol at 295 K. $H_{89}Fe_6K_4Na_7O_{117}Si_2W_{18}$ (5979.5): calcd. Fe 5.60, K 2.62, Na 2.69, OH_2 12.0, Si 0.94, W 55.3; found Fe 5.65, K 2.61, Na 2.64, OH_2 12.0, Si 0.94, W 54.9.

Crystallographic Studies of β1: Single-crystal X-ray crystallographic analysis of **β1** was performed at 100 K with a Bruker D8 SMART APEX CCD sealed tube diffractometer with graphite-monochromated Mo-K_α (0.71073 Å) radiation. Data collection, indexing, and initial cell refinements were carried out using SMART software.[14] Frame integration and final cell refinements were carried out using SAINT software.[15] Final cell parameters were determined from least-squares refinement on 7765 reflections. Absorption corrections were applied using SADABS.[16] The structure was determined using Direct Methods and difference Fourier techniques. No H atoms associated with the water molecules of **β1** were located in the difference Fourier maps. The final R_1 scattering factor and the anomalous dispersion correction were taken from International Tables for X-ray Crystallography.[17] Structure solution, refinement, and generation of publication materials were performed using SHELXTL V6.12 software. Additional details are provided in Table 2, and may also be obtained from the FIZ Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany, on quoting the depository number CSD-414457.

Table 2. Crystallographic data and structure refinement for **β1**.

[a] $R_1 = \Sigma||F_o| - |F_c||/|F_o|$. [b] $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{0.5}$.

Electrochemical Studies: Cyclic voltammetry studies were performed on 2×10^{-4} M solutions of **α1**, **α2**, or **β1** in a pH 5 acetate (0.5 M CH_3COONa/CH_3COOH) medium, unless otherwise stated. Solutions were de-aerated with Ar for 30 min prior to measurements and kept under positive pressure at all times. The source, mounting, and polishing of the glassy carbon electrodes (GC, Tokai, Japan, 3 mm diameter) have been described in previous work.[18] The counter electrode was a platinum gauze of large surface area. The electrochemical apparatus was a EG and G 273A under computer control (M270 software). All experiments were performed at ambient temperature, and potentials are quoted against a saturated calomel electrode (SCE). Controlled potential coulometry determinations were performed as described for the cyclic voltammetry experiments except that the working electrode used was a 4 cm^2 surface area glassy carbon plate. In addition, after deaeration, Ar was continuously bubbled through the solution to ensure a constant stirring of the mixture. The stability of the complexes in pH 3–7 buffer solutions was evaluated by UV/Vis prior to making any electrochemical measurements. The UV/Vis spectra of 0.016 mM solutions of the POMs are characterized by well-defined charge transfer peaks with a $\lambda_{max.}$ at 259 nm for **α1** and **α2** or 264 nm for **β1**. After 24 h, **α1** shows an 11% decrease in absorbance at pH 4 and is stable between pH 5–7; **β1** is stable between pH 5–7 and shows a 12% decrease in absorbance at pH 4; **α2** is stable at pH 4 and shows a slight shape modification at pH 5.

Supporting Information (see also the footnote on the first page of this article): Figure S1 shows a thermal ellipsoid plot of **β1** with 50% probability surfaces. Figure S2 shows cyclic voltammograms of 0.2 mM solutions of **β1** before and after the exhaustive reduction of the Fe^{III} centers in a pH 5 acetate (0.5 M CH_3COONa/CH_3COOH) buffer.

New Layered Polymeric Metamagnet Based on Copper(II) Complex with 3-Imidazoline Nitroxide

Alexei Burdukov,*[a] Yurii Shvedenkov,[a] Natalie Pervukhina,[a] and Vladimir Reznikov[b]

Keywords: Layered compounds / Copper / Nitroxides / Magnetic properties / Phase transitions

A new complex, bis[4-(2-oxido-1-butenyl)-2,2,5,5-tetramethylimidazolidine-1-oxyl]copper(II) (CuL^{Et}_2), has been synthesized. The synthesis, characterization, and magnetic properties as well as the crystal structure of CuL^{Et}_2 have been studied. The layered solid of the complex possesses a metamagnetic phase transition at 4.5 K and shows strong anisotropy of magnetic properties below the ordering temperature. The easy magnetization axis lies along the *b* axis. The hard magnetization axis is orthogonal to the polymeric layers. Effective anisotropy fields have been estimated ($H_\perp$ = 1390 Oe, $H_\parallel$ = 420 Oe).

Introduction

The design of molecular magnets demands the ability to engineer the desired crystal structure and the means to control the efficiency of interactions of a diverse nature between the paramagnetic centers.[1] One of the peculiarities of molecular magnets derived from coordination compounds is considerable local and bulk anisotropy introduced by transition-metal ions. The majority of coordination compounds have low symmetry in the solid phase and their crystal structures have low dimensionality. The energy of anisotropy of such systems depends appreciably on the dimensionality of the crystal structure and on the contribution of dipolar interactions to the onset of magnetic ordering.[2] The importance of the dimensionality is well illustrated by comparison of the chain polymeric (1D) complex $Mn(hfac)_2NIT$-*i*Pr (NIT-*i*Pr = derivative of 2-imidazoline nitroxide)[3] and of layered polymeric (2D) complex CuL_2 (L = derivatives of 3-imidazoline nitroxide),[4] the effective anisotropy field being approximately five times larger for the former. Also, anisotropic interactions of a nonexchange nature lead to the appearance of metamagnetism in coordination compounds such as $[(CH)_3NH]CuCl_3 \cdot 2H_2O$[5] and CuL^{Me}_2.[4]

With this contribution we continue our systematic studies on the magnetic anisotropy of heterospin compounds based on Cu^{II} complexes with enaminoketone derivatives of 3-imidazoline nitroxide.

These compounds provide a unique series of solids possessing similar layered topology but different structural details, thus providing a very good basis for revealing the correlations between structure and magnetic anisotropy. In this work we report the results of the structural and magnetic investigation of the complex CuL^{Et}_2.

Results and Discussion

The compound under investigation is built from CuL^{Et}_2 molecules, the copper atom occupying the inversion center [1/2,0,1/2]. The closest coordination environment of copper is formed by two nitrogens N(1) and two oxygens O(1) belonging to the enaminoketone moieties (Figure 1).

The bond lengths and angles within the molecules have the usual values. The axial positions around the copper atom are occupied by two nitroxide oxygens O(2) at a distance of 2.584(3) Å. The Cu–O(2) bond is almost perfectly perpendicular to the coordination square, the deviation being only 0.3°. With a connectivity of four at the copper atom, the molecules arrange into the 4^4 (in Wells notation[6]) chicken-wire nets parallel to the (0,0,1) plane (Figure 2). Within the frame of the *Pbca* space group the neighboring polymeric nets are related with the *c* glide plane with a net-to-net separation of 11.978 Å, as measured between the closest copper atoms. This is somewhat longer than the equivalent separation in CuL^{Me}_2, which is equal to 11.869 Å. This difference in separation between iso-

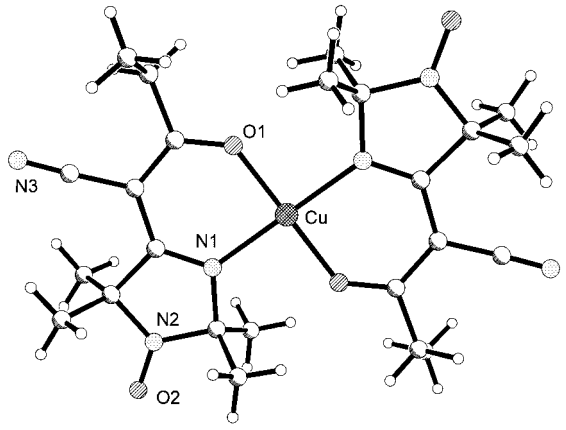

Figure 1. The molecule CuL^{Et}_2.

structural CuL^{Me}_2 and CuL^{Et}_2 is due to the different sizes of the Me and Et substituents which propagate into the interlayer space.

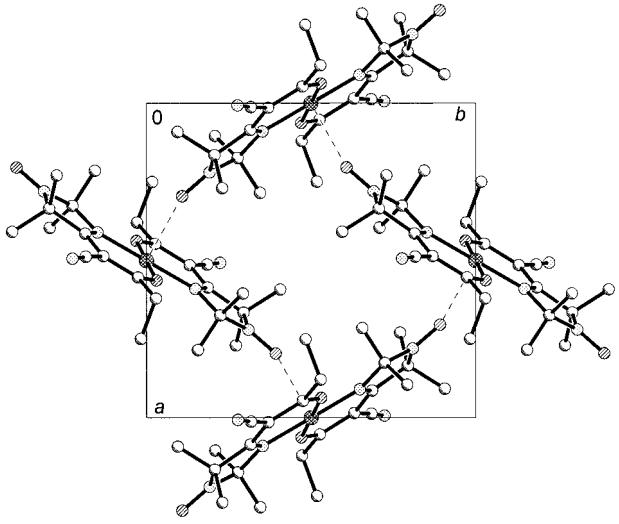

Figure 2. Fragment of the polymeric layered structure of CuL^{Et}_2 projected onto the (001) plane. Hydrogen atoms are omitted for clarity.

Figure 3 illustrates the effective magnetic moment of CuL^{Et}_2 measured along different crystallographic directions above 14 K. In this temperature range, CuL^{Et}_2 behaves as a paramagnet with dominating ferromagnetic exchange interactions between paramagnetic centers. The CuL^{Et}_2 complex possesses two main exchange channels. The first exchange channel is the intramolecular indirect exchange between the nitroxide and copper spins through the heterocycle of the ligand. The other exchange pathway is the direct exchange between the copper(II) ion and the nitroxide group belonging to the adjacent $\{CuL_2\}$ bis-chelate fragment. Both exchange pathways propagate ferromagnetic interactions[7] resulting in the rise of the $\mu_{eff}(T)$ curves with decreasing temperature. The $\mu_{eff}(T)$ curves measured along different directions are quite close (Figure 3). The observed discrepancy in the paramagnetic region is caused by the anisotropy of the copper(II) *g*-factors. An approximation of the experimental data in the 100−300 K temperature interval by the Curie–Weiss equation results in the optimal parameters C_a = 1.22, C_b = 1.24, C_c = 1.15 $cm^3 K mol^{-1}$, and θ_a = 12.6, θ_b = 13.8, θ_c = 11.9 K.

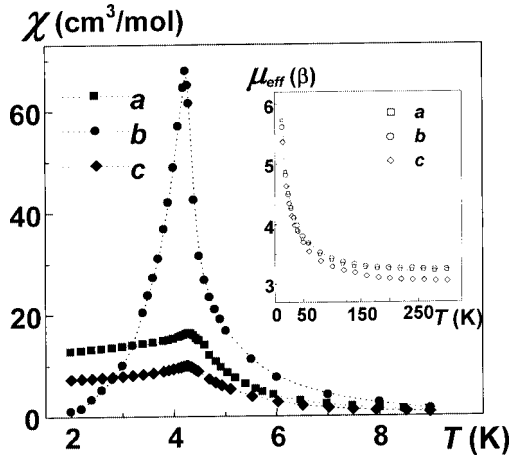

Figure 3. Low field $\chi(T)$ curves in the transition area and $\mu_{eff}(T)$ curves (inset) in the paramagnetic region for a CuL^{Et}_2 single crystal.

The set of constants obtained corresponds to **g**-tensor components along the directions of measurement: g_a = 2.24, g_b = 2.29, g_c = 2.06, which are in good agreement with *g*-factor values known for copper(II) coordination compounds.[8,9] The similarity of the Curie–Weiss parameters suggests that the CuL^{Et}_2 can be considered as an isotropic two-dimensional magnet.[10] On temperature lowering to 10 K, the CuL^{Et}_2 single crystal undergoes a phase transition to the magnetically ordered state. Measurements performed in zero magnetic field (1.2 ± 0.5 Oe) indicate that ordering occurs sharply at 4.5 K. Figure 4 shows the main curves of magnetization, $\sigma(H)$, at 2 K for the single crystal.

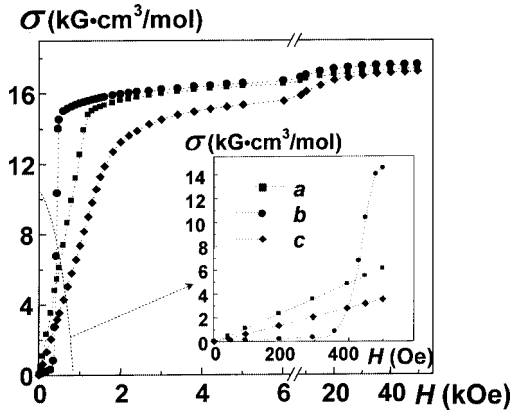

Figure 4. Magnetization curves for a CuL^{Et}_2 single crystal.

Below 400 Oe the magnetization of the CuL^{Et}_2 single crystal measured along unit-cell axes satisfies the equation $\sigma_i(H) = \chi_i H$, where $i = a, b, c$. Thus, a compensated antiferromagnetic structure is formed. At 2 K, the susceptibilities along *a*, *b*, and *c* are 12.515, 0.975, and 7.332 $cm^3 mol^{-1}$), respectively. The susceptibility ratio along different directions unambiguously suggests that $\chi_{||}$ corresponds to the *b* axis, and $\chi_{\perp}$ to the *a* and *c* axes. As follows from the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

magnetization curves, at low fields the antiferromagnetic axis is *b* and the easy magnetization axis is *a*. As the crystal structure of CuL^{Et}_2 is layered polymeric with ferromagnetic exchange interactions dominating inside the layers, it is logical to assume that the antiferromagnetic structure is formed by the magnetic moments of ferromagnetically ordered layers. The interactions leading to the collinear antiferromagnetic structure forming in CuL^{Et}_2 probably have a dipolar nature. For $H > 400$ Oe, the $\sigma(H)$ curves become nonlinear. Magnetization along the *b* axis increases sharply and tends to saturation $Ng\beta S$ for an $S = 3/2$ system. This effect indicates a metamagnetic phase transition in CuL^{Et}_2 with the critical field $H_c = 440$ Oe. The given value of the critical field corresponds to the absolute magnitude of the energy of the interlayer interactions ($3\beta H$) equal to 0.088 K. At high magnetic fields, the $\sigma(H)$ curves measured along different directions diverge because of the *g*-factor anisotropy of the copper(II) ion (Figure 4). No hysteresis effects were detected when CuL^{Et}_2 was subjected to supermagnetization. Thus, the easy magnetization axis coincides with the crystallographic *b* axis. The hard magnetization axis is orthogonal to the polymeric layers. The transition found in CuL^{Et}_2 is characterized by a low critical field, which has the same order of magnitude as that found in coordination compounds {$[(CH)_3NH]CuCl_3 \cdot 2H_2O$[5], CuL^{Me}_2[4]}. This field is 10–30 kOe for classical metamagnets ($MnBr_2$, $FeCl_2$, $CoCl_2$). The anisotropy energies were estimated for the CuL^{Et}_2 single crystal. The free energy of magnetic anisotropy may be represented as $F_i \approx -H_i\sigma_{sat}$, where $i = a, c$; H_i is the effective anisotropy field, and σ_{sat} is saturation magnetization.[11] The energy F_i was determined from the experimental magnetization curves by the numerical integration:

$$F_i = \int_0^{H_{max}} \sigma_b(H)dH - \int_0^{H_{max}} \sigma_i(H)dH$$

where H_{max} is the maximum field during the measurements. For the CuL^{Et}_2 single crystal, the lower bound on the integration domains of the $\sigma(H)$ curves is set by the value of the critical field H_c. The calculated effective anisotropy fields of the complex are $H_\perp = 1390$ Oe (along *c* axis) and $H_{||} = 420$ Oe (along *a* axis). The anisotropy of magnetic properties in a plane of the polymeric layers (*ab*) is much smaller than that in the perpendicular direction as a consequence of the quasi two-dimensional magnetic system. Thus, the anisotropy observed in CuL^{Et}_2 should be attributed to the "easy plane" type.

The single crystals of copper–3-imidazoline nitroxide complexes CuL^{R}_2 have similar structures. Also, their ordering temperatures are very close, indicating the same order of exchange interactions (Table 1).

All four complexes cannot be considered together as they have different symmetries. However, pairwise comparison of CuL^{Et}_2, CuL^{Me}_2 and $CuL^{C(O)OEt}_2$, $CuL^{C(O)OMe}_2$ reveals the decrease of the transition temperature on substitution of the methyl group with ethyl. This substitution also results in some elongation of bonds in the coordination environment of copper as well as the increase of interlayer separations (Table 1). Corresponding evolution is found in the mutual orientation of the {CuL_2} fragments as can be seen from the angles Cu–O (φ1), Cu–N (φ2), and Cu–$O^{(NO)}$ (φ3) between the *b* axis and the relevant bonds (Table 1). The magnetic behavior of the CuL_2 complexes is significantly different in the magnetically ordered phase. Under the transition temperature $CuL^{C(O)OEt}_2$ and $CuL^{C(O)OMe}_2$ are ferromagnets whereas CuL^{Et}_2 and CuL^{Me}_2 behave as metamagnets. At the same time the critical field of the metamagnetic transition for CuL^{Et}_2 is 3.6 times lower than in isostructural CuL^{Me}_2. The increase of the interlayer separation for CuL^{Et}_2 as compared with that of CuL^{Me}_2 correlates with the decrease of H_c. Assuming that metamagnetism originates from dipole interactions only, the $H_c(CuL^{Me}_2)/H_c(CuL^{Et}_2)$ ratio should be proportional to the $R^3(CuL^{Et}_2)/R^3(CuL^{Me}_2)$ ratio, *R* being an effective distance between magnetic dipoles as measured between copper ions belonging to the adjacent polymeric layers. But this supposition does not hold true. For this reason we suppose that the difference in magnetic properties of the CuL_2 complexes originates from the difference in magnetic anisotropy energy. The comparison of the critical fields and the anisotropy fields within the polymeric layers indicates that a large H_c corresponds to a large $H_{||}$, as sketched in Figure 5.

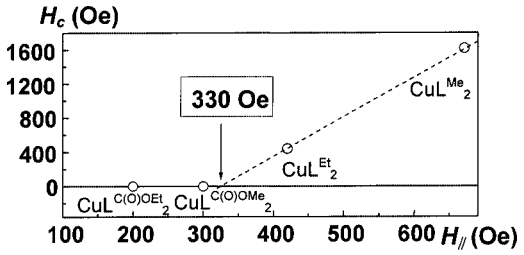

Figure 5. The H_c vs $H_{||}$ plot for the CuL_2 complexes.

The data available are too scarce to deduce the H_c versus $H_{||}$ dependence. However, linear approximation based on CuL^{Me}_2 and CuL^{Et}_2 yields the value 330 Oe for the intercept of $H_{||}$. Following this approximation, the metamagnetic transition does not exist for fields lower than 330 Oe; this conclusion is in agreement with the experimental data. The complexes $CuL^{C(O)OEt}_2$ and $CuL^{C(O)OMe}_2$ fall exactly within this range of the anisotropy field. In contrast to CuL^{Et}_2 and CuL^{Me}_2, the complexes $CuL^{C(O)OEt}_2$ and $CuL^{C(O)OMe}_2$ are monoclinic. Therefore, the free energy of magnetic anisotropy for the latter has a different set of anisotropy constants from that of CuL^{Et}_2 and CuL^{Me}_2. Generally, different values and temperature dependences of anisotropy constants for each type of symmetry can result in the overall stabilization of either the ferromagnetic or the antiferromagnetic ground state.

Conclusion

A novel layered polymeric complex, CuL^{Et}_2, is synthesized and characterized; the complex demonstrates metamagnetic phase transition at 4.5 K. The transition critical field is 440 Oe, corresponding to a magnetic energy of 0.088 K. Below the H_c the antiferromagnetic vector coincides with the b axis, and $\chi_\perp$ with the a and c axes. Above the H_c the easy magnetization axis runs along the crystallographic b direction, the hard magnetization axis being orthogonal to the polymeric layers. The onset of metamagnetic transition and the value of the critical field in the series of CuL_2 complexes are attributed to the difference in magnetic anisotropy energy within the polymeric layers of the complexes.

Experimental Section

General Remarks: All the solvents were used as purchased. The nitroxide HL^{Et} was synthesized according to ref.[12].

Synthesis of CuL^{Et}_2: A mixture of $CuCl_2{\cdot}2H_2O$ (55 mg, 0.32 mmol) and HL^{Et} (150 mg, 0.62 mmol) was dissolved in warm ethanol (15 mL). The solution was filtered and the pH adjusted to 8 with aqueous ammonia. In a span of time varying from hours to days, the solution yielded a light-green precipitate, which was collected, washed with ethanol, and recrystallized from boiling ethanol. Yield 105 mg (65%). M.p. 209−212 °C. Calcd. C 54.0, H 6.2, N 15.7; found C 54.1, H 6.4, N 15.7. The crystals of the complex suitable for an X-ray diffraction study and for magnetic measurements were obtained on slow crystallization of the material from ethanol.

X-ray Crystallographic Study: The X-ray single-crystal data for CuL^{Et}_2 were recorded with an Enraf–Nonius CAD4 four-circle diffractometer. The crystallographic data, conditions used for the intensity data collection, and some features of the structure refinement are listed in Table 2.

Table 2. Crystal data and structure refinement for CuL^{Et}_2.

	CuL^{Et}_2
Empirical formula	$C_{24}H_{34}CuN_6O_4$
Formula mass	534.11

λ(Mo-K_α) [Å]	0.71069
$d_{calcd.}$ [g cm^{-3}]	1.374
μ(Mo-K_α) [mm^{-1}]	0.887
R_1[a] [$I > 2\sigma(I)$]	0.0285
wR_2[b] [$I > 2\sigma(I)$]	0.0553

[a] $R_1 = \Sigma(|F_o| - |F_c|) / \Sigma|F_o|$. [b] $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2] / \Sigma[w(F_o^2)^2]\}^{1/2}$.

Graphite-monochromated Mo-K_α radiation (λ = 0.71069 Å) with the $\theta/2\theta$ technique was used to collect the data set. The accurate unit-cell parameters were determined from automatic centering of 24 reflections, $10° < \theta < 15°$, and refined by least-squares methods. 1726 reflections were collected in the range $1.90° < \theta < 24.96°$; 1064 reflections were assumed to be observed upon applying the condition $I > 2\sigma(I)$. Corrections were applied for Lorentz polarization effects. The structure was solved by direct methods, using the SIR97[13] program, and refined by full-matrix least-squares method with the SHEXL-97[14] package.

Magnetic Measurements: The magnetochemical experiment was run with an MPMS-5S ("Quantum Design") SQUID magnetometer at temperatures from 2 to 300 K in a homogeneous external magnetic field of up to 49.5 kOe. Magnetic measurements on a single crystal were performed along the crystallographic axes a, b, and c. The relation of the crystal appearance to the crystallographic axes was established by X-ray diffraction. The molar magnetic susceptibility χ of the complexes was calculated using Pascal's additive scheme including diamagnetic corrections and taking into account the temperature-independent paramagnetism of Cu^{II} ions, which was taken to be 60×10^{-6} cm^3 mol^{-1}. For the paramagnetic region, the effective magnetic moment was calculated by the formula $\mu_{eff} = [(3k/N_A\beta^2)\chi T]^{1/2} \approx (8\chi T)^{1/2}$, where k is Boltzmann's constant, N_A is the Avogadro number, and β is the Bohr magneton. The magnetic phase transition temperature was determined as the extremum of the derivative of magnetic susceptibility on temperature $\partial\chi/\partial T$. The magnetization dependences $\sigma(H)$ of the CuL^{Et}_2 single crystal in the ferromagnetic state were plotted with allowance for the demagnetization field of the sample. The actual field in the crystal was calculated for each direction by the formula $H_i = H - N_i\sigma_i$, where $i = a$, b, and c; and N is the demagnetization factor evaluated using the tables for a disk sample.[15]

CCDC-243550 and -192277 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Do Sodium Oxofluoroaluminates Exist at Room Temperature?

Marián Kucharík,[a] Miroslav Boča,*[a,c] Catherine Bessada,[b] and Hartmut Fuess[c]

Keywords: Oxofluoroaluminate species / Alumina / Cryolite

Alumina dissolution in cryolite melts is currently associated with the formation of oxofluorospecies. Mixtures of Na_3AlF_6 and Al_2O_3 were heated under different conditions of temperature, time and atmosphere. The existence of oxofluorospecies in solidified samples at room temperature was investigated by X-ray diffraction, IR and Magic Angle Spinning NMR spectroscopy. The formation of β-alumina ($NaAl_{11}O_{17}$) was detected depending on the heating conditions, but no oxofluoroaluminate species were found.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

During 50 years of structural investigation on cryolite–alumina melts, numerous suggestions on the nature of the possible oxygen-containing species in the melt have been presented.[1] Førland and Ratkje[2] from cryoscopic measurements on the sodium fluoride-rich side in the reciprocal salt system $NaF–AlF_3–Na_2O–Al_2O_3$ suggested the preferred formation of the $Al_2OF_x^{(4-x)}$ (x = 5–8) anion for an ionic ratio of Al^{3+}/O^{2-} greater than five. Based on vapour pressure measurements, Kvande[3] proposed that $Al_2OF_8^{4-}$ is the most important anion for low alumina content in cryolite melts. Sterten[4] developed an ionic structure model for NaF/AlF_3 melts containing alumina. The calculations of anion fractions as a function of the cryolite ratio (*CR*; molar ratio between NaF and AlF_3) suggested that $Al_2OF_6^{2-}$ and $Al_2O_2F_4^{2-}$ are the most frequent species for $1.5 < CR > 3$. For $CR > 5$ the complex anions $Al_2O_2F_4^{2-}$ and $Al_2O_2F_6^{4-}$ were most important. Bache and Ystenes[5] interpreted IR and X-ray diffraction results of quenched mixtures of cryolite and chiolite together with alumina as free of α-Al_2O_3 but consisting of some unspecified oxofluoroaluminates.

The Raman data and thermodynamic measurements of Gilbert et al.[6] and Robert et al.[7] indicate the formation of $Al_2OF_6^{2-}$ or $Al_2OF_8^{4-}$ ions for melts with low Al_2O_3 concentrations. However, at higher Al_2O_3 concentration, $Al_2O_2F_4^{2-}$ anions would be predominant. Daněk et al.[8] directly determined the presence of oxygen on samples from $MF–AlF_3–Al_2O_3$ (M = Li, Na, K) by using a LECO TC–436 Nitrogen/Oxygen analyser. They claim that three anion species are present in $NaF/AlF_3–Al_2O_3$ melts, that is, $Al_2OF_6^{2-}$, $Al_3O_3F_6^{3-}$and $Al_2O_2F_4^{2-}$. At up to 2 mol-% of Al_2O_3 only the $Al_2OF_6^{2-}$ and $Al_3O_3F_6^{3-}$ species are present. At high alumina content, $Al_2O_2F_4^{2-}$ species are abundant. The above assumption was also confirmed by Lacassagne et al.[9] They studied the structure of $NaF/AlF_3–Al_2O_3$ melts by high-temperature NMR spectroscopy for the four nuclei ^{27}Al, ^{23}Na, ^{19}F, and ^{17}O. ^{17}O NMR spectroscopy gave a selective view of the alumina dissolution in molten cryolite, because of its direct signature of the oxofluoride complexes. The variations in the ^{17}O chemical shift were explained by the presence of at least two different oxofluoroaluminate species: $Al_2OF_6^{2-}$ at low alumina content and $Al_2O_2F_4^{2-}$, which becomes the major species for higher amounts of alumina.

If the presence of these oxofluoroaluminate species in the molten state has been demonstrated by spectroscopy, it is difficult to prove their presence in the solidified state. Only Brooker et al.[10] observed Raman spectra with bands that could be assigned to the $Al_2OF_6^{2-}$ anion. Their Raman spectra were obtained from a premelted solid sample containing 5 mol-% Na_2O and 5 mol-% AlF_3 in FLINAK. The bands at 509 cm^{-1} were assigned to the oxide-bridged, totally symmetric stretching mode of $Al_2OF_6^{2-}$. The same bands were observed at 494 cm^{-1} in the molten system with identical composition.

For a better understanding of the spectroscopic signatures of the species formed in the melts, it would be of great interest to succeed in forming stable solid oxofluoroaluminate phases at room temperature.

In order to contribute to the knowledge of oxofluoro–aluminium species, we have studied different solidified mixtures of Na_3AlF_6 and Al_2O_3 by IR spectroscopy, X-ray powder diffraction and multinuclear MAS NMR spec-

troscopy. The combination of these different techniques provides a more precise identification of the different phases formed on cooling.

Results and Discussion

X-ray Powder Diffraction and IR Spectra

Heating under Inert Atmosphere

In the X-ray powder diffraction patterns of the samples **1a** and **1b** only the cryolite phase was clearly detected. The presence of crystalline alumina is not evident. The same conclusion can be reached by considering the IR spectra. No reaction products are therefore present in the mixture, as no reaction seems to take place between cryolite and alumina under inert atmosphere at these experimental conditions.

Heating under Air

X-ray powder diffraction patterns of the samples **2a**, **3a** and **4a** are displayed in Figure 1. After heating for 10 and 20 h only cryolite and α–alumina were detected in **2a** and **3a**. The XRD pattern of sample **4a**, after 50 h of heating, clearly corresponds to $NaAl_{11}O_{17}$. In the case of samples **2b**, **2c**, **3b** and **3c**, a mixture of all components was found (cryolite, α-Al_2O_3, NaF and $NaAl_{11}O_{17}$) while only $NaAl_{11}O_{17}$ was detected in **4b** and **4c**.

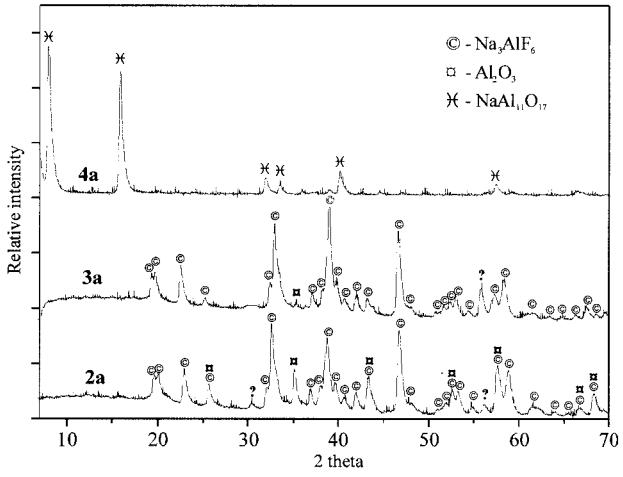

Figure 1. X-ray powder diffraction patterns of the samples **2a**, **3a** and **4a**.

In the IR spectra of all samples (**2b**, **2c**, **3a**, **3b**, **3c**, **4a**, **4b** and **4c**; see Figure 2) cryolite with different concentrations of α–alumina was detected, probably because of the incomplete reaction due to its high concentration. In all samples, except for **2a**, new peaks were detected. The intensities of these new peaks increase with increasing heating time. After 10 and 20 h of heating, peaks at 1135 cm^{-1} and 705 cm^{-1} were observed and after 50 h a peak at 1136 cm^{-1} splits into two peaks at 1148 cm^{-1} and 1121 cm^{-1}. Moreover, two new peaks are also detected at 627 cm^{-1} and at 667 cm^{-1}. The peak at 706 cm^{-1} remains unchanged.[11] These new peaks can be related to the formation of the sodium oxoaluminate $NaAl_{11}O_{17}$. This result will be supported by MAS NMR measurements in the following section.

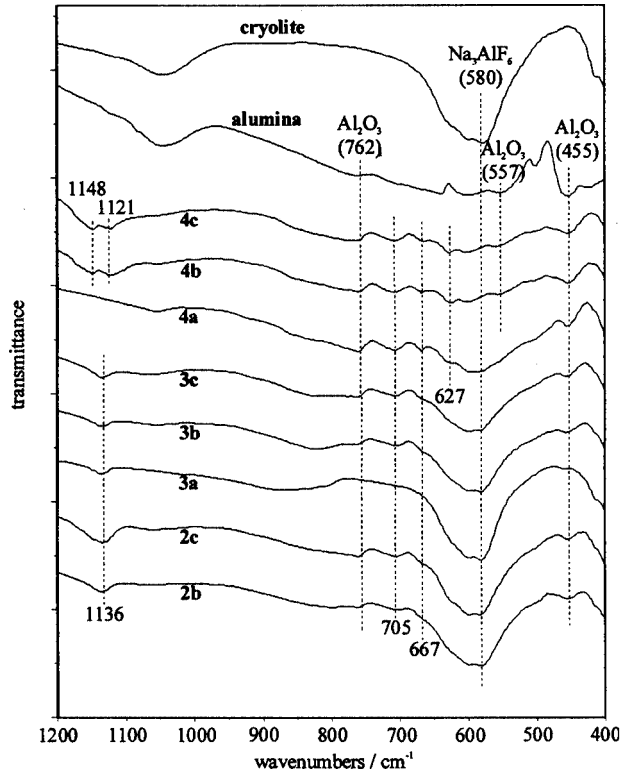

Figure 2. IR spectra of the samples **2b**, **2c**, **3a**, **3b**, **3c**, **4a**, **4b** and **4c**.

Heating in Closed Pt Tubes

The results for this series of experiments (**5a**, **5b**, **5c**, **6a**, **6b**, **6c**, **7a**, **7b**, **7c**, **8** and **9**) are surprisingly identical to those of samples **1a** and **1b**. Crystalline cryolite is detected clearly by both X-ray powder diffraction measurements and by IR spectroscopy while the presence of crystalline alumina is more questionable. No other phases were detected. The only difference can be observed in samples **8** and **9** where α-Al_2O_3 is clearly detected in the X-ray powder diffraction patterns and IR spectra. It means that on spontaneous cooling (samples **8** and **9**) crystalline α-Al_2O_3 can solidify, while for faster cooling (samples **5**–**7**) only crystalline cryolite can be detected without any doubt.

^{27}Al, ^{23}Na and ^{19}F MAS NMR Spectra

^{27}Al MAS NMR Spectra

Aluminium is a quadrupolar nucleus (I = 5/2) and spectra obtained in the solid phase, even at fast MAS conditions, can be very complex.[12] Because of the lines overlapping at 9.4 T, we also report some spectra obtained at higher field (17.6 T) in order to obtain a better resolution. The second order quadrupolar interaction is then minimized and leads to simplified line shapes.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

We have reported a comparison of ^{27}Al MAS spectra obtained at 9.4 T for different mixtures with those of the starting materials: cryolite and α-Al_2O_3 (see Figure 3). The ^{27}Al signature of cryolite is very simple and corresponds to a single $\{AlF_6\}$ site, with a chemical shift at ca. 0 ppm, and very low quadrupolar coupling ($\nu_Q \approx 150$ kHz).[13] For α-alumina, one peak is observed at about 14 ppm corresponding to the $\{AlO_6\}$ environment in the solid state at room temperature. For the mixture of 30 mol-% Al_2O_3 in cryolite heated for 20 h at 1010 °C under air (samples **3b** and **3c**) the spectra are rather complex. In addition to the peaks corresponding to different starting constituents of the mixture, that is, cryolite and α-alumina, we can also detect at least two other signals, with broad quadrupolar line shapes identified by their maxima at $\delta \approx 65$ ppm and at $\delta \approx 75$ ppm.[14] By combining the ^{27}Al MAS spectra obtained at 9.4 T and 17.6 T, we tried to model the NMR spectra more precisely and to determine the different contributions (see Table 2). We can propose some quantitative description of the different phases, in agreement with the XRD conclusions. In addition to the cryolite and α-Al_2O_3 signals, we can evidence typical signatures of transition alumina, with one signal at $\delta = 18$ ppm attributed to six-coordinate aluminium, and a signal at $\delta = 65$ ppm for four-coordinate aluminium (see Table 1).

Two contributions can be assigned to the two structurally non-equivalent tetrahedral $\{AlO_4\}$ environments of the $NaAl_{11}O_{17}$ phase. In the structure of $NaAl_{11}O_{17}$ both octahedral $\{AlO_6\}$ and tetrahedral $\{AlO_4\}$ fragments are clearly resolved.[15]

In order to discuss the broad "amorphous" component, $^{19}F/^{27}Al$ CP MAS coupled with 2D MQ MAS experiments are under progress and will give a more precise view of that complex system.

For the sample **4a**, heated for 50 h, the peak corresponding to alumina remains unchanged and the intensity of the signal of cryolite is rather lowered. Moreover, it was not observed in X-ray powder diffraction patterns, so this confirms its very low contribution. We still detect the very

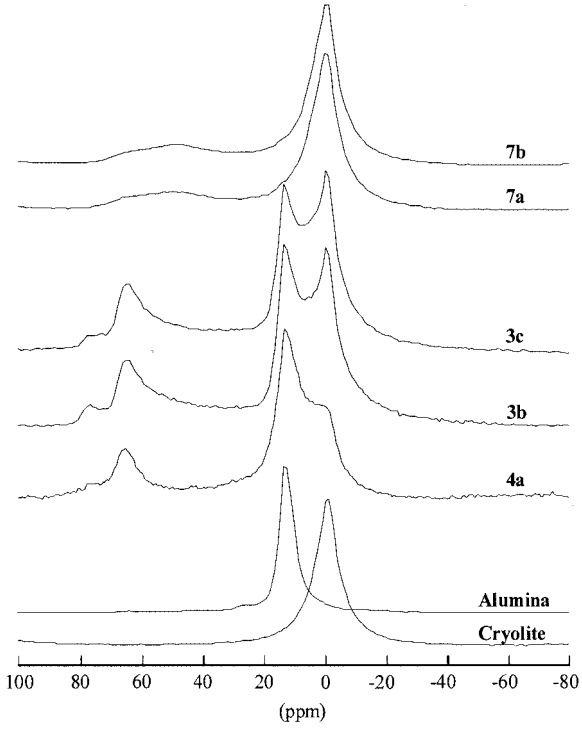

Figure 3. ^{27}Al MAS NMR spectra of the samples **4a**, **3b**, **3c**, **7a** and **7b** in relation with the spectra of the starting materials: cryolite and alumina. The spectra were obtained at 9.4 T with a spinning speed of 32.5 kHz.

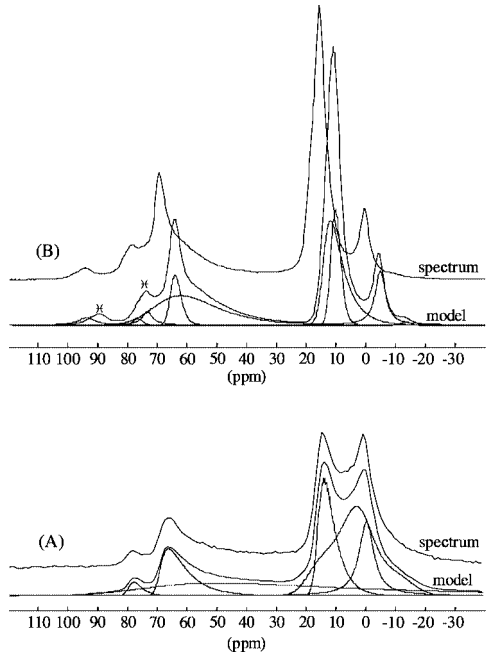

Figure 4. ^{27}Al MAS NMR spectra of the sample **3b** obtained at two different magnetic fields and its decomposition in different contributions.[26] The upper spectrum was obtained at 17.6 T (B) and the lower at 9.4 T (A). The model spectra were computed using the same set of parameters, considering six different sites: three $\{AlO_4\}$, two $\{AlO_6\}$ and one $\{AlF_6\}$. The NMR parameters deduced from the fit are reported in Table 2. The asterisks (*) represent spinning side bands.

Table 1. NMR parameters deduced from the fit[26] of the experimental ^{27}Al MAS spectrum of the sample **3b**. The same set of parameters was used for the fits at 9.4 T and 17.6 T. δ_{iso} is the isotropic chemical shift; ν_Q is the quadrupolar frequency; η is the asymmetry parameter; *I* is the relative intensity.

Sites	AlO_4 sites			AlO_6 sites		AlF_6
δ_{iso} (ppm)	78.5 ± 1.5	68.5 ± 1	77 ± 3	19 ± 0.5	15.5 ± 0.5	–0.5 ± 0.5
ν_Q (kHz)	300 ± 50	480 ± 40	1300 ± 150	700 ± 40	360 ± 40	150 ± 20
η	0.6 ± 0.2	0.6 ± 0.2	0.6 ± 0.2	1 ± 0.2	0.6 ± 0.2	0 ± 0.2
I (%)	1 ± 0.5	9 ± 2	32 ± 2	30 ± 4	15 ± 1	13 ± 1

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

broad contribution at around 75 ppm. From the ^{27}Al chemical shift range reported in oxides and fluorides,[16] this high chemical shift cannot be due to the oxofluoro environment for the aluminium atoms in the solidified samples but to the oxide environment (see Figure 4).

^{19}F MAS NMR Spectra

In the ^{19}F MAS NMR spectra we observed unambiguously the signal for cryolite (–190 ppm) and the signal for NaF (–225 ppm)[9] in the samples **3b**, **3c** and **4a**, in agreement with the X-ray powder diffraction and IR spectroscopy results. In the samples **7a** and **7b** only cryolite is present and no other fluoro-species were observed. The ^{19}F chemical shifts-range, reported by Chupas et al.[17] for octahedral aluminium environments with oxygen and fluorine in the first coordination sphere, lies between –115 and –170 ppm. No such signal is detectable in our ^{19}F MAS spectra.

From these experiments we can state the absence of all fluoro-species except for cryolite (see Figure 5).

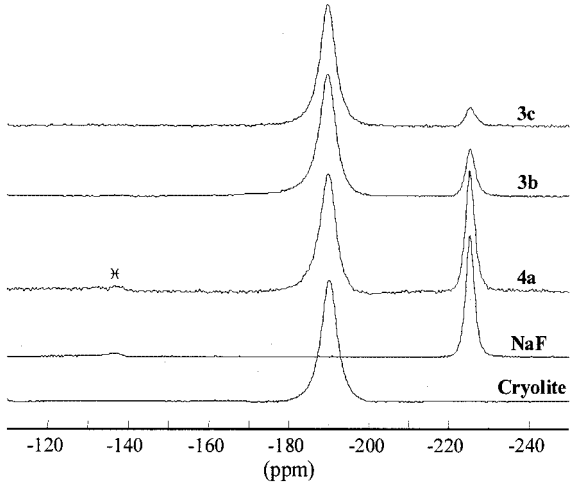

Figure 5. ^{19}F MAS NMR spectra of the samples **4a**, **3b**, **3c**, cryolite and NaF obtained at 9.4 T and at a spinning speed of 32 kHz. The asterisk (*) represents spinning side bands.

^{23}Na MAS NMR Spectra

The signals observed in **3b** and **3c** are superpositions of the cryolite signals ($\delta \approx 1$ ppm and $\delta \approx -11/-14$ ppm) and NaF at $\delta \approx 7$ ppm (see Figure 6).[9] A broad component (clearly visible in the **4a** spectrum) is also observed around –21 ppm. This peak is not easily assigned because of its strong overlap with the other signals, but it can be related to the $NaAl_{11}O_{17}$ phase detected by ^{27}Al NMR spectroscopy. A better resolution could be achieved by a ^{23}Na MQMAS experiment that would provide separation of these different contributions. In the case of samples **7a** and **7b**, again we observed only the signal for cryolite (not reported here).

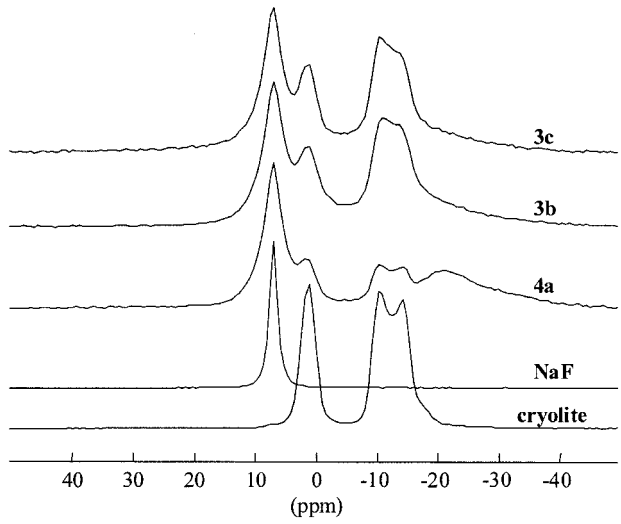

Figure 6. ^{23}Na MAS NMR spectra of the samples **4a**, **3b**, **3c**, cryolite and NaF obtained at 9.4 T and at a spinning speed of 32 kHz.

From different phase diagrams reported for the system Na_3AlF_6–Al_2O_3,[18–20] the eutectic point reported is around 10 wt.-% Al_2O_3 (18.6 mol-%) with an eutectic temperature of 966 °C. Skybakmoen et al.[20] determined the solubility of alumina in molten Na_3AlF_6 by measuring the weight loss of a rotating sinter-corundum disc in the cryolite melt. The results were fitted to [Equation (1)].

$$[Al_2O_3]_{sat} = A\left(\frac{t}{1000}\right)^B \quad (1)$$

where $A = 11.9$, $B = 4.8$ and t is the temperature in °C; the square brackets denote the weight percentage of alumina at saturation (the equation also contains terms for AlF_3, CaF_2, MgF_2 and LiF, which are not included here). According to the above equation, the solubility of alumina in cryolite at 1010 °C is 12.5 wt.-% (22.7 mol-%) Al_2O_3.

In our experiments, we have mainly used a composition of 30 mol-% (17.3 wt.-%) Al_2O_3 in the cryolite melt. At 1010 °C Al_2O_3 is 7.3 mol-% over the solubility limit. During prolonged heating, vapours of $NaAlF_4$ are expected to be formed,[21] as described by [Equation (2)].

$$Na_3AlF_6\ (l) = 2\ NaF\ (l) + NaAlF_4\ (g) \quad (2)$$

and consequently $NaAlF_4$ can decompose during condensation on the top parts of the apparatus according to [Equation (3)].

$$NaAlF_4\ (g) = 1/5\ Na_5Al_3F_{14}\ (s) + 2/5\ AlF_3\ (s) \quad (3)$$

In such a case, the system is enriched in NaF. According to the phase diagram of the system Na_6F_6–Al_2F_6–Al_2O_3–Na_6O_3, given by Foster,[22] the α–alumina in excess is transformed into β-alumina. This process can be expressed by [Equation (4)].

$$2\ NaF\ (l) + (3x + 1)/3\ Al_2O_3\ (s, \alpha) = Na_2O{\cdot}xAl_2O_3\ (s) + 2/3\ AlF_3\ (l) \quad (4)$$

where $x = 11$.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The above explanations are based on an open system. In the closed system, the results could be explained by the following considerations.

In molten cryolite, it is generally accepted that the ions present are Na^+, F^-, AlF_4^-, AlF_5^{2-} and AlF_6^{3-}. Alumina $[(Al_2O_3)_n]$ dissolves and provides the probable anions AlO_2^- and AlO^+ (the presence of other anions such as $Al_{2n+1}O^-_{3n+2}$ or $Al_{2n+1}O^+_{3n+1}$ cannot be excluded) that would give oxofluoro-anions by reacting in the melt. Even if fluoro- and oxo-anions react in the melt to form oxofluoroaluminates, the cooling rate of ca. 1000 °C/min is not high enough to trap them and may lead to the decomposition of oxofluoroaluminates into cryolite and some amorphous alumina phase (sample **7**). If the cooling rate is even slower (spontaneous cooling), there is enough time to form the crystalline phase of α-alumina (samples **8** and **9**). No reaction seems to take place between cryolite and alumina.

In the case of sample **7**, we observed the NMR signal of cryolite, and no signal for alumina. These results coincide rather well with the observations made by other authors who reported only the cryolite phase from X-ray powder patterns of quenched mixtures of alumina and cryolite.[23,24] An attempt to explain the nature of alumina in quenched cryolite–alumina melts was suggested by Foster.[25] He concluded that alumina dissolves in cryolite to produce one or more species, that is, oxoaluminates or oxofluoroaluminates. He was not able to prove or exclude the presence of oxofluoroaluminate species. Thus he stated that they are only stable in the liquid phase or in insufficient amounts in the mixture below the detection limit of the X-ray diffractometer. According to our investigation, we still cannot decide whether oxofluoroaluminates are stable only in melts but we can exclude their presence in the solidified samples.

Conclusions

The results obtained by X-ray powder diffraction, IR and NMR spectroscopy allow us to give some conclusions about the presence of oxofluoroaluminate species in the solidified mixtures of cryolite and alumina.

Heating 30 mol-% alumina in cryolite under air at 1010 °C for 50 h results in an almost complete reaction of the mixture in $NaAl_{11}O_{17}$ and NaF. The existence of oxofluoroaluminate species can be excluded in the solid phase.

Heating of the alumina–cryolite mixture in hermetically closed Pt tubes at 1500 °C or under an inert atmosphere at 1010 °C and subsequent quenching provides some amorphous alumina phases. No decomposition providing NaF was observed and the presence of oxofluoroaluminates in the solid phase can be excluded.

Heating of the alumina–cryolite mixture in hermetically closed Pt tubes at 1500 °C or under an inert atmosphere at 1010 °C and consequent, spontaneous cooling provides crystalline cryolite with a crystalline alumina phase. No decomposition leading to NaF was observed and the presence of oxofluoroaluminates in the solid phase can be further excluded.

Experimental Section

The chemicals used are hand-picked powdered cryolite from Greenland (m. p. 1009–1011 °C) and powdered Al_2O_3 (Merck, p.a.). The powders were treated in a resistance furnace with a Kanthal coil equipped with a vertical alumina tube and a calibrated Pt–Pt/10Rh thermocouple located close to a platinum crucible.

Heating under Inert Atmosphere: A mixture of Na_3AlF_6 and 30 mol-% Al_2O_3 was heated under nitrogen at 1010 °C for 30 h in the Pt crucible covered with a lid. The nitrogen was bubbled through concentrated sulphuric acid in order to remove water traces. The mixture was then quenched by immersing the platinum crucible with the sample into crushed ice, with a cooling rate of ca. 1000 °C/min. Two samples were collected and powdered. Sample **1a** corresponds to the bottom of the crucible while sample **1b** corresponds to the upper part of the crucible, where the sample condensed and "climbed up" during the experiment (see Figure 6).

Heating under Air: Three mixtures of Na_3AlF_6 and 30 mol-% Al_2O_3 were heated under air at 1010 °C for 10 h (**2**), for 20 h (**3**) and for 50 h (**4**) in the Pt crucible covered with the lid. The mixtures were then treated as in the previous experiment. For each experiment, three samples were collected and powdered: from the bottom of the crucible (**2a**, **3a**, **4a**), from the upper part (**2b**, **3b**, **4b**) and from under the lid (**2c**, **3c**, **4c**) (see Figure 7).

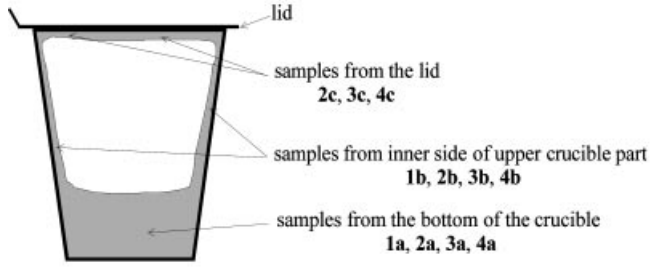

Figure 7. Schematic representation of the position of the investigated samples.

Heating in closed Pt tubes: The mixtures of Na_3AlF_6 and 10 mol-% Al_2O_3 (**5**), 20 mol-% Al_2O_3 (**6**) and 30 mol-% Al_2O_3 (**7**) were heated in the hermetically closed (by welding) Pt tubes at 1500 °C for 15 h and then quenched into ice. The tubes were opened with a saw and the samples collected were powdered. For each composition, three samplings were made from the bottom (**5a**, **6a**, **7a**), the middle (**5b**, **6b**, **7b**) and the top (**5c**, **6c**, **7c**) of the Pt tube.

The mixtures of Na_3AlF_6 and 20 mol-% Al_2O_3, (**8**) and 30 mol-% Al_2O_3, (**9**) were heated in hermetically sealed Pt tubes at 1500 °C for 5 h and left to cool spontaneously by switching off the furnace, which corresponds to a cooling rate of ca. 1.5 °C/min.

Compositions, heating and cooling conditions for the different samples are summarised in Table 2.

X-ray Diffraction Analysis: was carried out using the Philips PW1349/30 diffractometer with Cu-K_α radiation. The X-ray powder diffraction patterns were measured at room temperature in the range 7–70 °C (2θ). Identification of the different phases present in each sample was performed according to the PDF-2 International Centre for Diffraction Data database.

Infrared Spectra: were obtained using an FTIR spectrometer Nicolet Magna 750 equipped with a DTGS detector. The samples were analysed as KBr pellets.

Magic Angle Spinning NMR: experiments have been carried out on a Bruker DSX 400 NMR spectrometer (9.4 T) at operating fre-

9	30	1500	5	Pt crucible hermetically closed	slow cooling

quencies of 104.2 MHz for ^{27}Al, 105.8 MHz for ^{23}Na and 376.3 MHz for ^{19}F. ^{27}Al, ^{23}Na and ^{19}F chemical shifts are referenced to 1 M aqueous solutions of $Al(NO_3)_3$, NaCl and $CFCl_3$, respectively, at room temperature.

^{27}Al and ^{23}Na have nuclear spins of 5/2 and 3/2, respectively, and are thus quadrupolar. In solid state MAS spectra, even in high resolution conditions, line broadening and shifts caused by the second order quadrupolar effect can lead to important overlap of lines, therefore, separation of different peaks becomes difficult and sometimes inaccurate. These quadrupolar effects depend on the quadrupolar interactions and the external magnetic field strength. In order to better understand the ^{27}Al MAS spectra obtained at 9.4 T, we have performed the same experiments at 17.6 T on a Bruker Avance 750 spectrometer. The use of a very high field gives better separation of the different lines and allows us to assign each contribution to the different phases in the sample.

The NMR spectra were acquired using high- and very high-speed Bruker MAS probes with rotors of 4 and 2.5 mm in diameter, for spinning rates of 15 and 32 kHz, respectively. The NMR spectra were fitted using a modified version of the Bruker Winfit program.[26] ^{19}F, ^{27}Al, and ^{23}Na MAS spectra were typically acquired with short pulses of 0.5 μs, recycle delay of 2 s and 1 s, respectively, and each spectrum required approximately 128 acquisitions for fluorine and between 6000 and 12000 scans for ^{27}Al and ^{23}Na.

Synthesis, Crystal Structure and Magnetic Properties of Heterodimetallic $Re^{IV}Cu^{II}$ Complexes

Alina Tomkiewicz,[a] Jerzy Mroziński,*[a] Irene Brüdgam,[b] and Hans Hartl[b]

Keywords: Rhenium(IV) / Chain structures / Copper(II) / Heterometallic complexes

The two rhenium(IV)-copper(II) heterometallic complexes $[CuL_\beta][ReCl_4(ox)]\cdot DMF$ (**1**) and $[(CuL_\alpha)_2Cl][ReCl_4(ox)]Cl$ (**2**) (L_β = *N-dl*-5,7,7,12,14,14-hexamethyl-1,4,8,11-tetraazacyclotetradeca-4,11-diene and L_α = *N-dl*-5,7,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotetradeca-4,14-diene) were synthesized, and the crystal structures of both compounds were determined at 173(2) K. Complex **1** crystallizes in a monoclinic space group $P2_1$, with a = 9.365(2) Å, b = 15.150(2) Å, c = 10.776(1) Å, β = 110.01(1)°, Z = 2, whereas **2** crystallizes in an orthorhombic space group $Pca2_1$ with a = 16.660(5) Å, b = 16.017(5) Å, c = 17.066(5) Å, and Z = 4. The CuL_β macrocycle cation is approximately planar and coordinated from above and below by $[ReCl_4(ox)]^{2-}$ units through the bis(bidentate) oxalato ligands. It features an oxalato-bridged heterometallic Re^{IV}–Cu^{II} zigzag chain, the shortest intrachain metal–metal distances are Re···Cu = 5.568(2) and 5.870(2) Å in the direction of the *b* axis. The crystal structure of **2** consists of dinuclear complex cations $[(CuL_\alpha)_2Cl]^{3+}$ with $[ReCl_4ox]^{2-}$ and isolated Cl^- as counter anions. Cu atoms in CuL_α are only fivefold coordinated in a square pyramidal surrounding, and the cations $(CuL_\alpha)^{2+}$ are connected in pairs by chloride. The intramolecular Cu···Cu separation is 4.885(3) Å, the shortest Re···Cu distance is 7.612(3) Å. The magnetic behavior of **1** and **2** has been investigated over the temperature range 1.7–300 K. Compound **1** behaves like a ferrimagnetic Cu^{II}-Re^{IV} dimetallic, one–dimensional chain with intrachain antiferromagnetic coupling. Compound **2** shows weak antiferromagnetic interactions within the Cu^{II}–Cu^{II} units.

Introduction

The design and synthesis of multidimensional magnetic materials is a major focus of molecular-based materials research.[1–2] The typical approach relies on the synthesis of materials with direct exchange coupling between metal ions and coordinated open shell ligands. In the last twenty years several compounds of that type containing metal ions of the first-transition-metal series have been characterized. The magnetic properties of related complexes containing second and third series transition elements, which induce larger spin-orbit coupling effects and a greater degree of covalence, are much less known. This is the case for the rhenium(IV) complexes, where the $5d^3$ ion usually forms octahedral compounds. Numerous types of hexachloro-, hexabromo- and hexaiodorhenate complexes have previously been investigated in full detail.[3–6] The study of magnetic properties of mononuclear hexahalogeno complexes revealed the occurrence of an intermolecular antiferromagnetic interaction whose magnitude depends on the size of the organic cation (bulk effect). The exchange of two chloride ions by an oxalato ligand in the rhenium coordination sphere allows for the synthesis of new heterodinuclear Re^{IV}–Cu^{II} complexes. The oxalate dianion is a well-know ligand, which usually adopts a bidentate coordination mode when acting as a bridge between two metals. In fact, the coordination mode of the rhenium(IV) precursor $[ReCl_4ox]^{2-}$ changes with the nature of the other ligands in the coordination sphere of Cu^{II}, and is monodentate in $[Cu(bipy)_2ReCl_4(ox)]$ (forming a long Cu–O axial bond of 2.65 Å) and a very asymmetric bidentate in $[Cu(terpy)_2ReCl_4(ox)(H_2O)]$ (forming one short and one long Cu–O bond, 2.05 and 2.47 Å, respectively).[7] The coupling between Re^{IV} and Cu^{II} can be ferro- or antiferromagnetic but is very weak in all cases because of the long Cu^{II}–O bonds and bite angle of the oxalate ligand. Distortions in the coordination geometry in reported complexes introduce very poor orbital overlap, which makes the interaction weak. Analysis of literature data suggest that a quite strong coupling should be obtained if the ligand is coordinated is a symmetric bidentate way with two short Cu^{II}–O bonds. For this reason, it seemed interesting to examine macrocyclic copper(II) complexes CuL_α and CuL_β (where L_β = *N-dl*-5,7,7,12,14,14-hexamethyl-1,4,8,11-tetraazacyclotetradeca-4,11-diene and L_α = *N-dl*-5,7,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotetradeca-4,14-diene) (Scheme 1) in order to obtain heterometallic systems bridged by oxalato groups. The square planar macrocyclic complexes with two vacant coordination

sites at the metal atom play the role of the so-called "building block".[8] In this paper, we present results of investigations of coordinatively unsaturated complexes of copper(II) as well as of simple $[ReCl_4ox]^{2-}$ ions. It is interesting to show how the configuration of the nitrogen donor ligands influences the crystalline structure as well as the magnetic properties.

Results and Discussion

Description of the Structures

[CuLβ][ReCl4(ox)]·DMF (1)

Complex **1** crystallizes in a monoclinic space group $P2_1$ (Table 1). Figure 1 shows an ORTEP plot of the asymmetric unit $[ReCl_4(\mu\text{-ox})CuL_\beta]$ of this compound without the solvent molecule DMF.

In the crystal structure, the $[CuL_\beta]^{2+}$ cations and $[ReCl_4(ox)]^{2-}$ anions are arranged as polymeric chains running parallel to axis *b* (Figure 2). The rhenium atom is coordinated by four chloro and one chelating oxalato ligand.

The two remaining oxygen donor atoms of the tetradentate oxalato ligand are bound to two $[CuL_\beta]^{2+}$ units, widening the nearly planar coordination of Cu^{II} by the four N atoms of the L_β ligand to an elongated octahedron with the oxygen ligands in *trans* position. The bond lengths for Cu1–

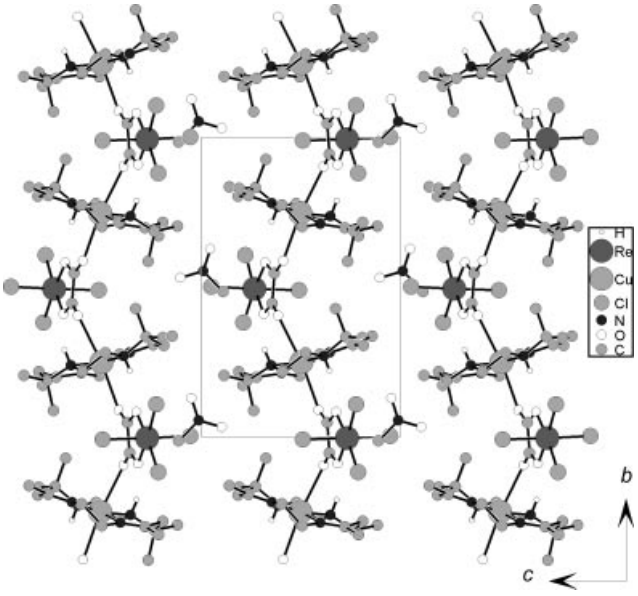

Figure 2. Crystal structure of **1** (view axis *a*; H atoms bound to C have been omitted for clarity).

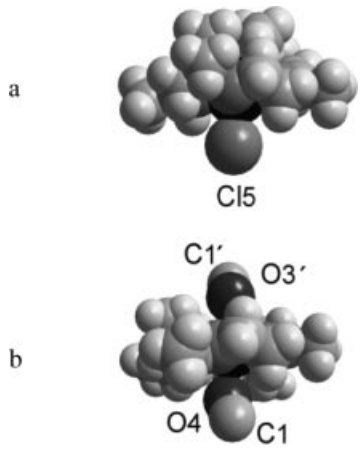

Figure 3. Space-filling model of the Cu surrounding in **2** (a) and **1** (b).

O(3′) and Cu1–O4 are 2.655(4) and 2.58(4) Å, respectively, the O3′–Cu1–O4 angle is 168.1(1)° (Figure 3a). Re^{IV} and Cu^{II} complexes are linked through oxalato bridges resulting in Re···Cu distances of 5.568(2) and 5.870(2) Å and a Cu···Cu interspace distance of 7.550(3) Å within the chains. The shortest interchain Cu···Cu separations are 7.072(4) and 7.596(4) Å.

The ligand L_β in compound **1** is approximately planar with maximum deviations of ±0.48 Å from the least-squares plane defined by the 14 ring atoms and Cu. However, the axial methyl substituents C52 and C141 are placed in *anti* configuration 1.902(4) Å above and 1.711(4) Å below that plane. The Cu^{II} atom in the center of the ligand is thus open for additional coordination from two sides.

The ring members N8 and C7, and N11 and C12 are connected by double bonds; N1 and N4 are protonated. Apart from the C–O and C–C bond lengths of the oxalato ligand, the $[Re(IV)Cl_4ox]^{2-}$ part of the crystal structure shows no apparent structural deviations from those in **2** or in related compounds in the literature.

[(CuL$_\alpha$)$_2$)Cl][ReCl$_4$(ox)]Cl (2)

Complex **2** crystallizes in an orthorhombic space group $Pca2_1$ (Table 1).

The crystal structure consists of dinuclear complex cations $[(CuL_\alpha)_2Cl]^{3+}$ and $[ReCl_4ox]^{2-}$, and isolated Cl^- as counter anions. An ORTEP plot of the asymmetric unit of the compound with the atom labelling is given in Figure 4.

The largest deviations of the 14 ring atoms and the central Cu^{II} from their least-square planes are +0.805(6)/–0.528(6) Å in the first $(Cu^{II}L_\alpha)^+$ complex and +0.514(7)/–0.794(6) Å in the second one with atom labels "a". The ring members N1–C2, N8–C9, N1a–C2a and N8a–C9a are connected by double bonds; N5, N12, N5a and N12a are protonated. The cationic complexes are linked in pairs by a chloride ligand with Cu–Cl bond lengths of 2.156 (2) Å and a Cu1–Cl–Cu1a angle of 152.2(1)°. The varying coordina-

tion behavior of Cu^{II} in the investigated compounds **1** and **2** results from the different configurations of the ligands L_α and L_β, respectively. The two axial methyl substituents of each ligand L_α (C42, C111 and C42a, C11c) are arranged in *syn* configuration 2.286(8)/2.353(9) Å above as well as 2.279(9)/2.320(9) Å below the appendant N_4 planes. The cap-shaped ligands enfold the copper atoms Cu1 and Cu1a, which are situated 0.153(3) and 0.143(3) Å out of their respective N_4 planes (Figure 3b). As there is no space for additional coordination on the outside of the cap (Figure 1), the Cu atoms are only fivefold coordinated in a square-pyramidal surrounding. The intramolecular Cu···Cu distance is 4.885(3) Å, and the shortest intermolecular Re···Cu and Re···Re distances are 7.612(3) and 8.581(2) Å, respectively. The $[ReCl_4ox]^{2-}$ anion with a chelating oxalato ligand shows no unusual structural features with respect to bond lengths or angles (Table 2).[9,10] A simplified view of the packing of the ions in the elementary cell is illustrated in Figure 5. The $[(CuL_\alpha)_2Cl]^{3+}$ cations are arranged in layers parallel to *ab* in $c = 0$ and $^1/_2$, the anions $[ReCl_4ox]^{2-}$ and Cl^- in $c = {}^1/_4$ and $^3/_4$, respectively.

Magnetic Properties of 1 and 2

The magnetic susceptibility studies for the examined complexes have been performed within the temperature range of 1.7–300 K. The experimental data show the product $\chi_M T$ as a function of temperature (Figure 6a and Figure 6b). The $\chi_M T$ data of $[Bu_4N]_2[ReCl_4ox]$ is also included for comparison.

Complex **1** shows a typical 1D ferrimagnetic behavior. At room temperature, $\chi_M T$ is 2.26 cm^3 mol^{-1} K, a value that is expected for an uncoupled Re^{IV} ($S_{Re} = {}^3/_2$) and Cu^{II} ($S_{Cu} = {}^1/_2$) pair. With decreasing temperature, $\chi_M T$ continuously goes down in value and reaches its minimum (see inset) at 8 K with $\chi_M T = 0.96$ cm^3 mol^{-1} K. The presence of a minimum in the $\chi_M T$ data is consistent with the 1D model, assuming the occurrence of antiferromagnetic exchange interactions between Re^{IV} and Cu^{II} ions.[11] When the temperature is lowered below 8.0 K, $\chi_M T$ increases and reaches a maximum at 2.0 K before rapidly decreasing to between 2.0and 1.80 K. Due to additional exchange interactions between spins of the nearest neighboring chains at these low

$$H = \sum_i \left\{ \begin{array}{l} -JS^z_{2i-1}S^z_{2i} + g_{\parallel Cu}\beta S^z_{2i-1}H_z + g_{\parallel Re}\beta S^z_{2i}H_z + \\ g_{\perp Cu}\beta\left(S^x_{2i-1}H_x + S^y_{2i-1}H_y\right) + g_{\perp Re}\beta\left(S^x_{2i}H_x + S^y_{2i}H_y\right) + 2D\left[\left(S^z_{2i}\right)^2 - \frac{5}{4}\right] \end{array} \right\} \quad (1)$$

temperatures, the system undergoes a change to 3D antiferromagnetic ordering.[11]

To quantitatively interpret the susceptibility data, we used a one-dimensional model in which the magnetic susceptibility in the high-temperature region of **1** can be described by two contributions: the susceptibility of the $^4A_{2g}$ term of the Re(IV) ions (with zero-field splitting) and that of the $^2T_{2g}$ term of the Cu^{II} ions modified by a factor predicted from the Ising model of the magnetic exchange interactions and different local g values of g_{Cu} and g_{Re}.[1,13,14] The relevant spin Hamiltonian is defined by Equation (1),[12] where the total spins are $S_{2i} = S_{Re}$ and $S_{2i-1} = S_{Cu}$. J is the exchange coupling parameter between the quartet Re^{IV} and doublet Cu^{II} local spins and $2D$ is the energy gap between the ±3/2 and ±1/2 Kramers doublets.

The least-squares fit of the experimental data using this equation was limited to the 8.0–300 K range and leads to $2D = 99.1\ cm^{-1}$, $g_{avRe} = 1.91$, $g_{avCu} = 2.27$ and $J = -3.36\ cm^{-1}$ for **1**. The agreement factor R defined as $R = \Sigma(\chi_{exp}T - \chi_{calc}T)^2/\Sigma(\chi_{exp}T)^2$ is $1.26\cdot10^{-4}$. The calculated curve agrees very well with the magnetic data and illustrates that the J parameter is clearly associated with the exchange pathway involving the oxalato bridge.

The variation of the magnetization M (in B.M. units) versus the magnetic field H at 1.8 K (Figure 7a and Figure 7b), i.e. below magnetic ordering, clearly supports the occurrence of spontaneous magnetic moments in complex **1**. As the magnetic field increases, the M versus H curve is linear up to 1000 G, and then shows a sinusoidal variation before reaching saturation at a value of Ms = 1.51 B.M. perrhenium-copper pair.[13] This value is smaller than that for the tetrabutylammonium compound $[Bu_4N]_2ReCl_4(ox)$, (Ms = 1.60 B.M. per rhenium atom).

The magnetization versus temperature curves (Figure 8) measured at 50 Oe reveal the presence of spontaneous magnetization below the transition temperature T_c = 3.50 K. Spontaneous magnetization appears as the result of switching of the interchain exchange interactions at low temperatures that leads to 3D magnetic ordering of $\{[CuL_\beta]ReCl_4ox\}_n$ ferrimagnetic chains.[13] The magnetic data show the predominance of one-dimensional exchange interactions at $T > 3.50$ K with a crossover to 3D ferrimagnetic ordering at $T \approx 3.50$ K.

Complex **2** exhibits different magnetic properties. The value of $\chi_M T$ at room temperature is $3.96\ cm^3 mol^{-1} K$, which is expected for uncoupled Re^{IV} and Cu^{II}–Cu^{II} units. The $\chi_M T$ value smoothly decreases for a wide temperature range before it rapidly decreases at the lower temperatures [Figure 6]. The slight decrease in $\chi_M T$ can be due to the zero-field splitting effect of Re^{IV} ions and to intramolecular

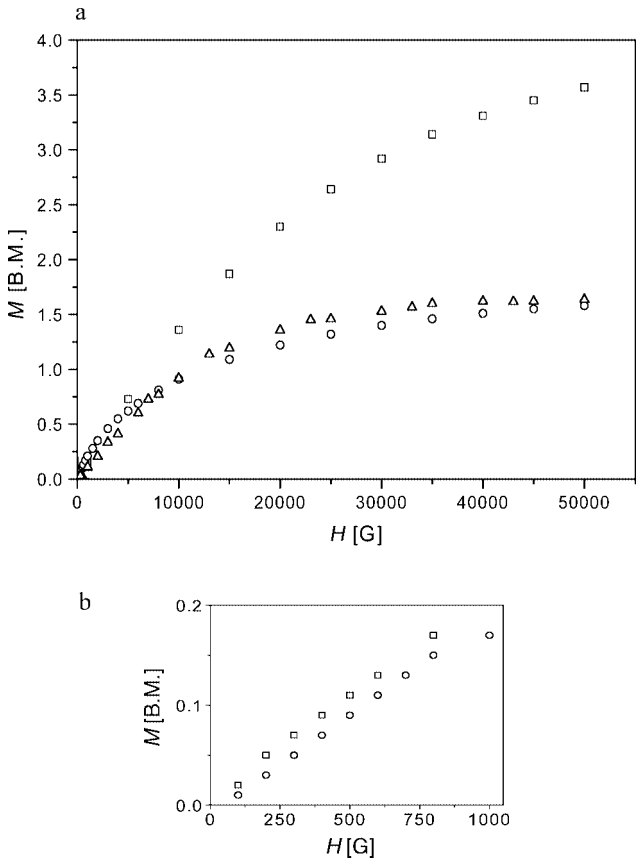

Figure 7. Field dependence of the magnetization for complexes for: (○) $[CuL_\beta][ReCl_4(ox)]\cdot DMF$ (**1**), (□) $[(CuL\alpha)_2Cl][ReCl_4(ox)]Cl$ (**2**), (Δ) $[Bu_4N]_2[ReCl_4(ox)]$.

exchange interactions between Cu^{II}–Cu^{II} ions. The crystal structure of **2** is built up by isolated paramagnetic ions $[(CuL_\alpha)_2Cl]^{3+}$ and $[ReCl_4ox]^{2-}$ and a diamagnetic Cl^- ion,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

so that Wiedemann's equation can be used to interpret the magnetic data. Since the two magnetic ions exist at a ratio of 1:1, the equation [Equation (2)] for molar magnetic susceptibilities of complex **2** can be reduced to the simple form:

$$\chi_{\text{sample}} = \chi_{\text{av}[\text{ReCl}_4\text{ox}]^{2-}} + \chi_{[(\text{CuL}_\alpha)_2\text{Cl}]^{3+}} + \chi_{\text{Cl}^-} \quad (2)$$

where the average magnetic susceptibility of Re^{IV} is equal to $\chi_{av} = \frac{1}{3}\cdot\chi_{II} + \frac{2}{3}\cdot\chi_{\perp}$

The parallel and perpendicular zero-field susceptibilities for $S = 3/2$ (Re^{IV}) with an axial crystal field distortion were described in a previous paper.[9] The magnetic susceptibility of the dinuclear copper unit was specified by the Bleaney–Bowers expression.[14]

A least-squares fit leads to the following set of parameters: $g_{avRe} = 2.30$, $g_{avCu} = 2.21$, $J = -2.81$, $2D = 91.2$ and $R = 5.36\cdot10^{-4}$.

The macrocyclic complex cations CuL_α^{2+} and CuL_β^{2+} used for the synthesis occur in the form of two isomers differing in the configuration of the donor nitrogen atoms. In complex **1** both methyl groups are found in an *anti* configuration, in which the central ion is accessible to the bridging oxalato ligands from both sides. The resulting oxalato bridges in the generated dimetallic zigzag chains are known to mediate magnetic interactions between metal centers. The possible mechanism for the one-dimensional ordering in **1** can be understood through orbital symmetry considerations. The magnitude of the interaction is due to the overlap of the magnetic orbital on either side of the bridge. Tetrahedral distortion of the copper environment is the apparent cause for the four short equatorial bonds to N(4), N(8), N(11), and N(15), which ensure the delocalization of the unpaired electron of the d_{z^2} magnetic orbital within the equatorial plane and disrupt the orthogonality between this orbital and the d_{xy} orbital of Re^{IV} through the oxalato ligand. The oxalato ligand between the Re(1)–Cu(1) pair causes poor overlap resulting in weak antiferromagnetic coupling $J = -3.36\ cm^{-1}$. It deserves to be noted that the $2D$ value for complex **1** is greater than that for $[Bu_4N]_2ReCl_4(ox)$ ($53\ cm^{-1}$).[9] These relatively large values of the $2D$ parameter for third-row transition-metal ions would account for the large value of the spin-orbit parameter ($\lambda \approx 1100\ cm^{-1}$ for the Re^{IV} single ion).

The differences in the crystalline structure of complex **2** compared to complex **1** has a significant influence on its magnetic properties.The partial conversion of the macrocyclic ring conformation in **2** is accompanied by a change of the methyl groups from *anti*- to *syn* conformation. As a consequence the methyl groups block one of the axial sites at the CuL_α^{2+} ion causing the availability of only one vacant site at the central copper(II) ion. This macrocycle ion with a Cu^{II} magnetic center is linked by a chloride bridge to another Cu^{II} unit. Halide bridges have been observed in other copper complexes, but most of these have at least two bridges with angular Cu–halogen–Cu bonds. The Cu–Cl bond distance in the present structure (2.156 Å) is shorter than the average of the bridging Cu–Cl bond distances: 2.514 Å in $[Co(en)_3]_2[Cu_2Cl_8]Cl_2\cdot2H_2O$,[15] 2.501 Å in [Cu(tet b)Cl]ClO_4, and 2.507 Å in $[Cu(L^1)Cl(CuCl_3)]$ (L^1 = 12-methyl-12-nitro-1,4,7,10-tetra-azacyclotridecane).[16] For dinuclear copper(II) compounds with bridging chloride ions, antiferromagnetic exchange interactions have been observed, and the singlet–triplet splitting ($2J$) varies linearly with φ, the bridging Cu–Cl–Cu angle. It should be noted that in the last reported compound $[Cu(L^1)Cl(CuCl_3)]$, which has the same square-based pyramid coordination geometry as complex **2**, there is no antiferromagnetic spin coupling. The magnetic susceptibility from 4.25 to 301.6 K follows the Curie low, with a magnetic moment of 1.86 B.M. In complex **2**, because of the very long Cu(1)···Re(1) axial distance, the overlap between the magnetic orbitals in the Re^{IV} and Cu^{II} dimeric units can be neglected, leading to a nonexchange interaction as observed. On the other hand, observed antiferomagnetic interactions can be understood in terms of the nonzero overlap between the copper(II) magnetic $d_{x^2-y^2}$ orbitals.[17–19] Studies of chloride-bridged dimeric systems have shown that the bridging angle Cu–Cl–Cu of 152.2(1)° generates an antiferromagnetic coupling of copper(II) magnetic centers.[19]

Conclusions

Our results show that it is possible to synthesize new Re^{IV}–Cu^{II} heterodimetallic complexes by using $[ReCl_4(ox)]^{2-}$ anions as components that bridge macrocyclic $[Cu^{II}L]^{2+}$ cations. The magnitude of magnetic coupling between Re^{IV} and Cu^{II} in the examined compounds can be tuned by changing the coordination geometry around the copper(II) ions. This coordination depends on the position of the methyl groups around the equatorial nitrogen atoms of the ligands. In the case of the nearly square-planar coordinated $[CuL_\beta]^{2+}$, a 1D ferrimagnetic chain compound was obtained. Each $[ReCl_4(ox)]^{2-}$ ion is bound by two long Cu^{II}–O bonds to two macrocyclic fragments. The magnetic measurements indicate weak antiferromagnetic interactions between the Re^{IV} and Cu^{II} metal ions within the chains. The temperature dependency of magnetization has revealed a transition from a one-dimensional ferrimagnetic system to a three-dimensional magnetically ordered system. In the case of a non-planar coordination sphere around Cu^{II}, the complex cation is open for coordination only on one side. This position is then occupied by a bridging chloro ligand, which connects two Cu^{II} macrocycle units, and the isolated anion $ReCl_4(ox)^{2-}$ is responsible for the charge balance. Strong antiferromagnetic interaction is not expected in the dimetallic Re^{IV}-Cu^{II} macrocyclic compounds **1** and **2** because of poor overlap of the magnetic orbitals. The analysis of these results suggest that a stronger magnetic interaction should be obtained if the rhenium(IV) ions were coordinated by other first-row transition-metal macrocycles.

Experimental Section

Physical Measurements: Magnetic measurements in the temperature range 1.7–300 K were performed using a Quantum Design SQUID-based MPMSXL-5-type magnetometer. The SQUID magnetometer was calibrated with the palladium rod sample (Materials Research Corporation, measured purity 99.9985%). The superconducting magnet was generally operated at a field strength ranging from 0 to 5 T. Measurements were made at a magnetic field of 0.5 T. Corrections are based on subtracting the sample-holder signal and contribution χ_D estimated from the Pascal constants.

Materials: All materials used in this work were of reagent grade purity and were used as commercially obtained. The compounds $[Bu_4N]_2[ReCl_4(ox)]$, $[CuL_\alpha](ClO_4)_2$, and $[CuL_\beta](ClO_4)_2$ were prepared as previously reported.[8,9]

Synthesis of the Complexes – $[CuL_\beta][ReCl_4(ox)] \cdot DMF$ (1): A solution of $CuL_\beta(ClO_4)_2$ (2.5 mg, 0.075 mmol) in a MeC/eNO_2 (10 mL) (5:1) mixture was added, dropwise, to a solution of $[Bu_4N]_2ReCl_4(ox)$ (6.7 mg, 0.075 mmol) in 10 mL of the same solvent. The mixture was subsequently stirred. After a few days, by slow evaporation a dark-violet crystalline solid was formed from the violet solution. It was filtered and washed using methanol (2 × 20 mL) and diethyl ether. Yield: 5.86 mg (96%). Polyhedral violet single crystals suitable for X-ray diffraction studies were obtained by the slow mixing of solution of both reagents in DMF/MeCN (8:1) at room temperature. IR: bands associated to the oxalato ligand appear at 1718 (m), 1663 (s), 1375 (m), 800 (m) cm^{-1}. $C_{38}H_{70}N_{10}Cl_8O_{12}Cu_2Re_2$ (821.06): calcd. C 28.44, H 4.21, Cl 18.67, N 7.37; found: C 27.51, H 4.36, Cl 19.42, N 6.99. The rhenium and copper content was determined by ICP method: calcd. Cu 7.73, Re 24.51; found Cu 7.05, Re 24.32.

Synthesis of the Complexes – $[(CuL_\alpha)_2Cl][ReCl_4(ox)]Cl$ (2): A solution of $[CuL_\alpha](ClO_4)_2$ (5.0 mg, 0.15 mmol) in methanol (10 mL) was added dropwise to a solution of $[Bu_4N]_2[ReCl_4(ox)]$ (6.7 mg, 0.075 mmol) in 10 mL of the same solvent. The mixture was subsequently stirred. The resulting pink precipitate was filtered off, washed with diethyl ether and dried in air. Yield: 4.01 mg (46%). Pink crystals of **2** suitable for X-ray diffraction studies were obtained by slow evaporation of a MeC/MF (5:1) solution of the previously prepared precipitate. IR: bands associated to the oxalato ligand appear at 1703 (m), 1666 (m), 1377 (s), 801 (m) cm^{-1}. $C_{136}H_{240}N_{32}Cl_{24}O_{16}Cu_8Re_4$ (1170.88): calcd. C 34.75, H 5.50, Cl 18.14, N 9.51; found: C 35.01, H 5.54, Cl 19.65, N 8.99. The rhenium and copper content were determined by ICP method: calcd. Cu 10.85, Re 15.86; found Cu 10.21, Re 15.12. Note: The chloride ligands on the copper(II) dimer are from the tetrachlorooxalato rhenium(IV) complex anions.

X-ray Crystallographic Study: Single crystal X-ray data was collected on a Bruker-XPS-diffractometer (CCD area detector, Mo-K_α radiation, λ = 0.71073 Å, graphite monochromator), empirical absorption correction using symmetry-equivalent reflections (SADABS),[20] structure solution and refinement by SHELXS-97[21] and SHELXL-97[22] in the WINGX system (Table 1) was performed.[23] Most of the hydrogen atoms were located by difference Fourier syntheses. CCDC-237149 and CCDC-237150 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Stereoisomerism in Pentaerythritol-Bridged Cyclotriphosphazene Tri-Spiranes: Spiro and Ansa 1,3-Propanediyldioxy Disubstituted Derivatives

Aylin Uslu,*[a] Simon J. Coles,[b] David B. Davies,[c] Robert J. Eaton,[c] Michael B. Hursthouse,[b] Adem Kılıç,[a] and Robert A. Shaw[c]

Keywords: Cyclotriphosphazene derivatives / Trispiranes

In each spirane structure in Figure 1 on p. 1043 of the original article[1] the spiro atom of the left-hand cyclophosphazene ring should be phosphorus rather than nitrogen; the correct Figure 1 is shown below.

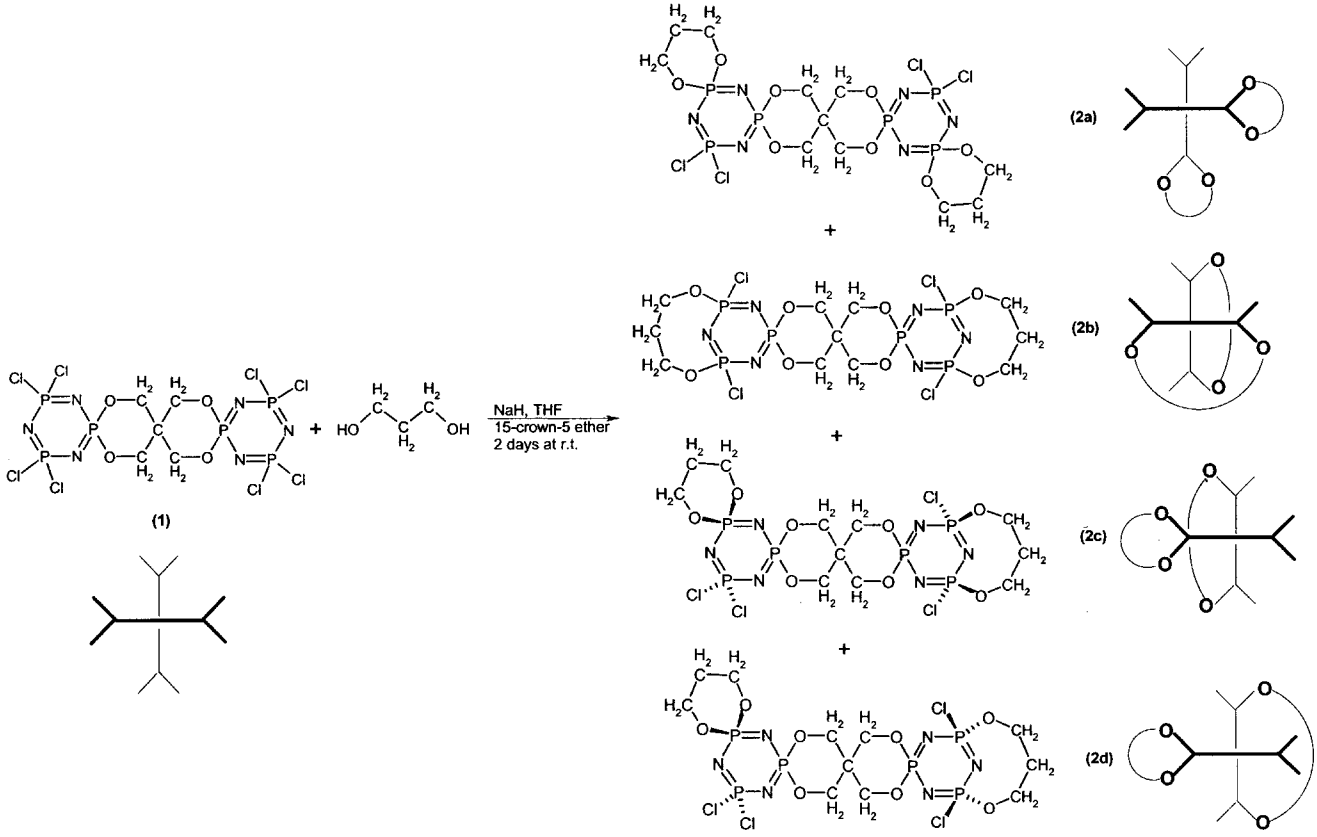

Figure 1. Structures of spirane-bridged unsubstituted, **1**, and disubstituted cyclotriphosphazene derivatives; di-monospiro **2a**, di-monoansa **2b**, and two monospiro-monoansa derivatives (**2c**, *syn*) and (**2d**, *anti*). A diagrammatic representation is also shown for compounds **1** and **2a**−**2d**. For clarity the inner organophosphate rings have been omitted and the outer cyclophosphazene rings, which are orthogonal to each other, are shown in the same projection with the ring to the front in bold type.

COVER PICTURE

The cover picture shows $[Pt(Me_2pipdt)_2][Pt(dtcr)_2]$ (Me_2-pipdt = *N*,*N*′-dimethylpiperazine-2,3-dithione; dtcr = dithiocroconate), an ion-pair CT salt formed by redox-active cationic and anionic platinum–dithiolenes arranged in an infinite, alternate one-dimensional stack. This salt exhibits a strong absorption in the near-infrared region that is assigned to a CT transition from the anion to the cation. NIR CT bands, and semiconducting and photoconducting properties are also observed for similar salts obtained on varying the anion. These properties strongly depend on the degree of electron donation, which in turn depends on the redox potential and on the planarity of the ionic components. Details are discussed in the article by P. Deplano et al. on p. 1829ff. This work has been performed in the framework of European COST action D14-003 "Towards New Molecular Inorganic Conductors".

Stabilization of Organometallic Species Achieved by the Use of N-Heterocyclic Carbene (NHC) Ligands

Natalie M. Scott[a] and Steven P. Nolan*[a]

Keywords: Carbene ligands / Ruthenium / Palladium / Nickel / Rhodium / Iridium

This review describes the stabilization of various coordinatively unsaturated metal centers through the incorporation of N-heterocyclic carbene (NHC) ligands. Such species are more thermally stable compared to the more ubiquitous tertiary phosphane systems. Although NHCs can be considered as phosphane mimics it has become apparent that there are substantial differences between the two ligand families. In general, NHC ligands are much more electron-donating and sterically demanding than bulky phosphane ligands. We also discuss the various thermochemical and infrared studies of metal carbene species that have provided insight into NHC ligands properties, and at last allowed meaningful comparison to tertiary phosphane ligands. While NHCs are generally viewed as strong binding low reactive ligands, in some instances they have been found to be not so innocent and can undergo facile intramolecular C–H activation as well as abnormal ligand binding [C-5(4) vs. C-2]. Here we highlight such reactions with late-transition metal centers that have allowed the isolation of various unsaturated LTM species. These have so far eluded isolation in analogous phosphane-based systems.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introductions

Since the first speculation on the existence of transient carbene intermediates in the early 1900s,[1,2] carbenes have evolved from real intermediates whose existence could be demonstrated by kinetic and trapping studies in the 1960s[3–5] to stabilized forms currently being studied in many research groups.[6–8] For the last 6 years we have been interested in the coordination of N-heterocyclic carbenes (NHCs) (imidazol-2-ylidenes, **1**; Scheme 1) to various metal centers and, like many other research groups, have found that NHCs stabilize highly reactive organometallic species.[9–13] Many of these carbene species show high catalytic activity in many metal-mediated organic transformations, e.g. ruthenium-mediated olefin metathesis,[14–19] iridium-catalyzed hydrogenation and hydrogen transfer[20–23] plati-

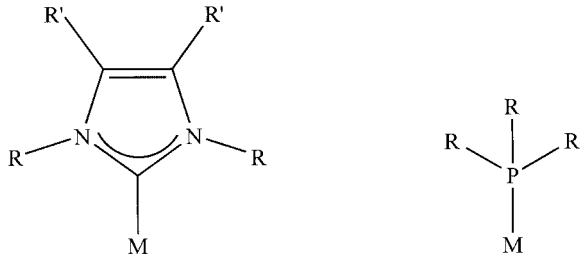
Natalie M. Scott was born in Australia in 1976. She received her B.Sc. (Honors) in chemistry from the Monash University and her Ph.D. from Monash University where she worked with Professor Glen Deacon. She was then awarded a Humboldt postdoctoral fellowship to carry out work with Professor Kempe in Bayreuth where she conducted research in lanthanide chemistry. She then accepted a postdoctoral position at the University of New Orleans where she has carried out late transition metal organometallic synthesis. Her research interests include organometallic chemistry (from early to late transition metals) and homogeneous catalysis.

Steven P. Nolan was born in Quebec City, Canada in 1962. He received his B.Sc. in chemistry from the University of West Florida and his Ph.D. from the University of Miami where he worked under the supervision of Professor Carl D. Hoff. After a postdoctoral stay with Professor Tobin J. Marks at Northwestern University, he joined the Department of Chemistry of the University of New Orleans in 1990. He now holds the rank of University Research Professor of Chemistry. His research interests include organometallic chemistry and homogeneous catalysis.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

num-catalyzed hydrosilylation,[24] and palladium C–C coupling reactions;[25–28] however, the strong σ-donor nature of the ligands often results in more stable catalysts than analogous phosphane-based systems.



Scheme 1.

A number of studies have suggested that as ligands, nucleophilic carbenes have similar properties to electron rich trialkylphosphanes (strong σ donors with negligible π-accepting ability) (Scheme 1).[17,29–36] Yet phosphane ligands suffer from significant P–C bond degradation at elevated temperatures,[29] while NHCs have been shown to possess greater thermal stability in addition to stronger donating ability.[37] Already, the easily modified NHC ligands are highly acclaimed affording more stable, yet highly reactive, metal catalysts where phosphane analogues have been found less effective or ineffective.[15,24,28,38–44] In addition, they have allowed the stabilization of many reactive organometallic intermediates that have never been fully characterized in analogous phosphane chemistry despite the use of sterically demanding ligands.[45–47] The pioneering studies of Tolman on phosphanes have had a major impact on the development of new and improved phosphane ligands for catalysis,[48] binding studies involving carbene ligands have only just begun to shed light on this ligand class.[36,45,49–53] In this report we describe efforts directed toward the understanding of the NHC ancillary system and their ability to stabilize unsaturated late-transition metal species.

Ruthenium NHC Metathesis Catalysts

The use of more thermally stable NHC-ruthenium catalysts (**1**,[16] **2**[54] Figure 1) in olefin metathesis has resulted in the preparation of new functionalized carbocycles and heterocycles from acyclic diene precursors unattainable using Grubbs catalyst **3**[55–57] or the alkoxy imido molybdenum catalyst **4** developed by Schrock.[58] The differences in reactivity between ruthenium and molybdenum arise from the fact that carbene ruthenium complexes have a greater functional group tolerance and higher moisture and atmospheric oxygen stability relative to those of the extremely sensitive molybdenum system.[59–61]

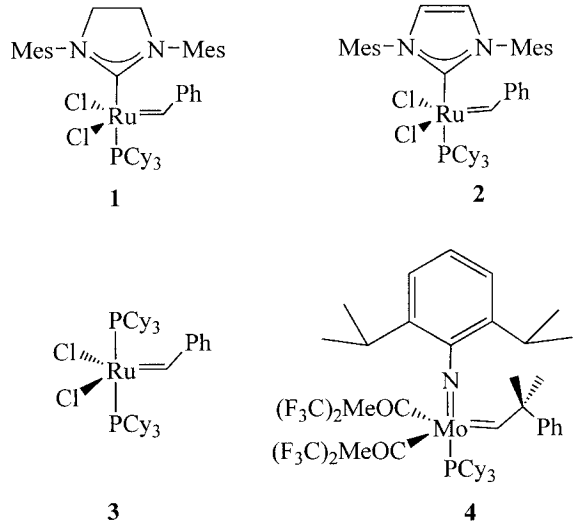


Figure 1. Olefin metathesis catalysts

We have been involved in the catalyst development efforts aimed at improving catalyst activity, functional group tolerance, and versatility for many years. In 1999 we examined electronic and steric properties of bulky NHC ligands with an unsaturated ruthenium complex and compared those results to a PCy_3-containing system.[15,36] The unsaturated tetrameric species $[Cp^*RuCl]_4$ ($Cp^* = \eta^5\text{-}C_5Me_5$)[62] rapidly reacts with sterically demanding phosphanes and various NHC ligands [Equation (1)] in THF to afford deep blue coordinatively unsaturated $[Cp^*Ru(PR_3)Cl]$ (R = cyclohexyl or isopropyl)[63] and [Cp*Ru(NHC)Cl] complexes. The reactions were exothermic and quantitative; facts that allowed for the determination of enthalpies of reaction by anaerobic solution calorimetry. In general, the results showed that the examined NHCs, with the exception of the sterically demanding IAd, are better donors than the best phosphane donor ligands.

$$[Cp^*RuCl]_4 + 4L \xrightarrow[\text{r.t.}]{\text{THF}} Cp^*Ru(L)Cl \qquad (1)$$

L	R		$-\Delta H_{rxn}$ (kcal/mol)	relative BDE (kcal/mol)
	cyclohexyl	ICy:	85.0(0.2)	21.2
	4-methylphenyl	ITol:	75.3(0.4)	18.8
	4-chlorophenyl	IpCl:	74.3(0.3)	18.6
	2,4,6-trimethylphenyl	IMes:	62.6(0.2)	15.6
	adamantyl	IAd:	27.4(0.4)	6.8
PCy_3:			41.9(0.2)	10.5
$PiPr_3$:			37.4(0.3)	9.4

These enthalpy values can be converted into relative bond dissociation enthalpies (BDE) on the basis of a mol of product and clearly indicate that NHCs are better donor ligands than PCy_3 in the [Cp*Ru(L)Cl] system. To further verify the thermochemical results, ligand exchange reactions between $[Cp^*Ru(PCy_3)Cl]$ and IMes or ICy were examined and indeed the formation of free PCy_3 and $[Cp^*Ru(PCy_3)Cl]$ was observed [Equation (2)].

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$$Cp^*Ru(PCy_3)Cl + NHC \xrightarrow[r.t.]{THF} Cp^*Ru(NHC)Cl + PCy_3 \quad (2)$$

NHC = IMes, ICy

The next step in our physicochemical studies was to examine whether this ligand substitution pattern was also valid for a catalytically related system: Ruthenium-based olefin metathesis. This did indeed proved feasible. The better donor ability of the NHC ligands (not including IAd) in supporting activity in metathesis-active ruthenium systems is thought to have a steric and an electronic component.

After our initial studies had been reported, Fürstner and Hermann[64] studied substitution effects on catalytic behavior (Figure 2). They observed that **7** and **8** bearing benzylic residues on the carbene ligands exhibit the lowest activity, whereas high activity was displayed for **5** and **6**. This result is in contrast to the behavior of **1**, in which replacement of PCy_3 by $PiPr_3$ results in a noticeable loss of catalytic activity. As we had observed, complexes bearing only one NHC ligand (**10**, **11**) showed significantly higher activity compared to bis-NHC systems. Mechanistically, since the Ru–NHC is a stronger bond than the Ru–PCy_3 bond, the mixed PR_3/NHC ligand system would proceed by phosphane ligand displacement if a dissociative-type pathway, leading to the active catalyst, is at play.[15,36] Another interesting result is that despite changing halogens in complexes **6** and **9** no difference in catalytic activity was observed. This result contrasts reactivity pattern for **1** where a decrease in activity from chloride to bromide to iodide was observed.[56]

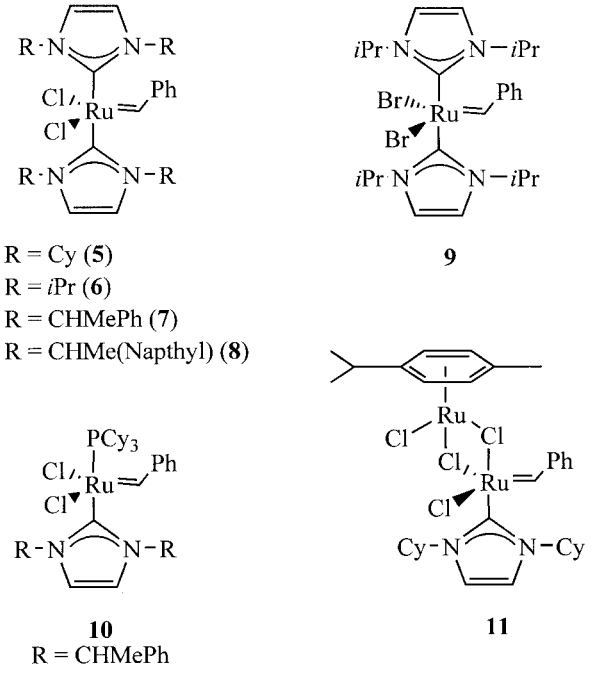

Figure 2. Substitution effects in Ru–NHC metathesis systems

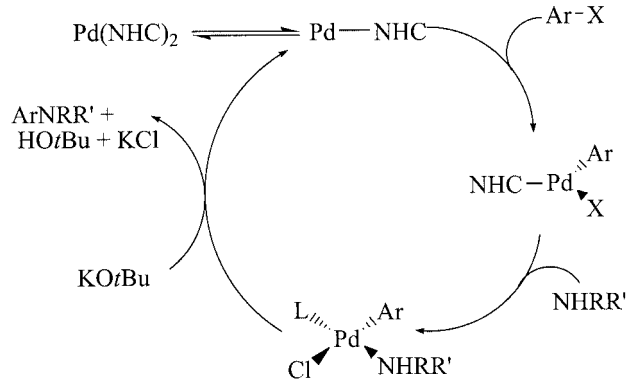
Much work has been and continues to be published in the area of ruthenium-based olefin metathesis since our initial observation of the beneficial use of NHC as supporting ligand. A fundamental understanding of the sterics and electronic properties of the ligands themselves proved invaluable. To say that these results provided a systematic ligand design approach would be incorrect but surely assisted our ligand exploration.

Palladium(0) NHC Complexes

The stability imparted by the NHC ligands to metal centers is further observed in palladium chemistry with the preparation of efficient catalysts that have been shown to possess considerable potential in many C–C bond forming reactions, which have included the Heck reaction,[65–69] the telomerization of alkenes[43,70,71] and the Suzuki–Miyaura cross-coupling reaction.[72–75] These Pd-mediated processes have been shown to proceed through a d^{10}-Pd^0 center. In particular, recent work by Hartwig,[76,77] Cloke[78] and Nolan[79] on reactions involving Ar–X with the precatalyst $[Pd(NHC)_2]$ suggest dissociation of one NHC to generate a PdL fragment, which then undergoes oxidative addition of aryl halide (Scheme 2), a reaction pathway similar to that proposed in analogous phosphane systems.[76,80,81]



Scheme 2. Proposed mechanism for aryl amination.

While Amatore and Jutand[82] proposed an alternative route for phosphane palladium-catalyzed systems through an anionic three-coordinate complex of the type $[Pd^0L_2Cl]^-$ or $[Pd^0L_2(OAc^-)]$ as the active intermediate, detailed kinetic studies by Cloke suggest that oxidative addition reactions occur via a two-coordinate 14-electron [Pd^0-NHC] complex.[83] Furthermore, the ability of the oxidative addition products $[Pd(ItBu)_2(R\text{-}4\text{-}C_6H_4)Cl]$ (R = Me, CO_2Me, OMe) to reversibly dissociate free carbene according to Scheme 3 was demonstrated. The Pd–NHC dissociation enthalpy value of 25.57 kcal/mol^{-1} for $[Pd(ItBu)_2(Me\text{-}4\text{-}C_6H_4)Cl]$ was determined suggesting that the three-coordinate arylpalladium chloride product was the most likely intermediate in amination reactions.

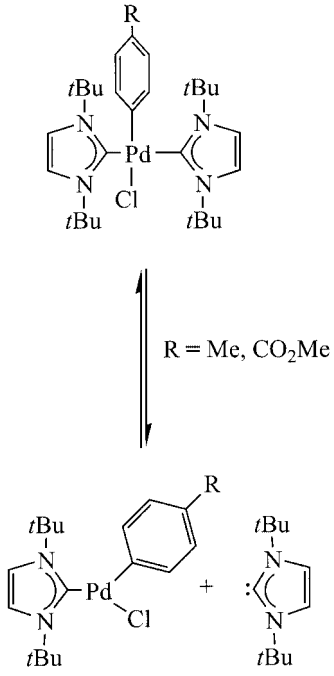
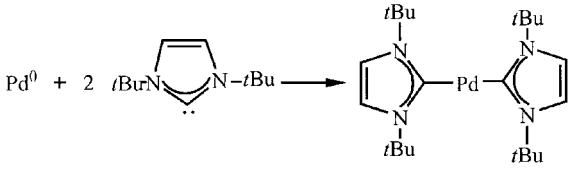
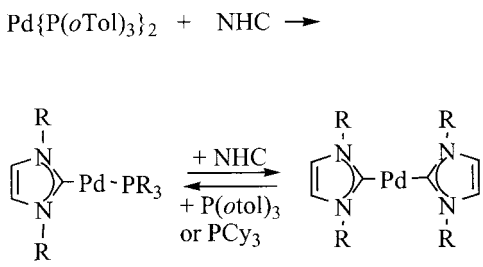


Scheme 3.

Studies by Hermann on the Heck reaction with $[Pd(NHC)_2]$ also suggest the intermediacy of this same Pd–L complex.[66] Hermann noticed short induction periods for Pd^{II} complexes on addition of a reducing agent. However, when Pd^0 was used no induction period was observed suggesting Pd^0 complexes enter in the catalytic cycle faster. Despite an increasing interest in this area over the last 5 years, there are only a few examples of fully characterized Pd^0-carbene complexes.[67,68,70,74,84–86] The isolation of two-coordinate unsaturated NHC Pd^0 complexes was first achieved by Cloke and co-workers.[84] While they prepared a homoleptic $[Pd(I\mathit{t}Bu)_2]$ (I*t*Bu = 1,3-di-*N*-*tert*-butylimidazol-2-ylidene) complex by co-condensation palladium vapor with *N*,*N*′-di-*tert*-butylimidazol-2-ylidene (I*t*Bu). This route was low yielding and limited to NHC ligands that could be sublimed [Equation (3)]. A ligand exchange reaction between $[Pd(PR_3)_2]$ (R = *o*-tolyl) and two equivalents of free NHC afforded $[Pd(NHC)_2]$ in higher yields. Furthermore addition of only one NHC equivalent to $[Pd(PR_3)_2]$ (R = *o*-tolyl) resulted in a mixed $[Pd(PR_3)(NHC)]$ species [Equation (4)]. Alternatively, the synthesis of mixed species can also be generated by mixing the $[Pd(NHC)_2]$ complex with free phosphane $[P(o\text{-tolyl})_3$, $PCy_3]$, suggesting some reversibility is associated with the reaction.[87,88]



(3)



(4)

The derivatives are readily prepared from reaction of [Pd(COD)(alkene)] (COD = cyclooctadiene) with the NHCs [1,3,4,5-tetramethylimidazol-2-ylidene (IMe) and IMes] to afford the complexes $[Pd(IMe)_2(alkene)]$ [alkene = maleic anhydride (MAH) (**12**), tetracyanoethylene (TCNE) (**13**)] (Figure 3).[67] Spectroscopic studies showed significant back-bonding of the olefin on the Pd center suggesting that the carbene ligands are strongly donating. Although **12** and **13** are envisaged as approaching Pd^{II} these complexes readily undergo oxidation reactions typical of Pd^0.

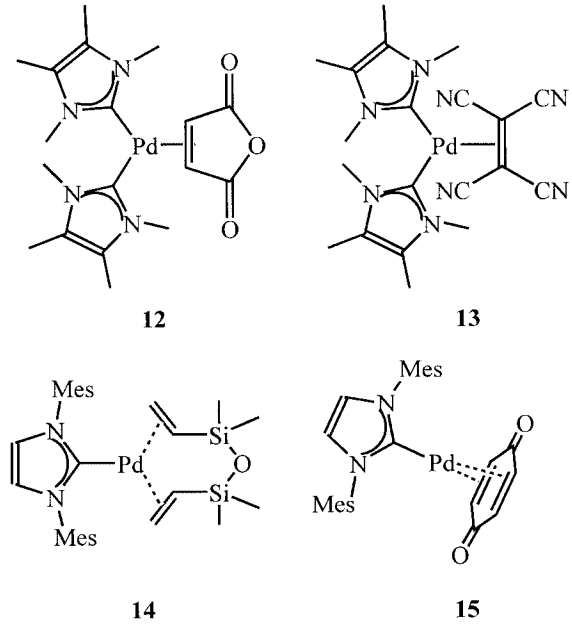


Figure 3. NHC–Pd^0 complexes

Reports of monocarbenepalladium(0) complexes without additional phosphane donors are scarce. Beller et al. recently synthesized a number of monocarbene(diolefin)palladium(0) complexes.[68,69] The addition of IMes to either palladium(0)–diallyl ether complex $[Pd_2(dae)_3]$ (dae = diallyl ether) in 1,1,3,3-tetramethyl-1,3-divinyldisiloxane or [(COD)Pd(quinone)] [quinone = *p*-benzoquinone (BQ), 1,4-naphthoquinone (NQ)] at low temperatures afforded the complexes [(IMes)Pd(dae)] (**14**), [(COD)Pd(BQ)] (**15**) and [(COD)Pd(NQ)] (**16**), respectively. Complexes **14**–**16** showed remarkable productivities and selectivity in a number of telomerization and Heck reactions, again concluding that the active species in carbene Pd-mediated organic transformations appears to be a Pd^0-carbene center.

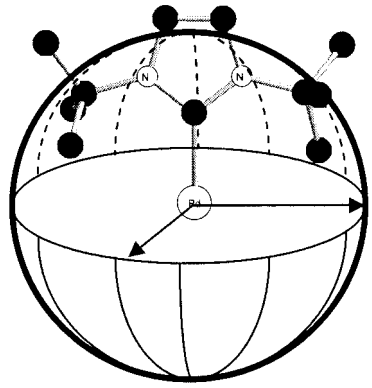
Steric Factors of NHC in Palladium(II) Complexes

Recently we reported the synthesis and cross-coupling catalytic reactivity of a family of [(NHC)Pd(allyl)Cl] complexes (Scheme 4).[50] These were synthesized either through addition of two equivalents of free carbene to $[Pd(allyl)Cl]_2$ under inert atmosphere (an adapted procedure from a protocol employed in the preparation of $[(PCy_3)Pd(allyl)Cl]$[89]) or by an in situ liberation of the imidazolium salts, followed by slow addition of $[Pd(allyl)Cl]_2$. The catalytic reactivity of these [(NHC)Pd(allyl)Cl] complexes varied substantially as a function of the identity of the NHC. While electronic differences were ruled out after crystallographic evidence showed little to no difference in the Pd–$C_{carbenic}$ bond lengths, this suggested that steric factors associated with the saturated and unsaturated imidazole backbone and side arm groups on the NHC were involved.

Prompted by this, we undertook a detailed investigation focusing on the steric factors of NHC ligands. The use of the classical "cone angle" steric factor described by Tolman for phosphane ligands[48] cannot be applied to the "fence"- or "fan"-type NHCs. Instead a wing-span model was conceptualized taking into account the wing-span angle (closest carbon substituent on the NHC) to the palladium center. This intial model was recently refined by imposing a sphere of radius (3 Å) centered around the palladium atom and the volume occupied by the ligand determined (Table 1) was then taken as the steric factor associated with any given NHC. Recently, a similar method was used to estimate the steric factor for a series of ruthenium-NHC complexes.[90]

By quantifying the steric demand of each NHC in these complexes, this has allowed a realistic comparison, not only between NHCs but also to tertiary phosphane ligands. The most sterically demanding I*t*Bu, IAd and SIPr ligands resulted in a decreased activity in the studied amination reaction. Furthermore IPr and IMes showed marked differences in reactivity compared to their saturated analoges SIPr and SIMes in spite of having almost identical structures. We associated this difference to the presence of two sp^3 carbon atoms inducing deformation of the dihydroimidazol-2-ylidene ring resulting in supplementary rotation of the aryl moieties around the N–C_{aryl} bond. As a consequence, the Pd center is more sterically protected, thereby presumably facilitating reductive elimination in Scheme 2.

Table 1. Buried volume calculated for [(NHC)Pd(allyl)Cl] complexes.



Complex	Buried volume[a] (%)	Buried volume[b] (%)
[(IPr)Pd(allyl)Cl]	26.10	24.99
[(IMes)Pd(allyl)Cl]	26.50	25.87
[(I*t*Bu)Pd(allyl)Cl]	33.37	32.25
[(ICy)Pd(allyl)Cl]	25.17	23.90
[(IAd)Pd(allyl)Cl]	33.56	32.20
[(SIPr)Pd(allyl)Cl]	33.03	32.27
[(SIMes)Pd(allyl)Cl]	27.49	26.91

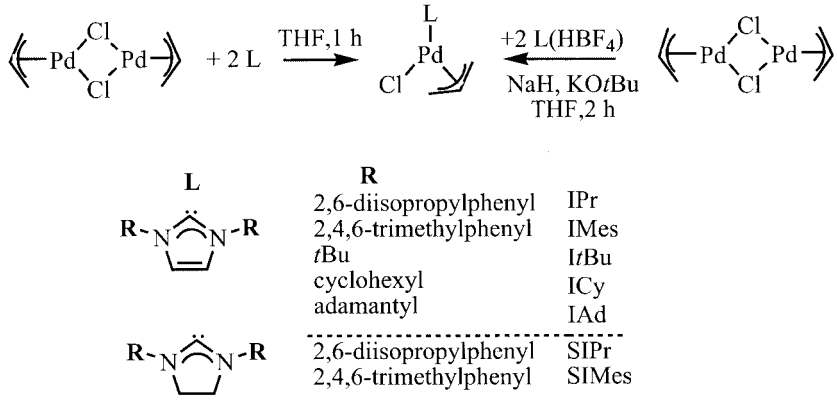
Carbonyl NHC Nickel Complexes

The importance of quantifying steric and electronic effects of ligands have had a major impact in the development of new and improved phosphane ligands for catalysis.[48] In the case of the NHC ligands surprising differences in catalytic activities of the corresponding metal catalysts have already been observed, but could not be rationalized or explained experimentally. Although many spectroscopic studies have indicated the similarities between NHCs and phos-



Scheme 4.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

phane, we felt that it was important to experimentally determine properties associated with the most widely used NHCs (depicted in Scheme 5). This would then allow for the direct comparison of NHC and phosphane steric/electronic properties.

The substitution reaction involving [Ni(CO)$_4$] and NHC ligands (IMes, SIMes, IPr, SIPr, ICy) gave rise to the expected, saturated complexes [Ni(CO)$_3$(IMes)], [Ni(CO)$_3$(SIMes)], [Ni(CO)$_3$(IPr)], [Ni(CO)$_3$(SIPr)], [Ni(CO)$_3$(ICy)] (Scheme 5), [Equation (5)].[49] However, the most bulky NHC ligands, I*t*Bu and IAd, led to the isolation of novel, unsaturated three-coordinate carbonyl nickel compounds [Ni(CO)$_2$(I*t*Bu)] and [Ni(CO)$_2$(IAd)].[91]

$$Ni(CO)_4 + NHC \xrightarrow[-CO]{} (NHC)Ni(CO)_3 \text{ or } (NHC)Ni(CO)_2 \quad (5)$$

X-ray characterization was obtained for most of the [Ni(CO)$_3$(NHC)] series and for both [Ni(CO)$_2$(NHC)] complexes (see below for discussion). Ball-and-stick diagrams of [Ni(CO)$_3$(IMes)] and [Ni(CO)$_3$(SIMes)] are presented in Figure 4 and [Ni(CO)$_3$(IPr)] and [Ni(CO)$_3$(SIPr)] in Figure 5. All complexes show the expected tetrahedral geometry around the metal center, with the Ni–C(NHC) bond lengths lying within the range of 1.96–1.98 Å {[(Ni(CO)$_3$(IMes)] 1.971(3) Å; [Ni(CO)$_3$(SIMes)] 1.960(2) Å; [Ni(CO)$_3$(IPr)] 1.979(2) Å; [Ni(CO)$_3$(SIPr)] 1.962(4) Å}. The saturated NHC ligands SIMes and SIPr showed slightly shorter bond lengths than their corresponding analogues containing the unsaturated NHC ligands. However, all the Ni–NHC distances are in good accordance with their exclusive σ donor characteristics.[67,92] As observed in other crystallographic studies on saturated NHC species, the presence of two sp^3 carbon atoms in the heterocyclic ring imidazole backbone, results in torsion angles of 6.4° {for [Ni(CO)$_3$(SIMes)]} and 2.6° {for [Ni(CO)$_3$(SIPr)]}. Surprisingly, the former value is significantly lower than the one for free SIMes (13.4°). The unsaturated NHCs have the aryl substituents disposed at an angle of 90° (+/–10°) with respect to the imidazole backbone plane.

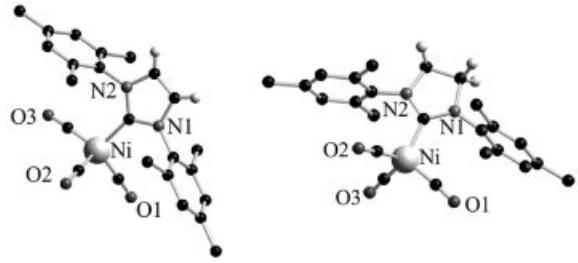


Figure 4. Ball-and-stick representation of [Ni(CO)$_3$(IMes)] (left) and [Ni(CO)$_3$(SIMes)] (right).

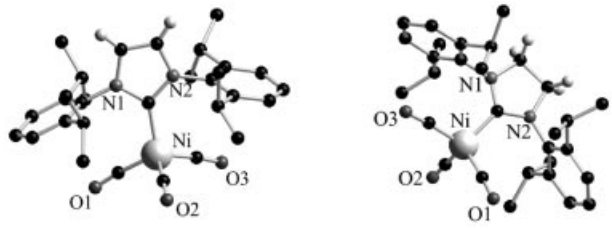

Figure 5. Ball-and-stick representation of [Ni(IPr)(CO)$_3$] (left) and [Ni(SIPr)(CO)$_3$] (right).

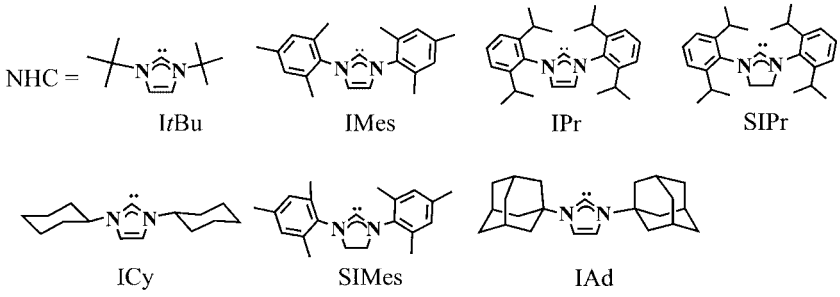
The CO infrared frequencies obtained for the [Ni(CO)$_3$(NHC)] complexes confirmed that N-heterocyclic carbenes are better σ donors than tertiary phosphanes (Table 2). Unlike the substantial electronic differences seen in phosphane ligands when moving from ary- to alkyl-substituted P ligands, the overall electronic difference in NHC data was relatively small. Expectably the NHC data showed that ICy was the most basic ligand due to its alkyl substitution. Furthermore, the saturated NHC ligands, SIMes and SIPr, were found to be slightly less electron-donating than their unsaturated analogues IMes and IPr. This supports our recently observed trends in the relative bond disruption enthalpies of ruthenium complexes involving the aforementioned ligands.[90] These experimental results clearly contradict the common assumption that saturated NHC ligands are more electron-donating and that metal complexes incorporating them perform better in catalysis for this reason. Our experimental data suggest that electronic factors are unlikely to play a major role in the differences in catalytic activity, or if this is indeed the case, substantial differences



Scheme 5.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

take origin in extremely small electronic differences within the NHC ligand class.

Table 2. CO infrared frequencies in $[Ni(CO)_3(L)]$ complexes.

Complex	ν_{CO} [A_1 (cm^{-1})]; CH_2Cl_2	ν_{CO} [E (cm^{-1})], CH_2Cl_2
$[Ni(CO)_3(IMes)]$	2050.7	1969.8

$[Ni(CO)_3(PPh_3)]$[a]	2068.9	1990

[a] Taken from ref.[48]

As previously mentioned the most bulky NHC ligands, I*t*Bu and IAd, led to the isolation of novel, unsaturated 16-electron three-coordinate carbonyl nickel compounds $[Ni(CO)_2(ItBu)]$ and $[Ni(CO)_2(IAd)]$ (Figure 6).[91] While carbonyl-free, three-coordinate Ni^0 complexes are not uncommon,[93–95] such unsaturated carbonyl nickel systems are exceedingly rare and the only example known in literature has been isolated as a mixture of $[Ni(CO)_3(L)]$ and $[Ni(CO)_2(L)]$ compounds.[96–102] The closest carbon atom on one of the side-arm R groups in $[Ni(CO)_2(NHC)]$ appears to approach the metal center. However, the distances lie outside the range seen for agostic interactions.[103,104] In fact, within the series of NHCs studied these two ligands are the only ones to contain α-carbon atoms in the side chains that are bound to three additional C atoms. While the aromatic IMes, SIMes, IPr and SIPr as well as ICy can minimize steric interactions with the metal center by orientation of their R-groups perpendicularly to the imidazole plane, such an arrangement cannot be reached for IAd and I*t*Bu.

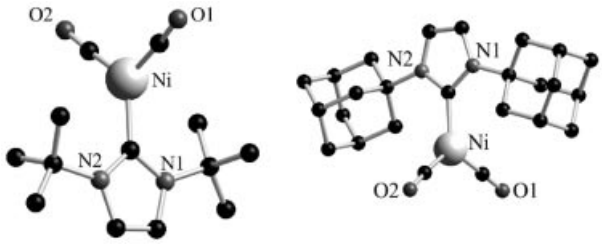

Figure 6. Ball-and-stick representation of $[Ni(CO)_2(ItBu)]$ (left) and $[Ni(CO)_2(IAd)]$ (right). Hydrogen atoms are omitted for clarity.

According to Equation (5), Ni–NHC bond energies could be determined if the reaction was reversible. For saturated complexes $[Ni(CO)_3(NHC)]$ no reactivity was observed, despite applying high CO pressures, showing these complexes to be inert towards displacement of NHC and carbonyl ligands. In contrast, the unsaturated analogues were highly reactive towards ligand substitution and oxidative addition of substrates. Reacting $[Ni(CO)_2(ItBu)]$ and $[Ni(CO)_2(IAd)]$ with 1 atm of CO resulted in the quantitative formation of $[Ni(CO)_4]$,[105] without any formation of $[Ni(CO)_3(NHC)]$ (NHC = I*t*Bu, IAd) complex and thus, allowed the determination of Ni–NHC bond dissociation energies (Table 3).

Table 3. CO and L BDE values, in kcal/mol, in the $[Ni(CO)_2(L)]$ and $[Ni(CO)_3(L)]$ complexes, L = NHC ligand or phosphane, and calculated $\%V_{Bur}$ of the free NHC and PR_3 ligands.

			BDE of L in Ni(CO)$_2$(L)	$\%V_{Bur}$
I*t*Bu	13.3 (15.6)[a]	24.0	44.3	37
SI*t*Bu	10.3 (13.1)[a]	21.8	45.1	38
IAd	7.6 (14.1)[a]	20.4	46.5	37
IMes	28.3 (27.2)[a]	41.1	46.5	26
SIMes	26.8 (26.4)[a]	40.2	47.2	27
IPr	26.7 (27.2)[a]	38.5	45.4	29
SIPr	25.6 (25.8)[a]	38.0	46.1	30
ICy	27.0 (26.1)[a]	39.6	46.3	23
PH_3	30.7	22.7	25.7	17
PPh_3	30.4	26.7	30.0	22
$PtBu_3$	27.4	28.0	34.3	30

[a] Values in brackets obtained with the QM/MM technique.

DFT-calculated BDE values indicated that CO is weakly bound to the SI*t*Bu-, Si*t*Bu- and IAd-based complexes (BDE around 10 kcal/mol). However, CO is much more strongly bound to the IPr, SIPr, ICy, IMes and SIMes complexes (BDE greater than 25 kcal/mol). These results are in good qualitative agreement with the experimental fact that $[Ni(CO)_2(NHC)]$ complexes are observed for NHC = IAd and I*t*Bu, while $[Ni(CO)_3(NHC)]$ complexes are observed for the other NHC ligands. Calculated BDE of the NHC ligands showed a similar pattern, with BDE of NHC ligands in the SI*t*Bu-, Si*t*Bu- and IAd-based $[Ni(CO)_3(NHC)]$ complexes roughly 20 kcal/mol lower than the BDEs of the NHC ligand in the IMes, SIMes, IPr, SIPr and ICy complexes. Furthermore, the calculated BDE of the NHC ligand in $[Ni(CO)_2(ItBu)]$ and $[Ni(CO)_2(IAd)]$ (46.5 and 44.3 kcal/mol, respectively) are in excellent agreement with the experimental values (43 ± 3 and 39 ± 3 kcal/mol, respectively). The BDE values were experimentally tested by treatment of $[Ni(CO)_2(ItBu)]$ with one equivalent of IAd [Equation (6)]. Quantitative formation of $[Ni(CO)_2(IAd)]$ was observed with no detection of the saturated, but sterically disfavored, $[Ni(CO)_2(IAd)(ItBu)]$ species.

$$Ni(ItBu)(CO)_2 + IAd \rightleftharpoons Ni(IAd)(CO)_2 + ItBu \quad (6)$$

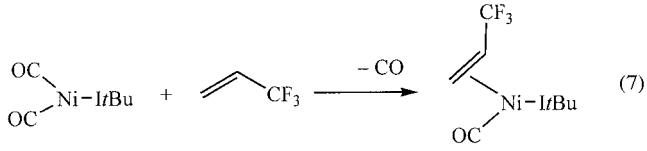
In view of the wing-span model seen to describe the steric influence of NHC ligands for palladium (see above), we have now used DFT-optimized geometry studies to extend this model for a greater number of free NHC ligands and again positioned a putative metal atom at 2 Å from the coordinating C atom. The volume as a sphere centered on the metal was measured, buried by overlap with atoms of the various NHC ligands, $\%V_{Bur}$. The volume of this sphere represented the space around the metal atom that must be shared by the different ligands upon coordination. For example bulkier NHC ligands require a larger occupied sphere volume ($\%V_{Bur}$). A list of $\%V_{Bur}$ values is presented in Table 3. The rather different values of $\%V_{Bur}$ between the

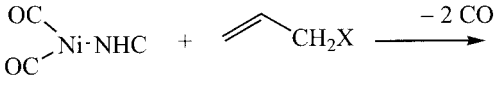
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

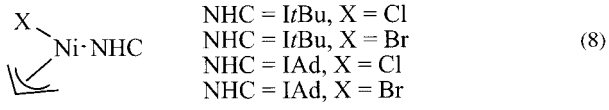
NHC ligands is in qualitative agreement with the different BDEs we calculated.

Unlike data obtained for NHC, the similar carbonyl values for the phosphane-based systems (Table 3) clearly indicated that the steric factor's influence is insignificant in determining the stability of the $[Ni(CO)_3(PR_3)]$ systems. Furthermore, comparison of the BDE of the CO values between the less bulkier NHC systems and the phosphane systems suggest a high stability of the phosphane-based tricarbonyl complexes. The remarkably higher BDE of the NHC–Ni systems vs. the BDE of the PR_3-Ni complexes is in good agreement that NHC ligands bind more tightly to transition metals.

Since the difference between $[Ni(CO)_3(NHC)]$ and $[Ni(CO)_2(NHC)]$ complexes was attributed to steric factors alone, a substitution reaction between $[Ni(CO)_2(NHC)]$ (I*t*Bu, IAd) and two equivalents of smaller NHC ligands, IMes and ICy, afforded the saturated complexes of general composition $[Ni(CO)_2(NHC)_2]$.[53] Other reactions showed that substitution of one carbonyl ligand when reacting $[Ni(CO)_2(NHC)]$ with trifluoropropene was possible and selectively afforded the unsaturated $[Ni(NHC)(CO)(C_3H_3F_3)]$ compound [Equation (7)]. Furthermore both CO ligands were displaced when $[Ni(CO)_2(NHC)]$ was treated with either allyl chloride or allyl bromide [Equation (8)]. The resulting allyl halide complexes of general formula $[NiX(C_3H_5)(NHC)]$ were obtained through oxidative addition of these substrates to the Ni^0 center.[49]



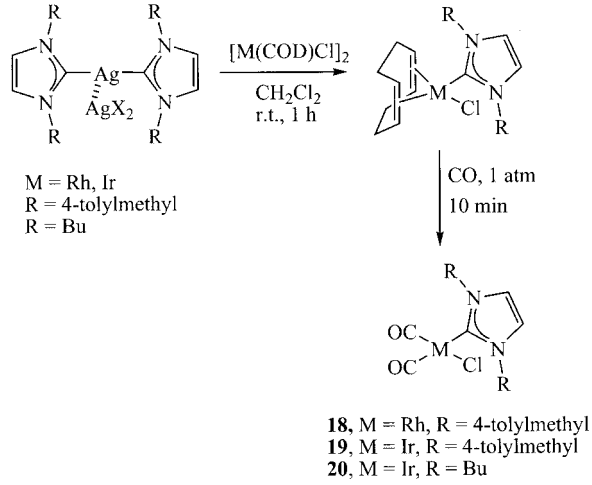




Overall, the performed DFT calculations on the series of $[Ni(L)(CO)_2]$ and $[Ni(L)(CO)_3]$ compounds (L = NHC, PR_3) are supported by experimental results, with the calculations showing that both $[Ni(IAd)(CO)_3]$ and $[Ni(I*t*Bu)(CO)_3]$ are inherently unstable as seen in the BDE values for both the CO and NHC ligands. The lower PR_3–Ni BDE values compared to NHC–Ni are in agreement with the common assumption that NHC ligands bind more tightly to metals. The establishment of a method to quantify the steric factors characterizing NHCs and phosphanes has at last been realized, finally enabling a direct comparison between these ligand classes. The values for the different ligands are measured as buried volume ($\%V_{bur}$). All of these values obtained are in perfect agreement with experimental data, showing that IAd and I*t*Bu are more bulky than $P(tBu)_3$ and other PR_3 and NHC ligands.

NHC Late-Transition Metal (LTM) Carbonyl Complexes

A recent study by Crabtree et al. also confirmed the stronger electron-donor properties of NHC ligands.[52] In lieu of using the synthetic approach of direct complexation of the free NHC to rhodium or iridium centers, a transmetalation reaction from the corresponding silver NHC salt to $[M(COD)Cl]_2$ (M = Rh, Ir) afforded the complexes [(TMIY)Rh(COD)Cl] [TMIY = 1,3-bis(4-tolylmethylimidazolin-2-ylidene], [(TMIY)Ir(COD)Cl] and [(IBu)Ir(COD)Cl] (IBu = 1,3-dibutylimidazolin-2-ylidene) in high yield (Scheme 6). COD was easily displaced from these complexes by CO (1 atm) to give the corresponding dicarbonyl compounds $[(TMIY)RhCl(CO)_2]$ (**18**), $[(TMIY)IrCl(CO)_2]$ (**19**) and $[(IBu)IrCl(CO)_2]$ (**20**) with CO (atm).



Scheme 6.

A mutually *cis* geometry of the carbonyl groups for complexes **18**–**20** was proposed despite ^{13}C NMR spectroscopy revealing two inequivalent CO carbon atoms. ^1H NMR spectroscopy supported the *cis* geometry with diastereotopic N–CH_2 protons. Low-temperature NMR studies on **18** and **19** showed that the metal–carbon bond had restricted rotation. The activation free energies for metal–carbene bond rotation in **18** and **19** [$\Delta G^{\ddagger}$(kcal·mol) 16.7 and 15.7, respectively] closely agreed to those of Doyle and Lappert[106] on **21** ($\Delta G^{\ddagger}$ = 16 kcal/mol) (Figure 7). Previous studies have strongly indicated that no electronic rotation barrier exists for NHCs. For the sterically crowded systems (**22**,[107] **23**[108] and **24**[109]) no M–C rotation at room temperature was evident. However, studies by Ender and Gielen[110] on **25** and **26** directly supported a steric origin to the rotation barrier, with **25** showing no rotation at room temperature, whereas a lower rotational barrier was observed for **26**.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

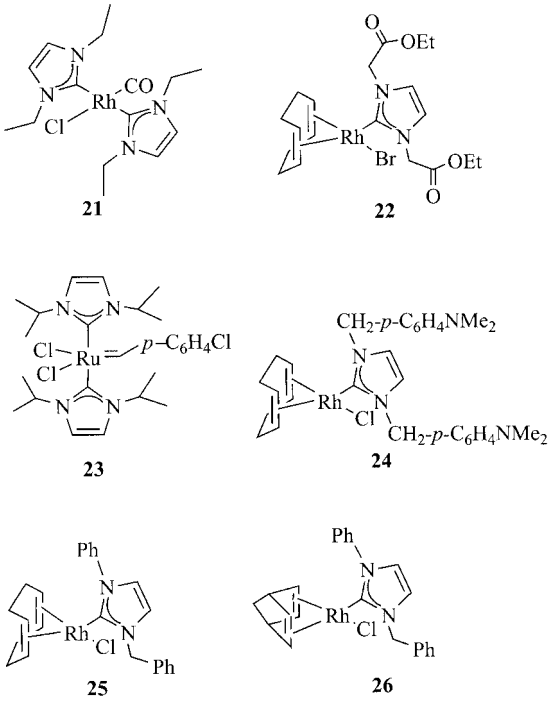


Figure 7. NHC complexes containing a low-energy rotational barrier.

Compounds **19** and **20** were investigated using FT-IR spectroscopy. A plot (Figure 8) of the average ν(CO) values for **19** and **20** together with the ν(CO) data for structurally analogous phosphane compounds $[Ir(PR_3)Cl(CO)_2]$[111,112] were plotted vs. the Tolman electronic parameter (TEP). Also included are the ν(CO) frequencies obtained for the $[Ni(CO)_3(NHC)]$ system described above. The plot shows a good linear correlation on exclusion of phosphite ligands. The IR data indicate that the NHCs listed are more electron donating than even the most basic phosphane ligand. This correlates well to other studies by Crabtree,[113] and with our own studies on $[Ni(CO)_x(NHC)]$ (x = 2,3) systems, in addition to the already discussed calorimetric investigation on ruthenium–NHC compounds.[90] Furthermore, a qualitative comparison of IR data obtained with our rhodium–NHC compound also supports this conclusion.[114]

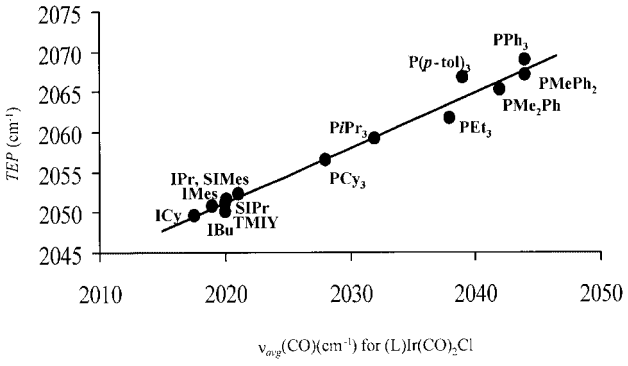

Figure 8. Plot of average ν_{CO} for $LIr(CO)_2Cl$ (L = NHC, PR_3) vs. ν_{CO} for $LNi(CO)_3$, the Tolman electronic parameter (TEP).

Abnormal Binding Modes for NHC Ligands

There have been an increasing number of reports of unexpected late-transition metal products with NHC ligands ranging from unusual binding modes to oxidative addition through C–H bond activation of alkyl side-arm substituents suggesting that these spectator ligands are much less innocent than originally thought. While previous examples in this review show normal metal binding at C-2 (Figure 9, **I**), abnormal C-5(4) (Figure 9, **II**) binding has now been reported.[115–118] The C-5(4) binding mode was previously considered as an unlikely binding possibility because free carbenes isolated by Arduengo et al.[119] always adopted a C-2 binding mode (Figure 9, **III**) with adjacent nitrogen atoms considered as stabilizing both the free carbene (Figure 9, **I**) and the M–C bond.

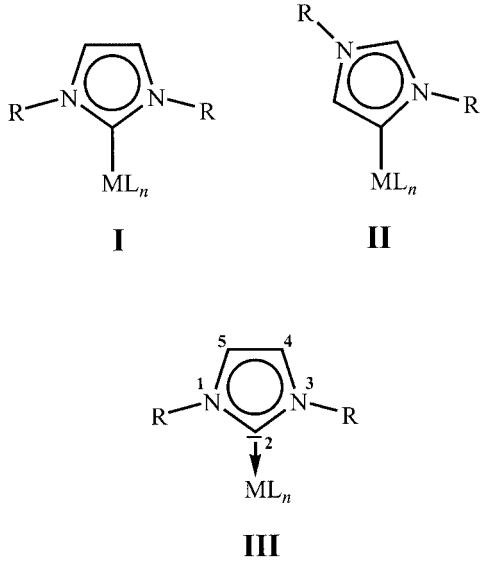

Figure 9. Alternative binding modes of NHC.

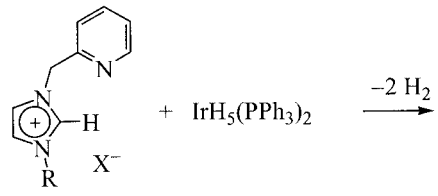
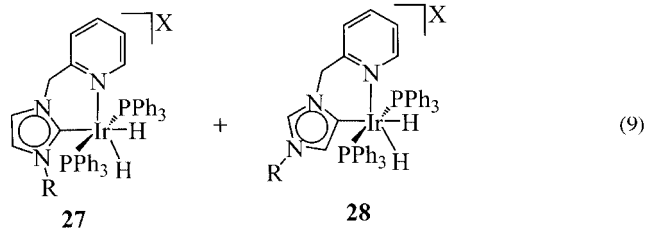
Nonclassical carbene formation has been obtained initially from mixing pyridine-substituted imidazolium salts (py-NHC) with $[IrH_5(PPh_3)_2]$ in refluxing C_6H_6. Subsequent loss of H_2 afforded complexes of general composition $[(py\text{-}NHC)IrH_3(PPh_3)_2]$ in moderate yield [Equation (9)].[115] The isolation of these first examples of C-4(5)-bound carbenes was surprising since not only **II** is more stable than **III**, but theoretical and density functional calculations[120] predict that binding at the C-4(5) position can be thermodynamically less favored (23.3 kcal/mol) than C-2 coordination.

In general, it is thought that C-4(5) binding is favored as a result of lower steric congestion around the metal center. Since the C-4(5) binding mode has only been isolated to date using limited variation in the imidazolium salts, the nature of the counterion (X = Br, BF_4, PF_6, SbF_6; R = Me, *i*Pr) was studied and indicated that it has a pronounced effect on the kinetic activity of C-2 vs. C-5(4) binding switching the kinetic product between **27** and **28** [Equation (9)]. The use of bromide afforded almost quantitative yields of C-2-bound iridium(III) NHC product **27**, while SbF_6 re-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

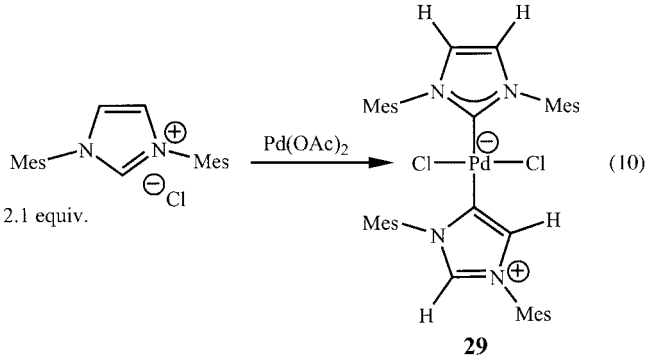




(9)

sulted in the formation of the abnormal C-4(5)-bound **28** as the major product.[121]

Until recently C-4(5) binding was only linked to chelating N-heterocyclic carbenes, and as a result it was reasoned to be mainly due to steric effects.[116] Lebel et al. recently isolated a [(IMes)(IMes′)$PdCl_2$] complex containing both C-2 and C-4(5) NHC ligands in high yield by reaction of palladium(II) acetate and the imidazolium salt IMes·HCl [Equation (10)] under standard reaction conditions (dioxane, 80 °C, 6 h).[118] In comparison, the C-2 ligated [$(IMes)_2PdCl_2$] could be obtained from $PdCl_2$, Cs_2CO_3, and 2 equivalents of IMes·HCl in high yield. However, complex **29** was found to have greater catalytic activity for Suzuki–Miyaura and Heck coupling reactions suggesting that this binding mode results in complexes with enhanced reactivity.



(10)

Recent studies by Crabtree et al.[117] on the electronic and steric properties of this abnormal C-4(5) coordination mode for a series of NHCs (in which the C-2 position has been blocked in one case) have allowed a useful comparison between the abnormal to the normal binding modes. Monodentate abnormal NHC iridium(III) complexes **30** and **31** were synthesized by refluxing their corresponding simple unsymmetrical imidazolium salts, pyridine and [$IrH_5(PPh_3)_2$] in tetrahydrofuran (Figure 10).

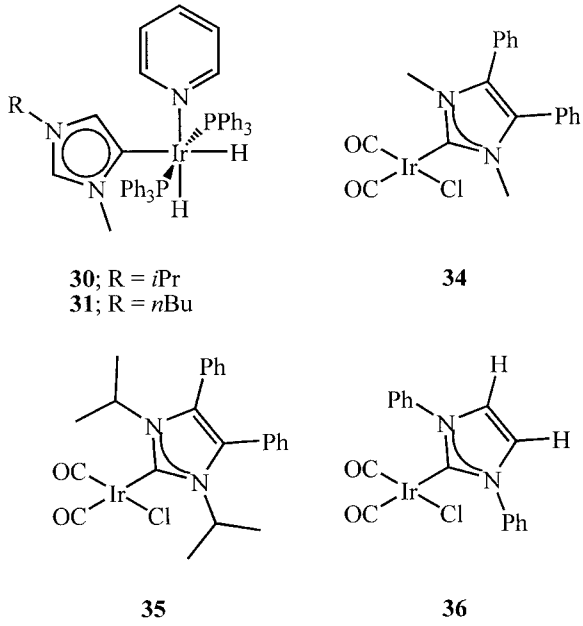


Figure 10. Monodentate abnormal (**30**, **31**) and normal (**34**–**36**) iridium complexes.

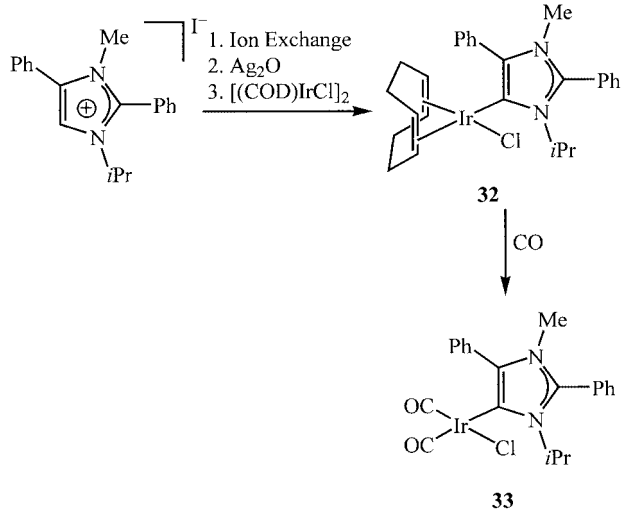
A more sophisticated route was developed by blocking the C-2 and C-4(5) positions with a phenyl group [NHC = 1-isopropyl-3-methyl-4,5-diphenylimidazolin-2-ylidene (PMINHC)] to generate the C-4(5) metal complex.[117] A transmetalation reaction between the silver salt of PMINHC and [$(COD)IrCl]_2$ resulted in the C-4(5)-bound complex [(PMINHC)Ir(COD)Cl] (**32**). Reaction of **32** with CO yielded [$(NHC)Ir(CO)_2Cl$] (**33**) (Scheme 7).



Scheme 7.

A plot of the IR ν(CO) measurements on the abnormal C-4(5)-bound derivative **33** (Figure 11) indicated that the NHC is substantially more electron donating than C-2-bound analogues (**34**–**36**, Figure 12) in addition to ν(CO) data for the [$(NHC)Ni(CO)_3$] system described above.[49] However, more data is clearly warranted to quantify the stronger donor properties of this C-4(5)-bound carbene.

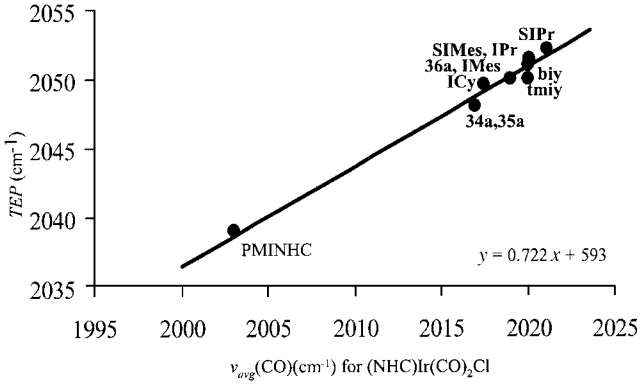

Figure 11. Plot of average ν_{CO} for (NHC)Ir(CO)$_2$Cl vs ν_{CO} for (NHC)Ni(CO)$_3$, the Tolman electronic parameter (TEP).

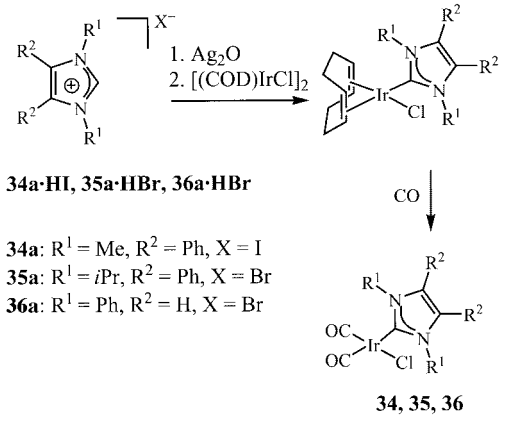

Figure 12. Preparation of (NHC)Ir(I) dicarbonyl complexes.

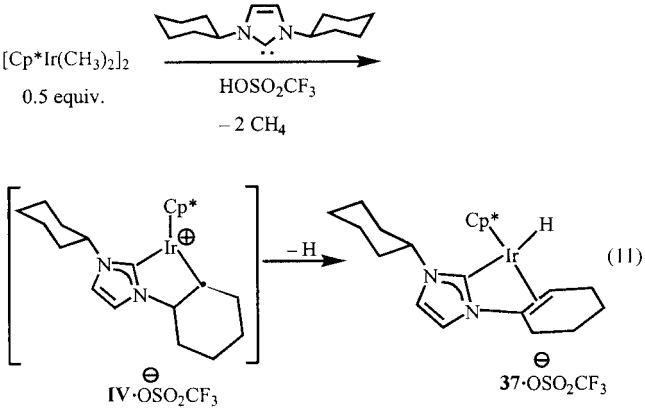
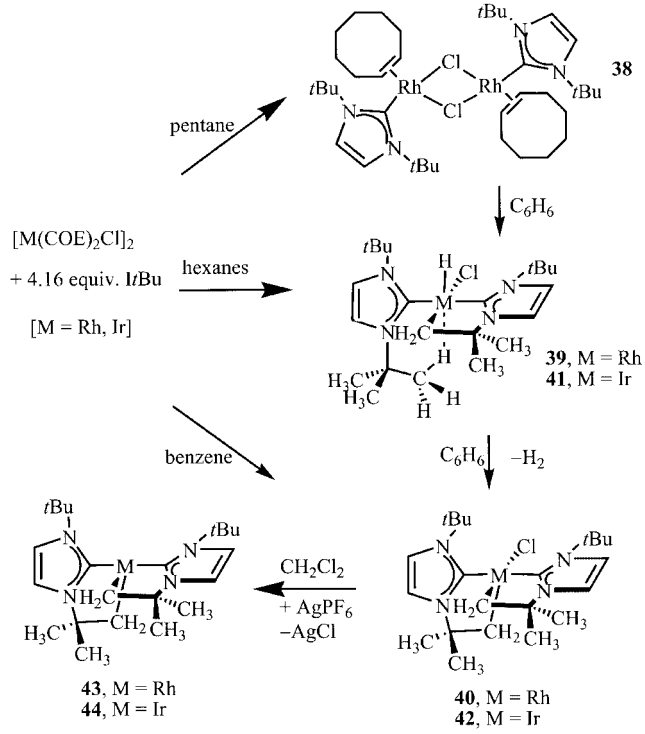
NHCs with late-transition metals have been found to undergo facile intramolecular C–H bond activation,[114,122–130] and in one example reported by Whittlesey et al. under more forcing conditions C–C bond activation.[131] In all but three of these cases, *N*-substituted phenyl and mesityl groups were present. Herrmann[132] has reported that ICy undergoes C–H bond cleavage by [(Cp*)IrCl$_2$]$_2$ (Cp* = η^5-C$_5$Me$_5$) [β-hydride elimination resulted in the rapid formation of 1-(2-cyclohexenyl)-3-cyclohexylimidazol-2-ylidene (L′) with no direct activation product observed (**IV**)] affording [Cp*(L′)IrH]$^+$(OSO$_2$CF$_3^-$) (**37**) [Equation (11)].



We have very recently described[45] the solvent-selective interaction of I*t*Bu [I*t*Bu = *N*,*N*-di(*tert*-butyl)imidazol-2-ylidene] with [Rh(COE)Cl]$_2$ (COE = *cis*-cyclooctene), which resulted in the isolation of [Rh(COE)(I*t*Bu)Cl] (**38**) as well as two precursors, [Rh(H)Cl(I*t*Bu′)(I*t*Bu)] (**39**) and [Rh(I*t*Bu′)$_2$Cl] (**40**), en route to a unique product by a double cyclometalation process. Analogous reactions with [Ir(COE)Cl]$_2$ led exclusively to the two *en route* precursors [Ir(H)Cl(I*t*Bu′)(I*t*Bu)] (**41**) and [Ir(I*t*Bu′)$_2$Cl] (**42**) with no observation of a [Ir(COE)(I*t*Bu)Cl]$_2$ species using hydrocarbon solvents (Scheme 8).[47] Abstraction of the chloride ion from [M(I*t*Bu′)$_2$Cl] (**40**, **42**) allowed the preparation of the unprecedented "naked" *cis*-divacant four coordinate 14-electron d^6-ML$_4$ Rh^{III} and Ir^{III} complexes of the type [M(I*t*Bu′)$_2$](PF$_6$) [M = Rh (**43**), Ir (**44**)]. These compounds are neither stabilized by agostic interactions, nor by a change in spin state as observed very recently by Caulton et al. for a Ru^{II} compound.[133] Interestingly, the chloride containing 16-electron precursors (**40**, **42**) give complexes that are stabilized by agostic interactions.



Scheme 8.

Further examination of the coordinatively unsaturated cationic 14-electron complexes [Rh(I*t*Bu′)$_2$]PF$_6$ (**43**) and [Ir(I*t*Bu′)$_2$]PF$_6$ (**44**) and of their neutral 16-electron analogues RhCl(I*t*Bu′)$_2$ (**40**) and IrCl(I*t*Bu′)$_2$ (**42**) by the small linear CO ligand generated the six-coordinate saturated complexes and as a result confirmed the unsaturated nature of the "precursor" complexes **40, 42**–**44** (Scheme 9).

The unusual stability of the unsaturated [M(I*t*Bu′)$_2$Cl] and [M(I*t*Bu′)$_2$](PF$_6$) compounds was attributed to the elec-

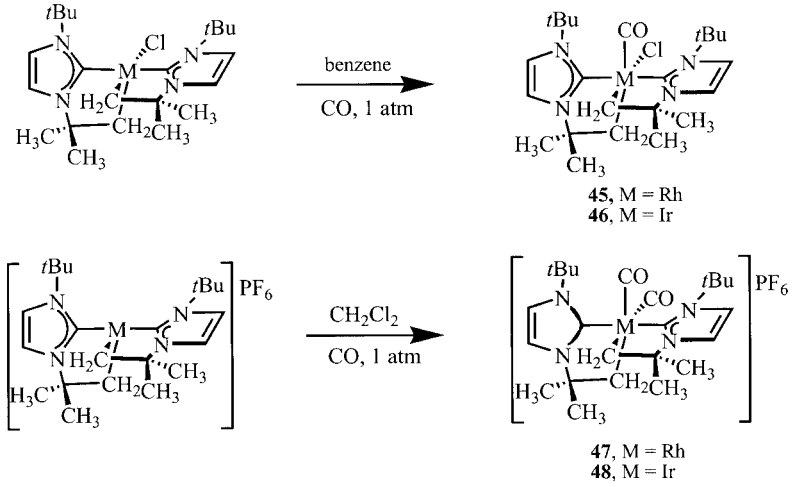
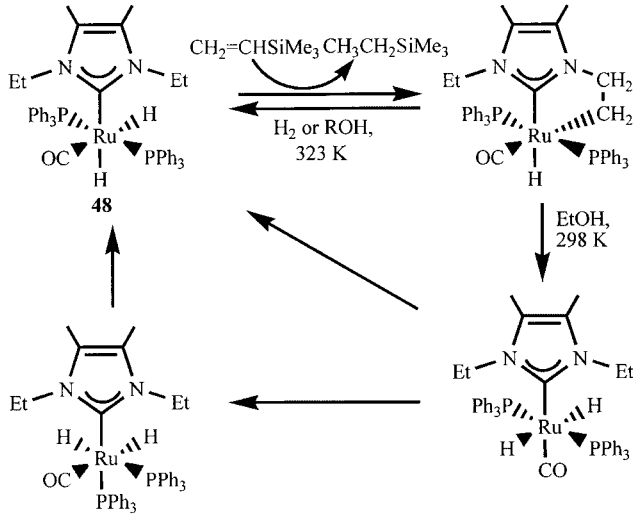


Scheme 9.

tron-donating nature of the all carbon-based NHC ligands surrounding the metals. Detailed DFT studies suggested that not only NHC ligands are simple σ donors but the π orbitals on the NHC ring can be deeply involved in the bonding of the metal. A similar finding was recently published by Meyer,[134] where NHCs were found to accept electron density from electron-rich metals through a d-π* back-donation scheme. Conversely, our study indicates that NHCs can also donate electron density to electron-poor metal atoms through a π-d donation scheme. The stabilization offered through this flexibility might certainly have important implications in catalysis explaining perhaps slower decomposition of catalytically active highly unsaturated species and increased thermal stability in comparison to analogous LTM-PR_3 systems.

Whittlesey and co-workers recently described a rare example of C–H bond activation of an alkyl-substituted N-heterocyclic carbene by thermolysis of $[Ru(IEt_2Me_2)(PPh_3)_2(CO)H_2]$ [IEt_2Me_2 = 1,3-bis(ethyl)-4,5-dimethylimidazol-2-ylidene] (**48**) in the presence of CH_2=$CHSiMe_3$



Scheme 10.

(Scheme 10).[135] The process interestingly proved to be reversible by H_2 or alcohols to afford different isomers of the starting dihydride complex.

Conclusions

The unique stabilization of coordinatively unsaturated metal centers by N-heterocyclic carbene ligands has now become well recognized. Many of these complexes have been shown to catalyze a variety of organic transformations through the stabilization of low-valent metal species. It is now evident from thermochemical, structural and infrared studies studies that NHCs are more electron donating and sterically more demanding than the most basic/bulky phosphane ligands. As a result, the stabilization of many reactive intermediates, which have been elusive so far in phosphane chemistry, has helped elucidate the precise effects of the NHC ligand in catalytic systems. Furthermore the versatility of NHCs has only begun to be realized with C-2 vs. abnormal C-4(5) binding modes possible in addition to facile intramolecular C–H activation of the nitrogen substituents with LTM. In this report, we have presented a short illustration of a selected number of important observations dealing with NHCs, it is our belief that this ligand family will continue to surprise.

Electro-Conducting Properties of Charge-Transfer Salts Based on Cationic and Anionic Platinum Dithiolenes − Crystal Structure of $[Pt(Me_2pipdt)_2][Pt(dtcr)_2]$

Paola Deplano,*[a] Maria Laura Mercuri,[a] Luciano Marchiò,[b] Luca Pilia,[a] Marco Salidu,[a] Angela Serpe,[a] Francesco Congiu,[c] and Samuele Sanna[c]

Dedicated to Prof. Emanuele F. Trogu on the occasion of his recent retirement

Keywords: Sulfur ligands / Platinum / Charge-transfer / Conducting materials

The structure/property relationship of the following CT salts, $[M(R_2pipdt)_2][M(mnt)_2]$ (where R_2pipdt = *N*,*N*′-dialkylpiperazine-2,3-dithione; mnt = maleonitrile-2,3-dithiolate), [R = Me, M = Pd (**1a**) and Pt (**2a**); R = Et, M = Pt (**2b**)],which were previously characterised, and $[Pt(R_2pipdt)_2][Pt(dtcr)_2]$ [R = Me, (**3a**); R = Et, (**3b**); dtcr = 4,5-disulfanylcyclopent-4-ene-1,2,3-trionate, known as dithiocroconate] are investigated here. These salts show strong near IR CT bands and semiconducting behaviour. The structural features of **3a** are similar to those found for **2a**: approximately square planar $[Pt(Me_2pipdt)_2]$ dications and regular square planar $[Pt(dtcr)_2]$ dianions form an infinite anion–cation one-dimensional stack along the *c* axis with a Pt···Pt *c*/2 distance of 3.408 (1) Å. In **3a**, a net of weak interactions between the N and O atoms of the cation and of the anion contributes to the alignment of **3a** in the stack. However, these interactions do not overcome the less favourable redox properties of the components, that is, promoting CT interactions with respect to the corresponding mnt salts. The specific electrical conductivity of pressed powder pellets ranges from 10^{-11} to $10^{-5}\ \Omega^{-1}cm^{-1}$ at room temperature, follows the Arrhenius law with activation energies in the range of 0.2–0.6 eV, and is related to the driving force of the electron transfer. Preliminary photoconductivity measurements performed on the two relatively more conducting samples, **2a** and **2b**, show a gain in current during illumination, similarly to that observed in organic–inorganic photoconductor CT salts $C[ML_2]$ (C^{2+} is 2,2′ or 4,4′-bipyridinium or similar derivatives, L^{2-} = dithiolato), which have been extensively investigated by the Kisch group. Crystal data for **3a**: triclinic, $P\bar{1}$; $Z = 2$; $T = 293(2)$ K; $a = 8.683(2)$ Å, $b = 14.009(5)$ Å, $c = 6.815(2)$ Å; $\alpha = 100.58(4)°$, $\beta = 98.99(3)°$, $\gamma = 100.69(3)°$. *R* indices (all data) $R1 = 0.0516$, $wR2 = 0.1412$.

Introduction

Among several applications in the molecular material field,[1] anionic, square planar d^8 metal bis-dithiolene complexes have been used to prepare ion-pair CT photoconducting salts of the type $\{(C^{2+})[ML_2]^{2-}\}$, (M = Ni, Pd, Pt; L^{2-} = dithiolato) where C^{2+} is a redox-active organic donor such as 4,4′ and 2,2′ bipyridinium derivatives.[2] An extensive investigation on these organic–inorganic CT salts by Kisch's group has led to an understanding of the main factors that affect the structure/property relationship. The supramolecular interaction between the ionic components is reflected by the presence of a strong CT band in the diffuse reflectance spectra of these salts, which exhibit electrical semiconducting behaviour. By applying the "Marcus-Hush model",[3] a linear correlation between thermal and optical electron transition and a linear correlation between the specific electrical conductivity and the free activation energy for the electron transfer is observed. Moreover these CT salts show interesting photoconducting properties. It has been shown that the planarity of the components and their capability to undergo minor structural changes on electron transfer are crucial factors for improving the CT interaction. Thus a rational synthesis of the desired products would allow us to tune the conductivity by a proper selection of the component ions. This prompted us to use metal dithiolenes as the two components of CT salts, extending the investigation from the largely investigated fully organic and organic–inorganic systems to the less common fully inorganic ones.[4] In fact, in d^8 metal dithiolenes the planarity of the central core is maintained by the metal atom which imposes the square planar geometry, while the electronic properties depend on the distribution of the π electrons in the $(C_2S_2)_2M$ core (14 electrons of which four

belong to the metal in the uncharged complex).[5] These species have a rich redox chemistry and the nature of their most accessible status is indicative of the basic *push* or *pull* character of the ligand. The nature of the substituents at the C_2S_2 moieties determines the stabilization of the ML_2 complex with a charge that varies between +2 and –2. The latter limits are due to the fairly isolated frontier MOs (HOMO and LUMO in the uncharged complex), which have π character and can be either empty or populated. In general, C_2S_2 π-donor substituents (*push*) in symmetric complexes raise the energy of both the HOMO and the LUMO so that the former is also preferentially depopulated (cationic complexes). In contrast, π-acceptor substituents (*pull*) lower the energies of the two levels and favour an anionic state of the complex. Thus mnt complexes (mnt = maleonitrile-2,3-dithiolate, *pull* ligand) are most readily synthesized as dianions while the R_2pipdt ones (R_2pipdt = *N*,*N*′-dialkylpiperazine-2,3-dithione, *push* ligand) are synthesized as dications.[6] On the basis of the above, new CT salts $[M(R_2pipdt)_2][M(mnt)_2]$ (M = Pd and Pt) have been recently described.[7,8] In the solid state these salts show features similar to those of $(C)[ML_2]$ compounds, where the acceptors (C) do not deviate too much from planarity.[2] In this paper the dark- and photo-conducting properties of $[M(R_2pipdt)_2][M(mnt)_2]$ {[R = Me, M = Pd (**1a**) and Pt (**2a**); R = Et, M = Pt (**2b**)]}, as well as of the novel salts of $[Pt(R_2pipdt)_2][Pt(dtcr)_2]$ (R = Me, (**3a**); R = Et, (**3b**); dtcr = 4,5-disulfanylcyclopent-4-ene-1,2,3-trionate) are reported; the structural characterization of **3a** is also described. The substitution of mnt by dtcr in **3** was performed in order to investigate the influence of the different redox potentials and of the electron-rich oxo-groups of the anionic component on the properties of these CT salts.

Results and Discussion

Preparations and Structures

$[Pt(R_2pipdt)_2][Pt(dtcr)_2]$ [where R = Me (**3a**); R = Et (**3b**)] were obtained by metathesis by treating equimolar amounts of $[Pt(R_2pipdt)_2](BF_4)_2$[7] with $(Bu_4N)_2[Pt(dtcr)_2]$[9] in CH_3CN. Crystals of **3a** suitable for X-ray characterization were grown by using a three-compartment diffusion cell, as described in the Exp. Sect.[10] A molecular drawing of the ionic complex components is depicted in Figure 1, selected bond lengths and angles are reported in Table 1.

In $[Pt(dtcr)_2]^{2-}$ and $[Pt(Me_2pipdt)_2]^{2+}$ the platinum atoms lie on inversion centres and are in a square planar geometry. They are bound by four sulfur atoms from two ligands. The complex cation and the complex anion are alternate and run parallel to the *c* crystallographic axis exhibiting a metal–metal interaction [Pt(1)–Pt(2) = 3.408(1) Å]. Despite the fact that the dtcr ligand can be formally formulated as a dithiolate, its C–S bond lengths are not significantly different from the ones observed for the dithione ligand (Me_2pipdt) in the complex cation (see Table 1). This is ascribed to a negative charge-delocalization on the oxo groups of the ligand (see Scheme 1). In fact, the C(9)–O(3) and C(11)–O(1) bonds are significantly longer than the C(10)–O(2) bond as they are in close proximity to the C(8)–S(4) and C(7)–S(3) groups, respectively, and the Pt–S bond lengths for the complex cation and the complex anion are only slightly different (Table 1). As regards the Me_2pipdt ligand, the thioamide groups are not coplanar {τ[S(1)–C(1)–C(2)–S(2)] = –16.9(8)°} and the C(1)–C(2) bond length [1.493(9) Å] is indicative of a single bond between these two atoms excluding an electron delocalisation between the thioamide moieties.

The ring conformation of the Me_2pipdt ligand {τ[N(1)–C(3)–C(4)–N(2)] = –53.0(9)°} limits the stacking between the cationic and anionic complexes; in fact they are skewed with respect to each other by ca. 45° {τ[S(1)–Pt(1)–Pt(2)–S(4)] = 43.75(7)°}.

A net of weak interactions between the N(1) and O(3) atoms [3.40(1) Å] of the cation and anion contributes to the alignment of $[Pt(Me_2pipdt)_2][Pt(dtcr)_2]$ along the *c* axis. The O(1)–N(2) intermolecular interaction [3.40(1) Å] generates a layer in the [0 1 0] crystallographic plane (Figure 2). To the best of our knowledge structural data on the [Pt-

$(dtcr)_2]^{2-}$ complex appear here for the first time and are consistent with those found in the crystal structures of $[Bu_4N]_2[ML_2]\cdot I_2$ (where L = 2-dicyanomethylene-4,5-disulfanylcyclopent-4-ene-1,3-dionate; M = Pd, Pt)[9] and of $(Ph_4P)_3[Co(dtcr)_3]\cdot 0.6$ acetone.[11]

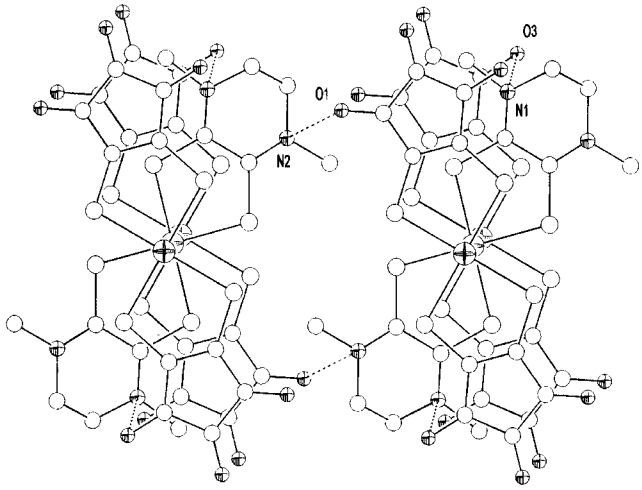

Figure 2. Perspective view of the unit cell content of $[Pt(Me_2pipdt)_2]$-$[Pt(dtcr)_2]$. Projection along the *c* axis.

Electronic Spectral Features

The comparison of the diffuse reflectance (DR) spectra of $[Pt(Me_2pipdt)_2][Pt(dtcr)_2]$ (**3a**) with those of $[Pt(Me_2pipdt)_2](BF_4)_2$ and $(Bu_4N)_2[Pt(dtcr)_2]$ is reported in Figure 3. In the spectrum of **3a**, one adjunctive, strong, long-wavelength absorption appears at 960 nm (930 nm for **3b**). Type **1** $[Pd(Me_2pipdt)_2][Pd(mnt)_2]$ and **2** $[Pt(R_2pipdt)_2]$-$[Pt(mnt)_2]$ (R = Me, Et) salts, where the redox-active planar anions and cations show a similar, alternating stacking, exhibit similarly strong near infrared peaks. These long wavelength absorptions are assigned to intermolecular charge transfer (ICT) transitions from the negatively charged to the positively charged complex.

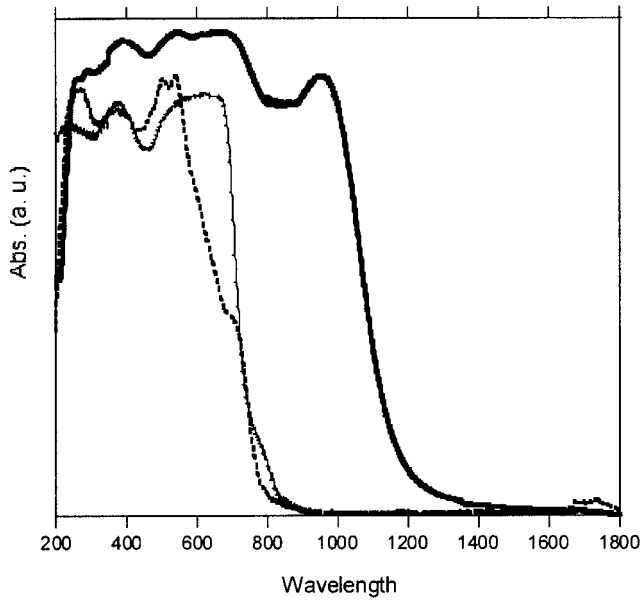

Figure 3. The diffuse reflectance spectra of $[Pt(Me_2pipdt)_2][Pt(dtcr)_2]$ (thick line) and, for comparison, of $[Pt(Me_2pipdt)_2](BF_4)_2$ (dotted line) and $(Bu_4N)_2[Pt(dtcr)_2]$ (thin line). The absorbances are reported in arbitrary units.

Theoretical calculations based on approximate Extended Hückel methods by using the CACAO program[12] have been performed to calculate the frontier orbitals of the cation and of the anions. These orbitals are π-type orbitals, and while a significant contribution of the metal d_{yz} orbital to the HOMOs occurs, the contribution of the metal to the LUMOs is negligible. The transition from the dithiolene metallate donor (HOMO) to the dicationic dithiolene acceptor (LUMO), symmetry allowed, will have charge-transfer character. The nature of the LUMO of the $[M(R_2pipdt)_2]^{2+}$ which is a π* ligand orbital can explain the observed similarity with the behaviour of $C[ML_2]$ Kisch salts (C^{2+} is almost planar, i.e. 2,2′ or 4,4′-bipyridinium derivatives, L^{2-} = dithiolato) where the CT peaks are assigned to a π→π* transition from the same platinum (or nickel) dithiolato donor to a planar organic acceptor based on bipyridinium cations (C^{2+}). The energy of the CT transition is relatable to the driving force of electron transfer from the cation to the anion ($[C]^{2+} + [A]^{2-} \rightarrow [C]^{+} + [A]^{-}$) through the following, modified Hush relation [Equation (1)].

$$E_{IPCT} = \chi + \Delta G_{12} \quad (1)$$

[E_{IPCT} is obtained from the IPCT peak in the reflectance spectra, χ represents the total reorganization energy and ΔG_{IP} is obtained from the components' redox potential difference, $E(C^{2+/+}) - E(A^{-/2-})$]. The redox features of the cation[7,13] and of the anion[9] have been previously reported. The reversible processes of interest here are shown below:

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$$[Pt(R_2pipdt)_2]^{2+} \underset{1e^-}{\overset{E_{1/2}}{\rightleftharpoons}} [Pt(R_2pipdt)_2]^{+}$$

$$[Pt(dtcr)_2]^{-} \underset{1e^-}{\overset{E_{1/2}}{\rightleftharpoons}} [Pt(dtcr)_2]^{2-}$$

Moreover, the free activation enthalpy of thermal electron transfer can be calculated according to Equation (2).

$$\Delta G^* = E^2_{IPCT}/4(E_{IPCT} - \Delta G_{12}) \quad (2)$$

The E_{IPCT}, ΔG_{12}, ΔG^* values, and the reduction potentials related to $[Pt(R_2pipdt)_2][Pt(dtcr)_2]$, as well as data for $[M(R_2pipdt)_2][M(mnt)_2]$, are reported in Table 2. The more positive reduction potential of $[Pt(dtcr)_2]^{-/2-}$ with respect to the corresponding mnt derivative is in agreement with the higher charge delocalisation in the dtcr ligand. Accordingly the position of the CT transition falls at higher energies.

Infrared results are also in agreement with a CT anion–cation description for **3a** and **3b**. The ν(CN) vibration of the ligand of the $[Pt(R_2pipdt)_2]^{2+}$ dication can be used as a probe to evaluate the extent of the charge transfer from the dianion to the dication. This vibration appears as a strong peak near 1550 cm^{-1} in the tetrafluoborate. When the dication accepts charge from the donor (the dianion), a partial population of the LUMO orbital that has CN antibonding character (see Figure 4) is expected. This should produce a shift of ν(CN) to lower frequencies, as observed, although these shifts do not strictly correlate with ΔG_{12}. Differently to what observed in mnt[14] and dmit[15] complexes, where the ν(C=C) of the bond vicinal to sulfur atoms is very sensitive to the charge of the complexes (due to the main C=C bonding contribution to the HOMO in the dianion), no similar ν(C=C) vibration sensitive to the charge is observed in the $[Pt(dtcr)_2]^{2-}$ salts in Table 3. This is related to the different nature of the HOMO (see Figure 4), with no corresponding C=C bonding contribution. Instead an extensive delocalisation involving also the peripheral C=O groups exists.[16] Thus a change in the charge, distributed over the entire complex, has a slight effect on any single vibration, as observed.

Conductivity Measurements

The above discussion shows that the structural and optical properties of this new class of ion-pair CT salts, $[M(R_2pipdt)_2][ML_2]$, are similar to those of the organic–inorganic Kisch salts, $C[ML_2]$. The electrical specific conductivity of Kisch salts gave values ranging from 10^{-10} to 10^{-3} $\Omega^{-1}cm^{-1}$ and these values are related to ΔG_{12} and ΔG^*. Moreover these salts exhibit photoconductive properties. In order to find further support in comparing the behaviour of metal-anion-dithiolene/metal-cation-dithiolene and metal-anion-dithiolene/viologen, ion pairs the dark- and photo-conductive properties of these salts were investigated.

In Figure 5 the DC specific conductivity of pressed powder pellets of samples **1a**, **2a**, **2b** and **3a** are shown. These values range from 10^{-11} to $10^{-5}\ \Omega^{-1}\,cm^{-1}$ and increase with increasing temperature according to the Arrhenius law $\sigma = \sigma_0 \exp(-E_a/k_B T)$ (where σ_0 is the pre-exponential factor, E_a is the activation energy, T is the absolute temperature and k_B is Boltzmann's constant). Due to the very large resistance of compound **3a**, only a limited temperature range could be explored. In general the lowest T for each sample corresponds to the lowest current measurable near the picoammeter limit. The pre-exponential factor, σ_0, calculated from the fit, is approximately $0.2\ \Omega^{-1}\,cm^{-1}$ for all compounds and the activation energies range between 0.2–0.6 eV. The value of the conductivity at room temperature, the large value of the activation energy and the fact that σ_0 is constant indicate that these compounds belong to the class of strongly temperature-activated charge-transfer materials, analogous to the segregated stacks systems whose mobility is temperature independent.[17]

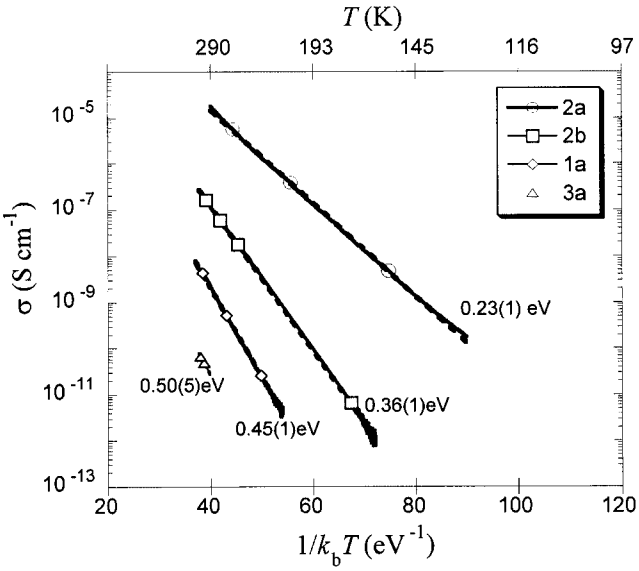

Figure 5. Semilogarithmic plot of the DC conductivity vs. $1/k_bT$, (where k_b = Boltzman costant, T = temperature) for the set of measured compounds. The dotted lines are the best fit of the exponential Arrhenius behaviour. The values of the activation energy E_a are also displayed.

In Figure 6 the σ values at 290 K vs. both the activation energy, E_a, and the free activation enthalpy of electron transfer, ΔG^*, are shown. The data vs. E_a for each compound can be fitted with the equation $\sigma(T_o = 290\ K) = \sigma_0 \exp(-E_a/k_B T_o)$ where σ_0 is approximately $0.2\ \Omega^{-1}\,cm^{-1}$. This behaviour indicates that changes in the conductivity are due only to changes in E_a while the pre-exponential factor σ_0 is approximately the same for all the compounds. For the three Pt salts (**2a**, **2b**, **3a**), where only changes in the nonmetallic sites occur, there is a linear dependence of $\ln\sigma(290K) = a + b\Delta G^*$, with $a \approx 7$ and $b \approx -76$, indicating that for these compounds the transport mechanism within the ion pair is mainly driven by the extent of the charge-transfer interaction, as expected.[18] It is noteworthy that the lnσ(290 K) value for M = Pd (**1a**) does not fall on the same line. Moreover the corresponding lnσ(290 K) vs. ΔG^* dependence for C[ML_2] Kisch salts[18] leads to a linear correlation with different coefficients ($a \approx -3$ and $b \approx -35$). These features suggest that the transport properties and hence the activation energy of CT salts are not simply governed by the activation enthalpy ΔG^*, and some other kind of mechanisms must be involved.

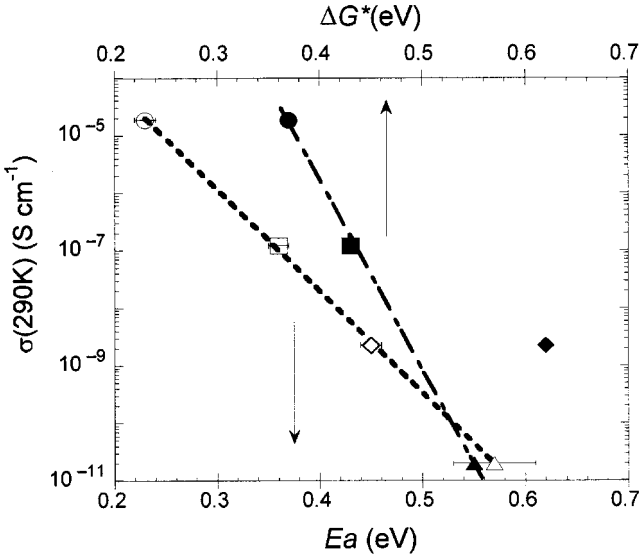

Figure 6. Semilogarithmic plot of the DC conductivity at room temperature vs. the activation energy, E_a, (open symbols) and the free activation enthalpy, ΔG^*, (shaded symbols). The symbols are the same as in Figure 5 (● **2a**, ■ **2b**, ♦ **1a**, ▲ **3a**).

Preliminary photoconductivity measurements have been performed on the two relatively more conducting samples, **2a** and **2b**, by using a lock-in phase, pulsed technique and a halogen lamp (250 W). A low gain in current was observed during illumination. The signal has a decay constant τ of the order of tens of milliseconds and is likely to be related to both the variation of resistance during two different choppered light pulses and to trapping of carriers. The observed photocurrent values I_{ph} ($I_{ph}/I_D \approx 10^{-3}$, where I_D is the dark current) are similar to those reported in Kisch CT salts.[19]

Conclusions

This study has confirmed that cationic and anionic metal-dithiolenes (Pd-Pt) are capable of forming salts that show charge-transfer interactions, responsible for strong NIR CT bands, semiconducting behaviour and photoconducting properties. The properties of these salts are comparable with those of salts formed by dianionic dithiolene metallates with planar organic dications. These properties strongly depend on the amount of electron donation from the donor to the acceptor, which in turn depends on the redox potential and on the planarity of the ionic components of the salt. Since d^8 metal dithiolenes have a rich redox chemistry, which depends on the nature of the substitu-

ents at the C_2S_2 moieties, and determines the nature of their most accessible status while the metal atom imposes the square planar geometry, they offer a wide range of suitable candidates for forming CT salts.

This study also reports the characterisation of $[Pt(R_2pipdt)_2][Pt(dtcr)_2]$, a new example of ion-pair charge-transfer salts formed by an infinite, mixed, planar anion–cation stack. The presence of peripheral C=O groups in the anion produces a net of weak interactions between the N and O atoms of the cation and of the anion inside the stacks thereby favouring the generation of a layer between them. However, these interactions do not overcome the less favourable redox properties of the components with respect to the corresponding mnt salts, that is, promoting anion–cation CT interactions and related properties.

Experimental Section

General Remarks: Reagents and solvents of reagent grade quality were used as supplied by Aldrich. The ligands and the complexes $[Pt(Me_2pipdt)_2](BF_4)_2]$ and $(Bu_4N)_2[Pt(dtcr)_2]$ were prepared according to references [7] and [9]. Microanalyses were performed on a Carlo–Erba CHNS elemental analyser model EA1108. IR spectra (4000–300 cm^{-1}) were recorded on a Bruker IFS55 FT-IR Spectrometer as KBr pellets. Raman spectra (2200–300 cm^{-1}) on single crystal was carried out at room temperature using a Raman microscope (BX, 40, Olympus) spectrometer (ISA xy 800) equipped with a He-Ne (λ = 632,817, Melles-Criot) laser. A 180° reflective geometry was adopted. The sample was mounted on a glass microscope slide and the scattering peaks were calibrated against an Si standard ($\tilde{\nu}$ = 520 cm^{-1}). The spectrum was collected with a 500 s time constant at a 1 cm^{-1} resolution and was averaged over 5 scans. No sample decomposition was observed during the experiments. Electronic spectra (2000–200 nm) were recorded on a Cary 5 spectrophotometer, equipped with a diffuse reflectance accessory. Diffuse reflectance spectra were run on KBr pellets. For electrical measurements the powder samples were pressed up to 0.4 GPa in rectangular bars of (2 × 1 × 13) mm^3 dimensions. Gold electrodes were sputtered on two point-like regions on the surface of the sample in order to favour the ohmic electrical contacts. The DC current measurements were performed by using a Keithley 485 picoammeter and by applying voltages in the range 0–100 V. The temperature was varied by a closed cycle refrigerator system in the range 100–310 K, regulated at the rate of 1 K/min and measured within an error of 1 K.

$[Pt(Me_2pipdt)_2][Pt(dtcr)_2]$ (3a): The blue CH_3CN solution (15 mL) of $(Bu_4N)_2[Pt(dtcr)_2]$ (72 mg; 0.07 mmol) was slowly added to the warm brown CH_3CN solution (20 mL) of $[Pt(Me_2pipdt)_2](BF_4)_2$ (50 mg; 0.07 mmol) and a quantitative precipitation of brown needle-shaped crystals occurred (yield 72 mg; 95%). Crystals suitable for X-ray characterization were grown using a diffusion cell with three compartments connected through porous glass frits. The solutions of the components were introduced in the terminal compartments, and the crystals were collected in the central compartment filled with CH_3CN. $C_{22}H_{20}N_4O_6Pt_2S_8$ (1083.11): calcd. C 24.40, H 1.86, N 5.17, S 23.68; found: C 24.76, H 1.68, N 5.20, S 22.81. IR (KBr pellets): $\tilde{\nu}$ = 3026 vw, 3000 vw, 2920 vw, 2857 vw, 2123 vw, 1684 vs, 1663 vs, 1629 vs, 1618 vs, 1541 s, 1406 ms, 1387 vs, 1362 sh, 1284 mv, 1265 ms, 1238 sh, 1189 m, 1146 mw, 1097 mw, 1064 w, 1027 mw, 924 w, 902 mw, 804 vw, 781 vw, 668 vw, 598 vw, 545 mw, 480 mw, 428 w cm^{-1}. UV/Vis-NIR (reflectance, KBr pellets) λ = 387, 540, 680, 960 nm.

$[Pt(Et_2pipdt)_2][Pt(dtcr)_2]$ (3b): This compound was prepared as described for **3a** (yield 111 mg; 97%), starting from the CH_3CN solutions of $[Pt(Et_2pipdt)_2](BF_4)_2$ (violet; 77 mg; 0.10 mmol) and $(Bu_4N)_2[Pt(dtcr)_2]$ (blue; 102 mg; 0.10 mmol). $C_{26}H_{28}N_4O_6Pt_2S_8$ (1139.22): calcd. C 27.41, H 2.48, N 4.92, S 22.51; found: C 26.73, H 2.52, N 4.86, S 22.65. IR (KBr pellets): $\tilde{\nu}$ = 2980 vw, 2940 vw, 2385 vw, 2350 vw, 2100 w, 1760 w, 1670 vs, 1657 vs, 1638 vs, 1615 sh, 1529 s, 1452 m, 1393 vs, 1360 vs, 1340 sh, 1278 ms, 1261 ms, 1229 ms, 1199 ms, 1126 ms, 1090 w, 1080 w, 1036 w, 970 m, 940 vw, 918 w, 896 m, 858 w, 801 w, 780 w, 760 w, 625 w, 610 w, 550 mw, 476 ms, 421 m, 355 w, 340 mw, 310 vw, 300 vw cm^{-1}. Raman (on single crystal): 2180 vw, 1702 vs, 1412 m, 1192 vs, 1052 vw, 562 vw, 478 s, 422 w cm^{-1}. UV/Vis-NIR (reflectance, KBr pellets) λ = 390, 544, 730, 930 nm.

The Role of C–H···O Interactions in the Solid and Liquid-Phase Structures of Methyltrioxo Rhenium

Pedro D. Vaz,*[a,b] and Paulo J. A. Ribeiro-Claro[a]

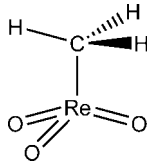
Keywords: Rhenium / C–H···O Hydrogen bonds / Ab initio calculations / Raman spectroscopy / Inelastic neutron scattering

The importance of C–H···O hydrogen bonds involving the less common Re=O acceptor group in the small organometallic methyltrioxorhenium (MTO) is studied by combined vibrational spectroscopy and ab initio calculations. The observed vibrational spectrum is well described by the calculated spectrum of a C–H···O bonded dimer, which accounts for the symmetry decrease and the intermolecular interactions in the solid. Spectral evidence indicates both C–H···O and O–H···O hydrogen bonds are formed in the MTO/methanol solutions. The Re=O stretching mode is sensitive to hydrogen bonding, but the major effects of intermolecular association are observed in the βC–H and νC–H modes of MTO. Ab initio calculations for the MTO/methanol system predict the coexistence of both the Lewis adduct and the hydrogen-bonded complex, with an energy difference of ca. 1.2 kJ·mol^{-1}.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Methyltrioxorhenium (MTO) is a small transition metal organometallic molecule that has been recently studied for its properties in catalysis, mainly as an oxidation catalyst,[1] see Scheme 1.



Scheme 1.

The structure of this compound has been previously reported.[2–6] These studies include single crystal neutron diffraction structure determination,[3] as well as several vibrational studies combined with ab initio calculations.[2,4–6] However, some questions concerning the intermolecular interactions in the liquid and solid phases still remain. In a recent work by Gisdakis et al., it was proposed that MTO can associate into dimers through oxo-bridges,[6] where two Re atoms are bound by two Re–O–Re bridges in order to preserve the stoichiometry. Ab initio calculations predicted that the formation of the four proposed geometries would be endothermic, with dimerization energies of between 7.1 kJ·mol^{-1} and 148.4 kJ·mol^{-1}.[6]

In this work, the role of C–H···O interactions in the structure of MTO is studied by vibrational spectroscopy and combined with ab initio calculations. FT-Raman spectra were obtained for the solid phase and as a function of concentration in different solvents. In addition, ab initio calculations were carried out in order to elucidate the structure and energy of possible C–H···O bonded forms and to simulate the corresponding vibrational spectra.

Results and Discussion

Figure 1 presents the fully optimised structure of MTO (a) and of the lowest energy MTO hydrogen-bonded dimer (b).

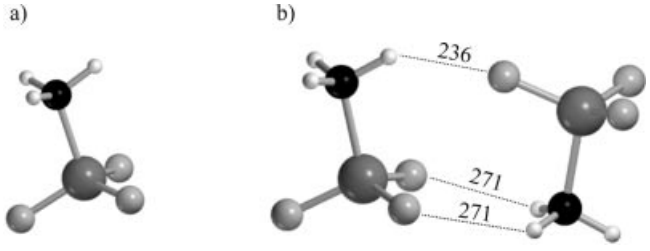


Figure 1. DFT-optimised geometries for a) monomer and b) dimer MTO structures. Distances are in pm.

This MTO dimer – corresponding to a real minimum, i.e. without negative eigenvalues from the frequency calculations – was found to be the most stable configuration among the several MTO dimers tested, and presents three

C–H···O hydrogen bond contacts. The dimerisation energy is –21.8 kJ·mol^{-1} (without corrections) and –15.9 kJ·mol^{-1} (after CP and ZPVE corrections), falling in the expected range for this type of interaction.[7–14] These values show that a C–H···O bonded dimer is clearly more stable than the previously reported dimers based on oxygen bridges.[6] In fact, the dimerisation energy for oxygen bridged dimers, evaluated at the same level of theory, ranges from 7.1 kJ·mol^{-1} to 148.4 kJ·mol^{-1} as mentioned above.

The optimised ab initio geometry for the dimer is in very good agreement with the structure determined by neutron diffraction for the solid,[3] considering the limitations of the "isolated dimer" approach (in the crystal, each molecule has several neighbours), whose structure is represented in Figure 2.

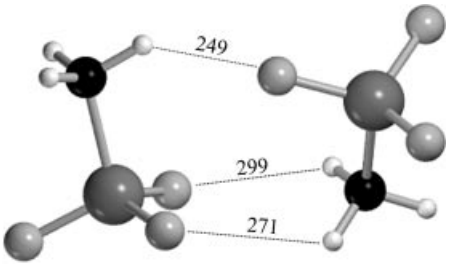

Figure 2. Representation of the interaction motif from the solid structure unit cell of MTO as determined by neutron diffraction.[3] Distances are in pm.

From the three C–H···O hydrogen bond contacts of the calculated geometry, one is clearly favoured by the geometrical orientation (C–H···O angle: 141°) over the other two (C–H···O angle: 128°), which results in a stronger C–H···O contact. The corresponding H···O contact distance (236 pm – ab initio, 249 pm – neutron diffraction) is clearly shorter than the remaining ones (271 pm – ab initio, 299 pm – neutron diffraction). In addition, the bond length of the C–H donor group of the most favoured contact is shorter than the others (ca. 0.1 pm – ab initio, 1.4 pm neutron diffraction). The shortening of the C–H bond length involved in the strongest C–H···O contact (an effect leading to the increase of the corresponding stretching frequency and to the designation of "blue-shifting hydrogen bond") indicates that the behaviour of the C(sp^3)–H···O=Re interaction is similar to that of C(sp^3)–H···O=C.

Figure 3 depicts the comparison between the experimental FT-Raman spectrum and the calculated spectra for both the monomer and the C–H···O bonded dimer. The calculated spectrum for the monomer is clearly oversimplified, as the single molecule model is inadequate to describe the crystal. However, there is an excellent agreement between the calculated and the experimental spectra for the dimer. Although the full description of the solid-state spectra would require a more sophisticated approach, this simple model has the merit of accounting for both the effects of the symmetry reduction and the effects of the most relevant intermolecular contacts. In particular, the magnitude of the splitting of the modes at ca. 750, 950, 1400, and 3000 cm^{-1} is correctly predicted from the fully optimized geometry.

The comparison between the calculated vibrational spectra of the MTO dimer and the experimental vibrational spectra of solid MTO is presented in Table 1 (the full assignment of the vibrational spectra has already been proposed by Parker et al.[5]). The approximate description of the vibrational modes presented in Table 1 assumes that the CH_3ReO_3 molecule is built from two XY_3 independent fragments. In this way, the 18 normal modes are described as 2×3 νXY stretching modes (3 νCH and 3 νReO), 2×5 XY_3 bending modes (3×βCH_3 + 2×CH_3 rocking and 3×βReO_3 + 2×ReO_3 rocking), one interfragment stretching mode (νC–Re) and one interfragment torsional mode (described as τCH_3, since the methyl group is the lighter fragment).

There is an excellent agreement between calculated and experimental assignments, but the results from ab initio calculations with the dimer model suggest a couple of changes relative to the previous vibrational studies.[2,5] The most obvious difference is related to the bands left unassigned previously by Parker at al.[5] (e.g. the bands at 2988, 1364, and 946 cm^{-1}) and not observed in the partial assignment of Mink et al.[2] (e.g. the second component of the 2986–2990 doublet). These bands are now clearly related with modes of the C–H···O bonded dimer. In some cases, the effect of the C–H···O contact yields a noticeable effect on the vibrational mode. For instance, according to ab initio calculations, C–H···O hydrogen bonds in the dimer produce a C–H bond shortening relative to the monomer, with a corresponding blue shift of the νC–H mode. The effect is also observed for the βC–H and γC–H modes, which are calculated at 1377 cm^{-1} and 763 cm^{-1}, respectively, blue-shifted from the predicted fundamentals of the monomer. In this way, the highest wavenumber νC–H, βC–H and γC–H bands have been assigned to the C–H bond engaged in the strongest C–H···O contact.

Another point of interest is the location of the H···O hydrogen bond stretching modes. Ab initio calculations predict the three νH···O modes at 26, 61 and 76 cm^{-1}, the last one being related to the strongest C–H···O bond. In the low wavenumber region, there are several bands observed in the INS spectrum – already assigned to librational and translational modes[5] – and a very weak band in the Raman spectrum at 84 cm^{-1}. On the basis of the proximity of the calculated wavenumber value and weak intensity, we tentatively assign the Raman band at 84 cm^{-1} to the strongest νH···O mode (predicted at 76 cm^{-1} from ab initio calculations). It should be stressed, however, that this is not a conclusive assignment and other bands (e.g. INS bands at 101 cm^{-1} or 50 cm^{-1}) can alternatively be related with this mode (Table 1).

In order to evaluate the relevance of C–H···O interactions in MTO/solvent systems, several solutions of MTO in solvents with acceptor/donor (e.g. CH_3OH, CD_3OD) and weak donor/non-acceptor (e.g. CD_2Cl_2) properties were prepared.

Ab initio calculations of MTO/solvent complexes were also performed, in order to evaluate the possible interactions between MTO and the solvents. As expected, the in-

teraction of MTO with CD_2Cl_2 is quite feeble and can be neglected. A different situation arises with methanol. Methanol molecules can interact with MTO either as hydrogen-bond donor or hydrogen-bond acceptor. The formation of a MTO/methanol Lewis acid/base adduct has been described previously by Herrmann et al., on the basis of ^{17}O-NMR spectroscopic data.[15] Figure 4 shows the energy minimized structure for the MTO/methanol hydrogen-bonded complex and for the MTO/methanol Lewis adduct. The hydrogen bonded complex presents a six-membered ring built from O–H···O C–H···O short contacts. In contrast, the adduct geometry only allows a distorted C–H···O contact. A relevant feature of Figure 4 is the small energy difference found between these two forms of MTO/methanol association (ca. 1.2 kJ·mol^{-1} after ZPVE correction), which strongly suggests that both forms can coexist in solution.

Figure 5 shows the Raman spectra of the MTO solutions in the Re=O and C–H stretching regions. These vibrational modes are clearly sensitive to the presence of C–H···O interactions, as well as stronger O–H···O(= Re) hydrogen bonds.

In the νRe=O wavenumber region (920–1020 cm^{-1}), several changes in the band profiles can be observed. Dilution in CD_2Cl_2 produces a shift to higher wavenumbers relative to the solid. This shift can be associated with the interac-

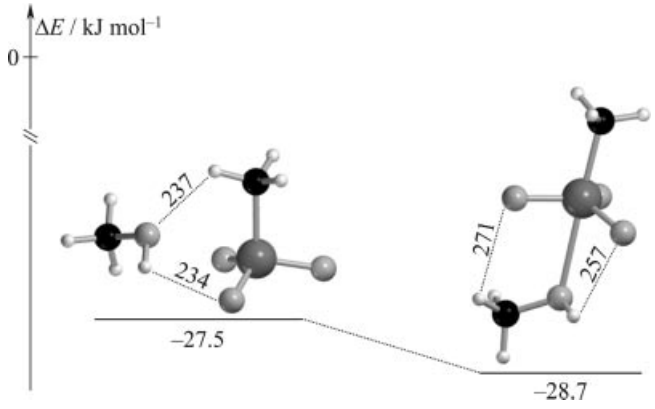

Figure 4. Optimised geometry of the lowest energy MTO/methanol complex based on O–H···O and C–H···O hydrogen bonds, and of the MTO/methanol Lewis adduct. Distances are in pm.

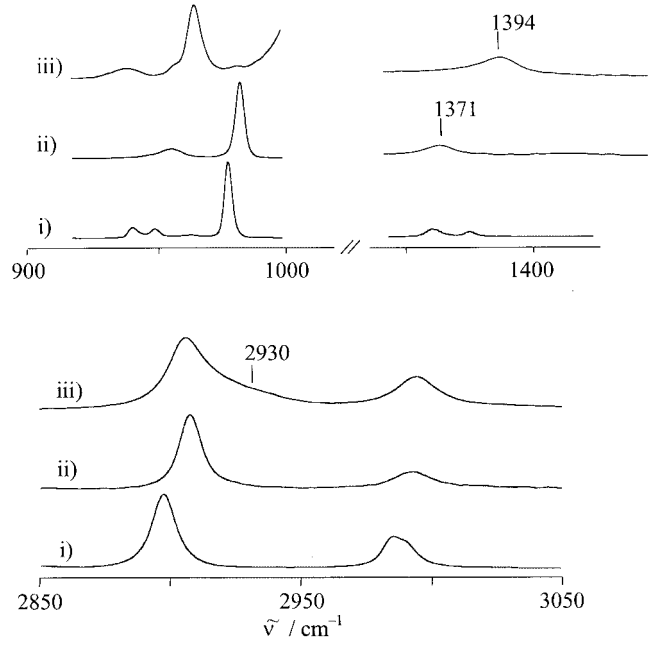

Figure 5. Raman spectra at room temperature of MTO solutions in various solvents in the νRe=O, βC–H and νC–H mode regions: i) pure solid, ii) 5% solution in CD_2Cl_2 and iii) 5% solution in CH_3OH or CD_3OD.

tion-free MTO molecules, as CD_2Cl_2 is not expected to interact with MTO, due to low-polarity of the solvent. Another noticeable effect is the merging of the two νRe=O asymmetric modes into a single broad feature, which is in agreement with the higher symmetry of MTO molecules in solution relative to the solid.

The dilution in methanol yields a large shift towards lower wavenumbers and a marked broadening of the νRe=O band. This large shift can be ascribed to the formation of Lewis adducts and a hydrogen-bonded complex between methanol and MTO, according to ab initio results described above. The presence of four bands in the νRe=O region of methanol solutions is consistent with the coexistence of the adduct and the hydrogen-bonded complex. In fact, the observed spectrum can be qualitatively described by the sum of the calculated spectra for the two species.

The same general behaviour is observed in the βC–H wavenumber region (1350–1450 cm^{-1}). However, the large shift observed from CD_2Cl_2 to methanol solutions can not be explained by bulk solvent effects, such as the change in the dielectric environment,[16] and is consistent with the presence of more specific interactions. According to the ab initio calculations, the MTO methyl group vibrations are virtually insensitive to the formation of the MTO/methanol adduct. On the other hand, C–H···O hydrogen bonds, such as those described in Figure 4, produce wavenumber shifts of the βC–H modes of ca. 23 cm^{-1}, in agreement with the observed value. These hydrogen bonds are expected to occur even for the MTO molecules already engaged in a MTO/methanol adduct (Figure 6). The MTO methyl group can interact through C–H···O hydrogen bonding with three surrounding methanol molecules, and the presence of such interactions can also explain the large asymmetry of the band.

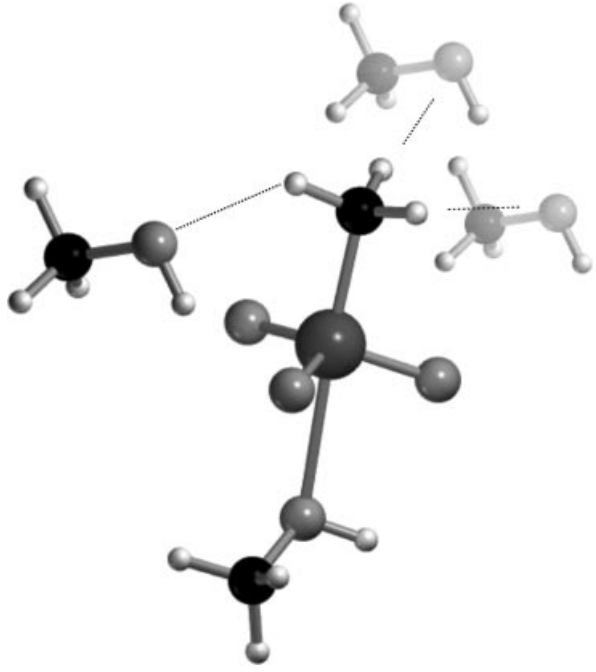

Figure 6. Optimised geometry for the interaction of the MTO/methanol Lewis adduct (O→Re bond length is 264 pm) with a second methanol molecule which is hydrogen bonded (H···O distance is 245 pm). The shadowed methanol molecules represent additional C–H···O contacts assumed to occur in the solution.

In the νC–H wavenumber region (2850–3050 cm^{-1}) some changes are also observed. The dilution in methanol gives rise to a general blue shift of all the νC–H bands. This effect is expected from the bulk solvent effects, due to the change of the dielectric constant.[16] In addition, there is an intensity increase in the higher wavenumber side of the band at 2906 cm^{-1}, leading to a clear band asymmetry. The effect is seen on the symmetric mode and not in the asymmetric ones, which is unexpected for a symmetry-breaking interac-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tion. Possible explanations are (i) the weakness of the effect (can be hidden due to band broadness) and (ii) the averaging effect of multiple interactions. By comparison with the βC–H region, this band asymmetry can be ascribed to the multiple C–H···O interactions between MTO and methanol solvent molecules. As stated before, C–H···O hydrogen bonds are predicted to result in the blue-shift of the corresponding νC–H modes. Being so, the intensity increase in the 2930 cm^{-1} region may be ascribed to blue-shifting C–H···O hydrogen bonds.

Conclusions

The present work presents evidence of intermolecular interactions through C–H···O hydrogen bonds in solid MTO. The shortening of the C–H bond length involved in the strongest C–H···O hydrogen bond (leading to the blue-shift of the corresponding C–H stretching frequency by ca. 23 cm^{-1}) indicates that the behaviour of the $C(sp^3)$–H···O=Re interaction is similar to that of $C(sp^3)$–H···O=C. To the best of our knowledge, this is the first report of a blue-shifting C–H···O hydrogen bond involving a Re=O acceptor group. Dilution of MTO in the non-polar solvent CD_2Cl_2 yields vibrational features easily interpreted in terms of isolated MTO molecules. On the other hand, with dilution in methanol, the spectral changes are complex and not easily interpreted. The presence of a MTO/methanol Lewis adduct, already described, can account for some of the changes. Nevertheless, a few other changes, such as those observed in the C–H bending and stretching modes of MTO, fit the changes expected from C–H···O hydrogen bonds. The presence of such interactions is also supported by ab initio calculations, which predict a comparable stability for the MTO/methanol Lewis adduct and for the MTO/methanol hydrogen-bonded complex.

Experimental Section

General Remarks: All reagents and solvents were provided by Aldrich Co. and used as received. Raman spectra were recorded on a Jobin–Yvon T64000 spectrometer with a CCD detector, using the 514.5 nm line of an Ar+ laser (Coherent-Inova 90) and on a FT Bruker RFS-100 spectrometer using a Nd:YAG laser (Coherent Compass-1064/500N) with excitation wavelength of 1064 nm, using 2 cm^{-1} resolution. The liquid samples were sealed in Kimax glass capillaires (i.d. 0.8 mm).

Ab initio calculations were performed using the Gaussian 98W program package, rev. A.11.[17] Molecular structures were fully optimised without constraints at the B3LYP with ECP's on the Re atom (short core approximation) and 6-311G(d,p) on all the remaining atoms. The basis set superposition error (BSSE) correction for the dimerisation energies has been estimated by counterpoise calculations using the MASSAGE option of Gaussian 98W. Harmonic vibrational wavenumbers were calculated at the level of theory and scaled by an adequate factor in order to provide the best fit with experimental results.

Supramolecular Copper Phenanthroline Racks: Structures, Mechanistic Insight and Dynamic Nature

Venkateshwarlu Kalsani,[a] Heinrich Bodenstedt,[a] Dieter Fenske,[b] and Michael Schmittel*[a]

Keywords: Rack / HETPHEN / Self-assembly / Phenanthroline / Dynamics

Herein, we describe the preparation of several dynamic multicomponent supramolecular racks based on copper phenanthroline complexes using the HETPHEN concept (**het**eroleptic bis**phen**anthroline complexes). This approach employs bulky aryl substituents at the bisimine coordination sites to control the coordination equilibrium. The racks were characterised by spectroscopic methods, both in solution (^{1}H NMR, ESI-MS, UV/Vis, vapour pressure osmometry) and in the solid state (X-ray). Ligand exchange studies established the reversible nature of the aggregates, the details of which are vital for the development of higher level multicomponent structures. In this regard, the present rack assemblies contrast to the large multitude of known rack motifs that are almost exclusively built using kinetically inert coordination building blocks.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Metallo-rack structures have a high standing in the burgeoning field of supramolecular chemistry due to their spatially well-defined linear array of metal ions that is attractive for many purposes, such as photoactive and electroactive nanowires.[1] Therefore, facile and quantitative access to rack aggregates is the goal of current research efforts.[1] Racks, however, by their very nature are multi-component structures that are most conveniently assembled under kinetic control, cf. the use of kinetically stable ruthenium coordination complexes,[1b,1c,1e–1g] even at the price of moderate yields. Preparation of rack structures under thermodynamic control is much more a challenge since in a dynamic multitopic aggregation scenario the requested heteroleptic combinations have to compete with homoleptic ones.[1d] Rewardingly, dynamic aggregation should allow for self-repair thus securing the most stable complex in very high yields if sufficient thermodynamic bias is installed.[2] Once the proof of principle is established one is set up to construe dynamic aggregates at surfaces that should be very useful for sensory purposes.[3]

At present, only one strategy is known to construct *dynamic* multicomponent rack structures (Scheme 1; strategy A).[4] Accordingly, ring constraints are utilised to prevent the formation of the homoleptic combination of one of the ligands, e. g. of an endotopic macrocyclic ligand. In combination with another rigid ligand the arrested ligand can combine to a heteroleptic rack-pseudorotaxane motif following the maximum site occupancy principle.[1d] A much easier way to *dynamic* multicomponent racks, however, should emerge from the HETPHEN[5] approach (strategy B). We have recently utilised the HETPHEN concept to establish **het**eroleptic bis**phen**anthroline copper complexes as building blocks for large nanostructures.[6] In our approach, heteroleptic aggregation is driven by steric and electronic factors which do not require an endotopic macrocycle. Instead, steric stoppers are required at the 2,9-positions of one of the bisimine coordination sites to prevent any homoleptic combination with itself. Therefore, in combination with another bisimine ligand only hetero combinations will result. This opens a much more facile way to heteroleptic dynamic aggregation than in previous reports.[7]

We have recently disclosed some preliminary results on dynamic rack structures in the context of our work on supramolecular nanogrids.[8] Herein, we now detail the potential of the HETPHEN[9] concept as a general strategy for the construction of multicomponent dynamic racks, provide structural insight into products and intermediates, and interrogate the dynamic nature of these unique assemblies.

Results and Discussion

Following the HETPHEN concept two approaches can be explored to prepare dynamic rack-type aggregates (Scheme 2). In both approaches one set of the ligand has to be instructed with the steric stoppers. In **approach I**, the linear bisphenanthroline is loaded with sterically bulky aryl

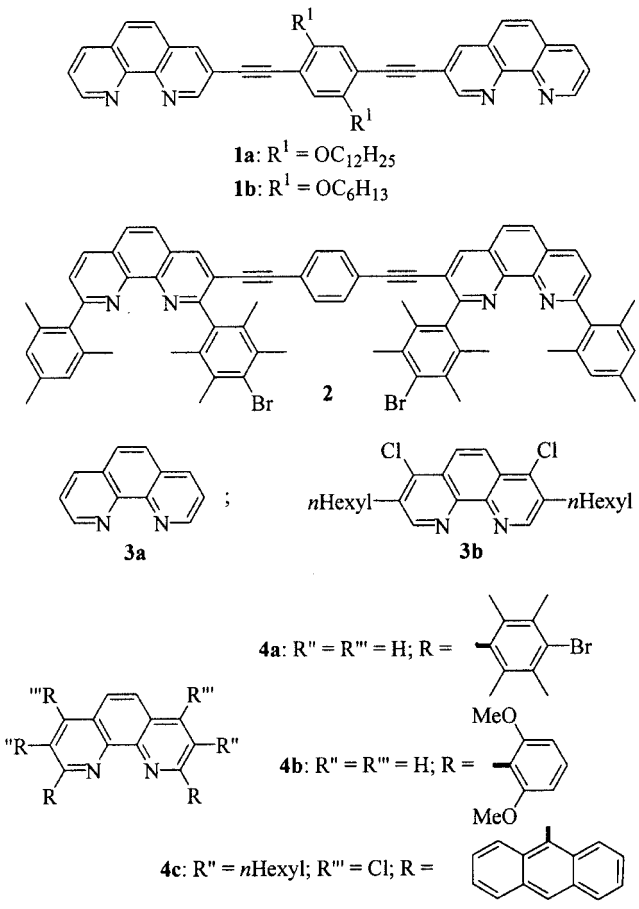
groups at the 2,9-positions of each phenanthroline site. In contrast, **approach II** makes use of monophenanthrolines that are equipped with the steric stoppers, while the linear bisphenanthroline is devoid of them.

