The focus of this paper is on structures with equal refractive-index steps at the two heterojunctions. However, we illustrate the previously predicted effect of additional features in far-field radiation pattern structure due to the presence of the p-type GaAs surface layer, using an experimental asymmetrical double-heterojunction structure where the radiation spreads preferentially toward one diode surface. Fig. 4 shows the cross section of such a diode together with the near-field radiation pattern calculated for the specific device parameters ($Al_{0.3}Ga_{0.7}As$-$Al_{0.09}Ga_{0.91}As$-$Al_{0.18}Ga_{0.82}As$) with appropriate Δn values [9]. It is evident from Fig. 4 that the field penetrates through the 1.4-μm-thick p-type (AlGa)As layer into the GaAs surface layer at the right. The far-field radiation pattern was calculated from the near-field curve of Fig. 4 and compared to the measured far field in Fig. 5. Both the experimental and theoretical far-field curves show the small additional peak expected when appreciable radiation propagates in the p-type GaAs surface layer. While an analysis of asymmetrical structures is outside the scope of this paper, we note that the room-temperature threshold current density of the above laser was 18 000 A/cm^2 and its total differential quantum efficiency was 7 percent (400-μm cavity length, broad area contact). The high threshold current density compared to typical (AlGa)As double-heterojunction lasers with submicron active regions [4] is due to both poorer radiation confinement and stronger absorption in the p-GaAs surface layer. The low differential quantum efficiency (compared to typical 40-percent values in good quality lasers) is directly related to excessive absorption in the previously described laser consistent with the radiation spread into the p-GaAs region.

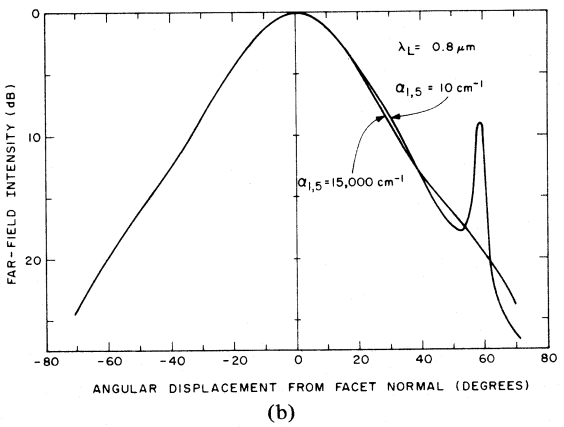

TABLE I
MATERIAL PARAMETERS FOR FIG. 3

Layer #	n	$\alpha(\text{cm}^{-1})$	Region Thickness (μm)
1	3.59	–	≥ 4
2	3.46	10	1
3	3.54	-40 [a]	0.25
4	3.46	10	2
5	3.59	–	> 1

[a] Choice of value is not critical in determining the radiation pattern.

(a)

(b)

Fig. 3. (a) Near field for a structure with parameters given in Table I for two values of the absorption coefficient in the GaAs regions 1 and 5. The lasing wavelength is taken as 0.8 μm. (b) Far field calculated from the near field shown in (a) for the two assumed absorption-coefficient values.

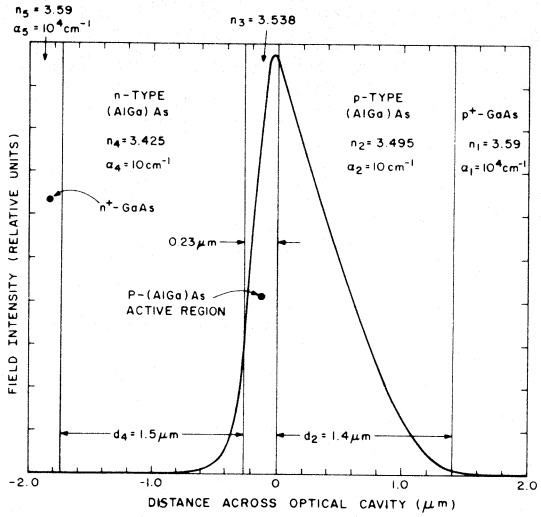

Fig. 4. Near field calculated for an asymmetrical laser in which the radiation is preferentially spreading toward the surface of the structure. The index values are indicated as well as the thickness of each relevant region. The index values were first estimated from the (AlGa)As compositions in each region and then "fine tuned" to match the experimental far-field pattern. The thicknesses were measured on the actual laser.

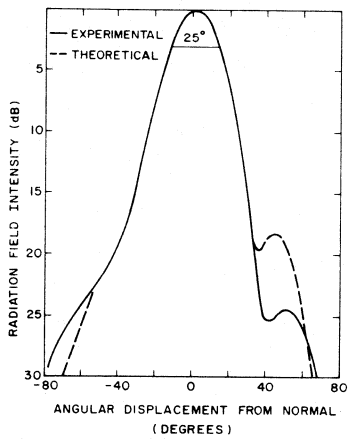

Fig. 5. Far field calculated from the near field of Fig. 4 compared to the experimentally measured pattern for the same laser to show the additional peak at the right due to radiation propagation in the highly absorbing p-type GaAs region 1.

Design Curves

The material in each of the five regions is characterized by its relative complex dielectric constant κ. The imaginary part of κ is related to the absorption coefficient while the real part is related to the index of refraction. The contributions to the effective absorption coefficient include free-carrier absorption within the recombination region, a weighted coefficient value $\bar{\alpha}$ from the other laser regions which takes into account the fraction of the radiation in each region, and the cavity-end loss α_{end}. We define the quantity Γ in the conventional sense as the fraction of the propagating power that lies within the recombination region 3. We define a quantity G_{th} in terms of $\bar{\alpha}$ and Γ

$$G_{th} = \frac{\bar{\alpha}}{\Gamma}. \tag{1}$$

Therefore, G_{th} represents the recombination-region gain coefficient at lasing threshold for a laser with no free-carrier absorption within the recombination region ($\alpha_{fc} = 0$) and no cavity-end losses ($\alpha_{end} = 0$).

For a laser of finite length and finite α_{fc}, the recombination-region gain coefficient at threshold g_{th} is

$$\Gamma(g_{th} - \alpha_{fc}) = \Gamma G_{th} + \alpha_{end}$$

or

$$g_{th} = G_{th} + \alpha_{fc} + \frac{1}{\Gamma}\alpha_{end}. \tag{2}$$

In terms of the above quantities, the external differential quantum efficiency η_{ext} is

$$\eta_{ext} = \eta_i \frac{\alpha_{end}}{\alpha_{end} + (\alpha_{fc} + G_{th})\Gamma} \tag{3}$$

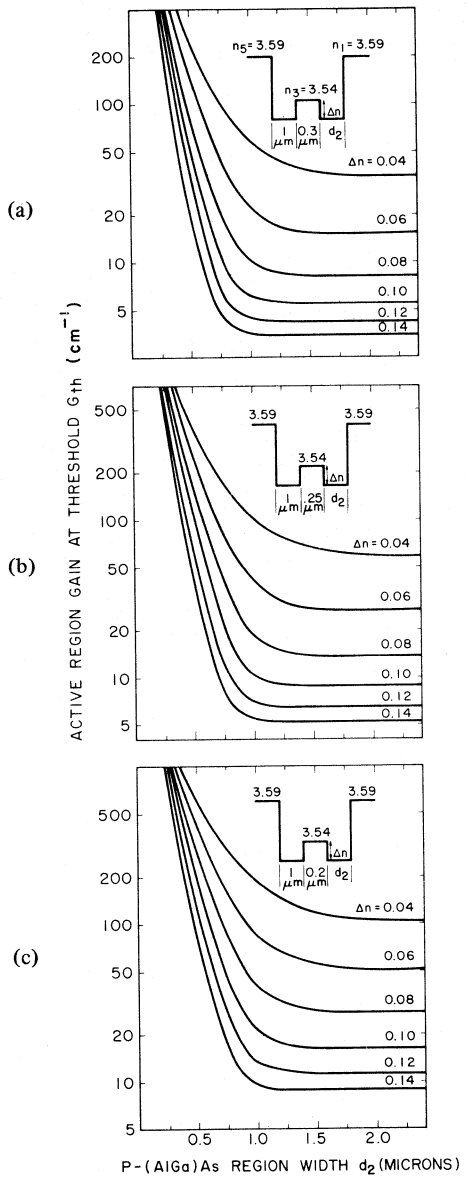

Fig. 6. The active-region gain coefficient ($\lambda_L = 0.8$ μm) at threshold G_{th} calculated for various device parameters with quantities noted in the insert sketch held constant. Both the refractive-index step Δn and the width d_2 of the p-type (AlGa)As region 2 are varied.

where η_i is the customary internal quantum efficiency. In the region where the linear theory of lasing is adequate, a cavity of length L and facet reflectivity R has $\alpha_{end} = (1/L) \ln (1/R)$; typically $\alpha_{fc} = 10\ cm^{-1}$.

Once g_{th} is known, the threshold current density J_{th} is determined by the thickness d_3 of the recombination region, the internal quantum efficiency, and the relationship between gain and injected carrier density. In the simplest case, the gain near threshold is assumed to be linearly related to the injected carrier density and

$$J_{th} \propto \frac{d_3}{\eta_i} g_{th}. \tag{4}$$

The theoretical curves presented in this section concern G_{th} for thin structures of particular interest to low-threshold cavities required for CW operation; for example, the diode structure with a recombination region of $Al_{0.1}Ga_{0.9}As$ (lasing wavelength ≈ 8000 Å), although the results have wider applicability. The parameters are: $n_3 = 3.54$; $n_1 = n_5 = 3.59$, and $\alpha_1 = \alpha_5 = 15\,000\ cm^{-1}$. In regions 2 and 4 the loss is due to free-carrier absorption and is relatively low: $\alpha_2 = \alpha_4 = 10\ cm^{-1}$. The calculations are presented in terms of the index difference $\Delta n \equiv n_3 - n_2$ between the recombination region and the adjacent layers, and the thickness of the adjacent layers.

Figs. 6-9 present analytical curves which are useful in predicting g_{th} for known parameter values. The first set of curves (Fig. 6) shows the effect on G_{th} of changes in the width of region 2 and of Δn for three different recombination-region thickness values: 0.2, 0.25, and 0.3 μm. For a given Δn, the narrower the recombination region, the greater the radiation spread, and hence the greater the effect of the absorption in

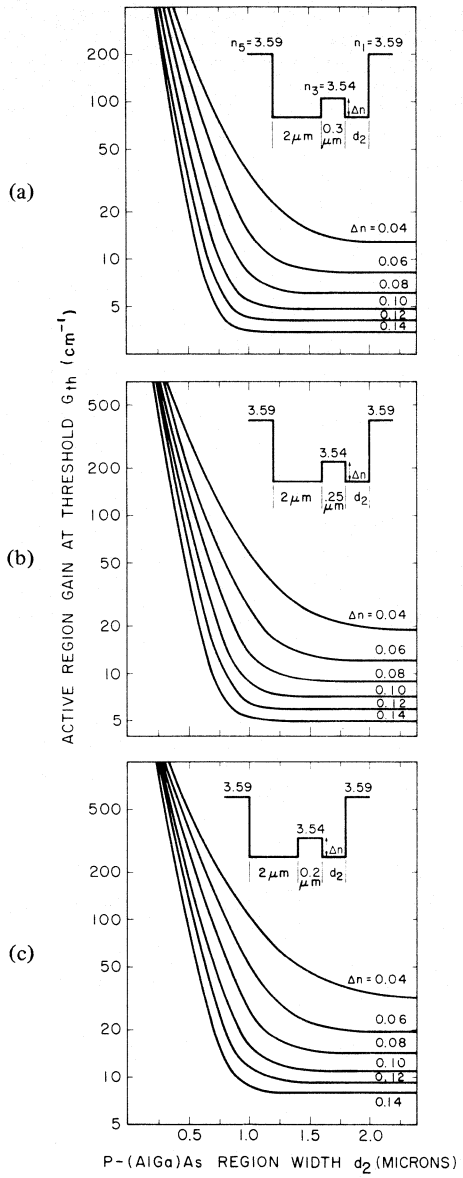

Fig. 7. The active-region gain coefficient (λ_L = 0.8 μm) at threshold G_{th} calculated for various device parameters with quantities noted in the insert sketch held constant. This figure differs from Fig. 6 in that the thickness of region 4, d_4, is 2 μm instead of 1 μm.

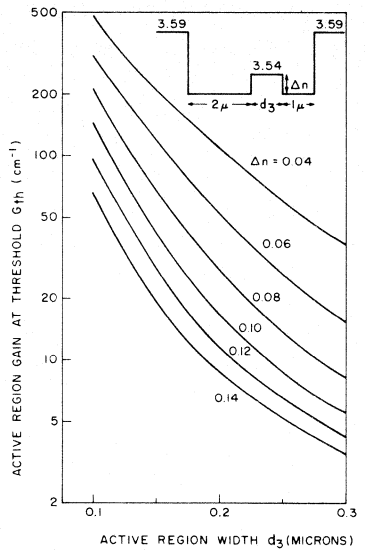

Fig. 8. The active-region gain coefficient (λ_L = 0.8 μm) at threshold as a function of the active-region width d_3 for various Δn values.

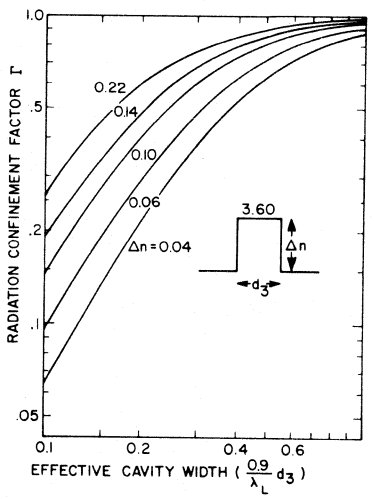

Fig. 9. The radiation-confinement factor Γ as a function the width of the recombination region d_3 for various Δn values. Note that the d_3 axis can be adjusted for different lasing wavelengths (in micrometers) by normalization.

the GaAs regions on G_{th}. Note the general result that the thickness of p-type (AlGa)As region no longer affects G_{th} when it exceeds ~1 μm. The curves in Fig. 7 show similar calculations with the thickness of the (AlGa)As-n-type region (d_4) assumed to be 2-μm thickness instead of 1 μm as in Fig. 6. Since the thermal resistance of the diodes when mounted with the p-side on the heat sink is not affected by the thickness of region 4, it is of interest to determine whether increasing its thickness has a significant effect on G_{th} with other factors being constant. Fig. 7 shows that G_{th} is indeed reduced by widening region 4 with the improvement being dependent on the design details. Fig. 8 shows comprehensive plots of G_{th} with the active-region width as a variable for a set of Δn values, keeping the thickness of regions 2 and 4 fixed at 1 and 2 μm, respectively.

Finally, we show in Fig. 9 the dependence of Γ on various structural parameters. The confinement to the thin recombination regions is seen to change rapidly with small changes in the refractive-index step Δn. However, as the recombination-region width approaches 1 μm, Γ is nearly unity for the broad range of parameters shown.

Conclusion

Theoretical calculations have been presented showing the relationship between the internal laser absorption and structural parameters appropriate for CW room-temperature lasers. These diodes have submicron-thick recombination regions, and very small spacings between the heat sink and the recombination region to minimize the thermal resistance. The optical loss is shown to be strongly dependent on the degree of radiation confinement to the active region. In particular, absorption in the surface GaAs layer providing the ohmic contact becomes

very significant when the intermediate (AlGa)As layer is reduced below about 1 μm. It has been further shown that excessive penetration into the GaAs regions gives rise to anomalies in the far-field radiation profiles in the direction perpendicular to the junction plane. Proper design of the internal structure of the laser avoids large increases of the threshold current density as well as large decreases in the external differential quantum efficiency from interaction with the contact layer. The design curves presented can be used to predict the gain required at threshold for a broad range of structural parameters of interest in low-threshold laser design.

Calculations of the Continuous-Wave Lasing Range and Light-Output Power for Double-Heterostructure Lasers

P. GAREL-JONES AND JOHN C. DYMENT

Abstract—**Procedures for calculating the range of currents and heat-sink temperatures in which continuous-wave (CW) operation is possible and the light-output power levels within this range are presented for double-heterostructure (DH) lasers with an oxide-insulated stripe geometry. A one-dimensional heat-flow model has been assumed within the device followed by two-dimensional heat flow into the heat sink. It is shown that a laser with stripe dimensions (13 μm × 400 μm) and typical thicknesses can achieve CW operation at heat-sink temperatures up to about 431 K. At 300 K, the theoretical power output is in the 40–50-mW range for $J = 2J_{th}$. The effects of varying thicknesses and the aluminum content in the GaAlAs confining layer are considered. The limitations of the calculation are discussed as well as its applicability to other stripe-geometry devices.**

Nomenclature

T_j Junction temperature.
$\Delta T(i)$ Temperature rise across layer (i).
$T(i)$ Temperature at boundary between layers (i) and $(i+1)$.
$D(i)$ Thickness of layer (i).
$K(i)$ Thermal conductivity of layer (i).
T_{HS} Heat-sink temperature.
L Length of stripe contact.
S Width of stripe contact.
A Area of stripe contact ($A = LS$).
x Fraction of Al in layer (2), $Ga_{1-x}Al_xAs$.
α Reduction in thermal conductivity due to presence of Al from [13]. For $x = (0,0.1,0.2,0.3,0.4)$, $\alpha = (1.00,2.33,3.06,3.76,4.45)$.
J Current density.
I Total current ($I = JA$).
V Total voltage ($V = V_0 + IR_s$).
V_0 Approximate junction voltage

$$V_0 = 1.49 - [0.00058\, T_j^2/(T_j + 300)].$$

R_s Series resistance.
$J_{th}(T_j)$ Threshold current density at junction temperature T_j.
$\eta(T_j)$ External differential quantum efficiency at junction temperature T_j.
P_L CW light output at current density $J > J_{th}$ ($P = \eta V A[J - J_{th}]$).
P_H Power dissipated as heat in the junction region.
$R_T(T_j)$ Thermal resistance from junction at T_j to the heat sink.

INTRODUCTION

IN THIS PAPER our purpose is twofold. In Part I, a set of procedures is developed for calculating the allowable range of currents and heat-sink temperatures in which continuous-wave (CW) operation is possible for double-heterostructure (DH) lasers with an oxide-insulated stripe-geometry contact [1]. In Part II, the permissable CW light-output power is calculated for any current within the CW lasing range. In stripe-geometry devices, the current through the junction is confined which thus creates a narrow source of heat. Because the oxide acts as a thermal barrier, the flow of heat can be considered as one-dimensional from the junction region to the stripe and then two-dimensional as the heat flows into the heat sink. The thermal resistances obtained from this model will be applicable to oxide stripe geometries [1], to buried layer heterostructures [2], which have an oxide barrier, and to etched mesa structures [3]. However, this model will overestimate the thermal resistance of devices in which current confinement is achieved by means of proton bombardment [4], various diffusion techniques [5]-[7], lateral injection techniques [8], or heteroisolation techniques [9]. In all of these latter devices, there is no oxide barrier and the heat flow from the junction region should be considered as two-dimensional [6], [10]. For these cases, the present calculation would overestimate the junction temperature and underestimate the light-output power. Further discussion on these points follows in Part II.

The concept of a CW lasing region boundary has been used by Dyment *et al.* [11] for a homostructure laser. These same concepts have been used in Part I, but the problem is now somewhat more complicated because of the multiple layers contained in a DH laser. In the present calculations, the experimentally known temperature dependences for threshold current density (J_{th}) are used along with estimates of the temperature dependences of the voltage (V) and thermal conductivities of GaAs and GaAlAs. Calculations of the light-output power within the CW lasing region boundary were not previously performed in [11], but become increasingly important in view of the current efforts to improve the reliability of DH lasers. The light-output powers calculated in Part II depend critically on the value of the junction temperature (T_j) and the associated values of $J_{th}(T_j)$ and external differential quantum efficiency $\eta(T_j)$. These temperature dependences were both obtained experimentally as described in the next section.

TEMPERATURE DEPENDENCES OF THRESHOLD CURRENT DENSITY AND EFFICIENCY

The temperature dependences of both J_{th} and η have been obtained from experimental measurements of light output as a function of pulsed current density using DH laser structures as shown in Fig. 1. A low duty cycle was used so that T_j was approximately equal to the heat-sink temperature (T_{HS}) which was increased in steps from 295-415 K.

From the sharp increases in light output which occur where $J = J_{th}$, we established that the typical temperature dependence has the form

$$J_{th}(T_j) = J_0 \exp(T_j/T_0) = 232 \exp(T_j/125). \quad (1)$$

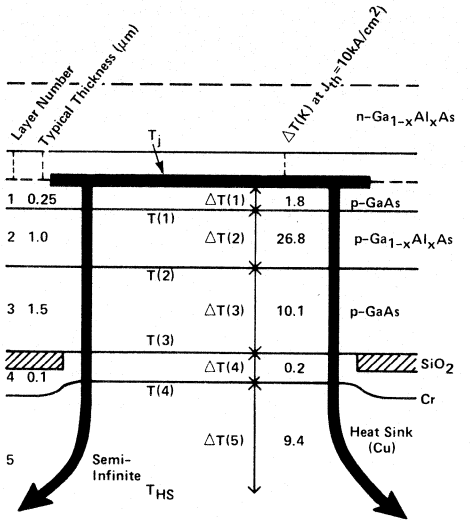

Fig. 1. Heat-flow model for a continuously operating DH laser with an oxide-insulated stripe geometry. Heavy lines represent the flow of heat from the center of the active region to the heat sink which is assumed to be Cu for the calculations. Assuming typical thicknesses as indicated and $x = 0.3$, $R_s = 1\ \Omega$, $S = 13\ \mu$m, and $L = 400\ \mu$m, the temperature rises for $J_{th} = 10$ kA/cm² are given. In experimental lasers, the heat sink actually has a layer of Au between the device and the Cu. This is neglected in the calculation due to the similar thermal conductivities of Au and Cu.

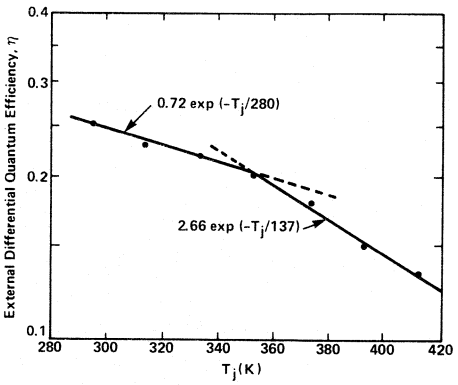

Fig. 2. Variation of external differential quantum efficiency (η) with junction temperature (T_j) for a typical DH laser with a stripe geometry.

By setting $J_0 = 232$ A/cm², we ensure that $J_{th} \simeq 2500$ A/cm² at room temperature, a value usually obtained in our CW lasers. The magnitude of $T_0 = 125$ K is the average of the measured values which ranged from 115 to 140 K.

The magnitudes of $\eta(T_j)$ were obtained from the slopes of the total light-output power from both mirrors for $J > J_{th}$. A typical set of data has been plotted in Fig. 2. It can be seen that η decreases from about 0.25 at $T_j \simeq 300$ K to about 0.13 at $T_j = 415$ K; however, the decrease is not linear but is slightly concave downward. To a reasonable degree of accuracy, the data can be approximated by two exponential regions as follows:

$$\eta(T_j) = 0.72 \exp(-T_j/280), \quad T_j < 350\ \text{K}$$
$$\eta(T_j) = 2.66 \exp(-T_j/137), \quad T_j > 350\ \text{K}. \quad (2)$$

The analytical expressions in (1) and (2) have been used in the computer calculations.

PART I—CALCULATION OF THE BOUNDARY OF THE CW LASING REGION ($J = J_{th}$)

Fig. 1 illustrates the heat-flow model for a DH laser with an oxide-insulated stripe contact. A source of heat power P_H of width (S) and length (L) is assumed localized at the center of the p-type GaAs active region although its exact location and extent is somewhat uncertain. Further discussion concerning this point is presented in the following. Heat flows linearly through successive layers of p-GaAs, p-GaAlAs, p-GaAs, and Cr before spreading into a semi-infinite Cu heat sink. In experimental devices, there is usually a thick layer of Au ($\simeq$15 μm) and a bond metal In ($\simeq$1 μm) between the Cr and the Cu heat sink but, since the thermal conductivities of Au and Cu are similar and the In is thin, little error is made by assuming that Au and Cu act together as a semi-infinite half-space (assumed to have the thermal conductivity of pure Cu). The heat flowing through these layers produces corresponding temperature rises $\Delta T(i)$ which have been calculated using the parameters and formulas given in the Nomenclature and Table I. Layers (1)-(5) are assumed to be at the constant temperatures T_j, $T(1)$, $T(2)$, $T(3)$, and $T(4)$, respectively, for the purposes of determining their thermal conductivities. The total temperature decrease from the junction to the heat sink is

$$T_j - T_{HS} = \sum_{i=1}^{5} \Delta T(i). \tag{3}$$

We now briefly discuss some of the differences between the present calculation for a DH laser and the calculation cited previously for the homostructure device [11]. The thermal conductivities $K(1)$ and $K(3)$ for the p-GaAs layers are required at temperatures above 300 K in contrast to the previous work in which temperatures far below 300 K were used. For this purpose we have plotted the data of Amith *et al.* [12], and have obtained the temperature dependences given in Table I. Unfortunately, the temperature dependence for the thermal conductivity of the p-$Ga_{1-x}Al_xAs$ layer (2) is not known. We have assumed that the temperature dependence will be the same as for p-GaAs [12], but we have reduced the overall magnitude by the term α (see Table I) since values of α are known from the recently published data of Afromowitz [13]. The Nomenclature lists values of α for Al contents ranging from $x = 0$ to $x = 0.4$, the range of interest to us. It is realized that the assumption of the same temperature dependence for GaAlAs will probably overestimate the temperature rise in layer (2). This can be inferred from data for another alloy ($GaAs_{1-x}P_x$) given by Carlson *et al.* [14], which suggests that the temperature dependence of thermal conductivity in an alloy will be less than in the pure material and indeed will also be different for different values of x. In view of the lack of experimental data on this parameter, the assumption of the same temperature dependence serves as a worst case calculation by overestimating $\Delta T(2)$.

For each given value of J_{th}, a ΔT value is calculated as in (3) assuming that all of the input electrical power $P_H = VAJ_{th}$ is dissipated as heat in the device where

$$V = V_0 + AJ_{th}R_s \tag{4}$$

TABLE I
FORMULAS FOR CALCULATING TEMPERATURE RISES IN A DH LASER WITH AN OXIDE STRIPE-GEOMETRY CONTACT OF WIDTH S (13 μM) AND LENGTH L (400 μM)

Layer	Material	Thickness (cm)	Thermal Conductivity [a] (W cm^{-1} K^{-1})	ΔT (K)
(1)	p-GaAs	$D(1) = 0.25 \times 10^{-4}$	$K(1) = 0.91 \exp\left(\frac{-T_j}{367}\right)$	$\Delta T(1) = \frac{P_H}{LS} \frac{D(1)}{K(1)}$
(2)	p-$Ga_{1-x}Al_xAs$	$D(2) = 1.0 \times 10^{-4}$	$K(2) = \frac{0.91}{\alpha} \exp\left(\frac{-T(1)}{367}\right)$	$\Delta T(2) = \frac{P_H}{LS} \frac{D(2)}{K(2)}$
(3)	p-GaAs	$D(3) = 1.5 \times 10^{-4}$	$K(3) = 0.91 \exp\left(\frac{-T(2)}{367}\right)$	$\Delta T(3) = \frac{P_H}{LS} \frac{D(3)}{K(3)}$
(4)	Cr	$D(4) = 0.10 \times 10^{-4}$	$K(4) = 0.86$	$\Delta T(4) = \frac{P_H}{LS} \frac{D(4)}{K(4)}$
(5)	Cu	Semi-Infinite	$K(5) = 3.90$	$\Delta T(5) = \frac{P_H \ln(4L/S)}{K(5)\pi L}$

[a] Thermal conductivities for Cr and Cu are assumed to be independent of temperature for these calculations. For the GaAs layers the temperature dependences $K(1)$ and $K(3)$ have been obtained from the data of [12] and are valid for temperatures $\geq$ 300 K. For the GaAlAs layer the same temperature dependence for $K(2)$ has been assumed but the magnitude has been reduced by the factor α (from [13]).

and

$$V_0 = 1.49 - \frac{0.00058T_j^2}{(T_j + 300)}. \tag{5}$$

In (4), V_0 and $AJ_{th}R_s$ represent the voltage contributions from junction and series resistance, respectively. In DH lasers, typical values of R_s (obtained from the slopes of I-V plots at high currents) are about 1 Ω. Such values are significantly higher than the 0.14-Ω values used for homostructures [11]. Higher R_s values mean that a much larger portion of the power is dissipated at contacts and throughout the bulk material outside the junction region. This creates a distributed heat source. In addition, a distributed source of heat will also arise from those photons which are created and subsequently absorbed in the device. Since the center of the active region is located within both of these distributed heat sources, there is reasonable justification for locating the entire source of heat within the active region itself.

In (5), the explicit form for V_0 assumes that the junction voltage will vary with the same temperature dependence as the GaAs bandgap. This variation, which is believed to be more accurate than the expression used in [11], has been taken from Panish and Casey [15] with the value of the constant term reduced by 0.030 eV since the recombination is assumed to occur through an acceptor level in p-type GaAs.

For each selected value of J_{th}, the ΔT values calculated from (3) to (5) are subtracted from the corresponding junction temperatures obtained from (1) to form the boundary of the CW lasing region. Fig. 3 shows the result of a typical computer calculation in which 80 values of J_{th} were used ranging from 0 to 40 kA/cm^2. For the typical parameters listed in the caption, the predicted maximum heat-sink temperature for CW operation is 431 K with the corresponding value of J_{th} being 14 000 A/cm^2. It is of interest to compare these numbers with the best experimental numbers in the literature. To date, the highest heat-sink temperature reported for CW

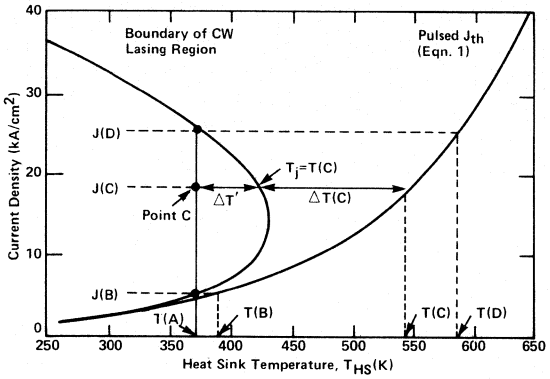

Fig. 3. Computer calculation of the CW lasing region for a DH laser with an oxide-insulated stripe geometry. Assuming parameter values as in Fig. 1, the highest heat-sink temperature for CW operation is 431 K. Superimposed on the calculation are some currents and heat-sink temperatures which will aid in the discussion of Fig. 4.

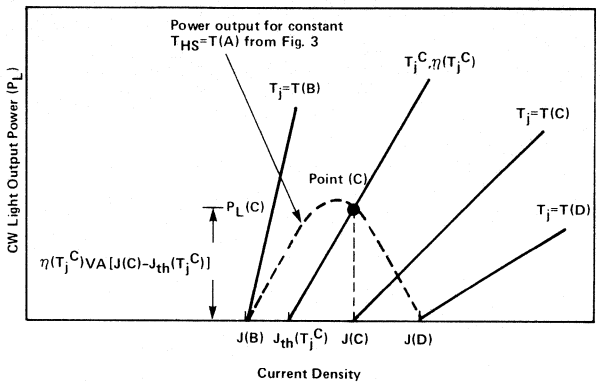

Fig. 4. Schematic illustrating how the light-output power P_L is derived for a general current density $J(C)$ within the CW lasing region. $J(C)$ lies between the turn-on current $J(B)$ and turn-off current $J(D)$. The dashed line is a schematic representation of how P_L would vary along the constant heat-sink temperature $T(A)$ of Fig. 3. Spontaneous light-output power is assumed to be zero in this figure. Typical computer results are presented in Figs. 5 and 6.

operation is 110°C (383 K) which occurred at J_{th} = 12 500 A/cm² [4]. This comparison should be reasonably valid since the layer thicknesses in the experimental device are nearly identical to those used in the calculation. The agreement is quite close with respect to current density; however, the calculated maximum CW operating temperature is considerably higher than the experimental value. In principle, since the experimental device has no oxide barrier, two-dimensional heat flow should be applicable and its maximum CW operating temperature should exceed the value calculated in Fig. 3. One possible explanation for the discrepancy is the fact that the experimental device could contain some voids between the bond metal and the heat sink.

Finally, in order to get some idea as to which layers contribute the largest temperature rises, values of $\Delta T(1)$-$\Delta T(5)$ have been given in Fig. 1 for a selected value of J_{th} = 10 kA/cm². Clearly, the p-GaAlAs layer (2) gives by far the largest temperature rise. In practice, it is unlikely that its thickness can be reduced very much below the 1 μm assumed here before an increase of optical loss occurs because of penetration of some of the guided light through the p-GaAlAs to the p-GaAs layer. The thickness of layer (3) might be reduced somewhat below 1.5 μm, but it should not be thinner than about 1 μm in order to ensure low thresholds and long lifetimes. Concerning the heat sink, replacement of the Au-Cu combination by a Au-diamond combination will provide only a small reduction in the overall temperature rise. This is due to the fact that the heat has to pass through about 15 μm of Au before reaching the diamond.

Part II—Calculation of the Light-Output Power Within the CW Lasing Region ($J > J_{th}$)

Suppose a line of constant heat-sink temperature labeled $T(A)$ in Fig. 3 is selected and the dc current is increased from zero. The laser will turn on at $J(B)$ where $T_j = T(B)$ and will continue to lase throughout the CW lasing region before turning off at $J(D)$ at which point $T_j = T(D)$. Turn-off is due to internal heating in the device at high-current densities. For a current density of $J(C)$ at point C, between $J(B)$ and $J(D)$, the emitted light-output power depends on both the junction temperature T_j^C and the corresponding external differential quantum efficiency $\eta(T_j^C)$. Suppose that these values are known so that $J_{th}(T_j^C)$ can be calculated from (1). Then, with reference to Fig. 4, which shows schematically the relationship between the various currents and temperatures noted in Fig. 3, the output light power $P_L(T_j^C)$ at point C [where $T_{HS} = T(A)$] is

$$P_L(T_j^C) = \eta(T_j^C)\, VA\, [J(C) - J_{th}(T_j^C)]. \tag{6}$$

For self-consistency, P_L must also satisfy the condition

$$T_j^C = T(A) + R_{th}(T_j^C)[VAJ(C) - P_L(T_j^C)] \tag{7}$$

where $R_{th}(T_j^C)$ is the thermal resistance for a junction temperature T_j^C which is already known from Part I. Equation (7) takes into account that the junction temperature is cooled because of the escape of the optical power from the device. Rapid convergence of (7) is achieved by assuming, as a first approximation, that T_j^C will be cooler than $T(C)$ by the amount which $T(A)$ is less than the heat-sink value at $J_{th} = J(C)$. That is

$$T_j^C = T(C) - \Delta T' \quad \text{(first approximation)} \tag{8}$$

where $\Delta T'$ is as indicated in Fig. 3. When the trial value of T_j^C and the calculated value from (7) agree to within 1 percent, the final value of P_L is calculated from (6).

In Fig. 5 the preceding procedures were used to calculate values of P_L for five different heat-sink temperatures (300, 325, 350, 375, 400 K). The parameters used in Fig. 3 were retained. At T_{HS} = 300 K, the laser must operate about 30 percent above J_{th} in order to have a power output of 10-20 mW; this prediction is in good agreement with our own experimental results and with those of Hartman *et al.* [16]. The locus of points at constant junction temperatures of T_j = 400 K and T_j = 450 K are also indicated in Fig. 5. Since the junction temperature can rise to over 600 K within the CW lasing region at T_{HS} = 300 K, the expressions used for J_{th} and η from (1) and (2) may no longer hold. It is known that these expressions are valid up to T_j = 415 K (the extent of our data) and probably it would be safe to extrapolate them to T_j = 450 K. Thus, in Fig. 5, all of the calculated values to

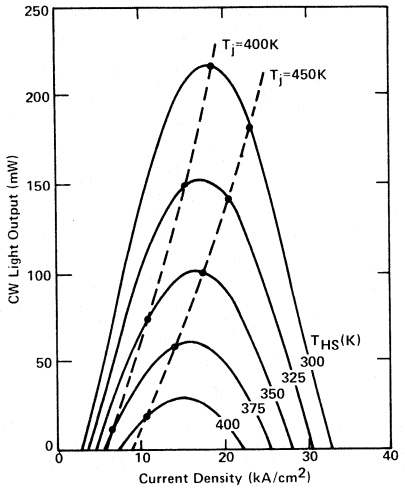

Fig. 5. Computer calculations of the CW light-output power as a function of current density for five selected values of heat-sink temperature (T_{HS}). Device parameters as in Fig. 1. Dashed lines join points of constant junction temperature for T_j = 400 K and T_j = 450 K.

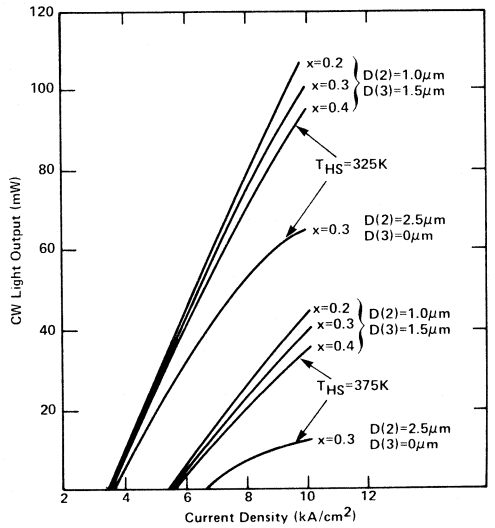

Fig. 6. Computer calculations of output for heat-sink temperatures of 325 K and 375 K. Effect of variations in Al content (x) and layer thicknesses [$D(2)$ and $D(3)$] are shown.

the left side of the T_j = 450 K line are based on known data and should closely correspond to the experimental situation. Those values to the right side of the T_j = 450 K line will be accurate only to the extent to which the extrapolations are valid.

Although light-output powers in excess of 200 mW are predicted by this calculation, these would not likely be achieved in practice because they are in the 10^6 W/cm^2 range where catastrophic degradation of the laser mirrors can occur [17]. In addition, it is unlikely that CW lasers will be operated at current densities above 10 kA/cm^2 under reliable conditions. For these two reasons, in Fig. 6 we have selected two heat-sink temperatures of 325 and 375 K and current densities less than 10 kA/cm^2 to ensure that light-output power levels are about 100 mW or less. Here we see what happens when the Al content is varied from $x = 0.2$ to $x = 0.4$. Note that there is relatively little effect on the power output when the layer thickness of p-GaAlAs is thin (i.e., $D(2) = 1.0$ μm). A much larger reduction in power output is obtained by making the p-GaAlAs thicker (i.e., $D(2) = 2.5$ μm, $D(3) = 0$ μm). This is particularly true at the higher heat-sink temperatures which would be appropriate for accelerated life testing.

Discussion and Conclusions

Procedures for calculating the CW lasing region and light-output power within the CW region have been presented for DH lasers with an oxide-insulated stripe-geometry contact [1]. One-dimensional heat flow has been assumed within the device followed by two-dimensional heat flow into the semi-infinite heat sink. The methods employed should be valid for other lasers such as the buried-layer heterostructure [2] which is also oxide insulated and the mesa structures [3]. In these devices, the one-dimensional heat-flow model may slightly overestimate the junction-temperature rise because it neglects sideways flow heat out through the oxide and heat loss through the sides or top. In addition, our assumption that the thermal conductivity for the p-GaAlAs alloy has the same temperature dependence as GaAs probably causes a further overestimate of the junction temperature. Thus our calculations will predict a CW lasing region which is too small and light-output power levels which are also too small.

For other structures in which current confinement is achieved by proton bombardment [4], diffusion techniques [5]-[7], lateral injection [8], or heteroisolation [9], a two-dimensional heat-flow model should be employed beginning at the junction. This will further lower the overall thermal resistance [6], [10] and will lead to even larger CW lasing regions and light-output power levels.

The calculations have pointed out two areas in which further work is required before more precise analyses of DH lasers are attempted at temperatures above 300 K. The first area concerns the unknown temperature dependence of the thermal conductivity of GaAlAs alloys. At present, our knowledge is limited to the room-temperature values measured by Afromowitz [13]. Since a large portion of the overall thermal resistance occurs in the GaAlAs layer, there is a definite need for measurements of thermal conductivity in such layers above 300 K. The second area of concern is the rather large values of the series resistance (≃1 Ω) in DH devices. From (4), we can estimate that at $J \simeq 25$ kA/cm^2, there is as much heat generated in the series resistance as at the junction. This reduces overall device efficiency and probably means that our assumption of a localized source of heat power in the center of the active region is less valid at high currents. One possible source of the high resistance could be high-resistivity interfacial layers introduced during crystal growth.

For oxide-stripe DH lasers with typical thicknesses and a heat-sink temperature of 300 K, the maximum predicted light-output power is in excess of 200 mW for a stripe width of 13 μm; these power levels are close to the catastrophic limit [17] and would require current densities about seven times higher than threshold. A more reliable operating current level for CW lasers would be below two times threshold in which case about 40–50 mW of light-output power would be expected for a heat sink at 300 K.

Oxygen-Implanted Double-Heterojunction GaAs/GaAlAs Injection Lasers

JOSEPH M. BLUM, MEMBER, IEEE, J. C. McGRODDY, MEMBER, IEEE, PAUL G. McMULLIN, MEMBER, IEEE, K. K. SHIH, MEMBER, IEEE, ARCHIBALD W. SMITH, SENIOR MEMBER, IEEE, AND J. F. ZIEGLER

Abstract—**We describe a new process for stripe formation in double-heterostructure GaAs/GaAlAs injection lasers. This process, which uses oxygen-ion implantation to form the stripe through a chemical doping effect, has several advantages over alternative methods, both with respect to device processing and device properties and has produced high yields of CW room-temperature lasers. We present the details of the device structure and fabrication processes. The results of annealing studies, optical measurements, and lifetesting are described.**

INTRODUCTION

A NEW PROCESS for the formation of stripe-geometry double-heterojunction GaAs/GaAlAs injection lasers has been developed and has the capability of producing high yields of CW room-temperature devices. These lasers utilize the doping effects of oxygen implantation first reported by Favennec *et al.* [1] to form high-resistance areas in the GaAs, thus providing the isolation necessary to pump only a narrow stripe laser region.

The use of a stripe geometry greatly facilitates the continuous operation of lasers at room temperature. There are, however, many different types of stripe-forming methods. The oxygen-implanted stripe devices have the advantage of requiring less critical processing than the other methods. For example, they do not require the diffusion [2], etching [3], or annealing [4], [5] control required for the diffused, mesa etch, or proton-bombarded stripe-geometry lasers, respectively.

The oxygen-induced damage is sufficiently annealed during a subsequent diffusion step that no special annealing process is required. Annealing and aging studies have shown that any residual damage due to the implantation does not cause detrimental effects on the lifetime of the oxygen-implanted lasers. It has also been found that oxygen-implanted devices offer the potential advantage of better lateral confinement than other structures due to the special nature of the edges of the oxygen-implanted regions.

Manuscript received December 12, 1974; revised February 5, 1975.
The authors are with the IBM Thomas J. Watson Research Center, Yorktown Heights, N. Y. 10598.

This paper will describe the fabrication processes used to make these devices as well as their optical characteristics which appear to be unique. The CW room-temperature aging characteristics will also be presented.

Fabrication

Fig. 1 is a sketch of an oxygen-implanted laser chip. The effects of the oxygen implantation are indicated as buried high-resistivity regions.

The material used for this device is a four-layer liquid-phase-epitaxy double heterostructure grown on an n-type silicon-doped ⟨100⟩ oriented GaAs substrate with a carrier concentration of 1-2 × 10^{18} cm^{-3}. An 8-μm buffer layer (not shown on the figure) of tin- or tellurium-doped GaAs with a carrier concentration of 1 × 10^{18} cm^{-3} is first grown on the substrate in order to smooth out irregularities sometimes seen at the interface between the substrate and the subsequent layer. The next four layers are grown as shown in the figure using state-of-the-art liquid-phase-epitaxial techniques [6]. The two GaAlAs layers above and below the silicon-doped active layer contain 30-percent aluminum. The active layer contains up to 10-percent aluminum.

A graphical representation of the oxygen distribution, calculated using LSS range theory [7] with modifications [8]-[10] due to the high energy of implantation (> 1 MeV), after it has been implanted into a typical laser wafer, is shown in Fig. 2. The Gaussian-like distribution of oxygen atoms is superimposed on the doping levels that would be found in such a four-layer laser structure. The typical carrier concentrations in each layer, starting from the surface of the wafer, are 1 × 10^{18}, 5 × 10^{17}, 5 × 10^{17}, and 1 × 10^{17} cm^{-3}. Isolation is provided in the regions where the oxygen-implanted level is higher than the background doping. According to Favennec *et al.* [1], these semi-insulating properties are due to the chemical doping effects of oxygen where each oxygen ion can remove two carriers. The chemical doping effect, as opposed to the implantation-induced damage, has been verified in our laboratory. A dose of 10^{14} ions/cm^2 was found to be an optimum level, i.e., sufficient to form the necessary isolation barrier but not so much as to produce damage which could not be annealed out conveniently. The energy used on each wafer was determined by the actual thickness of the upper two layers. In the case shown in this figure an energy of 2.5 MeV was found to be adequate for an upper-two-layer total thickness of 2.0 μm.

In order to form oxygen-implanted stripe-geometry laser devices from the liquid-phase-epitaxial wafer a number of processes are required. These processes are indicated in Fig. 3.

Fiducial lines are first formed by the chemical etching of a sputtered Al_2O_3 film [11] through a photoresist mask using a 1:1 H_3PO_4:H_2O solution (70-75°C). The lines are 25 μm wide on 200-μm centers and are parallel to the ⟨110⟩ direction. The middle drawing shows the wafer during and after oxygen implantation. Materials which have been successfully used to mask against oxygen ions with energy in the range 2-3 MeV include gold and nickel electroformed masks, and AZ 1350

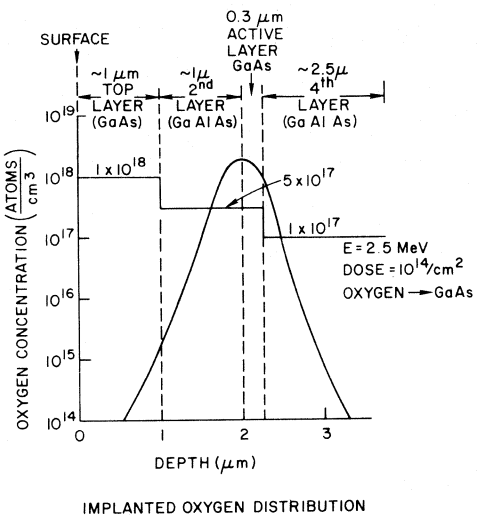

Fig. 2. Graphical representation of a typical oxygen-implanted distribution superimposed on the background impurity levels of a typical four-layer laser structure.

photoresist (~ 5 μm thick). These masks are aligned parallel and centered with respect to the Al_2O_3 marker lines.

The experimental arrangement for ion implantation consisted of a 3-MeV ion accelerator, a magnetic energy-analysis system, a 5-kG double-quadrupole focusing system, and a 5-keV sawtooth beam-sweep plate. The beam was raster scanned over the wafer at a repetition rate of 80 sweeps/s. The implant dose accuracy was estimated to be ±30 percent and the uniformity accuracy was ±10 percent. The broad band below the surface in the middle diagram represents the high-resistivity region due to the presence of both damage and oxygen atoms immediately after completion of the implantation step.

In the lower diagram the completed wafer can be seen. To get to this stage after the implantation process, zinc is diffused into the wafer to a depth of 0.4 μm at 600°C for 30 min using a $ZnAs_2$ source. The diffusion process not only provides low-resistance contacts but also conveniently serves as an annealing step to remove most of the defects produced by the implantation. Evaporated chromium-gold contacts are used for the p-contacts. The original Al_2O_3 marker lines are used once again to locate the p-metal photoetch mask and are etched away after the metal is removed in order to delineate each laser

contact. The 500 Å:5000 Å Cr:Au films are etched by first removing the gold layer using a KI-I_2 solution and then removing the chromium layer by etching in a 1:1:1 HCl:H_3PO_4:H_2O solution (65–70°C) after the surface has been activated by touching it with zinc. After lapping and polishing the substrate side to a total thickness of 100 μm, a 5000-Å evaporated gold-germanium-nickel alloy is used for the n-contact [12]. If required, viewing ports are also etched using the KI-I_2 solution into the n-type metal contacts prior to a 2-min 485°C alloying heat treatment in nitrogen. Isolated laser-array strips or individual laser chips are then cleaved and mounted on indium-plated copper heat sinks.

Implantation Damage and Annealing Studies

The oxygen-implanted regions can be seen on a cleaved laser chip using a scanning electron microscope in the cathodoluminescent mode as shown in Fig. 4. Here the effects of the oxygen implantation after annealing reduce the cathodoluminescent efficiency in the implanted region revealing the nonimplanted region which is 25 μm wide.

Fig. 5 shows the degree of damage produced by various oxygen-implant doses as measured by channeling and backscattering of 2.8-MeV He^+ ions. Data are shown for GaAs samples that have been implanted with 2.5-MeV oxygen ions with doses of 10^{14} cm^{-2}, 10^{13} cm^{-2}, and 10^{12} cm^{-2} as well as an unimplanted sample. These results indicate that about 15 percent, 5 percent, and 2 percent of the bonds in the GaAs have been damaged, respectively [13]. After annealing for 30 min at 600°C (the zinc-diffusion cycle) all of the backscattering data resulted in curves similar to the nonimplanted GaAs indicating that the crystal damage had been removed to a value of less than 2 percent. Preliminary data obtained from photoluminescence measurements have indicated that there is still some residual optical damage left after normal annealing during the diffusion cycle. This residual damage appears to be of little consequence since aging data show that no obvious detrimental effects have occurred, and measurements of the thermal resistance of packaged devices indicate that the thermal conductivity of the materials has not been adversely affected by implantation.

Continuous room-temperature operation has been achieved from devices both with and without annealing. In the unannealed devices the 30-min 600°C diffusion step was performed before the implantation process so that the only heat treatment those devices received was for 2 min at 485°C which removes very little damage. However, the yield of CW room-temperature devices is significantly higher from the annealed group than the unannealed group made from the same wafer.

This could be due to a higher thermal resistance of unannealed implanted material.

With oxygen implantation it is the presence of the chemical-dopant oxygen which causes the implanted regions to have high resistivity. This is in contrast to the proton-bombardment method where the damage causes the high resistivity. In the oxygen case the damage is (ideally) annealed out, while in the proton case some residual damage is essential and the subsequent annealing cycle [5] required to eliminate excessive optical loss is rather critical. The annealing of the oxygen bombardment-induced damage could be adequately performed by any temperature above the 600°C temperature used for the diffusion. However, by selecting the diffusion cycle, which must be done anyway to form low-resistance contacts, a special annealing cycle is conveniently avoided.

Optical Measurements

Spatial-intensity profiles of the spontaneous emission were measured on oxygen stripe-geometry devices for comparison with two other stripe-contact technologies: proton implantation and diffusion. In Fig. 6 is shown an oxygen-implanted test device which was fabricated as described before with a 50-μm-wide viewing port etched in the n-type contact metallurgy on the polished GaAs substrate. The spontaneous emission from the laser stripe was observed perpendicular to the ⟨100⟩ surface of the laser through the etched openings. The intensity profile of the spontaneous emission across the stripe (i.e., perpendicular to the lasing direction) was obtained by scanning an enlarged image of the stripe with a slit. A magnification of 20X was obtained with a NA 0.4 microscope objective. This gives a resolution of about 1 μm at 8500 Å. A slit width of 20 μm was used which gave an overall resolution of about 2 μm. The lasers were driven about 20 percent below threshold with 2-μs current pulses. The light passing through the scanning slit was detected with an S-1 photomultiplier and a boxcar integrator. The focusing and alignment of the stripe image of the slit were performed with the aid of an infrared (IR) TV system.

A range of profile shapes for a nominal implant mask width of 25 μm was observed in oxygen-implanted lasers made from different wafers which can be seen in Fig. 7. The shapes varied from sharp to diffuse and can be attributed to different degrees of oxygen doping or penetration into the active layer. If oxygen does not penetrate the active layer the stripe profile should be determined by the diffusion length of electrons into the p-type active layer. Using the theory derived by Hakki [14], this diffuse profile approximates a profile calculated from a diffusion length of 6 μm for carriers both in and out of the laser stripe. This is in good agreement with the value obtained by Hakki [14] for the case of proton-bombarded stripes without penetration. The unexpected sharp profile is believed to occur when the implanted oxygen penetrates into the active layer or deeper into the p-GaAlAs layer. In this case the oxygen doping has a significant effect on the diffusion of carriers out of the stripe.

The relationship between the stripe width and the threshold

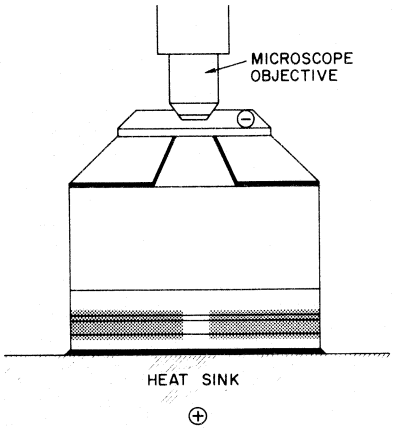

Fig. 6. Schematic view of specially prepared oxygen-implanted laser chip with viewing port for measurement of spatial intensity profiles of the spontaneous emission across the stripe (perpendicular to lasing direction).

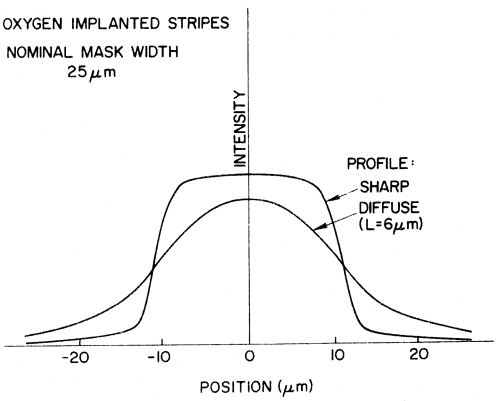

Fig. 7. Range of spatial-intensity profile shapes from sharp to diffuse as measured across the stripe. Nominal mask widths—25 μm.

current is also of interest. In order to investigate this, stripes of nominal widths of 12.5, 25, and 50 μm were fabricated on the same wafer using photoresist for the oxygen-implantation masks. Sharp profiles were obtained as shown in Fig. 8. The edges of the 50-μm profile trace were more tapered because the opening in the contact on the back of the wafer was too small for this case. The relative change in the threshold with stripe width is plotted in Fig. 9, along with data taken from published results for proton-bombarded [14] and diffused stripes [3]. The threshold current-density ratio increase is only 1.25 for the 12.5-μm oxygen-implanted stripes, compared to 1.9 for the other techniques. This result indicates that the sharp profile is not due to an increase in the nonradiative recombination rate in the implanted region. It should be noted that the oxygen-implanted ratio data were obtained from adjacent units on three bars which exhibited unusually uniform characteristics. It is unlikely that as reliable a result would have been obtained with individual chips. It should also be noted that the small change in threshold with stripe width was produced only from devices that had sharp profiles. The diffuse profiles produced results similar to the proton-bombarded and diffused stripe technologies. The sharp pro-

files are not always formed when the oxygen implantation extends into the active region and it is not known why the sharp lateral confinement is not found in all such cases. Once this phenomenon is better understood it should permit the fabrication of stripe contacts less than 10 μm wide without excessively high threshold current densities.

Aging Studies

From aging studies it is clear that oxygen-implanted devices are capable of stable operation above threshold. The thermal resistance of packaged units is typically 0.8°C cm²/kW indicating a substantial heat flow through the implanted regions. Fig. 10 shows the change in laser characteristics of a device which has been aged for more than 4000 h in a dry nitrogen atmosphere at 15°C (which was the temperature of the water-cooled heat sink). The current was adjusted to be about 10 percent above the CW threshold. The time dependence of the CW threshold for this device is shown in Fig. 11, together with data for another laser. It can be seen that after some initial increase the thresholds of both lasers are stable for long periods of time.

Oxygen-implanted devices have also exhibited a maximum CW power output at room temperature of as high as 1 mW/μm of junction width from a device with an active region thickness of 0.3 μm. Continuous operation has also been obtained at a maximum heat-sink temperature of 80°C.

Conclusions

In summary, we have developed a new stripe-geometry technology which utilizes high-resistivity regions produced by oxygen implantation to isolate the stripe region. This technology offers simplified processing insofar as it does not require any critical annealing to remove radiation damage. Whatever residual damage remains is not sufficiently detrimental to prevent long-lived room-temperature CW lasers from being fabricated.

In addition, the oxygen-implantation process apparently offers the possibility of a unique barrier to be formed along

the edges of the laser stripe which seems to affect carrier outdiffusion. With further understanding of this phenomenon it should be possible to fabricate practical lasers with stripe widths of less than 10 μm.

Acknowledgment

The authors wish to thank C. Burstell for skillful assistance with most of the device processing; J. DeGelormo for the wafer preparation; H. Ifill, F. Feigel, and A. Landon for the device testing; C. Bremer for his work on the SEM; G. Hutchins for packaging the devices; and V. Garrison, R. Potemski, and W. Hammer for their special assistance in the processing of the devices. They also wish to thank B. Monemar for the photoluminescence measurements, and B. Crowder, W. P. Dumke, and F. Morehead for helpful discussions.

Abstract—**A different type of stripe-geometry laser is demonstrated in which current confinement is achieved by selective diffusion of the n-type substrate prior to growth of the GaAs/GaAlAs heterostructure layers. This structure exhibits low room-temperature threshold currents resulting from the small lateral-current spreading from the edges of the stripe. Lowest order transverse-mode operation is achieved for stripe widths of 10 μm.**

Introduction

IN ORDER to achieve low-threshold room-temperature laser operation in double-heterostructure (DH) GaAs/$Ga_{1-x}Al_xAs$ injection lasers current must be restricted to flow across a small area of the device. Several methods have been developed which laterally confine the current by the use of selective diffusion techniques. These include the internal-stripe [1] and planar-stripe [2] geometries. In these devices the process of fabricating the current-confining stripe is performed after growth of the heterostructure layers.

The striped-substrate device which is shown schematically in Fig. 1 has a current-confining channel which is formed prior to growth of the heterostructure layers. When the diode is forward biased the p-n junction between the selectively diffused region in the substrate and the first n-type $Ga_{1-x}Al_xAs$ layer is reverse biased leading to current flow only through the narrow n-type channel in the substrate. Control of the depth of the diffusion defining the channel has little effect on current confinement leading to increased simplicity of fabrication and uniformity of devices. The width of the current-carrying stripe can be controlled quite easily and accurately by monitoring the time of diffusion. These stripes can also be made much narrower than those obtained with other diffused-stripe techniques [1], [2]. This is because with the striped-substrate technique the current-carrying channel is n-type and the

TABLE I
PARAMETERS FOR GROWTH, COMPOSITION, AND GEOMETRY OF A STRIPED-SUBSTRATE LASER

Layer	X	Ga (g)	Al (mg)	Doping (mg)	Initial Growth Temp. (°c)	Growth Time (min)	Thickness (μm)
1st n-$Ga_{1-x}Al_xAs$	.40	4	5	Te/0.05	780	3	0.65
2nd p-GaAs	—	4	—	Ge/15	778.5	1/2	0.45
3rd p-$Ga_{1-x}Al_xAs$	.40	4	5	Ge/25	778	5	1.4
4th p-GaAs	—	4	—	Zn/40	776.5	30	15

Note: (Cooling rate–0.5°C/min. Substrate doping–$N_D - N_A = 2 \times 10^{18}/cm^3$.

n-type channel narrows as the Zn-diffused p-type region widens. In contrast, for internal- [1] and planar-stripe [2] geometries, the current-carrying channel is p-type and therefore this channel widens as the diffusion of Zn proceeds. Finally, free-carrier absorption losses due to the absorption of the light wave which spreads into the n-$Ga_{1-x}Al_xAs$ layer should be lower than that of the internally striped laser [1] since the high p-type carrier concentration defining the channel is in close proximity to the unpumped region of the laser rather than the active region.

FABRICATION

The device consists of an n-type substrate which is selectively made p-type prior to growth. The n-type channel is formed by masking the top surface of the substrate with Si_3N_4 stripes (~18 μm wide) and then diffusing Zn from a Zn_3As_2 source at 700°C for 10 min. This results in a diffusion depth of ~5 μm and leaves an n-type channel width of 8 μm at the substrate surface. This channel width may be varied by changing either the diffusion time or the nitride stripe width. The nitride is then removed and ~1 μm of material is lapped from the top of the substrate in order to eliminate any surface damage caused by the diffusion. This leaves a final stripe width of ~10 μm. (No growths were made on unpolished substrates and therefore it is not known whether this step is necessary to insure good device performance.)

GaAs/$Ga_{1-x}Al_xAs$ layers are then grown on the selectively diffused substrate using conventional liquid-phase-epitaxy (LPE) techniques [3]. A chart of compositions, layer thicknesses, and growth conditions for a typical wafer are given in Table I. An SEM cross section of the device is shown in Fig. 2. No chemical etching is needed to delineate the various layers. The first n-$Ga_{1-x}Al_xAs$ grown layer is kept fairly thin (~0.7 μm) and slightly lower doped than in conventional DH lasers in order to increase the spreading resistance across this layer. This spreading resistance is further increased by a slight back diffusion of Zn into the first grown layer during LPE growth of the subsequent layers. For the growth conditions shown

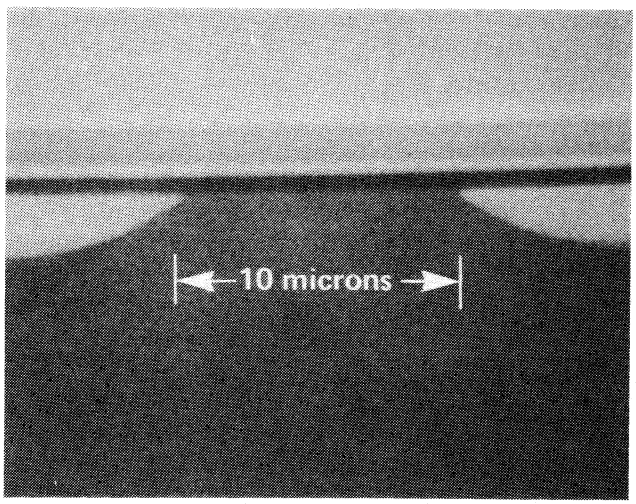

Fig. 2. SEM photograph of a cleaved cross section of the striped-substrate laser. The lower region is the n-type substrate, and the curved region is the p-type diffusion which defines the current-carrying n-type channel. The normal heterostructure layers are grown on top of the selectively diffused substrate. These are, from top to bottom, p-GaAs, p-$Ga_{0.6}Al_{0.4}As$, p-GaAs active layer, and n-$Ga_{0.6}Al_{0.4}As$.

above the Zn back-diffused ~0.1 μm into the first grown layer. The final p-GaAs layer was grown quite thick for ease in contacting. Since this layer was thick no attempt was made to heat sink the diodes for CW operation.

In order to saw the diodes into chips it was necessary to accurately position the saw wire between the buried channels. This registration was accomplished by scribing a shallow groove with a diamond scribe at the edge of the substrate parallel to a cleave plane prior to photoresist masking. The Zn diffusion mask was then positioned relative to this scribe line. After LPE growth this scribe line was still clearly visible on the top of the wafer and the saw wire was positioned relative to this registration mark.

Experimental Results

Pulsed threshold currents as low as 150 mA at room temperature were measured for diodes with diffused stripe widths of ~10 μm. This corresponded to a threshold current density of ~8000 A/cm^2 when measured by dividing the total current by the stripe width times the length of the diode. A "control" substrate with no selective diffusion was also grown simultaneously with the striped substrate in order to measure the increase in threshold current density in the stripe-geometry diodes. Large-area diodes from this control wafer exhibited threshold current densities of ~5000 A/cm^2. Thus the striped-substrate geometry showed a 60-percent increase in threshold current density as compared to large-area diodes from the same wafer. This increase is similar to that observed in the planar-stripe- [2] geometry diodes for 10-μm stripe widths.

An estimate of the dependence of this increase in threshold current density on current spreading in the first n-GaAlAs layer can be made based on a calculation by Dumke [4]. The assumptions made for this calculation are: 1) the n-GaAlAs layer is thin and can be characterized by a sheet resistivity R_s; 2) the junction has an exponential current-voltage characteristic; and 3) the final two p-layers of the device have very high conductivity so that the potential is uniform across them. If W is the actual stripe width in the laser, an effective stripe width (W_{eff}) can be found which is the sum of the actual stripe width (W) and the current-spreading term. That is

$$W_{\text{eff}} = W + 2^{3/2}\left(\frac{2kT}{R_s j_0 e}\right)^{1/2} \tag{1}$$

where j_0 is the threshold current density of a broad-contact laser, k is Boltzmann's constant, T is temperature, and e is electronic charge. For a laser with the first grown layer having a carrier concentration of $n \sim 10^{17}/\text{cm}^3$, a mobility of 150 cm^2/V · s, and a layer thickness of 0.6 μm, R_s is ~6700 Ω/□. If the threshold current density for a large-area diode is 5000 A/cm^2, then the effective stripe width assuming an actual channel width of 10 μm is 11 μm. Thus the current spread in the thin n-GaAlAs layer accounts for only 10 percent of the observed increase in threshold current density. The additional current spread may be accounted for by ambipolar diffusion of the injected carriers in the active layer. Such an effect has been observed experimentally in proton-implanted stripe-geometry lasers [5]. The limiting factor governing thresholds for narrow substrate stripes is therefore not current spreading in the n-GaAlAs layer. However, if this layer has a direct gap, the electron mobility can be substantially higher than that used for the indirect gap layer leading to appreciable current spreading in this layer. For example, an electron mobility of 4000 cm^2/V · s in direct GaAlAs leads to $R_s \sim 260$ Ω/□ and an effective stripe width of 16 μm disregarding the additional spread due to ambipolar diffusion in the active layer. Therefore, care should be taken to make the first layer indirect.

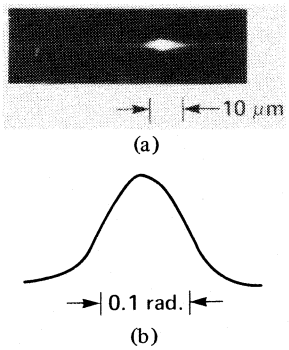

Fig. 3. Near- and far-field radiation patterns from a laser with a 10-μm stripe width. (a) Near-field pattern. (b) Far-field pattern.

Lowest order transverse-mode operation in the junction plane can also be readily achieved in striped-substrate lasers with stripe widths of 10 μm or less. Fig. 3 shows the near- and far-field pattern of a laser with a 10-μm stripe width. These data were taken at a current level 1.05 times threshold and confirm lowest order transverse-mode operation. At slightly higher currents (5-10 percent above threshold) first-order transverse modes are excited. Also, as larger stripe widths are used, higher order transverse modes are observed. The dependence of mode order on stripe width appears to be similar to that observed for the planar-stripe laser [2].

In conclusion, the striped-substrate planar laser can exhibit low room-temperature threshold current levels and fundamental transverse-mode operation. It is easy to fabricate since stripe width can be accurately controlled and the number of processes which must be performed after LPE growth are minimized.

New Heteroisolation Stripe-Geometry Visible-Light-Emitting Lasers

KUNIO ITOH, MORIO INOUE, AND IWAO TERAMOTO

Abstract—**Visible-light-emitting lasers were fabricated, using a new stripe-geometry double heterostructure. The distinct feature of the geometry is the isolation of the contact stripe electrode to p-GaAs by the use of a layer of n-$Ga_{1-z}Al_zAs$ epitaxially grown on top of p-GaAs. This geometry results in small internal strain, few crystal imperfections, and low thermal resistance in diodes so that high laser performance can be obtained. Lasing wavelengths as short as 7610 Å and 6680 Å have been attained in CW and pulsed operation, respectively, at room temperature. Various characteristic features of the lasers are described with regard to optical spectra, lasing thresholds, and external quantum efficiencies.**

I. Introduction

THE mixed compound $Ga_{1-y}Al_yAs$ has been the subject of recent investigations into visible-light-emitting lasers. Many types of lasers have been reported, and the shortest wavelengths reported for pulsed operation are 6380 Å at 77 K in p-n homojunction lasers [1]; 6280 Å and 7180 Å at 77 K and 300 K, respectively, in single-heterostructure lasers [2]; and 6190 Å and 6930 Å at 77 K and 300 K, respectively, in double-heterostructure lasers [3]-[5]. CW operation at room temperature at a wavelength of 7730 Å has been obtained using a double-heterostructure stripe geometry [6]. However, difficulty has been encountered in obtaining CW operation in the visible region because of poor thermal dissipation of an oxide-stripe geometry.

The present paper proposes a new type of stripe-geometry laser, here named the heteroisolation stripe (HIS) laser, in which thermal dissipation is improved, permitting room-temperature CW operation in the "visible" region. Also described are the properties of visible-light-emitting lasers using the HIS geometry covering the emission wavelength from 9000 Å to 7610 Å in CW operation and to 6680 Å in pulsed operation. Some properties are analyzed using the band model of $Ga_{1-y}Al_yAs$.

II. HIS Laser

Many kinds of stripe geometry have been proposed and developed up to the present, such as the oxide stripe [7], proton-bombardment stripe [8], planar stripe [9], mesa stripe [10], and internal stripe [11]. Most of these conventional stripe lasers can be classified into the following three types:

1) stripe lasers whose stripes are isolated with an insulator such as silicon dioxide, silicon nitride, or aluminum oxide;
2) stripe lasers which are isolated with zinc-diffused p-n junctions;
3) stripe lasers which are isolated with the bombarded high-resistivity regions.

When an insulator is used for isolation, a boundary strain occurs between GaAs and the insulator film because of the difference in their thermal-expansion coefficients. Furthermore, the resistance to heat flow is considerably high because of the low thermal conductivity of the insulator.

On the other hand, into stripe lasers isolated with zinc-diffused p-n junctions may be introduced crystal imperfections, such as dislocations and lattice defects in the vicinity of the active region. These crystal imperfections near the active region cause an increase of the threshold current density [11] and of the degradation rate [12].

Though the problems previously mentioned are almost negligible in the bombardment-stripe lasers, a proper annealing procedure is required to reduce the high optical absorption in the bombarded region [8].

The structure of the HIS laser is shown schematically in Fig. 1. The uppermost fifth layer of n-$Ga_{1-z}Al_zAs$ is epitaxially grown on the fourth p-GaAs layer, and this n-$Ga_{1-z}Al_zAs$ layer is partly etched in a stripe until the surface of the fourth layer is revealed. When a positive voltage is applied to the upper electrode in Fig. 1, current flows through the stripe. No current flows through other parts because the p-n junction of p-GaAs and n-$Ga_{1-z}Al_zAs$ is reverse biased. In other words, the contact stripe of p-GaAs is isolated by the n-$Ga_{1-z}Al_zAs$ layer epitaxially grown on top of p-GaAs.

The characteristics of the HIS laser are as follows.

1) Because of the close matching of the lattice constants between GaAs and $Ga_{1-z}Al_zAs$, much less boundary strain occurs than in other stripe lasers using insulator films. Fig. 2 shows the experimental and theoretical results of stresses in GaAs under a silicon dioxide film and a $Ga_{1-z}Al_zAs$ layer. GaAs wafers 100 μm thick were used as substrates on which silicon dioxide was deposited at 400°C. The $Ga_{1-z}Al_zAs$ layers were liquid-phase epitaxially grown at 850°C. The stress which occurs in GaAs just under the deposited silicon dioxide film was obtained from the observed deflected curvature of the substrate and the thickness of the silicon dioxide film [13].

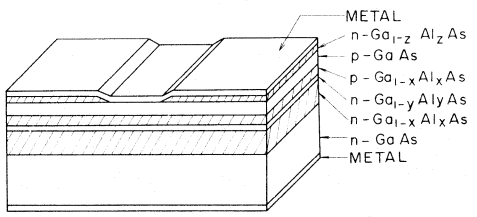

Fig. 1. Structure of the HIS laser.

Manuscript received December 2, 1974; revised January 15, 1975.

The authors are with the Research Laboratory, Matsushita Electronics Corporation, Takatsuki, Osaka, Japan.

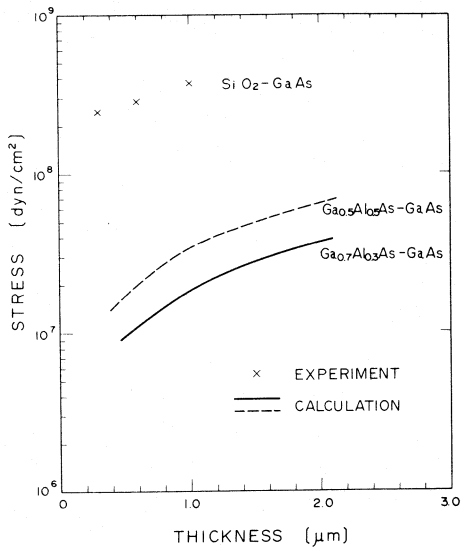

Fig. 2. Experimental and theoretical results of stresses in GaAs under a silica film and under a $Ga_{1-z}Al_zAs$ layer (see text).

The stress in GaAs just under the $Ga_{1-z}Al_zAs$ layer was estimated from the thermal-expansion-coefficient difference, because no detectable substrate deflection was found when the thickness of the epitaxial $Ga_{1-z}Al_zAs$ was less than 2 μm. From Fig. 2, it can be seen that the stress in GaAs under the $Ga_{1-z}Al_zAs$ layer is approximately one order of magnitude smaller than that under the silicon dioxide film. Therefore, it is possible to reduce the internal stress by using a $Ga_{1-z}Al_zAs$ layer instead of a silicon dioxide film.

2) The heat-flow resistance can be much lowered in comparison with that in the oxide-stripe geometry because the heat generated in the active region can be dissipated not only through the stripe window but also through the uppermost $Ga_{1-z}Al_zAs$ layer.[1]

3) The deep zinc-diffusion or proton-bombardment process, which may introduce crystal imperfections, is not required in this HIS laser.

III. Experiment and Measurement

A. Fabrication Method of the HIS Lasers

Five successive layers, as shown in Fig. 1, were grown on an n-GaAs substrate by the conventional liquid-phase-epitaxial method [14]. Table I shows the composition of each solution and the aluminum composition ratio of each layer. The active layer, which is practically undoped n-$Ga_{1-y}Al_yAs$, was grown from the second melt. The value of y was changed from 0 to 0.36 to make infrared and visible-light-emitting lasers. For infrared lasers, the value of x in the first and third $Ga_{1-x}Al_xAs$ layers was fixed to 0.3, while in the case of visible-light-emitting lasers, it was chosen to be 0.5–0.8 to assure the efficient confinement of the injected carriers. The thicknesses of the third and fourth layers were made as thin as 0.5 μm and 1 μm, respectively, to minimize the current spread in the active region. The aluminum fraction z of the isolating n-$Ga_{1-z}Al_zAs$ layer was 0.4–0.6 to facilitate the selective etching, and its thickness was 0.5–1 μm.

For the selective etching of $Ga_{1-z}Al_zAs$, hot phosphoric acid was used, since it dissolves only $Ga_{1-z}Al_zAs$ and not GaAs. Fig. 3 shows a photograph of the cross section after the selective etching. The etched surface is very smooth as shown in this photograph. For ohmic contact, a gold-tin alloy was deposited on both sides. The diode was finally mounted either on a copper block or on a diamond heat sink.

TABLE I
Composition of Each Solution and the Aluminum Composition Ratio of Each Layer

Layer	Ga [g]	GaAs [mg]	Al [mg]	Dopant [mg]	Values of x,y,z
1st n-$Ga_{1-x}Al_xAs$	1	50	2.3 - 6.4	120 (Sn)	0.3 - 0.8
2nd n-$Ga_{1-y}Al_yAs$	1	80	0 - 2.7	-	0 - 0.36
3rd p-$Ga_{1-x}Al_xAs$	1	50	2.3 - 6.4	50 (Zn)	0.3 - 0.8
4th p-GaAs	1	80	-	50 (Ge)	-
5th n-$Ga_{1-z}Al_zAs$	1	50	3.3 - 4.8	30 (Sn)	0.4 - 0.6

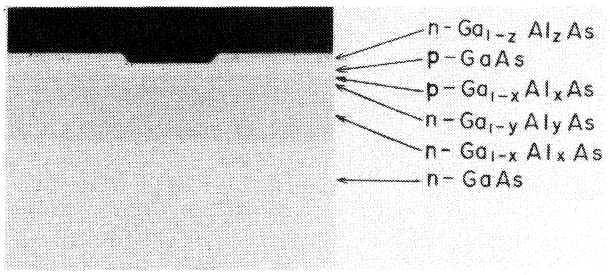

Fig. 3. Photograph of the cross section of the HIS laser. Stripe width is about 10 μm.

B. Measurement

The thickness of each layer was measured by means of an optical microscope or a scanning electron microscope. The solid compositions x and z were estimated by X-ray microanalysis, and the value of y was estimated from the lasing peak emission [2]. The near-field pattern was depicted on a Si vidicon. The optical power was measured by an integrating sphere or a calibrated p-i-n photodiode.

The pulsed operation measurements were made at a repetition rate of 100 Hz with a pulsewidth of 100 ns.

IV. Experimental Results

A. Threshold Current Density Versus Lasing Wavelength

Fig. 4 shows the relationship between the lasing wavelength and the threshold current density J_{th} of the HIS laser at room temperature. The black circles and white circles indicate the results for CW operation and pulsed operation, respectively. The stripe widths of these lasers are 20–30 μm, the cavity

[1] Quantitative analysis of the thermal resistance in the HIS geometry has not been performed yet. We observed, however, that the CW light output from the HIS lasers with 30-μm-wide stripes on copper heat sinks thermally saturates at the current density of about 7000 A/cm^2 which is approximately 1.3 times the saturation current density of the oxide-stripe lasers with 5000-Å-thick oxide films. This result may suggest that the thermal resistance is considerably lower in the HIS lasers than in the oxide-stripe lasers.

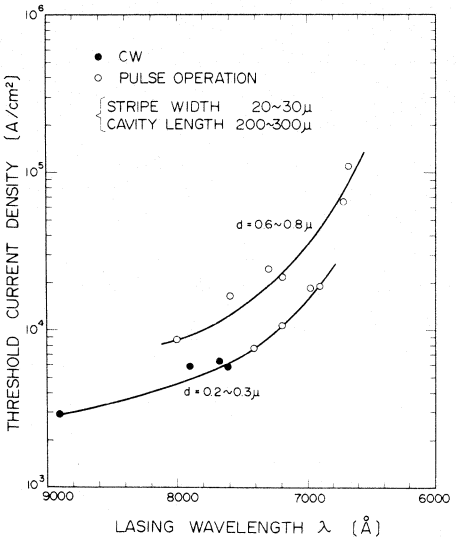

Fig. 4. Relationship between the lasing wavelength and the threshold current density. The black circles and white circles indicate the results of CW operation and pulsed operation, respectively.

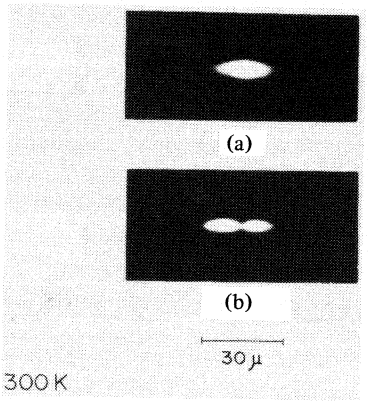
lengths are 200–300 μm, and the active region thicknesses are 0.2–0.3 μm and 0.6–0.8 μm.

Fig. 4 indicates that J_{th} increases as the lasing wavelengths becomes shorter, especially in the range of wavelengths shorter than 7500 Å. Further discussion is presented in Section V.

The shortest lasing wavelength attained at room temperature was 6680 Å with J_{th} of 1.1×10^5 A/cm^2. As far as we know, this is the shortest lasing wavelength ever attained in any injection-type semiconductor lasers at room temperature. The shortest lasing wavelength obtained in CW operation was 7610 Å, i.e., the "visible" wavelength, which is also the shortest wavelength ever attained in CW operation at room temperature. It is possible to see the near-field pattern of these lasers with the unaided eye and also the far-field pattern can be seen on a white screen in a darkened room.

B. Transverse and Axial Modes

The operating modes of these visible-light-emitting lasers can be observed at the junction plane through a microscope. In the HIS geometry it is easy to obtain single transverse modes, not only in the infrared region, but also in the visible region. In Fig. 5, the optical near-field patterns of the lower order modes are shown for lasers emitting visible light. Fig. 5(a) shows the fundamental transverse mode TE_{00}, which was obtained in CW operation at a wavelength of 7620 Å. Fig. 5(b) shows a first-order transverse mode TE_{01} at a lasing wavelength of 7200 Å. The lasing spectra of the laser in Fig. 5(a) are shown in Fig. 6. Fig. 6(a) shows the spectrum at a current level of 550 mA, which is 20 percent higher than the threshold (460 mA). The expected longitudinal mode spacing in this laser is 4.2 Å, assuming that the refractive index is 3.4. The oscillation in Fig. 5(a) is almost in a single axial mode of 7619 Å. Some of the HIS lasers operated not only in a single transverse mode, but also in a single axial mode. Fig. 6(b) shows the spectrum at a current level as high as 600 mA for the same laser, where two axial modes of 7609 Å and 7633 Å



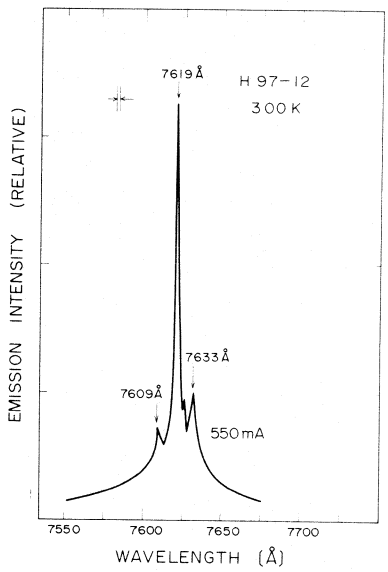


Fig. 5. Lower order modes of the optical near-field pattern of the visible-light-emitting lasers. (a) TE_{00} mode (H97 – 12). λ = 7620 Å: I = 550 mA: I_{th} = 460 mA. (b) TE_{01} mode (H104 – 14). λ = 7200 Å: I = 800 mA: I_{th} = 700 mA.

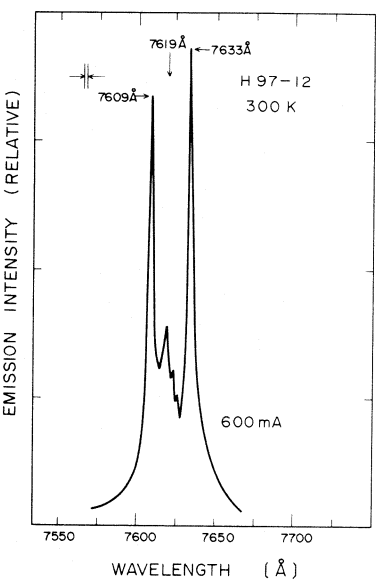

Fig. 6. Lasing spectra of lasers operating continuously at room temperature. (a) Spectrum at a current of 550 mA. (b) Spectrum at a current of 600 mA.

are dominant. At this current level, however, the transverse mode was still TE_{00}. As the current is further increased, more axial modes appear.

On the other hand, the pulsed lasing spectrum of Fig. 5(b) showed about ten axial modes, even just above the threshold.

Generally speaking, it is rather easy to fabricate lasers which operate in a single transverse mode, while it becomes increasingly difficult to obtain a single axial mode as the wavelength is decreased. This may be due to the poor homogeneity of the active region at relatively high aluminum fractions.

C. Temperature Dependence of Threshold Current Density

Temperature dependence of J_{th} of HIS lasers with the Al composition in the active region as a parameter is shown in Fig. 7. The active-region thickness of 1 μm is used as the normalizing value, assuming that J_{th} is proportional to the thickness. It is seen that the temperature dependence of J_{th} increases with increasing Al composition in the active region. A detailed discussion concerning this characteristic is presented in Section V.

D. External Differential Quantum Efficiency

External differential quantum efficiency $\Delta\eta$ decreases as the lasing wavelength becomes shorter. In the infrared region, the typical value of $\Delta\eta$ of HIS lasers is 30–40 percent, while $\Delta\eta$ is 10–20 percent at 7600 Å and 3 percent at 6900 Å. The main cause of the decrease of $\Delta\eta$ in the short-wavelength region is the decrease in the internal quantum efficiency due to the thermal transfer of electrons from the [000] conduction-band minimum into the ⟨100⟩ minima. The typical value of $\Delta\eta$ of infrared HIS lasers is relatively high among various kinds of stripe lasers. This could be, in the HIS geometry, attributed to the good current confinement just under the stripe contact obtained by making the third and fourth layers as thin as possible.

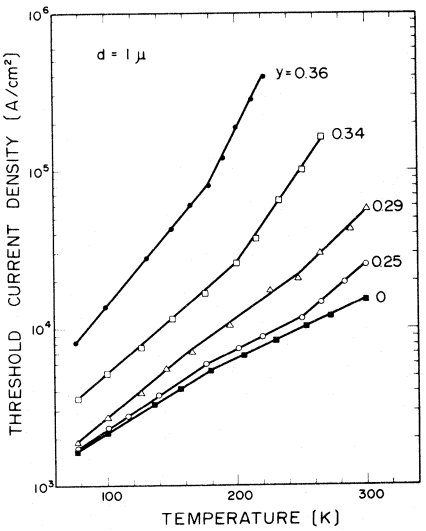

Fig. 7. Temperature dependence of the J_{th} of HIS lasers with a parameter of Al composition in the active region. The active-region thickness is normalized to 1 μm.

V. Discussion

A. Gain and Loss of Visible-Light-Emitting Lasers

The experimental relation obtained between the threshold current density and the lasing wavelength can be discussed in terms of the gain and loss of broad contact geometry lasers of double heterostructure. It has been empirically known that the gain per unit length g of GaAs double-heterostructure lasers is proportional to the mth power of the current density J, where m takes a constant value between 1 and 3 [15]. Since the gain is equal to the total loss at the threshold

$$g_{th} = \alpha + \frac{1}{L} \ln \frac{1}{R} \tag{1}$$

and

$$g_{th} = \beta J_{th}^{m} \tag{2}$$

where L is the cavity length, R is the reflectivity at the mirror, α is the internal loss, and β is the gain constant. For our lasers whose lasing wavelength and active-layer thickness are 9000 Å and 0.6 μm, respectively, the most appropriate value of m is found to be 2 as shown in Fig. 8. Provided $m = 2$ is valid throughout the wavelength range under consideration, the values of β and α can be estimated as a function of the lasing wavelength.

The results are given in Table II where, for comparison, the normalized gain constants βd^2 are also listed, assuming perfect carrier and optical confinement in the double heterostructure. It is seen that the normalized gain constant decreases as the

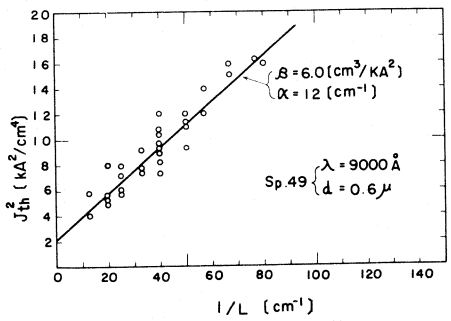

Fig. 8. Relation between the J_{th} and $1/L$, where L is the cavity length. The lasing wavelength is 9000 Å and the active-region thickness is 0.6 μm.

TABLE II
GAIN CONSTANT AND INTERNAL LOSS

Diode No.	49	80	102	101	35
λ (300K) [Å]	9000	8000	7500	7200	6900
d [μ]	0.6	0.8	0.4	0.15	0.2
β [cm³/kA²]	6.0	2.2	3.6	2.6	0.21
α [cm⁻¹]	12	15	20	20	25
βd^2 [cm³·μ^2/kA²]	2.2	1.4	0.58	0.059	0.0084

wavelength becomes shorter, probably resulting from the decrease of internal quantum efficiency.

On the other hand, the internal loss α increases only a little as the wavelength becomes shorter. This is presumably due to the slight increase of free-carrier absorption. It is known that the free-carrier-absorption constant is inversely proportional to the effective mass of an electron [16]. In $Ga_{1-y}Al_yAs$, the effective mass of an electron in the ⟨100⟩ minima is five to ten times larger than that in the [000] minimum. This heavy mass suppresses the increase of free-carrier absorption at the short wavelength in spite of the sharp increase of injected electrons in the ⟨100⟩ minima.

It follows that the increase of J_{th} of HIS lasers at short lasing wavelengths, as shown in Fig. 4, is predominantly due to the decrease of the gain constant rather than to the slight increase of the internal loss.

B. Temperature Dependence of the Threshold Current Density

As mentioned in Section IV-C, the temperature dependence of J_{th} increases with increasing aluminum composition. The most probable reason for this is the decrease of internal quantum efficiency η_i with increasing temperature due to thermal depopulation of the [000] minimum.

A simple calculation for η_i is carried out based on the following assumptions.

1) Both bands are parabolic.

2) The internal loss is independent of y of $Ga_{1-y}Al_yAs$.

3) The energy difference between the [000] and six ⟨100⟩ minima is independent of temperature.

4) All the carriers in the [000] minimum radiatively recombine, while those in the ⟨100⟩ minima recombine nonradiatively.

5) All the injected carriers are in the [000] minimum when $y = 0$.

6) J_{th} is inversely proportional to η_i.

From assumption 4), $\eta_i(y, T)$ is given by

$$\eta_i(y, T) = N_1(y, T)/[N_1(y, T) + N_2(y, T)] \tag{3}$$

where N_1 and N_2 are the injected electron concentrations in the [000] minimum and in the six ⟨100⟩ minima, respectively. From assumptions 2) and 4), N_1 is independent of y, i.e., $N_1(y, T) = N_1(0, T)$. From assumption 5) we can estimate $N_1(0, T)$ using the following relation [15]:

$$N_1(0, T) \approx J_{th}\bar{\tau}/ed \tag{4}$$

where e is the electron charge and $\bar{\tau}$ is the average spontaneous lifetime of the injected carriers. The value of $\bar{\tau}$ can be assumed independent of temperature and estimated by measuring the lasing delay time [17]. We obtained 10 ns for the value of $\bar{\tau}$ at room temperature. The injected electron concentrations N_1 and N_2 are described as follows [18]:

$$N_1 = 6.55 \times 10^{21} \int_0^{\infty} \frac{(m_1^*)^{3/2} E^{1/2} dE}{1 + \exp[(E - E_F)/kT]} \tag{5}$$

$$N_2 = 6.55 \times 10^{21} \int_{f(y)}^{\infty} \frac{6(m_2^*)^{3/2} [E - f(y)]^{1/2} dE}{1 + \exp[(E - E_F)/kT)} \tag{6}$$

where E_F is the Fermi level, $f(y)$ is the energy difference between the [000] and ⟨100⟩ minima, m_1^* and m_2^* are the effective electron masses in the [000] minimum and in the ⟨100⟩ minima, respectively. The effective masses m_1^* and m_2^* were assumed to be 0.072 and 0.35, respectively [2]. Since N_1 is given by (4), we can estimate N_2 from (6) using E_F determined by combination of (4) and (5).

From the assumption 5), the normalized threshold current density $J_{th}^*(y, T)$ is given by

$$J_{th}^*(y, T) \equiv \frac{J_{th}(y, T)}{J_{th}(0, T)} = \left(\frac{\eta_i(y, T)}{\eta_i(0, T)}\right)^{-1} = (\eta_i(y, T))^{-1}. \tag{7}$$

The calculated results of $J_{th}^*(y, T)$ with a parameter y of $Ga_{1-y}Al_yAs$ are shown by the solid curves in Fig. 9, where the experimental results are also plotted for comparison. The most reasonable conclusion to be drawn from Fig. 9 is that the temperature dependence of J_{th} can presumably be explained in terms of the temperature dependence of η_i, although quantitative agreement between the calculated and experimental results is not so excellent because of the over-simplified assumption. For a more precise calculation, it would be necessary to take the temperature dependence of $f(y)$, α, and $\bar{\tau}$ into account. In addition, the values of y should be estimated in a more appropriate way.

C. Laser Series Resistance

As mentioned in Section III, the value of x for the first and third layers in the present visible-light-emitting lasers was chosen to be 0.5–0.8, where $Ga_{1-x}Al_xAs$ has an indirect band gap. This might result in a laser series resistance much higher than that in the direct band-gap range. However, the product of the series resistance and the stripe area in HIS lasers was found to be in the range of 3×10^{-4}–6×10^{-4} $\Omega \cdot cm^2$, typically 4.5×10^{-4} $\Omega \cdot cm^2$, regardless of the values of x and y. This series resistance observed is one order of magnitude higher than the calculated value 3.1×10^{-5} $\Omega \cdot cm^2$, as shown in Table III. Therefore, it is suggested that the series resistance is determined predominantly by the contact resistance at the interface between the crystal and the heat sink rather than by

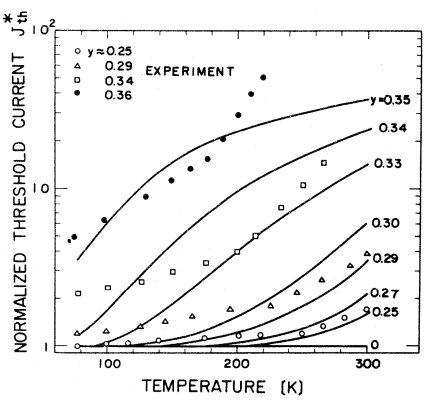

Fig. 9. Temperature dependence of the normalized J_{th} with a parameter y of $Ga_{1-y}Al_yAs$. The theoretical curve was calculated as described in the text.

TABLE III
CALCULATED SERIES RESISTANCE OF THE HIS LASER

Layer	Carrier concentration (cm^{-3})	Resistivity Rs (Ω.cm)	Thickness t (μm)	Rs X t ($\Omega.cm^2$)
n-GaAs	1.0×10^{18}	2.0×10^{-3}	100	2.0×10^{-5}
n-$Ga_{0.7}Al_{0.3}As$	1.0×10^{18}	7.0×10^{-3}	8.0	5.6×10^{-5}
n-GaAs	3.0×10^{16}	6.0×10^{-2}	0.3	1.8×10^{-6}
p-$Ga_{0.7}Al_{0.3}As$	5.0×10^{18}	2.5×10^{-2}	0.5	1.3×10^{-6}
p-GaAs	2.0×10^{18}	2.0×10^{-2}	1.0	2.0×10^{-6}
			Total	3.1×10^{-5}

Composition of the active region is GaAs.

the bulk resistance of the diode. As a result, the laser power-conversion efficiency should be little affected by the value of x even in the indirect band-gap range.

VI. SUMMARY AND CONCLUSION

A new stripe-geometry double-heterostructure laser, in which a contact stripe electrode to p-GaAs is isolated with an overgrown n-$Ga_{1-z}Al_zAs$ layer, is reported. This device has the practical advantages in low internal strain and low heat-flow resistance.

With this structure we obtained CW laser operation at a wavelength as short as 7610 Å at room temperature, which is the shortest "visible" wavelength ever attained.

In pulsed operation at room temperature, we observed the emission down to 6680 Å, also the shortest ever attained.

A single optical mode was often obtained in the axial mode as well as in the transverse mode.

The observed increase in threshold current density at short wavelength is ascribed mainly to the steep decrease in gain constant with increasing aluminum composition.

The temperature dependence of the threshold current density is discussed in terms of the internal quantum efficiency.

The external differential quantum efficiency at room temperature typically obtained in the infrared HIS lasers is as high as 40 percent. This high efficiency results from the reduced current spreading in the HIS geometry with the very thin third and fourth layers.

Transverse-Junction-Stripe Lasers with a GaAs p-n Homojunction

H. NAMIZAKI

Abstract—A new semiconductor laser structure named the transverse-junction-stripe (TJS) laser, in which the active region is a GaAs p-n homojunction sandwiched between GaAlAs layers, has been developed. It is possible to operate the laser continuously at room temperature below 100 mA. The minimum threshold current is 34 and 50 mA in pulsed and continuous operation, respectively. Relatively high efficiencies have been obtained, comparable to those of conventional double-heterostructure (DH) lasers. The transverse mode is fundamental in both directions and is almost independent of input current up to three times the threshold current. The longitudinal mode stays nearly single over a wide range of input current. The TE/TM power ratio exceeds 100 at 1.5 times the threshold current.

I. Introduction

In conventional homojunction lasers, a large amount of heat generation raises the temperature of the p-n junction, which increases the threshold current density further and prevents continuous lasing at room temperature. With double-heterostructure (DH) lasers, the threshold current density is reduced through carrier and optical confinement, allowing them to operate continuously [1]. It is also possible to operate homojunction lasers continuously without raising the threshold current density, if the heat produced at the p-n junction can be removed effectively. The transverse-junction-stripe (TJS) laser has a very small active region made of a GaAs p-n junction sandwiched between GaAlAs layers [2]. The generated heat is effectively removed through one of the GaAlAs layers, enabling this laser to operate continuously under 100 mA at room temperature.

In addition, the TJS-laser has the structure of a two-dimensional waveguide. It is well known that in most stripe-geometry DH lasers the active region has little guiding effect in the direction parallel to the junction so that when the stripe width becomes narrow, the optical field spreads into the adjacent absorbing region, and the threshold current increases rapidly [3]. To obtain a smaller active region and lower threshold currents, it is desirable that the active region be constructed into a two-dimensional waveguide. The TJS-laser presents a new structure to realize this idea, utilizing the automatic formation of a refractive index difference across the p-n junction.

II. Device Structure and Fabrication

A schematic diagram of the TJS-laser is shown in Fig. 1. The epitaxial wafers used in the experiment have layers of n-GaAlAs, n-GaAs, n-GaAlAs, p-GaAlAs, and p- or undoped-GaAs on n-GaAs substrates, being different from the usual DH wafers only in the location of the p-n junction. The typical

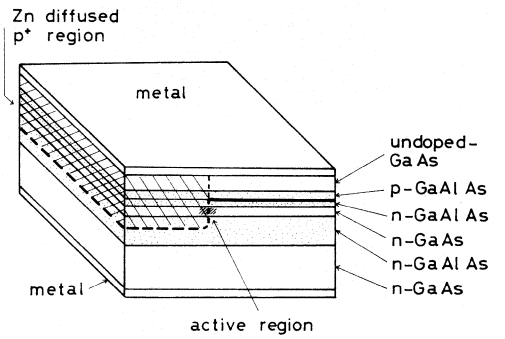

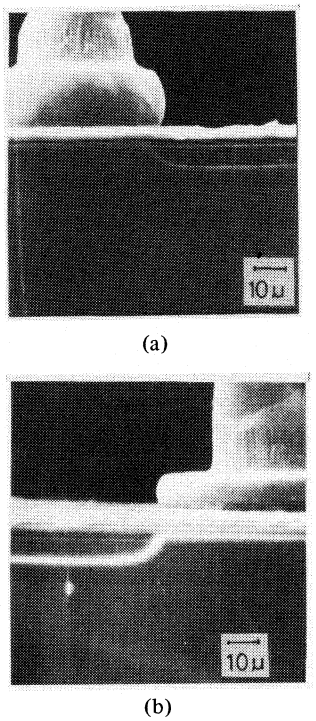

Fig. 1. Schematic diagram of the TJS-laser. P-n junctions are indicated by thick solid and dashed lines.

TABLE I
Parameters of Each Grown Layer of a TJS-Laser Wafer

layer	material	thickness (um)	Al content	carrier concentration (/cm^3)	dopant
1st	n-GaAlAs	12	0.42	1 x 10^{18}	Te
2nd	n-GaAs	0.35	---	1.5 x 10^{18}	Te
3rd	n-GaAlAs	0.8	0.42	1 x 10^{18}	Te
4th	p-GaAlAs	1.4	0.42	1 x 10^{18}	Ge
5th	undoped-GaAs	3	---	1 x 10^{16}	--

parameters of each grown layer are tabulated in Table I. Layer thicknesses were measured with an optical and scanning electron microscope. Carrier concentration and Al content were estimated from other wafers grown under similar conditions. TJS-lasers were fabricated from the wafers as follows. Zn was diffused selectively at 650°C into the second n-GaAlAs layer from the surface of the epitaxial layers using Si_3N_4 stripe films as a diffusion mask. Heat treatment was subsequently performed at 950°C for 2 h. During the heat treatment, diffusion fronts moved about 2 μm deeper and the carrier concentration in this rediffused region was about $1 \times 10^{19}/cm^3$, while that inside the formerly diffused region was about $1 \times 10^{20}/cm^3$. Metallic contact was made by evaporating Cr and Au. When the fifth GaAs layer was undoped, Si_3N_4 films were removed, marking the Zn-diffused region with shallow etched lines on the surface before the evaporation. The dimensions of chips were about 300 μm long, 150 μm wide, and 90 μm high. The width of the Zn-diffused region was 50 μm and the depth about 10 μm. For continuous operation, the chips were bonded upside down on Cu or type-2A diamond heat sinks with In solder.

In Fig. 1 thick solid and dashed lines show the p-n junctions, formed by epitaxial growth and Zn diffusion, respectively. The p-n junction consists of GaAs and GaAlAs homojunctions.

(a)

(b)

Fig. 2. Slightly etched mirror surfaces (a) without and (b) with an image of induced current, which shows the location of the p-n junctions.

As the diffusion potential of the GaAs junction is lower than that of the GaAlAs junction, current is concentrated towards the GaAs junction. Then lasing occurs near the GaAs p-n junction plane which lies across the second GaAs layer. The fifth p- or undoped-GaAs layer was introduced to obtain good ohmic contact. And, consequently, a fourth p-GaAlAs layer was added so as to prevent the shunt current, which would flow through the GaAs–GaAlAs heterojunction formed between the third GaAlAs and fifth GaAs layers. As can be seen from Fig. 1, the TJS-laser has an active region like a homojunction laser and like a DH laser in the directions parallel and transverse to the grown layers, respectively. The heat generated in the active region is removed through the third to the fifth layers into the heat sink, and these layers must be thin enough, especially the third and fourth GaAlAs layers, which have a lower thermal conductivity than GaAs. Fig. 2 shows a photograph made by a scanning electron microscope of a slightly etched mirror surface with and without an image of induced current, to show the location of the p-n junction.

III. Properties of the TJS-Lasers

A. Threshold Current

The development of the TJS-laser was intended to obtain low threshold current. It is possible to reduce the threshold current if a smaller cross-sectional area of the active region is obtained. In the usual DH lasers, the thickness of the active region is already reduced as much as possible, but it seems difficult to reduce the width. This difficulty arises mainly because precise control of dimensions near 1 μm can be achieved more easily by epitaxial growth than by etching or other macroscopic fabrication processes. In TJS-lasers, the width of the active region is automatically controlled by making a p-n junction transverse to the thin GaAs layer sandwiched between GaAlAs layers. This structure can be made by the usual fabrication processes.

If the threshold current density is assumed to be 40 000 A/cm^2 [4], one can expect the threshold current of the TJS-laser to be 36 mA when the cavity length is 300 μm and the active-region thickness is 0.3 μm. Fig. 3 shows typical current–light intensity characteristics of a TJS-laser in pulsed and continuous operation at room temperature. The threshold current is typically 40 mA and 50 mA in pulsed and continuous operation, respectively. Threshold currents of some representative diodes are tabulated in Table II with external quantum efficiencies and cavity lengths.

The temperature dependence of the threshold current has also been measured. An example is shown in Fig. 4. At low temperatures the threshold current increases in proportion to the cube of the absolute temperature T. Above a certain temperature, which is very close to room temperature, the threshold increases more rapidly. The relatively large difference in threshold current between pulsed and continuous operation is attributed to this behavior. The temperature rise at the active region in continuous operation is roughly estimated to be about 10°C, which corresponds to a thermal resistance of about 120°C/W. The relation $I_{th} \propto T^3$ is similar to that obtained with a conventional homojunction laser [5] and seems to be reasonable since the TJS-laser has an active region consisting of a p-n homojunction. On the other hand, the rapid increase of threshold current at a higher temperature may be attributed to an increase in the shunt current flowing through the GaAlAs homojunction outside the active region. An increase in the shunt current was suggested by an observed increase of spontaneous emission near 6600 Å. A rough estimation can be made with a method similar to that used to calculate the threshold current of the junction-stripe-geometry DH lasers [6]. Current densities J_1 and J_2, which flow through the GaAs and GaAlAs homojunction, respectively, have the following relation:

$$\Delta E_g - (kT/q) \ln (J_2/J_1) = J_2 R_2 - J_1 R_1 \quad (1)$$

where ΔE_g is the difference between the bandgap energies of GaAs and GaAlAs, k is Boltzmann's constant, and q is the electronic charge. R_1 and R_2 are the series resistances between the electrodes for the unit area of the junctions. The threshold current I_{th} is given with current densities at the threshold, J_{1th} and J_{2th}, as

$$I_{th} = J_{1th} S_1 + J_{2th} S_2 \quad (2)$$

where S_1 and S_2 are the areas of the junctions. To calculate the solid curves in Fig. 4, the following assumptions were made: 1) the shunt current through the epitaxially grown junction can be neglected because of high resistivity of the thin p-layer; 2) J_{1th} is proportional to T^3, and the proportionality constant was chosen to match the experimental threshold current at a low temperature; 3) ΔE_g is chosen to be 0.50 eV, which was estimated from the wavelength difference of two emission peaks corresponding to the GaAs and GaAlAs p-n junctions, and R_2 to be $1 \times 10^{-4}\ \Omega \cdot \text{cm}^2$, which is experi-

	B-3-6	316	51	13

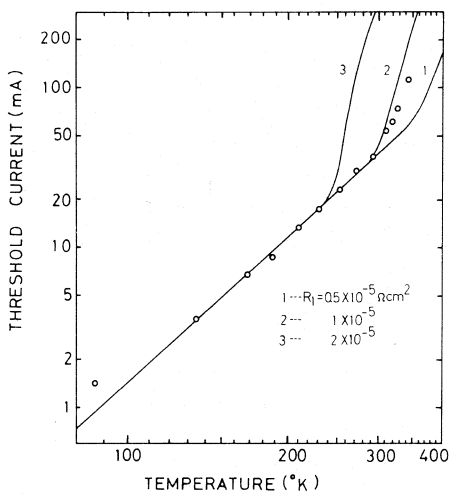

Fig. 4. Temperature dependence of threshold current. Experimental values are shown in open circles and the solid lines are calculated with (1) and (2). Relatively abrupt increase above room temperature can be attributed to the shunt current which flows through the GaAlAs homojunctions.

mentally obtained in broad-contact lasers with Cr and Au metallic contact. On setting the value of R_2 it is assumed that the current flowing through the GaAlAs junction does not spread in the lateral direction. However, the current flowing

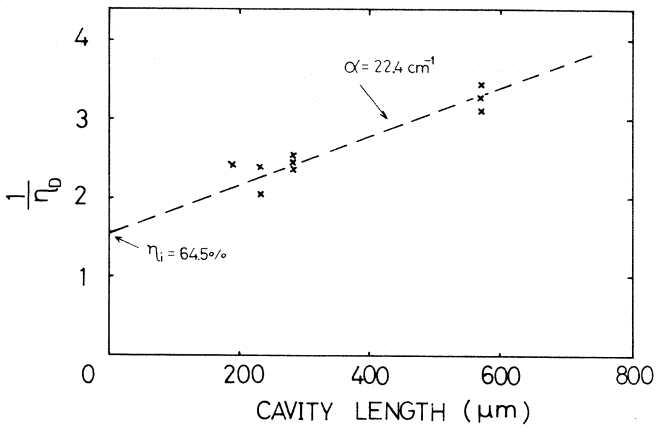

Fig. 5. Reciprocal of the external quantum efficiencies versus the cavity lengths.

through the GaAs junction seems to spread widely in both the p- and n-regions because of the very narrow width of the junction. The spreading of the current causes a reduction of the apparent resistance R_1, and some reasonable values for R_1 are used in the calculation. Although some discrepancies exist between the experimental and calculated slope of the curve, qualitative agreement, which is all that can be expected from these rough assumptions, is obtained. It is of interest to note that a reduction of R_1 allows the current to be confined in the active region even when J_1 is higher than a few tens of thousand amperes/square centimeter, which is not expected in the junction-stripe-geometry DH lasers [6].

B. External Quantum Efficiency and Light Output

External quantum efficiencies of some diodes are listed in Table II. The values seem to be somewhat scattered among wafers and locations in a wafer. However, some of the values are comparable with those obtained in conventional DH lasers [7]. And, especially, some values in continuous operation are higher than those of DH lasers. In Fig. 5 the reciprocal of the external quantum efficiency η_d for a series of diodes fabricated from a single wafer is plotted as a function of the cavity length L. These are related as

$$1/\eta_d = (1 + \alpha L/\ln R^{-1})/\eta_i \tag{3}$$

where η_i is the internal quantum efficiency, α the attenuation constant, and R the reflectivity of the mirror surface. From the dashed line in Fig. 5, α of 22.4 cm^{-1} and η_i of 64.5 percent are obtained. These values are close to those of the DH laser and differ from those obtained with conventional homojunction lasers [8]. The reason is not evident, but it may be supposed that the ratio of absorbed power in the p-region to the total power is smaller than in the conventional homojunction lasers. Fig. 6 shows an example of the temperature dependence of η_d. The slope of the curve below room temperature is relatively gentle, which seems to be an intrinsic characteristic of this structure. The abrupt decrease above room temperature, which also can be attributed to the shunt current, corresponds to the abrupt increase of the threshold current.

The maximum output power was measured using 500-ns pulses at low duty cycle. Fig. 7 shows an example of light out-

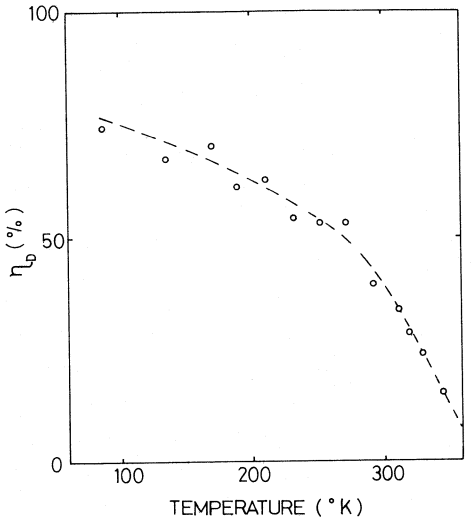

Fig. 6. Temperature dependence of the external quantum efficiency.

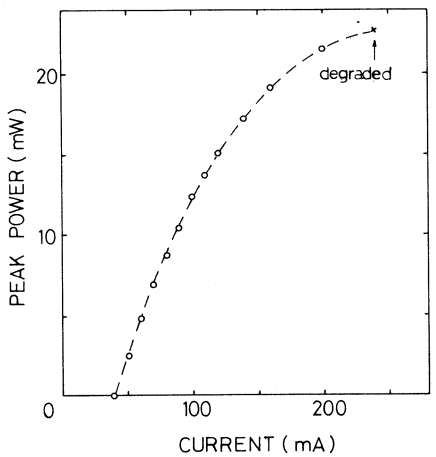

Fig. 7. Optical output power against input current. At an output power of about 23 mW from one mirror surface, the diode degraded. The value corresponds to the power density of about 3×10^6 W/cm^2 or 11 W/mm.

put in relation to the input current. At an output of 23 mW from one mirror surface, the diode degraded but still continued lasing. After the degradation, damage was observed near the active region on the mirror surfaces. As is described in Part C, the area on the mirror surface from which light is emitted is about 0.35×2.0 μm^2. The highest power of 23 mW corresponds to a power density of 3×10^6 W/cm^2, or 11-W/mm width of output face, which can be compared to the value of 16 W/mm in a usual DH laser with 0.45-μm active-region width [7].

C. Lasing Modes

In the TJS-laser optical confinement occurs due to the differences in refractive index in both the directions parallel and perpendicular to the grown layers. That is, the active region of the TJS-laser forms a two-dimensional dielectric waveguide. Transverse modes which are determined by the differences of refractive index are stable and can be well controlled by the dimensions of the waveguide. Experimentally, the fundamental transverse mode was observed in both directions when the

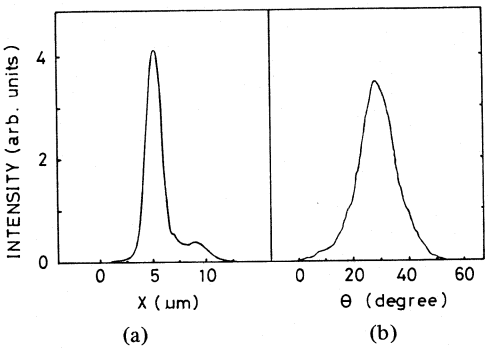

Fig. 8. An example of (a) near- and (b) far-field pattern in the direction parallel to the grown layers.

active region was thinner than 0.5 μm. The mode structure in the direction perpendicular to the grown layers is expected to be similar to that of usual DH lasers [3], [9] and this was confirmed experimentally. As for the direction parallel to the grown layers, the near- and far-field patterns are shown in Fig. 8. The distance between the half-power points in the near field is 1.5-2.0 μm, and the full beamwidth at the half-power points in the far field is 12-14°. These values are similar to those of homojunction lasers. Also, like conventional homojunction lasers, there often exists a subpeak in the near-field pattern, which always appears on the n-side of the p-n junction [10]. The subpeak appearing in the near-field pattern, which causes a perturbation in the far-field pattern, seems to be due to reflection by some small irregularities of the p-n junction plane. The location and the intensity of the subpeak is widely scattered among diodes, and sometimes the subpeak is separated from the main peak by more than 20 μm on the mirror surface where no gain can be expected. The near-field patterns stay unchanged when the input current increases even up to about three times the threshold current. In Fig. 9 two examples are shown in which the half-width of the near-field intensity is related to the input current. The transverse modes in TJS-lasers resemble TE and TM modes, because the confinement in the direction parallel to the grown layers is much weaker than in the perpendicular direction. The power ratio of TE/TM was measured with a Polaroid HR polarizer whose extinction coefficient was not certain but seemed to exceed 150. Fig. 10 shows an example. The ratio increases rapidly from the threshold and exceeds 100 at 1.5 I_{th} and 120 at twice I_{th}.

In most of the TJS-lasers from the two wafers ever fabricated, the longitudinal mode is almost single, as shown in Fig. 11, when driven continuously. Typically, as the input current increases to about twice I_{th}, the lasing wavelength jumps successively to longer values separated by an amount determined by the cavity length, due to the temperature rise of the active region with increasing input power. However, the range of input current in which two longitudinal modes are stable is very narrow compared to that of single-mode operation, which suggests that single-mode operation is more stable in TJS-lasers. The reason is not evident, but it may be supposed that in uniformly fabricated lasers some relation exists between longitudinal and transverse modes and that a single transverse mode leads to a single longitudinal mode. When diodes degrade

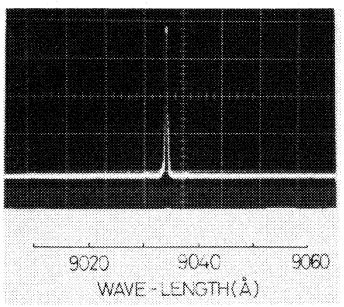

Fig. 11. Typical spectrum of the TJS-laser.

gradually through continuous operation, typically during several to several tens of hours, longitudinal modes tend to increase in number, which may be due to inhomogeneity arising in the active region during the operation.

IV. Summary

TJS-lasers with an active region consisting of a p-n homojunction have been developed. It is shown that it is possible to operate the homojunction laser continuously at room temperature if heat can be removed effectively. The TJS-laser has many distinct characteristics different from the conventional DH or homojunction lasers. It can have a low threshold current of about 50 mA and relatively high efficiency. The lasing mode is almost single in both the transverse and longitudinal directions.

TJS-lasers can be fabricated relatively easily, for they only need the usual fabrication techniques. A precise control of dimension is not required except for the thickness of the grown layers. For all these reasons, the TJS-laser has promise for application in integrated optics.

$Al_xGa_{1-x}As$ Double-Heterostructure Rib-Waveguide Injection Laser

T. P. LEE, MEMBER, IEEE, C. A. BURRUS, FELLOW, IEEE,
B. I. MILLER, AND R. A. LOGAN, SENIOR MEMBER, IEEE

Abstract—A "rib-guide" optical-waveguide structure proposed as a means of injection-laser transverse-mode control, independent of current distribution, has been demonstrated in an AlGaAs double-heterostructure (DH) diode laser. The new structure showed stable single-transverse-mode operation at currents to twice threshold with small rib dimensions, and the observed higher order modes in large structures are in reasonable agreement with theory.

TRANSVERSE-MODE control in an injection laser, particularly the suppression of higher order modes, is an extremely important factor in achieving efficient coupling of the light output into low-loss single-mode optical fibers. Stripe-contact [1]-[3], mesa-structure [4], and diffusion-isolation [5] geometries have all been used to effect some control of the spatial distribution of the current and, thus, to obtain a spatial-gain distribution in the junction plane that is conducive to single-mode operation. Recently, Miller [6] has proposed a "rib-guide" optical-waveguiding structure to restrict the number of propagating modes independent of the current distribution. This rib-guide configuration is one form of the slab-coupled waveguides which have been analyzed in connection with integrated optical circuits and optical-fiber transmission lines [7], and experimental passive single-heterostructures of this type have demonstrated good mode characteristics [8]. We report here an experimental demonstration of *active* rib-guide $Al_xGa_{1-x}As$ devices: double-heterostructure (DH) injection lasers which showed stable single-transverse-mode operation at currents up to twice threshold.

Fig. 1(a) is a schematic representation of the rib waveguide. The structure is comprised of a rectangular dielectric waveguide "rib" of refractive index n_1 resting on a slab having the same index. The slab and rib are sandwiched between dielectric layers of lower index n_2. In a waveguide separated from the slab, waveguide modes which have the same propagation constant k_z as modes in the slab couple strongly to each other when the waveguide and slab are in contact. Since the slab-guide modes can propagate in any direction, waveguide modes coupled to them leak away from the rib and are dissipated through radiation at the slab edges. Thus only modes with longitudinal propagation constants k_z *larger* than the slab fundamental propagation constant $[k^2n_1^2 - (\pi/t)^2]^{1/2}$ travel with low loss along the ribbed section. By adjusting the rib-guide dimensions and the slab thickness, the number of propagating modes can be selected. For the example illustrated in Fig. 1(b), the number of such modes is three.

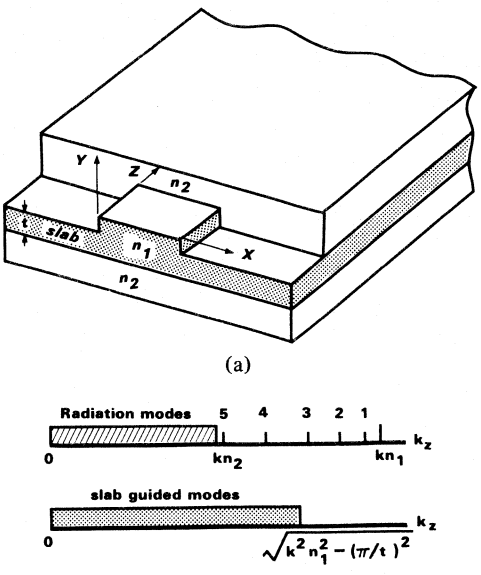

Fig. 1. (a) A schematic representation of the rib-guide structure. (b) A mode spectrum representation. The upper line is for the isolated rectangular optical waveguide and the lower line for the isolated slab guide, kn_1 and kn_2 are plane-wave propagation constants in medium n_1 and n_2, and $\sqrt{k^2n_1^2 - (\pi/t)^2}$ is the propagation constant of the fundamental mode in a uniform slab of thickness t.

Approximate formulas for characterization of the slab-coupled waveguide have been derived in [7]. The particular characteristics of interest to the design of a rib-guide laser are the number of propagating modes and the guide dimensions for single-mode operation. Using the notation of [7], the maximum number of field peaks P in the x direction and Q in the y direction of the highest order propagating mode E_{pq}^x (TE-like mode) or E_{pq}^y (TM-like mode) are given by

$$P = \frac{W}{T}\left[\sqrt{1 - (T/H)^2} + \frac{2}{\pi}\frac{T^2}{WH}\right] \tag{1}$$

and

$$Q = \frac{H}{T}\left[1 - \left(\frac{T}{W}\right)^2\left(1 - \frac{2T}{\pi H}\right)^2\right]^{1/2} \tag{2}$$

where W, H, and T are, respectively, normalized rib-guide width and height and normalized thickness of the slab guide.

Manuscript received December 9, 1974; revised January 9, 1975.

In particular, for a symmetrical rib guide as shown in Fig. 1(a),

$$W = w\left[1 + \frac{n_1^2}{n_2^2}\frac{2}{v}\left(\frac{h}{w}\right)\right] \tag{3}$$

$$H = h\left[1 + \frac{2}{v}\right] \quad \text{for } E_{pq}^x \text{ modes} \tag{4}$$

$$T = t\left[1 + \frac{2}{v}\left(\frac{h}{t}\right)\right] \tag{5}$$

and

$$W = w\left[1 + \frac{2}{v}\left(\frac{h}{w}\right)\right] \tag{6}$$

$$H = h\left[1 + \frac{n_1^2}{n_2^2}\frac{2}{v}\right] \quad \text{for } E_{pq}^y \text{ modes} \tag{7}$$

$$T = t\left[1 + \frac{n_1^2}{n_2^2}\frac{2}{v}\left(\frac{h}{t}\right)\right] \tag{8}$$

where

$$v = kt(n_1^2 - n_2^2)^{1/2} \tag{9}$$

and w and h are the actual dimensions of the rib, and t is the actual thickness of the slab as noted in Fig. 1(a).

If $T/H \ll 1$, [(1) and (2)], the rib guide is multimoded. Single-mode operation dictates $Q = 1$ and $P \leqslant 2$ (i.e., E_{21}^x is cut off), which yields the maximum rib-guide width for a given slab-guide thickness

$$\frac{W}{H} \leqslant \frac{2\left(\frac{T}{H}\right)}{\sqrt{1 - \left(\frac{T}{H}\right)^2}}\left(1 - \frac{1}{\pi}\frac{T}{H}\right). \tag{10}$$

In Fig. 2 we have plotted the geometry of the rib guide for single-mode operation (E_{11}^x mode only) in GaAs-$Al_xGa_{1-x}As$ DH structures using the values of indices shown in the insert. The two curves are for two GaAs-layer thicknesses chosen as examples of the rib-guide lasers.

Rib-guide lasers were fabricated in three steps by liquid-phase-epitaxy processes. First, two layers, n-AlGaAs followed by p-GaAs, were grown on a GaAs substrate. Second, controlled step-height ribs were formed on the GaAs layer by anodization etching procedures [8], [9] and standard photolithographic processes. Finally, the top confinement layer of p-AlGaAs and the p-GaAs layer for contacting purposes were grown [10].

Formation of the rib structure involves at least two difficulties not encountered in conventional multilayer liquid-phase epitaxy. First, regrowth takes place on surfaces which have been subjected to wet chemical processing; and second, etch-back at the start of regrowth should be controlled if rib heights of 0.02–0.1 μm are to be maintained.

An adequately clean surface for regrowth was prepared by removing the oxide remaining after the final anodization with HCl and a deionized water rinse, and a subsequent 2–3-min

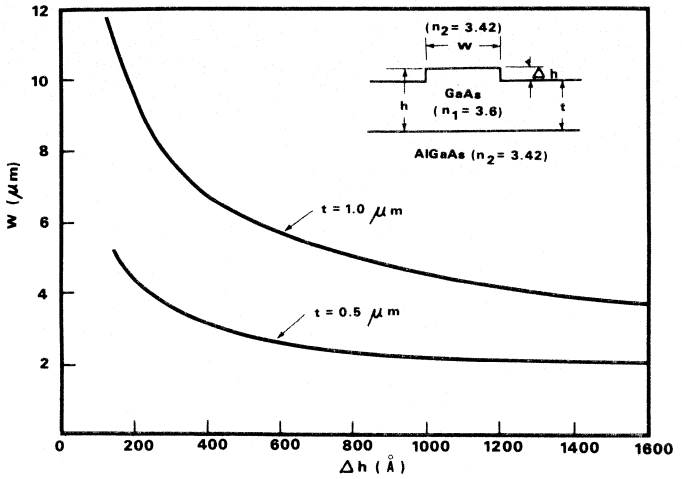

Fig. 2. Dimensions of rib guide in GaAs-AlGaAs DH's for single-mode operations.

etch in 0.01-percent Br-methanol to remove the thin oxide created by the water rinse. The oxide problem is greatly increased by the presence of aluminum in the GaAs layer, and thus drag-over of Al to the second grown layer (GaAs) should be minimized (we believe the Al content of the active GaAs layer should be less than 0.008). This problem was overcome by growing this layer in two steps from separate melts so that any Al drag-over was diluted in the melt from which the second portion of the GaAs layer was grown. With an initial growth of about 0.3 μm and a second layer of about 0.7 μm, the final GaAs layer was almost free of AlAs, with x, the mole fraction of aluminum, typically in the range of 0.003–0.005.

Immediate regrowth with minimal rounding of the rib-guide edges from etch-back was achieved by careful equilibration of the AlGaAs melt. The solution was maintained at 800°C for 2 h before a source seed [11] was slid under it for 15–30 min. Then, with the bottom of the melt (where growth occurs) at equilibrium, the furnace was cooled at 0.25°C/min through 3–4°C to start the growth on the source seed. Finally, the source seed was quickly replaced by the rib-guide substrate and growth was continued to the desired thickness.

It should be noted that the active layer was p-type and that the p-n junction was grown into the second layer at the n-AlGaAs/p-GaAs interface. Thus subsequent processing and regrowth did not affect the junction. However, n-type active regions also have been prepared successfully with the p-n junction at the regrowth interface.

Samples were grown with the GaAs active-layer thickness ranging from 0.3 to 0.8 μm, and the rib-guide step height varying from 250 to 2500 Å. Rib-guide widths of 5, 10, and 20 μm were made on the same sample so that mode properties could be compared. Ohmic contact stripes were aligned with the rib guides and applied to the top layer by conventional SiO_2 and photolithographic techniques. About six diodes of each width were measured, and the results for the better units are tabulated in Table I. The threshold currents were generally higher than those obtained with more conventional oxide-masked stripe-geometry layers, probably due to defects intro-

duced in the regrowth, although the best unit had a threshold current density (~3 kA/cm^2) comparable to typical values for the oxide-masked stripe-geometry devices of 25-μm stripe width.

All diodes operated in TE-like modes with a single field peak along the y direction (perpendicular to the junction plane) and several peaks along the x direction (in the junction plane). The maximum number of peaks increased with the rib-guide width. For Δh = 1000 Å and t = 0.6-0.8 μm, P = 2-3, 3-4, and 7-8 for w = 5 μm, 10 μm, and 20 μm, respectively. Values calculated from (1)-(5) rounded to the nearest lower integer would be P = 2, 4, and 9, respectively, in fairly good agreement with the observed modes. The modes were fairly stable with increasing current, in contrast to conventional stripe-geometry lasers in which the modes are usually unstable at high currents. A scanning-electron-microscope picture of a 5-μm-wide guide capable of supporting a second-order mode is shown in Fig. 3(a).

For a reasonably well-defined rib edge, a step height of about 500 Å is needed. With $\Delta h \approx$ 500 Å, the maximum rib-guide width for single-mode operation according to Fig. 2 is 3 μm for t = 0.5 μm, and 6 μm for t = 1.0 μm. Because the 500 Å ribs were not observable after the regrowth, an indexing method was employed to align the contact stripes to the rib guides. This method and the roughness of the regrown surface limited our alignment ability to 5 μm or larger rib-guide widths.

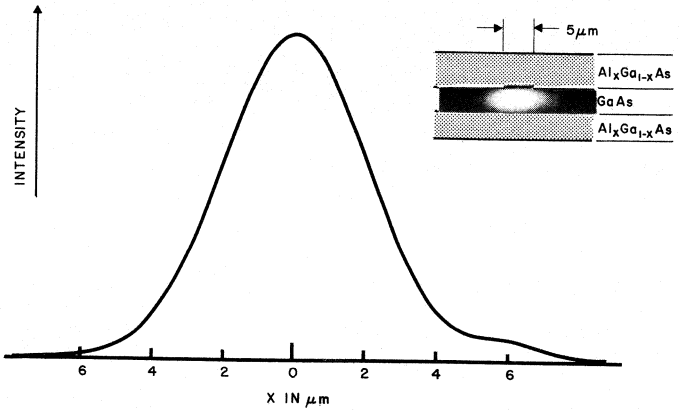

Fig. 4. Near-field radiation scan of the output from a laser producing single transverse mode.

Thus we were not able to realize the calculated single-mode structures.

However, single-mode operation was observed in more than half a dozen diodes from one wafer with rib-guide parameters $t = 0.6$ μm, $\Delta h \cong 500$ Å, and $w = 5$ μm, dimensions somewhat larger than those shown in Fig. 2. The discrepancy (fewer modes than calculated) may be due to the fact that the actual difference of the index of refraction between GaAs and $Al_xGa_{1-x}As$ layers is less than 5 percent, which is assumed in the calculation. A scanning-electron-microscope picture of the rib-guide cross section is shown in Fig. 3(b), and the near-field radiation patterns as scanned by a photodiode and seen with an infrared microscope are shown in Fig. 4. The mode was fairly pure and stable up to twice the threshold current.

The number of modes observed in the rib-guide lasers was higher than that of conventional stripe-geometry lasers of comparable width, which indicates that the modes were indeed strongly guided by the effective index differences at the rib edges. Stronger guidance rather generally implies smaller waveguide dimensions for single-mode operation. However, with the rib-guide structure there are several parameters for mode control in addition to stripe width. Thus, for example, all the dimensions could be increased proportionally without changing, in principle, the mode characteristics. Undoubtedly, threshold would increase for large thickness H, but reasonably low thresholds might be maintained by providing separate confinement of carriers by use of the large-optical-cavity structure.

We conclude that control of transverse laser modes in injection lasers by use of a rib-waveguide structure is feasible, and that stable single-mode operation at current densities several times threshold is possible. However, the requirements of uniform layer growth, smooth interfaces, reduced etch-back, and good regrowth on surfaces subjected to wet chemical processing are not easily met by present liquid-phase-epitaxial processes. Molecular-beam epitaxy [12] may offer an attractive alternative for making such sophisticated laser structures.

Acknowledgment

The authors wish to thank E. A. J. Marcatili for many helpful discussions, R. D. Standley for many SEM photographs of the waveguide structure, F. Favire for fabricating devices, and R. M. Derosier for testing.

GaAs–GaAlAs Double-Heterostructure Injection Lasers with Distributed Feedback

MICHIHARU NAKAMURA, K. AIKI, J. UMEDA, A. KATZIR, A. YARIV, MEMBER, IEEE, AND H. W. YEN

Abstract—**GaAs-GaAlAs double-heterostructure distributed-feedback injection lasers are investigated at temperatures between 80 and 150 K under pulsed operation. The optical feedback for laser oscillation is provided by a corrugated interface between the p-GaAs active layer and the p-GaAlAs layer. The corrugation is made by two methods, ion milling and chemical etching, and the latter method is found to give the lower threshold. The laser oscillation occurs in a single longitudinal mode, whose wavelength is stable against the change of the excitation level. The temperature dependence of the wavelength of the distributed-feedback laser is shown to be 0.5 A/deg, which is about $\frac{1}{3}$ to $\frac{1}{4}$ that of the conventional Fabry-Perot (FP) laser.**

I. INTRODUCTION

SHORTLY after the demonstration of the laser oscillation in distributed-feedback dye lasers [1]-[4] and the subsequent theoretical analysis [5], the feasibility of distributed-feedback GaAs lasers was investigated at 77 K by optical pumping [6]-[9]. Following this the effort shifted toward the realization of injection-type distributed-feedback lasers, and laser oscillation has recently been demonstrated in homojunction [10], single-heterostructure [11], and double-heterostructure [12], [13] lasers.

In a previous paper [12] we have reported briefly the observation of laser oscillation in GaAs-GaAlAs double-heterostructure distributed-feedback lasers. The optical feedback for the laser oscillation was provided by a corrugated interface between the p-GaAs active layer and the p-GaAlAs layer. In this paper we describe a detailed study of the properties of these distributed-feedback lasers in the temperature range of 80–150 K.

II. EXPERIMENTAL METHOD

Fig. 1 shows a typical cleaved cross section of the distributed-feedback lasers described in the following. The corrugation period is 3470 Å and the depth is 1800 Å. In the fabrication of such a structure, an n-$Ga_{0.7}Al_{0.3}As$ layer doped with Sn and a p-GaAs (active) layer doped with Ge were first grown on an n-GaAs substrate by conventional liquid phase epitaxy. The thickness of these layers was ~3 μm and ~1 μm, respectively.

The corrugation of the p-GaAs layer was achieved by ion milling [14] or by chemical etching [15]. In the case of ion milling, 5-keV Ar ions were incident on the p-GaAs layer

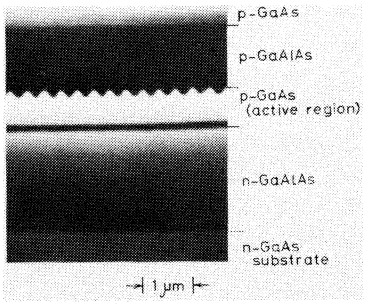

Fig. 1. A scanning electron microscope (SEM) photograph of the cross section of a distributed-feedback laser along the direction of light propagation. The corrugation period is 3470 Å.

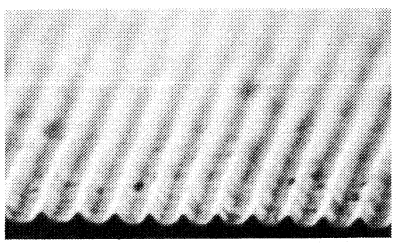

Fig. 2. A GaAs grating made by chemical etching. The period is 3470 Å.

through a photoresist mask produced by holographic photolithography. Fig. 2 shows the surface corrugation made by the chemical etching, where the grooves are composed of {111} *A*-side surfaces and a (100) bottom surface. The depth was 1500–1800 Å for the period of ~0.34 μm.

Next a p-$Ga_{0.7}Al_{0.3}As$ layer (~2 μm thick) and a p-GaAs layer (~1 μm thick), both doped with Ge, were grown on the corrugated surface of the p-GaAs layer by liquid phase epitaxy. The meltback of the corrugated surface during the epitaxial growth was avoided by growing the layers at relatively low temperatures (~700°C) with a cooling rate of 5°C/min as reported in [16].

Fig. 3 shows the schematic structure of the distributed-feedback laser. The laser has a mesa-stripe geometry [17] in order to limit the injection to a rectangular area. The width of the stripe is 50 μm. The metallic contacts of the laser were made by evaporating Cr and Au on the p-side, and Au-Ge-Ni on the n-side. The length of the Cr-Au contact in different lasers varied between 150 and 1100 μm. A lossy unexcited waveguide with a length of 2.5–3 mm was continuous to the current-excited section. This eliminated optical feedback from the end surface. The output was obtained through the front surface as shown in Fig. 3. The laser was pumped by applying current pulses with a duration of 50 ns and a repetition rate of 100 Hz.

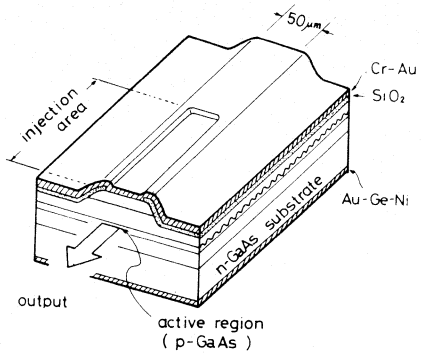

Fig. 3. The schematic structure of the distributed-feedback laser.

III. Results and Discussion

A. Spectral Characteristics

The emission spectra of a typical injection laser is shown in Fig. 4, where the period of the corrugation is 3470 Å, the length of the active region is 1050 μm, and the threshold current density is 750 A/cm^2. In this figure the spontaneous emission has a broad peak centered at 8255 Å. Just above the threshold (390 mA), a narrow peak of stimulated emission appears at 8225 Å. The linewidth of the stimulated emission is 0.5 Å. The diode lased in a single longitudinal mode, whose wavelength was stable with respect to changes of excitation level from threshold to over four times the threshold. The lasing light was polarized with the electric-field vector parallel to the junction plane.

Lasers in which the length of the unexcited waveguide was less than 1 mm exhibited the coexistence of two oscillations: one due to the grating and the other to feedback involving the end surface. The oscillation by grating feedback was identified by the small temperature dependence of the lasing wavelength. When the unexcited waveguide is longer than 2 mm, which is the case in the following experiments, the influence of the end surface is not observed in the emission spectrum.

Fig. 5 shows the spectrum of a typical laser as a function of temperature. The laser, whose length was 630 μm, required a threshold current density of 1.8 kA/cm^2 at 80 K and of 8.6 kA/cm^2 at 145 K. The current was chosen to be about 1.05 times the threshold at each temperature. In this figure, the peak wavelength of the spontaneous emission at 80 K is shorter by 78 Å than that of the stimulated emission. As the temperature increases, the peak of the spontaneous emission shifts more rapidly than the peak of the stimulated emission does. At 145 K, the peak wavelength of the spontaneous emission is longer by 17 Å than that of the stimulated emission.

A small auxiliary peak is seen in the spectrum of Fig. 5. We have no satisfactory explanation as to its origin, since its temperature dependence is inconsistent with either that of a normal Fabry-Perot (FP) mode or higher order DFB modes. It could, possibly, represent some hybrid combination. This peak is absent in lasers possessing longer unpumped corrugated end sections. Typical of the latter category is the laser whose spectrum is shown in Fig. 4.

Fig. 6 shows the wavelength of the stimulated-emission peak

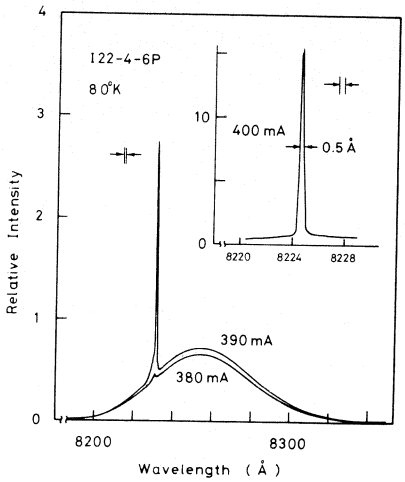

Fig. 4. The emission spectra of a typical laser. The period and the depth of the corrugation are 3470 Å and 1800 Å, respectively. The threshold current density is 750 A/cm^2 at 80 K.

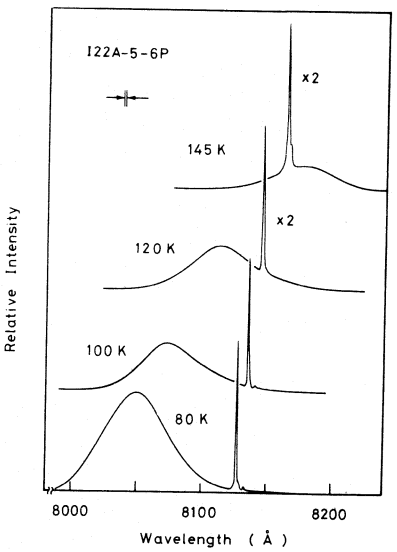

Fig. 5. Temperature dependence of the emission spectrum. The current is chosen to be ~1.05 times the threshold for each temperature.

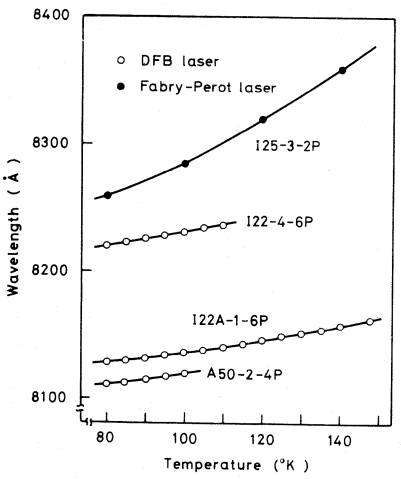

Fig. 6. The lasing wavelength as a function of temperature.

as a function of temperature. The temperature dependence of the main peak of a typical FP laser is also shown in this figure. It is seen from this figure that the wavelength of the distributed-feedback laser shifts at a rate of 0.5 Å/deg. Theoretically, the wavelength of the distributed feedback laser λ is given approximately by [5]

$$\lambda \simeq \frac{2n_g\Lambda}{l} \tag{1}$$

where n_g is the effective refractive index of the waveguide, Λ is the period of the corrugation, and $l = 3$. By differentiating (1) with respect to the temperature T, one gets the relation

$$\frac{d\lambda}{dT} = \frac{\lambda}{\bar{n}_g}\frac{\partial n_g}{\partial T} \tag{2}$$

where

$$\bar{n}_g = n_g - \frac{\partial n_g}{\partial \lambda}\lambda. \tag{3}$$

With $\bar{n}_g \simeq 4.5$ and $\partial n_g/\partial T \simeq 3 \times 10^{-4}$/deg [18], we have $d\lambda/dT \simeq 0.57$ Å/deg, which agrees with the experimental result in Fig. 6.

On the other hand, the peak wavelength of the FP laser changes at a rate of 1.5-2 Å/deg, reflecting the shift of the band-gap energy with temperature.

B. The Threshold Current Density

The threshold of the laser oscillation is a function of such structure parameters as the length and the thickness of the active region, and the depth of the corrugation. The dependence of the threshold current density on the length of the active region L is shown in Fig. 7. The lasers were made from two wafers with chemically etched corrugations, I18 and I22. The thickness of the active region and the depth of the corrugation are 0.9 μm and 1600 Å in I18, and 0.8 μm and 1800 Å in I22, respectively. The period of the corrugation is 3470 Å and the lasing wavelength is 8249 ± 5 Å for all the lasers. In Fig. 7 the threshold current density j_{th} decreases with the increase of L as $j_{th} \propto L^{-0.8}$.

For $L = 400$ μm and $T = 80$ K, the threshold current density was typically 10 kA/cm^2 in the laser with the ion-milled grating, and 2 kA/cm^2 in the laser with the chemically etched grating. The lowest threshold current density of 750 A/cm^2 was obtained in a chemically etched laser with $L = 1050$ μm whose emission spectrum is shown in Fig. 4.

The higher threshold current density in the ion-milled lasers was found to be due to the nonradiative recombination of injected carriers near the interface. This is clearly demonstrated by the photoluminescence measurement as shown in Fig. 8. In this measurement, a part of the p-GaAs layer was ion milled by ~1000 Å, and then a p-$Ga_{0.4}Al_{0.6}As$ layer was grown by liquid phase epitaxy at 700-670°C. The p-GaAs layer was excited by a Kr laser (6471 Å) through the top p-$Ga_{0.4}Al_{0.6}As$ layer at room temperature, and the photoluminescence from the p-GaAs layer was monitored by a TV camera. In this figure, the intensity of the photoluminescence is about two orders of magnitude weaker in the ion-milled GaAs layer than in the original GaAs layer. This fact demonstrates that ion milling produces nonradiative recombination centers thus increasing the threshold current density.

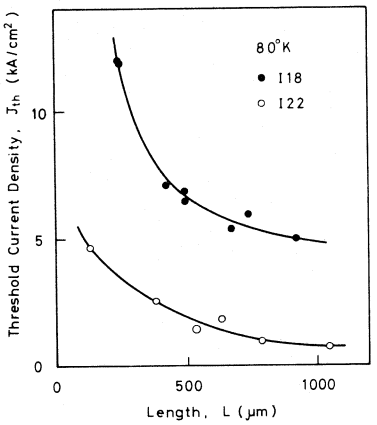

Fig. 7. The threshold current density as a function of the length of the active region.

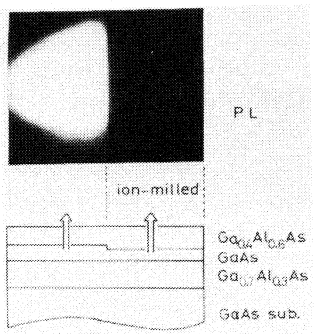

Fig. 8. Photoluminescence from a GaAs epitaxial layer. A part of the GaAs epitaxial layer was ion milled.

In the laser with the chemically etched grating, the number of nonradiative recombination centers was much reduced, and the lower threshold operation became possible. Further reduction of the threshold current density may be achieved by adopting the separate-confinement heterostructure with a corrugated interface as was proposed elsewhere [19]. In this structure, the effect of the nonradiative centers should be greatly reduced since the corrugated interface is separated from the active layer. The use of the fundamental grating with a period of 0.12 μm should lead to further reduction in the threshold current density.

IV. Conclusion

GaAs-GaAlAs double-heterostructure distributed-feedback injection lasers were investigated at temperatures between 80 and 150 K under pulsed operation. The grating was made by ion milling or by chemical etching. The laser oscillation occurred in a single longitudinal mode even at high current densities. The lasing wavelength was stable against the change of the excitation level. The temperature dependence of the lasing wavelength was found to be about 0.5 Å/deg and was explained by the temperature dependence of the refractive index of the waveguide. The lowest threshold current density of

750 A/cm^2 was obtained in a laser with a chemically etched grating. The threshold current densities of lasers with ion-milled gratings were found to be higher than those of chemically etched lasers because of the surface damage caused by the ion bombardment. Further reduction of the threshold current density is expected to result from the use of the separate-confinement heterostructure and a fundamental grating.

Single-Heterostructure Distributed-Feedback GaAs-Diode Lasers

ROBERT D. BURNHAM, DONALD R. SCIFRES, MEMBER, IEEE, AND WILLIAM STREIFER, SENIOR MEMBER, IEEE

Abstract—**This paper reports the fabrication, testing, and analysis of distributed-feedback (DFB) single-heterostructure (SH) electrically pumped GaAs lasers. The techniques of fabricating the DFB grating and diode using interferometric exposure of photoresist, development, ion milling, liquid-phase-epitaxial growth, and diffusion are described in detail. Next, experimental results on a variety of diodes operating at 77 K are presented. It is shown that narrow laser linewidth (< 0.15 Å) and low threshold operation (775 A/cm^2) can be obtained. Also reported is output coupling from the grating which results in highly collimated laser beams with divergence of approximately 0.35°. Coupling coefficients, which determine laser threshold, are computed as a function of device parameters including physical dimensions, refractive indices, grating size and shape, and Bragg order for single- and double-heterostructure geometries. Calculated and measured thresholds are shown to be in good agreement.**

I. Introduction

IN A RECENT LETTER we reported the first observation of laser operation in an electrically pumped distributed-feedback (DFB) diode [1]. Since this laser requires no discrete end mirrors as is the case with a conventional diode laser it is potentially useful as a source for integrated optical circuits. In addition, DFB injection lasers have several other unique features which make them potentially useful even as discrete devices. First, the feedback is frequency selective so that various laser wavelengths within the gain line may be obtained. Second, DFB lasers enhance the possibility of mode control [2]–[4] and, finally, the periodic DFB structure may be used as an output coupler to obtain a polarized low-divergence laser beam [5]. These attributes may make DFB injection lasers useful in point-to-point communications as well as enhancing their utility in fiber optic systems.

As described previously [6], the feedback mechanism in DFB lasers is that of backward Bragg scattering from a periodic perturbation of either the refractive index or gain in the laser waveguide. In our devices such feedback is provided by a periodic corrugation which is distributed along and integrated with the gain region in a GaAs/GaAlAs single-heterostructure (SH) diode. A schematic diagram of such a device is shown in Fig. 1. It consists of a GaAs n-type substrate (refractive index n_3), a GaAs p-type active region (index n_2), and a GaAlAs p-type grown layer (index n_1). Since n_2, the refractive index of the GaAs p-type layer, is greater than n_1 and n_3, light generated by minority-carrier injection across the p-n junction is guided in this layer. The thickness (t) of this active layer is, of course, critical in determining laser threshold of the device since it affects not only the current and wave confinement as in conventional SH diodes [7] but also the feedback from the grating. In Fig. 1 the grating period is Λ, w denotes the width of a rectangular tooth, and g is the peak-to-valley height of the grating. To satisfy the Bragg condition for DFB operation the periodic corrugations at the interface between the GaAs substrate and the GaAlAs layer must be spaced a multiple of a half wavelength of light in the medium. For a free-space wavelength of 8500 Å and $n_2 \simeq 3.6$

$$\Lambda \simeq 1180\, m \text{ Å}, \qquad m = 1, 2, 3, \cdots .$$

The diodes described herein have grating periods corresponding to $m = 3$ and $m = 4$.

This paper is divided into three main sections. In Section II, techniques used in fabrication of the grating and subsequent epitaxial growth are described. Next, in Section III experimental results are discussed. In particular, we point out that care must be taken to insure that DFB rather than unwanted discrete feedback from diode faces is the dominant feedback mechanism. For this reason diodes with both saw-cut- and antireflection- (AR) coated faces were used to minimize the discrete feedback. Thresholds of these diodes were compared with control diodes of similar geometry but with no DFB structure. Another quite conclusive test for DFB is correlation of grating spacing with the laser wavelength. Again, the use of control diodes for comparison is advantageous to insure that the observed wavelength shifts are not a function of diode geometry or doping concentrations. Finally, in Section IV we describe some analytic and numerical results relating to coupling coefficients and thresholds of DFB devices. These are found to be in good agreement with experimentally obtained values.

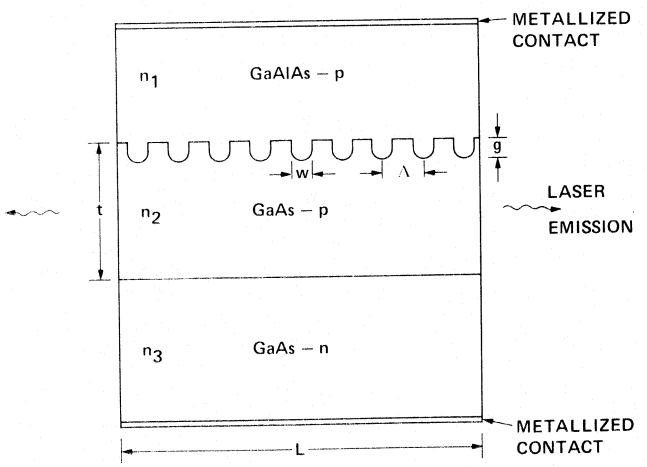

Fig. 1. The geometry of the SH DFB diode laser.

II. Device Fabrication

In this section steps for fabricating SH DFB lasers are described. These consist of 1) exposure of photoresist by two interfering laser beams [8], 2) development of photoresist, 3) ion-beam etching the pattern into the substrate [9], and 4) liquid-phase-epitaxial growth of GaAlAs over the corrugated substrate surface. We begin step 1) by spin coating photoresist (AZ 1350) onto a well-cleaned and dried Si-doped (N_d-N_a $\sim 2\text{-}4 \times 10^{18}$ cm^{-3}) GaAs substrate at 6000 r/min to achieve a film thickness of ~3000 Å. These films were further processed by baking at 125°C for 2.5 min to activate the resist.

To expose the film, a single-frequency Ar^+ laser (4579 Å) is split into equal-intensity beams by a variable-density beam splitter. This light is deflected by mirrors through a 10-μm spatial filter and interferes at an angle Θ on the photoresist film. To generate a 3600-Å spacing ($m = 3$) in the photoresist $\Theta \simeq 40°$. With a power density of ~2.5 mW/cm^2 in each beam a 15-s exposure followed by a 1-2-min development in undiluted AZ developer solution is used. A usable grating mask over approximately 1 in^2 of the substrate is produced.

The masked substrate is then ion-beam machined for ~1 h with a Commonwealth Scientific IMMI-IV ion miller set at ~100-μA beam current. The wafer is positioned so that the Ar beam is parallel to the grooves in the mask. The ion beam is also directed at an angle of 10-15° with the wafer plane to yield a smooth and unpitted grating. A scanning-electron-microscope (SEM) photograph of such a grating is shown in Fig. 2. Groove spacing is ~3500 Å and the groove depth is ~1700 Å. The smoothness of the groove is directly attributable to the grazing incidence of the ion beam which actually acts to correct defects created during the exposure and development processes. Milling at normal incidence results in a badly pitted surface. Various groove profiles result when the milling time is varied. For example, a flat-topped groove results if all photoresist is not removed during the milling process or if the photoresist is developed down to the substrate before milling. This groove shape may be advantageous during subsequent liquid-phase-epitaxy growth where meltback must be

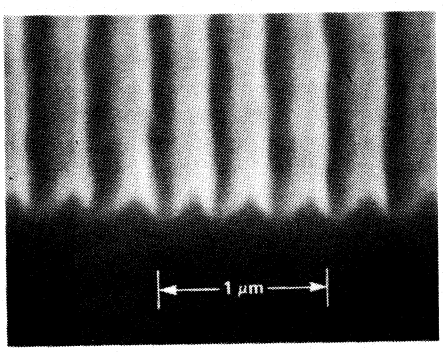

Fig. 2. SEM photograph of a grating.

avoided [10]. The diffraction efficiency of the gratings was measured for evaluation purposes prior to completing the fabrication process. The intensity of a He-Ne laser (6328 Å) beam diffracted at an angle of ~70° from the grating was compared to the intensity of the same beam reflected at near-normal incidence from an unmilled GaAs wafer. The efficiencies of these gratings are in the range of 30–40 percent.

After ion milling the remaining photoresist is removed with both acetone and plasma etching in an oxygen atmosphere. The wafer is then etched lightly with HCL and HF. Zn-doped GaAlAs layers are then grown on the corrugated GaAs substrates by conventional liquid-phase-epitaxy techniques. The mole fraction of Al is 0.3–0.7 at the interface between the substrate and the grown layer. After prebaking for ~1 h at 770°C the furnace is cooled at a rate of 1 deg/min. Then 15 min later the controllers are set 10°C cooler. 3 min after that the substrate, which is recessed as much as 1.5 mm, is then slid under the first melt which contains 4-g Ga, 6-mg Al, and 40-mg Zn, and also contains a polished undoped wafer of GaAs wetted to the top surface of the melt. The presence of this wafer is crucial since it guarantees that the entire melt is saturated with GaAs and thus prevents meltback of the corrugations on the substrate. It also results in the growth of layers which are more uniform in thickness and composition. The initial contact temperature is kept low (~750°C) to also reduce the effect of meltback [10]. The substrate remains beneath the first melt for 10 min and is then pulled into a melt containing 4-g Ga, 100-mg Zn, and a GaAs wafer for source material. From this melt a final layer of p-type GaAs is then grown for ease in making ohmic contact to the p-side of the wafer. The resulting layer thicknesses are ~6 μm of GaAlAs and 15–20 μm of GaAs. During growth of the two epitaxial layers the Zn diffuses $\sim\frac{1}{2}$ μm into the substrate. Following growth and cleaning of the Ga from the wafer a Zn_3As_2 diffusion is performed in an evacuated ampoule at ~800°C for 10 min to produce a p-n junction 1.5–2 μm from the GaAlAs grown layer. Previous reports [7] indicate that this is the optimum distance from the GaAlAs layer for low-threshold laser operation in cleaved-mirror SH diodes.

Next metallization of the entire wafer surface is performed. Ti, Pt, and Au are used for the p-alloy, whereas Au-Sn is used to make ohmic contact to the n-type substrate. In several cases the entire surface is not metallized. Instead a small ball of a p-type or n-type metal alloy (~5-mils diameter) is wetted to one side of the device in a hydrogen atmosphere while the other side is alloyed to a TO-5 Au-plated header. Since the spreading resistance is low, the devices appear to be uniformly pumped when viewed with an IR up-converting microscope. The wafer is next cleaved and/or sawed into chips which are mounted on headers. In some cases all four sides of a chip are saw cut to reduce reflections back into the active region of the laser and thus allow the grating to provide the dominant feedback mechanism. Also in order to isolate the effects of the grating "control" wafers are fabricated. A portion of the GaAs substrate is cleaved and cleaned before ion milling. All subsequent steps including LPE are simultaneously performed on this wafer. Therefore, the control and DFB diodes are identical except for the presence of the grating. These diodes are then compared as part of the experimental study reported in the next section.

III. Experimental Results

This section is divided into three subsections. First we discuss laser thresholds for DFB diodes of various geometries including those with saw-cut and AR-coated end reflectors. Second, spectral results obtained for DFB lasers are presented. Finally, the observation of radiation modes which lead to very low-divergence laser beams radiating normal to the plane of the p-n junction are discussed.

All experimental measurements were performed at liquid-nitrogen temperature. The diodes were excited with 0.5-μs pulses at a repetition rate of 1 kHz. Laser spectra were analyzed with a Spex 1-m spectrometer operating in first order and detected with an RCA C31034B photomultiplier. The near- and far-field patterns were observed with an IR up-converting microscope and the far-field patterns were also scanned by rotating a fiber light pipe angularly around the axis of the diode. The light output from this fiber was detected with a photomultiplier and plotted on a recorder.

Laser Thresholds

Threshold current densities for DFB diodes were measured for various geometries and cavity configurations. Three end-mirror configurations were used. First the end faces of the diodes were saw cut rather than cleaved in order to reduce the light reflected directly back into the active region. SEM photographs of the saw cut show that the surface is extremely rough when viewed on a scale comparable to a wavelength of light in the crystal (~1200 Å). Thus it should provide diffuse reflections when struck at normal incidence. This, of course, is not the case when struck at shallow angles as noted in the literature [11]. Control diodes (those with no grating near the junction) which are ~2 mm long showed an increase of 3–4 times in threshold current densities when their cleaved end faces were damaged by saw cuts. In these cases the diodes sometimes lased across the short diode dimension directly beneath the alloyed contact since this area was more highly and uniformly pumped. The mode spectra in the case of saw-cut control diodes consisted of a broad band of mostly unresolvable longitudinal modes with no strongly apparent mode spacing. In comparison, DFB diodes whose cleaved ends were saw cut showed only a 1.1 to ~2 times increase in threshold and lased over a narrower wavelength range. An example of this is shown in Fig. 3. As shown, a saw-cut diode 1.9 mm long and 0.46 mm wide lased at 8 A corresponding to a threshold current density of 775 A/cm^2. This threshold current density was as low as that obtained for any cleaved-mirror control diode.

Although saw cutting the diode end mirrors can be used to qualitatively look for the effects of DFB, it is difficult to characterize these devices quantitatively. Therefore, two other cavity configurations were tested. First, vacuum grease was applied to both cleaved faces of the diode and second an AR $\lambda/4$ coating was deposited on one cleaved end. In the case of vacuum grease with a refractive index of ~1.5 the power reflection at normal incidence was reduced from 33 to

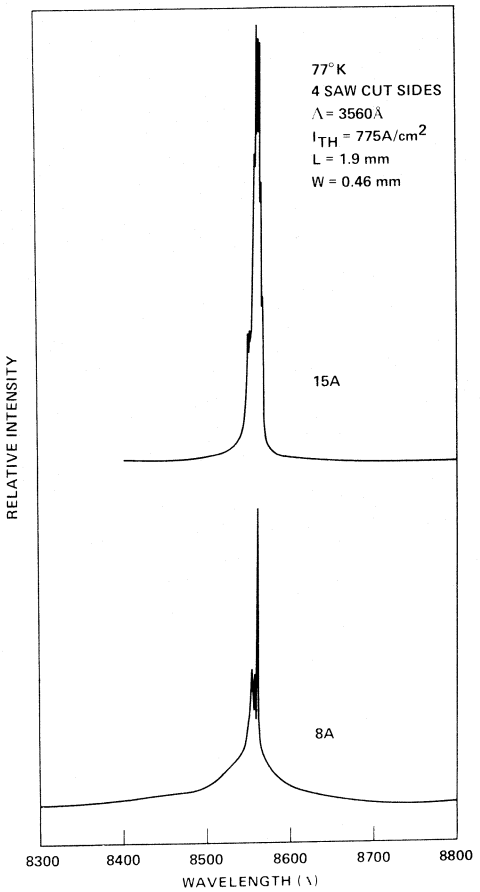

Fig. 3. Spectra of a low-threshold DFB diode laser.

~17 percent at the cleaved surface. The AR coating has a 0.2-percent power reflection at 8500 Å. Results of threshold current-density measurements for one set of diodes with these configurations are shown in Table I. For the control diode

$$\exp(2\alpha L) = (R_1 R_2)^{-1} \quad (1)$$

where α is the net threshold gain and R_1, R_2 are the power reflectivities at the mirrors. The numerical values listed for that diode in Table I agree almost exactly with those computed from (1) when an absorption of $\alpha_{abs} = 10$ cm^{-1} is taken into account. With that absorption the listed DFB diodes all exhibit smaller increases in measured threshold current than the control diode as the reflectivity was changed.

Spectral Results

In Fig. 4 spectra are shown for two DFB lasers with different grating spacings. For a spacing of $\Lambda = 3480$ Å [Fig. 4(a)] the spontaneous emission peaks at ~8470 Å, but the diode lases at ~8440 Å, on the high-energy side of the spontaneous-emission line. This diode was 825 μm long and had one end cleaved and the other saw cut. Since at 8440 Å there is significant absorption the threshold current density for this diode is quite high (6000 A/cm^2). Control diodes with cleaved ends lased between 8465 and 8500 Å (dependent on diode length) on the long-wavelength side of the spontaneous peak. The spectra shown in Fig. 4(b) are for a diode with $\Lambda = 3550$ Å. In this case laser emission occurs on the low-energy side of the spontaneous peak at 8550 Å. This diode was 1.5 mm long and

TABLE I
PUMPING THRESHOLDS OF FOUR DIODES WITH CLEAVED ENDS, INDEX-MATCHED ENDS, AND ONE CLEAVED-ONE AR-COATED END

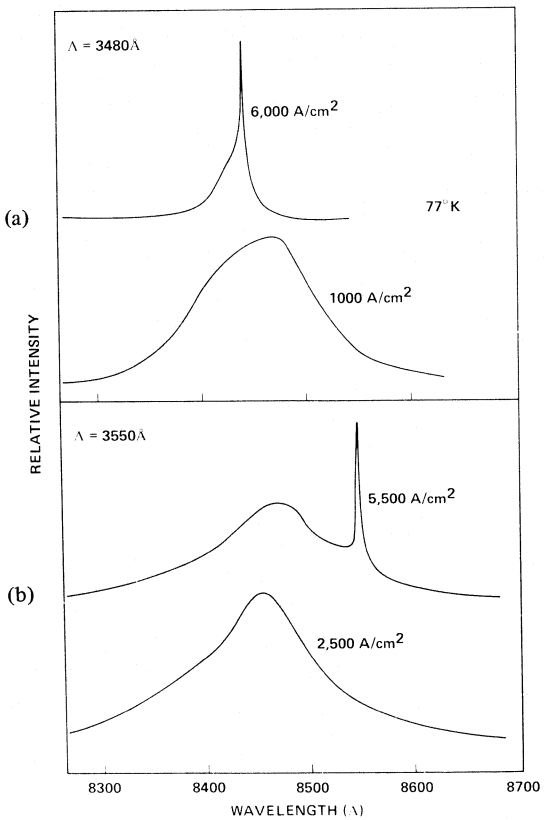

Fig. 4. Two spectra of DFB diode lasers oscillating far from line center.

saw cut on both ends. The threshold current density is again high because of the lower gain at wavelengths far from line center.

A plot of laser wavelength versus corrugation spacing for several diodes is shown in Fig. 5. The corrugation spacing is measured directly by observation in a calibrated high-power optical microscope and also indirectly by observation of the angle of diffracted light from the substrate surface. We estimate the measurement accuracy as ±4 Å. As indicated in the figure, the laser wavelength increases as the grating spacing is increased. However, no single straight line representing a particular refractive index can be drawn through the points because of dispersion at wavelengths near the band gap of the crystal. In fact, the Bragg formula yields $n_2 \simeq 3.59$ at 8583 Å and $n_2 \simeq 3.63$ at 8460 Å. The higher refractive index near the band edge has been observed by other workers for GaAs [12]. Some of the scatter in the points may result from the effects of nonuniform pumping which causes the index to vary along the crystal or because different longitudinal modes

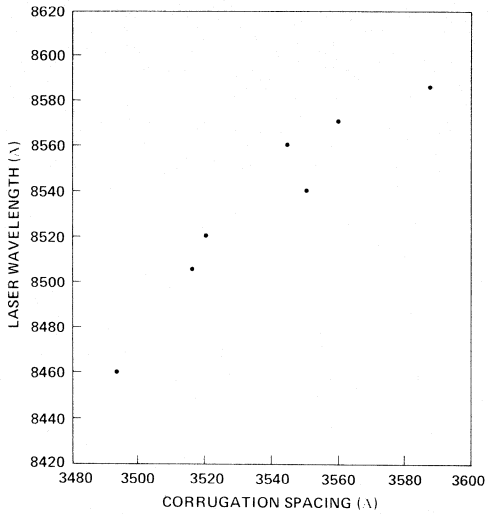

Fig. 5. Laser free-space wavelength versus corrugation spacing for several DFB diodes.

oscillate. Also, some shift in wavelength might be expected for diodes at different pumping levels.

Another important spectral property which theoretically should be achieved more readily in DFB than in cleaved-mirror lasers is that of single-mode operation. We have obtained narrow-linewidth single-mode operation in a DFB laser with one cleaved and one AR-coated face. These results are shown in the spectra of Fig. 6 for a diode of ~475-μm length and 200-μm width. At laser threshold of 3.3 A, the linewidth was measured to be a maximum of 0.15 Å which is the limiting spectrometer resolution at this wavelength. Therefore, the laser line might well be considerably narrower than this measurement indicates. Such narrow-linewidth single-mode laser operation is not normally achieved with SH diode lasers because of the lack of uniform excitation both in the direction perpendicular to the junction and in the junction plane [23]. At a current of 3.5 A, multimode oscillations were observed. Either other longitudinal modes attained threshold or other laser filaments formed along the junction plane. At ~3.7 A another filament was clearly visible when the cleaved face was viewed with the IR up-converting microscope.

The mode spectrum of another DFB laser near threshold with a 2.1-mm cavity length and one cleaved and one saw-cut end mirror is shown in Fig. 7. Several longitudinal modes are clearly resolvable and have a mode spacing of ~0.35 Å. This mode separation agrees well with that predicted by the equation

$$\Delta\lambda = \frac{\lambda^2}{2nL\,[1 - (\lambda/n)\,(dn/d\lambda)]} \tag{2}$$

which approximately holds for SH DFB lasers with small coupling as well as conventional lasers [2].

We have found analytically [2] that the physical position of the cleaved mirrors, relative to the grating peaks, greatly affects the longitudinal mode structure. Often the mode nearest the Bragg frequency has a substantially higher threshold than the other longitudinal modes and is not present in the measured spectra. As expected, other longitudinal modes nearest the Bragg frequency are most strongly affected by the

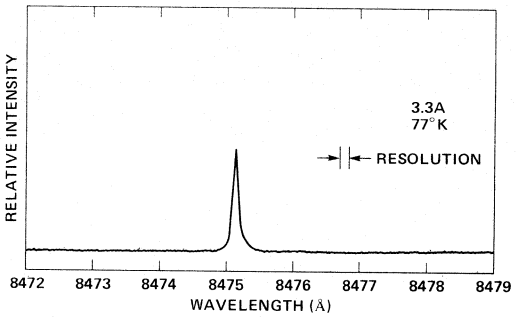

Fig. 6. Spectrum of a narrow linewidth DFB diode laser.

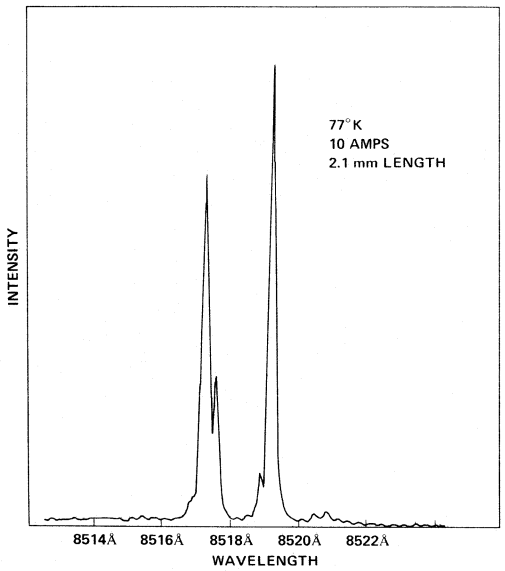

Fig. 7. Spectrum illustrating longitudinal modes of a DFB diode laser.

grating and their thresholds may be either increased or decreased relative to those determined by cleaves alone. However, mirror reflectivity determines threshold a few modes away from the Bragg frequency for small and moderate values of κL (κ is the coupling coefficient). In the spectrum shown in Fig. 7 the two modes nearest the apparent Bragg frequency do not oscillate. Such behavior is consistent with theoretical predictions [2], [19].

In the direction perpendicular to the p-n junction only the TE_0 and TM_0 modes are confined because of the small refractive-index difference of the p-n junction at one boundary of the 2.0-μm-thick waveguide. The existence of only lowest order transverse modes has been previously observed in cleaved-mirror SH lasers [13]. The transverse-mode structure in the plane of the p-n junction is not similarly constrained because no method for limiting the pumped junction area was used.

Radiation Modes

The last experimental results to be discussed involve the launching of radiation modes at angles to the plane of the p-n junction. Such modes have been observed in both optically pumped dye lasers [14], [15] and in optically pumped GaAs platelet lasers [16]. They occur because gratings diffract in several orders. For example, in Fig. 8 is shown a wave traveling

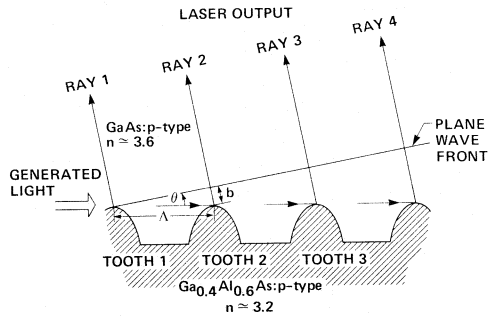

Fig. 8. Geometric representation of radiating modes in a DFB diode laser.

in the plane of the p-n junction which is diffracted out of this plane. The wavefront radiates at an angle Θ with the interface between the GaAs and GaAlAs p-type layers. An elementary view of this situation based on geometrical considerations follows. Ray 1 is in phase with ray 2 if Θ is such that

$$\sin \Theta = \frac{m\lambda_0}{n\Lambda} - 1 \tag{3}$$

where m is an integrer, λ_0 is the free-space laser wavelength, n is the equivalent refractive index of the waveguiding layer, and Λ is the corrugation spacing. For SH GaAs lasers $n \simeq n_2$. This equation is obtained by requiring that

$$\Lambda + b = \frac{m\lambda_0}{n} \tag{4}$$

in order for the wave to be in phase. When the radiation mode escapes the crystal the beam undergoes refraction so that the angle the wavefront makes with the top surface of the crystal (ϕ) is given by

$$\sin \phi = \frac{m\lambda_0}{\Lambda} - n\,. \tag{5}$$

In the case of a DFB laser (3) can be satisfied by $m = 0, 1, 2$ when $\lambda_0/n = \Lambda$, which is the condition for second-order Bragg scattering. Other grating spacings can be used to couple a beam out normal to the plane of the p-n junction. In general, if

$$\frac{\Lambda n}{\lambda_0} = p, \qquad p = 1, 2, 3, \cdots \tag{6}$$

there exists at least one solution of (3) such that $\phi = 0$ and the beam is radiated normal to the junction. This corresponds to Bragg scattering of order $2p$ in the DFB structure. In particular, if $p = 1$ only the radiation mode normal to the plane of the grating exists. This is not true for larger values of p.

A schematic of the DFB laser in which light is coupled out of the diode normal to the plane of the p-n junction is shown in Fig. 9. The diode is identical to the DFB structures described previously except that a grating period of 4693 Å (corresponding to fourth-order DFB) is fabricated between the p-GaAs and GaAlAs layers. This grating provides both DFB and output coupling of the guided wave in the cavity. As indicated in the figure a collimated beam is coupled out at 90° from the entire top surface of the n-GaAs layer. Two other beams, not shown, are also coupled into the GaAs n-layer at

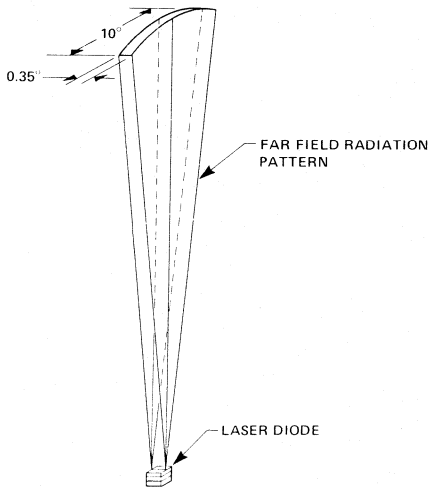

Fig. 9. Near- and far-field radiation pattern of a radiating DFB diode laser.

$\theta = +30°$ and 150°; the latter is produced by the left-going wave (see Fig. 8). However, these are totally internally reflected as are those coupled into the GaAlAs layer. A spacing of $\Lambda = 2400$ Å would not produce these beams.

In contrast to the DFB lasers described previously the cleaved end faces of these diodes are coated with a gold film of approximately 98-percent reflectivity. Thus most of the power output is scattered from the grating rather than being transmitted through the cleaves. The crystal faces orthogonal to the grating are saw cut. The diode is bonded with the p-side down on the header. A top contact (~1.25-μm diameter) is alloyed to one end of the device leaving a clear-surface emitting area over $\frac{2}{3}$ of the diode. The n-type GaAs substrate is sufficiently thick and heavily doped ($N_d - N_a \sim 2 \times 10^{18}$ Si) that current spreads nearly uniformly over the emitting area.

Laser threshold current densities were ~1.2 kA/cm^2 for a typical device of length 750 μm. The laser wavelength of this device was 8480 Å, which is both the expected laser wavelength for cleaved-mirror diodes without DFB and also the wavelength selected by this particular grating spacing. In general, thresholds and lasing wavelengths are determined by the combined effects of the distributed and discrete feedback. It is clear that the diode is lasing near the Bragg condition for DFB operation since the far-field pattern has only a single narrow lobe normal to the plane of the p-n junction.

A scan of the far-field pattern obtained by angularly rotating a light pipe connected to a photomultiplier about an axis centered on the diode is shown in Fig. 10. A 500-μm slit which gave an angular resolution of ~0.1° was employed before the light pipe. At a current of 7.2 A, which is ~1.7 times threshold, the bandwidth of the laser emission was 7 Å. By scanning across the diode axis the divergence of the beam in the direction determined by the grating along the length of the diode was measured to be only 0.35°. This is close to the predicted value of $\Delta\phi$, the angular divergence of the beam. By differentiating (5) we find

$$\Delta\phi = \frac{1}{\cos\phi}\left[\frac{m\lambda_0}{n\Lambda} - \frac{\lambda_0}{n}\frac{dn}{d\lambda}\right]\frac{\Delta\lambda}{\lambda_0}\,n. \tag{7}$$

For a grating spacing of 4693 Å (taking the dispersion term

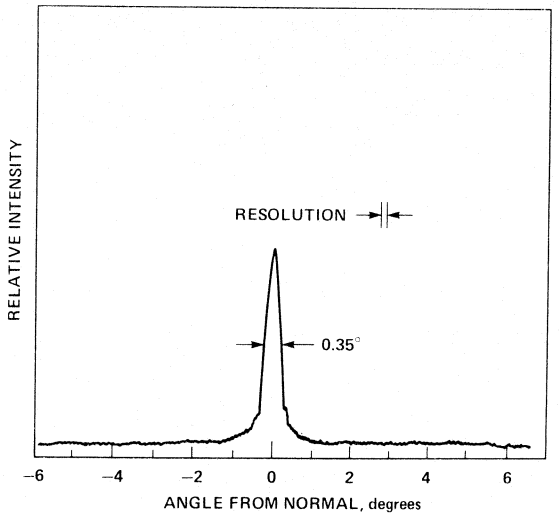

Fig. 10. Angular divergence of the far-field radiation parallel to the grating.

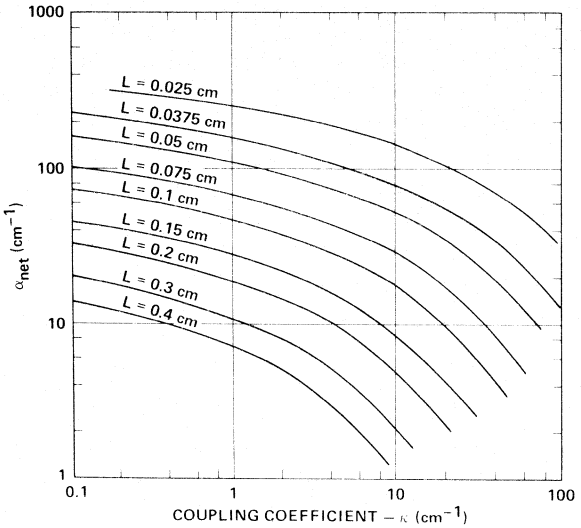

Fig. 11. Net gain at threshold versus coupling coefficient with length as a parameter.

