### 1. Introduction

The synthesis of fluorescent analogs of nucleotides with enzymic activity was recently reported [1]. The fluorescence properties of 1,*N*<sup>6</sup>-ethenoadenosine di- and triphosphate ( $\epsilon$ ADP and  $\epsilon$ ATP) promise to provide useful tools for the study of the interaction of adenine nucleotides with the energy conservation system of chloroplast membranes and the transport of nucleotides across these membranes, if these can replace nucleotides in the various chloroplast reactions.

This communication deals with the activity of  $\epsilon$ ADP as a substrate for photophosphorylation and of  $\epsilon$ ATP as substrate for several hydrolytic and exchange reactions related to photophosphorylation. Significant differences in the capability of the  $\epsilon$ -adenine analogs to replace adenine nucleotides in the various reactions tested suggest that more than one type of site, with different specificity for the nucleotide phosphates, exists.

### 2. Methods and materials

Chloroplasts were isolated from fresh market lettuce leaves by standard procedures. The coupling factor protein (CF<sub>1</sub>) was isolated from lettuce chloroplasts and purified following Lien and Racker [2].

#### Abbreviations:

- PMS – phenazine methosulfate;
- CF<sub>1</sub> – chloroplast coupling factor;
- NTP/e<sub>2</sub> or ATP/e<sub>2</sub> –  $\epsilon$ ATP or ATP formed per 2e<sup>-</sup> transferred;
- DTT – dithiothreitol.

Yeast hexokinase (Type III) and the sodium salts of ADP, ATP and GTP were purchased from Sigma Chemical Co.

$\epsilon$ ADP and  $\epsilon$ ATP were prepared by the method of Secrist et al. [1], and had satisfactory melting points. By the spectral criteria suggested by Secrist et al. [1] the nucleotides were at least 98% ethenoadenine derivatives. Thin-layer chromatography (on Merck microcrystalline cellulose sheets with fluorescent indicator using isobutyric acid–NH<sub>4</sub>OH–H<sub>2</sub>O (60:1:39 v/v/v) showed that the final products obtained ( $\epsilon$ ATP and  $\epsilon$ ADP) contained only traces of their corresponding hydrolysis products. [ $\gamma$ -<sup>32</sup>P]ATP was prepared from [<sup>32</sup>P]phosphate and ADP [3]. [ $\gamma$ -<sup>32</sup>P] $\epsilon$ ATP was similarly prepared from  $\epsilon$ ADP and was shown to be chemically identical to  $\epsilon$ ATP prepared as above, by co-chromatography on the above TLC system. Yeast hexokinase transferred the label from either [<sup>32</sup>P]nucleotide to glucose [3]. The [ $\gamma$ -<sup>32</sup>P]nucleotides were diluted with cold nucleotide triphosphates for ATPase activity assays. ATP formation and ferricyanide reduction were assayed as described [3, 4].

### 3. Results

$\epsilon$ ADP can replace ADP as the substrate for photophosphorylation in chloroplasts. Substrate amounts of  $\epsilon$ ADP were phosphorylated in this reaction, and it was demonstrated that the phosphorylated product obtained is in fact [ $\gamma$ -<sup>32</sup>P] $\epsilon$ ATP by co-chromatography with cold  $\epsilon$ ATP and by [<sup>32</sup>P]phosphate transfer to glucose with yeast hexokinase (EC 2.7.1.1) [5]. As shown in table 1 the apparent Michaelis constants for

Table 1  
Photophosphorylation with ADP and  $\epsilon$ ADP substrates.