The linear bisphenanthrolines **1a**,[10] **1b**[10] and **2**,[11] as well as the monophenanthrolines **3a**, **3b**,[13] **4a**,[6c] **4b**[12] and **4c**[13] were chosen for this study. Assembly of **1,2** with **3,4** in presence of metal ions of tetrahedral coordination geometry, such as copper(I) or silver(I) ions, is expected to yield the desired dynamic multicomponent racks.

To illustrate the need for control in the formation of dynamic rack assemblies using a coordination approach bisphenanthroline **1a** was treated with **3a** in the presence of $[Cu(MeCN)_4]PF_6$. The desired rack was obtained only as a

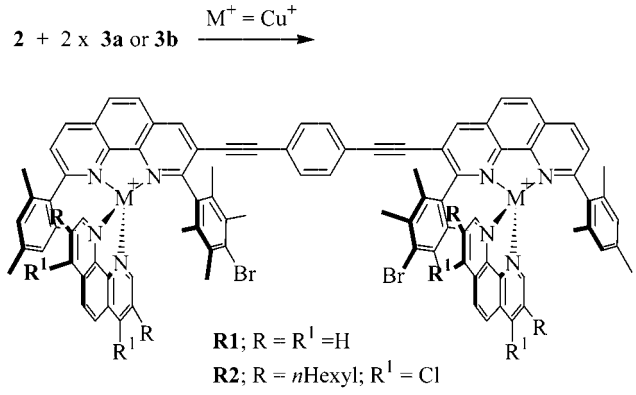
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



minor component as evidenced by ESI-MS and ^{1}H NMR spectroscopy. Rather, a complex mixture formed showing signals corresponding to the triangular-grid and signals corresponding to the homoleptic complex of **3a** as depicted in Scheme 3. ^{1}H NMR showed various sets of signals which arise from the resulting different aggregates. It is clear from the above experiment that cooperativity[7] can not be used solely to build dynamic heteroleptic aggregates.

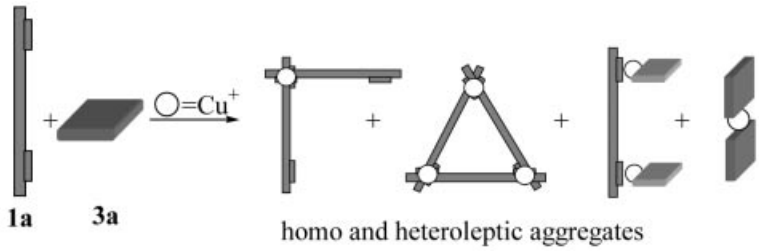
Approach I

As discussed above, approach I uses a bisphenanthroline that has steric stoppers (as in ligand **2**) in combination with any phenanthroline with no steric stoppers at 2,9-positions (i.e. **3a**–**3b**). The combination of these two building blocks and Cu^I salt should result in heteroleptic racks.[8] Indeed, upon addition of $[Cu(MeCN)_4]PF_6$ to a dichloromethane solution of **2** and **3** the rack structures **R1,R2** were exclusively furnished as demonstrated by ^{1}H NMR, ^{13}C NMR, ESI-MS, and elemental analysis.



Mechanistic Tests on the Formation of $[Cu_2(2)]^{2+}$. Rack **R1** $[Cu_2(\mathbf{2})(\mathbf{3a})_2]^{2+}$ was selected as a model system and its formation systematically investigated using a variety of spectroscopic techniques (by, ^{1}H NMR, ESI-MS and spectrophotometric titrations). Treatment of ligand **2** with 2 equiv. of $[Cu(MeCN)_4]PF_6$ resulted in a yellow solution, the analysis of which by UV/Vis (absence of a MLCT band at 430–550 nm of a $[Cu(phenanthroline)_2]^+$ complex), ESI-MS and ^{1}H NMR suggested the formation of $[Cu_2(\mathbf{2})(MeCN)_2]^{2+}$ as the sole species. As expected, ligand **2** acts as a **HETPHEN** ligand that is not able to self-assemble to a homoleptic grid.

Progressive addition of $[Cu(MeCN)_4]PF_6$ to **2** (in dichloromethane) provided valuable information about the intermediates as they could be readily detected by ESI-MS, ^{1}H NMR, and UV/Vis spectroscopy. In the ^{1}H NMR spectrum, for example, the mesityl protons Mes-*H* can be used as a diagnostic marker to assign the composition of the intermediate species present in the equilibrium. Addition of Cu^I salt to **2** in dichloromethane resulted in two new sets of signals, one of which built up at the initial stage of the titration and disappeared as the titration proceeded. The first set of signals, formed during addition of the first equiv. of Cu^I salt, was assigned to $[Cu(\mathbf{2})(MeCN)]^+$. After addition of 2 equiv. of Cu^I salt a single set of signals resulted which could be readily assigned to $[Cu_2(\mathbf{2})(MeCN)_2]^{2+}$. Im-



Scheme 3. Cartoon representation of the self-assembly of linear bisphenanthrolines and monophenanthrolines that are not instructed along the HETPHEN concept.

portantly, during the whole process no signals were detectable at 5–6 ppm, which is considered to be a characteristic range for mesityl protons of a $[Cu(phenanthroline)_2]^+$ complex.[9] ESI-MS titration results further supported the above assignments.

The UV/Vis titration revealed the absence of a band at ca. 500 nm, indicating that formation of a $[Cu(phenanthroline)_2]^+$ complex with its characteristic MLCT had not occurred. These results indicate that in line with the behaviour of monophenanthroline analogs[9] ligand **2** has been successfully instructed not to assemble with itself.

Most convincingly the structure of $[Cu_2(\mathbf{2})(MeCN)_2]^{2+}$ was supported by a single crystal structure analysis (Figure 1). It is worthwhile to note that, though the present system is a simple one, the solid state characterisation of such an intermediate in a coordination equilibrium is quite unique. $[Cu_2(\mathbf{2})(MeCN)_2]^{2+}$ has neither a *syn* or *anti* conformation with regard to the two phenanthroline binding sites. Instead, the two sites comprise a dihedral angle of ca. 122 deg. Each copper(I) center is coordinated to one phenanthroline and a single acetonitrile molecule. The average Cu–N_{phen} bond length is 204 ± 3 pm, while the Cu–N_{MeCN} distance is much shorter with 186 pm (Table 1). In conclusion, the solid-state structure along with the ^{1}H NMR, ESI-MS and UV/Vis studies proves unequivocally that the HETPHEN concept allows to control the coordination equilibrium of specially designed phenanthroline ligands and to prevent formation of any bishomoleptic complex formation.

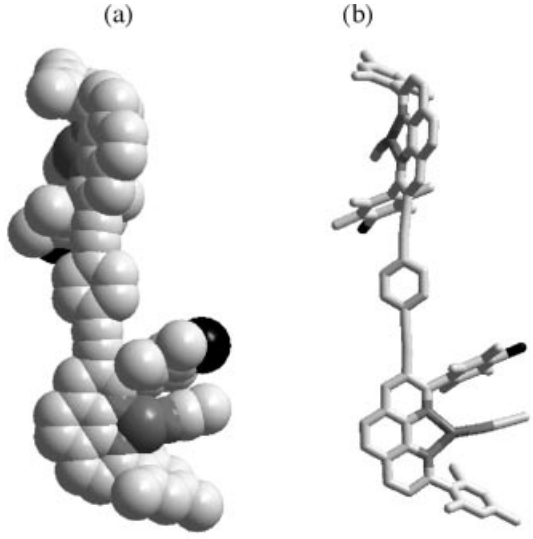

Figure 1. a) Space filling and b) stick representation of the crystal structure of $[Cu_2(\mathbf{2})(MeCN)_2]^{2+}$.

Mechanistic Tests on Formation of $[Cu_2(2)(3a)_2]^{2+}$. Upon addition of a second phenanthroline, such as **3a** or **3b**, to the intermediate $[Cu_2(\mathbf{2})(MeCN)_2]^{2+}$ in dichloromethane, the racks **R1** or **R2** were afforded in basically quantitative yield as evidenced by ^{1}H-NMR and ESI-MS. For example, in case of **R1** ESI-MS showed the presence of one single species at m/z = 814.5 which corresponds to $\mathbf{R1}^{2+}$. Equally, the ^{1}H-NMR illustrated the presence of a single symmetric species (Figure 2). The distinct high field shifts for the mesitylene protons (6.76 to 5.89 ppm) of **2** clearly indicated the formation of a bisheteroleptic complex.

Table 1. Selected Bond Lengths [Å] and Angles [°] for $[Cu_2(\mathbf{2})(MeCN)_2]^{2+}$.

Bond	Length [Å]	Angle	Angle [°]
N1–Cu1	2.016(17)	N1–Cu1–N5	146.14(1)
N2–Cu1	2.050(9)	N2–Cu1–N5	130.10(1)
N5–Cu1	1.856(18)	N2–Cu1–N1	82.91(2)
N3–Cu2	2.071(7)	N3–Cu2–N6	131.88(1)
N4–Cu2	2.017(21)	N4–Cu2–N6	142.61(2)
N6–Cu2	1.861(20)	N3–Cu2–N4	82.54(2)

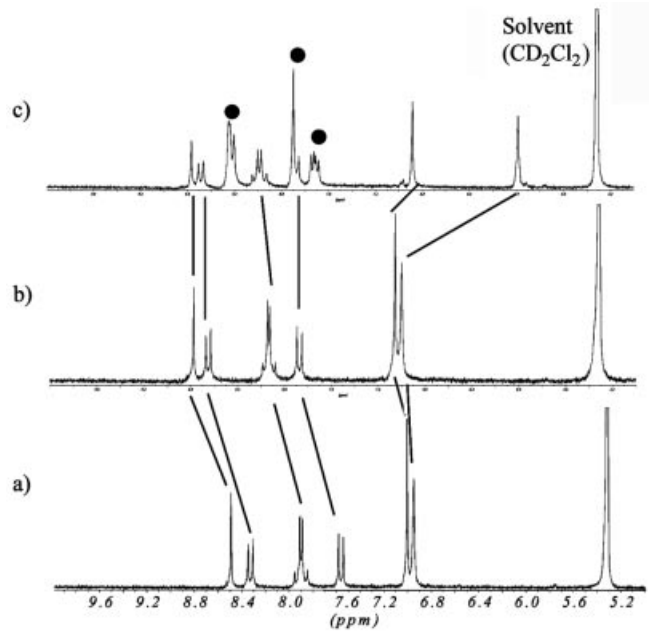

Figure 2. ^{1}H NMR changes in the aromatic region of **2** upon complexation with **3a**. a) free **2**; b) $[Cu_2(\mathbf{2})(MeCN)_2]^{2+}$; c) $[Cu_2(\mathbf{2})(\mathbf{3a})_2]^{2+}$. Signals in Figure **c** being marked by filled spheres belong to phenanthroline (**3a**) protons.

For further understanding, a titration was performed, in which **3a** was added to a dichloromethane solution of $[Cu_2(\mathbf{2})(MeCN)_2]^{2+}$ leading to pronounced changes in the ^{1}H NMR spectra. With the titration proceeding, two different sets of signals evolved for the mesityl protons that were readily assigned to $[Cu(\mathbf{2})(\mathbf{3a})]^+$ and $[Cu_2(\mathbf{2})(\mathbf{3a})_2]^{2+}$ using parallel ESI-MS results. While ESI-MS and ^{1}H NMR titrations proposed a qualitative picture of the mechanism of the self-assembly process, a UV/Vis titration was undertaken to determine the binding constants. It was performed by titrating **2** ($1.2\,10^{-6}$ M) and **3a** ($2.4\,10^{-6}$ M) with aliquot amounts of Cu^I solution in 20 additions (total 4 equiv. of Cu^+). Figure 3 displays the UV/Vis changes upon Cu^I salt addition showing the emerging MLCT transition at ca. 490 nm that is responsible for the red color. As shown in Scheme 4 a two step pathway seems most reasonable for the rack assembly process: it starts out with the formation of $[Cu(\mathbf{2})(\mathbf{3a})]^+$ taking up one more ligand **3a** and Cu^I to furnish the $[Cu_2(\mathbf{2})(\mathbf{3a})_2]^{2+}$ complex. The structure of

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$[Cu_2(\mathbf{2})(\mathbf{3a})_2]^{2+}$ was confirmed by its single crystal analysis.[8] Upon fitting this model with UV/Vis data using the SPECFIT program[14] binding constants could readily be extracted for complexes $[Cu(\mathbf{2})(\mathbf{3a})]^+$ (log K_{111} = 11.6) and $[Cu_2(\mathbf{2})(\mathbf{3a})_2]^{2+}$ (log β_{212} = 23.1). Models that did not fit were rejected.

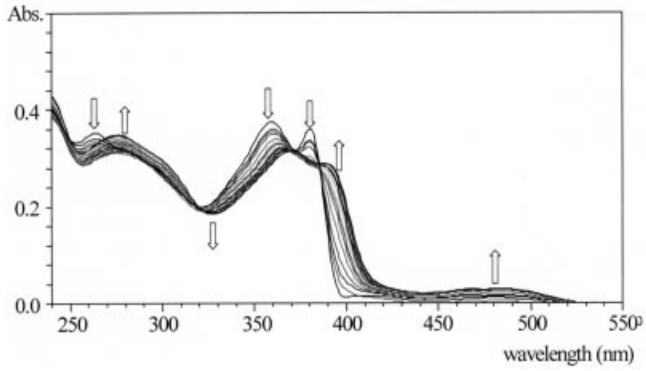

Figure 3. Spectrophotometric titration of **2** and 1,10-phenanthroline (**3a**) by aliquot amounts of Cu^I salt in 20 additions. Solvent: dichloromethane. T = 25(1) °C. [**2**] = 1.20×10^{-6} M and [**3a**] = 2.40×10^{-6} M.

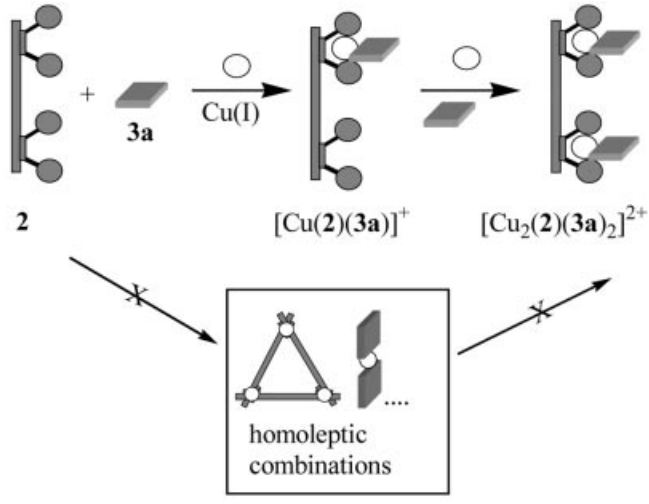
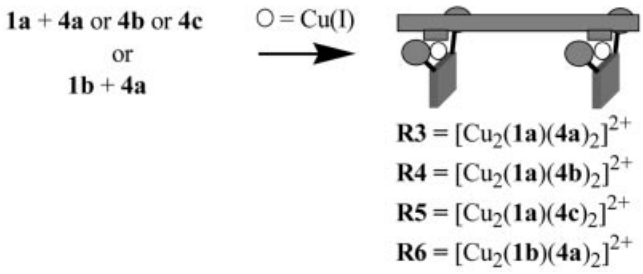


Scheme 4. Self-assembly path for **R1**.

Approach II

As suggested above, rack motifs should also be accessible by approach II. **4a**–**c** were designed according to the HETPHEN strategy, i.e. the 2,9-positions of all monophenanthrolines were loaded with steric stoppers while bisphenanthroline **1a** and **1b** were devoid of this element. Notably, racks **R3**–**R5** were readily afforded upon reacting **1a** with **4a**–**c** in presence of $[Cu(MeCN)_4]PF_6$ (Scheme 5). Similarly, **R6** was obtained by reacting **1b**, **4a** and Cu^I salt in dichloromethane (1:2:2 equiv.). All spectroscopic data was consistent with the proposed composition (see experimental section).



Scheme 5.

Apart from conventional characterisation techniques (^{1}H NMR, ESI-MS, UV/Vis, and elemental analysis), vapour pressure osmometry (VPO) was applied to characterise **R3** as one of the aggregates. VPO is a very useful method to analyse self assembled systems even if they are dynamic;[15] unfortunately, this technique has not been utilised frequently. For **R3** VPO provided a molar mass of 2417 Da, which is in excellent agreement (–2%) with the mass obtained from ESI-MS (2473). The characterisation of even larger dynamic structures by VPO is currently under investigation in our laboratory.

The structure of **R6** was solved by single-crystal X-ray analysis. The stick representation of the solid-state structure of **R6** is depicted in Figure 4. Unlike a previous structure[8] this rack has some deviation from prefect *transoid* conformation. Each copper(I) centre exhibits a pseudotetrahedral coordination geometry (N1–Cu1–N4 108.4°, N2–Cu1–N3 125.0°, N5–Cu2–N8 123.1°, N6–Cu2–N7 120.1°) and finds itself encapsulated by two bromoduryl rings of the bisphenanthroline (Table 2). The duryl groups of **4a** and the phen-

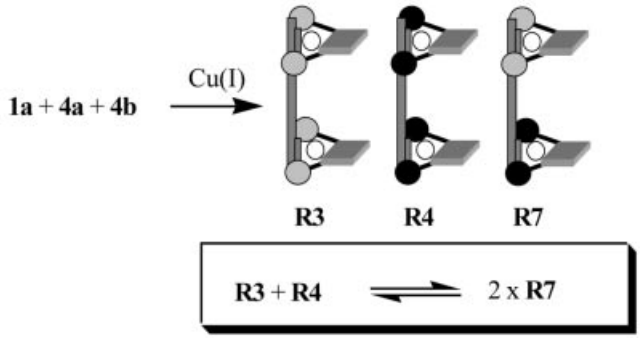
anthroline plane of the second ligand **1b** are oriented face-to-face separated by 3.5 Å, suggesting π-stacking.

Dynamic Nature of Rack Motifs

The dynamic nature of the rack motifs was tested by an exchange experiment.[16] Specifically, we monitored the ligand exchange between **R3** and **R4** by using ESI-MS, with ligand **1a** being common in both **R3** and **R4** (Scheme 6). ^{1}H NMR experiments on the **R3** + **R4** ⇋ **R7** equilibration could not be performed due to signal overlap. However, the present example was studied by ESI-MS furnishing sensible insight into the dynamics of such aggregates. Such investigations are very informative when NMR application is limited.



Scheme 6. Cartoon representation of ligand exchange equilibrium in solution after mixing **R3** and **R4**.

R3 and **R4** in dry dichloromethane were reacted in a 1:1 stoichiometric ratio. The ligand exchange process was observed readily (within ca. 5 min) by ESI-MS exhibiting signals corresponding to a mixture of the three racks **R3**, **R4** and **R7** in a %-ratio of 55, 55 and 100, respectively. This ratio did not change after longer times, indicating that equilibrium had been established at room temp. within less than 5 min (Figure 5). Analgous results were obtained when the racks were generated in one pot by reacting **1a**, **4a** and **4b** in presence of Cu^{I} salt. Isotopic distributions of **R3**, **R4** and **R7** were in excellent agreement with the calculated ones.

The composition was further confirmed by collisional fragmentation experiments. At higher voltages and temperature the ESI-MS is dominated by [Cu(**4a** or **4b**)(**1a**)]$^+$

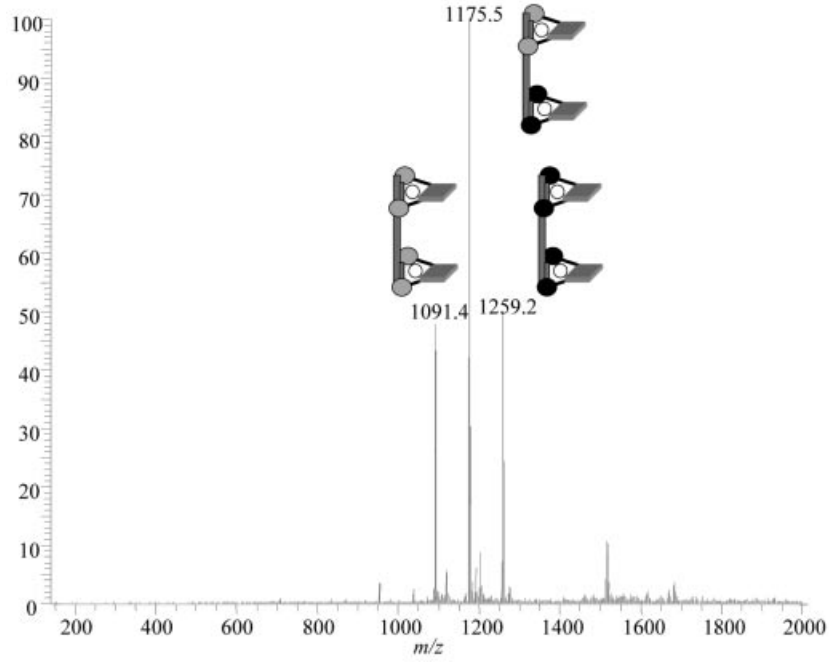


Figure 5. ESI-MS of the reaction mixture obtained when **1a**, **4a**, **4b** are treated with Cu^{I} salt in dichloromethane.

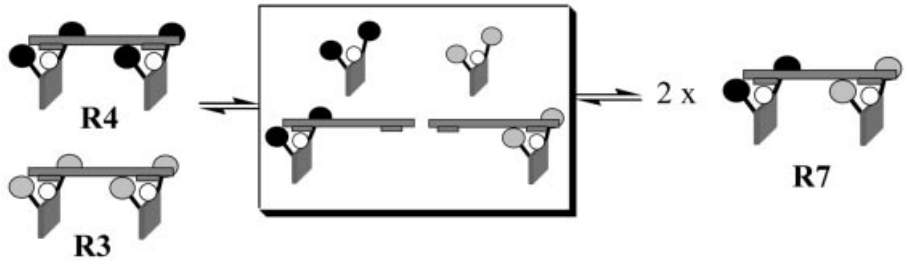

Scheme 7. Mechanism of the dynamic ligand exchange in the interconversion of racks.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and [Cu(**4a** or **4b**)]$^+$ as fragments. It is interesting to note that a similar behaviour was observed for all rack structures, i.e. it is always the sterically loaded ligand that is bound to the metal ion in fragmentation processes. Presumably due to cation-π interactions between Cu^+ and 2,9-aryl groups complexes [Cu(**4a** or **4b**)]$^+$ are more stable than other combinations. These findings were corroborated through collisional fragmentation experiments of **R3**, **R4** and **R7**. For example, fragmentation of **R4** produced signals corresponding to the [Cu(**4b**)(**1a**)]$^+$ and [Cu(**4b**)]$^+$ species. If we translate these ESI-MS results onto the equilibration process in solution then it is reasonable to assume that in the dynamic ligand exchange any dissociation occurs with the metal ions attached to the sterically shielded HETPHEN ligands (Scheme 7).

Conclusions

In summary, the HETPHEN concept proves its value for the clean preparation of racks **R1**–**R6** from various bisphenanthrolines and monophenanthrolines in presence of Cu^+. X-ray and solution spectroscopic data, including ESI-MS, UV/Vis titrations and vapour pressure osmometry, disclose a clear picture of the self-assembly pathway and the products. Accordingly, ligands shielded along the HETPHEN concept (**2** and **4**) bind strongly to the copper ions but are instructed not to undergo self-association to homoleptic complexes. In combination with unshielded ligands **1** and **3** racks **R1**–**R6** are formed in a stepwise manner. Racks **R1**–**R6** are dynamic in nature as demonstrated in exchange processes at room temperature. Since Cu^I-based bisphenanthroline complexes are potential photoactive devices,[17] the present results should open an easy venue to diverse functional aggregates. Studies are in progress to install multi-functionalities into these rack motifs and to study their properties as a function of the dynamic behaviour.

Experimental Section

Ligands, **1a**,[11] **1b**,[11] **2**,[11] **3b**,[13] **4a**,[6c] **4b**[12] and **4c**[13] were prepared according to known procedures. ^{1}H NMR and ^{13}C NMR were measured on a Bruker AC 200 (200 MHz) or Bruker AC 400 (400 MHz). All ^{1}H NMR measurements were carried at room temperature in [D_2]dichloromethane. ESI-MS spectra were measured on a LCQ Deca Thermo Quest. Typically, each time 25 scans were accumulated for one spectrum. UV/Vis spectra were recorded on a Tidas II spectrophotometer using dichloromethane as the solvent.

Spectrophotometric titrations: Equilibrium constants of the complexes were determined in dichloromethane. Ligands 2 and 3a were titrated with aliquot amounts of a stock solution of copper(I) tetrakisacetonitrile hexafluorophosphate. All stock solutions were prepared by careful weighing (microgram scale) on an analytical balance. Absorption spectra were recorded at 25.0±(0.1) °C. Since the formation is instantaneous as evidenced by proton NMR, ESI-MS analysis and visible colour changes, the solutions were immediately analysed spectroscopically to avoid problems with the volatile solvent. The wavelength region from 240 nm to 600 nm was taken into account. Two equivalents (total) of metal salt in dichloromethane solution were added in 20 portions. The entire data sets comprising absorbances measured with one nanometer resolution were decomposed in their principal components by factor analysis. Subsequently, formation constants and their standard deviations were calculated by using the SPECFIT[14] program. Binding constants were determined from two independent titrations.

Vapor-Pressure Osmometry: The instrument (EuroOsmo 7000) was operated at 27 °C, dry dichloromethane was used as solvent. Calibration was performed by using tetrabutylammonium hexafluorophosphate as standard.

General Procedure for the Preparation of Racks R1–R6: Racks **R1**–**6** were prepared by mixing **1** (or **2**) and **3** (or **4**) with [Cu(MeCN)$_4$]PF_6 (1:2:2 equiv., respectively) in dichloromethane. The resulting dark red compound was analysed without any further purification by ESI-MS, ^{1}H NMR, COSY, ^{13}C NMR, IR and elemental analysis.

[Cu_2(2)(3a)$_2$](PF_6)$_2$ (R1): M.p. > 300 °C. ^{1}H NMR (CD_2Cl_2, 400 MHz): δ = 8.81 (s, 2 H, phen), 8.73 (d, J = 8.1 Hz, 2 H, phen), 8.40–8.50 (m, 8 H, phen), 8.23 (dd, 4 H, J = 8.1, J = 4.0 Hz, phen), 7.94 (s, 4 H, phen), 7.92 (d, J = 8.1 Hz, 2 H, phen), 7.75 (m, 4 H, phen), 6.93 (s, 4 H, phenyl), 6.03 (s, 4 H, mes), 1.81 (s, 12 H, CH_3), 1.59 (s, 12 H, CH_3), 1.57 (s, 18 H, CH_3). ^{13}C NMR (CD_2Cl_2, 100 MHz): δ = 161.3, 159.9, 148.1, 144.3, 143.2, 142.9, 139.9, 139.1, 138.2, 138.1, 136.9, 135.0, 134.1, 133.6, 132.5, 131.9, 129.2, 129.1, 128.7, 128.1, 127.9, 127.6, 127.3, 125.1, 122.9, 122.5, 117.5, 117.1 (arom.); 96.7, 87.7 (ethynyl); 20.6, 20.3 (2C), 18.5 (aliph.). Crystal Structure Determinations: Crystals were obtained by slow diffusion of toluene into a solution of the complexes in dichloromethane. Due to the poor quality of the crystals the crystal data are not excellent. Solvent molecules are severely disordered. The measurements were carried out with a STOE-IPDS2 diffractometer with graphite-monochromatised Mo-*Kα* radiation. Table 3 summarises the crystal data, data collection, and refinement parameters. All calculations were performed with the SHELXS-97 package.

A Ruthenium(II)-Complexed Rotaxane Whose Ring Incorporates a 6,6′-Diphenyl-2,2′-bipyridine: Synthesis and Light-Driven Motions

Jean-Paul Collin,[a] Damien Jouvenot,[a] Masatoshi Koizumi,[b] and Jean-Pierre Sauvage*[a]

Keywords: Rotaxanes / Ruthenium / Light-driven motions

By incorporating a 6,6′-diphenyl-2,2′-bipyridine (dpbipy) fragment in a ring, *endo* coordination of a ruthenium(II) center is performed selectively and almost quantitatively. The threaded system, containing a helical fragment, could be fully characterized. When the terminal functions of the rod-shaped helical complex threaded through the macrocycle are phenol groups, the complete rotaxane is prepared by the classical Williamson stoppering reaction in moderate yield. Light-induced motions of the unstoppered system (pseudo-rotaxane) and the real rotaxane have been studied. Under visible light irradiation, quantitative decoordination of the dpbipy-containing ring is observed, leading to the separate fragments (ring and helical thread) or to a new rotaxane (uncoordinated ring threaded by the dumbbell).

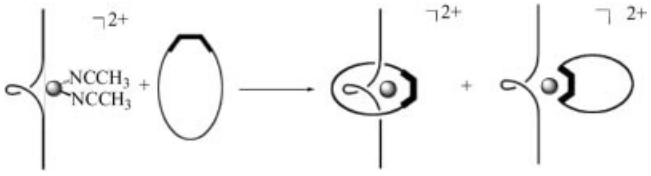
Introduction

The use of transition metals as templates to construct various interlocking and knotted topologies has been exploited by various groups in the course of the last few decades.[1–5] On the basis of related strategies, rotaxanes have also been prepared efficiently.[6,7] In the field of molecular machines and motors[8] light-driven machines are particularly promising.[9] In addition, several systems have been proposed which contain an electroactive transition-metal complex as the key component.[10] A related class of molecules is based on photoinduced electron transfer from the metal-to-ligand charge transfer excited state of a transition-metal complex [copper(I) or ruthenium(II)] to afford a new redox state, which will subsequently rearrange.[11] A very distinct family of dynamic molecular systems takes advantage of the dissociative character of ligand-field states in $Ru(diimine)_3^{2+}$ complexes.[12] In these compounds, one part of the system is set in motion by photochemically expelling a given chelate, the reverse motion being performed simply by heating the product of the photochemical reaction so as to regenerate the original state.

Results and Discussion

We have recently reported the synthesis of a [2]rotaxane constructed around a $Ru(diimine)_3^{2+}$ core.[13] The ring was a derivative of 6,6′-dimethyl-2,2′-bipyridine (dmbipy), and, in the course of the threading reaction, we noticed that both *exo*- and *endo*-coordination to the ruthenium(II) center of the rod-like fragment take place, as schematically represented in Scheme 1.



Scheme 1.

In order to circumvent this synthetic difficulty, we replaced the dmbipy motif by a 6,6′-diphenyl-2,2′-bipyridine chelate (dpbipy), which provides the system with greatly improved geometrical control. According to CPK models, exo coordination of a dpbipy-incorporating ring is virtually impossible, except with very large rings. As reported in this paper, this approach proved successful, and the desired rotaxane could be prepared in good yield, without formation of *exo*-coordinated species. In addition, the photochemical behavior of the compound and of its nonstoppered analogue has been investigated. In particular, it was shown that the ring is efficiently decoordinated from the ruthenium(II) center under visible light irradiation.

Synthesis of a Pseudo-Rotaxane

Preliminarily, we investigated the threading reaction leading to a pseudo-rotaxane, both ends of the helical rod-shaped fragment bearing inert $-OCH_3$ groups. As depicted in Figure 1, the starting ruthenium(II) complex $\mathbf{1}^{2+}$ [13] and

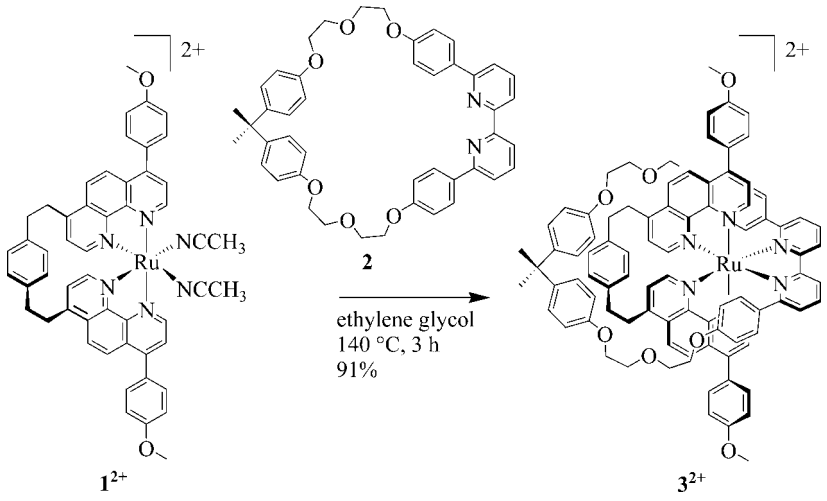

Figure 1. Synthesis of the threaded complex 3^{2+}.

ring **2**[14] reacted under relatively harsh conditions to afford the threaded complex 3^{2+} in good yield (91%) after chromatography (silica). Compound **2** is a 37-membered ring whose synthesis was recently described.[13] The presence of a dpbipy chelate and a bis(phenol) A unit ensures a certain rigidity to the ring, prohibiting swinging of the bis(phenol) A fragment "behind" the bipy chelate. Complex 1^{2+} is a ruthenium(II) complex that contains a helical bis(phenanthroline) organic fragment[13] (Figure 1).

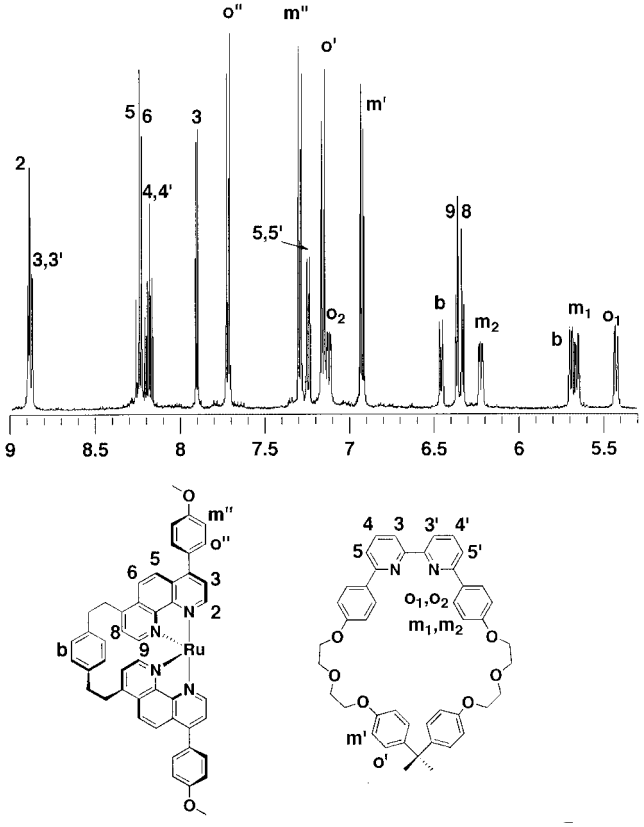

Figure 2. Aromatic region of the ^{1}H NMR spectrum of 3^{2+} in CD_3COCD_3, and proton indexation of the two parts of the molecule (thread and ring).

Complex $\mathbf{3[PF_6]_2}$ is a red complex, which can be recrystallized from an acetone/diethyl ether mixture. As expected, 3^{2+} is the *endo*-coordinated compound, with no contamination by a hypothetical *exo* isomer. ^{1}H NMR spectroscopy turned out to be particularly informative in this respect. The ^{1}H NMR spectrum of 3^{2+} is represented in Figure 2.

The assignment of the various H atoms (indicated on the drawing of the molecular fragments of 3^{2+}) could be done easily by analogy with related systems.[13,14] The most remarkable features of the spectrum are:

(i) The number of signals corresponding exactly to the expected number for a single and *symmetrical* complex ("upper" and "lower" parts of the screwlike fragment identical) and their sharpness.

(ii) The presence of four very well resolved signals for the protons of the two phenyl rings borne by the 2,2′-bipyridine fragment of the ring (o_1, o_2, m_1, m_2). Clearly, the "upper" part and the "lower" part of these phenyl rings are different and they do not interchange, at least at room temperature, as represented in a schematic fashion in the drawing of Figure 2.

Preparation of the Rotaxane

The complete rotaxane was prepared from **2** and 4^{2+}, the phenolic analogue of 1^{2+}, whose synthesis was previously reported.[13] The reaction is represented in Figure 3.

The "threading" step of 4^{2+} through ring **2** afforded the pre-rotaxane 5^{2+} in 82% yield. It was carried out in ethylene glycol at 140 °C. A high-purity sample was obtained by crystallization in acetone/diethyl ether. The "stoppering" reaction was performed using large tetraaryl-methane derivatives of the Gibbson type.[15] The precursor **6** was prepared as previously reported.[16] It reacted with $\mathbf{5[PF_6]_2}$ in DMF, at 60 °C, in the presence of a large excess of K_2CO_3 under argon. After work up and chromatography on silica the real rotaxane 7^{2+} was obtained as a red solid, in 56% yield. The compound can be crystallized in acetone/hexane.

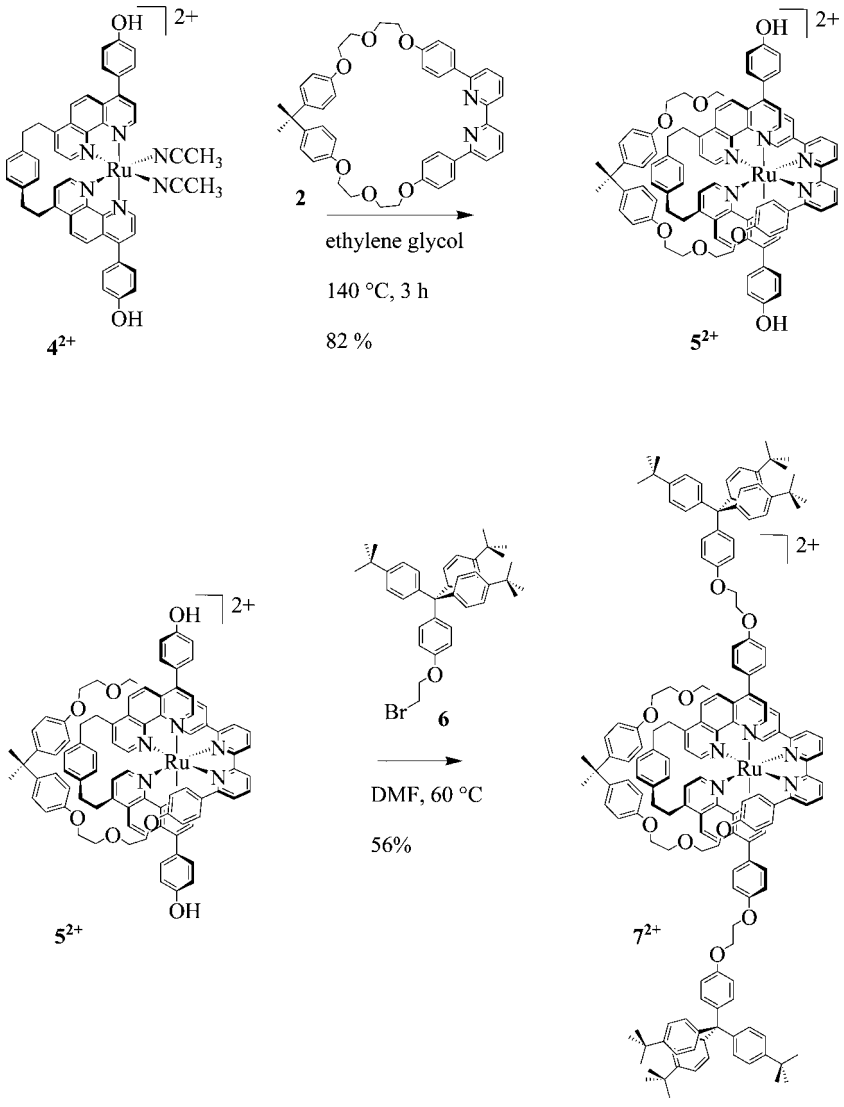

Figure 3. Sequence of reactions leading to the rotaxane 7^{2+}.

In the aromatic region, the ^{1}H NMR spectrum of $\mathbf{7^{2+}}$ is more or less identical to the superimposition of the spectra of $\mathbf{3^{2+}}$ and **6**. The "rope jump" phenomenon observed for pseudo-rotaxanes containing a larger and more flexible ring than in the present case, as already observed,[13,16] is not operative in $\mathbf{7^{2+}}$.

Light-Driven Molecular Motions in the Pseudo-Rotaxane 3^{2+} and in the Rotaxane 7^{2+}

In a first step, the photochemical behavior of complex $\mathbf{3^{2+}}$ was studied. By irradiating a solution of $\mathbf{3[PF_6]_2}$ in 1,2-dichloroethane, using a pass band filter centered around 470 nm and in the presence of a large excess of Cl^-, a clean photochemical reaction takes place. The reaction is schematically represented in Figure 4.

The photoinduced "unthreading" reaction was monitored by UV/Vis spectroscopy. The series of visible spectra, characteristic of metal-to-ligand charge transfer (MLCT) bands, is given in Figure 5.

From a band centered at 465 nm, typical of a Ru(diimine)$_3^{2+}$ complex,[17] a new spectrum is obtained by irradiation, which corresponds to a $RuCl_2$(diimine)$_2$ complex (λ_{max} = 562 nm). As expected, the MLCT band for the photochemical product is strongly bathochromically shifted from that of the tris(diimine) complex. The presence of a clean isosbectic point at 485 nm tends to indicate that the photochemical reaction is selective and quantitative. This has been confirmed by ^{1}H NMR spectroscopy and by thin-layer chromatography (silica; eluent: $CH_3CN/H_2O/KNO_3$, 100:10:1). Complex **8** is the only photochemical product detected and the starting complex $\mathbf{7^{2+}}$ has completely disappeared.

Similar experiments have been performed with the rotaxane. The reaction is represented in a schematic fashion in Figure 6.

The photochemical decoordination of the ring in $\mathbf{7^{2+}}$ is also selective and clean. Here again, in an analogous way as with $\mathbf{3^{2+}}$, an isosbectic point is observed at 486 nm. Thin-layer chromatography turned out to be particularly useful

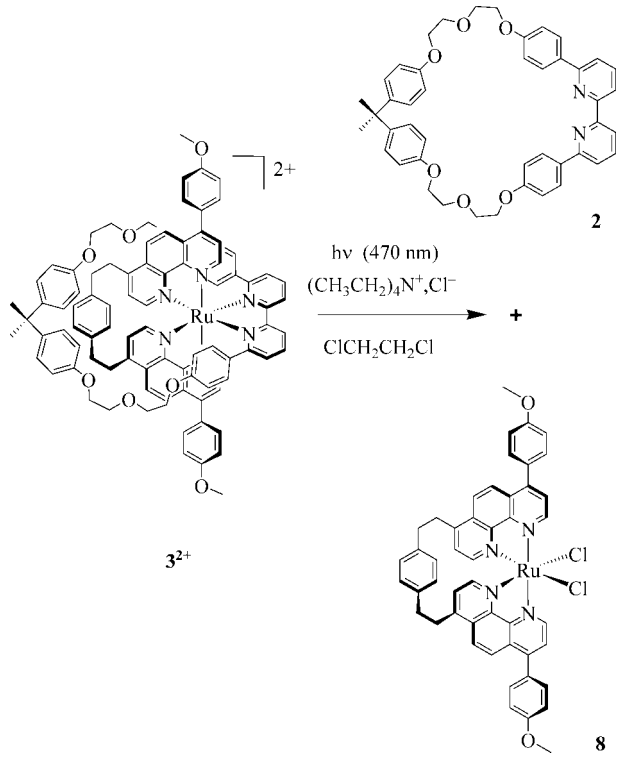

Figure 4. Photochemical expulsion of the macrocycle **2** from the threaded ruthenium complex $\mathbf{3}^{2+}$ in the presence of chloride anions.

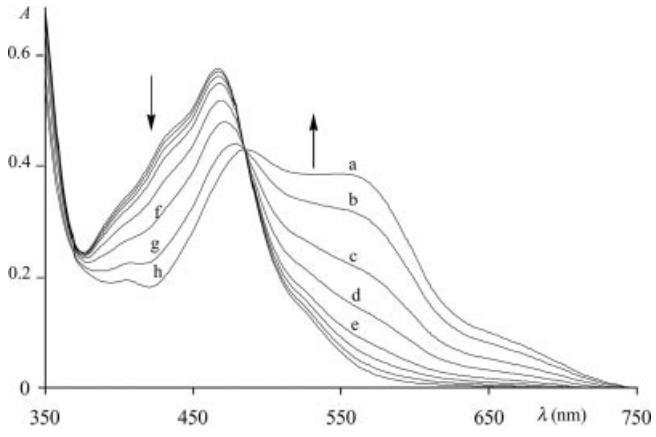

Figure 5. Absorption spectra (visible region) of a solution containing $\mathbf{7}^{2+}$ and $NEt_4^+Cl^-$ in $ClCH_2CH_2Cl$ before, during, and after irradiation. Spectra were recorded at t = 0 s (a), 15 s (b), 40 s (c), 90 s (d), 200 s (e), 400 s (f), 900 s (g), 2400 s (h).

to monitor the reaction. It showed that **7[PF$_6$]$_2$** is gradually converted to a single purple complex, **9**, under irradiation (470 nm). Importantly, traces of the free ring **2** could not be detected, demonstrating that both forms of the rotaxane, $\mathbf{7}^{2+}$ and **9**, do not undergo unthreading, even to a minor extent; The thermal recoordination reaction of **8**, leading back to $\mathbf{7}^{2+}$, is presently under investigation. Unfortunately, preliminary data seem to indicate that this reaction is not as clean and selective as in the case of a related catenane[10] nor as the presently described threading reaction of $\mathbf{1}^{2+}$ through **2**.

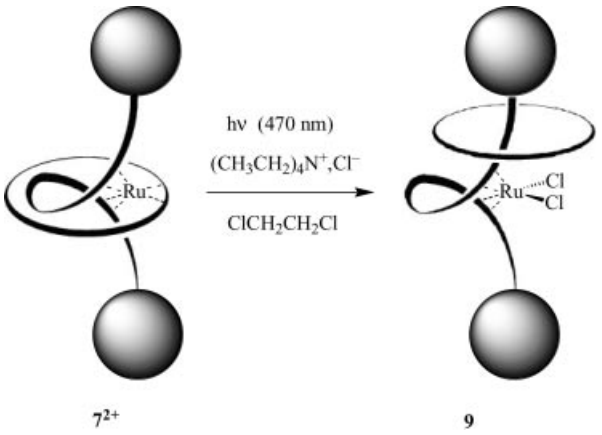

Figure 6. Schematic representation of the photochemical reaction leading to the disconnected rotaxane **9**.

Conclusions

The present report shows that a rotaxane and its non-stoppered analogue could be selectively prepared, the formation of *exo*-coordinated species being completely avoided. The size of the ring is important in controlling the course of the coordination reaction. In the present case, the 37-membered ring is large enough to accommodate the thick helical fragment by which it is threaded. However, it is neither so large nor flexible as to permit unthreading of the rotaxane dumbbell from the ring, once a decoordinated compound such as **9** has been formed.

Preliminary photochemical experiments demonstrated that clean and selective light-induced motions take place, the ring being decomplexed from the ruthenium(II) center. The thermal backward reaction is presently under investigation.

Experimental Section

General Methods: Oxygen- or moisture-sensitive reactions were performed in oven-dried glassware attached to a vacuum line with Schlenk techniques. Dry solvents were distilled from suitable desiccants under argon. Compounds **2** and **6** as well as complex **5[PF$_6$]$_2$** were prepared according to literature procedures.[13,16] All other chemicals were purchased from commercial sources and used without further purification. Column chromatography was carried out on silica gel 60 [Merck, 40–63 (fine) or 63–200 mesh]. Thin-layer chromatography (TLC) was performed on glass plates coated with silica gel 60 F254 (Merck). ^{1}H NMR spectra were recorded with either Bruker AVANCE 300 (300 MHz) or Bruker AVANCE 400 (400 MHz) spectrometers with the deuterated solvent as the lock and residual solvent as the internal reference. Electron-spray ionization mass spectra (ESI-MS) were recorded with a Bruker MicroTOF instrument. UV/Vis spectra (absorption spectroscopy) were recorded with a Kontron Instruments UVIKON 860 spectrometer at room temperature. All solutions were degassed and then saturated with oxygen-free argon. Light irradiation experiments: 3 mL of a sample solution of the complex (c = 10–5 M) were put in a closed UV-visible glass cell. The sample was irradiated with the beam of a 250 W slide projector, filtered by a water filter and focused on the cell. The evolution of the absorption spectrum of the solution was followed with respect to irradiation time.

3[PF$_6$]$_2$: A suspension of **2** (15.0 mg, 0.0212 mmol) and **1[PF$_6$]$_2$** (16.0 mg, 0.0135 mmol) in degassed ethylene glycol (5 mL) was heated at 140 °C for 2 h under argon. The orange suspension turned into a red solution. After cooling to room temperature, a saturated aqueous solution of KPF_6 (10 mL) was added. The orange precipitate was then filtered and washed with water. The crude product was purified by column chromatography on silica gel [eluent: acetone/H_2O/saturated aqueous KNO_3 (100:0:0 to 100:5:0.5)] affording **3[PF$_6$]$_2$** (22.2 mg, 0.0123 mmol) in 91% yield. Crystallization from acetone/diethyl ether afforded a highly pure sample of **3[PF$_6$]$_2$** (8.9 mg, 0.0051 mmol) in 38% yield. ^{1}H NMR (500 MHz, $(CD_3)_2CO$, 25 °C): δ = 5.43 (d, 2 H, ^3J = 8.6 Hz, H^{o1}), 5.66 (d, 2 H, ^3J = 8.6 Hz, H^{m1}), 5.69 (d, 2 H, ^3J = 9.8 Hz, H^b), 6.23 (d, 2 H, ^3J = 8.5 Hz, H^{m2}), 6.33 (d, 2 H, ^3J = 5.8 Hz, H^8), 6.37 (d, 2 H, ^3J = 5.6 Hz, H^9), 6.46 (d, 2 H, ^3J = 8.6 Hz, H^b), 6.93 (d, 4 H, ^3J = 8.9 Hz, H$^{m'}$), 7.13 (d, 2 H, ^3J = 8.6 Hz, H^{o2}), 7.16 (d, 4 H, ^3J = 9.0 Hz, H$^{o'}$), 7.25 (d, 2 H, ^3J = 7.6 Hz, H$^{5,5'}$), 7.30 (d, 4 H, ^3J = 8.8 Hz, H$^{m''}$), 7.73 (d, 4 H, ^3J = 8.8 Hz, H$^{o''}$), 7.91 (d, 2 H, ^3J = 5.6 Hz, H^3), 8.19 (dd, 2 H, J = 7.6 and 7.9 Hz, H$^{4,4'}$), 8.23 (d, 2 H, ^3J = 9.5 Hz, H^6), 8.26 (d, 2 H, ^3J = 9.4 Hz, H^5), 8.89 (d, 2 H, ^3J = 6.8 Hz, H$^{3,3'}$), 8.90 (d, 2 H, ^3J = 5.2 Hz, H^2) ppm. ESI-MS: m/z = 829.08 ([M – 2 PF_6]/2); calcd. for $C_{93}H_{82}F_6N_6O_8PRu/2$ 829.24.

5[PF$_6$]$_2$: A suspension of **2** (39.4 mg, 0.056 mmol) and **4[PF$_6$]$_2$** (42.5 mg, 0.037 mmol) in degassed ethylene glycol (10 mL) was heated at 140 °C for 2 h under argon. The orange suspension turned into a red solution. After cooling to room temperature, a saturated aqueous solution of KPF_6 (30 mL) was added. The orange precipitate was then filtered and washed with water. The crude product was purified 3 times by column chromatography on silica gel [eluent: acetone/H_2O/saturated aqueous KNO_3 (100:0:0 to 100:10:1)] affording **5[PF$_6$]$_2$** (54.0 mg, 0.03 mmol) in 82% yield. Crystallization from acetone/diethyl ether afforded pure **5[PF$_6$]$_2$** (7.7 mg, 0.0044 mmol) in 12% yield. ^{1}H NMR (300 MHz, $(CD_3)_2CO$, 25 °C): δ = 5.45 (d, 2 H, ^3J = 8.3 Hz, H^{o1}), 5.72 (m, 4 H, H^{m1}, H^b), 6.25 (d, 2 H, ^3J = 8.5 Hz, H^{m2}), 6.36 (d, 2 H, ^3J = 5.6 Hz, H^8), 6.40 (d, 2 H, ^3J = 5.5 Hz, H^9), 6.48 (d, 2 H, ^3J = 7.9 Hz, H^b), 6.96 (d, 4 H, ^3J = 8.8 Hz, H$^{m'}$), 7.22 (m, 12 H, H^{o2}, H$^{o'}$, H$^{5,5'}$, H$^{m''}$), 7.66 (d, 4 H, ^3J = 8.6 Hz, H$^{o''}$), 7.92 (d, 2 H, ^3J = 5.6 Hz, H^3), 8.3 (m, 6 H, H$^{4,4'}$, H^6, H^5), 8.92 (m, 4 H, H$^{3,3'}$, H^2) ppm. ESI-MS: m/z = 1483.65 ([M– 2 PF_6^- – H + e$^-$]); calcd. for $C_{91}H_{77}N_6O_8Ru$ 1483.48.

7[PF$_6$]$_2$: 5[PF$_6$]$_2$ (54.0 mg, 0.03 mmol) and **6** (183.5 mg, 0.3 mmol) were added to a vigorously stirred suspension of K_2CO_3 (42 mg, 0.3 mmol) in DMF (30 mL) under a stream of argon. The mixture was heated to 60 °C and stirred for 42 h. DMF was removed in vacuo and a saturated aqueous solution of KPF_6 (30 mL) was added. The orange precipitate was then filtered and washed with water. The crude product was purified by column chromatography on silica gel [eluent: acetone/H_2O/saturated aqueous KNO_3 (100:0:0 to 100:5:0.5)] affording **7[PF$_6$]$_2$** (39.8 mg, 0.017 mmol) in 56% yield. Crystallization from acetone/*n*-hexane afforded pure **7[PF$_6$]$_2$** (30.7 mg, 0.011 mmol) in 36% yield. ^{1}H NMR (500 MHz, $(CD_3)_2CO$, 25 °C): δ = 5.44 (d, 2 H, ^3J = 8.6 Hz, H^{o1}), 5.67 (d, 2 H, ^3J = 8.3 Hz, H^{m1}), 5.70 (d, ^3J = 8 Hz, 2 H, 6 Hz, H^b), 6.24 (d, 2 H, ^3J = 8.6 Hz, H^{m2}), 6.35 (d, 2 H, ^3J = 5.4 Hz, H^8), 6.38 (d, 2 H, ^3J = 5.4 Hz, H^9), 6.47 (d, 2 H, ^3J = 8.3 Hz, H^b), 6.93 (m, 6 H, H$^{m'}$, H^w), 7.16 (m, 22 H, H^{o2}, H$^{o'}$, H^x, H^y), 7.26 (d, 2 H, ^3J = 7.9 Hz, H$^{5,5'}$), 7.36 (d, 16 H, Hz, H$^{m''}$), 7.74 (d, 4 H, ^3J = 8.6 Hz, H$^{o''}$), 7.93 (d, 2 H, ^3J = 5.4 Hz, H^3), 8.20 (t, 2 H, ^3J = 7.9 Hz, H$^{4,4'}$), 8.23 (d, 2 H, ^3J = 9.4 Hz, H^6), 8.28 (d, 2 H, ^3J = 9.4 Hz, H^5), 8.9 (m, 4 H, H$^{3,3'}$, H^2) ppm. ESI-MS: m/z = 1272.81 ([M – 2 PF_6]/2); calcd. for $C_{169}H_{1706}N_6O_{10}Ru/2$ 1273.1.

A Theoretical Investigation of Substituent Effects on the Absorption and Emission Properties of a Series of Terpyridylplatinum(II) Acetylide Complexes

Xiao-Juan Liu,[a] Ji-Kang Feng,*[a,c] Jian Meng,[b] Qing-Jiang Pan,[a] Ai-Min Ren,[a] Xin Zhou,[a] and Hong-Xing Zhang[a]

Keywords: Density functional calculations / Electronic structure / N ligands / Platinum

A comprehensive calculational investigation has been carried out on a series of complexes of the type [(terpyridyl-R^1)-Pt(C≡C-R^2)], where terpyridyl-R^1 is a series of substituted 2,2′:6′,2′′-terpyridyl ligands and C≡C-R^2 is a series of substituted acetylide ligands. In one series of complexes (**I**), the energy of the electronic excited state is varied by changing the substituents on the terpyridyl ligand (R^1). In a second series of complexes (**II**), this electronic structure variation is obtained by changing the *para* substituents (R^2) of the acetylide ligand. The effect of varying the substituents on the lowest-energy excited states of the complexes has been assessed by calculating their electronic structures and excitation energies. We anticipated that introduction of electron-withdrawing substituents on the terpyridyl ligand will benefit the LLCT (or MLCT) and prohibit the nonradiative pathways via d-d transitions in these complexes; introduction of electron-donating substituents on the acetylide ligand can also prohibit the nonradiative pathways by increasing the energy gaps between the HOMO–LUMO and d-d transitions. The results also reveal that the lowest-energy excitations of all complexes of series **I** and **IIa–b** complexes are dominated by a π(C≡C)→π*(terp) (LLCT) transition mixed with some energetically dπ(Pt)→terpyridyl (MLCT) transition. However, for the complexes **IIc–IId**, in which phenyl rings are introduced on the acetylide ligand, the lowest-lying absorptions of **IIc** and **IId** are predominately LLCT in character, with less MLCT mixture, due to a lower contribution of the Pt(d) orbital to the HOMO, while for **IIe**, with a stronger donor on the acetylide, the lowest-lying absorption is completely LLCT in character. The absorption and emission calculations using the TDDFT method are based on the optimized geometries obtained at the B3LYP/LanL2DZ and CIS/LanL2DZ levels, respectively.

Introduction

Transition metal complexes that feature metal-to-ligand charge transfer (MLCT) excited states have fascinated photochemists for four decades.[1–12] This fascination derives from a combination of features exhibited by MLCT excited states, which include visible light absorption, photoluminescence, long lifetimes, and relative inertness toward unimolecular photochemistry.[9] By far the majority of the work that has been carried out on MLCT states has focused on d^6 metal–polypyridine complexes of Ru^{II}, Os^{II}, and Re^{I}.[8,9,13,14] However, recently there has been increasing interest in the properties of d^8 platinum(II) complexes such as [PtL_2(diimine)], where L = halide, nitrile, thiolate, isocyanide, and acetylide.[15–27] These Pt^{II}–diimine complexes feature long-lived excited states that are believed to be based on dπPt→π* diimine MLCT. Terpyridylplatinum(II) complexes have also attracted considerable attention in recent years, mainly because of their interesting spectroscopic behavior[28–33] and useful physical and biological properties.[34,35] Indeed, these complexes have been established as important DNA intercalators[34,36] and protein probes.[37] Their spectroscopic properties and low-energy absorptions generally arise from metal-to-ligand charge transfer (MLCT) transitions. However, the development of the photochemistry of these complexes is limited by their nonemissive or short-lived MLCT excited states in solution at room temperature.[28] This lack of emission originates from low-lying d-d excited states, which provide facile nonradiative deactivation pathways by molecular distortion. For these complexes, the d-d and MLCT excited sates are very close in energy, resulting in fast internal conversion from MLCT to d-d excited states. Many efforts have been performed to obtain emissive terpyridylplatinum(II) complexes with long-lived excited states and high emission quantum yields.[28–33] The main strategy to construct long-lived and emissive terpyridylplatinum(II) complexes involves utilizing substituted terpyridyl ligands with low-lying LUMOs and/or ancillary ligands on acetylide with a large electron-donating ability to raise the HOMO of the metal center, hence resulting in

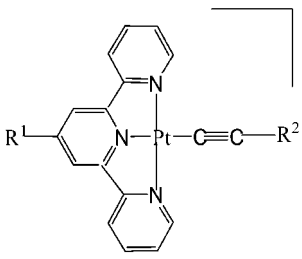
the reduction of the MLCT excited state energy. As a result, the energy difference between the MLCT and d-d state increases. Yam et al.[33] have synthesized a series of terpyridylplatinum(II) acetylide complexes and studied the absorption and emission properties of these complexes. They found that the emission energies depend on the nature of the acetylide ligands with different substituents on the phenyl ring, i.e., the more electron-withdrawing the group on the phenyl acetylide ligand, the higher the emission energy. This trend is consistent with an assignment of a triplet metal-to-ligand charge transfer (^{3}MLCT) state, probably mixed with some acetylide-to-terpyridine ligand-to-ligand charge transfer (^{3}LLCT) character. Tung et al.[38] have synthesized and investigated a series of 4-tolylterpyridylplatinum(II) acetylide complexes, which show high quantum yield and long lifetime photoluminescence from a triplet metal-to-ligand charge transfer (^{3}MLCT) excited state in fluid solution at room temperature. In their UV/Vis spectra, all the complexes exhibit intense vibronic-structure absorption bands at $\lambda < 350$ nm which come from the ligand-to-ligand (LLCT) transition of terpyridyl and acetylide ligands as well as the charge transfer transition involved in the Pt–C≡CR moieties, while the low-energy absorption bands at 400–500 nm are tentatively assigned to the $d\pi(Pt) \rightarrow \pi^*$(trpy) MLCT transition.

Our aim is to determine to what extent the substituents affect the low-lying electronic transitions of these complexes and thus assess the validity of the generally accepted MLCT assignments of the lowest-energy absorption bands. We hope that our theoretical investigation can provide an important guidance for the design of these metal coordination complexes. Two series of terpyridylplatinum(II) acetylide complexes have been studied. In one series, **Ia**–**Ic**, the substituents (R^1) on the tepyridyl ligand are varied (H, CH_3, and CN) while the structure of the acetylide ligands is held constant as -CH_2OH to investigate the effect of different terpyridyl substituents on the spectra; in the second series, **IIa**–**IIe**, the terpyridyl ligand is held constant (4-tolylterpyridyl) while the *para* substituents (R^2) on the acetylide ligands are varied (CH_2OH, *n*-propyl, C_6H_4Cl-4, C_6H_5, and -$C_6H_5NH_2$) to study the influence of different acetylide substituents. The electronic structures of the complexes were calculated by density functional theory, which was also used to determine the nature of the electronic transitions. The solvent effect was simulated by the polarizable continuum model (PCM).[39]

Results and Discussion

Ground-State Geometry Optimization

The complexes investigated are shown in Scheme 1. To provide the structures to be used for the calculation of the electronic spectra, ground-state geometry optimizations were first performed on the studied complexes. Because of the different substituents R^1 and R^2, the C_{2v} symmetry is broken and the entire molecular point group is reduced to C_1. Taking complex **IId** as an example, the perspective drawing is shown in Figure 1. Selected bond lengths and angles are tabulated in Table 1, along with the available experimental values of the X-ray crystal structure of complex **IId** for comparison.



Ia: R^1 = H, R^2 = CH_2OH
Ib: R^1 = CH_3, R^2 = CH_2OH
Ic: R^1 = CN, R^2 = CH_2OH
IIa: R^1 = *p*-tolyl, R^2 = CH_2OH
IIb: R^1 = *p*-tolyl, R^2 = *n*-propyl
IIc: R^1 = *p*-tolyl, R^2 = C_6H_4Cl-4
IId: R^1 = *p*-tolyl, R^2 = C_6H_5
IIe: R^1 = *p*-tolyl, R^2 = $C_6H_4NH_2$-4

Scheme 1. Illustration of the investigated complexes.

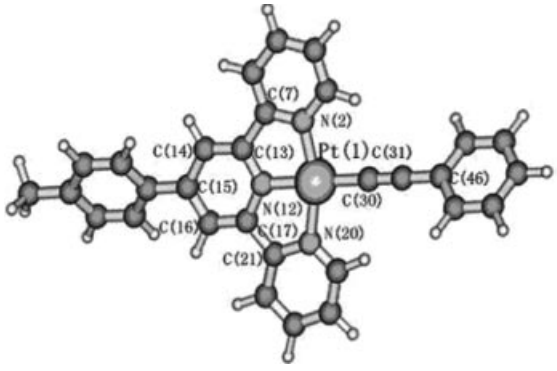


Figure 1. Complex structure and atom-numbering scheme taking complex **IId** as an example.

There is an overall satisfactory agreement between the theoretical and the available experimental data:[33] all the computed distances are within the experimental error (±0.04 Å). Table 1 shows that the variation of the substituents has more influence on the bond angles than on the bond lengths, as the bond lengths are almost unchanged while the bond angles undergo a comparatively large change. In particular, we should note the N(20)–Pt(1)–C(30) and Pt(1)–C(30)–C (31) angles, which show that when CH_2OH is connected to the acetylide ligand the Pt(1)–C(30)–C(31) angle deviates more from 180° (Table 1). This phenomenon is attributed to the weak interaction of CH_2OH with the Pt center. The coordination geometry about platinum is essentially square planar, with the bond length of the platinum to the central nitrogen atom [Pt(1)–N(12) = 1.99 Å] of the terpyridine ligand slightly shorter than to the other two outer nitrogen atoms [Pt(1)–N(2) and Pt(1)–N(20) are 2.05 Å and 2.04 Å, respectively], as required by the steric demands of the terpyridine ligand. These bond lengths are similar to the experimental[33] values of 1.97 Å, 2.01 Å, and 2.03 Å, respectively. Not surprisingly, the N–Pt–N angles [N(2)–Pt(1)–N(12) = 80.3°; N(12)–Pt(1)–N(20) = 80.3°; N(2)–Pt(1)–N(20) = 160.5°] deviate from the idealized values of 90° and 180° as a consequence of the geometric constraints imposed by the terpyridine ligand and the different substituents. The Pt–C bond length is 1.97 Å, which compares well with experimental

[a] From ref.[33]

value of 1.98 Å.[33] The C≡C bond length of 1.22 Å is comparable to the experimental value of 1.19 Å.

Molecular Orbital Analysis

Since the observed differences in the chemical and physical properties of the complexes rely primarily on the changes in the ground-state electronic structure, before dealing with the excited states we will discuss in detail the ground-state electronic structure of these complexes with a special emphasis on the frontier orbital components, HOMO–LUMO energy gaps, and metal–metal transition energies. The calculated frontier orbital energies are tabulated in Table 2 and plotted according to their energy levels in Figure 2. The assignment of the nature of each MO was made on the basis of its components, as shown in Figure 3 and 4, taking complexes **Ib** and **IId** as examples, respectively. Through the contour plots of Figures 3 and 4, we can see that there is a degree of interaction between the π-orbitals of the terpyridyl and acetylide moieties via the Pt dπ-orbitals, and so the substituent effect on both ligands can extend across the Pt center and influence the excitation

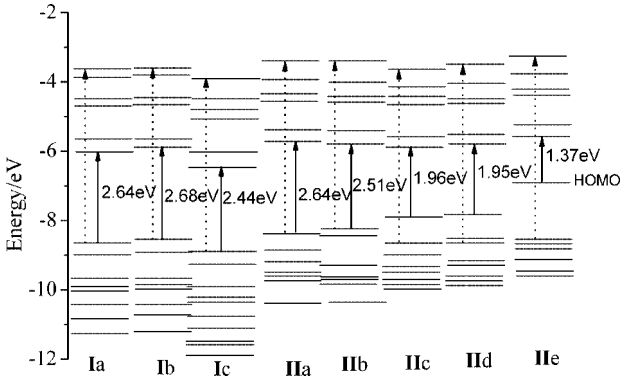

Figure 2. Molecular orbital energy level diagrams summarizing the B3LYP/LanL2DZ results. Solid and dotted arrows represent the energy gaps of HOMO and LUMO orbitals and that of d→d excitations.

nature of the complexes. A complete analysis of the highest occupied and lowest unoccupied molecular orbitals of all the complexes is presented in Table 3, where the orbital character and composition in terms of atomic contributions is presented. Percent contributions were calculated using

Table 2. Energies of the frontier molecular orbitals obtained from the B3LYP/LanL2DZ calculation.

Equation (1), where n is the atomic orbital coefficient and $\sum n^2$ is the sum of the squares of all atomic orbital coefficients in a specific molecular orbital.

$$[n^2/\sum n^2] \times 100 = \%\ \text{contribution} \quad (1)$$

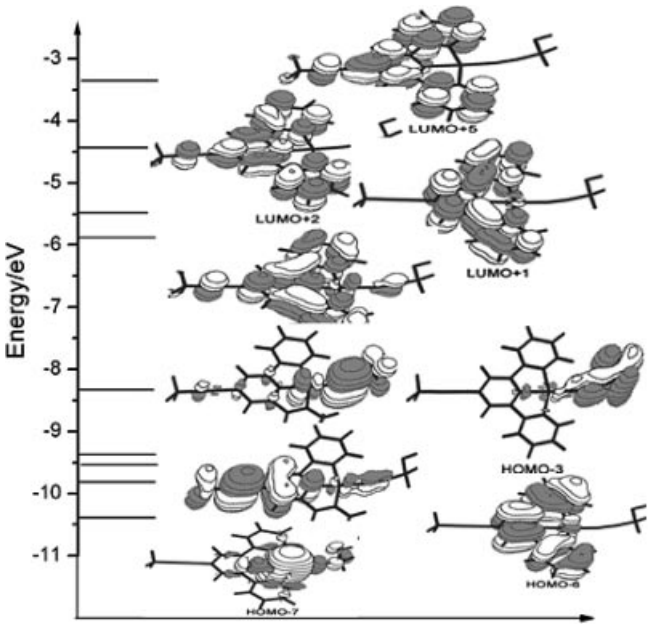

Figure 3. Frontier orbital diagram of complex **Ib** calculated at the B3LYP/LanL2DZ level. The plot on the right is the contour plot for each molecular orbital.

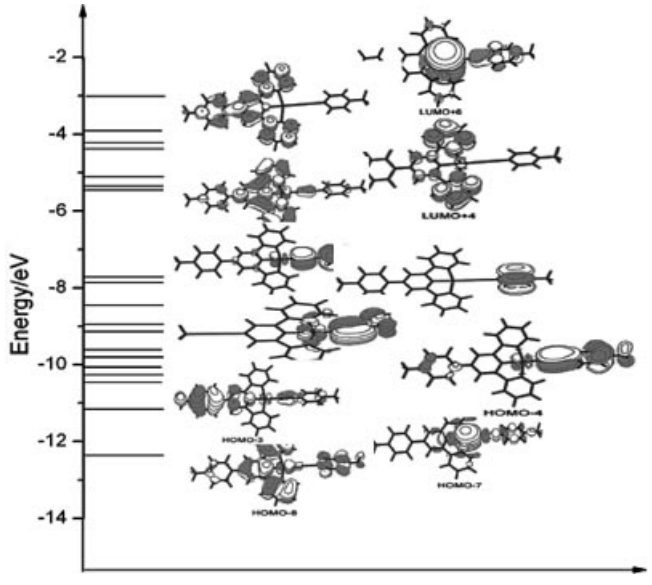

Figure 4. Frontier orbital diagram of complex **IId** calculated at the B3LYP/LanL2DZ level. The plot on the right is the contour plot for each molecular orbital.

Every complex is divided into three parts: the metal, the terpyridyl ligand with the substituent R^1, and the acetylide ligand with R^2. Each part of the percent contributions are the sum of the atomic coefficient squares.

In general, for all the investigated complexes, the first five unoccupied orbitals have the same character as the π*-orbital of the free terpyridyl ligand, although slightly perturbed by a small contribution from the d-orbital of Pt (about 6% for all the investigated complexes), and the LUMO+6 unoccupied orbitals are all composed of both Pt 3s and d_{z^2}orbitals and terpyridyl $2p_z$ orbitals. The low-energy transition character is therefore distinguished by the occupied orbital compositions. For series **I**, the occupied orbital compositions are perturbed by different substituted groups, but the relative ordering and characters are not changed: the HOMO orbitals have predominant -C≡C-R^2 character, mixed with Pt d-orbitals (24%, 37%, and 25% for **Ia**, **Ib** and **Ic**, respectively); the HOMO–3 and HOMO–7 orbitals are Pt- and terpyridyl-localized, respectively, and the HOMO–4 and HOMO–6 orbitals are a combination of Pt d-orbitals and terpyridyl π-orbitals (Table 3). Series **II** complexes can be separated into two groups: **IIa**,**b** (with -CH_2OH and -C_3H_7) in which the alkyl substituents are introduced on the acetylide and **IIc**–**e** in which phenyl rings are introduced on the acetylide. The HOMO orbitals for **IIa** and **IIb** have the same character as series **I** complexes, with predominant contributions from -C≡C-R^2 and some contributions from the Pt d-orbital (27% and 26%, respectively), while for **IIc**–**e** the HOMO orbitals are more –C≡C–R^2 in character due to the lower contributions from the Pt d-orbitals (8%, 10%, and 4% for **IIc**, **IId**, and **IIe**, respectively). In particular, the contribution of the Pt d-orbital to the HOMO (4%) in **IIe** is less than that to the LUMO (6%), so we characterized the HOMO in **IIe** as π(C≡C-R^2). It should be noted that introduction of a phenyl ring with a strong donor will lower the Pt d contribution to the HOMO (such as **IIc** and **IId**) or even change its character (such as **IIe**). According to the analysis of the frontier orbital compositions above, it can be found that the d-d excitations in complexes **Ia**–**c** and **IIa**,**b** occur between the HOMO to LUMO+6 transitions; while in complexes **IIc**–**e** the d-d excitations occur between the HOMO–1 to LUMO+6 transitions (see the dotted arrows in Figure 2).

We also investigated the substituent effects on the electronic orbital energy. Compared with those of complex **Ia**, the HOMO and LUMO molecular orbitals of **Ib** are lifted and the energy gap between the HOMO and LUMO ($\Delta E_{\text{HOMO–LUMO}}$) is increased ($\Delta E_{\text{HOMO–LUMO}}$ is 2.64 eV for **Ia** and 2.68 eV for **Ib**), while the HOMO and LUMO orbitals (especially the LUMO) of complex **Ic** are lowered greatly; the energy gap ($\Delta E_{\text{HOMO–LUMO}}$) decreases to 2.44 eV. According to the analysis above, the introduction of electron-withdrawing substituents on the terpyridyl ligands makes the HOMO→LUMO transition easier by lowering the $\Delta E_{\text{HOMO–LUMO}}$ energy gap, in particular by lowering the LUMOs, which are π* terpyridyl orbitals in this case. For the second series (**IIa**–**IIe**), it can be seen from Table 2 and Figure 2 that, first, compared with those of complexes **I**, the frontier molecular orbitals, especially the HOMOs, are lifted for all the series **II** complexes, and the energy gaps ($\Delta E_{\text{HOMO–LUMO}}$) are decreased further with the increase of the electron-donating ability of the substituents, and second, comparing the frontier orbitals of **IIc**, **IId**, and **IIe**, in which phenyl rings are included in the substituents,

[a] HOMO and LUMO orbitals are shown in bold.

with those of **IIa** and **IIb**, in which the substituents are only CH_2OH or C_3H_7, the energy gaps ($\Delta E_{HOMO–LUMO}$) are lower for **IIc**, **IId**, and **IIe**, thus indicating that introduction of a phenyl ring will enhance the HOMO→LUMO transition by virtue of the decreasing energy gaps ($\Delta E_{HOMO–LUMO}$). Finally, a comparison of the HOMO levels (see Table 2) and $\Delta E_{HOMO–LUMO}$ (see Table 2 and Figure 2) of complexes **IIa** and **IIb** shows that the donating ability of *n*-propyl is stronger than that of CH_2OH. Furthermore, in complexes **IIc**, **IId**, and **IIe** it is obvious

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

that the stronger donor group (NH_2 > H > Cl) on the phenyl rings leads to a greater decrease of the energy gaps ($\Delta E_{HOMO–LUMO}$ is 1.96 eV, 1.95 eV, and 1.37 eV for **IIc**, **IId**, and **IIe**, respectively).

The effect of the substituents on the electronic structures is described more quantitatively in Table 4, which lists the energy gaps of $\Delta E_{HOMO–LUMO}$, the d-d transition ($\Delta E_{d–d}$), and the energy difference between the HOMO–LUMO and the d-d transitions. The values of $\Delta E = \Delta E_{d-d} - \Delta E_{HOMO–LUMO}$ show that introduction of electron-withdrawing (donating) groups on the terpyridyl ligand makes this value larger (smaller) (in the first series this value is 2.35, 2.31, and 2.52 eV for complexes **Ia**, **Ib**, and **Ic**, respectively), and the introduction of electron-donating groups on the acetylide causes this value to increase (in the second series this value is 2.32, 2.37, 3.14, 3.19, and 3.97 eV for complexes **IIa**–**e**, respectively). As a result, with the increase of the energy difference between the HOMO–LUMO and the d-d transitions, the probability of nonradiative deactivation via the d-d state decreases. According to the analysis above, we can anticipate that the introduction of electron-withdrawing substituents on the terpyridyl ligand will benefit the LLCT (or MLCT) and prohibit the nonradiative pathways via d-d transitions in these complexes; the introduction of an electron-donating substituent on the acetylide ligand can also prevent the nonradiative pathways by increasing the energy gap between the HOMO–LUMO and d-d transitions. On the other hand, according to the energy gap law, the lower the energy of the excited state, the shorter the lifetime, so when we try to find effective light-emitting materials, we should consider these competing factors.

Table 4. The energy gaps (eV) of the $d\pi Pt \rightarrow d\pi^*Pt$ transitions ($\Delta E_{d–d}$) and HOMO → LUMO transitions ($\Delta E_{HOMO–LUMO}$), and the energy difference, ΔE, between them.

IId	5.14	1.95	3.19
IIe	5.34	1.37	3.97

Absorption Properties

The low-energy absorption bands are very solvatochromic. To decrease the difference between calculated and observed transition energies, the effect of the solvent was simulated by the polarizable continuum model included in the Gaussian 98 program. In general, all these complexes show a blue-shift in the polarized solution, and this is in agreement with the recently published experimental data by Che et al.,[40] who pointed out that when the polarity of the solvent increases from benzene to CH_2Cl_2, acetonitrile, and ethanol, the broad low-energy absorption band blue-shifts in energy (a further explanation for this blue-shift is presented later). Taking molecule **IIa** as an example, the calculated absorptions in the gas phase and in dichloromethane solution are comparatively listed in Table 5. It can be seen that the first two absorptions show a comparatively strong solvatochromic effect − the 545 nm and 394 nm absorptions in the gas phase correspond to the 460 nm and 361 nm absorptions in solution, respectively − while the other absorptions show little solvatochromic effect. This phenomenon is in accordance with the experimental results.[28–33,38] The complete absorption spectrum for complex **IIa** is plotted in Figure 5 (in the plot, every absorption with different oscillator strength is selected, *f* is the oscillator strength, and the horizontal axis is the absorption wavelength).

Table 5. Selected calculated TDDFT singlet excitation energies for complex **IIa** in the gas phase and in CH_2Cl_2 solution, together with experimentally observed values.

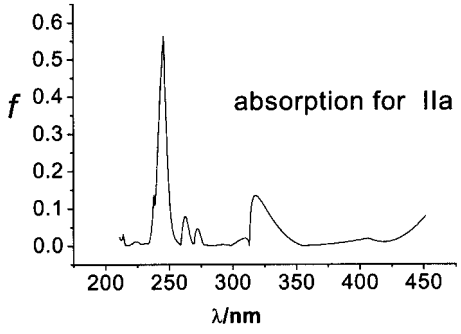

Figure 5. UV/Vis absorption spectrum of **IIa** in dichloromethane solution (*f* is the oscillator strength).

The calculated absorption results in dichloromethane solution from time-dependent DFT calculations (TDDFT) are listed in Table 6. In the first series, complexes **Ia**–**Ic**, introduction of a donor (CH_3 for **Ib**) on the terpyridyl ligands causes the absorptions to be blue-shifted (from 452 nm to 449 nm for the first absorption). This result is in accordance with the electronic-structure calculation results since introduction of an electron-donating group leads to the LUMO being lifted and the energy gap ($\Delta E_{HOMO–LUMO}$) being increased, which causes the absorption to be blue-shifted. This is consistent with the literature,[24] where the blue shift arising from methyl substitution of the bipyridyl ligand is attributable to destabilization of the π* level by electron-donating methyl substituents. The introduction of an electron-withdrawing group (CN) makes the absorption red-shift (from 452 nm to 487 nm for the first absorption). This result is also in accordance with

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the electronic-structure calculations since introduction of electron-withdrawing groups on the terpyridyl ligands leads the LUMO to be lowered and the energy gap ($\Delta E_{HOMO-LUMO}$) to decrease, which results in the red-shift. In the second series of complexes, **IIa**–**IIe**, it can be seen that the stronger the electron-donating nature of the substituents on the acetylide, the more red-shifted the absorptions. This is because the stronger donating substituents on the acetylide raise the molecular HOMO (see Figure 2), and, as a result, the energy gap between the HOMO and LUMO decreases. The first absorption, which is mainly made up of the HOMO→LUMO transition, is red-shifted with an increase of the substituent group donating ability. Interestingly, all our calculated results and conclusions are in accordance with a recently published paper by Che et al.,[33,38] who ascribed the lower-energy band in the absorption spectra to an allowed MLCT transition. This assignment is consistent with the fact that the absorption band is red-shifted by electron-rich acetylide and electron-deficient moieties on diimine (C^N^N)-6-aryl-2,2′-bipyridine.

[a] Taken from ref.[38]

The excited states that arise from transitions between orbitals that are located on different moieties were classified as charge transfer (CT) excited states. Those from π-occupied to π-virtual orbitals located on the same ligand are described as π-π* states (IL), but those from orbitals on different ligands are described as ligand-to-ligand charge transfer (LLCT) states. Metal-to-ligand charge transfer (MLCT) states involve transitions from the metal atom to ligand-centered orbitals. The excited state is platinum centered (MC) if the orbitals involved in the transition are primarily located on the Pt atom.

In order to assign all absorption bands unambiguously, taking complexes **Ib** and **IId** as examples, TDDFT was used to calculate results for both singlet and triplet absorptions, as listed in Table 7. The contour plots for the related orbitals refer to Figure 3 and Figure 4. Commonly, an excited state corresponds to the excitation of an electron from an occupied to a virtual molecular orbital (MO). However, the excited states calculated herein demonstrate that excited-state electronic structures are described in terms of multi-electronic states, wherein a linear combination of several occupied-to-virtual molecular orbital excitations comprises a given optical transition. For simplicity, Table 7 lists only the most significant contributions to each excited state. Where multiple excitations are of comparable importance (i.e., several excitations with coefficients less 50%), each is listed. Assignment of the character of each excited state was based on the components of the occupied and virtual MOs of the dominant excitation(s) for that excited state. The absorptions **Ib** and **IId** are analyzed completely.

For complex **Ib**, it can be seen that the oscillator strengths of the two lowest-energy singlet electronic transitions are weak, which is consistent with the experimental results.[14] The lowest-energy absorption band is assigned to the spin-allowed HOMO→LUMO transition, which can be characterized as a π(C≡C)/d(Pt)→π*(terp) transition and thus as LLCT mixed with MLCT (LLCT/MLCT). The second absorption band (HOMO→LUMO+1) has the same character as the lowest-energy absorption. The third and sixth transitions, which mainly come from the transitions of HOMO–3→LUMO+1 and HOMO–3→LUMO+2, have complete MLCT character due to the predominant metal character of the HOMO–3 orbital. The other absorptions are all characterized as LLCT or IL. Within the calculated range no transitions between mainly platinum-centered orbitals (MC) are found. If they occur, they must therefore be higher in energy than 200 nm, according to our calculated results.

The first triplet excited state is positioned at 2.34 eV, and is therefore lower than the first singlet excited state (2.76 eV). It results from a HOMO to LUMO transition, thus it is featured as LLCT/MLCT. Similarly, the next two excited states are also characterized as LLCT/MLCT. The higher-energy transitions, such as those at 3.23 and 3.44 eV, arising from the transitions of HOMO–4 to the LUMO and HOMO–5 to LUMO, respectively, were assigned as intraligand excited states within the terpyridyl ligand (IL).

In complex **IId**, the first three calculated absorptions are much stronger than those of **Ib**; this is primarily due to the increased strong donating ability of the phenyl ring on the acetylide, which results in facile charge transfer during the excitation. The lowest-energy absorption (503 nm, with an oscillator strength of 0.1065), arising from the HOMO→LUMO transition, is assigned as LLCT/MLCT. Similarly, the 368 and 311 nm absorptions (with oscillator strengths 0.1243 and 0.1825, respectively) result from the HOMO–2→LUMO and HOMO–7→LUMO transitions, respectively, and they were characterized as mixed LLCT and MLCT due to the mixed compositions of HOMO–2 and HOMO–7 (HOMO–2 is made up of 30% Pt d, 10% terpyridyl p, and 60% acetylide p; HOMO–7 is 62% Pt d and s orbitals as well as 38% terpyridyl p orbitals). For the same reasons as for the 251 and 252 nm absorptions, they are also assigned as mixed LLCT and MLCT. The other absorptions (227, 260, and 245 nm) are all assigned as

7	HOMO–6→LUMO	70%	3.19	389		LLCT+MLCT

LLCT between the $\pi(C{\equiv}C{-}R^2)$ and π^* (terp) orbitals. Again, within the calculated range no transitions between mainly platinum-centered orbitals (MC) were found. If they occur, they must be higher in energy than 200 nm.

The first triplet excited state is positioned at 2.23 eV, 0.23 eV lower than the first singlet excited state (2.46 eV). It results from a HOMO to LUMO transition, thus it is featured as LLCT/MLCT. Similarly, the third, fifth, and seventh excited states are also characterized as LLCT/MLCT. Other transitions, such as those at 2.63 and 3.08 eV, arise from the transitions of HOMO–1 to the LUMO and HOMO–4 to the LUMO+1, respectively, and were assigned as being due to ligand-to-ligand molecular charge transfer between the acetylide and terpyridyl ligand (LLCT). The 2.90 eV absorption, which comes from the HOMO–4 to LUMO transition, is characterized as IL.

According to the absorption character analysis of complexes **Ib** and **IId**, we can see that, although the transition character of HOMO to LUMO is the same for these two complexes (both are assigned as mixed LLCT/MLCT), the percentage of the MLCT is less in **IId** than that in **Ib**. However, his is not the case for the lowest-energy absorption of **IIe**. It should be noted that the Pt d orbital percentage in the HOMO (only 4%) is less than that of the LUMO (6%), so the lowest-energy transition, which comes from the HOMO to LUMO transition, should be assigned as LLCT.

Optimization of the Excited State

CIS (Configuration Interaction Singlets) has been extensively used to study the properties of excited states.[41–43] We

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

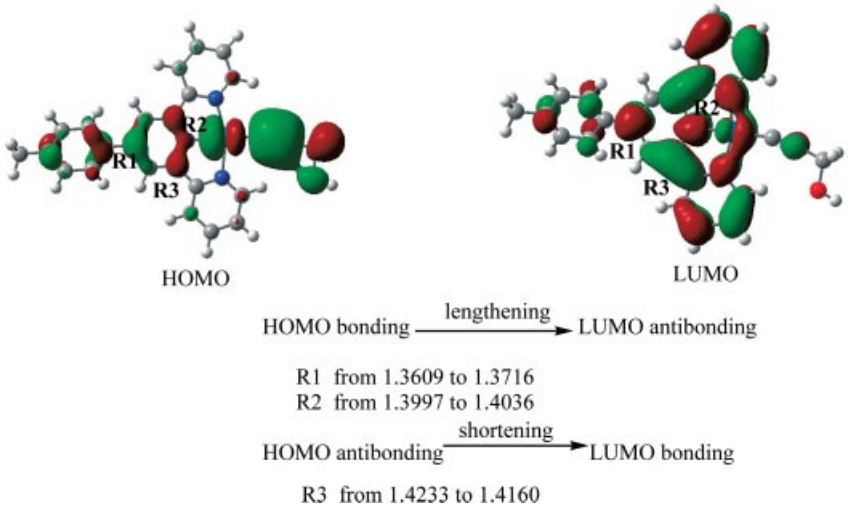

Figure 6. Prediction of the bond length changes between the ground and excited states according to the nodal of the frontier orbitals, taking complex **IIa** as an example (bond lengths in Å).

have examined the lowest triplet state of these complexes by carrying out CIS/LanL2DZ calculations. Comparing the optimized excited-state and ground-state geometries will provide an indication of overall geometry relaxations that occur in the excited state in possible emission processes. Taking complex **IIa** as an example, some of the geometrical parameters (bond lengths) for the optimized ground and excited states are shown in Figure 6. We investigated the geometry relaxations upon excitation by consideration of the nodal patterns of the HOMO and LUMO orbitals. It is considered that if there is no nodal across the bond in the HOMO, while there is a nodal across the same bond in the LUMO, then this bond will be elongated when the complex changes from the ground state to the excited state; in contrast, if there is no nodal across the bond in the LUMO, while there is a nodal across the same bond in the HOMO, then this bond will contract. According to this rule, we investigated the change in the bond lengths in complex **IIa**. The LUMO has nodes across R^1 and R^2, but there are no nodals across them in the HOMO. One would therefore expect elongation of these bonds, and Figure 6 shows that these bonds are in fact considerably longer in the excited state. The HOMO has a node across R^3, and it shows bonding in the LUMO; the data in Figure 6 confirm the anticipated contraction of this bond.

Solvatochromism is closely related to the ground- and excited-state dipole moment. Electronic excitations from HOMO to LUMO involve the displacement of electron charge from the Pt center and the C≡C-R^2 ligands towards the delocalized terpyridyl π*-orbitals. Thus, a reduction of the dipole moment in the excited state is expected, and, as a consequence, the excited state should be less stabilized by polar solvents than the ground state. To testify this assumption, we investigated the dipole moment of the ground and excited states. Taking complex **Ia** as an example, the ground-state dipole moment, μ_g, is –2.36 D and the first triplet excited-state dipole moment, μ_e, is 1.86 D, therefore $\Delta\mu$, the absolute difference between them, is 0.50 D. This dipole moment is in accordance with the assumptions above.

Emission Properties

Based on the optimized excited-state geometries of these complexes, the emission calculation was carried out using the TDDFT method at the B3LYP/LanL2DZ level. The emissions and the calculated Stokes shift are tabulated in Table 8, along with available experimental values for comparison. Obviously, the change tendency with the different substituents of emission is in parallel with those of absorption. The absolute emission value, taking **IId** as an example (693 nm), deviates from the experimental observation of 619 nm. We attribute this deviation to the following reasons: first, the excited-state geometries were obtained using CIS methods, and CIS represents excited states in a general zeroth-order method, just as Hartree–Fock for the ground state of molecular systems, and in CIS theory, the electron correlation effects and higher order excitations are neglected; in addition, the TDDFT approach neglects the spin–orbital coupling, which allows the triplet states to acquire intensity in both absorption and emission and to induce the triplet energies to be shifted. For third row transition metals one estimates the lowest triplet states to be low-

ered by 0.2–0.3 eV by interaction with higher states through spin–orbital coupling. However, the tendency of our calculated results changes parallel to the experimental ones, thus indicating that our method is reliable to gain reasonable results.

Conclusions

The ground-state geometries of several terpyridylplatinum(II) acetylide complexes have been calculated at the B3LYP/LanL2DZ level; the calculated geometrical parameters are in good agreement with the X-ray diffraction experiment results. The electronic structures are discussed completely. Introduction of electron-withdrawing groups on the terpyridyl ligand will lower the LUMO, and the introduction of electron-donating groups on the acetylide will raise the HOMO, thus decreasing the energy gap between the HOMO and the LUMO and, at the same time, increasing the energy gap between the lowest excited state and the d-d state, which prevents nonradiative deactivation through the pathways of d-d conversion. The absorptions and emissions for the investigated complexes were calculated at the B3LYP/LanL2DZ level at the optimized ground- and excited-state geometries, respectively. The calculated absorption results are in good agreement with the experimental values. For all the investigated complexes, excluding **IIe**, the lowest-energy absorption has been assigned as an admixture of metal-to-ligand transition to ligand-to-ligand transition (LLCT/MLCT-C≡C(π)/dπ(Pt)→trpy π*) (in **IIe** assigned as LLCT), while the absorptions at higher-energy levels are assigned as ligand-to-ligand charge transfer (LLCT) or IL. Furthermore, different substituents can modulate both the absorptions and emissions − the introduction of an acceptor on terpyridyl and a donor on acetylide induces the absorption and emission to be red-shifted. This result is in accordance with the calculated electronic structure.

The introduction of electron-withdrawing groups on the terpyridyl ligand and electron-donating groups on the acetylide ligand benefits the emission of this series of complex since it decreases the energy gap between the HOMO and the LUMO and increases the energy gap between the d-d transitions.

Computational Methods

Calculations on the electronic ground state of the investigated complexes were carried out using B3LYP density functional theory. B3LYP corresponds to the combination of Becke's three-parameter exchange functional (B3) with the Lee–Yang–Parr for the correlation functional (LYP). A LanL2DZ basis set was used for all the elements, including C, N, O, H, and Pt atoms. A relativistic effective core potential (ECP) on Pt replaced the inner-core electrons, leaving the outer-core [($5s^2$) ($5p^6$)] electrons and the ($5d^8$) valence electrons of Pt. For the C, N, and O atoms only the (1s) orbitals were replaced by effective core potentials; all the other orbital electrons were left as outer-core electrons or valence electrons. The basis sets were taken as Pt (8s6p3d/3s3p2d), C (10s5p/3s2p), N (10s5p/3s2p), O (10s2p/3s2p), and H (4s/2s). The equilibrium ground-state geometries were computed using the B3LYP functional with the LanL2DZ basis set and were fully optimized without symmetry constraints. At the correct ground-state geometry optimizations, time-dependent DFT (TDDFT) calculations using the B3LYP functional were performed to obtain both singlet and triplet absorption spectra. Then, the first triplet excited state (T_1) geometries for all the complexes (except for complex **IIe**) were optimized using an ab initio CIS method with the LanL2DZ basis set. Based on the CIS-optimized excited-state geometries, the luminescent spectra were calculated at the B3LYP/LanL2DZ level. The solvent effect was simulated using the polarizable continuum model (PCM), in which the solvent cavity is seen as a union of interlocking atomic spheres. All the calculations described here were carried out with the Gaussian 98 package.[44]

Structures, Electronic States and Electroluminescent Properties of a Series of Cu^{I} Complexes

Li Yang,[a] Ji-Kang Feng,*[a,b] Ai-Min Ren,[a] Ming Zhang,[c] Yu-Guang Ma,*[c] and Xiao-Dong Liu[b]

Keywords: Copper / Density functional calculations / N ligands / Photoluminescence

A series of new mixed-ligand copper(I) complexes [Cu(NN)-POP]BF_4, where NN = 1,10-phenanthroline (phen; **1a**), 2,9-dimethyl-phen (DMphen; **1b**), 4,7-diphenyl-phen (DPpehn; **1c**) and 2,2′-bipyridine (bpy; **2a**), have been synthesized. Density functional theory (DFT) was applied to study the ground- and excited-state properties of these copper(I) complexes. The electronic structure variation is obtained by changing the substituted positions on the phenanthroline ligand. A time-dependent-DFT approach (TDDFT) was used to interpret the absorption and emission spectra in this system based on the optimized geometries at the B3LYP/LANL2DZ and CIS/LANL2DZ levels of theory, respectively. The results show that the lowest-energy excitations of all complexes are dominated by $d\pi(Cu)\rightarrow\pi^*$(phen) or bpy (MLCT) excitations. In particular, the lowest triplet state (T_1) corresponds to an excitation from the HOMO to the LUMO in all considered complexes, and emissions occur from T_1, assigned to ^{3}MLCT. Steric effects exerted by the pendent groups at the 2- and 9-positions of the phenanthroline ligands increase the HOMO–LUMO gaps and thus lead to a blue-shift of both absorption and emission spectra and effectively prevent structural relaxation in the MLCT state, which may narrow the energy gap between the excited and ground states and therefore increase nonradiative decay.

Introduction

The development of practical components for chemical sensors,[1,2] display devices,[3,4] probes of biological systems,[5,6] phototherapy,[7] and solar-energy conversion[8] schemes has fuelled interest in complexes of polypyridine and phenanthroline ligands with transition metals, especially heavy metal ions such as ruthenium(II) or rhenium(I).[9] At the same time, the strongly appealing possibility of using cheap copper(I) complexes for replacing the more expensive compounds based on ruthenium(II) or other metal ions, along with the need for a deeper understanding of the correlation between structural processes and photophysical properties, have pushed a continuous progress in the design of photoluminescent Cu^{I} complexes. However, the emission signals from charge-transfer (CT) excited states of copper(I) complexes are typically weak and short-lived[10–12] because the lowest energy CT state of a d^{10} system involves excitation from a metal–ligand $d\sigma^*$ orbital.[10] An important consequence is that the excited state typically prefers a tetragonally flattened geometry whereas the ground state usually adopts a more tetrahedral-like coordination geometry appropriate for a closed-shell ion.[10,13] Aside from reducing the energy content, the geometric relaxation that occurs in the excited state facilitates relaxation back to the ground state.[14,15] Moreover, donor media also tend to quench the lifetime. Blaskie and McMillin first reported this type of exciplex quenching, and by now, many other studies have confirmed the mechanism. Mixed-ligand systems involving triphenylphosphane initially looked promising because they exhibit long lifetimes in the solid state and frozen solution.[16,17] However, detailed studies of $[Cu(phen)(PPh_3)_2]^+$ (phen = 1,10-phenanthroline) have shown that it is virtually nonemissive in methanol, while $[Cu(dmp)(PPh_3)_2]^+$ (dmp = 2,9-dimethyl-1,10-phenanthroline) has a lifetime of 330 ns in deoxygenated solution.[16] However, even with two bulky triphenylphosphanes and a sterically active dmp ligand in the coordination sphere, temperature-dependent emission studies suggest that photoexcited $[Cu(dmp)(PPh_3)_2]^+$ is still subject to exciplex quenching in methanol.[18] An obvious possibility was that incorporation of a chelating phosphane might suppress ligand dissociation.[19] In this context, a series of new mixed-ligand copper(I) polypyridine and phenanthroline complexes such as $[Cu(NN)(POP)]^+$ [POP = bis-{2-(diphenylphosphanyl)phenyl} ether] that are vastly superior luminophores have been synthesized. It is found that solvent-induced exciplex quenching is relatively

inefficient for the CT excited state of this POP system. On the other hand, introduction of sterically demanding ligands can impede geometric relaxation as well as solvent attack. Here, steric effects exerted by pendent groups at the 2,9- and different buttressing groups at the 3,7-phenanthroline positions cooperate to effectively block the excited state close to the ground-state geometry. A further approach for blocking structural rearrangements at the excited state is based on the use of aryl groups appended to the phen unit. The metal-to-ligand charge transfer (MLCT) excited states of cuprous diimine compounds are often luminescent and play important roles in photoinduced electron and energy transfer.

Reaction of $[Cu(NCCH_3)_4]BF_4$ with POP and a polypyridine or phenanthroline ligand gives good yields of the copper(I) complexes $[Cu(NN)POP]BF_4$, where NN = 2,2′-bipyridine and substituted bipyridine ligands or phenanthroline and substituted phenanthroline ligands. The emission from $[Cu(NN)(POP)]^+$ is very similar to that reported for the $[Cu(NN)(PPh_3)_2]^+$ system in room temperature DCM solution.[18] Whereas the photophysical properties of $[Cu(NN)(POP)]^+$ systems vary dramatically with the steric requirements of the NN ligand, the steric influence of the alkyl substituents is also evident in the electrochemistry.

In contrast to experimental studies, so far very little theoretical work is available on Cu^I systems. Despite this fact, density functional theory (DFT) has been successful at providing a means to evaluate a variety of ground-state properties with an accuracy close to that of post-HF methods.[20,21] As a consequence, time-dependent density functional theory (TDDFT) has emerged as an accurate method for the calculation of excited state properties of molecules.[22,23] Because of the low computational costs and complexity, TDDFT is applicable to fairly large systems (for recent applications see, for example, refs.[24,25]) for which traditional wavefunction-based methods are not feasible. Only very recently, a DFT study of the Cu^I systems limited to geometry optimization of the molecular structure and the electronic structure, but no excited geometry optimization of the molecular structure and emission spectra, have been performed.[26,27] On the other hand, a theoretical investigation has been performed at the complete DFT level for Ru^{II} complexes such as $[Ru(bpy)_3]^{2+}$ and [Ru(4,4′-COOH-2,2′-bpy)$(NCS)_2$], but there is still no excited state study.[28] In fact, until now the standard method for calculating excited state equilibrium properties of larger molecules is the configuration interaction singles (CIS) method. However, the calculation of excited-state properties typically requires significantly more computational effort than is needed for the ground states and is dramatically constrained by the size of the molecules.

In this paper we report on a series of new copper(I) mixed-ligand complexes, as well as the structures of complexes $[Cu(NN)POP]BF_4$, where NN = 1,10-phenanthroline (phen; **1a**), 2,9-dimethyl-phen (DMphen; **1b**), 4,7-diphenyl-phen (DPpehn; **1c**) and 2,2′-bipyridine (bpy; **2a**; Figure 1). Furthermore, we present a theoretical and experimental investigation of this series of copper(I) mixed-ligand complexes, including DFT calculations of the structural and electronic properties, as well as a TDDFT study of the main features of the near UV/Vis spectra and, more importantly, the excited state and photoluminescence character. The effect of variation of the substituted positions on the lowest-energy excited states of the complexes has been assessed by calculating their electronic structures and excitation energy. We show that with a reasonable computational effort TDDFT well reproduces the spectroscopic properties of the copper(I) mixed-ligand systems, suggesting that this approach could be used to provide insight into the design of new and more-efficient photoluminescent Cu^I complexes.

Results and Discussion

Molecular Structure and X-ray Single-Crystal Diffraction

The molecular structure of the Cu^I complexes was determined by X-ray single-crystal diffraction. The calculated

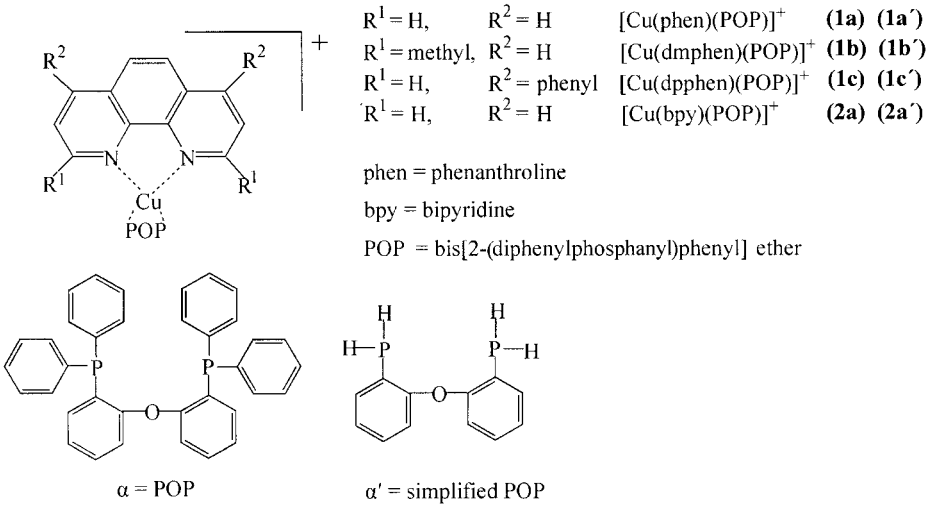

Figure 1. Schematic structures of complexes **1a**–**1c** and **2a** with the POP (α) ligand and **1a′**–**1c′** and **2a′** with the simplified POP ligand (α′).

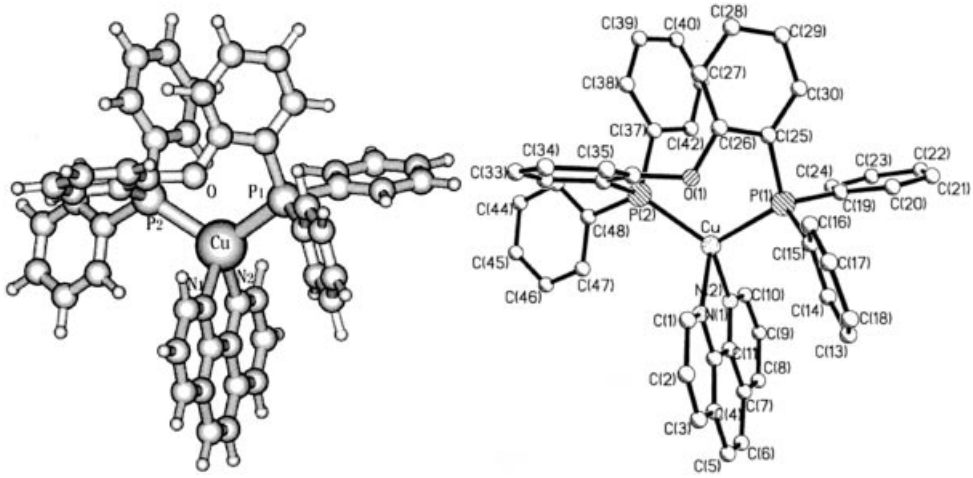

Figure 2. Calculated (left) and crystal (right) structures of complex **1a**.

and crystal structures of complex **1a** are shown in Figure 2, which shows that the calculated structure agrees well with experimental one. Both structures reveal a distorted tetrahedral coordination environment about Cu^{I} with P–Cu–P and N–Cu–N bond angles of 113.52° and 80.88°, respectively. The ether oxygen atom of POP is at a nonbonding distance (>3.1 Å) to the metal center. The resulting eight-membered ···C–C–P–Cu–P–C–C–O··· rings assume a tublike conformation in the solid state, with a dihedral angle between the phenyl rings of 77.9° for complex **1a**. All three $[Cu(NN)(POP)]^{+}$ complexes exhibit similar structures.

The only complex for which a significant intermolecular interaction is present in the solid state is compound **1a**, where the phen ligands of the pairs of symmetry-related cations partially overlay one another (Figure 3). The components of this pair are related to one another through a center of inversion that is located between the phen rings; the closest intermolecular C···C and C···N contacts are in the range 3.59–3.64 Å.

Selected bond lengths and angles for compounds **1a**–**1c** and **2a** are listed in Table 1. The introduction of POP suppresses ligand dissociation and unexpectedly makes the solvent-induced exciplex quenching relatively inefficient for the CT excited state. However, since these POP ligands have little influence on the study of UV/Vis spectra, the excited state, and photoluminescence character, the four phenyls bound to phosphorus but not to oxygen were substituted by hydrogen in order to simplify th calculation, as shown in Figure 1. This simplification has little effect on the molecular structure. In fact, the differences of bond lengths and angles between calculated and experimental structures are within 0.4 Å and 5°, respectively, in all cases. For **1a**, for example, the Cu–N(1) bond length and the N(1)–Cu–N(2) angle differ by 0.04 Å and 0.1°, respectively, from the experimental data; these values are 0.01 Å and 0.8° for **1a**′. The largest difference occurs for P(1)–Cu–P (2), which decreases by nearly 8° compared with the experimental value, although this does not influence the theoretical study of absorption and emission properties. Interestingly, a comparison of the calculated values of simplified structures shows

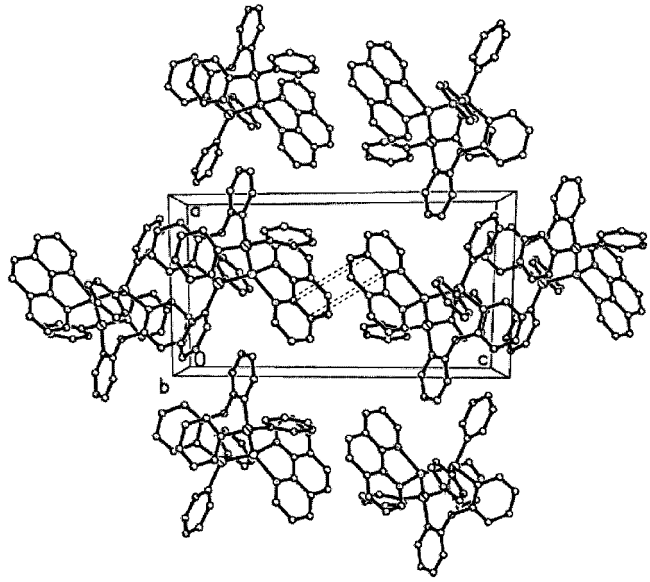

Figure 3. Crystal packing of complex **1a**.

that the Cu–N bond lengths are more strongly influenced than the Cu–P bond lengths by substituents at the 4,6-positions − the latter ones remain nearly equal, whereas the former differ by about 0.02 Å (comparison between **1a**′ and **1c**′). On the contrary, the substituents at the 2,9-positions have less influence on the Cu–N than on the Cu–P bond lengths; the latter differ by about 0.02 Å (comparison between **1a**′ and **1b**′). These structural characteristic should have significant effects on the orbital energy, absorption spectra, and luminescent properties.

A summary of the crystal data for complexes **1a**, **1b**, and **2a** can be found in the Experimental Section. These results indicate that the single crystal has good morphological, structural, and molecular stabilities.

Electronic Structure

Since the observed differences in the chemical and physical properties of the complexes rely primarily on the

changes in the ground-state electronic structure, before dealing with the excited states, we will discuss in detail the ground-state electronic structure of these complexes with a special emphasis on the frontier orbital components and HOMO–LUMO energy gaps. The assignment of the nature of each MO was made on the basis of its composition [see Tables 2 and 3 in which only the most important occupied and virtual (unoccupied) orbitals are listed] and by visual inspection of its three-dimensional representation (see Figures 4 and 5, which show complexes **1a′** and **1b′** as examples, respectively). The atomic orbital contributions for each complex, expressed in percent, are given in Tables 2 and 3. Percent contributions were calculated from Equation (1), where n is the atomic orbital coefficient and $\sum n^2$ is the sum of the squares of all atomic orbital coefficients in a specific molecular orbital.

$$[n^2/\sum n^2] \times 100 = \% \text{ contribution} \quad (1)$$

Every complex is divided into four parts: the metal Cu, pyridine ligand, simplified POP, and different substituents R. Each part of the percent contributions are the sum of the atomic orbital coefficient squares.

In general, for all the investigated complexes, their occupied orbital compositions are perturbed by different substitution positions, but the relative ordering and characters are not changed, as shown in Tables 2 and 3: the two highest occupied orbitals have predominant metal Cu d character (54%, 62%, 53% and 63% in HOMO and 64%, 56%, 59% and 54% in HOMO–1 for **1a′**, **1b′**, **1c′**, and **2a′**, respectively), admixed with some contributions from the phen (bpy) ligand and POP. The HOMO–3 orbital for substituted complexes **1b′** and **1c′** also features roughly metallic antibonding character (60% and 44%, respectively), but for unsubstituted complexes **1a′** and **2a′** the HOMO–3 orbitals are predominantly delocalized on the POP ligand (57% and 65%, respectively), although significant metal contributions (36% and 30%, respectively) remain. Some

[a] HOMO and LUMO orbitals are shown in bold.

lower-energy occupied MOs still have significant metal character, but the contributions from phen (bpy) and POP increase. In contrast, the two lowest unoccupied orbitals LUMO and LUMO+1 in each complex are essentially π*-orbitals localized on the phen or bpy moieties (over 90%). LUMO+2 is calculated to have dominant ligand phen or bpy π* character in each complex except for **1b′**, where it is POP-centered (88%). As shown in Tables 2 and 3 higher virtual orbitals are mainly delocalized over the bpy, phen, or POP ligands.

However, comparing **1a′**, **1b′**, and **1c′**, it can be found that there is a greater effect when substituted in the 2,9-phenanthroline positions than in the 4,7-phenanthroline positions. Firstly, the energy gaps (HOMO–LUMO) of **1a′** (3.73 eV) and **1c′** (3.74 eV) are close in energy, and are lower in energy than in **1b′** (3.87 eV). Secondly, the copper d-orbital character in the HOMOs are similar in **1a′** (54%) and **1c′**(53%) and are about 10% lower than that in **1b′** (62%). We interpret this different behavior in terms of structural factors, and suggest that substituents in the 2,9-

phenanthroline positions are optimal to prevent significant ground-state distortions.

The LUMOs of **1a′** and **2a′**, as has already been indicated, are characteristic ofr the two diimines, whereas the valence occupied orbitals exhibit the same character due to the identity of the POP and metal. As from the energetic viewpoint phen and bpy show an almost identical π*-accepting ability (Tables 2 and 3), it is expected that the HOMO–LUMO gap of these complexes will be very similar in energy (differs by 0.06 eV). From the orbital character point of view, the metal's contribution is greater in the latter (about 60%) than in the former (about 50%).

Contour plots of the characteristic occupied and virtual orbitals for molecules **1a′** and **1b′** are depicted in Figures 4 and 5, respectively. In these plots, the metal character is evident in the HOMO, which is an admixture with a phosphorus contribution from POP and a nitrogen contribution from phen (bpy), while the LUMO is delocalized over the phen ligand. Lower-energy occupied orbitals are mainly located on phen and one of POP phenyls, and the higher-energy virtual orbitals are also composed of phen and phenyls of POP.

Cation and Anion Properties

Additional information derived from our calculations provides insight into the interrelationship of structure and electronic behavior, in particular the response of the molecule to the formation of a hole or the addition of an electron. Table 4 contains the ionization potentials (IPs), electron affinities (EAs), and spin density. The vertical IP is obtained by differences in the total self-consistent energies of the cation and the neutral molecule based on the optimized neutral ground-state geometry, as is the EA. In all cases, the energy required to create a hole is about 10 eV and the energy cost to accept an electron is about 3 eV. As shown in Table 4, the cationic spin density for each complex is mainly on the Cu and POP [see Figure 6 (left), which shows **1b′** as an example], which is basically consistent with the orbital character of the HOMO. These all correspond to removal of an electron from the 5d orbital.

Four complexes show relatively weakly bound negative ions, corresponding to the electron affinity. In each complex the unpaired spin density is totally on the phen or bpy ligands [for example, the spin density is mainly on phen in

Table 4. Ionization potentials, electron affinities, and spin densities for the four complexes [eV]. See text for definitions. The IP and EA are vertical values.

		Spin density of cation [%]							Spin density of anion [%]

complex **1b′** as depicted in Figure 6 (right)]. This is consistent with the LUMO being primarily the phen or bpy π*-orbitals.

Absorption Spectra

With the prerequisite ground-state DFT calculation in hand, we proceeded to perform the time-dependent calculation of complexes **1a′** to **2a′** to find the characters and energies of their low-lying singlet and triplet excited states at the TDDFT//B3LYP/LANL2DZ level of theory. Selected low lying singlet and triplet excited states together with their vertical excitation energies and oscillator strengths for **1a′**–**1c′** and **2a′** are displayed in Tables 5, 6, 7, and 8, respectively.

An experimentally used model of an excited state corresponds to the excitation of an electron from an occupied to a virtual MO (i.e., a one-electron picture). However, the excited states calculated herein demonstrate that excited-state electronic structures are best described in terms of multiconfigurations, wherein a linear combination of several occupied-to-virtual MO excitations comprises a given optical transition. Assignment of the character of each excited state was based on the compositions of the occupied and virtual MOs of the dominant configuration(s) for that excited state. Excited states that arise from transitions between orbitals that are located on different moieties were classified as charge transfer (CT) excited states. Those from π-occupied to π-virtual orbitals located on the same ligand were described as π-π* states (IL), but those from orbitals on different ligands were described as ligand-to-ligand charge transfer (LLCT) states. Metal-to-ligand charge transfer (MLCT) states involve transitions from the metal atom to ligand-centered orbitals. For the majority of the excited states under investigation, most of the significant excited states exhibit mixed character as they consist of more than one transition. For example, S_{11} in **1a′** consists of two transitions of 102→109 (45%) and 103→108 (31%). The former transition is from orbital 102, which has mainly metal Cu character, to orbital 109, which is located on phen, and is thus assigned as MLCT, whereas the latter one is from 103(POP) to 108 (phen) and is denoted as LLCT. S_{11} therefore has a mixed character between MLCT and LLCT.

Furthermore, from Tables 5–8, it can be seen, as in the case of the energy gaps, that the lowest absorption energies in complexes **1a′** (2.81 eV) and **1c′** (2.83 eV) are similar, and both are lower than that of **1b′** (2.95 eV).

The 35 lowest-energy triplet excited states were also calculated by a similar TDDFT methodology. The first five triplet excited states in each complex are listed in Tables 5–8. MLCT, LLCT, and IL excited states are all observed, but

most of them are mixed-character excited states, as with the singlets. As expected from Hund's rule, transitions to the triplet states tend to be lower in energy than their corresponding singlets. For example, for complex **1a′** the first triplet vertical transition energy is at 2.64 eV, which is lower than that of the first singlet excited state (2.81 eV), although both represent (predominantly) HOMO and HOMO–1→LUMO transitions. The TDDFT results do not provide information on triplet–singlet absorption intensities since spin-orbit coupling effects are not included in current TDDFT approaches, which is why the oscillator strengths are all zero for triplet excited states. Spin-orbit coupling can, however, mix singlet and triplet states, thereby allowing the latter to acquire intensity in both absorption and emission. A second effect is that the triplet energies are shifted by coupling with higher singlet (or other triplet) states. For third row transition metals one[40] can estimate that the lowest triplet states are lowered by about 0.2–0.3 eV due to interactions with higher states through spin-orbital coupling.

Comparison with Experimental Results

Combined with experimental data gathered over time, computed spectra may provide a reference for monitoring the behavior and possible degradation of the organic material in the device. The results of the TDDFT calculations for all considered complexes have been compared with experimental absorption data (see Tables 5–8 and Figure 7). The spectral assignment is based on a comparison of experimental band maxima with calculated energies of transitions with significant oscillator strengths. However, oscillator strengths should be used rather qualitatively to distinguish allowed transitions from forbidden as very weak transitions to other excited states also occur in the relevant energy regions. Moreover, for the S_1 excited state the calculated spin density of positive and negative ions also has significant reference value for transition assignment. In general, the assignment of the character of each excited state was based on the components of the occupied and virtual MOs (see Tables 2 and 3 and Figures 4 and 5) of the dominant excitation(s) for that excited state.

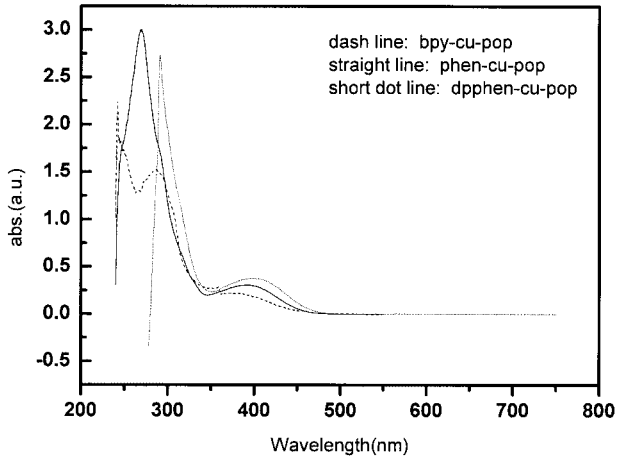

Figure 7. Experimental absorption data of complexes **1a′**, **1c′**, and **2a′** as measured in CH_2Cl_2 solution.

Most of the investigated complexes exhibit two absorption peaks. For complexes **1a′** and **1c′**, the low-energy absorptions are found experimentally at 391 nm and 400 nm,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

both of which are similar to the calculated d(Cu)→π*(phen) (MLCT) excitation arising from S_3 at 389 nm (3.19 eV) and 387 nm (3.20 eV). The other intense calculated absorption peak at 269 nm for **1a′**, arising from singlet state S_{19} at 279 nm (4.45 eV), is assigned as having mainly d(Cu)→π*(phen) (MLCT) character. For **1c′** this peak, which corresponds to excited state S_9, features mixed character between d(Cu)→π*(phen) (MLCT) and π→π* (LLCT), and the latter arises from a transition from the POP ligand (HOMO–4) consisting of the π-orbital of phenyl to ligand phen (LUMO).

For complex **1b′**, the low-energy band at 383 nm occurs in the same region as the singlet state S_3 calculated at 373 nm (3.32 eV), which arises from d(Cu)→π*(phen) (MLCT) consisting of HOMO–1→LUMO.

As with complexes **1a′** and **1c′**, the low-energy absorption peak arising from excited state 2 located at 393 nm (3.16 eV) results from d(Cu)→π*(bpy) (MLCT) and agrees with the experimental value of 383 nm in complex **2a′**. The other absorption band labeled as mixed transition of MLCT and π(bpy)→π*(bpy) (IL) is consistent with the experimental band at 285 nm.

It can be seen from the absorption analysis that substitution at the 3,7-phenanthroline positions has less effect than at the 2,9-phenanthroline positions on the absorption bands. for example, the low-energy bands in complexes **1a′** (389 nm) and **1c′** (387 nm) are similar, and are both at longer wavelength than that in **1b′** (373 nm) due to steric effects exerted by the pendent groups at the 2,9-positions. Different ligands bpy and phen have little influence on the absorption spectra. For example, the low-energy absorption band is found at 389 nm in **1a′** and 393 nm in **2a′**.

The good agreement between theory and experiment suggests that the character of the experimental absorption features can be inferred from our calculations. Specifically, the low-energy edge is largely MLCT in nature, whereas the strongest peaks contain significant contributions from LLCT or IL transitions. In fact, it has been shown before that TDDFT frequently underestimates the transition energies of excitations accompanied by a substantial charge density redistribution.[29–33] For example, TDDFT vacuum calculations of the complexes [Ru(X)(R)$(CO)_2$(diimine)] (X = Cl, Br, I, R = X, Me, $SnPh_3$; diimine = bpy or *N*,*N*′-bis-*i*Pr-1,4-diazabutadiene) have predicted that their low-lying MLCT and LLCT transitions occur at energies well below those of the lowest experimental absorption bands.[31–33] Moreover, this method cannot yet be used to study extended systems as it is not infrequent that the optical properties reach saturation already for quite short chain lengths, whereas the orbital energies still continue to change for longer oligomers. It is known that the exchange-correlation (XC) functionals must decrease with increasing chain length; this trend of variation is in line with the expectation that in more extended systems the electronic repulsion is smaller.[34,35] However, in this study the combined use of DFT//B3LYP/LANL2DZ and TDDFT//B3LYP/LANL2DZ provides a reliable theoretical tool to investigate the properties of $[Cu(NN)^2]^+$ systems.

Lowest Triplet States

Because the calculation of excited-state properties typically requires significantly more computational effort than is needed for the ground states, the lowest triplet states, T_1, of only molecules **1a′**, **1b′**, and **2a′** were fully optimized by carrying out ab initio CIS.[36,37] The optimized structure parameters are shown in Table 9.

Table 9. Calculated bond lengths of the lowest triplet state (T_1) for complexes **1a′**, **1b′**, and **2a′**.

	1a′	**1b′**	**2a′**
Cu–N(1)	2.196	2.195	2.172
Cu–N(2)	2.191	2.202	2.170
Cu–P(1)	2.612	2.598	2.633
Cu–P(2)	2.561	2.625	2.576
Cu···O	3.277	3.431	3.415
P(1)–Cu–P (2)	107.13	105.71	105.01
N(1)–Cu–N(2)	77.23	77.72	77.75
N(1)–Cu–P(1)	114.93	118.54	117.98
N(1)–Cu–P(2)	111.50	117.40	114.15
N(2)–Cu–P(1)	123.52	118.28	118.31
N(2)–Cu–P(2)	119.14	117.97	117.98

A general elongation of all the metal–ligand bond lengths between the excited and ground states is observed. For example, in complex **1a′** the Cu–N bond lengths in the triplet state (2.196 and 2.191 Å) are longer than those in the ground state(2.102 and 2.095 Å) by about 0.1 Å, and the distances between the metal atom and carbon atom (Cu–C) are also longer by about 0.2 Å in the triplet state (2.612 and 2.561 Å) than in the ground state (2.427 and 2.414 Å). As far as the angles are concerned, except for N(1)–Cu–N(2), which decreases from 80° to 77°, the other angles vary by 5°.

Emission Spectra

On the basis of the excited triplet-state geometry TDDFT was employed to calculate the emission spectra. The long-lived decay lifetime obtained experimentally revealed that the photoluminescence of the four complexes is

Table 10. Calculated emissions in thin film for complexes **1a′**, **1b′**, and **2a′**.

Complex	Compositions	ΔE [eV]/$\lambda_{calcd.}$ [nm]	$\lambda^{exp.}$ [nm]	Stokes shifts [nm]		Character
				calcd.	exp.	
1a′	107→108 (70%)	2.19/567	561	178	170	MLCT
1b′	115→117 (68%)	2.23/556	524	183	141	MLCT
2a′	101→102 (70%)	2.18/568	560	175	177	MLCT

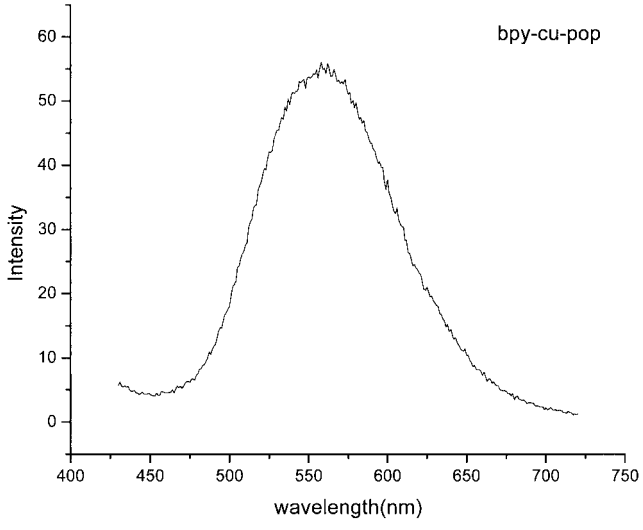

Figure 10. Experimental emission spectra for complex **1c**′ as a thin film.

due to a triplet state transition ($T_1 \rightarrow S_0$) and thus we only optimizes the lowest triplet state (T_1) and calculated the triplet emission spectra. The results of the TDDFT calculations for complexes **1a**′, **1b**′, and **2a**′ are summarized in Table 10, and the experimental emission spectra figures are depicted in Figures 8, 9, and 10 respectively.

The photoluminescence for each complex corresponds to the lowest triplet T_1, which consists of the transition from HOMO to LUMO or LUMO+1, and is thus assigned as having mixed character between MLCT [d(Cu)→π*(phen or bpy)]. The emissions predicted to be at 567, 556, and 568 nm for **1a**′, **1b**′ and **2a**′, respectively, agree well with the experimental values of 561, 524, and 560 nm, and are all assigned to d(Cu)→π*(bpy) (MLCT). It can be seen from these results that all the investigated complexes have large stokes shifts of about 170 nm. Obviously, the change tendency with the different substituted positions of emission is in parallel to that of absorption. In other words, appending groups at 2,9-positions blue-shift the emission spectra due to steric effects.

Conclusions

The ground-state geometries of a series of newly synthesized mixed-ligand, copper(I) polypyridine and phenanthroline complexes such as $[Cu(NN)(POP)]^+$ [POP = bis[2-(diphenylphosphanyl)phenyl] ether] have been calculated at the B3LYP/LANL2DZ level, and the calculated geometrical parameters are in good agreement with the X-ray diffraction experiment results. The electronic structures have been discussed completely. Introduction of groups at the 2,9-positions on the phen ligand lifts the energy gap between the HOMO and the LUMO, and, at the same time, strongly influence the characters of the HOMOs and LUMOs, whereas introduction of groups at the 4,7-positions has little effect on either the energy gap or the character of the frontier orbitals, but makes the orbital characters of the lower occupied and higher unoccupied orbitals change. In addition, there are no pure-metal-character orbitals − the amount of metal 5d character varies from 50% to 70%. Furthermore, substitution at the 2,9-positions makes both the absorption and emission spectra exhibit blue shifts due to steric effects. In all the investigated complexes the lowest-energy absorption and emission are dominant MLCT transitions with some admixture of LLCT transitions. Finally, the results of this work show that careful DFT/TDDFT calculations are capable of accurately describing the spectral features of our investigated complexes, with a quantitative agreement with the experimental data. This suggests that such a theoretical approach may provide useful insights into the design of new and more efficient phosphorescent materials. At the same time, however, it has some drawbacks, especially as it does not consider spin-orbit coupling effects.

Experimental Section

Material and X-ray Diffraction: All complexes, as depicted in Figure 1, were synthesized as described in the literature,[38,39] and then

purified by vapor diffusion of diethyl ether into an acetonitrile solution. They were all isolated as yellow crystals. Crystal data for **1a**, **1b**, and **2a** are given in Table 11. CCDC-224679 (for **1a**), -224680 (for **1b**) and -224681 (for **2a**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif. [Cu(phen)(POP)]PF_6 was characterized by ^{1}H NMR and, IR spectroscopy, and elemental analysis.

[Cu(phen)(POP)]PF_6: $C_{48}H_{36}CuF_6N_2OP_3$: calcd. C 62.17, H 3.91, N 3.02; found C 62.08, H 3.99, N 2.92.

Instrumentation: The samples for photophysical studies were prepared by spin-coating a mixture of the Cu complex (20 wt.-%) and poly(methyl methacrylate) (80 wt.-%) in dichloromethane onto a glass slide. UV/Vis absorption and PL spectra were recorded on a Perkin–Elmer Lambda 35 UV/Vis spectrophotometer and a Perkin–Elmer LS50B fluorescence spectrophotometer, respectively. The ^{1}H NMR spectra were recorded on an AVANCZ 5000 spectrometer at 298 K, utilizing deuterated chloroform as the solvent and tetramethylsilane (TSM) as the standard. IR spectra were recorded on a Perkin–Elmer spectrophotometer in the 400–4000 cm^{-1} region, using a model RF-5301PC spectrophotometer.

Computational Methods: Calculations on the electronic ground-state of the investigated complexes were carried out at the B3LYP level of density functional theory, which has been proved very useful to calculate molecular orbital distributions for the interpretation of electrochemical and photochemical results for Ru^{II}[40] and square-planar Pt^{II} complexes.[41] B3LYP corresponds to the combination of Becke's three parameter exchange functional (B3) with the Lee–Yang–Parr for the correlation functional (LYP), using the LANL2DZ basis set that includes Dunning/Huzinaga valence double-ξ on the first row and Los Alamos ECP plus DZ on Na–Bi. The excited-state geometries were optimized at the CIS level of theory.[42,43] Time-dependent density functional theory (TDDFT) has recently become a reliable method for calculation of excited-state energies and has proven useful in the assignment of systems as complex as Ru^{II} and Cr^{III} polypyridyl complexes.[42−44] The nature of the low-lying excited states was explored using the time-dependent density functional theory (TDDFT) approach to derive both absorption spectra and emission spectra at the respective ground-state and excite-state geometries, which were compared to existed spectroscopic data. This B3LYP/LANL2DZ level of theory has proven useful for other transition metal systems. McCusker et al. have employed the B3LYP/LanL2DZ level of theory to study the excited-state electronic structures of $[RuL'_2(NCS)_2]^{4-}$ (where L′ = 4,4′-dicarboxylato-2,2′-bipyridine).[42] Adamo and colleagues[45] have presented a combined DFT//B3LYP and TDDFT study to predict the absorption spectra of $[Ru(bpy)(tpy)dmso]^{2+}$ (bpy = 2,2′-bipyridine, tpy = 2,2′:6′,2"-terpyridine; dmso = dimethyl sulfoxide). A double-ζ quality LANL2DZ basis was used for all atoms except oxygen and sulfur, which were described by 6-31G*. The results show good agreement between theory and experiment, with errors within 0.2 eV corresponding to the lowest allowed transition. Hay[46] has well reproduced the low-lying excited electronic states in the Ir^{III} complex $Ir(ppy)_3$ and related complexes using the B3LYP functional. "Double-ζ" quality basis sets were employed for the ligands (6-31G) and the Ir(LANL2DZ). The nature of the excited states, as well as the positive and negative ions with regard to "electron-hole" creation, is relevant to their use in OLED materials. In all computations no constraints were imposed on the geometry. All calculations are performed with the Gaussian 03 program suite. The molecular orbitals were visualized with MOLDEN 3.9.[47] Moreover, the qualitative concepts and the graphs derived from the Chem3D program suite highlight the basic interactions resulting from the DFT calculations.

N-Bonded Monosilanols: Synthesis and Characterization of $ArN(SiMe_3)SiMe_2Cl$ and $ArN(SiMe_3)SiMe_2OH$ (Ar = C_6H_5, 2,6-$Me_2C_6H_3$, 2,6-$iPr_2C_6H_3$)

Vadapalli Chandrasekhar,*[a] Ramamoorthy Boomishankar,[a] Ramachandran Azhakar,[a] Kandasamy Gopal,[a] Alexander Steiner,[b] and Stefano Zacchini[b]

Keywords: Monosilanols / *N*-Bonded silanols / Hydrogen bonding / Aminosilanols

By the use of aniline and the sterically hindered aromatic primary amines, 2,6-$Me_2C_6H_3NH_2$ and 2,6-$iPr_2C_6H_3NH_2$, *N*-bonded monochlorosilanes, $ArN(SiMe_3)SiMe_2Cl$ [Ar = C_6H_5 (**1a**), Ar = 2,6-$Me_2C_6H_3$ (**1b**) and Ar = 2,6-$iPr_2C_6H_3$ (**1c**)] have been prepared by a sequential deprotonation at the nitrogen followed by reaction with silyl chlorides. Hydrolysis of the *N*-bonded monochlorosilanes afforded the *N*-bonded monosilanols $ArN(SiMe_3)SiMe_2OH$ [Ar = C_6H_5 (**2a**), Ar = 2,6-$Me_2C_6H_3$ (**2b**) and Ar = 2,6-$iPr_2C_6H_3$ (**2c**)]. The X-ray crystal structure of **1c** reveals a positional disorder of the Cl and CH_3 substituents on silicon. The X-ray crystal structure of **2c** shows that it is involved in an intermolecular O–H···O hydrogen bonding in the solid state to afford a dimeric structure containing the O_2H_2 ring.

Introduction

Silanols as compounds containing Si–OH units are attracting considerable interest in recent years because of various reasons. They are excellent precursors for the synthesis of main group and transition metal siloxanes containing the Si–O–M bonds.[1,2] Thus, the reaction of appropriate silanols with suitable metal substrates such as metal halide, hydride, -alkyl, amide or alkoxide leads to the formation of acyclic, cyclic or cage metallasiloxanes.[1,3,4] Often the nature of the synthesized metallasiloxane depends on the type of silanol chosen.[3] A second reason of interest in silanols is their utility to serve as models for silica surfaces particularly in the context of silica-supported transition metal catalysts.[5] More recently, there has also been considerable interest in silanols in organic synthesis.[6a] For example, silanols have been found to be excellent substrates for palladium-catalyzed (and fluoride-, cesium carbonate- or silver oxide-activated) cross-coupling reactions.[6b–6d] The utility of silanols in Mizoroki–Heck-type of coupling reactions has also been demonstrated.[6e] Finally silanols are also gaining importance as bioisosteres with specific interest as transition-state analogues for metalloproteases, aspartic proteases as well as HIV proteases.[7]

Among the various types of silanols that have been reported, monosilanols of the type R_3SiOH, $R_2R'SiOH$ and $RR'R''SiOH$ are the simplest examples as these contain only one Si–OH group per molecule.[8] Although several types of monosilanols are known,[8] there are *none* which contain Si–N bonds. One of the possible reasons for this lacuna is probably the high sensitivity of the Si–N bond towards hydrolysis.[9] On the other hand about 70 to 80% of all silanols are actually synthesized by a hydrolysis reaction of an appropriate Si–X bond (X = F, Cl, Br, I or OR).[8] Recent pioneering efforts of Roesky and coworkers,[10] and our interest in ***N***-bonded silanols[11] has prompted us to assemble *N*-bonded monosilanols. Accordingly, herein, we report the synthesis and spectroscopic characterization of $ArN(SiMe_3)SiMe_2Cl$ [Ar = C_6H_5 (**1a**), 2,6-$Me_2C_6H_3$ (**1b**), 2,6-$iPr_2C_6H_3$ (**1c**)] and $ArN(SiMe_3)SiMe_2OH$ [Ar = C_6H_5 (**2a**), 2,6-$Me_2C_6H_3$ (**2b**), 2,6-$iPr_2C_6H_3$ (**2c**)]. We also report the X-ray structural characterization of **1c** and **2c**.

Results and Discussion

Synthesis and Spectra: Sterically unencumbered as well as hindered aromatic amines (aniline, 2,6-dimethylaniline, 2,6-diisopropylaniline) were used as the starting materials. Sequential deprotonation at nitrogen followed by reaction with silyl halides afforded the *N*-bonded silyl chlorides **1a**, **1b** in excellent yields as distillable oils or as a solid (**1c**) (Scheme 1). In contrast to the situation with corresponding *N*-bonded silicon dichlorides and trichlorides **1b** and **1c** are quite stable to ambient moisture. The compound **1a**, however, is sensitive to ambient moisture and undergoes hydrolysis to the silanol **2a**.

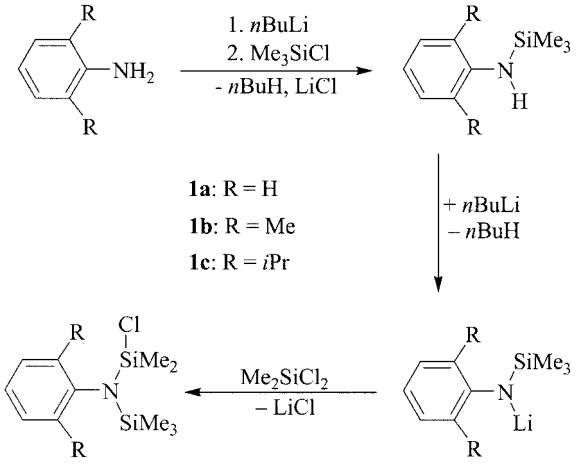
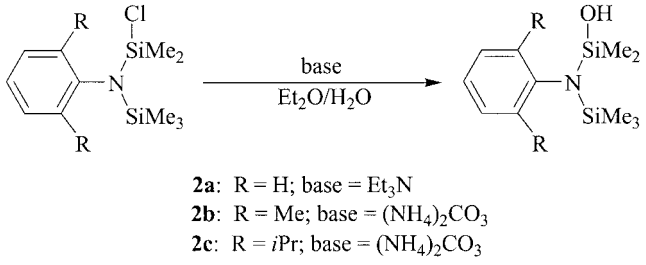


Scheme 1.



Scheme 2.

Hydrolysis of **1a**, **1b** and **1c** afford the corresponding monosilanols **2a**, **2b** and **2c** (Scheme 2). While hydrolysis of **1a** is effected by the use of triethylamine as the hydrogen chloride scavenger, hydrolysis of **1b** and **1c** require ammonium carbonate. It is important to note that the use of aniline, which is very effective as a mild base for the hydrolysis of *N*-bonded silicon dichlorides and trichlorides, does not result in clean hydrolysis of **1a**, **1b** or **1c**. Although the silanols **2a** and **2b** are isolated as oils, **2c**, which contains the sterically hindered aromatic amine substituent, is a solid. While **2a**, **2b** and **2c** are rare examples of *N*-bonded monosilanols, **2a** represents the first example of *any* silanol (monosilanol, silanediol or silanetriol) where the sterically *unencumbered* aniline is the substituent on silicon.

The new *N*-bonded silyl chlorides and silanols are extremely lipophilic and are soluble in a wide range of organic solvents. The compounds **1a**–**c** and **2a**–**c** have been characterized by mass spectroscopy, elemental analysis, IR spectroscopy and multi-nuclear NMR spectroscopy. The silyl chlorides and the monosilanols show prominent parent ion peaks in their FAB mass spectra. The ^1H NMR spectra of these compounds are consistent with their structures. The ^{29}Si $\{^1H\}$ NMR spectra of the silyl chlorides are characterized by chemical shifts for the $–SiMe_3$ and $–SiMe_2Cl$. While the former resonate between δ = 11.9 and 12.6 ppm the latter are seen at a slightly lower frequency between 7.8 and 8.6 ppm, respectively (Table 1). The $–SiMe_2Cl$ chemical shifts occur at a higher frequency than the corresponding $–SiMeCl_2$ (–1.3 and –1.4 ppm)[11a] and $–SiCl_3$ (–28.2 and –27.9 ppm).[10a] A movement of the ^{29}Si chemical shift to lower frequency occurs upon conversion of $ArSiMe_2Cl$ (**1a**–**1c**) to $ArSiMe_2OH$ (**2a**–**2c**). Thus the latter resonate at –1.7 (**2a**), –1.3 (**2b**) and –0.8 (**2c**) ppm, respectively. These chemical shifts are at a higher frequency in comparison to the corresponding silanediols (–29.4 and –29.6 ppm)[11a] and silanetriols (–66.2 and –65.3 ppm).[10a]

The IR spectra of the silanediols **2a** and **2b** in the solid sate in KBr pellets show broad bands at 3350 and 3416 cm^{-1}, respectively. In **2c** in addition to the peak at 3466 cm^{-1} a sharp peak at 3666 cm^{-1} is also observed. The observation of the latter shows that the formation of the KBr pellet disrupts some of the intermolecular hydrogen bonding in **2c** to give rise to free Si–OH.

X-ray Crystal Structures of 1c and 2c: The X-ray crystal structure of **1c** shows a positional disorder; the Cl and CH_3 groups attached to silicon are disordered over the same sites (Figure 1). Such a positional disorder occurs because of the similar volumes of the Cl and CH_3 groups. This results in the two Si–N distances being the same [1.729(1) Å]. The sum of the bond angles around nitrogen N1 equal 360° reflecting the perfect planarity around nitrogen.

Table 1. ^{29}Si NMR chemical shifts of *N*-bonded silicon chlorides and silanols and related dichlorides, trichlorides, diols and triols.

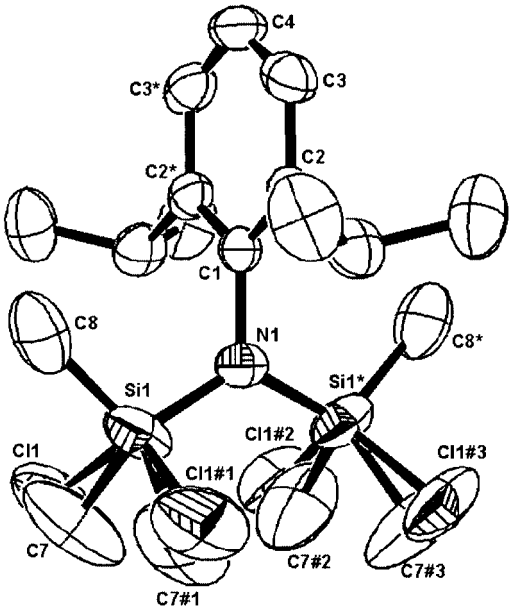

Figure 1. ORTEP diagram of **1c** shown at the 50% probability level. All the hydrogen atoms are omitted for clarity.

The ORTEP diagram of **2c** is shown in Figure 2. Unlike in **1c** two types of Si–N bond lengths are seen viz., Si1–N1, 1.731(1) and Si2–N1, 1.759(1) Å. The longer bond distance is associated with the silicon bearing less electronegative substituents while the shorter distance is associated with *N*-*Si*Me_2OH. The shorter Si1–N1 distance is however, longer than the corresponding distance of 1.7140(18) Å observed in 2,4,6-$Me_3C_6H_2$–N(SiMe_3)SiMe$(OH)_2$. The Si1–O1 distance of 1.648(2) Å is consistent with the trends found in other silanols. This value is shorter than the sum of the covalent radii of silicon and oxygen (1.74 Å). The geometry around nitrogen (N1) is perfectly planar with all the angles around it totaling to 360°.

Intermolecular hydrogen bonding in monosilanols can give rise to different types of arrangements in the solid state, such as a linear dimer,[14a] cyclic dimer,[14b] tetramer,[14c] zigzag polymer[14d] etc. The *N*-bonded monosilanol **2c** shows a cyclic dimer formation (Figure 3) which is quite rare and has been shown before only by the monosilanols containing direct Si–M bonds viz., [(η^5-Cp*)Ru$(CO)_2$]Si(*o*-Tolyl)$_2$-(OH)[14b] and [(η^5-Cp)Fe$(CO)_2]_2$Si(H)(OH).[14e] In the solid state two molecules of **2c** interact with each other and form a planar four-membered O_2H_2 ring. The intermolecular H···O distance is 2.057(1) Å, while the O···O contact is 2.857(2) Å. The O–H···O angle is 158.94(9)°. It is of interest to compare these parameters with those observed earlier. Thus for {(η^5-Cp*)Ru$(CO)_2$}Si(*o*-Tolyl)$_2$(OH) the hydrogen bonding parameters are H···O, 2.172(27) Å. O···O, 2.809(32) Å and O–H···O 134.57(2)°. For {(η^5-Cp)Fe-$(CO)_2\}_2$Si(H)(OH) these values are 2.197 and 2.991 Å and 157.95°.[14b] Thus, the observed hydrogen bonding parame-

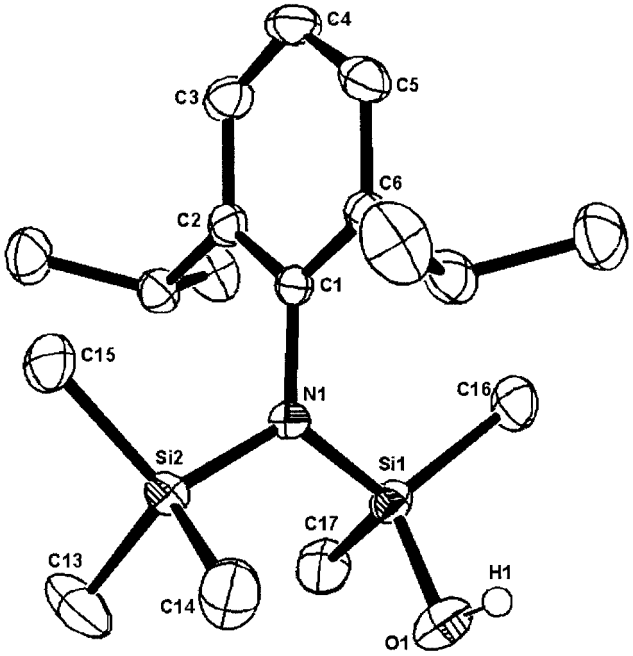

Figure 2. ORTEP diagram of **2c** shown at the 50% probability level. All the hydrogen atoms have been omitted except those of the hydroxy group.

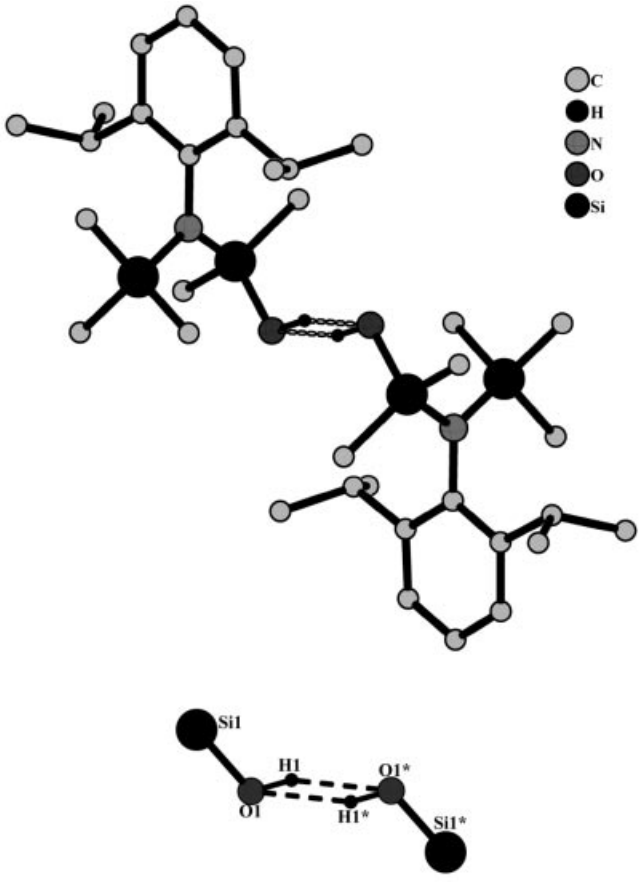

Figure 3. (Top). Formation of a cyclic dimer due to intermolecular hydrogen bonding between two silanol molecules. (Bottom). A perfectly planar arrangement of the four-membered O_2H_2 ring. The metric parameters are: O1–H1, 0.840(1) Å; H1···O1*, 2.057(1) Å; O···O*, 2.857(2) Å; O–H···O*, 158.94(9)°; symmetry, 1 – *x*, 1 – *y*, 2 – *z*.

ters in **2c** are quite reasonable and indicate the presence of a strong intermolecular hydrogen bonding.

Conclusions

In conclusion we have demonstrated the synthesis of the new examples of *N*-bonded monosilanols. These syntheses were accomplished starting from aromatic amines. A highlight of the synthesis was that for the first time unsubstituted aniline could be utilized to afford an *N*-bonded silanol. X-ray crystal structure of the monosilanol **2c** showed the presence of a hydrogen bonded dimer in the solid-state. All the silanols are extremely lipophilic and air-stable. The utility of these *N*-bonded monosilanols in the assembly of metallasiloxanes is under investigation.

Experimental Section

General Remarks: All manipulations and reactions were carried out under dry nitrogen by employing standard Schlenk techniques. Solvents were dried with sodium benzophenone ketyl and were collected from the still at the time of reaction. 2,6-Dimethylaniline and 2,6-diisopropylaniline (Fluka) were distilled under reduced pressure before use. Chlorotrimethylsilane, dichlorodimethylsilane (Fluka) and *n*-butyllithium (2.5 m solution in hexane) (Aldrich) were used as such without any further purification. Aniline (Spectrochem, India) was stored over CaH_2 and distilled before use. Infrared spectra were recorded in dichloromethane solution as well as neat liquid or as KBr pellets with a FT-IR Bruker-Vector Model. Elemental Analyses were performed with Thermoquest CE instruments CHNS–O, EA/110 model. FAB mass spectra were recorded with a JEOL-SX 102/DA-6000 mass spectrometer/data system using argon/xenon (6 kV, 10 mA) as the FAB gas. The accelerating voltage was 10 kV, and the spectra were recorded at room temperature. EI mass spectra were obtained with a JEOL-d-300 spectrometer. The ^{29}Si $\{^1H\}$, and ^1H NMR spectra were recorded in $CDCl_3$ solutions with a JEOL JNM LAMBDA 400 model spectrometer. Chemical shifts are reported with respect to TMS.

Synthesis: The *N*-bonded monochlorosilanes **1a**, **1b** and **1c** and the corresponding silanols **2a**, **2b**, and **2c** were synthesized by adopting the following general synthetic procedure. The ^{29}Si NMR spectroscopic data for these compounds along with some of the other related compounds are listed in Table 1.

Synthesis of the *N*-Bonded Monochlorosilanes, $ArN(SiMe_3)SiMe_2Cl$ (1a–1c) [Ar = C_6H_5 (1a), R = 2,6-$Me_2C_6H_3$ (1b), 2,6-*i*$Pr_2C_6H_3$ (1c)]: *n*-Butyllithium (75 mmol) was added at a constant rate to a solution of RNH_2 (75 mmol) in diethyl ether (60 mL) at –78 °C. The reaction mixture was stirred at this temperature for 4 h and then brought to ambient temperature. It was then treated with a solution of Me_3SiCl (75 mmol) in diethyl ether (40 mL) at –78 °C and allowed to come to room temperature. The precipitated LiCl was filtered and the filtrate was treated with *n*BuLi (75 mmol) at room temperature. After heating under reflux for 4 h the solution was transferred to a pressure-equalizing funnel and added drop wise to a solution of Me_2SiCl_2 (75 mmol) in diethyl ether (40 mL) and stirred overnight. The precipitated LiCl was filtered and the volatiles from the filtrate were removed in vacuo to give a yellow viscous oily product. Subsequent vacuum distillation afforded the pure silicon chlorides **1a** and **1b** as colorless oily liquids. Compound **1c** was isolated as a solid.

Synthesis of *N*-Bonded Monosilanols. Synthesis of $C_6H_5N(SiMe_3)SiMe_2OH$ (2a): A solution of $C_6H_5N(SiMe_3)SiMe_2Cl$ (**1a**) (12.2 mmol) in Et_2O (50 mL) was added to a well-stirred mixture of Et_2O (50 mL), water (12.2 mmol) and triethylamine (12.2 mmol) at 0 °C over a period of 1 h. It was then allowed to come to room temperature and stirred for 30 h. The precipitated triethylamine hydrochloride was filtered. Removal of solvent from the filtrate in vacuo afforded **2a** as a colorless oil.

Synthesis of 2b and 2c: $RN(SiMe_3)SiMe_2Cl$ (**1b** and **1c**) (12.0 mmol) in diethyl ether (20 mL) was added dropwise through a pressure-equalizing funnel for about 30 min into a rapidly stirred two-phase system consisting of 20 mL of water, 20 mL of diethyl ether and 1.0 g (10.0 mmol) of freshly titrated ammonium carbonate and sodium chloride (7.0 g). The solution was then stirred for another 2 h. The ether layer was separated and the aqueous layer was extracted twice with ether. The combined ether fractions were dried to get crude **2b** and **2c**. The compound **2b** was purified on a neutral alumina column using *n*-hexane/ethyl acetate (90:10) as the eluent to get a pale yellow oil. Compound **2c** was purified by repeated recrystallization from a solution of *n*-hexane.

Characterization Data for Compounds 1a–c and 2a–c

[$C_6H_5N(SiMe_3)SiMe_2Cl$] (1a): Yield 14.7 g (75.9%). B.p. 135 °C/0.08 Torr. $C_{11}H_{20}ClNSi_2$: calcd. C 51.23, H 7.82, N 5.43; found C 51.04, H 7.31, N 5.31. AXS Smart Apex CCD diffractometer. The details pertaining to the data collection and refinement for **1c** and **2c** are given in Table 2. The structures were solved by direct methods using SHELXS-97 and refined by full-matrix least-squares on F^2 using SHELXL-97.[12,13] The hydrogen atom attached to oxygen atom was located from the difference map and its position was refined. All other hydrogen atoms were included in idealized positions, and a riding model was used. Non-hydrogen atoms were refined with anisotropic displacement parameters. Selected bond lengths and bond angles of **1c** and **2c** are given in Table 3 and Table 4.

Characterization of Oligomers of AlCl: Al–Cl versus Al–Al Bonding

Hans-Jörg Himmel*[a]

Keywords: Subvalent compounds / Aluminium / Reaction mechanisms / Matrix isolation / Quantum chemical calculations

Oligomers of AlCl have been characterized. By using the matrix isolation technique, the dimer Al_2Cl_2, which exhibits a D_{2h}-symmetric ring structure, was generated in significant quantities and analyzed by its IR and Raman spectra in combination with quantum chemical calculations. The structures of the trimer and tetramer have also been evaluated. A surprising result is that the minimum energy structure of the trimer (C_s symmetry) features direct Al–Al bonds, two terminal Al–Cl bonds, and one bridging Cl atom. A weak, isotopically structured IR band can be assigned to the antisymmetric ν(Al–Cl_t) mode of this trimer (Cl_t denotes a terminal Cl atom). The enthalpy change for each of the oligomerization steps has been calculated. For the dimerization of AlCl to give Al_2Cl_2, the Gibbs energy change was calculated as a function of temperature at different pressures. It turns out that neither the Al_2Cl_2 dimer nor any higher oligomers are present in significant quantities in the gas phase, at least under the conditions of the experiments. The thermodynamic properties show that matrix isolation represents the optimal method of generating and characterizing these species. On the basis of the experimental results the barrier for dimerization of AlCl should be next to zero.

Introduction

AlCl is an interesting example of a very simple compound featuring Al in the formal oxidation state +1. Several possibilities for generating the molecule have been discussed.[1] These include the reaction of Al with $AlCl_3$, and the reaction of Al with HCl, both requiring high temperatures since AlCl is thermodynamically stable only at high temperatures and disproportionates to Al metal and $AlCl_3$ at lower temperatures. The temperature minimum needed for the generation depends, of course, on the pressure, e.g. under high vacuum (10^{-5} mbar) temperatures around 1250 K or more are needed to generate AlCl in the almost complete absence of $AlCl_3$. The monomer AlCl has already been studied intensively both in the gas phase[2–5] and in inert gas matrices (Figure 1).[6,7] Information about the compound in the solid phase and in solution is, however, sparse.[8]

By using a cocondensation technique and a mixture of solvents, it is possible to obtain metastable solutions of AlCl,[1] which have been used extensively for the preparation of new cluster compounds.[1,9] NMR spectroscopic studies[10] clearly show that the calculated chemical shift of the isolated AlCl molecule (δ = +150 ppm) does not match the position of the NMR signal observed for such solutions (δ = +35 ppm). The calculated NMR spectrum of the tetramer Al_4Cl_4 (δ = +235 ppm) is also not consistent with the experimentally observed spectrum. These results indicate a relatively strong solvent effect, and the AlCl molecules or, more likely, oligomers are coordinated by one or more solvent molecules. However, the exact composition still remains unknown.

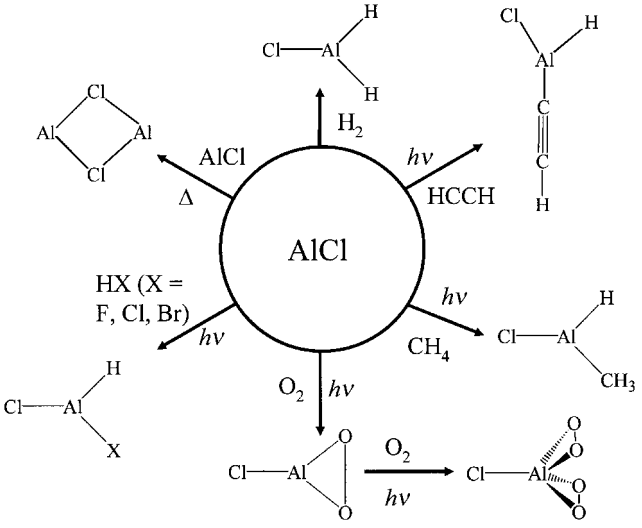

Figure 1. Known reactions of photoactivated AlCl molecules as studied in matrix isolation experiments.

Matrix isolation studies have permitted the reactivity of AlCl monomers to be assessed in some detail. AlCl in its ground electronic state ($^1\Sigma$) is not very reactive. Thus, no spontaneous reaction occurs with O_2 under the conditions of matrix experiments.[11] Only when O atoms are generated is reaction possible, which leads to OAlCl.[12] Photoactivated AlCl reacts, on the other hand, not only with O_2,[11]

but also readily with molecules such as CH_4,[13] H_2,[14] C_2H_2[15] and HX (X = F, Cl or Br).[16] The effect of photolysis has been shown to lead to excitation of an electron from a σ to a π orbital with strong p character localized mainly at the Al atom.[17] The reaction products are all Al^{III} species that are formed exothermally. Figure 1 summarizes the photoactivated reactions and their products which have been studied so far.

The dimer $[AlCl]_2$ had been sighted previously in matrix isolation experiments. Thus, a band at 270 cm^{-1} in the IR spectrum of AlCl that was isolated in an Ar matrix had been assigned to this dimer.[1] However, few details were given, and the fine structure that the band might be expected to show (see the results of this work) was not resolved. Here it will be shown with the aid of higher-resolution IR spectra that this band corresponds to two vibrational modes, each showing the isotopic splitting characteristic of two chemically equivalent Cl atoms in the molecule. In addition, Raman spectra will be reported for the first time, giving clear evidence of one of the $\nu(a_g)$ modes of the dimer. Theoretical studies of $[AlCl]_2$[18] predict a molecule that exhibits a planar, D_{2h}-symmetric structure for its global energy minimum. The experimentally measured frequencies will be used to estimate the bond angles in this ring.

Somewhat surprisingly, no experimental or theoretical information about the trimer Al_3Cl_3 has been available hitherto. Here, the structure of this molecule will be analyzed, and a weak, isotopically structured band in the IR spectrum can tentatively be assigned to it. The tetramer Al_4Cl_4 has been calculated previously,[10,24] and was shown to exhibit a tetrahedral structure with Al–Al and Al–Cl distances of 259.8–263.9 and 209.8–210.9 pm, respectively. Knowledge of the structure and bonding of $[AlCl]_n$ oligomers is desirable in order to anticipate possible structures for solid AlCl. So far, it has proved impossible to characterize the structure of this solid in a more than qualitative way.[8]

Results

IR Spectra

Figure 2a shows the IR spectrum measured for AlCl that was isolated in an Ar matrix. An intense absorption with a doublet pattern occurs at 455.1/449.8 cm^{-1}, as previously assigned to the AlCl monomer. The doublet pattern arises from the presence of the two isotopomers $Al^{35}Cl$ and $Al^{37}Cl$. Two weaker absorptions at high wavenumbers, 462.3 and 459.0 cm^{-1}, also exist. Besides these strong absorptions due to AlCl monomers, the spectrum presents a structured feature at 270 cm^{-1}, which clearly shows several maxima. The structure of the band can be seen in more detail in the higher-resolution spectrum illustrated in Figure 2b.

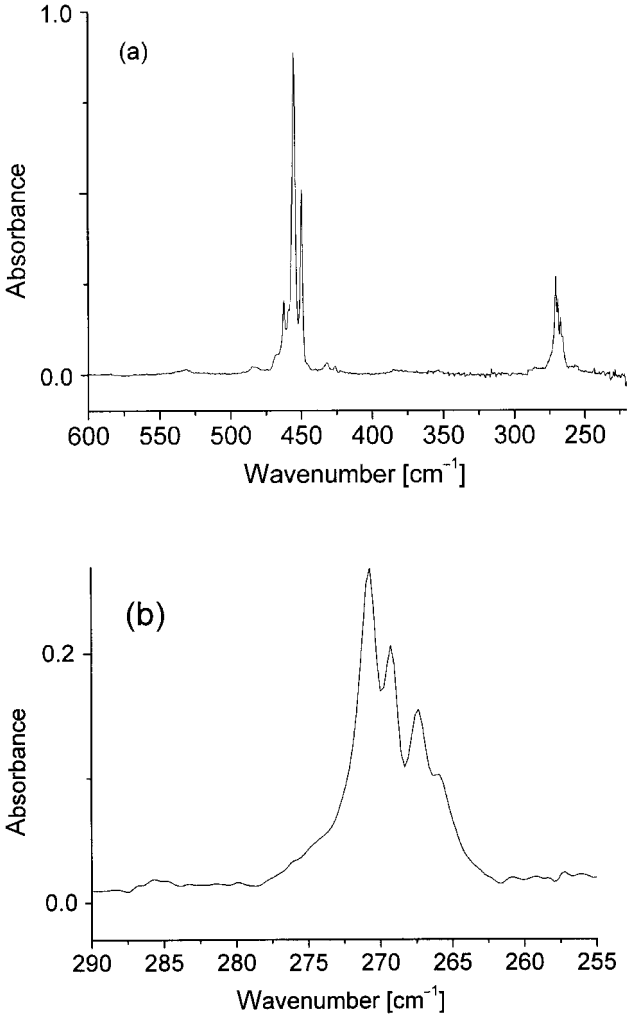

Figure 2. (a) IR spectrum of an Ar matrix containing AlCl vapour. (b) Detailed spectrum of the region around 270 cm^{-1}.

In addition to these intense absorptions, the IR spectrum gives evidence for a weak band, and its maximum is located at 531.3 cm^{-1} (see Figure 3). On the low-energy side of this band, two secondary maxima are visible (at 528.8 and 526.4 cm^{-1}), which are most likely to be due to the presence of different $^{35}Cl/^{37}Cl$ isotopomers.

Raman Spectra

Raman measurements were made to obtain further information. A typical spectrum is displayed in Figure 4a. The ν(Al–Cl) mode of the AlCl monomer near 450 cm^{-1} is clearly visible with the doublet pattern typical for the presence of a single Cl atom in the carrier. Another signal appears with a maximum at 298.6 cm^{-1}. Experiments with varying concentrations of AlCl in the matrix indicate that this signal belongs to the same species as the band near 270 cm^{-1} in the IR experiments.

Discussion

We start this section with a characterization of $[AlCl]_n$ oligomers (n = 1–4) on the basis of the experimental data

and the results from the quantum chemical calculations. There follows a discussion of the oligomerization process, which considers the enthalpy and Gibbs energy changes for the initial oligomerization reactions.

AlCl

The experimental data indicate that the AlCl monomer is the dominant guest species in the Ar matrices. According to our calculations and with the use of BP/SVP, the Al–Cl distance in the $^1\Sigma$ ground electronic state is 216.4 pm; MP2/TZVPP predicts a value of 215.1 pm. These results are in very good agreement not only with those calculated previously (213–216 pm),[19,20,24] but also with the well-defined experimental estimate (213.0 pm).[2] The IR band at 455.1/449.8 cm^{-1} has already been assigned to the AlCl monomer; the doublet pattern arising from the presence of the two isotopomers $Al^{35}Cl$ and $Al^{37}Cl$. The weaker extra doublet at 462.3/459.0 cm^{-1} also belongs to AlCl, in all probability. This component, shifted by 7.3 cm^{-1} from the main absorption, may well be due to the occupation of a different matrix site. The harmonic wavenumber is predicted to be 476.8 cm^{-1} according to BP/SVP, and 482.1 cm^{-1} according to MP2/TZVPP calculations. The calculated wavenumber is in good agreement with the experimental value of ω_e = 481.30 cm^{-1} for the gaseous molecule.[2,5] The anharmonicity $\omega_e x_e$ was previously determined to be 1.95 cm^{-1}.[5] As expected, a polar molecule like AlCl is subjected to a significant matrix shift (cf. InCl).[21] Analogies between compounds in the two series BF, AlF, AlCl and CO, SiO, SiS have already been discussed in detail.[22]

$[AlCl]_2$

There can be little doubt that the band at around 270 cm^{-1} visible in the IR spectrum can be assigned to an oligomer of AlCl, $[AlCl]_n$. The higher-resolution IR spectrum (see Figure 2a) shows a fine structure within the band which is caused by different isotopomeric forms and allows one to determine, with some confidence, the exact composition of the species. Inspection of the fine structure shows immediately that it cannot be explained by the isotopic pattern of a single mode, but must originate from two different modes with only slightly different wavenumbers. Attempts have been made to simulate the isotopic pattern on the basis of the presence of two Cl atoms in the molecule (with relative natural abundances of 75.8:24.2 for the ^{35}Cl and ^{37}Cl isotopes). In total, six Lorenz-type curves are thus involved in this fit. Figure 5 compares the simulated spectrum with that experimentally observed.

The three Lorentz-type curves of the first mode (which exhibit relative intensities of 57.5:36.7:5.8 reflecting the relative natural abundance of ^{35}Cl and ^{37}Cl) have their maxima at wavenumbers of 270.95, 269.29 and 267.51 cm^{-1}. The three Lorenz curves of the second mode, with the same relative intensities, are located at 267.24, 265.70 and 264.54 cm^{-1}. It can be seen that the simulated spectrum is in good agreement with that observed, a result appearing to confirm the presence of two equivalent Cl atoms in the molecule.

As already mentioned, the experiments give every reason to assume that the signal in the Raman spectrum with its maximum at 298.6 cm^{-1} belongs to the same molecule. Al-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

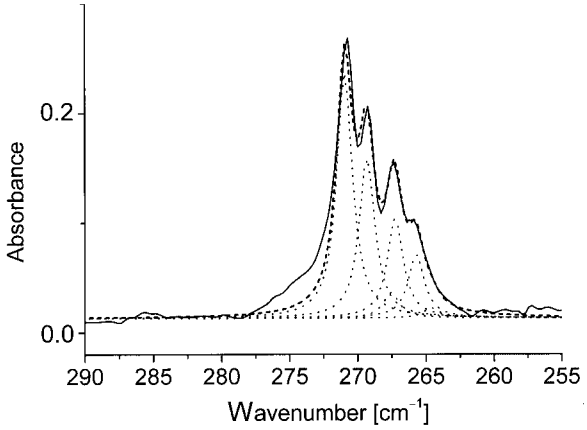

Figure 5. Experimental IR spectrum of $(AlCl)_2$ and fit on the assumption of the presence of two different modes, each with three isotopic components ($^{35}Cl^{35}Cl$, $^{35}Cl^{37}Cl$, and $^{37}Cl^{37}Cl$, in their natural abundances).

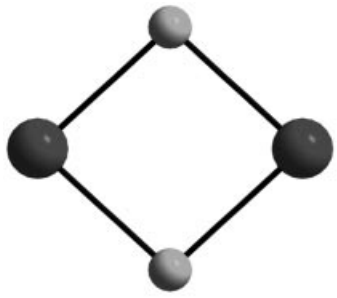
though the resolution of the Raman spectra (0.5 cm^{-1}) is unfortunately clearly insufficient to resolve any fine structure of this signal, the profile can be modeled with three Lorenz-type curves. Figure 3b shows the observed signal together with the simulation, again assuming the presence of two chemically equivalent Cl atoms. It can therefore be concluded that this species is most likely to be the dimer Al_2Cl_2.



$[AlCl]_2$

Table 1 summarizes the results of quantum chemical calculations on the dimer Al_2Cl_2. According to these calculations, the Al–Cl distance in the dimer is slightly longer than in the AlCl monomer (246.8 versus 216.3 pm). The Cl–Al–Cl and Al–Cl–Al angles are 84.7° and 95.3°, respectively, so that the Al atoms are separated by 364.8 pm. In Table 2, the wavenumbers calculated with BP/SVP are compared with those observed. The general level of agreement is very pleasing. The calculations also give an explanation of why the Raman spectra give evidence for the $\nu_1(a_g)$ mode, but not for the other two modes with *gerade* symmetry.

The Raman intensity calculated for $\nu_1(a_g)$ is more than four times larger than those calculated for $\nu_2(a_g)$ or $\nu_5(b_{3g})$.

It is worth mentioning that the difference in wavenumbers measured between the ν_3 and ν_4 modes of $Al(^{35}Cl)(^{37}Cl)Al$ is not the same as that between the corresponding modes of the $Al(^{35}Cl)_2Al$ and $Al(^{37}Cl)_2Al$ isotopomers. In the case of the ν_3 mode, for example, the $^{35}Cl^{37}Cl$ isotopomer has a wavenumber which is 1.54 cm^{-1} lower than that of the $^{35}Cl^{35}Cl$ isotopomer, but only 1.16 cm^{-1} higher than that of the $^{37}Cl^{37}Cl$ isotopomer. For the ν_4 mode, the situation is reversed, and the difference in wavenumbers from the $^{35}Cl^{37}Cl$ isotopomer is smaller for the $^{35}Cl^{35}Cl$ isotopomer (1.66 cm^{-1}) than for the $^{37}Cl^{37}Cl$ isotopomer (1.78 cm^{-1}). This observation can be explained as a consequence of the symmetry reduction from D_{2h} to C_{2v} in the $^{35}Cl^{37}Cl$ isotopomer. Because of this reduction, the symmetry of the modes changes [$\nu_1(a_g) \rightarrow \nu_1(a_1)$, $\nu_2(a_g) \rightarrow \nu_2(a_1)$, $\nu_3(b_{1u}) \rightarrow \nu_3(b_1)$, $\nu_4(b_{2u}) \rightarrow \nu_4(a_1)$, $\nu_5(b_{3g}) \rightarrow \nu_5(b_1)$, $\nu_6(b_{3u}) \rightarrow \nu_6(b_2)$]. In D_{2h} symmetry, the ν_3 and ν_4 modes belong to two different irreducible representations, b_{1u} and b_{2u}, respectively. There are no other modes with the same symmetry so that neither mode suffers any coupling. In the case of $Al(^{35}Cl)(^{37}Cl)Al$ with C_{2v} symmetry, however, the modes belong to the irreducible representations b_1 and a_1, respectively. The mode ν_5 now also belongs to b_1, and ν_1 and ν_2 belong to a_1. Since the wavenumber calculated for ν_5 (131.6 cm^{-1}) is close to that measured for ν_3 (269.29 cm^{-1}), and that observed for ν_1 (297.7 cm^{-1}) is even closer to that observed for ν_4 (265.70 cm^{-1}), mode coupling is expected to be significant between these two pairs of vibrations. The coupling between ν_3 and ν_5 must lead to an increase in the wavenumber of ν_3 (and a decrease in the wavenumber for ν_5). In the same vein, the coupling between ν_1 and ν_4 must lead to an increase in the wavenumber of ν_1 and a decrease in that of ν_4. This mode coupling is responsible for the wavenumber shifts displayed by the bands caused by $Al(^{35}Cl)(^{37}Cl)Al$, which do not fall midway between the positions of the corresponding modes of $Al(^{35}Cl)(^{35}Cl)Al$ and $Al(^{37}Cl)(^{37}Cl)Al$. The behaviour is thus a good indication that the molecule is, as suggested by the calculations, planar and of high symmetry (D_{2h}).

It should also be mentioned that the angles Cl–Al–Cl and Al–Cl–Al can be estimated purely on the basis of the IR spectra measured for the different isotopomers. In D_{2h} symmetry, the b_{1u} and b_{2u} fundamentals are each unique and do not couple with other modes. The G matrix element for b_{1u}, $G_S(b_{1u})$ (where S denotes G with respect to symmetry coordinates), is as follows:

$$G_S(b_{1u}) = \mu_{Al}(1 + \cos\alpha) + \mu_{Cl}(1 + \cos\alpha) \propto \nu_3^2$$

(α is the Cl–Al–Cl angle and μ_{Al} and μ_{Cl} the inverse masses of Al and Cl, respectively). The corresponding $G_S(b_{2u})$ element is:

$$G_S(b_{2u}) = \mu_{Al}(1 + \cos\alpha) + \mu_{Cl}(1 + \cos\alpha) \propto \nu_4^2$$

This implies that the ratio of ν_4 measured for the two isotopomers $[Al^{35}Cl]_2$ and $[Al^{37}Cl]_2$ is independent of the Cl–Al–Cl angle and should be 1.0120. On the other hand, the corresponding ratio of the ν_3 modes varies with the Cl–Al–Cl angle. The experimental ratios are 1.0129 and 1.0102 for ν_3 and ν_4, respectively. In the event of angles of 90°, the two ratios should be identical. From the experimental data, Cl–Al–Cl and Al–Cl–Al angles of 95° and 85°, respectively, can be calculated. Thus the angles are indeed close to 90° (the error caused by the fit of the experimental curve and the neglect of anharmonicity effects might be about 8°),

which is in good agreement with the results of the quantum chemical calculations.

$[AlCl]_3$

Calculations on the trimer have not been reported previously. Accordingly, quantum chemical calculations were first carried out for several possible structures. These included a six-membered ring in a planar (**I**) or folded (**II**) structure, and a structure with an Al_3 triangle and three terminal Al–Cl bonds with the Cl atoms either in the plane defined by the three Al atoms (**III**) or outside it (**IV**). Calculations on these four structures were carried out both with BP/SVP and with MP2/TZVPP. It turns out that none of these structures defines the global minimum on the potential energy hypersurface. Surprisingly, such a structure, **V**, features two terminal Al–Cl bonds, a bridging Cl atom, and an Al atom which is bound to two Al atoms, but not to a Cl atom. All five structures as calculated with MP2/TZVPP are shown in Figure 6. Table 3 includes the energies as calculated with BP/SVP and MP2/TZVPP, as well as some salient bond lengths and angles. According to the calculations, structures **I** and **III** do not define minima on the potential energy hypersurface, since the vibrational analysis yields imaginary frequencies. Deviations between the results of BP/SVP and MP2/TZVPP are generally small, the only exception arises in the case of structure **II**. The Al–Cl and Al–Al distances decrease steadily from structure **I** to structure **V**. At the same time, the energy also decreases.

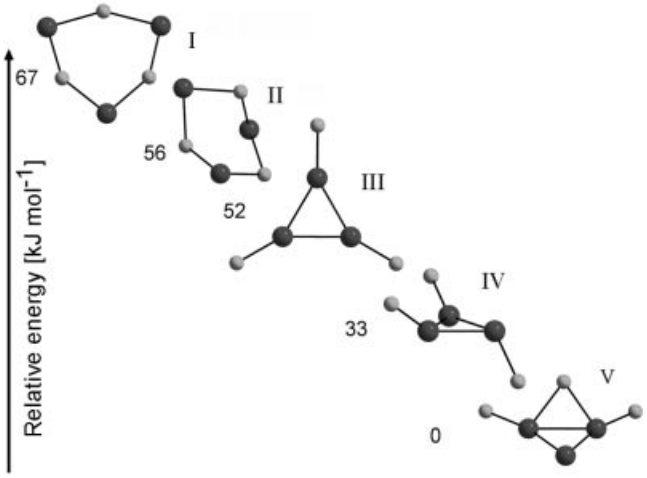

Figure 6. Possible structures of the trimer Al_3Cl_3 and their relative energies as calculated with MP2/TZVPP or BP/SVP.

Table 4 and Table 5 include the wavenumbers calculated for the vibrational modes of cyclic Al_3Cl_3 (structure **II**) and of Al_3Cl_3 in its C_s-symmetric energy minimum form (structure **V**). The mode of **V** which carries most of the IR intensity is located at 533.9 cm^{-1} [$\nu_8(a'')$] according to the calculations, which tallies very closely with the band near 530 cm^{-1} observed in the IR experiments. Although the observed band is weak, it shows evidence of a distinct isotopic pattern. In particular, there are three maxima at 531.3, 528.8 and 526.6 cm^{-1}; the band at 531.3 cm^{-1} carries most

[a] Structures **I** and **III** define no minima on the potential energy hypersurface since the vibrational analysis yields imaginary frequencies. [b] Cl_b means that the bridging Cl atom is considered.

of the intensity and that at 526.6 cm^{-1} is very weak. If this band indeed belongs to the trimer, it can be assigned to the antisymmetric ν(Al–Cl_t) mode. To simulate the isotopic pattern expected for the minimum energy structure, the wavenumbers for this mode have been calculated for all eight possible isotopomers ($^{35}Cl/^{37}Cl$). Isotopic substitution of the bridging Cl atom has, as anticipated, the smallest effect on the wavenumber of the mode. The $Al_3{}^{35}Cl_2(\mu\text{-}{}^{35}Cl)$ isotopomer has a wavenumber of 535.1 cm^{-1}. The $Al_3{}^{35}Cl_2(\mu\text{-}{}^{37}Cl)$ isotopomer has a corresponding wavenumber also of 535.1 cm^{-1}, and for the two $Al_3{}^{35}Cl^{36}Cl(\mu\text{-}{}^{35}Cl)$ isotopomers, a wavenumber of 532.5 cm^{-1} is found. In the case of two ^{37}Cl atoms and one ^{35}Cl atom in the molecule, a wavenumber of 532.5 cm^{-1} is found if the ^{35}Cl atom occupies a terminal position, while a wavenumber of 530.4 cm^{-1} results if the ^{35}Cl is in the bridging position. Finally, the $Al_3{}^{37}Cl_2(\mu\text{-}{}^{37}Cl)$ isotopomer is calculated to give a wavenumber of 530.4 cm^{-1}. In total, given the half width of the bands, an almost perfect triplet pattern results, which reveals distinct similarities between this and the observed pattern. The position and the isotopic pattern of the observed band is thus consistent with its belonging to the trimer Al_3Cl_3 in its C_s-symmetric energy minimum structure **V**.

In the case of the cyclic Al_3Cl_3 isomer, the mode with the highest wavenumber occurs at ca. 300 cm^{-1} according to the calculations (see Table 4). This implies that such a molecule cannot be responsible for the absorption at ca. 530 cm^{-1} detected in the IR experiment.

An alternative explanation for this band is that it represents the first overtone of the triplet at 267.24/265.70/264.54 cm^{-1} that belongs to Al_2Cl_2. The first overtone should occur at 534.5/531.4/529.1 cm^{-1} in the hypothetical case of zero anharmonicity. However, the wavenumber difference between the three resolved maxima observed within the band near 530 cm^{-1} (2.6 and 2.2 cm^{-1}) is somewhat smaller than that predicted for the overtone (3.1 and 2.3 cm^{-1}). Such an explanation is therefore less plausible. It is possible, on the other hand, that the overtone of the $\nu_3(b_{1u})$ and/or $\nu_4(b_{2u})$ mode of Al_2Cl_2 is responsible for the broader shoulder on the higher-wavenumber side of the band near 530 cm^{-1}. Unfortunately, because of the weak intensity, which also allows detection at very high AlCl concentrations in the matrix, Al_2Cl_2 cannot be distinguished with certainty from Al_3Cl_3 on the basis of intensity changes versus concentration in the matrix.

In comparison with the neutral Al_3R_3 species, there is a higher chance of stabilizing radical anions with the formula $[Al_3R_3]^{\cdot-}$. R should be a sterically demanding group, e.g. $Si(SiMe_3)_3$. Calculations were carried out to determine the possible structures of these species. Figure 7 shows two possible isomers in the case of R = SiH_3, which have been optimized with BP/TZVPP. It turns out that the minimum energy structure again features two terminal Al–Si bonds and a bridging SiH_3 group. Again, the metal atoms form a triangle, and one of the metal atoms is bound directly only to other metal atoms, but not to a silyl group. A structure in which all metal atoms are bound to one silyl group exhibits a slightly higher energy (+10 kJ mol^{-1}). Anions of the form $[Al_3R_4]^-$ are already known, but in those cases, two of the metal atoms are bound to one ligand, and the third metal atom, to two ligands (R = Si*t*Bu$_3$).[23]

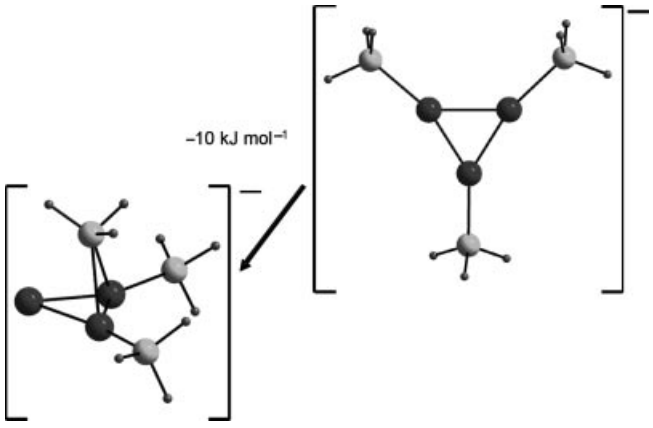

Figure 7. Calculated structures and relative energies for two isomers of $[Al_3(SiH_3)_3]^-$ (BP/TZVPP).

The formal oxidation states of the Al atoms in the minimum energy structure calculated for $(AlCl)_3$ vary. The structure might therefore be described as an intermediate on the way to disproportionation. The results presented herein might be of importance for a better understanding of the disproportionation mechanism.

$[AlCl]_4$

As already mentioned, the structure of the tetramer has already been evaluated before by quantum chemical calculations.[10,24] The molecule exhibits T_d symmetry, with Al–Cl and Al···Al distances (210.9 and 263.9 pm, respectively) that are in good agreement with those calculated previously.[24] Unfortunately, all attempts to gain experimental access to Al_4Cl_4 have so far failed. However, the compound $[AlC_5(CH_3)_5]_4$, featuring also an Al_4 tetrahedron, has been synthesized and structurally characterized.[25] There are also other known representatives of molecules with the overall formula Al_4R_4 [e.g. R = $Si(SiMe_3)_3$[26] or $N(SiMe_3)(2,6\text{-}iPr_2C_6H_3N(SiMe_3)$[27]].

Oligomerization Pathway and Thermodynamic Considerations

The dimerization of AlCl to the cyclic $[AlCl]_2$ dimer is associated with an energy change of –48 kJ mol^{-1} (–46 kJ mol^{-1} including ZPVE corrections) according to calculations with BP/SVP, and of –39 kJ mol^{-1} (–38 kJ mol^{-1} including ZPVE corrections) according to calculations based on MP2/TZVPP.

The question arises of whether the Al_2Cl_2 observed in the IR and Raman spectra is already formed in the gas phase or in the course of a reaction between two AlCl monomers either during or after deposition of the matrix. The relative intensities of the bands belonging to AlCl and to Al_2Cl_2 vary (a) with the rate of HCl which is passed over the aluminum within the Knudsen cell, and (b) with the rate of argon deposition. These findings indicate that most of the Al_2Cl_2 is formed during or after deposition of the matrix and not in the gas phase. However, it is difficult to guarantee exactly identical conditions in the experiments. To answer this question in a more quantitative way, therefore, the intensities of the bands observed in the IR spectrum were first used in combination with the calculated relative intensities to estimate the relative concentration of AlCl and Al_2Cl_2 in the matrix. This gives a ratio AlCl:Al_2Cl_2 of ca. 11:1 in the case of the representative experiment for which the IR spectrum is shown in Figure 2. In the next step, the calculations are used to estimate the equilibrium concentrations of the monomer and dimer in the gas phase. In Figure 8, ΔG for the dimerization reaction is shown as a function of temperature for two different pressures. At a pressure of 10^{-5} mbar and a temperature of 1300 K (conditions typical of a matrix isolation experiment), ΔG is estimated to be +296 kJ mol^{-1}. Accordingly, there is no significant partial pressure of dimer in the gas phase under these conditions. The dimer must therefore be formed almost exclusively either during or after deposition of the matrix. For this pressure, negative ΔG values can be realized only at a temperature below ca. 150 K. In the case of a total pressure of 1 bar, negative ΔG values can be expected up to temperature of ca. 350 K. At these low temperatures, however, AlCl is not stable, since disproportionation to Al and $AlCl_3$ occurs.

The fact that dimerization occurs during or after matrix deposition at very low temperature implies that the activation barrier to this reaction is close to zero. As two electrons in the σ orbital are mainly centered on the Al atom,[17] AlCl resembles silylene, SiH_2. It has been shown that dimerization of SiH_2 (with a $^1A_1$ ground electronic state) along a "least-motion path" to give H_2SiSiH_2 (either in its C_{2h}-energy minimum structure or in the ethylene-like form with D_{2h} symmetry) is symmetry forbidden and opposed by a substantial barrier due to "avoided crossing".[28] On the other hand, dimerization on a "non-least-motion" with low symmetry is possible without a barrier. Although the exact pathway for the dimerization of AlCl has still to be investigated, it is certain that the symmetry has to change during the approach of the two AlCl fragments, and the chances

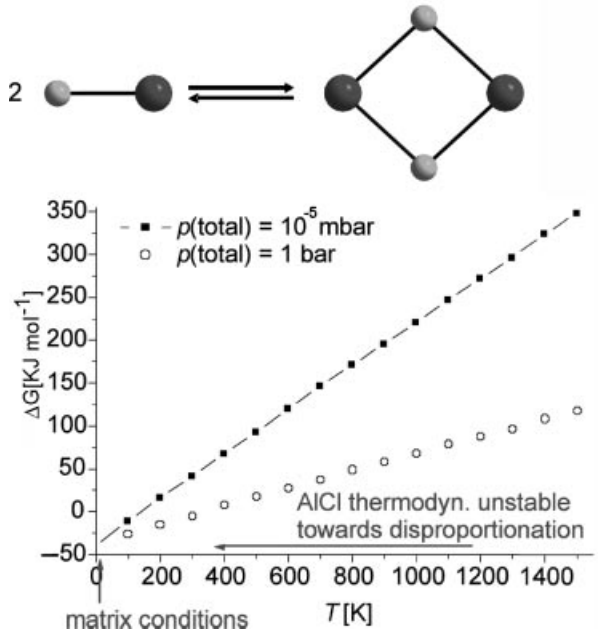

Figure 8. Dependence of ΔG on the temperature at 1 bar and 10^{-5} mbar total pressure for the dimerization of AlCl. Note that AlCl is thermodynamically not stable for temperatures below ca. 1200 K due to disproportionation into Al metal and $AlCl_3$.

of a pathway which includes a symmetry-restricted barrier are reduced. What seems clear, though, is that there is no significant barrier to dimerization.

The reaction of Al_2Cl_2 with another AlCl monomer to give Al_3Cl_3 in its C_s-symmetric energy minimum structure is also calculated to be exothermic. According to BP/SVP, the reaction energy is –78 kJ mol^{-1} without, and –71 kJ mol^{-1} with the inclusion of ZPVE corrections. By using MP2/TZVPP, the values are –84 kJ mol^{-1} without and –77 kJ mol^{-1} with the inclusion of ZPVE corrections. As expected, AlCl is therefore prone to oligomerization. Only at high temperatures do the significant entropy contributions to the Gibbs energy act to reverse this tendency.

Finally, formation of the Al_4Cl_4 tetramer from Al_3Cl_3 and AlCl is associated with an energy change of –218 kJ mol^{-1} (–211 kJ mol^{-1} with ZPVE corrections) at the BP/SVP level, and of –250 kJ mol^{-1} (–243 kJ mol^{-1} with ZPVE corrections) at the MP2/TZVPP level. Overall, the tetramerization energy for AlCl is –358 kJ mol^{-1} at the MP2/TZVPP level and with inclusion of ZPVE corrections. This value is in very good agreement with earlier estimates.[24]

Conclusions

The present studies draw on a combination of experimental and quantum chemical results to explore the oligomerization of AlCl monomers. Dimerization leads to cyclic, D_{2h}-symmetric Al_2Cl_2. This species isolated in an Ar matrix has been characterized in more detail by higher-resolution IR and Raman measurements. An evaluation of the thermodynamics of dimerization shows that the dimer cannot be present in significant amounts in the gas phase. The Gibbs energy change is negative only at low temperatures (but depends critically on the pressure), but at these low temperatures AlCl is thermodynamically unstable toward disproportionation into Al metal and $AlCl_3$. It follows that matrix isolation is the best method for gaining access to the dimer and higher oligomers. An isotopically structured, weak band in the IR spectrum of matrix-isolated AlCl has been assigned to the trimer Al_3Cl_3. This has a surprising structure, consisting of an Al_3 triangle with two terminal Al–Cl bonds and one Al–Cl–Al bridge; one of the Al atoms is directly bound to the other two metal atoms, but not to any of the Cl atoms. Thus, the formal oxidation states of the Al atoms vary. This might shed light on the disproportionation mechanism. Other possible structures have also been calculated, but exhibit a significantly higher energy. Quantum chemical calculations on the tetramer Al_4Cl_4 predict a molecule containing a tetrahedral Al_4 unit, in line with previous theoretical studies.

The results discussed here are of importance for a better understanding of the possible structures of not only solid AlCl but also the solvated species which have been exploited as a starting reagent for the synthesis of cluster compounds.[1] Figure 9 summarizes the oligomerization process and the calculated reaction energies of the relevant steps. It can be seen that the reaction energy is increasingly exothermal for each step.

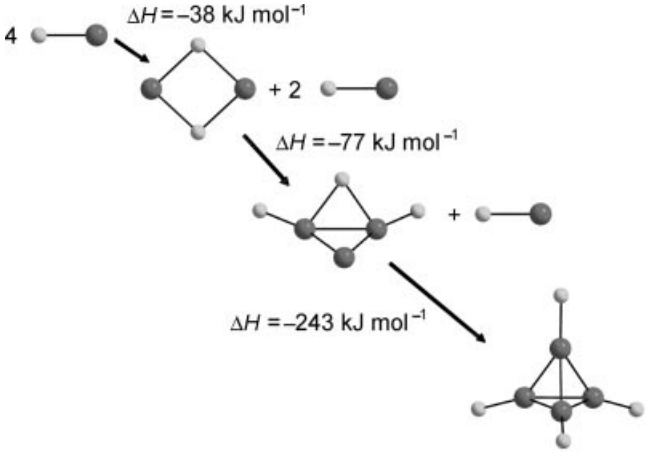

Figure 9. Reaction sequence leading from AlCl monomers via dimers and trimers to the Al_4Cl_4 tetramer. Reaction energies (MP2/TZVPP level, including ZPVE corrections) are given for each of the reactions in this sequence.

Experimental Section

In a resistively heated oven attached to a high vacuum apparatus, HCl was passed over liquid Al at a temperature of 1250 K. The AlCl thus generated was deposited together with excess Ar on a freshly polished Cu block kept at 12 K by means of a closed-cycle refrigerator (Leybold, LB115). Details of the matrix isolation technique can be found elsewhere.[29]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

IR spectra were recorded with a Bruker 113v spectrometer equipped with an MCT detector, a DTGS detector, or a bolometer for measurements in the spectral region 4000–650, 700–200, or 700–30 cm^{-1}, respectively. The spectra were recorded with a resolution of 0.1 cm^{-1}.

Raman spectra were recorded with a Jobin Yvon XY spectrometer equipped with a pre-monochromator with two grids, a spectrograph and a CCD detector (Wright Instruments, England). The spectra were excited with the 514 nm line of an Ar^+ ion laser. The resolution was 0.5 cm^{-1}.

Quantum chemical calculations were carried out with the TURBOMOLE program package.[30] DFT (BP) as well as ab initio (MP2) methods were used in combination with SVP and TZVPP basis sets.

The Structural Chemistry of *N*-Monolithium Borazines[‡]

Heinrich Nöth,*[a] Susana Rojas-Lima,[a] and Alexander Troll[a]

Dedicated to Prof. Dr. H. Schmidbaur on the occasion of his 70th birthday

Keywords: Boron / Borazines / Lithiation / N ligands

Trimethylborazine ($Me_3B_3N_3H_3$, **1**) reacts with RLi (R = *n*Bu, *t*Bu) in hexane solution by alkyl group exchange to give a mixture of borazines $Me_{3-n}R_nB_3N_3H_3$. In contrast, deprotonation of **1** to $Me_3B_3N_3H_2Li$ (**2**) occurs upon treatment with MeLi in diethyl ether solution or RLi (R = *n*Bu, *t*Bu) complexed with tetramethylethylenediamine (TMEDA), pentamethyldiethylentriamine (PMDTA), or trimethylhexahydrotriazine (TMTA) in hexane solution, to give solvates of **2**. $[(Me_3B_3N_3H_2)Li(OEt_2)]$ (**2a**), $[(Me_3B_3N_3H_2)Li(tmta)]$ (**2c**), and $[(Me_3B_3N_3H_2Li)_4(tmeda)_3]$ (**2b**) contain dimeric units of **2**. In the case of **2b** two of these dimers are bridged by one tmeda molecule, while the other two are coordinated to a lithium atom of one of its dimeric units, respectively. This molecule therefore contains tri- and tetracoordinated Li atoms. In contrast, $[(Me_3B_3N_3H_2)Li(pmdta)]$ (**2c**) is monomeric. The *N*-lithiation leads to a distortion of the planar B_3N_3 ring system: the B–N bonds at the metallated N atoms are short, the next opposite B–N pair is the longest, followed by a shorter B–N bond involving the B atom in the *para* position. However, all B–N bonds are longer than in the parent compound **1**. Reaction of $tBu_3B_3N_3H_3$ (**3**) with *t*BuLi in the presence of triisopropylhexahydrotriazine (TIPTA) in hexane leads to the salt $[(tipta)_2Li][tBu_4B_3N_3H_3]$ (**4**), while deprotonation occurs with *t*BuLi(tmta) to give monomeric $[(tBu_3B_3N_3H_2)Li(tmta)]$ (**5**) after refluxing the reaction mixture. Similarly, $(Me_2N)_3B_3N_3H_3$ (**6**) can be deprotonated with RLi in the presence of TMTA to give monomeric $[\{(Me_2N)_3B_3N_3H_2\}Li(tmta)]$ (**7b**). The *N*-lithiation has almost no influence on the shielding of the boron nucleus of the borazine nuecleus. Attempts to obtain di- and trilithiated **1** as pure compounds failed: alkyl group exchange and borate formation as well as destruction of the borazine ring were detected by NMR spectroscopy. However, treatment of these reaction mixtures with MeBr gave $Me_3B_3N_3NH_{3-n}Me_n$ (n = 0–3).

Introduction

Borazines are isoelectronic with benzene and its derivatives.[2] The term "inorganic benzene" has been coined for borazine ($B_3N_3H_6$) because many of its physical properties are similar to those of benzene. However, it is quite clear that the B–N bond polarity is responsible for the inherent chemical differences between the two compounds. For instance, the structure of $[(\eta^6\text{-}C_6Me_6)Cr(CO)_3]$[3] is different to that of $[(\eta^3\text{-}B_3N_3Et_6)Cr(CO)_3]$:[4] while the former shows a planar benzene ring with its MCO bonds pointing to the middle of the C=C bonds of benzene,[3] the borazine complex possesses a puckered six-membered ring where the MCO bond points towards the nitrogen atoms.[4] More recently, DFT calculations by Jemmis et al. have shown that borazine, in spite of its 6π-electron character, is not an aromatic system but is rather antiaromatic,[5] in spite of the fact that the borazine ring and most of its derivatives are planar and possess equal B–N bond lengths. As expected, $B_3N_3H_6$ exhibits two ^1H NMR signals at δ = 5.4 ppm ($^1J_{^{15}N,^1H}$ = 52 Hz) and δ = 4.65 ppm ($^1J_{^{11}B,^1H}$ = 134 Hz).[6] These protons are deshielded relative to those of benzene.

Due to the polarity of the B–N bond, the NH protons of borazines of type $(RB{=}NH)_3$ are acidic. Therefore, it should be easy to deprotonate the NH groups of these borazines. The first deprotonation reactions of borazines were reported by Wagner and Bradford.[7] The resulting *N*-lithioborazines were used to prepare *N*,*B*-borazinylborazines. These *N*-lithioborazines have a synthetic potential similar to aryllithium compounds[8] but, to the best of our knowledge, *N*-lithioborazines have never been isolated, and no structural information is available on these compounds to date. Here we report on the synthesis, characterization and structure determination of several *N*-lithioborazines of type $(R_3B_3N_3H_2)Li$ (R = Me, *t*Bu, Me_2N).

Results

N-Monolithiation of Borazines $(RBNH)_3$

Reactions in Non-Polar Solvents

2,4,6-Trimethylborazine (**1**)[9] is stable up to 450 °C and against photolysis.[10,11] It dissolves in many polar and non-

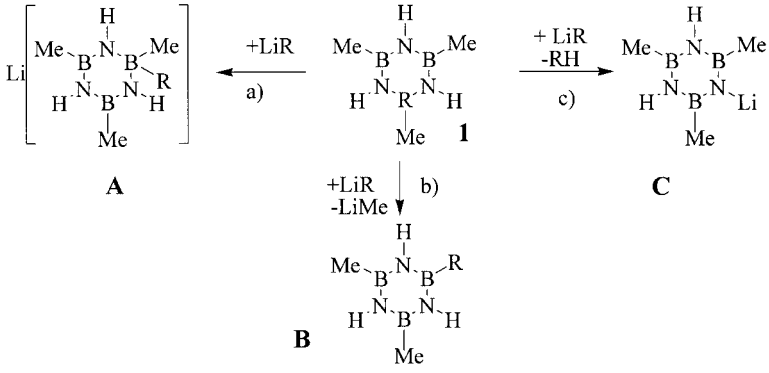

Scheme 1.

polar solvents. Three types of reactions can be expected with RLi compounds: a) addition of RLi across a B–N bond of the borazine derivative, b) exchange of the methyl groups by R of the organometallic compound, c) deprotonation of an NH group (see Scheme 1).

Compounds of type **A** may be precursors for compounds of type **B**, while compound of type **C** are the desired *N*-metallated borazines **2.** In addition, one may also expect ring-opening reactions which may finally lead to *N*-lithioaminoboranes of type R(Me)B–NHLi[12] in the presence of an excess of RLi. Although reactions of 2,4,6-triorganylborazines with *n*BuLi have been described,[8] the formation of *N*-lithioborazines has only been deduced from reaction products obtained with alkyl halides and *B*-haloborazines.[8]

Reaction of **1** with *n*BuLi or *t*BuLi in a 1:1 ration in hexane solution led to products containing tetracoordinate ($\delta_{^{11}B}$ ranging from –2.0 to –4.1 ppm) and tricoordinate boron atoms. Chemical shifts of 38.1 and 36.2 ppm are typical for borazines. A precipitate that formed in these reactions proved to be MeLi (qualitatively checked by gas evolution on hydrolysis). Mass spectrometry of the oily residue obtained from the hexane solutions showed a mixture of all possible *n*-butylmethylborazines $Bu_nMe_{3-n}B_3N_3H_3$ (n = 1, 2, 3). Surprisingly, the 1:1 reaction of *t*BuLi in hexane with **1** also leads to all members of the series $(t\text{Bu})_nMe_{3-n}B_3N_3H_3$ (n = 0, 1,2, 3) with $t\text{BuMe}_2B_3N_3H_3$ the main product ($\delta_{^{11}B}$ = 38.2, 36.0 ppm; ratio 1:2). We were, however, not able to reliably observe B–N cleavage reactions or the *N*-lithiation of **1** in non-polar solvents.

Reactions in the Presence of Auxiliary Bases

It is well known that the reactivity of organolithium compounds is strongly enhanced by polar solvents such as ethers or in non-polar solvents in the presence of donor molecules such as TMEDA because this changes the degree of association of the RLi molecules. Therefore, we studied the reaction of **1** with RLi compounds in diethyl ether solution. In our case both MeLi and *n*BuLi in diethyl ether reacted smoothly with deprotonation of **1** according to Equation (1). The resulting *N*-lithioborazine was isolated as the diethyl ether solvate **2a**. These reactions were quantitative after keeping the reaction mixture under reflux, and yields of up to 85% were obtained.

$$\underset{\mathbf{1}}{2\,Me_3B_3N_3H_3} + 2\,LiR + 2\,OEt_2 \rightarrow \underset{\mathbf{2a}}{Me_3B_3N_3H_2Li{\cdot}OEt_2} + 2\,RH \quad (1)$$

$$4\,Me_3B_3N_3H_3 + 4\,LiBu + 3\,TMEDA \rightarrow \underset{\mathbf{2b}}{(Me_3B_3N_3H_2Li)_4(tmeda)_3} + 4\,BuH \quad (2)$$

$$\underset{\mathbf{2c}}{(Me_3B_3N_3H_2Li)(tmta)} \qquad \underset{\mathbf{2d}}{(Me_3B_3N_3H_2Li)(pmdeta)}$$

$$\underset{\mathbf{3}}{t\text{Bu}_3B_3N_3H_3} + t\text{BuLi} + 2\,TIPTA \rightarrow \underset{\mathbf{4}}{[t\text{Bu}_4B_3N_3H_3]Li(tipta)_2} \quad (3)$$

$$t\text{Bu}_3B_3N_3H_3 + Lit\text{Bu} + TMTA \rightarrow \underset{\mathbf{5}}{t\text{Bu}_3B_3N_3H_2Li(tmta)} + t\text{BuH} \quad (4)$$

N-Lithiation of **1** can also be achieved in hexane upon treatment with *n*BuLi or *t*BuLi in the presence of TMEDA at –78 °C and refluxing the resulting suspension for several days. The precipitate proved to be compound **2b**, as shown in Equation (2). Single crystals of **2b** were obtained from the filtrate. This somewhat unusual stoichiometry is also observed when an excess of TMEDA was employed. When reaction (2) was followed by ^{11}B NMR spectroscopy a signal appeared at δ = 3.6 ppm along with those of the borazine, which indicates that the first step in the reaction is the addition of BuLi to **1** with formation of the borazinate $[(Me_3BuB_3N_3H_3)Li]$ (see Scheme 1). The solvates **2c** and **2d** were obtained from **1** in the presence of trimethylhexahydrotrazine (TMTA) or pentamethyldiethylenetriamine (PMDTA), respectively. All compounds of type **2** are moisture sensitive.

Reaction of $t\text{Bu}_3B_3N_3H_3$ (**3**)[13] with *t*BuLi in hexane at low temperature in the presence of tri(isopropyl)hexahydrotriazine (TIPTA) leads to the salt $[(t\text{Bu}_4B_3N_3H_3)Li(tipta)_2]$ (**4**), as depicted in Equation (3). However, the same reaction in the presence of TMTA yields compound **5** after

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

keeping the mixture at reflux. Compound **5** was obtained as single crystals from the solution.

In analogy to the reaction of **1** with *n*BuLi in hexane, we observed an Me_2N/nBu exchange with tris(dimethylamino) borazine (**6**),[14,15] which we prepared from the trichloroborazine $Cl_3B_3N_3H_3$ and Me_3SiNMe_2. However, deprotonation of **6** to **7a** occurred with RLi (R = Me, *n*Bu) in the presence of PMDTA, which on crystallization from CH_2Cl_2 gave compound **8**.[16] Single crystals of **7a** were obtained on crystallizing the precipitate from diethyl ether [see Equation (5) with R = Me]. Compounds **7b** and **7c** were obtained in a similar manner.

$$\underset{\mathbf{6}}{(Me_2N)_3B_3N_3H_3} + LiR + PMDTA \rightarrow \underset{\mathbf{7a}}{(Me_2N)_3B_3N_3H_2Li(pmdta)} + RH \quad (5)$$

$\underset{\mathbf{7b}}{(Me_2N)_3B_3N_3H_2Li(tmta)}$ $\underset{\mathbf{7c}}{(Me_2N)_3B_3N_3H_2Li(tmeda)}$

The *N*-lithiation of the triphenylborazine $Ph_3B_3N_3H_3$ is more complicated than those of the three borazines described in this study. We will report on this shortly.

Multilithiation of 2,4,6-Trimethylborazine

In principle it should be possible to deprotonate **1** not only once but also twice or even three times with RLi compounds. The reaction with MeLi (ratio 1:1) in diethyl ether proceeds quantitatively to give $[(Me_3B_3N_3H_2)Li]$, but all our attempts to isolate pure TMEDA, PMDTA or TMTA complexes of $[(Me_3B_3N_3H)Li_2]$ and $[(Me_3B_3N)Li_3]$ failed. In each case the formation of the tetramethylborate anion was detected in solution by ^{11}B NMR spectroscopy. This indicates that the borazine ring was cleaved to a degree of about 5%.

In order to demonstrate that multilithiation has indeed occurred we treated the solid reaction products with MeBr. After refluxing the mixture and removal of insoluble material (impure LiBr) the filtrate was distilled. A fraction with a boiling point of 85–104 °C (350–500 torr) was obtained for the 1:2 reaction and a fraction with a boiling point of 71–120 °C (300–400 torr) for the 1:3 reaction. NMR spectroscopy and particularly mass spectra showed that the product obtained by distillation contained 2,4,6-$Me_3B_3N_3H_3$, 1,2,4,6-$Me_3B_3N_3H_2Me$, 1,2,3,4,6-$Me_3B_3N_3HMe_2$ and $Me_3B_3N_3Me_3$. This reveals that mono-, di- and tri-lithiation has occurred.

Molecular Structures

Relevant structural parameters of the *N*-monolithioborazine solvates **2a** (Figure 1), **2b** (Figure 2), **2c** (Figure 3), **2d** (Figure 4), **5** (Figure 6), and **7a** (Figure 7) as well as the borazinate **4** (Figure 5) are summarized in Table 1 and Table 2.