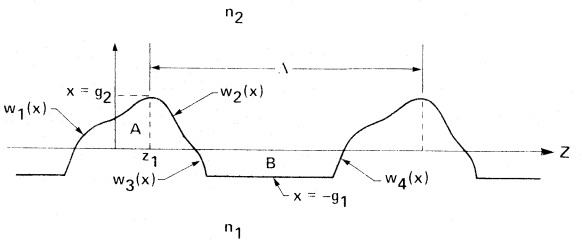

Fig. 12. Two arbitrarily shaped teeth of a corrugation grating.

$(\lambda_0/n)/(dn/d\lambda) = -0.25$), (7) yields an angular divergence of 3.7×10^{-3} rad or 0.21°. The slight discrepancy probably occurs because of the finite length of the diode. A uniform radiator 500 μm long would produce an angular divergence of ~0.1° with 8500-Å light. This enhancement of beam collimation occurs because the divergence is roughly inversely proportional to the size of the radiator and this diode radiates over its entire length rather than across the ~2-μm junction thickness.

Both the near- and far-field patterns were also examined through an infrared up-converting microscope. In the near field a single filament is observed across the entire length of the diode (except where covered by the contact). The far-field pattern showed a single sharp vertical stripe whose vertical divergence is typical of that determined by the width of a lasing filament. The output beam was found to be virtually 100-percent polarized with the E-field parallel to the grating grooves. This observation is in agreement with previous theoretical analysis [17]. Linear polarization is of course an added advantage to output coupling orthogonal to the junction.

IV. Analytic Results

The pumping thresholds and laser frequencies of DFB devices depend greatly on the strength of coupling between the left- and right-going traveling waves. The case of pure DFB (no external reflectors) was treated by Kogelnik and Shank [18] and their results are presented in a slightly different form as Fig. 11. Here is plotted net threshold gain versus coupling coefficient with device length as a parameter. Using this figure one can determine minimum necessary device length L given κ and available α or given α and L the plot specifies minimum values of κ. Chinn [19] studied DFB lasers with identical symmetrically located external reflectors and the present authors [2] have considered the general case of any external-reflector geometry. In all geometries device behavior depends critically on the coupling coefficient κ, but κ is usually defined in terms of a continuous variation in refractive index and/or gain along the length of the device. Many lasers, such as the one described earlier in this paper, have discrete periodic corrugations rather than continuous variations. Thus the coupling coefficient must be computed from the geometry of the corrugations.

Many authors [20]–[22] approach this problem by utilizing a perturbation technique. They consider a three-layer structure without corrugations which can model both single- and double-heterojunction GaAs lasers as well as thin-film dye lasers. Transverse modes are computed for the unperturbed geometry and the coupling of identical oppositely traveling modes via the corrugations is calculated. To carry out this procedure with greater accuracy, the boundary for the unperturbed mode calculation must be chosen at the area average of the corrugations (the areas labeled A and B in Fig. 12 are equal) and not at their base as in [3] and [22]. Thus in computing the unperturbed modes the thickness of the center layer is taken to be the distance from the n_2–n_3 interface to the z axis shown in Fig. 12, i.e., $\bar{t}$, and not t, the active-layer thickness prior to milling (cf. Fig. 1).

The coupling coefficient for TE modes is then given by [22]

$$\kappa = \frac{\omega^2 \mu_0 \epsilon_0 N_e^2}{2\beta_e} \int_{-\infty}^{\infty} \Delta\,[n^2(x,z)]\, \mathcal{E}_e^2(x)\, dx \tag{8}$$

where

$$\mathcal{E}_e(\chi) = \begin{cases} \exp(qx), & x \leqslant 0 \\ \cos(hx) + (q/h)\sin(hx), & 0 \leqslant x \leqslant t \\ [\cos(ht) + (q/h)\sin(ht)] & \\ \quad \cdot \exp[-p(x-t)], & t \leqslant x \end{cases} \tag{9}$$

$$N_e^2 = \frac{2h^2}{(h^2+q^2)(t+q^{-1}+p^{-1})} \tag{10}$$

$$q = \sqrt{\beta_e^2 - n_1^2 k^2}$$

$$h = \sqrt{n_2^2 k^2 - \beta_e^2}$$

$$p = \sqrt{\beta_e^2 - n_3^2 k^2} \tag{11}$$

and β_e is the propagation constant found by solving

$$\tan(h\bar{t}) = \frac{h(q+p)}{h^2 - pq}. \tag{12}$$

In (8), only the spatial harmonic of $\Delta[n^2(x,z)]$ appropriate to the Bragg-scattering order is to be retained, κ is defined by comparison with the equation connecting the opposite-going waves (cf. [18] and [22]), and

$$\Delta[n^2(x,z)] = \begin{cases} n_1^2 - n_2^2 & \text{in area } A \\ n_2^2 - n_1^2 & \text{in area } B \end{cases} \tag{13}$$

of Fig. 12. Since the corrugations are periodic so too is $\Delta[n^2(x,z)]$.

Consider now a single corrugation as shown in Fig. 12. Here $w_i(x)$, $i = 1, 2, 3, 4$ describe the tooth boundary. If any of these functions are not single valued, the tooth shape can be decomposed into two or more curves with single-valued boundaries. Then the results are superimposed by summing the contributions to κ. In the event the situation is as illustrated in Fig. 12 we have

$$\Delta[n^2(x,z)] = \begin{cases} (n_1^2 - n_2^2) \sum_{p=-\infty}^{\infty} \{u[w_2(x) - z + p\Lambda] \\ \quad - u[w_1(x) - z + p\Lambda]\}, \quad x > 0 \\ (n_2^2 - n_1^2) \sum_{p=-\infty}^{\infty} \{u[w_4(x) - z + p\Lambda] \\ \quad - u[w_3(x) - z + p\Lambda]\}, \quad x < 0 \end{cases} \tag{14}$$

where $u(z) = 1$ for $z > 0$ and 0, $z < 0$. Since (14) is periodic in z it can be expanded in a Fourier series whose coefficients depend on x. After some manipulation we obtain

$$\Delta[n^2(x,z)] = \begin{cases} (n_1^2 - n_2^2)\left[\frac{w_2(x) - w_1(x)}{\Lambda} - \frac{i}{2\pi}\sum_{m=-\infty}^{\infty}\frac{1}{m}\right. \\ \quad \cdot \{\exp[i2\pi m w_2(x)/\Lambda] \\ \quad - \exp[i2\pi m w_1(x)/\Lambda]\} \\ \quad \left.\cdot \exp(-i2\pi m z/\Lambda)\right], \quad x > 0 \\ (n_2^2 - n_1^2)\left[\frac{w_4(x) - w_3(x)}{\Lambda} - \frac{i}{2\pi}\sum_{m=-\infty}^{\infty}\frac{1}{m}\right. \\ \quad \cdot \{\exp[i2\pi m w_4(x)/\Lambda] \\ \quad - \exp[i2\pi m w_3(x)/\Lambda]\} \\ \quad \left.\cdot \exp(-i2\pi m z/\Lambda)\right], \quad x < 0. \end{cases} \tag{15}$$

Since the mth spatial harmonic acts to couple energy from the left- to right-going waves

$$\kappa_e = \frac{-i\omega^2\mu_0\epsilon_0(n_1^2 - n_2^2)N_e^2}{4\pi\beta_e m}\left\{\int_0^{g_2}\{\exp[i2\pi m w_2(x)/\Lambda] - \exp[i2\pi m w_1(x)/\Lambda]\}\,\mathcal{E}_e^2(x)\,dx - \int_{-g_1}^{0}\{\exp[i2\pi m w_4(x)/\Lambda] - \exp[i2\pi m w_3(x)/\Lambda]\}\,\mathcal{E}_e^2(x)\,dx\right\} \tag{16}$$

where, as shown in Fig. 12, g_1 and g_2 are the maximum tooth heights in media 1 and 2, respectively, and m is the Bragg-scattering order. An expression similar to (16) holds for TM modes.

For rectangular teeth $w_2(x) = -w_1(x) = w/2$, $w_3(x) = w/2$, $w_4 = \Lambda - w/2$, and the area averaging condition yields

$$g_1 = wg/\Lambda \tag{17a}$$

and

$$g_2 = (1 - w/\Lambda)g \tag{17b}$$

where g is the total tooth height. After integration (16) becomes

$$\kappa_e = \frac{\omega^2\mu_0\epsilon_0(n_1^2 - n_2^2)N_e^2}{4\pi\beta_e m}\sin\left(\frac{\pi m w}{\Lambda}\right) \cdot \left\{g_2 + \frac{\sin(2g_2h)}{2h} + \frac{q}{h^2}[1 - \cos(2g_2h)] + \frac{q^2}{h^2}\left[g_2 - \frac{\sin(2g_2h)}{2h}\right] - \frac{1}{q}[1 - \exp(-2qg_1)]\right\}. \tag{18}$$

It should be recalled that this equation is valid only for small values of $|\kappa|$ which result when $|n_1^2 - n_2^2|$ and/or the ratio $g/\bar{t}$ are small.

The coupling coefficients for both TE and TM modes appear to be proportional to $n_1^2 - n_2^2 \simeq (n_1 - n_2)(n_1 + n_2)$, but this is only approximately true since h, g, β, and N depend on n_1 and n_2. Dependence on the Bragg-scattering order m is completely described by the term

$$\frac{\sin(\pi m w/\Lambda)}{m} \tag{19}$$

and for integral values of mw/Λ, κ is zero, e.g., w/Λ, = 0.5, and $m = 2, 4, 6, \cdots$. The variation of κ with $n_2 - n_3$, t (the central-layer thickness), w/Λ, and the transverse-mode number are not evident from a superficial examination of (18) since they influence g, h, β, and N, and therefore are best displayed by means of plots. Also although the variation of $|\kappa|$ with tooth height g is completely contained in the bracketed expression in (18) that dependence is rather complex and best exhibited graphically. In Fig. 13 we show the variation of κ with g for a SH GaAs laser at $\lambda_0 = 8500$ Å, $t = 2.0$ μm, $m = 3$, and various values of w/Λ. Actually, as noted above, t is measured from the tooth base and $\bar{t}$ used for the unperturbed modes is

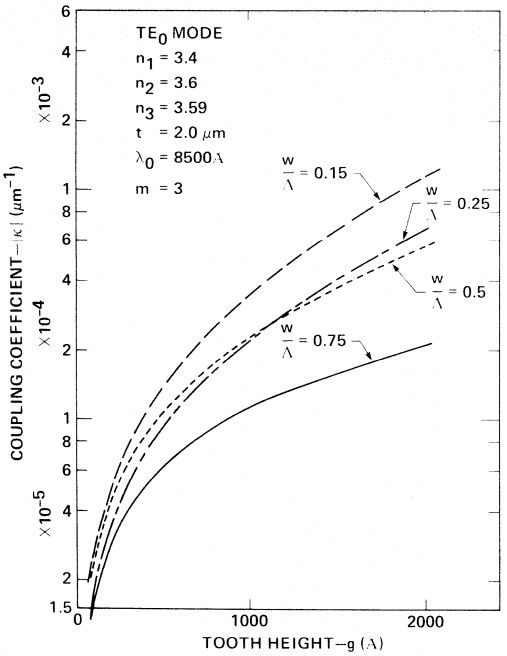

Fig. 13. Coupling coefficient versus tooth height for the TE_0 mode and rectangular teeth in a SH DFB diode laser.

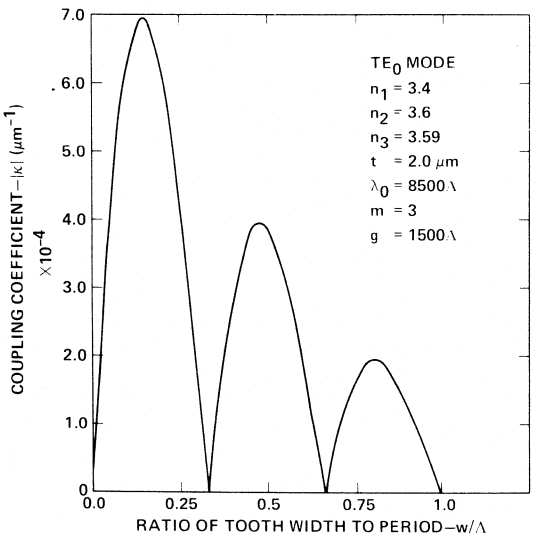

Fig. 14. Coupling coefficient versus the ratio of the tooth width to the period for a rectangular grating in a SH DFB diode laser operating in the TE_0 mode.

$$\bar{t} = t - g_1 = t - wg/\Lambda.$$

In this geometry only the TE_0 and TM_0[1] modes propagate and the latter coupling coefficient is approximately 0.9 of the former. For very small g the variation is linear, but this is not easy to detect on the semilog plot employed. Of the four values of w/Λ plotted, $w/\Lambda = 0.15$ yields the largest coupling coefficient, but actually the dependence of $|\kappa|$ on w/Λ is more complex. In Fig. 14 we plot $|\kappa|$ versus w/Λ for the same geometry with $g = 1500$ Å. The features exhibited by this plot depend on several factors. First, as w/Λ increases the boundary of the unperturbed modes and the teeth interact more and more with the evanescent part of the mode in region

[1] These were numbered as the first mode in our earlier papers.

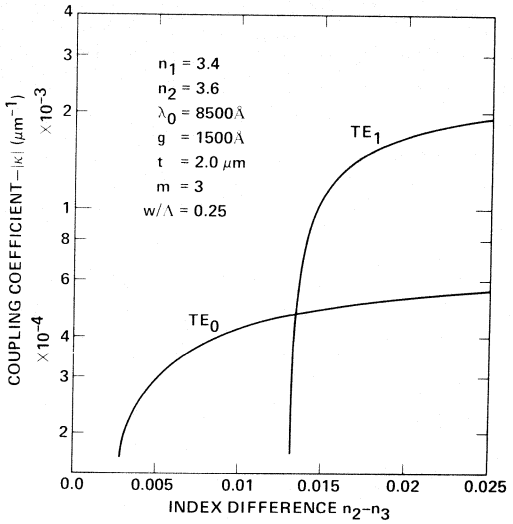

Fig. 15. Coupling coefficient versus index difference for the TE_0 and TE_1 modes and rectangular teeth in a SH DFB diode laser.

1 rather than the more intense oscillatory part of the mode in the center layer. This accounts for the general decrease in $|\kappa|$ with w/Λ. Second, as w/Λ changes there exist differing degrees of interference from various parts of the tooth along the z direction. This phenomenon accounts for the zeros in $|\kappa|$ [cf. (19)]. Finally, as w/Λ varies so too does $\bar{t}$, which changes the mode distribution. For $t = 2.0$ μm, the effect is to increase $|\kappa|$ for all w/Λ.

Fig. 15 is a plot of $|\kappa|$ versus $n_2 - n_3$ for TE modes in a SH diode laser. According to published results [13] the n-type GaAs index should be ~3.59 so that only the lowest mode will propagate. Note too that $|\kappa|$ becomes relatively independent of $n_2 - n_3$ once that index difference exceeds rather small values. Also as soon as the index difference becomes large enough to support two modes the second coupling coefficient exceeds the first. That this is generally the case is illustrated in Fig. 16 for a double-heterostructure geometry where κ is plotted versus t. The increase in coupling coefficient with transverse mode numbers occurs because well-confined higher order transverse modes have a greater fraction of their total energy in the vicinity of the corrugations. To take advantage of this fact the corrugation period should be selected to resonate these higher order transverse modes and thus achieve lower thresholds or use shorter lengths [3], [24].

Consider next a sinusoidal grating located symmetrically about the x and z axes. The integrals which result from substituting $w_i(x)$, $i = 1, 2, 3, 4$ in (16) can be evaluated either analytically after expanding $\mathcal{E}_e^2(x)$ in a power series or numerically. By employing the former procedure we obtain rapidly converging series for κ and plot $|\kappa|$ versus g for the TE_0 mode of a SH GaAs laser in Fig. 17. Also shown are plots of $|\kappa|$ versus g for rectangular teeth with $m = 1$ and 3. The coupling coefficients for $m = 1$ are of the same order of magnitude for rectangular and sinusoidal teeth; however, for $m = 3$, $|\kappa|$ is dramatically reduced with sinusoidal teeth in contrast to $|\kappa|$ for rectangular teeth. If, because of fabrication limitations, one can only produce teeth with a maximum aspect ratio g/Λ of say 0.5, then a third-order rectangular grating will yield a higher κ than its first-order counterpart, i.e., for $\Lambda = 3500$ Å, $g = 1750$ Å, $\kappa \simeq 5.6 \times 10^{-4}$ μm^{-1}, whereas with $\Lambda = 1167$ Å,

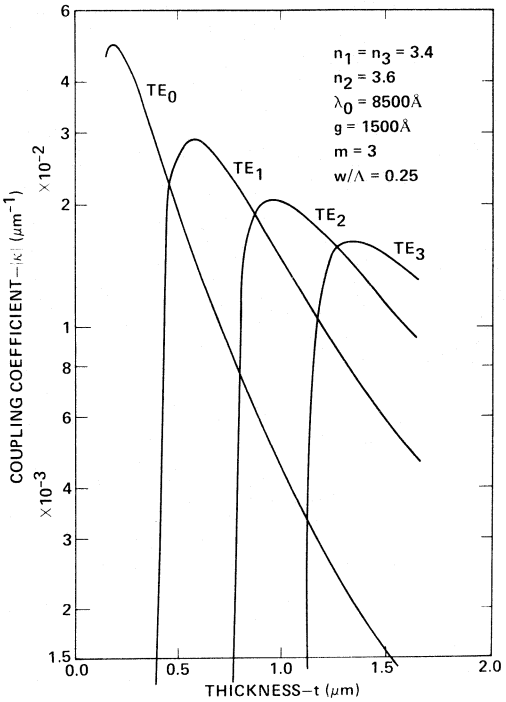

Fig. 16. Coupling coefficient versus active-region thickness for TE modes and rectangular teeth in a DH DFB diode laser.

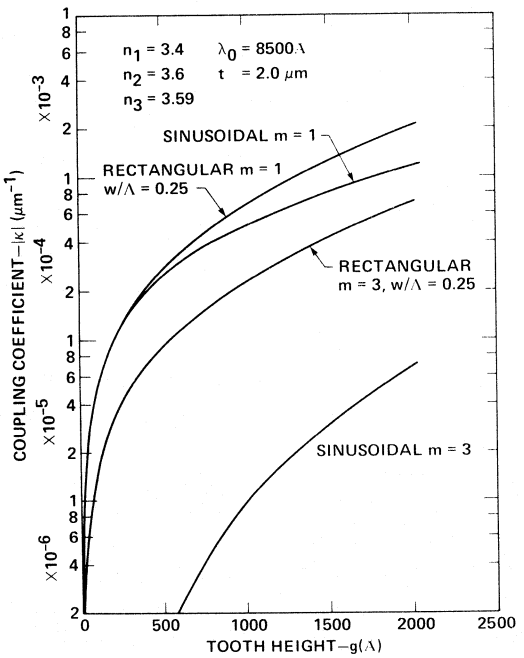

Fig. 17. Coupling coefficient versus tooth height for the TE_0 mode in a SH DFB diode laser with sinusoidal or rectangular teeth and first- or third-order Bragg scattering.

$g = 583$ Å, $\kappa \simeq 3.4 \times 10^{-4}\ \mu m^{-1}$. Of course the same is not true for other teeth shapes and the additional radiation losses which occur when higher order Bragg scattering is employed should also be taken into account.

According to Fig. 17 our rectangular grating with $m = 3$ and $g \simeq 1500$ Å, has $\kappa \simeq 4 \times 10^{-4}\ \mu m^{-1} = 4\ cm^{-1}$. Then from Fig. 11, for the 0.19-cm laser described in Section III (cf. Fig. 4) we require $\alpha_{th} \simeq 11\ cm^{-1}$. If the absorption and radiation losses are approximately $\alpha_{abs} \simeq 10\ cm^{-1}$ and $\alpha_{rad} \simeq 5\ cm^{-1}$ the gain at threshold is $g_{th} \simeq 26\ cm^{-1}$. Since for SH GaAs lasers [13]

$$g_{th} \simeq 30 \frac{cm}{kA} \times J_{th}$$

we obtain

$$J_{th} \simeq \frac{26}{30} \frac{kA}{cm^2} = 866 \frac{A}{cm^2}$$

which agrees well with the experimentally measured threshold value of 775 A/cm^2 reported earlier in this paper.

V. Conclusion

We have presented and discussed our fabrication technique's experimental results, and calculations of coupling coefficients for SH DFB lasers.

Semiconductor Lasers with the Light Output Through the Diffraction Grating on the Surface of the Waveguide Layer

ZH. I. ALFEROV, V. M. ANDREYEV, S. A. GUREVICH, R. F. KAZARINOV, V. R. LARIONOV, M. N. MIZEROV, AND E. L. PORTNOY

Abstract—In AlAs–GaAs semiconductor heterojunction lasers, due to the interaction of the waveguide modes with a diffraction grating on the surface of the waveguide layer, output of coherent radiation has been obtained through the plane parallel to the layer.

The angle of divergence of the radiation in this case was equal to 0.5° both with optical and injection pumping. The possibility of fabricating a new type of semiconductor laser with small radiation divergence has been proven experimentally.

COHERENT radiation in semiconductor lasers is usually generated in a thin active layer and is emitted through its cleaved facets. Diffraction divergence as large as several tens of degrees has been measured because of the extremely small radiating aperture. In order to reduce the diffraction divergence of radiation, it is necessary to increase the area of the radiating aperture. This can be achieved by coupling the radiation out through a surface parallel to the waveguide layer. With this aim, the diffraction grating was imbedded at the waveguide surface and radiation was coupled out due to the interaction between the waveguide modes and the grating [1].

Manuscript received December 16, 1974.
The authors are with the A. F. Ioffee Physico-Technical Institute, Leningrad, USSR.

This report concerns the experimental investigation of the possibility of coupling out coherent radiation at an angle to the waveguide surface, both by optical and injection pumping.

For the case of optical pumping two layers were grown in succession on a GaAs substrate oriented in the (100) plane, the first layer was an 80-μm-thick layer of n-$Al_{0.3}Ga_{0.7}As$ and the second layer was a 2-μm-thick layer of n-GaAs ($N_d = 10^{17}$ cm^{-3}). After growth the substrate was removed with a selective etch in order to observe the radiation coupled out through the n-$Al_{0.3}Ga_{0.7}As$ layer. The diffraction grating was made on the waveguide layer surface by using an interference photoetching technique [2]. The period of the grating is given by

$$|\sin \alpha| = n - \frac{\lambda_0}{a} \tag{1}$$

where α is the angle of radiation coupled out into the air, n is the refractive index of GaAs, λ_0 is the oscillation wavelength in a vacuum, and a is the grating period. Feedback is achieved by using the cleaved facets of the platelet as the Fabry–Perot resonator (Fig. 1).

The radiation spectra in the plane, perpendicular to the cleaved facets and the diffraction grating, represent two narrow peaks symmetrical, with respect to the normal, to the

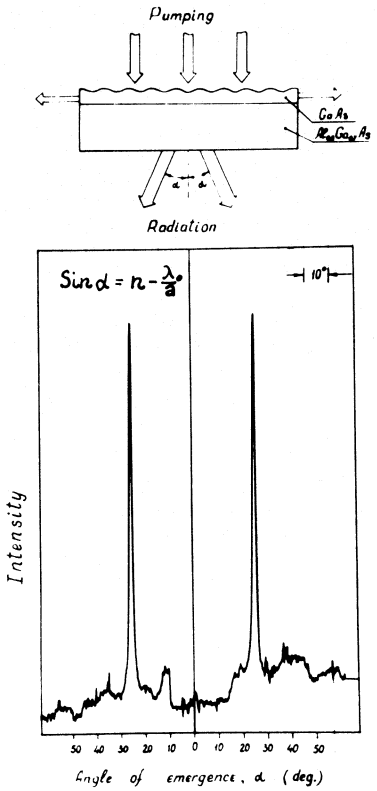

Fig. 1. A spectrum of distributed space radiation in a plane perpendicular to the cleaved facets and the diffraction grating by optical pumping.

waveguide surface (Fig. 1). The half-width of each of these peaks $\Delta\alpha$ is equal to 0.01 rad [3]. This value of divergence is determined by the multimode character of oscillation

$$\Delta\alpha = \frac{\Delta\lambda_0}{a \cdot \cos\alpha} \cdot \tag{2}$$

Measurements were performed at 77 K and 300 K and the samples were pumped by a pulse laser with a radiation wavelength of 3300 Å.

For injection pumping of the waveguide layer, specimens of low-threshold DH lasers with an undoped n-GaAs active layer were used [4]. In the central part of the laser on the side of the p-emitter, a window was etched right to the waveguide layer (Fig. 2). Then a diffraction grating with a period of $a = 0.22$ μm was etched at the waveguide surface (Fig. 3). As in the case of optical pumping, cleaved facets of the specimen parallel to grating lines served as a resonator, whereas the other two facets were saw cut. Current pulses were 100 ns at 300 K.

The radiation emitted through the window from the grating region were two pairs of narrow visible beams symmetrical with respect to the normal of the radiating surface. Their angular position is determined by the value of the longitudinal wave-vector components in the passive region of the waveguide K_m, and also by the grating period and the oscillation wavelength λ_0

$$\sin\alpha = \left| \frac{K_m - \beta}{K_0} \right| \tag{3}$$

where $\beta = 2\pi/a$, $K_m = 2\pi n_m/\lambda_0$, and $K_0 = 2\pi/\lambda_0$. Here n_m is

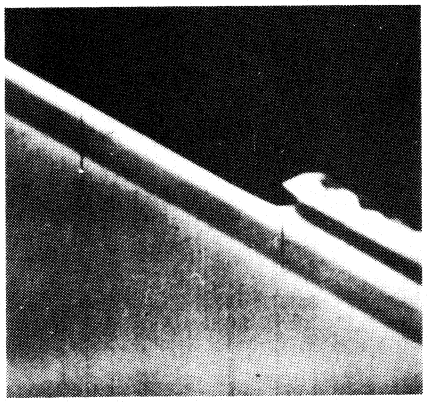

Fig. 2. A photograph of a four-layer heterolaser-structure cleaved facet locally etched down to the narrow-gap active layer 2 μm thick.

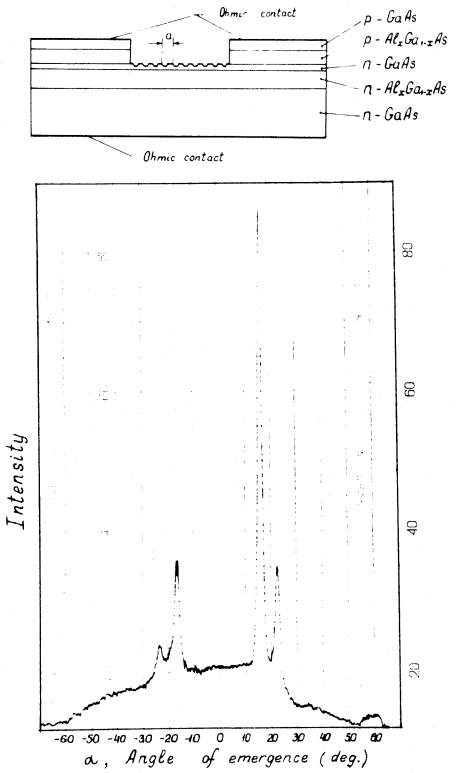

Fig. 3. An injection-laser spectrum with the diffraction grating on the surface of the waveguide layer and the diagram of distributed space radiation in a plane perpendicular to the cleaved facets and the diffraction grating.

the effective refractive index for the mode with transverse index m. Angular divergence for each beam was ~0.5° and was determined by the width of the oscillation line, corresponding to the case of optical pumping.

In spite of the resonator having a passive region, the threshold current of the structure in Fig. 3 was not significantly higher than that of conventional DH lasers without the passive region. The reason for this is due to the forbidden gap-width-narrowing effect [5] in regions of a high injection level. This allows the oscillation line to shift into the region of energies less than the forbidden gap width of the material in the passive region of the waveguide.

The forbidden gap-narrowing effect is easily observed in

lasers with constant composition in the undoped active layer. When we use the ordinary "sliding" boat construction for obtaining heterolaser structures there occurs a partial transferrence of Al into the melt from which the crystallization of the narrow-band active layer is grown. This leads to an inhomogeneity of the active-layer composition and to the shift of the generated radiation energy to a shorter wavelength region. To avoid this peculiarity we developed a boat construction in which the substitution of melts onto the substrate is not performed by shifting the substrate under melts of different composition, but by a compulsory displacement of one melt by another. By way of multiple melt substitution we manage to obtain a nearly complete homogeneity of the active-region composition with the generation energy equal to 1.39 eV when the undoped n-GaAs is grown. In this case, the energy of the coherent radiation is less than that of the absorption edge [6]. The corrugated passive region in this case does not yield absorption losses.

The proposed combination of an active region of the heterolaser structure occurring under ohmic contact and a corrugated passive region of the waveguide may be of use when fabricating injection distributed-feedback heterolasers. If the grating period is a multiple of half-wavelengths of light in the waveguide, the passive region of the heterolaser structure will serve as mirrors.

Grating-Coupled Double-Heterostructure AlGaAs Diode Lasers

P. ZORY, MEMBER, IEEE, AND L. D. COMERFORD, ASSOCIATE MEMBER, IEEE

Abstract—**Corrugated AlGaAs waveguide devices have been fabricated which emit low-divergence (~1° by 15°) laser beams nearly normal to the waveguide plane when pulsed electrically at room temperature. The devices are fabricated from material which is essentially the same as that used to fabricate CW room-temperature lasers, differing only in that the two top layers of AlGaAs and GaAs are very thin (~0.4 μm and 0.1 μm, respectively). Threshold current densities of 3000–4000 A/cm^2 are typical in these devices even though ~20 percent of the resonator length is unpumped. The far-field pattern produced by the TE polarized leaky-wave laser beams emanating from the unpumped region is usually composed of two mode lines. A theory is outlined which describes how these mode lines are generated. The possibility of obtaining distributed-feedback (DFB) oscillation in devices of this type is also discussed.**

I. Introduction

SOME of the basic properties of spatially periodic, grating-like structures utilized to couple light into and out of optical waveguides have been discussed recently by Ulrich [1]. There are basically two types: one which utilizes a corrugated grating-type structure [2]; and the other which utilizes a thick Bragg-grating-type structure [3]. The grating-coupler section(s) of a waveguide can also be utilized to couple light between guided modes in both the forward and backward directions. In addition, this guided mode coupling can occur simultaneously with input–output coupling. These coupling processes can be operative in various combinations in a grating-coupled (GC) waveguide laser, that is, a waveguide laser with a built-in grating(s), and can greatly influence its behavior.

In the first experiments with GC lasers [4], gratings of the thick Bragg type were integrated into the light-amplifying medium and were utilized to provide the feedback necessary for oscillation. Devices of this type are known as distributed-feedback (DFB) lasers. In subsequent experiments [5], gratings of the corrugated type were utilized to provide both DFB lasing and leaky-wave output coupling in optical waveguides. Grating structures which provide both DFB and leaky-wave output coupling are limited primarily to the corrugated types since it is difficult to fabricate high-quality "interleaved" Bragg gratings (two or more sets of diffracting planes) into potentially practical light-amplifying waveguides.

The possibility of corrugating double-heterostructure (DH) AlGaAs diode lasers in order to obtain low-divergence output beams has been a subject of considerable speculation over the last few years and has been discussed in some detail by Kazarinov and Suris [6]. If the device is designed so that first-order diffraction gives rise to a leaky-wave output beam(s) nearly normal to the plane of the waveguide, then the possibility exists that the DFB due to second-order backward diffraction within the waveguide [7] will be an important factor in determining the operational characteristics of the device even though the dominant feedback for oscillation is derived from

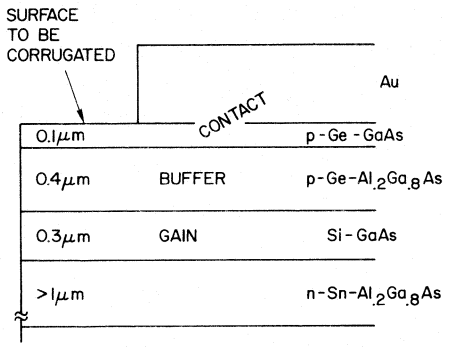

Fig. 1. Structure of the double-heterojunction material used to fabricate the GC diode lasers.

the mirror-like end facets [8]. AlGaAs devices which utilize third-order DFB for oscillation cannot generally emit output beams across the plane of the waveguide since the first- and second-order diffracted waves are trapped by total internal reflection within the planar structure. Such nonleaky DFB diode devices have been fabricated in single-heterojunction [9], homojunction [10], and DH configurations [11] and made operational in the vicinity of 100 K.

In this paper we report on the theory and observed behavior of corrugated DH-AlGaAs diode lasers which emit low-divergence (in one dimension) leaky-wave laser beams nearly normal to the waveguide plane when pulsed electrically at room temperature. The behavorial characteristics of other similar devices are also reported on in this journal (Alferov *et al.*). A recent publication [12] has reported the observation of a low-divergence output beam from a corrugated single-heterojunction diode laser cooled to 77 K. This device apparently behaves in a fashion similar to the corrugated fourth-order DFB dye-laser devices described in [5], although the presence of high-reflectivity coatings on the cleaved end facets tends to make it difficult to prove that the DFB mechanism is operable.

In Section II of this paper, the behavior of the TE_0-mode gain coefficient in thin buffer-layer DH material (see Fig. 1) is considered and the mode-coupling processes which can occur when material of this type is corrugated are described. In Section III, the device fabrication techniques utilized are briefly outlined and the operational characteristics of typical devices discussed. These are summarized as follows: 1) the leaky-wave laser beams are usually two in number and are emitted in directions nearly normal to the waveguide plane; 2) each beam has a rectangular divergence of about 1° by 15°; and 3) threshold current densities usually fall in the 3000–4000-A/cm^2 range even though the central region of the laser resonator (~70 μm long by 60 μm wide) is unpumped.

II. Theory

The main problem in fabricating low-threshold GC diode lasers is that of fabricating a diffraction grating sufficiently close to the gain layer to be functional without disrupting the injection and radiative recombination processes taking place in that layer. Since function in the case discussed here refers mainly to leaky-wave output coupling rather than DFB oscillation, the problem can be solved simply by fabricating the grating far from the gain layer as depicted in Fig. 1. The structural design shown is essentially the same as is used to make CW room-temperature diode lasers except that the p-AlGaAs buffer layer and the p-GaAs part of the contact are both much thinner than their usual values of about 1 μm [13]. Before discussing the details of the grating coupling processes, it is instructive to demonstrate that prior to grating fabrication, this configuration is not substantially lossy. This is accomplished using the upper curve in Fig. 2 which is a plot of the dependence of the TE_0-mode gain coefficient on buffer-layer thickness for the case where the contact layer is gold[1] (see the Appendix for details of the calculation). If it is assumed that the 0.3-μm-thick layer of silicon-doped GaAs has a gain coefficient of 25 cm^{-1}, then the gain available to the TE_0 mode of the structure for large buffer thickness is about 17 cm^{-1}. The 17/25 ratio is just a measure of how well the TE_0-mode field distribution overlaps the gain layer when the aluminum-gallium ratio in the layers above and below the gain layer is 0.25. If the contact layer is gold, it is seen that the TE_0-mode gain coefficient does not begin to drop substantially until the buffer thickness is less than 0.2 μm. In fact, the TE_0-mode gain coefficient reaches a maximum value when the buffer thickness is about 0.7 μm. This peaking behavior occurs because the absorptive loss introduced by bringing the gold contact closer to the gain layer is more than offset by the increase in mode overlap with the gain layer. The very thin layer (0.1 μm) of p-GaAs shown in Fig. 1 is incorporated into the design primarily for contacting purposes. It is expected that the loss factor associated with this thin layer is negligible in comparison to the loss factor introduced by the diffraction grating (see Section III). The addition of a layer of optical-quality gold on top of the grating should not, according to the data of Fig. 2, add any additional loss other than that due to the increased diffraction efficiency of the corrugated interface. If the contact layer is thick GaAs, as is the case in typical DH diode lasers, then the TE_0-mode gain coefficient begins to drop rapidly when the buffer-layer thickness approaches 0.7 μm (lower curve in Fig. 2). This phenomenon, commonly observed in internal reflection spectroscopy [14], is due primarily to leaky-wave excitation [15] rather than absorptive loss and is the basis for explaining the operation of prism couplers [16], [17].

If it is assumed that a grating of sinusoidal cross section is fabricated into the surface of an AlGaAs buffer layer, and that the grating is of amplitude a and period $d = \lambda/n_0$ (where n_0 is the effective refractive index of the TE_0 mode at vacuum wavelength λ), then an approximate expression for the power-loss coefficient due to first-order (−1) leaky-wave excitation normal to the waveguide plane is [18]

$$\alpha_0^{(-1)} \cong (ka)^2 \frac{n_g^2 - n_0^2}{2n_0 w_0} (n_b - \delta_c) \exp(-2p_0 t_b). \quad (1)$$

In this expression k is equal to $2\pi/\lambda$, n_g and n_b are the refractive indices (real parts) of the gain and buffer layers, δ_c is equal to 1 or 0 depending on whether the contact layer is air

[1] In the calculation, it is assumed that the 0.1-μm-thick GaAs layer shown in Fig. 1 is nonexistent.

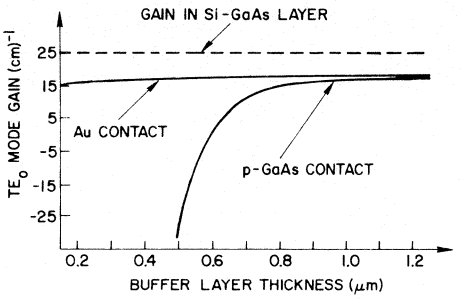

Fig. 2; Dependence of the TE_0-mode gain coefficient on buffer-layer thickness for the cases where the contact (defined in Fig. 1) is either gold or thick GaAs.

or gold, p_0 is the exponential decay factor of the TE_0 mode in the buffer layer, t_b is the buffer-layer thickness, and w_0 is the effective waveguide thickness or mode width $\equiv(2/p_0) + t_g$ (gain-layer thickness).

If $\delta_c = 1$ in (1), implying an AlGaAs-air corrugated interface, then two oppositely directed leaky waves are generated from unidirectional TE_0 light propagating in the waveguide. The wave which appears on the air side of the interface is called the transmitted leaky wave and the one which appears on the AlGaAs side of the interface is called the reflected leaky wave. The sum of the loss coefficients due to the transmitted leaky wave $\alpha_0^{(-1T)}$ and the reflected leaky wave $\alpha_0^{(-1R)}$ is equal to the expression for $\alpha_0^{(-1)}$ given in (1). They are related by the equation [18]

$$\alpha_0^{(-1R)} = n_b \alpha_0^{(-1T)}. \tag{2}$$

If it is assumed that $ka = 0.31$ (about one-half the maximum value which can be achieved if selective etching is used to make the grating [19]) and that t_b is 415 nm, then $\alpha_0^{(-1T)}$ is about 1 cm^{-1} (see the Appendix for other values used in the computation). This implies that in this configuration it takes a distance of 100 μm to convert about 1 percent of the power in a unidirectional TE_0 mode into transmitted leaky-wave power traveling normal to the waveguide plane. Although the loss coefficient associated with the reflected leaky wave is about 3.5 times larger than that associated with the transmitted leaky wave, the reflected wave is not easily utilized since its emission direction is into the relatively thick (~100-μm) lossy GaAs substrate normally present in these devices. If $\delta_c = 0$ in (1), implying an AlGaAs-gold corrugated interface, then only one leaky wave is generated, the reflected leaky wave. In this case, the associated loss coefficient $\alpha_0^{(-1R)} = \alpha_0^{(-1)}$ is equal to about 6 cm^{-1}. Since its direction is the same as the reflected leaky wave generated at the AlGaAs-air corrugated interface, the power in the beam cannot be fully utilized unless a window is opened for its exit through the lossy GaAs substrate. The evanescent wave interaction giving rise to these leaky waves is depicted in Fig. 3 for the case where two counter-running TE_0 waves, R_0 and S_0, are propagating in the waveguide. In drawing Fig. 3, it has been assumed that λ is not quite equal to $n_0 d$, as was previously assumed. In this case, the leaky waves associated with R_0 and S_0, viz., $R_0^{(-1)}$ and $S_0^{(-1)}$, are not emitted normal to the waveguide plane, and consequently are distinguishable from each other. The emis-

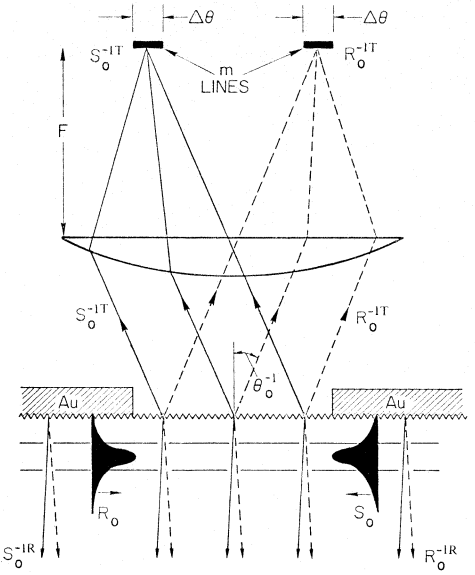

Fig. 3. Leaky waves $R_0^{(-1)}$ and $S_0^{(-1)}$ generated by the evanescent wave interaction of the counter-propagating waves R_0 and S_0 with the corrugated interface. $R_0^{(-1T)}$ and $S_0^{(-1T)}$ have spot sizes in the focal plane of the lens equal to the product of the lens focal length F and the beam divergence $\Delta\theta$. Aperture A mentioned in text is the opening between the gold contact pads.

sion angle $\theta_0^{(-1)}$ for first-order leaky waves which escape into the air (in this case, the transmitted leaky waves emitted through aperture A, viz., $R_0^{(-1T)}$ and $S_0^{(-1T)}$), is given by [5]

$$\sin\theta_0^{(-1)} = n_0 - \frac{\lambda}{d}. \tag{3}$$

For the case shown it is assumed that $n_0 \gtrsim \lambda/d$, so that the leaky waves are forward waves rather than backward waves. A forward leaky wave is one whose component in the plane of the waveguide has the same direction as the guided wave from which it is generated [15].

Since each leaky wave has a well-defined emission direction, they can be focused to different locations in the back focal plane of a lens as shown in Fig. 3. The spot size ΔX, or equivalently the beam divergence, $\Delta\theta \equiv \Delta X/F$, depends on a superposition of two divergence functions: $\Delta\theta(A)$—the divergence due to the finite spatial width A of the output aperture A; and $\Delta\theta(\Delta\lambda)$—the divergence due basically to the finite spectral width $\Delta\lambda$ of the laser oscillation.[2] An approximate expression for $\Delta\theta(A)$ is [20]

$$\Delta\theta(A) \cong \lambda/A \tag{4}$$

and an approximate expression for $\Delta\theta(\Delta\lambda)$, obtained from (3), is

$$\Delta\theta(\Delta\lambda) \cong |\Delta n(\Delta\lambda)| + |\Delta\lambda/d|. \tag{5}$$

In writing (5), it has been assumed that the mode dispersion is normal, i.e., n increases as λ decreases, so that the two terms on the right-hand side of (5) always add. In typical AlGaAs lasers, the dispersion term $\Delta n(\Delta\lambda)$ is dominated by the $\Delta\lambda/d$

[2] In computing $\Delta\theta(\Delta\lambda)$ for a given laser, it will be assumed that $\Delta\lambda$ is equal to the full width at half height of the laser-power spectral-envelope function.

term. If the output aperture is large and the laser bandwidth is small, output beams with very low divergence will be obtained. For example, the leaky waves generated in the corrugated DFB dye-laser devices described in [5] had measured divergences of less than 0.002°. If beam width in the lateral dimension of the waveguide is narrow (due, for example, to filamentary lasing), then the two focused spots of width $\Delta\theta$ shown in Fig. 3 will appear as two lines of width $\Delta\theta$ when viewed along the waveguide normal. Lines of this type, usually called mode lines or ***m*** lines [21] can be utilized to provide a great deal of information about the nature and behavior of such devices, especially those that support two or more transverse modes.

If $n_0 = \lambda/d$, then $\sin\theta_0^{(-1)}$ is equal to zero and all $R_0^{(-1)}$ and $S_0^{(-1)}$ leaky waves are directed precisely normal to the waveguide plane. In this situation, the two ***m*** lines in Fig. 3 coalesce into one ***m*** line in the center of the field and the second-order diffracted wave $R_0^{(-2)}$ feeds energy into S_0 while $S_0^{(-2)}$ feeds energy into R_0. Using the same assumptions and symbol definitions as those used in deriving (1), an expression can be derived for the backward-coupling coefficient specifying this second-order DFB process [18]

$$\kappa_{00}^{(-2)} \cong (ka)^2 \frac{n_g^2 - n_0^2}{2n_0 w_0} \sqrt{0.5(n_b^2 - \Delta_c)} \exp(-p_0 t_b). \qquad (6)$$

The new symbol Δ_c is equal to $+n_b$ or $-2(5.3)^2$ depending on whether the corrugated interface is AlGaAs-air or AlGaAs-gold, respectively. The argument of the exponential decay term has the value $(-p_0 t_b)$ rather than the value $(-2p_0 t_b)$ used in (1) since $\kappa_{00}^{(-2)}$ describes a coupling between mode amplitudes [22]. Using the same values as used in evaluating (1), we obtain $\kappa_{00}^{(-2)} \cong 26\ \text{cm}^{-1}$ for an AlGaAs-air corrugated interface and $\kappa_{00}^{(-2)} \cong 73\ \text{cm}^{-1}$ for an AlGaAs-gold corrugated interface. Although these values are fairly large, it is the product of $\kappa_{00}^{(-2)}$ with L, the device length, that determines to a large extent the degree to which the DFB mechanism influences device behavior. For example, it can be shown using the theory of Kogelnik and Shank [22] that the threshold for DFB oscillation is equal to the threshold for cleaved-facet mirror-feedback (MFB) oscillation in GaAs lasers when $\kappa L \cong 3.5$. Consequently, if the value of $\kappa_{00}^{(-2)}$ is less than $100\ \text{cm}^{-1}$ and device lengths are less than 350 μm, as is true for the devices in our experiments, cleaved-facet MFB oscillation will occur at lower pump currents than DFB oscillation. Of course, what actually happens in devices where the DFB and MFB mechanisms are comparable in strength can be quite varied depending on such factors as the differences between the frequency of peak gain and the resonant DFB frequency and the longitudinal mode frequencies [8], [23], [24], gain saturation [25], etc. For example, if we assume that $n_0 d$ is not equal to the peak-power MFB oscillation wavelength but is within a few nanometers of this value, then both DFB and MFB oscillation might be obtained separately. In this case, one would observe two ***m*** lines due to MFB oscillation as shown in Fig. 3 and one ***m*** line in the center of the field due to DFB oscillation. Some of the GC lasers studied in our experiments satisfied this "few nanometer" criterion, but none of them showed a single ***m*** line in the center of the far field even at high-current drive levels. These results are discussed in more detail in the next section. The reader will be able to follow the flow of the presentation in Section III more easily if he keeps in mind that the experimental approach was to attempt to fabricate GC TE_0 diode lasers which emit transmitted leaky waves normal to the waveguide plane—single ***m*** line devices. The longitudinal modes of such devices will normally give rise to unresolved fine structure within the ***m*** line.

III. Device Fabrication and Experimental Results

As discussed in Section II, GC lasers which emit leaky waves normal to the waveguide plane satisfy the relation $\lambda = n_0 d$. Consequently, in order to determine the corrugation period d to be fabricated into the DH material used to make these devices (see Fig. 1), one must know the wavelength λ that the material prefers to lase at and the effective refractive index n_0 of the TE_0 mode of the DH waveguide. The TM_0 mode is not considered since material of this type almost invariably lases on the TE_0 mode of the waveguide. The procedure then is to measure the output λ of some conventionally fabricated diodes and to estimate n_0 using calculation techniques described in the previous section. A grating with period $d = \lambda/n_0$ is then fabricated onto a piece of the DH material using the selective etching techniques described in [19]. In our case, the measured λ was in the vicinity of 865 nm and n_0 was the calculated value 3.532 for the model shown in Fig. 1. Consequently, a grating with $d = 244.9 \pm 0.1$ nm was fabricated.

The next procedure is to spin photoresist onto the corrugated wafer and open up a periodic array of holes into which 500-nm-thick gold contact pads are electroplated. It is important, of course, that the surface be properly cleaned and that a high-quality gold electroplating solution be used if good contacts are to be obtained. After plating and cleaning, a new layer of photoresist is spun onto the material and a parallel array of slots is opened between the contact pads. An etchant is then utilized to remove sufficient material at the bottom of the slots so that the resulting grooves electrically isolate the individual lasers on bars cleaved from this material. An operating GC diode laser on one such bar is shown in Fig. 4. The photograph was obtained from a TV monitor screen connected to an infrared-sensitive camera which views the laser through magnifying optics. The 70-μm dimension is the width of the output aperture A described in Section II and shown in a side view in Fig. 3. The bright-dark striations observed across the output aperture are due to interference effects in the glass plate covering the photocathode of the TV camera.

The main features of device operation which can be observed in Fig. 4 are: 1) the device lases in filaments; and 2) the strongest filaments tend to lase along the edges of the electroplated gold pads. These features were characteristic of almost all the GC lasers studied in the experiments. The particular device shown is lasing with a pulsed drive current twice its threshold drive current of 250 mA/pad. This corresponds to a threshold current density of about 3300 A/cm^2 since the dimensions of both contact pads are about 60 μm by 125 μm. The threshold current density for single-pad pumping was about 14 500 A/cm^2. On the other hand, uncorrugated de-

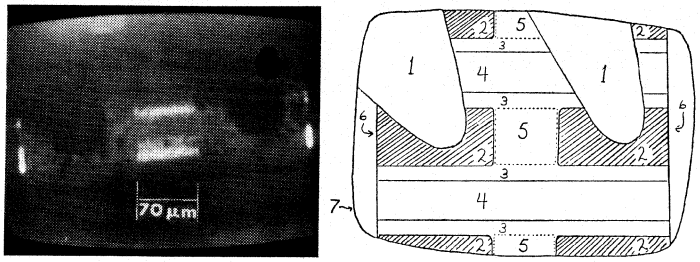

Fig. 4. Left: top view of an operating GC diode laser. It is located on a cleaved bar with several similar devices. The various features are numbered in the diagram on the right. 1) Contacting pins. 2) Gold contact pads. 3) Corrugated mesa surface. 4) Electrical isolation grooves. 5) Output aperture for transmitted leaky waves. Brightness distribution in corresponding area in photo at left indicates that lasing filaments along edges of contact pads are strongest. 6) Cleaved facets. Bright spots along cleaved facets in photo at left are due to scattered light coupled out from lasing filaments. 7) Edge of TV monitor screen.

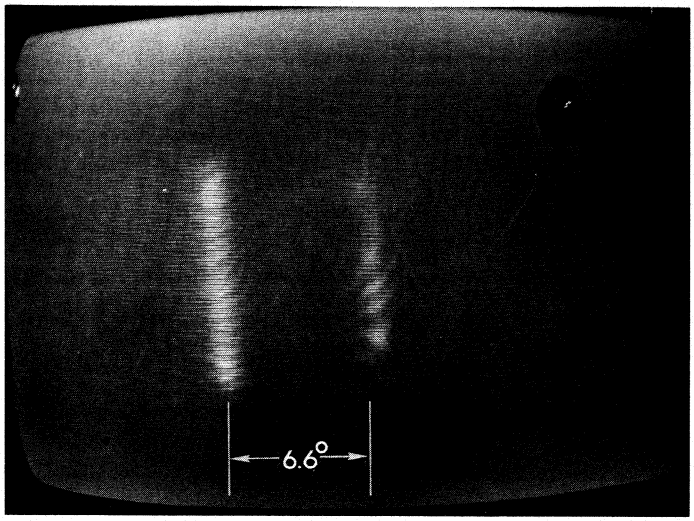

Fig. 5. Far-field pattern of the GC diode laser shown in Fig. 4. The two mode lines (*m* lines) are 6.6° apart and the beam divergence obtained from the left *m* line is about 1.2° by 11°.

vices with about the same cavity length and no openings in the contact layer had typical threshold current densities in the vicinity of 2000 A/cm^2. The current pulses used in all these experiments were bell shaped with a full width at half current of 450 ns. By changing the magnifying optics appropriately, the far field of the laser shown in Fig. 4 could be imaged onto the photocathode of the TV camera. A photograph of the TV screen in this case is shown in Fig. 5. As can be observed, the far field consists basically of two *m* lines of the type described in Section II. The bright–dark striations are due to the same interference effects as occur in the near-field photograph in Fig. 4. The angular scale is determined with good accuracy by replacing the laser with a photolithographically fabricated double slit which, when illuminated by a He–Ne laser, produces the well-known Young's double-slit interference pattern on the TV screen.

Before proceeding to discuss the fact that two *m* lines rather than one are observed and that they have different relative intensities, it is instructive first to compare the linewidth of the well-resolved *m* line on the left in Fig. 5 with the values calculated using (4) and (5). From (4), $\Delta\theta(A) \cong 0.7°$, and from (5), $\Delta\theta(\Delta\lambda) \cong 0.9°$. In evaluating (5), it was assumed that the $\Delta\lambda/d$ term was 4 times larger than the dispersion term and that $\Delta\lambda$ was approximately equal to 3 nm, the measured value. The theoretical value of $\Delta\theta$ to be compared with the measured $\Delta\theta$ is expected to be somewhat greater than 0.9° although its exact value is not easy to predict. The relatively large value obtained from Fig. 5, $\Delta\theta \cong 1.2°$, is easily accounted for if several filaments are lasing and the dispersion term is effectively larger due to mode-pushing effects. This view is supported by the fact that the higher threshold GC devices which tended to run in one or two well-separated filaments had *m* lines usually about 1° in width. The *m* line length of about 11° in Fig. 5 indicates, using (4), that the lasing filaments are about 4.5 μm wide. Most of the higher threshold devices measured had *m* line lengths in the vicinity of 15°, implying filament widths of about 3.3 μm.

Assuming that the two *m* lines of Fig. 5 are derived from $R_0^{(-1T)}$ and $S_0^{(-1T)}$ leaky waves, as shown in Fig. 3, then the fact that one line is weaker implies that R_0 is stronger than S_0 or vice versa. This was verified by noting that when one of the contacting pins shown in Fig. 4 was removed and the current through the other pad increased sufficiently to get strong lasing, the weak line disappeared almost completely. When the removed contacting pin was cleaned and replaced, both *m* lines were observed and were almost equally bright. The new threshold current in this case was only slightly lower than that previously stated. The fact that one *m* line disappears when one pad is pumped implies that the unpumped waveguide in this material is quite lossy since the wave traveling through the unpumped region is apparently reduced in intensity by at least an order of magnitude rather than the factor of 4 or so that would be expected from the cleaved facet and leaky-wave losses.

The question as to why two *m* lines are observed rather than one *m* line as predicted by the design criterion, $\lambda = n_0 d$, is best answered by assuming that the value of n_0 used in the design was incorrect. This assumption implies that the DH waveguide in the laser of Fig. 4 is not the same as the theoretical model shown in Fig. 1. Detailed scanning electron microscope (SEM) measurements on the cleaved facet of the laser in Fig. 4 showed in fact that the gain-layer thickness was very close to 0.2 μm rather than the 0.3 μm expected. The buffer-layer thickness, somewhat difficult to measure due to edge noise, was about the expected thickness of 0.42 μm. In addition, photoluminescence measurements on a beveled piece of the DH material indicated that more aluminum was present than assumed in the model—about 30 percent in the n-AlGaAs layer and about 25 percent in the buffer layer. Making the appropriate changes in the resonance equation parameters listed in the Appendix, and using the observed peak-power wavelength of 867 nm, a new value of the effective refractive index of the mode was obtained, $n_0 = 3.487$. Using these values in (3), one obtains $\theta_0^{(-1)} = -3.0°$, in good agreement with the measured value of 3.3° obtained from Fig. 5. The negative sign in front of the theoretical value of $\theta_0^{(-1)}$ arises because $n_0 < \lambda/d$ and, as mentioned in Section II, implies the existence of backward leaky waves. This was verified in the

single-pad pumping experiment previously described by relating the position of the single ***m*** line in the far field to the known direction of propagation within the waveguide of the strong component of the lasing mode giving rise to this ***m*** line.

Since the peak-power wavelength in the previously mentioned device was 867 nm, one would not expect the DFB mechanism to be operable since the DFB resonant wavelength of $n_0 d = 854$ nm would be too far removed from the peak gain region. However, other GC lasers fabricated from the same corrugated material had peak-power wavelengths and ***m*** line separations in the vicinity of 859 nm and 2°, respectively, consistent with the same $n_0 d$ previously given. As discussed at the end of Section II, one might expect that an 859 nm-2° device driven at high current would exhibit a single DFB ***m*** line between the two MFB ***m*** lines since there should be some gain available at 854 nm. Since such behavior was not observed and since the spectral width (full width at half laser power) for all devices was in the vicinity of 3 nm, it was concluded that the DFB mechanism was not operable in any of these devices.[3] This conclusion does not prove that the DFB mechanism could not be operable in devices with the theoretical coupling coefficients calculated in Section II since the detailed leaky-wave output power and corrugation-depth measurements needed to verify the existence of the coupling coefficients in our devices were not performed in this series of experiments.

IV. Conclusions

Corrugated DH-AlGaAs diode lasers were fabricated and low-divergence (in one dimension) leaky-wave output beams were observed when the devices were electrically pulsed at room temperature. It was concluded from ***m*** line and wavelength measurements that the DFB mechanism was not operable in the devices examined. From a practical point of view, it would be desirable to have a sufficiently strong DFB mechanism so that only one low-divergence narrow-bandwidth leaky laser beam would be emitted precisely normal to the plane of the waveguide. In addition, it would be desirable to cover aperture A with a gold contact (Fig. 3), cover the cleaved facets with a high-reflectivity protective coating, and exit the reflected leaky wave through a hole in the GaAs substrate. Based on these experiments, it appears that it may be possible to fabricate CW room-temperature devices of this type. Such devices would prove useful in optical communications and other applications where low-divergence laser beams are of importance.

Appendix

The two TE_0-mode gain-coefficient dependences on buffer-layer thickness (t_b) shown in Fig. 2 are obtained from exact solutions of the four-layer waveguide resonance equation [26] under the following assumptions:

1) the two contact layers and the lower n-AlGaAs layer are very thick;
2) the gain layer is 0.3 μm thick, as shown in Fig. 1;
3) the complex refractive indices of the layers at vacuum wavelength $\lambda = 865$ nm are [27], [28]: GaAs contact layer $n_c = 3.60 - (0.001)i$; gold contact layer $n_c = 0.16 - (5.3)i$; buffer layer and n-$Al_{0.2}Ga_{0.8}As$ layer $n_b = 3.47$; gain layer $n_g = 3.60 + (0.0017)i$.

The values of the parameters listed below can be utilized to evaluate (1) and (6) in the text. These values are roughly the same for all values of t_b in both curves of Fig. 2. The parameters are: 1) effective refractive index $\equiv n_0 = 3.532$; 2) real part of transverse wave vector in buffer layer $\equiv p_0 = 4.76$ μm^{-1}; and 3) effective waveguide thickness ≡ mode width $w_0 = 718$ nm. The values of the coupling coefficients calculated from (1) and (6) are reliable only if the corrugation is sinusoidal, $ka < 0.1$, $n_b \lesssim n_g$ and the gold contact is a good reflector, i.e., $n(\text{gold}) \cong -5.3i$.

Acknowledgment

The authors wish to thank the IBM Injection Laser Group, particularly J. Blum and K. K. Shih, for providing them with the DH material used in these experiments and for helpful advice. They also wish to thank V. Maniscalco, J. Marinace, B. Monemar, and A. Tuttle for useful technical assistance and advice, and L. Kuhn, E. Lean, A. Reisinger, E. Spiller, and J. White for many helpful discussions.

Integrated Twin-Guide AlGaAs Laser with Multiheterostructure

Y. SUEMATSU, MEMBER, IEEE, M. YAMADA, AND K. HAYASHI

Abstract—**An integrated twin-guide (ITG) laser which has an active waveguide for laser oscillation and an external waveguide for the light output is proposed as an integrated-optics laser or as a new semiconductor laser, and its properties are investigated theoretically and experimentally. ITG lasers were constructed in the form of an AlGaAs multiheterostructure, and their preliminary characteristics were obtained with both optical pumping and current injection at room temperature. The end mirrors of the active waveguide were fabricated by a back-sputtering method. The axial mode selectivity was predicted by the analysis and observed experimentally.**

I. INTRODUCTION

ONE OF THE MOST important problems for the realization of monolithic integrated-optical circuits is the formation of an integrated-optics laser with an optical output circuit. Semiconductor lasers, especially AlGaAs double-heterostructure (DH) lasers, are expected to be the most feasible candidates for integrated-optics lasers. A conventional semiconductor laser has already included many functions in itself, such as the current-injection pumping, the direct modulation, and the cavity constructions. However, the problem of the connection to the external waveguide in a monolithic way has not been fully investigated because the conventional semiconductor lasers utilize cleaved faces as the reflecting mirrors. The distributed-feedback laser might be considered along this direction of research [1]–[3]. The vapor-grown GaAs laser, whose mirrors are constructed at the walls of the mask, was also suggested [4].[1]

As another approach, we proposed an integrated twin-guide (ITG) laser [5] which integrates an external waveguide and an optically coupled active waveguide. In this paper we give a summary of the basic experimental characteristics of ITG AlGaAs lasers. This laser consists of an active waveguide (I) for the laser oscillation and an external waveguide (II) through which the laser beam is taken. The oscillating guided waves were coupled between the two waveguides in a way similar to that of a directional coupler. These waveguides were constructed in the form of a multiheterostructure by successive liquid-phase epitaxial growth. The mirror surfaces of the active waveguide were fabricated by RF backsputtering.

Manuscript received November 25, 1974; revised January 20, 1975. This work was supported in part by research foundations of the Monbusho and Electrical Communication Laboratories of the Nippon Telegraph and Telephone Public Corporation.

The authors are with the Department of Electrical and Electronic Engineering, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo, 152 Japan.

[1] During the preparation of this publication, a method for the connection between optical components by a monolithically prepared thick waveguide was also reported in AlGaAs-laser structures [9].

II. Theoretical Behavior of ITG Lasers

An analytical model for the ITG laser is shown in Fig. 1. Dielectric guides form a system of coupled waveguides consisting of guides (I) and (II). Mirrors are located at both ends of each waveguide, so that the resonator consists of a double-cavity type between guides (I) and (II). If mirrors at guide (II) are removed, the resonator becomes a single-cavity type. The coupling between the two waveguides is most effective when the guide system is degenerate [6], i.e., when the propagation constants of each guide are equal at the well-separated condition.[2] The coupled wave is expressed as a combination of the characteristic even and odd modes [7], with propagation constants β_e and β_o, respectively, which are determined by conventional methods [8]. The lengths of the active waveguide (I) and the arm of the external one (II) are l and l_s, respectively. The gains of the coupled waves are calculated by a perturbation term in the wave equation. The resonant and threshold conditions can be obtained from the calculations of the net gain and the phase shift of the coupled waves after one round trip in the resonator. Only typical results are mentioned here assuming the guide system is degenerate. The calculations and detailed discussion will be published later.

Assume the oscillation wavelength is λ, the effective refractive index of guide (I) is n, the reflection coefficients of the ends of active and external waveguides are unity and R, respectively, the net threshold mode gain $2(g - \alpha)l$ for the laser oscillation is shown in Fig. 2(a) with the horizontal axis, the normalized wavenumber. If the external waveguide (II) is lossless, the net mode gain $2(g - \alpha)l$ is expressed using the medium gain factor $\bar{g}$ and loss $\bar{\alpha}$ of guide (I),

$$2(g - \alpha)l \simeq 2(\bar{g} - \bar{\alpha})\,\xi_4 l \tag{1}$$

where ξ_4 is the fractional power of a normalized characteristic mode at guide (I) and becomes $\xi_4 \lesssim \frac{1}{2}$ in the degenerate guide system. The parameter C is the coupling coefficient between two waveguides and is expressed by

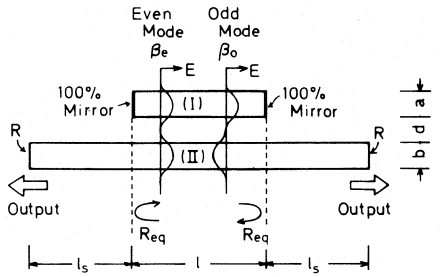
$$C = \sin^2\,[(\beta_e - \beta_o)l/2]. \tag{2}$$

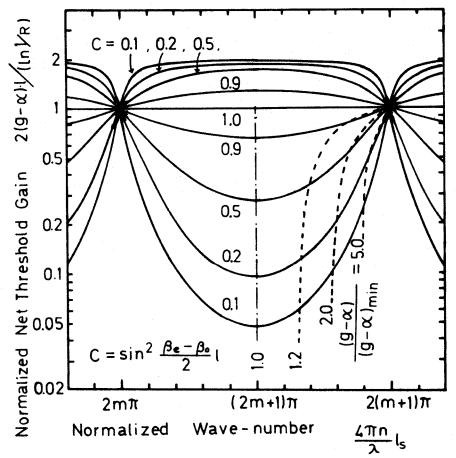
The threshold gain shows minimum value $(g - \alpha)_{\min}$ at $1/\lambda = (2m + 1)\pi/(4\pi n l_s)$ and increases for other values of λ, thereby providing axial mode selection in the ITG laser, particularly for the range of $C < 0.5$. The increasing rate of threshold gain is shown in Fig. 2(a) by dashed lines.

To consider this complicated system as a conventional single-guide laser, we define an equivalent reflection coefficient R_{eq} which shows overall power reflectivity at the end planes of the guide (I), as shown in Fig. 1. The relation between R_{eq} and the reflection coefficient R at the output end is shown in Fig. 2(b), for the minimum threshold gains, $2(g - \alpha)_{\min}l$. If there are no reflections at the output ends, namely $R = 0$ or nonresonant operation of the external guide, then $R_{eq} = 1 - C$. Using this R_{eq}, the threshold equation is written by

$$(\bar{g} - \bar{\alpha})\,\xi_4 = \ln\,(1/R_{eq})/l. \tag{3}$$

[2]The coupling problem between a slab laser and a slab waveguide was also treated at a weakly coupled condition by [10].





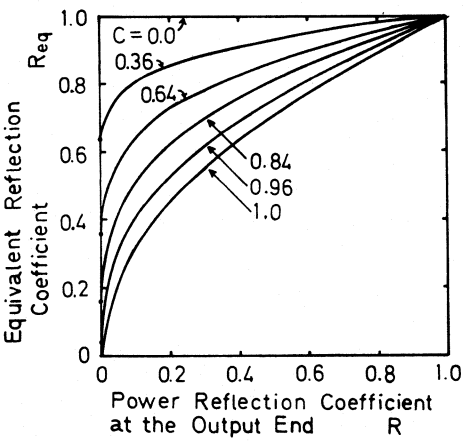


Fig. 1. Analytical model of the ITG laser.

(a)

(b)

Fig. 2. (a) Threshold gain versus oscillating wavelength. (b) Equivalent reflection coefficient R_{eq} versus reflection coefficient R at the output ends.

The total power efficiency is also expressed analogous to that of the conventional single-guide laser using R_{eq}.

Experimentally, the assumption of degeneracy of waveguides is not always satisfied. In the case of weak coupling, the coupling is severely reduced by a small parameter deviation from the degenerate condition, and the effect decreases with increasing the coupling, or decreasing the separation d [6]. In the case of strong coupling, the situation is a little different and complicated. In this case, coupling does not increase with decreasing d for very small d, and it is not so severely affected by the parameter deviations.

III. Fabrication of an ITG AlGaAs Laser

A. Determination of the Guide Parameters

The thicknesses of two waveguides a and b and refractive indices of each layer were chosen to give identical propagation constants β_I and β_{II} when the two waveguides are well separated. Efficient coupling is not obtained for $\beta_I \neq \beta_{II}$, as is likely to be the case in the experiment. However, this mismatching becomes more tolerable if the distance between the guides d is decreased. Therefore d was chosen as small as the limitation of the fabrication technique would permit.

B. Fabrication Process of an ITG AlGaAs Laser

$Al_xGa_{1-x}As$ multilayers were grown on the (100) face of the GaAs substrate using successive liquid-phase epitaxial growth. The layer thicknesses and Al contents of an actual ITG AlGaAs laser are shown in Fig. 3. These device parameters are almost identical to the ones required analytically. Since the Al content of the external waveguide was larger than that of the active waveguide, the absorption loss of the external waveguide was small at the oscillating wavelength. The p-n junction for the current injection was the lower boundary of the active waveguide. The p-type and n-type layers were doped with Ge and Sn, respectively.

Subsequently, we put a mask on the (100) surface of the aforementioned AlGaAs wafer for backsputtering, as shown in Fig. 4(a). The mask was a cleaved GaAs strip approximately 300 μm wide. The (110) surfaces of the mask were arranged to be parallel to (110) surfaces of the wafer within a few degrees. The exposed parts of wafer were etched off by the RF backsputtering, as shown in Fig. 4(b). The Ar gas pressure was 8×10^{-3} torr, the supplied field intensity was 100 V/cm, and the current density was 0.8 mA/cm^2. These conditions gave an etching rate of about 1 μm/h. The newly formed (110) walls were used as the mirror surfaces of the active waveguide, as indicated in Fig. 4(c). As shown in Fig. 5, the flatness of these (110) surfaces was not so inferior to that of the cleaved ones.

In the case of current-injection ITG lasers, all of the back-sputtered surfaces were coated with a RF sputtered glass film (Corning 7059) to prevent the flow of current. Metal electrodes were applied after the glass coating. The mirror surfaces of the active waveguide were also coated with metal (Au) to increase the reflectivity and to prevent completely the direct output through these surfaces. The end surfaces of the external waveguide for the output were prepared by cleaving.

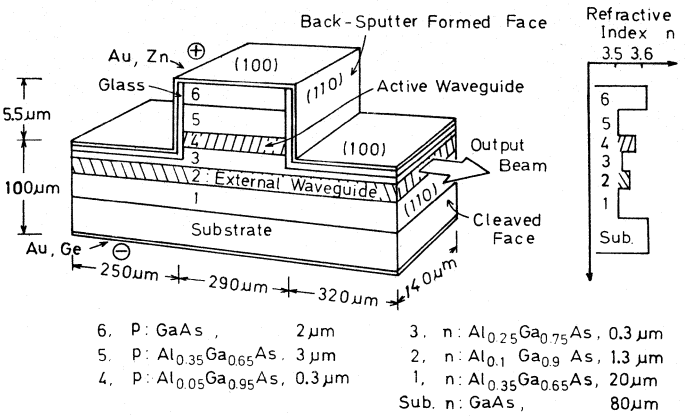

Fig. 3. Construction of the ITG laser.

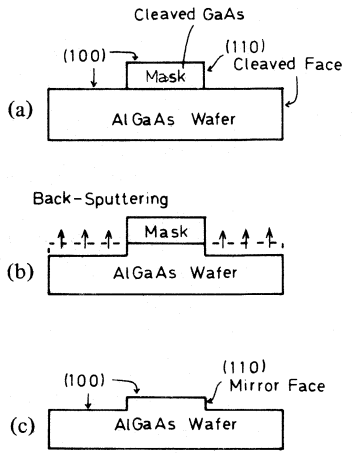

Fig. 4. Mirror fabrication by the back-sputtering method.

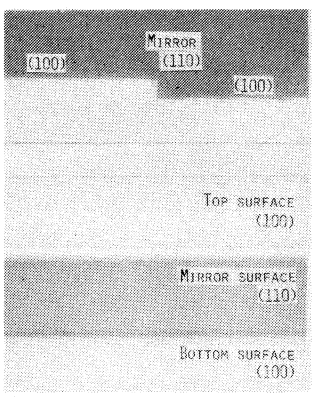

Fig. 5. Photographs of the back-sputter faces.

C. Experimental Results

Firstly, we examined the applicability of the back-sputter mirrors. Several DH lasers were constructed with three-layer AlGaAs prepared by epitaxial growth. All of the layers were n-type for the convenience of optical pumping. The end mirrors of the active waveguide were fabricated by back-sputtering. This DH laser was optically pumped by the second harmonics (λ - 0.53 μm) of a Q-switched YAG laser at liquid-nitrogen temperature. The pumping beam was focused to a stripe shape of 30×300 μm^2 with maximum peak-power density of 1.5×10^4 W/cm^2. The pulse rate was 400 Hz with a pulsewidth of 100 ns. The pumping power is considered to be absorbed in the top layer, namely the cladding of the active layer. Thus excited free carriers are believed to be diffused into the active layer. The oscillating beam was taken out directly from the back-sputter mirror. The output spectrum at the maximum pumping power is shown in Fig. 6. The threshold density of pumping power was 1×10^4 W/cm^2, which was about two times higher than that of the conventionally cleaved

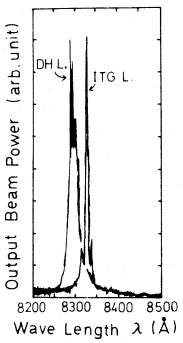

Fig. 6. Output spectra of AlGaAs DH laser with back-sputter mirrors and AlGaAs ITG laser. Both lasers were optically pumped at liquid-nitrogen temperature.

DH lasers prepared from the same wafer due, probably, to the incompleteness of mirrors.

Secondly, several optically pumped ITG lasers with an external waveguide were fabricated [5]. These lasers were constructed from five AlGaAs layers. All layers were n-type. The back-sputter mirrors were coated with Al. The pumping method was the same as that mentioned previously. A typical spectrum for those lasers at 77 K is shown in Fig. 6. The wavelength corresponds to the energy gap of the material of the active waveguide. The spectral width was about 5 Å which was about $\frac{1}{3}$ of the aforementioned DH laser. This spectral narrowing is considered to be due to the twin-guide-resonator structure, as expected from the aforementioned analysis.

Finally, ITG lasers were prepared as shown in Fig. 3, and these were operated by current pulses at room temperature. The pulse rate of the injection current was 500 Hz with the pulsewidth of 10 ns. The central wavelength of the output spectrum was 8420 Å, which corresponds to the energy gap of the material of the active waveguide. The spectra are not yet good enough. The threshold current density was about 1×10^4 A/cm^2. The output light from the external waveguide was observed by an infrared video camera.

IV. Conclusion

An ITG laser was fabricated in the form of an AlGaAs multiheterostructure. The mirrors for the active waveguide were successfully fabricated using the back-sputtering method. The laser operation was examined by both optical pumping at liquid-nitrogen temperature and the pulse current at room temperature. A tendency toward axial mode selectivity was observed experimentally as predicted by the theory outlined in this paper.

The independent choice of laser parameters is possible. For example, the thickness of the active waveguide can be selected thin enough for lower threshold, while that of the external waveguide can be thick enough for reduced beam angle of the output. The absorption loss of the external waveguide may be small at the laser wavelength.

Integrated GaAs–$Al_xGa_{1-x}As$ Double-Heterostructure Laser with Independently Controlled Optical Output Divergence

R. A. LOGAN, MEMBER, IEEE, AND F. K. REINHART, MEMBER, IEEE

Abstract—Liquid-phase-epitaxial growth procedures have been used to form a double-heterostructure (DH) laser in which the radiation is taper coupled from the active layer into a passive waveguide. The taper extends smoothly over distances ~100 μm and efficiently couples the radiation from the electrically pumped section into a low-loss adjacent waveguide of comparable dimension (0.5 μm). The passive-waveguide dimension beyond the taper coupler is widened to any desired dimension by inserting a cooling fin (or spacer) into the growth melt, permitting control of the laser output divergence without mode conversion. These structures have been made with the following properties: threshold current density 2.6 kA/cm^2; differential quantum efficiency 28 percent; taper coupling efficiency ~90 percent; and half-power radiation field angles of 48 and 29° from the active (0.5 μm thick) and passive (1.5 μm thick) regions, respectively. Using similar growth procedures, devices have been constructed where the laser radiation is taper coupled into passive waveguides permitting both laser mirrors to be formed in passive regions.

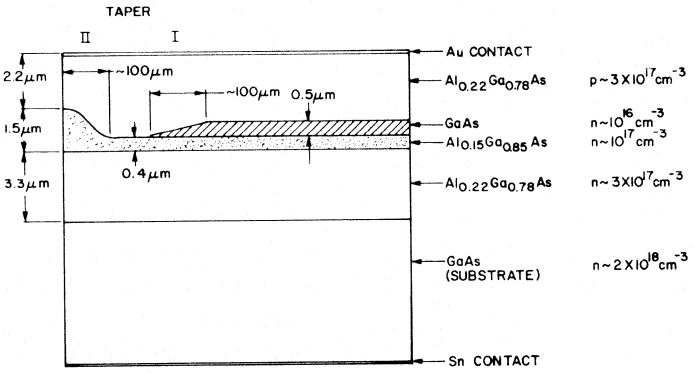

Fig. 1. Schematic cross section of a TCL. Coupling between active- and passive-waveguide sections occurs at taper I. Also shown is a thickness transition of the passive-waveguide section II for control of the radiation pattern.

I. INTRODUCTION

MONOLITHIC integration of double-heterostructure (DH) lasers with passive-single-heterostructure (SH) or DH waveguide elements has been achieved recently using modifications of liquid-phase-epitaxy (LPE) growth procedures to form GaAs–$Al_xGa_{1-x}As$ heterostructures [1]–[3]. The modifications described thus far can be characterized by the method of optical coupling between the active- (pumped) and passive-waveguide sections: 1) the composition coupled laser [1] (CCL) consists of a passive waveguide of increased band gap (and width) contiguous to the active layer in the laser; 2) the phase coupled laser [2] (PCL) is basically a simple sandwich structure of two waveguide layers of differing Al composition that should ideally carry a pair of degenerate modes; 3) the taper coupled laser [3] (TCL), like the PCL, is a simple sandwich structure in which the layer with the low Al concentration (active layer) tapers to zero thickness within the structure, causing the radiation to couple into an adjacent passive-waveguide layer. Continuous-wave integrated lasers could be constructed using any of these coupling methods with greatly varying degrees of difficulty. In this paper we shall restrict our discussion to the CCL and TCL. The growth of CCL structures is very simple in principle and exhibits mode coupling efficiencies from the active to the passive section near unity. These attractive features are, however, restricted by the dramatic increase of the growth rate of the waveguide layer under the melt divider used to grow the bicompositional layer. The increased growth rate makes precise thickness control difficult, particularly for the growth conditions of small melt spacer-to-substrate clearance, used when a sharp composition transition from the active- to the passive-waveguide-layer section is desired. This contrasts with the TCL structure fabrication where a sharp separation between active- and passive-waveguide sections is achieved but where the mode coupling efficiency is not *a priori* expected to be unity. For control of the radiation patterns and the power densities at the mirror of DH lasers, it becomes highly desirable to develop wide passive regions. A combination of the growth techniques for the CCL and TCL adds more flexibility in the fabrication of novel structures permitting construction of devices such as shown in Fig. 1. This structure is basically a TCL with a passive-waveguide thickness variation characteristic of the CCL. Thin active- and passive-waveguide layers provide for a very high taper coupling efficiency and a low-threshold current density. The wide passive waveguide at the mirror reduces the power density at the mirror and the angular width of the radiation field. The thin passive guide also acts as a mode filter if it is sufficiently narrow, thereby ensuring the stability of the transverse mode. The device construction does not preclude any of the techniques of lateral mode stabilization employed in standard DH lasers [4]. In Section II the novel growth procedures are discussed. The measurements and results are presented in Section III.

II. PROCEDURE

The device of Fig. 1 was grown with conventional LPE procedures [5] modified 1) to produce a layer with a rib of enhanced local growth by insertion of a spacer (or cooling fin) into the melt, and 2) to grow partial layers terminated by smooth tapers using a thin sapphire mask under a portion

of the growth melt. A schematic cross section of the growth boat is shown in Fig. 2(a). The boat was machined from dense carbon[1] and was contained in a pure H_2 ambient in a quartz furnace liner. The layers were grown by successively sliding a (100) oriented rectangular substrate with (110) edges, under saturated melts while cooling the furnace from 850°C at a rate of 0.2°C/min. Dopants and excess GaAs were added to the Ga melts after a preliminary bake out at 800°C for 16 h with access through a porthole in the quartz furnace liner so as not to reoxidize the baked-out Ga. Saturation at the bottom of the melt was insured by use of a saturation seed[2] which preceded the sample to the growth region.

The boat design differs from conventional ones in that each melt is contained in thin-walled (0.5-mm) modules that fit snugly into recesses in the main boat. This design[3] permits great flexibility in layer growth since individual modules can be modified to grow layers of varying complexity without disturbing the growth conditions of adjacent layers. For example, module 2 of Fig. 2(b) contains a thin partition that has permitted growth of a single bicompositional layer from two different adjacent melts in the module [1]. The use of a thin insulating mask at the bottom of module 3 of Fig. 2(b) causes layer growth to occur in two predetermined areas, with layer segments terminating in smooth tapers, decreasing to zero thickness in distances ~100 μm [3], [6].

The construction of the device of Fig. 1 requires the successive growth of four layers with modules 2 and 3 of Fig. 2(b) used to provide the enhanced local growth and tapered segments, respectively. The initial layer was grown using a melt composition [7] to grow $Al_{0.22}Ga_{0.78}As$ at 850°C by sliding the saturating seed and then the substrate under the first module, while cooling the furnace at a rate of 0.2°C/min. The furnace temperature profile was adjusted so that the exposed push rod [on the left side in Fig. 2(a)] extended into a zone about 3°C higher in temperature than the uniform zone of the boat. Thus, on the first movement of the push rod bringing the substrate to module 1, the boat temperature, monitored with a thermocouple as shown in Fig. 2(a), increased about 0.5°C causing melt back into the substrate. This procedure, which is similar to that developed by Hayashi *et al.* [5], causes improved wetting of the first layer to the substrate and improves the quality of the subsequent grown layers as well. As the slider is pushed to subsequent wells, no perceptible temperature rises were observed ($\Delta T \lesssim 0.1$°C).

Identical melt compositions were used on either side of the spacer in module 2 to grow $Al_{0.15}Ga_{0.85}As$. Since the carbon spacer acts as a cooling fin, the growth rate directly under the spacer is greater than that in the adjacent areas, so that layer 2 consists of two flat regions joined by a thicker region whose width is approximately that of the spacer. Using a given spacer, the growth rate under the spacer varies primarily with the spacer to substrate clearance. For a 100-μm-wide spacer

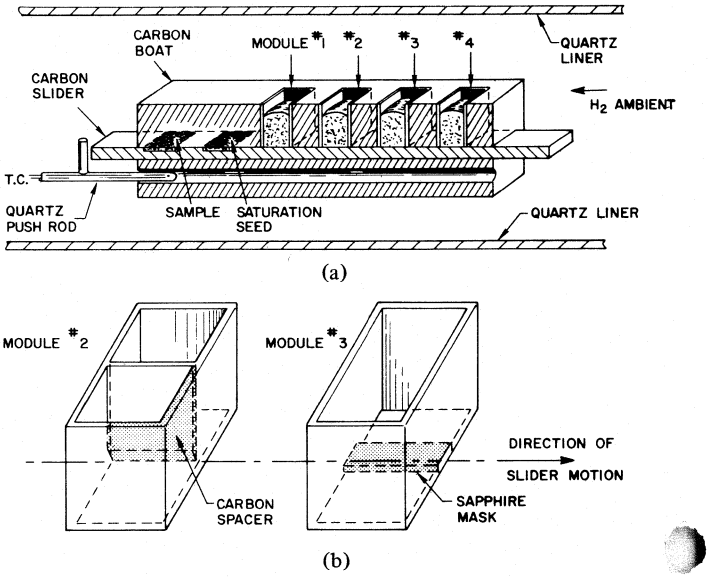

Fig. 2. (a) Schematic cross section of the growth apparatus. (b) Module inserts for obtaining tapers and enhanced local growth. The sample and saturation seed dimensions are ~1 × 1.5 × 0.025 cm^3.

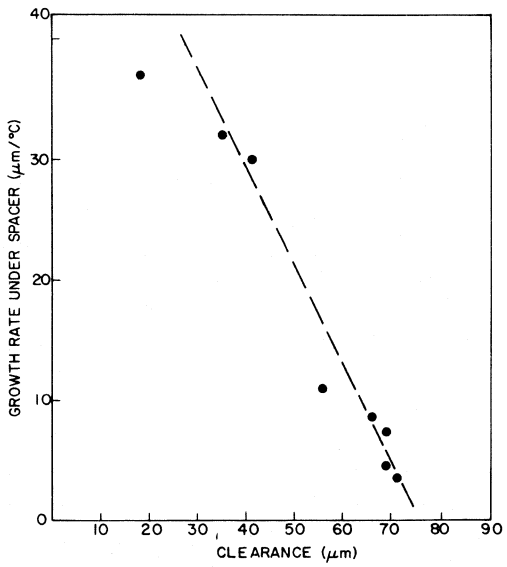

Fig. 3. Growth-rate dependence on the spacer-to-substrate clearance of module 2.

with a lower edge tapered to a width of 25 μm, the growth rate under the spacer is plotted against the spacer-to-substrate clearance in Fig. 3. The growth rates were determined from the observed growth obtained with a furnace cooling of 0.4°C, where the growth rate away from the spacer is ~1.25 μm/°C. The growth rate depends markedly on spacer-to-substrate clearance, as would the thermal gradient at the substrate; however, at the lowest clearance (18 μm) the replenishment of solute to the growth interface became a limiting factor, as evidenced by a small depression in the central region of the layer bulge directly under the spacer.

The growth of the GaAs layer segments with tapered edges was accomplished using the well containing module 3, which contains a 1.1-mm-wide sapphire mask, 0.25 mm thick centered on the same axis as the carbon spacer as shown in Fig. 2(b).

[2] A procedure developed by L. R. Dawson and described by D. L. Rode, "Isothermal diffusion theory of LPE: GaAs, GaP, bubble garnet," *J. Cryst. Growth*, vol. 20, pp. 13–23, 1973.

[3] This modular boat was designed by B. I. Miller.

The sample-to-sapphire mask clearance was 70 μm, and the separation between tapered layer segments was 1.1 mm, approximately the width of the mask. The layer edges taper smoothly to zero thickness over distances of 100–150 μm. The use of a carbon mask instead of sapphire enhances growth at the layer edge, causing the layer to terminate in an abrupt mound.

The top cladding of $Al_{0.22}Ga_{0.78}$ was grown from a conventional module. Cleaving the sample through the (110) plane centered on the maximum of the bulge in layer 2 produced two sets of devices shown in Fig. 1, all with nearly identical properties. In addition, test pieces were cleaved out of the uniform areas away from the tapers for evaluation. Prior to cleaving, conventional contacts were applied: a 0.1-μm-Zn diffused layer with subsequent evaporation and alloying of Au to the p-layer and Sn to the substrate.

III. Results and Discussion

All measurements were made at room temperature with excitation by 100-ns current pulses. Typical control section lasers cut from the uniform areas of the wafer had active-layer thicknesses, $d \simeq 0.5$ μm. For typical control laser cavity lengths, $l = 0.5$ mm, the threshold current density $j_{th} \simeq 2.6$ kA/cm^2, and the differential quantum efficiencies $\eta_d \simeq 38$ percent with approximately 80 percent of the mirror illuminated when lasing. The corresponding values for short control lasers with $l = 0.25$ mm were $j_{th} = 3$ kA/cm^2 and $\eta_d \simeq 43$ percent with 60 percent of the mirror illuminated when lasing. From these data one deduces an internal quantum efficiency $\eta_i \simeq 80 \pm 20$ percent with a typical loss constant $\alpha \simeq 16$ cm^{-1}.

Taper coupled lasers such as shown in Fig. 1 were cleaved from the wafers with typical active-region length $l_a \simeq 0.6$ mm and $d = 0.5$ μm. This resulted in $j_{th} \simeq 2.6$ kA/cm^2 and $\eta_d \simeq 28$ percent with typically 60 percent of the mirror illuminated in the lasing state. Using the methods described in [3], a taper coupling efficiency t was found to be ≈ 90 percent. In all of the TCL's measured, there was no indication of lasing perpendicular to the taper gradient. Furthermore, the tapers terminated cleanly without any evidence of ribbons of overgrowth beyond the taper section as sometimes previously encountered [3], [6].

All of the TCL's did show a very high degree of polarization of the lasing radiation in TE modes except near the edges of the device. The presence of the tapers only slightly modified the degree of polarization as compared with that in the control units. The polarization observation together with the preceding characterization experiments clearly demonstrate an adequate taper growth control, which permits small-scale integration of optical waveguide components. This coupling method also allows isolation of the active region entirely away from outside surfaces such as cleaved mirrors. A TCL with two active-layer tapers coupling the radiation into a passive waveguide of uniform thickness ($d \sim 0.5$ μm) was constructed and lased with $j_{th} \sim 5$ kA/cm^2 and $\eta_d \sim 14$ percent. In Fig. 4 the far field patterns are shown for a TCL such as shown in Fig. 1. From the narrow active region ($d \approx 0.5$ μm) the full half-power angle for the radiation field was $\approx 48°$, whereas the corresponding value from the wide passive guide ($d \simeq 1.5$ μm) was $\approx 29°$. These values agree quite well with the estimated ones based on the guide dimensions and indices of refraction [8]. The far field patterns were tested at several pumping levels up to currents corresponding to $2j_{th}$. No change in the shape of the patterns was observed over this large current-density range. The mode selection mechanisms, due to the narrow active- and passive-waveguide sections, are therefore very effective. This experiment also demonstrates that mode conversion in the thickness transition in the passive section is negligible, as evidenced by the narrow half-power radiation angle.

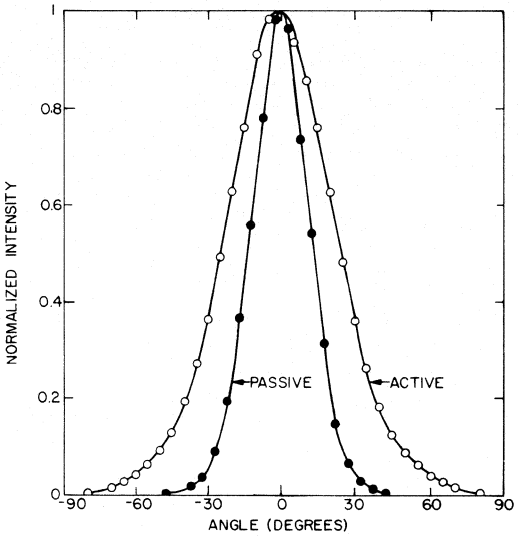

Fig. 4. Far field radiation patterns normalized to peak intensity. Radiation from active side ($d \approx 0.5$ μm)—open circles, and passive side ($d \approx 1.5$ μm)—solid dots.

The modular approach used in the layer growth thus permits a large variation of growth procedures that are required for growing integrated optical devices without constructing an entirely new growth boat for each desired sequence of epitaxial layers. Moreover, the variation of the properties of one layer, obtained by using an appropriately designed module, does not influence the growth conditions of the adjacent layers. While the use of a mask permits growth of layer segments with tapered edges, this technique may also be used to leave an area of the waveguide exposed. The passive-SH-waveguide section thus formed provides electrical isolation between adjacent devices, and on the exposed waveguide one may construct distributed Bragg reflectors [9], [10] or transmission filters [11], or rib waveguides [12] to enhance lateral passive-waveguide mode control and other devices whose operation does not require a regrowth of cladding layers. The ability to independently control the divergence angle permits optimization of the coupling of the laser to optical fibers.

Acknowledgment

The authors wish to thank H. G. White for growing the LPE layers and J. J. Schott for his assistance in device preparation and measurements. They also wish to thank B. I. Miller for generously providing the basic design of the growth boat with modular growth wells, and J. L. Merz, R. C. Miller, and C. H. Henry for many helpful discussions.

Monolithic $Ga_{1-x}In_xAs$ Diode Lasers

F. H. DOERBECK, K. L. LAWLEY, F. A. BLUM, MEMBER, IEEE, AND J. C. CAMPBELL, MEMBER, IEEE

Abstract—**Monolithic homojunction diode lasers have been fabricated from vapor-grown $Ga_{1-x}In_xAs$ ($0 \leq x \geq 0.06$) mesa structures with grown optical facets. The $Ga_{1-x}In_xAs$ lasers have been operated at 77 K, and similar GaAs mesa devices have lased between 77 K and 300 K. Monolithic arrays of up to six mesa lasers on a single substrate have been operated with all lasers oscillating simultaneously.**

I. INTRODUCTION

IN a preliminary letter [1], we reported the fabrication of monolithic GaAs injection mesa lasers with grown optical facets. The present work is based on previous experiments with optically pumped $Ga_{1-x}In_xAs$ mesa lasers [2], [3]. We have now fabricated $Ga_{1-x}In_xAs$ ($0 \leqslant x \leqslant 0.06$) mesa-laser diodes, demonstrating wavelength tunability in a monolithic laser. Also we have successfully operated monolithic arrays of up to six GaAs lasers on a single substrate with all devices oscillating simultaneously. Further details concerning the fabrication and properties of these diode mesa lasers are given in this article.

Manuscript received December 2, 1974; revised February 18, 1975. This work was supported in part by the U.S. Office of Naval Research.

The authors are with Texas Instruments Incorporated, Dallas, Tex. 75222.

Important to the development of integrated optical circuits (IOC's) is the need for a monolithic nondiscrete injection-laser source. Wavelength tunability of the laser is needed for matching regions of low loss for the dielectric waveguides of an IOC and for optical fiber links. Discrete wavelength tunability is achievable with the $Ga_{1-x}In_xAs$ lasers reported here since the laser emission shifts toward longer wavelengths with increasing InAs content. GaAs waveguides then become transparent to the emitted radiation. Only a few percent InAs is needed to achieve low-loss propagation. Thus the $Ga_{1-x}In_xAs$-GaAs system is a good candidate for IOC development.

Another advantage of the diode lasers described here lies in the elimination of cleaving or polishing the optical facets used in conventional discrete-diode laser fabrication. The cleaving process is a major factor in laser yield and may even play a role in limiting laser lifetimes. Growing the optical facets as described here obviates the necessity of cleaving. Also arrays of lasers are readily made using the monolithic techniques described below.

Section II of this article describes the material's growth and fabrication techniques for making the laser. It is particularly noteworthy that all the fabrication steps involve conventional semiconductor processing and photolithography. Measure-

ments of the laser-emission characteristics are described in Section III and conclusions are given in Section IV.

II. Materials and Fabrication

The $Ga_{1-x}In_xAs$ mesas are grown by the selective vapor-epitaxy technique described previously [2], [3] in which growth was restricted to diamond-shaped holes in the SiO_2 mask. The vapor-phase system uses AsH_3, HCl, H_2, and gallium and indium sources. The background doping level for as-grown n-type mesas is approximately 10^{16} cm^{-3}. Higher doping levels ($\sim 10^{18}$ cm^{-3}) are obtained by introducing sulfur into the hydrogen flow. Carrier concentrations are measured by point-contact breakdown on the mesas and Hall measurements on full-surface semi-insulating pilot slices grown with the mesas. The mesas are diamond-shaped pedestals with vertical {111} sides grown on n-type {110} GaAs substrates ($n \sim 10^{18}$ cm^{-3}). The {111} growth planes form the optical cavity. The molar percent of InAs is readily changed by altering the Ga-to-In ratio in the reactor source boats. No grading of the InAs content during growth has been attempted. The InAs content of the mesas is determined by room-temperature photoluminescence measurements.

A p-n junction is formed in the mesas by converting the top part of the mesa to p-type. The technique chosen to accomplish this is diffusion of Zn from Zn-doped SiO_2 layers positioned on the tops of the mesas only. Two techniques are used for making these layers. One is RF discharge deposition of a sandwich structure described previously [2]. Using conventional photolithographic masking, we remove the oxide sandwich from all portions of the slice except the tops of the mesas. A second technique is to implant Zn into a 500-Å-thick layer of SiO_2. This technique eliminates the necessity of photomasking and patterning the doped oxide since the Zn is not implanted in the oxide on the sides of the mesas. The Zn ions are implanted with an energy of 20 keV with a total dose of 10^{16} cm^{-2}. The entire slice is then coated with 2000 Å of undoped SiO_2 to protect the mesa walls during diffusion. The junction-formation steps are shown in Fig. 1. Diffusion of Zn into the slice is accomplished by heating the slice in a nitrogen atmosphere at 800–850°C for periods of 10–40 min. Junction depths of 1–6 μm are obtained with a surface Zn concentration of $\sim 10^{20}$ cm^{-3}. A plot of Zn concentration versus depth for a GaAs device is shown in Fig. 2. These data are taken using a calibrated spreading resistance probe on an angle-lapped device. Some of the devices have been diffused without patterning the Zn-doped oxide so that Zn enters both the sides and the tops of the devices. While this does produce a narrow lossy region at the edges of the optical cavity, low-threshold lasers have been successfully fabricated in this manner.

After removal of the SiO_2 layers, electrical contacts are formed by alloying selectively electroplated gold to the mesa tops and to the back of the slice. Photomasking is used to prevent plating on other parts of the slice. Both full-surface and 2.5-mil stripe contacts are used. Diced chips containing two-six mesa devices each are then soldered to a gold-plated header (mesa up).

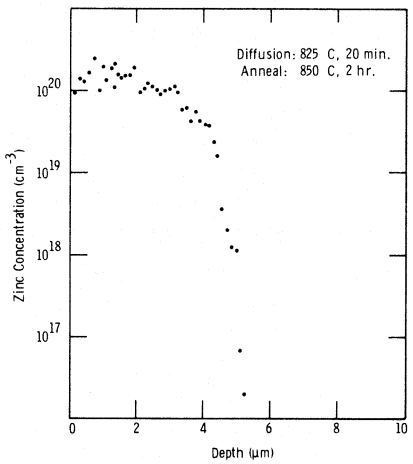

Fig. 2. Zn concentration versus depth for a mesa junction.

III. Laser Characteristics

After the mesa diodes have been fabricated and mounted on headers, the devices are attached to a copper cold finger in a Dewar and cooled (usually to 77 K). The diodes are excited with a 100–200-ns pulse at a repetition rate of 100–500 Hz. The laser-emission spectra are obtained with a 3/4-μm monochrometer and an ITT FW118 photomultiplier which has an S-1 photocathode. The peak output power of the lasers is measured with an ITT F-4000 biplanar photodiode.

Injection lasers have been fabricated from mesas with n-type carrier concentrations between 10^{16} cm^{-3} and 3×10^{18} cm^{-3}. The threshold current densities (at 77 K) of the GaAs lasers are strongly dependent on the carrier concentrations, ranging from ~ 2 kA/cm^2 for the best heavily doped devices to ~ 100 kA/cm^2 for lightly doped ones. The high thresholds for the lightly doped diodes are a result of the difficulty of achieving population inversion in these devices. Selected Zn-implant GaAs devices have been operated at dry-ice (200 K) and ambient (300 K) temperatures with threshold current densities of ~ 30 kA/cm^2 and ~ 100 kA/cm^2, respectively. Typical values for the total peak output power from heavily doped GaAs lasers are several tenths of a watt; however, a peak output in excess of 3 W with a drive current of 40 A has been

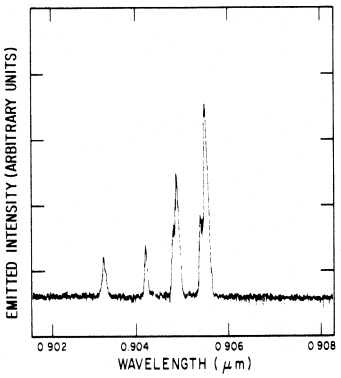

Fig. 3. Emission spectrum of a $Ga_{0.95}In_{0.05}As$ mesa laser driven with a bias current of 11 A at 77 K.

measured. In contrast, the peak power output of lightly doped lasers are usually a few milliwatts.

The lowest threshold observed for heavily doped $Ga_{1-x}In_xAs$ mesa lasers is 24 kA/cm^2 at 77 K, independent of the InAs content. Lower threshold currents have been reported recently by Nuese *et al.* [5] for discrete $Ga_{1-x}In_xAs$ lasers. The active layer of their lasers was grown by vapor phase and was separated from the GaAs substrate by a graded buffer layer. The higher threshold currents of our devices may be caused by lattice strain. We observe that the top surface of the $Ga_{1-x}In_xAs$ mesas appears pitted in comparison with the mirror-smooth surface of GaAs mesas.

An emission spectrum of a $Ga_{0.95}In_{0.05}As$ mesa laser is shown in Fig. 3. The laser emission is shifted almost 700 Å with respect to the GaAs mesas, thus making these $Ga_{1-x}In_xAs$ lasers compatible with GaAs waveguides. The spacing of these modes is approximately 6.3 Å, yielding $n_{eff} \simeq 3.7$. This value is consistent with a previous report for conventional discrete $Ga_{1-x}In_xAs$ laser diodes [4]. The highest peak power output observed for a $Ga_{1-x}In_xAs$ laser was 0.8 W at approximately 40 A.

The mesa laser readily lends itself to fabrication into arrays since several hundred lasers are grown adjacent to one another on a single chip. To make a linear array of mesa lasers we simply cut a strip containing the desired number of devices from a batch-processed slice and mount it on a header as shown in Fig. 4. This particular array contains six stripe-geometry GaAs mesa lasers. By connecting the diodes in parallel with an appropriate series resistance for each device, it is possible to obtain the rather uniform laser emission illustrated in Fig. 5. In this figure the radiation from the array has been focused on an infrared vidicon and displayed on a CRT. To obtain this picture, a 1-Ω resistor was placed in series with two of the lasers. This method of mounting lasers also allows us to check variations of the laser thresholds from one device to another along the chip. The laser threshold currents for the individual diodes in the array of Fig. 5 ranged from 1.2–2.6 A. A peak power output of 3 W was obtained from the six-laser array when driven by a total current of 50 A. Present mesa-laser arrays have higher threshold currents and lower efficiencies than conventionally fabricated laser arrays [5]. The observation that adjacent mesa lasers have similar parameters is, however, encouraging for future IOC development.

IV. Conclusion

We have demonstrated the feasibility of growing the optical facets of $Ga_{1-x}In_xAs$ semiconductor diode lasers. We have fabricated monolithic $Ga_{1-x}In_xAs$ ($0 \leqslant x \leqslant 0.06$) mesa diodes which operate as lasers at wavelengths between 8300 Å and 9100 Å at 77 K, demonstrating the wavelength tunability in a monolithic-mesa semiconductor laser. These devices have the potential of matching low-loss regions of optical fibers and GaAs dielectric waveguides for communications applications. They also readily lend themselves to the fabrication of laser arrays.

Acknowledgment

The authors wish to thank H. Hendricks and his colleagues of NASA, Langley Field, for preparing the Zn-ion-implanted samples. They also wish to thank D. W. Shaw for discussion of mesa growth; K. C. Wiemer, for advice on the Zn-doped SiO_2; A. R. Reinberg, for oxide deposition; and G. Pollack, for the spreading-resistance probe measurements. Also, they are indebted to W. Abercrombie, S. H. Howison, F. D. Sinclair, and W. A. Dillon for their expert technical assistance.

Application of Molecular-Beam Epitaxial Layers to Heterostructure Lasers

H. C. CASEY, JR., MEMBER, IEEE, A. Y. CHO, AND P. A. BARNES

Abstract—**GaAs-$Al_xGa_{1-x}As$ double-heterostructure (DH) lasers with Si-doped n-type active layers have been prepared by molecular-beam epitaxy (MBE) and the laser properties evaluated. With 0.2-μm-thick active layers and 300-μm cavity lengths, typical room-temperature threshold current densities J_{th} of 5.0×10^3 A/cm^2 and best values of 2.5×10^3 A/cm^2 have been obtained. Stripe-geometry devices were run CW up to 9°C. Photoluminescence (PL) studies of single layers grown with the donors Si, Ge, and Sn show that the luminescent intensity for MBE n-type layers depends on the substrate temperature during growth. The PL intensity for Sn-doped MBE layers was greater than for high-quality Sn-doped liquid-phase-epitaxial layers.**

I. INTRODUCTION

WITHIN the last year, sufficient results have been achieved to permit description of GaAs-$Al_xGa_{1-x}As$ double-heterostructure (DH) lasers prepared by molecular-beam epitaxy (MBE). Although MBE for this application is still in an early stage of investigation, threshold current densities are presently within about a factor of 2 of the values obtained for similar-geometry DH lasers prepared by liquid-phase epitaxy (LPE). If comparable-performance DH lasers can be prepared by MBE, then the improved-layer reproducibility and large-area growth would make MBE a reasonable alternative to consider. In addition to this immediate problem of GaAs-$Al_xGa_{1-x}As$ DH lasers, it is the structures, compounds, and devices that cannot be prepared by LPE that will require a new thin-film technology. Double heterostructures have been prepared by MBE to permit us to learn the techniques necessary for the preparation of layers and heterostructure interfaces that have the required optical and electrical properties. The results described in this paper are part of a continuing investigation to apply MBE to these requirements for new optoelectronic and integrated optics structures.

Manuscript received December 12, 1974; revised January 27, 1975.
The authors are with Bell Laboratories, Murray Hill, N.J. 07974.

The results for GaAs-$Al_xGa_{1-x}As$ DH lasers prepared by MBE with Mg-doped p-type active layers have been described previously [1]. For structures with 0.5-μm-thick active layers and 350-μm cavity length, pulsed-threshold current densities J_{th} at room temperature were 3.5×10^4 A/cm^2 for as-grown wafers. Annealing reduced J_{th} to 4.0×10^3 A/cm^3 [1]. It should be pointed out that the usual acceptors such as Zn or Cd are not useful acceptors for MBE. These impurities have a high vapor pressure and tend to reevaporate from the growing-layer surface rather than be incorporated in the growing layer. For MBE, Ge is an acceptor only for growth under the excess-Ga condition [2]. Since smoother layers are generally obtained for excess-As conditions, it may not be desirable to utilize Ge as a p-type dopant. Hole concentrations only up to $\sim 5 \times 10^{16}$ cm^{-3} can be achieved by Mg while retaining smooth layer growth at 650°C. Hole concentrations of $\sim 1 \times 10^{18}$ cm^{-3} may be obtained with Mn [3a)], and $\sim 4 \times 10^{19}$ cm^{-3} with Be [3b)]. Manganese has an acceptor ionization energy [3] near 0.1 eV and Be can diffuse rapidly. At the present time, DH lasers with Mn- or Be-doped active layers have not been prepared.

Because of these properties of acceptor impurities in GaAs MBE layers, DH lasers with n-type active layers have been investigated. The preparation of MBE lasers with Si-doped n-type active layers are described in Section II and the laser properties are summarized in Section III. Studies were also made of the influence of substrate temperature on the layer

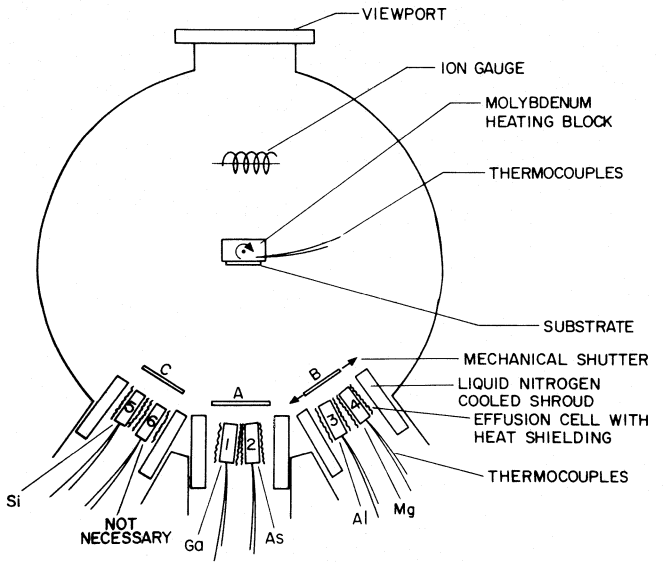

Fig. 1. Schematic representation of the MBE growth system.

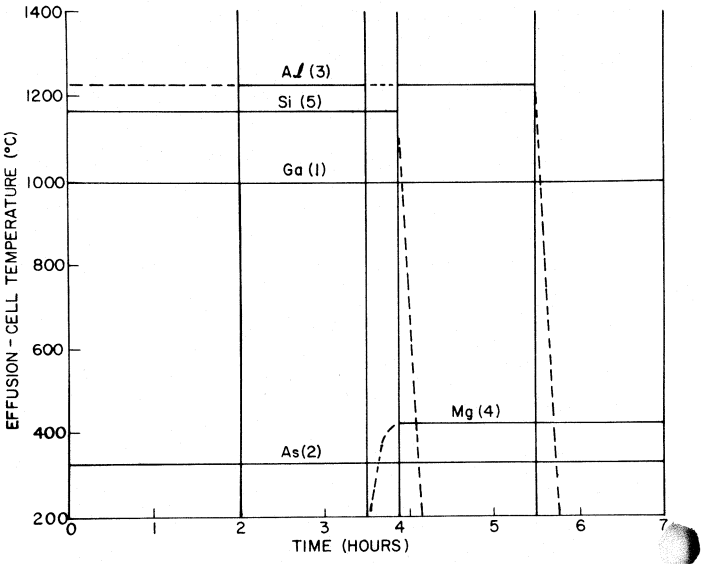

Fig. 2. Temperature–time cycles used to grow the five-layered DH lasers. Solid lines indicate an open shutter, while the dashed line indicates that the shutter is closed.

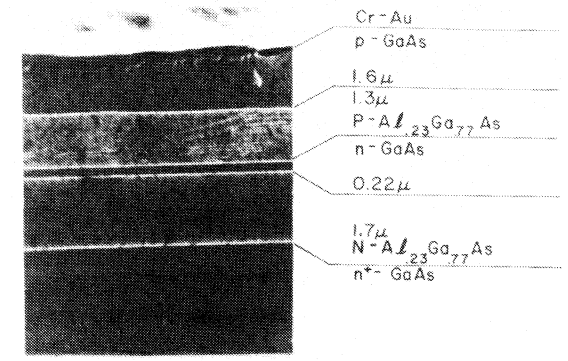
luminescence for layers doped with the donors Si, Ge, and Sn. These photoluminescence measurements on single layers are described in Section IV. The single-layer photoluminescence was found to be better for Sn-doped MBE layers than for Sn-doped LPE layers.

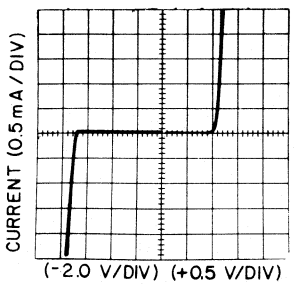
II. Layer Growth

A schematic representation of the growth apparatus is shown in Fig. 1. The layer growth takes place within a high-vacuum chamber. The pressure is $\sim 10^{-9}$ torr before heating the effusion cells. The substrate is 2 X 2 cm and is heated to between 600 and 650°C. For the heterostructure lasers with an n-type active layer, five effusion cells and three shutters are used. As described previously [1], six effusion cells are used for p-type active layers. The effusion cells are made of pyrolytic BN and are essentially a heated cylinder with one end open. The contents of each effusion cell are shown in Fig. 1. Silicon is the n-type impurity and Mg is the p-type impurity. Aluminum is very reactive, and therefore it tends to attack the effusion cell. The shutters permit instantaneous change from one layer composition to another.



The temperature-time cycles used to grow the DH lasers with the Si-doped n-type active layer are shown in Fig. 2. During growth the background pressure is in excess of 2×10^{-7} torr. The first layer to be grown is a Si-doped buffer layer and becomes an n-type $Al_xGa_{1-x}As$ layer by opening shutter *B*. It simplifies the arrangement of effusion cells to use the same donor for the n-type GaAs and $Al_xGa_{1-x}As$ layers. The remaining layers are then grown by opening and closing the shutters and heating the effusion cells to the temperatures indicated in Fig. 2. For MBE, the layer thickness varies linearly with growth time, and the growth rate used for this work is approximately 1 μm/h. The growth rate is determined by the Ga flux (or Ga and Al) for the excess As growth condition. Further description of MBE-layer growth has been given elsewhere [4], [5].

III. Laser Properties



Both broad-area and stripe-geometry DH lasers were prepared. The as-grown wafers with n-type active layers had much lower threshold current densities than the wafers with p-type active layers. For broad-area DH lasers with 0.2-μm active layers, 150-μm width, and 300-μm cavity lengths, typical pulsed values of J_{th} at 297 K were 5.0×10^3 A/cm^2 and best values were 2.5×10^3 A/cm^2. The electron concentration in the Si-doped n-type active layers was $\sim 1.5 \times 10^{18}$ cm^{-3}. Although annealing did not always reduce J_{th}, the best value was obtained for an annealed wafer. Differential quantum efficiencies were typically 30–40 percent. For an active-layer thickness of 0.2 μm, J_{th} for comparable geometry LPE DH lasers should be $\sim 1.5 \times 10^3$ A/cm^2.

Stripe-geometry DH lasers were fabricated in the same manner as for LPE wafers [6]. A scanning electron photomicrograph of the structure used is shown in Fig. 3(a). Some irregularity may be seen at the p-GaAs/P-$Al_{0.23}Ga_{0.77}As$ interface and is due to doping $Al_xGa_{1-x}As$ with Mg which has a low sticking coefficient and requires a high flux that interferes with smooth growth. The P-$Al_{0.23}Ga_{0.77}As$ layer was kept sufficiently thick to prevent this interface from affecting the optical field. The device properties for a 13-μm-wide stripe that was mounted p-side down on a Cu heat sink are summarized in Fig. 3(b). The current-voltage behavior appears completely normal and very good uniformity among the devices was observed. As indicated, CW operation has only been achieved up to 9°C with the stripe geometry. For CW operation, $J_{th} \approx 1.2 \times 10^3$ A/cm^2.

Continuous operation was limited to 9°C (282 K) due to a steep temperature dependence of the threshold current. A fit of experimental data to the empirical formula, $J_{th} \propto \exp(T/T_0)$, leads to an experimental value of $T_0 = 40 \pm 2$ K for several devices with 0.22-μm active layers. This value differs from the

values for LPE-DH lasers [7] of T_0 = 120 K for 1-μm active layers and T_0 = 165 K for 0.5-μm active layers. Further, at 9°C the CW current through the diode was 630 mA (~1.28 W) which would raise the temperature of the laser active layer approximately 50 K above the heat-sink temperature. This rise in junction temperature was observed from the wavelength shift of the spontaneous emission.

IV. Single-Layer Photoluminescence

It has been our experience that the heterostructure spontaneous-emission efficiency is directly related to J_{th}, and this variation in efficiency is related to the photoluminescence (PL) of single layers. A recent example is the behavior observed for the as-grown and annealed p-type MBE layers [1], [8]. Therefore the PL for single GaAs MBE layers was compared to Sn-doped LPE layers. No quantitative data can be extracted from this type of measurement alone, but PL serves as a useful guide to the luminescent behavior of layers prepared under various conditions and with designated impurities. As for acceptors, the high vapor-pressure donors such as S and Se are not incorporated into the growing layer. However, electron concentrations greater than 1×10^{18} cm^{-3} may readily be achieved with the group IV impurities. The results for Si, Ge, and Sn are shown in Figs. 4-6, respectively.

In Fig. 4, room-temperature PL (excitation λ = 5145 Å) intensities of single layers doped with Si are compared to the PL of Sn-doped LPE layers. The carrier concentrations were determined by Hall measurements. The Sn-doped LPE samples

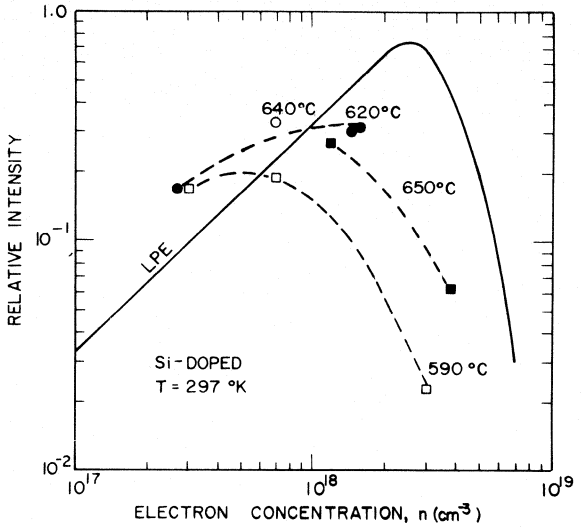

Fig. 4. Relative PL peak intensity. The LPE sample is Sn-doped. The numbers on the figure were the substrate temperature during growth of the Si-doped n-type MBE layers.

were previously studied [9] and have been found to be representative of the highest PL intensity n-type LPE layers. The data points for the LPE layers are not shown, but are the samples illustrated in [9, fig. 5]. The numbers in Figs. 4-6 are the MBE substrate temperature during growth. A detailed discussion of the interpretation of the PL intensity is beyond the scope of this paper [10]. At low excitation, the radiative recombination rate is proportional to the reciprocal of the radiative lifetime τ_r, and the total recombination rate is proportional to $(1/\tau_{nr} + 1/\tau_r)$, where τ_{nr} is the nonradiative lifetime. Therefore, the PL intensity at a given carrier concentration is proportional to the ratio of the nonradiative lifetime to the radiative lifetime for $\tau_r > \tau_{nr}$. When the sample is not closely compensated, the radiative lifetime depends only on the carrier concentration [11], and the PL intensity is a measure of the relative τ_{nr}. Hence, MBE data above the LPE curve represent less nonradiative recombination in the MBE layer than for the LPE layer, while data below the LPE curve represent greater nonradiative recombination.

For the Si-doped samples, a higher substrate temperature during growth improves the PL intensity for samples with electron concentrations n near 7×10^{17} cm^{-3}. At electron concentrations greater than ~1×10^{18} cm^{-3}, the PL intensity for a substrate temperature of 590°C is less than for higher substrate temperature; however, an increase from 620 to 650°C slightly reduces the PL intensity. This reversal is also observed in Fig. 5 for the data points near 2×10^{18} cm^{-3}. Since the electron concentration in this region does not increase with effusion-cell temperature as much as expected from the low-concentration behavior, the impurity concentration probably exceeds n, and the electrically inactive impurity may lead to an increase in nonradiative recombination. The active layers for the DH lasers described in Section III had $n \approx 1.5 \times 10^{18}$ cm^{-3}, and Fig. 4 indicates a PL intensity that is about a factor of 2 less than the LPE curve. This substrate temperature de-

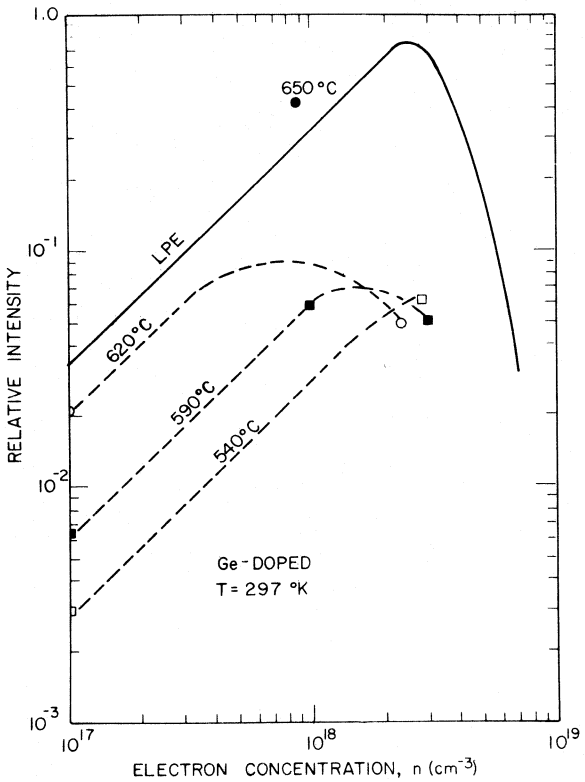

Fig. 5. Relative PL peak intensity. The LPE sample is Sn-doped. The numbers on the figure were the substrate temperature during growth of the Ge-doped n-type MBE layers.

pendence is in general agreement with the observation that the lower threshold DH lasers were grown at temperatures between 620 and 650°C. The substrate temperature is limited to about 650°C because higher temperatures result in poor surface morphology.

The PL intensities for the Ge-doped n-type layers are given in Fig. 5. The substrate temperature has a larger influence with Ge than for Si, and only for temperatures near 650°C does the PL intensity approach and exceed the LPE curve. Because of this result, Ge does not appear to be a favorable MBE donor for luminescent applications.

In Fig. 6, the PL intensity for Sn-doped n-type layers is shown. For the 640°C substrate temperature, the MBE PL intensity exceeds the LPE value. Although not shown in Fig. 6, a decrease by a factor of 10 in the electron concentration to 2.5×10^{16} cm^{-3} decreases the PL intensity by the same amount. The 570°C point shows that the Sn case does not have a strong substrate temperature dependence. This result of greater PL intensity for the MBE Sn-doped layers suggests that Sn is a good choice to consider for DH active layers.

V. Conclusions

Studies of GaAs-$Al_xGa_{1-x}As$ DH lasers prepared by MBE with Si-doped n-type active layers resulted in J_{th} within about a factor of 2 of the values obtained for comparable geometry LPE structures. Although annealing was required for MBE p-type active layers, low J_{th} was obtained for as-grown MBE wafers with n-type active layers. However, the best J_{th} was obtained for an annealed wafer. Preparation of stripe-geometry devices confirmed the uniformity of DH lasers expected for MBE wafers. Measurement of single-layer PL demonstrated

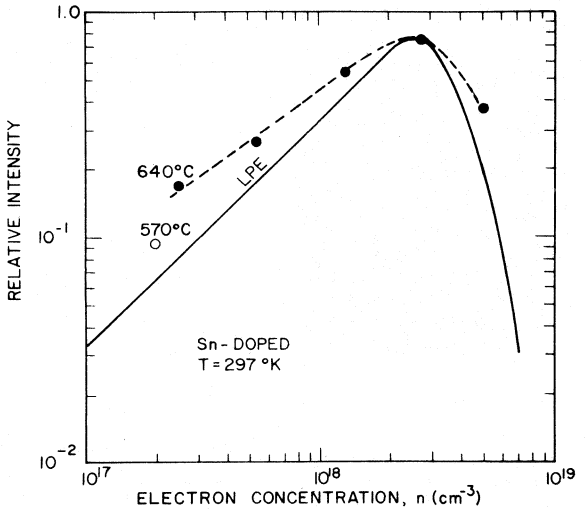

Fig. 6. Relative PL peak intensity. The LPE sample is Sn-doped. Th numbers on the figure were the substrate temperature during grow of the Sn-doped n-type MBE layers.

the influence of substrate growth temperature on the layer luminescence. Tin-doped MBE layers gave greater PL intensity than similarly doped LPE layers and appear promising for luminescent applications.

Acknowledgment

The authors wish to thank M. B. Panish for useful discussions during this study. They also wish to thank C. Radice for aid in preparation of the MBE samples and P. W. Foy for fabrication of the broad-area DH lasers.

Liquid Phase Epitaxial $In_{1-x}Ga_xP_{1-z}As_z/GaAs_{1-y}P_y$ Heterojunction Lasers

J. J. COLEMAN, STUDENT MEMBER, IEEE, N. HOLONYAK, JR., FELLOW, IEEE, M. J. LUDOWISE, P. D. WRIGHT, STUDENT MEMBER, IEEE, W. O. GROVES, AND D. L. KEUNE

Abstract—The growth and laser properties of $In_{1-x}Ga_xP_{1-z}As_z/GaAs_{1-y}P_y$ single heterojunction laser diodes are described. High-quality p-type $In_{1-x}Ga_xP_{1-z}As_z$ layers are grown by liquid phase epitaxy (LPE) on n-type VPE $GaAs_{1-y}P_y$ substrates of composition $y = 0.32 - 0.40$. Laser operation (77 K) of these quaternary-ternary heterojunctions is demonstrated at shorter wavelengths (<6300 Å) and lower thresholds ($J_{th} \lesssim 6.2 \times 10^4$ A/cm^2) than comparable $GaAs_{1-y}P_y$ homojunctions. The increase observed in threshold current ($5x$) between $y = 0.38$ and $y = 0.40$ $GaAs_{1-y}P_y$ substrates is attributed to the usual effect of E_X approaching E_Γ near the direct-indirect transition. From the well-defined cavity mode structure observed on these heterojunctions, data are obtained at relatively high energy on the index dispersion quantity $\{n - \lambda(dn/d\lambda)\}$, which increases monotonically with photon energy and provides a reference for the distinctly different behavior observed on N-doped $GaAs_{1-y}P_y$ ($h\nu \sim E_\Gamma \sim E_N$).

INTRODUCTION

FROM earlier work it is known that by means of liquid phase epitaxy (LPE) the quaternary AlGaAsP can be grown on the ternary GaAsP, thus permitting the formation of single and double heterojunction lasers [1], [2]. Unfortunately this method of forming a heterojunction on $GaAs_{1-y}P_y$ is difficult if the GaP percentage y in the ternary is appreciable ($y \gtrsim 0.10$), higher compositions y leading to relatively high (inconvenient) growth temperatures [3]. A different approach to the problem of growing a wide-gap emitter on $GaAs_{1-y}P_y$ is to utilize $In_{1-x}Ga_xP$, which can be grown of laser quality on $GaAs_{1-y}P_y$ or GaAs ($x = 0.52 + 0.48y$, $0 \leqslant y \leqslant 1$) by means of constant-temperature LPE [4]-[7]. The only problem relative to heterojunction fabrication via the approach of growing a second epitaxial layer (LPE) on a previously grown first layer (VPE) is that of defect formation at the metallurgical junction (not necessarily in the LPE layer itself) if a good lattice match is not accomplished. Achieving a good lattice match turns out to be a difficult procedure. That is, it is quite difficult to control all of the LPE growth parameters so that the $In_{1-x}Ga_xP$ layer is well lattice matched on the $GaAs_{1-y}P_y$ substrate in the sense that the metallurgical junction is adequately free of boundary ("surface") defects, and likewise the LPE layer itself (etch pit density $\lesssim 10^4/cm^2$).

We find that the problem of lattice matching $In_{1-x}Ga_xP$ on a $GaAs_{1-y}P_y$ substrate is eased if the ternary is rendered a quaternary by the incorporation of a small amount ($z \sim 0.01$) of As in the LPE layer changing it to $In_{1-x}Ga_xP_{1-z}As_z$ [8]. Small deviations Δx in the Ga composition x of $In_{1-x}Ga_xP_{1-z}As_z$ from the lattice-match condition on $GaAs_{1-y}P_y$ then are capable of being balanced by compensating small deviations Δz in As composition z that hardly change the electrical and optical behavior of the quaternary LPE layer, which itself ($z \sim 0.01$) is not much different in electrical and optical behavior from the ternary $In_{1-x}Ga_xP$ that lattice matches the $GaAs_{1-y}P_y$ substrate. If an increase (decrease) Δx in Ga percentage occurs in the $In_{1-x}Ga_xP_{1-z}As_z$ LPE layer from the proper composition for a lattice match on $GaAs_{1-y}P_y$, the lattice constant decreases (increases; see Fig. 1). This change in lattice constant is compensated by a corresponding increase (decrease) Δz of As in the crystal, which increases (decreases) the lattice constant sufficiently to keep it constant. The net

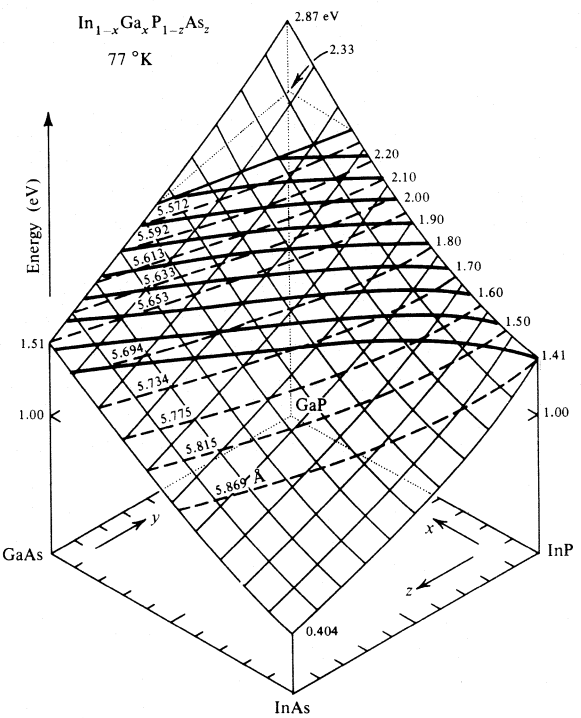

Fig. 1. Energy-gap surface (77 K) as a function of crystal composition for the quaternary alloy system $In_{1-x}Ga_xP_{1-z}As_z$. The edges are divided into mole fractions of the individual binary constituents. Plotted also on the surface are isolattice-constant lines (dashed, 5.869-5.572 Å) and isoenergy-gap lines (solid, 1.41-2.20 eV). From the fact that the isolattice-constant and isoenergy-gap lines intersect, it is apparent that a wide range of compositions of $In_{1-x}Ga_xP_{1-z}As_z$ of higher energy gap can be grown along an isolattice-constant line on $GaAs_{1-y}P_y$ of lower energy gap, making possible also the growth of $In_{1-x}Ga_xP_{1-z}As_z/In_{1-x'}Ga_{x'}P_{1-z'}As_{z'}$ ($x \neq x'$, $z \neq z'$) homoheterojunctions.

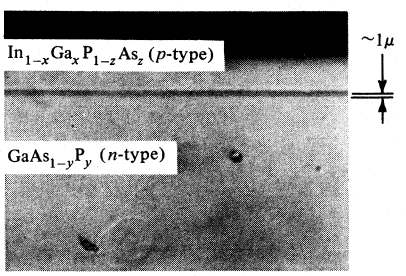
effect is a small overall decrease (increase) in the energy gap in the resulting $In_{1-x}Ga_xP_{1-z}As_z$, as is evident from Fig. 1 and the fact that the isoenergy-gap lines (solid) cross the isolattice-constant lines (dotted, 5.572-5.869 Å). Compared to homojunctions, the quality of the heterojunctions we have been able to construct on $GaAs_{1-y}P_y$ suggests that latching (one lattice locking on the other) [9] occurs when $In_{1-x}Ga_x \cdot P_{1-z}As_z$ is grown by LPE on $GaAs_{1-y}P_y$.

It is evident that the quaternary $In_{1-x}Ga_xP_{1-z}As_z$ ($z \sim 0.01$ or even larger) affords greater freedom and leeway than the ternary ($z = 0$) in fulfilling the basic lattice-match requirement of $GaAs_{1-y}P_y$ [1], [2], [8], [10] permitting in turn the LPE growth of high-quality heterojunctions on VPE $GaAs_{1-y}P_y$. In this paper we describe the growth of these heterojunctions and their laser operation in the crystal composition range $y = 0.32$-0.40, including at significantly shorter wavelengths and lower thresholds than comparable homojunctions [11].

Heterojunction Growth



By means of constant temperature LPE (~800°C, open-tube furnace) [4]-[8] we grow laser-quality (etch pit density $\lesssim 10^4/cm^2$)[1] p-type $In_{1-x}Ga_xP_{1-z}As_z$ layers lattice matched on n-type VPE $GaAs_{1-y}P_y$ substrates, where $x \approx 0.52 + 0.48y$ if $z = 0$ and is larger if $z > 0$. Heterojunctions are formed by dilute Zn diffusion from the melt into the $GaAs_{1-y}P_y$ substrate during the growth cycle. In the present work we have employed laser-quality $GaAs_{1-y}P_y$ substrates varying in composition from $y = 0.32$ to beyond $y = 0.40$ and have grown $In_{1-x}Ga_xP_{1-z}As_z$ epitaxial layers that are adjusted in composition x [4]-[8] to match each substrate composition y. Electron microprobe measurements indicate that the As fraction in the quaternary LPE layer is $z \sim 0.01$ but in some cases has been adjusted deliberately to be higher ($z \sim 0.10$) since there is much freedom in this variable and in x as long as the quaternary energy gap is maintained higher than that of the ternary substrate (see Fig. 1).

To grow the p-type quaternary layer, a cylindrical graphite boat with removable end caps is employed that contains an In-rich solution, the substrate crystal, and a source crystal of GaP which prevents Ga depletion from the solution [4]-[7]. Because of the large lattice mismatch between InP (5.869 Å) and GaP (5.451 Å) and the large Ga distribution coefficient [12], the choice of melt composition, and thus the crystal composition x, is sensitive to the composition y of the $GaAs_{1-y}P_y$ substrate. For $y \approx 0.40$ $GaAs_{1-y}P_y$, a typical melt consists of 10.5 g In, 0.20 g of InP, 0.13 g of GaP, 15 mg of InAs, and 75 mg of Zn.

Melt compositions, such as above, that will grow a lattice-matched quaternary epitaxial layer on a $GaAs_{1-y}P_y$ substrate are determined experimentally. First, from $In_{1-x}Ga_xP$ thermodynamic phase data [13] and experience [4], [7], an In-rich melt containing an approximately correct amount of InP and a purposefully insufficient amount of GaP is prepared which is intended to yield "lattice-matched" $In_{1-x}Ga_xP$ on the $GaAs_{1-y}P_y$ substrate. Then the amount of InAs necessary to grow a $z \sim 0.01$ quaternary layer is determined by trial and error, and is held constant in subsequent growth runs. Finally, the additional GaP necessary for saturation is provided by a GaP source wafer that is rotated into the melt during the saturation cycle (described below). After this procedure has been carried out once or twice, in later growths "fine tuning" of the composition is accomplished by varying slightly the amount of InP and GaP in the melt and correlating these values to crystal quality (etch pit density $< 10^4/cm^2$).

The LPE crystal growth procedure itself is carried out in two steps, with first the melt (once determined) being saturated at ~810°C for approximately 1 h. After the boat has cooled, a $GaAs_{1-y}P_y$ substrate crystal is placed off-center at one end, and a GaP source wafer is placed similarly off-center at the other end. The boat is reheated long enough to insure complete dissolution of the melt and the simultaneous incorporation of the Zn dopant, which is added to the boat after the saturation step because of the high Zn vapor pressure. After a 5-10°C cool-down to effect supersaturation, the boat is rotated to allow the melt to contact the substrate and permit the growth of a p-type quaternary layer. During the reheat cycle and growth of the p-type layer, Zn diffuses 1-2 μ into the n-type $GaAs_{1-y}P_y$ substrate, creating a thin compensated active region between the electrical junction and the metallurgical barrier.

A cleaved and etched cross section of a typical final structure ($y \approx 0.38$) is shown in Fig. 2. It is not a simple matter to determine directly the perfection of the ternary-quaternary heterojunction boundary, except by comparing heterojunction laser performance with that of homojunctions of the same composition y. The perfection of the LPE quaternary layer, however, is evident from its appearance after polishing and etching, and its behavior in photoluminescence. If the etch pit density is relatively low ($\lesssim 10^4/cm^2$; see [7, fig. 3]), as in the present work, the photoluminescence is strong and photopumped laser operation of thin samples of the $In_{1-x}Ga_xP_{1-z}As_z$ LPE layer is possible (5500 Å, $x \sim 0.70$, $z \sim 0.01$, 77 K). We infer that the ternary-quaternary heterojunction boundary itself is reasonably free of defects based on the energy range and quality of the diode laser performance that is described in what follows.

$In_{1-x}Ga_xP_{1-z}As_z/GaAs_{1-y}P_y$ Heterojunction
$x \sim 0.70, y \approx 0.38, z \sim 0.01$

Fig. 2. Cleaved and etched face of an $In_{1-x}Ga_xP_{1-z}As_z/GaAs_{1-y}P_y$ heterojunction grown by LPE. Both the metallurgical junction and a thin (~1 μ) compensated active layer in the VPE $GaAs_{1-y}P_y$ substrate are clearly distinguishable. The circular mottled areas are due to the etching process and cannot be correlated with any crystal imperfections.

[1]Thin photopumped samples of LPE $In_{1-x}Ga_xP_{1-z}As_z$ ($x \sim 0.70$, $z \sim 0.01$) operate as lasers at $\lambda \sim 5500$ Å (77 K), just as do similar $In_{1-x}Ga_xP$ ($x \sim 0.70$) samples [4] when the LPE layer is grown with a good lattice match on the substrate (i.e., when possessing less than 10^4 etch pits/cm^2, see [4] and [7]).

Threshold and Spectral Data

Although the entire $GaAs_{1-y}P_y$ crystal composition range $y < 0.40$ is of interest for various studies, in the work reported here we have been concerned mainly with $y \approx 0.32$ to 0.40 crystals. This is an interesting crystal composition range because, for example, in N-doped $GaAs_{1-y}P_y$ the isoelectronic trap state lies just above the Γ band edge ($E_N > E_\Gamma$) for $y \approx 0.38$ and just below ($E_N < E_\Gamma$) for $y \approx 0.40$. We mention that these heterojunctions are the first diodes in which the N isoelectronic trap has been involved in stimulated recombination. That is, the effect of the N trap (A-line) can be observed in $In_{1-x}Ga_xP_{1-z}As_z/GaAs_{1-y}P_y$:N heterojunctions but not in comparable homojunctions [14], [15]. Also, $y = 0.38$–0.40 crystals are of fundamental interest because of the proximity of the X-band minima to the Γ minimum in the composition range approaching the direct-indirect transition ($E_\Gamma = E_X$ at $y \equiv y_c \approx 0.46$, 77 K [16]). That is, as $y \to y_c \approx 0.46$, the direct band edge E_Γ approaches the indirect edge E_X and direct-gap band-to-band recombination weakens [17]. Moreover, donor states associated with the indirect band minima approach and become degenerate with E_Γ before the indirect band edge itself, and thus cause a premature weakening of the direct-gap band-to-band recombination. This is evident from the following energy estimates (77 K):

$$\begin{aligned} E_X - E_\Gamma \text{ [16]} &\approx 80 \text{ meV} && y = 0.38 \\ &\approx 60 \text{ meV} && = 0.40 \\ &\approx 39 \text{ meV} \sim E_D(X) = E_D(\text{Te}) \text{ [18]} && = 0.42. \end{aligned} \tag{1}$$

Depending upon the donor species and its depth, it is clear that the indirect behavior of $GaAs_{1-y}P_y$ intrudes rapidly in the range $y \sim 0.40$, and should be observable in laser thresholds as, in fact, is the case.

Heterojunction laser data on $y = 0.38$ $GaAs_{1-y}P_y$ (see Fig.) are shown in Figs. 3-5. At low-current levels (17.6 A/cm^2, Fig. 3), the emission is fairly broad and because of small filling of the donor band tail, peaks ~50 meV below the region of laser emission. As the current is increased, band filling causes the emission to shift (~50 meV) to higher energy but not as much (~100 meV) as in conventional Zn-diffused $GaAs_{1-y}P_y$ homojunctions of comparable donor doping ($n_d \sim 10^{18}$/cm^3) [19], which, incidentally, do not operate at these high energies and low thresholds. The small band-filling shift observed here may be an indication that during the LPE heterojunction growth process donors out-diffuse from the substrate while Zn in-diffuses.

For the $y = 0.38$ laser diode of Fig. 3, the spectral width is ~22 meV just below laser threshold and, as expected, narrows abruptly to ~3 meV at threshold ($J_{th} = 1.4 \times 10^4$ A/cm^2). As Fig. 4 shows, owing to the Zn acceptor, the heterojunction laser operates at considerably lower energy than the same n-type substrate $GaAs_{1-y}P_y$ when photopumped. When the heterojunction diode of Figs. 3-5 is driven harder (Fig. 5), a slight increase occurs in the range of laser operation on the shorter wavelength side of the emission spectrum and a much larger increase on the longer wavelength side. On the shorter wavelength side, laser modes exist to within about kT of

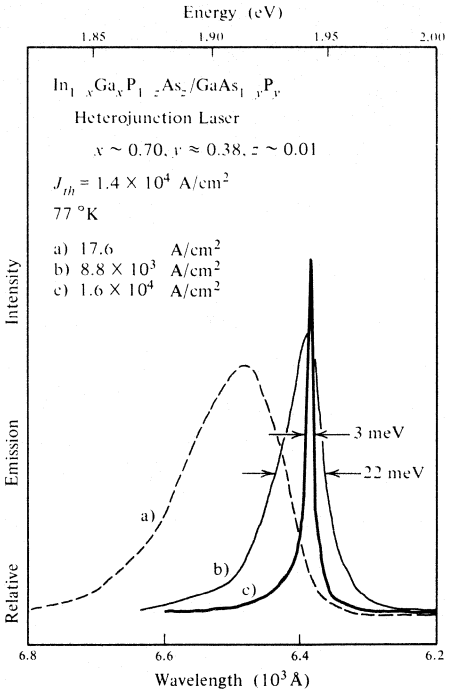


Fig. 3. Emission spectra (77 K) of an $In_{1-x}Ga_xP_{1-z}As_z/GaAs_{1-y}P_y$ ($x \sim 0.70$, $y \approx 0.38$, $z \sim 0.01$) heterojunction laser diode fabricated by the LPE growth of the quaternary on the VPE ternary substrate. At low excitation levels (17.6 A/cm^2) the emission spectrum (dashed) is fairly broad and occurs at low energy. At higher excitation, band filling occurs, the emission shifts (~50 meV), abrupt narrowing is observed, and laser operation is achieved at a current density of ~1.4×10^4 A/cm^2, or almost 20× smaller than for comparable homojunctions.

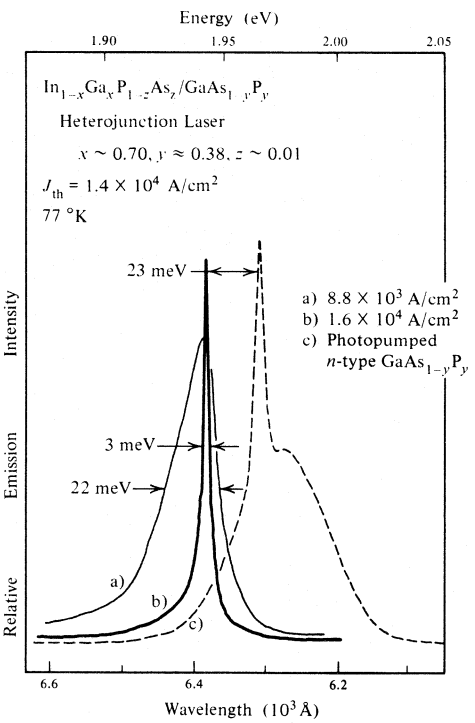

Fig. 4. Emission spectra (77 K) obtained on the $In_{1-x}Ga_xP_{1-z}As_z/GaAs_{1-y}P_y$ heterojunction laser diode of Fig. 3 just below and above laser threshold. At threshold, the spectrum narrows abruptly to a half-width of ~3 meV. Shown as a dashed curve for comparison are data obtained on a thin photopumped n-type $GaAs_{1-y}P_y$ platelet taken from the same substrate. The 23 meV downward energy shift is due to the Zn acceptor in the active region of the heterojunction.

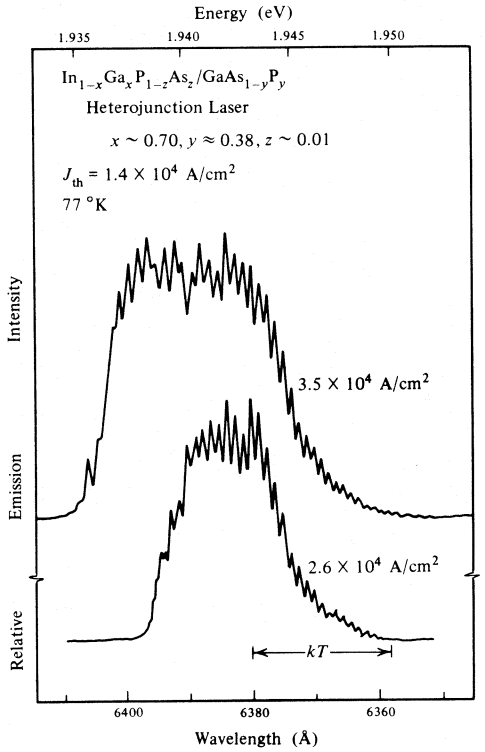

Fig. 5. Emission spectra (77 K) obtained at higher excitation levels on the $In_{1-x}Ga_xP_{1-z}As_z/GaAs_{1-y}P_y$ heterojunction laser diode of Figs. 3 and 4. Cavity modes are evident at wavelengths shorter than 6360 Å and at current densities well below (10×) those of comparable homojunctions. As the diode is driven harder, there is a large increase in the range of laser operation on the longer wavelength side of the emission spectrum and a smaller increase on the shorter wavelength side, which extends to within $\sim kT$ of $E_\Gamma - E_{Zn}$.

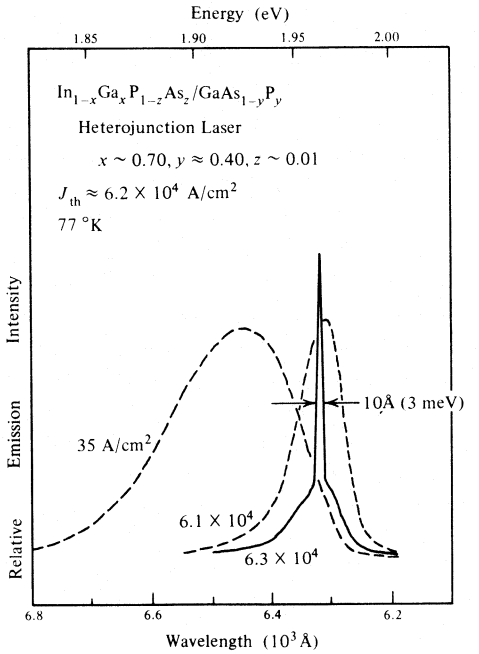

Fig. 6. Emission spectra (77 K) obtained on $y \approx 0.40$ $In_{1-x}Ga_x \cdot P_{1-z}As_z/GaAs_{1-y}P_y$ ($x \sim 0.70, z \sim 0.01$) heterojunction laser diode. At low excitation levels (35 A/cm^2) the emission is broad and is centered significantly below the stimulated emission peak. At higher excitation levels band filling occurs (~50 meV), abrupt spectral narrowing is observed, and laser operation is achieved at a current density of $\sim 6.2 \times 10^4$ A/cm^2. This higher threshold current density (5×) than for the diode of Figs. 2–5 is expected as the composition y of the $GaAs_{1-y}P_y$ substrate approaches the direct-indirect crossover y_c ($E_\Gamma = E_X$ at $y \equiv y_c \approx 0.46$, 77 K), and E_X approaches E_Γ ($E_X - E_\Gamma \approx 60$ meV at $y = 0.40$).

$E_\Gamma - E_{Zn} = 1.952$ eV. In this region a high-energy Boltzmann tail is observed because of the low optical losses of these diodes. As expected, band filling does not play much of a role beyond the point of threshold because of the increased (stimulated) recombination rate. We mention that the higher energy modes of Fig. 5 are comparable to the highest energies observed previously on $GaAs_{1-y}P_y$ homojunctions [11], but occur here at *10× lower* excitation levels, thus giving some indication of the quality of these heterojunctions.

Higher energy heterojunction laser operation has been obtained on $y \approx 0.40$ $GaAs_{1-y}P_y$ substrates as shown in Fig. 6 [8]. Although not shown in Fig. 6, the highest energy modes extend to well below 6300 Å, which is considerably shorter than for all previous $GaAs_{1-y}P_y$ diodes. We mention also that significantly lower excitation levels have been employed in the work reported here than for comparable $GaAs_{1-y}P_y$ homojunctions.

For the laser diodes of Fig. 6, the threshold currents ($J_{th} \approx 6.2 \times 10^4$ A/cm^2) are significantly higher (5×) than for $y = 0.38$ $GaAs_{1-y}P_y$, which in turn exhibits higher threshold currents than $y = 0.32$ crystal (see Figs. 3 and 7). As already mentioned, this behavior is expected as $y \to y_c$ and indirect donor states, as in (1), approach E_Γ. It is not clear, however, that the limit for $In_{1-x}Ga_xP_{1-z}As_z/GaAs_{1-y}P_y$ heterojunction laser operation occurs at $y = 0.40$. Rather, it is more likely that the limit is higher, perhaps as high as $y = 0.42$ according to the estimates of (1). This is suggested by two other observations. 1) The heterojunctions of this work have not been optimized in terms of doping, active layer thickness, or heat treatment effects, and probably can be extended in operation to higher limits, particularly if sophisticated stripe geometries are employed. 2) The heterojunction *I–V* characteristics of this work give no hint of "freeze-out" at 77 K to higher impedances, even for crystal compositions near $y_c \approx 0.46$ (77 K). On the other hand, homojunctions in this composition range generally exhibit a pronounced lean in the *I–V* characteristics at 77 K.

Index Dispersion

One of the desirable properties of the heterojunctions described here is that somewhat above laser threshold the emission is essentially all stimulated due to the relatively good carrier and optical energy confinement. This permits well-defined cavity modes to develop with little spontaneous background radiation as is shown for the $y = 0.32$ crystal of Fig. 7. We mention that this is not the case, however, for N-doped $GaAs_{1-y}P_y$ substrates, where the effect of the N trap is to introduce strong non-$k = 0$ recombination components and a relatively strong spontaneous radiation background [14]. This behavior is likely to occur also as $y \to y_c$ and, according to the estimate of (1), indirect-gap behavior begins to intrude due to the proximity of the *X*-band edge rather than the effect of the N trap.

From the usual laser-mode spacing formula

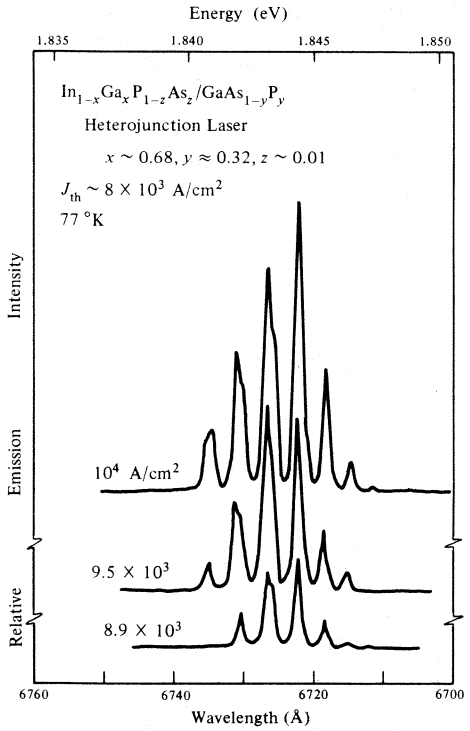

Fig. 7. Laser modes (77 K) of an $In_{1-x}Ga_xP_{1-z}As_z/GaAs_{1-y}P_y$ ($x \sim 0.68$, $y \approx 0.32$, $z \sim 0.01$) heterojunction just above threshold ($J_{th} \sim 8 \times 10^3$ A/cm^2). The emission is essentially all stimulated with well-developed cavity modes (and low spontaneous emission background) due to the relatively good carrier and optical energy confinement of the heterojunction.

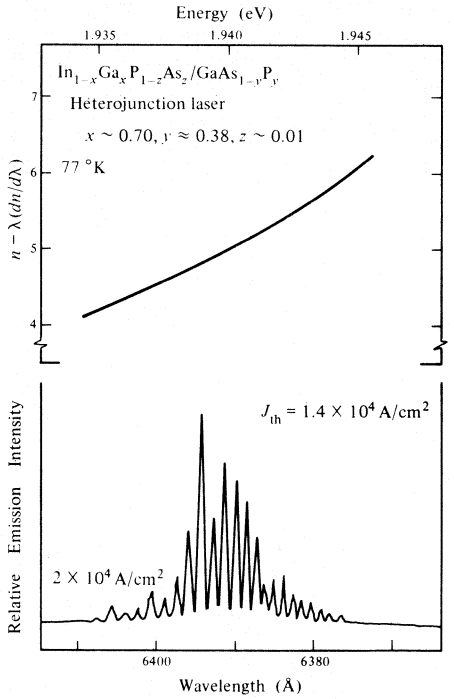

Fig. 8. Emission spectra (77 K) at high excitation level and index of refraction dispersion data $\{n - \lambda(dn/d\lambda)\}$ for an $In_{1-x}Ga_xP_{1-z}As_z/GaAs_{1-y}P_y$ heterojunction laser diode. The index expression increases monotonically with energy, indicating an increase in absorption at higher energy as expected. This device exhibits the typical mode structure of a Fabry–Perot structure operated well above laser threshold.

$$\Delta\lambda = (\lambda^2/2L)\,\{n - \lambda(dn/d\lambda)\}^{-1} \qquad (2)$$

where L is the diode length and n the index of refraction, the dispersion quantity $\{n - \lambda(dn/d\lambda)\}$ can be determined at various wavelengths if well-defined modes are observed, as in the present work. For example, for the diode of Figs. 2–5, we obtain the data of Fig. 8. To obtain the index dispersion quantity plotted in the upper part of Fig. 8, an expanded plot of the laser-mode spectrum has been employed to insure accuracy. The monotonically increasing character of the upper curve of Fig. 8 displays the classic behavior expected of direct-gap band-to-band laser diodes [20]. For example, a similar plot (4.2 K) for the $y \approx 0.40$ diode of Fig. 6 is shown in Fig. 9 and is almost identical to the curve of Fig. 8 except for the expected shift to shorter wavelength (6255 Å $< \lambda <$ 6270 Å). In N-doped $GaAs_{1-y}P_y$, however, more complicated behavior is observed, which also depends upon whether the N trap lies above or below the Γ band edge as is reported elsewhere [15]. Finally, we mention that only in these heterojunctions has the effect of the N trap in stimulated emission been observed in a current-driven structure [14], [15].

Conclusions

In comparison to LPE $In_{1-x}Ga_xP$ layers grown on $GaAs_{1-y}P_y$ substrates, which yield rather poor heterojunctions unless an excellent lattice match is realized accidentally, we find that a small addition of As to the LPE growth process leads to uniformly good $In_{1-x}Ga_xP_{1-z}As_z/GaAs_{1-y}P_y$ heterojunctions. Because the isolattice-constant lines of Fig. 1 *cross* the isoenergy-gap lines, it is possible to grow, along an isolattice-constant line, a wide range of compositions of $In_{1-x}Ga_x \cdot P_{1-z}As_z$ of higher energy gap on $GaAs_{1-y}P_y$ of lower energy gap. In the present work the As composition has been restricted to the range $z \sim 0.01$, but this is not necessary and it is possible to grow $In_{1-x}Ga_xP_{1-z}As_z/In_{1-x'}Ga_{x'}P_{1-z'} \cdot As_{z'}$ ($x \neq x'$, $z \neq z'$) homoheterojunctions on $GaAs_{1-y}P_y$ substrates.

In the present work, i.e., the simpler case of $In_{1-x}Ga_x \cdot P_{1-z}As_z/GaAs_{1-y}P_y$ single heterojunctions grown on $y =$ 0.32–0.40 substrates, we observe much lower laser threshold currents than for comparable $GaAs_{1-y}P_y$ homojunctions. In addition, laser operation has been achieved at considerably shorter wavelengths (<6300 Å) than for $y \approx 0.40$ $GaAs_{1-y}P_y$ homojunctions. Because of the relatively good carrier and optical energy confinement of these quaternary-ternary heterojunctions, above laser threshold the spontaneous radiation background is low and, as is typical of heterojunctions, very good cavity modes can be resolved. This permits measurement of the index expression $\{n - \lambda(dn/d\lambda)\}$ in an energy range not previously examined in $GaAs_{1-y}P_y$. These results turn out to be useful in comparison with those on N-doped $GaAs_{1-y}P_y$ in studying the peculiarities of the N isoelectronic trap in a ternary system in the range $E_N \sim E_\Gamma$.

Finally, we remark that because no attempt has been made to optimize the various geometrical and doping parameters of the heterojunctions of this work, it is almost certain that threshold currents can be reduced and the wavelength range be extended still further.

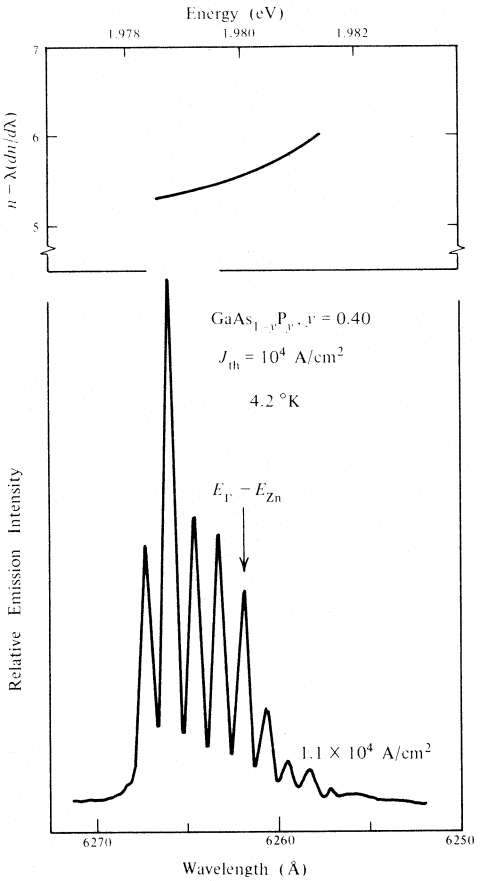

Fig. 9. Laser spectra (4.2 K) and index of refraction dispersion data $\{n - \lambda(dn/d\lambda)\}$ for an $In_{1-x}Ga_xP_{1-z}As_z/GaAs_{1-y}P_y$ heterojunction ($x \sim 0.70, y \approx 0.40, z \sim 0.01$) operated just above threshold. As expected, the index expression increases monotonically with energy through the donor band-tail region and into the band edge. Unlike these data, the first recorded for $y \sim 0.40$ $GaAs_{1-y}P_y$, structure is observed in the index data if N traps are introduced into the region (energy) of laser operation [15].

Efficient InSb Laser with Resonant Longitudinal Optical Pumping

N. MENYUK, A. S. PINE, AND A. MOORADIAN

Abstract—External quantum efficiency of > 20 percent has been achieved from tunable CW InSb lasers resonantly pumped with a CO laser. Thin InSb platelets at < 10 K were pumped in a longitudinal geometry with the InSb recombination emission parallel to the CO radiation. Single-longitudinal-mode operation with power up to 10 mW has been achieved with a 0.1-0.3-cm^{-1} linewidth, mechanically or thermally tunable over several cm^{-1}. Magnetic-field effects on the threshold and emission frequency have also been studied.

Introduction

OPTICAL PUMPING of semiconductor lasers provides a convenient means of excitation and investigation of those materials which are not readily available as injection lasers. The semiconductor laser can act as a tunable frequency converter for the usual fixed-wavelength pump. Several years ago, Phelan optically pumped InSb at ~10 K with pulsed GaAs diode lasers [1], [2] and flashlamps [3] in a transverse geometry where the 5.3-μm InSb laser radiation was emitted from cleaved edges perpendicular to the pumped face. This same geometry was used more recently to pressure tune InSb at 77 K with Q-switched Nd:YAG excitation [4], and to temperature and magnetic-field tune InSb at 10 K pumped with CW GaAs, Nd:YAG, and CO lasers [5]. The CW GaAs pumping led to a convenient tunable infrared source capable of Doppler-limited spectroscopy [5] of nitric oxide, ethylene, and water vapor in the 5.3-μm region. The transverse-pumped InSb typically yielded 1-10-μW output power for an incident power of 20-200 mW.

Much more efficient optical conversion has now been achieved by near-resonant excitation in a longitudinal geometry where the parallel incident radiation and stimulated emission are normal to the polished InSb platelet faces. A single-ended CW output of up to 10 mW has been obtained in a single-longitudinal Fabry-Perot mode with an incident CO laser power of 160 mW. This is almost a thousand times more output power than for the transverse geometry. An external quantum efficiency of ~ 21 percent is calculated from the double-ended output power divided by the absorbed incident power $(2P_{out}/(1-R)P_{in})$ where the reflectivity $R \simeq 44$ percent. Thresholds for the two geometries are comparable (10-20 mW) and the emission frequencies are 20-30 cm^{-1} higher for longitudinal pumping. Magnetic-field effects on the threshold and emission frequencies are similar for the two pumping schemes.

Longitudinal bulk pumping of semiconductor lasers was first accomplished by Stillman *et al.* [6] and Johnson and Holonyak [7] for Cd(SeS) and Ga(AsP) crystals in the red spectral region. They established that the platelet thickness L should be less than the carrier diffusion length or the pump light absorption depth. At the same time the Fabry-Perot mode spacing $\Delta\nu_L = 1/2\eta^* L$ should not be larger than the spontaneous-emission gain bandwidth. For InSb at liquid-helium temperatures the spontaneous bandwidth is on the order of $kT/hc \sim 5$ cm^{-1}; so for an effective refractive index $\eta^* = \eta - \lambda(\partial\eta/\partial\lambda) \sim 5$, the minimum thickness should be ~ 200 μm. Since this thickness is several times the carrier diffusion length, it is necessary to resonantly pump near the absorption edge of the crystal. The number of longitudinal cavity modes that can oscillate is roughly the gain bandwidth divided by $\Delta\nu_L$; so single-mode operation is easily achieved for platelets near the minimum thickness.

Experiment

The InSb platelet samples were prepared from ~ 1-cm^2 wafers cut from low-carrier-concentration (n or p ~ 10^{14} cm^{-3}) ingots grown by Cominco. The laser-cavity faces were etch-polished (2-percent Br in CH_3OH) to a high luster at the desired thickness with a parallelism better than 1 mrad. The platelets were spring clamped and thermal-compound greased to a helium-Dewar copper cold finger having a 3-mm optical aperture. The optical excitation was provided by a stable CW grating-tunable CO laser focused onto the sample with a spherical 10-cm-focal-length BaF_2 lens. The sample was tilted a few degrees from normal incidence to avoid feedback into the CO laser. Forward InSb laser emission was measured directly by a calibrated Eppley thermopile or with a Barnes InSb photovoltaic detector through a Spex $\frac{3}{4}$-m grating spectrometer and chopper. Forward, rather than backward, emission was monitored since the InSb provided partial filtering of the CO radiation, and since no beamsplitter would be required. The InSb could be probed spatially and wedge tuned by simple lateral motion of the sample. The magnetic field could be applied in the plane of the platelet normal to the optical propagation.

Thresholds, conversion efficiencies, and spectral properties were measured on a number of samples of varying carrier concentration and type, crystal orientation, and thickness. These variables had little systematic effect on the results, except for the thickness dependence of the number of Fabry-Perot modes. Also ⟨111⟩-face orientation was avoided because of poor surface polish. The data presented here (except where indicated) are for a Cominco (ingot #W501) p-type = 4×10^{13}-cm^{-3} ⟨110⟩-face crystal of thickness $L = 180$ μm operating in a single dominant longitudinal mode.

The CW thresholds of both longitudinal- and transverse-pumped InSb lasers are compared in Fig. 1 as a function of the near-resonant incident CO frequency. The threshold of the transverse-surface-pumped sample described earlier [5]

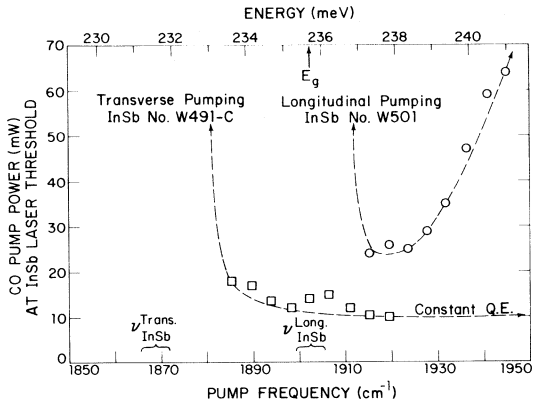

Fig. 1. Threshold power of InSb laser versus CO-pump laser frequency for transverse □ and longitudinal ○ geometry. InSb-laser-emission range and energy gap is indicated; extrapolated constant quantum efficiency (QE) curve is also shown.

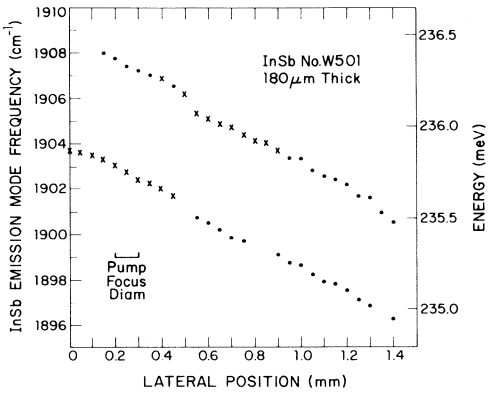

Fig. 2. Wedge tuning of longitudinal InSb laser modes by lateral displacement. Principal modes indicated by × and subsidiary modes by ·

(Cominco #W491-C, n ~ 1.4×10^{14} cm^{-3}, ⟨111⟩-face, ⟨110⟩ cleaved edges spaced by 300 μm, thickness ~ 30 μm) decreases just above the absorption edge to a shallow minimum and then increases slowly along a curve of roughly constant quantum efficiency all the way up to a near-IR Nd:YAG pump (65-mW threshold). The threshold of the longitudinal-bulk-pumped sample drops precipitously above the absorption edge to a sharper minimum and then rises steeply due to a decreasing absorption depth for the higher pump frequency. CW longitudinal laser emission could not be achieved with the Nd:YAG laser pump. Also indicated in Fig. 1 is the range of laser frequencies emitted by the two samples and the published band gap [8] E_g of the material.

There are several noteworthy points illustrated in Fig. 1. First, the shapes of the two threshold curves are characteristic of the pumping geometries and are qualitatively explained on the basis of surface and volume excitation. Second, the comparable magnitudes of the thresholds at minimum are probably due to the similar excitation volumes and population-inversion densities for the two schemes. The transverse pump is focused with a 10-cm cylindrical lens for a beam waist of ~ 100 μm and an excited volume of ~ 0.9×10^6 μm^3 assuming carrier diffusion to the rear surface and subsequent confinement. The longitudinally pumped volume is ~ 2×10^6 μm^3. The threshold-density agreement is fortuitous since thresholds varied by factors of 3–5 due to sample inhomogeneity.

The frequency shift exhibited by both the absorption edge and laser emission of the InSb in the two geometries is unexplained. It has been noted that sample inhomogeneity [5] and dopant variation [2] create frequency discrepancies of this magnitude. However, in these experiments a systematic trend toward higher frequencies for longitudinally pumped samples has been observed; the data shown are for typical samples. A similar pumping shift was observed on samples prepared from the same wafer and no overlap occurred for the highest frequency transverse and lowest frequency longitudinal samples tested.

Band-gap shifts could arise from temperature or stress variations or from the dynamic Burstein shift (band filling). However, the same cold-finger mounting techniques were used for all CO-pumped samples, so that stress and temperature shifts were not expected. In addition, since the incident power density was comparable for the two pumping cases, band filling should also have been comparable. The dynamic Burstein shift was directly observed in the longitudinal geometry as a highly nonlinear transmission (bleaching or saturable absorption) of the InSb platelet to the CO radiation above the band gap.

The longitudinally pumped InSb sample could be mechanically tuned continuously over several cm^{-1} by lateral displacement of the sample, as shown in Fig. 2. Here the lack of parallelism of the polished cavity surfaces (~ 0.5 mrad) results in wedge tuning of the Fabry–Perot modes. Principal modes are indicated by crosses; subsidiary modes, by dots; a single dominant mode was achieved over much of the range. Some sample inhomogeneity may also contribute to this tuning, particularly where the weaker modes are displaced beyond the original spontaneous gain bandwidth.

Spectral traces of the wedge-tuned InSb laser emission and transmitted CO-pump radiation are shown in Fig. 3. Here the resolution of the spectrometer (~ 0.1 cm^{-1}) is sufficient to observe a broadening of the InSb mode width over the CO linewidth. This broadening of from 0.1 to 0.3 cm^{-1} is attributed to a number of closely spaced transverse cavity modes associated with each longitudinal mode. The number of transverse modes allowed is roughly $\eta^* a^2/\lambda L$, the Fresnel number, where a is the aperture, or beam, radius. In the case of Figs. 2 and 3, $a \sim 50$ μm, $L \sim 180$ μm, so ~ 13 modes are supportable and are probably launched by the surface roughness and lack of parallelism. The wedge effect over the beam spot size is seen in Fig. 2 to correspond to the observed width. The surface roughness for etch-polished and $\frac{1}{4}$-μm-diam diamond-paste-polished InSb has also been probed with a 2.5-μm-radius Dektak stylus and is shown in Fig. 4. These surface irregularities, if accurately depicted, are less severe than the wedge effect for causing transverse modes. More refined polishing techniques could sharpen the InSb linewidth, but the Fresnel number is still unfavorably large. A longer cavity decreases the Fresnel number, but increases the possible number of longitudinal modes. Surface aperturing using photoresist etch-roughening could reduce a, but this would eliminate the possibility of wedge tuning or surface probing.

The forward InSb emission corresponding to the spectra of

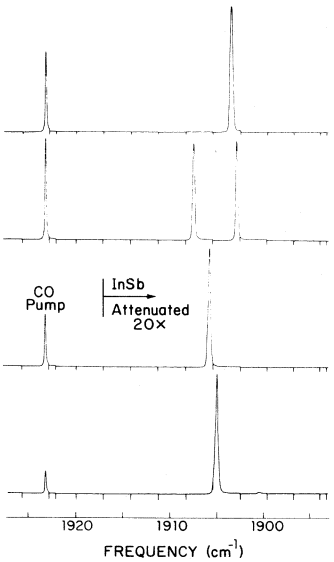

Fig. 3. Wedge-tuned InSb laser spectra. InSb #W501 corresponding to Fig. 2. The InSb emission is attenuated by a factor of 20 with a mica filter to avoid detector saturation for linewidth comparison to residual CO-pump line at 1923.5 cm^{-1}.

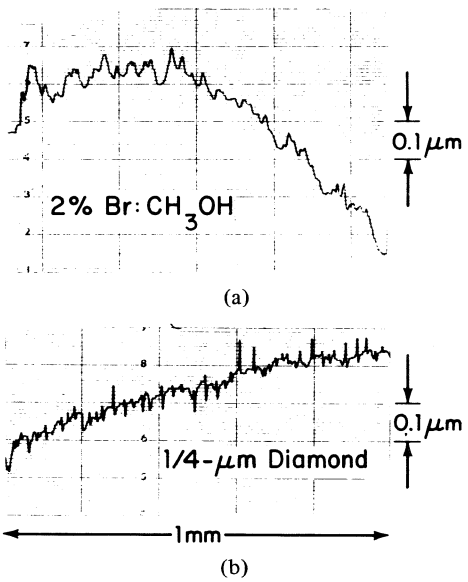

Fig. 4. Surface roughness of polished InSb samples. (a) 2-percent Br in CH_3OH etch-polish. (b) $\frac{1}{4}$-μm diamond-paste polish.

Fig. 3 was about 7.5 mW in the dominant mode for about 160 mW of incident CO radiation at 1923.5 cm^{-1} and a reflectivity of 44 percent. The double-ended efficiency was therefore ~ 17 percent which could be increased slightly with magnetic field.

Magnetic-Field Effects

The effects of magnetic field on the threshold, conversion efficiency, and emission frequency of InSb lasers have been the subject of a number of interesting studies for both optical [2], [5] and injection pumping [9]-[14]. It has been found previously [2], [5], [9], [11], [12] that magnetic fields decrease threshold and increase efficiency. This has been attributed [12] to a field-dependent condensation of the Landau-level density-of-states. Similar effects in InAs diode lasers [15] have been interpreted as magnetic deflection confinement of diffusing and drifting carriers. The magnetic-field dependence of the CW threshold of the longitudinal optically pumped InSb is given in Fig. 5. These results resemble previous optically pumped cases [2], [5] but are less dramatic than for InSb diode lasers [9], [11]. Here there are no drift fields and the illuminated region is already larger than the carrier diffusion length, so the confinement interpretation is not appropriate. The Landau condensation mechanism seems to be applicable and may explain the Fig. 5 threshold variations in correspondence with the mode shifts shown in Fig. 6(b).

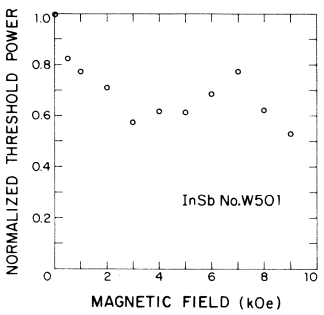

Fig. 5. Magnetic-field dependence of CW InSb threshold.

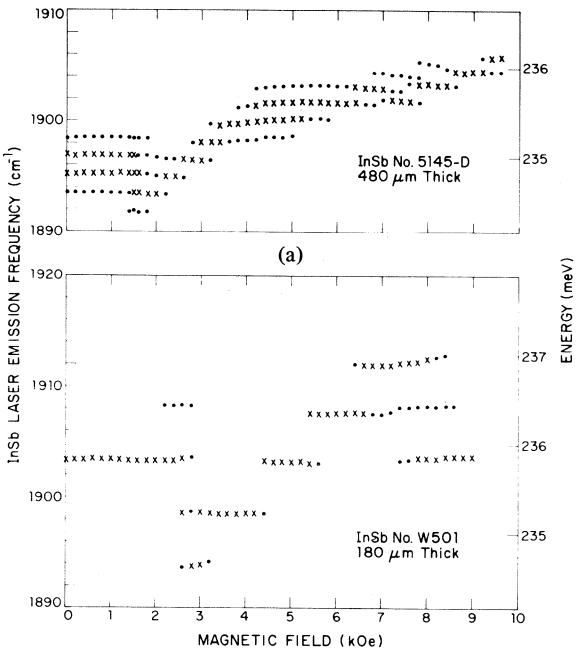

Fig. 6. Magnetic-field dependence of InSb laser mode frequencies for two sample thicknesses. Principal modes indicated by × and subsidiary modes by ·

The double-ended conversion efficiency in this case increases irregularly to ~ 21 percent at 8.5 kOe with 10-mW forward output for a 160-mW pump at 1923.5 cm^{-1} and $R = 44$ percent.

There is less universal experimental accord on the magnetic-field dependence of the emission frequency of InSb lasers. Phelan *et al.* [9] and Bell and Rogers [13] observed a strong

linear increase of frequency at moderate fields (20-30 kOe) followed by a sudden frequency drop and smaller linear increase at higher fields. These two segments were attributed to up and down spin states of the lowest Landau level. A different ordering was observed by Shotov *et al.* [14] with the large-slope segment at lower fields (4-10 kOe) at lower frequency than the high-field segment. This was explained by transitions of electrons to light and heavy hole bands, respectively. None of these studies gave zero field results because of the higher thresholds required.

For CW transverse optically pumped InSb [5], a low-field (1.5-2 kOe) minimum in the emission frequency was observed. Fig. 6 shows similar results for samples of two different thicknesses optically pumped in a longitudinal geometry. Though there are minor differences in the magnetic-field tuning between these samples and the transverse-pumped case [5], the presence of the low-field minimum seems to be independent of pumping geometry, field or crystal orientation, and sample concentration or type.

Prior to the CW transverse pumped case [5], no data on the emission frequency between 0 and 2 kOe had been reported. We speculated there [5] that the low-field minimum may be caused by a magnetic-field-induced increase in the exciton binding energy which allows the exciton peak to emerge from the continuum density-of-states at moderately low fields. The bound exciton is relatively stable in position for low fields since it tunes according to a quadratic Zeeman effect. The linear Landau-level tuning of the free carriers in the band therefore lifts the continuum away from the exciton. At zero field the band states and exciton (with finite linewidth due to lifetime effects) are not resolved, and the density-of-states may peak above the exciton level. As the field is raised the exciton becomes discrete and its peak defines the laser frequency. At still higher fields, when the cyclotron energy greatly exceeds the zero-field binding energy, the exciton level approaches the field dependence of the free-electron Landau level [16]. Such an effect has been advanced by Johnson [17] to interpret structure in the low-temperature magnetoabsorption spectrum of InSb.

Application to Spectroscopy

Doppler-limited spectroscopy at 5.3 μm has been demonstrated with CW InSb lasers optically pumped in the transverse geometry [5]. The longitudinally pumped lasers with tunable single-mode output of much higher power have an even greater potential for spectroscopy. At present the resolution of the device is limited by the broad linewidth (0.1-0.3 cm^{-1}) arising from the spurious transverse-cavity modes associated with the longitudinal peak. This linewidth, which is barely adequate for atmospheric-broadened spectroscopy, may be improvable with refined fabrication techniques.

The mechanical- and magnetic-field-tuning techniques are useful to obtain quasi-continuous coverage over tens of cm^{-1}. Mode hopping is prevalent with magnetic tuning as seen in Fig. 6 where each mode pulls very little with field. Significant mode pulling as a function of magnetic field has been observed in the InSb spin-flip Raman laser, where the spontaneous linewidth can be comparable to, or narrower than, the cavity linewidth [18], [19]. In the present case, the broader gain profile and small H-field dependence of η^* results in very small continuous tuning.

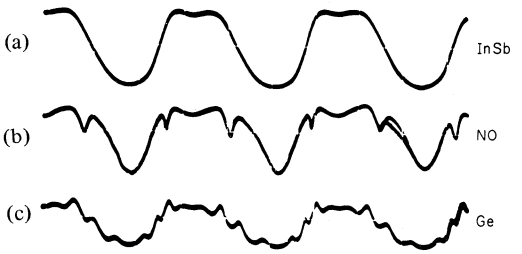

Fig. 7. Oscilloscope traces of real-time temperature tuning of longitudinal InSb laser by 60-Hz modulation of CO-pump intensity. (a) Direct frequency- and amplitude-modulated InSb emission at 1903.1 cm^{-1}. (b) Transmission through a 10-cm 10-torr cell of NO exhibiting $R_{1/2}(15/2)$ absorption dips upon heating and cooling. (c) Transmission through a Ge etalon with 0.13-cm^{-1} fringe spacing.