Reaction	Substrate	$K_m$ (appar) (mM)	$V_{max}$ (appar) ( $\mu$ moles ATP/mg CHL/hr)	NTP/ $e_2^*$
Ferricyanide	ADP	0.06	313	0.95
	$\epsilon$ ADP	0.11	162	0.65
Phenazine methosulfate	ADP	0.04	1193	—
	$\epsilon$ ADP	0.10	662	—

Reaction mixtures contained the following components in  $\mu$ moles in a total volume of 3 ml at pH 7.8: Tris-HCl, 90; NaCl, 150;  $MgCl_2$ , 10;  $P_i$ , 10 (containing  $4 \times 10^6$  cpm  $^{32}P$ ); chloroplasts containing about 50  $\mu$ g chlorophyll and  $K_3Fe(CN)_6$ , 1.0 or PMS, 0.1 as indicated. In the reaction with PMS, 60  $\mu$ moles of glucose and hexokinase, 2 mg were used. Light intensity was 160 000 lux. Samples were illuminated for 1 min at 22°C.

\* NTP/ $e_2$  was calculated at optimal  $\epsilon$ ADP concentrations.

ADP and  $\epsilon$ ADP are similar in the two photophosphorylation assays tested. In each case the maximal velocity observed with  $\epsilon$ ADP was about 50% of that attained with ADP. The NTP/ $e_2$  ratio with  $\epsilon$ ADP was somewhat lower than ATP/ $e_2$  suggesting less efficient coupling. In contrast,  $\epsilon$ ATP was not a good substitute for ATP in the partial reactions of photophosphorylation. In the light triggered chloroplasts ATPase or the  $CF_1$ - $Ca^{2+}$  ATPase reactions, maximal rates with  $\epsilon$ ATP were about 10–15% of those ATP (table 2). Even more striking was the low activity observed with  $\epsilon$ ATP in the  $ATP \leftrightarrow P_i$  exchange reaction (less than 1%).

$\epsilon$ ATP was found to be a competitive inhibitor of ATP in this reaction with  $K_i$  of the same order of magnitude as  $K_m$  for ATP, and  $\epsilon$ ADP inhibited the light triggered ATPase as ADP.

Since these reactions were performed with either purified, heat-activated  $CF_1$  or with modified chloroplasts, it might be argued that they are not directly comparable to a normal chloroplast preparation. We therefore examined the activity of  $\epsilon$ ADP in a photophosphorylation reaction in a medium containing DTT, conditions comparable to those of the light-triggered ATPase and  $ATP \leftrightarrow P_i$  exchange reactions.

Table 2  
 $\epsilon$ ATP as substrate in partial reactions of photophosphorylation.

Reaction	Substrate	Optimal concentration range (mM)	Rate *	Relative activity (%)
A) $CF_1$ -ATPase	ATP	4 – 10	17	12
	$\epsilon$ ATP	4 – 10	2	
B) Light-triggered ATPase	ATP	2 – 4	105	13
	$\epsilon$ ATP	2 – 5	14	
C) Light-dependent ATPase	ATP	0.4 – 0.9	23	28
	$\epsilon$ ATP	0.4 – 0.9	6.5	
D) $ATP \leftrightarrow P_i$	ATP	1 – 3	19	0.2
	$\epsilon$ ATP	1 – 3	0.03	

A) Desalted  $CF_1$  was heat activated in the presence of 33 mM ATP and 5 mM DTT at 60°C for 4 min. ATPase activity was determined using  $^{32}P$ -labelled substrates as described, [6] except that a constant  $Ca^{2+}/[NTP]$  ratio of 1 was maintained. Rates are given in  $\mu$ moles  $P_i$  released per mg protein per minute. B and C) ATPase activities were determined using  $^{32}P$ -labelled substrates as described [10] except that in the case of light-dependent ATPase assay a  $Ca^{2+}/[NTP]$  ratio of 5 was maintained. Rates are given in  $\mu$ moles  $P_i$  released per mg chlorophyll per hour. D)  $ATP \leftrightarrow P_i$  exchange activity was determined as described [11] except that  $MgCl_2$  and  $P_i$  were 10 and 5 mM, respectively.

\* Rates are given in  $\mu$ moles  $P_i$  exchanged per mg chlorophyll per hour.

Table 3  
Protection of CF<sub>1</sub> during heat activation.