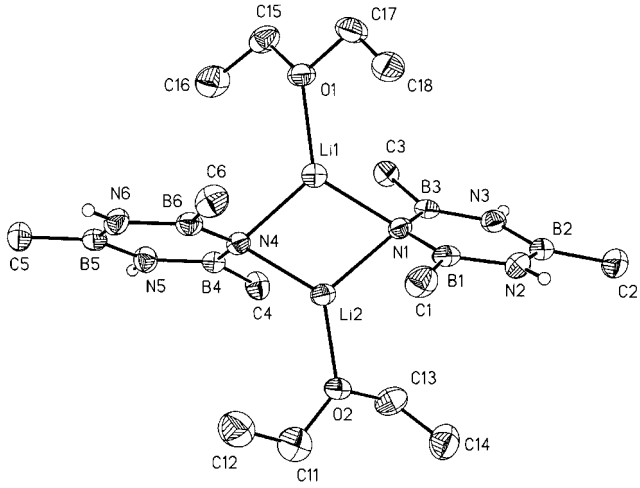

Figure 1. Molecular structure of **2a**. Thermal ellipsoids are shown with 25% probability. Selected atom distances [Å] and bond angles [°] (see also Table 1): Li1–O1 1.985(7), Li2–O2 1.914(7), B1–C1 1.601(6), B2–C2 1.578(6), B3–C3 1.585(6), B4–C4 1.588(5), B5–C5 1.579(6), B6–C6 1.585(6); O1–Li1–N1 128.8(3), O1–Li1–N4 124.3(3), N1–Li1–N4 106.9(3), O2–Li2–N1 121.0(3), O2–Li2–N4 129.4(3)], Li1–N4–Li2 72.4(3), B1–N1–B3 117.4(3), N1–B1–N2 120.2(4), B1–N2–B2 124.2(4), N2–B2–N3 113.4(4), B2–N3–B3 124.2(4), N3–B3–N1 120.4(4), B4–N4–B6 117.9(3), N4–B4–N5 119.0(3), B4–N5–B5 123.8.4(3), N5–B5–N6 114.4(4), B5–N6–B6 124.1(3), N6–B6–N4 119.8(4), N1–B1–C1 122.2(4), C1–B1–N2 117.6(4), C2–B2–N2 123.5(5), C2–B2–N3 123.1(4), C3–B3–N3 117.1(4), C3–B3–N1 125.2(5), Li1–O1–C15 124.9(3), Li1–O1–C17 119.8(3), C15–O1–C17 111.0(4), Li2–O2–C11 129.9(4), Li2–O2–C13 114.2(3), C11–O2–C13 113.4(4). Interplanar angles [°]: Li1N1Li2/B1N1B3 67.7, Li1N1Li2/Li1N4Li2 7.0, Li1N4Li2/B4N4B6 70.6, N4Li1N1/O1C15C17 46.3, C11O2C13/N4Li2N1 55.4. Maximum deviation from the borazine rings: 0.0278 Å for N1 and 0.0183 Å for N4.

All *N*-monolithiated borazines show a significant but systematic distortion of the borazine ring. Most rings remain planar but some of them show slight deviations from planarity. The greatest deviation is found for compound **2d**, where interplanar angles for B1B3N2N3e/-N1B1N3 of 4.5° and B1B3N2N3/N2B2N3 of 2.8° are observed, although these distortions are not highly significant. However, the changes in BN bond lengths for all *N*-monolithioborazines are significant as the BN bonds are no longer equal as found for the borazines **1**[17] and **4**,[18] and, most likely, the BN bonds of $tBu_3B_3N_3H_3$ are also of equal lengths. This change is due to the fact that the N1 ring atom becomes tetra-coordinated due to the dimerization of the $Me_3B_3N_3H_2Li$ units. In general, one can see that the BN bond lengths to the tetracoordinated N atoms are shorter than all other BN ring bonds (see Table 1). In addition, the BN bonds next to the BN bonds at N1, i.e. the pair B1–N2 and B3–N3, are longest while the BN bonds at atom B2 are closer to those of **1** (1.39 Å). However, even these are definitely longer than in the parent borazines, for example **1** with 1.39 Å.[17,18] This bond-length asymmetry also affects, of course, the bond angles, which are 121.0° for N–B–N

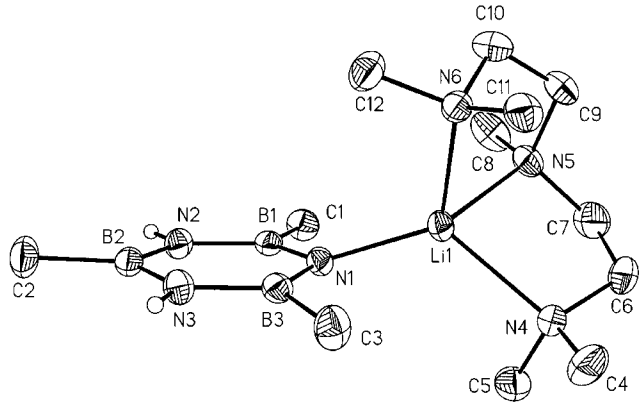

Figure 4. Molecular structure of **2d**. Thermal ellipsoids are depicted with 25% probability. Selected atom distances [Å] and bond angles [°] (see also Table 1): B1–C1 1.602(3), B2–C2 1.589(4), B3–C3 1.589(4), Li1–N1 1.975(4), Li1–N4 2.222(4), Li1–N5 2.203(4), Li1–N6 2.176(4); N1–B1–N2 120.1(2), B1–N2–B2 123.7(2), B2–N3–B3 122.5(2), N3–B3–N1 121.4(2), N1–B1–C1 124.0(2), N2–B1–C1 115.9(2), N3–B2–C2 122.1(2), N2–B2–C2 123.1(2), N3–B3–C3 115.8(2), N1–B3–C3 122.8(2), N1–Li1–N4 123.3(2), N1–Li1–N5 133.0(2), N1–Li1–N6 112.6(2), N4–Li1–N5 82.0(1), N4–Li1–N6 113.4(2), N5–Li1–N6 85.1(1). B2–N1–Li1 157.8. Interplanar angles [°]: Li1N1Li2/B1N1B2N2B3N3 76.7. Max. deviation from borazine plane: –0.0351 Å for N1.

and 119.8° for B–N–B in **1**. For all *N*-monolithioborazines we find a small bond angle at the *para* position B2, centered around 114°, while the B1–N1–B3 bond angles are close to 117°. All other endocyclic bond angles are 120° or up to 4° larger. This distortion leads to a lengthening of the B2–N1 distance across the six-membered ring. Relevant data are given in Table 2. The longest N1···B2 distance is found for the *t*Bu derivative **4** (3.005 Å).

The Li–N1(4) bond lengths are found to cover only a small range, but this bond is particularly short for the monomeric species **2d**, where the N1 atom remains tri-coordinated.

In general, the borazine units in the dimeric species are not orthogonal to the Li_2N_2 rings but neither are they parallel to one another. For instance, the borazine rings in **2a** are twisted against each other by 278.9°, and they form interplanar angles with the Li_2N_2 mean plane of 68.8° and 70.8°, respectively.

Compound **2b** is exceptional insofar as the dimeric *N*-lithioborazine rings contain a tri- and a tetracoordinated Li atom. This is due to the fact that one of the three TMEDA molecules forms a bridge between the two dimeric borazine units, while the other two bind to the remaining Li atoms in a bidentate manner. Consequently, the Li–N bond lengths to these ligands are different, being shorter for the tri-coordinated Li atoms.

Compound **2c** is centrosymmetric. It exhibits longer Li–N bonds both to N1 and the TMTA ligand as the Li atoms are pentacoordinate. Moreover, the TMTA molecule binds asymmetrically to the Li atoms. The borazine ring forms an interplanar angle with the Li_2N_2 plane of 84.8°.

Li1–N1–B2 130.1(3).

In contrast to **2c**, the *t*Bu derivative **5** is a monomer. We attribute this to a steric effect both of the *t*Bu groups and the bulky TIPTA ligand.

The strongest distortion of the borazine ring was observed in **7a**. Atoms B1 and B3 are found below the mean ring-plane. We regard this ring distortion as a consequence of a steric interaction of the Me_2N groups with the PMDTA ligands. The sum of the bond angles at atom N1 in this molecule is 342.5°. This is due to the fact that the Li atom is considerably bent out of the borazine mean-plane as shown by a B2–N1–Li1 angle of 124.4°. It is also worth noting that the exocyclic BN bonds next to atom N1 are longer [1.451 and 1.455(4) Å] than the exocyclic BN bond at atom B2 [1.436(4) Å].

The lithium borazinate **4** differs, of course, in its structure from the *N*-lithioborazines due to the presence of a tetracoordinated boron atom in the ring. The B–N bonds to this boron atom are longer than the other ring BN bonds as the B1–N2 and the N3–B3 bonds are the shortest, but the N2–B2–N3 bond angle is small (105.9°), while the B1–N1–B3 bond angle is wide. Therefore, the charge distribution is strongly influenced whether deprotonation has occurred or carbanion addition.

NMR Spectroscopy

Table 3 contains relevant NMR spectroscopic data of the *N*-monolithioborazines. For all compounds of type **2** the proton resonances of the BMe groups are deshielded relative to **1**, with the exception of **2d**. The protons of the *ortho*-BMe groups are usually more deshielded than those at the *para*-BMe group. The exception for **2d** is due to the fact that this compound is monomeric while **2a**–**c** are dimeric. This also has the consequence that the proton resonances for the NH units are more deshielded in **2d** than in the other solvates of type **2**. Moreover, the shielding of the BMe protons at the *ortho* positions is 0.33 to 0.40 ppm larger than at the *para* position. In the case of mononuclear **2d** the reverse situation is true, i.e. the protons of the *ortho*-BMe groups are more deshielded than those in the *para* position. This suggests that the charge distribution in mononuclear *N*-lithioborazines differs from that of dimeric *N*-lithioborazines.

The ^{13}C resonances of the boron-bonded C atoms could only be observed as broad signals for **2b**–**d**, but not for **2a** and **2e.** It is well known that the large quadrupole moment of boron has a great influence on the relaxation time of the ^{13}C resonance, leading to broad signals, and this may also prevent the observation of the expected ^{13}C NMR signal.

It is somewhat surprising that *N*-lithiation has only a marginal effect on the shielding of the boron nuclei, and there is also no drastic effect on the linewidths of these signals. On the other hand, the ^{7}Li resonances depend in a first approximation on the coordination number of the Li

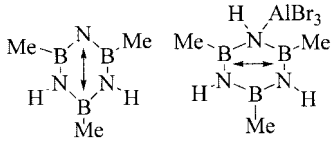
atoms. Those which are tricoordinate are at lower frequencies, the tetracoordinate ones are found at around δ = 2 to 2.4 ppm and the pentacoordinate Li atom of **2d** is even more strongly deshielded.

The protons of the Me_2N groups in compound **4a** are deshielded with respect to the parent borazine **4**. Those in compounds **7b** and **7c** are less influenced than those of the monomer **7a**. This suggests that compounds **7b** and **7c** are most likely dimeric with Li_2N_2 bridges. The protons of the NH groups of these latter compounds are slightly shielded compared with the parent molecule, while those of **7a** are deshielded. Compounds **7a** and **7c** show ^{7}Li resonances for tetracoordination at Li, and a higher coordination number is suggested by the stronger deshielding of the Li nucleus in compound **7b**. This could be achieved if the Li atom coordinate in a different way with the borazine N-atoms.

Discussion

The reaction of lithium organyls RLi (R = Me, Bu, *t*Bu) with 2,4,6-trimethylborazine in hexane leads to an exchange of the alkyl groups but not to deprotonation of an NH group of the borazine. This has also been observed for 2,4,6-tris(dimethylamino)borazine, where an Me_2N/R exchange occurs in hexane. However, **1** can be deprotonated at the NH groups in the presence of diethyl ether or an auxiliary nitrogen base such as TMEDA, PMDTA or TMTA. These reactions produce complexes of *N*-monolithioborazines. The characteristic features of these compounds are the small endocyclic ring angles at N1 and B2 while those at N2 and N3 span the range 120–124°. Even more pronounced are the long BN bonds between the *ortho* and *meta* positions of the ring (B1–N2 and N3–B3) while those at B2 and at N1 can be considered to be essentially equal. This shows that the negative charge at the atom N1 obviously weakens the B1–N2 and N3–B3 bonds inductively. Thus, we observe a distortion of the borazine rings, as shown in Scheme 2. In contrast, the $AlBr_3$ adduct of **1** shows the opposite effect, i.e. a widening of the endocyclic bond angles at N1 and B2 and a shortening of the B1–N2 and N3–B3 bonds due to electron withdrawal from the ammonium-type N atom by $AlBr_3$.[19] The small ring angles at atom N1 of the *N*-lithio derivatives of **2**, **5** and **7** can be explained by the VSERP theory of bonding, as the lone pairs of electrons at N1 occupy a larger space. Of course, one has to take the highly polar Li–N interactions into account. Although we have studied the *N*-lithiation of borazines by ab initio methods, we will report on theoretical studies at higher levels of theory in due course.[20]



Scheme 2.

It is quite clear that the Li compounds described here can be looked at as formal analogues of aryllithium compounds. For instance. $[LiPh(tmeda)]_2$[21] is structurally akin to compound **2b**, while $[Li(mes)(THF)_2]_2$[22] can be compared with **2a** although the latter has only tricoordinate Li atoms in contrast to the tetracoordinate Li atoms in the mesityl derivative. In this compound the longest C–C bonds are at the carbon atom bonded to Li [C1–C2 = 1.431(2) and C1–C6 = 1.424(2) Å]. Those adjacent to these [C2–C3 = 1.397(2) and C5–C6 = 1.399(2) Å] are shorter, followed by C4–C4 and C4–C5 with 1.393(2) and 1.394(2) Å, respectively. This suggest a different electron distribution in $[Li(mes)(THF)_2]_2$ compared to **2a**. These effects have been addressed H. Bock et al.[23]

However, the bond angles C6–C1–C2 and C3–C4–C5 in $[Li(mes)(THF)_2]_2$ are acute [113.1(1)° and 116.9(1)°] as is also the case for $[LiPh(tmeda)]_2$[24] A similar situation is also observed for tetrameric $[LiPh(OEt_2)]$.[25] There is also a shortening of the C–C bonds on going from the *ipso*-C atom to the *para*-C atom. So, similar to the *N*-lithioborazines described here, a lengthening of the C–C bonds from the *ipso*-C to the *ortho*-C carbon atom seems to be common for aryllithiums, in contrast to the alternating change in the B–N bond lengths in the *N*-lithioborazines.

So far there is no organometallic analogue of $[\{(Me_2NB)_3N_3H_2\}Li(pmdta)]$. We had expected that the Me_2N group may also coordinate to the Li atom, but this is not the case, most likely for two reasons. First, the Me_2N groups form BN π-bonds. This reduces their basicity and, therefore, also their tendency to act as a Lewis base. Secondly, for steric reasons these groups are not able to form chelates as observed in aryllithiums where the phenyl groups carries R_2NCH_2 substituents.[26–28]

The *N*-lithioborazines have proved to be useful reagents for the preparation of a large variety of borazine derivatives which are either not accessible or difficult to prepare by other routes. We will report on these results shortly.

Experimental Section

All experiments were performed by Schlenk techniques employing dry dinitrogen gas or argon as a protective gas. Glassware was heated to 400 °C, filled with dinitrogen gas and allowed to cool. Solvents were dried by conventional methods. NMR: Bruker ACP 200 (^{1}H, ^{7}Li, ^{11}B, ^{13}C), Jeol GSX 270 (^{1}H, ^{7}Li, ^{11}B, ^{29}Si) or Jeol EX 400 (^{1}H, ^{11}B,^{13}C). Standards: C_6D_6, $SiMe_4$, external 1 M aqueous LiCl, $BF_3{\cdot}OEt_2$. IR: Nicolet 520 FT-IR, Nujol hostaflon mulls. Raman: Perkin–Elmer PE 2000, 9324 cm^{-1}, 300 mW. X-ray: Siemens P4 diffractometer equipped with a CCD detector and a LT2 low temperature device. Mo-K_α radiation, graphite monochromator. Commercial chemicals: $BF_3{\cdot}OEt_2$ (BASF), BCl_3 (Elektroschmelzwerk Kempten), Me_3SiCl, $(Me_3Si)_2NH$ (Wacker Chemie), TMEDA, PMDTA, 1,3,5-trimethyl (or isopropyl)hexahydrotriazine (Fluka). Li compounds (Chemetall GmbH).

2,4,6-Trimethylborazine (1):[13] Freshly distilled $(Me_3Si)_2NH$ (250 mL, 1.2 mol, b.p. 134–127 °C) dissolved in CH_2Cl_2 (250 mL) was placed in a one-litre, three-necked flask fitted with a dry ice and an H_2O reflux condenser, a magnetic stirring bar and a pressure equalizer. After cooling to –78 °C $MeBCl_2$ (120.9 g, 1.25 mol) was condensed into the stirred solution within a period of 2 h. During this process a pressure equalizer was placed on top of the dry

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ice reflux condenser, and the water-cooled condenser was closed with a stopcock. Some smoke formation was observed at the beginning of the $MeBCl_2$ addition. The solid that formed was later isolated and characterized as NH_4Cl (3–5% based on $MeBCl_2$). The ^{11}B NMR signals found after that time were at δ = 2.8 ppm [$MeBCl_2$·$HN(SiMe_3)_2$], 36 ppm ($Me_3B_3N_3H_3$), 37.6 ppm [$MeClBN(SiMe_3)_2$], 43.3 $(MeBNH)_2$, 48.9 ppm [$MeB(NHBMe)_n$-$NHSiMe_3$] and 63.0 ppm ($MeBCl_2$) in a ratio of 1:12:4:3:2:1). The solution was then heated to reflux (water-cooled condenser) for 4 to 10 d until the ^{11}B NMR spectrum showed only the signal of **1** at δ = 36 ppm. The ^1H NMR spectrum demonstrated the presence of **1** (δ = 0.23 and 4.37 ppm) and Me_3SiCl (δ = 0.63 ppm, $^2J_{^{29}Si,^1H}$ = 7 Hz) with some minor impurities. The insoluble material was removed from the turbid solution by filtration through a G3 glass frit. Solvent and Me_3SiCl were stripped off in vacuo. The residue solidified within a few hours. Crystallization from hexane provided **1** in 95% yield (46.5 g, 379 mmol), m.p. 36 °C. ***Caution:*** *$MeBCl_2$ ignites in contact with air, therefore precautions have to be taken to avoid contact of the rather volatile boron halide with air. $MeBCl_2$ should be stored in a Schlenk tube equipped with a grease-free stopcock and stored at a temperature below –30 °C.* ^1H NMR (400 MHz, C_6D_6): δ = 0.23 (s, 9 H, C*H3*), 4.37 (br. s, 3 H, NH) ppm. ^{13}C NMR (100 MHz): δ = 1.34 ppm (CH_3). ^{11}B NMR (64 MHz): δ = 36.0 ppm.

Reaction of 1 with *n*BuLi in Hexane (1:1): The borazine **1** (1.15 g, 9.3 mmol) was dissolved in hexane (3.5 mL) and the solution cooled to –30 °C. A solution of *n*BuLi (6.1 mL, 1.6 M in hexane, 9.7 mmol) was slowly added while stirring. A white precipitate formed quickly. No gas evolution was noted. After allowing the suspension to attain ambient temperature it was heated to reflux for 2 h. The solid was then removed by filtration (G3 frit, MeLi, Li_2CH_2). All volatile material was removed in an oil-pump vacuum at 20 °C from 5 mL of the reaction solution and the residue dissolved in 1 mL of C_6D_6. This solution showed ^{11}B NMR signals at δ = 38.1 and 36.2 ppm. The residue obtained from the hexane solution exhibited the following prominent signals in the mass spectrum (correct isotopic pattern) at 70 eV: *m*/*z* (%) = 248 (61) (2,4,6-$Bu_3B_3N_3H_3$), 207 (66) (2,4,6-$Bu_2MeB_3N_3H_3$), 165 (31) (2,4,6-$BuMe_2B_3N_3H_3$), 123 (100) ($Me_3B_3N_3H_3$).

Reaction of 1 with *t*BuLi: Compound **1** (0.97 g, 7. 8 mmol) was dissolved in hexane (35 mL) and the solution cooled to –78 °C. While stirring, a solution of *t*BuLi in hexane (5.0 mL, 1.6 M, 8.0 mmol) diluted with hexane (20 mL) was added *slowly*. After addition of a few drops of the *t*BuLi solution a precipitate formed with no gas evolution. After addition was complete the suspension was allowed to attain room temperature and was then kept for 2 h under reflux. The solid was removed by filtration. The ^{11}B NMR spectrum of the filtrate showed that a Me/*t*Bu exchange had taken place ($\delta_{^{11}B}$ = 38.2, 36.0 ppm in a ratio of 1:2). The mass spectrum of the liquid that remained after evaporation of the solvent proved the presence of $tBu_3B_3N_3H_3$ (*m*/*z* = 248, 11%), $tBu_2MeB_3N_3H_3$ (*m*/*z* = 207, 32%), $tBuMe_2B_3N_3H_3$ (*m*/*z* = 165, 59%), and **1** (*m*/*z* = 123, 100%).

1-Lithio-2,4,6-trimethylborazine Diethyl Ether Adduct (2a): Trimethylborazine (**1**; 0.38 g, 3.1 mmol) was dissolved in diethyl ether (30 mL) and the solution cooled to –78 °C. With stirring, 1.95 mL of an *n*BuLi solution in hexane was added dropwise. This resulted in the formation of a white precipitate. After the suspension had attained room temperature it was heated to reflux until a slightly turbid solution had formed. Then, the very small amount of solid was removed by filtration and all volatile materials removed in vacuo. The oily residue, which was insoluble in pentane, solidified on cooling. It was dissolved in a minimum amount of diethyl ether from which single crystals of **2a** separated on cooling. Yield: 0.55 g (85%), m.p. 105 °C (dec.). ^1H NMR (C_6D_6; see also Table 2): δ = 0.98 (CH_2CH_3, 6 H), 3.17 (OCH_2, 4 H) ppm. ^{13}C NMR: δ = 14.7 (CH_2CH_3), 65.7 (OCH_2) ppm. IR (Nujol): $\tilde{\nu}$ = 3447 w, 3419 m, 2959 m, 1600 w, 1471 st, 1443 st, 1414 st, 1332 st, 1319 st, 1285 st, 1204 m, 1197 m, 1163 m, 1111 m, 1097 m, 1023 w, 886 st, 846 m, 785 m, 776 m, 758 st, 715 m, 587 st, 618 m, 392 m, 324 m. Raman: $\tilde{\nu}$ = 3430 w, 2970 st, 2934 vst, 2900 vst, 2844 m, 1459 m, 1440 m, 1071 w, 852 w, 519 st, 455 w, 340 w, 219 w, 120 m. $C_7H_{19}B_3LiON_3$ (202.63): calcd. C 41.49, H 10.44, N 20.73; found C 42.79, H 10.29, N 19.43.

1-Lithio-2,4,6-trimethylborazine Tetramethylethylenediamine (4/3) Adduct (2b): a) A solution of *n*BuLi in hexane (4.5 mL, 1.6 M, 7.2 mmol) was cooled to –78 °C and TMEDA (1.1 mL, 0.85 g, 7.3 mmol) dissolved in hexane (5 mL) was added with stirring. The precipitate that formed dissolved on warming the suspension to room temperature. This solution was placed into a cooled dropping funnel (–50 °C) and added with stirring to a solution of **1** (0.82 g, 6.7 mmol) in hexane (20 mL) kept at –78 °C. A slight gas evolution was noted and the formation of a suspension. This suspension was then kept at reflux for 4 d until no more gas evolution was observed. Solid material was then removed by filtration and dried in a stream of dinitrogen. Colorless crystals of **2b** separated from the filtrate on cooling to –25 °C. After crystallization from hexane the yield was 1.31 g (91%), m.p. 103–105 °C. ^1H NMR (C_6D_6; see also Table 2): δ = 1.95 (12 H, NMe), 1.97 (4 H, NCH_2) ppm. ^{13}C NMR: δ = 46.2 (NCH_3), 57.4 (NCH_2) ppm. IR (Nujol, Hostaflon): $\tilde{\nu}$ = 3447 w, 3430 m, 2993 m, 2957 st, 2885 m, 2877 m, 2825 st, 2775 st, 2726 w, 2704 w, 1475 vst, 1442 vst, 1414 st, 1370 w, 1358 w, 1331 w, 1286 st, 1249 w, 1217 m, 1179 w, 1158 m, 1130 w, 1110 w, 1100 m, 1074 m, 1034 m, 1024 m, 1008 m, 946 m, 880 st, 848 w, 838 w, 791 m, 715 st, 704 st, 684 w, 583 m, 524 m, 505 m, 458 w, 440 w, 346 m, 299 w, 286 w. Raman: $\tilde{\nu}$ = 3428 m, 2996 st, 2967 vst, 2903 vst, 2829 vst, 2778 st, 1474 st, 1448 m, 1435 m, 1409 w, 1312 w, 1290 w, 1220 w, 1159 w, 1073 w, 1026 w, 938 w, 870 w, 847 w, 793 w, 783 w, 521 st, 461 m, 449 m, 366 w, 121 m. $C_{30}H_{92}B_{12}Li_4N_{18}$ (862.70): calcd. C 41.77, H 10.74, N 29.33; found C 41.43, H 10.80, N 28.34.

b) A hexane solution of *n*BuLi (11.0 mL, 1.6 M, 17.6 mmol) was cooled to –30 °C and a hexane solution of TMEDA (10 mL, 4.2 g, 38 mmol) was added while stirring. The yellow solution was transferred into a dropping funnel and added to a stirred solution of **1** (1.98 g, 16.1 mmol) in hexane (40 mL). The resulting suspension was kept at reflux for 1 d. The solid was removed by filtration and dried (0.7 g of **2b**). It dissolved readily in diethyl ether. Crystals of **2b** were obtained from the diethyl ether solution as well as from the hexane solution on crystallization at –25 °C. Total yield: 3.1 g (90%). These crystals showed the same cell dimensions as those obtained by procedure a).

1-Lithio-2,4,6-trimethylborazine 1,3,5-Trimethylhexahydrotriazine Adduct (2c): Prepared in analogy to procedure a) for **2b**. A solution of *n*BuLi/tmta was prepared from *n*BuLi in hexane (4.90 mmol in 13 mL) and a solution of TMTA (0.63 g, 4.90 mmol) in hexane (5 mL). It was cooled to –50 °C and added to a solution of **1** (580 mg, 4.7 mmol) in hexane (30 mL) kept at –78 °C. The resulting mixture was kept at reflux for 2 d. After filtration crystals of dimeric **2c** separated from the filtrate on storing the solution at –5 °C. Yield: 0.43 g (89%); m.p. 116–119 °C. ^1H NMR (C_6D_6; see also Table 2): δ = 2.06 (9 H, NCH_3), 2.98 (br., 6 H, NCH_2) ppm. ^{13}C NMR: δ = 39.8 (NCH_3), 77.2 (NCH_2) ppm. IR (Nujol): $\tilde{\nu}$ = 3444 w, 3420 m, 2980 m, 1592 w, 1472 st, 1448 vst, 1434 vst, 1386

1-Lithio-2,4,6-trimethylborazine Pentamethyldiethylenetriamine Adduct (2d): A solution of MeLi in diethyl ether (6.6 mmol, 1.6 M, 4.5 mL) was cooled to –78 °C. Then, a solution of PMDTA in hexane (2.52 g, 19.6 mmol, 5 mL) was added while stirring. After the mixture had attained room temperature the clear solution was added to a solution of **1** in hexane (0.58 g, 4.7 mmol, 30 mL) at –78 °C. Gas evolution started immediately by adding the MeLi/PMDTA solution with formation of a white solid. The suspension was then kept at reflux for four days. The resulting turbid solution showed a single ^{11}B NMR signal at δ = 36.0 ppm. From the suspension 1.3 g of a solid was isolated which dissolved readily in diethyl ether. Colorless prisms of **2d** separated from this diethyl ether solution on storing at –25 °C. Yield: 1.24 g (62%); m. p. 161 °C (dec.). ^{1}H NMR (C_6D_6; see also Table 2): δ = 2.12 (12 H, NCH_3), 2.19 (3 H, NCH_3), 2.39 (4 H, NCH_2), 2.50 (4 H, NCH_2) ppm. ^{13}C NMR: δ = 42.9 (NCH$_3$), 45.8 [N(CH$_3$)$_2$], 56.6 (CH$_2$); 58.1 (CH$_2$) ppm. IR (Nujol): $\tilde{\nu}$ = 3442 w, 3423 w, 2987 m, 1473 st, 1459 st, 1431 st, 1365 m, 1356 m, 1312 st, 1303 st, 1291 st, 1278 st, 1251 st, 1236 m, 1178 w, 1164 m, 1152 m, 1130 m, 1110 m, 1099 w, 1088 st, 1064 m, 1036 m, 1021 m, 998 w, 985 m, 944 w, 935 m, 899 m, 889 m, 879 m, 839 w, 790 w, 778 m, 763 st, 748 w, 711 st, 675 w, 604 w, 574 m, 521 w, 504 m, 488 w, 460 2 w, 448 w, 431 w, 404 w. Raman: $\tilde{\nu}$ = 2985 st, 2961 vst, 2923 st, 2895 vst, 2836 vst, 2784 st, 1475 m, 1442 m, 1290 w, 1149 w, 1024 w, 945 w, 792 w, 518 w, 465 w. $C_{12}H_{24}B_3LiN_6$ (301.82): calcd. C 47.75, H 11.35, N 27.85; found C 46.68, H 11.11, N 27.52.

Reaction of 1 with MeLi (1:2): Trimethylborazine (**1**; 642 mg, 5.2 mmol) dissolved in diethyl ether (30 mL) was cooled to –78 °C and treated while stirring with a MeLi solution (10.3 mmol in 6.4 mL of diethyl ether). A precipitate formed, and the supernatant solution showed ^{11}B NMR signals at δ = –19.9 (BMe_4^-) and 37.3 ppm in an intensity ratio of 1:6. The suspension was cooled again to –78 °C and treated with a solution of MeBr (1.14 g, 12 mmol) in diethyl ether (5 mL). This mixture was kept at reflux for 2 d. The ether was then removed by distillation. An oily residue remained which was treated with hexane (50 mL) to give a suspension. From this suspension LiBr (0.9 g, 10.4 mmol) was isolated by filtration. The filtrate was distilled. A liquid fraction was obtained using a 30 cm Vigreux column to give 0.52 g of a fraction with a boiling range of 85–104 °C at 350–500 torr. MS (70 eV): *m*/*z* (%) = 165 (61) ($Me_3B_3N_3Me_3$), 151 (95) ($Me_3B_3N_3HMe_2$), 137 (100) ($Me_3B_3N_3H_2Me$), 123 (75) ($Me_3B_3N_3H_3$), 95 (33) ($Me_2B_2N_2HMe$), 81 (35) ($Me_2B_2N_2H_2$), 66 (41) (MeB_2N_2H), 55 (26) (MeBNMe), 41 (38) (MeBNH).

Reaction of 1 with MeLi (1:3): In analogy with the previous experiment a solution of **1** (1.06 g, 8.6 mmol) in diethyl ether (30 mL) was treated with MeLi (26.1 mmol, 16.3 mL of a 1.6 M diethyl ether solution) at –78 °C. The mixture was kept at reflux for 20 h showing ^{11}B NMR signals at δ = –19.9 and 37.3 ppm in a 1:7 ratio. Treatment of the suspension with MeBr (2.56 g, 27 mmol) and work up after refluxing for 2 d gave an oily fraction with a boiling range of 71–102 °C/300–400 torr. MS (70 eV): *m*/*z* (%) = 165 (65) ($Me_3B_3N_3Me_3$), 151 (100) ($Me_3B_3N_3HMe_2$), 137 (93) ($Me_3B_3N_3H_2Me$), 123 (62) ($Me_3B_3N_3H_3$), 95 (37) ($Me_2B_2N_2HMe$), 81 (26) ($Me_2B_2N_2H_2$), 66 (43) MeB_2N_2 H), 55 (57) (MeBNMe), 41 (14) (MeBNH).

Lithium Bis(1,3,5-triisopropylhexahydrotriazine)tetra(*tert*-butyl)borazinate (4): (tBu)$_3$B$_3$N$_3$H$_3$[13] (**3**; 1.45 g, 5.83 mmol) was dissolved in hexane (30 mL), and the solution cooled to –78 °C. Then, a solution of (iPr$_3$NCH$_2$)$_3$ (2.56 g, 12 mmol) and tBuLi (8.5 mL, 1.45 M, 12.3 mmol) in hexane (25 mL) was added slowly dropwise while stirring. Stirring was continued at ambient temperature for 2 h. The slightly turbid solution was filtered, and the filtrate reduced in volume by 1/3. Storing the solution at –25 °C produced a crop of single crystals (yield 1.5 g, 20%); X-ray structure analysis showed them to be compound **4**.

1-Lithio-2,4,6-tri(*tert*-butyl)borazine-1,3,5-trimethylhexahydrotriazine (5): A solution of tBu$_3$B$_3$N$_3$H$_3$ (1.70 g, 6.83 mmol) was dissolved in diethyl ether (20 mL). A solution prepared from a hexane solution of tBuLi (1.45 M, 4.8 mL, 6.96 mmol) diluted with 20 mL of hexane was then added at –30 °C. The mixture was heated to reflux for 24 h to give a turbid solution. After filtration the filtrate was kept at –25 °C. The crystals that formed within a few days were isolated. Yield: 1.65 g (66.6%). These proved to be compound **5** by X-ray structure analysis.

2,4,6-Tris(dimethylamino)borazine (6):[14] A solution of Me_2NSiMe_3 (11.73 g, 100 mmol) in CH_2Cl_2 (50 mL) was slowly added at –78 °C to a solution of $Cl_3B_3N_3H_3$ (6.1 g, 33 mmol) in dichloromethane (300 mL). After the solution had attained room temperature the ^{11}B NMR spectrum showed a quantitative conversion of the chloroborazine to **6**. All volatile material was removed under an oil pump vacuum and the solid residue crystallized twice from CH_2Cl_2 (80 mL each): Yield: 6.9 g (99%); m.p. 112–115 °C.

Reaction of 2,4,6-Tris(dimethylamino)borazine with *tert*-Butyllithium: The borazine **6** (923 mg, 4.4 mmol) was dissolved in hexane (25 mL) and cooled to –78 °C. Then a solution tBuLi in hexane (4.6 mmol, 16.9 mL) was added. The resulting suspension was kept at reflux for 2 d. 5 mL of the supernatant solution was taken as a probe. The solvent was removed in vacuo and the residue dissolved in C_6D_6 for NMR investigation. ^{1}H NMR (C_6D_6): δ = 0.92 (s, $BCMe_3$), 1.03 (s, $BCMe_3$), 1.08 (s, $BCMe_3$), 2.19 (s, NMe_2), 2.43 (s, NMe_2), 2.47 (s, NMe_2), 3.09 (br., NH), 3.22 (br., NH) ppm. ^{13}C NMR: δ = 30.1 (NMe_2), 32.1 (NMe_2), 36.5 (NMe_2), 36.7 (NMe_2), 36.9 (NMe_2), 37.9 ppm (br., BCMe$_3$). ^{11}B NMR: δ = 25.9, 37.9 ppm (2:1). ^{7}Li NMR: δ = 1.29 ppm.

1-Lithio-2,4,6-tris(dimethylamino)borazine Pentamethyldiethylenetriamine Adduct (7a): Compound **6** (1.25 g, 5.9 mmol) was dissolved in hexane (25 mL) and cooled to –78 °C. While stirring, a solution of nBuLi (3.9 mL, 1.6 M, 6.2 mmol) and PMDTA (4.0 mL, 3.32 g, 19.1 mmol) in hexane (24 mL) was added dropwise. The suspension that formed was kept at reflux for 12 h. The solid was separated by filtration. A small amount of **6** crystallized from the filtrate on reduction of the volume of the solution in vacuo. The solid was treated with diethyl ether (2 × 30 mL). Only about 25% dissolved. Crystals of **7a** separated from the diethyl ether solution on concentration and cooling to –25 °C; m.p. 119–121 °C. ^{1}H NMR (C_6D_6; see also Table 2): δ = 2.12 (s, 12 H, 2 NMe_2), 2.19 (s, 3 H, NMe), 2.31 (s, 4 H, NCH_2), 2.39 (s, 4 H, NCH_2) ppm. ^{13}C NMR: δ = 42.9 (NMe), 45.9 (NMe_2), 56.6 (NCH_2), 58.0 (NCH_2) ppm. IR (Nujol, Hostaflon): $\tilde{\nu}$ = 3481 st, 3463 st, 2957 m, 2969 m, 2862 st, 2821 m, 2801 m, 2773 m, 1520 vst, 1474 st, 1431 vst, 1416 m, 1402 m, 1370 st,1352 m, 1328 w, 1303 m, 1263 m, 1198 w, 1152 w, 1100 st, 1043 m, 1032 st, 978 m, 943 w, 897 w, 860 w, 793 m, 717 w, 701 w, 695 st, 662 w, 586 st, 491 w, 464 w, 408 w, 333 w, 311 w. $C_{15}H_{43}B_3LiN_9$ (388.9): calcd. C 46.32, H 11.14, N 32.41; found C 43.41, H 10.29, N 31.98.

1-Lithio-2,4,6-tris(dimethylamino)borazine Tetramethylethylendiamine Adduct (7b): Prepared in analogy to **5**, from a solution of **6**

(1.22 g, 5.8 mmol) in diethyl ether (25 mL), MeLi (commercial grade containing iodide; 3.8 mL, 1.6 M, 6.1 mmol) and TMEDA (3.0 mL, 20 mmol) diluted with diethyl ether (25 mL). The mixture was stirred for 4 d at room temperature. Half of the diethyl ether was then removed from the solution. Colorless prisms crystallized (105 mg, 2.87 mmol) at –25 °C which proved to be LiI(tmeda)$_2$.[30] After stirring the solution for 4 d and fractional crystallization (by removing solvent) **7b** separated as a microcrystalline powder. Yield: 731 mg (38%). Single crystals formed from the filtrate on standing for several days at –25 °C, m.p. 191–194 °C (dec.). ^{1}H NMR (C_6D_6): δ = 2.09 (s, 12 H, $CNMe_2$), 2.23 (s, 4 H, NCH_2) ppm. ^{13}C NMR: δ = 46.1 ($CNMe_2$), 58.2 (NCH_2) ppm. IR (Nujol, Hostaflon): $\tilde{\nu}$ = 3848 w, 3440 w, 2874 m, 2831 m, 2805 m, 2785 m, 1518 vst, 1492 st, 1431 st, 1415 vst, 1390 vst, 1371 st, 1342 st, 1325 st, 1306 m, 1295 m, 1274 m, 1213 w, 1197 w, 1165 m, 1150 w, 1115, 1099 st, 1063 m, 1055 m, 1044 w, 981 m, 955 st, 871 w, 844 m, 799 m, 727 w, 695 m, 680 w, 636 m, 587 w, 565 w, 520 m, 495 w. $C_{12}H_{36}B_3LiN_8$ (331.85): calcd. C 43.43, H 10.93, N 33.77; found C 41.24, H 10.88, N 32.91.

1-Lithio-2,4,6-tris(dimethylamino)borazine 1,3,5-Trimethylhexahydrotriazine Adduct (7c): A solution of MeLi in diethyl ether (2.8 mL, 4.5 mmol) and 2.8 mL of TMTA (19.8 mmol) was slowly added at –78 °C to a stirred solution of **6** (776 mg, 3.70 mmol) in diethyl ether (25 mL). A precipitate formed and a gas was produced. The suspension was kept for 17 h at reflux. Then the solid (1.05 g) was isolated by filtration. It dissolved completely in diethyl ether (50 mL). After removal of about 1/3 of the solvent the solution was kept at –25 °C where a crystal powder separated. The yield was not determined. Single crystals suitable for X-ray structure determination separated from the filtrate on further standing. ^{1}H NMR (C_6D_6): δ = 2.50 (s, 9 H, CH_2NCH_3), 2.62 (6 H, NCH_2) ppm. ^{13}C NMR: δ = 40.1 (CH_2NCH_3), 77.3 (CH_2N) ppm. IR (Nujol, Hostaflon): $\tilde{\nu}$ = 3480 m, 3405 m, 2970 w, 2926 m, 2865 st, 1520 vst, 1465 st, 1431 vst, 1416 vst, 1494 st, 1367 st, 1363 st, 1314 m, 1302 m, 1275 m, 1263 m, 1247 m, 1196 w, 1157 w, 1100 st, 978 st, 943 w, 915 w, 883 w, 861 w, 825 w, 768 w, 738 w, 716 m, 694 st, 587 br, 491 w, 453 w. $C_{12}H_{35}B_3LiN_9$ (345.85): calcd. C 41.76, H 10.49, N 36.45; found C 39.10, H 10.48, N 36.53.

X-ray Structure Determination: Relevant crystallographic data and information on data collection and structure solution are summarized in Table 4 and Table 5. Single crystals were placed in a poly(fluoro ether) oil (stock point –40 °C) and a suitable specimen selected and mounted on the tip of a glass fiber. An N_2 gas stream was cooled to –80 °C and the crystal, fixed on a goniometer head, was placed in the gas stream. Reflections of 5 sets of 15 frames were used to determine the unit cell with the program SMART.[31] Data collection was performed in the hemisphere mode, and the data reduced by applying the program SAINT.[32] No absorption correction was applied, except for **8**. The structures were solved with either SHELXTL or SHELX 90[33] Non-hydrogen atoms were refined with anisotropic thermal parameters. Most hydrogen atom positions were found from difference Fourier calculation, but in most cases their positions were calculated, and a riding model applied in the refinement with $U_i = 1.2U_{ij}$ of the corresponding C atom. The H position on the N atoms was taken from the difference Fourier map and refined isotropically. Compound **6a** showed

Synthesis, Structure, and Properties of μ-Oxo-Bridged Fe^{III}_2 and Heterometallic Azide-Bridged $Fe^{III}_2Cu^{II}$ Complexes of a Picolinamide In-Plane Ligand

José M. Domínguez-Vera,*[a] José Suárez-Varela,[a] Ikram Ben Maimoun,[b] and Enrique Colacio*[a]

Keywords: Azides / Heterometallic complexes / Iron / Magnetic properties / Oxo ligands

A new μ-oxodiiron(III) complex [{Fe^{III}(bpc)(H_2O)}$_2$O] (**1**) with the bis(picolinamide) N_4 in-plane ligand 4,5-dichloro-1,2-bis-(pyridine-2-carboxamido)benzene (H_2bpc) has been prepared by the reaction of [Fe(bpc)Cl(H_2O)] with a stoichiometric amount of cyanide, and characterized by X-ray structure analysis. The IR and UV/Vis spectroscopic results match well with those expected from the respective previously established spectro-structure correlation. Likewise, the temperature dependence of the magnetic susceptibility shows the existence of a strong antiferromagnetic coupling between the iron(III) centers [$S = 5/2$; with $J = -108.10(3)$ cm^{-1}] that is consistent with the radial and angular overlap Weihe–Güdel model in μ-oxodiiron(III) complexes. Two heterometallic Fe^{III}-$Cu^{II}Fe^{III}$ (**2**) and $Fe^{III}Ni^{II}Fe^{III}$ (**3**) complexes have been prepared from the reaction between [Fe^{III}(bpc)(N_3)$_2$] and [Cu(*meso*-CTH)]$^{2+}$ or [Ni(*meso*-CTH)]$^{2+}$ (CTH = 5,7,7,12,14,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane), respectively. The structure of **2** consists of heterometallic $Fe^{III}Cu^{II}Fe^{III}$ units formed by the simultaneous coordination of two [Fe^{III}-(bpc)(N_3)$_2$] units to the central [Cu(*meso*-CTH)] units through a $\mu_{1,3}$-azide bridging ligand. However, the structure of **3** contains isolated [Fe^{III}(bpc)(N_3)$_2$]$^-$ and [Ni(*meso*-CTH)]$^{2+}$ ions. The treatment of the magnetic data of **2** revealed the existence of a small ferromagnetic interaction between Fe^{III} and Cu^{II} metal ions, with $J_{FeCu} = 3.24(7)$ cm^{-1}. The existence of **2** opens up the possibility of obtaining, in a rational manner, azide-bridged heterometallic complexes starting from the block precursor [Fe^{III}(bpc)(N_3)$_2$]$^-$.

Introduction

Oxo-bridged diiron complexes have been extensively studied owing to the occurrence of the Fe–O–Fe fragment at the active sites of non-heme iron metalloproteins, such as hemerythrin,[1] ribonucleotide reductase,[2] or methane monooxygensase.[3] The synthetic, spectroscopic, and magnetic study of μ-oxodiiron complexes can provide a reference frame for these biological sites, and with this aim a great number of (μ-oxo)L_2Fe_2 complexes have been structurally characterized and their properties intensively studied.[4] In spite of this, the interest in preparing this kind of complexes remains because minor structural modifications in the L ligand or in the bridging region can generate drastic differences in their reactivity and properties, as is the case at the active site of metalloproteins.

One of the most commonly used strategies to prepare (μ-oxo)L_2Fe_2 complexes has been the hydrolysis, in a basic medium, of an in-plane ligand containing iron(III) complex. The ligand 4,5-dichloro-1,2-bis(pyridine-2-carboxamido)-benzene (H_2bpc) is a good candidate for preparing this kind of diiron(III) complex since it is forced to occupy four in-plane nitrogen coordinative positions around an iron(III) ion. Monodentate ligands such as water, chloride, cyanide, azide, etc. can be bound in axial positions to generate six-coordinate distorted octahedral complexes [Fe^{III}(bpc)X_2] and/or [Fe^{III}(bpc)XY][5,6] (Scheme 1).

In this paper, we report on the synthesis, crystal structure, and magnetic properties of the μ-oxo dimer complex [{Fe^{III}(bpc)(H_2O)}$_2$O] (**1**) and the heterometallic complexes [{Fe^{III}(bpc)(N_3)$_2$}$_2${Cu(*meso*-CTH)}] (**2**) and [{Fe^{III}(bpc)(N_3)$_2$}$_2${Cu(*meso*-CTH)}] (**3**). The former was prepared from the complex [{Fe^{III}(bpc)Cl(H_2O)], whereas **2** and **3** were prepared by the reaction between [Fe^{III}(bpc)-(N_3)$_2$]$^-$ and [Cu(*meso*-CTH)]$^{2+}$ or [Ni(*meso*-CTH)]$^{2+}$ (CTH = 5,7,7,12,14,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane), respectively. The existence of **2** suggests the possibility of preparing, in a rational manner, azide-bridged heterometallic complexes from the precursor [Fe^{III}(bpc)-(N_3)$_2$]$^-$.

Results and Discussion

As previously reported, the complex $[Fe^{III}(bpc)Cl(H_2O)]$ reacts with an excess of cyanide to produce the green complex $[Fe^{III}(bpc)(CN)_2]^-$.[6] However, when we carried out this reaction under stoichiometric conditions we obtained red crystals of the μ-oxodiiron(III) complex $[\{Fe^{III}(bpc)(H_2O)\}_2O]\cdot 3H_2O$ (**1**). This suggests that the role of the cyanide salt in this reaction is as a base rather than as a ligand. In fact, the same complex $[\{Fe^{III}(bpc)(H_2O)\}_2O]$ has previously been obtained using an inorganic base such as $(Bu_4N)(OH)$ instead of cyanide,[7] although its structure was not reported. The molecular structure of **1** is shown in Figure 1, and selected bond lengths and angles are listed in Table 1.

The structure consists of μ-oxo dinuclear molecules in which the two iron atoms have a distorted octahedral geometry, with the four nitrogen atoms of the bis(picolinamidate) ligand in basal positions and two oxygen atoms in axial positions, one belonging to the μ-oxo bridge and another one to a water molecule. The tetradentate behavior of the ligand results in the formation of three five-membered rings around each iron atom. The Fe–N distances involving the pyridine nitrogen atoms N1 (2.154 Å) and N4 (2.167 Å) are significantly longer than those for the amide nitrogen atoms N2 (2.059 Å) and N3 (2.086 Å). Similar bond-length patterns have been observed for other related iron(III) complexes.[8] The central oxygen atom of the Fe–O–Fe fragment lies on an inversion center, with an Fe–O–Fe angle of 180° and an Fe–Fe distance of 3.558 Å, which is typical of a monobridged Fe–O–Fe linear core.[4] The μ-oxo–Fe and Fe–O(water) distances of 1.779 and 2.145 Å are similar to those previously reported for related iron(III) complexes.[9] Within the dimer, essentially planar Fe(bpc) units stack in such a way that the Cl–Cl interactions are minimized, whereas extensive π-π interactions remain in the structure. As a result, the Fe(bpc) fragments are shifted with respect to each other and the angle formed between the μ-oxo oxygen atom O2 and the mean FeN_4 coordination plane increases from 90° to 98°.

The UV/Vis and IR spectroscopic properties of the μ-oxodiiron(III) system have been analyzed in detail, allowing the establishment of nice correlations between structural and spectroscopic data. The UV/Vis spectrum of **1** shows a unique band at 355 nm in the so-called "oxo dimer region", which is consistent with the linearity of the Fe–O–Fe unit found in the present complex.[4] The IR spectrum shows two bands at 837 and 442 cm^{-1}, attributed to the asymmetric and symmetric Fe–O–Fe vibrations, respectively, which usually are in the range 885–725 and 540–380 cm^{-1}.[4] As has been previously established, the location of these two bands depends strongly on the Fe–O–Fe angle: the lower the angle, the less energetic the asymmetric and more energetic the symmetric Fe–O–Fe vibrations observed.[4,10] Therefore, the two bands found for **1** at 837 and 442 cm^{-1} match well with the linearity of the Fe–O–Fe bridge.

As indicated elsewhere, complex **1** can also be obtained from the reaction between $[Fe^{III}(bpc)Cl(H_2O)]$ and cyanide in a 1:1 ratio (Scheme 1). When an excess of cyanide is used, two cyanide ligands coordinate to the iron ion to give the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

complex $[Fe^{III}(bpc)(CN)_2]^-$. Other related $[Fe^{III}(bpc)(X)_2]$ complexes (X = azide, pyridine, etc.) can also be prepared in the presence of an excess of the X ligand (Scheme 1).[5] We explored the possibility of making use of this kind of complex $[Fe^{III}(bpc)(X)_2]$ (X = CN^- or N_3^-) as a precursor of polymetallic complexes in a similar way to that used by Holm[11] and Murray et al.,[12] which is by the coordination of the axial X ligands to metal complexes with empty coordination sites. We observed in the course of this research that the reaction between $[Fe^{III}(bpc)(CN)_2]^-$ and [M(*meso*-CTH)]$(ClO_4)_2$ did not give rise to the expected heterometallic complex but to the μ-oxo dimer **1**. However, from the reaction between Na$[Fe^{III}(bpc)(N_3)_2]$ and [M(*meso*-CTH)]$(ClO_4)_2$ (M = Cu^{II}, Ni^{II}), we succeeded in obtaining the heterometallic complexes [{$Fe^{III}(bpc)(N_3)_2$}$_2${Cu(*meso*-CTH)}] (**2**) and [{$Fe^{III}(bpc)(N_3)_2$}$_2${Ni(*meso*-CTH)}] (**3**), whose structures were solved by X-ray diffraction.

The molecular structure of complex **2** is shown in Figure 2, and selected bond lengths and angles are listed in Table 2.

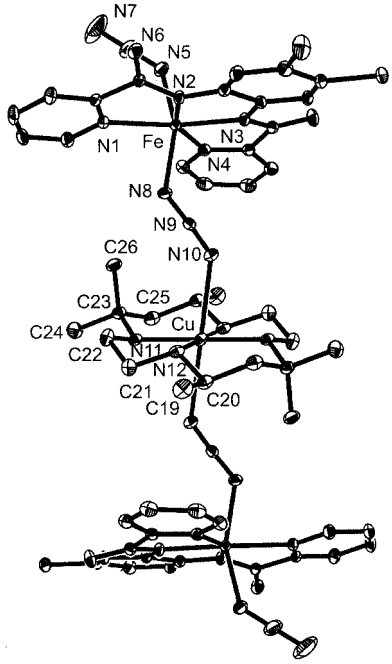

Figure 2. A perspective view of the structure of complex **2**. Hydrogen atoms and the lattice water molecule have been omitted for clarity.

The structure consists of centrosymmetric heterometallic $Fe^{III}Cu^{II}Fe^{III}$ complexes, which are formed by the simultaneous coordination of two $[Fe^{III}(bpc)(N_3)_2]^-$ anions to the central $[Cu(meso\text{-}CTH)]^{2+}$ cation through a single end-to-end azide bridging ligand. The inversion center is located at the Cu^{II} ion and the Fe–Cu distance is 6.43 Å. The ligand environment around the central Cu^{II} ion can be described as a distorted octahedron. The four nitrogen atoms of the CTH ligand are bound in equatorial positions with typical Cu–N distances of about 2 Å, whereas the two azide ligands occupy the axial positions at longer distances of 2.597 Å, giving rise to a *trans* arrangement with a Cu–N10–N9 bond angle of 138.7°. The coordination geometry of the terminal Fe^{III} ions is close to octahedral, with structural parameters in the Fe(bpc) fragment close to those observed in **1** and other related complexes,[5,6] and with Fe–N_{azide} distances of about 2.02 Å. The bond angles Fe–N8–N9 and Fe–N5–N6 are 129.3° and 130.5°. As usual, both the non-bridging and the azide-bridging ligands are practically linear, with values of 176.9(6)° and 174.3(5)°, respectively.

Table 2. Selected bond lengths [Å] and angles [°] for complex **2**.

However, when we tried to extend this strategy to obtain the heterometallic $Fe^{III}Ni^{II}Fe^{III}$ complex, by treating Na$[Fe^{III}(bpc)(N_3)_2]$ with [Ni(*meso*-CTH)]$(ClO_4)_2$, we obtained the complex [{$Fe^{III}(bpc)(N_3)_2$}$_2${Ni(*meso*-CTH)}], whose structure consists of isolated $[Fe^{III}(bpc)(N_3)_2]^-$ and $[Ni(meso\text{-}CTH)]^{2+}$ ions (Figure 3) with an Ni–N10 distance of 3.453 Å. Selected bond lengths and angles are listed in Table 3. The bond lengths and angles in both ionic units are close to those found in **2** and other analogous compounds

creases with the temperature, as expected for strongly antiferromagnetically coupled $S = 5/2$ pairs. The experimental data were analyzed using the van Vleck equation with $H = -2JS_1 \cdot S_2$ ($S_1 = S_2 = 5/2$). Because the χT plateau value at low temperature is not zero, the existence of a monomer impurity (p) was taken into account, which is a common feature of μ-oxodiiron(III) systems.

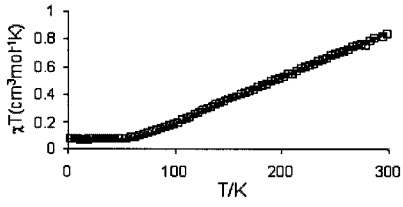

Figure 4. Temperature dependence of $\chi_M T$ for **1**. Solid lines represent the best data fit.

A very good fit of the data was obtained for $J = -108.1$ cm^{-1}, $p = 1.5\%$, and g fixed to 2.00. The J value of –108.1 cm^{-1} compares well with that calculated by using the angular and radial overlap model of Weihe and Gudel ($J = -106.1$ cm^{-1})[13] for μ-oxodiiron(III) complexes. In this model, the Fe–O–Fe angle and the average Fe–O distances are correlated with J. However, by using the empirical correlation obtained by Lippard,[14] which ignores the angular dependence and only includes the Fe–O distance, a J value of –92 cm^{-1} is obtained.

The magnetic susceptibility data for a polycrystalline sample of **2** were measured in the temperature range 2–300 K (Figure 5).

At room temperature, the $\chi_M T$ product (χ_M is the magnetic susceptibility per Fe_2Cu trinuclear molecule) is 8.83 cm^3 mol^{-1} K, which is close to the calculated value of 9.125 for an uncoupled system with two high-spin Fe^{III} ions ($S = 5/2$) and one Cu^{II} ion ($S = 1/2$), assuming an average g value of 2.0. As the temperature is lowered, $\chi_M T$ remains almost constant until about 12 K, then increases very slightly and finally decreases sharply upon cooling to 2 K. If the two iron(III) and the copper(II) ions were magnetically isolated, at low temperature the $\chi_M T$ product should decrease with the temperature in a similar manner as in the mononuclear complex $Bu_4N[Fe(L)(N_3)_2]$. However, as can be observed in Figure 5, the decrease in $\chi_M T$ for $Bu_4N[Fe(L)(N_3)_2]$ begins at higher temperatures, which might suggest the existence of a weak ferromagnetic interaction between the Fe^{III} and Cu^{II} ions in **2** similar to that observed for the closely related complex $[Cu(cyclam)\{Fe(L)(N_3)_2\}_2]$.[15] This fact prompted us to analyze in detail the experimental magnetic data of **2** in order to determine whether or not a weak ferromagnetic interaction exists. Because the sharp decrease in $\chi_M T$ due to local anisotropy of the Fe^{III} ions might mask the increase in $\chi_M T$ caused by a hypothetical ferromagnetic interaction, we removed the contribution of the decrease in $\chi_M T$ for two Fe^{III} ions with a similar coordination environment to that exhibited by the Fe^{III} ions in **2** from the experimental magnetic data. In this regard, we used the magnetic data of the complex $Bu_4N[Fe(L)(N_3)_2]$. As result of this, a different $\chi_M T$ vs. T dependence was obtained. As can be observed in Figure 5, as the temperature is lowered $\chi_M T$ remains almost constant until around 100 K, then increases to reach a maximum with a value of 11.55 cm^3 mol^{-1} K at 3 K. Such a magnetic behavior confirms our hypothesis of the existence of a ferromagnetic coupling between the central Cu^{II} ion and the terminal Fe^{III} ions. The modified data were fitted to the equation for three linearly coupled spins derived from the spin Hamiltonian $H = -J(S_{Fe1} \cdot S_{Cu} + S_{Fe2} \cdot S_{Cu})$. The remote coupling constant, J_{FeFe}, between terminal Fe^{III} ions separated by a distance higher than 12 Å, was assumed to be zero. It was necessary to include a constant, θ, to fit the decrease of $\chi_M T$ at very low temperature. The expression used was $\chi = (C/T - \theta) f(J_{FeCu}, T)$ where $C = Ng^2\mu_B^2/k$ and $f(J_{FeCu}, T)$ is derived from the theoretical equation. The best parameters obtained with this model were $J_{FeCu} = 3.24(7)$ cm^{-1}, $g_{av} = 2.001(1)$, and $\theta = -0.90(2)$. The ferromagnetic coupling observed can be explained in terms of orbital considerations. The magnetic orbital of the copper(II) atom is of the type $d_{x^2-y^2}$ − the x and y axes being defined by the short Cu–N(cyclam) bonds − with a very low spin density on the axial positions (z axis), which are filled by the N atoms of the bridging azide ligands. This leads to a negligible overlap ($J_{AF} \approx 0$) and to a weak ferromagnetic interaction ($J \approx J_F$). The large Cu–N_{azide} distance of 2.597 Å also accounts for the weakness of the magnetic coupling observed. Nevertheless, the value of J should be taken with caution because of the crude procedure followed in its estimation.

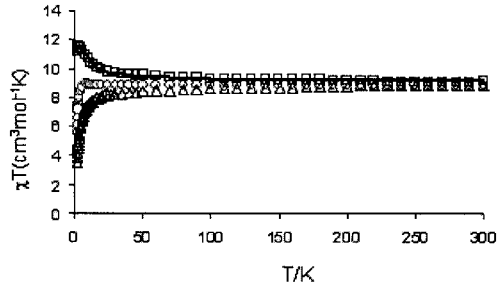

Figure 5. Temperature dependence of $\chi_M T$ for **2** (circles) and $NBu_4[Fe(L)(N_3)_2]$ (triangles). Temperature dependence of of $\chi_M T$ for **2** once the ZFS corresponding to two Fe^{III} ions has been removed (squares). The solid lines represent the best data fit to the theoretical model.

Experimental Section

Synthesis: The H_2bpc ligand[5] and the complexes $[Fe^{III}(bpc)Cl(H_2O)]\cdot H_2O$, $Na[Fe^{III}(bpc)(N_3)_2]$, $Na[Fe^{III}(bpc)(CN)_2]$,[6] [Cu(*meso*-CTH)]$(ClO_4)_2$. and [Ni(*meso*-CTH)]$(ClO_4)_2$[16] were prepared as previously reported.

Caution: *Perchlorate and cyanide salts are potentially explosive and poisonous, respectively, and should be used in small quantities. Due care must be taken when handling perchlorate and cyanide salts.*

$[\{Fe^{III}(bpc)(H_2O)\}_2O]\cdot 3H_2O$ (1): A methanol suspension (50 mL) of $[Fe^{III}(bpc)Cl(H_2O)]\cdot H_2O$ (0.512 g, 1.0 mmol) containing a stoichiometric amount of NaCN (49 mg) was stirred at room temperature for 1 h. The resultant red solution was kept at room temperature to produce orange crystals, which were filtered and air-dried. Yield: 68%. $C_{36}H_{32}Cl_4Fe_2N_8O_{11}$: calcd. C 42.94, H 3.18, N 11.13; found C 43.02, H 3.28, N 11.19.

$[\{Fe^{III}(bpc)(N_3)_2\}_2\{Cu(meso\text{-}CTH)\}]\cdot 2H_2O$ (2): A methanol suspension (30 mL) of $[Fe(L)Cl(H_2O)]\cdot H_2O$ (41 mg, 0.08 mmol) and NaN_3 (10.4 mg, 0.16 mmol) was stirred until the formation of a clear green solution. The solution was then filtered to remove any insoluble material. A methanol solution (20 mL) of [Cu(cyclam)$(ClO_4)_2$] (22 mg, 0.04 mmol) was slowly added to the filtrate, after which the mixture was stirred for 15 min. Dark-green crystals were obtained from the filtrate by slow concentration at room temperature for 2 d. Yield: 65% based on copper. IR (KBr): ν(N–N–N) = 2073 and 2050 cm^{-1}. $C_{52}H_{60}Cl_4CuFe_2N_{24}O_6$: calcd. C 43.67, H 3.95, N 23.50; found C 43.56, H 4.15, N 23.54.

$[\{Fe^{III}(bpc)(N_3)_2\}_2\{Ni(meso\text{-}CTH)\}]$ (3): This compound was obtained in a similar way as **2** using [Ni(*meso*-CTH)]$(ClO_4)_2$ instead of [Cu(*meso*-CTH)]$(ClO_4)_2$. Yield: 59%. IR (KBr): ν(N–N–N) = 2050 cm^{-1}. $C_{52}H_{56}Cl_4Fe_2N_{24}NiO_4$: calcd. C 44.78, H 4.02, N 24.11; found C 44.87, H 3.91, N 23.96.

Measurements: The IR spectra of powdered samples were recorded with a ThermoNicolet IR200FTIR and the UV/Vis spectra of **1** with a Thermospectronic UV300 spectrophotometer against a reference solution containing appropriate amounts of the ligand bpc. Variable-temperature (1.9–300 K) magnetic susceptibility measurements on polycrystalline samples were carried out with a Quantum Design Squid operating at different magnetic fields. Experimental susceptibilities were corrected for diamagnetism and magnetization of the sample holder.

X-ray Diffraction: The unit-cell parameters were determined and the data collected at room temperature with a Siemens STOE STADI4 four-circle diffractometer. The data were corrected for Lorentz polarization effects and for dispersion, and an empirical absorption correction was applied. The structures were solved by direct methods using SHELXS-97[17] and refined (full-matrix least squares on F^2) with all non-hydrogen atoms refined anisotropically with SHELXL97 and WINGX.[18] All hydrogen atoms were geometrically fixed and allowed to ride on the attached atoms. The crystal and refinement details for compounds **1**–**3** are listed in Table 4. CCDC-253934 to -253936 (**1**–**3**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Lanthanide Complexes of Disulfoxide Ligands with Varied Configurations: Influence of Lanthanide Contraction on the Structures of the Complexes

Jian-Rong Li,[a] Ruo-Hua Zhang,[a] and Xian-He Bu*[a,b]

Keywords: Disulfoxides / Lanthanides / Lanthanide contraction / Ligand configuration change / X-ray diffraction

Four new disulfoxide-Ln^{III} complexes, $[Ln(\mathbf{L})_2(NO_3)_3]_n$ {Ln = La (**1**), $n = n$; Ln = Gd (**2**), Dy (**3**) and Yb (**4**), $n = 2$}, have been prepared by the reaction of $Ln(NO_3)_3{\cdot}nH_2O$ with *meso*-1,3-bis(ethylsulfinyl)propane (*meso*-**L**) in methanol/triethylorthoformate, and their solid-state structures were characterized by IR spectroscopy, elemental analyses and X-ray diffraction. Complex **1** is a 1D double-bridged chain in which the La^{III} ions are ten-coordinate and the **L** ligands adopt both *meso* and *rac* configurations, and a bis-monodentate bridging coordination mode. While complexes **2**–**4** have isostructural dinuclear structures, in which the Ln^{III} ions are nine-coordinate and the ligands show two types of coordination fashions and configurations: bis-monodentate bridging with a *meso*-configuration, and monodentate coordination with a *rac*-configuration. The structural differences between **1** and **2**–**4** indicate the influence of lanthanide contraction on the complex structures. In addition, a change in configuration of the ligand occurs when it reacts with metal ions.

Introduction

Metal-organic architectures continue to be a subject of intense current interest,[1] because of their fascinating structural diversities and potential applications, such as in functional materials.[2] The rare earth coordination compounds may have interesting luminescence and magnetic properties,[3] and lanthanide cations usually have high coordination numbers and exhibit coordination diversity and flexibility.[4] As is well known, the structures of metal-organic architectures are influenced by many factors, such as the coordination nature of the metal ions and ligands, and reaction conditions etc.[5] Lanthanide contraction is also such a factor that affects the structures of the complexes, and is a significant research topic not only in structural control but also in the theoretical exploration of the electronic configuration of lanthanide elements.[6]

In recent years, we synthesized many metal-organic coordination compounds using flexible disulfoxide ligands,[7] which are a type of ditopic bridging ligands and have many intriguing features, such as a bidentate ditopic nature, and diastereomeric *meso* and *rac* forms. Some successful examples have shown that such ligands are able to generate unusual coordination polymers with unique structures that are governed not only by the spacer lengths and terminal groups of the ligands but also by counter anions and even solvents used in the synthesis.[7] As a continuation of such investigations, we report herein the synthesis and structures of a series of disulfoxide lanthanide complexes, $[Ln(\mathbf{L})_2(NO_3)_3]_n$ {Ln = La (**1**) $n = n$; Ln = Gd (**2**), Dy (**3**) and Yb (**4**), $n = 2$; **L** = 1,3-bis(ethylsulfinyl)propane} (for the *meso* isomer, see Scheme 1). The effect of lanthanide contraction on the structures of the complexes will also be discussed.

Scheme 1.

Results and Discussion

Syntheses and General Characterization

The *meso*-**L** ligand melts in a narrow temperature range of 101–103 °C, which indicates that it is a pure *meso* isomer. Complexes **1**–**4** were prepared by the reactions of *meso*-**L** with $Ln(NO_3)_3{\cdot}nH_2O$ in MeOH at room temperature with the use of triethylorthoformate as a dehydrating reagent. The results of the elemental analysis are consistent with the molecular formula evaluated by X-ray diffraction analyses for **1**–**3**, and complex **4** has a similar composition to that of complexes **2** or **3**. Such complexes are soluble in DMF and DMSO and slightly soluble in CH_3OH and CH_3CN, but almost insoluble in H_2O and acetone. The IR spectrum

[b] The State Key Lab of Rare Earth Materials and Chemistry, Peking University, Beijing 100871, P. R. China

of **1** has a $\nu_{S=O}$ band at 986 cm^{-1}; this band occurs at a lower frequency than that of the free ligand (1017 cm^{-1}). The peak at this frequency disappeared in **1** indicating that all the O atoms of the ligands are coordinated to the La^{III} ions.[8] While in the spectra of **2**–**4**, vibration peaks at around 986 and 1010 cm^{-1} were observed, which indicates the partial coordination of the O atoms of the S=O entities. These results are further confirmed by X-ray structural determinations. In addition, the existence of chelating bidentately coordinated nitrate anions in the complexes was also confirmed by their IR spectra.

Structural Descriptions and Discussion

Complexes **1–3** were characterized by X-ray crystallography. The selected bond lengths and angles are listed in Table 1 and Table 2.

The X-ray single crystal structure reveals that complex $[La(\mathbf{L})_2(NO_3)_3]_n$ (**1**) has a 1D, double-bridging chain structure. As shown in Figure 1, the La^{III} center binds to ten O atoms, four from S=O moieties of four distinct **L** ligands and six from three chelating coordinated nitrate anions. The overall geometry is best described as a distorted bi-capped square anti-prism with two O atoms of two distinct nitrate anions in the capped positions. As listed in Table 1, the bond lengths of the La–O bonds that involve the O atoms of the four bis-monodentate **L** ligands are different [2.378(5)–2.656(5) Å with a mean value of 2.522(5) Å], perhaps as a result of steric hindering. The La–O bond lengths of the chelating nitrate anions are in the range 2.579(3)–2.749(4) Å with an average value of 2.667(4) Å, which is longer than that of the disulfoxide ligands. The *cis* bond angles around the La^{III} ion lie in a range from 47.0(2) to 85.1(2)°.

In complex **1**, the ligands **L** act as bis-monodentate bridges to link the adjacent metal centers, and two such ligands link two La^{III} centers to form a 16-membered ring, which expends along the crystallographic *a* direction to form a 1D intercrossed, double-bridging chain (Figure 2). The distance between two metal centers within the ring unit is 8.898 Å. The S atoms of the ligands in **1** are disordered, each of which are refined over two positions with the occupying ratio of 6:4. Based on the higher occupation part, the ligands adopt three kinds of configurations: the *R*,*S*, *R*,*R*, and *S*,*S* forms (Figure 2); the same side chain takes one kind of configuration, either *meso* or *rac*. For the *rac* ligands, the *S*,*S* and *R*,*R* forms are arranged alternatively. The synchronous existence of two kinds of configurations in the complex reveals that the disulfoxide ligand **L** inverts part of its original configuration from *R*,*S* to either the *R*,*R* or the *S*,*S* form. The O coordination adopts a *trans*-*trans* arrangement; the La–O–S–C torsion angles range from 94.0(8) to 174.8(2)° (containing the atoms of the disordered parts). In addition, such 1D chains are parallel to each other in the crystal.

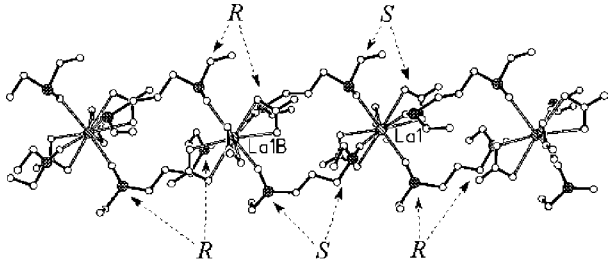

Figure 2. The 1D chain structure of **1** showing the configurations of the S atoms**.** The hydrogen atoms and lower occupancy part of the disordered atoms were omitted for clarity.

Complexes **2** and **3** are isostructural and the structures are composed of neutral dinuclear $[Ln(\mathbf{L})_2(NO_3)_3]_2$ (Ln = Gd, Dy, respectively) entities. The central metal ion is nine-coordinate and binds to three O atoms of distinct **L** ligands and six O atoms of chelating nitrate groups to give a highly disordered, tricapped, trigonal prism configuration (Figure 3). The Ln–O bond lengths involving the S=O and bidentate nitrate groups are in the normal ranges (Table 2), and lie in a more narrow range than those of **1**. The *cis* bond angles around the Ln^{III} ions range from 50.49(8) to 89.72(9)° for **2** and 51.0(1) to 90.3(1)° for **3**, respectively. As shown in Figure 4, in the binuclear entity, the two metal centers are linked by two bis-monodentate bridging ligands to form a twisted 16-membered ring with an Ln···Ln separation of 8.287 Å for **2** and 8.265 Å for **3**. It is interesting to note that the ligands **L** exhibit two kinds of coordination modes: bis-monodentate bridging and monodentate, which is a rare case in disulfoxide complexes.[7c] One of the S atoms of each monodentate disulfoxide is disordered in **2** and **3** (the occupying ratio is 9:1). On the basis of the main part of the disordered entities, the ligands adopt three kinds of configurations, *R*,*S*, *S*,*S*, and *R*,*R* forms (*meso* and *rac*) in **2** and **3**: two monodentate ligands adopt the *R*,*R* and *S*,*S* form, and two bridging ligands adopt the *meso* form. The two S atoms of the bridging ligands around the same metal center adopt the same *S* or *R* configuration, but differ from that of the mono-coordinated one. Thus, as a whole, complexes **2** and **3** are mesomeric. The O=S···S=O quasi-torsion angles between two sulfoxide groups of the ligands are 101.5 and 102.9° for the bridging ligands, and 22.8 and 22.5° for the mono-coordinated ligand in **2** and **3**, respectively. All the O coordinations adopt a *trans*-*trans* arrangement, which is exhibited by the M–O–S–C torsion angles of 109.1–143.4° for **2** and 108.5–144.4° for **3**. In addition, such dinuclear molecules are arranged in an interparallel superposition fashion in the crystal.

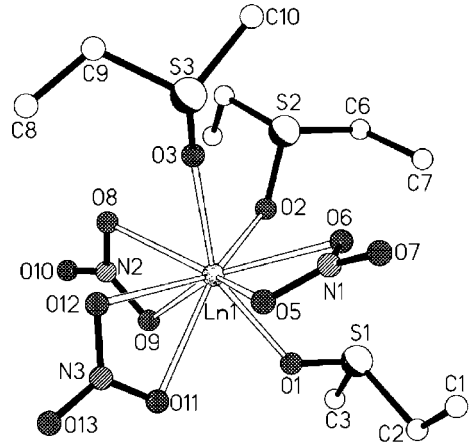

Figure 3. A view of the coordination environment of the Ln^{III} center in **2** and **3**. The hydrogen atoms and lower occupancy part of the disordered atoms were omitted for clarity.

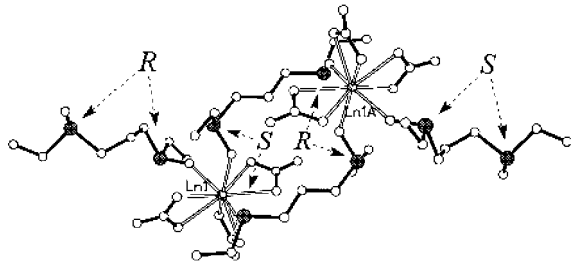

Figure 4. Dinuclear structures of **2** and **3** showing the configurations of the S atoms. The hydrogen atoms and lower occupancy part of the disordered atoms were omitted for clarity.

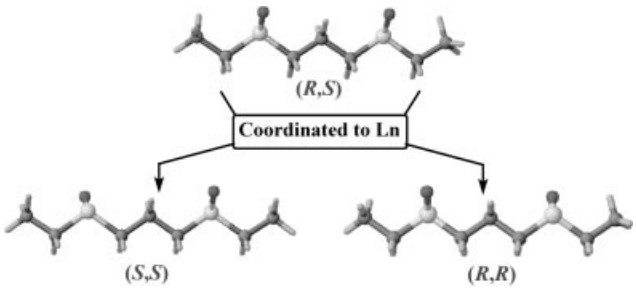
It should be noted that a partial configuration change of ligand **L** was observed at room temperature from *meso* to *rac* form (Scheme 2) when it reacted with lanthanide nitrate to form complexes with three stereoisomeric forms of the ligands. In some earlier investigations,[7a,9] a configurational change of the sulfoxide entities seems to occur at elevated temperatures (ca. 70–80 °C). This indicates that a metal-assisted configuration change of the disulfoxide compound may happen at room temperature.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 2.

The structural differences between **1** and **2** and **3** may be attributed to the difference in the lanthanide ion radii, i.e. lanthanide contraction. In **1**, the La^{III} ion is larger so that it can adopt a ten-coordination mode that can lead to the coordination of four O atoms from the S=O groups. While in **2** and **3**, the radius of Gd^{III} [and Dy^{III}] is smaller than that of La^{III}, so only three sulfoxide O donors take part in the coordination. Thus, **1** has a 1D structure but **2** and **3** are dinuclear.

XRPD Results; Isostructural Determination of 3 and 4

In order to further confirm if **3** and **4** have similar structures, as well as if the crystal structure of **3** is truly representative of its bulk material, X-ray powder diffraction (XRPD) experiments were carried out on the as-synthesized samples. The XRPD experimental patterns of **3** and **4**, and the computer-simulated patterns of **3** are shown in Figure 5. From the simulated and experimental patterns, we can consider that the synthesized bulk material and the as-grown crystals are almost the same for complex **3**, although there are a few unindexed diffraction lines and lines that are slightly broadened relative to those simulated from the single-crystal data. From the similar XRPD experimental patterns of **3** and **4** together with the elemental analysis results and IR spectra, we can conclude that **3** and **4** should have similar structures.

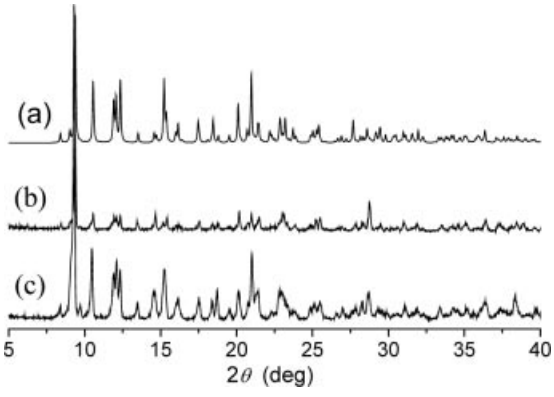


Figure 5. Powder X-ray diffraction patterns of **3** and **4**: (a) the simulated result of **3**, (b) the experimental result of **3,** and (c) the experimental result of **4**.

In addition, a suitable comparison can be made between **4** and a reported Yb^{III} complex, $[Yb(\mathbf{L}')_{1.5}(NO_3)_3]_n$,[7a] with a similar disulfoxide ligand, 1,2-bis(ethylsulfinyl)ethane (**L**′). Although **L**′ has a shorter spacer than **L**, the resulted complex has a 1D single-bridging chain structure. The structural difference may be attributed to the spacer lengths of the ligands.

In summary, a series of new Ln-disulfoxide complexes with 1D or dinuclear structures have been obtained by assembling $Ln(NO_3)_3$ and a flexible disulfoxide ligand. The structural differences between these complexes show the influence of lanthanide contraction on the structures of the complexes. The ligands exhibit different configurations in the complexes, which is interesting for the investigation of disulfoxide metal complexes. In addition, a change in configuration of the ligand at room temperature has been observed when it reacts with Ln^{III} ions.

Experimental Section

Materials and General Methods: All reagents for synthesis and analyses were of analytical grade and used as received. Elemental analyses were performed on a Perkin–Elmer 240C analyzer. IR spectra (KBr pellets) were recorded with a FT-IR 170SX (Nicolet) spectrometer. ^{1}H NMR spectra were measured on a Bruker AC-P500 spectrometer (300 MHz) at 25 °C with tetramethylsilane as the internal reference. Melting point measurements were measured on an X-4 melting point meter.

Synthesis of the Ligand: 1,3-Bis(ethylsulfinyl)propane was synthesized according to a similar method reported previously[10] by oxidizing the bis(thio) precursor 1,3-bis(ethylthio)propane (obtained by the reaction of 1,3-bis(bromo)propane with sodium ethylthiolate). The *meso* isomer was separated from the isomeric mixture products by fractional crystallization from acetone. Yield: 50%. M.p. 101–103 °C. ^{1}H NMR ($CDCl_3$): δ = 2.66–2.78 (m, 8 H, $–CH_2–S–CH_2–$), 2.35 (t, 2 H, $C–CH_2–C$), 1.37 (t, 6 H, $CH_3–$) ppm. IR: 2963 (s), 1427 (m), 1042 (m), 1017 (s), 974 (m), 785 (m), 650 (m) cm^{-1}.

Synthesis of Complexes 1–4: The four complexes were prepared at room temperature according to the following method. A solution of $Ln(NO_3)_3{\cdot}nH_2O$ (0.3 mmol) in methanol (10 mL) was added to a solution of *meso*-**L** (171 mg, 0.6 mmol) in methanol/triethylorthoformate (2:3, 15 mL). The reaction mixture was stirred for about 30 min and filtered to give a colorless solution. Slow solvent evaporation of the resulting solution gave rise to white solid products that contained a few colorless single crystals suitable for X-ray analysis.

$[La(L)_2(NO_3)_3]_n$ (1): Yield: 85 mg, 40%. $C_{14}H_{32}LaN_3O_{13}S_4$ (717.58): calcd. C 23.43, H 4.49, N 5.86; found C 23.11, H 5.02, N 5.65. X-ray Crystallography: Single-crystal X-ray diffraction for **1**–**3** was carried out with a Bruker Smart 1000 diffractometer. Intensities of reflections were measured by using graphite monochromatized Mo-K_α radiation (λ = 0.71073 Å) with ω-φ scan mode at room temperature. Unit cell dimensions were obtained with least-squares refinements, and semi-empirical absorption corrections were applied by using the SADABS program.[11] The structures were solved by direct methods by combining successive difference Fourier syntheses.[12] The final refinement was performed by full-matrix least-squares methods on F^2 with the SHELXL-97 program package.[12] For **1**, the ligand is highly disordered, and some C and S atoms were refined in two different positions (occupation ratio 6:4) and restrained. In **2** and **3**, some S and O atoms were also refined in two different positions with partial occupation factors of 0.9 and 0.1, respectively. Some hydrogen atoms of the ligands in **1**–**3** cannot be added due to the above-mentioned disorder. All added hydrogen atoms were included in calculated positions and refined with fixed thermal parameters riding on the parent atoms. Crystallographic data and experimental details for structural analysis are summarized in Table 3. CCDC-252924–252926 contain the supplementary crystallographic data for **1**–**3**. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

The X-ray powder diffraction patterns (XRPD) of **3** and **4** were recorded on a Rigaku D/Max-2500 diffractometer, operated at 40 kV and 100 mA, by using a Cu-target tube and a graphite monochromator. Fixed scatter and divergence slits of 1° and a 0.3-mm receiving slit were used. The intensity data were recorded by continuous scan in a $2\theta/\theta$ mode from 3° to 60°, with a step size of 0.02° and a scan speed of 8° min^{-1}. Simulation of the XRPD spectra was carried out by the single-crystal data and diffraction-crystal module of the commercially available Cerius2 program.[13]

Synthesis, Characterization and Photophysical Properties of Novel Dinuclear Silver(I) and Mononuclear Palladium(II) Complexes with 1,2-Bis[(anthracen-9-ylmethyl)amino]ethane

Guo-qi Zhang,[a] Guo-qiang Yang,*[a] Lan-ying Yang,[a] Qing-qi Chen,[b] and Jin-Shi Ma[a]

Keywords: N ligands / Palladium / Photophysics / Silver

Silver(I) (**3**) and palladium(II) (**4**) complexes of 1,2-bis-[(anthracen-9-ylmethyl)amino]ethane have been synthesized and structurally characterized. X-ray crystal structure analysis reveals that compound **3** exists as a dinuclear tris(ligand) complex with formula $[Ag_2(\mathbf{2})_3]\cdot 2NO_3$, in which each silver center is three-coordinate to form a slightly distorted planar-trigonal geometry with three nitrogen donors originating from two distinct ligands. Compound **4**, on the other hand, is a mononuclear bis(ligand) complex with formula $[Pd(\mathbf{2})_2]\cdot 2OAc$, in which the palladium center is four-coordinate with four nitrogen donors originating from two distinct ligands to form a square-planar geometry. In crystals of both **3** and **4** strong intermolecular edge-to-face C–H···π packing interactions are observed, which contribute to stabilize the crystalline solid. Studies of the photophysical properties of these compounds (**3**, **4**, and ligand **2**) show apparent fluorescence quenching effect by introduction of metal ions and likely "excimer" emission of anthracene in the crystalline solid.

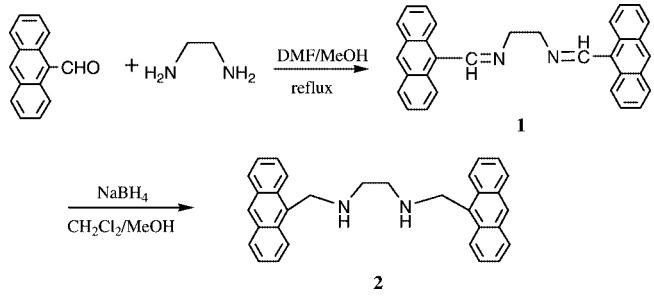
Introduction

Multichromophoric supramolecular architectures have been receiving increasing interest in recent years[1,2] because of their potential applications in the areas of biomedicine, molecular recognition, fluorescent sensors, and material sciences.[3–8] Anthryl and pyrenyl polyamine systems have been found to have potential uses in anion recognition, metal ion fluorescent sensors, as well as pH sensors.[9–11] Although a lot of anthryl polyamines and their metal ion complexes have been extensively investigated,[12] complexes of Ag^I and Pd^{II} are still unknown, hence it might be of considerable importance to study the structures of these complexes and correlate the structure and luminescent properties of the resultant Ag^I and Pd^{II} complexes due to the promise of polyamine systems for use as optical chemical sensors.[9] In this paper, we report the synthesis and characterization of 1,2-bis[(anthrancen-9-ylmethyl)amino]ethane (**2**) and its corresponding Ag^I complex **3** and Pd^{II} complex **4**, as well as the results of photophysical investigation on these systems.

Results and Discussion

Synthesis

The Schiff base **1** was synthesized in excellent yield by condensation of ethylenediamine with 2 equiv. of anthracene-9-carbaldehyde in DMF/MeOH at reflux. Upon treating **1** with an excess amount of $NaBH_4$ in CH_2Cl_2/MeOH at room temperature, the corresponding diamine **2** was obtained in good yield (Scheme 1). Both compounds **1** and **2** were fully characterized by combustion analysis, mass spectrometry, and ^1H and ^{13}C NMR spectroscopy.



Scheme 1.

Ligand **2** was treated with silver nitrate and palladium acetate in CH_2Cl_2/MeOH (2:1, v/v) to afford the corresponding complexes **3** and **4** in yields of 70% and 64%, respectively. Crystals of **3** and **4** are reasonably stable in the mother liquors in the dark, while they slowly decompose upon exposure to light and air for a long period. Complex **4** was found to have good solubility in most polar solvents such as methanol, ethanol, dichloromethane, chloroform, acetonitrile, THF, DMF, and DMSO, while complex **3** is soluble in dichloromethane, chloroform, acetonitrile, DMF, and DMSO and slightly soluble in THF, methanol, ethanol, acetone etc.

Crystal Structure of 3

The silver complex **3** crystallizes in the triclinic system with space group $P\bar{1}$. The unit cell contains two crystallographically independent dinuclear tris(ligand) complexes, three methanol molecules, and four nitrate counterions. An ORTEP drawing of the dinuclear complex cation $[Ag_2(\mathbf{2})_3]^{2+}$ is shown in Figure 1, and selected bond lengths and angles are given in Table 1. The structure consists of two Ag^I centers spanned by three ligands to form a unique dinuclear tris(ligand) complex. Each silver center is three-coordinate and adopts a slightly distorted planar-trigonal geometry with three nitrogen atoms, two of which are from one ligand, and one from the other ligand. Furthermore, two Ag atoms have almost identical coordination environments, with Ag–N bond lengths in the range 2.239(5)–2.474(5) Å. All the bond lengths are among the ranges of those found in analogous Ag^I complexes reported hitherto.[13] Moreover, the N–Ag1(A)–N bond angles of 76.6(2)° for N1(A)–Ag1(A)–N2(A), 141.4(19)° for N1(A)–Ag1(A)–N3(A), and 140.4(2)° for N2(A)–Ag1(A)–N3(A) are identical to the corresponding N–Ag1–N bond angles. In addition, two NO_3^- anions are present in the unit cell as counteranions; the Ag–O bond length is 3.761 Å, which is much longer than that of a normal Ag–O bond.[14] In the crystal of **3**, none of the anthryl moieties show intramolecular or intermolecular face-to-face π···π interactions, although significant intermolecular edge-to-face C–H···π contacts are present, and the shortest distance between an edge ring hydrogen atom and the anthracene ring center of another molecule is 2.833 Å [the angle C–H···M(mid) is 156.9°], which is in the usual range for C–H···π interactions.[15] Two adjacent molecules which show C–H···π interactions are depicted in Figure 2, where it can be seen that the C–H···π interactions serve to stabilize the crystalline solid.

Crystal Structure of 4

The palladium complex **4** also crystallizes in the triclinic system with space group $P\bar{1}$. The unit cell contains seven crystallographically independent methanol molecules and two acetate anions. An ORTEP view of the mononuclear complex cation $[Pd(\mathbf{2})_2]^{2+}$ is shown in Figure 3, and selected bond lengths and angles are given in Table 2. In the crystal, the palladium center is four-coordinate to two distinct ligands to form a slightly distorted square-planar geometry. Due to the steric hindrance of the bulky anthracene group, the Pd–NH bond lengths are found to be 2.061, 2.068, 2.071, and 2.089 Å, respectively, which are slightly longer than those distances found in regular (amino)Pd^{II} (Pd–NH) complexes.[16] Interestingly, in the crystals of **4**, very strong aromatic/aromatic interactions with intermolecular edge-to-face C–H···π packing are observed [the distance between one hydrogen atom from the center ring of one anthryl unit and another molecular anthracene ring center is 2.703 Å, and the angle C–H···M(mid) is 158.1°] in contrast to **3**, which are comparable to previously reported strong C–H···π interactions (Figure 2 and Figure 4).[15]

Spectroscopic and Photophysical Properties

^{1}H NMR Studies

The ^{1}H NMR spectrum of complex **3** in $CDCl_3$ shows a single set of proton resonances that can be fully assigned, which suggests that it exists as a single species in solution. Compared to the corresponding free ligand, complex **3** shows upfield shifts of 0.55–0.59 ppm for the protons of the CH_2 groups and 0.14–0.38 ppm for the protons of the anthracene rings, probably because of the intermolecular C–H···π interactions resulting from the molecular aggregation in concentrated solution, which is consistent with the case of the crystalline solid. Several attempts to measure the ^{1}H NMR spectrum of pure complex **4** in $CDCl_3$ or CD_3CN gave no satisfactory results for the signals of a single species; the spectrum shows the signals of both free ligand and a small amount of complex, which indicates that complex **4** is not very stable in solution and exists as an

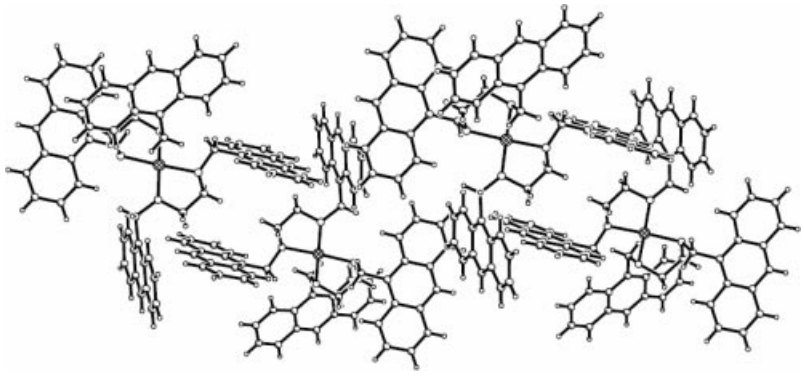

Figure 4. Packing model along the *b* axis in the crystals of complex **4** cations showing the intermolecular edge-to-face C–H···π interactions.

equilibrium between binding and disassociation due to the low binding constant of palladium ions and ligand **2**. Thus, we cannot measure the steady-state photophysics of **4** in solution, although the solid-state photoluminescence was obtained.

Photophysical Properties of 2 and 3 in Solution

The steady-state absorption and fluorescence emission spectra of **3** were measured and compared with those of the free ligand **2**. The results are reported in Table 3. The electronic absorption spectra of **2** and **3** obtained in acetonitrile at 5 μM concentration display the typical absorptions of the anthracene chromophore in the range 320–400 nm with a very slight (approximately 1–2 nm) bathochromic shift due to the introduction of silver ions (Figure 5). Moreover, in contrast to **2**, the UV/Vis spectrum of **3** shows remarkably strong absorptions at about 300 nm, which are absent in the case of the ligand as well as the silver salt under the same conditions, indicating a strong interaction between the ligand and silver ion (Figure 5).

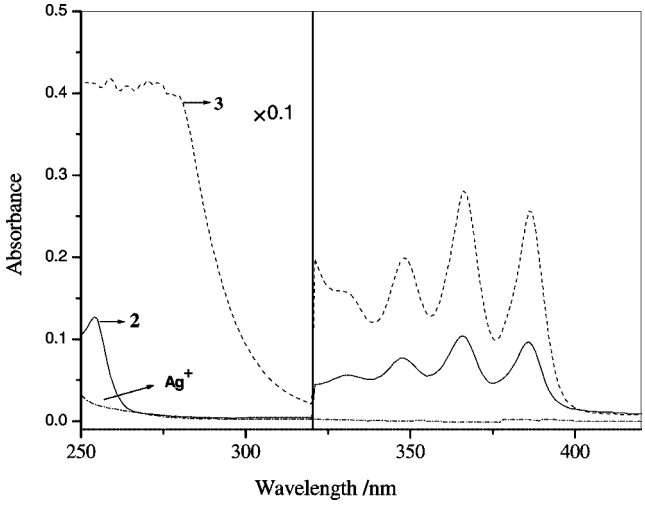

Figure 5. Electronic absorption spectra of ligand **2**, its silver complex **3**, and free Ag^+ ions in acetonitrile at room temperature (conc. 5 μM).

The fluorescence spectra of compounds **2** and **3** were recorded under the same conditions, and are given in Figure 6. The fluorescence excitation spectra were obtained by monitoring the emission at 415 nm. For **3**, except for the typical excitation spectra of the anthracene chromophore, a significantly strong excitation band in the region from 260 to 320 nm, with a maximum absorption at 293 nm, is consistent with the absorption spectra, which indicates that more efficient electronic energy transfer may take place from the metal-centered excited state to the lower energy excited state of the anthracene center.

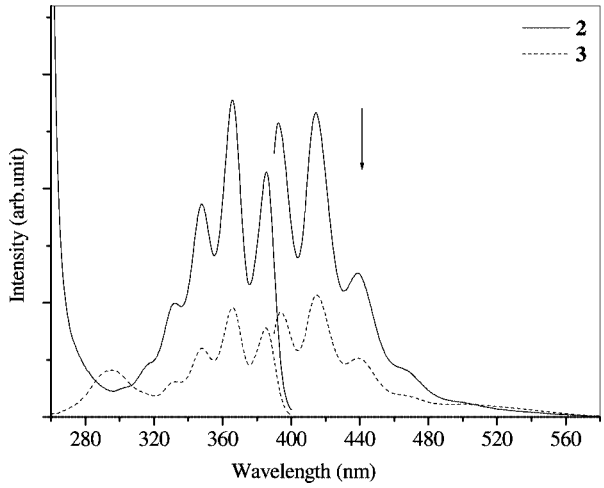

Figure 6. Fluorescence exitation (monitored at 415 nm) and emission spectra (excited at 367 nm) of **2** and **3** in acetonitrile at room temperature (conc. 5 μM).

The fluorescence intensity of the ligand **2** was found to be significantly smaller than the emission of the anthracene moiety due to a photoinduced intramolecular electron transfer (PET) process[17] from the amine lone pairs to the anthracene group, which is in agreement with previously reported anthryl or pyrenyl polyamine systems.[7,18] Upon excitation of the anthracene $S_0 \rightarrow S_1$ transition (λ_{ex} = 367 nm), emission from the anthracene chromophore is evident as a Frank–Condon vibrational process with an origin at 390 nm and a maximum intensity at 415 nm, which is in agreement with the corresponding excitation spectra. Furthermore, complex **3** displays the same quartet emission bands, in spite of the obvious difference of emission intensity. The quantum yields obtained for compounds **2** and **3** are 1.54×10^{-2} and 2.42×10^{-3}, respectively (relative to quinine sulfate in 0.1 N H_2SO_4[19]). The quantum yield of **3** is lower than that of **2**, which is indicative of a chelation-enhanced fluorescence quenching (CHEQ) effect, as reported previously for similar systems.[18] Furthermore, the measurement of fluorescence decay determines the fluorescence

Table 3. Steady-state spectroscopic data for ligand **2** and its complex **3** in CH_3CN.

Compound	Abs λ_{max} [nm]	ε_{max} ($M^{-1}cm^{-1}$]	Emission λ_{max} [nm]	Quantum yield, Φ_f	Decay times[a] τ [ns] (%)[b]	χ^2

decay behavior of the ligand and complex systems (see Figure 7 for the decay profiles). The fluorescence decays of both **2** and **3** were best fitted to double exponential decay processes.

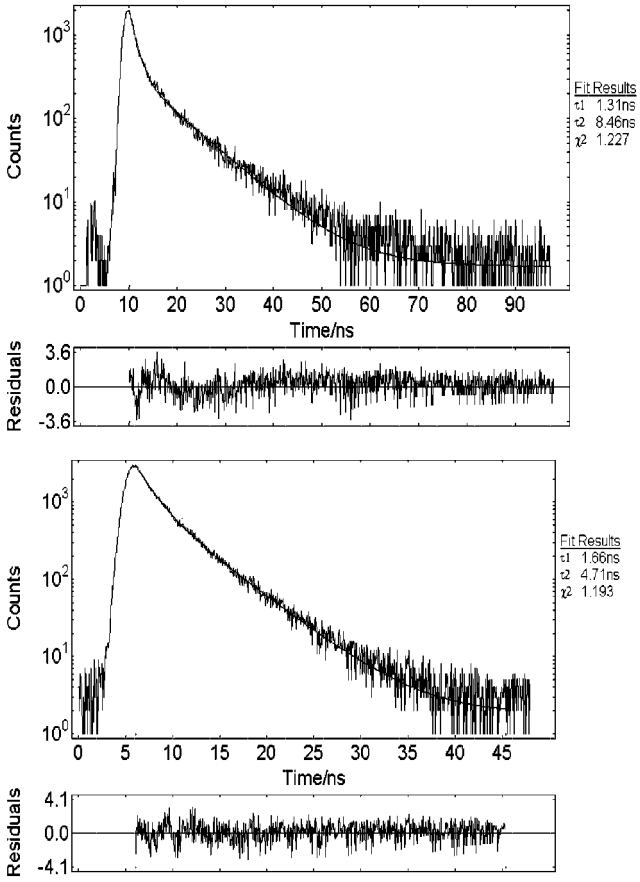

Figure 7. Fluorescence decay profiles of **2** (top) and **3** (bottom) in acetonitrile at an excitation wavelength of 367 nm. Emission monitored at 415 nm.

The transient absorption spectra of ligand **2** and its complex **3** were measured in argon-saturated acetonitrile at room temperature with concentrations of 5×10^{-4} M for **2**, and 2×10^{-4} M for **3**. The excitation wavelength generated by a nanosecond laser was 355 nm. The transient absorption spectrum of ligand **2**, depicted in Figure 8a, can be assigned to the triplet-triplet absorption (T_1-T_n absorption) of anthracene monomer based on the similarity of the spectra obtained in solutions.[20] It is known that the T_1-T_n absorption spectrum has a maximum peak at 423 nm with a molar extinction coefficient value of 64700 $M^{-1}cm^{-1}$ in cyclohexane.[20] In the given anthryldiamine compound, the transient absorption spectrum keeps the characteristic of the triplet-triplet absorption of anthracene monomer with maxima at about 400 nm and 423 nm. It decays without changing its shape and no new absorption band appears as a result of the decay, which suggests that no transient absorption of an intramolecular or intermolecular excimer occurs under these conditions. The transient absorption spectrum of complex **3** is shown in Figure 8b. No distinct absorption band appears at around 400 nm, except for a broad peak between 400 and 460 nm, and the maximum of the T_1-T_n absorption is still at about 423 nm. This may be due to the formation of new triplet species in acetonitrile from the metal-incorporated anthryldiamine **3**, although it maintains partially the characteristic of ligand **2**. In acetonitrile, the lifetime of the triplet species of ligand **2** was estimated to be 20 ± 1 μs based on the fitting to a single exponential decay curve. Obviously, a much faster triplet decay of the ligand occurs than that of triplet-state anthracene alone in solution.[20] The triplet lifetime of **3** was determined as 5.7 ± 0.1 μs with good single exponential decays, which shows that more efficient quenching occurs for the triplet species of the silver complex relative to that of the free ligand.

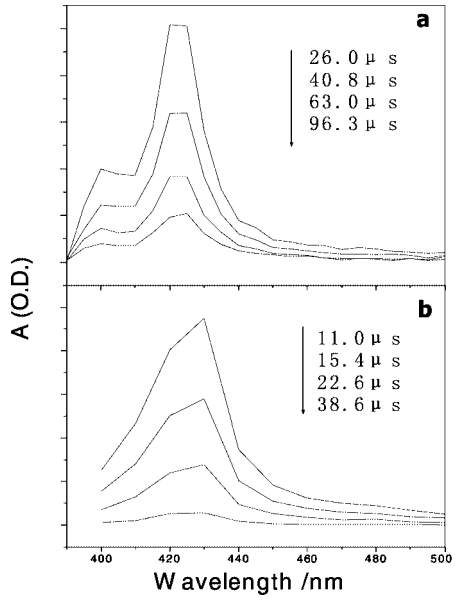

Figure 8. Transient absorption spectra of ligand **2** (a) and its silver complex **3** (b) in Ar-saturated acetonitrile at room temperature.

Photoluminescence in the Solid State

We measured the solid-state photoluminescence of both the ligand and complexes at room temperature. Although we could not measure the photophysical properties of complex **4** in solution due to its instability, the measurement of the solid-state photoluminescence is still helpful for understanding the emission behavior of the complex. More significantly, the solid-state spectra usually exhibit the features of the aggregated state of molecules in combination with the crystal structure in the solid state. Obviously, both the free ligand and complexes are photoluminescent in the solid state (Figure 9) when excited at 366 nm. However, the emission position is remarkably bathochromic relative to that in solution, which may be attributed to the increased intermolecular interaction as a result of closer packing of the molecules in the solid state, and, interestingly, both the ligand and complexes display emission even in the longer wavelength range (>500 nm), which is possibly attributed to an "excimer" emission of anthracene[21,22] reminiscent of the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

structural characterization of the two complexes depicted above. The obviously weak emission of **4** in the solid state may be due to a CHEQ effect similar to the situation of **3** in solution.

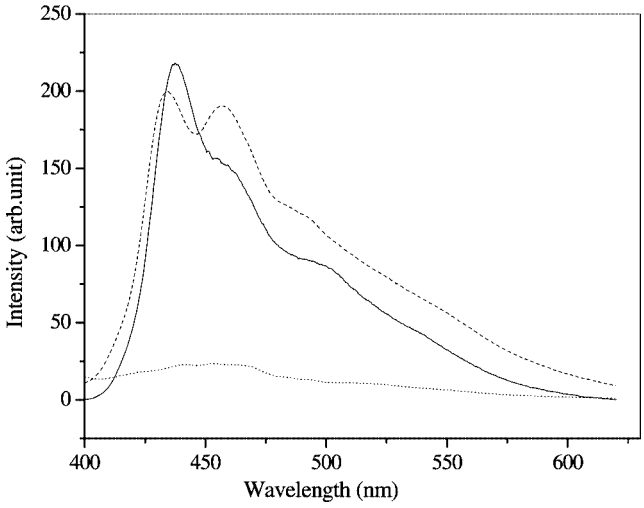

Figure 9. Solid-state photoluminescence spectra of **2** (solid), **3** (dot), and **4** (dash) at room temperature.

Conclusions

In summary, we have synthesized a new anthryldiamine ligand **2** as well as the corresponding silver complex **3** and palladium complex **4**. In the solid state, complex **3** forms a dinuclear tris(ligand) supramolecular architecture, while **4** is a mononuclear bis(ligand) complex. The preferential coordination in these complexes matches the requirements of the steric hindrance of the bulky ligands and the nature of the metal ions. Significantly strong intermolecular edge-to-face C–H···π packing interactions are observed in crystals of both **3** and **4**, which contribute to stabilize the crystalline solid. Complex **3** is very stable while **4** partially disassociates in solution due to its low binding constant. Photophysical studies have shown that the PET process is present in ligand **2** and an efficient CHEQ effect is also observed for its metal complexes. The transient absorption spectra allowed us to determine the absorption features and decay lifetimes of the triplet species of **2** and **3**. The solid-state photoluminescence studies showed the bathochromic emission relative to that in solution and likely "excimer" emission of anthracene in the crystalline solid, thereby indicating the presence of intermolecular interactions, in agreement with the results of ^{1}H NMR studies and the crystal-structure analysis.

Experimental Section

Materials and General Methods: All the reagents were commercially available. Anthracene-9-carbaldehyde, ethylenediamine, sodium borohydride, silver nitrate, and palladium acetate were used without further purification. Solvents for syntheses were purified according to standard methods, while those for spectral measurements were purchased as spectrophotometric grade. Samples for C, H, N analyses were dried under vacuum and the analyses were performed with a Carlo Erba-1106 Instrument. ^{1}H NMR spectra were measured with a Bruker dmx 300 MHz NMR spectrometer at room temperature in $CDCl_3$ with tetramethylsilane as the internal reference. The ESI and MALDI-TOF MS measurements were carried out with a Bruker APEX II instrument. UV/Vis absorption spectra were obtained with a Hitachi UV-3010 absorption spectrophotometer. Steady-state excitation and emission spectra were recorded with a Hitachi F-2500 fluorescence spectrophotometer. Fluorescence lifetime was detected at 415 nm with a fluorescence lifetime analytical spectrometer (Erdinburgh FLS-920) and the samples were excited at 367 nm (maximum absorption wavelength). Time-resolved transient absorption spectra were measured with an Edinburgh LP920 nanosecond flash photolysis instrument.

1,2-Bis[(anthracen-9-ylmethylene)amino]ethane (1): Anthracene-9-carbaldehyde (9.5 g, 46.1 mmol) was dissolved in 120 mL of DMF/MeOH (1:5, v/v), and then heated at reflux. A solution of ethylenediamine (1.6 mL, 23.0 mmol) in 10 mL of methanol was added dropwise to this mixture with vigorous stirring. A yellow precipitate appeared after a few minutes, and the mixture was refluxed for an additional 4 h. Upon cooling, the yellow precipitate was separated by filtration under reduced pressure, then washed with a few drops of DMF and a large volume of methanol. The product was recrystallized from CH_3OH/CH_2Cl_2 to give yellow plates. Yield: 9.2 g (92%), m.p. 229–230°C. ^{1}H NMR (300 MHz, $CDCl_3$, 25°C, TMS): δ = 4.52 (s, 4 H, CH_2), 7.11 (dd, J = 7.8, J = 7.8 Hz, 4 H, anthryl-H), 7.36 (dd, J = 7.8, J = 7.2 Hz, 4 H, anthryl-H), 7.96 (d, J = 8.4 Hz, 4 H, anthryl-H), 8.41 (s, 2 H, anthryl-H), 8.45 (d, J = 7.2 Hz, 4 H, anthryl-H), 9.50 (s, 2 H, imine-H) ppm. ^{13}C NMR (75 Hz, $CDCl_3$): δ = 31.0, 63.1, 125.0, 125.2, 126.5, 128.6, 129.3, 130.0, 131.2, 162.4 ppm. MALDI-TOF-MS: m/z = 436 [M^+]. $C_{32}H_{24}N_2$ (436.2): calcd. C 88.04, H 5.54, N 6.42; found C 87.58, H 5.56, N 6.29.

1,2-Bis[(anthracen-9-ylmethyl)amino]ethane (2): $NaBH_4$ (1.3 g) was dissolved in 10 mL of anhydrous methanol and then added in small portions to a suspension of **1** (1.3 g, 3 mmol) in 150 mL of CH_2Cl_2/MeOH (2:1, v/v) at 50 °C under N_2 over 2 h. The mixture turned gradually to a clear yellowish color and the resulting solution was allowed to react at room temperature overnight. The solvent was then removed under reduced pressure and the residue was treated with excess water. The insoluble materials were then collected by suction, and recrystallized twice from CH_2Cl_2 to give light-yellow needles. Yield: 0.9 g, 68%, m.p. 185–186 °C. ^{1}H NMR (300 MHz, $CDCl_3$, 25°C TMS): δ = 3.07 (s, 4 H, CH_2), 4.72 (s, 4 H, CH_2), 7.44 (m, 8 H, anthryl-H), 8.00 (d, J = 6.0 Hz, 4 H, anthryl-H), 8.29 (d, J = 7.89 Hz, 4 H, anthryl-H), 8.40 (s, 2 H, anthryl-H) ppm. ^{13}C NMR (75 Hz, $CDCl_3$): δ = 45.5, 49.6, 124.0, 124.8, 126.0, 127.1, 129.0, 130.1, 131.4 ppm. MALDI-TOF-MS: m/z = 440 [M^+]. $C_{32}H_{28}N_2 \cdot 1/4H_2O$ (444.7): calcd. C 86.28, H 6.40, N 6.29; found C 86.30, H 6.41, N 6.20.

Ag^I Complex 3: A solution of **2** (132 mg, 0.3 mmol) in CH_2Cl_2 (20 mL) was slowly added to 10 mL of a methanolic solution of $AgNO_3$ (25.5 mg, 0.15 mmol). The resulting colorless solution was stirred at room temperature for 30 min and then filtered. The clear filtrate was allowed to stand in the dark at room temperature, and after about two weeks colorless block-like single crystals suitable for X-ray analysis were collected by filtration. An analytical sample was dried under vacuum to remove the solvents. Yield: 87 mg (70%) based on $AgNO_3$. M.p. 161–162 °C. ^{1}H NMR (300 MHz,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$CDCl_3$, 25°C TMS): δ = 2.52 (s, 12 H, CH_2), 4.13 (s, 12 H, CH_2), 7.27–7.33 (m, 24 H, anthryl-H), 7.74 (d, J = 8.1 Hz, 12 H, anthryl-H), 7.91 (d, J = 7.89 Hz, 12 H, anthryl-H), 8.08 (s, 6 H, anthryl-H) ppm. MALDI-TOF-MS: m/z = 767.4 [M – 2 NO_3]$^{2+}$. $C_{96}H_{84}Ag_2N_2$·$2NO_3$·CH_3OH (1690.5): calcd. C 68.79, H 5.24, N 6.62; found C 68.91, H 5.24, N, 6.65.

Pd^{II} Complex 4: Complex **4** was prepared by a procedure similar to that of **3**. A solution of **2** (132 mg, 0.3 mmol) in CH_2Cl_2 (20 mL) was slowly added to 10 mL of a methanolic solution of $Pd(OAc)_2$ (33.7 mg, 0.15 mmol). The resulting orange solution was stirred at room temperature for 30 min and then filtered. The clear filtrate was allowed to stand at 5 °C, and after about one week, light-orange, block-like single crystals suitable for X-ray analysis were obtained. An analytical sample was dried under vacuum. Yield: 101 mg, 64%; M.p. 119–121 °C. ESI-MS: m/z = 985.5 [M – 2 OAc – H]$^+$. $C_{64}H_{68}N_4Pd$·2OAc·CH_3OH·H_2O (1154.4): calcd. C 71.71, H 5.93, N 4.85; found C 71.30, H 5.60, N 4.73.

X-ray Crystallography: Crystals suitable for X-ray diffraction studies were obtained by slow evaporation of the solvents from CH_2Cl_2/MeOH solutions. Accurate unit-cell parameters were determined by a least-squares fit of 2θ values measured for 200 strong reflections. Intensity data sets were measured with a Bruker Smart 1000 CCD or Rigaku Raxis Rapid IP diffractometer with Mo-K_α radiation (λ = 0.71073 Å) at room temperature. The intensities were corrected for Lorentz and polarization effects, but no corrections for extinction were made. All structures were solved by direct methods. The non-hydrogen atoms were located in successive difference Fourier syntheses. The final refinement was performed by full-matrix least-squares methods with anisotropic thermal parameters for non-hydrogen atoms on F^2. The hydrogen atoms were added theoretically as riding on the appropriate atoms. Crystallographic data and experimental details for structure analyses are summarized in Table 4. CCDC-230566 (**3**) and -230567 (**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

The 3D Channel Framework Based on Indium(III)–btec, and Its Ion-Exchange Properties (btec = 1,2,4,5-Benzenetetracarboxylate)

Zheng-zhong Lin,[a] Fei-long Jiang,[a] Da-qiang Yuan,[a] Lian Chen,[a] You-fu Zhou,[a] and Mao-chun Hong*[a]

Keywords: Indium / Benzenetetracarboxylate / Crystal structure / Ion exchange / Pyridine derivatives

Hydrothermal reactions of $InCl_3$ with pyromellitic dianhydride and pyridine derivatives produce three coordination polymers: $\{(HL)[In_3(btec)_2(OH)_2]\cdot L\}_n$ [btec = 1,2,4,5-benzenetetracarboxylate, L = 2-picoline (**1**), L = 4-picoline (**2**)] and $\{(Hdpea)[In_3(btec)_2(OH)_2]\}_n$ [dpea = 1,2-bis(4-pyridyl) ethane] (**3**). Single crystal X-ray diffraction and powder X-ray diffraction analyses reveal that compounds **1**–**3** are isostructural and possess the same 3D framework as 1D open channels. Thermal gravimetric studies show that compounds **1**–**3** are stable up to 300 °C. The guests of the protonated pyridine derivatives located at the channels in **1** and **2** can be fully exchanged by Ca^{2+} and Ba^{2+} ions.

Introduction

The construction of porous structures or open frameworks with new sizes, shapes, and chemical environments that can undergo solvent removal, solvent inclusion, solvent absorption, or ion exchange[1–4] represents one of the most challenging subjects in recent years. In this regard, various carboxylate-containing ligands, including 1,2,4,5-benzenetetracarboxylic acid (H_4btec), have been used in the assembly of such robust frameworks. H_4btec, which exhibits variation in the possible binding mode of the four acid groups and a strong tendency to form large, tightly bound metal cluster aggregates, has been applied as an organic component to construct porous coordination frameworks.[5] Moreover, the rigid conformation of H_4btec endows robustness to the resulting frameworks to make them thermally stable. With the aim of thoroughly investigating the coordination chemistry of H_4btec, we recently began studies on the assembly reactions of H_4btec with indium metal ions. The reason we selected indium(III) is that, in spite of the enormous number of coordination polymers assembled from divalent metal and H_4btec,[6–8] the field of indium(III) with btec ligands remains unexplored. Furthermore, it was postulated that the incorporation of trivalent metal ions might create diverse structures strikingly different from those containing divalent metal ions because of the increased valence charge of the metal centers. The indium ion is liable to hydrolyze, which limits its use in the construction of coordination polymers. However, by adding an appropriate basic reagent to deprotonate H_4btec and carefully controlling the reaction conditions, we have found that indium(III) ions can be used to construct the new frameworks. Herein we report three novel coordination polymers: $\{(HL)[In_3(btec)_2(OH)_2]\cdot L\}_n$ (**1**, L = 2-picoline; **2**, L = 4-picoline), and $\{(Hdpea)[In_3(btec)_2(OH)_2]\}_n$ [**3**, dpea = 1,2-bis(4-pyridyl)ethane]. Complexes **1**–**3** bear the same 3D channel frameworks. The protonated organic guests in complexes **1** and **2** can be fully exchanged by certain inorganic ions. Although a number of compounds based on {M–btc}[3c] or {M–1,4-bdc}[9] (M = metal ions, btc = 1,3,5-benzenetricarboxylate, and 1,4-bdc = 1,4-benzenedicarboxylate) systems are capable of guest exchange, the exchange behavior reported here is rarely found in the coordination polymers based on {M–btec}.

Results and Discussion

Syntheses and Crystal Structures

The hydrolysis reaction of pyromellitic dianhydride under hydrothermal conditions gives H_4btec, which further aggregates with indium(III) ions to produce compounds **1**–**3**. The in situ method of using pyromellitic dianhydride to synthesize {M–btec} compounds has been reported before.[10] The preparation depends on the pH value of the starting reaction mixture. Pyridine derivatives are added to adjust the pH value and act as templates. So the amount of pyridine derivatives is vital, and the proper pH value ranges between 5 and 6. With a pH value lower than 3 the reaction systems of compounds **1**–**3** produce a byproduct with a 3D structure formulated as $[In_2(H_2btec)_2(OH)_2]_n\cdot 2n\,H_2O$.[11] Thus, to ensure the purity of compounds **1**–**3**, an excessive amount of pyridine derivatives is needed.

As compounds **1**–**3** possess the same framework, compound **2** is selected to represent their structures. There are two kinds of indium coordination environments: the In1 center is bonded to four oxygen atoms from four $btec^{3-}$ ligands, and to two μ_3-OH groups (O9 and its symmetrically equivalent atom) to form a distorted octahedral geometry. Two μ_3-OH groups occupy the axial positions of an octahedron. The In2 center is coordinated to five oxygen atoms from four $btec^{3-}$ ligands, and two μ_3-OH groups to form a pentagonal bipyramidal motif. The two axial positions are occupied by a μ_3-OH group and a carboxylate oxygen atom (Figure 1). The In–O distances range from 2.094(5) to 2.314(5) Å, compatible with those observed in other In^{III}–carboxylate complexes.[12] Bond valence sum (BVS) calculations[13] confirm that all indium ions have an oxidation state of +3. To balance the charge, O9 can be considered to be a μ_3-OH group. This assumption is confirmed by BVS for O9, which gives a result of 1.22. The four carboxylate arms of the btec ligand are all deprotonated, two of them bidentately bind to four indium ions, and the other two adopt the chelating bidentate mode and the monodentate mode (Figure 1). The two μ_3-OH groups bridge indium ions to form an In_4O_{22} tetranuclear cluster in which four indium ions (two In1 and two In2) are in a plane. The two μ_3-OH groups are located at both sides of the plane (Figure 2). If four tetranuclear clusters and eight btec ligands are conceptually viewed as edges, then a subunit similar to a right prism is obtained (Figure 3). Four In1 vertexes are connected by four btec groups to give the rhombic top side of the prism. All btec benzene rings are perpendicular to the top side. The centroids of the four benzene rings connected to the In1 vertexes lie above and below the top side. Above the top side are two neighboring btec benzene rings whose centroids are situated at $x = 0.12608$; the other two btec benzene rings below the top side are located at $x = -0.12608$ (Figure 4). These two positions are related through the centrosymmetric operation. This situation can also be found

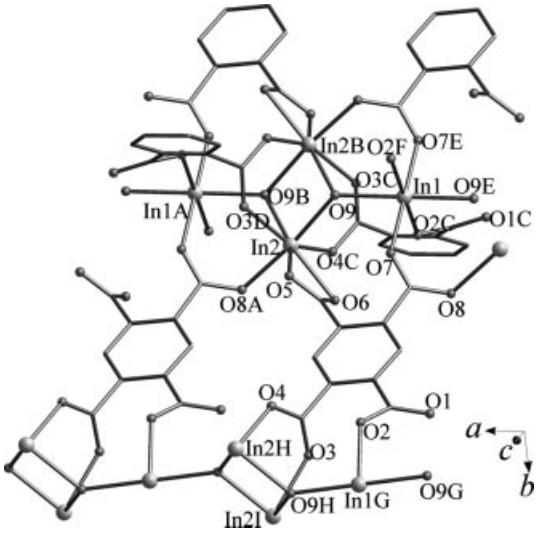

Figure 1. Coordination environment of indium ions in compound **2**. Symmetry code: (A) 1+*x*, *y*, *z*; (B) 1 – *x*, 1 – *y*, –*z*; (C) *x*, 1.5 – *y*, –0.5 + *z*; (D) 1 – *x*, –0.5 + *y*, 0.5 – *z*; (E) –*x*, 1 – *y*, –*z*; (F) –*x*, –0.5 + *y*, 0.5 – *z*; (G) –*x*, 0.5 + *y*, 0.5 – *z*; (H) *x*, 1.5 – *y*, 0.5 + *z*; (I) 1 – *x*, 0.5 + *y*, 0.5 – *z*. For clarity only two carboxylate arms of a part of the btec groups are drawn.

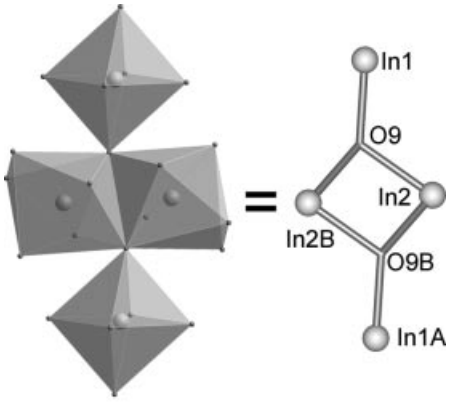

Figure 2. In_4O_{22} tetranuclear cluster and its conceptual representation. In1···In1A= 7.203 Å, In2···In2B = 3.268 Å

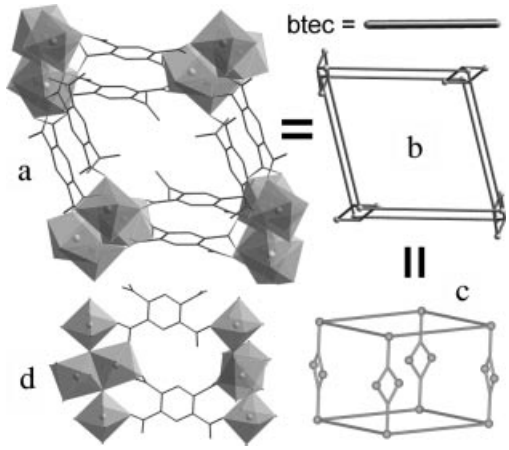

Figure 3. (a) A subunit constructed from four In_4O_{22} tetranuclear clusters and eight btec groups. In the subunit the opposite benzene rings are parallel to each other. It can be seen that the plane defined by four In ions in a tetranuclear clusters is parallel to the plane in the opposite tetranuclear cluster and perpendicular to the plane in the neighboring tetranuclear cluster. Figure 7. TG curves of **1–3** measured under flowing air.

when arranging the four btec benzene rings connected to the bottom-side In1 vertexes. Prisms are extended along [100], [011], and [0$\bar{1}$1] directions to generate a 3D network (Figure 5) containing the planar layers defined by In1 ions. By sharing In1 vertexes, tetranuclear clusters are extended through the crystallographic *a* axis to give infinite chains which act as pillars to support the planar layer. The shortest contact between the pillars is 5.496 Å (O4···O5). The btec groups reproduced along the [011] axis are alternately arranged above and below the In1 planar layer. This also applies to the btec groups reproduced along the [0$\bar{1}$1] direction. In such an arrangement mode, the btec groups fill in the space between the pillars and therefore prevent the framework from generating channels along the [011] and the [0$\bar{1}$1] directions. The only channel runs through the crystallographic *a* axis with diagonal dimensions as long as 13.425×17.544 Å^2. The organic guests, protonated pyridine derivatives, reside in the channels. The pyridine rings are parallel to each other and the centroid-to-centroid distances are longer than 4.5 Å, indicating no π–π contacts between pyridine rings. However, the centroid-to-centroid distances between pyridine rings and the nearest opposite btec benzene rings are 3.790 Å, indicating strong π–π contact. The nitrogen atoms in pyridine rings have no hydrogen bond interactions with the oxygen atoms in the framework. On the basis of PLATON calculations,[14] the solvent accessible volume constitutes 43.3% of the total crystal volume.

The homogeneities of compounds **1**–**3** are confirmed by X-ray powder diffraction (XRPD) patterns (Figure 6). The fact that the powder patterns obtained experimentally are in good agreement with the calculated patterns indicates that these three compounds are isostructural coordination polymers with the same 3D frameworks.

Thermal gravimetric (TG) data for compounds **1**–**3** under flowing air are shown in Figure 7. From 360 to 512 °C, compounds **1**–**3** dramatically lose the weight of both organic guests and btec ligands simultaneously. Powder X-ray diffraction for their residues shows that **1**–**3** are finally transformed to In_2O_3 after being heated at 512 °C. The total weight loss of **1**, **2**, and **3** is about 39.43%, 38.48%, and 40.34%, respectively, consistent with the calculated value of In_2O_3 (about 39.1%).

Ion-Exchange Analysis

In a typical ion-exchange experiment, original samples (about 25 mg) of compounds **1**–**3** were each immersed in a solution of $CaCl_2$ and $BaCl_2$ (10 mL, 1.0 M) for one day at 60 °C. The products were filtered, washed with distilled water and then dried in air. After exchange experiments, compounds **1** and **2** became less crystalline, while **3** remained in its crystalline form. Elemental analysis indicates that the guest cations in **1** and **2** can be fully exchanged by Ca^{2+} and Ba^{2+} ions, reflected by the significant decrease in C and N content. Only slight changes in C and N content[15] were observed for the exchanged sample of **3**, indicating that **3** cannot undergo ion exchange. The Hdepa molecule has a larger size than H2pic and H4pic; this inhibits it from moving freely along channels and therefore reduces its exchange ability. The major XRD reflections (Figure 6) of **1** and **2** can also be observed in their sample exchanged with Ba^{2+}, indicating that in both **1** and **2** the $[In_3(btec)_2(OH)_2]^-$ framework remains unchanged after the exchange.

Experimental Section

Preparation: A mixture of $InCl_3{\cdot}4H_2O$ (74.0 mg, 0.25 mmol), pyromellitic dianhydride (55 mg, 0.25 mmol), 2-picoline (typical example: 0.8 mL, 8 mmol), and H_2O (5.0 mL) in a 30-mL Teflon-lined stainless steel vessel was heated at 165 °C for 85 h, and then was cooled to room temperature at a rate of 6 °C·h^{-1}, giving light yellow prism crystals of **1**. The crystals were collected by density difference and washed with *N*,*N*-dimethylformamide (DMF) and water sequentially, giving an isolated yield of 62 mg (70%) based on $InCl_3{\cdot}4H_2O$. Compounds **2** and **3** were prepared in a similar way simply by replacing 2-picoline with 4-picoline (0.8 mL, 8 mmol) or with a mixture of pyridine (0.1 mL, 1.2 mmol) and dpea (368 mg, 2 mmol) and obtained in the yields of 60 mg (68%) and 53 mg (60%), respectively, based on $InCl_3{\cdot}4H_2O$. **1**: $C_{32}H_{21}In_3N_2O_{18}$ (1065.97): calcd. C 36.03, H 1.99, N 2.63; found C 36.22, H 2.12, N 2.66. IR (KBr): $\tilde{\nu}$ = 3503 (br), 3054 (m), 1613 (s), 1589 (vs), 1499 (s), 1411 (s), 1371 (vs), 1317 (m), 1252 (m), 1141 (m), 878 (w), 805 (m), 761 (m) cm^{-1}. **2**: $C_{32}H_{21}In_3N_2O_{18}$ (1065.97): calcd. C 36.03, H 1.99, N 2.63; found C 35.81, H 2.10, N 2.58. IR (KBr): $\tilde{\nu}$ = 3606 (m), 3523 (m), 3221 (m), 3086 (m), 1636 (m), 1595 (vs), 1548 (s), 1505 (m), 1427 (s), 1382 (s), 1337 (s), 1135 (m), 1005 (m), 941 (m), 857 (m), 805 (m), 779 (m), 755 (m) cm^{-1}. **3**: $C_{32}H_{19}In_3N_2O_{18}$ (1063.97): calcd. C 36.12, H 1.80, N 2.63; found C 36.44, H 2.10, N 2.67. IR (KBr): $\tilde{\nu}$ = 3422 (m), 3327 (m), 3129 (m), 1615 (s), 1590 (s), 1552 (sh, vs), 1497 (s), 1402 (s), 1373 (s), 1317 (m), 1140 (m), 932 (m), 878 (m), 815 (m), 761 (m) cm^{-1}.

Crystallographic Studies: Intensity data of **2** and **3**[16] were collected with a Rigaku mercury CCD diffractometer with graphite-monochromated Mo-K_α (λ = 0.71073 Å) radiation by using the ω–2θ scan method at room temperature. The structures were solved by direct methods using SHELXS-97[17a] and were refined on F^2 by the full-matrix least-squares methods SHELXL-97.[17b] Because of a disorder problem, some atoms of the dpea molecule in **3** could not be located. All non-hydrogen atoms were refined anisotropically except for the organic guest molecules. All hydrogen atoms were calculated at the ideal positions and refined isotropically. The crystallographic data, selected bond lengths and angles are summarized in Table 1 and Table 2.

Syntheses, Reactivity, and X-ray Structure Analyses of the Dimeric Pentaphosphides $[(t\mathrm{Bu_3Si})_3\mathrm{P_5M_2}]_2$ (M = Na, Ag) and the Bicyclo[2.1.0]pentaphosphane $(t\mathrm{Bu_3Si})_3\mathrm{P_5}$

Hans-Wolfram Lerner,[a]* Günter Margraf,[a] Linda Kaufmann,[a] Jan W. Bats,[b] Michael Bolte,[a] and Matthias Wagner[a]

Keywords: Phosphorus / Phosphane / Supersilyl phosphides / Silanide

The sodium pentaphosphide dimer $[(t\mathrm{Bu_3Si})_3\mathrm{P_5Na_2(THF)}]_2$ has been synthesized in high yield from the reaction of four equivalents of the sodium silanide $t\mathrm{Bu_3SiNa}$ with P_4. X-ray quality crystals of the sodium pentaphosphide dimer $[(t\mathrm{Bu_3Si})_3\mathrm{P_5Na_2(THF)}]_2$ (monoclinic, $P2_1/n$) were grown from benzene. The sodium pentaphosphide $(t\mathrm{Bu_3Si})_3\mathrm{P_5Na_2}$ can be oxidized with one equivalent of TCNE to give the bicyclo[2.1.0]-pentaphosphane $(t\mathrm{Bu_3Si})_3\mathrm{P_5}$; it also reacts with AgOCN to give the silver pentaphosphide $[(t\mathrm{Bu_3Si})_3\mathrm{P_5Ag_2}]_2$ (monoclinic, $P2_1/n$). Crystals of the pentaphosphane $(t\mathrm{Bu_3Si})_3\mathrm{P_5}$ (monoclinic, $P2_1/c$) suitable for X-ray diffraction were obtained from hexane at –25 °C.

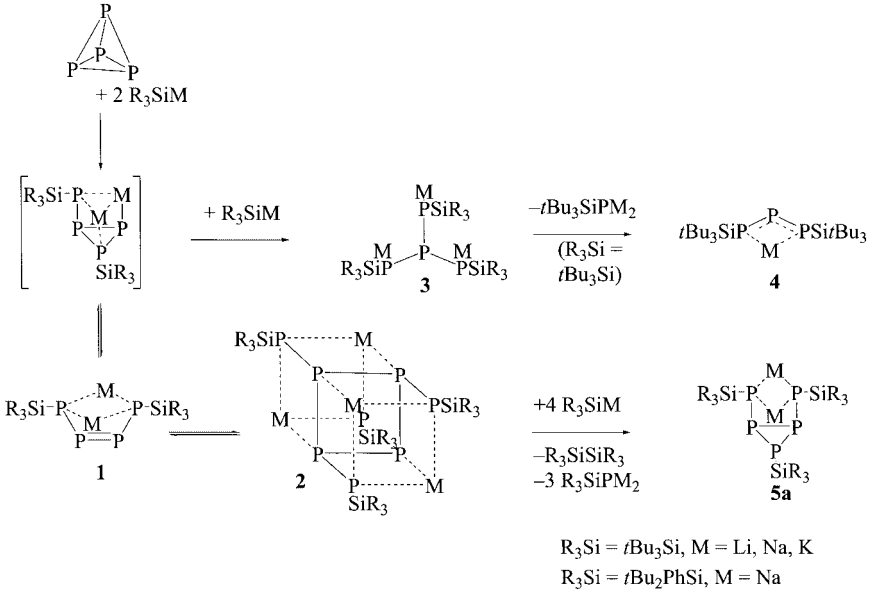
Introduction

The nucleophilic degradation of P_4 with $t\mathrm{Bu_3SiM}$ (M = Li, Na, K) or $t\mathrm{Bu_2PhSiNa}$ in a molar ratio of 1:2 leads to the tetraphosphenediides **1** $[(t\mathrm{Bu_3Si})_2\mathrm{P_4M_2}]$ (M = Li, Na, K) and $[(t\mathrm{Bu_2PhSi})_2\mathrm{P_4Na_2}]$, which dimerize in weakly polar solvents to form the octaphosphides **2** $[(t\mathrm{Bu_3Si})_4\mathrm{P_8M_4}]$ (M = Li, Na, K) and $[(t\mathrm{Bu_2PhSi})_4\mathrm{P_8Na_4}]$ (Scheme 1).[1–4]



Scheme 1.

Recently we have reported the reaction of P_4 with the silanides $t\mathrm{Bu_3SiM}$ (M = Li, Na) and $t\mathrm{Bu_2PhSiNa}$ in a 1:3 stoichiometry, which leads cleanly to the tetraphosphides **3** $[(t\mathrm{Bu_3Si})_3\mathrm{P_4M_3}]$ (M = Li, Na) and $[(t\mathrm{Bu_2PhSi})_3\mathrm{P_4Na_3}]$, respectively.[5] In contrast, when P_4 was treated with three equivalents of $t\mathrm{Bu_3SiK}$ in tetrahydrofuran, the potassium

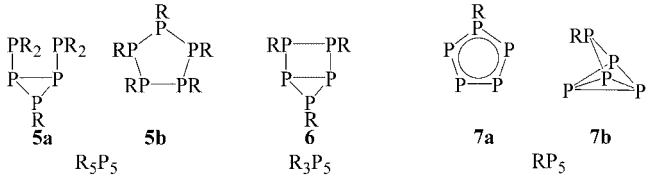
tetraphosphenediide $[(t\mathrm{Bu_3Si})_2P_4K_2]$ and the octaphosphide $[(t\mathrm{Bu_3Si})_4P_8K_4]$ were formed as the main products rather than the tetraphosphide $[(t\mathrm{Bu_3Si})_3P_4K_3]$.[4]

Surprisingly, treatment with tri-*tert*-butylsilylpotassium (supersilylpotassium, $t\mathrm{Bu_3SiK}$) slowly transforms the supersilylated potassium tetraphosphenediide $[(t\mathrm{Bu_3Si})_2P_4K_2]$ (**1K$_2$**) and the octaphosphide $[(t\mathrm{Bu_3Si})_4P_8K_4]$ (**2K$_4$**) into the triphosphide $[(t\mathrm{Bu_3Si})_2P_3K]$ (**4K**) and the pentaphosphide $[(t\mathrm{Bu_3Si})_3P_5K_2]$ (**5aK$_2$**), respectively.[4]

The sodium pentaphosphide $[(t\mathrm{Bu_3Si})_3P_5Na_2(THF)_4]$[6] is the first and only structurally characterized derivative of the pentaphosphane **5a** and is a constitutional isomer of the well-known cyclopentaphosphanes of type **5b** (Scheme 2).[7,8] Derivatives of **7a** have been described in a number of recent studies.[9–12] The cation $Br_2P_5^+$ features the structural motif of **7b**.[13,14] The theoretical studies of Böcker and Häser have shown that the bicyclo[2.1.0]pentaphosphane **6** (non-Baudler structure) should be stable.[15]



Scheme 2.

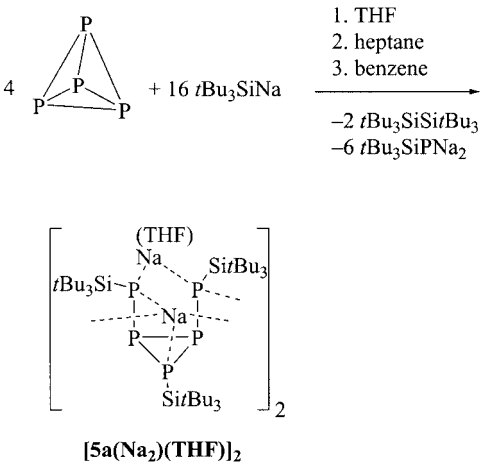
In this paper, the synthesis, reactivity and molecular structure of the bicyclo[2.1.0]pentaphosphane $(t\mathrm{Bu_3Si})_3P_5$, the first isolated derivative of the pentaphosphane **6**, is described. We also report here the crystal structures of the dimeric pentaphosphides $[(t\mathrm{Bu_3Si})_3P_5M_2]_2$ (M = Na, Ag).

Results and Discussion

Syntheses

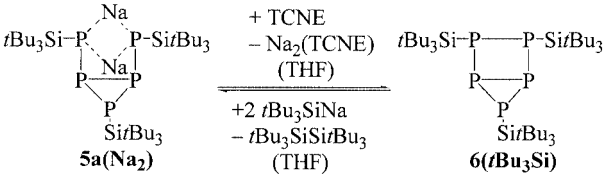
As we noted previously, the sodium pentaphosphide **5aNa$_2$** can be generated by several routes.[6] We have now developed a synthesis by which the sodium pentaphosphide dimer $[(t\mathrm{Bu_3Si})_3P_5Na_2(THF)]_2$ can be produced in large amounts.

The dimeric sodium pentaphosphide **[5aNa$_2$(THF)]$_2$** is accessible by treating P_4 with four equivalents of the sodium silanide $t\mathrm{Bu_3SiNa}$.[16] The first product of this reaction in THF is the sodium tetraphosphenediide $[(t\mathrm{Bu_3Si})_2P_4Na_2]$ (**1Na$_2$**). The ^{31}P NMR spectrum of the resulting THF solution shows signals that can be assigned unambiguously to the sodium tetraphosphenediide **1Na$_2$**. After removing the THF the reaction mixture was treated with heptane and stirred for 12 h. The main product of this procedure was the sodium octaphosphide $[(t\mathrm{Bu_3Si})_4P_8Na_4(THF)_4]$ **[2Na$_4$(THF)$_4$]**, which was characterized by X-ray crystallography. Removal of the heptane and addition of benzene, followed by stirring the resulting reaction mixture for 24 h at ambient temperature, gave the sodium pentaphosphide dimer **[5aNa$_2$(THF)]$_2$** in 77% yield. Superdisilane was produced as a side-product in this reaction, as shown in Equation (1). The dimeric pentaphosphide **[5aNa$_2$(THF)]$_2$** is transformed into the monomeric pentaphosphide **5aNa$_2$** in tetrahydrofuran.

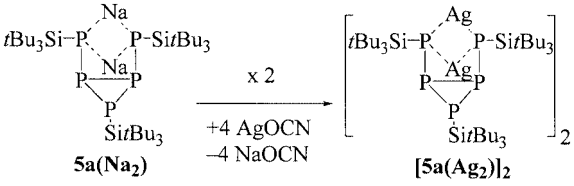


(1)

Interestingly, the pentaphosphide **5aNa$_2$** can be oxidized with TCNE to give the pentaphosphane **6(SitBu$_3$)** in quantitative yield. Treatment of this pentaphosphane with $t\mathrm{Bu_3SiNa}$ leads quantitatively to the pentaphoshide **5aNa$_2$** and the superdisilane $t\mathrm{Bu_3SiSi}t\mathrm{Bu_3}$, as shown in Equation (2). In contrast to the reaction of **5aNa$_2$** with Au$^{\mathrm{I}}$, where a redox process takes place,[17] the pentaphosphide **5aNa$_2$** reacts with AgOCN in a metathesis reaction to give the silver pentaphosphide **[5aAg$_2$]$_2$** in 53% yield [Equation (3)].

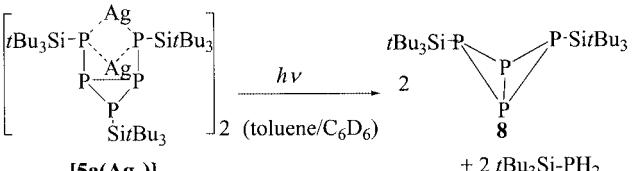


(2)



(3)

Surprisingly, the photolysis of **[5aAg$_2$]$_2$** in a mixture of toluene and $[D_6]$benzene at ambient temperature leads to the bicyclo[1.1.0]tetraphosphane **8**[1,3] and the supersilylphosphane **9**[3] in quantitative yield [Equation (4)].



(4)

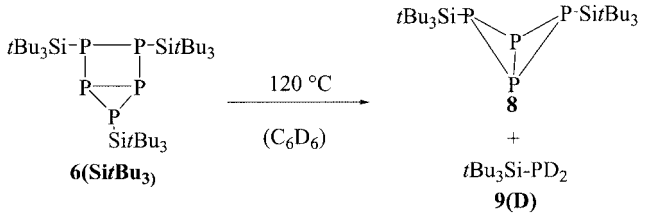
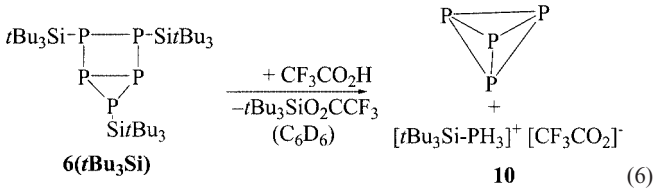
Reactivity of $(t\mathrm{Bu_3Si})_3\mathrm{P_5}$

In the thermolysis of the bicyclo[2.1.0]pentaphosphane **6(Si*t*Bu$_3$)** at 120 °C in [D$_6$]benzene the bicyclo[1.1.0]tetraphosphane **8**[1,3] and the deuterated supersilylphosphane **9(D)** were produced quantitatively, as shown in Equation (5). The formation of $t\mathrm{Bu_3SiPD_2}$ in the thermolysis of the bicyclo[2.1.0]pentaphosphane **6(Si*t*Bu$_3$)** can be explained by the reaction of transient supersilylphosphinidene $t\mathrm{Bu_3SiP}$ with [D$_6$]benzene.



(5)

The bicyclo[2.1.0]pentaphosphane **6(Si*t*Bu$_3$)** is sensitive to oxygen and moisture. It reacts spontaneously with CF_3CO_2H to give the supersilylphosphenium trifluoroacetate $[t\mathrm{Bu_3SiPH_3}][CF_3CO_2]$ and P_4. In this reaction $t\mathrm{Bu_3SiO_2CCF_3}$ is formed as a by-product [Equation (6)].



(6)

NMR Spectra

Generally, the NMR spectra of **[5aNa$_2$(THF)]$_2$** resemble those of the monomeric sodium phosphide **5aNa$_2$**.[6] As shown in Figure 2, the signals of all P nuclei of the pentaphosphide dimer **[5aNa$_2$(THF)]$_2$** are broadened, due to Na–P coupling. In contrast, the spectrum of monomeric pentaphosphide **5aNa$_2$** shows only broad signals for P(3) and P(4). The $^{31}P\{^1H\}$NMR spectrum of **5aNa$_2$** features three multiplets with the splitting pattern of an AA′BB′MM′ spin system, as shown in Figure 2.

When **[5a(Na$_2$)(THF)]$_2$** is dissolved in tetrahydrofuran the ^{31}P NMR spectrum becomes like that of **5aNa$_2$**. The $^{31}P\{^1H\}$NMR spectrum of the silver pentaphoshide **[5aAg$_2$]$_2$** resembles that of the dimeric sodium pentaphosphide **[5a(Na$_2$)(THF)]$_2$**. In an earlier report we discussed the NMR spectra of the monomeric pentaphosphide **5aNa$_2$** and the bicyclo[2.1.0]pentaphosphane **6(Si*t*Bu$_3$)** in detail.[6] The $^{31}P\{^1H\}$NMR spectra of the sodium octaphosphide $[(t\mathrm{Bu_3Si})_4P_8Na_4(THF)_4]$ and the DME-complexed sodium octaphosphide $[(t\mathrm{Bu_3Si})_4P_8Na_4(DME)_4]$[1] exhibit the same general features (Figure 1).

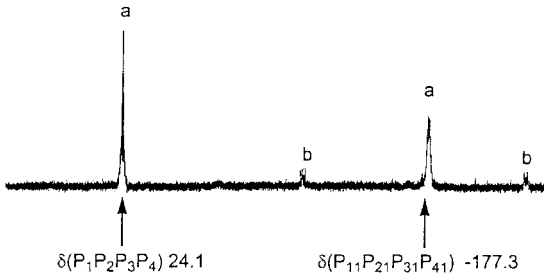


Figure 1. $^{31}P\{^1H\}$NMR spectrum of the reaction solution (after stirring for 12 h in heptane) in C_6D_6 at 161.96 MHz (25 °C, external H_3PO_4). Signal of (a) sodium octaphosphide $[(t\mathrm{Bu_3Si})_4P_8Na_4(THF)_4]$ and (b) dimeric pentaphosphide $[(t\mathrm{Bu_3Si})_3P_5Na_2(THF)]_2$.

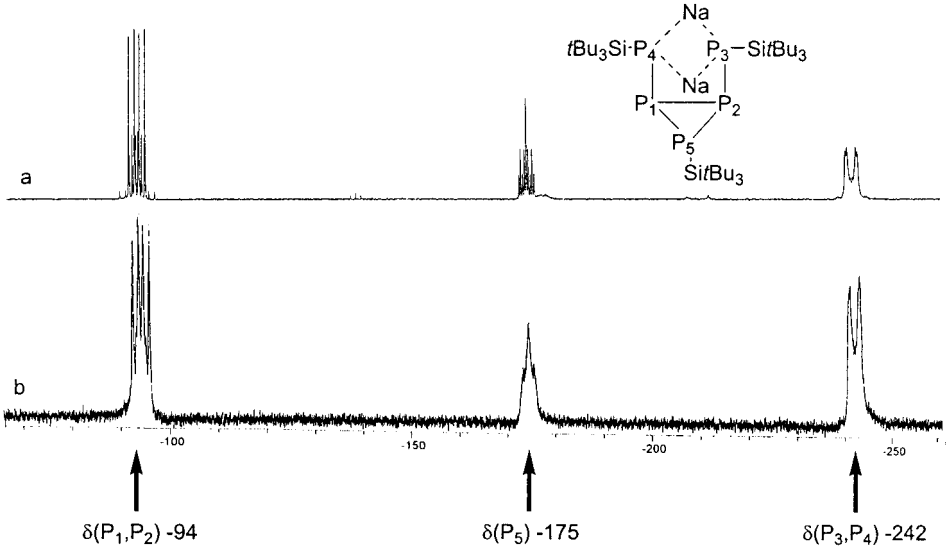

Figure 2. (a) $^{31}P\{^1H\}$NMR spectrum of the monomeric pentaphosphide $[(t\mathrm{Bu_3Si})_3P_5Na_2(THF)_n]$ in [D$_8$]THF at 161.96 MHz (25 °C, external H_3PO_4). (b) $^{31}P\{^1H\}$NMR spectrum of the dimeric pentaphosphide $[(t\mathrm{Bu_3Si})_3P_5Na_2(THF)]_2$ in C_6D_6 at 161.96 MHz (25 °C; external H_3PO_4). Contrary to the signal in the spectrum of the monomeric pentaphosphide, the signal of the P(5) nucleus of the pentaphosphide dimer $[(t\mathrm{Bu_3Si})_3P_5Na_2(THF)]_2$ is broadened due to Na–P coupling. The dimeric pentaphosphide $[(t\mathrm{Bu_3Si})_3P_5Na_2(THF)]_2$ is transformed in tetrahydrofuran into monomeric pentaphosphide $[(t\mathrm{Bu_3Si})_3P_5Na_2(THF)_n]$.

Structure of the Sodium Octaphosphide $[(t\mathrm{Bu_3Si})_4P_8Na_4(THF)_4]$

Figure 3 shows the molecular structure of the sodium octaphosphide $[(t\mathrm{Bu_3Si})_4P_8Na_4(THF)_4]$ (monoclinic, $P2_1/n$); selected bond lengths and angles are listed in the corresponding figure caption. The structure of $[(t\mathrm{Bu_3Si})_4P_8Na_4(THF)_4]$ shows two symmetrically independent molecules in the unit cell. The central core of $[(t\mathrm{Bu_3Si})_4P_8Na_4(THF)_4]$ possesses the structure of a double cube with four P atoms in the second layer and two P and two Na atoms in the first and third layers. The corners of the first and the third layer in these cubes are alternately occupied by two P and two Na atoms [molecule A: P–Na–P 79.58(16)°, Na–P–Na 86.27(16)°; molecule B: P–Na–P 80.03(19)°, Na–P–Na 84.53(19)°]. A similar structural motif has also been found for $[(t\mathrm{Bu_3Si})_4P_8Na_4(DME)_4]$.[1] Apart from the three P atoms, the Na atom in $[(t\mathrm{Bu_3Si})_4P_8Na_4(THF)_4]$ is coordinated by one molecule of tetrahydrofuran. In contrast to the pentacoordinate Na atoms in $[(t\mathrm{Bu_3Si})_4P_8Na_4(DME)_4]$, the sodium centers of $[(t\mathrm{Bu_3Si})_4P_8Na_4(THF)_4]$ are four-coordinate. The bond lengths and angles of the THF- and DME-solvated sodium octaphosphides $[(t\mathrm{Bu_3Si})_4P_8Na_4(L)_4]$ are quite similar.

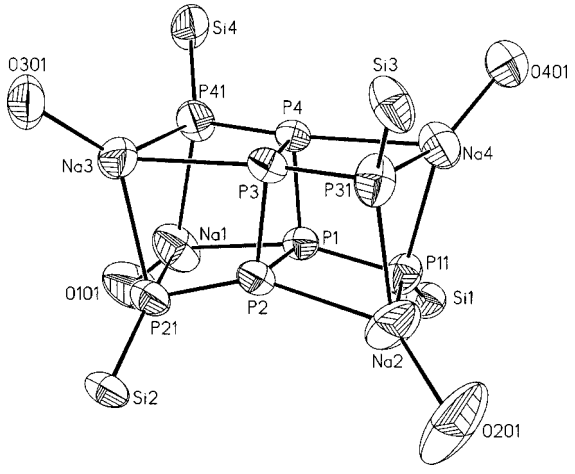

Figure 3. Thermal ellipsoid plot of $[\mathbf{2Na_4(THF_4)}]$ (molecule A), showing the atomic numbering scheme. The displacement ellipsoids are drawn at the 50% probability level. *t*Bu groups have been omitted for clarity. Structure of the Sodium Pentaphosphide Dimer $[(t\mathrm{Bu_3Si})_3P_5Na_2(THF)]_2$

X-ray quality crystals of the sodium pentaphosphide dimer $\mathbf{[5aNa_2(THF)]_2}$ were grown from benzene solution at ambient temperature. It crystallizes in the monoclinic space group $P2_1/n$, and the unit cell contains two formula units. As depicted in Figure 4, the two pentaphosphide dianions $[(t\mathrm{Bu_3Si})_3P_5]^{2-}$ are bridged by two Na cations to form a dimer in the solid state. The sodium pentaphosphide dimer $\mathbf{[5aNa_2(THF)]_2}$ features four P–Na contacts for the two bridging Na atoms and three P–Na contacts for the terminal Na atom. Apart from these three P atoms, the two terminal Na atoms are coordinated by one molecule of tetrahydrofuran. In contrast to the trigonal-planar sodium atom Na(2), the Na(1) center is four-coordinate in $\mathbf{[5aNa_2(THF)]_2}$. The bond lengths and angles of the sodium pentaphosphide dimer $\mathbf{[5aNa_2(THF)]_2}$ are similar to those of the monomeric sodium pentaphosphide $\mathbf{5aNa_2}$ (see caption to Figure 4).

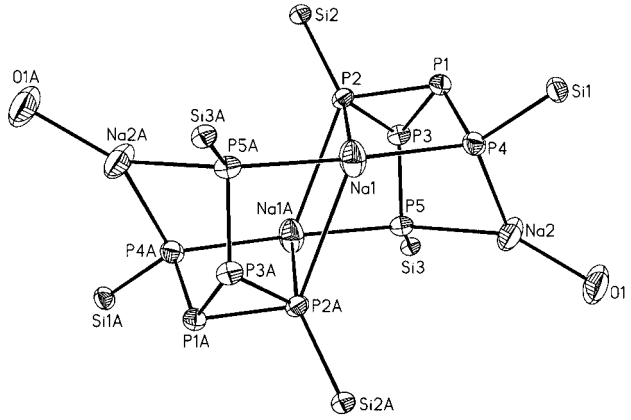

Figure 4. Thermal ellipsoid plot of $\mathbf{[5aNa_2(THF)]_2}$ showing the atom numbering scheme. The displacement ellipsoids are drawn at the 50% probability level. The *t*Bu groups of the pentaphosphide and the CH_2 units of the THF have been omitted for clarity. Selected bond lengths [Å] and angles [°]: P(1)–P(4) 2.1937(16), P(1)–P(3) 2.2393(15), P(1)–P(2) 2.2413(15), P(2)–P(3) 2.2287(15), P(2)–Si(2) 2.3150(15), P(2)–Na(1) 3.051(2), P(2)–Na(1A) 3.385(2), P(3)–P(5) 2.1866(15), P(4)–Si(1) 2.2612(15), P(4)–Na(2) 2.805(2), P(4)–Na(1) 2.846(2), P(5)–Si(3) 2.2648(15), P(5)–Na(2) 2.812(2); P(5)–Na(1A) 2.836(2), Na(1)–P(5A) 2.836(2), Na(1)–P(2A) 3.385(2), P(4)–P(1)–P(3) 111.46(6), P(4)–P(1)–P(2) 104.72(6), P(3)–P(1)–P(2) 59.66(5), P(3)–P(2)–P(1) 60.13(5). Symmetry transformations used to generate equivalent atoms: #1 $-x + 1, -y + 1, -z + 1$.

Structure of the Silver Pentaphosphide Dimer $[(t\mathrm{Bu_3Si})_3P_5Ag_2]_2$

X-ray quality crystals of the silver pentaphosphide dimer $\mathbf{[5aAg_2]_2}$ were grown from a toluene solution at 5 °C. It crystallizes in the monoclinic space group $P2_1/n$. The unit cell contains two formula units and two molecules of tolu-

ene. As depicted in Figures 5 and 6, the two pentaphosphide dianions $[(t\mathrm{Bu_3Si})_3\mathrm{P_5}]^{2-}$ cap a square-planar four-membered Ag_4 ring that contains a crystallographic inversion center at the midpoint of the molecule. The conformation of the pentaphosphide group is very similar to that of the related group in the crystal structure of **[5aNa$_2$(THF)]$_2$**. Figure 5 shows that the atoms P(1) and P(3) are coordinated to two Ag atoms, while P(2) is coordinated to only one Ag atom. The Ag–P distances range from 2.368(1) to 2.626(1) Å. The shortest Ag···Ag distances are 2.8985(5) and 3.0042(5) Å. The diagonal Ag2···Ag2′ distance of 3.3679(7) Å is slightly longer. The molecule shows nine intramolecular C–H···P contacts with H···P distances of between 2.61 and 2.88 Å. The crystal structure of **[5aAg$_2$]$_2$** features no short intermolecular contacts.

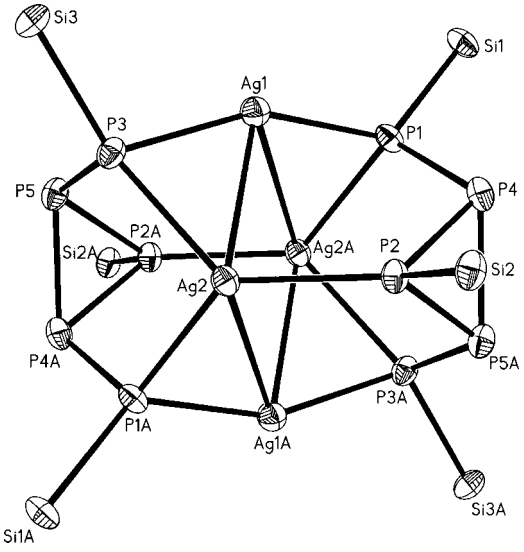

Figure 5. Thermal ellipsoid plot of **[5aAg$_2$]$_2$** showing the atom numbering scheme. The displacement ellipsoids are drawn at the 50% probability level. *t*Bu groups have been omitted for clarity. Selected bond lengths [Å] and angles [°]: Ag(1)–P(1) 2.3678(9), Ag(1)–P(3) 2.3916(9), Ag(1)–Ag(2) 2.8985(5), Ag(1)–Ag(2A) 3.0042(5), Ag(2)–P(1A) 2.5315(9), Ag(2)–P(2) 2.5436(9), Ag(2)–P(3) 2.6258(9), Ag(2)–Ag(1A) 3.0041(5), Ag(2)–Ag(2A) 3.3679(7), P(1)–P(4) 2.1820(13), P(1)–Si(1) 2.2786(12), P(1)–Ag(2A) 2.5315(9), P(3)–P(5) 2.1735(12), P(3)–Si(3) 2.2926(12), P(2)–P(4) 2.2031(12), P(2)–P(5A) 2.2371(12), P(2)–Si(2) 2.3349(12), P(4)–P(5A) 2.2528(13), Si(2)–C(17) 1.933(4), Si(2)–C(13) 1.944(4), Si(2)–C(21) 1.948(4), P(5)–P(2A) 2.2371(12), P(5)–P(4A) 2.2528(13); P(1)–Ag(1)–P(3) 154.41(3), P(1)–Ag(1)–Ag(2) 99.61(2), P(3)–Ag(1)–Ag(2) 58.59(2), P(1)–Ag(1)–Ag(2A) 54.69(2), P(3)–Ag(1)–Ag(2A) 101.94(2), Ag(2)–Ag(1)–Ag(2A) 69.555(14), P(1A)–Ag(2)–P(2) 131.19(3), P(1A)–Ag(2)–P(3) 94.89(3), P(2)–Ag(2)–P(3) 131.31(3), P(1A)–Ag(2)–Ag(1) 124.80(2), P(2)–Ag(2)–Ag(1) 85.07(2), P(3)–Ag(2)–Ag(1) 51.02(2), P(1A)–Ag(2)–Ag(1A) 49.75(2), P(2)–Ag(2)–Ag(1A) 85.80(2), P(3)–Ag(2)–Ag(1A) 125.04(2), Ag(1)–Ag(2)–Ag(1A) 110.447(14), P(1A)–Ag(2)–Ag(2A) 85.11(2), P(2)–Ag(2)–Ag(2A) 81.99(2), P(3)–Ag(2)–Ag(2A) 88.32(2), Ag(1)–Ag(2)–Ag(2A) 56.700(10), Ag(1A)–Ag(2)–Ag(2A) 53.747(10). Symmetry transformations used to generate equivalent atoms: #1 $-x + 1, -y, -z + 2$.

crystals were grown from hexane at –25 °C. It cocrystallizes with hexane in the monoclinic space group $P2_1/c$. The unit cell contains four formula units. It is interesting to note that $(t\mathrm{Bu_3Si})_3\mathrm{P_5}$ is the first structurally characterized pentaphosphane that features a bicyclus formed by annulated three- and four-membered rings in the solid state. The calculated strain energy of cyclotetraphosphane is lower (27 kcal mol^{-1}) than that of cyclobutane,[9] but only a limited number of compounds are known with a P_4-ring structure.[18–20] Generally, three- and four-membered ring systems of phosphorus are destabilized relative to five-membered ring structures.[7,15] The central core of this bicyclo[2.1.0]pentaphosphane possesses a distorted envelope structure, as shown in Figure 7. The molecular structure of **6(Si*t*Bu$_3$)** features six P–P bonds of around 2.2281(8) Å (av.). These distances are in the range of P–P single bonds. The four-membered ring in **6(Si*t*Bu$_3$)** is not planar, as confirmed by torsion angles of ±14.46(3)° (av.). The supersilyl groups at the P_4-ring are mutually *trans*. No significant variations between the P–Si bonds [2.3229(8) Å av.] are observed.

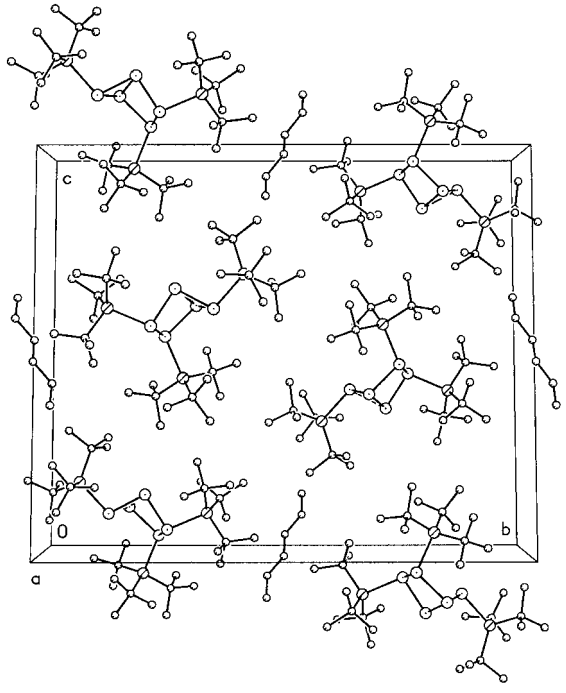

Figure 8. Crystal packing diagram of **6(Si*t*Bu$_3$)**.

Conclusions

In summary, it has been shown that the sodium pentaphosphide dimer **[5aNa$_2$(THF)]$_2$** can be cleanly prepared from $t\mathrm{Bu_3SiNa}$ and white phosphorus. The sodium pentaphosphide **5aNa$_2$** can be oxidized with one equivalent of TCNE to give the bicyclo[2.1.0]pentaphosphane $(t\mathrm{Bu_3Si})_3\mathrm{P_5}$ **[6(Si*t*Bu$_3$)]**. On the other hand, the pentaphosphide **5aNa$_2$** reacts with AgOCN to give the silver phosphide **[5aAg$_2$]$_2$** in 53% yield.

The bicyclo[2.1.0]pentaphosphane **6(Si*t*Bu$_3$)** is sensitive to protonolysis, yielding the supersilylphosphenium cation $[t\mathrm{Bu_3SiPH_3}.]^+$. Thermolysis of this compound in C_6D_6 at 120 °C gives the 1,4-bis(supersilyl)bicyclo[1.1.0]tetraphosphane $(t\mathrm{Bu_3Si})_2\mathrm{P_4}$ and the deuterio supersilylphosphane $t\mathrm{Bu_3SiPD_2}$ quantitatively.

The sodium octaphosphide **2Na$_4$(THF$_4$)**, the pentaphosphide dimers **[5aNa$_2$(THF)]$_2$** and **[5aAg$_2$]$_2$**, and the bicyclo[2.1.0]pentaphosphane **6(Si*t*Bu$_3$)** have been studied by X-ray crystallography. The phosphane **6(Si*t*Bu$_3$)** represents a novel type of pentaphosphane featuring a bicyclus formed by annulated three- and four-membered rings in the solid state.

Experimental Section

General Remarks: All experiments were carried out under dry argon with strict exclusion of air and moisture using standard Schlenk techniques. $t\mathrm{Bu_3SiNa}$[16] was prepared according to literature procedures. All other starting materials were purchased from commercial sources and used without further purification. The solvents (benzene, toluene, tetrahydrofuran) were distilled from sodium/benzophenone prior to use. C_6D_6 was dried over molecular sieves and stored under dry nitrogen.

The NMR spectra were recorded on a Bruker AM 250, a Bruker DPX 250, or a Bruker Avance 400 spectrometer. The ^{29}Si NMR spectra were recorded using the INEPT pulse sequence with empirically optimized parameters for polarization transfer from the *t*Bu substituents.

Synthesis of [(tBu$_3$Si)$_3$P$_5$Na$_2$(THF)]$_2$: A solution of $t\mathrm{Bu_3SiNa}$ (55.2 mmol) in tetrahydrofuran (100 mL) was added to a solution of freshly sublimed P_4 (1.456 g, 11.74 mmol) in 50 mL of tetrahydrofuran at –78 °C and stirred for 4 h. According to the ^{31}P NMR spectrum the tetraphosphide $(t\mathrm{Bu_3Si})_2\mathrm{P_4Na_2}$ was formed as the main product. After all volatile compounds were removed in vacuo the reaction mixture was treated with 50 mL of heptane and stirred for 12 h at ambient temperature. The product of this procedure was the sodium octaphosphide $[(t\mathrm{Bu_3Si})_4\mathrm{P_8Na_4(THF)_4}]$ (by ^{31}P NMR spectroscopy; Figure 1). Crystals of the sodium octaphosphide $[(t\mathrm{Bu_3Si})_4\mathrm{P_8Na_4(THF)_4}]$ suitable for X-ray diffraction were obtained in an NMR tube from [D$_6$]benzene at room temperature. The ^{31}P NMR spectrum of the reaction solution after stirring in heptane for 12 h showed the signal of $[(t\mathrm{Bu_3Si})_4\mathrm{P_8Na_4(THF)_4}]$ (main product 85% P atoms) and the dimeric sodium pentaphosphide $[(t\mathrm{Bu_3Si})_3\mathrm{P_5Na_2(THF)}]_2$ (minor component 15% P atoms; Figure 2). After the heptane was exchanged for benzene and the resulting reaction mixture was stirred again for 24 h at ambient temperature the sodium pentaphosphide dimer $[(t\mathrm{Bu_3Si})_3\mathrm{P_5Na_2(THF)}]_2$ was formed. X-ray quality crystals of $[(t\mathrm{Bu_3Si})_3\mathrm{P_5Na_2(THF)}]_2$ were grown after the reaction mixture had been concentrated in vacuo to a volume of 15 mL and kept at ambient temperature. Yield: 6.306 g (77%).

Selected Data for (tBu$_3$Si)$_2$P$_4$Na$_2$: ^{1}H NMR ([D$_8$]THF, internal TMS): δ = 1.10 (br., 54 H, *t*Bu) ppm. ^{13}C{^{1}H}NMR ([D$_8$]THF, internal TMS): δ = 25.5 (br., *C*Me$_3$), 32.5 (br., C*Me$_3$*) ppm. ^{29}Si{^{1}H}NMR ([D$_8$]THF, external TMS): δ = 22.7 (m, Si*t*Bu$_3$) ppm. ^{31}P{^{1}H}NMR (25 °C; external H_3PO_4): δ = 403.0 (m, $^1J_{P2,P3}$ = –502.6, $^1J_{P1,P2}$ = $^1J_{P3,P4}$ = –432.3, $^2J_{P1,P3}$ = $^2J_{P2,P4}$ = 33.87 Hz, P_2, P_3), –5.1 (m, $^3J_{P1,P4}$ = 184.1, $^1J_{P1,P2}$ = $^1J_{P3,P4}$ = –448.83, $^2J_{P1,P3}$ = $^2J_{P2,P4}$ = –34.7 Hz, P_1, P_4) ppm.

Selected Data for (tBu$_3$Si)$_4$P$_8$Na$_4$(THF)$_4$: ^{1}H NMR (C_6D_6, internal TMS): δ = 1.30 (br., 108 H, tBu), 1.41 (m, 16 H, CH_2), 3.59 (m, 16 H, OCH_2) ppm. ^{13}C{^{1}H}NMR (C_6D_6, internal TMS): δ = 25.9 (br., *C*Me$_3$), 33.0 (br., C*Me$_3$*), 25.3 (s, *C*H$_2$), 68.0 (s, O*C*H$_2$) ppm. ^{29}Si{^{1}H}NMR (C_6D_6, internal TMS): δ = 19.8 (m, SitBu$_3$) ppm. ^{31}P{^{1}H}NMR (25 °C; external H_3PO_4): δ = 24.1 (m, P_1, P_2, P_3, P_4), –177.3 (m, P_{11}, P_{21}, P_{31}, P_{41}) ppm.

Selected Data for [(tBu$_3$Si)$_3$P$_5$Na$_2$(THF)]$_2$: ^{1}H NMR (C_6D_6, internal TMS): δ = 1.28 (br., 54 H, tBu), 1.26 (br., 27 H, tBu), 1.40 (m, 8 H, CH_2), 3.54 (m, 8 H, OCH_2) ppm. ^{13}C{^{1}H}NMR (C_6D_6, internal TMS): δ = 25.7 (br., *C*Me$_3$), 25.9 (br., *C*Me$_3$), 32.6 (br., C*Me$_3$*), 33.0 (br., C*Me$_3$*), 25.1 (s, *C*H$_2$), 68.0 (s, O*C*H$_2$) ppm. ^{29}Si{^{1}H}NMR (C_6D_6, external TMS): δ = 30.8 (m, 2 SitBu$_3$), 17.8 (m, SitBu$_3$) ppm. ^{31}P{^{1}H}NMR (see Figure 2).

Synthesis of [(tBu$_3$Si)$_3$P$_5$Ag$_2$]$_2$: AgOCN (0.300 g, 2 mmol) was added to a solution of (tBu$_3$Si)$_3$P$_5$Na$_2$ (1 mmol) in 30 mL of tetrahydrofuran at –78 °C and stirred for 12 h. After warming to room temperature the solvent was removed in vacuo. The solid reaction product was extracted into 15 mL of toluene (brown solution). After filtration, [(tBu$_3$Si)$_3$P$_5$Ag$_2$]$_2$ was crystallized from the toluene filtrate at –25 °C. The NMR spectra of the filtrate show small signals which can be assigned to the bicyclo[2.1.0]pentaphosphane (tBu$_3$Si)$_3$P$_5$. Yield: 1.125 g (53%).

Selected Data for [(tBu$_3$Si)$_3$P$_5$Ag$_2$]$_2$: ^{1}H NMR (C_6D_6, internal TMS): δ = 1.38 (br., 27 H, tBu), 1.51 (br., 54 H, tBu) ppm. ^{13}C{^{1}H}NMR (C_6D_6, internal TMS): δ = 25.2 (br., *C*Me$_3$), 25.4 (br., *C*Me$_3$), 32.4 (br., C*Me$_3$*), 32.6 (br., C*Me$_3$*) ppm. ^{29}Si{^{1}H}NMR (C_6D_6, external TMS): δ = 32.2 (m, 2 SitBu$_3$), 18.9 (m, SitBu$_3$) ppm. ^{31}P{^{1}H}NMR (25 °C, C_6D_6, external H_3PO_4): δ = –97.2 (m, P_1, P_3), –160.6 (m, P_2), –252.8 (m, P_4, P_5) ppm.

Synthesis of the Bicyclo[2.1.0]pentaphosphane (tBu$_3$Si)$_3$P$_5$: TCNE (0.855 g, 6.39 mmol) in tetrahydrofuran (20 mL) was added to a solution of (tBu$_3$Si)$_3$P$_5$Na$_2$ (6.28 mmol) in 30 mL tetrahydrofuran at –78 °C and stirred for 5 h. After heating to room temperature the solvent was removed in vacuo. The solid reaction product was extracted into 30 mL of hexane (yellow solution). After filtration, (tBu$_3$Si)$_3$P$_5$ was crystallized from the hexane filtrate at –25 °C. Yield: 3.217 g (62%).

Selected Data for (tBu$_3$Si)$_3$P$_5$: Thermal decomposition of (tBu$_3$Si)$_3$P$_5$: 153 °C. ^{1}H NMR (C_6D_6, internal TMS): δ = 1.30 (br., 54 H, tBu), 1.29 (br., 27 H, tBu) ppm. ^{13}C{^{1}H}NMR (C_6D_6, internal TMS): δ = 26.0 (d, $^2J_{C,P}$ = 6.11 Hz, *C*Me$_3$), 26.5 (d, $^2J_{C,P}$ = 6.09 Hz, *C*Me$_3$), 26.7 (d, $^2J_{C,P}$ = 5.96 Hz, *C*Me$_3$), 31.9 (br., C*Me$_3$*), 31.4 (br., C*Me$_3$*), 32.8 (br., C*Me$_3$*) ppm. ^{29}Si{^{1}H}NMR (C_6D_6, external TMS): δ = 25.8 (m, SitBu$_3$), 24.0 (m, SitBu$_3$). 23.2 (m, SitBu$_3$) ppm. ^{31}P{^{1}H}NMR (25 °C, C_6D_6, external H_3PO_4): δ = –77.9 (m, $^1J_{P1,P5}$ = –154.1, $^1J_{P4,P5}$ = –143.4, $^2J_{P2,P5}$ = 115.5, $^2J_{P3,P5}$ = 44.0 Hz, P_5), –121.8 (m, $^1J_{P1,P3}$ = –115.3, $^1J_{P2,P3}$ = –231.6, $^1J_{P3,P4}$ = –236.7, $^2J_{P3,P5}$ = 44.0 Hz, P_3), –130.6 (m, $^1J_{P3,P4}$ = –236.7, $^1J_{P4,P5}$ = –143.4, $^2J_{P1,P4}$ = 12.0, $^2J_{P2,P4}$ = 13.4 Hz, P_4), –135.9 (m, $^1J_{P1,P2}$ = –193.3, $^1J_{P1,P3}$ = –115.3, $^1J_{P1,P5}$ = –154.1, $^2J_{P1,P4}$ = 12.0 Hz, P_1), –211.1 (m, $^1J_{P1,P2}$ = –193.3, $^1J_{P2,P3}$ = –231.6, $^2J_{P2,P4}$ = 13.4, $^2J_{P2,P5}$ = 115.5 Hz, P_2) ppm. $C_{36}H_{81}P_5Si_3$ (753.16): calcd. Thermolysis of $(t\mathrm{Bu_3Si})_3P_5$: A solution of $(t\mathrm{Bu_3Si})_3P_5$ (0.050g, 0.066 mmol) in 1 mL of C_6D_6 was heated at 120 °C for 24 h. The NMR spectra (^{1}H, ^{13}C, ^{31}P, ^{29}Si) showed only the signals of the bicyclo[1.1.0]tetraphosphane $(t\mathrm{Bu_3Si})_2P_4$ and the deuterated supersilylphosphane $t\mathrm{Bu_3SiPD_2}$. **$(t\mathrm{Bu_3Si})_2P_4$:** ^{1}H NMR (C_6D_6, internal TMS): δ = 1.21 (br., 6 *t*Bu) ppm. ^{13}C{^{1}H}NMR (C_6D_6, internal TMS): δ = 26.3 (br., *C*Me$_3$), 31.7 (br., C*Me$_3$*) ppm. ^{29}Si{^{1}H}NMR (C_6D_6, external TMS): δ = 16.4 (m, 2 Si*t*Bu$_3$) ppm. ^{31}P{^{1}H}NMR (25 °C, C_6D_6, external H_3PO_4): δ = –139.1 (t, $^1J_{P,P}$ = 100.5 Hz; PSi*t*Bu$_3$), –334.4 (t, $^1J_{P,P}$ = 100.5 Hz) ppm.

$t\mathrm{Bu_3SiPD_2}$: ^{1}H NMR (C_6D_6, internal TMS): δ = 1.11 (d, $^4J_{P,H}$ = 0.46 Hz; 3 *t*Bu) ppm. ^{13}C{^{1}H}NMR (C_6D_6, internal TMS): δ = 22.8 (d, $^2J_{C,P}$ = 6.14 Hz, *C*Me$_3$), δ = 30.9 (d, $^3J_{P,C}$ = 3.0 Hz, C*Me$_3$*) ppm. ^{29}Si{^{1}H}NMR (C_6D_6, external TMS): δ = 24.0 (d, $^1J_{P,Si}$ = 30.72 Hz, Si*t*Bu$_3$) ppm. ^{31}P{^{1}H}NMR (25 °C, C_6D_6, external H_3PO_4): δ = –268.86 (quint, $^1J_{P,D}$ = 29.43 Hz) ppm.

Reaction of $(t\mathrm{Bu_3Si})_3P_5$ with CF_3CO_2H: One drop of CF_3CO_2H was added to a solution of $(t\mathrm{Bu_3Si})_3P_5$ (0.026 g, 0.0340 mmol) in 1 mL of C_6D_6. The NMR spectra (^{1}H, ^{13}C, ^{31}P, ^{29}Si, ^{19}F) showed the signals of supersilylphosphenium trifluoroacetate $[t\mathrm{Bu_3SiPH_3}][CF_3CO_2]$, $t\mathrm{Bu_3SiO_2CCF_3}$, and P_4 as the main products.

$[t\mathrm{Bu_3SiPH_3}][CF_3CO_2]$: ^{1}H NMR ($C_6D_6$, internal TMS): δ = 0.97 (br., 3 *t*Bu) ppm. ^{13}C{^{1}H}NMR (C_6D_6, internal TMS): δ = 22.3 (br., *C*Me$_3$), 30.8 (br., C*Me$_3$*), 115.4 (q, $^1J_{C,F}$ = 284.6 Hz, *C*F$_3$), 159.3 (q, $^2J_{C,F}$ = 84.9 Hz, *C*O$_2$) ppm. ^{29}Si{^{1}H}NMR (C_6D_6, external TMS): δ = 18.3 (d, $^1J_{P,Si}$ = 24.3 Hz, Si*t*Bu$_3$).
$t\mathrm{Bu_3SiO_2CCF_3}$: ^{1}H NMR (C_6D_6, internal TMS): δ = 1.02 (s, 3 *t*Bu) ppm. ^{13}C{^{1}H}NMR (C_6D_6, internal TMS): δ = 23.2 (s, *C*Me$_3$), 29.2 (s, C*Me$_3$*), 114.8 (q, $^1J_{C,F}$ = 285.1 Hz, *C*F$_3$) 159.6 (q, $^2J_{CF}$ = 86.1 Hz, *C*O$_2$) ppm. ^{29}Si{^{1}H}NMR (C_6D_6, external TMS): δ = 22.8 (s, Si*t*Bu$_3$) ppm.

Photolysis of $[(t\mathrm{Bu_3Si})_3P_5Ag_2]_2$: A mixture of crystals of $[(t\mathrm{Bu_3Si})_3P_5Ag_2]_2 \cdot 2(C_6H_8)$ (0.044 g, 0.021 mmol) and 1 mL of C_6D_6 was irradiated at ambient temperature for 24 h. After irradiation the NMR spectra (^{1}H, ^{13}C, ^{31}P, ^{29}Si) of the reaction solution showed only the signals of the bicyclo[1.1.0]tetraphosphane $(t\mathrm{Bu_3Si})_2P_4$ and the supersilylphosphane $t\mathrm{Bu_3SiPH_2}$.

$(t\mathrm{Bu_3Si})_2P_4$: ^{1}H NMR (C_6D_6, internal TMS): δ = 1.21 (br., 6 *t*Bu) ppm. ^{13}C{^{1}H}NMR (C_6D_6, internal TMS): δ = 26.3 (br., *C*Me$_3$), 31.7 (br., C*Me$_3$*) ppm. ^{29}Si{^{1}H}NMR (C_6D_6, external TMS): δ = 16.4 (m, 2 Si*t*Bu$_3$) ppm. ^{31}P{^{1}H}NMR (25 °C, C_6D_6, external H_3PO_4): δ = –139.1 (t, $^1J_{P,P}$ = 100.5 Hz, PSi*t*Bu$_3$), –334.4 (t, $^1J_{P,P}$ = 100.5 Hz) ppm.

$t\mathrm{Bu_3SiPH_2}$: ^{1}H NMR (C_6D_6, internal TMS): δ = 1.09 (d, $^4J_{P,H}$ = 0.49 Hz, 3 *t*Bu) ppm. ^{13}C{^{1}H}NMR (C_6D_6, internal TMS): δ = 23.1 (d, $^2J_{C,P}$ = 5.86 Hz, *C*Me$_3$), 30.7 (d, $^3J_{P,C}$ = 2.44 Hz, C*Me$_3$*) ppm. ^{29}Si{^{1}H}NMR (C_6D_6, external TMS): δ = 24.1 (d, $^1J_{P,P}$ = 33.21 Hz, Si*t*Bu$_3$) ppm. ^{31}P{^{1}H}NMR (25 °C, C_6D_6, external H_3PO_4): δ = –263.82 (t, $^1J_{P,H}$ = 185.43 Hz) ppm.

X-ray Crystallographic Study: Data were collected on a Stoe-IPDS-II diffractometer or Siemens CCD three-circle diffractometer. An empirical absorption correction was performed using MULABS[21] and SADABS.[22] Structure solution was performed by direct methods,[23] and structure refinement by full-matrix least-squares on F^2 with SHELXL-97.[24] Hydrogen atoms were placed at ideal positions and refined with fixed isotropic displacement parameters using a riding model. Further details are given in Table 1.

CCDC-249924 (for **2Na**), -249925 (for **$[5aNa_2(THF)]_2$**), -253618 (for **$[5aAg]_2$**) and -249926 [for **6(Si*t*Bu$_3$)**] contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

Synthesis and Structure of the First η^3-1,2-Diphosphaallyl Complexes $[(\eta^5\text{-}C_5H_5)(CO)_2M\{\eta^3\text{-}RPPC(SiMe_3)_2\}]$ (M = Mo, R = *t*Bu, Cy; M = W, R = *t*Bu) from $[(\eta^5\text{-}C_5H_5)(CO)_2M{=}P{=}C(SiMe_3)_2]$ (M = Mo, W) and Inversely Polarized Phosphaalkenes $RP{=}C(NMe_2)_2$ (R = *t*Bu, Cy)

Lothar Weber,*[a] Gabriel Noveski,[a] Ulrich Lassahn,[a] Hans-Georg Stammler,[a] and Beate Neumann[a]

Keywords: Phosphavinylidene complexes / 1,2-Diphosphaallyl complexes / Phosphaalkenes / Molybdenum / Tungsten

Reaction of $[(\eta^5\text{-}C_5H_5)(CO)_2M{=}P{=}C(SiMe_3)_2]$ [where M = Mo (**2**), W (**5**)] with the phosphaalkene *t*BuP=C(NMe$_2$)$_2$ (**1a**) afforded the η^3-1,2-diphosphaallyl complexes $[(\eta^5\text{-}C_5H_5)(CO)_2M\{\eta^3\text{-}t\text{BuPPC}(SiMe_3)_2\}]$, [where M = Mo (**3a**); M = W (**6**)]. Similarly, **2** and CyP=C(NMe$_2$)$_2$ (**1b**; where Cy = cyclohexyl) gave rise to the formation of $[(\eta^5\text{-}C_5H_5)(CO)_2Mo\{CyPPC(SiMe_3)_2\}]$ (**3b**) by a phosphinidene transfer process. Small amounts of $[\{\eta^5\text{-}C_5H_5)(CO)_2Mo\}_2\{\eta^2{:}\eta^2\text{-}Cy_3P_5\}]$ (**4**) were formed as a minor product. However, treatment of **2** and **5** with HP=C(NMe$_2$)$_2$ (**1c**) yielded the complexes $[(\eta^5\text{-}C_5H_5)(CO)_2M\{\eta^2\text{-}(Me_3Si)_2CH\text{–}P{=}P\text{–}C(NMe_2)_2\}]$ [where M = Mo (**9**), W (**10**)]. The novel compounds **3a**, **3b**, **9** and **10** were characterized by means of spectroscopy (IR, ^{1}H, ^{13}C{^{1}H}, ^{31}P{^{1}H} NMR, MS). Moreover, the molecular structures of **3a**, **3b**, **4**, **6** and **10** were determined by X-ray diffraction analysis.

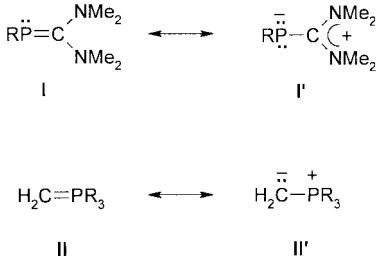
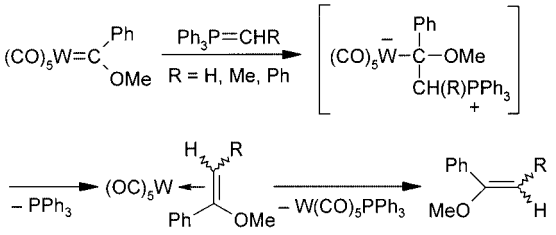
Introduction

Inversely polarized phosphaalkenes R–P=C(NMe$_2$)$_2$ (**I**) with an electron distribution $P^{\delta-}C^{\delta+}$ about the P=C double bond may be described by two canonical formulae (**I** and **I′**).[1] This situation may well be compared with the bonding in phosphorus ylides **II** (see Scheme 1).[2]



Scheme 1. Mesomeric structures of inversely polarized phosphaalkenes (**I**) and phosphorus ylides (**II**).

The chemical behavior of both classes of compounds (e.g. protonation, alkylation, complexation) can only be rationalized by using the zwitterionic structures **I′** and **II′**. Phosphorus ylides are prominent transfer reagents of alkylidene groups onto electrophilic functionalities (e.g. Wittig reaction). Phosphorus ylides undergo reaction with aryl(alkoxy)carbene complexes of the Fischer type to form enol ethers (see Scheme 2).[3]



Scheme 2.: Reaction of Fischer carbene complexes with Wittig reagents.

Recently, we discovered that inversely polarized phosphaalkenes R–P=C(NMe$_2$)$_2$ [where R = *t*Bu (**1a**), Me$_3$Si (**1b**)] react with aryl(alkoxy)carbene complexes affording novel phosphaalkene complexes by a formal transfer of the phosphinidene unit onto the carbene ligand (see Scheme 3).[4]

In contrast with this behavior, reaction of the carbene complex **III** (where Aryl = 2-MeOC$_6$H$_4$) with H–P=C(NMe$_2$)$_2$ (**1c**) yielded the phosphaalkene complex **IX** as a mixture of two isomers (see Scheme 4).[4]

In the present contribution we describe the smooth transfer of phosphinidene units from phosphaalkenes **1** to the electrophilic ligand in the phosphavinylidene complexes **2** and **5**.

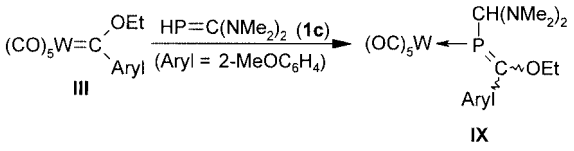
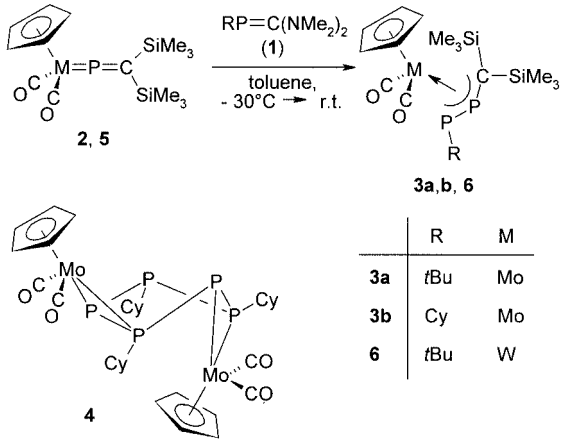


Scheme 4.: Formation of **IX**.

Results and Discussion

Reaction of the phosphavinylidene complex [(η⁵-C_5H_5)$(CO)_2$Mo=P=C$(SiMe_3)_2$] (**2**)[5] with an equimolar amount of phosphaalkene *t*BuP=C$(NMe_2)_2$ (**1a**)[4b] in toluene in the range of –30 °C to room temperature afforded the yellow complex **3a**, which was purified by column chromatography on silica (31% yield). The air- and moisture-sensitive compound is soluble in saturated hydrocarbons, ethereal and aromatic solvents (see Scheme 5). Similarly, compound **2** was converted into the orange product **3b** by treatment with CyP=C$(NMe_2)_2$ (**1b**) (49% yield). Reaction of (η⁵-C_5H_5)$(CO)_2$W=P=C$(SiMe_3)_2$ (**5**) with **1a** under comparable conditions led to the formation of complex **6** (18%yield).



Scheme 5.: Reaction of **2**, **5** with RP=C$(NMe_2)_2$ (R = *t*Bu, Cy).

Purification of **3b** was achieved by column chromatography and crystallization of the crude yellow product from *n*-pentane. A few crystals of the dinuclear complex **4** were obtained from the concentrated mother liquors by cooling. The $^{31}P\{^1H\}$ NMR spectra of **3a**, **3b** and **6** show doublets at δ = 18.1, 2.4 and –10.7 ppm for the terminal phosphorus atoms of the ligand whereas the central ones give rise to doublets at δ = –6.8, –32.9 and –61,6 ppm. The coupling constants $^1J_{PP}$ were determined as 407.0, 382.2 and 378.8 Hz, respectively. Only in the case of **3b**, the $^{13}C\{^1H\}$ NMR spectra displayed a doublet of doublets at δ = 43.8 ($^1J_{PC}$ = 94.4; $^2J_{PC}$ = 6.9 Hz), which we assigned to the carbon atom of the diphosphaallyl ligand. Two discrete doublets for the *ortho*- and *meta*-carbon atoms of the cyclohexyl substituent agree with a centre of chirality at the central P atom. The ^{13}C NMR resonances of the carbonyl ligands were observed as two singlets in **3a** (δ = 234.3, 235.5 ppm), as a doublet and a singlet at δ = 234.1 ($^2J_{PC}$ = 47.1 Hz) and δ = 235.6 ppm in **3b** and as a singlet and a multiplet at δ = 224.4 and 227.7 ppm in **6**. These resonances are shifted to lower field than those for precursors **2** (δ = 230.4 ppm)[5b] and **5** (δ = 218.9 ppm),[5b] indicating the improved donor capacity of the diphosphaallyl ligands. This is also mirrored by the carbonyl stretching frequencies in the IR spectra of **3a**, **3b** and **6**, which are observed as intense bands at $\tilde{\nu}$ = 1943, 1877 (**3a**); 1930, 1859 (**3b**) and 1938, 1851 cm^{-1} (**6**). The corresponding bands in the precursors **2** and **5** appear at $\tilde{\nu}$ = 1944, 1882 cm^{-1} (KBr) and 1952, 1880 cm^{-1} (*n*-hexane).[5b]

Single crystals of **3a** suitable for an X-ray diffraction study were grown from a diethyl ether/pentane mixture (1:9) at –30 °C (see Figure 1). Compound **6** is isostructural to **3a**, and only the latter will be discussed in detail.[21]

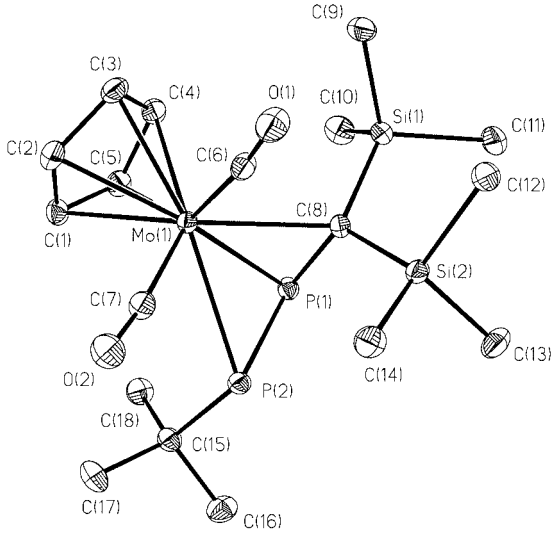


Figure 1. Molecular structure of **3a** in the crystal. Selected bond lengths [Å] and angles [°]: Mo(1)–C(6) 1.9595(12), Mo(1)–C(7) 1.9686(11), Mo(1)–C(8) 2.4372(11), Mo(1)–P(1) 2.4960(3), Mo(1)–P(2) 2.6756(3), P(1)–C(8) 1.7875(12), P(1)–P(2) 2.1234(4), P(2)–C(15) 1.8977(12), C(8)–Si(1) 1.9032(12), C(8)–Si(2) 1.9013(12), C(6)–Mo(1)–C(7) 80.84(5), C(6)–Mo(1)–C(8) 70.91(4), C(7)–Mo(1)–P(2) 64.05(4), C(8)–P(1)–P(2) 97.68(4), P(1)–P(2)–C(15) 103.75(4), P(1)–C(8)–Si(1) 108.09, P(1)–C(8)–Si(2) 123.52(6).

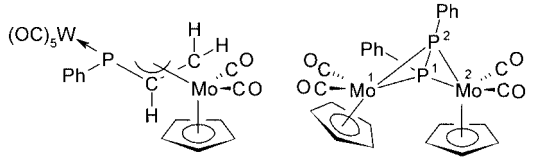
The analysis displays a molecule with a distorted pianostool geometry [P(2)–Mo(1)–C(7) 64.05(4)°, C(6)–Mo(1)–C(7) 80.84(5)°, C(6)–Mo(1)–C(8) 70.91(4)°] and two nearly linear carbonyl ligands [Mo(1)–C(6)–O(1) 173.84(10)°, Mo(1)–C(7)–O(2) 173.09(11)°]. The most interesting part of the molecule is the 1,2-diphosphaallyl ligand which is unsymmetrically linked to the metal atom in an η^3-fashion via bonds Mo(1)–P(1) [2.4960(3) Å], Mo(1)–P(2) [2.6756(3) Å] and Mo(1)–C(8) [2.4372(11) Å]. The latter bond length significantly exceeds the Mo(1)–C distances displayed by the [C_5H_5Mo] part of the molecule [2.3216(12)–2.3859(12) Å]. In the η^3-1-phosphaallyl complex **7** the observed bond lengths are Mo–C(1) 2.251(3) Å and Mo–C(2) 2.357(3) Å.[6] In complex **7** the Mo–C contact to the central C atom of the phosphaallyl ligand is markedly shorter than the corresponding bond to the terminal C atom. Similarly, in complex **3a** the bond length between the metal and the terminal phosphorus atom of the ligand Mo(1)–P(2) is strongly lengthened [2.6756(3) Å] relative to the Mo(1)–P(1) bond length [2.4960(3) Å]. In complex **7** a metal–phosphorus distance of 2.5343(8) Å was measured.[6] A comparable nonsymmetric ligation of the two phosphorus atoms is present in the "butterfly complex" **8**, featuring two short bonds Mo(1,2)–P(1) [2.466, 2.470 Å] and two longer bonds Mo(1,2)–P(2) [2.542, 2.546 Å].[7]



7 **8**

The distance P(1)–P(2) in **3a** [2.1234(4) Å] is intermediate between a double (ca. 2.00 Å)[8] and a single bond (ca. 2.22 Å).[9] In $Cp_2Mo(\eta^2\text{-}P_2H_2)$[10] and **8**, the P–P bond lengths amount to 2.146(3) Å and 2.136 Å, respectively. The bond length P(1)–C(8) in **3a** [1.7875(12) Å] exceeds that of a localized and unsupported P–C double bond (1.65–1.72 Å)[11] but is clearly shorter than a P–C single bond (av. 1.85 Å).[12] In **7** the corresponding bond length was determined as 1.755(3) Å. The η^3-1,2-diphosphaallyl ligand in **3a** is oriented in a fashion in which the terminal atoms P(2) and C(8) are directed towards the two carbonyl ligands. Moreover, the *tert*-butyl substituent at P(2) is located in a *syn* disposition with respect to P(1). The same is found for the atom Si(1). Atoms C(15) and Si(1) are nearly coplanar with the plane defined by the atoms P(2), P(1) and C(8) [torsion angles C(8)–P(1)–P(2)–C(15) = 170.3°; P(2)–P(1)–C(8)–Si(1) = –175.5°]. The substituent $Si(2)Me_3$ at C(8) is directed in an opposite way to the metal atom with a torsion angle P(2)–P(1)–C(8)–Si(2) = 47.1°.

Single crystals of **3b** were grown from pentane at +4 °C (see Figure 2). The analysis shows a molecule, the core of which is comparable to that of **3a** with the cyclohexyl substituent and the group $Si(2)Me_3$ directed towards the central atom P(2) of the η^3-diphosphaallyl ligand. All bond parameters are similar to those in **3a** and do not merit a detailed discussion.

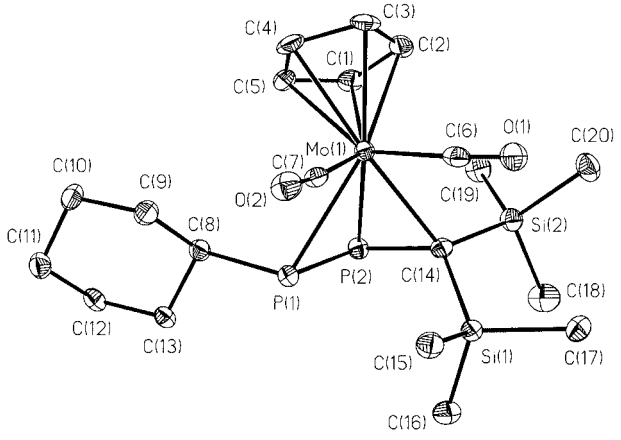


Figure 2. Molecular structure of **3b** in the crystal. Selected bond lengths [Å] and angles [°]: Mo(1)–C(6) 1.964(3), Mo(1)–C(7) 1.954(3), Mo(1)–C(14) 2.428(2), Mo(1)–P(1) 2.6538(6), Mo(1)–P(2) 2.4828(6), P(2)–C(14) 1.784(2), P(1)–C(8) 1.873(2), P(1)–P(2) 2.136(1), C(14)–Si(1) 1.907(2), C(14)–Si(2) 1.907(2); C(6)–Mo(1)–C(7) 79.51(9), C(6)–Mo(1)–C(14) 70.05(8), C(7)–Mo(1)–P(1) 64.63(7), C(14)–P(2)–P(1) 97.95(8), P(2)–P(1)–C(8) 101.18(8), P(2)–C(14)–Si(2) 110.28(12), P(2)–C(14)–Si(1) 120.21(12).

From the view-point of the rules according to Wade and Mingos, **3a** and **3b** display four skeleton atoms with 14 skeleton electrons and thus have to be regarded as *arachno* clusters.

A few crystals of compound **4** were collected from the concentrated *n*-pentane mother liquor at +4 °C (see Figure 3). The complex contains a nearly planar central 2,4,5-tri-cyclohexylcyclopentaphosphane-1,3-diyl ligand, which is

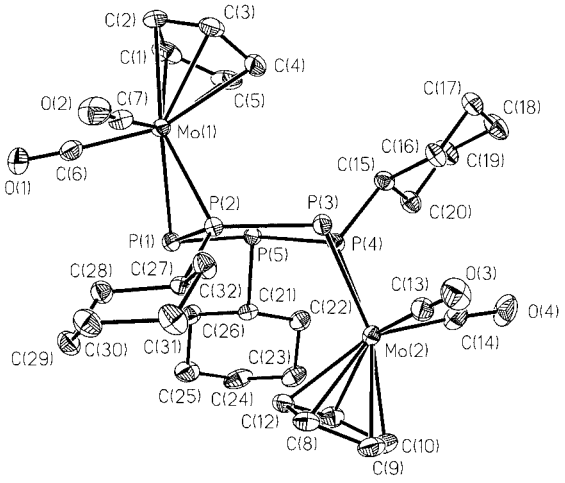

Figure 3. Molecular structure of **4** in the crystal. η^2-coordinated to the $Cp(CO)_2Mo(1)$ unit via P(1) and P(2) and to the $Cp(CO)_2Mo(2)$ group via atoms P(3) and P(4). Both metal complex fragments are located on opposite sides of the P_5 ring. The bonds Mo(1)–P(1) [2.6204(6) Å] and Mo(2)–P(3) [2.5964(6) Å] between the metal centers and the tricoordinate P atoms are significantly longer than the bonds between the metal centers and the four-coordinate phosphorus atoms [Mo(1)–P(2) 2.4272(6) Å; Mo(2)–P(4) 2.4480(6) Å]. The longer Mo–P contacts may result from repulsion between the lone pair of electrons at P(1) and P(3) and the electron-rich metal atoms.

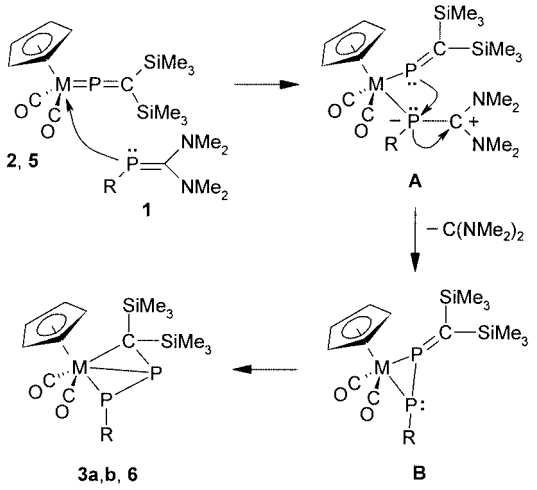
Interestingly, the η^2-ligated P–P bonds P(1)–P(2) [2.1224(8) Å] and P(3)–P(4) [2.1281(8) Å] are intermediate between double [2.00 Å][8] and single bonds [2.22 Å],[9] thus indicating some multiple bonding. In contrast to this, the endocyclic bonds P(2)–P(3) [2.1948(8) Å], P(4)–P(5) [2.2214(7) Å] and P(1)–P(5) [2.2320(8) Å] may be considered as single bonds. The cyclohexyl substituents at atoms P(2) and P(5) are directed to the face opposite Mo(1) but sterically approaching the $Mo(2)(CO)_2Cp$ moiety. To the best of our knowledge, this mode of coordination of a P_5 ring is without precedence.

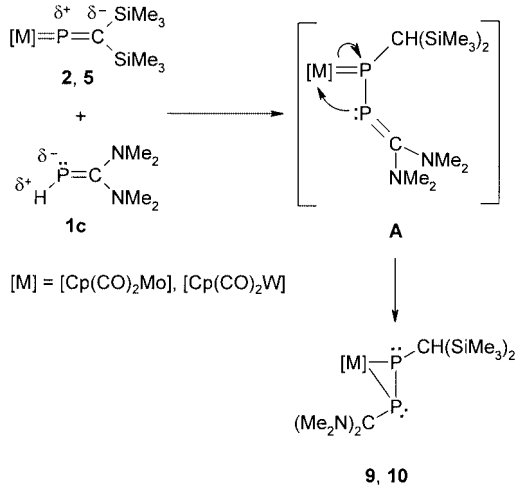
It is conceivable that the formation of complexes **3a**, **3b** and **6** is initiated by a nucleophilic attack of the phosphaalkene by its P atom on the metal centre of precursors **2** or **5** to give adduct **A**. Ring closure and extrusion of $C(NMe_2)_2$ would lead to metallodiphosphiranes **B**. A σ/π-type rearrangement of **B** furnishes the final products **3a**, **3b** and **6** (see Scheme 6). Previously, Mathey et al. observed an equilibrium between a vinylphosphenium tungsten complex and its η^3-phosphaallyl isomer.[6b]



Scheme 6. Proposed mechanism for the formation of **3a**, **3b** and **6**.

Reaction of 2a and 5 with $HP=C(NMe_2)_2$ (1c)

The phosphavinylidene complex **2** was treated with an equimolar amount of phosphaalkene $HP=C(NMe_2)_2$ (**1c**)[13] in diethyl ether in the range of –30 °C to room temperature. Workup by chromatography on a column packed with silica led to the isolation of the light yellow crystalline complex **9** in 21% yield. The corresponding reaction of the tungsten analog $[Cp(CO)_2W=P=C(SiMe_3)_2]$ (**5**) with **1c** was less straightforward and yielded only a few orange crystals of product **10** (see Scheme 7).



Scheme 7. Formation of **9** and **10**.

The products are very soluble in ethereal and aromatic solvents, whereas they appear to be nearly insoluble in saturated hydrocarbons. Compounds **9** and **10** are dicarbonyl(cyclopentadienyl) complexes featuring the yet unknown diphosphaallyl anion $[(Me_3Si)_2CH–P–P=C(NMe_2)_2]^-$ as an η^2 ligand. The $^{31}P\{^1H\}$ NMR spectra of **9** and **10** displayed AB spin systems at δ = –70 and –75 ppm ($^1J_{AB}$ = 421.9 Hz) and δ = –105.8 ($^1J_{WP}$ = 46.0 Hz) and –114.5 ppm ($^1J_{AB}$ = 400.0 Hz), respectively. In the ^1H NMR spectrum of **9**, the singlets at δ = 0.29, 0.51, 2.49 and 5.06 ppm are attributed to the CH and the Me_3Si groups of the $CH(SiMe_3)_2$ substituent, to the Me_2N unit and the C_5H_5 ligand, respectively. The ^{13}C NMR resonance of the carbonyl ligands of **9** was observed at δ = 203.7 ppm. In comparison with precursor **2** (δ = 230.4 ppm) this resonance is strongly shifted to high field. It is also obvious from the ν(CO) stretching frequencies in **9** ($\tilde{\nu}$ = 1889 s, 1803 cm^{-1}) and **2** (KBr, $\tilde{\nu}$ = 1944 s, 1882 cm^{-1}) that the novel ligand transfers more electron density onto the $[CpMo(CO)_2]$ unit than the phosphavinylidene ligand in **2**. Orange crystals of **10** suitable for X-ray diffraction analysis were grown from diethyl ether at 4 °C. The results of this study are shown in Figure 4, while selected bond lengths and bond angles are given in the caption. The compound consists of a central tungsten atom linked to a cyclopentadienyl ring, two terminal carbonyl ligands, and the η^2-$(Me_3Si)_2CH–P–P=C(NMe_2)_2$ diphosphaallylic ligand; the geometry around the tungsten atom is that of a "four-legged piano-stool" type. The W–P bond lengths [W(1)–P(1) 2.5352(7) Å, W(1)–P(2) 2.5695(7) Å] are not equivalent.

The longer bond is similar to the corresponding distances found in $[W(CO)_5(\mu,\eta^2{:}\eta^1{:}\eta^1)$-$P_2Cl_2\{W(CO)_5\}_2]$, that is, 2.573(4) and 2.582(4) Å.[14] According to structural work by Huttner et al.[15] or Mathey et al.[16] on $[W(CO)_5$-$(\mu,\eta^2{:}\eta^1{:}\eta^1)$-$P_2Ph_2\{W(CO)_5\}_2]$ the W–P bonds of the W–

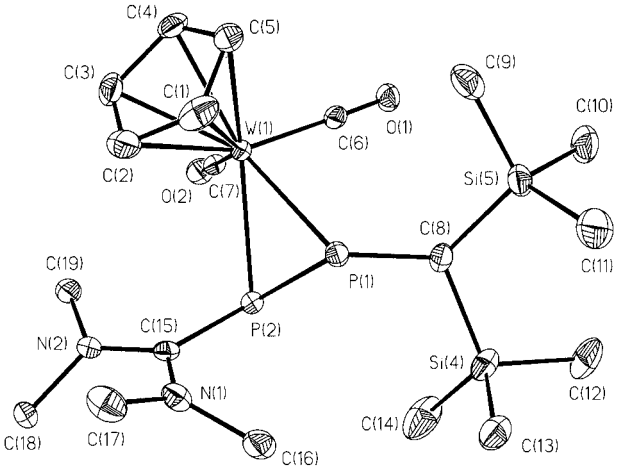

Figure 4. Molecular structure of **10** in the crystal. Selected bond lengths [Å] and angles [°]: W(1)–C(6) 1.946(3), W(1)–C(7) 1.957(3), W(1)–C(1–5) 2.337(3)–2.398(3), W(1)–P(1) 2.5352(7), W(1)–P(2) 2.5695(7), P(1)–P(2) 2.1739(9), P(1)–C(8) 1.889(3), C(8)–Si(4) 1.906(3), C(8)–Si(5) 1.916(3), P(2)–C(15) 1.878(3), N(1)–C(15) 1.342(3), N(2)–C(15) 1.356(3), N(1)–C(16) 1.472(3), N(1)–C(17) 1.477(4), N(2)–C(18) 1.478(3), N(2)–C(19) 1.468(3); C(6)–W(1)–C(7) 77.57(10), C(6)–W(1)–P(1) 84.84(7), C(7)–W(1)–P(2) 77.81(7), C(8)–P(1)–P(2) 107.60(9), P(1)–P(2)–C(15) 102.64(8), P(2)–C(15)–N(1) 123.15(19), P(2)–C(15)–N(2) 119.61(18), N(1)–C(15)–N(2) 117.1(2), C(8)–P(1)–P(2)–C(15) 150.4, P(2)–P(1)–C(8)–Si(4) –72.2, P(2)–P(1)–C(8)–Si(5) 160.0.

η^2-P_2Ph_2 unit are significantly longer [2.604 Å (av)] than in **10**. The elongation of the bond W(1)–P(2) with respect to the bond W(1)–P(1) may be the result of steric repulsion between the C_5H_5 ring and the bis(dimethylamino)carbenium unit. The P–P bond of 2.1739(9) Å is markedly longer than the bonds in complexes $[W(CO)_5(\mu,\eta^2{:}\eta^1{:}\eta^1)$-$P_2Cl_2\{W(CO)_5\}_2]$ [2.1460(6) Å] and $[W(CO)_5(\mu,\eta_2{:}\eta_1{:}\eta_1)$-$P_2Ph_2\{W(CO)_5\}_2]$ [2.140(15) Å[15] and 2.163(3) Å[16]]. It is possible to describe the bonding situation in **9** and **10** as that of a diphosphametallacyclopropane with essentially endocyclic single bonds, well aware of the fact that single bonds in cyclopropane derivatives are usually shorter than C–C bonds in unstrained C–C chains. The bond lengths P(1)–C(8) [1.889(3) Å] and P(2)–C(15) [1.878(3) Å] are as expected for single bonds. Carbon atom C(15) is trigonal planar, the formal positive charge of this carbenium center is stabilized by the planar atoms N(1) and N(2) by π conjugation, which becomes evident by the short C–N contacts [N(1)–C(15) 1.342(3) Å and N(2)–C(15) 1.356(3) Å]. Such a situation is well known from η^1 complexes of inversely polarized phophaalkenes.[1] The substituents at the P(2) unit are in an (*E*) disposition with the carbenium unit directed towards the $M(C_5H_5)$ fragment. The torsion angle C(8)–P(1)–P(2)–C(15) amounts to 150.4°. For a rationalization of the formation of **9** and **10** we postulate the formal addition of the P–H bond of the phosphaalkene **1c** to the P=C double bond of **2** and **5** to yield the intermediate **A**. Coordination of the second P atom to the metal atom with its lone pair gives the observed metalladiphosphiranes (see Scheme 7).