Wedge tuning provides potentially continuous coverage between modes as exhibited in Fig. 2. However, at present wedge tuning creates annoying amplitude fluctuations due to the stochastic nature of the transverse modes supported by the poorly polished surfaces. For these reasons, mechanical and magnetic-field tuning are most useful for biasing the emission in the spectral range of interest, where temperature tuning can be used for fast smooth scanning. Such thermal scanning can be achieved by simply modulating the incident pump intensity. An example of real-time temperature tuning is shown in Fig. 7 where the CO laser power is 20 percent modulated with a 60-Hz sine wave applied to the discharge voltage. The upper trace (a) is the resultant frequency- (and amplitude-) modulated output of the InSb at 1903.1 cm^{-1}; the middle trace (b) is a spectral absorption of the $R_{1/2}(15/2)$ line of nitric oxide at 10 torr in a 10-cm cell; the bottom trace (c) shows the interference fringes of a 0.96-cm-thick Ge etalon. The traces are poorly resolved because the laser linewidth is broader than the spectral features examined.

Conclusions

The high-power tunable single-mode operation of the longitudinal optically pumped InSb laser makes it a potentially attractive device for infrared spectroscopy and communications. The principal drawback is its broad linewidth which may be amenable to improvement. Some important features of this laser relative to the transverse pumped device are not understood. Foremost among these are: 1) the hundred-fold increase in conversion efficiency where the excitation density and thresholds are comparable, and 2) the shift to higher frequencies of the pump absorption and output emission of the longitudinal device. In addition, while the much broader mode width of the longitudinal-pumped device may be due to surface roughness and lack of parallelism, the mode purity of the transverse-pumped laser is surprising in view of its comparably large Fresnel number. The magnetic-field effects on the threshold and efficiency are similar to earlier results and are apparently related to magnetic condensation of the density-of-states and resultant mode shifts. Exciton effects are thought to be responsible for the low-field minimum in the emission frequency of InSb.

The Analysis of Optical Scattering in Double-Heterostructure and Five-Layer Heterostructure (GaAl)As/GaAs Injection Lasers

G. H. B. THOMPSON, P. A. KIRKBY, AND J. E. A. WHITEAWAY

Abstract—**The optical-absorption loss in (GaAl)As/GaAs heterostructure lasers with narrow active layers and passive layers doped below 5×10^{17} cm^{-3} should be less than 5 cm^{-1}. Measurements which have been made on a variety of three- and five-layer lasers have seldom shown such low figures. Optical-scattering loss at imperfections in the heterostructure interface could account for the discrepancy. An analysis of the scattering in both three- and five-layer heterostructures is presented. Curves are derived relating the absorption coefficient with the dielectric-constant step at the waveguide wall, the active-layer thickness, and the magnitude of the roughness. Measured losses as high as 12 cm^{-1} can be accounted for by a roughness amplitude of only 0.01 μm.**

Manuscript received January 8, 1975; revised February 10, 1975. This work was carried out with the support of the Procurement Executive, United Kingdom Ministry of Defence and sponsored by CVD.

I. INTRODUCTION

In a semiconductor laser optical absorption and dissipation processes decrease the external quantum efficiency and increase the threshold current density. Pinkas *et al.* [1] investigated these characteristics in double-heterostructure lasers with a variety of n- and p-type doping levels in the active layer. By measuring the dependence of incremental quantum efficiency on laser length they deduced values of the absorption coefficient α. The absorption coefficient was found to lie in the range 10 cm^{-1} and upwards. Pinkas *et al.* were satisfied that they could ascribe it to free-carrier absorption, either by the free carriers introduced by the doping or, when the doping was low, by the free carriers injected into the active layer to produce inversion.

We have investigated (GaAl)As/GaAs heterostructure lasers

in which the free-carrier absorption should be considerably reduced. In these layers the active layer was made particularly narrow so that the light was not strongly confined and could spread into the surrounding layers, which were deliberately doped at a low level ($< 5 \times 10^{17} cm^{-3}$) to reduce the free-carrier concentration. Some of these lasers were normal double heterostructures in which a wide spread of the optical distribution was desired for high peak power [2] and some were five-layer structures in which additional optical confinement barriers were provided by enclosing the first three layers between two additional layers of higher AlAs content [3]. Free-carrier losses should have been less than 5 cm^{-1}.

Only in one case have we measured a total optical-absorption loss low enough (4.8 cm^{-1}) to be accounted for by free carriers alone. In general, the absorption loss has been considerably greater than this. Although reasonably consistent for lasers from a given slice, it has varied apparently randomly from slice to slice. We believe that the additional loss can be attributed to optical scattering from roughness at the heterojunction interfaces and present here a theoretical analysis of the magnitude of the effects which may be expected. The analysis is based on the methods described by Marcuse [4] for determining the scattering from a slab dielectric guide, which we have extended to cover the range of dimensions and refractive-index steps appropriate to laser structures.

II. Analysis of Optical Scattering

A. Periodic and Statistical Roughness

A systematic sinusoidal undulation of the interface of a dielectric-slab guide scatters a guided wave into a directional beam of radiation. This makes an angle with the guide direction determined by the periodicity of the undulation, the relative dielectric constants of the inner and outer media of the waveguide, and the effective angle of incidence of the guided wave. The angle is given by an equation analogous to the equation for an optical grating. The general behavior is illustrated in Fig. 1.

The form of scattering produced by less regular imperfections in the interfaces of the dielectric guide depends on the Fourier spectrum of the roughness. Marcuse, in his analysis, defined the roughness in terms of an rms deviation of the interface from perfect planarity, given by an amplitude A, and described the particular form of the irregularity in terms of a correlation length B. The latter quantity, which roughly determines the extent of any given irregularity, is difficult to characterize precisely. In Marcuse's definition the correlation function of the roughness is assumed to decay exponentially with distance from any given point along the direction of the waveguide with a characteristic length B. Such an assumption still allows a wide range of irregularities to be included. Amongst these is one particularly simple example whose cross section is itself represented by an exponential shape, as illustrated in Fig. 2. It consists of a V-shaped groove, or ridge, with a width to the $1/e$ points of $2B$. Alternatively, a sawtooth groove or ridge would equally well satisfy the condition. Either of these are reasonably characteristic of the actual defects observed at the interface.

Fig. 3 shows the form of optical scattering induced by a guided wave at a rough interface with the previously stated characteristics, calculated according to the methods to be described. The dielectric guide illustrated is typical of that in a double-heterostructure laser with a thin active layer (the guide thickness is 0.12 μm and the dielectric-constant step is 1.3 at both guide interfaces). The polar diagram of the scattered intensity is shown for two values of the correlation length B. The scattered light emerges from the guide over a finite range of angles but is still fairly directional. The direction of peak intensity depends on $2\pi B$ in the case of a rough interface in a similar way to its dependence on the wavelength of the corrugation in the case of a sinusoidal interface. The angle ϕ indicates the direction of the scattered beam in the latter case. (Note, however, that for sinusoidal roughness ϕ becomes zero and then ceases to exist for long enough corrugation wavelength, in which case second-order effects should be taken into account.) The general tendency is for the polar diagram of the scattered intensity from the rough surface to rotate with ϕ, as B is increased, towards a more glancing angle of emergence, although it never drops to zero even for very large B.

Calculation of the total absorption loss of the fundamental guided mode due to scattering involves firstly obtaining the scattered intensity at any given angle of emergence, secondly

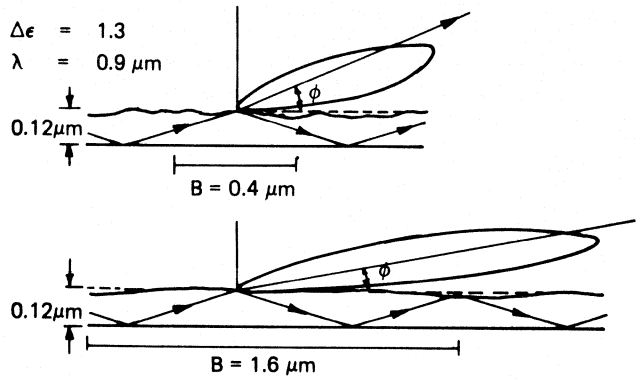

Fig. 3. Examples of beam radiated from dielectric-slab waveguide with rough interface.

integrating over all angles of emergence, and thirdly relating the total scattered intensity to the power carried by the fundamental mode. When additional modes can propagate in the guide it is necessary also to include in the scattering loss the power coupled to these modes. Although this power is not lost from the guide it is no longer coherent with the lasing mode and hence should not be included in determining the conditions which apply at threshold.

B. Scattering Theory for Three-Layer Guides

Marcuse gives an integral expression from which the absorption coefficient α, due to scattering from the fundamental mode into unguided waves, can be obtained in terms of the roughness amplitude A and the correlation length B. The variable parameters are the dielectric constants of the inner layer and the outer layers (a symmetrical guide is treated in which both outer layers have the same dielectric constant), the thickness of the center layer, and the wavelength. We will take the outer layers as having a dielectric constant of ϵ and the center layer as having a dielectric constant of $\epsilon(1 + \Delta)$ and a thickness of d. By judicious normalization it is possible to reduce the number of variable parameters and provide a more general expression better suited to numerical computation. We will define a normalized attenuation coefficient due to scattering α_0 such that

$$\alpha_0 = 2\pi\alpha/\Delta^2\beta_\epsilon^3 A^2 \tag{1}$$

where β_ϵ is the propagation constant of TEM waves in the outer layers of the dielectric guide ($= 2\pi\epsilon^{1/2}/\lambda$). We will also define a normalized correlation length B_n given by

$$B_n = \beta_\epsilon \Delta B. \tag{2}$$

The normalized absorption coefficient is then given, according to the Marcuse expression, by

$$\alpha_0 = \frac{2P_0\Delta Q_0^2}{x_0 B_n (P_0 D + 1)} \int_{-1}^{1} \frac{P}{(x_0 - x)^2 + (A/B_n)^2} \cdot \left\{ \frac{\cos^2 QD}{Q^2 - \cos^2 QD} + \frac{\sin^2 QD}{Q^2 - \sin^2 QD} \right\} dx \tag{3}$$

where

$$\begin{aligned} D &= \beta_\epsilon \Delta^{1/2} d/2 \\ Q_0 &\text{ satisfies } \cos(Q_0 D) = Q_0 \\ P_0^2 &= 1 - Q_0^2 \\ x_0^2 &= 1 + P_0^2 \Delta \\ P^2 &= (1 - x^2)/\Delta \\ Q^2 &= 1 + P^2 \end{aligned}$$

and we assume that both sides of the waveguiding layer are equally rough and described by the same parameters A and B. There are now only three variable parameters in the expression, namely Δ, D, and B_n.

Marcuse also gives an expression from which the absorption coefficient due to scattering from the fundamental mode into the mth-order mode can be obtained in terms of A and B. Using similar units to those in (3) above the normalized contribution α_m to the scattering loss is given by

$$\alpha_m = \frac{2\pi}{x_1 x_2 B_n} \cdot \left[\frac{Q_0^2 Q_m^2}{\{(x_0 - x_m)^2/\Delta^2 + (1/B_n)^2\}\{D + 1/P_0\}\{D + 1/P_m\}} \right] \tag{4}$$

where

$$\begin{aligned} Q_m &\text{ satisfies } \cos(Q_m D - m\pi/2) = Q_m \\ P_m^2 &= 1 - Q_m^2 \\ x_m^2 &= 1 + P_m^2 \Delta. \end{aligned}$$

We have computed the scattering coefficient from the fundamental mode into unguided radiation, and where relevant, into the higher order guided modes for two different values of Δ over a range of values of B_n and D. The results for the total scattering loss $(\alpha_0 + \Sigma\alpha_m)$ and the scattering into guided modes are shown for the two values of Δ in Figs. 4 and 5, respectively. The first point to be observed is that although the values used for Δ in the two figures differ by more than a factor of 5 (0.1115 compared with 0.0201) the two sets of curves are very similar and lie within 10 percent of one another over the major part of the range of interest. This is particularly convenient for interpolation of Δ, using a relatively small number of computed results, and indicates that Δ has been introduced in the most appropriate manner in the normalization of the quantities in (1) and (2).

The second point to be observed is that all the curves of scattering coefficient $(\alpha_0 + \Sigma\alpha_m)$ versus correlation length B_n for a given value of the guide thickness $2D$ show a relatively flat maximum. There is little variation in $(\alpha_0 + \Sigma\alpha_m)$ over an order of magnitude variation in B_n centered on the maximum. The results are therefore not very dependent on the particular type of surface roughness, which suggests that they should be reasonably reliable for predicting the actual behavior in practice. The value of B_n for which the maximum occurs lies close to unity ($B \simeq 0.5\ \mu$m) over the range of D from 0.6 to 1.3 (approximate range of guide widths 0.15-0.35 μm) becoming larger for narrower guides and also, as a result of coupling to higher order guided modes, for wider guides.

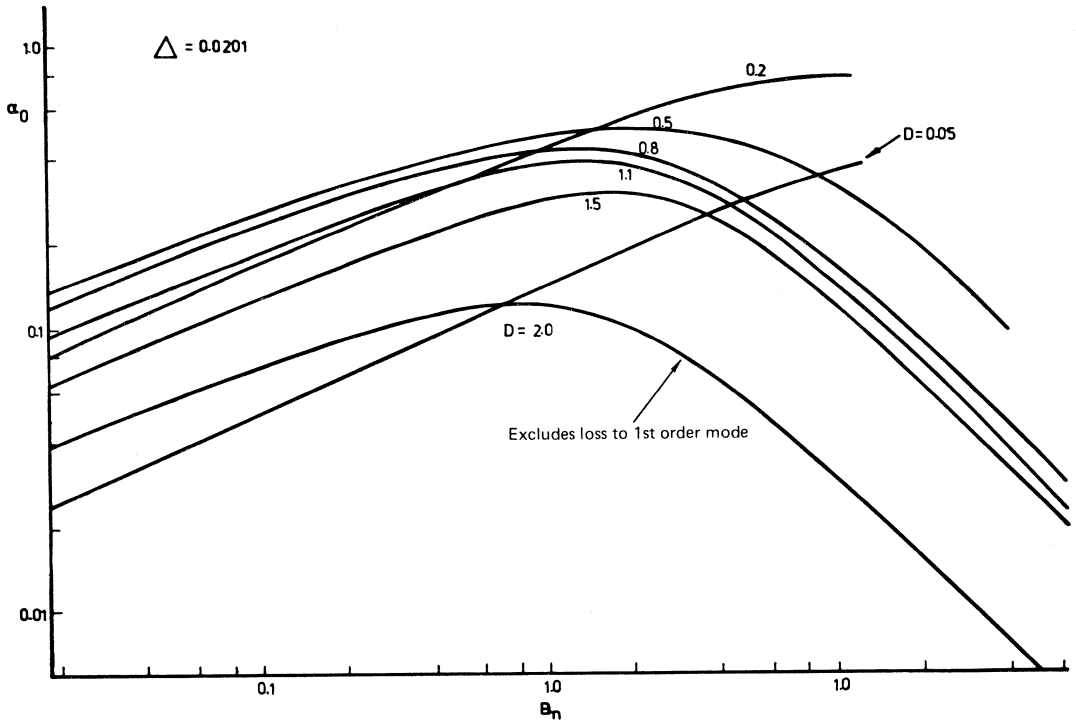

Fig. 4. Normalized absorption coefficient due to scattering as a function of correlation length with D as a parameter for a proportional step in ϵ of 0.0201.

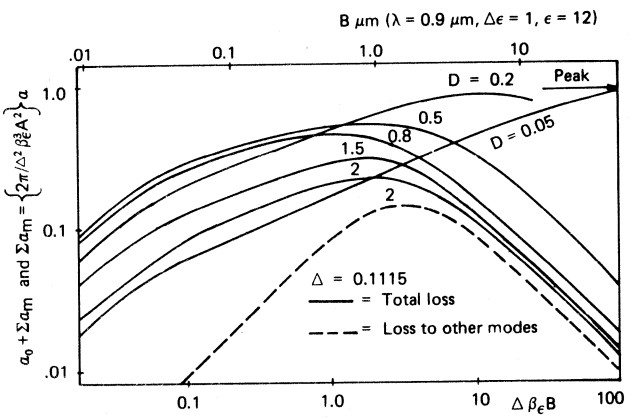

Fig. 5. Normalized absorption coefficient due to scattering as a function of correlation length with D as a parameter for a proportional step in ϵ of 0.1115.

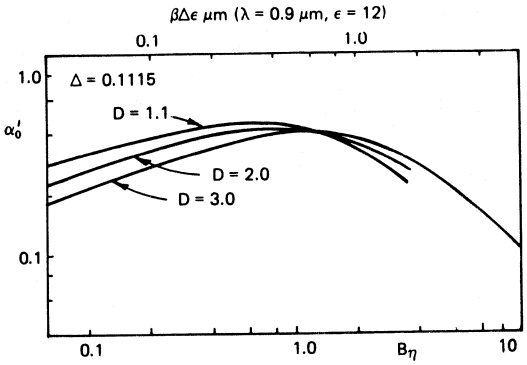

Fig. 6. Normalized absorption coefficient due to scattering from center layer of five-layer structure as a function of correlation length with D as a parameter.

C. Scattering Theory for Five-Layer Guides

In the five-layer laser it is necessary to take into consideration the additional scattering that occurs at the interfaces which bound the thin central layer. If the center layer is considered to be sufficiently narrow to avoid perturbing the overall optical distribution to any appreciable extent, then it is possible to modify Marcuse's expression quite simply to describe the new scattering situation. The expression contains the product of the fields due to the fundamental mode with the fields of the unguided continuum modes at the perturbing boundary, which is taken to be the outer boundary of the guided layer. If instead we take the product of the fields on the center line, we obtain an expression which would apply to roughness in the thin center layer of a five-layer structure. The new expression is

$$\alpha_0' = \frac{2\Delta}{(D + 1/P_0)x_0 B_n} \int_{-1}^{1} \frac{(Q^2 - 1)^{1/2}}{(x_0 - x)^2 + (\Delta/B_n)^2} \cdot \left\{ \frac{dx}{Q^2 - \cos^2 QD} \right\}. \tag{5}$$

The value of α'_0 is plotted in Fig. 6 against B_n for various values of D. It appears that over the range of values of D of interest the curves are very similar to each other and all peak at a value of α'_0 of around 0.42.

III. Application of Scattering Theory

We will use the results previously described as a basis for optimizing the dielectric waveguide structure for minimum scattering loss, in the presence of whatever unavoidable roughness may remain on the interfaces of the dielectric guide. The important variable parameters in the case of the three-layer

guide are the thickness of the center layer and the dielectric-constant step at the interfaces. In the case of the five-layer guide the effect of the dielectric-constant steps which bound the thin central layer must also be considered. We will not take the correlation length of the roughness into account but simply assume, in the numerical computations, that its value is such as to maximize scattering for given rms roughness amplitude in each particular situation. This will result in a slight overestimate of scattering loss in some cases although errors are unlikely to exceed a factor of 2.

A. Effect of Thickness of Dielectric Guide

We will first consider the direct effect of the thickness of the center layer of the dielectric guide on the scattering loss from the fundamental mode. This is plotted in Fig. 7, with α_0 as the ordinate and d as the abscissa. α_0, as previously described, is maximized with respect to B_n. The scale on the x axis for d applies to the situation where the center layer is bounded by a dielectric-constant step $\Delta\epsilon$ of unity, corresponding to steps in AlAs content at the boundary interfaces of about 23 at %. It may be adjusted to apply to other dielectric-constant steps by dividing by $(\Delta\epsilon)^{1/2}$. The curve shows that the peak scattering loss decreases monotonically, as the layer width is increased, by approximately an order of magnitude between $d(\Delta\epsilon)^{1/2} = 0.1$ μm and 0.9 μm. At a value of $d(\Delta\epsilon)^{1/2}$ of 0.44 μm the first-order mode becomes capable of propagating. There is a marked additional drop in scattering to unguided modes for widths greater than this value. This effect is compensated by the increased scattering to the first-order mode and the curve for the total scattering passes smoothly through the first-order mode cutoff. In practice, in a simple three-layer laser, operation switches to the first-order mode for center-layer thickness greater than about 0.6 μm. In such a case, it is necessary to consider the scattering out of the first-order mode and the curve of Fig. 7 is no longer applicable.

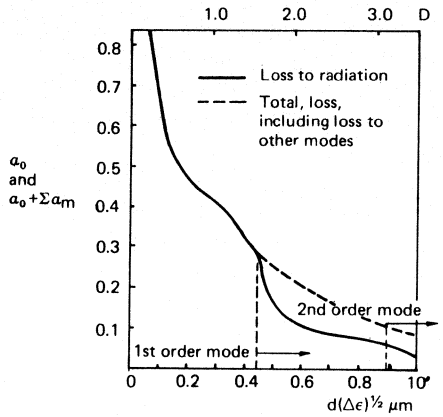

Fig. 7. Effect of thickness of center layer on absorption coefficient due to scattering. Loss to unguided modes and total loss, including loss to guided modes, is shown.

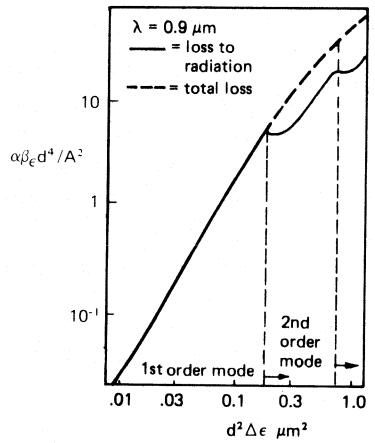

Fig. 8. Effect of step in dielectric constant on absorption coefficient due to scattering.

B. Effect of Step in Dielectric Constant

The second parameter available for adjustment is the dielectric-constant step $\Delta\epsilon$. The normalized scattering coefficient, as given by (1), contains the square of Δ and hence we must expect Δ to be an important factor. The effect on the scattering loss of varying $\Delta\epsilon$ for a fixed value of the layer thickness d and the roughness amplitude A is illustrated in Fig. 8. The quantity $\alpha\beta_\epsilon d^4/A^2$, proportional to the scattering coefficient, is plotted against $d^2\Delta\epsilon$. The scattering increases rapidly as $\Delta\epsilon$ is increased, showing an approximate square-law dependence on $\Delta\epsilon$ up to the point where the first-order mode starts to propagate. Beyond this point the increase is slower and a considerable proportion of the total scattering goes to exciting higher order guided modes. The dielectric-constant step is evidently the dominating factor in determining the scattering loss.

C. Optimized Structure

The general conclusion from the previous two sets of curves is that, in order to minimize scattering, the dielectric step should be reduced as much as possible and the guiding layer should be made as wide as possible. However, these two conclusions are not necessarily compatible with the other design requirements of a laser. The first requirement is that the composition step at the boundary of the active layer should be sufficient, in the case of the three-layer laser, to give carrier confinement. This requires a minimum dielectric-constant step, in most cases, of the order of 0.5. The second requirement is that the dielectric-constant step should be large enough, in conjunction with the value of d used, to confine the light to the width S required for the application. In the three-layer laser the interdependence of optical and carrier confinement imposes limitations. Increasing the width of the optical guiding layer increases the threshold current density directly, and this must be taken into account when considering how much the scattering can be reduced. In the five-layer laser there is scope for reduction of scattering losses without affecting threshold current density. The characteristics of the optical cavity affect threshold only via the effective optical width S and an optical coupling constant k [5]. Provided the thin layer of injected carriers lies centrally within the optical cavity, variations of k can be neglected. Hence combined changes of Δ and d (applying here to the total width of the three center layers) which keep S constant cause no appreciable change in threshold. It then becomes a useful exercise to optimize Δ and

d for given S to obtain minimum scattering from the outer boundaries of the three-layer resonator. It will, of course, also be necessary to consider what scattering is introduced by the presence of the additional thin active layer, lying close to the center of the resonator.

In Fig. 9 we plot the scattering loss for a range of dielectric guides, in all of which the optical distribution has the same effective width. The effective width S is defined in terms of the optical-intensity distribution $I(x)$ and the peak optical intensity I_0 by

$$S = \int_{-\infty}^{\infty} I(x)\,dx/I_0. \tag{6}$$

In a structure where d is adjusted to give maximum optical confinement for a given dielectric-constant step the width of the optical distribution is given by [5]

$$S = 0.391\lambda/(\Delta\epsilon)^{1/2}. \tag{7}$$

If d is adjusted up or down from the value required for this condition, then the dielectric-constant step must be increased. Hence we will label the dielectric-constant step which appears in (7) $\Delta\epsilon_{\min}$. Fig. 9 shows the relative change in the scattering coefficient α_0 as d is varied, the quantity plotted on the horizontal scale being $d(\Delta\epsilon_{\min})^{1/2}$, the wavelength being 0.9 μm, and the effective width of the optical distribution being $0.352/(\Delta\epsilon_{\min})^{1/2}$ μm. Minimum scattering, in fact, occurs in the region where the dielectric-constant step lies close to $\Delta\epsilon_{\min}$. There is a reasonably wide and flat minimum over the range of d given by

$$0.2/(\Delta\epsilon_{\min})^{1/2} < d < 0.45/(\Delta\epsilon_{\min})^{1/2}\ \mu\text{m}. \tag{8}$$

Because the dielectric constant has to be significantly increased at the extremes, the scattering loss rises, and it does so more markedly for small rather than large d. The limit for large d arises from scattering into the first-order mode, which can propagate for values of d greater than $0.38/(\Delta\epsilon_{\min})^{1/2}$. Optimum operation of the five-layer laser should therefore be obtained for values of d in the vicinity of $0.25/(\Delta\epsilon_{\min})^{1/2}$ where the minimum value of dielectric-constant step $\Delta\epsilon_{\min}$ applies.

On the assumption that the construction has been optimized for the optical width concerned let us see how the scattering loss actually depends on the width. Since operation is always at the same value of D of approximately 0.95, the normalized scattering coefficient has a value for all widths of $\alpha_0 = 0.42$ (maximized with respect to the correlation length), see Fig. 5. Using (1) in conjunction with the expression for D in (3) and the value of S in (7), gives the following relation for the optimized scattering coefficient in terms of the optical width, the amplitude of the roughness, and the free-space wavelength:

$$\alpha_{\min} = 0.388\,\frac{\lambda}{\epsilon^{1/2}}\,\frac{A^2}{S^4}. \tag{9}$$

Taking $\epsilon^{1/2} = 3.5$ and $\lambda = 0.9$ μm gives

$$\alpha_{\min} \simeq 10^3 A^2/S^4 \tag{10}$$

where $\alpha_{\min}$ is measured in cm^{-1} and A and S are measured in micrometers. The important thing to notice about (10) is the extreme sensitivity to the width S. The dependence is in proportion to the inverse fourth power. This is reminiscent of the Rayleigh scattering law where the scattering loss depends on the inverse fourth power of wavelength. In the present case S is related to the transverse component of wavelength, and so the analogy between the two relationships is close.

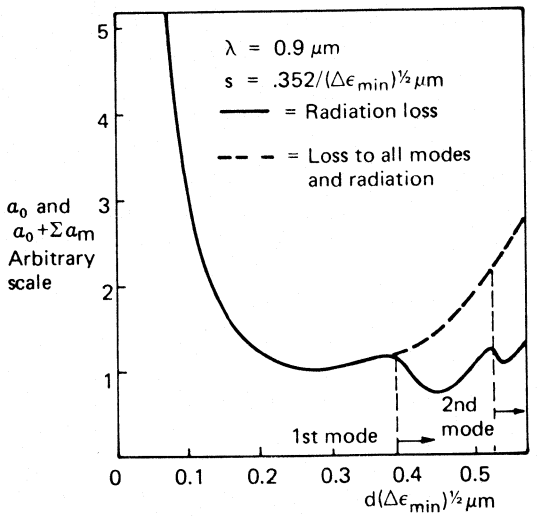

Fig. 9. Effect of thickness of center layer on absorption coefficient due to scattering under conditions where Δ is adjusted to keep width of optical distribution constant.

The minimum value of S which would normally be encountered in practice would be about 0.3 μm (corresponding to a difference in AlAs content between the center and outer layers of 30 at %. An rms roughness amplitude of 0.01 μm would, according to (10), give an attenuation coefficient of approximately 12 cm^{-1}.

The optical scattering from the center layer of a five-layer structure, according to the results in Fig. 6, is almost independent of d. Using the peak value of the normalized attenuation coefficient of 0.42, in conjunction with the normalization relation of (1), gives the following expression for the actual attenuation coefficient:

$$\alpha = 16.5\,\frac{(\Delta\epsilon)^2 A^2}{\epsilon^{1/2}\lambda^3}. \tag{11}$$

Taking $\epsilon^{1/2} = 3.5$ and $\lambda = 0.9$ μm then gives

$$\alpha = 6.5\,A^2(\Delta\epsilon)^2 \tag{12}$$

where α is measured in cm^{-1} and A is measured in micrometers. The minimum value of $\Delta\epsilon$ associated with good carrier confinement in the center layer is 0.5 (11 at % step in AlAs content). Inserting this in (12) and taking the rms roughness as 0.01 μm produces a scattering loss of 1.6 cm^{-1}. This is similar to the loss which would be produced by scattering from the outer boundaries of an optimized optical-confinement layer 0.5 μm thick. Hence, although the loss is not excessive, it does put an appreciable limitation on the effective improvement which can be obtained in the overall loss by widening S. Efforts at improving the smoothness of the interface should therefore be particularly applied to the active layer of a five-layer structure.

IV. Measurement and Interpretation of Optical-Absorption Coefficient

A. Theory

For currents up to about 50 percent above threshold the incremental quantum efficiency of a laser η is related to the laser length L, the end-face reflection coefficient R (assumed symmetrical at both ends), and the optical-absorption coefficient by [6]

$$\frac{1}{\eta} = \frac{1}{\eta_0}\left\{1 + \frac{\alpha L}{\log(1/R)}\right\} \tag{13}$$

where η_0 is the internal quantum efficiency. α is made up of various contributions, of which we are particularly concerned with the scattering contribution α_s and the free-carrier contribution α_{fc}. The free-carrier loss should be further subdivided into the contribution due to the original doping α_{fc0} and the contribution due to the injected carriers α_{fc1}. The latter has to be separated because it is the only contribution which varies with laser length, as a result of variations in gain and hence injected carrier concentration. To allow for this effect we use the following relation for laser gain g at threshold:

$$g = \alpha_s + \alpha_{fc0} + \alpha_{fc1} + \log(1/R)/L. \tag{14}$$

In addition we also need the relation between gain g and injected carrier concentration n. For values of n sufficiently greater than a fixed concentration n_0 we have found that for initial doping levels of 5×10^{17} cm^{-3} or less we can represent g by an expression of the form

$$g = \rho B(n - n_0) \tag{15}$$

where the factor B determines the gain if all the light is contained within the active layer, and ρ is a loading factor < 1 which depends on the proportion of the optical distribution which lies within the active layer. The free-carrier loss due to injected carriers is represented by

$$\alpha_{fc1} = \rho C n \tag{16}$$

where ρ is the same loading factor. We take the effect of the electrons and holes to be equal, which gives C a value of 10^{-17} cm^2, twice that quoted by Pinkas *et al.* [1] for electrons only. Eliminating g and n between (14)-(16) gives the following relation for the absorption loss due to the injected free carriers:

$$\alpha_{fc1} = \frac{C}{B - C}\{\alpha_s + \alpha_{fc0} + \rho B n_0 + \log(1/R)/L\}. \tag{17}$$

Inserting this into (13) gives the following relation between quantum efficiency and laser length:

$$\frac{1}{\eta} = \frac{B}{B - C}\frac{1}{\eta_0}\left\{1 + \frac{(\alpha_s + \alpha_{fc0} + \rho C n_0)L}{\log(1/R)}\right\}. \tag{18}$$

Comparing this expression with (13) we see that the effect of the injected free carriers is to contribute a length-independent attenuation of $\rho C n_0$ (corresponding to a free-carrier concentration of n_0) and to reduce the apparent internal efficiency by a factor of $(1 - C/B)$. Hence, by plotting the measured values of $1/\eta$ against $L/(\log(1/R))$, we obtain $(\alpha_s + \alpha_{fc0} + \rho C n_0)$ as the negative intercept on the axis of $L/(\log(1/R))$. If α_{fc0} and $\rho C n_0$ are known, the absorption coefficient α_s due to optical scattering may be found.

B. Results

We have evaluated optical-absorption coefficients for a range of double-heterostructure lasers and some five-layer lasers. These were obtained from $1/\eta$ versus $L/(\log(1/R))$ plots varying either L or R or varying both quantities. The total measured absorption coefficients lay mostly in the range 10–18 cm^{-1} with occasional lower or higher values. In general the estimated absorption due to free carriers lay in the approximate range 5–10 cm^{-1}. This leaves a margin of between 5 and 10 cm^{-1} which can be attributed to optical scattering. According to (10) this can be explained by an rms amplitude of roughness at the guide interfaces of around 0.01 μm. This is in reasonable agreement with observation.

In Figs. 10 and 11 we show the precise results obtained for a set of five-layer lasers and for a particularly low-loss double-heterostructure laser. In the case of the five-layer lasers the thickness of the center layer was 0.07 μm and the thickness of the center three layers was 0.35 μm. The step in AlAs content was 12 at % between the center and intermediate layers and was a further 27 percent between the intermediate and outer layers. The effective width of the optical distribution, as deduced from the far-field polar diagram, was 0.37 μm. In conjunction with the 0.07-μm center layer this gives a loading

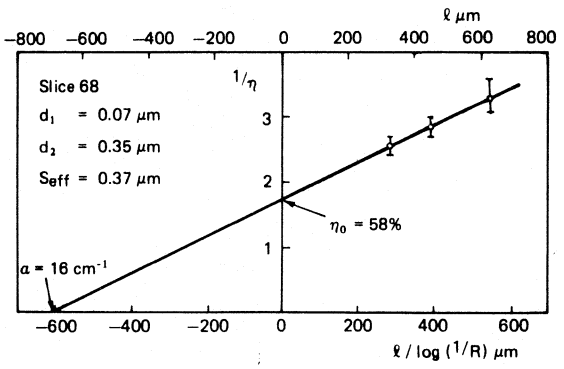

Fig. 10. Plot of measured reciprocal efficiency against length for five-layer lasers.

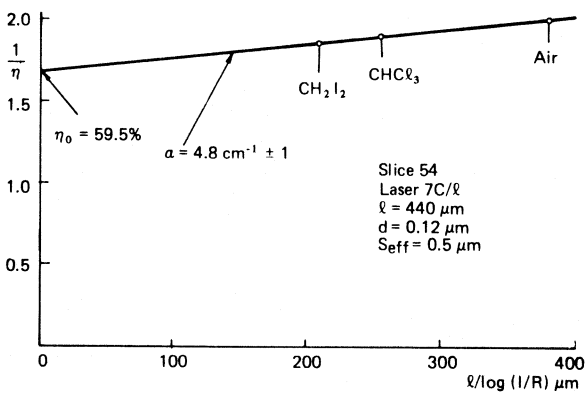

Fig. 11. Efficiency/reflection measurements in three-layer laser. Reflection coefficient varied by immersion of laser in various liquids.

factor ρ of 0.19. The doping level throughout the center three layers was $5 \times 10^{17}\,cm^{-3}$ and the injected carrier concentration n_0 was approximately $1.5 \times 10^{18}\,cm^{-3}$ as deduced from the threshold current variation with laser length and the measured spontaneous recombination time (derived from laser switch-on delay). Taking the effect of holes as being equal to that of electrons this combination should give a free-carrier absorption coefficient of approximately 5.5 cm^{-1}. The experimental plot in Fig. 10, which was obtained by measuring the efficiency of sets of lasers of three different lengths with five lasers in each set, gives an absorption coefficient of $16 \pm 3\ cm^{-1}$, which is about 10 cm^{-1} greater than the anticipated free-carrier loss, and corresponds to an rms roughness at the guide interfaces of about 0.015 μm.

In Fig. 11 we show the experimental results for an asymmetrical double-heterostructure laser with a 0.12-μm-thick active layer. The AlAs content of the p- and n-type (GaAl)As layers bounding the active layer were, respectively, 18 at % and 24 at %. This asymmetry produced a relatively wide optical distribution of 0.5 μm, displaced mainly towards the p-side of the structure. The doping level of all three layers was $5 \times 10^{17}\,cm^{-3}$ and the injected carrier concentration n_0 in the active layer was approximately $10^{18}\,cm^{-3}$. If we again take the holes as giving a loss equal to that of the electrons, we estimate a free-carrier absorption of 4.5 cm^{-1}. The measured results were obtained on a single laser. The reflection coefficient of the end faces was varied by immersing the laser in liquids of different refractive index. The measured optical-absorption coefficient was $4.8 \pm 1\ cm^{-1}$. Hence in this case the total optical absorption was little greater than the anticipated free-carrier absorption. The measurement accuracy was barely adequate to estimate the contribution of optical scattering, but it was of the order of 0.5 $cm^{-1} \pm 1\ cm^{-1}$. This corresponds approximately to an rms surface roughness of 0.004 ± 0.004 μm.

V. Conclusion

We have extended Marcuse's original analysis of scattering losses suffered by zero-order modes in symmetrical dielectric waveguides at imperfections in the boundary walls to cover the dimensions and the range of dielectric-constant steps applicable to double-heterostructure lasers. We have also analyzed the scattering losses from the thin center layer of five-layer lasers. In both cases the analysis was hampered by the difficulty of precise definition of the roughness. However, a reasonable estimate of the maximum expected losses can be made which is probably correct within a factor of 2. The important factors which determine the losses are the rms amplitude of the roughness and the magnitude of the dielectric-constant step. The losses vary as the square of both these quantities. In average double-heterostructure devices the dividing line between acceptable and unacceptable scattering loss ($\sim 5\ cm^{-1}$) occurs for a roughness amplitude of about 0.01 μm. Conditions are much alleviated in devices with wider than normal center layers, particularly if the dielectric-constant step is reduced to retain single-mode operation.

The total absorption loss has been measured in a variety of lasers. When the estimated free-carrier loss of around 5 cm^{-1} is subtracted the residual loss varies between about 1 and 10 cm^{-1}. According to our analysis this corresponds to a range in roughness amplitude of between 0.004 and 0.015 μm.

Depolarization of the Lasing Emission from CW Double-Heterostructure Junction Lasers

THOMAS L. PAOLI, MEMBER, IEEE

Abstract—Measurements of the polarization characteristics of the optical emission from CW $Al_zGa_{1-z}As$-$Al_xGa_{1-x}As$ double-heterostructure (DH) junction lasers are reported. Spectral observations demonstrate that in many lasers the lasing emission is not linearly polarized as expected from the conventional electromagnetic (EM) theory of the laser. A small but measurable field component is observed orthogonal to the main emission. In some lasers, the optical field is shown to be elliptically polarized, while in other devices the polarization state is more complex. The observed depolarization of the lasing modes is attributed to a strain-induced anisotropy in the dielectric properties of the laser waveguide. The anisotropic configuration which leads to elliptically polarized light is analyzed in detail and is shown to be equal to a pure shear in a plane parallel to the junction.

I. Introduction

WITHIN the conventional electromagnetic (EM) theory of the double-heterostructure (DH) junction laser, two classes of transverse modes can propagate in the laser waveguide [1]. For one class of waves, called transverse electric (TE), the electric field is transverse to the direction of propagation and linearly polarized parallel to the junction plane. For the other class, termed transverse magnetic (TM), it is the magnetic field which is normal to the axial direction and polarized parallel to the junction. However, since the Fresnel reflectivity of the semiconductor-air interface is largest for waves with an electric field perpendicular to the plane of incidence [2]-[4] the optical loss at a cleaved, uncoated mirror is greater for TM modes than for TE modes. Because other losses are normally low in the DH laser, the relative mirror losses for the bound waveguide modes usually determine which mode has the lowest threshold. Consequently, above the lasing threshold, the output power from DH lasers is most commonly observed to be highly polarized with the optical electric field parallel to the junction plane [4]-[8].

In the present paper, measurements of the polarization state of the spectrally resolved lasing emission from $Al_zGa_{1-z}As$-$Al_xGa_{1-x}As$ DH lasers are reported. In general, we find that when spectrally resolved the lasing emission is depolarized, i.e., the lasing emission is not linearly polarized as expected from the conventional EM theory of the laser. A small but measurable field component is observed orthogonal to the main emission. The external introduction of an optical phase difference between the orthogonal components demonstrates that the two polarizations are synchronous and consequently that the waves are not pure TE modes. With some lasers appropriate choice of the phase difference produces a linearly polarized field, indicating that the oscillating mode is in fact elliptically polarized. However, in other lasers, the polarization state is more complex. This observation differs from the previous work of Bogatov *et al.* [7], in which no synchronism between the orthogonally polarized modes was found.

As a possible cause for the depolarization of the lasing modes, anisotropies in the dielectric properties of the laser waveguide are proposed. The anisotropy which leads to an elliptically polarized wave is obtained from the analysis of McKenna and Morrison [9]. Additional experiments suggest that the observed mode distortion arises from strains, most probably induced by a nearby bonding surface. Consequently, an analysis of the strain configuration which produces the appropriate anisotropy is also presented.

II. Experimental Details

A. Lasers

In general, the DH lasers used in the present study were composed of a thin ($\leqslant$0.4-μm) active layer sandwiched between two layers of $Ga_{1-x}Al_xAs$ or $Ga_{1-x}Al_xP_yAs_{1-y}$ [10]. While all wafers were grown on {100} substrates, a wide variety of different combinations of waveguiding and active layers were used, including active layers with and without Al. Stripe-geometry lasers were fabricated from the epitaxial wafers by proton bombardment [11]. All lasers had stripe widths nominally equal to 13 μm and were 380 μm long. All mirrors were formed by uncoated facets cleaved on {110} planes. In most cases thick (~12-μm) gold pads were plated on the p-side before cleaving. For efficient heat sinking in continuous operation, each laser was bonded either to a metallized diamond mounted on a copper stud or directly to the copper stud.

B. Experimental Setup and Results

The polarization characteristics of the laser modes were studied with the system shown schematically in Fig. 1. In order to obtain optimum performance from optics used in the analysis, the laser emission was collimated by adjusting the

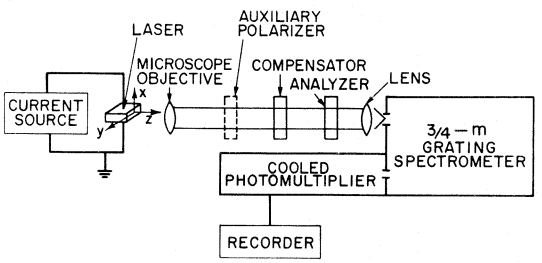

Fig. 1. Schematic diagram of the system used to observe and analyze polarization characteristics of optical spectra from CW stripe-geometry DH lasers.

axial position of the microscope objective to focus the emitted light at infinity as established by a telescope. A calcite prism, the analyzer, was then employed in the primary analysis of the polarization state of the optical beam before it was focused into the grating spectrometer. The spectrometer was used to resolve spectrally the TE and TM modes which in general are not degenerate in GaAs DH lasers [7].

A typical example of such an analysis performed on a laser which oscillated in a pure TE mode is shown in Fig. 2. Fig. 2(a) shows the spectrum of the oscillating TE modes, i.e., the analyzer was set to transmit light with an optical electric field parallel to the junction plane. Furthermore, amplification of this spectrum reveals that no additional weak modes with this polarization are present. With the analyzer rotated by 89.6° the combined spectra of the TE and TM modes displayed in Fig. 2(b) were obtained to show the lack of degeneracy between the two classes of modes. An additional rotation of the analyzer by 0.4° produced the spectrum of Fig. 2(c) in which the signals at frequencies corresponding to the TE modes have been eliminated, leaving only the nonlasing TM modes. This behavior demonstrates that the lasing TE modes (and equally well the nonlasing TM modes) are in fact linearly polarized to better than 1 part in 10^4. Furthermore, it establishes that there is essentially no depolarization of the beam by the optics.

With other DH lasers studied in the same way, the light emitted at the lasing wavelengths was not linearly polarized. For example, optical spectra obtained from another diode are shown in Fig. 3. The oscillating modes are shown in Fig. 3(a) and the spectrum of the orthogonally polarized light is shown in Fig. 3(b). While the signals at the wavelengths of the lasing modes showed a definite minimum as the polarizer was rotated, there was no angle at which they were zero. Furthermore, these signals were not due to leakage by the analyzer since insertion of a crossed polarizer between the analyzer and the spectrometer produced no detectable signal. The angle (θ) of the analyzer at which the intensities of the lasing wavelengths are minimal we take to be the most accurate measure of the nominal TM direction and define this angle[1] to be zero ($\theta = 0°$). We conclude then that the emission at wavelengths corresponding to the lasing modes in this device were not pure linearly polarized.

In order to identify the actual state of polarization of the emission at the lasing frequencies the standard analysis, as outlined, for example, by Jenkins and White [12], was performed. For this analysis an optical phase compensator was used in conjunction with the analyzer as shown in Fig. 1. The procedure consisted of aligning the optic axis of the compensator parallel to the direction of maximum optical intensity, in this case $\theta = 90°$, and then adjusting the phase difference produced by the compensator to give a minimum in the signal transmitted by the analyzer. If the minimum produced in this way is zero, the incident beam is uniquely determined to be in a pure state of elliptical polarization. If the minimum is not zero, but occurs at the initial analyzer angle, the incident beam is a mixture of linearly polarized and unpolarized light. On the other hand, if the angle at which the nonzero minimum occurs is changed, the incident beam is composed of linearly and elliptically polarized light.

[1]However, it should be noted that this direction is not necessarily perpendicular to the junction plane. From laser to laser the actual polarizer angle varied within a degree of its nominal value.

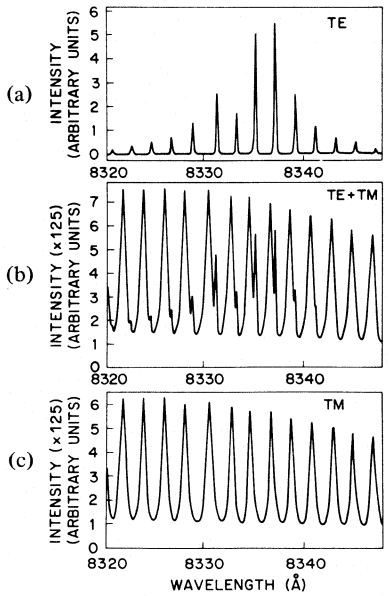

Fig. 2. CW spectra of a DH laser operating at 1.1 times threshold which does not show depolarization of the lasing emission. In (a) the polarizer angle is set to transmit the TE lasing emission while in (c) the angle corresponds to transmission of the subthreshold TM emission. Note the absence of the TE frequencies in (c) indicating the lasing emission is linearly polarized. In (b) the polarizer angle is rotated by +36′ [from (c)] to allow transmission of both TE and TM modes and thereby show the lack of degeneracy between their frequencies. In (a) the spectrometer slit width is 2 μm while in (b) and (c) it is 10 μm.

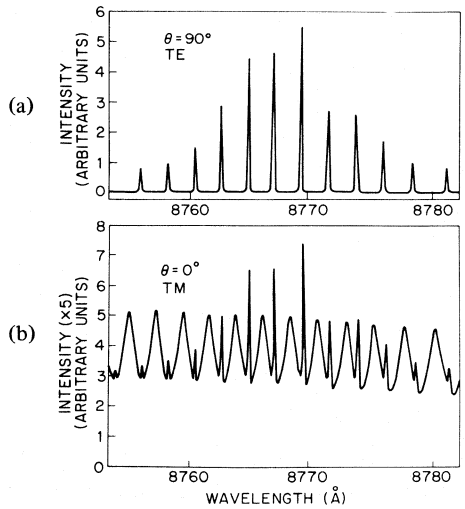

Fig. 3. Optical spectra from a CW DH laser operating at 1.05 times threshold. In (a) the analyzer angle θ is set at 90° corresponding to transmission of the TE polarized emission. In (b), $\theta = 0°$ corresponding to the minimum of the signals at the lasing wavelengths. Note the lack of degeneracy between the modes at the lasing wavelengths and the TM modes. The units of the vertical scales in (a) and (b) are the same.

To analyze the optical emission from the DH lasers in this way, we began by accurately aligning the optic axis of the compensator with the TE direction. This was accomplished by defining the TM direction as the angle at which the amplitudes of the lasing modes were a minimum and then crossing the auxiliary polarizer shown in Fig. 1 with the analyzer such that no signal was detected at the spectrometer output. The polarizer was then transmitting the TE polarized emission. An Ehringhaus compensator was next inserted between the polarizer and the analyzer and oriented with its optic axis parallel to the TE direction by minimizing the signal transmitted by the analyzer. For this orientation with incident linearly polarized light as established by the auxiliary polarizer, changes in the phase difference produced by the compensator had very little effect on the magnitude of the light transmitted by the analyzer, confirming that its optic axis was parallel to the TE direction.

With the auxiliary polarizer removed from the beam and the orientation of the compensator fixed, the phase compensation of the beam was adjusted to minimize the amplitude of the lasing modes as detected with the analyzer set at $\theta = 0°$. Then the analyzer orientation was adjusted if necessary to minimize further these amplitudes and thereby complete the polarization analysis procedure previously outlined.

An example of one class of results achieved with this procedure is shown in Fig. 4. Fig. 4(a) is the spectrum of the emitted light after passing through the compensator and analyzer set at 0°. Qualitatively, this spectrum is similar to one obtained without the compensator. However, rotation of the analyzer by only 1° produced the spectrum displayed in Fig. 4(b) in which signals at the wavelengths of the lasing modes [indicated by arrows in Fig. 4(a)] can no longer be detected. Furthermore, the suppression of the lasing modes in this way occurred only for the specific phase difference of approximately 0.6 π in this case. For other settings of the compensator, the signal amplitude at each lasing frequency was not fully suppressed for any angle of the analyzer. Similarly, with the compensator set at 0.6 π, the signals were zero only for $\theta = +1°$ so that this combination of compensator and analyzer settings was unique. For future reference we define this null angle to be θ_0. In view of the standard procedure for polarization analysis, we conclude that the polarization of the lasing emission from this diode was pure elliptical with a phase difference of approximately 0.6 π between the orthogonal components of the field.

With the phase compensation at 0.6 π, the direction of the maximum field was changed from the TE direction $\theta = 90°$ to $\theta = 90° + \theta_0$. The tilt results because when the orthogonal field components are in phase, as they are at the compensator output, the resulting linearly polarized field vector is given by their vector sum. Consequently, the tilt angle θ_0 should also be given by the ratio of the orthogonal field components themselves, as

$$\tan \theta_0 = \sqrt{\frac{I(0°)}{I(90°)}} \tag{1}$$

where $I(\theta)$ is the modal intensity corresponding to the analyzer set at θ. Thus, by measuring[2] the intensity of a mode with $\theta = 90°$ and the intensity of the orthogonal component at $\theta = 0°$, θ_0 can be independently estimated. For the laser used for Fig. 4, we found experimentally that $\theta_0 = 42'$. This value is in good agreement with the directly measured value of 1°.

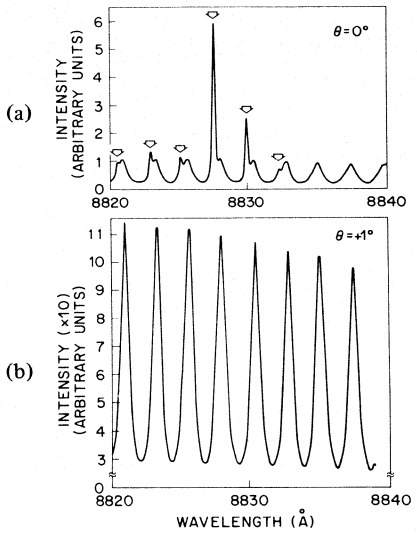

Fig. 4. CW spectra of emission from a second DH laser after passing through phase compensator set for a phase compensation of 0.6π and the analyzer. In (a) the analyzer angle θ is 0° while in (b) the analyzer angle is +1°. The absence of signals in (b) at the wavelengths corresponding to the TE-like modes [indicated by arrows in (a)] show that the lasing light after passing through the compensator is linearly polarized.

III. Discussion

In this section, we consider possible sources for the observed depolarization of the lasing modes. The existence of pure linear polarization in some lasers suggests that the depolarization of the field is not a result of the two-dimensional nature of the stripe-geometry waveguide [13]. On the other hand, the observed coherence between the orthogonally polarized field components makes optical scattering from randomly distributed centers or waveguide nonuniformities an unlikely source. Consequently, we turn our attention to mode-coupling processes which in general maintain coherence between the coupled waves.

It is well known that the propagating modes in anisotropic thin-film waveguides are in general neither pure TE nor TM [9], [14]. In view of the experimental results, the most likely source of the anisotropy is strain in the laser waveguide. Consequently, we shall discuss the effect of an anisotropic waveguide as if it were strain induced although much of the discussion is independent of the precise cause.

The lowest order perturbed modes of a dielectric waveguide in the presence of a small uniform strain have been calculated in detail by McKenna and Morrison [9]. In the presence of strain, the dielectric matrix for the waveguide is no longer

[2] By using the unpolarized spontaneous emission from a GaAs diode, the transmissivity of the spectrometer plus analyzer was observed to be essentially the same (within 10 percent) for $\theta = 0°$ and $\theta = 90°$.

diagonal in the coordinate system shown in Fig. 1. Following [9], we write the dielectric matrix elements as

$$K_{\alpha\beta}(x) = K_{\alpha}^{(0)}(x)\,\delta_{\alpha\beta} + \eta S_{\alpha\beta}, \qquad \alpha, \beta = 1, 2, 3$$
$$\delta_{\alpha\beta} = \begin{cases} 0, & \alpha \neq \beta \\ 1, & \alpha = \beta \end{cases} \tag{2}$$

where α, β are the coordinate indices, $K_{\alpha}^{(0)}(x)$ defines the waveguide in the absence of strain, and $\eta S_{\alpha\beta}$ is the matrix element arising from the photoelastic effect with η a small parameter used in the perturbation analysis. As a result of the off-diagonal elements in the dielectric matrix, the propagating fields are in general no longer pure TE or TM modes. An exception to this rule occurs when all off-diagonal elements except S_{13} are zero, in which case pure TE and TM modes are still allowed.

For the case in which S_{12} is the only nonzero off-diagonal element, analysis [9] shows that the x and y components of the electric field in the perturbed TE mode are in phase. Consequently, the perturbed TE mode is linearly polarized but at an angle with respect to the y axis, i.e., the direction of the polarization for the unperturbed TE mode. Because the x and y components of the field have slightly different shapes in the x direction, the angle of tilt varies slightly as a function of position x in the waveguide.

The final case to be considered is one in which the only off-diagonal element not taken equal to zero is S_{23}. From the analysis [9], it is straightforward to show that the x component of the perturbed TE mode is pure imaginary, indicating that the two orthogonal components are 90° out of phase with respect to each other. This phase shift corresponds to an elliptically polarized wave. However, the analysis also indicates that the ellipticity of the polarization varies with the transverse coordinate x due again to the different spatial distributions of the x and y components of the field.

Although the strain field actually obtained in a bonded DH laser is by no means as ideal as assumed in the analysis, nevertheless the calculations show that the observed elliptically polarized mode can be understood qualitatively in terms of a strain-induced anisotropy in the waveguide. Furthermore, elliptical polarization arises only for a particular anisotropy, namely, one in which $S_{23} \neq 0$. This element of the dielectric matrix can be related [15] to the stress field $\sigma_{\mu\nu}$ by the piezooptical coefficients $\pi_{\alpha\beta\mu\nu}$ as

$$\eta S_{23} = -n^4 \sum_{\mu,\nu=1}^{3} \pi_{23\mu\nu}\sigma_{\mu\nu} \tag{3}$$

where n is the index of refraction. GaAs or $Ga_{1-x}Al_xAs$ which are crystals of class $\bar{4}3m$ have only three different piezooptical coefficients when referred to the crystal axes. However, the coordinate system chosen for the modal analysis of the waveguide (shown in Fig. 1) does not in general correspond to the coordinate system defined by the crystal axes. For lasers grown on {100} substrates with mirrors cleaved on {100} planes, the coordinate system defined by the crystal axes is related to the system of Fig. 1 by a 45° rotation about the x axis. With the appropriate transformation of the piezooptical coefficients, it is straightforward to show that the important element of the dielectric matrix is generated as

$$\eta S_{23} = -n^4 \tfrac{1}{2} (\pi_{11} - \pi_{12})(\sigma_{32} + \sigma_{23}) \tag{4}$$

where the piezooptical coefficients have been expressed in standard contracted notation [15] and the stress components are in the waveguide coordinate system. Thus the ηS_{23} arises from a pure shear in the y-z plane. In terms of the stresses along the crystal axes, the shear can be written as

$$\sigma_{32} + \sigma_{23} = \sigma'_{22} - \sigma'_{33} \tag{5}$$

where σ'_{22} and σ'_{33} are the stresses along the (010) and (001) axes, respectively. Thus the shear is generated by unequal stresses along two crystal axes.

Within the perturbation theory of McKenna and Morrison [9], we can estimate the magnitude of ηS_{23} for the experimental lasers which in turn can be used to estimate the shear stress. As an example, we use the laser of Fig. 4 for which the undoped (n-type) active region was 0.4 μm thick and was bounded by layers of $Ga_{0.77}Al_{0.23}As_{0.994}P_{0.006}$. From the results of [9], we estimate a value $\eta S_{23} = 0.1$ for a tilt angle $\theta_0 = 1°$. Although this corresponds to a change of less than 0.08 percent in the dielectric constant of the active region, it is large enough to place some doubt on the applicability of the perturbation calculation in a quantitative estimate of the stress level.

With the inadequacy of the calculation in mind, we now use the value of ηS_{23} to estimate the stress level from (4). In addition, to obtain a room-temperature value for the piezooptical coefficient $\pi_{11} - \pi_{12}$ it is necessary to extrapolate the available experimental results [16]. Unfortunately, this is not straightforward in GaAs because of the large dispersion shown by $\pi_{11} - \pi_{12}$ near the bandedge. Nevertheless, we obtain a lower bound of 20×10^{-14} cm^2/dyn on $\pi_{11} - \pi_{12}$ by linearly extrapolating the data of [16] from 1.38 to 1.404 eV (8830 Å). From (4), we obtain an estimated stress level of approximately 6×10^9 dyn/cm^2. This value is certainly an upper limit on the stress level needed to produce the observed effect since our extrapolated value of $\pi_{11} - \pi_{12}$ may considerably underestimate the actual value.

Recent analysis [17] has indicated that the intrinsic stress in DH lasers due to the lattice mismatch of AlAs and GaAs is equivalent to a hydrostatic tension superimposed over a uniaxial pressure perpendicular to the {100} heteroboundary planes. Since for this stress distribution $\sigma'_{22} - \sigma'_{33} = 0$ it is unlikely that the shear necessary to induce depolarization originates in the interfacial strain inherent to the epitaxial growth. This conclusion is also supported by the experimental observation that depolarization also occurred in lasers with phosphorus added to the $Ga_{1-x}Al_xAs$ layers in order to relieve this interfacial strain [18].

On the other hand, it is certainly reasonable to expect that the necessary shear strains could develop during bonding of a laser to its heat sink and perhaps even be intensified as a result of the heating incurred during continuous operation. In

addition, high stress concentrations can develop [19] at the edges of thin films deposited on semiconductors. Consequently, the plated gold pad and its interaction with the heat sinking bond are also potential sources of a shear strain. Experimentally, the importance of the bonding situation was suggested, although not proved, in a comparison of the depolarization observed in a group of 20 lasers from the same wafer, half of which were bonded in the conventional manner with the p-side adjacent to the heat sink, while the remainder were bonded with the n-side adjacent to the heat sink. In the former case the waveguide was within a few microns of the bond, while with n-side bonding the waveguide was approximately 4 mils from the bond due to the substrate. Experimentally, *all* lasers with p-sided bonds showed oscillation in a mode which was not linearly polarized while only *half* of the devices with n-sided bonds showed this depolarization. A possible source of strain in lasers with n-side bonds is the top wire-bonded contact.

The presence of some strain was also detected in all these devices by observing transmitted infrared (IR) light with crossed polarizers [20]. In general, the strain appeared to be more intense in lasers with p-side than with n-side bonds. However, the observed strain was located primarily near the edges of the chip in most cases, suggesting that it was a result of the cleaving operation rather than bonding. In most lasers very little if any strain was detected with this technique near the active region defined by the stripe. In addition, there appeared to be no correlation between the strength of the depolarization in a single laser and the intensity of the strain detected with the crossed polarizers. We conclude that the depolarization of the lasing mode may be a more sensitive probe of at least the shear strain in the vicinity of the active region.

One further point which deserves some discussion is the observed mode coupling in the presence of the lack of degeneracy between the TE and TM modes, for example, as shown in Fig. 3. From a coupled-mode point of view [14], when it is applicable, it can be shown that the frequency splitting between the perturbed TE and perturbed TM modes is always larger than the frequency difference between the unperturbed modes. Consequently, it is not possible to conclude from a spectrum of the perturbed modes how far the uncoupled modes are from degeneracy.

In conclusion, we note that it was not possible to obtain the full compensation demonstrated in Fig. 4 with all lasers in which depolarization was observed. In most cases, adjustment of the compensator produced a nonzero minimum in the signal transmitted by the analyzer at an analyzer angle $1^\circ > \theta > 0^\circ$. From the polarization analysis described in Section II-B, this result suggests that the lasing emission is a mixture of linearly and elliptically polarized light such as is expected when both S_{12} and S_{23} are not zero. The lack of full compensation may also be due to the spatially varying ellipticity of the mode mentioned previously or to a strain field which is too strong or too spatially nonuniform to maintain the validity of the analytic model. A study of the polarization state as a function of position in the mirror illumination may help to distinguish these effects.

IV. Conclusion

In this work we have investigated the polarization characteristics of some stripe-geometry $Al_zGa_{1-z}As$-$Al_xGa_{1-x}As$ DH junction lasers operating continuously at room temperature. The experimental results demonstrate that many of these devices do not oscillate in a linearly polarized mode as predicted by the conventional EM theory of this laser. In some cases the field can be shown to be elliptically polarized, while in other devices the polarization state is more complex.

The observed depolarization of the lasing modes can be explained by an anisotropy in the dielectric properties of the laser waveguide. In particular, elliptically polarized modes are possible for one configuration of the anisotropy. The anisotropy itself is attributed to strains produced during the bonding of the laser to its heat sink. In such a case it is a shear strain which leads directly to the elliptical polarization. Consequently, the observation of depolarization in the lasing emission can serve as a sensitive test for the presence of undesirable strain in bonded lasers.

Acknowledgment

The author wishes to thank F. K. Reinhart, J. McKenna, and J. A. Morrison for many helpful discussions. He also wishes to thank L. A. D'Asaro and B. C. DeLoach for their critical reading of the manuscript, and J. F. Svacek for his technical assistance.

Thermal Characteristics of Buried-Heterostructure Injection Lasers

TOSHIHISA TSUKADA, MEMBER, IEEE, AND YASUJI SHIMA

Abstract—**The thermal characteristics and CW operation of buried-heterostructure (BH) injection lasers, in which the GaAs active regions are completely buried in $Ga_{1-x}Al_xAs$, are described. The narrow active regions of these diodes facilitate effective heat dissipation. Thus, the CW operation of these lasers has been achieved without the p-GaAs layers usually grown in double-heterostructure (DH) lasers for electrical contacting purposes and with the heat dissipation through n-GaAs substrates. Even in this disadvantageous configuration, the temperature rise in the active regions of BH lasers at threshold is much smaller than that of p-side-down DH lasers. The calculation using an approximate formula can explain these low experimental values fairly well. Due to low operating current and effective heat dissipation, BH lasers can be operated continuously at room temperature on very small heat sinks such as TO-5 transistor headers.**

I. Introduction

HETEROSTRUCTURE lasers have been studied extensively in recent years. Double-heterostructure (DH) injection lasers [1], [2] have especially attracted the interest of many workers, because of their low threshold current density and their capability of continuous operation at room temperature. In order to achieve low thresholds, the active layer thicknesses of DH lasers need to be smaller than 0.5 μm. However, the widths of the active layers are in the order of several tens of microns. Therefore, the widths are larger than the thicknesses by about two orders of magnitude. This large discrepancy between the width and the thickness has produced a detrimental effect on the electrical and optical characteristics of these lasers. The excitation of higher order modes, the instability of modes against the change in current, and the anisotropic beam divergence are some examples of undesirable properties.

We have developed buried-heterostructure (BH) lasers [3] which have narrow active regions in contrast to the slab-like active layers of conventional semiconductor lasers. In BH lasers, the cross sections of the active regions have their widths approximately equal to their thicknesses. Cross-sectional areas as small as 1 μm^2 or less have been realized. In [3], we described the fabrication and characteristics of BH lasers and some of the unique properties of these lasers, such as the low-current operation, the reproducible realization of the lowest order transverse mode (TE_{00}), the stability of mode patterns against changes in current, the isotropic beam divergence, etc. Moreover, BH lasers have superior thermal characteristics because of the filamentary nature of the active or heat-generating region. In this paper, we describe in some detail the thermal characteristics of these lasers and their CW operation on small heat sinks.

II. Thermal Properties

The heat removal from the active region of a laser diode as well as the threshold current density is of great importance for the CW operation of the diode [4]. Generally, the thermal resistance expressed in units of degree/watt represents the temperature rise for input power of 1 W into the active region. However, in the case of semiconductor devices such as injection lasers of various geometries, the thermal resistance multiplied by the area is a more meaningful and convenient quantity in representing their facility to remove the heat generated per unit area of the junction. Using this quantity we obtain the temperature rise ΔT in the active region at threshold

$$\Delta T = R_T (J_{th} V) \quad (1)$$

Manuscript received November 25, 1974; revised January 20, 1975.
The authors are with the Central Research Laboratory, Hitachi Ltd., Kokubunji, Tokyo, Japan.

where R_T is the thermal resistance multiplied by the area expressed in units of degree cm^2/watt, J_{th} is the threshold current density, and V is the junction voltage. Because the product of J_{th} and V is nearly constant in laser diodes of various geometries, R_T can be used as a measure in comparing the thermal properties of semiconductor lasers.

The rigorous calculation of the R_T for a laser diode is not always easy. However, it is possible to calculate the R_T of a BH laser approximately by using the formula given in the literature [5] when it is mounted with its p side up as shown in Fig. 1. The formula is given for the case of an isothermal rectangular parallelepiped buried in a semi-infinite medium having an isothermal surface, and is expressed as follows:

$$R_T = \frac{W}{1.685\kappa}\left[\log\left(1+\frac{h}{W}\right)\right]^{0.59}\left(\frac{h}{d}\right)^{0.078} \times 10^{-4} \qquad (2)$$

where κ (W/deg · cm) is the thermal conductivity of the medium, h (μm) is the distance from the active region to the heat sink which is nearly equal to the thickness of the n-GaAs substrate, W(μm) is the width, and d(μm) is the thickness of the active region. The value of κ used in the following calculation is the thermal conductivity of GaAs. The active region is surrounded by a thin layer of GaAlAs of which the thermal conductivity is about one-fourth that of GaAs. This GaAlAs region will increase the R_T to some degree. However, this effect will be partially at least canceled out by the transparency of the GaAlAs region to spontaneous emission below threshold. The high internal efficiency of the spontaneous emission in the active region and the transparency of the surrounding medium mean that heat is not localized at the active region but rather at interfaces between the GaAlAs region and the GaAs substrate where the absorption of the emission occurs. Thus, a substantial part of heat is transferred through the GaAlAs region without feeling its low thermal conductivity. This justifies the use of the approximate formula given in (2). The range of validity of this formula is not quite certain. However, as will be shown later, the calculated R_T represents fairly well the actual R_T in the range involved.

Fig. 2 shows a plot of R_T as a function of W. The R_T becomes very small as the width of the active region gets narrower. For $W = 1$ μm, which is realizable in BH lasers, the R_T is as low as 0.27×10^{-3} deg · cm^2/W. This value of the R_T corresponds to the temperature rise in the active region of 1°C [$J_{th} = 2$ kA/cm^2 and $V = 2$ V were substituted into (1)]. This low value of the R_T stems from the geometry of the BH laser where the heat-generating region is completely buried in a medium with a reasonable thermal conductivity. A curve of R_T versus W, when W is wide, is shown in Fig. 3 again for the case of the p-side-up bonding. Even if the width of the active region is as wide as 50 μm, the R_T is not so large, i.e., 5.80×10^{-3} deg · cm^2/W, and corresponds to the temperature rise of 23°C (again $J_{th} = 2$ kA/cm^2 and $V = 2$ V were used). This result suggests the possibility of continuous operation of ordinary DH lasers, bonded to heat sinks with their p sides up provided the active region is embedded in a proper medium.

We can also calculate the thermal resistance from these figures. The thermal resistance of a p-side-up diode of which the active region is 1 μm in its width, becomes 67.5 deg/W (the assumed cavity length is 400 μm). For a 50-μm-wide diode it becomes 29 deg/W. Thus, the thermal resistance of a 1-μm BH laser is higher than that of broader (50-μm) lasers by 2.3 times. However, this by no means implies poor thermal characteristics of BH lasers. The meaning of this description is

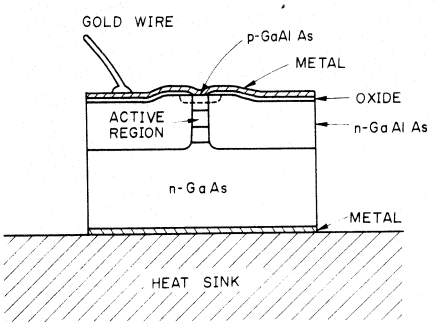

Fig. 1. BH injection laser mounted on a heat sink with its p side up. The lasers are typically 400 μm long, 300 μm wide, and 100 μm thick. The active regions are 1 μm^2 or less.

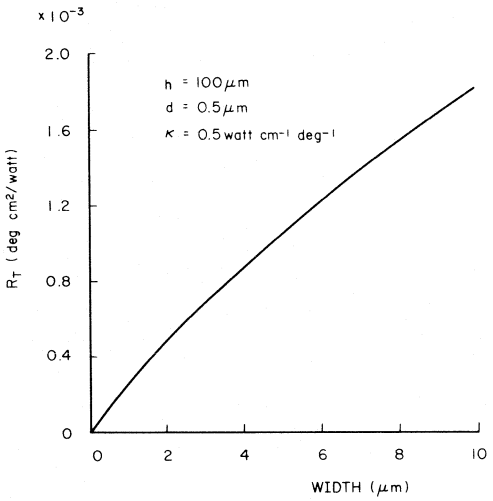

Fig. 2. R_T versus W for p-side-up lasers with narrow active region widths. The assumed thicknesses of the active region and the substrate are 0.5 μm and 100 μm, respectively. The thermal conductivity of GaAs was substituted into κ.

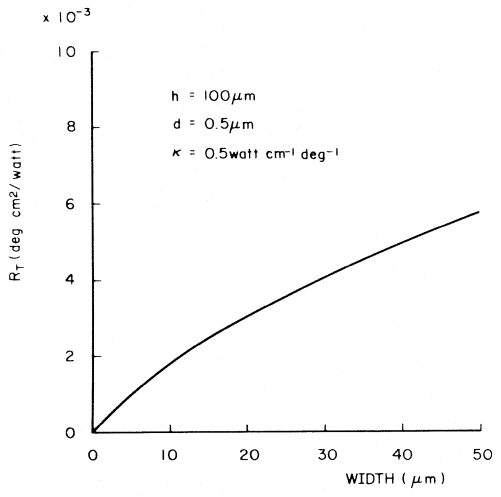

Fig. 3. R_T versus W for p-side-up lasers with wider active region widths. The assumed values of parameters are the same as in Fig. 2.

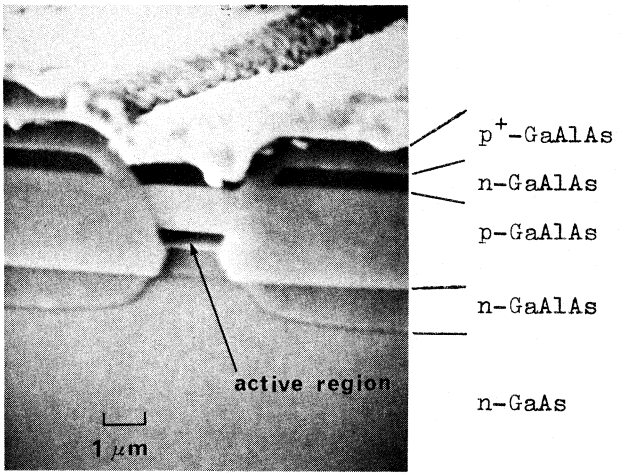

Fig. 4. Scanning electron photomicrograph of stain-etched facet of a BH laser. The thickness, the base, and the upside of the active region are 0.4, 1.1, and 1.3-μm, respectively. In this wafer, the n-p-n structure was grown in the secondary LPE and the p^+ layer was formed on top of the wafer by a Zn diffusion.

that the temperature rise of a BH laser is 2.3 times higher than that of a broad laser when the *same input power* was fed into these lasers. In reality, however, a BH laser at threshold needs a smaller input power than a broad laser by one order of magnitude or more. Therefore, the temperature rise of a BH laser at threshold is much smaller than that of a broad laser. This is due to the good heat dissipation of this laser.

In conclusion, the use of the R_T is appropriate in discussing thermal characteristics of semiconductor lasers of various geometries.

III. Experimental Procedures

BH lasers were fabricated using two-step liquid-phase-epitaxial (LPE) growth as described previously [3]. The first step in LPE is the consecutive growth of the four layers on an n-GaAs substrate. These layers are n-GaAs (~3 μm), n-$Ga_{1-x}Al_xAs$ (~1 μm), GaAs (~0.5 μm), and p-$Ga_{1-x}Al_xAs$ (~1 μm). The n and p layers were doped with Sn and Ge, respectively. The aluminum content x was chosen to be 0.2-0.4. The p-GaAs layer usually included for electrical contacting purposes in the double-heterostructure wafer was not grown in our experiments. This layer is not always necessary for the CW operation of BH lasers. The next step in the fabrication is the mesa etching of the epitaxial layers to define the narrow active region. The mesa etching must be deep enough to reach the n-GaAs epitaxial layer. Then the secondary LPE growth of $Ga_{1-z}Al_zAs$ ($z \geqslant x$) was performed completing the burying of the active region in the GaAlAs. This burying layer was usually undoped or lightly doped with n-type impurities. Controlling the growth time interval, we can adjust the thickness of this layer to the level of the crystal surface before etching. Then Zn was diffused through the oxide window 2 μm wide to form a shallow p^+ layer on top of the active region. Fig. 4 shows the stain-etched cleaved surface of a BH laser. In this wafer, the p-n-p-n structure was adopted to confine the current to the active region.

After thinning the wafer by polishing off the n-GaAs substrate to a thickness about 100 μm, Cr and Au was evaporated onto the p side of GaAlAs, and Au-Ge-Ni onto the n-GaAs substrate. BH lasers were bonded onto metallized diamonds mounted on copper heat sinks. Some of the BH lasers were bonded with their p sides down onto heat sinks as was described for DH lasers. However, most of the BH lasers were bonded with their p sides up. In this case, the contact to the p side of the laser was made with bonded gold wires. Several other lasers selected for low threshold were bonded with their p sides up on copper disks 0.4 mm in thickness and 1.8 mm in diameter which were mounted on TO-5 transistor headers.

The thermal resistance was calculated from the spectral peak shift of the spontaneous emission. The spectrum of the spontaneous emission of laser diodes operated with low-duty cycle pulses of a particular current level less than I_{th} was first recorded. Then these diodes were operated with dc current (or with high-duty cycle pulses) at the same current level. From the shift of the spectral peak between these two operations, the temperature rise in the active region was estimated. The wavelength shift of the spontaneous emission by a temperature increase of 1 deg was measured independently to be 3 Å.

IV. Results

Although p-GaAs layers for electrical contacting purposes were not used in our BH lasers, these lasers have operated continuously at room temperature due to their superior thermal characteristics. For diodes mounted with their p sides down onto heat sinks, the spectral shift from pulsed-to-dc operation was unmeasurable so far as our method is concerned. This means a very small temperature rise in the active region. A temperature rise of several degrees has been observed in diodes mounted with their p sides up onto heat sinks. The smallest value of R_T obtained in p-side-up diodes is 0.5×10^{-3} deg · cm^2/W. The active region width of this diode is 2 μm. Therefore, the measured R_T is in close agreement with the calculated value shown in Fig. 2. The temperature rise in the active region may be estimated to be about 2 deg, in contrast

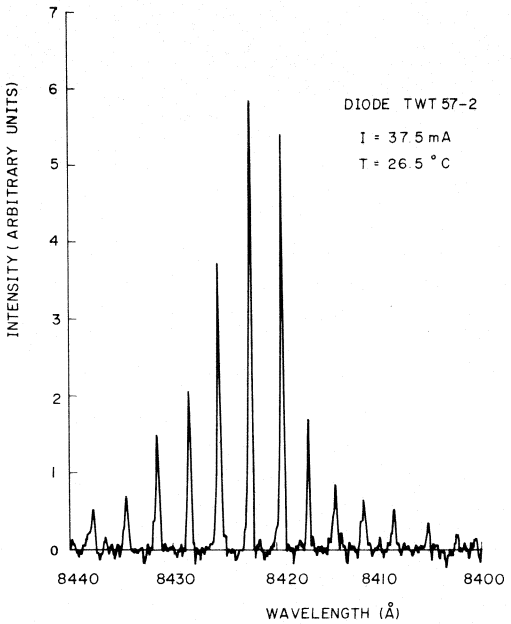

Fig. 5. Lasing spectrum of a continuously operating BH laser mounted on a TO-5 header.

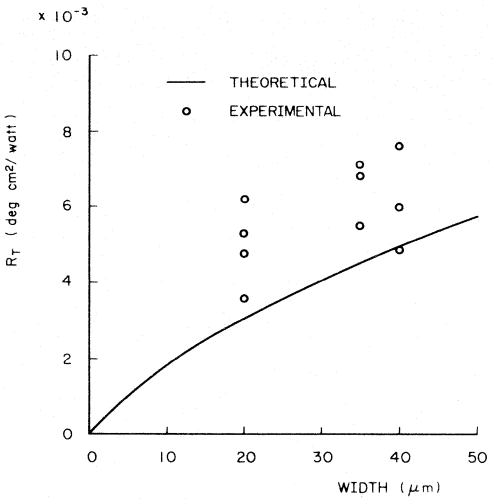

Fig. 6. Comparison of the experimental values of R_T with the calculated values. Experimental data were obtained in VLMS DH lasers operating continuously at room temperature. Although these data are somewhat scattered, the R_T nearly equal to the calculated value will be obtained reproducibly once the bonding conditions are determined.

to a temperature rise of 5-10°C usually observed in well-bonded DH lasers mounted with their p sides down onto heat sinks. Thus, the temperature rise of p-side-up BH lasers is several times lower than that of p-side-down DH lasers. The lowest dc threshold current so far obtained is 17 mA in a diode with 0.7 X 1 X 390-μm^3 active region. This diode was bonded with its p side up and its pulsed threshold current was 15 mA. The threshold current density of this diode was 3.8 kA/cm^2 which is rather high compared with the threshold of the wider (44 μm) laser fabricated from the same wafer, i.e., 1.6 kA/cm^2. This apparent high-current density of the narrow laser comes from the leakage of current through the GaAlAs p-n junction. The p^+ layer above the active region is wider than the 2-μm-wide oxide window due to the lateral diffusion of Zn, and is about 4 μm wide. Therefore, if the width of the active region is narrower than 4 μm, the apparent J_{th} becomes higher than the actual current density. In reality, a J_{th} as low as 1.6 kA/cm^2 has been obtained in a diode with an active region 4 μm wide.

Low threshold current and good heat dissipation have made it possible to realize the continuous operation of BH lasers with small heat sinks. A BH laser bonded with its p side up onto a copper disk mounted on a TO-5 transistor header has operated continuously at room temperature. The pulsed I_{th} of this diode was 18 mA and dc I_{th} was 37 mA. Because the heat capacity of a TO-5 header is small, the operating current level became higher compared with a diode mounted on a more bulky heat sink. Nevertheless, the temperature rise in the active region was estimated to be about 30°C, which is comparable to the values obtained in the usual mesa-stripe-geometry DH lasers [4]. Fig. 5 shows the lasing spectrum of a continuously operating BH laser mounted on a TO-5 header.

As was described in Section II, Fig. 3 implies that conventional DH lasers bonded with their p sides up can also be operated continuously at room temperature. This prediction has been confirmed experimentally. Fig. 6 shows the experimental and calculated values of the R_T of VLMS DH lasers [6]. Although the experimental values are somewhat scattered, there exist experimental values almost equal to the calculated values. This means that if optimized conditions are adopted in the bonding, an R_T equal to the calculated values is reproducibly obtainable.

V. Discussion

The bonding of injection lasers with their p sides up onto heat sinks has the following advantages over that of lasers with their p sides down. Firstly, stress-reduced bonding and stress-reduced operation are possible. The p-side-down lasers cannot be bonded without impressing stresses onto the active regions. Such stress tends to induce the multiplication of defects or dislocations along the active layer. However, the p-side-up lasers can be bonded and operated with minimal stress on the active regions. Another advantage of p-side-up bonding is the small scatter among the values of the R_T of bonded lasers. In p-side-down bonding, the bonding condition directly influences the value of the R_T. However, in p-side-up bonding, the contribution to the R_T mainly comes from the substrate. Therefore, the influence of the bonding conditions is small. Thus, the smaller scatter in the value of the R_T and the reproducibility of bonding can be obtained. In the third place, the degradation process in the active region may be observed by directly scanning the surface of the laser by SEM. This observation has been the main difficulty in observing the degradation processes of p-side-down lasers. The existence of defects and dislocations in the active region can be checked before operation or after limited operation of laser diodes. In this way, the selection of good diodes becomes possible. This inspection is rather important in the application of diodes as coherent sources in many fields.

In the bonding process of p-side-down lasers, delicate care must be taken not to short the p-n junctions of these diodes.

Moreover, the diodes must be bonded just at the edges of or overhanging heat sinks in order to avoid interference of the laser beam with the reflected beam from the heat sink. In p-side-up bonding, these restrictions can be slackened because the active regions are apart from the heat sinks.

VI. Conclusion

BH lasers have been shown to have superior thermal characteristics over conventional lasers. The narrow nature of the heat-generating region facilitates good heat dissipation from the active region. For this reason, the CW operation of BH lasers has been shown to be possible 1) without p-GaAs layers for electrical contacting purposes; 2) with heat dissipation through the n-GaAs substrate; 3) without diamond heat sinks; and 4) with very small heat sinks.

The CW operation on a TO-5 header is a typical demonstration of superior thermal characteristics of these lasers. The product of the thermal resistance and the area was calculated and was shown to decrease as the width of the active region decreases. This decrease means a small temperature rise in the active region with the same current density. The calculated value of this product has been shown to explain the experimental results fairly well. The extension of this calculation towards the broader active region has suggested the possibility of the continuous operation of stripe-geometry lasers with p-side-up bonding. This prediction was verified experimentally in VLMS DH lasers with their stripe widths ranging from 20 to 40 μm.

The reliability of p-side-up BH lasers has not been studied extensively in this work. However, highly reliable diodes are expected because of the stress-reduced bonding and operation, the low probability of including defects in the small active region, and the good heat dissipation from the narrow active region.

Acknowledgment

The authors would like to thank Dr. O. Nakada for his encouragement throughout the course of this work. They are also grateful to N. Chinone for his useful discussion and to S. Yamashita for his help in the bonding of diodes and for measurements of the thermal resistance.

A New Technique for Measuring the Thermal Impedance of Junction Lasers

THOMAS L. PAOLI, MEMBER, IEEE

Abstract—**A new method is presented to measure the temperature of the optical cavity of a junction laser as a function of the average electrical power supplied to the device. The technique relies upon a null measurement of the exact wavelength of a single Fabry-Perot mode and therefore does not require a preliminary calibration measurement. Because of the small linewidth of the mode, very small (<0.2°C) temperature differences are easily measured. The method is utilized to obtain the thermal impedance for several different types of bonded stripe-geometry junction lasers.**

I. Introduction

THE THERMAL impedance of a junction laser is an important parameter for achieving optimum performance in continuous or rapidly pulsed operation. For example, the useful lifetime of laser diodes is known to depend on their operating temperature [1]. Furthermore, a large temperature rise in a rapidly pulsed device during periods of heavy usage can produce temporary but undesirable changes in threshold or operating wavelength. Consequently, it is important to have an accurate but simple measure of the temperature, and hence the thermal impedance, of a bonded laser.

Any measurement of the thermal impedance of a diode involves determining the temperature change produced by a known variation of the input power. In the past, temperature shifts have usually been deduced from the observed changes in laser threshold or the total spectrum of spontaneous or stimulated emission [2], [3]. However, both methods are unsatisfactory for several reasons. First, they require a "calibration" measurement of the temperature dependence of the observed quantity. For maximum reliability the calibration should be performed on the actual device under study and so the complete measurement for each laser can be very time-consuming Secondly, neither the threshold nor the overall optical spectrum of present-day junction lasers is very sensitive to temperature. For example, in low-power double-heterostructure (DH) lasers where the temperature rise due to continuous operation is typically 5°C, the corresponding change in threshold may be 5 to 10 percent and the spectral shift is only 10 to 15 Å. On the other hand, a measurement of laser threshold involves a large uncertainty since the threshold is usually not well defined when measured by observing the far field or the spectrum [4]. Similarly, spectral shifts are difficult to measure accurately, due to the large radiative linewidth.

In this paper, we present a new method for measuring the temperature rise of a laser diode as a function of average electrical power supplied to the device. The method utilizes the temperature dependence of the refractive index within the laser waveguide and is therefore sensitive to the temperature within the optical cavity itself. The use of the refractive index differs from previously reported techniques which depend on the temperature variation of the bandgap energy [2], [3]. Furthermore, the present technique relies upon a null measurement of the exact wavelength of a single Fabry-Perot mode of the laser cavity and therefore does not require a preliminary calibration measurement. Consequently, a complete measurement on each laser can be performed very rapidly but accurately. In addition, because of the small linewidth of each mode, very small (<0.2°C) temperature differences are easily measured. In Section II, the method and its instrumentation are described in detail. Experimental results including some measured values of thermal impedance for several different types of stripe-geometry junction lasers are reported in Section III. Conclusions of the present work are presented in Section IV.

II. Experimental Technique

A. Principle of Null Measurement

Since the refractive index of a semiconductor is temperature dependent, the resonant frequency of each Fabry-Perot mode in a junction laser varies with the temperature of the laser resonator. At room temperature, this shift is more than 1 Å/deg [5]. Since the width of a Fabry-Perot mode near threshold can be less than 0.2 Å, the wavelength of a single longitudinal mode is a sensitive indicator of the temperature of the laser cavity.

In the present work, we determine the temperature rise associated with operating a laser continuously by measuring the drop in heat-sink temperature ΔT_{HS} which is required to maintain an individual Fabry-Perot mode at a preselected wavelength as the operational duty cycle is increased at constant current from near 0 to 100 percent. Since the laser current is a constant, nulling of the wavelength shift means that the optical cavity is at the same temperature in continuous operation as it was at very low duty cycle. Consequently, we can identify ΔT_{HS} as the temperature rise ΔT_{CW} for CW operation provided that the preselected wavelength corresponds to the optical cavity at the initial heat-sink temperature. This latter requirement is satisfied by operating the laser at a very low-duty cycle ($<10^{-3}$) where the average heating is negligible and selecting the wavelength for the designated mode at a time early within the current pulse in order to minimize the transient heating. However, as with all techniques which in some way utilize a pulsed measurement to avoid heating, the initial transient temperature rise leads to a systematic error in the measurement which will be discussed further in Section IV.

After the temperature rise ΔT_{CW} is determined, the thermal impedance R_{th} of the laser is calculated from the definition

$$\Delta T_{CW} = R_{th} P_{CW} \tag{1}$$

where P_{CW} is the average externally supplied electrical power given by the current I times the device voltage V. In order that P_{CW} actually represents the heat dissipated in the device, it is important that the current be chosen near and preferably below the laser threshold so that the radiative power is a small fraction of the input power.

With lasers for which continuous operation is not possible or undesirable, a variation of the above method can be used to determine the thermal impedance. In this case, the temperature of the laser cavity is measured as a function of the average electrical power P_{AV} supplied to the laser. P_{AV} is varied by changing the repetition frequency of the applied current pulses while the pulsewidth and amplitude are held constant. As a result of the increased heating, the wavelength of a Fabry-Perot mode observed at a fixed time during the pulse increases. The temperature rise is then measured directly by reducing the heat-sink temperature enough to compensate for the wavelength shift. In this way, a calibration of wavelength shift versus temperature is avoided. The thermal impedance is obtained from the slope of the temperature versus P_{AV} relation, and a pulsed measurement of the voltage, thereby eliminating the necessity of continuous operation.

B. Measurement System

The temperature rise associated with operating a laser continuously was measured with the system shown schematically in Fig. 1. In order to select a Fabry-Perot mode for use in the null measurement, each laser was pulsed on for typically 500 ns at 2000 pulses/s. The amplitude of the pulse current was chosen as near to threshold as allowed by the system sensitivity. The laser light was focused into a $\frac{3}{4}$-m Spex Spectrometer whose optical output was detected by a cooled photomultiplier. The output of the photomultiplier was amplified and displayed on a real-time oscilloscope for observation of the light pulse for the wavelength interval (≈0.2 Å) selected by the spectrometer. Typically, the light pulse observed at a fixed wavelength was much shorter than the total current

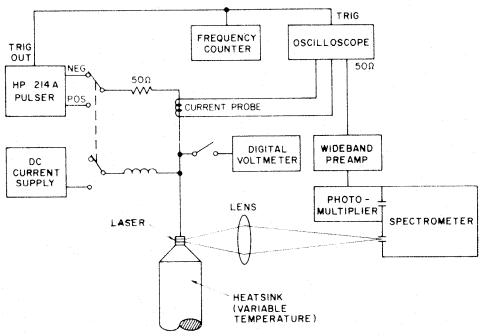

Fig. 1. Schematic diagram of the system used to measure the thermal impedance of stripe-geometry junction lasers. For duty cycles less than 50 percent, the pulser was used alone to pulse the laser on. For duty cycles greater than 50 percent, the pulser was used in conjunction with the dc supply to pulse the laser off.

pulse since the wavelength of each mode is shifted during the current pulse due to transient heating. To minimize the transient temperature difference between the laser and the heat sink, the initial wavelength for the mode was selected within the first 50 ns of the pulse and after initial transient oscillations had ceased. In addition, the rise time of the current pulse was adjusted to be a few nanoseconds less than the sample time to decrease further the initial heat input. After the wavelength had been set on the spectrometer in this way, no further adjustments to the spectrometer were made during the measurement. By convention, the heat-sink temperature for this initial setup was 25°C.

In practice the selected mode was tracked from low-duty cycle to continuous operation by reducing the heat-sink temperature slowly while simultaneously increasing the duty cycle at which constant current pulses were applied to the laser. In this way increases in the average input power were used to compensate for the cooling and thereby maintain the wavelength of the longitudinal mode at its preselected time-resolved value. Because of the unavailability of a pulser tunable from low to 100 percent duty cycle, it was necessary to make the transition in two stages. For duty cycles less than 50 percent, the limit of the pulser, the pulser was used alone and increases in the duty cycle were produced by increasing the pulse rate with a fixed pulsewidth. For operation at duty cycles greater than 50 percent, laser excitation was supplied by a pulser with reversed polarity in conjunction with a dc supply as shown in Fig. 1. In this stage, the effective duty cycle was increased by decreasing the pulsewidth. When the width had been reduced to its minimum value, the pulse amplitude was decreased to zero and the laser was operated continuously. The temperature rise ΔT_{CW} of the laser resonator was then determined by adjusting the heat-sink temperature at which the peak of the mode occurred at the preselected wavelength.

For determination of the thermal impedance, the laser voltage was measured with the digital voltmeter shown in Fig. 1. The heat-sink temperature for this measurement was always set at 25°C - ΔT_{CW}. Consequently, the measured values correspond to the laser resonator at approximately 25°C.

C. Lasers

Lasers used in the present study were either conventional DH devices intended for continuous operation with relatively low optical power output of P-p-n-N lasers intended for high-power pulsed operation in a fundamental mode [6]. The multilayered structure of the DH laser consists of a thin ($\lesssim 0.4$ μm) active layer of p-type GaAs sandwiched between p- and n-type layers of AlGaAs. The P-p-n-N laser is also a multilayered heterostructure device with the difference that the p-n junction is located within a relatively thick (2 to 3 μm) optical waveguide as described previously [6]. All lasers were fabricated into stripe-geometry devices by proton bombardment [7]. Stripe widths were nominally 13 μm. All lasers were bonded with indium on to diamonds bonded to Cu studs or directly to the Cu studs. A detailed description of the heat sinks and bonds is given in [8].

III. Experimental Results

The temperature rise associated with CW operation and the corresponding thermal impedance are summarized in Table I for the several different lasers studied in this work. The values for ΔT_{CW} listed in this table were all obtained by nulling the wavelength shift of an individual Fabry-Perot mode from low-duty cycle to continuous operation. The temperature rise ΔT_{CW} corresponds to an operating current near threshold.

To confirm the tabular value for L-734HA-2.3, the shift of the total spectrum of spontaneous emission at 50 mA was also measured as shown in Fig. 2. The current is chosen to be well below threshold in order to avoid modulation of the spectra by Fabry-Perot modes, which tend to obscure the spectral peak. As usual, the experimental points show considerable scatter, but their average value gives R_{th} = 22.1°C/W which is consistent with the value given in Table I. The scatter and uncertainty shown in Fig. 2 demonstrate the difficulty encountered when measuring R_{th} by this method in lasers where the temperature rise is only a few degrees.

In some devices such as P-p-n-N lasers intended for high-power pulsed operation, continuous operation may be undesirable due to the high level of input power required. With such devices, the temperature rise ΔT as a function of average input power can be used to estimate the thermal impedance. As an evaluation of this technique, R_{th} for L-734HA-2.3 was also measured in this way. As shown in Fig. 3 the temperature rise ΔT measured by the null technique is proportional to the duty cycle from 0 to 100 percent, indicating that the measurement is sensitive to the average dissipated power. From the slope of the line determined by the points below 50 percent and the measured voltage for continuous operation, we calculate R_{th} for this laser to be 20.9°C/W, which also is in good agreement with the value obtained by taking the laser to CW conditions. However, it should be noted that many points must be taken to determine the slope accurately.

Also shown in Fig. 3 is the rise in temperature with duty cycle for another laser from the same batch, L734HA-4.2. Again the dependence is linear to 100 percent and gives R_{th} = 56.4°C/W in close agreement with the tabled value.

The experimental points of ΔT versus duty cycle for a short P-p-n-N laser L714-6-3 are shown in Fig. 4 for different sample times t_s within the current pulse. From the slope of the line, we calculate R_{th} for this laser to be 94°C/W which is the value given in Table I. Also it is clear from the figure that at least for times less than 400 ns the measured value of ΔT is not sensitive to the exact time t_s at which the modal wavelength shift is nulled.

TABLE I

LASER No.	TYPE	LENGTH	HEATSINK	ΔT_{CW} (°C)	R_{th} (°C/watt)
L734HA-2.3	DH	380 μm	p side down on copper	8.1 (160 mA)	22.2
L734HA-4.2	DH	380 μm	p side down on copper	21.5 (150 mA)	57.8
L714-6-3	PpnN	102 μm	p side down on diamond	not operated continuously	94 (260 mA)
L714-6-2	PpnN	127 μm	p side down on diamond	not operated continuously	75 (380 mA)
L684S-00	DH	152 μm	n side down on copper	21.2 (80 mA)	146.8
L736HA-1.3	DH	380 μm	p side down on copper	6.6 (180 mA)	22.1

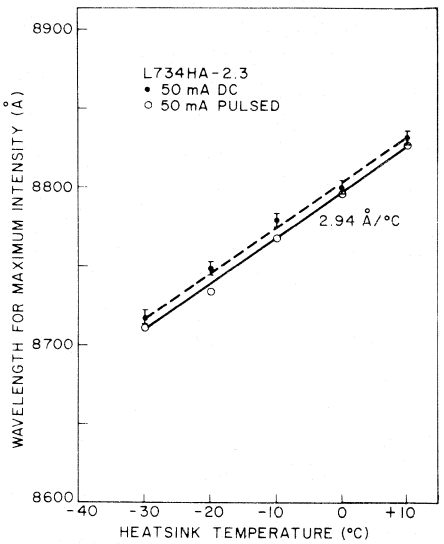

Fig. 2. Spectral shift of the spontaneous emission peak as a function of heat-sink temperature for L734HA-2.3 operated pulsed and continuously. The points obtained with pulsed operation are used to calibrate the temperature dependence of the spectral peak for this laser. The temperature rise obtained from the wavelength shift between the dc and pulsed points at a constant heat-sink temperature is used to calculate the thermal impedance.

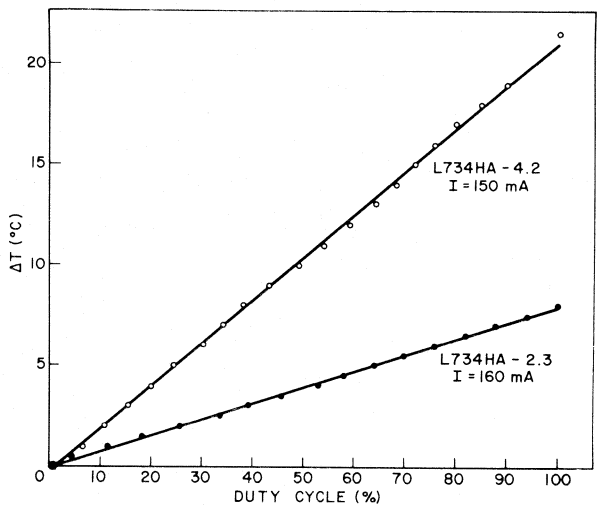

Fig. 3. Temperature rise measured by the null technique as a function of duty cycle for a DH laser, L734HA-2.3. Note that the dependence is quite linear from 0 to 100 percent and that the ΔT_{CW} obtained this way is the value given in Table I.

As a check on the measured value, the thermal impedance for L714-6-3 was also estimated from the shift of the total spectrum of spontaneous emission produced by changing from low-duty-cycle operation to continuous operation. Although the experimental data obtained at 100 mA show considerable scatter as indicated in Fig. 5, the average of the values obtained this way, R_{th} = 90°C/W, is consistent with the value obtained by the null measurement.

The variation of ΔT with duty cycle for the last three diodes listed in Table I is shown in Fig. 6. From these measurements, we find R_{th} = 75°C/W for L714-6-2, R_{th} = 142°C/W for L684S-00, and R_{th} = 23.1°C/W for L736HA-1.3. The latter two values also agree quite well with the values in Table I.

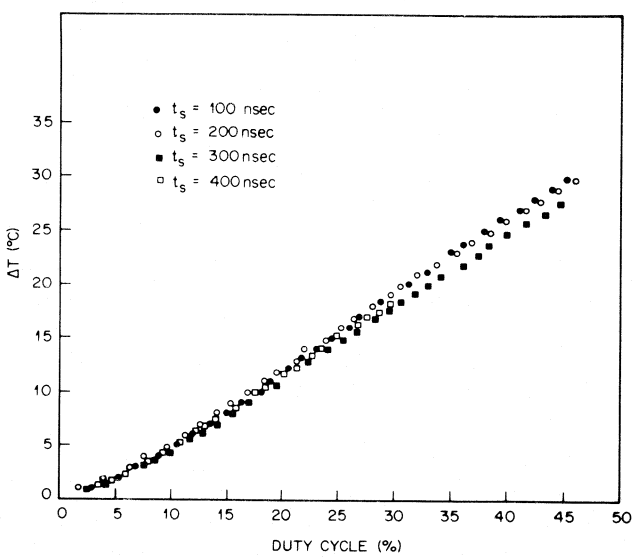

Fig. 4. Temperature rise as a function of duty cycle for a P-p-n-N laser L714-6-3. The parameter t_s is the time between the start of the current pulse and the point at which the wavelength shift of the Fabry-Perot mode is nulled. Note that the slope of the line is relatively insensitive to this time.

IV. Conclusion

In this work, we have shown that the thermal impedance of stripe-geometry junction lasers can easily be determined with a null measurement of the wavelength of an individual Fabry-

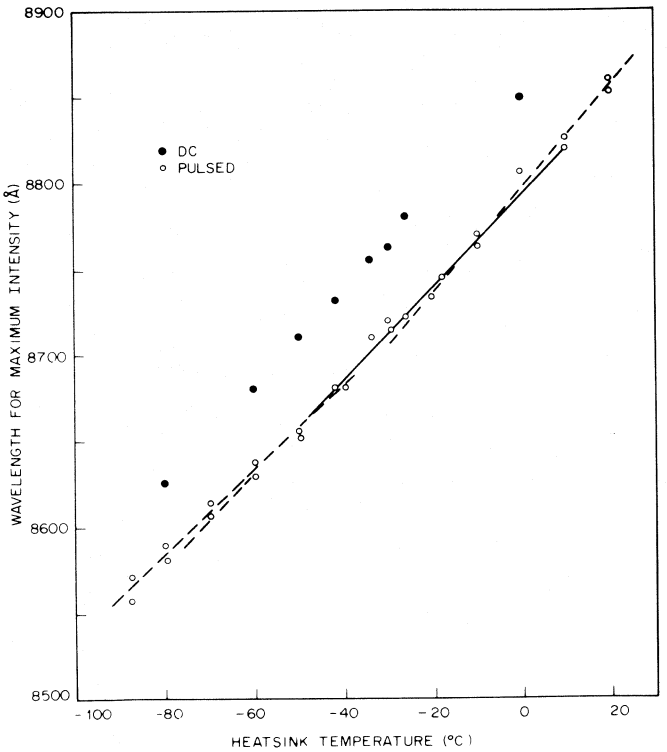

Fig. 5. Spectral shift of the spontaneous emission peak at 100 mA as a function of heat-sink temperature for a P-p-n-N laser, L714-6-3. These data are used to calculate the thermal impedance of this laser for comparison with the value obtained with the null measurement.

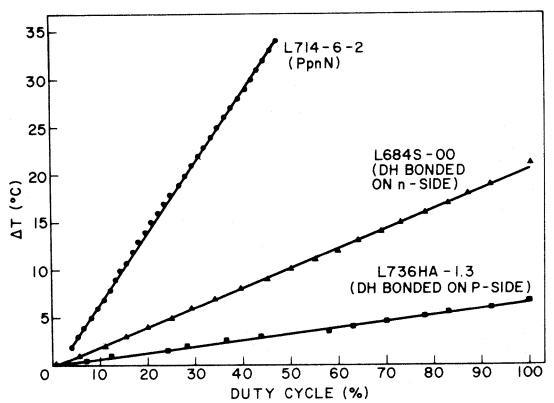

Fig. 6. Temperature rise as a function of duty cycle for a short P-p-n-N laser, a DH laser bonded on its p side, and a short DH laser bonded on its n side.

Perot mode of the laser cavity. The technique does not require a preliminary calibration and can be performed quickly and accurately. Because of the relative ease with which the measurement is performed, studies of the thermal impedance as a function of current level or absolute laser temperature are feasible. The technique should also be useful in an assessment of the relative importance of heat transfer by spontaneous emission.

Since the modal wavelength is used as the temperature indicator, the technique acutally is sensitive to the temperature within the optical resonator rather than the temperature at the p-n junction. Furthermore, the measured value is in some way an average over the transverse spatial distribution of temperatures which may exist in the stripe-geometry device [8], as well as over local hot spots which may exist along the laser axis. Consequently, the technique has the distinct advantage of measuring an average internal temperature for the laser as compared to the local temperature indicated by observation of the spontaneous emission generated near a laser mirror.

We have also demonstrated in this work that a null measurement of the modal wavelength can be used to measure the average temperature of a pulsed laser as a function of its duty cycle. From such a measurement, the thermal impedance of the laser can be estimated without operating the device continuously. However, since the measurement technique is somewhat more involved and involves an extrapolation to CW conditions, this method is considered to be less reliable than the direct measurement of the temperature associated with continuous operation.

The measurement technique has been illustrated with measurements on several stripe-geometry lasers including P-p-n-N and conventional DH lasers. The values obtained are consistent with those obtained by using the spectral shift of the spontaneous emission. Since R_{th} is expected to be inversely proportional to the device length L, comparison of different devices is facilitated by use of the coefficient $R_{th}L$. For two P-p-n-N lasers, $R_{th}L$ was measured to be approximately 375 deg mil/W which is consistent with the nominal value calculated [8] recently for this type of structure. For a conventional DH laser with good thermal characteristics, $R_{th}L$ was measured to be approximately 331 deg mil/W which is somewhat lower than the minimum value expected [8] for this structure. The difference may be due to the systematic error introduced by the initial transient temperature rise described in Section II. For a nominal DH laser, an initial rise of about 2 to 3°C might be expected from simple thermal considerations [9]. In terms of the small ΔT_{CW} being measured with DH lasers, this systematic error may be appreciable. Consequently, a further assessment of its actual magnitude is necessary before a detailed comparison with the theoretical values is justified. In addition, the discrepancy may also be partly due to incomplete confinement of the current to the assumed stripe width and/or to some heat generation between the active region and the heat sink. In the latter case, the generated heat would have a minimal effect on the temperature of the optical cavity. On the other hand, for another DH laser from the same wafer, $R_{th}L \approx 867$ deg mil/W was obtained, indicating some of the variability obtained with these devices. Finally, with a conventional DH laser bonded n-side down, a value of approximately 881 deg mil/W was obtained for $R_{th}L$. This relatively high value of thermal impedance reflects the effect of the thick substrate layer which is between the junction and the heat sink. As with the other DH laser, the measured value is somewhat lower than calculated [8] for this bonding geometry.

Transverse Mode Control of Junction Lasers Optically Coupled to Single-Mode Fibers

D. C. KRUPKA, MEMBER, IEEE, AND THOMAS L. PAOLI, MEMBER, IEEE

Abstract—**Preliminary experimental results are reported to demonstrate that fundamental transverse mode operation can be obtained from a multimode double-heterostructure (DH) junction laser while simultaneously coupling its output into a single-mode optical fiber. Mode selection has been achieved by three different methods: 1) incorporating the fiber into the resonant cavity; 2) using the reflections off the diode-fiber interface; and 3) by a combination of the aforementioned methods. In all approaches the diode-fiber interface effectively becomes a mirror with a reflectivity which is higher for the fundamental mode than for all other modes of the DH waveguide. By using the reflections off the diode-fiber interface, a peak pulsed power of 80 mW has been obtained from the uncoated end of a single-mode fiber butted against a P-p-n-N junction laser. This laser radiated a peak power of 165 mW in a first-order mode when operated without coupling to the fiber.**

I. Introduction

IN THIS WORK, we present preliminary results to show that a single-mode optical fiber can be effectively used to obtain transverse mode control in a multimode double-heterostructure (DH) junction laser while simultaneously coupling its output into the fiber. In principle, mode selection may be achieved either by incorporating the fiber into the resonant cavity (intracavity selection) or by using reflections off the diode-fiber interface (reflective selection). In both approaches the diode-fiber interface can be considered as a mirror which preferentially excites the fundamental mode of the DH waveguide.

In Section II, calculations are presented for the efficiency of optical coupling between a stripe-geometry junction laser with a thick waveguide and available low-loss optical fibers. The calculations indicate the conditions required for efficient coupling. In Section III, experiments are described which demonstrate the use of a fiber as a mode-selecting element. The results indicate that the intracavity and reflectivity effects may be present simultaneously with varying relative contributions. In the conclusions presented in Section IV, it is argued that the intracavity effect is to be preferred and that it may help in suppressing filamentation in lasers operated well above threshold.

II. Diode-Fiber Coupling

Coupling from a stripe-geometry DH laser operating in the fundamental mode to an optical fiber with a round core is inherently inefficient because of the ellipticity and astigmatism [1] of the GaAs laser beam. An estimate of the coupling efficiency κ may be obtained by approximating the modes of the laser and fiber by equivalent Gaussian modes and using expressions derived by Kogelnik [2] for the coupling coefficient. If the beam astigmatism is neglected, it is found that optimum coupling is achieved when the mode cross-sectional areas are equal. For a laser having a 12-μm stripe width, and for typical laser and fiber refractive index profiles, this criterion leads most often to the requirement that the fiber be single mode. More accurate formulas for coupling have been derived by Cook [3] who represented the fundamental mode of the GaAs laser by a product of two Gaussian functions but used an exact expression for the fiber's fundamental (HE_{11}) mode.

Using the formulas given in [3], the coupling coefficient as a function of fiber core diameter, for the case of a fiber butted against the laser, has been calculated for a Gaussian laser mode with a $2w_{0x} = 9$ μm parallel to the junction plane and different waists $2w_{0y}$ perpendicular to the junction plane. The choice of $2w_{0x}$ is a nominal value taken from previous measurements [1]. The beam's astigmatism has been taken into account by assuming that the "perpendicular waist" is located at the mirror while the "parallel waist" has been placed 35.5 μm inside the laser [1]. The fiber core index is $n_1 = 1.458$ and the cladding index is $n_2 = 1.454$. These indices are

appropriate for the fibers available to us at the time of the experiment and, as outlined in the following, do not represent an optimum choice of $n_1 - n_2$. The results are plotted in Fig. 1.

The calculations show that for a given fiber core diameter, the coupling coefficient is a strong function of ellipticity $\epsilon = 2w_{0x}/2w_{0y}$, and that, as predicted on the basis of the simple Gaussian model, optimum coupling for typical values of ϵ is attained with single-mode fibers. Furthermore, it is found that the fiber core which optimizes κ is a very weak function of the core diameter for $\epsilon \gtrsim 2$. This may be appreciated on the basis of the simple model [2] which dictated equal mode areas for optimum coupling.

As ϵ is increased, the laser mode area is decreased (since $2w_{0x}$ is kept fixed), and the fiber mode diameter must be reduced to maintain optimum coupling. However, the fiber mode area may not be reduced indefinitely. As the core diameter is reduced a minimum value of mode diameter is attained, after which, further reduction of the core diameter leads to a growth of the mode area with an increasingly larger fraction of the mode power being carried in the cladding [4]. For the fiber used in the calculations, the minimum mode diameter, measured between $1/e^2$ points of intensity, is approximately 5.8 μm at a core diameter of 4.2 μm [4]. This is in reasonable agreement with the more rigorous calculations presented in Fig. 1 which suggest that the minimum effective mode diameter occurs at a core diameter of approximately 4.5 μm. Thus, in order to improve the coupling to the lasers with $\epsilon \geqslant 2$, one requires fibers having larger values of $n_1 - n_2$ which lead to smaller minimum mode diameters.

From Fig. 1 it is noted that in order to exceed $\kappa \approx 0.5$, one is forced to use a laser with $2w_{0y} \gtrsim 2$ μm. With a cavity thickness giving rise to such mode dimensions, it becomes increasingly difficult to maintain operation of a GaAs laser in the fundamental mode perpendicular to the junction plane. However, as will be shown in Section III, a short section of single-mode fiber butted against the laser mirror face, with a mirror at its remote end, can be used to force the laser to switch to fundamental mode operation.

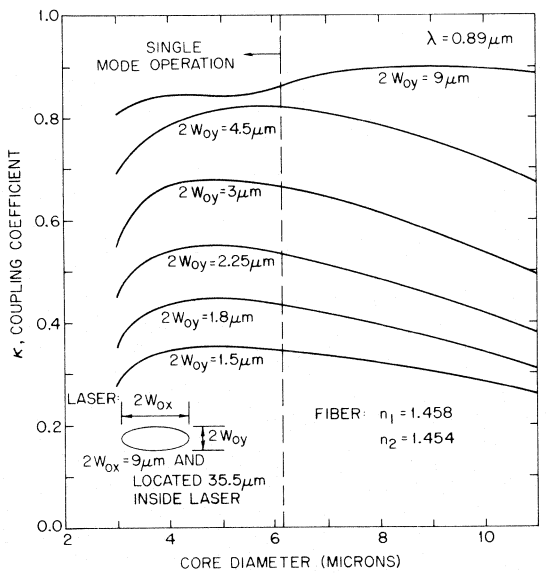

Fig. 1. Coupling coefficient κ as a function of fiber core diameter for lasers assumed to have Gaussian modes. In all cases the field at the laser mirror is assumed to have a width $2w_{0x} = 9$ μm and to be located 35.5 μm inside the laser face. The fiber has a core index $n_1 = 1.458$ and a cladding index $n_2 = 1.454$. Each curve is characterized by a different value of $2w_{0y}$. The calculations are carried out for a wavelength of 0.89 μm.

The mode selection can be understood as follows. Each mode transmitted through the diode-fiber interface may be expanded in terms of the single guided mode (HE_{11}) and the continuum (or cladding) modes of the fiber. However, the largest coupling efficiency occurs between the fiber mode and the fundamental mode of the DH waveguide because of the similarity of their spatial distributions. Immersion of the fiber in an index matching fluid strips or eliminates the cladding modes with the result that the power reaching the remote end of the fiber is entirely in the HE_{11} mode. A mirror is placed at the end of the fiber in order to return a portion of this power to the diode-fiber interface where it is again preferentially coupled to the fundamental mode of the DH waveguide. This output mirror effectively increases the reflectivity of the laser mirror for the fundamental mode by an amount

$$\Delta R_0 = \kappa^2 R_f \tag{1}$$

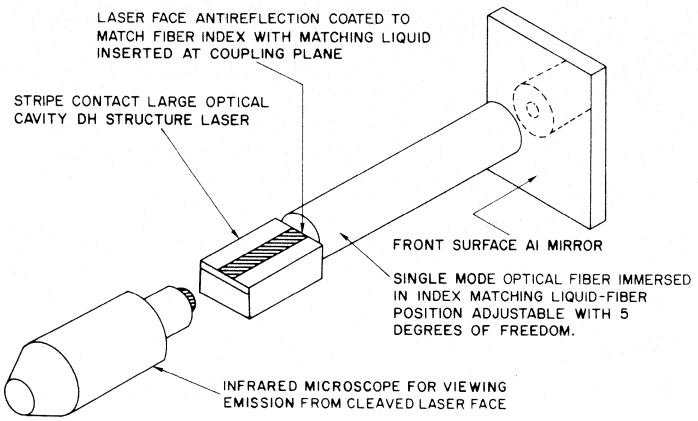
where R_f is the reflectivity of the HE_{11} mode at the fiber's remote end and κ appears squared because the wave passes through the coupling plane twice. It is assumed that the fiber is much longer than the laser. If ΔR_0 is sufficient to overcome the difference between the net gain of the fundamental mode and that of the oscillating mode, the laser will be forced to switch to fundamental mode operation. For lower values of ΔR, it is also possible to have the fundamental mode coexist with a higher order mode.

The use of a passive section in tandem with a laser has been advanced by Snitzer and LaMarre [5] and also by Miller [6]. The first two proposed a single-mode fiber in series with a laser, while the latter suggested the use of an intracavity dielectric guide with a cross section "substantially congruent with the shape of the cross section of the active region" of a solid state laser.

Mode selection can also result from positioning the laser and fiber such that the reflectivity of the fundamental mode is made higher than that of the other mode. An analysis of transverse mode selection by means of a distant mirror in a more controlled situation has been carried out by Hakki [7].

III. Experimental Results

To demonstrate the feasibility of the mode selection technique in a case where the intracavity effect is dominant, an experiment was set up as indicated schematically in Fig. 2. The laser selected was an $Al_xGa_{1-x}As$-GaAs heterostructure of the P-p-n-N type [8] with a waveguide thickness of 3 μm which lased in the first-order mode perpendicular to the junction plane ($m = 1$). Along the junction plane the contact current was confined to 12 μm by proton bombardment [9]. A quarter-wave layer of ZnS was coated [10] on one face of the diode to serve as an antireflective coating between the DH waveguide and the optical fiber [$n_{ZnS} \approx (n_{fiber} \cdot n_{GaAs})^{1/2}$]. This AR coating is useful to reduce the reflections from the diode-fiber interface which tend to preferentially excite modes other than the fundamental in the DH waveguide. A single-



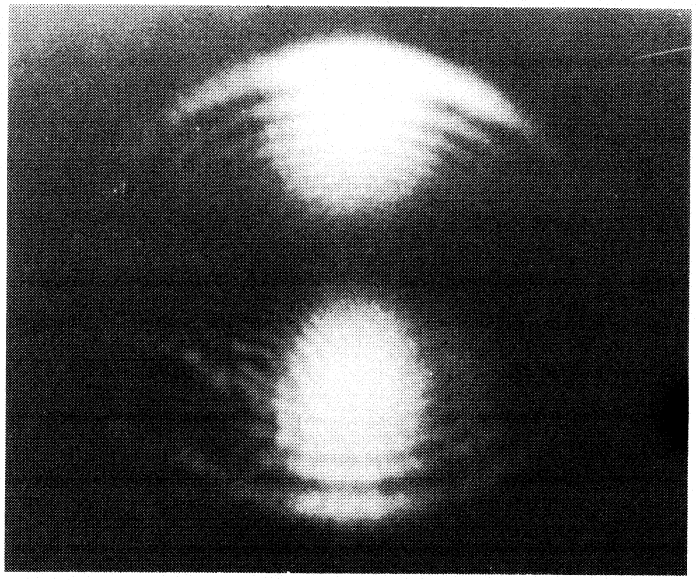


Fig. 2. Experimental setup. The fiber, approximately 10 cm long and immersed in index matching fluid to strip the cladding modes, may be positioned to have its end accurately parallel to the laser face and its core aligned with the laser waveguide. One face of the laser is AR coated to minimize reflections from the fiber-laser interface while the other is simply as cleaved. Changes in the radiation from the cleaved face induced by motion of the mirror are monitored by an infrared microscope.

mode fiber, approximately 10 cm long, with a core diameter of 5.7 μm (HE_{11} mode diameter ≈ 6.3 μm) was nestled in a trough containing index matching fluid. The index of refraction of the core was 1.458 while that of the fiber cladding was 1.454. A drop of index fluid was also placed on the fiber's tip before butting it against the coated face of the diode.

The position of the fiber was then adjusted with a micromanipulator having 5° of freedom to yield maximum transmitted power. During this phase the far-field radiation pattern from the uncoated diode face showed little change indicating minimal reflection from either end of the fiber. However, as a front surface Al mirror with its plane accurately adjusted to be perpendicular to the fiber's axis was advanced toward the free end of the fiber, notable changes occurred in the far field.

When the mirror was approximately 100 μm from the fiber's end, the laser mode was observed to begin a transition from the $m = 1$ to the $m = 0$ mode. The change appeared to be complete when the fiber-mirror separation was approximately 13 μm. When the mirror was pulled back, the laser reverted to $m = 1$ mode operation. First-order-mode operation was likewise obtained by keeping one end of the fiber butted against the laser and the other against the mirror, but displacing the fiber in a random manner by distances of a few microns. In all cases there was a unique position of the fiber which led to $m = 0$ operation. It was possible to break the index matching fluid seal between the laser and the fiber and then to remake it and obtain behavior identical to that described previously. There was no observable difference in threshold between the $m = 0$ obtained with the fiber and the $m = 1$ mode obtained without the fiber.

Fig. 3(a) shows a photograph of the far-field radiation pattern taken through the infrared microscope with the mirror removed, while Fig. 3(b) is a similar photograph taken with the Al mirror butted against the fiber's free end. The fiber's position relative to the laser is the same for both figures. The change from $m = 1$ to $m = 0$ operation is clearly seen. A scan of the far-field radiation pattern perpendicular to the junction

Fig. 3. Photographs of far-field patterns. (a) The $m = 1$ mode radiating from the cleaved face of the laser when the fiber is butted against its other face and the Al mirror is removed. $I = 1.4$ A. Exposure time in 2 s. The ring pattern is caused by the lens. (b) The $m = 0$ mode induced by butting the Al mirror against the fiber's remote end. The current is the same as in (a) but the exposure time is 0.5 s.

plane is shown in Fig. 4 and yields a full width at half-power of 19.4°. The refractive index profile obtained from the nominal doping levels [11], [12] may be used to calculate a far-field pattern [13] yielding a full width at half-power of 21° in reasonable agreement with observation. A far-field scan parallel to the junction plane gave a full width at half-power of approximately 10° implying operation in a filament with $2w_{0x} = 4$ μm.

Spectra were also observed for this laser in order to assess the degree of coupling achieved between the DH waveguide and the optical fiber. Fig. 5(a) shows the spectrum of the $m = 1$ mode obtained without the Al mirror, while Fig. 5(b) is the spectrum of the fundamental mode as selected by the external cavity. The shift of the oscillation spectrum to longer

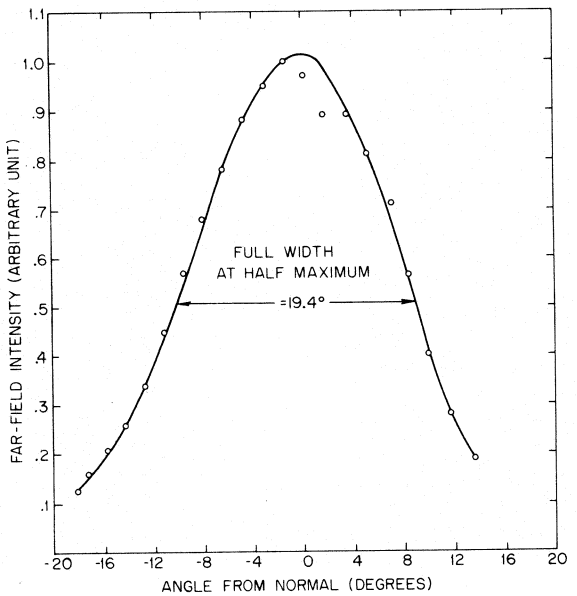

Fig. 4. Far-field scan perpendicular to junction plane when Al mirror is butted against the fiber's remote end. I = 1.4 A. For the laser used, the calculated full width at half maximum is 21°.

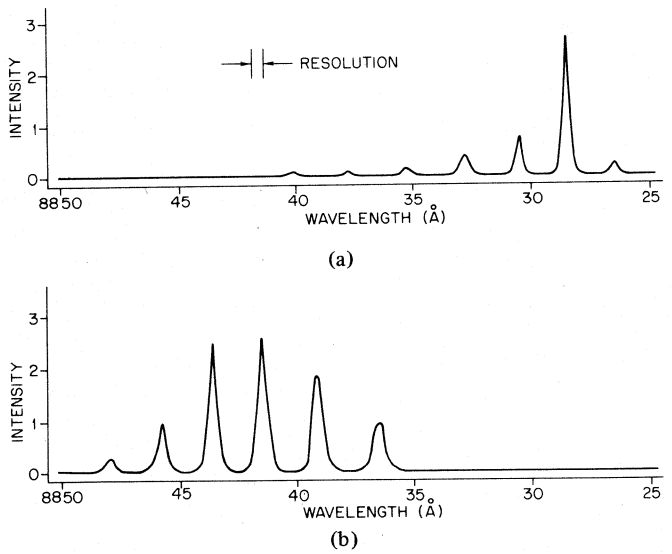

Fig. 5. Lasing spectra of the laser whose optical output is coupled into a single-mode optical fiber. (a) Mirror out. The output of the remote end of the fiber is not reflected back into the fiber and the laser oscillated in an m = 1 mode perpendicular to the junction. (b) Mirror in. An Al mirror is used to return the fiber output to the laser, thereby switching the oscillation to a fundamental mode perpendicular to the junction plane.

wavelengths achieved with the external feedback is consistent with the improved cavity Q demonstrated by the mode selection shown in Fig. 3(b). In addition, there is no evidence in the spectrum of Fig. 5(b) of the m = 1 modes indicating that oscillation is occurring predominantly in the fundamental mode. However, the spacing of the modes obtained with the external feedback corresponds to the longitudinal mode separation of the 375-μm diode alone (≈2 Å). Since the spacing of longitudinal resonances in the diode plus fiber cavity is much smaller than 2 Å, it is clear that oscillation in the external cavity occurs only at frequencies within the linewidth of the diode resonances. This observation indicates that there is a significant reflection for the fundamental mode at the diode-fiber interface, although it is not sufficient by itself to produce oscillation.

The absence of oscillation between the resonances of the short cavity can be attributed to either weak coupling between the fiber and DH waveguide or to a high reflectivity at the diode-fiber interface. For the laser used in the experiment with $2w_{0y}$ estimated to be 2 μm[1] and $2w_{0x}$ taken to be 4 μm, a value for κ of approximately 0.5 is expected on the basis of Gaussian approximations and the Kogelnik formulas [2]. With no reflectivity at the diode-fiber interface and an R_f near 100 percent, κ = 0.5 should provide a ΔR_0 of approximately 30 percent which should be sufficient to produce oscillation at frequencies between the resonances of the diode cavity. This conclusion suggests the possibility that it is primarily the reflectivity of the diode-fiber interface which is substantially reducing the "effective" coupling between the DH waveguide and fiber, and thereby preventing oscillation at these off-resonance frequencies.

In another experiment using a different laser and fiber, we realized the situation in which reflectivity selection dominated. In this case the laser's oscillating mode was changed from m = 1 to m = 0 by judicious positioning of the fiber (with no mirror on its free end) in relation to the laser's waveguide. In this case it was also possible to locate the fiber to produce m = 0 operation without maximizing the power coupled into the fiber mode, indicating that the interface reflectivity was dominant. However, it was possible to maintain mode selectivity while simultaneously maximizing the power transmitted through the fiber. Under optimal conditions, a peak power of 80 mW (100 ns pulses, 100 pulses per second) arising from the HE_{11} mode was radiated from the remote end of the fiber. Without the fiber in place, the laser operating at the same current, radiated a peak power of 165 mW in the m = 1 mode.

It was also possible to obtain an intermediate situation where neither the intracavity nor the reflectivity effects dominated. Using yet another laser-fiber combination, it was found that butting a fiber with its end coated with index matching oil against the laser switched its operation from pure m = 1 to a mixture of m = 0 modes. However, when a mirror was brought up against the fiber's remote end, the conversion to m = 0 was completed.

IV. Conclusion

In this work, we have demonstrated the possibility of obtaining fundamental transverse mode operation from a multimode DH junction laser while simultaneously coupling its output into a single-mode optical fiber. One way of achieving this result is to utilize the reflections from the diode-fiber interface to select the fundamental mode of the diode waveguide. Although this was successfully accomplished, it is at best difficult and unreliable, depending to a large extent on the details of the fiber surface.

The alternate and preferred method of incorporating the single-mode fiber into the resonant cavity has been successfully used to obtain fundamental mode operation from a large-cavity DH laser which otherwise oscillated in a first-order

[1] This estimate is based on the thickness of the epitaxial layer thicknesses measured using a scanning electron microscope.

mode perpendicular to the junction plane. This result was achieved with a net coupling efficiency of much less than 50 percent due to a substantial reflectivity at the diode-fiber interface. In principle, it should be possible to reduce the mode reflectivities at the laser-fiber interface to less than 1 percent by tailoring the AR layer.

Another potential benefit of intracavity selection, for which there exists but meager evidence at present, concerns filamentation. If the laser-fiber coupling can be increased sufficiently so that the region of the diode in which lasing occurs is determined primarily by the optical fiber, then the deleterious effects of filamentation such as beam steering and erratic light pulses, which are so common in junction lasers operated at high levels above threshold and at high duty cycles, may be eliminated. In this situation, the optical properties of the output beam will be independent of the pumping current since the fiber mode is independent of the internal dynamics of the laser diode.

Acknowledgment

The authors wish to thank B. W. Hakki for many useful discussions and suggestions, and for providing the AR-coated lasers used in this work. They also wish to thank D. D. Cook for making available his computer program for the evaluation of laser-fiber coupling coefficients, W. G. French for providing the single-mode fibers, and L. A. D'Asaro and R. C. Miller for their helpful comments on the manuscript.

Multimode Operation and Mode-Locking Effect in Injection Lasers

H. BACHERT, P. G. ELISEEV, M. A. MANKO, V. P. STRAHOV, S. RAAB, AND CHAN MIN THAY

Abstract—**The oscillation regime of GaAs injection lasers has been investigated by methods of time-resolved spectroscopy and nonlinear interferometry. The relative roles of random and correlated process were studied. Spectroscopic data and interferometric investigations of laser samples in CW as well as in pulse regimes show that in most cases multimode operation occurs with random phase fluctuations. However, in some cases signs of mode locking of longitudinal modes were observed with ultrashort pulsation. The duration time of the pulsation is estimated to be about 3 ps.**

I. Introduction

AS IS WELL KNOWN, GaAs injection lasers operating well above threshold emit radiation distributed over a large number of spectral modes. Previous time-resolved spectroscopic studies [1]–[4] have shown a connection between the multimode regime of emission and nonstationary phenomena such as self-induced pulsation. Most informative investigations were performed with stripe-geometry double-heterostructure lasers providing single-filament operation [2], [3]. It was shown that there is a tendency to single-frequency operation when steady-state emission takes place. However, the behavior of lasers is quite different when self-induced pulsation appears. Probability of excitation of several other

spectral modes has increased. We shall discuss a difference of spectral output of laser emission for a nonstationary and stationary oscillation and consider the number of spectral modes excited versus pumping current (Section II). Then we will consider autocorrelation data on laser emission to single out the phase-locking effects which can also influence the multimode regime of oscillation in semiconductor lasers (Section III).

II. Spectroscopic Data on Injection-Laser Emission for Nonstationary and Stationary Conditions of Operation

Previous experiments on time-resolved spectroscopy of laser emission from injection lasers have included a comparison of the averaged and instantaneous spectral distribution of the laser emission [1] and classification of the regimes of operation of semiconductor lasers [2], [3]. The influence of an external high-frequency modulation of the pumping current on the spectral distribution of laser emission was also investigated [4]. It is worthwhile to review results of these investigations.

1) Steady-state oscillation is mostly single-frequency oscillation, while interruption of the oscillation leads to excitation of several new spectral modes, at least for a short duration of time. Such an interruption may be produced by external modulation or may happen due to self-induced pulsation.

2) Oscillation regimes of injection lasers appear when current grows above the threshold as follows: stationary (single-frequency) regime; similar regime interrupted by switching of dominant mode; regular self-induced pulsation (multifrequency) regime; irregular self-induced pulsation regime.

3) Laser-emission spectrum averaged over time coincides with instantaneous spectrum only in the stationary regime. When self-induced pulsation takes place, the spectral distribution of laser emission changes randomly from one spike to another. The latter statement is valid if intensity falls down to the spontaneous level after every spike.

Fluctuations of the spontaneous level of radiation intensity have been suggested to be responsible for such a random variation of the spectral distribution of laser emission [1]. Recently, Morozov [5] has treated the physical model of nonstationary operation of injection lasers taking into account the fluctuation of the spontaneous emission.

On the basis of this approach the number of longitudinal modes involved in laser oscillation can be predicted as a function of the pumping level. This number M_q is determined by the following expression which is valid in the case of regular pulsation:

$$M_q \simeq 0.84 \left(\tan \frac{\tau_p}{\tau_e} \cdot \frac{1}{C} \cdot \frac{I - I_{th}}{I_{th}} \right)^{0.25} \left(\frac{\delta\alpha}{\alpha} \right)^{-0.5} \quad (1)$$

where τ_p and τ_e are the lifetimes of photons and electrons, respectively, C is the parameter of pulsation [5], I is the pumping current, I_{th} is the threshold current, $\delta\alpha/\alpha$ is the relative deficit of the optical gain at the neighboring longitudinal mode at threshold. The top of the gain spectral contour is assumed to be of parabolic form. Parameter C is slowly dependent on the pumping level. Therefore, the number M_q would follow approximately a power dependence on relative overdrive $Y = (I - I_{th})/I_{th}$ with an exponent $\frac{1}{4}$. Calculated curves are shown in Fig. 1 for two values of $\delta\alpha/\alpha$, 1) 10^{-4} and 2) 10^{-3}. In the figure we have plotted the experimental points corresponding to various injection lasers, having cavities of the Fabry-Perot type. Obviously, there is a tendency for these experimental points to follow in the same manner as the calculated curve, when $Y > 0.1$. Another manner of dependency M_q on Y is seen at smaller Y and also in Fig. 2, where $M_q(Y)$ is plotted for an injection laser with a selective cavity [6]. Such a laser operates at $M_q = 1$ up to some value of Y, and M_q grows rapidly above this value and approaches the calculated curve 4 corresponding to curve 2 in Fig. 1. It is found that the self-induced pulsation can be suppressed by the mode-selection operation in a certain range of Y. Thus there is an extended range of Y, where the laser operates in a stationary manner with $M_q = 1$. At higher Y spiking appears and M_q increases. These results are in good agreement with the preceding discussed representation.

In essence, the number of excited spectral modes M_q at a definite pumping level may be equal to 1, if stationary oscillation takes place, or follows expression (1), if self-induced regular pulsation takes place. We see that there is serious evidence of the strong influence of spontaneous emission on the appearance of the laser spectrum in the nonstationary condition. Further investigation and discussion in the paper will concern the problem of the phase-locking phenomena in semiconductor lasers in multimode operation.

III. Interferometric Measurements

For the investigation of the temporal-emission structure of the injection lasers a typical scanning Michelson interferometer was used [7] with a delay of 0.8 m. Linear and nonlinear registration methods for the output of the scanning Michelson interferometer [8] have been applied for these investigations in the time range of 10^{-13}-10^{-9} s.

The linear registration method of the output measures the temporal autocorrelation function of the pulse amplitude $G_\omega(\tau)$, and the detector output signal is

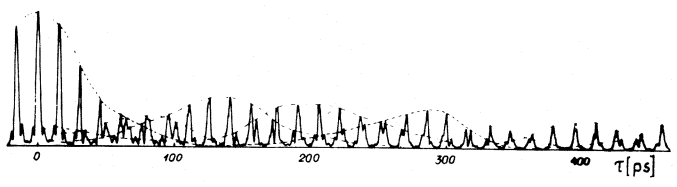
$$S_\omega(\tau) = I_\omega [1 + G_\omega(\tau)] \tag{2}$$

where τ means the variable delay time introduced to one part of the split beam and I_ω is the pulse energy.

Principally, the linear interferometer can only measure the power-density spectrum. But it is also possible to measure the coherence time τ_c, because this parameter is related to the spectral bandwidth. In any case, $S_\omega(0) = 2I_\omega$ and the highest contrast of the signal $S_\omega(\tau)$ cannot be more than 2. The injection lasers which have been investigated were excited at 77 K continuously or with 0.5-μs current pulses at a 50-kHz repetition rate.

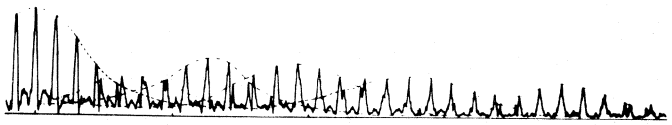
A typical linear interferogram is shown in Fig. 3. In this way it is possible to obtain information about the coherence time τ_c of the stimulated emission, about the spectral modes half-width, and about the time τ_1 of one round trip in the cavity (the influence of different mode frequencies can be seen).

It can be seen that the position of these peaks is not influenced by different excitations of the injection laser. In the case of the nonlinear registration method of $LiIO_3$ crystal was used and the temporal autocorrelation function of the pulse intensity $G_{2\omega}(\tau)$ can give information about the real pulse length $\Delta\tau_\omega$ of the ultrashort pulses. The output signal of the detector is given by



$$S_{2\omega}(\tau) = \chi\eta_{2\omega} I_\omega^2 [1 + 2G_{2\omega}(\tau)] \tag{3}$$

where χ is the efficiency of the nonlinear effect and $\eta_{2\omega}$ is the efficiency of the applied photodetector for the frequency 2ω. If the stimulated radiation of the injection laser after a temporal period $(2n^*l/c)$ (where n^* is the effective refractive index, l is the length of the resonator, and c is light velocity) have pulses and the nonlinear detection of the output signal $S_{2\omega}(\tau)$ shows a contrast ratio of 3 that means phase synchronization occurred. For this case, $G_{2\omega}(0) = 1$, and for $\tau > \Delta\tau_{2\omega}$ the received value of $G_{2\omega}(\tau) = 0$. In this way it is possible to decide if mode locking takes place or not.



In the nonlinear interferogram shown in Fig. 4, near zero for several pulses, a contrast ratio of nearly 3:1 can be observed. Similar interferograms are seen in Fig. 5. Figs. 4 and 5 show that the picosecond pulses are limited to 5-10 round-trip times because of the simultaneous spiking with a pulse duration of 0.1 ns. Within the spiking pulse, random phase fluctuation is observed. The half-widths $\Delta\tau_{2\omega}$ of these

picosecond pulses from Fig. 5 are less than 1 ps. An estimation by the method of Kuznetsova [9] gives values of 3 ps in accordance with the measured 1-ps pulses.

IV. Conclusion

Thus we have evidence of the mode locking of the longitudinal modes in injection lasers with a rather short cavity. This effect may originate from an internal optical nonlinearity of the semiconductor medium favoring the ultrashort pulses in the picosecond range. Hypothetically, a nonlinearity was found recently in GaAs. This is a self-induced transparency for two-photon absorption [10] which was observed when ultrashort pulses of a neodymium-glass laser passed through GaAs samples at a low temperature. It was found that at high radiation intensity the two-photon absorption coefficient decreases for very short pulses in comparison with its value for pulses of nanosecond duration. If two-photon absorption occurs within the active region of a semiconductor laser, the ultrashort pulsing operation will have lower optical losses than random phase operation.

Because the mode-locking effect takes place simultaneously with a self-induced pulsation of the laser emission its regularity is strongly limited by interruption of oscillation. Thus the deep nanosecond pulsation restricts the regularity of the ultrashort pulsation.

Anomalous Interaction of Spectral Modes in a Semiconductor Laser

A. P. BOGATOV, P. G. ELISEEV, AND B. N. SVERDLOV

Abstract—**Anomalous asymmetric interaction of the closely spaced spectral modes of a semiconductor laser is found experimentally in lasers with selective external cavities. The stimulated scattering of the laser radiation by dynamic inhomogeneities of the electron density is considered to be responsible for the anomalous mode interaction.**

I. Introduction

SEMICONDUCTOR media are optical materials of significant nonlinearity. Self-induced modulation of the intensity and frequency of oscillation in semiconductor lasers [1]-[5] can be pointed out as examples of the nonlinear effects on laser oscillation dynamics. A nonlinear part of the complex dielectric constant $\tilde{\epsilon}$ was taken into account when laser spiking in semiconductor lasers was treated theoretically [6], [7].

Manuscript received November 20, 1974; revised January 29, 1975.

The authors are with the P. N. Lebedev Physical Institute, Academy of Science of the USSR, Moscow, USSR.

In this paper a new nonlinear effect is considered which leads to an anomalous mode interaction in laser spectra. The effect differs from the usual competition of modes appearing due to homogeneous broadening. The new effect is asymmetric: the longer wavelength spectral mode of two neighboring modes dominates. Such an interaction occurs at small spectral distances (not greater than about 10^{11} Hz) which is smaller than the homogeneous bandwidth (10^{12}-10^{13} Hz). The physical model of the effect is a stimulated scattering of the laser radiation inside the laser medium by dynamic inhomogeneities of $\tilde{\epsilon}$ appearing due to variation of the electron density. Such variation in electron density depends upon the radiation intensity which determines the rate of stimulated transitions. As is well known, the real part of $\tilde{\epsilon}$ of a semiconductor depends on the electron concentration n because the plasma resonance frequency and absorption edge are dependent on n. An estimation of the value of Re $(\partial\tilde{\epsilon}/\partial n)$ for GaAs at its own laser wavelength near the absorption edge gives about 10^{-20} cm^3. Thus variation of the electron density n

produces a variation of the dielectric constant (real part, due to the previously mentioned reasons; imaginary part, due to the inversion of the population).

An asymmetric spectral-mode interaction occurs due to the radiation scattering by a dynamic variation of electron density. These variations are a kind of "recombination wave" appearing due to deviations of the pumping-emission balance, but not due to a virtual displacement of the plasma. Therefore, scattering processes can occur without limitation from the momentum-conservation rule (no dispersion law for these "waves").

In Section II the experimental observation is presented which suggests the anomalous mode interaction. In Section III a theoretical treatment is given of the perturbation of the spectral-gain curve in the vicinity of the laser frequency ω_0. The change of the gain is described by an odd function of the frequency difference $\Omega = \omega_0 - \omega$, which can provide the asymmetric mode interaction.

II. Experimental Results

Our experiments were performed with room-termperature single-heterostructure GaAs-AlGaAs lasers with an antireflective coating operated with an external cavity containing spectrally selective elements (Fig. 1). The laser action has been obtained with a linear and with a ring cavity including a reflective diffraction grating [Fig. 1(a) and (b)], and with the cavity containing two independently controlled gratings [Fig. 1(c)]. Single-grating cavities [8]-[11] allowed a narrow-line laser output tunable within a certain spectral range. The largest output power up to 5 W has been obtained with the bandwidth less than 0.1 nm, whereas at lower power level (0.5 W) the bandwidth may be less than 0.01 mm [11]. Such a spectral line is called nominally "spectral mode" even if it contains several longitudinal modes of the external cavity. The reason is that their spatial distribution inside the active medium coincides closely until their spectral bandwidth is much less than the intermode spacing of the diode resonator. At a high level of pumping, the internal-mode lasing appears, sometimes simultaneously with the external narrow-line lasing. It has been noticed that a strong external spectral mode suppresses weak internal modes more effectively on the shorter wavelength side than on the longer wavelength side.

To investigate this mode-interaction phenomenon, the double-grating cavity has been arranged. Operation in two spectral modes has been observed. Mode interaction was found to be dependent on the spectral distance between them and on the position of one relative to the other. Two experiments were performed. The first involved a measurement of the intensity of a tunable mode as a function of wavelength at fixed pumping current. Results are presented in Fig. 2. Value Φ_λ^0 was measured when only one tunable mode was excited (the second grating was blocked by a black screen). When the fixed spectral mode at λ_0 was excited simultaneously with the tunable mode, the dependency Φ_λ was modified [Fig. 2(b)], the range of tuning was decreased from 4 nm to 3 nm, and a discontinuity appeared at λ_0. Notice a nonmonotonic dependence of Φ_λ at the left side of λ_0. Value Φ_{λ_0} is the intensity of the fixed mode at λ_0 as a function of the wave-

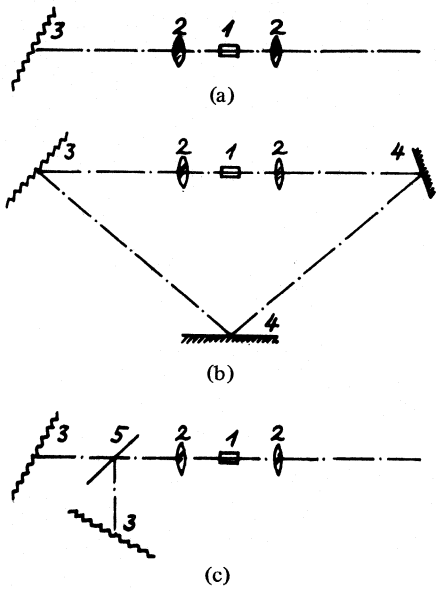

Fig. 1. Schemes of the external selective cavities used in this study. (a) A linear autocollimation scheme. (b) A ring scheme. (c) A double-grating autocollimation scheme. 1: laser diode; 2: lens; 3: reflecting diffraction grating; 4: mirror; 5: beam splitter.

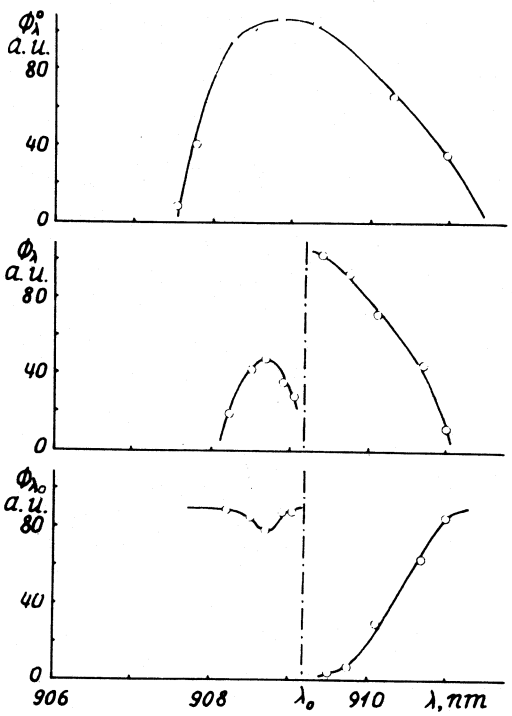

Fig. 2. Dependences of values Φ_λ^0, Φ_λ, and Φ_{λ_0} on the wavelength of the tunable spectral mode when optical scheme of Fig. 1(c) is used. Φ_λ^0 is the intensity of the tunable spectral mode when only one diffraction grating is open. Φ_λ is the intensity of the tunable mode when both gratings are open and lasing at λ_0 occurs. Φ_{λ_0} is the intensity of the fixed spectral mode which lases at λ_0. A single-heterostructure diode is used with the antireflection-coated Fabry-Perot cavity of length 1 mm at 300 K driven by 80-A current pulses of duration time 0.25 μs and of repetition-frequency rate 200 Hz. Thickness of the active layer is about 2 μm.

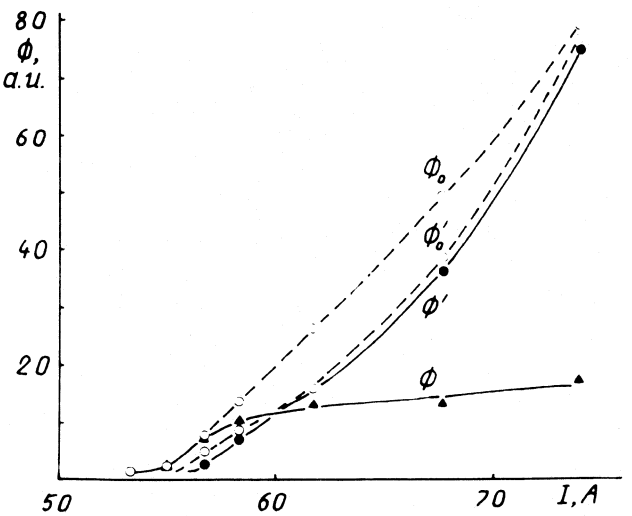

Fig. 3. Current dependence of intensities of two spectral modes, operating at 908.9 nm (Φ), and at 909.2 nm (Φ′) with the same scheme, diode, and pulsing regime as in Fig. 2. Index 0 corresponds to measurements when only one diffraction grating is open.

length of a tunable mode when both modes are excited simultaneously. Thus the tunable mode was quenched effectively when it approached the fixed mode at the shorter wavelength side.

In the second experiment, the intensities of two spectral modes spaced 0.3 nm apart were measured as a function of pumping current (see Fig. 3). It has been found that the intensity of the shorter wavelength mode saturated at a high pumping current whereas that of the longer wavelength mode grew with increasing current.

These results show that the mode interaction at small spectral distances ($\leqslant 10^{11}$ Hz) becomes asymmetric in favor of the longer wavelength mode when the intensity of laser radiation is high enough ($\geqslant 10^4$ W/cm^2). Electron concentration in these experiments is as large as about 10^{18} cm^{-3}, which corresponds to the highest pump-current density up to 4×10^4 A/cm^2.

III. Analysis of the Mechanism of Anomalous Spectral-Mode Interaction

Asymmetric perturbation of the spectral-gain profile may be provided by a nonlinear stimulated scattering of laser radiation at frequency ω_0 by dynamic inhomogeneities of the electron density. The analysis will be limited to the case of a weak signal at a probe frequency $\omega_1 = \omega_0 - \Omega$; it will also be assumed that the relaxation time of the polarization of the medium is small in comparison with $1/\Omega$, thus the amplitude of polarization P follows closely the field amplitude. The effect under investigation is a nonlinear addition of P_{NL} to a linear polarization

$$P = \tilde{\epsilon}_0 \mathcal{E} + 4\pi P_{NL} \tag{1}$$

where P is the polarization vector of the medium, $\mathcal{E}$ is the electric-field vector, and $\tilde{\epsilon}_0 \equiv \epsilon + i\epsilon'$ is the complex dielectric constant which involves a linear real part and an imaginary part.

Our physical model is based on two equations, one of them is for the electromagnetic field [12], [13], another is for the electron density n, which includes the effects of diffusion, and spontaneous and stimulated recombination [14]

$$(\tilde{\epsilon}_0/c^2)(\partial^2 \mathcal{E}/\partial t^2) - \nabla^2 \mathcal{E} = -(4\pi/c^2)(\partial^2 P_{NL}/\partial t^2) \tag{2}$$

$$\partial n/\partial t - D\nabla^2 n + n/\tau + \alpha n|\mathcal{E}|^2 = G \tag{3}$$

where D is a diffusion constant, τ is the electron lifetime in the absence of the electromagnetic field, G is the pumping rate, and α is a proportionality coefficient for the rate of stimulated recombination.

Let us present the electromagnetic field as a series over modes of an ideal resonator [15]

$$\mathcal{E}(r, t) = \sum_j [E_j(t) + \text{c.c.}]\ \varphi_j(r). \tag{4}$$

The orthogonal normalized functions $\varphi_j(r)$ are solutions of the wave equation

$$\nabla^2 \varphi_j(r) + k_j^2 \varphi_j(r) = 0 \tag{5}$$

where k_j is the wave vector. Our analysis will be limited to a case when strong oscillation exists in the only mode

$$\mathcal{E}_0(r, t) = [E_0(t) + \text{c.c.}]\ \varphi_0(r) \tag{6}$$

whereas in other modes oscillations are very weak (single-mode laser operation)

$$|E_0(t)| >> |E_j(t)|, \quad j \neq 0. \tag{7}$$

Now we would like to investigate the behavior of the field in one of the nonlasing modes $\mathcal{E}_1(r, t)$ in the presence of the strong field $\mathcal{E}_0(r, t)$. We substitute (4) into (2), multiply both sides of the equation obtained by $\varphi_j(r)$, and then integrate over the volume of the resonator V. This procedure leads to a following equation:

$$(\partial^2 E_1/\partial t^2) + \tilde{\omega}_1^2 E_1 = -(4\pi/\tilde{\epsilon}_0) \int_V (\partial^2 P_{NL}/\partial t^2)\, \varphi_1(r)\, dV \tag{8}$$

where $\tilde{\omega}_1 = \omega_1 - i\gamma_1$, γ_1 is a damping parameter of a corresponding mode of oscillation. To calculate the right side of (8), it is necessary to find the form of the inhomogeneity of a nonlinear polarization, which can be approximated by a linearization as

$$P_{NL} = (\mathcal{E}_0/4\pi)\, \delta\tilde{\epsilon} = (\mathcal{E}_0/4\pi)(\partial\tilde{\epsilon}/\partial n)\, \delta n \tag{9}$$

where $\delta\tilde{\epsilon}$ is the variation of dielectric constant, and δn is the variation of electron density. Both variations appear due to the superimposing of two fields $\mathcal{E}_0$ and $\mathcal{E}_1$, and they are oscillating values with frequency Ω. Such a variation of electron density does not influence the oscillation regime at ω_0 until E_1 is small enough and Ω is larger than the oscillation bandwidth. Threshold level of the optical gain is supplied by the value of the electron density averaged over time, whereas the instantaneous deviation δn is quite usual for the multimode oscillator.

The deviation produces a dynamic phase lattice

$$\delta\tilde{\epsilon}(r, t) \approx (\partial\tilde{\epsilon}/\partial n)\, \delta n(r, t)$$

which scatters laser radiation ω_0 in the same direction, with a Stoke's shift by Ω. This nonlinear contribution to the polarization of the medium at frequency $\omega_1 = \omega_0 - \Omega$ is presented by the right side of (8). Oscillations E_1 would have an increasing amplitude if this contribution could compensate a damping term in the left side of the equation. As to scattering into the back direction, it seems to be less important because the small distance variations of n are smoothed effectively due to electron diffusion. We shall deal with variations δn which are averaged over distances as large as $(\lambda/2)(\epsilon)^{-1/2}$, and this approach corresponds to neglect of the backscattering. To obtain $\delta n(r, t)$, one has to consider (3). In the Appendix it is shown that the right side of (8) may be approximately expressed by a combination of averaged values of electron density $\bar{n}_0$, recombination probability Γ, and intensity $|E_0|^2$. Now the equation for E_1 may be expressed as follows:

$$(\partial^2 E_1/\partial t^2) + \tilde{\omega}_1^2 E_1 = -(\omega_1^2/\tilde{\epsilon}_0)(\partial\tilde{\epsilon}/\partial n) \cdot (\alpha\bar{n}_0 K E_1 |E_0|^2)/(i\Omega + \Gamma) \tag{10}$$

where K is an "overlap coefficient" also explained in the Appendix. This equation has an unstable solution if the following expression is valid:

$$(\omega_1/2)(\alpha\bar{n}_0 K|E_0|^2)\,\mathrm{Im}\,[(1/\tilde{\epsilon}_0)(\partial\tilde{\epsilon}/\partial n)/(i\Omega + \Gamma)] > \gamma_1 . \tag{11}$$

It is possible to use the following expression:

$$\mathrm{Im}\left(\frac{1}{\tilde{\epsilon}_0}\cdot\frac{\partial\tilde{\epsilon}}{\partial n}\cdot\frac{1}{i\Omega+\Gamma}\right) \approx -\frac{1}{\epsilon}\left(\frac{\Omega}{\Omega^2+\Gamma^2}\,\mathrm{Re}\,\frac{\partial\tilde{\epsilon}}{\partial n} - \frac{\Gamma}{\Omega^2+\Gamma^2}\cdot\mathrm{Im}\,\frac{\partial\tilde{\epsilon}}{\partial n}\right) = -\frac{1}{\epsilon}\,\mathrm{Re}\,\frac{\partial\tilde{\epsilon}}{\partial n}\cdot\frac{\Omega-\Gamma\xi}{\Omega^2+\Gamma^2}$$

$$= -\frac{1}{\epsilon\Gamma}\cdot\mathrm{Re}\,\frac{\partial\tilde{\epsilon}}{\partial n}\cdot F(\Omega,\xi) \tag{12}$$

where

$$\xi \equiv [\mathrm{Im}\,(\partial\tilde{\epsilon}/\partial n)]/[\mathrm{Re}\,(\partial\tilde{\epsilon}/\partial n)]$$

and function F is

$$F(\Omega,\xi) = \frac{\Gamma(\Omega-\Gamma\xi)}{(\Omega^2+\Gamma^2)} . \tag{13}$$

From the result it is seen that the spectral-mode interaction which is treated here gives an additional gain (or absorption) in the weak mode due to the parametric influence of strong mode. Spectral shape of this additional gain is determined by the function $F(\Omega)$ presented in Fig. 4 for the particular value of $\xi = 0.3$ (approximate estimation). This additional gain

$$\delta g = -\frac{\omega_1}{c(\epsilon)^{1/2}}\left(\mathrm{Re}\,\frac{\partial\tilde{\epsilon}}{\partial n}\right)\alpha\bar{n}_0|E_0|^2 KF(\Omega)/\Gamma \tag{14}$$

superimposes two effects: namely, laser radiation scattering by variation of Re $\tilde{\epsilon}$ with an odd contour $\Omega/(\Omega^2+\Gamma^2)$, and laser radiation scattering by variation of Im $\tilde{\epsilon}$ with an even contour $\xi\Gamma/(\Omega^2+\Gamma^2)$. The former type of stimulated scattering is an important explanation of the asymmetric mode interaction. The value δg is positive at $\Omega > \Gamma\xi$ and is negative for the shorter wavelength side where $\Omega < \Gamma\xi$. The latter type of scattering gives a negative addition which does not influence the qualitative results; however, it shifts the asymmetric curve from the zero point $\Omega = 0$. Extrema of δg are at the following points:

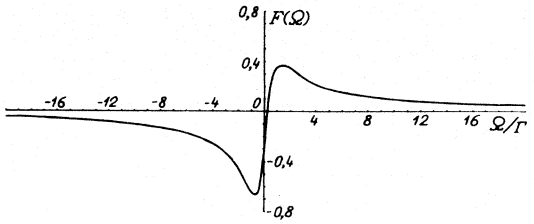

Fig. 4. Computed shape of $F(\Omega)$ spectral distribution of additional gain produced by the nonlinear scattering process analyzed in this paper. Notice that Γ is a rather small value, and experimentally it is possible to follow only peripheral parts of the curve $F(\Omega)$.

$$\Omega_{1,2} = \Gamma[\xi \pm (1+\xi^2)^{1/2}] . \tag{15}$$

The maximal value of δg saturates at $\alpha|E_0|^2 >> 1/\tau$ and it shifts to the longer wavelength side if the intensity $|E_0|^2$ grows. This maximal value can be expressed as follows:

$$\delta g_m \approx -\frac{\bar{n}_0\omega_1}{4c\sqrt{\epsilon}}\left(\mathrm{Re}\,\frac{\partial\tilde{\epsilon}}{\partial n}\right)\frac{\sqrt{1+\xi^2}}{1+\xi+(1+\xi^2)^{1/2}} \tag{16}$$

where the estimation of K performed in the Appendix is used. The limiting value of the additional gain for the GaAs laser from expression (16) is dependent on the mean electron density and is equal to about

$$\delta g_m \approx (2 \times 10^{-16}\ \mathrm{cm}^2)\,\bar{n}_0 . \tag{17}$$

Expression (17) is valid for estimation of additional gain due to stimulated scattering only in order of value. Because of the finite bandwidth of the laser radiation at ω_0 such a value on the additional gain may not be observed. At larger Ω, additional gain decreases approximately as $1/\Omega$. Its value at the neighboring longitudinal mode of a typical diode cavity appears to be about 10^{-1} cm^{-1}, which is quite comparable with the gain deficit. Therefore, this mechanism can provide an instability of single-frequency oscillation at a high level of optical flux.

IV. Discussion and Conclusion

We believe that the experimental observation presented gives evidence for a new type of mode interaction. It cannot be understood as a result of producing a simple dip of optical gain near the laser frequency because of the asymmetric nature of the experimental curve. Furthermore, the usual asymmetry of the gain contour in a semiconductor laser is not enough for fitting of the experimental data. It is obvious from Fig. 2(b) that the efficiency of the asymmetric interaction of spectral modes is larger at small distances between them and decreases at large spectral distances. It was found recently [16], [17] that the delay time of the lasing, relative to beginning of current pulse, could be spectrally dependent. But near the optimal spectral point there is a wide range where this delay, as well as the threshold current, is quite constant. All our

observations were obtained for this range. We have also shown that there was no significant difference in temporal behavior of the two interacting modes by additional experiments mentioned in [18].

The intensity dependence of the interaction presented in Fig. 3 appears to be similar to that for various mechanisms of stimulated scattering (see, for example, such dependences for Mandelshtam-Brillouin backscattering [19]). The saturation is typical for the shorter wavelength component which is a pumping wave.

The experimental conditions described here are favorable for the observation of the anomalous mode interaction because they avoid masking effects due to space inhomogeneity of the diode and due to the broadening of laser-output spectrum. Also it is important to perform these measurements at a high level of electron density, as high as 10^{18} cm^{-3}, which corresponds to our experiments. We could observe the asymmetric spectral-distance-dependent mode competition which was found to be in qualitative agreement with the theoretical model of stimulated scattering of laser radiation by dynamic inhomogeneities of electron density. This new mechanism is quite specific only for an inverted medium where the real dielectric constant is dependent on inversion of population.

We believe that the mechanism can act in a much wider range of experimental conditions where its direct observation is difficult. Let us remember that in semiconductor lasers there are many spectral modes which have approximately the same net gain above the threshold. Small perturbation of the gain curve due to the anomalous mode interaction can produce a significant change of the laser output like switching of the dominant mode and failure of the single-frequency oscillation observed in [4]. On the basis of this model one can explain why introduction of the spectrally selective element into the laser cavity leads to suppression of self-induced pulsation [4]. Unfortunately, very interesting problems concerning the multimode laser dynamics are too complicated to be solved taking into account this new mechanism of mode interaction. We have restricted the theoretical treatment to the case of a small signal in the probe mode for this reason. Similarly, we have estimated the contribution of other types of stimulated scattering in semiconductor lasers due to temperature variations ("temperature" scattering) and due to repulsion of electrons from the regions of strong radiation intensity. The contribution appears to be less important than that from the previously described mechanism.

Appendix
Calculation of the Nonlinear Polarization

The electron density $n(r, t)$ may be presented in the following form:

$$n(r, t) = n_0(r) + \delta n(r, t) \tag{18}$$

where $n_0(r)$ is the stationary part of the local electron density and $\delta n(r, t)$ is the time-dependent part, the mean value of which is equal to zero. Substitution of (18) into (3) leads to its separation into equations where only terms linear in $\delta n(r, t)$ and $\mathcal{E}_1$ are kept. The first equation relates to coordinate variation of $n_0(r)$

$$-D\nabla^2 n_0(r) + [n_0(r)/\tau] + \alpha n_0(r)\,|\mathcal{E}_0(r, t)|^2 = G \tag{19}$$

and the second equation relates to $\delta n(r, t)$

$$(\partial \delta n/\partial t) + (\delta n/\tau) - D\nabla^2 \delta n + \alpha \delta n\,|\mathcal{E}_0|^2 = -\alpha n_0 \mathcal{E}_0^* \mathcal{E}_1 + \text{c.c.} \tag{20}$$

where the asterisk labels the complex-conjugate value. A reasonable simplification of (20) may be obtained if one performs averaging of δn over small distances along the resonator axis z. Because of fast electron diffusion, periodic variation of δn due to a standing wave can be neglected. Therefore it is not necessary to deal with small scale variation of values $|\mathcal{E}_0|^2$ and $\mathcal{E}_0^* \mathcal{E}_1$. Smoothing action of the diffusion will be effective when the following expression is valid:

$$(4D\epsilon/\lambda^2) > \Omega. \tag{21}$$

On the other hand, a longer scale variation of δn is not influenced by electron diffusion because the expression

$$[c/(\epsilon D\tau)^{1/2}] > \Omega \tag{22}$$

is valid. With these assumptions one may drop out a diffusion term and perform averaging

$$\overline{|\varphi_0|^2} = [2(\epsilon)^{1/2}/\lambda] \int_z^{z+\lambda/2(\epsilon)^{1/2}} |\varphi_0|^2\, dz' \tag{23}$$

$$\overline{\varphi_0 \varphi_1} = [2(\epsilon)^{1/2}/\lambda] \int_z^{z+\lambda/2(\epsilon)^{1/2}} \varphi_0 \varphi_1\, dz'. \tag{24}$$

Thus (20) can be rewritten in the following way:

$$(\partial \delta n/\partial t) + (\delta n/\tau) + \alpha \delta n\,|E_0|^2\,\overline{|\varphi_0|^2} = -\alpha n_0 E_0^* E_1 \overline{\varphi_0 \varphi_1} + \text{c.c.} \tag{25}$$

Solution of this equation is

$$\delta n = -\frac{\alpha n_0 E_0^* E_1 \overline{\varphi_0 \varphi_1}}{i\Omega + (1/\tau) + \alpha |E_0|^2 \overline{|\varphi_0|^2}} + \text{c.c.} \tag{26}$$

Now we use expressions (9) and (26) to rewrite (8) for E_1

$$\frac{\partial^2 E_1}{\partial t^2} + \tilde{\omega}_1^2 E_1 = \frac{1}{\tilde{\epsilon}} \frac{\partial \tilde{\epsilon}}{\partial n} \cdot \int \frac{\alpha n_0 \varphi_0(r)\, \varphi_1(r) \overline{\varphi_0 \varphi_1}\, [\partial^2 (E_0 E_0^* E_1)/\partial t^2]}{i\Omega + (1/\tau) + \alpha |E_0|^2 \overline{|\varphi_0|^2}} dV$$

$$= -\frac{\omega_1^2}{\tilde{\epsilon}} \frac{\partial \tilde{\epsilon}}{\partial n} |E_0|^2 E_1 \int \frac{\alpha n_0 \varphi_0(r)\, \varphi_1(r)\, \overline{\varphi_0 \varphi_1}\, dV}{i\Omega + (1/\tau) + \alpha |E_0|^2 \overline{|\varphi_0|^2}}. \tag{27}$$

Further analysis needs accurate calculation of the distributions of n_0 and mode configurations. If the Q-factor of the cavity is high enough, these distributions are not too significant for estimation of the effect under investigation. Assume the following approximation:

$$\int \frac{\alpha n_0 \varphi_0 \varphi_1 \overline{\varphi_0 \varphi_1}\, dV}{i\Omega + 1/\tau + \alpha |E_0|^2 |\varphi_0|^2} \approx \frac{\alpha \bar{n}_0}{i\Omega + \Gamma} K \tag{28}$$

where $\bar{n}_0$ and Γ are mean values of the stationary electron density and effective recombination probability, correspondingly, and K is an "overlap" coefficient of inversion and combinated mode configurations. For example, in the case of the ideal resonator and in approximation of plane waves, this coefficient is equal to about $0.5/V$, where V is the volume of the cavity.

Injection-Induced Modulation of Laser Light by the Interaction of Laser Diodes

JUN-ICHI NISHIZAWA, FELLOW, IEEE, AND KATSUHIKO ISHIDA

Abstract—**The experimental investigation of laser-light modulation by injecting laser light of a frequency, which is slightly different from the cavity resonant frequency, into a laser-diode cavity is reported. For this investigation, the interaction of two laser diodes was used and the relation between the oscillation frequency spectra and the lasing frequency difference of the two diodes was measured where the frequency difference was greater than the locking frequency range. The sidebands generated by the injection of laser light were measured to judge an appearance of the injection-induced modulation of light intensity. Modulation in the frequencies from 10 to 90 GHz was achieved by using laser diodes of 60–130-μm length. It was experimentally shown that the upper frequency limit of the injection-induced modulation was related to the Q value of the laser-diode cavity.**

Manuscript received November 28, 1974; revised February 25, 1975.

I. Introduction

NISHIZAWA showed that when a laser beam whose frequency is slightly different from the cavity resonant frequency is injected into a laser diode, the electromagnetic field of the injected laser light starts to oscillate in the active region of the laser diode [1]–[3]. The electromagnetic field of the injected laser light is coupled with the oscillating cavity modes through the injected carriers [2], [4], so that the electromagnetic fields of the cavity modes are also forced to oscillate. This results in an injection-induced modulation of the laser output intensity and oscillation spectra consisting of equally spaced frequencies separated by the frequency of the injection-induced modulation.

In order to realize highly efficient modulation of laser-light intensity, the length of laser diodes must be taken into con-

sideration [1]. Nishizawa *et al.* [5] succeeded in modulating the light intensity of laser diodes at 46 GHz using laser diodes whose longitudinal-mode separations were nearly equal to the modulation frequency. And it was also reported that the degree of modulation becomes largest when the modulation frequency is a multiple of the fundamental frequency of the cavity [6]. On the other hand, it is possible to realize efficient high-frequency modulation by using a laser diode whose cavity bandwidth is large enough for the sidebands generated due to modulation. In other words, higher frequency modulation is possible in the laser diodes with a lower Q value. First-order mode locking, in spite of the appreciable dispersion of the refractive index, has been obtained in a very long (4–20-mm) electron-beam-pumped laser [7] due to the low Q value of the semiconductor laser cavity.

In this report, it is experimentally demonstrated that the modulated laser-light beam can be obtained from a laser-diode cavity by injecting a laser beam whose frequency is different by more than the locking frequency range from the cavity resonant frequency, and that the upper limit of the modulation frequency is related to the Q value of the laser-diode cavity. Our experimental results show that injection-induced modulation up to frequencies as high as 90 GHz can be obtained through the interaction of laser diodes in this way.

II. Experimental Procedure

The experimental arrangement is shown in Fig. 1. Two laser diodes A and B, whose lasing wavelengths differ by less than about 5 Å, were aligned end to end to be optically coupled to each other with a separation d. For improvements of optical coupling between the two laser diodes, it is most important to align the active regions of the two diodes in the same plane. In the present study, the two diodes were aligned as follows: one diode was set to lase itself and the other to exhibit a maximum photovoltage. The separation d was controlled with high accuracy by the use of a micrometric screw and a piezoelectric element and was held rigidly to obtain stable coupling [8]. Then the currents above their thresholds were supplied to diodes A and B.

The relation between the frequency spectra of the output light from diode B and the lasing frequency of diode A was measured with the lasing frequency of diode B kept constant while that of diode A was varied. It was not possible to directly observe the time variation of light intensity in the millimeter-wave region for lack of such a high-speed photodetector. Instead, the appearance of the sidebands due to the injection of laser light from A was used as a measure of the injection-induced modulation. That is, sidebands were detected and their intensities relative to the main peak were measured. This method was previously used to detect 46-GHz modulation of a laser diode [5].

There are two methods to achieve high-frequency modulation. In one, the diode length is chosen so that the modulation frequency f is nearly equal to the fundamental frequency of the cavity [5] expressed as

$$f = \frac{c}{2L\left(n + \omega \dfrac{dn}{d\omega}\right)}.$$

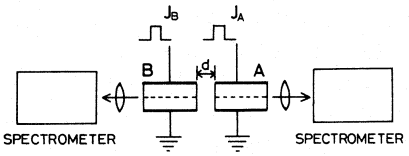

Fig. 1. The experimental arrangement for the interaction of laser diodes A and B.

Here L is the diode length, n is the refractive index, c is the velocity of light in the vacuum, and ω is optical angular frequency. In the other method, the Q value of a laser-diode cavity is made very small so that at least one of the sidebands generated by the modulation is included within the bandwidth of the cavity resonance [3]. The latter method was used in our present experiments. The Q value was lowered by reducing the length of the laser diodes (60–130 μm).

When laser diodes lasing at many longitudinal modes are optically coupled to each other, lasing frequencies easily hop to other frequencies, at least some of which are common to the two diodes when the lasing frequency difference is small [8]. But this hopping of lasing frequency was found to be experimentally difficult to obtain in the optical coupling of two laser diodes which lase at a single longitudinal mode when operated alone. Therefore, laser diodes which lased in a single longitudinal mode were describable in our experiments. The laser diodes having lengths less than 100 μm lase very easily in a single frequency. So it is most convenient to use shorter laser diodes not only for reducing the Q value but also for a single-frequency operation. The enhanced mode selectivity [8] is difficult to obtain due to the large longitudinal-mode separation in laser diodes shorter than 90 μm, and the lasing wavelengths do not jump from the self-oscillation frequencies to other frequencies by the optical coupling of the two diodes. The diodes used were GaAs–GaAlAs stripe-geometry double-heterostructure laser diodes whose stripe width was 20 μm. These diodes were operated at room temperature and pulsed at 500 Hz with 100-ns pulses. The lasing frequency of A was shifted due to the change of the active-region temperature by varying the dc current supplied to A. For a shift of the lasing frequency by as much as 9.8×10^{11} rad/s, which corresponds to the shift of the wavelength of 4 Å, the output intensity of A changed by less than 10 percent.

III. Experimental Results and Considerations

The change of the output spectra of B was measured as the lasing frequencies of A were varied. ω_A, ω_B represent the lasing angular frequency self-oscillation, $\delta\omega_A, \delta\omega_B$ the fundamental frequency separation of the laser cavity, J_A, J_B the current supplied to A and B, respectively.

When the lasing frequency difference between ω_A and ω_B satisfies the condition $\Delta\omega_m < |\omega_A - \omega_B| < \delta\omega_B/2$, the peaks of the output frequency spectra were given by only ω_A and ω_B, and new oscillation peaks other than ω_A and ω_B were not observed. Here $\Delta\omega_m$ is the largest difference between ω_A and ω_B at which new oscillation peaks other than ω_A and ω_B were observed. New oscillation peaks appeared when the lasing frequency difference became less than some value $\Delta\omega_m$. Thus, when $|\omega_B - \omega_A| \leqslant \Delta\omega_m$, diode B was operated at ω_A, ω_B and the induced frequency ω_i, but when $|\omega_A -$

$\omega_B| > \Delta\omega_m$, diode B operated only at ω_A and ω_B. Various pairs of optically coupled laser diodes were used and the new oscillation peak ω_i was never observed when the oscillation frequencies of two diodes satisfied the condition of $|\omega_B - \omega_A| > \Delta\omega_m$, whether $\omega_A < \omega_B$ or $\omega_A > \omega_B$. The frequency of the induced oscillation peak ω_i generated when $|\omega_B - \omega_A| < \Delta\omega_m$ was changed by varying the lasing frequency ω_A. These experimental results show that the induced oscillation peaks are not due to the growth of new lasing spots, which might occur due to optical coupling of diodes A and B, but that the generation of the new oscillation peaks is a fundamental phenomenon induced by the coexistence of the two electromagnetic fields having very close frequencies.

Although J_B was variously changed, the induced oscillation peaks other than ω_A and ω_B were not generated when J_B was below the threshold current (J_{Bth}) of B, but were observed only when $J_B > 1.07\ J_{Bth}$. Thus, one of the required conditions for the appearance of the induced signal at ω_i is that diode B have some high gain or that a signal exists at ω_B.

Fig. 2 shows the change of the output spectra of B as ω_A was varied. As the fundamental cavity frequency A is 2.7×10^{12} rad/s, which corresponds to 11 Å, there is only one mode of A included in the output spectra of B. P_A is the output power from A when $J_B = 0$, and P_B is for B when $J_A = 0$. For d equal to 30 μm, the optical coupling coefficient between A and B is about 0.04 [8]. Therefore the actually injected laser power into B from A is about 0.8 mW in this case. The output spectra consist of only two peaks at ω_A and ω_B in the case of $\omega_A - \omega_B = 8.1 \times 10^{11}$ rad/s, which corresponds to $\lambda_B - \lambda_A = 3.3$ Å, as shown in Fig. 2(a) (1). But a new oscillation peak ω_i appears on the low-frequency side of ω_B when $|\omega_A - \omega_B| \leqslant 5.4 \times 10^{11}$ rad/s, which corresponds to $|\lambda_B - \lambda_A| \leqslant 2.2$ Å. The frequency of this induced oscillation ω_i was changed by varying the lasing frequency of A, but always $\omega_A - \omega_B = \omega_B - \omega_i$; i.e., the induced oscillation is generated at the frequency of $2\omega_B - \omega_A$. The induced oscillation appears either at $2\omega_B - \omega_A$ [e.g., Fig. 2(a)] or at $2\omega_A - \omega_B$ [e.g., Fig. 2(b)] or at both frequencies of $2\omega_B - \omega_A$ and $2\omega_A - \omega_B$. These experimental results show that sidebands at $\omega_B \pm (\omega_B - \omega_A)$ and $\omega_A \pm (\omega_B - \omega_A)$ are generated by injecting laser light of frequency ω_A into B oscillating at ω_B; thus the output intensity of B can be modulated at the frequency of $|\omega_B - \omega_A|$ by the injection of laser light.

These experimental results can be explained by the mechanism which was proposed by Nishizawa [1]-[3]. When the laser beam frequency ω_A is injected into B oscillating at ω_B for $|\omega_A - \omega_B| < \Delta\omega_m$, the electromagnetic field corresponding to ω_A in the active cavity of B is modulated at frequency f given by [1]-[3]

$$f = \frac{c}{2\sqrt{\epsilon}\, l_B} \cdot \frac{|\lambda_B - \lambda_A|}{\delta\lambda_B} = \frac{|\omega_A - \omega_B|}{2\pi}$$

where l_B is the length of B; c is the velocity of light in the vacuum; ϵ is the dielectric constant of the active region of B; λ_A and λ_B are the lasing wavelengths corresponding to ω_A and ω_B, respectively; and $\delta\lambda_B$ is the longitudinal-mode separation corresponding to $\delta\omega_B$.

The electromagnetic field of the cavity resonant mode corresponding to ω_B is forced to oscillate due to the oscillation of

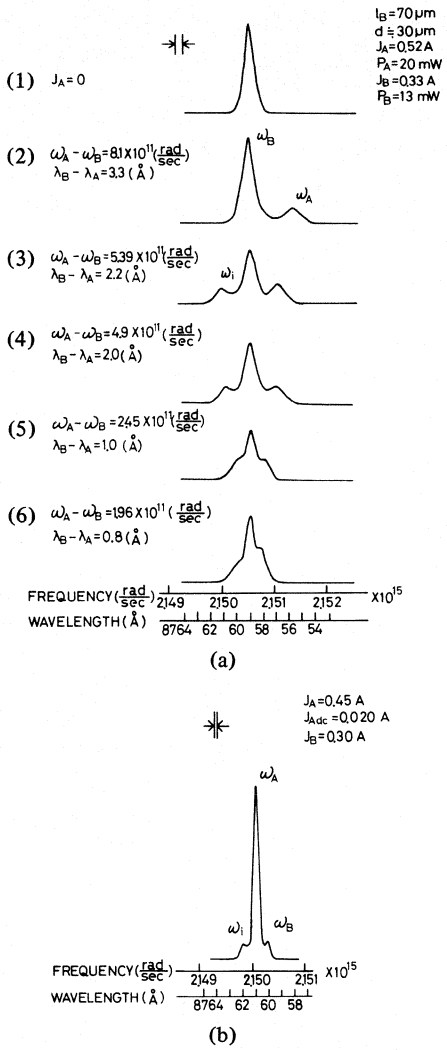

Fig. 2. The change of the output spectra of B as the lasing frequency of A was varied. The length of B is 70 μm and its fundamental cavity frequency $\delta\omega_B$ is 3.18×10^{12} rad/s, which corresponds to 13 Å. ω_A and ω_B are the lasing frequency of A and B, respectively. ω_i is the frequency of the induced oscillation. J_{Ath} is 0.37 A and J_{Bth} is 0.29 A.

the amplitude of the injected laser-light field and the coupling between the laser modes through the population inversion [2], [4]. As the light-field amplitude of the injected mode becomes larger, the partition ratio of population inversion for the cavity resonant mode becomes smaller due to the interaction between laser modes through the population inversion [2], [4]. Therefore, the amplification factor for the injected mode becomes higher, and that for the cavity resonant mode becomes smaller. When the light-field amplitude of the injected mode is smaller, the cavity resonant mode strongly lases. This phenomenon is similar to super regenerative detection [1]-[3]. As the amplitudes of the electromagnetic fields of the laser modes in the active region oscillate in this way, oscillation spectra consist of equally spaced frequency with the separation corresponding to $|\omega_A - \omega_B|$. In the example shown in Fig. 2(a), ω_A and $\omega_i (= 2\omega_B - \omega_A)$ are sidebands of ω_B. The degree of modulation, which is obtained from the ratio of the intensity of sidebands to that of carrier wave, is about 98 percent in the case of $\omega_A - \omega_B = 4.9 \times 10^{11}$ rad/s, which corresponds to $\lambda_B - \lambda_A = 2$ Å. Thus the

output intensity is considered to be modulated in the degree of 98 percent at 83 GHz. As ω_A approaches ω_B, then the ratio of the oscillation intensity at sidebands to that of main peak (ω_B) becomes larger and thereby overmodulation occurs. The degree of modulation can be changed by varying the current supplied to A and B. Fig. 2(b) shows the results for the same diode pair as Fig. 2(a) when ω_A was made lower than ω_B by increasing the dc current supplied to A, and J_A and J_B were changed. The degree of modulation is about 60 percent in this case.