Additions to heat activation mixture	ATPase ( $\mu$ moles P <sub>i</sub> /mg protein/min)	(% of control)
None	0	0
ATP	14.5	100
GTP	0	0
$\epsilon$ ATP	8.5	59
PP <sub>i</sub>	0	0

Heat activation of CF<sub>1</sub> was as described in table 2. The concentration of nucleotides or PP<sub>i</sub> during heat activation was 33 mM. ATPase activity was then determined using [ $\gamma$ -<sup>32</sup>P]ATP [10]. ATPase activity obtained after heat activation in the presence of ATP is referred to as 100%.

The relative rates of phosphorylation of  $\epsilon$ ADP (70% of ADP) was similar to that obtained with normal chloroplast preparations. Although  $\epsilon$ ATP was a relatively poor substrate for ATPase activities, the competitive nature of the inhibition of the ATP  $\leftrightarrow$  P<sub>i</sub> exchange by  $\epsilon$ ATP suggested that it could bind to the protein(s) involved in these reactions. Therefore we tested the ability of  $\epsilon$ ATP to replace ATP in protecting the latent CF<sub>1</sub>-ATPase during heat activation of the protein. As shown in table 3,  $\epsilon$ ATP was 60% as effective as ATP, while heating CF<sub>1</sub> with GTP or pyrophosphate was much less effective [6].

#### 4. Discussion

It has been assumed that the ATPase and ATP  $\leftrightarrow$  P<sub>i</sub> exchange reactions represent reversal of one or more of the last steps in ATP formation during photophosphorylation [7]. This assumption implies that these reactions occur at a catalytic site identical with that involved in photophosphorylation. One might therefore expect a similar specificity towards the adenine nucleotide substrates in all these reactions. The results described above, contrary to this expectation, show large differences among the specificities of these reactions.  $\epsilon$ ADP is nearly as good (50–70%) a substrate as ADP for photophosphorylation, while  $\epsilon$ ATP is a very poor substrate (0.2% of ATP rate) for the ATP  $\leftrightarrow$  P<sub>i</sub> exchange reaction. In none of the ATPase reactions was the relative effectiveness of  $\epsilon$ ATP comparable to

that of  $\epsilon$ ADP in photophosphorylation even with similar chloroplast preparations. However,  $\epsilon$ ATP was a competitive inhibitor of the ATP  $\leftrightarrow$  P<sub>i</sub> exchange, and could protect CF<sub>1</sub> from heat inactivation. Published data involving comparison of other nucleotides also suggests that the ATP  $\leftrightarrow$  P<sub>i</sub> exchange reaction is highly specific [7], while photophosphorylation has a much wider specificity for nucleotides [8, 9].

One explanation for these results is the existence of at least two types of catalytic sites involved in the reactions studied, and that those sites with high nucleotide specificity may not be directly related to the process of ATP formation. It is of interest that other workers have found evidence for multiple nucleotide sites in chloroplast and mitochondrial isolated coupling factors, although the relevance of these observations to the problem raised here is uncertain. Roy and Moudrianakis, in proposing a mechanism for the formation, from ADP, of ATP tightly bound to the isolated CF<sub>1</sub> protein, have suggested that the protein has two different ADP binding sites [12]. It has recently been reported that the solubilized mitochondrial ATPase has two nucleotide binding sites with different base specificities [13]. Investigation of the binding of nucleotides to the isolated CF<sub>1</sub> protein and the membrane-bound enzyme, as well as fluorescence studies with  $\epsilon$ -adenine analogues, should provide further information regarding the interactions between these nucleotides and the membrane-bound enzymes, and should help clarify the relevance of these interactions to the energy conservation mechanism in chloroplasts.

#### Acknowledgements

We wish to thank Mrs Ruth Yaniv and Miss Zvia Maimon for technical assistance and Dr. L.J. Altman for helpful discussions and assistance in the early stages of this work, which was supported in part by Grant 21-A of the Israeli National Science Foundation.