Conclusion

Inversely polarized phosphaalkenes $RP{=}C(NMe_2)_2$ serve as convenient sources of the phosphinidene unit PR, which can be transferred onto carbene ligands to afford η^1-phosphaalkene complexes, as was shown previously. In this paper, this synthetic principle is consistently extended to electrophilic phosphavinylidene complexes, which are cleanly converted into coordination compounds featuring the novel η^3-1,2-diphosphaallylic ligand. It is obvious that the performed synthetic method may easily be generalized with other electrophilic complexes containing vinylidene, phosphinidene, isocyanide and even carbonyl ligands. Moreover, it is tempting to also test this kind of transfer reactions with inversely polarized arsaalkenes.

Experimental Section

General: All manipulations were performed under dry, oxygen-free nitrogen using standard Schlenk techniques. Solvents were vigorously dried with an appropriate drying agent and freshly distilled under N_2 before use. The following compounds were prepared according to literature procedures: $[Cp(CO)_2M{=}P{=}C(SiMe_3)_2]$ M = Mo (**2**); M = W (**5**),[5] *t*BuP=$C(NMe_2)_2$ (**1a**),[4b] HP=$C(NMe_2)_2$ (**1c**);[13] $CyPH(SiMe_3)$,[17] $[(Me_2N)_2CSMe]I$.[18] IR spectra: Bruker FT-IR VECTOR 22. ^{1}H-, ^{13}C- and ^{31}P-NMR spectra: room temp., Bruker AM Avance DRX 500 (^{1}H, 500.13 Hz; ^{13}C, 125.75 MHz; ^{31}P, 202.46 MHz). References: $SiMe_4$ (^{1}H, ^{13}C), 85% H_3PO_4 (^{31}P). MS: Bruker Esquire Ion Trap mass spectrometer. Silica 60 (Merck) was purchased commercially.

CyP=C(NMe$_2$)$_2$ (1b): A solution of cyclohexyltrimethylsilylphosphane (18.8 g, 10.0 mmol) in 100 mL of THF was combined with an equimolar amount of a 1.6 M solution of *n*-butyllithium in *n*-hexane (6.25 mL, 10.0 mmol). The resulting slurry was added dropwise at 20 °C for 2 h to a slurry of *N*,*N*,*N*′,*N*′,*S*-pentamethylthiuronium iodide (27.4 g, 10.0 mmol) in THF (20 mL). Stirring was continued for 15 h. The solvent was removed in vacuo to afford an orange, viscous residue. The latter was triturated with *n*-pentane (150 mL) and filtered. The filter cake was washed with *n*-pentane (2 × 20 mL) and subsequently with diethyl ether until the washings became colorless. The orange-red filtrate was freed from solvents in vacuo at 20 °C. The remaining oil was distilled to give 12.0 g (56%) of **1b** as a yellow oil (b.p. ca. 100 °C at 1.5×10^{-4} bar). ^{1}H NMR (C_6D_6): δ = 1.9 (m, 11 H, C_6H_{11}), 2.56 (s, 12 H, NMe_2) ppm. ^{31}P{^{1}H} NMR (C_6D_6): δ = 57.5 (s) ppm. Because of the sensitivity of the phosphaalkene no reliable elemental analyses were obtained.

[Cp(CO)$_2$Mo{η^3-*t*BuPPC(SiMe$_3$)$_2$}] (3a): A solution of **1a** (0.24 g, 1.28 mmol) in toluene (10 mL) was added dropwise to a well-stirred, chilled solution (–30 °C) of **2** (0.52, 1.29 mmol) in toluene (15 mL). It was slowly warmed to ambient temperature and stirring was continued for 72 h. The reaction mixture was freed from solvent and volatile compounds. The black residue was transferred onto a column (d = 1.5 cm, l = 6 cm) charged with silica. A yellow phase was eluted with 40 mL of a diethyl ether/pentane mixture (1:9). Removal of solvents in vacuo afforded 0.20 g (31%) of orange crystalline **3a**. IR (KBr): $\tilde{\nu}$ = 1943 vs (CO), 1877 vs (CO), 1247 m [$\delta(SiMe_3)$], 847 m [$\rho(SiMe_3)$] cm^{-1}. ^{1}H NMR (C_6D_6): δ = 0.17 (d, $^4J_{PH}$ = 1.3 Hz, $SiMe_3$), 0.47 (d, $^4J_{PH}$ = 1.3 Hz, $SiMe_3$), 1.04 (dd, $^3J_{PH}$ = 10.8, $^4J_{PH}$ = 1.9 Hz, 9 H, *t*Bu), 4.85 (s, 5 H, Cp) ppm. ^{13}C{^{1}H} NMR (C_6D_6): δ = 4.5 (d, $^3J_{PH}$ = 9.8 Hz, $SiCH_3$), 8.8 (d, $^3J_{CP}$ = 11.3 Hz, $SiCH_3$), 32.0 [dd, J_{PC} = 14.4; 8.6 Hz, C(CH_3)$_3$],

32.6 [d, $^2J_{PC}$ = 47.1 Hz, $C(CH_3)_3$], 90.7 (s, C_5H_5), 234.3 (s, CO), 235.2 (s, CO) ppm. $^{31}P\{^1H\}$ NMR (C_6D_6): δ = 18.1 (d, $^1J_{PP}$ = 407 Hz, P-terminal), –6.8 (d, $^1J_{PP}$ = 407 Hz, P-central) ppm. $C_{18}H_{32}MoO_2P_2Si_2$ (494.50): calcd. C 43.72, H 6.52; found C 43.61, H 6.52.

[Cp(CO)$_2$Mo{η³-CyPPC(SiMe$_3$)$_2$}] (3b) and [{Cp(CO)$_2$Mo}$_2$-η²,η²-{P$_2$(PCy)$_3$}] (4): A solution of CyP=C(NMe$_2$)$_2$ (**1b**) (0.27 g, 1.32 mmol) in toluene (15 mL) was added dropwise at room temp. to a vigorously stirred solution of **2** (0.52 g, 1.32 mmol) in toluene (15 mL). Stirring was continued for 72 h. Solvent and volatile components were removed in vacuo to give a dark-brown solid residue. The latter was chromatographed on a column (l = 6.5 cm, d = 20 cm) filled with silica. An orange-yellow zone was eluted with *n*-pentane to afford 0.30 g (44%) of orange crystalline **3b** after recrystallization. A few orange crystals of compound **4** were isolated from the mother liquor. IR (KBr): $\tilde{\nu}$ = 1930 vs (CO), 1859 vs (CO), 1246 m [δ(SiMe$_3$)], 844 m [ρ(SiMe$_3$)] cm^{-1}. ^{1}H NMR (C_6D_6): δ = 0.18 (s, 9 H, SiMe$_3$), 0.45 (s, 9 H, SiMe$_3$), 0.88–1.90 (m, 11 H, C_6H_{11}), 4.79 (s, 5 H, C_5H_5) ppm. $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 3.90 (d, $^3J_{PC}$ = 9.2 Hz, SiMe$_3$), 8.1 (d, $^3J_{PC}$ = 10.3 Hz, $SiCH_3$), 26.0 (s, C–Cy), 27.1(d, $^1J_{PC}$ = 8.1 Hz, PCH), 32.9 (dd, J_{PC} = 14.4, 5.2 Hz, C–Cy), 37.3 (dd, J_{PC} = 15.5, 2.9 Hz, C–Cy), 42.7 (d, J_{PC} = 13.8 Hz, C–Cy), 43.0 (d, J_{PC} = 13.8 Hz, C–Cy), 43.8 (dd, $^1J_{PC}$ = 95.4, $^2J_{PC}$ = 6.9 Hz, PP*C*), 91.4 (s, C_5H_5), 234.1 (d, $^2J_{PC}$ = 47.1 Hz, CO), 235.6 (s, CO) ppm. $^{31}P\{^1H\}$NMR (C_6D_6): δ = –32.9 (d, $^1J_{PP}$ = 382.2 Hz, P-central), 2.4 (d, $^1J_{PP}$ = 383.2 Hz, P-terminal). $C_{20}H_{34}MoO_2P_2Si_2$ (520.54): calcd. C 46.15, H 6.58; found C 46.13, H 6.53.

[Cp(CO)$_2$W{η³-*t*BuPPC(SiMe$_3$)$_2$}] (6): A solution of **1a** (0.224 g, 1.3 mmol) in toluene (25 mL) was added dropwise at room temp. to a well-stirred solution of **5** (0.65 g, 1.3 mmol) in toluene (25 mL). After stirring for 48 h, solvent and volatile compounds were removed in vacuo. The dark-brown solid residue was chromatographed on silica with pentane, as described before. A yellow zone was eluted with pentane (230 mL). From this elute, compound **6** was isolated as a yellow solid (0.14 g, 18% yield). IR (KBr): $\tilde{\nu}$ = 1938 vs (CO), 1851 vs (CO), 1246 m [δ(SiMe$_3$)], 847 m [ρ(SiMe$_3$)] cm^{-1}. ^{1}H NMR (C_6D_6): δ = 0.16 (d, $^4J_{PH}$ = 1.3 Hz, 9 H, SiMe$_3$), 0.54 (s, 9 H, SiMe$_3$), 1.04 (dd, $^3J_{PH}$ = 10.7, $^4J_{PH}$ = 1.3 Hz, 9 H, *t*Bu), 4.89 (s, 5 H, C_5H_5) ppm. $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 4.2 (d, $^3J_{PC}$ = 9.2 Hz, SiMe$_3$), 9.0 (d, $^3J_{PC}$ = 11.5 Hz, SiMe$_3$), 32.1 (dd, J_{PC} = 14.4, 8.6 Hz, $C(CH_3)_3$), 32.3 (dd, J_{PC} = 49.6, 2.5 Hz, *C*-$(CH_3)_3$), 89.1 (s, C_5H_5), 224.4 (s, CO), 222.7 (m, CO) ppm. $^{31}P\{^1H\}$ NMR (C_6D_6): δ = –10.7 (d, $^1J_{PP}$ = 378.8 Hz, P-terminal), –61.6 (d, $^1J_{PP}$ = 378.8 Hz, P-central) ppm. MS (ESI): m/z = 583 [M + H$^+$], 555 [M – CO + H$^+$], 527 [M – 220 + H$^+$]. $C_{18}H_{32}O_2P_2Si_2W$ (582.41): calcd. C 37.12, H 5.54; found C 37.31, H 5.67.

[Cp(CO)$_2$Mo{η²-(Me$_3$Si)$_2$CH–P=PC(NMe$_2$)$_2$}] (9): A solution of **1c** (0.17 g, 1.31 mmol) in diethyl ether (10 mL) was added dropwise with vigorous stirring to a chilled solution (–30 °C) of **2** (0.53 g, 1.31 mmol) in diethyl ether (15 mL). The brown reaction mixture was warmed to ambient temp. and stirred for 24 h. Solvent and volatile components were removed in vacuo. The black, oily residue was transferred to a column (d = 1.5 cm, l = 6 cm) filled with silica. A yellow phase, eluted with 40 mL of a diethyl ether/*n*-pentane mixture (1:9) was discarded. Subsequently, a burgundy-red phase was eluted with 40 mL of diethyl ether. Removal of solvent led to the isolation of the orange solid **9**. IR (KBr): $\tilde{\nu}$ = 1889 (s, CO), 1803 s (CO), 1260 m [δ(SiMe$_3$)], 840 s [ρ(SiMe$_3$)] cm^{-1}. ^{1}H NMR (C_6D_6): δ = 0.29 (s, ^{1}H, $CHSi_2$), 0.51 (s, 18 H, SiMe$_3$), 2.49 (s, 12 H, NMe$_2$), 5.06 (s, 5 H, C_5H_5) ppm. $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 2.3 (d, $^2J_{CP}$ = 7 Hz, $SiCH_3$), 3.7 (d, $^2J_{CP}$ = 7 Hz, $SiCH_3$), 16.9 (d, $^1J_{CP}$ = 79.3 Hz, $CHSi_2$), 42.5 (br. s, NCH_3), 44.2 (br. s, NCH_3), 91.3 (s, C_5H_5), 203.7 (s, CO) ppm. $^{31}P\{^1H\}$ NMR (C_6D_6): δ = –70.0, –75.0 [AB-spin system, $^1J_{PP}$ = 421 Hz, (Me$_2$N)C*P* and *P*CH(SiMe$_3$)$_2$] ppm. X-ray Crystallography: Crystallographic data were collected with a Nonius Kappa CCD diffractometer with Mo-K_α radiation (graphite monochromator, λ = 0.71073 Å) at 100 K. Crystallographic programs used for the structure solution and refinement were from SHELXS-97,[19] SIR-97,[20] and SHELXL-97.[19] The structures were solved by Direct Methods and were refined by using full-matrix least squares on F^2 of all unique reflections with anisotropic thermal parameters for all non-hydrogen atoms. Hydrogen atoms were included at calculated positions with U(H) = 1.2 U_{eq} for CH_2 groups, U(H) = 1.5 U_{eq} for CH_3 groups. Crystal data of the compounds are listed in Table 1.[21]

Extended Structures and Magnetic Properties of Lanthanide–Copper Complexes with Picolinic Acids as Bridging Ligands

A-Qing Wu,[a] Guang-Hua Guo,[a] Chun Yang,[a] Fa-Kun Zheng,[a] Xi Liu,[a] Guo-Cong Guo,*[a] Jin-Shun Huang,[a] Zhen-Chao Dong,*[b] and Yoshihiko Takano[c]

Keywords: Heterometallic complexes / Magnetic properties / Crystal structures / Picolinic acid / Coordination polymers

The first examples of 3d–4f heterometallic complexes containing picolinic acid ligands were synthesized and characterized. Three series of complexes were obtained by the reaction of presynthesized "metallo ligands" $Cu(pic)_2$ and $Ln(ClO_4)_3$ in 2:1, 3:1, and 4:1 mole ratios. Complexes **1**–**3** (denoted as the first series), $[LnCu_2(pic)_4(H_2O)_6](ClO_4)_3{\cdot}H_2O$ (Ln = Sm, Nd, and Pr), are isomorphous and exhibit infinite 1D zigzag chain structures with rare earth ions in tricapped trigonal prismatic coordination. Complexes **4**–**10** (denoted as the second series), $[Ln_2Cu_5(pic)_{10}(H_2O)_8](ClO_4)_6{\cdot}2H_2O$ (Ln = Gd, Nd, Sm, Dy, Eu, Pr, and Yb), are isomorphous too, and exhibit extended 2D layered structures constituted by $Cu(pic)_2$ moieties bridging the zigzag chains. Complex **11** (denoted as the third-type complex), $\{NdCu(pic)_2[CO(NH_2)_2]_4(H_2O)_3\}(ClO_4)_3{\cdot}[Cu(pic)_2]_2$, exhibits another type of nearly linear chain structure with additional $Cu(pic)_2$ moieties trapped in the lattice by hydrogen bonds. Temperature-dependent magnetizations of complexes **2**–**4**, **6**, and **11** indicate that these complexes follow the Curie–Weiss paramagnetic behavior down to 5 K.

Introduction

Studies on the syntheses, structures and properties of 3d–4f heterometallic complexes are currently of great interest because they are good models for the investigation of the nature of the magnetic interactions between 3d and 4f metal ions in magnetic materials.[1] The main synthetic strategy for 3d–4f complexes is to use bridging ligands to link 3d and 4f paramagnetic building blocks to generate discrete polynuclear or extended topological complexes of high dimensionalities, while the latter may enhance and improve bulk magnetic properties due to the increased number of interacting neighbors.[2] Since the Ln and M (M = transition metal) ions may be connected through bidentate carboxylate groups, efforts have been made to use carboxylate acids and carboxylate-like betaines as ligands. Many such studies focused on discrete polynuclear complexes such as LnM, LnM_2, Ln_2M_2, Ln_2M_4, Ln_2M_8 etc.[3–7] In comparison, multidimensional heterometallic complexes are relatively rare,[8] and the synthesis of the multidimensional 3d–4f complexes is still a great challenge. An effective strategy employed is the use of relatively stable metal complexes containing potential coordinating atoms, that is "metallo ligands", to link rare earth ions to form polymeric networks. This strategy is called stepwise synthesis.[4b,9] In our laboratory, we have synthesized a series of polymeric 3d–4f complexes through the use of carboxylate groups as bridging units.[10] As an extension of this work, picolinic acid (Hpic) was used as a chelating ligand to make the $[COH(NH_2)_2]_2[Cu(pic)_2(ClO_4)_2]$ precursor by reaction with $Cu(ClO_4)_2$;[11] The monomer $Cu(pic)_2$ can be used as a "metallo ligand" to bind lanthanide metal ions for the preparation of complexes containing rare earth and transition metals. We have successfully obtained three novel series of one- and two-dimensional 3d–4f coordination polymers, namely, $[LnCu_2(pic)_4(H_2O)_6](ClO_4)_3{\cdot}H_2O$ [Ln = Sm (**1**), Nd (**2**), and Pr (**3**)] (1D), $[Ln_2Cu_5(pic)_{10}(H_2O)_8](ClO_4)_6{\cdot}2H_2O$ [Ln = Gd (**4**), Nd (**5**), Sm (**6**), Dy (**7**), Eu (**8**), Pr (**9**), and Yb (**10**)] (2D) and $\{NdCu(pic)_2[CO(NH_2)_2]_4(H_2O)_3\}(ClO_4)_3{\cdot}[Cu(pic)_2]_2$ (**11**) (1D). Although picolinic acid ligands were previously used to synthesize a number of metal complexes with transition metals or rare earths alone,[12] to the best of our knowledge, mixed multinuclear or multidimensional 3d–4f heterometallic complexes with picolinic acid ligands have not been reported. Herein, we report the syntheses and structures of **1**–**11**, as well as the magnetic properties of **2**–**4**, **6**, and **11**.

Results and Discussion

Syntheses

In order to construct such extended 3d–4f heterometallic structures, an assembly reaction is designed to have the $Cu(pic)_2$ complex acting as a 3d-component precursor and $Ln(ClO_4)_3$ as a 4f-component. The $Cu(pic)_2$ complex with two non-coordinated oxygen atoms of carboxyl groups may function as a "metallo ligand" to the Ln^{III} component. In the course of the investigation, the one-dimensional chain complexes **1**–**3**, $[LnCu_2(pic)_4(H_2O)_6](ClO_4)_3{\cdot}H_2O$, were obtained by the reaction of a 2:1 mole ratio of $Cu(pic)_2$ and $Ln(ClO_4)_3$ in C_2H_5OH/CH_3CN mixed solution at room temperature. Structural analyses indicate that the Ln^{III} atoms in **1**–**3** are surrounded by three $Cu(pic)_2$ moieties in a T-shape fashion to form a zigzag chain structure with large open spaces on the Ln ions (see Figure 1), which suggests that the Ln ions can be further coordinated by more $Cu(pic)_2$ ligands to form higher dimensional structures. On the basis of this idea, the mole ratio of $Cu(pic)_2$ to $Ln(ClO_4)_3$ was increased to 3:1, and seven expected two-dimensional heterometallic isomorphs, $[Ln_2Cu_5(pic)_{10}(H_2O)_8](ClO_4)_6{\cdot}2H_2O$ (**4**–**10**), were successfully obtained. However, we failed to synthesize a three-dimensional heterometallic complex by further increasing the mole ratio to 4:1 with the addition of more carbamide to maintain the pH at 5. Instead, a new structure with a nearly linear one-dimensional chain, $\{NdCu(pic)_2[CO(NH_2)_2]_4(H_2O)_3\}(ClO_4)_3{\cdot}[Cu(pic)_2]_2$ (**11**), showed up with "superfluous" $Cu(pic)_2$ moieties trapped in the lattice. The failure may be related to the large steric effect of $Cu(pic)_2$ ligands and competition coordination of carbamide.

Crystal Structures

The crystal structures of **1**–**11** were determined by single-crystal X-ray diffraction analyses. The crystallographic data are summarized in Table 1 for **1**–**3**, Table 2 for **4**–**6**, Table 3 for **7**–**9**, and Table 4 for **10** and **11**. Complexes **1**–**3** and **4**–**10** are isomorphous, so we chose complexes **1**, **4,** and **11** to

$[LnCu_2(pic)_4(H_2O)_6](ClO_4)_3\cdot H_2O$ [Ln = Sm (1), Nd (2), and Pr (3)]

Complex **1** consists of one-dimensional chain $\{[SmCu_2(pic)_4(H_2O)_6]^{3+}\}_\infty$ cations, $[ClO_4]^-$ anions, and lattice water molecules, as shown in Figure 1. The coordination polyhedron of the nine-coordinate Sm atom can be described as a distorted tricapped trigonal prism, which is constructed by three carboxylic oxygen atoms from $Cu(pic)_2$ moieties and six water oxygen atoms. The two trigonal surfaces are both defined by two water O atoms and one carboxylic oxygen atom of one $Cu(pic)_2$ moiety (O2W, O6W and O12 atoms for the top surface, and O3W, O5W and O32 atoms for the bottom surface), while the three capping atoms are occupied by the remaining three coordinated oxygen atoms (O1W, O4W and O22), the Sm^{III} atom deviating from the plane by 0.034(1) Å. The O(cap)-Sm-O(cap) bond angles are 119.41(6) ° for O1W–Sm1–O22, 124.8 ° for O1W–Sm1–O4W, and 115.72(6) ° for O22–Sm–O4W; these are close to 120 ° in a regular triangle. The average Sm–O(prism) bond

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

lengths of 2.471(2) Å are shorter than average Sm–O(cap) bond lengths of 2.556(2) Å, as in the case found in Ln complexes.[13,10] The Ln–O bond lengths in **1**–**3** become shorter with increasing atomic number of Ln, because of the lanthanide contraction.

The $Cu(pic)_2$ moieties are nearly coplanar with a maximal deviation of 0.093(4) Å of Cu(2) in the $Cu(2)(pic)_2$ moiety, in which the Cu^{II} atom possesses an approximate centro-symmetric square-planar coordination environment, chelated by two picolinic acid ligands through the nitrogen atoms and carboxylic oxygen atoms of pic ligands. Four donor atoms N_2O_2 of pic ligands form a rectangle with angles close to 90 ° (88.01–92.48 °). The average Cu–N and Cu–O bond lengths are 1.972(3) and 1.940(2) Å, respectively; these lengths are consistent with those found in the $Cu(pic)_2$ complex reported previously.[11]

The Sm^{III} centers act as two-connected nodes and are bridged by two uncoordinated carboxylic O atoms of $Cu(1)(pic)_2$ moieties to form an infinite zigzag 1D chain extending along the *b* direction with the angle Cu1–Sm–Cu1 = 78.474(4) ° and Sm–Cu1–Sm = 174.89(1)° (Figure 1). Simultaneously, there exists a kind of intramolecular hydrogen bond between the atoms O21 and O2W (O2W···O21#A = 2.725(2) Å, symmetry code #A: *x*, –0.5 + *y*, 0.5 – *z*) as shown in Figure 2. The $Cu(2)(pic)_2$ moiety acts as a terminal ligand coordinated to the Sm^{III} ion through one of two uncoordinated carboxylic oxygen atoms. The Sm^{III} and Cu^{II} ions in the chain are nearly coplanar. The shortest intrachain Sm···Cu, Cu···Cu, and Sm···Sm separations are 5.8524(6), 7.4301(3), and 11.7349(5) Å, respectively. The adjacent chains are linked into two-dimensional structure along the *c* direction by intermolecular hydrogen bonds of O1W···O42#B and O5W···O42#B (symmetry code #B: –*x*, 1 – *y*, –*z*) with an average length of 2.837(3) Å, as shown in Figure 2. In each layer, there also exist π–π stacking interactions between the pyridine rings of the terminal coordinated $Cu(2)(pic)_2$ moieties from the adjacent chains with the centroid-centroid distance of 3.766 Å and the dihedral angle of 2.39 °. The lattice water molecules and ClO_4^- anions with hydrogen bonds among them are located between the layers (O7W···O16#C = 3.046 Å; O7W···O33#C = 3.051 Å, symmetry code #C: *x* – 1, *y*, *z*). These lattice molecules form hydrogen bonds with the coordinated water molecules in the layer. These hydrogen bonds bridge the layers to form a three-dimensional framework along the *a* direction. Such π–π stacking and hydrogen bonding interactions lead to the stabilization of the crystal structure.

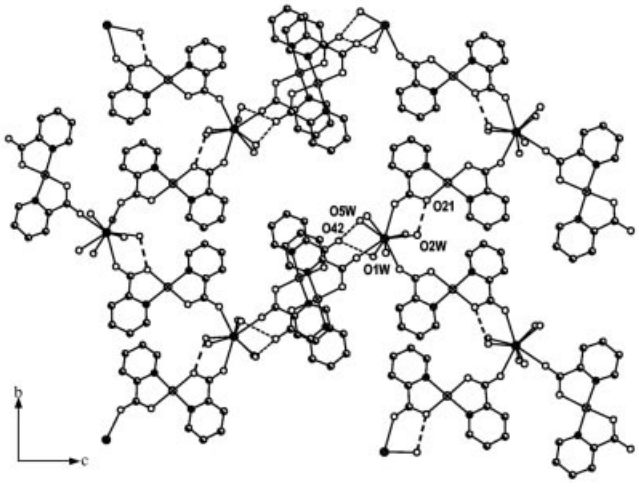

Figure 2. The hydrogen bonding and π–π stacking interactions link the chains into a layer-like structure in **1** along the *c* axis. The intermolecular hydrogen bonds are represented by the thin dashed lines and the intramolecular hydrogen bonds by the thick dashed lines.

[$Ln_2Cu_5(pic)_{10}(H_2O)_8$][$(ClO_4)_6$·$2H_2O$ [Ln = Gd (4), Nd (5), Sm (6), Dy (7), Eu (8), Pr (9) and Yb (10)]

Figure 3 shows the structure of **4** with the asymmetric atoms labeled. The coordination polyhedron of eight-coordinate Gd^{III} can be viewed as a distorted square antiprism, formed by the four carboxylic oxygen atoms from four picolinic acid ligands and four neutral water molecules. One square plane is defined by three water O atoms and one carboxylic oxygen atom of one $Cu(pic)_2$ moiety (O1W, O2W, O3W and O2) with a maximal deviation of 0.059 Å of the O2 atom, while the other square plane is defined by one water O atom and three carboxylic oxygen atoms from three different $Cu(pic)_2$ moieties (O4W, O22, O32, and O42) with a maximal deviation of 0.145 Å of the O22 atom. The O–O–O bond angles in the two square planes range from 81.31 to 98.45 °, they are close to 90 ° for a regular square. The two square planes are nearly parallel with the dihedral angle of 6.63 °. The Gd–O bond lengths are almost identical with a maximal difference of 0.14 Å.

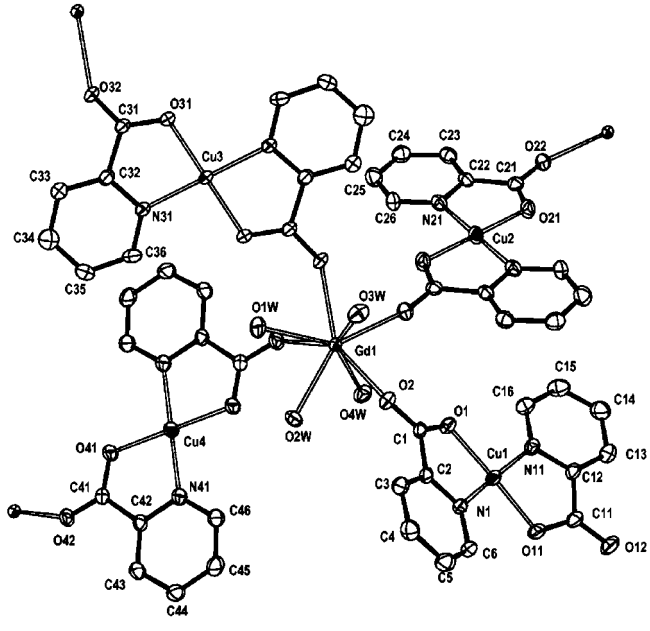

Figure 3. Basic structure unit of **4** with 30% thermal ellipsoids.

There are four $Cu(pic)_2$ units around each Gd^{III}, as shown in Figure 3. The Gd^{III} atoms are linked by the unco-

ordinated carboxylic O atoms of the $Cu(4)(pic)_2$ and the $Cu(3)(pic)_2$ moieties to form a pseudozigzag chain along the *b* direction. These chains are further bridged by $Cu(2)(pic)_2$ moieties through their two uncoordinated carboxylic O atoms along the *c* direction to form extended two-dimensional layers (Figure 4). The $Cu(1)(pic)_2$ moiety acts as a terminal ligand to Gd^{III} through coordination by one of its two uncoordinated carboxylic oxygen atoms. The closest intralayer separations of Sm···Cu, Cu···Cu, and Sm···Sm are 5.755, 7.45, and 11.510 Å, respectively. The adjacent layers are indirectly connected by hydrogen bonds consisting of coordinated water molecules and oxygen atoms of perchlorate anions or lattice water molecules located between layers, with O···O distances ranging from 2.743(5) to 3.002(6) Å. Simultaneously, the lattice water molecules and oxygen atoms of perchlorate anions form hydrogen bonds among themselves with an O···O distance of 2.933(6) Å.

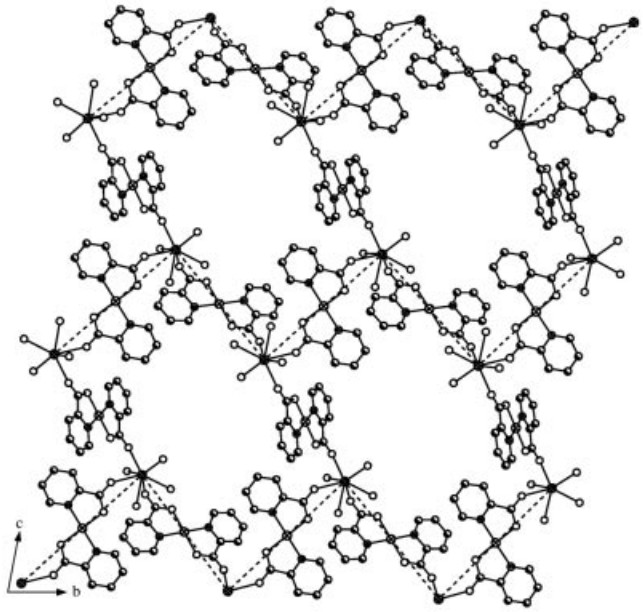

Figure 4. The layer sketch structure of **4** with the zigzag chain represented by dashed lines. Terminal $Cu(1)(pic)_2$ moieties were omitted for clarity.

{NdCu(pic)$_2$[CO(NH$_2$)$_2$]$_4$(H$_2$O)$_3$}(ClO$_4$)$_3$·[Cu(pic)$_2$]$_2$ (11)

Complex **11** consists of $\{NdCu(pic)_2[CO(NH_2)_2]_4(H_2O)_3\}_\infty$ cationic chains, ClO_4^- anions, and two lattice $Cu(pic)_2$ species. The coordination polyhedron of Nd^{III} can be viewed as a slightly distorted square antiprism, formed by two carboxylic oxygen atoms of two $Cu(pic)_2$ moieties (O2, O12), four oxygen atoms of carbamide (O13, O23, O33, O43), and two water oxygen atoms (O1W, O2W). One of the square planes consists of O12, O33, O43, and O2W atoms with a mean deviation of 0.01 Å from the least-squares plane, while O2, O13, O23, and O1W atoms form the other square plane with a mean deviation of 0.004 Å. The two square planes are nearly parallel with a dihedral angle of 5.75 °. The O–O–O bond angles in the two square planes range from 84.34 to 95.123 °. The Nd-O(pic) bond lengths are 2.496 Å for O2 and 2.537 Å for O12, which are longer than those in the reported Nd^{III} complex with the pic ligand (2.400–2.454 Å).[14] The Nd-O(carbamide) bond lengths are nearly identical, spanning a narrow range of 2.381–2.413 Å. The Nd^{III} ions are alternately bridged by $Cu(1)(pic)_2(H_2O)$ moieties through the O2 and O12 carboxylic oxygen atoms of picolinic acid ligands to form a nearly linear chain with a Cu–Nd–Cu angle of 171.32 ° and an Nd–Cu–Nd angle of 171.32 ° extending along the *a* direction, as shown in Figure 5. The closest intrachain Nd···Cu, Cu···Cu, and Nd···Nd separations are 5.326, 10.514, and 10.514 Å, respectively. Unlike the $Cu(pic)_2$ moieties in **1**–**10**, the Cu1 ion in **11** is five-coordinate by the four donor atoms of pic ligands, O1, O12, N1, and N11, and one water molecule (O3W) with a longer distance of 2.413(3) Å due to the Jahn–Tellller effects of the Cu^{II} atom. The O1, O12, N1, and N11 atoms form roughly a planar N_2O_2 with a maximal deviation of 0.145 Å and the copper ion is displaced from this plane toward the axial O3W by 0.183 Å. The average Cu1–O and Cu1–N bond lengths are 1.949 and 1.975 Å, respectively; these are also comparable with the normal value for copper(II) coordinated by pic ligands.[11]

The lattice $Cu(2)(pic)_2$ moieties and ClO_4^- ions are located between the chains. The lattice $Cu(2)(pic)_2$ moieties bridge the adjacent chains to form a double-chain structure through the hydrogen bonds of O21···O1W [2.914(2) Å], O32···O2W [2.738(3) Å] and O22···O3W [2.849(3) Å], while

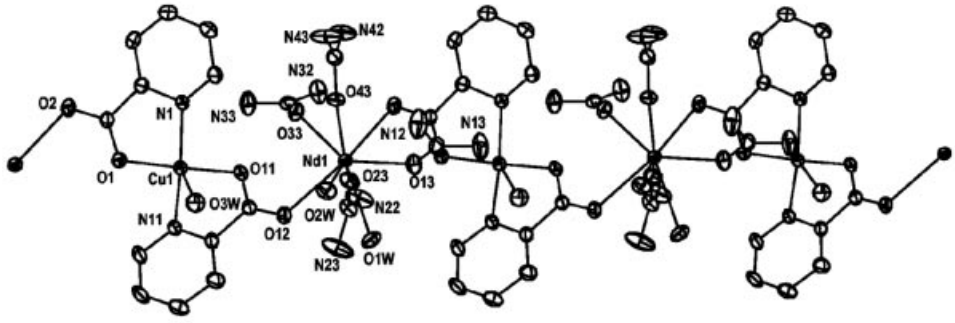

Figure 5. The nearly linear chain structure of **11** with 30% thermal ellipsoids.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the $Cl(3)O_4^-$ ions are anchored to the chains by hydrogen bonds of O34···O2W (2.797 Å) and O34···O3W (2.986 Å), as shown in Figure 6. In addition, there exist intramolecular hydrogen bonds between the N atom of one of coordinated urea molecules and O3W [N13···O2W = 3.023(3) Å] (Figure 6). The $Cu(3)(pic)_2$ moieties are located at two sides of the double chains.

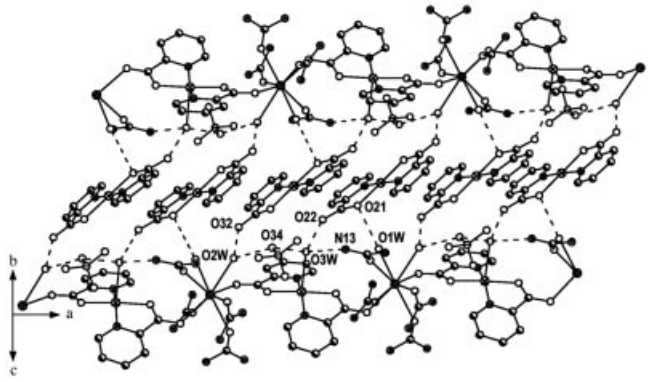

Figure 6. The double chain structure of **11** linked by the hydrogen bonds between lattice $Cu(2)(pic)_2$ moieties and carboxylic O atoms of single chains; the hydrogen bonds are represented by dashed lines.

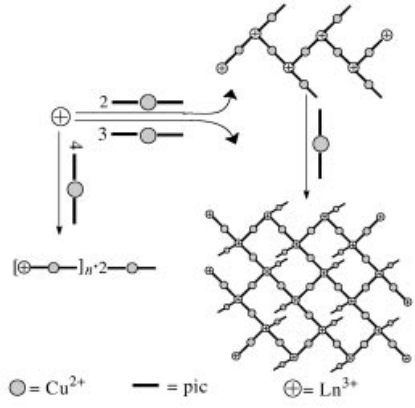
The relations of mole ratios of different reactants and structures in the three series of complexes are shown in Scheme 1. The layered structures of the second series of complexes may be considered as being composed of the $Cu(pic)_2$ moieties bridging the zigzag chains in a similar manner to that of the first series complex. The Cu–Gd–Cu and Gd–Cu–Gd bond angles of the zigzag chain in **4** are 79.504 and 180.00 °, respectively, which are comparable to those of the first series of complexes [78.474(4) and 174.89(1) °, respectively]. The third series complex is very different from the former two series, in the sense that the $Cu(pic)_2$ moieties bridge lanthanide atoms in a nearly linear chain, with additional $Cu(pic)_2$ moieties serving as lattice molecules located in the lattice.



Scheme 1. The relations of mole ratios of different reactants and structures.

Magnetic Properties of Complexes 2–4, 6, and 11

The variable-temperature magnetic susceptibilities for crystalline samples **2**–**4**, **6**, and **11** were measured in the 6–300 K temperature range with an applied field of 1 T. Table 5 shows the non-linear fitting data to $\chi_M = C/(T - \theta) + \chi_0$ above 50 K and the effective magnetic moments, μ_{eff}, of all complexes, in which μ_{eff} is defined as $2.828C^{1/2}\mu_B$, χ_M the molar magnetic susceptibility, C the Curie constant, θ the Weiss constant, and χ_0 the background susceptibility. A Curie–Weiss paramagnetic behavior is observed for all these compounds. The observed effective magnetic moment for each compound is very close to the theoretical value at 293 K, expected for a coupling-free system of isolated Ln^{III} and Cu^{II} ions, which confirms the assignment of oxidation states as judged by the neutrality requirement. As shown in Figure 7, upon cooling, the $\chi_M'T$, where $\chi_M' = \chi_M - \chi_0$, decreases gradually from 300 to 15 K for all complexes. The nature of such antiferromagnetic-like behavior remains to be clarified for 4f–3d compounds, but it may be related to

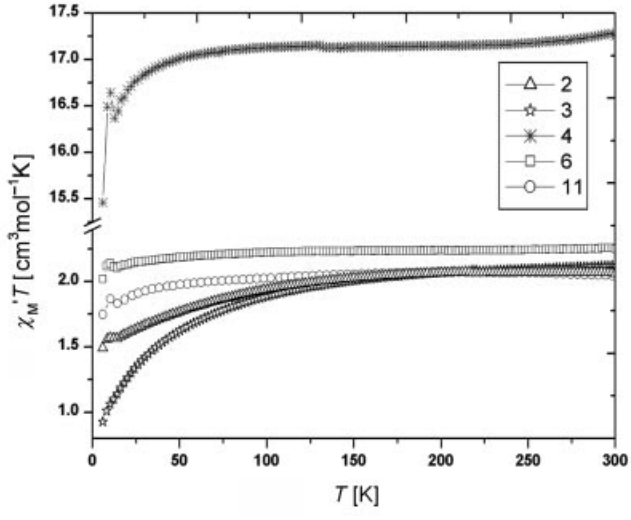


Figure 7. Thermal dependence of $\chi_M'T$ for complexes **2**–**4**, **6** and **11**.

the progressive thermal depopulation of the Ln^{III} Stark components and a possible the Ln^{III}–Cu^{II} interaction.[15] Because of the large separation between the Ln^{III} ions and the well-shielded 4f orbitals by the outer shells of 5s and 5p orbitals as well as relatively low covalence of the lanthanide-to-ligand bonds, the Ln–Ln interactions are expected to be negligibly small. The origin of the small bumps around 15 K for **2**, **4**, **6**, and **11** is still unclear, though the possibility of a systematic error cannot be completely excluded. To date, the understanding of the magnetic interactions containing rare-earth ions in molecular magnets is still a challenge, particularly when the contribution of the first-order orbital momentum is involved. Further experiments are needed for better understanding of the nature of the 4f–3d magnetic interactions in these systems.

Conclusion

In summary, we have demonstrated a facile and controllable approach to 3d–4f heterometallic extended framework complexes. Firstly, we obtain one-dimensional array complexes in a T-shape fashion with a large open space on the other side. The introduction of more $Cu(pic)_2$ precursors into this open space leads to the formation of higher dimensional structures. A series of two-dimensional 3d–4f heterometallic complexes have been obtained in this way by increasing the mole ratio of metal complex precursor to Ln^{III} from 2:1 to 3:1. However, increasing the mole ratio further to 4:1 failed to yield three-dimensional heterometallic complexes, probably because of large steric effects of $Cu(pic)_2$ precursors and the competitive coordination of carbamide. Instead, an unexpected nearly linear heterometallic chain emerged. The present work may provide a useful approach to tuning structural dimensionality and thus magnetic properties through reactant mole ratios.

Experimental Section

Materials and Measurement: All starting reagents, except for $Ln(ClO_4)_3$ and $Cu(ClO_4)_2$, were commercial grade materials and used as received. $Ln(ClO_4)_3$ and $Cu(ClO_4)_2$ were prepared by the reactions of Ln_2O_3 or CuO and perchloric acid in aqueous solution. Elemental analyses (C, H, N) were performed with an Elementar Vario ELIII analyzer. IR spectra were measured on KBr pellets with a Nicolet Magna 750 FTIR spectrometer in the range of 400–4000 cm^{-1}. Magnetic susceptibilities of complexes **2**–**4**, **6**, and **11** were measured by using a Quantum Design SQUID magnetometer in the temperature range 6–300 K at a field of 1 T. The raw data were corrected for the magnetization of the sample holder.

Syntheses: *Caution!* Although we have experienced no problems in handling metal perchlorates, these should be handled with great caution because of the potential for explosion.

Synthesis of the $Cu(pic)_2$ Complex Precursor: The mononuclear precursor $[COH(NH_2)_2]_2[Cu(pic)_2(ClO_4)_2]$ was obtained according to the literature.[11]

Preparations of $[LnCu_2(pic)_4(H_2O)_6](ClO_4)_3\cdot H_2O$ [Ln = Sm (1), Nd (2), and Pr (3)]: A mixture of $Cu(pic)_2$ precursor (0.630 g, 1 mmol) and $Ln(ClO_4)_3$ aqueous solution (0.5 mL, 1 M) was added into C_2H_5OH/CH_3CN (volume ratio 1:1) solution (40 mL), followed by the addition of carbamide to adjust pH = 5, and the solution was stirred thoroughly at room temperature for 12 h and then filtered. The filtrate was concentrated to 20 mL and allowed to stand at room temperature. Deep-blue prismatic crystals were obtained after a few days. Yield: 52.5% (based on Sm) for **1**; 59.3% (based on Nd) for **2**; 62.8% (based on Pr) for **3**. IR (KBr): 1626 (vs), 1598 (vs), 1572 (s), 1481 (w), 1450 (w), 1404 (s), 1386 (m), 1298 (w), 1269 (w), 1144 (vs), 1115 (vs), 1089 (vs), 1053 (m), 1032 (w), 860 (w), 766 (m), 694 (m), 660 (w), 626 (m), 561 (w), 463 (w) cm^{-1} for **1**; 1625 (vs), 1598 (vs), 1569 (vs), 1481 (w), 1450 (w), 1404 (s), 1297 (w), 1269 (w), 1141 (vs), 1113 (vs), 1091 (vs), 1051 (m), 1031 (w), 860 (w), 767 (m), 692 (m), 659 (w), 626 (m), 561 (w), 461 (w) cm^{-1} for **2**. 1629 (vs), 1598 (vs), 1569 (s), 1481 (w), 1450 (w), 1404 (s), 1297 (m), 1268 (w), 1143 (vs), 1114 (vs), 1089 (vs), 1051 (m), 1030 (w), 858 (w), 765 (m), 694 (m), 657 (w), 626 (m), 563 (w), 460 (w) cm^{-1} for **3**. **1**: calcd. C 24.22, H 2.54, N 4.71; found C 24.25, H 2.58, N 4.70. **2**: calcd. C 24.34, H 2.89, N 4.73; found C 24.11, H 2.60, N 4.69. **3**: calcd. C 24.41, H 2.90, N 4.74; found C 24.32, H 2.57, N 4.67.

Preparations of $[Ln_2Cu_5(pic)_{10}(H_2O)_8](ClO_4)_6\cdot 2H_2O$ [Ln = Gd (4), Nd (5), Sm (6), Dy (7), Eu (8), Pr (9) and Yb (10)]: The second series complexes were prepared as mentioned above but the mole ratio of $Cu(pic)_2$ to $Ln(ClO_4)_3$ was changed to 3:1. Deep-blue prismatic crystals were obtained after a few days. Yield: 43.5% (based on Gd) for **4**; 48.3% (based on Nd) for **5**; 41.7% (based on Sm) for **6**; 35.6% (based on Dy) for **7**; 56.9% (based on Eu) for **8**; 42.6% (based on Pr) for **9**; 51.2% (based on Yb) for **10**. IR (KBr): 1631 (vs), 1599 (vs), 1570 (vs), 1481 (m), 1452 (w), 1404 (vs), 1390 (vs), 1352 (m), 1298 (s), 1267 (w), 1242 (w), 1144 (s), 1117 (vs), 1088 (vs), 1053 (s), 1033 (m), 864 (w), 831 (w), 771 (w), 762 (m), 713 (m), 696 (m), 659 (w), 626 (m), 565 (w), 469 (w) cm^{-1} for **4**; 1632 (vs), 1599 (vs), 1570 (vs), 1481 (m), 1452 (w), 1402 (s), 1389 (s), 1352 (m), 1298 (m), 1269 (w), 1242 (w), 1142 (s), 1115 (vs), 1090 (vs), 1051 (s), 1032 (m), 864 (w), 831 (w), 762 (m), 713 (m), 696 (m), 660 (w), 625 (m), 563 (w), 469 (w) cm^{-1} for **5**; 1627 (vs), 1599 (vs), 1570 (vs), 1481 (m), 1452 (w), 1402 (vs), 1389 (s), 1352 (s), 1297 (s), 1269 (m), 1242 (w), 1112 (vs), 1089 (vs), 1051 (s), 1032 (m), 863 (w), 831 (w),773 (m), 762 (m), 711 (m), 696 (m), 657 (w), 624 (m), 561 (w), 470 (w) cm^{-1} for **6**. 1627 (vs), 1602 (vs), 1569 (vs), 1482 (m), 1451 (w), 1402 (s), 1385 (s), 1354 (m), 1299 (m), 1265 (w), 1241 (w), 1143 (vs), 1115 (vs), 1088 (vs), 1052 (s), 1032 (m), 865 (w), 833 (w), 772 (m), 762 (m), 713 (m), 696 (m), 658 (w), 624 (m), 563 (w), 468 (w) cm^{-1} for **7**. 1630 (vs), 1600 (vs), 1570 (vs), 1480 (m), 1455 (w), 1402 (s), 1388 (s), 1354 (m), 1295 (m), 1267 (w), 1240 (w), 1145 (vs), 1110 (vs), 1092 (vs), 1054 (s), 1032 (m), 867 (w), 829 (w), 772 (m), 762 (m), 715 (m), 696 (m), 658 (w), 627 (m), 561 (w), 467 (w) cm^{-1} for **8**. 1633 (vs), 1598 (vs), 1571 (vs), 1481 (m), 1452 (w), 1401 (s), 1390 (s), 1352 (m), 1299 (m), 1269 (w), 1243 (w), 1154 (vs), 1111 (vs), 1091 (vs), 1052 (s), 1033 (m), 864 (w), 831 (w), 773 (m), 762 (m), 713 (m), 697 (m), 659 (w), 623 (m), 562 (w), 469 (w) cm^{-1} for **9**. 1632 (vs), 1601 (vs), 1573 (vs), 1479 (m), 1450 (w), 1410 (s), 1386 (s), 1286 (m), 1267 (w), 1242 (w), 1144 (vs), 1113 (vs), 1086 (vs), 1051 (m), 1032 (w), 862 (w), 837 (w), 762 (m), 694 (m), 650 (w), 625 (m), 561 (w), 463 (w) cm^{-1} for **10**. **4**: calcd. Preparation of $\{NdCu(pic)_2[CO(NH_2)_2]_4(H_2O)_3\}(ClO_4)_3\cdot[Cu(pic)_2]_2$ (11): The procedure of synthesis for the third series complex is similar to that for the first series compounds, but the mole ratio of $Cu(pic)_2$ to $Ln(ClO_4)_3$ is 4:1. Deep-blue prismatic crystals were obtained after a few days. Yield: 46.1% (based on Nd). IR (KBr): 1700 (m), 1660 (s), 1633 (vs), 1604 (vs), 1572 (m), 1480 (m), 1448 (w), 1406 (w), 1371 (s), 1358 (m), 1300 (m), 1290 (w), 1267 (w), 1242 (w), 1146 (s), 1117 (s), 1086 (s), 1049 (m), 1032 (w), 858 (w), 769 (w), 762 (w), 714 (w), 694 (m), 660 (w), 627 (m), 461 (w) cm^{-1}. Calcd. C 28.94, H 2.79, N 11.81; found C 28.89, H 2.77, N 11.78.

X-ray Crystallographic Studies. The crystal structures of the complexes were studied by single-crystal X-ray diffraction analyses. Data collections were performed at 293(2) K with a Siemens SMART CCD diffractometer for **1**–**3**, and **5**–**10** with graphite monochromatic Mo-K_α radiation (λ = 0.71073 Å),[16] with a Rigaku AFC7R diffractometer for **4** with graphite-monochromatic Mo-K_α radiation (λ = 0.71073 Å),[17] and a Rigaku Mercury CCD for **11** with graphite monochromatic Mo-K_α radiation (λ = 0.71073 Å).[18] The structures were solved by direct methods, the positions of the metal atoms were calculated by using the SIEMENS SHELXTL Version 5.0 package of crystallographic software.[19] The remaining non-hydrogen atoms were located by successive different Fourier syntheses. Hydrogen atoms were added according to theoretical models. The structures were refined using full-matrix least-squares refinement on F^2. All non-hydrogen atoms were refined anisotropically. Pertinent crystal data and structure refinement results for the complexes are listed in Table 1 for **1**–**3**, Table 2 for **4**–**6**, Table 3 for **7**–**9**, and Table 4 for **10** and **11**.

CCDC-237564 to -237574 (for **1**–**11**), contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Synthesis and Reactions of Mixed N,P Ligands

Richard J. Bowen,*[a,b] Manuel A. Fernandes,[a] Patricia W. Gitari,[a] Marcus Layh,*[a] and Richard M. Moutloali[a]

Keywords: Cyclic phosphonium salts / Gold phosphane complexes / β-Keto thiophosphane oxide / Keto-enol / Imine-enamide tautomerism

The gold complexes [RN=C(R′)CH(R)PPh$_2$(AuCl)] (**6a**, R′ = *t*Bu; **6b**, R′ = Ad; R = SiMe$_3$) were synthesised from the ketimines RN=C(R′)CH(R)PPh$_2$ (**2a**, R′ = *t*Bu; **2b**, R′ = Ad; R = SiMe$_3$) and Me$_2$SAuCl. The hydrolysis of the complexes to [H$_2$NC(R′)=CHPPh$_2$(AuCl)] (**8a**, R′ = *t*Bu; **8b**, R′ = Ad) in protic solvents was studied and the reaction intermediate [H(R)NC(*t*Bu)=CHPPh$_2$(AuCl)] (**7a**) was isolated. The ketimines were further reacted with PhPCl$_2$ to the cyclic phosphonium salts [Ph$_2$PP(Ph)N(H)C(R′)=CH]X (**3a**, R′ = *t*Bu, X = Cl; **3c**, R′ = Ad, X = Cl; **3d**, R′ = Ad, X = BPh$_4$) and in the case of **3a** oxidised with sulfur to give the ring-opened β-keto thiophosphane oxide Ph$_2$P(S)CH$_2$C(O)*t*Bu (**9**). All compounds were fully characterised by NMR spectroscopy and in the case of **6b**, **8a** and **9** by X-ray crystallography.

Introduction

While the use of 1-azaallyllithium complexes as ligand transfer agents has received considerable attention,[1] the development of their utility in the context of phosphorus chemistry is in its infancy. In two recent papers,[2,3] it was shown that treatment of the ketimine Me$_3$SiN=C(*t*Bu)-CH(SiMe$_3$)PPh$_2$ (**2a**) with R′′′PCl$_2$ or PCl$_3$ gave the cyclic phosphonium salts [Ph$_2$PP(R′′′)N(H)C(*t*Bu)=CH]Cl **3** (**3a**, R′′′ = Ph; **3b**, R′′′ = Et) and [Ph$_2$PP(Cl)N(R)C(*t*Bu)=CH]-Cl (R = SiMe$_3$) **4**, respectively (Scheme 1). Conversely, treatment of the related ketimine Me$_3$SiN=C(*t*Bu)-CH(SiMe$_3$)$_2$ (**2c**) with PCl$_3$ generated the *trans*-1,3,2,4-diazadiphosphetidine **5** in moderate yield (Scheme 1). The key ketimines **2a** and **2c** were formed by the reactions of the 1-azaallyl RNC(*t*Bu)C(Li)HR (**1a**) with Ph$_2$PCl or CF$_3$SO$_3$R (R = SiMe$_3$), respectively.[2] The successful preparation of compounds such as **1** is dependent on the availability of suitable 1-azaallyl precursors which react preferentially as *C*-centred rather than *N*-centred nucleophiles.[4] For an ambidentate N,C-monoanionic ligand, *C*- over *N*-centred nucleophilicity is often favoured by utilising solvent-free 1-azaallyllithium precursors.[4] The presence of donor solvents such as tetramethylethylenediamine significantly enhances N-nucleophilicity. In preliminary studies, the solvent-free 1-azaallyl, RNC(Ad)C(Li)HR (Ad = adamantyl) (**1b**), was prepared by the reaction of LiCHR$_2$ and AdCN in pentane under ambient conditions.[1] Consequently, it was envisaged that **1b** could be utilised as a *C*-centred nucleophile to prepare adamantyl derivatives of **3**. This present study was stimulated by the emergence of interest in lipophilic cations as a new class of antitumour drugs with the potential to selectively target mitochondria in tumour cells.[5] Several structurally diverse lipophilic cations have demonstrated strong activity by concentrating in mitochondria, for example, rhodamine 123,[6] dequalinium,[7] pyronine Y,[8] ditercalinium,[9] AA-1[10] and MKT-077,[11] the latter having been advanced to phase I clinical trials. Several classes of lipophilic cations have demonstrated that antitumour selectivity is increased as the lipophilic-hydrophilic balance is varied (e.g. bisquaternary ammonium heterocycles,[12] [Au(P-P)$_2$]$^+$, where P-P is a bisphosphane[5,13] and triarylalkylphosphonium salts[14]). Consequently, herein the preparation of lipophilic cations is reported, that is, the cyclic phosphonium salts derived from **1** and chlorophosphane precursors. The chemistry of formation and stability of these compounds is presented with a view of evaluating their potential as a new class of antitumour agent.

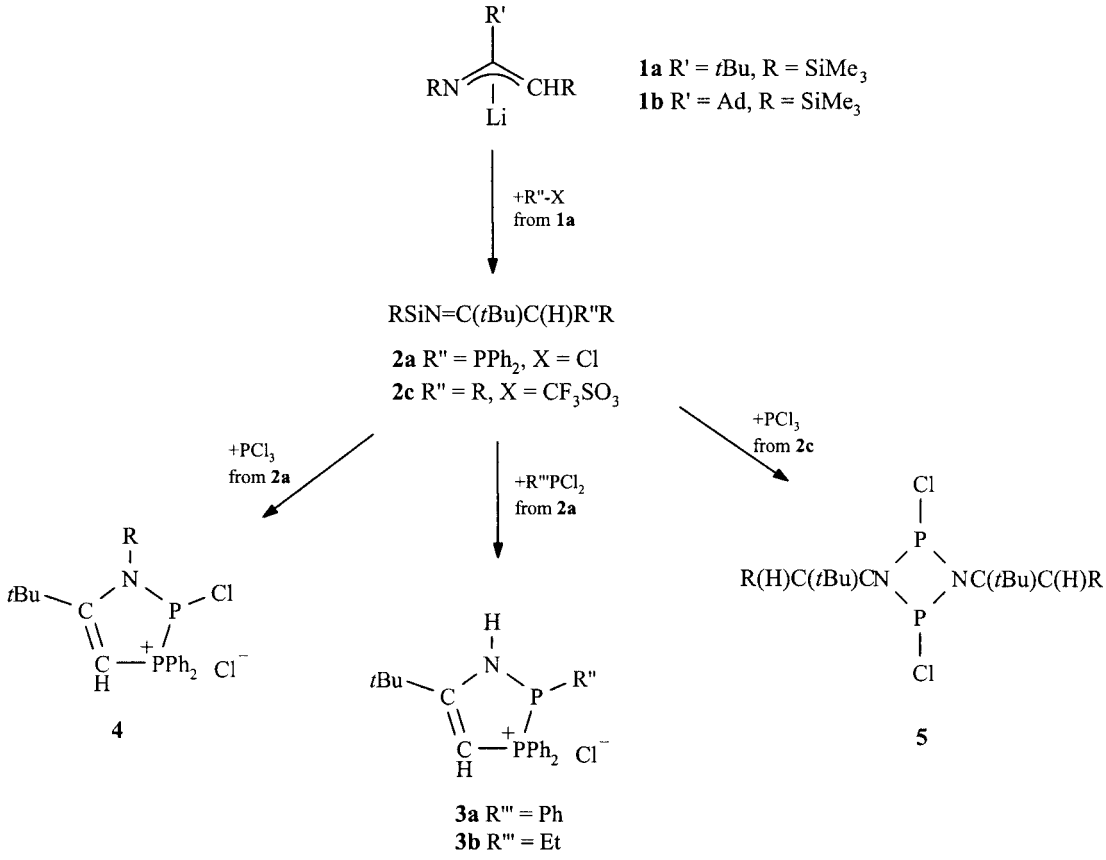
Results and Discussion

Synthesis

In the present study, the solvent-free 1-azaallyllithium, RNC(Ad)C(Li)HR (**1b**) was prepared in high yield by the reaction of LiCHR$_2$ (R = SiMe$_3$) and AdCN (Ad = adamantyl) in hexane at low temperature. This type of reaction has previously been rationalised by insertion of the alkyllithium reagent into the CN bond of the organonitrile to form a lithioaldimine, followed by a 1,3-Me$_3$Si shift to give the 1-azaallyl.[4] Compound **1b**, behaving as a *C*-centred nu-



Scheme 1. Reactions of ketimines with phosphorus halides.

cleophile, was reacted with the phosphanyl chloride, Ph_2PCl, to give the novel ketimine $RN=C(Ad)CH(R)PPh_2$ (**2b**) (i, Scheme 2) in a yield comparable to the analogous reaction involving $RNC(tBu)C(Li)HR$ and chlorodiphenylphosphane.[2] The purification of **2b** by distillation was not attempted owing to reports that the corresponding *t*Bu derivative, $RN=C(tBu)CH(R)PPh_2$ (**2a**) isomerised to give the (*Z*)-enamine upon heating under reduced pressure, while subsequent irradiation of the (*Z*)-enamine using a medium-pressure mercury lamp afforded an equilibrium mixture of the *Z* and *E* isomers [Equation (1)].[2] Owing to the stability that a number of transition metals can afford to phosphanes, by σ-donation of the ligand and backbonding from the metal to the vacant d-orbitals of the phosphane, the Au^I complex of **2b** was prepared (ii, Scheme 2). The expected stability and linear two-coordinate geometry of the complex was observed (**6b**), allowing unambiguous assignment of **2b** as a coordinated adduct by NMR and X-ray crystallographic analysis. Similarly, $[Me_3SiN=C(tBu)CH(SiMe_3)PPh_2(AuCl)]$ (**6a**) was prepared in high yield from the reaction of $Me_3SiN=C(tBu)CH(SiMe_3)PPh_2$ (**2a**) and $ClAuSMe_2$ in THF. In both cases, the 1:1 complex was formed irrespective of stoichiometry, and an excess of ligand was typically used to ensure complete complexation. While enhanced thermal stabilities of the ketimines were achieved by coordination of P to Au^I it was found that the $SiMe_3$ group attached to N was readily hydrolysed in the presence of moisture (treatment of **6** with methanol) to give the complexes $[H_2NC(R')=C(H)PPh_2(AuCl)]$ (Scheme 2; **8a**, R′ = *t*Bu; **8b**, R′ = Ad) in high yields. The structure of the *t*Bu derivative was confirmed by crystallographic analysis. The process presumably involves cleavage of the terminal trimethylsilyl group (Scheme 2, iii), followed by a 1,3 trimethylsilyl shift from C to N (Scheme 2, iv) and isomerisation of the ketimine (the sequence of rearrangement iv and isomerisation v may well be reversed or a simultaneous process) to the thermodynamically favoured enamine (Scheme 2, v). The latter intermediate $[H(SiMe_3)NC(R')=CHPPh_2(AuCl)]$ was NMR spectroscopically identified for R′ = *t*Bu (**7a**) as the major product (with **6a** and **8a** as side products) when **6a** was treated with a mixture of diethyl ether and hexane. Hydrolysis of the remaining trimethylsilyl group (Scheme 2, vi) completed a template-assisted synthesis of novel bidentate ligands. For comparison the non-hydrolysable ketimine $Ph_2PCH_2C(Ph)=N(C_6H_3Me_2\text{-}2,6)$[15] was reacted with Me_2SAuCl to synthesise a *N*-aryl analogue of **6**. The gold complex was isolated in good yield (66%) and found to exist in solution as a mixture of four isomers (two tautomers analogous to the ones shown for equilibrium v in Scheme 2 and their respective *Z*/*E* isomers). No decomposition or change in the isomer ratio was observed in acetone solution over a period of two weeks. The described synthesis of **8** represents a new route to mixed P, N donor ligands with C–C backbone. Typically, ligands of this sort are generated by the AIBN-assisted free radical-catalysed[16] (or base-cat-

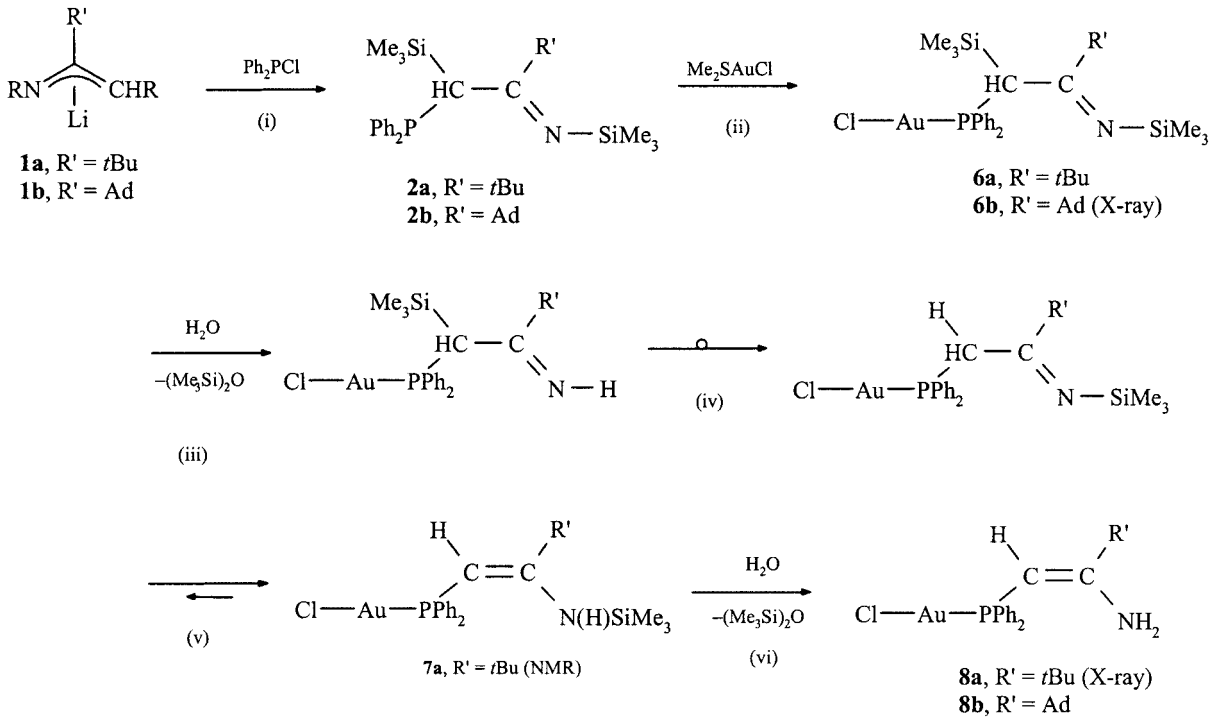
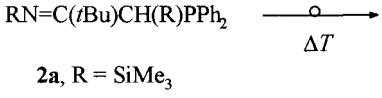
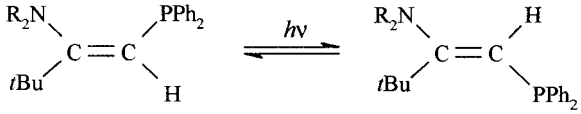


Scheme 2. Synthesis of gold phosphane complexes.

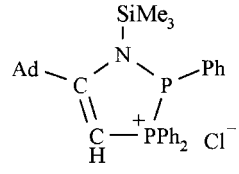
alysed[17]) addition of P–H bonds to vinylamides [e.g. CH_2=C(O)NH_2] or possibly the reaction of N-nucleophiles to ω-chloroalkylphosphanes. The procedure reported here, beginning with *C*-centred nucleophilic attack of a 1-azaallyl on a phosphanyl chloride, followed by template-assisted hydrolysis, not only provides a route to mixed P, N donor ligands, but allows for further alkyl substitution at a single carbon atom.



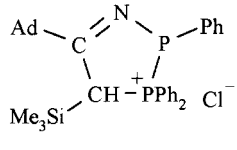


(1)

Since the reaction of Me_3SiN=C(*t*Bu)CH($SiMe_3$)PPh_2 (**2a**) with R′′′PCl_2 proceeded to give the cyclic phosphonium salts [Ph_2PP(R′′′)N(H)C(*t*Bu)=CH]Cl (Scheme 1, R′′′ = Ph, **3a** or Et, **3b**),[2] the Ad-substituted analogue, [Ph_2PP(Ph)N(H)C(Ad)=CH]Cl (**3c**) was prepared by a similar reaction involving Me_3SiN=C(Ad)CH($SiMe_3$)PPh_2 (**2b**) and $PhPCl_2$, albeit in lower yield. In a process that was used to rationalise the formation of the *t*Bu-substituted cyclic phosphonium salts,[2] the formation of [Ph_2PP(Ph)N(H)-C(Ad)=CH]Cl (**3c**) from Me_3SiN=C(Ad)CH($SiMe_3$)PPh_2 (**2b**) is likely to involve, firstly, *N*-centred nucleophilic attack of Me_3SiN=C(Ad)CH($SiMe_3$)PPh_2 at the P atom of $PhPCl_2$, yielding the ketimidophosphorous(III) chloride PhP(Cl)N=C(Ad)CH(R)PPh_2 with concomitant Me_3SiCl elimination. Secondly, cyclisation is invoked by a rearrangement (1,3-$SiMe_3$ shift from C to N) of PhP(Cl)N=C(Ad)-CH(R)PPh_2 into the isomeric enamidophosphorus(III) chloride PhP(Cl)N(R)C(Ad)=C(R)PPh_2 followed by intramolecular nucleophilic displacement of the chloride to give the cyclic phosphonium salt **I**. Hydrolysis completes the conversion to [Ph_2PP(Ph)N(H)C(Ad)=CH]Cl (**3c**). Alternatively, the transformation could proceed through cyclisation of the ketimidophosphorus(III) chloride PhP(Cl)N=C(Ad)-CH(R)PPh_2, to give the cycloketimidophosphonylphosphonium salt [Ph_2PP(Ph)N=C(Ad)CHR]Cl **II**, which subsequently undergoes rearrangement to **I** and hydrolysis to complete the process.



I



II

Fulfilment of the requirement of stability is necessary before proceeding with biological evaluations. While isolation and characterisation of the cyclic phosphonium salts were possible under inert gas conditions, instability of the five-membered ring (a solution of **3c** in $CDCl_3$ decomposed

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

within 24 h completely into two major products on exposure to moist air) necessitated strategies to attempt to induce stability. Consequently, metathesis reactions involving replacement of the chloride with bulkier anions were undertaken. The reaction of $[Ph_2PP(Ph)N(H)C(Ad)=CH]Cl$ (**3c**) with $NaBPh_4$ proceeded almost quantitatively to give $[Ph_2PP(Ph)N(H)C(Ad)=CH]BPh_4$ (**3d**), while the synthesis of related compounds with NO_3^-, $CH_3CO_2^-$, BF_4^- or ClO_4^- as counterion from **3c** and the corresponding silver salts was unsuccessful. ^{31}P NMR analysis of **3d**, however, revealed that the instability under atmospheric conditions was persistent, with decomposition of the five-membered ring being particularly rapid in foetal calf serum (fcs) containing cell-culture medium. Subsequently, in an attempt to acquire an insight into the factors which were responsible for this decomposition, a reaction was undertaken with $[Ph_2PP(Ph)N(H)C(tBu)=CH]Cl$ (**3a**) and one equivalent of sulfur in dichloromethane, since thiol-containing compounds are constituents of fcs and the interaction with sulfur is a reasonable comparison for the observed oxygen- and moisture-facilitated decomposition pathways. Removal of the solvent in vacuo, and recrystallisation of the crude product from propan-1-ol, gave colourless crystals in good yield. Crystallographic analysis of the product revealed that a rare example of a β-keto thiophosphane, i.e. $Ph_2P(S)CH_2C(O)tBu$ (**9**) was obtained. It is plausible that the formation of the β-keto thiophosphane oxide involved initial sulfuration of the quarternary P and concomitant P–P bond scission of the cyclic phosphonium salt $[Ph_2PP(Ph)N(H)C(tBu)=CH]Cl$ to give an intermediary chlorophosphane $Ph_2P(S)CH=C(tBu)N(H)P(Ph)Cl$ (Scheme 3, i). Facile elimination of ClPPhOPr or a related species (Scheme 3, ii), followed by nucleophilic attack of water on the *t*Bu-substituted carbon in a Michael-type addition reaction (the related P^{III} compounds **8** in Scheme 2 are in contrast unreactive) produces a zwitterionic intermediate (Scheme 3, iii) whose negative charge is stabilised by the P=S double bond. Ethene bond reformation is accompanied by the elimination of ammonia (Scheme 3, iv), with enol-keto tautomerism (Scheme 3, v) completing the envisaged reaction pathway involving the formation of $Ph_2P(S)CH_2C(O)tBu$ (**9**) from $[Ph_2PP(Ph)N(H)C(tBu)=CH]Cl$. Reaction of **3c** with oxygen-free water in CH_2Cl_2 resulted in a solid that showed two major signals at δ = 22.5 and 23.3 ppm in the ^{31}P NMR spectrum that were within 1 ppm identical to those found in the above-mentioned decomposition study of **3c** in $CDCl_3$. This implicates the reaction with water as a major reason for the instability of the phosphonium salts. Attempts to isolate the products were unsuccessful and a mass spectrum of the product mixture was inconclusive. The further reaction of **3c** with dry oxygen yielded after removal of the solvent a solid that consisted of a mixture of numerous compounds with unreacted starting material being one of the major components. The mass spectrum of the mixture showed *m*/*z* values consistent with **3c** and an oxygen analogue $[Ph_2P(O)CH_2C(O)Ad]$ of **9**. The persistent instability of the phosphonium salts under atmospheric conditions precluded further biological testing and further development as potential antitumour drugs is at this stage doubtful.

Solid-State Structures of Compounds 6b, 8a and 9

The molecular structures of $[RN=C(Ad)CH(R)PPh_2(AuCl)]$ (**6b**) (R = $SiMe_3$) and $[H_2NC(tBu)=C(H)PPh_2(AuCl)]$ (**8a**) with the atom numbering scheme are shown in Figure 1 and Figure 2, while selected bond lengths are compared in Table 1. Complex **6b** crystallises as a discrete monomer with the Au atom adopting a linear geometry [P–Au–Cl 178.74(9)°]. The Au–P and Au–Cl distances of 2.245(2) and 2.296(2) Å are unexceptional and compare well to those found in related two-coordinate phosphane complexes such as iBu_3PAuCl,[18] Et_3PAuCl,[19] Ph_3PAuCl,[20] $(2\text{-}Pyr)_3PAuCl$[21] or iPr_3PAuCl.[22] The short

C2–N [1.266(6) Å] and long C1–C2 [1.558(6) Å] distances are consistent with the alkyl substituent at P being an iminoalkyl. There is considerable steric repulsion between the bulky adamantyl and trimethylsilyl groups attached to the two sp^2 hybridised atoms C2 and N, respectively, as is evident from the deviation of the angles C3–C2–N [123.9(4)°] and C2–*N*–Si3 [151.9(4)°] from the idealised geometry of 120°.

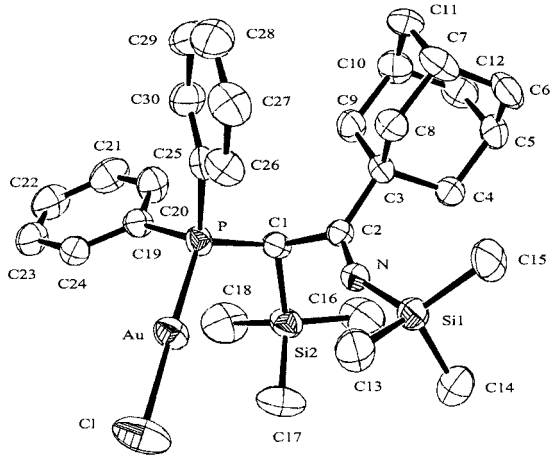

Figure 1. Molecular structure of $ClAuPPh_2CH(SiMe_3)C(Ad)NSiMe_3$ (**6b**). Thermal ellipsoids are drawn at the 50% probability level. H atoms have been omitted for clarity.

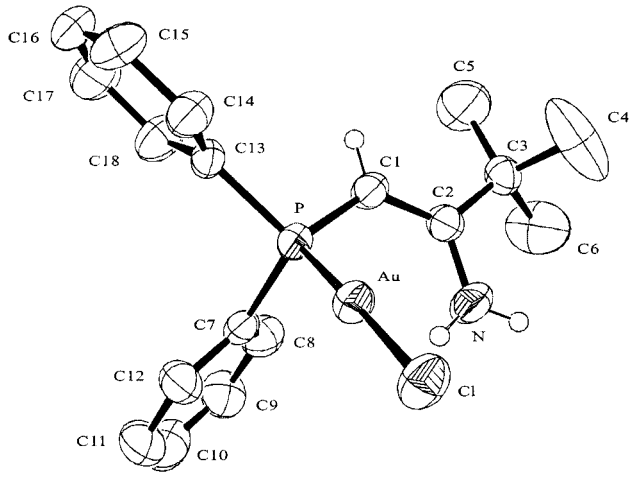

Figure 2. Molecular structure of $ClAuPPh_2CHC(tBu)NH_2$ (**8a**). Thermal ellipsoids are drawn at the 50% probability level. H atoms (except at N, C1) have been omitted for clarity.

Compound **8a** crystallises as a centrosymmetric dimer (Figure 3) as a consequence of conventional hydrogen bonding between the Cl and NH_2 groups of adjacent molecules hereby forming a 14-membered heterocycle $R_2^2(14)$. The Cl···N contacts [3.345(7) Å] are close to the mean value of 3.299(6) Å reported in the literature.[23] The dimers are further weakly hydrogen-bonded by short C–H···Cl interactions (C4–H4···Cl: 2.76 Å, 172°) between the Cl atom and one of the methyl groups of the *t*Bu substituent in the backbone of an adjacent dimer (Figure 3, Table 2). The existence of C–H···Cl (H···A) interactions has been discussed in several recent papers[24] and a C–H···Cl distance of close to 3 Å has been suggested as reasonable.[24a] The closest contact in compound **6b** (C9–H9B···Cl: 2.94 Å, 148°) is in comparison considerably longer. In this context it is noteworthy that the distance between the methyl group (C4) involved in non-classical H-bonding and the central carbon atom of the *t*Bu group (C3) in **8a** [1.54(1) Å] is longer than those to the non-hydrogen-bonded methyl groups [1.52(1), 1.50(1) Å].

Table 1. Selected bond lengths [Å] and angles [°] for compound **6b**, **8a** and **9**.

Bond length/angle	**6b**	**8a**	**9**
Au/S–P	2.245(2)	2.243(2)	1.9563(9)
Au–Cl	2.296(2)	2.295(2)	–
P–C1	1.825(6)	1.777(7)	1.822(2)
P–C[a]	1.838(5)	1.837(7)	1.820(2)
P–C[b]	1.830(6)	1.819(6)	1.821(2)
N/O–C2	1.266(6)	1.369(9)	1.209(3)
C1–C2	1.558(6)	1.361(9)	1.523(3)
P–Au–Cl	178.74(6)	177.24(6)	–

[a] C = carbon C19 (**6b**); carbon C7 (**8a**, **9**). [b] C = carbon C25 (**6b**); carbon C13 (**8a**, **9**).

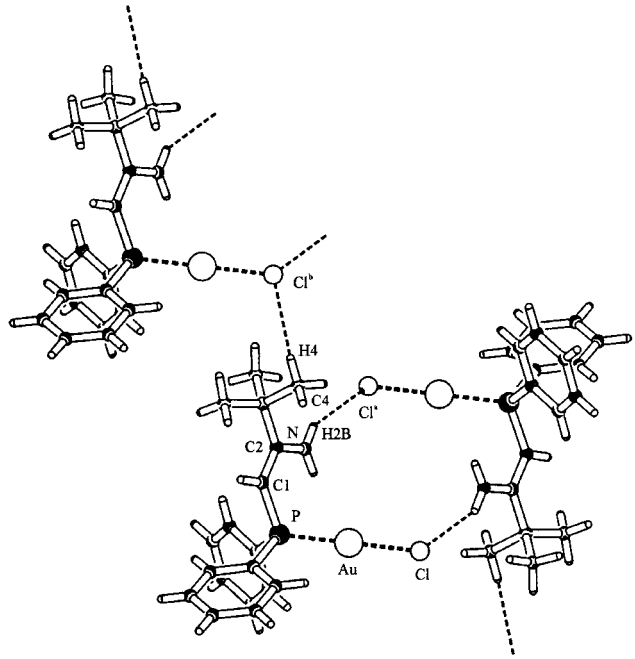

Figure 3. H bonding and intermolecular contacts in compound **8a**. (For symmetry codes see Table 2).

The bond lengths and geometry of the Au atom [Au–P: 2.243(2) Å, Au–Cl: 2.295(2) Å, P–Au–Cl 177.24(6)°] in complex **8a** are similar to those in complex **6b**. The short CN single bond [C1–N 1.369(9) Å] and comparatively long CC double bond [C1–C2 1.361(9) Å] in the phosphane substituent indicate considerable delocalisation within the enamine backbone (*Z* isomer) of the ligand that may extend to some degree to the phosphorus atom (c.f. short P–C1 as compared to long P–Ph distances).

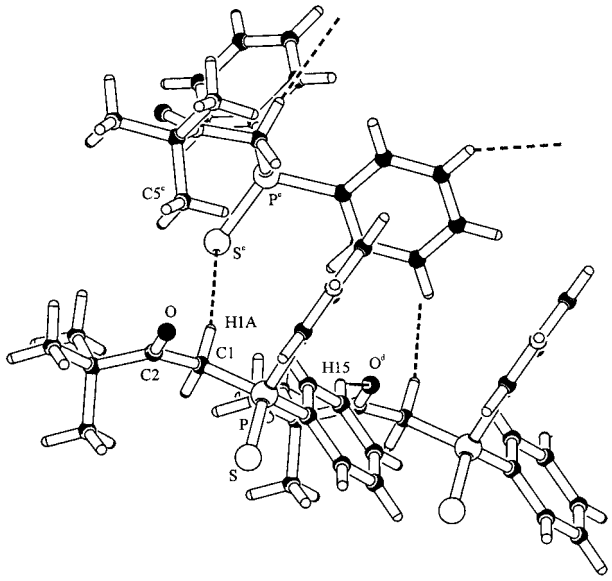

Figure 5. Intermolecular contacts in compound **9**. (For symmetry codes see Table 2).

plexes[26] in the case of less bulky phosphanes are not observed in compound **6b** or **8a**.

The molecular structure of compound **9** and the atom numbering scheme is illustrated in Figure 4. The bond lengths and angles (Table 1) are unexceptional and compare well to the related dimethyl and diphenylphosphane sulfides $Me_2P(S)C(Me)OHC(O)Me$,[27] $Me_2P(S)C(Ph)OHC(O)Ph$[27] and $Ph_2P(S)CHC(O)(CH_2)_4$.[28] The PS and CO groups are not coplanar as indicated by an angle of 71.5(2)° between the two planes formed by the atoms S, P, Cl and C1, C2, O. This facilitates weak intermolecular C–H(Ph)···O and C–H(CH_2)···S interactions (Table 2) between adjacent molecules of **9** (Figure 5). There is also a close contact between C5 and O (C5···O: 3.130 Å).

Experimental Section

All manipulations were carried out under argon, using standard Schlenk techniques. Solvents were distilled from drying agents and degassed. The NMR spectra were recorded in $CDCl_3$, [D_6]acetone and [D_6]DMSO at ambient probe temperature by using the following Bruker instruments: DRX 400 (^{1}H 400.13; ^{31}P 161.9; ^{13}C 100.6 MHz), Avance 300 (^{1}H 300.13; ^{13}C 75.5 MHz) or AC200 (^{1}H 200.13 MHz) and referenced internally to residual solvent resonances (chemical shift data in δ). ^{13}C and ^{31}P NMR spectra were all proton-decoupled. Elemental analyses were determined by the Institute for Soil, Climate and Water, Pretoria, South Africa. The following abbreviations are used throughout the experimental section: s = singlet, br. s = broad singlet, d = doublet, dd = doublet of doublet, m = multiplet, mm = multiple multiplets. Coupling constants (J) are given in Hz.

Synthesis of $Me_3SiNC(Ad)CH(SiMe_3)PPh_2$ (2b): Ph_2PCl (0.38 g, 1.71 mmol) in hexane (15 cm^3) was added dropwise to a magnetically stirred solution (–80 °C) of the 1-azaallyllithium complex **1b** (0.56 g, 1.71 mmol) in hexane (30 cm^3). After stirring for 12 hours, the solution was filtered and the solvent removed in vacuo to give **2b** as a yellow oil (0.73 g, 80%). ^{1}H NMR ($CDCl_3$): δ = –0.04 (s, 9 H, $CSiMe_3$), 0.28 (s, 9 H, $NSiMe_3$), 1.25–1.83 (mm, 15 H, Ad), 3.95 [d, $^2J_{H,P}$ = 6.1 Hz, 1 H, CH] and 7.19–7.74 (mm, 10 H, Ph) ppm. ^{31}P NMR ($CDCl_3$): δ = –2.1 ppm. ^{13}C NMR ($CDCl_3$): δ = 0.4 (s, $CSi\mathit{Me_3}$), 0.5 (s, $NSi\mathit{Me_3}$), 28.6 (s, CH-Ad), 36.5 (s, CH_2-Ad), 31.6 (s, *ipso*-C-Ad), 38.9 [d, $^1J_{C,P}$ = 27.3 Hz, CH], 39.5 (s, CH_2-Ad), 127.7 [d, $^3J_{C,P}$ = 7.1 Hz, *m*-Ph], 128.2 [d, $^3J_{C,P}$ = 7.7 Hz, *m*-Ph], 128.5 (s, *p*-Ph), 129.0 (s, *p*-Ph), 134.3 [d, $^2J_{C,P}$ = 21.8 Hz, *o*-Ph], 134.6 [d, $^2J_{C,P}$ = 19.1 Hz, *o*-Ph], 138.7 [d, $^1J_{C,P}$ = 16.3 Hz, *ipso*-C], 140.3 [d, $^1J_{C,P}$ = 28.5 Hz, *ipso*-C] and 183.1 [d, $^2J_{C,P}$ = 2.2 Hz, CN] ppm.

Synthesis of $Ph_2P^+P(Ph)N(H)C(Ad)CH\ Cl^-$ (3c): $PhPCl_2$ (0.57 g, 3.16 mmol) was added to $Me_3SiN{=}C(Ad)CH(SiMe_3)PPh_2$ (**2b**) (1.60 g, 3.16 mmol). After complete addition, the mixture was heated at 50 °C for 30 min. It liquefied as the $ClSiMe_3$ was given off. The mixture was then dried in vacuo to give a yellow solid (1.43 g, 90%). $C_{27}H_{32}ClNP_2$: calcd. C 69.30, H 6.85, N 2.99; found C 68.52, H 6.87, N 2.47 (the compound incorporates varying amounts of toluene). Pale yellow crystals were obtained from hot toluene (0.40 g, 25%). ^{1}H NMR ($CDCl_3$): δ = 1.71–1.84 (mm, 15 H, Ad), 4.63 [d, $^2J_{H,P}$ = 15.6 Hz, 1 H, NH], 6.90–7.20 (mm, 5 H, Ph), 7.38–7.87 (mm, 10 H, Ph) and 9.99 [dd, $^2J_{H,P}$ = 32.0, $^3J_{H,P}$ = 21.2 Hz, 1 H, CH] ppm. ^{31}P NMR ($CDCl_3$): δ = 13.5 [d, $^1J_{P,P}$ = 239.2 Hz, λ^3P], 41.9 [d, $^1J_{P,P}$ = 239.2 Hz, λ^4P$^+$] ppm. ^{13}C NMR ($CDCl_3$): δ = 28.3 (s, CH-Ad), 36.2 (s, CH_2-Ad), 40.4 [d, $^3J_{C,P}$ =

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

11.3 Hz, *ipso*-C-Ad], 41.0 (s, CH_2-Ad), 64.1 [d, $^1J_{C,P}$ = 72.9 Hz, CH], 118.1, [d, $^1J_{C,P}$ = 82.5 Hz, *ipso*-C], 124.2 [dd, $^2J_{C,P}$ = 75.0, $^3J_{C,P}$ = 18.8 Hz, *ipso*-C], 125.2 (s, *ipso*-C), 128.7 (mm of aromatic C atoms) and 186.8 [overlapping dd, $^2J_{C,P}$ = 27.9, $^3J_{C,P}$ = 14.4 Hz, CN] ppm.

Synthesis of $Ph_2P^+P(Ph)N(H)C(Ad)CH\ BPh_4^-$ (3d): $NaBPh_4$ (0.37 g, 1.08 mmol) was added to a magnetically stirred solution of CH_2Cl_2 (20 cm^3) and $Ph_2P^+P(Ph)N(H)C(Ad)CH\ Cl^-$ (**3c**) (0.54 g, 1.07 mmol) at –30 °C. The reaction mixture was stirred for 12 hours and warmed to room temperature giving an off-white solution. It was filtered and the solvent removed in vacuo to give a yellow solid. Various recrystallisation attempts led to the decomposition of the compound. **3d** (crude: 0.76 g, 92%). ^{1}H NMR ($CDCl_3$): δ = 1.57–1.89 (mm, 15 H, Ad), 4.64 [d, 1 H, $^2J_{H,P}$ = 15.3 Hz, NH], 6.00 [dd, $^2J_{H,P}$ = 22.0, $^3J_{H,P}$ = 8.0 Hz, 1 H, CH], 6.84–7.10 (mm, 5 H, Ph) and 7.36–7.64 (mm, 10 H, Ph) ppm. ^{31}P NMR ($CDCl_3$): δ = 10.8 [d, $^1J_{P,P}$ = 241.4 Hz, λ^3P], 43.8 [d, $^1J_{P,P}$ = 241.4 Hz, λ^4P^+] ppm. ^{13}C NMR ($CDCl_3$): δ = 28.0 (s, CH-Ad), 36.0 (s, CH_2-Ad), 39.8 (s, *ipso*-C-Ad), 41.0 (s, CH_2-Ad), 66.4 [d, $^1J_{C,P}$ = 71.4 Hz, CH], 117.3 [d, $^1J_{C,P}$ = 81.0 Hz, *ipso*-C], 121.7 (s, BPh), 122.4 [d, $^1J_{C,P}$ = 32.5 Hz, *ipso*-C], 125.5 (s, BPh), 129.2 [d, $J_{C,P}$ = 5.6 Hz, Ph], 129.5 [d, $J_{C,P}$ = 19.0 Hz, Ph], 130.3 [d, $J_{C,P}$ = 12.6 Hz, Ph], 132.8 [d, $J_{C,P}$ = 10.4 Hz, Ph], 136.3 (s, BPh), 164.2 [q, $^1J_{C,B}$ = 49.3 Hz, *ipso*-C] and 184.8 [d, $^2J_{C,P}$ = 13.0 Hz, CN] ppm.

Synthesis of $ClAuPPh_2CH(SiMe_3)C(tBu)NSiMe_3$ (6a): $ClAuSMe_2$[29] (0.24 g, 0.82 mmol) was added to a solution of $Ph_2PCH(SiMe_3)C(tBu)NSiMe_3$ (**2a**) (0.30 g, 0.85 mmol) in THF (10 cm^3) at 0 °C. The solution was stirred at 0 °C for 10 minutes, warmed to room temperature and stirred for further 15 minutes. The solvent was removed in vacuo to yield a sticky yellow compound (**6a**, 0.45g, 83%). ^{1}H NMR ($CDCl_3$): δ = 0.17 (s, 9 H, $CSiMe_3$), 0.33 (s, 9 H, $NSiMe_3$), 0.88 (s, 9 H, *t*Bu), 4.46 [d, $^2J_{H,P}$ = 15.8 Hz, 1 H, CH] and 7.44 –7.81 (mm, 10 H, Ph) ppm. ^{31}P NMR ($CDCl_3$): δ = 40.7 ppm. ^{13}C NMR ($CDCl_3$): δ = 0.8 [d, $^3J_{C,P}$ = 4.3 Hz, $CSiMe_3$], 3.1 (s, $NSiMe_3$), 29.0 (s, CMe_3), 38.8 [d, $^1J_{C,P}$ = 30.4 Hz, CH], 43.6 (s, *C*Me_3), 128.5 [d, $^2J_{C,P}$ = 11.6 Hz, *o*-Ph], 131.0 [d, $^3J_{C,P}$ = 9.9 Hz, *m*-Ph], 131.8 [d, $^4J_{C,P}$ = 2.4 Hz, , *p*-Ph], 132.8 [d, $^1J_{C,P}$ = 79.0 Hz, *ipso*-C] and 179.4 [d, $^2J_{C,P}$ = 6.0 Hz, CN] ppm.

Synthesis of $ClAuPPh_2CH(SiMe_3)C(Ad)NSiMe_3$ (6b): $ClAuSMe_2$[29] (0.30 g, 1.02 mmol) was added to a solution of $Ph_2PCH(SiMe_3)C(Ad)NSiMe_3$ (**2b**) (0.78 g, 1.54 mmol) in THF (20 cm^3) at 0 °C. The solution was stirred for 15 minutes and the solvent was removed in vacuo to yield a yellow solid. Colourless crystals of **6b** (0.25 g, 33%) were obtained from CH_2Cl_2 at –60 °C. ^{1}H NMR ($CDCl_3$): δ = 0.07 (s, 9 H, $CSiMe_3$), 0.25 (s, 9 H, $NSiMe_3$), 1.26–1.86 (mm, 15 H, adamantyl), 4.37 (d, $^2J_{H,P}$ = 15.9 Hz, 1 H, CH), 7.41–7.43 (mm, 6 H, Ph), 7.71–7.74 (mm, 2 H, Ph) and 7.92–7.98 (mm, 2 H, Ph) ppm. ^{31}P NMR ($CDCl_3$): δ = 40.9 ppm. ^{13}C NMR ($CDCl_3$): δ = 1.0 [d, $^3J_{C,P}$ = 4.0 Hz, $CSiMe_3$], 3.7 (s, $NSiMe_3$), 28.5 (s, CH-Ad), 36.2 (s, CH_2-Ad), 37.6 [d, $^1J_{C,P}$ = 30.2 Hz, CH], 39.6 (s, CH_2-Ad), *ipso*-C-Ad not observed, 128.5 [d, $^3J_{C,P}$ = 11.7 Hz, *m*-Ph], 131.3 [d, $^4J_{C,P}$ = 2.8 Hz, *p*-Ph], 132.3 [d, $^1J_{C,P}$ = 79.9 Hz, *ipso*-C], 134.3 [d, $^2J_{C,P}$ = 14.2 Hz, *o*-Ph] and 179.5 (s, CN) ppm.

Synthesis of $ClAuPPh_2CHC(tBu)N(H)SiMe_3$ (7a): $ClAuPPh_2CH(SiMe_3)C(tBu)NSiMe_3$ (**6a**) was dissolved in a mixture of ether/hexane. A yellow powder of **7a** (0.37 g, 66%) was obtained at –60 °C. ^{1}H NMR ($CDCl_3$): δ = 0.14 (s, 9 H, $SiMe_3$), 1.23 (s, 9 H, *t*Bu), 4.33 [d, $^2J_{H-P}$ = 5.6 Hz, 1 H, CH], 4.81 [br. s, 1 H, NH], 7.42–7.69 (mm, 10 H, Ph) ppm. ^{31}P NMR ($CDCl_3$): δ = 10.6 ppm. ^{13}C NMR ($CDCl_3$): δ = 2.5 (s, $SiMe_3$), 29.8 (s, CMe_3), 38.3 [d, $^3J_{C,P}$ = 8.5 Hz, *C*Me_3], 86.4 [d, $^1J_{C,P}$ = 72.3 Hz, CH], 129.1 [d, $^3J_{C,P}$ = 11.7 Hz, *m*-Ph], 131.2 [d, $^1J_{C,P}$ = 84.5 Hz, *ipso*-C], 131.4 [d, $^4J_{C,P}$ = 2.6 Hz, *p*-Ph], 133.2 [d, $^2J_{C,P}$ = 13.6 Hz, *o*-Ph] and 173.3 (s, CN) ppm.

Synthesis of $ClAuPPh_2C(H)C(tBu)NH_2$ (8a): $ClAuPPh_2CHC(tBu)N(H)SiMe_3$ (**7a**) was dissolved in hot methanol. Colourless crystals of **8a** (0.06 g, 14%) were obtained after slow cooling of the solution at room temperature. $C_{18}H_{22}AuClNP$: calcd. C 41.92, H 4.30, N 2.72; found C 41.20, H 4.33, N 2.70. ^{1}H NMR ($CDCl_3$): δ = 1.23 (s, 9 H, *t*Bu), 4.32 [d, $^2J_{H-P}$ = 8.8 Hz, 1 H, CH], 4.82 (br. s, 2 H, NH_2), 7.44 (6 H, Ph) and 7.57–7.63 (mm, 4 H, Ph) ppm. ^{31}P NMR ($CDCl_3$): δ = 7.1 ppm. ^{13}C NMR ($CDCl_3$): δ = 29.1 (s, CMe_3), 37.2 [d, $^3J_{C,P}$ = 9.8 Hz, *C*Me_3], 72.8 [d, $^1J_{C,P}$ = 71.9 Hz, CH], 129.0 [d, $^3J_{C,P}$ = 11.7 Hz, *m*-Ph], 131.2 [d, $^4J_{C,P}$ = 2.3 Hz, *p*-Ph], 131.9 [s, *ipso*-C], 132.9 [d, $^2J_{C,P}$ = 13.5 Hz], *o*-Phand 168.9 (s, CN) ppm.

Crude **6a** (0.45 g, 0.68 mmol) was dissolved in methanol (20 cm^3) and after a period of 5 minutes a white precipitate started to form. After stirring the reaction mixture for 30 minutes at room temperature the solvent was carefully decanted and the residue dried in vacuo to give 0.31 g (88%) of **8a**.

Synthesis of $ClAuPPh_2C(H)C(Ad)NH_2$ (8b): $ClAuPPh_2CH(SiMe_3)C(Ad)NSiMe_3$ (**6b**) was dissolved in hot methanol. It was cooled slowly and yielded **8b** (0.13 g, 65%) as a pale yellow powder. $C_{24}H_{28}AuClNP$: calcd. C 48.50, H 4.75, N 2.36; found C 48.33, H 4.85, N 2.27. ^{1}H NMR ($CDCl_3$): δ = 1.67–1.83 (mm, 15 H, adamantyl), 4.28 [d, $^2J_{H-P}$ = 9.1 Hz, 1 H, CH], 4.81 (br. s, 2 H, NH_2), 7.42–7.44 (mm, 6 H, Ph) and 7.56–7.64 (mm, 4 H, Ph) ppm. ^{31}P NMR ($CDCl_3$): δ = 7.1 ppm. ^{13}C NMR ($CDCl_3$): δ = 28.4 (s, CH-Ad), 36.5 (s, CH_2-Ad), 38.9 [d, $^3J_{C,P}$ = 9.5 Hz, *ipso*-C, Ad), 40.9 (s, CH_2-Ad), 72.5 [d, $^1J_{C,P}$ = 72.0 Hz, CH], 129.0 [d, $^3J_{C,P}$ = 11.8 Hz, *m*-Ph], 131.2 [d, $^4J_{C,P}$ = 2.5 Hz, *p*-Ph], 132.1 (s, *ipso*-C), 132.9 [d, $^2J_{C,P}$ = 13.4 Hz, *o*-Ph] and 169.1 (s, CN) ppm.

Synthesis of $ClAuPPh_2CH_2C(Ph)N(C_6H_3Me_2$-2,6): $ClAuPPh_2CH_2C(Ph)N(C_6H_3Me_2$-2,6) was obtained from $PPh_2CH_2C(Ph)N(C_6H_3Me_2$-2,6)[15] (0.18 g, 0.44 mmol) and $ClAu(SMe_2)$ (0.11 g, 0.38 mmol) following the same procedure as described for compound **6**. The solvent was removed and the residue recrystallised by layering a toluene solution of the title compound with hexane (approx. ratio 1:4) yielding $ClAuPPh_2CH_2C(Ph)N(C_6H_3Me_2$-2,6) as a colourless powder (0.16 g, 66%). In solution the compound was found to exist as a mixture of two tautomers and their respective *Z*/*E* isomers (the ratio is given in bracket):

$ClAuPPh_2CH_2C(Ph)=N(C_6H_3Me_2$-2,6). Major Isomer (4): ^{1}H NMR ($CDCl_3$): δ = 1.73 (s, 6 H, Me), 3.86 (d, $^2J_{H-P}$ = 13.5 Hz, 2 H, CH) ppm. ^{31}P NMR ($CDCl_3$): δ = 23.8 ppm. ^{13}C NMR ([D_6]acetone) (only CH_2 and CN are assigned): δ = 39.9 [d, $^1J_{C,P}$ = 44 Hz, CH], 165.5 (s, CN) ppm. **Minor Isomer (3):** ^{1}H NMR ($CDCl_3$): δ = 1.88 (s, 6 H, Me), 4.24 (d, $^2J_{H-P}$ = 9.9 Hz, 2 H, CH) ppm. ^{31}P NMR ($CDCl_3$): δ = 25.8 ppm. ^{13}C NMR ([D_6]acetone): not observed.

$ClAuPPh_2CH=C(Ph)N(H)(C_6H_3Me_2$-2,6). Major Isomer (8): ^{1}H NMR ($CDCl_3$): δ = 2.33 (s, 6 H, Me), 4.33 (d, $^2J_{H-P}$ = 5.3 Hz, 1 H, CH), 5.64 (d, $^4J_{H-P}$ = 3.3 Hz, 1 H, NH) ppm. ^{31}P NMR ($CDCl_3$): δ = 17.9 ppm. ^{13}C NMR ([D_6]acetone) (only CH and CN are assigned): δ = 78.9 [d, $^1J_{C,P}$ = 87 Hz, CH], 163.3 (d, $^2J_{C,P}$ = 21 Hz, CN) ppm. **Minor Isomer (1.2):** ^{1}H NMR ($CDCl_3$): δ = 2.11 (s, 6 H, Me), 4.74 (d, $^2J_{H-P}$ = 9.9 Hz, 1 H, CH), 6.55 (br. s, 1 H, NH) ppm. ^{31}P NMR ($CDCl_3$): δ = 8.8 ppm. ^{13}C NMR ([D_6]acetone): not observed. FAB-Mass spectrum: *m*/*z* (%) = 1243 (21) [$(M^+)_2$ – Cl], 639 (20) [M^+], 604 (92) [M^+ – Cl].

Synthesis of $Ph_2P(S)CH_2C(O)tBu$ (9): Sulfur (0.026 g, 0.81 mmol) was added to a magnetically stirred solution of $Ph_2P^+P(Ph)N(H)C(tBu)CH\ Cl^-$ **(3a)** (0.33 g, 0.77 mmol) in CH_2Cl_2 (15 cm^3) at –30 °C. The colourless solution was stirred for 12 hours at room temperature; the solvent was then removed in vacuo to yield a white compound. Colourless crystals of **9** (0.15 g, 61%) were obtained from propanol at –60 °C. Melting point: 210–212 °C. Mass spectrum: m/z = 316 (85) [M$^+$], 259 (15) [M$^+$ – tBu], 231 (65) [Ph_2PSCH_2]. ^{1}H NMR (DMSO): δ = 1.07 (s, 9 H, tBu), 4.32 [d, $^2J_{H-P}$ = 13.1 Hz, 2 H, CH_2], 7.47–7.52 (mm, 6 H, Ph) and 7.88–7.95 (mm, 4 H, Ph) ppm. ^{31}P NMR (DMSO): δ = 38.9 ppm. ^{13}C NMR (DMSO): δ = 25.3 (s, CMe_3), 26.1 [d, $^1J_{C,P}$ = 76.1 Hz, CH_2], 44.4 (s, CMe$_3$), 128.1 [d, $^2J_{C,P}$ = 12.4 Hz, o-Ph], 130.7 [d, $^3J_{C,P}$ = 10.6 Hz, m-Ph], 131.0 [d, $^4J_{C,P}$ = 2.7 Hz, p-Ph], 133.3 [d, $^1J_{C,P}$ = 82.9 Hz, $ipso$-C] and 207.1 [d, $^2J_{C,P}$ = 6.7 Hz, C=O] ppm.

X-ray Crystallography: Intensity data were collected with a Bruker SMART 1K CCD area detector diffractometer with graphite-monochromated Mo-K_α radiation (50 kV, 30 mA). The collection method involved ω-scans of width 0.3°. Data reduction was carried out using the program SAINT+,[30] with face-indexed absorption corrections (compounds **6b** and **8a**) and semi-empirical absorption corrections (compound **9**) carried out using the program XPREP[30] and SADABS,[30] respectively. The crystal structures were solved by direct methods using SHELXTL.[31] Non-hydrogen atoms were first refined isotropically followed by anisotropic refinement by full-matrix least-squares calculation based on F^2 using SHELXTL. Hydrogen atoms were positioned geometrically and allowed to ride on their respective parent atoms. Further crystallographic data are summarised in Table 3. Diagrams and publication material were generated using SHELXTL,[31] PLATON[32] and ORTEP3.[33]

CCDC-244675 to -244677 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Di-2-pyridyl Ketone Oxime in Zinc Chemistry: Inverse 12-Metallacrown-4 Complexes and Cationic Pentanuclear Clusters

Maria Alexiou,[a] Eugenia Katsoulakou,[b] Catherine Dendrinou-Samara,[a] Catherine P. Raptopoulou,[c] Vassilis Psycharis,[c] Evy Manessi-Zoupa,[b] Spyros P. Perlepes,*[b] and Dimitris P. Kessissoglou*[a]

Keywords: Cluster compounds / Inverse metallacrowns / Oximato complexes / X-ray crystallography / Zinc

The use of di-2-pyridyl ketone oxime (Hpko)/X^- "blends" (X^- = $PhCO_2^-$, N_3^-, NCO^-, $acac^-$, NCS^-) in zinc chemistry yields neutral tetranuclear and cationic pentanuclear clusters. Various synthetic procedures have led to the synthesis of compounds $[Zn_4(OH)_2(O_2CPh)_2(pko)_4]\cdot 3MeCN$ (**1**·3MeCN), $[Zn_4(OH)_2(N_3)_2(pko)_4]\cdot 4DMF$ (**2**·4DMF), $[Zn_4(OH)_2(NCO)_2(pko)_4]\cdot 3DMF\cdot H_2O$ (**3**·3DMF·H_2O), $[Zn_4(OH)_2(acac)_2(pko)_4]\cdot 4CH_2Cl_2$ (**4**·4CH_2Cl_2), $[Zn_5Cl_2(pko)_6][ZnCl(NCS)_3]\cdot 2.5H_2O\cdot 1.5MeOH$ (**5**·2.5H_2O·1.5MeOH) and $[Zn_5(NCS)_2(pko)_6(MeOH)][Zn(NCS)_4]\cdot 2.5H_2O\cdot MeOH$ (**6**·2.5H_2O·MeOH). The structures of the six complexes have been determined by single-crystal X-ray crystallography. The tetranuclear molecules of **1**–**4** lie on a crystallographic inversion centre and have an inverse 12-metallacrown-4 topology. Two triply bridging hydroxides are accommodated in the centre of the metallacrown ring. The pko^- ligands form a propeller configuration that imposes absolute stereoisomerism with Λ and Δ chirality. Two metal ions are in distorted O_2N_4 octahedral environments, whereas the rest are in severely distorted tetrahedral or trigonal bipyramidal environments. The five Zn ions of the cations of **5** and **6** are held together by six pko^- ligands which adopt three different coordination modes; the chloro (**5**) and isothiocyanato (**6**) ligands are terminal. The five Zn ions define two nearly equilateral triangles sharing a common apex, and the novel Zn_5 topology can be described as two "collapsed" 9-metallacrown-3 structures sharing a common Zn apex. Besides the pentanuclear cations, the structures of **5** and **6** contain slightly distorted tetrahedral $[ZnCl(NCS)_3]^{2-}$ and $[Zn(NCS)_4]^{2-}$ ions, respectively, with the isothiocyanato ligands binding the metal ion in a virtually linear fashion.

Introduction

Metallamacrocycles have gained increasing attention over the past decade due to their potentially unique properties. These molecules have already been used in applications as diverse as catalysis,[1] sensors[2] or as chiral building blocks for two and three-dimensional solids.[3] Metallamacrocycles include complexes such as metallacrowns,[4] metallacrowns containing carbon in the macrocycle,[5] azametallacrowns,[6] anticrowns,[7] metallacrown ethers,[8] metallahelicates,[9] metallacalixarenes,[10] metallacryptates,[11] molecular squares and boxes[1,2,12]and polynuclear alkoxo- or oxometal complexes.[13]

Metallacrowns (MCs),[4] the inorganic structural and functional analogues of crown ethers,[14] are usually formed with transition metal ions and a nitrogen replacing the methylene carbon atoms. MCs exhibit selective recognition of cations and anions, and can display intramolecular magnetic-exchange interactions. The isolation of MCs requires the employment of tri- and tetradentate ligands containing hydroxamate or oximate functionalities to provide a scaffolding within which the desired metal-containing core can be realized. The first MCs were prepared using the triply deprotonated form (shi^{3-}) of salicylhydroxamic acid as ligand.[4,15] This dinucleating agent contains four heteroatoms that are potential metal-binding sites: one metal atom can bind in a five-membered chelate ring formed through the hydroximate group while a second metal atom can bind in a six-membered chelate ring through the iminophenolate group, i.e., shi^{3-} can act as a 2.1111 ligand using Harris notation.[16] This approach yields clusters with M–N–O–M networks linking the ring metal atoms and forms the basis of MCs (Figure 1). The synthesis of MCs is not necessarily restricted to the use of organic ligands with a hydroximate moiety, however. The same M–N–O–M connectivity can be achieved using oximate ligands that can form six- and/or five-membered chelate rings.[4] One example of such a ligand is di-2-pyridyl ketone oxime (Hpko),[17] whose anion (pko^-) can adopt a variety of coordination modes (Figure 1); pko^- is the ligand used in the present study. Even

more interesting are MCs composed of a combination of oximate and hydroximate ligands, e.g., pko^- and shi^{3-}.[4,18]

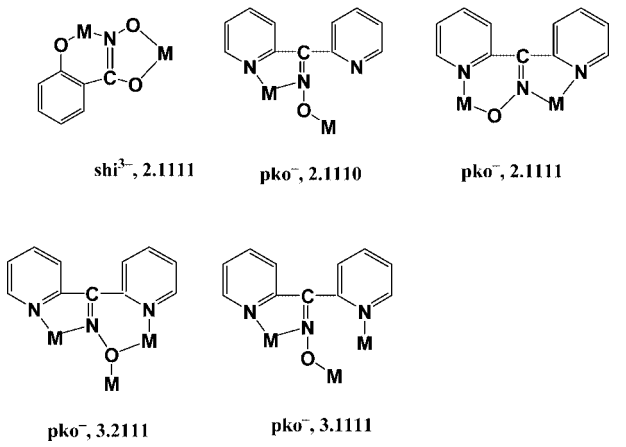

Figure 1. Some of the crystallographically established coordination modes of the ligands shi^{3-} and pko^- discussed in the text, and the Harris notation that describes these modes.

Metallacrown nomenclature is discussed in several key references.[4,18,19] There are now examples of [9-$MC_{M(ox)N(ligand)}$-3],[20] [12-$MC_{M(ox)N(ligand)}$-4],[15,18,19,21] [15-$MC_{M(ox)N(ligand)}$-5][19,22] and [24-$MC_{M(ox)N(ligand)}$-8][17] structural types, as well as fused, dinuclear and mixed-metal MCs.[4,18,19,23] There are nine metals in four oxidation states (II–V) that have been incorporated into the MC ring, while more than 20 metal ions, i.e., lanthanide, actinide, alkali, alkaline earth and transition metal ions have been captured in the central cavity of MCs.

For 12-MC-4 complexes, two structural motifs have been reported: classical or regular[15,18,19,21] and inverse,[24] with most 12-MC-4 compounds belonging to the former type. In the regular motif, there is an N–O–M–N–O–M linkage, i.e., an $[M–N–O]_n$ repeat unit, with the oxygen atoms oriented towards the centre of the cavity and capable of binding cations.[4] In the inverse motif, which has been realized only for Zn[24] and Co,[25] the ring metal ions are oriented towards the centre of the cavity which is now capable of encapsulating anions, whereas the connectivity is transposed to N–O–M–O–N–M.

Our groups have been exploring the chemistry of MCs[17,19,21a,21e,22a,22f,23b,24b,25] and the coordination chemistry of 2-pyridyl oximes,[26,27] the latter not necessarily in relation to the former. There is currently a renewed interest in the coordination chemistry of oximes.[28] Research efforts are driven by a number of considerations, including the solution of pure chemical problems,[29] the development of new oxygen activation catalysts,[30] the application of metal/oxime systems as simple and efficient catalysts for the hydrolysis of organonitriles,[31] the mechanistic study of corrosion inhibition by Acorga P5000 (a modern corrosion inhibitor) on Fe surfaces,[32] and the employment of oximate ligands in the synthesis of homometallic or heterometallic clusters[28a,33,34] and chains[35] with interesting magnetic properties, including single-molecule magnetism[34e] and single-chain magnetism[35] behaviour. For example, the pure chemical interest arises from the ability of the oximate(1–) group (–C=N–O$^-$) to stabilize higher metal oxidation states,[36] such as Ni^{III} or Ni^{IV}, and the fact that the activation of oximes by transition metal centres towards further reactions seems to be an excellent area of modern synthetic chemistry.[28] In contrast to the great number of studies concerning metal complexes of simple oximes and salicylaldoxime,[28,34d,32] little is known about complexes of pyridyl oximes, although this class of compounds could offer unique features in terms of structural characteristics and physical properties.

Di-2-pyridyl ketone oxime (Hpko) occupies a special position amongst the 2-pyridyl oximes. One area to which the ligand pko^- is relevant is the chemistry of MCs (see above). Another attractive aspect of pko^- is its great coordinative flexibility and versatility, characteristics that have led to polynuclear 3d-metal complexes with impressive structures and interesting magnetic properties.[26,27a,27e,37] A last interesting feature is the activation of Hpko by 3d-metal centres, which appears to be a fruitful area of synthetic inorganic chemistry. Examples of this activation are the Mn-assisted transformation of Hpko into the coordinated dianion of the *gem*-diol form of di-2-pyridyl ketone through NO_3^- generation,[27a] and the in-situ transformation of Hpko into the coordinated ligands di-2-pyridylimine, (amino)di-2-pyridylmethyl ethyl ether and (amino)di-2-pyridylmethyl methyl ether upon its reaction with $[V^{III}Cl_3(THF)_3]$ in various solvents.[38]

Zinc(II)/Hpko chemistry has attracted some prior interest. Pecoraro and co-workers have prepared the tetranuclear species $[Zn_4(OH)_2(O_2CMe)_2(pko)_4]$ or $\{(OH)_2$[inv12-$MC_{Zn^{II}N(pko)}$-4]$(O_2CMe)_2\}$[24a] (using the metallacrown nomenclature), which is the archetype of the inverse 12-MC-4 complexes. Some of us have also prepared and studied[24b] $[ZnCl_2(Hpko)]$, $[Zn_4(OH)_2Cl_2(pko)_4]$ or $\{(OH)_2$[inv12-$MC_{Zn^{II}N(pko)}$-4]$Cl_2\}$ and $[Zn_8(shi)_4(pko)_4(MeOH)_2]$; the second of these complexes is also an inverse 12-MC-4 species, while a part of the octanuclear cluster can be described as having a formally anionic [12-$MC_{Zn^{II}N(shi)}$-4]$^{4-}$ core with the 12-membered ring acting as host agent for a dinuclear $Zn_2(pko)_4$ unit and with two of the MC ring Zn^{II} ions creating dinuclear moieties with the remaining metal ions. Using these prior observations as a starting point and seeking to extend the family of the inverse 12-$MC_{Zn^{II}N(pko)}$-4 complexes, to incorporate pseudohalides (N_3^-, NCO^-, SCN^-), carboxylates other than acetates or anionic chelates into the Zn^{II}/pko^- chemistry, and to examine the possibility of creating novel cluster topologies within this chemistry, we report here the successful development of synthetic routes to cationic pentanuclear Zn^{II}/pko^- clusters and to new examples of inverse 12-$MC_{Zn^{II}N(pko)}$-4 compounds featuring N_3^-, NCO^-, SCN^-, $PhCO_2^-$ or $acac^-$ coligands [acac = acetylacetonate(–1) ion].

Results and Discussion

Synthesis

As stated above, we were interested in extending the very small family of inverse 12-$MC_{Zn^{II}N(pko)}$-4 complexes. In an earlier report, Pecoraro's group reported the preparation of the inverse metallacrown $[Zn_4(OH)_2(O_2CMe)_2(pko)_4]$.[24a] Thus, we decided to seek the benzoate version of this complex. Our main goal was to determine whether the benzoate cluster would have a similar molecular structure. The preparation of compound **1** can be achieved by the 1:1 reaction of $Zn(O_2CPh)_2{\cdot}2H_2O$ with pko^- in MeCN at room temperature [Equation (1)]. Note that both Et_3N and the released $PhCO_2^-$ groups can act as proton acceptors to facilitate formation of OH^- and pko^- ligands.

$$4\ Zn(O_2CPh)_2{\cdot}2H_2O + 4\ Hpko + 4\ Et_3N \xrightarrow{MeCN} [Zn_4(OH)_2(O_2CPh)_2(pko)_4]\ (\mathbf{1}) + 2\ PhCO_2H + 4\ Et_3NHO_2CPh + 6\ H_2O \quad (1)$$

Similar results were obtained in the absence of the external Et_3N base; however, the yield (about 20%) was lower. The formation of **1** in the absence of Et_3N (not reported in the Experimental Section) is summarised by Equation (2).

$$4\ Zn(O_2CPh)_2{\cdot}2H_2O + 4\ Hpko \xrightarrow{MeCN} [Zn_4(OH)_2(O_2CPh)_2(pko)_4]\ (\mathbf{1}) + 6\ PhCO_2H + 6\ H_2O \quad (2)$$

Two years ago we reported[24b] the preparation of the inverse 12-MC-4 $[Zn_4(OH)_2Cl_2(pko)_4]$ from the reaction of $ZnCl_2$ with pko^- or by addition of NaOH to a MeOH/DMF solution of the mononuclear complex $[ZnCl_2(Hpko)]$. We wondered whether pseudohalide analogues of the chloro cluster could be prepared. For example, we could envisage that complexes $[Zn_4(OH)_2X_2(pko)_4]$ (X = N_3^-, SCN^-, OCN^-, ...), with two terminal X^- ligands instead of two terminal chloro ligands, should be stable. Reactions between convenient Zn^{II} sources and a combination of N_3^- or OCN^- and pko^- (ca. 2:1:2) in DMF or DMF/MeOH led to subsequent isolation of pure crystalline complexes **2** and **3** in good yields (ca. 70%) [Equations (3) and (4)]. Single-crystal X-ray crystallography revealed the expected structural similarity between **2** and **3** and the chloro cluster.

$$4\ Zn(NO_3)_2{\cdot}4H_2O + 2\ NaN_3 + 4\ Hpko + 4\ NaOH \xrightarrow{DMF} [Zn_4(OH)_2(N_3)_2(pko)_4]\ (\mathbf{2}) + 6\ NaNO_3 + 2\ HNO_3 + 18\ H_2O \quad (3)$$

$$4\ ZnCl_2 + 2\ NaOCN + 4\ Hpko + 4\ NaOH \xrightarrow{DMF/MeOH} [Zn_4(OH)_2(NCO)_2(pko)_4]\ (\mathbf{3}) + 6\ NaCl + 2\ HCl + 2\ H_2O \quad (4)$$

Two features of the Equations (3) and (4) deserve comments. First, the reaction "solutions" should be filtered before crystallisation to remove a small amount of $NaNO_3$ or NaCl which remains insoluble in DMF. Second, the employment of DMF is beneficial to the syntheses as DMF solvate molecules stabilize the crystal lattices of **2** and **3** and also possibly aid in the "neutralisation" of the produced *dilute* HCl or HNO_3 and, thus, the latter do not decompose the hydroxo clusters.

The next questions we addressed were whether the monodentate ligands $PhCO_2^-$, N_3^-, OCN^- and Cl^- in **1**, **2**, **3** and $[Zn_4(OH)_2Cl_2(pko)_4]$,[24b] respectively, or the *nearly* monodentate $MeCO_2^-$ ligand (in fact the acetato ligand is anisobidentate) in $[Zn_4(OH)_2(O_2CMe)_2(pko)_4]$,[24a] could be replaced by anionic chelates and whether this replacement would preserve the inverse 12-MC-4 structural type. The anionic chelating ligand chosen was the acetylacetonate(–1) ion ($acac^-$). The procedure that leads to pure **4** involves the reaction of $Zn(acac)_2{\cdot}H_2O$ with an almost equimolar amount of Hpko in CH_2Cl_2 under reflux [Equation (5)]. The source of the hydroxo ligands is moisture from the starting materials, and the solvents used for the preparation (CH_2Cl_2) and/or crystallisation (Et_2O) of the complex. Single-crystal X-ray crystallography revealed the existence of an inverse 12-MC-4 motif in **4**. The isolation of the hydroxo cluster **4** from non-polar solvents is strong evidence of the great thermodynamic stability of the $\{Zn_4(\mu_3\text{-}OH)_2(pko)_4\}^{2+}$ unit.

$$4\ Zn(acac)_2{\cdot}H_2O + 4\ Hpko \xrightarrow[T]{CH_2Cl_2} [Zn_4(OH)_2(acac)_2(pko)_4]\ (\mathbf{4}) + 6\ Hacac + 2\ H_2O \quad (5)$$

We initially came across complexes **5** and **6** when we tried to prepare the isothiocyanato analogue of $[Zn_4(OH)_2Cl_2(pko)_4]$, **2** and **3**. These at first glance trivial efforts led to dramatic nuclearity and structural changes. The initial reaction explored was that between $ZnCl_2$, half an equivalent of SCN^- and one equivalent of pko^- (prepared in situ from Hpko and NaOH) in MeOH. The colourless solution obtained gradually turned to pale yellow upon stirring. Concentration of the resulting solution at room temperature gave a mixture of colourless prisms and pale-yellow needles. Their not-too-dissimilar solubility prevented chemical separation; however, the differences in colour and crystal shape allowed manual separation of the two materials. The colourless and pale-yellow crystals were crystallographically identified as complexes $[Zn_5Cl_2(pko)_6][ZnCl(NCS)_3]{\cdot}2.5H_2O{\cdot}1.5MeOH$ (**5**$\cdot 2.5H_2O\cdot 1.5MeOH$) and $[Zn_5(NCS)_2(pko)_6(MeOH)][Zn(NCS)_4]{\cdot}2.5H_2O{\cdot}MeOH$ (**6**$\cdot 2.5H_2O\cdot$MeOH), respectively. Stoichiometric reactions of the formation of **5** and **6** are represented by Equations (6) and (7), respectively.

With the identities of **5** and **6** established, convenient syntheses of pure materials were sought under alternative reaction conditions. Complex **6** has a Zn^{II}/SCN^- ratio of 1:1, whereas the initial reaction solution had a Zn^{II}/SCN^- ratio

$$6\ ZnCl_2 + 3\ NaSCN + 6\ Hpko + 6\ NaOH \xrightarrow{MeOH} [Zn_5Cl_2(pko)_6][ZnCl(NCS)_3] + 9\ NaCl + 6\ H_2O \quad (6)$$

5

$$6\ ZnCl_2 + 6\ NaSCN + 6\ Hpko + 6\ NaOH + MeOH \xrightarrow{MeOH} [Zn_5(NCS)_2(pko)_6(MeOH)][Zn(NCS)_4] + 12\ NaCl + 6\ H_2O \quad (7)$$

6

of 2:1; thus, attempts to obtain pure **6** were made by decreasing this ratio. Somewhat to our disappointment, the use of $ZnCl_2$/NaSCN ratios of 1:1 or even of 1:2 again gave mixtures of **5** and **6**. It is likely that the reaction solution contains a complicated mixture of several species in equilibrium, with factors such as relative solubility, lattice energy, crystallisation kinetics amongst others determining the identity of the isolated products. Since complex **6** is chloride-free, the next logical step to prepare the pure compound was to exclude Cl^- ions from the reaction mixture. The preparation of pure **6** was achieved by the reaction of a slight excess of $Zn(O_2CMe)_2{\cdot}2H_2O$ with one equivalent of NaSCN and one equivalent of Hpko in MeOH [Equation (8)].

$$6\ Zn(O_2CMe)_2{\cdot}2H_2O + 6\ NaSCN + 6\ Hpko + MeOH \xrightarrow{MeOH} [Zn_5(NCS)_2(pko)_6(MeOH)][Zn(NCS)_4] + 6\ NaO_2CMe + 6\ MeCO_2H + 12\ H_2O \quad (8)$$

6

In seeking to prepare the pure complex **5**, it was logical to carry out reactions employing high $ZnCl_2$/NaSCN ratios. The 3:1:3 and 4:1:4 $ZnCl_2$/NaSCN/pko^- reaction mixtures in MeOH led to precipitation of *almost* pure colourless **5** in good yields (typically higher than 50%). However, careful examination of the crystalline powders from these reactions revealed trace amounts of pale-yellow microcrystals and/or specks which were shown to be complex **6** by IR spectroscopy. Thus, the manual separation of colourless crystals from their above-described mixtures with **6** remains the only source of complex **5** to date for further measurements.

Since complexes **5** and **6** contain different Zn^{II}/SCN^- ratios, it seemed reasonable to suspect that they could be interconverted by treatment of the performed materials with appropriate reagents. The conversion of **5** to **6** can be accomplished quite easily by treatment of the former with an excess of NaSCN in MeOH at 45 °C [Equation (9)]. Addition of a small amount of external H_2O to the reaction mixture is necessary to achieve a clean conversion of **5** to **6**, presumably by keeping the produced NaCl soluble. All efforts to prepare **5** by the reaction of **6** with an excess of NaCl in MeOH or MeOH/H_2O were in vain.

$$[Zn_5Cl_2(pko)_6][ZnCl(NCS)_3] + 3\ NaSCN + MeOH \xrightarrow[45\ ^oC,\ exc.\ NaSCN]{MeOH/H_2O\ (10:1\ v/v)} [Zn_5(NCS)_2(pko)_6(MeOH)][Zn(NCS)_4] + 3\ NaCl \quad (9)$$

5 → **6**

The isolation of **5** and **6** was surprising and, needless to say, unexpected. We suspected that the formation of the pentanuclear clusters might be related to their cationic character. Thus, we tried to prepare such clusters with N_3^- and OCN^- ligands under conditions that favour formation of anionic compounds, i.e., employing bulky non-coordinating counteranions. Synthetic studies of hundreds of ZnX_2/OCN^- or N_3^-/pko^-/Y^- reaction mixtures (X = Cl, NO_3, $MeCO_2$; Y = PF_6, ClO_4, BPh_4) repeatedly led to microcrystalline materials. Analytical data were consistent with the formulation $[Zn_5(OCN)_2(pko)_6]Y_2$ or $[Zn_5(N_3)_2(pko)_6]Y_2$ and IR data indicated the presence of Y^- counterions, but, unfortunately, numerous attempts to obtain crystals suitable for crystallographic studies all were in vain. We were luckier, but at the same time unlucky again, when we employed $acac^-$ (instead of N_3^- or OCN^-) in the above-mentioned reaction mixtures. The reaction, summarised in Equation (10), gave pale-yellow prisms, which were proven to be single crystals.[39] Unfortunately, the crystals were of bad quality and poor diffractors of X-rays and, therefore, we refrain from presenting a full structural analysis here. Nevertheless, single-crystal crystallographic studies clearly revealed the presence of the $[Zn_5(acac)_2(pko)_6]^{2+}$ ion in the product, further emphasising our belief that the pentanuclear clusters are isolable only as cations.

$$5\ Zn(acac)_2{\cdot}H_2O + 6\ Hpko + 3\ NH_4PF_6 \xrightarrow{MeOH} (NH_4)[Zn_5(acac)_2(pko)_6](PF_6)_3 + 6acacH + 2\ NH_4acac + 5\ H_2O \quad (10)$$

Description of Structures

$[Zn_4(OH)_2(O_2CPh)_2(pko)_4]{\cdot}3MeCN$ (1·3MeCN), $[Zn_4(OH)_2(N_3)_2(pko)_4]{\cdot}4DMF$ (2·4DMF), $[Zn_4(OH)_2(NCO)_2(pko)_4]{\cdot}3DMF{\cdot}H_2O$ (3·3DMF·H_2O) and $[Zn_4(OH)_2(acac)_2(pko)_4]{\cdot}4CH_2Cl_2$ (4·4CH_2Cl_2)

Partially labelled plots of the tetranuclear molecules present in compounds **1**·3MeCN, **2**·4DMF, **3**·3DMF·H_2O and **4**·4CH_2Cl_2, are shown in Figures 2, 3, 4, and 5, respectively. Selected interatomic distances and angles are listed in Tables 1, 2, 3, and 4, respectively. The molecular structures of the four complexes are similar in many aspects and, thus, only the structure of the representative complex **1**·3MeCN will be described in detail.

The tetranuclear molecule of **1**·3MeCN lies on a crystallographic inversion centre and has a planar, nearly rhombic arrangement of the metal centres. The two diagonals of the rhombus correspond to the interatomic distances Zn(1)···Zn(1′) and Zn(2)···Zn(2′) which are equal to 5.815(1) and 3.224(1) Å, respectively, the short diagonal being very similar to the sides of the rhombus. Due to the presence of the crystallographic inversion centre, the $\{Zn(2)Zn(2')O(21)O(21')\}^{2+}$ subcore is strictly planar. The metallacrown is characterised as inverse because the Zn ions, rather than the oximate oxygen atoms, are oriented towards the centre of the cavity, while the connectivity is

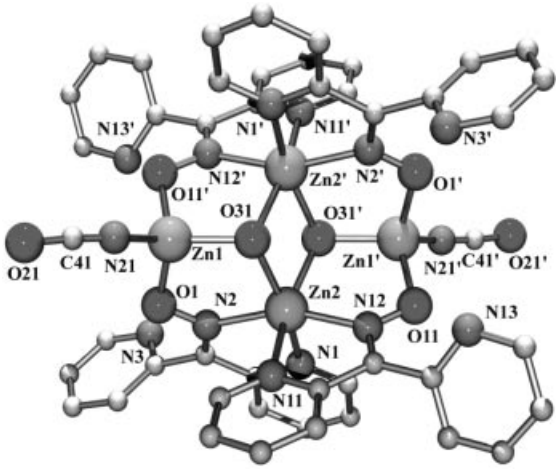

Figure 4. Partially labeled POV-RAY plot of the tetranuclear molecule of complex **3**·3DMF·H_2O. Primed and unprimed atoms are related by the crystallographic inversion centre. O(31) and O(31′) are the hydroxo oxygen atoms. The connectivity of the inverse metallacrown ring has been highlighted.

N–O–Zn–O–N–Zn. The Zn centres are bridged along each side of the rhombus by one μ_3-hydroxide [O(21),O(21′)] and one oximate(–1) group. The pko$^-$ ligands adopt an η^1:η^1:η^1:μ_2 (or 2.1110[16]) coordination mode. The coordination about the hydroxo oxygen atom, O(21), is markedly pyramidal [sum of Zn–O(21)–Zn angles: 319.7°].

The metal ions exhibit two coordination geometries. Zn(2) and Zn(2′) are in distorted O_2N_4 octahedral environments, whereas Zn(1) and Zn(1′) are in severely distorted O_4 tetrahedral environments. Each hydroxo oxygen atom bridges to two octahedral Zn ions and one tetrahedral Zn ion. The octahedral Zn ions are bound to two pko$^-$ moieties by pyridyl nitrogen atoms [N(1), N(11), N(1′), N(11′)] and the oxime nitrogen atoms [N(2), N(12), N(2′), N(12′)] in two five-membered chelating rings. The remaining two coordination sites of the octahedron are filled by the two μ_3-hydroxide ions accommodated in the centre of the MC ring. The ligands form a propeller configuration that imposes absolute stereoisomerism, with Λ chirality at Zn(2) and Δ chirality at Zn(2′). Each tetrahedral Zn ion is bound to one of the bridging hydroxo ligands and to two oximate oxygen atoms, while the fourth site is occupied by an oxygen atom [O(31), O(31′)] from a coordinated benzoate ion. The longer Zn(2)–O bonds [2.085(3), 2.088(4) Å] compared to the Zn(1)–O ones [1.925(5)–1.991(3) Å] are a consequence of the higher coordination number of Zn(2). The angles around Zn(1) [and Zn(1′)] are in the wide 100.9(3)–133.3(2)° range. The benzoate oxygen atom [O(31)] forms a strong bond with Zn(1) [1.925(5) Å]. As is sometimes (but not always) observed for monodentate RCO_2^- groups, there

O(31)–Zn(1)–N(1)	159.9(2)	Zn(1)–O(31)–Zn(1′)	100.4(2)

[a] Primed atoms are related to the unprimed ones by the symmetry transformation $-x + 2, -y + 1, -z + 1$.

is evidence for an additional weak interaction between Zn(1) and Zn(1′), and the "free" benzoate oxygen atoms O(32) and O(32′), which generates an asymmetric chelating carboxylate group. Further support for this structural assignment comes from the coordination environment around Zn(1), which is very distorted from tetrahedral geometry; thus, an alternative description for the Zn(1) polyhedron is as an edge-capped tetrahedron.

The separations between neighbouring metal ions in **1** [3.315(1), 3.334(1) Å] are significantly shorter than those

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

observed in regular 12-MC-4 complexes [M···M distances are approx. 4.6 Å].[15,18,19,21a] If we consider that, in the inverse 12-MC-4 compounds, the M···M separation is the bite distance, then this separation is longer than the O···O distance in regular MCs (ca. 2.6 Å) which is considered as the bite distance.

Complex **1** is only the second structurally characterised example of a tetranuclear zinc(II) benzoate cluster, the first being $[Zn_4O(O_2CPh)_6]$.[40]

The molecular structures of **2**·4DMF, **3**·3DMF·H_2O and **4**·4CH_2Cl_2 are similar to the structure of **1**·3MeCN except that the two terminal $PhCO_2^-$ ligands of **1** are replaced by two monodentate azido (**2**·4DMF), two monodentate isocyanato (i.e. *N*-bonded, **3**·3DMF·H_2O) or two bidentate chelating acetylacetonate groups (**4**·4CH_2Cl_2). Due to the presence of the purely monodentate N_3^- and NCO^- ligands in **2**·4DMF and **3**·3DMF·H_2O, respectively, instead of the anisobidentate benzoate ligands in **1**·3MeCN, the coordination environments of the tetrahedral Zn ions are less distorted; the angles around these metal ions in **2**·4DMF and **3**·3DMF·H_2O are in the ranges 102.0(1)–119.5(2)° and 101.6(2)–122.2(3)°, respectively [vs. the 100.9(3)–133.3(2)° range observed in **1**·3MeCN]. The presence of the chelating $acac^-$ ligands in **4**·4CH_2Cl_2 creates a truly five-coordination at two metal ions [Zn(2) and Zn(2′) in Figure 5]. The five donor atoms around Zn(2) [and Zn(2′)] do not create a regular polyhedron. Analysis of the shape-determining angles using the approach of Reedijk and coworkers[41] yields a value for the trigonality index, τ, of 0.61 (τ = 0 and 1 for perfect square-pyramidal (spy) and trigonal-bipyramidal (tbp) geometries, respectively). Thus, the geometry about Zn(2) is significantly distorted and can better be described as distorted tbp. With use of this description, the axial sites of Zn(2) are occupied by atoms O(31) and O(42) with atoms O(1), O(11′) and O(41) making up the equatorial plane (Figure 4 and Table 3).

The $Zn–N_{azido}$ [1.925(5) Å] and $Zn–N_{isocyanato}$ [1.918(7) Å] bond lengths in **2**·4DMF and **3**·3DMF·H_2O, respectively, are typical for such terminal bonds in tetrahedral zinc(II) complexes. For comparison, the $Zn–N_{azido}$ bond lengths in $[Zn(N_3)_2(py)_2]$ (py = pyridine)[42] are 1.928(16) and 1.945(17) Å, while the $Zn–N_{isocyanato}$ bond lengths in $[Zn(NCO)_2(4\text{-dmap})_2]$, where 4-dmap is 4-(dimethylamino)pyridine, are 1.909(5) and 1.942(5) Å. The azido and isocyanato ligands are almost linear [N(21)–N(22)–N(23) = 175.8(12)°, N(21)–C(41)–O(21) = 176(2)°]; these ligands are coordinated in a bent (N_3^-) or slightly bent (NCO^-) fashion as indicated by the Zn–N–N [134.0(7)°] and Zn–N–C [160.7(10)°] angles, respectively (Table 4).

The benzoate cluster **1** has a similar structure to its acetate version,[24a] while the molecular structures of the pseudohalide inverse 12-MC-4 complexes **2** and **3** are also very similar to the structure of the halide analogue $[Zn_4(OH)_2Cl_2(pko)_4]$.[24b] Obviously, the replacement of $MeCO_2^-$ by $PhCO_2^-$, and of Cl^- by N_3^- and NCO^- has little structural effect. Rather than discuss similarities, we list in Table 5 comparative structural parameters for the $\{(OH)_2[inv12\text{-}MC_{Zn^{II}N(pko)}\text{-}4]X_2\}$ complexes (X = Cl, N_3, NCO). The remarkable similarity of the molecular structures of the three complexes is clearly evident. The presence of the two five-coordinate Zn anions in **4** {instead of two four-coordinate Zn ions in $[Zn_4(OH)_2Cl_2(pko)_4]$, **2** and **3**} has few slight structural consequences. The $Zn_{five\text{-}coord}–O_{hydroxo}$ [2.082(5) Å] and $Zn_{five\text{-}coord}–O_{oximate}$ [mean value: 1.994(5) Å] bond lengths are longer than the corresponding $Zn_{tetr}–O_{hydroxo}$ and mean $Zn_{tetr}–O_{oximate}$ ones (Table 5), as expected. The $Zn_{five\text{-}coord}\cdots Zn_{five\text{-}coord}$ separation [6.132(1) Å] is longer than the $Zn_{tetr}\cdots Zn_{tetr}$ ones (Table 5), whereas the $Zn_{oct}\cdots Zn_{oct}$ interatomic distance [3.164(1) Å] and the mean $Zn_{oct}–O_{hydroxo}$ bond length [2.059(6) Å] are shorter than the corresponding distances in $\{(OH)_2[inv12\text{-}MC_{Zn^{II}N(pko)}\text{-}4]X_2\}$ (X = Cl, N_3, NCO).

Table 5. Selected, comparative structural data for the halide/pseudohalide inverse 12-MC-4 complexes $[Zn_4(OH)_2Cl_2(pko)_4]$, $[Zn_4(OH)_2(N_3)_2(pko)_4]$ (**2**) and $[Zn_4(OH)_2(NCO)_2(pko)_4]$ (**3**).

[a] Mean value.

$[Zn_5Cl_2(pko)_6][ZnCl(NCS)_3]$·2.5$H_2O$·1.5MeOH (5·2.5$H_2O$·1.5MeOH) and $[Zn_5(NCS)_2(pko)_6(MeOH)][Zn(NCS)_4]$·2.5$H_2O$·MeOH (6·2.5$H_2O$·MeOH)

Fully or partially labelled plots of the cations and anions present in compounds **5**·2.5H_2O·1.5MeOH and **6**·2.5H_2O·MeOH, are shown in Figures 6, 7, 8, and 9. Selected interatomic distances and angles are listed in Tables 6, 7, 8, and 9. The molecular structures of the pentanuclear cations $[Zn_5Cl_2(pko)_6]^{2+}$ and $[Zn_5(NCS)_2(pko)_6(MeOH)]^{2+}$ are similar in many aspects and, thus, only the structure of the chloride-containing cation will be described in detail.

Complex **5**·2.5H_2O·1.5MeOH crystallises in the triclinic space group $P\bar{1}$. Its structure consists of the pentanuclear $[Zn_5Cl_2(pko)_6]^{2+}$ cation, the novel $[ZnCl(NCS)_3]^{2-}$ anion, and solvate H_2O and MeOH molecules; the solvate molecules will not be further discussed. The five Zn ions of the cation are held together by six pko^- ligands which adopt three different coordination modes. Two pko^- ligands adopt the coordination mode 2.1110, two are in the rare 3.1111 fashion, while the rest behave as 3.2111 ligands (see Figure 1). The five metal ions define two nearly equilateral triangles sharing a common apex at Zn(1). The "central" Zn(1) ion is in a distorted $O_2(N_{pyridyl})_2(N_{oximate})_2$ *cis-trans-cis* octahedral environment. Zn(2) and Zn(3) are bound to an $O_2(N_{pyridyl})_2(N_{oximate})$ set of donor atoms, while Zn(4) and Zn(5) are bound to an $O(N_{pyridyl})_2(N_{oximate})Cl$ set. The

five donor atoms around Zn(2) and Zn(3) create a very distorted polyhedron. The τ values[41] for Zn(2) and Zn(3) are 0.48 and 0.54, respectively. We prefer to describe the geometry about these metal ions as very distorted tbp. With use of this description, the axial sites of Zn(2) are occupied by atoms O(11) and N(23), while those of Zn(3) by atoms O(1) and N(33). The Zn(4) and Zn(5) coordination geometries are better described as very distorted spy with the 2-pyridyl nitrogenatoms N(3) and N(13) occupying the apical positions for Zn(4) and Zn(5), respectively; The τ values[41] are

gands. This causes two "collapsed"[4,18] 9-metallacrown-3 structures sharing a common apex at Zn(1). Each "collapsed" structure is essentially a cation-vacant metallacrown.

Besides the pentanuclear cation, the structure contains a novel (from the chemical composition viewpoint) chlorotris(isothiocyanato)zincate(2–) anion (Figure 7). Three NCS^- ions coordinating through their nitrogen atoms and one terminal chloro ligand surround Zn(6). The bond angles about the metal ion are in the range 106.1(5)–111.7(6)°, and show a slight distortion of the ZnN_3Cl tetrahedron. The three isothiocyanate groups bind the zinc ion in a virtually linear fashion, with the C–N–Zn bond angles in the range of 158.2(13)–171.3(11)°.

The molecular structure of the pentanuclear cation of **6**·2.5H_2O·MeOH is similar to the structure of the cation of **5**·2.5H_2O·1.5MeOH except that the two terminal chloro ligands of the latter are replaced by two terminal isothiocyanato ligands in the former and one of the five-coordinate metal ions of **5**·2.5H_2O·1.5MeOH [Zn(5) in Figure 6] has become six-coordinate in **6**·2.5H_2O·MeOH [Zn(5) in Figure 8] through coordination of one terminal MeOH ligand. Again, the five metal ions define two nearly equilateral triangles sharing a common apex [at Zn(3)], the six pko^- ligands adopt three different coordination modes (2.1110, 3.1111, 3.2111, see Figure 1) and the Zn_5 topology can be described as two fused "collapsed" 9-MC-3 rings [in this case the Zn(2) and Zn(1) ions reach across their respective 9-MC-3 rings and bind to the oxime oxygen atoms O(11) and O(1) of the opposite pko^- ligands]. Another slightly different structural feature of **6**·2.5H_2O·MeOH is worthy of comment. In **5**·2.5H_2O·1.5MeOH the two five-coordinate, chloride-bound metal ions [Zn(4) and Zn(5) in Figure 6] have a distorted spy coordination environment, whereas the polyhedron of the unique five-coordinate, isothiocyanate-bound metal ion [Zn(4) in Figure 8] in **6**·2.5H_2O·MeOH is better described as a very distorted trigonal bipyramid (τ = 0.45) with atoms O(1) and N(51) occupying the axial sites. The Zn(4)–$N_{isothiocyanate}$ bond [1.959(6) Å] is shorter than the Zn(5)–$N_{isothiocyanate}$ bond [2.020(6) Å], which is consistent with the lower coordination number for Zn(4) [five vs. six for Zn(5)] (Table 8).

Besides the pentanuclear cation, the structure contains a tetraisothiocyanatozincate(2–) anion (Figure 9). Four NCS^- anions almost equivalently surround Zn(6), coordinating through the nitrogen atoms such that a slightly distorted tetrahedral geometry occurs. The Zn–N bond lengths [1.922(9)–1.962(9) Å] and N–Zn–N bond angles [105.8(4)–111.8(4)°] are typical for complexes containing the $[Zn(NCS)_4]^{2-}$ anion.[45] All the NCS^- groups bind the metal ion in a virtually linear fashion, with the C–N–Zn bond angles in the range 168.4(10)–175.4(9)° (Table 9).

The cations present in compounds **5** and **6** represent the third and fourth, respectively, structurally characterised examples of non-organometallic, pentanuclear Zn^{II} complexes with *O*,*N* ligation (there are several examples with S-, Te- or P-containing ligands). The other two examples are $[\{Zn_2L(O_2CMe)_2\}_2Zn(H_2O)_4]$[46a] and $[Zn_5(poap\text{-}H)_6](ClO_4)_4$,[46b] where L is the trianion of a Schiff base derived from glycine and poap-H the monoanion of an alkoxydiazine polydentate ligand.

A remarkable structural feature of complexes **5** and **6** is the presence of pko^- ligands that adopt three different coordination modes. Since most complexes containing *bridging* pko^- ligands have been reported only recently, we felt it timely to collect all metal complexes of bridging pko^- ligands in Table 10, together with the pko^- coordination modes for convenient comparison. Inspection of Table 10 clearly shows that the 2.1110 ligation mode (Figure 1) is the most common one and that only two previously characterised clusters, namely $[Ni_4(pko)_6(MeOH)_2](OH)(ClO_4)$[26a] and $[Zn_8(shi)_4(pko)_4(MeOH)_2]$,[26b] contain di-2-pyridyl ketone oximate(1–) ligands exhibiting two different coordination modes; thus, the cations of **5** and **6** are unique in exhibiting three different coordination modes of the pko^- ligands.

IR Spectra

The IR spectra of **1**, **2**·4DMF and **4** exhibit a medium band at 3414–3386 cm^{-1} assignable[47a] to $\nu(OH)_{OH^-}$. The

[a] Counterions and solvate molecules have been omitted; 3,4-D = the anion of 3,4-dichlorophenoxyacetic acid; Hshi = the dianion of salicylhydroxamic acid; MCPA = the anion of 2-methyl-4-chlorophenoxyacetic acid; $(py)_2CO_2$ = the dianion of the *gem*-diol form of di-2-pyridyl ketone; shi = the trianion of salicylhydroxamic acid; R = Me, Ph; X = Cl, Br; X′ = Cl, NCS; Y = NCS, Cl, NCO; Z = $PhCO_2$, N_3, NCO, acac. [b] Using Harris notation[16] (see also Figure 1). [c] This complex also contains N,N′-chelating, i.e., terminal, pko⁻ ligands.

presence of both hydroxo ligands and water solvate molecules in **3**·3DMF·H_2O is manifested by a broad IR band of medium intensity at about 3400 cm^{-1}.[47b] The ν(OH) band in the spectra of the crystals of **5**·2.5H_2O·1.5MeOH and **6**·2.5H_2O·MeOH appears at 3330 and 3415 cm^{-1}, respectively. The presence of DMF in **2**·4DMF and **3**·3DMF·H_2O is manifested by a strong band at 1672–1665 cm^{-1} and a weak band at around 640 cm^{-1}, assigned to ν(C=O) and δ(OCN), respectively.[48] The absence of shifts of these bands in the complexes, when compared with the corresponding bands in the spectrum of free DMF,[48] confirms that there is no interaction between DMF and the Zn^{II} atoms.

Two bands, one strong at about 1595 cm^{-1} and one of variable intensity at about 1220 cm^{-1}, are common in the spectra of **1**–**6**; these bands are tentatively assigned to the oximate ν(C=N) and ν(N–O) vibrational modes,[24b] respectively, although the higher-wavenumber band may also have an aromatic stretch character.

The strong bands at 1566 and 1366 cm^{-1} in the spectrum of **1** are assigned to the $\nu_{as}(CO_2)$ and $\nu_s(CO_2)$ modes of the benzoate ligands, respectively;[49] the former may also involve a 2-pyridyl stretching character. The difference Δ [$\Delta = \nu_{as}(CO_2) - \nu_s(CO_2)$] is 200 cm^{-1}, more than that for NaO_2CPh (184 cm^{-1}), as expected for monodentate ligation.[49] In the spectrum of **4**, the bands at 1594 and 1518 cm^{-1} certainly involve a $\nu(C{=}C)_{acac^-}$ [coupled with $\nu(C{=}O)_{acac^-}$] character and a $\nu(C{=}O)_{acac^-}$ [coupled with $\nu(C\text{–}C)_{acac^-}$] character, respectively;[50] however, overlap with other modes renders exact assignments difficult. The spectrum of **2**·4DMF exhibits an intense band at 2070 cm^{-1}, assigned to the asymmetric stretching mode of the azido ligands.[50] Similarly, the strong band at 2236 cm^{-1} in the spectrum of **3**·3DMF·H_2O is assigned to the ν_{as}(NCO) [consisting mainly of ν(CN)] vibrational mode of the isocyanato ligands.[50,51] The spectra of the dried samples **5**·2.5H_2O and **6**·2.5H_2O exhibit the ν(CN) mode at 2076 and 2074 cm^{-1}, respectively; These wavenumbers are typical of terminal isothiocyanato groups.[50] The existence of the isothiocyanato ligands at different Zn^{II} coordination environments (tetrahedral, trigonal-bipyramidal, octahedral) in **6** does not lead to two or three ν(CN) bands and, thus, the different environments cannot be differentiated by IR spectroscopy. The expected ν_s(NNN), δ(NNN) [**2**·4DMF], ν_s(NCO) [consisting mainly of ν(CO)], δ(NCO) [**3**·3DMF·H_2O], ν(CS) and δ(NCS) [**5**·2.5H_2O, **6**·2·5H_2O] bands could not be located because they are obscured by pko⁻ absorptions.

Conclusions and Perspectives

The further use of di-2-pyridyl ketone oxime in Zn chemistry has provided access to six new clusters, four tetranuclear and two pentanuclear. Complexes **1**–**4** are valuable additions to the small, but growing, family of inverse metallacrown complexes. The present work also extends the body of results that emphasise the ability of the monoanionic ligand pko⁻ to form new structural types in 3d-metal chemistry. Complexes **5** and **6** are rare examples of pentanuclear zinc complexes with ligands containing N- and/or O-donors. Moreover the "collapsed" double, fused 9-metallacrown-3 structural type observed in these clusters is novel. The structural diversity displayed by the reported complexes stems from the coordinating versatility of pko⁻ and its ability to exhibit two or even three distinct coordination modes in the same compound. The general structure of **5** and **6** is distinctly different from that of **2**, **3** and $[Zn_4(OH)_2Cl_2(pko)_4]$[24b] (these three complexes also have terminal pseudohalide or chloride ligands like **5** and **6**) emphasising the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

dependence of the product identity on the charge of the complex (neutral vs. cationic).

The isothiocyanate analogue of compounds **2** and **3** is not known, at least to date, and it is currently not evident whether the preparation and stability of the neutral $[Zn_4(OH)_2X_2(pko)_4]$ clusters are dependent on the particular nature of the pseudohalide ligand. Work is in progress to clarify this matter, and the use of $SeCN^-$ and $N(CN)_2^-$ is planned. The $PhCO_2^-$, N_3^-, NCO^- and $acac^-$ terminal ligands present in **1**–**4** could have future utility as sites for facile incorporation of other monodentate/bidentate ligands by metathesis, or as a means to access higher-nuclearity neutral or cationic Zn clusters using bis(monodentate)/bis(bidentate) bridging ligands, including aromatic heterocycles and dicarboxylates.

Results at the time of writing reveal that the nature of pko^- makes it a versatile ligand for a variety of objectives/advantages, including μ_3 behaviour, high-nuclearity cluster formation with a variety of 3d-, 4d- and 5d-metals, linking of clusters into polymeric arrays, 3d-4f mixed-metal chemistry and ferromagnetic exchange interactions. Clearly, the use of other polypyridyl oximes offers a potential route to other new clusters, and such studies − already well advanced − will be reported in due course.

Experimental Section

Materials and Physical Measurements: All manipulations were performed under aerobic conditions using materials and most solvents as received. DMF and MeOH were distilled from CaH_2 and Mg, respectively; they were both stored over molecular sieves (3 Å). $Zn(O_2CPh)_2{\cdot}2H_2O$ was prepared by the reaction of $Zn(O_2CMe)_2{\cdot}2H_2O$ with an excess of $PhCO_2H$ in $CHCl_3$ under reflux. C, H and N elemental analyses were performed with Perkin–Elmer 240B and EA 108 Carlo Erba analyzers. Zn was determined for some complexes by atomic absorption with a Perkin–Elmer 1100B spectrophotometer. IR spectra were recorded with Perkin–Elmer PC 16 and 1650 FT-IR spectrometers with samples prepared as KBr pellets.

$[Zn_4(OH)_2(O_2CPh)_2(pko)_4]{\cdot}3MeCN$ (1·3MeCN) or $\{(OH)_2[inv12\text{-}MC_{Zn^{II}N(pko)}\text{-}4](O_2CPh)_2\}{\cdot}3MeCN$: Treatment of a stirred, colourless solution of Hpko (0.120 g, 0.60 mmol) in MeCN (20 mL) with Et_3N (0.100 mL, 0.72 mmol) resulted in a pale-yellow solution. Solid $Zn(O_2CPh)_2{\cdot}2H_2O$ (0.207 g, 0.60 mmol) was slowly added to this solution and it soon dissolved to give an essentially colourless solution. The filtered solution was allowed to slowly concentrate by solvent evaporation at room temperature for a period of 3–4 d. Well-formed colourless cubes appeared which were collected by filtration, washed with ice-cold MeCN (5 mL) and Et_2O (2.5 mL), and dried in air. Yield (based on the oxime): 0.130 g (65%). The dried solid was analysed as MeCN-free **1**. $C_{58}H_{44}N_{12}O_{10}Zn_4$ (1330.7): calcd. C 52.35, H 3.34, N 12.63; found C 52.51, H 3.40, N 12.49. The obtained crystals were good diffractors of X-rays, as long as they were kept in contact with the mother liquor to prevent solvent loss. Selected IR data (KBr pellet): $\tilde{\nu}$ = 3414 cm^{-1} (m, broad), 1596 (s), 1566 (s), 1366 (s) 1214 (m) cm^{-1}.

$[Zn_4(OH)_2(N_3)_2(pko)_4]{\cdot}4DMF$ (2·4DMF) or $\{(OH)_2[inv12\text{-}MC_{Zn^{II}N(pko)}\text{-}4](N_3)_2\}{\cdot}4DMF$: a solution of NaN_3 (0.065 g, 1.00 mmol), Hpko (0.398 g, 2.00 mmol) and NaOH (0.080 g, 2.00 mmol) in DMF (50 mL) was added to a stirred solution of $Zn(NO_3)_2{\cdot}4H_2O$ (0.523 g, 2.00 mmol) in the same solvent (50 mL). The resulting colourless solution was stirred for 1 h, filtered and then allowed to very slowly concentrate at room temperature for a period of 15 d. X-ray quality colourless crystals formed, which were collected by filtration, washed with Et_2O (5 mL) and dried in air. Yield (based on the oxime): 0.51 g (70%). $C_{56}H_{62}N_{22}O_{10}Zn_4$ (1464.8): calcd. C 45.92, H 4.27, N 21.04, Zn 17.85; found C 46.10, H 4.17, N 19.44, Zn 18.80. The crystals of **2**·4DMF were found to be slightly hygroscopic, and they were kept in the mother liquor until a suitable crystal had been found for X-ray crystallography. Selected IR data (KBr pellet): $\tilde{\nu}$ = 3386 cm^{-1} (m, broad), 2070 (s), 1672 (s), 1596 (s), 1218 (s), 640 (w) cm^{-1}.

$[Zn_4(OH)_2(NCO)_2(pko_4]{\cdot}3DMF{\cdot}H_2O$ (3·3DMF·H_2O) or $\{(OH)_2[inv12\text{-}MC_{Zn^{II}N(pko)}\text{-}4](NCO)_2\}{\cdot}3DMF{\cdot}H_2O$: A solution of NaOCN (0.065 g, 1.00 mmol), Hpko (0.398 g, 2.00 mmol) and NaOH (0.080 g, 2.00 mmol) in MeOH (50 mL) was added to a stirred solution of $ZnCl_2$ (0.273 g, 2.00 mmol) in the same solvent (50 mL). The resulting solution was stirred vigorously for about 1 h, filtered and then DMF (50 mL) was added. The new colourless solution obtained was allowed to concentrate by solvent evaporation at room temperature for about 10 d. Well-formed colourless crystals appeared, which were collected by filtration, washed with Et_2O (2 × 3 mL) and dried in air. Yields (based on the oxime) as high as 0.48 g (68%) were obtained. $C_{55}H_{57}N_{17}O_{12}Zn_4$ (1409.65): calcd. C 46.86, H 4.08, N 16.90, Zn 18.55; found C 47.10, H 3.73, N 16.85, Zn 19.06. The crystal selected for X-ray crystallography was kept in contact with the mother liquor to prevent H_2O loss. Selected IR data (KBr pellet): $\tilde{\nu}$ = 3400 cm^{-1} (m, broad), 2236 (s), 1665 (s), 1595 (s), 1216 (s), 638 (w) cm^{-1}.

$[Zn_4(OH)_2(acac)_2(pko)_4]{\cdot}4CH_2Cl_2$ (4·4CH_2Cl_2) or $\{(OH)_2[inv12\text{-}MC_{Zn^{II}N(pko)}\text{-}4](acac)_2\}{\cdot}4CH_2Cl_2$: A solution of Hpko (0.040 g, 0.20 mmol) in CH_2Cl_2 (10 mL) was added dropwise to a colourless slurry of $Zn(acac)_2{\cdot}H_2O$ (0.052 g, 0.18 mmol) in the same solvent (15 mL). No noticeable colour change occurred. The mixture was refluxed under vigorous stirring for 15–20 min, a small quantity of undissolved material was removed by filtration and the filtrate layered with Et_2O (20 mL). Slow mixing gave X-ray quality crystals of **4**·4CH_2Cl_2. The crystals were collected by filtration, washed with cold CH_2Cl_2 (5 mL) and Et_2O (2 × 5 mL) and dried in air. Yield (based on Zn^{II}): 0.036 g (63%). The dried solid was analysed as CH_2Cl_2-free **4**. $C_{54}H_{48}N_{12}O_{10}Zn_4$ (1286.7): calcd. C 50.40, H 3.77, N 13.07; found C 50.53, H 3.71, N 13.00. The obtained crystals were stable as long as they were kept in contact with the mother liquor to prevent CH_2Cl_2 loss. Selected IR data (KBr pellet): $\tilde{\nu}$ = 3378 cm^{-1} (m, broad), 1594 (m), 1518 (s), 1222 (m) cm^{-1}.

$[Zn_5Cl_2(pko)_6][ZnCl(NCS)_3]{\cdot}2.5H_2O{\cdot}1.5MeOH$ (5·2.5H_2O·1.5MeOH) and $[Zn_5(NCS)_2(pko)_6(MeOH)][Zn(NCS)_4]{\cdot}2.5H_2O{\cdot}MeOH$ (6·2.5H_2O·MeOH) as a Mixture: A solution of NaSCN (0.081 g, 1.00 mmol), Hpko (0.398 g, 2.00 mmol) and NaOH (0.080 g, 2.00 mmol) in MeOH (50 mL) was added to a stirred solution of $ZnCl_2$ (0.273 g, 2.00 mmol) also in MeOH (50 mL). The resulting colourless solution was stirred for 1 h and during this time its colour turned to pale yellow. The pale-yellow solution was filtered and allowed to slowly concentrate by solvent evaporation at room temperature. After several days, an approximately 1:3 mixture of colourless prisms and pale-yellow needles formed. The crystals were carefully collected by filtration. The two products were readily separable manually, and the colourless and pale-yellow crystals proved by single-crystal X-ray crystallography to be complexes **5**·2.5H_2O·1.5MeOH and **6**·2.5H_2O·MeOH, respectively. A batch of colourless crystals were used for analyses and IR spectroscopy. The dried (in air) sample was analysed as MeOH-free **5**·2.5H_2O.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$C_{69}H_{53}Cl_3N_{21}O_{8.5}S_3Zn_6$ (1907.2): calcd. C 43.45, H 2.81, N 15.43; found C 43.67, H 2.77, N 15.36. Selected IR data (KBr pellet): $\tilde{\nu}$ = 3330 cm^{-1} (m, broad), 2076 (s), 1597 (s), 1214 (m) cm^{-1}.

$[Zn_5(NCS)_2(pko)_6(MeOH)][Zn(NCS)_4]\cdot 2.5H_2O\cdot MeOH$ ($6\cdot 2.5H_2O\cdot$ MeOH). Method A: A colourless solution of Hpko (0.060 g, 0.30 mmol) and NaSCN (0.024 g, 0.30 mmol) in MeOH (25 mL) was added to a colourless solution of $Zn(O_2CMe)_2\cdot 2H_2O$ (0.085 g, 0.39 mmol) in the same solvent (10 mL). The resulting pale-yellow solution was stirred for about 10 min and was then allowed to stand undisturbed in a closed flask at room temperature for 2 d. Well-formed pale-yellow crystals appeared, which were collected by filtration, washed with ice-cold MeOH (5 mL) and Et_2O (2 × 5 mL), and dried in air. Yield (based on the oxime): 0.083 g (83%). The crystals, which were kept in contact with the mother liquor to prevent MeOH loss, had identical unit-cell dimensions with those identified as $6\cdot 2.5H_2O\cdot$MeOH in the above-mentioned experiment. The dried solid was analysed as MeOH-free $6\cdot 2.5H_2O$. $C_{73}H_{57}N_{24}O_{9.5}S_6Zn_6$ (2007.2): calcd. C 43.68, H 2.87, N 16.75; found C 44.32, H 2.86, N 16.51. Selected IR data (KBr pellet): $\tilde{\nu}$ = 3415 cm^{-1} (m, broad), 2074 (s), 1596 (s), 1216 (w) cm^{-1}. **Method B:** A suspension of compound $5\cdot 2.5H_2O$ (0.191 g, 0.10 mmol) in warm MeOH/H_2O (40 mL, 10:1, v/v) was treated with an excess of NaSCN (0.041 g, 0.50 mmol). The mixture was stirred overnight at 45 °C, filtered to remove some undissolved starting material, and then allowed to stand undisturbed in closed vials at room temperature. Pale-yellow crystals formed within 12 h, and these were collected by filtration and washed with cold MeOH. Yield (based on $5\cdot 2.5H_2O$): 0.070 g (35%). The product was identified by microanalyses and IR comparison with material from method A.

X-ray Crystallographic Studies: Crystals of $1\cdot$3MeCN, $2\cdot$4DMF, $3\cdot$3DMF$\cdot H_2O$, $4\cdot 4CH_2Cl_2$, $5\cdot 2.5H_2O\cdot 1.5$MeOH and $6\cdot 2.5H_2O\cdot$MeOH were mounted in capillaries filled with drops of mother liquor. Diffraction measurements for $1\cdot$3MeCN, $2\cdot$4DMF, $3\cdot$3DMF$\cdot H_2O$ and $6\cdot 2.5H_2O\cdot$MeOH were carried out with a Crystal Logic Dual Goniometer diffractometer using graphite-monochromated Mo-K_α radiation. The X-ray data sets for $4\cdot 4CH_2Cl_2$ and $5\cdot 2.5H_2O\cdot 1.5$MeOH were collected with a $P2_1$ Nicolet diffractometer upgraded by Crystal Logic using graphite-monochromated Cu-K_a radiation. Complete crystal data and parameters for data collection and refinement are listed in Tables 11 and 12. Unit-cell dimensions were determined and refined by using the angular settings of 25 automatically centred reflections in the ranges $11° < 2\theta < 23°$ (for $1\cdot$3MeCN, $2\cdot$4DMF, $3\cdot$3DMF$\cdot H_2O$ and $6\cdot 2.5H_2O\cdot$MeOH) and $22° < 2\theta < 54°$ (for $4\cdot 4CH_2Cl_2$ and $5\cdot 2.5H_2O\cdot 1.5$MeOH). Intensity data were recorded using the θ-2θ scan method. Three standard reflections monitored every 97 reflections showed less than 3% variation and no decay. Lorentz, polarisation and Ψ-scan absorption (for $3\cdot$3DMF$\cdot H_2O$, $4\cdot 4CH_2Cl_2$, $5\cdot 2.5H_2O\cdot 1.5$MeOH and $6\cdot 2.5H_2O\cdot$MeOH) corrections were applied using the Crystal Logic software package.

The structures were solved by direct methods using SHELXS-86[52a] and refined by full-matrix least-squares techniques on F^2 with SHELX-93[52b] ($1\cdot$3MeCN, $4\cdot 4CH_2Cl_2$ and

Table 11. Crystal data and structure refinement for $[Zn_4(OH)_2(O_2CPh)_2(pko)_4]\cdot$3MeCN ($1\cdot$3MeCN), $[Zn_4(OH)_2(N_3)_2(pko)_4]\cdot$4DMF ($2\cdot$4DMF) and $[Zn_4(OH)_2(NCO)_2(pko_4]\cdot$3DMF$\cdot H_2O$ ($3\cdot$3DMF$\cdot H_2O$).

5·2.5H_2O·1.5MeOH) or SHELX-97[52c] (**2**·4DMF, **3**·3DMF·H_2O and **6**·2.5H_2O·MeOH). For **2**·4DMF almost all hydrogen atoms were located by difference maps and were refined isotropically, whereas for **3**·3DMF·H_2O, **5**·2.5H_2O·1.5MeOH and **6**·2.5H_2O·MeOH all hydrogen atoms were introduced at calculated positions as riding on their parent atoms. For **1**·3MeCN and **4**·4CH_2Cl_2 some hydrogen atoms were located by difference maps and were refined isotropically, and some were introduced at calculated positions as riding on bonded atoms. For example, in **4**·4CH_2Cl_2 all hydrogen atoms were located by difference maps and were refined isotropically, except those of the methyl groups of the $acac^-$ ligand which were introduced at calculated positions as riding on their parent carbon atoms. All non-hydrogen atoms of **4**·4CH_2Cl_2 were refined anisotropically. For the remaining structures, almost all non-hydrogen atoms were refined anisotropically. One of the solvate MeCN molecules of **1**·3MeCN was refined with occupation factor 0.50. For **2**·4DMF, one of the crystallographically independent solvate DMF molecules was refined isotropically; thus, no hydrogen atoms for that molecule were included. For **3**·3DMF·H_2O, one DMF and the H_2O solvate molecules were refined isotropically with occupation factors fixed to 10.5; no hydrogen atoms for these solvate molecules were included in the refinement. All the solvate molecules of **5**·2.5H_2O·1.5MeOH and the H_2O molecules of **6**·2.5H_2O·MeOH were refined isotropically. CCDC-254415 (**1**·3MeCN), -254416 (**2**·4DMF), -254417 (**3**·3DMF·H_2O), -254418 (**4**·4CH_2Cl_2), -254419 (**5**·2.5H_2O·1.5MeOH) and -254420 (**6**·2.5H_2O·MeOH) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Acknowledgments

E. K., E. M.-Z. and S. P. P. thank the European Social Fund (ESF), the Operational Program for Educational and Vocational Training II (EPEAEK II) and particularly the Program PYTHAGORAS, for funding the above work. M. A., C. D.-S. and D. P. K. wish to thank The Greek General Secretariat for Research and Technology for the financial support of this research through PENED 2001/1034 Grant.

Perfluorinated Alkoxyaluminate Salts of Cationic Brønsted Acids: Synthesis, Structure, and Characterization of $[H(OEt_2)_2][Al\{OC(CF_3)_3\}_4]$ and $[H(THF)_2][Al\{OC(CF_3)_3\}_4]$

Ingo Krossing*[a,b] and Andreas Reisinger[a,b]

Keywords: Acidity / Aluminum / Brønsted acids / IR spectroscopy / Hydrogen bonds

The strong cationic Brønsted acids $[H(OEt_2)_2][Al\{OC(CF_3)_3\}_4]$ (**1**) and $[H(THF)_2][Al\{OC(CF_3)_3\}_4]$ (**2**) were prepared in up to 95 % yield by reacting stoichiometric amounts of diethyl ether/THF solutions of $Li[Al\{OC(CF_3)_3\}_4]$ and HX (X = Cl, Br), removing the solvent, and extracting the residue with CH_2Cl_2. Compounds **1** and **2** were characterized by multinuclear NMR and IR spectroscopy as well as by their single crystal X-ray structures and additional quantum chemical calculations. The cation in **1** probably contains an unsymmetrical O–H···O hydrogen bond, while in **2** the protic hydrogen atom was not found in the difference Fourier map. From an analysis of all published $[H(OEt_2)_2]^+$ structures, we show that for an unsymmetrical H-bridge further rearrangement of the structure occurs leading to the structural type **III** that may formally be viewed as ethanol coordinating to an ethyl cation. This point of view has hitherto been neglected in the discussion of the nature of short, strong, low-barrier H-bonds, although it needs to be accounted for. Both **1** and **2** are suitable starting materials to introduce the weakly coordinating and chemically very robust $[Al\{OC(CF_3)_3\}_4]^-$ anion by protonolysis.

Introduction

Salts of protonated ether solvents in superacidic solutions have been known for about 40 years.[1] In 1985 an isolated report of the structure of $[H(OEt_2)_2]_2[Zn_2Cl_6]$ appeared,[2] but in recent years salts of the oxonium acids $[H(OEt_2)_2]^+$ and $[H(THF)_2]^+$ with several weakly coordinating anions (WCAs),[3] such as $[BAr^F{}_4]^-$ [Ar^F = C_6F_5,[4] $C_6H_3(CF_3)_2$],[5,6] $[CHB_{11}R_5X_6]^-$ (R = H, CH_3; X = Cl, Br),[7] $[(F_5C_6)_3B(\mu\text{-}X)B(C_6F_5)_3]^-$ (X = $C_3N_2H_3^-$,[8] NH_2^- [9]) or $[C_6F_4\text{-}1,2\text{-}\{B(C_6F_5)_2\}_2(\mu\text{-}OCH_3)]^-$ [10] have been prepared and characterized by different spectroscopic methods as well as X-ray crystallography. $[H(OEt_2)_2]^+$ salts in particular have emerged as very versatile reagents in organometallic synthesis and catalysis.[4–10,11] However, all the currently known $[H(OEt_2)_2]^+$ salts are hampered by either their low thermal solution stability {i.e. $[H(OEt_2)_2][BAr^F{}_4]$ [Ar^F = $C_6H_3(CF_3)_2$]} or difficulties in obtaining the starting materials due to the need to intermediately prepare explosive C_6F_5Li or the carborane anions. Thus, there is demand for further, easily accessible and in solution thermally stable $[H(OEt_2)_2]^+$ salts.

Recently, we reported the facile preparation of nonoxidizing weakly coordinating anions of type $[Al(OR^F)_4]^-$ [R^F = $CH(CF_3)_2$, $C(CH_3)(CF_3)_2$, $C(CF_3)_3$][12,13] and their use to stabilize weakly bound silver complexes such as $Ag(\eta^2\text{-}P_4)_2^+$ [14] and $Ag(\eta^4\text{-}S_8)_2^+$ [15] as well as highly electrophilic cations like PX_4^+, $P_2X_5^+$, $P_3I_6^+$, and $P_5X_2^+$ (X = Br, I),[16,17] $CS_2Br_3^+$,[18] and CI_3^+.[19] Li^+,[12,13] Ag^+,[12] Tl^+,[20] Cs^+, Ph_3C^+,[21] and NR_4^+ [13,22] salts of these anions are available as starting materials; however, cationic Brønsted acids with the $[Al(OR^F)_4]^-$ anions are still unknown.

Herein we report the synthesis and characterization of $[Al(OR^F)_4]^-$ salts [R^F = $C(CF_3)_3$] of the oxonium acids $[H(OEt_2)_2]^+$ and $[H(THF)_2]^+$. Due to their facile access, the commercial availability of $Li[Al(OR^F)_4]$ (Strem) as well as the weakly coordinating and stable counterion, these compounds are a good alternative to the widely used $[H(OEt_2)_2][BAr^F{}_4]$ salts. Moreover, during the last ten years a considerable experimental and theoretical debate has been going on as to whether a truly symmetrical hydrogen bond exists or not.[7,23] A complete understanding and proof of one of the models has still not been achieved and the nature of these short, strong, low-barrier H-bonds remains somewhat unclear.

Results and Discussion

Synthesis

$LiAl[OC(CF_3)_3]_4$ was prepared by reaction of $LiAlH_4$ with $HOC(CF_3)_3$ in toluene.[12,13] The Li salt was suspended in CH_2Cl_2 and treated with diethyl ether/THF solutions of HX (X = Cl, Br) to produce precipitation of LiX. The products $[H(OEt_2)_2][Al\{OC(CF_3)_3\}_4]$ (**1**) and $[H(THF)_2][Al\{OC(CF_3)_3\}_4]$ (**2**) were isolated after work-up in up to 95% yield [Equation (1)].

$$\begin{array}{l} Li^+[Al(OC(CF_3)_3)_4]^- + 2\,L + HX \\ \qquad\qquad \downarrow\ CH_2Cl_2 \qquad\qquad X = Cl, Br \\ [H(L)_2]^+[Al(OC(CF_3)_3)_4]^- + LiX \qquad L = Et_2O, THF \end{array} \quad (1)$$

Compound **1** was obtained as a white powder by redissolving the residue from the reaction in CH_2Cl_2. This air- and moisture-sensitive powder is stable at room temperature and soluble in several moderately polar organic solvents, such as diethyl ether, diethyl ether/toluene mixtures, chloroform, dichloromethane, and 1,2-dichloroethane. Solutions of **1** in CD_2Cl_2 are stable for at least a week at ambient temperature. Solid **1** is stable for several months at room temperate and may be heated up to 75 °C without alteration (DTA analysis); further heating causes decomposition. In the DTA trace only variations of the gradient at 103 °C (18% weight loss) and 148 °C (further 60% weight loss) can be observed, with no distinct steps. From other DTA traces, and the fact that $LiAl[OC(CF_3)_3]_4$ can be sublimed at about 130–140 °C without decomposition,[12] it seems likely that the decomposition starts with the loss of two diethyl ether molecules (18% obsvd. weight loss vs. theoretical value of 13%). However, it cannot be excluded that $HOC(CF_3)_3$ and one molecule of OEt_2 are ejected first to leave $Et_2O{\cdot}Al[OC(CF_3)_3]_3$ as a nonvolatile residue. The second step between 100 °C and 150 °C results from decomposition of the anion. During that decomposition one equivalent of $HOC(CF_3)_3$ and two equivalents of $F_2COC(CF_3)_2$ are presumably formed, in agreement with a total weight loss of 60% (theory: 60%), to leave the relatively stable $AlF_2(OR)$. Further decomposition and weight loss is slow and spread over 200 °C. The observed weight loss is in agreement with the formation of another equivalent of the epoxide $F_2COC(CF_3)_2$ (exp. 13%; theory 19%). This results in a total weight loss of 91% (theoretical value: 92%) and the formation of nonvolatile AlF_3 at approximately 350 °C. Figure 1 shows a likely route for the thermal decomposition and the differential temperature analysis of **1** between 30 and 350 °C.

The preparation of **2** is less straightforward. After filtration and removal of all volatiles an oily brown residue remained that probably contains THF polymerization products[7] in addition to the product **2**, which is the major component (approx. 80% of the oil, by NMR spectroscopy). Compound **2** crystallized as less-rhombus-shaped crystals in good yield (65%) within two days directly from this oily residue. The crystals were isolated from the oil by decantation followed by several washings with pentane. Crystalline air- and moisture-sensitive **2** is stable at room temperature and soluble in the same solvents as **1** (see above).

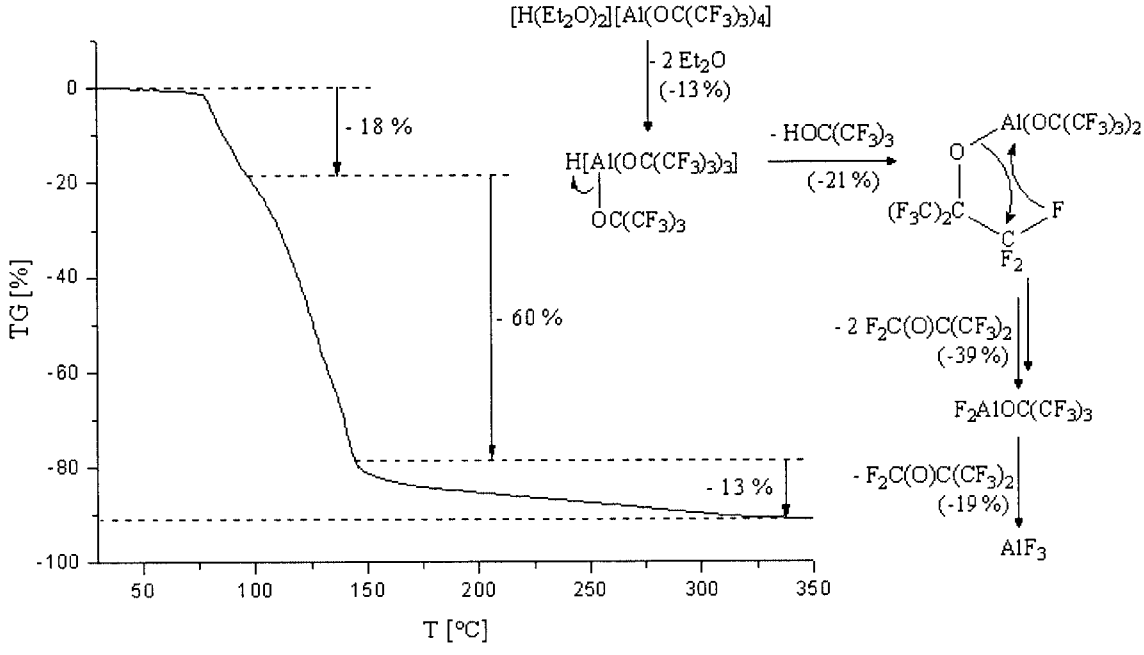

Figure 1. DTA analysis of **1** between 30 and 350 °C (left) and hypothetical route for the decomposition (right).

Thermodynamics of the Formation of 1

We assessed the driving force for the formation of **1** in more detail. Assuming that the isodesmic reaction (2) takes place in CH_2Cl_2, it is possible to reliably obtain its reaction enthalpy by quantum chemical calculations (see computational details). The part of the anion cancels.

$$[Li(OEt_2)_2]^+_{(solv.)} + [Al(OC(CF_3)_3)_4]^-_{(solv.)} + HBr_{(solv.)}$$

$$\downarrow \quad \Delta G°_{solv.} = -81 \text{ kJ mol}^{-1} \text{ (MP2/TZVPP and BP86/TZVPP)}$$

$$[H(OEt_2)_2]^+_{(solv.)} + [Al(OC(CF_3)_3)_4]^-_{(solv.)} + LiBr_{(s)} \quad (2)$$

As expected for an isodesmic reaction, BP86/TZVPP (DFT) and MP2/TZVPP (ab initio) calculations agree on the same value for $\Delta G°_{solv.}$ of –81 kJ mol^{-1}. However, for the calculations to form an isodesmic reaction, Equation (2) assumes that the rather odd $Li(OEt_2)_2^+$ cation is present in solution. However, the cation $Li(OEt_2)_4^+$ is more likely, as shown by various crystal structures of $Li(L)_4^+$ salts (L = ethereal solvent).[8] Therefore, we assessed reaction (3), which is no longer isodesmic and thus $\Delta G°_{solv.}$ may be less accurate; however, the species presented in (3) are very close to the situation actually taking place in solution.

$$[Li(OEt_2)_4]^+_{(solv.)} + [Al(OC(CF_3)_3)_4]^-_{(solv.)} + HBr_{(solv.)}$$

$$\downarrow \quad \Delta G°_{solv.} = -135 \text{ kJ mol}^{-1} \text{ (BP86/TZVPP)}$$

$$[H(OEt_2)_2]^+_{(solv.)} + [Al(OC(CF_3)_3)_4]^-_{(solv.)} + 2\ OEt_{2(solv.)} + LiBr_{(s)} \quad (3)$$

Again, the part of the anion cancels. Equation (3) is additionally favored by entropy due to the release of two ether molecules. $\Delta G°_{solv.}$ of this reaction is exergonic by –135 kJ mol^{-1} and is thus very favorable, in agreement with the facile preparation of **1**. We assume a similar situation for **2**, although this is not explicitly discussed.

NMR Spectroscopy

Protonated Diethyl Ether Moiety

The ^{19}F and ^{27}Al NMR spectroscopy show one characteristic sharp signal for the intact counterion. In the ^1H NMR spectrum a broad downfield-shifted signal at δ = 18.2 ppm (OH) and signals for the CH_3 and CH_2 protons of the coordinating diethyl ether molecules are observed. The OH signal varies greatly from sample to sample, with values between δ = 14.5 and 18.2 ppm. The integration of the signals shows the constitution as two coordinated diethyl ether molecules per proton, similar to all the earlier synthesized etherates.[4–10] Compared to free diethyl ether,[24] these two signals are slightly shifted downfield (Table 1). The ^{13}C NMR spectrum shows the signals of the anion and two signals which were assigned to the methyl and methylene groups of the cation. In Table 1, the observed ^1H and ^{13}C signals of the cation are collected and compared to different salts of $[H(OEt_2)_2]^+$ as well as the shifts calculated by DFT.

In the article[10] on $[H(OEt_2)_2][C_6F_4\text{-}1,2\text{-}\{B(C_6F_5)_2\}_2(\mu\text{-}OCH_3)]$, the ^{13}C signal at δ = 57.9 ppm was assigned to the methylene group of the cation. Since all the other data of this signal, including the DFT calculations, range from δ = 67.8 to 70.4 ppm it was probably incorrectly assigned. The authors also observed one signal at δ = 69.0 ppm which was assigned to the methoxy group of the anion;[10] however, the collection of chemical shifts in Table 1 clearly indicates that this assignment is erroneous and the shifts must be reversed. i.e. the signal at δ = 69.0 ppm belongs to the CH_2 group of protonated diethyl ether and the signal at δ = 57.9 ppm to the methoxy group of the anion.

^1H and ^{13}C solid-state MAS NMR measurements matched with the solution spectra: in the ^1H NMR spectrum signals are observed at δ = 1.32, 3.90 and 16.6 ppm. Apart from the typical anion signals,[12] the ^{13}C NMR spectrum shows one signal at δ = 12.7 ppm and two signals at δ = 71.1 and 71.6 ppm. None of these signals can be assigned to free diethyl ether since that signal has a chemical shift of δ = 65.2 ppm.[24] This suggests an asymmetric envi-

ronment of the two coordinated ether molecules in the solid state.

Protonated THF

NMR spectroscopy gave the expected sets of signals that match with the DFT calculations and that of the only other reported compound ($[H(THF)_2][CHB_{11}R_5X_6]$, Table 2).[7]

Table 2. Comparison of NMR shifts of $[H(THF)_2]^+$ with two anions and shifts calculated by DFT.

	$[H(THF)_2]$-$[Al\{OC(CF_3)_3\}_4]$	$[H(THF)_2]$-$[CHB_{11}R_5X_6]$[7]	BP86/SV(P)

$\delta_{^{13}C}(CH_2)$	25.5	–	29.1
$\delta_{^{13}C}(OCH_2)$	70.6	–	73.8

Vibrational Spectroscopy

The IR spectrum of **1**, especially the portion shown in Figure 2, exhibits the typical bands of the perfluorinated aluminate anion in the range between 286 and 1353 cm^{-1}. They can easily be assigned by comparison with other salts of this anion as well as with the calculated vibrational frequencies, as demonstrated in Table 3. The most characteristic anion vibrations are the very strong bands at 727 and 973 cm^{-1} as well as those between 1219 and 1353 cm^{-1}. The fact that the positions of the anion bands remain unchanged relative to the calculated frequencies and the NEt_4^+ salt indicates that there is no coordination of the anion as, for example, occurs with the naked Li^+ or Ag^+ cation. The anion bands of the Raman spectrum of **1** match well with the IR spectrum. The most important differences between the spectra arise from the two strong bands at 744 and 798 cm^{-1} and the absence of the very strong IR bands in the range between 1200 and 1320 cm^{-1}, as can be seen in Table 3.

The remaining bands of the IR spectrum at $\tilde{\nu}$ = 769, 907, 1013, 1063, 1092, 1166, 1366, and 1536 cm^{-1} can now be assigned to vibrations of the cation. Table 4 shows the experimental bands compared to the carboranate anion of Reed,[7] the maxima of the simulated calculated cation spectrum, as well as the experimental[25] and calculated bands of free diethyl ether in the range between 700 and 3000 cm^{-1}. This table also contains an assignment of the calculated bands and the related experimental modes. Compared to the calculated frequencies, the experimental bands match well. The expected bands at 726, 1212, 1312, and around 3000 cm^{-1} are likely overlapped by strong anion or Nujol bands. As already noted earlier, the cation bands are rather broad.[7,23] Similarly to Reed's $[H(OEt_2)_2]$-$[CHB_{11}H_5Cl_6]$ salt, the very strong sharp ν_{as}(C–O–C) band of free Et_2O (1120 cm^{-1}) disappears.[7]

The Raman spectrum of **1** obtained at low temperature shows several bands in the range between 2850 and 3010 cm^{-1} which can be assigned with no doubt to C–H vibrations of the cation. At lower energy two bands at 1467 and 1496 cm^{-1} are in good agreement with the calculated bands at 1450 and 1480 cm^{-1}. Furthermore, there are three bands at 1017, 1082, and 1151 cm^{-1} that may be associated with the IR bands at 1013, 1092, and 1166 cm^{-1}. Finally, the Raman spectrum reveals one band at 472 cm^{-1} which

matches with the calculated frequency at 480 cm^{-1}. This frequency refers to a vibration of the oxygen atoms of the cation. All cation bands are shown in Table 4 and are compared to several experimental IR bands as well as selected calculated frequencies.

Figure 3 shows a section of the IR spectrum of **2** between 400 and 1500 cm^{-1}. Again, the typical bands of the perfluorinated *tert*-butoxyaluminate anion are clearly visible (Table 3), as discussed above. Similarly, the position of the bands relative to the calculated frequencies and the NEt_4^+ salt indicates a distinct salt structure, which is proved by the solid-state structure (Figure 5).

In Figure 3, the bands at $\tilde{\nu}$ = 603, 775, 894, 918, 1043, 1167, 1365, and 1448 cm^{-1} can be assigned to vibrations of the cation. Table 5 shows the experimental bands compared to the carboranate anion of Reed,[7] the maxima of the simulated calculated cation spectrum, as well as experimental[25] and calculated bands of free THF in a range from

700 to 3000 cm^{-1}. Compared to the calculated frequencies, the experimental bands match well; however, the expected bands at 726, 1212, 1312, and around 3000 cm^{-1} are again overlapped by strong anion or Nujol bands.

Solid-State Structures

The solid-state structure of **1** was determined, confirming the NMR spectroscopic data and showing an ionic lattice containing $[H(OEt_2)_2]^+$ and $[Al\{OC(CF_3)_3\}_4]^-$. The molecular structure of one formula unit is shown in Figure 4.

For the anion, typical structural parameters to those reported earlier[12] were found. In contrast to the anion, the structural parameters of the cation show some interesting details: the position of the (O)H atom was found in the difference Fourier map and suggests the presence of an unsymmetrical O–H···O bond with an O–O separation of 242.4 pm (cf. 240 to 245 pm in other $[H(OEt_2)_2]^+$

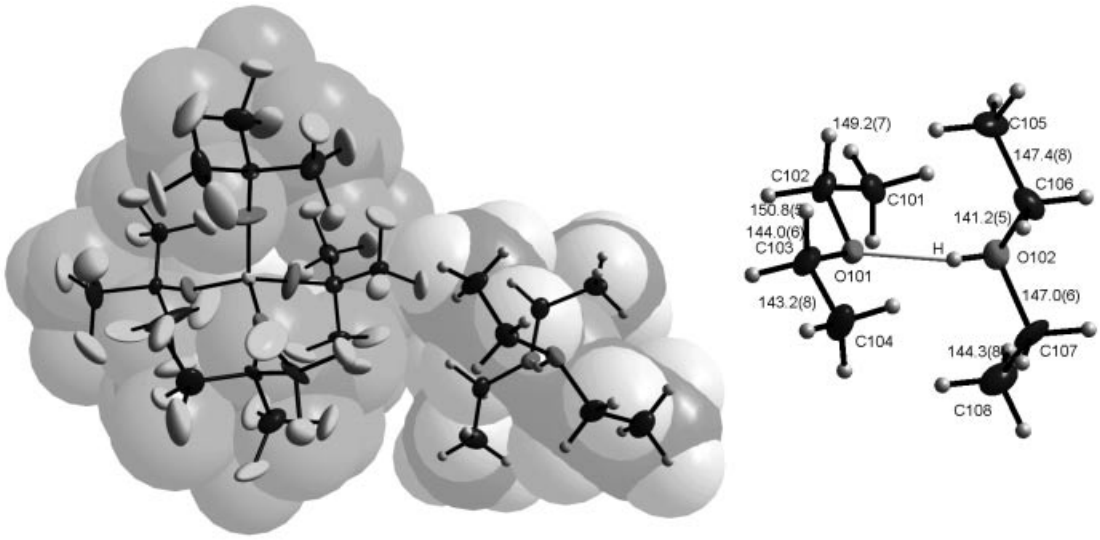

Figure 4. Section of the solid-state structure of **1**. Superposition of a space-filling (light gray) and a thermal ellipsoid model drawn at the 25% probability level.

salts[4,7,10]). No disorder was evident from the structure. The asymmetric coordination also followed from the C–O bond lengths: compared to free solid diethyl ether,[26] which has an average O–C bond length of 142.8 pm the average C–O separations of the diethyl ether molecules are elongated by 5.6 (coordinated ether) and 1.3 pm (protonated ether; Δd = 4.3 pm). This implies that the two diethyl ether molecules in **1** are different and, since the C–O bonds of the coordinated diethyl ether molecules of our oxonium acid are elongated unsymmetrically, the proton is presumably located at one of the two molecules.

The solid-state structure of **2** was also determined by X-ray crystallography. The NMR spectroscopic data could be confirmed as well as the existence of an ionic lattice of $[H(THF)_2]^+$ and $[Al\{OC(CF_3)_3\}_4]^-$. However, the quality of the data does not allow for extensive discussions and the structure is mainly seen as additional evidence for the nature of **2** being a salt of $[H(THF)_2]^+$. The acidic proton was not located in the difference Fourier map and is, therefore, not shown. Figure 5 shows one formula unit of the molecular structure.

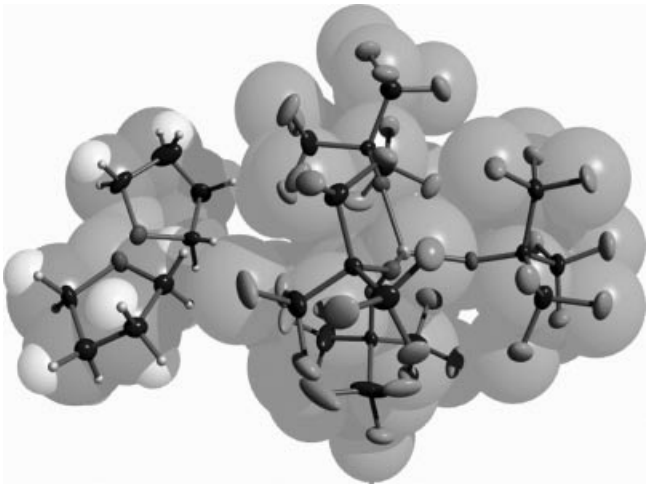

Figure 5. Section of the solid-state structure of **2**. Superposition of a space-filling (pale gray) and a thermal ellipsoid model drawn at 25% probability level.

On the Structure of $[H(OEt_2)_2]^+$

It is clear from first principles as well as the DFT calculations of the structures of $H–OEt_2^+$ vs. symmetric $[H(OEt_2)_2]^+$ in Table 6 that the protonation of the oxygen atom should lead to an elongation of the adjacent C–O bonds. However, if this is true, the acidic proton in **1** is attached to the wrong oxygen atom. Still, a similar unsymmetrical elongation with the apparently wrong oxygen atom protonated also occurs for Jutzi's acid $[H(OEt_2)_2][B(C_6F_5)_4]$ (Δd = 4 pm).[4] A closer analysis shows that the two C–O bond lengths in the nonprotonated diethyl ether molecule are not similar but differ greatly (144.0 vs. 150.8 pm in **1** and 146.6 vs. 154.2 pm in Jutzi's acid). On the other hand, there are two reports of a symmetrically bridged proton in the center of two Et_2O molecules.[2,10] In these cases all four C–O bond lengths are similar and amount to approximately 146 pm. These initial observations suggest that the position of the proton as determined by X-ray diffraction is unreliable and should not be used for the discussion of a symmetrical or unsymmetrical H-bridge. The C–O and C–C bond lengths were determined with much higher accuracy and should, therefore, be used for the comparison. However, although five crystal structures of $[H(OEt_2)_2]^+$ have been published,[2,4,7–9] hitherto nobody has analyzed the structures in detail. Therefore, the structural parameters of all published $[H(OEt_2)_2]^+$ solid-state structures as well as the DFT-calculated parameters of Et_2O, $[HOEt_2]^+$, and symmetrical $[H(OEt_2)_2]^+$ are collected in Table 6.

An analysis of Table 6 underlines the conclusion that the experimentally determined positions of the acidic protons

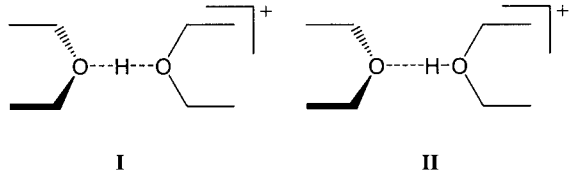
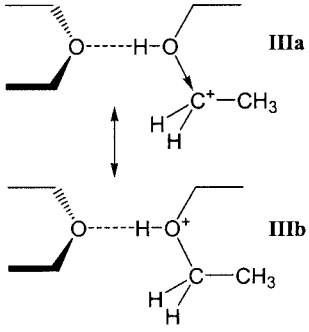
[f] This side of the cation was disordered and, therefore, bond lengths are less accurate and not included.

are unreliable; however, this is common knowledge. More importantly, one realizes from Table 6 that, when concentrating on the C–O and C–C separations, the nature of the H-bridge in $[H(OEt_2)_2]^+$ may not simply be reduced to symmetric (**I**) or asymmetric (**II**) but that in the asymmetric case further rearrangements of the structure occur (**IIIa,b** in Scheme 1).



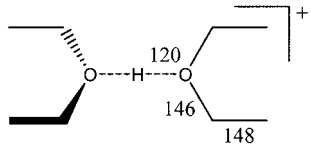
I **II**



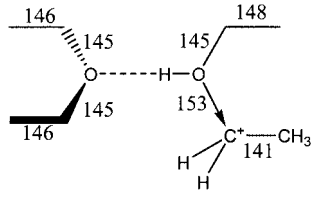
Scheme 1. Possible structures of $[H(OEt_2)_2]^+$.

In structure type **II** the C–O bond lengths of the protonated diethyl ether molecule should be symmetrically elongated. This is obviously not the case (Table 6) and therefore structure **III** is important; resonance form **IIIa**, which formally may be viewed as ethanol coordinated to an ethyl cation, accounts for the unsymmetrical C–O bond lengths of the protonated diethyl ether molecule. From the two symmetric and four asymmetric structures in Table 6 one may therefore extract average structural parameters for **I** and **III**; a schematic representation of the parameters of both forms is given in Scheme 2. A detailed description of the procedure to obtain the average structural data is available as Supporting Information

Symmetrically bridged cation **I**
structures: **A**, **E**



Asymmetric cation **III**
structures: **1**, **B**, **C**, **D**



Scheme 2. Average structural parameters of **I** and **III** [pm] extracted from the solid-state structures in Table 6.

The structure of **I** is in very good agreement with that predicted on the basis of the BP86/TZVPP calculations (Table 6). However, regardless of whether one starts with a slightly asymmetric or strongly asymmetric structural type **III** the DFT calculations (gas phase!) always lead to the symmetric structure type **I**. Nevertheless, the average structural parameters of **III** in Scheme 2 are likely and may be compared to related moieties: the short C–C bond length of 141 pm of the formal ethyl cation in **III** may be compared to the BP86/SV(P)-optimized distances of the free ethyl cation (141.2 pm), free ethane (153.1 pm), and the base-stabilized ethyl cations D → $^+CH_2CH_3$ [D = OH_2, d(C–C) = 150.0 pm; D = OMe_2, d(C–C) = 150.7 pm]. The

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

formal donor–acceptor C–O bonds in the D → $^{+}CH_2CH_3$ cations are 156.3 pm (H_2O) and 152.9 pm (OMe_2), in good agreement with our estimate of 153 pm in **III**. All other distances are normal. The data in Scheme 2 may not be taken as absolute, however, since libration has not been accounted for and the structures may be affected by a superposition of the asymmetric structures **III** (i.e. the site may partly be occupied as $Et_2O\cdots HO^{+}Et_2$ and partly as $Et_2O^{+}H\cdots OEt_2$; structure **C**, for example, appears to be afflicted by this type of disorder). However, the general trend of the completely asymmetric structural type **III** holds. Further evidence for this assumption comes from the solid state MAS NMR spectrum of **1**: two lines at δ = 71.1 and 71.7 ppm were observed for the OCH_2 groups of the diethyl ether molecules. This again points to an asymmetric coordination in the solid state and supports the formulation of structure **III**. Thus, it appears likely that forms **I** and **III** may be stable in the solid state and the final decision as to which isomer is formed is governed by subtle differences of the anion–cation contacts of the different salts in the solid state. Moreover, it is evident that the discussion of the nature of the short- strong- and low-barrier H-bonds in $[H(OEt_2)_2]^{+}$ may not be reduced to the question of a symmetrical (O···H···O) or asymmetrical (O–H···O) H-bond. If an asymmetrical H-bond is formed, this leads to a further rearrangement of the structure of the $[H(OEt_2)_2]^{+}$ cation, which may be described by the resonance structures **IIIa,b**.

Conclusions

A facile preparation of **1** and **2** as stable salts of the oxonium acids $[H(OEt_2)_2]^{+}$ and $[H(THF_2)_2]^{+}$ has been achieved. Both compounds were fully characterized by experimental and quantum chemical methods; they are strongly Brønsted acidic reagents. Due to the facile preparation, the commercial availability of $Li[Al(OR)_4]$, the good thermal solution stability (especially of **1**), and the weakly coordinating and chemically robust nature of the $[Al(OR)_4]^{-}$ counterion, **1** is an attractive reagent for synthesis, particularly in organometallic chemistry and homogeneous catalysis (for applications of $[H(OEt_2)_2]^{+}$ salts see ref.[4–11]). Interestingly, the solid-state structure of **1** includes an asymmetrically bridging H-atom; symmetric H-bridges have also previously been observed.[10] A symmetric H-bridge is also the minimum structure of the quantum chemical calculations. From an analysis of all published $[H(OEt_2)_2]^{+}$ structures we have shown that if an asymmetric H-bridge is formed, this leads to a further rearrangement of the structure and to the structural type **III** in Scheme 2, which is further supported by solid state MAS NMR spectroscopy. This point has hitherto been neglected in the discussion of the nature of short, strong, low-barrier H-bonds, although it should be taken into account. We conclude that the final decision as to the formation of a symmetrical or an unsymmetrical H-bridge is balanced by subtle differences between the anion–cation contacts of the salts in the solid state. Finally, we have been able to revise some erroneously assigned NMR shifts and give the most complete vibrational characterization of the $[H(OEt_2)_2]^{+}$ and $[H(THF)_2]^{+}$ cations currently available.

Experimental Section

General Procedures: Due to the air- and moisture-sensitivity of most materials all manipulations were undertaken using standard vacuum and Schlenk techniques as well as in a glove box with an argon atmosphere (H_2O and $O_2 < 1$ ppm). All solvents were dried by conventional drying agents and distilled afterwards. The solutions of HX (X = Cl, Br) in Et_2O and THF were prepared by condensing HX from a flask with known volume and pressure. Solution NMR spectra were recorded in CD_2Cl_2 at room temperature on a Bruker AC 250 spectrometer; data are given in ppm relative to the solvent signals, aqueous $AlCl_3$ (^{27}Al) and CF_3Cl (^{19}F). Solid-state NMR spectra were obtained with a Bruker Avance 500 MHz spectrometer. IR spectra were obtained in nujol mull between CsI plates on a Bruker IFS 66 IR spectrometer, Raman spectra were recorded on a Bruker RFS 100/S Raman spectrometer. The differential temperature analysis measurements were performed with a Netzsch STA 429 DSC/DTA unit. About 20 mg of **1** was used for the experiment; preparation of the measurement and weighing were done in a glove box. The DTA curves were recorded at a heating rate of 5 K min^{-1}.

Preparation of $[H(OEt_2)_2][Al\{OC(CF_3)_3\}_4]$ (1): a) $LiAl[OC(CF_3)_3]_4$ (20.02 g, 20.06 mmol) was weighed into a 1-L round-bottomed flask with a glass valve and suspended in a mixture of CH_2Cl_2 (approx. 500 mL) and Et_2O (6.4 mL, 61.7 mmol). The suspension was frozen in liquid nitrogen and HBr (1.746 g, 21.6 mmol) was condensed directly onto the mixture. This mixture was allowed to reach room temperature and stirred overnight; white colloidal LiBr was formed. The LiBr precipitate was filtered off to give a solution of **1** in CH_2Cl_2. After removing all volatiles in vacuo from the filtrate, pure **1** was isolated as a white powder (21.80 g, 94.8%). Larger crystals were obtained by recrystallization of the powder from a mixture of toluene and diethyl ether (10:1).

b) $LiAl[OC(CF_3)_3]_4$ (0.740 g, 0.76 mmol) was suspended in pure diethyl ether (approx. 30 mL) and gaseous HCl (0.030 g, 0.84 mmol) was condensed directly onto the frozen (77 K) mixture. All other manipulations were undertaken according to the description in part a). Yield: 0.766 g (87%). ^{1}H NMR (250 MHz): δ = 1.34 (t, $^{3}J_{H,H}$ = 7.138 Hz, 12 H), 3.90 (br., 8 H), 14.68 (br., 1 H) ppm. $^{13}C\{^{1}H\}$ NMR (63 MHz): δ = 13.8 (s), 69.3 (s), 121.5 (q, $^{1}J_{C,F}$ = 292.2 Hz) ppm. ^{19}F NMR (235 MHz): δ = –75.43 (s) ppm. ^{27}Al NMR (78 MHz): δ = 36 (s). IR (CsI plates, Nujol): $\tilde{\nu}$ = 206 (mw), 286 (mw), 314 (m), 375 (m), 447 (ms), 537 (m), 561 (m), 572 (mw), 727 (vs), 756 (m), 769 (mw), 832 (m), 907 (mw), 973 (vs), 1013 (m), 1063 (mw), 1166 (ms), 1219 (s), 1243 (s), 1276 (s), 1300 (s), 1353 (ms), 1366 (ms), 1377 (s), 1457 (vs), 1536 (mw) cm^{-1}.

Preparation of $[H(THF_2)_2][Al\{OC(CF_3)_3\}_4]$ (2): $LiAl[OC(CF_3)_3]_4$ (0.700 g, 0.719 mmol) was weighed into one side of a two-bulb, frit-plate flask with a glass stem that was closed with two greaseless Young valves, and suspended in CH_2Cl_2 (approx. 30 mL). On the opposite side, HBr (0.95 mL of a 0.834 M solution) dissolved in THF was added with a syringe through a septum. Cooling the suspension to –80 °C caused HBr and THF to condense onto the Li salt. The mixture was allowed to reach ambient temperature and stirred for 48 h to form white colloidal LiBr. After removing all volatiles under vacuum, a dark brown oily residue formed from which **2** precipitated as rhombus-shaped crystals in 65% yield. ^{1}H NMR (250 MHz): δ = 2.05 (m, 8 H), 3.95 (m, 8 H), ca. 8 (broad,

1 H) ppm. $^{13}C\{^1H\}$ NMR (63 MHz): δ = 25.5 (CH_2), 70.6 (OCH_2), 121.5 (q, $^1J_{C,F}$ = 291.7 Hz) ppm. ^{27}Al NMR (78 MHz): δ = 36 (s) ppm. IR (CsI plates, Nujol): $\tilde{\nu}$ = 446 (ms), 537 (m), 561 (m), 571 (mw), 603 (ms), 727 (vs), 755 (m), 775 (m), 831 (m), 894 (w), 918 (w), 973 (vs), 1043 (w), 1167 (ms), 1220 (s), 1242 (s), 1276 (s), 1300 (s), 1353 (ms), 1365 (ms), 1376 (ms), 1448 (s), 1457 (s), 1626 (w), 2724 (w), 2853 (ms), 2921 (ms), 2957 (ms) cm^{-1}.

X-ray Structure Determination: Suitable crystals of **1** were formed by cooling a solution in toluene containing a small amount of diethyl ether to 5 °C. Crystals of **2** precipitated directly from the oily residue after removal of all volatiles. Data were collected on a Stoe IPDS II diffractometer using Mo-K_α radiation (λ = 0.71073 Å) at 150 K. Single crystals were mounted in perfluoro ether oil on top of a glass fiber and then placed in the cold stream of a low-temperature device so that the oil solidified. Unit-cell parameters were calculated from a least-squares refinement of the setting angles of 5000 reflections collected. The space groups were identified as $P2_1$ (**1**) and $P2_1/c$ (**2**). The structures were solved with the SIR2002 program[27] (**1**) or direct methods in SHELXS[28] (**2**) and successive interpretation of the difference Fourier maps using SHELXL-97. Refinement against F^2 was carried out with SHELXL-97. All non-hydrogen atoms were included anisotropically in the refinement; all hydrogen atoms except the acidic proton in **1** were included isotropically at the calculated positions based on a riding model. The acidic proton in **1** was located in the difference Fourier map and included isotropically in the refinement. The lattice parameters of **1** are very close to being tetragonal (approx. 9, 14, 14 Å; 90, 90, 90°; V = 1950 $Å^3$); in fact, the $[PX_4][Al(OR^F)_4]$ salts (X = Br, I)[17b] crystallize with a very similar truly tetragonal cell (approx. 9, 13.5, 13.5 Å; 90, 90, 90°; V = 1850 $Å^3$; X = I). In the latter structures the Al and P atoms reside on special positions with $\bar{4}$ site symmetry and Z = 2. When a cation with lower symmetry but similar size crystallizes with the symmetric $[Al(OR^F)_4]^-$ anion and the lattice parameters are almost the same, this necessarily leads to twinning, as previously observed when exchanging PX_4^+ for $P_2X_5^+$.[17b] In the case of **1** the $[H(OEt_2)_2]^+$ cation also has less symmetry than PX_4^+, which implies that the symmetry had to be reduced to at least monoclinic. We were able to solve the structure in the space group $P2_1$ and finally solved the twin law (i.e.: TWIN 0 0 1 0 1 0 1 0 0 with BASF 0.43362) that lowered the R_1 value immediately from 15.6% to 4.8%. Relevant data concerning crystallographic data, data collection and refinement details are compiled in Table 7.
CCDC-239426 (for **1**) and -239427 (for **2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Computational Details: All quantum chemical calculations were carried out with the TURBOMOLE program package.[29] The geometries of $[H(OEt_2)_2]^+$ and $[H(THF_2)_2]^+$ were optimized in C_1 symmetry by DFT calculations using the BP86/SV(P)[30] or BP86/TZVPP[31] basis sets, as well as RI-MP2 methods using the TZVPP basis set.[32] Vibrational frequencies were calculated at the BP86/SV(P) level and used to verify the nature of the obtained minima.[33]

For the estimation of the reaction enthalpies of the formation of compounds **1** and **2**, the oxonium acids as well as a Li cation coordinated by two diethyl ether molecules were calculated by using the same procedure as above. The resulting reaction (2) is isodesmic and inaccuracies arising during the calculation are minimized due to error cancellation. The calculated enthalpies were also corrected for the influences of the Gibbs energy at 298 K (with the semi-empirical PM3 method implemented in Gaussian 98)[34] as well as solvent effects (COSMO model, CH_2Cl_2 solvent with ε_r = 8.93).[35]

Supporting Information: Simulation of IR spectra based on calculations of vibrational frequencies, Raman spectra, IR spectra (200–700 cm^{-1}), tables of optimized atomic coordinates from density functional calculations, tables for the extracted average structural parameters of **I** and **III** in Scheme 2.

COVER PICTURE

The cover picture shows the reaction of a calix[4]arene methyl ether stabilized nitridomolybdenum complex [MoN(MeCalix)] with $GaCl_3$ to yield the compound [Mo(NGaCl_3)(MeCalix)]. This complex represents the first structurally characterized example of a nitrido-bridged dinuclear compound of a group 6 metal and a group 13 halide [EX_3]. Both metal atoms are unsymmetrically bridged with a short [Mo≡N] and a long [Ga–N] contact. Details on synthesis and structural characterization are discussed in the article by U. Radius et al. on p. 2037ff. In the background there is a view from the University of Karlsruhe (TH) to the adjacent "Hardtwald" on a stormy day photographed by Bernhard Mühr (www.wolkenatlas.de).