Now the slight asymmetry of the sideband peaks, which is observed in Fig. 2(a), may be due to the additional laser power from A injected into B.

In the normal injection-locking experiments when the frequency difference is greater than the locking range, the frequency of the oscillator shifts toward the frequency of the locking signal [9]. The same phenomenon occurs also in the injection locking of lasers [10]. But this shift of the lasing frequency could not be observed in our experiments, since the shift is too small to be resolved by the spectrometer used in our experiments.

The frequency range for injection-induced modulation is shown in Fig. 3, where δ shows the frequency separation between the lowest frequency and the highest frequency of the oscillation spectra of B. That is, $\delta = (\omega_A - \omega_i)/2\pi$, corresponding to Fig. 2(a). But δ can be represented as $\delta = P|\omega_A - \omega_B|/2\pi$, where P is an integer. $P = 1$ indicates that the frequencies of the oscillation spectra are only at ω_A and ω_B, and that injection-induced modulation does not occur [e.g., Fig. 2(a) (1)]. The induced signal appears at the frequency of $2\omega_B - \omega_A$ or $2\omega_A - \omega_B$ for $P = 2$, but for $P = 3$ the induced signal appears at both frequencies of $2\omega_B - \omega_A$ and $2\omega_A - \omega_B$. Fig. 3(a) shows the results in the case of $l_B = 90$ and 70 μm. The data points satisfy the relation $\delta = 2 \cdot |\omega_A - \omega_B|/2\pi$ in the frequency range of $|\omega_A - \omega_B|/2\pi \leqslant \Delta\omega_m/2\pi = 87$ GHz, but the relation $\delta = |\omega_A - \omega_B|/2\pi$ holds well in the range of $|\omega_A - \omega_B|/2\pi > 97$ GHz. As the maximum frequency of the injection-induced modulation is obtained from $\Delta\omega_m/2\pi$, the maximum modulation frequency of the diode having $l_B = 70$ μm is about 90 GHz. Fig. 3(b) shows the results for the diode having $l_B = 130$ μm, where the maximum modulation frequency is about 50 GHz.

Fig. 4 shows the relation between the longitudinal-mode separation $\delta\omega_B$ of B and the maximum frequency difference $|\omega_B - \omega_A|_{\max}/2\pi = \Delta\omega_m/2\pi$ at which modulation occurs. The $\delta\omega_B$ is expressed as

$$\delta\omega_B \doteqdot \pi c/\sqrt{\epsilon}\, l_B.$$

Therefore, higher frequency modulation is possible in the shorter laser diodes. The Q value of a laser-diode cavity is given (11) as

$$Q = \omega_c \tau_c = \frac{\omega_c}{\Delta\omega_c}$$

where the cavity lifetime τ_c is

$$\frac{1}{\tau_c} = \frac{1}{\tau_m} + \frac{1}{\tau_s}.$$

τ_m is the contribution to the cavity lifetime, resulting from

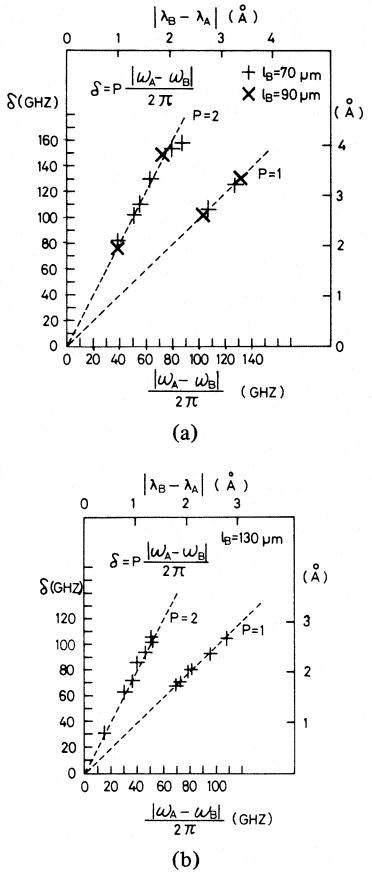

Fig. 3. The frequency range for modulation. δ is the difference between the lowest and the highest frequency in the output of B. $P = 1$ indicates that injection-induced modulation does not occur and $P = 2$ indicates the occurrence of modulation. (a) For $l_B = 90$ μm and $l_B = 70$ μm. (b) For $l_B = 130$ μm.

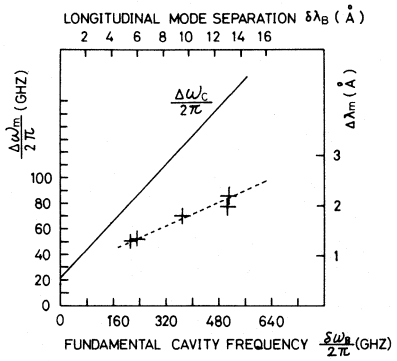

Fig. 4. The relation between the fundamental cavity frequency of B and the maximum frequency difference at which injection-induced modulation occurs, i.e., the maximum modulation frequency. The solid line shows the bandwidth of the laser-diode cavity. Here, $\Delta\lambda_m = (2\pi c/\omega_m^2) \cdot \Delta\omega_m$.

the loss of radiation through the mirrors alone, and is given as $\tau_m = -2\sqrt{\epsilon}\, l/c \ln(\rho_1 \cdot \rho_2)$, where ρ_1, ρ_2 are reflectivities, and τ_s corresponds to the scattering and absorption losses. $\Delta\omega_c$ is the bandwidth of the cavity. So $\Delta\omega_c$ can be expressed as

$$\Delta\omega_c = \frac{1}{2\pi}\left\{\ln\left(\frac{1}{\rho_1 \cdot \rho_2}\right)\right\} \delta\omega_B + \frac{\alpha c}{\sqrt{\epsilon}}.$$

Here, $\alpha c/\sqrt{\epsilon} = 1/\tau_s$. α is experimentally determined from the

relation of

$$J_{th} = \frac{1}{\beta}\left\{\alpha - \frac{1}{l}\ln(\rho_1 \cdot \rho_2)\right\}.$$

The calculated bandwidth of the laser cavity is shown in Fig. 4. It can be seen that the higher frequency modulation is realized in the laser diode with lower Q value. The appearance of sidebands indicates that the modulation of population inversion induced by the injection of laser light reacts back on the oscillating laser modes. This reaction is effective when the sidebands generated to the oscillating laser frequencies are included within the bandwidth of the cavity. Therefore the frequency range of the injection-induced modulation is reasonably considered to be related to the Q value of the laser cavity.

Direct Modulation of a Double-Heterostructure Laser Using a Schottky-Barrier-Gate Gunn-Effect Digital Device

HISAYOSHI YANAI, SENIOR MEMBER, IEEE, MITSUHIRO YANO, STUDENT MEMBER, IEEE, AND TAKESHI KAMIYA

Abstract—**By using a Schottky-barrier-gate Gunn-effect digital device the direct modulation of a GaAs-$Al_xGa_{1-x}As$ double-heterostructure laser was achieved with a rise time of 250 ps. The dependence of the optical waveforms on the bias-current levels was investigated in detail. The results are compared with a rate-equation analysis. A discrepancy between the present theory and the experiment indicates the existence of an additional relaxation mechanism.**

Introduction

THE CAPABILITY of high-speed direct modulation is one of the most attractive features of GaAs injection lasers, and a number of modulation schemes have been proposed and investigated in the range between 200 Mbit/s and 2.3 Gbit/s [1]-[8]. Among them, Thim *et al.* utilized a two-terminal Gunn-effect digital device and successfully obtained subnanosecond pulses [8], [9]. One of the authors (H. Y.) has been developing a three-terminal Gunn-effect digital device (a Schottky-barrier-gate Gunn-effect digital device [10], hereafter denoted as SBG-GEDD), which generates constant current pulses of very fast rise time and has the capability of handling fairly high current levels. It is expected therefore that this type of device is also useful for the pulse modulation of an injection laser.

The advantage of using a Gunn-effect digital device may lie principally in the fact that it can supply fast current pulses of constant waveforms without any shaping. Due to the simplicity of the circuit, it is easy to minimize the parasitic impedance effect. On the other hand, in combining the laser and the SBG-GEDD, we must choose a suitable bias-current level considering both the threshold current of the laser and the SBG-GEDD. As the dynamic behavior of the laser changes strongly as a function of injection current, it seems important to investigate the time-response characteristics of this modulation scheme as a function of bias current.

In this report experimental investigation of direct modulation of a double-heterostructure (DH) laser diode using a SBG-GEDD is described, with special emphasis on the bias-current dependence of the time-response characteristics. By attaching a parallel resistor to the SBG-GEDD, we were able to operate a variety of combinations of laser and SBG-GEDD's, with different threshold levels.

Manuscript received November 25, 1974; revised January 20, 1975. This work was supported by the Toray Science Foundation, Japan. Part of this work was presented at the 4th European Solid State Device Research Conference, Nottingham, England, September 1974.

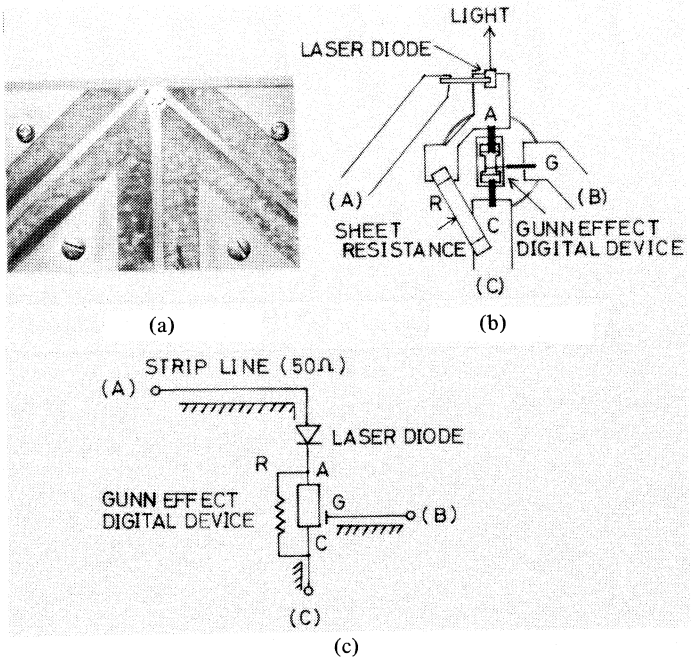

Fig. 1. Circuit diagram of a laser-modulation scheme using a SBG-GEDD. (A) is connected to a bias-pulse generator (pulsewidth of 100 ns), (B) is connected to a word generator, and (C) is grounded or connected to a current waveform monitor. A, G, C, and R denote the anode, gate, cathode of the SBG-GEDD, and the sheet resistor, respectively. (a) Photograph. (b) Construction of circuit. (c) Equivalent circuit.

It should be noted that by connecting the two devices in series we obtain negative optical pulses, where the transient behaviors are somewhat different from positive pulse modulation. In both cases the occurrence of spiking oscillations is an important problem.

After examining the time response of the photodiode, we will compare the experimental results with the analysis using rate equations. The observed changes of rise time and of ringing frequency are reasonably explained by the conventional model, but the observed damping-time constant associated with the ringing phenomenon is found to be shorter than the calculated value. It is also observed that an exponentially decaying component is superimposed on the oscillatory transient. The possible cause of these discrepancies is also discussed.

Experiments

The modulation circuit consists of a laser diode, a SBG-GEDD, and a sheet resistor. These elements are connected as depicted in Fig. 1. The bias-current level is chosen slightly below the Gunn oscillation threshold and simultaneously above the laser threshold by a certain amount. Without a triggering pulse, the laser operates continuously. When a triggering pulse is applied at the gate, the SBG-GEDD generates a single negative current pulse, causing a reduction of the lasing output, i.e., a negative optical pulse.

By properly choosing the value of resistance R of the sheet resistor, we can operate various combinations of laser and SBG-GEDD's with different threshold currents. Through a simple circuit-theoretical consideration the formula for determining R is found as

$$R = V_{\text{th}}^{G}/(I^{L} - I_{\text{th}}^{G}) \tag{1}$$

where V_{th}^{G}, I_{th}^{G}, and I^{L} are the threshold voltage of the SBG-GEDD, the threshold current of the SBG-GEDD, and the bias-current level of the laser, respectively. The relation between the current drop of the laser ΔI^{L} and that of the SBG-GEDD ΔI^{G} is

$$\Delta I^{L} = \frac{R}{R + R_i + R^{L}} \cdot \Delta I^{G} \tag{2}$$

where R_i and R^{L} denote the output impedance of the bias source and the internal resistance of the laser, respectively.

Only pulsed operation is used with a pulsewidth of 100 ns in order to avoid heating and possible degradation of the laser or of the SBG-GEDD. A 1-Gbit/s word generator (Iwatsu WG-101) is used as a trigger source and modulation up to 500 Mbit/s was successfully made. In this paper, however, we shall confine ourselves to the single pulse-response characteristics. The studies of the word effects will be reported later.

The upper trace of Fig. 2 shows the current waveform of the SBG-GEDD and the lower trace shows the triggering pulse waveform. It is seen from the figure that the pulsewidth is 1.1 ns according to an active length of 90 μm, the rise time is less than 100 ps, and the current drop ΔI^{G} is 40 mA.

Fig. 3 shows the relation between the injection current I^{L} and the output light intensity I_L of the laser used. The laser has a threshold current I_{th}^{L} of 225 mA, a cavity length l^{L} of 210 μm, a stripe width w^{L} of 15 μm (fabricated by the proton-bombardment technique), and an active-region thickness t^{L} of 0.5 μm (measured by SEM observation of the cleaved surface).

A silicon avalanche photodiode (a product of Nippon Electric Co.) is used to detect the output signal. Although the specification by the manufacturer ensured the frequency re-

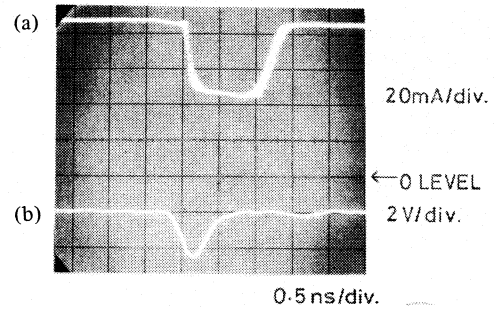

Fig. 2. Current waveform of the SBG-GEDD. (a) The upper trace is the current pulse. (b) The lower trace is the trigger pulse. Time scale: 1 div = 0.5 ns.

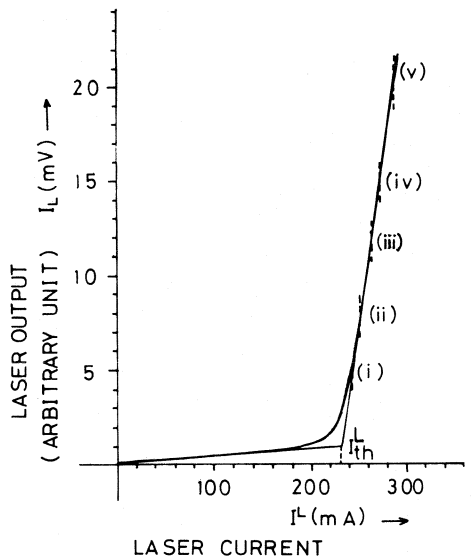

Fig. 3. Output characteristics of a stripe-geometry DH laser. Threshold current is 225 mA. The bias points used in observations of modulated waveforms (Fig. 4) are indicated by roman numbers.

sponse only up to 1 GHz at $\lambda = 0.6328\ \mu m$, our diode showed better response, as will be discussed later (see Fig. 5).

We have observed the output-pulse waveforms under various bias-current levels. In Fig. 4 the upper traces show the current waveforms and the lower traces show the output signals of the avalanche photodiode. Fig. 4 (i)-(v) correspond to the normalized bias-current levels (I^L/I^L_{th}) of 1.09, 1.13, 1.18, 1.22, and 1.29, respectively. As shown in this figure, the rise time shortens from 800 ps to 240 ps as the bias level is increased from 1.09 to 1.29. The fall time remains constant at 240 ps. It is probably limited by the fall time of the current pulse.

The optical signal of our device also shows a relaxation oscillation. This behavior is qualitatively in agreement with previous observations on positive optical pulse modulation. Examining the traces in detail, however, we find that an exponentially decaying component is presented in addition to the damped oscillatory transient

$$A_1 e^{-(t/\tau_d)} \cos(2\pi f_r t) + A_2 e^{-(t/\tau')}. \tag{3}$$

The determination of f_r, τ_d, and τ' is performed as follows. First we determine f_r from the interval between the maxima in the damped oscillations. Next, by plotting the light intensity for the times $t = (2N-1)/4f_r$, where N is an integer, we obtain A_2 and τ'. Subtracting then the second term from the total curve we determine τ_d. The results are tabulated in Table I(a).

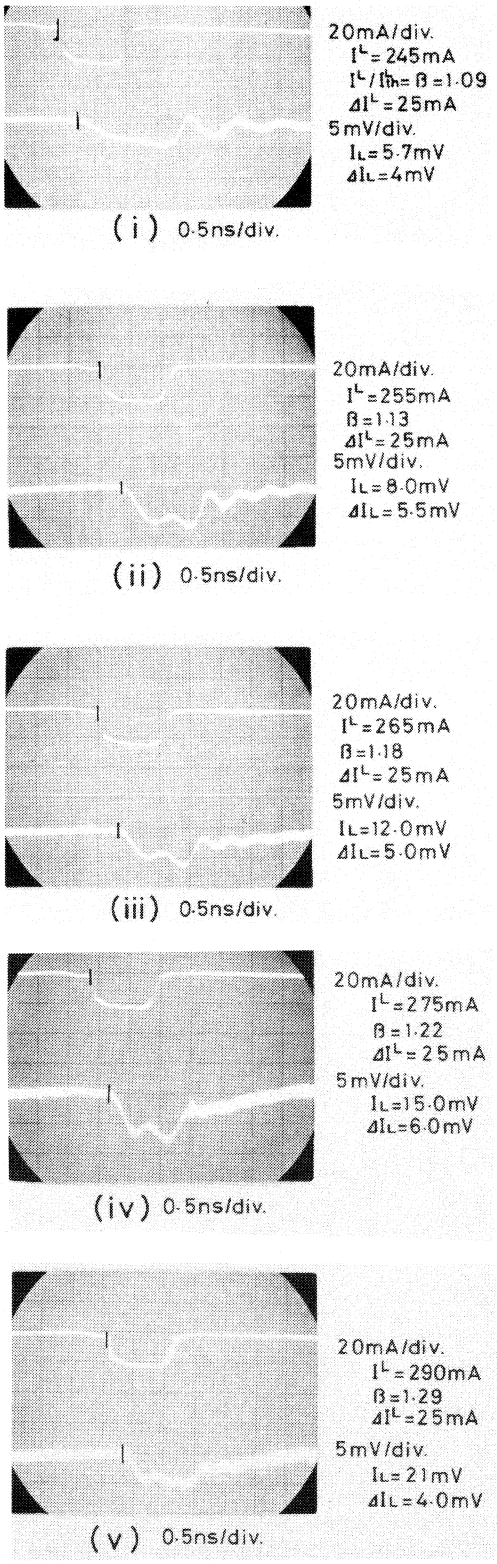

Fig. 4. Dependence of the observed optical-pulse waveforms on current-bias level. The upper traces give the current pulse; the lower traces show the optical pulses.

In order to check the effect of the time-response characteristics of the avalanche photodiode on the observed waveforms in Fig. 4, the following additional experiment was performed. The light pulse of an identical pulse-modulated laser with in-

*$1/(2f'_r)$ is listed, where f'_r is calculated by (5), substituting $(I^L - \Delta I^L)$ instead of I^L.

**Not determined due to the insufficient quality of the experimental data.

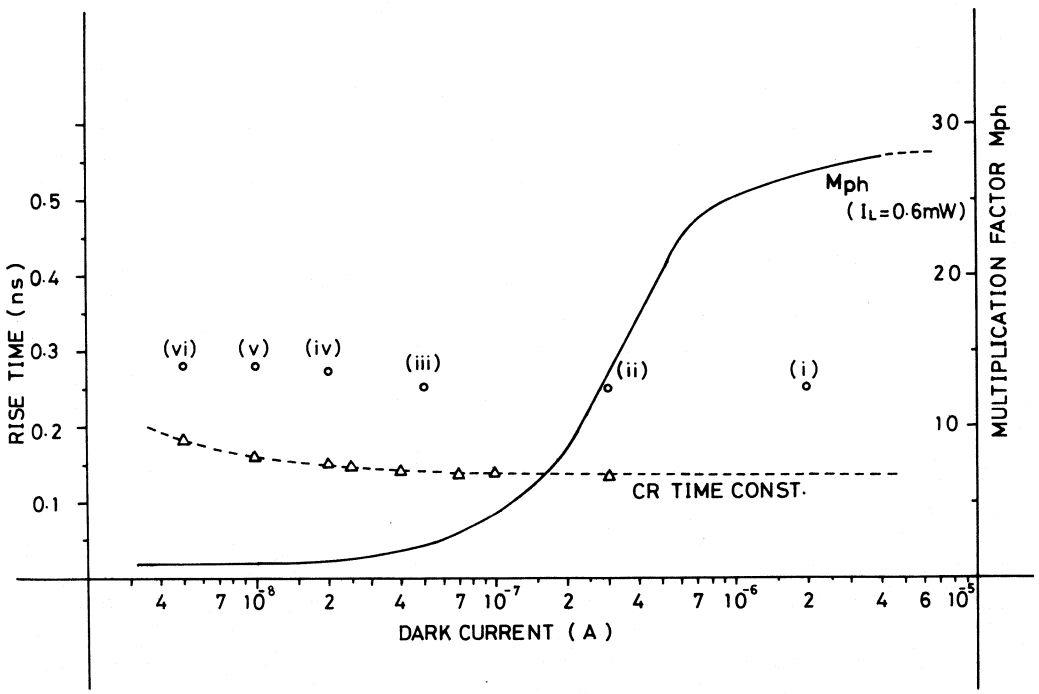

Fig. 5. Reverse-bias dependence of the time-response characteristics of a silicon avalanche photodiode. The bias conditions are expressed by the dark current. The solid curve is the multiplication factor *Mph*, the broken curve gives the *RC* time constant, and the circles with roman numbers indicate the rise time observed with an identical laser-light pulse. The scale for the rise time and for the *RC* time constant is common.

tensity I_L of 0.6 mW is detected by the avalanche photodiode under various reverse-bias conditions. As the reverse voltage is changed from 10 V to 72 V, the dark current increases from 5×10^{-8} A to 7×10^{-6} A, and at the same time the multiplication factor changes from 1 to 28. In contrast to this large change of sensitivity, the observed waveforms show only little change. The observed rise time is indicated in Fig. 5 as a function of the dark current by circle marks accompanied by roman numbers. The change of the multiplication factor is plotted by the solid curve. It is clear that the observed rise time is scarcely affected by the avalanche phenomenon in the photodiode. The junction capacitance of the avalanche photodiode was also measured as a function of the reverse-bias condition and the result is displayed in Fig. 5 with triangle marks connected smoothly with a dashed curve, representing the *RC* time constant. Here the value of the resistance means the load resistance of the photodiode, in our case equal to 50Ω. As the *RC* time constant is less than half of the observed rise time, it can be said that the effect of the *RC* time constant on the rise time is also small.

We have also measured the turn-on delay time. For the case of strong excitation, a narrow-pulse emission is observed at the onset of the laser oscillation. The narrowest pulse observed by our avalanche photodiode has a width of 250 ps. This observation also indicates the speed of the avalanche photodiode.

Discussions

From the experimental observations (Figs. 2, 4, and 5) we conclude that the time response of the modulation scheme investigated here is mainly limited by the dynamics of the laser itself, rather than by the SBG-GEDD or by the avalanche photodiode.

It is interesting to compare the observed damped oscillatory behavior with the rate-equation analysis of transient response of lasers due to Adams [11], although his model of analysis does not give the second term of (3). In his analysis, the current dependence of the gain is assumed as follows:

$$g = g_0 (I^L/I^L_{\text{th}})^b. \tag{4}$$

A small-signal analysis gives the damped harmonic oscillation with relaxation frequency f_r and a damping time constant τ_d as

$$f_r = \{b(I^L/I^L_{\text{th}} - 1)/\tau_e \cdot \tau_{\text{ph}}\}^{1/2} \cdot \frac{1}{2\pi} \tag{5}$$

and

$$\tau_d = 2\tau_e \{b(I^L/I^L_{\text{th}} - 1) + 1\}^{-1} \tag{6}$$

where τ_e and τ_{ph} are the electron lifetime and photon lifetime, respectively.

The electron lifetime τ_e at threshold in our experiment can be estimated from the measurement of the excitation current dependence of the turn-on delay time t_d [12]:

$$\tau_e = td \left(\ln \frac{I^L}{I^L - I^L_{\text{th}}}\right)^{-1}. \tag{7}$$

For the laser used in the observations of Fig. 4, τ_e is thus estimated as $\tau_e = 5.0$ ns.

The photon lifetime τ_{ph} is defined by the following expression [13]:

$$\tau_{\text{ph}} = \frac{n}{c}\left(\alpha - \frac{\ln r}{L^L}\right)^{-1} \tag{8}$$

where n, c, and r are refractive index of the active region of the laser, the light velocity in the vacuum, and the reflection coefficient at the cleaved surfaces of the laser, respectively. α is the internal optical loss coefficient (cm^{-1}), and the length of the cavity is expressed by L^L.

Furthermore, because it has been shown by Pinkas *et al.* that in DH lasers the injected electrons are nearly perfectly confined to the active region, the gain is expressed as a function of current density divided by the thickness of the active region t^L [14]. The threshold condition for laser oscillation is given by the following equation, assuming the bth power dependence of gain on current, (4):

$$B(J_{\text{th}}/t^L)^b = \left(\alpha - \frac{\ln r}{L^L}\right). \tag{9}$$

Here J_{th} is the threshold current density of the laser and B is the proportionality constant.

For an active region, as was used in the present experiment ($\text{Na} \approx 10^{18}$ cm^{-3}), it has been reported that a typical value of the normalized threshold current density (J_{th}/t^L) is about 5 $\text{kA/cm}^2 \cdot \mu\text{m}$ [13], [14] for a cavity length of 380 μm, with an internal loss coefficient $\alpha \fallingdotseq 10\ \text{cm}^{-1}$, which corresponds to a photon lifetime of 3 ps. For the laser in the experiment of Fig. 4, the normalized threshold current density is 14.3 $\text{kA/cm}^2 \cdot \mu\text{m}$.

Using these values and (5), (8), and (9), the relaxation frequency is calculated with b as a fitting parameter. The best fit is obtained when $b = 2.0$, and the result is tabulated in Table I(a). As a reference, the results for the other laser are also shown in Table I(b). The value of b is roughly in agreement with previous reports [13], [14]. The agreement between the calculated relaxation frequency is rather good. The observed rise time is also in rough agreement with $1/2f_r'$, where f_r' is calculated by (5), substituting $(I^L - \Delta I^L)$ instead of I^L. On the other hand, the damping-time constant calculated by using (6) shows a remarkable disagreement with the experimental value. This fact suggests that some other relaxation mechanism beyond Adams' model exists in our lasers and should be incorporated in the model. An improvement of the model is required also from the existence of the additional decaying component as expressed by the second term of (3).

Russer *et al.* have performed a computer simulation of positive optical pulse modulation using a set of multimode rate equations [15], in which the contribution of spontaneous emission is retained in the rate equation of the photon density of each mode. They found a decreased damping-time constant due to the spontaneous-emission term. The laser used by us has a relatively thick active region and it is possible that the transient interaction of different transverse modes provides an additional path of energy flow. Another possibility is the thermalization process inside the conduction band. Recently, Brosson *et al.* showed experimentally that the intraconduction-band thermalization time in semiconductor lasers is much longer than had been expected for heavily doped ($\text{Na} \simeq 10^{18} \sim 10^{19}$ cm^{-3}) samples [16].

In the present stage it is difficult to identify which mechanism is playing an important role in our experimental situation. We expect that a measurement of the time response as a function of the doping and of the size of the active region may provide the necessary information.

Conclusion

We find the following characteristic features in the time response of a DH laser using a Schottky-barrier-gate Gunn-effect digital device: 1) the combination of lasers with SBG-GEDD's with different threshold current can be achieved by attaching a parallel resistor to the SBG-GEDD; 2) by increasing the bias current up to 1.29 times the threshold current, the rise time shortens monotonically down to 240 ps; 3) the dependence of the rise time and of the observed ringing frequency on the bias current can well be fitted to the theoretical expression for the relaxation frequency of the laser based on a rate-equation analysis; 4) in the fitting procedure, the power factor of the

current dependence of the gain $b \equiv [\log (g/g_0)]/[\log (I^L/I^L_{th})]$ is estimated to be 2.0; 5) the observed damping-time constant associated with the ringing is substantially shorter than the calculated value, which suggests the existence of an additional relaxation mechanism; 6) an additional exponentially decaying component in the damped oscillatory transient is observed. Typically, the time constant ranged between 0.5 ns and 0.8 ns. Through these observations the feasibility of subnanosecond pulse modulation of a DH laser using a SBG-GEDD, and the importance of selecting the proper bias-current level have been indicated.

Suppression of Intensity Self-Pulsations in CW Junction Lasers by Frequency-Selective Optical Feedback

THOMAS L. PAOLI, MEMBER, IEEE, JOSÉ E. RIPPER,
A. C. MOROSINI, AND N. B. PATEL, MEMBER, IEEE

Abstract—**Suppression of the self-induced intensity pulsations from CW junction lasers has been achieved by operating the laser with frequency-selective optical feedback. The feedback is achieved by optically coupling a diffraction grating to a laser mirror. The feedback suppresses all longitudinal modes except one or two and thereby eliminates the mode interactions necessary for sustained optical pulsing. The experimental results directly support the previously proposed model for self-induced optical pulsing in semiconductor lasers.**

SELF-INDUCED pulsations in the output intensity have been reported for both homostructure junction lasers operating continuously at liquid-nitrogen temperatures [1] and double-heterostructure (DH) lasers operating continuously at room temperature [2]. Such optical pulsations have been attributed [3] to the excitation of the relaxation oscillations of the laser through the nonlinear mixing of three or more longitudinal modes in the active medium. Consequently, self-pulsations by this mechanism can occur only in the presence of several longitudinal modes. In this paper, we experimentally confirm this conclusion by demonstrating that suppression of all but one or two modes in a self-pulsing junction laser leads directly to elimination of the intensity pulsations. Mode suppression is achieved by optically coupling a diffraction grating to the laser.

The lasers used in the present work were all stripe-geometry diodes fabricated from either GaAs-AlGaAs DH material grown by liquid-phase epitaxy or GaAs homostructure material with shallow junctions made by Zn diffusion. For the DH lasers, the current-confining stripes were formed with the technique of proton bombardment [4], while stripes in the homostructure diodes were defined by the metallic contacts [5]. All stripes were nominally 12 μm wide. Lasers were 380 μm long and had cleaved uncoated facets. Each laser was bonded to a metallized copper stud for continuous operation at room or liquid-nitrogen temperature. The copper studs were beveled on each side to allow unobstructed emission of light from both mirrors of the laser.

Frequency-selective optical feedback was applied to a laser by optically coupling one mirror of the diode to a diffraction grating through a microscope objective (numerical aperture = 0.8, focal length ≈ 4 mm) as shown schematically in Fig. 1.

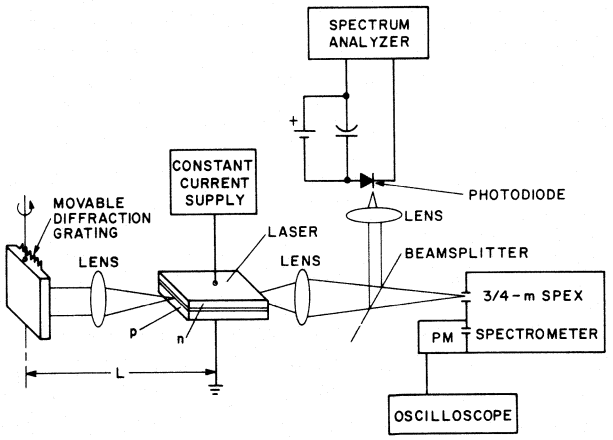

Fig. 1. Schematic diagram of system used to provide frequency-selective optical feedback to a self-pulsing junction laser and to observe simultaneously the optical spectrum and time variation of the light intensity. The spectrometer is equipped with a rotating diffraction plate synchronized with the oscilloscope.

The grating was ruled with 590 lines/mm, blazed for 7500 Å, and positioned at a variable distance L from the laser. With the laser and grating properly aligned, only light in a narrow band of optical frequencies was reflected back into the active region. For the DH lasers the orientation of the grating and laser was as shown in Fig. 1, where the ruling is perpendicular to the junction. This orientation avoided the critical alignment required in the customary arrangement [6] where the rulings are parallel to the junction plane. The frequency selectivity obtained with this type of optical feedback applied to nonpulsing DH lasers has been demonstrated previously [7]. However, the alignment is not so critical with homostructure lasers because of their wider waveguide perpendicular to the junction plane. Consequently, for these lasers the parallel orientation of grating and laser was utilized to achieve a narrower bandwidth for the reflectivity. The center wavelength of the grating reflectivity was reproducibly tuned by rotating the grating angle about an axis perpendicular to the junction plane of the DH lasers and about an axis parallel to the junction of the homostructure diodes.

The time variation of the laser intensity was monitored by focusing a portion of the light emitted from the second laser mirror into a fast photodiode coupled to a microwave spectrum analyzer. Simultaneously, the remainder of the output was used to observe the optical spectrum of the light with a grating spectrometer equipped with a rotating diffraction plate [8]. In this way, the effect of the grating on the optical spectrum and the intensity pulsations were observed in real time.

A typical example of the effect produced by coupling the grating to a self-pulsing DH junction laser is shown in Fig. 2. The top portion of part (a) of this figure is the optical spectrum of the laser light obtained without the grating and shows the multimode emission characteristic [2], [3] of lasers undergoing self-induced intensity pulsations. The fundamental (630 MHz) and first harmonic (1260 MHz) of the intensity pulsations, as observed with the photodiode and spectrum analyzer, are shown in the top half of Fig. 2(b).

With the grating optically coupled to the laser and properly aligned, the dispersion of the grating produced an optical feedback which was frequency selective. As a result, the optical spectrum was narrowed as indicated in the lower portion of Fig. 2(a). The width of this spectrum corresponds to at most two longitudinal modes and was determined primarily by the grating. In this case, the grating was positioned at $L \approx 28$ cm, but the experimental results were not critically dependent on this distance. Simultaneous with the reduction of the number of oscillating modes, the intensity pulsations were eliminated, as shown by the lower microwave spectrum in Fig. 2(b). The weak signal in this spectrum has a frequency (1040 MHz) corresponding to twice the frequency separation ($c/2L$) of cavity resonances formed by the grating and the diode face and probably originates in beats between modes of the external cavity.

Similar results were obtained with homostructure lasers. As shown in Fig. 3, the intensity pulsations were completely suppressed when the optical feedback from the grating induced oscillation in a single longitudinal mode of the laser. As is evident from a comparison of Figs. 2 and 3, the optical spectra obtained with the homostructure lasers were somewhat narrower than those obtained with the DH lasers. This result is probably due to the narrower bandwidth of the reflectivity obtained with the parallel orientation of grating and homostructure laser as compared to that obtained with the perpendicular arrangement used with the DH laser.

Results similar to those shown in Figs. 2 and 3 were also obtained as the bandwidth selected by the grating was tuned from one side of the optical spectrum to the other. However, as the suppression of the majority of the modes was reduced as a result of tuning to the wings of the optical spectrum, the amplitude of the pulsation was increased. In addition, the observed suppression was not dependent on the distance L between the laser and grating.

The suppression of the pulsations obtained with frequency-selective feedback contrasts markedly with the enhancement and locking produced by feeding back all frequencies in the laser output. The nonselective feedback reinforces all lasing modes of the internal cavity and thereby enhances the mode interactions producing the self-pulsations [3]. Furthermore, modes of the external cavity are phase locked (with a frequency spacing equal to the pulse rate) in groups centered about the internal cavity mode frequencies [9]. As previously reported [10], nonselective optical feedback narrows the pulses and pulls the pulse rate to a frequency greater than the self-induced rate. The pulling is always to frequencies higher than the self-induced rate because the feedback signal is actually a trigger pulse which must arrive before the laser spontaneously emits a pulse in order to be effective. This behavior

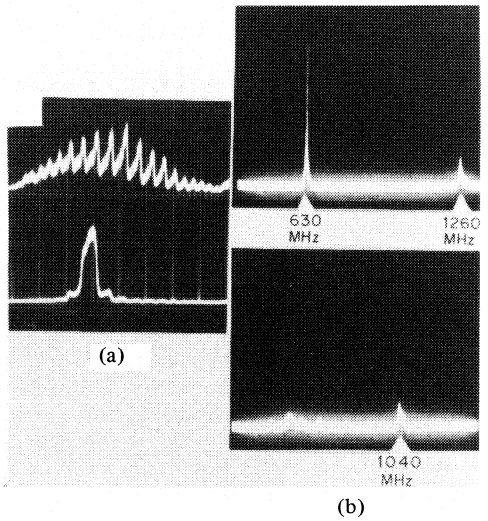

Fig. 2. (a) Optical spectra and (b) intensity-modulation spectra obtained from a continuously operating stripe-geometry DH junction laser. For the upper half of (a), the laser is operated *without* external feedback and exhibits self-induced intensity pulsations as indicated by the intensity spectrum shown in the top half of (b). For the lower traces in (a) and (b), the laser is operated *with* a diffraction grating optically coupled to the laser.

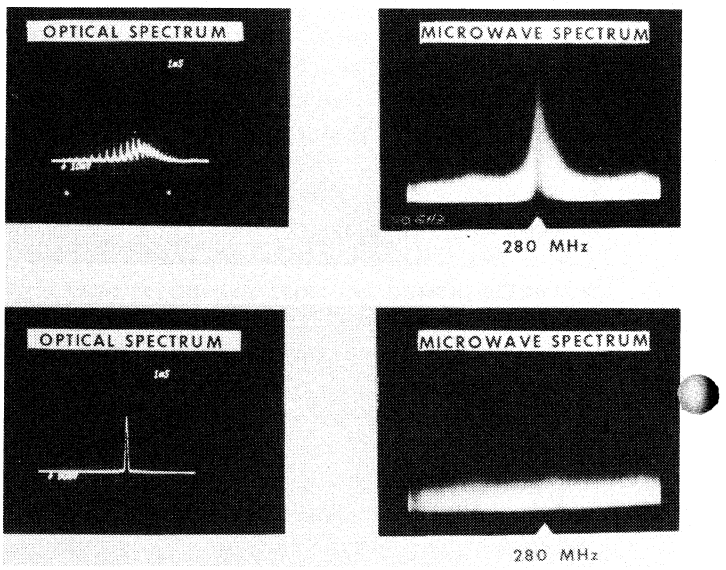

Fig. 3. Optical spectra and intensity-modulation (microwave) spectra obtained for a stripe-geometry homostructure junction laser operating continuously at 77 K. For the upper half of the figure, the laser is operated *without* feedback and exhibits self-induced intensity pulsations at 280 MHz as indicated by the microwave spectrum. For the lower traces, the laser is operated in a single longitudinal mode selected by optically coupling the diffraction grating to the laser. The microwave spectrum shows no evidence of any modulation of the laser intensity. The laser current is 1.3 times threshold.

is illustrated in Fig. 4 by the spectral display of the pulse rate obtained with optical feedback from a mirror positioned at various distances L from the laser. As the distance L is decreased from L_0 + 9.7 cm to L_0 + 0.9 cm ($L_0 \approx 75$ cm), the pulse rate ν_P moves continuously higher according to the relation $\nu_P = N(c/2L)$, where N is an integer and c is the speed of light. However, when the optical-feedback signal becomes less than the minimum required for locking (at $L \approx L_0$), the

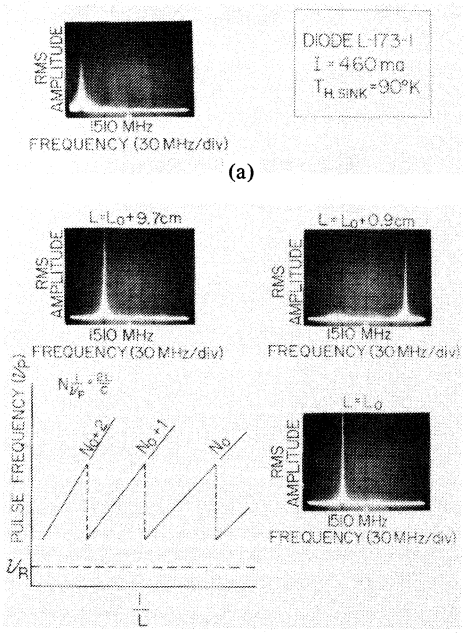

Fig. 4. Experimentally observed frequency pulling produced by the optical feedback of self-induced intensity pulsations from a continuously operating GaAs homostructure junction laser. (a) Without feedback. The pulses were spontaneously generated at a rate of 1390 MHz. (b) With feedback. The laser was operated with the reflection of the pulsing light from an external mirror focused back into the laser. The mirror was placed a distance L away from the laser diode with the distance L_0 approximately equal to 75 cm.

pulse rate changes discontinuously to a lower frequency corresponding to $(N-1)(c/2L)$. With further decreases in L, the process repeats itself as illustrated in Fig. 4.

The experimental results demonstrate that self-induced pulsations of the intensity from a CW junction laser are eliminated when the number of oscillating longitudinal modes is reduced to one or two. Consequently, the present experiments suggest that frequency-selective feedback may be a useful technique to eliminate self-pulsations when an unmodulated optical beam is desired. In addition, these observations support the previous proposal [3] that the interaction of several longitudinal modes is required to establish self-induced pulsations in some semiconductor lasers.

Acknowledgment

The authors wish to thank the GaAs Laser Department at Bell Laboratories, Murray Hill, N.J., for providing some of the lasers used in this work, L. A. D'Asaro for a critical reading of the manuscript, and Telecomunicacões Brasileiras S.A. for their support.

A Comprehensive Model for Q Switching in Semiconductor Lasers

BEN THOMAS, M. J. ADAMS, AND STEPHAN GRÜNDORFER

Abstract—**By combining a carrier concentration-dependent loss term with our earlier time-dependent saturable absorption loss term we have produced a comprehensive theory for Q switching which successfully accounts for the results so far reported. The concentration-dependent loss term shows a superlinear dependence with current due to the decrease of real guiding at the p-n junction. This increase in loss, however, reaches a maximum and shows a slight decrease at higher concentrations due to the onset of weak imaginary guiding.**

I. Introduction

THE transient effects of long time delays and internal Q switching in semiconductor lasers are by now well documented [1]-[8], [12]. Since our ideas on long time delays have already been reported [5]-[7], this paper will be concerned with the Q-switching mechanism. The effect is observed in lasers which also show long time delays, and previous theories have attributed Q switching to the saturable absorption process involved in the time delays. A recent review [8] highlighted the unsatisfactory state of the theories for Q switching, and in this paper we will show that the additional effects of optical confinement are necessary for a satisfactory account.

Our theory of long time delays [5], [6] involved saturable absorption via energy states in an impurity band tail not in thermal equilibrium with the main part of the conduction band. This theory was successful in providing an explanation for both the current and temperature dependence of long time delays and was also used to predict certain spectral changes in the light output. A subsequent experimental search for and successful observation of these spectral changes provided further confirmation of the model [7]. During the setting up of the model it became apparent that the different current and temperature dependences of long time delays and Q switching indicated the presence of two distinct processes and also that our saturable absorption model as it stood could not provide a satisfactory explanation for Q switching. We therefore considered in detail the current and temperature dependence of the loss and gain necessary to explain Q switching and concluded that a superlinear dependence of loss with current was required and that such a dependence was provided by a consideration of optical confinement [9], [10], [16]. Combining the saturable absorption process with the mechanism resulting from the effects of optical confinement produces a comprehensive model which provides an explanation for long time delays [7], [8], H-pulsing (discussed in detail in this issue) [9], and Q switching [16].

II. Experimental Details and Results

The laser diode driving and light-recording system described previously [5], [7] was used for these measurements and in order to avoid appreciable heating effects pulse lengths between 20 and 180 ns were used at low duty cycles. To minimize transient effects from irregularities in the current the 50-Ω line producing the rectangular current pulse (rise time <1 ns) was carefully matched to the laser mounted in the familiar pill-type package. Various injection lasers for this study were kindly selected and provided by P. R. Selway and A. R. Goodwin, Standard Telecommunications Laboratories, Harlow, England; we shall illustrate the agreement between experimental and theoretical results by showing the characteristics for laser type H139.

This is a GaAs-$Ga_xAl_{1-x}As$ single-heterostructure laser fabricated in the usual way by liquid-phase epitaxy on a Si-doped substrate having an electron concentration of 3.2×10^{18} cm^{-3}. This laser had an active-region width of $d = 1.3$ μm and showed a characteristic critical temperature $T_c = 220$ K marking the onset of saturable absorption and long time delays. It is necessary at this stage to stress the importance of distinguishing between the various time delays. Thus the intrinsic time delay (ITD) is required to produce population inversion at temperatures $T < T_c$; the long time delays (LTD's) are introduced by the saturable absorption mechanism at temperatures $T > T_c$ (both ITD and LTD decrease with increasing current), and abnormal time delays (ATD) increase with increasing current leading to the effect of Q switching. For temperatures below and above T_c, single-heterostructure laser H139 had a difference between ITD and LTD at $I/I_{th} = 1.2$ of the order of 4 ns, and because this could easily be masked by uncertainties in I_{th}, a method of determining I_{th} from the onset of a single mode on the spontaneous background was used [7].

The increasing time delay due to the ATD at higher currents and temperatures characteristic of Q-switching lasers is easily seen in Fig. 1. These data are summarized in Fig. 2(a) for ratios of $I/I_{th} = 1.2$ and 1.5, and Fig. 2(b) shows the threshold-current curves for lasing and Q switching. Incidentally, this curve is very similar to the threshold-current curves produced

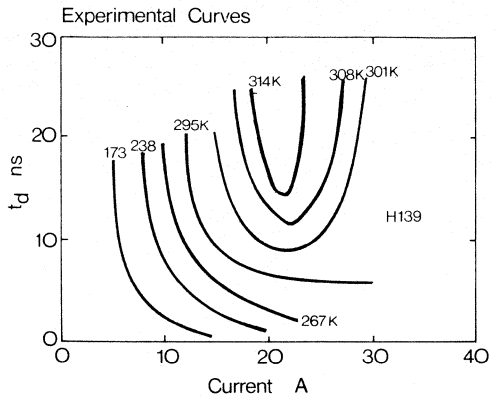

Fig. 1. Time delay t_d versus current I measured at various temperatures.

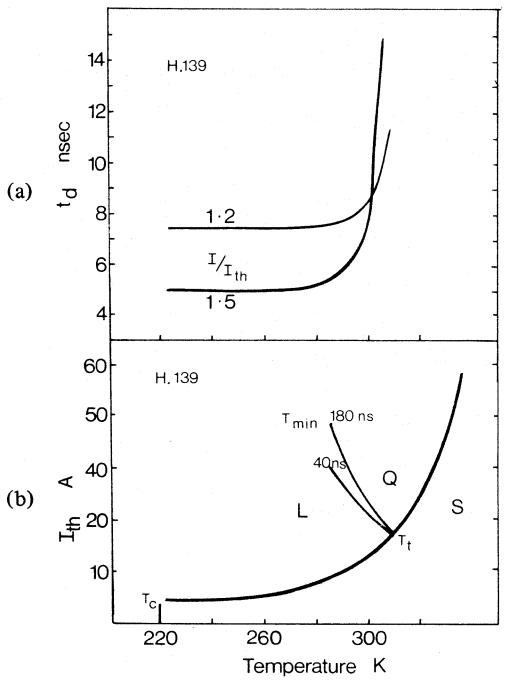

Fig. 2. (a) Time delay t_d versus temperature T curves for ratios of I/I_{th} (1) 1.2, (2) 1.5 showing rapid increase in t_d due to the ATD. (b) Characteristic threshold-current curve separating the spontaneous, lasing, and Q-switching regions. T_t = 320 K, the triple-point temperature where the three regions meets. $T_{min} \simeq 270$ K, the minimum temperature at which Q switching can occur. The difference between the effect of 40 and 180-ns pulses is indicated.

for H-pulsing lasers [9]. To characterize the Q switching we have considered two temperatures: T_t the triple-point temperature at the point where the spontaneous, lasing, and Q-switching regions meet (320 K for H139), and T_{min} the minimum temperature at which Q switching can occur (about 270 K for H139). Both these temperatures, however, are slightly affected by the length of the current pulse and show a decrease for shorter pulses. The critical temperature T_c is in general distinct from T_t and T_{min}.

III. The Comprehensive Model

Our theory of saturable absorption for LTD's has been discussed in considerable detail previously [5], [6], and we have presented a detailed consideration of optical confinement and waveguiding efficiency elsewhere in this issue [9]. To combine the two processes we construct a total laser loss term as the sum of a time-dependent loss plus a carrier concentration-dependent loss. The expression becomes

$$\text{total loss} \propto \frac{bN_t}{An + 1/\tau_t}\left\{\frac{1}{\tau_t} + An \exp\left(-\left(An + \frac{1}{\tau_t}\right)t\right)\right\} + (u + vn^2) \quad (1)$$

where the meaning of the symbols and the numerical values for a typical GaAs-$Ga_xAl_{1-x}As$ single-heterostructure laser used in the calculations are given in Table I.

The variation of this total loss coefficient with increasing carrier concentration n is shown by the curved traces in Fig. 3 where the temporal variation of the total loss is indicated by the curve sequence a, b, c. Curve a shows loss versus n for time $t = 0$, i.e., when the laser is switched on, curve b shows the loss versus n after a time t = 100 ns into the current pulse, and curve c shows the loss versus n after infinite time, i.e., CW operation. The straight lines T_1, T_2, and T_3 show the gain as

TABLE I

Symbol	Meaning	Value
τ_e	lifetime for conduction-band electrons	1 ns
τ_t	lifetime for tail electrons in deep tail-states	100 ns
u	current-independent optical loss	2×10^{11} s^{-1} (24 cm^{-1})
v	effect of electron concentration on the loss	2×10^{-24} cm^6 s^{-1}
A	rate coefficient for conduction band to tail states transitions	2×10^{-11} cm^3 s^{-1}
bN_t	rate coefficient for absorbing transitions into tail states	10^{12} s^{-1}
c	coefficient in gain expression	65 cm^3 s^{-1} K^3
d	active-region width	1.6 μm

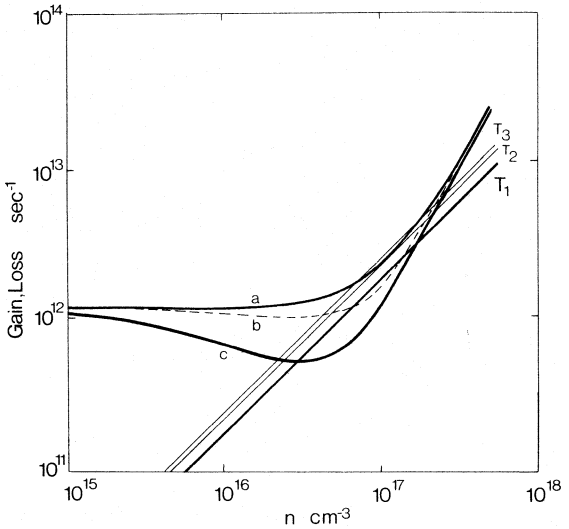

Fig. 3. Theoretical total loss coefficient a, b, and c, and laser gain T_1, T_2, and T_3 as functions of carrier concentration. Curves a, b, and c show the total loss after times $t = 0$, $t = 100$ ns, and $t = \infty$ into the current pulse, respectively. Straight lines T_1, T_2, and T_3 show the gain for different temperatures with $T_1 > T_2 > T_3$. The small time dependence of the gain due to heating effects is not shown.

a linear function of carrier concentration n for three different temperatures with $T_1 > T_2 > T_3$. The gain is independent of time except for a small heating effect not shown here.

The bold gain line T_1 does not intersect curve a and it is clear there is always a delay time for this temperature; the delay is represented in this picture by the lowering of the loss curve with time. For the $t = 100$-ns loss curve we have two intersections with the gain line T_1 indicating the two carrier concentrations at which a delay of 100 ns will appear on the time delay versus current curves. For the two intersections between curve c ($t = \infty$) and line T_1, the lower point gives the lasing threshold for CW operation and the upper the Q-switching threshold for this situation.

More detailed results, however, were obtained using the three rate equations for $T > T_c$ in [6, eqs. (8)-(10)] by assuming a specific temperature dependence for the gain and replacing the photon lifetime term $(1/\tau_p)$ by the concentration-dependent loss term $(u + vn^2)$. Solving the equations as outlined in [6] gave the following expression for time delay as a function of carrier concentration n and temperature T:

$$t_d = \frac{1}{\left(An + \frac{1}{\tau_t}\right)} \ln \left\{ \frac{bN_t An}{\left(An + \frac{1}{\tau_t}\right)\left(\frac{cn}{T^3} - u - vn^2 - \frac{bN_t}{(An\tau_t + 1)}\right)} \right\}. \tag{2}$$

A threshold value for the electron concentration in this case was also obtained by solving the equation

$$\frac{cn}{T^3} = u + vn^2 + \frac{bN_t}{(An\tau_t + 1)}. \tag{3}$$

Solutions of (2) for time delay t_d versus carrier concentration n at various temperatures and using again the typical values for the single-heterostructure laser (Table I) are shown in Fig. 4. The striking resemblance of these curves to the experimentally recorded curves in Fig. 1 is immediately apparent, including the ATD leading to Q switching. Furthermore, solutions for (2) and (3), Fig. 5(a) and (b), show good agreement with the curves of Fig. 2(a) and (b) recorded for the single-heterostructure laser H139 which has a triple-point temperature $T_t = 320$ K. The overall form of the threshold current versus temperature characteristic including the boundary between lasing and Q switching is also in good agreement with other experimental observations published for single-heterostructures [4], [11], homostructures [3], [12], and for electron-beam-pumped lasers [13]. Although the curves of Fig. 5(b) were calculated assuming an infinitely long pulse, further calculations for a 20-ns pulse showed a movement of T_t and the boundary between lasing and Q switching towards lower temperatures. This is in agreement with the results for 40 and 180-ns pulses in Fig. 2(b) and with the results reported in [3].

In spite of the excellent agreement between theory and experiments over the current densities so far considered, our theory has not covered the experimental results reported for very high current densities in single heterostructures [4] and in stripe-geometry GaAs lasers [3], [12]. These results show

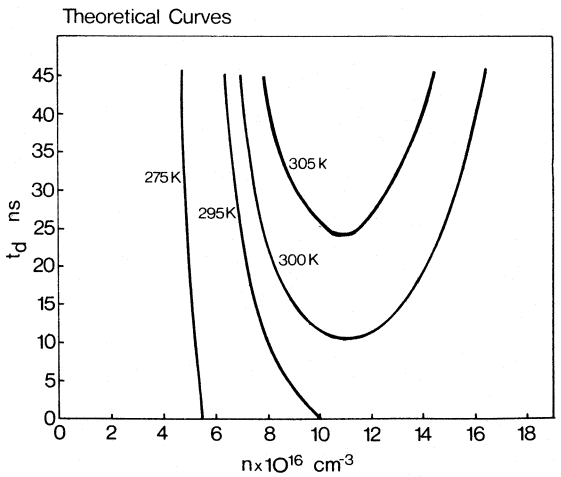

Fig. 4. Theoretical curves for time delay t_d versus carrier concentration n at various temperatures obtained as solutions to (2) using the parameters from Table I.

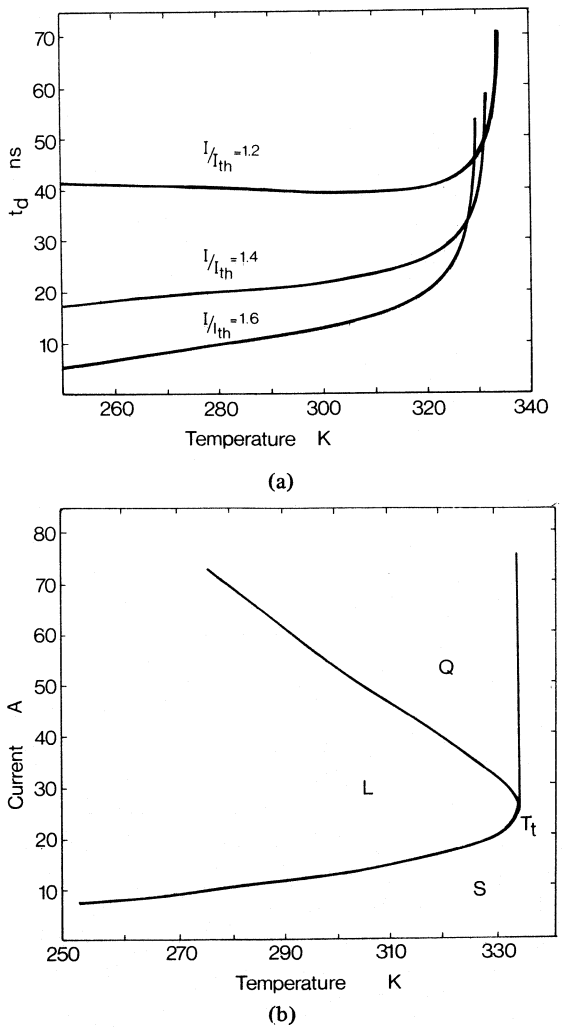

Fig. 5. (a) Theoretical curves obtained from computation of (2) giving time delay as a function of temperature for various ratios of I/I_{th}. (b) Equation (3) giving the threshold- and boundary-current curves versus temperature for the spontaneous, lasing, and Q-switching regions. $T_t \simeq 335$ K.

that the *Q*-switching region is bounded from the lasing region by a further curve on the high-current side of the *Q* region on the current-temperature plots. This produces a characteristic S loop of the boundary between *Q* switching and normal lasing.

Extending our theory into this regime is relatively simple if we consider the complete concentration-dependent loss curve in the high carrier-concentration region [10]. The superlinearity of the loss curve with current arises due to a decrease in the efficiency of real guiding on the n-side of the active lasing region. This superlinear increase, however, reaches a maximum and the loss decreases to a constant relatively high level at high current densities. Taking into account the complex dielectric-constant change which should be used [10] shows that the breakdown of real guiding is now replaced by a weaker, but nevertheless important imaginary guiding due to high absorption losses in the n-type region.

A qualitative consideration of the theory and of the intersection of the complete loss-gain curves at higher current densities, Fig. 6(a), results in a threshold-current characteristic with temperature shown schematically in Fig. 6(b). The boundary between lasing and *Q* switching does indeed map out an S-shaped curve in agreement with experimental observations [3], [4], [12]. This S shape provides a further characteristic parameter for the *Q* switching, namely the minimum temperature $T_{\min}$ representing the low-temperature limit of the *Q*-switching region. A simple analysis reveals that this temperature is given by

$$T_{\min} = \left[\frac{c^2}{4v(u + bN_t)}\right]^{1/6}. \tag{4}$$

$T_{\min}$ is also dependent to a certain extent on pulse length, but for an infinite pulse and the values from Table I, $T_{\min} = 276$ K was obtained.

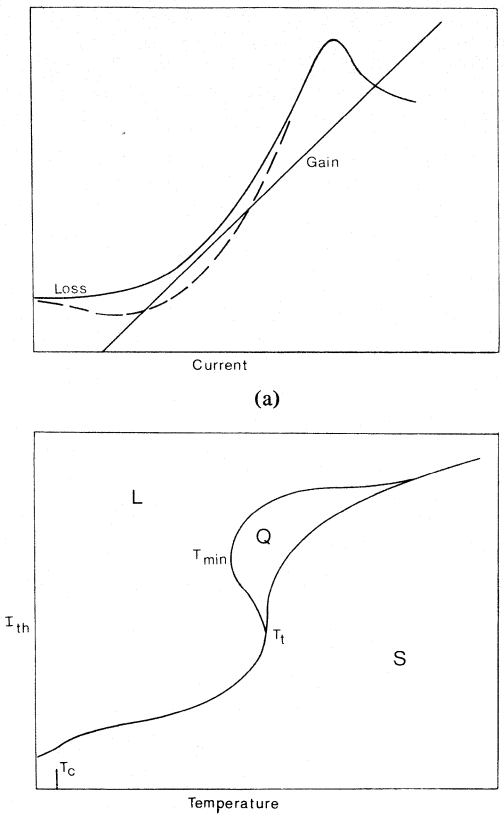

Fig. 6. Schematic diagrams showing (a) the concentration-dependent loss versus *n* curve obtained by taking into account both the real and imaginary waveguiding for a 3-layer dielectric slab; and (b) the characteristic S curve obtained for the boundaries separating the spontaneous, lasing, and *Q*-switching regions in the threshold current versus temperature plot from a qualitative consideration of the gain–loss curves in (a).

IV. Conclusions

The good agreement between the theory and published experimental results, together with its comprehensive nature, makes this model for transient effects particularly attractive. Further support for confidence in the model was provided by solving the full rate equations using a Runge-Kutta numerical procedure and integration in the time domain. The results of these detailed calculations were in good agreement with the simplified calculations and showed the complicated processes occurring during LTD's and *Q* switching. On switching off the current for laser action the solutions showed that the photon density depletes with a lifetime of the order of picoseconds, the electron concentration in the conduction band decreases with a lifetime of nanoseconds, whilst the electron concentration in band tails has a long lifetime of the order of microseconds. For the *Q*-switching region, on the other hand, although n and n_t decrease as before, the photon density shows a peak of half-width ~100 ps occurring after a period of less than 200 ps from the switchoff. The width of the pulse is in agreement with experimental estimates of the width from observations.

It is clear that an explanation for the spectral emission for *Q* pulses [5] will now be provided by a consideration of band filling and the detailed wavelength variation of the concentration-dependent loss curve. It is also clear to us that the theory could provide an explanation for the interesting wavelength-dependent time delays [14], [15] reported for lasers operated with an external grating cavity. This explanation would rely upon the wavelength variation of the concentration-dependent loss term. What is certain is that the theory has an important rôle in the design of lasers for low thresholds, high-temperature operation, minimal time delays, and with no *Q* switching [17]. In the event of *Q* switching not being entirely undesirable for an optical-communication application, the theory may indicate that in order to achieve extremely short pulses *H*-pulsing lasers [9] modulated at high repetition rates should be used at currents which minimize the initial pulse during switchon.

H-Pulsing: A Transient Effect in GaAs/$Ga_xAl_{1-x}As$ Injection Lasers

STEPHAN GRÜNDORFER, M. J. ADAMS, AND BEN THOMAS

***Abstract*—"H-shape" light pulses, i.e., short light pulses superimposed on the beginning and end of a steady laser emission, are observed from pulsed single-heterostructure lasers operated at particular temperatures and currents. At a slightly higher current the steady laser emission is extinguished leaving the two peaks. The effect, observed in single-heterostructure lasers fabricated on low doped n-type substrates, was studied for various driving currents and laser temperatures.**

A theoretical study involving computations with standard laser parameters has resulted in light-output curves having a similar form. The rate equations computed contained a superlinear carrier-concentration-dependent loss term as well as the term for the emission of spontaneous photons into the laser mode. Loss of optical confinement due to carrier-induced changes in refractive index is proposed as an explanation for the superlinear carrier-dependent loss.

Manuscript received November 25, 1974; revised February 6, 1975. This work was supported in part by the Science Research Council and in part by a CVD contract, and is published by permission of the Ministry of Defence (Procurement Executive). The original idea for the model was first presented at ESSDERC 1973, Munich, Germany, September 18–21, 1973. This paper was presented at the IEEE International Semiconductor Laser Conference, Atlanta, Ga., November 18–20, 1974.

I. Introduction

THE suggested application of semiconductor lasers in, for example, optical-communication systems, makes a thorough study of their time-dependent behavior a necessity [1]–[3]. Indeed, for any kind of pulse modulation, long time delays between the beginning of the current pulse and the onset of stimulated light emission or a Q-switching effect at the end of the current pulse are both undesirable in an uncontrolled form. In order to prevent these effects or, on the other hand, to make use of them, it is necessary to develop a comprehensive theory for them [4]–[7]. In the process of investigating the transient effects of GaAs/$Ga_xAl_{1-x}As$ single-heterostructure injection lasers we have observed a further effect which has to be considered in addition to long time delays and Q switching. The effect consists essentially of two sharp short light pulses, one occurring immediately after the beginning of the current pulse and the other one immediately after the end of the current pulse [20] and has been termed "H-pulsing" by us. The light spikes are superimposed on a steady laser-emission pulse. Since the second light pulse looks very much like the familiar Q-switching pulse, the first light pulse was initially thought to be due to distortions at the beginning of the current pulse, e.g., overshooting. Careful examination of current rise and decay characteristics has

revealed, however, that irregularity in the driving-current pulse can be excluded as being the source of the initial light pulse. An explanation of *H*-pulsing, therefore, must be sought in terms of the properties of the injection lasers showing the effect, rather than by an external agency.

The behavior of the effect was studied over a range of temperatures and injected currents for a variety of lasers. The effect was easily observed in single-heterostructure lasers fabricated on relatively low doped ($\simeq 2.5 \times 10^{18}$ cm^{-3}) n-type substrates with active-region thickness d, less than the optimum active-region thickness $d \simeq 2$ μm, i.e., in lasers for which the optical confinement of the electromagnetic wave is poor [8], [9]. It was not observed, however, in double-heterostructure lasers, where the optical confinement is always good [8]. In the lasers investigated, *H*-pulsing occurred over a narrow range of temperatures and injected current levels. The minimum current I_H for the effect to show was always greater than the threshold value I_{th}, and I_H/I_{th} showed a slight increase with decreasing temperature.

II. Experimental Details and Results

This effect was brought to our attention by P. R. Selway and A. R. Goodwin of the Standard Telecommunications Laboratories, Harlow, England, who also supplied the lasers used in this study. Although we initially considered that the peak at the beginning of the light-output pulse could be due to an overshoot effect of the driving current into the laser, an examination of the current rise and decay characteristics, together with careful matching of the laser into the 50-Ω line, dispelled this idea. In addition, *H*-pulsing was observed over a narrow temperature range in lasers fabricated on a relatively low doped n-type substrate with a narrow active-region width d.

Typical examples of lasers showing the effect are the following: Type H34 Te-doped substrate electron concentration 2.7×10^{18} cm^{-3}, $d = 1.9$ μm and Type H64 Si-doped substrate electron concentration 2.6×10^{18} cm^{-3}, $d = 1.8$ μm. The *H*-pulse form, together with the extinction of the steady output for a slightly higher value of the 40-ns current pulse, is shown in Fig. 1 for laser H34. A light-output pulse having

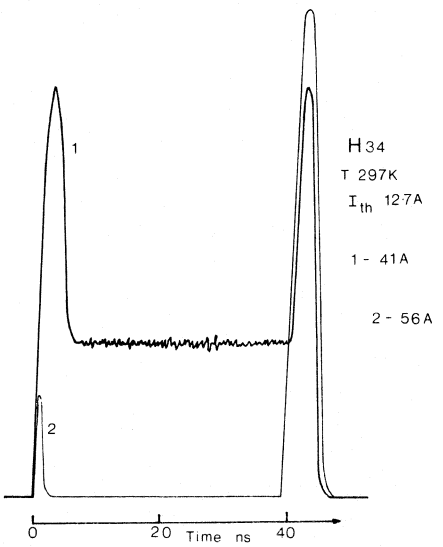

Fig. 1. Recording of the light-output pulse versus time showing the *H*-pulse effect 1) and the extinguishing of the steady laser output 2) at a slightly higher current.

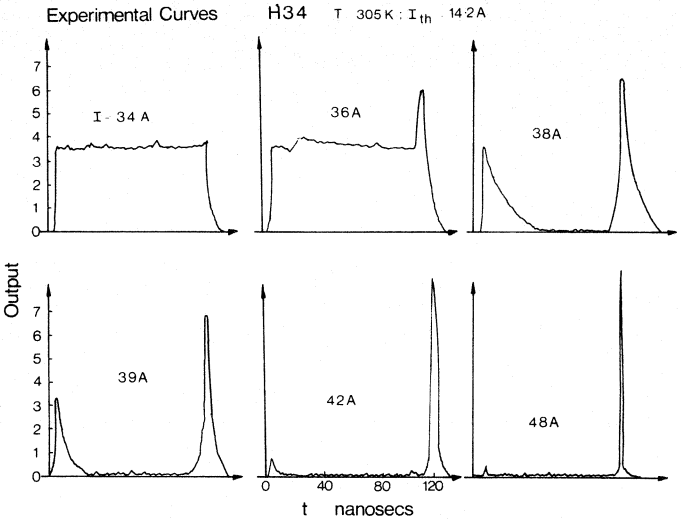

Fig. 2. High output pulses versus time recorded for a series of increasing current pulse values.

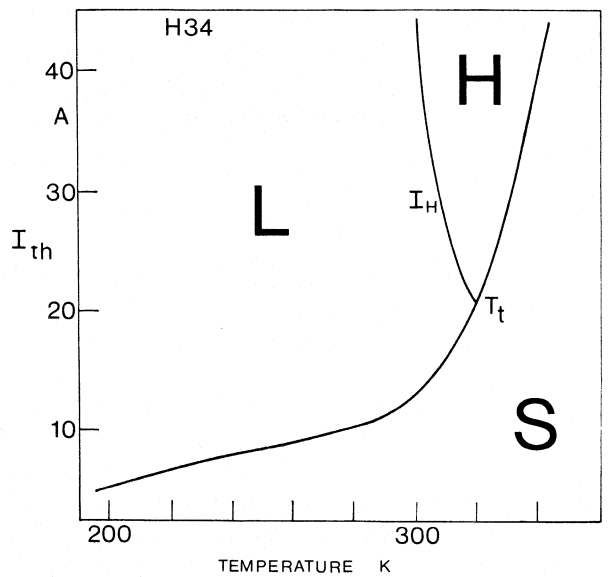

Fig. 3. Threshold current versus temperature characteristic showing the lasing, *H*-pulsing, and spontaneous regions. The I_H boundary between lasing and *H*-pulsing gives the minimum current at which *H*-pulsing will occur at a particular temperature.

similarities to those shown in Fig. 1 has also been reported by Kressel [20]. The complicated variation in form of the pulse with increasing current is shown in Fig. 2, whilst the measurement of the variation of lasing threshold current (I_{th}) with temperature resulted in a characteristic curve (Fig. 3) very similar to those recorded for internal Q switching [4], [7]. A triple-point temperature (T_t) as well as I_H the boundary current separating the lasing and *H*-pulsing regions are also seen in the figure. The laser did not show a temperature T_c characteristic of the onset of long time delays. All the measurements on the lasers previously reported were carried out using driving and detection equipment described previously [4].

III. Mathematical Development of the Model

The appropriate way to investigate time-dependent behavior in semiconductor lasers is a rate-equation approach [1]-[5]. For a single-mode approximation, these rate equations for the

electron concentration in emitting states n, and the photon density in the lasing mode N, can be written as

$$\frac{dn}{dt} = P - \frac{n}{\tau_e} - g(n)N \tag{1}$$

$$\frac{dN}{dt} = g(n)N - L(n)N + r_{\text{spon}} \tag{2}$$

where P is the pumping rate for the electrons associated with the injected current, τ_e is the electron lifetime in the emitting states, and $g(n)$ is proportional to the peak of the gain-frequency curve for the laser. $L(n)$ is the optical loss of the laser, under normal conditions taken constant, and r_{spon} is the spontaneous emission of photons into the lasing mode. The normal transient behavior of this system is the buildup of n to the threshold value n_{th}, found as usual by neglecting the spontaneous emission and equating the gain and the loss under steady-state conditions

$$g(n_{\text{th}}) = L(n_{\text{th}}). \tag{3}$$

This threshold is reached in a short time delay (t_d), necessary to build up the population inversion, which is found by integrating (1) whilst neglecting the last term, since the photon concentration is considered negligible before the onset of lasing. The time delay is given by [10]

$$t_d = \tau_e \ln\left[\frac{P}{P - P_{\text{th}}}\right] \tag{4}$$

where $P_{\text{th}} = (n_{\text{th}}/\tau_e)$. When lasing commences, the electron concentration n saturates at n_{th}, and all further pumping power goes into output by increasing the photon density N. In order to achieve a light spike instead of a continuous light output, however, the optical loss must become bigger than the gain shortly after threshold is reached and lasing starts.

It is easily seen that one way to achieve such a system is by assuming a loss which is not constant but varies with a higher power of n than the gain. Fig. 4(a) shows such a situation, where the gain is assumed to be linear in n, i.e., $g(n) = an$, while the loss is assumed to be quadratic in n, i.e., $L(n) = u + vn^2$. Here a contains the square of the matrix element for the stimulated emission, u is the optical loss before onset of the current pulse (i.e., for $n \simeq 0$), and v is a small factor taking the influence of the electron concentration on the loss into account.

Assuming a rectangular current pulse the electron concentration builds up with a time constant essentially given by τ_e. From Fig. 4(a) and (b) it can be seen that as the electron concentration increases with time, n_1 is reached, and lasing can commence. But the electron concentration "overshoots" due to the fact that in (1) the third term on the right-hand side becomes big only after some time when the photon density has increased enough. If n_1 and n_2 are not too far apart, and the pumping rate P is big enough, the electron concentration will increase beyond n_2, the loss therefore will again be higher than the gain, and the photon concentration will decrease forming the short initial light pulse.

After the end of the current pulse, on the other hand, when the electron concentration is decaying, one again passes through the region where the gain is bigger than the loss,

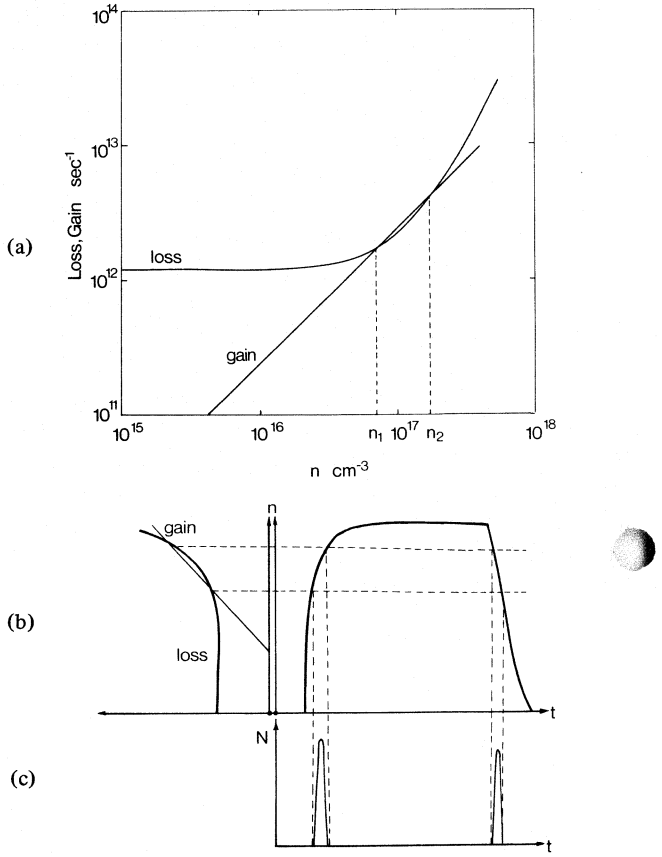

Fig. 4. (a) Curves showing linear gain and superlinear loss dependence with electron concentration. (b) Combination of the loss and gain curves from (a) and the variation of electron concentration with time for a rectangular current input pulse. (c) Light-output pulses produced as the electron concentration passes through regions with gain > loss.

producing a short light pulse as shown schematically in Fig. 4(c).

The two spikes are dependent on the rise and fall time of the electron concentration, as can be seen from Fig. 4(b) and (c). The bigger the current, the steeper will be the rise in the region between n_1 and n_2, i.e., the shorter and smaller the first light pulse will be in comparison with the second one, as can also be seen from the experimental results. Also, if the current pulse cannot be assumed rectangular, this will have an influence on the width and rise time of the light spikes, since it alters the rate of rise and decay of the electron concentration.

In the numerical integration of (1) and (2), the spontaneous emission r_{spon} is not neglected (as is normally the case), since it seems to be essential to introduce the right boundary conditions. If the photon density were assumed to be zero (as is done by neglecting the spontaneous emission), then it cannot build up in the very short time available when the electron concentration is between n_1 and n_2. Due to the spontaneous emission, however, there is always a finite concentration of photons present, which facilitates buildup of the photon population in a very short time.

IV. Discussion of the Superlinear Loss

Various forms for the gain function $g(n)$ have been proposed in the literature, including a linear variation with carrier concentration n [11]-[13], logarithmic variation with n [1], and more complicated forms of functional dependence on n [14],

[2], [15]. In the present instance we will choose for simplicity a linear dependence, as was used in previous rate-equation calculations [5]. It remains to discuss the assumption of the superlinear dependence of the laser loss on the carrier concentration. It should be emphasized that any superlinear dependence will produce similar results for a linearly dependent gain function; our assumption of a quadratic dependence was used for simplicity and merely served to illustrate the behavior. The crucial point is that the loss should vary with a higher power of n than the gain, so that two points of intersection are possible, as is illustrated in Fig. 4(a). The physical reason for this superlinear loss function can be found in the reduced waveguiding, and hence higher diffraction losses which occur with increasing carrier concentration, i.e., injected current density, in single-heterostructure lasers [6], [9].

The effect occurs only in single-heterostructure lasers with low substrate doping and an active-layer thickness of less than some optimum value, $d \lesssim 2\ \mu$m. Fig. 5 illustrates schematically the electromagnetic-confinement features of the single-heterostructure laser at (a) low and (b) high current levels. For low currents, the refractive-index distribution is modeled by a 3-layer dielectric slab with the index of the active layer at about 3.6, that of the passive p^+-AlGaAs layer at about 3.4, and that of the passive n-layer at about 3.59. These figures are typical for single-heterostructure lasers and have been calculated for typical doping levels and have been successfully used in previous waveguiding studies of these devices [8]. The corresponding distribution of electromagnetic-field intensity in the device is also shown in Fig. 5(a) and is seen to be slightly asymmetric, as one would expect, showing a deeper penetration of the light into the n-type layer than into the p^+-side.

For high currents [Fig. 5(b)], we must allow for the effect of increased electron concentration on the refractive index of the semiconductor. In the passive regions, the effect of current density will be negligible, since the carrier densities are determined principally by the doping levels via the requirement of charge neutrality. For the active region, however, at high current densities the electron concentration will increase and produce a consequent decrease in the refractive index. The index change occurs in two ways: 1) by the plasma interaction, and 2) by the Kramers-Kronig relationship from the change in absorption edge with increasing carrier concentration [9]. It has been shown [15] that the second of these mechanisms is dominant and that the refractive-index variation depends linearly on carrier concentration to a good approximation, as

$$\Delta\mu \simeq -k\Delta n \tag{5}$$

where $\Delta\mu$ is the change in refractive index due to a change Δn in electron concentration in the active region, as is shown in Fig. 6(a). The coefficient k can be found from the following:

1) experimental measurements of wavelength shift below threshold [16];
2) the Kramers-Kronig analysis of Thompson [15];
3) a series expansion of the expression for refractive index deduced by Adams and Cross [8], [9];
4) the far-field measurements of Selway *et al.* [23].

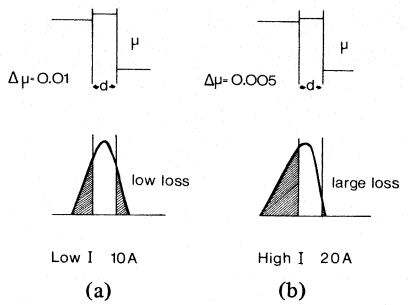

Fig. 5. Refractive index μ and optical losses for a single heterostructure. Diagram indicates the refractive-index levels of a 3-layer-slab dielectric waveguide of n-type passive region, p-type active-region thickness d, and $Ga_xAl_{1-x}As$ region. $\Delta\mu$ gives the refractive-index step between n-type and p-type regions. The penetration of the electromagnetic-field intensity into the passive regions is also indicated. (a) Low current, $\Delta\mu = 0.01$. (b) High current, $\Delta\mu = 0.005$.

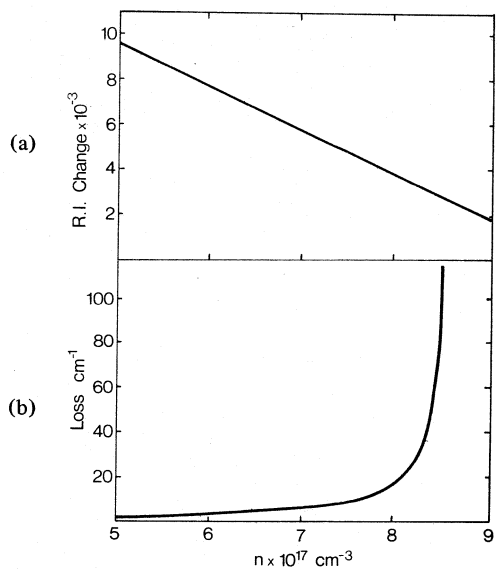

Fig. 6. (a) Variation of refractive index with electron concentration $\Delta\mu = -k\Delta n$. (b) Variation of diffraction loss with electron concentration for the 3-layer-slab dielectric waveguide (Fig. 5).

The values found from 1)-4) for GaAs differ by, at most, a factor of 2, and the value to be used here is that calculated as in 3), viz., $k = 2 \times 10^{-20}$ cm^3.

Returning to Fig. 5, we see that the reduction of refractive index in the active region as a result of increased current density leads to much worse confinement of the electromagnetic field than for low currents. This is manifested by the penetration of the light into the n-region, with an associated large increase of diffraction loss. $\Delta\mu$ follows the form given by (5), and this has been used in waveguiding calculations for the 3-layer dielectric slab of the type described in [17] to compute the variation of diffraction loss α with n. The result shown in Fig. 6(b) is a steep rise in α as the electron concentration reaches the critical value corresponding to equality of the refractive indices in the n-type passive and p-type active regions.

This provides the mechanism for our assumed superlinear variation of laser loss with injected-electron concentration or, equivalently, current density.

The current-dependent loss mechanism discussed here is

clearly only important when the refractive-index values in the n-type passive and p-type active regions are fairly close, say less than 0.01 of each other. Since n-type index decreases for increasing doping levels, very high current density would be needed for the effect to occur for medium or highly doped substrates. It is therefore clear that the mechanism is only important for low substrate doping levels, especially near the critical value of $1\text{-}2 \times 10^{18}$ cm^{-3}, where waveguiding can break down completely in single-heterostructure lasers. This is entirely in agreement with the experimental fact that H-pulsing only occurs in single-heterostructure lasers whose substrate doping level is low.

V. Theoretical Results and Comparison with Experiment

For the comparison of the experimental results given in Section II with our model, a numerical integration of the rate equations (1) and (2) was performed. For the computation the gain and loss functions were assumed as indicated: $g(n) = an$ and $L(n) = u + vn^2$. Using (3) one finds the threshold value of n as being the lower one of the two possible solutions

$$n_{th} = n_1 = \frac{a - \sqrt{a^2 - 4uv}}{2v} \tag{6}$$

while

$$n_H = n_2 = \frac{a + \sqrt{a^2 - 4uv}}{2v} \tag{7}$$

is the minimum electron concentration to be reached if H-pulsing is to occur. The temperature dependence of both n_{th} and n_H (associated with I_{th} and I_H, respectively, and shown for laser H34 in Fig. 3) is easily understood when one takes the temperature dependence of the gain function $g(n)$ into account. In this case a cannot be assumed constant anymore but is a function of temperature. From a theoretical treatment of threshold-current temperature dependence [18], [19] or from empirical expressions for this dependence, one can find a specific temperature dependence for $g(n)$. Since a simple T^{-3} dependence is frequently observed at higher temperatures, it seems to be appropriate to assume

$$g(n) = an = \frac{cn}{T^3}. \tag{8}$$

In Fig. 4(a) an increase in temperature is resembled by a bodily shift of the $g(n)$ line to lower values. It can now easily be seen that as the temperature increases n_{th} increases, while n_H decreases, as was also observed experimentally (Fig. 3).

For the computer calculation of the current dependence we used for simplicity a fixed temperature (represented by a = constant) and the following parameters for gain and loss: $a = 2.01 \times 10^{-5}$ cm^3 s^{-1}, $u = 10^{12}$ s^{-1}, and $v = 1.01 \times 10^{-22}$ cm^6 s^{-1}. The other parameter values in (1) and (2) were: $\tau_e = 10^{-9}$ s and $r_{spon} = 5 \times 10^4\, n(\text{cm}^{-3}\ \text{s}^{-1})$.

Fig. 7(a)-(d) show computed solutions for a rectangular current pulse with a 7-ns pulsewidth and different pumping rates P/P_{th} or I/I_{th}, respectively, as indicated in the figure.

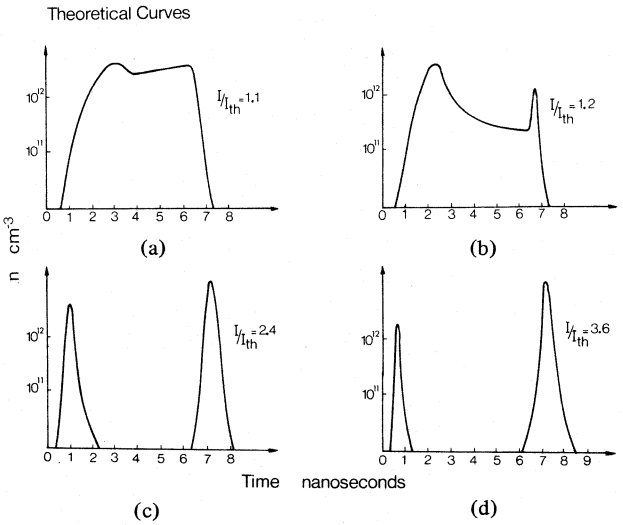

Fig. 7. Theoretical light-output pulses versus time calculated for increasing ratios of I/I_{th} using parameters indicated in the text.

For increasing pumping rates the sequence of Fig. 7(a)-(d) illustrates the following:

1) the shortening of the delay before the first light spike, in accordance with the behavior anticipated from (4);
2) an increase of the delay between the end of the current pulse and the onset of the second light spike;
3) the constant-decay rate of the electrons, and consequently similar width and height of the second light pulse;
4) the decrease of both height and width of the first pulse, as discussed in Section IV.

All of points 2)-4) are in good agreement with the experimental observations of H-pulsing, Fig. 2.

VI. Conclusion

The excellent agreement between the results of our theoretical model and the results of our observations of H-pulsing is indisputable. On the other hand, the value of our explanation lies in its use in laser design for avoiding the effect or alternatively utilizing it to the best advantage. Thus the H-pulsing effect is obviously avoided in the excellent optical confinement achieved in double-heterostructure lasers and in high-power single-heterostructure lasers fabricated on n-doped substrates doped to higher electron concentrations, e.g., laser-type AGA 251/1, [21]. Single-heterostructure lasers with n$^+$-doped regions grown by liquid-phase epitaxy also show superior optical confinement [22]. It appears to us, however, that it may be possible to use the model in designing a laser with superior high-frequency characteristics, since 1) the photon lifetime involved with the loss of optical confinement is measured in picoseconds and 2) the long time delays due to saturable absorption are not present in H-pulsing lasers. The light pulse at the beginning of the current pulse is easily suppressed by rapid current rise time.

A further value of the model is described in [7], where it has been combined with our earlier saturable absorption model to produce a comprehensive theory of long time delays, H-pulsing, and Q switching. Saturable absorption is considered

to be absent from *H*-pulsing lasers since lasing occurs immediately from the conduction band and there are insufficient states in the band tail of the low doped n-type substrate to produce appreciable saturable absorption.

ACKNOWLEDGMENT

The authors wish to thank P. R. Selway, A. R. Goodwin, and G. H. B. Thompson of Standard Telecommunication Laboratories for supplying lasers and for many useful discussions. They also wish to thank W. Kleinert of the Institut für Mathematik, Technische Hochschule, Vienna, Austria, for useful discussions and Prof. E. Bukovics for the use of a hybrid computing system.

The Gain Profile and Time-Delay Effects in External-Cavity-Controlled GaAs Lasers

J. A. ROSSI, J. J. HSIEH, AND H. HECKSCHER

Abstract—**An external dispersive cavity is used to map out the gain profile of single-heterostructure (SH), double-heterostructure (DH), and large-optical-cavity (LOC) lasers. The variations in gain profile with dopant and device operating conditions are reported. With certain cavity arrangements, long time delays in DH devices are observed; this shows that saturable absorption can be present in these as well as in all other types of GaAs diodes. A model combining saturable absorption with a breakdown in optical guiding makes it possible to consistently interpret all reported time-delay data for GaAs diffused-junction (DJ) and SH diode lasers, including Q-switching and abnormal-delay effects. Finally, experiments where two gratings are used to oscillate a diode simultaneously at two different, independently variable frequencies are described.**

I. Introduction

TO REDUCE the large emission bandwidth and the large divergence found in most III-V compound diode lasers, several workers have utilized the operation of diodes in an external cavity (EC). By this method, some control over the longitudinal [1]-[4] or transverse [5] (or both) mode patterns is obtained; this has already proved useful for some applications [6]. This paper describes results obtained by operating GaAs heterostructure lasers in an EC. Specifically, the gain profile has been measured for single, double, and large-optical-cavity heterostructures with different active-region dopants and under different device operating conditions. We find that double-heterostructure (DH) diodes have a flat symmetric gain profile which can yield >300-Å tunable output from a single diode. In contrast, the single-heterostructure (SH) gain profile is quite asymmetric and is generally about 200 Å wide. In addition to these spectral data, we present new experimental results which show that long time delays can occur in DH and large-optical-cavity (LOC) lasers in which one of the diode end faces is antireflection (AR) coated. Since the coating lowers the intensity of the electromagnetic wave in the active region, the observation of delays in these structures is consistent with the saturable absorption model used to account for the long time delays observed in conventional (i.e., cleaved uncoated faces) SH and diffused-junction (DJ) lasers. We hypothesize that the delays in the conventional lasers occur because the intensity of the electromagnetic wave in the active region is lower in these structures than in uncoated DH lasers. We show that this reduced-intensity model is also consistent with other data, including the abnormal delay and Q-switching effects, reported for SH and DJ diodes. Finally, we briefly describe the operation of diodes in a double-grating cavity in which a diode can be forced to oscillate at two different, independently variable frequencies.

II. Previous Work on Time-Delay Effects

Because the EC gain-profile results which we will discuss also involve important time-delay effects, we will first briefly review the delay effects reported for conventional lasers with cleaved uncoated faces. Several workers [7]-[9] have shown that the time dependence of the laser emission from SH or DJ devices depends strongly on the operating temperature. When operated at temperatures below a critical temperature T_c, the time delay τ_d, between the application of the current pulse I and the onset of lasing follows the relation [10]

$$\tau_d = \tau_s \ln \frac{I}{I - I_{\text{th}}} \tag{1}$$

where τ_s is the injected carrier spontaneous lifetime and I_{th} is the threshold current. If we assume that the smallest controllable value of I/I_{th} is ~ 1.02, then for spontaneous lifetimes on the order of 1-2 ns, the observed value of τ_d should never be more than 4-8 ns. According to the literature, this is in fact the case, and (1) adequately describes the time dependence for SH [11] and DJ [7] diodes for $T < T_c$, and for DH and LOC diodes at all operating temperatures since no T_c has yet been reported for these structures [12], [13]. For temperatures above T_c, SH and DJ diodes show long time delays, typically $\tau_d \sim 20$-100 ns, and hence (1) was presumed to be invalid. The long delays were attributed to an absorption process which saturates at some time during the pulse [7], [14]. Fig. 1 summarizes these reported effects.

	$T < T_c$	$T > T_c$
DJ, SH	$\tau_d = \tau_s \ln I/I-I_{th} \lesssim 8$ nsec	$\tau_d \sim 50$-100 nsec
DH, LOC	$\tau_d = \tau_s \ln I/I-I_{th} \lesssim 15$ nsec	

Fig. 1. Summary of reported time-delay phenomena for DJ, SH, DH, and LOC laser diodes. The maximum values of τ_d for $T < T_c$ are computed by multiplying the spontaneous lifetime τ_s by the current overdrive factor, assuming $I = 1.02 I_{\text{th}}$.

There are four additional effects which are important for SH and DJ devices. First, for some diodes at or near T_c, the time delay increases when the current amplitude is increased [14], [15]. This effect has been called "abnormal delay" and typically exists over a small temperature or current interval. Second, for some diodes there is no emission during the current pulse, but a "Q-switched" light pulse occurs after the end of the pulse [9], [16]. Third, as T approaches T_c, I_{th} increases very rapidly [7], [9]. Fourth, as T approaches T_c, there is a considerable change in the temperature dependence of the lasing energy. For $T \ll T_c$, the rate of change of the lasing energy is ~ -0.4 me V/°C; but for temperatures near T_c, the rate is much smaller and, in some cases, may even be positive over a small temperature range before again returning to a negative rate [17]. (This spectral behavior is nicely illustrated in [17, fig. 2].) The significance of these four points will become evident in the discussion of EC results below.

III. Experimental Results

A. SH Devices

To map the gain profile for a device, a single-ended dispersive external cavity was used. In this arrangement described previously [3] and shown here schematically in Fig. 2, light emitted from a cleaved AR-coated face is collimated by a lens and dispersed by a diffraction grating. The diode light is reimaged in the focal plane of the lens, but spatially dispersed so that only a small wavelength interval is reincident on the diode active region for amplification and lasing. By rotating the grating, the feedback wavelength and hence the lasing wavelength can be changed. For measuring the time dependence of the emitted light, we used a wide-bandwidth oscilloscope in conjunction with either a silicon avalanche photodiode or a calibrated vacuum phototube; in either case the response time of the detection system was <1 ns. For spectral measurements, the emitted light was analyzed by a 1-m spectrometer (resolution ~ 0.2 Å). The infrared microscope shown in Fig. 2 was used for cavity alignment as well as for observations of the lasing pattern on the diode facet. Throughout this work, the diodes were operated at or above room temperature and were driven by a low duty cycle ($f \sim 100$ Hz) rectangular current pulse 100 ns long with a rise time of less than 1 ns.

Fig. 3 shows the curve of threshold current versus lasing energy, or gain profile, for an SH device operated at room temperature. The data were obtained by aligning the grating for operation at a certain photon energy $h\nu$ and increasing the current until lasing occurred. The grating was then rotated and the procedure repeated. For $h\nu < 1.365$ eV, the curve is double valued. For example, if the grating is lined up to operate at $h\nu = 1.360$ eV and the current is increased, lasing begins at ~ 6 A and stops at ~ 13.5 A. This feature is characteristic of all SH diodes we have examined.

Fig. 4 shows schematically the time dependence of the laser emission from these SH diodes. With the grating set to provide feedback at energy $h\nu_2$, the light-output pulse for three rectangular current pulses of different amplitudes ($I_A < I_B < I_C$) is shown by the right-hand portion of the figure. In this case, the light output follows the current according to (1), and little or no delay is observed. The amplitude of the light output increases as the current amplitude is increased (this is not indicated in the figure). If the grating is lined up to operate at $h\nu_1$, then as the current amplitude is increased a significant delay develops between the current pulse and the light-output pulse, until at I_C the light pulse is delayed almost to the end of the current pulse. For $I > I_C$, only spontaneous emission is observed. Thus, the gain profile is composed of two portions: a lower energy portion, characterized by a delay that increases

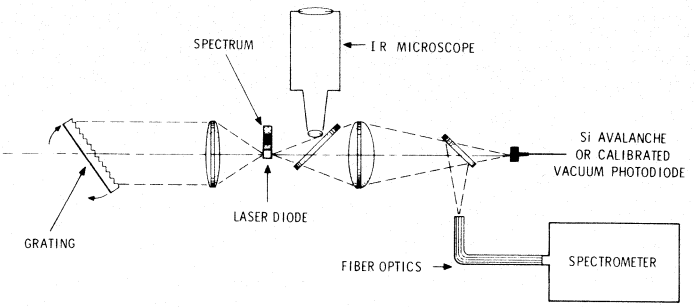

Fig. 2. Schematic illustration of the EC and associated detection apparatus used in this work.

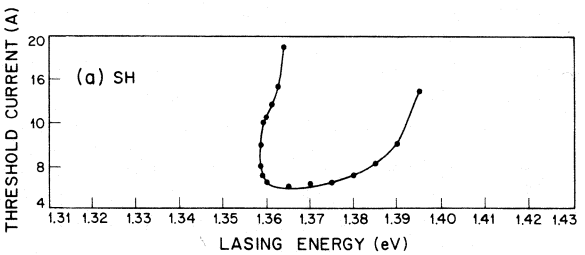

Fig. 3. Threshold current versus lasing energy for a typical SH diode operated pulsed (100 ns) at room temperature. (If the current pulse is only 50 ns, the left-hand branch of the curve is rotated clockwise.)

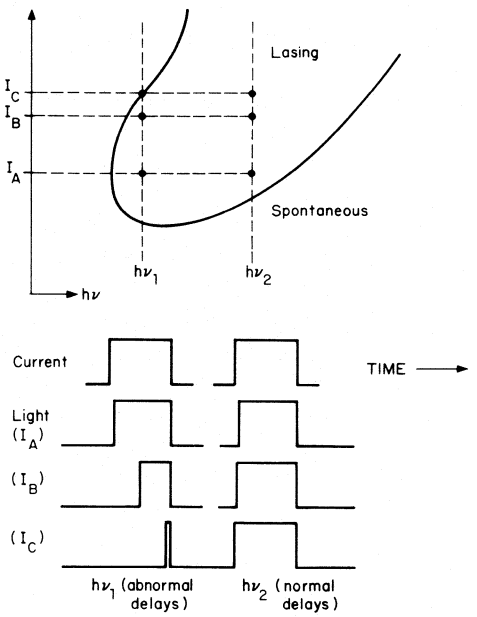

Fig. 4. Schematic of the SH gain profile showing the light output versus current ($I_A < I_B < I_C$) when the diode is lased at $h\nu_1$ or $h\nu_2$. For lasing at $h\nu_1$, the delay increases with increasing current (abnormal-delay effect), whereas at $h\nu_2$ the time-delay behavior is normal [described by (1)]. The change in amplitude of the light output is not indicated.

with increasing current, i.e., an abnormal-delay region; and a higher energy portion characterized by normal time behavior. At high injection levels the abnormal region monotonically moves into the higher energy portion.[1]

Fig. 5 shows the gain profiles for another SH at several different operating temperatures. At 20°C, the profile is similar to that shown in Fig. 3, having a "toe" region with abnormal delays and a region without these effects at higher energies. When the temperature is increased to 52°C, the entire curve shifts to higher currents and lower energy, as expected, but the low-energy portion moves only slightly, while the high-energy portion moves faster. The net effect is a significant decrease in the tuning width. Increasing the temperature to 60°C continues this trend, and in addition, causes the toe region to disappear. At this temperature a significant delay between the current pulse and the light output (20-30 ns at $I \simeq 1.5I_{th}$) is observed over the entire profile; however, this delay is "normal," since it does not increase with increasing current. In fact, in this temperature range the behavior of these diodes is typical of uncoated SH diodes as their temperature of operation approaches the transition temperature [9], [11]. A further increase in the temperature to 64°C results in a more symmetric gain profile and in an increase in the delay to about 40-50 ns measured at $1.5I_{th}$. In summary, as the temperature is increased, the gain profile moves to lower energy, the abnormal-delay region disappears, and a long delay is observed over the entire profile.

By examining the EC data it is possible to predict the behavior of an uncoated diode. For example, in Fig. 5 there is a minimum threshold current $(I_{th})_{min}$ at each temperature. If we plot $(I_{th})_{min}$ versus T for these and several other temperatures, we obtain the data shown in the inset. These data are obviously similar to reported data [9], [11] for the variation of I_{th} with temperature for SH and DJ devices: $(I_{th})_{min}$ increases sharply as T_c is approached. As another example, if we assume that an uncoated diode would lase at the energy for which $(I_{th})_{min}$ occurs, it follows that the rate of change of the lasing energy with temperature will first be negative, then approach zero, and perhaps even become positive, and finally be increasingly negative as $T \rightarrow T_c$, in qualitative agreement with the data in [17] discussed above.

B. LOC and DH Devices

In Fig. 6 we show the gain profiles for LOC and DH devices operated at room temperature. For these structures the gain profiles are fairly symmetric around a center energy which depends on the active-region dopant. Diodes from two different LOC wafers were measured. The gain profile centered at 1.375 eV was obtained for diodes made from a wafer whose active region was doped with both Zn and Si. The profile centered at ~ 1.355 eV was obtained for diodes with only Si doping in the active region. For DH diodes, changing from Zn and Si doping of the active region to heavy Si doping (1.5-

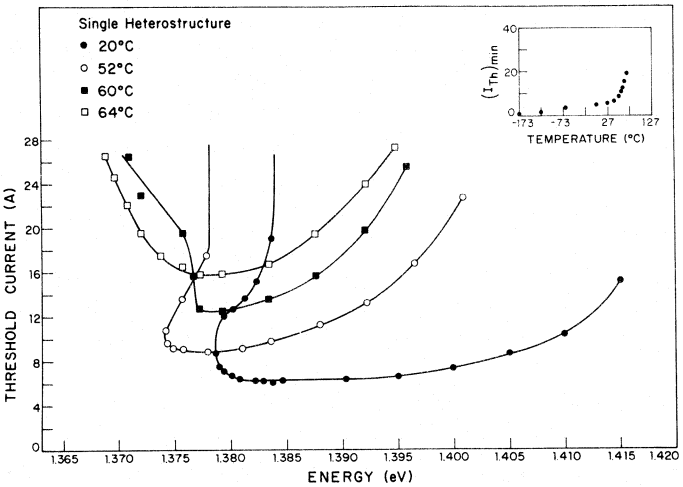

Fig. 5. The variation in the SH gain profile with temperature. Note that the abnormal-delay region (where lasing stops at sufficiently high currents) is eliminated at higher temperatures. The inset shows a plot of the minimum threshold current $(I_{th})_{min}$ needed for lasing at several different temperatures.

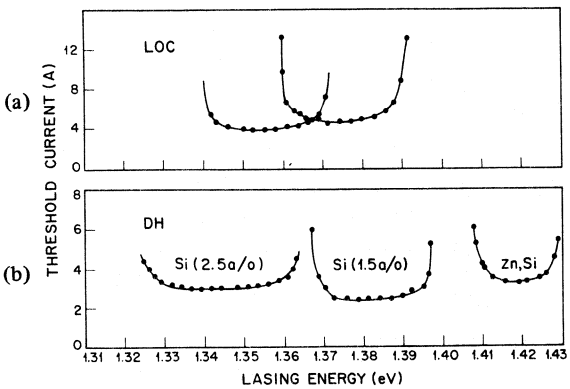

Fig. 6. Gain profiles for (a) LOC and (b) DH devices. Note the more symmetric appearance when compared to the SH gain profile (Fig.3). The different gain profiles were obtained by changing the active-region dopant.

atomic-percent Si in the solution used to grow the active layer) both broadens the tuning curve and shifts the centroid of the curve to a lower energy. Even heavier Si doping (2.5-atomic-percent Si in the solution) continues this trend, yielding diodes which may be continuously tuned over a 40-meV (300 Å) range.

For LOC or DH lasers there are no regions of the gain profile where the diode stops lasing as the current is increased. Also, for these structures, as the temperature is increased the whole tuning curve shifts to lower energy at a rate of ~ -0.4 meV/°C, as shown in Fig. 7. This rate is in good agreement with the reported shift of the bandgap with temperature [18].

In this section we report the observation of long time delays in DH and LOC devices. No such delays in devices of these types were observed in the studies discussed in Section II and summarized in Fig. 1. In Fig. 8 we have plotted the delay time τ_d versus current overdrive factor $\ln I/(I - I_{th})$ for two DH diodes made from the same wafer. The triangular points were taken on a conventional diode with cleaved uncoated faces ($R_1 = R_2 \simeq 0.3$). The variation is linear and the parameter τ_s

[1]According to the discussion in Section II, this means that the whole emission line is subject to a breakdown in guiding as $T \rightarrow T_c$. However, below T_c the portion of the gain profile subject to abnormal delays depends on the current density.

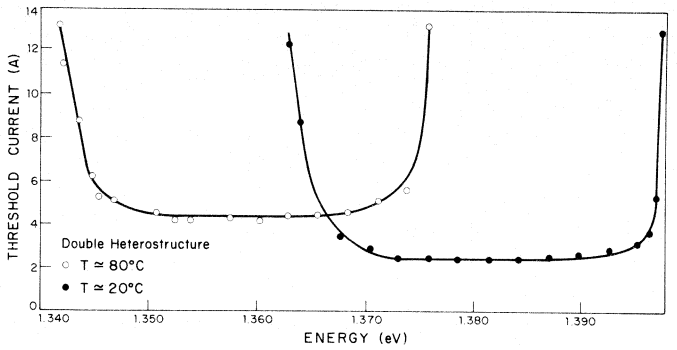

Fig. 7. The variation in the DH gain profile with temperature. The whole profile shifts to lower energy with increasing temperature at a rate ~−0.4 meV/°C.

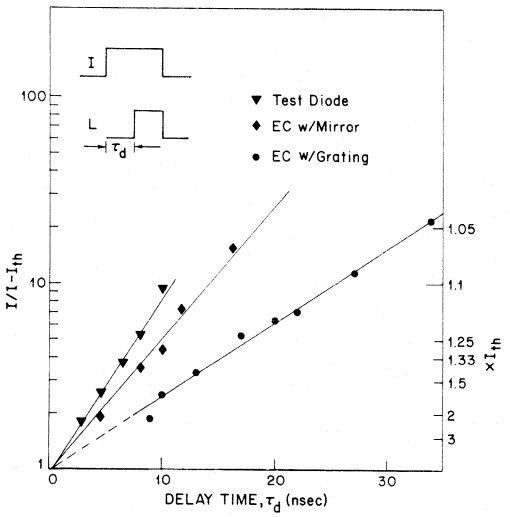

Fig. 8. The measured time delay between the current pulse and light-output pulse τ_d versus $I/(I - I_{th})$ for three different cavity configurations of a DH diode.

in (1) is 4.5 ns. All the uncoated diodes made from this wafer yield the same results to within experimental error, ± 1 ns. The rectangular points were taken on a diode with one face AR coated which was operated in an EC with a flat Au mirror as the back resonator face. Note that the data are shifted toward longer τ_d for the same value of $I/(I - I_{th})$, but the variation is still linear, with $\tau_s \sim 6$ ns. This trend continued when the Au mirror was replaced by a diffraction grating; for this case the data are represented by the circular points which again vary linearly, but with τ_s increased to ~ 11 ns.

Fig. 9 shows the same type of data for two LOC diodes. The square points were obtained from an uncoated diode (both faces cleaved, $R_1 = R_2 \simeq 0.3$). The data are linear with $\tau_s \simeq 3$ ns. The circular data points were obtained from a diode with one uncoated face and one coated face ($R_1 \simeq 0.3, R_2 \sim 0.01$). In this case the value of τ_s is increased to about 60 ns, well beyond the estimates of the injected carrier lifetime [12].

C. Double-Grating and Composite-Resonator Experiments

In this section we will briefly describe some experiments made in a double-gravity cavity. The experimental arrangement is exactly the same as before, except that we introduce a 50-50 beam splitter into the collimated beam path and add a

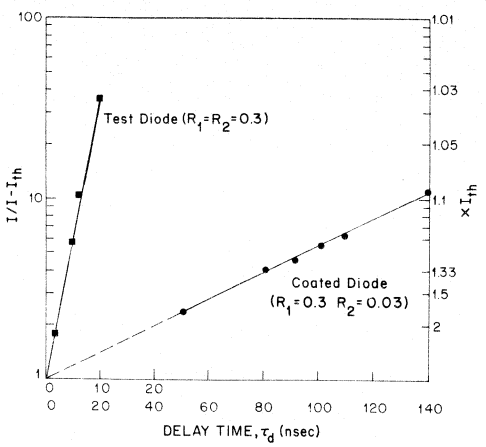

Fig. 9. Time delay versus current overdrive for two LOC devices.

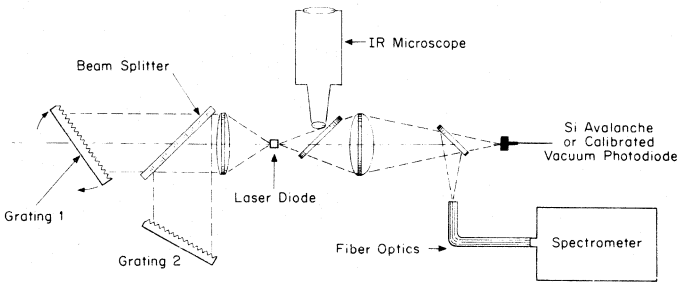

Fig. 10. Schematic illustration of a double-grating cavity which allows the diode to be lased at either the frequency controlled by grating 1, the frequency of grating 2, or at both frequencies simultaneously.

second grating to the cavity, as shown in Fig. 10. Now the diode can oscillate at two different frequencies depending on the setting of the gratings, as illustrated by the spectra for a DH diode shown in Fig. 11. The upper spectrum [Fig. 11 (a)] was obtained by blocking off the feedback from one grating so that the diode lases only in one narrow line. The lower spectrum [Fig. 11 (b)] was obtained by introducing feedback from the second grating, causing a second line to oscillate simultaneously with the first. We feel this technique may be useful in studying the dynamics of the gain profile for any semiconductor laser. We have also done double-grating experiments on an SH diode, with results similar to those in Fig. 11 in that two lines will oscillate. However, because of the abnormal delay region,[2] the results are very complicated and will not be discussed here [19].

Finally, we have also operated uncoated diodes in an external cavity with a grating. In this case the situation is very similar to that discussed by Bjorkholm *et al.* [20] for dye lasers. The spectra obtained for an SH diode are shown in Fig. 12. In the uppermost spectrum the diode is lasing in several longitudinal Fabry-Perot modes without any grating feedback. In Fig. 12 (b)-(f), the grating feedback is added and tuned through the modes. When the grating is tuned close to the modes, all the power is pulled into the grating line, so that an

[2]The time-delay data are affected because a high-energy line (with normal delay) can saturate the absorbers, thereby allowing a low-energy line to oscillate.

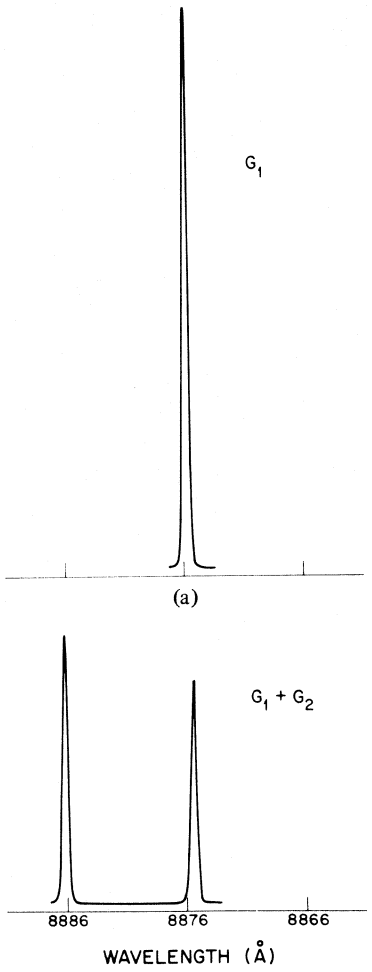

Fig. 11. The spectral output from a DH diode operated in a double-grating cavity. (a) Upper trace–grating G_1 feeds back radiation at 8876 Å. (b) Lower trace–both gratings feed back: G_1, at 8876 Å; G_2, at 8886 Å. The amplitude scale is not the same for both traces.

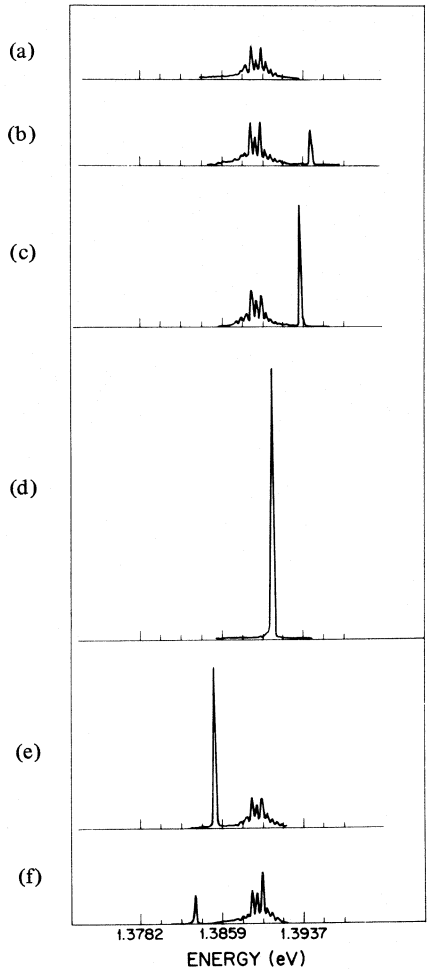

Fig. 12. The spectral output from an uncoated SH diode operated in an external cavity. In spectrum (a) the diode is lasing with the grating feedback blocked. In (b)–(f) the grating feedback is unblocked and the grating-controlled line is tuned through the diode's own self-lasing spectrum.

AR coating is clearly not necessary for all applications. We note, however, that the tuning range over which the diode radiates all its power in a single narrow line is only ~ 5 meV (30 Å), which is greatly reduced from the AR-coated case. Furthermore, Paoli and Ripper [21], who have operated uncoated CW diodes in this way, found that this tuning is only quasi-continuous.

IV. Discussion

The data of Figs. 8 and 9 show that long delays can be observed in DH and LOC devices, but only under certain operating conditions. The common feature of these conditions is that they cause a reduction in the electromagnetic wave intensity inside the active region. Thus, for the AR-coated diode of Fig. 8, I_{th} is increased by ~ 5 percent when the Au mirror is replaced by the diffraction grating. However, the photon density inside the cavity is greatly lowered because the grating is highly dispersive and returns only a very small portion of the emission to the active region. In contrast, the mirror returns all the emission (except for small reflection losses), since in this case the junction is reimaged in the lens focal plane. Thus, for the grating, the small increase in photon density due to a higher I_{th} is more than offset by the loss of photons due to dispersion. There is a similar difference between the conventional diode and the AR-coated diode with the Au mirror. In this case, the addition of external optics causes a loss which is not quite offset by the decrease in the transmission loss of the resonator. This must be the case because I_{th} is essentially unchanged for the two configurations, but the calculated transmission losses are cut in half (~ 47 to 23 cm^{-1}). Hence for Fig. 8 we expect the highest wave intensity inside the cavity for the cleaved uncoated diode; a lower intensity is expected for the coated diode-mirror combination, and an even lower intensity for the coated diode-grating combination.

On the basis of this analysis, we believe that the long time delays in the AR-coated DH and LOC devices are fundamentally due to a saturable absorption process, just as in DJ and SH diodes. Although this process is also operative in uncoated DH and LOC devices, because of their superior optical confinement the photon density in these devices is high enough to saturate the absorption so rapidly that long delays do not occur. By applying an AR coating we can reduce

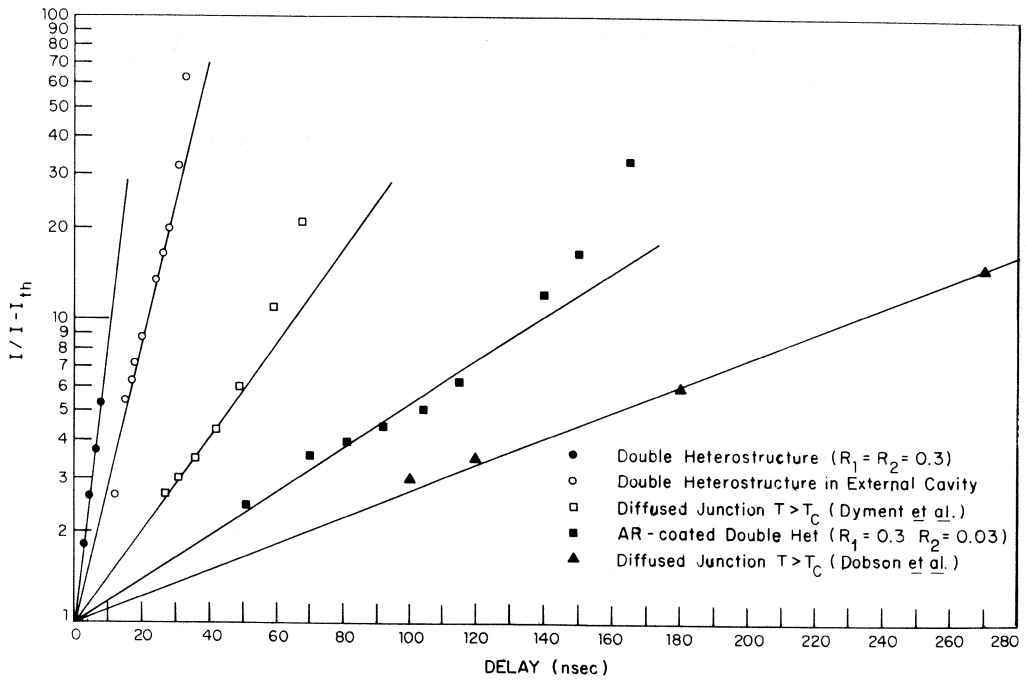

Fig. 13. Time delay versus current overdrive curves illustrating the similarity between our results for coated DH or LOC devices and the results for DJ devices operated above T_c reported by Dyment and Ripper [7] and Dobson *et al.* [22].

the photon density to the point where the time required to saturated the absorption becomes appreciable, and long delays can be observed.

This explanation of long delays in DH and LOC devices suggests that the long-delay effects in SH and DJ diodes at $T > T_c$ are also due to a reduction in the electromagnetic wave intensity in the active region. This proposal is strongly supported by the data shown in Fig. 13, which include curves of τ_d versus $\ln I/(I - I_{th})$ for a DH device, a DH device in an EC, and a coated DH device lased without an EC, together with data taken from Dyment and Ripper [7] and from Dobson *et al.* [22] for DJ diodes operated above T_c. The data for DJ diodes below T_c, which would lie on a nearly vertical line located near our DH data, have been omitted from Fig. 13 for clarity. The straight lines drawn in Fig. 13 are not intended to compare the data with (1), but are used to emphasize the trend in the variation of the time delay for different diodes [23]. Thus, as discussed above, the data for the DH devices show a decreasing slope for a decreasing photon density in the active region, and the data for the DJ diodes go from nearly vertical at $T < T_c$ to a greatly decreased slope at $T > T_c$. We propose that in a SH or DJ diode, at the current levels necessary to drive the device, as $T \to T_c$ there is a breakdown in waveguiding which reduces the intensity of the wave in the active region sufficiently for the saturable absorption to cause a long time delay. This model, which combines a breakdown in waveguiding with a saturable absorption, is also consistent with all other reported time-delay effects, as we will now show [24].

First, we consider the case of abnormal delays, in which the time delay between the current pulse and the diode light output *increases* with increasing current, exactly opposite to what is predicted by (1). In this case we assume that the increase in current amplitude decreases the waveguiding of the structure, causing the intensity of the wave in the active region to decrease. It therefore takes longer to eliminate the saturable absorption, and the time delay is increased. For a diode operated in an EC where the lasing wavelength is fixed, the diode will eventually be shut off, as reported previously [25] (see Figs. 3 and 4). A conventional diode will try to oscillate at a shorter wavelength which still can "fit" into the guide or which has the gain needed to overcome the additional diffraction loss; this has also been observed [11], [17] as discussed above. There are at least two ways [26]-[28] in which the refractive index (and therefore the waveguiding) of the active region can change with drive level: 1) by the negative contribution to the index from injected minority carriers (plasma effect), and 2) through the Kramers-Kronig integral which relates the absorption coefficient α, or changes in α, to the index of refraction. These changes in the index with current are probably small ($\sim$ 0.1-1 percent) but are important in a SH or DJ diode because the waveguide is asymmetric and is, in fact, established by small index variations. Therefore, the losses can be increased greatly by a small index change at one of the waveguide boundaries. Thus abnormal time delays may be attributed to a breakdown in guiding coupled with saturable absorption. This explanation is also consistent with the fact that no abnormal delays have ever been reported for DH or LOC devices; in these devices, because of the large index of refraction discontinuities ($\sim$ 5-10 percent), a breakdown in guiding with current is not likely to occur.

By using the same model, Q-switching effects can be qualitatively explained as follows. Immediately after the application of the current pulse, the saturable absorption losses dominate and prevent lasing. Although the saturable losses decrease with time during the current pulse, the diffraction loss

from a breakdown in guiding still prevents the diode from lasing. If, following the current pulse, the guiding is restored faster than the injected carriers are lost, a Q-switched output pulse can result. Since the guiding is expected to change rapidly with carrier density, this assumption is not unreasonable.

Additional features of the waveguide-breakdown model make it consistent with other reported data. A breakdown in guiding should first affect the longest wavelengths because these no longer fit into the guide or, alternately, they do not have the gain needed to overcome the additional diffraction loss. EC data [25] showing that the time delay increased as the lasing wavelength increased are thus in agreement with the model. According to Thomas *et al.* [29], the model can also account for H-pulsing [30]. The model is also consistent with all previous data on the dependence of delay effects on active-region doping and width. For example, for a fixed lasing frequency in the p-side of a DJ or SH diode, increasing the substrate doping (n-side) leads to a decrease in the index of refraction on the n-side of the junction [31], [32] which results in an improved guiding in the unexcited structure. Hence, a higher T_c would be expected for devices with a higher substrate doping; this is in agreement with the experimental results for these structures [7], [24c)]. Similarly, a smaller active-region width should lead to a decrease in guiding resulting in a lower T_c, as observed experimentally [9], [24c)]. Changes in the near-field pattern showing a spreading of the light emission as $T \rightarrow T_c$ [33], and changes in the far-field pattern showing a narrowing of the beamwidth as $T \rightarrow T_c$ [34] are also consistent with the model.

V. Conclusions

We have shown how the dispersive EC can be used to study the gain profile types of heterostructures, for differently doped active regions and different device operating conditions. We have also shown that long time delays can be observed in DH and LOC diodes, which indicates that saturable absorption can occur in these as well as in all other types of GaAs diodes. Although saturable absorption has recently been attributed to a nonequilibrium process [23], this model conflicts with some experimental results. For example, according to the nonequilibrium model, diodes with heavily Si-doped active regions should show long time delays, but we did not observe such delays in Si-doped diodes lasing near 9250 Å. Further, we doubt that the saturable absorption occurs in the n-type passive layer of a SH diode because in that case, uncoated LOC structures should show long delays, and of course the highest energy transitions should be affected first, contrary to EC data. Thus the conclusive identification of this absorption mechanism, in our opinion, still remains open. More important, the removal (if possible) of this absorption from the active region may yield improved lasers and light-emitting diodes. The existence of H-pulsing indicates that there is material available without significant saturable absorption.

To test the breakdown-in-guiding model a quantitative treatment should be developed. The observed variation of the cutoff energy with injected carrier density (cf. Figs. 3, 4, upper branch) could then be compared to that expected from theory. Finally, we note that the photon density in the active region may be reduced in structures that do not utilize a Fabry-Perot cavity with uncoated faces. Such a structure—for example, a laser physically coupled to a fiber through an index matching medium—might therefore show time delays that would be detrimental for wide-band applications in integrated optical circuits or optical communication systems.

Degradation and Intensity Fluctuations in CW AlGaAs Double-Heterostructure Junction Lasers

SHUN-ICHI GONDA AND SEIJI MUKAI

Abstract—**The intensity fluctuations in the output of CW AlGaAs semiconductor lasers were measured as functions of pumping current and operating time. The magnitude of fluctuation decreases with increasing aging time. The shift after degradation in the resonant-peak frequency for the normalized pumping rate is small. An increase of the half-width of the resonance peak is also observed, together with an increase of the threshold current and a decrease of the external differential quantum efficiency. The fluctuation spectra due to the quantum shot noise were calculated using rate equations with parametric variation of the pumping rate and the internal quantum efficiency. From the qualitative agreement between calculated and experimental results, changes in the intensity fluctuations after degradation are considered to be partly due to a decrease of the internal quantum efficiency or gain.**

I. Introduction

DEGRADATION of CW AlGaAs double-heterostructure lasers is characterized by a decrease of the emission intensity, an increase of the threshold current, and a decrease of the external differential quantum efficiency. This behavior can be explained by the formation of "dark lines" [1]–[3] which are nonradiative recombination regions and crystalline defects observed in degraded lasers.

Another characteristic of interest is the intrinsic intensity fluctuations in the output of semiconductor lasers. Armstrong and Smith [4] investigated the intensity fluctuations in the light emitted by a GaAs laser operated continuously near 10 K in the frequency range between 2 kHz and 10 MHz as a function of pumping current, and observed the fluctuation

maximum near the threshold current. McCumber [5] calculated the intensity fluctuations due to the quantum shot noise, expected in the output of four-level CW laser oscillators, using linearized rate equations, and Haug [6] made similar calculations for semiconductor lasers. They found that above threshold there is a sharp resonance in the gigahertz region. The existence of a sharp peak in the fluctuation spectrum was shown indirectly by Ikegami and Suematsu [7] investigating the resonance frequency by using a modulated driving current. On the other hand, D'Asaro *et al.* [8] observed a peak in the gigahertz region of the fluctuation spectrum of semiconductor lasers. They concluded that this peak was not due to the quantum shot noise, because the dependence of the fluctuations on the pumping current was not correct. Paoli [9], [10] observed directly the peak due to the excitation of the natural resonance by the quantum shot noise in the above-threshold frequency spectrum of the output of AlGaAs junction lasers operated CW at 77 K and room temperature.

The internal change of the lasing process after degradation is reflected in the intensity fluctuations. For example, Yang *et al.* [11] reported that self-pulsation was observed in the output after degradation. The present paper presents experimental results on the rms intensity fluctuations in the frequency region below 10 MHz and the fluctuation spectra in the region 0.1~2 GHz as a function of pumping current in the output of AlGaAs junction lasers operated continuously at room temperature. The change in the intensity fluctuations was measured after an appropriate aging time. The relation between the degradation and the intensity fluctuations will be discussed using simple rate equations.

II. Experimental

Samples used in the present work were fabricated from double-heterostructure material grown by liquid-phase epitaxy. The active layer of this material was less than 1 μm thick and contained a small amount of Al. As for the stripe geometry, two types were used. One type was native-oxide stripe-geometry (NOS) lasers [12] fabricated by Toshiba. The active layer of this type was doped with Si. Lasers were about 150 μm long with stripe width nominally equal to 20 μm. The other was planar stripe-geometry (PS) lasers [13] fabricated by the Nippon Electric Co. The active layer was doped with Ge. Lasers were about 240 μm long with a stripe width of 15 μm. For CW operation at room temperature, each laser was bonded to a copper heat sink.

The rms intensity fluctuations for the low-frequency part between 2 kHz and 10 MHz were measured with a single-detector arrangement similar to that used by Armstrong and Smith [4]. The fluctuations in the output current of a p-i-n photodiode (UDT PIN-10) were measured with an rms voltmeter (HP 3400A). The dc photocurrent was determined simultaneously by using an RC divider network. The low-frequency cutoff of 2 kHz was fixed by the divider, the high-frequency cutoff of 10 MHz by the voltmeter. The rise time of the photodiode was about 15 ns.

The frequency spectrum of the intensity fluctuations was measured with a single-detector system similar to that used by Paoli and Ripper [9]. The laser light was passed through a chopper and focused onto a coaxially mounted p-n avalanche photodiode whose rise time was about 0.1 ns. The output of the photodiode was coupled to a spectrum analyzer (HP 851B/8551B) whose output was directed to a lock-in amplifier for phase-sensitive detection. For optical isolation a lens with a small diameter and focal distance was placed near the laser and away from the photodiode. The output from the system $P(\omega)$ was corrected using the frequency-response function of the system which was measured by observing the spectrum generated by white light. The relative photon noise $S(\omega)$ is related to the calibrated output by the following equation:

$$S(\omega) \equiv \int \langle \Delta N_p(t) \Delta N_p(t+\tau) \rangle e^{i\omega\tau}\, d\tau / \langle N_p \rangle^2 = (P(\omega)/2\,\Delta_f)/P_{\mathrm{dc}} \quad (1)$$

where Δ_f is the bandwidth of the spectrum analyzer and $N_p(t)$ the photon number.

Some of the lasers measured show sharp peaks and narrow half-width in the frequency spectra. Modulation of this type can be observed in the time domain with a sampling oscilloscope. The modulation was observed using a delay line and the modulation itself as a trigger, with care to reducing the trace jitter due to incomplete periodicity of the signal.

III. Experimental Results

The frequency spectra of the intensity fluctuations for various lasers are shown in Figs. 1 and 2 as a function of pump level. The ordinate shows the relative noise power $S(\omega)$ defined by (1). No appreciable difference in the fluctuation characteristics was found between the NOS and PS lasers. The relative noise spectra observed in a laser, $L1$, which has an intermediate external differential quantum efficiency (about 10 percent) is shown in Fig. 1. After 98 h and 260 h of continuous operation at 100 mA (the output was about 1 mW) at 22°C, the threshold current of this laser increased from 83.8 mA to 92.9 mA and 102.1 mA, respectively. Solid lines and dashed lines in Fig. 1 are the spectra before and after the operation.

The above-threshold spectra show the resonant peaks. The relative noise increases with increasing pumping current. As pointed out before [10], this absence of stabilization at room temperature may be due to an ineffective response to the fluctuating intensity because of longer thermalization times. After long-term operation the magnitude of the resonant peak decreases, as shown in Fig. 1. The tendency of the absence of stabilization is unchanged. The relative noise spectra observed in a laser, $L2$, which has a rather high external differential quantum efficiency (more than 20 percent), and in a laser, $L3$, which has a rather low efficiency (about 5 percent), are shown in Fig. 2 with solid lines and broken lines, respectively. In laser $L2$, at currents a little above threshold, the fluctuations increase abruptly and show anomalous peaks, and the peaks due to higher harmonics grow at the high-noise power level. The fluctuations with these sharp peaks may be incipient self-pulsation due to second-order mode locking [14]. After

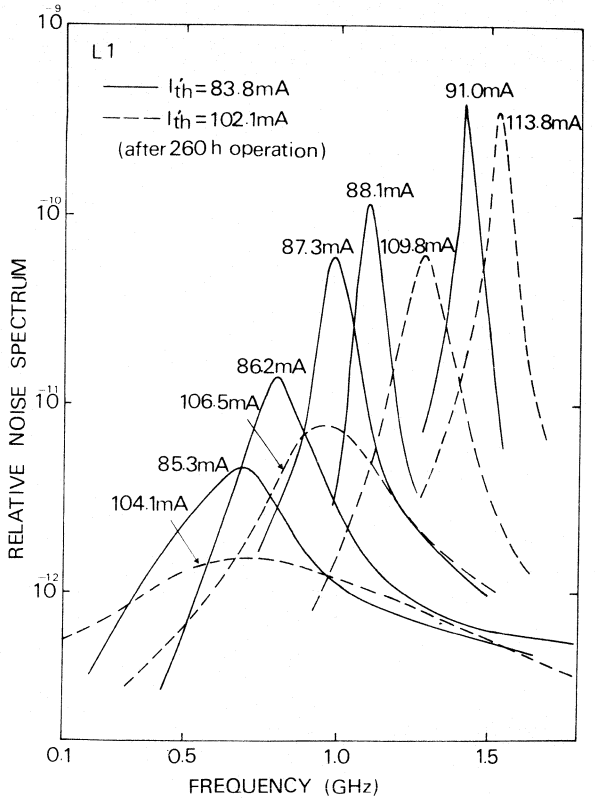

Fig. 1. Intensity-fluctuation spectra obtained from a semiconductor laser, $L1$, with an intermediate quantum efficiency before operation, and after operating continuously for about 260 h.

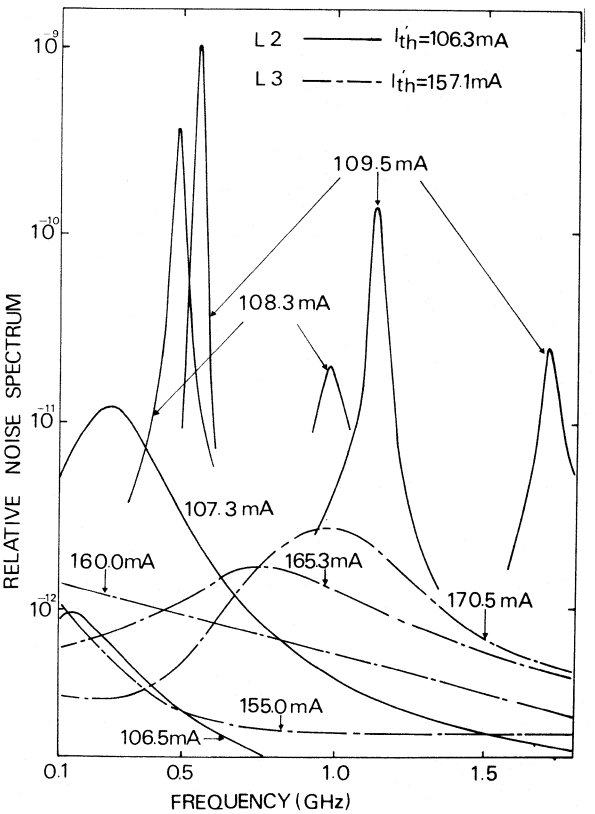

Fig. 2. Intensity-fluctuation spectra from a semiconductor laser, $L2$, with high quantum efficiency and a laser, $L3$, with low quantum efficiency.

operation there are no drastic changes in these spectra. In laser $L3$ with low efficiency, the peak of the fluctuation does not grow so rapidly and the half-width of the peak does not decrease greatly with increasing pumping current.

The relation between the peak frequency ν_R and the current I expected for the small-signal fluctuations excited by the quantum shot noise is given by [5]

$$\nu_R^2 = \alpha^2(I/I'_{th} - 1) \tag{2}$$

where I'_{th} is the threshold current when $\nu_R = 0$, and this is almost coincident with the threshold current I_{th} obtained from the current-output power characteristics. The dependence of the peak frequency on the pumping current for laser $L1$ is shown in Fig. 3 together with that for another laser $L2'$ which shows fluctuation spectra similar to $L2$ in Fig. 2. Equation (2) holds for laser $L1$. This dependence indicates that the fluctuations in laser $L1$ are caused by a resonant mechanism excited by the quantum shot noise. The coefficients α in (2) have nearly the same values, 4.7 GHz, for each stage of operation. The fluctuations after degradation, therefore, are also due to the quantum shot noise. The relation $\nu_R^2 = \alpha^2(I/I'_{th} - 1)$ also holds for laser $L3$. At first sight, the shift of the peak frequency seems to be small for laser $L3$, but the dependence of the peak frequency on the current normalized by the threshold current is of the same order as in the case of Fig. 1. On the other hand, (2) does not hold for laser $L2'$, as shown in Fig. 3. This deviation, abrupt increase, large values of peak height, and the existence of higher harmonics indicate that the fluctuations make a transition from small-signal fluctuation to incipient pulsation with in-

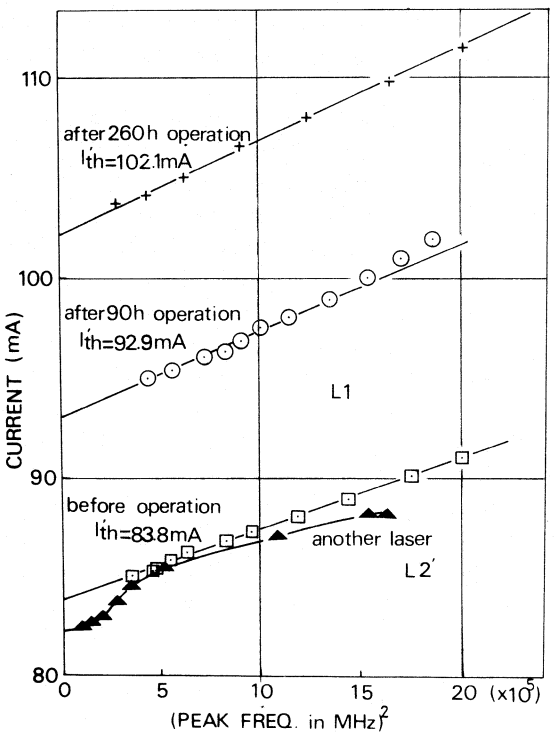

Fig. 3. The relations between the pumping current and the peak frequency of intensity-fluctuation spectra ν_R after various periods of continuous operation for laser $L1$ and the relation for laser $L2'$, showing deviations from the formula $\nu_R^2 = \alpha^2(I/I_{th} - 1)$.

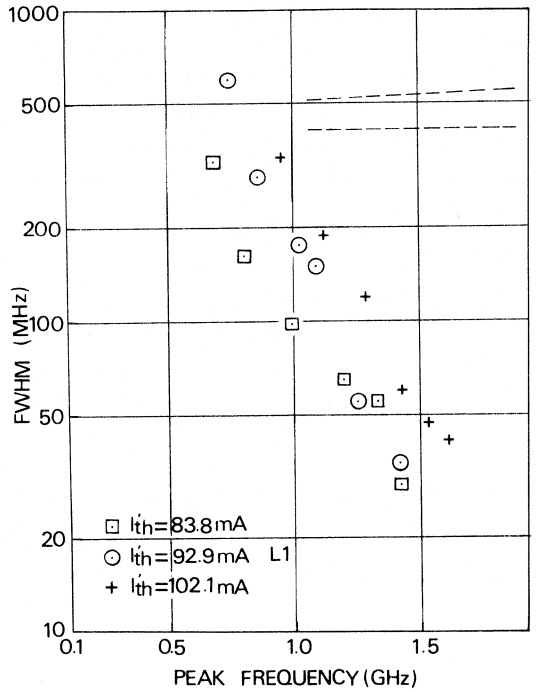

Fig. 4. The relations between the FWHM and the peak frequency in the intensity-fluctuation spectra after various periods of continuous operation for laser $L1$. The dashed line is a relation calculated from the quantum shot-noise model.

creasing pumping current. Abrupt decrease of the full width at half maximum (FWHM) of the peak shows that the noise becomes nearly periodic when the pulsation occurs.

Fig. 4 shows the FWHM of the fluctuation spectra of laser $L1$. The FWHM of spectra decreases rapidly with increasing pumping current. This is not consistent with a tendency expected from the quantum shot-noise model, which is shown with dashed lines.

In some cases, after degradation, very sharp and large peaks were observed in the frequency spectrum of intensity fluctuations, together with their high harmonics. This phenomenon appears to be the self-pulsation and may be caused by repetitive Q switching, with dark-line regions in the degraded lasers acting as saturable absorbers, as reported previously [11].

The absolute rms values of the low-frequency part (<10 MHz) of the intensity fluctuations for lasers $L2$ and $L3$ are shown in Fig. 5 as a function of pumping current. The dashed curves are output-current characteristics. The rise and fall of the rms fluctuations for laser $L2$ having higher external differential quantum efficiency near threshold are very sharp. The rise of the fluctuations for laser $L3$ having low efficiency is gradual and the magnitude of the peak is small. Although not shown here, the rise and fall of the fluctuation for laser $L2$ are intermediate. As the degradation proceeds, the rise and fall become gradual and the magnitude of the peak becomes small. The fall after the rise is due to the saturation of the gain [4]. The tendency for the peak to broaden after degradation is thought to be caused by the decrease of the gain.

Fig. 6 shows the sampling-oscilloscope traces of the fluctuations in the output of laser $L2$ with high external differential quantum efficiency. When the pumping current is 116.1 mA, the period (about 1 ns) of the fluctuations in Fig. 6 corresponds to the peak frequency (955 MHz) in the frequency spectrum. With decreasing pumping current the period becomes longer, corresponding to the shift of the peak to lower frequency. When the pumping current is 116.1 mA, the ratio of the rms fluctuations of the output current of the photodiode obtained from Fig. 6 to the dc component of the current is about 17 percent. The depth of the modulation again indicates that this fluctuation is self-pulsation.

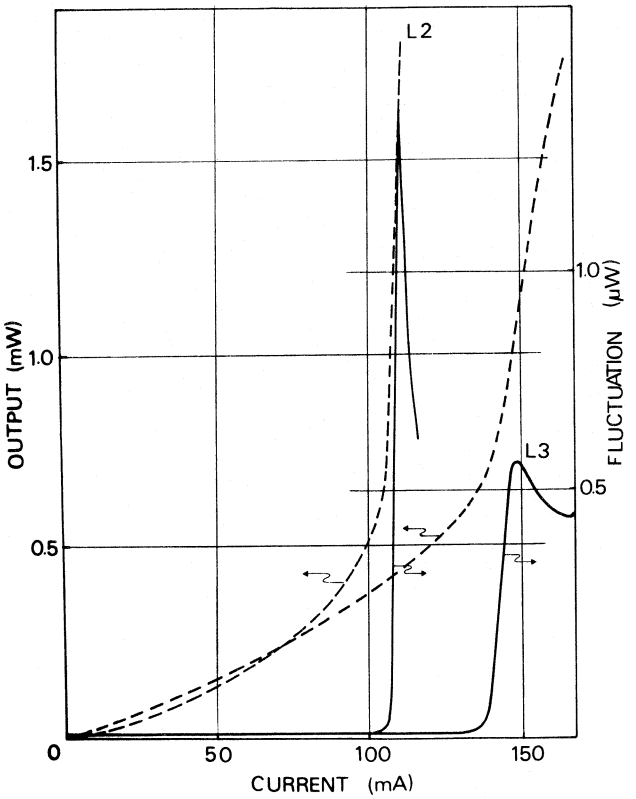

Fig. 5. Low-frequency intensity fluctuations in the output of lasers $L2$ and $L3$ as a function of pumping current. The dashed curves give the total output power.

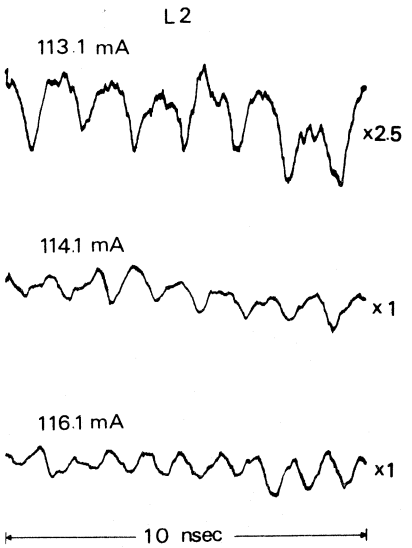

Fig. 6. Sampling-oscilloscope traces of intensity fluctuations in the output of a laser with high quantum efficiency.

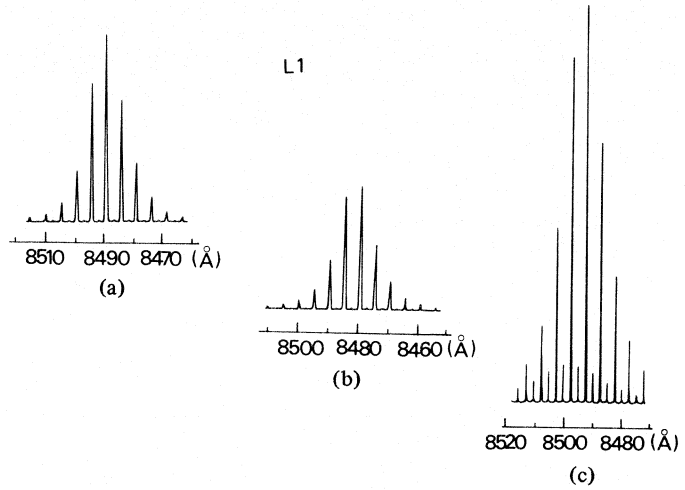

Fig. 7. The emission spectra of laser $L1$ with intermediate external differential quantum efficiency after various periods of continuous operation. (a) Before operation. (b) After 187-h operation. (c) After 497-h operation.

Fig. 7 shows the emission spectra of laser $L1$. The spectrum (a) was observed before long-term operation and (b) was observed after operating continuously for 187 h, showing no significant change in spite of the change in the fluctuation spectra. In the emission spectrum (c) after 497-h operation, another longitudinal mode family appeared. However, no drastic change in the intensity fluctuations was found at this stage of degradation. This may indicate that there is no large correlation between the change of the intensity fluctuations and the emission spectra within the limits of this experiment.

IV. Discussion and Conclusion

The change in the intensity fluctuations after degradation is the decrease of the relative noise due to the quantum shot noise, and in some cases self-pulsation occurs due to the formation of the absorption region. Since the occurrence of self-pulsation has already been discussed, let us discuss the change in the relative noise due to the quantum shot noise in this section.

Yonezu *et al.* [3] considered the dark line in a degraded laser as a fast nonradiative recombination center, and investigated the quantitative relation between the number of dark lines in a laser cavity and degraded lasing characteristics such as threshold current and external differential quantum efficiency. Little or noninverted population of the minority carriers is achieved in the dark line due to the fast dissipative nonradiative process in the degraded region, which makes the gain of the region low or even absorptive.

Morgan and Adams [15] calculated the noise spectrum of single-mode junction lasers generated by the quantum shot noise by assuming homogeneous gain and photon distribution in the cavity. We have examined the effect of degradation on the fluctuation spectra on the basis of their calculation by changing the parameter, internal quantum efficiency η, as a most fundamental result of dark line formation [16]. Values of the parameters used in this calculation are [15]: temperature 320 K; rate coefficient containing the matrix element for

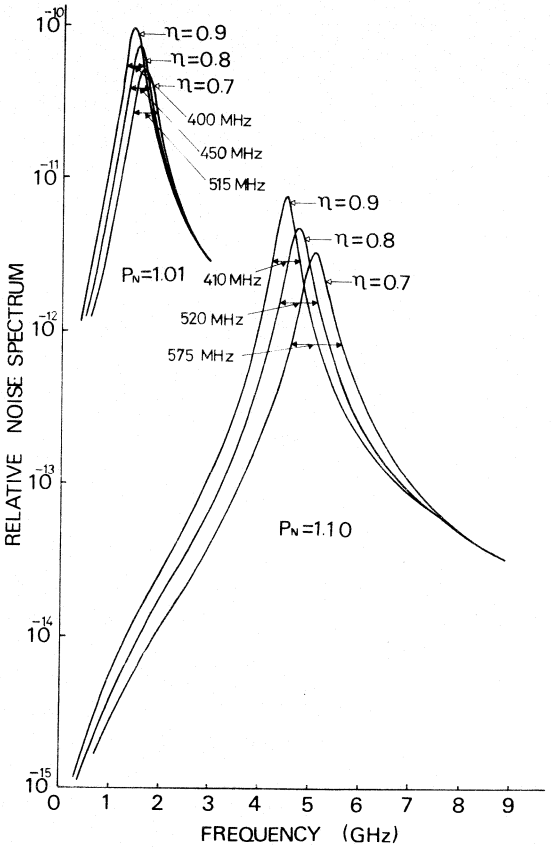

Fig. 8. Calculated intensity-fluctuation spectra of a semiconductor laser for the normalized pumping rates $P_N = 1.01$ and $P_N = 1.10$ with the parametric variation of internal quantum efficiency η.

lasing process 7.5×10^{-11} cm^3 s^{-1}; number of modes per unit energy per unit volume 9×10^{26} erg^{-1} cm^{-3}; volume of the active region 10^{-9} cm^3; effective mass for electrons in the conduction band 6.37×10^{-29} g; effective mass for holes in the valence band 4.55×10^{-28} g; and photon lifetime 10^{-12} s. Photon lifetime used here is the reciprocal of the rate of all the photon-annihilating processes except the process in which an electron-hole pair is created by photon absorption. This is already taken into account in the gain term of a basic rate equation. The lifetime is therefore assumed to be constant throughout the aging process.

Fig. 8 shows the dependence of the fluctuation spectra on the pumping current $P_N = I/I_{th}$ and the internal quantum efficiency η. With the same value of the internal quantum efficiency the current dependence of the fluctuations is as follows: 1) the peak frequency ν_R increases following the relation $\nu_R^2 = \alpha^2(I/I_{th} - 1)$; 2) the relative magnitude of the fluctuation decreases with increasing pumping current; and 3) the FWHM of the peak increases slightly with increasing pumping current. Let us compare these features with experimental results before degradation. Feature 1) is consistent with the experiment qualitatively, but the absolute value of ν_R in the calculation is larger than that of the experiment. This may depend on the selection of values of parameters. Feature 2) is contrary to the experiment. As discussed before [10], this may be due to long thermalization times. Feature 3) is also contrary to the experiment. With decreasing internal

quantum efficiency η from 0.9 to 0.7, the resonance peak shifts to higher frequency, the magnitude of the peak decreases, and the FWHM increases. For comparison, the change in the threshold current might be taken as a measure of degradation. The calculated threshold currents which correspond to $\eta = 0.9$, 0.8, and 0.7 are $I_{th} = 119.8$, 134.7, and 153.5 mA, respectively. The ratio is 1:1.12:1.28. The stages of degradation in the experiment are considered to be the stage of $\eta = 0.9$, $\eta = 0.8$, and between $\eta = 0.8$ and $\eta = 0.7$. As for the magnitude of the peak, there are some ambiguities in the experimental results and it is difficult to make a quantitative comparison, but qualitatively both calculated and observed magnitude decrease with increasing aging time. The value in (2) changes from $\alpha(\eta = 0.9) = 14.3$ in the first stage to $\alpha = 15.6$ GHz in the third stage. The relative change is larger than the experimental results, but the descrepancy is not so large. The FWHM increases by 20 ~ 30 percent in the calculation and increases by 100 ~ 200 percent in the experiment. Taking into account the roughness of the model, qualitatively the calculated results are thought to be in reasonable agreement with experimental results.

In conclusion, experimental results observed after degradation: 1) a decrease of the magnitude of the fluctuations; 2) no appreciable shift in the resonant peak frequency for the normalized pumping current; and 3) an increase of the FWHM of the resonant peak, can be qualitatively explained from a decrease of internal quantum efficiency after degradation in the quantum shot-noise model.

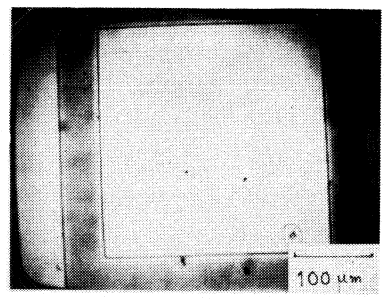
Degradation Sources in GaAs–AlGaAs Double-Heterostructure Lasers

RYOICHI ITO, HISAO NAKASHIMA, MEMBER, IEEE, SEIGO KISHINO, AND OSAMU NAKADA

Abstract—Several sources of the dark-line defect (DLD) that causes rapid degradation of GaAs–AlGaAs double-heterostructure (DH) lasers have been identified by means of photoluminescence (PL) topography and a laser-induced degradation technique. All the sources that have been identified correspond to crystal defects, among which dark-spot defects (DSD) that are native to as-grown wafers are found to be most important. The growth and propagation processes of DLD's and DSD's have also been investigated. These defects are found to be highly mobile under high-intensity laser pumping. The correlation between the substrate dislocations and the DSD's has been examined by etching and X-ray topography. Although most DSD's correspond to etch-pits in epilayers, they are not always correlated with substrate dislocations.

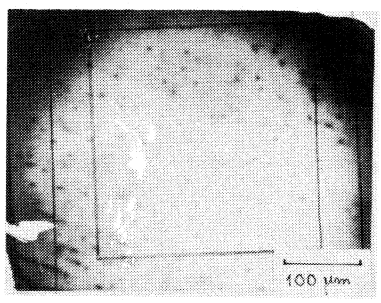
I. Introduction

IT IS NOW well established that rapid degradation of GaAs-$Al_xGa_{1-x}As$ double-heterostructure (DH) lasers is caused by the development of local regions of low luminescence efficiency, or dark-line defects (hereafter denoted as DLD) in the active layer during device operation [1]-[3]. Furthermore, DLD's have been identified as dislocation networks by a transmission-electron-microscope observation [4]. Dislocations threading through the active layer have been proposed to generate DLD's.



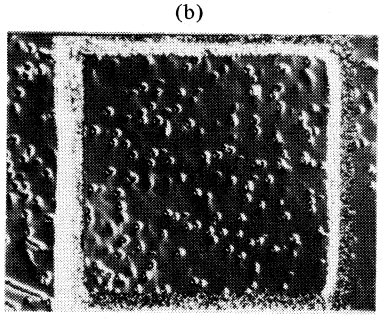
Experimentally, however, little has been reported on the sources and growth processes of DLD's. A remarkable feature of the DLD is that the ease with which it is generated is very sensitive to the location on the wafer. We have attempted to clarify the factors leading to the growth of DLD's, or more practically, which part of a wafer is susceptible to degradation. If this objective can be achieved, the yield of degradation-resistant devices should be significantly increased.

The purpose of this paper is to show that the majority of DLD's originate at crystal defects, both gross and microscopic, that can be identified by spatially resolved photoluminescence (PL) observation, or PL topography. Some new features will also be reported on the growth processes of DLD's, which may provide a new insight on the nature of DLD's.



II. Experimental

The growth processes of DLD's in DH crystals have been investigated by means of PL topography and a laser-induced degradation technique. PL topography, which has been developed independently by us [5] and Johnston and Miller [6], provides a simple, rapid, and nondestructive means of assessing the overall quality of DH wafers. The only requirement is that the pumping laser power reach the active layer: the p^+-GaAs layer normally grown to reduce the contact resistance has to be removed, and the p-$Al_xGa_{1-x}As$ layer has to be transparent to the pumping beam. The latter requirement leads to $x \gtrsim 0.5$ for the 6471-Å line of the krypton-ion laser. DH wafers employed in our experiments were composed of a Te-doped n-GaAs substrate (300-500 μm thick), a Sn-doped n-$Al_xGa_{1-x}As$ layer ($x \cong 0.5$, 5 μm thick), an undoped $Al_yGa_{1-y}As$ active layer ($y \cong 0.05$, 0.3-1 μm thick), and a Ge-doped p-$Al_xGa_{1-x}As$ cap layer ($x \cong 0.5$, 2-11 μm thick).



A variety of growth imperfections have been revealed by PL topography; an example is shown in Fig. 1 which compares

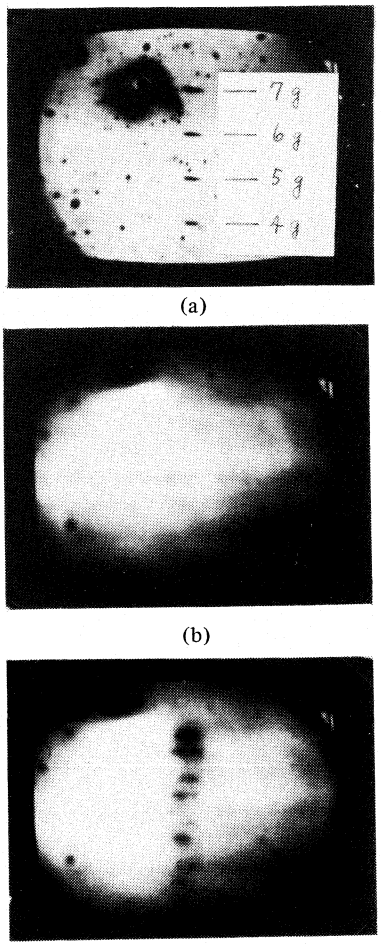
the surface of the top ternary layer, the PL pattern of the active layer, and the surface of the active layer that has been exposed by removing the ternary layer. Dark spots apparent in the PL pattern coincide precisely with physical defects localized in the active layer [5]. These physical or morphological defects can also be observed by IR transmission image and should be distinguished from microscopic defects which are more subtle in nature and more important in generating DLD's, as will be discussed later.

When the pump intensity is increased to several kilowatts/square centimeter, DLD's are often observed to grow, whether the sample is lasing or not [7], [8]. In fact, most of our experiments were done on as-grown wafers. If the carrier lifetime is assumed to be 5 ns [3], the concentration of excited electron-hole pairs is estimated to be $3.3 \times 10^{18}/cm^3$ for $d = 0.5$ μm and a pump power of 10 kW/cm^2. The temperature rise at the pumped region has been estimated to be at most 80°C at an intensity of 10 kW/cm^2. This estimate was based on the measurement of the spectral shift in homoepitaxial wafers. In the case of DH crystals, large spectral distortions, or even the peak shift to higher energies with an increase of pump power, negated any attempt to estimate the temperature rise.

The features of optically induced DLD's are so similar to those of electrically induced DLD's that there is little doubt about the identity of both the defects. This has been recently confirmed by Petroff *et al.* by TEM observation [9].



III. Results and Discussions

A. Sources of Dark-Line Defects

We have found that DLD's originate at particular sites in wafers where crystal defects exist. Dark-line sources, which we have identified, include various kinds of surface damages induced by scratches, indentations, nonuniform bonding, etc., crystal edges, stacking faults, and small dark spots observed in PL patterns of undegraded wafers. Areas free from these dark-line sources have been found to suffer little, if any, degradation. Once a DLD is generated, however, it can be propagated into any part of the wafer by moving the laser beam.

Any surface damage is almost certainly lethal with respect to long-life device operation. Relatively deep surface damage, irrespective of whether it reaches the active layer or not, causes darkening in the PL pattern instantly [10], [11]. More slight or shallow damage does not cause darkening unless the sample is highly pumped. With high-intensity laser pumping, however, DLD's are developed in the damaged area.

In order to gain more quantitative information, we have damaged a wafer with a Knoop indenter. In Fig. 2 are shown (a) the photomicrograph of a surface indented with a load of 4 ~ 7 g, (b) the undegraded PL pattern, and (c) the PL pattern after 10-min laser pumping. The top ternary layer is 11 μm thick. The longer diagonal of the indentation under a load of 8.6 g was found to be 12.9 μm. This yields a Knoop hardness value of 740 kg/mm^2. The depth of the indentation is roughly an order of magnitude smaller than the longer diagonal. As seen in Fig. 2(c), DLD's show up as doublets at every indented site. The relation between the thickness of the ternary layer and the separation of the doublet DLD suggests

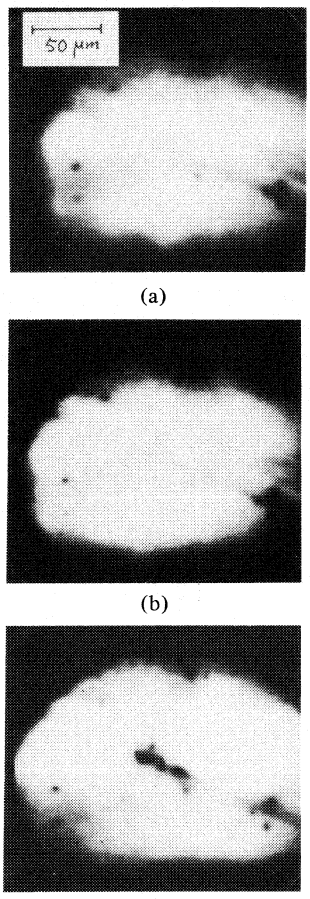
that the defects, presumably dislocations, have penetrated from the surface with an angle of 50 ~ 60°.

The fact that the ternary layer is extremely susceptible to damage is also evidenced by the observation that an Ar 4880-Å beam, which is almost totally absorbed in the ternary layer, burns holes in the surface at a power density exceeding ~10 kW/cm^2, as shown in Fig. 3. DLD's are naturally developed in the active layer, as seen in Fig. 3(b). This and other surface-damage effects could probably be explained by penetration of dislocations from the surface which is highly strained owing to the binary-ternary lattice mismatching. Obviously, we should avoid any processes that might exert local stresses at the surface [10], [11].



We have checked the effect of temperature rise on the development of DLD's in scratched wafers. In Fig. 4 are shown PL patterns of (a) an undegraded part scratched with tweezers, (b) the same region after being heated at 180°C for 10 min and then cooled to room temperature, and (c) the same region after a 5-kW/cm^2 pumping for 2 min at room temperature. The heat treatment had no effect, while the laser pumping produced DLD's rapidly. This observation indicates that high pump intensity is far more effective in generating DLD's than

is temperature rise. It is to be noted that the temperature rise of the active layer of laser diodes operated CW is normally $10 \sim 20$°C.

Stacking faults, which are observed as short-line defects oriented along ⟨110⟩ directions on (100) wafers, have been found to nucleate DLD's. A sequence of photographs shown in Fig. 5 show how a DLD is developed from a stacking fault. Under high-intensity pumping, dark spots appear at the end points, marked by the arrows *a* and *b*, of a stacking fault. They grow darker, and eventually a DLD is grown from one of the dark spots. Presumably DLD's originate at partial dislocations threading through the active layer.

We have found that some crystal edges, both cleaved and scribed, give rise to DLD's. Dislocation generation from the crystal edge is well known in silicon technology. Stress concentration as well as microdefects produced in the process of cleaving and scribing are probably responsible for the generation of DLD's. In fact, differential-interference-contrast microscopy reveals in a number of cases the existence of microsteps in the cleaved facet, particularly in epilayers, as illustrated in Fig. 6. Although the correlation between these microsteps and degradation is yet to be established, more attention should be paid to the process of preparing mirror facets.

DLD's have also been found to originate at those defects

that appear as dark spots, several micrometers in extent, observed in PL patterns of undegraded samples. A typical example is illustrated in Fig. 7, where PL patterns before and after high-intensity laser pumping are shown. In this case, DLD's in Fig. 7(b) were grown from several dark spots marked as *a–h* in Fig. 7(a). Under laser pumping, dark spots become darker, and eventually DLD's develop from these spots. Since almost all dark spots give rise to DLD's, they are considered to be the most important sources of rapid degradation, at least in our DH wafers, at the present stage.

Several attempts have been made to identify the nature of these defects. First of all, the dark-spot defects (hereafter denoted as DSD) in question are different from the dark spots as shown in Fig. 1. The latter are morphological defects caused by the imperfect epitaxial growth and can be eliminated by addition of a small amount of aluminum ($x \cong 0.01 \sim 0.05$) in the active layer [10]. It seems that a small but finite amount of thermodynamic activity of aluminum in the melt facilitates the smooth growth of the active layer on the n-type ternary layer.

A comparison was made between the PL pattern of the active layer and that of the underlying substrate. In a number of cases a good correspondence was obtained as regards the position of DSD's [8]. An etching study showed that while the majority of etch-pits correspond to DSD's, as illustrated in Fig. 8, the contrary is not always true. Furthermore, an X-ray topographic examination indicates that dislocations inherited from the substrate do not always give rise to DSD's and therefore DLD's.

These observations suggest that DSD's have several origins. Although the substrate dislocation is certainly one candidate, it is not always active. Segregated impurities and macroscopic foreign particles such as carbon powder are other possibilities. More detailed study is needed to clarify the nature of DSD's. It seems obvious, however, that the use of good substrates with low dislocation-densities and a careful control of crystal-growth processes are highly beneficial in obtaining good diodes.

B. Some Features of Dark-Line-Defect Propagation

The growth velocity of DLD's is typically $10^{-6} \sim 10^{-5}$ cm/s at a power density $\sim$10 kW/cm^2, and somewhat increases at elevated temperatures. In certain cases, fast-growing ⟨110⟩-oriented DLD's, with a velocity as high as $10^{-3} \sim 10^{-2}$ cm/s, have been observed. In such cases, minute step-lines, quite similar to slip bands observed in plastically deformed metals, can be seen on the surface of the wafer with differential-interference-contrast microscopy, as illustrated in Fig. 9. DLD's exactly corresponding to the surface step-lines are developed in the active layer.

Some DSD's have been observed to move along ⟨110⟩ directions under high-intensity laser pumping. Fig. 10 illustrates an example. DSD's marked as $a \sim d$ have changed their position and contrast as a result of a short-period (several seconds) pumping. The velocity is very fast, on the order of $10^{-3} \sim 10^{-2}$ cm/s. This observation clearly indicates that dislocations are involved in these DSD's.

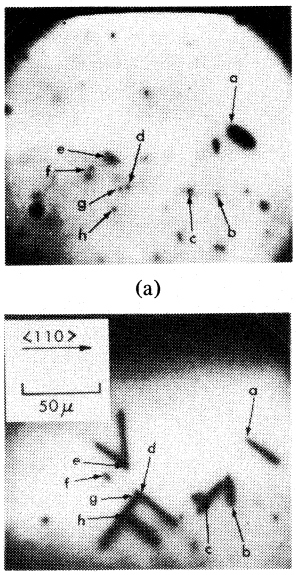

Fig. 7. DLD generation from DSD's that are native in as-grown wafers. (a) PL pattern before degradation. (b) PL pattern after laser pumping.

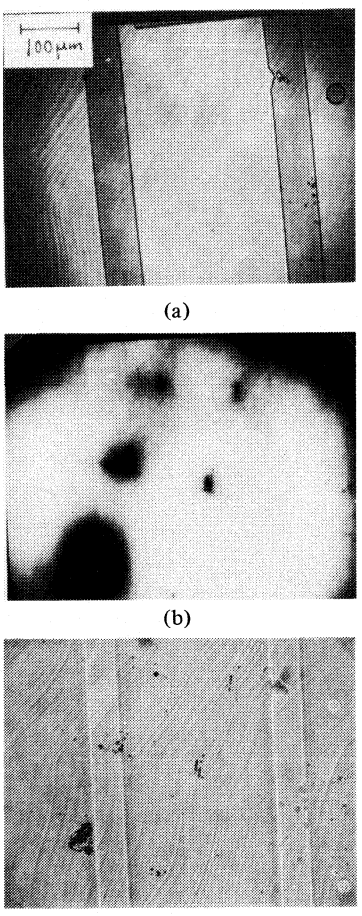

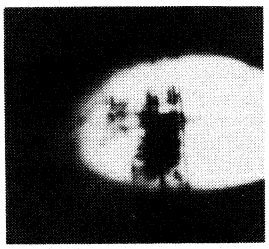

Fig. 8. DSD's and etch-pits. (a) Surface of a DH crystal. The stripes are oxide overlays. (b) PL pattern of the active layer. (c) Etch-pits in the epilayer revealed by the *AB*-etchant [17].

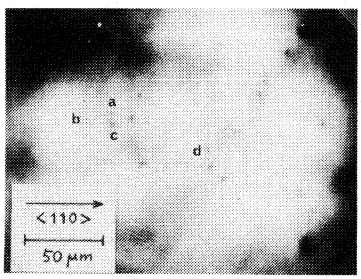
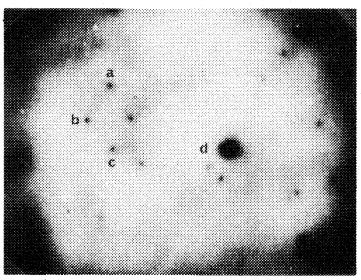


(a)



(b)

(c)

Fig. 10. Movement of DSD's under high-intensity laser pumping. (a) Initial PL pattern. (b), (c) PL patterns after pumping for several successive seconds.

The contrast of a DLD depends on the pump intensity and pump time. The observation that the DLD becomes darker as the pumping is continued suggests that the DLD has an internal structure, consistent with the three-dimensional dislocation-network structure as revealed by TEM study [4].

The previous observations indicate that both climb and, possibly, glide processes of dislocations are responsible for the DLD propagation. The remarkably high velocity of the DLD propagation and the motion of DSD's is puzzling [12], even if account is taken of the misfit-induced stresses [13].

Quite recently, DLD's and DSD's similar to those in the DH crystal were observed in electrically pumped single-heterostructure and homoepitaxial crystals [14]; also in optically pumped GaP crystals [15]. In view of these facts, we are inclined to regard the DLD generation as a rather prevailing phenomenon in III-V semiconductors. The unusually high mobility of dislocations and the very rapid climb in the presence of high-density carriers should be studied in more detail not only from the viewpoint of device physics but also from that of dislocation theory.

IV. Conclusions

Various sources of DLD's in GaAs-AlGaAs DH lasers have been identified by means of PL topography and a laser-induced degradation technique. Degradation sources that have been identified include various kinds of surface damages, crystal edges, stacking faults, and DSD's observed in PL patterns of undegraded wafers. All these sources are considered to involve dislocations [18]. Some DSD's are dislocations inherited from the substrate, while others are created only in the epilayers. Although not all the substrate dislocations are active as degradation sources, the use of low-dislocation-density substrates tends to provide a higher yield of long-life devices.

Under high-intensity pumping, some DSD's move with unusually high velocities, and DLD's grow with unexpected rapidity. The mechanisms of the dynamical behaviors of these defects are not yet understood.

Although PL topography has proved to be very useful in evaluating three-layer DH crystals, it cannot be applied straightforwardly to the four-layer structure that is normally employed in CW lasers. However, the improved mesa-stripe geometry that we have developed [16] is amenable to PL inspection, since in this geometry mesa-etching is stopped halfway in the p-type ternary layer and thus the active layer beneath the etched region can be inspected by PL topography.

This selection method and other improvements in fabrication processes have resulted in the increased yield of obtaining devices that have a CW life exceeding 1000 h. In order to obtain a CW life exceeding, say, 10 000-h reproducibly, it is felt that degradation mechanisms other than the DLD should be intensively investigated.

Degradation in Injection Lasers

G. R. WOOLHOUSE

Abstract—**The climb networks to be expected in an injection laser through 1) electromigration and 2) thermomigration are considered. It is shown that a model involving electromigration and dislocation pipe diffusion can explain the experimental results [1], [2], [7]. It is predicted that thermomigration may be important in optically pumped devices. It is further shown that elastic strain, *per se*, cannot be responsible for the degradation.**

Where numerical reduction is appropriate, parameters of the GaAs-$Ga_{1-x}Al_xAs$ system are used. The activation energy for pipe diffusion in GaAs is estimated to be 0.75 eV and the process is believed to be controlled by the diffusion of arsenic vacancies.

I. INTRODUCTION

THE short lifetime of CW-operated GaAs-$Al_xGa_{1-x}As$ injection lasers is a problem that has stimulated much recent interest [1]-[5]. The degradation is associated with the appearance of dark-line defects (DLD's) in electroluminescent patterns of the operating device. Despite much speculation, the nature of the DLD remained a mystery until Petroff and Hartman [1] showed by transmission electron microscopy that it was due to the development of a densely packed dislocation network extending through the active region of the device and into the neighboring Al-rich regions. It was apparent that the network originated from a single threading dislocation (one passing through all the epitaxial layers from the substrate to the epilayer surface). In addition, Petroff and Hartman [7] reported that the loops present within the network were of the *vacancy* type, i.e., formed by the precipitation of vacancies on the threading dislocation. However, more recent results due to Hutchinson *et al.* [2] indicate that the networks are basically of the *interstitial* type although some vacancy loops were found due to a pinching-off process within the body of the network. These apparently divergent results can be brought into concordance by assuming that the loops examined by Petroff and Hartman were formed by a pinching-off process within the body of an otherwise interstitial-type network as proposed by Hutchinson *et al.* In any event, both sets of observations rule out the possibility that the dislocations in the network are generated solely by

Manuscript received December 26, 1974; revised January 29, 1975.

The author is with the IBM Thomas J. Watson Research Center, Yorktown Heights, N.Y. 10598.

the action of a stress (glide) and indicate that climb is operative. In the absence of large stresses this process necessitates diffusion (a very slow process in GaAs at room temperature [6]). It is therefore, at first sight, surprising that the networks develop so rapidly (typically, within a few hours).

The purpose of this paper is to show how the development of dislocation networks such as those observed by Petroff and Hartman [1] and Hutchinson *et al.* [2] can be accounted for semiquantitatively. The model presented invokes the mechanism of *pipe diffusion* and the phenomenon of *electromigration* (EM). Effects of *thermomigration* (TM) are also considered. Unfortunately, certain parameters for these processes in GaAs are not known accurately. The theory can therefore only be shown to be plausible at this stage.

II. Point-Defect Sources and Migration Forces

To account for the extensive climb of a threading dislocation it is necessary to understand the source of the point defects (whether vacancies or interstitials). Petroff and Hartman [7] invoke the existence of a quenched-in vacancy supersaturation associated with the epilayer interfaces, whereas Hutchinson *et al.* [2] believe that there exists a quenched-in supersaturation of free interstitials in doped GaAs. It is the central theme of this paper that a dislocation is induced to climb at points along its length where *divergences* of the *atomic flux due to pipe diffusion* exist. There are two cases to consider.

Case 1: The divergence is such that a *supersaturation* of vacancies arises at some point in the dislocation pipe. The dislocation is forced to climb at that point to return the vacancy concentration to its equilibrium value thus creating a *vacancy*-type network, i.e., the excess vacancies are *absorbed* by the dislocation.

Case 2: The divergence is such that a local *undersaturation* of vacancies arises at some point in the dislocation pipe. It is then forced to climb creating an *interstitial*-type network, i.e., vacancies are *emitted* by the dislocation in an attempt to bring the local concentration back up to equilibrium. These processes are shown schematically in Fig. 1 for a threading dislocation (taken to be pure edge for the sake of simplicity).

Friedel [18, p. 107] has an expression for the *climb force* which for a pure-edge dislocation reduces to

$$F_c = \frac{kT}{b^2} \ln\left(\frac{c}{c_0}\right) \tag{1}$$

where

- b Burgers vector of the dislocation;
- c actual vacancy concentration in the neighborhood of the dislocation;
- c_0 equilibrium vacancy concentration in the neighborhood of the dislocation.

Case 1 corresponds to $c \gg c_0$: the climb force is large and positive and acts to decrease the area of extra half-plane. This is consistent with Thompson and Balluffi's [41] definition of *positive climb*.

Case 2 corresponds to $c \ll c_0$: the climb force is large and negative and acts to increase the area of extra half-plane. This is consistent with Thompson and Balluffi's definition of *negative climb*.

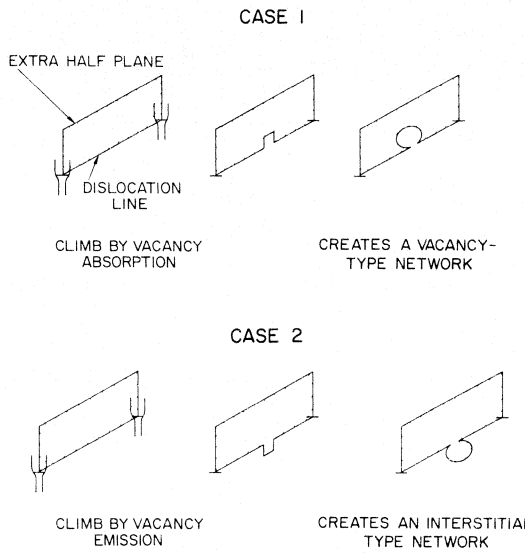

Fig. 1. Dislocation climb due to vacancy supersaturation (Case 1) and vacancy undersaturation (Case 2). See text for further explanation.

In this paper the existence of such divergences is sought and found to be an *intrinsic* function of the operation of the device rather than being dependent upon the *thermal history* of the epitaxially grown material [2], [7]. It is not hereby claimed that point-defect supersaturations do not preexist in laser material, but merely that their preexistence is not required for the development of climb networks.

III. Electromigration (EM)

Whenever an electric current flows in a material it is accompanied by a flow of atoms. This phenomenon, EM [8], [9] is due to two driving forces.

1) Electrostatic Drive: This is the force acting on the ions due to the electric field analogously to the force acting on the ions in an electrolytic cell. This always acts to drive the positive ions in the direction of the electric field and has the same sense on a given ion in p-type as in n-type material.

2) Carrier-Wind Force: This is a frictional force acting on the atoms of a solid due to the motion of the charge carriers. For the sake of simplicity we will consider the forces acting on vacancies. An analogous argument could easily be constructed for interstitials. In n-type material the carriers (electrons) flow opposite to the applied electric field and hence the atoms are also forced in this direction. Thus vacancies are forced parallel to the electric field. In p-type material, on the other hand, the carriers (holes) flow parallel to the electric field, forcing vacancies opposite to the applied electric field. This argument was apparently first given by Fiks [11] and extensive experimental confirmation of it has been reported in the Soviet literature on Si, Ge, and InAs [34]-[40]. In addition, this reversal effect, which is summarized in Fig. 2, has been observed for Cu and Li impurities in GaAs by Boltaks and Dzhafarov [10]. Carrier-wind effects are expected to become important in semiconductors when the carrier concentration reaches the 10^{17}-10^{19}/cm^3 range [11]. Laser material for electrically pumped de-

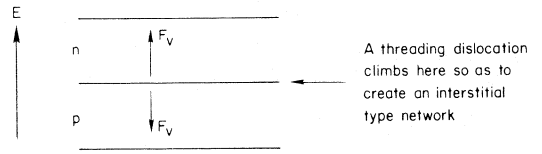

Fig. 2. Vacancy driving forces due to carrier-wind effects (electromigration) at a p-n junction operated in forward bias.

vices is usually doped to these levels so that we anticipate that carrier-wind effects will be important. In the case of a forward-biased p-n junction illustrated in Fig. 2, carrier-wind effects lead to a net flux of vacancies away from the junction and thus to the development of an *interstitial-type network* (Case 2). This is consistent with the experimental results as discussed in Section I.

It is usual to combine both electrostatic drive and carrier-wind effects by writing the complete force for EM as

$$F_{EM} = Z^* e \rho j \tag{2}$$

where

Z^* effective atomic number of a moving ion;
e electronic charge;
ρ the resistivity of the material in question;
j the current density.

All these parameters are known in the GaAs-$Ga_{1-x}Al_xAs$ system except for Z^* which has not been measured for vacancies as far as the author is aware. However, to predict the rate of climb of the dislocation we need ΔZ^*, the change in Z^* across the p-n junction. In general this will be a function of the carrier concentrations in the p- and n-regions and also possibly the temperature. According to the data of Boltaks and Dzhafarov for Cu in GaAs, its value lies in the neighborhood of 0.47 at 820-830°C, which, fortuitously, is identical to the value obtained by Rembeza [40] for Au in InAs at 520-670°C with $1.6 \times 10^{17}/cm^3$ carriers in the n-region and $3 \times 10^{19}/cm^3$ carriers in the p-region. Although the data of Sterkhov and Pavlov [38] indicate that ΔZ^* for self-diffusion may be larger than this, we will take $\Delta Z^* \simeq 0.5$. Typical values for some of the other parameters in (1) are: $\rho = 0.2\ \Omega \cdot$ cm (Ge-doped $Ga_{0.7}Al_{0.3}As$, $n = 5 \times 10^{17}/cm^3$) [12] and $j = 2 \times 10^3$ A/cm^2 (typical threshold current density) [13]. Thus $\Delta F_{EM} \simeq 1.2 \times 10^2$ eV/cm, where ΔF_{EM} is the change in driving force across the junction. This result will be used later to evaluate the rate of climb.

IV. Thermomigration (TM)

The active region of a laser is hotter than anywhere else since this is where electron-hole recombination takes place, and a substantial fraction of this recombination is nonradiative. Because of the need to conduct this heat away, temperature gradients exist in the device which can give rise to vacancy driving forces. The force for TM [9], [14] is

$$F_{TM} = -\frac{Q^*}{T}\frac{dT}{dZ}. \tag{3}$$

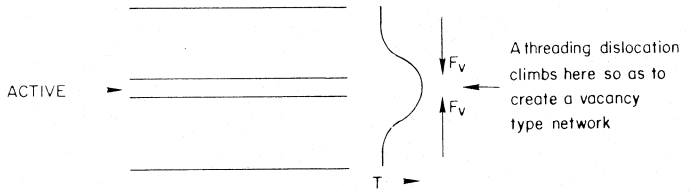

Fig. 3. Schematic temperature distribution and vacancy driving forces due to thermomigration in an injection laser. Q^* is assumed to be positive (see text).

Here, dT/dZ is the temperature gradient, T the temperature, and Q^* is the heat of transport.

The sense of F_{TM} is such that if Q^* is positive (which it is in most materials for which data exist [30]), matter is driven down the temperature gradient, and vacancies are driven into the active region from both sides. This is shown schematically in Fig. 3. It should be emphasized, however, that the vacancies are not merely driven in order to reestablish the equilibrium vacancy concentration in the active region—the driving force persists as long as the heat flow exists.

In order to evaluate (3) numerically we need to know the active-region temperature rise. The literature values for this are somewhat variable, running from 5°C to 50°C [3], [13], [15]. The average figure of 30°C is still unreasonably high by present standards for a well-heat-sunk electrically pumped device, but it is not believed to be an overestimate for optically pumped material. Using this figure we can calculate the temperature gradients in the device using values for the thermal conductivity of GaAs and $Ga_{0.7}Al_{0.3}As$ measured by Afromowitz [16]. Taking 0.7 μ and 1.0 μ for the thicknesses of the p-$Ga_{0.7}Al_{0.3}As$ and p-GaAs layers, respectively, we find the temperature gradient across the p-$Ga_{0.7}Al_{0.3}As$ layer to be a maximum because its thermal conductivity is a minimum. It has the value 3×10^5°C/cm under these conditions. If in addition we take Q^* for GaAs to be 1 eV (this has not been measured, but is a reasonable guess based on the values measured for other materials [30]), we obtain

$$\Delta F_{TM} \simeq 2 \times 10^3 \text{ eV/cm}$$

where ΔF_{TM} is the change in driving force across the active region. It is likely that TM will give rise to the development of *vacancy-type* networks (Case 1) although this depends on the assumption of a positive Q^*. It is anticipated that it will be important in optically pumped devices. It should be pointed out that the thermal gradients in an optically pumped heterojunction device arise from the fact that the absorption coefficient for the pumping light is much higher in the active region than in the bounding Al-rich layers. As the optical absorption is roughly uniform throughout a homojunction laser we would not expect it to degrade rapidly. Petroff *et al.* [31] have reported that optical pumping does not result in network formation in *homo*junctions while it does in *hetero*junctions. In addition, they reported that the networks developed are of the vacancy type consistent with the reasoning just presented, although they did not appear to determine this directly. Lastly, it should be mentioned that homojunction devices

are expected to degrade by DLD formation when electrically pumped as has been observed [29].

V. Elastic Strain

Another factor which has been invoked to explain the development of climb networks is elastic strain. This arises during the epitaxial growth of a layer on a substrate when there is misfit between the lattice parameters of overgrowth and substrate. The misfit can be accommodated in two ways: coherently or incoherently. In coherent accommodation there is perfect continuity between lattice planes of overgrowth and substrate and the misfit manifests itself in a bowing of the resultant wafer. In incoherent accommodation the misfit is taken up by regular arrays of misfit dislocations at each interface. For an up-to-date review of the subject of misfit dislocations see Matthews [43]. In both coherent and incoherent cases elastic strains exist in the wafer, and it is instructive to examine whether these strains can give rise to point-defect driving forces. To do this we have recourse to elasticity theory and write for the interaction energy between a vacancy and an elastic stress field σ_{ij}

$$E_{\text{int}} = - V_v \delta \sigma_{mm}. \tag{4}$$

Here V_v is the volume of a vacancy, δ is a parameter describing the relaxation around a vacancy (equal to one-third of the change of volume associated with it), and σ_{mm} is the trace of the stress tensor σ_{ij}. Thus the force on a vacancy is

$$F_{el} = - \frac{\partial E_{\text{int}}}{\partial z} \tag{5}$$

where z is taken normal to the epitaxial layers. The stress gradient can be estimated from the bowing of the wafer

$$\frac{\partial \sigma_{mm}}{\partial z} = \frac{6K}{R} \left(\frac{1 - 2\nu}{1 - \nu} \right). \tag{6}$$

Here K is the bulk modulus, ν is the Poisson's ratio, and R is the radius of curvature of the wafer; we have ignored local inhomogeneities in wafer composition. Taking

$V_v = 3.3 \times 10^{-23}$ cm^3 (estimated from [17])
$\delta \simeq 0.03$ (a typical value—see Friedel [18, p. 80])
$K = 7.5 \times 10^{11}$ dyn/cm^2 (from Brantley [19])
$\nu = 0.31$ (from Brantley [19])
$R = 7$ m (Rozgonyi *et al.* [20])

we find $F_{el} \simeq 2 \times 10^{-3}$ eV/cm.

There are two points to make about this result. The first is that it is a uniform force driving vacancies from the epilayer surface to the substrate—there are no divergences associated with it. Secondly, its magnitude is at least five orders of magnitude less than the migration forces discussed earlier.

Although with the epilayer thickness usually chosen, GaAs-$Ga_{1-x}Al_xAs$ lasers almost certainly have coherent interfaces, the case of incoherent interfaces will also be discussed here for the sake of completeness. A practical example is that of devices prepared from $In_xGa_{1-x}As$ on GaAs substrates which apparently do have incoherent interfaces [21]. One can say the following: the elastic stresses vanish at points farther from the interfaces than the misfit-dislocation spacing. Making certain simplifying assumptions about the nature of the misfit dislocations and using the known stress fields around them, one can evaluate the vacancy driving forces. We find that the forces are significant only very close to (within about 50 Å of) the misfit-dislocation core. Moreover, they fall off very rapidly (with the reciprocal of the square of the distance) in and away from the interface. Compared with the migration forces discussed earlier they can safely be neglected.

VI. Mode of Point-Defect Transport

It is possible to estimate the actual rate of accumulation of point defects in a degrading laser from Petroff and Hartman's published pictures [1]. They found that the dislocations in the network lay in the (001) plane. Thus the number of point defects in the network can be found by dividing the total area of the loops and dipoles by the cross-sectional area of a point defect. Taking 10^{-15} cm^2 for this [17], and 100 h for the degradation time, we arrive at a point-defect accumulation rate $\simeq 3 \times 10^3$/s, a value which cannot be accounted for by bulk diffusion alone: a simple calculation using the most recent values for the self-diffusion coefficient for Ga vacancies [6] predicts a point-defect accumulation rate which is 19 orders of magnitude too small.

The most likely explanation for the observed dislocation network development is that it is due to *pipe diffusion* along the threading dislocation. This is a phenomenon which has been fairly well studied in metals [22] and has also been observed in semiconductors [23]-[25]. Briefly, what happens in pipe diffusion is that the disordered material in the neighborhood of a dislocation permits much faster diffusion than in the bulk. Activation energies much smaller than in the bulk are found. To estimate the effect of this, it is usual to assume that the vacancies move in a "pipe" typically one or two atomic spacings in diameter.

We can calculate the activation energy for pipe diffusion (U_p) necessary to explain the observed point-defect accumulation rate (PDAR) as follows:

$$\text{PDAR} = D_0^p \exp\left(- \frac{U_p}{kT} \right) \cdot \frac{A_D}{V_v} \cdot \frac{\Delta F}{kT}. \tag{7}$$

In (7), PDAR is the point-defect arrival (or departure, in Case 2) rate at the point of divergence of the flux, and is obtained from the Einstein relationship for the drift velocity of a diffusing species due to a driving force. The velocity is multiplied by the cross-sectional area of the dislocation pipe A_D, and the concentration of vacancies in the pipe to give PDAR. The vacancy formation energy in the pipe is combined with the vacancy motion energy in the diffusion coefficient of a single defect in the pipe to give U_p, the activation energy for self-diffusion in the pipe. D_0^p is the preexponential factor in the pipe diffusion coefficient, ΔF is the change in driving force at the point of divergence, and the other quantities have their usual meanings.

We now assume that D_0^p is equal to the bulk value (examination of Balluffi's data for fcc metals shows that on the average this is a reasonable approximation). However, we are in a dilemma as to which species controls the diffusion rate: Ga or As vacancies. Examination of the data of Chiang and Pearson [6] indicates that the diffusivity of As vacancies is 31 orders of magnitude smaller than the diffusivity of Ga vacancies at room temperature. Since the process will be controlled by the slower diffusing species, it seems logical to take D_0^p equal to the preexponential factor for the diffusivity of As vacancies.

We can equate PDAR to the observed value (3×10^3/s) and set

$$\Delta F = 1.2 \times 10^2 \text{ eV/cm } (\Delta F_{EM})$$

$$A_D = 5.5 \times 10^{-15} \text{ cm}^2$$

$$D_0^p = 7.9 \times 10^3 \text{ cm}^2/\text{s for As vacancies [6]}.$$

We find $U_p = 0.75$ eV.

The activation energy for pipe diffusion is about one-fifth of the corresponding bulk value [6]. This ratio is low, but not totally unreasonable (Balluffi [22] reports values for this ratio between 0.4 and 0.7, and a value as low as 0.3 has also been reported [26], although these data relate only to fcc metals. There appears to be a shortage of equivalent data for semiconductors). In addition, the value of 0.75 eV is in good agreement with the value of the activation energy for degradation of GaAs light-emitting diodes (LED's) [32] (0.8 eV). Such precise agreement must be considered fortuitous at this stage, in view of the uncertainty about some of the parameters of the theory. Furthermore Hartman *et al.* [33] have obtained a value of 0.93 eV for the activation energy for degradation of GaP LED's. Thus it seems that the rate of DLD growth can be explained with this model, assuming reasonable values for the parameters. However, it is instructive to determine how sensitive the derived value of U_p is to some of these parameters. The DLD growth time was taken to be 100 h which seems to be a reasonable average figure for the lifetime of a laser failing by DLD formation. In fact, the derived value of U_p is relatively insensitive to the assumed value of the DLD growth time: it is 0.69 eV if the growth time is 10 h and 0.81 eV if it is 100 h. U_p varies with the assumed value of D_0^p in a similar manner.

Additional support for an EM model of the kind developed here lies in the experiments of Newman and Ritchie [27]. They found that the rate of degradation of heterojunction devices increased with the current density at the same rate, independent of whether the current was below or above the threshold value for lasing action, indicating that the degradation may be a purely electrical effect in this case, independent of the optical density in the device.

This model provides an alternative rationalization of the experimental data of McMullin *et al.* [13]. They found that lasers whose active regions were doped with Sn and Te degraded very much faster than those with active regions doped with Si and Ge. Kirkby [42] has argued on the basis of strain energy considerations that the tendency for dopant segregation to a dislocation would be greater in the case of Sn and Te than in the case of Si and Ge. Thus, in the former case, carrier-wind effects would be enhanced and ΔZ^* would be bigger, causing more rapid degradation.

This model also offers a possible explanation for the degradation of homojunction lasers [28] and LED's [29].

VII. Conclusions

1) EM and TM both can give rise to point-defect driving forces which are adequate to explain the observed development rates of climb networks.

2) EM probably predominates in well-heat-sunk electrically driven devices, and is predicted to give rise to interstitial-type networks consistent with the experimental evidence [1], [2], [7], as discussed in Section I.

3) TM is probably important in optically pumped devices, and is predicted to give rise to vacancy-type networks, consistent with a reported experimental observation [31]. This conclusion depends upon the assumption that Q^* is positive.

4) Elastic strain gives rise to driving forces many orders of magnitude less than migration effects.

5) The activation energy for pipe diffusion of vacancies in GaAs is estimated to be about 0.75 eV.

Acknowledgment

The author wishes to thank Dr. P. S. Ho and also various members of the IBM CW injection-laser group for useful discussions. Thanks are also due to Dr. P. W. Hutchinson, Dr. P. S. Dobson, and Dr. D. H. Newman for useful discussions and for access to their paper prior to publication. Particular thanks are due to Dr. A. W. Smith and Dr. J. C. McGroddy for advice and encouragement. The reviewers are to be thanked for pointing out some errors and numerous obscurities.

Dislocation Pinning in GaAs by the Deliberate Introduction of Impurities

P. A. KIRKBY

Abstract—Recent work has shown that the primary cause of rapid degradation in GaAs-(GaAl)As lasers is the propagation of dark-line defects which originate at threading dislocations present in the as-grown material.

This paper considers the effect of first-order elastic interactions between dislocations and deliberately added impurities, such as the commonly used dopants and group III or V impurities. Strongly interacting impurities tend to concentrate preferentially around dislocations in positions where they relieve stress, thus forming an impurity cloud. Subsequent movement of the dislocation then becomes energetically unfavorable. For impurities such as In, Sb, and N the pinning forces can be as large as 10^{10} dynes/cm^2.

It seems likely that this type of dislocation pinning can be used to eliminate or greatly reduce the probability of a threading dislocation initiating a dark-line defect.

Introduction

RECENT WORK on [1]-[3] degradation in GaAs-(GaAl)As double-heterostructure lasers has shown that one of the primary degradation mechanisms results from the rapid movement and elongation of dislocations that thread the active layer of the device. The dislocations involved move at velocities of at least 10^{-7} cm/s, despite the fact that the average temperature of the active region is below 50°C. Dislocations are not normally mobile in GaAs at such a low temperature because of the high Peierls stresses resulting from the covalent bonding of GaAs. A temperature of over 200°C and stresses of over 10^8 dynes/cm^2 are needed to produce glide velocities greater than 10^{-7} cm/s [4], [5], the velocity being strongly dependent on dopant type. The dislocations have been found to move predominantly by climb rather than glide. Thus point defects must be intimately related to this process.

In many metals dislocations can be immobilized by the deliberate introduction of impurities. For instance, the hardness of aluminium is greatly increased by the introduction of impurities such as Si, Fe, Cu, and others [6]. This paper discusses the possibility of pinning dislocations in double-heterostructure lasers by the use of similar interactions. This would then eliminate the rapid degradation of lasers containing threading dislocations. The magnitude of the pinning force that results from the addition of various impurities at concentrations which will not deleteriously affect laser performance is calculated. It appears that certain group III or V impurities such as In, Sb, and Tl are the most suitable for this purpose. The pinning force resulting from their elastic-misfit interaction with dislocations will resist stresses approaching 10^{10} dynes/cm^2.

Dislocation-Impurity Interactions

Any interaction between an impurity and a defect such as a dislocation will alter the equilibrium impurity concentration c around the dislocation with respect to its concentration c_0 at a large distance from the dislocation. If the total interaction energy at any point is E_t, then the equilibrium concentration c of the impurity at that point, provided the solid solution is dilute, is given by the Boltzmann equation

$$c = c_0 \exp(-E_t/kT). \tag{1}$$

There are many contributions to the total interaction energy E_t between an impurity and a dislocation. Fiore and Bauer [6] describe the components of the total interaction that result from elastic misfit, elastic modulus, electrical, chemical, and other forces. Bullough and Newman [7] show that in silicon and germanium the elastic-misfit interaction is by far the most significant in all cases except when the impurity atom is of very similar radius to the host lattice atom for which it substitutes. Electrical interactions [6], [7], which result from interaction between a charged impurity atom and the electrical field of a dislocation may be significant for dopant impurities at a low temperature. However, when considering the uncharged group III or V impurities in GaAs we can ignore the electrical interaction. Let us therefore consider the elastic-misfit interaction between an impurity and the common 60° dislocation in GaAs.

Impurity Distribution Around 60° Dislocation

The energy of the elastic-misfit interaction between a 60° dislocation in GaAs and an impurity atom of radius R is given by [8, pp. 462–465]

$$E_i = \frac{\beta \sin\theta}{r} \tag{2}$$

where

$$\beta = \frac{4}{3}\frac{(1+\nu)}{(1-\nu)}\mu b_e R_0^3 \epsilon$$

where r and θ define the position of the impurity atom;

- ν Poisson's ratio is 0.3;
- μ Voight average shear modulus [8, pp. 398–405] is 4.9×10^{11} dynes/cm^2;
- b_e edge component of Burger's vector is 3.5 Å;

R_0 radius of host-lattice atom for which impurity substitutes;
ϵ $= (R - R_0)/R_0$.

Thus, assuming that the elastic-misfit interaction is dominant, the impurity concentration around the dislocation is given by

$$c \simeq c_0 \exp(-\beta \sin\theta / rkT). \tag{3}$$

These equations, which assume linear elasticity theory, break down very close to the core of the dislocation where the stresses are so large that the atomic displacements are an appreciable fraction of the interatomic distances. It is usual to assume that the interaction energy limits at a maximum value $E_{i\max} \simeq |\beta/b|$. The value of the interaction coefficient β, which is directly proportional to the impurity misfit parameter ϵ, indicates the strength of the interaction between any given impurity and a dislocation of a particular Burger's vector. As would be expected, small impurity atoms have increased concentration on the side of the dislocation containing the extra half-plane and reduced concentration on the opposite side. This is illustrated in Fig. 1. For weak interactions ($\beta/b < kT$), the increase of impurity concentration on one side of the dislocation is equal to the decrease on the opposite side so that, averaged around the dislocation, there is no net effect on impurity incorporation. For strong interactions, however, there is a net increase in the concentration of impurity atoms around the dislocation. This region of local accumulation is referred to as an impurity cloud. For strong interactions at sufficiently low temperatures the impurity concentration can reach the atomic density of the host lattice and precipitation occurs. Under these conditions it is necessary to use the Fermi-Dirac distribution to obtain the impurity concentration [8, pp. 465-468]. The linear impurity concentration along the dislocation core c_d is then given to a better approximation by

$$c_d \simeq \left(a + \frac{na}{c_0} \times \exp(-E_{t\max}/kT)\right)^{-1} \tag{4}$$

where

a separation of atoms along core of dislocation (= 4 Å);

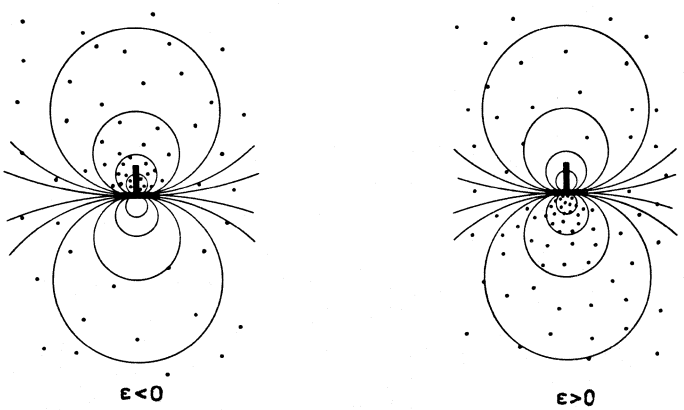

Fig. 1. The impurity distribution around an edge dislocation. The circles represent contours of constant hydrostatic pressure. Small impurity atoms ($\epsilon < 0$) concentrate on the side of the dislocation containing the extra half-plane; large atoms ($\epsilon > 0$) opposite.

n density of possible impurity sites;
$E_{t\max}$ maximum total interaction energy.

The equilibrium impurity distribution given in (3) is a strong function of temperature. Thus the impurity distribution will alter during the cool-down after growth and become "frozen in" when the diffusion coefficient of the impurity becomes low enough. Bullough and Newman [7] show that the equilibrium distribution around a dislocation is reached in a time such that $\sqrt{Dt} = 10^{-6}$ cm. For a typical impurity atom such as Sn the temperature at which the impurity concentration freezes in is 700-750°C for postgrowth cooling rates between 0.1 and 2.0°C/s. The freeze-in temperature will increase as the diffusion constant of the impurity concerned decreases or as the postgrowth cooling rate increases.

Dislocation Climb in an Impurity Atmosphere

The effect of an impurity cloud on dislocation climb involves interaction between impurities and the dislocation, and interaction between the impurities and the point defects which are absorbed or generated by the climbing dislocation. The interaction between a climbing dislocation and an impurity cloud does not appear to have been discussed in the literature, probably because climb usually occurs only at high temperatures where the impurities themselves have a high mobility. This results in an impurity drag on the dislocation but not a definite pinning action. During the rapid degradation of double-heterostructure lasers the average active-region temperature does not exceed about 50°C. Thermal calculations indicate that the actual temperature of the dislocation is unlikely to exceed 400°C at the very most [9]. Thus, under normal circumstances, group III or V impurities, which seem most appropriate for dislocation pinning, will have an extremely low diffusion coefficient. An immobile cloud formed by such impurities can produce large pinning forces against dislocation climb and glide. Let us investigate the strength of this pinning interaction.

The impurity cloud around the dislocation partially relieves its stress energy. If the dislocation is displaced by a distance y, while the impurity cloud remains fixed, then the total interaction energy per unit length increases by $W(y)$. This results in a restoring force per unit length, $F = dW/dy$, acting on the dislocation and pinning it to its initial position. This pinning force has been calculated rigorously for the case of weak impurity interactions on dislocation glide by Hirth and Lothe [8, pp. 619-620]. The maximum restoring force is given by $c_0\beta^2/b_e kT$. The pinning force has not previously been calculated for the case of dislocation climb. We present here a treatment of dislocation climb which uses a method directly analogous to that used by Hirth and Lothe for dislocation glide. The increase in interaction energy per unit length of the displaced dislocation is given by (Fig. 2)

$$W = \int_{r=b}^{\infty} \int_{\theta=0}^{2\pi} (c - c_0)\{E_T(r,\theta) - E_T(r',\theta')\}\, r \cdot dr \cdot d\theta \tag{5}$$

where the origin of the polar coordinates r and θ is the original

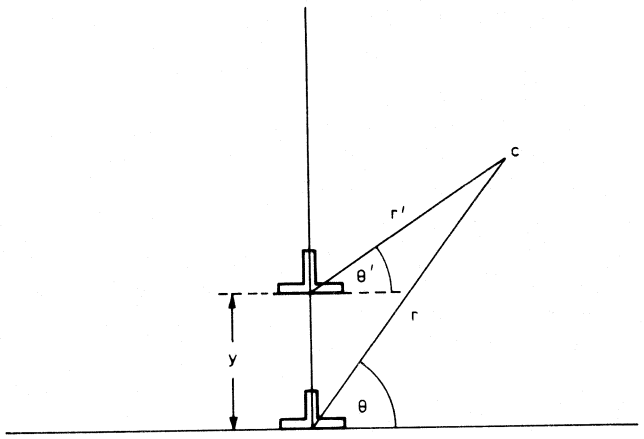

Fig. 2. Dislocation climbing in a fixed-impurity atmosphere.

position of the dislocation and the origin of r' and θ' is the new position of the dislocation, displaced by a distance y.

If the elastic-misfit interaction is dominant, then substitution from (2) and (3) gives

$$W = \int_{r=b}^{\infty} \int_{\theta=0}^{2\pi} c_0 \left(\exp \frac{\beta \sin \theta}{rkT} - 1\right) \left(\frac{\beta \sin \theta'}{r'} - \frac{\beta \sin \theta}{r}\right) \cdot r \cdot dr \cdot d\theta. \tag{6}$$

This expression cannot be evaluated analytically for the case of climb. In the case of dislocation glide, Hirth and Lothe show that a good result can be obtained by considering only the row of atoms closest to the core of the dislocation. For strong interactions the approximation is even better because $c - c_0$ decreases more rapidly with r than for weak interactions. It therefore seems reasonable to make this approximation for the calculation of the effect of strongly interacting impurities upon dislocation climb.

Consider, for example, a 60° dislocation moving by pure climb, as shown in Fig. 3(a). The dislocation illustrated is an α dislocation of the shuffle set [10]. For clarity the lattice is shown undistorted and is drawn with all the bonds in the missing half-plane stretched. The absorption of a Ga and an As interstitial, or the capture of a Ga and an As atom from the adjacent lattice with the resultant generation of a Ga and an As vacancy, moves the dislocation downwards a distance $S = a_0/\sqrt{3} = 3.2$ Å to position 1 (extrinsic). The reverse process moves the dislocation upwards to position 2 (intrinsic). The positions of the first four atoms that would be added in extrinsic climb are also shown, with their atomic bonds missing. The lattice is shown in Fig. 3(b), with the atomic bonds distorted in a more realistic manner. For strongly interacting impurities with a large atomic radius ($\beta > 0$), the row of atoms labeled A will be nearly saturated with impurity atoms at a linear density c_d. For strongly interacting impurities with a small atomic radius ($\beta < 0$), row B will be nearly saturated. The approximate coordinates of these respective rows of impurity atoms are $y = \pm S/2 \simeq \pm 1.6$ Å positive for $\beta < 0$ and negative for $\beta > 0$. Equation (6) now reduces to

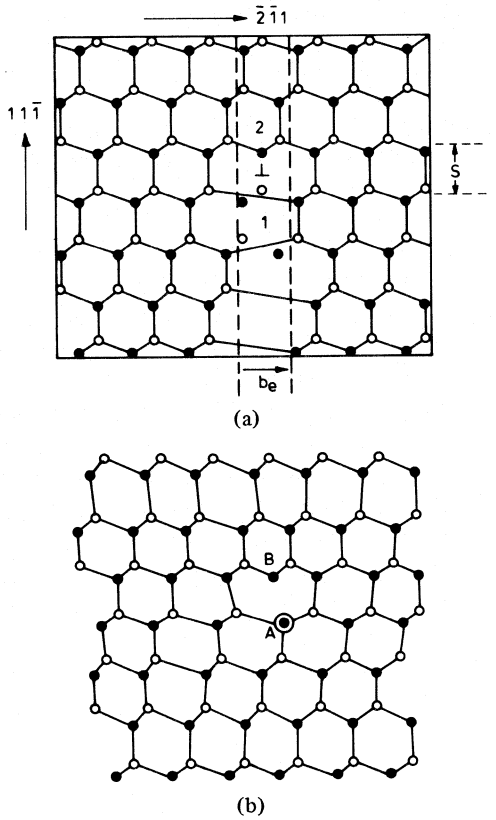

Fig. 3. (a) Pure climb of a 60° α dislocation of the shuffle type viewed along its length (011 direction). The Burger's vector is 101, hence pure climb is in the $11\bar{1}$ or $\bar{1}\bar{1}1$ direction to position 1 extrinsic or position 2 intrinsic. (b) A more realistic view of the same dislocation illustrating pinning by row A (large impurity atoms) or row B (small impurity atoms).

$$W = c_d(E_i(p) + E_{i\max}) \tag{7}$$

where $E_{i\max} = |\beta/S| \simeq |\beta/b|$, and $E_i(p)$ is the interaction energy of an impurity atom with the dislocation when they ar separated by a distance p given by $p = (S/2 - y)$ for $\beta < 0$ and $p = -(S/2 + y)$ for $\beta > 0$. $E_i(p)$ is found by substitution into (2) with $\theta = 90°$. For $|p| < S$ we will assume that the interaction limits at $\pm E_{i\max}$. The interaction changes from positive to negative between the rows of atoms on either side of the dislocation. A physically reasonable approximation to $E_i(p)$ is given by

$$\begin{aligned} E_i(p) &= \beta/p, && |p| > S \\ &= \pm E_{i\max}, && S/2 < |p| < S \\ &= 2\beta p/S^2, && |p| < S/2. \end{aligned} \tag{8}$$

Substitution of (8) into (7) then gives the distribution of W as plotted in Fig. 4(a) ($\beta < 0$, in this case). The potential distribution in the direction of climb is noticeably different from that in the direction of glide [8, pp. 619-620]. For glide the dislocation simply has to move out of a potential well. For climb, however, the dislocation not only has to climb out of a potential well, but also, in the direction of the pinning-

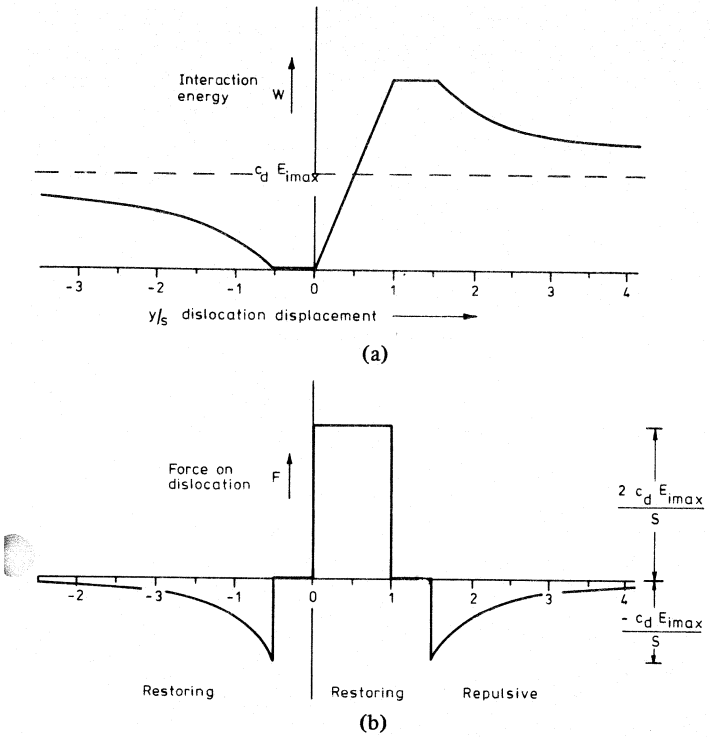

Fig. 4. Interaction between a row of pinning atoms at position $y/S = \frac{1}{2}$ and a dislocation displaced in the y direction. (a) Total interaction energy. (b) Force on dislocation.

impurity row, it has to climb over a potential barrier of equal height to the depth of the well. Until the top of this barrier is reached ($0 < y < S$), the restoring force per unit length pinning the dislocation is very large and given by

$$\frac{dW}{dy} = \frac{2c_d E_{imax}}{S}. \tag{9}$$

Once over this barrier, however, ($y > 3S/2$), there is a repulsive force per unit length given by

$$F = -c_d \beta (y - S/2)^{-2}. \tag{10}$$

For dislocation displacement away from the pinning-impurity row ($y < -S/2$) there is a restoring force per unit length again given by (10). This has a maximum value at $y = -S/2$ of

$$F_{max} = \frac{c_d \beta}{S^2} = \frac{c_d E_{imax}}{S}. \tag{11}$$

These pinning forces are very similar to those found for strongly interacting impurities in dislocation glide where the maximum pinning force is given by $F = c_d E_{imax}/b$, [8, pp. 619-620].

This reasoning assumes that the dislocation is reasonably straight. In reality the situation is more complex since the dislocation climbs by the motion of jogs [8, pp. 519-526]. Hence the forces that have been derived are only approximate.

This treatment of the pinning force will not, of course, be applicable if the point defects involved in the climb process enhance the mobility of the impurities to such an extent that the impurities move with the dislocation, despite the low temperature at which the climb is occurring. Vacancies could enhance the impurity mobility, whereas interstitials could not. It is, however, still controversial whether interstitials or vacancies [1], [2] are involved in the climb process; but even if it were vacancies, it is doubtful if the mobility of the impurity cloud would be sufficiently enhanced to destroy the pinning action.

Force on the Climbing Dislocation

Equations (9) and (11) give the maximum force resulting from impurity interaction which is capable of pinning the climbing dislocation. Peierls stresses will also contribute to the pinning of the dislocation. These result from periodic changes in potential energy as the dislocation moves between the atomic planes forming the crystal. The magnitude of the Peierls stress can be very high in covalent crystals, up to $10^{-2}\ \mu = 5 \times 10^9$ dynes/cm^2. However, this stress reduces exponentially with temperature and also reduces greatly if the dislocation is not exactly aligned with a low-index crystallographic direction [8, pp. 506-510]. It therefore may not produce significant dislocation pinning and will be neglected in this treatment. Let us assume therefore that if the impurity-pinning force alone is exceeded, then the dislocation will break away from its impurity cloud. Comparison of the pinning force with the actual force on the dislocation will determine the significance of the pinning force.

For the dislocation climb in the y direction this force per unit length is given by

$$F_y = F_{yel} + F_{yos} \tag{12}$$

where F_{yel} is the total elastic force on the dislocation in the y direction, and F_{yos} is the osmotic force on the dislocation resulting from point-defect supersaturation.

The elastic force on the dislocation includes a contribution from both the edge b_e and screw b_s components of the dislocation Burger's vector.

$$F_{yel} = \sigma_{xx} b_e + \sigma_{xz} b_s \tag{13}$$

where

σ_{xx} normal stress;
σ_{xz} shear stress.

Reinhart and Logan [10] have estimated the residual elastic stresses in the epitaxial layers of a double-heterostructure laser to be in the range $1\text{-}5 \times 10^8$ dynes/cm^2 as a result of the thermal-expansion differences between GaAs and GaAlAs. Ishida *et al.* [9] have estimated that thermal stresses resulting from local heating at the dislocation could reach 10^9 dynes/cm^2. This stress could result in a maximum force per unit length on the dislocation (13) of 35 dynes/cm.

The osmotic force on a dislocation in GaAs is a complex function of the defect distribution, as GaAs is a binary compound and there are four native point defects. Hirth and Lothe [8, pp. 201-249] treat the case of dislocation climb

by vacancy absorption in an elemental material. This can be extended to the case of GaAs as follows.

If the dislocation climbs from the origin to position y (see Fig. 2), then the number of point defects absorbed is related to the distance y that the dislocation has climbed by

$$\frac{yb_eL}{v} = n(\mathrm{As}_v) - n(\mathrm{As}_I) = n(\mathrm{Ga}_v) - n(\mathrm{Ga}_I) \tag{14}$$

where

L	length of dislocation;
v	volume of Ga + As atom;
$n(PD)$	number of point defects absorbed, a negative value corresponds to point-defect generation;
subscript v	vacancies;
subscript I	interstitials.

It is implicit in this expression that one type of point defect from each sublattice of the GaAs crystal must be involved in the climb process. The free energy liberated when a point defect is absorbed is given by the chemical potential $G(PD)$ of the point defect concerned which can be expressed as

$$G(PD) = kT \ln \frac{c(PD)}{c_0(PD)} \tag{15}$$

where $c(PD)$ is the concentration of the point defect and $c_0(PD)$ is the equilibrium concentration of the defect. Thus the total energy δG liberated as the dislocation climbs in the y direction is given by

$$\delta G = G(\mathrm{As}_v) \cdot n(\mathrm{As}_v) + G(\mathrm{Ga}_v) \cdot n(\mathrm{Ga}_v) - G(\mathrm{As}_I) \cdot n(\mathrm{As}_I) - G(\mathrm{Ga}_I) \cdot n(\mathrm{Ga}_I). \tag{16}$$

The osmotic force per unit length on the dislocation is

$$F_{yos} = \frac{\delta G}{Ly}. \tag{17}$$

Substitution of (14)-(16) into (17) gives the osmotic force on the dislocation in terms of the proportional supersaturation $c(PD)/c_0(PD)$ of the point defects concerned. For instance, if Ga_v and As_v only are involved then

$$F_{yos} = \frac{kTb_e}{v} \ln \left(\frac{c(\mathrm{As}_v) \times c(\mathrm{Ga}_v)}{c_0(\mathrm{As}_v) \times c_0(\mathrm{Ga}_v)} \right). \tag{18}$$

A similar expression can be written for any pair of point defects which might produce climb. The coefficient of the logarithm in this expresison, kTb_e/v (= 30 dynes/cm at room temperature), is the osmotic force produced in the presence of a point-defect supersaturation of e. The actual point-defect supersaturation in the vicinity of a dislocation in a laser under operating conditions is not known. Both Petroff and Hartman [1] and Woolhouse [12] have discussed the behavior. Factors of importance in determining the point-defect concentration are the thermal quenching history of the GaAs, the point-defect mobility, the elastic stresses, the electrical effects on charged point defects, and possibly the concentration of impurities. This last possibility has been discussed by McMullin *et al.* [13] who suggested that interactions between point defects and dopants might explain variations of rapid degradation rate with dopant type. The quasi-equilibrium point-defect concentration in the vicinity of the dislocation is also not known and will depend on thermal and other effects. Hence it is clearly impossible to estimate the magnitude of the osmotic force with any accuracy. We can, however, adopt the inverse procedure and estimate the maximum amount of point-defect supersaturation which, in conjunction with the elastic forces, would be just insufficient to overcome the pinning force of the impurity cloud.

It will be noticed from the previous treatment that the osmotic force on the dislocation is comparable with the estimated elastic forces at a point-defect supersaturation of e, and that these correspond to stresses of about 10^9 dynes/cm^2. At higher supersaturation the osmotic force becomes dominant, but on account of the logarithmic term in (18) the equivalent stress does not increase by an order of magnitude (to 10^{10} dynes/cm^2) until the supersaturation has increased by 10^4. Let us therefore consider the pinning forces produced by impurities in GaAs in terms of equivalent breakaway stress σ_{By} and attribute significance to values of σ_{By} lying within or above the range 10^9-10^{10} dynes/cm^2.

Impurities Suitable for Dislocation Pinning in Double-Heterostructure Lasers

The most suitable impurities for dislocation pinning are the group III or V impurities which have a large misfit parameter ϵ. These impurities usually form complete solid solutions with GaAs [e.g., Ga(AsP); (GaIn)As; Ga(AsSb)]. The maximum concentration at which they can be incorporated into practical double-heterostructure devices is at least as high as 1 at % being only limited by lattice-mismatch problems [14]. Since they have the same valence as the atom for which they substitute, they have a negligible electrical effect at this concentration, even at low temperature; thus their effect on dislocation motion can be considered entirely in terms of the elastic-interaction model.

The size-effect elastic interactions of various group III or V impurities are shown in Table I, with the most strongly interacting of these at the top and the weakest at the bottom. The radius of the impurity atom [15], its misfit parameter ϵ, interaction coefficient β, and maximum elastic-interaction energy $E_{i\max}$ are given. The strongest interactions are with B and N. The author is not, however, aware of experimental evidence of their easy incorporation into GaAs. The more commonly used elements In, Sb, and Tl have strong interactions, and P can just be classed as a strong interaction. Al has virtually no size-effect interaction whatsoever.[1] Consider, for example, the case of the addition of indium to GaAs at a low level of say 1 at %. Substitution into (4) gives $c_d = 6 \times 10^6$ cm^{-1} assuming a freeze-in temperature of 700°C. This corresponds to about 25-percent substitution of In atoms for Ga atoms at the core of the dislocation. The elastic or osmotic

[1] Second-order interactions, such as elastic-modulus interactions, may be important for the case of Al which can be added at high concentration ≃ 10 at % to the active layer, see [6]-[8, p. 469].

TABLE I
DISLOCATION PINNING RESULTING FROM THE ADDITION OF VARIOUS GROUP III OR V IMPURITIES TO GaAs

Dislocation Pinning in GaAs using group III or V impurities

	Dopant (site)	R_{imp} Å	ϵ %	β x 10^{-22} cgs	$E_{i\ max}$ eV	σ_{BY} dynes/cm^2
Strong interaction	N (As)	0.7	−40	−500	0.90	2×10^{10}
	Tl (Ga)	1.47	17	210	0.38	5×10^{9}
	Sb (As)	1.36	15	190	0.34	5×10^{9}
	In (Ga)	1.44	14	175	0.31	3×10^{9}
	P (As)	1.10	−7	−90	0.16	6×10^{8}
Weak interaction	Al (Ga)	~ 1.26	10^{-2}	0.1	0.00	~ 10^{4}

stress σ_{By} required to cause the dislocation to break away from such an impurity cloud is given by (9) or (11) as 3 or 6×10^9 dynes/cm^2. Table I gives the lower of these values of σ_{By} for all the impurities considered based on the same assumptions. The upper value, appropriate when the dislocation is trying to climb towards, rather than away from the pinning impurity row is given by multiplying these values by 2. Several of these impurities such as In, Sb, Tl, and N produce pinning forces appreciably greater than the likely elastic and osmotic forces with values of σ_{By} approaching or greater than 10^{10} dynes/cm^2. Such a pinning force could also pin against osmotic forces resulting from proportional point-defect supersaturations of $e^{10} = 2 \times 10^4$ at room temperature.

It seems unlikely that any of the commonly used dopant impurities would be suitable for dislocation pinning. This is because the maximum concentration c_0 at which they can be added to the double heterostructure without deleterious side effects is usually about 3×10^{18} atoms/cm^3. The elastic interactions for such impurities are given in Table II. Even for the more strongly interacting of these impurities (Cd, for example) the linear density of the impurity at the dislocation core $c_d = 2.5 \times 10^5$ cm^{-1}, assuming a 700°C freeze-in temperature. The resultant maximum pinning force, (9) or (11), is 5 or 10 dynes/cm and $\sigma_{By} = 1.5$ or 3.0×10^8 dynes/cm^2. This is unlikely to pin the dislocation effectively. It is possible, of course, that electrical interactions may be significant with charged impurities such as these. However, it seems unlikely that this will affect c_d because the freeze-in temperature is about 700°C where the electrical effect of charged impurities is likely to be screened by the high intrinsic free-carrier density.

EXPERIMENTAL EVIDENCE

There is no information in the literature relating to the degradation properties of double-heterostructure lasers with suitable group III or V impurities included in the active region. Perhaps the only relevant information comes from Ettenberg *et al.* [16] who have recently reported results of the degradation of (GaIn)As double-heterostructure light-emitting diodes. Despite the fact that these diodes contained

TABLE II

a high density of dislocations, when the indium content of the active layer was 20 percent, the degradation rate was found to be independent of dislocation density in the range 10^6–10^9 dislocations/cm^2. Furthermore, the diodes were reported to be very resistant, from the point of view of degradation, to mechanical stresses resulting from device mounting. This is in marked contrast to GaAs/GaAlAs double-heterostructure lasers which are extremely sensitive to device mounting stresses [17]. These results are consistent with the assumption that the dislocations are strongly pinned when the active region contains an appreciable fraction of In.

CONCLUSIONS

The addition of certain group III or V impurities to GaAs is likely to produce dislocation pinning against stresses approaching 10^{10} dynes/cm^2 without deleteriously affecting double-heterostructure laser performance. Such pinning forces will almost certainly overcome the likely elastic stresses on the dislocation, although it remains to be determined experimentally whether they will overcome the osmotic forces which also contribute to the force on a climbing dislocation. It is therefore possible that the addition of these impurities to the active layer of double-heterostructure lasers will eliminate or inhibit the type of rapid degradation which results from dislocation motion. Experimental evidence relating to this suggestion is sparse at present; however, degradation results of GaInAs/(GaAs) LED's is consistent with the assumption that the dislocations are strongly pinned in GaInAs.

An Infrared Heterodyne Radiometer for High-Resolution Measurements of Solar Radiation and Atmospheric Transmission

BERNARD J. PEYTON, SENIOR MEMBER, IEEE, ANTHONY J. DiNARDO, STEVEN C. COHEN, JOHN H. McELROY, SENIOR MEMBER, IEEE, AND ROBERT J. COATES, FELLOW, IEEE

Abstract—A tunable, Dicke-switched, infrared heterodyne radiometer (IHR) has been designed, fabricated, tested, and used to observe solar radiation and determine the atmospheric transmissivity in the 9-11-μm spectral band. The IHR provides a spectral resolution of 6.7×10^{-3} cm^{-1}, a minimum detectable power level of 2.9×10^{-23} W/Hz, and a temperature resolution of less than 1 K for a source temperature of 1000 K, an IF predetection bandwidth of 100 MHz, and an integration time of 30 s. Detailed design equations and measured IHR performance are presented. The IHR was used to make solar and atmospheric transmission measurements and a vertical path atmospheric attenuation of 2.3 dB has been established under favorable weather conditions. The attenuation of solar radiation due to cloud cover and haze have also been investigated.

I. Introduction

DIRECT detection-type infrared radiometers have been widely used for a variety of astrophysical and atmospheric propagation measurements [1], [2]. The recent development of high-resolution infrared heterodyne receivers now permits similar measurements with an instrument which exhibits nearly quantum-noise-limited receiver sensitivity and previously unattainable spectral resolution [3]-[5]. Potential applications of IHR have been described [6]-[11] and solar measurements using an infrared heterodyne radiometer (IHR) have been reported [12]-[17].

II. Overview of IHR

In an IHR, the incident infrared radiation collected at the input aperture and a coherent laser local oscillator (LO) beam simultaneously illuminate a photomixer forming a heterodyne band-limited signal. The collected infrared signal energy spans the frequency intervals $\nu_{LO} + \nu_{IF} - B/2 < \Delta\nu < \nu_{LO} + \nu_{IF} + B/2$ (sum band) and $\nu_{LO} - \nu_{IF} - B/2 < \Delta\nu < \nu_{LO} - \nu_{IF} + B/2$ (difference band), where ν_{LO} is the laser local oscillator frequency of the IHR. The IF signal is amplified, synchronously detected, and integrated, providing a dc voltage proportional to the incident infrared radiation intensity. The predetection electronic bandwidth (B) of 100 MHz establishes the instantaneous infrared bandwidth of the IHR (6.7×10^{-3} cm^{-1}) while even finer resolution (1.33×10^{-4} cm^{-1}) has been achieved by inserting a 2-MHz IF filter. The spectral resolution of the IHR is ultimately limited to several kilohertz by the short-term frequency stability of the laser LO [18]. The resultant spectral resolution of the IHR is 2 to 4 orders of magnitude finer than that presently obtainable with conventional passive spectroscopic measurement techniques.

III. IHR Minimum Detectable Power and Signal-to-Noise Ratio

The heterodyne receiver sensitivity as a function of IF frequency, noise equivalent power (NEP) (f), for a reverse biased photovoltaic photomixer is given [3] by

$$\mathrm{NEP}(f) = \frac{h\nu}{\eta}\left\{1 + \frac{2k(T_m + T'_{IF})G_D}{qI_0}\left[1 + (f/f_c)^2\right]\right\} = \frac{h\nu}{\eta'} \quad (1)$$

where $h\nu$ is the photon energy, T_m is the photomixer temperature, T'_{IF} is the effective input noise temperature of the IF preamplifier, G_D is the reverse shunt conductance of the photomixer, I_0 is the LO induced photocurrent, q is the electronic charge, and f_c is the 3-dB cutoff frequency of the photomixer. For convenience these latter terms are grouped into an effective receiver quantum efficient η'. For the case where the operating instantaneous IF bandwidth B is less than f_c, the receiver sensitivity, NEP, is given by

$$\mathrm{NEP} = \frac{h\nu}{\eta'}B. \quad (2)$$

The IHR postdetection signal-to-noise ratio (SNR) for an extended thermal source is given by

$$\mathrm{SNR} = \frac{P_s\alpha(B\tau)^{1/2}}{\mathrm{NEP}\,\mathcal{K}} = \frac{P_s\eta'\alpha(B\tau)^{1/2}}{h\nu B\mathcal{K}} \quad (3)$$

where P_s is the power received from the thermal source within the diffraction limited IHR field of view, contained in a spectral window of extent $2B$, and of correct polarization for heterodyne detection, $\mathcal{K}$ is the sensitivity constant = 2 for a 50-percent Dicke-type radiometer, τ is the postdetection integration time of an ideal integrator, and α is the transmittance of the media and optics between the thermal source and the infrared photomixer.

When observing a thermal source of temperature T_s, the IHR SNR is given by

$$\mathrm{SNR} = \frac{\eta'\alpha(B\tau)^{1/2}}{e^{h\nu/kT_s} - 1}, \qquad f_c > B \quad (4)$$

where k is the Boltzmann's constant. For the case of solar

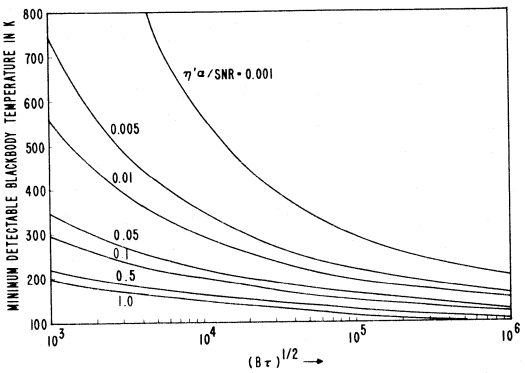

Fig. 1. Calculated minimum detected blackbody temperature versus $(B\tau)^{1/2}$ at $\lambda = 10.6$ μm with $\eta'\alpha$/SNR as a parameter.

measurements at $\lambda = 10.6$ μm and the conditions of $T_s = 5000$ K, $B = 10^8$ Hz, $\tau = 3$ s, $\alpha = 0.25$, and $\eta' = 0.1$, the calculated post-detection SNR is approximately 32 dB.

Using (3) and (4), the IHR minimum detectable source power and temperature can be determined for the effective receiver quantum efficiency η' and $(B\tau)^{1/2}$ product. The calculated $T_{s\min}$ is given in Fig. 1 as a function of $(B\tau)^{1/2}$ with $\eta'\alpha$/SNR as a parameter. For the measured IHR NEP of 2×10^{-19} W/Hz ($\eta' = 9.35$ percent), $B = 100$ MHz, $\tau = 30$ s, and an approximate optical transmittance of $\alpha = 0.25$, the calculated IHR minimum detectable thermal source power for $\text{SNR}_p = 1$ is, $P_{s\min} = 3 \times 10^{-15}$ W and the corresponding source temperature is $T_{s\min} = 190$ K.

IV. IHR Temperature Resolution

For the case of a thermal source, the IHR temperature resolution, $\Delta T_s/T_s$, defined as the normalized change in source temperature for which a change in the IHR output level can be observed is given (Appendix A) by

$$\frac{\Delta T_s}{T_s} = \frac{k^2 T_s}{2h^2\nu^2} \cdot \frac{[\exp(h\nu/kT_s) - 1]^2}{\alpha \exp(h\nu/kT_s)} \cdot \frac{K}{(B\tau)^{1/2}} \cdot \left[\frac{2h\nu\alpha}{k[\exp(h\nu/kT_s) - 1]} + \int_{f_1}^{f_2} \frac{\text{NEP}(f)\, df}{kB} \right]. \quad (5)$$

For $\alpha = 1$, $\eta' = 0.1$, $B\tau = 10^8$ ($B = 100$ MHz and $\tau = 1$ s, for example), $T_s = 100$ K, the IHR resolution is 8.6×10^{-4}, while for $B\tau = 10^{10}$, the resolution improves to 8.6×10^{-5}. For solar measurements, $T_s \approx 5000$ K [19], the calculated IHR temperature resolution is approximately 7×10^{-5} for $B\tau = 10^9$ and degrades to approximately 2.3×10^{-4} for $B\tau = 10^8$.

V. IHR Instrumentation

A. Equipment Description

The infrared heterodyne radiometer is made up of a diffraction limited collecting telescope, an optical Dicke switch, a wide-band heterodyne receiver, a discretely tunable laser LO, a variable temperature blackbody reference source, and radiometric processing electronics (see Fig. 2). In operation, the infrared energy from the source is collected by a 6-in off-axis

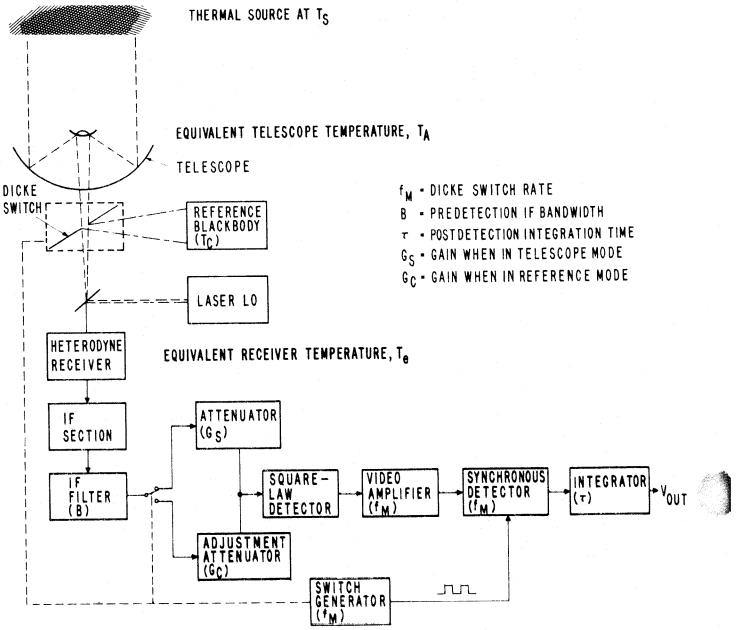

Fig. 2. Block diagram of infrared heterodyne radiometer (IHR).

telescope and compared to the output of a variable temperature (300-1500 K) reference blackbody by means of an optical Dicke switch that alternately switches the receiver field of view (FOV) between the collecting telescope and the reference blackbody. The heterodyne radiometer output voltage is proportional to the difference between the collected source energy and the reference blackbody energy within the IF bandwidth; therefore, when the reference temperature is made equal to the source temperature, their respective energies at the photomixer are equal and the radiometer output voltage is zero (null-balanced).

A liquid nitrogen cooled PV-HgCdTe photodiode is employed as the photomixer and has a measured quantum efficiency of 13 percent and a 3-dB cutoff frequency of greater than 125 MHz at $\lambda = 10.6$ μm and $T_m = 77$ K. The measured receiver sensitivity (NEP) is less than 2×10^{-19} W/Hz at 10.6 μm. The IF and video portion of the IHR provides flexibility in the choice of IF predetection bandwidth, postdetection integration time, and electronic gain.

B. Null-Balanced Operation with Gain Modulation

The calculated temperature resolution for a null-balanced Dicke-switched IHR assumes a balanced receiver in which the source temperature T_s and blackbody reference temperature T_c are equal. When the source temperature exceeds the maximum available reference temperature as for the case of solar measurements, the employment of gain modulation is a useful technique for obtaining a null-balanced output. Gain modulation is achieved by providing different IF gains during the observation times of the source and reference temperatures. In practice, two stable, precise IF attenuators are switched alternately in synchronism with the Dicke switch. The IF gain is G_s when the receiver is observing the telescope and G_c when the receiver observes the radiation from the reference (see Fig. 2). The radiometer will be null-balanced for the condition

$$G_s(\text{NEP} + P_s) = G_c(\text{NEP} + P_c) \tag{6}$$

where P_s is the net source power received at the IHR of IF bandwidth B. The heterodyne receiver NEP defines the receiver noise level equation (1)[1] and the blackbody reference power at the IHR is given by

$$P_c = \frac{2h\nu B}{\exp(h\nu/kT_c) - 1} \tag{7}$$

under coherent diffraction limited constraints (see Appendix A), unity transmissivity, $\alpha = 1$, and where T_c is the actual reference temperature. The reference blackbody used in the IHR has a maximum temperature of 1300 K, and therefore direct null-balanced radiometer operation is not possible when observing very hot sources such as the sun.

The temperature resolution with which the IHR can measure the source temperature for a gain-modulated IHR is given by

$$\frac{\Delta T_s}{T_s} = \Delta T_c \frac{T_s}{T_c^2}\left\{\frac{2h\nu B}{\exp(h\nu/kT_c) - 1}\right\}^2 \frac{G_c \exp(h\nu/kT_c)}{\left[\text{NEP}(G_c - 1) + \dfrac{G_c h\nu B}{\exp(h\nu/kT_c) - 1}\right]\left[\text{NEP}(G_c - 1) + h\nu B + \dfrac{G_c h\nu B}{\exp(h\nu/kT_c) - 1}\right]}. \tag{8}$$

Therefore, a measurement of the reference temperature resolution $(\Delta T_c/T_c)$, the infrared wavelength, the reference temperature, the transmissivity, the gain modulation, the receiver sensitivity, and the IF bandwidth can be used to calculate the temperature resolution for a source temperature which is larger than the reference temperature.

For the case of zero gain modulation ($G_c = G_s = 1$ and $\Delta G = 0$), (8) reduces to $\Delta T_s = \Delta T_c\,(T_s/T_c)^2$ and for the null-balanced case where $T_s = T_c$, then $\Delta T_s = \Delta T_c$. The calculated 10.6-μm IHR temperature resolution with gain modulation is identical to that obtained when the IHR is null-balanced by means of a reference source whose temperature is equal to the source temperature; therefore, no degradation in temperature resolution is incurred when gain modulation is employed.

C. Solar Resolution Elements

The diffraction-limited IHR field of view is

$$\theta_{DL} = 2.44\frac{\lambda}{D} \approx 1.7 \times 10^{-4} \text{ rad} \tag{9}$$

where $\lambda = 10.6$ μm and D is the telescope diameter (6 in). When the photomixer area matches the diffraction limited spot size, the number of resolution elements across the solar disk is approximately given by

$$N \approx \left(\frac{\theta_s}{\theta_{DL}}\right)^2 \approx 3025 \tag{10}$$

where θ_s is the solar angle $= 9.3 \times 10^{-3}$ rad.

[1]For this discussion it is assumed that the laser LO power is much larger than the reference and the source power. Therefore, the NEP is fixed near the quantum limit condition and does not vary with source or reference power.

VI. IHR Laboratory Measurements

A. Measured Temperature Resolution

The IHR temperature resolution was measured using a calibrated blackbody source for the experimental conditions of: $\lambda_{LO} = 10.6$ μm, NEP $= 2 \times 10^{-19}$ W/Hz at the photomixer input, $B = 100$ MHz, and $\tau = 3$ s. The calculated and measured values of the IHR temperature resolution for several values of media transmittance α are given in Fig. 3. The measured data indicate that the IHR media transmissivity is approximately $\alpha = 0.25$. The nonideal transmissivity is due to the optic losses, the nonsquare Dicke switch, the 25-percent obscuration caused by the laser LO injection mirror, and the fact that the diffraction limited spot size of the IHR is slightly smaller than the active area of the photomixer.

The measured resolution was $\Delta T_s/T_s = 3 \times 10^{-3}$ for $T_s = 1000$ K and increased to $\Delta T_s/T_s = 5.3 \times 10^{-2}$ for $T_s = 300$ K. The calculated and measured values of IHR temperature resolution are in reasonably good agreement and it appears that the effects of fast laser LO amplitude fluctuations which were excluded from the calculations (Appendix A) do not significantly degrade the IHR temperature resolution. The discrepancy between the calculated and measured values of IHR temperature resolution near $T_s = 300$ K may be due to the nonzero emissivity of the optical surfaces which are expected to be most significant for nearly ambient sources.

For comparison the calculated temperature resolution of an IHR with $\alpha = 1$, and $B\tau = 10^{10}$ is also shown in Fig. 3. This improved performance represents an IHR with an integration time of 10 s and a presently achievable [5] heterodyne receiver IF bandwidth of $B = 1$ GHz.

The null-balanced IHR output data distribution given in Fig. 4, is nearly Gaussian; a condition which indicates random

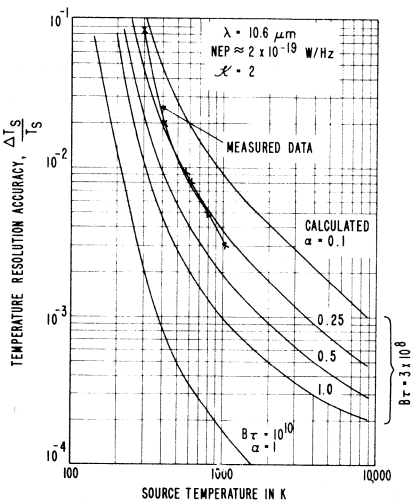

Fig. 3. Calculated and measured temperature resolution of a null-balanced Dicke-switched IHR.

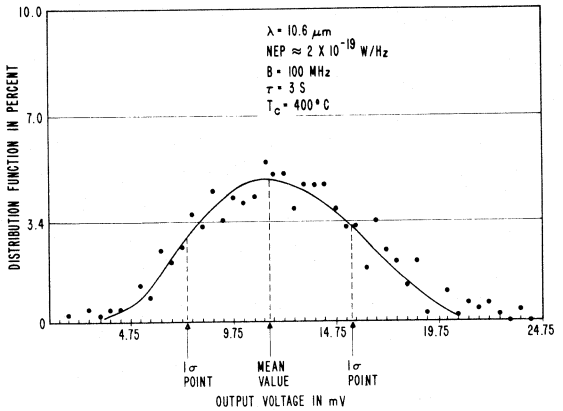

Fig. 4. Measured IHR output voltage distribution for null-balanced condition.

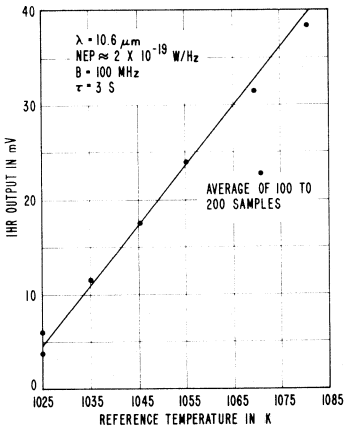

Fig. 5. Measured IHR output voltage as a function of reference temperature.

noise fluctuations. The IHR temperature resolution can be determined from the output data distribution since the 1σ points of a Gaussian distribution are the rms data error of the IHR [2]. Translation of this voltage distribution to a temperature distribution can be accomplished when the variation of the IHR output voltage with source temperature is known.

B. Measured Linearity

The IHR output voltage was sampled once per second with a digital millivoltmeter. The average values of data samples measured for the condition of a fixed source temperature and a variable reference temperature are given in Fig. 5. The IHR was null-balanced at a reference temperature T_c = 1085 K, and the measurement data were taken over a 23-min test period as T_c was lowered in 10-K steps to a value of 1025 K. Each measurement point shown in Fig. 5 represents the average value of about 150 data samples and the measured output voltage was found to be nearly linear with changing reference temperature.

VII. Solar and Atmospheric Transmittance Measurements

A. Solar Disk

The IHR has been installed at the Goddard Space Flight Center's Optical Research Facility at 76° west longitude and 39° north latitude where it has been used to make solar disk

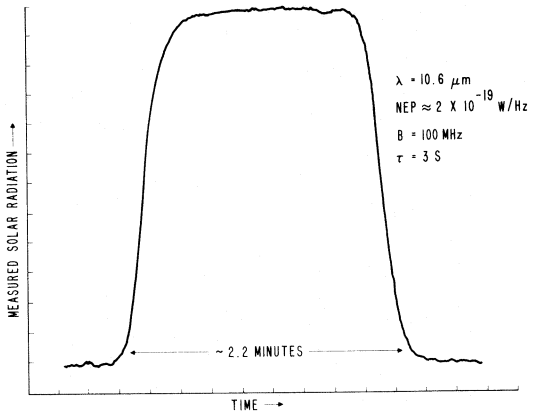

Fig. 6. Solar scan measured with an IHR.

and atmospheric transmission measurements at selected CO_2 laser wavelengths. A coelostat mounted on concrete piers was used to track the sun and direct the incoming radiation onto the collecting telescope. The scan of the solar disk, shown in Fig. 6, was obtained by interrupting the coelostat drive and allowing the sun to traverse the field of view of the IHR telescope. During some of the solar measurements, SNR's in excess of 25 dB were obtained compared to a calculated SNR of 28 dB.

The amplitude fluctuations in the scan shown in Fig. 6 indicate temperature variations of less than 3 percent across the solar disk and represent an upper limit on the measured solar uniformity.

B. Atmospheric Transmission

The solar radiation $P(\nu)$ collected at the IHR is the product of the incident unattenuated solar radiation P_0 and an exponential attenuation term due to the intervening atmospheric losses. Thus

$$P(\nu) = P_0 \exp(-\alpha_a(\nu)\, h \sec\theta) \tag{11}$$

where $\alpha_a(\nu)$ is the atmospheric attenuation coefficient at the laser LO frequency, h is the vertical height of the atmosphere, θ is the zenith angle of the sun, and $h \sec\theta$ is the path length of the sunlight through the atmosphere. When the IHR is operated in an unbalanced mode ($T_s >> T_c$), the output voltage is proportional to the collected source energy. The slope of the logarithm of $P(\nu)$ plotted against sec θ is $-\alpha_a(\nu)\, h$ and $\exp(-\alpha_a(\nu)\, h)$ is the vertical path attenuation. The decrease in the IHR output voltage as the sunlight propagates through longer atmospheric paths was measured under reasonably clear atmospheric conditions. The data are plotted in Fig. 7. The vertical path attenuation was 2.3 dB and is principally due to the line absorption of atmospheric CO_2.

In addition to making clear sky measurements, the effects of cloud cover on direct path propagation were examined and it was found that even small changes in light cloud cover can produce significant changes in the collected solar energy. IHR measurements have demonstrated that summer haze can produce 6-dB additional attenuation fluctuations in the infrared sunlight signal, while heavier cloud covers may produce attenuations in excess of 25 dB. A portion of one observation during a period of light cloud cover is shown in Fig. 8. Peak to valley

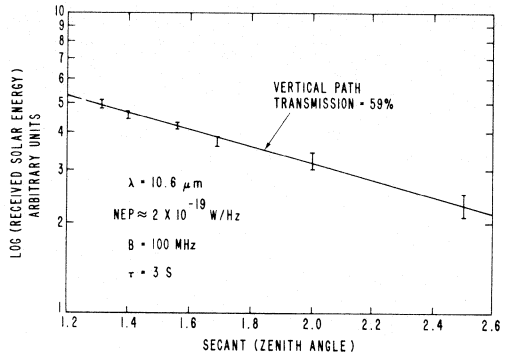

Fig. 7. Variation of solar energy collected at IHR versus secant of solar zenith angle. Measurements were made on March 28, 1973 for a temperature of 56°F and relative humidity of 35 percent.

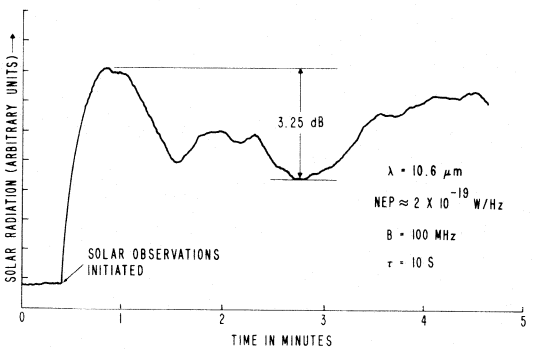

Fig. 8. Measured solar radiation through light patchy clouds using an IHR.

variations of 3.25 dB were observed over the 4-min measurement interval.

VIII. Conclusions

An IHR having a spectral bandwidth of 6.7×10^{-3} cm^{-1} ($2B = 2 \times 100$ MHz) has been developed and used to measure solar radiation near 10.6 μm. Using the solar measurement data, the vertical path atmospheric transmissivity and the effects of cloud cover have been determined. The atmospheric attenuation has been measured over the narrow spectral interval of the IHR rather than the wider spectral bandwidths realized with conventional receivers and the improved spectral resolution is significant since the absorption linewidths of atmospheric constituents are about 10^{-1} cm^{-1} while the separation between absorption lines is about 1.7 cm^{-1} [2]. In a related measurement program, the IHR has been modified to operate with a cooled 8.5-μm diode laser LO and used to measure the infrared emissions of Mars and the moon [22].

It has been proposed that the IHR can be used for the determination and vertical profiling of atmospheric gases by setting the laser LO to overlap the spectral signature line of a selected molecular constituent [9], [23], [24]. IHR spectral bandwidths of up to 10^{-1} cm ($2B = 2 \times 1.5$ GHz) are achievable near 10.6 μm [25] and therefore the spectral profiles of molecular signature lines can be precisely examined. Cooled diode lasers [26], [27] which exhibit low power and wide tunability, may be particularly useful as LO's in heterodyne receivers which are specially designed to overlap the signature lines of specific atmospheric constituents.

Appendix A
Temperature Resolution Accuracy of an Infrared Heterodyne Radiometer

The IHR temperature resolution ΔT_s defined as the maximum change in source temperature for which no change in output SNR is observable at the radiometer output can be obtained by employing the classical definition of temperature resolution ΔT for an RF-microwave radiometer [28], [29] which is given by

$$\Delta T = \frac{K T_{sys}}{(B\tau)^{1/2}}. \tag{12}$$

where T_{sys} is the equivalent system temperature = $T_a + T_e$, T_a is the equivalent source temperature at the receiver telescope, and T_e is the equivalent receiver noise temperature[2] (see Fig. 2), B is the IF bandwidth, τ is the integration time, and $K = 2$ for a Dicke-switched radiometer.

A. Receiver Noise Temperature

The equivalent heterodyne receiver noise power of the IHR is given by

$$P_n = \int_{f_1}^{f_2} \mathrm{NEP}(f)\, df = kT_e B \tag{13}$$

where P_n is the receiver noise power and the receiver noise equivalent power [NEP (f)] is given by (2) for a reverse biased photovoltaic photomixer.

B. Equivalent Source Temperature

The total power emitted into a hemisphere, within a spectral interval $\Delta\nu$ from a small area, ΔA, due to a thermal source at temperature T_s is given [30] by

$$\Delta P_s = \frac{2\pi}{\lambda^2} \cdot \frac{h\nu\, \Delta\nu\, \Delta A}{\exp(h\nu/kT_s) - 1}. \tag{14}$$

Since the power per steradian emitted normal to the surface is $\Delta P_s/\pi$ and only one-half of the emitted power on average is of the correct polarization for heterodyne detection, the net power received by a diffraction limited heterodyne receiver having a captured area A and subtending a solid angle Ω is

$$P_s = \frac{h\nu\, d\nu\, \alpha}{\exp(h\nu/kT_s) - 1} = kT_a B \tag{15}$$

where $A\Omega = \lambda^2$ for diffraction limited heterodyne operation [30] and α is the media transmittance. The frequency interval $d\nu$ of a heterodyne receiver is fixed by the IF bandwidth and is equal to $2B$ for spectrally broad-band sources since there is both a sum and difference frequency band.

C. IHR Temperature Resolution Accuracy

The temperature resolution with which the IHR can measure a thermal source of temperature T_s is obtained by recognizing that the total power in the IHR is given by

[2] T_a and T_e are not physical temperatures.

$$P = P_s + P_n. \tag{16}$$

Taking the first derivative of P with respect to the source temperature and letting $dP/dT_s = \Delta P/\Delta T_s$, one obtains

$$\Delta T_s = \Delta P \frac{dT_s}{dP_s} = kB\Delta T \frac{dT_s}{dP_s}. \tag{17}$$

Using (15)

$$\frac{dT_s}{dP_s} = \frac{kT_s^2}{h^2\nu^2} \cdot \frac{[\exp(h\nu/kT_s) - 1]^2}{2\alpha \exp(h\nu/kT_s) B}. \tag{18}$$

Combining (13), (15), (17), and (18) the IHR temperature resolution is given by

$$\frac{\Delta T_s}{T_s} = \frac{k^2 T_s}{2h^2\nu^2} \cdot \frac{[\exp(h\nu/kT_s) - 1]^2}{\alpha \exp(h\nu/kT_s)} \cdot \frac{K}{B\tau} \cdot \left\{ \frac{2h\nu\alpha}{k\{\exp(h\nu/kT_s) - 1\}} + \int_{f_1}^{f_2} \frac{\text{NEP}(f)\, df}{kB} \right\}. \tag{19}$$

The IHR temperature resolution can be degraded by laser amplitude fluctuations which occur faster than the Dicke-switch rate. Optic losses are included in the media transmittance term α as a general loss of efficiency.

Thermooptical Effects of Intracavity $Ba_2Na(NbO_3)_5$ on a Frequency-Doubled Nd:YAG Laser

JAMES D. BARRY, MEMBER, IEEE, AND CHANDLER J. KENNEDY

Abstract—**The two major thermooptical influences on a frequency-doubled Nd:YAG laser by an intracavity $Ba_2Na(NbO_3)_5$ crystal are discussed and theoretically examined. The absorption of λ106- and λ0.53-μm power by the crystal is shown to lead to the formulation of a thermally induced lens and diffraction loss due to the aspherical distortion. Equations for each are formulated. The effects of the lens and diffraction loss to the performance of the laser are illustrated. The modification to the laser resonator due to the inclusion of these effects is discussed.**

I. Introduction

THE internally frequency-doubled Nd:YAG laser has received considerable attention for use in space laser communications. The use of this laser in space demands the most efficient utilization of the second-harmonic conversion process and pump light due to power limitations on board any spacecraft. Since it is at least possible in theory to convert 100 percent of the optimally coupled fundamental power to second-harmonic power using an intracavity frequency doubler [1], we have chosen this design for space use. However, the introduction of the doubling element in the laser cavity introduces additional losses which were not present in the fundamental wavelength laser, so that 100-percent conversion is not possible in practice. We report on our investigation of what we believe to be the most fundamental causes of the deoptimization of the laser due to the presence of the doubling crystal.

The perturbation to the laser system by the doubling crystal is caused by its absorption of λ1.06- and λ0.53-μm radiation. This influence has been recognized as a thermal distortion but the importance, especially for an optimized space laser, has not been previously studied. The general thermooptical influence to the laser occurs in a twofold manner [2]. The first is due to the added power-dependent cavity loss due to the aspherical components of the thermal lens and the second is due to the modification of the laser resonator by the thermal lens.

These effective losses are not generally recognized and must be included in any effort to optimize the laser resonator. Additionally, the induced thermal profile can disrupt the frequency-doubling process and lead to degraded λ0.53 output power. The basic influences of the absorption of optical power have been previously recognized [3], [4] and the distortion of uniform frequency doubling in the $Ba_2Na(NbO_3)_5$ crystal reported [5]. These effects are dependent upon crystal quality and impurities. A summary of present $Ba_2Na(NbO_3)_5$ crystal properties is listed in Table I.

Manuscript received November 26, 1974; revised March 27, 1975.

TABLE I
SUMMARY OF THE IMPORTANT PROPERTIES OF THE PRESENTLY AVAILABLE FREQUENCY-DOUBLING CRYSTAL $Ba_2Na(NbO_3)_5$

	Structure	Orthorhombic (T<300°C)
ρ	Density	5.42 gm cm^{-3}
T_c	Curie Temperature	560°C
T_m	Melt Temperature	1450°C
T_s	Storage Temperature	150°C
T_p	Phase Match Temperature	85.0°C
ΔT_p	Phase Match Temperature, FWHM	1°C
α	Thermal Coefficient Expansion	1 x 10^{-5} $°C^{-1}$
n	Index of Refraction (λ1.06u, o-ray, z axis)	2.26
$\frac{\partial n}{\partial T}$	Thermal Coefficient of Index of Refraction (e-ray)	8 x 10^{-5} $°C^{-1}$
	(o-ray)	-2.5 x 10^{-5} $°C^{-1}$
K	Thermal Conductivity	0.035 w $cm^{-1}°C^{-1}$
d	(λ1.06/λ0.53) Conversion Coefficient	1.1 x 10^{-22} mV^{-1}
α_1	λ1.06 Absorption Coefficient	2.0 x 10^{-3} cm^{-1}
α_2	λ0.53 Absorption Coefficient	40 x 10^{-3} cm^{-1}
L_B	Crystal Dimensions, Commercial	0.5 cm (cube)

II. Approach

The intracavity frequency-doubled laser considered here is being developed for the Air Force Space Laser Communications Program 405B. The ferroelectric crystal $Ba_2Na(NbO_3)_5$ has been chosen for use as the intracavity frequency-doubling element. The crystal is an optimum choice for Nd:YAG laser systems where damage problems may be ignored and high-conversion efficiency is required.

The arrangement of the intracavity frequency-doubled Nd:YAG laser is illustrated in Fig. 1. An intracavity lens is used to collimate the beam within the laser rod and to place the beam waist at a position where the proper value of the beam diameter in the frequency-doubling crystal may be achieved. The position of the crystal is fixed due to its use as an acoustooptical mode-locking element and the spatial limitations of the acoustical column. The position and focal length of the lens is varied to achieve the desired results. The design of the laser is specifically orientated towards a confocal arrangement for insensitivity to misalignment and thermal changes [6].

The theoretical analysis of the laser proceeded by first determining the thermal profile within the $Ba_2Na(NbO_3)_5$ crystal due to the absorption of the incident radiation. The thermal profile is related to the induced lens focal length. The induced

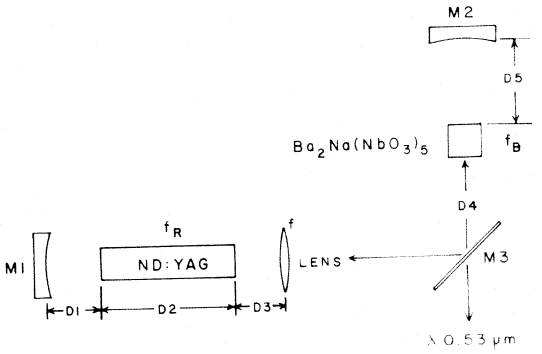

Fig. 1. Schematic of the configuration of the intracavity frequency-doubled Nd:YAG laser under development for space use. The intracavity lens is used to obtain a collimated beam through the rod and to focus the beam into the $Ba_2Na(NbO_3)_5$ crystal. The λ0.53-μm light generated exits the laser through mirror $M3$.

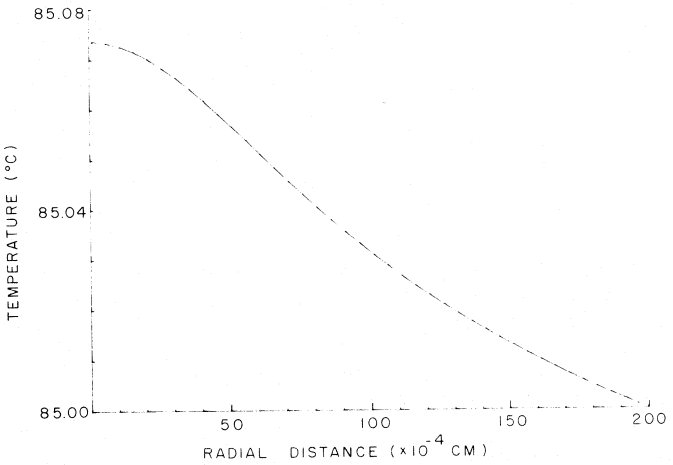

Fig. 2. The radial temperature profile in the $Ba_2Na(NbO_3)_5$ crystal due to the absorption of λ1.06-μm power. The values $W_B = 75 \times 10^{-4}$, $\alpha_1 = 0.002\ cm^{-1}$, and $2I = 20$ W are used.

lens modifies the laser optical cavity parameters and alters the original resonator design. Calculations show that the modifications lead to deleterious effects to the laser. The theoretical resonator analysis of the intracavity frequency-doubled laser proceeded by a closed-form self-consistent computer technique using the *ABCD* matrix representation of optical elements for Gaussian beam propagation [7].

III. Thermal Profile

The radial temperature distribution in the anisotropic $Ba_2Na(NbO_3)_5$ crystal due to the heat generated by the absorption of λ1.06- and λ0.53-μm radiation is assumed to be described in the steady state by the approximate relation

$$\frac{1}{r}\frac{\partial}{\partial r}\left(Kr\frac{\partial T}{\partial r}\right) + W(r) = 0 \tag{1}$$

where cylindrical symmetry has been assumed for mathematical simplicity, K is the thermal conductivity of $Ba_2Na(NbO_3)_5$, $K = 0.035$ W $cm^{-1}/°C^{-1}$ [8], and the heat source term is related to the assumed TEM_{00} Gaussian mode by

$$W(r) = Q_0 \exp(-2r^2/w_B^2) \tag{2}$$

where w_B is the $\exp(-2)$ power point of the laser in the $Ba_2Na(NbO_3)_5$ crystal.

The heat quantity Q_T is determined by spatial integration over $W(r)$ and is the total heat resulting from the absorbed laser radiation, so that $Q_T = Q\pi w_B^2 L\,[1 - \exp(-2R_0^2/w^2)]/2$ where R_0 is the radius at which the boundary is practically established. The exponential is negligible for $R_0 > w_B$ but should be retained for configurations where the crystal and beam dimensions are not too dissimilar. The total heat deposited is also given by the bidirectional incident λ1.06-μm power and the total λ0.53-μm power times their respective absorption factor $[1 - \exp(-\alpha_i L_B)]$ where α_1 is the λ1.06-μm absorption coefficient, α_2 is the λ0.53-μm absorption coefficient, and L_B is the crystal length, so that $Q_T = (2\alpha_1 I + \alpha_2 P_{2\omega})L_B$. The λ1.06-μm absorption dominates since the λ1.06-μm power is at least fifty times greater than that due to λ0.53 μm.

We are presently using $Ba_2Na(NbO_3)_5$ crystals which have relatively low absorption coefficients at λ1.06 and λ0.53 μm. A normal value for α_1 is $<0.002\ cm^{-1}$ and for α_2 is $\simeq 0.04\ cm^{-1}$ [9].[1] These crystals were specifically developed for low iron content for the space laser and may not be commercially available at this time. The circulating λ1.06-μm power of the space Nd:YAG laser is about 10 W with frequency doubling and about 30 W without. The λ0.53-μm power is of order 200 mW. The heat absorbed Q_T in the crystal is then of order 24 mW · cm^{-1} with frequency doubling and 60 mW · cm^{-1} without.

The solution of (1) is achieved by placing the physically satisfying boundary conditions of $\partial T/\partial r = 0$ at $r = 0$ and $T(r) = T_0$ at $r = R_0$ of the $Ba_2Na(NbO_3)_5$ crystal. The thermal profile is effectively given by

$$T(r) = T_0 + \frac{2\alpha_1 I}{4\pi K}\left\{\sum_1 \frac{(-2r^2/w_B^2)^n}{n\cdot n!} - \sum_1 \frac{(-2R_0^2/w_B^2)^n}{n\cdot n!}\right\} \tag{3}$$

which differs somewhat from previous forms for $T(r)$ in that (3) reduces to the isothermal condition when the heat input is zero and is valid beyond $r = w_B$ due to the retention of the R_0 and $n > 1$ terms. We presently use $R_0 = 0.025$ cm and w_B is of the order 75×10^{-4} cm. The series is numerically caused to converge using a CDC 3600 computer; several hundred terms are required [10].[2] The thermal difference $\Delta T = T(r = 0) - T(r = w_B)$ is essentially equal to

$$\frac{I\alpha_1}{2\pi K}(-1)\sum_1 \frac{(-2)^n}{n\cdot n!}$$

where the series converges with $n = 15$ to ~1.32 and $\Delta T \simeq 6.2 \times 10^{-3} \times I$ °C when $\alpha_1 = 0.002\ cm^{-1}$. The change in temperature ΔT will be used to define the thermally induced focal length. An example of the form of $T(r)$ from (2) is shown in Fig. 2 for $w_B = 75 \times 10^{-4}$ cm, $\alpha_1 = 0.002$, and $2I = 20$ W. The form will remain similar for other I and w_B, but the absolute value of $T(r)$ will vary.

[1] The absorption coefficients of $Ba_2Na(NbO_3)_5$ crystals have been measured at λ0.488, λ0.53, and λ1.06 μm using the pyroelectric signal method induced by absorbed laser radiation, Air Force Avionics Laboratory, Wright-Patterson Air Force Base, Ohio.

[2] A unique computer program subroutine was generated to solve the summation involving large integers raised to large powers and divided by large number factorials.

IV. Thermal Lens

The focal length f_B of the induced lens in the $Ba_2Na(NbO_3)_5$ is found from the relation of the lens power of a thick lens formed by a radial thermal gradient [11]. The radius of curvature of the deformed plane surfaces of the crystal faces perpendicular to the laser axis is $R = a^2/2\Delta nL$, where a is the effective radial range of the thermal influence and ΔnL is the optical path length change induced by the thermal effect. We set $a = w_B$, and the focal length is given by

$$f_B = \frac{w_B^2}{4(n-1)L_B(\alpha n + \partial n/\partial T)\,\Delta T - \dfrac{4L_B(n-1)}{n}\{L_B(\alpha n + \partial n/\partial T)\,\Delta T\}^2/w_B^2} \tag{4}$$

where n is the index of refraction of $Ba_2Na(NbO_3)_5$, α is the coefficient of linear expansion, $\partial n/\partial T$ is the thermal coefficient of the ordinary ray index of refraction, and L_B is the crystal length. The form of f_B can be simplified greatly since $L_B(n-1)^2/nR^2 \ll 1$ thereby eliminating the second term of the denominator, and the resulting form of f_B is that familiar to most [6]. The focal length, using the previously noted ΔT, is equivalent to $f_B = -1.5 \times 10^7 w_B^2/I$, and negative due to the negative value of the $\partial n/\partial T$.

We use the value for the induced focal length to modify the $ABCD$ matrix for the $Ba_2Na(NbO_3)_5$ crystal. The crystal is treated as a lenslike medium [7]. The radial index parameter n_{2B} is related to the index n by $n = n_0 - n_{2B}r^2/2$ and to f_B by

$$f_B = \frac{\sqrt{n_0/n_{2B}}}{n_0 \sin\left(L_B\sqrt{n_{2B}/n_0}\right)} \tag{5}$$

which is interpreted as a negative focal length for use in the matrix. The 2×2 $ABCD$ matrix C element is subsequently positive due to the negative values of f_B. Using the preceding relations, $f_B = -84.4$ cm when $w_B = 75 \times 10^{-4}$ cm and $2I = 20$ W and $f_B = -28.1$ cm when $w_B = 75 \times 10^{-4}$ cm and $2I = 60$ W. The associated n_{2B} values are 2.4×10^{-2} and 7.2×10^{-2}, respectively.

A similar concept holds for the laser rod which also has a thermally induced focal length [2], [4]. The relation is somewhat modified by the equation for ΔT when nonuniform heating occurs, as is the case with KRb lamps, and evidently with Kr lamps of the 6-mm bore design.

V. Wavefront Aberration Losses

Even though we use the induced lens as a simple lens effect, we also recognize that the $n > 1$ terms on $T(R)$ include aspherical effect and give rise to diffraction losses due to the thermal profile in the $Ba_2Na(NbO_3)_5$ crystal.

Let $\Phi(r)$ be the purely radial aberration function introduced by the thermally distorted crystal. Then the far-field intensity as a function of angle from the beam axis is [12]

$$I(\beta\Theta) = \frac{8\pi}{R^2\lambda^2 w^2} \cdot \left| \int_0^\infty r \exp\left[i\Phi(r)\right] \exp\left(-r^2/w^2\right) J_0(\beta\Theta r)\, dr \right|^2 \tag{6}$$

where $\beta = 2\pi/\lambda$, λ is the wavelength, and R is the range of the image plane. For small aberrations, we approximate the exponent by $1 + i\,\Phi(r)$ and we use the lowest order thermally induced aberration, letting $\Phi(r) = p(r/w)^4$. In this analysis, the integral form

$$\int_0^\infty x^{\mu-1} \exp\left(-x^2\right) J_0(bx)\, dx$$

occurs and has the value [13],

$$\tfrac{1}{2}\,\Gamma(\mu/2)\, M(-\mu/2 + 1, 1, b^2/4) \exp\left(-b^2/4\right) \tag{7}$$

where M is the confluent hypergeometric function. The first term in (7) has $\mu = 2$ and $b = \beta\Theta w$, the second integral has $\mu = 6$ and the same b. Therefore, we obtain

$$I(\beta\Theta) = \frac{8\pi}{R^2\lambda^2 w^2} \left| \frac{w^2}{2} \exp\left(-(\beta\Theta w)^2/4\right) M(0, 1, (\beta\Theta w)^2/4) + ipw^2 \exp\left(-(\beta\Theta w)^2/4\right) M(-2, 1, (\beta\Theta w)^2/4) \right|^2. \tag{8}$$

Since $M(0, 1, z) = 1$ and $M(-2, 1, z) = z^2 - 4z + 2$, we have

$$I(\beta\Theta) = \frac{2\pi w^2}{R^2\lambda^2} \left[1 + 4p^2 \left(\frac{(\beta\Theta w)^4}{16} - (\beta\Theta w)^2 + 2 \right)^2 \right] \cdot \exp\left[-(\beta\Theta w)^2/4\right]. \tag{9}$$

Integrating the power in the far field at a range R, we have

$$P = \frac{2\pi R^2}{w^2\beta^2} \int_0^\infty I(\beta\Theta w) \cdot \beta\Theta w \cdot d(\beta\Theta w) \tag{10}$$

and evaluating the integral, and normalizing to unity relative to the unaberrated condition $p = 0$, we have for the far-field power

$$P = \frac{1}{1 + 6p^2} \simeq 1 - 6p^2. \tag{11}$$

Since P increases as the aberration increases, the aberrated beam has a smaller total power in the TEM_{00} mode than the nonaberrated beam. The power loss must be

$$\alpha_d = 6p^2. \tag{12}$$

The diffraction loss is related to the thermal distortion by realizing the definition for aberration function $\Phi = \Delta(nL)^{(4)}(2\pi/\lambda) = p(r/w)^4$, where the fourth-order factor is assumed, as noted before.

We compute α_d by using $\Delta(nL)^{(4)}$ as defined by

$$\Delta(nL)^{(4)} = L_B(\alpha n + \partial n/\partial T)\,\Delta T^{(4)}$$
$$\Delta T^{(4)} = \frac{\alpha_1 I}{2\pi K}\left(\frac{2r^2/w_B^2}{2 \cdot 2!}\right)^2 \tag{13}$$

and with $\alpha_1 = 0.001$, we have that

$$\alpha_d = 5 \times 10^{-6} I^2. \tag{14}$$

When $\alpha_d = 0.001$, $I = 14.1$ W.

VI. Laser Power Influence

The frequency-doubled laser power is related to the circulating power at phase match by [14]

$$P_{2w} = 2\epsilon I^2 \tag{15}$$

where the temperature phase match condition for ϵ is assumed, $\epsilon = 5.65 \times 10^{-8} L/w_B^2$, and L is the conversion length within the crystal, normally assumed to be 0.3 cm. The circulating power with the influence of frequency was shown to be [8]

$$I = \frac{\alpha\beta + \epsilon}{2\epsilon\beta} \left\{ \sqrt{1 + \frac{4\epsilon\beta(g_0 - \alpha)}{(\alpha\beta + \epsilon)^2}} - 1 \right\} \tag{16}$$

where the single direction properties are used; α is the passive cavity losses, β is the saturation parameter for the Nd:YAG medium, and $\beta = k/w_R^2$ with $k = 2.89 \times 10^{-4}$, and g_0 is the unsaturated gain. This equation reduces to the familiar expression, $P_w = (g_0/\alpha - 1)/\beta$ when $\epsilon = 0$. Optimum coupling occurs when $\epsilon = \alpha\beta$. The beam diameter in the laser rod is denoted by w_R and the waist diameter in the resonator by w_0.

We analytically illustrate in Fig. 3 the effect to the laser resonator by inclusion of the $Ba_2Na(NbO_3)_5$ lens. We plot the variation of the three important beam diameters in the laser cavity, $2w_R$, $2w_B$, and $2w_0$, as the intracavity lens-to-rod separation is varied. The resonator configuration is $R = -300$ cm, $R = +2.5$ cm, $f = 11$ cm, and the rod thermally induced focal length is 140 cm. The dashed curves represent the relationship when $I = 30$ W, $\epsilon = 0$, and only $\lambda 1.06$-μm absorption occurs, so that $f_B = -28.1$ cm. The solid curves represent the relationship when $I = 10$ W, $\epsilon > 0$, and both $\lambda 1.06$- and $\lambda 0.53$-μm absorption occurs, so that $f_B = -84.4$ cm. It is clear that the beam diameters change as the $Ba_2Na(NbO_3)_5$ lens focal length varies. The difference between the curves increases as the lens position is moved from the confocal position. Since the $\lambda 0.53$-μm laser power is proportional to w_R^4 and w_B^{-2}, by (15), the effect of f_B has an influence upon the laser operation. The laser should be optimized when $\epsilon > 0$ rather than when $\epsilon = 0$ due to the resonator variations. We have found that the resulting $\lambda 0.53$-μm power obtained can be different by 10-20 percent.

The curves of Fig. 3 are not general in nature but are particular to the resonator configuration used. Each individual resonator design must be examined relative to its parameters, and the appropriate $Ba_2Na(NbO_3)_5$ thermally induced focal length included so that an optimum configuration may be achieved.

The influence of the diffraction loss $\alpha_d = \gamma I^2$ is to reduce the available $\lambda 1.06$-μm circulating power and degrade the $\lambda 0.53$-μm performance. The effect of an additional 0.001 loss due to diffraction effects in the space laser would be to decrease the $\lambda 0.53$-μm power by about 10 percent. This value

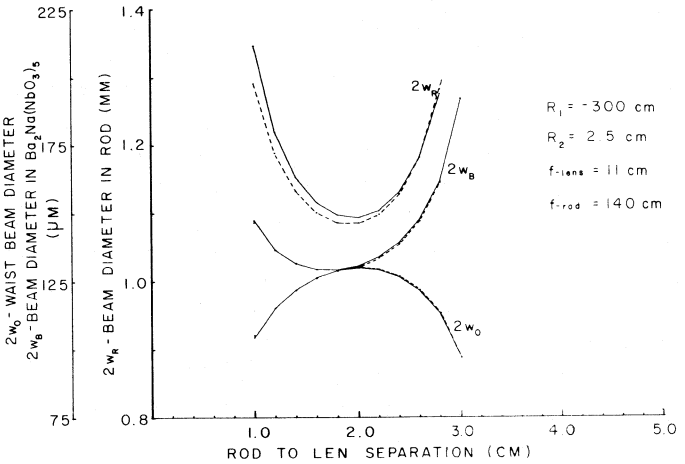

Fig. 3. The effect of the $Ba_2Na(NbO_3)_5$ thermally induced lens to the laser resonator is illustrated by the variation of $2w_R$, $2w_B$, and $2w_0$ as the lens-to-rod separation is varied. The solid curve represents the relationship when $I = 10$ W, $\epsilon > 0$, and $f_B = -84.4$ cm. The dashed curve represents that when $I = 30$ W, $\epsilon = 0$, and $f_B = -28.1$ cm.

is, of course, dependent upon the values α, β, and g_0, and may increase or decrease for other values of the laser parameters.

We have found that the inclusion of the diffraction loss term allows greater agreement between experiment and theory. For example, ambiguities arose after an experiment was performed with an end-pumped ND:YAG laser operating CW, TEM_{00}, and with an intracavity frequency-doubling crystal [15]. The $\lambda 1.06$-μm leakage power through an end mirror and the $\lambda 0.53$-μm power generated were monitored as the $Ba_2Na(NbO_3)_5$ crystal temperature was varied through phase match. The ratio of the circulating power, as measured by the leakage power, when $\epsilon = 0$ to that at phase match was determined. The ratio of the calculated circulating powers using (16) was much different until the diffraction loss was included. The results were then consistent with the experiment. The circulating power was calculated by numerical iteration since the equation for I which results from the inclusion of the diffraction loss in the rate equations is cubic and does not have a simple solution.

It is important to note that the diffraction loss is real and cannot be removed by resonator optimization as can the apparent loss due to the $Ba_2Na(NbO_3)_5$ thermal lens. Losses of order 0.001 are of significant consequence to the space laser and great effort is being made here to minimize all losses.

VII. Conclusion

It is clear that the $Ba_2Na(NbO_3)_5$ losses, whether by diffraction or apparent losses from the thermal lens, must absolutely be considered in the design of a laser of this type. Such losses and effects should be considered in other lasers with intracavity elements. We expect similar losses to be present due to acoustical absorption in the $Ba_2Na(NbO_3)_5$ as well, when the acoustooptical mode locking is included. The losses and effects are more or less small effects for the low-power lasers of the type we are presently developing. However, the addition of 10 percent in frequency-doubled power represents a large benefit to the space laser due to required conservation of energy. The added losses will have a greater effect upon

more powerful lasers due to the circulating power dependence of the loss.

Theory of Porous Wall Capillary Tubes for Flowing Gas Lasers

ARISTOTLE PAPAYOANOU AND AKIRA FUJISAWA

Abstract—**Flowing gas capillary lasers exhibit high optical gains. However, as a result of the linear axial pressure variation in the tube bore, gain and saturation intensities are not axially uniform. This pressure variation can be reduced by introducing the gas into the tube bore through the walls of a porous capillary tube. Analysis of the gas flow shows that the axial pressure variation in the porous wall tubes is more gradual than for dense wall tubes leading to more uniform gain conditions. The saturation intensity is more uniform not only due to the reduced pressure anisotropy but also, at higher flow rates, because of axially varying particle dwell times in the discharge region.**

I. INTRODUCTION

WAVEGUIDE capillary lasers exhibit high optical gains and saturation intensities for flowing gas CO_2 systems [1]-[3]. However, axial flow systems give rise to a linearly varying pressure distribution which can cause highly variable gains and saturation intensities along the tube axis [1]-[2]. For narrow bore tubes, fast flow or long capillaries this axial pressure differential can become large thereby limiting the optimum pressure, for gain, to a relatively short length of the tube axis. As previously discussed [4] this establishes realistic limits in scaling such amplifier tubes to long lengths. A method introduced to reduce the pressure anisotropy is to use porous walled capillary tubing. The gas enters the capillary bore discharge region by being pumped from a high-pressure chamber, surrounding the tube, through the pores of the tube wall as shown in Fig. 1. An earlier paper [4] cited experimental and analytical results indicating that more uniform gain conditions are attainable in porous walled capillary tubes for flowing CO_2 laser amplifiers. This paper analyzes the applicable flow conditions and determines the pressure and fluid velocity distributions. It also considers the effect of such flow on the saturation intensity. Finally, experimental data on an improved porous wall capillary tube system are presented.

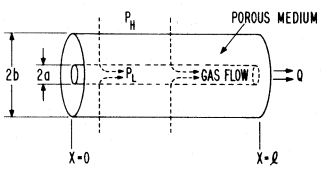

Fig. 1. Representation of gas flowing through porous wall of capillary tube. Gas enters bore along tube length from a high-pressure chamber and is pumped, at volume rate Q, through capillary. The pressure P_H is uniform while P_L, a function of x, varies along the bore.

II. Theory

To analyze the flow situation and determine the pressure distribution we first discuss certain basic viscous flow characteristics.[1]

A gas flowing axially in a dense walled capillary tube of length ℓ and bore radius a obeys the Hagen-Poiseuille viscous flow equations. In this case a pressure gradient is established between the ends of the capillary to overcome gas viscosity η and maintain the flow. In the following discussion the gas temperature is taken to be T, k is the Boltzmann constant, and the pressure difference ΔP is equal to $P_1 - P_2$ where P_1 is the input pressure at $x = 0$ and P_2 is the lower exit pressure at $x = \ell$. $\bar{P}$ represents the average pressure $(P_1 + P_2)/2$. The flow $\mathcal{F}$ in particles per second is given by [5], [6]

$$\mathcal{F} = \frac{\pi a^4 \bar{P}}{8\eta k T} \frac{1}{\ell} \Delta P. \tag{1}$$

Hence, for given capillary bore radius a, and gas properties η and T, the particle current $\mathcal{F}$ depends on $\Delta P/\ell$. In analogy with electrical flow [7] we associate $\mathcal{F}$ with the current i, ΔP with the potential difference and the axial flow resistance $\mathcal{R}$ with the ohmic resistance. Then

$$\mathcal{R} = \frac{8\eta k T}{\pi a^4 \bar{P}} \ell. \tag{2}$$

For viscous flow of fluids through porous media Darcy's law states [6]-[8]

$$v_0 = \frac{\kappa}{\eta} \nabla P \tag{3}$$

where ∇P is the pressure gradient across the porous medium having a "permeability" κ and η is the fluid viscosity. The fluid velocity v_0 is considered to be averaged over a region of space small with respect to macroscopic dimensions in the flow system but large with respect to pore size. For steady-state isothermal flow of an ideal gas, as assumed here, it can be shown [6] that the radial flow through a cylindrical shell of length ℓ, inner radius a, and outer radius b, has a volume flow rate Q given by

$$Q = \frac{\pi \kappa \ell \rho_0 (P_H^2 - P_L^2)}{\eta \ln (b/a)} \tag{4}$$

where ρ_0 is the gas density at unit pressure (equation of state $\rho = \rho_0 P$ assumed), P_H represents the high pressure at the outer tube walls and P_L the lower bore pressure as in Fig. 1. The mass current is $\rho Q = \mathcal{F}_P$. As in the case of Hagen-Poiseuille flow the term analogous to the electrical potential difference is the pressure differential $P_H - P_L$ and the radial flow resistance $\mathcal{R}_P$ is given by

$$\mathcal{R}_P = \frac{\eta \ln (b/a)}{\pi \kappa \rho \rho_0 (P_H + P_L)} \frac{1}{\ell}. \tag{5}$$

[1] Viscous flow occurs at pressures, applicable here, in which the particle mean free path is much less than the bore or pore dimensions. In this case the transport rates of the gaseous components are equalized as a result of collisions between unlike particles and the gas flows as a fluid.

It is the form of (5) which is of interest in further calculations. One notes that $\mathcal{R}_P$ is proportional to $1/\ell$. This allows us to represent the radial flow through the walls of the porous tube, by electrical analogy, as current flow in an equivalent parallel circuit.

Axial flow resistance in a dense wall capillary, see (2), is proportional to tube length ℓ so that the applicable equivalent circuit in this case is that of a series resistance. This is represented in Fig. 2(a) where the tube is divided into N equal length sections each having resistance r. Voltages V_1' and V_N' are the respective analogs of P_1 and P_2 as defined in (1). Fig. 2(b) represents the circuit analog for flow in the porous wall capillary tube having the same bore radius and length as the dense wall capillary. V and V_N are the respective analogs of the uniform high-pressure P_H at the outer tube walls and the exit pressure at the capillary end, $x = \ell$. For purposes of this analysis flow is taken to be in the $+x$ direction.

We have calculated the current distribution appropriate to Fig. 2(b) in terms of ϵ, where $\epsilon = r/R$, and find

$$i_1 = i_2 \frac{1}{1+\epsilon}$$

$$i_2 = i_3 \frac{1}{(1+\epsilon) + \dfrac{\epsilon}{1+\epsilon}}$$

$$i_3 = i_4 \frac{1}{(1+\epsilon) + \dfrac{\epsilon}{(1+\epsilon) + \dfrac{\epsilon}{1+\epsilon}} + \dfrac{1}{1+\epsilon} \dfrac{\epsilon}{(1+\epsilon) + \dfrac{\epsilon}{(1+\epsilon)}}} \tag{6}$$

etc.

Assuming that terms in ϵ^2 can be neglected one finds to first order that, for $n = 1, 2, 3, \cdots, N$

$$i_{n+1} = i_n(1 + n\epsilon) \tag{7}$$

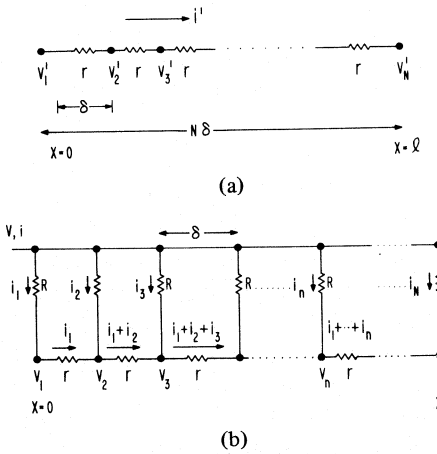

Fig. 2. (a) Electrical circuit analog of flow through capillary of dense walled tube. The resistance to flow over a length segment δ is taken to be r and the particle current remains fixed along the tube axis. (b) Electrical circuit analog for flow in porous wall capillary tube with same bore and length as dense wall tube represented in (a). For length segments δ the radial resistance to flow through the porous wall is R and axial resistance to flow is r. The particle current is no longer uniform along the tube axis.

or in terms of i_1 on the right-hand side

$$i_n = i_1 \left(1 + \epsilon \frac{n(n-1)}{2}\right). \tag{8}$$

Using the preceding one compares the total voltage (i.e., pressure) drop in the bores of the porous and dense walled tubes.

$$\frac{\Delta V_{1-N}^{\text{porous}}}{\Delta V_{1-N}^{\text{dense}}} = \frac{r[i_1 + (i_1 + i_2) + (i_1 + i_2 + i_3) + \cdots + (i_1 + i_2 + \cdots + i_N)]}{i'Nr}. \tag{9}$$

If it is assumed that $i_1 \simeq i_2 \simeq i_3 \simeq \cdots \simeq i_N$, so that $i_1 \simeq i/N$, the numerator in (9) is simplified and one need only use the summation formula for the arithmetic progression, i.e., $1 + 2 + 3 + \cdots + N = N(N+1)/2$. The assumption made in the preceding is discussed in the Appendix. From (9) it now follows that

$$\frac{\Delta V_{1-N}^{\text{porous}}}{\Delta V_{1-N}^{\text{dense}}} = \frac{(i/N)\left(\frac{N(N+1)}{2}\right)}{i'N} = \frac{1}{2}\frac{i}{i'}, \quad \text{for } N \gg 1. \tag{10}$$

Now i and i' can be described by the system standard flows so that for identical system standard flow rates, i.e., $i = i'$

$$\Delta V_{1-N}^{\text{porous}} = \tfrac{1}{2}\,\Delta V_{1-N}^{\text{dense}}. \tag{11}$$

Next we determine the pressure distribution in the bore of the porous wall tube. For $n \leqslant N$ one can write

$$\frac{V_1 - V_n}{V_1 - V_N} = \frac{r[i_1 + (i_1 + i_2) + \cdots + (i_1 + i_2 + \cdots + i_n)]}{r[i_1 + (i_1 + i_2) + \cdots + (i_1 + i_2 + \cdots + i_N)]} \tag{12}$$

and again assuming that $i_1 \simeq i/N$ one can write

$$\frac{V_1 - V_n}{V_1 - V_N} = \frac{(i/N)\left(\frac{n(n+1)}{2}\right)}{(i/N)\left(\frac{N(N+1)}{2}\right)} \approx \frac{n^2}{N^2} \tag{13}$$

for $n, N \gg 1$.

Since the tube is divided into sections of length δ such that $n\delta = x$ and $N\delta = \ell$, it follows that

$$\frac{V_1 - V_n}{V_1 - V_N} = \frac{x^2}{\ell^2}. \tag{14}$$

Since $V_1 = P_A$ is the high pressure at $x = 0$ of the porous capillary bore, V_n is the pressure $P(x)$ at position x along the capillary axis, and $V_N = P_B$ is the exit low pressure one can write

$$P(x) = P_A - (P_A - P_B)(x/\ell)^2. \tag{15}$$

From (11) it is noted that for identical system standard flow rates in the dense and porous wall systems that

$$(P_A - P_B)^{\text{porous}} = \tfrac{1}{2}(P_1 - P_2)^{\text{dense}}. \tag{16}$$

Hence for identical system standard flow rates the total pressure drop in the porous wall system is half that in the dense wall system and, furthermore, the pressure drop from the high- to the low-pressure side is considerably more gradual in the porous wall tube since it declines according to $(x/\ell)^2$ rather than (x/ℓ).

It can also be shown using assumptions previously made that the mass current distribution in the porous wall capillary is given by

$$i(x) = i\frac{x}{\ell}. \tag{17}$$

Since the pressure distribution in the bore falls from some initial pressure P_A to a lower exit pressure P_B it follows, because $i(x) = \pi a^2 \bar{m} n(x) \cdot v(x)$ and $P(x) = n(x) \cdot kT$, that the fluid velocity v increases along the tube axis. Assuming an axially constant gas temperature T one can write

$$v(x) = i\frac{kT}{P_A \bar{m}\pi a^2}\frac{x/\ell}{[1 - (1 - P_B/P_A)(x/\ell)^2]} \tag{18}$$

where $\bar{m}$ is the average particle mass.

III. Saturation Intensity

The saturation intensity I_s can be written as [9]

$$I_s = \frac{8\pi^2 hc\Delta\nu}{\lambda^3(\tau_u + \tau_\ell)} t_{\text{sp}} \tag{19}$$

where τ_u, τ_ℓ are the lifetimes of the upper and lower laser states, respectively, neglecting degeneracies of levels, λ is the wavelength, t_{sp} is the lifetime for spontaneous radiative transition between upper and lower laser levels, h is Planck's constant, c is the speed of light, and $\Delta\nu$ is the Lorentzian half-width of the transition. For fast flowing systems the upper and lower lifetimes are reduced by the rapid introduction of unexcited gas molecules, i.e., CO_2, into and excited molecules out of the discharge region. Then [10]

$$\tau_u = \frac{\tau_2 \tau_F}{\tau_2 + \tau_F}; \quad \tau_\ell = \frac{\tau_1 \tau_F}{\tau_1 + \tau_F} \tag{20}$$

where τ_F is the dwell time of the flowing gas in the discharge region and τ_2, τ_1 are the upper and lower level collisional lifetimes which are inversely dependent on the pressure. Typically, $\tau_1 \ll \tau_2$ and $\tau_1 \ll \tau_F$ so (19) can be written

$$I_s = \frac{8\pi^2 hct_{\text{sp}}}{\lambda^3}\frac{\Delta\nu}{\tau_2}\frac{\tau_2 + \tau_F}{\tau_F}. \tag{21}$$

In the limit of zero flow, i.e., $\tau_F \to \infty$, the right-hand side depends on the ratio $\Delta\nu/\tau_2$. Since $\Delta\nu \propto P$ and $\tau_2 \propto 1/P$ one obtains the familiar result [11], [12] that $I_s \propto P^2$. However, in the case of flow where τ_F becomes comparable to τ_2 the saturation intensity increases beyond the values established by collisional effects. The value applicable to our CO_2 mixture [4] was estimated from published data of relaxation time constants [13] and compared with average values of τ_F applicable to the flow rates used in our experiments. At moderate to high standard flow rates, 15-30 sccm/s in our 1-mm bore tubes, we have found that the average τ_F becomes

comparable to τ_2 and thus must contribute to increasing I_s.

The more interesting aspect is the effect that this flow has on the axial dependence of the saturation intensity. One notes that

$$\tau_F = \frac{\ell - x}{v(x)}. \tag{22}$$

Hence for particles introduced through the pores, into the bore, near the tube ends τ_F becomes very small not only because the numerator in (22) decreases but also because $v(x)$ increases as x increases as seen from (18). Thus the flow acts to increase I_s near the end of the capillary tube thereby countering the effect of the axially decreasing pressure. The net effect is a tendency to maintain I_s axially constant over the capillary length.

IV. Experimental Results

Experimental data for flowing CO_2 gas mixtures using an improved porous wall gain system have been obtained. The basic system configuration was similar to that previously reported [4]. However, the active gain length was increased to 15 cm, an improved cooling block was used, overall system purity was considerably improved, and antireflection coated ZnSe windows were used.

Fig. 3 shows measured small signal gains, on the $P(22)$ line, at a near optimum, 1.8-mA discharge current, using tapwater cooling. Gains up to 21 dB/m were measured. Subsequent measurements made with the probe laser stabilized on the $P(20)$ line center indicates gains approximately 6 percent higher than shown in Fig. 3. Somewhat higher values could be obtained, especially at lower pressures, with higher discharge currents. The largest value measured, on the $P(20)$ line, was 24.3 dB/m at 2.2 mA, a mean pressure of 62 torr, and a flow rate of 12.8 sccm/s. The gain characteristics found appear consistent with the experimental data obtained with conventional CO_2 lasers [10, pp. 739-742]. Included in Fig. 3 are the E/N values for the three flow rates investigated. E

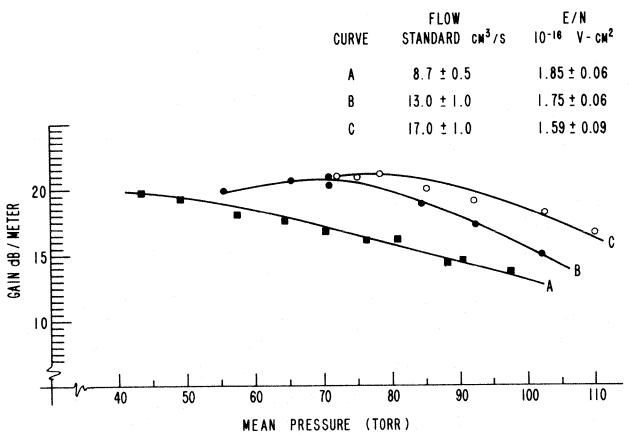

Fig. 3. Small signal gain characteristics of 15-cm-long porous wall capillary tube having a 1-cm bore diameter. Discharge current was 1.8 mA and the gas mixture ratio was $He:CO_2:N_2 = 5:3:2$. Measurements made on $P(22)$ line. Tube wall temperatures were in range 17-23°C. Gas was pumped equally out both tube ends. Total system flow rate is double value given in figure.

is the axial electric field and N is the mean particle number density. Neglecting differences between our mixture ratio and that used in the quantitative analysis of Nighan and Bennett [14] one sees that our experimental E/N values correspond to discharge conditions in which electronic collisions efficiently populate the upper laser vibrational level of CO_2 as well as the first eight vibrational levels of N_2. The gain tube thus operates at near optimum pumping conditions.

The gain tube was also used as part of an oscillator. Dielectric coated cavity mirrors with a 12.5-cm radius of curvature but different reflectivities were used. Optimum spacing of the mirrors from the tube ends was found to be 11.5 ± 0.3 cm. Operating at a mean pressure of 103 torr, a flow rate of 13 sccm/s a current of 1.8 mA, and a tube voltage of 9.4 kV we have measured the output power as a function of mirror transmissivity. For mirror transmissivities of 10, 22, and 34 percent the laser power was 0.36, 0.66, and 1.0 W. Higher transmissivity mirrors are required, but were not available, to experimentally determine the optimum transmission. Peak output was on the $P(20)$ line. Higher powers could be attained at higher discharge currents but this was not systematically investigated. The beam cross section, as observed on a thermal image plate, was a well-defined circle with no visible outer ring.

Appendix

On proceeding from (9) to (10) and (12) to (13) in the text it has been assumed that $i_1 \simeq i_2 \simeq i_3 \simeq \cdots \simeq i_N$ so that $i_1 \simeq i/N$. The following discussion reveals the conditions under which $i_1 \simeq i/N$. Such conditions are similar to those necessary in assuming that $i_1 \simeq i_2 \simeq i_3 \simeq \cdots \simeq i_N$. From Fig. 2(b) one notes that $i = i_1 + i_2 + i_3 + \cdots + i_N$. Using (8) from the text one can write

$$i = i_1 \left[N + \epsilon \sum_1^N \frac{n(n-1)}{2} \right]. \tag{A1}$$

From the summation formulas, $\Sigma n^2 = N(N+1)(2N+1)/6$ and $\Sigma n = N(N+1)/2$ with the sums going from 1 to N, it follows that

$$i = i_1 N \left[1 + \epsilon \frac{(N-1)(N+1)}{6} \right] \tag{A2}$$

and for $N >> 1$

$$i_1 = \frac{i}{N} \frac{1}{(1 + \epsilon N^2/6)}. \tag{A3}$$

But $\epsilon = r/R$ and from the definitions of r and R, i.e., $r = \mathcal{R}/N$ and $R = N\mathcal{R}_P$, one sees that $\epsilon = (1/N^2)(\mathcal{R}/\mathcal{R}_P)$. Thus

$$i_1 = \frac{i}{N} \frac{1}{(1 + \mathcal{R}/6\mathcal{R}_P)}. \tag{A4}$$

The simplification introduced in deriving (10) and (13) that $i_1 = i/N$, is justified when the total capillary flow resistance is less than the total radial flow resistance of the porous shell.

The ratio $\mathcal{R}/\mathcal{R}_P$ depends on various known tube dimensions such as bore diameter, capillary length, shell thickness, average pressures, etc., as well as terms less susceptible to direct deter-

mination such as the permeability κ and the effective viscosity η for gas flow through the pores. Our experimental measurements indicate that $\mathcal{R}/\mathcal{R}_P$ is considerably less than 1 for the porous capillary used. Furthermore, unless tubes of higher porosity or thinner shells (our wall thickness was 3 mm) are used the simplifications used in the text seem reasonable for most experimental setups.

TE CO_2 Laser Pulse Decay and Molecular Relaxation Rates

BRIAN K. GARSIDE, JOHN REID, AND EDWARD A. BALLIK, MEMBER, IEEE

Abstract—**A theoretical model for TE CO_2 laser dynamics is presented, incorporating the effects of coupling between the rotational sublevels of the laser vibrational states associated with the 10.4-μm transition. It is shown that proper incorporation of this coupling is extremely important for modeling both the initial gain-switched output peak and the subsequent rate at which the radiation energy decays away. In particular, it is demonstrated that the latter rate is a measure of the rate at which energy is removed from the lower laser level.**

The lower laser level is coupled to the bending mode by several relatively rapid vibrational energy exchange processes. The coupled bending and asymmetric stretching modes then lose energy at a much slower rate, controlled by the conversion of vibrational energy to translational energy. A proper choice of initial laser level populations allows the decay rate of the pulse tail to be controlled by either one of these. A novel experimental technique is described which allows the two ranges of operation to be explored. A comparison between theory and experiment produces excellent agreement, and the results are employed to determine values for the relevant rates.

Manuscript received January 6, 1975; revised March 27, 1975. This work was supported in part by the National Research Council and the Defence Research Board of Canada.

I. Introduction

IT HAS BEEN demonstrated elsewhere that, to generate theoretical laser output pulses in agreement with experiment, it is essential to allow explicitly for the coupling between the rotational sublevels of the vibrational states associated with the 10.4-μm laser transition in CO_2 [1]. The importance of allowing for this coupling is self-evident for nanosecond pulses, but is less apparent for pulses two orders of magnitude longer than the rotational level coupling time. Nevertheless, proper allowance for this coupling makes a great difference to the predicted temporal shape of the gain-switched laser output, particularly for discharges at moderate gas pressures. Furthermore, the proper incorporation of rotational level coupling has a considerable impact on the modeling of the rate at which the laser energy decays away following the initial gain-switched peak. In this case, the impact of the rotational coupling rate is less direct; its importance lies mainly in the fact that the appropriate conditions of inversion and radiation density in the output pulse "tail" can be reproduced.

In what follows, it will be shown that the behavior of the laser pulse tail is sensitive to the various molecular vibrational energy relaxation rates controlling the decay of the lower laser level population. A comparison between observations

of the laser energy decay and a laser model properly incorporating rotational level coupling permits determination of the rates controlling deactivation of the lower level.

Fig. 1 shows the relevant energy levels of the CO_2 molecule. The lower laser level ($10^0 0$) is coupled to the bending mode by several decay mechanisms [2], [3]. These are represented by 1(*a*), 1(*b*), and 1(*c*), and the resultant overall (fast) equilibrium rate is called Rate 1 with a relaxation time τ_1. On a longer time scale, it is known that the decay of the $10^0 0$ population is controlled by the emptying of the bending mode via collisionally induced transfer of vibrational energy from the $01^1 0$ level to translational energy (*V-T* collisions) [4], [5]. This *V-T* rate will be represented by a time constant τ_{VT}, and is generally supposed to be much slower than Rate 1. In the present work, we have employed a laser technique which permits the decay of the laser energy to be controlled by either τ_1 or τ_{VT}. The experimental approach involves the use of a *Q* switch in a TE CO_2 laser resonator. This switch permits the time at which the laser pulse appears, relative to the discharge current pulse, to be varied at will. A proper choice of this time allows either τ_1 or τ_{VT} to dominate the laser decay. This facility has been employed to determine both relaxation rates under conditions appropriate to laser operation.

Several authors have reported experiments aimed at determining CO_2 ($10^0 0$) decay rates employing conventional longitudinal discharge CO_2 lasers at low pressure [6], [7]. The techniques involve the use of pulsed discharges, in which the decay of the laser radiation, after discharge deactivation, was studied. In particular, the results obtained by Bulthuis [7] indicate that the $10^0 0$ level is apparently weakly coupled to the bending mode, a result also obtained by Rosser *et al.* [8]. These results are at variance with calculations of the coupling rates 1(*a*), 1(*b*), and 1(*c*) [2], [3]. Furthermore, using the most direct measurement technique reported to date, Stark has shown that rate 1(*b*) alone is an order of magnitude faster than the *V-T* rate [9]. We have demonstrated previously, from studies of the small-signal gain in TE CO_2 lasers, that Rate 1 is at least as fast as the *V-T* rate [10]. It is apparent that the relaxation behavior of the $10^0 0$ level in CO_2 is still the subject of much uncertainty. In the present work, we exploit the experimental capability of adjusting the timing of the laser output pulse relative to the discharge pulse to investigate the impact of the various lower laser level deactivation mechanisms. The approach has the twofold advantage that it permits the rate coefficients to be observed under actual lasing conditions, and that the output pulse can, if necessary, be far removed from the influence of the discharge. The previously described techniques lack this capability in that the decay of the laser energy commences during, or very shortly after, the discharge.

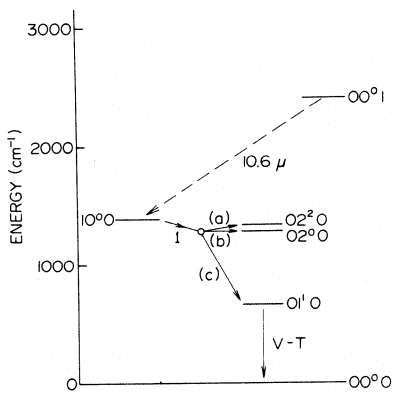

Fig. 1. Energy levels of the CO_2 molecule, and relaxation mechanisms of the lower laser level.

In the following sections, the relevant theoretical model of the laser system will be discussed, and the importance of incorporating rotational coupling into the model will be demonstrated. The experimental system will be described, and it will be demonstrated that the tail of the laser output pulse is controlled by the *V-T* rate when the laser pulse appears well before the occurrence of the gain peak. On the other hand, for operation at times beyond the occurrence of the gain maximum, the pulse tail is controlled by Rate 1. Values are thus determined for the relevant molecular relaxation rates. In particular, it is found that the vibrational coupling of the $10^0 0$ level to the bending mode is much faster than the $01^1 0$ *V-T* deactivation rate. The value obtained for this vibrational energy transfer rate is consistent with the calculations of Seeber [3] and Sharma [2], and the experiments of Stark [9]. It is not in agreement with the results of Bulthuis [7] and Rosser *et al.* [8].

II. Theoretical Model

The laser model employed here is similar to that used by Manes and Seguin [11]; but with the major difference that it has been extended to allow explicitly for the effects of rotational level coupling. The excess population in the lower laser level relaxes to the combined bending and symmetric stretching mode (BS mode) with a time constant τ_1. The BS mode thereafter loses energy at the *V-T* rate. We have simplified the model by considering all relaxation rates as constant throughout the laser pulse. This assumption is reasonable when, as in the case here, all mode temperatures remain small during the pulse [11], [12].

The differential equations governing the system, after completion of the electrical discharge pulse, are as follows:

$$\frac{dN_u}{dt} = -g_\alpha c(n^u_{J-1} - n^l_J)\rho - \frac{N_u}{\tau_u} \tag{1}$$

$$\frac{dN_l}{dt} = +g_\alpha c(n^u_{J-1} - n^l_J)\rho - \frac{N_l - N^e_l(T_1)}{\tau_1} \tag{2}$$

$$\frac{d(n^u_{J-1} - n^l_J)}{dt} = -2g_\alpha c(n^u_{J-1} - n^l_J)\rho - \frac{(n^u_{J-1} - n^l_J) - K(J)\Delta N}{\tau_R} \tag{3}$$

$$\frac{d\rho}{dt} = g_\alpha c(n^u_{J-1} - n^l_J)\rho - \frac{\rho}{\tau_c} \tag{4}$$

$$\frac{dE_{bs}}{dt} = \frac{E_u}{\tau_u} + \frac{E_l - E^e_l(T_1)}{\tau_1} - \frac{E_{bs} - E^e_{bs}(T)}{\tau_{VT}} \tag{5}$$

where $N_u(E_u)$, $N_l(E_l)$ are the populations (energies) in the upper and lower laser levels, $\Delta N = N_u - N_l$, n^u_{J-1} and n^l_J are the populations of the particular rotational sublevels on which lasing occurs, and $K(J)\Delta N$ is the equilibrium value of the rotational inversion ($\sim\frac{1}{15}$ of the total inversion for $P(18)$). ρ is the in-cavity photon density and τ_c is the cavity decay time. The parameter E_{bs} is the energy in the combined BS mode, excluding the lower laser level, which is treated separately. When a parameter is written with the superscript e, e.g., $E^e_{bs}(T)$, it represents the equilibrium value of that parameter at a temperature T. The coefficient, g_α (gain per unit length for unit inversion), is easily determined for any gas mixture and pressure using the data of Robinson [13]. In general, g_α and $K(J)$ have slightly different values for the upper and lower levels, but the average values can be used without any significant loss of accuracy. The other parameters occurring in these equations are the relaxation times; τ_R is the rotational relaxation time and τ_u is the upper laser level decay time.

Observe that, provided the small-signal gain (which is a function of time) and the cavity decay time are known, the major unknown parameters are the relaxation times τ_R, τ_1, and τ_{VT}. The appropriate values of τ_R have been determined previously from a study of the gain-switched output pulse, for the experimental conditions employed in the present work [1]. (For the 10-percent CO_2:90-percent He mixture, this rotational relaxation rate is $3.6 \times 10^6\ s^{-1}\ torr^{-1}$.) Accordingly, for our present purposes, τ_R will be treated as a known parameter, and we concentrate on the importance of the parameters τ_1 and τ_{VT} in determining the behavior of the output pulse. A term was incorporated into the set of (1)-(5) representing the pumping of the $00^\circ1$ level from combination levels such as 01^10. The rate constant determined by Burak *et al.* [14] was used for this purpose, but it turned out that this term made very little difference to the computed pulses. The same result was found for other similar pumping terms such as $CO_2(00^\circ2) + CO_2(00^\circ0) \rightarrow 2CO_2(00^\circ1)$. Starting conditions for numerical calculation employ a small initial value of ρ at the instant of Q switching.

In the following sections, we shall discuss experimental observations of the laser pulse tails and employ the above theory in their interpretation. Prior to proceeding with this plan, the predictions of the above theory for typical experimental circumstances are compared with those deduced by taking $\tau_R = 0$. That is, a comparison is made between the present and previously employed theories describing TE CO_2 lasers [11], [15]-[17]. Parameters typical of a 10-percent CO_2:90-percent He gas mixture, at a total pressure of 27 torr, were employed for the calculations. This gas pressure is typical of those employed in the subsequent experiments. Similar differences between the two theories also occur at higher pressures. Fig. 2 shows the predicted behavior of the laser pulse and the gain in the $P(18)$ transition as a function of time, obtained when the rotational levels maintain thermal equilibrium throughout the laser pulse. Observe that the laser pulse has a main peak which decays away rapidly, and is followed by a subsidiary peak. This reflects the behavior of the inversion. The main laser pulse depletes the inversion almost to zero, and so (provided the cavity decay time is much faster than τ_1) the pulse decays away at a rate close to the cavity decay rate. The inversion then recovers as the excess population is removed from the lower laser level on a time scale commensurate with τ_1. If this recovery produces a sufficiently large inversion, the radiation density will build up to another smaller peak. This order of events may occur several times; a third pulse is in fact produced 3 μs after the main peak in this case. Such behavior has been predicted previously using similar laser models, but has not usually been observed for gas mixtures without N_2 [17]. Fig. 3 shows the behavior of the laser pulse and gain predicted when the finite rotational level coupling time is taken into account. For purposes of

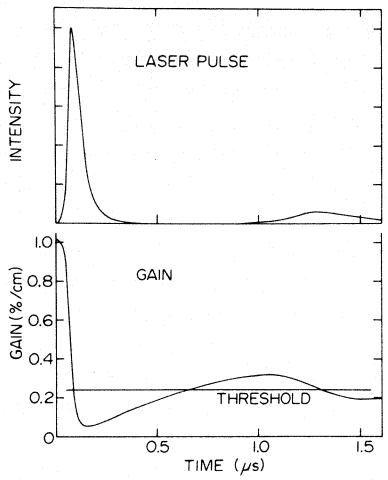

Fig. 2. Laser pulse and gain, calculated employing a model which does not include rotational coupling. The cavity length is 200 cm, with a cavity decay time of 33 ns, and the amplifier length is 92 cm. All vibrational relaxation rates used in the calculations are chosen to correspond to a 10-percent CO_2:90-percent He mixture at 27 torr total pressure; the values of Rate 1 and the V-T rate used are those determined in Section III. Lasing takes place at the peak of the time-dependent gain.

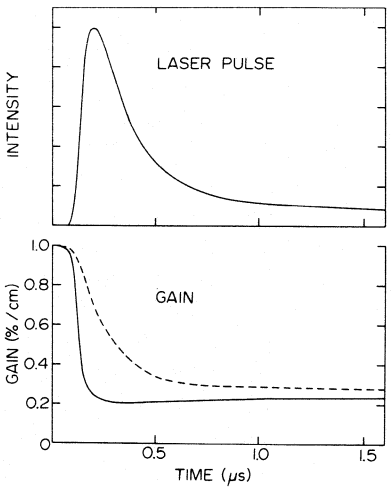

Fig. 3. Laser pulse and gain calculated employing a model including the finite rotational level coupling time ($\tau_R = 10$ ns). All other parameters are the same as for Fig. 2. The dashed line indicates the time dependence of $g_\alpha K(J)\Delta N$. Note the large departure from rotational equilibrium at the time of the laser pulse peak. The threshold gain is 0.24 percent/cm, the same as in Fig. 2.

comparison, the gain corresponding to the thermal equilibrium inversion is also plotted for the same transition (dashed line). Observe that the laser output pulse now decays away monotonically and that the $P(18)$ inversion is reduced to a value considerably less than the equilibrium value. In this case, the transfer of energy from other rotational lines at a finite rate prevents the main peak of the pulse from depleting the entire inversion, and serves to hold the gain close to threshold at the start of the pulse tail. The tail then subsequently decays at a rate determined by the emptying of the lower laser level. For the situation shown, the lower laser level emptying is controlled by τ_1. In the next section, we shall show that observed output pulses are of the general form given in Fig. 3. Furthermore, experimental conditions can be chosen so that *either* τ_1 *or* τ_{VT} determines the rate at which the pulse tail decays.

III. Experimental Methods and Observations

Fig. 4 is a schematic diagram of the apparatus used to observe the laser pulse decay. The laser cavity contains a resistor-pin discharge tube [18] and two 1-in focal length antireflection-coated Ge lenses. A diffraction grating acts as one mirror of the resonator, and permits the laser wavelength to be selected from a range of rotational lines. The cavity can be Q switched by means of a rapidly rotating slotted disk, which is positioned to intersect the cavity at the common focus of the two lenses. The activation time of the Q switch is considerably faster than the buildup time of the laser pulse, and introduces no additional losses into the cavity during lasing. The timing of the Q switching relative to the firing of the gain tube is controlled using a 6328-Å He-Ne laser "trigger" beam. This beam passes through a second slot in the rotating disk and is incident on a photodiode. This arrangement produces a train of output pulses from the photodiode synchronized with the laser resonator switching times. The pulse train is fed to a repetition rate control unit, which counts down the repetition rate to 2 or 3 pulses per second (pps) while maintaining time synchronization. These pulses, suitably delayed, are employed to trigger both the gain tube and the monitoring oscilloscope. The time delay controlling the firing of the laser discharge can be adjusted so that the laser pulse is located at any interval during the time-dependent gain. Two apertures were positioned in the cavity to ensure that lasing occurred in the TEM_{00} mode, and that no higher order transverse modes were present. Lasing generally occurred on several longitudinal modes, as evidenced by nanosecond spiking structure in the pulse. It was experimentally determined that the laser pulse envelope did not depend upon the details of this structure. Consequently, the detector system response time was adjusted to display only the pulse envelope.

The shape of the laser output pulse was studied at various stages during the time development of the laser gain. Fig. 5 illustrates the laser pulses observed prior to, and just after, the peak of the gain. Notice particularly the relatively large and very long pulse tails which occur for laser operation at times well before the gain maximum. The pulse tails which occur for times at, and beyond, the gain peak are well defined but relatively smaller in magnitude. Furthermore, the tails in this region decay away at a rate roughly an order of magnitude faster than those observed during the rise time of the gain.

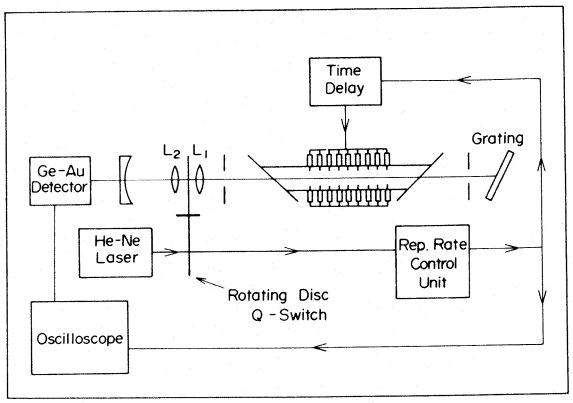

Fig. 4. Schematic diagram of apparatus. The total cavity length is 200 cm, with a decay time of 33 ns, and the length of the active medium is 92 cm.

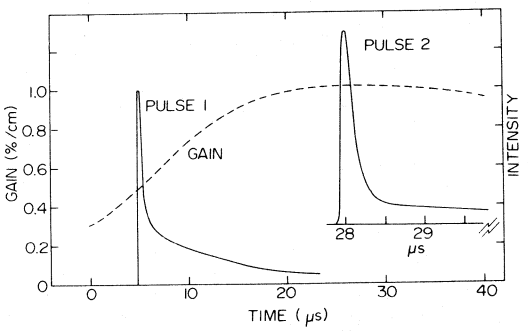

Fig. 5. Two experimentally observed laser pulses together with the small-signal gain profile. A 10-percent CO_2:90-percent He gas mixture was employed, at a total pressure of 36 torr. Pulse 1 is obtained when no Q switch is used; lasing occurs early in the rise time of the gain. Pulse 2 is typical of the pulses obtained when lasing is arranged to take place at, or just beyond, the peak of the gain. Note that an expanded time scale is employed in plotting Pulse 2. The peak intensity of Pulse 2 is 5 times that of Pulse 1.

The great differences observed in the pulses which occu before or after the gain peak arise in the following manner. During the early part of the gain rise time, there is a large population in both the upper and lower laser levels. The gain increases as the population decays away from the lower laser level. The BS modes are in thermal equilibrium during this decay, which arises through V-T transitions of the 01^10 level. If lasing occurs during the early part of this decay, there is a large population remaining in the lower laser level after the peak of the laser pulse. This population is near equilibrium with the rest of the BS modes. It decays away at the V-T rate and so serves to pump the inversion on this time scale. This pumping thereby controls the decay time of the laser pulse tail. When lasing occurs after the peak of the gain pulse, the situation is very different. In this case, the initial energy pumped into the BS modes has decayed away, and these modes are near equilibrium with the translational degree of freedom. As a consequence, the lower level is almost empty just prior to the onset of lasing. The population transferred to the lower laser level during the main laser pulse can now relax to the rest of the BS mode with the time constant τ_1. Again, this produces a pumping of the inversion which serves to control the decay rate of the laser pulse tail. The time scale is naturally much shorter in this case than when the decay is controlled by the V-T rate.

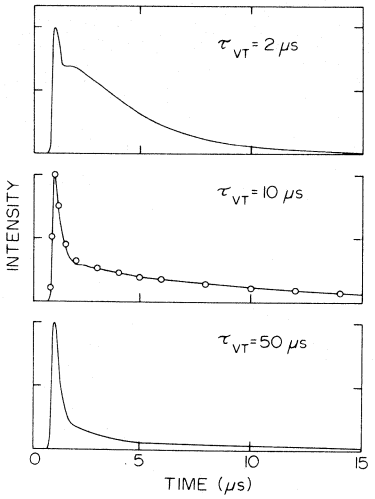

Fig. 6. Computed laser pulses (solid lines) for a range of τ_{VT} values. All other parameters correspond to the experimental conditions appropriate to Pulse 1 in Fig. 5; this pulse is indicated on the central plot as a series of experimental points.

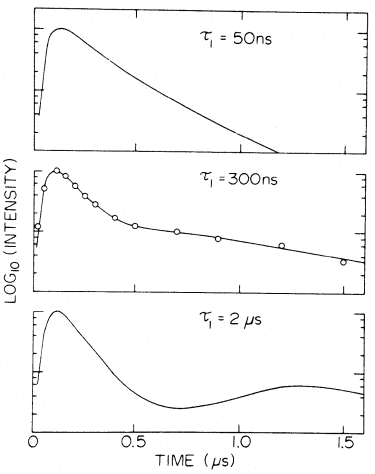

Fig. 7. Computed laser pulses (solid lines) for a range of τ_1 values. All other relaxation rates are chosen to correspond to a 10-percent CO_2:90-percent He mixture at the experimental pressure of 72 torr. The experimental pulse indicated in the central plot was obtained by Q switching the cavity to give lasing at the gain peak (1-percent/cm). To better demonstrate the behavior in the laser pulse tails, the laser intensities have been plotted on a logarithmic scale.

The behavior of the pulse in the two different operating regimes can now be compared with the theory presented in Section II. Furthermore, if sufficiently good agreement is obtained between the laser model predictions and the experimental observations, then values for the relevant molecular relaxation rates can be determined. In what follows, it will be shown that the agreement between theory and observation is excellent. This is particularly satisfying because it has not required the use of a many variable-parameter fit. Applying methods described elsewhere, all the relevant laser parameters, such as values of the gain and laser resonator losses, are experimentally measured [10], [18]. In essence, the fit to the gain-switched peak is a zero parameter fit, and only either τ_1 or τ_{VT}, whichever is appropriate, is varied to obtain the correct behavior of the laser pulse tail.

Fig. 6 shows a typical example of an output pulse obtained for lasing during the rise time of the gain. The output pulse was displayed on an oscilloscope and then photographed. Experimental points, taken from such a photograph, are shown in the figure. Also indicated are pulses predicted from the theory for different values of τ_{VT}. In order to provide a stringent test of the theory, τ_{VT} was not arbitrarily chosen to give the best fit. Instead, the value of τ_{VT} deduced from the data of Taylor and Bitterman [5] was used. For the gas mixture employed (10-percent CO_2:90-percent He at 36 torr), τ_{VT} is 10 μs. This value of τ_{VT} not only gives the excellent fit to the experimental laser pulse seen in Fig. 6, but also accurately models the time dependence of the experimental small-signal gain, when the lasing terms are removed from (1)-(5). (The value of τ_1 employed is of little consequence provided that it is less than τ_{VT}.)

Fig. 7 shows an example of an output pulse, observed at a time just beyond the small-signal gain peak. Little change is observed in the general shape of the experimental pulse for

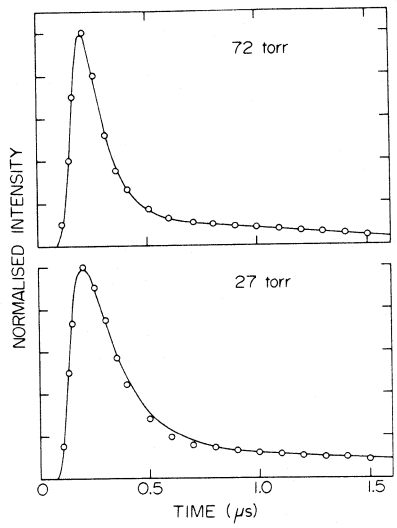

Fig. 8. Comparison of computed (solid lines) and observed laser pulses for two widely different gas pressures in a 10-percent CO_2:90-percent He mixture. In each case, lasing took place just after the peak of the time-dependent gain (1 percent/cm). Rate 1 is set at 4.6×10^4 s^{-1} $torr^{-1}$ in each calculation, and all other relaxation rates are similarly scaled with pressure.

later and later times during the decay of the gain. This indicates that once the gain has attained its peak value, all influence of extraneous discharge products has disappeared. In Fig. 7, the experimental pulse is compared with pulses generated by employing several different values of τ_1 in the theoretical model. To better demonstrate the behavior of the laser pulse tails, the laser intensities have been plotted on a logarithmic scale. Evidently, the pulse tail is very sensitive to the value of this parameter. The present apparatus could not be operated above 150 torr, since this marked the onset of intermittent air breakdown at the common focus of the two lenses employed in the Q switch. However, this is no real disadvantage, because at high pressures Rate 1 is so fast that the laser tails cannot be distinguished from the falling edge of the main peak. Over the range of pressure studied, the output pulse tail is sensitive to the value of τ_1 to the extent that it can be employed as a measure of the effective relaxation rate. This rate was found to scale with pressure and had a value of 4.6×10^4 s^{-1} $torr^{-1}$ for a 10-percent CO_2:90-percent He mixture. Fig. 8 shows the fits obtained, using this value, for two widely different gas pressures. It is a source of satisfaction that such excellent fits can be obtained by simply scaling all relaxation rates with pressure. It is noteworthy that the experimental change in the relative intensity of the laser pulse is also reproduced closely by the theory. In the following section, the significance of these observations is discussed, and the results are related to the work of others.

IV. Discussion and Conclusions

Previous models of gain-switched TE CO_2 lasers have not taken account of the finite coupling time between rotational sublevels of the 10.4-μm band [11], [15]-[17]. We have demonstrated here and elsewhere [1] that, in order to obtain good fits with experimentally observed laser pulses, it is necessary to include the effects of rotational coupling. The laser model described in Section II not only fits the observed rise and fall times of the main laser pulse, but also reproduces the appropriate conditions of inversion and radiation density in the initial part of the laser pulse tail. These correct starting conditions are essential for subsequent comparisons between the theoretical and experimental behavior of the laser pulse tails.

It is shown that the behavior of the laser pulse tail is controlled by the emptying of the lower laser level. The relaxation of the lower laser level takes place in two stages: 1) A fast relaxation into the bending mode levels (Rate 1), and 2) a subsequent slower relaxation of the bending mode (V-T). By carefully controlling the experimental parameters, we have measured both these rates under actual lasing conditions. The results obtained for the V-T rate are in agreement with the data given by Taylor and Bitterman [5]. We have measured Rate 1 over a wide range of pressure for a 10-percent CO_2:90-percent He mixture. The rate constant for the mixture is 4.6×10^4 s^{-1} $torr^{-1}$. Assuming that CO_2 is twenty times more effective than He for this relaxation [9], the effective relaxation rate for CO_2 is $\sim 3 \times 10^5$ s^{-1} $torr^{-1}$. This value is in good agreement with the calculations of Seeber [3] and Sharma [2], and with the experimental results of Stark [9]. Seeber calculates an effective value for Rate 1 of $\sim 2 \times 10^5$ s^{-1} $torr^{-1}$, while Sharma gives an estimate of $\sim 6 \times 10^5$ s^{-1} $torr^{-1}$. Stark has directly measured the $10^0 0 \rightarrow 02^0 0$ relaxation rate and obtains a value of 1.4×10^5 in CO_2. Manes and Seguin [11] have used a technique somewhat akin to the method reported here to estimate the coupling rate between the symmetric stretching mode and the bending mode in CO_2. By comparing experimental laser pulses at atmospheric pressure with a theoretical model, they determined that the intermode coupling rate was $\sim 1.4 \times 10^6$ s^{-1} $torr^{-1}$. However, their theoretical model did not explicitly include rotational relaxation, with the result that their estimated coupling rate is probably too fast.

It follows from the above that the lower laser level in CO_2 is very strongly coupled to the bending mode levels, with a coupling rate certainly greater than 10^5 s^{-1} $torr^{-1}$. This is much greater than the results reported by Bulthuis [7] and Rosser *et al.* [8], who obtain coupling rates of 1.5×10^4 and 10^3 s^{-1} $torr^{-1}$, respectively. Undoubtedly, these rates are incorrect for the lasing conditions reported here. The source of the very large disagreement is not clear and merits further investigation.

We have chosen to determine relaxation rates by fitting to the shape of the experimental pulses. In principle, the rates can be determined by fitting to the absolute intensity of the pulses, but this requires a calibrated detector and an accurate knowledge of cavity mode and active medium volumes. These additional complications make intensity comparisons inherently less accurate than pulse-shape comparisons. This is particularly true in the pulse tails, which contain only a small fraction of the total energy of the pulse.

Although relaxation rates reported here were measured in a 10-percent CO_2:90-percent He mixture, the technique can easily be extended to measure rates in other He:CO_2 mixtures. Preliminary observations using other mixtures indicate that the

V-T is helium controlled, as is expected from the data of Taylor and Bitterman [5]. Preliminary results on the variation of Rate 1 with mixture indicate that CO_2 is an order of magnitude more effective than He at relaxing the lower laser level into the bending mode. The addition of N_2 to the laser gas mixture produces laser pulses with very long tails which obscure the CO_2 relaxation rates. Nevertheless, by extending the theoretical model to include a nitrogen ($v = 1$) pump term, the CO_2-N_2 coupling rate can, in principle, be determined.

The in-cavity laser technique described in this paper is an extremely versatile method of measuring relaxation rates. We have employed it to measure relaxation times in CO_2 which differ by more than three orders of magnitude; from *V-T* times of tens of microseconds to rotational coupling times of nanoseconds. The method has the additional advantage that it measures directly relaxation rates which are relevant to the laser dynamics.

The Influence of Oxygen on CO-Laser Performance

H. KEREN, P. AVIVI, AND F. DOTHAN

Abstract—**Additions of a few parts per thousand of oxygen to a CO-He mixture change drastically the laser output power, the axial field in the positive column, and the slope of the *E-I* curve of the discharge. The intensity of the spectrum of vibrational transitions of the CO molecule increases when oxygen is added; the increase is especially pronounced for transitions from higher ($v > 7$) levels. The most prominent feature in the visible spectrum is the disappearance of the C_2-Swan bands with the addition of oxygen. The populations of CO vibrational levels were derived from the IR spectra; they increase by more than an order of magnitude for $v > 7$. The electron energy distribution was derived from measured E/N and the Boltzmann equation. Oxygen affects the Boltzmann equation (and thus the electron energy-distribution function) through the change in E/N, which is in turn determined by ionization and deionization processes. The fractional power transfer from electrons increases to vibrational levels and decreases to electronic levels.**

I. Introduction

THE strong influence of the addition of small quantities of oxygen on the output power of a CO laser is well known. Osgood *et al.* [1], who investigated a mixture of He-N_2-CO-O_2, believe that oxygen prevents the dissociation of CO and the subsequent formation of CN, a relaxant of CO vibrational levels. Taieb and Legay [2] excited N_2 vibrationally and mixed it with neutral CO. They found that increasing additions of O_2 to the CO-N_2 mixture produced first an *increase* of CN and of the laser power, and then a decrease of both. Jöeckle and Peyron [3] investigated the infrared fluorescence of CO excited by active nitrogen. They found that small additions of oxygen lead to an increase of radiation from vibrational levels of CO in the ground state. Larger quantities of O_2 produce a decrease of the infrared radiation. Bhaumik *et al.* [4] maintained that in the presence of oxygen the reaction

$$CO \rightleftarrows C + O$$

is driven preferentially to the left. Larger additions of oxygen change the discharge properties and inhibit lasing. Hartwick and Walder [5] observe that the influence of O_2 cannot be explained solely by the prevention of CO dissociation. They point out that changes of the electron energy distribution and electron density have to be considered.

The purpose of this research is to contribute to the understanding of the effect of oxygen on electronic and vibrational excitation, on ionization, and on macroscopical discharge properties. For this purpose, we recorded and studied the visible and infrared spectra and obtained populations of CO vibrational levels with and without oxygen. We calculated the fractional power transfer from electrons to electronic excitation and to vibrational levels with the help of the Boltzmann equation and from experimental data. In the following we postulate and discuss possible physical mechanisms to explain the influence of oxygen.

II. Experimental Arrangement

A schematic drawing of the experimental arrangement is given in Fig. 1.

The gases used were Matheson research grade. All experiments were performed at room temperature and the partial pressures were CO, 1.4 torr and He, 18 torr. The axial field strength was measured by means of probes and an electrostatic voltmeter.

The infrared radiation was measured by means of a Perkin-Elmer Model 210-B grating monochromator and a PbS (Type B Infratron Products) uncooled detector. In front of the PbS detector a germanium lens was placed to prevent high orders of visible lines entering the detector.

The near UV and the visible spectrum were obtained by means of a $\frac{3}{4}$-m Spex grating spectrometer.

Phase-sensitive detection was used for the UV, visible, and IR spectroscopy.

III. Results

A. Discharge Properties

Fig. 2(a) shows the lasing power at a discharge current of 17 mA as a function of the partial pressure of oxygen. Without oxygen there was no lasing at any current and at any CO or He pressure. The lasing threshold is obtained with the addition of 20-m · torr oxygen, and the maximum laser power (3.8 W) with 50-m · torr oxygen. Further addition of oxygen results in a gradual decrease of laser power, until it becomes zero at oxygen pressures above about 230 m · torr.

Fig. 2(b) shows the axial field in the positive column of the discharge (current 17 mA) as a function of oxygen pressure. Between oxygen pressures of 10 and 25 m · torr there is a drop in the axial field strength from 136 to 88 V/cm. Laser action appears just before the axial field reaches its minimum value. Further additions of oxygen up to 400 m · torr do not change the axial field.

Moving striations at a frequency of about 9 kHz were observed in the He-CO discharge. Upon addition of O_2 these striations disappear gradually and are not observed at all in the partial pressure range from 20- to 400-m · torr oxygen. This indicates that the measured decrease in E/N is the true dc value and not an average of an oscillatory *E*-field.

Fig. 3 shows *E-I* curves (axial field in the positive column as a function of the discharge current) without oxygen (curve 1) and with 50-m · torr oxygen (curve 2). Without oxygen the *E-I* curve has a positive slope; above 17 mA an abrupt change in the discharge characteristics occurs: it becomes unstable in the form of moving "snakelike" patterns. With addition of

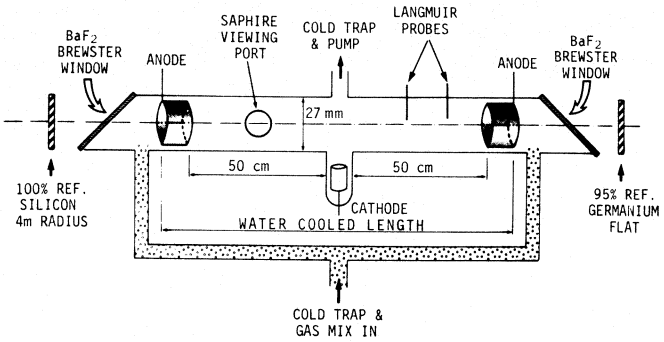

Fig. 1. Schematic of experimental setup.

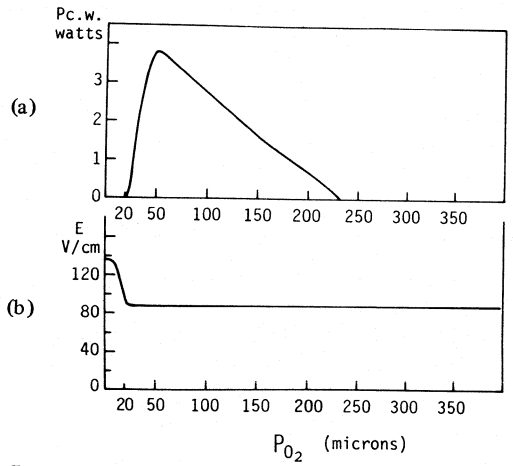

Fig. 2. Influence of partial pressure of O_2 on (a) lasing power and (b) axial electric field in discharge.

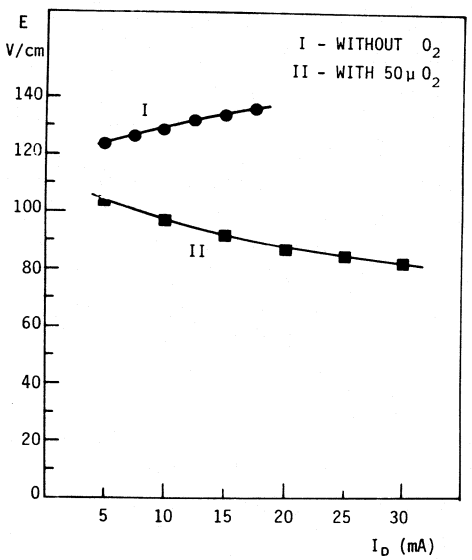

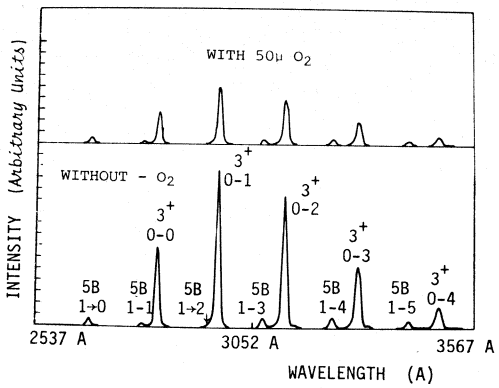

Fig. 3. Influence of partial pressure of O_2 on *E-I* curves of the discharge.

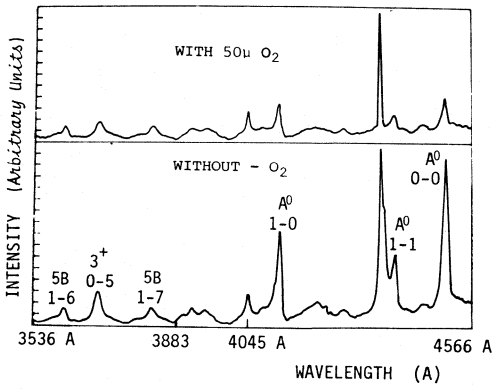
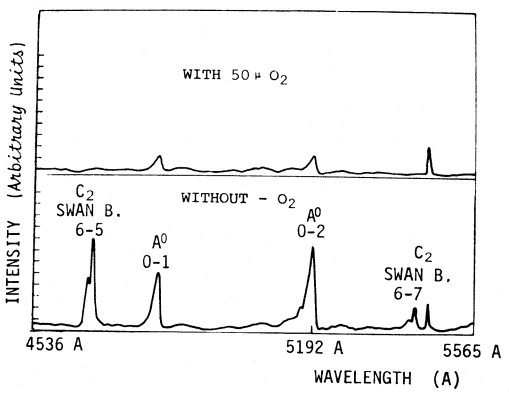
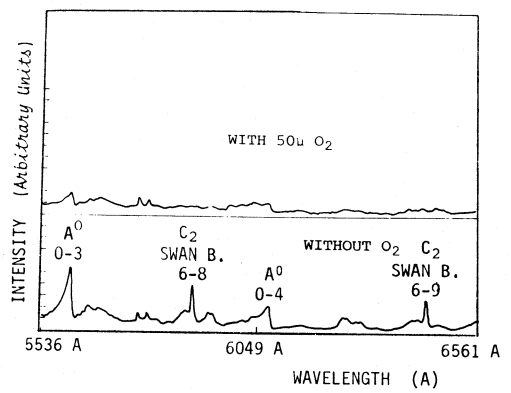


50-m · torr oxygen the slope of the *E-I* curve becomes negative and the discharge is stable at any current value.

B. Spectroscopical Properties of the Discharge



The near UV and visible spectra are given in Fig. 4(a)-(d) (bottom—without oxygen; top—with 50-m · torr oxygen; current strength in both cases, 10 mA). Without oxygen the following bands are detected (see Figs. 5 and 6 for the relevant



(a)

(b)

(c)

(d)

Fig. 4. (a) Influence of 50 m · torr of oxygen on the emission spectrum in the near UV. (b) Influence of 50 m · torr of oxygen on the emission spectrum between 3536 and 4566 Å. (c) Influence of 50 m · torr of oxygen on the emission spectrum between 4536 and 5564 Å. (d) Influence of 50 m · torr of oxygen on the emission spectrum between 5536 and 6561 Å.

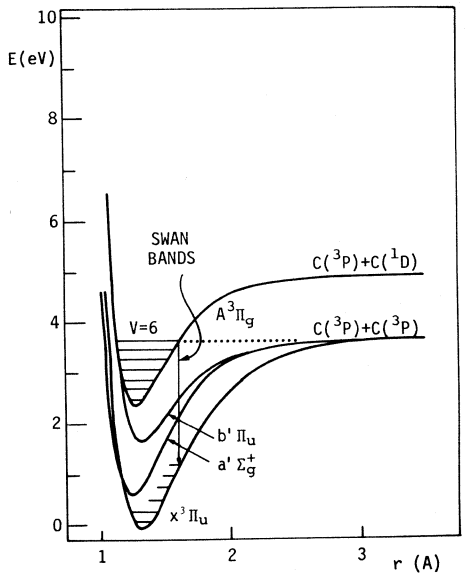

Fig. 6. Potential curves of the low electronic states of the C_2 molecule.

transitions): CO-3$^+$, 5B, A°, C_2-Swan bands. The lines of the 3$^+$ band have the highest intensity. The Swan bands are due to transitions from $v' = 6$ of the $A^3\Pi_g$ electronic level to $v'' = 5, 7, 8, 9$ of the electronic ground state.

The addition of 50-m · torr oxygen results in a decrease of the intensity of the 3$^+$ and A° bands of CO by a factor of 3, and of the 5B band by a factor of 2. The C_2 bands disappear entirely.

In the infrared region, the first overtone (transitions between vibrational levels $n + 2$ and n) of CO were recorded. The relative response of the instrument train as a function of wavelength was determined by scanning a blackbody source. Fig. 7 shows the results, corrected for system sensitivity. The slit width of the spectrometer was 400 μm (low-resolution measurement). The lower curve is the IR spectrum of the discharge without oxygen. The current was 12 mA and the axial field 132 V/cm. The upper curve shows the spectrum with 50-m · torr oxygen, at a current of 18 mA and an axial field of 88 V/cm. The power input, and thus the gas temperature of

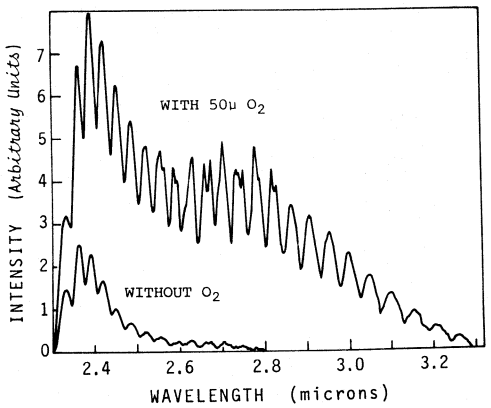

Fig. 7. Influence of the partial pressure of O_2 on the IR first-overtone emission spectrum of the CO–He mixture.

the discharge, was the same in both cases. It can be seen that the ratio of intensities, with and without oxygen, becomes greater for transitions involving high vibrational levels.

C. Distribution of Vibrational-Level Population

The procedure for the calculation of the distribution of CO molecules within vibrational levels (unfolding) was similar to that used by Horn and Oettinger [6]. To perform the unfolding of the low-resolution spectrum, the instrumental linewidth was found ($\Delta\lambda_{1/2}$ = 67 Å) by means of calibration with the sixth order of the 4358-Å Hg line. The rotational temperature was determined from the high-resolution spectrum (slit width, 25 μm). The R rotational transitions of the vibrational $2 \rightarrow 0$ transition do not overlap with higher vibrational-rotational transitions; from the relative line intensities the rotational temperature was found to be T_R = 460 K.

The populations of the vibrational levels are determined by finding the best fit of a synthetic spectrum to the measured spectrum. The synthetic spectrum is calculated from assumed vibrational populations, taking into account the rotational temperature and instrumental width. For the purpose of the calculation, 40 rotational lines of each of the P and R branches were considered. The synthetic spectrum (not shown here) is nearly identical with the measured one.

Fig. 8 shows the population distribution of vibrational levels which results from the unfolding procedure. The increase of the population of higher vibrational levels with the addition of 50-m · torr oxygen to the CO–He mixture is striking. While the populations for the $v = 1$ level are approximately equal with and without oxygen, they are different by a factor of 10 for $v = 7$, and by a factor of 20 for $v = 13$; the difference is presumably much greater for $v > 15$ (see Fig. 7).

IV. Electron Energy Distribution and Fractional Energy Transfer

The fraction of energy transferred by electrons to CO vibrational levels and to CO electronic levels was determined by solving numerically the Boltzmann equation for our experimental conditions. The form of the Boltzmann equation was that used by Nighan [7]. Cross sections for vibrational excitation were taken from Schulz [8] and for electronic excita-

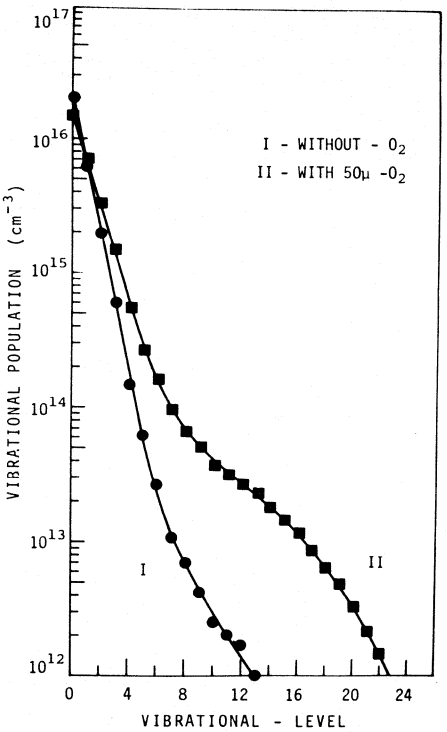

Fig. 8. Calculated vibrational population distribution as derived from Fig. 7.

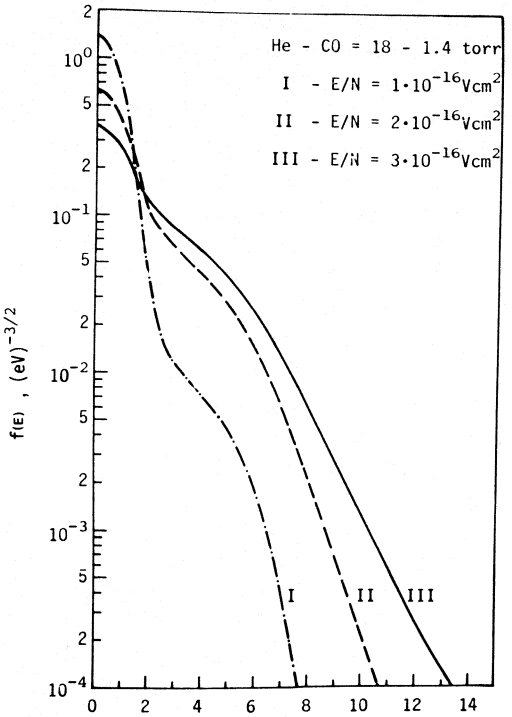

Fig. 9. Calculated electron energy distribution for different values of E/N.

tion from Chung and Lin [9]. Momentum-transfer cross sections for He and CO were used, as given by Massey *et al.* [10] and Hake and Phelps [11], respectively. Superelastic collisions between electrons and CO vibrational levels were not considered. The influence of the small quantities of oxygen on the energy transfer from electrons was neglected because the loss of electron energy is predominantly determined by CO. This is so because the relative gas densities are $\delta[O_2]:\delta[CO] = 1:30$; moreover, the relative cross sections for O_2 are smaller than for CO, [11].

Oxygen affects the Boltzmann equation (and thus the electron energy-distribution function) through the change in E/N, which is in turn determined by ionization and deionization processes.

Fig. 9 shows the calculated electron energy-distribution function for three different values of E/N. Two of the curves are for E/N values used in our experiments: $E/N = 3 \times 10^{-16}$ V/cm^2, without oxygen, and $E/N = 2 \times 10^{-16}$ V/cm^2, with 50-m · torr oxygen. The non-Maxwellian form of the distribution is pronounced. The similarity of the distributions to those obtained by Nighan [12] should be noted.

The reduction of E/N in the positive column caused by the addition of O_2 produces a change in the electron energy distribution, leading to a depletion of high-energy electrons and an overall shift of the distribution to lower energies. As a consequence, there is less excitation of electronic levels and more of vibrational levels.

Fig. 10 shows the fractional energy transfer from electrons as a function of E/N. In our experimental conditions *without oxygen* 63 percent of the energy is expended for electronic excitation and 37 percent for vibrational excitation. With the addition of 50-m · torr oxygen the figures are: 36-percent electronic, 64-percent vibrational. This means the energy transfer into vibrational levels was increased by 75 percent, and the transfer into electronic levels decreased by 45 percent.

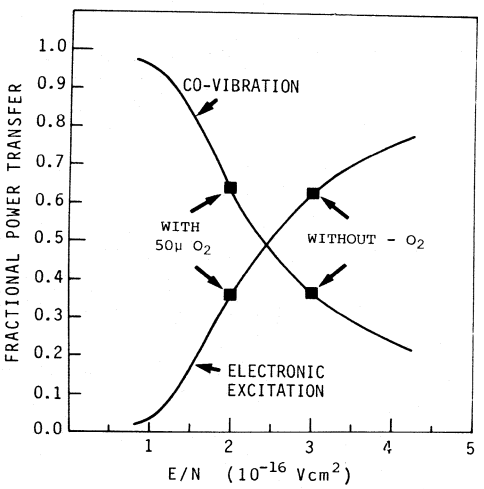

Fig. 10. Fractional electron–molecule power transfer as computed for experimental conditions.

V. Discussion and Conclusion

The axial field is drastically reduced when about 1 percent of oxygen is added to the CO-He mixture [Fig. 2(b)]; from this we conclude that the oxygen strongly influences the ionization process. A further indication in the same direction is the change of the slope of the *E-I* curve (Fig. 3) from a positive slope (without oxygen) to a negative one (with

oxygen). This can be explained by stage processes such as excitation and subsequent ionization of metastable states, probably of the oxygen molecule. More direct evidence for this mechanism should be provided by the identification of the dominant ion in the discharge. Without oxygen the ionization is probably from the ground state of the CO molecule, and not from the metastable $a^3\Pi$ level, as this level is efficiently relaxed by collisions with CO in the ground state (rate constant 1.1×10^{-10} cm^{3}s^{-1}), [13]. An interesting feature in the visible spectrum is the disappearence of C_2-Swan bands when oxygen is added. As mentioned before, only the transitions from $v' = 6$ of the $A^3\Pi_g$ electronic level to $v'' = 5, 7, 8, 9$ levels of the ground state are involved. This indicates that the origin of the radiation from the C_2 molecule is due to the recombination of the C atom into the excited C_2 molecule.

The intensity of A°, $5B$, and 3^+ bands of CO decrease when oxygen is added (see diagram of CO levels given in Fig. 5). There is also indirect evidence for the decrease of the population of the metastable $a^3\Pi$ level of the CO molecule, which is populated either by direct electronic excitation or by radiative transitions $5B$ and 3^+ from the upper levels. The disappearance of the C_2 bands can be explained by the decrease of the $a^3\Pi$ population, as most of the carbon is produced by the reaction

$$CO(a^3\Pi) + CO(v \geqq 0) \rightarrow CO_2 + C + KE.$$

The energy levels of the O_2 molecule (see Fig. 11) include metastable levels at 1 eV, 1.5 eV, 5 eV, 6 eV, and possibly also at higher levels. The relaxation of the $CO(a^3\Pi)$ level by the reaction

$$CO(a^3\Pi) + O_2 \rightarrow CO + O_2 + KE$$

is very efficient (relaxation constant 2×10^{-10}cm^{3}s^{-1}), [13]. In this process the energy of the $CO(a^3\Pi)$ levels is not converted to kinetic energy, but is stored in a long-lived metastable level of the oxygen molecule.

In conclusion, it seems from our experiments and calculations that small additions of O_2 to CO-He laser mixtures cause primarily a change in the electron energy distribution. This change reveals itself by an increase of the relative fraction of energy transferred by electrons to vibrational levels in the ground state of CO at the expense of energy transferred to electronic levels. This results in an increase of lasing power, as has indeed been observed.

We suggest here that O_2 depopulates, very efficiently, the $a^3\Pi$ level of CO, which is a sink of wasted electron energy in the absence of O_2. In addition, the striking evidence for stepwise excitation in the presence of O_2 leads us to believe that the following processes occur: electrons excite CO molecules to the $a^3\Pi$ level, which is then efficiently quenched by O_2 molecules and its energy transferred to a metastable level of O_2. The ionization proceeds from such a metastable level. This mechanism implies that the main positive-charge carrier in a lasing mixture with small additions of O_2 should be oxygen-molecular ions. This implication is currently being investigated, and the results will be reported in due course.

Multiphoton Optical Heterodyne Detection

MALVIN CARL TEICH, SENIOR MEMBER, IEEE

Abstract—**After reviewing recent work on multiphoton direct detection and single-photon heterodyne detection, we examine the behavior of a multiphoton absorption heterodyne receiver. Expressions are obtained for the detector response, signal-to-noise ratio (SNR), and minimum detectable power for a number of cases of interest. Receiver performance is found to depend on the higher order correlation functions of the radiation field and on the local oscillator (LO) irradiance. Although performance similar to that of the single-photon heterodyne receiver can theoretically be achieved, practical problems would appear to make this difficult. A physical interpretation of the process in terms of the absorption of monochromatic and nonmonochromatic photons is given. The double-quantum case is treated in particular detail; the results of a preliminary experiment are presented and suggestions for future experiments are provided.**

I. Introduction

Inasmuch as single-quantum optical heterodyne detection and multiple-quantum optical direct detection are by now well-understood processes, it seems natural to investigate the properties of a detection scheme in which both are performed simultaneously. In this paper, we obtain the response and the signal-to-noise power ratio for a multiple-quantum absorption heterodyne receiver, with particular attention devoted to the simplest case, i.e., the mixing of two waves in a double-quantum infrared or optical device.

After briefly considering the relevant results pertinent to each of the processes individually (Section I), we derive the combination device response for the general multiple-quantum photomixing process in Section II. In Section III, the response for the important two-quantum case is obtained and given a physical interpretation. In Section IV, we obtain the signal-to-noise ratio (SNR) for a receiver using a multiphoton optical heterodyne device, and compare it with the SNR for conventional optical heterodyne detection. The results of a two-photon experiment are presented in Section V, while a suggested setup for future experiments, as well as the applicability of the scheme in general, is reserved for Section VI.

A. Multiphoton Direct Detection

The ordinary photoeffect was discovered by Hertz in 1887 and explained in terms of the absorption of a single quantum of light by Einstein in his now famous work published in 1905 [1]. It was not until 1959, however, that the relationship between the statistics of an arbitrary incident radiation field and the emitted photoelectrons was firmly established by Mandel [2]. Consideration of the general photodetection process in terms of quantum-electrodynamic coherent states of the radiation field was undertaken by Glauber [3] in 1963, and by Kelley and Kleiner [4] in 1964, and provides a convenient starting point for calculations involving multiple-photon as well as single-photon absorptions.

Multiple-quantum photoemission, being a higher order effect, is most easily observed in the absence of ordinary (first-order) photoemission. For the two-quantum case, it becomes important when

$$\tfrac{1}{2}\, e\phi < h\nu < e\phi \tag{1}$$

where $h\nu$ is the photon energy of the incident radiation and $e\phi$ is the work function of the material under consideration. (Even when (1) is satisfied, however, it should be kept in mind that small amounts of single-quantum photoemission can arise from excited electrons in the Fermi tail [5].) The two-quantum photoeffect was first experimentally observed in 1964. Using a GaAs laser, Teich *et al.* [6] observed the effect in sodium metal, while Sonnenberg *et al.* [7] induced it in Cs_3Sb with a Nd-doped glass laser. Since that time, there have been a number of experimental measurements of second- and higher order photoelectric yields in a variety of materials [8]-[12].

Theoretical work has focused on two aspects of the problem: perturbation theory and other calculations of the transition probabilities in the material, and the effect on the transition probability of the statistical nature of the radiation field. Makinson and Buckingham [13] were the first to predict the second-order effect and calculate its magnitude based on a surface model of photoemission; this work was expanded by Smith [14], Bowers [15], and Adawi [16]. The analogous volume calculation was performed by Bloch [17] and later corrected by Teich [8], and Teich and Wolga [9].

All of the models predict a two-quantum dc photocurrent $W_{dc}^{(2)}$ (expressed in amperes) proportional to the square of the incident radiation power P and inversely proportional to the irradiated area A. Using the results of a number of authors [8], [9], [14]-[17], we can therefore write the double-quantum dc photocurrent as

$$W_{dc}^{(2)} = \Lambda^{(2)}(\lambda, T)\, P \propto IP. \tag{2}$$

Here $\Lambda^{(2)}$ is the two-quantum yield expressed in amperes per watt [9], λ is the radiation wavelength, T is the sample temperature, P is the radiation power expressed in watts, and I is the irradiance at the detector expressed in watts per square centimeter. The two-quantum efficiency (electrons/photon) is denoted by η_2, and is related to the two-quantum yield by the relationship

$$\Lambda^{(2)} = (e/h\nu)\, \eta_2 \propto I. \tag{3}$$

Here, the quantity $(h\nu/e)$ is the incident photon energy expressed in electronvolts and is of order unity. For the k-photon process, defining $W_{dc}^{(k)}$, $\Lambda^{(k)}$, and η_k as the k-photon analogs of the quantities defined above, the following generalized results

Manuscript received January 27, 1975. This work was supported in part by the National Science Foundation, and in part by the John Simon Guggenheim Memorial Foundation.

The author is with the Department of Electrical Engineering and Computer Science, Columbia University, New York, N.Y. 10027, and is a Fellow of the John Simon Guggenheim Memorial Foundation, New York, N.Y.

are obtained:

$$W_{dc}^{(k)} = \Lambda^{(k)}(\lambda, T)\, P \propto I^{k-1} P \tag{4}$$

and

$$\Lambda^{(k)} = (e/h\nu)\, \eta_k \propto I^{k-1}. \tag{5}$$

Typical numerical values for the two-quantum yield are [9] $\Lambda_{Na}^{(2)}(8450\ \text{Å}, 300\ \text{K}) \sim 8 \times 10^{-16} I$ and $\Lambda_{Cs_3Sb}^{(2)}(10\,600\ \text{Å}, 300\ \text{K}) \sim 5 \times 10^{-11} I$ A/W. Again I represents the irradiance at the detector in watts per square centimeter. These values, even when precisely measured, can vary by a factor (usually $\leqslant 2$) depending on the coherence properties of the inducing radiation, as we now consider.

Theoretical work relating to multiple-quantum statistical effects began in 1966 with an examination of the higher order field correlation functions by Teich and Wolga [18] and by Lambropoulos *et al.* [19]. This was followed by more detailed calculations by Mollow [20] and by Agarwal [21]. All of these studies predicted a factor of $k!$ enhancement for the magnitude of certain k-quantum processes induced by chaotic (rather than coherent) sources. This enhancement was later observed in the two-quantum photoeffect by Shiga and Imamura [10], and in second-harmonic generation (SHG) by Teich *et al.* [22]. The theoretical relationship between two-quantum photocurrent spectra and the incident radiation statistics was then obtained by Diament and Teich [23], and compared with the analogous single-quantum results previously given by Freed and Haus [24]. In 1969 two-quantum photocounting distributions were calculated for amplitude-stabilized, chaotic, and generalized laser sources by Teich and Diament [25]. This work was extended to higher order photocounting distributions by Barashev in 1970 [26], who also wrote an excellent and comprehensive review article on multiple-quantum photoemission and photostatistics in 1972 [27].