Molecular Recognition: Use of Metal-Containing Molecular Clefts for Supramolecular Self-Assembly and Host–Guest Formation

James D. Crowley[a] and Brice Bosnich*[a]

Keywords: Supramolecular / Self-assembly / Host–guest adducts / Molecular cleft receptors / Molecular recognition forces

Molecular clefts consisting of a rigid spacer linked to two parallel cofacially disposed terpy-M–X (M = Pd^{2+}, Pt^{2+}) units, which can vary in separation from 6.6 to 7.2 Å, have been used as molecular receptors and for self-assembly with linear and triangular linkers to produce rectangles and trigonal prisms, respectively. Aromatic molecules form multiple host–guest adducts with the molecular cleft receptors and with the rectangles and trigonal prisms. Planar complexes of Pt^{2+} also form host–guest adducts. The forces that control this molecular recognition, namely, π-π interactions, charge-induced dipole interactions, charge-charge forces, weak metal-metal interactions and solvation effects, are discussed and assigned to the various adducts.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Fundamental to the functioning of biological systems are the phenomena of molecular recognition and self-assembly. The former relies on the concerted interaction of weak, noncovalent forces[1] for selectivity. Generally, the adducts that are formed by weak forces are (kinetically) labile but can be very (thermodynamically) stable. Self-assembly in biological systems usually involves the use of weak noncovalent forces for the formation of secondary and tertiary structures rather than for the generation of primary sequences of large molecules. The latter usually rely on kinetically controlled covalent bond formation. However, studies in supramolecular chemistry, have generated large complex structures by self-assembly, usually by deploying covalent (metal) coordinate bonds.[2] The present review focuses on our studies in molecular recognition and self-assembly using the receptors **1**.[3]

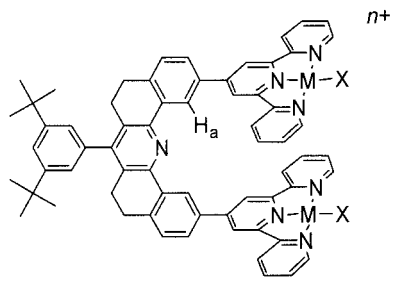
James D. Crowley was born in "windy" Wellington, New Zealand. He obtained his BSc(Hons) in Chemistry in 1997 and an MSc in 1999 from Victoria University of Wellington. He is currently completing his PhD work under the direction of Professor Brice Bosnich at The University of Chicago. His research interests are in self-assembly, molecular recognition and the development of molecular motors and machines.

Brice Bosnich was born in Queensland, Australia. He received his undergraduate degree in the University of Sydney and his Ph.D. in the John Curtin Medical School of the Australian National University, Canberra. He has held posts in University College, London, the University of Toronto and is currently in The University of Chicago. He has worked in the areas of coordination chemistry as well as organometallic chemistry. An underlying theme of his work is the relationship between reactivity and stereochemistry, especially absolute configurations. His current interests are in aspects of supramolecular chemistry, which may be incorporated into the design of molecular switches and motors.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

 DOI: 10.1002/ejic.200500091 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



M = Pd^{2+}, Pt^{2+} X = Cl, CH_3CN

1

Receptor **1** incorporates the square-planar metals, Pd^{2+} or Pt^{2+}, and, if X = CH_3CN, this weak ligand is readily displaced. The two terpy-M–X units are parallel to each other and their separation can be modulated by concerted rotation about the spacer while preserving an essentially eclipsed conformation. The terpy-M–X units are charged, are aromatic and, consequently, are expected to incarcerate polarizable aromatic guests, especially those that are negatively charged. The ability of the system to vary the terpy-M–X unit separation allows the receptor to achieve the optimal cleft separation for a particular guest. More complex host structures can be generated from the cleft, **1**, when good leaving groups, X, are present and these clefts are reacted with molecular linkers. Thus linear linkers **2**, or trigonal linkers **3** can provide molecular rectangles **4** or molecular trigonal prisms **5**, respectively.

Self-Assembly: It is well known that Pd^{2+} complexes are more kinetically labile and thermodynamically less stable than the analogous Pt^{2+} complexes. As a consequence the ligands of Pd^{2+} complexes are substituted more readily than analogous ligands of corresponding Pt^{2+} complexes. The relative substitution rates are such that, generally, Pd^{2+} complexes are readily substituted at ambient temperatures whereas Pt^{2+} complexes require higher temperatures to achieve equivalent rates. Thus, whereas the Pd^{2+} complexes have moderate kinetic lability, those of Pt^{2+} are kinetically stable at room temperature.[4] Molecular rectangles **4** can be self-assembled exclusively by mixing the Pd^{2+} molecular cleft, X = CH_3CN, in acetone or acetonitrile with any of the linear linkers **6** to **10**.[5] The isolated yields are essentially quantitative. The Pt^{2+} analogues can also be prepared but require a different route and more forcing conditions. The more flexible linkers **11** react with the Pd^{2+} receptor cleft **1** to give an equilibrium mixture of the desired rectangle and what, by ^1H NMR spectroscopy and electrospray MS,[6] appears to be a macrocycle where a linker joins the two Pd^{2+} atoms of the receptor. Scale molecular models indicate that linkers **7**, **9** and **10** are unlikely to form macrocycles with the receptors. Thus, it appears that molecular rectangles will form exclusively with linear linkers of any practical length provided lengthwise linker rigidity is maintained.

By similar methods the three trigonal linkers **12**, **13** and **14** can be combined with the Pd^{2+} receptor to give quantitative yields of the trigonal prisms, **5**.[7] Because of the insolubility of the trigonal linkers in common solvents, the self-assembly reaction takes several hours with the Pd^{2+} complex. The molecular rectangles **4** and trigonal prisms **5** are distinct from the usual supramolecular structures reported, in that the present structures provide specific binding sites for guests, namely, in the molecular clefts.

Crystal structures of the free ligand[8a] (Figure 1) and that[8b] of the Pd^{2+} receptor, X = Cl, as the PF_6^- salt (Figure 2) are shown. The structures are similar in that pairs of molecules interpenetrate one another; in the case of the free ligand, a terpy unit of one molecule lies between two terpy units of another, and a similar structure is obtained for the terpy-Pd–Cl units of the Pd^{2+} receptor.

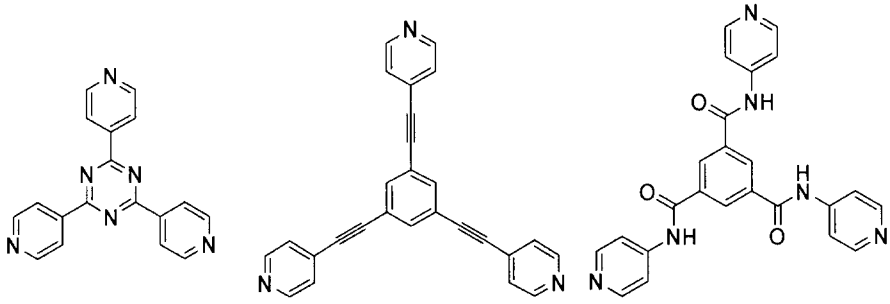
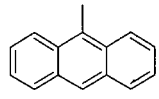
6 **7** **8** **9** **10** **11**



12 **13** **14**

Host–Guest Adducts: The Pd^{2+} or Pt^{2+} receptors **1** (X = Cl or pyridine) form adducts with a variety of guest molecules.[1] Included among these are large aromatic molecules especially those that are electron rich and planar neutral or anionic Pd^{2+} and Pt^{2+} complexes. Although anionic, planar Pd^{2+} and Pt^{2+} complexes, such as [Pd(dipicolinate)Cl]$^-$ and $[Pt(CN)_4]^{2-}$, appear to form red-colored adducts with the receptors **1**. They are invariably insoluble in all common solvents and are very difficult to characterize. Cationic planar complexes such as $[M(terpy)Cl]^+$, (M = Pd^{2+}, Pt^{2+}) do not form adducts with the cationic receptors presumably because of electrostatic repulsion between the positively charged entities. The structure in Figure 2 shows that the cationic terpy-Pd–Cl units can stack on each other in the solid state despite their positive charge. In this case the counterions neutralize the charge repulsion. In solution the receptor shown in Figure 2 shows no evidence of association probably because, as conductivity studies indicate, little or no ion association is present to neutralize the electrostatic repulsion that would ensue upon association.

Host–Guest Adducts with 9-Methylanthracene: Both the Pd^{2+} and Pt^{2+} receptors **1** (X = Cl), form pale yellow solutions, but upon addition of 9-methylanthracene (**15**), (9-MA), the solutions became deep red, indicative of host–guest formation.



15

Using the ^1H NMR titration mole ratio method (see later),[9] it was found that 1:2 host–guest adducts were formed for both the Pd^{2+} and the Pt^{2+} receptors. The Pd^{2+} receptor has microscopic[10] stability constants[3] of 650 and 100 M^{-1}, which are similar to those for the Pt^{2+} receptor, 800 and 100 M^{-1}, all constants were obtained in CD_3CN solutions at 27 °C. Nuclear Overhauser (^1H ROESY) experiments show[11] that one 9-MA guest resides in the molecular cleft, as expected, but that the other 9-MA molecule lies on the outside faces of the terpy-M–Cl units of the receptors. This solution structure obtains in the solid state for the Pd^{2+} receptor (Figure 3) where pairs of host–guest molecules stack but each receptor carries two 9-MA guests. As will be seen presently, the 9-MA guest always forms a 1:2 host–guest adduct with the molecular cleft, despite the presence of two sterically equivalent outer faces of the

terpy-M–X units. However, it is not obvious why 1:3 host–guest adducts are not formed except to suggest that the association of one 9-MA to the outside face of one terpy-M–X unit might lead to electronic polarization of the molecular stack so that the other outer terpy-M–X face is deactivated to association of a 9-MA guest.

The host–guest adducts are very labile. Thus in $(CD_3)_2CO$ solution ^1H NMR spectra indicate that the 9-MA guests are undergoing rapid inter- and intramolecular exchange even at –90 °C. We have addressed the question of the rate of intramolecular exchange as well as the preferred occupancy of the 9-MA guest by studying the two molecules **16** and **17**. The intramolecularly tethered anthracene molecule could lie in the cleft as shown in **16**, or it could lie on the outside face of one of the terpy-Pd–Ligand units. ^1H ROESY spectra show that the anthracene fragment of **16** lies exclusively within the cleft.[11] Hence, we conclude that the larger of the two stability constants for the adducts formed with the receptors **1** and free **15** refers to the case of the guest residing in the cleft, as expected.

At 25 °C in $(CD_3)_2CO$ solution the ^1H NMR spectrum of the system **17** indicates that the two anthracene groups are rapidly exchanging their sites by an intramolecular process.[11] As the temperature is lowered, some of the signals first became broad, and then separate into two signals, a process that was complete at –90 °C. By analyzing this data, it was found that the average residence time (life-time) of the guests in **17** in any site is 1.6×10^{-5} s at 20 °C and 1.3 s at –90 °C. Because of the intramolecular tethering of the guests, their stability within the respective sites is expected

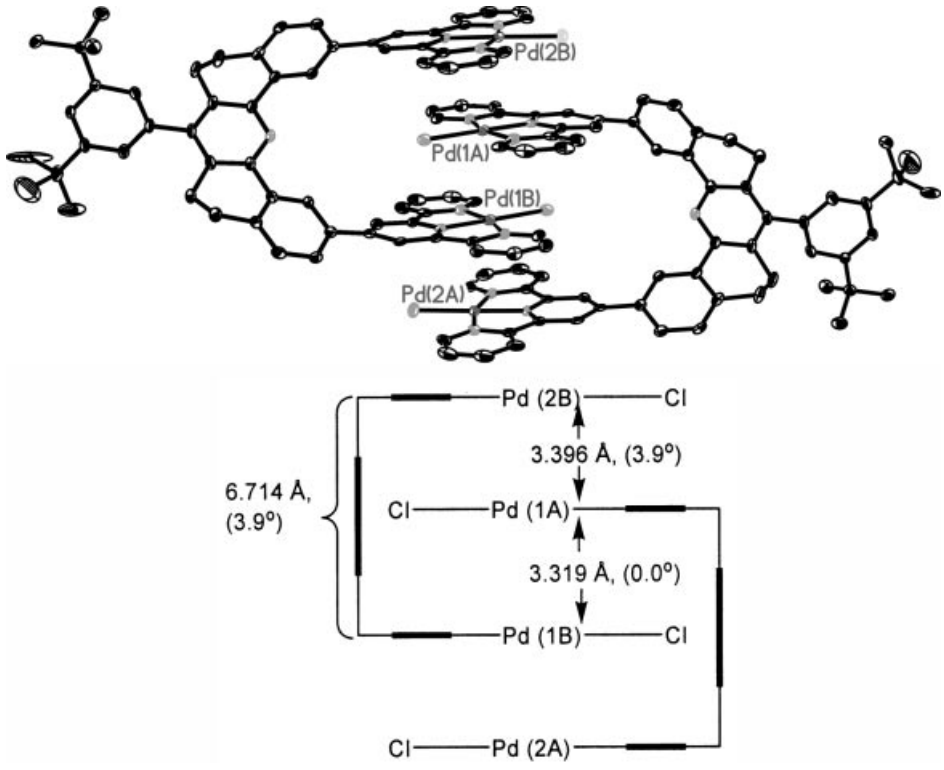

Figure 2. The ORTEP diagram showing a "side" view of the interlocking structure that is present in the crystal of [**1**-Pd^{2+}(X = Cl)]$^{2+}$-$(PF_6)_2$·5CH_3CN. The solvent and counterions have been removed for clarity. Hydrogen atoms were not located. Thermal ellipsoids are shown at 50% probability. Below, a schematic representation of the important structural details from the crystal structure of the receptor, it is noted that the all the terpy-Pd–Cl unit planes are essentially parallel. The interplanar distances are given and the interplanar angles are shown in brackets.

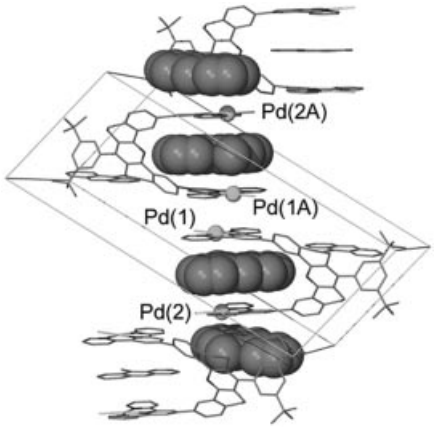

Figure 3. An illustration of the extended crystal structure of [1-Pd^{2+}(X = Cl)]$^{2+}$$(PF_6)_2$·2(9-MA). The box is the unit cell, 9-MA molecules of the stack are shown as space-filling models and the terpy-Pd–Cl units are shown as stick models, as are all other molecules not involved in this stack. Palladium atoms in the stack are shown as spheres.

to be very high, even so, very rapid site exchange occurs. The crystal structure of **17** is shown in Figure 4.

The molecular rectangles **4** derived from **6** and **8**, and the Pd^{2+} receptor form 1:4 9-MA host–guest complexes.[5] This is consistent with two 9-MA molecules residing in the two clefts of the rectangle and with the other two guests residing on the (four) outside faces the terpy-Pd–Ligand units, similar to that observed for the single receptors **1**. This site occupancy is supported by the ^{1}H NMR spectra chemical shifts of requisite protons of the rectangular receptors. The molecular trigonal prisms **5** behave in a similar manner. The Pd^{2+} trigonal prism derived from **12** forms a 1:6 host–guest complex with 9-MA.[7] The larger prism formed by the extended linker **13** gives a 1:7 host–guest adduct with 9-MA. Figure 5 shows ^{1}H NMR titration plots for the host–guest adducts formed by the smaller and larger trigonal prisms with 9-MA. For the smaller prism, the six 9-MA guests reside in the three clefts and on the (six) outer terpy-Pd–Linker unit faces. The seventh 9-MA molecule is assumed to reside between the two phenyl groups of the linker in the larger prism. Molecular models show that the tritopic guest **18** registers almost exactly with the trigonal prism formed with the larger linker **13,** where each of the three anthracene groups occupies a cleft site. Addition of **18** to a solution of the smaller trigonal prism formed from **12** leads to the destruction of the prism presumably because the guest **18** cannot fit strainlessly within this prism. Such decomposition does not occur in [D_7]dimethylformamide (DMF) solutions at 70 °C with the larger prism formed from **13**. In this case a 1:2 host–guest complex is formed, where one guest **18** lies inside of the prism with each an-

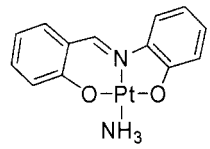
18

receptors. Furthermore, the host–guest chemistry that obtains for the rectangles and trigonal prisms is different from that usually studied where only one single cavity is present. In the present cases, several cavity sites are presented for host–guest formation.

Host–Guest Adducts with Planar Metal Complexes: Magnus' Green Salt[12] $[Pt(NH_3)_4][PtCl_4]$ has long been recognized as the first discovered member of a series of systems containing weak Pt–Pt bonds.[13] Whereas $[Pt(NH_3)_4]^{2+}$ is very pale yellow and $[PtCl_4]^{2-}$ is salmon pink, the green color of Magnus' salt is due to electronic transitions between the states that arise from Pt–Pt bonding.[14] We were interested in determining if weak Pt–Pt (or Pt–Pd) bonds could be used for molecular recognition. The neutral complex **19** was used as a potential guest for both the Pd^{2+} and Pt^{2+} receptors **1** (X = Cl).[13] The guest **19** forms very stable 1:1 adducts with both the Pd^{2+} and Pt^{2+} receptors. At 70 °C in CD_3CN solutions, it was found that the stability constants for the Pd^{2+} and Pt^{2+} receptors are 12000 M^{-1} and 51000 M^{-1}, respectively. ^{1}H NOE spectroscopy of these two adducts shows that the guest **19** lies in the molecular cleft in both cases.[15] The solid-state structure of the **1**-Pt^{2+}·**19** adduct (X = Cl) is shown in Figure 6, where the Pt–Pt distances are 3.303 and 3.262 Å, indicating substantial Pt–Pt interaction.[13] Thus, it is likely that weak metal–metal bonding contributes to host–guest stability.



19

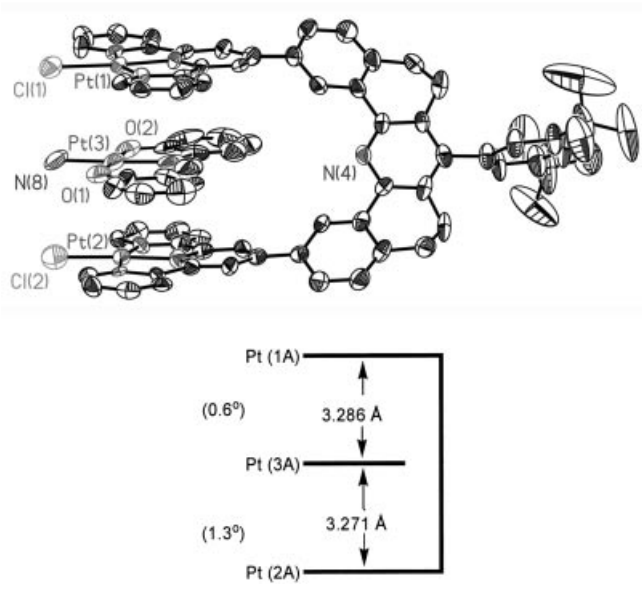


Figure 6. The ORTEP diagram showing a "side" view of the host–guest adduct formed between [**1**-Pt^{2+}(X = Cl)]$^{2+}$(SbF_6)$_2$ and **19**. The solvent and counterions have been removed for clarity. Hydrogen atoms were not located. Thermal ellipsoids are shown at 50% probability. Below, a schematic representation of the important structural details from the crystal structure of the host–guest adduct. The interplanar distances are given and the interplanar angles are shown in brackets.

Solvent Effects: The stability of these adducts depends on the solvent employed. The same host–guest adduct stability constants in [D_7]DMF at 70 °C are an order of magnitude smaller than in CD_3CN solution at 70 °C, namely, 2600 M^{-1} and 4100 M^{-1} for the Pd^{2+} and Pt^{2+} receptors, respectively. Solvent effects in controlling host–guest stability have been considered before.[16] The solvent factors controlling host–guest stability can be delineated by the thermodynamic cycle shown in Scheme 1. The free energy of host–guest formation in solution, $\Delta G_s^{H.G}$, is enhanced by the solvation energy of the host–guest complex, ΔG_{gs}^{H}, and by the intrinsic (gas phase) stability, $\Delta G_g^{H.G}$, but formation is inhibited by the solvation energies of the host, ΔG_{gs}^{H}, and of the guest, ΔG_{gs}^{G}.

Thus, for example, the stability of a host–guest adduct in water will be high when a hydrophobic guest is used. Many of the host–guest complexes reported by Fujita[17] rely on the hydrophobic character of the guests that are incarcerated into water-soluble receptors.

Aside from solvation effects, the stabilities of the host–guest complexes described using 9-MA as a guest are probably controlled by two factors.[1] One is π-π interactions and

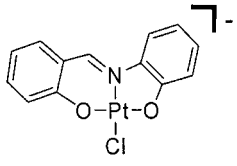
$$-\Delta G_s^{H.G} = -\Delta G_{gs}^{H.G} - \Delta G_g^{H.G} + \Delta G_{gs}^{H} + \Delta G_{gs}^{G}$$

Scheme 1.

the other may involve charge-induced dipole effects, the charge being that carried by the terpy-M–Ligand units. The interplanar separations between the guest in the cleft and the terpy-M–Cl units of the receptor are found to be 3.44 and 3.48 Å (Figure 3), essentially those expected for π-π stacking (3.45 Å).[18] For the case of the 1:1 adduct between the Pt^{2+} receptor and **19,** the separation between the planes of terpy-Pt–Cl units and **19** in the cleft are quite short, 3.286 and 3.271 Å, indicating that the Pt–Pt bonding leads to contraction of the distances from that expected for only π-π stacking.

Electrostatic Interactions: Electrostatic attraction can also be used for host–guest formation.[19] The Pd^{2+} and Pt^{2+}dicationic receptors, **1**, X = Cl, form very insoluble products when their solutions are mixed with solutions of anionic planar complexes, as noted earlier. The potential guest, **20**, however, can be induced to form 1:1 host–guest crystals with **1**, Pd^{2+}, X = Cl and with PF^{-}_{6} as the counterion.[20] The guest, **20**, lies within the cleft and the two terpy-Pd–Cl planes and that of the guest are parallel with separations of 3.21 and 3.29 Å, which are much shorter than those found for π-π interactions. The short spacings appear to be due to electrostatic attraction rather than to metal–metal bonding because the metal–metal distances are 4.0, 4.7 Å, distances much too large for metal–metal bonding.

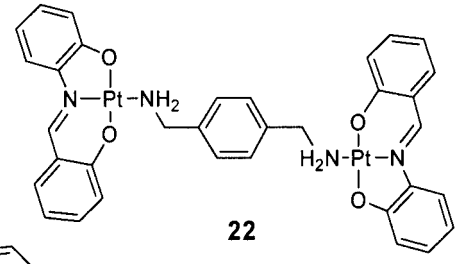


20

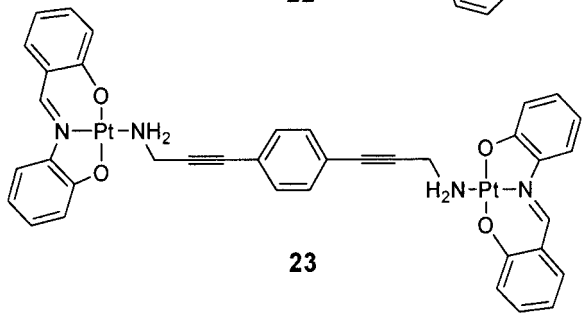
The potential guest **21** resembles **19**, but unlike **19** it carries a (free) basic nitrogen atom that can be protonated. Using the Pd^{2+} receptor **1**, X = Cl, in acetonitrile solutions at 70 °C, **21** forms a stable, red 1:1 complex (K = 21000 M^{-1}).[8] Sequential addition of trifluoroacetic acid to an acetonitrile solution of 1:1 host–guest adduct progressively leads to dissociation of the guest, which is accompanied by the loss of the red color. Addition of sufficient base (Et_3N) to such acidified solutions leads to the complete restoration of the adduct (and the red color). The proton-induced dissociation of the guest appears to be controlled by electrostatic repulsion between the cationic receptor and the cationic protonated guest (The nitrogen atom of the spacer is not protonated under the conditions). Thus, electrostatics can be used to control host–guest adduct formation. As noted in our paper,[8] the protonmotive dissociation of the guest can be described in terms of the mechanisms by which molecular motors operate[21,22] although the simple one-stroke process can hardly be described as a motor. However, studies in this area are a prerequisite to designing synthetic molecular motors, machines and switches.

21

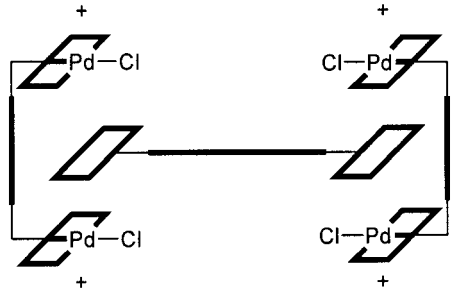
We present one final example where electrostatics appears to play a role in host–guest formation but it is of an unconventional kind. Using the two ditopic guests **22** and **23**, and the Pd^{2+} receptor **1** (X = Cl), it was considered possible to form the assembly **24**.[23] The two ditopic guests



22



23



24

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

are derivatives of **19** and hence 2:1 host–guest adducts of the kind **24** are expected to form. Molecular models indicate that there are no steric impediments to the formation of the structure **24** with either **22** or **23**, where the closest Pt···Pt distances between receptors are 12.2 and 18.8 Å, respectively. ^{1}H NMR titration of the Pd^{2+} receptor with the two ditopic guests **22** and **23** in [D_7]DMF solutions at 70 °C, shows that **22** forms a 1:1 host–guest adduct (K = 1100 ± 100 M^{-1}) but with the longer guest **23** a 2:1 host–guest complex is formed (K_1 = 1000 ± 100 M^{-1}, K_2 = 400 ± 50 M^{-1}), all Ks are microscopic constants. The negative cooperativity observed with the longer guest **23**, and the extreme case of negative cooperativity seen with the shorter guest **22** suggests that the most likely source of the negative cooperativity is electrostatic repulsion between the two receptor molecules.[23] Approximate electrostatic calculations[23] give results consistent with the host–guest stoichiometries observed.[23]

By the observation of a 1:1 adduct formed between **22** and the Pd^{2+}-based molecular rectangle derived from linker **6** it was demonstrated that the shorter ditopic guest can form adducts with two receptor units. The equilibrium constant was found to be $K^{DMF}_{70\,°C}$ = 1500 ± 200 M^{-1}.

Structure of the Molecular Spacer: The structure of the molecular receptors incorporates important characteristics necessary for the incarceration of the guests in the cleft. As we have noted, the cofacial terpy-M–X units can rotate about the single bonds of the spacer, so that the separation between the terpy-M–X units can be adjusted to optimize the cleft separation for the guest. The result of the concerted rotation of the terpy-M–X unit about the spacer is that the mean molecular plane of the spacer is tilted with respect to the terpy-M–Cl planes. This is illustrated by the "front" view of the structure of the host **1**-Pt^{2+}(X = Cl)$(SbF_6)_2$, with the guest, **19** (Figure 7).

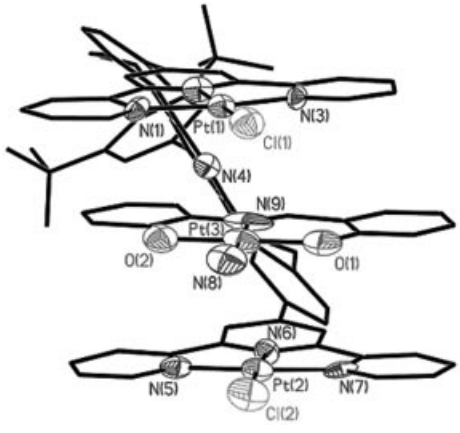


Figure 7. A "front view" of the host–guest complex, [**1**-Pt^{2+}(X = Cl)]$^{2+}$$(SbF_6)_2$:**19**. Note that the mean molecular plane of the spacer is tilted with respect to the terpy-M–Cl and the guest, **19**, planes which are essentially parallel. The tilt of the spacer with respect to the terpy-M–Cl and **19** planes is 42°. Solvent and counterions have been removed for clarity. Thermal ellipsoids are shown at 50% probability.

In addition to terpy-M–X unit rotations, the spacer in all of the crystal structures determined exists in the racemic conformation. The racemic conformation of the spacer causes the M–X vectors of the two terpy-M–X units to twist with respect to each other in a sense dictated by the absolute configuration of the spacer (Figure 7). The rate of interconversion of the puckered spacer from the racemic to the *meso* conformations is likely to be a very rapid process. The large chemical shifts of ^{195}Pt NMR spectra allowed us to determine the rate of this conformational interchange.

Figure 8 shows the temperature variation of the ^{195}Pt NMR in CD_3CN solution of the free Pt^{2+} receptor **1** (X = Cl).[15] At lower temperatures two signals of roughly equal intensities are observed. These are assigned to the racemic and *meso* forms of the spacer. At higher temperature these signals coalesce. Analysis of the spectra indicates that the lifetime of any conformational state at 20 °C is about 5×10^{-4} s, the enthalpy of activation is 2.7 kcal·mol^{-1}, and the statistically adjusted entropy of activation is –34 cal·mol^{-1} K^{-1}. As is evident from the two spectra of the host–guest adduct between **1**, Pt^{2+}, (X = Cl) and **19** shown in Figure 9, rapid conformational interchange also occurs between the racemic and *meso* forms which, at 20 °C, are again approximately in equal proportions. These spectra indicate that the host–guest adduct is supported by both the racemic and *meso* forms of the host which is undergoing

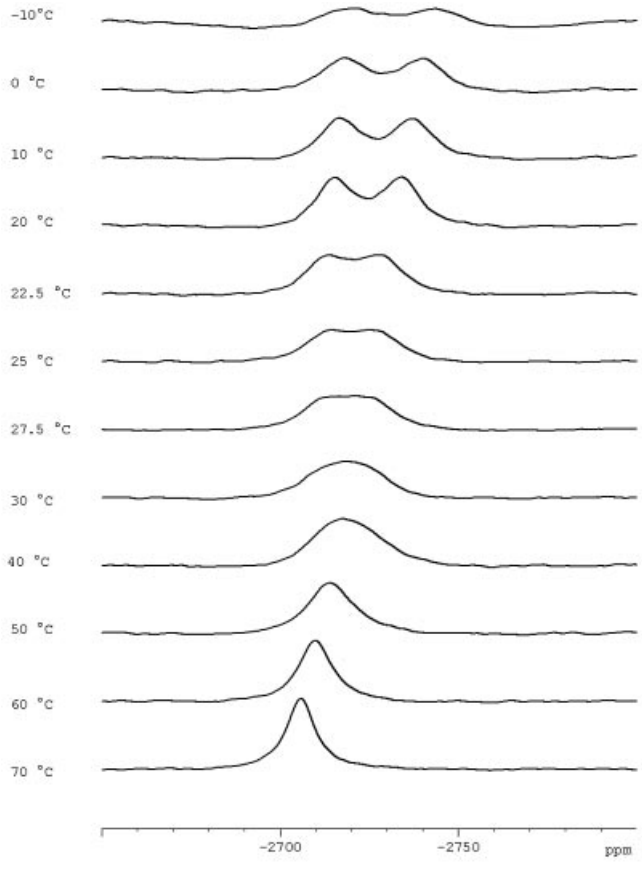

Figure 8. Variable temperature ^{195}Pt NMR spectra of [**1**-Pt^{2+}, (X = Cl)]$^{2+}$$(SbF_6)_2$ in CD_3CN. The chemical shifts (δ scale) are vs. $K_2[PtCl_6]$ in water as an external reference.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

rapid conformation interchange. Thus it is probable that our other host–guest adducts are formed with fluxional receptors.

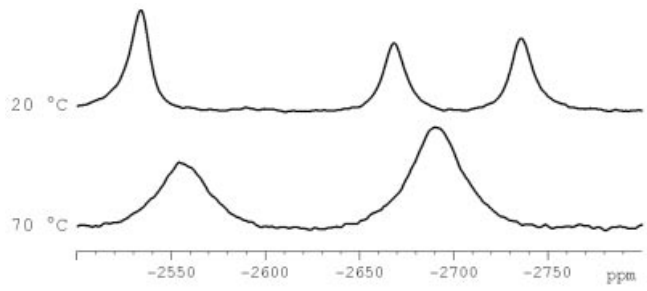

Figure 9. ^{195}Pt NMR spectra of the host–guest adduct formed between [**1**-Pt^{2+} (X = Cl)]$^{2+}$(SbF$_6$)$_2$ and **19** in CD$_3$CN solution (δ scale). No Pt–Pt coupling is observed because of the broadness of the peaks. Three signals are observed for the host–guest adduct at 20 °C; the receptor shows two broad signals at δ = –2669 and –2736 ppm of similar intensities and the incarcerated guest provides a signal at δ = –2534 ppm. Upon raising the temperature to 70 °C, the two receptor signals coalesce to a single peak at δ = –2690 ppm and the guest signal occurs at δ = –2554 ppm.

Conclusions

This brief review of our studies of host–guest formation with the receptors **1**, and the molecular rectangles and trigonal prisms derived from them, serves to illustrate some of the forces that can control molecular recognition. The guest 9-MA (**15**) associates with the molecular clefts by forming 1:2 host–guest adducts so that when the clefts are incorporated in molecular rectangles or trigonal prisms, multiple guest association occurs. The forces that cause these molecular associations are probably π-π interactions, supplemented by charge-induced dipole attractions. A new molecular recognition force, namely weak metal–metal bonding in d^8 complexes, has been shown to add stability to host–guest formation. The strongest of the molecular recognition forces is electrostatic interaction where cationic receptors, such as **1**, do not associate with cationic guests in solution. This has been demonstrated in several ways but perhaps most persuasively by the dissociation of a neutral guest in a cationic cleft after protonation of the guest. Anionic guests form what appear to be strong complexes with the cationic receptors. Electrostatics are responsible for controlling the stoichiometry of ditopic guest interaction with the molecular clefts. An understanding of the forces that control molecular recognition form the basis for designing molecular motors, switches and machines.

Synthesis and Characterisation of a Novel Copper(II) Azamacrocycle-Phosphonate 3D Polymeric Network

Giuliano Giambastiani,[a] Werner Oberhauser,[a] Claudio Bianchini,[a] Franco Laschi,[b] Lorenzo Sorace,[c] Peter Brueggeller,[d] Rene Gutmann,[d] Annabella Orlandini,[a] and Francesco Vizza*[a]

Keywords: Copper / Azamacrocycles / Coordination polymers / Macrocyclic ligands

A new azamacrocycle phosphonate in its hydrocloride form (**1**) has been synthesized and characterised by multinuclear NMR spectroscopy and by a single X-ray analysis. The reaction of **1** with Cu^{II} ions gives a polymeric compound (**2**), which exhibits an unprecedented three-dimensional network containing two-dimensional channels filled with guest molecules. The solid-state structure of **2** and its properties have been characterised by means of various analytical methods which include single-crystal X-ray structure analysis, X-ray powder diffraction, thermogravimetric studies as well as magnetic susceptibility and EPR measurements.

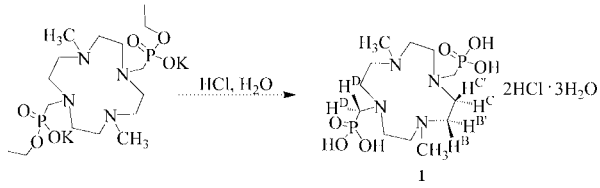
Introduction

Polymeric matrices made up of metal phosphonates and macrocyclic ligands constitute an innovative class of compounds with potential application in catalysis, as sensoring and switching devices, liquid crystals and molecular magnets.[1]

Metal complexes with azacrown ethers, containing phosphonic acids, are often characterised by unusual structures and can also form porous lamellar-structured materials.[2] To the best of our knowledge, no multidimensional network containing channels or cavities assembled by Cu^{II} ions and azamacrocycle phosphonate ligands has been reported in the literature. Indeed, the "macrocyclic effect" exerted by azamacrocycle ligands favours the formation of stable 1:1 adducts, where the nitrogen atoms bind metal ions, such as Co^{II}, Cu^{II} and Ni^{II}. The resulting ML units may be further assembled only in a mono-dimensional chain by hydrogen bonds involving the uncoordinated phosphonate units.[3] In this communication we present the synthesis and characterisation of a new azamacrocycle phosphonate in its HCl-form (**1**), and the synthesis and characterisation of a novel three-dimensional network containing two-dimensional channels assembled by Cu^{II} ions in conjunction with the new macrocycle phosphonate ligand.

Results and Discussion

The new macrocycle 4,10-dimethyl-1,4,7,10-tetraazacyclododecane·-1,7-bis(methanephosphonic acid)·2HCl·3H_2O, Me_2DO2P-4H·2HCl·3H_2O (**1**) was obtained by acid hydrolysis (HCl) of the known ligand 4,10-dimethyl-1,4,7,10-tetraazacyclododecane·-1,7-bis(methanephosphonic acid monoethyl ester)dipotassium salt, $K_2Me_2DO2PME$ (Scheme 1).[4]



1

Scheme 1.

The X-ray structure of **1** consists of two conformations of the new cationic macrocyclic units $[Me_2DO2P\text{-}6H]^{2+}$, chloride anions and solvent water molecules. An ORTEP plot of **1** is presented in Figure 1.

The phosphonate units and the chloride anions are interlinked by water molecules through hydrogen bonding. The two cationic conformations are very similar, as the methyl and the phosphonate groups are oriented on the same side of the planes defined by the four nitrogen atoms N1–N4 and N5–N8. Furthermore, in both macrocyclic cations the phosphonate groups are doubly protonated. As evidenced

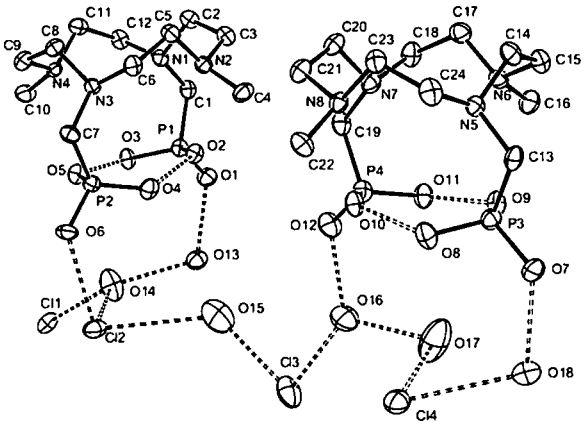

Figure 1. Perspective view of the asymmetric unit of **1**, showing conformer A (left) and conformer B (right) involved in the most important hydrogen-bonding interactions; hydrogen atoms have been omitted for clarity.

by a difference Fourier map, the protonation involves the oxygen atoms O1, O3, O4, O6 of conformer A and the oxygen atoms O7, O8, O11, O12 of conformer B, which is in agreement with the values of the corresponding P–O lengths ranging from 1.530(3) Å to 1.562(2) Å.[5] As expected, the P–O double bonds show bond lengths ranging from 1.489(3) Å to 1.493(3) Å. Both conformers show strong intramolecular hydrogen bonds between P=O and POH units of different phosphonate groups in order to stabilise eight-membered O–H–O–P–O–H–O–P rings. The protonated oxygen atoms O1, O6, O7, and O12 are strongly bonded to water molecules or to chloride anions in order to build up a complex network of hydrogen bonds. In both conformers, the nitrogen atoms bearing the methyl groups are protonated also (the four protons were detected in difference Fourier maps and successfully refined).

^{1}H NMR studies of **1** in D_2O at pH = 1 and room temperature have revealed that the protons of the ethylenic bridge (B, B′ and C, C′) are diastereotopic. This indicates that the system is locked in a rigid conformation on the NMR timescale.

Bright-blue crystals of the polymeric compound $\{[Cu_2Cl_2(Me_2DO2P\text{-}2H)(H_2O)]\cdot(0.5\,C_3H_6O)\cdot(2.5\,H_2O)\}_n$ (**2**) were isolated from the reaction of an equimolar amount of **1** with $Cu(OAc)_2\cdot H_2O$ or $CuCl_2\cdot 2\,H_2O$ in water/acetone at room temperature in the pH range from 1 to 8 (Scheme 2).

When the reaction was carried out in the pH range 9–14, no formation of **2** was observed, which indicates a strong control of both the pH and chloride ligands on the product formation. Indeed, the reaction of the ligand in its potassium salt form (K_4Me_2DO2P) with $Cu(OAc)_2\cdot H_2O$ or with $CuCl_2\cdot 2\,H_2O$ does not yield **2**, yet an undefined compound is produced. It is worth stressing that **2** was obtained even when the ratio between **1** and $Cu(OAc)_2\cdot 2\,H_2O$ or $CuCl_2\cdot 2\,H_2O$ was much greater than the stoichiometric ratio.

The single-crystal X-ray structure analysis of **2** revealed a structural organization that has never been reported for Cu^{II} diphosphonate compounds.[6a] Indeed, **2** adopts a three-dimensional layered structure containing $\{CuClN_4\}$ units and phosphonate O-bridged $\{Cu_2Cl_2O_6\}$ dimers. An ORTEP plot of compound **2** is presented in Figure 2.

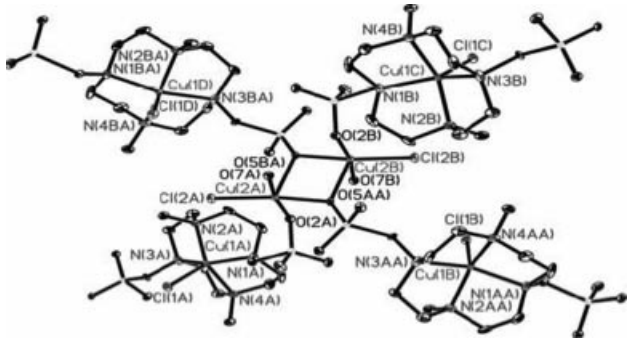

Figure 2. X-ray crystal structure of **2**, showing the connectivity of the centrosymmetric moieties $\{Cu_2Cl_2O_6\}$, projected perpendicular to the *a* axis. Hydrogen atoms and noncoordinating solvent molecules are omitted for clarity.

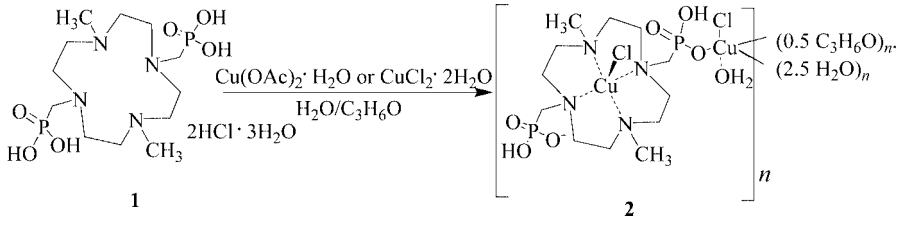
A three-dimensional porous structure with continuous channels (Figure 3) is apparently formed with no need for a templating agent.[6]

The 12-membered azamacrocycles are tilted towards each other by 35.3°. The methyl and phosphonate groups bound to the nitrogen atoms are all oriented on the same side of the N_4 plane.[7] The Cu^{II} centres of **2** exhibit two different distorted square-pyramidal coordination geometries, which represents an unprecedented structural feature for layered Cu^{II} diphosphonates. The Cu(1A) atom lies 0.546 Å above the N_4 ring, while Cu(2A) deviates by 0.105 Å from the basal plane defined by Cl(2A), O(2A), O(5AA), and O(7A). Typically, the apical Cu(2A)–O(5BA) bond length of 2.241(3) Å is significantly longer than the Cu(2A)–O(5AA) bond length of 1.989(3) Å.[6a,8] The oxygen bridged $\{Cu_2(\mu\text{-}O)_2\}$ dimeric units show a Cu(2A)···Cu(2B) distance of 3.140(1) Å, which is in line with comparable structures.[8a,9] The next larger Cu···Cu distances within the layers are 6.403(1) Å for Cu(1B)···Cu(2B) and



Scheme 2.

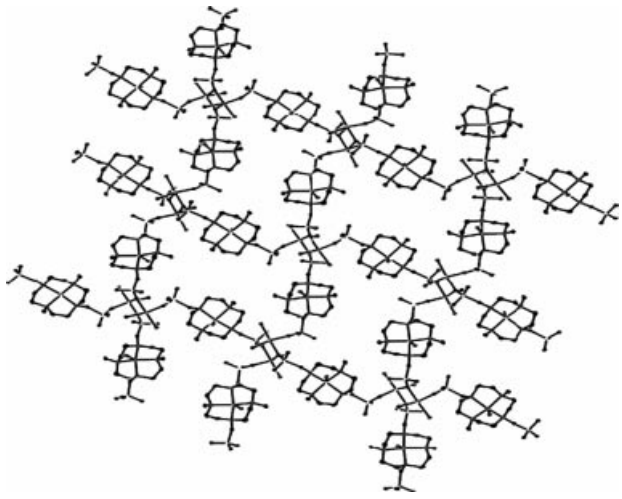


Figure 3. ORTEP plot, showing the propagation of the asymmetric unit in two dimensions, with the projection direction perpendicular to the *a* axis; hydrogen atoms and solvent molecules are omitted for clarity.

6.545(1) Å for Cu(1A)···Cu(2A). The shortest Cu···Cu distance between the layers is 8.277(1) Å. Considering the packing in $\{[Cu_2Cl_2(Me_2DO2P\text{-}2H)(H_2O)]\cdot(0.5\,C_3H_6O)\cdot(2.5\,H_2O)\}_n$ for $n = 2$, four water molecules hold together two adjacent layers by strong hydrogen bonding to two different phosphonate anions. Four O···O contacts in the range 2.54–2.91 Å have been detected. The central disordered water molecule also makes a short contact of 2.83 Å to this chain of hydrogen bonds. Disordered acetone molecules fill up the continuous channels (Figure 4).

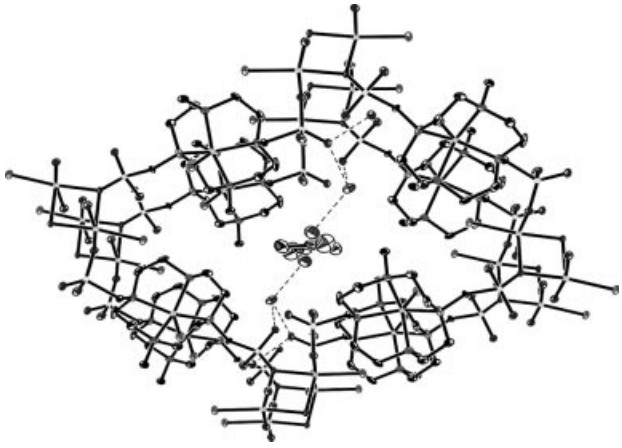

Figure 4. Packing diagram of **2** revealing the continuous channel in the projection plane perpendicular to the *a* axis, occupied by solvent molecules and formed through stacking of macrocyclic moieties. The chain of solvent molecules is indicated with a broken line.

The polymeric compound **2** is soluble in water but insoluble in all common organic solvents. When a sample of **2** is heated in air at 125 °C, its colour becomes bright green, due to the loss of the coordinated water. The crystal morphology does not change even at 160 °C. When the green solid is allowed to cool to room temperature, it again turns dark blue indicating that the coordination of water to the metal centre is restored. The removal of the guest molecules (water, acetone) and its reversible process, which is very important for designing new architectures of porous materials or chemical sensors, was studied by means of a thermogravimetric analysis (TGA) and X-ray powder diffraction (XRPD).

The thermogravimetric analysis of **2**, in the temperature range 36–160 °C, showed a 7% loss of weight, which corresponds to the release of half a molecule of acetone and one molecule of coordinated water per asymmetric unit. Between 160 and 190 °C, a further weight loss of 1.2% was detected, due to the release of the water molecule (half a molecule per formula unit) located in the channel and that shows a short contact of 2.83 Å to the water molecule hydrogen-bonded to two phosphonate units (Figure 4). No chemical decomposition was observed up to 200 °C, yet the bright-green solid lost the original crystal morphology. The X-ray powder diffraction (XRPD) pattern of **2** did not show any change after a dehydration/rehydration cycle conducted by heating of **2** at 160 °C for 10 min and rehydrating at room temperature in a water/acetone (1:10) (v/v) mixture. The sample changed its colour from dark blue to bright green during the heating step, while it turned back to deep blue during cooling and exposure to the water/acetone mixture.

Apparently, the three-dimensional network is sufficiently robust to show reversible coordination of water molecules as well as inclusion of acetone as the guest molecule.

Magnetic susceptibility measurements of **2** showed a Curie–Weiss behaviour down to 5 K. The calculated value of the Curie constant per asymmetric unit, $C = 0.413\ cm^3\,K\,mol^{-1}$ (corresponding to a μ_{eff} value of 1.82 μ_B), indicates that only one Cu^{II} centre, namely that pertaining to the ($CuClN_4$) unit, contributes to the magnetic moment of the system. Consistently, the Cu^{II} centres in the ($Cu_2Cl_2O_6$) units did not display any EPR signal, due to the very intense Cu^{II}–Cu^{II} antiferromagnetic coupling. The observed g values [$g_{\|} = 2.15(3)$, $g_{\perp} = 2.07(1)$], which did not change on cooling, suggest that the signal can be assigned to the $Cu^{II}N_4$ moiety.[10,11]

Conclusions

We synthesized a very rare organic–inorganic Cu^{II} polymer, which represents the first example of a polymeric coordination network obtained by combining an azamacrocycle phosphonate ligand with Cu^{II} ions. Given the hemilability of **1**, the formation of **2** may be seen as a weak-link approach to supramolecular coordination complexes.[12] TGA and XRPD experiments clearly indicate that guest molecules, like water and acetone, can be removed from the three-dimensional network without affecting the solid-state morphology. Intercalation reactions of amines and other organic solvents with the dehydrated compound **2** are being investigated in our laboratories.

Experimental Section

Elemental analyses were performed with a Carlo–Erba model 1106 elemental analyser. The IR spectroscopic measurements were performed with a FT-IR Spectrum GX instrument. TGA measurements were performed with a TA SDT Q600 apparatus at a heating rate of 2 °C min^{-1} in the range of 30–200 °C. XRPD measurements were performed with a Philips PW 3830 diffractometer (Co, λ = 1.7889 Å) with a voltage of 40 kV and a current of 40 mA. The magnetic susceptibility measurements were carried out in a temperature range from 2 to 300 K at a magnetic field of 1 T with a Cryogenic S600 SQUID magnetometer. The EPR powder spectra were recorded with a Varian E9 spectrometer equipped with a ^{4}He continuous flow cryostat for variable temperature measurements. ^{1}H, ^{13}C, and ^{31}P{^{1}H} NMR spectra were recorded at 200.13, 50.32, and 81.01 MHz, respectively, with a Bruker ACP-200 spectrometer or at 400.13, 100.62, and 161.97 MHz, respectively, with a Bruker Avance DRX-400 spectrometer. Chemical shifts are relative to tetramethylsilane as external reference or were calibrated against solvent resonances. The assignments of the signals resulted from 2D-^{1}H COSY and proton detected ^{1}H-^{13}C correlations using degassed nonspinning samples. 2D-NMR spectra were recorded with a Bruker Avance DRX-400 spectrometer.

1. Synthesis of 4,10-Dimethyl-1,4,7,10-tetraazacyclododecane-1,7-bis(methanephosphonic acid)·2 HCl·3 H_2O [(Me_2DO2P-4H)·2 HCl·3 H_2O, 1]

A solution of 4,10-dimethyl-1,4,7,10-tetraazacyclododecane-1,7-bis(methanephosphonic acid monoethyl ester) dipotassium salt, (K_2Me_2DO2PME) (2.4 g, 4.23 mmol) in HCl (35 mL of a 6 M solution) was stirred at reflux for 3 days in a sealed Schlenk tube. Afterwards, the solvent was concentrated to a small volume (10 mL), and then the slow addition of acetone (5 mL) led to the precipitation of a white crystalline product. The solution was was decanted, and the solid dried under vacuum. The hygroscopic compound was used without further purification and stored under N_2 at room temperature. Yield: 2.1 g (88%). $C_{12}H_{38}Cl_2N_4O_9P_2$ (515.30): calcd. C 27.97, H 7.43; N 10.87; found: C 27.69, H 7.40, N 10.61. ^{1}H NMR (400.13 MHz, D_2O, pH = 1, 25 °C): δ = 3.37 (ddd, $^2J_{B,B'}$ = 14.1, $^3J_{C,B}$ = 3.5, $^3J_{B,\ C'}$ = 7.1 Hz, 4 H, H_B), 3.18 (ddd, $^3J_{B',C}$ = 7.5, $^3J_{B',C'}$ = 2.9 Hz, 4 H, $H_{B'}$), 3.07 (ddd, $^2J_{CC'}$ 14.9 Hz, 4 H, H_C), 2.93 (s, 6 H, CH_3), 2.86 (ddd, 4 H, $H_{C'}$), 2.79 (d, H_D, $^2J_{H,P}$ = 11.07 Hz, 4 H) ppm. ^{13}C{^{1}H} NMR (100.62 MHz, D_2O, pH = 1.0, 25 °C): δ = 54.18(s,C_B), 51.73 (d, ^3J(P,C) = 4.53 Hz, C_c), 52.03 (d, $^1J_{C,P}$ = 108.69 Hz, C_D), 44.12 (s, CH_3) ppm. ^{31}P{^{1}H} NMR (161.97 MHz, D_2O, pH = 1.0, 25 °C): δ = 22.48 ppm. IR features (KBr disk): $\tilde{\nu}$ = 3276 s, 3136 s, 1734 s, 1469 s, 1216 m, 1200–900 s cm^{-1}.

2. Synthesis of {[Cu_2Cl_2(Me_2DO2P-2 H)(H_2O)]·(0.5 C_3H_6O)·(2·5 H_2O)}$_n$ (2)

Method A: Me_2DO2P-4H·2 HCl·3 H_2O (0.3 g, 0.580 mmol) was dissolved in water (10 mL). The reaction mixture was then treated with a solution of $Cu(OAc)_2$·H_2O (0.115 g, 0.58 mmol) in water (5 mL) at room temperature. The resulting blue solution was layered with acetone (15 mL), and on standing, blue crystals separated, which were filtered off and recrystallised from a water/acetone solution (1:1, v/v). Yield: 0.35 g, (44%). $C_{13.5}H_{38}Cl_2Cu_2N_4O_{10}P_2$ (676.40): calcd. C 23.97, H 5.66, N 8.28; found: C 24.02, H 5.80, N 8.59. IR features (KBr disk): $\tilde{\nu}$ = 3412 s (hydrogen bonded water), 3200 s (coordinated water), 2370 m, 2210 w, 2920 s, 2850 s, 1712 s, 1160 s, 1050–915 s cm^{-1}.

Method B: Me_2DO2P-4H·2 HCl·3 H_2O (0.3 g, 0.58 mmol) was dissolved in water (10 mL) and the pH was adjusted to 8 by addition of 1 M KOH. The reaction mixture was then treated with a solution of $CuCl_2$·2 H_2O (0.1 g, 0.58 mmol) in water (5 mL) at room temperature. The resulting blue solution was layered with acetone (15 mL), and on standing, blue crystals separated, which were filtered off and washed with a water/acetone solution (1:1, v/v). Yield: 0.30 g, (38%).

X-ray Crystallographic Studies

X-ray quality crystals of **1** and **2** were obtained from a mixture of water/acetone solution (1:10, v/v) of the respective compounds.

Compound 1: $C_{12}H_{38}Cl_2N_4O_9P_2$, M_r = 515.30, dimensions 0.450 × 0.275 × 0.075 mm, triclinic, space group P-1, a = 14.244(3) Å, b = 15.374(7) Å, c = 11.109(1) Å, α = 97.72(2)°, β = 95.89(1)°, γ = 86.62(3)°, V = 2395.4(12) Å^3, Z = 4, D_c = 1.429 g cm^{-3}, μ(Mo-K_α) = 0.452 mm^{-1}. X-ray data were collected with an Enraf–Nonius CAD4 automatic diffractometer at 293(2) K in the range of 2.01 < Θ < 23.47°. Unit cell parameters were determined by least-squares refinement of the setting angles of 25 carefully centred reflections. The structure was solved by direct methods and refined by full-matrix on F^2, with the WINGX package,[13a] converging at R = 0.0488 [$I > 2\sigma(I)$] with a goodness-of-fit on F^2 of 0.885 for 579 parameters and 7550 reflections, 7046 unique reflections.

Compound 2: $C_{13.5}H_{38}Cl_2Cu_2N_4O_{10}P_2$, M_r = 676.40, dimensions 0.100 × 0.08 × 0.03 mm, monoclinic, space group $P2_1/n$, a = 8.2771(3) Å, b = 20.8384(8) Å, c = 14.9980(4) Å, β = 98.548(2)°, V = 2558.12(2) Å^3, Z = 4, D_c = 1.756 g cm^{-3}, μ(Mo-K_α) = 2.051 mm^{-1}. X-ray data were collected with a Nonius–Kappa CCD diffractometer at 243(2) K in the range of 2.39 < Θ < 26.02°. Cell refinement, data reduction, and the empirical absorption correction were done by Denzo and Scalepack programs.[13b] Unique reflections were used to solve the structure by direct methods with SHELXS-97.[13c] Structure refinement on F^2 by full-matrix least-square methods were carried out with SHELXL-97,[13d] converging at R = 0.030 [$I > 2\sigma(I)$] with a goodness-of-fit on F^2 of 1.014 for 342 parameter and 9687 reflections, 4932 unique reflections.

CCDC-262040 (for **1**) and -242225 (for **2**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Supporting Information: See also footnote on the first page of this article. A thermogravimetric study of compound **2**, a comparison of the XRPD patterns before and after the dehydration/hydration cycle, and magnetic susceptibility as well as EPR measurements of **2** are included.

Vanadium(V) Oxoperoxo Complexes with Side Chain Substituted *N*-Salicylidenehydrazides: Modeling Supramolecular Interactions in Vanadium Haloperoxidases

Simona Nica,[a] Axel Pohlmann,[a] and Winfried Plass*[a]

Dedicated to Professor Dirk Walther on the occasion of his 65th birthday

Keywords: Hydrogen bonds / Oxidative bromination / Peroxo ligands / Salicylidenehydrazide ligand / Vanadium

The Schiff-base ligand derived from salicylaldehyde and γ-hydroxybutanoic acid hydrazide (H_2Salhyhb) reacts with potassium metavanadate and hydrogen peroxide in a water/methanol solution with a pH value of around two to yield the corresponding vanadium(V) oxoperoxo complex [VO(O_2)-HSalhyhb(H_2O)] (**1**). Complex **1** crystallizes with one molecule of water as **1**·H_2O in the monoclinic space group $P2_1/n$. For the vanadium atom a pentagonal-bipyramidal coordination geometry is observed, with a side-on bonded peroxo ligand in the equatorial plane. The hydroxy side chain of the hydrazide ligand is involved in a hydrogen-bond network with the peroxo ligand at the vanadium atom. This network shows some similarities with the hydrogen-bonding scheme found for the peroxo form of vanadium haloperoxidases. The stoichiometric reaction of **1** with 1,3,5-trimethoxybenzene (TMB) in the presence of tetrabutylammonium bromide leads to the formation of 1-bromo-2,4,6-trimethoxybenzene (Br-TMB), thus mimicking the oxidative halogenation function of the native enzyme. Complex **1** is also capable of oxidizing triphenylphosphane and methylphenylsulfane, yielding a *cis*-dioxovanadium(V) complex and the corresponding phosphane or sulfane oxide, respectively.

Introduction

Vanadium haloperoxidases (VHPO) are enzymes capable of catalyzing halide oxidation by hydrogen peroxide to give the corresponding hypohalous acid.[1] This oxidized intermediate can halogenate various organic substrates,[2] or react with a second equivalent of hydrogen peroxide to produce singlet oxygen.[3] Moreover, these enzymes can also catalyze the oxidation of organic sulfanes to sulfane oxides.[4] The active site of this class of enzyme consists of a vanadate moiety with proposed trigonal bipyramidal geometry covalently bonded to a histidine residue and held within the protein by strong hydrogen-bonding interactions with several amino acid residues.[5] This active site architecture is also found in certain acid phosphatases,[6] but subtle differences concerning the relative positions of the amino acid residues are apparent,[7] in particular, for those residues that can potentially hydrogen bond with the equatorial oxygen atoms of the vanadate moiety (i.e. lysine, arginine, and serine). Recent theoretical studies and spectroscopic data for vanadium haloperoxidases suggest that the prosthetic group is a doubly protonated $[VO_2(OH)_2]^-$ vanadate moiety.[8]

Spectroscopic and kinetic studies of the native enzyme showed that no change occurs in the redox state of the prosthetic during the catalytic cycle.[9] Thus, it was proposed that the vanadate functions as a Lewis acid catalyst, reacting with hydrogen peroxide first to form a side-on bonded peroxo ligand, which in turn may be activated through hydrogen-bonding interactions with the first shell of amino acids and nearby water molecules.[10] This is proposed to activate the peroxo intermediate by protonation which would increase the electrophilicity of the oxygen atoms of the peroxo group, thus making attack by a halide ion more favorable.[11] This mechanistic feature is also found for the heterolytic cleavage of O–O bonds in heme-based peroxidase enzymes.[12] On the basis of this aspect of the biological function of vanadate in VHPO, the synthesis of structural models with relevant hydrogen-bonding interactions has recently been reported.[13–18]

Renirie et al. spectrophotometrically determined the stability and reactivity of such a peroxo intermediate.[19] The peroxo complex is very stable at a pH value of 8 and exists for a long period of time, but is less stable at a pH value of 5 (the pH for optimum activity for the native enzyme). However, under both conditions, the enzyme is capable of oxidizing chloride ions to hypochloric acid by a pseudo first

order reaction. Moreover, mutagenesis studies of vanadium chloroperoxidase proved that the amino acid residues His404, Arg490, Arg360, and Ser402 perform an essential role in haloperoxidase-catalyzed reactions.[20] All of these residues are involved in hydrogen-bonding interactions with the prosthetic group. The proposed bromination of the serine residue during the catalytic turnover has become a matter of debate in recent years.[21] This crucial role could neither be confirmed by site-directed mutagenesis studies,[22] nor by catalytic studies of model systems containing a relevant hydroxy side chain.[17] However, in mutagenesis studies a significant decrease in the enzyme activity could be observed for the chlorination and bromination reactions to about 4 and 20%, respectively.[22] This indicates that the serine residue, although not crucial, plays an important role in affecting the reactivity of the active site.

We recently reported on vanadium(v) complexes derived from the *N*-salicylidene-hydrazide ligand system that exhibit extensive hydrogen bonding.[13–17] Herein we report on the structure and reactivity of the first vanadium(v) oxoperoxo complex with a hydroxy substituted side chain, a basic ligand system that participates in hydrogen-bonding interactions relevant for vanadium haloperoxidases.

Results and Discussion

The new Schiff base ligand derived from 4-hydroxybutanoic acid hydrazide and salicylaldehyde (H_2Salhyhb) reacts with potassium vanadate and hydrogen peroxide in a methanol/water solution at 0 °C in the presence of perchloric acid to afford the orange vanadium(v) oxoperoxo complex [VO(O_2)HSalhyhb·H_2O] (**1**). Due to the acidic reaction conditions the tridentate carbonic acid hydrazide ligand is present in the mono anionic form, and upon coordination it yields the neutral complex **1**. It is worth noting that for vanadium(v) complexes with this kind of ligand system, it has been shown that the N–H proton of the amide group can be reversibly removed, leading to a variable protonation state for this ligand.[14,15,17] Complex **1** dissolves in various organic solvents like alcohols, acetonitrile, and DMF, without undergoing decomposition. The ^{51}V NMR spectrum of **1** recorded in CD_3OD reveals a single resonance in the typical range, i.e. at –551 ppm with a peak width at half height of $\Delta\nu_{1/2}$ = 105 Hz. In [D_6]DMSO complex **1** undergoes fast decomposition as indicated by the appearance of two resonance peaks in the ^{51}V NMR spectrum. The peak at –539 ppm ($\Delta\nu_{1/2}$ = 860 Hz) is attributed to the *cis*-dioxocomplex and the second peak at –572 ppm ($\Delta\nu_{1/2}$ = 1100 Hz) is assigned to the corresponding dimeric *cis*-dioxocomplex; the intensity ratio for the two peaks is approximately 10:1. Both resonances are present immediately after the dissolution of compound **1** in [D_6]DMSO. The molecular structure of complex **1**, as determined by X-ray crystallography, reveals a pentagonal-bipyramidal geometry for the coordination around the vanadium atom, as depicted in Figure 1. The hydrazide ligand coordinates in the mono anionic form, providing an ONO donor set. In the equatorial plane, the vanadium atom is coordinated to atoms O2 and O3 of the side-on bonded peroxo group, and to the donor atoms O4, O5, and N1 of the tridentate hydrazide ligand. The axial positions of the coordination polyhedra are occupied by the oxo group O1 and by the oxygen atom O7 of the coordinated water molecule. The structural parameters given in Figure 1 are consistent with those observed for other vanadium(v) complexes containing hydrazide ligands,[14,15,17,23] and with those reported for vanadium(v) oxoperoxo complexes which generally feature the vanadium atom coordinated to the oxo group in the axial position and the peroxide bound in the equatorial position.[11,18,24] Complex **1** crystallizes with one molecule of water (O8) leading to an extensive hydrogen-bond network in the solid state, as depicted in Figure 2. The first sphere of hydrogen-bonding interactions shown in Figure 2 is located below the plane of the ligand arrangement in a *trans* orientation with respect to the oxo group O1. Consequently, the oxo group O1 and the carbonyl group O5 of the hydrazide ligand are not involved in the hydrogen-bond network, which is in agreement with their relatively low donor ability. Both enantiomers are present in the crystal structure of **1**·H_2O and form hydrogen-bonded chains through the interaction between the protonated hydrazide nitrogen atom, N2, and the peroxo group of a neighboring complex of same enantiomeric form (N2···O2A 280, N2···O3A 305 pm). These two enantiomeric chains form a bilayer that incorporates the hydrogen-bond network shown in Figure 2, and in turn leads to one-dimensional hydrogen-bonded chains parallel to [010] (see Figure 3).

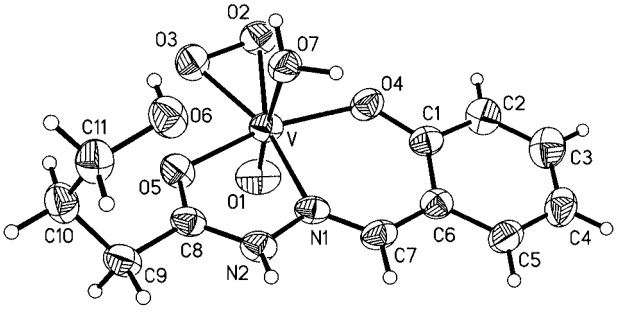

Figure 1. Molecular structure and numbering scheme for **1**. Thermal displacement ellipsoids are drawn at the 50% probability level. Selected bonds lengths [pm] and angles [°]: V–O1 157.8(3), V–O2 189.1(3), V–O3 187.6(3), V–O4 197.6(3), V–O5 207.6(3), V–O7 225.8(3), V–N1 213.2(3), O2–O3 142.9(4); O1–V–O2 103.48(13), O1–V–O3 101.94(14), O1–V–O4 97.52(15), O1–V–O5 94.26(14), O1–V–O7 170.08(13), O2–V–O3 44.57(12), O2–V–O4 79.39(12), O2–V–O5 119.93(12), O2–V–O7 86.31(12), O3–V–O4 123.41(13), O3–V–O5 75.86(12), O3–V–O7 86.08(12), O4–V–O5 154.21(12), O4–V–O7 82.58(11), O5–V–O7 81.95(11), O1–V–N1 94.16(13), O2–V–N1 155.91(12), O3–V–N1 146.81(13), O4–V–N1 82.17(12), O5–V–N1 74.14(12), O7–V–N1 76.01(11).

A situation reminiscent of the role of the active site lysine residue in VHPO[10] is found by considering the hydrogen-bond interaction between the peroxo ligand (O2 and O3) and the acidic N–H group of the hydrazide ligand (N2).[14,15,17] A second type of hydrogen-bond pathway related to the peroxo group originates from the hydroxy side

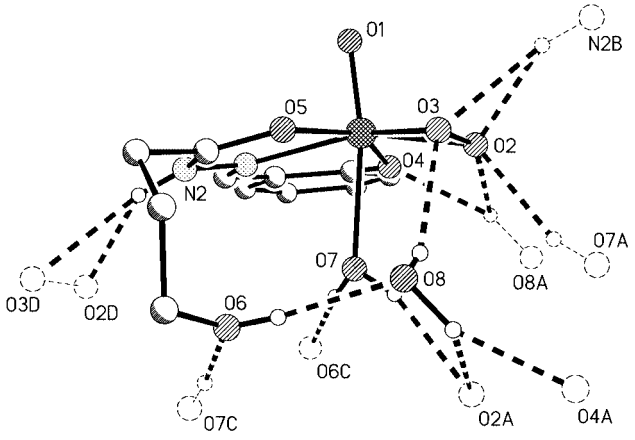

Figure 2. Hydrogen-bond network for complex **1**·H_2O. Only hydrogen atoms bonded to non-carbon atoms are shown, broken lines represent hydrogen bonds, dashed circles and lines represent symmetry equivalent atoms and the bonds between them, respectively (symmetry operators A: 1 – *x*, –*y*, –*z*; B: *x*, *y* – 1, *z*; C: 1 – *x*, 1 – *y*, –*z*; D: *x*, 1 + *y*, *z*). Selected hydrogen bond lengths [pm]: N2···O2D 280.2, N2···O3D 305.2, O6···O8 286.0, O7···O2A 282.7, O7···O6C 271.1, O8···O2A 306.0, O8···O3 299.8, O8···O4A 295.8.

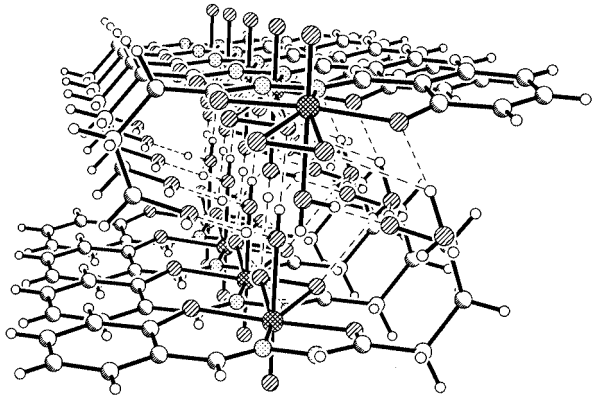

Figure 3. Representation of the hydrogen-bonded bilayer for complex **1**·H_2O, as viewed approximately along the [010] direction.

chain (O6) of the hydrazide ligand system. This side chain is involved in a hydrogen-bonding cascade that includes the water oxygen atom O8 (O6···O8 286 pm); this then leads to an intramolecular interaction with the oxygen atom O3 of the peroxo group (O8···O3 299 pm), and an intermolecular interaction with the peroxo oxygen atom O2 (O8···O2A 306 pm) of a neighboring complex. The latter of these hydrogen bonds is part of a bifurcated interaction between O8 and atoms O2 and O4 (see Figure 2). The hydrogen-bond network is completed by the oxygen atom of the coordinated water molecule, O7, which forms intermolecular contacts with the hydroxy side chain oxygen atom O6 (O6C···O7 271 pm) and with the peroxo oxygen atom O2 (O7···O2A 283 pm) of two different neighboring molecules from opposite enantiomeric chains. The observed hydrogen-bonding interactions are of specific interest due to the presence of the Ser402 residue in the active site of VHPO, in particular, they are of possible relevance to proton transfer reactions.[8]

For VHPO enzymes, a peroxo species has been proposed as an intermediate in the catalytic cycle.[10] Moreover, *cis*-dioxovanadium(V) complexes have been reported as structural and functional models for vanadium haloperoxidases that are capable of catalyzing bromination reactions with hydrogen peroxide in DMF.[25] To probe the haloperoxidase activity of complex **1**, we investigated its ability to catalyze the formation of an oxidizing bromine species. We monitored the formation of the bromo derivatives of 1,3,5-trimethoxybenzene (TMB). TMB is strongly activated towards electrophilic substitution, and can act as a quenching agent. Complex **1** reacts with one equivalent of TMB, in the presence of excess tetra-*n*-butylammonium bromide, and one equivalent of perchloric acid to yield Br-TMB. About 90% of TMB was converted to the corresponding brominated compound in less than 30 min (as monitored by HPLC). It should be noted that in the absence of acid no brominated products could be observed.

Another important reaction catalyzed by VHPO is the oxidation of organic sulfanes to sulfane oxides.[4] Although the mechanism for this reaction is not yet known, it is thought to proceed via a peroxo intermediate. To probe the sulfoxidation reactivity of the reported vanadium(V) oxoperoxo complex, **1** was treated with one equivalent of methylphenylsulfane in a methanol/dichloromethane mixture as solvent. The methylphenylsulfane was oxidized slowly, and about 75% conversion to the corresponding sulfane oxide occurred in about 48 h. It is interesting to note that this is about the same length of time usually observed for a comparable rate of conversion in model systems in which only 1 mol-% of the vanadium catalyst is present.[26] The oxidative capacity of **1** was further tested by investigating its reaction with triphenylphosphane in acetonitrile solution. This reaction was monitored by ^{31}P NMR spectroscopy – the phosphane oxide is readily formed together with the corresponding *cis*-dioxovanadium(V) complex, implying that full conversion of the reactants had occurred.

Conclusions

In this contribution the first example of a vanadium(V) oxoperoxo complex with a hydroxy side chain substituted ligand system is reported. This complex is of interest due to the presence of a serine residue within the active site environment of the prosthetic group. The importance of this residue is exemplified by the vast number of hydrogen-bonding interactions observed, which are involved in pathways relevant to the enzymatic activity. The complex is capable of generating hypobromic acid, which in turn can brominate 1,3,5-trimethoxybenzene as the organic substrate, thus modeling the corresponding enzyme reaction. Moreover, the oxidation of methylphenylsulfane and triphenylphosphane can be preformed by the reported vanadium(V) oxoperoxo complex.

Experimental Section

General Remarks: *N*,*N*-Dimethylformamide was purified and distilled prior to use. All other chemicals and solvents were of analyti-

cal reagent grade and were used as received. The reaction with triphenylphosphane was carried out under argon using standard Schlenk techniques. Perchloric acid was standardized by potentiometric titration with 1 M NaOH solution utilizing a Mettler Toledo DL 50 titrator. ^{1}H, ^{13}C, and ^{51}V NMR spectra were recorded with Bruker AVANCE 200 and 400 MHz spectrometers. The chemical shift values for ^{51}V are reported relative to $VOCl_3$ as external standard. All NMR spectra were recorded at room temperature. Elemental analyses (C, H, N) were carried out with a Leco CHNS-932 elemental analyzer. Mass spectra were measured with a MAT95XL Finnigan instrument utilizing electron spray ionization and observations were made in the negative mode. IR spectra were recorded with a Bruker IFS55/Equinox spectrometer on samples prepared as KBr pellets. Gas chromatography measurements were performed with a SRI 8610 gas chromatograph using a MXT-1 Restek column. HPLC analyses were performed on a Jasco MD-1515 system equipped with a multiwavelength detector and a Spherisorb ODS-2 column.

Preparation of [VO(O$_2$)HSalhyhb(H$_2$O)]·H$_2$O (1·H$_2$O): KVO_3 (0.69 g, 5 mmol) was dissolved in water (20 mL) and H_2O_2 (0.75 mL of a 30% aqueous solution). A solution of H_2Salhyhb (1.11 g, 5 mmol) in methanol (25 mL) was added dropwise to the KVO_3 solution, which had been cooled to 0 °C, while constantly stirring. The pH of the resulting orange-red solution was adjusted to about 2 with perchloric acid. The solution was stirred at 0 °C for an additional 30 min, and during this time an orange solid precipitated. This was filtered off and washed with cold methanol. The filtrate solution was kept at 5 °C in a closed vessel for about one week. Orange crystals grew, and these were filtered off and dried in vacuo. Yield: 1.38 g (3.9 mmol, 77%). $C_{11}H_{17}N_2O_8V$ (**1**·H_2O) (356.21): calcd. C 37.09, H 4.81, N 7.86; found C 37.73, H 4.71, N 8.09. ^{1}H NMR (400 MHz, CD_3OD): δ = 1.96 (tt, J = 6.8 Hz, 2 H, CH_2CH$_2$OH), 2.52 (t, J = 7.6 Hz, 2 H, CH_2CO), 3.67 (t, J = 6.4 Hz, 2 H, CH_2OH), 4.83 (s, H_2O), 6.91–7.01 (m, 2 H, arom. CH), 7.49–7.58 (m, 2 H, arom. CH), 8.56 (s, 1 H, CH=N) ppm. $^{13}C\{^{1}H\}$ NMR (50 MHz, CD_3OD): δ = 29.0 (*C*H$_2$CO), 30.5 (*C*H$_2$CH$_2$OH), 62.4 (*C*H$_2$OH), 117.7, 121.4, 121.5, 133.4, 133.7 (arom. CH), 153.2 (CH=N), 165.1 (arom. C), 179.7 (C=O) ppm. ^{51}V NMR (105 MHz, CD_3OD): δ = –551 ppm ($\Delta\nu_{1/2}$ = 105 Hz). Selected IR data (KBr): $\tilde{\nu}$ = 978 (V=O), 921 (O–O, peroxo), 765 [asym. V(O)$_2$], 562 [sym. V(O)$_2$] cm^{-1}. ESI-MS (negative mode): m/z = 318.9 [M$^-$, – H, – H_2O].

Bromide Oxidation: The oxidative bromination of 1,3,5-trimethoxybenzene (TMB; 25 mg, 0.15 mmol) with complex **1** (54 mg, 0.15 mmol) in the presence of a 10-fold excess of tetrabutylammonium bromide (0.483 g, 1.5 mmol) and one equivalent perchloric acid, was performed in DMF (30 mL, 5 M in TMB). The reaction (i.e. the formation of Br-TMB) was monitored by HPLC with a Sperisorb ODS-2 column; the solvent system used was a H_2O/CH_3OH (50:50) mixture.

Reaction with Methylphenylsulfane: A solution of complex **1** (19 mg, 0.05 mmol) in a dichloromethane/methanol solution (10 mL of a 7:3 solution) reacted with one equivalent of methylphenylsulfane at room temperature. The reaction (i.e. the formation of methylphenylsulfane oxide) was monitored qualitatively by thin-layer chromatography using an eluent mixture of ethyl acetate/chloroform/methanol (5:10:3), and monitored quantitatively by gas chromatography.

Reaction with Triphenylphosphane: Triphenylphosphane (13 mg, 0.05 mmol) was added to a solution of **1** (19 mg, 0.05 mmol) in acetonitrile (15 mL), and the resulting solution was refluxed for 1 h. Upon cooling to room temperature, a yellow precipitate was formed. This was removed by filtration, and the filtrate solution kept at 5 °C. Additional precipitate formed, which resulted in an overall yield of 9.8 mg (0.03 mmol; 64%) of the *cis*-dioxovanadium(V) complex. ^{51}V NMR (105 MHz, [D$_6$]DMSO): δ = –539 ppm. The formation of triphenylphosphane oxide was monitored by ^{31}P NMR spectroscopy.

X-ray Crystallographic Study for 1·H$_2$O: $C_{11}H_{17}N_2O_8V$, M_r = 356.21 g mol^{-1}, monoclinic, space group $P2_1/n$, a = 1034.3(2), b = 698.86(14), c = 2006.6(4) pm, β = 100.74(3), V = 1425.0(5)·10^6 pm^3, Z = 4, μ(Mo-$K\alpha$) = 0.740 mm^{-1}, 14918 reflections measured with a STOE IPDS imaging plate system at 293 K in the 3.09–29.39° θ range, 3887 unique reflections (R_{int} = 0.1472) were used in the data analysis. The structure was solved by direct methods with SHELXS-97 and subsequently refined against F^2 with SHELXL-97.[27] The refinement converged at $R1$ = 0.0454 for 1467 observed reflections with $I > 2\sigma(I)$, and $wR2$ = 0.0807 for all unique reflections. The goodness-of-fit on F^2 was 0.768. The anisotropic displacement parameters for all non-hydrogen atoms were refined. All hydrogen atoms bonded to carbon atoms were introduced at theoretical positions, and were not refined. The hydrogen atoms bonded to nitrogen and oxygen atoms were located in the difference Fourier map and their isotropic displacement parameters were refined, with the exception of the hydrogen atoms of the free water molecule. The isotropic displacement parameters for these hydrogen atoms were fixed to 1.5 times that of the oxygen atom O8. The largest positive and negative residual Fourier peaks after the refinement were equal to 0.29 and –0.44, respectively. CCDC-258615 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Synthesis, Molecular Structure and Reactivity of a Calix[4]arene Monomethyl Ether Supported Nitridomolybdenum Complex

Jürgen Zeller,[a] Susanne Büschel,[a] Benjamin K. H. Reiser,[a] Farida Begum,[b] and Udo Radius[a]*

Keywords: Calixarenes / Density functional calculations / Gallium / Molybdenum / Nitrides

The calix[4]arene monomethyl ether supported nitridomolybdenum complex [MoN(MeCalix)] (**1**) was obtained in high yield from the reaction of [MoN(O*t*Bu)$_3$] and calix[4]arene methyl ether (H_3MeCalix). Contrary to the calix[4]arene dimethyl ether supported dioxomolybdenum complex [MoO_2(*paco*-Me_2Calix)] published earlier, the calix[4]arene ligand in **1** adopts a cone conformation. Complex **1** reacts smoothly with $GaCl_3$ and $GaEt_3$ to yield the compounds [Mo($NGaCl_3$)(MeCalix)] (**2**) and [Mo($NGaEt_3$)(MeCalix)] (**3**), respectively. Complex **2** is the first structurally characterized example of a nitrido-bridged dinuclear compound of a group 6 metal and a group 13 halide (EX_3). The [Mo≡N–$GaCl_3$] unit, in which both metal atoms are unsymmetrically bridged with a short Mo≡N and a long Ga–N contact, shows significant bending at the nitrido bridge. This deviation from a linear alignment is attributed to packing forces.

Introduction

Calix[*n*]arenes are macrocyclic molecules made of *n* phenol units connected by *ortho* methylene groups.[1–3] Calix[4]arenes (*p*-*tert*-butylcalix[4]arene = H_4Calix) are the simplest and most common compounds of this family, with four phenolic residues in the macrocyclic ring. Because of these four phenoxy groups in the calix[4]arenes, reactions with transition metal complexes can produce metal phenolate complexes with substitution of one to four hydrogen atoms.[4] The fully deprotonated form of the parent calix[4]arene acts as a tetraanionic ligand and almost exclusively assumes the cone conformation in metallacalix[4]arenes, which keeps the set of oxygen donor atoms quasi planar. The charge of the O_4 set can be tuned by etherification or esterification of the lower rim of the calix[4]arene. The Me_2-Calix homologues, in particular, have received much attention in organotransition metal chemistry over the last 10 years, and a rich chemistry has emerged comprising mainly mononuclear group 4 and 5 metals. In these complexes, the $[R_2Calix]^{2-}$ ligands usually provide two negatively charged phenolate oxygen donor atoms and two neutral anisole oxygen donors to a transition metal. If the calix[4]arene ethers coordinate in their elliptically distorted cone conformations, these ligands provide a robust and well-defined O_4 coordination environment, similar to other widely used supporting dianionic ligands such as the O_2,N_2-donor ligands of salen-type Schiff bases or N_4-donor ligands such as porphyrins and dibenzotetraaza[14]annulenes.[5–7] In contrast to these nitrogen-containing ligand systems, the calix[4]arene dialkyl ethers are conformationally flexible.

The coordination form of calix[4]arene alkyl ethers is largely determined by the nature of the ether group, the coordination number of the metal, and the nature of the co-ligands. We have shown that the calix[4]arene ligand in the d^0 transition metal complex [$TiCl_2$(Me_2Calix)] (**A**) adopts an elliptically distorted cone conformation, whereas in the related d^0-transition metal complex [MoO_2(*paco*-Me_2-Calix)] (**B**) the metalated calix[4]arene ligand is coordinated in a partially flattened cone conformation, a form reminiscent of the partial cone (*paco*) conformation of calix[4]arene, in the solid state as well as in solution (see Scheme 1).[8] In compound **B**, the [Mo(Me_2Calix)] complex fragment is further stabilized by two additional oxo ligands, which exhibit a strong *trans* influence, and DFT calculations on models of different isomers of **A** and **B** indicate that this phenomenon is mainly driven by the co-ligands employed in these complexes.

Furthermore, in compounds of the type [Ti(O-4-C_6H_4R)$_2$-(Me_2Calix)] (R = Me or *t*Bu; **C**), both types of coordination behavior have been observed.[9] Bis(phenolate) compounds with *para*-substituted phenolate ligands have been isolated in good to excellent yields from reaction of the imidotitanium complex [Ti(N*t*Bu)(Me_2Calix)] and two equivalents of the corresponding phenol to afford complexes in which the calix[4]arene is coordinated in an elliptically distorted cone conformation. These complexes undergo elimination and/or rearrangement reactions in non-

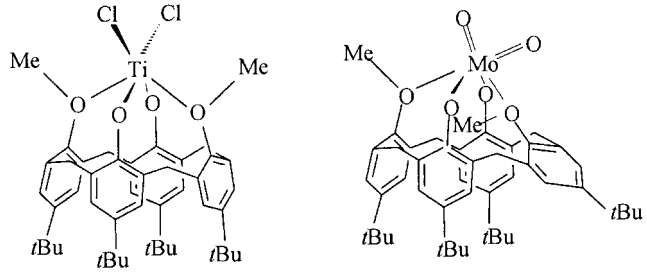


Scheme 1. Coordination of the calix[4]arene ligands in $[TiCl_2(Me_2$-Calix)] (**A**) and $[MoO_2$(*paco*-Me_2Calix)] (**B**).

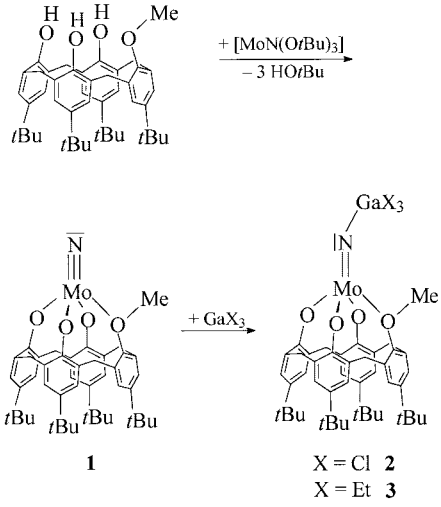
polar solvents such as pentane or hexane. The metal-containing products of the elimination reactions are dinuclear complexes $[\{Ti(O\text{-}4\text{-}C_6H_4R)(MeCalix)\}_2]$ and the products of the rearrangement reactions are $[Ti(O\text{-}4\text{-}C_6H_4R)_2$(*paco*-$Me_2$Calix)]. In these compounds, one of the methoxy groups is located inside the cavity of the calix[4]arene ligand. DFT calculations on model compounds $[Ti(OC_6H_5)_2$(*cone*-Me_2Calix)] and $[Ti(OC_6H_5)_2$(*paco*-Me_2Calix)] reveal a slight thermodynamic preference for the *paco* isomer. Furthermore, *paco* coordination has only been observed in complexes of the calix[4]arene dimethyl ether in distorted octahedrally coordinated compounds of the type $[MX_2(Me_2$-Calix)].

In titanium complexes of the type [TiX(MeCalix)] (X = Cl, OR, SR, NR_2)[10] the calix[4]arene ligand adopts an elliptically distorted cone conformation in which the Ti–O distances to the anisole oxygen atoms vary in the solid-state structures in a range between 234.2 and 243.8 pm.[11] MP2 calculations on model complexes have revealed that this titanium–anisole oxygen bond is relatively weak, and, particularly in the region between 230 and 280 pm, the potential energy surface is very shallow. Thus, the MeCalix ligand acts in these complexes as a tris(phenolate) ligand with a hemilabile anisole group. Despite the labile anisole ether–titanium bond, isomerization reactions of the calix[4]arene ligand leading to a *paco* coordination have never been observed in these complexes and MP2 calculations have revealed a considerable thermodynamic preference for the cone isomers.

At this point we were interested in extending our studies to calix[4]arene monomethyl ether stabilized complexes of the type [MoX(MeCalix)] (X = ligand with *trans* directing properties), and we wish to report here our first results on the synthesis and molecular structure of the nitridomolybdenum complex [MoN(MeCalix)] and its reaction with Lewis acids of the type GaX_3 (X = Cl, Et).

Results and Discussion

Most of the calix[4]arene-stabilized molybdenum complexes known so far are compounds of the parent *p-tert*-butylcalix[4]arene.[11,12] For calix[4]arene ethers there are, to the best of our knowledge, three complexes available in the literature, $[MoOCl_2(R_2Calix)]$ (R = Me, Et) synthesized by Young et al. starting from $[MoOCl_4]$ and calix[4]arene dialkyl ether,[12j] and a dinuclear complex $[Mo_2(MeCalix)_2]$, prepared in Chisholm's group, in which the metal–metal triple bond is supported by calix[4]arene methyl ethers.[12g] This complex was synthesized by amine or butanol elimination starting from $[Mo_2(NMe_2)_6]$ or $[Mo_2(OtBu)_6]$, respectively, and the calix[4]arene ether. For the preparation of [MoN(MeCalix)] (**1**) we decided to follow a similar strategy and treated $[MoN(OtBu)_3]$[13] with H_3MeCalix in toluene (Scheme 2).



Scheme 2. Synthesis of [MoN(MeCalix)] (**1**) and reaction of **1** with $GaCl_3$ and $GaEt_3$.

This reaction proceeds cleanly with elimination of *tert*-butyl alcohol to afford the calix[4]arene ether-stabilized, neutral nitridomolybdenum(VI) complex **1** in excellent yield. Contrary to the calix[4]arene oxomolybdenum(VI) compound $[MoO(Calix)(H_2O)(PhNO_2)(H_4Calix)]$ reported by Floriani et al.,[12a] the nitrido compound is readily soluble in most organic solvents such as benzene or toluene. Compound **1** is stable with respect to either isomerization of the calix[4]arene ligand or rearrangement to a calix[4]arene-stabilized imidomolybdenum complex [Mo(NMe)(Calix)]. Analytical and spectroscopic data are in accordance with monomeric molecular units in solution as well as in the solid state, in which the calix[4]arene binds in a distorted cone conformation to the molybdenum atom. The ^1H NMR spectrum of **1** reveals a signal pattern typically found for those ligand systems in C_s symmetrical complexes, with three resonances for the *tert*-butyl protons at δ = 0.71, 0.79, and 1.37 ppm in the ratio 1:1:2 and four doublets between δ = 3.10 and 4.71 ppm with coupling constants of 12.4 Hz and 12.7 Hz. Most significantly, the methoxide resonance is detected as a sharp singlet at δ = 4.25 ppm and is not shifted to lower field as usually observed for endohedrally located anisole methyl groups, which are typically found at approximately δ = 0.8 ppm. In the IR spectrum of the complex, an intense absorption is detected in the region of the [Mo≡N] stretch at 1045 cm^{-1}.

Crystals of **1** suitable for X-ray diffraction were obtained by cooling saturated diethyl ether solutions to –40 °C. The molecular structure of **1** is shown in Figure 1; selected bond lengths and bond angles are given in the figure caption. The structural analysis confirms the proposed mononuclear nature of **1** in the solid state and the cone conformation of the calix[4]arene ligand. In contrast to many solid-state structures of nitrido complexes, in which molecules aggregate through Mo–N···Mo contacts, we observe no intermolecular molybdenum–nitrogen interactions here. The coordination polyhedron at the molybdenum atom is best described as a square pyramid with the calixarene oxygen atoms O(1) to O(4) in the basal plane and the nitrogen atom occupying the apex. The molybdenum atom is displaced out of the calixarene O_4 plane towards the nitrogen atom of the complex, which is indicated by the N–Mo–O angles in a range between 92.4(2)° and 102.7(2)°. The Mo–O distances to the phenoxide entities [191.4(4) pm to 192.5(4) pm] and to the anisole unit [226.3(4) pm] of the calix[4]arene ligand are unexceptional. The Mo–N distance of 163.9(5) pm in **1** is significantly (approximately 8 pm) shorter than Mo–N bonds observed in calix[4]arene imidomolybdenum(VI) complexes[12b,12d] but similar to those found in other mononuclear nitridomolybdenum(VI) complexes such as $[MoN(NtBuPh)_3]$ [165.8(5) pm],[14a] $[MoN(NPh_2)_3]$ [163.4(3) pm],[14b] $[MoN(OtBu)_3]$ [166.1(4) and 167.3(5) pm],[13] $[MoN(Mes)_3]$ [164.9(4) pm],[14c] and $(Ph_4P)[MoNX_4]$ (X = Cl, Br) [163.7(4) and 162.8(15) pm].[14e,f]

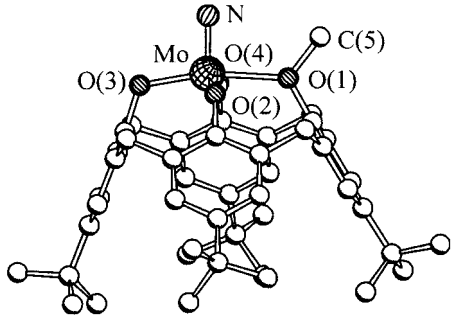

Figure 1. Schakal plot of the molecular structure of the [MoN(MeCalix)] (**1**) unit in **1**·1.5 Et_2O. H atoms and solvent molecules have been omitted for clarity. Selected bond lengths [pm] and angles [°]: Mo–N 163.9(5), Mo–O(1) 226.3(4), Mo–O(2) 191.4(4), Mo–O(3) 192.5(4), Mo–O(4) 192.0(4); N–Mo–O(1) 92.4(2), N–Mo–O(2) 102.8(2), N–Mo–O(3) 100.7(2), N–Mo–O(4) 102.7(2), O(1)–Mo–O(2) 81.29(16), O(1)–Mo–O(3) 166.92(14), O(1)–Mo–O(4) 81.41(15), O(2)–Mo–O(3) 96.21(18), O(2)–Mo–O(4) 149.62(16), O(3)–Mo–O(4) 95.03(17), Mo–O(1)–C(10) 121.7(3), Mo–O(1)–C(5) 124.5(3), Mo–O(2)–C(20) 137.4(4), Mo–O(3)–C(30) 117.6(3), Mo–O(4)–C(40) 138.1(3).

Transition metal nitrido complexes with a terminal nitrido ligand usually show Lewis basic behavior and can thus form nitrido bridges to Lewis acidic species. Compounds that contain a transition metal–nitrogen–main group element linkage have been proven to be a versatile class of compounds that exhibit vastly different chemical behavior depending on the nature of the transition metal and the main group element.[15] The structure of the compounds can range from species that have a linear transition metal–nitrogen–main group element moiety up to molecules where the nitrido linkage is strongly bent. Some compounds are monomeric while others are oligomeric or polymeric. Because of their rich chemistry, nitrido complexes have been the subject of experimental as well as theoretical studies. Whereas the formation and the chemistry of complexes with an $[Re{\equiv}N–EX_3]$ (E = group 13 element) linkage has been rather thoroughly investigated, mainly by the groups of Strähle and Abram,[16] there are few known examples of similar complexes of group 6 metals. With the exception of the complex [*trans*-$Mo(N–BPh_3)(OTf)$(*anti*-Me_8[16]aneS_4)] (Me_8[16]aneS_4 = 3,3,7,7,11,11,15,15-octamethyl-1,5,9,13-tetrathiacyclohexadecane, OTf = SO_3CF_3) published by Yoshida et al.,[17] this type of compound is, to the best of our knowledge, unknown in group 6 chemistry. Therefore we were interested in the adduct formation of complex **1** with group 13 tris(halide) and tris(alkyl) compounds. Calculations published by Frenking and coworkers[18] on model complexes of the type $[Re({\equiv}N–EX_3)(PH_3)_3Cl_2]$ have shown that in the series EH_3 (E = B, Al, Ga) the $[Re{\equiv}N–GaH_3]$ linkage is particularly weakly bonded. The zero-point-corrected dissociation energies at the MP2 level given in this paper are, for the trihydrides, 29.3 kcal mol^{-1} for E = B, 25.3 kcal mol^{-1} for E = Al, and 17.0 kcal mol^{-1} for E = Ga, and in the case of the trichlorides 31.2 kcal mol^{-1} for E = B, 42.6 kcal mol^{-1} for E = Al, and 33.5 kcal mol^{-1} for E = Ga. Because of the lack of known ER_3 and EX_3 adducts of nitridomolybdenum compounds, and the presumably weak interaction with gallium Lewis acids, we decided

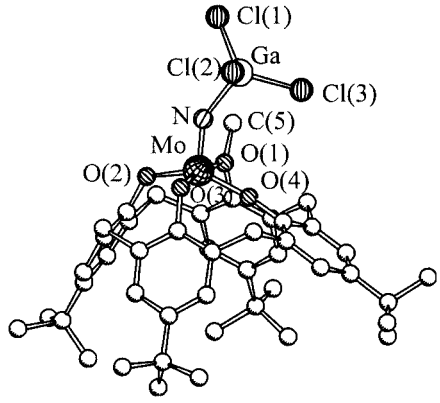

Figure 2. Schakal plot of the molecular structure of the [Mo(N-$GaCl_3$)(MeCalix)] (**2**) unit in **2**·3 C_7H_8. H atoms and solvent molecules have been omitted for clarity. Selected bond lengths [pm] and angles [°]: Mo–N 168.0(5), Mo–O(1) 223.5(4), Mo–O(2) 187.9(4), Mo–O(3) 191.6(3), Mo–O(4) 182.9(4), Ga–N 196.0(5), Ga–Cl(1) 214.1(2), Ga–Cl(2) 213.2(2), Ga–Cl(3) 218.3(3), C(5)–O(1) 146.0(7); Mo–N–Ga 147.2(3), N–Ga–Cl(1) 107.60(14), N–Ga–Cl(2) 104.27(16), N–Ga–Cl(3) 104.11(19), N–Mo–O(1) 91.3(2), N–Mo–O(2) 104.9(2), N–Mo–O(4) 111.2(3), N–Mo–O(3) 98.4(2), O(1)–Mo–O(2) 84.98(15), O(1)–Mo–O(3) 168.97(14), O(1)–Mo–O(4) 79.77(16), O(2)–Mo–O(3) 97.55(16), O(2)–Mo–O(4) 140.9(2), O(3)–Mo–O(4) 91.72(16), Cl(1)–Ga–Cl(2) 113.50(10), Cl(2)–Ga–Cl(3) 115.44(13), Cl(1)–Ga–Cl(3) 110.93(10), Mo–O(1)–C(10) 118.9(3), Mo–O(1)–C(5) 127.5(4), Mo–O(2)–C(20) 130.2(3), Mo–O(3)–C(30) 117.2(3), Mo–O(4)–C(40) 170.7(4).

to investigate adduct formation of **1** with alkylgallium compounds and gallium halides.

Surprisingly, complex **1** reacts swiftly with $GaCl_3$ and $GaEt_3$ (see Scheme 2). According to NMR investigations, these compounds form the adducts [Mo(N$GaCl_3$)(MeCalix)] (**2**) and [Mo(N$GaEt_3$)(MeCalix)] (**3**) quantitatively without decomposition of the starting material. In the reaction products, the [Mo≡N] stretch does not change very much after coordination of the GaX_3 moieties: we observe these stretching frequencies in the IR spectra at 1046 cm^{-1} (**2**) and 1055 cm^{-1} (**3**). In the NMR spectra of these complexes, the resonances of the calix[4]arene ligands are slightly shifted compared to the resonances found for **1**. In the case of complex **3** the proton and carbon resonances of the $GaEt_3$ group are significantly shifted with respect to the noncoordinated molecule. By way of an example, in the ^1H NMR spectrum they are shifted from δ = 0.56 and 1.28 ppm to δ = 1.02 and 1.74 ppm. To confirm the adduct formation beyond doubt single crystals of the chloride complex **2** were grown from saturated toluene solutions at –40 °C and an X-ray diffraction study was undertaken. The molecular structure of **2** is shown in Figure selected bond lengths and bond angles are given in the figure caption.

Complex **2** crystallizes in the monoclinic space group $P2_1/c$ with three additional toluene molecules in the asymmetric unit. One of these solvent molecules is located inside the calix[4]arene cavity, whereas the others occupy general positions in the lattice. The endohedrally bound toluene molecule does not interact with the metal atom. The molecular structure confirms the composition of **2** as the $GaCl_3$ adduct of [MoN(MeCalix)] (**1**), in which the gallium atom is mounted on the nitrido nitrogen atom of **1**. Although various complexes of group 6 metal nitrido complexes with homoatomic and heteroatomic nitrido bridges [M≡N–M′] to other transition metal complex fragments are known,[19,20] complex **2** is the first structurally characterized example of a dinuclear compound of a group 6 metal complex and a group 13 halide EX_3 (E = B, Al, Ga, In; X = F, Cl, Br) with a central [M≡N–EX_3] nitrido bridge. This nitrido bridge is asymmetric; the molecular structure reveals a short Mo–N bond and a long Ga–N contact. The Mo–N distance of 168.0(5) pm in **2** is approximately 4 pm longer than the Mo–N bond observed in **1**. The Ga–N distance of 196.0(5) pm is similar to other Ga–N distances found in adducts of $GaCl_3$ with nitridorhenium complexes such as [Re(N$GaCl_3$)Cl_2(PMe_2Ph)$_3$] [197(1) pm], [Re(N$GaCl_3$)-Cl(PMe_2Ph)$_3$(NCMe)]$^+$[$GaCl_4$]$^-$ [195.9(4) pm], [Re(N$GaCl_3$)(PMe_2Ph)(Et_2dtc)] [191.6(6) pm; Et_2dtc = diethyldithiocarbamato], or [Re(N$GaCl_3$)Cl(PMe_2Ph)(H_2Et_2tcb)]$^+$-[$GaCl_4$]$^-$ [194.5(3) pm; Et_2tcb = *N*,*N*-diethylcarbamoylbenzamidate].[16b,21] The [Mo–N–Ga] linkage is significantly bent towards O(4) with an angle of 147.2(3)° at the nitrogen atom. The best planes defined by Mo, N, Ga and N, Mo, O(4) intersect each other with an angle of 5.8(6)°. This deviation from linearity is presumably due to packing forces in the lattice, since the distance of one of the chlorine atoms [Cl(1)] to the *tert*-butyl and ring *meta* carbon atoms of the phenolate entities at O(3) and O(4) of the next molecule in the lattice is slightly below 400 pm and would get even closer for an almost linear coordination. Furthermore, the coordination of $GaCl_3$ to [MoN(MeCalix)] (**1**) is accompanied by a distortion of the first coordination sphere at the molybdenum atom. The electron density at the molybdenum atom in **2** is lower than that in complex **1** due to the electron-withdrawing properties of the $GaCl_3$ moiety in the molecule. This is reflected by the shorter Mo–O contacts observed for complex **2** in general. Most significantly, the Mo–O(4) bond length is reduced from 192.0(4) pm in **1** to 182.9(4) pm in **2**, and this phenolate unit of the calixarene ligand coordinates almost linearly to the molybdenum atom [Mo–O(4)–C(40): 170.7(4)°].

The model complex [Mo(N$GaCl_3$)(MeCalix^H)] $\mathbf{2^H}$, in which the *tert*-butyl groups of the calix[4]arene have been replaced by hydrogen atoms to reduce computational effort, optimizes in DFT calculations[22] with a structure with slightly longer Mo–N and Ga–N distances of 169.74 pm (Mo–N) and Ga–N 202.12 pm (Ga–N) compared to the molecular structure of **2**. The calculated Mo–N–Ga angle of 169.74°, however, is closer to linearity than the angle observed in the molecular structure. The distortion of the calix[4]arene ligand in the coordination sphere of the molybdenum atom is also well reproduced in the computations. The zero-point-corrected dissociation energies calculated at the level employed here for the gallium–nitrogen bond in $\mathbf{2^H}$ is 25.8 kcal mol^{-1} and therefore slightly smaller than the dissociation energies computed by Frenking and coworkers for the nitridorhenium system mentioned above (33.5 kcal mol^{-1}) and similar to the dissociation energy calculated for [Cl_3W≡N–$AlCl_3$] (22.06 kcal mol^{-1}) by the same group.[23]

Conclusions

We have shown that [MoN(MeCalix)] (**1**) can be synthesized in high yield in an alcohol elimination reaction starting from [MoN(O*t*Bu)$_3$] and the calix[4]arene H_3MeCalix. Contrary to the dioxomolybdenum complex [MoO_2(*paco*-Me_2Calix)] (**B**) the calixarene ligand in **1** is coordinated in the cone conformation. Complex **1** is stable with respect to either isomerization of the calix[4]arene ligand or rearrangement to a calix[4]arene-stabilized imidomolybdenum complex. The calix[4]arene ether ligand provides enough electron density to the [Mo≡N] moiety in **1** that reactions with $GaCl_3$ and $GaEt_3$ proceed smoothly and afford the complexes [Mo(N$GaCl_3$)(MeCalix)] (**2**) and [Mo(N$GaEt_3$)(MeCalix)] (**3**). Complex **2** is the first structurally characterized nitrido-bridged compound of a group 6 metal complex and a group 13 metal halide [EX_3]. The [M≡N–EX_3] linkage is significantly bent at the nitrido nitrogen atom, which is attributed to packing forces.

Experimental Section

General Remarks: All air/moisture-sensitive manipulations were performed using standard Schlenk-line (N_2) and dry-box (Ar) tech-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

niques. Solvents were pre-dried and refluxed over sodium, potassium, or sodium-potassium alloy (1:3 w/w; benzene, toluene, pentane, hexane, diethyl ether, THF), or P_2O_5 (acetonitrile, dichloromethane) under N_2. Solvents were distilled at atmospheric pressure prior to use. Deuterated solvents were dried with sodium. $GaEt_3$ was obtained from commercial sources and distilled prior to use.

^1H and $^{13}C\{^1H\}$ NMR spectra were recorded on a Bruker AC 250 spectrometer at 298 K. Spectra are referenced internally to residual protonated solvent resonances (^1H; C_6D_6: δ = 7.15 ppm) or solvent (^{13}C; C_6D_6: δ = 128.0 ppm) and are reported relative to tetramethylsilane (δ = 0.00 ppm). Chemical shifts are quoted in δ (ppm) and coupling constants in Hertz. Standard DEPT-135 experiments were recorded to distinguish CH_3- and CH-type carbon atoms from C- or CH_2-type carbon atoms in the ^{13}C NMR spectrum. IR spectra were recorded on a Bruker IFS28 spectrometer as KBr pellets. All data are quoted in wavenumbers (cm^{-1}). Mass spectra were recorded on a Finnigan MAT 900 XLT. All data are quoted as their mass/charge (*m*/*z*) ratios. Elemental analyses were carried out by the analytical laboratory of the Institute of Inorganic Chemistry of the University Karlsruhe (TH). [Mo(N)(O*t*Bu)$_3$][13] and H_3MeCalix[24] were synthesized according to literature procedures.

[MoN(MeCalix)] (1): Toluene (50 mL) was added to a mixture of H_3MeCalix (15.00 g, 22.6 mmol) and [MoN(O*t*Bu)$_3$] (7.44 g, 22.6 mmol). The initially orange-colored solution turned red after a short time and the resulting reaction mixture was stirred for three hours and then filtered through a pad of Celite. The filtrate was evaporated to dryness to afford [MoN(MeCalix)] (**1**) as an orange-red powder. Yield: 16.50 g (21.5 mmol, 95%). Crystals suitable for X-ray diffraction were obtained either from hot saturated toluene solutions or from saturated diethyl ether solutions at –40 °C. $C_{45}H_{55}MoNO_4$ (769.9): calcd. C 70.21, H 7.20, N 1.82; found C 70.48, H 7.30, N 1.84. EI/MS: *m*/*z* (%) = 769 (27) $[M]^+$. IR (KBr): $\tilde{\nu}$ = 1045 cm^{-1} (vs) ν(Mo≡N). ^1H NMR (C_6D_6): δ = 0.71 [s, 9 H, C(CH_3)$_3$], 0.79 [s, 9 H, C(CH_3)$_3$], 1.37 [s, 18 H, C(CH_3)$_3$], 3.10 (d, $^2J_{H,H}$ = 12.7 Hz, 2 H, CH_2), 3.16 (d, $^2J_{H,H}$ = 12.4 Hz, 2 H, CH_2), 4.25 (s, 3 H, OCH_3), 4.35 (d, $^2J_{H,H}$ = 12.4 Hz, 2 H, CH_2), 4.70 (d, $^2J_{H,H}$ = 12.7 Hz, 2 H, CH_2), 6.81 (s, 2 H, Aryl-H_m), 6.88 (s, 2 H, Aryl-H_m), 7.19 (s, 4 H, Aryl-H_m) ppm. $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 30.5, 30.9, 31.9 [C(*C*H$_3$)$_3$], 32.8, 33.4 (*C*H$_2$), 33.7, 33.9, 34.3 [*C*(CH$_3$)$_3$], 76.2 (O*C*H$_3$), 124.4, 125.9, 126.0, 127.0 (Aryl-C_m), 129.5, 129.6, 131.1, 134.7 (Aryl-C_o), 144.7, 146.2, 150.8 (Aryl-C_p), 149.4, 151.6, 156.1 (Aryl-C_i) ppm.

[Mo(NGaCl$_3$)(MeCalix)] (2): [MoN(MeCalix)] (**1**; 0.77 g, 0.99 mmol) was dissolved in toluene (20 mL) and a solution of $GaCl_3$ (0.18 g, 1.01 mmol) in toluene (10 mL) was slowly added at room temperature. The resulting reaction mixture was stirred overnight at room temperature, filtered through a pad of Celite, and the volatile components of the filtrate were removed in vacuo. The resulting solid was suspended in hexane and filtered off to afford **2** as a brown powder Yield: 0.72 mg (0.76 mmol, 77%). Crystals suitable for X-ray diffraction were obtained from saturated toluene solutions at –40 °C. $C_{45}H_{55}Cl_3GaMoNO_4$ (946.0): calcd. C 57.74, H 5.86, N 1.48; found C 58.19, H 5.60, N 1.42. IR (KBr): $\tilde{\nu}$ = 1046 cm^{-1} (vs) ν(Mo≡N). ^1H NMR (C_6D_6): δ = 0.63 [s, 9 H, C(CH_3)$_3$], 0.72 [s, 9 H, C(CH_3)$_3$], 1.33 [s, 18 H, C(CH_3)$_3$], 2.97 (d, $^2J_{H,H}$ = 13.3 Hz, 2 H, CH_2), 3.08 (d, $^2J_{H,H}$ = 12.9 Hz, 2 H, CH_2), 4.07 (d, $^2J_{H,H}$ = 12.9 Hz, 2 H, CH_2), 4.26 (s, 3 H, OCH_3), 4.29 (d, $^2J_{H,H}$ = 13.3 Hz, 2 H, CH_2), 6.72 (s, 2 H, Aryl-H_m), 6.75 (s, 2 H, Aryl-H_m), 7.13 (s, 2 H, Aryl-H_m), 7.14 (s, 2 H, Aryl-H_m) ppm. $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 30.4, 30.7, 31.9 [C(*C*H$_3$)$_3$], 32.6, 33.1 (*C*H$_2$), 33.8, 33.9, 34.6 [*C*(CH$_3$)$_3$], 76.1 (O*C*H$_3$), 125.7, 125.0, 126.0, 126.6 (Aryl-C_m), 129.7, 129.9, 131.9, 133.0 (Aryl-C_o), 149.3, 149.0, 151.0 (Aryl-C_p), 149.1, 151.6, 155.9 (Aryl-C_i) ppm.

[Mo(NGaEt$_3$)(MeCalix)] (3): [MoN(MeCalix)] (**1**; 0.40 g, 0.52 mmol) was dissolved in toluene (20 mL) and a solution of $GaEt_3$ (0.08 g, 0.52 mmol) in toluene (10 mL) was slowly added at room temperature and stirred for an hour. The volatile components of the reaction mixture were removed in vacuo to afford **3** as an orange-brown powder. Yield: 0.48 g (0.51 mmol, 98%). $C_{51}H_{70}GaMoNO_4$ (926.8): calcd. C 66.10, H 7.61, N 1.51; found C 65.98, H 7.39, N 1.41. IR (KBr): $\tilde{\nu}$ = 1055 cm^{-1} (vs) ν(Mo≡N). ^1H NMR (C_6D_6): δ = 0.67 [s, 9 H, C(CH$_3$)$_3$], 0.75 [s, 9 H, C(CH$_3$)$_3$], 1.08 (q, $^3J_{HH}$ = 8.0 Hz, 6 H, GaCH_2R), 1.36 [s, 18 H, C(CH$_3$)$_3$], 1.74 (t, $^3J_{HH}$ = 8.0 Hz, 9 H, GaCH$_2$CH_3), 3.05 (d, $^2J_{H,H}$ = 12.9 Hz, 2 H, CH$_2$), 3.11 (d, $^2J_{H,H}$ = 12.7 Hz, 2 H, CH$_2$), 4.24 (d, $^2J_{H,H}$ = 12.5 Hz, 2 H, CH$_2$), 4.32 (s, 3 H, OCH$_3$), 4.59 (d, $^2J_{H,H}$ = 12.8 Hz, 2 H, CH$_2$), 6.77 (s, 2 H, Aryl-H_m), 6.82 (s, 2 H, Aryl-H_m), 7.15 (s, 4 H, Aryl-H_m) ppm. $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 7.2 (Ga*C*H$_2$CH$_3$), 11.7 (GaCH$_2$*C*H$_3$), 30.5, 30.8, 31.9 [C(*C*H$_3$)$_3$], 32.7, 33.4 (*C*H$_2$), 33.7, 33.9, 34.3 [*C*(CH$_3$)$_3$], 76.0 (O*C*H$_3$), 124.5, 125.9, 126.1, 127.2 (Aryl-C_m), 129.4, 129.5, 130.9, 134.4 (Aryl-C_o), 145.3, 146.8, 149.1 (Aryl-C_p), 150.9, 151.0., 155.8 (Aryl-C_i) ppm.

X-ray Crystallographic Study of [MoN(MeCalix)]·1.5 Et$_2$O and [Mo(NGaCl$_3$)(MeCalix)]·3 C$_7$H$_8$: Crystal data collection and processing parameters are given in Table 1. The crystals were immersed in a film of perfluoropolyether oil on a glass fiber and transferred to a Stoe-STADI 4 (**1**·1.5 Et_2O, Mo-K_α radiation) or Stoe IPDS I diffractometer (**2**·3 C_7H_8, Ag-K_α radiation) equipped with an FTS AirJet low-temperature device. Data were collected at 203 K. The IPDS images were processed with the Stoe IPDS software package and equivalent reflections were merged. Corrections for Lorentz-polarization effects and absorption were performed if necessary and the structures were solved by direct methods. Subsequent difference Fourier syntheses revealed the positions of all other non-hydrogen atoms; hydrogen atoms were included in calculated positions. Extinction corrections were applied as required. Crystallographic calculations were performed with SHELXS-97 and SHELXL-97.[25] For compound **2**·3 C_7H_8 the methyl carbon atoms of two *tert*-butyl groups of the calixarene ligand [C(27) to C(29)] and [C(47) to C(49)] were disordered over two sites and were isotropically refined with occupancy factors of 70 and 30%. The visualization of the molecular structures was performed with the program Schakal 99.[26]

CCDC-256140 (for **1**·1.5 Et_2O) and CCDC-256141 (for **2**·3 C_7H_8) contain the supplementary crystallographic data for this paper.

Table 1. X-ray data collection and processing parameters.

	1·1.5 Et_2O	**2**·3 C_7H_8
Formula	$C_{51}H_{70}MoNO_{5.50}$	$C_{66}H_{79}Cl_3GaMoNO_4$
Formula mass	881.02	1222.31
Crystal system	monoclinic	monoclinic
Space group	*I*2/*a*	$P2_1/c$

[22] The DFT calculations were carried out with the TURBOMOLE set of programs within the RI-J approximation. Standard SV(P) basis sets and auxiliary basis sets as implemented in the TURBOMOLE package were used for all atoms. Quasi-relativistic pseudo-potentials were used for Mo. All calculations were performed including gradient corrections, Becke's nonlocal correction for exchange, and Perdew's nonlocal correction for correlation to the local density approximation part of the density functional: a) M. Mono- and Dinuclear Cu^{II} and Zn^{II} Complexes of Cyclen-Based Bis(macrocycles) Containing Two Aminoalkyl Pendant Arms of Different Lengths

Carmen Anda,[a] Andrea Bencini,[b] Emanuela Berni,[b] Samuele Ciattini,[b] Françoise Chuburu,[c] Andrea Danesi,[b] Claudia Giorgi*[b] Henri Handel*[c] Michel Le Baccon,[c] Piero Paoletti*[b] Raphaël Tripier,[c] Véronique Turcry,[c] and Barbara Valtancoli[b]

Keywords: Copper / Coordination modes / Macrocyclic ligands / N ligands / Zinc

The basicity and coordination properties towards Cu^{II} and Zn^{II} of the bis(macrocycles) **L1**, **L2** and **L3** have been investigated by means of potentiometric, ^1H NMR and UV/Vis spectroscopic titrations in aqueous solutions. The synthesis of **L1** and **L3** is also described. The three ligands are composed of two [12]aneN$_4$ units separated by a *p*-phenylene spacer and differ in the length of the aminoalkyl pendant arms linked to each macrocyclic unit. **L1**–**L3** form mono- and dinuclear complexes in aqueous solutions; in the dinuclear species each metal ion is coordinated by one of the two identical [12]aneN$_4$ ligand moieties, as shown by the crystal structures of the complexes $[Cu_2\mathbf{L1}]Cl_4\cdot 8H_2O$, $[Zn_2\mathbf{L2}](ClO_4)_4$ and $[Zn_2\mathbf{L3}](ClO_4)_4\cdot H_2O$. In all structures the metal ion is pentacoordinate, and is bound to the four nitrogen donors of the cyclic unit and to the amine group of the side arm. The stability of both the $[ML]^{2+}$ and $[M_2L]^{4+}$ complexes in aqueous solution decreases in the order **L1** > **L2** > **L3**. At the same time, both the $[Cu_2L]^{4+}$ and $[Zn_2L]^{4+}$ complexes show a different ability in proton binding among the three ligands, with the $[M_2\mathbf{L1}]^{4+}$ complexes displaying the highest basicity. These results are explained in terms of the decreasing number of nitrogen donors involved in Cu^{II} or Zn^{II} binding on passing from **L1** to **L3**; in other words, while in the **L1** dinuclear complexes each metal ion is coordinated to the four amine groups of a [12]aneN$_4$ moiety and to the amine group of the side arm, in the **L3** ones the metal cations are bound only to the four donor atoms of a cyclic moiety, the aminobutyl group not being coordinated.

Introduction

There is a continuing interest in the chemistry of polyazamacrocycles because of their ability to form chelates in aqueous solutions and to act as selective complexing agents for metal cations. Structural factors, such as ligand rigidity and the electron-donor properties of the nitrogen atoms and their disposition, have been shown to play significant roles in determining the binding features of macrocycles toward metal cations.[1–17]

Among polyazamacrocycles, the investigations have been focused on tetraazamacrocycles owing to their proven ability in binding biologically relevant metal ions. For example, cyclen and cyclam and their derivatives have been studied as carriers of metal ions in antitumour and imaging applications.[18–22] Furthermore, metal complexes with these polyazamacrocyclic ligands can behave as metallo-receptors for organic and inorganic anions (similar to thymidine mono- and diphosphate nucleotides).[23,24]

From this point of view the introduction of structural features that impart high selectivity in the recognition of different guests into the molecular framework is one of the goals in the design of synthetic receptors. Aromatic subunits are often introduced into the host molecules. The presence of rigid aromatic systems gives particular coordination properties to the ligands defining distinct preorganized binding sites for the metal ions within the ligand itself. Furthermore, the attachment of an aminoalkyl side arm can strongly effect the coordination properties of the ligand,[25–48] depending on the nature of the donors of the pendant arms.

To gain further insight into the coordination chemistry of cyclen derivatives, we have now synthesised the two homoditopic ligands **L1** and **L3**, which are composed of two [12]aneN$_4$ units separated by a rigid *p*-phenylene spacer; each tetraazamacrocyclic moiety bears an aminoalkyl pendant arm (an aminoethyl pendant arm in the case of **L1** and an aminobutyl one in the case of **L3**).

With the aim of making a comparative study of the coordination properties of these homoditopic ligands, the proton binding and Cu^{II} and Zn^{II} complexation with **L1**, **L3** and **L2**,[49] which displays a similar molecular architecture but contains two aminopropyl side arms, were studied in the solid state by X-ray diffraction methods and in aqueous solution by potentiometric and ^1H NMR measurements.

Results and Discussion

Ligand Protonation

The protonation equilibria of **L1**–**L3** were studied by means of potentiometric measurements in 0.1 M Me_4NCl aqueous solution at 298.1 K; the corresponding basicity constants are reported in Table 1.

Table 1. Logarithms of the protonation constants of ligands **L1**, **L2** and **L3** determined by means of potentiometric measurements in 0.1 M Me_4NCl at 298.1 K.

Reaction	log*K*		
	L1	**L2**	**L3**
$LH^+ + H^+ \rightleftharpoons LH_2^{2+}$	9.74(3)[a]	10.07(2)	10.30(2)
$LH_2^{2+} + H^+ \rightleftharpoons LH_3^{3+}$	8.88(5)	9.24(3)	9.54(3)
$LH_3^{3+} + H^+ \rightleftharpoons LH_4^{4+}$	8.39(4)	8.87(2)	9.08(2)
$LH_4^{4+} + H^+ \rightleftharpoons LH_5^{5+}$	7.33(6)	7.69(3)	7.80(4)
$LH_5^{5+} + H^+ \rightleftharpoons LH_6^{6+}$	6.67(6)	7.22(3)	7.40(3)

[a] Values in parentheses are standard deviations in the last significant figure.

Ligands **L1**–**L3** behave as hexaprotic bases, at least in the pH range investigated (2–11). **L1**–**L3** display almost equal basicity constants for the first protonation step (10.07–10.34 log units). Similar high values for the first protonation constant are often found in polyamine macrocycles and are generally attributed to the simultaneous involvement of two or more amine groups in proton binding.[50] The data in Table 1 also show that the first six basicity constants range between about 10 and 7 log units. Further protonation steps are not detectable by potentiometry under our experimental conditions. This behaviour can be rationalised in terms of minimisation of the electrostatic repulsion between the positive charges in the protonated species of polyazamacrocycles. In other words, the first six protons can occupy alternate positions in the macrocycles, separated by a non-protonated amine group and/or by the *p*-phenylene linkage, while three or more protonated nitrogen atoms would necessarily be contiguous in the species with a protonation degree greater than six. For this reason, the $[H_xL]^{x+}$ species with $x > 6$ (L = **L1**, **L2** and **L3**) are not formed, at least in the pH range investigated (2–11).

To shed further light on the basicity properties of these ligands, we carried out ^1H NMR titrations in aqueous solutions. The spectral features of **L1** at pH = 11.0, where the free amine predominates in solution, account for a D_{2h} time-averaged symmetry of the ligand, which is preserved over all the pH range investigated. The pH dependence of the ^1H NMR signals is shown in Figure 1, together with the distribution diagram of the protonated species of **L1**.

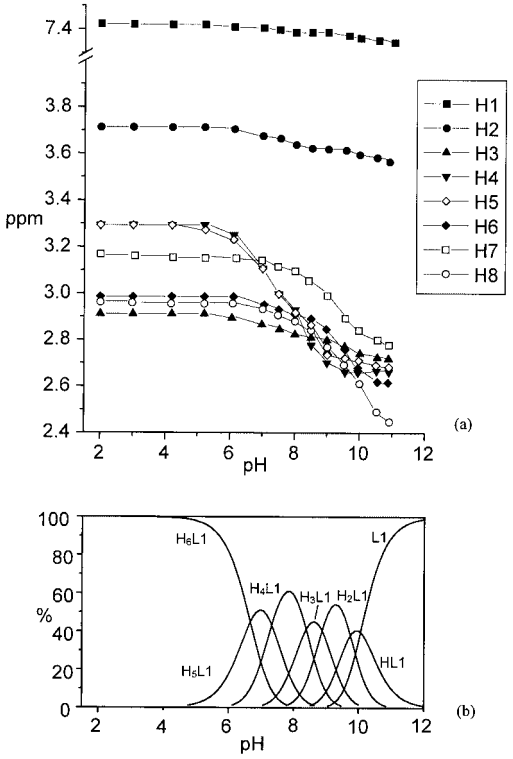

Figure 1. (a) pH dependence of the ^1H NMR signals of **L1**. (b) Distribution diagram of protonated species formed by **L1** as a function of pH (0.1 M Me_4NCl, 298.1 K, [L] = 1×10^{-3} M).

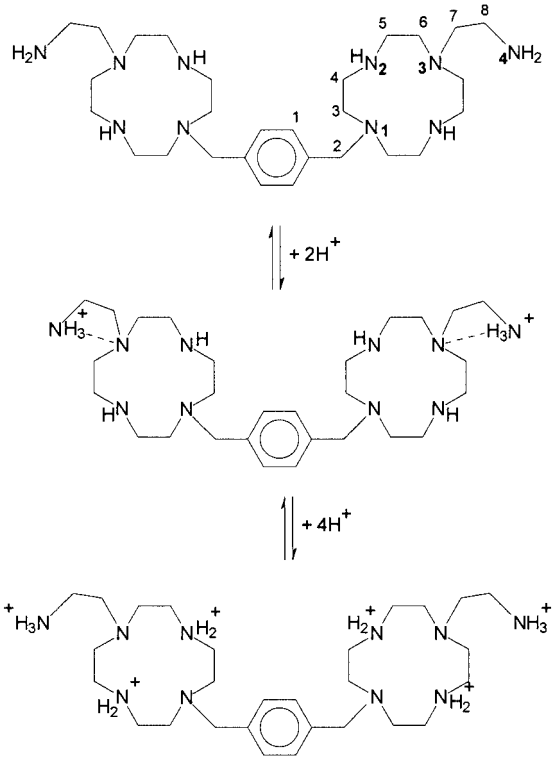
At first glance, Figure 1a shows an overall downfield shift of the resonances of all the methylene groups, with the exception of the signals of H2 and H3, which are adjacent to the tertiary amine group N1, in the pH range 11.0–6.0. This clearly indicates that the tertiary nitrogen atoms N1 are not involved in proton binding over the pH range investigated. A more accurate analysis of the pH dependence of the signals in Figure 1a shows that in the pH range 11.0–9.0, where the first two protons bind to the ligand, the resonance of H8, in the α-position with respect to N4, gives rise to the highest downfield shift (ca. 0.4 ppm), which shows that the first two protonation steps take place on the primary amine groups of the pendant arms. In the same pH range, however, a marked downfield shift (almost 0.3 ppm) is also observed for the H6 and H7 signals, which are adjacent to N3, thereby suggesting the presence of a hydrogen bond between the protonated N4 nitrogen atom and N3 and/or to a partial localisation of the acidic proton on the N3 tertiary nitrogen atom (Scheme 1).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 1.

The signals of H4 and H5, which are adjacent to the N2 nitrogen atoms, do not shift remarkably (less than 0.1 ppm) up to pH = 9. In the pH range 9–6, however, these signals give rise to a remarkable downfield shift, thus indicating that the further four protonation steps occur on the secondary amine groups of the macrocyclic ring.

Similar protonation patterns, involving initial protonation of the aminoalkyl function and then proton binding to the secondary amine groups of the macrocycle, are also found for **L2** and **L3**.

Metal Coordination

*Crystal Structure of [{Cu_2**L1**}Cl_4]·8H_2O*

The molecular structure consists of centrosymmetric $[Cu_2\mathbf{L1}]^{4+}$ complex cations, chloride anions and water molecules. An ORTEP[51] drawing of the $[Cu_2\mathbf{L1}]^{4+}$ cation is shown in Figure 2, and Table 2 reports selected distances and angles for the coordination environment of the metals.

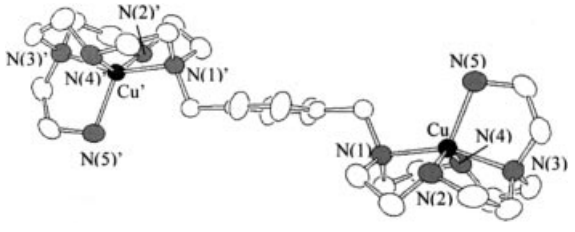


Figure 2. ORTEP drawing of the $[Cu_2\mathbf{L1}]^{4+}$ cation.

Each metal ion is lodged in a cyclic tetraaza moiety and the coordination sphere is completed by the nitrogen atom of the side arm, giving rise to an overall pentacoordination which can best be described as a distorted square pyramid. The axial position is occupied by the N5 nitrogen atom of the side arm, while N1, N2, N3 and N4 define the basal plane [maximum deviation from the mean plane of 0.075(1) Å for N4]. The Cu atom lies 0.512(1) Å above this plane and is shifted toward the apical position, with an angle of 16.65(1)° between the Cu–N5 bond and the normal to the basal plane. The Cu–N bond lengths range between 2.004(6) and 2.127(6) Å (Table 2).

Table 2. Bond lengths [Å] and angles [°] for the metal-ion coordination environments in the $[Cu_2\mathbf{L1}]^{4+}$ cation.

Cu–N1	2.040(6)	N4–Cu–N1	86.1(2)
Cu–N2	2.027(6)	N2–Cu–N1	86.9(2)
Cu–N3	2.049(6)	N4–Cu–N3	86.8(2)
Cu–N4	2.004(6)	N2–Cu–N3	86.0(2)
Cu–N5	2.127(6)	N1–Cu–N3	155.3(3)
		N4–Cu–N5	107.4(2)
		N2–Cu–N5	104.9(3)
		N1–Cu–N5	119.0(2)
		N3–Cu–N5	85.7(2)

Considering the overall conformation of the complex, the ligand presents a rather flat conformation, with the two symmetry-related tetraazamacrocycles lying on two parallel planes and forming an angle of 7.20(1)° with the plane defined by the aromatic unit. In consequence of this flat conformation of the ligand the two Cu^{II} ions lie at a rather long distance [11.447(1) Å].

*Crystal Structures of [{Zn_2**L2**}(ClO_4)$_4$] and [{Zn_2**L3**}(ClO_4)$_4$]·H_2O*

The molecular structures consist of centrosymmetric $[Zn_2L]^{4+}$ (L = **L2** and **L3**) complex cations, perchlorate anions and, in the case of the **L3** complex, water molecules. ORTEP[51] drawings of the $[Zn_2\mathbf{L2}]^{4+}$ and $[Zn_2\mathbf{L3}]^{4+}$ cations are shown in Figure 3a and 3b, respectively, and Table 3 reports selected distances and angles for the metal-ion coordination environments.

The coordination sphere of the Zn^{II} ions is almost equal in the two structures. Each metal ion, in fact, is five-coordinate to the four nitrogen atoms of a cyclic [12]aneN_4 moiety and the nitrogen atom of the side arm. The coordination geometry can be described as a distorted square pyramid; the basal planes are defined by the four amine groups of the [12]aneN_4 units, with maximum deviations from the mean planes being 0.0587(2) Å for N3 (**L2**) and 0.0398(2) Å for N1 (**L3**). The axial positions are occupied by a nitrogen atom of the side arm, with angles of 7.70(1)° (for **L2**) and 4.10(1)° (for **L3**) between the Zn1–N5 bond and the normal to the corresponding basal planes. Finally, the two Zn^{II} cations lie 0.783(2) Å (**L2** complex) and 0.786(2) Å (**L3** complex) above the basal plane, shifted toward the apical position.

The Zn–Zn distances are 11.776(1) and 11.770(1) Å in the Zn^{II} complexes with **L2** and **L3**, respectively.

As far as the overall conformation of the ligand is concerned, it adopts an overall flat conformation in both struc-

		N2–Zn1–N1	81.77(16)
		N3–Zn1–N1	140.43(17)

tures. The two symmetry-related [12]aneN$_4$ units form an angle of 18.83(2)° (**L2** complex) and 22.52(1)° (for **L3** complex) with the plane defined by the aromatic unit. The two zinc ions are lodged within a symmetry-related cyclic unit at each extremity of the ligand, and the nitrogen atoms of the side arms lie *trans* with respect to the plane of the benzene unit.

Cu^{II} and Zn^{II} Coordination in Aqueous Solution

The coordination properties of **L1**–**L3** were studied by means of potentiometric measurements in aqueous solution. Table 4 lists the stability constants of the Cu^{II} and Zn^{II} complexes determined in 0.1 M NMe_4Cl at 298.1 K.

The data in Table 4 clearly outline that all ligands display similar binding features toward Cu^{II} and Zn^{II}, above all a marked ability to form both mono- and dinuclear complexes. Furthermore, the mononuclear $[ML]^{2+}$ complexes show a high tendency to protonate in solution, the three first protonation constants being only slightly lower than the corresponding basicity constants of the free ligands. The rather high values of the equilibrium constants for the protonation of the $[ML]^{2+}$ species can be reasonably ascribed to the protonation of nitrogen atoms not bound to the metal cation in the mononuclear Zn^{II} and Cu^{II} complexes the metal ion is most likely coordinated to a single macrocyclic unit, while the second one is not involved in metal-ion binding and can easily be protonated.

Considering the mononuclear complexes, it was of interest to compare the stability of the present complexes with

Table 4. Stability constants (log K) of the Cu^{II} and Zn^{II} adducts with **L1**, **L2** and **L3**, determined by means of potentiometric measurements in 0.1 M Me_4NCl at 298.1 K.

that of the corresponding complex with 1,7-dimethyl-1,4,7,10-tetraazacyclododecane (**L4**), which contains two secondary and two tertiary nitrogen donors. The stability of the $[Cu\mathbf{L3}]^{2+}$ complex is somewhat lower than those of $[Cu\mathbf{L4}]^{2+}$ (log K = 16.09 and 17.89 for the equilibrium $Cu^{2+} + L \rightleftharpoons [CuL]^{2+}$, with L = **L3** and **L4**, respectively), while the **L1** complex displays a higher affinity for Cu^{II} than **L4** (log K = 20.16 and 17.89 for the equilibrium $Cu^{2+} + L \rightleftharpoons [CuL]^{2+}$, with L = **L1** and **L4**, respectively). These data suggest that in the $[Cu\mathbf{L3}]^{2+}$ complex the amine group of the side arm is not involved in metal-ion coordination, while in $[Cu\mathbf{L1}]^{2+}$ the amine pendant arm is coordinated to the metal ion. In the case of ligand **L2**, the stability constant of the $[Cu\mathbf{L2}]^{2+}$ complex is intermediate between those observed for the corresponding **L1** and **L3** complexes, suggesting that in $[Cu\mathbf{L2}]^{2+}$ the amine group of the pendant arm is weakly involved in metal-ion coordination.

Considering the formation of the dinuclear complexes, the equilibrium constant for the addition of a second metal ion to the mononuclear $[ML]^{2+}$ complexes is similar to that found for the formation of the corresponding $[ML]^{2+}$ species (for instance, log K = 20.16 for the equilibrium $Cu^{2+} + \mathbf{L1} \rightleftharpoons [Cu\mathbf{L1}]^{2+}$, and log K = 19.77 for the equilibrium $[Cu\mathbf{L1}]^{2+} + Cu^{2+} \rightleftharpoons [Cu_2\mathbf{L1}]^{4+}$). This is in agreement with the involvement of the two identical ligand moieties in the coordination of each metal ion in the dinuclear complexes, as shown by the crystal structures of the dinuclear complexes $[Cu_2\mathbf{L1}]Cl_4 \cdot 8H_2O$, $[Zn_2\mathbf{L2}](ClO_4)_4$ and $[Zn_2\mathbf{L3}](ClO_4)_4 \cdot H_2O$ (see above). This behaviour is clearly depicted by the distribution diagrams of the complexes, as shown in Figure 4 for the system Zn^{II}/**L2**. Both mononuclear and dinuclear complexed species are present in solutions containing the ligand and the metal ion in an equimolecular ratio (Figure 4a). On the other hand, for a 2:1 Zn^{II}/L molar ratio, the formation of monometallic complexes is depressed and only minor percentages of protonated mononuclear complexes are formed at acidic pH (Figure 4b).

The process of Zn^{II} coordination was also monitored by means of ^1H NMR titrations in D_2O at pH = 10, carried out by successive addition of $Zn(ClO_4)_2$ to a ligand solution. Figure 5 displays the ^1H NMR spectra of **L1** in the absence and presence of different amounts of Zn^{II}. Upon adding 0.25 equiv. of Zn^{II} to a solution of **L1**, a different set of signals appears in the ^1H NMR spectrum, together with the resonances of the ligand alone. Although the signals of the ethylenic chains of **L1** are affected by a certain degree of fluxionality in the presence of the metal ion and cannot be confidently attributed, the appearance of a new singlet for the aromatic protons (H1A) and of a doublet for the benzylic hydrogen atoms (H2A) is clearly recognisable, pointing out the formation in solution of a metal complex (**A** species) that is slowly exchanging on the NMR timescale with the free ligand. On addition of further Zn^{II}, the signals of this species are enhanced, while the resonances of L decrease in intensity. With an M^{II}/L molar ratio of 0.5:1, however, a third set of signals (H1B and H2B) appears in the spectrum, due to the formation of a second complexed species (**B** com-

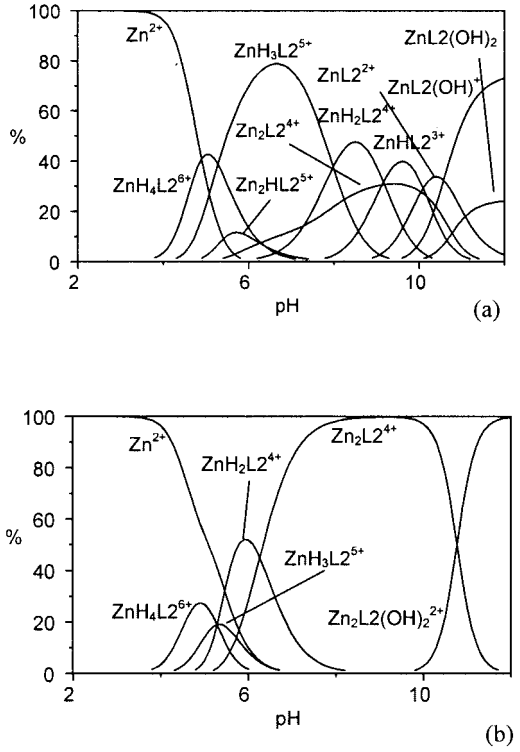

Figure 4. Distribution diagrams of the species for the system Zn^{2+}/**L2** in 1:1 (a) and 2:1 (b) molar ratios ([L] = $[Zn^{2+}] = 1 \times 10^{-3}$ M, 0.1 M Me_4NCl 298.1 K) as a function of pH.

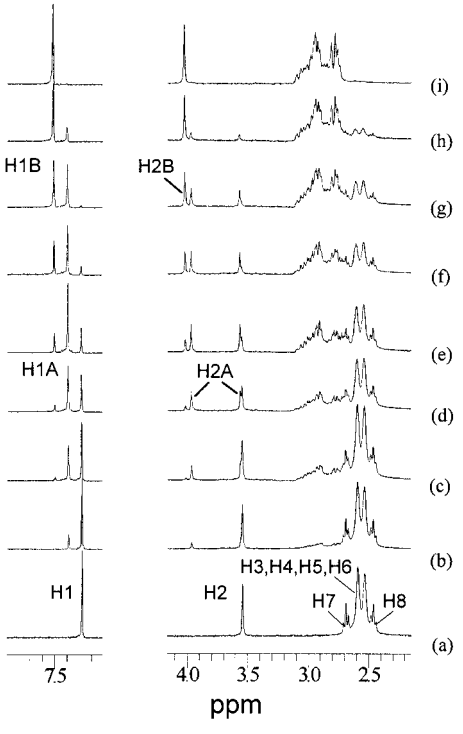

Figure 5. ^1H NMR spectra of **L1** in D_2O in the absence (a) and presence of Zn^{II} in different molar ratios: (b) R = 0.25; (c) R = 0.5; (d) R = 0.75; (e) R = 1.0; (f) R = 1.25; (g) R = 1.5; (h) R = 1.75; (i) R = 2.0; R = $[Zn^{II}]/[\mathbf{L1}]$.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

plex) that is slowly exchanging with the **A** complex on the NMR timescale. When a 1:1 M^{II}/L molar ratio is reached, the predominant species in solution is the **A** complex, most likely the mononuclear Zn^{II} complex. Further additions of Zn^{II} lead to the progressive enhancement of the signals of the **B** complex, accompanied by the disappearance of the signals of the mononuclear complex and of the free ligand. Finally, with a 1:2 **L1**/Zn^{II} molar ratio the $[Zn\mathbf{L1}]^{2+}$ subspectrum disappears and the resulting spectrum can be attributed to a unique dinuclear $[Zn_2\mathbf{L1}]^{4+}$ complex. A similar behaviour is also found for **L2** and **L3**.

A more accurate analysis of the data in Table 4 shows some relevant differences in the coordination properties of the three ligands. First of all, the stability of both the $[ML]^{2+}$ and $[M_2L]^{4+}$ complexes (M = Cu^{II}, Zn^{II}) decreases in the order **L1** > **L2** > **L3** (for instance, log K = 19.77, 17.19 and 14.66 for the equilibrium $Cu^{2+} + [CuL]^{2+} \rightleftharpoons [Cu_2L]^{4+}$ with L = **L1**, **L2** and **L3**, respectively). Second, both the $[Cu_2L]^{4+}$ and $[Zn_2L]^{4+}$ complexes show a different ability in proton binding among the three ligands. The equilibrium constant for the addition of an acidic proton to the $[M_2L]^{4+}$ complexes, in fact, increases in the order **L1** < **L2** < **L3**. In particular, the protonation constants of the $[M_2\mathbf{L1}]^{4+}$ complexes are rather low, less than 5 log units, as expected in the case of protonation of metal-ion-bound amine groups. On the contrary, the protonation constants of the $[M_2\mathbf{L3}]^{4+}$ dinuclear complexes are remarkably high (ca. 9 log units), just slightly lower than the corresponding constants of the "free" ligand, as generally found in the case of nitrogen atoms not involved in metal-ion binding. Finally, the ability of $[M_2L]^{4+}$ complexes to form hydroxylated species decreases from **L3** to **L1** (for instance, log K = 7.17 and 6.11 for the equilibrium $[Zn_2L]^{4+} + 2\ OH^- \rightleftharpoons [Zn_2L(OH)_2]^{2+}$ with L = **L3** and **L2**, respectively, while the $[Zn_2\mathbf{L1}]^{4+}$ complex does not form any hydroxo complex). In polyamine complexes, an increasing tendency to form hydroxo complexes is generally related to a lower number of metal-ion-bound nitrogen donors.

These experimental observations suggest that a decreasing number of nitrogen donors is involved in Cu^{II} or Zn^{II} binding on passing from **L1** to **L3**; in other words, while in the **L1** dinuclear complexes each metal ion is coordinated to the four amine groups of a cyclen moiety and the amine group of the side arm, in the **L3** ones the metal cations are bound only to the four donor atoms of the cyclic moieties. The amine group of the pendant arms seems not to be involved in metal-ion coordination, at least in aqueous solution. In the **L3** complexes a water molecule most likely occupies the apical position in the coordination sphere of both metal ions. In the case of **L2**, the stability constants of the $[M_2\mathbf{L2}]^{4+}$ complexes as well as the equilibrium constants for proton addition to the $[M_2\mathbf{L2}]^{4+}$ species are intermediate between those observed for the corresponding **L1** and **L3** complexes, suggesting that in $[M_2\mathbf{L2}]^{4+}$ the amine groups of the pendant arms are weakly involved in metal-ion coordination.

These hypotheses are confirmed by the UV/Vis spectral features of the dinuclear Cu^{II} complexes. The $[Cu_2L]^{4+}$ complexes display a single band at 610 (ε = 805), 640 (ε = 836) and 693 nm (ε = 888 $cm^{-1}\,mol^{-1}\,L$) for L = **L1**, **L2** and **L3**, respectively (Figure 6). The observed red shift of the absorption maximum on passing from $[Cu_2\mathbf{L1}]^{4+}$ to $[Cu_2\mathbf{L3}]^{4+}$ suggests a decreasing ligand-field splitting at the Cu^{II} centres, in agreement with an increasing number of coordinated nitrogen atoms from the **L3** dinuclear complex to the **L1** one.[52,53]

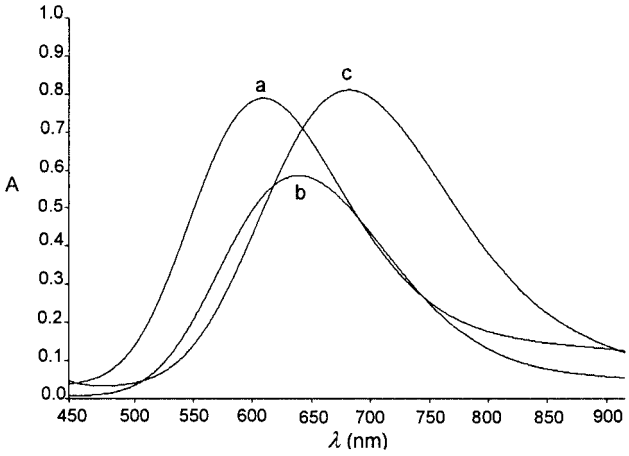

Figure 6. Absorption spectra of $[Cu_2L]^{2+}$: (a) L = **L1**, pH = 8.04; (b) L = **L2**, pH = 8.75; (c) L = **L3**, pH = 10.91 in aqueous solution.

In the case of the dinuclear Zn^{II} complexes, the involvement of the amine group of the pendant arm in metal-ion binding can be determined by analysis of the pH dependence of the ^1H NMR signal of the adjacent methylene group. In the case of $[Zn_2\mathbf{L1}]^{4+}$ and $[Zn_2\mathbf{L2}]^{4+}$ protonation of the complexes gives rise to an upfield shift of this signal (0.2 and 0.15 ppm in the case of the **L1** and **L2** complexes, respectively). This strongly suggests that the formation of protonated complexes implies detachment of the ethyl- or propylamino groups from the metal ion due to protonation of a primary amine function.[54] On the contrary, protonation of the $[Zn_2\mathbf{L3}]^{4+}$ complex is accompanied by a downfield shift of the signal of the methylene group in the α-position with respect to the primary nitrogen atom, as generally observed (see above) in the case of proton binding by amine groups not involved in metal-ion coordination.

The crystal structure of the complex $[Cu_2\mathbf{L1}]Cl_4{\cdot}8H_2O$ shows each metal ion coordinated to the nitrogen atoms of the cyclen unit and to the amine group of a pendant arm, in agreement with the structural hypothesis made on the basis of the solution data. Interestingly, the reflectance spectrum of solid $[Cu_2\mathbf{L1}]Cl_4{\cdot}8H_2O$ shows a single band with λ_{max} = 615 nm, which is very similar to that found for the $[Cu_2\mathbf{L1}]^{4+}$ complex in aqueous solution (λ_{max} = 610 nm), thereby supporting the hypothesis of a similar coordination sphere of the metal ion in the solid state and in solution. In the case of **L3**, however, the crystal structure of $[Zn_2\mathbf{L3}](ClO_4)_4{\cdot}H_2O$ shows that each metal ion is pentacoordinate by the four nitrogen donors of the macrocycle and by the nitrogen donor of the side arm, in contrast to

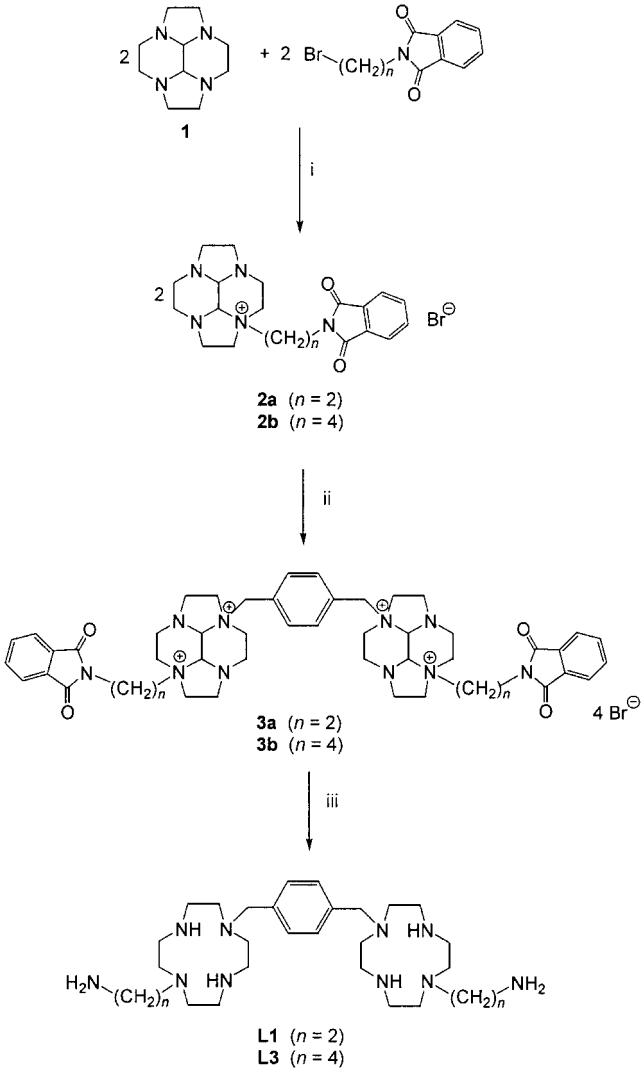
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the conclusions derived from the solution study. Although no Cu^{II} complex with **L3** was structurally characterised, it is of interest to note that the reflectance spectrum of solid $[Cu_2\mathbf{L3}](ClO_4)_4$ shows a band at 620 nm, which is blue-shifted by 70 nm with respect to that of the $[Cu_2\mathbf{L3}]^{4+}$ complex in solution. This experimental result may suggest a higher number of coordinated nitrogen donors in solid $[Cu_2\mathbf{L3}](ClO_4)_4$. While in the solid state the NH_2 group of the pendant arm is coordinated to the metal ion in a similar fashion to that found in $[Zn_2\mathbf{L3}](ClO_4)_4{\cdot}H_2O$, in the $[Cu_2\mathbf{L3}]^{4+}$ species in solution the alkylamino pendant would most likely not be involved in metal-ion coordination.

In conclusion, in the case of $[M_2\mathbf{L1}]^{4+}$ and $[M_2\mathbf{L2}]^{4+}$ all nitrogen donors are coordinated to the metal ions; the solution data, however, suggest a weaker interaction of the amine group of the pendant arm in the **L2** complex. Protonation of the $[M_2L]^{4+}$ species takes place on the aminoethyl or aminopropyl side arms, with consequent detachment of the primary nitrogen donor from the metal ion. In other words, the coordination sphere of the two metal ions is modulated by the pH of the medium. On the contrary, in the $[M_2\mathbf{L3}]^{4+}$ complexes the butylamino side arms are not involved in metal-ion coordination and facile protonation of the primary nitrogen atoms occurs. This different behaviour can be ascribed to the different length of the chelate ring formed by coordination of the aminoalkyl pendant arm to Cu^{II} or Zn^{II}. In the case of $[M_2\mathbf{L1}]^{4+}$, coordination of the primary nitrogen atom gives rise to a stable five-membered chelate ring, whereas in the $[M_2\mathbf{L3}]^{4+}$ complexes coordination of the NH_2 group would lead to the formation of a less stable seven-membered chelate ring. As a consequence, binding of a water molecule in the apical position of the coordination sphere of the metal ion in the $[M_2\mathbf{L3}]^{4+}$ complexes would be energetically more favoured, and, therefore, the aminoalkyl side arm would not be involved in metal-ion coordination in aqueous solution.

Experimental Section

General Procedures: 3-[7-{4-[{7-(3-Aminopropyl)-1,4,7,10-tetraazacyclododecan-1-yl}methyl]benzyl}-1,4,7,10-tetraazacyclododecan-1-yl]propylamine (**L2**) was prepared as previously reported,[49] recrystallised from an ethanol/water mixture and isolated as **L2**·6HCl·2H_2O. **L1**–**L3** require a suitable protection of two opposite nitrogen atoms of cyclen and, moreover, the control of the two successive steps of N-1 and N-7 alkylations. The bis(aminal) resulting from the reaction of cyclen with aqueous glyoxal proved to be an excellent tool for the synthesis of such dissymmetrical dialkylated macrocyclic adducts.[49,55] The synthetic route used for the synthesis of **L1** and **L3** is depicted in Scheme 2. Cyclen reacts with glyoxal in methanolic solution to give *cis*-decahydro-2a,4a,6a,8a-tetraazacyclopenta[*fg*]acenaphthylene (**1**) quantitatively.[56] The reaction with an electrophilic moiety leads to a stable quaternary ammonium salt; the use of an appropriate solvent in which the solubility of this salt is low prevents further alkylation and allows the control of the monoalkylation of **1**. Salts **2** were found to precipitate in CH_3CN and were subsequently isolated by filtration; salts **3** were obtained in a second step by reaction of the monosalts **2** with 0.5 equiv. of the bis(electrophile) (α,α′-dibromo-*p*-xylene) in DMF, in which salts **2** are partially soluble. Subsequent refluxing of **3** in hydrazine monohydrate according to a previously described procedure[49] afforded ligands **L1**–**L3** in good yields.



Scheme 2. (i) Stirring in CH_3CN for 2 d at 50°C or at room temp. for **2a** and **2b**, respectively; (ii) α,α′-dibromo-*p*-xylene in DMF at room temp.; (iii) H_2NNH_2, H_2O, reflux overnight.

2a-[3-(1,3-Dioxo-1,3-dihydro-2*H*-isoindol-2-yl)ethyl]decahydro-4a,6a,8a-triaza-2a-azoniacyclopenta[*fg*]acenaphthylene Bromide (2a): A solution of *N*-(bromoethyl)phthalimide (2.9 g, 11 mmol) in dry acetonitrile (5 mL) was added to a stirred solution of **1** (2.0 g, 10 mmol) in 5 mL of dry acetonitrile,. The mixture was stirred at 50 °C for 2 d. The precipitate was collected by filtration, washed with acetonitrile and dried in vacuo to give the monosalt as a white powder. Yield: 1.79 g (40%). ^{13}C NMR (D_2O): δ = 172.3 (CO), 138.0, 133.9, 126.6 (C_{ar}), 87.0, 74.4 (C_{aminal}), 65.1, 60.1, 57.4, 54.1, 51.2, 50.9, 50.7, 50.4, 46.4 (CH_2N), 34.6 ($N^+CH_2CH_2N_{pht}$) ppm. $C_{20}H_{26}BrN_5O_2$ (448.36): calcd. C 53.58, H 5.84, Br 17.82, N 15.62; found C 53.26, H 5.89, Br 17.73, N 15.51.

2a-[3-(1,3-Dioxo-1,3-dihydro-2*H*-isoindol-2-yl)butyl]decahydro-4a,6a,8a-triaza-2a-azoniacyclopenta[*fg*]acenaphthylene bromide (2b): Compound **2b** was obtained from **1** (2.0 g, 10 mmol) and *N*-(bromobutyl)phthalimide (3.2 g, 11 mmol) at room temperature by applying the same procedure as for **2a**. Yield: 4.43 g (93%). ^{13}C

NMR (D_2O): δ = 173.4 (CO), 137.7, 134.0, 126.2 (C_{ar}), 86.6, 74.6 (C_{aminal}), 64.9, 60.6, 59.7, 54.1, 51.3, 51.0, 50.6, 50.5, 46.5 (CH_2N), 39.5 ($N^+CH_2CH_2CH_2CH_2N_{pht}$), 27.7, 22.9 ($N^+CH_2CH_2CH_2CH_2N_{pht}$) ppm. $C_{22}H_{30}BrN_5O_2$ (476.41): calcd. C 55.46, H 6.35, Br 16.77, N 14.70; found C 55.19, H 6.37, Br 16.64, N 14.61.

2a-[4-{[6a-{2-(1,3-Dioxo-1,3-dihydro-2*H*-isoindol-2-yl)ethyl}decahydro-4a,8a-diaza-2a,6a-diazoniacyclo-penta[*fg*]acenaphthylen-2a-yl]methyl}benzyl]-6a-[2-(1,3-dioxo-1,3-dihydro-2*H*-isoindol-2-yl)ethyl]decahydro-4a,8a-diaza-2a,6a-diazoniacyclopenta[*fg*]acenaphthylene Tetrabromide (3a): A solution of α,α′-dibromo-*p*-xylene (0.6 g, 2.38 mmol) in 50 mL of dry DMF was added dropwise to a suspension of **2a** (2.1 g, 4.75 mmol) in 100 mL of dry DMF. The mixture was stirred at room temperature for 2 weeks. The solvent was evaporated, 10 mL of dry acetonitrile was added to the residue and the mixture was stirred for some minutes. The precipitate was collected by filtration, washed with acetonitrile and dried in vacuo. The white crude product was used without further purification. Yield: 2.45 g (89%). ^{13}C NMR (D_2O): δ = 172.4 (CO), 138.3, 136.7, 134.2, 132.4, 126.9 (C_{ar}), 82.1, 80.9 (C_{aminal}), 64.9, 64.3, 63.5, 59.0, 58.2, 57.6, 49.5, 49.0, 45.6 (NCH_2), 34.8 (CH_2N_{pht}) ppm.

2a-[4-{[6a-{2-(1,3-Dioxo-1,3-dihydro-2*H*-isoindol-2-yl)butyl}decahydro-4a,8a-diaza-2a,6a-diazoniacyclopenta[*fg*]acenaphthylen-2a-yl]methyl}benzyl]-6a-[2-(1,3-dioxo-1,3-dihydro-2*H*-isoindol-2-yl)butyl]decahydro-4a,8a-diaza-2a,6a-diazoniacyclopenta[*fg*]acenaphthylene Tetrabromide 3b: Compound **3b** was obtained from α,α′-dibromo-*p*-xylene (0.6 g, 2.38 mmol) and **2b** (2.3 g, 4.75 mmol) by the same procedure as **3a**. The white crude product was used without further purification. Yield: 2.63 g (91%). ^{13}C NMR (D_2O): δ = 173.4 (CO), 137.7, 136.5, 134.1, 132.2, 126.2 (C_{ar}), 81.3, 80.8 (C_{aminal}), 64.5, 64.0, 63.2, 60.2, 58.2, 49.1, 45.5 (NCH_2), 39.6 (CH_2N_{pht}), 27.6, 24.3 ($CH_2CH_2CH_2CH_2$) ppm.

2-[7-{4-[{7-(2-Aminoethyl)-1,4,7,10-tetraazacyclododecan-1-yl}-methyl]benzyl}-1,4,7,10-tetraazacyclododecan-1-yl]ethylamine Hexahydrochloride Dihydrate (L1·6HCl·2H$_2$O): Compound **3a** (2.3 g, 2 mmol) and 6 mL of hydrazine monohydrate were heated at 120 °C overnight. After cooling, the solid was filtered off, dissolved in ethanol and the solvent was evaporated. The resulting oil was dissolved in 10 mL of ethanol and 10 mL of concentrated HCl was added dropwise. The precipitate was filtered off, dissolved in 3 M HCl and the solvent was evaporated. The white solid was recrystallised from an ethanol/water mixture (1:1). Yield: 1.12 g (72%). ^{13}C NMR (D_2O): δ = 137.2, 133.5, 58.7, 52.0, 50.0, 49.7, 45.5, 43.9, 37.2 ppm. $C_{28}H_{66}Cl_6N_{10}O_2$ (787.61): calcd. C 42.70, H 8.45, Cl 27.01, N 17.78; found C 42.45, H 8.53, Cl 26.89, N 17.54.

4-[7-{4-[{7-(4-Aminobutyl)-1,4,7,10-tetraazacyclododecan-1-yl}-methyl]benzyl}-1,4,7,10-tetraazacyclododecan-1-yl]butylamine Hexahydrochloride Dihydrate (L3·6HCl·2H$_2$O): Compound **3b** was treated as above to give a white solid. Yield: 1.48 g (93%). ^{13}C NMR (D_2O): δ = 137.7, 133.4, 58.8, 54.5, 50.0, 49.9, 45.4, 45.3, 42.2, 27.5, 23.0 ppm. $C_{32}H_{74}Cl_6N_{10}O_2$ (843.71): calcd. C 45.55, H 8.84, Cl 25.21, N 16.60; found C 45.81, H 8.87, Cl 25.57, N 16.68.

Synthesis of [{Cu$_2$L1}Cl$_4$]·8H$_2$O: A solution of $Cu(ClO_4)_2·6H_2O$ (14 mg, 0.038 mmol) in water (5 mL) was slowly added to an aqueous solution (10 mL) containing **L1**·6HCl·2H$_2$O (15 mg, 0.019 mmol). The pH was adjusted to 8.0 with 0.01 M NaOH and then $NaClO_4$ (30 mg) was added. Blue crystals of the complex suitable for X-ray analysis were obtained by slow concentration at room temperature. Yield: 11 mg (61%) $C_{28}H_{72}Cl_4Cu_2N_{10}O_8$ (945.85): calcd. C 35.56, H 7.67, N 14.81; found C 35.45, H 7.60, N 14.78.

Caution! Perchlorate salts of organic ligands and their metal complexes are potentially explosive; these compounds must be handled with great care.

Synthesis of [Zn$_2$L2](ClO$_4$)$_4$: Crystals of [{Zn$_2$**L2**}(ClO$_4$)$_4$] suitable for X-ray analysis were obtained by slow concentration, at room temperature, of an aqueous solution containing **L2**·6HCl·2H$_2$O (11 mg, 0.013 mmol) and $Zn(ClO_4)_2$ (10 mg, 0.027 mmol) at pH = 9.0. Yield: 11.72 mg (80%). $C_{30}H_{60}Cl_4N_{10}O_{16}Zn_2$ (1089.4): calcd. C 33.07, H 5.55, N 12.86; found C 33.40, H 5.45, N 12.93.

Synthesis of {[Zn$_2$L3](ClO$_4$)$_4$}·H$_2$O: This complex was synthesised according to the procedure reported for **L2** adjusting the solution pH to 9.3. Yield: 9.45 mg (64%). $C_{32}H_{66}Cl_4N_{10}O_{17}Zn_2$ (1135.5): calcd. C 33.85, H 5.86, N 12.33; found C 33.80, H 5.90, N 12.37.

X-ray Structure Analyses: Analyses on prismatic, blue single crystals of [{Cu$_2$**L1**}Cl$_4$]·8H$_2$O (a), prismatic colourless crystals of [{Zn$_2$**L2**}(ClO$_4$)$_4$] (b) and [{Zn$_2$**L3**}(ClO$_4$)$_4$]·H$_2$O (c) were carried out with CCD SMART 1K (**L1**) and SIEMENS P4 (**L2** and **L3**) diffractometers. A summary of the crystallographic data is given in Table 5. Empirical absorption corrections (SADABS for **L1** and ψ-scan methods for **L2** and **L3**) were applied. No loss of intensity was observed during data collection. Both structures were solved by direct methods with the SIR97 program.[57] Refinements were performed by the full-matrix least-squares method with the SHELXL-97 program.[58] All non-hydrogen atoms were refined anisotropically while hydrogen atoms, except those of the water molecules, were introduced in calculated positions and their coordinates refined according to the linked atom. As is common for perchlorate ligands, in the structure of [{Zn$_2$**L3**}(ClO$_4$)$_4$]·H$_2$O the perchlorate anion Cl1 exhibits disorder (six oxygen peaks, three assigned 33% and three 66% occupancy). CCDC-240959, -240960 and -240961 (**L1**–**L3**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Potentiometric Measurements: All the pH-metric measurements (pH = –log [H$^+$]) were carried out in degassed 0.1 M Me_4NCl, with CO_2-free solutions, at 298.1 K, with equipment and procedures that have already been described.[59] The combined Ingold 405 S7/120 electrode was calibrated as a hydrogen concentration probe by titrating known amounts of HCl with CO_2-free Me_4NOH solutions and determining the equivalent point by Gran's method,[60,61] which allows the determination of the standard potential, E^o, and the ionic product of water [pK_w = 13.83(1) at 298.1 K in 0.1 M Me_4NCl]. A ligand concentration, [L], of 1×10^{-3} M and metal-ion concentration, [M], from 0.5•[L] to 1.8•[L] were adopted in the complexation experiments. The emf data were treated with the computer program HYPERQUAD[62] which furnished the equilibrium constants reported in Table 1 and Table 4. All titrations were treated either as single sets or as separate entities for each system without significant variation in the values of the determined constants. In the HYPERQUAD[62] program the sum of the weighted square residuals of the observed emf values is minimised. The weights were derived from the estimated errors in emf (0.2 mV) and titrant volume (0.002 mL). The most probable chemical model was selected by using a strategy based on the statistical inferences applied to the variance of the residuals, σ^2. The sample standard deviation should be 1 in the absence of systematic errors and when a corrected weighting scheme is used. However, the agreement is considered good for standard deviation values smaller than 3 ($\sigma^2 < 9$). Values of σ^2 lower than 6 were obtained for all the refined equilibrium models in the present work. If more than one model gave an acceptable σ^2 value the reliability of the proposed specia-

tion models was checked by performing F tests at the 0.05 confidence level, using the method reported in ref.[63] and ref.[64] for two different proposed models, A and B. Assuming that the minimum value of the sample variance, σ_A^2, has been reached for the proposed model A, an alternative model B, which supplies a value of the variance σ_B^2, was rejected if $\sigma_B^2/\sigma_A^2 > F$, where σ_A and σ_B are given directly by data treatment with the HYPERQUAD[62] program. The F values were taken from ref.[63] For all the systems investigated this method provided only one acceptable system.

NMR Spectroscopy: 300.0 MHz ^{1}H, 75.46 MHz ^{13}C NMR spectra in D_2O solutions at different pH values were recorded at 298 K with a Varian 300 MHz spectrometer. In the ^{1}H NMR spectra the peak positions are reported relative to HOD at δ = 4.75 ppm. Dioxane was used as reference standard in ^{13}C NMR spectra (δ = 67.4 ppm). ^{1}H-^{1}H and ^{1}H-^{13}C 2D correlation experiments were performed to assign the signals. Small amounts of 0.01 M NaOD or DCl solutions were added to a solution of the three ligands to adjust the pD. The pH was calculated from the measured pD values using the relationship pH = pD – 0.40.[65]

Electronic Spectroscopy: Absorption spectra were recorded with a Perkin–Elmer Lambda 25 spectrophotometer. HCl and NaOH were used to adjust the pH values, which were measured with a Metrohm 713 pH meter.

Mono- and Bilayered Lead(II)–bpno Polymers with Unusual Low Energy Emission Properties (bpno = 4,4′-Bipyridine *N*,*N*′-Dioxide)

Yanqing Xu,[a] Daqiang Yuan,[a] Lei Han,[a] En Ma,[a] Mingyan Wu,[a] Zhengzhong Lin,[a] and Maochun Hong*[a]

Keywords: Lead complexes / 4,4′-Bipyridine *N*,*N*′-dioxide / Coordination polymers / Phosphorescence

Reaction of 4,4′-bipyridine *N*,*N*′-dioxide (bpno) and lead(II) nitrate with or without dicyanamido ions (dca) in aqueous solution yielded polymeric complexes $\{Pb_2(bpno)_4(dca)_2(NO_3)_2Pb_2(bpno)_4(NO_3)_4\cdot 5H_2O\}_n$ (**1**) and $\{Pb(bpno)(NO_3)_2\cdot H_2O\}_n$ (**2**), respectively. The single-crystal X-ray analyses show that the structures of both complexes consist of dinuclear Pb^{II} units which are bridged through bpno ligands in novel modes to extend their topologies. Compound **1** exhibits a bilayered rhombus grid, while **2** displays a monolayered rhombus grid. The different excitations of solid samples of **1** and **2**, at room temperature, produced intense emission bands which are almost the same in appearance with peak maxima at 616 nm and 617 nm, respectively. Both low-energy emissions were determined to be phosphorescence by their long decay lifetime at room temperature.

Introduction

The s^2 materials can be important in applications like electroluminescent devices[1] or organic light-emitting diode (OLED) technology etc.,[2] and so have stimulated many scientists' interest. As far as the intrinsic appeal of Pb^{2+} is concerned, the presence of an $6s^2$ outer electron configuration not only leads to interesting topological arrangements,[3] but also plays an important role in the luminescence action of the complex.[4] Consequently, a remarkable amount of studies have been done on the optical properties of lead(II) centers.[5] In 1986 R. Ballardini et al. reported that the Pb(8-quinolinolate)$_2$ chelates exhibit a very weak red intraligand (IL) phosphorescence in addition to a much stronger green IL fluorescence in fluid solution.[6] S. K. Dutta et al. further put forward that Pb^{2+} could act as its own luminescent sensor via the highly luminescent lead halide cluster $Pb_4Br_{11}^{3-}$ due to a delocalized cluster state.[5b] More recent studies by A. Strasser and A. Vogler focused on IL phosphorescence research of the lead(II) β-diketonates at both low temperatures and room temperature.[7] In fact, little attention has been focused on luminescent lead polymers even though there are many interesting structure reports. Taking into account that the presence of lead in coordination polymers will reduce the radiative lifetime of triplets by increased spin-orbit coupling and generate a room-temperature phosphorescence, as is largely related to the application of triplet emitters in OLED technology, we have recently become interested in the phosphorescence properties of lead coordination polymers.

On the other hand, 4,4′-bipyridine *N*,*N*′-dioxide (bpno) possesses a longer bridging spacer and richer coordination modes, compared with 4,4′-bipyridine. As shown in Scheme 1, there are five possible kinds of connection modes for the bpno ligand.[8] The *cis* and *trans* modes have been observed in many compounds.[9] The four-connecting coordination mode (μ-4,4,4′,4′) was newly found in La–bpno.[10] However, the three-connecting mode (μ-4,4,4′) remains unknown. Another ligand, the dicyanamido ion (dca), also exhibits various coordination modes, which makes it a fairly good building block for crystal engineering.[11] By the self-assembly of bpno and/or dca ligands with transition metal ions, coordination frameworks with larger cavities or channels may be expected.[12] Thus, by the reaction of Pb^{2+} and

Supporting information for this article is available on the WWW under http://www.eurjic.org or from the author.

bpno with or without dca, two novel polymeric complexes, $\{Pb_2(bpno)_4(dca)_2(NO_3)_2Pb_2(bpno)_4(NO_3)_45H_2O\}_n$ (**1**), and $\{Pb(bpno)(NO_3)_2H_2O\}_n$ (**2**) were obtained. Herein, we wish to report their syntheses, crystal structures, TG, IR spectroscopic and luminescent properties. To the best of our knowledge, the three-connecting mode (μ-4,4,4′) has been confirmed for the first time in both compounds.

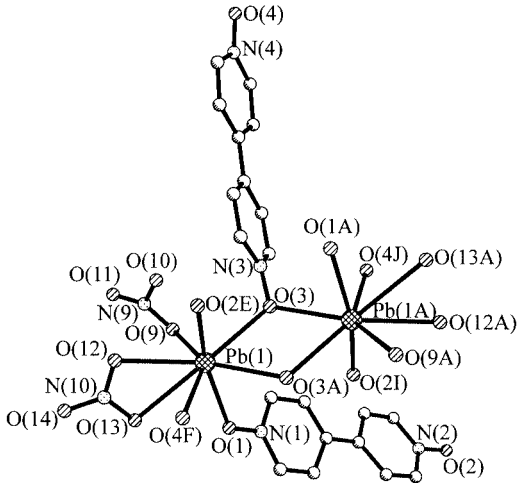
Results and Discussion

Heating of the mixture of 4,4′-bpno, dca and $Pb(NO_3)\cdot 2H_2O$ in a methanol solution led to yellow prismatic crystals of compound **1**, while heating of the mixture of 4,4′-bpno and $Pb(NO_3)\cdot 2H_2O$ in a methanol solution led to orange prismatic crystals of compound **2**. Single crystal analyses show that both complexes have polymeric structures based on dinuclear Pb^{II} units bridged by bpno ligands.

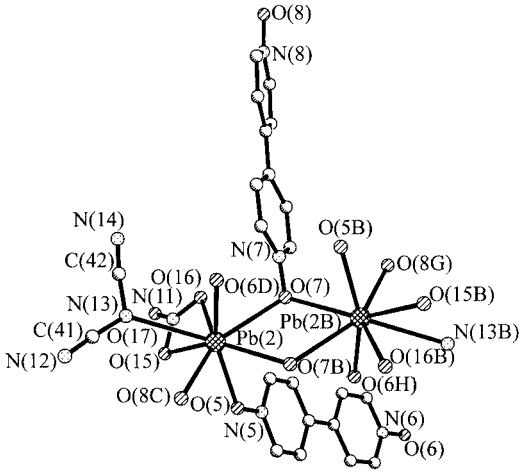
Crystal Structure of Compound 1

The asymmetric unit of compound **1** consists of two crystallographically independent lead(II) motifs, as well as two and a half free lattice water molecules. As shown in Figure 1a, Pb1 is in an eight-coordinate environment, surrounded only by O atoms, of which five are from bpno ligands, two from a bidentate NO_3^- and one from a monodentate NO_3^- group. Pb1 atoms are linked by the O(3) atoms of the bpno groups, forming a planar four-membered ring Pb(1)–O(3)–Pb(1A)–O(3A) with O–Pb–O bond angles of 62.93° and Pb–O–Pb bond angles of 117.07°. This Pb_2O_2 unit is nearly symmetric with the Pb–O distances being 2.633(9) Å for Pb(1)–O(3) and 2.690(10) Å for Pb(1)–O(3A), respectively. The Pb–(μ-O) bond lengths are comparable to those found in other crystallographically characterized $Pb_2(\mu\text{-}OR)_2$ systems.[3d,13] The distance between the two nonbonded Pb atoms [Pb(1)–Pb(1A)] is about 4.541 Å. The Pb_2O_2 units are bridged by two parallel bpno ligands along the *oa* direction with Pb(1)–O(4F) [2.511(11) Å] and N(3)–O(3) [1.317(14) Å] yielding a double-stranded chain, in which bpno adopts both μ-4,4,4′ and *trans* connection modes. It is noted that bonding in the μ-4,4,4′ mode is exclusive and has been observed in the structure of **1** for the first time. These adjacent chains are further linked through double bpno ligands along the *ob* direction with Pb(1)–O(2D) [2.461(10) Å] and Pb(1)–O(1) [2.647(10) Å] leading to a 2D bilayered coordination network as illustrated in Figure 2a.

The dca ligand is not involved in the Pb1 motif but is in the Pb2 part (Figure 1b). The Pb2 part also adopts an eight-coordination geometry. Because of the existence of the dca ligand, there is only one NO_3^- ion involved in the coordination sphere, which adopts a chelating coordination mode and occupies two coordination points. The dca ligand in this structure bonds to the Pb atom by its amine nitrogen but not the nitrile nitrogen atom. The extended structure is shown in Figure 2b, and no significant differences are observed between the Pb2 and Pb1 grids except that one NO_3^- ion in the Pb1 grid is replaced by dca ligand in the Pb2 grid. The two grids exhibit large open frameworks with the same dimensions 13.465 × 13.465 Å, but unfortunately the two sets of networks cross over in the common stacking form to reduce the dimension of the framework (Figure 3).



(a) Structure of Pb1 part.



(b) Structure of Pb 2 part.

Figure 1. Coordination environment of two Pb^{II} motifs in compound **1**, hydrogen atoms are omitted. Symmetry code: (a) A: $-x + 2, -y, -z + 1$; B: $-x + 1, -y + 1, -z$; D: $x, y + 1, z$; F: $x - 1, y, z$; I: $-x + 2, -y - 1, -z + 1$; J: $-x + 3, -y, -z + 1$; (b) B: $-x + 1, -y + 1, -z$; C: $x + 1, y, z$; D: $x, y + 1, z$; G: $-x, -y + 1, -z$; H: $-x + 1, -y, -z$.

Crystal Structure of Compound 2

From the structural analysis above, we surmised that the occurrence of two different motifs in **1** might be due to the introduction of the dca ligand into the reaction system. Thus, we were interested in continuing our research without the addition of dca to see if the same structure of the Pb1 grid in **1** could be obtained. However, the result seems to be quite unexpected, and a novel structure of **2** was produced (Figure 4), in which the Pb atom is eight-coordinate with two chelating NO_3^- ions, three bpno ligands, and one water

molecule. Although the $Pb_2(\mu\text{-}4,4,4'\text{-bpno})_2$ unit is again found in this structure, except for the absence of two bpno ligands (contrasted with **1**), the extended structure only leads to a monolayer topology with the dimensions of a rhombus grid 13.814×13.814 Å (Figure 5). All bpno ligands in **2** adopt a μ-4,4,4′ connection mode. As a result of compact stacking in crystallography, the dimension of the open framework is also to be reduced (Figure 6).

IR Spectroscopy

The infrared spectra of solid samples of **1** and **2** are notably different apart from the characteristic bands of the organic ligand. Compound **1** displays absorption peaks at 2257, 2194 and 2144 cm^{-1}, which correspond to $\nu_{sym} + \nu_{asym}(C{\equiv}N)$, $\nu_{sym}(C{\equiv}N)$ and $\nu_{asym}(C{\equiv}N)$ of the dca ligand. The values of the stretching frequencies are relatively lower than those of Na(dca), observed at 2286, 2232 and 2179 cm^{-1}.[14] The shift towards lower frequencies of these peaks reflects the coordination mode of dca through the amide nitrogen atom, which results in decreasing electron density at the cyano groups.[15] A broad absorption band at 3400 cm^{-1} assigned to ν(OH) appears in the spectra, showing the presence of water molecules in both complexes.

Luminescence Properties

Figure 7 shows the emission spectra of **1** and **2** measured at room temperature. The emission spectra of both compounds are dominated by an intense and broad emission band at λ = 616 nm for **1** (λ_{ex} = 388 nm) and λ = 617 nm for **2** (λ_{ex} = 510 nm). The further lifetime measurements at room temperature of each emission maximum gave the results 17.89 μs for **1** and 3.50 μs for **2**. Based on their 10^{-5}–10^{-6} s range lifetime at room temperature, both low-energy emissions could be determined to be phosphorescence, as is consistent with the general idea that the appearance of a room-temperature phosphorescence requires the presence of a heavy metal ion which reduces the radiative lifetime of triplets by increased spin-orbit coupling.[7b] Commonly, the emitting triplets are frequently of the CT (charge transfer) or IL (intraligand) type while LF (ligand field) states are mostly deactivated by radiationless processes.[7b] In order to assign the type of the luminescence, luminescent measurements were taken of both free bpno ligand and bpno complexes. The free bpno ligand in the solid state at room temperature was found to emit at 459 nm under 396 nm radiation (see Figure S1; Supporting Information). But bpno in the *cis* mode (see Scheme 1) was reported to be incapable of activating emission from Eu^{III} in a one-dimensional coordination polymer.[16] We have also reported a mononuclear complex $[Cd(dca)_2(bpno)_2{\cdot}(H_2O)_2]$,[17] in which bpno acts as a terminal ligand. The recent emission measurement on it showed a narrow emissive band at 399 nm (λ_{ex} = 376 nm) (see Figure S2; Supporting Information). From the above measurements, we feel confident to surmise that as an organic fluorophore, the emission action of bpno may vary with the change of the coordination mode and the coordinated metal ion. As a result, increased spin-orbit coupling induced by the heavy-atom effect of lead(II) facilitates intersystem crossing, and the IL phosphorescence is fast enough to successfully compete with radiationless deactivations.[7a] In addition, the $(\mu\text{-}4,4,4'\text{-bpno})_2Pb_2$ dinuclear cluster cannot be neglected in both structures. From the lead halide cluster $Pb_4Br_{11}^{3-}$ it has been reported that the charge transfer states and states delocalized over the bromide-bridged lead ions are important.[5b] Comparably, the emissions in this work may be assigned partly to the delocalized cluster state of the oxygen-bridged lead ions. To the best of our knowledge, such a long lifetime and low-energy luminescence has never been reported for Pb^{2+} coordination polymers. This study suggests that bpno is an appropriate ligand for lead complexes to generate room-temperature phosphorescence, and the results are interesting for finding the long-lived room-temperature phosphorescence relating to Pb^{2+} coordination polymers. We are actively moving towards other related bpno and heavy main group metals with s^2 electron configurations in order to make further progress on the molecule-based functional solids.

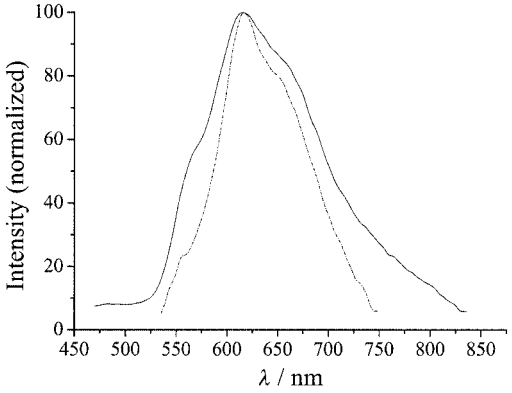

Figure 7. Emission measured for **1** (λ_{ex} = 388 nm) and **2** (λ_{ex} = 510 nm) at room temperature. Solid line for compound **1** and dash-dotted line for **2** and normalized at maximum intensity.

TGA Study

To access the thermal stability of the two compounds, TG analyses were carried out. The TGA diagrams of the crystalline samples showed weight loss in the temperature range 90–165 °C in **1**, corresponding to five free water molecules (3.19%; calculated 3.07%). The anhydrous compound began to decompose at 260 °C. However, the decomposition was still not complete at 800 °C, as could be confirmed by the black color of the residual and the slope of the TGA curves.

For compound **2**, only one coordination aqua ligand exists in the structure. The weight loss was found to be 3.42% in the range of 80–110 °C, which is a little higher than the calculated value of 3.35%. The weight was unchanged until the temperature increased to 309 °C, indicating that the thermal stability of **2** is higher than **1**. Similarly for compound **1**, the decomposition process was incomplete, which was also confirmed by the black color of the residual and the slope of the TGA curves.

Conclusions

In summary, two novel luminescent Pb^{II} coordination polymers with different types of layered grid structures were synthesized. This paper investigated the microscopic features of molecular packing, the luminescent essence and the thermal stability of both compounds. These results are

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

interesting not only for confirming new coordination modes of bpno for the first time, but also for finding the long-lived phosphorescence at room temperature emitted from lead coordination polymers, which may have some potential application in OLED technology. Further studies on analogous functional solids will be carried out in the proceeding work.

Experimental Section

General: All chemicals were of reagent-grade quality obtained from commercial sources and used without further purification. Elemental analyses were performed with a German Elementary Varil EL III instrument. IR spectra were recorded in the range 4000–400 cm^{-1} with a Magna 750 FT-IR spectrometer using KBr pellets. TGA analyses were carried out with a Netzsch STA449C unit, at a heating rate of 15 °C min^{-1} under nitrogen from 30 to 800 °C. Fluorescent spectra were measured at room temperature with an Edinburgh FL-FS90 TCSPC system.

Synthesis of 1 and 2: Ligand 4,4′-bpno (0.25 mmol, 0.056 g) and $Pb(NO_3)_2{\cdot}2H_2O$ (0.25 mmol, 0.042 g) were mixed in a methanol (20 mL) solution. Ligand dca (0.50 mmol, 0.045 g) was added to the above solution. The mixture was heated for 15 min with stirring and then filtered. Slow concentration of the filtrate at room temperature led to yellow prismatic crystals of compound **1**. Yield: 0.105 g, 58%. Compound **2** was synthesized by the same procedure as above but without the addition of dca. The resulting solution was allowed to stand at room temperature. Orange prismatic crystals were obtained after 2 d. Yield: 0.088 g, 65%. **1:** $C_{84}H_{74}N_{28}O_{39}Pb_4$ (2928.47): calcd. C 34.40, H 2.55, N 13.38; found C 34.38, H 2.58, N 13.37. IR (KBr): $\tilde{\nu}$ = 3434 (m), 3098 (m), 3064 (m), 3036 (w), 2257 (m), 2194 (m), 2144 (s), 1625 (m), 1545 (m), 1477 (vs), 1384 (vs), 1351 (s), 1240 (s), 1221 (vs), 1184 (vs), 1026 (s), 834 (s), 699 (m), 548 (s), 517 (w), 478 (m) cm^{-1}. **2:** $C_{10}H_{10}N_4O_9Pb$ (537.41): calcd. C 22.30, H 1.87, N 10.41; found C 22.31, H 1.89, N 10.39. IR (KBr): $\tilde{\nu}$ = 3445 (m), 3099 (m), 3074 (m), 3038 (w), 1624 (w), 1545 (m), 1478 (vs), 1380 (vs), 1348 (s), 1243 (s), 1224 (vs), 1183 (vs), 1027 (s), 836 (s), 700 (m), 548 (s), 515 (m), 477 (m) cm^{-1}.

Crystal Structure Characterization: Single crystals of the compounds with approximate dimensions 0.22 mm × 0.19 mm × 0.17 mm for **1** and 0.19 mm × 0.16 mm × 0.15 mm for **2** were coated with epoxy glue and mounted on a glass fiber in a random orientation for data collections. The intensity data were collected with a Smart CCD diffractometer with graphite-monochromated Mo-K_α (λ = 0.71073 Å) radiation at room temperature in the ω-2θ scan mode. An empirical absorption correction was applied to the data using the SADABS program.[18] The structures were solved by direct methods and refined on F^2 by full-matrix least-squares, employing the SHELXTL program.[19] All non-hydrogen atoms were refined with anisotropic thermal parameters. H atoms bonded to C atoms were positioned geometrically (C–H bond fixed at 0.93 Å) and H atoms bonded to O atoms were placed at calculated positions by the HYDROGEN computer program (O–H bond fixed at 0.85 Å),[20] assigned isotropic displacement parameters and allowed to ride on their respective parent atoms. Crystal data and structure refinement parameters are summarized in Table 1. Selected bond lengths and angles are presented in Table 2. CCDC-236662 (**1**) and -236663 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Synthesis of $H_2V_3O_8$ Single-Crystal Nanobelts

Gui-cun Li,*[a,b] Shu-ping Pang,[b] Zhao-bo Wang,[b] Hong-rui Peng,[b] and Zhi-kun Zhang*[a,b]

Keywords: Vanadium / Layered compounds / Nanobelts / Nanostructures

Orthorhombic $H_2V_3O_8$ single-crystal nanobelts with a thickness of less than 30 nm and a length up to several hundreds of micrometers have been synthesized using bulky divanadium pentoxide powders as a precursor. The synthetic process is free of any templates and reducing agents. Divanadium pentoxide undergoes a redox reaction under hydrothermal conditions. The influences of pH, reaction time, and temperature on the morphologies of the resulting products have been investigated. The belt-like $H_2V_3O_8$ with a high surface area may be beneficial to lithium insertion between the V_3O_8 layers for application in batteries.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

In recent years, there has been increased interest in synthesizing one-dimensional (1D) nanostructures of vanadium oxides and their derivative compounds, such as nanorod, nanowires, nanotubes, nanobelts, and nanoribbons, because of their diverse physicochemical properties and potential applications including use as cathode materials for lithium batteries,[1] and as electric field-effect transistors.[2,3] Among them, the belt-shaped 1D nanostructures are expected to represent important building blocks for nanodevices.[4,5] Vanadium oxide hydrate ($H_2V_3O_8$), one of the vanadium oxyhydroxides containing V^{5+} and V^{4+} in a ratio of 2 to 1,[6] is of interest because of its layered structure and redox activity. Considerable efforts have been made on the synthesis of 1D nanostructures of vanadium oxide and their derivative compounds. For example, Pinna et al.[7,8] synthesized divanadium pentoxide nanorods and nanowires by a colloidal self-assembly made up of sodium bis(2-ethylhexyl)sulfosuccinate Na(AOT)/isooctane/H_2O. Nesper et al.[9] used neutral surfactant molecules such as primary aliphatic amines, together with vanadium alkoxide precursors to generate redox-active vanadium oxide nanotubes. Yu et al.[10] reported the synthesis of multicomponent $Na_2V_6O_{16}\cdot 3H_2O$ single-crystal nanobelts in the presence of F^- ions, however, without F^- ions or in the presence of other anions such as Cl^-, Br^-, NO_3^-, and SO_4^{2-}, nanobelts could not be obtained. Qian et al.[11] prepared single-crystal $VO_x\cdot nH_2O$ nanoribbons relying on the presence of polyethylene glycol 400, but the values of x and n are uncontrolled. Li et al.[12] reported that metastable vanadium dioxide single-crystal nanobelts were synthesized by hydrothermal synthesis using formic acid as the reducing agent. However, the synthesis of pure $H_2V_3O_8$ 1D nanostructures remains challenging to material scientists. In this paper, we report a low-cost and simple approach for the synthesis of $H_2V_3O_8$ single-crystal nanobelts by hydrothermal processing of bulky divanadium pentoxide (V_2O_5) powders in hydrochloric acid solution without the aid of any templates or reducing agents.

Results and Discussion

XRD patterns of the V_2O_5 precursor and $H_2V_3O_8$ nanobelts are shown in parts A, B of Figure 1, respectively. All the peaks in Figure 1 (see A) can be indexed to the orthorhombic crystalline phase of V_2O_5 in agreement with literature values (JCPDS 89–0612). After hydrothermal treatment, a pure orthorhombic crystalline phase of $H_2V_3O_8$ [space group: *Pnam*] (see B in Figure 1) with calculated lattice contents a = 16.99 Å, b = 9.40 Å, c = 3.64 Å, was obtained, which is consistent with literature values (JCPDS 85–2401). From the structural data, it is expected that the ratio of V^{5+} and V^{4+} in the product is 2 to 1, indicating that V^{5+} is reduced partly to V^{4+}.

Figure 2 shows SEM images of $H_2V_3O_8$ nanobelts synthesized at pH 4. Lower magnification SEM images (see A in Figure 2 and in the Supporting Information Figure 1S) reveal that the precipitates consist of a large quantity of uniform 1D nanostructures with typical lengths in the range of several tens to several hundreds of micrometers. The long fibrillar morphologies can even be seen with the naked eye. A magnified SEM image (B in Figure 2) indicates that the

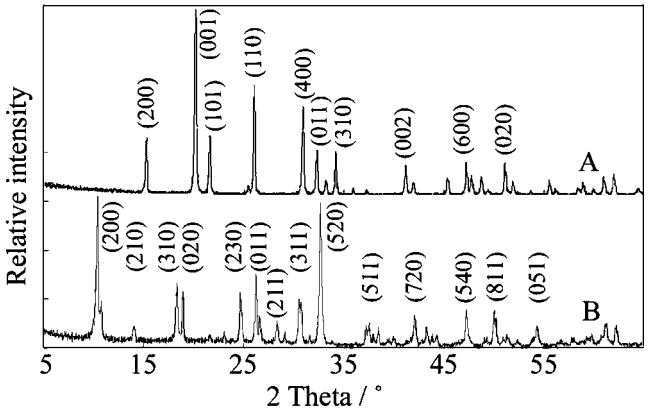

Figure 1. XRD patterns of the initial V_2O_5 precursor (A) and $H_2V_3O_8$ nanobelts synthesized at pH 4 (B).

geometrical shape of the $H_2V_3O_8$ nanostructures is a belt. The ends of these nanobelts are irregular. The typical thickness and width are less than 30 nm and 100–300 nm, respectively. In addition, some nanobelts have terraces of the different $H_2V_3O_8$ layers, indicating that some of the nanobelts stick together. The cleaved $H_2V_3O_8$ layers are clearly visible as indicated by an arrow in Figure 2 (C), so it can be inferred that the belt-like materials may be derived from the cleavage of $H_2V_3O_8$ layers in the reaction process. A typical TEM image of $H_2V_3O_8$ nanobelts is presented in Figure 2 (D). The width is consistent with SEM images (B in Figure 2). The ripple-like strain contrast can also be seen clearly in $H_2V_3O_8$ nanobelts. The selected area electron diffraction (SAED) pattern (E in Figure 2) taken from a single nanobelt indicated that the nanobelts are single crystals and the growth occurs along the [001] direction. The HRTEM image (F in Figure 2) shows the clearly-resolved interplaner distances d_{011} = 0.339 nm and d_{020} = 0.468 nm, which further confirms the growth direction of the nanobelts. The $H_2V_3O_8$ nanobelts are constructed from both VO_6 octahedra and VO_5 trigonal bipyramids. Two VO_6 octahedra are piled up along the *c* axis by sharing edges, which are connected by two-shared VO_5 trigonal bipyramids along the *b* axis, and then a V_3O_8 layer along the *a* axis is formed.[6] The layered structures composed of V_3O_8 layers seem to favor insertion and deinsertion of lithium for application in batteries.[13,14]

The pH value, reaction time, and temperature are important factors for the formation of $H_2V_3O_8$ nanobelts. The width of $H_2V_3O_8$ nanobelts can be controlled by adjusting the pH value. At pH 5, nanobelts with a width of 1 μm are obtained as shown in Figure 3 (A). The nanobelts can be folded without fracture, indicating that their flexibility is very high. At pH 3, the width of the nanobelts in Figure 3 (B) decreased to 90–110 nm. The reaction can proceed without the addition of any hydrochloric acid, but the reaction rate is very slow. It is found that the reaction rate increases when pH values decrease from 7 to 3 possibly because of the formation of various polyvanadate ions at different pH values in aqueous solution. When the reaction is carried out at pH 4 for 6 h, little green product is generated because of

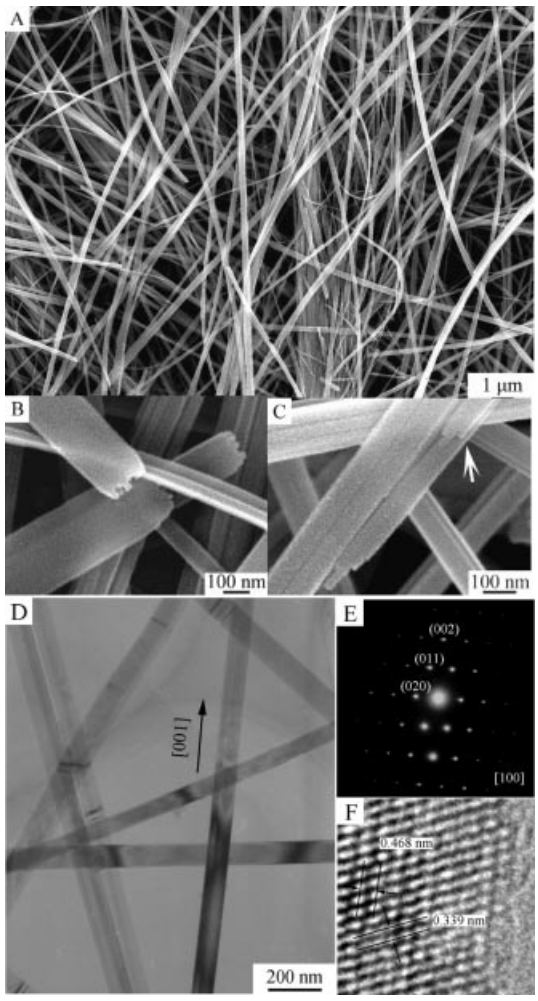

Figure 2. SEM (A, B, and C), TEM (D), and HRTEM (F) images of $H_2V_3O_8$ nanobelts synthesized at pH 4. Figure 2E shows the SAED pattern taken from a single nanobelt.

the inefficient reduction. With an increased reaction time, the color of the product changes from yellow to green. After hydrothermal treatment at pH 4 at 160 °C for 24 h, the reduction is also incomplete, so the nanobelts coexist with particles in the product (see Supporting Information, Figure 2S).

Figure 4 (A, B) present UV/Vis spectra of the initial V_2O_5 precursor and $H_2V_3O_8$ nanobelts synthesized at pH 4, respectively. Part B of Figure 4 shows a broad adsorption peak centered around 850 nm and a weak shoulder around 630 nm, corresponding to the *d–d* electronic transitions of V^{4+} in $H_2V_3O_8$ nanobelts,[15–17] so the product is green. In comparison with Figure 4 (A), the intensity of the adsorption peak of V^{4+} increases greatly, indicating the reduction of V^{5+} to V^{4+} during the course of hydrothermal treatment.

The reaction was carried out in the absence of any reducing agent, so V_2O_5 may undergo a redox reaction under hydrothermal conditions and it is difficult to completely reduce V_2O_5 to VO_2. The basic reaction process for the synthesis of $H_2V_3O_8$ nanobelts may be expressed as follows:

$$6\,V_2O_5 + 4\,H_2O \rightleftharpoons 4\,H_2V_3O_8 + O_2$$

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

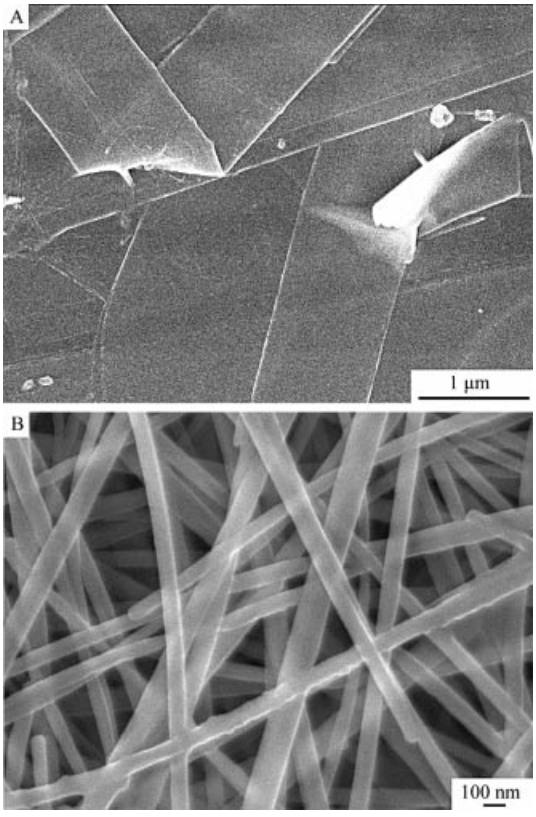

Figure 3. SEM images of $H_2V_3O_8$ nanobelts synthesized with different pH values. (A) at pH 5, (B) at pH 3.

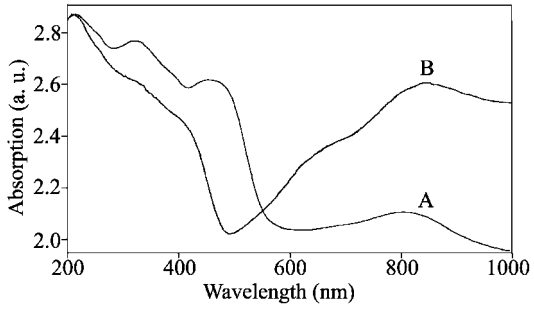

Figure 4. UV/Vis spectra of the initial V_2O_5 precursor (A), and $H_2V_3O_8$ nanobelts synthesized at pH 4 (B).

The redox reaction process is free of any templates and surfactants, so it is supposed that the formation of the belt-like $H_2V_3O_8$ is probably related to the layered structure of $H_2V_3O_8$. V_2O_5 partly dissolves in water to produce various polyvanadate ions at different pH values in aqueous solution, which can undergo a redox reaction to form $H_2V_3O_8$ clusters under hydrothermal conditions. Then, the $H_2V_3O_8$ clusters serve as the sites for the heterogeneous nucleation of the nanobelts, which subsequently crystallize along the [001] direction of $H_2V_3O_8$ single crystals and grow in belt-like structures through a topotactic transformation mechanism.

Conclusions

In conclusion, we have demonstrated a facile route to the synthesis of $H_2V_3O_8$ nanobelts. The synthetic process is free of any templates and reducing agents. The thickness and length of $H_2V_3O_8$ nanobelts are less than 30 nm, and up to several hundreds of micrometers, respectively. The width of $H_2V_3O_8$ nanobelts can be controlled by adjusting the pH values. The belt-like $H_2V_3O_8$ with a high surface area may be beneficial to lithium insertion between the V_3O_8 layers for application in batteries.

Experimental Section

An optimized procedure for the synthesis of $H_2V_3O_8$ single-crystal nanobelts is described as follows: V_2O_5 powder (0.15 g) was dispersed into distilled water (40 mL). Then, an appropriate amount of hydrochloric acid was added dropwise to the orange mixture to adjust pH values in the range of 3–5. The slurry solution was placed in a 50-mL autoclave with a Teflon liner after ultrasonic vibration for 10 min. The autoclave was maintained at 190 °C for 24 h and then air cooled to room temperature. The green precipitate was collected and washed with distilled water and anhydrous alcohol several times, and then dried in vacuo at 60 °C for 10 h. The yield of the $H_2V_3O_8$ nanobelts is estimated to be higher than 90%.

The crystal structures of the initial V_2O_5 precursor and the resulting product were characterized by an X-ray diffractometer (Rigaku D-max-γA XRD with Cu-K_α radiation, λ = 1.54178 Å). The morphologies and sizes of the resulting products were observed by field-emission scanning electron microscopy (FE-SEM, JSM 6700F) and high-resolution transmission electron microscopy (HRTEM, JEOL 2010), respectively. The optical properties of the initial V_2O_5 precursor and the resulting product were determined by UV/Vis spectroscopy (Cary 500 UV/Vis-NIR spectrophotometer).

Oxalate-Based 3D Chiral Magnets: The Series $[Z^{II}(bpy)_3][ClO_4][M^{II}Fe^{III}(ox)_3]$ (Z^{II} = Fe, Ru; M^{II} = Mn, Fe; bpy = 2,2′-Bipyridine; ox = Oxalate Dianion)

Keywords: Coordination chemistry / Molecular materials / Magnetic properties / Mössbauer spectroscopy

The synthesis, structure, and physical properties of the oxalate-based molecular magnets with the formula $[Z^{II}(bpy)_3][ClO_4][M^{II}Fe^{III}(ox)_3]$ (Z^{II} = Fe, Ru; M^{II} = Mn, Fe; bpy = 2,2′-bipyridine; ox = oxalate dianion) are presented here. All compounds are isostructural and crystallize in the chiral cubic space group $P4_132$, and contain three-dimensional dimetallic networks formed by alternating M^{II} and M^{III} ions that are connected by oxalate anions. These compounds exhibit strong antiferromagnetic interactions that give rise to magnetic ordering as ferrimagnets or weak ferromagnets, with critical temperatures of up to 20 K, which is twice as high as those found for the isostructural magnets based on Cr^{III}, as determined by magnetic measurements and Mössbauer spectroscopy.

Introduction

Coordination chemistry has yielded many examples of molecule-based magnets. The nature of the ligands, responsible for promoting strong enough magnetic exchange, will be key for the physical properties found in these novel compounds. Most of these magnets are based on coordination polymers with metal centers that are connected by short ligands with a π-extended system such as cyanide,[1] dicyanamide[2–4], oxalate[5–7] and some other organic ligands.[8]

Polynuclear complexes from the oxalato ligand have been shown to be very versatile for the construction of magnetic materials, with one of the key reasons being the synthetic control over the lattice dimensionality. This has been demonstrated with the controlled obtention of dimers,[9] trimers,[10] 1D chains,[11] and extended 2D[5,6] and 3D lattices[12,13] from essentially the same building blocks. Interestingly, some of these coordination polymers are anions that form salts with a variety of molecular cations.

Bulky organic monocations promote the synthesis of compounds with the formula $[A][M^{II}M^{III}(ox)_3]$ ($A = NR_4^+$, PPh_4^+; M^{II} = Mn, Fe, Co, Ni, Cu; M^{III} = Cr, Fe, Ru, Rh),[5,6,14–16] formed by two-dimensional oxalate bridged dimetallic networks. The sign of the magnetic interaction is determined by the nature of the metals – Cr^{III} and Ru^{III} promote ferromagnetic interactions, while Fe^{III} promotes antiferromagnetic interactions. These materials behave as ferromagnets with critical temperatures of up to 15 K, and as ferri- or weak ferromagnets with critical temperatures of up to 44 K. The combination of different trivalent metals in the 2D lattice has given rise to materials with tunable magnetic properties, and large hysteresis loops with coercive fields of over 2 T.[17] On the other hand, insertion of electroactive organometallic or organic molecules in these 2D systems has yielded magnetic multilayers,[18] ferromagnetic metals,[19,20] or photochromic magnets.[21]

Chiral octahedral complexes of the type $[Z(bpy)_3]^{2+}$ (bpy = 2,2′-bipyridine) and analogs favor the formation of the series $[Z^{II}(bpy)_3][ClO_4][M^{II}M^{III}(ox)_3]$ (Z^{II} = Ru, Fe, Co, Ni; M^{II} = Mn, Fe, Co, Ni, Cu; M^{III} = Cr),[12] formed by three-dimensional chiral oxalate-based networks that behave as ferromagnets, but with critical temperatures that are much lower than those of their 2D counterparts. This has been related to the weaker magnetic interactions present in this case, promoted by a different relative orientation of the magnetic orbitals and to larger metal-to-metal distances. Most of these compounds show T_c below 3 K, with a few exceptions that reach up to 6 K.

The added value of these 3D magnets is their chirality, especially as the crystallites are chiral through self-assembly, even starting from a racemic mixture of building blocks. This family constitutes a nice example of chiral magnets, a very sought after combination in recent years[22–24] because of the interest in the investigation of how chirality affects the magnetic properties: it is easy to understand that the imposed anisotropy in such systems will be a key factor that controls the magnetic behavior, but

further, that these systems could also exhibit new physical phenomena, for example, the so-called magnetochiral dichroism.[25]

While the dimetallic 2D magnets have been obtained with a variety of trivalent metals, the analogous 3D systems have only been obtained so far for Cr^{III}. The reason is that the synthetic conditions required for the preparation of the 3D systems are much more exigent. For instance, the presence of alkali metals in solution needs to be avoided, since alkali metals can also form 3D networks with trivalent metals with the general formula $[Z^{II}(bpy)_3][A^IM^{III}(ox)_3]$ (Z^{II} = Ru, Fe, Co, Ni; A^I = Li, Na, K; M^{III} = Cr).[26] These materials have shown interesting electronic properties, such as photoinduced energy transfer, electron transfer,[27] and spin transition in one case, namely $[Co(bpy)_3][LiCr(ox)_3]$,[28,29] but no magnetic ordering since the paramagnetic centers are isolated by diamagnetic alkali neighbors. In addition, more synthetic difficulties need to be overcome, as the trisoxalate complexes are less stable towards ligand substitution. In this work, we present our successful extension of this series to the $[Fe^{III}(ox)_3]^{3-}$building block while searching for increased ordering temperatures for these magnets, as observed in the 2D analogs.

Results and Discussion

Synthesis and Structure

For the synthesis of the desired $[M^{II}M^{III}(ox)_3]^-$ 3D network, the possible formation of the 3D $[A^IM^{III}(ox)_3]^{2-}$ analog, where A^I is an alkali metal or a small cation such as NH_4^+, is one of the main synthetic problems to overcome. Thus, the common $A_3[M^{III}(ox)_3]$ salts cannot be used in this synthesis. Bulky cations cannot be used either, since they template the formation of the corresponding 2D honeycomb networks. To form the 3D $[M^{II}Cr^{III}(ox)_3]^-$ network we already described the use of the silver salt $Ag_3[Cr^{III}(ox)_3]$. The same procedure, however, cannot be used to prepare the $M^{II}Fe^{III}$ derivatives since the $Ag_3[Fe(ox)_3]$ salt is unstable. Thus, we used an analogous procedure, but starting from the slightly more soluble $Tl_3[Fe(ox)_3]$ salt that allows for the precipitation of TlCl, and for the preparation of the desired solution containing the M^{II} and $[Fe(ox)_3]^{3-}$ building blocks exclusively. The mixture of this solution with one containing $[Z^{II}(bpy)_3][ClO_4]_2$ yields a fine powder that must be settled before filtering. Particle sizes are typically uniform and of the order 0.5–3 μm.

Even under these conditions not all possible Z/M^{II} combinations that may be suitable for the formation of oxalate complexes could be obtained, as the $[Fe(ox)_3]^{3-}$ complex is not completely stable in solution when competing with other cations. Because of this reason, the nature of the solvent mixture and temperature are crucial to obtain pure products, and even under such circumstances, some disorder between the alternating positions for trivalent and divalent metals in the network cannot be avoided in some cases, as will be discussed in this paper.

All compounds were structurally characterized by powder X-ray diffraction, which indicates that all compounds are isostructural as the salt $[Ru^{II}(bpy)_3][ClO_4][Mn^{II}Cr^{III}(ox)_3]$ already reported.[12] The structure of these salts consists of 3D oxalate-bridged dimetallic networks that host the cations $[Z^{II}(bpy)_2]^{2+}$ (Figure 1). In the anionic network, the bidentate chelating oxalate ligands connect the metals in an alternating way such that each M^{II} center is surrounded by three M^{III} centers and vice versa, to form 10-unit rings with a (10,3) topology. In a given crystal, all metal centers are of the same chirality, although crystallites of both chiralities are obtained when starting from racemic mixtures of the reagents, as in the compounds prepared for this study. The cations $[Z^{II}(bpy)_3]^{2+}$ of each chiral group template the formation of the corresponding chiral network, and are located in the tunnels left by the polymeric structure. Perchlorate anions fill up the remaining holes in the structure.