B. Single-Photon Heterodyne Detection

Being a first-order effect, ordinary optical and infrared heterodyne detection has received far more attention than has multiple-quantum detection. The usefulness of the technique in applications ranging from spectroscopy to radiometry has been well documented. The effect was first observed by Forrester *et al.* [28] in a classic experiment using two Zeeman components of a visible (incoherent) spectral line. With the development of the laser, photomixing became relatively easy to observe and was studied by Javan *et al.* [29] at 1.15 μm using a He-Ne laser, and by Siegman *et al.* [30b)] at 6943 Å with a ruby laser. Extending this work into the middle infrared, Teich *et al.* used a CO_2 laser at 10.6 μm in conjunction with a copper-doped germanium photoconductive detector operated at 4 K [31], and with a lead-tin selenide photovoltaic detector operated at 77 K [32].

The observed signal-to-noise power ratio for these experiments was found to behave in accordance with the theoretical expression obtained for parallel plane-polarized beams under ideal conditions [31]-[34], i.e.,

$$\text{SNR}^{(1)} = \eta_1 P_1 / h\nu \Delta f. \tag{6}$$

Here, η_1 is the detector quantum efficiency (electrons per photon), P_1 is the received signal radiation power, $h\nu$ is the photon energy, and Δf is the receiver bandwidth. For radiation beams which are not parallel to within an angle $\theta = \lambda/d$, with d the detector aperture, the SNR is reduced below the value given in (6) by spatial averaging of the mixing signal over the detector aperture. This effect was studied in detail by Siegman and by Mandel and Wolf [34], and is frequently referred to as "wash-boarding." Similar calculations have been effected for focused radiation beams, as first considered by Read and Fried [35].

Shortly thereafter, this work was extended to experimental and theoretical studies of the statistical nature of the heterodyne signal resulting from the beating of a coherent wave with a Gaussian scattered wave [36], [37]. Although the stochastic nature of this signal depends in detail on the irradiance statistics, the SNR is found to be essentially independent of the higher order correlation functions of the field [36], [37]. Furthermore, using the first-order coherent field results of Titulaer and Glauber [38] for absorption detectors, an explicit calculation for the case of two-beam photomixing has shown that sum- and double-frequency components do not appear in the detected current, and that the heterodyne process can be interpreted in terms of the annihilation of a single (nonmonochromatic) photon [39], [40], as was qualitatively appreciated by Forrester *et al.* [28]. Finally, a concise review of the basic theoretical and experimental aspects of heterodyne detection in the infrared and optical, as well as a partial review of the literature, was prepared by Teich in 1970 [41]. Another such review, emphasizing nonlinear heterodyne detection, will appear shortly [42].

II. Multiphoton Photomixing

We begin this section by considering a two-quantum absorption detector initially in the ground state. The detector response $W^{(2)}$ at the space-time point $x_a = \vec{r}_a, t_a$ may be written in terms of the second-order correlation function $G^{(2)}$ [3], [18], [20], [25], and is given by

$$W^{(2)} \propto \text{tr}\,\{\rho E^-(x_a) E^-(x_a) E^+(x_a) E^+(x_a)\} \equiv G^{(2)}(x_a x_a x_a x_a). \tag{7}$$

Here, ρ is the density operator for the field, and E^- and E^+ represent the negative- and positive-frequency portions of the electric field operator E, respectively. We assume that the final state of the detector is much broader than the bandwidth of the incident radiation, and that a broad band of final states is accessible [20], [21].

If we specifically consider the mixing of two single-mode, amplitude-stabilized, first-order coherent waves, both of which are well collimated, parallel, plane polarized along a common unit vector, and normally incident onto a photosensitive material, we may write the positive portion of the electric field operator E^+ as the superposition of two scalar fields

$$E^+ = \mathscr{E}_1^0\, e^{-i\omega_1 t} + \mathscr{E}_2^0\, e^{-i\omega_2 t} \tag{8}$$

with angular frequencies ω_1 and ω_2. This is equivalent to assuming a semiclassical approach which makes use of the analytic signal [43]. The complex wave amplitude $\mathscr{E}_i^0$ can be expressed in terms of its absolute magnitude $|\mathscr{E}_i^0|$ and a phase

factor $e^{i\alpha_i}$ such that

$$\mathcal{E}_1^0 = |\mathcal{E}_1^0| e^{i\alpha}$$
$$\mathcal{E}_2^0 = |\mathcal{E}_2^0| e^{i\beta}. \tag{9}$$

Under these conditions, the quantum-statistical detector responses can be written in terms of the fields as

$$\text{tr}\{\rho E^- E^+\} \Rightarrow |\mathcal{E}_1^0|^2 + |\mathcal{E}_2^0|^2 + 2|\mathcal{E}_1^0||\mathcal{E}_2^0| \cos[(\omega_1 - \omega_2)t + (\beta - \alpha)] \tag{10}$$

and

$$\text{tr}\{\rho E^- E^- E^+ E^+\} \Rightarrow (|\mathcal{E}_1^0|^2 + |\mathcal{E}_2^0|^2 + 2|\mathcal{E}_1^0||\mathcal{E}_2^0| \cos[(\omega_1 - \omega_2)t + (\beta - \alpha)])^2. \tag{11}$$

These expressions are scalar quantities and contain no spatial dependence because of the assumptions of plane polarization, parallel beams, and normal incidence.

Generalizing these results to sinusoidal beam photomixing in which the k-photon detector response is the normally ordered product [3]

$$W^{(k)} \propto \text{tr}\{\rho[E^-(x_a)]^k [E^+(x_a)]^k\} \tag{12}$$

and using the binomial theorem leads to a heterodyne signal given by

$$\begin{aligned} W^{(k)} = \zeta_k(&\{|\mathcal{E}_1^0|^2 + |\mathcal{E}_2^0|^2\}^k \\ &+ \binom{k}{1}\{|\mathcal{E}_1^0|^2 + |\mathcal{E}_2^0|^2\}^{k-1}\{2|\mathcal{E}_1^0||\mathcal{E}_2^0| \\ &\cdot \cos[(\omega_1 - \omega_2)t + (\beta - \alpha)]\} \\ &+ \binom{k}{2}\{|\mathcal{E}_1^0|^2 + |\mathcal{E}_2^0|^2\}^{k-2}\{2|\mathcal{E}_1^0||\mathcal{E}_2^0| \\ &\cdot \cos[(\omega_1 - \omega_2)t + (\beta - \alpha)]\}^2 + \cdots \\ &+ \binom{k}{r}\{|\mathcal{E}_1^0|^2 + |\mathcal{E}_2^0|^2\}^{k-r}\{2|\mathcal{E}_1^0||\mathcal{E}_2^0| \\ &\cdot \cos[(\omega_1 - \omega_2)t + (\beta - \alpha)]\}^r + \cdots \\ &+ \{2|\mathcal{E}_1^0||\mathcal{E}_2^0| \cos[(\omega_1 - \omega_2)t + (\beta - \alpha)]\}^k). \end{aligned} \tag{13}$$

Here ζ_k represents a proportionality constant for the k-photon process. The leading dc terms are proportional to $|\mathcal{E}_1^0|^{2k}$ and $|\mathcal{E}_2^0|^{2k}$, and may be associated with the absorption of k monochromatic photons, each of which arises from a given beam (1 and 2, respectively). The highest frequency current component is proportional to

$$|\mathcal{E}_1^0|^k |\mathcal{E}_2^0|^k \cos[k(\omega_1 - \omega_2)t + \phi]$$

and corresponds to the absorption of k nonmonochromatic photons, each of which must be associated with both of the beams. It is evident from the above that multiple- and sum-frequency terms do not appear in the k-photon absorption heterodyne detector output, in analogy with the result for the one-quantum case [39]-[41].

III. Two-Photon Photomixing

Inserting the constants ζ for the one- and two-quantum cases in (13), the detector responses for coherent signal mixing are, respectively,

$$W^{(1)} = \zeta_1(|\mathcal{E}_1^0|^2 + |\mathcal{E}_2^0|^2 + 2|\mathcal{E}_1^0||\mathcal{E}_2^0| \cos[(\omega_1 - \omega_2)t + (\beta - \alpha)]) \tag{14}$$

and

$$\begin{aligned} W^{(2)} = \zeta_2(&|\mathcal{E}_1^0|^4 + |\mathcal{E}_2^0|^4 + 2|\mathcal{E}_1^0|^2 |\mathcal{E}_2^0|^2 \\ &+ 4|\mathcal{E}_1^0|^3 |\mathcal{E}_2^0| \cos[(\omega_1 - \omega_2)t + (\beta - \alpha)] \\ &+ 4|\mathcal{E}_1^0||\mathcal{E}_2^0|^3 \cos[(\omega_1 - \omega_2)t + (\beta - \alpha)] \\ &+ 4|\mathcal{E}_1^0|^2 |\mathcal{E}_2^0|^2 \cos^2[(\omega_1 - \omega_2)t + (\beta - \alpha)]). \end{aligned} \tag{15}$$

Using the double-angle formula for the last term in (15), $W^{(2)}$ may also be written as

$$\begin{aligned} W^{(2)} = \zeta_2(&|\mathcal{E}_1^0|^4 + |\mathcal{E}_2^0|^4 + 4|\mathcal{E}_1^0|^2 |\mathcal{E}_2^0|^2 \\ &+ 4|\mathcal{E}_1^0|^3 |\mathcal{E}_2^0| \cos[(\omega_1 - \omega_2)t + (\beta - \alpha)] \\ &+ 4|\mathcal{E}_1^0||\mathcal{E}_2^0|^3 \cos[(\omega_1 - \omega_2)t + (\beta - \alpha)] \\ &+ 2|\mathcal{E}_1^0|^2 |\mathcal{E}_2^0|^2 \cos[2(\omega_1 - \omega_2)t + 2(\beta - \alpha)]) \end{aligned} \tag{16}$$

when this $\cos^2$ term is present. As noted previously, double- and sum-frequency terms are absent.

It is not difficult to associate various second-order correlation functions $G^{(2)}(x_a x_b x_c x_d) \equiv [abcd]$ with (15). (When two beams are present, we must consider a space-time point for each of the beams so that the index in $G^{(2)}$ takes on two values [18].) Thus the first term, $|\mathcal{E}_1^0|^4$, may be associated with [1111], the second with [2222], the third with [1221] and [2112], the fourth with the four permutations of [1112], the fifth with the four permutations of [2221], and the sixth with the four permutations of [1212], with $b \neq c$. The coefficient of each term in (15) is therefore equal to the number of permutations in the appropriate form of the correlation function for that term. The physical interpretation follows immediately: the first two dc terms in (15) arise from the absorption of two monochromatic photons, both from the same beam. The third dc term, which exists in two permutations with $b = c$, arises from the two ways in which two single monochromatic photons can be absorbed, one from each beam. The fourth and fifth terms correspond to the absorption of a single monochromatic photon from one of the beams plus a single nonmonochromatic photon which must be associated with both beams. These terms therefore contribute currents at the difference frequency $(\omega_1 - \omega_2)$, in analogy with the single-quantum heterodyne interference term [39]-[41]. The final term corresponds to the absorption of two nonmonochromatic photons, and therefore varies at double the difference frequency, i.e., at $2(\omega_1 - \omega_2)$; clearly there is no analogous process possible in the one-quantum case.

We note that the absorption of two nonmonochromatic photons imparts an additional dc value to the double-difference-frequency term, as may be seen by comparing (15) and (16). This additional term, of magnitude $2|\mathcal{E}_1^0|^2 |\mathcal{E}_2^0|^2$, appears in the presence of double-quantum photomixing; in the absence of such photomixing, we must obtain $W^{(2)}$ from (15) and *not* from (16). In this latter case, the detector response reduces to the previously obtained result [18]

$$\begin{aligned} W^{(2)}[\text{mixing absent}] &= \zeta_2(|\mathcal{E}_1^0|^4 + |\mathcal{E}_2^0|^4 + 2|\mathcal{E}_1^0|^2 |\mathcal{E}_2^0|^2) \\ &= \zeta_2'(I_1 + I_2)^2 \end{aligned} \tag{17}$$

where I_i represents the intensity of the ith beam and ζ_2' is a new proportionality constant.

The results presented above can be expanded to modulated, noncoherent, and nonparallel beam mixing. As an example, we consider two ideal amplitude-stabilized nonparallel ($\theta > \lambda/d$) plane traveling waves impinging on a two-quantum detector, so that washboarding can occur. In contrast to the one-quantum case, the detector responds to the *square* of the spatial intensity variation across the detector aperture at every instant of time, resulting in a factor of 2 enhancement in the dc cross term, as obtained with pure temporal mixing. Thus the two-quantum dc photocurrent will in general be enhanced due to spatiotemporal intensity variations (interference fringes); the magnitude of this enchancement depends on the system configuration. Experimental evidence for two-quantum enhancement due to spatial variations has, in fact, been provided by Shiga and Imamura [10] and by Teich *et al.* [22].

As a final example, we consider mixing due to radiation which is nonsinusoidal (i.e., not coherent to all orders). We consider two parallel, plane-polarized, normally incident superimposed beams of radiation from the same chaotic source, one of which is a time-delayed version of the other (delay τ_δ) entering one double-quantum detector. This was previously shown to be equivalent to a self-integrating Hanbury-Brown-Twiss device [18]. For a thermal source in the absence of a beat signal, we find

$$W^{(2)}[\text{mixing absent}] = 2\zeta_2'(I_1^2 + 2I_1 I_2 + I_2^2), \qquad \tau_\delta < \tau_c \quad (18)$$

and

$$W^{(2)}[\text{mixing absent}] = 2\zeta_2'(I_1^2 + I_1 I_2 + I_2^2), \qquad \tau_\delta > \tau_c \quad (19)$$

where τ_c is the coherence time of the source. For $\tau_\delta < \tau_c$, (18) represents the enhancement of both the single-beam and the mixed-beam counting rates, arising from the tendency of these photons to arrive in correlated pairs (assuming that the detector intermediate state lifetime $\tau_l \ll \tau_c$). For $\tau_\delta > \tau_c$, however, there is no correlation between the arrival time of a photon from one beam and the arrival time of a photon from the other. Thus the absorption of two photons from a single beam is enhanced by a factor of 2 relative to the absorption of one photon from each beam, leading to a cross term of 1. This can also be qualitatively understood from the point of view of additive Gaussian fields; the sum of two fully correlated Gaussian random processes ($\tau_\delta < \tau_c$) has a greater variance than that of two independent Gaussian random processes ($\tau_\delta > \tau_c$) leading to an enhanced value for the cross term when $\tau_\delta < \tau_c$.

From the foregoing, it is clear that the double-quantum current can be calculated for a variety of configurations involving different relative time scales, angular separations, polarization properties, and statistical characteristics. Some additional examples are treated in [18]. Clearly, the second-order correlation functions of the field play an important role in determining the magnitude of the signal, in distinction to the one-quantum case.

IV. Signal-to-Noise Ratio

We now follow the usual procedure used for the single-quantum case [31]-[33], [37] to calculate the approximate SNR for k-photon sinusoidal heterodyne detection. We begin with two-quantum photomixing, neglecting the double-difference-frequency component and assuming that the ac signal is at the fundamental-difference-frequency (IF) between the two waves. Thus, considering the mixing of two parallel coherent waves as described in Section II, (16) yields

$$W_{\text{IF}}^{(2)} = 4\zeta_2(|\mathcal{E}_1^0|^3\,|\mathcal{E}_2^0| + |\mathcal{E}_1^0|\,|\mathcal{E}_2^0|^3) \cdot \cos[(\omega_1 - \omega_2)t + (\beta - \alpha)] \quad (20)$$

and

$$W_{\text{dc}}^{(2)} = \zeta_2(|\mathcal{E}_1^0|^4 + |\mathcal{E}_2^0|^4 + 4|\mathcal{E}_1^0|^2\,|\mathcal{E}_2^0|^2) \quad (21)$$

so that

$$W^{(2)} = \left\{1 + \frac{4(|\mathcal{E}_1^0|^3\,|\mathcal{E}_2^0| + |\mathcal{E}_1^0|\,|\mathcal{E}_2^0|^3)\cos[(\omega_1 - \omega_2)t + (\beta - \alpha)]}{|\mathcal{E}_1^0|^4 + |\mathcal{E}_2^0|^4 + 4|\mathcal{E}_1^0|^2\,|\mathcal{E}_2^0|^2}\right\} W_{\text{dc}}^{(2)}. \quad (22)$$

We now assume that one of the waves (which we call the local oscillator or LO) is strong, i.e., $E_2 \gg E_1$, in which case

$$W_{\text{IF}}^{(2)} \simeq 4(|\mathcal{E}_1^0|/|\mathcal{E}_2^0|)\,W_{\text{dc}}^{(2)} \cos[(\omega_1 - \omega_2)t + (\beta - \alpha)] \quad (23)$$

and

$$\langle[W_{\text{IF}}^{(2)}]^2\rangle \simeq 8(|\mathcal{E}_1^0|^2/|\mathcal{E}_2^0|^2)\,[W_{\text{dc}}^{(2)}]^2. \quad (24)$$

The noise power can be obtained from the two-quantum photocurrent spectrum [23] which, in turn, is related to the stochastic nature of the radiation source. For a coherent and strong LO, however, the k-quantum counting statistics will be Poisson [25], [26], and the two-quantum (shot) noise power is then

$$\langle[W_n^{(2)}]^2\rangle = 2e[W_{\text{dc}}^{(2)}]\Delta f. \quad (25)$$

Thus using (2), (24), and (25), the two-quantum SNR can be written as

$$\text{SNR}^{(2)} \simeq \frac{4P_1}{e\Delta f}\left(\frac{W_{\text{dc}}^{(2)}}{P_2}\right) = \frac{4P_1}{e\Delta f}\Lambda^{(2)}. \quad (26)$$

Using the relationship between the two-quantum yield $\Lambda^{(2)}$ and the two-quantum efficiency η_2 given in (3), we finally obtain

$$\text{SNR}^{(2)} \simeq 4\eta_2 P_1/h\nu\Delta f. \quad (27)$$

We recall from (3) that η_2 is itself proportional to the irradiance of the LO, and we must have $4\eta_2 < 1$. The result is therefore similar to that for the single-quantum heterodyne detector given in (6); in that case, however, η_1 is independent of the LO. The two-quantum minimum detectable power (MDP) [31], [32] therefore becomes

$$\text{MDP}^{(2)} \simeq h\nu\Delta f/4\eta_2. \quad (28)$$

This corresponds to a minimum number of photons $\mathfrak{N}_{\text{min}}^{(2)}$, detectable in the resolution time of the receiver [$\tau_r \sim (\Delta f)^{-1}$],

given by

$$\mathfrak{N}_{\min}^{(2)} \simeq (4\eta_2)^{-1}. \tag{29}$$

We note that SNR at the double-difference frequency, corresponding to the absorption of two nonmonochromatic photons, is reduced by the factor (P_1/P_2). Clearly, using methods similar to those presented above and in [18] and [37], we can obtain analogous SNR expressions for photomixing with nonsinusoidal beams.

The SNR at the fundamental-difference frequency $(\omega_1 - \omega_2)$ may also be obtained for coherent beam mixing in the k-photon absorption heterodyne detector. Following a series of steps similar to those given above, we find

$$\mathrm{SNR}^{(k)} \simeq c_k \eta_k P_1/h\nu\Delta f \tag{30}$$

$$\mathrm{MDP}^{(k)} \simeq h\nu\Delta f/c_k\eta_k \tag{31}$$

and

$$\mathfrak{N}_{\min}^{(k)} \simeq (c_k\eta_k)^{-1} \tag{32}$$

where c_k is a constant (dependent on k), and η_k is proportional to I^{k-1}, where I is the LO irradiance [see (5)]. Here $c_k\eta_k < 1$.

V. Experiment

In this section we describe a preliminary set of experiments in which double-quantum photoemission was observed from a sodium surface simultaneously illuminated by two superimposed beams of laser radiation. While ac photomixing terms were not observed in these experiments, the measurements are consistent with the theoretical calculations given in Section III.

A. Configuration

The apparatus used for the experimental measurement of two-quantum photomixing is shown in the block diagram of Fig. 1. The radiation source was a pulsed GaAs multimode semiconductor injection laser operated at 77 K and emitting a peak radiation power of 400 mW at about 8450 Å. Mode shifts due to laser heating occurred during the pulse duration, which was about 35 μs. The radiation was collimated by a 10-cm focal length lens, passed through an iris, and then through a configuration of dielectric beam splitters and antireflection coated prisms resembling a Mach-Zender interferometer. The beam splitters were approximately $\frac{2}{3}$ transmitting and were flat only to about 1 wavelength; the optical phase across the beam could therefore be considered to vary. The purpose of the interferometer configuration was to allow the irradiance of each beam (denoted as 1 and 2) to be independently controlled by means of calibrated attenuating filters. Beam 1 could also be time-delayed with respect to beam 2 by means of a sliding prism (see Fig. 1), but this capability was not important in these experiments where τ_δ was always greater than τ_c due to the very small value of τ_c. After passing through a second iris and a (6-cm focal length) focusing lens, the radiation was allowed to impinge on a specially constructed Na-surface photomultiplier tube, which has been described previously [6], [8], [9]. A Polaroid type HN-7 sheet polarizer was almost always placed at the front face of the photomultiplier as shown in Fig. 1 (the one exception will be noted later). The electron-multiplied current was passed through a 1-MΩ load resistor which fed a Princeton Applied Research (PAR) low-noise preamplifier followed by a PAR lock-in amplifier. Phase-sensitive detection was performed at 2.2 kHz, which is the fundamental repetition frequency of the pulsed laser output. Large integration times were used so that only the dc or average value of this current component was measured. The reference signal for the lock-in amplifier was obtained directly from the silicon-controlled-rectifier power supply [44] used to drive the laser.

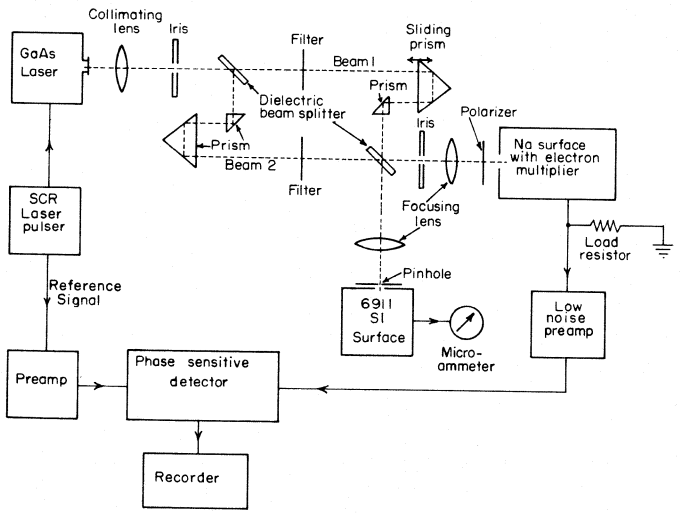

Fig. 1. Block diagram of the double-quantum photomixing experimental arrangement.

Radiation from the other leg of the interferometer was focused onto a 25-μm diameter pinhole which acted as an aperture stop at the face of a standard Dumont 6911 type S-1 photomultiplier. This provided a relatively accurate method for superimposing the two beams [8]. This is critical since the double-quantum response is inversely proportional to the illuminated area A. The beams were adjusted to achieve maximum output from the 6911 photomultiplier tube, a procedure which was often difficult and required a great deal of care.

B. Method

The following procedure was used in making a measurement. 1) The beams were aligned to provide maximum current from the 6911 photomultiplier. 2) Beam 1 was blocked and the double-quantum current $\overline{W_2^{(2)}}$ from beam 2 was maximized by imaging the laser junction on the sodium surface, and then recorded. Using a calibrated attenuating filter, it was ascertained that pure two-quantum emission was occurring, i.e., that $\overline{W_2^{(2)}} \propto I_2^2$, where I_2 represents the irradiance of beam 2. 3) Beam 2 was blocked and the double-quantum current from beam 1 was recorded, after verifying that it was $\propto I_1^2$. (The constant of proportionality was taken to be the same in both cases.) 4) Both beams were then unblocked and, after once again verifying that pure double-quantum emission was occurring, the total average double-quantum current $\overline{W^{(2)}}$ (at the fundamental repetition frequency of 2.2 kHz) was recorded.

Experiments were performed with different value of I_1/I_2,

obtained by attenuating one of the beams relative to the other by means of thin gelatin (Kodak Wratten) filters. Ordinary glass filters could not be used to provide the decrements of light intensity because refraction in the glass caused the imaged spot size and position to change thus altering the two-quantum current in an unpredictable way.

C. Results

The total average fundamental-repetition-frequency two-quantum photoelectric current $\overline{W^{(2)}}$, for different intensity ratios of the two constituent beams (I_1/I_2), is presented in Fig. 2. The solid curve represents the equation $W^{(2)} \propto (I_1 + I_2)^2$ which is simply the parabola $(1 + I_1/I_2)^2$ when the intensity I_2 is normalized to unity. This represents a cross term of $2I_1I_2$, and is so labeled. The cross term of $4I_1I_2$, on the other hand, is shown by the dashed line in Fig. 2. Only the highest observed values of $\overline{W^{(2)}}$ are plotted in Fig. 2, many more points having been found to lie below the curves. This has been attributed to the difficulty in obtaining precise alignment of the two radiation beams, and therefore superposition of the focused spots on the sodium surface.

The triangles in Fig. 2 represent data for linearly or partially polarized radiation, while the circle is for cross-polarized radiation (this is the one exception mentioned previously). The experimental measurements are consistent with the following interpretation. The laser output consists of a number of more-or-less independent Fabry–Perot modes which are changing during the pulsewidth due to heating of the laser junction [8]. The radiation may therefore be considered to behave as a Gaussian source with a coherence time $\tau_c \sim (\Delta\nu)^{-1} \sim 10^{-13}$ s. Since the intermediate-state lifetime for the double-quantum sodium photodetector is much shorter than the radiation coherence time, the irradiance fluctuations result in a factor of 2 enhancement of the single-beam photocurrents. As far as the irradiance cross term is concerned, the two-quantum current will also be enhanced by a factor of 2 owing to the random spatial irradiance fluctuations across the detector for the superimposed beams. Thus we obtain a relative cross terms of 2, i.e., $\overline{W^{(2)}} \propto I_1^2 + 2I_1I_2 + I_2^2$, in agreement with the data.

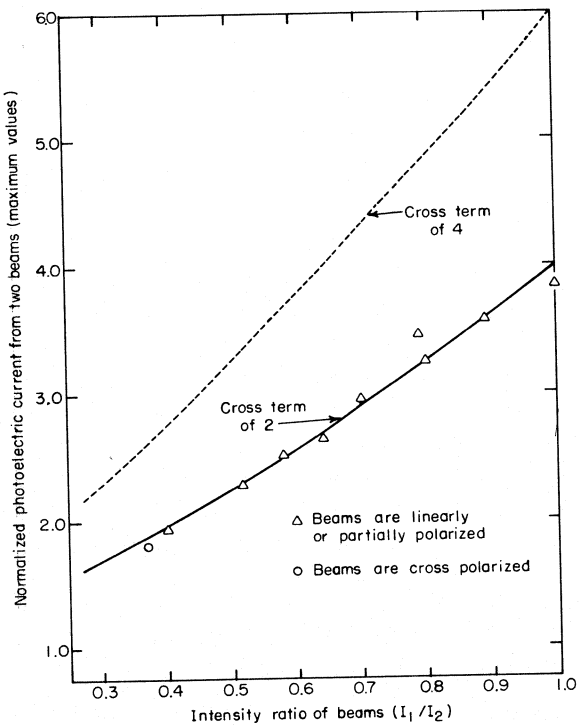

Fig. 2. The average double-quantum photocurrent from two beams (maximum values) versus the intensity ratio of the beams.

VI. Discussion

From the foregoing, it is clear that multiple-quantum heterodyne detection is somewhat more complex than the analogous single-quantum process. In particular, the average detector response and the SNR are found to depend on the higher order correlation functions of the radiation field and on the LO irradiance. From a physical point of view, it has been possible to associate various terms in the detected current with specific kinds of photon absorptions. Calculations of the SNR and MDP for a number of cases have been carried out. The results of a preliminary two-quantum photomixing experiment are in agreement with the theory.

Although it appears that the k-photon heterodyne detector can be made to perform as well as the single-photon heterodyne detector by simply increasing the LO intensity, a number of practical problems would likely make this difficult. Inasmuch as the transition probabilities decrease rapidly as k is increased, and are furthermore proportional to A^{1-k}, it appears that very high LO intensities would be required to place η_k anywhere in the vicinity of 0.1 for $k > 2$. Aside from alignment problems, these high intensities could result in thermionic emission from cathode heating, or possibly cathode damage.

The two-quantum case is therefore likely to be the most interesting, and also the easiest to examine experimentally. A possible arrangement for studying the effect in a more detailed and controlled fashion is the following. The radiation from a 0.5-mW He–Ne laser, operating at a wavelength of 1.15 μm, is passed through an acoustooptic modulator (which splits it into two frequencies) and a focusing lens. A 5-μm focused spot size, corresponding to an area of 2.5×10^{-7} cm^2, would then provide an incident irradiance $I \sim 2 \times 10^3$ W/cm^2. Using a Cs_3Sb photocathode with a work function ~2.05 eV and a yield [7] $\sim 5 \times 10^{-11}\, I$ A/W, a two-quantum current $\sim 5 \times 10^{-11}$ A may then be obtained. An experiment of this nature would allow the validity of (15), (16), and (27) to be examined. A YAG:Nd laser could be substituted for the He–Ne laser for an even simpler experimental configuration, since focusing would not then be required.

We observe that the use of a two-quantum photomixer in a three-frequency nonlinear heterodyne detection receiver [45] would result in a reduction of the SNR by the factor (P_1/P_2), corresponding to the absorption of 2 nonmonochromatic photons as discussed earlier. It therefore does not appear to be suitable for this application. We also note that information relating to the intermediate-state lifetime of the detector (τ_I) can be obtained by measuring the two-quantum detector output for various values of τ_c.

Although the emphasis in this paper has been on linearly polarized incident radiation, considerable enhancement of

the k-quantum photocurrent may occur for circularly (or elliptically) polarized radiation, as recently discussed by a number of authors [46].

Acknowledgment

The author wishes to thank Prof. G. J. Wolga of Cornell University for many valuable discussions in connection with the experiments reported here.

Studies of Relaxation Oscillations in Organic Dye Lasers

CHINLON LIN

Abstract—**The transient phenomena of relaxation oscillations and "initial spikes" in organic dye lasers are studied experimentally and theoretically. Both damped relaxation oscillations and initial spikes are clearly observed in N_2 laser-pumped dye lasers under appropriate conditions which are furthermore shown to agree with theoretical considerations. Linearized rate equations obtained with small-signal approximation are used to describe the initial-spiking phenomenon; for the more general phenomenon of relaxation oscillations computer solutions of the coupled rate equations are obtained. Comparisons with experimental observations show excellent qualitative agreement. Based on the results of these studies, a general technique using the idea of controlled resonator transients is described for tunable subnanosecond pulse generation from laser-pumped dye lasers in the near UV and the visible region of the spectrum.**

I. Introduction

THE PHENOMENON of relaxation oscillations or "spiking" has been observed and studied extensively in solid-state lasers under pulsed excitation [1], [2]. Although in most cases random spiking with pulses of irregular spacings and amplitudes were observed, there were observations of perfectly regular damped relaxation oscillations [2], [3]. Such regular damped relaxation oscillations are expected from theoretical analyses using the coupled rate equations [4]-[6]. It is generally recognized to be a phenomenon due to the interaction between the excess population inversion of the active medium and the photon energy of the electromagnetic field inside the resonator. The characteristics of the relaxation oscillations depend on the rate of change of the population inversion due to pumping, spontaneous decay and stimulated emission, and the rate of buildup and decay of photons in the resonator due to stimulated emission and various loss mechanisms such as output coupling, scattering, diffraction, and absorption.

In addition to being a common phenomenon in solid-state lasers, relaxation oscillations have also been observed and studied in gas lasers [7]. In the case of dye-solution lasers, relaxation oscillations have not been previously reported. However, in the first organic dye laser, Sorokin *et al.* [8] noticed that under certain conditions a Q-switched ruby laser-pumped dye laser had an "initial spike" in the output, which otherwise displayed the time variation similar to that of the pumping pulse. The observation was shown to agree qualitatively with the expected transient response of the dye laser under the corresponding experimental conditions. Miyazoe and Maeda [9] have further applied small-signal analysis to study the conditions for the appearance of such initial spikes. They pointed out that dye lasers are generally operated close to the border region between spiking and nonspiking. This is in contrast to solid-state lasers for which the spiking phenomenon is almost ubiquitous.

In this paper we report the observation and investigation of regular damped relaxation oscillations in N_2 laser-pumped dye lasers. Pulses with an initial spike are also observed; it is shown to be a special case of the more general phenomenon of relaxation oscillations. The characteristics of these transient responses are studied experimentally and compared with theoretical considerations. Excellent qualitative agreement is obtained. Because of the relative ease and large workable range in choosing desired dye-laser parameters (e.g., dye-laser medium and resonator length, resonator mirror reflectivities, dye-solution concentration, dye-fluorescence lifetime, etc.) laser-

Manuscript received February 7, 1975.
The author is with Bell Laboratories, Holmdel, N.J. 07733.

pumped organic dye lasers provide a new, convenient laser system for studies of relaxation oscillations, an important phenomenon manifesting the transient interaction of radiation with matter through stimulated emission.

We also describe a general technique for short-pulse generation from laser-pumped dye lasers. The technique makes use of the dye-laser resonator transients which are in the form of damped relaxation oscillations. From the result of our studies on these relaxation oscillations we show that dye-laser pulses much shorter than the pumping pulse can be obtained by proper choices of parameters such as photon-cavity decay time, the level of pumping, etc. Based on this general technique of controlled-resonator transients high repetition-rate subnanosecond pulses tunable in the near UV and the visible region have been obtained from N_2 laser-pumped dye lasers.

In the following sections previous studies of the initial spikes in both ruby laser-pumped and flashlamp-pumped dye lasers [8], [9] are first reviewed and then compared with our observations and studies of the more general phenomenon of damped relaxation oscillations. The technique of short-pulse generation by means of controlled resonator transients is then briefly described.

II. Rate Equations

To facilitate our later discussions let us first write down the well-known rate equations [5], [6]. Assuming a dye laser can be represented by an ideal four-level system, neglecting the triplet states for short-pulse excitation [10], the rate equations describing the population inversion and the photons are

$$\frac{dn}{dt} = W - Bnq - \frac{n}{\tau} \tag{1}$$

$$\frac{dq}{dt} = Bnq - \frac{q}{t_c} \tag{2}$$

where n is the inversion and is nearly equal to the upper state population; q is the number of photon quanta in the resonator; B is the Einstein coefficient for stimulated emission; W is the pumping rate; τ is the fluorescence lifetime; and t_c is the photon-cavity decay time. If the cavity losses are assumed to be primarily transmissive ones, then

$$t_c = \frac{T_c}{1-R} = \frac{\eta l + (L-l)}{C(1-R)} \tag{3}$$

where R is the geometric mean, $R = (R_1R_2)^{1/2}$, of the cavity mirror reflectivities, and T_c is the cavity transit time; $T_c = [\eta l + (L-l)]/C$, where L is the cavity spacing, l and η are the length and the refractive index of the active medium, respectively, and C is the speed of light. In equilibrium $(dn/dt) = (dq/dt) = 0$ and we have

$$n = n_0 = \frac{1}{Bt_c} \tag{4}$$

$$q = q_0 = \frac{W - \frac{n_0}{\tau}}{Bn_0}. \tag{5}$$

Note n_0 is the threshold inversion above which $(dq/dt) > 0$. The threshold pumping rate W_t is defined as

$$W_t = \frac{n_0}{\tau} = \frac{1}{Bt_c\tau}. \tag{6}$$

Using (4), rate equations (1) and (2) can be written as

$$\frac{dn}{dt} = W - \frac{n}{n_0}\frac{q}{t_c} - \frac{n}{\tau} \tag{7}$$

$$\frac{dq}{dt} = \frac{q}{t_c}\left(\frac{n}{n_0} - 1\right). \tag{8}$$

III. Initial Spikes

In this section we first review the observation and studies of initial spikes in ruby laser-pumped dye lasers by Sorokin *et al.* [8], and in flashlamp-pumped dye lasers by Miyazoe and Maeda [9]. Both the results of a small-signal analysis and the computer solutions are examined and compared with experimental observations in various dye lasers. The study of this special case of spiking behavior provides the basis for a better understanding of the more general phenomenon of relaxation oscillations.

A. Experimental Observations of Initial Spikes

In the study of the output characteristics of their first dye laser, Sorokin *et al.* [8] noticed the presence of a fast rise-time initial peak in the laser pulse which otherwise had a time variation roughly similar to the shape of the ruby laser-pumping pulse. They observed that this CAP (chroloaluminum phthalocyanine) dye laser had an initial peak, which became a sharper spike for a more lossy cavity; on the other hand, the output of another dye laser, DTTC (3,3′-diethylthiatricarbocyanine iodide), operated in a different cavity configuration, displayed no such initial spike. They obtained computer solutions of the coupled rate equations using parameters of the CAP dye laser and found good resemblance with experimental results. The DTTC dye laser was not studied in detail; they suggested that the presence of self-absorption might account for the absence of the initial peak.

Subsequently, Miyazoe and Maeda [9], noting that spiking behavior is in general seldom observed in dye lasers, applied the standard small-signal analysis to obtain the conditions for the appearance of initial spikes. It was pointed out that dye lasers are generally operated close to the border region between spiking and nonspiking. By using a special flashlamp-pumped rhodamine 6G dye laser with a 25-mm-long dye cell and a resonator length of 5 cm, they observed an initial spike; the spike disappeared when a 18-cm resonator length was used. Similar experiments were attempted under various resonator conditions by using several kinds of ruby laser-pumped polymethine dyes, but they could not observe such a distinct initial spike. Comparing their observation with that of the CAP dye laser they stated that although the reason for the absence of spiking is not obvious, one important reason seems to be the fact that the fluorescence lifetime of CAP or rhodamine 6G dye is about 6-10 ns while that of polymethine dyes is smaller than 3 ns.

In our experiments with N_2 laser-pumped dye lasers we have observed not only the initial spikes but also the more general

phenomenon of damped relaxation oscillations. A typical pulse with an initial spike is shown in Fig. 1(c). The theoretical considerations and the comparisons with various experiments for the initial-spike case are discussed in the following; the physical picture of spiking is more readily visualized in this case.

B. Small-Signal Analysis

Small-signal analysis has commonly been applied to study the relaxation oscillations in solid-state lasers. It is better suited for studying initial spikes because of the small-signal approximation. Coupled rate equations (1) and (2) can be linearized to be

$$\frac{d^2 n_1}{dt^2} + W_0 B t_c \frac{dn_1}{dt} + \left(W_0 B - \frac{1}{\tau t_c}\right) n_1 = 0 \tag{9}$$

$$\frac{d^2 q_1}{dt^2} + W_0 B t_c \frac{dq_1}{dt} + \left(W_0 B - \frac{1}{\tau t_c}\right) q_1 = 0 \tag{10}$$

where n_1 and q_1 are the small-signal perturbations and W_0 is the assumed constant excitation. The equations are identical in form and have solutions of the form of an exponentially damped sinusoid, with the damping time constant t_d and oscillation frequency ω given by

$$t_d = \frac{W_0 B t_c}{2} \tag{11}$$

$$\omega = \frac{1}{2}\sqrt{\frac{4\left(W_0 B t_c - \frac{1}{\tau}\right)}{t_c} - (W_0 B t_c)^2}. \tag{12}$$

The solution is truly oscillatory only if ω is real. Regarding a single damped oscillation as the initial spike, Miyazoe and Maeda [9] obtained the following condition for spiking as, for ω to be real:

$$\frac{4\left(W_0 B t_c - \frac{1}{\tau}\right)}{t_c} - (W_0 B t_c)^2 > 0. \tag{13}$$

We can rewrite this condition as

$$\frac{4\left(\frac{1}{t_c} - \frac{1}{\tau}\right)}{t_c} - \left(W_0 B t_c - \frac{2}{t_c}\right)^2 > 0 \tag{14}$$

from which we can see $\tau > t_c$ is a necessary but not sufficient condition for spiking. Defining $m = (W_0/W_t) = W_0 B t_c \tau$ as the ratio of the actual pumping level to the threshold pumping rate we obtain from (14) the necessary and sufficient condition required for the initial spike to appear

$$\frac{\tau}{t_c} > \frac{m^2}{4(m-1)}. \tag{15}$$

For $m = 2$, $\tau > t_c$ is required; for $m \gg 1$ the condition becomes $\tau > (m/4)\, t_c$.

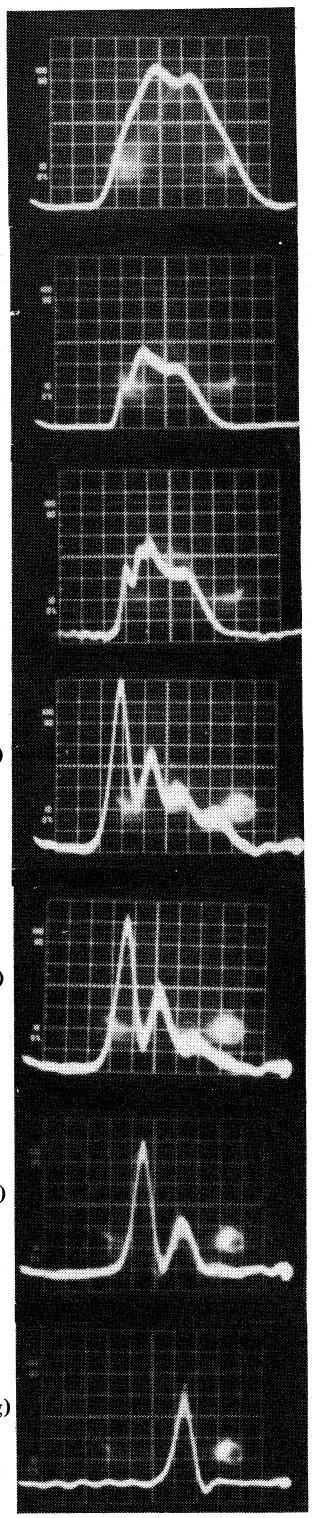

Fig. 1. (a) N_2 laser pulse. (b)–(g): Output pulse from a 7D4MC dye laser ($t_c \sim 50$ ps) as the pump power is decreased. Time scale: 2ns/cm for (a)–(c); 1 ns/cm for (d)–(g). Vertical scale arbitrary.

C. Computer Solutions

Without making use of the small-signal approximation and assuming a more realistic time-varying excitation (Gaussian for a Q-switched ruby laser pulse) Sorokin *et al.* [8] obtained

numerical solutions to the coupled rate equations (7) and (8), using parameters appropriate for their dye-laser experiments. The computer plots strongly resembled the observed pulse characteristics. In particular, the computer solutions indicated 1) that for higher mirror reflectivities (or larger t_c) the initial peak is either less prominent or absent; 2) that in the case when an initial spike is seen the initial peak becomes less sharp and smaller in amplitude (e.g., becomes a small step) as the pumping level is increased; and 3) that in a certain range of pumping levels the time variation of the pulse subsequent to the initial peak is similar to that of the pumping pulse.

We have also obtained computer solutions for the case of our N_2 laser-pumped dye lasers. Assuming a trapezoidal excitation pulse [see Fig. 1(a)] and using parameters of our experiments, we have found essentially the same qualitative behavior for the initial spikes. Our computer solutions are to be described in Section IV where the initial spike is shown to be a special case of the more well-known phenomenon of damped relaxation oscillations.

Note that a close comparison will show that the results of the small-signal analysis are well consistent with the computer solutions for the initial spike case.

D. Comparisons and Discussions

The results of the theoretical considerations previously described can explain a number of experimental observations. 1) The more lossy cavity (higher output coupling) [8] and the shorter cavity length [9] favor the appearance of a more distinct initial peak because of shorter t_c. 2) The absence of the initial spike in the polymethine dye lasers reported in [9] is due to the small values of the fluorescence lifetime. 3) The absence of the initial spike in the DTTC iodide laser reported in [8] can also be explained as due to a small τ/t_c ratio. Not only does DTTC iodide, also a polymethine dye, have a shorter τ, but also the length of the cavity used (22 cm) was much larger than that (5 cm) used for the CAP dye laser, with mirror reflectivities being about the same. 4) Our experimental observations of the initial spike in a N_2 laser-pumped dye laser, as shown in Fig. 1(b) and (c), agree very well with the computer results. That is, in the range when an initial spike is observed, the spike becomes less distinct and smaller in amplitude as the pumping power is increased. 5) For most dye lasers t_c is usually of the same order as τ in the nanosecond range; hence, spiking or nonspiking are observed depending upon the laser parameters. In solid-state lasers τ is usually (microsecond or millisecond) much larger than t_c; hence, strong spiking behavior is often seen. An exceptional case is the $CaF_2:Sm^{2+}$ laser [3], in which the spiking was not observed. This is probably also due to its shorter excited-state lifetime ($\tau \approx 1\,\mu s$) as compared with the large value of t_c for the very high mirror reflectivities used.

Thus it is seen that the physical picture as well as the conditions of the initial spike could be well described by the small-signal analysis, which is in turn consistent with the computer results for the case of the initial spike. For the studies of damped, strongly modulated relaxation oscillations, however, the small-signal approximation is not applicable and computer solutions have to be used.

IV. Relaxation Oscillations in Dye Lasers

A. Experimental

We have observed regular, damped relaxation oscillations in a N_2 laser-pumped dye laser. The N_2 laser pulse (~10 ns, 100 kW, 100 pulses per second (pps), λ = 337 nm) is focused with a quartz cylindrical lens (f = 7.5 cm) in a standard transverse pumping geometry. Different dye-cell lengths and cavity spacings are used. For cavity reflectors we used various combinations of dielectric mirrors, uncoated cell windows, and diffraction gratings. For clear observation of damped relaxation oscillations a photon-cavity decay time t_c much shorter than the dye-fluorescence lifetime τ is needed. This is easily obtained in the N_2 laser-pumped dye lasers where short cavity length and high output coupling (cavity loss) can be conveniently used.

For detection of the laser pulse-time characteristics a Korad KD-1 vacuum photodiode and a Tektronix 7904 oscilloscope are used. The system response time is ~800 ps.

In the following we use the experimental results from 7D4MC (7-diethylamino-4-methylcoumarin) and rhodamine 6G dye lasers as our examples. Qualitatively similar results have also been obtained from several other dyes in the near UV and the visible region. The concentration of the dye solutions used was in the 5×10^{-3}-5×10^{-4}-M range.

Fig. 1(b)-(g) show typical pulse developments observed from a 7D4MC dye laser (1-cm dye cell with uncoated windows aligned; $t_c \sim 50$ ps) as the N_2 laser-pumping power is decreased from high values to low values. The level of pumping can be varied either by changing the N_2 laser power-supply discharge voltage, or by inserting UV absorbing attenuators before the lens. The N_2 laser pulses from AVCO C950 systems are approximately trapezoidal, typically as shown in Fig. 1(a). Fig. 1(b) and (c) show that, when the pumping level is much higher than threshold, the dye laser pulse displays roughly the time variation of that of the N_2 laser pulse, though shortened by the intensity dependence. An initial peak of much faster rise time is seen; and, as previously mentioned, the initial peak is sharp and large, or is less distinct and small in amplitude, depending on the pumping level. As the level of pumping is decreased enough the damped relaxation oscillations begin to appear, as shown in Fig. 1(d)-(g). The number of oscillations is reduced when the pumping power is decreased; eventually only a single spike remains. This functional dependence on the pumping power of the damped relaxation oscillations, as well as other experimental observations to be described in the following, will be shown to have excellent qualitative agreement with computer solutions pertaining to our experimental conditions.

Fig. 2(a)-(c) are the damped relaxation oscillations observed in a rhodamine 6G dye laser with $t_c \sim 60$ ps (1-cm dye cell, ~1.3-cm-long cavity formed by a diffraction grating and one uncoated cell window). The general characteristics are almost identical to those of the 7D4MC dye laser. Similar damped re-

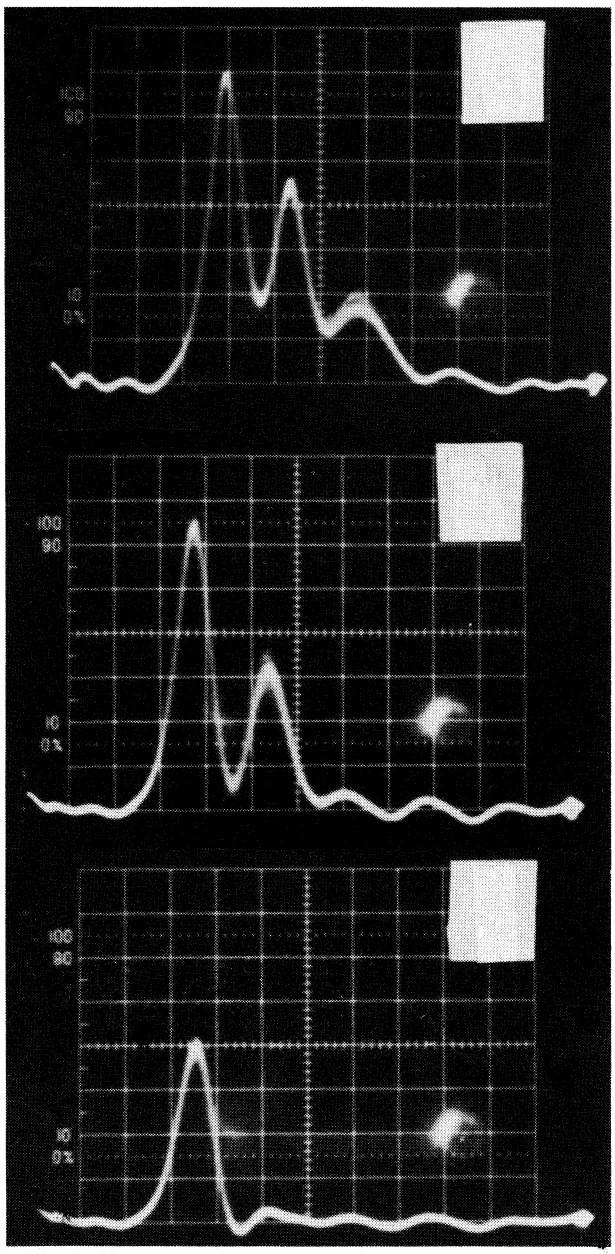

Fig. 2. (a)-(c): Damped relaxation oscillations observed in a rhodamine 6G dye laser ($t_c \sim 60$ ps) as a function of decreasing pump power. Time scale: 1 ns/cm.

laxation oscillations are observed in the following dyes (for $t_c \sim 50$ ps): rhodamine B, fluorescein disodium salt, coumarin 120, butyl-PBD, and Pilot Chemical Co.'s dye #386. We have also noticed that, for UV dyes which have shorter excited-state lifetimes [11], the oscillation peaks are often less regular or less distinct. Nevertheless, from these experimental observations it can be stated that damped relaxation oscillations is a general transient behavior readily observed in N_2 laser-pumped dye lasers with short t_c. This provides a new, convenient laser system to study the basic transient interaction between the excess population inversion and the cavity photons, and to compare it with that in solid-state lasers.

B. Computer Analyses

Our experimental conditions differ from those of [8], primarily in that we have a much shorter cavity length and much lower cavity reflectivities. Secondly, the N_2 laser pulse in our case is more of a trapezoidal than a Gaussian time variation, although this turns out to be of minor significance for the observation of damped relaxation oscillations, as our computer results show.

In our computer analyses the notations of [8] are used: $x = t/t_c$ is the normalized time; $y_1(x)$ is the normalized photon quanta ($y_1(0) = 10^{-7}$ assumed); $y_2(x)$ is the normalized population inversion ($y_2(0) = 0$); α is the level of pumping above threshold ($\alpha = 1$ at threshold); $\beta = \tau/t_c$ is the ratio of fluorescence lifetime over photon-cavity decay time; and γ is a measure of the pumping pulse duration normalized to t_c. Because of the much smaller values of t_c in our dye lasers the parameters β and γ of our computer solutions are much larger than those of [8]. We have assumed three different excitation pulses: Gaussian, square wave, and trapezoidal, of comparable full width at half maximum (FWHM) pulsewidths. Although the rise time of the population inversion ($y_2(x)$ or $n(t)$) is dependent on the pumping pulse waveform, as is expected from the rate equation (7), the general characteristics of the photon intensity ($y_1(x)$ or $q(t)$) in the region of damped, strongly modulated relaxation oscillations are not appreciably different for the three excitations assumed.

Using a GE Mark III time-sharing system and the mathematical subroutine RKPB/DRKPB (Runge-Kutta method) for solving coupled differential equations, we obtained computer plots typically as shown in Figs. 3 and 4. From our computer plots using various values of t_c, α, β, and γ, the results of our computer analyses can be summarized as follows.

1) The initial spike is a special case of damped relaxation oscillations.

2) In the case when relaxation oscillations are present, larger α (higher pumping level) increases the number of oscillations and decreases the spacings between oscillation peaks, eventually leading to the case of the initial spike.

3) Although each "spike" in the damped relaxation oscillations has a different duration (increasing with time and decreasing with α), which is also smaller than the spike spacing, there is indeed a fairly constant (slightly decreasing with time) spacing between peaks which can be designated as the period of oscillation.

4) The damping of the well-defined relaxation oscillations, such as shown in Figs. 3 and 4, can be roughly approximated by an exponential decay. For example, the semilog plot for the oscillation peaks of Fig. 3(h) is roughly a straight line from which $t_d \approx 1.3$ ns is obtained.

5) Smaller values of t_c (corresponding to larger values of β and γ) favor the development of more distinct relaxation-oscillation peaks.

C. Comparisons with Experiments and Discussions

There is excellent qualitative agreement between our experimental observations and the results of the computer analyses previously summarized. Notably, the functional dependence of the relaxation oscillations on the pumping power is clearly observed (as Figs. 1 and 2 indicate), the number of oscillations is reduced, and the spacing between oscillation peaks increased as the level of pumping is gradually decreased. Furthermore, a close examination of these figures shows that indeed each spike in the damped relaxation oscillations has a different

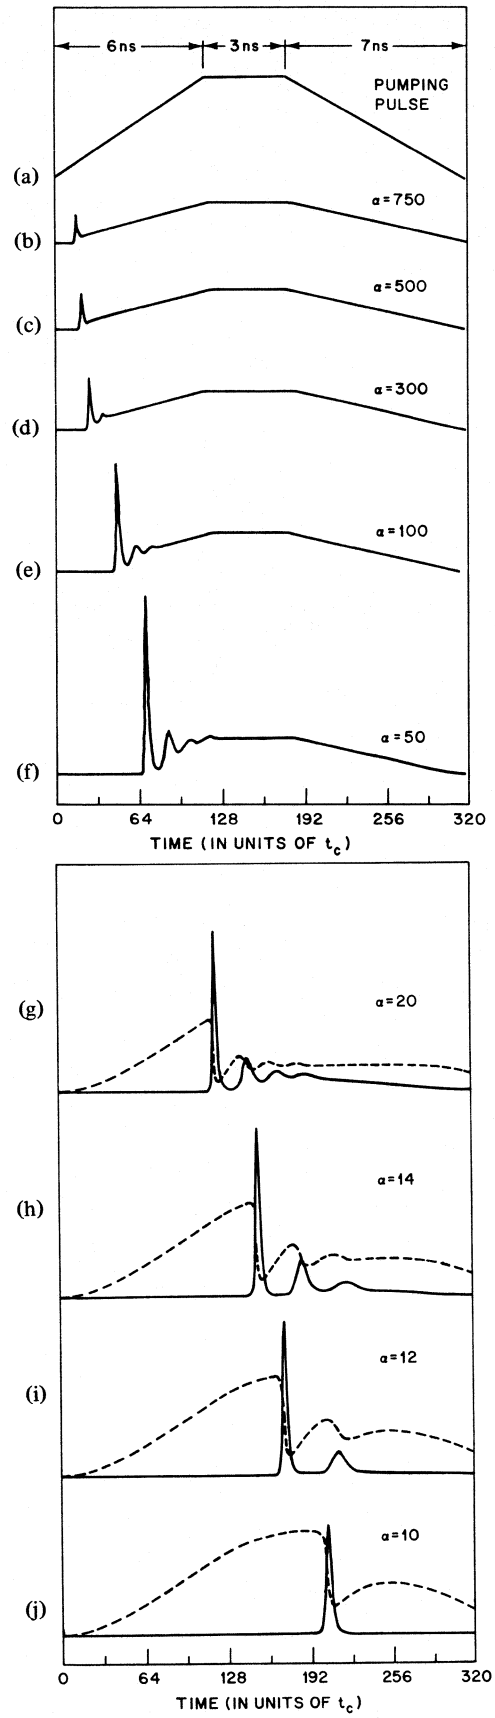

Fig. 3. Computer plots of the solutions of coupled rate equations. t_c = 50 ps, β = 40 (τ = 2 ns), and γ = 1 ns/t_c = 20. Parameter α (level of pumping above threshold) is varied from (b) to (j) as indicated. (a) The approximated N_2 laser pumping pulse. The solid curve represents normalized photon intensity; the dashed curve corresponds to normalized inversion.

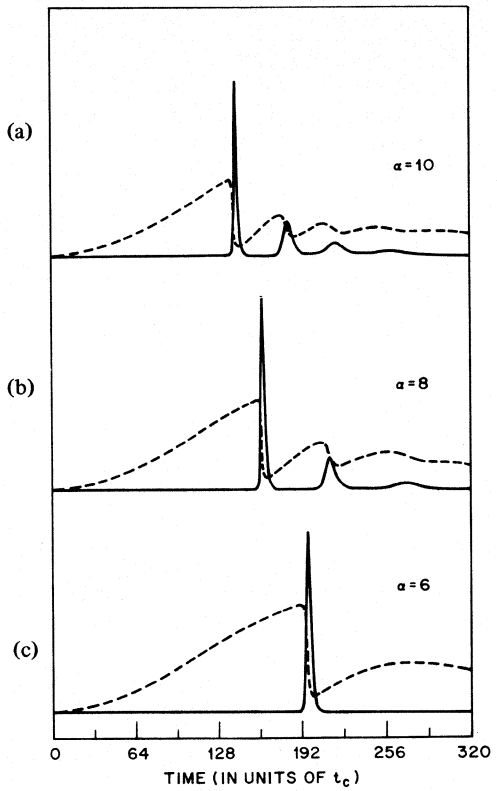

Fig. 4. Same as Fig. 3(h)–(j), except β = 120 (τ = 6 ns) and different α as indicated.

duration which increases with the oscillation number and decreases with pumping level, and that there is a fairly constant oscillation period which is larger than the duration of the spikes. It is also found that semilog plots of the oscillation peaks versus time, of the damped relaxation oscillations, such as shown in Fig. 1(e) and Fig. 2(a), do not deviate much from straight lines, so that the damping for these cases is approximately exponential. Finally, concerning t_c, it is observed that, in a 7D4MC dye laser for which t_c is increased to about 300 ps (a 4-cm dye cell, with an external 99-percent reflector aligned with one uncoated cell window) we found that, although initial spikes can clearly be seen, no well-defined damped relaxation oscillations developed. Undoubtedly, the required ratio of τ/t_c for the observation of regular damped relaxation oscillations is larger than that for the appearance of an initial spike, which is consistent with our computer analyses.

Thus we have shown that there is excellent qualitative agreement between theoretical considerations and experimental results. Quantitatively, the agreement is satisfactory though not as impressive. For example, from Fig. 3(h) the approximated decay-time constant $t_d \simeq 1.3$ ns; the corresponding decay-time constant from Fig. 1(e) is $\simeq 2.3$ ns. The spacing between oscillation peaks is 1.6 ns from the computer plot, which compares well with the experimental result of 1.5 ns. In general, the experimentally observed damping rate is slower, and the obtained spike durations larger than would be predicted from the computer solutions using the appropriate parameters.

Note that in flashlamp-pumped solid-state lasers the parameters γ (pumping pulse duration) and β (fluorescence lifetime τ over t_c) are usually much larger than in the case of dye lasers. As a consequence, many periods of distinct relaxation oscillations, with a slow damping rate (of the order of τ), are ob-

served in contrast to just a few cycles observed in our experiments. Except for this time-scale difference the general behavior of the damped relaxation oscillations should be the same for both laser systems. It is particularly interesting to compare the observations in a four-level, $CaF_2:U^{+3}$ laser [3] with ours in dye lasers. In this flashlamp-pumped solid-state laser it was observed that, when the pump power was reduced in a range close to threshold, the oscillatory output showed a gradual decrease in the number of spikes and an increase in the spike spacing. Such behavior is qualitatively identical to our experimental observations, which have been shown to agree well with theoretical expectations. It may thus be stated that with appropriately selected cavity and pumping parameters the phenomenon of damped relaxation oscillations, with initial spiking as a special case, is a general one observable in all lasers which can be described by the coupled rate equations [1], [2], [5]. This is so simply because it is a consequence of the transient interaction between population inversions and cavity photons, a consequence of the very process of the stimulated emission in lasers.

V. Short-Pulse Generation by Controlled Transients

The previous experimental and theoretical studies of the transient response of dye lasers show that it is possible to generate dye-laser pulses much shorter than the pumping pulse by careful control of dye-laser and pumping parameters. Normally, the laser-pumped dye lasers are operated with large values of t_c and at such a high pumping level that dye-laser pulses largely similar to those of the pumping pulse are obtained. From Figs. 1-4 it is obvious that one can choose a small t_c dye-laser cavity and obtain a single spike of a duration considerably shorter than that of the pumping pulse by carefully controlling the pumping power. Computer plots (Figs. 5 and 6) also show that similar short-duration single pulses can be obtained with a Gaussian excitation pulse; therefore, a Q-switched ruby laser, Nd^{3+} lasers, or their harmonics can similarly be used as the pumping source.

We have applied this general technique of controlled resonator transients to N_2 laser-pumped dye lasers and obtained high repetition-rate subnanosecond pulses tunable in the near UV and the visible region of the spectrum. The detail of the experiment is described elsewhere [12]. We would like to mention that while computer analyses indicate a single pulse of less than 250 ps should be obtained in our N_2 laser-pumped dye lasers [Figs. 3(j) or 4(c)] our experimental results are in the 600–900-ps range. Just how short a pulse can one obtain depends on the particular parameters; computer solutions show that the pulse obtainable in general is at least greater than a few t_c. Since a dye laser is a high-gain medium for which very small values of t_c can be used, one can in principle expect to obtain pulses less than 100 ps with carefully chosen parameters. Tunable pulses of controlled duration in the nanosecond range can also be obtained with the same technique.[1]

[1] An interesting finding is that in 1966 D. Röss proposed a method for "giant pulse shortening" for solid-state lasers, which turns out to be a special case of our general technique. See D. Röss, "Giant pulse shortening by resonator transients," *J. Appl. Phys.*, vol. 37, pp. 2004–2006, Apr. 1966.

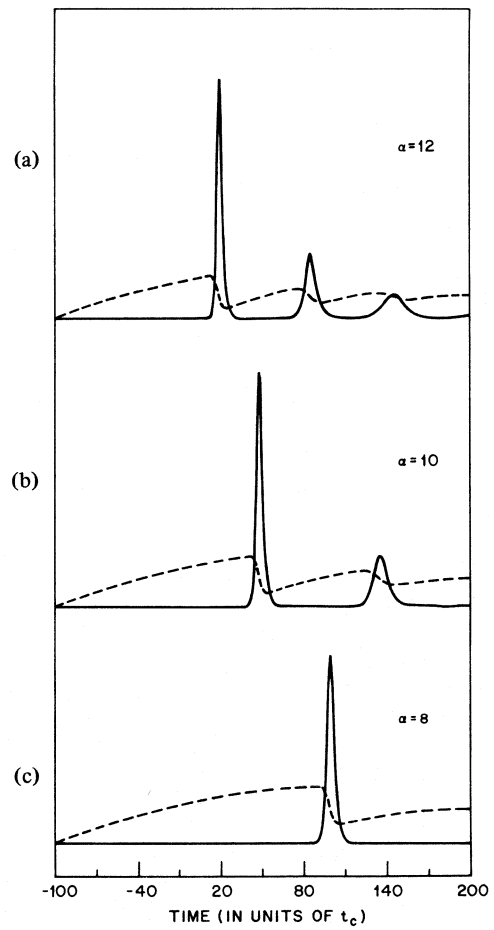

Fig. 6. Same as Fig. 5, except $\beta = 120$ and different α as indicated.

VI. Conclusion

In this paper we have studied and compared, experimentally and theoretically, the phenomena of initial spikes and regular damped relaxation oscillations in laser-pumped dye lasers. We have shown excellent qualitative agreement between experimental observations and theoretical considerations. We have

also pointed out the idea of controlled resonator transients as a general technique for short-pulse generation.

ACKNOWLEDGMENT

The author wishes to thank C. V. Shank for helpful discussions and W. J. Tomlinson for assistance with the time-sharing system. He also wishes to thank A. Ashkin for reading and commenting on the manuscript.

10.6-μm Waveguide Laser Power Amplifier

MARVIN B. KLEIN AND RICHARD L. ABRAMS, MEMBER, IEEE

Abstract—**The results of a study intended to characterize the properties of CW 10.6-μm waveguide power amplifiers are reported. The analysis considers both single- and double-pass devices, and includes the effects of gain narrowing and power broadening. Experiments on a 1.65-mm-bore device with an active length of 77 cm have been performed. Gains as high as 17 dB/m have been measured at room temperature.**

I. INTRODUCTION

THE DEVELOPMENT of the waveguide gas laser concept [1]–[3] and its extension to small high-pressure sealed-off waveguide CO_2 lasers [4] has led to the consideration of other CO_2 laser devices in capillary bores. Among the devices of interest are tunable lasers for use as Doppler tracking local oscillators [5] and high-gain wide-band power amplifiers for laser radar systems. Conventional CO_2 laser devices are inadequate for these applications because their gain bandwidth is limited to a Doppler broadened value of $\approx$50 MHz. However, in a waveguide device, the high operating pressure ($\approx$150 torr) results in a pressure-broadened gain linewidth in excess of 750 MHz. Furthermore, the efficient guiding properties of waveguide devices insure low optical losses for long active lengths.

Manuscript received February 10, 1975; revised March 31, 1975. The research reported in this paper was sponsored by the Advanced Research Projects Agency, monitored by the Office of Naval Research.

The authors are with Hughes Research Laboratories, Malibu, Calif. 90265.

In this paper we report the results of a study intended to characterize the properties of wide-band high-power CW laser amplifiers. This study includes the analysis of amplifier performance in terms of independent design parameters and experiments on a prototype 1-m device. The results obtained permit the confident design of larger devices to meet specific performance goals.

II. WAVEGUIDE AMPLIFIER THEORY

A. Basic Equations

In this section we will derive expressions relating independent amplifier parameters such as overall length, small-signal gain coefficient, and linewidth to system design requirements such as overall gain, output power, and output linewidth. The solutions will include the effects of distributed loss as well as gain saturation. The application of the theory to a double-pass configuration also will be considered.

For a monochromatic input beam at frequency ν, the frequency-dependent saturation of small-signal gain in a homogeneously broadened amplifier is described by

$$\alpha(\nu) = \frac{\alpha_0}{\left[1 + \frac{I(\nu)}{I_s(\nu)}\right][1 + \delta^2]}. \tag{1}$$

In this equation $\alpha(\nu)$ is the saturated gain at frequency ν, α_0 is the small-signal gain at line center, $I(\nu)$ and $I_s(\nu)$ are the beam intensity and saturation intensity at frequency ν, and δ

is the normalized frequency detuning given by

$$\delta = \frac{2(\nu - \nu_0)}{\Delta\nu} \tag{2}$$

where $\Delta\nu$ is the unsaturated gain linewidth and ν_0 is the line center frequency. The saturation intensity $I_s(\nu)$ may be related to the saturation intensity at line center by

$$I_s(\nu) = (1 + \delta^2) I_s(\nu_0). \tag{3}$$

Substituting this expression into (1) and writing $\gamma(\nu) = I(\nu)/I_s(\nu_0)$, we obtain

$$\alpha(\nu) = \frac{\alpha_0}{1 + \delta^2 + \gamma(\nu)}. \tag{4}$$

The incremental gain may be written as

$$\frac{1}{I(\nu)} \frac{dI(\nu)}{dz} = \alpha(\nu) - \beta \tag{5}$$

where β is the distributed loss. Combining (4) and (5) and solving by separation of variables, we obtain

$$\frac{\alpha_0 L}{1 + \delta^2} - \beta L = \ln \frac{\gamma_2(\nu)}{\gamma_1} - \frac{\alpha_0}{\beta(1 + \delta^2)} \cdot \ln \frac{\alpha_0 - \beta(1 + \delta^2) - \beta\gamma_2(\nu)}{\alpha_0 - \beta(1 + \delta^2) - \beta\gamma_1} \tag{6}$$

where γ_1 is the normalized input intensity (assumed constant with frequency), $\gamma_2(\nu)$ is the normalized output intensity, and L is the amplifier length.

For a given set of required amplifier conditions, (6) may be used to study design tradeoffs in small-signal gain, linewidth, and overall length. In the device under study here, the distributed loss is much less than the line center gain coefficient, so that except in the far wings of the gain profile, the relationship $\beta(1 + \delta^2) << \alpha_0$ is satisfied. In this case, (6) reduces to

$$\alpha_0 L = (1 + \delta^2) \ln \frac{\gamma_2(\nu)}{\gamma_1} + [\gamma_2(\nu) - \gamma_1]. \tag{7}$$

For large gains ($\gamma_1 << \gamma_2$) at line center ($\delta = 0$), (7) becomes

$$\gamma_2(\nu_0) = \alpha_0 L - \ln \frac{\gamma_2(\nu_0)}{\gamma_1}. \tag{8}$$

The last term in (8) is related to G, the saturated gain (at line center) in decibels, by

$$G = 4.34 \ln \frac{\gamma_2(\nu_0)}{\gamma_1}. \tag{9}$$

Combining (7)-(9) and solving for δ, we obtain

$$\delta = \frac{2(\nu - \nu_0)}{\Delta\nu} = \left(\frac{\gamma_2(\nu_0) - \gamma_2(\nu) - \ln \dfrac{\gamma_2(\nu)}{\gamma_2(\nu_0)}}{\ln \dfrac{\gamma_2(\nu)}{\gamma_2(\nu_0)} + 0.23G} \right)^{1/2}. \tag{10}$$

Equation (10) may be used to obtain the frequency dependence of $\gamma_2(\nu)$ for various values of the system gain G and the output intensity at line center $\gamma_2(\nu_0)$. The variation of the half-power linewidth $\Delta\nu_{3\ \mathrm{dB}}$ of $\gamma_2(\nu)$ may be obtained (for large gain) from (10) using $\gamma_2(\nu) = 1/2\ \gamma_2(\nu_0)$. Thus we find

$$\Delta\nu_{3\ \mathrm{dB}} = \Delta\nu \left(\frac{\gamma_2(\nu_0)/2 + \ln 2}{0.23G - \ln 2} \right)^{1/2}. \tag{11}$$

The effects of gain saturation on the output linewidth are clearly evident in (11). At low levels of saturation ($\gamma_2(\nu_0) << 1$), the output linewidth is reduced (gain narrowing) by a factor approximately proportional to $G^{-1/2}$, or $(\alpha_0 L)^{-1/2}$. As saturation becomes important, the output is broadened again (power broadening), and the linewidth may even exceed the small-signal gain linewidth $\Delta\nu$. This variation is displayed in Fig. 1, which is a plot of the normalized output linewidth as a function of the normalized line center intensity for various values of the overall gain. In Fig. 2 we have also plotted complete line profiles for several typical sets of amplifier parameters (using (10)). Power broadening is effective throughout the line profile. This is not true when distributed loss is present; in this case, the amplifier line shape is truncated at the frequencies where the unsaturated gain equals the distributed loss.

B. Double-Pass Amplifier

The extension of the above approach to a double-pass configuration is straightforward. We consider the experimental arrangement shown in Fig. 3. The intensities of waves traveling the $+z$ and $-z$ directions are now labeled $I_+(\nu)$ and $I_-(\nu)$, respectively. The gain saturation equation may now be written as

$$\alpha(\nu) = \frac{\alpha_0}{1 + \delta^2 + \dfrac{I_+(\nu) + I_-(\nu)}{I_s(\nu_0)}}. \tag{12}$$

By definition, the incremental gain may also be written as

$$\alpha(\nu) = \frac{1}{I_+} \frac{dI_+}{dz} \tag{13}$$

$$\alpha(\nu) = \frac{1}{I_-} \frac{dI_-}{dz}. \tag{14}$$

If we now substitute $\gamma_+(\nu) = I_+(\nu)/I_s(\nu_0)$ and $\gamma_-(\nu) = I_-(\nu)/I_s(\nu_0)$ into (13) and (14) and then combine the two equations, we obtain

$$\frac{d\gamma_+(\nu)}{\gamma_+(\nu)} = -\frac{d\gamma_-(\nu)}{\gamma_-(\nu)}. \tag{15}$$

The solution to this equation is

$$\gamma_+(\nu)\gamma_-(\nu) = C \tag{16}$$

where C is a constant. Combining (12), (13), and (16), we obtain

$$\frac{1}{\gamma_+(\nu)} \frac{d\gamma_+(\nu)}{dz} = \frac{\alpha_0}{1 + \delta^2 + \gamma_+(\nu) + \dfrac{C}{\gamma_+(\nu)}}. \tag{17}$$

By separation of variables and integration from 0 to L, we

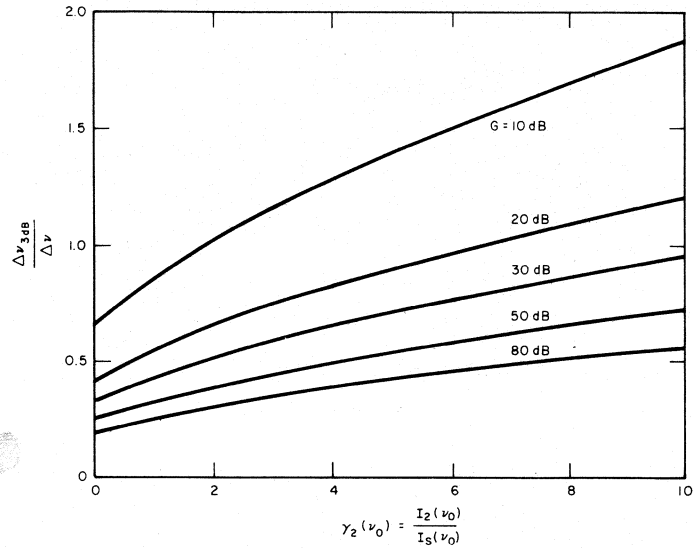

Fig. 1. Normalized output linewidth versus normalized output intensity for several values of overall gain.

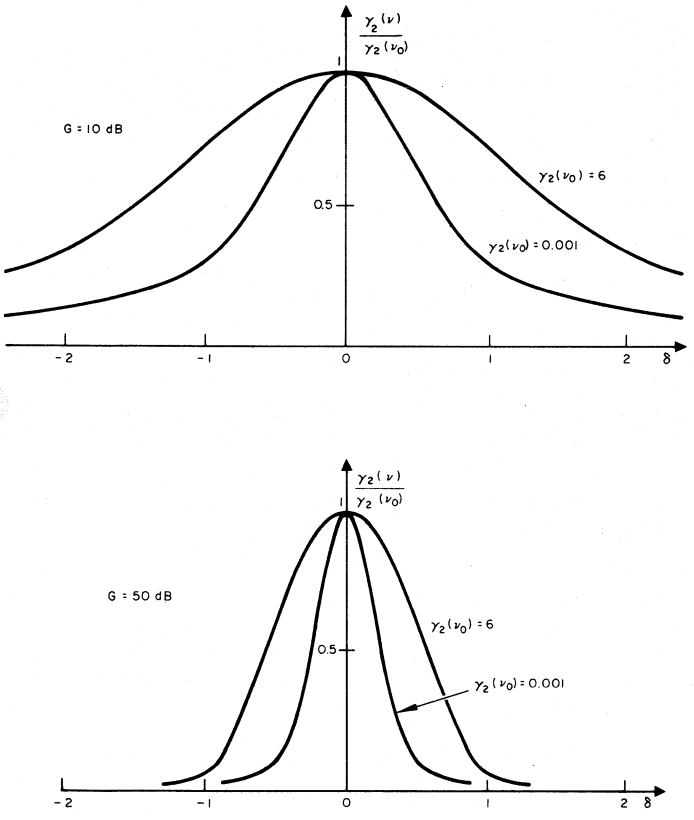

Fig. 2. Normalized line profiles for $G = 10$ dB (upper) and $G = 50$ dB (lower).

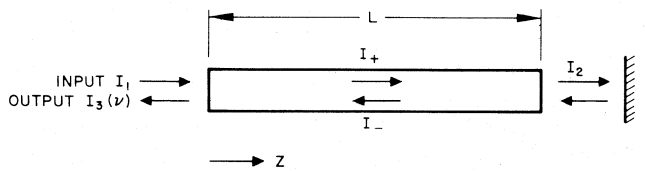

Fig. 3. Double-pass amplifier configuration.

obtain

$$(1+\delta^2)\ln\frac{\gamma_2(\nu)}{\gamma_1}+[\gamma_2(\nu)-\gamma_1]+\frac{C}{\gamma_1}-\frac{C}{\gamma_2(\nu)}=\alpha_0 L. \quad (18)$$

To eliminate γ_2, we make use of (16), applied at each end of the amplifier:

$$\gamma_1\gamma_3(\nu)=[\gamma_2(\nu)]^2=C \quad (19)$$

where γ_1, $\gamma_2(\nu)$, and $\gamma_3(\nu)$ are defined in Fig. 3. By combining (18) and (19) we obtain

$$(1+\delta^2)\ln\frac{\gamma_3(\nu)}{\gamma_1}+2[\gamma_3(\nu)-\gamma_1]=2\alpha_0 L. \quad (20)$$

By comparison, a single pass through the length L yields the relation (see (8))

$$(1+\delta^2)\ln\frac{\gamma_3(\nu)}{\gamma_1}+[\gamma_3(\nu)-\gamma_1]=\alpha_0 L. \quad (21)$$

A more convenient comparison between the single-pass and double-pass configurations may be obtained (using the preceding equations) by writing expressions for the device length required to produce a given line center output $\gamma_3(\nu_0)$ and saturated gain G, for a given incremental gain α_0 (we also assume $\gamma_3 \gg \gamma_1$).

$$\text{Single Pass:}\quad L=\frac{1}{\alpha_0}[\gamma_3(\nu_0)+0.23G] \quad (22)$$

$$\text{Double Pass:}\quad L=\frac{1}{\alpha_0}\left[\gamma_3(\nu_0)+\frac{0.23G}{2}\right]. \quad (23)$$

Thus the potential length decrease in going to a double-pass configuration (assuming 100-percent reflectivity at the end mirror) can be as much as 50 percent, depending on the relative magnitudes of $\gamma_3(\nu_0)$ and G.

Another parameter of interest is the half-power bandwidth; this may be obtained from (20) by setting $\gamma_3(\nu)=\gamma_3(\nu_0)/2$ with the result

$$\Delta\nu_{3\,dB}=\Delta\nu\left(\frac{\gamma_3(\nu_0)+\ln 2}{0.23G-\ln 2}\right)^{1/2}. \quad (24)$$

By comparison, a single pass through the same amplifier yields

$$\Delta\nu_{3\,dB}=\Delta\nu\left(\frac{\gamma_3(\nu_0)/2+\ln 2}{0.23G-\ln 2}\right)^{1/2}. \quad (25)$$

Thus in addition to the increased small-signal gain, the double-pass configuration yields a considerably larger linewidth, due to the increased saturation produced at the input (and output) end of the device.

C. Amplifier Design Procedure

In order to design a laser amplifier with given performance characteristics, we require knowledge of the small-signal gain coefficient α_0, the line center saturation intensity $I_s(\nu_0)$, and the linewidth $\Delta\nu$, as functions of pressure, current, and tube diameter. By making use of these parameters in the analytical relationships derived in the previous section, we can calculate the minimum active device length required to achieve given design goals. This calculation can be repeated for a

variety of experimental conditions, so that optimum conditions requiring the shortest amplifier length may be found. This approach will be followed in the device design procedure given in Section VII.

III. Test-Bed Description

In designing a waveguide amplifier of 1-m nominal length, several problems are met. As a first consideration, it should be noted that ceramic sections with 1- to 2-mm drilled holes cannot be obtained in lengths greater than 12 to 15 cm. Thus in our device we have made use of a segmented design which incorporates seven separate ceramic (BeO) sections and connecting Kovar flanges. Each section is 12.5 cm long, with a 1.65-mm bore. The use of separate ceramic segments suggests a parallel connection of electrical power and gas flow, as represented schematically in Fig. 4 and shown in more detail in Fig. 5. The electrical connections are arranged so that all of the connecting flanges are grounded (for safety reasons) and the center electrodes serve as cathodes (to eliminate sputtering near the windows at each end). The 2-mm spacing between sections is large enough to allow adequate gas flow, but small enough to maintain a low theoretical value of optical loss (0.09 percent). The individual segments are attached to separate heat sink mounts which are in turn fastened to an I-beam support. Each discharge region is 5.5 cm in length so that the overall length of the active region (with 14 discharges) is 77 cm.

An important consideration in the amplifier construction is

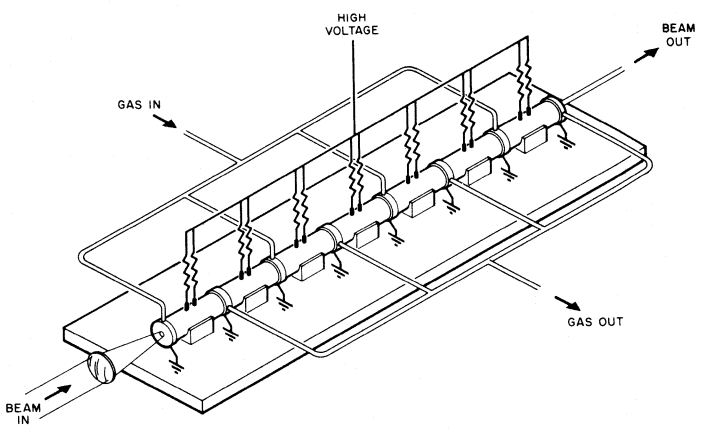

Fig. 4. Amplifier assembly.

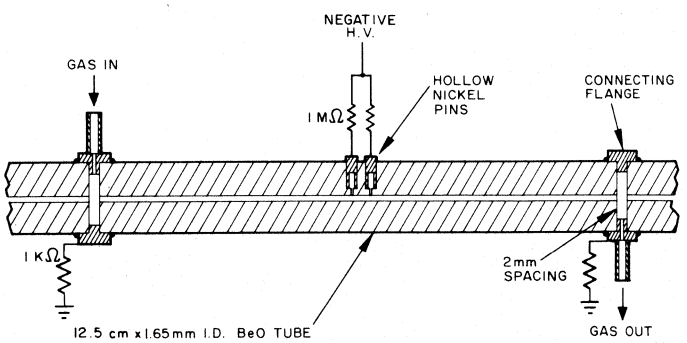

Fig. 5. Detail of electrical and gas flow connections.

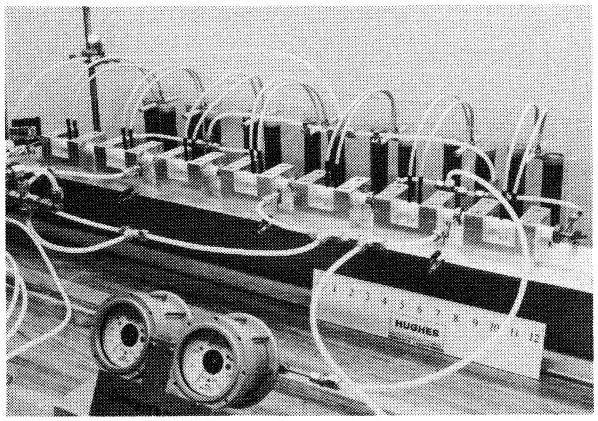

Fig. 6. Completed amplifier.

the mechanical alignment of the separate ceramic sections. For the device under consideration here, two optical techniques were used for achieving optimum alignment. First, an unfocused 6328-Å laser beam was passed down the amplifier bore. As each ceramic section was added, its lateral position at the new joint was adjusted for minimum scattering of the He-Ne beam at the joint (as observed in a darkened room). The angular alignment of each section was optimized by minimizing the scattered light within the bore itself, and by optimizing the symmetry of the output beam. After each section was aligned in this fashion, it was fastened securely to the I-beam.

After all sections had been aligned and fastened in the above manner, the overall transmission at 10.6 μm was measured. This was accomplished by first passing the beam from a 1-W CO_2 laser through a telescope adjusted to provide optimum coupling into the low loss EH_{11} waveguide mode. After several alignment attempts, we were able to achieve an overall 10.6-μm transmission of 92 percent. The theoretical transmission, accounting for both coupling and guiding losses, is approximately 97 percent. We believe that the additional loss in this case is due to residual misalignment at the joints between sections. As the final step in the assembly, the connecting flanges were epoxied to the ceramic; the Brewster window material was CdTe. A photograph of the completed device is shown in Fig. 6.

IV. Gas Flow Considerations

As discussed earlier, the seven ceramic sections have parallel gas flow connections to minimize the pressure drop across the total device length. A schematic diagram of the gas flow system is given in Fig. 7. Helium, nitrogen, and carbon dioxide in ultra-pure form (99.999-percent purity) are fed from separate tanks through individual flowmeters and needle valves to a mixing manifold, and then into the discharge region. The flow then passes through a throttle valve (for control of the amplifier pressure) and is exhausted through a (Welch 1402) 5.6-ft^3/min mechanical pump.

The gas flowmeters can be connected and calibrated to read mass flow (e.g., torr-liters per second) or volumetric flow (e.g., liters per second). Greater accuracy and ease in calibration is obtained by maintaining the flow tubes at constant pressure

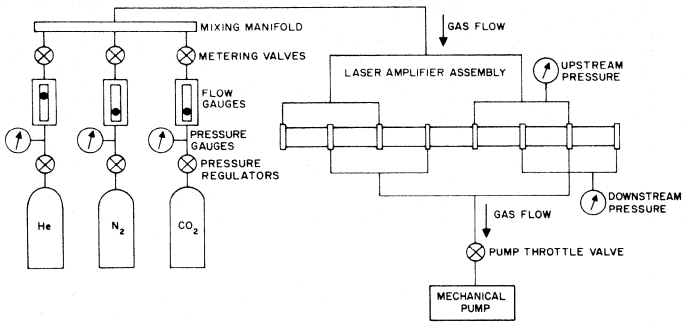

Fig. 7. Schematic diagram of gas flow system.

and regulating the flow with downstream needle valves (as shown in Fig. 7). In this mode of operation the flowmeter reading is proportional to mass flow. For the purpose of relating amplifier parameters to flow rates, the flow is best specified by the number of gas fill changes per second for each separate flow length. This quantity may then be compared directly to the rates of other relevant processes in the discharge. For the geometry of our flow system, we have

$$N = 5.33 \times 10^2 \frac{Q_T}{P_0} \text{ changes/s} \tag{26}$$

where Q_T is the total mass flow in torr-liters per second, and P_0 is the average pressure in torr.

V. Electrical Circuitry

As mentioned earlier, the separate ceramic sections each contain two centrally located hollow nickel cathodes. The Kovar connecting flanges serve as common anodes for adjacent discharges. The high-voltage power supply (with positive ground) provides negative high voltage to the cathodes through separate 1-MΩ ballast resistors. The anodes are connected to ground through separate 1-kΩ resistors. The voltage drop across these resistors is a convenient measure of the discharge current.

Although the high-voltage power supply has an option which provides rapid application of a preset voltage to the 14 amplifier discharges, simultaneous ignition of all discharges is very difficult to achieve except at low pressures, or in helium-rich mixtures. In order to avoid this problem, we inject a high-voltage pulse (60 kV) into the negative high-voltage lead from the dc power supply at the same time that this supply is switched on. The combination of these two fast rising voltage sources produces reliable ignition of all discharges in most cases.

VI. Experimental Results

In this section we report the results of measurements of small-signal gain coefficient and saturation intensity for a variety of experimental conditions. The experimental arrangement for all optical experiments is identical. The source oscillator is a 1-W conventional bore CO_2 laser tuned to line center of the $P(20)$ transition. The output from this laser is focused onto the entrance aperture of the first amplifier section by passing through a telescope adjusted for optimum coupling to the EH_{11} mode. A variable attenuator is also

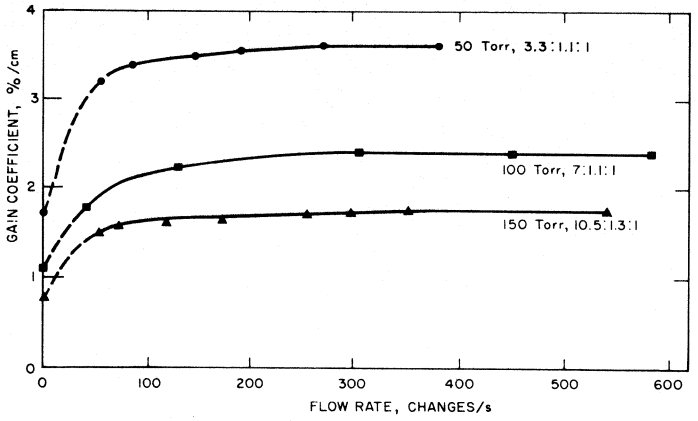

Fig. 8. Gain versus flow rate for 50-, 100-, and 150-torr pressure. The gas mixtures are presented in the ratios He:Ne:CO_2. The discharge current was 3 mA.

provided at the input to the amplifier. A power meter at the amplifier exit is used to measure transmitted power. In order to obtain the input power to the amplifier, the transmitted power through the passive amplifier (with 8-percent transmission loss) was multiplied by 1.08. The amplifier gain was then given by the ratio of the transmitted power through the active amplifier divided by input power as given above. In general, our gain measurements were performed using a constant input power of 100 mW in the expectation that saturation effects would be unimportant at this power level. Our subsequent measurements of saturation intensity (presented in a later section) indicate that this assumption is accurate at 150 torr with small errors being introduced at lower pressures. However, even at 50 torr, the errors introduced in the measured gain coefficient are less than 10 percent.

During the course of our measurements, care was taken to ensure that spontaneous emission noise and absorption by the cold gas were negligible factors. We also examined the discharge voltage at various times for signs of high-frequency oscillations and none were observed.

A. Small-Signal Gain versus Flow Rate

Before proceeding with gain measurements as a function of pressure, it is important to know the effects of gas flow on the gain. We have measured gain versus gas flow (measured in changes per second) at three different pressures; the gas mixture at each pressure has been adjusted for maximum gain. The results are shown in Fig. 8. The dashed line for each plot is an extension of the measured data to the sealed-off measured values of Abrams and Bridges [4]. At each pressure the gain rises rapidly, and then approaches a constant value for flow rates greater than ~200 changes/s. All subsequent gain measurements have been performed at flow rates of this magnitude.

B. Small-Signal Gain versus Pressure

In Fig. 9 we show values of gain measured as a function of pressure for gas mixtures optimized at 50, 100, and 150 torr. The flow rate for all measurements was kept constant at 200 changes/s. For reference purposes the gain is given in %/cm,

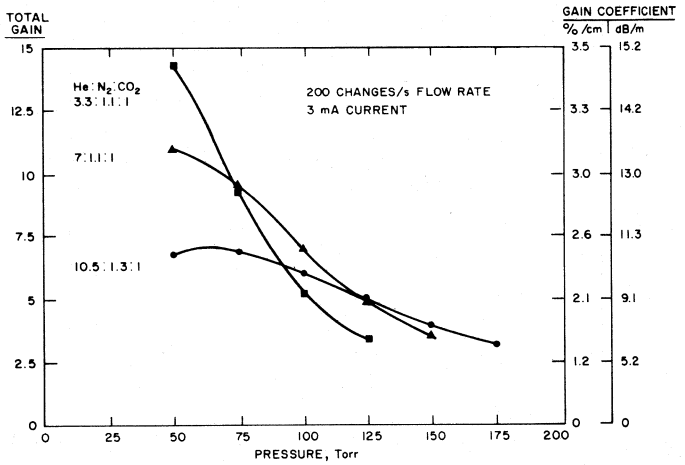

Fig. 9. Gain versus pressure at constant flow rate (200 changes/s) and current (3 mA), for mixtures shown.

dB/m, and overall gain for the device under investigation. The displayed data were taken at 3-mA current. In general, the gain at 2 mA and 4 mA is slightly lower. The data of Fig. 9 do not extend below 50 torr because we were not able to maintain the required flow rate in this range. However, measurements at approximately 120 changes/s yielded an overall gain of 17.5 at 38 torr (in a 3 : 1 : 1 mixture), corresponding to gain coefficients of 3.7%/cm, or 16.1 dB/m.

C. Measurement of Saturation Intensity

Many techniques for measuring the saturation intensity (using both oscillator and amplifier configurations) are available, and we have chosen one which we feel is particularly suitable to our experimental conditions. We make use of the same laser source (tuned to line center) used in the gain measurements, and adjust the attenuator to provide a variable power input in the range 0.1 to 1.0 W. The relation describing the interaction of such a source in the amplifier is given by (7), written explicitly in terms of laser power (with $\delta = 0$)

$$P_2(\nu_0) - P_1(\nu_0) = -P_s(\nu_0) \ln \frac{P_2(\nu_0)}{P_1} + P_s(\nu_0)\alpha_0 L. \qquad (27)$$

Thus, by measuring output power $P_2(\nu_0)$ for a range of input powers $P_1(\nu_0)$ and plotting $P_2(\nu_0) - P_1(\nu_0)$ as a function of $\ln [P_2(\nu_0)/P_1]$, we obtain a straight line with slope $-P_s(\nu_0)$. This technique is applicable for any range of input powers, but is most accurate when the range is large and appreciable saturation is produced.

Using the above technique, we have measured saturation power for five pressures in the range of 50 to 150 torr and for discharge currents of 2, 3, and 4 mA. The gas mixture at each pressure is that which produces maximum gain. For each setting of pressure and current, the data were plotted as described above. A straight line was then fitted (by the method of least squares) to each set of data points. The saturation power was obtained from the slope of each curve, and is plotted as a function of pressure (for each current) in Fig. 10. The saturation intensity may be obtained by dividing the power by πw^2, where w is the e^{-1} intensity radius of the Gaussian beam which best matches [6] the EH_{11} waveguide mode ($w/a = 0.455$).

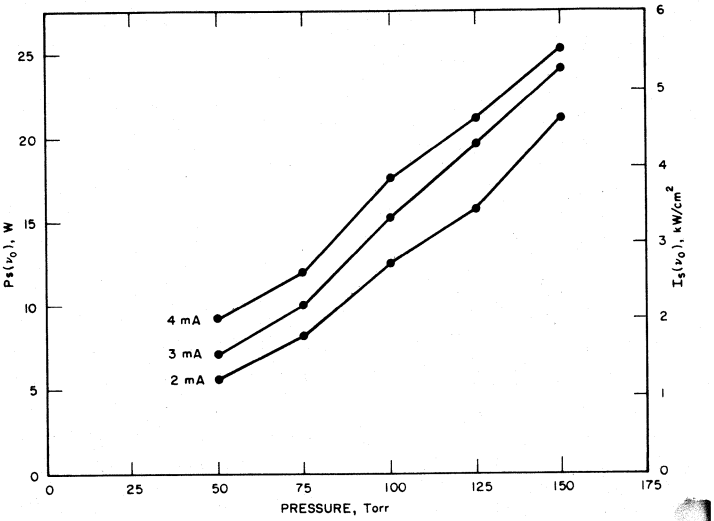

Fig. 10. Saturation power and intensity versus pressure (flow rate = 200 changes/s).

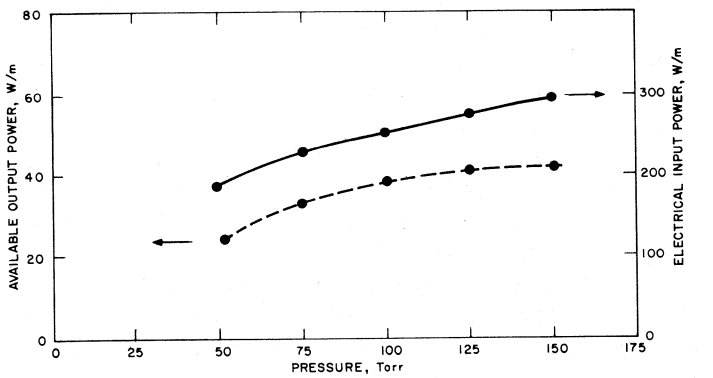

Fig. 11. Available output power and input electrical power versus pressure. Discharge current = 3 mA.

As expected, the saturation intensity increases with pressure (due to molecule-molecule collisions) and with current (due to electron-molecule collisions). The values of this parameter are approximately a factor of 2 lower than the measured values of Abrams and Bridges [4] for a sealed-off oscillator using He-CO_2 mixtures. The reasons for this discrepancy are not well understood; however, it is felt there may be some systematic errors in the previously published data.

In a highly saturated amplifier, one relevant measure of device performance is the power extraction capability (in watts per meter), given by the product of small-signal gain coefficient and the saturation power. In Fig. 11 we plot values of $a_0 P_s(\nu_0)$ as a function of pressure (at 3-mA current) using previously plotted values of gain and saturation power. We have also plotted measured values of electrical input power per unit length for the same condition. It is apparent that power extraction efficiencies as high as 20 percent are possible.

VII. Characterization of Full Scale Device

On the basis of the measurements described in the preceding sections, we are in a position to determine the amplifier length required to meet specific performance requirements. The length is related to other amplifier parameters by

$$\alpha_0 L = \gamma_2(\nu_0) + \ln \frac{\gamma_2(\nu_0)}{\gamma_1}. \tag{28}$$

Solving for L and writing in terms of power instead of intensity, we obtain

$$L = \frac{1}{\alpha_0}\left[\frac{P_2(\nu_0)}{P_s(\nu_0)} + \ln \frac{P_2(\nu_0)}{P_1}\right]. \tag{29}$$

As an example, in Fig. 12 we have made use of the above expression to plot the required length L as a function of line center output power $P_2(\nu_0)$ for three different pressures, using the gain and saturation power data of previous sections. We have assumed a constant 1-W input and a discharge current of 3 mA. The curves for 2 and 4 mA are very close to those plotted in Fig. 12. It should also be noted that the straight line nature of the plots in Fig. 12 follows directly from differentiation of (29), in the limit $P_2(\nu_0) >> P_s(\nu_0)$. The slope of each plot is just $[\alpha_0 P_s(\nu_0)]^{-1}$, or the inverse of the extractable power per unit length.

Using (11) we have also calculated the 3-dB amplifier linewidth for the range of parameters plotted in Fig. 12. We find that at 150 torr, $\Delta\nu_{3\,\mathrm{dB}} > 500$ MHz for the entire plotted range of output powers. At 100-torr pressure, $\Delta\nu_{3\,\mathrm{dB}} > 500$ MHz for output powers greater than 80 W. Finally, at 50 torr, we find $300 < \Delta\nu_{3\,\mathrm{dB}} < 500$ MHz over the entire plotted range of output powers. In each of these cases, the amplifier is strongly saturated at the output, resulting in significant power broadening of the amplifier bandwidth.

We see from Fig. 12 that the optimum amplifier pressure over the plotted range of output powers is near 100 torr. However, even at the optimum pressure, the required lengths range from 3 m (for 17-dB overall gain) to 7 m (for 23-dB overall gain). Thus the required amplifier length depends critically on the required system gain.

There are several refinements which can be made to further improve the amplifier performance. Most importantly, cooling of the amplifier is known to produce a significant improvement in small-signal gain coefficient, with a 50-percent increase at $-60°$C being typical [3]. Secondly, a double-pass configuration may be used to provide length reductions approaching a factor of 2.

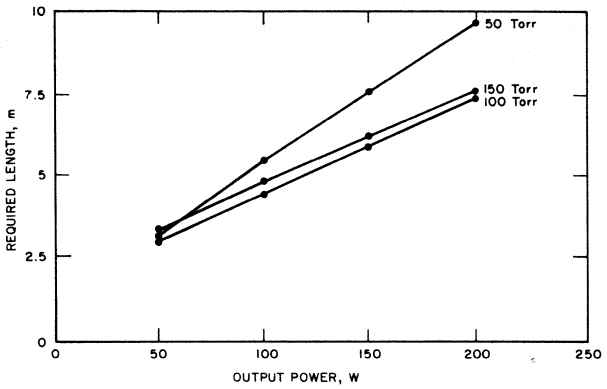

Fig. 12. Required length as a function of output power for a 1-W input.

VIII. Conclusions

We have shown that high-pressure waveguide laser devices provide a practical means for achieving high-gain wide-band amplification at 10.6 μm. Our study has included the analysis of high-gain saturated amplifiers, and experiments on a prototype 1-m device. As a result of this study, we are able to specify the design parameters required for construction of a device to meet specific performance goals.

Influence of Two-Photon Absorption on Second-Harmonic Generation in Semiconductors— Part I: Theoretical Analysis and Application to the Case of Tellurium

CHRISTIANE A. SCHWARTZ, MEMBER, IEEE, JEAN-LOUIS OUDAR, AND EDMOND M. BATIFOL

Abstract—**The competition between two-photon absorption and second-harmonic generation (SHG) in semiconductors is analyzed; particular attention is given to the linear absorption and change of phase-matching conditions caused by the two-photon induced free carriers. The system of equations is solved numerically in the case of tellurium, and this analysis enables prediction of an improvement of harmonic conversion efficiency when using shorter pulses.**

I. Introduction

ONE OF THE very few problems of second-order nonlinear optics which has not yet received a definite solution is the parametric oscillation in the medium infrared (5-30 μm). The frequency dependence of the parametric gain [1] makes the requirement on infrared materials for parametric oscillation quite drastic. Empirical and theoretical considerations show that noncentrosymmetric crystals with high refractive indices [2] are more likely to exhibit the required high nonlinear susceptibility. Since only low-gap semiconductors have these high refractive indices, this choice also selects the materials where multiphoton absorption easily occurs under the high power density necessary to reach a large conversion efficiency. Multiphoton absorption in solids promotes extra free carriers which in turn produce absorption (α) and refractive index variations and therefore together decrease the power density and break the phase-matching conditions. These effects, particularly strong for infrared wavelengths λ ($\alpha \propto \lambda^2$) can be more or less important depending on the carrier lifetime and the pulse duration. As a consequence the determination of maximum parametric gain must consider the competition of two nonlinear processes: harmonics generation and multiphoton absorption.

In this paper we wish to present a detailed analysis of the competition of second-order nonlinear processes and two-photon absorption in semiconductors.

In Part I, we consider the set of equations describing second-harmonic generation (SHG) in presence of two-photon absorption (TPA) as well as linear absorption and change of refractive indices induced by free carriers. This system is numerically solved in the case of tellurium. This crystal was chosen as an example for two reasons: a great number of experimental data is available on this material, and the multiphoton induced free carriers produce very strong effects. In the numerical analysis some unknown parameters are fitted to reproduce the experimental results of Gandrud and Abrams [3]. The same set of parameters enables one to explain other observations such as those made by Malz and Staupendhal [4], as well as our own. Then the model is used to predict the conversion efficiency for various experimental conditions. Two interesting results are obtained: the reduction of pulse duration leads to a significant decrease of the free carriers effects [5], and, at fixed pulsewidth, there is an optimum fundamental power density nearly independent of the total incident power.

In Part II[1] we test the analysis of Part I by measuring the absorption at 10.6 μm (CO_2 laser) induced in tellurium by 5-μm radiation (CO laser). The time dependence is analyzed by varying the delay between the two laser pulses. The power dependence is examined by varying independently the power of the two lasers. Then the frequency dependence is examined by varying the wavelength of the CO laser. These additional experimental data lead to a more precise analysis of the processes involved as well as the values of two-photon absorption coefficients in tellurium.

II. Equations Describing Simultaneous SHG and TPA in Semiconductors

Let us first give a brief summary of the experimental observation on SHG at high conversion efficiency in the medium infrared. First, a saturation of SHG is observed which cannot be explained only by power conversion from fundamental to harmonic frequencies. The observed depletion of the pump is much larger than the conversion efficiency (in $CdGeAs_2$ [6] 60-percent pump depletion for 15-percent efficiency; in tellurium [3] 70-percent pump depletion for 15-percent efficiency). In tellurium, a photoconductivity signal has been observed simultaneously with the laser pulse, indicating the creation of extra free carriers [3]. A shift and a deformation of phase-matching curve have also been mentioned [4]. Generally, the fundamental and harmonic pulse shapes are distorted: in the case of tellurium the distortion is assymmetric [3], leading to a narrowing of the pulses, conversely to $CdGeAs_2$ [6].

These observations strongly suggest that the mechanism is

[1] See pp. 623-629, this issue.

the following: at high conversion efficiency, the second-harmonic intensity becomes large enough to induce non-negligible TPA. Depending on the energy gap compared to the laser wavelength, two processes are possible: simultaneous absorption of 1) one photon from the fundamental beam and one from the harmonic, or 2) two photons at harmonic frequency. We symbolize henceforth the first process 1) by $(\hbar\omega_1 + \hbar\omega_2)$ and the second 2) by $(\hbar\omega_2 + \hbar\omega_2)$, where $\hbar\omega_1$ and $\hbar\omega_2$ are the fundamental and harmonic photon energies. We do not consider here another possibility, the process $(\hbar\omega_1 + \hbar\omega_1)$, for we assume the energy gap E_g is greater than $\hbar\omega_2 = 2\hbar\omega_1$. These absorptions create extra free carriers which in turn modify together the linear absorption and the refractive indices of the material.

To explain these observations, we build a model in the following way. We start from the usual system of equations describing SHG, slightly modified to include the aperture length effect. New terms taking TPA into account variation of refractive indices and of linear absorption due to induced free carriers are added. Then a rate equation for the evolution of induced free carriers population is coupled to the nonlinear system.

A. Set of Equations Describing SHG

The method of Boyd and Kleinman [7] is very powerful to describe focusing and aperture effects in SHG, but fails in taking into account the pump depletion. On the other hand, a plane-wave analysis in the line of Armstrong *et al.* [1] is more simple and well fitted to variations of the pump level.

These equations are

$$\frac{\partial \rho_1}{\partial z} = -C_0 \rho_1 \rho_2 \sin\theta - (\alpha_1/2)\rho_1$$

$$\frac{\partial \rho_2}{\partial z} = C_0 \rho_1^2 \sin\theta - (\alpha_2/2)\rho_2$$

$$\frac{\partial \theta}{\partial z} = 2C_0(\rho_2 - (\rho_1^2/2\rho_2))\cos\theta + \Delta k \qquad (1)$$

where $\rho_{1,2}$ are the electric field amplitudes, defined with the following notations: the indices 1 and 2 refer to the fundamental and harmonic beams and the plane-wave electric fields $\bar{E}_{1,2}(z, t)$ with $\bar{k}_1$ and $\bar{k}_2$ along z axis are

$$\bar{E}_{1,2}(z, t) = \tfrac{1}{2}\,\mathrm{Re}\,(\bar{E}_{1,2}\, e^{i(k_{1,2}z - \omega_{1,2}t)})$$

where

$$\bar{E}_{1,2} = \hat{u}_{1,2}\,\rho_{1,2}\, e^{i\phi_{1,2}}$$

$$\theta = 2\phi_1 - \phi_2 + \Delta k z$$

with

$$\Delta k = 2k_1 - k_2.$$

$\alpha_{1,2}$ are the absorption coefficients at $\omega_{1,2}$, the fundamental and harmonic frequencies. C_0 is equal to

$$C_0 = \frac{4\pi}{n_1 c}\,\omega_1\, d_{\mathrm{eff}}$$

where n_1 is the refractive index of the crystal at fundamental frequency, and d_{eff} is the effective SHG coefficient [7].

It is well known, from [7], that due to the focusing effect the variation of the harmonic power P_2, at phase-matching is

$$\begin{cases} P_2 \propto z^2, & \text{for } z \ll l_a, l_f \\ P_2 \propto z l_a, & \text{for } l_a \ll z \ll l_f \end{cases} \qquad (2)$$

where $l_a = \sqrt{\pi}\, w_0/\rho$ is the aperture length, w_0 is the minimum beam radius, ρ the walk-off angle; $l_f = \pi b/2$ where b is the confocal parameter.

Since in experimental configuration both strong focusing is required and large variations of pump level are observed, we choose to use the system (1) adequately modified to give the asymptotical behavior (2). This is performed in the following way. We replace the Gaussian beams by quasi-plane waves. When $z \ll l_a$, both treatments lead to the same result, i.e., the phase-matched second-harmonic power is proportional to z^2, when using the correspondence

$$\begin{cases} P_1 = \dfrac{\pi w_0^2}{2} I_1 = \dfrac{\pi w_0^2}{2}\dfrac{n_1 c}{8\pi}\rho_1^2 \\ P_2 = \dfrac{\pi w_0^2}{4} I_2 = \dfrac{\pi w_0^2}{4}\dfrac{n_2 c}{8\pi}\rho_2^2 \end{cases} \qquad (3)$$

and thus (1) lead to: $P_2 \propto z^2$ when $\Delta k = 0$ and P_1 remains constant.

For practical purposes, the same correspondence (3) is used even in the case $z \geqslant l_a$. This assumption leads to slight overestimation of the harmonic intensity of the fundamental beam axis, but a more sophisticated treatment would be too complicated. The relations $P_2 \propto \rho_2^2$ and $P_2 \propto z l_a$ when neglecting the pump depletion involve

$$\frac{\partial \rho_2}{\partial z} \propto z^{-1/2}.$$

Consequently, in order to obtain the asymptotic behaviors (2) when using (3), we replace C_0 in (1) by C, defined as follows:

$$\begin{cases} C = C_0, & \text{for } z \leqslant \gamma l_a \\ C = \dfrac{C_0}{2}\sqrt{\dfrac{l_a}{z}}, & \text{for } z > \gamma l_a. \end{cases} \qquad (4)$$

As (2) are only asymptotic, we adjust the numerical coefficient γ in such a way as to obtain the correct value of SHG efficiency when the pump can be taken as constant (γ is not far from one).

B. TPA and Induced Free Carriers

Whenever the fundamental photon energy exceeds the fourth part of the energy gap of the material ($\hbar\omega_1 > E_g/4$), new terms due to TPA must be introduced into (1). We consider the general case where both processes $(\hbar\omega_1 + \hbar\omega_2)$ and $(\hbar\omega_2 + \hbar\omega_2)$ can occur.

In the first process $(\hbar\omega_1 + \hbar\omega_2)$ the power absorption in a unit volume is proportional to the product of the fundamental

and harmonic intensities, whereas in $(\hbar\omega_2 + \hbar\omega_2)$ it is proportional to the square of the harmonic intensity. TPA can be described in terms of the imaginary part of the third-order nonlinear susceptibility χ_3''. The third-order polarizations $\bar{P}^{(3)}_{NL1}$ and $\bar{P}^{(3)}_{NL2}$ at fundamental and harmonic frequencies are

$$\begin{cases} \bar{P}^{(3)}_{NL1} = i\vec{\vec{\chi}}_3''(\omega_1, \omega_2, -\omega_2) \vdots \bar{E}_1 \bar{E}_2 \bar{E}_2^* \\ \bar{P}^{(3)}_{NL2} = i\vec{\vec{\chi}}_3''(\omega_2, \omega_1, -\omega_1) \vdots \bar{E}_2 \bar{E}_1 \bar{E}_1^* \\ \qquad + i\vec{\vec{\chi}}_3''(\omega_2, \omega_2, -\omega_2) \vdots \bar{E}_2 \bar{E}_2 \bar{E}_2^*. \end{cases} \tag{5}$$

We define two effective third-order coefficients by

$$\begin{cases} \Gamma_{12} = \hat{u}_1 \cdot \vec{\vec{\chi}}_3''(\omega_1, \omega_2, -\omega_2) \vdots \hat{u}_1 \hat{u}_2 \hat{u}_2 \\ \qquad = \hat{u}_2 \vec{\vec{\chi}}_3''(\omega_2, \omega_1, -\omega_1) \vdots \hat{u}_2 \hat{u}_1 \hat{u}_1 \\ \Gamma_{22} = \hat{u}_2 \cdot \vec{\vec{\chi}}_3''(\omega_2, \omega_2, -\omega_2) \vdots \hat{u}_2 \hat{u}_2 \hat{u}_2. \end{cases} \tag{6}$$

The energy densities W_1 and W_2 dissipated by the two beams in a unit volume of the crystal are given by

$$\begin{cases} \dfrac{dW_1}{dt} = \dfrac{\omega_1}{2} \Gamma_{12} \rho_1^2 \rho_2^2 \\ \dfrac{dW_2}{dt} = \left(\dfrac{dW_2}{dt}\right)_{12} + \left(\dfrac{dW_2}{dt}\right)_{22} = \dfrac{\omega_2}{2} \Gamma_{12} \rho_1^2 \rho_2^2 \\ \qquad + \dfrac{\omega_2}{2} \Gamma_{22} \rho_2^4. \end{cases} \tag{7}$$

Then the absorption coefficients due to TPA are

$$\begin{cases} \alpha_1' = \dfrac{4\pi}{n_1 c} \omega_1 \Gamma_{12} \rho_2^2 = \beta_{12} I_2 \\ \alpha_2' = \dfrac{4\pi}{n_2 c} \omega_2 (\Gamma_{12} \rho_1^2 + \Gamma_{22} \rho_2^2) = 2\beta_{12} I_1 + \beta_{22} I_2 \end{cases} \tag{8}$$

where

$$\beta_{12} = \frac{(8\pi/c)^2}{n_1 n_2} \frac{\omega_1}{2} \Gamma_{12}; \quad \beta_{22} = \left(\frac{8\pi}{n_2 c}\right)^2 \frac{\omega_2}{2} \Gamma_{22}$$

(these last expressions should be multiplied by 10^{13} if I_1 and I_2 are in megawatts per square centimeter—β in centimeters per megawatt). These instantaneous absorption terms must be added to the static absorption coefficients α_1 and α_2 in (1).

The last modification brought to (1) accounts for the TPA-induced free carriers. A rate equation for the induced carriers should include:

1) a source term, equal to the rate of the two-photon processes,
2) a diffusion term,
3) a recombination term, due to electron-hole pairs finite lifetime.

We assume that the two last terms lead to an exponential decay, with time constant τ. Since the transverse variations of the beam intensities are ignored in (1), there is, strictly speaking, no diffusion term. Actually, the initially Gaussian carrier distribution is spread by diffusion out of the focus region. This involves a diffusion time constant [3]

$$\tau_D = \frac{e w_0^2}{4 \mu k T}$$

where μ is the carrier mobility and T the temperature of the crystal. Therefore, the single time constant τ includes both contributions of τ_D and the carrier lifetime.

If N_e and N_h are the excess of electron and hole densities, the source term is

$$\frac{dN_e}{dt} = \frac{dN_h}{dt} = \frac{1}{\hbar\omega_2}\left(\frac{dW_2}{dt}\right)_{12} + \frac{1}{2\hbar\omega_2}\left(\frac{dW_2}{dt}\right)_{22} \tag{9}$$

as only one $\hbar\omega_2$ photon is absorbed in the process $(\hbar\omega_1 + \hbar\omega_2)$, while in the other process, two $\hbar\omega_2$ photons are absorbed.

Assuming the same decay time constant τ for electrons and holes, comparison of (7) and (9) leads to

$$\begin{cases} N_e = N_h = N \\ \dfrac{dN}{dt} = \dfrac{\Gamma_{12}}{2\hbar} \rho_1^2 \rho_2^2 + \dfrac{\Gamma_{22}}{4\hbar} \rho_2^4 - \dfrac{N}{\tau}. \end{cases} \tag{10}$$

The last step is now to describe the influence of the free carriers on the propagation of the two beams. As the absorption coefficients and refractive index variations due to free carriers are proportional to the carrier density, we define $\Sigma(\omega)$ and $\Lambda(\omega)$ as follows:

$$\begin{cases} \alpha_1'' = \Sigma(\omega_1) N \\ \alpha_2'' = \Sigma(\omega_2) N \\ \delta n_1 = \Lambda(\omega_1) N \\ \delta n_2 = \Lambda(\omega_2) N \end{cases} \tag{11}$$

where $\alpha_{1,2}''$ are the excess free carrier absorption coefficients at fundamental and harmonic frequencies and δn_1, δn_2 are the free carrier index variations at these frequencies. $\Sigma(\omega)$ corresponds to the carrier absorption cross section at ω frequency. Of course the contribution of the equilibrium carriers is already included in the static coefficients $\alpha_1, \alpha_2, n_1, n_2$ in (1).

The coefficients Σ and Λ can be estimated by means of the Drude model. In principle, this model may only lead to a rough estimate of Σ and Λ, but, as will be seen later, it gives fairly good results with tellurium, in regard of the dispersion of the available experimental data.

In the Drude model the dynamical conductivity is

$$\sigma(\omega) = e^2 \left(\frac{N_e}{m_e} \frac{\tau_e}{1 - i\omega\tau_e} + \frac{N_h}{m_h} \frac{\tau_h}{1 - i\omega\tau_h}\right) \tag{12}$$

where m_e and m_h are the electron and hole effective masses, τ_e and τ_h their relaxation times.

The absorption coefficient α_j'' is proportional to the real part σ_r of the conductivity

$$\alpha_j'' = \frac{4\pi}{n_j c}\,\sigma_r(\omega_j), \qquad j = 1, 2 \tag{13}$$

and the index variation δn_j is proportional to the imaginary part σ_i

$$\delta n_j = -\frac{2\pi}{n_j \omega_j}\,\sigma_i(\omega_j). \tag{14}$$

Thus, (11)-(14), together with $N_e = N_h = N$ and $\omega\tau_e, \omega\tau_h >> 1$ give $\Sigma(\omega_j)$ and $\Lambda(\omega_j)$

$$\Sigma(\omega_j) = \frac{4\pi}{n_j c}\,\frac{e^3}{\omega_j^2}\left(\frac{1}{m_h^2\mu_h} + \frac{1}{m_e^2\mu_e}\right)$$

$$\Lambda(\omega_j) = -\frac{2\pi}{n_j}\,\frac{e^2}{\omega_j^2}\left(\frac{1}{m_h} + \frac{1}{m_e}\right) \tag{15}$$

where

$$\mu_e = e\tau_e/m_e \quad \text{and} \quad \mu_h = e\tau_h/m_h.$$

Two effects can be expected from the index variation. First, as δn_j is frequency dependent ($\delta n_1 = 4\delta n_2$ in the Drude model), it induces a phase mismatch between the fundamental and harmonic waves [4]. In addition, if the incident beam is strongly focused ($w_0 \leqslant 100\ \mu$m), the refractive index gradient can cause self-defocusing. It will be seen in Part II that this effect may be quite important in some cases. Here we neglect self-defocusing, taking only the phase mismatch into account. Using $\delta n_1 = 4\delta n_2$ and (11), the induced phase mismatch Δk_i is

$$\Delta k_i = \frac{2\omega_1}{c}(\delta n_1 - \delta n_2) = \frac{3\omega_1}{2c}\,\delta n_1 = \frac{3\omega_1}{2c}\,\Lambda(\omega_1)N. \tag{16}$$

It is convenient to express Δk_i in terms of α_1'', thus keeping only one parameter proportional to the free carrier density, i.e., α_1''; using (13)-(15) we obtain

$$\Delta k_i = -\frac{3R}{4}\alpha_1'' \tag{17}$$

where $R = \sigma_i(\omega_1)/\sigma_r(\omega_1)$ is the ratio of imaginary to real part of the dynamical conductivity. When the relaxation times τ_e and τ_h are equal, the physical meaning of this dimensionless ratio is more apparent

$$R = \omega_1\tau_e = \omega_1\tau_h. \tag{18}$$

C. Equations Including SHG, TPA, and Free Carriers Effects

To describe the influence of TPA and of the induced free carriers, the SHG system (1) can be now modified in the following way:

a) α_j ($j = 1, 2$) becomes $\alpha_j + \alpha_j' + \alpha_j''$ using (8) and (11),
b) Δk becomes $\Delta k_e + \Delta k_i$ using (17) (Δk_e is any constant phase mismatch, depending on external conditions–crystal orientation, temperature, etc.),
c) the rate equation (10) is added to the original system (1) (we multiply each term of (10) by $\Sigma(\omega_1)$ to obtain $\partial\alpha_1''/\partial t$ using (11)).

With all these modifications, system (1) is replaced by

$$\begin{cases} \dfrac{\partial\rho_1}{\partial z} = -C\rho_1\rho_2\sin\theta - (\alpha_1 + D\rho_2^2 + \alpha_1'')\,\dfrac{\rho_1}{2} \\[2ex] \dfrac{\partial\rho_2}{\partial z} = C\rho_1^2\sin\theta - \left(\alpha_2 + 2D\rho_1^2 + D'\rho_2^2 + \dfrac{\alpha_1''}{4}\right)\dfrac{\rho_2}{2} \\[2ex] \dfrac{\partial\theta}{\partial z} = 2C\left(\rho_2 - \dfrac{\rho_1^2}{2\rho_2}\right)\cos\theta + \Delta k_e - \dfrac{3R}{4}\alpha_1'' \\[2ex] \dfrac{\partial\alpha_1''}{\partial t} = B\rho_1^2\rho_2^2 + B'\rho_2^4 - \dfrac{\alpha_1''}{\tau} \end{cases} \tag{19}$$

where C is defined in (4), R in (17), and

$$B = \frac{\Sigma(\omega_1)}{2\hbar}\,\Gamma_{12} \qquad B' = \frac{\Sigma(\omega_1)}{4\hbar}\,\Gamma_{22}$$

$$D = \frac{4\pi\omega_1}{n_1 c}\,\Gamma_{12} \qquad D' = \frac{4\pi\omega_2}{n_2 c}\,\Gamma_{22}.$$

An order of magnitude of these coefficients will be given in the next section where we apply this analysis to the case of tellurium.

Here we want to stress the importance of the free carrier terms compared to the pure TPA terms. Assume, for example, that the $(\hbar\omega_1 + \hbar\omega_2)$ process is predominant (which is the case when $B \sim B'$ and $\rho_1^2 >> \rho_2^2$). Under these conditions α_1'' is roughly proportional to $\rho_1^2\rho_2^2$, whereas α_1' (TPA term) is proportional to ρ_2^2. Therefore, at some fundamental intensity I_1^*, α_1'' and α_1' are nearly equal, and for $I_1 >> I_1^*$, the pure TPA term α_1' is negligible. Let us now estimate the value of I_1^* and for this purpose let us set an approximate expression for α_1''

$$\alpha_1'' \simeq B\rho_1^2\rho_2^2\tau_{\text{eff}}.$$

When evaluating α_1'' at the maximum of the pulse, τ_{eff} has two asymptotic expressions, depending on the relative value of τ (carrier lifetime) and Δt (pulsewidth)

$$\tau << \Delta t, \qquad \tau_{\text{eff}} \simeq \tau$$

$$\tau >> \Delta t, \qquad \tau_{\text{eff}} \simeq \frac{\Delta t}{2}.$$

The comparison of $\alpha_1' = (4\pi/n_1 c)\,\omega_1\,\Gamma_{12}\rho_2^2$ and $\alpha_1'' = (\Sigma(\omega_1)/2\hbar)\,\Gamma_{12}\,\tau_{\text{eff}}\rho_1^2\rho_2^2$ shows that the same magnitude is reached for

$$I_1^* = \frac{n_1 c}{8\pi}\,\rho_1^2 = \frac{\hbar\omega_1}{\Sigma(\omega_1)\,\tau_{\text{eff}}}. \tag{20}$$

The typical values for tellurium (see next section) of $\tau_{\text{eff}} = 100$ ns and $\Sigma(\omega_1) = 5 \times 10^{-17}$ cm^2 at 10.6 μm lead to $I_1^* \simeq 3.5$ kW/cm^2. So this situation is quite unusual: *the higher order effect (induced free carriers absorption) may easily be preponderant on the lower order effect (TPA).*

The very low value obtained for I_1^* is partly due to the frequency dependence of $\Sigma(\omega)$–according to the Drude model $\Sigma \propto \omega_1^{-2}$, leading to $I_1^* \propto \omega_1^3$.

III. Resolution and Comparison with Experimental Data on Tellurium

Solutions of system (19) have been computed in the case of SHG in tellurium at 10.6 μm. In a first step, the unknown parameters are fitted to reproduce the experimental results of Gandrud and Abrams [3]. Then the same set of parameters is used to explain other experimental observations. Before describing the procedure of numerical calculations and the results, let us discuss the case of SHG in tellurium using a CO_2 laser.

In this case both processes are possible: $(\hbar\omega_1 + \hbar\omega_2)$ and $(\hbar\omega_2 + \hbar\omega_2)$, since the bandgap is $E_g = 0.33$ eV and $\hbar\omega_1 = 0.177$ eV. B and B' are expected to be of the same order of magnitude (this is confirmed in Part II). Therefore, the first process is much more important when $\rho_1^2 >> \rho_2^2$. In order to reduce the number of parameters we neglect the contribution of the second process ($B' = D' = 0$). Since the free carriers terms are prevailing over the pure TPA terms, D cannot be adjusted separately. Hence the ratio B/D must be fixed, by a proper estimation of the free carrier absorption cross section $\Sigma(\omega_1)$, that we take equal to 5×10^{-17} cm^2 (for justification of this value, see Appendix).

With these assumptions, only three parameters are unknown—B, proportional to the two-photon absorption coefficient; R, related to the free carrier relaxation time; and τ the free carrier lifetime. C is easily calculated using [8] $d_{11} = 2.2 \times 10^{-6}$ ESU. Δk_e is another adjustable parameter which depends on the crystal orientation. In all the calculations where Δk_e is not specified, we used the value of Δk_e giving the maximum harmonic output, since one can assume that this optimization is made experimentally.

The numerical computation uses the following boundary conditions:

1) $\rho_2(t, z = 0) = 0$; $\alpha_1''(t = 0, z) = 0$; $\theta(t, z = 0) = \pi/2$;
2) the time variation of the incident electric field $\rho_1(t, z = 0)$ is approximated by a Gaussian pulse of given duration and maximum value.

At a given time t_i, the spatial integration is performed on the first three equations, using the previously calculated value $\alpha_1''(t_{i-1}, z)$. Then $\alpha_1''(t_i, z)$ is calculated by means of the last equation. It can be noticed that the calculation is rather simple, for the first three equations contain no time derivative: the pulse duration is very large compared to the transit time of the light through the crystal; in addition the last equation contains no spatial derivative: diffusion of the free carriers along z is negligible.

The three unknown parameters, B, R, and τ are adjusted to fit the results given in [3]. The main experimental data we have used are the time variation of P_2/P_1 during one pulse as a function of the instantaneous value of P_1, where P_2 is the harmonic output power and P_1 the fundamental input power. These experimental data are reproduced on Fig. 1, as well as the best fit we have obtained, with $B = 7$ ESU, $R = 25$, $\tau = 1$ μs.

The value of τ is not critical, and may be compared with the values of 0.5 μs measured in [3], and 0.4 μs obtained in Part II of this paper. The value of R is in good agreement with that estimated from the Drude model (with $\mu_h = 1000$ cm^2/V · s and $m_e = 0.2$ m, (18) leads to $R = 20$ at 10.6 μm). The value

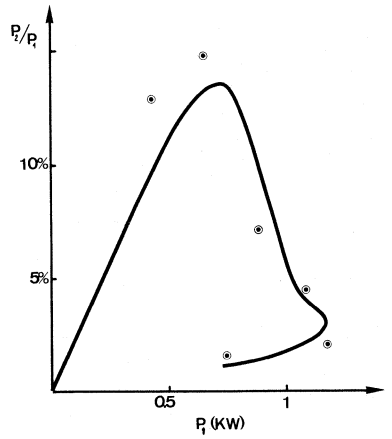

Fig. 1. Instantaneous variation of P_2/P_1 versus P_1 during one pulse. ⊙: Experimental data reproduced from [3]; ___: best fit calculated from system (19) with $B = 7$ ESU, $R = 25$, $\tau = 1$ μs (other input data according to the experimental conditions described in [3], i.e., crystal length is 9.8 mm, pulse duration of 200 ns, and beam radius $w_0 = 140$ μm).

of B corresponds to the third-order susceptibility: $\Gamma_{12} = 3 \times 10^{-10}$ ESU. It will be seen in Part II that this value is underestimated by our plane-wave treatment, since we have neglected the aperture length effects that are likely to appear not only on SHG but also in the TPA generation of carriers. Therefore, a better value of Γ_{12} (as well as Γ_{22}) will be given in Part II, where the new experimental data can be analyzed more precisely.

In Fig. 2 are reproduced some calculated curves of instantaneous conversion efficiency P_2/P_1, with the same fundamental peak power P_1 as in Fig. 1, but with different values of B, R, and τ. It is difficult to analyze the influence of each parameter separately, but some general trends are apparent in Fig. 2.

If all the processes were instantaneous ($\tau \to 0$), then the curve would show no loop. For a nonzero lifetime, the generated harmonic power is larger during the raising part than the decreasing part of the fundamental pulse, due to the accumulation of the carriers during the pulse. Consequently, the curve $P_2/P_1 = f(P_1)$ shows a loop, a smaller value of τ corresponding to a tighter loop, as is shown with $\tau = 20$ ns in Fig. 2.

The value of B fixes the magnitude of the total effect, whereas R describes the relative importance of the index variation and of the induced absorption. It can be seen in Fig. 2 that a larger value of R ($R = 50$) results in strong oscillations of the harmonic pulse, as can be expected from the variation of the phase-matching conditions during the pulse. B and R are independently adjustable parameters and we verified that the best fit also corresponds to the pump depletion of 70 percent experimentally observed [3].

With the same set of parameters as in Fig. 1, this analysis can now be used to explain some other experimental observations on SHG in tellurium. Nonsymmetrical harmonic pulse deformations with some oscillation at the end of the pulse can be observed with fundamental intensities near 10 MW/cm^2, as shown in Fig. 3(a). This kind of deformation is explained by our model, and Fig. 3(b) shows two calculated harmonic

pulse shapes, one without induced absorption, and the other with the free carrier effects. Intensity changes in the phase-matching angle are also observed [4]. Fig. 4 shows the calculated phase-matching curves for various pump intensities. Simultaneous shift of the maximum and broadening of the curve occur, in agreement with the results of Malz and Staupendhal [4].

In conclusion, the effect of the free carriers on SHG efficiency is summarized in Fig. 5, where the conversion efficiency is plotted at given fundamental power P_1 but increasing power density in three cases; without pump depletion [7] (curve 1), including pump depletion (curve 2), and finally with TPA induced free carriers (curve 3). Here it must be stressed that these curves are drawn *at constant power* P_1 (2.4 kW), which explains that in curve 2 the asymptotic value of P_2/P_1 is not 100 percent even in absence of any absorption.

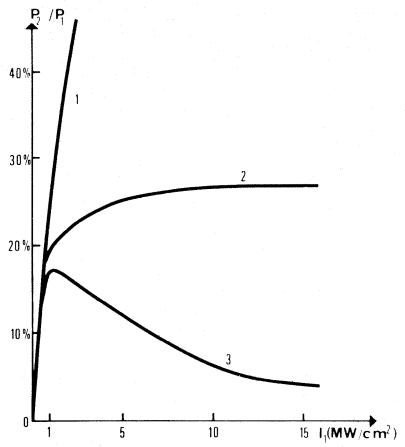

Fig. 5. Peak power conversion efficiency at P_1 = 2.4 kW as a function of power density I_1; 1 and 2 without TPA induced free carriers—1 neglecting pump depletion [6], 2 including pump depletion (see (1)); 3 calculated with system (19).

IV. Optimization of SHG Efficiency

This model provides a useful means to optimize the conversion efficiency of SHG in Te using a CO_2 laser. Two main results are obtained: at given pulse duration there is an optimum fundamental *power density*, and in addition the reduction of the pulse duration should appreciably increase the conversion efficiency.

A. Conversion Efficiency at Fixed Pulsewidth

The calculations have been performed with 120-ns fundamental pulsewidth (half-height), which is a typical value for the output pulses from low-pressure CO_2 lasers. The crystal length is 1 cm and the adjustable parameters have the same value as in Fig. 1.

In the usual case, the condition for optimum conversion efficiency is expressed in terms of geometrical quantities, e.g., focusing and double-refraction parameter [7]. In addition to these quantities, the TPA effects lead to consider an important parameter: the fundamental power density. The main result is that, as far as the conversion efficiency is concerned, there is an optimum fundamental power density, nearly independent of the total power incident on the crystal. This result is apparent on Fig. 6, where the peak power conversion efficiency is plotted as a function of intensity I_1, at different powers P_1 of the fundamental beam (each calculated value of P_2/P_1 has been optimized with respect to Δk_e). For instance, a curve at fixed power P_1, but increasing power density I_1, represents the variation of second-harmonic output with increasing focusing. It can be seen that the optimum I_1 is relatively low, between 1 and 2 MW/cm^2. In addition, with funda-

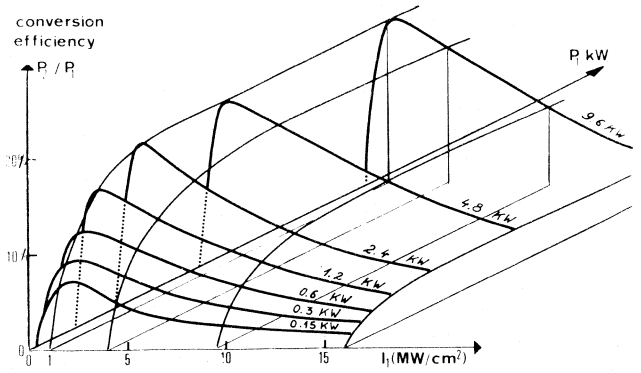

Fig. 6. Peak power conversion efficiency versus fundamental intensity I_1, at different powers P_1. Half maximum pulse duration is 120 ns.

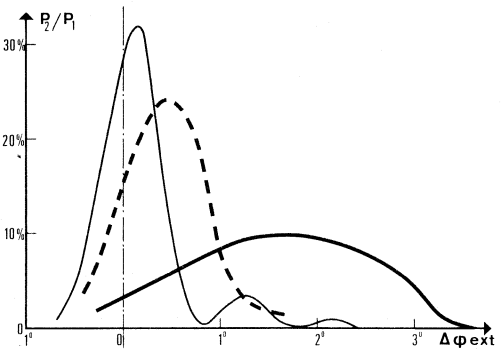

Fig. 7. Phase-matching curves at $I_1 = 11$ MW/cm^2 calculated with different half maximum pulse duration Δt: ——: $\Delta t = 1.2$ ns; – – –: $\Delta t = 12$ ns; ▬▬: $\Delta t = 280$ ns.

mental powers P_1 larger than 1.5 kW, the maximum conversion efficiency (15–17 percent) is practically independent of P_1. Thus experimentally, with increasing peak power it is necessary to increase the beam-waist size in order to keep I_1 around 1 MW/cm^2, and the only limit of the harmonic power generated is the size of the input face of the crystal, assuming the pump power is not limited (the same type of limitation occurs–at much higher intensity–when the harmonic generation is limited by the damage threshold instead of the TPA effects). With increasing fundamental power P_1 –in the range of 100 kW-1 MW–this model might slightly overestimate P_2/P_1, due to the fact that aperture length effects have been neglected in the TPA generation of free carriers.

B. Influence of Pulse Duration

It is clear from the above analysis that a long free carrier lifetime (which is the case in tellurium) results in an accumulation of the carriers during the pulse. In such a case, a reduction of the pulsewidth should increase the conversion efficiency. So we have made quantitative predictions about the efficiency that could be reached with shorter pulses. Fig. 7 shows the calculated phase-matching curves with 0.33-cm-long crystal and 5-kW fundamental power (11 MW/cm^2) at different pulsewidths. The 1-ns curve is practically the nominal phase-matching curve, indicating a large reduction of the free carriers density. This is confirmed in Fig. 8, which shows that the conversion efficiency with 1-ns pulses is not far from the efficiency that would be predicted without TPA.

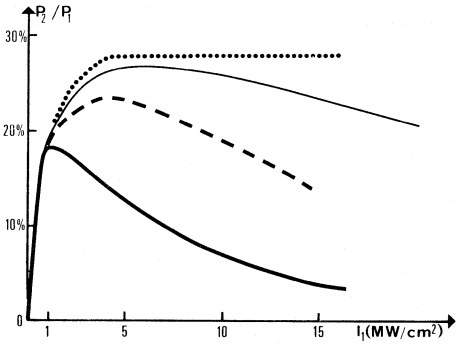

Fig. 8. Peak power conversion efficiency at $P_1 = 9.6$ kW as a function of power density I_1, calculated with different Δt: ——: $\Delta t = 1.2$ ns; – – –: $\Delta t = 12$ ns; ▬▬: $\Delta t = 120$ ns. Also shown (●●●●) is the curve calculated without TPA induced free carriers.

V. Conclusion

In Part I of this paper we have analyzed the second-harmonic generation in semiconductors in the presence of two-photon induced free carriers. For quantitative analysis the case of tellurium was considered. The model explains all the experimental data on SHG with a CO_2 laser. It can be also used to optimize the conversion efficiency. Two main results have been pointed out: first, the advantage of using shorter pulses to increase the harmonic conversion efficiency, and, second, the existence of an optimum fundamental intensity, near 1 MW/cm^2, practically independent of the total power incident on the crystal.

Appendix

We give here some details about the free carrier absorption cross section used in the text for tellurium at 10.6 μm. This free carrier absorption exhibits an important dichroism, due to intervalence band transition around 10 μm [9], [10]. This transition is forbidden for an electric field E perpendicular to the optic axis Z, so it need not be taken into account, because the only electric-field components involved in phase-matched SHG are E_Y at fundamental frequency and E_X at harmonic frequency (d_{XYY}). Therefore, the relevant value of $\Sigma(\omega)$ is the sum of the electron and hole absorption cross sections $\Sigma_e^{\perp}(\omega)$ and $\Sigma_h^{\perp}(\omega)$ for $E \perp Z$: $\Sigma(\omega) = \Sigma_h^{\perp}(\omega) + \Sigma_e^{\perp}(\omega)$.

The lack of experimental data makes it difficult to obtain a precise value of $\Sigma(\omega)$ for intrinsic tellurium at room temperature. With p-type extrinsic crystals the wavelength dependence is between $\lambda^{1.8}$ and $\lambda^{2.8}$ ([9] and [11]) at wavelengths greater than 15 μm. At 5 or 10 μm, the absorptions are slightly larger than the values extrapolated from longer wavelengths, but it is probably due to impurity transitions. At 20 μm and 300 K, the values of $\Sigma_h^{\perp}$ lie between 6.6×10^{-17} and 8.8×10^{-17} cm^2 in p-type crystals [9], [11], and $\Sigma_e^{\perp} + \Sigma_h^{\perp} \simeq 19 \times 10^{-17}$ cm^2 in intrinsic crystals [9].

So the cross section of electrons appears to be slightly larger than that of the holes. Thus it appears reasonable to take $\Sigma(\omega_1) = 5 \times 10^{-17}$ cm^2 at 10.6 μm, with an uncertainty of about 40 percent. It can be seen that the Drude model leads to the same estimation: with $\mu_e \simeq \mu_h \simeq 1000$ cm^2/V · s [12] and $m_h \simeq m_e \simeq 0.2$ m where m is the electron mass, (15) gives: $\Sigma = 6 \times 10^{-17}$ cm^2 at 10.6 μm.

Influence of Two-Photon Absorption on Second-Harmonic Generation in Semiconductors— Part II: Measurement of Two-Photon Absorption in Tellurium

JEAN-LOUIS OUDAR, CHRISTIANE A. SCHWARTZ, MEMBER, IEEE, AND EDMOND M. BATIFOL

Abstract—**The effect of the free carriers generated by two-photon absorption in tellurium has been studied by using a CO_2 and a CO laser. Time and power dependence of the induced absorption has been measured, as well as the variation of the two-photon process with the wavelength of the CO laser. These observations confirm the assumptions of the analysis described in Part I.**

I. INTRODUCTION

THEORETICAL analysis of the influence of two-photon absorption (TPA) on second-harmonic generation (SHG) has been given in Part I[1] of this paper. It has been shown that the influence of photo-induced carriers is particularly important in small gap semiconductors, which is the case of tellurium. This analysis has explained previous experimental data on the limitation of conversion efficiency of SHG in tellurium at 10.6 μm. Nevertheless, many assumptions have been made and adjustable parameters have been introduced to give a quantitative account of the experimental data.

So, in order to confirm the validity of this model, the principal hypothesis has been checked directly by measuring the absorption at 10.6 μm (CO_2 laser) induced by a CO laser beam in a crystal of tellurium. The time dependence is analyzed by varying the delay between the two laser pulses. The power dependence is obtained by independently varying the power of the two lasers. Then the frequency dependence is examined by selecting different lines from the CO laser. Comparison of these data with the results of Part I confirms the principal assumptions of our analysis. It also enables a more detailed interpretation of some parameters that have been introduced; finally, a more reliable value of TPA coefficient in tellurium is obtained.

II. EXPERIMENTAL SETUP

The experiment has been performed by mixing the output beams of a CO_2 and a CO laser. These lasers are simultaneously Q switched by means of the same rotating mirror. The geometrical configuration is sketched on Fig. 1. The cavity of the CO_2 laser is ended by a Littrow-mounted diffraction grating, which allows a selection of each emitted rotational line. As the grooves of the grating are vertical and the axis of the rotating mirror is horizontal, a rotation of the grating around the vertical axis selects the emitted line, whereas a rotation around the horizontal axis is used to adjust the delay between the pulses of the two lasers within a small range of time (0–2 μs). Inside the cavity of the CO laser

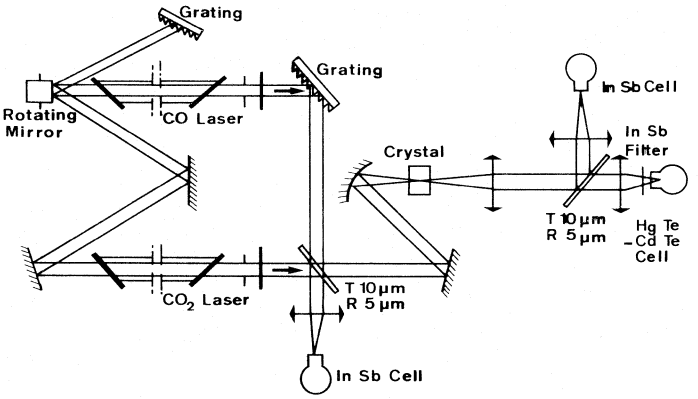

Fig. 1. Experimental arrangement for measuring TPA in tellurium.

there is no wavelength selection; the output beam is diffracted by a grating of 150 grooves per millimeter, which enables one to choose a small number of lines ($\Delta\lambda = 300$ Å) among the total spectrum of the laser output. The overlapping and colinearity of the two laser beams is achieved by a dielectric-coated germanium plate; then the beams are focused in the crystal by a concave mirror ($f = 10$ cm). Both lasers can be operated in the mode TEM_{00} and the spot size at focus was checked in these conditions. This measurement was performed for each laser by comparing the size of damages caused by the beam on a previously exposed Polaroid film, at different incident powers. The measured values agree within 30 percent with the calculated ones; we have obtained $w_1 = 100\ \mu m$ ($1/e^2$ radius) for the CO_2 laser and $w_2 = 65\ \mu m$ for the CO laser. The crystal of tellurium is 8 mm long and its optic axis is perpendicular to the beam axis. As the polarizations of the two beams are perpendicular to the optic axis, no three-wave interaction can be phase-matched; so in the following, we neglect all the effects due to second-order nonlinear processes. Behind the crystal, the beam is split by another germanium plate. The power at 5-6 μm is measured by an InSb photovoltaic detector; the power at 10.6 μm is detected by a Hg-CdTe detector in front of which an InSb filter stops any residual 5-6-μm radiation. Both signals from these detectors could be seen on an oscilloscope. The signal from the Hg-CdTe detector was detected by a gate integrator, and then recorded.

III. Experimental Results

When the pulses of the two lasers are simultaneous, the crystal transmission at 10.6 μm is greatly reduced in presence of the CO laser beam. We measured a reduction of transmission up to a factor 10, for some incident powers. At higher power levels, heating of the crystal became important and no reproducible data could be obtained.

In addition, the crystal transmission at 5-6 μm was also reduced by the presence of the CO_2 laser beam. The induced absorption at 5-6 μm was found smaller than the induced absorption at 10.6 μm, by a factor varying from 3 to 6. A factor of about 4 would be expected from the Drude model (free carrier absorption proportional to λ^2) but, as will be described hereafter, it depends also on the relative size and position of the two beams in the crystal. Therefore, we did not measure systematically the induced absorption at 5-6 μm and all the results given below concern the change of transmission at 10.6 μm. This induced absorption is the sum of two terms

$$\alpha_{ind} = \alpha_1' + \alpha_1'' = \beta_{12} I_2 + \Sigma(\omega_1) N \tag{1}$$

where β_{12} is the TPA coefficient and I_2 the power density at frequency ω_2; Σ is the free carrier absorption cross section at frequency ω_1 and N the induced free carrier density. As discussed in Part I, the first term is usually small compared to the free carrier term (when $I_1 \gg I_1^* = \hbar\omega_1/\Sigma(\omega_1)\tau_{eff}$); this is confirmed by the study of the power dependence of the induced absorption in the range of intensities where the effect can be observed.

The induced free carriers can be generated by two processes $-(\hbar\omega_1 + \hbar\omega_2)$ and $(\hbar\omega_2 + \hbar\omega_2)$, that is, absorption of one photon from each laser beam or two photons from CO laser beam. Each process can easily be observed separately from the other, for the first process is negligible when the intensity I_1 at frequency ω_1 is very small, while it is preponderant when I_1 is much greater than I_2.

A. Time Dependence

A convenient way to study the time dependence of the induced absorption is to gradually vary the delay between the pulses of the two lasers and to observe the variation of the absorption as a function of this delay.

Two different behaviors can be distinguished, depending on which process is preponderant. In the first case $(\hbar\omega_1 + \hbar\omega_2)$, the induced absorption occurs only when the two pulses are time-overlapping. This clearly proves that the free carriers are generated by simultaneous absorption of one photon from each laser. This behavior is sketched in Fig. 2(a). In this figure there has been schematically drawn a superposition of the oscilloscope traces of several transmitted pulses at 10.6 μm (lower trace), with gradually varying delay with respect to the CO laser pulse (upper trace). The incident peak powers are typically 1 kW at 10.6 μm and 6 W at 5.3 μm, outside the crystal.

Conversely, when the second process $(\hbar\omega_2 + \hbar\omega_2)$ is preponderant, some absorption remains after the end of the CO laser pulse. This is due to the fact that the induced free carriers are generated by the CO laser beam alone, the other beam acting merely as a probe. Fig. 2(b) shows what is obtained when superposing several pulses as in Fig. 2(a), but in this case the incident powers are 1 W at 10.6 μm and about 30 W at 5.3 μm.

The envelope of the transmitted pulse maxima at 10.6 μm provides a direct measurement of the lifetime of the free carriers. In order to get a more precise measurement we used the CO_2 laser operating in CW mode and observed the transient signal due to the induced absorption. The decay time constant is $\tau = 0.4\ \mu s$. This value is in good agreement with the measurement of Gandrud and Abrams [1] and not far from the estimate made in Part I from the analysis of instantaneous SHG conversion efficiency.

B. Power Dependence

We measured the relative value of the transmitted power at 10.6 μm when 1) both beams are sent together in the crystal and when 2) the CO laser beam is stopped by a shutter. The

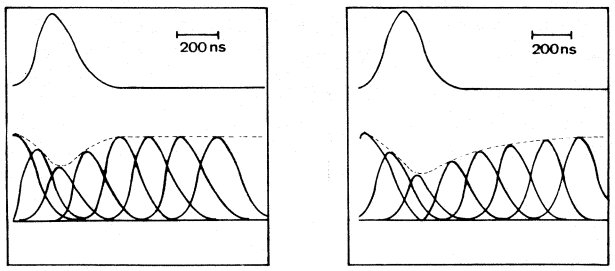

Fig. 2. Schematic diagram of the time dependence of the induced absorption. Superposition of several transmitted 10.6-μm pulses (lower trace), with variable delay with respect to the CO laser pulse (upper trace). (a) Free carriers generated by absorption of one photon from each laser ($\hbar\omega_1 + \hbar\omega_2$). (b) Free carriers generated by absorption of two-photons from CO laser ($\hbar\omega_2 + \hbar\omega_2$).

ratio T of these transmitted powers gives an average absorption coefficient $\langle\alpha\rangle$ defined by

$$T = e^{-\langle\alpha\rangle d} \tag{2}$$

where d is the thickness of the crystal. We point out that it is a mean value because the powers of the beams decrease along the crystal and therefore the free carrier density is also decreasing.

The wavelength selected from the CO laser was chosen near 5.3 μm to make easier the comparison with the SHG case. Figs. 3 and 4 give the variation of $\langle\alpha\rangle$ as a function of the incident peak powers P_1 (10.6 μm) and P_2 (5.3 μm) *inside* the crystal. The results were obtained under two different experimental conditions. Without selection of the fundamental TEM_{00} mode, the peak power of the CO laser is larger, and the process ($\hbar\omega_2 + \hbar\omega_2$) more easily observed. The results obtained in these conditions are given on Fig. 3. On the contrary, when operating the CO laser in the TEM_{00} mode, more precise absolute values can be expected; indeed the results, given in Fig. 4, are slightly different.

Two typical variations are apparent from these results: 1) with 5.3-μm power smaller than 5 W, the induced absorption coefficient $\langle\alpha\rangle$ is proportional to the product P_1P_2, 2) with 10.6-μm power smaller than 10 W, $\langle\alpha\rangle$ is proportional to the square of 5.3-μm power P_2.

In case 1) the major process is ($\hbar\omega_1 + \hbar\omega_2$), while the other process is preponderant in case 2). When $\langle\alpha\rangle$ is smaller than 0.5 cm^{-1}, the curves interpolated from the experimental points follow the simple relation

$$\langle\alpha\rangle = WP_1P_2 + W'P_2^2 \tag{3}$$

where W and W' are some coefficients, proportional to TPA coefficients β and free carrier cross section Σ. However, when $\langle\alpha\rangle$ is greater than 0.5 cm^{-1} this relation is not obeyed. This point will be discussed in the next section, when analyzing the results more precisely.

C. Wavelength Dependence of TPA

We measured the variation of the induced absorption as a function of the frequency ω_2 selected from the CO laser output; the other frequency ω_1 was kept constant. These measurements were made in the range of powers P_1 and P_2 where $\langle\alpha\rangle$ is smaller than 0.5 cm^{-1}, so that (3) is valid. In Fig. 5 is

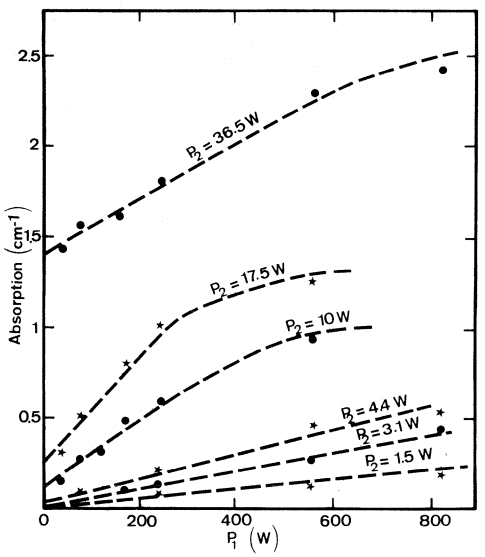

Fig. 3. Variation of the induced absorption $\langle\alpha\rangle$ as a function of the incident peak powers. Experimental points obtained with multimode CO laser operation. The dotted curves are interpolations of the experimental points.

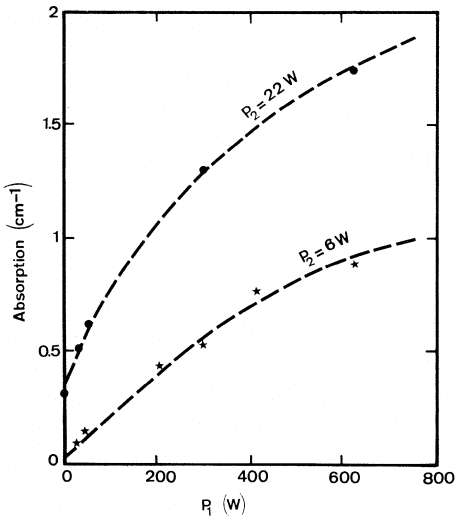

Fig. 4. Variation of $\langle\alpha\rangle$ as a function of incident peak powers. Experimental points and interpolating curves obtained with TEM_{00} CO laser.

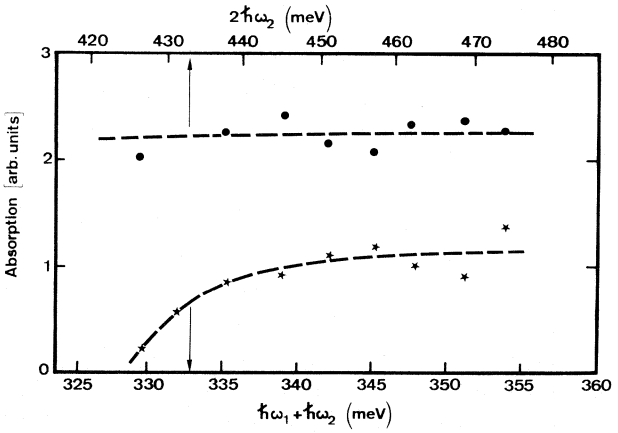

Fig. 5. Variation (at constant powers) of the induced absorption with the wavelength of the CO laser. Upper curve: ($\hbar\omega_2 + \hbar\omega_2$) process—Lower curve: ($\hbar\omega_1 + \hbar\omega_2$) process.

shown the variation of the coefficients W and W' as a function of $\hbar(\omega_1 + \omega_2)$ and of $2\hbar\omega_2$, respectively. It can be seen that W', related to the process $(\hbar\omega_2 + \hbar\omega_2)$, does not depend strongly on ω_2; besides, W becomes negligible when $\hbar(\omega_1 + \omega_2)$ approaches the value of 0.328 eV, which is the value of the energy gap E_g in tellurium [2], [3].

The symmetry properties of valence and conduction states near the minimum gap of tellurium indicate that "allowed-allowed" transitions can take place [4]. In this case, theoretical calculations [5] predict that the wavelength dependence of TPA should be $\propto(\hbar\omega_1 + \hbar\omega_2 - E_g)^{1/2}$ with parabolic energy bands, but the experimental uncertainties make the comparison with this theoretical dependence difficult. However, one can see in Fig. 5 that the agreement with this prediction is not too bad.

IV. Analysis of the Results

These experimental results are clearly understood within the frame of the previous analysis and they confirm the validity of the hypothesis made in Part I. Nevertheless, the power dependence of the induced absorption must be discussed more carefully, in order to compare the absolute values of induced absorption with the adjustable coefficient B, introduced in Part I, describing the probability of two-photon transition.

It has been seen in Figs. 3 and 4 that, above 0.5 cm^{-1}, the measured induced absorption is lower than the values that could be predicted using (3) with W and W' deduced from the smaller induced absorptions. One possible explanation is that what is measured is a mean absorption coefficient, which we have called $\langle\alpha\rangle$. This coefficient is expected to be smaller than the local absorption coefficient at the front plane of the crystal. So it seems that the departure from (3) is caused by the difference between $\langle\alpha\rangle$ and the front-plane induced absorption. In order to test this hypothesis we have calculated what should be the mean absorption, taking account for the decrease of the induced absorption coefficient along the crystal. To achieve this, one can use the system of equations (19) given in Part I (with $C = 0$ since here we neglect SHG). As the relative phase of the two waves is irrelevant here, these equations can simply be expressed in terms of the intensities I_1 and I_2 instead of the electric field amplitudes. One obtains

$$\frac{\partial I_1}{\partial z} = -(\alpha_1 + \alpha_1'' + \beta_{12} I_2) I_1 \tag{4a}$$

$$\frac{\partial I_2}{\partial z} = -\left(\alpha_2 + \left(\frac{\omega_1}{\omega_2}\right)^2 \alpha_1'' + \frac{\omega_2}{\omega_1}\beta_{12} I_1 + \beta_{22} I_2\right) I_2 \tag{4b}$$

$$\frac{\partial \alpha_1''}{\partial t} = \Sigma(\omega_1)\left(\frac{\beta_{12}}{\hbar\omega_1} I_1 I_2 + \frac{\beta_{22}}{2\hbar\omega_2} I_2^2\right) - \frac{\alpha_1''}{\tau} \tag{4c}$$

with the same notations as in Part I.

In this system the quantities I_1, I_2, and α_1'' are functions of x, y, z, and t. Thus an exact solution of this system would require a knowledge of the transverse variation (x, y) of the beam intensities I_1 and I_2 on the front plane of the crystal $(z = 0)$. As one set of experimental results was obtained with multimode CO laser operation, one can only expect an approximate description, due to incomplete knowledge of the transverse variations of the beams. This is why we use a simplified formulation of (4). First, we neglect the pure TPA terms, that is the terms $\beta_{12} I_1 I_2$ and $\beta_{22} I_2^2$ in (4a) and (4b), since we have shown they were very small compared to the terms containing α_1''. Second, we express the equations in terms of the powers P_1, P_2 of the beams, and an average absorption coefficient $\bar{\alpha}$, defined by

$$\iint \alpha_1'' I_1 \, dx \, dy = \bar{\alpha} \iint I_1 \, dx \, dy = \bar{\alpha} P_1. \tag{5}$$

Further we also assume that

$$\iint \alpha_1'' I_2 \, dx \, dy = \bar{\alpha} P_2$$

which is justified inasmuch as the spot sizes are not very different.

The integration of both terms of (4a) and (4b) with respect to x and y leads to

$$\begin{cases} \dfrac{\partial P_1}{\partial z} = -(\alpha_1 + \bar{\alpha}(z, t)) P_1 \\ \dfrac{\partial P_2}{\partial z} = -\left(\alpha_2 + \dfrac{\omega_1^2}{\omega_2^2}\bar{\alpha}(z, t)\right) P_2 \\ \dfrac{\partial \bar{\alpha}}{\partial t} = F P_1 P_2 + F' P_2^2 - \dfrac{\bar{\alpha}}{\tau} \end{cases} \tag{6}$$

where F and F' are proportional to β_{21} and β_{22}, respectively; the relations between these coefficients can be calculated in the case of Gaussian beams and the derivation will be given hereafter.

Numerical solutions of system (6) have been computed, with proper adjustment of F and F'. Then $\langle\alpha\rangle$ was derived by means of (2). The results are given in Figs. 6 and 7 together with the interpolated curves of Figs. 3 and 4. In Fig. 6 we used the values

$$F = 0.43 \times 10^4 \text{ cm}^{-1} \text{ s}^{-1} \text{ W}^{-2}$$

$$F' = 1.4 \times 10^4 \text{ cm}^{-1} \text{ s}^{-1} \text{ W}^{-2}$$

to fit the results of Fig. 3 (multimode CO laser), and in Fig. 7 the values

$$F = 1.2 \times 10^4 \text{ cm}^{-1} \text{ s}^{-1} \text{ W}^{-2}$$

$$F' = 2 \times 10^4 \text{ cm}^{-1} \text{ s}^{-1} \text{ W}^{-2}$$

were used to fit the results of Fig. 4 (TEM_{00} CO laser).

As was expected from qualitative arguments, the calculated curves are not straight lines, but their curvature is less pronounced than that of the experimental curves. So this model is not sufficient to explain the experimental results at high induced absorption.

We propose another explanation, taking into account the refractive index variation due to the free carriers. This variation gives rise to a considerable refractive index gradient which is thought to cause defocusing of the beams. This point was not investigated experimentally but a rapid estimate suggests that this effect may be important. Consider a Gaussian beam incident on the front face of the crystal $(z = 0)$. Assuming the shape of the amplitude profile to be unchanged (aberationless approximation [6]) the electric field amplitude E can be

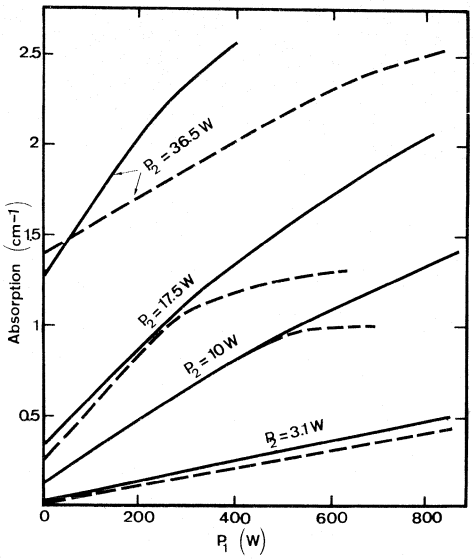

Fig. 6. Numerical solutions of system (6) with $F = 0.43 \times 10^4$ and $F' = 1.4 \times 10^4$ cm^{-1} s^{-1} W^{-2} (solid lines), together with the experimental curves of Fig. 3 (dotted lines).

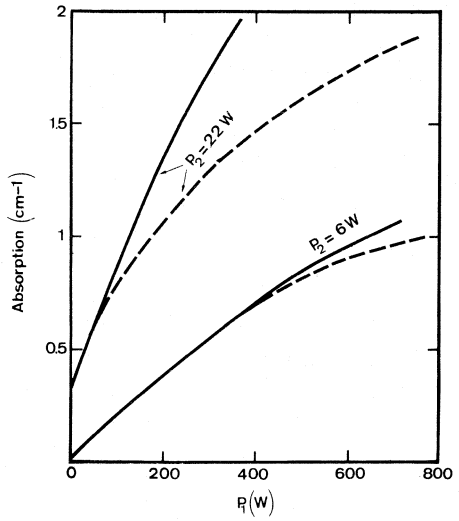

Fig. 7. Numerical solutions of system (6) with $F = 1.2 \times 10^4$ and $F' = 2 \times 10^4$ cm^{-1} s^{-1} W^{-2} (solid lines), together with the experimental curves of Fig. 4 (dotted lines).

written in the form

$$E(r,z) = \frac{E_0}{f(z)} \exp\left(-r^2/w_0^2 f^2(z)\right). \tag{7}$$

The refractive index is

$$n = n_0 + \delta n_0 \exp\left(-r^2/a_0^2\right) \tag{8}$$

where the second term is the variation induced by the free carriers in excess. When this term is approximated by $\delta n_0(1 - r^2/a_0^2)$, then $f(z)$ is given by

$$\frac{d^2 f}{dz^2} = \frac{-2}{a_0^2} f \frac{\delta n_0}{n_0}. \tag{9}$$

As δn_0 is negative (see (14) in Part I) the solution is

$$f = \cosh(\kappa z), \qquad \kappa = (-\delta n_0/n_0)^{1/2}/a_0.$$

Using the estimation of $\delta n_0/\alpha_1''$ made in Part I, one can calculate that when the induced absorption α_1'' at 10.6 μm is equal to 1 cm^{-1}, $\delta n_0 \simeq -2 \times 10^{-3}$; this leads to $\kappa = 4.5$ cm^{-1} with $a_0 = 45$ μm, which means that the *intensity of the CO_2 laser beam is reduced by a factor 2 after a length of only 2 mm in the crystal.*

So this quick estimate shows that very probably the effect of self-defocusing is responsible for the discrepancy between the experimental and calculated curves of Figs. 6 and 7, when $\langle\alpha\rangle \sim 1$ cm^{-1}. Nevertheless, in the limit of small induced absorptions any defocusing is expected to be negligible so that the results can be used to calculate the TPA coefficient in tellurium.

To achieve this it is necessary to derive the relation between the coefficients F and F' in (6) and the two-photon coefficients β_{12} and β_{22} of system (4). This derivation is only possible in a simple way when:

1) the intensity profile of the beams is known; that is why we will use only the data relative to TEM_{00} CO laser operation;
2) this profile is unchanged all along the crystal, which occurs when the induced free carrier density is so small that there is no defocusing, and only slight absorption takes place;
3) any diffusion of the free carriers is neglected.

Assume that these conditions are fulfilled, and that the intensities I_1 and I_2 can be written as

$$\begin{cases} I_1(x,y,z,t) = I_1^0(z,t)\, e^{-q_1(x^2+y^2)} \\ I_2(x,y,z,t) = I_2^0(z,t)\, e^{-q_2(x^2+y^2)} \end{cases} \tag{10}$$

where $q_1 = 2/w_1^2$ and $q_2 = 2/w_2^2$. Then, using (4c), α_1'' is the sum of two terms

$$\alpha_1'' = \alpha_{12}''(z,t)\, e^{-(q_1+q_2)(x^2+y^2)} + \alpha_{22}''(z,t)\, e^{-2q_2(x^2+y^2)} \tag{11}$$

where α_{12}'' and α_{22}'' are given by

$$\begin{cases} \dfrac{\partial \alpha_{12}''}{\partial t} = \Sigma(\omega_1) \dfrac{\beta_{12}}{\hbar\omega_1} I_1^0 I_2^0 - \dfrac{\alpha_{12}''}{\tau} \\ \dfrac{\partial \alpha_{22}''}{\partial t} = \Sigma(\omega_1) \dfrac{\beta_{22}}{2\hbar\omega_2} (I_2^0)^2 - \dfrac{\alpha_{22}''}{\tau}. \end{cases} \tag{12}$$

So, when using (5), (10), and (11) one readily obtains

$$\bar{\alpha} = \frac{q_1}{2q_1 + q_2} \alpha_{12}'' + \frac{q_1}{q_1 + 2q_2} \alpha_{22}''. \tag{13}$$

This equation shows that, due to the Gaussian beam shape, the absorption efficiency of the free carriers is divided by a factor depending on the relative sizes of the beams.

As $\bar{\alpha}$ is a linear combination of α_{12}'' and α_{22}'' the two equations (12) can be joined together to give

$$\frac{\partial \bar{\alpha}}{\partial t} = \frac{\Sigma(\omega_1)}{2 + w_1^2/w_2^2} \frac{\beta_{12}}{\hbar\omega_1} I_1^0 I_2^0 + \frac{\Sigma(\omega_1)}{1 + 2\, w_1^2/w_2^2} \frac{\beta_{22}}{2\hbar\omega_2} (I_2^0)^2 - \frac{\bar{\alpha}}{\tau}. \tag{14}$$

This equation is equivalent to the last equation of system (6), so F and F' are given by

$$\begin{cases} F = \dfrac{\Sigma(\omega_1)}{2 + w_1^2/w_2^2} \dfrac{\beta_{12}}{\hbar\omega_1} \dfrac{\pi^2}{4w_1^2 w_2^2} \\ F' = \dfrac{\Sigma(\omega_1)}{1 + 2\, w_1^2/w_2^2} \dfrac{\beta_{22}}{2\hbar\omega_2} \dfrac{\pi^2}{4w_2^4}. \end{cases} \tag{15}$$

To calculate β_{12} and β_{22} we use the values of F and F' relative to TEM_{00} CO laser operation (Figs. 4 and 7). With these values one obtains

$$\beta_{12} = 0.2 \text{ cm/MW}$$

$$\beta_{22} = 0.8 \text{ cm/MW}.$$

Let us now compare these values of TPA coefficients with other estimations or measurements on tellurium.

First an estimate of β_{12} is readily calculated from the results of Part I, where a good agreement with SHG data was obtained when using (19) of Part I with $B = 7$ ESU and $B' = 0$. With the simplifying assumption that the beams are collimated plane waves one can relate B to β_{12} and one obtains $\beta_{12} = (8\pi/c)^2 \cdot \hbar\omega_1 B/(n_1 n_2\, \Sigma(\omega_1))$. The numerical value is of the order of 10^{-2} cm/MW, which is much smaller than the value obtained here. This discrepancy is probably due to the crudeness of the collimated plane-wave approximation. We can see in (13) and (15) that, in the case of Gaussian beams, the effect of this transverse variation is *to reduce* the absorption by a geometrical factor (for instance $2 + w_1^2/w_2^2$). With the experimental conditions of phase-matched SHG, this situation is complicated by the influence of double refraction. Qualitatively, one can foresee that the reduction is more important than in the above case. Roughly speaking, the geometrical factor should depend on z, the correction being greater when z is larger than the "aperture length" ($z \gtrsim l_a$) due to a smaller overlap of the fundamental (extraordinary) and harmonic (ordinary) waves. So it is not surprising to encounter such a difference when making a plane-wave treatment as in Part I. But a more refined treatment would have involved much more complicated computations and we can consider the value of B given in Part I as an effective coefficient. In addition, the maximum SHG conversion efficiency does not depend critically on the exact value of B. For example, using $B = 100$ ESU instead of 7 ESU, 8-percent conversion efficiency is still predicted by our model in the case of tellurium.

Our value for β_{12} can also be compared to the estimate given by Malz *et al.* [7]. Their observations on photoconductivity led to $\beta_{12} \simeq 0.7 \times 10^{-2}$ cm/MW, which is also a very small value compared to ours. It should be noted that such discrepancies frequently occur between TPA measurements [8]-[10], due to the fact that the magnitude of the process is very sensitive to the mode structure (and hence the spatial intensity distribution) of the incident beam. In addition to a photoconductive signal proportional to the product of 5.3 μm and 10.6 μm intensities, these authors have also observed a signal when the crystal was irradiated with a CO_2 laser, even without second-harmonic phase matching. The generated free carriers were cubic in the laser intensity ($\propto I_1^3$) and this has been attributed to *three-photon absorption*. This contribution seems very unlikely, and we think that the second harmonic generated in the crystal—even in the case of phase mismatch—may have sufficient power density to induce TPA with the fundamental wave. The same cubic law is then expected since the harmonic intensity is $\propto I_1^2$. With a coherence length of $l_c = 106$ μm and the TPA coefficient $\beta_{12} = 0.2$ cm/MW, we find

$$dN_e = C I_1^3\, dt, \qquad \text{with } C = 430 \text{ cm}^3 \text{ W}^{-3} \text{ s}^{-1}.$$

This value is in quite good agreement with the experimental estimate [7] of $C \simeq 10^3$ cm^3 W^{-3} s^{-1}. So, the observation reported by Malz *et al.* is probably due to not-phase-matched SHG followed by TPA, rather than to a direct three-photon process.

V. Conclusion

In Part I, we have set up a system of equations to describe the competition between SHG and TPA in semiconductors, and particular attention has been given to the effects of the TPA-induced free carriers. It has been found that the numerical solution of these equations could give account of the experimental results of SHG in tellurium, with a suitable choice of three adjustable parameters. Then we have used these equations to make some predictions about the optimization of harmonic conversion efficiency. The results obviously show there exists an optimal value of the fundamental intensity, and make clear the advantage of using short pulses. For instance, conversion efficiency up to 25-30 percent could be obtained by using 1-ns pulses; so far, such a conversion has never been reached in the medium infrared.

Then, in Part II, owing to the number of unverified assumptions that had been made, we have reported a direct measurement of the absorption at 10 μm induced by an independent 5-μm beam. This experiment has confirmed the principal hypothesis made in Part I, and the three adjustable parameters have been related to some physical quantities of tellurium, namely, the TPA coefficient, and the lifetime and absorption cross section of the free carriers. In addition, this experiment has shown the importance of the free carriers induced by a CO laser beam alone—with 200-ns pulses, a 5.5-μm beam of only 100 kW/cm^2 is sufficient to induce a free carrier density of about 10^{15} cm^{-3}. So, as a consequence, it would be hopeless to attempt any parametric oscillation in tellurium using a 5-μm pump.

This conclusion can probably be extended to any semiconductor whose energy gap is smaller than twice the photon energy of the pump beam. A shorter carrier lifetime could reduce the free carrier density, but not enough; with a lifetime as short as 1 ns and approximately the same two-photon cross section as in tellurium, a pump intensity of 10 MW/cm^2 would induce 10^{17} carriers per cubic centimeter. The absorption caused by such a carrier density, nearly negligible in the visible range or the near infrared, would prevent parametric oscillation in the medium infrared. So this effect is a major obstacle to the use of small-gap semiconductors in parametric devices, in spite of their other advantages.

Acknowledgment

The authors wish to thank Dr. J. Jerphagnon for his stimulating interest during this work. They wish to acknowledge very fruitful discussions with Dr. D. S. Chemla, Dr. G. Rebmann,

and Dr. R. Eymard, and they would like to thank Dr. P. Kupecek and Dr. G. Duraffourg for their comments on the manuscript.

Chirp Modulated CO_2 Waveguide Laser

ALEXANDER STEIN

Abstract—**Repetitive chirp modulation of a stable CO_2 waveguide laser yielded chirps of 75-MHz width and 2-μs duration. A demodulation technique is demonstrated which permits coherent detection of such a signal for periods extending over many chirps.**

With the development of CO_2 waveguide lasers of GHz tuning range [1], these devices are finding application as master oscillators in certain 10-μ radar systems, where one measures the fine structure in range and Doppler shift in analogy to high-resolution radar.

In considering the modulation formats of equivalent microwave radars, one finds that periodic chirp modulation is ideally suited for adaptation to optical systems [2].[1] Each returning chirp pulse yields the instantaneous range pattern, while the Doppler fine structure manifests itself in a slow variation of the optical phase which must be observed over an entire chirp train.

We report here the demonstration of a demodulation technique which permits the detection of slow phase variations in the presence of the much larger—but rapid and repetitive—phase excursions imparted by the chirps.

The device consisted of a 5-in-long BeO capillary tube with a 1.5-mm bore. Pyrex assemblies containing the electrodes, the evacuation port, and Brewster windows were epoxied to the capillary tube. This vessel was evacuated and back-filled with a mixture of He, CO_2, N_2, and Xe in the ratio 4:1:1:0.15 to a total pressure of 100 torr. A metallized, highly reflecting mirror of 15-cm radius of curvature and a dielectric multilayer mirror of 0.02 transmission with a 20-cm radius of curvature were placed at 14.5- and 19.5-cm distance, respectively, from either capillary aperture. An output power of 1.75 W was measured for this configuration. When an AR-coated 4-cm-long cadmium telluride modulator crystal was inserted between the metallized mirror and the plasma tube (and the mirror position adjusted for the effective change in reflector curvature) the output was reduced to 0.3 W. The sharp drop in power was caused by an increase in resonator loss from 0.04 to 0.12 per round trip upon insertion of the modulator; the round-trip gain was 0.19.

The CdTe crystal was cut for optimum phase modulation; i.e., the applied electrical field and the optical polarization were aligned with the ⟨111⟩, and the optical propagation direction with the ⟨110⟩ crystal axis [3]. The half-wave voltage for this modulator was V_0 = 6.9 kV, and the frequency shift for a voltage V

$$f_B = \frac{c}{2L}\frac{V}{V_0} \tag{1}$$

where c is the velocity of light and L the optical resonator length.

Maximum unambiguous frequency excursion, equal to the resonator free spectral range, is obtained at the half-wave voltage. For a cavity free spectral range of $c/2L$ = 300 MHz we attained a chirp width of 75 MHz at an output power of 0.3 W, while an equivalent extracavity modulation technique yielded 0.002 W of modulated optical power [4]. A proportionally larger chirp width can be attained by increasing the resonator free spectral range and/or the modulator voltage. The following describes the demodulation experiment which is a crucial part of the referenced lidar development.

In the experimental setup illustrated in Fig. 1, the master oscillator was chirped over 20 MHz by applying a ramp voltage, 0–500 V in 2 μs, to the crystal. (While a 75-MHz chirp width was obtained for a peak voltage of 1750 V, we reduced the voltage for the demodulation experiment to obtain a linear ramp.) The modulated laser output was optically mixed with the reference laser such that the IF signal swept from 10 to 30 MHz. The photoelectric sweep signal was first amplified and then mixed with a 20-MHz RF signal to yield a frequency sweep going through a zero beat. Fig. 2 shows an example of a demodulated chirp together with the modulation voltage. Note, one zero beat appears during the voltage ramp and a second one during flyback. We are interested in the signal value at the first zero beat and will show how it relates to the carrier phase.

The signal current at the RF-mixer output can be described by the expression

$$\begin{aligned} i &= i_0 \cos\left[-\Delta\omega t + \frac{\omega_B}{T}t^2 + \psi(t)\right] \\ &= i_0 \cos\left[\frac{\omega_B}{T}\left(t - \frac{\Delta\omega T}{2\omega_B}\right)^2 - \frac{\Delta\omega^2 T}{4\omega_B} + \psi(t)\right] \end{aligned} \tag{2}$$

where $\Delta\omega$ is the IF subcarrier; ω_B and T the chirp width and chirp period; and $\psi(t)$ is the phase modulation of interest. (In an actual lidar system master and local oscillators are locked

[1] Demonstrated in the ALCOR Radar System.

and $\psi(t)$ represents the modulation of the return signal's optical phase due to the Doppler signature of the target.) Note that a zero beat occurs at $t_1 = (\Delta\omega T/2\omega_B)$ and that the relative value of the signal current at that point determines $\psi(t_1)$ since the term $(\Delta\omega^2 T/4\omega_B)$ is known. The next chirp, which is a replica of the first one at a period τ later, yields

$$i = i_0 \cos\left[-\Delta\omega(t+\tau) + \frac{\omega_B}{T}t^2 + \psi(t+\tau)\right]$$
$$= i_0 \cos\left[\frac{\omega_B}{T}\left(t - \frac{\Delta\omega T}{2\omega_B}\right)^2 - \frac{\Delta\omega^2 T}{4\omega_B} - \Delta\omega\tau + \psi(t+\tau)\right] \quad (3)$$

where t is always counted from the beginning of each chirp. The zero beat occurs at $t_1 + \tau$ and the inverse cosine of the relative signal value at that point yields the phase value $\psi(t_1 + \tau)$ but for the known constant $-(\Delta\omega^2 T/4\omega_B) - \Delta\omega\tau$. For convenience, one may lock the chirp initiation to the IF carrier such that $\Delta\omega\tau = m2\pi$ ($m = 1, 2, \cdots$). In general we find for the nth chirp then

$$\psi(t_1 + n\tau) = \cos^{-1}\left[\frac{i(t_1 + n\tau)}{i_0}\right] + \frac{\Delta\omega^2 T}{4\omega_B}. \quad (4)$$

The phase modulation of interest is thus sampled through an entire train of chirp pulses. Precise chirp repetition is critical; as an example: for $(\Delta\omega/2\pi) = 10$ MHz, $\omega_B/2\pi = 75$ MHz, $T = 2$ μs, a 1-percent variation in chirp rate (ω_B/T) results in a phase error of 0.04 rad.

For an actual sampling circuit an electronic sampling window must be placed at zero beat; i.e., at time position t_1 after each ramp initiation.

From (2) we ascertain that the signal current at zero beat is essentially constant for a period $\delta t << \sqrt{(2\pi T/\omega_B)}$. For the chirp illustrated in Fig. 2, $T = 2 \times 10^{-6}$ s and $(\omega_B/2\pi) = 20$ MHz, yielding $\sqrt{(2\pi T/\omega_B)} = 300$ ns as a lower limit on the accuracy of the delay time t_1.

In summary, a demodulation technique previously used in microwave chirp radar [2] was demonstrated for a 10-μ system. This is an important step towards the construction of coherent lidars.

A Recirculating, Self-Contained DF/HF Pulsed Laser

D. W. FRADIN, P. P. CHENAUSKY, AND R. J. FREIBERG

Abstract—**The operation of the first self-contained, recirculating, electrically initiated, pulsed chemical laser is reported. A unique combination of scrubber beds selectively removes ground-state DF(HF) and other deleterious gases from the recirculating gas flow. By providing a small gas replenishment, it is possible to operate the laser for extended periods of time with little loss in power. The processes that degrade the power output in the absence of chemical scrubbing are discussed.**

The range of applications for pulsed HF/DF laser technology has been limited by the inherent safety hazards associated with both the laser fuels and the toxic laser exhaust. In addition, the weight and inconvenience of the vacuum pump needed for many conventional systems have precluded applications where portability is required. In recent years technological advances have provided specialized solutions to some of these problems. Such alternate fuel sources [1] as SF_6 have been successfully used in pulsed [2]-[4] and CW [5] HF/DF lasers operating at low and moderate power levels. In addition, chemical scrubber beds [6] have been found to be effective in reducing the concentrations of poisonous gases in the laser effluence. Despite these advances, conventional open-cycle HF/DF chemical lasers are generally bulky and poorly suited to applications outside the laboratory.

In this correspondence we report the successful operation of the first self-contained, recirculating DF/HF chemical laser. This laser, which utilizes a pulsed electrical discharge in a 95-torr mixture of SF_6 and either D_2 or H_2 [2]-[4], [7], provides solutions to several of the remaining problems that had previously prevented practical field applications of pulsed DF and HF lasers. In this system the laser effluence is chemically scrubbed within the low-pressure vacuum envelope, thereby removing the DF(HF) and other discharge by-products that tend to degrade laser action. The chemically scrubbed gas is then recirculated into the common laser cavity and discharge region. By providing a small replenishment of SF_6 and $D_2(H_2)$ to compensate for the gas removed in the scrubbing process, it is possible to operate the laser for long periods of time as a closed system. The recirculation and reclamation of the major portion of the premixed gas reduces the measured-gas consumption rate to less than 2 percent of that needed for comparable output power under open-cycle conditions. The bulky vacuum pump, required for conventional open-cycle chemical lasers, is replaced by a small gas circulator that is relatively lightweight [8]. In addition, details of operation in the recirculating mode provide insight into certain reaction mechanisms initiated with the laser discharge as well as aspects of the subsequent gas chemistry occurring within the vacuum envelope.

Fig. 1 summarizes the basic design of the DF/HF recirculating laser. The laser channel is a scaled-down version of the multipin electrical discharge of [3]. A gas mixture of 85-torr SF_6 and 10 torr of either D_2 or H_2 is normally used with this system. Voltage pulses of up to 32 kV with a 50 ns [full width at half maximum (FWHM)] duration provide a spatially averaged E/p of about 250 $Vcm^{-1}torr^{-1}$ at the peak of the discharge pulse. Output energies per pulse of up to 28 mJ with DF and 32 mJ with HF and electrical efficiencies of over 2 percent have been obtained in an active volume of 9 cm^3. After being

lased, the deexcited laser gas is convected out of the optical cavity and into the scrubber beds. In the experiments with DF reported here, solid pellets of NaOH and zeolite (Molecular Sieve type 5A) were used. Neither bed was cooled. The NaOH was used primarily to neutralize the DF in the circulating gas flow through the reaction DF + NaOH → NaF + DHO. The zeolite served to effectively remove the water vapor released in the neutralization process as well as any residual DF which was not converted by the NaOH. Small quantities of SF_6 and D_2 were replenished in the selectively scrubbed effluence prior to reentering the laser cavity. Gas-flow conditioning was employed to correct the nonuniform velocity profile of the gas flow.

Data demonstrating the efficacy of the scrubber beds are shown in Fig. 2. Although these data and the subsequent discussion apply specifically to the DF laser, virtually the same results were obtained with HF. With a total mass of NaOH and zeolite of approximately 450 g, the laser could be operated for 1 h, suffering a power loss of only about 19 percent. Under these conditions, the average power at the start of lasing was 0.13 W at a pulse-repetition frequency (PRF) of 10 Hz. When the beds were removed, about 30 percent of the power was lost during the first 2 min of operation, and the remaining power decayed exponentially with a time constant of about 5 min. In a similar experiment utilizing 290 g of zeolite and no NaOH, 1-h operation resulted in a 25-percent power loss. This result indicates that zeolite itself is very efficient in removing DF from the circulating flow.

For an average laser output of 0.13 W, the measured-gas replenishment rates for the DF laser were 1.6 torr/min of D_2 (or 2.7×10^{-4} moles/min) and 0.8 torr/min of SF_6 into a total gas ballast of 3.5 l. This replenishment rate exactly compensated for the pressure reduction in the system resulting from the gas removal by the scrubbing beds. The power output was generally much more sensitive to the D_2 replenishment rate than the SF_6 rate, and, in fact, no measurable power loss was observed over 15-min operating periods when only D_2 was replenished. Under the conditions of gas recirculation without electrical-discharge initiation, the gas pressure stayed constant without replenishment, thus indicating that the beds, as expected, removed neither SF_6 nor D_2 from the flowing gases.

The rapid loss in laser power exhibited by the data in Fig. 2 when the recirculating laser was operated without scrubber beds might be attributed to a combination of the following three processes: radiation trapping of the $v = 1$ to $v = 0$ transitions due to the accumulated ground-state DF molecules; vibrational relaxation of DF* by collisions with ground-state DF; and other processes in the active medium in which accumulated reaction by-products effectively reduce either the rate of fluorine-atom production or the rate of DF* formation.

A preliminary experiment was performed to assess the relative importance of radiative trapping processes in the temporal decay of the recirculating laser output when the beds were absent. These processes will occur predominantly in the $v = 1$ to $v = 0$ band whose lasing transitions initially comprise about 30 percent of the total laser output. The approximate magnitude of this effect is calculated from a simple argument. If no DF were lost from the recirculating gas flow, then after about 40 s of operation at a PRF of 10 Hz, the average concentration of accumulated ground-state DF in the gas ballast (3.5 l) would be equal to the instantaneous concentration of DF* created in the active medium (9×10^{-3} l) by a single electrical-discharge pulse. Under these conditions self-absorption from the ground-state DF should effectively quench lasing on the $1 \rightarrow 0$ band. In order to observe this selective quenching, the intensity of $P9(1 \rightarrow 0)$ laser transition, one of the most intense lines in the $1 \rightarrow 0$ band, was monitored with an Au:Ge detector and a 0.5-m Jarrel-Ash spectrometer. The temporal behavior of the laser transition was compared to a simultaneous measurement of the temporal decay of the total average laser power in the absence of gas scrubbing. As is shown in Fig. 3, the power in $P9(1 \rightarrow 0)$ did indeed fall rapidly to zero; in fact, more rapidly than the total laser power. The fact that several minutes of operation were required for the power loss as compared to the estimated time of 40 s is not surprising since this simple argument ignores both complications from rotational substructure and the fact that initially the DF molecules may be removed from the gas flow by reacting with the various surfaces in the recirculating flow channel.

Various vibrational transfer processes may also contribute to the power loss when the beds are removed. Because of the complexity of the physical and chemical mechanisms [7] occurring within the active medium and in the subsequent gas flow, the relative influence of such processes upon the temporal behavior of the laser output cannot be accurately determined without considerable analysis and additional experimental data. It is interesting to note, however, that the measured time constant of ~5 min for the DF-laser power loss would imply a vibrational energy-loss constant of about 8×10^5 s^{-1} $torr^{-1}$. This assumes that the rate of contamination buildup is equal to the estimated rate of DF formation (2.7×10^{-4} moles/min). By comparison, the measured vibrational energy-loss constant [9] for the self-deactivation of DF* ($v = 1$) by ground-state DF is only 0.24×10^5 s^{-1} $torr^{-1}$ at room temperature. This observation suggests that other vibrational deexcitation mechanisms may play an important role in the temporal decay of the DF-laser power when the gases are recirculated without scrubber beds. In order to more accurately assess the role of vibrational energy-loss processes, a mass-spectroscopic analysis is being conducted. The results of this study will be presented elsewhere.

In conclusion, a totally self-contained recirculating chemical laser has been successfully operated. This device operates by using room-temperature scrubber beds to selectively remove ground-state DF and other deleterious reaction by-products that would otherwise accumulate within the vacuum envelope. The viability of the recirculating chemical-laser device should

greatly expand the range of applications available for pulsed DF and HF laser systems.

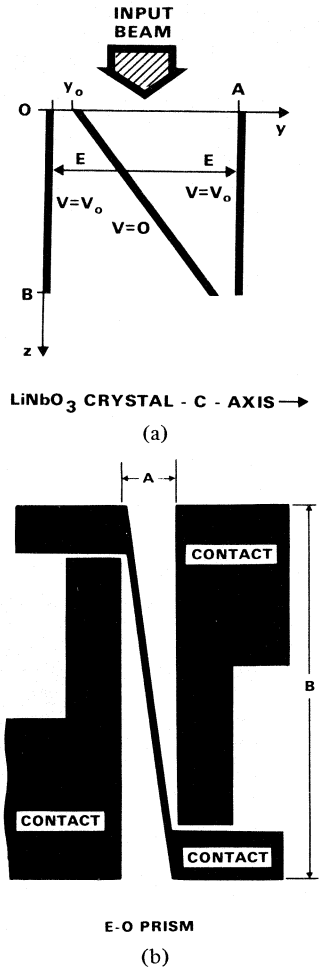

Fig. 1. Prism-electrode pattern. (a) Schematic. (b) Experimental.

A Planar Electrooptic-Prism Switch

I. P. KAMINOW AND L. W. STULZ

Abstract—**A novel electrode configuration for producing a prism-like deflector when applied to a planar optical waveguide is described. A prism deflector on a Ti-diffused $LiNbO_3$ waveguide was operated as a bipolar switch for electrode voltages of ±15 V.**

An electrooptically controlled prism deflector can serve as a multiport switch, the simplest example of which is a bipolar switch, which can also be operated as an optical shutter. We describe here an electrode pattern that can be applied to a planar optical waveguide in order to approximate an electrooptic prism in the planar geometry. The device is demonstrated using a titanium-diffused $LiNbO_3$ waveguide [1] operating at 0.633 μm as a bipolar switch requiring ±15 V for the two states. The electrode configuration is entirely different from those described earlier [2].

The prism-electrode pattern is illustrated schematically in Fig. 1(a). If we assume the width of the diagonal electrode to be much smaller than the separation A between the outer electrodes, then the distance from the left-hand electrode to the diagonal electrode is

$$d = y_0 + az \tag{1}$$

where a is the slope. The thickness of the planar waveguide is assumed to be much less than the spacing A. Hence the field $E_y(y, z)$ just below the surface of the crystal is [3]

$$E_y(y,z) = -\frac{V}{\pi}[y(d-y)]^{-1/2}, \qquad 0 < y < d$$

$$= +\frac{V}{\pi}[(A-y)(y-d)]^{-1/2}, \qquad d < y < A. \tag{2}$$

The electrooptically induced phase shift $\eta(y)$ for light polarized in the y direction and traveling along z at a given value of y is

$$\eta(y) = -\frac{\pi n_e^3 r_{33}}{\lambda}\int_0^B E_y(y,z)\,dz$$

$$= \eta_0 \begin{cases} \left(\dfrac{A-y_0-y}{y}\right)^{1/2} - \left(\dfrac{y_0-y}{y}\right)^{1/2}, & 0 < y < y_0 \\ \left(\dfrac{A-y_0-y}{y}\right)^{1/2} - \left(\dfrac{y-y_0}{A-y}\right)^{1/2}, & y_0 < y < A-y_0 \\ \left(\dfrac{y_0+y-A}{A-y}\right)^{1/2} - \left(\dfrac{y-y_0}{A-y}\right)^{1/2}, & A-y_0 < y < A \end{cases} \tag{3}$$

Manuscript received April 2, 1975; revised April 4, 1975.

The authors are with Bell Laboratories, Crawford Hill Laboratory, Holmdel, N.J. 07733.

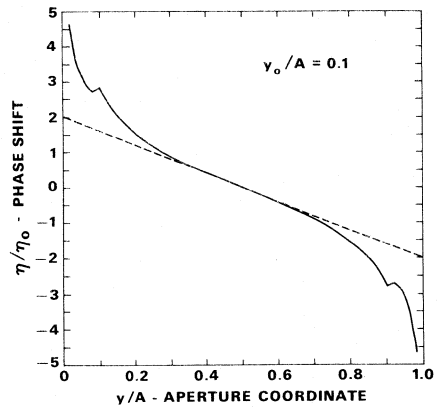

Fig. 2. Theoretical phase shift across electrode aperture and linear approximation for $y_0/A = 0.1$ (dashed).

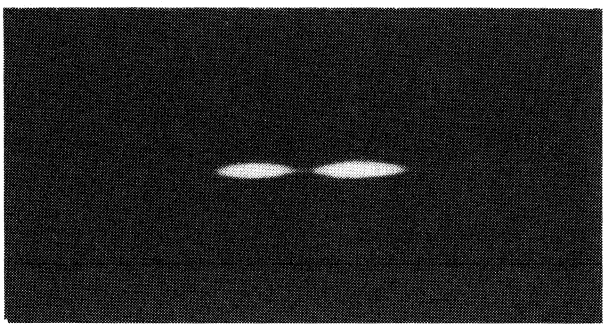

Fig. 3. Output spots for electrode voltages ± 15 V.

with

$$\eta_0 = \frac{2n_e^3 r_{33} V_0}{\lambda a} \tag{4}$$

where n_e is the extraordinary refractive index and r_{33} is the appropriate electrooptic coefficient.

In the approximation

$$y \approx A/2 \quad y_0 << A \quad a = A/B$$

the prismlike linear phase shift becomes

$$\eta(y) \approx 2\eta_0(1 - 2y/A). \tag{5}$$

This linear approximation is compared with the function (3) in Fig. 2 for $y_0/A = 0.1$. It can be seen that the approximation is satisfactory over about 70 percent of the aperture A.

The linear phase shift across the aperture causes the wavefronts to be rotated through a scan angle θ given by

$$\tan\theta = \frac{\lambda\eta(0)}{\pi n_e A} = \frac{4n_e^2 r_{33} B V_0}{\pi A^2}. \tag{6}$$

For a Gaussian beam having a diameter D at its waist, which is at the center of the prism, the beam angle between $1/e^2$ points is

$$\phi = \frac{4\lambda}{\pi n_e D} \tag{7}$$

and the number N of resolvable spots is, for small θ,

$$N = \frac{\theta}{\phi} = \frac{n_e^3 r_{33} B D V_0}{\lambda A^2}. \tag{8}$$

The experimental aluminum-electrode pattern shown in Fig. 1(b) was evaporated through a photolithographic mask onto a $LiNbO_3$ crystal having a Ti-diffused waveguide, approximately 1 μm thick, on its surface [1]. The effective prism-electrode dimensions are $A = 100$ μm, $B = 6$ mm, $y_0 = 10$ μm, and the width of the diagonal electrode is 5 μm. Light from a 0.633-μm laser was focused by a 14-cm lens and coupled into the guide by a rutile prism. The estimated waist diameter D is 66 μm.

Fig. 3 shows two well-resolved spots coupled through the output prism for applied voltages of ±15 V. According to (8) [with $n_e = 2.2$, $r_{33} = 3 \times 10^{-11}$ m/V, $B = 6$ mm, $D = 6.6$ μm, $V_0 = 30$ V (±15 V), $\lambda = 0.633$ μm, and $A = 100$ μm], we calculate $N = 0.6$ spots with $1/e^2$ resolution. It may be seen that this resolution criterion is more conservative than the usual Rayleigh criterion. For $N = 1$, the net required voltage is $V_0 = 50$ V (±25 V).

The switching voltage can be reduced at the expense of ease of alignment by using diffraction-limited electrode dimensions

$$A^2/B = \frac{4\lambda}{n_e \pi}, \qquad A = \sqrt{2}\, D. \tag{9}$$

Then

$$V_0 = \frac{4\sqrt{2}}{\pi} \frac{N\lambda^2}{n_e^4 r_{33} A} \tag{10}$$

which yields $V_0 = 20$ V (±10 V) for $N = 1$ and $A = 50$ μm.

Bipolar switches of the type described here might serve as elements of larger optical switching networks analogous to

electrical switching networks [4]. For this purpose, strip waveguides would have to be incorporated in the deflectors in order to interconnect the switches.

Prepulse Extinction-Ratio Measurements on a CO_2-Laser System

K. R. MANES, D. L. SMITH, R. A. HAAS, AND S. S. GLAROS

Abstract—**Prepulse extinction-ratio measurements performed on two pulse-selection systems at the input and the output of a CO_2-amplifier chain are described.**

During laser-target interaction experiments with a 50-J 1.3-ns CO_2-laser system it rapidly became apparent that low-intensity prepulses were strongly affecting the target behavior. A TEA CO_2-oscillator mode locked by a Ge Brewster's-angle acoustooptic modulator produced a train of pulses which were directed into a switch-out system intended to select the largest pulse [1], [2]. The pulse-train envelope had the ~100-ns-duration gain-switched spike characteristic of TEA CO_2 lasers. The first series of target experiments used the pulse-selection technique indicated schematically in Fig. 1(a). Low-level pulses separated by 20 ns eventually produced enough ionization in the laser-triggered spark gap to cause it to close, launching a 10-kV square wave of 20-ns duration. When this voltage appeared across the CdTe electrooptic crystal, it caused the next mode-locked pulse's polarization to be rotated by $\pi/2$, and consequently that pulse was reflected off the output Brewster plate. Small alignment errors and residual strain-induced birefringence in the CdTe crystal prevented this pulse-selection system from having an adequate rejection ratio.

Fig. 2 shows the experimental arrangements used to determine the efficacy of this pulse-selection technique by measuring the ratio of the switched-out pulse amplitude to the immediately preceding mode-locked pulse amplitude; i.e., the prepulse extinction ratio. A photograph obtained with this apparatus is shown in Fig. 3. The Tektronix 519 oscilloscope was internally triggered by the prepulse entering the cooled Hg:Ge detector after traversing the 10-ns-long unattenuated leg. The next pulse, 10 ns later, is the switched-out pulse attenuated by calibrated CaF_2 plates. It was found that with

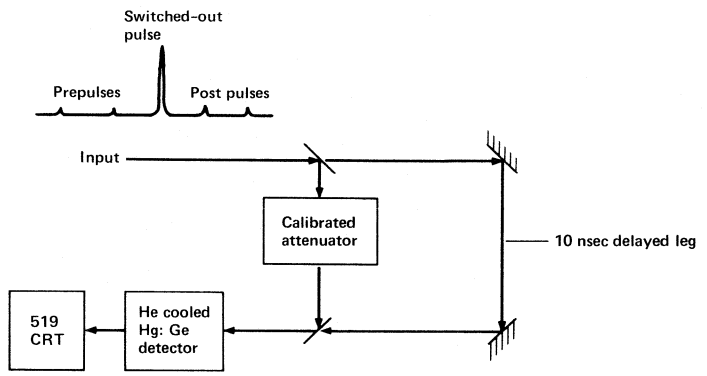

Fig. 2. Extinction-ratio measuring apparatus.

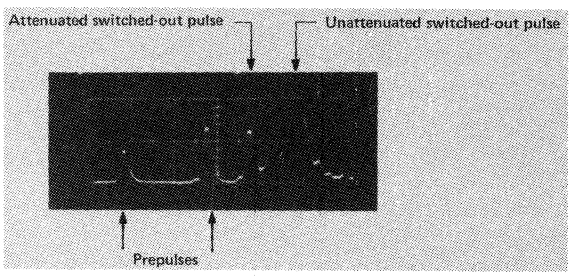

Fig. 3. Photograph obtained with apparatus indicated in Fig. 2.

the switch-out system shown in Fig. 1(a) an extinction ratio of $2 - 5 \times 10^4$ was typical. These pulses were directed into an amplifier chain consisting of 1 m of 4.5-cm clear-aperture TEA preamplifier, a Keplerian beam-expander followed by 1 m of 9-cm-aperture TEA amplifier, and finally two 11-cm clear aperture by 1-m-long cold-cathode electron-beam-sustained power amplifiers operated at two atmospheres. Upon emerging in the target area a portion of the laser signal was directed into another prepulse measuring apparatus identical to that described in Fig. 2. It was found that the saturation properties of the CO_2 amplifiers had deteriorated the extinction ratio to only 20–50. In fact, when this beam was focused to a nearly diffraction-limited spot $\lesssim 140\ \mu m$ in diameter on a 10-μm-thick CH_2 foil target, negligible

Manuscript received May 2, 1975. This work was performed under the auspices of the U.S. Energy Research and Development Administration.

The authors are with the University of California, Lawrence Livermore Laboratory, Livermore, Calif. 94550.

quantities of X-rays were observed even though the switched-out pulse contained 30–40 J. The target foil was disassembled prematurely by prepulses and was not there when the main pulse arrived.

In response to this problem, the switch-out system indicated in Fig. 1(b) was devised. Essentially, a second stage has been added. In principle, additional stages may be added until losses and mismatching degrade the 10-kV pulse. Synchronization between the 10-kV pulse and the optical pulse may be maintained by folding the optical path. Using the same evaluative technique, an extinction ratio of 2×10^6 was measured at the oscillator and 2×10^3 after amplification at the target. Separate measurements established that 10-μm CH_2 foils could survive irradiation by pulses with energies of $\sim$100 mJ. Consequently, it was not surprising to find that copious quantities of X-radiation, ions, and electrons were produced when the large switched-out pulse reached the thin CH_2 target.

The importance of establishing the integrity of fragile laser-fusion targets immediately prior to irradiation cannot be overemphasized [3]. The saturation property of CO_2 amplifiers which contributes to their relatively high efficiency also severely degrades the prepulse extinction ratio and can lead to premature target damage [4]. A two-stage switch-out system has been demonstrated which provides an extinction ratio at the target sufficiently large to permit laser–target interaction experiments with 10-μm-thick CH_2 foil targets.

New CO_2 Pumped CW Far-Infrared Laser Lines

D. A. JENNINGS, K. M. EVENSON, AND J. J. JIMENEZ

Abstract—**A single-frequency CW CO_2 laser has been used to pump ethyl alcohol, methyl chloride, ethyl chloride, and methylene chloride, generating 8 new CW far-infrared (FIR) laser lines from 254 to 1700 μm.**

Far-infrared (FIR) lasers are becoming useful radiation sources for use in spectroscopy, and many molecules exhibit lasing action when optically pumped with a CO_2 laser. We report here several new molecules and 8 new wavelengths to provide additional sources in this spectral region.

A single-frequency grating-tuned CW CO_2 laser, with a PZT for fine tuning, provided the pump source. Maximum power of 20 W in the 9.6-μm band with tuning from $P(8)$ to $P(42)$ and $R(8)$ to $R(36)$, and 40 W in the 10.6-μm band with tuning from $P(0)$ to $P(50)$ and $R(0)$ to $R(44)$ was obtained.

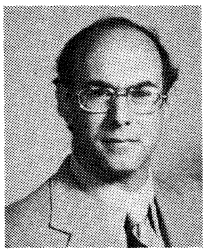
The FIR laser was of the waveguide design. The waveguide was a polished copper tube, of 14-mm diameter and 2.1 m long. The input and output mirrors were of copper and polished flat. FIR power was extracted through a 0.25-mm-thick fused-quartz window which covered a 2.5-mm coupling hole in the output mirror. The CO_2 pump radiation was focused through a salt window and through a 1-mm hole in the input mirror by a 6.4-cm focal-length germanium lens. The input mirror was moved via a micrometer from 1 to 5 mm from the end of the waveguide.

The FIR-laser radiation was detected by a quartz-window Golay cell with various attenuators between the FIR laser and the Golay cell, depending on the signal strength. The optimum pressure was in nearly all cases around 100-μm Hg. No attempt was made to determine the FIR-laser polarization relative to the CO_2-laser polarization.

The results of our measurements are summarized in Table I. The FIR power is listed as either M (medium) or W (weak) where $M \approx 0.1$ mW and $W \approx 0.01$ mW.

It is interesting to note that the ethyl alcohol line lased very well on vodka, gin, and rum, but it lased on only 1 line and rather weakly compared with methyl alcohol. It is quite obvious that there are better uses of ethyl alcohol.

TABLE I



Material	Wavelength μm	CO_2 Pumpline	Pressure μ Hg	Power
Ethyl Alcohol (C_2H_5OH)	396	9 P (32)	100	W
Methyl Chloride (CH_3Cl)	254	10 P (10)	100	M
	354	10 R (18)	100	W
	968	9 R (12)	100	W
Ethyl Chloride C_2H_5Cl	900	10 R (30)	100	M
	1350	10 R (30)	100	W
	1400	10 R (38)	100	
	1720	10 R (28)	100-200	M
Methylene Chloride CH_2Cl_2	258	10 P (26)	100	M

J. J. Jimenez is with the Centre National de la Recherche Scientifique and Bureau National de Metrologie, Paris, France. He is a guest worker at the Precision Laser Metrology Section, National Bureau of Standards, Boulder, Colo. 80302.

Contributors

Richard L. Abrams (M'68) was born in Cleveland, Ohio, in 1941. He received the B.S. degree in engineering physics and the Ph.D. degree in applied physics from Cornell University, Ithaca, N.Y., in 1964 and 1968, respectively.

From February 1968 to September 1971 he was employed at Bell Laboratories, where he worked on optical communications, infrared modulators, infrared detectors, and CO_2 lasers. Since October 1971 he has been employed at the Hughes Research Laboratories, Malibu, Calif., as a Senior Staff Physicist and is Head of the Electro-Optics Section. He conducts research in the areas of optical modulation, communications, laser spectroscopy, and gas lasers.

Dr. Abrams is a member of the Americal Physical Society, Phi Kappa Phi, and Tau Beta Pi.

James D. Barry (S'66-M'72) was born in Washington, D.C., on February 8, 1942. He received the B.S. degree in applied physics, the M.S. degree in physics, and the Ph.D. degree in interplanetary space physics, all from the University of California, Los Angeles, in 1964, 1966, and 1969, respectively.

He has pursued research in the areas of interplanetary space physics, ionospheric plasma, and laser technology. He is currently at the Air Force Avionics Laboratory, Wright-Patterson Air Force Base, Ohio, where he is the Technical Director of the Air Force Program for Space Laser Communications. He has several patents in the laser area.

Dr. Barry is a member of the American Geophysical Union and Sigma Xi. He is Chairman of the DOD/NASA Optical Communications Working Group. He is also a member of several Department of Defense planning and coordinating committees in space laser communications, and serves on an advisory panel on medical applications of laser communications.

Edmond M. Batifol was born in Lozère, France, on November 20, 1930.

Since 1962 he has been involved in the development of laser sources and research in nonlinear optics in the Department of Physics and Electronics of the Centre National d'Etudes des Télécommunications, Bagneux, France.

*

Robert J. Coates (A'47-M'55-SM'56-F'71) was born in Lansing, Mich., on May 8, 1922. He received the B.S. degree in electrical engineering from Michigan State University, East Lansing, in 1943, the M.S. degree in electrical engineering from the University of Maryland, College Park, in 1948, and the Ph.D. degree in physics from The Johns Hopkins University, Baltimore, Md., in 1957.

From 1943 to 1959 he was at the U.S. Naval Research Laboratory engaged in millimeter-wave radio astronomy. Since 1959 he has been at the NASA Goddard Space Flight Center, Greenbelt, Md. He was Chief of the Space Data Acquisition Division, the Advanced Development Division, and the Advanced Data Systems Division at Goddard, developing antennas, RF systems, data handling and processing, and optical systems for spacecraft tracking and data acquisition. In 1974 he became the Senior Scientist of the Applications Directorate at Goddard, becoming responsible for the very long baseline interferometer and satellite laser tracking programs for determining tectonic-plate motions, geodesy, and earth dynamics.

Dr. Coates is a member of Tau Beta Pi, Phi Kappa Phi, Sigma Xi, t[illegible] American Physical Society, the American Geophysical Union, and t[illegible] American Association for the Advancement of Science.

*

Steven C. Cohen was born in New Kensington, Pa., on August 17, 1947. He received the B.S. degree in physics from Drexel University, Philadelphia, Pa., in 1970, and the M.S. and Ph.D. degrees in physics from the University of Maryland, College Park, in 1972 and 1973, respectively.

From 1966 to 1970 he was an undergraduate cooperative education student in the physical sciences at the NASA Goddard Space Flight Center, Greenbelt, Md. Since 1970 he has been a member of Goddard's Laser Technology Branch, where he has carried out research in heterodyne detection principles and applications, molecular energy-transfer theory, and gas-laser kinetics.

Dr. Cohen is a member of the American Physical Society, the Optical Society of America, Phi Kappa Phi, Sigma Xi, Sigma Pi Sigma, and Pi Mu Epsilon.

Anthony J. DiNardo was born in New York, N.Y., on June 14, 1941. He received the B.S. degree in electrical engineering from the City College of New York, in 1964, and the M.S. degree from the Polytechnic Institute of Brooklyn, Brooklyn, N.Y., in 1969.

He joined AIL, Melville, N.Y., in 1966 as an Electronics Engineer in the Applied Electronics Division. He is a Senior Engineer in the Infrared and Electro-Optics Department, and is engaged in the development of infrared receivers for radiometry, optical radar, and communications applications. He was Project Engineer on a NASA program which successfully developed and fabricated a unique infrared, 10.6-μm heterodyne radiometer (IHR). This program included the development of a new approach in analyzing the IHR's performance and the corroboration of the analysis with the experimental data in the field as well as in the laboratory. The IHR was employed for solar and atmospheric transmission measurements. He has performed in-depth computer studies of the Fraunhoffer diffraction patterns of an array of 10.6-μm coherent heterodyne mixers [illegible] determined the optimum optical photomixer geometry for maximum signal-to-noise performance. He has done complete systems modeling of heterodyne reception, heterodyne radiometry, and optical radar and analyzed these by computer-assisted variation of the key operational parameters. Previous to these assignments, he was engaged in the study of superconducting tunneling devices and superconducting filters. This work aimed at the development of a Josephson tunnel junction microwave mixer and a superconducting microwave microstrip reselector and filter for a cryogenic X-band receiver front end. Prior to joining AIL, he was associated with the Electronic Division of the General Dynamics Corporation from 1964 to 1966.

Akira Fujisawa was born in Tokyo, Japan, on March 15, 1931. He received the B.S. degree in electrical engineering from Waseda University, Tokyo, in 1954.

He has since been employed at the 1st Research Center of the Technical Research and Development Institute, Japanese Defense Agency, Tokyo. Between 1954 and 1961 he was employed in R&D work on infrared equipment. During the academic year 1962 to 1963 he studied laser physics at Waseda University. He has since worked in fundamental and applied areas of solid and gaseous lasers as well as in the development of range finders, gated viewing systems, and underwater optical transmission systems. During a one year interval between 1965 and 1966 he was employed at the Night Vision Laboratory in Fort Belvoir, Va., and also spent the year 1974 at the U.S. Army Electronics Command Laboratories, Fort Monmouth, N.J., on an exchange program. He is the Chief of the Laser Project Team at TRDI.

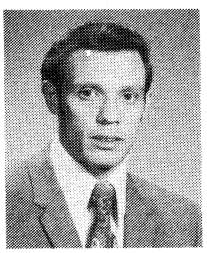
John H. McElroy (S'63–M'66–SM'71) was born in Marion, Ohio. He received the B.S.E.E. degree from the University of Texas, Austin, and the M.E.E. degree from the Catholic University of America, Washington, D.C., where he is currently a part-time doctoral student.

From 1954 to 1957 he served with various U.S. Army airborne units, and from 1957 to 1963 he taught and prepared instructional materials on electronics, physics, and mathematics at the U.S. Army Air Defense School, Fort Bliss, Tex. Until 1966 he was a Research Assistant in the Quantum Electronics Research Laboratory of the University of Texas, where he assisted in research on laser-induced ionization of gases. Since joining the NASA Goddard Space Flight Center, Greenbelt, Md., in 1966, he has been responsible for developing laser systems and components for use in satellite data transmission and tracking.

Mr. McElroy is a member of the Optical Society of America, Tau Beta Pi, Eta Kappa Nu, and Omicron Delta Kappa, and an associate fellow of the American Institute of Aeronautics and Astronautics.



*

Jean-Louis Oudar was born in Lille, France, in 1949. He graduated from the Ecole Polytechnique of Paris, Paris, France, in 1970, and received the Diplôme d'Etudes Approfondies in solid state physics from the University of Orsay, Orsay, France, in 1972.

He is currently working in the Department of Physics and Electronics at the Centre National d'Etudes des Télécommunications (CNET), Bagneux, France, where he is interested in nonlinear optics and materials.

*

Aristotle Papayoanou was born in New York, N.Y., on July 7, 1936. He received the B.S. degree from the City College of New York and the M.S. and Ph.D. degrees in physics from the Stevens Institute of Technology, Hoboken, N.J., in 1958, 1965, and 1972, respectively.

Since 1961 he has been employed as a Research Physicist at the U.S. Army Electronics Command Laboratories at Fort Monmouth, N.J. Between 1961 and 1965 he performed research in ionospheric and radio wave physics. Since 1965 he has worked in various areas of laser physics including optical pumping, pulsed ion lasers, and CO_2 lasers. His thesis dealt with the Brillouin spectrum of laser light scattered by monomeric liquids.

*

Bernard J. Peyton (M'60–SM'69) was born in New York, N.Y., on April 11, 1937. He received the B.S. degree from the City College of New York, N.Y., in 1959, and the M.S. degree from the Polytechnic Institute of Brooklyn, N.Y., in 1964, both in electrical engineering.

He joined the Applied Electronics Division of AIL, a division of Cutler-Hammer, Inc., Melville, N.Y., in 1959. He is currently the Deputy Department Head of the Infrared and Electro-Optics Department, where he is responsible for and directs programs in the development of coherent and incoherent infrared receivers for communications, radar, atmospheric physics, and radiometric applications, the evaluation of a variety of detection techniques, and laser communications. He has investigated the noise properties and frequency-response characteristics of infrared photoconductors, photovoltaic diodes, and avalanche photodiodes. He previously worked on the development of advanced solid-state devices including maser, semiconductor, and ferrite components for the microwave and millimeter wavelength region, nonlinear up-conversion, radiometry, and microwave spectroscopy.

Christiane A. Schwartz (S'68–M'70) was born in Paris, France, in June 1947. She received a degree in electronic engineering from the Ecole Supérieure d'Electricité of Paris in 1969, and a Diplôme d'Etudes Approfondies in quantum optics from Orsay University, Orsay, France, in 1970, and the Diplôme de Docteur de 3° Cycle in 1973 for work on nonlinear devices based on tellurium.

She has worked in the Nonlinear Optics Department of the Centre National d'Etudes des Télécommunications, Bagneux, France. She is now with the Centre Commun d'Etudes de Télévision et Télécommunications, Rennes, France.

*

Malvin Carl Teich (S'62–M'66–SM'72) was born in New York, N.Y., on May 4, 1939. He received the S.B. degree in physics from the Massachusetts Institute of Technology, Cambridge, Mass., in 1961, the M.S. degree in electrical engineering from Stanford University, Stanford, Calif., in 1962, and the Ph.D. degree from Cornell University, Ithaca, N.Y., in 1966. While at M.I.T. he received the Frank W. and Carl S. Adams Memorial Scholarship, and at Cornell University he received the James Clerk Maxwell Fellowship and a Ford Foundation Grant.

He has held summer research positions at the Motorola Corporation, Rockwell International's Space and Information Systems Division, and the Mitre Corporation in 1959, 1961, and 1963, respectively. In the summer of 1960 he participated in a student technical exchange program at N.V. Philips Gloeilampenfabrieken in Eindhoven, The Netherlands. In 1966 he joined the M.I.T. Lincoln Laboratory, Lexington, Mass., where he was engaged in work on coherent infrared detection and modulation. In 1967 he became a Member of the Faculty of the Department of Electrical Engineering and Computer Science, Columbia University, New York, N.Y., where he is now teaching and pursuing his research interests in the areas of detection theory, quantum electronics, and optical communications.

Dr. Teich is a member of Sigma Xi, the American Physical Society, the American Society for Engineering Education, and the Optical Society of America. In 1969 he was the recipient of the IEEE Browder J. Thompson Award for his paper "Infrared Heterodyne Detection," and in 1974 was a Fellow of the John Simon Guggenheim Memorial Foundation.

Preface

THIS Special Issue of the IEEE JOURNAL OF QUANTUM ELECTRONICS is devoted to papers presented at the 4th Conference on Chemical and Molecular Lasers held in St. Louis, Mo., October 21-23, 1974. This conference was held in cooperation with the AIP/IEEE Joint Council on Quantum Electronics and the IEEE Quantum Electronics Council, and received financial support from the Chemistry Directorate of the Air Force Office of Scientific Research. The purposes of the Conference were principally to bring together people active in the area and to present new research results.

One hundred five papers were presented at the meeting; included in this JOURNAL are 7 full length papers and Digests of the remaining 98 papers. The work presented at the conference was grouped into sessions as follows.

MA: Electrically-Pumped Lasers
MB: New IR Laser Reactions
MC: Chemically-Pumped Electronic Transition Lasers
MD: Vibrational Energy Transfer
TA: Pulsed Chemical Lasers and Q-Switching
TB: CO Lasers
TC: Post-Deadline Papers
TD: Post-Deadline Papers
WA: Electronic Energy Transfer
WB: DF-CO_2 Lasers
WC: cw HF/DF Chemical Lasers I
WD: Laser-Controlled Chemistry
WE: Modeling and Theory
WF: cw HF/DF Chemical Lasers II

The work presented at the St. Louis Conference has undergone a continuous evolution since the 2nd Conference on Chemical and Molecular Lasers in 1969. Some subjects have continued as active areas through the 1974 Conference, notably CW HF/DF chemical lasers, CO chemical lasers, CO electric discharge lasers, vibrational energy transfer, and IR laser reactions. In the area of vibrational energy transfer, the recent work on collisions between vibrationally excited molecules and atoms is noteworthy. The area of collisional transfer lasers as represented by the DF-CO_2, H_2-HCl, and D_2-CO_2 systems continues to be an active area of research and, in the case of DF-CO_2, development. Supporting all of these is the continuing work in modeling of lasers.

The newer research areas represented at the 4th Conference on Chemical and Molecular Lasers include the search for visible chemical lasers and laser-induced or laser-controlled chemistry, with particular emphasis on isotope effects. The visible laser field was also represented in the papers on electrically pumped lasers; the work on electronic energy transfer is of importance to visible lasers.

Thanks are extended to the members of the Organizing Committee and the Program Committee listed below for their efforts on behalf of the conference.

Organizing Committee: D. P. Ames, *Chairman*; W. Q. Jeffers; J. D. Kelley, *Treasurer*; and T. J. Menne.
Program Committee: W. Q. Jeffers, *Chairman*; J. R. Airey; B. R. Bronfin; A. N. Chester; T. Cool; J. D. Kelley; G. Pimentel; and H. T. Powell.

The committee members and the reviewers of the full-length papers in this JOURNAL both gave generously of their time and efforts. Mrs. Judy Thomas handled the secretarial work associated with the Conference.

TA4—Characteristics of a High-Energy Hydrogen Fluoride (HF) Laser Initiated by an Intense Electron Beam

E. L. PATTERSON, MEMBER, IEEE, AND R. A. GERBER

Abstract—**The characteristics of a high-energy hydrogen fluoride (HF) laser and the effects of optical elements on beam quality and on energy extraction are described. The HF laser is initiated by injecting a 2-MeV electron beam into a mixture of SF_6 and C_2H_6. With 300-torr SF_6 and 30-torr C_2H_6, the radiated energy with a flat mirror on one end of the laser cell is ≈80 percent of the two-way energy when no mirrors are used. The effect of a confocal unstable resonator in providing collimation of the laser beam was studied. The maximum laser energy measured was 380 J in a 23-ns full width at half maximum (FWHM) pulse. The maximum electrical efficiency measured was 14 percent, which is about 60 percent of the maximum theoretical value.**

I. INTRODUCTION

THERE HAS recently been considerable interest in initiating hydrogen fluoride (HF) lasers by intense electron beams [1]-[8] because electron beams have been shown to be efficient in releasing fluorine atoms from fluorine compounds. Electron beams have been used to initiate HF lasers in mixtures of SF_6 and H_2 or C_2H_6 [1], [3], [5], [7], [8] and of H_2 and F_2 [2], [4], [6]. With electron beams it is possible to uniformly excite large laser volumes in nanosecond time scales. The availability of large electron beams has led to the production of high-energy HF lasers. Laser energies >200 J have been measured with SF_6 and C_2H_6 [1] and >2 kJ have been produced with H_2 and F_2 [2]. One of the major problems associated with the high-energy superradiant lasers reported in [1] and [2] is the poor optical beam quality of the amplified spontaneous emission. The purposes of this experiment are to determine the effect of optical feedback on a high-gain HF laser, to determine the characteristics of an electron-beam initiated laser, and to evaluate the electron-beam energy deposition and resulting excitation as a function of distance and pressure.

The laser described in [1] consisted of a straight tube with an absorber on one end. In that experiment, the maximum measured electrical efficiency η_e (η_e = laser energy out/deposited electron-beam energy) was about 8 percent from which a true electrical efficiency of 16 percent was inferred by assuming equal laser radiation in both directions. Access to both ends of the laser cell in the present experiment allows the verification of this inference. The electron beam was magnetically guided into the laser cell so that mirrors could be used at both ends. The electrons were transported along the laser-cell axis rather than transversely [6]-[8] because, for the reactant pressures of interest, the laser length is comparable to the stopping distance of the high-energy electrons. Detailed electron-beam deposition measurements were performed over the length of the laser cell. These measurements allow one to determine the optimum laser length for a given gas pressure. Other improvements over the experiments in [1] include detailed measurements of the laser spectrum as well as better laser-energy measurements as a function of gas mixtures and pressure. Total laser energy was measured in this experiment so that assumptions about beam uniformity are not required.

Manuscript received November 26, 1974; revised March 14, 1975. This work was supported by the Environmental Research and Development Agency.

The authors are with the Sandia Laboratories, Albuquerque, N. Mex. 87115.

II. EXPERIMENTAL APPARATUS

The experimental arrangement is shown in Fig. 1. The geometry is similar to that used with a smaller accelerator [3]. The table in Fig. 1 lists the conditions for two series of experiments described in this paper. In the first experiment, the laser medium was longer and the electron-beam energy was lower than in the second set of experiments. The active length is defined as the distance between the location where the electron beam enters the laser cell and where the residue of the beam is guided into the cell wall (near B_T in Fig. 1). The laser cell had a diameter of 14.9 cm giving laser volumes for the first and second series of experiments of 39 and 26.3 l, respectively. Measurements obtained on the first experiments were laser pulsewidths, delay times, spectra, energy as a function of SF_6 pressure for fixed C_2H_6/SF_6 ratio, and energy as a function of C_2H_6 concentration for fixed SF_6 pressure. The effect of a mirror on one end of the cell was also investigated. These same measurements, except for the spectra and variation of laser energy with ethane concentration, were repeated on the second experiments. In addition, an unstable optical resonator was used on the second series for a limited number of shots.

The REBA electron accelerator [2 MeV, 55 kA, 70-ns full width at half maximum (FWHM)] is the same as that used in [1] and [2]. The repetition rate of this machine is approximately ten shots per day. Magnetic-field coils around the laser cell and accelerator diode provide an axial magnetic field B_a to guide the electrons through the cell. The axial magnetic field was 2.0 and 2.5 kG, respectively, for the first and second series of experiments. Two coils in a Helmholtz configuration near the far end of the laser cell produced a transverse magnetic field B_T to guide the residue of the electron beam into the cell wall. GE-125 quartz [9] windows 0.51 cm thick and 16.5 cm in diameter sealed the ends of the laser cell.

Scientech [19] Model 36-0801 calorimeters having apertures of 20.3 cm were used to measure laser energy. All energy measurements discussed in this paper have been corrected for the 15-percent loss of the windows. This permits an accurate calculation of the electrical and chemical efficiencies. For the first experiments either a flat 15-cm-diam or a spherical 12.5-cm-diam (5-m-focal-length) mirror was used on the near end to

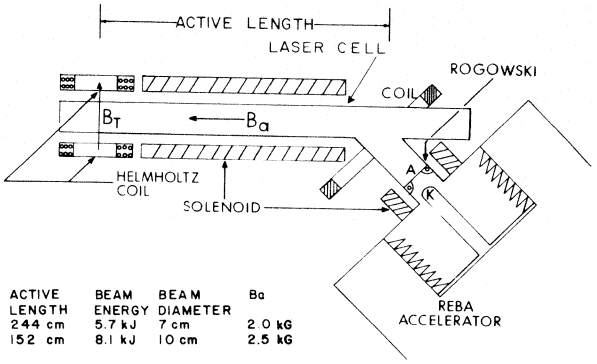

Fig. 1. Schematic view of the experimental apparatus.

compare with the case with no mirrors. In the second series a flat 15-cm-diam mirror on the near end and a confocal unstable resonator with a geometrical magnification of 2 were utilized. All mirrors were gold coated. Time-resolved measurements of the laser radiation were obtained with gold-doped germanium detectors [11] having a measured response time of about 1 ns. Time-integrated spectra were obtained for various conditions using a grating together with a focusing mirror and "footprint" paper [12]. Wavelength calibration was obtained by using the fourth and fifth orders of a He-Ne laser.

The electron-beam energy was measured at various gas pressures and positions in the laser cell using a total-stopping carbon calorimeter [13]. The accelerator diode current was measured with a fast Rogowski coil [14] and was time correlated with the laser detector signal.

III. Experimental Results and Discussion

The laser energy as a function of SF_6 pressure for a C_2H_6/SF_6 ratio of 0.10 and as a function of ethane concentration at an SF_6 pressure of 300 torr was measured to compare with the results reported in [1]. Since the optimum conditions were obtained in that experiment for a 0.10 ratio of C_2H_6/SF_6 at an SF_6 pressure of 300 torr, these conditions were used to obtain preliminary measurements. These measurements are shown in Fig. 2. The data associated with the lower curve in Fig. 2 are those taken with the long cell with either the flat or the 5-m-focal-length mirror. The same laser energy was obtained with either mirror because the *e*-beam excitation diameter was smaller than that of either mirror. The upper curve in Fig. 2 represents the data obtained with the short cell with the 15-cm-diam flat mirror on the near end. The laser energy is larger with the short cell because the electron-beam energy, and hence the deposition, was larger than in the long cell. In Fig. 2 the initial increase in laser energy with increasing SF_6 pressure is due to the increased fluorine atom concentration provided by the larger electron-beam energy deposition at higher pressures. This increase in energy deposition continues throughout the pressure range investigated. However, the deposition rate becomes increasingly nonuniform with axial position at SF_6 pressures above 200 torr causing a decrease in laser energy. At higher pressures the measured energy decreases because the nonuniform deposition effectively decreases the length and thus increases the divergence of this highly superradiant laser. Since the solid angle subtended by the laser

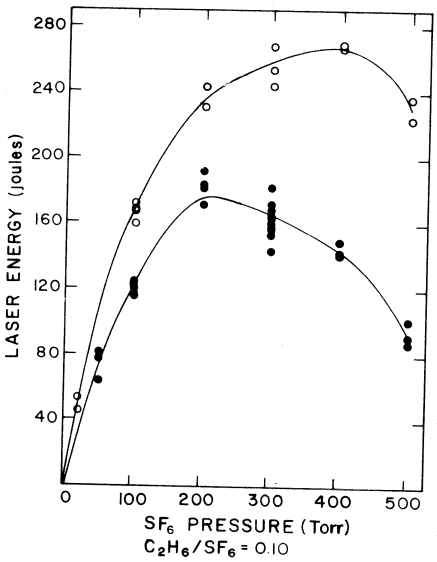

Fig. 2. Laser energy measured at the far end of the laser cell as a function of SF_6 pressure for a fixed C_2H_6/SF_6 ratio of 0.10. Mirror on near end. Closed circles are data taken with long (244-cm) cell; open circles are data taken with short (152-cm) cell.

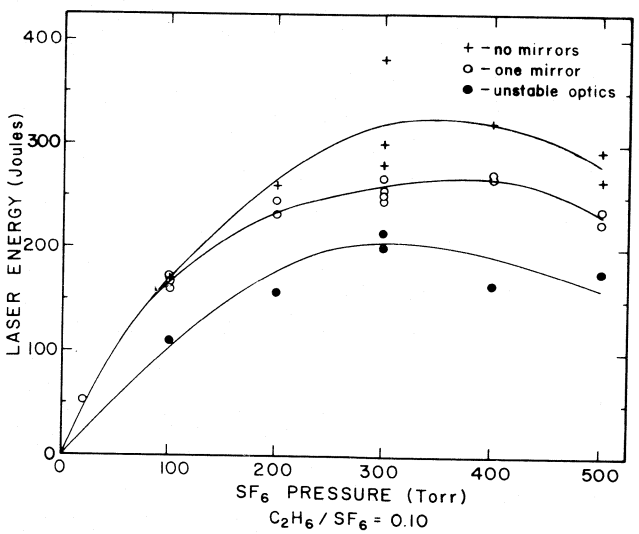

Fig. 3. Laser energy versus SF_6 pressure. Upper curve–sum of both ends with no mirrors. Middle curve–flat mirror on one end. Lower curve–unstable optics.

window is constant, a smaller portion of the total radiation can escape to be measured by the calorimeter. This same effect causes the maximum laser energy collected by the calorimeter to occur at an SF_6 pressure of 400 torr in the short tube as compared with 200 torr in the long tube.

Fig. 3 shows the effect of three optical configurations on the laser energy for the short cell. The upper curve represents the sum of the energies measured at each end of the laser cell at the various SF_6 pressures when no mirrors were used. A maximum energy of 380 J was obtained with 300-torr SF_6. The data associated with the middle curve are the same as those displayed in Fig. 2 for the energy measured at the far end with a flat mirror. The lower curve gives the energy measurements obtained with the confocal unstable resonator. These measurements were obtained after the convex mirror in the resona-

tor had been damaged by laser radiation. This damage, which began with the first shot, removed the gold coating from a 5-cm-diam area exposing the Kanigen coating on the copper mirror. Because of this damage, a direct comparison of energy obtained with the unstable optics and with the other optical arrangements cannot be expected. The total energy measured without mirrors is larger than that measured with the flat mirror by a factor of about 1.2. This ratio is consistent with values calculated for a uniformly excited superradiant laser [15]. The decrease in total laser energy with a flat mirror as compared to the two-way energy is primarily due to a decrease in the solid angle over which the radiation can escape from the cell. The mirror essentially doubles the length of the cell. For a medium excited uniformly in the axial direction, the backward-going and forward-going radiation should be equal. In the present experiment, the average ratio of the backward-to-forward radiation was 0.8.

Fig. 4 shows the measured laser energy as a function of C_2H_6 concentration for a fixed SF_6 pressure of 300 torr. These data were obtained with the long laser cell using the 5-m-focal-length mirror on the near end. The initial linear increase in laser energy with ratios of C_2H_6/SF_6 up to about 0.01 corresponds to approximately one 2.7-μ photon per initial ethane molecule. The abrupt saturation in laser energy with increasing ethane concentration is caused by the depletion of the free fluorine atoms. Following the argument of [1] and assuming that the entire measured electron-beam energy deposition was used to produce fluorine atoms, the time-integrated fluorine production was 8.2×10^{16} cm^{-3} at an SF_6 pressure of 300 torr. An ethane concentration equal to this F-atom density occurs for a relative concentration of 0.01. The fact that the optimum ethane concentration is about 0.02 rather than 0.01 is due to the decreased HF* formation rate as the fluorine and ethane are depleted. In [1] the maximum fluorine density at 300-torr SF_6 was about three times that calculated above, and the laser energy versus ethane concentration was maximum in the range from 0.06 to 0.10. This correlation was also observed in [3]. Therefore, the ethane concentration at maximum laser energy can serve as a rough indication of the free-fluorine production by the electron beam. The decrease in laser energy for ethane concentrations larger than optimum is due to HF* deactivation by C_2H_6. The decrease in laser pulsewidth with increasing C_2H_6 concentration can be explained by using the rate constant for deactivation of HF* by C_2H_6 [16]. The measured laser pulsewidth at half maximum (FWHM) for the data shown in Fig. 4 decreased from 120 ns at a C_2H_6/SF_6 ratio of 0.005 to 45 ns for a ratio of 0.3.

The relationship between the timing of the accelerator diode current and photodetector signals obtained with the short cell for various SF_6 pressures is shown in Fig. 5. The flat mirror was on the near end of the cell for these measurements. The amplitudes of the photodetector signals are not calibrated and are not all at the same sensitivity since various attenuators were required to prevent saturation of the detectors. The detector signals have been corrected in time to account for the optical transit time to the detector from the near end of the laser cell. The SF_6 pressures associated with the detector signals are shown above each trace. At low pressures there are two pulses. This behavior, which was also observed by Gross and Wesner [8], is probably due to relaxation oscillations. The average delay times between the electron-beam current and photodetector signal for an SF_6 pressure of 300 torr were 43 ns using no mirrors, 38 ns with one flat mirror, and 48 ns with the unstable resonator. As shown in Fig. 5, there was no systematic change in delay time with SF_6 pressure over the SF_6 pressure range from 100 to 500 torr. The delay time at an SF_6 pressure of 20 torr increased to 67 ns when no mirrors were used and to 45 ns when one flat mirror was used. The longer delay times at lower pressures are due to longer reaction times and to a reduced fluorine-atom production rate. The laser pulsewidth (FWHM) at 300-torr SF_6 as measured with the short cell varied between 10 and 50 ns with no correlation between pulsewidth and optical arrangement used. Part of the large variation in pulsewidth is due to the structure on the laser pulse.

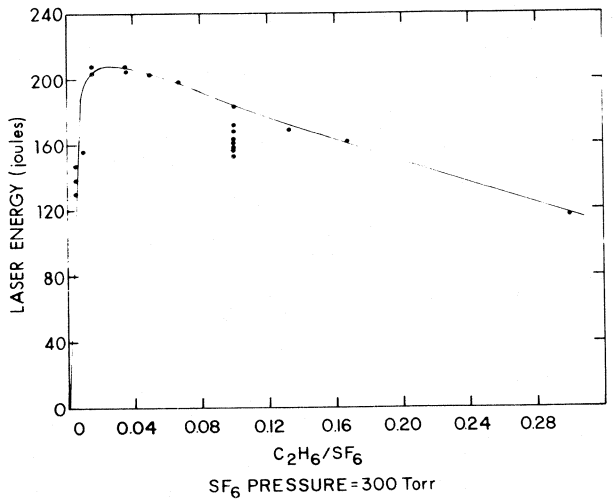

Fig. 4. Laser energy as a function of C_2H_6 concentration for a fixed SF_6 pressure of 300 torr for the long cell.

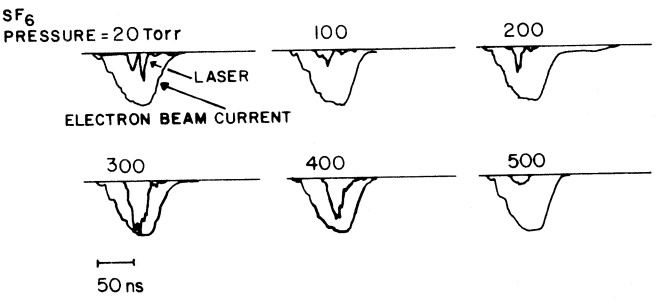

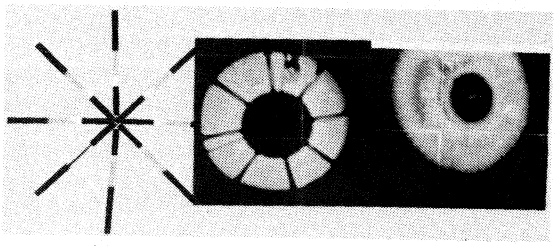

Fig. 5. Time-correlated electron-beam current and photodetector signals for the short cell with flat mirror on near end for $C_2H_6/SF_6 = 0.10$. SF_6 pressure in torr is shown above each trace.

The maximum divergence of the laser with and without a mirror, obtained by comparing the window diameter with the largest diameter of a damage pattern, was about equal to the geometrical divergence. In the case of the unstable resonator, damage patterns were taken on the first two shots with the film located first at a distance of 2.5 m from the convex mirror and then at a distance of 11.6 m. In both cases it was necessary, because of space limitations, to first turn the beam with a front surface aluminum mirror which was damaged during the shot. Fig. 6 shows the near-field radiation pattern obtained at various distances. The angular array of 6-mm-wide strips

(a) (b) (c)

Fig. 6. Near-field radiation pattern with an unstable cavity. (a) Angular array located 37.5 cm from cavity. (b) Full pattern 2.5 m from cavity. (c) Full pattern 11.6 m from cavity.

shown in Fig. 6(a) was located in front of the turning mirror 37.5 cm from the convex mirror. The shadow cast by one of the three mirror-support struts is visible on one of the lower left spokes. The pattern shown in Fig. 6(b) was obtained at a distance of 2.5 m. The irregular shadow in the upper part was cast by a small pick-off mirror used to relay a portion of the laser beam to the photodetectors. The damage pattern shown in Fig. 6(c) was taken at a distance of 11.6 m from the cavity. Because of poor access to the location where the film was placed, it was not possible to locate the film perpendicular to the beam axis. This accounts for the noncircular shape of the pattern and the fact that the pattern is not centered on the film. The three light shadows were cast by the support web for the output mirror of the unstable optics. The central shadow has decreased in diameter to ≈5 cm from the original 7.5 cm at the mirror, and the spot of Arago [17] is visible in the center of this shadow. The maximum divergence obtained from Fig. 6(a) and (c) was 1.4 mrad. The significant result is that the unstable resonator was successful in controlling this highly superradiant medium to produce a collimated laser beam.

The laser spectrum was measured for several gas compositions in the long laser cell with a mirror on one end. Only *P*-branch transitions were observed. Identification and a qualitative comparative ranking of line strengths were assigned for the various transitions. The results of these measurements are shown in Table I. In this table *W*, *M*, and *S* refer to weak, medium, and strong lines. As would be expected from the exothermic energy release in the reaction $F + C_2H_6 \rightarrow HF^* + C_2H_5$, only the $v \leqslant 3$ levels are excited. A comparison of the line strengths for the given shots indicates that usually the intensity of lines forming a cascading series tends to increase with decreasing v. The largest number of transitions are observed for the lowest SF_6 pressure. The latter result is opposite to that observed previously using a transverse discharge with various electrode configurations [18].

In order to use the electrical efficiency of an electron-beam pumped laser to determine some important parameters of the laser, it is necessary to determine the amount of energy actually deposited in the gas. Measurements of the deposited energy will also allow an estimate of the efficiency of the electron beam in producing fluorine atoms from SF_6 molecules. Total-stopping calorimetric measurements were made as a function of distance in the long laser cell at various SF_6 pressures. Ethane was not mixed with the SF_6 because the small amounts of ethane do not greatly affect the beam propagation. In addition, if ethane is used, then the calorimeter also measures the laser energy which then must be taken into account to obtain the true electron-beam deposition. The results of the calorimetric measurements for the long cell and an axial magnetic field of 2 kG are shown in Fig. 7. The axial distance is the distance measured from the accelerator anode. The dashed line at 33 cm indicates the point at which the electron beam reaches the axis of the laser cell. Each point shown on the figure represents one shot. Some of the scatter of the data is due to shot-to-shot variations in beam energy. However, the large measurement errors at 50 cm are largely due to the calorimeter not measuring the entire beam energy at all pres-

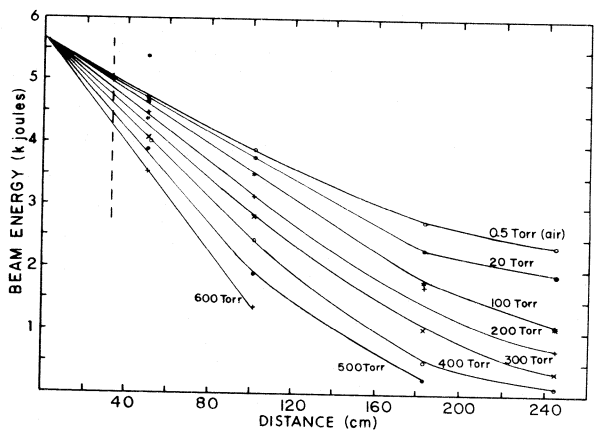

Fig. 7. Measured electron-beam energy as a function of distance, measured from the accelerator anode, for the long cell.

sures. This location is near the position where the electrons entered the laser cell. The segmented calorimeter did not always receive the entire beam energy because the electron trajectories in the magnetic field changed with pressure. The curves shown in Fig. 7 were for the most part drawn using the energy at the anode (0 cm) and the energy at the other three distances. As will be shown, the amount of energy actually deposited in the laser cell depends almost entirely on the deposition measurements at the distance of 244 cm. In addition to the propagation at various pressures of SF_6, the propagation in 0.5-torr air is also shown. These data taken with 0.5-torr air were obtained to determine the maximum beam propagation for this cell at a magnetic field of 2.0 kG. It has previously been shown that beam propagation efficiency is a maximum at about this pressure [19]. The measured beam energy shown in Fig. 7 follows an exponential decay with distance in 0.5-torr air and decreases monotonically with increasing SF_6 pressure at a given distance. A subsequent experiment using a straight tube showed that the propagation is very similar to that shown in Fig. 7. In fact, a comparison of the data shows that less than 5 percent of the beam was lost because of the bend.

Fig. 8 shows the percentage of beam energy lost as a function of density-length product. The percentage of the beam energy lost, given by the upper curves, is the difference between the measured beam energy at the anode and at each location shown on the curve. ρ is the density of gas in the cell. The data associated with curves labeled 50, 101, 183, and 244 cm were obtained from the curves in Fig. 7. The data labeled 152 cm were obtained with the short cell and an axial magnetic field of 2.5 kG. The lower solid curve is the beam-energy loss due to absorption calculated using a numerical one-dimensional computer code [20]. Results from this code are in good agreement with measurements under conditions where only deposition is important [21]. If there were no scattering of electrons out of the cell and no effect from the magnetic field, the deposited energy should only be a function of ρl. It is evident from the rapid decrease in beam energy with distance at 0.5 torr in Fig. 7, and from the large discrepancy between measured beam loss and calculated deposition in Fig. 8, that a large portion of the energy is lost by scattering to the wall. This scattering occurs because the magnetic field is not large enough to contain the electrons. The data shown by the crosses were obtained using a 140-cm-long straight cell similar to that of [1]. Starting from the upper cross, the magnetic-field values were 0, 2.0, and 4.5 kG. These points show that as the magnetic field is increased the measurements approach the calculated values. Fig. 8 shows that a determination of the deposited energy, using the difference between the energy at the anode and the measured energy at a given location, will be in error. This error will be greater for low magnetic fields and/or long laser cells. In order to take into account the amount of energy scattered to the cell walls, the energy deposited in the gas at a given SF_6 pressure is obtained by subtracting the energy measured at the given SF_6 pressure from that measured with 0.5-torr air. The energy loss at a pressure of 0.5-torr air is the amount of energy scattered to the wall since, at this pressure, less than 1 percent of the beam energy is actually deposited in the gas. This method of determining the deposited

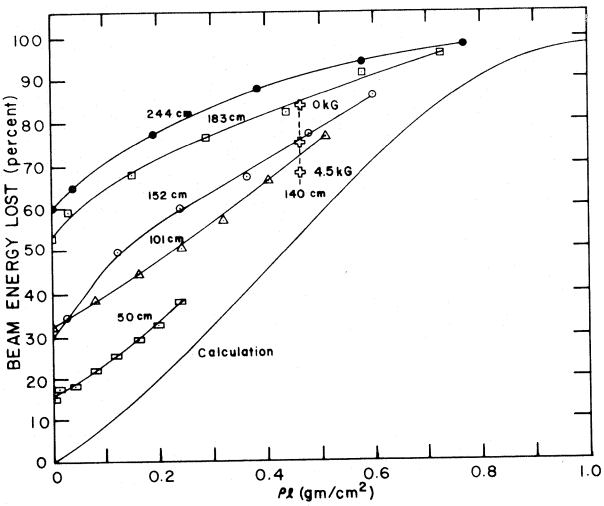

Fig. 8. Measured beam-energy loss and calculated beam absorption as a function of density-length product.

energy assumes that the scattering does not increase with cell length or with SF_6 pressure. Measurements show that scattering losses increase slightly with pressure and cell length; however, the difference between the value of the measured energy at 0.5 torr and at a given SF_6 pressure gives an upper bound to the amount of energy deposited.

Fig. 9 shows the beam-energy deposition, obtained in the manner just described, as a function of distance for the long laser cell. As was previously mentioned, the curves can be considered the upper bound on the true energy deposition in the gas. These data show that at low pressures the deposition is more or less linear with pressure over the full laser length. This means that the lasing medium is uniformly excited along the axis. At higher pressures the deposition rate decreases rapidly with increasing distance. At 600 torr, for example, most of the electron-beam energy is deposited in a length which is less than half the laser length. This nonlinear deposition with distance, along with the strong superradiance of the laser, accounts for the laser energy decrease with increasing SF_6 pressure in this experiment and that of [1]. The amount of energy actually deposited in the laser cavity is the difference between that deposited at 257 cm (extrapolated) and at 33 cm (shown by the dashed line in Fig. 9). From Fig. 9 the optimum laser length for a given reactant pressure can be determined if one uses uniform energy deposition as a criterion. Thus, for 2-MeV electrons, a laser length of 224 cm is about optimum for 200-torr SF_6 but this length decreases to 70 cm at 600 torr. Of course, the divergence angle of radiation will increase as the laser length is decreased.

Fig. 10 shows the electrical efficiencies obtained for several experiments as a function of SF_6 pressure and a C_2H_6/SF_6 ratio of 0.10. The electrical efficiency η_e was obtained by dividing the measured laser energy by the electron-beam energy deposited within the laser cavity. These are therefore minimum values of η_e since the upper bounds of deposited energy were used. Also shown are the efficiencies inferred in [1]. The maximum η_e observed is 14 percent compared to the maximum theoretical value of $\approx$24 percent [1]. The overall electrical efficiency of the laser is considerably less than that

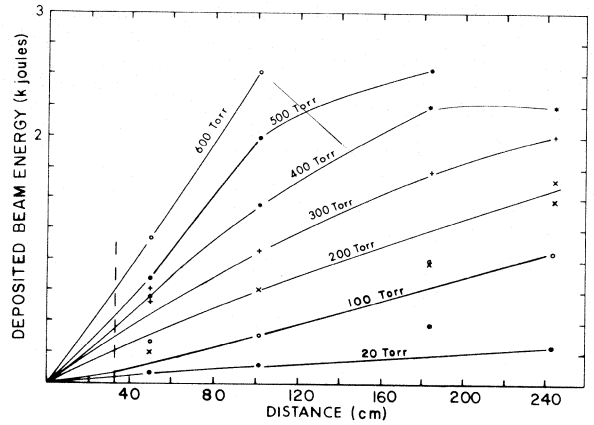

Fig. 9. Electron-beam energy deposition as a function of distance for the long cell.

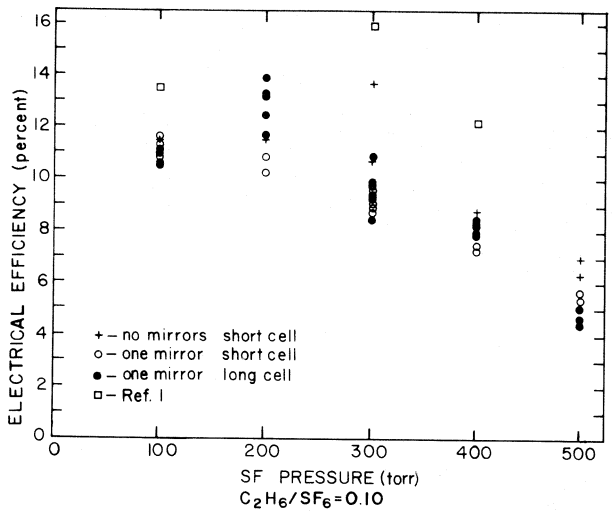

Fig. 10. Electrical efficiency η_e as a function of SF_6 pressure.

shown in Fig. 10 because the energy loss in the electron accelerator, the portion of the electron beam not used, and the energy required to produce the magnetic field have not been included. With the use of existing technology in building efficient electron-beam machines and by using transverse excitation, which uses no external magnetic field, it should be possible to obtain an overall electrical efficiency of >10 percent. The variation of efficiency with SF_6 pressure has the same general shape for all experimental conditions. Above 300 torr the decrease in efficiency is due to the decrease in laser energy caused by nonlinear electron-beam deposition.

The electrical efficiency can be used to determine several important parameters of the laser. The chemical efficiency (η_c) is defined as the fraction of the exothermic energy that appears as laser radiation. The dissociation efficiency (η_D) is the minimum energy required to produce a free fluorine atom divided by the actual energy expended in producing a free fluorine atom. The relationship between these three efficiencies is given by

$$\eta_c = \frac{\eta_e(75.9)\,[\mathrm{F}]}{\eta_D(38)\,[\mathrm{HF}^*]}. \tag{1}$$

The brackets denote the time-integrated production densities of F and HF* particles. The numerical quantities 75.9 and 38 are the endothermic and exothermic energies in kilocalories per mole associated with the reactions $SF_6 + e \rightarrow SF_5 + F + e$ and $F + C_2H_6 \rightarrow HF^* + C_2H_5$, respectively. For 300-torr SF_6 the maximum η_e observed was 14 percent. The maximum possible η_c, calculated in a manner similar to that used in [22], is 56 percent. This value is obtained by taking the percentage of the exothermic energy not remaining in the excited HF molecules after the inversion is terminated. The minimum η_c, obtained from (1) when [HF*] = [F] and $\eta_D = 1$, is 28 percent. That is, at least 28 percent of the exothermic energy appears as laser radiation. Using this range of values of η_c along with the measured laser energy, laser volume, and exothermic energy, one obtains 1.0×10^{17} cm$^{-3} \leqslant$ [HF*] $\leqslant 2.0 \times 10^{17}$ cm^{-3}. The maximum [F] is found by using the measured beam deposition, the laser volume, and the minimum energy required to produce a fluorine atom. The minimum density must be equal to the minimum [HF*] density. The limits on [F] turn out to be the same as those on HF*. The minimum value for [F] corresponds to at least 50 percent of the deposited energy being used to produce fluorine atoms. This means that the energy required to produce a free fluorine atom from SF_6 was less than 6.6 eV. This can be compared with the 4.5 eV reported in [8]. The values are in agreement since our value is an upper bound.

IV. Conclusions

The effects of optical elements on the operation of a high-energy HF laser have been investigated. The use of a single mirror on one end of the laser cell is found to reduce the laser energy to ≈80 percent of the value obtained when no mirrors are used. The effective control of the high-gain medium with a confocal unstable resonator has been demonstrated. A measured electrical efficiency of 14 percent was obtained. The minimum chemical efficiency for this laser was 28 percent. The overall efficiency ($\eta = (\eta_e \eta_c / \eta_e + \eta_c)$) for the laser is greater than 9.3 percent. Detailed measurements of electron-beam deposition in the laser gas provide a means for selecting an optimum laser length for a given operating pressure.

TA5—H_2/F_2 Flame Propagation and Repetitively Pulsed Hydrogen Fluoride (HF) Chain-Reaction Chemical Laser

HAO-LIN CHEN, JACK D. DAUGHERTY, AND WALTER FYFE

Abstract—**The burning velocity and the nature of the H_2/F_2 flame at various gas compositions have been experimentally determined. It was found that reactions induced by a diffusion-type flame proceed rather slowly, but reactions triggered by a compression wave proceed with supersonic speed. Based on the measurements of gas stability, repetitive pulse operation of H_2/F_2 chemical lasers at atmospheric pressure has been achieved.**

The second and third explosion limits of $H_2 + F_2$ reactions in O_2/He mixtures were also studied experimentally to improve our understanding of the nature of a $H_2 + F_2$ explosion. The apparatus allowed the simultaneous time-resolved measurement of both gas pressure and temperature at the center of the spherical reaction vessel. It was found that, for fixed $H_2 + F_2$ total pressure and O_2 concentration, mixtures with higher F_2/H_2 ratios are less stable and explode at a lower temperature. It appears quite certain that molecular O_2 plays an important role in the chain termination reaction. However, the addition of CF_4, SF_6, or N_2 showed no effect on the boundaries of the H_2/F_2 explosion.

I. Introduction

ALTHOUGH the H_2/F_2 chain reaction is attractive for use in chemical lasers, and efficient single-pulse lasing systems have been demonstrated, no multipulse operation has ever been achieved. This is because of the difficulties encountered in 1) handling H_2/F_2 mixtures—their chemical stability against preignition, and 2) H_2/F_2 flame control—particularly in the suppression of self-sustained chemical reactions at the upstream end of the lasing cavity. These reactions are triggered by the detonation wave or flame originating from preceding lasing pulses. During the course of this study, two separate small-scale experiments have been conducted on each of these key problems. It was found that brief preignition stability over a wide range of parameters can be achieved with suitable additives. Using a small-scale flowing apparatus, we have also measured the H_2/F_2 flame speed for various gas mixtures and have demonstrated that repetitively pulsed operation in certain mixtures of H_2, F_2, O_2, and He is possible without producing detonation-wave propagation. The flame generated by preceding pulses could be completely quenched to permit repetitive pulse operation of H_2/F_2 chemical lasers at atmospheric pressure.

Ignition of the H_2/F_2 chemical reactions from the lasing medium to the unreacted regions could be triggered by the following three different mechanisms: 1) by diffusion of active centers like F, H, HF*, and H_2^* which initiate the chain or branched chain reaction; 2) by heat transport or diffusion of translationally hot molecules or atoms which heat up the gas and perturb the stationary reaction kinetics; and 3) by pressure waves propagating from the locally heated gases with supersonic speed, which changes the stationary reaction

kinetics. At constant volume condition, both mechanisms 2) and 3) could vary the pressure and temperature of reactants drastically and lead to explosive reactions. Since both mechanisms 1) and 2) are caused from gas diffusion, the propagation speed is normally very slow and less than that of the speed of sound in the mixture. Mechanism 3) could be very fast and is normally faster than the speed of sound. Grosse and Kirshenbaum [1] have systematically measured the diffusion-flame burning velocity of pure H_2/F_2 mixtures at 90 K, and a speed of 3.5×10^3 cm/s was reported. The estimated value at room temperature was about 10^4 cm/s. Similar measurements in He diluent show much slower burning velocities at lower $H_2 + F_2$ concentrations. In our present work, a maximum burning velocity of greater than three times the speed of sound in He was observed under some conditions.

To aid our understanding of the nature of H_2/F_2 explosions triggered by the compression wave, the second and third explosion limits of the $H_2 + F_2$ reaction in O_2/He mixtures were also studied experimentally. Simultaneously, time-resolve measurements were made of both the pressure and the gas temperature at the center of the spherical reaction vessel. In general, rapid exothermic gas reactions could lead to explosions in a closed vessel by two fundamentally different mechanisms. First, by thermal explosion; it arises from the self-heating of exothermic chemical reactions, and results directly from the imbalance between generation and transport of heat. This process depends strongly on the geometry of the reacting system, but not on the nature of the surface or detailed reaction mechanism. Second, by chain-branching explosion; it depends strongly on some particular chain-branching steps, the concentration of chain—or branching—inhibitors, or the nature of the reaction vessel surface. Kapralova and Chaikin [2a)] have demonstrated the nonthermal nature of the second explosion limit of a H_2/F_2 reaction at a total $H_2 + F_2$ pressure less than 0.05 atm. In this study, the total pressure of $H_2 + F_2$ is far above 0.05 atm, and a third limit was observed. In reducing the pressure from values below the third limit down to vacuum, the existence of a second limit, reported by Kapralova *et al.* [2b)], was also confirmed.

II. Experimental Apparatus and Procedures

A diagram of the experimental arrangements for the determination of H_2/F_2 explosion limits is shown in Fig. 1. The reaction vessel is a fully passivated stainless-steel 8-l sphere. Gases were admitted into the vessel through two separate tubes with small jet holes for the purpose of rapid mixing. The estimated mixing time was less than a few minutes. A thermal bath capable of temperature variations between -80 and 100°C was used for uniform variation of vessel temperature. Cu-Constantan thermocouples with response time less than 0.1 s were used to measure the temperature of the reactants. A Kistler pressure gauge with a rise time shorter than 10^{-3} s was used to monitor the pressure inside the vessel and to confirm the time of explosion. Both signals were displayed on synchronously swept X-Y recorders. All stainless-steel flanges were vacuum sealed by metal O rings.

Before each experiment, the reaction vessel was evacuated to 10^{-3}-mmHg pressure and then cooled down to -80°C. F_2/He/O_2 gases were also precooled to -80°C, then admitted separately into the vessel until a total pressure of 1 atm was reached. The gases were allowed to mix for at least $\frac{1}{2}$ h. For the determination of the conditions of the third limit, the temperature was slowly raised (about 0.5°C/min) by adjusting the temperature of the thermal bath until an explosion occurred. To locate the region of the second limit, mixtures of identical compositions and pressures were allowed to warm up to temperatures less than that of the third explosion limit. The pressure inside the vessel was then slowly reduced until explosion commenced.

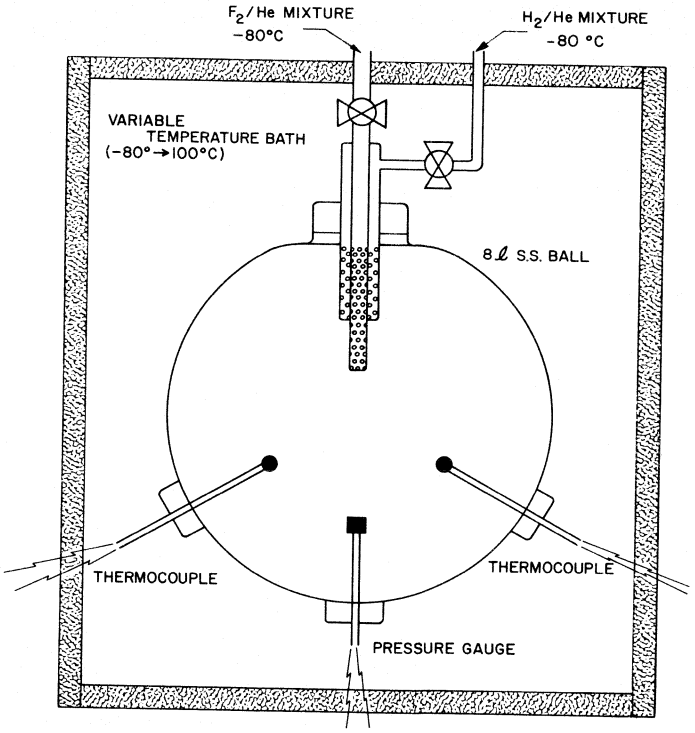

Fig. 1. Schematic diagram of apparatus used for determination of H_2 and F_2 explosion limits.

The small-scale flowing apparatus for flame-speed measurement is shown schematically in Fig. 2. Fluorine and hydrogen are each premixed with diluent helium in separate storage tanks at pressures of about 10 and 5 atm, respectively. During the experiment, fast-acting electrically operated valves, coupled with sonic metering orifices, open to admit these gases to a mixing manifold which distributes the gases in the mixing region in alternate sheets 2 mm thick as shown in Fig. 2. The cross section of this mixing region is 1.2×10 cm. The gases mix as they flow toward the test cell. From the test region, the gases flow into a dump tank. Three sets of viewing quartz windows were installed as shown in Fig. 2. In the cell, the reaction is initiated by a flash lamp located along the middle quartz window. The lamp is set to fire at a given time after the fast-acting valves open. The ultraviolet light from the lamp passes through quartz windows into the initiation section. Hg lamps emitting at 2537 Å and IP28 photomultiplier tubes coupled with 30-Å bandwidth filters located across the viewing windows are used to monitor the time history of the F_2 concentration. Kistler pressure gauges, mounted upstream and

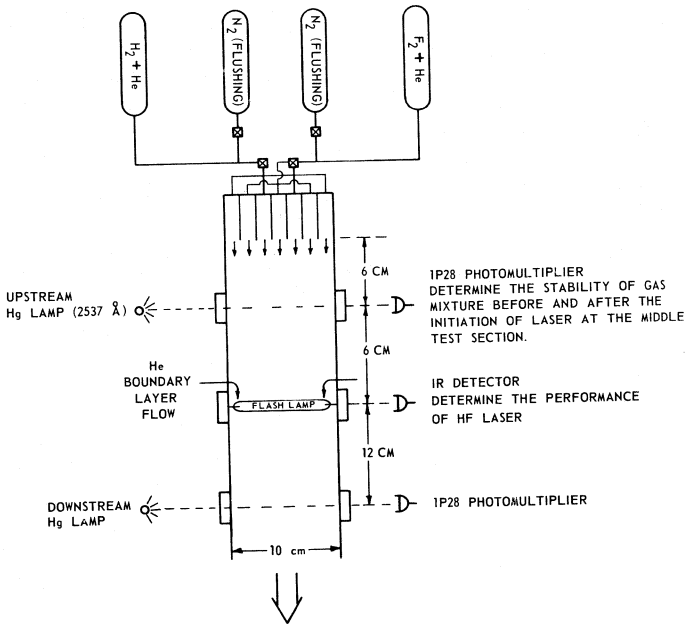

Fig. 2. Schematic diagram of apparatus used for the determination of the transient concentration of F_2 in the test cell as the reaction in the middle section was volumetrically triggered by a photolysis flashlamp. A change of F_2 concentration indicates chemical reaction in the mixture.

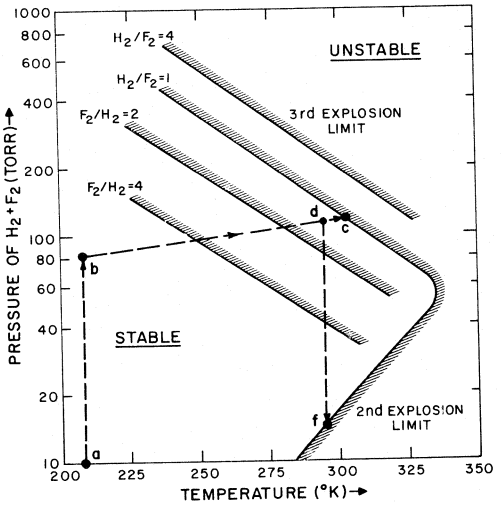

Fig. 3. The second and third explosion limits observed in H_2/F_2 mixture. The oxygen concentration was kept at 0.2 percent. The total pressure was 1 atm balanced by He. The reaction vessel was a fully passivated stainless-steel 8-l sphere. For determination of the third explosion limit for H_2/F_2 mixtures of stoichiometric H_2/F_2 ratio, the precooled H_2/He and F_2/O_2/He gases were first admitted into the vessel of same temperature (shown as line *ab*). The vessel was then allowed to warm up slowly until the explosion commenced (*bc*). For determination of the second explosion limit, an identical mixture was prepared and warmed up to point *d*. The reactant was then pumped down to lower pressure until explosion commenced (shown as line *df*).

downstream of the initiation section, are used to measure the pressure in the test cell and confirm the time of explosion if it occurs. Both the photomultiplier and pressure-gauge signals are displayed on oscilloscopes and photographed.

In the lasing experiments, the middle quartz windows were replaced by a Cu mirror with a 20-cm radius of curvature and a 20-percent output dielectric mirror. Measurements of the laser output energy were made with a calibrated calorimeter. The temporal variation of the laser duration was monitored with an InSb detector.

Matheson prepurified grade H_2 (99.95 percent), high purity grade He (99.99 percent), and high purity grade O_2 (99.95 percent), were used without further purification. In order to remove any HF contamination (~1 percent) in the Matheson F_2 gas (98 percent), it was passed through a NaF-HF adsorber prior to the preparation of the $F_2/He/O_2$ mixture. The final HF concentration in F_2 was found to be less than 0.1 percent.

III. Data

A. The H_2/F_2 Explosion Limits

Fig. 3 shows the data obtained with various $H_2/F_2/He/O_2$ mixtures. Lines *ab* and *bc* show the steps used to obtain the third-limit *P-T* data. Lines *ab*, *bd*, and *df* indicate the steps of locating regions for the second limit. It was found that for fixed O_2 concentration, the third explosion limit shifts toward higher *P-T* values as the H_2/F_2 ratio increases to values higher than stoichiometric (as shown in Fig. 3). For fixed H_2/F_2 compositions, the position of the third limit shifted to higher *P-T* values as more and more O_2 was added to the gases. The influence of other additives like SF_6, CF_4, and N_2 to the locations of the third limit was separately tested. Within the concentration range studied (<4 percent), no effect due to these additives was observed. The influence of the surface/volume ratio to the explosion boundary was also determined. By using a spherical vessel of 2-l volume, the third limit was found to be slightly shifted toward even higher pressures possibly due to heterogenous chemical reactions.

To determine the nature of the explosion—thermal or branching chain—simultaneous measurements of pressure and temperature were also made. Fig. 4 shows a typical pressure and temperature versus time record taken at pre-explosion conditions. The mixture was 5 percent H_2, 5 percent F_2, 0.2 percent O_2, and 89.8 percent He. It was found that within the response time of these measurements (for both second and third limit regions), the onset of the explosion was abrupt and no preexplosion temperature rise was observed.

B. The Results of H_2/F_2 Flame-Speed Measurements

By monitoring the time history of F_2 concentration across the viewing windows (see Fig. 2), the gas flow speeds were experimentally determined. For mixtures of 12 percent H_2, 4 percent F_2, and 84 percent He, a flow speed of (3.5 ± 1) 10^3 cm/s in our apparatus was observed. The speed varies as both gas density and tank pressure changes. The flame speed in $H_2/F_2/O_2$/He mixtures was found to depend strongly on its composition. In general, the flame speeds observed in mixtures containing a higher percentage of O_2 and larger H_2/F_2 ratios are slower than that of the gas flow speed. The data obtained in mixtures of lower O_2 concentration and larger F_2/H_2 ratios show flames propagated with supersonic speeds. For convenience, we shall call the former composition a weak-reaction mixture and the later one a strong-reaction mixture.

Fig. 5 shows the temporal intensity variation of 2537-Å

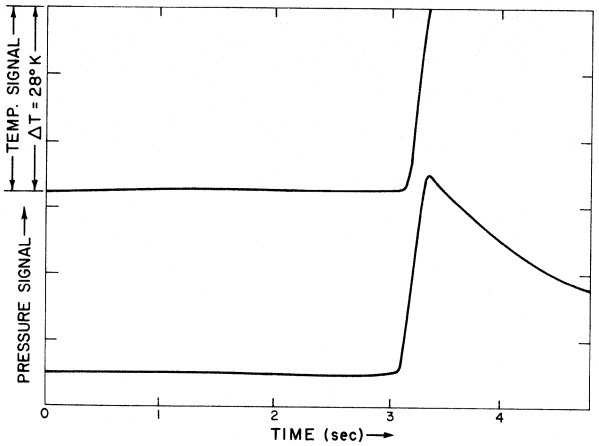

Fig. 4. The pressure and temperature time histories of H_2/F_2 reaction observed at the third explosion limit region. The upper trace shows the temperature signal and the lower trace shows the pressure pulse. No preexplosion heating was observed.

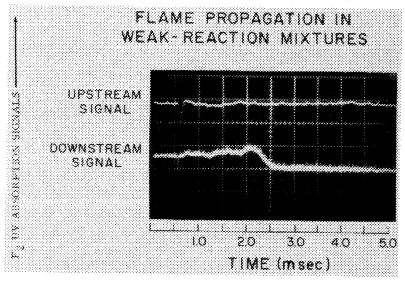

Fig. 5. Results of the transient chemical stability experiments in typical weak-reaction mixtures. The upper trace shows the transient F_2 concentration monitored at the upstream windows. The lower trace shows the signal monitored at the downstream windows. The first sharp spikes observed at each trace are the scattered light from the flashlamp. The gas composition was 12 percent H_2, 4 percent F_2, 0.4 percent O_2, and 83.6 percent He at a total pressure of 1 atm.

radiation transmitted through the two end windows monitored in a weak-reaction mixture. The gas composition was 12 percent H_2, 4 percent F_2, 83.6 percent He, and 0.4 percent O_2. The top trace, obtained at the windows upstream of the initiation section, shows no change in F_2 concentration. However, the observations at the downstream window show a decrease in F_2 absorption and hence concentration at about 1.7 ms after the initiation pulse. Since the distance between downstream windows and initiation section is about 12 cm and gas flow speed is about 3.5×10^3 cm/s, the flame velocity must also be about 3.5×10^3 cm/s. The fact that there was no apparent F_2 consumption at the upstream windows also indicates that the flame velocity for this mixture must be smaller than the flow speed.

Fig. 6 shows a set of temporal signals for a strong-reaction mixture observed at upstream, downstream, and initiation windows. The gas composition was 12 percent H_2, 8 percent F_2, 79.6 percent He, and 0.4 percent O_2. Consumption of F_2 was observed at all sections. The middle trace shows the disappearance of F_2 immediately after the flash. However, a delay of about 45 μs was observed at the downstream window, and 25 μs at the upstream window. Since the distance between windows is 12 and 6 cm, respectively (see Fig. 2), the flame speed induced in this strong-reaction mixture should be

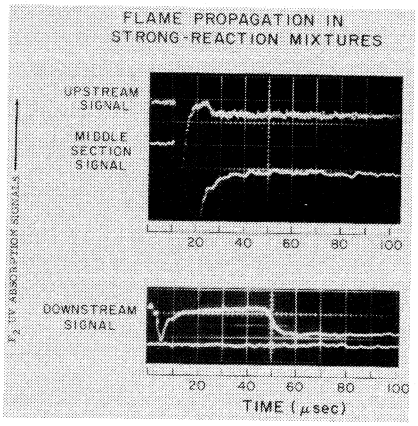

Fig. 6. Results of the transient chemical stability experiments in typical strong-reaction mixtures. The upper and middle traces show the F_2 concentration changes observed at the upstream and middle section windows, respectively. The lower trace shows the signal monitored at the downstream window. The first spikes resulting from flashlamp scattered light indicate the original triggering time of chemical reaction. The gas composition was 12 percent H_2, 8 percent F_2, 0.4 percent O_2, and 79.6 percent He at a total pressure of 1 atm.

about 2.4×10^5 cm/s or greater. Observations over extended time periods show that the upstream burning lasts for about 10 ms, but burning is sustained for more than 100 ms at downstream. By using He bleed gas to sweep out the residual gases, the duration of burning was found to be considerably shortened. Since the flame speed observed in the weak-reaction mixtures is far less than the speed of sound, flame propagation in these mixtures is probably the result of gas diffusion. The fact that the flame speed in strong-reaction mixtures was found to be far in excess of the speed of sound in gas indicates that flames in these mixtures must be propagated by a detonation wave.

C. Repetitively Pulsed H_2/F_2 Chain-Reaction Laser

For multipulse operation of H_2/F_2 chain-reaction lasers, the chemicals must stay unreacted before entering the laser cavity. Since the upstream chemicals of the strong-reaction mixtures are easily detonated by the preceding lasing pulses, they are not suitable for repetitive pulsing. Parametric determinations on the compositions that behave like strong-reaction mixtures were performed. Fig. 7 shows the short-term stability boundaries observed at various H_2, F_2, He, and O_2 compositions. These boundaries were found to shift toward higher $H_2 + F_2$ concentrations as more O_2 was added to the mixture. For a fixed O_2 concentration, the H_2-rich and F_2-lean mixtures are more stable and thus suitable for multipulse lasing.

Based on the flame data previously determined, lasing actions for weak-reaction mixtures at 10-pulses-per-second (pps) levels were successfully achieved. Fig. 8 shows the laser pulses, monitored by an InSb PEM detector, obtained in 4-percent F_2, 4-percent H_2, 91.6-percent He, and 0.4-percent O_2 mixtures. The total output energy is about 100 mJ/pulse. The laser active volume is $10 \times 1.2 \times 0.8$ cm or 10 cm^3 at atmospheric pressure. Thus a laser energy density of 10 J/l atm was demonstrated. Although the energy density obtained from this device is not optimum [3], the reproducibility between

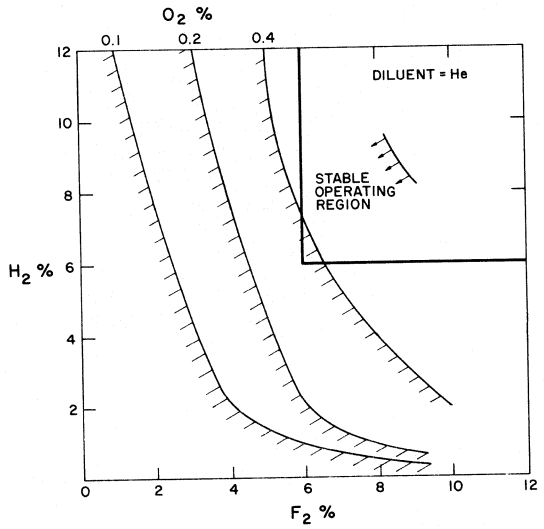

Fig. 7. Results of H_2 and F_2 short-term chemical stability mapping. Mixtures listed on the left of dashed curves are weak-reaction mixtures. The upstream reactant stays unreacted all the time. Mixtures listed on the right of dashed curves are strong-reaction mixtures. The upstream gas mixtures get detonated by the over pressure generated from the preceding laser pulse.

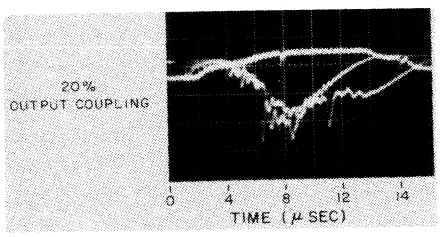

Fig. 8. The temporal behavior of HF laser outputs operated at 10-pps level. Only two pulses are shown. The flattened trace shows the transient F_2 concentration monitored at the He upstream windows. The time between pulses is about 80 ms. The decrease of F_2 concentration observed at the end of the flattened trace is due to the decrease of reactant supply pressure.

successive pulses is good. The repetition rate is design limited and could be improved to 100 pps or higher values.

IV. Discussion

A. On the Nature of H_2/F_2 Explosion

For exothermic chemical reactions in a closed spherical vessel and under conditions of conduction-dominated heat transport, the magnitude of preignition temperature rise at the center of the vessel can be approximated [4] as $\Delta T = 1.6RT_w^2/E$, where T_w is the temperature at the wall of the vessel, R is the gas constant, and E is the activation energy required for reaction. Adopting an upper limit of activation energy E of 10 kcal/mole [5] and T_w of 300 K, a preexplosion temperature rise of 28°C should be observed. Since no indication of preexplosion heating was observed, the explosion does not seem to be the result of thermal imbalance between chemical reaction and heat conduction. However, this does not rule out the possibility of a convection-controlled thermal explosion. The fact that the third limit was found to be shifted toward higher pressure, as a smaller reaction vessel was used, does indicate that the third explosion limit might still be a thermal one in nature.

It is generally believed that the first explosion limit is controlled by diffusion of the chain centers (F, H, and vibrationally excited H_2^*, HF* molecules) and hence, at low enough pressure (typically 0.01 atm or less, depending on the geometry of the reaction vessel), mixtures of H_2 and F_2 will be stable. The second explosion limit is postulated by Kapralova *et al.* [2b)], and is believed to be controlled by the branching reactions involving vibrationally excited HF* and H_2^* molecules

$$HF^* + F_2 \xrightarrow{k_1} HF + 2F \quad (1)$$

$$H_2^* + F_2 \xrightarrow{k_2} HF + H + F \quad (2)$$

and homogeneous chain-breaking reactions, like vibrational relaxation of HF*, H_2^*, or termolecular reaction of HO_2 formation

$$HF^* \text{ or } H_2^* + M \xrightarrow{k_3} HF \text{ or } H_2 + M + \Delta E \quad (3)$$

$$H + O_2 + M \xrightarrow{k_4} HO_2 + M. \quad (4)$$

Due to the similarity in P-T relations resulting from both thermal and branching-chain initiations at the high-pressure region, it is difficult to make a decisive interpretation for the third limit. Talroze *et al.* [6] proposed that the third limit might be triggered by the regeneration of chain centers through two-body reactions involving HO_2

$$HO_2 + F_2 \xrightarrow{k_5} HF + O_2 + F. \quad (5)$$

Adding excess F_2 into the $H_2/F_2/O_2/He$ mixture of stoichiometric H_2/F_2 ratio might result in three effects. First, it increases the overall heat-generation rate by enhancing reactions such as

$$F_2 \xrightarrow{\text{collisions}} 2F \quad (6)$$

$$H + F_2 \longrightarrow HF + F \quad (7)$$

where reaction (7) is the rate-limiting step involved in the H_2/F_2 chain reaction. Second, it decreases the overall thermal transport rate. Third, it increases the amount of F atoms that might be generated from reaction (5). Thus, for fixed $H_2/O_2/He$ concentrations at fixed temperature, increasing the F_2 concentration tends to lower the stability of the mixture. Since reaction (4) was thought to be the major chain termination reaction, its effect is quite straightforward. Therefore, the stable region (between the second and third limits) becomes wider as more O_2 molecules are added and narrower as the concentration of F_2 increases. With the limiting information on rate constants of the above-mentioned reactions [7]-[9] it is not possible to make precise quantitative modeling calculations or predictions about the explosion boundaries of $H_2 + F_2$ reactions. Since the boundary changes with the concentration of O_2 and not N_2, CF_4, or SF_6, molecular oxygen must have played an important role in chain-branching or breaking reactions and not merely served as an additional heat sink.

B. On the Nature of Flame Propagation

The characteristics of short-term gas stability in strong-reaction mixtures can be well explained by the long-term

explosion limits determined in Section III-A. The upstream reactant is originally stable and located at pressure-temperature conditions below the third limit. As the over pressure due to the preceding laser pulse arrives, the mixture changes into a different pressure-temperature relation and passes the boundary of the third explosion limit. Thus the reactant becomes unstable and reactive in nature. However, as more O_2 is added to the mixture, the boundary of the third explosion limit is pushed toward higher pressure and temperature. If the final pressure-temperature relation still falls within the boundary of the third explosion limit, the mixture will stay unreacted. Since the boundary of the third explosion limit lies at a region of higher pressure and temperature for H_2-rich and F_2-lean mixtures, a larger over pressure will be needed for triggering the reaction upstream.

Since the flame speeds measured in weak-reaction mixtures were found to be much slower than the gas flow speed (3.5×10^3 cm/s), the reactant at the upstream end will stay unreacted before entering the laser cavity. The flames must be propagated by diffusion mechanisms.

V. Conclusions

The two explosion limits (second and third) were studied experimentally in an apparatus which permits the simultaneous measurement of pressure and local gas temperature at the center of the spherical reaction vessel. No noticeable preexplosion heating was observed. For fixed $H_2 + F_2$ total pressure and O_2 concentration, mixtures with higher F_2/H_2 ratios are less stable and explode at lower temperature regions. Although there is not enough information available for the detailed explanation on the mechanism of H_2/F_2 explosions, molecular O_2 was observed to play an important role in the chain termination reaction. Additions of CF_4, SF_6, or N_2 showed no effect on the boundary of H_2/F_2 explosions.

In a separate small-scale flowing device, the flame propagation in H_2/F_2 was also studied. The short-term gas stability for various H_2/F_2/He and O_2 compositions was systematically determined. It was found that flames in weak-reaction mixtures are propagated by diffusion mechanism and in strong-reaction mixtures by detonation waves. Employing these weak-reaction mixtures, repetitive pulsing of H_2/F_2 lasers at atmospheric pressure was successfully demonstrated.

TB3—Measurement of Vibrational-Vibrational Exchange of Highly Excited States of Diatomic Molecules where the Collisional Probability is Approaching Unity

YEHUDA NACHSHON, STUDENT MEMBER, IEEE, AND PAUL D. COLEMAN, FELLOW, IEEE

Abstract—An experimental method, employing a fast population perturbation technique, is described to measure the vibrational-vibrational (VV) collisional probability $P_{r,r-1}^{v,v+1}$ of a diatomic molecule for large vibrational quantum numbers r and v. The relaxation of the perturbed gain of a pair of vibrational levels is a function of the vibrational populations and VV rate constants $k_{r,r-1}^{v,v+1}$. The numerical inversion of the VV master rate equations determining this relaxation does not give unique value for $k_{r,r-1}^{v,v+1}$ (or $P_{r,r-1}^{v,v+1}$), but lower bounds can be evaluated and with empirical formulas, having several adjustable constants, it can be shown that probabilities of the order of unity are required to satisfy the experimental data. The method has been specifically applied to the CO molecule, but other molecules such as $HX(X = F, Cl, Br)$, NO, etc., could also be measured.

INTRODUCTION

IN MANY molecular laser systems, the excitation mechanism produces appreciable population of highly excited ground-electronic vibrational states. This is particularly true for chemical lasers using large exothermic reactions, i.e., the CO chemical laser employing the O + CS reaction where $\Delta H = 85$ kcal/mole. Energetically, CO vibrational excitation up to $v = 16$ is allowed. The peak in the vibrational population distribution has been experimentally measured [1]-[4] to be around $v = 12$ or 13 as seen in Fig. 1.

This means that the initial vibrational-vibrational (VV) energy exchange processes of importance

$$CO(r) + CO(v) \rightleftarrows CO(r-1) + CO(v+1) \tag{1}$$

will be for both r and v in the range 8-16. Hence a quantitative understanding and analysis of this laser system requires that the rate constants $k_{r,r-1}^{v,v+1}$ (or probabilities $P_{r,r-1}^{v,v+1}$) be known for large r and v. The probability is related to the rate constant by the expression $k_{r,r-1}^{v,v+1} = P_{r,r-1}^{v,v+1}\,\bar{\sigma}\bar{v}$, where $\bar{\sigma}$ is the hard sphere cross section and $\bar{v}$ is the average thermal velocity.

Previous experimental work [5]-[8] on VV collisions of CO has been for the case $P_{r,r-1}^{0,1}$, where the transition probability is small ($\leqslant 10^{-2}$). Theoretical calculations of $P_{r,r-1}^{0,1}$ have been made by Jeffers and Kelley [9], and calculations of $P_{r,r-1}^{v,v+1}$ have been reported by Rockwood *et al.* [10], Dawson and Tam [11], Dillon and Stephenson [12], and Kelley [13]. The last two papers also consider $P_{r,r-2}^{v,v+2}$ (i.e., a $\Delta v = \pm 2$ transition), which may become important, of large v and r.

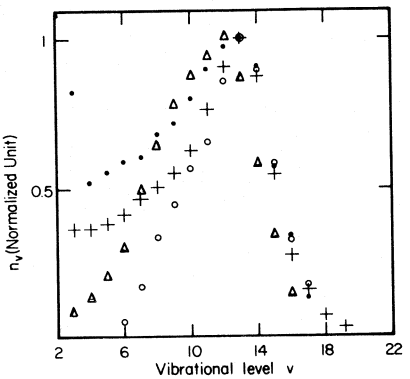

Fig. 1. Vibrational distribution from the chemical reaction $O + CS_2$. (○) Hancock *et al.* (○) Tsuchiya *et al.* (+) Powell and Kelley. (Δ) Djeu.

In this paper an experimental technique has been devised to measure $P_{r,r-1}^{v,v+1}$ for large r and v for a diatomic molecule. The method consists of first producing a peaked excited vibrational population of a diatomic molecule via a chemical reaction [14], specifically O + CS.

A short time (~ 16 μs) after electrical initiation and completion of the chemical reaction, the populations of a particular pair of CO vibrational levels are rapidly perturbed ($\leqslant 1$ μs) by means of a laser Q switch, i.e., $n_v \rightarrow n_v + \Delta n$ and $n_{v+1} \rightarrow n_{v+1} - \Delta n$. A CW CO probe laser, monitoring the gain of various pairs of vibrational levels, is used to measure the decay time of Δn. It is assumed that rotational equilibration exists and that the decay of Δn on the time scale of the experiment is determined solely by VV processes. The chemical mixture, prior to the chemical reaction, was 0.23-0.33 torr CS_2, 2.23 torr O_2, and 6.88 torr He, which should yield a large collision frequency for the CO product and a fast RT relaxation.

The calculation of the population perturbation Δn recovery time requires solving the master VV equations [15]

$$\frac{dn_v}{dt} = \sum_{r=1}^{\infty} \left(k_{r-1,r}^{v+1,v}\, n_{v+1}\, n_{r-1} - k_{r,r-1}^{v,v+1}\, n_v n_r\right) - \sum_{r=0}^{\infty} \left(k_{r,r+1}^{v,v-1}\, n_v n_r - k_{r+1,r}^{v-1,v}\, n_{v-1}\, n_{r+1}\right) \tag{2}$$

for the case where the populations of some particular levels,

P. D. Coleman is with the Electro-Physics Laboratory, Department of Electrical Engineering, University of Illinois at Urbana-Champaign, Urbana, Ill. 61801.

for example, $n_{11} \rightarrow n_{11} - \Delta n$ and $n_9 \rightarrow n_9 + \Delta n$ have been been perturbed.

The solution of (2) will be of the form

$$-\frac{1}{\Delta n}\frac{d\Delta n}{dt} = f(k, n) = \frac{1}{\gamma_{v,v-1}}. \tag{3}$$

Over a 1-3-μs time interval, associated with the decay of Δn, the populations n_r will be essentially constant which in turn will make the function f (or decay constant γ which can be measured) essentially constant.

Since γ will depend on a large number of rate constants, a unique set of rate constants cannot be determined from a few measured γ's, i.e., the problem is underdetermined. However, a lower bound can readily be calculated for the maximum rate constants or an empirical formula, having several adjustable parameters, can be assumed and the parameters determined. These procedures lead to the results for CO that $P_{r,r-1}^{v,v+1} \geqslant 0.3$ for r and v of the order of 10.

Experiment

A schematic diagram of the experimental apparatus is shown in Fig. 2. The CW CO (LN_2) electrical laser, with a single-line single-mode output power of several milliwatts, is used as a gain probe for the pulsed Q-switched CO chemical laser. This CW CO probe signal is of sufficiently low intensity as to have negligible effect on the populations of the pairs of energy levels being examined. The signals from the two CO lasers are orthogonally polarized to make it convenient to separate the CW CO signal by means of the Brewster windows and 0.35-m spectrometer. An InSb (77 K · pV) detector (0.4-μs time constant), with a 2-mm-thick Te-crystal, AR coated for 5.4 μm, filter in front of it, is used to monitor the gain.

The electrically initiated pulsed Q-switched CO chemical laser consists of a 1-in OD glass tube with electrode spacing 122 cm. A 0.015-μF capacitor, charged to 30 kV is used to initiate a chemical reaction in a mixture of 0.23-0.33 torr CS_2, 2.23 torr O_2, and 6.88 torr He to form a vibrational population of excited CO, peaked around $v = 12$. A 500-l/min mechanical vacuum pump was used to exhaust the gases which were completely exchanged after each chemically initiating electrical discharge. It is assumed that no buildup of CO($v = 0$) was occurring, that the O + CS reaction proceeded to completion, and that no appreciable amounts of OCS or CS_2 were present at the time of Q switching.

The Q switching is accomplished by a rotating mirror (300 Hz) which is synchronized with the electrical pulse so as to produce a 16-μs delay between the two. Since the round-trip gain of the Q-switched laser system is about 200 percent, it is difficult to operate on a single laser line. Generally, two laser lines go simultaneously, but this does not cause any appreciable complication in the analysis of the data. Frequency selectivity and laser-line selection are achieved in both lasers by means of reflection gratings blazed at 5.18 μm.

Experimental Data

The gain α as a function of time was measured for a number of vibrational-rotational transitions, two different cases being displayed in Fig. 3.

With the $v = 11 \rightarrow 10$, $P(17)$ and $v = 10 - 9$, $P(23)$ transitions lasing in the Q-switched mode, the gains $\alpha_{12-11}\,P(13)$ and $\alpha_{9-8}\,P(12)$ were measured as shown in the oscilloscope traces of Fig. 3(a) and (b). The gain perturbation caused by the laser Q switching is seen to appear above the normal gain versus time curve. The short (<1 μs) Q-switch laser pulse perturbs the populations about 3 percent, but this is sufficient to observe a much larger perturbation of the gain.

The gain perturbations of α_{12-11} and α_{9-8} relax back to the normal gain curves with time constants γ_{12-11} and γ_{9-8} of 1.0 and 2.2 μs, respectively. The accuracy of these time-constant data is mainly limited by the length and decay time of the lasing Q-switched pulse, hence the error in determining γ_{12-11} is greater than that in γ_{9-8}. An estimate would be ± 0.2 μs for γ_{12-11} and ± 0.1 μs for γ_{9-8}. The gain curves of Fig. 3 are tracings from the oscilloscope pictures, which degrades the data somewhat. The quoted data were obtained from the oscilloscope pictures where the base line could be determined

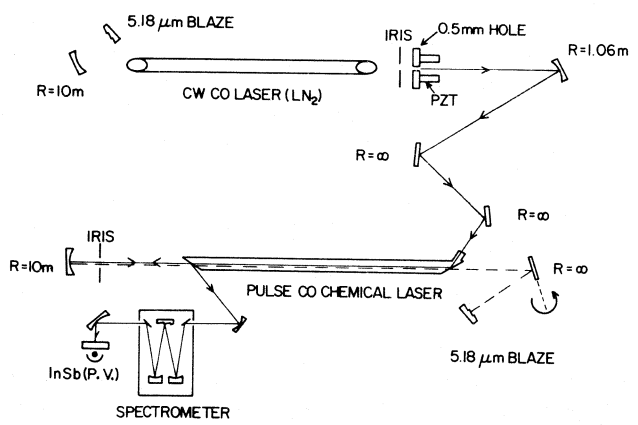

Fig. 2. Experimental configuration for measuring *VV* energy exchange on highly excited states of CO.

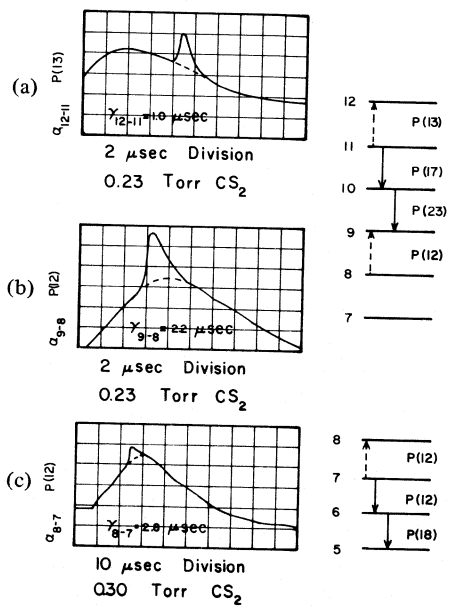

Fig. 3. The gain versus time for various P-branch transitions showing the effect of the vibrational population perturbation.

more accurately. However, the principal limitation on the accuracy of the data is the length of the Q-switched laser pulse.

With the $v = 7 \rightarrow 6$, $P(12)$ and $v = 6 \rightarrow 5$, $P(18)$ transitions lasing equally in the Q-switched mode, the decay constant of the $\alpha_{8-7}P(12)$ perturbed gain was determined from Fig. 3(c) to be 2.8 μs for the condition 0.30 torr CS_2. Over the pressure range 0.23-0.30 torr, the vibrational populations will scale as the pressure, i.e., $(n_r)_1/P_1 = (n_r)_2/P_2$. Hence, referring to (19), it is seen that $(\gamma_{8-7})_1 P_1 = (\gamma_{8-7})_2 P_2$, which will yield a value of 3.6 μs for γ_{8-7} at 0.23 torr, with an estimated error of ± 0.2 μs.

Population Distribution Measurement

It was seen from (3) that the decay constant $\gamma_{v,v-1}$ is a function of the rate constants k and the populations n_r during the time interval being considered. In order to obtain any information on the k's for a given $\gamma_{v,v-1}$, n_r must be measured.

The population distribution was determined by first measuring the gain $\alpha(J)$, $r = 9 \rightarrow 8$ for $8 \leqslant J \leqslant 16$, the P-branch transitions, and matching the experimental data to the theoretical gain curves computed from the expression [16]

$$\alpha(J)_{r,r-1} = \frac{\lambda^2 A_{r,r-1} S(\nu)}{8\pi kT} J \{n_r B_r \exp[-F(J-1)/kT] - n_{r-1} B_{r-1} \exp[-F(J)/kT]\} \quad (4)$$

where λ is the wavelength, A is the Einstein coefficient, $S(\nu)$ is the line-shape factor, B is the rotational constant, $F(J)$ is the rotational energy, k is the Boltzmann constant, and T is the translational-rotational temperature.

The problem in curve matching, using (4), is that three unknowns are present n_{r-1}, n_r (or $R = n_r/n_{r-1}$), and T. It would be desirable to obtain an independent estimate or measurement of the temperature or range of temperatures expected in the experiment to reduce the curve-fitting procedure to just two unknowns n_{r-1} and n_r.

One estimate of T can be made from a heat-balance calorimetric calculation. The pertinent chemical reactions are

$$O_2 + e \longrightarrow 2O + 117 \text{ kcal/mole} \quad (5)$$

$$O + CS_2 \xrightarrow[k_1]{} CS + SO - 32 \text{ kcal/mole} \quad (6)$$

$$O + CS \xrightarrow[k_2]{} CO + S - 85 \text{ kcal/mole} \quad (7)$$

along with the 1.4-cal electrical input from the charged capacitor.

The complete combustion of the 8.2×10^{-6} moles of CS_2 used in the experiment will require at least 8.2×10^{-6} moles of O_2 (12 percent dissociation) to be dissociated or a minimum of 1 cal of energy. Hence most of the electrical input will go into O_2 dissociation.

Assuming 25 percent of the 85 kcal/mole of reaction (7) goes into translation [1] and all of the 32 kcal/mole of reaction (6), the chemical energy input is 0.4 cal. Using 5 cal/mole for O_2 (7×10^{-5} moles) and SO (8.2×10^{-6} moles) and 3 cal/mole for He (2.4×10^{-4} moles) and S (8.2×10^{-6} moles), the temperature rise ΔT is estimated to be in the range 400-700 K.

A second estimate of the temperature can be obtained by measuring the overall $\Delta v = 1$ fluorescence of the excited $CO(v)$ produced by reaction (7) and determining the rise time which is dependent on the rate constants k_1 and k_2 and the chemical concentrations. This measurement with an InSb (Philco 301-77 K · pV) detector and an OCLI W-05050-9 wide-band interference filter yielded a time constant τ of 7 μs.

For a simple harmonic oscillator, the total fluorescent intensity for $\Delta v = 1$ transitions is independent of the VV energy-exchange process in the molecule [17]. It was found by Yardley [18] that a perturbation in the population of highly excited vibrational states of CO did not change the total fluorescence for $\Delta v = 1$ and that to see VV relaxation he had to examine $\Delta v = 2$ transitions. Hence the total fluorescent intensity for $\Delta v = 1$ transitions gives a good indication of the CO concentrations.

To relate the time constant τ to the rate constants, the rate equations for reactions (6) and (7) need to be solved.

$$\frac{dx}{dt} = k_1(a - x - y)(b - x) \quad \frac{dy}{dt} = k_2(x - y)(a - x - y) \quad (8)$$

where a and b are the initial concentrations of O and CS_2 and x and y are the concentrations of CS and CO.

Since $k_2 \gg k_1$ [19], then $dx/dt \simeq dy/dt$ and an approximate solution for y can be readily found to be

$$y \simeq \frac{a}{2}[1 - \exp(-2k_1 bt)] = \frac{a}{2}[1 - \exp(-t/\tau)]. \quad (9)$$

Hence, using the rate constant k_1 expression of Westenberg and DeHaas [19],

$$k_1 = 1.2 \times 10^{13} \exp(-525/T) = (2b\tau)^{-1} = 0.55 \times 10^{13} \text{ cm}^3 \text{ mole}^{-1} \text{ s}^{-1} \quad (10)$$

for $b = 1.3 \times 10^{-8}$ moles/cm^3, yielding a value of T of 680 K.

While these estimates of the temperature are not precise, they do suggest the theoretical gain curves be examined over the temperature range 700-1000 K. The end result of matching experimental and theoretical gain curves for $\alpha(J)$, $v = 9 \rightarrow 8$, gave a best fit for $T = 800$ K and $R = n_9/n_8$ of 1.10, from which the values of n_8 of 2.24×10^{14} and n_9 of 2.46×10^{14} cm^{-3} were obtained.

The curve-fitting details will now be summarized. Using the data $S(\nu_0) = 3.3 \times 10^{-9}$ s for a Voight profile [$S(\nu_0) = 4.3 \times 10^{-9}$ s for a pure Doppler line], $\lambda = 5.27 \times 10^{-4}$ cm, $A_{9,8} = 216.8$ s^{-1}, and $T = 800$ K, (4) can be rewritten for the case $r = 9$ as

$$\frac{\alpha(J)_{9,8}}{n_8} = 1.43 \times 10^{-17} J \{R_{9,8} B_9 \exp[-F(J-1)/556] - B_8 \exp[-F(J)/556]\} \text{ cm}^2. \quad (11)$$

The right-hand side of (11) is plotted in Fig. 4 as a function of J with the inversion ratio $R_{9,8} = n_9/n_8$ as a parameter. The experimental data for $\alpha(J)_{9-8}$ for various P-branch transitions are listed in Table I. These experimental gain data were superimposed on the theoretical gain curves of Fig. 4 by taking $\alpha(8)$

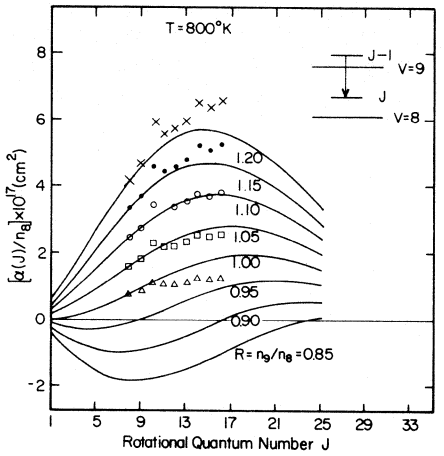

Fig. 4. The ratio of experimental gain α normalized to the vibrational population n_8 versus rotational quantum number J superimposed on theoretical curves.

TABLE I
EXPERIMENTAL DATA FOR $\alpha(J)_{9-8}$ FOR VARIOUS *P*-BRANCH TRANSITIONS

P(J)	$\alpha \times 10^3 cm^{-1}$	P(J)	$\alpha \times 10^3 cm^{-1}$	$n_8 \times 10^{-14} cm^{-3}$	$\alpha(8)/n_8 \times 10^{17}$
P(8)	5.41	P(13)	7.75	7.55	0.717
P(9)	6.03	P(14)	8.43	3.44	1.572
P(10)	7.68	P(15)	8.23	2.24	2.413
P(11)	7.20	P(16)	8.51	1.64	3.300
P(12)	7.42	-	-	1.31	4.130

and finding a value of n_8 (also listed in Table I) that matched the ratio $\alpha(8)/n_8$ to the various R parameter curves. Using these respective values of n_8, the remaining $\alpha(J)$ data were normalized to n_8 and plotted. It is seen that the experimental data most closely follow the $R_{9-8} = 1.10$ curve for the normalized density of n_8 of 2.24×10^{14} cm^3. Knowing n_8 and R_{9-8}, the value $n_8 = 2.24$, $n_9 = 2.46 \times 10^{14}$ was deduced. A similar matching of the data to theoretical curves for $T = 1000$ K, gave values $n_8 = 2.34$ and $n_9 = 2.64 \times 10^{14}$ mole/cm^3. Hence the curve-fitting procedure was not particularly sensitive to the temperature chosen. However, it is believed that the temperature can be estimated to be closer than 200 K and that 800 K gave the best fit which would suggest that error in determining the populations was less than 10 percent.

Next, by measuring the gain of the $P(12)$ transitions for $r \rightarrow r-1$ from $r = 6$ to 13, the values of n_r from $r = 6$ to 13 can be determined. This distribution of n_r, at 16 μs after initiation of the chemical reaction, is plotted in Fig. 5.

The vibrational distribution n_6-n_{13} at 16 μs after initiation of the chemical reaction is very similar to that of Fig. 1 since it has not had sufficient time to evolve. Hence to obtain values of n_r from $r = 5$ to 0 and $r = 13$ to 18, the measured curve has been extrapolated using Fig. 1 as a guide. The value of n_0 may be in question, but if all the n_r are summed, the total density of CO is 3×10^{15} cm^{-3} which would correspond to a pressure of 0.25 torr at 800 K. This pressure closely agrees with the experimental value so that assuming a value of $n_0 = 1.1 \times 10^{14}$ cm^{-3} does not seem to be incompatible.

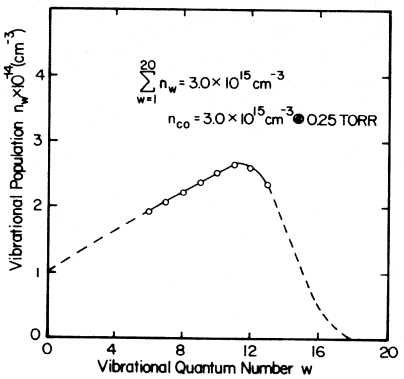

Fig. 5. The experimentally measured vibrational distribution of CO versus vibrational quantum number w, 16 μs after initiation of chemical reaction.

CALCULATION OF THE RATE CONSTANTS

At time $t = 16$ μs, when the chemical reaction was completed, the laser Q switch was applied which caused a perturbation in the CO vibrational populations. Referring to Fig. 3, in one case $P(17)_{11-10}$ and $P(23)_{10-9}$ were allowed to lase equally to produce gain perturbations of $\alpha_{12,11}$ and $\alpha_{9,8}$ as monitored by the probe CO laser.

This Q switching resulted in the population at $t = 16$ μs changing as follows:

$$n_{11} \longrightarrow n_{11} - \Delta n \quad n_{10} \longrightarrow n_{10} \quad n_9 \longrightarrow n_9 + \Delta n. \tag{12}$$

The gain $\alpha_{9,8}$ will be proportional to the population difference $[(n_9 + \Delta n) - n_8]$ so that

$$\frac{d}{dt}(\alpha_{9,8} + \Delta\alpha_{9,8}) \propto \frac{d}{dt}(n_9 + \Delta n - n_8). \tag{13}$$

If the population expressions of (12) are substituted into the master VV equation (2), the result is

$$\frac{d}{dt}(n_9 + \Delta n - n_8) = \left(\frac{d}{dt}(n_9 - n_8)\right)_{\Delta n=0} - \Delta n \left\{ 2(k^{9,10}_{9,8} + 2k^{9,8}_{9,10})n_9 + \sum_{\substack{r=1 \\ r\neq 9,11}}^{\infty} k^{9,10}_{r,r-1} n_r + 2 \sum_{\substack{r=0 \\ r\neq 9,11}}^{\infty} k^{9,8}_{r,r+1} n_r \right\} \tag{14}$$

from which the Δn term can be separated to yield

$$-\left(\frac{1}{\Delta n}\frac{d\Delta n}{dt}\right)_{9,8} = \frac{1}{\gamma_{9,8}} \tag{15}$$

where $\gamma_{9,8}$ is seen to be

$$\frac{1}{\gamma_{9,8}} = 2(k^{9,10}_{9,8} + 2k^{9,8}_{9,10})n_9 + \sum_{\substack{r=1 \\ r\neq 9,11}}^{\infty} k^{9,10}_{r,r-1} n_r + 2 \sum_{\substack{r=0 \\ r\neq 9,11}}^{\infty} k^{9,8}_{r,r+1} n_r. \tag{16}$$

A similar calculation yields for $\gamma_{12,11}$

$$\frac{1}{\gamma_{12,11}} = 2(k_{11,12}^{11,10} + 2k_{11,10}^{11,12})n_{11} + 2\sum_{\substack{r=1 \\ r\neq 9,11}}^{\infty} k_{r,r-1}^{11,12}\, n_r + \sum_{\substack{r=0 \\ r\neq 9,11}}^{\infty} k_{r,r+1}^{11,10}\, n_r. \quad (17)$$

Finally, if $P(12)_{7-6}$ and $P(18)_{6-5}$ were allowed to lase equally so that

$$n_7 \longrightarrow n_7 - \Delta n \quad n_6 \longrightarrow n_6 \quad n_5 \longrightarrow n_5 + \Delta n \quad (18)$$

the time constant $\gamma_{8,7}$ will be given by the expression

$$\frac{1}{\gamma_{8,7}} = 2(k_{7,8}^{7,6} + 2k_{7,6}^{7,8})n_7 + 2\sum_{\substack{r=1 \\ r\neq 5,7}}^{\infty} k_{r,r-1}^{7,8}\, n_r + \sum_{\substack{r=0 \\ r\neq 5,7}}^{\infty} k_{r,r+1}^{7,6}\, n_r. \quad (19)$$

As a set of algebraic equations in the rate constants, the three equations (16), (17), and (19) are greatly underdetermined since there are many more rate constants than equations. Hence a large number of sets of k's could, in principle, be found that would satisfy the three conditions. Nevertheless, without any recourse to a VV theory for the k's or a knowledge of the distribution of any set of k's, it is possible from a strictly mathematical argument to find a lower bound on the maximum k.

Consider any one of the three equations (17), (18), or (19) alone. For each equation, given the populations n_r and γ, there are a number of sets of k's, say $(k_{r,r-1}^{v,v+1})_j$ in which each $k_{r,r-1}^{v,v+1}$ is positive, that would satisfy the equations.

In each of these sets, there must be a maximum $(k_m)_j$. If one considers the maxima of all the sets, there must be a least maxima, say for the ith set, having the value $(k_m)_i$. This ith set is the distribution with all the k's equal, as can be seen from a simple example.

Let

$$a = bk_1 + ck_2 \quad (20)$$

where a, b, and c are positive constants. From a graph of (20), shown in Fig. 6, it is seen that the least maxima of k_1 and k_2 occurs when

$$k_1 = k_2 = \frac{a}{b+c} = \min\,(k_m)_i. \quad (21)$$

Any other pairs of k's will have one of the k's larger than the value of k given by (21). This argument can be extended to (17), (18), and (19).

If all the k's in (17) for the ith distribution are now placed by $(k_m)_i$, the following expression results:

$$(k_m)_j \geqslant (k_m)_i = \frac{1}{\gamma_{12,11}\left(3(n_{11} - n_9) - 2n_0 + 3\sum_{r=0}^{\infty} n_r\right)} = 1.0 \times 10^{-10}\ \mathrm{cm^3\,s^{-1}} \quad (22)$$

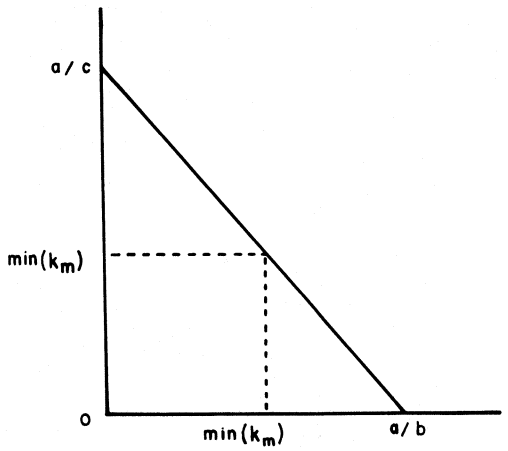

Fig. 6. Example of least maximum k's.

TABLE II
MEASURED VERSUS CALCULATED POPULATION PERTURBATION DECAY CONSTANT γ USING THE DATA $a = 3.60 \times 10^{-12}$ CM^{3}S AND $c = 0.35$

	γ_{CAL}	γ_{MEAS}
v → 12-11	1.08×10^{-6} sec	1.0×10^{-6} sec
v → 9-8	2.29	2.2
v → 8-7	3.65	3.6

corresponding to a probability $P_m \geqslant 0.3$ per hard sphere collision.

This probability, which is approaching unity, is the minimum of the least maximum probability distribution that will satisfy the equations, and it has been deduced without any appeal to any VV theory of any type.

If the VV theories, based on short-range [20] and long-range [21] (dipole-dipole interaction) potentials, are used as a guide to construct a simple empirical formula containing several adjustable parameters for the rate constants, another approximation can be made. For example, in most theories the probability per collision is proportional to the squares of the dipole matric elements of the transitions and has a maximum at resonance.

Hence the following empirical formula for the rate constant will be assumed:

$$k_{r,r-1}^{v,v+1} = a(v+1)r \exp\,[-c|v+1-r|] \quad (23)$$

where a and c are constants to be determined.

The results of using this formula in (16), (17), and (19) and the values obtained for a and c are given in Table II.

DISCUSSION

While there is a large body of literature on the theory of VV exchange in molecular collisions [22]-[24], few papers exist on the problem of exchange between highly excited states. Hence it is difficult to compare or relate the experimental work of this paper to a theory.

In most of the theoretical calculations, using both long- and short-range potentials, some perturbation technique is employed which usually requires that the interaction energy be small compared with the translational energy, and that the

transition probability be small compared with unity. Clearly, the experimental results of this paper can only be explained by taking the transition probabilities close to one, which makes comparing the results to a perturbation theory suspect.

Rockwood *et al.* [10] scaled the $k^{0,1}_{r,r-1}$ calculation of Jeffers and Kelley [9] on CO to obtain $k^{v,v+1}_{r,r-1}$ for $1 \leqslant r \leqslant 24$ and $0 \leqslant v \leqslant 10$, for a temperature of $T = 300$ K. Following the same procedure, a curve of $k^{9,10}_{r,r-1}$ versus r for $T = 800$ K was computed and plotted in Fig. 7. Superimposed on this figure is a plot of the empirical function $k^{9,10}_{r,r-1} = 10\,ar \exp[-c|10 - r|]$, whose constants were determined in this experiment. As will be noted, this empirical curve lies above the theory curve, with the peak values at $r = 10$ being 3.6×10^{-10} versus 2.45×10^{-10} $cm^3 s^{-1}$, for a rather good but perhaps coincidental fit.

Dillon and Stephenson [12] made a calculation of *VV* energy exchange which does not rely on the first Born approximation, and applied it to the dipole-dipole interaction of CO, taking the temperature to be 200 K. Their curves were not presented in the same form as those of Rockwood, but if the few data points that were available were plotted on a "Rockwood plot" of $k^{v,v+1}_{r,r-1}$ versus r, the results at 200 K would show values on resonance from one to two orders of magnitude lower while far-off resonance would show values substantially larger. There is no reason to believe that this disagreement would be substantially different at 800 K. Hence the experimental results of this paper correlate very poorly with Dillon and Stephenson's calculation.

Kelley [13], using a short-range potential, calculated a few values of $P^{v,v+1}_{r,r-1}$ for $r = 15$, $v = 13$ and $r = 21$, $v = 19$ for the collision of two diatomic molecules and obtained values as large as 0.35. If the long-range dipole-dipole interaction and the short-range interaction add in some positive manner, then Kelley would predict a total probability exceeding 0.35.

A point made by both Dillon and Stephenson and Kelley, which was not taken into account in this paper, is the probability for *VV* collisional exchanges for $\Delta v > \pm 1$, i.e., multiquantum vibrational-energy exchange. Dillon and Stephenson would predict $P^{v,v+2}_{r,r-2} \leqslant 0.1 P^{v,v+1}_{r,r-1}$ while Kelley would predict that $\Delta v = \pm 2$ transitions in CO would not be important for $v < 11$, and that a $k^{v,v+2}_{r,r-2}$ versus r curve would be sharply peaked compared to a $k^{v,v+1}_{r,r-1}$ versus r curve. If these predictions are valid, it would be difficult to see their effect on a measurement of perturbed gain decay constant γ within the experimental error.

Referring to the schematic vibrational-energy-level drawing of CO in the upper right part of Fig. 3, the gain α_{8-7} versus time was also measured. The perturbed part of the gain was also positive similar to that in Fig. 3(c). Since the population of level $v = 10$ was not perturbed, it could not transfer by a $\Delta v = 2$ *VV*-process additional perturbed population to level $v = 8$. However, level $v = 9$ could transfer additional perturbed population to level $v = 7$ by a $\Delta v = 2$ *VV* process. This would reduce the perturbed gain of α_{8-7} since it would compete with the $\Delta v = 1$ process from $v = 9$-8. These effects were not noted and hence it is concluded that the $\Delta v = 2$ processes were negligible in this experiment.

The question that always arises in this type of measurement is the effect of collision partners other than CO in the *VV* processes. Hancock and Smith [5] also addressed this problem in their paper, and it is believed that these effects are negligible in this work.

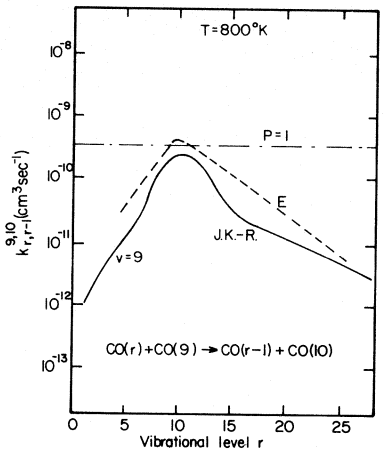

Fig. 7. Rate constants $k^{9,10}_{r,r-1}$ versus vibrational level r. The solid curve is an extrapolation of the work of Jeffers and Kelley and Rockwood *et al.* The dashed curve is a plot of the empirical formula $10\,ar \exp[-c|10 - r|]$.

The concentration of OCS that is present at 16 μs after initiation of the chemical reaction is negligible. Also the probability for the process

$$CO(v) + OCS(000) \longrightarrow CO(v - 1) + OCS(001) \qquad (24)$$

never exceeds 0.15 for all v [6].

The time scale of the gain perturbation measurements are in the range 1-2 μs. Hence the rate constants and/or the concentrations of the collision partners must be large to see an effect. Species such as He, O_2, or S do not satisfy these requirements [6].

Acknowledgment

The authors wish to thank J. T. Yardley, T. A. DeTemple, and L. H. Sentman for many discussions on the general problem of *VV* energy exchange. They also wish to thank their colleagues in the Electro-Physics Laboratory, in particular Y. Hirose, for their help.

TB4—Modeling of the CW CO Chemical Laser

H. V. LILENFELD, R. F. WEBBINK, W. Q. JEFFERS, MEMBER, IEEE, AND J. D. KELLEY

Abstract—**A computer code modeling the CS_2/O CW CO chemical laser (CL) is reported. The accuracy of the code has been tested by calculations of small-signal gain, output power, and chemical species densities in devices for which experimental data are available. Generally, good agreement is obtained. The code was also used to predict gain variations with diluent/fuel ratio, initial temperature, and cavity pressure.**

I. INTRODUCTION

MATHEMATICAL modeling of chemical and molecular lasers has been done for most of the important laser systems. Practically all of the work on chemical lasers (CL's) has concerned hydrogen halide lasers such as HCl and HF; early work was done on the pulsed HCl laser [1]-[3], followed by extensive and sophisticated efforts on the CW HF (or DF) laser [4]-[7]. The CW CO CL has received only limited analytical attention [8], [9]. This paper reports results on modeling of the CW CO CL; earlier publications documented the development of the model and computer code [10], [11]. The present version of this code is termed COMOD.

There are two important reasons to model CL systems. The first is to test the accuracy and completeness of the model's assumptions as to the phenomena occurring in laser devices. If good agreement with experimental laser performance is obtained, the model can be used to investigate the sensitivity of laser performance to variations in the values of parameters used; for example, variations in the rates of individual chemical reactions or collisional energy transfer processes. The second reason is the predictive function of laser modeling, that is, predictions of laser performance under conditions significantly different from those used in presently operating laser devices. An example of the predictive function which is particularly appropriate for CO CL's is the question of pressure scaling. The modeling code described in this paper predicts very favorable pressure scaling of the CO CL [10].

Briefly, the model described in Section II is chosen to approximate a transverse-flow CL. The fluid flow is one dimensional in that no gradients transverse to the flow direction are allowed. Mixing in the optical cavity region is described phenomenologically by an exponential mixing length. As the

fuel and oxidizer streams mix, reactions are allowed to begin; concurrently, formation and relaxation of vibrationally excited CO (CO*) are calculated along with the resultant optical gain on CO transitions. Stimulated emission is treated by an amplifier model.

In Section III results from the modeling code are compared with experimental data. Detailed measurements of small-signal gain are available for a laser device [12], and it will be shown that such data provide a stringent test of the accuracy of the model. In fact, this comparison will be used to test various pumping reaction distributions which have been reported [13]-[15]. The code has also been used to model an existing laser [16]; again good agreement with experiment is obtained. Having tested the model by comparison to experiment, Section IV concludes with predictive results on the variations of small-signal gain with pressure, diluent-to-fuel mole ratio, and initial gas temperature.

II. Chemical Laser Model

The following is a condensed description of our model for a subsonic transverse-flow CL; more detailed discussions are available [10], [11], although the treatment of reaction chemistry and vibration-vibration (VV) relaxation rates described here differs somewhat from that presented in the earlier reports.

A. Fluid Flow and Mixing

The device geometry assumed in the model is shown in Fig. 1. The model starts with an initial set of chemical species $[A]$ in the major injector A at pressure and temperature p_A and T_A. This gas is injected through a slot of width w_A and length L transverse to the flow direction, which is taken to be the x axis, and expands into the cavity region at pressure p_{cav}; the expansion is assumed to be adiabatic. Given the initial stream area and cavity pressure, the initial species densities, temperature, and stream velocity v are obtained. At point $x = 0$, the stream encounters the transverse injector B containing species $[B]$ at p_B and T_B. At $x = 0$, the stream properties are recalculated assuming that $[A]$ and $[B]$ undergo instantaneous physical (but not chemical, *vide infra*) mixing and come to an internal pressure p_{cav}. The new stream quantities (e.g., width and flow velocity) are determined using conservation of mass, number of particles, degrees of freedom, x momentum, and energy. The model has the capability of describing two distinctly different fluid-flow situations. In the first, the cavity pressure p_{cav} is held constant. Temperature increases caused by heat liberated from chemical reactions expand the stream width while the stream velocity v remains constant. This describes a situation where the stream width is much smaller than the cavity width, and the stream is allowed to expand unbounded. In the second situation, the stream width is determined externally, and any heating effects cause a change in the stream velocity and internal pressure. This describes a situation where the stream width is determined by the cavity width. This mode has previously proved useful in describing the effect of supersonic nozzle cooling on a CW CO CL [11].

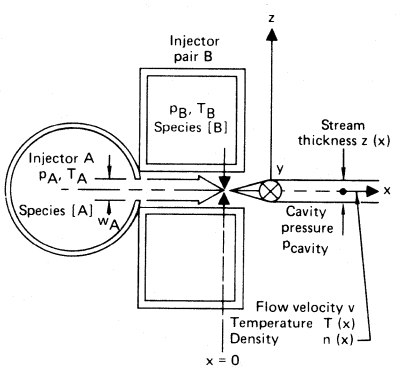

Fig. 1. Transverse-flow geometry and stream parameters used in the COMOD modeling code.

B. Chemical Reaction

Reactions between the species in $[A]$ and $[B]$ begin at $x = 0$, but to model the real situation of finite mixing rate, a phenomenological chemical mixing length l_{mix} is defined such that

$$\frac{d\xi_i}{dx} = \frac{n_i - \xi_i}{l_{mix}} - \frac{\xi_i}{z}\frac{dz}{dx} - \frac{\xi_i}{v}\frac{dv}{dx} \tag{1}$$

where n_i is the density of the ith reacting species in $[B]$ and ξ_i is that portion of n_i available for reaction with set $[A]$. The second term arises from stream expansion transverse to the flow, and the third term arises from changes in the stream velocity. The parameter l_{mix} can be estimated from experimental considerations and/or can be used as an adjustable parameter.

The model allows up to 20 chemical reactions involving up to 12 different species. In this study (see Table I), we used and compared a 3-reaction (reactions 1a, 2, 3) and 11-reaction (reactions 1-9) model. The rate constants used were experimental values, where available, or estimates. In computing stream

properties beyond injector B, account was taken of the influence of chemical reactions since the reactions change the stream composition and release heat. In calculating the reaction-generated heat release, allowance was made for the amount of energy stored in CO vibration. In most of the calculations reported here, the pumping reaction (number 2 in Table I) was assumed to form excited CO with the vibrational distribution labeled Powell and Kelley (PK) [14] in Fig. 2, although some comparison with results obtained with the Hancock, Morley, and Smith (HMS) [13] and Djeu (D) [15] distributions, also shown in Fig. 2, was also made.

C. Vibrational Relaxation

As the vibrationally excited CO is formed, collisional relaxation processes begin which modify the CO vibrational distribution as the gas mixture proceeds downstream. Thus the time-dependent or, equivalently, x-dependent CO vibrational state populations must be obtained by including the coupled rate equations for formation and relaxation into and out of each CO vibrational level. The model can treat up to 50 levels, but the calculations reported here include only the first 25 levels. In this treatment, only one quantum VV and vibration–translation (VT) process is allowed, and every species in the stream is considered separately as a relaxation partner with CO.

An important relaxation process is the redistribution of vibrational energy in the chemically pumped CO by VV transfer

$$\mathrm{CO}(m) + \mathrm{CO}(n) \rightarrow \mathrm{CO}(m-1) + \mathrm{CO}(n+1). \tag{2}$$

Probabilities for the general process in (2) were constructed from experimental measurements at 100 K (m = 2-7, n = 0) [25], 300 K (m = 2-11, n = 0) [24], [25], and 500 K (m = 2-12, n = 0) [25]. These experimental values were divided by m to obtain a reduced probability curve as a function of energy defect at each temperature. The three resulting curves were then extrapolated to m = 25, and the general temperature dependence for a given defect was obtained by fitting the three probability values to the functional form $P(T) = \exp(a + bT^{-1/3} + CT^{-1})$. The general probability, (2), was calculated by finding the appropriate defect and multiplying the reduced probability by m and n. For near resonance ($m \approx n$) with large m and n, perturbation-theory scaling with m and n leads to P values larger than unity. For large P, perturbation theory is inappropriate, and a more exact treatment [26] leads to a slower than linear increase in P with increasing m and n. To account for this, the probabilities were redefined as

$$P'(T) = \frac{P(T)}{1 + eP(T)} \tag{3}$$

with e = 2.72.

A similar procedure was used to obtain VV probabilities for $\mathrm{CO}(m) + M \rightarrow \mathrm{CO}(m-1) + M^*$. As an example, with M taken to be NO, the 300-K data [13] for m = 4-14 and for m = 1 [27] were converted to a reduced probability curve by dividing by m and using detailed balance to convert probabilities in the exothermic direction to endothermic probabilities. The curve was extrapolated to m = 25, and the temperature dependence was constructed, assuming that, for a given energy defect, the reduced endothermic probabilities vary with temperature in the same way as the CO–CO probabilities at that defect. The same procedure was used for M = O_2, NO, N_2, OCS, and N_2O with data taken from [13] and [27]. To treat CS_2 and SO_2 as transfer partners, the procedure must be modified since data are available only for CO(m = 1). For CS_2, the measured probability [28] at 300 K is 1.6×10^{-3}. If the transfer occurred to CS_2 (001), the defect would exceed 600 cm^{-1} and the probability would be expected to be much smaller than the measured value. We therefore assumed that transfer occurs to CS_2 (101) which is nearly resonant with CO(m = 1). The 300-K reduced probability curve was then generated by further assuming that the defect dependence is the same as that observed for CO–OCS VV transfer [13]; the general temperature dependence was obtained as described previously. For SO_2, the procedure was similar; the measured probability [28] for $\mathrm{CO}(1) + \mathrm{SO}_2 \rightarrow \mathrm{CO}(0) + \mathrm{SO}_2^*$ was used along the assumption that the SO_2 final state is the (011) state. For CS and SO, which are always in low concentration, no data are available, and the VV probabilities with CO were calculated from a simple short-range force theoretical model [29]. The VT probabilities for all species were calculated using standard SSH theory [30] with the range parameter l = 0.2 Å.

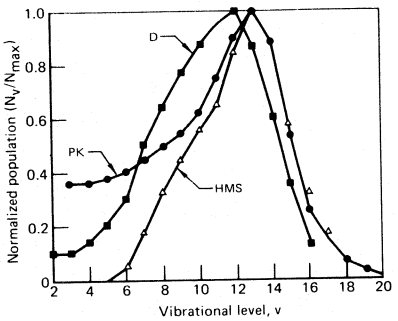

Fig. 2. Chemical distribution normalized to N_{max} = 1.0 versus vibrational level v for levels greater than v = 1. Curve labeled D is from [15], that labeled PK, from [14], and that labeled HMS, from [13].

D. Stimulated Emission

The calculation of laser output power was performed using an amplifier model; that is, an x-dependent input optical field is assumed to begin at some position x' and to vary with x. The optical path has a length L transverse to the flow direction x, and power is transferred from the medium to the field. The frequency spectrum of the field includes up to 50 P- or R-branch CO transition center frequencies, and the field intensities along the x direction may assume an arbitrary shape; Gaussian and step function intensity distributions have been the primary choices in our work. The program calculates the x-dependent optical gain coefficient, including Doppler and pressure broadening [31], for each transition of interest; the power transfer between the field and medium in an incremental distance dx along the flow is then calculated by a differential form of Beer's law

$$dP_{v,J} = I_{v,J}(x)\,[\exp(\alpha_{v,J}L) - 1]\,z(x)\,dx \tag{4}$$

TABLE II
INPUT CONDITIONS USED IN THE GAIN AND GAIN RELAXATION COMPARISON [12]

Injector A		mole/s
Flow rates	He	0.032
	O	0.001
	O_2	0.0156
P_A(Torr)	10	
T_A(K)	300	
Injector B		
Mole flow rates	CS_2	0.000526
P_B(Torr)	10	
T_B(K)	300	
Mixing length (cm)	0.5	
Cavity		
P_{cav}(Torr)	5.9	

where

$I_{v,J}(x)$ the input field intensity distribution for the transition with upper state v and lower state J;
$\alpha_{v,J}(x)$ the optical gain coefficient on the $v, J \pm 1 \rightarrow v-1$, J transition;
L the length of the stream in the y direction;
$z(x)$ the width of the stream in the z direction.

The total power delivered to the optical fields is then

$$P_{\text{rad}}(x) = \sum_{v,J} \int_{x'}^{x} \frac{dP_{v,J}}{d\xi}\, d\xi. \tag{5}$$

The saturating effects of the fields on the medium are accounted for following the technique described by Emanuel [32].

Additional quantities defined and computed are the vibrational power in the medium

$$\frac{dP_{\text{vib}}}{dx} = \overline{E}\,\frac{d\tilde{n}_{\text{CO}}}{dx}\, z(x)\, L v \tag{6}$$

and the chemical efficiency

$$\eta_{\text{chem}}(x) = \frac{P_{\text{rad}}(x)}{P_{\text{vib}}(x)} \tag{7}$$

where $\overline{E}$ is the average vibrational energy per CO molecule formed by the pumping reaction, assuming the PK distribution, $d\tilde{n}_{\text{CO}}/dx$ is the derivative of the CO density resulting only from chemical formation from reaction 2, Table I, and v is the stream flow velocity.

III. COMPARISON OF CALCULATIONS WITH EXPERIMENT

We have compared the predictions of the model for gain, gain relaxation, power output, species densities, and gas additive effects with the experimental results of various CO CL's with differing flow geometries [12], [16] in order to test the accuracy and completeness of the model and its usefulness in predicting experimental performance.

A. Comparison of Gain and Gain Relaxation Predictions with Experiment

The experimental results and flow geometry used for this set of calculations are those reported by Ultee and Bonczyk [12]. The flow rates and operating conditions used in this calculation are listed in Table II; the stream width was externally determined. For x less than 1.3 cm, dz/dx was set equal to 0.25. For x greater than 1.3 cm (the width of the flow channel), dz/dx was set equal to 0. The initial pressure in the stream was 5.9 torr and decreased less than 0.2 percent over the length of the calculation.

The gain calculated by this model will depend upon the choice of the vibrational distribution resulting from reaction 2 (Table I). A comparison was made between experimental results and the predicted gain coefficients resulting from three different experimentally determined distributions [13]-[15]. These distributions are in relatively good agreement for the higher vibrational levels ($v \geqslant 13$, see Fig. 2). The largest disagreement occurs in the lower vibrational levels. The results of this comparison are shown in Fig. 3. The HMS distribution overestimates the gain on all three lines and is clearly the least preferable. For the lowest two lines $P_7(13)$ and $P_9(11)$, the PK distribution gives the best agreement with experiment for maximum gain; gain relaxation, i.e., the rate of decrease of gain with distance downstream from the maximum, is approximately the same for all three distributions. For the highest measured line $P_{11}(10)$, the D distribution and the PK distribution yield nearly the same agreement with experiment for the maximum gain. The PK distribution was used in all subsequent calculations.

As a further check on the accuracy of the model, the J dependence of the gain on the $9 \rightarrow 8$ transition was compared with the experimental values at $x = 1.5$ cm. The results of this

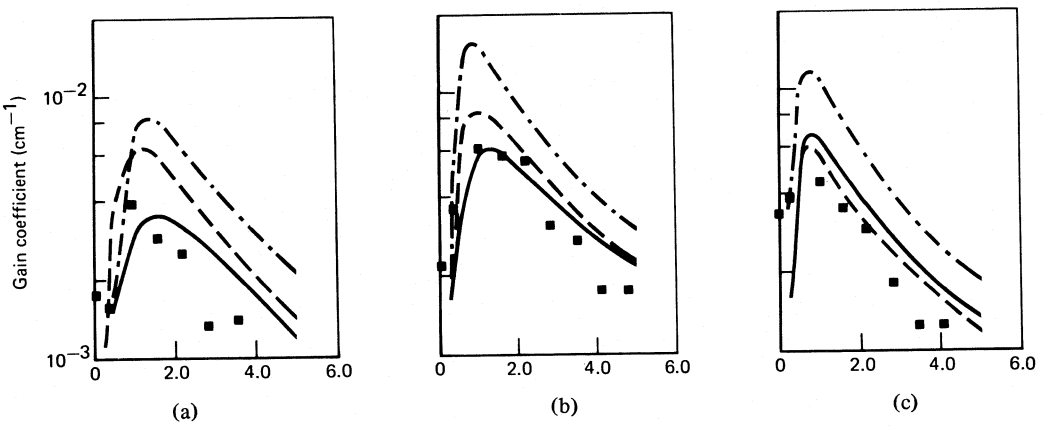

Fig. 3. Comparison of experimental and calculated gain coefficients as a function of distance downstream from the injector (cm). Three transitions are shown. (a) 7-6, $P(13)$. (b) 9-8, $P(11)$. (c) 11-10, $P(10)$. The calculations use three different initial vibrational distributions: ____PK, – – –D, and ____ ____HMS; ■ denotes data points from [12].

comparison are shown in Fig. 4. The prediction of maximum gain on $J = 12$ and the absolute value calculated agree with the experimental results within the reported experimental accuracy. The experimental and calculated values of the gain for J above and below the maximum differ appreciably. The temperature and inversion ratio predicted by the model for this position were 400 K and 1.1, respectively. An investigation of the J dependence of the gain with variable temperature and inversion ratios was made. For reasonable estimates of both of these quantities (i.e., inversion ratios from 0.95 to 1.3 and temperatures from 300 to 500 K), the calculations showed maximum gain variations of 9 percent from $J = 10$ to $J = 14$. Since no combination of inversion ratio and temperature in the gain equation could produce the large variations observed, we conclude that the actual error in the experimental data may be somewhat larger than suggested by the error bars of [12]. Alternatively, our model may overestimate the gain by ~20 percent; such a reduction in the calculated gain curve in Fig. 4 would improve the agreement.

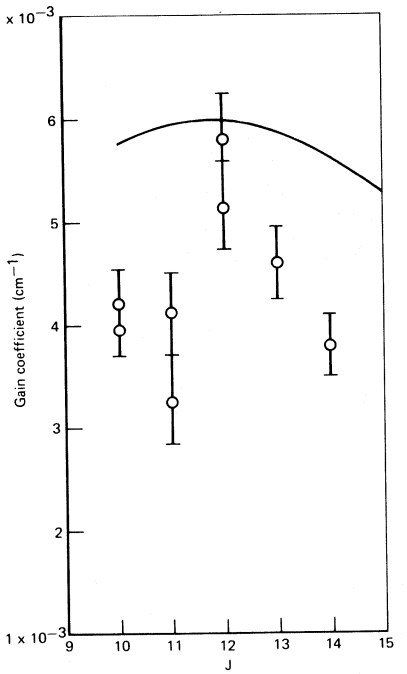

Fig. 4. J dependence of gain coefficient on the $9 \rightarrow 8$ transition at $x = 1.5$ cm. Experimental points are from [12].

B. Comparison of Predicted Output Power and Chemical Composition with Experiment

For this set of calculations, the geometry of a transverse-flow CO CL was used; experimental results are those of Jeffers and Wiswall [16]. The calculation was performed in the constant pressure mode at 5.2 torr, and the initial flow rates and injector conditions are listed in Table III. The amplifier fields used in this calculation are listed in Table IV; the field intensities were chosen to duplicate the intracavity flux of the experimental device. As a test of the degree of saturation of the medium by the input fields, the field intensities were increased by a factor of 3, resulting in an increase of only 25 percent in the calculated output power.

The effects of the chemical kinetics on predicted output power were investigated by comparison of calculations including all reactions listed in Table I with identical calculations using an abbreviated model including only three reactions (1a, 2, and 3 in Table I). These three reactions have been used previously to describe low-temperature CO CL's. The results of these calculations are listed in Table V. The predicted output power is reduced by inclusion of the eight additional reactions from 38.1 to 20.1 W. There are two important reasons for the reduced output power.

1) The inclusion of reactions 1b and 1c in the kinetics allows about about 20 percent of the CS_2 fuel to be consumed in forming the products OCS, S, S_2, and unexcited CO. This CS_2 would otherwise be available to form CS and subsequently excited CO via reaction 2. The net effect should be to reduce output power by about 20 percent.

2) The OCS formed efficiently relaxes the excited CO. The effect of OCS relaxation is shown in Fig. 5. Curve A shows the output power band spectrum predicted by the 11-reaction model ($x = 0 \rightarrow 1.5$ cm). Curve B shows the result of the

TABLE VI
COMPARISON OF 11-REACTION MODEL TO EXPERIMENT AT x = 1.5 CM

Species Densities (cm^{-3})	11-Reaction Model	Experiment[16]
He	6.0×10^{16}	6.4×10^{16}
CO	1.6×10^{15}	1.4×10^{15}
O_2	1.3×10^{16}	1.3×10^{16}
Ar	1.0×10^{16}	9.8×10^{15}
CS	3.3×10^{13}	2.7×10^{14}
SO	3.0×10^{15}	3.3×10^{14}
OCS	2.0×10^{14}	2.1×10^{14}
SO_2	1.0×10^{14}	2.3×10^{15}
CS_2	3.0×10^{14}	5.0×10^{14}
S_2O	---	1.1×10^{15}
Temperature (K)	557	520

To test the kinetics, we compared the chemical species densities and temperature predictions with the experimentally determined values. The comparison is shown in Table VI.

The good agreement between the model and experiment for the densities of the diluents (He and Ar) and O_2 indicates that the calculated stream width (z) at $x = 1.5$ is approximately correct. The CO densities in both model and experiment indicate that the formation of this species is virtually complete at this distance.

The OCS density predicted by the model is in good agreement with the experimental results. The predicted CS_2 density is in reasonably good agreement with experiment. Both model and experiment indicate that most of the CS_2 has been reacted. By adjusting the mixing length of the model (to about 0.8 cm), the model would be in better agreement with experiment. The model predicts a faster consumption rate for CS than the experiment shows. This comparison may suggest an error in the rate of reaction 2.

The predicted densities of the sulfur oxides (SO, SO_2, and S_2O) are in poorest agreement with the experiment. The mass spectroscopic results indicate more SO_2 and less SO than

predicted by the model. Lowering the activation energy of reaction 5 by an amount equal to one vibrational quanta of SO (i.e., assuming the SO produced by reaction 1a is vibrationally excited) fails to significantly influence the calculation. Thus this discrepancy remains, although we should point out that mass spectrometric sampling of radicals such as SO is very difficult and there is a possibility of forming SO_2 by wall reactions in the probe of the mass spectrometer. There is very little kinetic information on reactions forming S_2O in the chemical literature. Indeed, there are few possibilities of forming S_2O exothermically from any two-body reactions involving species found in the laser. Thus S_2O is not included in this laser kinetics code.

Finally, the temperature increase predicted by the model of 247 K (from 310 to 557 K) is in good agreement with the experimentally measured temperature rise of 210 K.

The addition of N_2O to the CO CL has been shown to increase total laser power and to shift the output power spectrum to lower bands [16]. This effect has been explained in terms of the N_2O-CO *VV* transfer probabilities [16]. The addition of N_2O to the laser modeling code does indeed increase the predicted output power from 20.0 W using Ar as the diluent to 35.1 W when N_2O is substituted for Ar. The output power band spectra for both the model and experiment are shown in Fig. 6. The calculation indicates that the power output increase occurs in the lower bands. The effect of power shift to the lower bands is clearly not as extensive as indicated by the experimental result. A possible cause of this discrepancy is the use of the amplifier field as an approximation to the laser oscillator. Table VII indicates, however, that the total power predicted by the model is in good agreement with experiment.

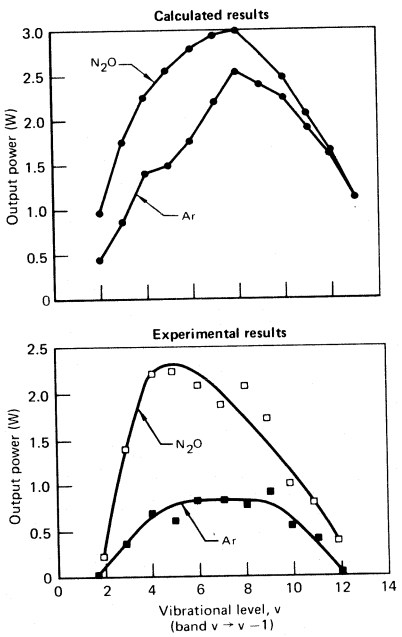

Fig. 6. Calculated output power band spectra with Ar and N_2O gas additives and the corresponding experimental results [16].

TABLE VII
PERFORMANCE COMPARISON BETWEEN MODEL AND EXPERIMENT

	11-Reaction Model	Experiment[16]
cw power (W)	35.1	28.8 (closed cavity)
Specific power (J/g)	77.1	65.5
Chemical efficiency (%)	.349	.211

IV. PREDICTIVE RESULTS

The small-signal gain [$\exp(\alpha_{v,J}L) - 1$] was investigated as a function of diluent/fuel ratio, injector temperature, and pressure.

The initial flow rates and flow geometry used in this set of calculations are listed in Table VIII. The flow rates of the reactants were held constant during all variations. The injector length was varied to ensure that the flow velocity was the same for all calculations (100 m/s).

A. Variation of Diluent/Fuel Flow Rates

It is useful to define a quantity β_F to represent the ratio of diluent flow rates to fuel flow rates by the following equation:

$$\beta_F = \frac{F(O_2) + F(N_2)}{F(CS_2)} \tag{8}$$

where $F(A)$ is the flow rate of chemical species A (in moles/s). The O_2 is included as a diluent in this definition since it is present in large excess compared with the other reactants in the $O/O_2/CS_2$ CL. The results of the variation of β_F on a typical vibrational band are listed in Table IX. The temperature increase as a result of chemical reactions in the flow stream is inversely proportional to the total heat capacity of the gases in the stream. Therefore, decreasing β_F increases the operating temperature of the laser. This in turn causes increases in the rates of the chemical reactions and the relaxation processes. The temperature increase also decreases the laser gain. Thus the maximum gain and the position of the maximum gain (determined by the chemical kinetics and relaxation processes) decrease monotonically with decreasing β_F. In some applications of high-power lasers, it is important to maximize the output power per unit mass flow. The maximum gain per unit mass flow for this system with nitrogen diluent occurs at $\beta_F = 25$.

The gain per unit mass flow can be further increased by using a lighter weight diluent like helium instead of nitrogen. Helium was therefore substituted for nitrogen in the model, and the results are shown in Fig. 7. The temperature rise in the laser is inversely proportional to the quantity η, which is defined by

$$\eta \equiv F(O_2)\, C_p(O_2) + F(\text{dil})\, C_p(\text{dil}) \tag{9}$$

where $C_p(A)$ is the constant pressure heat capacity of chemical species A in units of the gas constant R, and dil is either the chemical species N_2 or He. At identical values of η, a CL using either nitrogen or helium as diluent should produce nearly

equal output power; however, the specific output power will be greater using helium as the diluent.

B. Variation of Injector Temperature

The variation of gain with injector gas temperature is shown in Fig. 8. The gain decreases monotonically with increasing

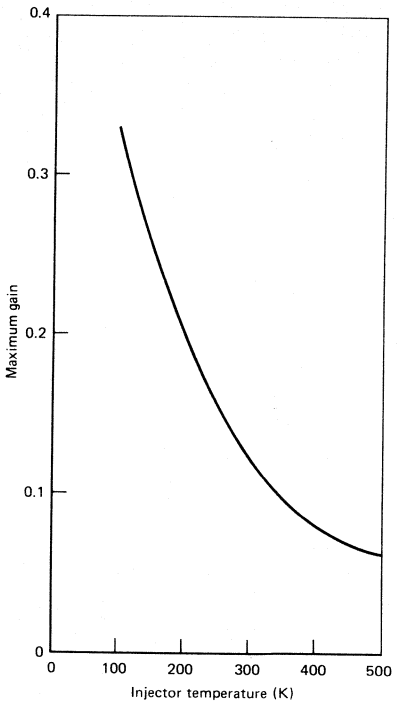

Fig. 8. Maximum gain (as in Fig. 7) versus injector temperature for the 7 → 6 band.

temperature. The calculation shows that cooling the CL medium should significantly enhance the small-signal gain.

C. Cavity Pressure Variations

The calculations of this section were designed to show the variation with cavity pressure of total gain produced by constant input flows of both reactants and diluents. As in the previous calculations of this section, the injector length was decreased with increasing pressure to maintain constant flow velocity. With constant relative amounts of input species, the rates of all two-body processes, including relaxation and chemical reactions, scale in the same way with total pressure. If only two-body processes were considered, the maximum gain in our calculation would be pressure independent; the downstream position of maximum gain on any transition would vary inversely with pressure. Processes which cause deviations from such simple pressure scaling are: 1) variations of mixing length with pressure; 2) pressure broadening of the optical line shape; and 3) three-body reactions.

The value chosen for the mixing length becomes an important consideration at pressures high enough so that mixing becomes slow compared with the chemical formation rates. To investigate the effect of mixing length on calculated laser performance, we performed two sets of calculations with pressure variations from 5 to 100 torr. In the first set, l_{mix} was taken to be 0.5 cm, a value which is appropriate to experimental devices [16]; in the second set, l_{mix} was 0.01 cm so that mixing would be rapid relative to the chemical formation rates even at 100 torr. The results of these calculations are shown in Fig. 9. Even at pressures as low as 10 torr, the in-

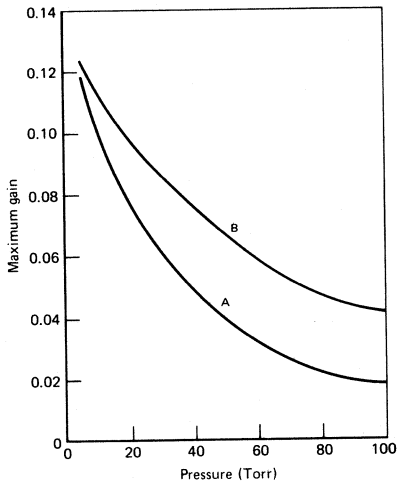

Fig. 9. Maximum gain (as in Fig. 7) versus cavity pressure for the $7 \rightarrow 6$ band. Curve A represents the calculations with $l_{mix} = 0.5$ cm. Curve B represents the calculations with $l_{mix} = 0.01$ cm.

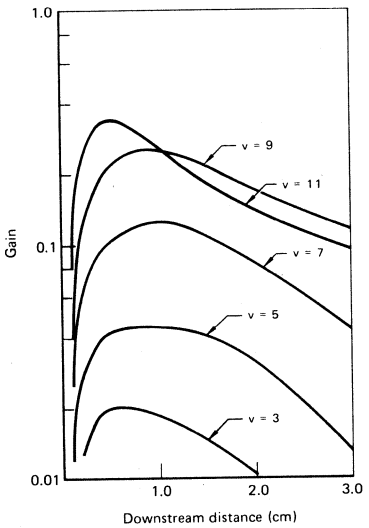

Fig. 10. Maximum gain with respect to J versus downstream position for the odd bands from $v = 3$ to $v = 11$ at 5 torr.

fluence of the 0.5-cm mixing length becomes noticeable and is increasingly important as the pressure increases. Thus mixing may be the dominant parameter determining the performance of CO CL's at high pressure.

The pressure scaling of gain relaxation is a second important effect on the operation of high-power laser systems. Gain as a function of downstream position is plotted in Fig. 10 for bands from $3 \rightarrow 2$ to $11 \rightarrow 10$. Gain relaxation after the maximum gain is reached occurs mainly by two-body collisional processes and hence will occur in a time inversely proportional to pressure. Table X shows the pressure-time products $(p \cdot \tau_{1/2})$ for gain to relax to one-half the maximum value for bands $2 \rightarrow 1$ up to $13 \rightarrow 12$. Comparison of the 5- and 100 torr $p \cdot \tau_{1/2}$ values for a given band shows deviations of less than 20 percent.

TABLE X
PRESSURE-TIME PRODUCTS FOR GAIN TO RELAX TO ONE-HALF ITS MAXIMUM VALUE

Band (v→v-1)	5 Torr $p \cdot \tau_{1/2}$ (ms Torr)	100 Torr $p \cdot \tau_{1/2}$ (ms Torr)
2	0.5	0.4

WA5—Laser-Excited Electronic-to-Electronic Energy Transfer in Sodium

HAO-LIN CHEN AND STEVE FRIED

Abstract—**Energy-transfer rates for the $E \rightarrow E$ process Na($^2P_{3/2}$) + Na ($^2S_{1/2}$) $\rightleftarrows$ Na ($^2P_{1/2}$) + Na ($^2S_{1/2}$) + ΔE = 17.2 cm^{-1} have been measured following direct excitation of specific ^2P levels with a pulsed tunable dye laser of 10^{-2}-Å linewidth and 5-ns duration. The cross sections for the forward and backward reactions at 272°C have been found by Pitre and Krause to be 250 ± 40 and 480 ± 80 Å, respectively.**

INTRODUCTION

THE DEVELOPMENT of an electronic-transition (visible or UV) gas-laser system for high-energy and high-efficiency applications has been one of the main interests in laser research for many years. In indirectly pumped laser systems, the energy-transfer rate must compete with the spontaneous-radiation rate. Since the radiative lifetimes of most known electronically excited states are rather short, between 10^{-7} and 10^{-9} s, a rapid energy-transfer rate for the upper lasing level is generally necessary. In order to measure these rates, the pulse length of the excitation source has to be sufficiently short compared with the radiative lifetime of the excited state. By using a Na resonance lamp and a Kerr-cell arrangement, Kibble *et al.* [1] have been able to generate 10-ns pulses of Na *D*-line radiation for measurement of Na (3^2P)-state lifetime. Using conventional resonance and sensitized fluorescence technique, Pitre and Krause [2] have also determinded the quenching, excitation, and doublet mixing cross sections of alkali metals. However, in order to avoid trapping of resonance radiation, all these measurements were carried out at extremely low alkali vapor pressures and at correspondingly low fluorescent intensity. In the case of near-resonant energy transfer, the small separation between the emitting lines presents additional experimental problems. In this work, by using a tunable laser of 10^{-2}-Å linewidth, we have developed a different method for measurement of these near-resonant energy-transfer processes at relatively high

metal vapor pressures. Instead of avoiding the imprisonment of radiation, we take advantage of the slow effective radiation loss and look at the wing radiations which directly reveal the translationally equilibrated populations of the excited states. In this paper, the experimental details on measurements of Na (^2P)-Na (^2S) collisional energy-transfer rates will be described.

Kinetic Scheme

The basic concept of the experiment was to selectively populate one particular excited state and to monitor the fluorescence from both the excited and collisionally transferred states. The vapor density was purposely kept at a level higher than 10^{13} atom/cm^3 to assure that the rate of radiation loss was kept small by the process of radiation trapping. Thus collision-dominated kinetics could be studied by monitoring the temporal intensity of untrapped radiation in the far wings from the excited states.

When a pure Na vapor is excited by a laser pulse of 5896 Å or 5890 Å, energy is transferred rapidly out of the excited ^2P to the other ^2P level of different J quantum number, by the processes of 1) electronic-to-electronic energy transfer between colliding atoms and/or 2) spin-orbital relaxation of the excited atom. For simplicity we shall consider only the three lowest states of Na $^2S_{1/2}$, $^2P_{3/2}$, and $^2P_{1/2}$. Sodium is excited by the laser photons of resonance frequency

$$\mathrm{Na}(^2S_{1/2}) + h\nu_{\mathrm{Laser}} \longrightarrow \mathrm{Na}(^2P_{3/2})$$

$$\mathrm{Na}(^2P_{3/2}) + \mathrm{Na}(^2S_{1/2}) \underset{k_{e'}}{\overset{k_e}{\rightleftharpoons}}$$

$$\cdot \begin{cases} \mathrm{Na}(^2P_{1/2}) + \mathrm{Na}(^2S_{1/2}) + \Delta E = 17.2\ \mathrm{cm}^{-1} \\ \mathrm{Na}(^2S_{1/2}) + \mathrm{Na}(^2P_{1/2}) + \Delta E = 17.2\ \mathrm{cm}^{-1}. \end{cases} \quad (1)$$

After the final equilibrated concentration ratio of

$$\frac{\mathrm{Na}(^2P_{3/2})}{\mathrm{Na}(^2P_{1/2})} = \frac{g_{3/2}}{g_{1/2}} \exp(-\Delta E/kT)$$

is reached, the electronic energy is subsequently depleted by energy transfer to translation in collisions with other Na atoms or by spontaneous radiations from the ^2P states

$$\mathrm{Na}(^2P_{3/2}) + \mathrm{Na}(^2S_{1/2}) \xrightarrow{k_{20}} 2\,\mathrm{Na}(^2S_{1/2}) + \Delta E$$
$$= 5890\ \text{Å} = 1.7 \times 10^4\ \mathrm{cm}^{-1} \quad (2)$$

$$\mathrm{Na}(^2P_{3/2}) \xrightarrow{k_{ir2}} \mathrm{Na}(^2S_{1/2}) + h\nu_{20} \quad (3)$$

$$\mathrm{Na}(^2P_{1/2}) + \mathrm{Na}(^2S_{1/2}) \xrightarrow{k_{10}} 2\,\mathrm{Na}(^2S_{1/2}) + \Delta E$$
$$= 5896\ \text{Å} = 1.7 \times 10^4\ \mathrm{cm}^{-1} \quad (4)$$

$$\mathrm{Na}(^2P_{1/2}) \xrightarrow{k_{ir1}} \mathrm{Na}(^2S_{1/2}) + h\nu_{10} \quad (5)$$

where k_{ir1}, k_{ir2} = [the imprisoned radiative lifetime of Na ($^2P_{1/2}$), Na($^2P_{3/2}$)]$^{-1}$, which is a constant for fixed vapor density and temperature.

The time dependence of the Na($^2P_{1/2}$) and Na($^2P_{3/2}$) concentrations is determined by the rate constants of (1)-(5). Each concentration can be described by a sum of two exponential decays [3]

$$\mathrm{Na}(^2P_{3/2})(t) = A \exp(-\lambda_1 t) + B \exp(-\lambda_2 t) \quad (6)$$

$$\mathrm{Na}(^2P_{1/2})(t) = D[-\exp(-\lambda_1 t) + \exp(-\lambda_2 t)]. \quad (7)$$

When the electronic-energy equilibration rates are faster than both the E-T and radiation losses, the λ_1 and λ_2 values can be approximated [3] as

$$\lambda_1 \approx [k_e\,\mathrm{Na}(^2S_{1/2}) + k_e'\,\mathrm{Na}(^2S_{1/2})] + \frac{k_e}{k_e + k_e'}$$
$$\cdot [k_{20}\,\mathrm{Na}(^2S_{1/2}) + k_{ir2}] + \frac{k_e'}{k_e + k_e'}$$
$$\cdot [k_{10}\,\mathrm{Na}(^2S_{1/2}) + k_{ir1}] \quad (8)$$

$$\lambda_2 \approx \frac{k_e}{k_e + k_e'} [k_{20}\,\mathrm{Na}(^2S_{1/2}) + k_{ir2}]$$
$$+ \frac{k_e'}{k_e + k_e'} [k_{10}\,\mathrm{Na}(^2S_{1/2}) + k_{ir1}] \quad (9)$$

$$(\lambda_1 - \lambda_2) \approx (k_e + k_e')\,\mathrm{Na}(^2S_{1/2})$$
$$= 1 + \frac{g_{3/2}}{g_{1/2}} \exp(-\Delta E/kT)]\, k_e\,\mathrm{Na}(^2S_{1/2}). \quad (10)$$

Thus, by measurement of λ_1 and λ_2 values at known Na ($^2S_{1/2}$) vapor pressure, it is possible to obtain the rate constants k_e and k_e'.

Experiment and Results

A simplified scheme of the experimental setup is shown in Fig. 1. The narrow-band tunable dye laser, side pumped by a nitrogen laser, emits about 5-μJ, 5-ns, and 10^{-2}-Å bandwidth pulses. Using an oscillator-amplifier arrangement, output energy of 50 μJ/pulse with similar beam quality was also obtained. The detailed laser setup is identical to that reported by Itzkan and Cunningham [4] and will not be described here.

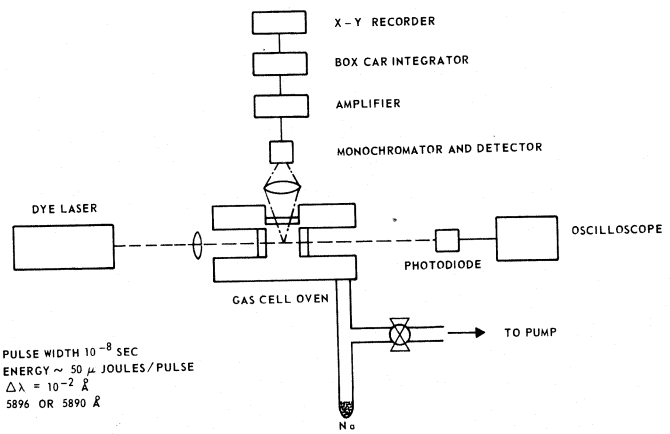

Fig. 1. Experimental apparatus for electronic energy-transfer experiments using a tunable dye laser.

The high-temperature fluorescence cell is constructed by three sapphire windows brazed in stainless-steel flanges which are sealed with the stainless-steel cell body by metal O rings. The cell is heated by an electric oven. The metallic Na reservoir is heated separately and kept at a temperature lower than that of the cell. The temperature of both the cell and reservoir are monitored by calibrated thermocouples. The vapor pressure of Na in the cell was determined from the temperature of the sidearm by means of Nesmeyanov's empirical equation and experimental data [5].

The pulse duration and energy were measured with a calibrated p-i-n photodiode. The signals were displayed on oscilloscopes and photographed. The final tuning of the excitation pulse was made by the fine adjustment of the etalon. For monitoring the resonance and sensitized fluorescence signals, a $f3.5$ light-collecting optics and $\frac{1}{4}$-m Jarrell-Ash monochromator fitted with a EMI 9529B photomultiplier were used. The signal was amplified and averaged with a PAR 160 boxcar integrator and displayed on the X-Y recorder. The overall electronic response time was less than 0.2 μs.