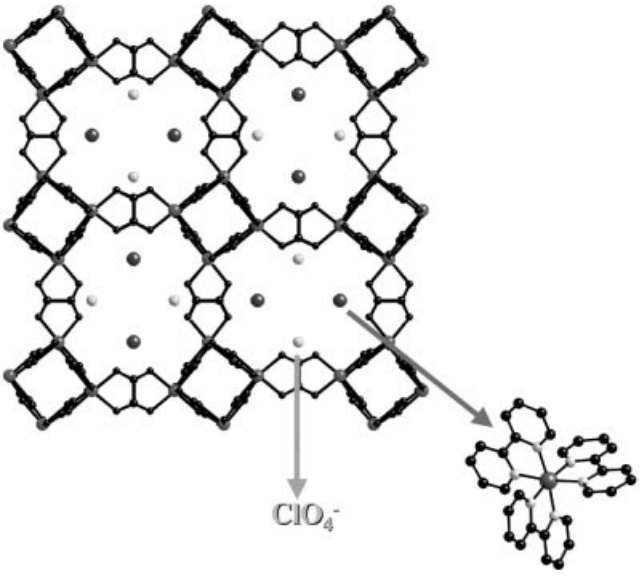

Figure 1. Projection on the *bc* plane of the structure of the family of molecule-based magnets $[Z^{II}(bpy)_3][ClO_4][M^{II}M^{III}(ox)_3]$. Only the Z^{II} ion of the $[Z^{II}(bpy)_3]^{2+}$ cations and the Cl atom of the ClO_4^- anions are drawn in the cavities.

Magnetic Properties

Magnetic susceptibility measurements for the $[Fe^{II}(bpy)_3][ClO_4][M^{II}Fe^{III}(ox)_3]$ derivatives (M^{II} = Mn, Fe) are shown in Figure 2. Both compounds present a clear decrease in the $\chi_m T$ product as the temperature is decreased. This high-temperature regime follows a Curie–Weiss law, and gives Curie constants slightly higher than that expected for spin-only, and large and negative Weiss constants (Table 1), which is indicative of the presence of antiferromagnetic interactions between the metal centers in the network, as is expected for oxalate-bridged dimetallic M^{II}-Fe^{III} compounds. The variation of χ_m with temperature shows a deviation from the regular paramagnetic behavior at low temperatures for both compounds –a jump appears below

Z^{II}	M^{II}	T_c [K]	θ [K]	C [emu K mol^{-1}]	$C_{spin\text{-}only}$ [emu K mol^{-1}]	$H_{coer.}$ [mT]
Fe	Mn	20.0	–58	9.53	8.75	25
Fe	Fe	9.1	–41	7.67	7.375	97
Ru	Mn	17.2	–81	9.46	8.75	30
Ru	Fe	7.9	–46	7.67	7.375	86

[a] T_c, ordering temperature; θ, Weiss constant; C, Curie constant; $H_{coer.}$, coercive field at 2 K.

25 K for Mn^{II} (Figure 2 bottom) and below 12 K for Fe^{II}. After this jump, χ_m does not tend to saturation at very low temperatures in either compound, showing a Curie tail probably because of the presence of small amounts of paramagnetic impurities. These features suggest the appearance of a magnetically ordered regime. This was confirmed by the temperature dependence of the AC magnetic susceptibility (Figure 3), that shows, in both cases, a maximum in χ'_m that corresponds to a peak in χ''_m, with T_c (when χ''_m becomes non zero) at 20.0 K for the Mn derivative and 9.1 K for the Fe derivative. Due to the nature of the short-range interactions in both cases, the Mn^{II} derivative can be considered to be a weak ferromagnet, and the origin for net magnetization comes from canting between the antiferromagnetically aligned $S(Mn^{II}) = S(Fe^{III}) = 5/2$ moments, while the Fe^{II} derivative can be considered to be a ferrimagnet, because of the non total compensation of the antiferromagnetically coupled spins $S(Fe^{III}) = 5/2$ and $S(Fe^{II}) = 2$. In this last compound, a small frequency dependence of the AC peaks is observed, similar to those observed in the analogous 2D network. As in these cases, such a feature can be associated to a disorder in the magnetic 3D network generated by partial substitution of the Fe^{II} centers by Fe^{III}, and vice versa. The field dependence of the magnetization at 2 K for both compounds (Figure 4) shows an almost linear increase, and is far from saturation even at 5 T, confirming the nature of the magnetic ordering. Both compounds show small hysteresis loops at 2 K with coercive fields of 25 (Mn^{II}) and 97 mT (Fe^{II}).

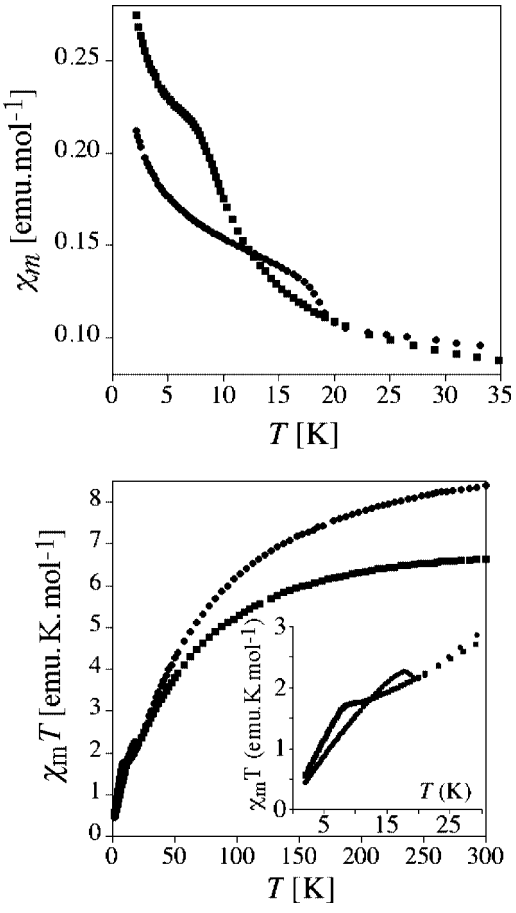

Figure 2. Thermal variation of the magnetic susceptibility χ_m (top) and of the $\chi_m T$ product (bottom) for the salts $[Fe(bpy)_3][ClO_4][M^{II}Fe(ox)_3]$; M^{II} = Mn (circle), Fe (square).

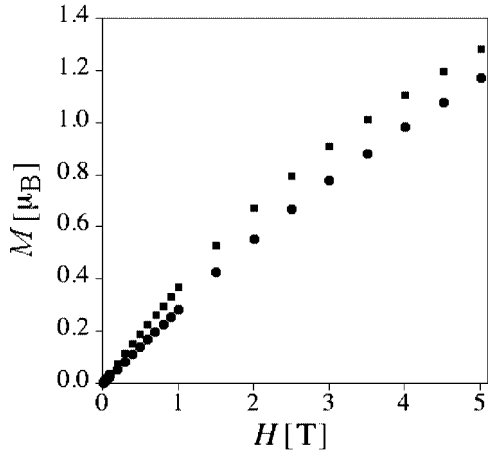

Figure 4. Field dependence of the magnetization at 2 K for the salts $[Fe(bpy)_3][ClO_4][M^{II}Fe(ox)_3]$; M^{II} = Mn (circle), Fe (square).

The $[Ru^{II}(bpy)_3]^{2+}$ derivatives show, as expected, an analogous magnetic behavior, with magnetic parameters very similar to those of the $[Fe^{II}(bpy)_3]^{2+}$ counterparts (see Table 1). The critical temperatures, however, are slightly lower for these derivatives. As mentioned before, this effect of the templating cation on the magnetic properties was also observed in the Cr^{III} derivatives, and works here in the same direction. The AC magnetic susceptibility measurements (Figure 5) show ordering temperatures at 17.2 K for Mn^{II} and 7.9 K for Fe^{II}. The Mn^{II} salt shows a small maximum in χ'_m after the peak, unseen in the rest of materials. This feature has no frequency dependence and no clear origin. As seen before, the Fe^{II} salt shows a small frequency dependence of the peaks. Both compounds show hysteresis loops below T_c, with coercive fields and field dependence of the magnetization at 2 K, which is almost identical to those of their $[Fe^{II}(bpy)_3]^{2+}$ counterparts. The weaker magnetic exchange when going from $[Fe^{II}(bpy)_3]^{2+}$ to $[Ru^{II}(bpy)_3]^{2+}$ has been explained in terms of the different size of the cations, which leads to larger unit cells, and therefore larger intermetallic distances; an effect that obviously influences the magnetic properties.

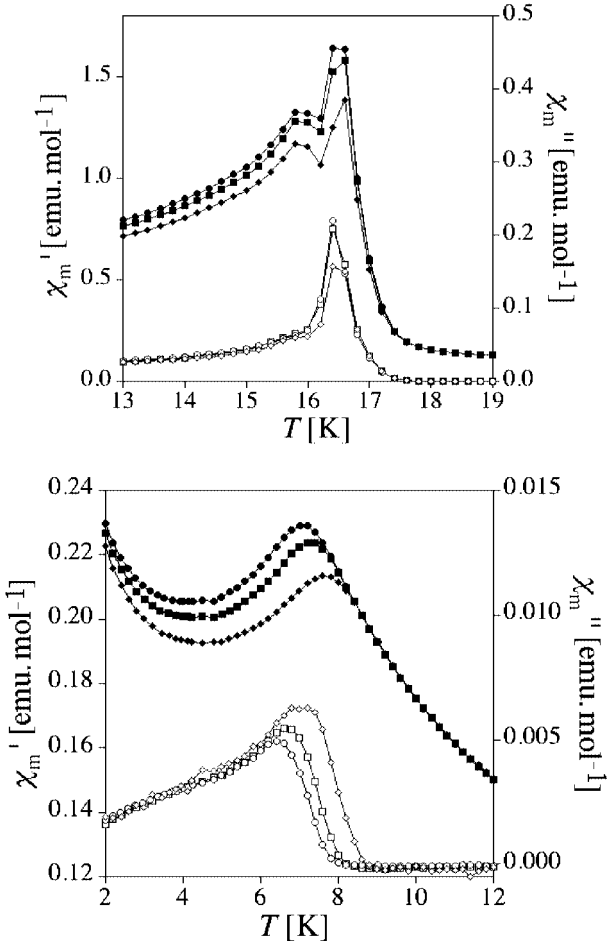

Figure 5. Frequency dependence of the in-phase (filled symbols, χ'_m) and out-of-phase (empty symbols, χ''_m) AC magnetic susceptibility for the salts $[Ru(bpy)_3][ClO_4][M^{II}Fe(ox)_3]$ at 1 (circle), 10 (square) and 332 Hz (diamond); M^{II} = Mn (top), Fe (bottom).

Mössbauer Spectroscopy

Mössbauer spectra of $[Fe(bpy)_3]ClO_4[MnFe(ox)_3]$ were taken at 100 and 6 K (Figure 6). At 100 K, the spectrum consists of three different doublets whose estimated parameters, isomer shift, δ, and quadrupole splitting, Δ, (Table 2), are typical of low-spin (LS) Fe^{II} in a $[Fe(bpy)_3]^{2+}$ complex, of high-spin (HS) Fe^{III} within the anionic oxalate net, and of HS Fe^{II} in the same oxalate net. This HS Fe^{II} is certainly due to impurities in the sample. Incorporation of Fe^{II} into the anionic network was already observed in similar $[Fe(bpy)_3][Mn_2(ox)_3]$ compounds.[32] The spectrum at 6 K (Figure 6) shows a doublet due to LS Fe^{II} in the $[Fe(bpy)_3]^{2+}$ complex (Table 2), a sextet with broad peaks attributed to HS Fe^{III} and a third set of low-intensity peaks. The HS Fe^{III} contribution is a sextet because the relaxation frequency of the corresponding Fe spins strongly decreases between 100 K and 6 K, and becomes significantly lower than the Larmor period of the nuclear moment. This is a strong indication that the $[MnFe(ox)_3]^-$ net is magnetically ordered at 6 K, which is in agreement with the T_c value deduced from magnetization data. It should be noted that LS Fe^{II} in the $[Fe(bpy)_3]^{2+}$ complex remains unaffected by the internal magnetic field.

[a] δ, isomer shift relative to metallic α-Fe at 295 K; Δ, quadrupole splitting in the paramagnetic state; Δ' and ε, quadrupole interaction and quadrupole shift in the magnetically ordered state for Fe^{II} and Fe^{III}, respectively; B_{hf}, magnetic hyperfine field; η, asymmetry parameter; Θ and Φ, angles between B_{hf} and the main axis V_{zz} of the electric field gradient and between B_{hf} and the main axis V_{xx}; %, percentage of the total area corresponding to each subunit. Estimated errors are $\leq$0.02 mm s^{-1} for δ, Δ, Δ' and <0.2 T for B_{hf}. Values of Θ, Φ and η, kept constant during the fitting procedure, are those corresponding to the best final adjustments.

Considering the 100 K spectrum, the third set of low-intensity peaks observed at 6 K is most likely due to the HS Fe^{II} impurities in the oxalate net. These Fe^{II} atoms are also magnetically ordered. However, as previously shown,[14] their contribution cannot be fitted assuming a simple magnetic sextet. In fact, the quadrupole hyperfine interaction cannot be treated as a perturbation of the magnetic hyperfine interaction. The position and relative intensities of the absorption lines of the magnetically ordered HS Fe^{II} atoms therefore have to be calculated by solving the complete Hamiltonian for the hyperfine interactions in both the excited and ground nuclear states of the ^{57}Fe nuclei. In the present work, this calculation was performed following the procedure described by Ruebenbauer and Birchall.[30] The best fit was obtained assuming that the angle between B_{hf} and the main axis of the electric field gradient, V_{zz}, is Θ = 90, and between V_{xx} and B_{hf} is Φ = 0. The final values obtained for the fitted parameters, δ, B_{hf}, the asymmetry parameter η, and $\Delta' = e^2QV_{zz}$ (where e is the electron charge and Q is the ^{57}Fe nuclear quadrupole moment at the 14.4 keV level), are given in Table 2. The estimated parameters obtained are indeed consistent with a HS Fe^{II} atom and similar to those reported for compounds containing $[Fe^{II}(ox)_{3/2}]^-$ units.[14,31] The random substitution of Mn^{II} by these Fe^{II} impurities within the oxalate network gives rise to different environments for the HS Fe^{III} atoms. Differences in the magnetic exchange interactions, which correspond to distinct environments, may be large enough to be observed as a distribution of B_{hf}. This distribution, approximately described by two sextets, whose parameters are summarized in Table 2, explains the broadness of the observed peaks due to the HS Fe^{III} atoms in the oxalate layers and the small frequency dependence of the χ'' peak observed in the AC susceptibility data.

The relative areas estimated for LS Fe^{II} and HS Fe^{III} change significantly between 100 K and 6 K. This fact had already been observed in $[Fe(bpy)_3][M^{II}_2(ox)_3]$ (M = Mn, Fe) compounds that also contained HS Fe^{II} impurities.[32] It may be explained by the different temperature dependence of the Debye–Waller factors for LS Fe^{II} and HS Fe^{III}. Considering that the values of these factors are closer at the lowest temperatures, the relative areas estimated at 6 K are a better approximation to the relative amounts of the different Fe species in the sample. This implies that the HS Fe^{II} impurities that substitute Mn^{II} in the oxalate layers are approximately 10% of the total Fe in the present $[Fe(bpy)_3][ClO_4][MnFe(ox)_3]$ sample; a value similar to those reported for the $[Fe(bpy)_3][M^{II}_2(ox)_3]$ salts.[32]

The Mössbauer spectra of $[Fe(bpy)_3][ClO_4][FeFe(ox)_3]$ at 294 K and 100 K (Figure 7) consist of three doublets attributed to LS Fe^{II} in $[Fe(bpy)_3]^{2+}$, HS Fe^{III} and HS Fe^{II} in the inorganic network (see estimated parameters for $[Fe(bpy)_3][ClO_4][FeFe(ox)_3]$ and $[Fe(bpy)_3][ClO_4][MnFe(ox)_3]$ in Table 2 and Table 3). At 6 K, the spectrum shows that the HS Fe^{III} and HS Fe^{II} atoms in the inorganic network have a slow relaxation, which is consistent with the magnetic ordering of these Fe species and in agreement with the magnetic data. As in the case of $[Fe(bpy)_3][ClO_4[MnFe(ox)_3]$, LS Fe^{II} in $[Fe(bpy)_3]^{2+}$ remains unaffected by the internal

[a] Parameters as defined in Table 2.

magnetic field. The relative areas estimated for HS Fe^{III} and Fe^{II} at 6 K suggest that in $[Fe(bpy)_3][ClO_4][FeFe(ox)_3]$, there is an excess of HS Fe^{II} that could replace HS Fe^{III} in random positions in the oxalate layer. This disorder may be responsible for the observation of a distribution of B_{hf} for HS Fe^{III}, again approximated by two magnetic sextets with large peak widths, as in $[Fe(bpy)_3][ClO_4][MnFe(ox)_3]$. Furthermore, the same disorder may explain why acceptable fits of the 6 K spectrum could only be obtained if a doublet corresponding to paramagnetic HS Fe^{II} was considered in addition to the main magnetically ordered contribution of this Fe species (Table 3). In fact, the disorder resulting from the presence of excess HS Fe^{II} may be associated with the existence of small fractions of these ions that experience rapidly fluctuating B_{hf} even at temperatures lower than T_c (although still close to T_c).

Conclusions

In this paper we have demonstrated that 3D chiral molecular magnets based on dimetallic oxalate complexes can be prepared from the $[Fe(ox)_3]^{3-}$ building block given the right synthetic conditions and with the use of different $[Z^{II}(bpy)_3]^{2+}$ complexes (Z^{II} = Fe, Ru) as templating cations. The salts $[Z^{II}(bpy)_3][ClO_4][M^{II}Fe^{III}(ox)_3]$ (M^{II} = Mn, Fe) are isostructural to the $[Cr(ox)_3]^{3-}$-based ferromagnets and are of identical stoichiometry, while the different sign and strength of the magnetic exchange promoted by the presence of Fe^{III} instead of Cr^{III} yields quite different magnetic properties. As these compounds exhibit strong antiferromagnetic interactions, they behave as ferrimagnets (M^{II} = Fe) or weak ferromagnets (M^{II} = Mn) with critical temperatures in the range 7–20 K, which are much higher than those observed for the analogous ferromagnets, in which the ordering only occurred close to 2 K. This fact must be important in the future studies that investigate the interplay between magnetism and chirality.

Another consideration that needs to be stressed is the effect of the nature of the $[Z^{II}(bpy)_3]$ complex on the magnetic properties. With the same crystal structure, the different sizes of the cations promote an enlargement of the unit cell parameters by 0.2 Å. Such small differences are enough to provoke a change of a few degrees in T_c, as seen in this and other cases. This suggests that hydrostatic pressure should also be able to affect the magnetic properties in these materials. Thus, magnetic measurements under pressure are in progress.

Experimental Section

Synthesis: The complexes $[Z^{II}(bpy)_3]^{2+}$ (Z^{II} = Ru, Fe) were prepared according to literature methods.[33,34] The precursor salt $Tl_3[Fe(ox)_3]\cdot nH_2O$ was prepared by metathesis from the corresponding potassium salt.[35] All other materials and solvents were commercially available and used without further purification.

$[Z^{II}(bpy)_3][ClO_4][M^{II}Fe^{III}(ox)_3]$ (Z^{II} = Fe, Ru; M^{II} = Mn, Fe): $M^{II}Cl_2$ (1.56 mmol) was added in excess to a water solution (10 mL) of $Tl_3[Fe(ox)_3]\cdot nH_2O$ (0.3 g, 0.31 mmol). After stirring for 10 min, a white precipitate of TlCl was removed by filtration. DMF (20 mL) was added to this green solution, which then turned yellow, and this mixture was added dropwise to a DMF (15 mL) solution of $[Z^{II}(bpy)_3][ClO_4]_2$ (0.4 mmol). After stirring for 30 min, the mixture was cooled down to 5 °C overnight. The product was isolated by filtration with use of a vacuum, washed thoroughly with methanol and acetone, and dried at room temperature.

FeMnFe: Yield 61% (183 mg). $C_{36}H_{24}ClFe_2MnN_6O_{16}$ (998.70): calcd. C 43.30, H 2.42, N 8.42; found C 43.18, H 2.30, N 8.35.

FeFeFe: Yield 55% (165 mg). $C_{36}H_{24}ClFe_3N_6O_{16}$ (999.61): calcd. C 43.36, H 2.42, N 8.41; found C 42.95, H 2.11, N 8.10.

RuMnFe: Yield 75% (235 mg). $C_{36}H_{24}ClFeMnN_6O_{16}Ru$ (1043.92): calcd. C 41.42, H 2.32, N, 8.05; found C 41.20, H 2.22, N 7.99.

RuFeFe: Yield 80% (251 mg). $C_{36}H_{24}ClFe_2N_6O_{16}Ru$ (1044.87): calcd. C 41.38, H 2.32, N 8.04; found C 40.93, H 2.12, N 7.80.

Structural Characterization: X-ray powder profiles were collected with a Siemens D-500 X-ray diffractometer (Cu-K_α radiation, λ_α = 1.54184 Å) at 293(2) K. Samples were grounded and mounted on a flat sample plate. Typically, profiles were collected as step scans over a 12 h period in the $2 < 2\theta < 60$ range with a step size of 0.02. The powder diffraction profiles indicate that all compounds are isostructural and show analogous patterns to the simulated profile[36] from the atomic positional parameters of the published crystal structure of $[Ru(bpy)_3][ClO_4][MnCr(ox)_3]$,[12] which has the cubic space group $P4_132$ (see Supporting Information). of the main reflections[37] gave the unit cell parameters shown in Table 4.

Table 4. Crystallographic data for the salts $[Z^{II}(bpy)_3][ClO_4]$-$[M^{II}M^{III}(ox)_3]$.

$Z^{II}M^{II}M^{III}$	a [Å]	V [Å^3]
FeMnFe	15.39(3)	3645(1)
FeFeFe	15.33(2)	3603(1)
RuMnFe	15.48(4)	3709(1)
RuFeFe	15.44(4)	3681(1)

Magnetic Measurements: Magnetic susceptibility measurements were performed on polycrystalline samples with a Quantum Design MPMS-XL-5 susceptometer equipped with a SQUID sensor. The susceptibility data were corrected from the diamagnetic contributions as deduced by using Pascal's constant tables. DC data were collected in the range 2–300 K with an applied field of 0.1 T, and hysteresis loops were collected between –5 and +5 T at 2 K. AC data were collected in the range 2–30 K with an applied alternating field of 0.395 mT at different frequencies in the range 1–997 Hz.

Mössbauer Spectroscopy: ^{57}Fe Mössbauer measurements were recorded in transmission mode with a conventional constant acceleration spectrometer and a 25-mCi ^{57}Co source in Rh matrix. The velocity scale was calibrated by using an α-Fe foil at room temperature. Isomer shift values are given relative to this standard. Spectra were collected with the absorbers between 296 K and 5 K. Low-temperature measurements were obtained with a flow cryostat (temperature stability 0.5 K). The spectra were fitted to Lorentzian lines by using a non-linear least-squares fitting method as described previously.[38]

Preparation and Crystal Structures of Benzoylhydrazido- and -diazenidorhenium Complexes with N,O-Ligands and Their Catalytic Activity Towards Peroxidative Oxidation of Cycloalkanes

Alexander M. Kirillov,[a] Matti Haukka,[b] M. Fátima C. Guedes da Silva,[a,c] and Armando J. L. Pombeiro*[a]

Keywords: Alkanes / Homogeneous catalysis / N,O ligands / Oxidation / Rhenium

The η^2-(benzoylhydrazido)rhenium(V) complex [Re{$(OCH_2CH_2)_2N(CH_2CH_2OH)$}{N=NC(O)Ph}$(PPh_3)$] (**2**) and the η^1-(benzoyldiazenido)rhenium(III) compounds [ReCl{$N(CH_2COO)(CH_2CH_2OH)(CH_2CH_2OH)$}{N=NC(O)Ph}$(PPh_3)$] (**3**) and [ReCl(*O*,*N*-L){N=NC(O)Ph}$(PPh_3)_2$] [*O*,*N*-L = N(=O)-CH_2COO (**4**), HN=C(Me)COO (**5**), $C_5H_4N(COO)$ (**6**)], with chelating N,O-ligands (amino alkoxides, amino-, oxyamino-, imino- and pyridinocarboxylates) have been prepared by treatment of [$ReCl_2${N=NC(O)Ph}$(PPh_3)_2$] (**1**) with triethanolamine [$N(CH_2CH_2OH)_3$], *N*,*N*-bis(2-hydroxyethyl)glycine [$N(CH_2CH_2OH)_2(CH_2COOH)$], *N*-hydroxyiminodiacetic acid [$HON(CH_2COOH)_2$], *N*-hydroxy-2,2′-iminodipropionic acid [$HON\{CH(Me)COOH\}_2$] and picolinic acid (NC_5H_4COOH-2), respectively. The N,O-ligands in **4** and **5** result from fragmentation of the *N*-hydroxyiminodicarboxylic acids. All the complexes have been characterized by IR, ^1H and ^{13}C NMR spectroscopy, FAB$^+$-MS, elemental analysis and X-ray diffraction structural analysis, which indicate a π-delocalized chelated benzoylhydrazidorhenium ring in **1** and **2**, and, in the other complexes, an essentially linear η^1-diazenido ligand that is always *trans* to the O-coordinated carboxylate moiety of the N,O-ligand. The complexes act as catalysts (TON values up to about 45) for peroxidative oxidation, by radical mechanisms, of cyclohexane and cyclopentane to the corresponding alcohols and ketones, under mild conditions (room temperature, use of aqueous H_2O_2 and without added acid). This is an unprecedented use of inorganic Re coordination compounds as catalysts in alkane functionalization.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

The coordination chemistry of rhenium[1] is a field of current growing interest from various viewpoints, especially for improving fundamental knowledge (e.g. on structural and physicochemical properties and on reactivity) and in topics with an applied character such as the development of diagnostic/radiotherapeutic cancer agents,[2,3] nitrogen fixation (a good number of Re dinitrogen and formally derived organodiazo-type complexes are known)[4–13] and catalysis.[14–24]

For the synthesis of diazenido and dinitrogen complexes with phosphorus-containing coligands, the benzoylhydrazide complex [$ReCl_2${N=NC(O)Ph}$(PPh_3)_2$] (**1**) is a key starting material,[25–28] but its use as a precursor for complexes with N-based coligands is still very rare and is usually limited to amines.[29–31] Hence, one of the aims of this work is to extend the application of complex **1** to the synthesis of benzoyldiazenido complexes with coligands of the latter type.

Another objective of this study is to find catalytic applications of such complexes, thus providing a contribution towards widening the field of catalysis with inorganic coordination compounds of rhenium, which still remains little explored.[32–41] This contrasts with the recently discovered catalytic behaviour of high-valent organorhenium oxides,[14–24] in particular the methyltrioxide [$(Me)ReO_3$], whose catalytic behaviour has been extensively studied for a variety of processes, such as epoxidation and hydroxylation of olefins, oxidation of alkynes, aromatic hydrocarbons, sulfides, amines, silanes, alcohols and ketones, and cyclization reactions.

As the catalytic reaction to be tested, we chose the oxidation of cyclohexane and of cyclopentane to the corresponding alcohols and ketones, as examples with industrial significance within the challenging field of functionalization of alkanes.[42–47] In fact, the cyclohexanol/cyclohexanone mixture is used[42,48–50] for the synthesis of adipic acid, Nylon-6,6′, polyamide-6 and urethane foams and as an acidulant in baking powder and lubricating additives, whereas cyclopentanol and cyclopentanone are used[51–57] in the

preparation of perfumes, dibasic carboxylic acids, dyes and liquid herbicide compositions. We have previously found that the peroxidative oxidation of cyclohexane and cyclopentane to those products is catalyzed by some vanadium(IV) or (V) complexes with N,O-ligands,[58] as well as by heteronuclear iron(III)–chromium(III) hydroxo complexes and hydroxides.[59]

For the current study, as sources of N-ligands we have addressed N,O-types (or related compounds) that we have used for the preparation of vanadium catalysts for alkane functionalization reactions, namely peroxidative hydroxylation, oxygenation and halogenation,[58] and carboxylation.[60] They are the amino alcohol $N(CH_2CH_2OH)_3$, the glycine derivative $N(CH_2CH_2OH)_2(CH_2COOH)$, picolinic acid ($NC_5H_4COOH$-2), *N*-hydroxyiminodiacetic acid [$HON(CH_2COOH)_2$, HIDA] and *N*-hydroxy-2,2′-iminodipropionic acid [$HON\{CH(Me)COOH\}_2$, HIDPA].

Hence, we report herein the synthesis and characterization, including the crystal structures, of a series of new benzoylhydrazido- and -diazenidorhenium complexes with these, or derived, chelating N,O-ligands, as well as their catalytic activity for the peroxidative oxidation under mild conditions (room temperature, aqueous H_2O_2 and without added acid) of cyclohexane and cyclopentane to the corresponding alcohols and ketones, which, to the best of our knowledge, is the first example of such a type of alkane functionalization with Re coordination compounds as catalysts.

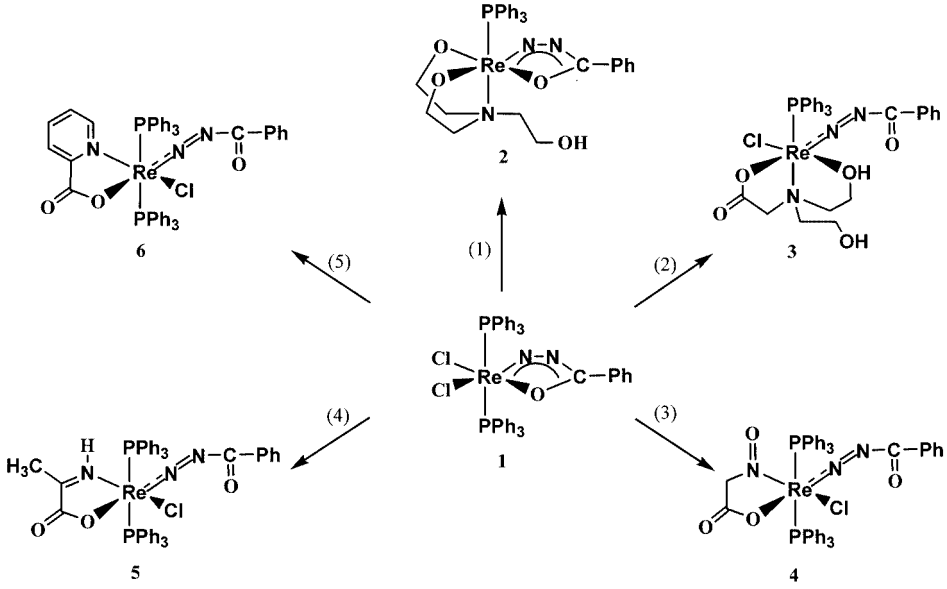
Results and Discussion

Synthesis and Spectroscopic Characterization

The reaction of the benzoylhydrazido chelate **1** with various potential N,O-polydentate ligands in refluxing methanol led to the formation of neutral benzoylhydrazido (**2**) and diazenido (**3**–**6**) complexes, in 30–55% yields, as shown in Scheme 1. All complexes were characterized by IR, FAB^+-MS, ^1H and $^{13}C\{^1H\}$ NMR spectroscopy, elemental analysis and single-crystal X-ray diffraction analysis.

In the reaction of **1** with triethanolamine (reaction 1, Scheme 1) the latter, upon deprotonation of two alcohol moieties, provides a dianionic tridentate N,O,O-ligand that replaces one triphenylphosphane and two chloride ligands, with preservation of the chelated benzoylhydrazido fragment in the green product $[Re\{(OCH_2CH_2)_2N(CH_2CH_2OH)\}\{N{=}NC(O)Ph\}(PPh_3)]$ (**2**). *N*,*N*-Bis(2-hydroxyethyl)glycine [bicine, $N(CH_2CH_2OH)_2(CH_2COOH)$] also generates an N,O,O-ligand by deprotonation of the carboxylic acid group. Reduction of the metal to the +3 oxidation state also occurs, the chelated benzoylhydrazido ring opens to form the η^1-NNCOPh diazenido ligand and only one ligated chloride is replaced (besides one of the phosphanes) to afford the greenish-blue complex $[ReCl\{N(CH_2COO)(CH_2CH_2OH)(CH_2COOH)\}\{N{=}NC(O)Ph\}(PPh_3)]$ (**3**) (reaction 2, Scheme 1). In complexes **2** and **3** the N,O,O-ligands contain hydroxyethyl arms, in agreement with the detection, in the IR spectra, of strong and broad bands in the 3500–3200 cm^{-1} range assigned to ν(OH). The IR spectra of **3** and all the other benzoyldiazenido compounds show a strong band in the 1700–1630 cm^{-1} range assigned to ν(C=O), whereas for all the complexes ν(N=N), associated to either η^2- or η^1-NNC(O)Ph, is observed in the 1513–1436 cm^{-1} range.

In their reactions with complex **1**, the *N*-hydroxyiminodicarboxylic acids (HIDA and HIDPA) undergo fragmentation, leading to the formation of the $O{\leftarrow}NCH_2COO^-$ (*N*-oxyaminoacetate) and $HN{=}C(Me)COO^-$ (2-iminopropionate) ligands in the η^1-benzoyldiazenidorhenium(III) products $[ReCl\{N(=O)CH_2COO\}\{N{=}NC(O)Ph\}(PPh_3)_2]$ (**4**)



Scheme 1. (1) $N(CH_2CH_2OH)_3$; (2) $N(CH_2CH_2OH)_2(CH_2COOH)$ (bicine); (3) $HON(CH_2COOH)_2$ (HIDA); (4) $HON\{CH(CH_3)COOH\}_2$ (HIDPA); (5) NC_5H_4COOH-2.

[ν(N=O) = 1626 cm^{-1}] and [ReCl{HN=C(Me)COO}{N=NC(O)Ph}(PPh_3)$_2$] (**5**), respectively (reactions 3 and 4, Scheme 1). HIDPA fragmentations have been rarely characterized, although some examples[61] are provided by the reaction with [PPh_4][$ReOBr_4$], [$ReOCl_3(PPh_3)_2$], [$ReOCl_2$(OEt)(PPh_3)$_2$] or [PPh_4][$MoOCl_4(H_2O)$], leading to the formation of 2-[(1-carboxyethoxy)imino]propionic acid [HOOCC(Me)=N{OCH(Me)COO^-}], 2-iminopropionate [HN=C(Me)COO^-], 2,2′-iminodipropionate [HN{CH(Me)COO^-}$_2$] and 2-oxidoiminopropionic acid [HOOCC(Me)=N→O] ligands, respectively. The 2-iminopropionate ligand in **5** has a precedent in [PPh_4][$ReOBr_3${HN=C(Me)COO}],[61] whereas the *N*-oxyaminoacetate in **4** appears to result from a different type of HIDA fragmentation.

Similar to complexes **4** and **5**, the η^1-benzoyldiazenidorhenium(III) product [ReCl{C_5H_4N(COO)}{N=NC(O)Ph}(PPh_3)$_2$] (**6**) obtained from the reaction of picolinic acid with **1** (reaction 5, Scheme 1) also has an anionic bidentate N,O-ligand, in this case simply corresponding to the basic form of the acid reagent.

The molecular ions were clearly observed with the expected isotopic patterns in the FAB^+-mass spectra of all compounds, except **3**. Other typical peaks correspond to the stepwise fragmentations by loss of Cl, N_2COPh, PPh_3 and N,O-ligand fragments. The ^1H and $^{13}C\{^1H\}$ NMR spectra show resonances at the usual chemical shifts for the coordinated PPh_3, N_2COPh and N,O-ligands.[29–31,62–69] Elemental analyses are also consistent with the proposed formulations, which were authenticated by single-crystal X-ray diffraction studies, as indicated below.

X-ray Crystal Structures

Green single crystals of the starting material **1**·C_6H_6 were grown by slow evaporation at 5 °C of an EtOH/C_6H_6 solution and the crystal structure was solved in order to compare its crystal data with those of the newly obtained complexes. The molecular structure of **1** (Figure 1) consists of discrete mononuclear species of distorted octahedral geometry with *trans* phosphane ligands and the other ligands in equatorial sites. Hence, the chloride ligands are *trans* to the nitrogen and carbonyl oxygen donors of the chelating benzoylhydrazido ligand. The bonding parameters (Table 1) are similar to those of the analogous complex [$ReCl_2${N=NC(O)C_6H_4Cl-4}(PPh_3)$_2$].[70]

All the other complexes also exhibit distorted octahedral coordinations and, for those with two phosphanes (**4**–**6**), these bulky ligands are *trans* to each other, as in complex **1**, in agreement with steric requirements.

In complex **2** (Figure 2), one triethanolamine is deprotonated at two oxygen atoms (O2, O3) and binds the metal through the amino-N and these atoms. The Re–N1, Re–O1, Re–P1 and N1–N2 distances (Table 1) are similar to those of **1**. Within the chelating benzoylhydrazide ligand, the short Re–N1 [1.776(5) and 1.798(3) Å in **1** and **2**, respectively] and N1–N2 [1.309(6) and 1.336(4) Å, respectively]

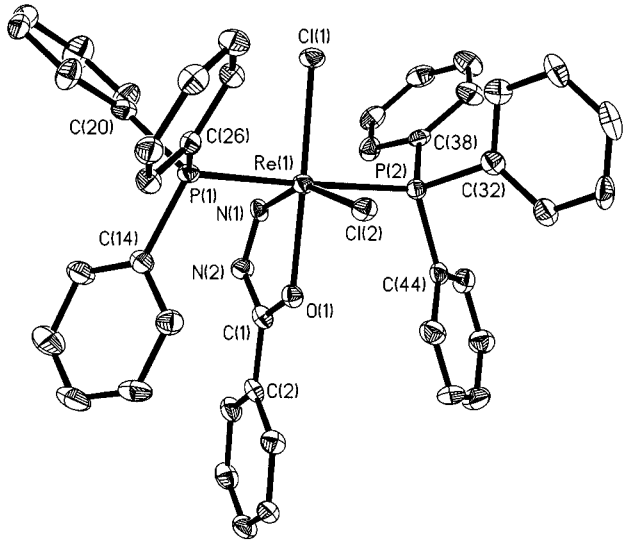

Figure 1. An ORTEP-3 representation of **1**. Hydrogen atoms and solvent molecule have been omitted for clarity.

bond lengths indicate significant multiple bonding character, and therefore a delocalized π-system, which is also in agreement with the Re–N1–N2 angles of 133.4(4)° in **1** and 131.7(3)° in **2**.[70,71] According to a classification of organohydrazido ligands[71] (assuming the convention that all electrons involved in the Re–N bond are donated by the hydrazine precursor), the benzoylhydrazido ligand in the chelates **1** and **2** exhibits features of both a hydrazido(3–) (**a**) and a diazenido(1–) (**b**) species.

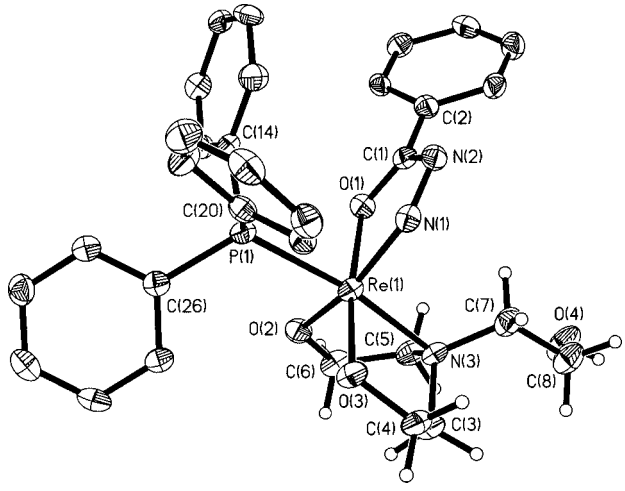

Figure 2. An ORTEP-3 representation of **2**. Ph hydrogen atoms have been omitted for clarity.

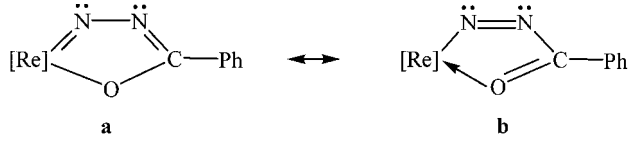

In **2** the Re–O2 and Re–O3 lengths of 1.94–1.97 Å are unexceptional for deprotonated oxygen atoms bonded to a metal centre, and are shorter than Re–O1 [2.170(3) Å]. The

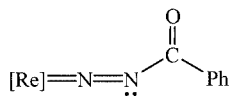
binding of the triethanolamine ligand involves the chelate rings Re–N3–C3–C4–O3 and Re–N3–C5–C6–O2 with O3–Re–N3 and O2–Re–N3 bite angles of 82.14(12)° and 79.51(12)°, respectively. The Re–N3 bond [2.217(3) Å] is significantly longer than Re–O2 [1.944(3) Å] and Re–O3 [1.974(3) Å], as commonly observed for O,N,O- or N,O-donor ligands,[61,72] and is also longer than the Re–N1 bond [1.798(3) Å], as anticipated for sp^3 hybridization at the N3 site and sp^2 hybridization at N1, and in agreement with the appreciable double-bond character of the latter bond.

In the structures of **3**–**6** (Figures 3, 4, 5 and 6, respectively), the opening of the chelated benzoylhydrazido ring has occurred and the Re–N1–N2 angle of the resulting η^1-diazenido ligand is essentially linear [176.0(3)° in **3**, 169.3(6)° in **4**, 177.4(3)° in **5** and 168.3(6)° in **6**]. The Re–N1, N1–N2 and C1–O1 distances (Table 1) are slightly shorter than those in the η^2-NNC(O)Ph ligand in **1** and **2**, which is indicative of a slight increase of the double-bond character. According to the above classification,[71] the η^1-NNC(O)Ph ligand in compounds **3**–**6** exhibits features of a linear, four-electron donor diazenido(1–) (**c**). In all these complexes, this ligand adopts the position *trans* to the O-coordinated carboxylato group of the chelating N,O-ligand, in preference to being *trans* to any N, Cl or P atoms.



c

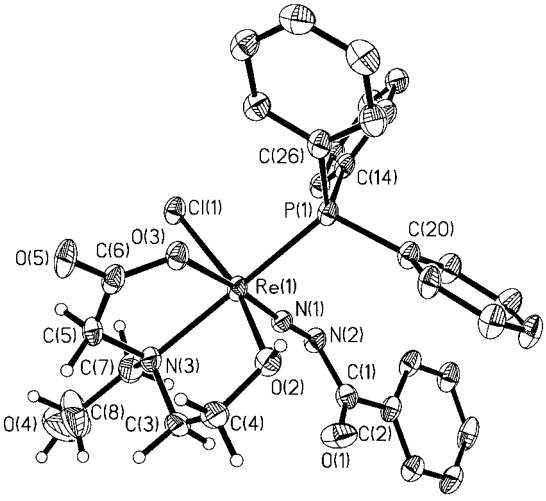


Figure 3. An ORTEP-3 representation of **3**. Ph hydrogen atoms and solvent molecules have been omitted for clarity.

The bicine ligand in **3** involves the chelate rings Re–N3–C3–C4–O2 and Re–N3–C5–C6–O3, with O2–Re–N3 and O3–Re–N3 bite angles of 80.27(13)° 78.84(12)°, respectively. The Re–N3(amine) distance of 2.243(4) Å (Table 1) is comparable with the corresponding one observed for complex **2**, although the Re–O2 and Re–O3 bond lengths of 2.119(3) and 2.095(3) Å are slightly longer than those in **2**.

In the structures of **4**–**6** (Figures 4, 5 and 6, respectively) most of the corresponding bond lengths and angles are sim-

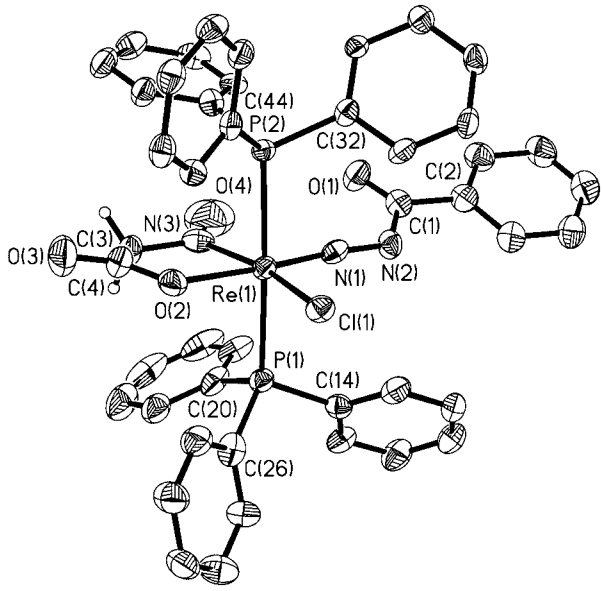

Figure 4. An ORTEP-3 representation of **4**. Ph hydrogen atoms have been omitted for clarity.

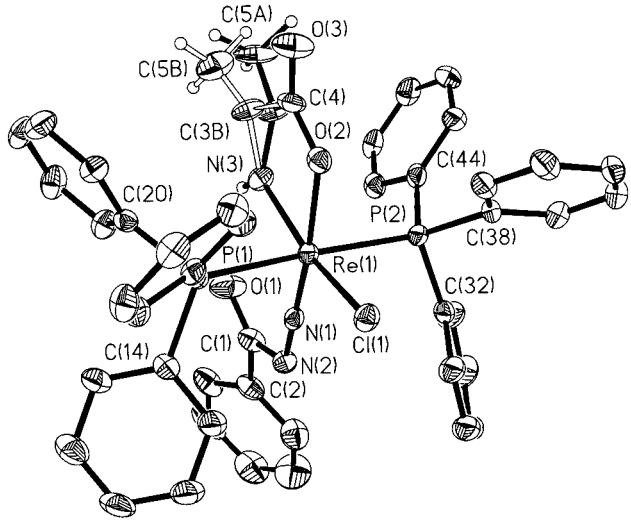

Figure 5. An ORTEP-3 representation of **5**. Ph hydrogen atoms and solvent molecules have been omitted for clarity.

ilar (Table 1). Each N,O-ligand forms a chelate ring with a restricted O–Re–N bite angle, the N3 atom being always *trans* to the chloride and the O2 atom *trans* to the diazenido ligand. The Re–O2 and Re–N3 bond lengths are usually similar to those of other Re complexes.[61,73] Hence, for example, for complex **6** most of the bond lengths are similar to those of related complexes with picolinate or 3-hydroxypicolinate ligands such as $[ReO(Me)(NC_5H_4COO)_2]$, $[ReH(NC_5H_4COO)_2(PPh_3)_2]$, $[ReOI_2\{NC_5H_3(OH\text{-}3)COO\}(PPh_3)]$ and $[ReOCl_3\{NC_5H_3(OH\text{-}3)COO\}]$.[74–77] However, the Re–N3 bond length [2.175(3) Å] in **5** is longer than the Re–O2 distance [2.089(3) Å].

In the $HN{=}C(CH_3)COO^-$ ligand in **5**, the C3–N3 distance of 1.417(15) Å is much longer than the corresponding

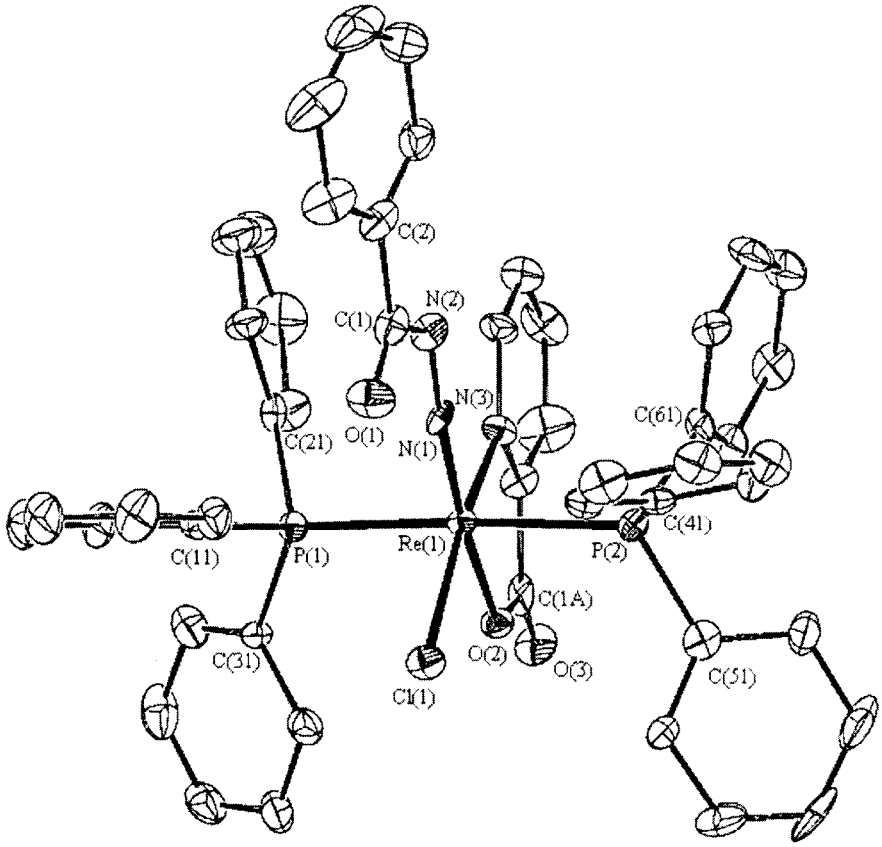

Figure 6. An ORTEP-3 representation of **6**. Hydrogen atoms and solvent molecule have been omitted for clarity.

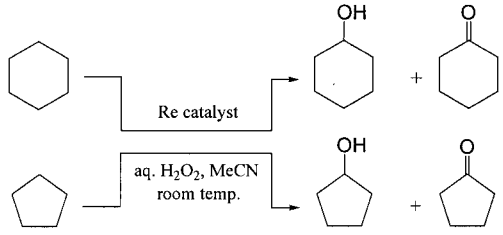
C=N bond length in $[PPh_4][ReOBr_3\{HN=C(Me)COO\}]$,[61] even though the X-ray diffraction analysis shows that there is no hydrogen at the C3 atom.

Peroxidative Oxidation of Cyclohexane and Cyclopentane

Acetonitrile solutions of all our complexes **1**–**6** exhibit catalytic activity for the peroxidative oxidation of cyclohexane to the corresponding cyclohexanone and cyclohexanol *at room temperature* (see Scheme 2 and Table 2 for selected data and Table S1 in the Supporting Information). The amount of hydrogen peroxide has a strong effect, and increasing the peroxide-to-catalyst molar ratio within the 2000–32000 range leads to an enhancement of the turnover numbers (TONs); for example, the total TON when using complex **3** as a catalyst increases from 5 to 43 on increasing this ratio from 4000 to 32000 (Figure 7). The highest activity is displayed by complexes **3** and **6**, followed by the chelate **1**, with total TONs of 43, 42 and 39 and turnover frequency (TOF) values of 7.2, 7.0 and 6.5 h^{-1}, respectively, for the latter peroxide-to-catalyst ratio. These values are comparable to those we have achieved (maximum TON of 46)[58] with vanadium catalysts like Amavadine $[V(O,N\text{-}L)]^{2-}$ (*O*,*N*-L = tribasic form of HIDPA) and $[VO\{N(CH_2CH_2O)_3\}]$. The other complexes (**2**, **4** and **5**) are less active for sufficiently high H_2O_2/catalyst ratios, with total TONs (ca. 21–22) that are half of those of the other complexes, for the above peroxide-to-catalyst ratio.



Scheme 2.

Table 2. Peroxidative oxidation of cyclohexane catalyzed by the Re complexes.[a]

Catalyst	Turnover number (TON)[b]			Turnover frequency (TOF)[d]
	Cyclohexanol	Cyclohexanone	Total[c]	
1	24	15	39	6.5
2	13	8	21	3.5
3[e]	27	16	43	7.2
4	14	8	22	3.7
5	13	9	22	3.7
6[f]	25	17	42	7.0

[a] Selected data from Table S1. $n(H_2O_2)/n(C_6H_{12})$ = 2:1, $n(H_2O_2)/n$(Re catalyst) = 32000, molar yield (% relative to substrate) = $6.3 \times TON \times 10^{-3}$, unless stated otherwise. [b] Mol product/mol Re catalyst precursor. [c] Cyclohexanol + cyclohexanone. [d] Mol products/mol Re catalyst precursor per hour. [e] For $n(H_2O_2)/n(C_6H_{12})$ = 16:1 the molar yield is 1.9%. [f] For $n(H_2O_2)/n(C_6H_{12})$ = 16:1 the molar yield is 2.4%.

Higher catalytic activities would be expected upon further increase of the peroxide-to-catalyst ratio (see Figure 7), but this was not tested for safety reasons. All catalysts display a higher selectivity towards the formation of cyclohexanol, in comparison with cyclohexanone, and the average alcohol/ketone molar ratio is within the 1.5–1.8 range.

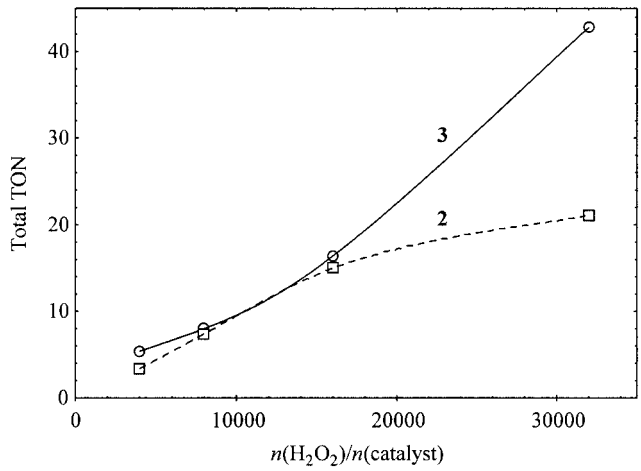


Figure 7. Effect of the oxidant-to-catalyst molar ratio on the total TON values in the oxidation of cyclohexane catalyzed by complexes **2** and **3**.

The Re complexes also catalyze the peroxidative oxidation of cyclopentane to the corresponding cyclopentanol and cyclopentanone, but the catalytic activity (Table S2 in the Supporting Information) is lower than for the oxidation of cyclohexane. The TONs also increase with the amount of hydrogen peroxide. For a peroxide-to-catalyst molar ratio of 32000, the total TON is 13 when using complex **6** as a catalyst, whereas the other complexes exhibit lower TON values (from 3 to 8).

In contrast with the lower activity for cyclopentane than for cyclohexane oxidation, a higher selectivity is observed for the formation of the alcohol, i.e. cyclopentanol, for moderately high peroxide-to-catalyst molar ratios. In fact, cyclopentanol is the only oxidation product detected for all the complexes at $n(H_2O_2)/n$(catalyst) = 16000. However, the formation of cyclopentanone, a more oxidized product, also occurs for complexes **3** and **6** at the higher value of 32000 for the peroxide-to-catalyst molar ratio.

The peroxidative oxidation of cycloalkanes is believed to proceed by a radical mechanism since no traces of cyclohexanol or cyclohexanone are detected when the above reactions that normally lead to the highest TON values are performed in the presence of a radical trap like 2,6-di-*tert*-butyl-4-methylphenol (BHT; 0.5 molar ratio with respect to the alkane). Although we have not yet succeeded in the isolation and full characterization of intermediates, the process conceivably involves[46,47,50,58,78–80] the formation of intermediate peroxo and oxo complexes. It is noteworthy that the oxo-peroxomethylrhenium(VII) complex $[(Me)ReO(O_2)_2]$ is the active species of the known $[(Me)ReO_3]/H_2O_2$ system in olefin and aromatic oxidations.[16] Peroxo-derived radical complexes could abstract an H atom from the alkane (RH) to generate an R˙ radical, which, on reaction with a hydroperoxo or hydroxo complex, could lead to the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

alcohol ROH; further oxidation of the latter would yield the corresponding ketone.

The role of the chelating N,O and diazenido ligands in our systems is still unclear but one can postulate their involvement (e.g. upon decoordination, in the former, of a single N or O atom) in proton-transfer steps among oxo-, peroxo- and hydroxo-Re complexes. Such a role in the promotion of proton transfer from coordinated H_2O_2 to oxo ligands has been proposed[78,79] for some vanadium systems with N,O additives as cocatalysts.

Re-catalyzed alkane oxidations are essentially unexplored. In the only previously published case, the organometallic [(Me)ReO_3]/pyrazine-2-carboxylic acid system was found to be active for the peroxidative oxidation of cyclohexane by anhydrous H_2O_2 in refluxing acetonitrile solution at 80 °C (TON of 126);[80] however, if aqueous 30% H_2O_2 was used almost no oxidation of cyclohexane occurred.[80] Our systems have the advantage of operating under milder conditions, i.e. at room temperature, with aqueous H_2O_2 and without added acid. Nevertheless, in all the cases the yields (based on the alkane), under the experimental conditions used, are still modest (not above 3% for our complexes and even lower (1.5%) for [(Me)ReO_3]), although these are still significant in the field of alkane functionalization under mild or moderate conditions. A maximum yield of 9% was achieved[58] for the same alkane reaction with the above vanadium catalysts.

Conclusions

This work has shown that the benzoylhydrazido chelate [$ReCl_2${NNC(O)Ph}$(PPh_3)_2$] (**1**), which is a recognized key starting material for a diversity of hydrazido, diazenido and even dinitrogen Re complexes with P-based coligands (organophosphanes, -phosphites or -phosphonites), can also provide a convenient entry point for the synthesis of benzoylhydrazido and benzoyldiazenido complexes of Re (in the +5 and the +3 oxidation states) with chelating N,O,O- and N,O-coligands of various types, including amino alkoxides and amino-, oxyamino-, imino- and pyridinocarboxylates. π-Electron delocalization along the hydrazido- and diazenidorhenium moiety has been observed, with the Re–N bond exhibiting some double-bond character. The benzoyldiazenido ligand occupies the *trans* position relative to the O-ligated carboxylato group, preferably to the softer N atom of the N,O- or N,O,O-ligand, an observation that may be of synthetic significance and deserves further exploration.

This study also demonstrates, for the first time, that Re coordination compounds can act as catalysts for alkane hydroxylation and oxygenation, by showing the unprecedented catalytic activity of such a type of complexes, under mild conditions, in the peroxidative oxidation of cycloalkanes to the corresponding alcohols and ketones. The reactions appear to follow a radical mechanism, although complete details have yet to be established. The catalytic activity, although appreciable in the field of mild alkane functionalization, is still modest. Hence, this study provides a contribution towards the development of the still underdeveloped field of catalysis with rhenium inorganic coordination compounds. However, more-effective systems are needed, as well as the extension to other types of alkane-functionalization reactions, points that are currently being addressed in our laboratory.

Experimental Section

General Materials and Procedures: All synthetic work was performed under nitrogen using standard Schlenk techniques. The solvents were dried over appropriate drying agents and degassed by standard methods. Potassium perrhenate (Merck), triphenylphosphane (Aldrich), benzoylhydrazine (Aldrich), triethanolamine (Fluka), *N*,*N*-bis(2-hydroxyethyl)glycine (bicine; Aldrich), picolinic acid (Aldrich), 2,6-di-*tert*-butyl-4-methylphenol (BHT; Aldrich), bromoacetic acid (Merck), hydroxylammonium chloride (Aldrich) and zinc acetate (Aldrich) were obtained from commercial sources and used as received. [*N*-Benzoylhydrazido(3–)-*N*′,*O*]dichlorobis(triphenylphosphane)rhenium(v) [$ReCl_2${NNC(O)Ph}$(PPh_3)_2$] (**1**),[25,26] *N*-hydroxyiminodiacetic acid[81] and *N*-hydroxy-2,2′-iminodipropionic acid[81] were prepared by published methods.

Elemental analyses were carried out by the Microanalytical Service of the Instituto Superior Técnico. Melting points were determined on a Kofler table. Positive-ion FAB mass spectra were obtained on a Trio 2000 instrument by bombarding 3-nitrobenzyl alcohol (NBA) matrices of the samples with 8 keV (ca. 1.18×10^{15} J) Xe atoms. Mass calibration for data system acquisition was achieved with CsI. IR spectra (4000–400 cm^{-1}) were recorded on a Jasco FT/IR-430 instrument as KBr pellets. ^1H and $^{13}C\{^1H\}$ NMR spectra were measured on a Varian UNITY 300 spectrometer at ambient temperature.

[Re{$(OCH_2CH_2)_2N(CH_2CH_2OH)$}{NNC(O)Ph}$(PPh_3)$] (2): An excess of triethanolamine (43 μL, 0.327 mmol) was added to a suspension of **1** (100 mg, 0.109 mmol) in 7.5 mL of MeOH and the reaction mixture was refluxed for about 5 h. The resulting dark-brown clear solution was concentrated under reduced pressure and then treated with 20 mL of Et_2O. The solid (triethanolamine hydrochloride) that separated out from the resulting solution was filtered off and discarded. The filtrate was evaporated under reduced pressure to give a green oil, which was dissolved in 1.5 mL of C_6H_6. The addition of *n*-pentane (20 mL) caused the precipitation of a solid, which was filtered off, washed with *n*-pentane (3 × 10 mL) and dried in vacuo to yield complex **2** as a green solid. Yield: 43 mg (54% based on **1**). Product **2** is soluble in MeOH, Me_2CO, Et_2O and C_6H_6. M.p. 153 °C (dec.). $C_{31}H_{33}N_3O_4PRe$ (728.79): calcd. C 51.02, H 4.56, N 5.76; found C 50.50, H 4.53, N 5.56. FAB$^+$-MS (NBA): *m*/*z* = 730 [M^+ + H], 612 [M^+ – (N_2COPh) + O], 596 [M^+ – (N_2COPh)], 467 [M^+ – PPh_3]. FTIR (KBr): $\tilde{\nu}$ = 3416 and 3311 (s br.) ν(OH), 2960 (m) ν_{as}(CH), 2853 (m) ν_s(CH), 1436 (s) ν(NN), 1355 (s) ν(C–O) cm^{-1}. ^1H NMR ($CDCl_3$): δ = 7.88–7.83 (m, 5 H, Ph), 7.49–7.32 (m, 15 H, PPh_3), 3.66 (t, *J* = 5.4 Hz, 4 H, CH_2-O), 2.69 (t, *J* = 4.8 Hz, 4 H, CH_2-N), 2.37–2.18 (m, 4 H, CH_2CH_2OH) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 134.2, 134.1, 130.0, 129.7, 128.1 and 128.0 (PPh_3), 132.9, 131.6, 130.6 and 127.6 (Ph), 60.3, 58.1, 59.6 and 56.7 (*C*H_2) ppm; Ph*C*O was not observed. X-ray quality crystals were grown at 5 °C by vapour diffusion of *n*-C_5H_{12} into an Et_2O or an acetone solution of **2**.

[ReCl{$N(CH_2COO)(CH_2CH_2OH)(CH_2CH_2OH)$}{N=NC(O)Ph}$(PPh_3)$] (3): A mixture of **1** (50 mg, 0.055 mmol) and bicine (27 mg, 0.165 mmol) was refluxed in MeOH (10 mL) for about 8 h. The

resulting dark-brown clear solution was concentrated to 5 mL under reduced pressure and 30 mL of Et_2O was added. The obtained greenish-brown solution was left to stand for 2 d at room temperature. During this time greenish-blue microcrystals of **3** separated out of the solution. They were collected, washed with MeOH (3 × 10 mL) and dried in vacuo. Yield: 21 mg (48% based on **1**). Product **3** is slightly soluble in DMSO and insoluble in C_6H_6, MeOH, Me_2CO, $CHCl_3$ and CH_2Cl_2. M.p. 201 °C (dec.). $C_{31}H_{32}ClN_3O_5PRe$ (779.24): calcd. C 47.78, H 4.14, N 5.39; found C 47.57, H 3.96, N 5.21. FAB$^+$-MS (NBA): *m*/*z* = 744 [M^+ – Cl], 610 [M^+ – Cl – (N_2COPh)], 582 [M^+ – Cl – {$N(CH_2CH_2OH)_2$-(CH_2COO)}]. FTIR (KBr): $\tilde{\nu}$ = 3429 and 3265 (s br.) ν(OH), 2925 (m) ν_{as}(CH), 2854 (m) ν_s(CH), 1631 (s) ν(C=O), 1458 (s) ν(N=N) cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 7.77–7.33 (m, 20 H, PPh_3 + Ph), 4.25–3.59 and 3.15–2.97 (m, 10 H, CH_2) ppm. ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 179.1 (Ph*C*=O), 167.6 (CH_2*C*=O), 134.1, 133.6, 132.9, 131.6, 130.7, 130.3, 129.3, 128.7 and 128.1 (PPh_3 + Ph), 56.0, 55.6, 54.9, 53.6, and 16.2 (*C*H_2) ppm. X-ray quality crystals of **3**·H_2O were grown by slow evaporation at 5 °C of Et_2O/MeOH or MeOH/Me_2CO solutions.

[ReCl{N(=O)CH_2COO}{N=NC(O)Ph}(PPh_3)$_2$] (4): An excess of HIDA (28 mg, 0.18 mmol) was added to a suspension of **1** (50 mg, 0.055 mmol) in 10 mL of MeOH and the reaction mixture was refluxed for about 7 h. The resulting reddish-yellow clear solution was concentrated under reduced pressure and then treated with 30 mL of Et_2O. The solid that separated out from the resulting solution was filtered off and discarded. The filtrate was evaporated under reduced pressure to give a light-brown oil, which was dissolved in 5 mL of C_6H_6 to form a yellow cloudy solution. Filtration, followed by concentration under reduced pressure, yielded a yellow oil to which 1 mL of benzene was added. The addition of *n*-pentane (20 mL) led to the precipitation of a solid that was filtered off, washed with *n*-pentane (3 × 10 mL) and dried in vacuo to yield complex **4** as a yellow powder. Yield: 19 mg (35% based on **1**). Product **4** is soluble in MeOH, EtOH, Me_2CO, Et_2O, C_6H_6 and $CHCl_3$. M.p. 220 °C (dec.). $C_{45}H_{37}ClN_3O_4P_2Re$ (967.40): calcd. C 55.84, H 3.83, N 4.34; found C 55.73, H 3.77, N 4.07. FAB$^+$-MS (NBA): *m*/*z* = 966 [M^+ – H], 879 [M^+ – ($ONCH_2COO$)], 832 [M^+ – (N_2COPh) – 2H], 746 [M^+ – ($ONCH_2COO$) – (N_2COPh)]. FTIR (KBr): $\tilde{\nu}$ = 2925 (w) ν_{as}(CH), 1700 (s) ν(C=O), 1626 (s) ν(N=O), 1513 (s) ν(N=N) cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 7.74–7.70 and 7.41–7.43 (m, 30 H, PPh_3), 7.62–7.58 (m, 5 H, Ph), 2.32 (s, 2 H, CH_2) ppm. ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 195.5 (Ph*C*=O), 174.5 (CH_2*C*=O), 134.4, 134.3, 130.4, 128.4 and 128.4 (PPh_3), 133.7, 132.4, 128.8 and 127.9 (Ph), 29.0 (*C*H_2) ppm. X-ray quality crystals were grown by slow evaporation at 5 °C of an EtOH/Me_2CO solution of **4**.

[ReCl{HN=C(Me)COO}{N=NC(O)Ph}(PPh_3)$_2$] (5): Compound **5** was prepared by following the general procedure described for **4**, but using HIDPA instead of HIDA. Yield: 21 mg (40% based on **1**). It is soluble in MeOH, EtOH, Me_2CO, Et_2O, C_6H_6 and $CHCl_3$. M.p. 114 °C (dec.). $C_{46}H_{39}ClN_3O_3P_2Re$ (965.43): calcd. C 57.20, H 4.07, N 4.35; found C 57.50, H 4.29, N 4.09. FAB$^+$-MS (NBA): *m*/*z* = 967 [M^+ + 2H], 932 [M^+ – Cl + 2H], 879 [M^+ – {HN=C(CH_3)COO}], 834 [M^+ – (N_2COPh) + 2H], 799 [M^+ – Cl – (N_2COPh) + 2H], 746 [M^+ – {HN=C(CH_3)COO} – (N_2COPh)], 711 [Re(PPh_3)$_2$]. FTIR (KBr): $\tilde{\nu}$ = 3280 (w) ν(N–H), 1656 (s br.) ν(C=O), 1630 (m) ν(C=N), 1436 (s) ν(N=N) cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 7.88–7.84 and 7.17 (m, 5 H, Ph), 7.73–7.32 (m, 30 H, PPh_3), 1.46 (s) + 1.43 (s) (3 H, CH_3) ppm; N*H* was not observed. ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 192.4 (Ph*C*=O), 182.2 (N=C(Me) *C*=O), 134.3, 134.0, 132.2, 132.0, 128.6 and 128.5 (PPh_3), 130.5, 128.9, 128.1, 128.0 and 127.4 (Ph), 51.3 (*C*H_3) ppm; *C*=N was not observed. X-ray quality crystals of **5**·2 EtOH were grown by slow evaporation at 5 °C of EtOH/C_6H_6 or EtOH/CH_2Cl_2 solutions.

[ReCl{C_5H_4N(COO)}{N=NC(O)Ph}(PPh_3)$_2$] (6): A mixture of **1** (50 mg, 0.055 mmol) and picolinic acid (21 mg, 0.165 mmol) was refluxed in MeOH (10 mL) for about 12 h. The resulting deep-red cloudy solution was taken to dryness under reduced pressure to give a red residue to which 30 mL of MeOH was added to obtain a suspension of **6**. This was filtered off, washed with MeOH (3 × 15 mL) and dried in vacuo to furnish complex **6** as a red solid. Yield: 30 mg (55% based on **1**). Product **6** is soluble in Me_2CO, Et_2O, C_6H_6, CH_2Cl_2 and $CHCl_3$. M.p. 232 °C (dec.). $C_{49}H_{39}ClN_3O_3P_2Re$ (1001.5): calcd. C 58.73, H 3.93, N 4.20; found C 58.45, H 4.16, N 4.02. FAB$^+$-MS (NBA): *m*/*z* = 1002 [M^+ + H], 966 [M^+ – Cl], 868 [M^+ – (N_2COPh)], 879 [M^+ – (C_5H_4NCOO)], 833 [M^+ – Cl – (N_2COPh)], 746 [M^+ – (C_5H_4NCOO) – (N_2COPh)], 711 [Re(PPh_3)$_2$], 571 [M^+ – Cl – (N_2COPh) – PPh_3], 448 [RePPh_3]. FTIR (KBr): $\tilde{\nu}$ = 1673 and 1638 (s) ν(C=O), 1456 (s) ν(N=N), 1307 (m) ν(C–O) cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 7.80–7.73 (m, 4 H, Py*H*), 7.59–7.43 (m, 30 H, PPh_3), 6.95–6.85 (m, 5 H, Ph) ppm. ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 134.6, 134.5, 134.2, 133.8, 130.2, 130.0, 128.4, 128.3, 128.0 and 127.8 (Py*C*, PPh_3 and Ph) ppm; *C*=O was not observed. X-ray quality crystals of **6**·Me_2CO were grown by slow evaporation at 5 °C of an acetone solution.

Catalytic Studies: The reaction mixtures were prepared as follows: MeCN (3.00 mL), H_2O_2 (30% in H_2O; 10.00 mmol) and cycloalkane (cyclohexane or cyclopentane; 5.00–0.625 mmol) were added, in this order, to 0.313–5.00 × 10^{-3} mmol of the Re complex **1**–**6** (used either as a solid or as a 0.02 M MeCN solution) in the reaction flask. The reaction mixture was stirred for 6 h at room temperature and normal pressure, then 90 μL of cycloheptanone (as internal standard) and 10.00 mL of diethyl ether (to extract the substrate and the organic products from the reaction mixture) were added. The obtained mixture was stirred for 10 min and then a sample was taken from the organic phase and analyzed by gas chromatography using a FISONS Instruments GC 8000 series gas chromatograph with a DB WAX fused silica capillary column (P/N 123-7032) and the JASCO-BORWIN v.1.50 software. The obtained results for cyclohexane and cyclopentane oxidation are given as Supporting Information (Tables S1 and S2, respectively); selected values are given in Table 2.

Blank experiments were performed for both cycloalkanes with H_2O_2 and confirmed that no product of alkane oxidation was obtained in the absence of metal catalyst.

X-ray Crystal Structure Determinations: Crystals of **1**–**5** were immersed in perfluoropolyether, mounted in a cryo-loops and measured at 100 K. The X-ray diffraction data were collected with a Nonius-Kappa CCD diffractometer (for **1**–**5**) or an Enraf–Nonius MACH3 diffractometer (for **6**), equipped with graphite monochromator and using Mo-K_α radiation. The Denzo-Scalepack program package[82] was used for cell refinements and data reductions for **1**–**5**. All structures were solved by direct methods using the SIR97 or SIR2002 programs[83,84] with the WinGX graphical user interface.[85] An empirical absorption correction was applied to all data (**1**–**5**) using XPREP in the SHELXTL v.6.12 program[86] (T_{min}/T_{max}: 0.21031/0.28346, 0.11746/0.15556, 0.21094/0.26735, 0.12878/0.17642, 0.16825/0.21003 for **1**–**5**, respectively). All structures were refined with the SHELXL-97 program.[87] In the structure of **5** C3 and C5 were refined over two positions with occupancies of 0.57 and 0.43 and the position of the OH hydrogen (H98) was estimated with the CALC-OH program.[88] Other OH, H_2O and NH hydrogens were located from the difference Fourier map. All other hydrogens were placed in idealized positions and constrained to ride on

their parent atom. The crystallographic data are summarized in Table 3 and selected bond lengths and angles are given in Table 1. CCDC-256902 to –256907 (for **1**·C_6H_6, **2**, **3**·H_2O, **4**, **5**·2 EtOH and **6**·Me_2CO, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Supporting Information: Supplementary tables with the TON values for the peroxidative oxidation of cyclohexane (Table S1) and cyclopentane (Table S2) catalyzed by the Re complexes **1**–**6** (see also footnote on first page of this article).

Acknowledgments

This work was partially supported by the Fundação para a Ciência e a Tecnologia (FCT) and its POCTI programmes (FEDER funded; project POCTI/QUI/43415/2001), Portugal, as well as by a Human Resources and Mobility Marie Curie Research Training Network (AQUACHEM project, CMTN-CT-2003-503864). A.M.K. is grateful to the FCT and the POCTI program for a fellowship (BD/6287/01). The authors also thank Dr. Nadia Bokach for some NMR experiments, Dr. José Armando L. Silva for stimulating discussions, Dr. Maria Cândida Vaz for the direction of the elemental analysis service and Mr. Indalécio Marques for recording the FAB$^+$-mass spectra.

Synthesis, Structure, and Ligand Redistribution Equilibria of Mixed Ligand Complexes of the Heavier Group 2 Elements Containing Pyrazolato and β-Diketiminato Ligands

Hani M. El-Kaderi,[a] Mary Jane Heeg,[a] and Charles H. Winter*[a]

Keywords: N ligands / Group 2 elements / Calcium / Strontium / Barium

Treatment of $M[N(SiMe_3)_2]_2(THF)_2$ (M = Ca, Sr, Ba) with various stoichiometries of *N*-*tert*-butyl-4-(*tert*-butylimino)-2-penten-2-amine ($L^{tBu}H$) and 3,5-di-*tert*-butylpyrazole (tBu_2pzH) afforded $[(\eta^2\text{-}tBu_2pz)Ca(\mu\text{-}\eta^5{:}\eta^2\text{-}tBu_2pz)(\mu\text{-}\eta^2{:}\eta^2\text{-}tBu_2pz)Ca(\eta^5\text{-}L^{tBu})]$ (17 %), $[Sr(\mu\text{-}\eta^5{:}\eta^2\text{-}tBu_2pz)(\eta^5\text{-}L^{tBu})]_2$ (50 %), and $[Ba(\mu\text{-}\eta^5{:}\eta^2\text{-}tBu_2pz)(\eta^5\text{-}L^{tBu})]_2$ (66 %) as colorless crystalline solids. The formulations of the new complexes were assigned from spectral and analytical data and by X-ray crystal structure determinations. In the solid state, $[(\eta^2\text{-}tBu_2pz)Ca(\mu\text{-}\eta^5{:}\eta^2\text{-}tBu_2pz)(\mu\text{-}\eta^2{:}\eta^2\text{-}tBu_2pz)Ca(\eta^5\text{-}L^{tBu})]$ exists as a dimer that is held together by $\mu\text{-}\eta^5{:}\eta^2$- and $\mu\text{-}\eta^2{:}\eta^2$-pyrazolato ligands, with a terminal $\eta^2\text{-}tBu_2pz$ ligand on one calcium ion and an $\eta^5\text{-}L^{tBu}$ ligand on the other. The dimeric structures of $[Sr(\mu\text{-}\eta^5{:}\eta^2\text{-}tBu_2pz)(\eta^5\text{-}L^{tBu})]_2$ and $[Ba(\mu\text{-}\eta^5{:}\eta^2\text{-}tBu_2pz)(\eta^5\text{-}L^{tBu})]_2$ are connected by two $\mu\text{-}\eta^5{:}\eta^2$-pyrazolato ligands, and the coordination sphere of each metal ion is capped with an $\eta^5\text{-}L^{tBu}$ ligand. In toluene solution, $[(\eta^2\text{-}tBu_2pz)Ca(\mu\text{-}\eta^5{:}\eta^2\text{-}tBu_2pz)(\mu\text{-}\eta^2{:}\eta^2\text{-}tBu_2pz)Ca(\eta^5\text{-}L^{tBu})]$ exists as an equilibrium mixture of at least four compounds. In toluene solution, $[Sr(\mu\text{-}\eta^5{:}\eta^2\text{-}tBu_2pz)(\eta^5\text{-}L^{tBu})]_2$ exists in equilibrium with $Sr(\eta^5\text{-}L^{tBu})_2$ and $Sr_4(tBu_2pz)_8$. A van't Hoff analysis of this equilibrium between 46 and 104 °C afforded $\Delta H° = 22.2 \pm 0.7$ kcal/mol, $\Delta S° = 43.7 \pm 1.9$ cal/mol·K, and $\Delta G°(298\ K) = 9.2 \pm 0.9$ kcal/mol. $[Ba(\mu\text{-}\eta^5{:}\eta^2\text{-}tBu_2pz)(\eta^5\text{-}L^{tBu})]_2$ exists in toluene solution as a single, pure species between –60 and +80 °C. The overall results suggest that the $\eta^5\text{-}L^{tBu}$ ligand is better at saturating the coordination sphere of the metal ion to which it coordinates than is the tBu_2pz ligand, and is suggested as a more promising ligand for the construction of practical, volatile chemical vapor deposition film growth precursors.

Introduction

Recent efforts in the coordination chemistry of calcium, strontium, and barium have been driven by applications in polymerization catalysis, organic synthesis, and film growth by chemical vapor deposition (CVD) and related techniques.[1–5] Solid state materials containing the group 2 elements have many significant technological applications, and CVD is commonly used for the growth of thin films of these materials.[1–3] Despite intense investigation, CVD precursors of the heavier group 2 elements remain problematic.[1–3] It has been difficult to identify structures that combine sufficient volatility and thermal stability, due to the high molecular weights, the high coordination numbers, and the low formation constants of complexes containing these elements. The key to future developments in this area must reside with ligand design. To date, the most widely used group 2 CVD precursors have employed substituted cyclopentadienyl[2] or β-diketonato[3] ligands.

Our laboratory has devoted considerable effort to the development of new nitrogen-based pyrazolato[6] and β-diketiminato[7] ligands for the group 2 elements. In particular, we have found that group 2 bis(pyrazolato) complexes form monomers only in the presence of neutral donor ligands, but these complexes decompose prior to sublimation with loss of the neutral ligands to afford oligomeric pyrazolato complexes with very low vapor pressures.[6] We have also recently reported that β-diketiminato ligands with alkyl substituents on the nitrogen atoms bond to group 2 metal centers with π- or η^5-coordination modes, and that these ligands coordinate unexpectedly well to the larger group 2 metal ions.[7] Herein we describe a surprising series of dimeric calcium, strontium, and barium complexes that contain both β-diketiminato and pyrazolato ligands. The β-diketiminato ligands coordinate to the metal centers with a terminal η^5-coordination mode, while the pyrazolato ligands adopt terminal η^2-, $\mu\text{-}\eta^2{:}\eta^2$-, or $\mu\text{-}\eta^5{:}\eta^2$-coordination modes. Documentation of pyrazolato ligand coordination modes has been a central theme of many research reports in recent years,[8] but there have been few reports of heavier group 2 pyrazolato complexes.[6b,9] The results described herein afford unusual examples of pyrazolato ligand coordination to group 2 centers, provide a conceptual method for

reduction of oligomerization in pyrazolato complexes through inclusion of terminal η^5-β-diketiminato ligands, allow direct comparison of the donor characteristics of β-diketiminato and pyrazolato ligands, and suggest new directions for the development of ligands that can be used to manipulate the properties of group 2 complexes. We also describe ligand redistribution equilibria of the new heteroleptic complexes and provide thermodynamic parameters for the $[Sr(\mu\text{-}\eta^5\text{:}\eta^2\text{-}t\text{Bu}_2\text{pz})(\eta^5\text{-L}^{t\text{Bu}})]_2$ equilibria.

Results

Synthetic Chemistry

Treatment of $M[N(SiMe_3)_2]_2(THF)_2$ (M = Ca, Sr, Ba)[10] with various stoichiometries of *N*-*tert*-butyl-4-(*tert*-butylimino)-2-penten-2-amine ($L^{t\text{Bu}}H$)[11] and 3,5-di-*tert*-butylpyrazole ($t\text{Bu}_2\text{pzH}$) as described in Equation (1) afforded $[(\eta^2\text{-}t\text{Bu}_2\text{pz})\text{Ca}(\mu\text{-}\eta^5\text{:}\eta^2\text{-}t\text{Bu}_2\text{pz})(\mu\text{-}\eta^2\text{:}\eta^2\text{-}t\text{Bu}_2\text{pz})\text{Ca}(\eta^5\text{-L}^{t\text{Bu}})]$ (**1**, 17%), $[Sr(\mu\text{-}\eta^5\text{:}\eta^2\text{-}t\text{Bu}_2\text{pz})(\eta^5\text{-L}^{t\text{Bu}})]_2$ (**2**, 50%), and $[Ba(\mu\text{-}\eta^5\text{:}\eta^2\text{-}t\text{Bu}_2\text{pz})(\eta^5\text{-L}^{t\text{Bu}})]_2$ (**3**, 66%) as colorless crystalline solids. Variations in the $L^{t\text{Bu}}H/t\text{Bu}_2\text{pzH}$ stoichiometries away from those required for **1** did not lead to new products, and only **1** crystallized from the reaction mixtures. Interestingly, the highest crystallized yields of **1** were obtained with an $L^{t\text{Bu}}H/t\text{Bu}_2\text{pzH}$ ratio of 2:2 and not 1:3 as required for the stoichiometry of **1**. The order of reagent addition was important in the synthesis of **1**–**3**. If $t\text{Bu}_2\text{pzH}$ was added first, followed by $L^{t\text{Bu}}H$, then complex product mixtures resulted. Complex **1** is soluble in hexane, while **2** and **3** are insoluble in hexane and are moderately soluble in toluene at room temperature. The structural assignments for **1**–**3** were based upon spectral and analytical data as well as X-ray structure determinations. In solution, **1** exists as an equilibrium mixture of at least four species at ambient temperature, while **2** exists as an equilibrium mixture of three species. By contrast, **3** is a single species in solution between –60 and +80 °C. The variable-temperature NMR spectroscopic data for these complexes are described below.

X-ray Crystal Structure Determinations

The crystal structures of **1**–**3** were determined in order to understand their molecular structures. Perspective views of **1**–**3** are shown in Figures 1, 2 and 3. The crystal data are given in Table 1. Selected bond lengths and angles are presented in Tables 2, 3 and 4.

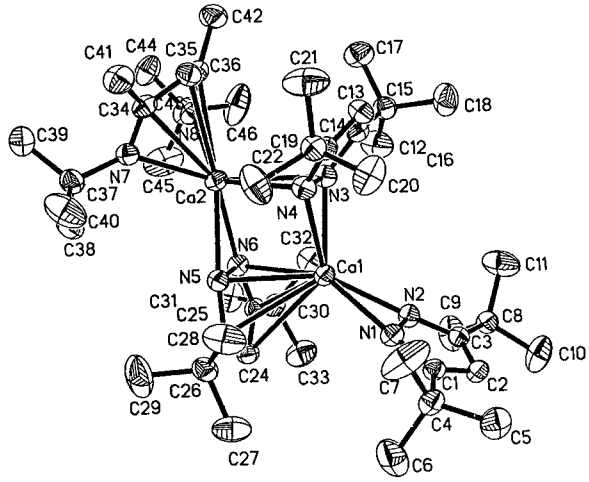

Figure 1. Perspective view of **1** with thermal ellipsoids at the 50% probability level.

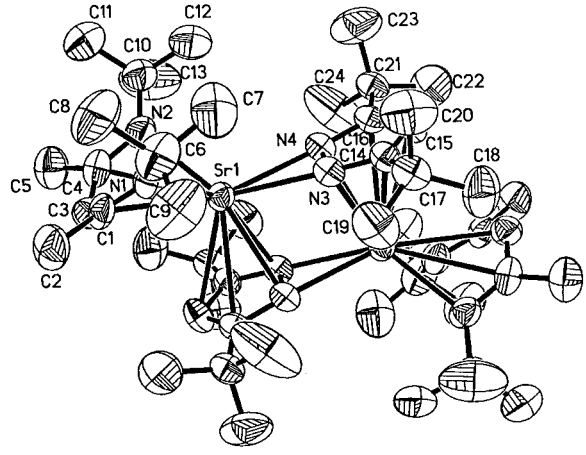

Figure 2. Perspective view of **2** with thermal ellipsoids at the 50% probability level.

In the solid state, **1** can be thought of as $Ca(\eta^5\text{-L}^{t\text{Bu}})(\eta^2\text{-}t\text{Bu}_2\text{pz})$ and $Ca(\eta^2\text{-}t\text{Bu}_2\text{pz})_2$ fragments that dimerize through formation of $\mu\text{-}\eta^5\text{:}\eta^2$- and $\mu\text{-}\eta^2\text{:}\eta^2$-pyrazolato ligands (Figure 1). The $\eta^5\text{-L}^{t\text{Bu}}$ ligand has calcium–nitrogen bond lengths of 2.322(2) and 2.342(2) Å, while the calcium–carbon bond lengths range between 2.741(3) and 2.827(3) Å. These values are slightly shorter than those observed in $Ca(\eta^5\text{-L}^{t\text{Bu}})_2$ (Ca–N 2.342–2.358, Ca–C 2.817–2.901 Å).[7b] The terminal η^2-pyrazolato ligand has cal-

cium–nitrogen bond lengths of 2.315(2) and 2.299(2) Å, which can be compared to the corresponding values in complexes of the formula Ca(η^2-$R_2pz)_2$L (R = Me, *t*Bu;L = neutral donor; Ca–N = 2.311–2.529 Å).[6b] The calcium–nitrogen bond lengths for the μ-η^2:η^2-*t*Bu_2pz ligand are 2.438(2) and 2.433(2) Å for Ca(1) and 2.588(2) and 2.642(2) Å for Ca(2). Thus, the μ-η^2:η^2-*t*Bu_2pz ligand is more strongly bonded to Ca(1), and this metal center is assigned as the Ca(η^2-*t*Bu_2pz)$_2$ fragment. For Ca(2), the calcium–nitrogen bond lengths for the μ-η^5:η^2-*t*Bu_2pz ligand are 2.452(2) and 2.480(2) Å, while for Ca(1) these values are 2.583(2) and 2.598(2) Å. The calcium–carbon bond lengths range from 2.832(2) to 2.997(2) Å. Based upon bond lengths, Ca(2) is more strongly bonded to the pyrazolato ligand containing N(5) and N(6), and thus Ca(2) is assigned as the Ca(η^5-L$^{t\mathrm{Bu}}$)(η^2-*t*Bu_2pz) fragment. The Ca(1)–carbon(pyrazolato) distances are longer than the Ca(2)–C(η^5-L$^{t\mathrm{Bu}}$) distances in **1**, and are comparable to those observed in Ca(η^5-L$^{t\mathrm{Bu}}$)$_2$.[7b] The calcium–carbon bond length in Ca($C_5Me_5)_2$ is 2.64(2) Å.[12] Thus, the η^5-pyrazolato ligand interaction involving Ca(1) within **1** is best described as a π-donor interaction and is different from the terminal η^5-pyrazolato ligand bonding that has been described in several ruthenium complexes.[13]

The overall molecular structures of **2** and **3** are similar, and can be viewed as dimers of two M(η^5-L$^{t\mathrm{Bu}}$)(η^2-*t*Bu_2pz) fragments (Figures 2 and 3). The η^5-L$^{t\mathrm{Bu}}$ ligand in **2** has strontium–nitrogen bond lengths of 2.512(4) and 2.516(5) Å, while the strontium–carbon bond lengths range between 3.004(6) and 3.052(6) Å. The analogous barium–nitrogen distances in **3** are 2.633(6) and 2.642(6) Å, while the barium–carbon distances range between 3.110(8) and 3.176(8) Å. The values are comparable to those of Sr(η^5-

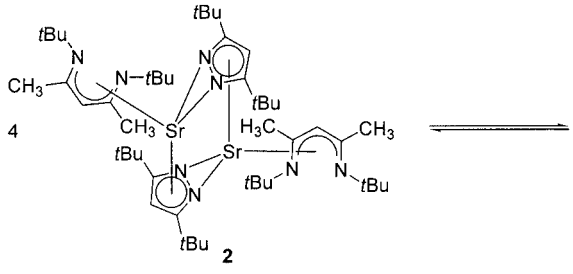
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$L^{tBu})_2$ [Sr–N 2.473(2)–2.517(2) Å, Sr–C 2.928(2)–3.004(2) Å] and Ba(η^5-L^{tBu})$_2$ (Ba–N 2.617–2.680 Å, Ba–C 3.055–3.157 Å).[7b] The metal–carbon distances in **2** and **3** are slightly longer than the metal–carbon distances in Sr[C_5(tBu)$_3H_2$]$_2$(THF) (Sr–$C_{Cp'}$ 2.87 Å avg.)[14] and Ba(C_5Me_5)$_2$ [2.98(1), 2.99(2) Å].[12] The μ-η^5:η^2-tBu$_2$pz ligand in **2** possesses strontium–nitrogen bond lengths of 2.614(5) and 2.618(5) Å for the η^2-interaction, and 2.855(4) and 2.897(4) Å for the η^5-bonded fragment. For **3**, the related values are 2.776(6) and 2.793(6) Å for the η^2-interaction, and 3.004(6) and 3.036(6) Å for the η^5-bonded fragment. The metal–carbon distances associated with the μ-η^5:η^2-tBu$_2$pz ligand range between 3.083(5) and 3.229(5) Å for **2** and 3.189(8)–3.325(8) Å for **3**. These values are similar to or longer than those associated with the η^5-L^{tBu} ligand in **2** and **3** and M(η^5-L^{tBu})$_2$,[7b] and are 5–10% longer than the related distances in Sr[C_5(tBu)$_3H_2$]$_2$(THF) (Sr–$C_{Cp'}$ 2.87 Å avg.)[14] and Ba(C_5Me_5)$_2$ [2.98(1), 2.99(2) Å].[12] Again, the bond lengths associated with the μ-η^5:η^2-tBu$_2$pz ligand suggest that the η^5-interactions are best described as π-donation to satisfy the Lewis acidity of the unsaturated metal centers. The angle between the planes of the β-diketiminato and pyrazolato C_3N_2 cores is 20.8(3)° in **2** and 23.5(3)° in **3**, which can be compared with C_5Me_5(centroid)–metal–C_5Me_5(centroid) angles of 26–33° in the monomeric, base-free metallocenes M(C_5Me_5)$_2$.[12]

Variable-Temperature NMR Behavior of 1–3

Having established the solid-state structures, we next explored the solution structures using NMR spectroscopy. The solution NMR behavior of **1**–**3** differed significantly. Complex **1** exhibited four β-diketiminato ligand β-CH ^{1}H NMR resonances in [D_8]toluene at ambient temperature at δ = 4.60, 4.44, 4.22, and 4.20 ppm, in a ratio of 26:15:12:47. The resonance at δ = 4.22 ppm was identified as the β-CH resonance of Ca(η^5-L^{tBu})$_2$, by comparison with authentic material {also δ = 1.98 (CH_3), 1.34 [C(CH_3)$_3$] ppm}.[7b] Thus, Ca(η^5-L^{tBu})$_2$ is a minor constituent of the solution. A species with resonances consistent with **1** was observed in the ^{1}H NMR spectrum {δ = 6.19, 6.08, 6.04 (tBu$_2$pz β-CH), 4.20 (L^{tBu} β-CH), 1.96 (L^{tBu} CH_3), 1.45, 1.40, 1.28 [L^{tBu} C(CH_3)$_3$]}, and accounted for 47% of the integrated β-CH signals. The remaining two β-diketiminato ligand L^{tBu} β-CH resonances correspond to unknown species, but probably contain mixed pyrazolato/L^{tBu} ligand spheres. The complex Ca$_3$(tBu$_2$Pz)$_6$ has been recently described,[9d] and has tBu$_2$pz β-CH resonances at δ = 6.20, 6.08, and 6.00 ppm and a *tert*-butyl methyl resonance at δ = 1.37 ppm in the ^{1}H NMR in [D_8]toluene at –55 °C. In the ^{1}H NMR spectrum of **1** in [D_8]toluene at –60 °C, tBu$_2$pz β-CH resonances were observed at δ = 6.34, 6.29, 6.23, 6.18, and 6.08 ppm. These resonances do not match those reported for Ca$_3$(tBu$_2$pz)$_6$. It is possible that Ca$_3$(tBu$_2$pz)$_6$ precipitates from [D_8]toluene at –60 °C, and is thus not observed. The presence of **1**, Ca(η^5-L^{tBu})$_2$, and one or two other unidentified species in solutions derived from pure **1** suggest that multiple equilibria are present.

In [D_8]toluene at ambient temperature, **2** exhibited a mixture of two complexes containing β-diketiminato ligands [δ = 4.21, 4.19 (L^{tBu} β-CH) ppm] in a 13:87 ratio. The major species exhibits the resonances expected for **2** {δ = 6.26 (tBu$_2$pz β-CH), 4.19 (L^{tBu} β-CH), 1.99 (L^{tBu} CH_3), 1.47, 1.30 [L^{tBu}, tBu$_2$pz C(CH_3)$_3$]}. The minor species matches the resonances that we have previously reported for Sr(η^5-L^{tBu})$_2$.[7b] The presence of Sr(η^5-L^{tBu})$_2$ suggests the equilibrium depicted in Equation (2), wherein **2** converts partially in [D_8]toluene to Sr(η^5-L^{tBu})$_2$ and the recently reported tetramer Sr$_4$(tBu$_2$pz)$_8$.[9d] The ^{1}H NMR spectrum of **2** at –60 °C in [D_8]toluene revealed 1:1:1 pyrazolato β-CH resonances at δ = 6.35, 6.26, and 6.07 ppm and a *tert*-butyl methyl resonance at δ = 1.44 ppm, after the resonances for Sr(η^5-L^{tBu})$_2$ and **2** had been excluded. For comparison, the ^{1}H NMR spectrum of Sr$_4$(tBu$_2$pz)$_8$ at –60 °C in [D_8]toluene is reported to have pyrazolato β-CH resonances at δ = 6.31, 6.16, and 6.08 ppm and a *tert*-butyl methyl resonance at δ = 1.48 ppm.[9d] Thus, our ^{1}H NMR spectrum at –60 °C supports the presence of Sr$_4$(tBu$_2$pz)$_8$ in the equilibrium mixture. Below 46 °C, the mixture of Sr(η^5-L^{tBu})$_2$ and **2** remained approximately constant, possibly due to a kinetically slow approach to the equilibrium. Above 46 °C, however, the Sr(η^5-L^{tBu})$_2$/**2** ratio increased with temperature (Table 5). Accordingly, we carried out a van't Hoff analysis of the equilibrium depicted in Equation (2). The equilibrium constants shown in Table 2 were determined between 46 and 104 °C by integration of the β-diketonate β-CH resonances of Sr(η^5-L^{tBu})$_2$ and **2**, and then calculating the concentrations of each species. The concentration of Sr$_4$(tBu$_2$pz)$_8$ could not be measured directly between 46 and 104 °C due to very broad signals,[9d] but was calculated at each temperature by assuming a stoichiometry of 1:4 with Sr(η^5-L^{tBu})$_2$. Analysis of the data for the equilibrium depicted in Equation (2) using standard procedures for van't Hoff analyses[15] afforded $\Delta H°$ = 22.2 ± 0.7 kcal/mol, $\Delta S°$ = 43.7 ± 1.9 cal/mol·K, and $\Delta G°$(298 K) = 9.2 ± 0.9 kcal/mol. Consistent with an equilibrium process possessing a positive $\Delta G°$, the equilibrium at 298 K lies strongly toward **2** and is reflected by the small K_{eq} values in Table 2.



K_{eq} = [Sr(η^5-L^{tBu})$_2$]^4[Sr$_4$(tBu$_2$pz)$_8$]/[**2**]^4 (2)

Table 5. Equilibrium constants for **2** at various temperatures.

T [K]	K_{eq} [M]
319.2	2.17×10^{-6}
323.7	3.20×10^{-6}
328.1	5.26×10^{-6}
332.6	8.60×10^{-6}
337.0	1.39×10^{-5}
341.5	2.54×10^{-5}
345.6	4.52×10^{-5}
350.2	6.66×10^{-5}
354.4	9.74×10^{-5}
358.3	1.19×10^{-4}
363.8	1.41×10^{-4}
368.2	1.93×10^{-4}
372.7	3.29×10^{-4}
377.2	4.40×10^{-4}

In contrast to **1** and **2**, the ^{1}H NMR spectra of **3** between –60 and +80 °C in [D$_8$]toluene revealed a single species with resonances consistent with the solid-state structure. Thus, **3** shows no evidence for equilibria similar to those described for **1** and **2**.

Discussion

The η^5-coordination of the diketiminato ligands is a prominent structural feature of **1**–**3**. We have recently reported that complexes of the formula M(η^5-L$^{t\mathrm{Bu}}$)$_2$ (M = Ca, Sr, Ba) adopt sandwich-like structures with η^5-L$^{t\mathrm{Bu}}$ ligands.[7] In our paper on M(η^5-L$^{t\mathrm{Bu}}$)$_2$,[7b] we analyzed the η^5-L$^{t\mathrm{Bu}}$ bonding in terms of the planes incorporating the atoms MN$_2$ (a), N$_2$(C$_\alpha$)$_2$ (b), and (C$_\alpha$)$_2$C$_\beta$ (c). For M(η^5-L$^{t\mathrm{Bu}}$)$_2$, the a/b angles were between 70 and 72° and the b/c angles were between 25 and 26°, and these metrical parameters were used to support the η^5-coordination mode and differentiate it from the more common η^2-form (which has much smaller a/b and b/c values[7]). The corresponding metrical parameters for **1**–**3** are as follows: **1**: a/b = 74.9° and b/c = 29.4°; **2**: a/b = 70.5° and b/c = 29.0°; **3**: a/b = 70.5° and b/c = 28.7°. These values are close to those of M(η^5-L$^{t\mathrm{Bu}}$)$_2$, and are consistent with similar η^5-bonding of the L$^{t\mathrm{Bu}}$ ligands in **1**–**3**. All of the other heavier group 2 β-diketiminato complexes described to date feature 2,6-diisopropylphenyl,[4d,5,16] 2-methoxyphenyl,[17] or cyclohexyl[18] moieties as the nitrogen substituents. Calcium, strontium, and barium complexes containing the 2,6-diisopropylphenyl-substituted ligand [CH{C(CH$_3$)N(2,6-*i*Pr$_2$C$_6$H$_3$)}$_2$]$^-$ (L$^{\mathrm{Ar}}$) exhibit the η^2-coordination mode, through the nitrogen atoms of L$^{\mathrm{Ar}}$. Use of the *N*-cyclohexyl-substituted diketiminato ligand [CH{C(CH$_3$)N(C$_6$H$_{11}$)}$_2$]$^-$ (L$^{\mathrm{Cy}}$) afforded the dimeric barium complex Ba$_2$(L$^{\mathrm{Cy}}$)$_3$[N(SiMe$_3$)$_2$], which contains η^5-, μ-η^2:η^2:η^5-, and μ-η^2:η^3-β-diketiminato ligands.[18] Adoption of the η^2-coordination mode in complexes containing L$^{\mathrm{Ar}}$ is presumably a steric effect that is driven by the bulky aromatic isopropyl substituents. The various coordination modes of β-diketiminato ligands have been recently reviewed.[19] The η^5-β-diketiminato ligand has been structurally documented in a few main group, lanthanide, and early transition metal complexes, but still remains rare.[7b,18,19] The present results, our previous report on M(η^5-L$^{t\mathrm{Bu}}$)$_2$,[7b] and Ba$_2$(L$^{\mathrm{Cy}}$)$_3$[N(SiMe$_3$)$_2$][18] suggest that the η^5-β-diketiminato coordination mode should be common in the heavier group 2 complexes when alkyl groups or less bulky aromatic rings are present on the nitrogen atoms.

Complex **1** contains terminal η^2-, μ-η^5:η^2-, and μ-η^2:η^2-pyrazolato ligands, while **2** and **3** possess μ-η^5:η^2-pyrazolato ligands. The terminal η^2-coordination mode has been documented in Ca(R$_2$pz)$_2$(L$_n$) (L$_n$ = polydentate oxygen or nitrogen donor),[6b] M(Ph$_2$pz)$_2$(THF)$_4$ (M = Ca, Sr, Ba),[9c] M(Ph$_2$pz)$_2$(DME)$_n$ (M = Ca, Sr, *n* = 2; M = Ba, *n* = 3),[9c] M(Me$_2$pz)$_2$(Me$_2$pzH)$_4$ (M = Ca, Sr),[9c] Ca$_3$(*t*Bu$_2$pz)$_6$,[9d] Sr$_4$(*t*Bu$_2$pz)$_8$,[9d] and Ba$_6$(*t*Bu$_2$pz)$_{12}$.[9d] Terminal η^2-pyrazolato ligands are thus common in the heavier group 2 metal complexes, and are probably driven by achieving maximum electrostatic interactions between the pyrazolato ligand in-plane nitrogen-based orbitals and the group 2 metal ions. One pyrazolato ligand in **1** adopts the μ-η^2:η^2-coordination mode. This coordination mode has been previously observed in Ca$_3$(*t*Bu$_2$pz)$_6$[9d] and in lanthanide complexes such as Ln$_3$(Ph$_2$pz)$_9$ (Ln = La, Nd).[21] The similar ionic radii[22] of Ca$^{\mathrm{II}}$ (1.00 Å), La$^{\mathrm{III}}$ (1.032 Å), and Nd$^{\mathrm{III}}$ (0.983 Å) are most likely the origin of the similar pyrazolato ligand coordination modes. Finally, **1**–**3** contain μ-η^5:η^2-pyrazolato ligands. This coordination mode has been previously observed in the group 2 complexes Ca$_3$(*t*Bu$_2$pz)$_6$,[9d] Sr$_4$(*t*Bu$_2$pz)$_8$,[9d] and Ba$_6$(*t*Bu$_2$pz)$_{12}$,[9d] and in lanthanide complexes such as Ln$_3$(Ph$_2$pz)$_9$ (Ln = La, Nd)[21] and Eu$_4$(*t*Bu$_2$pz)$_8$.[23] Formation of μ-η^5:η^2-pyrazolato ligands appears to arise due to the coordinative unsaturation at the group 2 and lanthanide metal ions, which can be satisfied in the absence of good neutral donor ligands by donation of the out-of-plane π-orbitals of the pyrazolato ligand C$_3$N$_2$ cores to an adjacent metal ion. In **1**–**3**, the μ-η^5:η^2-pyrazolato ligands lead to dimeric species, whereas in the other group 2 and lanthanide complexes, trimers, tetramers, and even hexamers are obtained through formation of μ-η^5:η^2-pyrazolato ligands. It is clear that the good donor capabilities of L$^{t\mathrm{Bu}}$ restrict the degree of oligomerization in **1**–**3**.

The overall structures of **1**–**3** can be compared with those of Ca$_3$(*t*Bu$_2$pz)$_6$,[9d] Sr$_4$(*t*Bu$_2$pz)$_8$,[9d] Ba$_6$(*t*Bu$_2$pz)$_{12}$,[9d] and Eu$_4$(*t*Bu$_2$pz)$_8$.[23] Table 6 compares selected metal–nitrogen bond lengths in **1**–**3** with the related fragments in Ca$_3$(*t*Bu$_2$pz)$_6$,[9d] Sr$_4$(*t*Bu$_2$pz)$_8$,[9d] and Ba$_6$(*t*Bu$_2$pz)$_{12}$.[9d] Remarkably, the Ca$_2$(η^2-*t*Bu$_2$pz)(μ-η^5:η^2-*t*Bu$_2$pz)(μ-η^2:η^2-*t*Bu$_2$pz) fragment in **1** is virtually identical structurally to the coordination sphere of the outer and middle calcium ions in Ca$_3$(*t*Bu$_2$pz)$_6$. Indeed, if an outer Ca(*t*Bu$_2$pz)$_3^-$ fragment in Ca$_3$(*t*Bu$_2$pz)$_6$ is replaced by L$^{t\mathrm{Bu}}$, the molecular structure of **1** is obtained. Such similarity suggests that the Ca$_2$(η^2-*t*Bu$_2$pz)(μ-η^5:η^2-*t*Bu$_2$pz)(μ-η^2:η^2-*t*Bu$_2$pz) fragment is particularly stable. The structural parameters of the M$_2$(μ-η^5:η^2-*t*Bu$_2$pz)$_2$ core fragments in **2** and **3** show a similar high degree of congruence with the inner metal ion M$_2$(μ-η^5:η^2-*t*Bu$_2$pz)$_2$ substructures of Sr$_4$(*t*Bu$_2$pz)$_8$, Ba$_6$(*t*Bu$_2$pz)$_{12}$, and Eu$_4$(*t*Bu$_2$pz)$_8$. In fact, as shown in Table 6, the metal–nitrogen bond lengths of the M$_2$(μ-η^5:η^2-*t*Bu$_2$pz)$_2$ substructures in **2** and Sr$_4$(*t*Bu$_2$pz)$_8$ and **3** and Ba$_6$(*t*Bu$_2$-

$pz)_{12}$ are very similar. Replacement of the outer two $Sr(tBu_2pz)_3^-$ fragments in $Sr_4(tBu_2pz)_8$ by L^{tBu} ligands affords the molecular structure of **2**. In $Ba_6(tBu_2pz)_{12}$, replacement of outer $Ba(tBu_2pz)_3^-$ and $Ba_3(tBu_2pz)_7^-$ fragments by two L^{tBu} ligands affords the molecular structure of **3**. Such close structural similarities suggest that the $M_2(\mu\text{-}\eta^5\text{:}\eta^2\text{-}tBu_2pz)_2$ substructure is particularly stable, and that this unit is likely to be observed in other strontium and barium complexes that contain tBu_2pz ligands. As in **1**, the L^{tBu} ligands in **2** and **3** are sterically saturating and block these complexes from forming higher oligomeric structures.

The redistribution equilibria of **1**–**3** are of relevance to recent reports of lactide polymerization catalysis by unsymmetrical group 2 complexes (LMX) containing β-diketiminato ligands (L).[4e,16,17] In such catalysis, it is presumably the unsymmetrical LMX complex that is the active and desired precatalyst, since X^- possesses the needed nucleophilic properties to initiate catalysis and the steric properties of L are designed to promote stereoselectivity in the polymerizations. By contrast, ML_2 is unlikely to initiate catalysis efficiently and MX_2 may not promote stereoselective polymerization. A recent report by Hill has explored the stability of β-diketiminato complexes of the formula $L^{Ar}M[N(SiMe_3)_2](THF)$ toward ligand redistribution in solution.[16a] Interestingly, $L^{Ar}Ca[N(SiMe_3)_2](THF)$ was found to be inert toward ligand redistribution in [D_8]toluene solution at ambient temperature, while $L^{Ar}Ba[N(SiMe_3)_2](THF)$ was in equilibrium with $Ba(L^{Ar})_2$ and $Ba[N(SiMe_3)_2](THF)_x$ under the same conditions. Thermodynamic parameters were not reported for the latter system. It was proposed that the larger size and lower Lewis acidity of the barium ion makes it more susceptible toward ligand redistribution, compared to $L^{Ar}Ca[N(SiMe_3)_2](THF)$.[16a] The equilibrium trend observed for $L^{Ar}M[N(SiMe_3)_2](THF)$ is the opposite of what we have observed in the present study. Qualitatively, **1** undergoes more ligand redistribution at ambient temperature than **2**, since the percentage of the dimeric starting material present in **1** (47%) is lower than in **2** (87%). Thus, the order of ligand redistribution in solution is **1** > **2** >> **3**. While it was not possible to carry out a van't Hoff analysis on **1**, due to the multiple equilibria, the thermodynamic parameters for **2** provide some insight into the factors that stabilize the heteroleptic structures for **1**–**3**. In view of the positive $\Delta G°$ values for **2** in the temperature range that was studied (46–104 °C), the K_{eq} values are very small and strongly favor the heteroleptic starting material. In **2**, $\Delta H°$ is large (22.2 ± 0.3 kcal/mol), but this value is offset by a large $\Delta S°$ value (43.7 ± 0.3 cal/mol·K), which allows the ΔG° values to decrease and the K_{eq} values to increase with increasing temperature. We have previously proposed that the L^{tBu} ligands in $M(\eta^5\text{-}L^{tBu})_2$ bond most strongly to the barium ion and least strongly to the calcium ion, based upon comparison of the metal–nitrogen and metal–carbon bond lengths with those of Cp^*_2M.[7b] If this proposal holds for **1**–**3**, then the $\Delta H°$ values should increase in the order **1** < **2** < **3**, which follows the qualitative trend in redistribution equilibria. It is also likely that there is an entropic contribution to the equilibria, since the homoleptic pyrazolato complexes adopt the oligomeric structures $Ca_3(tBu_2pz)_6$, $Sr_4(tBu_2pz)_8$, and $Ba_6(tBu_2pz)_{12}$ in the solid state and appear to adopt similar structures in solution.[9d] Thus, the $\Delta S°$ values should decrease in the order **1** > **2** > **3** to reflect the increasing organization required for the oligomeric series. It is likely that the resistance of **3** toward ligand exchange in solution results from a combination of optimum bonding to the L^{tBu} ligands and the entropic penalty associated with the formation of the hexameric product $Ba_6(tBu_2pz)_{12}$. These results suggest that the nature of the ligands has a pronounced effect upon redistribution equilibria of heteroleptic group 2 complexes, and that appropriate choice of ligands can reverse the normal redistribution equilibrium trend of Ca > Sr > Ba.[16a] There are few other equilibrium constant data with which those of **2** can be compared. Cp*CaI(THF)$_2$ is

reported to dissociate in [D$_8$]THF to afford Cp*$_2$Ca(THF)$_2$ and CaI$_2$(THF)$_2$ with K_{eq} = 4.[24] (C$_5$*i*Pr$_4$H)CaI(OEt$_2$)$_n$ dissociates in diethyl ether to Ca(C$_5$*i*Pr$_4$H)$_2$ and CaI$_2$(OEt$_2$)$_n$ with an estimated K_{eq} of 2.[25] Mixtures of Ba(CH$_2$C$_6$H$_5$)$_2$(THF)$_2$ and Ba(C$_5$Me$_4$SiMe$_2$C$_6$H$_5$)$_2$ favor the heteroleptic complex Ba(C$_5$Me$_4$SiMe$_2$C$_6$H$_5$)(CH$_2$C$_6$H$_5$)(THF) with K_{eq} values that are much greater than one.[26] The complex [Ba(C$_5$H*i*Pr$_4$)(I)(THF)$_2$]$_2$ resists ligand redistribution in tetrahydrofuran, but does scramble ligands in less coordinating solvents such as benzene.[27] Redistribution equilibria are also important for the heavier group 2 Grignard analogs.[28]

With regards to the design of heavier group 2 metal complexes for thin film growth applications, our previous study of M(η^5-L$^{t\mathrm{Bu}}$)$_2$[7b] and the results herein demonstrate that the L$^{t\mathrm{Bu}}$ ligand is very effective at blocking a face of the metal ion to which it coordinates toward further oligomerization. By contrast, the *t*Bu$_2$pz ligand does not provide the same degree of steric saturation as the L$^{t\mathrm{Bu}}$ ligand, which leads to oligomeric complexes containing various pyrazolato ligand coordination modes in the absence of neutral amine or ether donor ligands. While Ca$_3$(*t*Bu$_2$pz)$_6$, Sr$_4$(*t*Bu$_2$pz)$_8$, and Ba$_6$(*t*Bu$_2$pz)$_{12}$ are reported to be volatile,[9d] our experience with Ca(*t*Bu$_2$pz)$_2$(L$_n$)[6b] suggests that the vapor pressures are very low and probably not high enough for practical use in CVD processes employing thermal source delivery. Thus, pyrazolato ligands are not likely to be as promising as other donor ligands in the search for improved volatile group 2 CVD precursors.

Experimental Section

General Considerations: All reactions were performed under argon using either glovebox or Schlenk line techniques. M[N(SiMe$_3$)$_2$]$_2$(THF)$_2$ (M = Ca, Sr, Ba),[10] *N*-*tert*-butyl-4-(*tert*-butylimino)-2-penten-2-amine (L$^{t\mathrm{Bu}}$H),[11] and 3,5-di-*tert*-butylpyrazole[29] were prepared according to reported methods. ^{1}H and ^{13}C{^{1}H} NMR spectra were obtained at 400 and 100 MHz, respectively, in [D$_8$]-toluene. Infrared spectra were obtained using Nujol as the medium. Elemental analyses were performed by Midwest Microlab, Indianapolis, IN. Melting points were obtained with a Haake-Buchler HBI digital melting point apparatus and are uncorrected.

Synthesis of [(η^2-*t*Bu$_2$pz)Ca(μ-η^5:η^2-*t*Bu$_2$pz)(μ-η^2:η^2-*t*Bu$_2$pz)Ca(η^5-L$^{t\mathrm{Bu}}$)] (1): A 100-mL Schlenk flask was charged with Ca[N(SiMe$_3$)$_2$]$_2$(THF)$_2$ (0.420 g, 0.831 mmol) and toluene (30 mL). This solution was treated with L$^{t\mathrm{Bu}}$H (0.175 g, 0.831 mmol) and was stirred at ambient temperature for 3 h. The resultant solution was then treated with *t*Bu$_2$pzH (0.150 g, 0.831 mmol) in small portions and was further stirred for 18 h. The volatile components were removed under reduced pressure and the crude material was extracted with hexane (30 mL). The hexane extract was filtered through a 2-cm pad of Celite on a coarse glass frit to afford a colorless solution. The filtrate was concentrated to a volume of 10 mL and was stored at –30 °C for 24 h to afford **1** as colorless crystals {0.06 g, 17%, based on Ca[N(SiMe$_3$)$_2$]$_2$(THF)$_2$}: m.p. 184–186 °C (dec). IR (Nujol): $\tilde{\nu}$ = 1632 (m), 1500 (m), 1250 (m), 1215 (w), 1188 (w), 1007 (w), 976 (w), 810 (w), 797 (w), 767 (w) cm^{-1}. ^{1}H NMR ([D$_8$]toluene, 23 °C): δ = 1.45, 1.40, 1.34, 1.32, 1.28, 1.13 [pyrazolato and L$^{t\mathrm{Bu}}$ C(C*H*$_3$)$_3$], 1.99, 1.98, 1.96, 1.85 (L$^{t\mathrm{Bu}}$ C*H*$_3$), 4.60, 4.44, 4.22, 4.20 (L$^{t\mathrm{Bu}}$ β-C*H*), 6.22, 6.19, 6.08, 6.04, 5.98 (pyrazolato ring β-C*H*) ppm. C$_{46}$H$_{82}$Ca$_2$N$_8$ (827.36): C 66.78, H 9.99, N 13.54; found C 66.46, H 9.89, N 13.30.

Synthesis of [Sr(μ-η^5:η^2-*t*Bu$_2$pz)(η^5-L$^{t\mathrm{Bu}}$)]$_2$ (2): In a fashion similar to the preparation of **1**, treatment of Sr[N(SiMe$_3$)$_2$]$_2$(THF)$_2$ (0.459 g, 0.831 mmol) with L$^{t\mathrm{Bu}}$H (0.175 g, 0.831 mmol), followed by *t*Bu$_2$pzH (0.150 g, 0.831 mmol) in toluene (30 mL), afforded **2** as colorless crystals upon cooling of a hot toluene solution to –30 °C {0.20 g, 50%, based on Sr[N(SiMe$_3$)$_2$]$_2$(THF)$_2$}: m.p. 245–247 °C. IR (Nujol): $\tilde{\nu}$ = 1250 (m), 1210 (m), 1186 (m), 1025 (w), 994 (w), 797 (w), 768 (w), 757 (w) cm^{-1}. ^{1}H NMR ([D$_8$]toluene, 23 °C): δ = 1.30 [s, 36 H, L$^{t\mathrm{Bu}}$ C(C*H*$_3$)$_3$], 1.47 [s, 36 H, pyrazolato C(C*H*$_3$)$_3$], 1.99 (s, 12 H, C*H*$_3$), 4.19 (s, 2 H, β-C*H*), 6.26 (s, 2 H, pyrazolato ring C*H*) ppm. ^{13}C{^{1}H} NMR ([D$_8$]toluene, 23 °C): δ = 25.21 [s, C(*C*H$_3$)], 31.57 [s, pyrazolato C(*C*H$_3$)$_3$], 32.62 [s, pyrazolato *C*(CH$_3$)$_3$], 33.01 [s, L$^{t\mathrm{Bu}}$ C(*C*H$_3$)$_3$], 54.18 [s, L$^{t\mathrm{Bu}}$ *C*(CH$_3$)$_3$], 92.00 (s, β-*C*H), 102.62 (s, pyrazolato ring *C*H), 160.21 [s, pyrazolato ring *C*C(CH$_3$)$_3$], 164.37 (s, *C*CH$_3$) ppm. C$_{48}$H$_{88}$N$_8$Sr$_2$ (952.50): C 60.53, H 9.31, N 11.76; found C 59.50, H 9.05, N 11.41. In addition to the resonances reported for **2**, 13% of Sr(η^5-L$^{t\mathrm{Bu}}$)$_2$[7b] was also observed in the ^{1}H NMR spectrum at ambient temperature in [D$_8$]toluene, and was identified by comparison of its ^{1}H NMR resonances with those of authentic material.

Synthesis of [Ba(μ-η^5:η^2-*t*Bu$_2$pz)(η^5-L$^{t\mathrm{Bu}}$)]$_2$ (3): In a fashion similar to the preparation of **2**, treatment of Ba[N(SiMe$_3$)$_2$]$_2$(THF)$_2$ (1.00 g, 1.66 mmol) with L$^{t\mathrm{Bu}}$H (0.350 g, 1.66 mmol), followed by *t*Bu$_2$pzH (0.300 g, 1.66 mmol) in toluene (30 mL), afforded **3** as a colorless crystals from toluene (0.580 g, 66%, based on Ba[N(SiMe$_3$)$_2$]$_2$(THF)$_2$): m.p. 289–291 °C. IR (Nujol): $\tilde{\nu}$ = 1247 (w), 1208 (m), 1185 (m), 1042 (w), 1023 (w), 967 (w), 793 (m), 765 (m) cm^{-1}. ^{1}H NMR ([D$_8$]toluene, 23 °C): δ = 1.30 [s, 36 H, L$^{t\mathrm{Bu}}$ C(C*H*$_3$)$_3$], 1.47 [s, 36 H, pyrazolato C(C*H*$_3$)$_3$], 2.00 (s, 12 H, C*H*$_3$), 4.18 (s, 2 H, L$^{t\mathrm{Bu}}$ β-C*H*), 6.27 (s, 2 H, pyrazolato ring C*H*) ppm. ^{13}C{^{1}H} NMR ([D$_8$]toluene, 23 °C): δ = 24.76 [s, C(*C*H$_3$)], 31.63 [s, pyrazolato C(*C*H$_3$)$_3$], 32.31 [s, pyrazolato *C*(CH$_3$)$_3$], 32.88 [s, C(*C*H$_3$)$_3$], 54.27 [s, *C*(CH$_3$)$_3$], 90.41 (s, β-*C*H), 103.25 (s, pyrazolato ring *C*H), 157.86 [s, pyrazolato ring *C*C(CH$_3$)$_3$], 162.68 (s, *C*CH$_3$) ppm. C$_{48}$H$_{88}$Ba$_2$N$_8$ (1051.94): C 54.81, H 8.43, N 10.65; found C 54.88, H 8.47, N 10.38.

X-ray Crystallography: Crystals of **1–3** were grown as described above. Diffraction data were collected with a Bruker P4/CCD diffractometer equipped with Mo radiation and a graphite monochromator at –80 °C (**1**) or at ambient temperature with the crystals mounted in glass capillaries (**2** and **3**). A sphere of data was measured at 10–20 s/frame and 0.2–0.3° between frames. The frame data were indexed and integrated with the manufacturer's SMART, SAINT, and SADABS software.[30] All structures were refined using Sheldrick's SHELX-97 software.[31] In the model for **1**, one of the *tert*-butyl groups was severely disordered and was assigned partial atoms [C(20)–C(22)]. All three structures show typically large thermal parameters in the *tert*-butyl groups. All non-hydrogen atoms were refined anisotropically and the hydrogen atom positions were calculated. Complexes **2** and **3** occupy crystallographic inversion centers. CCDC-260847 (**1**), -260848 (**2**), and -260849 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

van't Hoff Analysis of 2: A 5-mm NMR tube was charged with **2** (0.0150 g, 0.0157 mmol) and [D$_8$]toluene (0.85 mL) and was sealed with a plastic cap. ^{1}H NMR spectra were recorded between 46 and

First-Row Transition Metal Bis(amidinate) Complexes; Planar Four-Coordination of Fe^{II} Enforced by Sterically Demanding Aryl Substituents

Christian A. Nijhuis,[a] Erica Jellema,[a] Timo J. J. Sciarone,[a] Auke Meetsma,[a] Peter H. M. Budzelaar,[b] and Bart Hessen*[a]

Keywords: Transition metals / Solid-state structures / Ligand effects / Amidinate / Density functional calculations

The sterically hindered benzamidinate ligand $[PhC(NAr)_2]^-$ (Ar = 2,6-*i*$Pr_2C_6H_3$) has been employed to prepare bis(amidinate) complexes $[\{PhC(NAr)_2\}_2M]$ of the divalent first-row transition metals Cr–Ni (**1**–**5**). For Cr (planar), Mn and Co (tetrahedral) the observed structures follow the electronic preference for the metal ion in its highest spin multiplicity, as determined by DFT calculations. Remarkably, the Fe derivative adopts a distorted planar structure while retaining the high-spin (S = 2) configuration. This rare combination is due to reduced interligand steric interactions in the planar vs. the tetrahedral structure, combined with a relatively small electronic preference of Fe^{II} for the tetrahedral environment. Thus, the simple bidentate ligand *N*,*N*′-diarylbenzamidinate provides a convenient means to make this unusual species accessible for further study.

Introduction

Amidinate anions, with general formula $[R'NC(R)NR'']^-$, have been employed widely as ligands in transition metal and in main group chemistry.[1,2] Their steric and electronic properties are readily modified through variation of the substituents on the carbon and nitrogen atoms, and they have been employed as ancillary ligands in various catalytic conversions, e.g. oligomerisation[3,4] or polymerisation[5–20] of olefins or of cyclic esters.[21,22] Due to the geometric constraints of the NCN ligand backbone, amidinates have small N–M–N bite angles (typically 63–65°). They have a rich coordination geometry in which both chelating and bridging coordination modes can be achieved. The latter has allowed the synthesis of a range of dinuclear complexes with short metal–metal separations.[23–34] The balance between chelating and bridging coordination is critically governed by the substitution pattern of the amidinate ligand. Steric interactions between the substituents on the carbon and nitrogen atoms influence the orientation of the nitrogen lone pairs. Large substituents on the carbon atom induce a convergent orientation of the lone pairs (favouring chelation), while small substituents lead to a more parallel orientation of the lone pairs (enabling bridging).[34,35]

The substituents on the amidinate nitrogen atoms can be used to tune the steric demand of the ligand, influencing the coordination geometry of the metal centre in bis(amidinate) complexes with chelating amidinate ligands. Thus, Winter et al. have demonstrated that an increase in steric demand of the alkyl substituent R in $[\{MeC(NR_2)\}_2Cr]$ from R = *i*Pr to *t*Bu results in a change from square-planar to tetrahedral coordination of the high-spin Cr^{II} centre.[36] For R = *t*Bu, interligand steric interactions apparently become dominant over an electronic preference for square-planar coordination.[37]

The steric hindrance imparted by alkyl substituents on the amidinate nitrogen atoms has its main effect in the NMN coordination plane. To effect steric shielding above and below this coordination plane, two approaches are possible. Introduction of a terphenyl substituent on the amidinate backbone *carbon* atom provides such shielding (as shown by Arnold et al. in complexes of Li^I, Mg^{II}, Al^{III}, Y^{III} and a series of first-row transition metals),[38–43] but relatively remote from the metal–ligand bonds. Another approach is the use of *ortho*-disubstituted aryl groups on the *nitrogen* atoms. By virtue of the perpendicular orientation of the aryl moieties with respect to the NCN backbone (especially when relatively large substituents on the carbon atom are used), the *ortho* substituents provide steric protection to the sites above and below the coordination plane. The 2,6-(diisopropyl)phenyl group (Ar = 2,6-*i*$Pr_2C_6H_3$) has proven to be very efficient in this respect, and has been used successfully in the development of late transition metal olefin polymerisation catalysts with neutral diimine li-

gands[44–47] and in the synthesis of low-coordinate, electron-deficient metal complexes stabilised by β-diketiminates.[48] With amidinate ligands, these substituents have been used only sparingly thus far. The amidines $[RC(NAr)_2]H$ (R = CH_3, 4-MeC_6H_4, 4-$MeOC_6H_4$) were synthesised by Boeré et al., who also reported some initial studies of their Mo^0 coordination chemistry.[49] The amidinates $[tBuC(NAr)_2]^-$, $[4\text{-}MeC_6H_4C(NAr)_2]^-$ and $[PhC(NAr)_2]^-$ have been used as ligands for Al^{III},[50] Ni^{II},[7] group 3 and lanthanide metals.[9,20,22] Due to the positioning of the steric hindrance of these ligands, interesting interligand steric interactions may be anticipated when two of these ligands are attached to (relatively small) first-row transition metals.

Bis(amidinate) complexes of the divalent first-row transition metal ions have been found to adopt either a (distorted) tetrahedral or a (distorted) square-planar geometry. The former is observed for bis(amidinates) complexes of Mn^{II}–Co^{II},[41,51–54] while for bis(amidinate) complexes of Cr^{II} and Ni^{II} both types of geometry have been found to occur.[34,36,41,55–58] In this paper we describe the synthesis and characterisation of the bis(benzamidinate) complexes $[\{PhC(NAr)_2\}M]$ (M = Cr–Ni, Ar = 2,6-$iPr_2C_6H_3$, Figure 1). Interligand interactions between the sterically demanding amidinate ligands are found to enforce a distorted square-planar geometry onto high-spin Fe^{II}, which is exceptional for this ion when bound to two bidentate ligands.

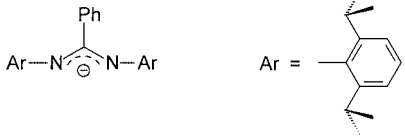

Figure 1. *N*,*N*′-Bis(2,6-diisopropylphenyl)benzamidinate

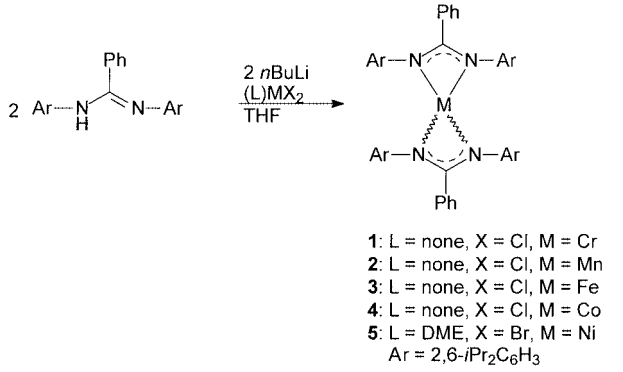
Results and Discussion

Synthesis

The bis(amidinate) complexes $[\{PhC(NAr)_2\}_2M]$ [M = Cr (**1**), Mn (**2**), Fe (**3**), Co (**4**)] were obtained by reaction of the anhydrous metal chlorides with the lithium amidinate $Li[PhC(NAr)_2]$ (Scheme 1). The latter was generated in situ by deprotonation of the amidine by *n*BuLi in THF. The products were isolated by extraction with hexanes or pentane and crystallisation from the same solvents, affording the air-sensitive, crystalline bis(amidinate) complexes in 48 (**2**) to 91% (**3**) isolated yield. The Ni complex $[\{PhC(NAr)_2\}_2Ni]$ (**5**) was prepared from the lithium amidinate and $[(DME)NiBr_2]$. This complex was obtained in 47% yield after crystallisation from toluene.



Scheme 1.

The complexes were characterised by elemental analysis, X-ray diffraction, ^1H NMR and IR spectroscopy and solid-state variable-temperature magnetic susceptibility measurements.

Molecular Structures

The molecular structures of the bis(amidinate) complexes were determined by single-crystal X-ray diffraction. Geometric parameters for the structures displayed in Figure 2 are given in Table 1.

All structures show symmetric, chelating coordination of the amidinate ligands with the aryl and phenyl substituents making angles of 61–86° (Ar) and 23–51° (Ph) with the N–M–N coordination planes. The C–N bonds in the amidinate backbones do not differ significantly in length and the nitrogen atoms deviate only slightly from planarity ($\Sigma_{\angle N}$ = 354–360°), suggesting full electron delocalisation in the NCN framework. The bite angle of the ligand is restricted to 64–69° by the geometry of the amidinate backbone.

The Mn and Co complexes **2** and **4** are best described as distorted tetrahedral, in which the NMN coordination planes of the two amidinate ligands are inclined at 74.18(15)° (Mn) and 69.5(4)° (Co), respectively. The average bite angles in the Mn complex (63.59°) are ca. 2° smaller than those in the Co analogue (66.3°) reflecting the smaller ionic radius of the latter metal ion.[59] Consistently, the M–N distances in the Mn^{II} complex are ca. 0.1 Å longer than in the and Co^{II} derivative.

The Cr and Ni complexes **1** and **5** show a distorted planar arrangement of the four coordinating nitrogen atoms. For bis(amidinate) derivatives of Cr^{II}, this coordination geometry is commonly observed,[34,36,57] but planar coordination in Ni^{II} bis(amidinates) is less common, the only example being the complex $[\{PhC(NXyl)(NSiMe_3)\}_2Ni]$ (Xyl = 2,6-$Me_2C_6H_3$) reported recently by Lee et al.[56] The amidinate NMN coordination planes are inclined at 7.73(10)° (Cr) and 4.13(13)° (Ni), respectively. The average bite angles in the Cr complex are approximately 4° smaller than in the Ni complex, consistent with the smaller ionic radius for square planar Ni^{II}.[59] The same trend is observed in the M–N bond lengths, which are significantly shorter for the Ni derivative.

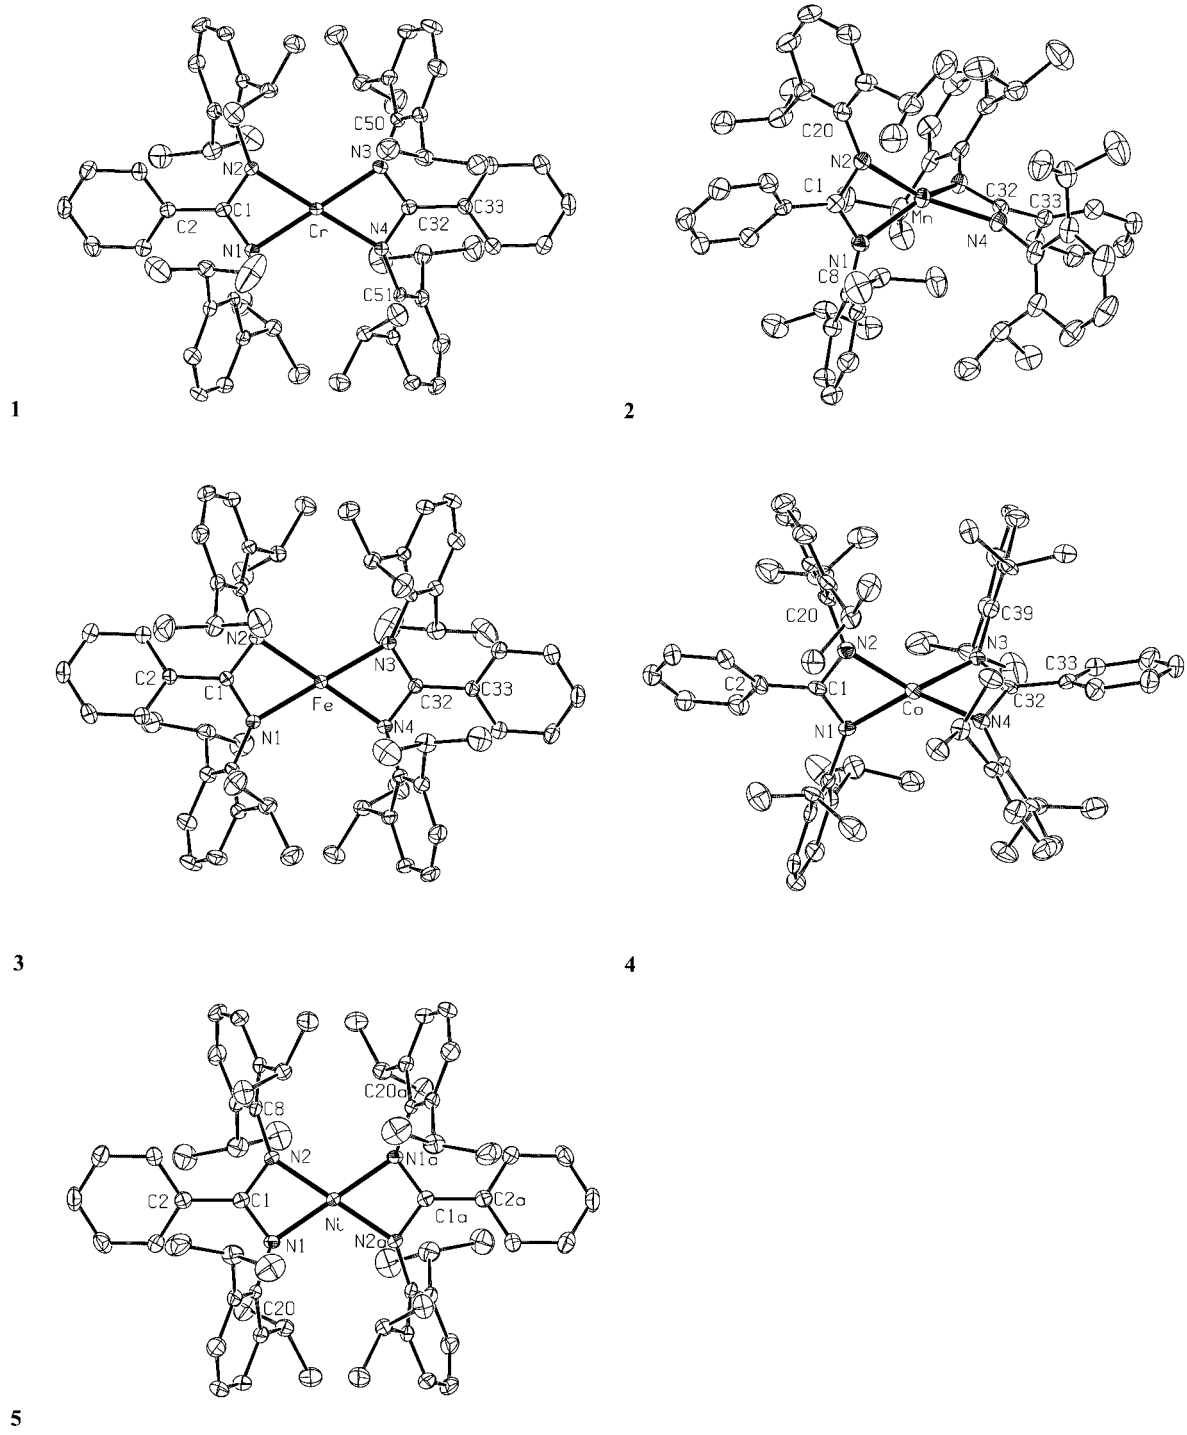

Figure 2. Molecular structures of complexes [{PhC(NAr)$_2$}$_2$M] (**1–5**) (50% ellipsoids). Hydrogen atoms and cocrystallised solvent molecules have been omitted for clarity.

Surprisingly, the Fe complex **3** is also found to adopt a distorted-planar coordination geometry. The angle between the two NMN coordination planes of 12.37(8)° is slightly larger than for the Cr and Ni analogues, but still warrants a description of **3** as a distorted planar structure. The planar coordination geometry in **3** is in sharp contrast to the other homoleptic bis(amidinate) complexes of Fe^{II},[51–54] which are exclusively tetrahedral. Planar structures for Fe^{II} are commonly found with (macrocyclic) tetradentate donor ligands, which are preorganised for this geometry.[60,61] Examples include salen [salen = *N*,*N*′-ethylenebis(salicylideneimine)],[62] calix[4]arene,[63] porphyrins,[64,65] phthalocyanines[66–69] and a number of macrocyclic bis(β-diiminato) ligands.[70–73] Planar coordination of Fe^{II} by two bidentate

[a] For ease of comparison, the atoms of the Ni complex (**5**) have been labelled here in analogous fashion to that in the other complexes, in spite of its crystallographic C_2 symmetry (N1_a → N3, N2_a → N4, C1_a → C32 etc.).

ligands is exceptional, although some bis(dithiolato)Fe^{II} dianions have been structurally characterised as distorted square-planar.[74,75]

A prominent feature of the complexes with the planar structure, **1**, **3** and **5**, is that the Ar substituents are all tilted relative to the coordination plane to minimise interligand repulsion by interlocking the *i*Pr substituents. This imparts to these compounds an approximate D_2 symmetry. It is seen by NMR spectroscopy that this behaviour is also present in solution (vide infra).

Magnetic Properties

Except for the diamagnetic Ni derivative **5**, all the bis(amidinate) derivatives reported here are paramagnetic. Variable-temperature magnetic susceptibility measurements were performed on crystalline samples of **1**–**4**. In view of the low symmetry of the complexes, *d*-orbital degeneracy is expected to be largely removed, thus quenching most orbital contributions to the ground state. Normal Curie–Weiss behaviour is therefore anticipated. Indeed, plots of χ^{-1} vs. T in the range 25–300 K (Figure 3) show good linear correlation for the Cr, Mn and Fe complexes with θ = –2.3, –1.3 and 2.5 K, respectively. For the Co derivative **4** a departure from the Curie–Weiss law is seen at elevated temperatures. This behaviour indicates the presence of a temperature-independent paramagnetism (TIP) contribution, which is not unusual for tetrahedral Co^{II}.[76] Over the temperature range of 25–175 K, the susceptibility of **4** can be described by Curie–Weiss behaviour with θ = –5.6 K.

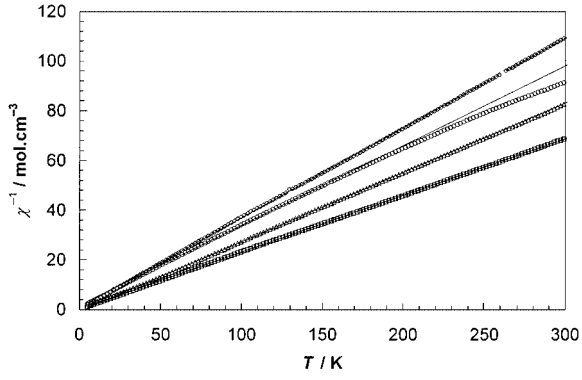

Figure 3. Temperature dependence of reciprocal susceptibility for **1** (diamonds), **2** (squares), **3** (triangles) and **4** (circles). Solid lines represent best fits to Curie–Weiss law.

The room temperature magnetic moments of the complexes **1** (4.7 μ_B), **2** (5.9 μ_B), **3** (5.4 μ_B) and **4** (5.1 μ_B) are

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

indicative of maximum spin multiplicity for all four compounds. The observed magnetic moments for **1**, **3** and **4** deviate noticeably from the spin only values [4.90 μ_B for S = 2 (Cr and Fe) or 3.87 μ_B for S = 3/2 (Co)], but are well within the ranges usually observed for high-spin d^4, d^6 and d^7 metals.[77]

The high spin (S = 2) ground state of planar bis(amidinate) **3** contrasts with the more usual observation of an intermediate spin state (S = 1) for Fe^{II} complexes with this geometry,[60,61] and is more common for tetrahedral Fe^{II}.[37,78] The planar Fe^{II} complexes of N_4 macrocycles and dithiolates all exhibit intermediate spin states,[64,66–75] with the planar, but high-spin, salen[62] and calix[4]arene[63] complexes of Fe^{II} constituting the only exceptions.

^{1}H NMR Spectroscopy

The room-temperature ^{1}H NMR spectrum of the diamagnetic Ni complex **5** in [D_6]benzene shows two septuplets for the isopropyl methine protons and four doublets for the isopropyl methyl protons. This is consistent with the approximate D_2 symmetry observed in the solid state in which the aromatic rings are tilted with respect to the N_4Ni coordination plane. This inclination establishes a propeller-like arrangement of the six aromatic rings, thus imparting a screw-sense to the molecule. Apparently, libration of the aryl groups, inverting the screw sense through a D_{2h}-symmetric transition state (Figure 4), is slow on the NMR time scale at ambient temperature. Warming a solution of **5** in [D_8]toluene results in gradual broadening of the isopropyl resonances, but coalescence is not yet reached at 110 °C. Nevertheless, slow chemical exchange of the two isopropyl methine and the two sets of methyl signals is confirmed by positive cross-peaks in the EXSY 2D-spectrum.

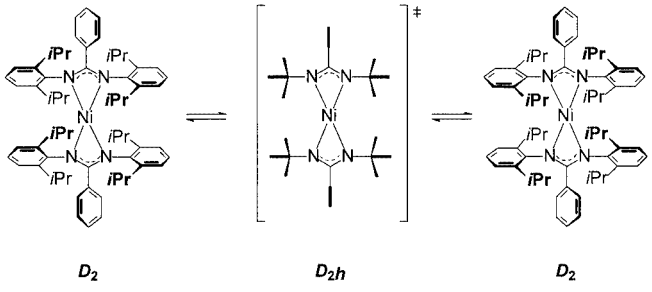

Figure 4. Epimerisation process in [{PhC(NAr)$_2$}$_2$Ni] (**5**).

The rate constant for the interconversion of the enantiomers k = 2.25(38) s^{-1} at 338 K was obtained by plotting the extent of exchange vs. the mixing time.[79] The free energy of activation $\Delta G^{\ddagger}_{338}$ = 80.9(4) kJ·mol^{-1} was calculated from the rate constant k.[80]

In contrast to the Ni complex, the paramagnetic bis(amidinates) **1**–**4** exhibit broad, shifted lines in their ^{1}H NMR spectra in [D_6]benzene. The Cr complex **1** shows resonances in the region +20 to –10 ppm. Severe overlap of the resonances renders the spectrum uninformative. The resonances of the Mn derivative **2** appear in the same spectral region, with even more line-broadening and inherent overlap of resonances. In contrast, the Fe and Co bis(amidinate) complexes display spectra that consist mainly of well-separated, broad singlets. The chemical shifts in the ^{1}H NMR spectrum of the Fe complex **3** span a range from ca. +60 to –30 ppm, displaying 11 lines. For the Co complex **4**, twelve lines are observed from ca. +120 ppm to –140 ppm. Full interpretation of these spectra is complicated, but the number of resonances indicates that the solution structures have symmetries lower than D_{2h} (**3**) and D_{2d} (**4**). This strongly suggests that also for the Fe and the Co derivatives the sterically demanding aryl substituents cause restricted motion of the aryl rings in solution.

Calculations

DFT calculations were used to obtain more insight into the factors that determine the coordination geometry of these complexes. In order to separate electronic from steric contributions, calculations were performed on the model complexes [{HC(NH)$_2$}$_2$M] containing an unsubstituted formamidinate ligand. The system was studied at the B3LYP/SV level using the GAMESS-UK program,[81] using the spin-restricted (S = 0) or spin-unrestricted ($S > 0$) formalism; see Exp. Sect. for details. For every metal, both planar and perpendicular geometries were optimised (constrained to D_{2h} and D_{2d} symmetry, respectively); the spin states assumed for these calculations were the ones found experimentally for the fully substituted system. In Table 2, the geometries calculated to be most stable for the model system are compared to those observed experimentally. The energy differences between the calculated perpendicular and planar geometries are included.

Table 2. Relative energies of tetrahedral vs. planar geometries of [{HC(NH)$_2$}$_2$M] by DFT calculations.

	X-ray [{PhC(NAr)$_2$}$_2$M]	S	B3LYP/SV [{HC(NH)$_2$}$_2$M]	$\Delta E_{\text{tet.–pla}n}$ [kJ·mol^{-1}]
Cr	planar	2	planar	100
Mn	tetrahedral	5/2	tetrahedral	–27.3
Fe	planar	2	tetrahedral	–10.1
Co	tetrahedral	3/2	tetrahedral	–23.2
Ni	planar	0	planar	–[a]

[a] No reasonable orbital occupation for perpendicular S = 0 structure.

For the model complexes, most of the geometries predicted on electronic grounds match the experimental ones, except for Fe (Table 2). However, the calculated energy difference between the two geometries is significantly smaller for Fe than for either Mn or Co. These results for the model system indicate that the observed geometries are determined mainly by the intrinsic electronic preference of the metal. For the special case of Fe, where this preference is calculated to be small, steric factors probably dominate; these seem to favour the planar structure due to a more efficient reduction of interligand repulsion by tilting of the aryl substituents.

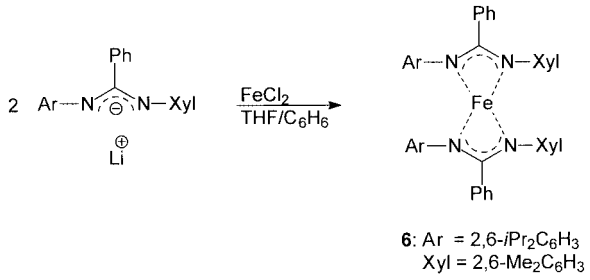
Decrease of Ligand Size

To see whether a slight decrease in ligand steric demand could already cause a reversion of the Fe^{II} bis(amidinate) structure to distorted tetrahedral, the asymmetric amidinate ligand $[PhC(NAr)(NXyl)]^-$ (Ar = 2,6-$iPr_2C_6H_3$, Xyl = 2,6-$Me_2C_6H_3$) was prepared. Reaction of $FeCl_2$ with 2 equiv. of the amidinate lithium salt resulted in formation of *cis*-$[\{PhC(NAr)(NXyl)\}_2Fe]$ (**6**, Scheme 2) that was characterised by single-crystal X-ray diffraction.



6: Ar = 2,6-$iPr_2C_6H_3$
Xyl = 2,6-$Me_2C_6H_3$

Scheme 2.

The molecular structure of **6** is shown in Figure 5 and selected bond angles and bond lengths are listed in Table 3. It is seen that even with this smaller, asymmetric ligand, the complex still adopts a distorted square-planar geometry. Remarkably, the two 2,6-$iPr_2C_6H_3$ groups are located on the same side of the molecule, with their *i*Pr substituents interlocking in a similar fashion as observed in complex **3**. The NFeN coordination planes in **6** are inclined at an angle of 14.21(6)°, which is only about 2° larger than in **3**. The room-temperature magnetic moment of **6** is 5.6 μ_B, indicative of high-spin Fe^{II}. Despite the difference in steric demand of the substituents, the two Fe–N distances in **6** are essentially equal, but the interligand N–Fe–N angle is noticeably larger on the side with the Ar substituents [125.51(4)°] than on the side with the Xyl substituents [105.97(4)°]. As is the case in the other complexes, the NAr nitrogen atom deviates slightly from planarity ($\Sigma_{\angle N1}$ = 354.64°), whereas the NXyl nitrogen atom is close to perfectly planar ($\Sigma_{\angle N2}$ = 359.03°).

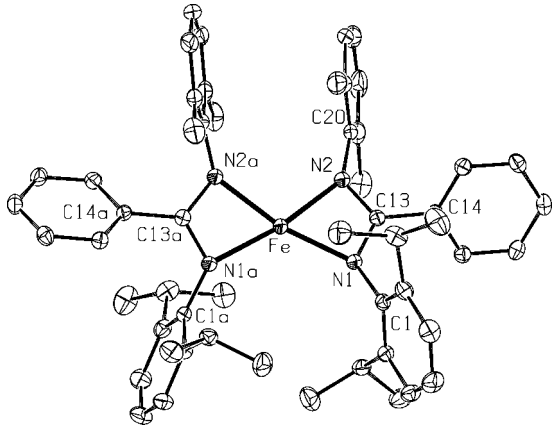


Figure 5. Molecular structure of [{PhC(NAr)(NXyl)}Fe] (**6**) (50% ellipsoids). Hydrogen atoms and cocrystallised benzene molecule have been omitted for clarity.

Conclusions

The coordination geometry of the bis(amidinate) complexes of the divalent first-row transition metal ions is governed by a subtle balance between electronic and steric factors. This balance can be tipped by variation of the substituents on the amidinate nitrogen atoms. It was shown by Winter et al. that substituents with steric demand in the amidinate plane (*t*Bu) can force an ion with an electronic preference for a planar geometry (Cr^{II}) to adopt a tetrahedral structure.[36] The work presented here shows that substituents with steric demand above and below the amidinate plane (2,6-$iPr_2C_6H_3$) can force an ion with a mild preference for a tetrahedral geometry (Fe^{II}) to adopt a planar one. Apparently, in this geometry the interligand steric interactions can be more effectively diminished by tilting the aryl rings to allow interlocking of the *i*Pr substituents.

These substituted amidinate ligands provide a simple way to generate rare high-spin (S = 2) Fe^{II} complexes with a planar geometry. It should be interesting to study the reactivity of these species (especially towards oxygen transfer agents) and compare that with the more extensively studied reactivity of planar intermediate spin (S = 1) Fe^{II} systems such as porphyrin and phthalocyanin complexes.

Experimental Section

General Remarks: All manipulations involving air-sensitive compounds were carried out under nitrogen using standard Schlenk and drybox techniques. Diethyl ether and THF (99.9% Aldrich) were percolated through a column of Al_2O_3 and stored under nitrogen. Toluene, hexane and pentane (99.9% Aldrich) were percolated through a column packed with molecular sieves (4 Å) (90 wt-%) and Al_2O_3 (10 wt-%) and stored under nitrogen. Benzene was distilled from Na/K alloy. Deuterated solvents (Aldrich) were dried with Na/K alloy and vacuum-transferred before use. Magnetic susceptibility measurements were performed with a Quantum Design MPMS-7 SQuID magnetometer of the department of Solid State Chemistry at the University of Groningen. NMR spectra were recorded with Varian Inova 500, VXR 300 and Gemini 200 instruments. IR spectra were recorded with a Mattson 4020 Galaxy FT–IR spectrometer. Elemental analyses were performed by the Microanalytical Department at the University of Groningen or by Mikroanalytisches Laboratorium H. Kolbe, Mülheim an der Ruhr,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Germany. Anhydrous $FeCl_2$[82] and $CoCl_2$[83] and [(DME)$NiBr_2$][84] were prepared according to published procedures. All other chemicals were commercially available products, which were used without further purification.

***N*-(2,6-Diisopropylphenyl)benzanilide:** Benzoyl chloride (39 mL, 0.33 mol) was added to a vigorously stirred mixture of 10% aqueous NaOH (240 mL) and 2,6-diisopropylaniline (57.0 mL, 0.30 mol). After 60 min, the solid was collected on a glass filter and washed several times with water, and once with ethanol. The product was dried in vacuo and isolated as a white powder. Yield: 57.6 g (0.19 mol, 65%). ^{1}H NMR (200 MHz, [D_1]chloroform, room temp.): δ = 7.92 (d, J = 6.6 Hz, 2 H, ArH), 7.58–7.05 (m, 8 H, ArH), 3.15 (sept, J = 6.8 Hz, 2 H, *i*Pr-CH), 1.22 (d, J = 6.8 Hz, 6 H, *i*Pr-CH_3) ppm. IR (KBr): $\tilde{\nu}$ = 3302 cm^{-1} (m), 3293 (m), 3270 (m), 2956 (m), 2923 (s), 2854 (m), 1640 (s), 1580 (w), 1515 (m), 1486 (m), 1463 (m), 1453 (m), 1380 (w), 1361 (w), 1291 (w) cm^{-1}.

***N*-(2,6-Diisopropylphenyl)benzimidoyl Chloride:** A mixture of *N*-(2,6-diisopropylphenyl)benzanilide (57.6 g, 0.19 mol) and thionyl chloride (43.1 mL, 0.58 mol) was refluxed for 1 h. The remainder was distilled using a Kugelrohr apparatus (oven 200 °C, 0.02 Torr), to give the imidoyl chloride as a yellow, slowly solidifying oil. Yield: 51.3 g (0.17 mol, 90%). ^{1}H NMR (300 MHz, [D_1]chloroform, room temp.): δ = 8.26 (d, J = 5.2 Hz, 2 H, ArH), 7.61–7.50 (m, 3 H, ArH), 7.24 (s, 3 H, ArH), 2.88 (sept, J = 4.4 Hz, 2 H, *i*Pr-CH), 1.27 (d, J = 4.4 Hz, 6 H, *i*Pr-CH_3), 1.21 (d, J = 4.4 Hz, 6 H, *i*Pr-CH_3) ppm. IR (KBr): $\tilde{\nu}$ = 2959 (s), 2926 (s), 1665 (s), 1582 (w), 1462 (m), 1451 (m), 1167 (m), 398 (m), 797 (w), 760 (m), 986 (m) cm^{-1}.

***N*,*N*′-Bis(2,6-diisopropylphenyl)benzamidine and *N*-(2,6-Diisopropylphenyl)-*N*′-(2,6-dimethylphenyl)benzamidine:** The amidines were prepared from *N*-(2,6-diisopropylphenyl)benzimidoyl chloride and the appropriate aniline according to a previously reported procedure.[9] Yield and characterisation data for *N*,*N*′-bis(2,6-diisopropylphenyl)benzamidine have been published.[9] Data for *N*-(2,6-diisopropylphenyl)-*N*′-(2,6-dimethylphenyl)benzamidine (obtained as a mixture of isomers): Yield: 7.4 g (19 mmol, 84%). ^{1}H NMR (300 MHz, [D_1]chloroform, room temp.): δ = 7.53–6.70 (m, 11 H, ArH), 5.78, 5.75 (2× s overlapping, 1 H, NH), 3.62–3.11 (4× sept overlapping, 2 H, *i*Pr-CH), 2.42, 2.17, 2.10 (3× s overlapping, 6 H, Xyl-CH_3), 1.42, 1.30, 1.07, 0.97 (4× d, J = 6.6 Hz, 12 H, *i*Pr-CH_3) ppm. ^{13}C NMR (75 MHz, [D_1]chloroform, room temp.): δ = 154.0, 153.5 (N*C*N), 145.8, 144.9, 143.4, 139.2, 137.1, 135.4, 134.6, 134.4, 134.0 (ArC_{ipso}), 129.3, 129.2 (Ar*C*H), 128.8 (ArC_{ipso}), 128.6, 128.4, 128.0, 127.6, 127.5, 126.9, 126.3, 123.5, 123.3, 122.9 (Ar*C*H), 28.4, 28.1 (*i*Pr-*C*H), 24.4, 24.3, 22.8, 21.9 (*i*Pr-*C*H_3), 18.9, 17.6 (Xyl-*C*H_3) ppm. IR (KBr): $\tilde{\nu}$ = 3424 (w, NH), 3354 (m, NH), 3058 (m), 2942 (s), 2915 (s), 1642 (s), 1614 (s), 1588 (s), 1574 (s), 1494 (m), 1435 (s), 1355 (s), 1326 (m), 1301 (w), 1273 (w), 1255 (w), 1220 (w), 1192 (m), 1179 (m), 1162 (w), 1109 (w), 1099 (w), 1077 (w), 1060 (w), 1043 (w), 1026 (w), 923 (w), 898 (w), 835 (w), 806 (w), 775 (s), 742 (w), 697 (s), 616 (w), 600 (w), 577 (w), 543 (w), 516 (w), 507 (w), 487 (w) cm^{-1}. HRMS (EI): calcd. for $C_{27}H_{32}N_2$: 384.2565; found: 384.2571.

Complexes [{PhC(NAr)$_2$}$_2$M] (1–5). General Procedure: [PhC(NAr)$_2$]H (1.0 g, 2.3 mmol) was dissolved in THF (10 mL). *n*BuLi (2.5 M in hexanes, 0.91 mL, 2.3 mmol) was added and the solution was stirred for 30 min. The solution of Li[PhC(NAr)$_2$] thus obtained was added dropwise to a suspension of MCl_2 (1.1 mmol) in THF (10 mL). The mixture was stirred under the conditions mentioned below for the various derivatives. After the reaction, the solvent was pumped off and the residue was freed of any residual THF by suspending it in pentane (10 mL) and subsequent removal of all volatiles in vacuo. The residue was repeatedly extracted with pentane (10 mL, unless mentioned otherwise) until the extracts were colourless. The extract was concentrated and cooled to afford the crystalline bis(amidinate) complex, which was isolated by filtration and dried in vacuo.

[{PhC(NAr)$_2$}$_2$Cr] (1): The general procedure was applied using 0.76 g [PhC(NAr)$_2$]H (1.7 mmol) and 0.11 g $CrCl_2$ (0.86 mmol). The reaction was stirred for 15 h at room temperature. Extraction and crystallisation were carried out using hexanes. The product was obtained as red crystals. Yield: 0.48 g (0.52 mmol, 61%). ^{1}H NMR (300 MHz, [D_6]benzene, room temp.) by deconvolution: δ ($\Delta\nu_{1/2}$) = 15.3 (194), 14.4 (239), 7.0 (140), 5.0 (939), 2.5 (250), 0.9 (5396), –7.6 (205) ppm (Hz); integral ratio 2:2:2:23:1:20:1. $C_{62}H_{78}CrN_4$ (931.32): calcd. C 79.96, H 8.44, N 6.02; found C 79.31, H 8.49, N 5.95.

[{PhC(NAr)$_2$}$_2$Mn] (2): The general procedure was applied for ligand deprotonation using 1.0 g amidine (2.3 mmol). $MnCl_2$ (143 mg, 1.1 mmol) was added as a solid to the Li[PhC(NAr)$_2$] solution. The reaction mixture was stirred for 2 h at room temperature, during which no significant colour change was observed. Off-white crystals were obtained from pentane at –25 °C. Yield: 0.51 g (0.54 mmol, 48%). ^{1}H NMR (300 MHz, [D_6]benzene, room temp.) by deconvolution: δ ($\Delta\nu_{1/2}$) = 15.1 (2761), 14.1 (566), 6.2 (1465), 3.5 (230), –4.2 (784) ppm (Hz); integral ratio 1:2:11:1:6. $C_{62}H_{78}MnN_4$ (934.27): calcd. C 79.71, H 8.42, N 6.00; found C 79.97, H 8.48, N 5.89.

[{PhC(NAr)$_2$}$_2$Fe] (3): The general procedure was applied. The reaction mixture was stirred for 2 h at room temperature, during which the solution turned dark green. Extraction was performed with hexanes. The product was isolated as dark green crystals after recrystallisation from hexanes. Yield: 0.98 g (1.0 mmol, 91%). ^{1}H NMR (300 MHz, [D_6]benzene, room temp.): δ = ($\Delta\nu_{1/2}$, integral) = 57.4 (952, 4 H), 31.9 (74.6, 4 H), 22.2 (74.5, 4 H), 16.8 (61.0, 4 H), 14.8 (158, 12 H), 6.23 (140, 4 H), 3.80 (126, 12 H), –2.05 (54.5, 2 H), –5.19 (89.7, 12 H), –6.18 (64.5, 4 H), –29.2 (274, 12 H) ppm (Hz); one of two expected *i*Pr-CH resonances not observed, possibly due to extreme line-broadening. $C_{62}H_{78}FeN_4$ (935.18): calcd. C 79.63, H 8.41, N 5.99; found C 79.44, H 8.47, N 6.05.

[{PhC(NAr)$_2$}$_2$Co] (4): The general procedure was applied, but in this case no colour change was observed after stirring at room temperature for 30 min. Upon warming the suspension at 50 °C for 30 min, a colour change from green to dark red was observed. The Co complex was obtained as red crystals after recrystallisation of the crude product from hexanes. Yield: 0.70 g (0.74 mmol, 65%). ^{1}H NMR (500 MHz, [D_6]benzene, room temp.): δ ($\Delta\nu_{1/2}$, integral) = 115 (697), 60.9 (140, 4 H), 45.3 (1994), 35.0 (80.9, 2 H), 24.8 (110, 12 H), 21.2 (129, 4 H), 2.77 (119, 4 H), –19.0 (86.6, 4 H), –69.6 (1007), –73.2 (431, 12 H), –84.0 (85.8, 12 H), –138 (2461) ppm (Hz); integration of resonances at δ = 115, 45.3, –69.6 and –138 ppm inaccurate due to extreme broadness. $C_{62}H_{78}CoN_4$ (938.26): calcd. C 79.37, H 8.38, N 5.97; found C 78.60, H 8.42, N 5.88.

[{PhC(NAr)$_2$}$_2$Ni] (5): The general procedure was applied using 0.53 g (1.2 mmol) [PhC(NAr)$_2$]H and [(DME)$NiBr_2$] (0.19 g, 0.6 mmol) as Ni source. The reaction mixture was stirred under reflux conditions for 66 h. The crude product was recrystallised from toluene and the resulting red crystals were washed with diethyl ether. Yield: 0.26 g (0.30 mmol, 47%). ^{1}H NMR (300 MHz, [D_6]benzene, room temp.): δ = 6.87–7.03 (m, 12 H), 6.41–6.64 (m, 10 H), 4.24 (sept, J = 7.0 Hz, 4 H), 3.13 (sept, J = 7.0 Hz, 4 H), 2.31 (d, J = 7.0 Hz, 12 H), 1.55 (d, J = 7.0 Hz, 12 H), 0.60 (d, J = 7.0 Hz, 12 H), 0.49 (d, J = 7.0 Hz, 12 H) ppm. ^{13}C NMR (75 MHz, [D_6]benzene, room temp.): δ = 175.1 (NCN), 144.5, 143.3, 141.5

(3 × *ipso*-C), 130.8, 130.4 (*ipso*-C), 129.6, 126.8, 125.7, 124.9, 123.6, 29.4, 28.5 (2 × *i*Pr-CH), 24.4, 24.0, 22.3, 21.4 (4 × *i*Pr-CH_3) ppm. $C_{62}H_{78}N_4Ni$ (938.04): calcd. C 79.38, H 8.38, N 5.97; found C 79.37, H 8.29, N 5.88.

[{PhC(NAr)(NXyl)}$_2$Fe] (6): $LiCH_2SiMe_3$ (0.13 g, 1.4 mmol) was added to a stirred solution of *N*-(2,6-diisopropylphenyl)-*N*′-(2,6-dimethylphenyl)benzamidine (0.53 g, 1.4 mmol) in 15 mL 1% THF/C_6H_6 at room temperature. After 15 min, $FeCl_2$ (0.09 g, 0.7 mmol) was added to the yellow solution. The colour of the mixture changed from yellow to green. The reaction mixture was stirred for 2 h after which the solvents were removed in vacuo. Residual THF was removed by suspending the residue in pentane that was subsequently pumped off. The solid was extracted with benzene (40 mL) until the extracts were colourless. The crude product was recrystallised from hot benzene, affording **6**·C_6H_6 as green crystals. Yield: 0.32 mg (0.4 mmol, 50%).^{1}H NMR (300 MHz, [D_6]benzene, room temp.): δ = ($\Delta\nu_{1/2}$, integral): 26.07 (25, 4 H), 25.15 (25, 4 H), 16.55 (18, 4 H), 11.79 (235, 12 H), 4.02 (74, 4 H), 0.46 (43, 12 H), –2.57 (19, 2 H), –5.48 (183, 12 H), –7.24 (22, 2 H), –9.24 (22, 2 H) ppm (Hz). $C_{54}H_{62}FeN_4$·C_6H_6 (901.07): calcd. C 80.0, H 7.6, N 6.2; found C 79.6, H 7.8, N 6.3.

Determination of *k* and $\Delta G^{\ddagger}$ for Epimerisation of 5: ^{1}H 2D EXSY spectra (500 MHz, [D_8]toluene, 338 K) were obtained using the NOESY sequence (d_1–90°–d_2–90°–τ–90°–FID) with an extra gradient during the mixing time τ. The spectral width was 8000 Hz. Mixing times of 0.2, 0.3, 0.4 and 0.5 s were used. The relaxation delay d_1 was 1 s and the increment for the evolution time d_2 was 98 μs. Peak volumes of the isopropyl methine resonances (δ = 4.24 and 3.13 ppm) and their cross-peaks were determined by means of the Gaussian method in the integration program Sparky.[85] The ratio of the peak volumes of the cross-peaks and the diagonal peaks (I_x/I_d) was plotted vs. mixing time τ. The rate constants k for the exchange process was determined by fitting the data to the equation[79]

$$\frac{I_x}{I_d} = \frac{1 - e^{-2k\tau}}{1 + e^{-2k\tau}}$$

The free energy of activation $\Delta G^{\ddagger}$ at 338 K was calculated by substitution of k_{338} according to the relation[80]

$$k = \frac{\kappa k_b T}{h} \cdot e^{-\Delta G^{\ddagger}/RT}$$

Magnetic Measurements: Data were collected on crystalline samples (ca. 25 mg) from 300 to 5 K at a field of 1000 G. Measured magnetic susceptibilities are corrected for diamagnetism using Pascal's constants.[86] Effective magnetic moments are calculated as

$$\mu_{eff.} = 2.828\sqrt{\chi_m T}$$

X-ray Crystallographic Study: Single crystals suitable for X-ray diffraction were obtained by recrystallisation from pentane (**1**), hexanes (**2**, **3**), benzene (**4**, **6**) or diethyl ether (**5**). Some crystals were found to contain cocrystallised solvent molecules (**2**·*n*-hexane, **4**·2C_6H_6 and **6**.C_6H_6). The crystals were mounted on top of a glass fibre, by using inert-atmosphere handling techniques, and aligned on a Bruker[87] SMART APEX CCD diffractometer (Platform with full three-circle goniometer). The diffractometer was equipped with a 4 K CCD detector set 60.0 mm from the crystal. The crystals were cooled using the Bruker KRYOFLEX low-temperature device. Intensity measurements were performed using graphite-monochromated Mo-K_α radiation from a sealed ceramic diffraction tube (SIEMENS). Generator settings were 50 kV/40 mA. SMART[87] was used for preliminary determination of the unit cell constants and data collection control. The intensities of reflections of a hemisphere were collected by a combination of 3 sets of exposures (frames). Each set had a different φ angle for the crystal and each exposure covered a range of 0.3° in ω. A total of 1800 frames were collected with an exposure time of 20.0 s (**1**, **2**, **5**) or 10.0 s (**3**, **4**, **6**) per frame. Data integration and global cell refinement was performed with the program SAINT.[87] The final unit cell was obtained from the *xyz* centroids of 5709 (**1**), 3348 (**2**), 6534 (**3**), 4586 (**4**), 5447 (**5**), 9843 (**6**) reflections after integration. Intensity data were corrected for Lorentz and polarisation effects, scale variation, for decay and absorption: a multi-scan absorption correction was applied, based on the intensities of symmetry-related reflections measured at different angular settings (SADABS),[88] and reduced to F_o^2. The program suite SHELXTL was used for space group determination (XPREP).[87] The unit cells[89] were identified as monoclinic; reduced cell calculations did not indicate any higher metric lattice symmetry.[90] For **4**, The |*E*| distribution statistics were ambiguous about a centrosymmetric/non-centrosymmetric space group.[91] The space groups were derived from the systematic extinctions. Examination of the final atomic coordinates of the structure did not yield extra symmetry elements.[92] The structures of **1**, **2**, **4**, **5** and **6** were solved by Patterson methods and extension of the model was accomplished by direct methods applied to difference structure factors using the program DIRDIF.[93] For **3**, the structure was solved by direct methods with SIR-97.[94,95] The positional and anisotropic displacement parameters for the non-hydrogen atoms were refined. The unit cell of **2** contains a molecule of hexane solvent of which one end is highly disordered. One of the C atoms (C68) was described as occupying two positions with separately refined site occupancy factors. The s.o.f. of the major fraction refined to a value of 0.625(13). Refinement for **4** was complicated by a twinning problem. After introducing a twin matrix as detected by PLATON ([–1 0 0 0 –1 0 0.99 0 1], 180° rotation about the *c** axis), with scale factors for the fractional contributions of the various twin components, the structure refined smoothly. The s.o.f. of the major fraction of the component of the twin model refined to a value of 0.629(3). All hydrogen atoms of **1**, **2**, **5** and **6** (except those belonging to the disordered hexane solvent molecule in **2**) were located from a subsequent difference Fourier synthesis, and their coordinates and isotropic displacement parameters were refined. For **3**, Fourier synthesis resulted in the location of most of the hydrogen atoms. The remaining hydrogen atoms in **3** and all hydrogen atoms in **4** were included in the final refinement riding on their carrier atoms with their positions calculated by using sp^2 or sp^3 hybridisation at the C atom as appropriate with U_{iso} = c × U_{equiv} of their parent atom, where c = 1.2 for the non-methyl hydrogen atoms and c = 1.5 for the methyl hydrogen atoms and where values U_{equiv} are related to the atoms to which the H atoms are bonded. The methyl groups were refined as rigid groups, which were allowed to rotate freely. Neutral atom scattering factors and anomalous dispersion corrections were taken from International Tables for Crystallography.[96] All refinement calculations and graphics were performed with the program packages SHELXL[97] (least-square refinements) and PLATON[98,99] (calculation of geometric data and ORTEP illustrations). No classic hydrogen bonds, no missed symmetry (MISSYM), but potential solvent-accessible

area [voids of 325.2 (**1**), 78.7 (**2**), 372.6 (**3**), 111.2 (**4**) and 296.4 (**5**) Å^3/unit cell] were detected by procedures implemented in PLATON.[98,99] Crystallographic data for **1**–**6** and details of the refinement are listed in Table 4 and Table 5. CCDC-247623 to -247628 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

DFT Calculations: All calculations on the model complexes [{HC(NH)$_2$}$_2$M] were carried out with the GAMESS-UK program.[81] Geometries were optimised at the B3LYP level[100–102] within either D_{2h} or D_{2d} symmetry using the 3-21G basis set[103] on the ligand atoms and LANL2DZ (small-core pseudopotential) on the metal atom.[104–106] Calculations used the spin-restricted (for $S = 0$ states) or spin-unrestricted (for $S > 0$ states) formalism; in the latter case, spin contamination was uniformly found to be negligible.

Supporting Information (see also footnote on the first page of this article): IR data for complexes **1**–**6** and total energies and S^2 values for all calculations mentioned in the text (Table S.1).

Acknowledgments

We thank J. Baas for performing the magnetic susceptibility measurements.

Bis(salicylaldiminato)titanium Complexes Containing Bulky Imine Substituents: Synthesis, Characterization and Ethene Polymerization Studies

Antti Pärssinen,[a] Tommi Luhtanen,[b] Martti Klinga,[a] Tapani Pakkanen,[b] Markku Leskelä,[a] and Timo Repo*[a]

Keywords: Titanium / Polymerization / Homogeneous catalysis / Molecular modeling / N,O ligands

A series of titanium complexes bearing two anionic [N, O$^-$] bidentate salicylaldiminato ligands, namely bis[(*N*-salicylidene)anilinato]titanium(IV) dichloride (**1**), bis[(*N*-salicylidene)-2,6-dimethylanilinato]titanium(IV) dichloride (**2**), bis[(*N*-salicylidene)-2,6-di-*i*- propylanilinato]titanium(IV) dichloride (**3**), bis[(*N*-salicylidene)-(1-naphthalenylimino)]titanium(IV) dichloride (**4**), bis[(*N*-salicylidene)-2,6-difluoroanilinato]titanium(IV) dichloride (**5**), and bis[(*N*-3-fluorosalicylidene)-2,6-difluoroanilinato]titanium(IV) dichloride (**6**) have been synthesized with good yields by a two-step procedure. The X-ray structure analysis reveals that in complex **2**, titanium has a distorted octahedral coordination sphere in which the oxygen atoms and the chloride ligands form the basal plane. Both the chloride and the phenoxy moieties have a *cis* orientation and the angle between the chloride ligands is 93.05°. The imine nitrogen atoms complete the octahedral coordination of the Ti center by occupying the axial positions. The newly synthesized (**2** and **4**–**6**) and already known complexes (**1** and **3**) were introduced in detailed ethene-polymerization studies. The activities achieved were low to moderate depending on the size and nature of the imino substituents. The polyethenes (PEs) produced had high molar masses, and the modalities of the molecular weight distributions varyied with polymerization temperature. Based on the results of ab initio calculations and on the experimental data obtained, an explanation for uni- and bimodal polymerization behavior and the differences in catalytic activities are given.

Introduction

In the middle of the 80s chiral group 4 *ansa*-metallocenes were successfully used for the first time in the homogeneous polymerization of isotactic polypropene with excellent activities when activated with methylaluminoxane (MAO).[1–3] This fundamental observation initiated intensive research activities in academia as well as in the polyolefin industry, and a lot of theoretical and synthetic resources were focused on the development and the understanding of metallocene-catalyzed polymerization reactions.[4,5] At the same time there have also been significant efforts to transfer this know-how to other types of metal complexes that are mainly based on titanium and zirconium. An enormous increase in the number of publications on non-metallocene olefin polymerization catalysis started in the middle of the 90s, and this seems to be an ongoing trend as the research has spread from group 4 metals to nearly all other transition metals. Non-metallocene catalysts and their ethene polymerization properties have been reviewed rather extensively.[6–8]

Fujita and coworkers at Mitsui Chemicals have so far reported the most efficient homogeneous non-metallocene catalysts for ethene polymerization. An activity as high as 80 kg_{PE}/(mmol·bar·h) was achieved for a MAO-activated bis[*N*-(3-*tert*-butylsalicylidene)-2,3,4,5,6-pentafluoroanilinato]zirconium(IV) dichloride catalyst precursor.[9] These types of catalysts are sensitive to the applied substituent pattern on the ligand framework, and depending on the ligand structure, the polymerization activities can vary from 0.1 to 10 kg_{PE}/(mmol·bar·h).[9–12] The structure of the catalyst precursor as well as the polymerization conditions also influence the properties of polyethene. As an augmentation to our earlier studies on non-metallocene polymerization catalysis,[13–15] we report herein a straightforward and efficient synthetic strategy to prepare (salicylaldiminato)-based titanium dichlorides. The ethene polymerization reactions of the newly synthesized (**2** and **4**–**6**) and already known complexes (**1** and **3**) with different aromatic substituents on the imine nitrogen atom were studied in order to evaluate the steric and electronic influences caused by the ligand substituents on the polymerization properties (Scheme 1).

Results and Discussion

Synthesis of Ligand Precursors

Ligands containing phenoxy-imino groups are well known and are common in coordination chemistry. In our case, the synthesis of the ligands (**a**–**d**) was performed by the direct reaction between salicylaldehyde and the corresponding aniline by heating the reaction mixture in an oil bath at 110 °C in an open, round-bottomed flask overnight to ensure evaporation of water.[16–18] The novel ligands (**e** and **f**) were synthesized in a similar manner to ligands (**a**–**d**) with two exceptions: the former ligands required a catalytic amount of sulfuric acid to achieve high yields, and the reactions were performed in toluene. The crude products from the reactions with all ligands were isolated in high yields. The color of ligand **d** was dark brown, **e** and **f** were orange, and the others were yellow. According to ^{1}H NMR spectroscopy all these salicylaldimines were pure and no further purifications were required.

Synthesis of Complexes

There are several methods that can be used successfully in the complexation of salicylaldiminato ligands with group 4 metals. *n*BuLi is consistently applied as reagent for ligand deprotonation, and in subsequent complex preparation, metal halides are employed. The yields of the desired bis(salicylaldiminato)titanium dichloride complexes achieved with *n*BuLi varied between (20–80) percent depending on the corresponding ligand.[11] This method produces the insoluble LiCl salt as a side product, and in the case in which the desired metal complex has low solubility, further purification of the product might be complicated as, for example, filtration causes problems. Another interesting complexation method was published by Erker et al., which afforded complexes by direct reaction between $TiCl_4$ and the salicylaldimine ligand in yields of around 60%.[19] The main target in the complex preparation described here was to find a synthesis route that consists of a few high-yield steps and where side products are either volatile or otherwise easily removable. Two improved routes for the preparation of bis(salicylaldiminato)titanium dichlorides from the ligand precursors (**a**–**f**) were developed, and they both fulfill the above-mentioned requirements and are described below.

Method A

The silylation of the phenolic hydroxyl group with a common silylation reagent like trimethylsilyl chloride has been known to be quantitative under mild reaction conditions. Unfortunately, its use with compounds that contain nitrogen can lead to the formation of the undesired intramolecular iminium salt through elimination of HCl. To avoid salt formation, Me_3SiCl was replaced by 1,1,1,3,3,3-hexamethyldisilazane.[20] It is suitable in this context because hexamethyldisilazane residues (bp. 125 °C) as well as

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the by-product 1-trimethylsilylamine (bp. 57 °C) can be easily removed in vacuo after formation of the desired silyl compound.

Complex preparation with silyl-substituted ligand precursors has some limitations. The silylated phenoxy-imine compounds react fast and unselectively with $TiCl_4$. This phenomenon was observed, for example, in the complexation of the silylated ligand precursor **a**. Together with the desired 1:2 complex (L_2TiCl_2), complexes with the stoichiometry $LTiCl_3$ and L_3TiCl were also observed. We assume that the observed unselectivity is due to lack of the steric bulkiness of the aniline substituents; with ligand precursors **(c** and **d)** that have bulky substituents, the complexation proceeded selectively by simple treatment of two molar equivalents of silylated ligand with $TiCl_4{\cdot}(THF)_2$ at –78 °C (Scheme 1).[21] After the reaction, toluene and the by-product trimethylsilylchloride were removed under vacuum, and the corresponding complexes **3** and **4** were isolated with nearly quantitative yields.

Method B

Method B consisted of two steps that were easy to perform as a one-pot reaction. Compounds containing a phenolic hydroxyl proton are susceptible to direct metallation with $Ti(NMe_2)_4$ followed by cleavage of dimethylamine.[22,23] With this method the formation of the bis(salicylaldiminato)$Ti(NMe_2)_2$ complexes was smooth and proceeded with higher selectivity than with method **A**, e.g. complexation of the ligand precursors (**a**, **b**, **e** and **f**) with $Ti(NMe_2)_4$ produced only the desired 1:2 complexes ($L_2Ti(NMe_2)_2$. Despite the low boiling point of the released $(Me)_2NH$, the complete removal of this by-product does not occur even after an extended period under vacuum at 50 °C. This might be due to partial coordination of dimethylamine to the titanium complex. Free rotation of the amine methyl groups is prohibited and therefore in the ^1H NMR spectrum, the signal for the methyl groups are split into two peaks δ = 1.69 and 2.3 ppm.

Titanium amido complexes are known to be less active catalyst precursors in ethene polymerization than their dichloro derivatives,[24] and hence the obtained bis(salicylaldiminato)$Ti(NMe_2)_2$ complexes were converted directly to the corresponding bis(salicylaldiminato)$TiCl_2$ complex with excess chlorotrimethylsilane.[22] The chlorinated complexes formed selectively and quantitatively. The progress of the chlorination reaction can be followed by ^1H NMR spectroscopy. When 75% of the amido groups were converted to chlorides, three different signals from the imine protons can be detected. For example, in the spectrum of complex **1**, one signal can be assigned to L_2TiCl_2 (δ = 8.06 ppm) and two to $L_2TiClNMe_2$ (δ = 7.92 and 8.22 ppm). Further, the signals for the methyl groups in $L_2TiClNMe_2$ appear as two distinct broad signals at δ = 3.6 and 4.0 ppm. When the reaction was continued, signals from the dimethylamido group gradually disappeared, and in the end, only one imine signal at δ = 8.06 ppm remained. After the removal of the coordinated $(Me)_2NH$, the only by-product from the chlorination procedure was soluble Me_3SiNMe_2, which was easy to remove by recrystallization of the bis(salicylaldiminato)$TiCl_2$ complexes. If the coordinated $(Me)_2NH$ was not removed before chlorination was started, it was possible to observe an additional broad signal at δ = 9.0 ppm in the ^1H NMR spectrum, which is evidence for the formation of a salt-like by-product between $(Me)_2NH$ and Me_3SiCl. However, after refluxing and removal of the solvent, only traces of the by-product remained. The isolated yields for all complexes prepared by method **B** were above 90%.

X-ray Studies of Complex 2

Red crystals of complex **2** suitable for X-ray determination were grown at –20 °C from a saturated toluene solution. The solid-state structure is shown in Figure 1, and crystallographic data as well as selected bond lengths and angles are given in Table 1 and Table 2. The titanium center has a distorted octahedral coordination and is located in the plane of the O_2Cl_2 core. The oxygen atoms are oriented *cis* to each other with nearly equidistant bond lengths (Ti–O1 = 1.8432 Å and Ti–O2 = 1.8629 Å). The octahedral coordination of Ti is accomplished by a *trans* orientation of the imine nitrogen atoms with a dihedral angle of 178.69°. Because of the different coordination mode, the Ti–N bonds are significantly longer than the Ti–O bonds (Ti–N1 = 2.21068 Å and Ti–N2 = 2.1949 Å). The chloride ligands

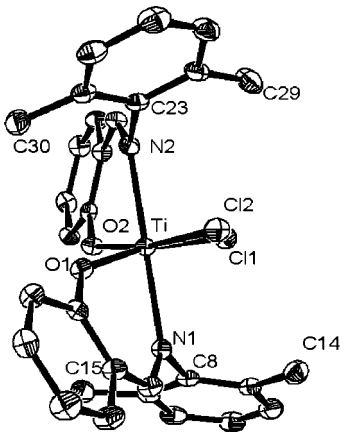

Figure 1. ORTEP plot of **2** with thermal ellipsoids drown at 50% probability level. All hydrogen atoms are omitted for clarity.

Ethene Polymerization

Herein the series of new (**2**, **4**–**6**) and already known (**1** and **3**) bis(salicylaldiminato)$TiCl_2$ complexes with different substituents were introduced in detailed polymerizations after MAO activation to investigate the influence of the ligand structure on the ethene polymerization properties. Because of simple phenyl substitution on the imine nitrogen, **1**/MAO was considered as a reference catalyst. The activity of **1**/MAO, which was 67 $kg_{PE}/(mol_{Ti}\cdot h\cdot bar)$ at (60 °C, 3 bar), rose slowly but constantly with increasing monomer pressure (Table 3). When the pressure was kept constant (5 bar), the activity was enhanced with elevated temperatures and a maximum of 143 $kg_{PE}/(mol_{Ti}\cdot h\cdot bar)$ was achieved at 80 °C. Under harsher polymerization conditions (100 °C, 10 bar), the activity was not significantly better. Irrespective of the applied polymerization conditions, molar masses were between 300–500 kg/mol and the polydispersity (PD) values obtained were narrow. Catalyst **2**/MAO carrying 2,6-methyl-substituted anilines had activities of less than 10 $kg_{PE}/(mol_{Ti}\cdot h\cdot bar)$ under all polymerization conditions, but the molar masses of the polyethenes were twice as high than those obtained with **1**/MAO. All GPC chromatograms represented polymers with unimodal and narrow polydispersities. A subtle tailing toward the low molar mass region was observed only for polymerizations at 80 °C.

The replacement of 2,6-methyl substituents with isopropyl groups further increases the steric congestion aroundthe catalytic active metal center and results in a quite interesting polymerization behavior for **3**/MAO. The polymer produced was clearly bimodal, and the relative ratios between the two molar mass areas varied as a function of temperature. At 40 °C, the distribution curves partly overlapped and therefore the PD value was broad (≈ 14). The average value for the molar mass was around 600 kg/mol. At 60 °C, the catalyst had a distinct bimodal behavior, as two separate curves with narrow distribution were recorded. Molar masses of the separate peaks were 100 and 1000 kg/mol, which is consistent with two active sites. At 80 °C, the molar mass was 350 kg/mol, and the distribution curve was more or less unimodal again with a small shoulder at around 100 kg/mol. Polymerization activities were lower throughout than those with **1**/MAO under similar conditions as they remained below 50 $kg_{PE}/(mol_{Ti}\cdot h\cdot bar)$.

Under the applied polymerization conditions, the activity of naphthyl-substituted **4**/MAO remained below 30 $kg_{PE}/(mol_{Ti}\cdot h\cdot bar)$, and the polymer had a bimodal character. At 40 °C, the distribution curves overlapped, and as a consequence, the observed curve was rather broad and almost flat from the top. This complicated the determination of accurate molar mass values, but the average value for the molar masses was around 800 kg/mol. Polymers prepared at 80 °C have molar masses of 600 kg/mol and a compara-

tively unimodal distribution curve. Only a small shoulder was observed around the 100 kg/mol region.

The replacement of aniline with 2,6-difluoroaniline changes the catalyst performance considerably. At 40 °C, the activity of **5**/MAO [165 kg_{PE}/(mol_{Ti}·h·bar)] was significantly higher than **1**/MAO [63 kg_{PE}/(mol_{Ti}·h·bar)], but by increasing the temperature its activity decreased to same level as catalyst **1**/MAO. This, together with the fact that the molar mass distributions were considerably expanded with a bimodal behavior at higher temperatures, might indicate changes in the catalytically active species. Catalyst **5**/MAO showed a rather linear enhancement of its activity with increasing ethene pressure. Actually, the highest activity for **5**/MAO [265 kg_{PE}/(mol_{Ti}·h·bar)] was achieved at 100 °C and 10 bar. At lower ethene pressures, the catalyst tended to produce polymers with bimodal distributions; however, with sufficient monomer concentrations, single-center behavior of the catalyst appeared, and polydispersities of the polymers were below 2.

In general, **6**/MAO had similar trends in the variation of polymerization conditions as **5**/MAO. It was slightly more tolerant against thermal changes since only a bimodal distribution curve was observed at 80 °C. The catalyst **6**/MAO revealed the highest activity, 713 kg_{PE}/(mol_{Ti}·h·bar) and gave polyethene with the highest molar mass (2000 kg/mol) (Table 4, runs 28 and 29). The molar mass distribution of polyethene was less than four and unimodal under all conditions. Only at 80 °C was the PE formed bimodal, and the chromatogram consisted of two overlapping curves with equal areas (Figure 2, Figure 3).

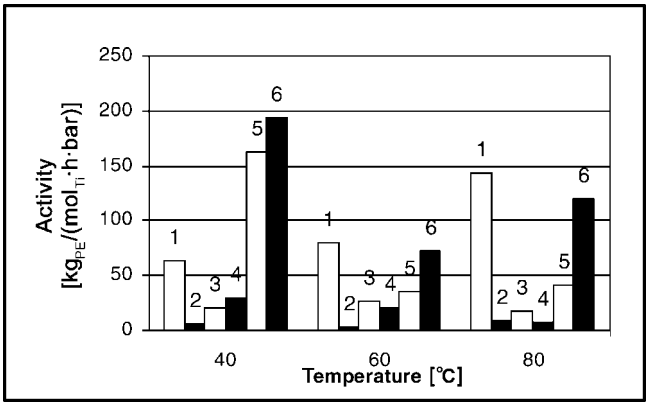

Figure 2. Activities of the catalysts (**1**–**6**)/MAO at different temperatures in ethene polymerization at 5 bar.

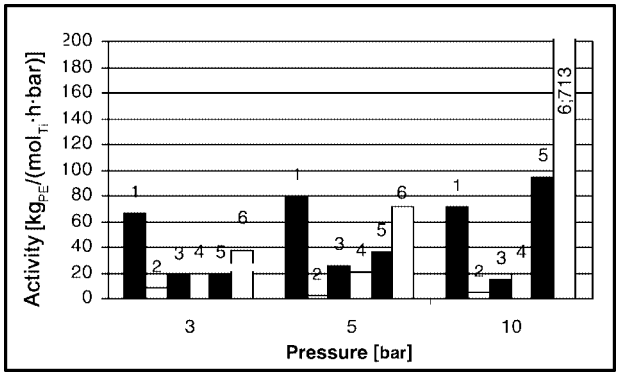

Figure 3. Activities of the catalysts (**1**–**6**)/MAO at different pressures in ethene polymerization at 60 °C.

Correlation Between Complex Structure and Polymerization Behavior

Bis(salicylaldiminato)$TiCl_2$ complexes have three isomers that could be considered as active precatalysts in ethene polymerization as they all have chloride ions in a *cis* position (Figure 4). In two of the possible conformations, the imine nitrogen atoms are in *cis*- and the oxygen atoms, in *trans* positions, or vice versa. In the third conformation both the nitrogen and oxygen atoms occupy the *cis* orientation. The existence of all of these isomers has been experimentally verified by crystal-structure determination.[19,25] The com-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

plexes bearing bulky imino substituents have nitrogen atoms in a *cis* orientation, while complexes having fluorine or hydrogen at the 2,6-positions in the anilino part favor a *trans* orientation.

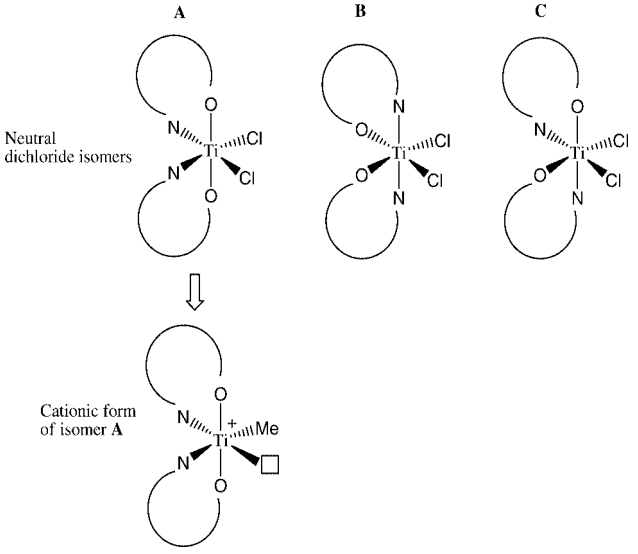

Figure 4. Schematic presentation of the neutral and active isomers in ethene polymerization.

The structures of the complexes calculated with ab initio methods[26,27] and those measured experimentally by X-ray diffraction are indeed in good agreement for complexes **1**–**3**. According to the solid-state structure, in complex **1**, the imine nitrogen atoms are in *cis* positions (Figure 4, A), and this conformer has a significantly lower energy than the isomer in which the nitrogen atoms occupy the axial corners of the octahedra (Figure 4, B). Due to steric interactions, the increasing bulkiness on the aniline moiety raises the energy level of the *cis* isomer, and the *trans* isomer is favored. This is in accordance with the solid-state structures of complexes **2** and **3**. The structural data for the rest of the complexes studied were calculated by theoretical methods only: *trans* isomer for complex **4**, while for **5** and **6**, which both have 2,6-fluoroaniline, the *cis* isomer was the most stable isomer.

In the solid state, complex **1** has the imine nitrogen atoms *cis* to each other, and the angle between the chloride ligands is 97°. In complex **2**, which carryies 2,6-dimethylaniline, the imine moieties are *trans* to each other (179°), and the angle between the chloride ligands is reduced to 89°. When the size of the aniline substituents is increased, the angle between the nitrogen atoms (172°) in **3** becomes smaller, and the angle between chloride ligands increases (94°). By comparing the polymerization activities and the geometries of the complexes, a clear dependence can be observed – the catalyst precursors that prefer the imine nitrogen atoms in the *cis* position, **1**, **5** and **6**, are more active in ethene polymerization than those that have a *trans* configuration. In any event, this observation does not provide answers to the question "what will happen after activation and why does PE have uni- and bimodal distribution curves". Therefore, the stability of the bis(salicylaldiminato)Ti^+–Me species was the subject of further calculations as the stability of the metal cation is one of the crucial parameters which determines polymerization activity of a certain catalytic species (Figure 4).[28]

The energy differences between the dichloro complexes and corresponding monomethyl cation forms were calculated for each isomer. According to the data, the relative stability of the structural isomers is altered after activation, e.g. complex **6** prefers a *cis* orientation but for the cation, the *trans* isomer has the lowest energy (Table 5). This phenomenon complicates the direct comparison of the calculated stability values and the experimental polymerization activities, and raises the question whether the species responsible for the catalytic activity has the same conformation as the corresponding dichloro complex. In fact, elegant ^{15}N NMR spectroscopic studies by Fujita et al. indicate that some of the bis(salicylaldiminato)$ZrCl_2$ complexes possess fluxional behavior, and intramolecular change of the complex geometry can occur.[29]

Table 5. The relative stability energies E_{Rel} in kJ/mol of the dichloro complexes **1**–**6** $E_{Rel}(Cl_2)$ and their cationic forms $E_{Rel}(Ti^+)$ including different isomeric structures. The most stable isomer has been marked. In the calculations the *trans* isomer of each catalyst precursor has been chosen as a point of reference. The stability of Ti^+ was compared with the cationic form of $TiCl_4$.

Complex	$E_{Rel}(Cl_2)$	$E_{Rel}(Ti^+)$	Stability of Ti^+
1-*cis*	**–21**	**0**	–435
1-*ciscis*	–8	0	–448
1-*trans*	0	**0**	**–456**
2-*cis*	40	**0**	**–479**
2-*ciscis*	48	79	–409
2-*trans*	**0**	**0**	–439
3-*cis*	43	**–26**	**–495**
3-*ciscis*	65	0	–491
3-*trans*	**0**	0	–426
4-*cis*	3	**0**	–453
4-*ciscis*	13	**0**	**–463**
4-*trans*	**0**	**0**	–450
5-*cis*	**–7**	15	–440
5-*ciscis*	31	3	**–490**
5-*trans*	0	**0**	–462
6-*cis*	**–17**	10	–437
6-*ciscis*	21	5	**–479**
6-*trans*	0	**0**	–464

Whenever the conformation of the catalyst changes, one of the coordination bonds is released, after which rotation of the ligand can take place. This gives an option that the *cis* or *trans* isomers can be converted directly into the *ciscis* isomer, which is also the required intermediate isomer if ever the exchange between *cis* and *trans* isomer takes place. Taking this possibility into account, the observed activities as well as the multisite behaviors of the complexes can be rationalized.

In the series complexes, **1** prefers a *cis* conformation, and after MAO activation, it produces polyethene with good activity. At low polymerization temperatures, **1**/MAO gives PE with unimodal PD, while at higher temperatures, bimodal behavior is apparent. According to the calculations, all cationic isomers have an equal possibility of occurring,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

while the *trans* geometry gives the most stable active center and it should be the dominant species in the polymerization (Table 5). The neutral and cationic form of **2** prefers the *trans* isomer, and in addition the *ciscis* isomer is located significantly higher in energy and, therefore, the geometry of the catalyst is frozen to the initial *trans* conformer with low stability. This is in accordance with the observed low activity and unimodal behavior of the catalyst. As a neutral complex, **3** favors the *trans* conformer, while in the cationic form the *cis* isomer is more favorable. Because the *ciscis* intermediate is low in energy such a change in the coordination sphere is easily achievable and is reflected in the polymerization behavior of 3/MAO. The interchange of catalyst geometries can be seen as a broad distribution curve at 40 °C, bimodal at 60 °C, but at 100 °C, PE with narrow PD (1.84) is obtained, which implicates the presence of only one type of active center (*cis*). Complex **4** prefers the *cis* form, but after activation all isomers have an equal possibility of occurring – the stability of the *ciscis* isomer is only slightly favorable. Therefore, under certain conditions, **4**/MAO produced PE with trimodal character. Before activation, **5** and **6** adopt a *cis* conformation, but in the cationic form the *trans* isomers are slightly favored. In fact, catalyst **6**/MAO produces PE with a high activity and mainly with a unimodal distribution. Only at 80 °C is the polymer clearly bimodal, which is in accordance with the presence of the higher energy *ciscis* isomer. Due to the lower energy gap between the *trans*- and *ciscis* isomers, **5**/MAO is more prone to produce bimodal PE.

In addition to the stability of the cation, the steric shielding of the catalyst is also one of the crucial factors that determine the activity in polymerization. In the series of catalysts, **3** exhibits the highest calculated stability value but only medium catalytic activity has been detected. This raises the question about the steric shielding of the metal center. In fact, Fujita et al. have also reported the deleterious effects of aniline's alkyl substituents on the catalytic activity and they suggested that the alkyl groups increase the steric congestion around the active site.[12,30] We assume that the low activity of **3** as well as **2** and **4**, combined with low stability of the cation, arises from the same origin. Tuning of the size of the substituent has a significant influence on the average polymerization activity.[31]

Electron-withdrawing fluoro substituents on aniline have been considered as highly desirable as they give catalyst precursors with highest activities. We assume that the coordination between imino-N and Ti weakens, and affords, therefore, rapid intramolecular exchange towards the conformation with the highest stability even at low polymerization temperatures (25 °C and below). When the polymerization temperature is increased (above 60 °C), the catalyst precursor with aniline (**1**) possesses similar or even higher activities than that bearing 2,6-difluoro aniline (**5**).

Conclusions

Bis(salicylaldiminato)$TiCl_2$ complexes are often described as catalyst precursors that are able to produce polyethene with narrow polydispersities, and even a living polymerization of α-olefins has been reported.[11] The series of bis(salicylaldiminato) catalysts described here posses a tunable multisite character with high activity. Similar multisite behavior of bis(salicylaldiminato)$TiCl_2$ catalyst precursors has been reported only for bis[(3-(3,5-dicumyl)salicylidene) anilinato]zirconium(IV) dichloride; depending on polymerization conditions uni-, bi- and trimodal polyethene have been obtained.[29]

Subtle variations in the ligand structure and polymerization conditions can significantly change the polymer properties. What is apparent from this study is the fact that the structure of the catalyst precursor does not predict the polymerization properties of the activated complex. The most important factor is the conformation of the active catalyst. The catalysts studied here are prone to change their coordination sphere after the activation process, and the relative stability energies of the different cation isomers vary with the ligand substituents. The relative stabilities of the different isomers depend on the ligand substituents. Different conformers of the active species can be present at the same time, which is seen by a multimodal behavior in polymerization. The ratio of the active species present in polymerization can be also fine tuned by the reaction temperature. In this series of catalysts, the metal cations with a *trans* conformation possess highest activities. For example, the activity of the catalyst **1**/MAO is three times greater than that of catalysts **3**/MAO and **4**/MAO, for which the most stable isomer is the *cis* isomer. It is reasonable to assume that in the *trans* conformation, the active center is sterically protected by the imino substituents. As a conclusion, the phenomenon described above illustrates the fluxional character of bis(salicylaldiminato)$TiCl_2$ complexes, which depends on the ligand substituents, and is therefore unique for each catalyst.

Experimental Section

All organometallic syntheses were performed under argon using standard Schlenk techniques and dry solvents.

Materials: Toluene, *n*-hexane, and tetrahydrofuran (THF) of HPLC grade were dried and purified by refluxing over sodium and benzophenone, followed by distillation under argon. Dichloromethane (CH_2Cl_2) was dried and purified over CaH_2 by refluxing for 4 h and subsequent distillation. Toluene, *n*-hexane, and THF were stored with sodium flakes under argon. Salicylaldehyde (Fluka), 3-fluorosalicylaldehyde (Aldrich), 3-*tert*-butylsalicylaldehyde (Aldrich), aniline (Aldrich), 2,6-dimethylaniline (Aldrich), 2,6-diisopropylaniline (Aldrich), naphthylamine (Aldrich), 2,6-difluoroaniline (Aldrich), 2,3,4,5,6-pentafluoroaniline (Aldrich), Tetrakis(dimethylamino)titanium (Aldrich), and $TiCl_4$ (Riedel-de Haën) were used as received, methylaluminoxane (MAO, 30 wt.-% solution in toluene) was received from Borealis Polmers Oy.

^1H- and ^{13}C NMR spectra were collected on a Varian Gemini 2000 (200 MHz) spectrometer. Chemical shifts were referenced internally with respect to $CHCl_3$ (δ =7.27 and 77.23 ppm, respectively). Mass spectra (EI) were acquired by a JEOL-SX102 spectrometer. DSC

measurements (melting point) were performed on a Perkin–Elmer DSC-2, calibrated with indium (temperature scanning 20 °C/min). Scan area was from 25 °C to 232 °C. Mass average molecular weights (M_w), number average molecular weights (M_n), and molecular weight distribution (MWD, M_w/M_n) of the polyethene samples were determined by GPC (Waters Alliance GPCV 2000, high-temperature gel chromatographic device). HMW7, 2*HMWGE and HMW2 Waters Styrogel columns were used for GPC. Measurements were performed in 1,2,4-trichlrobentzene (TCB) at 160 °C relative to polyethene standards, and 2,6-di-*tert*-butyl-4-methylphenol was used as a stabilizer.

Syntheses of the Compounds a–f

***N*-(Salicylidene)aniline (a):** Fully detailed analyses can be found in the literature.[16] Salicylaldehyde (5 ml, 1.146 g/ml, 0.047 mol) and aniline (4.82 mL, 93.13 g/mol, 0.047 mol) were added to a 100-mL round-bottomed flask at room temperature and were warmed to 120 °C. The heated mixture was stirred overnight. The crude product was recrystallized from propanol (8.34 g, 90%). ^{1}H NMR (200 MHz, $CDCl_3$, 29 °C): δ = 6.93–7.08 (m, 2 H, H–Ph) 7.26–8.63 (m, 5 H, H–Ph), 8.63 (s, 1 H, CNH), 13.31 (s, 1 H, OH) ppm.

***N*-(Salicylidene)-2,6-dimethylaniline (b):** Fully detailed analyses can be found in the literature.[17] Compound **b** was prepared by a similar method as described above for **a**. Salicylaldehyde (5 ml, 1.146 g/ml, 0.047 mol) and 2,6-dimethylaniline (5.9 mL, 121.18 g/mol, 0.047 mol) were mixed. The product was isolated as yellow crystals. Yield: 9.53 g, 90%. ^{1}H NMR (200 MHz, $CDCl_3$, 29 °C): δ = 2.24 (s, 6 H, CH_3), 6.95–7.12 (m, 5 H, H–Ph), 7.35–7.48 (m, 2 H, H–Ph), 8.37 (s, 1 H, CNH), 13.13 (s, 1 H, OH) ppm. MS (EI): *m*/*z* = 224–225 with appropriate isotope ratio for [$C_{15}H_{15}NO^+$].

***N*-(Salicylidene)-2,6-diisopropylaniline (c):** Fully detailed analyses can be found in the literature.[17] Compound **c** was prepared by a similar method as described above for **a**. Salicylaldehyde (5 mL, 1.146 g/ml, 0.047 mol) and 2,6-diisopropylaniline (17.7 mL, 177.29 g/mol, 0.047 mol) were mixed. The product was isolated as yellow crystals. Yield: 10.58 g, 80%. ^{1}H NMR (200 MHz, $CDCl_3$, 29 °C): δ = 1.26 (d, 12 H, CH_3), 3.08 (sept, 2 H, CH), 7.05–7.55 (m, 7 H, H–Ar), 8.39 (s, 1 H, CNH), 13.18 (s, 1 H, OH) ppm.

***N*-Naphthylsalicylaldimine (d):** Fully detailed analyses can be found in the literature.[18] Compound **d** was prepared by a similar method as described above for **a**. Salicylaldehyde (5 mL, 1.146 g/ml, 0.047 mol) and naphthylamine (6.73 g, 0.047 mol) were mixed. The product was isolated as a brown powder. Yield: 8.14 g, 70%. ^{1}H NMR (200 MHz, $CDCl_3$, 29 °C): δ = 6.67–6.97 (m, 3 H, H–Ar), 7.12–7.32 (m, 3 H, H–Ar), 7.49–7.53 (m, 2 H, H–Ar), 7.56–7.65 (m, 2 H, H–Ar), 7.95–8.03 (m, 2 H, H–Ar), 8.42 (s, 1 H, CNH) ppm.

***N*-(Salicylidene)-2,6-difluoroaniline (e):** Salicylaldehyde (5 mL, 1.146 g/ml, 0.047 mol) and 2,6-difluoroaniline (5.1 mL, 1.199 g/ml, 0.047 mol) were added to a 100-mL round-bottomed flask at room temperature. To the mixture were added a catalytic amount of concentrated sulfuric acid and toluene (40 mL), and the mixture was warmed to 110 °C. The heated mixture was stirred overnight. The formed imine was dissolved in CH_2Cl_2, dried with solid Na_2SO_4, and the mixture was filtered. The product was isolated as an orange–yellow powder. Yield: 9.86 g, 90%. ^{1}H NMR (200 MHz, $CDCl_3$, 29 °C): δ = 6.93–7.22 (m, 5 H, H–Ar), 7.38 and 7.42 (d, 2 H, H–Ar), 8.88 (s, 1 H, CNH), 12.94 (s, 1 H, OH) ppm. ^{13}C{1H} NMR (50.3 MHz, $CDCl_3$, 29 °C): δ = 107.27 (Ar), 112.05–112.53 (m, 2 H, Ar), 117.76 (Ar), 119.34 (Ar), 126.71 (t, 1 H, Ar), 132.98 (Ar), 134.12 (Ar), 153.64 and 153.75 (d, Ar), 158.65 and 158.79 (d, Ar), 161.63 (Ar), 168.93 (t, Ar) ppm. MS (EI): *m*/*z* = 233–234 with appropriate isotope ratio for [$C_{13}H_9F_2NO^+$].

***N*-(3-Fluorosalicylidene)-2,6-difluoroaniline (f):** Compound **f** was prepared by a similar method as described above for **e**. 3-Fluorosalicylaldehyde (1.0 g, 0.00713 mol) and 2,6-difluoroaniline (0.77 mL, 0.00713 mol) were mixed. The product was isolated as an orange–yellow powder. Yield: 1.61 g, 90%. ^{1}H NMR (200 MHz, $CDCl_3$, 29 °C): δ = 6.84–8.94 (m, 6 H, H–Ar), 8.94 (s, 1 H, CNH), 13.21 (s, 1 H, OH) ppm. MS (EI): *m*/*z* = 250–251 with appropriate isotope ratio for [$C_{13}H_8F_3NO^+$].

Syntheses of the Complexes 1–6

Bis[*N*-(salicylidene)anilinato]titanium(IV) Dichloride (1): Fully detailed analyses of complex **1** can be found in the literature.[19] Compound **a** (2.0 g, 0.010 mol) was dissolved in toluene (60 mL), and cooled to –78 °C, after which it was slowly transferred with a syringe to a precooled solution of toluene (60 mL) and $Ti(NMe_2)_4$ (1.2 mL, 224.21 g/mol, 0.0050 mol). The solution obtained was stirred overnight at room temperature. Quantitative formation of the complex bis(dimethylamino)bis[*N*-salicylidene)anilinato]titanium was observed. ^{1}H NMR (200 MHz, $CDCl_3$, 29 °C): δ = 1.69 (s, 6 H, HN*Me*$_2$), 2.30 (s, 6 H, HN*Me*$_2$), 3.5 (b, 12 H, TiN*Me*$_2$), 4.83 (s, 2 H, *H*NMe_2), 5.89 and 5.93 (d, 2 H, H–Ar), 6.58–7.57 (m, 16 H, H–Ar), 8.49 (s, 2 H, CNH) ppm. MS (EI): *m*/*z* = 528 with appropriate isotope ratio for [$C_{30}H_{32}N_4O_2Ti^+$]. The amount of the solvent was reduced to 40 mL, and trimethylsilylchloride (20× excess, 25 mL, 0.856 g/ml, 0.2 mol) was added at room temperature. The reaction mixture was stirred overnight, followed by 2 h of heating in refluxing toluene and removal of side-product residues at 70 °C in vacuo. The procedure was repeated twice (may be necessary). Traces of unidentified amine compounds were still observed by ^{1}H NMR spectroscopy, otherwise the product was pure according to EA, NMR, MS. Yield: 2.55 g, 98%. ^{1}H NMR (200 MHz, $CDCl_3$, 29 °C): δ = 6.47 and 6.51 (d, 2 H, H–Ar), 6.98–7.34 (m, 16 H, H–Ar), 8.27 (s, 2 H, CNH) ppm. MS (EI): *m*/*z* = 511 with appropriate isotope ratio for [$C_{26}H_{20}Cl_2N_2O_2Ti^+$]. $C_{26}H_{20}Cl_2N_2O_2Ti$: calcd. C 61.08, H 3.94, N 5.48; found C 61.22, H 4.01, N 5.57.

Bis[*N*-(salicylidene)-2,6-dimethylanilinato]titanium(IV) Dichloride (2): Complex **2** was prepared by a similar method as described above for **1**.

Analyses of the quantitative formation of the intermediate product bis(dimethylamino)bis[*N*-salicylidene)-2,6-dimethylanilinato]titanium. ^{1}H NMR (200 MHz, $CDCl_3$, 29 °C): δ = 2.16 (s, 6 H, Ar–CH_3), 2.35 (s, 6 H, Ar–CH_3), 2.56 (s, 6 H, NCH_3), 2.87 (s, 6 H, CH_3, NCH_3), 6.37 and 6.41 (d, 2 H, H–Ar), 6.59 (t, 2 H, H–Ar), 7.00–7.27(m, 10 H, H–Ar), 8.06 (s, 2 H, CNH) ppm. MS (EI): *m*/*z* = 584 with appropriate isotope ratio for [$C_{34}H_{40}N_4O_2Ti^+$].

Analyses of the final product. The product was isolated as yellow crystals. Yield: 2.55 g, 90%. ^{1}H NMR (200 MHz, $CDCl_3$, 29 °C): δ = 2.47 and 2.50 (d, 12 H, Ar–CH_3), 6.76 and 6.80 (d, 2 H, Ar), 6.98–7.17 (m, 8 H, H–Ar), 7.53–7.65 (m, 4 H, H–Ar), 8.38 (s, 2 H, CNH) ppm. ^{13}C{1H} NMR (50.3 MHz, $CDCl_3$, 29 °C): δ = 19.15 (s, Ar–*C*H_3), 19.85 (s, Ar–*C*H_3), 115.48 (Ar), 122.11 (Ar), 124.34 (Ar), 126.95 (Ar), 127.81 (Ar), 129.06 (Ar), 130.11 (Ar), 131.54 (Ar), 134.64 (Ar), 137.04 (Ar), 154.01 (Ar), 164.01 (Ar), 169.58 (Ar) ppm. MS (EI): *m*/*z* = 566 with appropriate isotope ratio for [$C_{30}H_{28}Cl_2N_2O_2Ti$]$^+$.

Bis[*N*-(salicylidene)-2,6-diisopropylanilinato]titanium(IV) Dichloride (3): Fully detailed analyses of the complex **3** can be found in the literature.[19] Compound **c** (3.0 g, 10.6 mmol) was dissolved in dry CH_2Cl_2 (30 mL) in a Schlenk flask, under argon. Hexamethylsilazane (3.0 mL, 0.765 g/ml, 14.22 mmol) was added to the solution with a syringe. The reaction mixture was kept at room temperature

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and was stirred overnight. Evaporation of excesshexamethylsilazane and by-products under vacuum at 50 °C over 5 h purified the product. The silylated *N*-(salicylidene)-2,6-diisopropylaniline was a slightly yellow, viscose liquid. The yield was quantitative (3.15 g). ^{1}H NMR (200 MHz, $CDCl_3$, 29 °C): δ= 0.37 (s, 9 H, SiCH_3), 1.28 (d, 12 H, CH_3), (sept, 2 H, CH), 6.97 (d, 1 H, H–Ar), 7.15–7.33 (m, 4 H, H–Ar), 8.45 (t, 1 H, H–Ar), 8.29 (d, 1 H, H–Ar), 8.62 (s, 1 H, CNH) ppm. The silylated compound **c** (3.55 g, 10.07 mmol) was dissolved in dry THF (60 mL) in a Schlenk flask, and cooled to the freezing point of THF with liquid nitrogen. The same cooling procedure was performed with $TiCl_4$·$(THF)_2$ (2.23 g, 5.04 mmol), which was dissolved on THF (150 mL). Precooled silylated compound **c** was slowly transferred to the titanium solution with syringe under an argon flow. The solution immediately turned to light red. The reaction mixture was stirred overnight, and allowed to come to room temperature. During that time, the color of the mixture turned to deep red. The titanium complex was purified by evaporation of the formed trimethylsilylchloride and THF. Recrystallization was performed from *n*-hexane/THF (7:1). Yield: 2.91 g, 85%. ^{1}H NMR (200 MHz, $CDCl_3$, 29 °C): δ = 1.14 (d, 12 H, CH_3), 1.30 (d, 6 H, CH_3), 1.46 (d, 6 H, CH_3), 1.90 (4 H, THF), 3.62 (sept, 4 H, CH), 3.80 (4 H, THF), 6.78 (d, 2 H, H–Ar), 7.10 (t, 2 H, H–Ar), 7.17 (m, 6 H, H–Ar), 7.48 (m, 4 H, H–Ar), 8.42 (s, 1 H, CNH) ppm. MS (EI): *m*/*z* = 679–684 with appropriate isotope ratio for [$C_{38}H_{44}N_2O_2TiCl_2^+$]. $C_{38}H_{44}N_2O_2TiCl_2$: calcd. C 67.16, H 6.53, N 4.12, Ti 7.05; found C 66.84, H 6.71, N 4.26, Ti 7.17.

Bis[*N*-(naphthylsalicylaldiminato]titanium(IV) Dichloride (4): Complex **4** was prepared by a similar method as described above for **3**. Silylated compound **d** was a slightly yellow, viscous liquid. The yield was quantitative (3.39 g). ^{1}H NMR (200 MHz, $CDCl_3$, 29 °C): δ = 0.33 (s, 9 H, SiCH_3), 6.90–7.20 (m, 3 H, H–Ar), 7.18–7.58 (m, 4 H, H–Ar), 7.77 (d, 1 H, aromatic), 7.85 (m, 1 H, H–Ar), 8.38 (m, 1 H, H–Ar), 8.90 (s, 1 H, CNH) ppm. MS (EI): *m*/*z* = 319–322 with appropriate isotope ratio for [$C_{20}H_{21}NOSi^+$]. The desired titanium complex precipitated out as a powder from an *n*-hexane/THF (5:1) solution. Yield: 2.62 g, 90%. ^{1}H NMR (200 MHz, $CDCl_3$, 29 °C): δ = 1.86 (4 H, THF), 3.76 (4 H, THF), 5.62 (d, 1 H, H–Ar), 6.02 (d, 1 H, H–Ar), 6.20 (d, 1 H, H–Ar), 6.50–8.40 (m, 19 H, H–Ar), 8.70 (s, 2 H, CNH) ppm. ^{13}C{1H} NMR (50.3 MHz, $CDCl_3$, 29 °C): δ = 25.85 (THF), 68.28 (THF), 116.24 (Ar), 116.76 (Ar), 117.52 (Ar), 119.00 (Ar), 119.23 (Ar), 121.56 (Ar), 121.92 (Ar), 122.54 (Ar), 123.56 (Ar), 123.99 (Ar), 125.00 (Ar), 125.24 (Ar), 125.76 (Ar), 126.88 (Ar), 123.99 (Ar), 125.00 (Ar), 125.24 (Ar), 125.76 (Ar), 126.88 (Ar), 127.80 (Ar), 128.44 (Ar), 133.87 (Ar), 134.69 (Ar), 135.02 (Ar), 136.33 (Ar), 137.06 (Ar), 149.60 (Ar), 162.13 (Ar), 162.53 (Ar), 168.47 (Ar), 169.05 (Ar), 169.62 (Ar) ppm. MS (EI): *m*/*z* = 610–615 with appropriate isotope ratio for [$C_{34}H_{24}N_2O_2TiCl_2^+$]. $C_{34}H_{24}N_2O_2TiCl_2$: calcd. C 66.83, H 3.93, N 4.58, Cl 11.62, Ti 7.86; found: C 64.89, H 4.41, N 4.18, Cl 10.14, Ti 8.69.

Bis[*N*-(salicylidene)-2,6-difluoroanilinato]titanium(IV) Dichloride (5): Complex **5** was prepared by a similar method as described above for **1**. Yield: 2.33 g, 80%. ^{1}H NMR (200 MHz, $CDCl_3$, 29 °C): δ = 6.43–6.47 (m, 4 H, H–Ar), 6.97–7.01 (m, 6 H, H–Ar), 7.36–7.40 (m, 4 H, H–Ar), 8.25 (s, 2 H, CNH) ppm. MS (EI): *m*/*z* = 583–586 with appropppriate isotope ratio for [$C_{26}H_{16}Cl_2F_4N_2O_2Ti^+$]. $C_{26}H_{16}Cl_2F_4N_2O_2Ti$: calcd. C 53.55, H 2.77, N 4.80; found C 53.16, H 3.16, N 4.4.

Bis[*N*-(3-fluorosalicylidene)-2,6-difluoroanilinato]titanium(IV) Dichloride (6): Complex **6** was prepared by a similar method as described above for **1**. Yield: 1.11 g, 90%. ^{1}H NMR (200 MHz, $CDCl_3$, 29 °C): δ = 6.30 (b, 2 H, H–Ar), 6.88–7.40 (m, 10 H, H–Ar), 8.30 (s, 2 H, CNH) ppm. MS (EI) *m*/*z* = 619–620 with appropriate isotope ratio for [$C_{26}H_{14}Cl_2F_6N_2O_2Ti^+$]. $C_{26}H_{14}Cl_2F_6N_2O_2Ti$: calcd. C 50.44, H 2.28, N 4.52; found C 49.91, H 2.46, N 4.10.

Polymerization Experiments: Polymerization runs were performed in a Büchi 1.0-dm^3 stainless steel autoclave equipped with a Julabo ATS-3 and Lauda RK 20 temperature controlling unit. Mechanical stirring was applied with a stirring speed of 800 r.p.m. During polymerization, the partial pressure of ethene and the temperature were kept constant. Ethene consumption was measured with a calibrated mass flow meter and monitored online together with the temperature and pressure inside the vessel by using the Genie™ computer program for data acquisition.

Toluene (250 cm^3) and the cocatalyst (MAO) were introduced to the argon-purged reactor. Once the polymerization temperature had been reached, the vessel was charged with ethene to the appropriate pressure. Polymerization was started by injecting 20 cm^3 of the catalyst precursor solution (5–20 μmol solution in toluene) into the reactor. The polymerization was completed by pouring the contents of the vessel into methanol, acidified with a small amount of concentrated hydrochloride acid. The solid polyethene was collected by filtration, washed with methanol, and dried overnight at 70 °C.

X-ray Crystallographic Study: A single crystal of compound **2** was selected for the X-ray measurement and mounted on the glass fibre using the oil-drop method (Kottke & Stalke, 1993). Data were collected at 120(2) K with a Nonius KappaCCD diffractometer. The intensity data were corrected for Lorentz and polarization[32] effects and for absorption by multi-scan method.[33] The structures were solved by direct methods (SHELXS-97).[34] The refinements and graphics were performed by using the SHELXL-97 and SHELXTL/PC program packages, respectively.[35] All non-hydrogen atoms were refined anisotropically. The H atoms were introduced in calculated positions and refined with fixed geometry with respect to their carrier atoms.

X-ray Data for Complex 2: Z, calculated density 2, 1.347 Mg/m^3, absorption coefficient 0.527 mm^{-1}, F(000) 588, crystal size 0.35 × 0.15 × 0.10 mm, θ range for data collection 2.08 to 26°, reflections collected 27130, unique reflections 5489(R_{int} = 0.0925), completeness to θ = 26.00: 99.7%, absorption correction semi empirical from equivalents, max. and min. transmission 0.9492 and 0.8372, refinement method full-matrix least-squares on F^2, data/restraints/parameters 5489/0/339, goodness of fit on F^2 = 1.120, final R indices [$I > 2\sigma(I)$] R_1 = 0.0492, wR_2 = 0.01252, R indices (all data) R_1 = 0.0570, wR_2 = 0.1298, extinction coefficient 0.0098(19), largest diff. peak and hole 0.538 and –0.672 eÅ^{-3} (see also: Table 1, Table 2, and Figure 1).

CCDC-235033 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Theoretical Calculations: Geometry optimisations were performed at the HF/3-21G* level, which has been shown to provide reliable structures for group 4 transition-metal complexes, especially for titanium-based complexes. Based on our earlier studies, neither increasing the size of the basis set nor inclusion of electron correlation at the MP2 level has a significant influence on the geometries, but would certainly increase calculation times. Single-point MP2 calculations were performed to confirm the relative stability order of conformations of the studied titanium complexes. At the single-point calculations, basis set 6-31G* for C, H, O and N, and

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

equal-level generated basis set for Ti were used. The stability orders, produced by both methods, are generally in good agreement with each other. The geometry minima were confirmed by frequency calculations. All calculations were carried out by the Gaussian 03 program package.[26]

Lanthanide(III) Chelates of DTPA Bis(amide) Glycoconjugates: Potential Imaging Agents Targeted at the Asyaloglycoprotein Receptor

Paula Baía,[a] João P. André,*[a] Carlos F. G. C. Geraldes,[b] José A. Martins,*[a] André E. Merbach,[c] and Éva Tóth[c]

Keywords: Chelates / Contrast agents / Lanthanides / Glycoconjugates / Receptors

The synthesis and characterisation of a new class of DTPA bis(amide) linked glycoconjugates of different sugars [lactose (Lac) and galactose (Gal)] and valencies (di and tetra) and their Ln^{III} complexes is reported. The ^1H NMR spectra of the Sm^{III} and Eu^{III} complexes of $DTPAGal_2$, $DTPAGal_4$, and $DTPALac_2$, obtained between 7 and 80 °C, indicate that several of the four possible diastereoisomeric pairs of structures resulting from the chirality of the three bound DTPA nitrogen atoms are present in solution, with different relative populations. The dynamic effects of racemisation of the central nitrogen atom in the NMR spectra show that this process is fast at 60 °C for the Sm^{III} complexes and slow at 7 °C for the Eu^{III} complexes. The in vitro r_1 nuclear magnetic relaxation dispersion (NMRD) of the water protons of the Gd^{III}–DTPA bis(amide) glycoconjugate containing two lactosyl moieties [Gd^{III}–$DTPALac_2$] was studied, yielding the molecular parameters that govern its relaxivity. Its r_1 value, at 25 °C and 20 MHz, is 13 % higher than that reported for Gd^{III} chelates of lower molecular weight DTPA bis(amides), such as DTPA-BMA, consistent with a five times larger τ_R value. The water exchange rate, k_{ex}, and the electron spin relaxation parameters of the Gd^{III}–$DTPALac_2$ complex are within the usual range for similar Gd^{III}–DTPA bis(amide) chelates.

Introduction

Magnetic resonance imaging (MRI) is one of the fastest growing techniques in medical diagnosis due to the excellent spatial resolution and contrast, in particular for soft tissues. The image contrast is based mainly on the differences of water proton longitudinal ($1/T_1$) and transversal ($1/T_2$) relaxation rates in different tissues. This contrast can be enhanced with the administration, prior to the scan, of paramagnetic contrast agents (CAs), usually Gd^{III} ($4f^7$) complexes,[1,2] which accelerate the proton relaxation processes in the surrounding water through dipolar interactions between the unpaired electron spin of the metal ion and the proton nuclei of the water molecules. The Gd^{III} chelate of DTPA [DTPA = 3,6,9-tris(carboxymethyl)-3,6,9-triazaundecane-1,11-dioic acid)], $[Gd(DTPA)(H_2O)]^{2-}$, was the first contrast agent (CA) used for human MRI, under the name of Magnevist®.[3] Its success stimulated further studies on modifications of its structure, leading, amongst others, to the neutral derivative [Gd(DTPA-BMA)(H_2O)] [Omniscan®; DTPA-BMA = diethylenetriaminepentaacetic acid *N*,*N*′′-bis(methylamide)], in which two carboxylate groups have been converted into amide functions.[4] These, as well as other hydrophilic linear or macrocyclic Gd^{III} chelates of similar dimensions and simplicity, once injected, rapidly diffuse from the intravascular space into the interstitial space, but do not enter the intracellular space. Their rapid renal elimination produces a rapid decrease in tissue Gd concentration.[5]

Although much used, for example in neuropathological conditions, which are often associated with disruption of the blood brain barrier (BBB) or altered capillary permeability, these extracellular fluid (ECF) CAs also have inherent disadvantages due to their lack of biospecificity, low relaxivities, and poor uptake elsewhere in the body. Their rapid diffusion from the vasculature limits their uses as blood pool agents, for example in estimates of blood flow and perfusion. For such applications, several formulations of DTPA conjugates have been tested, both through covalent binding of the Gd^{III} chelate to suitable macromolecules (albumin,[6] dextran,[7] polylysine,[8] dendrimers[9]) or noncovalent binding to HSA (human serum albumin),[10] for example the Gd–DTPA derivative MS-325.[11] The search for new ligands with high tissue and/or organ specificity

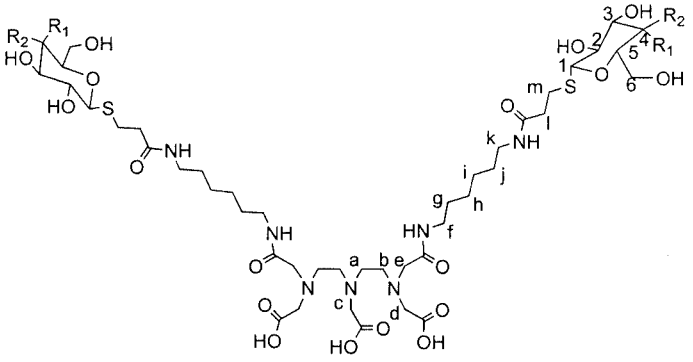
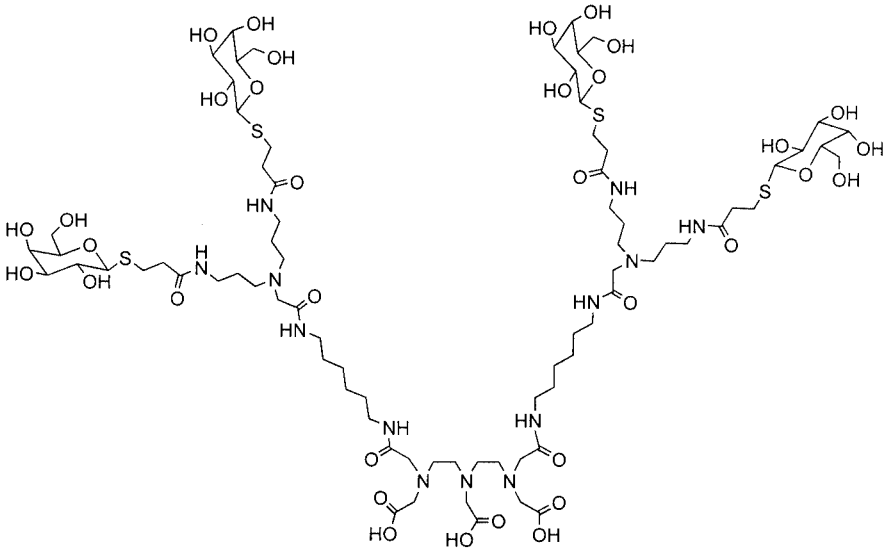
started with hepatobiliary CAs, such as Gd^{III} chelates, which are hepatocyte-specific and are excreted through the hepatobiliary system. Amongst these are Gd^{III} chelates of DTPA-derived ligands bearing various lipophilic substituent groups which promote specific carrier-mediated uptake into the hepatocytes, such as benzyloxymethyl in $[Gd(BOPTA)(H_2O)]^{2-}$ [BOPTA = 4-carboxy-5,8,11-tris(carboxymethyl)-1-phenyl-2-oxa-5,8,11-triazatridecan-13-oic acid][12] and ethoxybenzyl in $[Gd(EOB\text{-}DPTA)(H_2O)]^{2-}$ [EOB-DTPA = (*S*)-*N*-{2-[bis(carboxymethyl)amino]-3-(4-ethoxyphenyl)propyl}-*N*-{2-[bis(carboxymethyl)amino]-ethyl}glycine].[13] Liposomes can also be efficient carriers to deliver Gd^{III}-based CAs to the liver and spleen and hence enhance their MRI image contrast. The amphiphilic Gd(DTPA)–stearylamide, for example, is incorporated into the phospholipid lamella of egg lecithin and cholesterol liposomes.[14]

The hepatocyte cells on liver express a tissue-specific lectin (hepatic lectin) that recognizes terminal β-galactosyl residues on desialylated glycoproteins − the asialoglycoprotein receptor (ASGPR).[15] Liver targeting has been successfully achieved through conjugation of pharmaceutical agents to galactose/lactose.[16] Moreover, a multivalence effect has been demonstrated on the liver uptake of glycoconjugates (tetra > tri > di > mono).[17] Several agents that rely on macromolecular bioconjugates and on polymer scaffolds have been described for hepatic imaging through the targeting of the ASGPR.[18–25] These agents have the drawback of being inherently polydisperse and ill characterised.

In a previous paper we reported the synthesis and physicochemical characterisation of a new class of multivalent glycoconjugates − Ln^{III} chelates of the tetraazatetracarboxylate chelator DOTA conjugated to glycodendrimeric moieties [DOTA = 1,4,7,10-tetrakis(carboxymethyl)-



1a R^1 = OH and R^2 = H **DTPA(Gal)$_2$**
1b R^1 =H and R^2 = β–D-galactopyranosyl **DTPA(Lac)$_2$**



2 DTPA(Gal)$_4$

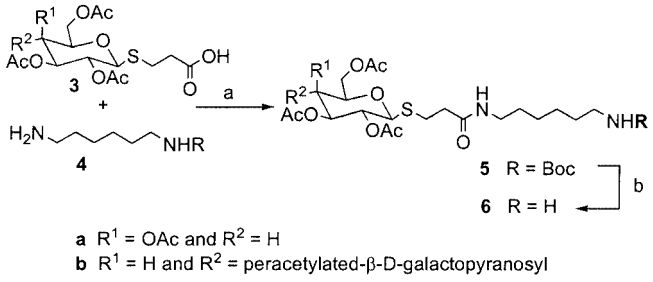
1,4,7,10-tetraazacyclododecane].[26] Previous to our work, only a class of low molecular weight and well-characterised galacto/mannopyranosyl conjugates of DOTA-like chelators had been described for potential MRI and scintigraphic applications.[27] These monovalent Gd^{III}–glycoconjugates are responsive contrast agents activated by galactosidase/mannosidase-mediated hydrolysis.[28] In this paper we report the synthesis and characterisation of (thio)glycoconjugates of the linear chelator DTPA, namely the DTPA bis(amides) **1** and **2** with different terminal sugar residues − galactose (Gal) and lactose (Lac) − and different valences (2 and 4; Figure 1). The thioglycosides are galactosidase-resistant ligands that probe a conformational space and display biological activities very similar to that of their *O*-linked natural counterparts, thus ensuring an increased metabolic stability in vivo.[29] The physicochemical characterisation of some of their Ln^{III} complexes in aqueous solution by ^1H NMR and water ^1H NMRD studies is also described. The proton relaxivity of the Gd^{III} chelates describes the efficiency of the magnetic dipolar coupling between the water proton nuclei and the paramagnetic metal ion, therefore it is a direct measure of the efficacy of the chelate as a CA.

Results and Discussion

Synthesis of the Ligands

The synthesis of the DTPA bis(amides) **1** and **2** (Figure 1) was undertaken through a well-established route consisting of the derivatisation of the commercially available DTPA bis(anhydride) with amine-functionalised blocks. Two different types of amine-functionalised sugar blocks were prepared: a monovalent block **5** (Scheme 1) and a divalent glycodendrimer block **9** (Scheme 2).[26,31] The standard DCC/HOBT coupling procedure was found to be successful for preparing the fully protected amino-functionalised sugar blocks. These compounds were deprotected with TFA/CH_2Cl_2 to afford the terminal amines **6** and **10** as their TFA salts.



Scheme 1. a) DCC/HBT, DCM; b) TFA/DCM (1:3).

In order to ensure the formation of the required bis(amides), the amino-functionalised blocks **6** and **10** were used in a slight excess, over two mol-equiv. in relation to the DTPA bis(anhydride) block (Scheme 3). The intermediate sugar-protected bis(amides) were carried through and deprotected with KOH in methanol/water to give the final compounds **1** and **2** in reasonable yields.

NMR Studies of the Ln^{III} Glycoconjugates

The ^1H NMR spectra of the 1:1 diamagnetic (La^{III}) and paramagnetic (Sm^{III} and Eu^{III}) complexes with the ligands $DTPAGal_2$, $DTPALac_2$ and $DTPAGal_4$ were obtained in D_2O at pH = 7.5 as a function of temperature (7, 25, 40, 60 and 80 °C; see Figures 2–4 for some typical spectra). The spectra of the La^{III} complexes show many identical resonances to those of the corresponding free ligand at the same pH for the protons of the sugar rings and bridging arms (Figure 2). However, the protons of the DTPA moiety, or next to it, such as CH_2(f), give more complex resonances as a result of ion coordination: a multiplet at δ = 2.92 ppm for CH_2(f), multiplets at δ = 2.95, 2.78, 2.68 and 2.45 ppm for the backbone NCH_2CH_2N protons, and a series of partially

overlapping AB patterns in the δ = 3.2–3.5 ppm region for the CH_2 protons of the acetate and amide arms, quite similar to what has been described for $[La(DTPA)]^{2-}$ and other La[DTPA bis(amides)].[32–36] For the Sm^{III} and Eu^{III} complexes, the ligand protons far from the paramagnetic centre, at the sugar rings (H-1–H-6) and at bridging arms [CH_2(g–m)], show very small paramagnetic broadenings and their shifts are easily assigned (see Figure 3).[36] The strongly shifted and broadened proton resonances of the side chain CH_2(f) and the CH_2 of the DTPA amide moiety could not be specifically assigned, despite showing some features similar to the corresponding paramagnetic complexes of the parent DTPA and some DTPA bis(amide) ligands.[36–42]

For the Sm^{III} complexes, most of these strongly shifted resonances are too broad to be detected at 25 °C but sharpen at higher temperatures. At 60 °C some appear in the diamagnetic region (δ = 5.8–4.8 and 3.3–0.6 ppm) and seven are shifted to the low frequency δ = 0.1 to –1.4 ppm region (Figure 3). In contrast, in the Eu^{III} complexes the shifted resonances are quite sharp at low temperature (7 °C, see Figure 4): ten resonances are observed in the high-frequency δ = 35–15 ppm region, about eight in the δ = 10–5 ppm region and about twenty in the δ = –3 to –18 ppm region. These are totally broadened when the temperature is increased to 25 °C, but at 60 °C some sharp, less shifted resonances reappear, for example in the δ = 6.2 to –10.2 ppm region (data not shown).

In Ln^{III} complexes of DTPA bis(amides) with non-chiral centres in the side chains, with a cation nine-coordinate by one inner-sphere water molecule and eight ligand donor atoms, all three bound nitrogen atoms are chiral and four diastereoisomeric pairs of enantiomers are possible, leading to a maximum of eight NMR signals for each group of magnetically equivalent protons.[36,40] This type of complex can undergo two distinct isomerisation processes in solution. The racemisation of the terminal N atoms, involving decoordination-inversion-coordination of the N atoms and the neighbouring acetate groups, has a high energy barrier. A lower energy process involves racemisation of the central nitrogen atom by interconversion between the two possible conformations of the ethylene bridges, which results in the magnetic averaging of the two halves of the complex around the central glycinate group of DTPA and reduces by half the number of observed resonances.[36,40] This is the dynamic process observed in the present study, which is fast at 60 °C for the Sm^{III} complexes and slow at 7 °C for the Eu^{III} complexes due to the much larger dipolar shifts induced by Eu^{III} relative to Sm^{III}.

The total number of strongly shifted proton resonances observed for the Sm^{III} and Eu^{III} complexes studied here, although they could not be assigned, leads to the unambiguous conclusion that they occur as more than one isomer in solution. A comparison of the ^{1}H NMR spectra with those of corresponding DTPA complexes[33,39] suggests that

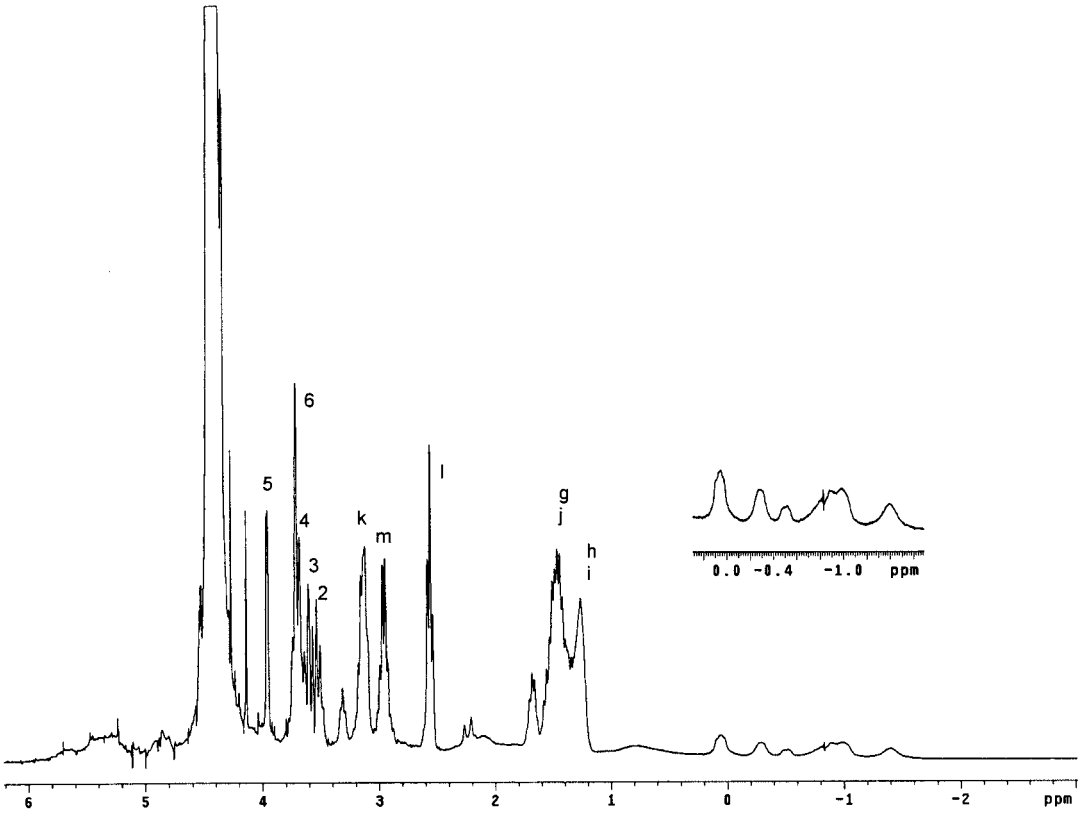

Figure 3. ^{1}H NMR spectrum of Sm^{III}–DTPAGal$_2$ glycoconjugate in D_2O, pH = 7.0, T = 60 °C.

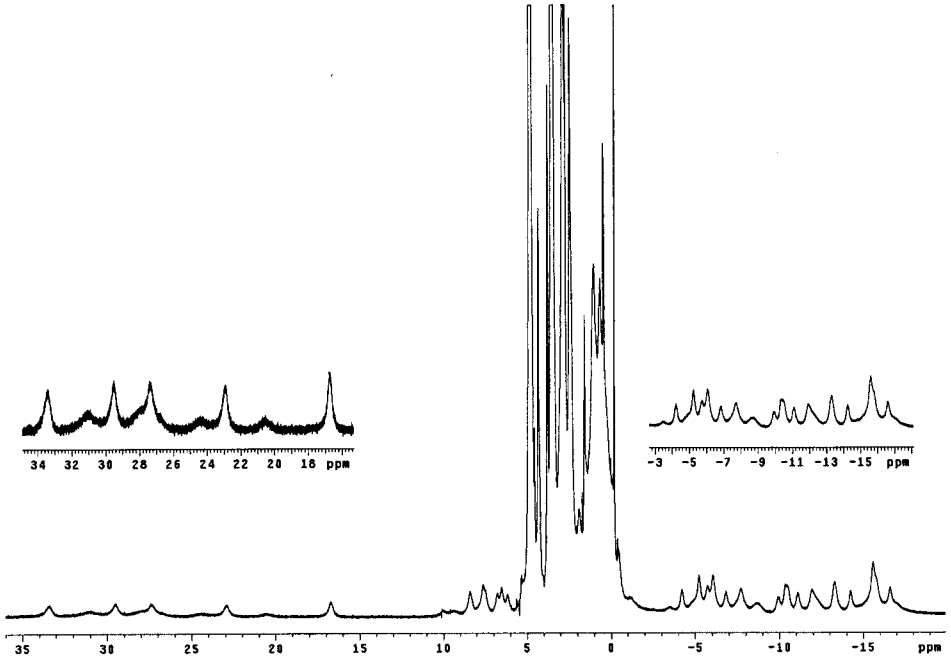

Figure 4. ^{1}H NMR spectrum of Eu^{III}–DTPAGal$_2$ glycoconjugate in D_2O, pH = 7.0, T = 7 °C.

the strongly shifted resonances at low frequencies for the Sm^{III} complex and at high frequencies for the Eu^{III} complex correspond to two CH_2 protons of the DTPA ethylenediamine backbone, which, in the DTPA complexes, have the largest induced dipolar shifts.[36,39] With this assumption, the minimum of seven low-frequency-shifted resonances observed for the Sm^{III} complex at high temperature (Figure 3), resulting from two ethylenic protons, confirms that several of the four possible isomers are present in solution. This is also in agreement with the observation of a mini-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

mum of ten high-frequency-shifted resonances in the Eu^{III} complex at high temperature (out of a maximum of sixteen) for these two ethylenic protons (Figure 4). The Ln^{III} complexes of other DTPA bis(amides), such as DTPA-BPA [BPA = bis(propylamide)] and DTPA-BENGALAA {BENGALAA = *N*,*N*′′-bis[*N*-(aza-D-galacto-5,6,7,8,9-pentahydroxynonyl)carbamoylmethyl]amide},[35,41] show the presence of four diastereoisomeric pairs, while for bis(amides) containing long (C_{14} to C_{18}) aliphatic chains only two pairs have been detected in solution.[42]

Water Proton Relaxation (NMRD) Studies of Gd^{III}-DTPALac$_2$

The efficiency of a contrast agent is given by its proton relaxivity, defined as the paramagnetic enhancement of the longitudinal water proton relaxation rate at a concentration of 1 mM (r_1, in $s^{-1}mM^{-1}$). Proton relaxivity has contributions from interactions of the Gd^{III} ion with the inner-sphere water protons (inner-sphere relaxivity) as well as with the bulk water protons (outer-sphere relaxivity). The inner-sphere term is determined by the exchange rate of the inner-sphere water protons (usually equal to the water exchange rate, k_{ex}), the rotational correlation time of the complex (τ_R) and the longitudinal and transverse electronic relaxation rates of the Gd^{III} ($1/T_{1e}$ and $1/T_{2e}$). The outer-sphere contribution to the overall proton relaxivity depends on the electron spin relaxation rates and the diffusion coefficient for the diffusion of a water proton away from a Gd^{III} chelate (see Supporting Information).[43]

The water proton longitudinal relaxivity of the Gd^{III}–DTPALac$_2$ chelate was measured in aqueous solution at 25 and 60 °C at proton Larmor frequencies between 0.2 and 20 MHz. The NMRD profiles obtained (Figure 5) are typical of low molecular weight Gd^{III} chelates. They were fitted to the usual Solomon–Bloembergen–Morgan relationship that relates the paramagnetic relaxation rates to the microscopic parameters of the Gd^{III} chelates (see equations in Supporting Information). In the analysis of the NMRD profiles we fixed the number of inner-sphere water molecules to one, and the water exchange rate and its activation enthalpy to values that were previously determined for similar DTPA bis(amide) complexes ($k_{ex}^{298} = 0.40 \times 10^6\ s^{-1}$ and $\Delta H^{\ddagger} = 40.0\ kJ\,mol^{-1}$).[43] The diffusion coefficient and its activation energy were also fixed to common values ($D_{GdH}^{298} = 24 \times 10^{-10}\ m^2\,s^{-1}$; $E_{DGdH} = 20\ kJ\,mol^{-1}$), as these two parameters are not particularly dependent on the nature of low molecular weight complexes.[43,44] Thus, in the analysis of the proton relaxivities we fitted the rotational correlation time, τ_R, its activation energy, E_R, and the parameters describing the electron spin relaxation, i.e. the trace of the square of the transient zero-field-splitting (ZFS) tensor, Δ^2, and the correlation time for the modulation of the ZFS, τ_v.[45] The parameters obtained for the Gd^{III}–DTPALac$_2$ conjugate are presented in Table 1 and compared with those available for other relevant small Gd^{III} complexes. The fits of the NMRD profiles obtained are shown in Figure 5.

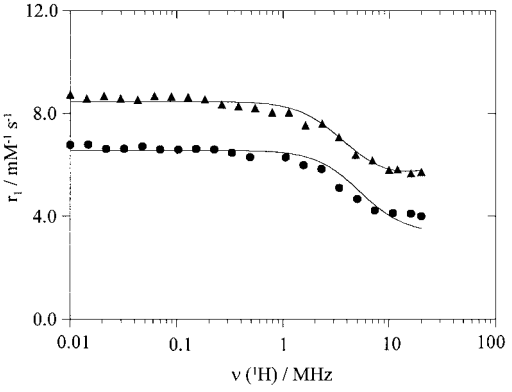

Figure 5. Variable-temperature NMRD profiles for Gd^{III}–DTPALac$_2$; T = 25 °C (triangles); and 60 °C (circles). The lines represent the least-squares fit to the experimental data points as described in the text.

The relaxivity of Gd^{III}–DTPALac$_2$ (mol. wt. = 1569) at 25 °C and 20 MHz is $5.72\ mM^{-1}\,s^{-1}$, which corresponds to an increase of 13% compared to that for the commercial contrast agent Gd^{III}–DTPA-BMA, which is a lower molecular weight DTPA bis(amide) complex (mol. wt. = 574).[44] This relaxivity difference is consistent with the five-fold increase in the rotational correlation time, as it is τ_R that dominates the high-field NMRD values. Another DTPA bis(amide) chelate, Gd^{III}–DTPA-BENGALAA, with an intermediate molecular weight (963), also has an intermediate τ_R value.[41] The temperature dependence of the NMRD profiles clearly shows that the proton relaxivity of these small molecular weight chelates is limited by fast rotation: proton relaxivities increase when the temperature decreases; thus, the rotation slows down. The parameters obtained for the electron spin relaxation of the Gd^{III} complex

are also within the usual range for similar Gd^{III}–DTPA bis(amide) chelates. Although the simplified model of electron spin relaxation used here is not fully adequate to describe Gd^{III} chelates,[46] the application of the novel theories requires EPR data in a large field range, which is beyond the scope of the present study.

Conclusions

We have devised the synthesis of a new class of hydrophilic glycoconjugate DTPA bisamides. Their dendrimeric architecture is especially suited for the variation of the valence of the glycoconjugates from a reduced number of building blocks in an interactive fashion. The ^1H NMR studies of the Sm^{III} and Eu^{III} chelates of these glycoconjugates in aqueous solution, despite being too complex to be fully assigned, unambiguously show that these complexes occur as more than one of the isomers that result from the chirality of the three bound ligand nitrogen atoms. This is to be compared with the presence of the four possible diastereoisomeric pairs of enantiomers for the Ln^{III} complexes of other DTPA bis(amides) with smaller substituents, such as DTPA-BMA and DTPA-BENGALAA,[35,41] while for bis(amides) containing long, micelle-forming, aliphatic chains, only two pairs have been detected in solution,[42] possibly stabilized by intermolecular interactions.

The NMRD studies of the Gd^{III}–$DTPALac_2$ glycoconjugate chelate are compatible with the presence of one inner-sphere water molecule. The value found for its r_1 relaxivity at 25 °C and 20 MHz is 13% higher than that reported for Gd^{III} chelates of lower molecular weight DTPA bis(amides), such as DTPA-BMA, consistent with a larger τ_R value. The τ_R value of these Gd^{III} chelates is expected to increase linearly with molecular weight, as long as the internal mobility of the side chains does not change significantly, thereby leading to a proportional increase of the 20 MHz relaxivity. This result suggests that the relaxivity of the tetravalent Gd^{III}–$DTPAGal_4$ glycoconjugate (mol. wt. = 2088) would be substantially higher. Their potential to target the ASGPR (studies under way), makes these compounds potentially useful for medical imaging agents using gamma scintigraphy, while they also constitute a promising first step towards the design of ASGPR-targeted MRI contrast agents, which will depend on the optimisation of their relaxivity.

Experimental Section

Materials and Equipment: Chemicals were purchased from Sigma–Aldrich and used without further purification. Solvents used were of reagent grade and were purified by usual methods. Reactions were monitored by TLC on Kieselgel 60 F_{254} (Merck) on aluminium support. Detection was by examination under UV light (254 nm), by adsorption of iodine vapour or by charring with 10% sulfuric acid in ethanol. Flash chromatography was performed on Kieselgel 60 (Merck, mesh 230–400). The relevant fractions from flash chromatography were pooled and concentrated under reduced pressure, at a temperature below 40 °C. FAB mass spectra (positive mode) were recorded with a VG Autospec mass spectrometer with 3-nitrobenzyl alcohol (NBA) as matrix. Electrospray ionisation (ESI) mass spectra were obtained for compounds with molecular weights above 2000. ^1H (1D and 2D) and ^{13}C NMR spectra were recorded with a Varian Unity Plus 300 NMR spectrometer operating at 299.938 MHz and 75.428 MHz, for ^1H and ^{13}C, respectively. Chemical shifts (δ) are given in ppm relative to the $CDCl_3$ solvent (^1H: δ = 7.27 ppm; ^{13}C: δ = 77.36 ppm) as internal standard. For ^1H and ^{13}C NMR spectra recorded in D_2O, chemical shifts (δ) are given in ppm relative to TSP as internal reference (^1H: δ = 0.0 ppm) and *tert*-butyl alcohol as external reference (^{13}C: CH_3 δ = 30.29 ppm). ^{13}C NMR spectra were proton broad-band decoupled using a GARP-1 modulated decoupling scheme. Assignments of the ^1H and ^{13}C NMR spectra were aided by recording two-dimensional DQF-COSY and HMQC spectra. The pD of the D_2O solutions was adjusted with DCl or CO_2-free NaOD and converted to pH values using the isotopic correction pH = pD – 0.4. The pD values were measured with a HANNA pH-meter with a HI1310 combined electrode (HANNA instruments, Italy). The $1/T_1$ nuclear magnetic relaxation dispersion (NMRD) profiles of the water protons at 25 and 60 °C were obtained with a Spinmaster FFC fast cycling NMR relaxometer (Stelar), covering a continuum of magnetic fields from 5×10^{-4} to 0.47 T (corresponding to a proton Larmor frequency range of 0.022–20 MHz). The Gd^{III} concentration was verified by ICP measurement (Perkin–Elmer Instruments, Optim 2000 DV).

Synthesis of Fully Protected Hexanediamine-Functionalised Monovalent Thioglycosides 5a and 5b. Typical Procedure for 5a: A solution of peracetylated (galactosylthio)propionic acid (**3a**;[29a] 0.375 g, 0.859 mmol), 1,6-hexanediamine monoBoc (**4**; 0.169 g, 0.781 mmol) and HBT (1-hydroxybenzotriazol; 0.140 g, 0.940 mmol) in dichloromethane (10 mL) was ice-cooled. A solution of DCC (dicyclohexylcarbodiimide; 0.194 g, 9.40 mmol) in dichloromethane (5 mL) was added dropwise to this solution. After 15 min, the reaction mixture was removed from the ice bath and allowed to reach room temperature. The reaction mixture was further stirred at room temperature overnight. The DCU (dicyclohexylurea) precipitate was removed by filtration and washed with dichloromethane. The filtrate was concentrated under reduced pressure to give a viscous syrup. This material was taken up in ethyl acetate (100 mL) and sequentially washed with $KHSO_4$ (aq. 1 M; 3×50 mL), $NaHCO_3$ (satd. sol.; 3×50 mL) and brine (50 mL). The organic phase was concentrated under reduced pressure to give a white foam. Purification by flash chromatography (CH_2Cl_2/MeOH; 100% CH_2Cl_2 → 50% MeOH) afforded the title compound as a white foam (0.480 g, 97% yield). ^1H NMR (300 MHz, $CDCl_3$): δ = 1.34 (m, 4 H, $NHCH_2CH_2CH_2$), 1.43 (s, 9 H, *t*Bu), 1.50 (m, 4 H, $NHCH_2CH_2$), 1.99, 2.05, 2.06 and 2.16 (s, 12 H, $4\times$OAc), 2.50 (m, 2 H, SCH_2CH_2), 2.88–3.06 (m, 2 H, SCH_2), 3.09 [m, 2 H, $CH_2NHC(O)OtBu$], 3.24 [m, 2 H, $C(O)NHCH_2$], 3.48 (br. m, 1 H), 3.95 (ddd, J = 7.2, 5.7 and 0.9 Hz, 1 H, H-5), 4.11 (dd, J = 11.2 and 5.7 Hz, 1 H, H-6a), 4.19 (dd, J = 11.2 and 7.2 Hz, 1 H, H-6b), 4.54 (d, J = 9.9 Hz, 1 H, H-1), 5.04 (dd, J = 10.2 and 3.3 Hz, 1 H, H-3), 5.23 (app t, J = 9.9 Hz, 1 H, H-2), 5.43 (dd, J = 3.3 and 0.9 Hz, 1 H, H-4), 5.98 (br. t, 1 H, N*H*) ppm. HRMS (FAB^+, NBA): calcd. for $C_{28}H_{47}N_2O_{12}S$ $[M + H]^+$ 635.2844; found 635.2856. **5b:** Starting from peracetylated (lactosylthio)propionic acid (**3b**;[29a] 1.70 g, 2.35 mmol) and 1,6-hexanediamine monoBoc (**4**; 0.507 g, 2.35 mmol), the title compound **5b** was obtained as a white foam (2.01 g, 93%). ^1H NMR (300 MHz, $CDCl_3$): δ = 1.33 (m, 4 H, $NHCH_2CH_2CH_2$), 1.42 (s, 9 H, *t*Bu), 1.70 (m, 4 H, $NHCH_2CH_2$), 1.97, 2.04, 2.05, 2.07, 2.13 and 2.16 (s, 21 H, $7\times$OAc), 2.46 (t, J = 6.6 Hz, 2 H, SCH_2CH_2), 2.81 (m, 1 H,

SCH_aH_b), 3.03 (m, 1 H, SCH_aH_b), 3.08 [m, 2 H, CH_2NHC(O)-O*t*Bu], 3.21 (m, 2 H, $NHCH_2$), 3.45 (m, 1 H) 3.59 (m, 1 H, H-5), 3.78 (app t J = 9.6 Hz, 1 H, H-4), 3.89 (app t, J = 7.0 Hz, 1 H, H-5′), 4.03–4.16 (m, 3 H), 4.28 (m, 1 H), 4.52 (d, J = 7.8 Hz, 1 H, H-1′), 4.65 (d, J = 10.5 Hz, 1 H, H-1), 4.90 (app t, J = 9.6 Hz, 1 H, H-2), 4.96 (dd, J = 10.2 and 3.3 Hz, 1 H, H-3′), 5.09 (dd, J = 10.5 and 7.8 Hz, 1 H, H-2′), 5.19 (app t, J = 9.3 Hz, 1 H, H-3), 5.34 (d, J = 2.4 Hz, 1 H, H-4′), 6.30 (br. t, 2 H, *NH*CO) ppm. MS (FAB^+, NBA): *m*/*z* (%) = 923 (3) $[M + H]^+$. HRMS (FAB^+, NBA): calcd. for $C_{40}H_{63}N_2O_{20}S$ $[M + H]^+$ 923.3695; found 923.3683.

Synthesis of Fully Protected Amino-Functionalised Divalent 9: A solution of divalent thiogalactoside **7**[26] (0.968 g, 0.895 mmol) was stirred overnight in CH_2Cl_2/TFA (3:1, 10 mL). The solvent was removed under reduced pressure to give a light yellow foam, which was redissolved in dichloromethane (DCM; 10 mL). The solvent was then removed under reduced pressure. This procedure was repeated several times and the material was further dried under vacuum to give the carboxylic acid deprotected compound **8** as a viscous, light-yellow foam. ^{1}H NMR analysis revealed the disappearance of the signal at δ = 1.4 ppm assigned to the *tert*-butyl group. No further purification or characterisation was carried on this material. All the material obtained (we assumed a 100% yield for the deprotection reaction) was dissolved in ice-cooled DCM (10 mL) and titrated (pH paper) to pH = 9–10 with DIPEA (diisopropylethylamine). To this solution was added a solution of 1,6-hexanediamine monoBoc (**4**; 0.230 g, 1.07 mmol) in dichloromethane (5 mL) and HBT (0.140 g, 0.940 mmol). A solution of DCC (0.230 g, 1.10 mmol) in dichloromethane (5 mL) was then added dropwise. After 15 min, the reaction mixture was removed from the ice bath and allowed to reach room temperature. The reaction mixture was further stirred at room temperature overnight. The DCU precipitate was removed by filtration and washed with dichloromethane. The filtrate was concentrated under reduced pressure to give a viscous syrup. This material was taken up in ethyl acetate (150 mL) and sequentially washed with $NaHCO_3$ (satd. sol.; 3 × 100 mL) and brine (100 mL). The organic phase was concentrated under reduced pressure to give a light-yellow foam. Purification by flash chromatography (CH_2Cl_2/MeOH; 100% CH_2Cl_2 → 50% MeOH) afforded the title compound as a white foam (1.01 g, 92% yield). ^{1}H NMR (300 MHz, $CDCl_3$): δ = 1.32 [m, 4 H, C(O)$NHCH_2CH_2CH_2$], 1.43 (s, 9 H, *t*Bu), 1.51 [m, 4 H, C(O)$NHCH_2CH_2$], 1.72 (m, 4 H, NCH_2CH_2), 1.99, 2.05, 2.06 and 2.16 (s, 24 H, 8 × OAc), 2.52 (m, 8 H, overlapping signals from SCH_2CH_2 and NCH_2), 2.88–3.14 [m, 8 H, overlapping signals from SCH_2, NCH_2C(O) (singlet at 3.02) and CH_2NHC(O)O*t*Bu], 3.29 [m, 6 H, $NCH_2CH_2CH_2$ and $NCH_2C(O)NHCH_2$], 3.40–3.56 (m, 1 H), 3.96 (td, J = 6.4 and 0.9 Hz, 2 H, H-5), 4.09 (dd, J = 11.4 and 6.3 Hz, 2 H, H-6a), 4.20 (dd, J = 11.2 and 6.4 Hz, 2 H, H-6b), 4.56 (d, J = 10.2 Hz, 2 H, H-1), 4.74 (br. t, 1 H, N*H*), 5.05 (dd, J = 10.0 and 3.3 Hz, 2 H, H-3), 5.25 (app t, J = 9.9 Hz, 2 H, H-2), 5.44 (dd, J = 3.3 and 0.9 Hz, 2 H, H-4), 6.74 (br. t, 2 H, N*H*), 7.10 (br. t, 2 H) ppm. MS (FAB^+, NBA): *m*/*z* (%) = 1223 (100) $[M - H]^+$. HRMS (FAB^+, NBA): calcd. for $C_{53}H_{86}N_5O_{23}S_2$ $[M + H]^+$ 1224.5155; found 1224.5119.

Synthesis of DTPA Glycoconjugate Bis(amides9 1 and 2. Typical Procedure Illustrated for DTPAGal$_2$ (1a): A solution of fully protected amino-functionalised monovalent thiogalactoside **5a** (0.618 g, 0.973 mmol) was stirred overnight in CH_2Cl_2/TFA (3:1, 10 mL). The solvent was removed under reduced pressure to give a light-yellow foam, which was redissolved in DCM (10 mL); the solvent was then removed under reduced pressure. This procedure was repeated several times and the material was further dried under vacuum to give a viscous, light-yellow foam of **6a**. ^{1}H NMR analysis revealed the disappearance of the signal at δ = 1.47 ppm assigned to the *tert*-butyl group. No further purification or characterisation was carried out on this material. All the material obtained (we assumed a 100% yield for the deprotection reaction) was dissolved in ice-cooled DCM (5 mL) and titrated (pH paper) to pH = 9–10 with DIPEA. This solution was added to a solution of DTPA bis(anhydride) (0.158 g, 0.442 mmol) in DMF (40 mL) and pyridine (1 mL). The reaction mixture was stirred at room temperature overnight and concentrated under reduced pressure to give a colourless oil. This material was carried through without further purification or characterisation. The residue was redissolved in a mixture of ethanol (10 mL) and KOH (aq. sol. 1 M, 10 mL) and stirred at room temperature overnight. The reaction mixture was adjusted to pH ≈ 1 with Amberlyst 15. The resin was transferred into a column, thoroughly washed with water and eluted with aq. 0.5 M NH_3. The relevant fractions were pooled and concentrated under reduced pressure (temperature < 40 °C) to give the fully deprotected glycoconjugate as an off-white solid (0.342 g, 71% yield over two steps). ^{1}H NMR (300 MHz, D_2O, pH = 7.0): δ = 4.48 (d, J = 9.0 Hz, 2 H, H-1), 3.54 (app t, J = 9.0 Hz, 2 H, H-2), 3.64 (dd, J = 9.0 and 3.3 Hz, 2 H, H-3), 3.70 (m, 2 H, H-4), 3.96 (app d, J = 3.3 Hz, 2 H, H-5), 3.73 (m, 4 H, H-6a + H-6b), 1.32 [m, 8 H, C(O)$NHCH_2CH_2CH_2$], 1.51 [m, 8 H, C(O)$NHCH_2CH_2$], 3.20 [m, 8 H, C(O)$NHCH_2$], 2.60 (m, 4 H, SCH_2CH_2), 2.95–3.01 (m, 4 H, SCH_2), 3.24 [s, 4 H, DTPA amide $NCH_2C(O)$], 3.76 (s, 2 H, DTPA central acetate $NCH_2CO_2^-$), 3.40 (s, 4 H, DTPA terminal acetate $NCH_2CO_2^-$), 3.34, 3.08 (two m, 8 H, DTPA skeleton NCH_2) ppm. ^{13}C NMR (75.6 MHz, D_2O): δ = 86.18 (C-1), 69.67 (C-2), 74.05 (C-3), 79.07 (C-4), 68.94 (C-5), 61.30 (C-6), 25.90, 25.83 [C(O)$NHCH_2CH_2CH_2$], 28.29, 28.42 [C(O)$NHCH_2CH_2$], 39.23, 39.54 [C(O)$NHCH_2$], 26.49 (SCH_2), 36.57 (SCH_2CH_2), 58.86 [DTPA amide $NCH_2C(O)$], 54.58 (DTPA central acetate $NCH_2CO_2^-$), 58.95 (DTPA terminal acetate $NCH_2CO_2^-$), 50.59, 52.79 (DTPA skeleton NCH_2), 170.77, 173.02, 174.28, 178.40 [DTPA acetate $NCH_2CO_2^-$ and amide $NCH_2C(O)$, other $CH_2C(O)NH$] ppm. MS (FAB^+, NBA): *m*/*z* (%) = 1091 (23) $[M + H^+]$. HRMS (FAB^+, NBA) calcd. for $C_{44}H_{80}N_7O_{20}S_2$ $[M + H]^+$: 1090.4899; found 1090.4859.

DTPALac$_2$ (1b): Fully protected monovalent thiolactoside **5b** (0.997 g, 1.08 mmol) was deprotected as described for compound **1a**. Reaction with DTPA bis(anhydride) (0.183 g, 0.512 mmol), followed by deprotection and purification afforded glycoconjugate **1b** as an off-white solid (0.345 g, 48% yield over two steps). ^{1}H NMR (300 MHz, D_2O, pH = 7.0): δ = 4.46 (d, J = 7.8 Hz, 2 H, H-1), 3.54 (dd, J = 10.2 and 7.8 Hz, 2 H, H-2), 3.63 (dd, J = 10.2 and 3.3 Hz, 2 H, H-3), 3.66 (m, 2 H, H-4), 3.94 (app d, J = 3.3 Hz, 2 H, H-5), 3.70 (m, 4 H, H-6a + H-6b), 4.58 (d, J = 10.2 Hz, 2 H, H-1′), 3.36 (app t, 2 H, H-2′), 3.64 (app t, 2 H, H-3′), 3.68 (dd, 2 H, H-4′), 3.99 (m, 2 H, H-5′), 3.72 (m, 4 H, H-6a′ + H-6b′; Gal unit: H-1–H-6b; Gluc unit: H-1′–H-6b′), 1.32 [m, 8 H, C(O)-$NHCH_2CH_2CH_2$], 1.52 [m, 8 H, C(O)$NHCH_2CH_2$], 3.20 [m, 8 H, C(O)$NHCH_2$], 2.61 (m, 4 H, SCH_2CH_2), 2.98–3.01 (m, 4 H, SCH_2), 3.23 [s, 4 H, DTPA amide $NCH_2C(O)$], 3.76 (s, 2 H, DTPA central acetate $NCH_2CO_2^-$), 3.38 (s, 4 H, DTPA terminal acetate $NCH_2CO_2^-$), 3.37, 3.08 (8 H, two m, DTPA skeleton NCH_2) ppm. ^{13}C NMR (75.6 MHz, D_2O): δ = 103.08 (C-1), 71.15 (C-2), 78.42 (C-3), 72.71 (C-4), 60.49 (C-5), 75.55 (C-6), 85.59 (C-1′), 72.11 (C-2′), 78.82 (C-3′), 75.92 (C-4′), 68.76 (C-5′), 61.22 (C-6′) (Gal unit: C-1–C-6; Gluc unit: C-1′–C-6′), 25.86, 25.94 [C(O)$NHCH_2CH_2CH_2$], 28.33, 28.47 [C(O)$NHCH_2CH_2$], 39.26, 39.58 [C(O)$NHCH_2$], 26.45 (SCH_2), 36.61 (SCH_2CH_2), 58.86 [DTPA amide $NCH_2C(O)$], 54.33 (DTPA central acetate $NCH_2CO_2^-$), 59.03, 59.11 (DTPA terminal acetate $NCH_2CO_2^-$), 50.53, 52.88

(DTPA skeleton NCH_2), 170.60, 173.41, 174.24, 178.82 [DTPA acetate $NCH_2CO_2^-$ and amide NCH_2C(O), other CH_2C(O)NH] ppm. HRMS (ESI): calcd. for $C_{56}H_{100}N_7O_{30}S_2$ $[M + H]^+$ 1414.5950; found 1414.5971.

$DTPAGal_4$ (2): Fully protected amino-functionalised divalent thiogalactoside **9** (0.464 g, 0.379 mmol) was deprotected as described for compound **1a**. Reaction with DTPA bis(anhydride) (0.064 g, 0.179 mmol), followed by deprotection and purification afforded glycoconjugate **2** as an off-white solid (0.240 g, 69% yield over two steps). ^{1}H NMR (300 MHz, D_2O, pH = 7.0): δ = 4.46 (d, J = 9.0 Hz, 4 H, H-1), 3.52 (app t, J = 9.0 Hz, 4 H, H-2), 3.64 (dd, J = 9.0 and 3.3 Hz, 4 H, H-3), 3.68 (m, 4 H, H-4), 3.95 (app d, J = 3.3 Hz, 4 H, H-5), 3.71 (m, 8 H, H-6a + H-6b), 1.28 [m, 8 H, C(O)NHCH$_2$CH$_2$*CH$_2$*], 1.49 [m, 8 H, C(O)NHCH$_2$*CH$_2$*], 3.18 [m, 8 H, C(O)NH*CH$_2$*], 3.48 [m, 4 H, N*CH$_2$*C(O)], 2.75 (m, 8 H, N*CH$_2$*), 1.83 (m, 8 H, NCH$_2$*CH$_2$*), 3.20 (m, 8 H, NCH$_2$CH$_2$*CH$_2$*), 2.59 (m, 8 H, SCH$_2$*CH$_2$*), 2.97 (m, 8 H, S*CH$_2$*), 3.20 [s, 4 H, DTPA amide N*CH$_2$*C(O)], 3.71 (s, 2 H, DTPA central acetate N*CH$_2$*CO_2^-), 3.33 (s, 4 H, DTPA terminal acetate N*CH$_2$*CO_2^-), 3.34, 3.18 (two m, 8 H, DTPA skeleton N*CH$_2$*) ppm.^{13}C NMR (75.6 MHz, D_2O): δ = 86.29 (C-1), 69.66 (C-2), 74.09 (C-3), 79.08 (C-4), 68.95 (C-5), 61.41 (C-6), 25.33 [C(O)NHCH$_2$CH$_2$*CH$_2$*], 28.53 [C(O)NHCH$_2$*CH$_2$*], 39.32, 39.18 [C(O)NH*CH$_2$*], 56.57 [N*CH$_2$*C(O)], 52.51 (N*CH$_2$*), 25.38 (NCH$_2$*CH$_2$*), 37.11 (NCH$_2$CH$_2$*CH$_2$*), 26.70 (S*CH$_2$*), 36.52 (SCH$_2$*CH$_2$*), 59.20 [DTPA amide N*CH$_2$*C(O)], 54.50 (DTPA central acetate N*CH$_2$*CO_2^-), 59.11 (DTPA terminal acetate N*CH$_2$*CO_2^-), 50.51, 52.89 (DTPA skeleton N*CH$_2$*), 170.51, 173.40, 174.48, 178.85 [DTPA acetate $NCH_2CO_2^-$ and amide NCH_2C(O) NH, other CH_2C(O)NH] ppm. MS (FAB^+, NBA): *m/z* (%) = 1932 (20) $[M^+]$, 1055 (100). HRMS (FAB^+, NBA): calcd. for $C_{78}H_{142}N_{13}O_{34}S_4$ $[M + H]^+$ 1932.8665; found 1932.8576.

Preparation of Ln^{III} Glycoconjugates for NMR Studies: The Ln^{III} glycoconjugates were prepared by adding a slight excess (1.1 equiv.) of $LnCl_3$ aqueous solution to an aqueous solution of the glycoconjugate. The pH of the solution was slowly adjusted to 5 with KOH (aq.), stirred at 70 °C for 8 h and adjusted to pH = 7 with KOH (aq.). Any precipitate was filtered off. The solution was concentrated and purified by gel filtration with Sephadex G10, eluting with water. The relevant fractions were pooled and freeze-dried to afford the Ln^{III} complexes.

Preparation of Gd^{III}-$DTPALac_2$ for NMRD Measurements: Initially, the $DTPALac_2$ conjugate was left to react with an excess of $Gd(ClO_4)_3$ stock solution and the excess of metal ion was back-titrated with Na_2H_2EDTA solution, allowing the calculation of the exact concentration of glycoconjugate. The Gd^{III} chelate of $DTPALac_2$ was prepared by adding an appropriate quantity of the glycoconjugate to an aqueous solution of gadolinium perchlorate (3–5% glycoconjugate excess). The solution pH was slowly adjusted to 7 with KOH (aq.). The Gd^{III} glycoconjugate solution was freeze-dried and diluted with 25 mM phosphate buffer (pH = 7.4). The absence of free Gd^{III} in the solution was verified by addition of xylenol orange indicator.[30] The Gd^{III} concentration (4.63 mM) was verified by ICP measurement.

Supporting Information (see also the footnote on the first page of this article): Table containing the proton relaxivities of Gd^{III}–$DTPALac_2$, and equations for the determination of the relaxivity parameters.

Acknowledgments

This work was performed within the framework of the EU COST Action D18 "Lanthanide chemistry for diagnosis and therapy". The work was supported by the Foundation of Science and Technology (F.C.T.), Portugal (project POCTI/QUI/47005/2002) and FEDER. É. T. and A. E. M. acknowledge the Swiss National Science Foundation and the Swiss Federal Office for Education and Science for financial support. The authors are grateful to László Burai for his help with the NMRD measurements.

On the Redox Chemistry of Ge^{I} Bromide

Andreas Schnepf*[a]

Keywords: Cage compounds / DFT calculations / Germanium / Redox reactions

First results on the redox chemistry of Ge^{I} bromide are reported herein. During the attempt to solubilize $Ge^{I}Br$, which is synthesized in preparative scale using a co-condensation technique of the high-temperature molecule $Ge^{I}Br$, a redox reaction with the solvent acetone occurs. During this unexpected redox reaction Ge^{I} is oxidized to Ge^{IV} and acetone is reductively coupled to 1,1-dimethyl-3-oxobutan-1-yl.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

$Ge^{I}Br$ is a good starting material for the synthesis of germanium cluster compounds with "naked" germanium atoms,[1] which represent a new class of cluster compounds in germanium chemistry.[2] $Ge^{I}Br$ can be synthesized by a preparative co-condensation technique, in which the high-temperature molecule $Ge^{I}Br$, synthesized at 1600 °C, is condensed together with a solvent at –196 °C.[3] When toluene is used as the solvent during the co-condensation reaction, $Ge^{I}Br$ is isolated as an orange solid. Sadly, this solid $Ge^{I}Br$ is insoluble in inert solvents such as THF, Et_2O, or $C_2H_4Cl_2$ and therefore it cannot be used for the synthesis of molecular cluster compounds of germanium, which is our main goal. To get $Ge^{I}Br$ in a soluble form we performed in the following co-condensation reactions where we used a mixture of toluene and a donor molecule as the solvent. During these experiments, it turned out that donor molecules such as THF, Et_2O, NEt_3, or CH_3CN, which worked quite well in the case of subvalent group 13 halides such as $Ga^{I}Br$ or $Al^{I}Br$,[4] are not capable to solubilize $Ge^{I}Br$, and thus we always obtained the solid $Ge^{I}Br$. However, the use of amines with long alkyl chains such as N*n*Pr_3 or N*n*Bu_3 led to a different result.

When a mixture of toluene/N*n*Pr_3 is used as the solvent during the co-condensation reaction, an emulsion of a dark-red oil in a pale yellow solution is obtained after heating the co-condensate to –78 °C. This means, if either N*n*Pr_3 or N*n*Bu_3 are used as the donor component during the co-condensation reaction, $Ge^{I}Br$ is obtained in the form of a dark-red oil which can be used for subsequent reactions. Using this emulsion as the starting material, we synthesized the cluster compounds $Ge_8[N(SiMe_3)_2]_6$[5] and $\{Ge_9[Si(SiMe_3)_3]_3\}^-$[6] by the reaction with $Li[N(SiMe_3)_2]$ and $Li[Si(SiMe_3)_3]$, respectively.

These reactions are carried out inside the co-condensation apparatus, because isolation of the emulsion leads to a great loss in yield of $Ge^{I}Br$, as the dark-red oil remains almost quantitatively inside the apparatus. Since the performance of these reactions inside the co-condensation apparatus are very complex − e.g. it is difficult to observe and to monitor the reaction process − it is desirable to obtain $Ge^{I}Br$ solutions, which might then be isolated and used outside the apparatus for subsequent reactions. Thus, we expect to obtain better control of the reaction conditions (temperature, stoichiometry etc.) and we will be able to observe the color gradient during the reaction, which, for technical reasons, is not possible inside the co-condensation apparatus. Therefore, we had to find a solvent or a mixture of solvents for the co-condensation reaction which would lead to $Ge^{I}Br$ solutions. Herein we report on the attempt to obtain such $Ge^{I}Br$ solutions.

Results and Discussion

$Ge^{I}Br$ appears to be soluble in acetone, since while cleaning the co-condensation apparatus with acetone, we observed that the remaining $Ge^{I}Br$ gave initially a dark-red solution. Consequently, we conducted a co-condensation experiment of $Ge^{I}Br$ with dry acetone as the solvent. After allowing the temperature of the co-condensate to increase from –196 to –78 °C, a dark-red solution was obtained and no residue remained inside the apparatus. This means that $Ge^{I}Br$ was quantitatively dissolved. Unfortunately, it turned out that $Ge^{I}Br$ is not stable in acetone, as the dark red color of the solution vanishes on warming to room temperature leading to a pale yellow solution. On concentrating this solution, we were able to isolate a product of the reaction in the form of colorless crystals. X-ray crystal structure analysis of these crystals reveals that the compound

$Br_3GeC_6H_{11}O$ (**1**), whose molecular structure is shown in Figure 1, was formed in 30% yield.

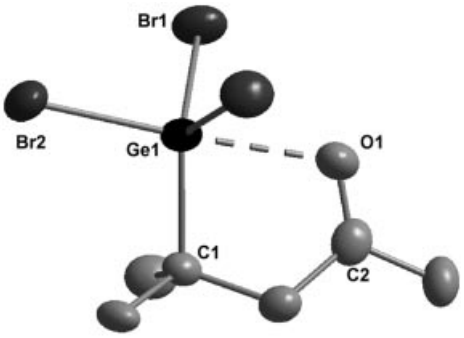

Figure 1. Molecular structure of $C_6H_{11}Br_3GeO$ (**1**) (hydrogen atoms are ommited). Selected bond lengths [pm] and angles (°): Ge1–Br1: 230.6(1), Ge1–Br2: 238.9(1); Ge1–C1: 198.3(8), Ge1–O1: 242.4(1); C2–O1: 120.8(1); Br1–Ge1–C1: 120.4(3); Br2–Ge1–C1: 104.2(1).

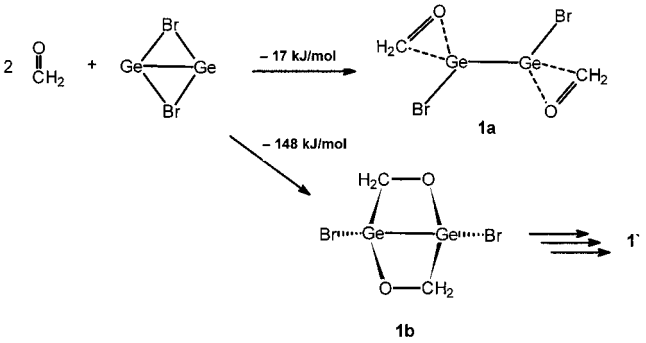
Clearly compound **1** contains germanium in the oxidation state +4. The central germanium atom is surrounded tetrahedrally by three bromine atoms and a carbon atom of the organic ligand 1,1-dimethyl-3-oxobutan-1-yl.

The organic ligand in **1** is oriented in such a way that an additional Ge–O contact is formed (dashed bond in Figure 1). Because of this Ge–O contact, the Ge–Br bond length to the oppositely-bound bromine atom is elongated by 9 pm (239 pm) with respect to the other Ge–Br bond lengths (230 pm), which are as long as those found in other $RGeBr_3$ compounds.[7] Therefore, a 4+1 coordination of the Ge atom is found, which leads to a strong distortion of the tetrahedral surrounding of the Ge atom towards a trigonal-bipyramidal surrounding.

The organic ligand in **1** originates from the solvent acetone, as acetone was the only organic compound present during the reaction. The ligand is built up from two molecules of acetone, in which the carbonyl function of one molecule is completely reduced.

This means that $Ge^{I}Br$ reacts with acetone in a redox reaction in which Ge^{I} is oxidized to Ge^{IV} and acetone is reductively coupled to 1,1-dimethyl-3-oxobutan-1-yl in which the former carbonyl carbon atom (formal oxidation state +2) is bonded directly to the germanium atom (formal oxidation state –1). Such a redox reaction is not known for Ge^{II} halides, which indicates that the redox potential of Ge^{II} halides is too small to reduce acetone which has a reduction potential of –2.84 V.[8] As the redox reaction works with Ge^{I} bromide, the minimum redox potential for the oxidation of Ge^{I} bromide in this reaction is –2.84 V and is therefore in the range of the alkali metals (Na = –2.71 V; K = –2.93 V[8]), showing that Ge^{I} bromide is a strong reducing agent.

To get a first insight into the reaction mechanism of this redox reaction, we performed DFT calculations[9] for the initial step of the reaction on the model system GeBr and H_2CO, taking into account the reaction sequence outlined in Scheme 1.[10]



Scheme 1. Possible first step for the model redox reaction of GeBr and H_2CO.

The calculations show that the formation of three-membered Ge–C–O rings (**1a**) is energetically favored by only 17 kJ mol^{-1}, which can therefore be regarded as a weak complex in which H_2CO is only coordinated to the germanium center leading to a small elongation of the C–O bond length to 128 pm, with respect to uncoordinated H_2CO where the C–O bond length is 121 pm. The formation of four-membered C–O–Ge–Ge rings (**1b**) is energetically favored by 148 kJ mol^{-1}, which can therefore be regarded as a possible first product in the redox reaction, where the C–O bond length is now considerably elongated to 139 pm.

The formation of a similar four-membered M_2CO ring is also known for the adsorption of acetone on a (2×1)-reconstructed Si(001) surface, where the surface-lattice structure undergoes a reconstruction in which adjacent silicon dimers pair together and form dimers through a σ bond and a π bond.[11] In this system the carbonyl function reacts with silicon dimers in a similar way to a [2+2] cycloaddition reaction.[12] Such a [2+2] cycloaddition is also possible for the redox reaction discussed here, as the bond between the germanium atoms in BrGeGeBr can formally be seen as a "triple" bond (Br–Ge≡Ge–Br). Therefore, it seems plausible that the first step of the discussed redox reaction is a [2+2] cycloaddition of the carbonyl function to $(GeBr)_2$, which is also suggested by the results of the quantum chemical calculations.

The oxygen atom that originates from this redox reaction is found in a second compound, which can also be isolated in the form of colorless crystals on further concentration of the reaction solution. Crystal structure analysis of these crystals shows that **2** is a cationic germanium oxocluster compound $[Ge_6O_8R_6{\cdot}2H_2O]^{2+}$ (R = $C_6H_{11}O$) which crystallizes together with two $GeBr_3^-$ anions. The molecular structure of **2** is shown in Figure 2.

The Ge–O backbone of **2** consists of a central Ge_4O_4 eight-membered ring in chair conformation. Two planar Ge_3O_3 six-membered rings are condensed on opposite sides of the eight-membered ring. Structurally, **2** can be compared with $Ge_6O_8R_6Cl_2$ (R = *t*Bu) (**3**) which was synthesized by Puff et al. by careful hydrolysis of *t*BuGeCl_3.[13] The major difference between **2** and **3** is the fact that **2** is a cationic species while **3** is neutral. As **2** is a cationic compound, two different Ge sites are found inside the cluster

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

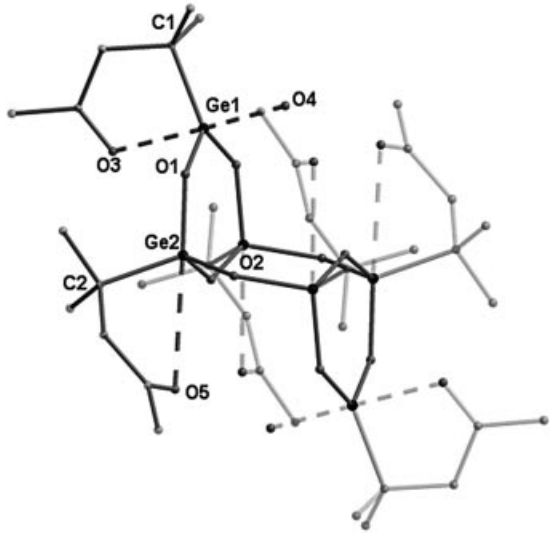


Figure 2. Molecular structure of $[Ge_6O_8(C_6H_{11}O)_6{\cdot}2H_2O]^{2+}$ (**2**) (hydrogen atoms are ommited for clarity and two five-membered GeC_3O rings are highlighted). Selected bond lengths [pm] and angles (°): Ge1–O1: 174.3(3); Ge1–O3: 222.5(3); Ge1–O4: 199.8(3); Ge1–C1: 196.3(4); Ge2–O1: 178.3(3); Ge2–O2: 175.8(3); Ge2–O5: 282.4(4); Ge2–C2: 197.3(4); O1–Ge1–C1: 119.91(18); O3–Ge1–O4: 178.17(13); O1–Ge2–O2: 104.80(13); Ge1–O1–Ge2: 126.51(16).

core. Four germanium atoms are tetrahedrally coordinated by three oxygen atoms (Ge–O: 177 pm) and the carbon atom of the organic ligand (Ge–C: 197 pm). Two germanium atoms have a trigonal-planar geometry and are surrounded (sum of angles: 358.5°) by two oxygen atoms (Ge–O: 174 pm) and a carbon atom of the organic ligand (Ge–C: 196 pm). Additionally, two further germanium oxygen contacts are found: one to the oxygen atom of the keto group of the organic ligand (Ge–O: 222 pm) and one to the oxygen atom of a water molecule (Ge–O: 200 pm). Therefore, the coordination number is 3+2. The reason why **2** is isolated as a cationic species might be the fact that the carbonyl function of the organic ligand is able to stabilize the cationic center, forming a five-membered GeC_3O ring. On the other hand, the presence of the Br^- acceptor $GeBr_2$ is necessary. The formation of a five-membered ring is also found in the case of the tetrahedrally coordinated germanium atoms, although in this case the germanium–oxygen contact between the germanium atom and the oxygen atom of the carbonyl function is much longer (282 pm), but is still significantly shorter than the sum of the van der Waals radii (ca. 310 pm).

Conclusions

The results presented here show that it is possible to get Ge^IBr solutions. Ge^IBr is hereby, as expected, more reactive than the corresponding $Ge^{II}Br_2$ for which no comparable redox reactions are known. In the case of acetone, this reactivity is too high to apply acetone as a solvent. However, this redox capability might be of great interest for redox reactions and C–C coupling reactions in organic chemistry.

In the case of our planned chemistry where we would like to use the disproportionation reaction of Ge^IBr to get to cluster compounds, such a redox reaction has to be ruled out. Therefore, we had to search for other solvents which would be able to solubilize Ge^IBr and which would be stable enough towards reduction to act only as a solvent. Another suitable method might be the introduction of donor molecules to lower the reactivity of the Ge^I halide. These investigations are the subject of current experiments.

Experimental Section

Liquid germanium was treated with HBr under high vacuum at 1550 °C, and the resulting gaseous products (ca. 15 mmol GeBr) were condensed together with acetone (150 mL) at a surface at –196 °C. After the co-condensate was allowed to warm to –78 °C a dark-red solution was obtained. The solution was heated to room temperature. During the heating process the color of the solution changed from dark red to pale yellow. The solution was concentrated and stored at –28 °C, whereby colorless crystals of $Br_3GeC_6H_{11}O$ (**1**) formed (600 mg, 30%). Unfortunately, for technical reasons (hydrolyses or oxidation of the microcrystalline samples) it proved impossible to obtain a satisfactory elemental analysis.

The solution was filtered and further concentrated to yield colorless crystals containing $[Ge_6O_6(C_6H_{11}O)_6{\cdot}2H_2O]^{2+}$ (**2**) (20 mg, 0.6%).

Compound 1: ^{1}H NMR (250 MHz, C_6D_6): δ = 1.03 (s, 6 H, CH_3), 1.42 (s, 3 H, CH_3), 2.90 (s, 2 H, CH_2) ppm. ^{13}C NMR (63 MHz, C_6D_6): δ = 23.9 (CH_3), 30.3 (CH_3), 46.2 (C), 51.7 (CH_2), 205.8 (C=O) ppm.

Crystal Structure Data of $Br_3GeC_6H_{11}O$: M_r = 411.47 g mol^{-1}, monoclinic, $P2(1)$, a = 7.2981(15), b = 12.119(2), c = 20.085(4) Å, β = 97.40(3), V = 1761.6(6) Å^3, Z = 6, $\rho_{calcd.}$ = 2.327 g cm^{-3}, μ_{Mo} = 12.768 mm^{-1}, $2\theta_{max}$ = 52.10°, 13708 measured reflections, 6338 independent reflections [R(int.) = 0.0550], numerical absorption correction (min./max. transmission 0.0402/0.1019), R_1 = 0.0360, wR_2 = 0.0856. Phys.* **1992**, *97*, 2571.
[10] As no structural information was available about $Ge^{I}Br$ in solution, we had to assume an initial structure for the calculations. Here we assumed, that the monomeric $Ge^{I}Br$ radical which was trapped in the matrix of solvent molecules during the co-condensation dimerizes first to give Ge_2Br_2. This process is energetically favored by 238 kJ mol^{-1} according to quantum chemical calculations (ref.[9]). This dimer (Ge_2Br_2) is then used as starting point for the calculations.

In Situ XAS and XRD Studies on the Structural Evolution of Ammonium Paratungstate During Thermal Decomposition

Olga Kirilenko,[a] Frank Girgsdies,[a] Rolf E. Jentoft,[a] and Thorsten Ressler*[a]

Keywords: In situ studies / X-ray absorption spectroscopy / X-ray diffraction / Tungsten / Oxidation / Decomposition / Structure–activity relationships / Heterogeneous catalysis

The bulk structural evolution during the decomposition of ammonium paratungstate (APT) under various oxidizing and reducing gases was elucidated by the complementary techniques, in situ XAS, in situ XRD, and TG/DSC, combined with mass spectrometry. In the temperature range from 300 to 650 K, the decomposition of APT proceeds nearly independently of the gas employed. At higher temperatures, an oxidizing gas results in the formation of crystalline triclinic WO_3 as the majority phase at 773 K, while mildly reducing gases (propene, propene and oxygen, and helium) result in the formation of partially reduced and highly disordered tungsten bronzes. No further reduction is observed under propene or helium, and this indicates a strongly hindered oxygen mobility in the tungsten oxide lattice in the temperature range employed. The decomposition of APT under hydrogen results in the formation of WO_2 and, eventually, tungsten metal. During the thermal treatment of APT, major changes occur at ca. 500 K where a complete structural rearrangement takes place that results in the destruction of the polyoxotungstate ion of APT and the formation of a tungsten oxide bronze. The rather low temperature for the formation of a three-dimensional lattice compared to the thermal treatment of common polyoxomolybdate precursors indicates the lower stability of the precursor and intermediates as ligands are removed. For tungsten to act as a potential structural or electronic promoter in molybdenum oxide based catalysts, tungsten needs to be incorporated in regular molybdenum oxide structures already at a very early stage of the catalyst preparation.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2005)

Introduction

Molybdenum oxide based catalysts are extensively employed for the partial oxidation of light alkanes and alkenes.[1] Binary molybdenum oxides have a limited catalytic applicability, mostly because of their tendency to readily transform into the less active molybdenum trioxide, MoO_3, under the reaction conditions. Thus, it would be desirable to stabilize the active nanostructure of the molybdenum oxides (e.g. Mo_5O_{14}-type structures[2]) with the substitution of some of the molybdenum by additional metal centers such as vanadium, niobium, or tungsten.

Mixed oxide catalysts are commonly prepared by chemically or physically mixing suitable catalyst precursors. In order to prepare and stabilize the appropriate molybdenum oxide phase, the behavior of the catalyst precursors during thermal treatment needs to be elucidated. Previously, we reported on the structural evolution of ammonium heptamolybdate (AHM)[3] and heteropolyoxomolybdates (HPOM)[4] during thermal activation.

Ammonium paratungstate [$(NH_4)_{10}H_2W_{12}O_{42}{\cdot}4H_2O$, APT] is a common precursor for the preparation of Mo/W mixed oxides. Because they are less complex than the industrially employed catalysts, these oxides constitute suitable model systems to reveal structure–activity relationships of mixed oxides under the reaction conditions. Therefore, investigations of the decomposition of APT are required to identify and quantify tungsten oxide phases and their formation under various gases, and to reveal correlations between catalytic activity and the structural evolution of APT.

The thermal decomposition of APT has been investigated by numerous authors who employed a variety of methods.[5–18] Thermal analysis studies[14] combined with in situ Fourier transform infrared (FT-IR) spectroscopy[13] identified WO_3 as the product of decomposition at temperatures above ca. 650 K. The mechanism for thermal decomposition of APT in air has been studied by X-ray diffraction, thermogravimetry, and IR and UV/Vis diffuse reflectance spectroscopy.[15] Ammonium tungsten bronze, $(NH_4)_{0.33}WO_3$, and hexagonal WO_3 were identified in the calcination reaction of APT at 673 K for 2 h under static air. On heating up to 770 K, the tungsten bronze together with hexagonal WO_3 transformed completely into triclinic tungsten trioxide.

In more detail, the decomposition of APT in air has been studied by in situ laser Raman spectroscopy (LRS) combined with thermal gravimetric analysis (TGA), differential

 DOI: 10.1002/ejic.200400872

thermal analysis (DTA), and X-ray diffraction (XRD).[16] It was found that the decomposition in air proceeds through three steps in the temperature ranges 300–473 K, 473–623 K and 623–773 K. The formation of WO_3 was detected at temperatures above 623 K. Besides studies in air, the thermal decomposition of APT was also investigated under hydrogen.[17,18] In the temperature range 470–520 K, APT was found to decompose into $(NH_4)_{0.33}WO_3$. This compound is stable in the temperature range 520–840 K, and is reduced to a mixture of WO_2 and tungsten metal at 870 K, while complete reduction to tungsten metal is achieved at about 1000 K. In total, although the decomposition of APT has been investigated before, several questions remain unanswered with regard to the sequence of formation of the intermediates, their characterization, and the dependence of the decomposition pathways on the reaction gases for catalytically relevant gas phases (e.g. propene, and propene and oxygen).

The catalytic properties of tungsten trioxide has been investigated in a variety of reactions.[19–25] The selective oxidation of propene to acrolein has been studied with two series of mixed molybdenum/tungsten oxide catalysts.[24,25] The first series of oxides exhibits the typical WO_3-type structure, which consists of corner-sharing WO_6 units and the general formula $Mo_xW_{1-x}O_3$ (x = 0.4–0.9). The second series, with the general formula $(Mo_xW_{1-x})_nO_{3n-1}$ (x = 0.4–0.9; n = 8–14), comprises crystallographic shear structures. Members of the latter series showed a higher conversion and selectivity than the corresponding members of the first series. Selectivity was found to decrease as the tungsten content increased and as the density of crystallographic shear planes decreased. In situ oxidation of the reduced molybdenum oxide series of catalysts $(Mo_xW_{1-x})_nO_{3n-1}$ resulted in little change in selectivity but a significant decrease in conversion.

In this work, the decomposition of APT was studied with in situ X-ray diffraction (XRD) and in situ X-ray absorption spectroscopy (XAS) to reveal the influence of different treatment parameters on the decomposition process, and to provide a detailed analysis of the short- and long-range structure evolution during the treatments. The decomposition of APT was studied under various oxidative and reductive gases (oxygen, propene and oxygen, helium, propene, and hydrogen), and the structural changes detected are discussed and compared with the mechanism for the decomposition of common polyoxomolybdates.

Results

Characterization of Ammonium Paratungstate

The experimental X-ray diffraction pattern of APT is depicted in Figure 1 together with a simulated pattern and a schematic structural representation. The simulated pattern of APT was obtained by using the corresponding single-crystal structural data of APT [$(NH_4)_{10}H_2W_{12}O_{42}\cdot4H_2O$, ICSD 15237, $P2_1/n$, a = 15.08 Å, b = 14.45 Å, c = 11.00 Å, β = 109.4°]. The refined lattice constants are a = 15.04 Å, b = 14.46 Å, c = 10.95 Å, and β = 109.1°, which are in good agreement with the single-crystal data. The crystallite size calculated from XRD peak-broadening was about 600 nm. No further crystalline phases were detectable in the experimental pattern of APT. Figure 2 shows the experimental and theoretical WL_{III}-edge EXAFS FT[$\chi(k)\cdot k^3$] of APT. The corresponding distances and Debye–Waller factors obtained from the XAFS refinement are given in Table 1. The model of the local structure around the W centers in the polyoxotungstate ion of APT is adequate to simulate the WL_{III} EXAFS spectrum. The good agreement between the theoretical structural data (XRD, XAS, TG) and the experimental data confirms that the ammonium paratungstate tetrahydrate used does indeed correspond to $(NH_4)_{10}H_2W_{12}O_{42}\cdot4H_2O$ (ICSD 15237) and excludes the presence of major impurity phases, either crystalline or amorphous.

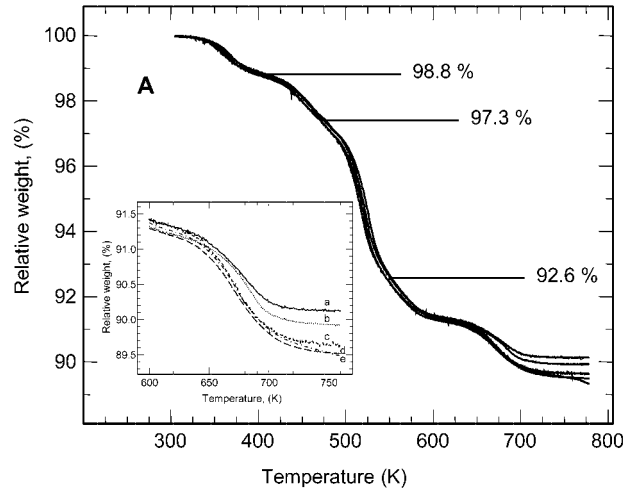
Thermal Decomposition of Ammonium Paratungstate (TG/DSC)

The evolution of the mass loss during thermogravimetric measurements of APT under various gases (helium, 5% hydrogen in helium, 20% oxygen in helium, 10% propene in helium, and 10% propene, and 10% oxygen in helium) is shown in Figure 3. The measurements were conducted at a heating rate of 6 K min^{-1} and a total gas flow of 100 mL min^{-1}. Additionally, the evolution of the MS signals for water (m/z = 18) and ammonia (m/z = 15) measured during the decomposition of APT under 20% oxygen are depicted in Figure 3. The gas-phase product composition is nearly identical for decomposition under oxygen, helium and hydrogen, even during the last step of the decomposition. In addition to the signals for water and ammonia, signals at m/z = 30 and m/z = 44 were also detected. These signals could be assigned to NO and N_2O; however, the intensity of these signals follows the intensity of the signal for ammonia throughout the decomposition, and they may be artifacts formed by the mass spectrometer. Additionally, mass signals m/z = 30 and m/z = 44 were also detected during thermal decomposition of ammonium iodide (NH_4I) in an inert gas, and this corroborates the assumption that these masses cannot be assigned unambiguously to the evolution of NO or NO_2 at particular reaction temperatures during the decomposition of APT.

In the temperature range 300–650 K, the evolution of the mass loss from APT during thermal decomposition is nearly independent of the gas employed. Four decomposition steps at 360, 470, 520, and 680 K can be distinguished in the TG and MS traces measured. The decomposition steps at 470, 520, and 680 K are accompanied by the evolution of water and ammonia, whereas for the decomposition steps at 360 K, only water is detectable in the gas phase. The weight loss after the first decomposition step at 360 K is 1.2% and corresponds to a loss of 2 equiv. of water of crystallization (1.1%). Apparently, the treatment under helium performed prior to the TG/DSC measurements to remove adsorbed water already reduced the number of equiv. of water of crystallization from the initial 4 to 2. The major mass loss of 8.8% at about 520 K is accompanied by the largest signals in the water and ammonia MS traces. The total weight loss after the forth decomposition step at 680 K depends on the gas used and is 9.9% under oxygen, 10.1% under propene and oxygen, 10.4% under helium, 10.5% under propene, and 10.8% under hydrogen. Because the decomposition under oxygen resulted in WO_3, the other weight losses indicate the formation of partially reduced tungsten oxide species under reducing gases. Assuming that the initial material is identical, or alternatively, that the intermediates at 400 K are identical in composition, then the extent of reduction of the tungsten oxide at the end of the decomposition can be calculated. For the hydrogen-containing gas, this partial reduction results in an oxide formula of about $WO_{2.85}$. The difference between a theoretical mass change when decomposing APT to WO_3 of 11.2% and the loss of 9.9% measured here during the decomposition under oxygen is accounted for by the above-mentioned loss of 2 equiv. of water of crystallization before the start of the TG experiments.



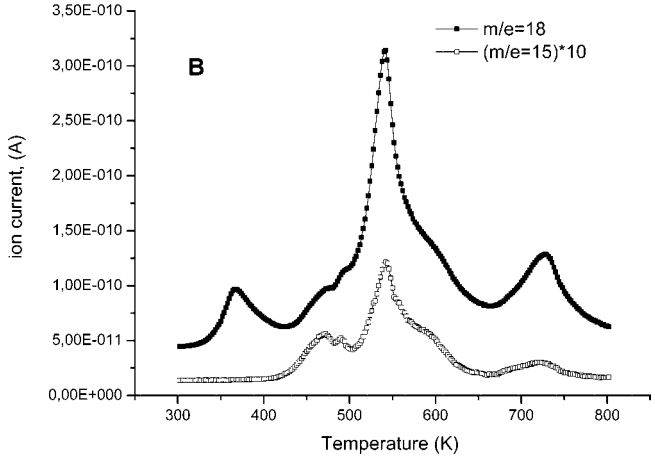


Figure 3. Evolution of relative weight during decomposition of ammonium paratungstate under (a) 20% oxygen in helium, (b) 10% propene and 10% oxygen in helium, (c) helium, (d) 10% propene in helium, and (e) 5% hydrogen in helium (flow rate 100 mL min^{-1}, heating rate 6 K min^{-1}), together with the MS signals for H_2O (m/z = 18) and NH_3 (m/z = 15) measured for the decomposition of APT in 20% oxygen in helium.

The differential scanning calorimetry traces measured during the decomposition of APT under various gases are depicted in Figure 4. Independent of the gas-phase composition, each of the first three mass losses shows one or more endothermic signals; the strongest endothermic signal accompanies the third decomposition step at about 520 K. The DSC measurements indicate an endothermic decomposition step at 700 K under reducing gases. However, a strong exothermic signal is observed at 700 K during the decomposition of APT under oxygen. Because the gas-phase products are nearly identical for both the oxygen and helium decomposition, the exothermic signal must be due either to a phase change, or to a reaction such as the re-oxidation of a somewhat reduced tungsten oxide, which would give no gas-phase products.

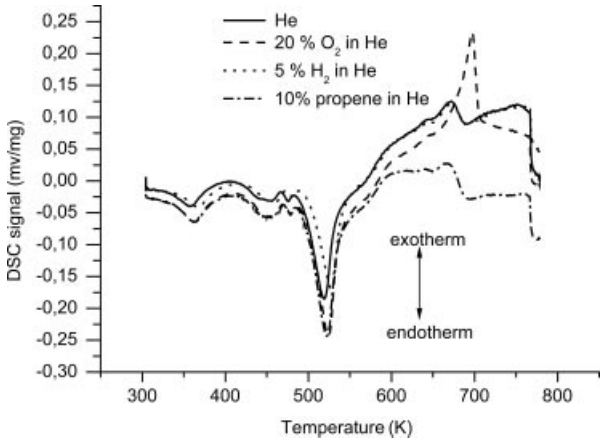

Figure 4. Comparison of the DSC signal measured during decomposition of ammonium paratungstate under helium (solid), 20% oxygen in helium (dashed), 5% hydrogen in helium (dotted), and 10% propene in helium (dash-dotted) (for the corresponding weight loss evolution see Figure 3).

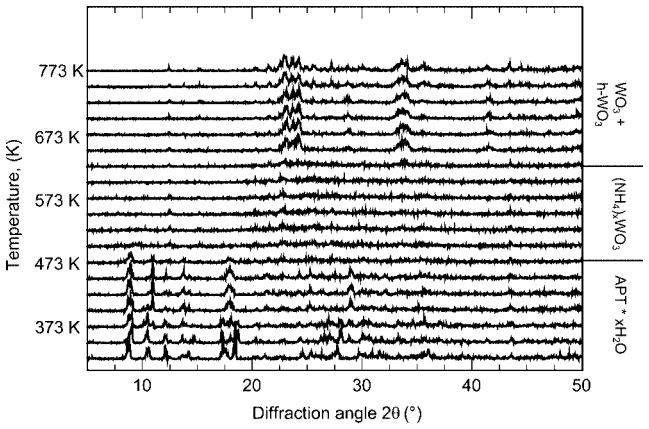

Figure 5. Evolution of X-ray diffraction patterns measured during decomposition of ammonium paratungstate under 20% oxygen in helium in the temperature range 300–770 K (effective heating rate 0.1 K min^{-1}, flow rate 80 mL min^{-1}). Three major stages of the decomposition are indicated.

The WL_{III}-edge XAFS FT[$\chi(k)\cdot k^3$] of APT measured during decomposition under 20% oxygen in helium in the temperature range 300–770 K are shown in Figure 6. Three temperature regions in the evolution of the local structure around the W centers can be distinguished. At 500 K, the initial APT spectrum exhibits changes, particularly, in the region between 2 and 4 Å (not phase-shift-corrected). The decreasing amplitude in this region indicates a significant loss of structural order. Conversely, the increasing amplitude of the first shell at ca. 1.5 Å indicates a decreasing degree of distortion in the first W–O coordination. At ca. 650 K, a decrease in the amplitude of the first shell and distinct changes in the region between 2 and 4 Å can be observed in the experimental FT[$\chi(k)\cdot k^3$], which corresponds to the last step in the decomposition of APT.

Thermal Decomposition of Ammonium Paratungstate (in Situ XRD and XAS)

Decomposition of APT under 20% Oxygen

The evolution of X-ray diffraction patterns measured during decomposition of APT under 20% oxygen in helium in the temperature range 300–770 K is depicted in Figure 5. Three major stages of the decomposition are indicated. The first series of patterns up to ca. 450 K corresponds to APT – a decreasing amount of water of crystallization accounts for the changes in peak intensities and phase composition observed. In the region from 450 K to about 620 K, a pronounced loss of crystallinity is visible from the XRD patterns. The few reflections detectable could not be assigned to any particular tungsten phase on the basis of the ICDD-PDF database. The last step in the structural evolution during decomposition of APT under oxygen at 620 K is accompanied by the occurrence of distinct XRD reflections, which can be assigned to triclinic WO_3 as the majority phase.

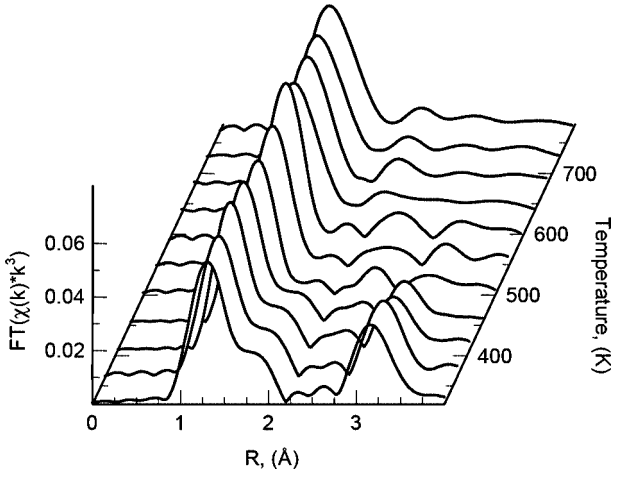

Figure 6. Evolution of WL_{III}-edge XAFS FT[$\chi(k)\cdot k^3$] of ammonium paratungstate during decomposition under 20% oxygen in helium (heating rate 5 K min^{-1}, flow rate 40 mL min^{-1}). Three principle regions can be distinguished: (300–500 K) APT, (500–650 K) $(NH_4)_xWO_3$, (650–770 K) triclinic WO_3.

Decomposition of APT under Reducing Gases

The evolution of X-ray diffraction patterns measured during the decomposition of APT under 5% hydrogen in helium in the temperature range 300–770 K is depicted in Figure 7. Similar to the decomposition of APT under 20% oxygen, the first series of patterns up to about 450 K corresponds to APT with a decreasing amount of water of crystallization. In the region from 450 K to about 620 K, a complete loss of crystallinity is visible resulting in an X-ray-amorphous phase. At 620 K, the formation of highly disordered hexagonal and triclinic WO_3 and tungsten oxide bronzes $(NH_4)_xWO_3$ is observed. The WO_3 formed exhibits a much lower crystallinity than that obtained during decomposition of APT under oxygen. Eventually, at 770 K under 5% hydrogen, the onset of the reduction of tungsten oxides to tungsten metal is detected in the XRD patterns. The evolution of the WL_{III}-edge FT[$\chi(k)\cdot k^3$] measured during decomposition of APT under the reducing gases studied (i.e. propene, hydrogen, helium, propene and oxygen) is very similar to that of the decomposition under oxygen.

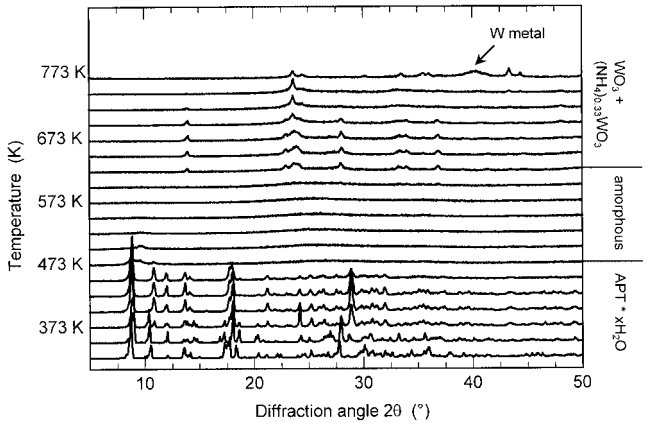

Figure 7. Evolution of X-ray diffraction patterns measured during decomposition of ammonium paratungstate under 5% hydrogen in helium in the temperature range 300–770 K (effective heating rate 0.1 K min^{-1}, flow rate 80 mL min^{-1}). Three major stages of the decomposition are indicated.

Decomposition of APT in Air (Static Conditions)

The evolution of X-ray diffraction patterns measured during the decomposition of APT in static air in the temperature range 300–770 K is shown in Figure 8. Similar to the decomposition of APT under oxygen, three major stages can be distinguished. The first series of patterns up to about 470 K corresponds to APT with a decreasing amount of crystal water. In the region from 470 K to about 550 K, the formation of an X-ray-amorphous phase is detected. Eventually, at 570 K, the formation of well-ordered and phase-pure triclinic WO_3 is observed. The temperature range over which no crystalline phase is detected is smaller in static air than under flowing oxygen and hydrogen, and an increased stability of APT in the temperature region below 470 K and an accelerated formation of crystalline WO_3 at 570 K already are observed. The onset temperature for the decomposition of APT to the amorphous phase is increased by about 25 K, while the formation temperature of WO_3 is lowered by about 25 K.

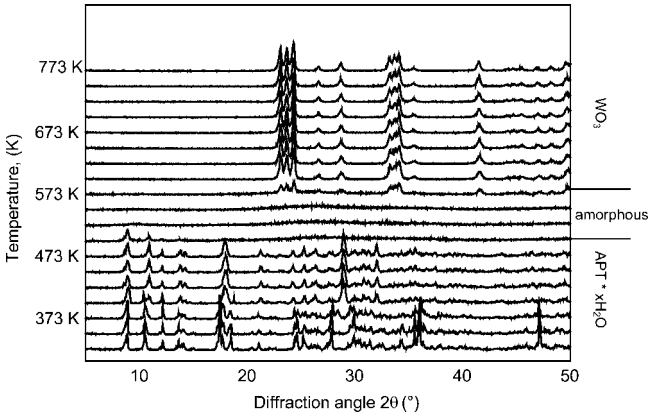

Figure 8. Evolution of X-ray diffraction patterns measured during decomposition of ammonium paratungstate in static air in the temperature range 300–770 K (effective heating rate 0.1 K min^{-1}, flow rate 80 mL min^{-1}). Three major stages of the decomposition are indicated.

Characterization of the Decomposition Intermediates and Products

The XRD pattern of the crystalline product of the decomposition of APT under 20% oxygen in helium can be simulated very well by a mixture of hexagonal and triclinic WO_3 (Figure 9). A Rietveld refinement of the corresponding model structures to the experimental pattern resulted in a phase composition of ca. 90% triclinic WO_3 and ca. 10% hexagonal WO_3, with crystallite sizes of 60 nm and 120 nm, respectively, and lattice constants that are in good agree-

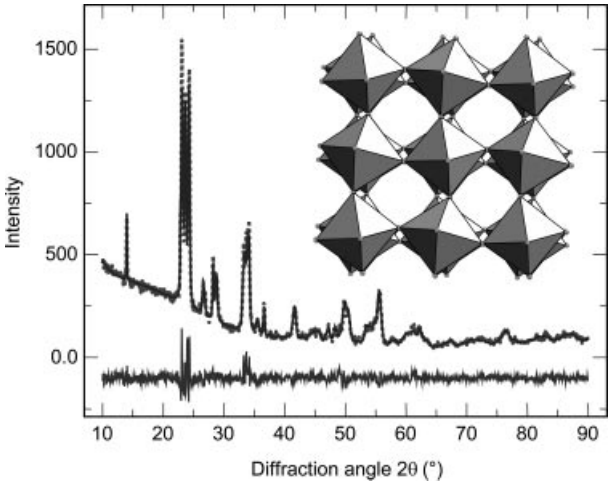

Figure 9. Experimental (dotted) and simulated (solid) X-ray diffraction pattern of the product of the decomposition of ammonium paratungstate under 20% oxygen in helium (300–770 K), together with a schematic structural representation of the corresponding triclinic WO_3 phase.

ment with the single-crystal data [triclinic WO_3 (ICSD 1620, a = 7.31 Å, b = 7.52 Å, c = 7.68 Å, α = 88.8°, $\beta = \gamma$ = 90.9°) a = 7.34 Å, b = 7.53 Å, c = 7.69 Å, α = 89.6°, $\beta = \gamma$ = 90.5°]. A schematic representation of the structure of triclinic WO_3 is depicted in Figure 9. The nearest-neighbor distances in triclinic WO_3 are given in Table 2. The structure is related to the ReO_3 structure and consists of edge-sharing WO_6 units with W–O distances ranging from 1.8 to 2.2 Å. In comparison with the ReO_3 structure, the WO_6 units in triclinic WO_3 are strongly tilted with respect to each other resulting in a triclinic unit cell.

Table 2. Structural parameters [type of pairs and number (N) of nearest neighbors at distance R] obtained from a refinement of a triclinic WO_3 model structure (based on ICSD 1620) and a hexagonal $(NH_4)_{0.25}WO_3$ model structure (ICSD 23537) to the experimental XAFS functions $\chi(k)$ of the product (at 300 K; Figure 10B) and of an intermediate (at 545 K; Figure 10A) of the decomposition of APT under oxygen at the WL_{III} edge (N_{ind} = 28, N_{free} = 16, 12 single-scattering paths and 29-multiple scattering paths, R range 0.8–4.2 Å, k range 1.7–13.1 $Å^{-1}$, E_0 = 6.2 eV, S_0^2 = 0.9).

W–W	2	3.71	3.71	0.0060	4	3.70	3.65	0.0084
W–W	3	3.80	3.81	0.0060	2	3.78	3.74	0.0084
W–W	1	3.86	3.90	0.0060	–	–	–	–

A detailed XAFS analysis of the APT decomposition product under oxygen and of a representative intermediate of the decomposition from the amorphous region in the XRD series was performed to elucidate the local structure around the W centers in the two stages of decomposition. The experimental and theoretical WL_{III} FT[$\chi(k)\cdot k^3$] of the intermediate of the thermal decomposition of APT at 523 K and of WO_3 as the product of the decomposition at 773 K are depicted in Figure 10, A and B, respectively. The corresponding structural parameters are given in Table 2. It can be seen that the local structure around the W centers in the product WO_3 is in good agreement with that in the triclinic WO_3 model structure. Similarly, the local structure around the W center in the intermediate of the decomposition at 523 K can also be simulated by the triclinic WO_3 model structure. However, characteristic deviation in the first W–O distances (i.e. absence of neighbors at 2.2 Å) indicates a higher degree of regularity in the WO_6 units of the intermediate phase relative to those of triclinic WO_3. Moreover, the W–W distances obtained are slightly smaller than those determined for triclinic WO_3. It emerges that the local structure around the W centers in the intermediate phase at 523 K can be better explained by assuming a hexagonal tungsten bronze such as $(NH_4)_{0.25}WO_3$ (ICSD 23537). A schematic structural representation of $(NH_4)_{0.25}WO_3$ is depicted in Figure 11.

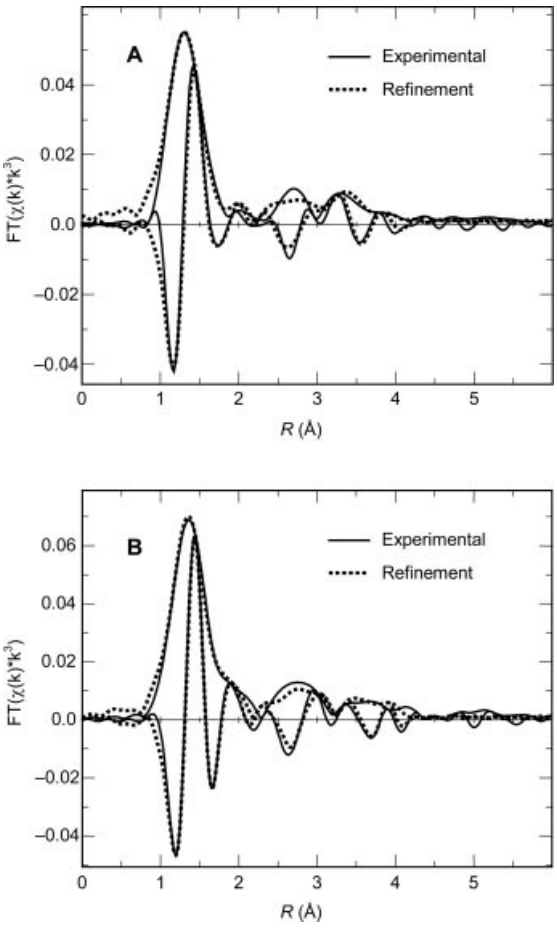

Figure 10. Experimental (dotted) and theoretical (solid) WL_{III} XAFS FT[$\chi(k)\cdot k^3$] of the intermediate of the thermal decomposition of ammonium paratungstate at 523 K (A) and of WO_3 as the product of the decomposition at 773 K (B) measured at 300 K. The corresponding structural parameters are given in Table 2.

Discussion

Thermal Decomposition of Ammonium Paratungstate

The thermal analysis data shown in Figures 3 and 4 for the decomposition of APT under the various gases em-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ployed indicate that up to a temperature of ca. 650 K, the decomposition proceeds largely independently of the gas. This is corroborated by the XRD data presented in Figures 5, 7, and 8, which exhibit a series of patterns corresponding to a loss of water of crystallization up to 470 K, and transformation into a poorly crystalline or amorphous phase that persists up to ca. 650 K. At temperatures above 650 K, the product of decomposition depends on the gas-phase composition. This holds for both the phase composition and the crystallinity of the products obtained.

While under oxidizing gases triclinic WO_3 is formed as the majority phase,[14,18] the decomposition under reducing gases results in the formation of partially reduced tungsten bronzes.[16] However, reduction of WO_{3-x} formed at 650 K under reducing gases (i.e. helium, propene, and hydrogen) to WO_2 or tungsten metal is detected during the decomposition of APT under hydrogen only.[17,26–28] Apparently, propene is not capable of further reducing WO_3 in the temperature range employed. This difference between the reducing powers of hydrogen and propene has already been observed for the reduction of MoO_3 under propene and hydrogen.[29] While hydrogen is capable of entering the lattice of MoO_3 and WO_3, reduction of the oxide by propene requires the facilitated diffusion of oxygen to the surface to react with the propene molecules adsorbed at the surface. On the one hand, this is the case for the reduction of MoO_3 under propene and helium, where oxygen can readily diffuse in the layer structure of orthorhombic MoO_3. On the other hand, diffusion of oxygen appears to be considerably hindered in the ReO_3-type structure of WO_3. Thus, no lattice oxygen is made available at the surface of the WO_{3-x} crystallites formed in the decomposition of APT, and no significant oxidation of propene by lattice oxygen with the corresponding reduction of the WO_3 lattice occurs.

The major mass loss (Figure 3) and thermal DSC event (Figure 4), together with the major structural changes (e.g. Figure 5) during the decomposition of APT proceeds at ca. 520 K. The amorphous or poorly crystalline phase detected by XRD at temperatures above 500 K can be identified by XAS to correspond to a 3D network structure similar to that of triclinic WO_3. While the local coordination of tungsten by the nearest-neighbor oxygen atoms in the intermediate phase at 500 K exhibits a characteristic distortion very similar to that of triclinic WO_3 (and different from that of hexagonal WO_3), the medium-range order appears to be more similar to that of a hexagonal WO_3 structure, $(NH_4)_{0.25}WO_3$. A schematic representation of $(NH_4)_{0.25}WO_3$ is depicted in Figure 11. The rather short W–W distances found in the local structure around the W center in the intermediate at ca. 500 K is characteristic for this hexagonal tungsten oxide. Hence, the major decomposition stage observed at ca. 500 K corresponds to a complete destruction of the polyoxo ions of APT, followed by a restructuring and formation of a three-dimensional network of corner-sharing WO_6 units. During the decomposition in the temperature range 470–650 K prior to the formation of triclinic WO_3, the evolution of FT[$\chi(k)\cdot k^3$] shows that the distortion in the first oxygen coordination sphere decreases resulting in more regular WO_6 units similar to those characteristic of tungsten bronzes. With increasing temperature, the last decomposition stage and formation of triclinic WO_3 at ca. 650 K results in an increased distortion of the WO_6 units characteristic of triclinic WO_3.

Decomposition of APT under Partial Oxidation Reaction Conditions

During the decomposition of APT under propene, and propene and oxygen no significant amounts of oxidation products of propene (i.e. acrolein or carbon dioxide) are detected in the gas phase. As mentioned above, no reduction of WO_3 by propene is detected, indicating no availability of lattice oxygen for propene oxidation. The absence of propene oxidation activity in the temperature range studied is in agreement with a generalized mechanism of propene oxidation, which requires a certain weakening of the metal–oxygen bonds to ensure the presence of characteristic surface defects required for the activation of gas-phase oxygen and propene and the availability of oxygen to the gas-phase reactants.[30,31] The invariance of the WO_3 structure under propene, and propene and oxygen at temperatures above 600 K indicates that the W–O bonds in the more regular WO_6 building units of WO_3, relative to the highly distorted MoO_6 building units of α-MoO_3, are less susceptible of forming non-oxygen-terminated catalytically active surface sites. Conversely, treatment of MoO_3 under propene and oxygen clearly shows that the onset of catalytic activity at ca. 600 K is correlated to the mobility of lattice oxygen at this temperature. The latter is evident from the onset of reduction of MoO_3 under propene at the same temperature. In contrast with the characteristic layer structure of orthorhombic MoO_3, which is capable of accommodating oxygen vacancies by the formation of crystallographic shear defects, the corner-sharing octahedrons in the triclinic WO_3 structure are less flexible, energetically more stable and are thus not capable of permitting an increased amount of oxygen vacancies in the tungsten oxide lattice. Under the decomposition conditions investigated, which encompass those used for the calcination of catalyst precursors in the literature, no catalytically active tungsten oxide bronzes or tungsten oxide shear-structures are obtained. The rather stable ReO_3-like three-dimensional tungsten oxides that already form at temperatures as low as 500 K exhibit no sufficient oxygen mobility and, hence, no partial oxidation activity in the temperature range employed.

Comparison of the Decomposition of APT and Polyoxomolybdates

In previous works, we reported on the characteristic evolution of phases during the decomposition of ammonium heptamolybdate (AHM)[3] and heteropolyoxomolybdate (HPOM)[4] under various reaction gases. In Figure 12 the schematic pathway for the decomposition of APT is compared to those determined for the decomposition of AHM

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

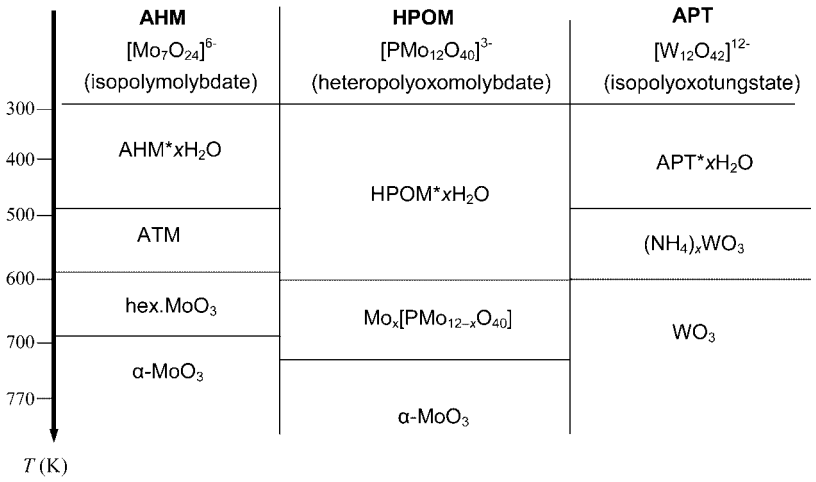

Figure 12. Schematic representation of the structural evolution during decomposition of ammonium heptamolybdate (AHM), a Keggin-type heteropolyoxo molybdate ($[PMo_{12}O_{40}]^{3-}$), and ammonium paratungstate $[(NH_4)_{10}H_2W_{12}O_{42}\cdot 4H_2O]$ under 20% oxygen in helium in the temperature range 300–773 K.).

and HPOM under oxygen. In all three cases, decomposition starts with the loss of water of crystallization, present in varying amounts in the three materials. The decomposition of the relatively small Anderson-type polyoxomolybdate ions of AHM proceeds according to a series of polycondensation steps that result in an increasing dimensionality of the structure of the decomposition intermediates.[3] The X-ray-amorphous phase that forms at ca. 500 K during the decomposition of AHM under flowing reactants could be identified as ammonium tetramolybdate possessing a 1D chain structure. A three-dimensional lattice structure (hexagonal MoO_3) forms at ca. 600 K and is eventually transformed into orthorhombic MoO_3 at ca. 700 K. Evidently, the thermal decomposition of both APT and AHM proceeds through the formation of an ammonium- and water-containing hexagonal phase, which eventually decomposes into mainly triclinic WO_3 and orthorhombic MoO_3, respectively. In contrast to the decomposition of APT, the products obtained from the decomposition of AHM depend strongly on the gas employed.[3]

Heteropolyoxomolybdates of the Keggin type, $[PMo_{12}O_{40}]^{3-}$, exhibit a significantly increased stability compared to APT, with a similar stoichiometry. Partial decomposition and reduction of the Keggin ion starts at about 600 K, which coincides with the formation of a three-dimensional lattice during decomposition of AHM. At 600 K, the HPOM forms a lacunary Keggin ion with one molybdenum center on an extra-Keggin framework position. This arrangement is stable to about 700 K where a complete structural rearrangement and formation of α-MoO_3 is detected. While the extra-Keggin Mo center certainly acts as the first step towards "condensation" of the Keggin ions and formation of the extended MoO_3 structure, no further well-defined intermediates with an increasing degree of condensation are observed. Because the decomposition of HPOM results eventually in the formation of MoO_3 at temperatures above 700 K, the final product composition at 773 K is strongly dependent on the gas used (i.e. MoO_3 under oxidizing gases, MoO_2 under moderately reducing gases, and Mo metal under hydrogen). Thus, two effects result in a pronounced stability of the Keggin-type HPOM relative to APT. First, the stability of the three-dimensional network of edge-sharing WO_6 units in WO_3 favors the decomposition of polyoxotungstate and the formation of WO_3. Second, the Keggin ions of heteropolyoxomolybdates are considerably stabilized by the phosphorus heteroatom. With respect to the preparation of tungsten-containing, mixed-metal oxide, the differences in the decomposition schemes revealed for ammonium paratungstate relative to other common catalyst precursors such as ammonium heptamolybdate and heteropolyoxomolybdates indicate certain prerequisites for suitable preparation routes. Because of the low formation temperature of a stable 3D lattice structure during decomposition of APT, precursor mixtures with APT as a separate phase will most likely result in oxide mixtures containing catalytically less interesting triclinic or hexagonal tungsten oxides. Hence, in order to use the structure-promoting and stabilizing effect of the W centers in mixed molybdenum oxide catalysts, tungsten has to be incorporated into the Mo precursors to ensure the presence of W in the final catalyst.

Conclusions

The bulk structural evolution during the decomposition of APT under various oxidizing and reducing gases was elucidated by the complementary techniques in situ XAS, in situ XRD, and TG/DSC combined with mass spectrometry. In the temperature range 300–650 K, the decomposition of APT proceeds nearly independently of the gas employed. Oxidizing gases result in the formation of crystalline triclinic WO_3 as the majority phase at 773 K, while mildly reducing gases (propene, propene and oxygen, and helium) result in the formation of partially reduced and highly disordered tungsten bronzes. No further reduction is observed

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

under propene or helium, indicating strongly hindered oxygen mobility in the tungsten oxide lattice in the temperature range employed. Because of the particular reducing capabilities of hydrogen (i.e. incorporation in the lattice and formation of bronzes), the decomposition of APT under hydrogen results in the formation of WO_2 and, eventually, tungsten metal.

During the thermal treatment of APT major changes occur at ca. 520 K where a complete structural rearrangement takes place which results in the destruction of the polyoxotungstate ion of APT and the formation of a tungsten oxide bronze. This bronze already exhibits a three-dimensional structure consisting of corner-shared WO_6 units with a local structure around the W centers similar to that in triclinic WO_3. The rather low temperature for the formation of a three-dimensional lattice relative to the thermal treatment of common polyoxomolybdate precursors indicates the particular structural stability of the arrangement of corner-sharing WO_6 units in WO_3 and tungsten oxide bronzes. For tungsten to act as a potential structural or electronic promoter in molybdenum oxide based catalysts, tungsten needs to be incorporated in regular molybdenum oxide structures already at a very early stage of the catalyst preparation instead of employing paratungstate-containing phase mixtures.

Experimental Section

Ammonium Paratungstate Tetrahydrate, $(NH_4)_{10}H_2W_{12}O_{42}\cdot 4H_2O$: Ammonium paratungstate tetrahydrate [APT, $(NH_4)_{10}H_2W_{12}O_{42}\cdot 4H_2O$] was used as purchased (Osram). For the investigations described here, a sieved fraction with particles in the size range 100–200 μm was employed (Figure 13).

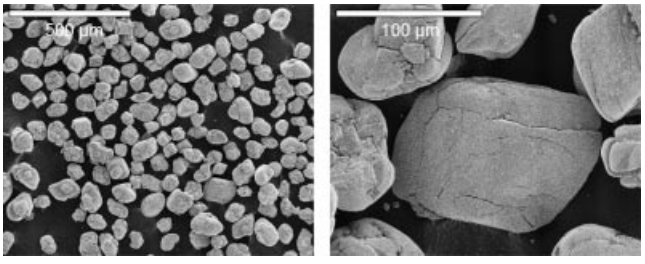

Figure 13. Scanning electron micrographs of a sieved fraction of as-purchased ammonium paratungstate [$(NH_4)_{10}H_2W_{12}O_{42}\cdot 4H_2O$] with particles in the size range 100–200 μm.

X-ray Diffraction (XRD): In situ XRD studies were performed with a STOE Bragg–Brentano diffractometer (Ge secondary monochromator, Cu-K_α radiation) equipped with a Bühler HDK S1 high-temperature cell. The product composition in the gas phase was continuously monitored by using a mass spectrometer in a multiple ion detection mode (Pfeiffer QMS 200). XRD measurements were conducted in the temperature range 323–773 K with an effective heating rate of 0.1 K min^{-1}. Diffraction patterns were recorded every 25 K in a 2θ range of 5–50°. Analysis of experimental diffraction patterns was performed by using the software TOPAS (Bruker AXS) Version 2.1. Crystallite sizes were estimated by using the Scherrer equation. The ICDD-PDF (International center for diffraction data) database and the ICSD (Inorganic crystal structure database) were used for phase analysis and structure refinement.

X-ray Absorption Spectroscopy (XAS): Transmission X-ray absorption spectra were measured in situ with the sample pellet in a flow reactor under a controlled reactant gas.[32] In situ XAS experiments were performed at the WL_{III} edge (10.204 keV) (Hamburger Synchrotronstrahlungslabor, HASYLAB, beamline X1), by using an Si (311) double crystal monochromator. Temperature-programmed decomposition of APT was conducted at temperatures between 293 and 773 K under helium, 5% hydrogen in helium, 20% oxygen in helium, 10% propene in helium, and 10% propene and 10% oxygen in helium. For the in situ XAS measurements, 4 mg of APT was mixed with 30 mg of boron nitride and pressed into pellets of 5 mm in diameter (edge jump $\Delta\mu_x \approx 1.5$ at the WL_{III} edge). The gas-phase composition was continuously monitored by using a mass spectrometer in a multiple ion detection mode (Omnistar, Pfeiffer). Data analysis of XAFS spectra was performed with the software WinXAS 3.0.[33] The spectra were energy-calibrated with respect to a tungsten metal foil reference spectrum. For background subtraction and normalization, first-order polynomials were refined to the pre-edge and EXAFS region. Spectra were converted to k space using an E_0 defined as the first inflection point in the WL_{III} edge. Atomic absorption, μ_o, fitting was performed by using a cubic spline with 7 knots to minimize peaks at low R values (<1 Å) in the Fourier-transformed EXAFS $\chi(k)$. The pseudo radial distribution function FT[$\chi(k)\cdot k^3$] was calculated by Fourier transforming the k^3-weighted experimental $\chi(k)$ function, multiplied by a Bessel window, into the R space. EXAFS data analysis was performed by using theoretical backscattering phases and amplitudes calculated with the ab initio multiple-scattering code FEFF7.[34] Single-scattering and multiple-scattering paths in monoclinic APT, hexagonal $(NH_4)_{0.25}WO_3$ (intermediate), and triclinic WO_3 (decomposition product) were calculated up to 6.0 Å with a lower limit of 8.0% in amplitude with respect to the strongest backscattering path. EXAFS refinements were performed in R space simultaneously to magnitude and imaginary part of a Fourier transformed k^3-weighted and k^1-weighted experimental $\chi(k)$ by using the standard EXAFS formula.[34] Structural parameters that are determined by a least-squares EXAFS refinement of a model structure to the experimental spectra are (i) one overall E_0 shift, (ii) Debye–Waller factors for single-scattering paths, and (iii) distances of single-scattering paths. Coordination numbers (CN) and S_0^2 were kept constant in the refinement.

Thermal Analysis (TG and DSC): Thermal analysis [thermogravimetry (TG) and differential scanning calorimetry (DSC)] was performed with a Netzsch STA 449 C TG/DSC instrument combined with an Omnistar (Pfeiffer) mass spectrometer under pure helium, 5% hydrogen in helium, 20% oxygen in helium, 10% propene in helium, and 10% propene, and 10% oxygen in helium. Measurements were carried out at heating rates of 6 K min^{-1}, and at a total flow of 100 mL min^{-1}.

Scanning Electron Microscopy: Scanning electron microscopy (SEM) was conducted with an S 4000 FEG microscope (Hitachi). The acceleration voltage was set at 10 kV, the objective aperture was 30 mm, and the working distance was 10 mm.

Acknowledgments

The Hamburger Synchrotronstrahlungslabor, HASYLAB, is acknowledged for providing beamtime for this work. G. Weinberg is acknowledged for conducting the SEM measurements. We thank B. Kniep, A. Szizybalski, E. Rödel, J. Osswald, and J. Wienold for

assistance at the beamline and for numerous valuable discussions. The authors are grateful to Prof. R. Schlögl for his continuous support.

Surface Segregation in SnO_2–Fe_2O_3 Nanopowders and Effects in Mössbauer Spectroscopy

Ricardo H. R. Castro,*[a,b] Pilar Hidalgo,[a] José A. H. Coaquira,[c] Jefferson Bettini,[d] Daniela Zanchet,[d] and Douglas Gouvêa[a]

Keywords: Materials science / Nanostructures / Semiconductors / Electron microscopy / Moessbauer spectroscopy

SnO_2–Fe_2O_3 nanopowders prepared by the polymeric precursor method were studied by combined conventional and high-resolution techniques. The powders treated at 500 °C were analyzed by EDS local probe associated with HRTEM to directly detect surface segregation of Fe ions onto SnO_2 nanoparticles over a broad range of concentrations. The segregation of these ions controls the system microstructure by changing the surface energies and acting as nucleation sites for the formation of a Fe oxide phase (magnetite) at high Fe concentrations. A technologically interesting core–shell-type particle structure, with a magnetic shell and semiconductor core, was observed for the first time. The influence of the segregated Fe ions in Mössbauer spectra is also addressed as a new proposal for the interpretation of the effects of composition changes in both the bulk and at the interface of particles. In this proposal, the two observed sites in Mössbauer spectra would be independently related to bulk-substituted and surface-segregated Fe ions.

Introduction

In the past few decades the electrical and magnetic properties of oxide systems containing Fe ions have greatly increased commercial interest in such materials for application as gas sensors, catalysts and other devices.[1,2] These properties have been extensively studied for many systems,[1–13] and a number of efforts have been carried out to establish the relationship between the observed properties and structural features of these solids. However, since most of the techniques used are not suitable for detecting surface-segregated atoms,[3,9] the discussions rarely consider this phenomenon as a relevant issue, and its influence on the structure and microstructure are usually disregarded. This could lead to incomplete microstructure characterizations that could have reflected in unreliable conclusions about the related properties. In fact, the presence of atoms at the surface can change the interpretation of several phenomena and open up new perspectives for the development of new devices.

Techniques such as X-ray photoelectron spectroscopy (XPS) have shown that surface segregation of components occurs in a wide range of compositions in a large number of systems and, moreover, these segregated components should play an important role in oxide systems.[12–17] This role should involve not only effects on the final properties of the materials, such as electrical and optical, but also on their microstructure and structure evolution.

Although considered an extensive solid-solution system, and with a number of studies concerning this topic,[18–20] surface segregation has recently been hypothesized in the technologically relevant Fe_2O_3–SnO_2 system.[21,22] The hypothesis firstly emerged from the fact that, despite the similarity between the ionic radii of Fe^{3+} and Sn^{4+}, which should induce the formation of an extensive solid solution, Fe_2O_3 (hematite) possesses a corundum-type structure whereas Sn^{4+} hardly forms this structure type and, therefore, their mutual solubility should be lower than that expected by the radius analysis. Actually, only some indirect evidence, fundamentally based on surface IR spectroscopy and surface charges, has indicated that the lower concentration component of this system, instead of forming a bulk solid solution, could be segregating onto the surface of the particles as a surface solid solution. This conclusion was based on the very pronounced effects of the components in the surface sensitivity measurements even at low concentrations and, moreover, on the lack of apparent peak dislocations or second phases in the XRD patterns.[23]

This paper intends to address the surface segregation in the Fe_2O_3–SnO_2 system by using energy dispersive spectroscopy (EDS), XRD, and HRTEM to clarify the ions' distribution in this system and also consider the microstructure of different compositions. Moreover, since the segrega-

tion of the lower concentration component on the surface of the power can be confirmed by these techniques, this work also readdresses Mössbauer spectroscopy in this system by taking into account the influence of the segregated components. Although this spectroscopy has been the subject of several studies in this system[3,19] and, moreover, this technique has already been independently described to consist of a crystalline contribution and an interface one,[24] surface segregation and its influence on the interface contribution have not been addressed, and even nowadays, Mössbauer studies of the SnO_2–Fe_2O_3 system are still exclusively based on the same solid-solution concepts.[18]

Results and Discussion

Figure 1(a) shows the XRD patterns of SnO_2 powders containing increasing amounts of Fe prepared by a polymeric precursor method.[25,26] Up to 30 mol-% Fe all reflection peaks can be assigned to the SnO_2 tetragonal phase. In 50 and 80 mol-% Fe samples, additional peaks appear in the XRD patterns indicating a second-phase nucleation that could be related to the (220) and (311) reflections of both

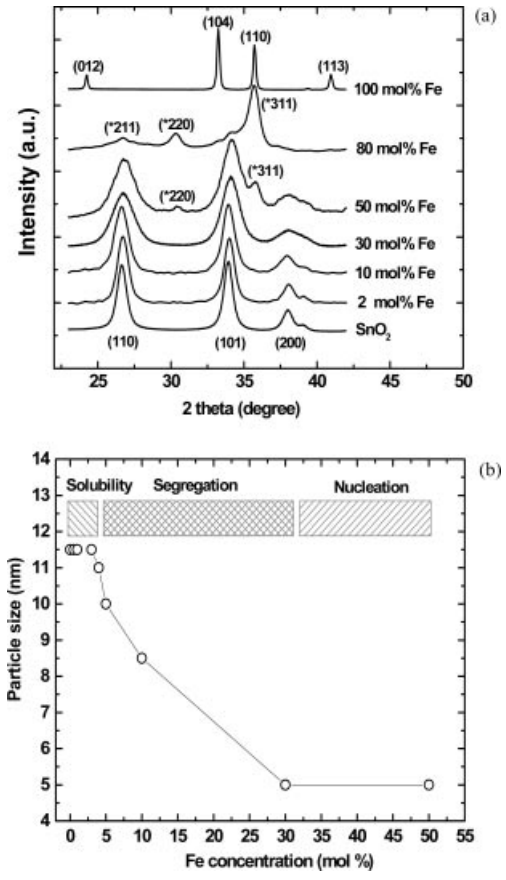

Figure 1. (a) XRD spectra of SnO_2 powders containing different amounts of Fe. The peaks identified by * correspond to the formation of a second phase. (b) SnO_2 particle diameters estimated by the Sherrer method as a function of Fe concentration. Note the three distinct regimes: solubility, segregation, and second-phase nucleation.

magnetite and maghemite phases. The XRD pattern of the 100 mol-% Fe sample corresponds to pure hematite phase.

Since only slight changes can be observed in the diffractograms up to 50 mol-% Fe, one may suggest the solubility and segregation ranges of Fe in the SnO_2 structure to be below 50 mol-% Fe, after which nucleation of the second phase occurs. The solubility range can be determined from the data in Table 1, where the lattice parameters of the SnO_2 phase, extracted from the XRD patterns of 0–10 mol-% Fe samples, are presented. Note that the lattice parameter *a* remains almost constant with increasing Fe concentration, whereas lattice parameter *c* increases with increasing Fe content up to about 4 mol-%. The distortion of the SnO_2 lattice can be attributed to the incorporation of Fe^{3+}, thus suggesting that the solubility limit for this system is around this concentration. A further increase of the Fe content does not significantly change the lattice parameters. Since no crystalline second phases are observed at this stage, both amorphous second phase or the surface segregation of Fe ions can be considered. Based on the literature reports and the HRTEM and EDS data presented below, an amorphous phase can be disregarded. That is to say, after saturation of the lattice by the additive, and above this limit, the segregation of atoms onto the particle surface is supposed to be relatively energetically favorable for the additive. The existence of a solubility limit, however, does not mean that segregation is not occurring before it, but that a smooth transition between both phenomena should exist. This explains why surface-segregation effects are already observed with 2 mol-% Fe but are much more pronounced at about 5 mol-% Fe.[23]

Table 1. Refined values of unit-cell parameters of SnO_2 containing different Fe contents.

Sample	*a* [Å]	*c* [Å]	*c*/*a*
SnO_2[a]	4.7367(1)	3.1855(1)	0.672
SnO_2	4.7406(1)	3.238(4)	0.683
1 mol-% Fe	4.7402(3)	3.263(7)	0.688
2 mol-% Fe	4.7406(2)	3.277(6)	0.691
4 mol-% Fe	4.7401(1)	3.296(7)	0.695
5 mol-% Fe	4.7403(1)	3.291(8)	0.694
10 mol-% Fe	4.7406(5)	3.30(2)	0.696

[a] Data taken from the literature.[27]

The particle size changes as a function of Fe concentration shown in Figure 1(b) reinforce the segregation hypothesis and allow a more precise determination of its occurrence range. The particle diameters were estimated from the XRD peaks by the Sherrer method and confirmed by HRTEM images. Note that below the solubility limit the particle size remains almost constant, suggesting that the inclusion of the additive inside the lattice does not significantly increase the diffusion mechanisms responsible for grain growth. After this point, and between 4 and 30 mol-%, the particle diameters decrease substantially. This is coherent with the proposition of segregation occurrence beyond 4 mol-% Fe, i.e., after the matrix saturation by the additive, an excess of Fe ions segregate onto the particle surfaces, slightly reducing the surface energies and, conse-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

quently, decreasing the final particle sizes, as predicted by the Ostwald ripening model.[22,23,28–30] Since the surface energy is highly dependent on the Fe surface concentration, the particle size of the system decreases as the Fe surface concentration increases until the total coverage of the surface, determined as the segregation limit. Above the segregation limit, the nucleation of a second phase becomes energetically favorable for the additive. This is the case for concentrations higher than about 30 mol-%; in this case the SnO_2 particle diameter remains approximately constant.

A local probe technique (EDS) associated with HRTEM images is a conclusive tool to prove surface segregation and is particularly useful for understanding the second-phase nucleation mechanism. Figure 2(a) shows a 2 mol-% Fe micrograph where only SnO_2 particles, identified by the lattice fringes, have been confirmed (corresponding to the (110) planes). Figure 2(b) shows particles of 30 mol-% Fe for comparison. A decrease in particle sizes is clearly seen, as discussed previously.

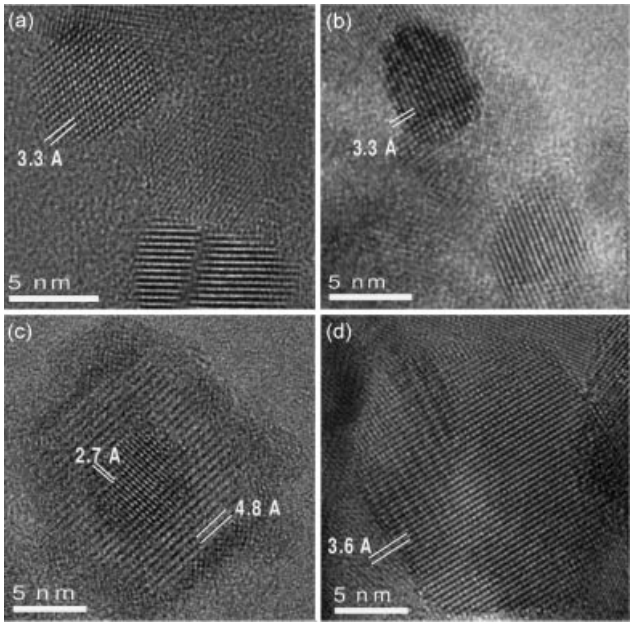

Figure 2. HRTEM images of SnO_2 powders containing: (a) 2, (b) 30, (c) 80, and (d) 100 mol-% Fe. Lattice fringes correspond to (a) and (b) (110) tetragonal SnO_2 planes; (c) core: (101) tetragonal SnO_2 planes, shell: (111) cubic Fe oxide; (d) (110) hematite.

Segregation of Fe onto the surface is, however, only confirmed by EDS measurements when collecting data at the center and at the edge of SnO_2 particles containing different Fe contents (3 nm beam probe). A general EDS was also measured for comparison purposes. Figure 3 compiles the results of the 30 mol-% Fe and demonstrates that there is indeed an excess of Fe ions located on the SnO_2 particle surface. The concentration at the surface is about 1.3-times higher than that computed at the center of this particle. Similar effects are observed in particles containing 10, 50, and 80 mol-% Fe, with different ratios, showing that the segregation occurs in a broad range of compositions. These results are shown in the inset of Figure 3. A relatively high ratio is observed in particles containing 80 mol-% Fe; this is related to the particular second-phase nucleation process, as explained below.

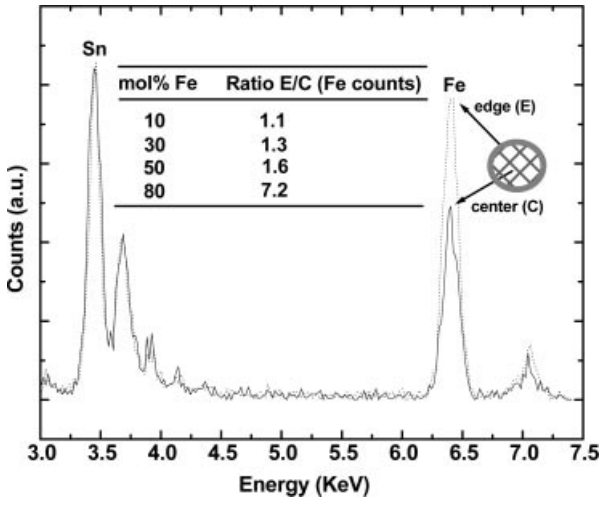

Figure 3. EDS spectra at the center (C) and at the edge (E) of a 30 mol-% Fe particle. Inset: EDS results as a function of Fe concentration, at 6.3 keV. The data is presented as the height peak of the edge-to-center ratio (E/C) after normalization to the Sn peak intensity.

Increasing the Fe content in the SnO_2-based powder saturates the segregation path and induces the second-phase nucleation regime. This was observed by XRD measurements, but the mechanism of the process that takes place and the nature of the new phase could not be conclusively identified. Using HRTEM images both aspects are now better addressed. Figure 2(c) shows an HRTEM image of an 80 mol-% Fe particle, where an interesting core–shell structure can be identified. This result confirms the formation of a second phase and reveals that, in fact, it nucleates on the surface of the SnO_2 particle forming a surface coating. This can be understood based on the segregation of Fe on the surface of SnO_2, where the segregated atoms work as heterogeneous nucleation sites for the new phase growth. Interestingly, since the nucleation occurs on the surface of SnO_2, an epitaxial-type growth may be expected, and a metastable Fe oxide phase other than the thermodynamically stable hematite has been detected. Hematite is the phase formed in the absence of SnO_2 by this synthesis method, as shown by XRD, and confirmed by HRTEM [Figure 2(d); lattice fringes correspond to the (110) planes]. In Figure 2(c), lattice fringes crossing the core–shell structure suggest an epitaxial-type growth. The center of the particle shows the (101) planes of the SnO_2 structure, whereas the shell lattice fringes correspond to either the (111) planar distances of maghemite or magnetite. These results thus explain the high ratio observed for 80 mol-% Fe samples by EDS, indicating that the probe is in fact detecting the Fe_2O_3 surface nucleated phase. The nature of the nucleated phase was further clarified by Mössbauer spectroscopy measurements.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The segregation regime occurring between solid solution and second phase nucleation appears as a new element in this system evolution, and therefore the Mössbauer spectroscopy results should be revised by considering these three additive incorporation regimes. In fact, Mössbauer spectra have already been described to consist of a crystalline component and an interface one.[23] Therefore, especially when dealing with nanometric particle sizes, characterized by a high specific surface area, one may argue that Mössbauer spectroscopy signals may be strongly affected by the segregated atoms, and neglecting this phenomenon may lead to mistaken conclusions.

Figure 4 shows the Mössbauer spectra at room temperature for 2–100 mol-% Fe samples. For 2, 10, and 30 mol-% Fe, the experimental data have been adjusted using least-squares criteria by considering the presence of two doublets (sites I and II). The obtained parameters are shown in Table 2. In this concentration range, only electric quadrupoles (doublets) are detected, with no indication of magnetic hyperfine structures (sextets). A magnetic interaction does not appear even when the data were colleted at 78 K. This indicates that, if there is any superparamagnetic relaxation, it is occurring at temperatures below 78 K. This class of spin relaxation is expected because of the observed small particle sizes (ca. 5 nm) and is related to the relaxation time of the atom spin (spin–spin or spin–orbital) smaller than the Larmor precession time.[31]

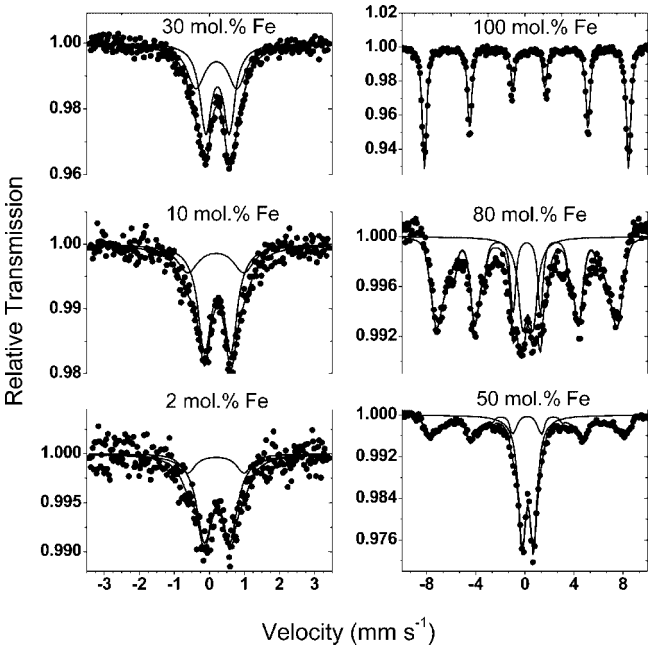

Figure 4. Mössbauer spectra at room temperature for SnO_2 powders containing different contents of Fe.

An important point to note is that the area of site I decreases and that of site II slightly increases with increasing Fe content, as noted in the deconvolution of the peaks. Upon varying the concentration of Fe from 2 to 30 mol-% the area of site I decreases by about 30%. A similar behavior has been observed previously, although no reasonable explanation was given.[19] The phenomenon may be explained by considering the spectra to consist of both interface and bulk contributions. That is to say, each of the observed sites corresponds to a different position of the Fe ions. The Fe atoms located inside the SnO_2 lattice would contribute to the Mössbauer signal in site I and those segregated on the surface would be responsible for the site-II signal. This is coherent with the model described above concerning the solubility and segregation of the low component atom in the system SnO_2–Fe_2O_3. Since the solubility limit is observed at about 4 mol-% for the Fe ion in the SnO_2 lattice, any further increase in the concentration of the additive causes it to segregate on the surface. Such segregated atoms are not well crystallized and give rise to high electric quadrupoles due to local lattice distortions. With increasing Fe content, the surface coating is increased, and the site-II area increases as well.

Such an area increase in the Mössbauer spectra is observed until the second-phase nucleation occurs. Therefore, a nuclear hyperfine magnetic structure is observed for the powder containing 50 mol-% of Fe_2O_3. This hyperfine magnetic structure is the same as that detected in the 80 mol-% Fe_2O_3 sample, but different from that observed for 100 mol-% Fe (hematite). Since the hyperfine parameters of maghemite and magnetite are very similar,[31,32] these data confirm the presence of the new phase but could not be used to clearly identify the phase. Note the presence of the doublet due to Fe ions incorporated in the SnO_2 lattice (site I) when dealing with the samples with 50 and 80 mol-% Fe, which is related to the SnO_2 cores found by the micrograph [Figure 2(c)] saturated by Fe ions. Site II, related to segregated Fe, is not observed in these samples since it has been replaced by the hyperfine magnetic structure grown on the surface.

Table 2. Mössbauer spectroscopy parameters. Isomer shifts are related to metallic Fe. 50 and 80 mol-% samples were fitted with just one doublet and a magnetic sextet; 100 mol-% sample has just the magnetic component as presented in the table. HF means hyperfine field in Tesla [T]. Site I is related to Fe inside SnO_2 lattice. Site II is related to surface-segregated Fe.

Conclusions

The distribution of the components in SnO_2–Fe_2O_3 nanopowders in different compositions can be understood based on the correlation of XRD with spatial high-resolution characterization tools, such as EDS and HRTEM, thus avoiding the loss of information about segregated components. At lower concentration (<4 mol-%), the Fe ions are preferentially incorporated in the SnO_2 lattice to form a solid solution; at intermediate values (4–30 mol-%) the Fe ions segregate onto the SnO_2 surface, as confirmed by EDS. The segregated atoms have important effects in Mössbauer spectroscopy measurements, suggesting that the spectra are a combination of the independent effects of bulk and interface components. At higher concentrations (>30 mol-%) a second phase is nucleated and corresponds to an unexpected magnetite or maghemite phase. Core–shell-type particles with an SnO_2 core structure and a magnetic shell structure are observed for the first time at high Fe contents.

Experimental Section

SnO_2–Fe_2O_3 nanopowders were prepared based on Pechini's method.[24] The process can be briefly described as follows: (a) The cationic precursors were introduced into a mixture of ethylene glycol (20.6 wt.-%) and citric acid (47.7 wt.-%). $Sn_2(C_6O_7H_4)\cdot H_2O$ (tin citrate, prepared from $SnCl_2\cdot 2H_2O$; Synth P.A.) and $Fe(NO_3)_3\cdot 9H_2O$ (Synth P.A.) were used as the precursors and HNO_3 was added to the system to promote the solubilization of the citrate. The amounts of precursors were calculated to achieve the desired molar concentrations. (b) The prepared solution was heated to 180–200 °C to promote polyesterification, i.e. polymerization between citric acid and ethylene glycol to give rise to a polymer chain with sites available to react with the ions present. These sites randomly react with tin or iron ions. (c) The obtained liquid precursor was thermally treated at 450 °C for 4 h to give a dry carbon-rich powder. After grinding, the powder was treated at 500 °C for 15 h to guarantee total carbon elimination and an energetically stable distribution of the additives and particle size.[22,25,26] XRD measurements were carried out with a Philips X'Pert MPD diffractometer, using Cu-K_α radiation (λ = 1.5406 Å), at room temperature. A step of 0.05° with an exposure time of 5 s per step was used in the measurements. To determine the lattice parameters, however, XRD was carried out using θ = 0.02° with an exposure time of 10 s and using an internal Si standard. Mössbauer spectra were obtained in the transmission geometry and the γ-radiation source was ^{57}Co atoms immersed in an Rh matrix. The radioactive source was mounted in a constant acceleration transductor and the maximum speed was determined by calibrating the system with a metallic Fe sheet; γ-ray detection was carried out with a proportional detector and the electronically amplified signal was sent to a digital analyzer. EDS and HRTEM images were acquired with a JEM 3010 URP microscope operating at 300 keV (0.17 nm resolution). For EDS a 3-nm beam-size was used and the background obtained for the Cu grid was then subtracted.

A New Series of Homologous Cluster Complexes $[Mo_3(M'EPh_3)Q_4Cl_4(H_2O)_5]$ (M′ = Ni, Pd; E = P, As, Sb; Q = S, Se)

Maxim N. Sokolov,*[a] Elena V. Chubarova,[a] Rita Hernandez-Molina,[b] Maria Clausén,[b] Dmitry Yu. Naumov,[a] Cristian Vicent,[c] Rosa Llusar,[c] and Vladimir P. Fedin[a]

Keywords: Molybdenum / Nickel / Palladium / Chalcogenide clusters / Triphenylphosphane and analogs

Cluster aqua complexes $[Mo_3(M'Cl)S_4(H_2O)_9]^{3+}$ (M′ = Ni, Pd) react with EPh_3 (E = P, As, Sb) in HCl/CH_3OH to give neutral $[Mo_3(M'EPh_3)S_4Cl_4(H_2O)_5]$ (M′ = Pd, E = P (**1**), E = As (**2**), E = Sb (**3**); M′ = Ni, E = P (**4**), E = As (**5**); E = Sb (**6**). $[Mo_3(PdPPh_3)Se_4Cl_4(H_2O)_5]$ (**7**) was also obtained. X-ray crystal structures were determined for **3**, **4** and **5**. The role of supramolecular interactions in crystal packing is discussed. ESI-MS spectra were also studied and were used to follow the coordination of the solvent molecules at Mo sites and to assess relative strength of bonding in the clusters. Thermal properties were studied for **4** and **5**.

Introduction

The extensive family of cuboidal clusters with a tetrahedral M_4 core, $M_3M'Q_4$ (where M = Mo, W; Q = S, Se; M′ can be one of more than 20 transition or post-transition metals) has attracted interest because it provides a good opportunity to study how the metal-metal bonding and reactivity at metal centres are affected by changes in the nature of M, M′ and Q.[1] The bioinorganic significance of metal sulfide clusters is well known, and it has been put forward that the $Mo_3M'S_4$ (M′ = Co, Ni) clusters in particular can constitute molecular models for the active sites of the industrial heterogeneous Co/MoS_2 or Ni/MoS_2 catalysts.[2] The $Mo_3PdS_4^{4+}$ clusters catalyze nucleophilic addition to alkynes[3] and $[Mo_3NiS_4(H_2O)_{10}]^{4+}$ has proved to be efficient in various heterogeneous catalytic processes.[4,5] Recently it was found that the heterometal in $M_3M'S_4^{4+}$ clusters (M = Mo, W; heterometal (M′) = Ni, Pd) stabilize very labile molecules of $P(OH)_3$, $RP(OH)_2$ (R = H, Ph) and $Ph_2P(OH)$ by coordination at phosphorus[6–8]. Nonlinear optical properties of $[M_3(CuX)Q_4(dmpe)_3X_3]PF_6$ (M = Mo, W; X = Cl, Br; Q = S, Se) were also studied.[9]

A rational synthesis of these clusters is based on an addition of a heterometal in a low oxidation state (or even M'^0) to the trinuclear complexes with the $M_3Q_4^{4+}$ cores. Especially productive are incorporations into the aqua complexes $[M_3Q_4(H_2O)_9]^{4+}$ (M = Mo, W; Q = S, Se),[10] into the complexes with diphosphanes such as $[M_3Q_4(dmpe)_3X_3]^+$,[9,11] and $[M_3S_4Cp'_3]^+$ (Cp′ = methylcyclopentadienyl).[12–14] Dithiophosphates, dithiophosphinates, and dithiocarbamates $[M_3S_4((RO)_2PS_2)_4L]$, $[M_3S_4(R_2PS_2)_4L]$, $[M_3S_4(R_2NCS_2)_4L]$ were used for incorporation of Cu^I (and $d^{10}s^2$-post-transition metal ions).[15] Metal incorporation into the aqua complexes has been most widely used and it was found that even a noble metal, Pd (taken as Pd black), reacts with $[Mo_3Q_4(H_2O)_9]^{4+}$ in HCl to give $[Mo_3(PdCl)Q_4(H_2O)_9]^{3+}$ (Q = S, Se).[16,17] Extensive aqueous solution chemistry of these clusters has been reviewed.[10] The crystallization problems are efficiently dealt with by using *p*-toluenesulfonate as a counterion, and by formation of well-defined supramolecular complexes with cucurbit[6]-uril.[10] However, ligand substitution has not been widely used so far for the isolation of the heterometallic clusters from aqueous solutions. A few examples are transformation of $[Mo_3(PdCl)S_4(H_2O)_9]^{3+}$ into $[Mo_3(PdCl)S_4(tacn)_3]^{3+}$[16] and $[Mo_3(Pd(dppe))S_4(dppe)_3Cl_3]Cl$[18], and of $[Mo_3(NiCl)S_4(H_2O)_9]^{3+}$ into $[Mo_3(NiCl)S_4(dppe)_3]Cl$.[18] Substitution of water ligands by nitrylotriacetate (nta^{3-}) is also possible and was used to prepare $[Mo_3(CuCl)S_4(Hnta)_3]^{2-}$ and $[Mo_3(NiCl)S_4(Hnta)(nta)_2]^{5-}$.[19,20] This scarcity may be attributed to enhanced lability of the cluster cores upon changing the coordination environment, which leads to the loss of the heterometal. Increasing of pH, necessary for complexation of various ligands, may have the same effect, as well as cause undesirable hydrolysis.

Here we report facile synthesis and structural characterization of a family of cluster complexes, $[Mo_3(M'EPh_3)Q_4Cl_4(H_2O)_5]$ (M′ = Ni, Pd; E′ = P, As, Sb; Q = Se), obtained by adding EPh_3 to solutions of $[Mo_3(M'Cl)Q_4(H_2O)_9]^{3+}$ in HCl/CH_3OH mixtures. These products are air-stable, soluble in polar organic solvents and are convenient starting materials for introduction of various ligands into the cluster coordination sphere.

Results and Discussion

Synthesis

Addition of methanolic solutions of EPh_3 (E = P, As, Sb) to the solutions of $[Mo_3(M'Cl)S_4(H_2O)_9]^{3+}$ (M′ = Ni, Pd) in HCl produces characteristic color changes to brown in the case of Pd, and to various shades of blue in the case of Ni. Methanol enhances the ligand solubilities and is essential for the reaction, which does not take place without it. It is worth mentioning that under the employed conditions, no substitution at the Mo atoms takes place. Slow evaporation of methanol from resulting solutions leads to crystallization of the neutral complexes **1–7**. However, the ^{31}P NMR spectroscopic monitoring of the complexation shows that in the reaction solutions of $[Mo_3(PdCl)S_4(H_2O)_9]^{3+}$ + PPh_3 (**1a**), $[Mo_3(PdCl)Se_4(H_2O)_9]^{3+}$ + PPh_3 (**7a**) and $[Mo_3(NiCl)S_4(H_2O)_9]^{3+}$ + PPh_3 (**4a**) three closely spaced singlets are observed in each case: at δ = 31.6, 32.5 and 33.4 ppm for **1a**, 31.3, 32.2 and 33.3 ppm for **7a**, and at δ = 39.7, 40.7 and 41.9 ppm for **4a**. This can be explained by the formation of either different isomers or of several species $[Mo_3(M'PPh_3)S_4(H_2O)_{9-x}Cl_x]^{(4-x)+}$ in solution, that are sufficiently kinetically inert in the NMR time-scale. Note the high-field shift on going from Ni to Pd, just as was observed for corresponding Cp derivatives.[12]

The electronic spectra show little, if any, dependence on the change of EPh_3, but there is a strong hypsochromic shift on going from Ni to Pd. The complexes are air stable, soluble in common organic solvents, and slowly, but completely soluble in water, apparently undergoing a hydrolytic decomposition.

ESI-MS Spectrum of $[Mo_3(M'EPh_3)S_4(H_2O)_5Cl_4]$ (M′ = Ni, Pd; E = P, As, Sb)

Electrospray mass spectrometry (ES-MS) is becoming a valuable tool for the investigation of coordination compounds allowing the study of solution speciation,[21] formation of aggregates,[22,23] or identification of major and minor products in solutions on a microscale,[24] since it allows pre-existing ions to be transferred into the gas phase with minimal fragmentation. Applications to a number of inorganic and organometallic systems have demonstrated the versatility of the technique.[25] In this work we have studied the family of cuboidal cluster complexes $[Mo_3(M'EPh_3))S_4(H_2O)_5Cl_4]$ (M′ = Ni, Pd; E = P, As, Sb) by ESI-MS in the 400–1100 *m*/*z* range in methanol. All compounds **1–7** show similar fragmentation pathways, although the relative intensities of the fragmentation peaks depend on the nature of the incorporated heterometal M′. Figure 1 shows the ESI-MS for compound **5** in methanol at different cone voltages.

The ionisation of these neutral complexes takes place by the loss of one chloride ligand and is accompanied by complete replacement of the coordinated water molecules by methanol except for compound **7** where only a partial substitution is found (see Table 1). A typical pattern is shown in Figure 1 (illustrated here by complex **5**): at low cone voltages a peak corresponding to the $[Mo_3(Ni(AsPh_3))S_4(CH_3OH)_6Cl_3]^+$ ion (*m*/*z* = 1078 a.m.u.) is detected, where the vacant position left by the chloride ion is replaced by methanol keeping the octahedral environment around the molybdenum atoms. Additional peaks due to the sequential loss of methanol molecules are also present, even

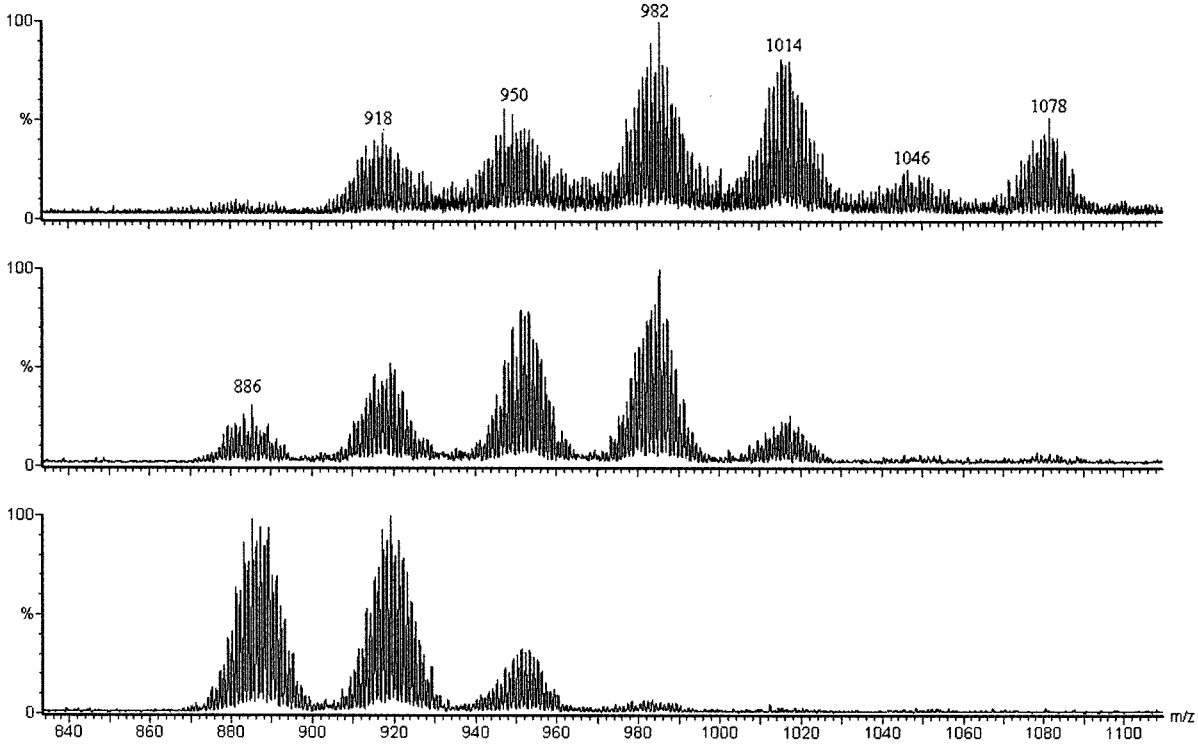

Figure 1. ESI-MS spectra of compound **5** at 10 V (top), 30 V (medium) and 50 V (bottom).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

at 10 V (Figure 1 top). Increasing the cone voltage results in the consecutive losses of methanol molecules (Figure 1, bottom) up to 80 V, where the neutral EPh_3 is also lost. The cluster core $[Mo_3M'S_4]$ does not fragment under these experimental conditions as is also seen for the $[Mo_3Q_4(dmpe)_3Cl_3]^+$, $[Mo_3M'Q_4(dmpe)_3Cl_3]^+$ (Q = S, Se; M′ = Ni, Co) complexes demonstrating robustness of the Mo_3Q_4 and $Mo_3M'Q_4$ cluster units.[11,26–28] Additional experiments using CH_3CN or THF as solvents resulted in substitution of water molecules by acetonitrile in the former case, analogously as described for methanol, whereas no substitution is observed for THF. Thus the qualitative order of substitution of coordinated water molecules in the large excess of another solvent is $CH_3OH \approx CH_3CN >> THF$.

Table 1. Listing of the ions detected upon increasing the cone voltage for compounds **1**–**7**.

	Chemical composition of the ions	Main ion peak (a.m.u.). and intensity at 50 V and 30 V
1	$[Mo_3(PdPPh_3)S_4Cl_3]^+$	891 (100) (87)

	$[Mo_3(PdPPh_3)Se_4(MeOH)Cl_3]^+$	1010 (42) (100)
	$[Mo_3(PdPPh_3)Se_4(MeOH)(H_2O)Cl_3]^+$	1028 (60) (69)

It is well known that the efficiency of the ionization varies with the ion size and in our study only minor changes are expected based on the similar charge and size of the complexes **1**–**7**. Therefore, we assume that the ratios of the apparent intensities of each peak are proportional to the relative abundance of the corresponding species. In order to obtain some insight into the energetics of the molybdenum–solvent bonds, we have analyzed the relative intensity of the different fragments obtained upon increasing the cone voltage from 30 V to 50 V to establish qualitatively how the nature of M′, E and Q affects the binding energy of the $Mo–O_{(MeOH)}$ bond. Table 1 shows the ions detected and the peak intensities at 30 and 50 V for sample solutions in methanol.

Clusters containing nickel (**4**–**6**) all show as base peaks $[Mo_3(NiEPh_3)S_4(MeOH)_3Cl_3]^+$ and $[Mo_3(NiEPh_3)S_4(MeOH)Cl_3]^+$ at 30 and 50 V, respectively, whereas the palladium derivatives **1**–**3,7** show $[Mo_3(PdEPh_3)S_4(MeOH)Cl_3]^+$ at 30 V and $[Mo_3(PdEPh_3)Q_4Cl_3]^+$ at 50 V under identical conditions. These experimental observations clearly show that the binding Mo–MeOH energy is affected by the nature of the heterometal that is incorporated, which then interacts with the molybdenum atoms by direct metal–metal bonding. In particular the Mo–MeOH bond in the palladium derivatives is more prone to rupture than in the nickel analogs. In contrast, no clear tendency is observed upon substitution of either the PPh_3, $AsPh_3$ and $SbPh_3$ nor the chalcogen atom (in the case of the $PdPPh_3$ derivatives **1** and **7**).

Crystal Structures of $[Mo_3(M'EPh_3))S_4(H_2O)_5Cl_4]\cdot n\,H_2O$ (M′ = Ni, Pd; E = P, As, Sb)

The structures of the compounds **3**, **4** and **5** have been determined by single-crystal X-ray diffraction. They all crystallize in the same triclinic space group *P*-1 and share the structural features with previously reported $[Mo_3(PdPPh_3))S_4(H_2O)_5Cl_4]\cdot 3\,H_2O\cdot 0.5\,CH_3OH$ (**1**).[6] Figure 2 shows the structure of the neutral complex $[Mo_3(NiAsPh_3))S_4(H_2O)_5Cl_4]\cdot 3\,H_2O$ (**5**), with the atom numbering Scheme.

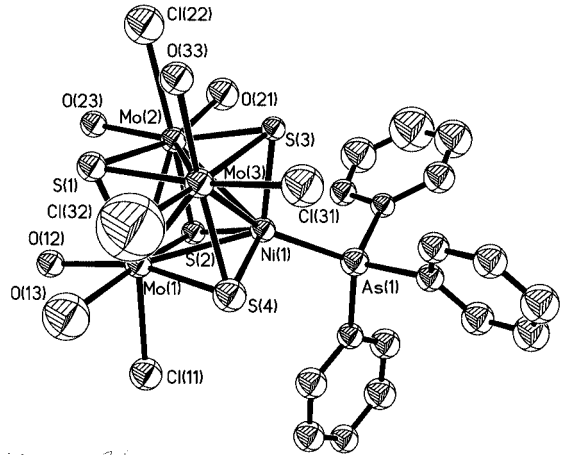

Figure 2. ORTEP representation (50% ellipsoid probability) of the neutral complex **5** with the atom numbering scheme.

The cluster core consists of a slightly distorted tetrahedral arrangement of one nickel/palladium and three molybdenum atoms. Each tetrahedral face is capped by a μ_3-coordinated sulfide ligand thus generating a cubanelike structure. The coordination sphere on one molybdenum atom is completed by one water molecule and two chlorine atoms while the two remaining molybdenum atoms fill their octahedral environment with two water molecules and one chlorine atom. Cl(31) and Cl(11) are *trans* to the unique S(1) atom, while Cl(32) and Cl(22) occupy *cis*-positions. It is re-

[a] Averaged values are given in square brackets.

markable that from several possible geometric isomers expected from various ways of occupying nine coordination sites available to four chloride ligands, only one is realised in **1**, **3**, **4** and **5**. This is most probably dictated by packing requirements, which lead to formation of large channels, defined by Cl···H_2O hydrogen bonds (Figure 4, see the discussion below). Three bridging sulfur atoms and the EPh_3 ligand define the tetrahedral environment on the heterometal. The tetrahedral coordination is severely distorted due to a bending of EPh_3 ligands to one side. This distortion is strongest in **3**, where the angles around Pd vary from 103.3(2) to 118.3(4)°. The geometries of the cuboidal units $[Mo_3M'S_4]$ (M′ = Pd, Ni) in the crystal structures determined in this work are similar to those found in other related complexes. Table 2 shows the most relevant bond lengths within the cluster unit together with those of previously reported structures.

The Mo–Mo bond lengths are consistent with single bonds between metal atoms and no significant differences are detected upon changing either the heterometal M′ or the EPh_3 fragment. However an increase of ca. 0.08 Å is observed by replacement of the Mo-bonded ligands, water and chloride, by the Cp′ groups. The Mo–Ni and Mo–Pd bond lengths are slightly shorter on going from P to Sb, but again the largest difference is due to the substitution of the Mo-bonded ligands, the η^5-Cp′ derivatives having the longest Mo–M′ (by ca. 0.04 Å) bonds. The Mo–M′ and M′–E bonds regularly expand on going from nickel to palladium (0.18 Å for complexes **1** and **4)** and from P to Sb as expected, due to the increase in the covalent radii. The same tendency has been described previously for the isostructural family $[M_3(M'EPh_3)S_4(\eta^5\text{-Cp}')][pts]$ (M = Mo, W; M′ = Ni, Pd, Pt; E = P, As).[12,13]

Supramolecular Structure and Thermal Properties

A current challenge of crystal engineering is to control the assembly and orientation of solid-state structures in three dimensions.[29,30] This task is of a great complexity because the ionic/molecular building blocks can adopt a vast number of conformations in the crystal, thus making structural predictions extremely difficult. Covalent interactions or supramolecular connections (such as hydrogen bonds or π–π interactions) have been widely used to prepare coordination polymers and much effort has been devoted to control and predict the assembled motifs.[31–33] In this context it appears that compounds **1**, **3**, **4** and **5** are promising candidates to form supramolecular networks since they contain: a) five strong hydrogen-bond donors (water molecules); b) four strong electronegative atoms (chlorine) which are capable of propagating networks through Cl···Cl or Cl···H_2O interactions;[34] c) an organic part consisting of three phenyl rings which can expand the network by π–π interactions. These three potential sources of interactions, which can play a significant and predictable structure-determining role, can be grouped based on their hydrophilic (points a and b) or hydrophobic (point c) nature. Both functionalities (hydrophilic and hydrophobic) are located at opposite ends of the discrete molecular cluster, thus we can anticipate that the resulting supramolecular network will be expanded by bringing face to face ends of a similar nature.

A detailed analysis of the packing of neutral complexes **1**, **3, 4** and **5** shows that all of them are expanded in the crystalline lattice through π–π interactions (from the organic end) and short Cl···H_2O contacts (both from the outer water ligands and water of crystallization) as will be described below. Regarding the organic part, it is well known that molecules containing PPh_3 ligands and PPh_4^+ cations commonly associate in crystals in different supramolecular patterns such as the sextuple phenyl embrace (SPE).[35,36] The source of the substantial attraction in these motifs is the interaction between phenyl groups where three types of pair-wise phenyl-phenyl configurations are recognized, namely the offset face-to-face **off**, edge-to-face **ef**, vertex-to-face **vf** and intermediate situations between these three configurations. The intermolecular structure of compounds **1**, **3**, **4** and **5** shows centrosymmetrical dimers formed by π–π interactions involving the phenyl rings through one offset face-to-face and two vertex-to-face interactions as depicted in Figure 3, a) for compound **5**.

Following the nomenclature introduced by Dance et al. this supramolecular motif belongs to the parallel quadruple phenyl embrace **PQPE** type. The values of the intercentroid distances between phenyl groups are 4.27 and 6.05 Å for the **off** and **vf** configurations (similar values are observed for complexes **1**,**3** and **4**) which are comparable to those published by Dance in his comprehensive structural report.[36] These dimers are further connected along the three crystallographic axes through weaker additional π–π interactions with **off**, **vf** and **ef** configurations. Even though these secondary interactions are weaker than those of PQPE type, the intercentroid distances between the phenyl

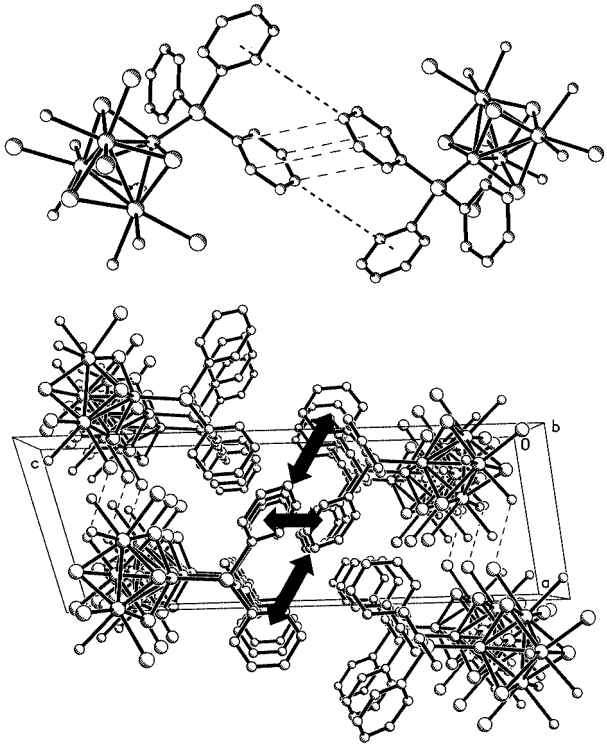

Figure 3. (a) PQPE type configuration of the phenyl rings where dashed lines show the **off** and the **vf** contacts. (b) View across the *ac* plane emphasizing the phenyl ring interactions (PQPE type contacts are shown by black narrows) which lead to the formation of organic columns along the *a* direction.

rings are below 8 Å and also contribute to the stabilization of organic columns as shown in Figure 3, b).

These well-defined π–π interactions force the cluster discrete units to arrange one to each other forming columns, thus applying a key constraint for the accommodation of the remaining molecules in the solid-state structure. As a consequence of this constraint, the remaining molecules are also forced to reproduce this arrangement, and to direct the hydrophilic ends in such a way that additional short contacts between chlorine and water molecules, either of crystallization or coordinated to molybdenum atoms, arise. This arrangement also expands the solid structure through the three dimensions leaving hydrophilic cavities running along *a* and *b* axes. The complementarity of both packing principles leads to a supramolecular 3D network formed by segregated inorganic-organic columns where the water molecules of crystallization are accommodated in the hydrophilic cavities as shown in Figure 4.

Recently, the importance of preparing porous solids where labile terminal ligands are present pointing toward the center of the voids has been outlined. This makes them susceptible to both dissociation and evacuation from the pores, thereby producing periodically unsaturated open-metal sites to allow the study of metal site reactivity.[30,37] In order to evaluate this possibility, TGA-measurements for compounds **4** and **5,** representative of the whole family, were carried out in the 25–200 °C range (Figure 5), coupled with monitoring the peak at m/z = 18 a.m.u. during the

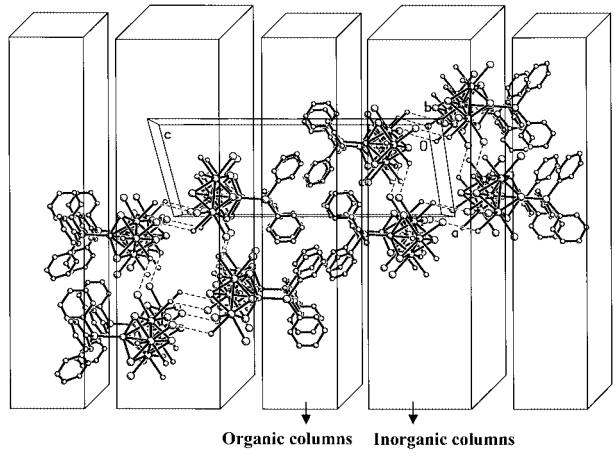

Figure 4. Supramolecular 3D network showing the alternate organic-inorganic columns and the voids left by the inorganic part.

thermal process by mass-spectroscopy. The first weight loss step (3.9% and 4.4% for **4** and **5**, respectively) at 25–80 °C corresponds to the loss of water of crystallization, which closely matches the percentage of water calculated from the X-ray structure determinations (4.6% and 5.3% for compounds **4** and **5**, respectively). The second weight loss of 8.1% and 7.8% (8.5% and 9.2% calculated from the X-ray analysis) for compounds **4** and **5**, respectively, between 100–150 °C is attributed to the loss of water molecules coordinated to molybdenum atoms. Simultaneously, XPD experiments at different temperatures for compound **5** showed a gradual lost of crystallinity from 25 to 250 °C to yield an amorphous solid above 150 °C clearly showing that the 3D network collapses. The low thermal stability of these compounds can be attributed to the evacuation of water molecules belonging to the cluster units, which as mentioned before connect the discrete molecular clusters along the three crystallographic axes and therefore are essential for the support of the 3D network. In this context it would be interesting to study the effect on the thermal stability upon replace-

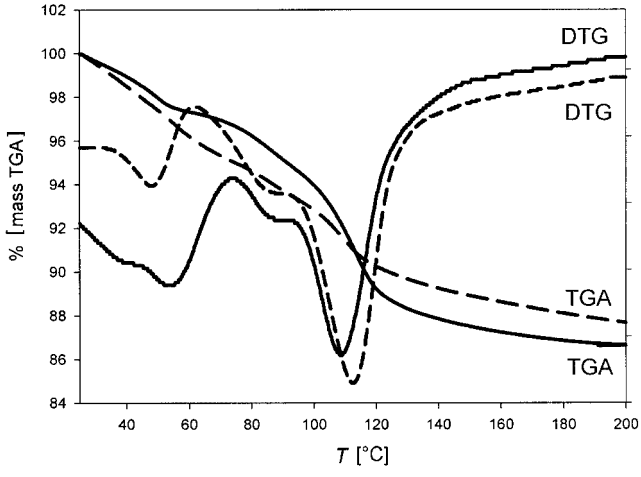

Figure 5. TGA and DTG curves for neutral complexes **4** and **5** (dashed lines) in the 25–200 °C range.

ment of the chlorine ligands by other monoanionic ligands with the aim to obtain more robust solid-state structures.

Experimental Section

General Procedures

The solutions of $[Mo_3(PdCl)S_4(H_2O)_9]^{3+}$ and $[Mo_3(NiCl)S_4(H_2O)_9]^{3+}$ were prepared by published procedures[16,38] and concentrated by absorption on a cation-exchange Dowex 50W-X2 column, followed by elution with 4 M HCl. Triphenylphosphane (CHEMAPOL) was recrystallized from ethanol. $AsPh_3$ (Aldrich), $SbPh_3$ (Aldrich) and other reagents were used as purchased.

The electronic spectra were recorded with a UV-2201 "Shimadzu" UV/Vis spectrophotometer. The ^{31}P NMR spectra were measured with a Bruker 250 MHz spectrometer using 85% H_3PO_4 as external standard. A Quattro LC (quadrupole-hexapole-quadrupole) mass spectrometer with an orthogonal Z-spray-electrospray interface (Micromass, Manchester, UK) was used. The drying gas, as well as nebulizing gas, was nitrogen at flow rates 400 L/h and 80 L/h, respectively. Sample solutions in methanol (ca.10^{-4} M) were infused via syringe pump directly to the interface at a flow rate of 6 μL/min. The temperature of the source block was set to 120 °C and of the interface to 150 °C. A capillary voltage of 3.5 kV was used in the positive scan mode and the cone voltage varied between +10 and +80 V. The signal intensities were obtained by averaging approximately 40 scans and measuring the intensities of the three most intense peaks within the isotopic pattern of each signal. The chemical composition of each peak was assigned by comparison of the experimental and calculated isotopic patterns using the MassLynx 3.5 program. TGA/SDTA analysis were measured on a Mettler Toledo 851e instrument in the 25–300 °C range at 20 °C/min coupled to a ThermoStar Balzers GSD300T mass spectrometer. XPD pictures were obtained at 25, 100, 200 and 250 °C on a SIEMENS D5000 diffractometer using Cu-K_α radiation.

Preparation of $[Mo_3(PdPPh_3)S_4(H_2O)_5Cl_4]\cdot 0.5\,CH_3OH\cdot 3\,H_2O$ (1): The complex was prepared as described in ref.[6]

Preparation of $[Mo_3(PdAsPh_3)S_4(H_2O)_5Cl_4]$ (2): A solution of $AsPh_3$ (30 mg, 0.09 mmol) in methanol (5 mL) was added to 10 mL of a solution of $[Mo_3(PdCl)S_4(H_2O)_9]^{3+}$ (4 mM, 0.04 mmol) in 2 M HCl. The solution rapidly turned from blue to brown. Keeping it in an open vial for 2 days gave a crop of brown crystals, which were filtered off. Yield quantitative. The compound was kept in a vacuum desiccator over P_4O_{10} to remove all solvent molecules. Electronic spectrum [λ_{max}, nm (ε, $M^{-1}\,cm^{-1}$ in $CHCl_3$)]: 308 (15412), 441(4077), 480 (sh, 3378).

Preparation of $[Mo_3(PdSbPh_3)S_4(H_2O)_5Cl_4]\cdot 3\,H_2O$ (3): In the same manner, brown complex **3** was prepared from 10 mL of a 4 mM solution of $[Mo_3(PdCl)S_4(H_2O)_9]^{3+}$ (0.04 mmol) in 2 M HCl and a solution of $SbPh_3$ (30 mg, 0.08 mmol) in methanol (5 mL) in quantitative yield. The compound was kept in a vacuum desiccator over P_4O_{10} overnight before elemental analysis in order to remove all solvent molecules. For $C_{18}H_{25}Cl_4O_5SbS_4Mo_3Pd$: calcd. C 19.52, H 2.28, S 11.58; found C 19.60, H 2.36, S 11.53. Electronic spectrum [λ_{max}, nm (ε, $M^{-1}cm^{-1}$ in $CHCl_3$)]: 311 (16227), 438 (4776), 473 (sh, 3846).

Preparation of $[Mo_3(NiPPh_3)S_4(H_2O)_5Cl_4]\cdot 3\,H_2O$ (4): A solution of PPh_3 (62 mg, 0.238 mmol) in MeOH (11 mL) was added to a solution of $[Mo_3(NiCl)S_4(H_2O)_9]^{3+}$ (8.5 mL, 14 mM, 0.119 mmol) in 2 M HCl. The reaction mixture was heated while stirring at 40 °C for 30 min. The color slowly changed from olive-green to wine-red. Blue-violet crystals appeared after a few days of slow evaporation. Yield 60%. For $C_{18}H_{25}Cl_4O_5PS_4Mo_3Ni$: calcd. C 20.75, H 3.17, S 12.30, found C 21.16, H 2.96, S 12.40 (after drying). Electronic spectrum [λ_{max}, nm (ε, $M^{-1}cm^{-1}$ in $CHCl_3$)] 316 (15369), 488 (1667), 574 (940).

Preparation of $[Mo_3(NiAsPh_3)S_4(H_2O)_5Cl_4]\cdot 2.5\,H_2O$ (5): A solution of $AsPh_3$ (30 mg, 0.09 mmol) in methanol (5 mL) was added to 10 mL of a solution of $[Mo_3(NiCl)S_4(H_2O)_9]^{3+}$ (4 mM, 0.04 mmol) in 2 M HCl. The color slowly turned from green to purple. Keeping the solution in an open vial for 2 days gave a crop of dark blue crystals, which were filtered off. Yield quantitative. The compound was kept in a vacuum desiccator over P_4O_{10} overnight before elemental analysis to remove all solvent molecules. For $C_{18}H_{25}Cl_4O_5AsS_4Mo_3Ni$: calcd. C 21.34, H 2.49, S 12.66; found, C 21.75, H 2.55, S 12.59. Electronic spectrum [λ_{max}, nm (ε, $M^{-1}cm^{-1}$ in $CHCl_3$)] 313 (13879), 491 (1405), 573 (898).

Preparation of $[Mo_3(NiSbPh_3)S_4(H_2O)_5Cl_4]\cdot 2.5\,H_2O$ (6): Prepared in the same way as **5**. Yield quantitative. Electronic spectrum [λ_{max}, nm (ε, $M^{-1}cm^{-1}$ in $CHCl_3$)] 315 (18315), 491 (1745), 578 (958). For $C_{18}H_{25}Cl_4O_5SbS_4Mo_3Ni$: calcd. C 19.10, H 2.92, S 11.31; found C 19.16, H 2.99, S 12.03.

Preparation of $[Mo_3(PdPPh_3)Se_4(H_2O)_5Cl_4]$ (7): A solution of PPh_3 (70 mg, 0.27 mmol) in methanol (10 mL) was added to 10 mL of a solution of $[Mo_3(PdCl)Se_4(H_2O)_9]^{3+}$ (25 mM, 0.25 mmol) in 4 M HCl.[17] The color of the solution rapidly turned to brown. Excess PPh_3 precipitated and was filtered off. Keeping the solution in an open vial for 2 days gave a crop of brown crystals which were filtered off and thoroughly washed with diethyl ether to remove any PPh_3. Electronic spectrum [λ_{max}, nm (ε, $M^{-1}cm^{-1}$ in $CHCl_3$)] 326 (10659), 473 (3588).

X-ray Crystallography: The data collection on **4** was performed with a Bruker Smart CCD diffractometer using graphite-monochromated Mo-$K\alpha$ radiation (λ = 0.71073 Å) with a nominal crystal-to-detector distance of 40 mm. A hemisphere of data was colleted based on three ω-scan runs (starting ω = –28°) at values φ = 0°, 90° and 180° with the detector at 2θ = 28°. At each of these runs, frames (606, 435 and 230, respectively) were collected at 0.3° intervals and 25 seconds per frame. The diffraction frames were integrated using SAINT, and corrected for absorption with the SADABS package. The data collection for **3** and **5** was performed on a Bruker–Nonius X8APEX CCD diffractometer using graphite-monochromated Mo-$K\alpha$ radiation (λ = 0.71073 Å) with a nominal crystal-to-detector distance of 37.5 mm. The data was colleted based on a full range φ-scan run (739 frames were collected at 0.5° intervals and 30 seconds per frame). The diffraction frames were integrated using the program SAINT package and corrected for absorption with SADABS.[39,40] The crystal parameters and basic information relating to the data collection and structure refinement for the three compounds are summarized in Table 3.

The positions of the heavy atoms were determined by direct methods and successive difference electron density maps using the SHELXTL 5.10 software package were calculated to locate the remaining atoms.[41] Refinement was performed by the full-matrix least-squares method based on F^2. All cluster atoms in compounds **3**, **4** and **5** were refined anisotropically except phenyl carbon atoms in compound **4**. Hydrogen atoms of the phenyl groups and water molecules were refined geometrically except for the water molecules in compound **4** which were not included in the refinement. Although the crystal quality of **4** was poor, the bond length analysis and the packing diagram enabled comparisons to be made.

CCDC-251550, -252539 and -252540 contain the supplementary crystallographic data for this paper (for **3**, **4** and **5**, respectively).

A Rearrangement of Azobenzene upon Interaction with an Aluminum(I) Monomer LAl {L = HC[(CMe)(NAr)]$_2$, Ar = 2,6-*i*Pr$_2$C$_6$H$_3$}

Hongping Zhu,[a] Jianfang Chai,[a] Hongjun Fan,[b] Herbert W. Roesky,*[a] Umesh N. Nehete,[a] Hans-Georg Schmidt,[a] and Mathias Noltemeyer[a]

Keywords: Aluminum / Azobenzene / N ligands / Rearrangement

Reaction of LAl (**1**) or [LAl{η^2-C$_2$(SiMe$_3$)$_2$}] (**2**) {L = HC[(CMe)(NAr)]$_2$, Ar = 2,6-*i*Pr$_2$C$_6$H$_3$} with azobenzene affords a five-membered ring compound [LAl{N(H)-*o*-C$_6$H$_4$N(Ph)}] (**3**). In the formation of **3** a three-membered intermediate [LAl(η^2-N$_2$Ph$_2$)] (**A**) is suggested by a [1 + 2] cycloaddition reaction; **A** is not stable and further rearranges to **3**. DFT calculations on similar compounds with modified L′ {L′ = HC[(CMe)(NPh)]$_2$} show that the complexation energy of the reaction of L′Al with azobenzene to form [L′Al(η^2-N$_2$Ph$_2$)] is about –39 kcal mol^{-1}, and the best estimate of the energy difference between [L′Al(η^2-N$_2$Ph$_2$)] and [L′Al{N(H)-*o*-C$_6$H$_4$N(Ph)}] is –76 kcal mol^{-1}.

Introduction

The reactions of Group 13 metal(I) tetramers (RM)$_4$ (R = organic group, M = Al, Ga, In) with unsaturated molecules [H$_2$C=C(Me)–C(Me)=CH$_2$, PhC(O)–C(O)Ph, RN=C(H)–C(H)=NR, R = Me, *i*Pr][1–3] allow the trapping of the corresponding monomer RM, and are also an interesting oxidative addition of compounds with unsaturated bonds to low-valent metal centers.[4] This leads to heterocyclic compounds containing novel heavier main-group elements that have potential applications in pharmaceutical, agrochemical, and materials science.[5] We have recently prepared the aluminum(I) monomer LAl {**1**, L = HC[(CMe)(NAr)]$_2$, Ar = 2,6-*i*Pr$_2$C$_6$H$_3$}, which has a singlet carbene character.[6] The reductive coupling reaction of LAlI$_2$ with potassium in the presence of alkynes follows a [1 + 2] cycloaddition pathway to yield the aluminacyclopropene [LAl{η^2-C$_2$(R)(R′)}] (R = R′ = SiMe$_3$, Ph; R = Ph, R′ = SiMe$_3$).[7] A direct coupling reaction between LAl and alkyne (Me$_3$SiC≡CC≡CSiMe$_3$) is subsequently realized to form [LAl{η^2-C$_2$(SiMe$_3$)(C≡CSiMe$_3$)}].[8] In this context, we are interested in the interaction of the Al^I center with compounds containing an N=N double bond. The reaction of **1** or [LAl{η^2-C$_2$(SiMe$_3$)$_2$}] (**2**) with azobenzene unexpectedly resulted in the formation of the five-membered ring complex [LAl{N(H)-*o*-C$_6$H$_4$N(Ph)}] (**3**). Compound **3** contains an N(H)-*o*-C$_6$H$_4$N(Ph) moiety which is formed by an isomerization of azobenzene. Obviously, a rearrangement of azobenzene is occurring upon interaction with LAl.

Results and Discussion

Upon stirring of a toluene solution of **1** and azobenzene at elevated temperature (80 °C) for 5 h, the red color changed to orange. Partial removal of the solvent in vacuo and addition of *n*-hexane led to the crystallization of **3**, at 4 °C, as orange crystals in good yield. An alternative route to **3** was investigated by treating **2** with azobenzene in the temperature range from –50 °C to room temperature. The result indicated that **2** could be used as a good precursor for **1**.

Compound **3** is thermally stable, as indicated by its high melting point (260–261 °C) and its most intense molecular ion peak {*m*/*z* (%) = 626 (100) [M$^+$]} found in the EI mass spectrum. Complex **3** has been fully characterized by spectroscopic, analytical, and X-ray single-crystal measurements.

The molecular structure of **3** is shown in Figure 1. The central Al atom is involved as part of two fused five- (AlN$_2$C$_2$) and six-membered (AlN$_2$C$_3$) rings. The corresponding AlN$_4$ core appears in a distorted tetrahedral geometry. The Al–N bond lengths within the AlN$_2$C$_2$ ring are 1.807(2) Å [Al–N(H)] and 1.847(1) Å [Al–N(Ph)], and are similar to those of the AlN$_4$ ring complex [1.815(2), 1.851(2) Å].[9] The Al–N$_{\beta\text{-diketiminato}}$ bond lengths [1.893(1) and 1.862(1) Å] fall in the range [1.874(1)–1.959(3) Å] observed for other four-coordinate (β-diketiminato)aluminum compounds,[7,10] although one bond is a little shorter than these values. The AlN$_2$C$_2$ ring is nearly planar (Δ = 0.0719 Å) and this planar character can be extended to the

adjacent disubstituted phenyl group (Δ = 0.0816 Å). It is interesting to note that, within the AlN_2C_2 ring, the C(31)–C(36) bond [1.429(2) Å] is longer than the remaining ones of the phenyl ring [1.382(2)–1.393(2) Å]. This obviously contributes to the AlN_2C_2 ring formation. The phenyl groups involved in different structural environments [disubstituted C_6H_4, N(Ph), Ar] exhibit diverse resonances for their aromatic protons in the ^1H NMR spectrum of **3**. An unambiguous assignment of the resonances was not possible. The NH proton resonates at δ = 3.06 (s) ppm and in the IR spectrum the absorption at 3220 cm^{-1} is assignable to ν_{NH}.

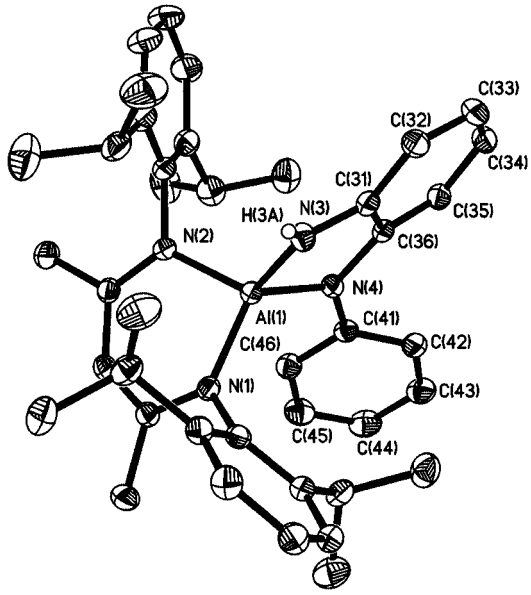

Figure 1. Molecular structure of compound **3**. The hydrogen atoms of the C–H bonds have been omitted for clarity. Selected bond lengths [Å] and angles [°]: Al(1)–N(1) 1.862(1), Al(1)–N(2) 1.893(1), Al(1)–N(3) 1.807(2), Al(1)–N(4) 1.847(1), N(3)–C(31) 1.386(2), C(31)–C(36) 1.429(2), C(36)–N(4) 1.420(2); N(1)–Al(1)–N(2) 97.68(6), N(3)–Al(1)–N(4) 90.39(6), Al(1)–N(3)–C(31) 109.86(10), N(3)–C(31)–C(36) 115.57(14), C(31)–C(36)–N(4) 113.40(10), C(36)–N(4)–Al(4) 108.44(10).

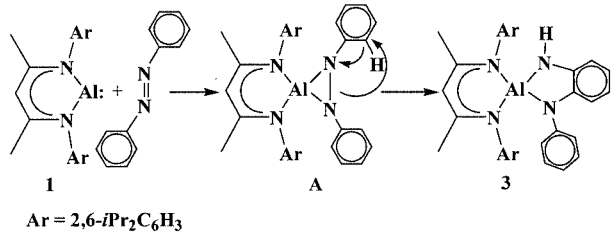
The reaction of **1** with azobenzene may initially proceed through an [LAl(η^2-N_2Ph_2)] (**A**) intermediate, which is formed by a [1 + 2] cycloaddition reaction. **A** is not stable due to the highly strained, metal-containing, three-membered AlN_2 ring, and therefore rearranges by cleaving the N–N bond, with migration of a hydrogen atom from the *ortho* position of one adjacent phenyl ring to yield **3** (Scheme 1). Compounds with similar structures to **A** are known for transition and lanthanide metals, for which different electronic interaction modes (π-bonds and one-electron transfer) have been discussed.[11–13] A three-membered AlN_2 heterocycle bearing an exocyclic N=C double bond at one of the two N atoms has also been reported.[14] Correspondingly, an easy cleavage of the N–N bond and the rearrangement of the adjacent *ortho*-phenyl hydrogen atom of azobenzene have also been observed in the reaction of an FeH-containing active site with azobenzene,[15,16] and in a cyclometalation[17,18] and a substitution[19] reaction.



Scheme 1. Proposed formation of **3** from the reaction of **1** and PhNNPh.

A further insight into this proposed mechanism can be gained from theoretical calculations.[20] The computed results show that the complexation energy of the initial reaction of L′Al with azobenzene to form [L′Al(η^2-N_2Ph_2)] {L′ is HC[(CMe)(NPh)]$_2$ for simplicity of calculation} is about –39 kcal mol^{-1}. This indicates a reasonable possibility that **A** is an intermediate in the reaction of **1** with azobenzene. The value of –39 kcal mol^{-1} is even lower than that calculated for the complexation energy of LAl with alkyne (ca. –21 kcal mol^{-1}) using the same method.[10] When [L′Al(η^2-N_2Ph_2)] is further converted into [L′Al{N(H)-*o*-C_6H_4N(Ph)}], a best estimate of the energy difference between these two isomers is –76 kcal mol^{-1}. This suggests an energetically favored stable rearrangement, and is also in agreement with the rearrangement of a three- to a five-membered ring. Furthermore, the D_{298}(Al–η^2-N_2) value is comparable to that of the Al–N bond strength in donor–acceptor $H_3Al{\cdot}NH_3$ species predicted by ab initio studies with a zero-point vibrational energy correction [D_{298}(Al–N) = 26 kcal mol^{-1}].[21] This implies a reasonably strong Al–η^2-N_2 bonding. Therefore, the cleavage of the corresponding N–N bond in the rearrangement of **A** to **3** is highly favored, although no such bond dissociation energy data are available for comparison.[22]

Conclusions

In summary, we have investigated the reaction of aluminum(I) monomer LAl (**1**) with azobenzene. The formation of a five-membered AlN_2C_2 ring containing product **3** is different to the [1 + 2] cycloaddition product formed in the reaction of LAl with alkyne, and indicates an interesting rearrangement of azobenzene via a possible three-membered AlN_2 intermediate (**A**) upon interaction with LAl.

Experimental Section

General: All manipulations were carried out under purified nitrogen using Schlenk techniques. The solvents were dried by standard methods. Chemicals were purchased from Aldrich or Fluka and were used as received. LAl (**1**)[6] and [LAl{η^2-$C_2(SiMe_3)_2$}] (**2**)[7] were prepared as described in the literature. Elemental analyses were performed by the Analytisches Laboratorium des Instituts für Anorganische Chemie der Universität Göttingen. ^1H (300.13 MHz) and ^{13}C (125.76 MHz) NMR spectra were recorded with a Bruker AM 300 spectrometer and IR spectra with a Bio-Rad Digilab FTS-7 spectrometer. EI mass spectra were recorded with a Finnigan

MAT 8230 or a Varian MAT CH5 instrument. Melting points were measured in sealed glass tubes and are not corrected.

Synthesis of [LAl{N(H)-*o*-C_6H_4N(Ph)}] (3). Method A: A toluene solution (30 mL) of LAl (**1**, 0.22 g, 0.5 mmol) and PhNNPh (0.09 g, 0.5 mmol) was stirred and heated slowly to 80 °C for 5 h. The color of the solution changed from red to orange. The volume of the solution was reduced in vacuo (ca. 10 mL) and *n*-hexane was added (10 mL). Upon keeping this solution at 4 °C for one week, orange X-ray quality crystals of **3** were obtained (0.15 g) and collected. The mother liquor was concentrated again (ca. 4 mL) and *n*-hexane added (8 mL). Another crop of orange crystals (0.10 g) was obtained by keeping the solution at –26 °C for 24 h. Total yield: 0.25 g (81%). M.p. 260–261 °C. ^{1}H NMR (300.13 MHz, C_6D_6, 298 K): δ = 0.90 [d, $^3J_{H,H}$ = 6.8 Hz, 2×3 H, CH(CH_3)$_2$], 0.92 [d, $^3J_{H,H}$ = 6.8 Hz, 2×3 H, CH(CH_3)$_2$], 1.07 [d, $^3J_{H,H}$ = 6.8 Hz, 2×3 H, CH(CH_3)$_2$], 1.23 [d, $^3J_{H,H}$ = 6.8 Hz, 2×3 H, CH(CH_3)$_2$], 1.47 (s, 2×3 H, β-CH_3), 3.05 [sept, $^3J_{H,H}$ = 6.8 Hz, 2×1 H, CH(CH$_3$)$_2$], 3.06 (s, 1 H, NH), 3.14 [sept, $^3J_{H,H}$ = 6.8 Hz, 2×1 H, CH(CH$_3$)$_2$], 5.12 (s, 1 H, γ-CH), 6.31–6.34 (m, 1 H), 6.58–6.66 (m, 2 H), 6.82–6.92 (m, 3 H), 6.94–7.02 (m, 4 H), 7.22–7.30 (m, 4 H), 7.48–7.52 (m, 15 H, Ar-H and Ph-H) ppm. ^{13}C{^{1}H} NMR (125.77 MHz, C_6D_6, 298 K): δ = 23.4, 24.2, 24.5, 24.9, 25.1, 28.3, 29.2 [CH(*C*H$_3$)$_2$, β-*C*H$_3$], 99.2 (γ-*C*), 112.3, 114.0, 115.1, 118.8, 124.0, 125.1, 127.9, 128.2, 129.0, 139.5, 143.1, 143.7, 145.3, 148.8 (Ar-*C*, Ph-*C*), 171.5 (*C*N) ppm. IR (Nujol mull): $\tilde{\nu}$ = 3220 (NH) cm^{-1}. EI-MS: *m*/*z* (%) = 626 (100) [M$^+$]. $C_{41}H_{51}AlN_4$ (626.87): calcd. C 78.56, H 8.20, N 8.14; found C 78.23, H 8.18, N 8.24. **Method B:** A toluene solution (5 mL) of PhNNPh (0.18 g, 1 mmol) was added to a toluene solution (20 mL) of [LAl{η^2-C_2(SiMe$_3$)$_2$}] (**2**; 0.62 g, 1 mmol) at –50 °C. The mixture was allowed to warm to room temperature whilst being stirred. The solution changed from black to orange. After continuing the stirring for 12 h, the solution was concentrated to dryness in vacuo and washed with *n*-hexane (10 mL) to afford an orange crystalline solid, which was characterized as **3** by m.p. and EI mass measurements.

X-ray Structure Determination and Refinement: The crystallographic data for compound **3** were collected with a Stoe IPDS II array detector system with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The structure was solved by direct methods (SHELXS-96)[23] and refined against F^2 using SHELXL-97.[24] All non-hydrogen atoms were located by difference Fourier synthesis and refined anisotropically; hydrogen atoms were included using the riding model with U_{iso} tied to the U_{iso} of the parent atoms. A summary of cell parameters, data collection, and structure solution and refinement is given in Table 1. CCDC-253931 (**3**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Synthesis and Structure of a 2,4-Unsubstituted *cis*/*trans*-1,3-Disilacyclobutane by Dehydrofluorination of a Highly Hindered Fluorosilane

Rudolf Pietschnig,*[a] Stefan Spirk,[a] Ferdinand Belaj,[a] and Klaus Merz[b]

Keywords: Dimerization / Silanes / Silenes / Silicon / Strained molecules

The preparation, molecular structure, and metalation behavior of a sterically highly congested fluorosilane (*t*BuTipMeSiF) are described. This silane is subjected to dehydrofluorination under thermally mild conditions. A *C*-unsubstituted transient intermediate – either the silene or the corresponding silenoid – is generated in a metalation/elimination sequence at low temperatures, and this intermediate dimerizes to give the corresponding 1,3-disilacyclobutane exclusively, even in the presence of a trapping agent. The significant steric hindrance in the starting fluorosilane and the final 1,3-disilacyclobutane is corroborated by their crystal structures.

Introduction

Since the preparation of the first stable silenes a broad variety of methods to synthesize such compounds has been developed.[1,2] *C*-Substituted transient and stable silenes can be prepared under especially mild conditions by a metalation/elimination sequence. For this approach, all so-far-known examples carry activating silyl groups at the carbon atom designated for metalation. Besides steric protection of the resulting silene, these substituents also provide an increase of the acidity of the neighboring C–H unit due to the α-silyl effect.[3] Alternatively, α-lithiohalosilanes have also been prepared by conjugate addition of organolithium reagents to halovinylsilanes. Since the first reaction of this type, described by Jones and Lim in 1977,[4,5] many other transient silenes have been synthesized by this route, particularly by Auner and coworkers,[6] but also by some other authors.[7] Despite the use of more and more bulky substituents, all these silenes are unstable at room temperature and lead to dimeric 1,3-disilacyclobutanes (head-to-tail dimerization), except for the stable dimesitylneopentylsilene.[8] Since in these silenes the multiply bonded carbon atom also carries at least one substituent, we were interested in whether the scope of the metalation/elimination technique could be extended to silenes without any activating or protecting groups at the carbon end of the silene unit. In this contribution, we describe the preparation and structure of a sterically crowded fluorosilane which should be a suitable precursor for a *C*-unsubstituted α-lithiofluorosilane. Upon metalation, the corresponding transient silenoid is formed, which subsequently eliminates LiF. The resulting silene is unstable and dimerizes to the corresponding 1,3-disilacyclobutane. The precursor for metalation as well as the resulting *cis*-1,3-disilacyclobutane have been characterized spectroscopically and by X-ray diffraction on single crystals.

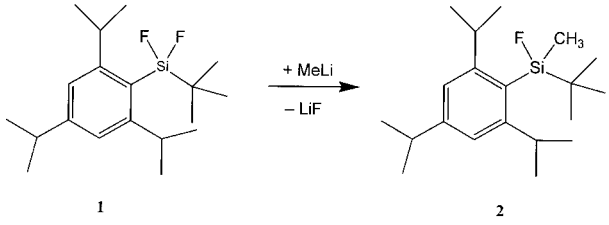
Results and Discussion

In the reaction of sterically encumbered halosilanes with organolithium compounds direct nucleophilic halide displacement competes with lithiation of activated sites such as the α-position. Therefore, the steric protection of the silicon center in fluorosilanes is crucial to favor metalation over nucleophilic displacement. To accomplish the formation of a silenoid by direct deprotonation of a methyl group adjacent to a fluorosilyl, we synthesized a suitable precursor starting from *t*BuTipSiF_2 (**1**, Tip = 2,4,6-triisopropylphenyl).[9,10] Since no C–H bonds are available in the α-position to the silicon atom in this fluorosilane, we selectively introduced a methyl group as the designated site for further metalation. The methyl group can be introduced in a straightforward manner by treating **1** with methyllithium at low temperature to cleanly afford **2** (Scheme 1). The NMR spectra of **2** show a ^{19}F resonance at δ = –160.5 ppm, and the ^{29}Si signal at δ = 25.0 ppm is split into a doublet with a $^1J_{Si,F}$ coupling constant of 287 Hz (Figure 1). We were able to obtain a crystal structure of **2** which illustrates the steric situation within the molecule (Table 1).

Even though **1** and **2** are isoelectronic, the steric situation around the silicon center appears to be even more congested in **2**. Accordingly, the Si(1)–F(1) bond length increases from 1.595(2) Å in **1**[9] to 1.625(2) Å in **2** and is even longer than in the closely related compound *i*Pr_2TipSiF.[11] Also, the silicon–carbon distances for the *tert*-butyl and the



Scheme 1. Synthesis of **2**.

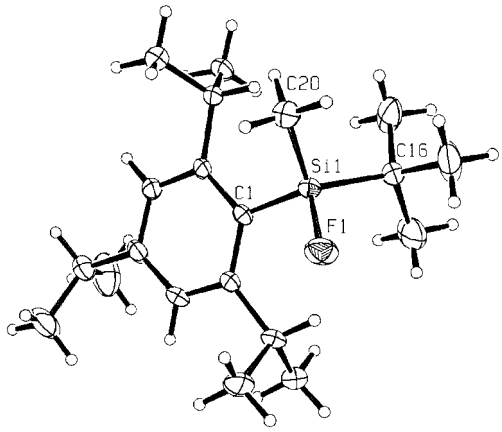


Figure 1. Molecular structure of **2** in the solid state.

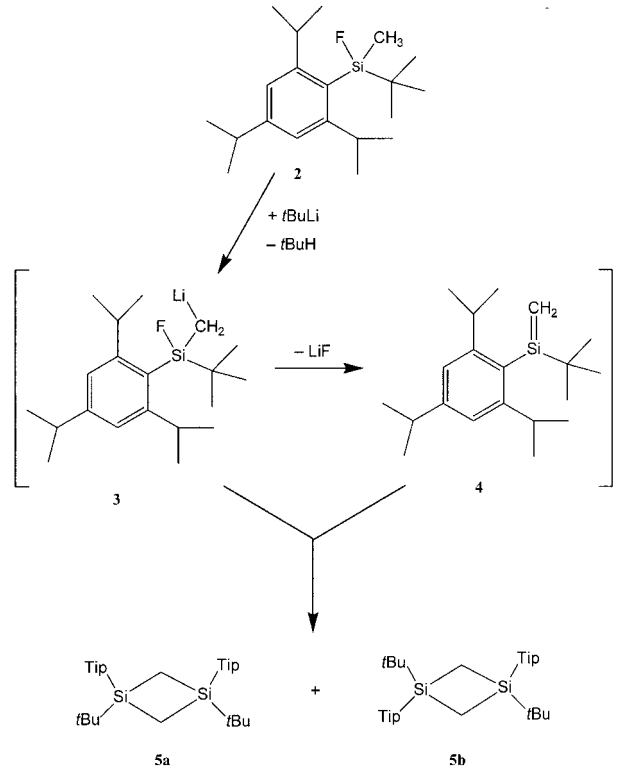
Table 1. Selected bond lengths [Å] and angles [°] for **2**.

Si(1)–F(1)	1.625(2)	F(1)–Si(1)–C(20)	101.17(14)
Si(1)–C(20)	1.866(4)	F(1)–Si(1)–C(16)	106.18(14)
Si(1)–C(16)	1.883(3)	F(1)–Si(1)–C(1)	107.42(12)
Si(1)–C(1)	1.892(4)	C(20)–Si(1)–C(16)	111.27(16)
C(16)–Si(1)–C(1)	114.09(15)	C(20)–Si(1)–C(1)	115.36(16)

2,4,6-triisopropylphenyl group in **2** are, at 1.883(3) and 1.892(4) Å, respectively, longer than in **1**, while the bond to the methyl carbon atom is slightly shorter [1.866(4) Å]. Surprisingly, the bond between Si(1) and the aryl carbon atom C(1) is longer than the corresponding Si–C_{alkyl} distances of the molecule. The steric repulsion of the substituents at silicon is also obvious from the angles between the groups adjacent to this atom. Hence, the C–Si–C angles are, at 111.27(16)°, 114.09(15)°, and 115.36(16)°, larger than the corresponding F–Si–C angles [101.17(14)°, 106.18(14)°, and 107.42(12)°].

The sterically congested situation in **2** combined with the absence of activated C–H bonds other than in the methyl group makes this fluorosilane an ideal starting material for the generation of a Li–F silenoid without further substituents on carbon. To achieve metalation of the methyl group, we treated **2** with *tert*-butyllithium at low temperature (–100 °C). No reaction could be detected in apolar solvents such as pentane, even when the mixture was warmed to room temperature. In contrast, the onset of a reaction can be observed by the formation of a precipitate along with a color change on addition of stoichiometric amounts of coordinating reagents such as TMEDA or THF, even at –100 °C. After warming to room temperature, the corresponding 1,3-disilacyclobutane (**5**) was obtained as the final product (Scheme 2).



Scheme 2. Metalation of **2** and formation of **5** (Tip = 2,4,6-triisopropylphenyl).

In the ^{29}Si NMR spectrum **5** shows a resonance for each of the two isomers [*cis* (**5a**)/*trans* (**5b**)] which appear very close to each other at δ = 9.2 and 9.3 ppm. The ratio of the isomers is approximately 1:1, which in related cases has been found to be indicative of the formation of the 1,3-disilacyclobutane from intermediate silenes rather than silenoids.[12,13] Upon recrystallization we were able to obtain crystalline samples of the *cis*-isomer of **5** that were suitable for analytical purposes and X-ray diffraction.

The molecular structure of **5** proves the presence of a central 1,3-disilacyclobutane system, where the ring carbon atoms are unsubstituted while the silicon atoms carry sterically demanding 2,4,6-triisopropylphenyl and *tert*-butyl groups (Figure 2). The internal angles of the 1,3-disilacyclobutane ring are all approximately 90°, with smaller values found at the silicon atoms [88.31(10)°, 88.37(10)°, 90.86(10)°, and 91.28(11)°] (Table 2).

The ring-puckering angle [11.79(11)°], which is defined by the dihedral angle of the two Si–Si–C planes of the ring, falls well within the range of such angles in other structurally characterized 1,3-disilacyclobutanes (0–25.5°).[14–17] As a consequence of the steric repulsion of the substituents at the silicon atoms, the Si–C distances within the ring [1.901(2)–1.909(2) Å] are the longest observed so far for 1,3-disilacyclobutanes without substituents at the ring carbon atoms. According to previous studies long Si–C bond lengths in the ring correspond to reduced puckering angles.[18] The steric pressure at the silicon atoms is also

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

obvious from the exocyclic Si–C distances, which are significantly longer than standard Si–C bond lengths.[19] Therefore, as expected, the Si–C_{aryl} distances [1.907(2) and 1.909(2) Å] are slightly shorter than the Si–C_{alkyl} distances [1.932(3) and 1.933(3) Å]. The solution NMR spectra corroborate the steric pressure within **5** derived from the static picture of the crystal structure. Hence, in the ^{13}C NMR spectra the CH_3 units of the isopropyl groups in the *ortho* position of the Tip substituent are not equivalent at room temperature. Obviously, the rotation by which they would become equivalent is prevented by the proximity of the *tert*-butyl group. As a consequence of the puckered structure of the disilacyclobutane ring, the dihedral angles between the methylene carbon atoms and the transannular methylene hydrogen atoms differ significantly [C(1)–Si(1)–C(2)–H(21) = 124.6°; C(1)–Si(1)–C(2)–H(22) = –108.1°]. Therefore, in the proton-coupled ^{13}C NMR spectra the coupling of only one of these protons with the carbon atom is observed ($^3J_{C,H}$ = 4.9 Hz) apart from the coupling with the directly bonded chemically inequivalent methylene protons ($^1J_{C,Ha}$ = 117.9, $^1J_{C,Hb}$ = 121.7 Hz).

Although we were unable to directly observe any of the intermediates discussed in the formation of **5**, this process is likely to proceed by the initial formation of silenoid **3**, which could either dimerize to yield **5** directly, or eliminate LiF to form silene **4** which, on dimerization, would yield the same product (**5**). As is known from the literature, the ratio of the *cis*/*trans* isomers of the resulting 1,3-disilacyclobutane can be used as an indicator of which of the above mechanisms is dominant.[12,13] According to these findings, the 1:1 ratio of the isomers found in our experiments should be indicative of the formation of **5** from transient silene **4**. In contrast, the occurrence of a precipitate, along with the color change observed on addition of stoichiometric amounts of THF at low temperature, could be interpreted as a hint for the formation of silenoid **3**. The identity of this precipitate was elucidated with a trapping experiment with a reactive chlorophosphane. On addition of the latter at low temperature the precipitate disappears. However, in the ^{31}P NMR spectra the resonance of the resulting product indicates that the initially formed precipitate is not silenoid **3** but rather an etherate of butyllithium.[20]

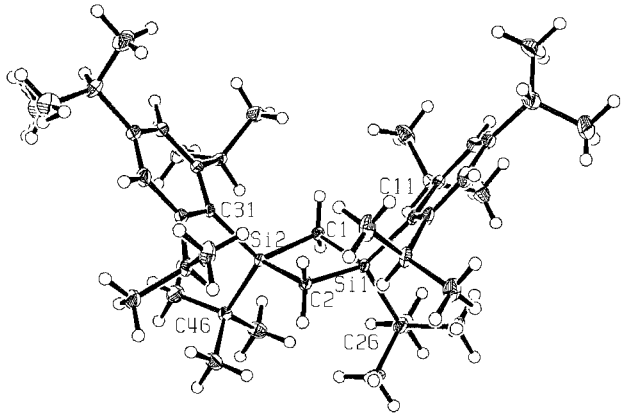


Figure 2. Molecular structure of **5a** in the solid state.

Conclusions

Compound **2** is a sterically hindered fluorosilane that can be metalated selectively in the α-position despite of the absence of activating groups. The resulting Li–F silenoid carries no further substituents at the carbon end of the metalated unit and spontaneously eliminates LiF below room temperature. Due to insufficient steric protection, transient silenoid **3** or silene **4** dimerize to the corresponding 1,3-disilacyclobutane. The ratio of the *cis* and *trans* isomers indicates formation from the silene rather than from the silenoid, although no direct evidence for the silene could be found. The sterically highly congested silenoid precursor **2** and the final product **5** have been fully characterized and their crystal structures determined. From their geometric parameters, as well as from spectroscopic data, the steric hindrance within both molecules is evident. However, to accomplish the stabilization of a C-unsubstituted silene a further increase of the steric congestion at the silicon end of the unsaturated unit will be necessary.

Experimental Section

All chemical experiments were performed under argon using standard Schlenk techniques or a glovebox. Solvents other than $CDCl_3$ were dried with sodium/potassium alloy and stored under argon.

^{1}H, ^{13}C, ^{19}F, and ^{29}Si NMR spectra were recorded on Bruker AMX 360 or Bruker Avance DRX 500 instrument. Mass spectra were measured on a Masslab VG 12-250 by the electron impact ionization technique. Melting points were determined on a Mettler FP 61 in glass capillaries. *tert*-Butyldifluoro(2,4,6-triisopropylphenyl) silane [tBu(2,4,6-iPrC_6H_2)SiF_2] was prepared according to literature procedures.[9,10] Other chemicals were obtained from different chemical suppliers and used as received.

Synthesis of *tert*-Butylfluoro(methyl)(2,4,6-triisopropylphenyl)silane (2): A solution of MeLi (1.6 M in diethyl ether; 8.8 mL, 14 mmol) was added, at –100 °C, to a solution of tBu(2,4,6-iPrC_6H_2)SiF_2 (4.17 g, 12.8 mmol) in diethyl ether (40 mL), while stirring. The mixture was warmed to room temperature; the precipitate that formed at –80 °C redissolved at higher temperatures. Stirring was continued for 16 h, after which the solvent was removed in vacuo. The residue was extracted with hexanes (2 × 30 mL) and the insoluble precipitate (LiF) was separated by filtration. The filtrate was recovered and removal of the solvent in vacuo and recrystallization from chloroform yielded **2** as colorless, deliquescent crystals (4.09 g, 98.9%); m.p. 49.4 °C. ^{1}H NMR ($CDCl_3$, 360 MHz, 25 °C): δ = 7.08 (s, 2 H), 3.23 (sept, $^{3}J_{H,H}$ = 6.6 Hz, 1 H), 2.90 (sept, $^{3}J_{H,H}$ = 7.0 Hz, 2 H), 1.29 (d, $^{3}J_{H,H}$ = 7.0 Hz, 12 H), 1.26 (d, $^{3}J_{H,H}$ = 6.6 Hz, 6 H), 1.08 (s, 9 H), 0.57 (d, $^{3}J_{H,F}$ = 10.3 Hz, 3 H) ppm. ^{13}C NMR ($CDCl_3$, 91 MHz, 25 °C): δ = 156.58 (s), 150.54 (s), 127.04 (d, $^{2}J_{C,F}$ = 11.1 Hz), 121.70 (s), 34.12 (s), 33.84 (s), 26.63 (s), 25.61 (s), 23.74 (s), 20.12 (d, $^{2}J_{C,F}$ = 12.5 Hz), 0.16 (d, $^{2}J_{C,F}$ = 18.7 Hz) ppm. ^{19}F NMR ($CDCl_3$, 471 MHz, 25 °C): δ = –160.5 (q, $^{3}J_{F,H}$ = 9.9 Hz) ppm. ^{29}Si NMR ($CDCl_3$, 72 MHz, 25 °C): δ = 25.0 (d, $^{1}J_{Si,F}$ = 287 Hz) ppm. MS: *m*/*z* (%) = 322.2494 (high resolution: Δ = 0.89 ppm) (8) [M^+], 265.1 (100) [M^+ – tBu], 245.1 (12) [M^+ – tBu– HF], 187.1 (10), 77.0 (19). $C_{20}H_{35}FSi$ (322.58): calcd. C 74.47, H 10.94; found C 74.41, H 11.25.

Synthesis of *cis*/*trans*-1,3-Di-*tert*-butyl-1,3-bis(2,4,6-triisopropylphenyl)-1,3-disilacyclobutane (5): A solution of **2** (0.85 g, 2.6 mmol) in pentane (10 mL) was cooled to –100 °C and 1.7 mL (2.9 mmol) of a solution of tBuLi (1.7 M in pentane) was added while stirring. Upon addition of THF (0.74 mL, 9 mmol) the mixture turned yellow and a precipitate was observed. The temperature was maintained for 2 h and the mixture was then slowly warmed to room temperature. Stirring was continued for 12 h, after which the solution was concentrated under reduced pressure to obtain a sample suitable for the recording of ^{29}Si NMR spectra [^{29}Si NMR (THF/$CDCl_3$, 72 MHz, 25 °C): δ = 9.3, 9.2 ppm]. After complete removal of the solvent in vacuo, the residue was extracted with hexanes (2 × 30 mL) and the insoluble precipitate (LiF) was separated by filtration. The filtrate was recovered and removal of the solvent in vacuo and recrystallization from acetone yielded *cis*-**5** as colorless crystals (0.7 g, 44.0%); m.p. 243 °C (dec.). ^{1}H NMR ($CDCl_3$, 360 MHz, 25 °C): δ = 6.94 (s, 4 H), 3.26 (sept, $^{3}J_{H,H}$ = 7.0 Hz, 4 H), 2.84 (sept, $^{3}J_{H,H}$ = 7.0 Hz, 2 H), 1.25 (d, $^{3}J_{H,H}$ = 7.0 Hz, 24 H), 1.19 (d, $^{3}J_{H,H}$ = 7.0 Hz, 12 H), 1.15 (s, 18 H), 0.44 (s, 4 H) ppm. ^{13}C NMR ($CDCl_3$, 91 MHz, 25 °C): δ = 154.75, 149.18, 133.82 ($^{1}J_{C,Si}$ = 45.8 Hz), 121.57, 34.00, 33.79, 30.59, 25.84, 25.45, 23.75, 17.94 ($^{1}J_{C,Si}$ = 32.6 Hz), 8.12 ($^{1}J_{C,Si}$ = 36.8 Hz) ppm. ^{29}Si NMR ($CDCl_3$, 72 MHz, 25 °C): δ = 9.3 ppm. MS: *m*/*z* (%) = 604.5 (3) [M^+], 547.5 (100) [M^+ – tBu], 302, (25) [M^+/2], 245.1 (15) [M^+/2 – tBu], 57.1 (8) [tBu$^+$]. $C_{40}H_{68}Si_2$ (605.14): calcd. C 79.39, H 11.33; found C 78.85, H 11.70.

Trapping Experiments: The procedure for the synthesis of **5** was followed to the point where a precipitate occurred on addition of the lithiating reagent. After addition of chlorobis(diethylamino)-phosphane as trapping reagent, at –70 °C, we observed no conversion of the starting fluorosilane **2** in the NMR spectra. The trapping reagent, in contrast, was completely converted into *tert*-butylbis(diethylamino)phosphane under these conditions, as is evident from its ^{31}P NMR chemical shift.

Crystallographic Details for 2: A colorless crystal of **2** with dimensions 0.1 × 0.2 × 0.1 mm^3 was coated in paraffin oil, mounted on a glass fiber, and placed under a cold stream of nitrogen. All the measurements were performed using graphite-monochromated Mo-K_α radiation at 213 K. A total of 3201 reflections were collected (θ_{max} = 23°), of which 2238 were unique (R_{int} = 0.0162). Additional experimental details are given in Table 3. The structure was solved by direct methods (SHELXS-97) and refined by full-matrix least-squares techniques against F^2 (SHELXL-97).[21,22] The non-hydrogen atoms were refined with anisotropic displacement parameters without any constraints. For 199 parameters final R indices of R = 0.0539 and $wR2$ = 0.1553 (GOF = 1.102) were obtained.

Crystallographic Details for 5a: A colorless crystal of **5a** with dimensions 0.15 × 0.10 × 0.10 mm^3 was coated in paraffin oil, mounted on a glass fiber, and placed under a cold stream of nitrogen. All the measurements were performed with graphite-monochromated Mo-K_α radiation at 100 K. A total of 8923 reflections were collected (θ_{max} = 26.0°), of which 7606 were unique (R_{int} = 0.0472), with 5689 having $I > 2\sigma(I)$. The structure was solved by direct methods (SHELXS-97) and refined by full-matrix least-squares techniques against F^2 (SHELXL-97).[21,22] One methyl group was disordered over two positions (C41 and C51). The atoms C41 and C51 have site occupation factors of 0.454(18) and 0.546(18), respectively, and were isotropically refined with the constraint of equal bond lengths to C40. All other non-hydrogen atoms were refined with anisotropic displacement parameters without any constraints. The H atoms of the CH_2 groups were refined with common isotropic displacement parameters for the H atoms of the same group and idealized geometry with approximately tetrahedral angles and C–H distances of 0.99 Å. The C atoms of the phenyl rings were refined without any constraints. The H atoms were put at the external bisector of the C–C–C angle at a C–H distance of 0.95 Å and common isotropic displacement parameters were used for the H atoms of the same phenyl group. The H atoms of the tertiary C–H groups were refined with all X–C–H angles equal at

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

a C–H distance of 1.00 Å and with common isotropic displacement parameters for the H atoms of the tertiary C–H groups bonded to the same phenyl ring. The H atoms of the methyl groups were refined with common isotropic displacement parameters for the H atoms of the same group and idealized geometry with tetrahedral angles, enabling rotation around the X–C bond, and C–H distances of 0.98 Å. For 419 parameters final R indices of $R = 0.0600$ and $wR_2 = 0.1401$ (GOF = 1.042) were obtained. The largest peak in the difference Fourier map was 0.479 e Å^{-3}. CCDC-254269 (for **2**) and -254270 (for **5a**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Pyridine- and Imidazoledicarboxylates of Zinc: Hydrothermal Synthesis, Structure, and Properties

Partha Mahata[a] and Srinivasan Natarajan*[a]

Keywords: Luminescence / N ligands / Pi interactions / Zinc

The reaction of hetrocyclic dicarboxylic acids, such as pyridine-2,5-dicarboxylic acid and imidazole-4,5-dicarboxylic acid, under hydrothermal conditions in the presence of an appropriate zinc salt yields three new zinc coordination polymers $^{0}_{\infty}[\{Zn_2(H_2O)_4\}\{C_5H_3N(COO)_2\}_2]$ (**1**), $^{1}_{\infty}[\{Zn(C_{12}H_8N_2)\}\{C_5H_3N(COO)_2\}\cdot 0.5H_2O]$ (**2**), and $^{1}_{\infty}[\{Zn(C_{12}H_8N_2)\}\{C_3HN_2(COO)_2\}]$ (**3**). While **1** forms with a zero-dimensional molecular rectangular box structure, **2** and **3** have zig-zag one-dimensional chain structures. The Zn^{2+} ions are coordinated by both the carboxylate oxygen atoms and also by the nitrogen atoms of the heterocycles. The 1,10-phenanthroline molecules in **2** and **3** act as a secondary ligands and occupy the inter-chain spaces. The moderate hydrogen-bond interaction energy in **1** and the π···π interactions in **2** and **3** appear to play an important role for the structural stability. The structures of **2** and **3** appear to be related, even though they are formed with different carboxylic acids. All three compounds exhibit photoluminescence at room temperature.

Introduction

Research in the area of metal-organic frameworks (MOFs) exhibiting open structures continues to be interesting due to their many applications, both actual as well as potential.[1] Of the many MOF compounds investigated, those containing benzenecarboxylates constitute an important family[1–10] as they combine the principles of supramolecular chemistry along with favorable π···π interactions that give rise to fascinating crystal structures. The role of hydrogen bonding in metal-coordinated network structures is beginning to gain importance as it results in a large number of coordination polymers. Recently, the scope of the investigations on benzenecarboxylates has been enhanced by the use of heterocyclic carboxylic acids such as pyridine-, pyrazole-, and imidazolecarboxylic acids. These acids can act both as a multiple proton donor and acceptor and can use their carboxylate oxygen and nitrogen atoms, which are highly accessible to metal ions, to form interesting network structures. Thus, Lin and co-workers have employed pyridinecarboxylic acid to prepare a series of Zn^{2+} and Cd^{2+} coordination polymers using a molecular building-block approach.[11–14] Pyrazoledicarboxylates have also given rise to interesting network structures of varying dimensionality.[15–17] Although many polymeric complexes have been prepared employing heterocyclic carboxylates, previously uncharacterized compounds with novel crystal structures often emerge during hydrothermal synthetic conditions. We have combined the advantages of the hydrothermal method of synthesis and multifunctional carboxylic acids in the presence of 1,10-phenanthroline to form a large number of new inorganic coordination polymers.[18,19] In continuation of this theme, we have now synthesized three new Zn coordination polymers, namely $^{0}_{\infty}[\{Zn_2(H_2O)_4\}\{C_5H_3N(COO)_2\}_2]$ (**1**), $^{1}_{\infty}[\{Zn(C_{12}H_8N_2)\}\{C_5H_3N(COO)_2\}\cdot 0.5H_2O]$ (**2**), and $^{1}_{\infty}[\{Zn(C_{12}H_8N_2)\}\{C_3HN_2(COO)_2\}]$ (**3**), by employing pyridine- and imidazoledicarboxylic acids. Compounds **1** and **2** were prepared from pyridine-2,5-dicarboxylic acid, whereas **3** was prepared from imidazole-4,5-dicarboxylic acid. While **1** possesses a zero-dimensional structure with a rectangular molecular-box arrangement, **2** and **3** have one-dimensional structures and all the structures are stabilized by hydrogen-bonding and π···π interactions. In this paper we describe the synthesis, structure, and properties of these compounds.

Results and Discussion

The asymmetric unit of **1** consists of 30 non-hydrogen atoms, of which two zinc atoms are crystallographically independent (Figure 1). Both the Zn^{2+} ions have a distorted square-pyramidal geometry formed by two carboxylate oxygen atoms, two bonded water molecules and a nitrogen atom of the pyridine ring. An average distance of 2.0395 and 2.092 Å for the Zn–O and Zn–N bonds, respectively, results from this connectivity. The O/N–Zn–O/N bond angles are in the range 78.01(2)–156.2(2)°. There are two different pyridine-2,5-dicarboxylate anions present in the structure and all the carboxylate groups have only mono-

dentate connectivity with the Zn^{2+} cations. The bond lengths and angles associated with the pyridine-2,5-dicarboxylate anions are in the range expected for this type of bonding. The terminal Zn–O bonds formed by the oxygen atoms [O(1) and O(4) for Zn(1) and O(6)and O(8) for Zn(2)] are formally water molecules. The two proton positions observed in the difference Fourier map for each of these oxygen atoms also confirm this. Selected bond lengths and angles are listed in Table 1. The connectivity between Zn^{2+} and the pyridine-2,5-dicarboxylate anions gives rise to a zero-dimensional unique molecular box. Each molecular box consists of four Zn^{2+} cations and four carboxylate anions, as shown in Figure 2a. The terminal water molecules and the presence of terminal C–O bonds in **1** gives rise to a large number of significant O–H···O hydrogen bonds. The hydrogen-bond interactions between the molecular box units form an extended two-dimensional structure (Figure 2b and c). Both intra- and intermolecular box hydrogen bonds are observed in **1**; a complete list of these interactions is given in Table 2.

The asymmetric unit of **2** consists of 28 non-hydrogen atoms, of which only one Zn atom is crystallographically independent (Figure 3). The Zn^{2+} ions have a distorted octahedral geometry formed by three carboxylate oxygen atoms and three nitrogen atoms, two of which belong to the 1,10-phenanthroline ligand. The Zn–O and the Zn–N bonds have average values of 2.162 and 2.145 Å, respectively. The O/N–Zn–O/N bond angles are in the range 58.98(2)–164.70(2)°, thereby indicating the heavy distortion of the Zn^{2+} octahedra (ideal octahedral values are 90° and 180°). The two carboxylate units of the pyridine-2,5-dicarboxylate show differences in their connectivity with respect to the Zn^{2+} ions − one has a monodentate connectivity and the other a bis(didentate) connectivity. The bond lengths and angles associated with the carboxylate group have typical values. Selected bond lengths and angles are listed in Table 3. In **2**, the connectivity between Zn^{2+} and the pyridine-2,5-carboxylate units gives rise to one-dimensional zig-zag chains (Figure 4). The 1,10-phenanthroline molecules act as a ligand to the Zn^{2+} ions and occupy the inter-chain spaces, along with the lattice water, and contribute to the stability of **2** by forming favorable π···π interactions (Figure 4). The presence of these interactions gives rise to a channel-like structure in **2**. Unlike **1**, no significant hydrogen-bond interactions are observed in **2**.

The asymmetric unit of **3** consists of 26 non-hydrogen atoms, of which only one Zn atom is crystallographically independent (Figure 5). The Zn^{2+} ions have a distorted octahedral geometry formed by two carboxylate oxygen atoms and four nitrogen atoms, two of which belong to the 1,10-phenanthroline ligand and the other two to the imidazole ring. The Zn–O and Zn–N bonds have average values of 2.225 Å and 2.151 Å, respectively. The O/N–Zn–O/N bond angles are in the range 74.63(8)–171.54(8)°, thereby indicating distortion of the Zn^{2+} octahedra. Both the carboxylate groups of the imidazole-4,5-dicarboxylate have only monodentate connectivity with Zn^{2+} ions. The bond lengths and angles associated with the imidazole-4,5-dicarboxylate have typical values. Selected bond lengths and angles are given in Table 3. The connectivity between the Zn^{2+} and the imidazole-4,5-carboxylate units gives rise to one-dimensional zig-zag chains (Figure 6). The 1,10-phenanthroline molecules act as a ligand to the Zn^{2+} ions and occupy the inter-chain spaces (Figure 6).

Room-temperature solid-state photoluminescence studies performed on powdered samples are presented in Figure 7. Photoluminescence studies of coordination polymers of the type discussed here have been investigated in great detail during the past few years.[19–28] In our present study, we found that coordination polymers **1**–**3** all exhibit photoluminescence. Compound **1** exhibits a single broad emission band at 430 nm, whilst compounds **2** and **3** exhibit two peaks at about 375 nm and at 390 nm when excited at 337 nm. The emission peak at 430 nm for **1** and at about 375 nm for **2** and **3** can be assigned to the intraligand fluorescent emission, since the acid displays a rather weak emission (λ_{max} = 410 nm). The lifetime, τ, for the emissions are 0.016 and 0.018 ns for **2** and **3**, respectively. This indicates that the luminescence should be assigned to fluorescence. The peak at 390 nm observed for **2** and **3** can be assigned to intraligand emission from the 1,10-phenanthroline ligand.[28] Similar ligand-to-metal charge transfer (LMCT)

transitions have been observed in many metal-organic coordination polymers.[19–28] It is known that free 1,10-phenanthroline exhibits weak emission peaks at 425 and 445 nm in the solid state at room temperature (see Supporting Information). The enhancement and the blue shift of the luminescence of the 1,10-phenanthroline ligand compared to that of free 1,10-phenanthroline may, therefore, be attributed to the chelating effect of the 1,10-phenanthroline ligand to the Zn^{2+} ion. This effectively enhances the rigidity of the ligand and reduces the loss of energy by radiationless decay of the intraligand emission of the excited state. Similar blue-shifts involving rigid ligand molecules and coordination polymers have been observed before.[28–30] In addition, fluorescent emission of carboxylate ligands resulting

from the π* → n transition is very weak compared with that of the π* → π transition of the 1,10-phenanthroline ligand. The strongly electron-withdrawing carboxylate group results in a fluorescence quenching, so the carboxylate ligands hardly contribute to the fluorescent emission of the as-synthesized polymers. As can be seen, the main emission bands of **2** and **3** are located almost at the same position, but with differences in the band shapes, which has been attributed to the π* → π transition of the coordinated 1,10-phenanthroline ligand.[28–30] The differences in the band shape might also be due to the minor differences in the structural topologies of the two structures.

The three new compounds were obtained by employing hydrothermal methods. The compounds have zero- and one-dimensional structures. While **1** forms with a zero-dimensional molecular box structure, **2** and **3** are formed with zig-zag one-dimensional chain structures. However, all three compounds are related in a subtle way. While compound **2** is formed by adding 1,10-phenanthroline to the synthesis mixture of **1**, **3** is obtained by replacing pyridine-2,5-dicarboxylic acid with imidazole-4,5-dicarboxylic acid in the synthesis mixture of **2**. The secondary ligand, 1,10-phenanthroline, replaces the terminal water molecules in **1** and, during this process, the coordination environment of the Zn^{2+} ions also changes from distorted square-pyramidal (five-coordinate) to an octahedral one (six-coordinate). In addition, the coordination mode of the pyridine-2,5-dicarboxylate also changes from being a simple monodentate coordination in **1** to a combination of mono- and bis(didentate) in **2**. In **3**, however, the imidazole-4,5-dicarboxylate has

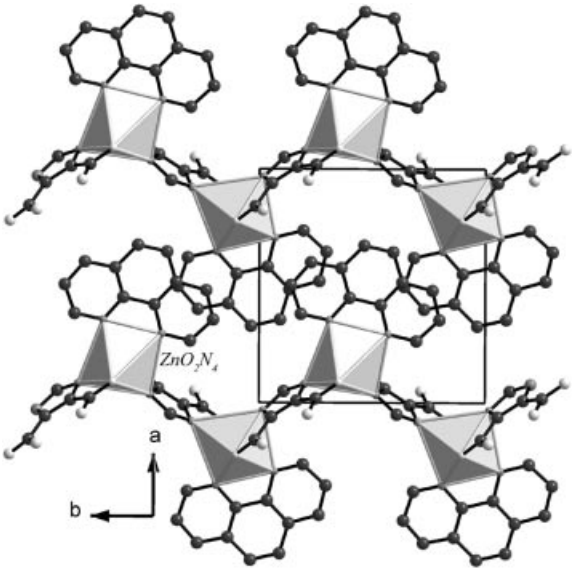

Figure 6. One-dimensional chains observed in **3** in the *ab* plane. Note that the 1,10-phenanthroline ligands occupy the inter-chain spaces and interact through π···π interactions (see text).

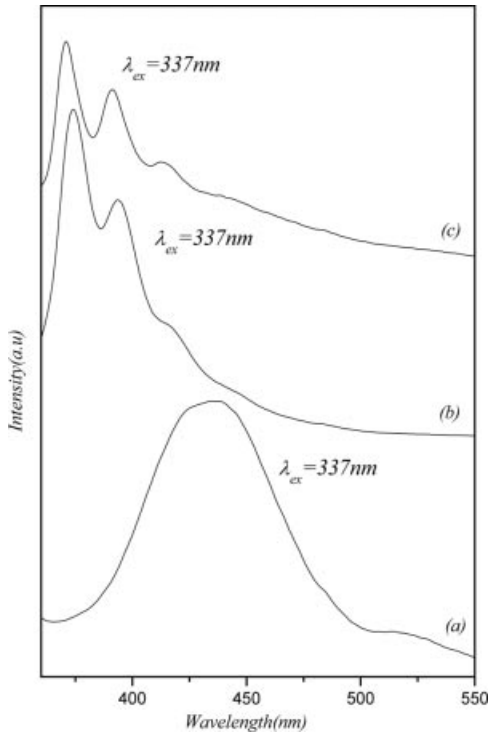

Figure 7. Emission spectra in the solid state at room temperature for (a) **1**, (b) **2**, and (c) **3**.

a simple monodentate connectivity with Zn^{2+} ions. The striking similarities between **2** and **3** can best be seen when viewing the structures down the chain axis. The 1,10-phenanthroline ligands occupy similar positions in both **2** and **3**, thus indicating that the favorable π···π interactions between the ligand molecules play an important role in the formation and stability of these compounds.

The use of heterocyclic carboxylic acids provides both the proton donor as well as the acceptor through the carboxylate oxygen and the ring nitrogen atoms. Both these centers are highly accessible to the participating metal ions during the synthesis for the formation of both monodentate and/or multidentate M–O and M–N bonds. The structural motifs thus formed can then readily participate in hydrogen bonding to give rise to a variety of networks. In the present system of compounds, we observe differences in the connectivity of the carboxylate oxygen atoms but the nitrogen atom, in all cases, participates in bonding with the Zn^{2+} ions. Similar behavior has been observed before.[17] In addition, moderate O–H···O-type hydrogen bonding is observed in **1** that gives rise to extended networks. It is likely that the presence of the rather bulky 1,10-phenanthroline as the secondary ligand in **2** and **3** prevents the formation of any hydrogen-bond interactions and only π···π interactions are observed (Figure 8).

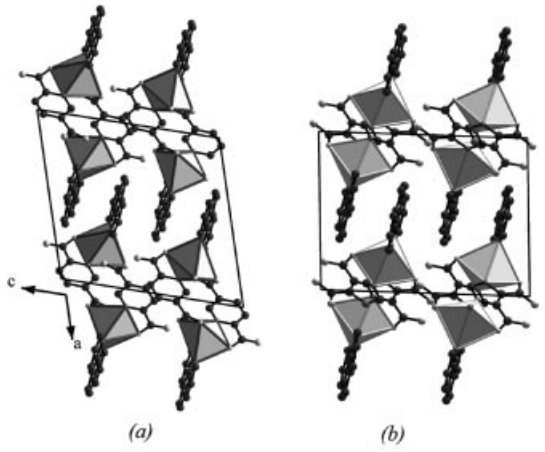

Figure 8. Arrangement of the one-dimensional chains in the *ac* plane for (a) **2** and (b) **3**. Note the similarity between the two structures and the arrangement of the 1,10-phenanthroline ligands.

The role of π···π interactions in the stability of lower dimensional structures in metal-organic coordination polymers has been a topic of much interest.[31,32] In the present compounds π···π interactions involving the 1,10-phenanthroline ligands are observed, especially in **2** and **3**. The centroid–centroid distance (*d*) between the 1,10-phenanthroline rings and their interplanar angles (θ) for **2** and **3** are shown in Figure 9. Favorable π···π interactions between these rings, with d = 3.66 Å and 3.45 Å and θ = 0.8° and 1.93° for **2** and **3**, respectively, are observed. From the interplanar angles (θ), it is clear that the two 1,10-phenanthroline rings are arranged one over the other, but are stacked anti-parallel to each other. This type of anti-parallel arrangement of aromatic rings is commonly observed in systems exhibiting dipolar properties. To understand the role of π···π interactions, we have performed preliminary calculations using the AM1-parameterized Hamiltonian available in the Gaussian program suite.[33,34] AM1 methods, together with a semi-classical dipolar description, have been employed recently to establish the relationship between the stability and geometries of organic molecules.[35]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

From these calculations, the dipole moment of the independent single 1,10-phenanthroline molecules was found to be 2.8 Debye; in **2** and **3**, the dipole moment values for the stacked arrangement were found to be exactly zero. It is likely that the anti-parallel arrangement of the 1,10-phenanthroline molecules reduces the dipole–dipole repulsion and paves the way for π-electron polarizations.

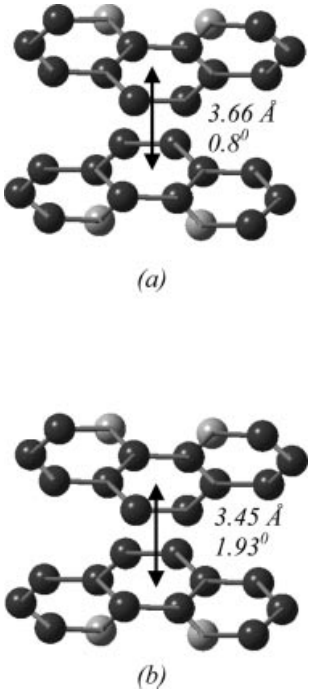

Figure 9. Stacking of the 1,10-phenanthrolines in **2** and **3**. Note that in both the cases the molecules are in an anti-parallel arrangement.

We also evaluated the strength of the π···π interactions in **2** and **3** based on single-point energy calculations, without symmetry constraints, on the basis of the crystal structure geometry. The π···π interaction energies were found to be 7.27 and 7.32 kcal mol^{-1}, respectively, for **2** and **3**. These energies are comparable to the intermediate hydrogen-bond strengths (approx. 10–15 kcal mol^{-1}) in N–H···O and O–H···O hydrogen-bond systems.[36] It should be noted that the carboxylate groups in **1** are stacked exactly one over other, while in **2** and **3** they are in an anti-parallel arrangement (Figure 10). It is likely that the presence of 1,10-phenanthroline ligands and their π···π interactions influence the geometry of the carboxylate groups in **2** and **3**, although all the carboxylate groups are separated by 6–7 Å in the structures. When the separation between the benzene rings is greater, as for instance between the pyridinecarboxylates in **1** and **2** and between the imidazolecarboxylates in **3**, the π···π interactions are negligible. Of the three compounds described in this paper, the moderate hydrogen-bond interaction energy in **1** and the π···π interactions in **2** and **3** appear to play an important role for the observed structural stability. It is likely that the study of similar systems would open up new avenues for our understanding of the nature of π···π interactions and their role in structural stability.

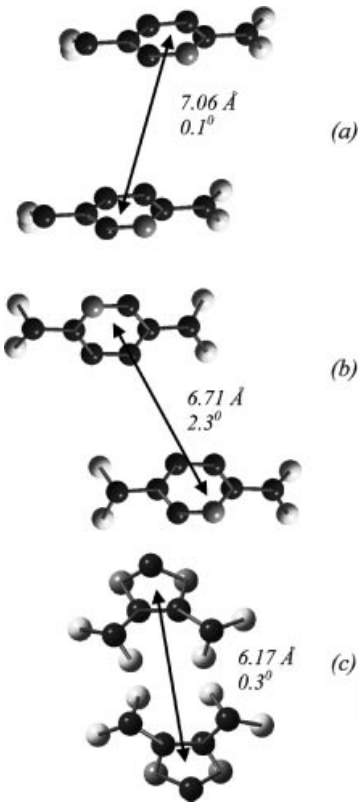

Figure 10. Arrangement of the carboxylate units in (a) **1**, (b) **2**, and (c) **3**.

Experimental Section

General: All three compounds were synthesized by hydrothermal methods. In a typical synthesis of **1**, $ZnSO_4 \cdot 7H_2O$ (0.144 g, 0.5 mmol) was dissolved in 4 mL of 0.125 M NaOH solution. Pyridine-2,5-dicarboxylic acid (H_2PyDC; 0.085 g, 0.5 mmol) and 0.03 mL of triethylamine (Et_3N) were then added, with continuous stirring, and the mixture was homogenized at room temperature for 30 min. The final mixture was sealed in a 7-mL PTFE-lined stainless-steel acid digestion bomb and heated at 150 °C for 5 d. The initial and final pH of the reaction mixture were 4 and 3.5, respectively. The final product contained large quantities of colorless rectangular crystals, which were filtered off, washed with copious quantities of deionized water under vacuum, and dried under ambient conditions. Compound **2** was prepared under identical synthetic conditions but with the addition of 0.1 g of 1,10-phenanthroline to the reaction mixture. For **3**, zinc acetate (0.056 g, 0.25 mmol) was dissolved in 10 mL of water along with imidazole-4,5-dicarboxylic acid (0.085 g, 0.5 mmol), NaOH (0.04 g, 1 mmol), Et_3N (0.03 mL, 0.25 mmol), and 1,10-phenanthroline (0.05 g, 0.25 mmol). The reaction mixture was heated in a 23-mL autoclave at 150 °C for 7 d. The initial and final pH of the reaction mixture were 10 and 6, respectively. The colorless crystals obtained were filtered, washed with water, and dried under ambient conditions. **1:** $C_{14}H_{14}N_2O_{12}Zn_2$ (533.01): calcd. C 31.52, H 2.66, N 5.25; found C 31.4, H 2.53, N 5.1. **2:** $C_{19}H_{12}N_3O_{4.5}Zn$ (419.68): calcd. C 54.33, H 2.85, N 10.01; found C 54.4, H 2.79, N 10.14. **3:** $C_{17}H_9N_4O_4Zn$ (398.65): calcd. C 51.17, H 2.26, N 14.05; found C 51.27, H 2.33, N 13.96. The powder XRD patterns were recorded on crushed single crystals in the 2θ range 5–50° using Cu-K_α radiation (Rich-Seifert, 3000TT). The XRD patterns indicated that the products were new materials; the patterns were entirely consistent with the structures

determined by single-crystal X-ray diffraction. Thermogravimetric analysis (TGA) was carried out (Metler-Toledo) under oxygen (flow rate = 50 mL min^{-1}) in the temperature range 25–700 °C (heating rate = 5 °C min^{-1}). The studies showed similar results for the compounds, with one weight loss. The total observed weight losses of 73, 79, and 78.5% for **1**, **2**, and **3**, respectively, correspond well with the loss of the carboxylate and bonded water in **1** (calcd. 70%), carboxylate, lattice water, and 1,10-phenanthroline in **2** (calcd. 79.5%), and carboxylate and 1,10-phenanthroline in **3** (calcd. 80%). The final calcined product was found to be crystalline by powder XRD and corresponded to ZnO (JCPDS: 36-1451). IR spectroscopic studies were carried out in the mid-IR region on KBr pellets (Bruker IFS-66v). The spectra show characteristic sharp lines with almost similar bands. Minor variations between the bands were found between the compounds. **1:** $\tilde{\nu}$ = 3467 (m) (ν_{as}OH), 2889 (w) [ν_s(C–H)$_{aromatic}$], 1633 (m) [ν_s(C=O)], 1605 (w) (δ_sH$_2$O), 1575 (m) (C–C)$_{skeletal}$, 1362 (s) [δ_s(COO)], 1041 (s) [δ(C–N$_{skeletal}$)], 803 (s) [δ(CH$_{aromatic}$)$_{out\text{-}of\text{-}plane}$] cm^{-1}. **2:** $\tilde{\nu}$ = 3475 (m) (ν_{as}OH), 1645 (s) [ν_s(C=O)], 1605 (w) (δ_sH$_2$O), 1351 (s) [δ_s(COO)], 1294 (m) [δ(CH$_{aromatic}$)$_{in\text{-}of\text{-}plane}$], 1036 (s) [$\delta$(C–N$_{skeletal}$)], 848 (s) [$\delta$(CH$_{aromatic}$)$_{out\text{-}of\text{-}plane}$] cm^{-1}. **3:** $\tilde{\nu}$ = 2888 (w) [ν_s(C–H)$_{aromatic}$], 1567 (s) [ν_s(C=O)], 1552 (s) [(C–C)$_{skeletal}$], 1392 (s) [δ_s(COO)], 1299 (s) [δ(CH$_{aromatic}$)$_{in\text{-}of\text{-}plane}$], 1034 (w) [$\delta$(C–N$_{skeletal}$)], 910 (s) [$\delta$(CH$_{aromatic}$)$_{out\text{-}of\text{-}plane}$] cm^{-1}. A suitable single crystal of each compound was carefully selected under a polarizing microscope and glued to a thin glass fiber. Crystal structure determination by X-ray diffraction was performed with a Siemens Smart-CCD diffractometer equipped with a normal focus, 2.4 kW sealed-tube X-ray source (Mo-K_α radiation, λ = 0.71073 Å) operating at 40 kV and 40 mA. An empirical absorption correction was applied using the SADABS program.[37] The structure was solved and refined with the SHELXTL-PLUS suite of programs.[38] All the hydrogen atoms of the carboxylic acids and the bound water molecules were located in the difference Fourier maps. For the final refinement, the hydrogen atoms on the carboxylic acid were placed geometrically and held in the riding mode. Final refinement included atomic positions for all the atoms, anisotropic thermal parameters for all the non-hydrogen atoms, and isotropic thermal parameters for all the hydrogen atoms. Full-matrix least-squares refinement against $|F^2|$ was carried out with the SHELXTL-PLUS[38] suite of programs. Details of the structure solution and final refinement for all three compounds are given in Table 4. CCDC-258001 to -258003 (**1**–**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Effects of Anthracene and Pyrene Units on the Interactions of Novel Polypyridylruthenium(II) Mixed-Ligand Complexes with DNA

Mariappan Mariappan*[a] and Bhaskar G. Maiya[a][†]

Keywords: DNA cleavage / Electrophoresis / Inhibitors / N ligands / Radicals / Ruthenium

2-(9-Anthryl)-1*H*-imidazo[4,5-*f*][1,10]phenanthroline (aip) and [2-(1-pyrenyl)-1*H*-imidazo[4,5-*f*][1,10]phenanthroline (pyip) and their complexes $[Ru(phen)_2(aip)]^{2+}$ (**1**) and $[Ru(phen)_2(pyip)]^{2+}$ (**2**) (phen = 1,10-phenanthroline) have been synthesized and characterized by elemental analysis, UV/Vis, IR and ^1H NMR spectroscopy, FAB-MS and cyclic voltammetry methods. Both **1** and **2** are redox-active and undergo oxidation at 1.43 and 1.47 V (vs. SCE), respectively. Both **1** and **2** show only the ^{3}MLCT emission typical of any polypyridylruthenium(II) complex. These new complexes are seen to be excellent binders of calf-thymus (CT) DNA, as revealed by the results of absorption, luminescence, viscometric titrations, and thermal denaturation studies. These results also indicate that while ruthenium-bound aip and pyip intercalate within the base pairs of the duplex, the phen moieties act only as spectator ligands in each case. Steady-state emission studies carried out in aqueous media with and without DNA reveal that $[Ru(phen)_2(pyip)]^{2+}$ is a better "molecular light switch" for DNA than $[Ru(phen)_2(aip)]^{2+}$. Under an identical set of experimental conditions of light and drug dose, the DNA photocleavage ability of $[Ru(phen)_2(pyip)]^{2+}$ is also higher than that of $[Ru(phen)_2(aip)]^{2+}$. "Inhibitor studies" suggest that the oxygen species are mainly responsible for the DNA photocleavage by these complexes.

Introduction

Considerable attention is being directed towards the design of DNA-binding and -photocleaving ruthenium(II) complexes in order to develop novel therapeutic agents, chemical probes for nucleic acids, and novel diagnostic agents targeted to double-helical DNA.[1–4] Presently, most attention has centered upon metal complexes that are capable of binding DNA by intercalation.[5–11] Due to their luminescent characteristics and strong DNA-binding affinity, the polypyridylruthenium(II) class of metallointercalators have received particular attention.[12–14] Barton and co-workers have shown that the strong binding of $[Ru(L)_2(dppz)]^{2+}$ complexes (L = 2,2′-bipyridine or 1,10-phenanthroline) to DNA gives rise to the "molecular light-switch effect", where the nearly undetectable emission from the triplet metal-to-ligand charge transfer (MLCT) excited state of $[Ru(L)_2(dppz)]^{2+}$ in water is strongly enhanced due to the intercalation of the planar dppz ligand between the base pairs of DNA.[10,15–17] One important characteristic of these ligands is that they all possess extended π-aromatic structures and are planar, which is crucial for the intercalation of the Ru^{II} complexes containing them. In our efforts to design metal complexes coordinated to ligands having planar, aromatic subunits, we have recently reported a series of complexes containing modified phen/dppz ligands (phen = 1,10-phenanthroline and dppz = dipyrido[3,2-*a*:2′,3′-*c*]-phenazine). These new ligands have been designed so that besides containing the expansively aromatic "dppz" type of structure, they are also endowed with other electroactive subunits that impart special properties for the complexes in the presence of DNA.[18–21]

Some of the complexes containing a non-planar ligand also exhibit interesting properties upon binding to DNA,[22,23] It is well known that the five-membered imidazole ring is a component of the purine bases in DNA. Ji and co-workers have reported a series of imidazole-modified phen/bpy ligands where the imidazole ring is out of the plane of the phen moiety, and also biphenyl derivatives of phen/dppz, all of which help to explain the effect of ligand planarity on the DNA binding strength of the complexes.[24–28] The ancillary ligands of polypyridylruthenium(II) complexes have also been shown to have a significant effect on the spectral properties and the DNA-binding behavior of the complexes.[29–31] All the above studies revealed that modification of the ligands would lead to subtle or substantial changes in the binding modes, location, and affinities, and provide the chance to explore various valuable conformation- or site-specific DNA probes and potential chemotherapeutical agents. Thus, we focused on the construction of novel polypyridyl ligands containing fluorophores such as pyrene and anthracene in their imidazole architecture. This paper deals with the synthesis, characteri-

zation, DNA binding, and photocleavage studies of the mixed-ligand Ru^{II} complexes $[Ru(phen)_2(aip)]^{2+}$ and $[Ru(phen)_2(pyip)]^{2+}$ containing ligands which have anthracene [viz. 2-(9-anthryl)-1*H*-imidazo[4,5-*f*][1,10]phenanthroline (aip)] or pyrene {viz. [2-(1-pyrenyl)-1*H*-imidazo[4,5-*f*][1,10]phenanthroline (pyip)} fluorophores in their architecture.

Results and Discussion

Synthesis and Characterization

The ligands aip and pyip were prepared by a method similar to that described by Steck and Day.[32] Condensation reactions of 1,10-phenanthroline-5,6-dione and 9-anthraldehyde or 1-pyrenecarboxaldehyde in the presence of ammonium acetate and glacial acetic acid produced aip and pyip, respectively. The corresponding ruthenium(II) complexes were synthesized by treating $[Ru(phen)_2Cl_2]\cdot 2H_2O$ with either aip or pyip (Figure 1). Each synthetic step involved here is straightforward and provides a good-to-moderate yield of the desired product in pure form. These products were characterized by elemental analysis, ^1H NMR, IR, luminescence, and UV/Vis spectroscopy, and MALDI-TOF mass spectrometry. The MALDI-TOF spectra show the base-peak at m/z = 396 for aip and at m/z = 420 for pyip. In the case of the corresponding mixed-ligand Ru^{II} complexes, peaks are seen at m/z = 1003 $[M - PF_6]^+$ and 858 $[M - 2\ PF_6]^+$ for $[Ru(phen)_2(aip)](PF_6)_2$ and similarly at m/z = 1026 $[M - PF_6]^+$ and 883 $[M - 2\ PF_6]^+$ for $[Ru(phen)_2(pyip)](PF_6)_2$, typical of PF_6 salts of polypyridylruthenium(II) complexes.[18–20,33]

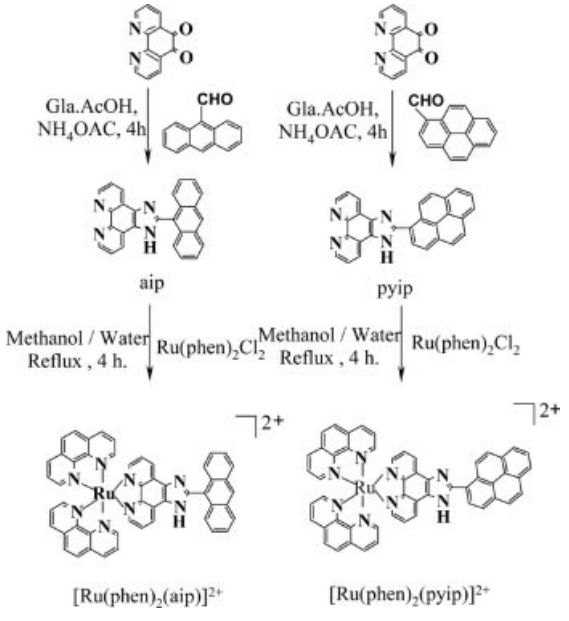

Figure 1. Scheme showing the synthesis of aip and pyip and their mixed-ligand ruthenium(II) complexes.

The ^1H NMR spectra of the two ligands (Figure 2) display a characteristic broad peak at δ = 14.20 (aip) and 13.73 ppm (pyip) for the N–H group of the imidazole ring.[27,28] In each of the two complexes, the signal of the proton on the nitrogen atom of the imidazole ring was not observed. Metal coordination causes electron deficiency in the ligand and, as a result, the imidazole proton becomes active and there is fast proton exchange between the two imidazole nitrogen atoms. Similar observations have been reported earlier.[27,28,34] In both complexes the signals of the *ortho*- and *para*-protons of the phenanthroline fragment of the ligands are shifted downfield and those of the *meta*-protons are shifted upfield compared to the free ligands. However, the proton signals of the anthracene and pyrene fragments of the ligands do not experience much shift compared to the free ligands. The other protons of both the complexes and the ligands give well-defined ^1H NMR spectra, which permit their unambiguous identification and assessment of purity.

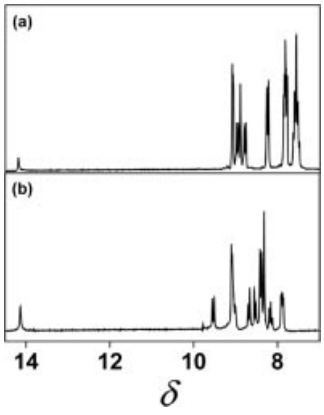

Figure 2. ^1H NMR spectra of (a) aip and (b) pyip in $CDCl_3$/CD_3OD and $[D_6]DMSO$.

The UV/Vis spectra of aip, pyip, and their ruthenium(II) complexes, along with the corresponding reference compounds synthesized during this study, are summarized in Table 1. The UV/Vis and luminescence spectra of both complexes are shown in Figure 3. As can be seen, the spectra of aip and pyip are characterized by low intensity but structured $\pi\rightarrow\pi^*$ transition absorption bands at 383 and 366 nm for aip and at 368 nm for pyip. These bands are ascribed to the anthracene and pyrene chromophores attached to the phenanthroline moiety.[35,36] The high-energy bands (aip: 251 nm; pyip: 234 and 280 nm) are attributed to the $\pi\rightarrow\pi^*$ transitions corresponding to the phenanthroline moiety of the ligands.

The low-energy bands at 452 (ε = 19675 $M^{-1}cm^{-1}$) and 457 nm (ε = 24066 $M^{-1}cm^{-1}$) are assigned as the MLCT $Ru(d\pi)\rightarrow aip/pyip(\pi^*)$ transitions for the complexes $[Ru(phen)_2(aip)]^{2+}$ and $[Ru(phen)_2(pyip)]^{2+}$, respectively, typical of any polypyridylruthenium(II) complex. The λ_{max} values of the MLCT transitions of these new complexes are bathochromically shifted in relation to the MLCT band of $[Ru(phen)_3]^{2+}$ (446 nm), with $[Ru(phen)_2(pyip)]^{2+}$ showing a higher red shift of 5 nm than $[Ru(phen)_2(aip)]^{2+}$ due to the extent of π delocalization of the chromophore. The bands centered at 254 and 264 nm are attributed to an in-

[a] Spectra were recorded in CH_3CN. [b] Error limits: λ_{max}: ±1 nm; log ε: ±10%. [c] Error limits: λ_{em}: ±1 nm; φ: ±10%.

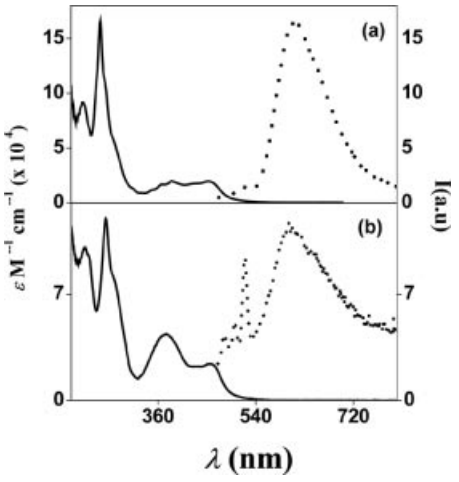

Figure 3. UV/Vis (– – –) and luminescence (·····) spectra of $[Ru(phen)_2(aip)]^{2+}$ (a) and $[Ru(phen)_2(pyip)]^{2+}$ (b) in CH_3CN.

traligand (IL) π→π* transition for $[Ru(phen)_2(aip)]^{2+}$ and $[Ru(phen)_2(pyip)]^{2+}$, respectively.

When aip is excited at 360 nm, the emission maximum appears at 535 nm (φ = 0.81 in CH_3CN). In the case of pyip (excited at 330 nm), the emission maximum appears at 494 nm (φ = 0.63 in CH_3CN). The steady-state and time-resolved absorption and fluorescence spectroscopic properties of aip, which is a bichromophoric molecule, reveal that a rapid and efficient intra-EET process dominates its excited-state relaxation dynamics in solution.[37] $[Ru(phen)_2(aip)]^{2+}$ and $[Ru(phen)_2(pyip)]^{2+}$ show an emission band centered at 604 and 601 nm with quantum yields of 0.005 and 0.0006, respectively in CH_3CN (λ_{exc} = 450 nm; see Figure 3). The origin of the spike at around 520 nm in the emission spectrum (Figure 3b) is due to Raman scattering. Since $[Ru(phen)_2(pyip)]^{2+}$ is weakly fluorescent and the gain of the instrument has to be increased to compensate for the low quantum yield (φ = 0.0006 in CH_3CN), the Raman scatter becomes visible. For highly fluorescent $[Ru(phen)_2(aip)]^{2+}$ (φ = 0. 005 in CH_3CN), the emission spectra overwhelms the Raman peak and thus it is not observed. The spectral shape and the λ_{em} values are quite similar to those of $[Ru(phen)_2(dppz)]^{2+}$, the ^{3}MLCT emission band maximum of which has been reported to be located at 618 nm.[17] The emission quantum yields of the complexes (Table 1) investigated here are lower than that of $[Ru(phen)_3]^{2+}$ (φ = 0.028 in CH_3CN)[38] and the order is $[Ru(phen)_3]^{2+}$ > $[Ru(phen)_2(aip)]^{2+}$ >> $[Ru(phen)_2(pyip)]^{2+}$.

Electrochemistry

During the cathodic scans in the cyclic voltammetric experiments, carried out in DMF containing 0.1 M TBAP, ligands aip and pyip show reversible (i_{pc}/i_{pa} = 0.9–1.0) and diffusion-controlled [$i_{pc}/v^{1/2}$ is constant in the scan-rate (v) range 50–500 mV s^{-1}] one-electron transfer (ΔE_P = 60–70 mV; ΔE_P = 65 ± 3 mV for the Fc^+/Fc couple)[39] responses at –1.48 and –1.46 V (vs. SCE), respectively. These potentials are close to those observed for the one-electron reductions of phen-dione (–1.47 V). The second reduction step appears as either quasi-reversible (i_{pc}/i_{pa} = 0.2–0.7 and ΔE_P = 90–200 mV at a scan rate over the range of 100–500 mV s^{-1}) or totally irreversible responses for aip and pyip at –1.61 and –1.64 V, respectively. The oxidation of pyip occurs at +1.42 V, whereas for aip it occurs at +1.38 V. The oxidation potential shifts more positively for pyip than for aip due to the greater π-delocalized nature of the pyrene moiety in the case of pyip when compared to anthracene in aip.

The cyclic and differential-pulse voltammograms of the two new complexes are compared with that of $[Ru(phen)_3]^{2+}$ in Figure 4. Each complex exhibits well-shaped oxidation and reduction waves in the sweep range from –2.0 to +1.6 V vs. SCE containing 0.1 M TBAP. The complex $[Ru(phen)_2(aip)]^{2+}$ exhibits a well-shaped reversible oxidation wave (+1.43 V) in acetonitrile and three reduction waves –1.29, –1.49, and –1.96 V in DMF. The first two reduction waves are reversible and the last one at –1.96 V is a poorly shaped quasi-reversible wave. For $[Ru(phen)_2(pyip)]^{2+}$, a reversible oxidation wave at +1.47 V in acetonitrile and two reversible reduction waves at –1.21 and –1.43 V in DMF are observed. The redox potential data for all the above compounds as measured by the cyclic and differential-pulse voltammetric method are summarized in Table 2.

Oxidation of the complexes involves removal of an electron from the dπ orbital of Ru^{II}, while reduction involves transfer of an electron to the ligand-centered orbitals.[28] As expected, the oxidation potential of $[Ru(phen)_2(pyip)]^{2+}$ is 40 mV more positive than $[Ru(phen)_2(aip)]^{2+}$. The attachment of a pyrene ring (extended hydrophobicity/aromaticity) to the IP (imidazophenanthroline) moiety expands the π delocalization and thus decreases the σ-donor capacity of pyip, which leads to a decrease in the electron density on the Ru^{II} ion and, in turn, stabilizes the metal π (t_{2g}) orbital.[40] As a result, the oxidation potential shifts positively for $[Ru(phen)_2(pyip)]^{2+}$ when compared to $[Ru(phen)_2(aip)]^{2+}$. The first reduction in both the complexes is expected to be centered at aip/pyip because of the availability of the most stable LUMO.[41] The other reductions observed for both complexes are characteristic of the ancillary phen ligands.[42] Thus, in the case of $[Ru(phen)_2(aip)]^{2+}$, reductions at –1.29, –1.49, and –1.96 V are assigned to aip/$aip^{\cdot-}$, $phen_1/phen_1^{\cdot-}$, and $phen_2/phen_2^{\cdot-}$ couples, respectively. For $[Ru(phen)_2(pyip)]^{2+}$, the reductions at –1.21 and –1.43 V are assigned to pyip/$pyip^{\cdot-}$ and $phen_1/phen_1^{\cdot-}$ processes, respectively; the second reduction associated with $phen_2$ could not be observed.

DNA-Binding Experiments

Binding of the chloride salts of the two Ru^{II} complexes synthesized in this study with CT DNA were monitored by absorption, luminescence, thermal denaturation, and viscosity methods, and the results are summarized in this section, which also discusses aspects related to the ability of these complexes to act as "molecular light switches" for DNA.

Absorption Titration

Both $[Ru(phen)_2(aip)]^{2+}$ and $[Ru(phen)_2(pyip)]^{2+}$ were titrated with CT DNA. The change in the spectral profiles during titration is shown in Figure 5a and b. As the DNA concentration is increased, $[Ru(phen)_2(aip)]^{2+}$ and $[Ru(phen)_2(pyip)]^{2+}$ show hypochromicity (39% and 61%,) and isosbestic points (482 and 496 nm), along with bathochromic shifts of 6 and 9 nm, respectively. To compare quantitatively the affinity of the two complexes towards

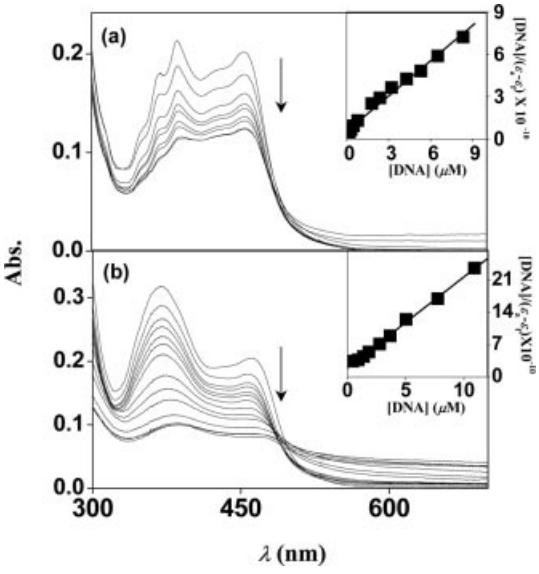

Figure 5. UV/Vis spectra of (a) $[Ru(phen)_2(aip)]^{2+}$ (5 μM) and (b) $[Ru(phen)_2(pyip)]^{2+}$ (5 μM) in the absence (top curve) and presence (subsequent curves) of increasing concentrations (0–100 μM) of CT DNA in buffer A. The inset graph shows a fit of the absorbance data used to obtain the binding constant.[56]

DNA, the intrinsic binding-constant values (K_b) were determined by monitoring the absorbance at the MLCT band position and were found to be as high as $1.01 \pm 0.1 \times 10^6$ and $1.57 \pm 0.8 \times 10^6$ M^{-1} for $[Ru(phen)_2(aip)]^{2+}$and $[Ru(phen)_2(pyip)]^{2+}$, respectively (Table 3). The extent of hypochromism commonly parallels the intercalative strength of the ligand and, moreover, a higher planar area, an extended π system, hydrophobicity, and aromaticity lead to deep penetration and hence more stacking within the base-pairs of DNA. Thus, the intercalative strength follows the order $[Ru(phen)_2(dppz)]^{2+} \approx [Ru(ip)_2(dppz)]^{2+} \geq [Ru(phen)_2(pyip)]^{2+} > [Ru(phen)_2(aip)]^{2+} > [Ru(phen)_3]^{2+}$ (ip = imidazo[4,5-*f*][1,10]phenanthroline).[29]

Luminescence Titration

The steady-state emission spectra of 7 μM solutions of $[Ru(phen)_2(aip)]^{2+}$ and $[Ru(phen)_2(pyip)]^{2+}$ in Tris buffer (5 mM Tris, 50 mM NaCl, pH = 7.1) show an increase in the emission intensity with successive addition of CT DNA. In the case of $[Ru(phen)_2(aip)]^{2+}$, the emission maximum at 604 nm due to the ^{3}MLCT [dπ(Ru)→π*(aip)][38] state increases initially at low [DNA nucleotide phosphate]/[Ru] ratio, but reaches a plateau, with an apparent enhancement factor of about 5, at a higher [DNA nucleotide phosphate]/[Ru] ratio of 27. The complex has an appreciable emission in the buffer in the absence of DNA and shows a marginal red-shift of 2 nm on addition of DNA (Figure 6a). The luminescence due to $[Ru(phen)_2(pyip)]^{2+}$ at 601 nm is assigned as a ^{3}MLCT [dπ(Ru)→π*(pyip)] state, and increases steadily with increasing addition of CT DNA, reaching a maximum (approx. 9 times) at a [DNA nucleotide phosphate]/[Ru] ratio of 43 (see Figure 6b). The complex has very weak emission in the aqueous medium in the absence of DNA, but on addition of increasing amounts of DNA the emission intensity increases with a bathochromic shift of about 4 nm. The emission enhancement of both complexes in the presence of DNA is much smaller than that observed for the dppz-based polypyridylruthenium(II) intercalators reported by Barton et al.[10,15,17] The shielding of the nitrogen atoms on the intercalating ligands, especially the imidazole nitrogen atoms, from protonation in the bulk solvent medium causes an emission enhancement, which has been extensively characterized and described as a "molecular light switch".[10,15,17] The mobility of these complexes is restricted at the binding site and so the vibrational modes of relaxation (collision and energy dissipation) decrease on intercalation.[28] The binding constants obtained are reasonably well in agreement with the values from the absorption titration experiment. The binding site sizes (n) for $[Ru(phen)_2(aip)]^{2+}$ and $Ru(phen)_2(pyip)]^{2+}$ are evaluated as 2 and 3.

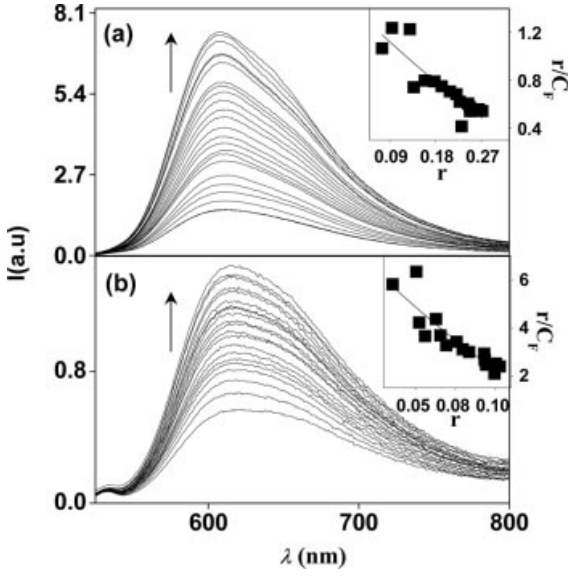

Figure 6. Luminescence spectra of (a) $[Ru(phen)_2(aip)]^{2+}$ (7 μM) and (b) $[Ru(phen)_2(pyip)]^{2+}$ (7 μM) in the absence (bottom curve) and presence (subsequent curves) of increasing concentrations (0–300 μM) of CT DNA in buffer A (λ_{exc} = 450 nm). The inset graph shows a fit of the emission data to Equation (4).

DNA Melting Experiments

Other strong evidence for the intercalation of both the complexes into the helix was obtained from the DNA melting studies. Intercalation of small molecules into the double helix is known to increase the helix melting temperature (T_m), the temperature at which the double helix denatures into single-stranded DNA.[43] The extinction coefficient of DNA bases at 260 nm in the double-helical form is much less than in the single-stranded form; hence, melting of the helix leads to an increase in the absorption[44] at this wavelength. CT DNA was seen to melt at 61 ± 1 °C (2 mM NaCl, 1 mM phosphate) in the absence of any added complex. The T_m of DNA is increased by 4 and 5 °C in the presence of $[Ru(phen)_2(aip)]^{2+}$ and $[Ru(phen)_2(pyip)]^{2+}$ (at [DNA nucleotide phosphate]/[complex] = 25), respectively. The DNA melting curves in the absence and in the presence of both complexes are presented in Figure 7 and the T_m and the σ_T values of CT DNA in the absence and presence of the

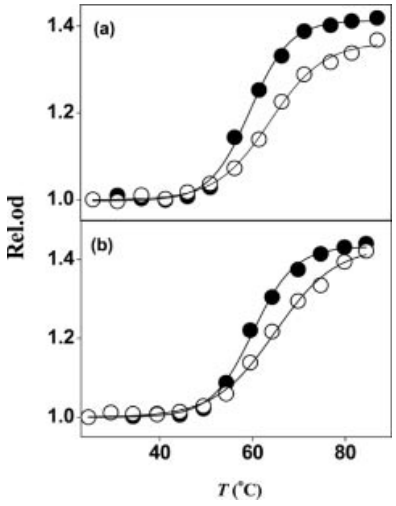

Figure 7. Melting curves for CT DNA in the absence (filled circles) and in the presence (open circles) of $[Ru(phen)_2(aip)]^{2+}$ (a) and $[Ru(phen)_2(pyip)]^{2+}$ (b) in buffer B.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

complexes are tabulated in Table 3. These establish the increased stability of the double helix when $[Ru(phen)_2(aip)]^{2+}$ and $[Ru(phen)_2(pyip)]^{2+}$ bind to DNA. The increases in the melting temperatures are comparable to the values observed with the classical intercalator ethidium and lend strong support for intercalation into the helix.[44,45]

Viscometric Titration

Intercalation of a ligand into DNA is known to cause a significant increase in the viscosity of a DNA solution due to an increase in the separation of the base pairs at the intercalation site and, hence, an increase in the overall DNA molecular length (contour length). In contrast, a ligand that binds in the DNA grooves causes a less-pronounced change (positive or negative) or no change in the viscosity of a DNA solution.[46] The effects of $[Ru(phen)_2(aip)]^{2+}$, $[Ru(phen)_2(pyip)]^{2+}$, ethidium bromide (EtBr), and $[Ru(phen)_3]^{2+}$ on the viscosity of CT DNA solution were studied in order to assess the binding mode of these complexes with DNA. Plots of $(\eta/\eta_o)^{1/3}$ vs. [Drug]/[DNA] are shown in Figure 8. The viscosity of DNA bound with $[Ru(phen)_2(aip)]^{2+}$, $[Ru(phen)_2(pyip)]^{2+}$, and EtBr increases dramatically, thus indicating that both complexes, as well as the classical intercalator EB, intercalate the base pairs of DNA and that $[Ru(phen)_2(pyip)]^{2+}$ has a slightly stronger binding affinity than $[Ru(phen)_2(aip)]^{2+}$**.** However, addition of $[Ru(phen)_3]^{2+}$ has no effect on the DNA viscosity, as reported previously.[46]

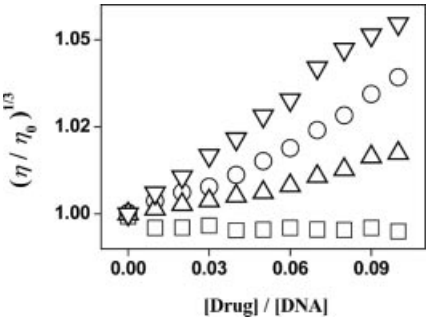

Figure 8. Results of viscometric titrations carried out for CT DNA (300 μM) in the presence of $[Ru(phen)_3]^{2+}$ (squares), $[Ru(phen)_2(aip)]^{2+}$ (triangles, tip up), $[Ru(phen)_2(pyip)]^{2+}$ (open circles) and EB (triangles, tip down) in buffer C.

DNA Photocleavage

When circular plasmid DNA is subjected to electrophoresis relatively fast migration is observed for the supercoiled form (form I), whereas if scission occurs on one strand (nicking), the supercoils will relax to generate a slower moving open circular form (form II). DNA photocleavage experiments were carried out with both the complexes and with $[Ru(phen)_3]^{2+}$ (for comparison). Figure 9 summarizes the results. Control runs in the agarose-gel electrophoresis experiments suggested that untreated pBR 322 DNA does not show any cleavage in the dark, and even upon irradiation with a 450 ± 5 nm light (compare lanes 1 and 2; Figure 9). Lower activity was observed for pBR 322 treated with $[Ru(phen)_2(aip)]^{2+}$, $[Ru(phen)_2(pyip)]^{2+}$, and $[Ru(phen)_3]^{2+}$ in the dark experiments (lanes 3, 5, and 7; Figure 9). After irradiation for 60 min (see lanes 4, 6, and 8; Figure 9) single-strand nicking is observed, and the percentage of conversion from form I to form II was calculated with Equation (5) (see Exp. Sect.). Based on the percentage conversion from form I to form II for these complexes, DNA-nicking efficiencies were seen to roughly follow the trend $[Ru(phen)_2(pyip)]Cl_2$ > $[Ru(phen)_2(aip)]Cl_2$ > $[Ru(phen)_3]Cl_2$. These can be explained on the basis of the binding nature of the intercalating ligands in the complexes due to the extended π-aromatic nature in the case of pyip when compared to aip. The photocleavage efficiencies of these complexes are similar to those of $[Ru(bpy)_2(ip)]^{2+}$ and $[Ru(bpy)_2(pip)]^{2+}$ (ip = imidazo[4,5-*f*][1,10]phenanthroline; pip = 2-phenylimidazo[4,5-*f*][1,10]phenanthroline) reported in the literature.[28]

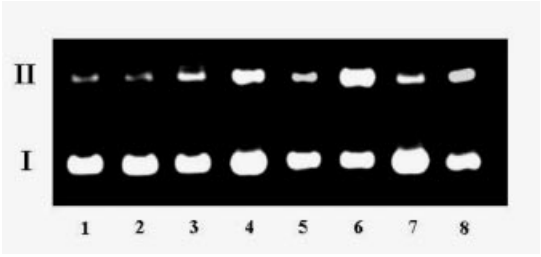

Figure 9. Light-induced nuclease activities of the investigated ruthenium(II) complexes. Dark and light experiments: lanes 1 and 2: untreated pBR 322 (100 μM) in the dark and upon irradiation. Lanes 3, 5, and 7: pBR 322 + $[Ru(phen)_2(aip)]^{2+}$, $[Ru(phen)_2(pyip)]^{2+}$, and $[Ru(phen)_3]^{2+}$ respectively (10 μM) in the dark. Lanes 4, 6, and 8: pBR 322 + $[Ru(phen)_2(aip)]^{2+}$, $[Ru(phen)_2(pyip)]^{2+}$, and $[Ru(phen)_3]^{2+}$, respectively, upon irradiation. λ_{irr} = 450 ± 5 nm (60 min) in each case.

In attempts to unravel the probable DNA photocleavage mechanism of these new complexes, a few control experiments were conducted in the presence of various "inhibitors". Photocleavage by $[Ru(phen)_3]Cl_2$ has been reported[47] to involve a $^1O_2$-based mechanism. In the case of $[Ru(phen)_2(aip)]^{2+}$ (see Figure 10), irradiation for 60 min in the presence of DABCO (lane 5; a $^1O_2$ "quencher") or Tiron (lane 7; a superoxide anion radical quencher) does not affect the photocleavage mechanism. Purging the reaction mixture with N_2 (lane 3) for 15 min to remove O_2 was also found not to inhibit the photocleavage mechanism. Inhibition was seen in the presence of DMSO (lane 4) and manni-

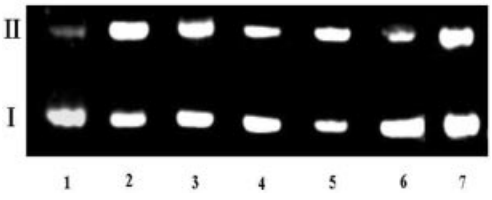

Figure 10. Effect of "inhibitors" on the light-induced nuclease activity of $[Ru(phen)_2(aip)]^{2+}$. Lanes 1 and 2: pBR 322 and $[Ru(phen)_2(aip)]^{2+}$. Lanes 3–7: pBR 322 + $[Ru(phen)_2(aip)]^{2+}$ in the presence of N_2, DMSO (200 mM), DABCO (10 mM), mannitol (100 mM), and Tiron (10 mM), respectively, upon irradiation for 60 min at 450 ± 5 nm in each case.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tol (lane 6), and mannitol is a better inhibitor than DMSO. Both DMSO and mannitol are scavengers of hydroxyl radicals.

In the case of $[Ru(phen)_2(pyip)]^{2+}$ (Figure 11), moderate activity was still observed in the presence of DABCO (lane 5) and DMSO (lane 4), whereas no effect was observed with N_2 (lane 3) or Tiron (lane 7). However, the activity is inhibited very strongly in the presence of mannitol (lane 6). These results suggest that the reactive oxygen species ·OH and singlet oxygen (to a lesser extent) play a significant role in the cleavage mechanism for $[Ru(phen)_2(pyip)]Cl_2$, whereas for $[Ru(phen)_2(aip)]Cl_2$ only the hydroxyl radical plays a role in the photocleavage mechanism.[48]

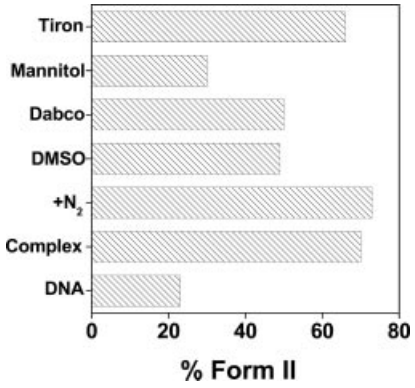

Figure 11. Bar diagram representation of the effect of "inhibitors" on the light-induced nuclease activity of $[Ru(phen)_2(pyip)]^{2+}$. Lanes 1 and 2: pBR 322 and $[Ru(phen)_2(pyip)]^{2+}$. Lanes 3–7: pBR 322 + $[Ru(phen)_2(pyip)]^{2+}$ in the presence of N_2, DMSO (200 mM), DABCO (10 mM), mannitol (100 mM), and Tiron (10 mM), respectively, upon irradiation for 60 min at 450 ± 5 nm in each case.

Conclusions

Two new anthracene/pyrene chromophore-appended polypyridyl ligands (aip and pyip), and their mixed-ligand ruthenium(II) complexes $[Ru(phen)_2(aip)]^{2+}$ and $[Ru(phen)_2(pyip)]^{2+}$, have been synthesized and fully characterized by spectroscopic and electrochemical methods. Studies with DNA have revealed that these complexes bind to DNA, mainly in an intercalative mode, with moderate strengths. The observation that $[Ru(phen)_2(pyip)]^{2+}$ binds DNA more strongly than $[Ru(phen)_2(aip)]^{2+}$ suggests that the increased surface area available for stacking by this complex within the duplex leads to a substantial increase in its intercalative binding affinity. In accordance with this interpretation, $[Ru(phen)_2(pyip)]^{2+}$ is found to be a better "molecular light switch" for DNA than $[Ru(phen)_2(aip)]^{2+}$. The photonuclease activity is also higher for $[Ru(phen)_2(pyip)]^{2+}$ than $[Ru(phen)_2(aip)]^{2+}$ and is comparable to that of $[Ru(bpy)_2(ip)]^{2+}$ and $[Ru(phen)_3]^{2+}$. Moreover, the reactive oxygen species ·OH plays a significant role in the cleavage mechanism of both $[Ru(phen)_2(pyip)]Cl_2$ and $[Ru(phen)_2(aip)]Cl_2$. Studies carried out so far have revealed that modification of phen, especially extension of the planarity of the ligand and attaching aromatic chromophores to it, will increase the strength of interaction of its complexes with DNA.

Experimental Section

Materials: All common chemicals and solvents utilized in this study were obtained in their highest available purity from B.D.H (Mumbai, India). Ruthenium trichloride hydrate, tetrabutylammonium perchlorate (TBAP), and tetrabutylammonium chloride (TBACl) were obtained from Aldrich Chemical Co. (USA). Pyrene, 1-pyrenecarboxaldehyde, 9-anthraldehyde, the deuterated solvents, and the calf-thymus DNA (CT DNA) were also purchased from Aldrich. Agarose (molecular biology grade) and ethidium bromide were purchased from Bio-Rad Laboratories Inc. (USA). Supercoiled pBR 322 DNA (CsCl purified) was obtained from Bangalore Genie (Bangalore, India) and was used as received. All the solvents utilized for spectroscopic and electrochemical work were rigorously purified before use according to standard procedures.[49] Deionized, triply distilled water was used for preparing various buffers. 1,10-phenanthroline-5,6-dione,[50] and $[Ru(phen)_2Cl_2]\cdot 2H_2O$,[51] were synthesized by applying the reported procedures.

2-(9-Anthryl)-1*H*-imidazo[4,5-*f*][1,10]phenanthroline (aip): A mixture of phen-dione (0.53 g, 2.50 mmol), 9-anthraldehyde (0.72 g, 3.50 mmol), ammonium acetate (3.88 g, 50.00 mmol), and glacial acetic acid (15 mL) was refluxed for 4 h and then cooled to room temperature. It was diluted with water and dropwise addition of concentrated aqueous ammonia gave a yellow precipitate, which was collected, washed with water, and dried. The crude product obtained was purified by recrystallization from $CHCl_3$/MeOH (4:1, v/v) and dried. Yield: 0.71 g (72%). $C_{27}H_{16}N_4$ (396.45): calcd. C 81.70, H 4.04, N 14.13; found C 81.63, H 4.11, N 14.19. MALDI-TOF: *m*/*z* = 396 $[M]^+$. IR (KBr): $\tilde{\nu}$ = 3441 (N–H), 1604 (C=N) cm^{-1}. ^1H NMR ([D$_6$]DMSO, 200 MHz, TMS): δ = 14.20 (s, 1 H), 9.09 (dd, J_1 = 2, J_2 = 3 Hz, 2 H), 8.94 (dd, J_1 = 2, J_2 = 6 Hz, 2 H), 8.80 (d, J = 7.8 Hz, 1 H), 8.26 (d, J = 7.8 Hz, 2 H), 7.84 (m, 4 H), 7.57 (m, 4 H) ppm.

2-(1-Pyrenyl)-1*H*-imidazo[4,5-*f*][1,10]phenanthroline (pyip): A mixture of phen-dione (0.53 g, 2.50 mmol), 1-pyrenecarboxaldehyde (0.81 g, 3.50 mmol), ammonium acetate (3.88 g, 50.00 mmol), and glacial acetic acid (15 mL) was refluxed for 4 h The above solution was cooled to room temperature and diluted with water. Dropwise addition of concentrated aqueous ammonia gave a yellow precipitate, which was collected, washed with water, and dried. The crude product thus obtained was purified by recrystallization from pyridine/water (9:1, v/v) and dried. Yield: 0.71 g (68%). $C_{29}H_{16}N_4$ (420.48): calcd. C 82.77, H 3.81, N 13.32; found C 82.81, H 3.74, N 13.39. MALDI-TOF: *m*/*z* = 420 $[M]^+$. IR (KBr): $\tilde{\nu}$ = 3426 (N–H), 1602 (C=N) cm^{-1}. ^1H NMR ($CDCl_3$/[D$_6$]DMSO, 200 MHz, TMS): δ = 13.73 (s, 1 H), 9.28 (d, J = 9.8 Hz, 1 H), 9.12 (dd, J_1 = 5, J_2 = 6 Hz, 2 H), 8.93 (d, J = 8 Hz, 1 H), 8.52 (d, J = 8.8 Hz, 1 H), 8.18 (m, 8 H), 7.66 (dd, J_1 = 3.4, J_2 = 3.4 Hz, 2 H) ppm.

{2-(9-Anthryl)-1*H*-imidazo[4,5-*f*][1,10]phenanthroline}bis(1,10-phenanthroline)ruthenium(II) Bis(hexafluorophosphate) Dihydrate $[Ru(phen)_2(aip)](PF_6)_2\cdot 2H_2O$: This complex was prepared by refluxing aip (0.30 g, 0.76 mmol) with $[Ru(phen)_2Cl_2]\cdot 2H_2O$ (0.43 g, 0.75 mmol) in CH_3OH/H_2O (1:1, v/v) for 4 h. The resulting solution was cooled to room temperature, then 15 mL of water was added and the mixture filtered. Addition of a saturated solution of NH_4PF_6 to the filtrate precipitated bright orange-red crude $[Ru(phen)_2(aip)](PF_6)_2$, which was purified by column chromatography [alumina and acetonitrile/toluene (3:2, v/v)] and further recrystallized from acetone/diethyl ether (1:5, v/v). Yield: 0.48 g (54%). $C_{51}H_{36}F_{12}N_8O_2P_2Ru$ (1183.9): calcd. C 51.71, H 3.04, N 9.46; found C 51.86, H 2.98, N 9.53. MALDI-TOF: *m*/*z* = 1003 $[M - PF_6]^+$, 858 $[M - 2\ PF_6]^+$. IR (KBr): $\tilde{\nu}$ = 3381 (N–H), 1601 (C=N), 837 (PF_6) cm^{-1}. ^1H NMR ([D$_6$]DMSO, 200 MHz, TMS):

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

δ = 8.97 (d, J = 7.5 Hz, 1 H), 8.81 (m, 4 H), 8.42 (s, 4 H), 8.26 (m, 4 H), 8.09 (m, 5 H), 7.82 (m, 9 H), 7.61 (m, 4 H) ppm.

Bis(1,10-phenanthroline){2-(1-pyrenyl)-1*H*-imidazo[4,5-*f*][1,10]phenanthroline}ruthenium(II) Bis(hexafluorophosphate) Dihydrate [Ru(phen)$_2$(pyip)](PF$_6$)$_2$·2H$_2$O: This mixed-ligand Ru^{II} complex was prepared by refluxing pyip (0.34 g, 0.82 mmol) with [Ru(phen)$_2$Cl$_2$]·2H$_2$O (0.45 g, 0.80 mmol) in CH$_3$OH/H$_2$O (1:1, v/v) for 4 h. The crude bright orange-red [Ru(phen)$_2$(pyip)](PF$_6$)$_2$ was obtained upon adding a saturated solution of NH$_4$PF$_6$. It was purified by column chromatography [alumina, acetonitrile/toluene (3:2, v/v)] and further recrystallized from acetone/diethyl ether (1:5, v/v). Yield: 0.49 g (53%). C$_{53}$H$_{36}$F$_{12}$N$_8$O$_2$P$_2$Ru (1207.9): calcd. C 52.67, H 2.98, N 9.28; found C 52.78, H 3.06, N 9.19. MALDI-TOF: m/z = 1026 [M – PF$_6$]$^+$, 883 [M – 2 PF$_6$]$^+$. IR (KBr): $\tilde{\nu}$ = 3377 (N–H), 1599 (C=N), 837 (PF$_6$) cm^{-1}. ^{1}H NMR ([D$_6$]DMSO, 200 MHz, TMS): δ = 9.43 (d, J = 10 Hz, 1 H), 9.19 (d, J = 7.6 Hz, 2 H), 8.80 (m, 4 H), 8.69 (d, J = 7.8 Hz, 1 H), 8.58 (d, J = 8.8 Hz, 1 H), 8.43 (m, 8 H), 8.15 (m, 6 H), 7.82 (m, 6 H), 7.20 (m, 2 H) ppm.

The hexafluorophosphate salts of the complexes were converted into the water-soluble chloride salts by treating the former salt solutions with an excess of TBACl in acetone. The chloride salts, which are insoluble in acetone, instantaneously precipitated from the solution. They were filtered and vacuum-dried before use. The yield was about 90% of the theoretical value in each case.

Spectroscopy and Electrochemistry: Care was taken to avoid the entry of direct, ambient light into the samples in all the spectroscopic and electrochemical experiments described below. Unless otherwise specified, all the experiments were carried out at 293 ± 3 K. Elemental analyses were performed with a Flash EA 1112 series CHNS (Thermo Finnigan/Eager 300) analyzer. Acetanilide was used as the reference standard. Mass (MALDI-TOF) spectra were recorded with a Kompact MALDI 4 mass spectrometer (Kratos Analytical Ltd.). The instrument was operated in reflection time-of-flight mode with an accelerating potential of 20 kV and in the negative ion recording mode. The IR spectra were recorded with a Jasco Model 5300 FT-IR spectrophotometer. The spectra of the solid samples were recorded by dispersing the samples as KBr pellets. The ^{1}H NMR spectra were recorded with a Bruker NR-200 AF-FT NMR spectrometer, with CDCl$_3$ or [D$_6$]-DMSO as the solvent and tetramethylsilane (TMS) as the internal standard. The UV/Vis spectra were recorded with a Shimadzu model UV-3101 spectrophotometer. A matched pair of quartz cuvettes (path length 1 cm) was employed. Steady-state fluorescence spectra were recorded with a Spex Fluoromax-3 spectrophotometer using a 1-cm quartz cell. Detection of emission was done at right angles to the incident beam. The excitation and emission slit widths employed were, typically, 5 nm. While hexafluorophosphate salts of the complexes were employed for the luminescence measurements in nonaqueous solvents (rigorously dried CH$_2$Cl$_2$, THF, 1,4-dioxane, CH$_3$CN, and DMF), the corresponding chloride salts were used for measurements in aqueous and aqueous buffered solutions. The optical densities of the samples were adjusted to ≤0.2 at the excitation wavelength in each case. Emission quantum yields (φ) were estimated by integrating the area under the fluorescence curves and by using the formula given in Equation (1),[52] where A is the area under the emission spectral curve and OD is the optical density of the compound at the excitation wavelength. 1,6-Diphenyl-1,3,5-hexatriene (dpht, φ = 0.80 in cyclohexane)[53] was used as the standard for the calculation of the quantum yield values of the new ligands aip and pyip. The standard used for emission quantum yield measurements for the ruthenium(II) complexes was [Ru(phen)$_3$](PF$_6$)$_2$ (φ = 0.028 in CH$_3$CN).[38] Refractive index corrections were incorporated when reporting the emission data in various solvents.[54]

$$\phi_{sample} = \frac{OD_{standard} \times A_{sample}}{OD_{sample} \times A_{standard}} \times \phi_{standard} \quad (1)$$

Cyclic and differential-pulse voltammetric experiments (CH$_3$CN/DMF/CH$_2$Cl$_2$, 0.1 M TBAP) were performed with a CH Instruments model CHI 620A electrochemical analyzer (working and auxiliary electrodes: Pt; reference electrode: SCE). The Fc$^+$/Fc (Fc = ferrocene) couple was used to calibrate the redox potential values.

DNA-Binding and Photocleavage Studies: The concentration of CT DNA was calculated from its known extinction coefficient at 260 nm (6600 M^{-1} cm^{-1}).[55] Unless otherwise specified, the concentration of DNA is expressed in base pairs (BP) throughout this manuscript. Buffer A (5 mM Tris, 50 mM NaCl, pH = 7.1), buffer B (1 mM phosphate, 2 mM NaCl, pH = 7.0), and buffer C (1.5 mM Na$_2$HPO$_4$, 0.5 mM NaH$_2$PO$_4$, 0.25 mM Na$_2$EDTA, pH = 7.0) were used for absorption and luminescence titration, thermal denaturation, and viscometric experiments, respectively. TAE (tris-acetate ethylenediaminetetraacetate) 1X buffer was used for gel electrophoresis cleavage and inhibition experiments. Absorption titration experiments were performed by maintaining a constant metal complex concentration (5 μM) and varying the nucleic acid concentration (0–100 μM). After the addition of DNA to the metal complex, the resulting solution was allowed to equilibrate at 25 °C for 10 min, after which the absorption readings were noted. The data were then fit to Equation (2) to obtain the intrinsic binding constant K_b,[56] where ε_a, ε_f, and ε_b are the apparent, free, and bound metal complex extinction coefficients, respectively.

$$[DNA]/(\varepsilon_a - \varepsilon_f) = [DNA]/(\varepsilon_b - \varepsilon_f) + 1/K_b(\varepsilon_b - \varepsilon_f) \quad (2)$$

A plot of [DNA]/(ε_a – ε_f) vs. [DNA] gave a slope of 1/(ε_b – ε_f) and a Y intercept equal to 1/K_b(ε_b – ε_f); K_b is the ratio of the slope to the Y intercept. Luminescence titration experiments were performed at a fixed metal complex concentration (7 μM) to which increments of a stock DNA solution (0–300 μM) containing the same concentration of the metal complex were added. After the addition of DNA to the metal complex, the resulting solution was allowed to equilibrate at 25 °C in the dark for 10 min before being excited by 450 ± 5 nm light. The data obtained were fitted to Equation (3), where C_T is the concentration of the complex added, C_F is the concentration of the free complex, and I_o and I are the fluorescence intensities in the absence and in the presence of DNA, respectively; P is the ratio of the observed fluorescence quantum yield of the bound complex to the free complex.

$$C_F = C_T[(I/I_o) - P]/[1 - P] \quad (3)$$

The value of P was obtained from a plot of I/I_o vs. 1/[DNA] such that the limiting fluorescence yield is given by the Y intercept. The amount of bound complex (C_B) at any concentration is equal to $C_T - C_F$. A plot of r/C_F vs. r, where $r = C_B$/[DNA], was constructed according to the modified Scatchard equation given by McGhee and Von Hippel [Equation (4)],[57] where K_b is the intrinsic binding constant and n is the binding-site size in base pairs.

$$r/C_F = K_b(1 - nr)\{(1 - nr)/[1 - (n - 1)r]\}^{n-1} \quad (4)$$

DNA melting experiments were carried out by monitoring the absorption (260 nm) of CT DNA (160 μM, nucleotide pairs, NP) with a Shimadzu model UV-160A spectrophotometer coupled with a

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

temperature controller model Julabo-F12, at various temperatures, in the absence and presence of the complex. The melting temperature (T_m) and the curve width σ_T (temperature range where 10–90% of the absorption increase occurred) were calculated as described previously.[47,58] Viscometric titrations were performed at 25 ± 1 °C with a Cannon-Ubblehode viscometer. Titrations were performed for $[Ru(phen)_3]^{2+}$, $[Ru(phen)_2(aip)]^{2+}$, $[Ru(phen)_2(pyip)]^{2+}$, and ethidium bromide (EtBr; 3–40 μM). Each compound was introduced into the degassed DNA solution (300 μM) present in the viscometer using a Hamilton syringe fitted with a glass extender. Bubbling with nitrogen produced mixing of the drug and DNA. Flow times were measured, with a digital stopwatch, at least three times and were accepted if they agreed within 0.1 s. Reduced specific viscosities were calculated according to Cohen and Eisenberg.[59] Plots of $(\eta/\eta_o)^{1/3}$ (η and η_o are the reduced specific viscosities of DNA in the presence and absence of the drug, respectively) vs. [drug]/[DNA] were constructed. Plots of $(\eta/\eta_o)^{1/3}$ vs. [EtBr]/[DNA] and $[Ru(phen)_3]^{2+}$]/[DNA] were found to be similar to those reported in the literature.[46] For the gel electrophoresis experiments, supercoiled pBR 322 DNA (100 μM in nucleotides) in Tris-HCl buffer (pH = 8.0) was treated with the metal complex (10 μM) and the mixture was incubated in the dark for 1 h. The samples were analyzed by 0.8% agarose gel electrophoresis (Tris-acetate/EDTA buffer, pH = 8.0), stained with EtBr (1 μg/mL, 0.5 h) and then the data were documented with a UVITEC Gel Documentation system. Irradiation experiments were carried out by keeping the pre-incubated (dark, 1 h) samples inside the sample chamber of a JASCO model FP-777 spectrofluorimeter for 60 min (λ_{ex} = 450 ± 5 nm; slit width = 5 nm). The percentage of cleavage (C) was calculated according to Equation (5).

$$C = \frac{[\text{Form II}] + 2[\text{Form III}]}{[\text{Form I}] + [\text{Form II}] + 2[\text{Form III}]} \quad (5)$$

In order to identify the actual reactive oxygen species responsible for DNA damage, a number of control experiments were carried out using various types of quenchers ("inhibitor studies"). Nitrogen gas was used to flush out dioxygen, DABCO (10 mM) was used as a $^1O_2$ quencher, and DMSO (200 mM) and mannitol (100 mM) were used as ·OH scavengers. Tiron (10 mM) was used as a superoxide anion radical quencher.

Acknowledgments

Financial support received for this work from DST New Delhi is gratefully acknowledged. M. M. thanks CSIR for a research fellowship. The authors are thankful to the University Grant Commission, New Delhi, for the facilities provided under the Universities with Potential for Excellence (UPE) programme. We thank Prof. Samudranil Pal for his valuable suggestions.

Keywords: Coordination polymers / Copper / Self-assembly / Supramolecular chemistry / Topology

A series of Cu^{II} coordination polymers with different topologies, namely $[CuL(L^1)]\cdot 2H_2O$ (**1**), $[CuL_{1.5}(L^2)]\cdot 3H_2O$ (**2**), $[CuL(L^3)]\cdot 3H_2O$ (**3**) and $[Cu_2L_{2.5}(L^4)(H_2O)]\cdot 10H_2O$ (**4**) [L = 1,1′-(1,4-butanediyl)bis(imidazole), H_2L^1 = fumaric acid, H_2L^2 = 1,1′-ferrocenedicarboxylic acid, H_2L^3 = succinic acid, and H_4L^4 = pyromellitic acid], are presented. Different polymeric frameworks are obtained by varying the polycarboxylate anions. These include the threefold interpenetrated diamond structure of **1**, the rare twofold interpenetrated 4^66^4 network of **2**, and two planar four-connected networks of **3** and **4**, which display an unusual Archimedean-type $(6^58)(6^48^2)$ net containing two different types of nodes and a $(56^48)(5^26^28^2)_2(68^410)(5^46^2)$ net containing four different types of nodes, respectively. Thermogravimetric analysis (TGA) curves of **1**, **2**, **3**, and **4** exhibit three similar weight-loss stages.

Introduction

The construction of coordination networks with novel topologies is of particular current interest due to their intriguing structural diversity.[1] The analysis of network topology acts as an important role in the discussion and design of crystal structures. Wells has listed a large number of topologies in his classic monographs on networks.[2] Numerous reported fascinating archetypal structures, including diamond (6^6),[3] $SrSi_2$ (10^3-a),[4] α-$ThSi_2$ (10^3-b),[5] SiO_2 (6^48^2-b),[6] and PtS (4^28^4),[7] have provided experimental examples of these theoretical topologies. All of these extraordinary structures are of fundamental importance in structural design and in the understanding of structure–property correlations.

In recent years many rational synthetic strategies have been proposed for the design of metal-based coordination supramolecular structures. Application of these strategies allows the assembly of a target compound with novel topology.[8] However, general and precise principles for controlling the structures of the target products still need to be further classified and improved. An understanding of the factors that govern the assembly process is therefore necessary for the development of the synthetic strategies. In molecular self-assembly processes many factors influence the formation of the final architectures, such as the solvent system, template, central metal, and anion. We are particularly interested in the effects of anions on the architectures of the final complexes.[9] In an attempt to investigate the design and control of the preparation of coordination compounds, the first square-planar four-connected (8^6) or (8,4) nets have been rationally synthesized by Tong et al. and us.[10] As a continuation of our work, we present here four novel coordination polymers with different organic anions, namely $[CuL(L^1)]\cdot 2H_2O$ (**1**), $[CuL_{1.5}(L^2)]\cdot 3H_2O$ (**2**), $[CuL(L^3)]\cdot 3H_2O$ (**3**), and $[Cu_2L_{2.5}(L^4)(H_2O)]\cdot 10H_2O$ (**4**) [L = 1,1′-(1,4-butanediyl)bis(imidazole), H_2L^1 = fumaric acid, H_2L^2 = 1,1′-ferrocenedicarboxylic acid,[11] H_2L^3 = succinic acid, and H_4L^4 = pyromellitic acid; see Scheme 1]. Single-crystal X-ray analyses show that the organic anions play an important role in directing the final structural motifs of the polymers.

Results and Discussion

Syntheses and Characterization

Complexes **1**–**4** are insoluble in water and common organic solvents, and crystals suitable for X-ray diffraction analysis cannot be obtained by evaporating an appropriate solution of **1**–**4**. We found that they can be dissolved in a concentrated solution of ammonia by segregating the ligands from Cu^{II} cations owing to the coordinating role of ammonia toward the Cu^{II} cation. Their crystals were there-

fore obtained by an unusual crystallization process by evaporating an ammoniacal solution of **1**–**4**.

The elemental analysis data for the four compounds are in good agreement with the formulae $[CuL(L^1)]\cdot 2H_2O$ (**1**), $[CuL_{1.5}(L^2)]\cdot 3H_2O$ (**2**), $[CuL(L^3)]\cdot 3H_2O$ (**3**), and $[Cu_2L_{2.5}(L^4)(H_2O)]\cdot 10H_2O$ (**4**). In order to characterize the compounds **1**–**4** more fully in terms of thermal stability, we studied them by TGA. Compounds **1**–**4** were heated from 35 to 750 °C under N_2. When crystals of **1**–**4** were removed from the mother liquor, they lost some of their water molecules. TGA was performed with these partially dehydrated samples. As expected, the TGA curves of compounds **1**–**4** exhibit three similar weight-loss stages. The first weight loss, corresponding to the remaining water molecules, is observed over the wide temperature ranges 35–96 °C, 35–90 °C, 35–92 °C, and 35–89 °C for **1**–**4**, respectively. The second weight loss is 46.2% (calculated 43.6%) for **1** in the range 237–477 °C, 43.4% (calculated 42.2%) for **2** in the range 232–340 °C, 45.9% (calculated 44.8%) for **3** in the range 233–468 °C, and 47.3% (calculated 45.2%) for **4** in the range 227–330 °C, assigned to the release of L molecules. Drastic weight losses corresponding to the removal of L^1, L^2, L^3, and L^4 were observed from 477 to 530 °C for **1**, from 340 to 528 °C for **2**, from 468 to 530 °C for **3**, and from 400 to 505 °C for **4**, respectively.

Crystal Structures

Selected bond lengths and angles for complexes **1**–**4** are listed in Table 1. In the crystal structure of **1** there is one unique four-coordinate Cu^{II} atom. Each Cu^{II} center has a square-planar coordination sphere, with two nitrogen atoms from two L and two oxygen atoms from two L^1 ligands (see a in Figure 1), which provide the four-connected nodes resulting in an unsymmetrical adamantane-type 6^6 net (see b in Figure 1). Water molecules are found in the cage of the adamantane unit and distortions of the unit can arise from the application of different ligands (L and L^1).[12] The distance between the Cu^{II} centers is determined by the length of L (11.784 Å) or L^1 (9.714 Å). Three-fold interpenetration occurs for the 6^6 nets of **1** to diminish the void volume of the structure. Figure 1 (see c) shows that three independent equivalent networks are interpenetrated within the structure of **1**. Each pair of nets (I and II, II and III) display a normal mode of interpenetration.[13] For example, four rods from the node of net II inside the cavity of one adamantane unit of net I penetrate one six-membered window of the adamantane unit of net I.

The coordination environment of the Cu^{II} atom in **2** is shown in Figure 2 (see a). The copper(II) center adopts a distorted square pyramidal geometry by coordinating to three nitrogen atoms (N1, N3, and N5) from three L ligands and two oxygen atoms (O1 and O3A) from two L^2 ligands. The N1, N3, N5, and O1 atoms constitute the base of the pyramid, whereas O3A occupies the apical position at a Cu–O3A distance of 2.268(3) Å.

The Cu^{II} cations in **2** are bridged by L to form 2D (6,3) networks (see b in Figure 2). These 2D (6,3) networks are further connected by bridging L^2 ligands to give rise to a 3D network which can be classified as a 4^66^4 topological type based on pure five-connected nodes (see c in Figure 2). It is noteworthy that this 4^66^4 net is topologically analogous to the inorganic network B_2 in AlB_2.[13] Interestingly, as shown in Figure 2 (see d), the identical 4^66^4 networks are twofold interpenetrated to form an interlocked 3D structure. To the best of our knowledge, this structural topology is very rare in coordination polymer chemistry.[14]

The structure of **3** contains two crystallographically unique Cu^{II} cations, two unique L ligands, and one unique L^3 ligand. As shown in part a of Figure 3, each Cu^{II} cation is four-coordinate in a square-planar four-connected geometry with two nitrogen atoms from two L molecules and two oxygen atoms from two L^3 ligands. There exist some unique shortest six- and eight-membered circuits through Cu^{II} cations in **3** (see Figures S1–S4 in the Supporting Information). Figure 3 (see b) shows the unusual network displayed by the structure of **3**. This net contains two types of nodes (Cu1 and Cu2). For Cu1, each of four sets of *cis* links is contained in a six-membered ring (circuit II), and each of two sets of *trans* links is contained in an eight-membered

ring (circuit IV), so the square-planar four-connected Cu1 cation serves as an NbO-like node that also exists in the network of quartz (Schläfli symbol $6^4 8^2$).[15] For Cu2, each of four sets of *cis* links and one set of two *trans* links can be used to construct a six-membered ring (circuits I and II), and the other set of *trans* links is contained in an eight-membered ring (circuit III). Thus, the Cu2 cation can be described as a $CdSO_4$-like node (Schläfli symbol $6^5 8$).[15] Structures based solely on rare NbO or $CdSO_4$ have been explored, but networks containing both an NbO node and a $CdSO_4$ node have not previously been reported in coordination polymers.[15] The network of **3** based on Cu1 and Cu2 cations can be symbolized as an Archimedean-type $(6^5 8)(6^4 8^2)$ net with planar four-connected nodes.[2]

In the structure of **4**, there exist three crystallographically unique Cu^{II} cations (Cu1, Cu2, and Cu3), two unique L^4 ligands, and three unique L molecules. As shown in Figure 4a, each of the Cu1 and Cu3 cations is four-coordinate in a square-planar geometry with two nitrogen atoms from two L molecules and two oxygen atoms from two L^4 anions, while the Cu2 cation center has a distorted square-pyramid coordination sphere defined by one carboxylate oxygen atom, one water molecule, and three nitrogen atoms from three L molecules. The two unique L^4 anions display different coordination modes: one coordinates to four Cu^{II} cations through four carboxylate groups, acting as a tetradentate ligand, while the other coordinates to two Cu^{II} cations using two *para*-carboxylate groups and is a bidentate ligand.

For complex **4**, the benzene ring of the tetradentate L^4 anion can be considered as a four-connected node, thus there exist four kinds of planar four-connected nodes in the framework (Cu1, Cu2, Cu3 and the benzene ring of the L^4 anion). There exist some unique shortest five-, six-, eight-, and ten-membered circuits through nodes in **4** (see Figures S5–S12 in the Supporting Information). For Cu1, each of four sets of *cis* links is contained in a six-membered ring (circuit II), while two sets of *trans* links are contained in a five-membered ring (circuit I) and an eight-membered ring (circuit **III**), respectively (see Figure S13 in the Supporting Information). Thus, the Cu1 cation has the Schläfli symbol $5 6^4 8$. For Cu2, each of two sets of *cis* links is contained in a five-membered ring (circuit I), while each of the other two sets of *cis* links is contained in a six-membered ring (circuit IV); each of two sets of *trans* links is contained in an eight-membered ring (circuit V and circuit VI; see Figure S14 in the Supporting Information). Thus, the Cu2 cation has the Schläfli symbol $5^2 6^2 8^2$. For Cu3, each of four sets of *cis* links is contained in an eight-membered ring (circuit VI), while two sets of *trans* links are contained in a six-membered ring (circuit IV) and a 10-membered ring (circuit VII; see Figure S15 in the Supporting Information). Thus, Cu3 has the Schläfli symbol $6 8^4 10$. For the benzene ring of the tetradentate L^4 ligand, each of four sets of *cis* links is contained in a five-membered ring (circuit I), while each of two sets of *trans* links is contained in a six-membered ring (circuits II and VIII; see Figure S16 in the Supporting Information). Thus, the benzene ring of the tetradentate L^4 anion has the Schläfli symbol $5^4 6^2$. The molar ratio of these four kinds of nodes is 1:2:1:1, thus the network of complex **4** can be described as an Archimedean-type net with four kinds of nonequivalent points: $(56^4 8)(5^2 6^2 8^2)_2(68^4 10)(5^4 6^2)$

(see b in Figure 4). To the best of our knowledge, complex **4** is the first example of a coordination polymer which displays a $(56^48)(5^26^28^2)_2(68^410)(5^46^2)$ topology.[1]

Role of the Anions in the Self-Assembly Processes

From the above descriptions it is clear that the choice of anions is critical in determining the molecular structures of the resultant complexes. In this study, the nature of the anions such as rigidity, flexibility, and the length of the spacer is the underlying reason behind the differences in the structure of this series of copper(II) complexes:·L^1 possesses rigidity due to the presence of a –C=C– spacer between the two carboxylate moieties, whereas L^3 possesses flexibility owing to the presence of a $–CH_2CH_2–$ spacer between the two carboxylate moiety;·L^2 is a ferrocene-based ligand, which can freely rotate around the organoferrocene "ball-joint" to meet the requirements of the coordination geometries of metal ions in the assembly process. Compared with L^1, L^2, and L^3, L^4 is a planar multi-carboxylate anion, which can adopt various coordination modes.

The ratios of Cu:L^n (n = 1, 2, 3, and 4) are determined by the negative charges of the anions. Thus, the ratios of Cu:L^n (n = 1, 2 and 3) are 1:1, and the ratio of Cu:L^4 is 2:1. Since the compounds are isolated by evaporation of the corresponding solutions, the Cu:L ratios of 1:1 for **1** and **3**, 1:1.5 for **2**, and 1:1.25 for **4** may be affected by the solubility of the compounds. The different network topologies of the compounds are related to the Cu:L:L^n ratios (n = 1, 2, 3 and 4). The topological difference between **1** and **3** should result from the structural features of L^1 and L^3: L^3 is more flexible than L^1, and due to its flexibility L^3 forms a $(6^58)(6^48^2)$ network with less void volume, and the rigid ligand L^1 forms a 6^6 network of **1** with large void volume, which is eliminated by the interpenetration. In addition, it should be pointed out that the change of copper(II) and L compositions used in the preparations of these complexes cannot have an effect on their final structures. Thus, the formation of these different frameworks is due solely to the effects of the organic anions.

Conclusions

A series of Cu^{II} coordination polymers with different topologies has been synthesized due to the effect of the organic anions on the formation of the final frameworks. When L^1 was used as the bidentate carboxylate anion, a coordination polymer **1** with a threefold interpenetrated diamond structure was obtained. Coordination polymer **2**, containing a Cu^{II} atom and L^2, displays a rare twofold interpenetrated $4^6 6^4$ topology. Two planar, four-connected Cu^{II} coordination polymers **3** (with L^3) and **4** (with L^4) display an interesting Archimedean-type $(6^5 8)(6^4 8^2)$ net containing two different types of square-planar nodes and a $(56^4 8)(5^2 6^2 8^2)_2(68^4 10)(5^4 6^2)$ net containing four different types of square-planar nodes, respectively.

Experimental Section

Materials and Methods: All reagents and solvents for syntheses were purchased from commercial sources and used as received. A Perkin–Elmer 240 elemental analyzer was used to collect microanalytical data. TGA was performed on a Perkin–Elmer TG-7 analyzer in nitrogen. The FT-IR spectra were recorded from KBr pellets in the range 4000–400 cm^{-1} on a Mattson Alpha-Centauri spectrometer.

Synthesis of 1,1′-(1,4-Butanediyl)bis(imidazole) (L): A mixture of imidazole (3.4 g, 50 mmol) and NaOH (2.0 g, 50 mmol) in DMSO (10 mL) was stirred at 60 °C for 1 h, and then 1,4-dichlorobutane (3.2 g, 25 mmol) was added. The mixture was cooled to room temperature after stirring at 60 °C for 2 h and then poured into 200 mL of water. A white solid formed immediately, which weighed 4.1 g (86%) after drying in air. $C_{10}H_{14}N_4$ (190.25): calcd. C 63.16, H 7.37, N, 29.47; found C 63.11, H 7.42, N 29.31.

Synthesis of $[CuL(L^1)]\cdot 2H_2O$ (1): A mixture of $CuCl_2\cdot 2H_2O$ (0.171 g, 1 mmol), NaOH (0.080 g, 2 mmol), and fumaric acid (H_2L^1; 0.116 g, 1 mmol) in water was stirred for 10 min at 60 °C, then 1,1′-(1,4-butanediyl)bis(imidazole) (L; 0.190 g, 1 mmol) was added to the mixture. After stirring for 30 min, the blue precipitate was collected and dissolved in a minimum amount of ammonia (14 M). Blue single crystals of **1** were obtained by slow evaporation of the ammoniacal solution at ambient temperature. Yield: 66% (266 mg). $C_{14}H_{20}CuN_4O_6$ (403.88): calcd. C 41.60, H 4.99, N 13.87; found C 40.89, H 4.60, N 13.49. IR (KBr): 3436 cm^{-1} (s), 3125 (w), 2950 (m), 1619 (s), 1526 (m), 1451 (m), 1285 (w), 1238 (s), 1107 (vs), 948 (w), 849 (w), 771 (w), 756 (m), 664 (m).

Synthesis of $[CuL_{1.5}(L^2)]\cdot 3H_2O$ (2): The same procedure was used to synthesize compound **2** from 1,1′-ferrocenedicarboxylic acid (H_2L^2). Yield: 72% (324 mg). $C_{27}H_{35}CuFeN_6O_7$ (675.00): calcd. C 48.04, H 5.23, N 12.45; found C 48.43, H 5.63, N 12.79. IR (KBr): 3439 cm^{-1} (vs), 3127 (w), 2941 (m), 1606 (vs), 1561 (s), 1527 (m), 1454 (m), 1363 (s), 1237 (m), 1103 (s), 758 (m), 655 (m).

Synthesis of $[CuL(L^3)]\cdot 3H_2O$ (3): The same procedure was used to synthesize compound **3** from succinic acid (H_2L^3). Yield: 78% (331 mg). $C_{14}H_{24}CuN_4O_7$ (423.91): calcd. C 39.63, H 5.71, N 13.22; found C 39.29, H 5.60, N 13.49. IR (KBr): 3437 cm^{-1} (vs), 3123 (w), 2952 (m), 1617 (s), 1526 (m), 1453 (m), 1286 (w), 1240 (s), 1102 (vs), 952 (w), 846 (w), 773 (w), 659 (m).

Synthesis of $[Cu_2L_{2.5}(L^4)(H_2O)]\cdot 10H_2O$ (4): The same procedure was used to synthesize compound **4** from pyromellitic acid (H_4L^4).

Yield: 81% (340 mg). $C_{35}H_{59}Cu_2N_{10}O_{19}$ (1051.0): calcd. C 39.97, H 5.66, N 13.33; found C 39.71, H 5.53, N 13.48. IR (KBr): 3441 cm^{-1} (vs), 3133 (w), 2947 (m), 1609 (vs), 1559 (s), 1530 (m), 1452 (m), 1367 (s), 1240 (m), 1106 (s), 653 (m).

X-ray Crystallography: Single-crystal X-ray diffraction data for complexes **1**–**4** were recorded on a Rigaku RAXIS-RAPID image-plate diffractometer using the *ω*-scan technique with Mo-K_α radiation (λ = 0.71073Å). Absorption corrections were applied using the multi-scan technique. All structures were solved by direct methods with SHELXS-97[16] and refined by full-matrix least-squares techniques using the SHELXL-97 program.[17] All non-hydrogen atoms were refined with anisotropic temperature parameters; the hydrogen atoms of the ligands were refined as rigid groups. Further details of the structural analysis are summarized in Table 2.
CCDC-253915 (for **1**), -228776 (for **2**), -216566 (for **3**), and -216568 (for **4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Powder X-ray Diffraction Analyses: The powder X-ray diffraction patterns for the polymers **1**–**4** agree well with those simulated. The diffraction peaks of both experimental and simulated patterns match well in position, thus indicating the phase purity of polymers **1**–**4**. The difference in reflection intensities between the simulated and experimental patterns is due to the different orientation of the crystals in the powder samples.

Supporting Information: Figures of circuits around the copper cations of **3** and **4** (Figures S1–S16).

Synthesis and Crystal Structures of Four Cyanide-Bridged Coordination Polymers

Xiang He,[a] Can-Zhong Lu,*[a] Da-Qiang Yuan,[a] Shu-Mei Chen,[a] and Jiu-Tong Chen[a]

Keywords: Bridging ligands / Coordination polymers / Copper / Cyanides / Heterometallic complexes

The hydrothermal reaction of $Cu(NO_3)_2 \cdot 3H_2O$, $K_3Fe(CN)_6$, and 1,10-phenanthroline (1,10-phen) or 2,2′-bipyridine (2,2′-bpy) gives rise to the three one-dimensional helical-chain complexes $[Cu_2Fe(CN)_4(1,10\text{-phen})_3]_n \cdot 0.5n\,H_2O$ (**1**), $[Cu_3(CN)_3(1,10\text{-phen})_3]_n$ (**2**), and $[Cu_3(CN)_3(2,2'\text{-bpy})_3]_n$ (**3**), and the two-dimensional layer complex $[Cu_3Fe(CN)_5(2,2'\text{-bpy})_2]_n$ (**4**). The structure of **1** contains a cyanide-bridged $Cu^I \cdots Fe^{II} \cdots Cu^I$ chain in which the two copper and one iron centers exhibit different coordination environments. The structures of **2** and **3** are both monometallic. Complex **4** is constructed alternately from fused 6- and 14-metal-membered nonplanar centrosymmetric rings that form a 2D layer architecture.

Introduction

The chemistry of spontaneously self-assembled supramolecular architectures based on transition metal complexes is currently an active and rapidly expanding research area. Transition metal cyanides have been studied for a long time because such compounds possess various interesting physical and chemical properties and have important applications in many fields, such as catalysis, molecular-based magnets, and zeolitic materials.[1–3] The cyanide group is a versatile ligand that can act as a monodentate ligand or as a bridging ligand adopting end-on (I) or end-to-end (II) modes to generate interesting complexes that may exhibit intriguing architectures and new topologies. As copper normally adopts three-, four-, five-, or sixfold coordination to form diverse geometric structures, much research has focused on the copper cyanide system from the viewpoint of structural engineering.[4,5] Helical structures have received special attention in the past decades as helicity is an essential element for bioactivity and also due to their potential applications in asymmetric catalysis and nonlinear optical materials.[6] To date, quite a few single- or double-helical chains have been generated,[7–9] with most helical polymers being obtained by using chiral ligands[10,11] or oligopyridines and other optically active ligands. In addition, the design and synthesis of novel coordination architectures can be controlled by varying the reaction conditions, including temperature,[12] metal-to-ligand ratio,[13] pH value,[14] solvents,[15] and counteranions.[16]

Generally, it is difficult to synthesise Fe^{II}-containing coordination polymers because the Fe^{II} ion is air-sensitive and hydrolyzes easily, and this might be the main reason why such Fe^{II} polymers are rare. In this article we report the syntheses and crystal structures of two Cu/Fe bimetallic cyanide-bridged coordination polymers − $[Cu_2Fe(CN)_4(1,10\text{-phen})_3]_n \cdot 0.5n\,H_2O$ (**1**) and $[Cu_3Fe(CN)_5(2,2'\text{-bpy})_2]_n$ (**4**) − and two copper polymers − $[Cu_3(CN)_3(1,10\text{-phen})_3]_n$ (**2**) and $[Cu_3(CN)_3(2,2'\text{-bpy})_3]_n$ (**3**).

To the best of our knowledge, compound **1** is the first example of a one-dimensional helical chain structure that contains different metal atoms with quite different coordination environments, while compound **4** is the first example of a bimetallic neutral 2D lamella framework compound built up by cyanide-bridged 6- and 14-metal rings.

Results and Discussion

Hydrothermal methods are important in the synthesis of novel multidimensional open-framework materials as a change of reaction conditions for the preparation of these complexes can also have an effect on their structures, although it is difficult to control and predict the crystal structures under hydrothermal methods. It is known that the architectures of the products depend on many factors, such as temperature, the anions involved, the molar ratios of the precursors, the pH etc., and subtle adjustments of these parameters often result in the formation of quite different structures. For example, Forster and his co-workers have carried out systematic studies on the effect of temperature on the structures of the products.[12] Our syntheses under hydrothermal conditions provide four novel compounds with different structural frameworks (Scheme 1). Interestingly, we obtained two monometallic compounds and two

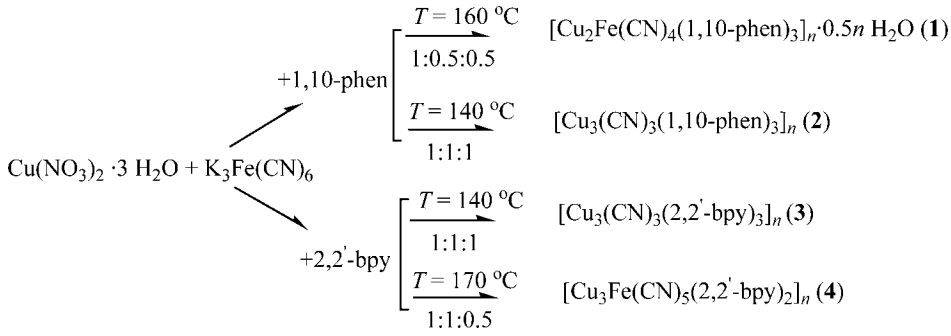

Scheme 1. Cyanide-bridged coordination polymers.

bimetallic materials from similar precursors. The reason for the different results obtained from these reactions is perhaps due to the temperature and the molar ratio of the precursors, although the details are not clear. From these processes $K_3Fe(CN)_6$ appears to be a promising precursor to obtain more new compounds.

The IR bands corresponding to CN stretching vibrations for compounds **1**–**4** appear in the range 2080–2116 cm^{-1}, which is typical for bridging cyanide groups. For **1**, two different absorptions at 2102 and 2080 cm^{-1} indicate the existence of two types of cyanide groups. The lower wavenumber band can be assigned to a terminal cyanide group, while the band at 2102 cm^{-1} is attributed to the stretching vibration of a linear bridging cyanide.

To study the stability of the polymers, thermogravimetric analysis (TGA) was performed for complexes **2**–**4**. These studies show that these complexes are stable up to 280 °C. The stabilities of these compounds make them potential candidates for practical applications.

Electron probe analyses revealed that there are two kinds of metals (copper and iron) in compounds **1** and **4**, the molar ratios of the two metals being 2:1 and 3:1, respectively, in agreement with the structural results. The magnetic susceptibilities of **1** and **4** are negative, which is typical of a diamagnetic behavior. This indicates that the iron atoms in these compounds are in the low-spin Fe^{II} ($S = 0$) state and the copper centers are in the Cu^{I} oxidation state.

$[Cu_2Fe(CN)_4(1,10\text{-phen})_3]_n \cdot 0.5n\,H_2O$ (1): A 1D Framework

The hydrothermal reaction of $Cu(NO_3)_2 \cdot 3H_2O$, $K_3Fe(CN)_6$, and 1,10-phen led to the formation of red crystals of compound **1**. X-ray analysis revealed that compound **1** has a one-dimension neutral helical-chain architecture. As the reaction was carried out under hydrothermal conditions, it is not surprising that the Cu^{II} and Fe^{III} ions have been reduced to Cu^{I} and Fe^{II} ions by cyanide or N-heterocyclic ligands, such as 1,10-phen or pyridine derivatives.[17–19] The cyanide in **1** is provided by the ferricyanide anions. A view of the metal coordination environment is presented in Figure 1. Two copper atoms have different co-

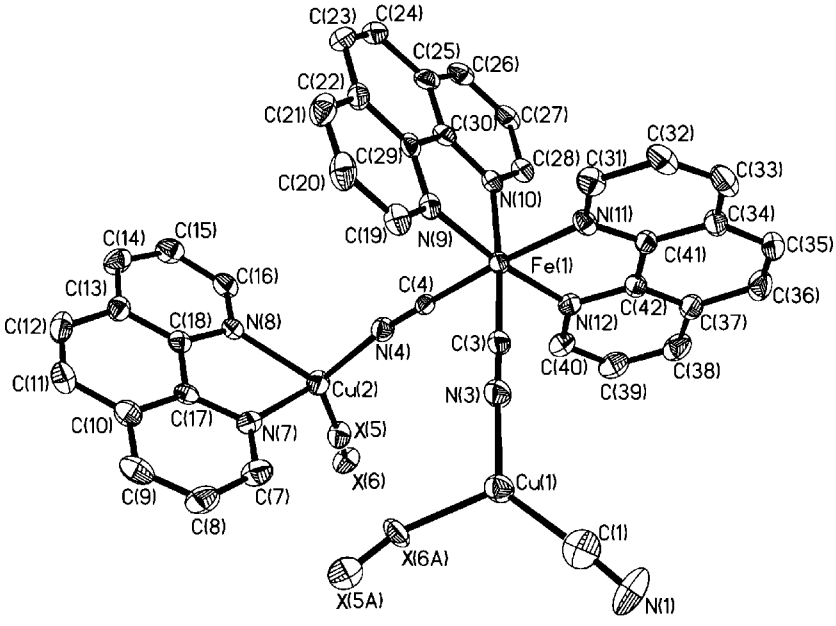

Figure 1. ORTEP representation of the polymeric structure of **1**, showing the coordination environments of the Cu and Fe centers (hydrogen atoms and solvent molecules have been omitted for clarity). Atoms from the disordered CN bridging groups are labeled as X.

ordination environments: the first Cu^{I} is coordinated by two cyanide [Cu–X = 1.904(7) Å and Cu–N = 1.969(5) Å] and two nitrogen atoms from 1,10-phen [Cu–N = 2.128(5) Å] and exhibits a distorted tetrahedral coordination environment, whereas the second Cu^{I} is coordinated by three nitrogen atoms from three cyanides [Cu–X = 1.932(9)–1.989(6) Å] and exhibits a distorted trigonal planar coordination environment. The heterocyclic 1,10-phen ligand is planar and the copper atom lies within this plane. The bond lengths and angles within the 1,10-phen group are in agreement with those reported for the free 1,10-phen molecule.[20] An intramolecular hydrogen bonding interaction C(28)–H(28A)···N(12) of about 3.098(8) Å is also present.

Each iron atom exhibits a distorted octahedral coordination environment and is coordinated by the carbon atoms from two cyanides and four nitrogen atoms from two bidentate 1,10-phen ligands. The bond lengths for the iron atom [Fe–C = 1.903(6)–1.928(5) Å and Fe–N = 1.973(5)–2.006(5) Å] and the corresponding angle subtended by the bidentate 1,10-phen ligand [N–Fe–N = 81.9(2)–82.2(2)°] agree well with those reported for the low-spin iron(II) complex $[Fe(1,10\text{-phen})_2(CN)_2]$.[21]

The intrachain distances Cu1···Fe1, Fe1···Cu2, and Cu1···Cu2 across cyanide bridges are 5.033(3), 4.985(2), and 4.939(2) Å, respectively. Each pair of adjacent metal atoms is bridged by cyanides to form a helical chain along the *b* axis with a pitch of 10.267(1) Å (Figure 2). The shortest interchain iron–iron, iron–copper, and copper–copper distances are 8.778(3) Å [Fe1···Fe1 (0.5 – *x*, 0.5 + *y*, 0.5 – *z*)], 6.574(1) Å [Cu1···Fe1 (1 – *x*, 1 – *y*, –*z*)], and 5.998(3) Å [Cu1···Cu1 (1 – *x*, 1 – *y*, –*z*)], respectively.

$[Cu_3(CN)_3(1,10\text{-phen})_3]_n$ (2): A 1D Framework

Compound **2** was obtained by varying the temperature and the composition of the reaction mixture used for the preparation of **1**. The X-ray diffraction study revealed that the copper atom is coordinated by two cyanide [Cu–X = 1.914(7)–1.919(9) Å] and two nitrogen atoms from 1,10-phen [Cu–N = 2.096(8)–2.138(8) Å] to give a distorted tetrahedral coordination environment (Figure 3). The cyanide ligands are linearly coordinated [C–N–Cu angles range from 173.3(7)° to 175.4(5)°] and bridge adjacent Cu^{I} atoms to form a one-dimensional helical chain running along the *c* axis with a long pitch of 24.485(10) Å (see a in Figure 4). The intrachain Cu···Cu distance across the cyanide bridges is 4.962 Å. This chain is decorated by 1,10-phen ligands above and below the helical chain. Figure 4 (see part b) shows that five copper atoms form two approximately equilateral triangles that have the same vertex, with the butterfly shape viewed down the *c* axis. The shortest interchain copper–copper distance is 7.751(3) Å [Cu1···Cu1 (0.5 + *x*, 1.5 – *y*, 1 – *z*)].

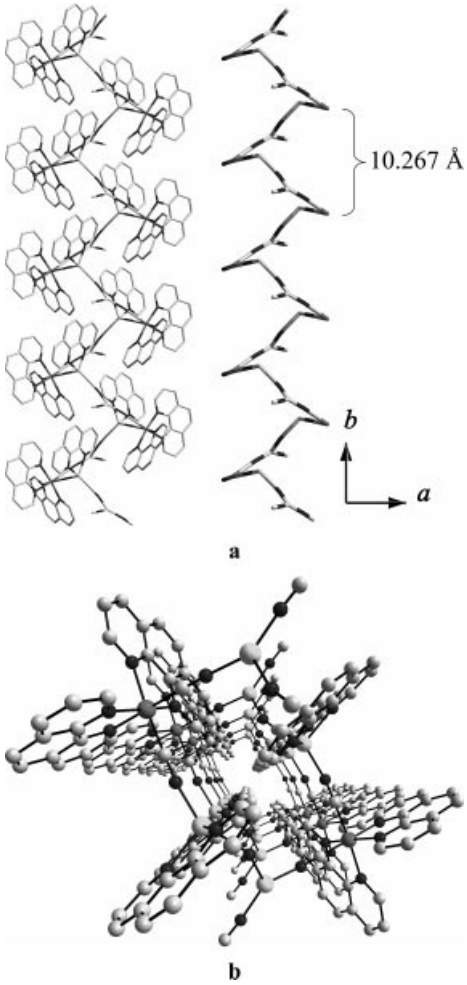

Figure 2. a) Schematic view of the helical chain of **1**. b) View along the helical axis.

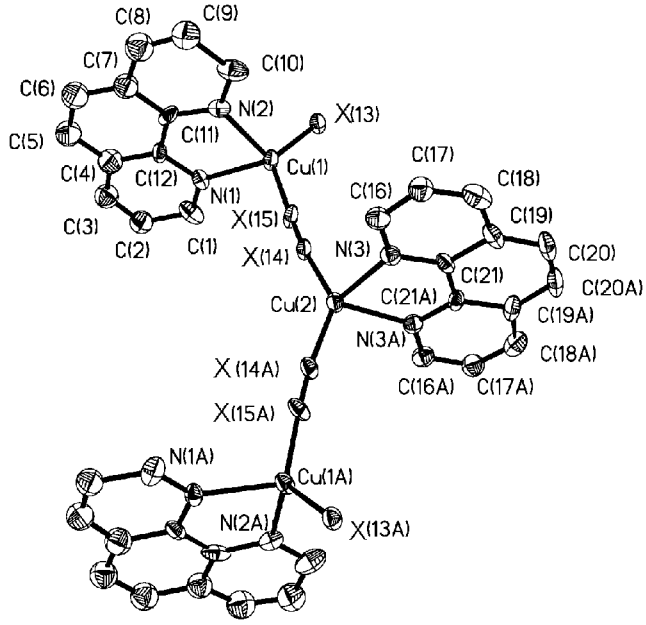

Figure 3. The coordination environments of the copper atoms in complex **2**.

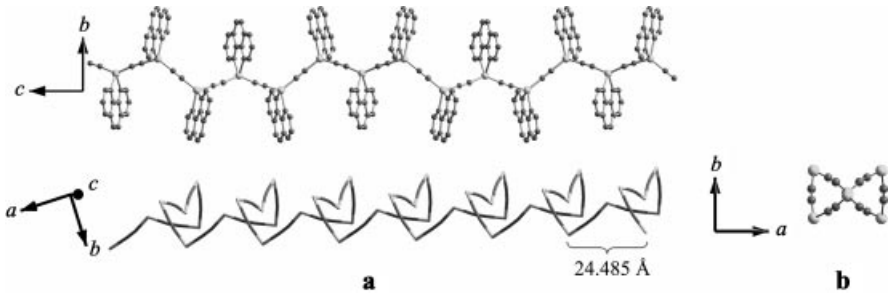

Figure 4. a) The 1D helical chain framework of **2**. b) View along the helical axis.

[Cu(CN)(2,2′-bpy)]$_n$ (3): A 1D Framework

X-ray analysis revealed that the asymmetric unit of compound **3** consists of three neutral mononuclear molecules with copper center in a distorted tetrahedral environment. As shown in Figure 5, each copper atom is coordinated by two cyanides [Cu–X = 1.882(6) Å–1.930(5) Å] and two nitrogen atoms from 2,2′-bpy [Cu–N = 2.078(6) and 2.112(5) Å]. Every two adjacent Cu^I atoms are bridged by cyanides to form a chiral helical chain along the 3_2 screw axis with a long pitch of 12.898(1) Å (see a in Figure 6). The intrachain Cu···Cu distance across cyanide bridges is 4.973(1) Å. The helical chain with only a Cu–Cu backbone has a trigonal shape when viewed down the *c* axis, with each copper atom as the vertex of an approximately equilateral triangle. The angle subtended at the copper atom by two cyanide linkages is reduced to 126.8(2)° (b in Figure 6). This chain is also decorated by 2,2′-bpy ligands along both sides of the chain. The shortest interchain copper–copper distance is 7.371(1) Å [Cu1···Cu3 (1 – *x* + *y*, 1 – *x*, – 0.66667 + *z*)], which is slightly shorter than that for compound **2**.

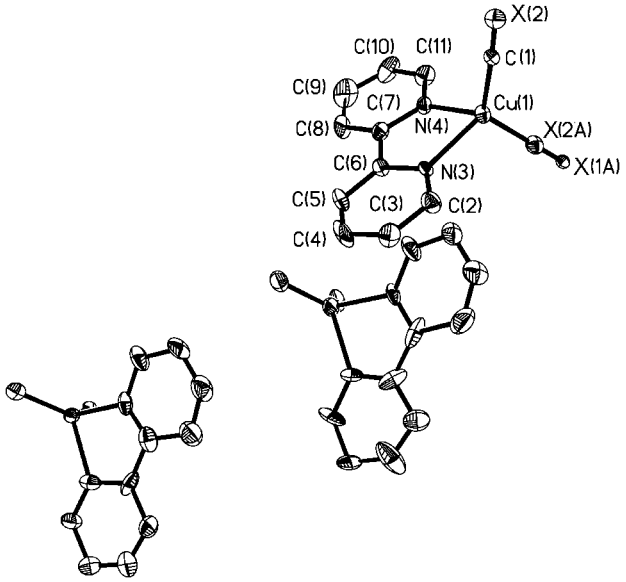

Figure 5. The coordination environments of the copper atoms in complex **3**.

[$Cu_3Fe(CN)_5(2,2'\text{-bpy})_2$]$_n$ (4): A 2D Network

Compound **4** was obtained by varying the temperature and the composition of the reaction mixture used for the preparation of **3**. The X-ray analysis revealed that the structure of **4** (Figure 7) consists of neutral corrugated sheets constructed alternately from fused 6- and 14-metal-membered nonplanar centrosymmetric rings, which are bridged by cyanide groups. Each 6-metal-ring contains two iron and four copper atoms, and the Fe^{II} atom is in a distorted octahedral environment containing four nitrogen atoms from two bipyridine ligands and two carbon atoms from two cyanide groups [Fe–N = 1.958(2)–1.986(3) Å; Fe–C = 1.909(3)–1.913(3) Å]. The values of the bond lengths in **4** for the iron atom are comparable to those found in compound **1** and other cyanide-bridged bimetallic complexes containing the [$Fe(bpy)_2(CN)_2$] building block.[22]

The two Cu^I atoms have two different coordination environments, with the first coordinated by three cyanide groups in a triangular geometry and the second coordinated by two cyanide groups in a linear geometry.

The Fe1···Cu1, Cu1···Cu4, Cu1···Cu2, and Cu2···Cu3 distances across cyanide bridges are 4.988(6), 4.870(7),

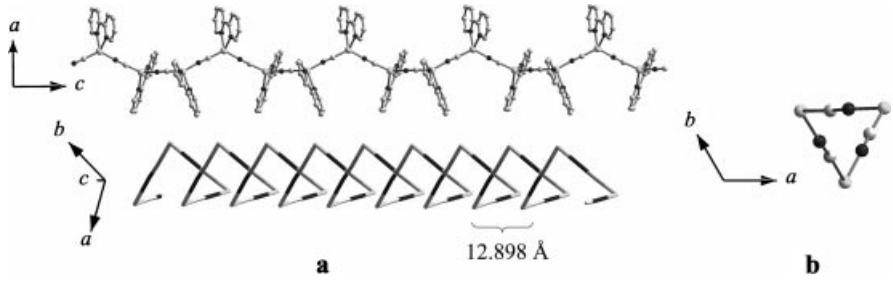

Figure 6. a) The 1D helical chain framework of **3**. b) View down the helical chain.

b

Figure 8. a) Perspective view of the 2D layer structure of **4**. b) Schematic representation of the interpenetrated 2D lamella framework.

4.901(13), and 4.840(16) Å, respectively. The structure consists of 2D layers, parallel to the *ac* plane, constructed by alternating 6- and 14-metal-membered centrosymmetric rings in which the metal centers are bridged by cyanide groups. The 6-metal rings adopt a chair conformation for the Cu···Fe···Cu···Cu···Fe···Cu unit. The size of these rings is about 8.9×8.0 Å^2. Four adjacent rings 6-metal rings add four two-coordinate copper atoms to form a larger 14-metal-membered ring {Fe-$(Cu)_6$-Fe-$(Cu)_6$} of approximately 13×22 Å^2. Each 14-metal-membered ring shares four sides with four adjacent 14-metal-membered rings and four sides with four adjacent 6-metal-membered rings; each 6-metal-membered ring shares all its edges with four 14-metal-membered rings to form a 2D framework. A view down the *b* axis shows that the actual crystal structure of compound **4** is a twofold interpenetrating 2D supramolecular framework (Figure 8). This is consistent with the fact that crystal structures with such large cavities are stabilized either by inclusion of suitable guests or by interpenetrating lattices.[23]

Intramolecular hydrogen-bonding interactions [C(9)–H(9A)···N(12) = 3.078(4) Å; C(19)–H(19A)···N(10) = 3.065(4) Å] also exist in **4**.

A method for preparing bimetallic compounds from hexacyanoferrate(III) under hydrothermal conditions has been reported previously.[24] Upon comparing the structure of **4** with the reported compound $[Fe(bipy)_2(CN)_4Cu_2]$, it can be seen that the latter compound is constructed by alternately fused 6- and 10-metal-membered rings to form an ABAB pattern layer instead of the twofold interpenetrating structure found in compound **4**.

Conclusions

Three novel one-dimensional helical-chain coordination polymers and one two-dimensional layer complex have been obtained by hydrothermal synthesis. Under hydrothermal conditions, high-valence ions are reduced to low-valence ions by N-heterocyclic ligands or cyanide from ferricyanide anions. Furthermore, slow release of CN^- might play an

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

important role in the formation of these compounds. The successful isolation of these four compounds demonstrates that it is promising to use $K_3Fe(CN)_6$ as a precursor along with N-heterocyclic ligands, particularly derivatives of 2,2′-bpy and 1,10-phen, to construct novel coordination compounds under hydrothermal reaction conditions.

Experimental Section

General Remarks: All the syntheses were performed in poly(tetrafluoroethylene)-lined stainless steel autoclaves under autogenous pressure. Reagents were purchased commercially and were used without further purification. Elemental analyses of C and H were performed with an EA1110 CHNS-0 CE elemental analyzer. IR (KBr pellet) spectra were recorded on a Nicolet Magna 750FT-IR spectrometer. TGA analyses were carried out under nitrogen with a heating rate of 15 °C min^{-1} on a STA449C integration thermal analyzer. Electron probe analysis was performed with an EPM-810 EDAX9100 SHIMADZU electron probe microanalyzer. Variable-temperature (5–300K) magnetic susceptibility measurements were carried out on a Quantum Design MPMS-7 SQUID magnetometer at 5 T magnetic field using the SQUID method.

$[Cu_2Fe(CN)_4(1,10\text{-phen})_3]_n \cdot 0.5n\,H_2O$ (1): A mixture of $Cu(NO_3)_2 \cdot 3H_2O$ (0.02 g, 0.1 mmol), $K_3Fe(CN)_6$ (0.015 g, 0.05 mmol), and 1,10-phen (0.01 g, 0.05 mmol) in 20 mL of H_2O was stirred for 20 min at room temperature. The mixture was then transferred into a 30-mL, Teflon-lined stainless-steel vessel. The mixture was heated at 160 °C for two days under autogenous pressure. After the reaction mixture had slowly cooled down to room temperature, red prism-shaped crystals of **1** (0.02 g, 45% based on Cu) were collected. $C_{40}H_{25}Cu_2FeN_{10}O_{0.50}$ (863.65): calcd. C 57.42, H 3.01, Cu 15.19, N 16.74; found C 57.25, H 3.03, Cu 15.56, N 16.60. IR (KBr pellet): $\tilde{\nu}$ = 3552 m, 3421 m, 3049 m, 2102 vs, 2080 vs, 1628 m, 1421 s, 1342 m, 1205 m, 1142 m, 1051 m, 847 s, 777 w, 723 s, 633 w, 559 m cm^{-1}.

$[Cu_3(CN)_3(1,10\text{-phen})_3]_n$ (2): $Cu(NO_3)_2 \cdot 3H_2O$ (0.02 g, 0.1 mmol), $K_3Fe(CN)_6$ (0.03 g, 0.1 mmol), and 1,10-phen (0.02 g, 0.1 mmol) in 20 mL of H_2O were stirred for 20 min at room temperature. The mixture was then transferred into a 30-mL, Teflon-lined stainless-steel vessel. The mixture was heated at 140 °C for two days under autogenous pressure. After the reaction mixture had quickly cooled down to room temperature, red prism-shaped crystals were obtained (0.01 g, 45% based on Cu). $C_{39}H_{24}Cu_3N_9$ (809.29): calcd. C 57.88, H 2.99, Cu 23.56, N 15.58; found C 57.42, H 3.03, Cu 23.78, N 15.60. IR (KBr pellet): $\tilde{\nu}$ = 3415 m, 3057 m, 2107 vs, 2008 m, 1620 m, 1583 m, 1568 w, 1505 m, 1492 w, 1418 m, 1139 m, 841 s, 768 m, 727 s, 631 m cm^{-1}.

$[Cu_3(CN)_3(2,2'\text{-bpy})_3]_n$ (3): $Cu(NO_3)_2 \cdot 3H_2O$ (0.02 g, 0.1 mmol), $K_3Fe(CN)_6$ (0.03 g, 0.1 mmol), and 2,2′-bpy (0.016 g, 0.1 mmol) were added to 20 mL of H_2O. This mixture was stirred for 20 min at room temperature and was then transferred into a 30-mL, Teflon-lined stainless-steel vessel. The mixture was heated at 140 °C for two days under autogenous pressure. After the reaction mixture had slowly cooled down to room temperature, dark-red, prism-shaped crystals were obtained (0.01 g, 65% based on Cu). $C_{33}H_{24}Cu_3N_9$ (737.23): calcd. C 53.76, H 3.28, Cu 25.86, N 17.10; found C 54.02. H 3.36, Cu 25.53, N 17.53. IR (KBr pellet): $\tilde{\nu}$ = 3421 m, 3059 m, 2108 vs, 1593 m, 1470 m, 1439 s 1309 m, 1155 m, 1007 m, 764 s, 650 w, 417 w cm^{-1}.

$[Cu_3Fe(CN)_5(2,2'\text{-bpy})_2]_n$ (4): $Cu(NO_3)_2 \cdot 3H_2O$ (0.02 g, 0.1 mmol), $K_3Fe(CN)_6$ (0.03 g, 0.1 mmol), and 2,2′-bpy (0.008 g, 0.05 mmol) were added to 20 mL of H_2O. This mixture was stirred for 20 min at room temperature and was then transferred into a 30-mL, Teflon-lined stainless-steel vessel. The mixture was heated at 170 °C for two days under autogenous pressure. After the reaction mixture had slowly cooled down to room temperature, dark-red, prism-shaped crystals were obtained (0.006 g, 45% based on Cu). $C_{25}H_{16}Cu_3FeN_9$ (688.94): calcd. C 43.58, H 2.34, Cu 27.67, N 18.30; found C 43.56, H 2.64, Cu 27.89, N 18.49. IR (KBr pellet): $\tilde{\nu}$ = 3057 m, 2123 m, 2116 s, 2107 s, 1592 s, 1571 m, 1469 m, 1438 s, 1308 m, 1279 w, 1246 m, 1006 m, 792 s, 649 m cm^{-1}.

X-ray Crystallographic Study: Suitable single crystals of compounds with dimensions 0.34 × 0.32 × 0.30 mm (**1**), 0.30 × 0.20 × 0.20 mm (**2**), 0.50 × 0.18 × 0.10 mm (**3**), and 0.30 × 0.25 × 0.10 mm (**4**) were carefully selected and glued to thin glass fibers with epoxy resin. Crystal structure measurements for

[a] Symmetry transformations used to generate equivalent atoms: I: $-x + 3/2$, $y + 1/2$, $-z + 1/2$; II: $-x$, y, $-z + 1/2$; III: x, $-y + 2$, $-z + 1$; IV: $-x + 2$, $-y$, $-z + 1$.

compounds **1**–**4** were performed on a Rigaku Mercury CCD diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) at room temperature. A total of 6060, 3051, 5435, and 5718 unique reflections were collected in the $\omega/2\theta$ scan mode for **1**–**4**, respectively. The structures were solved by direct methods and refined on F^2 with the SHELXL97 program.[25] For all complexes the bridging cyanide group between two Cu^{I} atoms was disordered with respect to the C and N termini; this disorder was treated by performing test refinements with C and N atoms with partial occupancies. The disordered CN atoms positions are labeled in the tables and drawings as X. All non-hydrogen atoms were refined with anisotropic displacement parameters, and the hydrogen atoms were treated as riding atoms using the SHELX97 default parameters. For **1**, the hydrogen atoms of the water molecules were neither found nor calculated. For **2**, rigid refinement about the next six carbon atoms C4, C5, C6, C7, C11, and C12 was used to form a phenyl ring. The absolute structure parameters of compound **2** and **3** are 0.05(5) and 0.00, respectively. The crystal data and details of refinement for compounds are summarized in Table 1; selected bond lengths and angles are listed in Table 2.

CCDC-236440 (for **1**), -227060 (for **2**), -227061 (for **3**), and -243534 (for **4**) contain the supplementary crystallographic data for this pa-

1,3,5-Triazapentadienes as Chelating Ligands: 1,2,4-Triphenyl-1,3,5-triazapentadiene Complexes of Cobalt(II), Nickel(II), Palladium(II), Copper(II) and Zinc(II)[‡]

Nadine Heße,[a] Roland Fröhlich,[a] Ionel Humelnicu,[b] and Ernst-Ulrich Würthwein*[a]

Dedicated to Prof. Paul v. R. Schleyer on the occasion of his 75th birthday

Keywords: Chelates / Ligand design / Triazapentadienes / N ligands / Tautomerism / DFT calculations

1,2,4-Triphenyl-1,3,5-triazapentadiene (**1a**), prepared from benzamidine and *N*-phenylbenzimidoyl chloride, was treated at room temperature with $CoCl_2$, $Ni(NO_3)_2$, Na_2PdCl_4, $CuCl_2$ and $ZnCl_2$ to form the corresponding six-membered 1:1 chelate complexes **1a·CoCl$_2$**, **1a·Ni(NO$_3$)$_2$**, **1a·PdCl$_2$**, **1a·CuCl$_2$**, and **1a·ZnCl$_2$**. In the solid state **1a·Ni(NO$_3$)$_2$** forms infinite linear chains, bridged by nitrate ions. From **1a** and $Cu(OTf)_2$ a 2:1 copper complex was obtained [(**1a**)$_2$·Cu(OTf)$_2$]. In all cases a proton shift from nitrogen atom N1 in the free ligand to N3 in the complex was observed. All complexes were completely characterized including X-ray crystallography. Quantum chemical DFT calculations indicate that triazapentadiene is a better ligand for $ZnCl_2$, $PdCl_2$ and $CuCl_2$ compared to β-diimines and *N*-acylamidines.

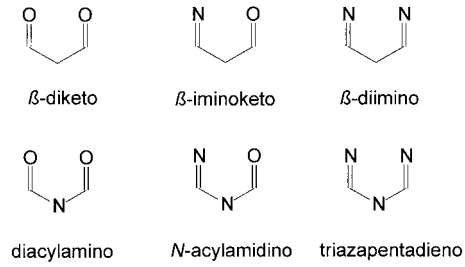
Introduction

1,3-Dicarbonyl derivatives and their nitrogen analogues (β-iminoketones and β-diimines) present valuable ligands for metal-ion chelation, either as neutral or as anionic species. Our synthetic interest is directed towards the development of analogous ligands, which bear a nitrogen atom in the central position instead of a carbon atom. From this point of view, diacylamines ("imides" in organic nomenclature) may be regarded as nitrogen analogues of β-diketones, *N*-acylamidines as nitrogen analogues of β-iminoketones (β-ketimino) and 1,3,5-triazapentadienes[1] (tap) as nitrogen analogues of β-diimines (Scheme 1). Some of these compounds have found intensive application in coordination chemistry, as they are quite potent bidentate chelating ligands [see, for example (β-diketiminato)metal complexes[2]]. The three nitrogen analogues deserve special attention of coordination chemists as they offer an additional coordination site at the central nitrogen atom, especially in their anionic form.



Scheme 1. Chelating ligands.

1,3,5-Triazapentadienes have rarely been used for the synthesis of metal complexes. However, already in 1907 Ley and Müller reported on the preparation of triazapentadienes and their successful complexation with cobalt(II) acetate, copper(II) acetate and nickel(II) acetate.[3] However, the nature of these complexes remained unclear. Many years later, Breuer and Small prepared a 1,3,5-triazapentadiene ligand starting from benzylamine, ethyl orthoformate and *N,N*-dibenzylformamide.[4] They obtained a blue (1,3,5-triazapentadiene)copper(II) chelate complex after treatment with copper(II) acetate in methanol. Siedle et al. treated a perfluorated imidoyl fluoride with 2 mol-equiv. of aniline to obtain a perfluorated 1,3,5-triazapendiene derivative, which may be converted into the corresponding 1,3,5-triazapentadienyl anion using *n*-butyllithium.[5] Treatment with silver oxide afforded the respective six-membered ring chelate silver complex, which in turn could be transmetallated to the

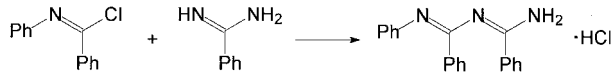
corresponding Pd^{II}, Ir^{II} and Rh^{II} chelate complexes. Similarly, Fe^{II}, Co^{II} and Cu^{II} complexes were obtained by transmetallation of the corresponding potassium compound. Copper(I) and silver(I) complexes of fluorinated triazapentadienyl ligands were recently reported by Dias and Singh.[6,7]

However, there are several examples in the literature, where 1,3,5-triazapentadienes have been formed in situ from simpler amino compounds in the course of template reactions. For instance, Turnbull et al. treated $Cu(ClO_4)_2 \cdot 6H_2O$ with triazine in 95% methanol.[8] They obtained in 25% yield a 2:1 six-membered chelate Cu^{II} complex of the parent 1,3,5-triazapenta-1,4-diene, which was interpreted to be the result of copper(II)-catalyzed hydrolysis of triazine.[9] Analogously, tris(2-pyridyl)triazine may be hydrolyzed in the presence of copper(II) acetate to give bis[2,4-di(2-pyridyl)-1,3,5-triazapentadienyl]copper(II) complexes, either employing the corresponding triazapentadienes as neutral ligands or as anions after deprotonation.[10] Interestingly, the two nitrogen atoms in 1 and 5 position of the triazapentadiene act as coordination sites, not the 2-pyridyl subunits. Barker et al. reported on the in situ formation of the 2,4-diphenyl-1,3,5-triazapentadienyl ligand, when lithiobenzamidine was treated with $Pt(PhCN)_2Cl_2$ in ethereal solution. They isolated the 2:1 Pt^{II} chelate complex as a result of a nucleophilic attack of the benzamidine anion on the complexed benzonitrile. Similarly, a Pd^{II} complex was obtained from lithiobenzamidine and $Pd(PhCN)_2Cl_2$.[11] Acetamidine undergoes a self-condensation reaction to form a 2,4-dimethyl-1,3,5-triazapentadiene ligand when treated with nickel(II) chloride hexahydrate in methanol. The resulting Ni^{II} chloride chelate complex contains two neutral tautomers of the triazapentadiene units each with a proton at the central N3 position.[12] Nickel(II) chloride reacts with nitriles in the presence of oximes to form 2:1 chelate complexes.[13]

In this report we describe our experiments on the synthesis and thorough structural characterization of (1,3,5-triazapentadiene)metal complexes, of which some examples already were obtained by Ley and Müller in 1907.[3] These studies were part of an extended project concerning the application of 1,3,5-triazapentadienes for the synthesis of longer oligonitriles of the general formula $R_2N–(CR=N)_n–CR=NR$.[14]

Results and Discussion

As a typical, stable example 1,2,4-triphenyl-1,3,5-triazapentadiene (**1a**) was chosen as starting material for various complexation experiments. Its preparation is based on a procedure given by Ley and Müller,[3] according to which benzamidine is treated with *N*-phenylbenzimidoyl chloride. These authors used an equimolar surplus of amidine to trap the formed hydrochloride. In our experiments, this procedure did not work very successfully because of severe separation problems. We found it easier to use equimolar amounts of amidine and imidoyl chloride. Under these conditions mixtures of amidine hydrochloride and triazapentadienylium chloride **1a·HCl** are formed. However, the amidine hydrochloride was easily removed by washing with hot water in an ultrasonic bath. The free triazapentadiene **1a** was subsequently obtained in 29% yield after treatment with 2 N sodium hydroxide solution and repeated extraction with dichloromethane.



1a·HCl

Triazapentadienes are expected to be subject of tautomerism.[14] However, in our NMR, IR and X-ray studies all evidence is in favor for the indicated 1,3,5-triazapenta-1,3-diene structure **1a**. Indications for a tautomeric 1,3,5-triazpenta-1,4-diene structure were not observed.

Metal Complexes

Various metal complexes of triazapentadiene **1a** were easily obtained by co-dissolving metal salts with the ligand **1a** and crystallization, which was usually induced by adding less polar solvents to the reaction mixture.

Complex 1a·CoCl₂

The deep blue complex **1a·CoCl₂** is obtained from **1a** and cobalt(II) chloride hexahydrate after stirring of the components in acetonitrile in 72% yield as a fine precipitate. Recrystallisation from acetonitrile/DMF (1:1) and little diethyl ether produced a single crystal, suitable for X-ray analysis. The crystal system is triclinic ($P\bar{1}$) with two molecules in the unit cell. As Figure 1 shows, the ligand adopts now the tautomeric structure of a triazapenta-1,4-diene acting as a chelating ligand forming a six-membered 1:1 chelate with a tetrahedral Co^{II} moiety (compare ref.[15]).

Complex 1a·Ni(NO₃)₂

From equimolar amounts of **1a**, dissolved in DMF, and nickel(II) nitrate hexahydrate, dissolved in ethanol, an amorphous lilac precipitate **1a·Ni(NO₃)₂** is formed upon diffusion of diethyl ether. Dissolving in acetonitrile and repeated diffusion of diethyl ether yields turquoise needles in 76% yield, which are monoclinic ($P2_1/c$) and contain four molecules and four ethanol molecules in a unit cell. As Figures 2 and 3 display, a six-membered 1:1 chelate complex is formed and again a proton shift in the ligand from N1 to N3 is observed. In addition to ligand **1a**, one nitrate unit is coordinated in a bidentate fashion and two other ones are coordinated in a monodentate fashion to the Ni^{II} ion, forming an infinite chain structure with octahedral coordination sphere around Ni^{II}. A 2:1 nickel complex of another triazapentadiene system (acetimidoylacetamidine) has been reported by Norrestam.[12] Some of the corresponding diiminonickel complexes (β-iminoamino complexes) are known.[16]

Complex 1a·PdCl$_2$

A Pd^{II} complex was obtained from equimolar amounts of **1a** and Na_2PdCl_4 in DMF as solvent upon diffusion of diethyl ether into the reaction mixture. Orange small tiles

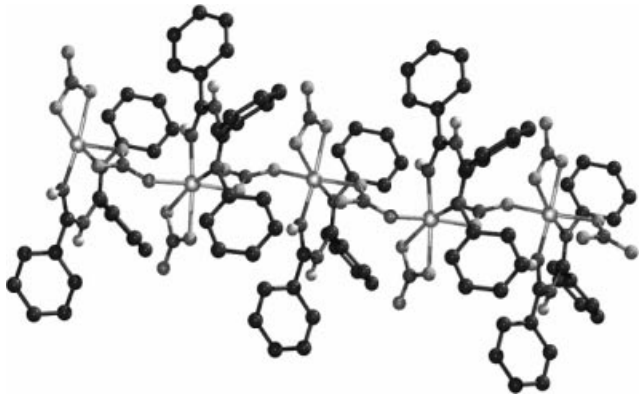

Figure 3. Plot of a part of the infinite chain structure of **1a·Ni(NO$_3$)$_2$** in the solid state.

were formed in 66% yield. They form a triclinic lattice ($P\bar{1}$) with two molecules and four DMF molecules in the unit cell. The X-ray diffraction of **1a·PdCl$_2$** (Figure 4) shows again the formation of a six-membered chelate 1:1 complex with a proton at the central nitrogen atom as a result of a proton shift. The chelate ring is not exactly planar, but slightly distorted with torsional angles up to 10° in a boat-shape fashion. As expected, Pd^{II} is square-planar coordinate. The corresponding (β-diimino)Pd^{II} complexes are reported to have catalytic activity in ethylene polymerization reactions.[17]

Selected structural parameters: Bond lengths [Å] Pd–Cl1 2.2968(6), Pd–Cl2 2.3087(6), Pd–N1 2.0421(17), Pd–N5 1.9809(18), N1–C2 1.293(3), C2–N3 1.376(3), N3–C4 1.368(3), C4–N5 1.280(3); bond angles [°] N1–Pd–N5 89.49(7), N1–Pd–Cl1 93.51(5), N5–Pd–Cl1 176.96(6), N1–Pd–Cl2 175.85(5), N5–Pd–Cl2 87.70(6), Cl1–Pd–Cl2 89.33(2), N1–C2–N3 124.41(19), C2–N3–C4 129.36(18), N3–C4–N5 121.49(19); torsional angles [°] Pd–N1–C2–N3 0.78, N1–C2–N3–C4 –9.96, C2–N3–C4–N5 5.01, N3–C4–N5–Pd 8.79, N5–Pd–N1–C2 7.55, C2–N1–C11–C12 93.78, N1–C2–C21–C22 –66.94, N5–C4–C41–C46 39.49.

Complexes 1a·CuCl$_2$ and (1a)$_2$·Cu(OTf)$_2$

Equimolar amounts of ligand **1a** and copper(II) chloride dihydrate in ethanol yielded dark green little tiles in 46% yield after diffusion of diethyl ether. They crystallize in the triclinic space group $P\bar{1}$ with two molecules and two molecules of ethanol in the unit cell. Figure 5 shows the 1:1 chelate complex formed, again with a proton at N3 after a shift from position N1 of the free ligand. The six-membered

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

chelate ring has a clear boat shape with Cu^{II} and N3 significantly above the plane of the four other atoms. The Cu^{II} ion displays a distorted tetrahedral coordination as a result of a Jahn–Teller distortion in this d^9 copper compound.

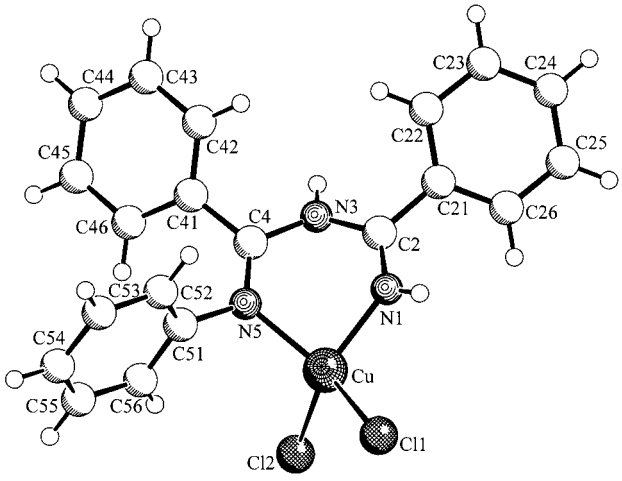

Figure 5. Molecular structure of one independent unit of **1a·CuCl$_2$** in the solid state (crystallographic numbering). Selected structural parameters: Bond lengths [Å] Cu–Cl1 2.2290(8), Cu–Cl2 2.2281(8), Cu–N1 1.928(2), Cu–N5 1.986(2), N1–C2 1.278(3), C2–N3 1.372(3), N3–C4 1.386(3), C4–N5 1.298(3); bond angles [°] N1–Cu–N5 87.90(9), N1–Cu–Cl1 97.87(8), N5–Cu–Cl1 142.89(7), N1–Cu–Cl2 138.42(8), N5–Cu–Cl2 99.28(7), Cl1–Cu–Cl2 100.21(3), N1–C2–N3 121.2(2), C2–N3–C4 126.5(2), N3–C4–N5 119.9(2); torsional angles [°] Cu–N1–C2–N3 19.50, N1–C2–N3–C4 19.74, C2–N3–C4–N5 –26.38, N3–C4–N5–Cu –5.96, N5–Cu–N1–C2 –35.97, N1–C2–C21–C26 37.39, N5–C4–C41–C46 –41.60, C4–N5–C51–C52 –70.68.

Reaction of ligand **1a** with copper(II) triflate in the molar ratio 2:1 in acetonitrile yielded a dark green solution, from which blue-violet rod-like crystals were obtained in 54% yield after diffusion of diethyl ether.[18] They crystallize in the triclinic space group $P\bar{1}$ with two molecules and two molecules of diethyl ether in the unit cell. From Figure 6 a 2:1 chelate complex can be derived. The ligands from two six-membered chelate rings with the mobile protons at position N3/N3*. Cu^{II} is square-planar coordinate with two additional longer contacts to the triflate counterions (2.498 Å). A 2:1 chelate complex of the parent 1,3,5-triazapentadiene, which was formed in situ by hydrolysis of triazine, has been reported by Turnbull et al.[8]

Complex 1a·ZnCl$_2$

Addition of a solution of zinc(II) chloride hydrate in ethanol to an ethanolic solution of triazapentadiene **1a** leads to a fine, colorless precipitate, from which a few single crystals **1a·ZnCl$_2$** were obtained after dissolving in little DMF and infusion of diethyl ether. **1a·ZnCl$_2$** crystallizes in the triclinic space group $P\bar{1}$ with two molecules in the unit cell. The X-ray analysis indicates the formation of a 1:1 chelate complex (Figure 7). The Zn^{II} ion displays a tetrahedral coordination. The complex **1a·ZnCl$_2$** is not planar, but shows a weak distortion towards boat shape. As in the other examples discussed before, a proton shift from the terminal amino group of **1a** to nitrogen atom N3 accompanies the

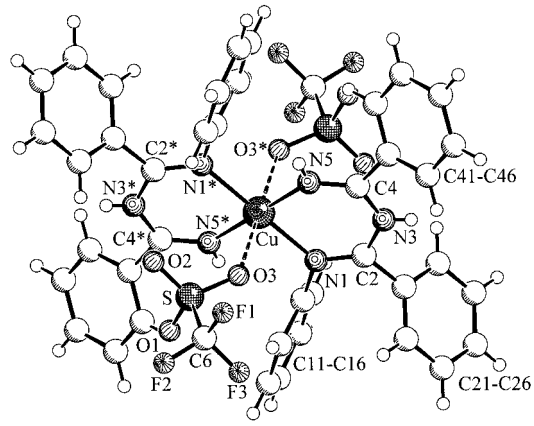

Figure 6. Molecular structure of one independent unit of **(1a)$_2$·Cu(OTf)$_2$** in the solid state (crystallographic numbering). Selected structural parameters: Bond lengths [Å] Cu–N1 2.0613(17), Cu–N5 1.9466(18), Cu–O3(18), 2.498(18), N1–C2 1.291(3), C2–N3 1.376(3), N3–C4 1.371(3), C4–N5 1.286(3); bond angles [°] N1–Cu–N5 86.36(7), N1–Cu–N1* 180.00(10), N5–Cu–N1* 93.64(7), N1–Cu–N5* 93.46(7), N5–Cu–N5* 180.00(10), N1*–Cu–N5* 86.36(7), N1–C2–N3 123.29(18), C2–N3–C4 127.62(18), N3–C4–N5 121.45(19); torsional angles [°] Cu–N1–C2–N3 9.89, N1–C2–N3–C4 2.08, C2–N3–C4–N5 –3.99, N3–C4–N5–Cu –7.47, N5–Cu–N1–C2 –14.13, C2–N1–C11–C12 –73.41, N1–C2–C21–C22 –63.75, N5–C4–C41–C42 –41.03, N1*–Cu–N5–C4 –166.64, N5*–Cu–N1–C2 165.87.

complexation. 2,4,6,8,8-Pentakis(dimethylamino)-1-oxa-3,5,7-aza-1,3,5,7-octatetraene, which may be regarded to include a triazapentadiene subunit, forms with $ZnCl_2$ a six-membered chelate complex, where $ZnCl_2$ bridges oxygen and nitrogen atoms.[19] (β-Diimino)Zn complexes are well known for their catalytic activity in CO_2/oxirane copolymerisations.[20]

Quantum Chemical Calculations

In order to rationalize the ability of the triazapentadiene ligand to coordinate to metal ions in comparison with similar systems (β-diimines, *N*-acylamidines) and to investigate their propensity for proton shifts in going from the free ligand to the chelate complex quantum chemical model calculations on the DFT level were performed. Zn^{II} and Pd^{II} complexes were investigated as typical (diamagnetic) examples of the complexes experimentally studied. The B3LYP hybrid functional was used together with the basis sets 6-31G*, 6-31+G(d,p), and MP2 and SCS-MP2[21]single points for the Zn^{II} compounds, and 6-31G*, 6-31+G(d,p) for C, H, N, O, Cl and the Stuttgart-Dresden Pd-ECP MWB[22] for the Pd^{II} complexes. All structures were completely optimized. The energies reported include zero point correction (no scaling). The G98 program[23] was employed using the build-in basis sets. BSSE effects[24] were considered using the counterpoise method as implemented in G03.[25]

As a measure for the tendency of the ligand to form chelate complexes simply the reaction energy of the complexation reaction was calculated, starting from free $ZnCl_2$ or

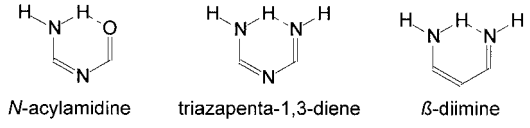
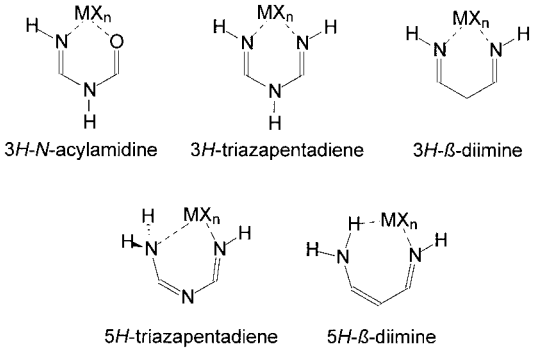
$PdCl_2$ in the gas phase and the free ligands in their lowest energy hydrogen-bonded conjugated form (Scheme 2).[16] For triazapentadiene and β-diimine two types of complexes were considered: first, the chelate complex involving a ligand after proton shift ("3*H* ligand"), second, a complex with a ligand in its original enolized form ("5*H* ligand") (Scheme 3). For the latter structures, at higher levels of DFT theory, the geometry optimizations opened the chelate structure in favor of hydrogen bonds from the chlorine atoms to the amino groups. In substituted derivatives as studied experimentally 5*H*-type structures were not observed (see above).



Scheme 2. Free ligands in their best gas phase structure (reference structures).

Among the $ZnCl_2$ compounds on all levels of theory triazapentadiene forms the strongest complexes acting as symmetrical ligand after proton shift from N1 to N3 (3*H* form) (Table 1). Indeed, this kind of coordination is experimentally observed (see above). The β-diimino ligand comes second in its two tautomeric forms, whereas (*N*-acylamidine) $ZnCl_2$ complexes are significantly less stable (by 5.0–5.7 kcal/mol). The β-diimino ligand is surprisingly differently treated by the theoretical methods employed. The DFT methods predict a better complexation energy for the ligand in its 5*H* form compared to the 3*H* form, probably



Scheme 3. Types of complexes (first row involving 3*H* ligands, second row 5*H* ligands.

due to the hydrogen bond formed. The MP2 single points, however, strongly favor the 3*H* form, which is known from many complexes.[2] The reason for this special behavior of the DFT methods remains unclear. For triazapentadiene, all methods prefer the 3*H* complexes over the 5*H* forms by 2.2–7 kcal/mol.

In the $PdCl_2$ series of chelate complexes (Table 2) a similar superiority of the triazapentadiene complex in its 3*H* form is found in accordance with the experimental findings (see above). Here, the β-diimine complexes come second (3.7–6.5 kcal/mol), whereas *N*-acylamidine forms the weakest complexes towards $PdCl_2$.[26,27] Both 5*H* forms of triazapentadiene and β-diimine bind significantly weaker than their 3*H* isomers and are therefore not expected to coordinate without tautomerism.

(*N*-Acylamidine)-[26] and (β-diimine)$PdCl_2$[17] complexes have found interest due to their potential as catalyst precursors.

For $CuCl_2$ preliminary UB3LYP/6-31+G(d,p) calculations (including ZPE and BSSE), which may probably be insufficient for such open-shell systems, indicate again best binding to triazapentadiene (–19.5 kcal/mol), whereas *N*-acylamidine and β-diimine coordinate weaker (–15.8 and –12.9 kcal/mol, respectively).

It is interesting to note that according to the gas-phase calculations triazapentadiene generally is a better ligand for $ZnCl_2$, $PdCl_2$ and $CuCl_2$ compared to β-diimine. Besides the electron-donating influence of the central nitrogen atom its abilility to allow π-conjugation over all five centers of the neutral ligand may be the reason for this observation. Thus, the introduction of the nitrogen atom in 3-position of β-diimine enhances the coordination ability of such chelating systems. This conclusion may be of importance with regard to the catalytic properties of such chelate complexes, e.g. as polymerization catalysts.

The comparison of the $ZnCl_2$, $PdCl_2$ and $CuCl_2$ complexation energies at similar levels of theory quantifies the common experience of significantly higher values for the $PdCl_2$ complexes as metal ion of the second transition row, whereas $CuCl_2$ and $ZnCl_2$ are coordinated with similar strength.

Conclusions

Triazapentadienes, easily prepared from amidines and imidoyl halides, are potent chelating ligands for metal complexation. 1,2,4-Triphenyl-1,3,5-triazapentadiene (**1a**) forms 1:1 six-membered chelate complexes with $CoCl_2$, $Ni(NO_3)_2$, Na_2PdCl_4, $CuCl_2$ and $ZnCl_2$, and additionally one 2:1 complex with $Cu(OTf)_2$. In the case of the Ni^{II} complex, a linear chain structure resulting from NO_3 bridging was observed. All new complexes have been fully characterized including X-ray crystallography.

By use of DFT-B3LYP calculations the relative complexation energies of model triazapentadiene, *N*-acylamidine and β-diimino ligands binding to $ZnCl_2$, $CuCl_2$ and $PdCl_2$ in the gas phase were evaluated. According to these theoretical results triazapentadiene binds stronger to these metal salts than β-diimine and *N*-acylamidine. For β-diimine and triazapentadiene, tautomeric complexes, characterized by the 3*H* and 5*H* form of the ligand, respectively, are discussed.

Experimental Section

Materials and Methods: IR: Nicolet 5DXC. ^{1}H NMR: Bruker WM 300 (300.13 MHz), Bruker AM 360 (360.13 MHz), Bruker AMX 400 (400.13 MHz) and Varian Unity plus (599.86 MHz), internal reference tetramethylsilane. ^{13}C NMR: Bruker WM 300 (75.47 MHz), Bruker AMX 400 (100.61 MHz) and Varian Unity 600 plus (150.85 MHz), internal reference tetramethylsilane or solvent. MS: MAT C 312, Finnigan (70 eV). ESI-MS: Quattro LC-Z, Micromass. MALDI (16–19 kV), nitrogen (337 nm, 3 ns); matrix: DTBC (2-[(2*E*)-3-(4-*tert*-butylphenyl)-2-methylprop-2-enylidene] malononitrile). UV/Vis: Cary 1 Bio, Varian. CHN: Elementar Vario El III. Melting points are uncorrected.

1,2,4-Triphenyl-1,3,5-triazapenta-1,3-diene (1a): In analogy to a literature procedure,[3] 7.73 g (64.7 mmol) of benzamidine was suspended in 20 mL of diethyl ether. 13.88 g (64.7 mmol) of *N*-phenylbenzimidoyl chloride,[28] dissolved in 40 mL of diethyl ether, was added dropwise. After stirring at room temperature for 2 h, the reaction mixture was heated to reflux for 1 h. The precipitate was removed by filtration and was treated with hot water in an ultrasonic bath in order to remove benzamidine hydrochloride. The remaining light yellow residue was separated and treated with 50 mL of 2 N sodium hydroxide solution. The suspension was extracted with portions of dichloromethane as long as solid was present in the reaction mixture. The combined organic layers were dried with magnesium sulfate. The solvent was removed under reduced pressure. Yield 5.54 g (18.5 mmol, 29%), light yellow solid, m.p. 143 °C (ref.[3] 152 °C). IR (KBr): $\tilde{\nu}$ = 3483, (s, NH_2), 3379 (s, NH_2), 3057 (m, $CH_{arom.}$), 3026 (w, $CH_{arom.}$), 2997 (w, $CH_{arom.}$), 1645 (vs, C=N), 1599 (vs, C=$C_{arom.}$), 1586 (vs, C=$C_{arom.}$), 1483 (m), 1448 (m), 1367 (s), 1315 (m), 1269 (m), 1227 (m), 1175 (w), 1074 (w), 1013 (m), 935 (w), 921 (w), 837 (m), 810 (m), 787 (m), 758 (s), 702 (vs) cm^{-1}. ^{1}H NMR (300 MHz, $CDCl_3$): δ = 6.80 (br., 2 H, NH_2), 6.93–6.99 (m, 1 H, $CH_{arom.}$), 7.05–7.08 (m, 2 H, $CH_{arom.}$), 7.22–7.28 (m, 2 H, $CH_{arom.}$), 7.41–7.51 (m, 6 H, $CH_{arom.}$), 7.78–7.81 (m, 2 H, $CH_{arom.}$), 8.01–8.05 (m, 2 H, $CH_{arom.}$) ppm. ^{13}C NMR (75.47 MHz, $CDCl_3$): δ = 122.0, 123.1, 128.0, 128.7, 128.9, 131.0, 131.3 ($C_{arom.}$), 135.4 (*i*-$C_{arom.}$), 136.9 (*i*-$C_{arom.}$), 151.8 (*i*-$C_{arom.}$), 154.7 (C=N), 161.7 (C=N) ppm. Towards Understanding of the Selective Precipitation of Alkali Metal Cations in Presence of Dipicrylamine Anion

Suresh Eringathodi,[a] Pragati Agnihotri,[a] Bishwajit Ganguly,[a] Pragnya Bhatt,[a] Palani Sivagnana Subramanian,[a] Parimal Paul*[a] and Pushpito K. Ghosh*[a]

Keywords: Dipicrylamine / Alkali and alkaline earth metals / Selectivity / Single-crystal X-ray structure / Structure-selectivity correlation

Dipicrylamine anion (DPA^-) precipitates out [K(DPA)] with high selectivity from salt bitterns containing Na^+, K^+, and Mg^{2+}, whereas the same ligand shows poor selectivity towards K^+ – and much higher selectivity towards Cs^+ – in studies conducted with a mixture of K^+, Rb^+, and Cs^+. Their single-crystal structures reveal that the K^+ and Rb^+ salts have similar layered structures, with 8 oxygen atoms from seven DPA^- anions encapsulating the metal cation, whereas the Cs^+ salt possesses a channel-like structure with the metal ion encapsulated by ten oxygen atoms from six DPA^-. The conformation of DPA^- in the [Cs(DPA)] single crystal matches closely that of DPA in crystalline state. M···O and intermolecular C–H···O interactions together stabilize the structures. The ^{133}Cs NMR spectrum of the poorly soluble [Cs(DPA)] shows an upfield shift of the peak with respect to CsCl as a result of the interaction with the oxygen atoms of DPA^-, whereas ^{23}Na NMR spectrum of the highly soluble [Na(DPA)] shows no such upfield shift compared to NaCl. Powder XRD patterns of bulk [M(DPA)] (M = K^+, Rb^+, and Cs^+) precipitates show that these are similar to the patterns obtained by simulation of the single-crystal X-ray data. The selectivity of precipitation correlates qualitatively with the size and hydration enthalpies of the ions.

Introduction

Dipicrylamine (2,2′,4,4′,6,6′-hexanitrodiphenylamine, DPA) anion (Figure 1) has been used for the extraction of K^+ from sea bittern (mixture of K^+, Na^+, and Mg^{2+}).[1] The process of such extraction is depicted in Scheme 1. In a study conducted with a mixture of K^+, Rb^+, and Cs^+, it has been reported that the Cs^+ ion shows maximum selectivity towards DPA.[2] Indeed, recovery of Cs^+ from radioactive waste has been reported.[3] In spite of the large number of reports on the utility of DPA^-, little is known about the factors which control its selectivity towards the different alkali and alkaline earth metal ions.

DPA possesses some interesting structural features, namely: (i) six nitro groups that are flexible and can interact and adjust in the space, (ii) a secondary amine group that can be deprotonated with $Ca(OH)_2$ to form a water soluble salt, and (iii) partial delocalization of the resultant charge mediated by the aromatic rings, that may facilitate coordination of the oxygen atoms with suitable metal ions. Single-crystal X-ray structures of DPA and some of its organic

Supporting information for this article is available on the WWW under http://www.eurjic.org or from the author.

salts have been reported.[4] Computational study on the intermolecular interactions observed in the crystal structure of DPA has also been reported recently.[5] Crystal structures of K^+ and Ag^+ salts of DPA^- have been reported, although no detailed analysis of the former compound was carried out in absence of adequate refinement of the structure.[6a,6b] In the case of Rb^+ and Cs^+ salts of DPA^-, only unit cell parameters have been reported earlier.[6b–6d]

Herein, we report quantitative ion-chromatographic studies of DPA^- selectivity towards bittern and an equimolar aqueous mixture of K^+, Rb^+, and Cs^+ salts. We also report the synthesis and single-crystal X-ray structures of K^+, Rb^+, and Cs^+ salts of DPA^- to unravel the causes underlining selectivity, and further show that the powder XRD patterns simulated from these structures tally well with those of the bulk precipitated salts. ^{133}Cs and ^{23}Na solution NMR studies of the poorly soluble and highly soluble DPA^- salts of Cs^+ and Na^+, respectively, were also undertaken. These studies have enabled us to understand the possible factors that govern observed selectivity.

Results

Ion Selectivity

Ion selectivity was estimated by analyzing the composition of metal ions in the precipitate formed upon addition of $Ca(DPA)_2$ into aqueous mixtures of cations, as described in the experimental section. Our initial study was focused on the selectivity towards K^+ in bittern. The concentrations of Na^+, K^+, Mg^{2+}, and Ca^{2+} in bittern used for this study were estimated to be 0.8 M, 1.2 M, 2.1 M, and 0.2 M, respectively, from ion chromatographic analysis of the bittern. The precipitate obtained upon addition of $Ca(DPA)_2$ into bittern was similarly analyzed for the metal ion composition after destructive degradation of the complex. The chromatogram shows complete absence of Mg^{2+} despite its high concentration in bittern whereas the relative concentration of K^+ was found to 97.1% (Figure S1, Supporting Information, see also the footnote on the first page of this article). Na^+ and Ca^{2+} were present in the chromatograms to the extent of 2.7% and 0.2%, respectively, but these peaks were found even for a blank chromatogram with Milli Q water. The high selectivity evident for K^+ was reproducible on larger scale and corroborates earlier findings of high selectivity.[1] However, when the studies were conducted with equimolar mixture of KCl, RbCl, and CsCl, the observed selectivities were: 2.6%, 6.6%, and 90.7% for K^+, Rb^+, and Cs^+, respectively, i.e., very poor selectivity towards K^+ in marked contrast to the behavior found with bittern.[1]

Synthesis of the Complexes

[M(DPA)] [M = Na^+ (**1**), K^+ (**2**), Rb^+ (**3**), and Cs^+ (**4**)] salts of alkali metal ions were synthesized. The K^+, Rb^+, and Cs^+ salts **2**–**4** were synthesized by the reaction of the respective metal chloride salts with aqueous solution of the soluble $Ca(DPA)_2$. The K^+ salt has also been prepared following the same method using bittern instead of aqueous solution of metal chloride. The Na^+ salt **1** could not, however, be synthesized by this method because of its very high solubility in water. **1** was instead prepared from the reaction of NaOH and DPA in water followed by evaporation of solvent to dryness. All these compounds gave satisfactory elemental analysis. UV/Vis spectra of **1**–**4** in water were similar; the only band observed for all compounds showing similar λ_{max} (426 nm) and molar absorptivity ($\varepsilon \approx 3.5 \times 10^4$ $M^{-1}cm^{-1}$). X-ray quality single crystals of **2**, **3**, and **4** were grown by slow evaporation of the respective aqueous solutions at room temperature. However, attempts to grow the crystals of **1** were unsuccessful.

Crystal Structures

[K(DPA)]·0.5H_2O (2) and [Rb(DPA)]·H_2O (3): Crystallographic data for complexes **2, 3** and **4** are summarized in Table 4. Compounds **2** and **3** are isostructural. The DPA^- anions in these structures are arranged in a manner that allows the metal ions to interact strongly with eight nitro oxygen atoms of the DPA^- ligands, which is similar to that found in the crystal structure of [K(DPA)], reported earlier.[6a] PLUTO view of **2** showing the metal–oxygen interactions are illustrated in Figure 2. Oxygen atoms (O5 and O6) of one of the *o*-nitro groups (N3) are not involved in interaction with metal ion, otherwise at least one oxygen atom from all other nitro groups makes strong M···O interactions. The interacting metal–oxygen distances for **2** (Table 1) are in the range of 2.767 to 3.022 Å (average K–O distance is 2.916 Å), which is close to the value of 2.76 to 3.04 Å found earlier for [K(DPA)]. In the case of **3**, the Rb–O distances are in the range of 2.911 to 3.150 Å, with average Rb–O distance of 3.023 Å (Table 1). These values are comparable to the reported metal–oxygen distances.[7] In the case of N5 and N7 nitro groups, all of the four oxygen atoms (O7, O8, O11, and O12) interact with the metal ion, in which O7 shows μ-type interaction involving the neighboring metal ion. The K···K and Rb···Rb distances in **2** and **3** are 4.413 and 4.835 Å, respectively. Values of the mean plane distortion between the two phenyl rings of the DPA^- in **2** and **3** are 78.78° and 79.75°, respectively. The two *o*-nitro groups, N1–O1/O2 and N5–O7/O8, are rotated with respect to the phenyl rings to which they are attached by 33.7° and 32.40° in **2** and 34.22° and 31.3° in **3**, respectively.

Figure 3 shows the packing diagram of **2** viewed down the *a* axis. The metal ions and the lattice water molecules are located between the adjacent ligand layers running along the *c* axis in the overall layered architecture. The corrugated organic layer formed in the case of **2** is held in place by C–H···O interaction between the phenyl H11 hydrogen with the O10 nitro oxygen along *c*-direction, and between the phenyl H9 hydrogen and O3 nitro oxygen from the adjacent corrugated organic layer almost along *b* axis. These interactions create the layered architecture. The oxygen

atom of the lattice water molecule also interacts with the H4 hydrogen of the phenyl ring. These observations are in contrast to the earlier report, where it was stated that no intermolecular interactions were found. The water molecule seen in the lattice of the present structure was also not observed in the earlier structure.[6a] In the case of **3**, only one C–H···O intermolecular interaction along *c* axis exists forming the corrugated layer as mentioned above for **2**, but no cross linking C–H···O interaction connecting the adjacent layers is observed. This could be due to the larger ionic radius of Rb^+ compared to K^+, and also inclusion of more water molecules between the layers, which prevents the sterically hindered ligands from coming closer to make such interaction along the *b* axis. The water molecules in **3** exhibit strong C–H···O interactions with a single DPA^- ligand, whereas in the case of **2** similar interactions of the water molecules with two DPA^- ligands are evident. Details of the H-bonding interactions found in complexes **2**, **3**, and **4** are given in Table 2.

[Cs(DPA)] (4): The molecule crystallises in centrosymmetric space group *C*2/*c* with Cs atom occupying a special position falling in the two-fold axis passing through the amino nitrogen atom of the deprotonated DPA moiety. Ten oxygen atoms of the surrounding nitro groups from six ligands make strong interactions with the metal ion. The PLUTO diagram showing the metal-oxygen interactions is depicted in Figure 4. At least one oxygen atom of each nitro group from the symmetry-related DPA ligand is involved in Cs···O interactions, the distances of which are in the range of 3.268 to 3.410 Å (average distance is 3.313 Å). These are in close agreement with the reported values.[7e,8] Oxygen atoms, O3 and O4, which are attached to N2, interact with the same metal ion; in addition O3 also makes μ-type of interaction involving the neighbouring metal ion. The Cs···Cs distance observed in this structure is 5.788 Å. The mean plane distortion between the phenyl rings of the DPA^- is 61.35°, while the *o*-nitro group N1–O1/O2 is rotated by 23.79° with respect to the phenyl ring to which it is attached.

The molecular packing (Figure 5) and C–H···O interactions in this molecule are quite different from that found in **2** and **3**. The H4 hydrogen atom shows strong intermolecular C–H···O interaction with O1 oxygen atoms of the *o*-nitro groups of a neighbouring molecule of DPA^-. Four such pairs of ligands assemble to create cavities down the *c* axis, in which the Cs^+ is encapsulated making interactions with the surrounding ten oxygen atoms from six ligands. The hydrogen bonding parameters with symmetry code is given in Table 2.

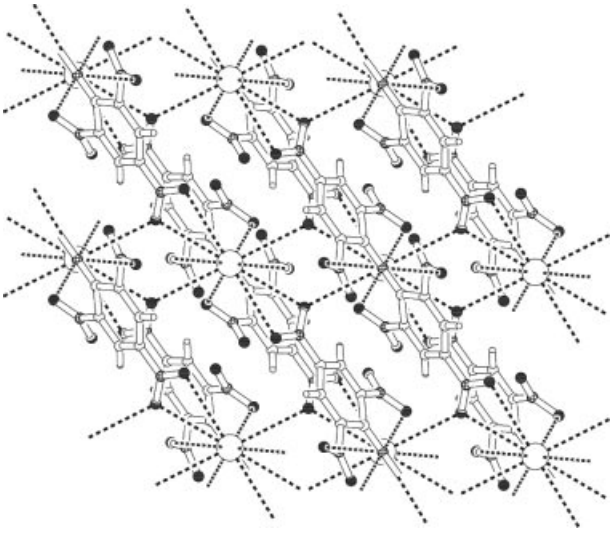

Figure 4. PLUTO view of [Cs(DPA)] (**4**) showing the interaction between the metal ion (open circles) and oxygen atoms (dark circles) of DPA^-.

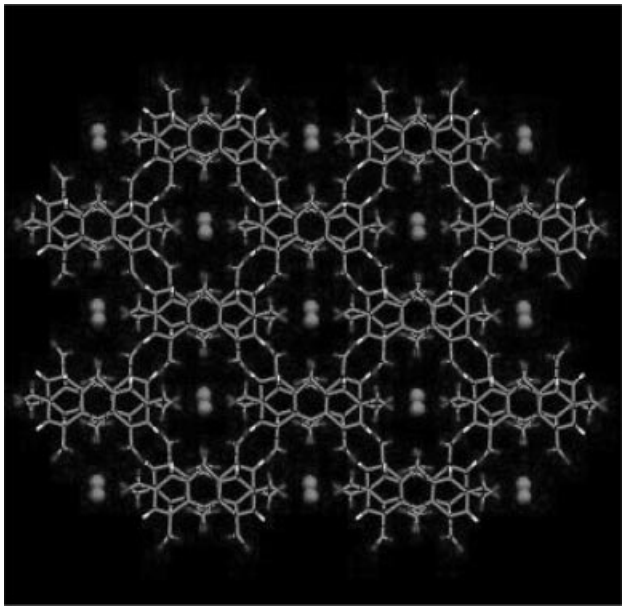

Figure 5. Molecular packing diagram of [Cs(DPA)] (**4**) showing the architecture, in which the metal ions (solid circles) are encapsulated in regular intervals.

NMR Study

To investigate possible differences in the coordination environments of metal ions in **1** and **4**, ^{23}Na and ^{133}Cs NMR spectra of the corresponding compounds were recorded and compared with those of NaCl and CsCl, respectively, in D_2O. ^{23}Na signal of **1** (Figure 6b′) appeared at the same position as of NaCl (Figure 6a′). In the case of **4**, on the other hand, the ^{133}Cs signal (Figure 6b) was shifted upfield significantly compared to that of CsCl (Figure 6a). Initially, soon after preparation of the solution, one signal was observed at –49.70 ppm (considering the signal of CsCl at 0.0 ppm), however, after 20 min, an additional signal appeared at –31.12 ppm (Figure 6c), and finally after 1 h, a third signal of low intensity appeared at –20.19 ppm (Figure 6d).

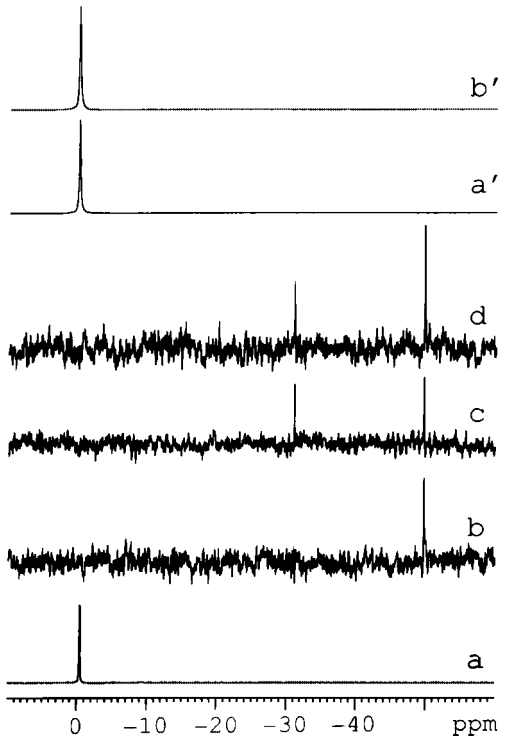

Figure 6. ^{133}Cs NMR spectra of CsCl (a) and [$Cs^+(DPA)^-$], recorded just after making solution (b), after 20 min (c) and after 60 min (d); and ^{23}Na NMR spectra of NaCl (a′) and [$Na^+(DPA)^-$] (b′). All spectra were recorded at room temperature in D_2O. Chemical shift position was taken as 0 ppm for the chloride salts of Na^+ and Cs^+.

Powder X-ray Diffraction

Powder XRD profiles of bulk precipitates of **2**–**4** obtained spontaneously upon addition of a solution of pure salt of the alkali metal ion into aqueous $Ca(DPA)_2$ were recorded. The XRD patterns of the same compounds **2**–**4** were also generated by simulation from the single-crystal X-ray data (Figure 7). The simulation was carried out following the method of Speak.[9] Good match between the experimental and simulated diffractograms was found. The diffractogram was also recorded of the highly water soluble **1** by evaporating the aqueous solution to dryness to obtain a solid powder. Unit cell parameters of **1**–**4** obtained from Powder XRD data and that of **2**–**4** obtained from single-crystal X-ray is shown in Table 3. The unit cell of **1** obtained from powder XRD data was found to be triclinic

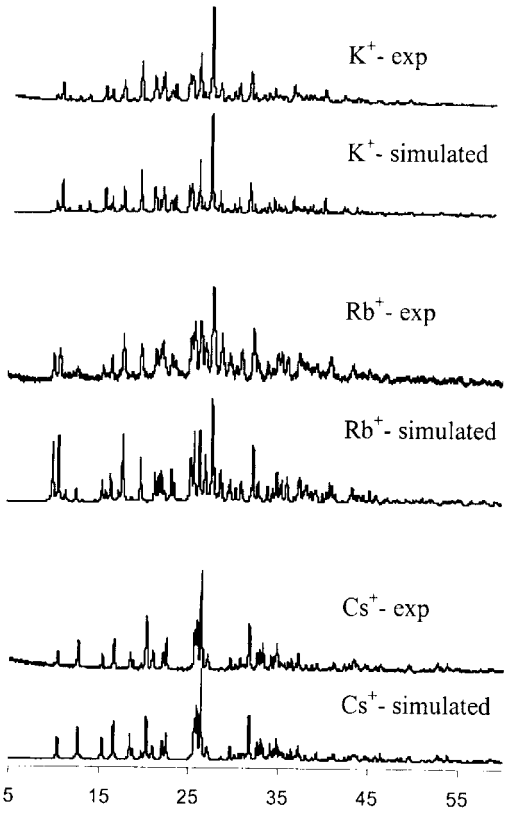

Figure 7. Experimental powder XRD data of bulk precipitates of K^+, Rb^+, and Cs^+ salts of DPA^- vs. powder XRD patterns simulated from the single-crystal X-ray data of the corresponding crystalline salts grown from the bulk precipitates.

Table 3. Crystal systems and unit cell parameters obtained from powder and single-crystal X-ray diffraction data for DPA and its compounds **1**–**4**.

DPA/complexes	Method	Crystal system	Unit cell dimensions *a*, *b*, and *c* [Å]	*α*, *β*, and *γ* [°]	Cell volume [Å^3]
DPA	SCXRD[a]	orthorhombic	7.370, 11.664, 18.894		1624.1
	PXRD[b]	orthorhombic	11.689, 18.992, 7.376		1637.5

whereas those of **2**–**4** were monoclinic, i.e., the same as that of single crystals of **2**–**4** reported above. The unit cell dimension and volume of the cell obtained from powder and single-crystal X-ray data also matched well.

Discussion

As mentioned above, selectivity was estimated through analysis of the precipitate obtained when a mixture of cations (bittern comprising mainly Na^+, K^+ and Mg^{2+} in one case and K^+, Rb^+ and Cs^+ in another case) was contacted with aqueous $Ca(DPA)_2$. When bittern is used, K^+ is found to be highly selective whereas Cs^+ is the most selective when the mixture comprises K^+, Rb^+ and Cs^+. To rationalize the observations of the second case, we sought to establish whether bulk precipitates are structurally similar to the single-crystal structures so that the latter may provide an understanding of selectivity. The similarity between experimental powder XRD data of bulk precipitates of **2**–**4** − that are formed almost instantaneously − and simulated diffractograms from the single-crystal data (Figure 7),[9] lead us to propose that the former are indeed structurally similar to the latter and, therefore, understanding of the crystal structures may provide vital clues on the selectivity trend. The unit cell dimensions obtained from powder X-ray data of **2**–**4** also matched well with those obtained from single-crystal X-ray data (Table 3) providing further support to this thesis. A similar comparison was not possible in the case of **1** in view of the inability to grow its single crystal.

As can be seen from the single-crystal structures of **2**–**4**, these structures are held in place by M···O and C–H···O interactions. Reduced exposure of the polar groups of the ligand to water by tying these up internally in the structure would lead to reduced solubility and, consequently, precipitation. The precipitation of $M^{n+}(DPA)_n$ can be depicted by Equation (1) (see also Scheme 1).

$$M^+_{(aq)} + [Ca(DPA)_2]_{aq} \rightarrow M(DPA)_n\downarrow + Ca^{2+}_{(aq)} \quad (1)$$

It can be seen from Equation (1) that the reaction will be favored with decrease in hydration enthalpy of $M_{(aq)}{}^+$. The values of hydration enthalpies follow the trend: M^{2+} (Mg, Ca) >> Na^+ (–97 kcal/mol) >K^+ (–77 kcal/mol) > Rb^+ (–70 kcal/mol) > Cs^+ (–63 kcal/mol). Thus for the mixture of K^+, Rb^+, and Cs^+, the selectivity would be highest for Cs^+ and least for K^+.[10] For the bittern system comprising Na^+, K^+, and Mg^{2+}, K^+ would be expected to have the highest selectivity on the basis of hydration enthalpy alone.

However, there are, other factors that also control selectivity besides hydration enthalpy. From packing diagrams of the K^+, Rb^+, and Cs^+ compounds **2**–**4**, space-filling models of the respective cavities comprising the metal ion and metal-bound oxygen atoms have been generated. The diagram for **4** is given in the figure in the table of contents of this issue and those of **2** and **3** are deposited as Supporting Information (Figures S4 and S5). The eight oxygen atoms around K^+/Rb^+ and ten oxygen atoms around Cs^+ make near-spherical cavities, the diameters of which can be determined from the respective distances between the *trans* oxygen atoms. The approximate diameters of the cavities (average of the distances between the *trans* oxygen atoms having O–M–O angle > 150°) are 5.720, 5.865, and 6.561 Å for K^+, Rb^+, and Cs^+, respectively. This increasing order of diameter of the cavities qualitatively follows the increasing order of the ionic sizes of these ions (2.66 Å, 2.94 Å, and 3.34 Å, for K^+, Rb^+, and Cs^+, respectively).[11] However, compared to the differences in the sizes of K^+ and Rb^+, the difference in the cavity diameters is less pronounced. Two opposite factors control cavity size: (i) short M···O distance and small size of the cation that can reduce the size of the cavity, and (ii) steric hindrance and electrostatic repulsion that prevent ligands from coming closer, and thereby increasing the cavity size. In the case of K^+, the latter may be the more dominant factor that prevents further shrinkage of the cavity diameter and weakens the M···O interactions which may, in addition to the hydration enthalpy difference, account for its lower selectivity in comparison to Rb^+, despite the similarities of the structures. Na^+, having smaller ionic size (1.94 Å), may be too small to fit in this cavity to make significant M···O interaction to form a stable assembly, if a similar structure were to apply in its case also. Alternative structures are, of course, possible, but comparative NMR study of **1** and NaCl suggests lack of metal-ligand interaction in solution, as ^{23}Na signal of both of them appeared at the same position, i.e., their environments are likely to be the same, namely Na^+ in hydrated state.

In the case of Cs^+, a large upfield shift (δ = 49.7 ppm) of the ^{133}Cs NMR signal of **4**, compared to CsCl, indicates strong metal-ligand interactions in solution. Ten oxygen atoms in the vicinity of the metal ion make strong Cs^+···O interactions, which decreases effective positive charge on the metal ion resulting in shielding of the Cs^+ ion. The additional NMR signals, which grow in with progress of the experiment, could be due to some new species formed in solution by dissociation of the supramolecular assembly. However, in all cases the observed peaks are shifted upfield indicating significant Cs^+···O interactions in solution state. Thus the selective formation may be assumed to originate in the solution phase and cascades to the solid precipitates. The larger cavity size in **4** allows for a higher coordination number (10) of Cs^+, which may lead to a greater degree of stabilization of the structure than with Rb^+ and K^+. Differences in ligand conformations may also have an effect on energetics and, consequently, selectivity. It is interesting to note that the DPA^- conformation in **4** has the closest match to that of DPA in crystalline state, the mean plane distortion being 61.35° compared to 50.5° for neutral DPA.[5] The deviations are much larger for **2** & **3**.

Alkaline earth metal ions, which are divalent in nature and have much higher hydration enthalpies ((Mg^{2+}, –459.1 mkcal/mol; Ca^{2+}, –376.9 kcal/mol; Sr^{2+}, –344.9 kcal/mol; Ba^{2+}, –311.9 kcal/mol),[10] are more difficult to complex with DPA^- which accounts for the high solubility of $Ca(DPA)_2$ and the lack of any $Mg(DPA)_2$ precipitation despite its high concentration in bittern. The relatively small ionic sizes of these cations may also be another factor that

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

thwarts complex formation and precipitation. This is borne out by our preliminary studies with the larger Sr^{2+} and Ba^{2+} (ionic diameters: 2.26 and 2.68 Å, respectively) ions,[11] wherein crystals of $[Sr(DPA)_2]\cdot 4H_2O$ and $[Ba(DPA)_2]\cdot 4H_2O$ could be obtained from the solution on slow evaporation of the solvent.[12]

Conclusions

We conclude from the present study that the selectivity of formation of $[M^{n+}(DPA^-)_n]$ can be divided into two broad categories: (i) cations such as K^+, Rb^+, and Cs^+ that favorably form precipitates almost instantaneously upon contact and (ii) those such as Na^+ and Ca^{2+} that do not form any precipitate. The former case pertains to compounds where the cation and DPA^- readily form complexes. The latter case, as exemplified by the ^{23}Na NMR studies with aqueous Na(DPA) wherein the environment of Na^+ is the same as that of Na^+ in aqueous NaCl, pertains to the situation wherein complex formation is unfavorable for a variety of reasons such as large hydration enthalpy and unfavorable ionic size. Sr^{2+} and Ba^{2+} represent an intermediate case where the complexes are moderately soluble and crystal formation does occur, albeit sluggishly, upon slow evaporation of the solution. Where alkali metal ions precipitate instantaneously with DPA^-, the observed selectivities are nicely explained on the basis of the structures of the complexes, which, in turn, are controlled by the relative sizes and hydration enthalpies of the cations. Kinetic factors could also contribute to some degree towards the selectivities.

Experimental Section

Materials: Dipicrylamine was purchased from National Chemical Co., India and used as received. AR grade KCl, RbCl, CsCl, CaO, and NaOH were obtained from S. D. Fine Chemicals. Double distilled water was used for the synthesis of compounds and Milli-Q (Millipore Corporation) water was used for ion chromatographic study.

Instrumentation: Elemental analyses (C,H,N) were performed with a model 2400 Perkin–Elmer elemental analyzer. The UV/Vis spectra were recorded with a model 8452A Hewlett–Packard diode array spectrophotometer. Cation concentration was measured with a Dionex 500 ion chromatograph. NMR spectra were recorded in D_2O with a model DPX 200 Bruker FT NMR instrument. X-ray powder diffraction data were collected using Philips X′ Pert MPD system with Cu-K_α irradiation. Single-crystal structures were determined using either Enraf–Nonius CAD-4 or Bruker SMART APEX (CCD) diffractometers.

Selectivity Studies with DPA^-: Selectivity studies were carried out by precipitating metal ions as DPA^- salts from bittern (the mother liquor obtained after recovery of common salt from brine, which contains a mixture of Na^+, K^+, Mg^{2+}, Ca^{2+}, SO_4^{2-}, and Cl^-) and also from a solution containing equimolar amount of KCl, RbCl and CsCl. In a typical experiment $[Ca(DPA)_2]$ was prepared first by adding solid CaO (0.067 g, 1.2 mmol) into an aqueous (10 mL) suspension of DPA (0.439 g, 1 mmol) followed by stirring of the reaction mixture for 5 min. 10 mL of this (filtered) aqueous $[Ca(DPA)_2]$ (1 mmol) was added with stirring into bittern (20 mL) or into an aqueous solution (50 mL) containing 2 mmol each of KCl, RbCl, and CsCl. The precipitate, which was instantaneously separated, was isolated by filtration and washed with diethyl ether and dried in vacuo. 10 mg of this material was calcined at 550 °C in a furnace and the residue was dissolved in nitric acid, which was evaporated and the residue was further dissolved in deionised water (20 mL) and filtered through 0.2 μm filter paper. The concentrations of the metal ions in the filtrate were determined by ion chromatography using Ion Pac CS12 (2 mm) analytical column and 20 mM methylsulphonic acid as eluent with a flow rate of 0.25 mL/min. Quantification was made using standard solutions containing Na^+, K^+, Mg^{2+}, and Ca^{2+} in one case and K^+, Rb^+, and Cs^+ in the other case.

Synthesis of Metal Salts of DPA^-

$[Na(DPA)]\cdot H_2O$ (1): To an aqueous (10 mL) suspension of DPA (0.439 g, 1 mmol) 2 mL of NaOH (0.04 g) was added dropwise and the reaction mixture was stirred at room temperature for 2 h, during which a dark brown solution was formed. After stripping off the water in a rotavap, the dry mass was dissolved once again in 5 mL volume of water and filtered to remove traces of insoluble material. The water was then evaporated and the compound was dried in vacuo, yield 94% (0.45 g). $C_{12}H_6N_7NaO_{13}$ (479.0): calcd. C 30.09, H 1.26, N 20.46; found C 30.31, H 1.03, N 20.02. UV/Vis (H_2O): λ_{max} (ε) = 426 nm (3.3×10^4).

$[K(DPA)]\cdot 0.5H_2O$ (2). Method I, from Bittern: 10 mL of aqueous $[Ca(DPA)_2]$ (1 mmol) was added into bittern (10 mL) and stirred for 5 min. The brown precipitate, which formed almost instantaneously, was isolated by filtration, washed with water and diethyl ether and recrystallised from a large volume of water. Yield: 0.41 g (85%). **Method II, from KCl:** Solid KCl (0.075 g, 1 mmol) was added into the above-mentioned dark brown solution (Ca^{2+} salt of DPA^-) and stirring was continued for 5 min, during which a brown precipitate was separated. The precipitate was isolated and purified following the procedure mentioned in method I, yield 86% (0.4 g). $C_{12}H_5KN_7O_{12.5}$ (486.1): calcd. C 29.65, H 1.04, N 20.16; found C 29.70, H 0.95, N 19.90. UV/Vis (H_2O): λ_{max} (ε) = 426 nm (3.5×10^4).

$[Rb(DPA)]\cdot H_2O$ (3): This compound was synthesized following the same procedure as that described for method II of complex **2**, replacing KCl with RbCl, yield 85% (0.46 g). $C_{12}H_6N_7O_{13}Rb$ (541.5): C 26.61, H 1.12, N 18.09; found C 26.28, H 1.02, N 17. 86. UV/Vis (H_2O): λ_{max} (ε) = 426 nm (3.5×10^4).

$[Cs(DPA)]$ (4): This compound was synthesized following the same procedure as that described for method II of complex **2**, replacing KCl with CsCl, yield 84% (0.47 g). $C_{12}H_4CsN_7O_{12}$ (570.9): C 25.24, H 0.71, N 17.16; found C 25.19, H 0.86, N 17.11. UV/Vis (H_2O): λ_{max} (ε) = 426 nm (3.4×10^4).

X-ray Crystallography: Cell parameters and diffraction intensities for complex **2** were measured at room temperature with the CAD-4 X-ray diffractometer using graphite-monochromatised Mo-$K\alpha$ radiation (0.7107 Å) in the range θ = 2–25°, for complexes **3** and **4** data were collected on the CCD diffractometer (Table 4). In the case of complex **2**, 25 reflections with θ in the range 9–12° were used for getting the accurate cell dimensions. Three standard reflections were monitored after every 100 reflections during the entire period of data collection, which showed no significant variation, indicating the stability of the crystal. The crystal orientation, refinement of the cell parameters and intensity measurements were carried out using the program CAD-4 PC.[13] Raw intensity data were corrected for Lorentz polarization effects but not for absorp-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tion. The Lorentz polarization corrections and data reduction were carried out using NRCVAX program.[14] The data for DPA and complexes **3** and **4** were corrected for Lorentz polarization and absorption effects. SHELXL-97[15] was used for structure solution and full-matrix least-squares refinement on F^2 for all these data. H atoms were included in the structure as riding model or obtained from the difference Fourier map.