Typical fluorescence signals recorded by X-Y recorders are shown in Fig. 2. The cell temperature was 272°C and Na density of 8.2×10^{13} atom/cm^3. The lower trace shows the resonance-fluorescence signal from the Na($^2P_{1/2}$) state after the laser excitation. A rapid fall followed by a slower decay, as predicted by (6), was observed. The upper trace displays the sensitized fluorescence signal of Na($^2P_{3/2}$) after energy transfer from Na($^2P_{1/2}$). A fast rise and a slower decay was shown. This is again in agreement with the prediction of (7). Fig. 3(a) and (b) show the semilog plot of these data. Note that the τ_{fast} and τ_{slow} values deduced from both figures are almost identical. In exciting Na($^2P_{3/2}$) by laser pulses, a similar pattern of fluorescence signals was observed; namely, that the resonance-fluorescence signals were composed of two exponential decays and the sensitized fluorescence signal was found to rise exponentially and then decay with a slow rate. Data analysis adopting (10) yields k_e and k'_e values of $3.1 \pm 0.4 \times 10^7$ and $5.9 \pm 0.8 \times 10^7$ s^{-1}torr^{-1}, respectively. The error bars are caused mainly by uncertainties of vapor pressure of Na in the cell. The cross sections of these processes deduced from the relationship of $\sigma = k/v$ give 250 ± 40 Å [2],

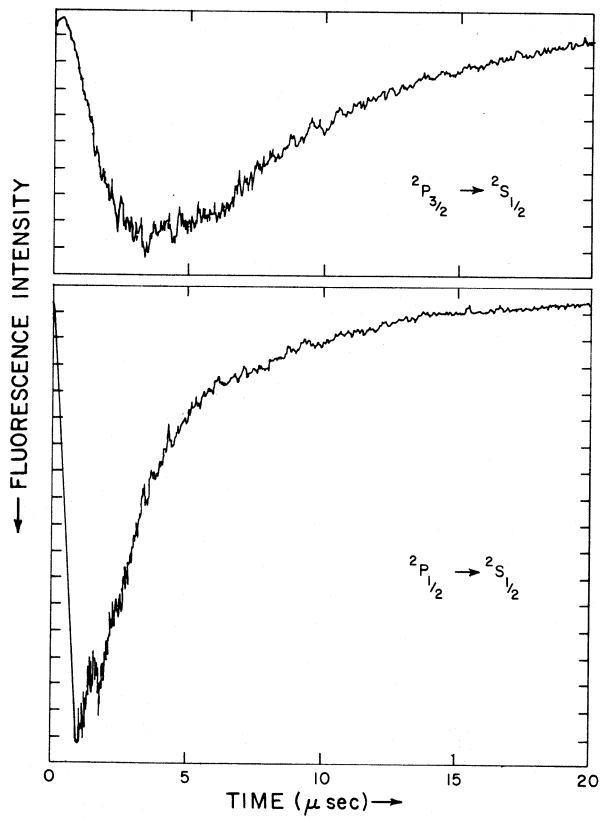

Fig. 2. Resonance and sensitized fluorescence signals of Na. The dye laser was tuned to 5896 Å. The upper trace shows the sensitized fluorescence signal of $^2P_{3/2}$-$^2S_{1/2}$ transition after laser excitation and collisional energy transfer. The bottom trace shows the resonance-fluorescence signal of $^2P_{1/2}$-$^2S_{1/2}$ transition.

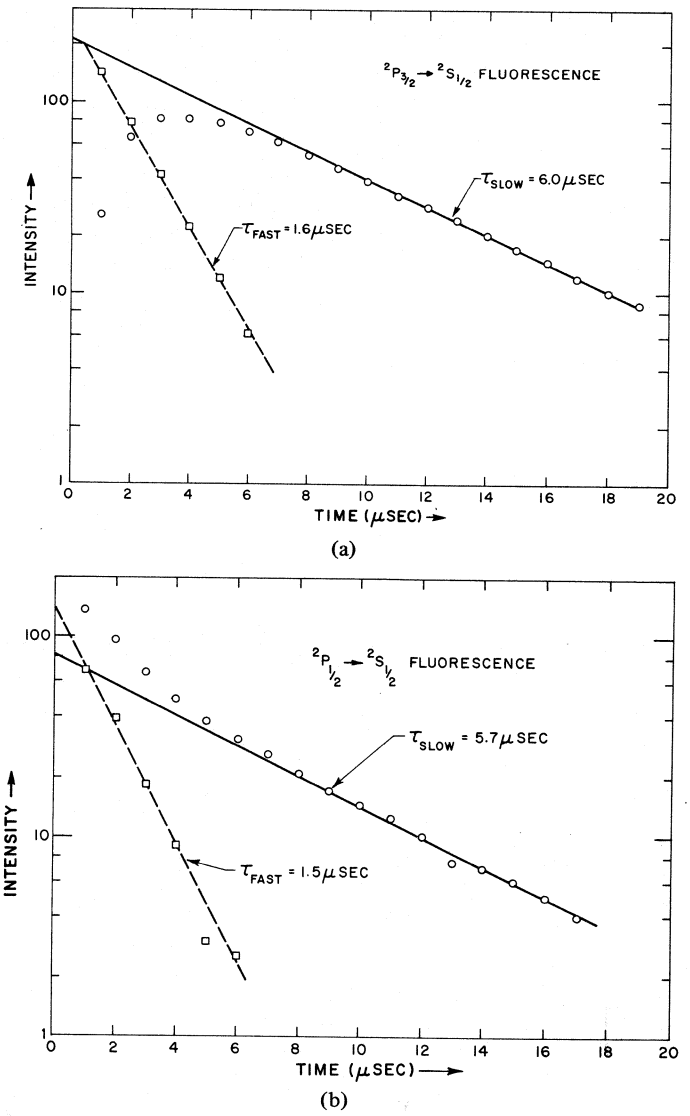

Fig. 3. Fluorescence signals analysis. (a) Semilog plot of sensitized fluorescence data. (b) Semilog plot of resonance fluorescence data. Note that the slopes of the semilog plot of both sensitized and resonance-fluorescence data are almost identical. The difference between the fluorescence trace during the first few microseconds and the solid line gives the squares (⊡) from which the τ_{fast} values are determined.

and 480 ± 80 Å [2] for transferring electronic energy from $^2P_{3/2}$ to $^2P_{1/2}$ and from $^2P_{1/2}$ to $^2P_{3/2}$, respectively. The large error bars are caused by additional uncertainty in the velocity profile or velocities of emitters.

The slow decay rate (λ_2) is believed to result mainly from the imprisoned radiative process and from *E-T* energy transfer or energy losses due to collisions with the wall. Calculations based on Milne's theory of radiation trapping [1], [6] for our experimental condition yields about 5-10 μs of imprisoned radiative lifetime, in good agreement with the observation of 6 μs.

Our measured total cross sections for $^2P_{1/2}$-$^2P_{3/2}$ mixing or the *E-E* energy-transfer process between excited and unexcited sodium atoms appears to be slightly smaller than that obtained from Pitre and Krause's data 283 Å [2] and 532 Å [2] at 151°C. The decrease in mixing cross sections in going from 283 Å [2] at 151°C to 250 Å [2] at 273°C appears to agree qualitatively with the theoretical prediction derived by Dashevskaya *et al.* [7] for the $^2P_{3/2}$-$^2P_{1/2}$ transition in the region of exchange interaction, where the total cross section decreases at $T^{-2/3}$. Of course, with the magnitude of the error bars, the limited number of data available and for the temperature ranges studied, it is difficult to draw any conclusion as to the dominating mechanism involved in the near-resonant electronic energy-transfer process in sodium. A wide temperature-variation study of these rates may provide a detailed mechanism on *E-E* energy transfer and the nature of the dominating interaction potential involved.

Owing to the very nature of radiation imprisonment in gas, caution should be exercised in obtaining *E-E* energy-transfer rate constants utilizing the "wing radiation" technique discussed previously. In order to assure translational equilibration and a slower rate of radiation loss, the vapor pressure of metal has to be kept at relatively high levels. However, it is also known that alkali metal dimerizes as the atomic density increases. For avoiding any possible complication introduced by atom-dimer collisions, it is important that the concentration of dimer in the vapor be kept at relatively low levels. Thus it is crucial that both the metallic vapor pressure and composition be accurately controlled.

WB6—DF-CO_2 Transfer Laser Development

G. W. TREGAY, M. G. DREXHAGE, L. M. WOOD, AND S. J. ANDRYSIAK

Abstract—**Power extraction and chemiluminescence experiments have been conducted in the large-scale DF-CO_2 transfer chemical laser (TCL) (IRIS-I and IRIS-II) facility at Bell Aerospace Company (BAC). The modular design of the device allowed testing to be conducted with both a supersonic nozzle bank and also in subsonic flow with sonic injection for the deuterium. Power levels of 15 kW at 10.6 μ were obtained in IRIS-I (subsonic) employing an unstable resonator with a 50-percent output coupling ratio and cavity pressure of 35 torr. For IRIS-II (supersonic) somewhat lower power was obtained. In both systems the fluorine dissociation ($\alpha = F/F + 2F_2$) was less than 0.01. Chemiluminescent emission from HF and DF was monitored under zero-power conditions along an axis parallel to the laser-mirror axis. From the measured DF-concentration profiles it can be inferred that vibrationally excited DF is being produced throughout the cavity and, accordingly, the production of DF must be attributed largely to the chain reaction.**

Manuscript received November 28, 1974; revised March 19, 1975. The chemiluminescence measurements reported here were sponsored by the U.S. Air Force Weapons Laboratory, Air Force Systems Command, Kirtland Air Force Base, N. Mex., under Contract F29601-74-C-0100. This work contains data obtained at the IRIS Transfer Chemical Laser Facility at the Bell Aerospace Company.

The authors are with Textron Bell Aerospace, P.O. Box One, Buffalo, N.Y. 14240.

Introduction

At the Third Conference on Chemical and Molecular Lasers (May 1-3, 1972) the development of the transfer chemical laser (TCL) was briefly reviewed by Cool [1]. At that time, the maximum power that had been achieved from a DF-CO_2 TCL was 563 W [2]. In this instance, the device was operated in a subsonic mode with gaseous flow transverse to

the optical axis. Atomic fluorine was generated in a precombustor by means of the reaction

$$F_2 + NO = FNO + F.$$

Deuterium was injected into the flow containing He, CO_2, F_2, FNO, and F immediately upstream of the cavity. Chemical efficiences (ratio of output power to total energy available calculated from F_2 flow rate) in the neighborhood of 4 percent were obtained from the system. From this and other evidence, it was inferred that the D_2-F_2 reaction sequence was operating in a chain mode. From the results of this [2] and other studies [3], Cool [1] was able to make optimistic predictions that the DF-CO_2 TCL laser operated in supersonic modes. Thus chemical efficiencies of 5 percent and operating pressures high enough to allow recovery to atmospheric conditions were indicated. It was further pointed out that the achievement of these goals would require an extensive engineering effort.

A large subsonic device, IRIS, has recently been developed at the Bell Aerospace Company (BAC), with goals outlined by Cool [1] kept in mind. The device has an optical-gain path of 76 cm, and to date output powers in excess of 15 kW have been obtained. Efficient system operation has been demonstrated over a wide range of parameters, including pressures as high as 60 torr. The fabrication of the IRIS device has also been modified to allow for supersonic operation. To accomplish this, the D_2 spray bars of the subsonic device were incorporated into a nozzle bank designed for an exit velocity of Mach 1.75 at 15 torr. Although precombustor chemistry and the optics available for efficient power extraction severely restrict the operational parameters, 8 kW of outcoupled power has been obtained and lasing demonstrated at cavity pressures as high as 31 torr.

The successful operation of a large DF-CO_2 TCL in both the subsonic and supersonic modes makes it appropriate to address the question of the contribution of D_2-F_2 chain-reaction chemistry to the overall laser performance in much greater detail than has been done heretofore. Accordingly, experiments have been conducted at BAC which were designed to give quantitative information regarding concentration levels for the upper vibrational states of chemically produced DF within the cavity. From the rapid quenching of the DF chemiluminescence in the presence of CO_2 [4], [5], it was anticipated that the DF concentration would be greater than the detection limit of 10^{11} molecules/cm^3, only in the vicinity of DF production. Concentrations of DF ($v \geq 3$) in the range of 2×10^{11} to 10^{14} molecules/cm^3 were observed throughout the lasing zone, from which it can be inferred that the chain reaction is the dominant mechanism of DF production.

Experimental

IRIS Laser Facility

The power tests and chemiluminescence experiments described herein were conducted on the IRIS laser shown in Fig. 1. The IRIS-I precombustor injector contains 168 elements arranged in 28 linear rows. Each row contains 6 Fuel-Ox-Fuel triplet slots, shown to exhibit the most rapid mixing.

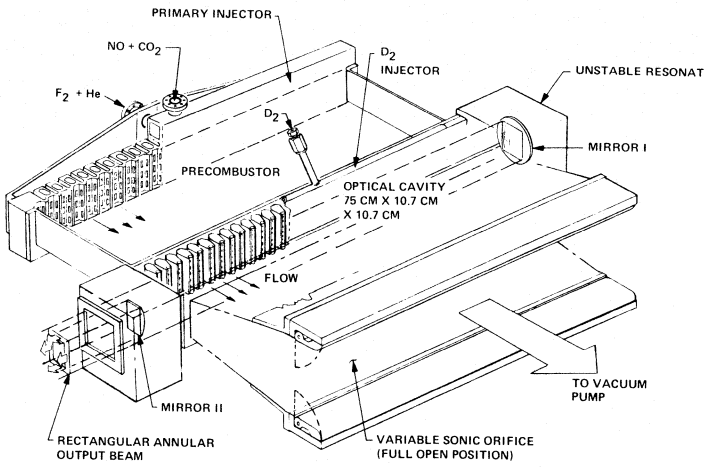

Fig. 1. IRIS laser.

Helium and fluorine comprise the oxidizer, and carbon dioxide and nitric oxide are the fuel materials. The F_2 and He as well as the CO_2 and NO are premixed prior to entering the injector in a mixer section immediately downstream of the individual gas-flow measurement sonic orifices. The precombustor consists of a rectangular TIG welded aluminum duct coated on the inside with Teflon to minimize the wall recombination. The combustor is uncooled and contains provisions for both pressure and static-temperature measurements along the combustor length. The nominal combustor length of 42 cm was derived from a complete combustor analysis to achieve a near steady-state reaction of the NO and F_2. Combustion test data substantiate the analyses performed, as indicated by the static temperature rise of the gas flow in the chamber.

The deuterium injection is accomplished through 4368 sonic orifices (0.028-cm diameter) contained in a 78-element array of 0.32-cm-diameter spray bars. Each spray bar contains two staggered rows of orifices which provides an effective orifice spacing of 0.18 cm. The spray-bar spacing is sufficiently fine (1 cm) to allow efficient penetration of the adjacent rows of D_2 sonic jets into the precombustor gas flow.

The optical cavity for IRIS is an area-defined flow channel of 5° half-angle divergence to compensate for heat release and thereby eliminate any risk of thermal choking in the flow channel. The optical-cavity portion of the flow channel measures 10.7×10.7 cm by 76 cm in width with provision for temperature and pressure measurements along the bottom wall. The optical-cavity pressure is regulated by a two-bladed variable-area sonic flow valve allowing optical-cavity pressure variation during a test from approximately 5 to 100 torr. The power-extraction optics consists of a confocal unstable resonator of 50-percent geometric output coupling. Several mirror arrangements are available for variation of beam cross-sectional area and geometry. The mirrors are uncooled copper with a nickel layer and silver coatings with thorium tetrafluoride overcoats. Power measurements are obtained by either close-coupling the beam onto a water-cooled copper calorimeter or outcoupling the beam to atmospheric pressure through NaCl or KCl windows and then onto a water-cooled aluminum calorimeter. These fast-response (1-s rise time) water-cooled

calorimeters were specially designed to operate in the range of 1-25 kW.

The IRIS-II device employs all of the IRIS-I components with the addition of a supersonic nozzle array. The deuterium-injector spray bars in IRIS-I form the base region of the IRIS-II supersonic nozzle array. The nozzle array fits over the D_2-injector spray bars. Although the IRIS-II nozzle array uses the IRIS-I optical cavity, the flow is not bounded by the flow channel and exists as a free jet. This is due in part to the large base region and the somewhat smaller supersonic nozzle height as compared to optical-cavity height. The IRIS-II flow reattaches to the flow-channel wall downstream of the optical-cavity section. Optical-cavity pressure is not finely controllable by the sonic throttling valve used for IRIS-I but is a function of precombustor operating pressure and heat release within the flow. The supersonic design Mach number is 1.75, which is quite low for an efficient system but is necessary due to chemical/gas dynamic limitations of the IRIS device. Specifically, precombustor chamber pressures less than 2 psia are desirable to minimize production of NOF, which markedly degrades laser performance, whereas cavity pressures greater than 15 torr are required to increase the chemical production rates sufficiently to confine most of the gain region within the optical cavity. The resulting 6:1 pressure ratio dictates a Mach number ~1.75.

Optical System

Spontaneous emission was monitored along an axis which was parallel to the laser mirror axis. The lens was stopped down to restrict the extent of the sample volume to less than 1 cm in the direction of the gas flow and the height varied from 2.5 to 6.5 cm over the test series. The table supporting the optical system was mounted on a translation stage, permitting the radiation to be monitored at any distance from 1 to 10.5-cm downstream. Measurements near the top of the cavity were made by displacing the optical axis 3.8 cm above the horizontal centerline of the cavity. The radiant energy emitted by the test gases was dispersed by a 0.3-m McPherson monochromator and detected by means of a RCA 7102 photomultiplier tube which was cooled to dry-ice temperatures. The signal was amplified with a high-impedance PAR amplifier, after which it was recorded on magnetic tape. A strip-chart recording was generated from the magnetic tape and used in the data reduction.

Spontaneous-Emission Measurements

Measurement of spontaneous emission originating from the upper vibrational levels is an established method [6]-[10] for obtaining concentrations of infrared active diatomic molecules. The relation between emission intensity and population is well known [11] and is reviewed briefly here. Two cases are considered: 1) determination of the population of a specific vibration-rotation state $N^{v',J'}$ from an isolated line; and 2) determination of $N^{v'}$ from unresolved lines. Rotational temperatures were obtained from the distribution of $N^{v',J'}$ in the conventional manner [6]-[9].

The intensity $I_{v,J}^{v',J'}$ due to a transition between an upper state designated by v', J' and a lower state v, J depends on the number of molecules in the initial state. The energy emitted in all directions by $N^{v',J'}$ molecules/cm^3 is given by the product of $N^{v',J'}$, the energy per photon $hc\nu$, and Einstein coefficient for spontaneous emission $A_{v,J}^{v',J'}$, i.e.,

$$I_{v,J}^{v',J'} = N^{v',J'}\, hc\nu\, A_{v,J}^{v',J'}. \tag{1}$$

An expression analogous to (1) can be derived for the relationship of vibrational populations $N^{v'}$ to the intensity of an entire vibrational-rotation band, i.e.,

$$I_v^{v'} = N^{v'}\, hc\nu_0\, A_v^{v'} \tag{2}$$

where ν_0 is the frequency of the band origin.

The Einstein coefficient for an entire vibration-rotation band $A_v^{v'}$ is related to that for an isolated rotational line of that band $A_{v,J}^{v',J'}$ by means of the following expression:

$$A_{v,J}^{v',J'} = A_v^{v'} \left(\frac{J+J'+1}{2}\right) (\nu/\nu_0)^3 F_{v,J}^{v',J'}. \tag{3}$$

Here $F_{v,J}^{v',J'}$ is the vibration-rotation interaction factor for the rotational line and $\frac{1}{2}(J+J'+1)$ is the associated line strength for a transition having on P and R branches.

It is desirable whenever possible to use single lines to determine $N^{v',J'}$; however, there are several instances where this may become difficult. For systems with HF or DF, partial pressures of several torr and long path lengths (10 cm or greater), an additional effect must be considered. Thus emission from one region may be absorbed by unexcited molecules in another (self-absorption) and (1) and (2) will not be valid [8]. This problem can be largely avoided by monitoring emission from the overtone bands which have smaller Einstein coefficients and by properly adjusting the depth of the media from which radiation is extracted. The Einstein coefficients [12] decrease rapidly with increasing v; for DF, $A_2^3 = 130\ s^{-1}$; $A_1^3 = 14\ s^{-1}$; and $A_0^3 = 0.18\ s^{-1}$. A compromise [6]-[8] which has been successfully used is to monitor the $\Delta v = 3$ bands of HF and the $\Delta v = 3$ and $\Delta v = 4$ bands of DF with one of the very sensitive near-infrared photomultiplier tubes. To resolve individual spectral lines, however, there must be sufficient intensity to reduce the spectrometer slit widths to obtain a resolution smaller than the line spacing. These conditions are more easily realized for HF with its large transition probability ($A_0^3 = 1.22\ s^{-1}$, rotational spacing ~50 cm^{-1}) than for DF ($A_0^3 = 0.18\ s^{-1}$, rotational spacing ~25 cm^{-1}).

If the individual lines are not resolved the vibrational population may still be determined from a group of lines [7], [10]. For the particular case of DF, the rotational constants are such that bandheads occur at $J' = 9$-10 in the R branch of the second and third overtone bands of DF. If the overlapping lines are properly accounted for, then the bandhead intensity is a specific fraction of the band intensity and therefore proportional to $N^{v'}$. Evaluation of the proportionality constant S involves a summation within the bandhead of the individual rotational line intensities weighted by the spectrometer slit function ϕ, which is evaluated at the bandhead frequency, i.e.,

$$S = \sum_{J'} [(\nu/\nu_0)^4 F_{v,J}^{v',J'} Q_{\text{rot}}^{-1} \tfrac{1}{2}(J+J'+1) \cdot \exp[-J'(J'+1) B_{v'} hc/(kT)]\ \phi(\nu_{\text{bandhead}} - \nu)]. \tag{4}$$

In practice the experimentally determined bandhead intensity must be corrected for the contribution of neighboring bands. For a single-band sequence this correction factor varies from 1.0 to 0.75 and must be determined numerically. The previous equations have been derived for radiation into a sphere; however, the spectrometric system collects only a small portion of the light emitted. By carefully defining the solid angle this fraction could be determined to within 10 percent.

Results and Discussion

Power Measurements

The output power of IRIS-I has been measured over a wide variation in pressure, gas composition, and mass flow (see Figs. 2 and 3). The interrelation of these parameters is complex; nevertheless, correlations can be pointed out to illustrate trends. As noted, the optical system is a 50-percent output-coupled unstable resonator with a large output beam (7.2 X 10 cm) or a small beam of 6.0 X 9.5 cm. Fig. 2 shows that the best performance at the low-pressure end of the operating range is obtained with the larger mirror set. The smaller beam more efficiently outcouples power from the narrower lasing zone present at pressures above 35 torr. At the highest pressures for this study (60 torr), the most power is obtained at high CO_2/F_2 ratios. The CO_2 in this instance acts as an added heat sink or diluent which keeps efficient chain operation from being affected by excessive heat release downstream. More power is obtained with high NO concentrations at pressures below 30 torr; whereas best high-pressure operation occurs at low NO levels (see Fig. 3). The product molecule NOF acts as a deactivator and also may take a minor part in the reaction; thus NOF acts to decrease the available power at high pressure.

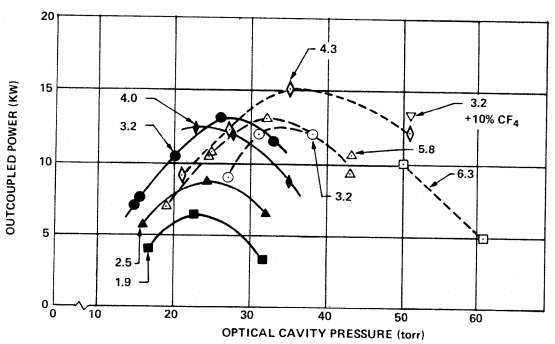

Fig. 2. IRIS-I: Effect of carbon dioxide flow rate on outcoupled power. The CO_2/F_2 ratios are noted in the figure. Closed symbols are for a beam size of 10 X 7.2 cm and open symbols are for a beam size of 9.5 X 6.0 cm. The mole ratio of NO to F_2 was held approximately constant at 0.22.

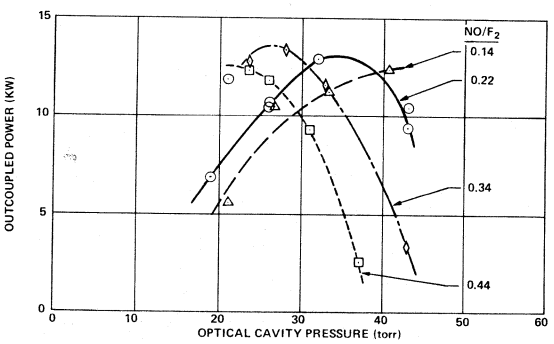

Fig. 3. IRIS-I: Effect of nitric oxide flow rate on outcoupled power. The beam size was 9.5 X 6.0 and the mole ratio of CO_2 to F_2 was held approximately constant at 5.8.

The intensity distribution within the outcoupled laser beam has been analyzed along the flow direction for a number of test conditions. Fig. 4 presents the intensity profile for the conditions which closely parallel those selected for IRIS-I chemiluminescence measurements. Interpretation of the power and intensity is largely a matter of proper evaluation of the chemical phenomena. Insertion of the chain TCL chemistry into any good one-dimensional laser model [13], [14] should provide a reasonable representation of the laser phenomena. Fig. 4 illustrates the comparison of two such analytical treatments with the experimental intensity data for an IRIS-I experiment at 41 torr. The experiment achieved 65 percent of the output power computed with the 1974 kinetic-rate review [14]. Similar results are obtained over the range of IRIS-I operational conditions.

As mentioned earlier, only a restricted range of flow conditions can be examined in IRIS-II and only a limited number of power tests have been conducted in supersonic flow (see Table I). The relative intensity distribution for one case is presented in Fig. 5 and exhibits a stretched power zone over that found

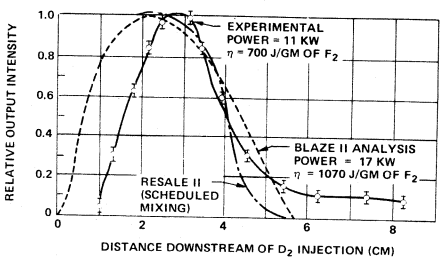

Fig. 4. IRIS-I: Typical beam-intensity profile. The test conditions were: precombustor pressure ~44 torr, optical-cavity pressure ~41 torr, and molar composition; 76.5 percent He, 3.1 percent F_2, 0.7 percent NO, 12.9 percent CO_2, and 6.8 percent D_2.

TABLE I
IRIS-II Power Tests

Power (kw)	Pressures		Molar Ratios		
	Precombustor (torr)	Optical Cavity (torr)	D_2/F_2	NO/F_2	CO_2/F_2
6.0	77.2	22.6	1.10	0.45	8.68
5.2	86.5	30.7	0.84	0.39	6.66
7.7	74.7	14.1	1.40	0.45	11.03

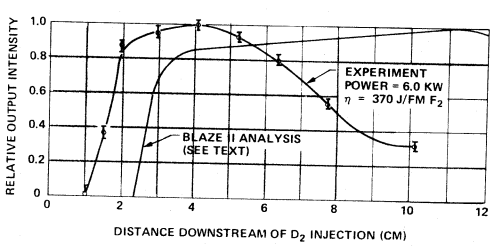

Fig. 5. IRIS-II: Typical beam-intensity profile. The test conditions were: precombustor pressure ~1.5 psia, optical-cavity pressure ~23 torr, and molar composition; 59.5 percent He, 3.6 percent F_2, 1.6 percent NO, 31.3 percent CO_2, and 3.9 percent D_2.

in the IRIS-I device. The 1-D analysis (1974 rates) for the flow predicts 6.5 kW can be extracted by 10 cm, but that a total of 12.5 kW should be obtained if the cavity were 25 cm long. Since 6.0 kW were extracted in this particular experiment over a 10-cm lasing length, it is likely that significantly better performance can be obtained from a supersonic transfer chemical laser.

Chemiluminescence Experiments

The primary objective of the chemiluminescence experiments was to measure the concentration of the upper vibrational levels of DF as a function of distance in both supersonic and subsonic flows. The mass flow, gas composition, and cavity pressure used in these tests are given in Table II. The supersonic case is similar to the test conditions given in Fig. 5, except that two-thirds of the CO_2 was replaced with nitrogen to keep the DF chemiluminescence from being completely quenched. The 10-percent CO_2 remaining in the mixture would have been sufficient for lasing if power extraction has been attempted with this gas composition. The subsonic case closely parallels the power test conditions given in Fig. 4. Emission from DF levels 3-11 were monitored along the centerline for both cases and also near the edge of the flow (3.8 cm above the cavity centerline) for the subsonic case.

Rotational temperature measurements were desired to further characterize the flow field. However, in neither subsonic nor supersonic flow was the intensity sufficient to resolve individual DF rotational lines with the present spectrometer configuration. A series of tests were conducted substituting H_2 for D_2, and thereby obtaining HF rotational temperatures in flows similar to the D_2 system. In an isentropic system at pressures of 20-40 torr, the rotational temperature of a diatomic molecule will approach the static translational temperature of the gas [8]. Where mixing limits the homogenity of the gas (as is the case here) the apparent rotational temperatures will be a weighted average over the temperature and concentration variations. Since the HF/DF is formed concurrently with heat release, the HF/DF concentration will be greater in the hotter regions and thus the apparent rotational temperature is likely to represent the upper extreme of the temperature fluctuations across the flow field [8].

The HF temperature profiles obtained for supersonic flow are presented in Fig. 6. The values shown represent an average of the HF-3-0, 4-1, and 5-2 bands weighted by the number of rotational lines utilized in each band. The rotational temperatures are about 20 percent above thermocouple measurement at the same distance downstream. It would be fortunate if a direct correlation between the temperatures of the hydrogen and deuterium systems could be made. However, the differences in kinetic-rate constants are significant enough to make this approach questionable. A more reasonable assumption is that deviation between actual temperature and those of the thermocouple would be in the same proportion for both HF and DF. On this basis, we estimate the equivalent rotational temperature of the DF system to be as depicted in Fig. 6.

TABLE II
TEST CONDITIONS FOR CHEMILUMINESCENCE MEASUREMENTS

Test	Cavity Pressure (torr)	Total Mass Flow (g/sec)	Composition (Mole Percent)						
			D_2	H_2	F_2	NO	CO_2	He	N_2
IRIS-II	21.5	382	3.9	–	3.4	1.6	10.5	58.8	21.8
	19	367	–	4.0	2.7	1.3	10.6	59.6	21.8
IRIS-I	39.6	171	6.5	–	3.1	0.7	9.7	80.1	–
	39.0	168	–	6.6	3.1	0.7	9.7	79.9	–

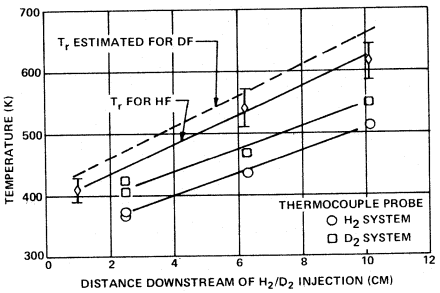

Fig. 6. IRIS-II: Comparison of temperature measurements for H_2 and D_2 systems.

In subsonic flow at 40 torr, an unusual situation arises. Thus, while thermocouple readings are similar for hydrogen and deuterium flows, there exist very large discrepancies between these temperatures and the corresponding HF rotational temperatures (see Fig. 7). The correlation of these values with mean gas temperature and also the analogous DF system presents a perplexing problem. The slower reaction rate of D_2 versus H_2 combined with the lower injection velocity of D_2 (for sonic injection) would moderate the rapid temperature rise observed with H_2. It is unlikely, however, that these effects would reduce the experimental HF temperature profile to values compatible with either the thermocouple values or the calculated DF temperature profile shown in Fig. 7. The temperature determined in BLAZE-II analyses (with revised kinetic rate review) are sensitive to the rate constant for the reaction[1]

$$D + FNO = DF + NO$$

which reduces the number of active chain carriers, and thereby slows the chain reaction. In view of such large discrepancies, the temperature profile in the DF system cannot be estimated with certainty. For purposes of data reduction the DF rotational temperature profile is assumed to be the same as the measured HF rotational temperature.[2]

The concentrations of the DF($3 \leqslant v \leqslant 11$) were determined from a band spectrum in which the major features were the

[1]The rate constant estimated in [14] is too large to account for the unpublished results of J. M. Herbelin of the Aerospace Corp., private communication, October 1974.

[2]The use of HF rotational temperatures in the DF system is, of course, a very crude approximation. Nevertheless, the error introduced in the calculated number density is still less than that associated with the transition probabilities.

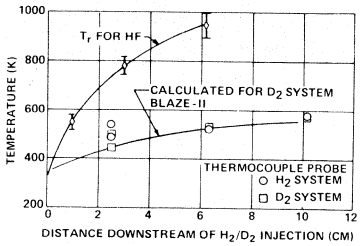

Fig. 7. IRIS-I: Comparison of temperature measurements for H_2 and D_2 systems.

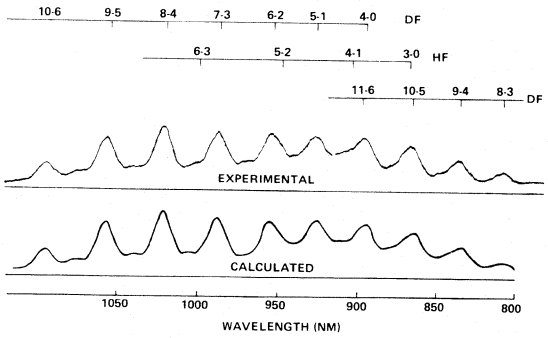

Fig. 8. DF vibrational-band system.

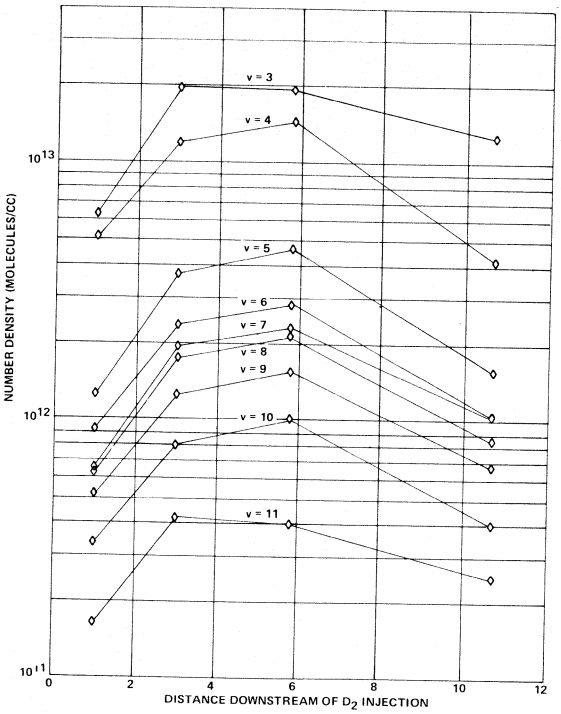

Fig. 9. IRIS-II: DF vibration populations. Test conditions are given in Table II.

R-branch bandheads (see Fig. 8). The accuracy with which the concentrations can be calculated depends on the rotational temperature and the complexity of the spectrum. For the bandpass of 10.6 nm employed in these experiments the maximum intensity of an isolated band is very insensitive to T_r. Rotational temperatures do, however, influence the extent of overlap between adjacent bands; thus a more accurate knowledge of the rotational temperature enters into data reduction as only a second-order correction. Use of an assumed rotational temperature greater than the actual value results in an overcorrection of band overlap, and consequently the actual DF concentrations will be slightly greater than the calculated value. The band spectrum is complex; however, if only a single-band sequence is present, such as DF $4 \rightarrow 0, 5 \rightarrow 1, 6 \rightarrow 2$, etc., the population of each level can be determined uniquely with a high degree of confidence. Interference by HF bands due to trace amounts of H_2 present in the D_2 will not contribute appreciably to the error due to small amounts of emission originating from HF. A serious problem does, however, arise in the overlap of the 4-0, 5-1, and 6-2 bands by the next overtone series. Concentrations of DF ($v = 10$, 11, and probably 12) are significant enough to cause appreciable interference in the bands selected for analysis. For this reason, it was necessary to use an iterative fit to the spectrum in the regions of 4-0, 5-1, and 6-2 bands. The population of DF ($v = 4$, 5, and 6), calculated from these bands are not unique due to uncertainties in the transition probabilities [12]. The populations of DF ($v = 7$-10) are calculated in a straightforward manner with the experimental error being less than that associated with the transition probability. The error associated with DF ($v = 3$) and DF ($v = 11$) increased slightly due to reduced sensitivity of the optical system in the region of the 3-0 and 11-7 bands.

The number densities of DF ($v = 3$-11), measured in supersonic flow, are presented in Fig. 9. The magnitude of the populations reach a maximum in the center of the cavity; however, the relative distribution of DF in the upper levels is virtually constant throughout the cavity. The large number of data points on Fig. 9 does not allow error brackets to be included in the figure; however, the uncertainties shown in Fig. 10 are applicable to the corresponding DF levels. DF-concentration measurements were obtained at three locations for one subsonic flow condition (Fig. 10). At each location the concentrations along the centerline were identical to those near the upper cavity wall. As with the supersonic case, the magnitude of the number density goes through a maximum, yet relative vibrational distribution, essentially unchanged from 1 to 6-cm downstream. The calculated DF vibrational distribution is in good agreement with the experimental values, especially in view of the complexity of the vibrational manifolds of the DF/CO_2 system. For comparison, the distribution of DF(v) was calculated assuming that only the fluorine atoms initially present in the flow reacted (cold reaction). In this case, upper DF levels are immediately quenched, and therefore it becomes obvious that the observed concentrations of DF(v) would be present only if DF is being produced throughout the cavity region via the chain reaction. The same argument would apply even at the higher flow velocities encountered in the supersonic case.

An independent verification of the contribution of the chain reaction to laser power can also be made from thermo-

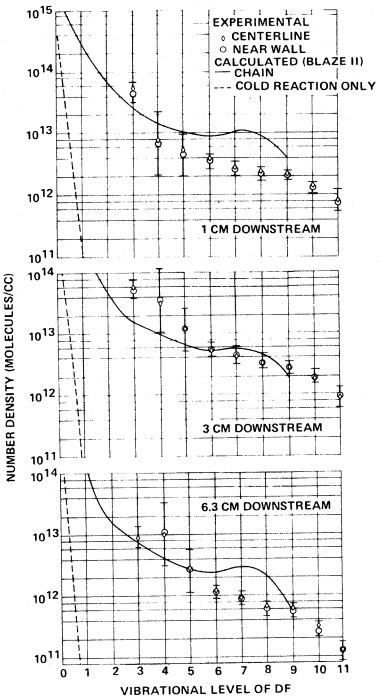

Fig. 10. IRIS-I: DF vibrational populations. Test conditions are given in Table II.

dynamic arguments. Taking the power measurement given in Fig. 4 as an example, the power that could be obtained from the initial fluorine-atom concentration is 0.5 kW. Similarly, incorporating chain-reaction chemistry and utilizing the reference flow rates allows one to compute a maximum theoretical value of 275 kW. A measured value of 11 kW is obtained in the experiment, again ruling out a dominant contribution from the "cold" reaction. Converting the experimental figures previously given to the conventional efficiency numbers provides an overall chemical efficiency of 4 percent for the chain laser in the reference experiment.

Conclusions

A large-scale DF-CO_2 TCL has been operated in both subsonic and supersonic flow. Output powers as high as 15 kW have been obtained and efficient operation has been demonstrated over a wide range of parameters, including pressures as high as 60 torr. The population profiles of the DF ($3 \leqslant v \leqslant 11$) have been determined by chemiluminescence measurements. In both subsonic and supersonic flows the concentrations are significantly greater than that derived from the initial concentration of fluorine atoms ($\alpha \equiv F/(F + 2F_2) < 0.01$), and accordingly the production of DF must be attributed largely to the chain reaction. This conclusion is substantiated by the fact that it is energetically impossible to attain the measured output power with the energy provided by the cold reaction alone.

WE5—Intermolecular Vibration-to-Vibration Energy Transfer in HF/DF(v = 1) + HF/DF(v = 1) ⟶ HF/DF(v = 0) + HF/DF(v = 2) Through the Formation of Dimers

HYUNG KYU SHIN

Abstract—A theory of vibration-to-vibration energy transfer is developed for HF/DF(v = 1) + HF/DF(v = 1) → HF/DF(v = 0) + HF/DF(v = 2) based on the model of dimer formation. This model is shown to be primarily responsible for the energy transfer below 500 K where a strong negative temperature dependence of energy-transfer rates is found; above this temperature the rapid rotational motion of the colliding molecules causes the energy exchange to take place with the result that the rate increases with temperature in a normal fashion. The model represents the low-temperature limit of the energy-transfer process, while the rapid rotational model gives the high-temperature limiting rate, so the overall collision process can be explained in terms of these two contributions. The sum takes a minimum value near 700 K in both HF + HF and DF + DF collisions.

Introduction

THE vibration-to-vibration (VV) energy-transfer process HF/DF(v = 1) + HF/DF(v = 1) → HF/DF(v = 0) + HF/DF(v = 2) + ΔE is of great importance in gas lasers and is responsible for the buildup of HF/DF(v = 2) in the laser pulse pumping of the first vibrational level. For this process the energy mismatches ΔE are only 180 and 91.6 cm^{-1} for HF + HF and DF + DF, respectively, so the energy-transfer rates may be very fast. Recent experimental studies [1]-[5] show the rate coefficient k to be about 10^{13} cm^3/mole · s near room temperature for both HF + HF and DF + DF and the inverse temperature dependence [4] of k for DF + DF in the temperature range of 295-739 K. In these collision systems, there are strong attractive forces acting between the colliding partners due to the presence of the hydrogen-bond interaction; the hydrogen-bond energy is known to be about 6 kcal/mole [6]. In the presence of such a strong attraction the colliding molecules can form a loosely bound complex, and unless the temperature is high, the loosely bound complex can exist with a long lifetime—much longer than the vibrational period of the molecule—thus causing an efficient energy exchange. However, such an energy-exchange process cannot be explained with the conventional vibration-to-translation (VT) [7] or vibration-to-rotation (VR) [8] energy-transfer theories.

It is the purpose of this paper to calculate the VV energy-transfer rates of HF/DF(v = 1) + HF/DF(v = 1) → HF/DF(v = 0) + HF/DF(v = 2) + ΔE on the basis of a mechanism that the energy exchange takes place through the formation of dimers [9]. In this model the molecules are considered to maintain the preferred orientation of the H · · · F interaction in the near-equilibrium configuration for an efficient VV energy transfer. While the molecules maintain the preferred orientation, they also undergo slow "back-and-forth" translational motion which is responsible for the removal of the energy mismatch ΔE, which is normally very small compared to vibrational quanta. We shall only consider zero-impact parameter collisions in treating the relative motion between two HF molecules. The result of this model will be compared with that of the complete rotational motion [8] of the colliding molecules.

Hydrogen-Bond Attraction

There are strong attractive forces, due to the hydrogen-bond interaction, between two HF molecules. The energetically preferred orientation for such strong attractions in the interaction of the H atom of one molecule, say $(HF)_1$, with F of the other, $(HF)_2$. Although this is not a favorable orientation for intermolecular VV energy transfer, because it represents the interaction of a light atom with a heavy atom of which the position is only slightly displaced from the equilibrium geometry, the presence of strong molecular attraction can allow the molecules to form dimers, thus causing them to remain in close proximity of each other for a long time for an efficient energy transfer. As temperature is raised, the thermal motion tends to destroy such an energetically favored orientation so the probability of energy transfer should decrease. Once we invoke the predominance of the hydrogen-bond attraction in the interaction of two HF molecules, the VR energy-transfer theory [8], which is based on the rapid, complete rotational motions of the colliding molecules, cannot therefore be applied to the present VV process, at least at low temperatures.

When the colliding molecules make complete rotational motions, two peripheral hydrogen atoms come into close range of each other. In this case, H of $(HF)_1$ is then in strong interaction with H of $(HF)_2$ in which both atoms are undergoing large displacements from the equilibrium bond distance, thus leading to an efficient intermolecular VV energy transfer [10]. The energy mismatch ΔE is now transferred to the rotational motion of the colliding partners (i.e., a VR mechanism). The overall process is then the combination of VV and VR mechanisms; *the VVR process*. Note that in this case two light atoms are squeezed close together by two heavy atoms, so the main interaction which causes the VVR energy transfer to take place is strongly repulsive, and that

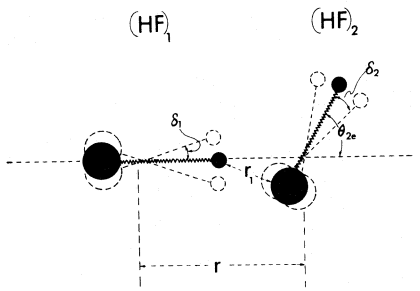

Fig. 1. Collision coordinates; the equilibrium orientation angles are taken as $\theta_{1e} = 0°$ and $\theta_{2e} = 60°$.

the hydrogen-bond energy for this configuration is negligible. The probability of energy transfer obtained for such a model should then increase with temperature in a "normal" fashion because of the increasing degree of the rotational motion of H atoms which leads to an efficient removal of the vibrational energy. In the VR model the molecular attractions do not make a large contribution to the energy transfer because, for the F-H $\cdots$ H-F encounter, which is the most favorable orientation for VV and VR energy transfer, the hydrogen-bond attraction is very weak, if not zero, and the dipole-dipole interaction becomes positive (i.e., repulsive). In [11] we have included, based on physical arguments, the hydrogen-bond and dipole-dipole attractions in the VR theory to investigate the self-relaxation of HF, but the study showed such a procedure to seriously overestimate the energy-transfer probability at low temperatures (~300 K) [12]. We should note that the hydrogen-bond energy of HCl is only about 2 kcal/mole [13], which is far less than that in HF, so the formation of the dimers may not be important in exchanging the vibrational energy intermolecularly even at low temperatures (~300 K). In fact, we have recently applied the VVR model, with the inclusion of the effects of hydrogen-bond and dipole-dipole attractions, to this system and found reasonable agreement between theory and experiment [10].

The collision coordinates of HF + HF in the near-equilibrium configuration are shown in Fig. 1. The equilibrium separation r_e is 2.79 Å, $\theta_{1e} = 0°$, and $\theta_{2e} = 60$-$70°$, [14]-[16]. The hydrogen bond is maintained through a strong interaction between H of $(HF)_1$ and F of $(HF)_2$. In the presence of such a bond, the molecules can neither make complete rapid rotational motion nor rapid translational motion; then the potential energy of the interaction of the molecules confined in the vicinity of the equilibrium coordinates θ_{1e}, θ_{2e}, and r_{1e} can be expressed in the exponential form

$$U(r_1) = D_0 \left[\exp\left(\frac{r_{1e} - r_1}{a}\right) - 2\exp\left(\frac{r_{1e} - r_1}{2a}\right)\right] \tag{1}$$

where r_1 is the H $\cdots$ F distance, D_0 is the hydrogen-bond energy (6 kcal/mole [6]), and a is a potential parameter. Since $r_e = 2.79$ Å [14] and the equilibrium bond distance is 0.917 Å, the H $\cdots$ F distance around the equilibrium separation can be approximated as $r_1 = r - q_F(d + x_1)\cos\theta_1 - q_H(d + x_2)\cos\theta_2$, where $q_{H,F} = m_{H,F}/(m_H + m_F)$, and x_1 and x_2 are the displacements of the bond distances of $(HF)_1$ and $(HF)_2$ from their equilibrium value d, respectively. In the dimer the molecules can make only small displacements from the equilibrium separation r_e; therefore, we can expand (1) as

$$U(r, \theta_1, \theta_2, x_1, x_2) = D_0(f_1 - 2f_2) + (f_1 - f_2)\left(\frac{r_e - r}{a}\right) + 2(f_1 - f_2/2)\left(\frac{r_e - r}{2a}\right)^2 + \cdots \tag{2}$$

where

$$f_1 = f_1(\theta_1, \theta_2, x_1, x_2) = \exp\left[\frac{r_{1e} - r_e}{a} + \frac{q_F(d + x_1)}{a}\cos\theta_1 + \frac{q_H(d + x_2)}{a}\cos\theta_2\right]$$

$$f_2 = f_2(\theta_1, \theta_2, x_1, x_2) = \exp\left[\frac{r_{1e} - r_e}{2a} + \frac{q_F(d + x_1)}{2a}\cos\theta_1 + \frac{q_H(d + x_2)}{2a}\cos\theta_2\right].$$

The orientational motion of the molecules in the dimer is confined to the immediate neighborhood of θ_{1e} and θ_{2e}, i.e., hindered rotational motion, and we shall neglect its coupling with the vibrational motion, as well as the back-and-forth motion, of individual molecules. However, such restricted rotational motion would modify the strength of the hydrogen-bond interaction; we shall discuss this aspect later. We can now replace the angles in (2) by their equilibrium values; i.e.,

$$f_1(\theta_{1e}, \theta_{2e}, x_1, x_2) = 1 + \frac{q_F x_1}{a}\cos\theta_{1e} + \frac{q_H x_2}{a}\cos\theta_{2e} + \frac{q_H q_F}{a} x_1 x_2 \cos\theta_{1e}\cos\theta_{2e} + \cdots \tag{3}$$

and a similar expression for $f_2(\theta_{1e}, \theta_{2e}, x_1, x_2)$. For $x_1 = x_2 = 0$, (2) reduces to $U(r, \theta_{1e}, \theta_{2e}, 0, 0) = D_0[((r_e - r)/2a)^2 - 1]$ as it should. In (3) the term which is responsible for the coupling between the vibrational motion of $(HF)_1$ and $(HF)_2$ is that containing the product x_1x_2, so the interaction potential energy which causes the VV energy transfer can be obtained from (2) and (3) as

$$U(r, \theta_{1e}, \theta_{2e}, x_1x_2) = D_0\left[\left(\frac{r_e - r}{2a}\right)^2 - 1\right] + \frac{1}{2}D_0\left[1 + \frac{3(r_e - r)}{2a}\right]\left(\frac{q_H q_F}{a^2}\right) x_1x_2 \cos\theta_{1e}\cos\theta_{2e} \equiv U_0(r) + U'(r, x_1x_2). \tag{4}$$

The potential energy $U_0(r)$ describes the relative motion of the centers of mass of the molecules in the dimer and determines the trajectory $r(t)$ of the collision in the neighborhood of the equilibrium separation. The orientation dependence should not then appear in the expression of $r(t)$. Since the molecules are loosely bound to each other in dimers, they make only slow translational motion back-and-forth in the neighborhood of r_e, this motion being responsible for the removal of the energy mismatch ΔE.

Energy-Transfer Probability

The probability of the vibrational transitions HF($v = 1$) + HF($v = 1$) → HF($v = 0$) + HF($v = 2$) + ΔE can be given by the expression [17], [18]

$$P_{11}^{02} = \left| \left\langle 02 \left| \exp\left[-\frac{i}{\hbar} \int_{-\infty}^{\infty} U'(r, x_1 x_2) \cdot \exp(i\Delta E t/\hbar)\, dt \right] \right| 11 \right\rangle \right|^2 . \tag{5}$$

To evaluate the vibrational matrix elements, we introduce the operators [19]-[21] $a_i^\dagger$ and a_i, which are Hermitian conjugates of each other satisfying the commutation relation $[a_i, a_i^\dagger] = 1$. The vibrational coordinates are then $x_i = (\hbar/2M\omega)^{1/2}(a_i^\dagger + a_i)$, $i = 1, 2$, where ω and M are the vibrational frequency ($2\pi\nu$) and the reduced mass of HF, respectively. By use of these operators we write the probability as

$$P_{11}^{02} = |\langle 02 |\exp\left[-iG(a_1^\dagger + a_1)(a_2^\dagger + a_2)\right]| 11\rangle|^2 \tag{6}$$

where

$$G = \left(\frac{3}{4M\omega}\right)\left(\frac{q_H q_F}{a^2}\right) \cos\theta_{1e} \cos\theta_{2e} \cdot \left[\int_{-\infty}^{\infty} D_0 \left(\frac{r_e - r}{2a}\right) \exp(i\Delta E t/\hbar)\, dt\right].$$

When we expand the exponential part and approximate as $\exp\left[-iG(a_1^\dagger + a_1)(a_2^\dagger + a_2)\right] \simeq 1 - iG(a_1^\dagger a_2^\dagger + a_1^\dagger a_2 + a_1 a_2^\dagger + a_1 a_2)$, (6) reduces to the first-order result $P_{11}^{02} = 2G^2$. This result will be used in the following derivation.

To evaluate the integral in the quantity G we write $U_0(r) = -D_0 + \frac{1}{2} f y^2$, where $f = D_0/2a^2$ and $y = r - r_e$. From the equation of motion $\mu\ddot{y} = -dU_0/dr = -fy$, where μ is the reduced mass of the collision system

$$t = (\mu/f)^{1/2} \int_{y_0}^{y} [(2E/f) - y^2]^{-1/2}\, dy$$

which gives [9]

$$\left(\frac{r_e - r}{2a}\right) = (E/D_0)^{1/2} \cos\left[(D_0/2\mu)^{1/2}(t/a)\right]. \tag{7}$$

Here we set $\frac{1}{2} f y_0^2 = E$, the initial relative energy. The dimer can therefore be treated as a "pseudo" oscillator with the force constant $f = D_0/2a^2$. When the colliding molecules are far apart (i.e., at large t) they undergo complete rotational motion which cannot be treated by the present model of dimer formation. When the molecules approach each other in the neighborhood of r_e, the rotational motion ceases and the dimer will be formed; thus the collision model restricts the limits of integration appearing in G to a narrow time interval, which is of the order of the vibrational period of the pseudooscillator τ. Equation (7) indicates that the displacement ($r_e - r$) of the pseudooscillator is maximum at $\tau = 0$. The displacement is zero at $-\tau/4$ and $\tau/4$. Therefore, the amplitude changes from zero at $-\tau/4$ to a maximum value at $\tau = 0$ and returns to zero at $\tau/4$. If we set $(D_0/2\mu)^{1/2}(t/a) = x$, then this one-half the period of vibration of the pseudooscillator corresponds to the range from $-\pi/2$ to $\pi/2$. During this period the amount of the energy mismatch ΔE, which is very small compared to the vibrational quantum of HF itself, can be effectively removed by the back-and-forth motion of the pseudooscillator. Therefore, we shall take the limits of the integration from $x = -\pi/2$ to $\pi/2$ to obtain the result [9], [22]

$$I = D_0 \int_{-\infty}^{\infty} \left(\frac{r_e - r}{2a}\right) \exp(i\Delta E t/\hbar)\, dt \simeq (2\mu E)^{1/2} \cdot a \int_{-\pi/2}^{\pi/2} \cos(x) \exp(isx)\, dx = \frac{(2\mu E)^{1/2} a\pi}{4} \cdot \frac{1}{B\left(\frac{3+s}{2}, \frac{3-s}{2}\right)} \tag{8}$$

where B is the beta-function and $s = (\Delta E a/\hbar)(2\mu/D_0)^{1/2}$. With this expression, the transition probability takes the form

$$P_{11}^{02}(E) = \left(\frac{3\pi q_H q_F}{8Ma\omega}\right)^2 \left[\frac{\cos\theta 1_e \cos\theta_{2e}}{B\left(\frac{3+s}{2}, \frac{3-s}{2}\right)}\right]^2 \mu E. \tag{9}$$

The structure of the dimer, or the pseudooscillator, under consideration is not rigid. The molecules in the dimer undergo hindered rotational motion about the equilibrium angles (θ_{1e}, θ_{2e}) and back-and-forth translational motion about the equilibrium separation (r_e). Because of these displacements from the equilibrium geometry, the attractive energy between two HF molecules in the dimer is less than the strength of the hydrogen bond D_0. We shall refer to this energy as the "effective" hydrogen-bond energy and denote it by D_0^*. The colliding molecules with the relative energy less than D_0^* will be attracted to each other to form a nonrigid dimer, so the initial collision energy is modified by D_0^*. This modification will have to be taken into consideration in averaging $P_{11}^{02}(E)$ over the distribution of initial collision energies. To determine the effective hydrogen-bond energy, we write

$$\bar{U}(r) = (2\pi)^{-2} \int_0^{2\pi} \int_0^{2\pi} U(r_1)\, d\theta_1\, d\theta_2 \tag{10}$$

where $U(r_1)$ is given by (1) and $r_1 = r - q_F d \cos\theta_1 - q_H d \cdot \cos\theta_2$ for $x_1 = x_2 = 0$. In the dimer, the molecules undergo small displacements (δ_1, δ_2) from θ_{1e} and θ_{2e}, so we can approximate $\cos\theta_1 = \cos(\theta_{1e} + \delta_1) \simeq (1 - \delta_1^2/2)\cos\theta_{1e}$ and $\cos\theta_2 = \cos(\theta_{2e} + \delta_2) \simeq (1 - \delta_2^2/2)\cos\theta_{2e} - \delta_2 \sin\theta_{2e}$. In

deriving these approximate relations, we took $\theta_{1e} \simeq 0$ and $\theta_{2e} = 60$–$70°$. With these expressions we now obtain

$$\bar{U}(r) = \frac{D_0}{(2\pi)^2}\left[\exp\left(\frac{r_e - r}{a}\right)\int_{-\infty}^{\infty}\exp\left(-\frac{q_F d}{2a}\delta_1^2\right)d\delta_1 \cdot\int_{-\infty}^{\infty}\exp\left(-\frac{q_H d\cos\theta_{2e}}{2a}\delta_2^2 - \frac{q_H d}{a}\sin\theta_{2e}\delta_2\right)d\delta_2 - 2\exp\left(\frac{r_e - r}{2a}\right)\int_{-\infty}^{\infty}\exp\left(-\frac{q_F d}{4a}\delta_1^2\right)d\delta_1 \cdot\int_{-\infty}^{\infty}\exp\left(-\frac{q_H d\cos\theta_{2e}}{4a}\delta_2^2 - \frac{q_H d}{2a}\sin\theta_{2e}\delta_2\right)d\delta_2\right] \tag{11}$$

in which we extended the integration limits from $-\infty$ to ∞ because of the steepness of the exponential functions. The result is

$$\bar{U}(r) = \frac{D_0}{2\pi}\left(\frac{a}{q_F d}\right)^{1/2}\left(\frac{a}{q_H d\cos\theta_{2e}}\right)^{1/2} \cdot\left[\exp\left(\frac{q_H d}{2a}\frac{\sin^2\theta_{2e}}{\cos\theta_{2e}}\right)\exp\left(\frac{r_e - r}{a}\right) - 4\exp\left(\frac{q_H d}{4a}\frac{\sin^2\theta_{2e}}{\cos\theta_{2e}}\right)\exp\left(\frac{r_e - r}{2a}\right)\right] \equiv D_0\left[\bar{A}\exp\left(\frac{r_e - r}{a}\right) - 2\bar{B}\exp\left(\frac{r_e - r}{2a}\right)\right]. \tag{12}$$

The equilibrium separation r_e^* of the dimer represented by the average energy $\bar{U}(r)$ is no longer r_e. This distance can be readily determined from (12) as $(r_e - r_e^*) = 2a \ln(\bar{B}/\bar{A})$. The effective hydrogen-bond energy is therefore

$$\bar{U}(r_e^*) = D_0\left[\bar{A}\exp\left(\frac{r_e - r_e^*}{a}\right) - 2\bar{B}\exp\left(\frac{r_e - r_e^*}{2a}\right)\right] \equiv -D_0^*. \tag{13}$$

The incident molecules with relative kinetic energies less than the effective hydrogen-bond energy D_0^* are primarily responsible for the production of dimers. The approaching molecules are attracted to each other through the potential energy well of depth D_0^*, and the dimers are confined to the well so the energy distribution should therefore be shifted to higher energy by the amount D_0^*. With the modification of the initial energy as $E + \bar{U}(r_e^*) = E - D_0^*$, we can therefore carry out the average of (9) over the Boltzmann distribution as

$$P_{11}^{02}(T) = (kT)^{-1}\int_0^{\infty} P_{11}^{02}(E)\exp\left[-(E - D_0^*)/kT\right]dE = \left(\frac{3\pi q_H q_F}{8Ma\omega}\right)^2\left[\frac{\cos\theta_{1e}\cos\theta_{2e}}{B\left(\frac{3+s}{2}, \frac{3-s}{2}\right)}\right]^2 \cdot \mu(kT + \Delta E/2)\exp(D_0^*/kT) \tag{14}$$

where $\Delta E/2$ is due to the symmetrization of the initial and final energies of the relative motion. Although it is less important, those collisions with $E > D_0^*$ can also produce the dimers; therefore, the integration limits are extended from 0 to ∞ in (14). The major contribution to the dimer formation comes from the energy range of 0-D_0^*. If the integral is evaluated over the latter limits, the result is smaller than that obtained from (14) by the factor $1 - [1 + D_0^*/(kT + \Delta E/2)] \cdot \exp(-D_0^*/kT)$. Since $D_0^* \gg kT$ near room temperature, this factor is very close to unity.

Numerical Results and Discussion

To calculate the vibrational energy-transfer probability $P_{11}^{02}(T)$, we shall use the following molecular and potential constants [23]: $\Delta E(\mathrm{HF}) = 180\ \mathrm{cm}^{-1}$; $\Delta E(\mathrm{DF}) = 91.6\ \mathrm{cm}^{-1}$; $\omega(\mathrm{HF}) = 7.45 \times 10^{14}\ \mathrm{s}^{-1}$; $\omega(\mathrm{DF}) = 5.47 \times 10^{14}\ \mathrm{s}^{-1}$; $d = 0.917$ Å; and $D_0 = 6$ kcal/mole. We choose the equilibrium orientation angles to be $\theta_{1e} = 0°$ and $\theta_{2e} = 60°$. The values of the potential parameter a are given in [11], and vary from 0.202 Å at 300 K to 0.183 Å at 2000 K, but (14) is only weakly dependent on the change of the value of a. We shall convert the calculated values of $P_{11}^{02}(T)$ to the rate coefficient k in units of cubic centimeters/mole · second through the expression $k = ZP_{11}^{02}(T) = 4.74 \times 10^{10} r^{*2}(T\mu^*)^{-1/2}P_{11}^{02}(T)/\mathrm{s} \cdot \mathrm{atm}$, where μ^* is the reduced mass in *amu*; we take [14] $r^* = 2.79$ Å. When this expression is multiplied by RT (i.e., $82T$), we obtain the rate coefficient in units of cubic centimeters/mole · second.

The model above developed is considered to represent the energy-transfer process at low temperatures. As the temperature increases, the molecules tend to undergo complete rotational motion so that the energy mismatch is transferred to the rotational motion of the colliding partner through the strong interaction of the peripheral hydrogen atoms; i.e., the VVR model. As the temperature is lowered, say below 1000 K, the molecules slow down their rotational motion, thus leading to less efficient rotational energy transfer. At such temperatures the effects of dipole-dipole and hydrogen-bond attractions can become important, thus leading to the situation that the molecules spend more time in those orientations for which the energy is small (i.e., more attractive). However, such orientations are due to the interaction of H of $(\mathrm{HF})_1$ with F of $(\mathrm{HF})_2$ for which orientation the intermolecular energy transfer is not efficient. In fact, in the VVR model the interaction energy between two peripheral H atoms dominates all other atom-atom interactions. Therefore, the application of the VVR model to low-temperature energy-transfer processes is unrealistic because the molecules can no longer undergo complete rotational motion. The introduction of the effects of dipole-dipole and hydrogen-bond energies in the model of complete rotational motion of colliding molecules has been discussed in [11], but the approach can produce a serious overestimate of the energy-transfer rate at lower temperatures. For example, for HF at 300 K we find $k = 1.5 \times 10^{14}\ \mathrm{cm}^3/\mathrm{mole} \cdot \mathrm{s}$, which is about five times the experimental data [1], [2] (see Fig. 2 shown below). When there are such strong attractive energies, however, it would not be possible to explain the process with the VVR model. On the other hand, the VVR model should describe the

energy-transfer process reasonably well at higher temperatures, but the effects of the dipole-dipole and hydrogen-bond attractions are now not important. Therefore, we shall compare the result of the dimer model with that of the VVR model which does not include the effects of dipole-dipole and hydrogen-bond energies. The probability for the latter model can be readily obtained from [10] in the form

$$P_{11}^{02}(T) = 8\left(\frac{\pi\phi\Delta E}{\hbar\omega}\right)^2 (1+\alpha)^4 \left(\frac{4\pi\chi}{3kT}\right)^{1/2} \cdot \exp\left[-\frac{3\chi}{kT} + \frac{4(D\chi)^{1/2}g}{\pi kT} + \frac{16Dg^2}{3\pi^2 kT} + \frac{\Delta E}{2kT}\right] \quad (15)$$

with

$$g = 2^{1/2}\,[Q_F^{-1}\sinh(Q_F/2) + Q_H^{-1}\sinh(Q_H/2)]\,/ \cdot (Q_F^{-1}\sinh Q_F + Q_H^{-1}\sinh Q_H)^{1/2}$$

$$\phi = (\cosh Q_F + \cosh Q_H)/ \cdot [\sinh Q_F + (Q_F/Q_H)\sinh Q_H] - Q_F^{-1}$$

$$\chi = [(M/2q_F)^{1/2}\pi(1+\alpha)(\Delta E/\hbar)akT]^{2/3}$$

$$\alpha = (9/2Q_F^2)\,[1 + (4/3Q_F^2)]$$

where $Q_{H,F} = q_{H,F}d/a$. In deriving the preexponential part of this expression, we have neglected some factors which are not significantly different from unity. We shall use (15) with D = 400 K [11] to calculate energy-transfer probabilities at higher temperatures.

In Fig. 2 we plot the calculated values of the rate coefficient k for *the dimer model* and that for *the VVR model* over the temperature range of 300-2000 K. The rate calculated from the dimer model is very large at room temperature and sharply decreases with rising temperature, while the VVR model gives large rates at higher temperatures but decreases rapidly as the temperature is lowered. At a given temperature the colliding molecules can transfer the vibrational energy through both the formation of dimers (i.e., the dimer model) and the rotational motion of the colliding partners (i.e., the VVR model). The sum of these two contributions should then represent the overall process taking place during collision at any temperature. In both mechanisms, the vibrational energy transfer takes place intermolecularly. In the dimer mechanism, the vibrational energy is transferred through the interaction of H of $(HF)_1$ with F of $(HF)_2$ in the neighborhood of the equilibrium separation under the influence of the strong hydrogen-bond *attraction*. On the other hand, in the VR mechanism, the vibrational energy transfer takes place through the interaction of H of $(HF)_1$ with H of $(HF)_2$; i.e., between two rapidly rotating peripheral atoms in the region of strong *repulsion*. In the dimer model, the energy mismatch is taken away by the relative translational motion of the colliding molecules which are loosely bound to each other, while in the VVR model it is transferred to the rotational motion of the colliding partner.

In Fig. 2 we show the sum of the probabilities calculated with the dimer and VVR models; the solid curve represents this sum. A probability minimum appears at 700 K; below this temperature the energy transfer through the formation of dimers dominates in the sum and the temperature dependence of the rate is negative. On the other hand, above 700 K the rotational motion of two colliding molecules becomes increasingly important and the VV process, as well as the removal of ΔE, takes place through the interaction of two peripheral hydrogen atoms. The calculation also shows that over the temperature range under consideration, the rate is fast (of order of 10^{13} cm^3/mole · s. Near room temperature, the calculated values are in reasonable agreement with the experimental data [1], [2]. Since experimental data at higher temperatures are not available at present, the negative temperature dependence between 300 and 700 K and the appearance of the probability minimum in the neighborhood of 700 K predicted by the present approach cannot be tested.

For DF, similar plots are made in Fig. 3; the overall rates calculated between 300 and 750 K are somewhat less than experimental data [3]-[5]. The negative temperature dependence of the experimental data is seen over this temperature range as in the HF system, the result being in agreement with the present calculation. A minimum value of the probability which is obtained by summing the results of the dimer and

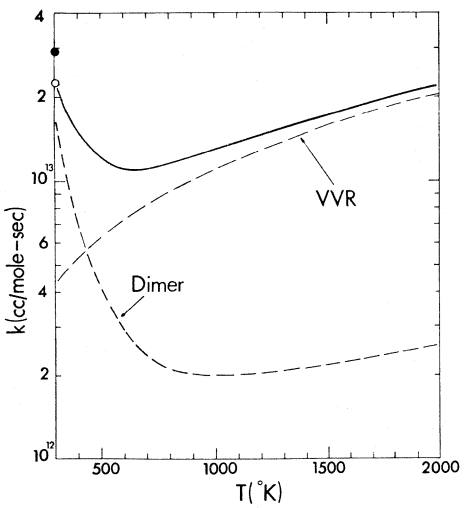

Fig. 2. Temperature dependence of the rate constant k for HF. Experimental data: ○, [1]; ●, [2].

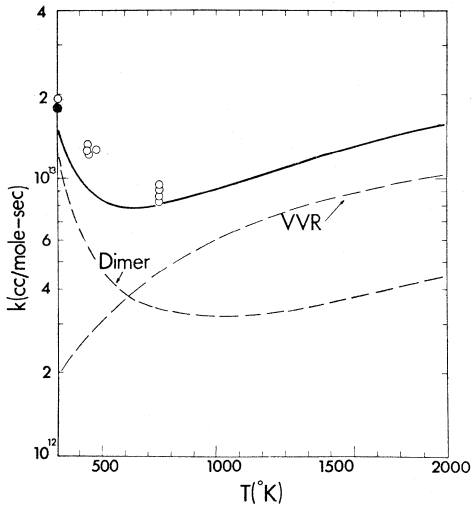

Fig. 3. Temperature dependence of the rate constant k for DF. Experimental data: ○, [3] and [4]; ●, [5].

VVR models occurs near 700 K. The probability starts to increase slowly at 750 K with rising temperature, but no experimental data are available to test such a temperature dependence.

By comparing Figs. 2 and 3 we find that the rates for HF are always larger than those for DF by a factor of about 1.5 over the entire temperature range under consideration in spite of the fact that the energy mismatch is smaller in DF + DF. As shown by broken curves, the VVR rate of HF, which is the major contribution to the sum at higher temperatures, is always greater than that of DF, the result being in accordance with the isotope effect predicted by the VR theory [8]. Note that the VVR approach is based on the rapid rotational motion of the colliding molecules, which is responsible for the isotope effect. As noted in the foregoing sections, the dimer rate dominates in the sum below 500 K. At such temperatures the dimer rate of HF is greater than that of DF.

Concluding Remarks

The VV energy transfer HF/DF($v = 1$) + HF/DF($v = 1$) → HF/DF($v = 0$) + HF/DF($v = 2$) at low temperatures has been examined with the hydrogen-bond dimer model. Because only a limited amount of experimental data is available, it is difficult to make a rigorous test of the present model. However, the model, which is admittedly a simplified one, has the advantage of conceptual and mathematical simplicity and gives the result which does seem to correspond to the observed rates. In particular, it gives a negative temperature dependence of the energy-transfer rate for DF + DF which essentially agrees with experiment. We may therefore state that at lower temperatures the VV energy transfer through the formation of dimers is primarily responsible for the overall process, whereas at higher temperatures, the major contribution to the energy transfer comes from the rapid rotational motion of HF molecules which leads to a strong interaction of two hydrogen atoms at close range. At a given temperature, the sum of these two contributions should represent the overall process. The sum takes a minimum value near 700 K.

SESSION MA

Electrically-Pumped Lasers
Monday, October 21, 8:30 A.M.

MA1. Electron Beam Excitation of Argon-Nitrogen Mixtures,[1] S. K. Searles and G. A. Hart,[2] *Naval Research Laboratory.*

Argon-nitrogen mixtures were excited with a pulsed 500 keV electron beam (e-beam). The N_2 $C(^3\pi_u)$ state was found to be populated efficiently. This state emits from $v = 0$ to $v = 0, 1, 2$ of the $N_2B(^3\pi_g)$ state at 3371, 3577, and 3805 Å, respectively. Laser emission at 3577 Å and side fluorescence at 3371, 3577, and 3805 Å were observed over a wide range of total pressures and mixture compositions. A kinetic model was developed to explain both the absolute magnitude and temporal dependence of the $N_2(C)$ population. In the model only the argon is directly pumped by the e-beam. This is justified by the high fraction of argon in the mixture. The key steps in the model include neutral excitation and ionization of the argon. Charge recombination produces an excited state of argon Ar* with unit yield. The Ar* transfers energy to N_2 to create $N_2(C)$. A comparison of absolute experimental fluorescence intensities from $N_2(C)$ with the model showed close agreement. The total pressure range was 200–5000 torr at $Ar:N_2$ ratios of 100, 20, and 10.

The energy transfer process also created a partial population inversion on the 3577 Å transition. Intense superfluorescence was detected from 400–5000 torr in a $Ar:N_2$ mixture of 20:1. A totally reflecting dielectrically coated mirror and a quartz window formed the laser cavity. Over a limited range of pressures laser action would occur with only two quartz windows serving as the laser cavity. Laser efficiency based on the calculated energy input measured by calorimetry was 0.4% while efficiency based on chemical dosimetry was somewhat lower.

MA2. Laser Oscillation on the Green Bands of Xenon Oxide,[1] H. T. Powell, J. R. Murray, and C. K. Rhodes, *Lawrence Livermore Laboratory.*

Lasing has been achieved on the green bands of the XeO excimer using direct electron beam excitation of high pressure Xe with small additions of either O_2, CO_2, or N_2O. These bands are transitions between $^1\Sigma^+$ molecular levels correlating with the $^1S_0$ and $^1D_2$ metastable levels of atomic oxygen plus ground state Xe. The lasing wavelengths, near 5400 Å, are not far removed from the atomic oxygen, $^1S_0 - {}^1D_2$ line at 5577 Å since the bindings of the upper and lower levels are only about 0.06 and 0.33 eV respectively.[2] The XeO laser is representative of possible lasers based on the properties of the $O(^1S_1)$ metastable.[3,4]

A high pressure cell was irradiated by a 2×10 cm^2, 1 MeV electron beam lasting 50 ns. A Monte-Carlo electron trajectory calculation[5] predicts an energy deposition of approximately 1 J/cm^3 in the 50 cm^3 active volume. The optical cavity was formed by mirrors nominally 99.9% and 99% reflectivity which were separated by 15 cm. The operating pressures are from 10–15 atm of Xe and 5–15 Torr of added gas. Under these conditions the XeO fluorescence is characterized by a linear growth during the e-beam pulse, a sharp rise doubling its value at the end of the current, and then a decay with a half-life of 100 ns. The laser exhibits a smooth rise and fall with a maximum about 100 ns after the end of the e-beam and a FWHM of 75 ns. Using O_2, an output power of 75 kW and an output energy of 5 mJ have been measured with a calibrated photodiode.

Spectrograms with 0.2 Å resolution have been taken of both the XeO laser and fluorescence. For our pressures the $^1\Sigma^+ - {}^1\Sigma^+$ fluorescence extends over about 300 Å with a series of peaks associated with the various band heads, the 0–5 at 5377 Å and the 0–6 at 5433 Å being the most intense. The rotational lines are broadened and overlap producing only a small modulation in the spectral profile. The laser spectrum shows considerable narrowing. The strongest lasing occurs at the peaks of the fluorescence produced by the 0–5 and 0–6 band heads. The modulation of the gain caused by the rotational structure is greatly amplified in the laser spectrum.

The time dependence of the laser suggests that the output is limited by a low gain coupled with a short inversion lifetime rather than saturation effects. A sidelight monitor shows only a slight decrease in fluorescence caused by lasing which supports this conclusion. Further both the temporal and spectral data suggest that the gain is simply proportional to the fluorescence intensity indicating that the lower state population is negligible.

The authors are indebted for the contributions of numerous members of the Gas Laser Research and Gas Laser Technology groups and in particular to L. P. Bradley, T. Kan, and L. G. Schlitt.

MA3. Quasi-cw Laser Emission from the Second Positive Band of Nitrogen,[1] S. N. Suchard and D. G. Sutton, *The Aerospace Corp., El Segundo, Calif.*

Since the discovery of superradiant laser emission on the Second Positive band of nitrogen in 1964, there has been a considerable amount of research performed on this molecule in an attempt to increase the maximum output energy obtainable and the overall electrical efficiency. To this end several very difficult forms of initiation have been applied. The main difficulty that has arisen, however, has been caused by the ratio of the radiative lifetimes of the upper laser level ($C^3\pi_u$, $\tau_r = 40$ nsec) to the lower laser level ($B^3\pi_g$, $\tau_r = 5$–8 μs). Population inversion between $C^3\pi_u$ and $B^3\pi_g$ states can only take place during a time on the order of, but shorter than, the radiative lifetime of the $C^3\pi_u$ state.

This talk will report on the first observation of a Second Positive N_2 laser with a pulse length much longer than the radiative lifetime of the $C^3\pi_u$ state. Preliminary measurements of the temporal behavior of this laser indicate that it is operating in a "quasi-cw" manner and, in addition, the laser output is extremely sensitive to the alignment of the optical cavity placed around the discharge tube.

The primary difference between the N_2 laser which we are reporting upon and a "conventional" N_2 laser is the addition of SF_6 to the N_2 in the discharge region. Preliminary studies indicate that the SF_6 is extremely efficient at quenching the $B^3\pi_g$ state, thereby reducing the population of this state and "unblocking" the laser transition. Under our initiation conditions, the dis-

charge risetime is 130 ns; considerably longer than the radiative lifetime of the $C^3\pi_u$ state. Without addition of SF_6 to the N_2, no laser action is observed at a pressure of 50 torr. Upon adding SF_6 to a total pressure of 70 torr, non-superfluorescent N_2 laser emission is observed. Optimal laser output for 50 torr N_2 occurs at 50 torr of added SF_6.

We believe that the appearance of the N_2 laser action is a consequence of the "unblocking" of the lower laser level. Temporal measurements of the laser pulse indicate a risetime of 75 ns and a duration (FWHM) of 80 ns; these times are found to be independent of the SF_6/N_2 ratio, total pressure, and discharge voltage. The long duration of the pulse, in addition to the fact that the laser operates within optical cavity 3-m long (roundtrip transit time = 20 ns), strongly indicates a rapid deactivation of the $B^3\pi_g$ state.

Measurement of the laser pulse duration was also made using a discharge of twice the risetime (260 ns) and duration. These results showed that the laser pulse duration has also been extended by almost a factor of two. Since an increase in the discharge risetime would decrease the rate of pumping of the upper laser level, an experimental fact not observed, it appears as if the SF_6 is truly "unblocking" the N_2 laser bottleneck and allowing the laser to operate quasi-cw.

MA4. N_2 Infrared Laser Operation in an Electron Beam Controlled Discharge, L. Newman, T. A. DeTemple, and P. D. Coleman, *Electro-Physics Laboratory, University of Illinois, Urbana, Ill. 61801.*

Recently much interest has centered on the use of intense electron beams as the excitation source for gas lasers operating on electronic transitions. One possible alternate to this method would be to use an ionizer-sustainer discharge which has the advantage of depositing more energy into the gas than can be obtained conveniently from an electron beam. As a preliminary to applying this method to eximer, atomic, and transfer-type lasers, we have undertaken a study of the near-infrared first positive system N_2 laser (FPSL) operating in an ionizer-sustainer device.

Previous studies on the FPSL were concerned mainly with the temporal behavior of the pulse and the output power.[1,2] In this work we present a detailed parametric study of the FPSL operating in an ionizer-sustainer as well as results of a kinetic model for the laser system.

The significant findings to date are laser action up to 200 torr of pure N_2 (limited by the sustainer voltage available), pulse power in the tens of kW with pulsewidths ~ 150 ns and conversion efficiencies ~ .01%. In addition, the results of the kinetic model indicate that the metastable $A^3\Sigma_u^+$ population is comparable with that obtained with a direct electron beam excited system.[3] This in turn implies that the ionizer-sustainer mode of operation may be useful in studying transfer type lasers such as the N_2-NO system or the Ar-N_2 system for UV and IR transitions.[4,5]

MA5. A New Pumping Technique and New V-V Transfer Molecule for the CS_2 Laser, L. Y. Nelson, C. H. Fisher, and S. R. Byron, *Mathematical Sciences Northwest, Inc., Seattle, Wash.*

The intractability of CS_2 in self-sustained discharges has discouraged additional experiments with this molecule beyond Patel's original report of a CS_2 laser in 1965.[1] His laser operated at low pressures (2 torr) in a flowing system in which the CS_2 was mixed with excited N_2 after it left the electrical discharge region. We have found that the laser emission Patel observed at 11.5 μm can also be produced by exciting directly mixtures of $He/N_2/CS_2$ or $He/CO/CS_2$ in a low $E/N(2 \times 10^{-16}$ V-cm^2), electron beam stabilized discharge. The discharge currents were limited to 1 A/cm^2 by the attachment rate of CS_2 (6×10^{-11} cm^3 sec^{-1}). It was found that gas mixtures containing CO provided far better laser output than those using N_2, which permitted laser operation at pressures up to one atmosphere for $He/CO/CS_2$ (75/24/1) mixtures. Helium, H_2, or D_2 was needed in the laser mixture for preferential de-excitation of the lower CS_2 laser level.

Laser assignments based on laser emission at 12.2 μm for 91 percent ^{13}C enriched samples, indicate that both the $001 \rightarrow 100$ and $01^11 \rightarrow 11^10$ transitions of $^{13}CS_2$ contribute to the lines observed. Line coincidences, which are very likely for these transitions in both $^{13}CS_2$ and $^{12}CS_2$ may be the cause of the anomalous laser intensity distribution among the rotational states observed at low pressures. For $^{12}CS_2$, the $02^01 \rightarrow 12^00$ and $101 \rightarrow 200$ transitions may also have line coincidences with $001 \rightarrow 100$. Our results with $He/CO/^{12}CS_2$ are not compatible with a laser assignment of $02^01 \rightarrow 12^00$ because the CO fundametnal (2143 cm^{-1}) is too far below the 02^01 level for effective V-V transfer.

The maximum laser output energy obtained with approximately 4 percent output coupling was 24 mj at 150 torr total pressure in a $He/CO/CS_2$ mixture. This corresponds to an energy of 0.4 j/l-atm and an electrical efficiency of 0.5 percent.

MA6. A Fifteen Atmosphere Electron-Beam-Controlled CO_2 Laser, N. W. Harris, F. O'Neill, and W. T. Whitney, *Naval Research Laboratory, Washington, D. C. 20375.*

High pressure molecular gas lasers are of interest because the broad bandwidth provided by the mutual overlapping of pressure broadened rotational lines will permit continuous frequency tuning of these devices. These high-power high-efficiency lasers will be useful as tunable infrared sources for isotope separation and laser induced chemistry applications. Highest gain has been achieved with atmospheric pressure CO_2 lasers using electron-beam-controlled discharges and we have recently reported[1] on the successful operation of a 15 atm. electron-beam-controlled CO_2 laser (active volume 22 cc).

In this paper we will describe the results of a more complete investigation of the gain characteristics of the high-pressure laser. Measurements were taken using a stabilized low pressure cw CO_2 laser. Gain results will be presented for a range of laser gas mixtures and for different settings of the probe laser wavelength. The dependence of the electric discharge properties and the gain pulse profile, on the gas composition will also be discussed. A multimode laser output of 1.2 J has been obtained from the above device for an overall efficiency of 2.5%. The peak laser power was ~50 MW.

The laser described[1] was powered by a high-current variable-parameter cold-cathode electron gun[2] designed primarily for use with large volume atmospheric pressure CO_2 amplifiers. We have recently constructed a more compact electron gun which has been successfully used to operate a bench top high-pressure laser. The operation of this device will be described and we will

discuss recent experiments on the use of thin etalons to obtain frequency tuning of this laser.

MA7. Vibrational Excitation of HCl by Electron Impact, R. E. Center and H.-L. Chen, *AVCO Everett Research Lab., Inc.*

The direct electrical excitation of the vibrational mode of the hydrogen halides is of interest in the possible development of efficient electrically excited lasers in the 2.5 to 4.5 μ region. Stimulated emission from HF and DF has been recently observed[1] in experiments with direct electrical discharge excitation. However, there is a lack of information on the fundamental vibrational excitation cross sections for electron impact on the hydrogen halides. This paper presents a measurement of the vibrational excitation rate constant of HCl excited by electron impact. The experiments were performed in a uniform electron beam sustained discharge over the range of electron temperature from 0.3 eV to 1.7 eV. Mixtures of HCl, CO, and N_2 dilute in Ar were used in the discharge and the IR emission from the fundamental bands of HCl and CO were monitored. Typical mole fractions of HCl, CO, and N_2 were 0.003, 0.003, and 0.1, respectively, the N_2 being used to specify the electron distribution function. Under these conditions the vibrational excitation rate constant in the trace CO could be readily calculated based on previously measured cross-section data.[2] The vibrational excitation rate constant was then derived from the ratio of the simultaneous IR emission from both the CO and HCl taking into account the relevant V-V and V-T kinetics. A value of $(1.2 \pm .4) \times 10^{-8}$ cm^3/s was obtained for the vibrational rate constant in HCl at a mean electron temperature of 1 eV. It was also determined with the aid of a HCl absorption filter, that the dominant cross section was for the excitation of $v = 1$ with only 20% of the emission coming from levels $v \geqslant 2$.

MA8. Negative Ion Production and Influences in CO_2 Discharge Lasers, J. F. Prince, W. H. Long, Jr., and A. Garscadden, *Aerospace Research Laboratories, Wright-Patterson AFB, Ohio.*

Experiments on the effects of contaminants in CO_2 laser discharges and theoretical analyses of the properties of CO_2 molecular discharge lasers show that both the steady-state discharge properties and the stability of the plasma are very sensitive to the presence of negative ions. Scaling of these effects and the comparison of theoretical predictions with experiments depends upon the unambiguous identification of the ionic and neutral species that are generated under typical CO_2 laser discharge conditions. This identification has been accomplished using an on-line mass spectrometer to examine the negative ion, positive ion and neutral gas species in sealed-off and in slowly flowing CO_2-N_2-He cylindrical discharges (22mm i.d.). Measurements have been obtained of the equilibrium concentrations for given conditions and of the rate of change of the concentrations after turn-on of the discharge to a constant-current condition. For sealed-off operation at 10 mAcm^{-2}, the dominant negative ions are NO_2^-, O^-, NO_3^-, O_2^-, and CO_3^-. At very low current densities ($\sim$0.5 mAcm^{-2}) CO_3^- is the dominant negative ion, however, although the formation rate is very rapid it appears to saturate early with increasing current while the other negative ions increase in concentration. The dominant positive ions are typically NO^+, CO^+, O_2^+, and CO_2^+ with smaller amount of other species. The relative concentrations are strong functions of the discharge current, plasma homogeneity and the initial gas mixtures. The measurements have been obtained over the range 0.50 to 2 Torr for discharge currents 0.1 to 80 mA. The consequences of the negative ion formation on the impedance of the discharge, the power loading and gas heating are evaluated using a theoretical model of the positive column. The application of these results in predicting the onset of the attachment-detachment plasma instability will also be demonstrated.

SESSION MB

New IR Laser Reactions

MB1. Cyanide Radical Photodissociation and Predissociation Chemical Lasers: Molecular Electronic and Vibrational Laser Emissions, G. A. West and M. J. Berry, *Department of Chemistry, University of Wisconsin, Madison, Wis. 53706.*

Molecular electronic [$CN^*(A^2\Pi_3, v' = 0) \rightarrow CN(X^2\Sigma^+, v'' = 0, 1, 2)$] and vibrational [$CN\dagger(X^2\Sigma^+, v')^2 \rightarrow CN(X^2\Sigma^+, v' - 1)$, $v' = 5, 4, 3, 2$] cyanide radical laser emissions have been observed following photolysis of several cyanide parents [HCN, ClCN, BrCN, ICN, $(CN)_2$, CH_3NC, CF_3CN, C_2F_5CN] at $\lambda > 1550$ Å. In the electronic lasers, only Q_1 and P_1 branch transitions oscillate, indicating that rapid spin-orbit and rotational relaxations produce thermalized distributions within the $^2\Pi_1$, $v = 0$ and $^2\Pi_3$, $v = 0$ vibronic manifolds. From the highest gain transitions within the (0, 0), (0, 1), and (0, 2) CN* red bands, we find that electronic population inversions are total:

$$N_{A^2\Pi_i,v}/N_{X^2\Sigma^+,v''} \geqslant 1.6.$$

In the vibrational lasers, the highest gain transitions indicate that total vibronic population inversions are present:

$$(\text{e.g., } N_{v'=4}/N_{v''=3} \geqslant 1.2).$$

The electronic lasers can be quenched by high parent gas pressures or by addition of xenon and krypton.

We have used the observed laser transitions and their relative gain coefficients and quenching behaviors, together with spectroscopy and fluorescence experiments, to formulate a state-to-state photochemical reaction mechanism, *viz.*

$$RCN \xrightarrow{\hbar\omega} R + CN^*(A^2\Pi_i, v' = 0 \text{ primarily})$$
$$CN^*(A^2\Pi_i, v' = 0) + M \rightarrow CN(X^2\Sigma^+, v'' = 4 \text{ primarily}) + M.$$

In this mechanism, nascent photochemical products are formed with high electronic population inversion and *no* vibronic population inversion within the $A^2\Pi_i$ manifolds. Near-resonant collision-induced intersystem crossing preferentially populates $v = 4$ within the $X^2\Sigma^+$ electronic manifold.

We have treated electronic population inversions *via* state-to-state adiabatic correlation diagrams. In addition, we have calculated reaction product vibronic state distributions in photodissociative excitation of $CN^*(A^2\Pi_i, v')$, $CN^*(B^2\Sigma^+, v')$ and photosensitized excitation of $CN^*(B^2\Sigma^+, v')$ *via* a simple dynamical model. We find that photodissociation reactions are often very favorable candidates for molecular electronic chemical laser systems.

MB2. The Chloroethylene Photochemical Lasers: Vibrational Energy Content of the HCl Molecular Elimination Products, M. J. Berry, *Department of Chemistry, University of Wisconsin, Madison, Wis. 53706.*

Hydrogen chloride molecular vibrational laser emissions [$HCl\dagger$ $(X^1\Sigma^+, v') \rightarrow$

HCl ($X^1\Sigma^+$, $v'-1$), $v'=4, 3, 2, 1$] have been identified following flash photolysis of chloroethylenes ($CH_2=CHCl$, $CH_2=CDCl$, $CH_2=CCl_2$, *cis*-CHCl=CHCl, *trans*-CHCl=CHCl, $CHCl=CCl_2$) at $\lambda \geqslant 1550$ Å. Hydrogen chloride is produced as a vibrationally excited molecular photoelimination product:

$$\text{(e.g.,) } CH_2=CHCl \xrightarrow{\hbar\omega} HCl\dagger(v') + HC\equiv CH.$$

The grating selection technique [M. J. Berry, *J. Chem. Phys.*, vol. 59, p. 6229, 1973] has been used to measure relative gain coefficients of HCl vibration-rotation transitions, thereby permitting calculations of $HCl\dagger(v' \leqslant 4)$ product virbonic state distributions. The observed highly nonstatistical product vibronic state distributions are successfully matched by a bootstrap reaction dynamics model (M. J. Berry, *Chem. Phys. Lett.*, in press) which considers sudden structural distortion and intramolecular relaxation of HCl as it separates from acetylene or haloacetylene products in the primary photochemical act.

Chemical laser techniques have also been used to measure relative quantum yields of photochemical product types (e.g., the yield of chlorine atomic photodetachment relative to hydrogen chloride molecular photoelimination). In addition, spectroscopy experiments have been performed to determine the photochemical reactant states responsible for HCl elimination.

All available spectroscopic, photochemical, and product energy data are used to formulate a state-to-state photochemical reaction mechanism for HCl photoelimination from the chloroethylenes. Certain features of this mechanism operate in other elimination chemical lasers, such as those produced by the fragmentation of chemically activated fluoroethanes (e.g., $CH_3CH_2F\dagger \rightarrow HF\dagger + CH_2=CH_2$; *cf.* E. R. Sirkin and M. J. Berry, Paper G-2, VIII International Quantum Electronics Conference, San Francisco, Calif., June 11, 1974).

MB3. Temperature Dependence of the Vibrational Energy Distribution of HF Formed in the Reactions of NH with the Fluoromethanes, P. R. Poole and G. C. Pimentel, *Chemistry Department, University of California, Berkeley, Calif. 94720.*

Tandem chemical laser techniques[1] have been applied to study vibrational distributions of HF produced in the reactions of HN_3 photolysis products with the fluoromethanes, CH_3F, CH_2F_2, CHF_3, and CF_4. The reactions occurring are believed to be insertion of $NH(a^1\Delta)$ into the C-H and C-F bonds, with subsequent elimination of HF from the excited intermediate species. As well, there may be some fluorine atom abstraction by hot H atoms which may also be formed in the HN_3 photolysis.

$$NH + CHF_3 \longrightarrow CF_3NH_2^\dagger \longrightarrow CF_2=NH + HF$$

$$NH + CHF_3 \longrightarrow CF_2HNHF\dagger \longrightarrow CF_2=NH + HF.$$

Only the $v=1$ and $v=0$ HF vibrational levels are significantly populated in these systems. The N_1/N_0 vibrational population ratios for CF_4 and CF_3H are dissimilar but both decrease as temperature is raised. The opposite dependence is found for CF_2H_2 and CFH_3. The results have been interpreted in terms of characteristic temperature-dependent ratios for the isolated C-F and C-H insertion reactions, and in terms of the results obtained earlier for the $F+H_2$ and $F+D_2$ reactions.[2]

MB4. Rotational Chemical Lasers from HX Elimination Reactions, E. Cuellar and G. C. Pimentel, *Department of Chemistry, University of California, Berkeley, Calif. 94720.*

We have recently reported rotational laser emission from hydrogen fluoride elimination reactions, both from chemically activated $CH_3CF_3^\dagger$ and from photoexcited $CH_2CF_2^*$. The spectral range studied, 850 to 470 cm^{-1}, has been extended to 300 cm^{-1} and our search for laser emission at these longer wavelengths will be described. In addition, modifications to the system have been made to give a shorter flash pulse (1.2 μs rise time). We have also observed HF or HCl rotational laser emission in the photolysis of vinyl fluoride, vinyl chloride, and 1,1-dichloroethylene. In $CH_2=CHF$, HF laser transitions have been identified as $v=0$, $J=14\rightarrow13$, $v=0$, $J=13\rightarrow12$, and $v=1$, $J=14\rightarrow13$. In the case of the chloroethylenes, we have identified the following HCl transitions: $v=0$, $J=29\rightarrow28$ and $v=0$, $J=28\rightarrow27$ for CH_2CHCl, and $v=3$, $J=28\rightarrow27$ for $CH_2=CCl_2$. We believe that the most likely mechanism of excitation is that the HX molecules are probably born rotationally excited, with the implication that a substantial fraction of the available energy is being lodged in rotation. In addition, we feel that the rotational laser emission may be sustained after photolytic pumping has ended by near resonant $V\rightarrow R$ energy transfer processes. Preliminary results will also be presented on the rotational laser emission from HF produced in some F atom abstraction reactions.

MB5. HF Laser Emission and CO Population Distribution Studies of the $O(^3P)+CHF$ Reaction, R. G. Shortridge[1] and M. C. Lin.

HF stimulated emission was observed when mixtures of $CHFCl_2$ and SO_2 were subjected to flash photolysis above 165 nm. Vibrational analysis of the emission revealed that Δv ($2\rightarrow1$) and ($1\rightarrow0$) transitions were lasing. The effects of various additives (He, Ar, SF_6, D_2, N_2O, and CO_2), flash energy, temperature, and total pressure have been examined. Gas analysis of the flashed samples indicated the presence of CO, HCl, CO_2, and other minor sulfur-containing products. The observed HF laser emission is believed to result from the reaction

$$O(^3P) + CHF \longrightarrow HFCO\dagger \longrightarrow HF\dagger + CO$$

$$\Delta H^\circ \cong -181 \text{ kcal/mole.}$$

On account of the absence of CO emission and the small fraction of energy carried by HF (<10% on the basis of HF laser emission observed), the CO population distribution was measured by means of a cw CO laser. These experiments showed that CO was formed vibrationally excited up to $v=11$ without inversion.

HF laser emission was also observed in the flash-photolyzed mixtures of $CH_2FCl+SO_2$ and CHF_2Cl+SO_2. The pumping mechanisms of these two systems will also be discussed.

MB6. Parametric Investigation of the Na-N_2O + CO Chemical Laser,[1] R. C. Benson, C. B. Bargeron, and R. E. Walker, *Johns Hopkins Applied Physics Lab.*

The effect of several parameters on the gain of the Na-N_2O + CO chemical laser system has been studied. The chemical reaction mechanism in its simplest form consists of the following reaction chain:

$$Na + N_2O \longrightarrow N_2 + NaO + 21.0 \text{ kcal/mole}$$

$$NaO + CO \longrightarrow CO_2 + Na + 66.2 \text{ kcal/mole.}$$

[1] Supported by the Department of the Navy.

The reaction proceeds rapidly at room temperature and is accompanied by intense sodium *D*-line chemiluminescence. At low combustion efficiencies (10–20%) and an excess of N_2O, the system lases at 10.8μ with N_2O as the optically active specie.[2] Helium is used as the diluent and as the carrier of the sodium vapor which is derived from thermally decomposing the easily handled NaN_3 powder. In a coaxial flow configuration, lasing has been achieved using potassium, rubidium, and cesium catalysts in addition to sodium; the laser performance with all catalysts is nominally the same. A transverse flow system has been constructed in order to probe the flame perpendicular to the flow axis. Gain measurements have been made along the reaction length as a function of the CO/N_2O ratio, combustion efficiency, pressure, and catalyst concentration. Experiments to date indicate that 15–30% of the chemical energy is available for laser pumping. In addition, several aspects of the chemical processes have been investigated. It has been determined that molecular oxygen is produced in a chain-breaking mechanism. Various species have been added to the flame in order to study their effect on the overall reaction. As expected, N_2 and Ar have no effect on the reaction process, but CO_2, O_2, and NO when added to the flame in concentrations of a few mole percent, are quite detrimental to the combustion efficiency. Preliminary studies on the kinetic processes occurring in the $Na-N_2O + CO$ chemical laser indicate that at least six chemical reactions need to be considered.

MB7. Spectroscopic Studies of HCl‡ Producing Reactions,[1] –I. Cl + HI → HCl‡ + I, R. A. Carabetta and M. J. Linevsky, *Space Sciences Laboratory, General Electric Company, King of Prussia, Pa. 19406.*

An optional diagnostic technique has been developed for the study of vibrationally excited HCl produced by chemical reaction. Among the most efficient pumping reactions examined using this method was the exchange:

$$Cl + HI \longrightarrow HCl‡ + I \quad \Delta H = 32 \text{ kcal/mole.} \qquad (1)$$

Reaction (1) was studied using a subsonic flow reactor of rectangular cross section (1.5 cm × 15 cm) in which chlorine atoms, produced by microwave discharge in chlorine–helium mixtures, could be rapidly mixed ($t_{mix} \leqslant 15$ μs) with HI introduced into the laser section of the tube via an injector array. Associated optics were arranged to permit lasing and spectroscopic measurements to be made transverse to the gas flow. At a pressure of 3.6 torr, it was possible to couple 5 W of power from a Cl_2/HI/He mixture having the molar ratio 1/2.3/140. In these experiments, the Cl_2 flow rate was 0.51 millimoles/second and the average linear flow velocity was 166 m/s. Based on the spectroscopic measurements of the total HCl produced by reaction, the chemical efficiency of the system under conditions of maximum power was found to be 7.5%.

Measurements of the laser lines showed that the output consisted of a number of *P*-branch transitions from the $v = 3$, 2, and 1 levels of HCl^{35}; except for the appearance of several relatively weak lasing transitions from the HCl^{37} isotope, the spectra obtained were similar to those previously reported for (1) by Rosen, Sileo, and Cool[2] and others.

Spatially (time) resolved measurements of the spontaneous HCl‡ emission were carried out at ten positions along the flow reactor using a light gatherer/interferometer combination. The spectra obtained consisted of individual vibrational-rotational lines from HCl^{35} and HCl^{37}, and transitions were observed from $v = 5$ (a result of V-V pumping from lower v levels) through $v = 1$, from rotational levels $J = 0$ through 10. Typically, the spatial resolution of the optical system was 0.5 cm, which under the conditions of the experiment, represents a time resolution of about 30 μs.

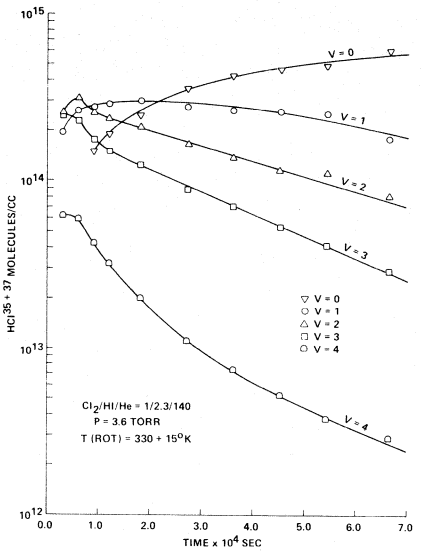

Fig. 1. Absolute HCl^{35+37} population profiles.

From the above data, the rotational temperature and relative HCl vibrational population distributions (for v's > 0) were obtained as a function of flow time. These relative concentrations were placed on an absolute bases from a knowledge of the threshold conditions for a given transition, the cavity loss, and the vibrational population ratios measured at threshold. Populations in $v = 0$ were obtained from an HCl mass balance and checked by a self-absorption technique involving the measurement of relative intensities of HCl^{35} and HCl^{37} for several *R*-branch transitions to the $v = 0$ level.

The resulting HCl profiles are shown in Fig. 1. The data shown were employed to compute the small-signal-gain for a number of transitions, the power output of the laser at several stations along the flow and to obtain estimates for V-T quenching of HCl‡. The calculated gain values were in good qualitative agreement with estimates of gain derived from the HCl^{35}/HCl^{37} isotopic intensity ratios observed in spontaneous emission for several *P*-branch transitions. The power calculations were in excellent agreement with measured power profiles.

MB8. Metal Atom Oxidation Lasers—A New Family of Chemical Lasers,[1] W. W. Rice, *Los Alamos Scientific Laboratory.*

At the time of the "3rd Conference on Chemical and Molecular Lasers" there were about six different chemical

[2] D. I. Rosen, R. N. Sileo, and T. A. Cool, "WB4—A spectroscopic study of CW chemical lasers," *IEEE J. Quantum Electron.*, vol. QE-9, pp. 163–172, Jan. 1973.

[1] Work performed under the auspices of the U. S. Atomic Energy Commission.

laser molecules (isotopic variations not considered). We wish to report a group of almost thirty additional chemical laser molecules from exothermic exchange reactions of the type suggested by J. C. Polanyi at the first "Conference on Chemical and Molecular Lasers": $M + XY \rightarrow MX^* + Y$ where M is a metal atom, XY is a gaseous oxidizer, and MX^* is an excited diatomic molecule.

These new laser molecules and their bond strength are as follows:

MX	D° (kJ/mol)	MX	D° (kJ/mol)	MX	D° (kJ/mol)
LiF	582	NiF	435	TaF	607
CO	1075	CuF	368	WO	674
CF	540	ZnF	364	WF	544
MgF	448	ZrN	561	PtF	–
AlF	669	ZrO	812	AuF	305
TiO	707	ZrF	615	PbF	314
TiF	619	MoO	519	UO	749
VO	615	MoF	502	UF	653
VF	536	AgF	347	UCl	615
FeF	448	TaO	824		

In the majority of these experiments exploding wire techniques were used to generate the metal atoms. However, one series of laser shots employed explosively shocked, grooved metal plates as metal vapor generators. In each experiment infrared emission lasting tens of microseconds was observed following the generation of metal atoms and the mixing of the metal vapor with oxidizers (O_2, Cl_2, F_2, and NF_3). With proper optical feedback strong infrared pulses, two to three orders of magnitude greater than the fluorescence level and $\leqslant 3$ μs duration, were observed.

These laser pulses appeared in the infrared spectral regions of the MX diatomic molecules. However, several systems lased at much shorter wavelengths than would be expected from the fundamental vibrational–rotational transitions within the MX electronic ground state. Thus population inversion among low lying electronic states is suggested.

MB9. Can We Beat F_2 & H_2 for HF Lasers?[1] G. L. Schott, S. W. Rabideau, A. V. Nowak, and R. W. Getzinger, *Los Alamos Scientific Laboratory.*

We explore potential new chain reaction mechanisms for pumping HF vibrational lasers by the basic process $F + HR \rightarrow HF^* + R$ (1). Our first starting point is the chain sequence, Reactions (1) and $R + F_2 \rightarrow RF + F$ (2). To avoid marginal-at-best stability of mixtures of hydrogenous fuels with elemental F_2, we tested possible reactions of difluorodiazine, N_2F_2, isomers with H atoms, $H + N_2F_2 \rightarrow HF^* + N_2 + F$(3), and other free radicals, e.g., $CF_3 + N_2F_2 \rightarrow CF_4 + N_2 + F$ (4), which regenerate an F atom exoergically. Reaction (3) was tested in a conventional fast flow mixing reactor with a TOF mass spectrometer, using H atoms from a microwave discharge. From the HF produced in 43 ms, we estimate k_3 as $10^{9.3}$ $cm^3 mol^{-1}$ s^{-1}, which is about 10^{-3} of the value of k_2 (R = H) at 300 K. Thus Reaction (3) appears too slow for a laser-pumping chain reaction. Occurrence of Reaction (4) or its CH_3 radical analog during near UV photolysis of CF_3I or CH_3I mixed with N_2F_2, was tested, using postreaction IR absorption for analysis. Since the N_2F_2 survived the photolytic decomposition of these iodides with little or no consumption, chains propagated by steps such as (4) appear far too slow to provide secondary F atoms for HF laser pumping.

In a second line of study, rapid branched chain reactions between fuels and undissociated F_2, producing F atoms, were sought. Here the starting point was the known, nonchain reaction pair $NO + F_2 \rightarrow FNO + F$ (5), $F + NO + M \rightarrow FNO + M$ (6). The guiding hypothesis is that strongly bound, polyatomic fluorides are formed by successive attack of incompletely fluorinated fragments upon F_2, as in Reaction (5), thus liberating several F atoms. These studies used a 24 mm i.d. conventional, low pressure, fast mixing flow apparatus of Al and sapphire, with reagents at 10–50 Pa partial pressure in an Ar carrier, and linear flows up to 10 m/s. The simplest reagents examined, besides NO, were PF_3, SF_4, and SO_2, which can each accommodate two F atoms in steps like (5) and (6). PF_3 reacted faster with F_2 than did NO, while SF_4 and SO_2 didn't react detectably in up to 0.1 s at 10 Pa partial pressures. Hydrogenous fuels were also tested. In approximate order of increasing speed, these were H_2, HBr, C_2H_6, H_2S, C_2H_4, HI, AsH_3, and PH_3. The reaction of H_2 with F_2 in the flow system behaved as a flame propagated by material and thermal transport, and not as a spontaneous reaction between original, room temperature reactants. The fastest of these reactions, with PH_3 and AsH_3, produced strong 2.5 μm and overtone HF emissions, plus near UV chemiluminescent bands from the respective $B^3\Pi - X^3\Sigma$ systems of PF and AsF, including many previously unreported PF bands with $v' - v'' \leqslant 7$. Our attempt at TOF mass monitoring of the $PH_3 + F_2$ system was stymied by accumulation of orange P-F polymer, but preliminary results showed PF_2 to be a major prompt gaseous product, and no higher fluorides.

[1] Work performed under the auspices of the U.S. Atomic Energy Commission.

SESSION MC

Chemically-Pumped Electronic Transition Lasers
Monday, October 21, 2:00 P.M.

MC1. Parametric Evaluation of Potential Electronic Transition Chemical Lasers,[1] D. G. Sutton and S. N. Suchard, *The Aerospace Corp., El Segundo, Calif.*

There has been intense interest over the past years in the demonstration of a chemically pumped electronic transition laser. A laser of this type would be similar to the well studied HF, HCl, HBr, and CO vibrational chemical lasers; however, the laser photons that would be extracted from the product molecules of the chemical reaction would be produced from electronic, not vibrational, transitions. Hence laser outputs would be expected in the visible and ultraviolet regions of the spectrum rather than the infrared.

The major difficulty faced by anyone contemplating the construction of such a laser is the lack of data crucial to the selection of an appropriate molecule and chemical reaction. Very few reactions have had their energy partitioning among available electronic states of the products characterized and little is known about the associated vibrational–rotational distributions. In addition, much more kinetic data, such as reaction rates, quenching and deactivation cross sections and radiative lifetimes is needed before accurate kinetic modeling can be used to help in the selection of suitable laser species.

There is available, however, a larger reservoir of spectroscopic data for dia-

[1] This work reflects research supported by the Advanced Research Projects Agency of the Department of Defense under U.S. Air Force Space and Missile Systems Organization (SAMSO) Contract F04701-73-0074.

tomic molecules.[2] It is our intention in this talk to exploit this information, with the aid of a static model, in order to isolate the parameters which influence the achievement of positive gain for electronic transitions in diatomic molecules.

Utilizing this generalized computer code which calculates the minimum reactive branching ratio required for a species to display optical gain, a parametric study was performed to ascertain which properties of the electronic potential curves of a diatomic molecule have the greatest effect on the suitability of this molecule as a potential electronic transition laser. The results of this study demonstrate that diatomic systems separate into different classes when the question of the minimum required reactive branching ratio is confronted. Using compiled molecular constants, this separation of molecular systems was translated into a determination of which vibrational level distribution class is most favorable for specific molecules to display optical gain. Potential laser candidates are pointed out.

[2] S. N. Suchard, "Spectroscopic constants for selected heteronuclear diatomic molecules," The Aerospace Corp., El Segundo, Calif., Tech. Rep. TR-0074(4641)-6, vol. I-III, May 1974.

MC2. Low Lying Excited Electronic States of BrCl and GeO, R. A. Harris, J. R. Lillis, *Air Force Weapons Laboratory*, J. A. Montgomery, Jr., *Columbia University*, and H. H. Michels, *United Aircraft Research Laboratories.*

Ab initio quantum mechanical calculations for the first 62 valence molecular states of GeO have been carried out using a valence configuration interaction method. A minimum basis set of Slater orbitals was used in conjunction with a complete set of valence configurations. Comparisons of theoretically determined spectroscopic constants and experimentally determined constants were made for those cases where experimental data exist. The results were also compared with theoretical calculations on CO and SiO.

Ab initio calculations have been completed for all molecular states of BrCl arising from the ground states of the separated atoms Br and Cl. A minimum basis set of Slater orbitals was used in conjunction with a complete set of valence configurations. Only two bound states were found to exist in the approximation used. These correspond to the $X^1\Sigma^+$ and the $a^3\pi$ electronic states. From the predicted ordering of the excited electronic states a correlation diagram is presented which aids in interpreting the observed predissociation in BrCl.

MC3. The Potential for Electronic Transition Lasers with Molecules from the Carbon Group Oxides, L. E. Wilson, S. G. Hadley, R. A. Harris, and G. Hager, *U.S. Air Force Weapons Laboratory, Kirtland AFB, N. Mex.*

Radiative electronic transitions between the lowest triplet and ground states of GeO and SiO have been studied as potential lasers. In order to observe the radiation we have employed the following chemical excitation scheme:

$$Si(^3P) + N_2O \longrightarrow N_2 + SiO$$

$$\Delta H = -150 \text{ kcal/mole}$$

$$Ge(^3P) + N_2O \longrightarrow N_2 + GeO$$

$$\Delta H = -130 \text{ kcal/mole.}$$

Due to spin conservation both reactions produce a triplet oxide product. The spectra of GeO and SiO, which appeared pale blue and violet to the eye, respectively, were recorded with a scanning spectrometer, photomultiplier and a lock in amplifier. We have assigned the emission spectrum of GeO to $a^3\Sigma^+ \rightarrow X^1\Sigma^+$ with $T_0 = 27\ 552\ \text{cm}^{-1}$ and $\omega_0' = 628\ \text{cm}^{-1}$. We have also assigned the emission spectrum of SiO to $a^3\Sigma^+ \rightarrow X^1\Sigma^+$ and $b^3\Pi \rightarrow X^1\Sigma^+$. Values of $T_0 = 33\ 409\ \text{cm}^{-1}$ for the $a \rightarrow X$ system, and $T_0 = 33\ 853\ \text{cm}^{-1}$ for the $b \rightarrow X$ system have been obtained.

The gain for vibrational transitions for the GeO $a^3\Sigma \rightarrow X^1\Sigma$ electronic transition have been calculated from the expression

$$\alpha = \left(\frac{\ln 2}{\pi}\right)^{1/2} \frac{\lambda_{21}^2}{\Delta\nu_0} \frac{A_{21}}{4\Pi} N_{JMAX}$$

where

$$A_{21} = \frac{\nu_{\nu'\nu''}^3 \left(\int \psi_{\nu'}\psi_{\nu''} d\tau\right)^2}{\tau \sum_{\nu''} \nu_{\nu'\nu''}^3 (\psi_{\nu'}\psi_{\nu''} d\tau)^2}.$$

The gain has been calculated by assuming the line is Doppler broadened and the vibrational levels have a Boltzmann population distribution. The A_{21} coefficient has been evaluated using Rydberg Klein potential energy curves in Schrodinger equation for nuclear motion. The Schrodinger equation was evaluated numerically and the integrals computed using a Simpson's rule method.

The requirements for producing a GeO laser on the $a \rightarrow X$ transition will be discussed. Estimates of radiative lifetimes will allow discussion of potential lasing from other carbon group oxides.

MC4. Studies of Visible Chemical Lasers Based on Reactions of Metal Atoms with Various Oxidizers,[1] D. J. Eckstrom, S. A. Edelstein, D. L. Huestis, M. Luria, B. E. Perry, and S. W. Benson, *Stanford Research Institute.*

As part of a program aimed at the development of visible chemical lasers, we have been studying the chemiluminescence of reactions of evaporated metal atoms with various oxidizers. Reactions that have been found to produce high photon yields now include: $Ba + N_2O$ (25%); $Ba + O_3$ (~35%); $Eu + N_2O$ (~20%); $Sm + N_2O$ (38%); and $Sm + F_2$ (61%). The peak yield usually occurs at a few torr pressure of inert gas, indicating that the initial reaction populates a reservoir state that does not radiate in the visible. We will discuss kinetic models of the $Ba + N_2O$ reaction that satisfactorily predict the variation of photon yield with pressure. Even in this well-studied reaction, however, we cannot specify the reservoir state with confidence.

Most of these flame spectra contain metal-atom emission. In the case of $Ba + N_2O$, however, when the reaction rates are increased to a level anticipated for laser threshold, the metal-atom emission becomes dominant at the expense of the diatomic emission. This energy-transfer rate is quite high, and may be an important quenching process for a diatomic upper laser level.

Experiments with $Ba + N_2O$ using a long-path burner (45 cm) in an optical cavity have not shown any evidence of gain in the 6000 to 8000 Å region.

[1] This work was sponsored by the Defense Advanced Research Projects Agency and monitored by the Army Missile Command.

MC5. Experimental Studies of Reaction Systems of Interest for Chemical Laser Operation at Short Wavelengths, M. S. Chou and T. A. Cool, *Department of Applied & Engineering Physics, Cornell University, Ithaca, N.Y. 14850.*

Experiments have been conducted to determine the feasibility of short duration pulsed discharges for the initiation of chemical reactions of potential interest for chemical laser operation at visible wavelengths. Double discharge preionization has been employed for rapid initiation of chemical reactions. The present technique accomplished uniform reaction on a time scale comparable to that (10^{-7} s) for spontaneous emission. Reaction initiation in pre-

mixed room temperature reagent combinations of several metal methyl compounds, $M(CH_3)_n$, with N_2O and O_2 have been extensively studied. High yields of metal atoms are provided by the reaction sequence

$$M(CH_3)_n + CH_3 \longrightarrow M(CH_3)_{n-1} + C_2H_6 \quad (1a)$$

$$\longrightarrow M(CH_3)_{n-1} + C_2H_4 + H_2. \quad (1b)$$

The observed visible chemiluminescence is believed to originate from the reactions

$$M + N_2O \longrightarrow N_2 + MO \quad (2)$$

or

$$M(CH_3) + O \longrightarrow MO + CH_3. \quad (3)$$

Spontaneous emission spectra have been recorded for several dozen reactant combinations which exhibit strong chemiluminescence. Photon yield measurements for the spectral region from 3000 Å to 9000 Å have been completed for several reagent combinations of interest.

The scope of application of discharge dissociation techniques for chemical laser reaction initiation with various reagent mixtures is discussed. Recent attempts at visible chemical laser operation with discharge reaction initiation are described.

MC6. Chemiluminescence and Photoluminescence Spectroscopy of the Barium Monohalides,[1] R. S. Bradford, Jr., and H. P. Broida, *University of California, Santa Barbara, Calif.*

In search of visible chemical laser candidates, Ba metal vapor, entrained in a flowing insert carrier gas, has been reacted with F_2, SF_6, Cl_2, Br_2, and I_2. Diatomic barium monohalides (BaX) have been produced in ground and electronic excited states. Bright green chemiluminescence flames occur at pressures from 0.1 to 10 Torr.

BaX chemiluminescent spectra, observed from 300–1100 nm have been corrected for absolute instrument response and are shown for the first time. The A through I electronic states have been found for BaF in emission where many high lying states were previously seen only in absorption. Vibrational structure is so closely spaced that there are more than 30 bands in a 6-mm spectral region. Rotational structure is only partially resolved with 0.01-nm resolution. Similar spectra are obtained from BaBr, BaCl, and BaI. New emission in the near infrared from BaBr and BaI is ascribed to transitions to the ground state from previously unobserved electronic states (analogous to A and B in BaF and BaCl). In BaBr, electronic state energies for B $^2\Sigma^+$, A $^2\Pi_{3/2}$ and A $^2\Pi_{1/2}$ have been found to be 11325, 10604, and 9980 cm^{-1}, respectively; while in BaI, corresponding values are 10417, 9921, and 9268 cm^{-1}, respectively.

Spectra of C $^2\Pi - X^2\Sigma^+$ transitions show thermal distributions in both vibration and rotation corresponding to population temperatures of approximately 3000 K for BaF and 2000 K for BaBr, BaCl, and BaI. BaX emission shows only slight dependence on pressure (0.1 to 10 Torr) and type of carrier gas (Ar, He, N_2).

Laser-induced photoluminescence has been observed with laser wavelengths of 496.5 and 514.5 in BaF; 488.0, 514.5, 520.8, and 530.8 in BaCl; as well as 514.5 and 520.8 nm in BaBr. Little pressure or carrier gas dependence has been found.

Production efficiencies into electronically excited states have been obtained from chemiluminescent spectra. BaX molecules are found to be produced with moderate efficiency into lower lying electronic states (80–98% in A and B) with an absolute efficiency of approximately 1 photon for each 100 reacted barium atoms. Electronic population temperatures obtained from efficiency measurements show trends similar to temperatures observed in vibration and rotation.

Electronically excited BaX species appear to be formed in two ways: 1) direct reaction, and 2) formation of long-lived BaX_2^* (asterisk indicates electronically excited) which then reacts with Ba to form BaX* + BaX. The second step allows equilibration of electronic, vibrational and rotational degrees of freedom as indicated by observed population temperatures.

MC7. The Diatomic Oxides and Halides of Ca and Sr: Photon Yields and $A'^1\pi$ Molecular Constants,[1] G. A. Capelle, *The Aerospace Corporation*, and H. P. Broida, *University of California, Santa Barbara, Calif.*

The diatomic metal oxides and halides of Ca and Sr have been formed by reacting the respective metal vapors with N_2O, NO, O_2, C_3, Br_2, Cl_2, and F_2 in 1 to 10 torr of argon buffer gas. Photon yields for the chemiluminescent emission from these systems were measured in the region 250–1100 nm. Photon yields for CaO (A-X) emission were measured to be as high as 1% with N_2O at 1.2 torr total pressure. Sr + N_2O at the same pressure also gave a yield of slightly over 1% for A-X emission. Total photon yields for the calcium halides were strongest (up to 0.9%) with F_2 and weakest (0.03%) with Br_2. The greatest contribution to the total yield came from A-X photons (~74% at 1.2 torr); about 24% of the yield was due to B-X emission and the remainder (1–2%) from C-X. The corresponding numbers for strontium are similar.

With both Ca + N_2O and Sr + N_2O, the $A'^1\pi$-$X^1\Sigma$ system was observed where it had recently been predicted[2] to lie. Bandheads were measured in the 550-840 nm region and molecular constants were calculated. For CaO($A'^1\pi$) we found:

$$\nu_{00} = 8340(6)cm^{-1}$$
$$\omega_e = 545.7(8)$$
$$\omega_e\chi_e = 2.54(3)$$
$$B_e = 0.3372(67)cm^{-1}$$
$$\alpha_e = 0.0021(7)$$

and for SrO ($A'^1\pi$):

$$\nu_{00} = 9778(7)cm^{-1}$$
$$\omega_e = 468.7(1.4)$$
$$\omega_e\chi_e = 2.06(6)$$
$$B_e = 0.2548(18)cm^{-1}$$
$$\alpha_e = 0.0017(3)$$

These values are in good agreement with those found by Field[2] through the use of perturbation analysis.

MC8. Production Efficiencies and Radiative Lifetime of FeO Produced in Low Pressure Flames,[1] J. B. West[2] and H. P. Broida, *Department of Physics, University of California, Santa Barbara, Calif.*

Chemiluminescent reactions between iron atoms and various oxidants are investigated[3,4] as possible mechanisms for electronic transition chemical lasers. Diatomic iron oxide (FeO) is produced[5] by reaction of either N_2O, O_3, NO_2, discharged O_2, or O_2 with iron vapor entrained in a flowing, inert carrier gas

(typically argon). Band emission from the infrared, orange, and blue systems of FeO is observed in chemiluminescent flames resulting from the reaction of Fe with O_3, N_2O, NO_2, or discharged O_2. Reaction of Fe with O_2 produces continuum-like emission of unidentified origin; however, laser photoluminescence studies confirm ground state FeO is present. Bands not previously reported are observed in flames of Fe reacting with O_3, N_2O, and discharged O_2. On the basis of vibrational spacings, some of these bands are ascribed to FeO.

Excited state production efficiencies (photon yield ≡ rate of photon emission from flame/rate of reaction of iron atoms) are measured for the band systems of FeO produced in the reactions of Fe with N_2O and O_3. For the reaction with N_2O at a pressure of 1.5 torr, photon yields for the infrared, orange, and blue systems of FeO are 0.7%, 0.15%, and 0.01%, respectively. Photon yields for these band systems produced in the reaction of iron with O_3 are about an order of magnitude greater.

Radiative lifetimes of FeO are measured by monitoring the decay of photoluminescence excited by a pulsed, tunable laser. Measurements on the 0, 0 band of the FeO orange system B at $\lambda = 579$ nm yield a lifetime of 450 ± 100 ns. A quenching rate constant for FeO by argon of $k = 3.4 \times 10^{-12}$ cm^3/s is found.

Reactions of Fe with Cl_2 and Br_2 produce only weak visible chemiluminescence. F_2 produces a bright blue flame with an unidentified, complex spectrum between 450 and 650 nm. Also, bands previously ascribed to FeF are observed near 330 nm. The photon yield for the unidentified emission between 450 and 650 nm is 1% at a pressure of 1.3 torr. No photoluminescence is observed from any of the lines of the argon ion laser or from a CW dye laser which is tunable between 570 and 620 nm. This observation indicates that the lower level of the visible emission could either be an electronically excited state or a high ground state vibrational level.

MC9. Population Inversions Measured in Alkali Metal-Halogen Reaction Systems, L. H. Hall, *Rocketdyne Division Rockwell International Corporation, Canoga Park, Calif.*

We have recently measured a number of population inversions in alkali metal atoms of the highly exothermic Cs + F_2 and Rb + F_2 reaction systems. The excitation process is probably a two-step process:

$$Cs + F_2 \longrightarrow CsF(v) + F$$

primary reaction

$$CsF(v) + Cs \longrightarrow CsF + Cs^*$$

transfer reaction.

The energy is initially created in vibrationally excited cesium fluoride and then is transferred to electric excitation of the cesium atom. Another reaction is possible based on the cesium dimer,

$$Cs_2 + F \longrightarrow CsF(v) + Cs^*$$

secondary reaction.

This reaction can create either vibrationally excited cesium fluoride or electronically excited cesium atoms. Under our experimental conditions (300°C initial reactant temperature, 1 torr total pressure, and 10:1 halogen to alkali metal ratio) only 1% of the cesium vapor is present in the form of dimers. We conclude that the secondary reaction is probably not a significant excitation mechanism in our experiments. The populations of the excited states of the alkali metal atoms were determined by chemiluminescence measurements combined with published values for the radiative oscillator strengths. For both the Cs + F_2 system and the Rb + F_2 system a substantial number of population inversions were measured indicating the potential for lasing at wavelengths as short as 1 micron. Parametric studies are currently underway on these and other alkali metal-halogen reaction systems.

MC10. F_2 Reactions as Possible Laser Candidates, S. J. Davis, G. Hager, S. G. Hadley, *Air Force Weapons Laboratory, Device Branch, Advanced Laser Technology Division, Kirtland AFB, N. Mex. 87117.*

Several chemiluminescent reactions involving molecular fluorine are being investigated in a flow tube apparatus. Reactions studied are those of I_2, Br_2, SiH_4, GeH_4, AsH_3, and PH_3 with F_2. The flames, produced in a concentric burner, are analyzed with a 1 m spectrometer and displayed on a strip-chart recorder via a phase sensitive detector. The $I_2 + F_2$ reaction yielded an orange appearing flame. The spectrum, which consisted of a series of red degraded bands extended from ~4500 to ~7000 Å. The chemiluminescence was due to the $A^3\Pi \rightarrow X^1\Sigma$ transition of IF. The mixing of Br_2 with F_2 produced no detectable emission. The reactions of F_2 with germane and silane yield extremely intense blue-violet flames. An analysis of the SiH_4, F_2 flame showed it to be due to the $A^2\Sigma^+ \rightarrow X^2\Pi$ SiF transition. It consists of a complex system of red degraded bands extending from ~4000 to ~4800 Å. The most intense bands are the vertical transitions (0, 0) and (1, 1) as expected from the near identical internuclear distances of the $A^2\Sigma^+$ and $X^2\Pi$ states. The possibility of an $a^4\Sigma^- \rightarrow X^2\Pi$ emission ($T = 29\,805$ cm^{-1}) was investigated but was not observed. The GeH_4, F_2 reaction was also spontaneous and the chemiluminescence was found to be due to $A^2\Sigma^+ \rightarrow X^2\Pi\,\frac{1}{2}$ and $A^2\Sigma^+ \rightarrow X^2\Pi\,\frac{3}{2}$ transitions. The large spin-orbit splitting (934 cm^{-1}) of the ground state leads to two subsystems each consisting of a series of red degraded bands. Strong $v'' = 0$ and $v'' = 1$ progressions were observed. Apparently, in both the GeH_4 and SiH_4 reactions, the fluorine strips the hydrogen, then we postulate that the following reactions occur:

$$Si + F_2 \longrightarrow SiF + F$$

$$\Delta H = -79 \pm 5 \text{ kcal/mole}$$

$$Ge + F_2 \longrightarrow GeF + F$$

$$\Delta H = -79 \pm 5 \text{ kcal/mole.}$$

The reactions of AsH_3 and PH_3 with F_2 yield what appears to be continuum spectra in the spectral region of ~3300 to 4700 Å. Further investigations of these two reactions are planned. RKR calculations have been performed for GeF and SiF using the known spectroscopic constants and are compared to the observed spectra. The calculated Franck–Condon factors are compared with those experimentally determined.

MC11. Metal-Oxident Flames: Visible Chemiluminescence Studies Using a Shock Tunnel Apparatus, P. B. Scott, S. Johnson, and G. Watson, *Xonics, Inc.*

A shock tube is used to vaporize metal (aluminum, boron, barium, carbon, copper, magnesium, silicon, strontium, titanium, uranium, tungsten, and zirconium have been used) powders in an argon gas carrier.[1] The argon-metal vapor mixture is then expanded through supersonic nozzles and an oxident (oxygen, nitrous oxide, chlorine or fluorine) mixes after injection downstream.

Flow duration is over 1 ms of steady flow and the resulting chemiluminescence is adequate to expose a spectral plate with 0.1 nm resolution. Emission spectra of numerous visible chemical laser candidates have been obtained. Systems of particular interest which produce strong spectra are as follows.

[1] S. Johnson *et al.*, *J. Chem. Phys.*, accepted for publication.

Metal	Oxident	Molecule	Electronic Transition	$\Delta\lambda$(nm)
B	N_2O	BO	$A^2\pi - X^2\Sigma$	320–550
	O_2	BO	$A^2\pi - X^2\Sigma$	320–550
Ba	N_2O	BaO	$A^1\Sigma - X^1\Sigma$	430–680
Cu	F_2	CuF	$A^1\pi, B^1\Sigma, C^1\pi - X^1\Sigma$	410–450
Si	N_2O	SiO	$D^1\pi - X^1\Sigma$, weak	230–300
	F_2	SiF	$A^2\Sigma - X^2\pi, C^2\pi$	410–460

The system can also be set up for laser gain observation or for lower state population measurements.

SESSION MD

Vibrational Energy Transfer
Monday, October 21, 2:00 P.M.

MD1. Vibrational Relaxation in HF and DF between 200-300°K,[1] J. K. Hancock and W. H. Green, *Naval Research Laboratory.*

Vibrational relaxation rates in HF-He and DF-He mixtures and pure DF samples have been measured between 200–300°K using the laser excited fluorescence technique. Rate constants are reported for the following collisional processes:

$$HF(v = 1) + HF \xrightarrow{k_{11}} 2HF + \Delta E = 3961\ cm^{-1}$$

$$HF(v = 1) + DF \xrightarrow{k_e + k_{12}} HF + DF(v = 1, 0) + \Delta E = 1055, 2906\ cm^{-1}$$

$$DF(v = 1) + DF \xrightarrow{k_{22}} 2DF + \Delta E = 2906\ cm^{-1}$$

$$DF(v = 1) + He \xrightarrow{k_{2m}} DF + He + \Delta E = 2906\ cm^{-1}.$$

The low temperature fluorescence cell consists of a stainless steel vacuum Dewar containing an internally mounted sample cell with appropriate window ports for the entrance and exit of the laser beam and collection of IR fluorescence. Gases to be studied were slowly flowed through coils surrounding the cold trap before entering the sample cell. Temperatures accurate to ±3 K were recorded using a Copper–Constantan thermocouple which had been calibrated with the known vapor pressure–temperature relationship of propane gas.

An HF TEA laser (<1 mj/pulse) was used as an excitation source for both the HF and DF measurements. A 2% HF impurity present in our DF sample cylinders was sufficient to allow direct DF($v = 1$) excitation through rapid V → V transfer from HF.

A summary of measured rates at 300 K and 200 K are listed in the table below (error limits shown are least squares values and indicate only the precision of the measured data).

System	Rate Constant	Temp. 300 K $k(sec^{-1}\ torr^{-1}) \times 10^4$	Temp. 200 K $k(sec^{-1}\ torr^{-1}) \times 10^4$
DF (pure gas)	k_{22}	1.77 ± 0.07	8
	$k_e + k_{12}$	7.2 ± 0.5	30
DF (dilute in He)	k_{22}	1.46 ± 0.09	6
	$k_e + k_{12}$	9.5 ± 0.4	30
	k_{2m}	$\leqslant 4 \times 10^{-3}$	$\leqslant 2 \times 10^{-3}$
HF (dilute in He)	k_{11}	4.7 ± 0.2	10–20

Preliminary temperature dependence results between 300 and 220 K suggest that room temperature rates increase only about a factor of two. Between 220 and 200 K, however, rates increase rapidly and vary nonlinearly with pressure. We report the asymptotic rates ($X_{HF,DF} \leqslant 0.005$) which represent the *slowest* rates measured in HF and DF at 200 K. At higher molefractions $0.005 \leqslant X_{HF,DF} \leqslant 0.015$, measured rates become up to five times faster.

Experiments are now in progress which will attempt to clarify some of the anomolous features of the low temperature relaxation measurements which have been observed.

MD2. DF* Laser Deactivation Kinetics, C. P. Wendelken, L. E. Wilson, C. Clendening, and J. Noetzel, *U.S. Air Force Weapons Laboratory, Kirtland AFB, N. Mex.*

Alternate reactant systems are being sought for combustion driven DF* lasers to replace the $H_2/F_2/D_2$ reactant system. Improved storage and handling are the primary reasons for this search, but the reduction of DF* deactivators in the laser cavity is also of major importance.

This paper presents results of a laboratory study of DF* deactivation rates by alternate laser reactants and their combustion products. The measurements were performed at 295 K using a flowing gas cell. Test species, diluent, and DF were mixed in a manifold with concentrations determined by differential pressure measurements. The DF was excited to the $V = 1$ state by a DF* pulse laser. The DF* deactivation rates were measured as a function of DF mole fraction; results were then extrapolated to zero mole fraction DF to obtain the deactivation rate of the test species.

Test species of interest include NF_3 for an oxidizer, C_2H_2, C_6H_6, and CS_2 for combustor fuels, DBr and deuterated hydrocarbons for cavity fuels, and N_2 and CF_4 products of the combustor reactants. The following DF rates were measured:

$$k_{DF^*-NF_3} = 4.86 \times 10^2\ s^{-1}\ torr^{-1};$$

$$k_{DF^*-N_2} = 7.3 \times 10^2\ s^{-1}\ torr^{-1};$$

$$k_{DF^*-CF_4} = 1.11 \times 10^3\ s^{-1}\ torr^{-1};$$

and

$$k_{DF^*-DBr} = 2 \times 10^4\ s^{-1}\ torr^{-1}.$$

A shortage of DF prevented measurement of DF* deactivation rates by the alternate combustor fuels at this time. To estimate the effect of alternate combustion fuels, HF* deactivation was measured. The following rates were obtained:

$$k_{HF^*-C_2H_2} = 3 \times 10^5\ s^{-1}\ torr^{-1};$$

$$k_{HF^*-C_6H_6} = 3.6 \times 10^5\ s^{-1}\ torr^{-1};$$

and

$$k_{HF-CS_2} = 1.6 \times 10^4\ s^{-1}\ torr^{-1}.$$

The DF rates are expected to be of the same order of magnitude.

Some preliminary conclusions may be drawn from these results. The HF*-hydrocarbon rates are extremely rapid; therefore, complete reaction of the fuel in the combustor is extremely important. On the other hand, the DF*-NF_3 rate is relatively low. Unreacted NF_3 would be relatively innocuous in the cavity. The DF*-DBr rate is essentially the same as DF*-DF so there is not advantage of either in the area of deactivation rates. The products formed have relatively low deactivation rates and should cause little problem in the cavity. Current operating

[1] This work was supported in part by AFWL under Contract 73-232.

characteristics of DF lasers with various fuels and oxidizers in both the combustor and the lasing cavity will be discussed.

MD3. Flow Tube Kinetics Studies: $DF(v) + HF$, $DF(v) + D_2$, and $HF(v) + H_2$ Systems,[1] M. A. Kwok and R. L. Wilkins, *The Aerospace Corporation.*

The medium pressure (1 torr), large diameter (10 cm) flow tube has been used to measure overall relaxation rates at room temperature for $DF(v) + HF$, $DF(v) + D_2$, and $HF(v) + H_2$ systems for $v = 1, 2, 3$, and 4. Computer model studies have been conducted on the kinetics of the $DF(v) + D_2$ and $HF(v) + H_2$ systems in order to predict the (VV) energy transfer rates for these systems which reproduce the observed overall rates.

The flow tube includes a side arm which provides the generation of F atoms by passing Ar diluent and SF_6 through a continuous RF discharge, and a movable fuel injector, which permits the reaction zone to be displaced with respect to a fixed optical station. Spectroscopic techniques monitor the emission (VR) bands of HF or DF. Average number densities of $HF(v)$ and $DF(v)$ exhibit exponential decays. From the sensitivity of the decays to HF, H_2, or D_2 concentrations, experimental rate coefficients can be determined.

As a trial experiment, the flow tube was used to measure HF vibrational deactivation of $HF(v)$ for $v = 1, 2$, and 3 and the measured rate coefficients are found to be in good agreement with reported experimental results.[2,3,4] Rate coefficients k_v for HF deactivation of $DF(v)$ are found to have a linear v dependence. The rate coefficients for vibrational de-excitation of $DF(v)$ by D_2 are found to have the values $(k_2/k_1) = 1.4$, $k_3/k_1 = 1.6$, and $k_4/k_1 = 1.8$, where $k_1 = 2.5 \times 10^{11}$ cm^3 mole^{-1} s^{-1}.

The rate coefficients for $HF(v) + H_2$ $(DF(v) + D_2)$ are determined by using a nonequilibrium chemistry flow model with three specialized components: 1) an H_2-HF (D_2-DF) VV rate package, 2) an HF-HF (DF-DF) VV rate package, and 3) a velocity profile adjustment. Of secondary importance, the HF-HF VV package must be included for the proper coupling behavior. An HF-HF VV rate package has been developed which fits known experimental data.[3] The model corrects for the paraboloid velocity profile which distorts the number density of $HF(v)$ or $DR(v)$ along the tube diameter. The successful H_2-HF VV rate package postulates strong multivibrational quantum processes, and uses a simple model to generate the required H_2-HF VV energy transfer rates.

[4] Eight experiments for HF(1) + HF.

MD4. Rotational Relaxation of Hydrogen Fluoride,[1] J. J. Hinchen, *United Aircraft Res. Lab.*

Rotational relaxation effects in HF were observed with double resonance IR experiments that employed two single wavelength lasers. A pulsed laser is used to pump the population to a particular V, J level, and the absorption of stable CW laser radiation is used as a probe to determine the loss or arrival of population in specific V, J levels. Observations were made of collisional energy transfer by vibrational–translational, vibrational–vibrational, and rotational–rotational processes in HF. The results for V-T and V-V transfer are in agreement with data from laser-induced fluorescence experiments. Preliminary results will be described for the temporal behavior of the population distribution over rotational levels after the population was placed in a single level, and also for individual level rotational relaxation rates.

[1] This work was sponsored by the Air Force Office of Scientific Research and by the Naval Research Laboratory.

MD5. Relaxation of $HCl(v = 1)$ and $DCl(v = 1)$ by Cl and O Atoms, R. D. H. Brown, G. P. Glass, and I. W. M. Smith, *Department of Physical Chemistry, University Chemical Laboratories, Cambridge, England.*

$$Cl' + HCl''(v = 1) \rightarrow Cl'H(v = 0) + Cl'' \quad (1a)$$

$$Cl' + HCl''(v = 1) \rightarrow Cl' + HCl''(v = 0). \quad (1b)$$

Rate coefficients for the relaxation of $HCl(v = 1)$ and $DCl(v = 1)$ by Cl and O atoms have been determined experimentally by making time-resolved measurements of the vibrational fluorescence from these molecules following their excitation with a pulsed laser.

A discharge-flow system was used to produce a mixture of HCl, the atomic species, and Ar. O_2, diluted in Ar, was partially dissociated in a microwave discharge, and the flow of O atoms was measured by titration with NO_2. Where needed, Cl atoms were created by adding sufficient Cl_2 to convert the O atoms quantitatively to Cl through the reactions: $O + CL_2 \rightarrow ClO + Cl$ and $O + ClO \rightarrow O_2 + Cl$. HCl could be added through one of several inlets; the extent of the slow, thermal reaction between O and HCl[1] was minimized by adding the HCl just upstream of the window through which the fluorescence was observed.

The laser was a pulsed HCl chemical laser of the TE type. It produced ~2 mJ (the energy from the DCl laser was $\sim\frac{2}{3}$ mJ) of which $\gtrsim$60% was in the (1, 0) band. The radiation from the laser was directed along the axis of the flow tube. Infrared fluorescence was observed perpendicular to the direction of the laser beam using a cooled InSb detector (time response, 1 μs). The level of scattered light was low and it was unnecessary to use a narrow-band filter in front of the detector. This allowed us to use low HCl concentrations ($0.6 - 3 \times 10$ molecule cm^{-3}), which was particularly valuable in the O + HCl experiments since the extent of the thermal reaction could be reduced to negligible proportions at all but the highest temperature used (397 K). The main flow-tube was positioned in a lagged metal box which could be filled with coolant or heated oil.

In the absence of Cl or O, the HCl or DCl fluorescence decayed to half its initial intensity in ~3–4 ms. At the total pressures (~2 torr) in the flow tube, this was consistent with diffusion-controlled surface loss. Sufficient concentrations of either Cl or O could be added to reduce the lifetime of the vibrationally excited molecules to ~0.5 ms.

For $HCl(v = 1) + Cl$, rate coefficients have been determined for $263 \leqslant T \leqslant 397$ K. No distinction can, of course, be made between "reactive" and nonreactive processes, i.e.,

The data are matched quite well by the Arrhenius expression, $k_1 = (k_{1a} + k_{1b}) = 7.9 \times 10^{-11} \exp(-1.3 \text{ kcal mole}^{-1}/RT)$ cm^3 molecule^{-1} s^{-1}. Our value at 298 K, $k_1 = 8.8 \times 10^{-12}$ cm^3 molecule^{-1} s^{-1} is in good agreement with that of Craig and Moore[2] (11×10^{-12} cm^3 molecule^{-1} s^{-1}) and with more recent data from Moore's laboratory.[3] It appears that the value of k_1

[1] R. D. H. Brown and I. W. M. Smith, *Int. J. Chem. Kinetics*, in press.

[2] N. C. Craig and C. B. Moore, *J. Phys. Chem.*, vol. 75, p. 1622, 1971.

[3] G. Macdonald, C. B. Moore, I. W. M. Smith, and F. J. Wodarczyk, to be published.

obtained by Ridley and Smith[4] must be in error. The overall rate constants for deactivation of DCl($v = 1$) by Cl are approximately 0.6 k_1.

For HCl($v = 1$) + O, the reactive and nonreactive channels,

$$O + HCl(v = 1) \rightarrow OH + Cl \quad (2a)$$
$$O + HCl(v = 1) \rightarrow O + HCl(v = 0) \quad (2b)$$

are quite different, but they have not been distinguished in the present work. Measurements on HCl($v = 1$) between 196 and 397 K have given values of $k_1 = (k_{1a} + k_{1b})$ which can be fitted quite well to the expression, $k_1 = 8.2 \times 10^{-12} \exp(-1.3 \text{ kcal mole}^{-1}/RT)$ cm^3 molecule^{-1} s^{-1}. The rate coefficient at 298 K, 9.0×10^{-13} cm^3 molecule^{-1} s^{-1}, is four times smaller than that reported by Arnoldi and Wolfrum.[5] In the case of O atoms, DCl($v = 1$) is deactivated faster than HCl($v = 1$), the difference being greatest at 196 K where it amounts to a factor of two.

MD6. Vibrational Relaxation in Potentially Reactive Collisions: Temperature and Isotope Effects, I. W. M. Smith, *Department of Physical Chemistry, University Chemical Laboratory, Cambridge, England.*

Vibrationally excited molecules appear to be deactivated much more rapidly by potentially reactive atoms (e.g., F, Cl, H, O) than by inert gases. This surely reflects differences in the intermolecular potentials. Two kinds of difference may be distinguished. First, the interaction between molecule and reactive atom may be characterized by more than one electronic potential: thus, Cl(^{2}P) + HCl ($^1\Sigma^+$) yields $^2\Pi$ and $^2\Sigma$ states in $C_{\infty v}$ symmetry and $2\,^2A' + {}^2A''$ in C_s symmetry. This may lead to an electronically nonadiabatic mechanism for energy transfer.[1] Secondly, the form of one or more of the potentials must reflect the possibility of chemical reaction, and this may lead to enhanced probabilities of energy transfer by an electronically adiabatic mechanism. In the present work, this possibility was investigated by means of classical trajectory calculations for systems modeled on HCl ($v = 1$) + Cl and DCl ($v = 1$) + Cl.

The simple LEPS expression was used to represent the potentials. The single adjustable parameter was chosen to give: a) a surface with a 6.2 kcal mole^{-1} barrier for H-atom transfer, and b) a surface with a 6.2 kcal mole^{-1} 'well', corresponding to a linear, symmetric, weakly bound collision complex. These choices were made to give a crude match with the two, apparently conflicting, pieces of empirical evidence[2,3] about the ClHCl potential. The general computational procedure was similar to that of Smith and Wood[4] except that all the initial collision parameters except E_{vib} were chosen by Monte Carlo methods, calculations being performed for $T = 1000$, 500, and 333.3 K.

For surface a), the calculated rate coefficients for deactivation were quite well-matched by Arrhenius expressions = $2.5 \times 10^{-11} \exp(-2.7 \text{ kcal mole}^{-1}/RT)$ cm^3 molecule^{-1} s^{-1} for HCl ($v = 1$) and $1.6 \times 10^{-11} \exp(-3.3 \text{ kcal mole}^{-1}/RT)$ cm^3 molecule^{-1} s^{-1} for DCl ($v = 1$). Compared with experimental values,[5] these are much too small and show too great a dependence on temperature and isotopic substitution. For both species on surface b), the rate coefficients were essentially independent of temperature and equal to 1.0×10^{-10} cm^3 molecule^{-1} s^{-1}. This time the absolute magnitude of the rate coefficients was too great and the temperature and isotope dependence too slight.

In view of the large discrepancy between the experimental results and both sets of calculated rate coefficients, a third series of calculations were carried out with the barrier for H-atom transfer adjusted to 1.9 kcal mole^{-1} The results of these calculations agreed quite well with those determined experimentally in regard to magnitude, temperature dependence, and isotope effect. It therefore seems that either the barrier on the ClHCl surface is lower than that deduced from the experiments of Klein *et al.*,[2] or possibly that an electronically nonadiabatic mechanism is operative. The latter seems somewhat unlikely as HCl is deactivated faster than DCl.

Some empirical evidence for a lower barrier for H-atom transfer in this system comes from comparing the activation energies for pairs of reactions involving OH and Cl. With H_2, CH_4, HBr, and HI these are similar, but the activation energy for OH + HCl → H_2O + Cl is only 1.0_6 kcal mole^{-1} [6] much less than the 6.6 kcal mole^{-1} given by Klein, Pensky, and Weston for ClCl* + HCl → Cl*H + Cl.

MD7. H Atom Deactivation of HF($v = 1$),[1] R. F. Heidner and J. F. Bott, *The Aerospace Corporation.*

Relaxation times of HF($v = 1$) by H atoms have been measured in a discharge flow tube. A microwave discharge dissociates the H_2 to give H atoms, and a small amount of HF is injected downstream to yield a gas mixture containing H atoms, H_2, HF, and He. The HF($v = 0$) is pumped to HF($v = 1$) by a pulsed HF laser. IR fluorescence from the HF($v = 1$) is monitored with and without the H atoms by switching on and off the microwave discharge. The H atom concentration is measured by a Pt-Rh catalytic probe with a calibrated recombination efficiency. We obtain a rate coefficient for HF($v = 1$) + H → HF($v = 0$) + H of $(1.4 \pm 1) \times 10^{11}$ cc/mole-s. This is lower by an order of magnitude than previous estimates of this rate and is much smaller than a similar measurement for HCl ($v = 1$) + H → HCl($v = 0$) + H. We have also measured rate coefficients for D + DF($v = 1$), D + HF($v = 1$) and H + DF($v = 1$).

MD8. Vibrational Deactivation of HF($v = 1$), DF($v = 1$), and HCl($v = 1$), by Collisions with Atoms, G. P. Quigley and G. J. Wolga, *Cornell University, Ithaca, N.Y. 14850.*

An experimental program has been set up to measure the rate of deactivation of hydrogen halide molecules by selected atomic collision partners. These rates are important for several reasons. First, within HX chemical laser media atoms are present as a result of the initiation means employed and due to chemical reactions that occur. Second, in general these deactivation rates have not previously been measured in the temperature range of laser operation. Finally, there is theoretical interest in the operative mechanisms that lead to these deactivations. Thus, the atoms selected for study include those that are found within chemical lasers as well as those whose deactivation efficiency should be compared in attempting to make correlations with theory.

The experimental approach employs a

fast, subsonic flow system. Laser induced fluorescence using a TEA pin-type chemical laser for excitation of the molecule to $v = 1$ is the chosen method for measurement of vibrational relaxation. Microwave paramagnetic resonance is employed to make absolute atomic density determinations using $O_2(^3\Sigma)$ and certain atoms as standards according to methods developed by Westenberg. Fast, digital signal averaging is employed to improve the precision of the results. The measurements to be reported were all done about 300 K.

The data to be reported concern the deactivation of: $HF(v = 1)$ by H, D, O, F, Cl, Br; $DF(v = 1)$ by H, D, O, F^-, Cl; $HCl(v = 1)$ by H, D, O, F, Cl. These rates will be correlated with other data in the literature and with such parameters as molecular dipole moments, atomic polarizability, and the reduced mass of the colliding complex. The theoretical position of I. I. Nikitin will be examined in light of our results and, in particular, his predictions of enhanced deactivation efficiency by atoms possessing orbital angular momentum degeneracy. Our work appears to broadly substantiate this position in that S state atoms such as H, D, and N are much less efficient deactivators of HF than is O, F, Cl, and Br. Among the halogen atoms deactivation efficiency increases in the order F, Cl, Br.

MD9. Vibrational Deactivation of $CO_2(^3\Sigma)$ by Collisions with Atoms, M. I. Buchwald and G. J. Wolga, *Cornell University, Ithaca, N.Y. 14850.*

The great interest in CO_2 lasers has prompted extensive investigation of the vibrational relaxation and energy transfer resulting from collisions between CO_2 and other molecules. In many types of CO_2 lasers atoms as well as molecules are present as a result of the excitation scheme employed. Few low temperature rates for the deactivation of the CO_2 upper level, $(00^\circ 1)$, by atoms have been available heretofore. The experimental work to be presented will describe our studies of the deactivation of $CO_2(00^\circ 1)$ by various atoms.

The experimental method employed is laser induced fluorescence on a flowing gas stream to measure vibrational relaxation, with microwave paramagnetic resonance to make absolute atom density determinations. In combination with known molecule-molecule deactivation rates this method has permitted us to determine or place upper bounds on a large number of atom-CO_2 rates. In the course of this work measurements have also been made on deactivation rates of certain atoms with $N_2(v = 1)$ and $CO(v = 1)$.

We shall report our studies of the deactivation of $CO_2(00^\circ 1)$ by H, D, O, N, F, and Cl. In addition we shall discuss our studies of $N_2(v = 1)$ deactivated by H and N and of $CO(v = 1)$ deactivated by H. This work was all done about 300 K.

In our discussion we shall contrast the relatively inefficient effects of S state atoms (H, D, N) with the relatively efficient effect of atoms possessing orbital angular momentum degeneracy (O, F, Cl). This distinction will be discussed in the light of I. I. Nikitin's theoretical prediction of deactivation enhancement by atoms possessing orbital degeneracy. We shall also contrast the relatively slow rates of deactivation of CO_2 with the more rapid deactivation of $HF(v = 1)$ by the same atomic collision partners. The advantages and limitations of our experimental method will be discussed as will the special problems attendant to slowly relaxing molecules like CO_2.

MD10. Vibrational Relaxation of N_2 and $CO_2(001)$ by Alkali Metal Atoms,[1] R. C. Benson, D. J. Benard, and R. E. Walker, *Johns Hopkins Applied Physics Lab.*

The efficient vibration-to-translation (V-T) relaxation of molecules by reactive atoms is of interest from both an experimental and a theoretical view. All results to date indicate that reactive atoms are at least an order of magnitude more efficient than typical molecules (e.g., CO, CO_2, N_2) in the vibrational relaxation of molecules. These high efficiencies cannot be explained by conventional theories and have been attributed to strong attractive intermolecular forces. We have devised a new technique to measure small signal gain and have applied this method to determine the V-T relaxation rates of N_2 and $CO_2(001)$ by alkali metal atoms. Basically the technique is to fluid-modulate trace amounts of CO_2 which are added to a fast-flowing, alkali metal-active N_2 mixture. The extremely fast resonant V-V transfer between $N_2(v = 1)$ and $CO_2(001)$ inverts the $CO_2(001)$ level which is then probed with a conventional CO_2 laser. By measuring the optical gain with and without the alkali metal, the V-T rates can be determined. The method is quite sensitive and gain changes as small as 0.1 percent can be measured. The effective rate,

$$k_{\text{eff}} = k_{N_2\text{-M}} + 0.914(X_{CO_2}/X_{N_2}) \cdot k_{CO_2\text{-M}},$$

for the coupled N_2 and CO_2 levels has been determined for $X_{CO_2}/X_{N_2} = 0.071$ and M = Li, Na, K and Cs: Li, $k_{\text{eff}} = 1500 \pm 500$; Na, $k_{\text{eff}} = 1400 \pm 200$; K, $k_{\text{eff}} = 4600 \pm 1000$; and Cs, $k_{\text{eff}} = 7900 \pm 2000$, all in units of $\text{torr}^{-1}\ \text{s}^{-1}$. In the case of Na, X_{CO_2} was also varied in order to determine the individual rates: $k_{N_2\text{-Na}} = 920 \pm 100\ \text{torr}^{-1}\ \text{s}^{-1}$ and $k_{CO_2\text{-Na}} = 8100 \pm 2000\ \text{torr}^{-1}\ \text{s}^{-1}$. These experimental rates differ by orders of magnitude from theoretically predicted values based on an ionic-intermediate curve-crossing model.[2]

[1] Supported by the Department of the Navy.

MD11. Infrared Laser Enhanced Reactions: An Application of the Technique for the Measurement of V-T, and V-V Deactivation Rates in the 10_3 and O_3-SiF_4-O_2 Systems, A. Kaldor, *Corporate Research Labs, Exxon Research & Engineering Co.,* and W. Braun and M. J. Kurylo, *Physical Chemistry Div., National Bureau of Standards, Washington, D.C. 20234.*

A laser technique to study the chemical dynamics of vibrationally, excited species is described. The technique employs chemiluminescence and/or resonance fluorescence monitoring of the temporal or steady-state behavior of reactants or products in reactions of vibrationally excited (laser excited) species. In the chemiluminescence reaction of $O_3^\dagger$ with NO the method of measurement of deactivation (V-T) rates for vibrationally excited species is described, and rate constants for deactivation of $O_3^\dagger$ by He, Ar, H_2, N_2, O_2, H_2O, CO_2, SO_2, CH_4, and SF_6 are reported.

Rate Constants for the Deactivation $O_3^\dagger$ in the (100), (010), and (001) Manifold

Deactivant	$k(\text{cm}^3\ \text{molec}^{-1}\ \text{s}^{-1})$
Ar	$7.27 \pm 1.77 \times 10^{-15}$
O_2	$1.31 \pm 0.13 \times 10^{-14}$
N_2	$1.94 \pm 0.06 \times 10^{-14}$
He	$6.02 \pm 0.29 \times 10^{-14}$
CO_2	$1.06 \pm 0.08 \times 10^{-13}$
SO_2	$2.35 \pm 0.12 \times 10^{-13}$
CH_4	$4.83 \pm 0.44 \times 10^{-13}$
H_2	$1.18 \pm 0.07 \times 10^{-12}$
SF_6	$1.92 \pm 0.11 \times 10^{-12}$
H_2O	$3.53 \pm 0.24 \times 10^{-12}$

Rapid V-V energy transfer between SiF_4 and O_3 has been observed following laser excitation of either O_3 or SiF_4. In experiments where only the SiF_4 is vibrationally excited, the V-V transfer to O_3 and subsequent reaction of $O_3^\dagger$ with NO were used to obtain the rate constant for the V-T deactivation of $SiF_4^\dagger$ by O_2.

$$SiF_4^\dagger = O_2 \xrightarrow{h} SiF_4 + O_2$$

$k = 6.3 \pm 1.4$

$\times 10^{-13}$ cm^3 molec^{-1} s^{-1}.

Fractional modulation measurements of the chemiluminesence generated by the $O_3 + NO$ reaction were used in experiments where primarily the O_3 is excited to obtain the rate constant for the V-V energy transfer between $O_3^\dagger$ and SiF_4

$$O_3^\dagger + SiF_4 \xrightarrow{k} SiF_4^\dagger + O_3$$

$k = 3.8 \pm 0.5$

$\times 10^{-11}$ cm^3 molec^{-1} s^{-1}.

SESSION TA

Pulsed Chemical Lasers and Q-Switching
Tuesday, October 22, 8:30 A.M.

TA1. N_2F_4 as a Saturable Absorber of CO_2 Laser Radiation, R. D. Suart.

Tetrafluorohydrazine exhibits a moderately strong IR absorption spectrum around 10 microns. A cell containing low pressures of this gas, mixed with He, induced passive Q-switching of a continuous wave CO_2 laser when inserted into a frequency selective cavity. This effect was observed near the P and R branches of the CO_2 (0,0,1) to (1,0,0) laser system on all transitions accessible in the laser.

Experiments were performed in a 2.8 m long cavity with a 75 line/mm frequency tuning grating and a 98% reflectivity output mirror. The cavity contained a 30 cm long CO_2 gain tube and a 53 cm long, 2.5 cm bore absorption cell. The gain tube was capable of pumping the cavity to 150% of the threshold gain measured with the absorption cell empty.

Although ultra high resolution absorption spectra of N_2F_4 are not available, experiments with various pressures of N_2F_4 in the cavity suggest that there is not a great deal of fine structure in the absorption spectrum of this molecule near the R branch of the (0,0,1) → (1,0,0) transition. This follows from the fact that the absorption due to N_2F_4 required to reduce the cavity gain to threshold at each R branch transition lay on a smooth curve identical with the profile of small signal gains over the same transitions.

The introduction of larger pressures of N_2F_4 into the cell in a nonfrequency selective cavity forced the laser to oscillate on the (0,0,1) → (0,2,0) transitions near 9.4 microns. This occurs because the absorption due to N_2F_4 is less in this region. Oscillation can be forced on either the P or R branch of the 9.4 micron system depending on the N_2F_4 pressure, because of differing absorption intensities in each branch.

From the measured rise and fall times of the Q-switched pulse and the cavity photon lifetime, it was possible to compare the observed pulse shape to that predicted by the theory of Zsabo and Stein.[1] It was concluded that the absorption cross section for N_2F_4 is at least ten times greater than the cross section of stimulated emission by CO_2 (0,0,1) at the laser wavelengths.

The observed properties of N_2F_4 suggest that this molecule might be useful for the isolation of high power CO_2 laser amplifier sections, for passive mode locking of pulsed CO_2 lasers and for forcing CW lasers into the lower gain 9.4 micron laser system.

TA3. Mixture Stability in High-Power Pulsed H_2-F_2 Chemical Lasers,[1] R. W. Getzinger, L. S. Blair, and N. R. Greiner, *Los Alamos Scientific Laboratory.*

Interest in using H_2-F_2 mixtures in high-power pulsed chemical lasers has focused attention on the problems of mixture stability. Because the output power increases with the chemical reaction rate, it is desirable to have high H_2-F_2 concentrations and a considerable temperature rise during the burn. Therefore, addition of other components to enhance stability should be minimized. Although mixture stability improves at low temperature, the design requirements and operation are simpler at room temperature. Furthermore, we need a variety of readily workable construction materials that are themselves stable in this harsh environment and do not cause instability in the mixture.

We wish to present the results of a systematic study of the behavior of atmospheric-pressure mixtures of H_2, O_2, and F_2 at ambient temperatures carried out to determine a range of conditions under which the reagents can be combined nonexplosively. The $P_1(7)$ line from an HF probe laser was used to monitor formation of hydrogen fluoride in the reaction cells during and, in the absence of explosion, for some 30 minutes after the mixing process. A detailed empirical calibration of beam transmission versus known partial pressure of HF in each of the gases of interest yielded pressure broadening parameters for the $P_1(7)$ line, and permitted determination of the absolute amount of HF formed during reaction.

In the absence of explosion conversion of reagents to HF during the period of observation was always less than 5%. Reaction to form HF was seen to take place "promptly" during mixing and at an essentially constant rate thereafter. The magnitudes of these two quantities increased together, and were clearly related to the difficulty of reproducibly bringing the reagents together without explosion. As little as 5% O_2 as the only additive was sufficient to prevent explosion in stoichiometric H_2/F_2 mixtures. The dependence of the reaction rate on partial pressure O_2, initial H_2/F_2 ratio, total gas density, and temperature was examined. Various considerations, including computations based on a plausible steady-state chemical mechanism with constant reagent concentrations and literature values for the pertinent rate coefficients, indicate that heterogeneous reaction steps significantly influence the long-term deterioration of the mixtures.

Stable mixtures could be made in contact with any of the following: Kel-F, Teflon, Viton, brass, aluminum, stainless steel, quartz, sapphire, or calcium fluoride. This list affords materials suitable for building H_2-F_2 lasers initiated by flash photolysis, electric discharge, or electron beams. Examples of each type have been built and successfully operated in this laboratory, including an e-beam initiated device 28 l in volume operated at 1.5 atm.

[1] Work performed under the auspices of the U.S. Atomic Energy Commission.

TA6. Chemically Pumped Hydrogen Fluoride Overtone Laser, J. F. Hon and J. R. Novak, *Rodketdyne Division/Rockwell International, Canoga Park, Calif. 91304.*

It has been shown by several workers that substantial fractions of the energy of reaction of F-atoms with H atom donors (HR) are distributed initially (primative distribution) into vibrationally excited states ranging from $v = 1$ to the highest v state possible for the energy available in a specific reaction. For a wide range of F plus HR reactions, this results in the population of $v = 3$ and higher. The gain on $\Delta v = 1$ transitions for HF can be quite high for these systems and a multitude of F + HR reactions have produced HF $\Delta v = 1$ lasing. Because the $\Delta v = 1$ transitions have very high gain, appreciable gain can be expected on $\Delta v = 2$ transitions although much lower than that of $\Delta v = 1$ transitions. Calculated[1] matrix elements for the low J, $v = 3 \rightarrow 1$ transitions are about 0.16 the values calculated for low J, $v = 2 \rightarrow 1$ transitions, so that for equivalent population inversion the overtone gain would be about 2.5×10^{-2} that of the fundamental. Provided that the optical resonator is sufficiently selective, there is no basic reason why $\Delta v = 2$ transitions should not be lasable, given a sufficiently long gain path. Indeed,

[1] R. E. Meredith and F. G. Smith, *Investigations of Fundamental Laser Process*, vol. II, Willow Run Laboratories, Nov. 1971 (ARPA Contract DAHC-15-67-C-0062).

$\Delta v = 2$ transitions have been reported for a DF chemical laser.[2] However, subsequent to this, no other overtone lasers have been reported in the literature.

Here we report the lasing of five overtone transitions in an electrical pulse-initiated chemically pumped HF laser. Chemical pumping of HF was achieved with a standard pin discharge laser employing SF_6 in the discharge to produce F atoms and HBr as the H atom donor. The discharge tube was 1 m long, terminated with CaF_2 Brewster angle windows and operated at low pressure ($\sim$1 torr). The optical resonator consisted of two 10-m radius dielectric-coated mirrors tuned for maximum reflectivity (>99.5%) at 1.3 μ. Published results on the primative vibrational distribution of HF(v) from the reaction of F with HBr indicate the relative rates[3]: $v = 0$, 0.2; $v = 1$, 0.62; $v = 2$, 1.00; $v = 3$, 0.9; $v = 4$, 0.67. Thus, $v = 3$ and $v = 4$ are well-populated initially. Lasing transitions corresponding to three $v = 3 \rightarrow 1$ transitions, P(3), P(4), and P(5), and two $v = 4 \rightarrow 2$ transitions, P(4) and P(5), were observed.

The overtone wavelengths observed and the transition assignments are shown in Table I. Also shown are the computed wavelengths. Transition assignments were made by comparing the two. The agreement, as assigned, with calculated wavelengths is quite good and this along with the J-value sequencing provides high confidence in the line assignments.

TABLE I
HF OVERTONE RESULTS

Observed (cm^{-1})	Assignment	Calculated[a]
7285 ± 1	3 ⟶ 1 P(3)	7284.3
7235	P(4)	7236.1
7187	P(5)	7185.2
6914	4 ⟶ 2 P(4)	6911.2
6864	P(5)	6862.0

TA7. Theoretical Investigation of the Effect of Rotational Nonequilibrium on Predicted Performance of Pulsed HF Chemical Lasers, J. J. T. Hough and R. L. Kerber, *Michigan State University, E. Lansing, Mich. 48824.*

A rate equation model is developed based on the interaction of the chemical kinetic and radiative phenomena within the active medium; the model simulates cavity transients such as the interaction of intensity and gain in the pulsed HF chemical laser. Calculations show that the growth in intensity is sufficiently slow that the gain may attain levels far above threshold before lasing begins. Intensity increases sharply after the gain is far above threshold causing the gain to drop rapidly and oscillate near the threshold value. This fluctuation in gain, which is a result of fluctuation in HF (v, J) populations, makes the calculations more sensitive to relaxation processes than has been shown by earlier constant gain models. The present model, which is capable of predicting time histories of intensities of laser transitions and chemical species concentrations is further expanded to study the effects of preferential pumping into rotational levels, rotational relaxation, and rotational nonequilibrium. Due to the length of the numerical calculations, this latter expansion was limited to the less complicated case of the SF_6/H_2 laser pumped by the $F + H_2$ reaction. Rotational relaxation is modeled by associating with each (v, J) state a relaxation time constant τ consistent with available experimental data and theoretical calculations. The results show that as the rotational relaxation rate decreases the laser output decreases and pulse energy is more uniformly distributed among the lasing transitions within a given band. The predicted time-resolved spectrum exhibits strong simultaneous lasing on many vibrational–rotational transitions; a situation that is found experimentally but cannot be predicted by earlier models. The normal J-shift pattern is also predicted. This unique model is capable of predicting the performance of lasers operating in the line-selected mode. A comparison is made of the output from a three transition cascade consisting of $P_1(8)$, $P_2(7)$, $P_3(6)$ with the same three transitions operated in the single-line mode. The sum of the output from the three single line calculations is just 65% of the output from the cascade.

TA8. Calculation of Rotational Nonequilibrium in a Pulsed HF Laser,[1] J. R. Creighton, *Lawrence Livermore Laboratory, Livermore, Calif. 94550.*

Several numerical models of the HF laser have been published.[2] These have generally assumed rotational equilibrium within each vibrational level and have used a steady-state (gain equals loss) model for lasing. We have developed a numerical model which extends these calculations by treating each vibrational–rotational state separately and allows rotational relaxation. This model can test the validity of assuming rotational equilibrium. The model also extends the calculations by using simplified semiclassical laser equations rather than the steady-state approximation.

The computer code produces waveforms for each P-branch transition. These waveforms are in good agreement with experimental waveforms from a pulsed $NF_3 + H_2$ laser initiated by a 70 ns discharge.[3,4] The calculated and experimental waveforms agree as to which transitions lase, the delay between initiation and laser turn on, and the shape and relative amplitudes of the individual waveforms, including spikes. The differences between calculated and experimental waveforms are comparable to the experimental variation from one shot to another.

The experiment used a mixture of 13 torr of NF_3 and 2.5 torr of H_2. The principal effect of the discharge was to dissociate a fraction of the NF_3 to produce atomic fluorine. Vibrationally excited hydrogen fluoride was produced by the reaction $F + H_2 \rightarrow HF + H$. The discharge volume was 0.50 m long and the output mirror was 8% reflective. The calculation used the same conditions, and the experimental and calculated output energies agreed when 1.25% dissociation of NF_3 was assumed.

The calculations show that rotational equilibrium at the translational temperature is not achieved, mainly because the chemical reaction pumps states with relatively large J. Near the end of the pulse, the rotational distribution approaches equilibrium; even then, the ratio of populations of adjacent states differs significantly from a Boltzmann factor.

The calculations also show a sizable delay between the time that a transition reaches threshold inversion and the time that lasing begins. This is followed by a spike in the laser intensity due to excess inversion. The P3 and P4 transitions are dominated by this spike. The calculation shows simultaneous lasing of several transitions, in agreement with experiment. Some J-shifting is also observed.

The interaction of all of the populations and laser intensities is portrayed in a computer generated 16-mm movie.

SESSION TB

CO Lasers
Tuesday, October 22, 8:30 A.M.

TB1. Chemically Pumped CO_2 and N_2O Lasers: $CO^{\dagger}/(CO_2 \cdot N_2O)$, A. B. Petersen and C. Wittig, *Electrical Engineering Department, University of Southern California.*

CO_2 and N_2O chemically pumped lasers are discussed. Excitation of the (001) state has been achieved by energy transfer from vibrationally excited CO ($CO^\dagger$). $CO^\dagger$ is produced in the chemical reaction: $O + CS \rightarrow CO^\dagger + S$. Both pulsed (flash photolysis initiated) and CW fluid mixing systems are discussed, and, in the pulsed systems, detailed small-signal gain measurements are presented. Because of energy transfer considerations, the $CO^\dagger/N_2O$ system appears more promising than $CO^\dagger/CO_2$. The stability of N_2O in the chemical system described in this work, compared to an electric discharge where irreversible dissociation occurs, makes the system quite attractive. It is shown that in addition to the enhancement of CO laser output by resonant energy transfer to triatomics such as N_2O, stimulated emission at the triatomic laser frequencies provides a further means of removing energy from the undesirable "bottleneck" in the CO system. This is the basis of a "bootstrap" operation of the $CO^\dagger/CO_2$ and $CO^\dagger/N_2O$ systems in which the total photon flux is enhanced through this coupling. This idea will be discussed in detail and experimental results will be presented. Kinetics of the systems will also be discussed in light of our data. Comparison between our results, theory, and other chemically pumped CO_2 and N_2O systems will be made with respect to important considerations such as efficiency, energy storage, etc.

TB2. Experimental Investigation of a Supersonic CO Electric Discharge Laser, M. J. Plummer, J. L. Wagner, and W. J. Glowacki, *Naval Ordnance Laboratory*.

A supersonic expansion offers a simple means of providing volume-type cooling of a gas to cryogenic temperatures. It has also been shown that a pulsed CO electric discharge laser operating at cryogenic temperatures is very efficient. It was therefore decided to investigate a CO laser where the gas is first cooled by a supersonic expansion and then flows through a discharge-cavity region where electrical power is added to the gas and optical power is extracted. To improve the stability and efficiency of the discharge, an e-beam-sustainer is used. While the laser is a CW device, it operates something like a pulsed device because at the typical flow velocities and cavity sizes used the gas residence time in the discharge is of the order of a few hundred microseconds.

In the NOL laser, the gas is cooled to 75 K by expansion through a supersonic nozzle and then flows through an e-beam (15 cm × 50 cm window) sustained discharge and optical cavity. The discharge volume (5 cm high × 50 cm wide × 15 cm in the flow direction) is 4.5 l and the optical volume (stable resonator) is 0.79 l and is centered 11.4 cm from the beginning of the discharge. A power output of 28 kW at 4.7 percent efficiency has been obtained. The pulse duration was 900 μs (three flow times) and is indicative of CW-type operation. Power outputs up to 67 kW have been obtained for 300 μs pulses (one flow time). Typical e-beam current densities used are 0.3 to 0.6 mA/cm^2 in the gas. The multiline spectral output ranges from 5.09 μ to 5.55 μ with the most intense lines being concentrated at the shorter wavelengths.

Input powers up to 600 kW have been achieved for CW-type operation (three to six flow times) and are presently arc limited. Preliminary results indicate substantial heating of the gas by the discharge.

Comparison of the experimental results with a theoretical CO kinetics model are made and future experiments include interferometry to look at the cavity density disturbances introduced by the supersonic flow and the discharge.

TB5. Near Single-Line Operation of a Free Burning $CS_2/O_2/N_2O$ Flame Laser with a Non-dispersive Optical Cavity, K. D. Foster, G. H. Kimbell, and D. R. Snelling, *Defence Research Establishment Valcartier*.

CO laser output spectra between 5 and 5.5 μm for the free-burning CS_2/O_2N_2O flame laser were examined. Under certain conditions of high O_2 and high N_2O flow, the spectra were found to be nearly single line in nature with most of the laser output occurring on the $P_{10-9}(17)$ line at 5.4265 μm. This is the same line that was reported to lase in a nearly single-line fashion in an electrically-assisted longitudinal CO chemical laser.[1]

Under certain conditions where the multiline power output was high (12 to 15 W), the $P_{10-9}(17)$, line was found to be absent from the laser output spectra. The multiline spectra showed that normally about 40 lines were lasing.

The explanation for the tendency to operate on a single line under certain conditions, which was proposed by Coleman and co-workers relied upon rapid V-V exchange between vibrationally-excited CO molecules. It was suggested that the coupling between vibrational levels of CO was so strong that lasing may occur on the line exhibiting the highest gain while other lines would be kept below threshold.

The fact that nearly single-line operation has been observed in the present purely chemical flame laser where conditions of temperature and pressure are very different from the above longitudinal laser, suggests that an additional explanation is required. It is proposed here, that the $P_{10-9}(17)$ line itself is somewhat unique since it is almost coincident with the $P_{9-8}(23)$ line. Linewidth calculations show that if the line-center separation of this line pair is within about 0.3 Å then the overlap in the line profiles is sufficient to cause an increase of more than 10% in the peak gain over that of the isolated lines. The anomalously high gain of the $P_{10-9}(17)$ line, such that near single-line operation can occur under very different experimental conditions, may thus be due to an overlap in the line profiles.

The unique behavior of the $P_{10-9}(17)$ has manifested itself previously in pulsed chemical CO lasers. In the first report of laser action in the CS_2/O_2 system in a flash photolysis system, Pollack[2] found the highest J value for any lasing band to be $J = 14$ except for the 10-9 band which was found to lase on the P(10), P(11), P(12), P(13), and P(17) lines. This anomalous presence of the $P_{10-9}(17)$ line was also observed in a TEA style pulsed CS_2/O_2 laser by Jacobson and Kimbell.[3]

TB6. Role of Atomic Sulfur in the $O + CS_2$ Reaction, L. T. Cupitt and W. L. Gamble, *U.S. Army Missile Command*.

Preliminary and continuing experiments in our laboratory have demonstrated that one can observe both the atomic oxygen and atomic sulfur EPR resonances simultaneously in a reacting mixture of $O + CS_2$ if no O_2 is present. Atomic O is generated in a flowing system by the reaction $N + NO \rightarrow O + N_2$. The simultaneous measurement of concentrations of O, S, SO, etc. will, when fully analyzed, allow a severe test of some of the relative branching rates in the initial reactions of CS_2 with O. Some of the pertinent kinetic pathways are $CS_2 + O \rightarrow CS + SO$, $CS_2 + O \rightarrow COS + S$, and $CS + O \rightarrow CO + S$. This last reaction rate is reasonably well known. Measurement of SO_2 concentrations allow the O removal by means of $SO + O + M \rightarrow SO_2 + M$ to be monitored. The reaction of $O + COS$ is another method for O removal, but, because of its kinetic simplicity and

relative slowness, it should provide no complication to the analysis of the kinetic data.

We are unaware that anyone has ever observed resolved O and S resonances simultaneously in this system. The deposition of sulfur (or sulfur compounds) on the walls is the major uncertainty which we are having to deal with currently. The experiments are being conducted in a relatively fast flow system (velocities 10 to 100 m/s). The reaction tube is a 1.1 in diam quartz tube. Resolved O and S resonances are obtainable for overall pressures less than a torr.

Experimental results along with the theoretically predicted results using the accepted rate constants for the various reactions considered, will be presented.

TB7. Vibrational Deactivation and Atom Exchange in $O(^3P) + CO(^1\Sigma^+)$ Collisions,[1] J. D. Kelley, *McDonnell Douglas Research Laboratories*, and R. L. Thommarson, *McDonnell Douglas Astronautics Company*.

We report a quasiclassical Monte Carlo trajectory study of the electronic ground state $O(^3P) + CO(^1\Sigma^+)$ collision system. Oxygen atoms have been shown to effectively deactivate $CO(v = 1)$ above 1800 K with a collisional probability of about 10^{-2}, which is quite high relative to those values observed for chemically inert collision partners. The potential surface for this system is not purely repulsive, however, but can lead to O-atom exchange.

The observed activation energy for the exchange reaction was about 7 kcal/mole.[2] An energy barrier of about 5 kcal/mole for O, CO recombination to an excited triplet CO_2 was derived from spectroscopic studies;[3] the CO_2 is presumably in $^3B_2$ or $^3A_2$ at least initially.[3,4] These bent triplet CO_2 states represent spin-allowed intermediates for the $O(^3P) + CO(^1\Sigma^+)$ system when one considers that these states have A' and A'' symmetry, respectively, in the C_s point group. The three asymptotic states derived from $^3\Sigma_u^-$ and doubly degenerate $^3\Pi g$ for $O(^3P) \ldots . CO(^1\Sigma^+)$ also have A'' and A', A'' symmetry in the C_s group. Avoided crossings between the A' states and between the A'' states in the general C_s collision configuration then lead to two possible adiabatic surfaces which connect ground state reactants and the $^3B_2$ and $^3A_2$ states of CO_2. These states are bound by about 45 and 35 kcal/mole relative to the reactants.[4]

We have assumed that these adiabatic surfaces can be represented by one "effective" surface, and that an analytical representation can be constructed.[5] The resulting surface has an angle-dependent barrier for O-atom approach with a minimum height of 6.8 kcal/mole at an O-C-O angle of 120°; there is a basin corresponding to triplet CO_2 with $r_{eq.}$ (C-O) = 1.255 Å, an equilibrium angle of 120°, and a depth of 42 kcal/mole. Trajectories have been calculated for CO initially vibrating with energies corresponding to $v = 0$ and 1. Various initial collision energies and CO rotational energies were selected and averages taken over the other initial variables, e.g., impact parameter, orientation angles, etc., using Monte Carlo techniques.

Results thus far show that the calculated 1-0 deactivation rates from 2000–4000 K are in reasonably good agreement with Center's data,[6] i.e., about a factor of two faster over this temperature range. The calculated atom exchange rates for $CO(v = 0) + O$ are also within a factor of two of the data[2] taken from 300–400 K. The calculations predict a 1-0 deactivation rate of about 2.5×10^6 1 mole^{-1} s^{-1} at 300 K, which is about 2.5 times faster than the calculated atom exchange rate for $v = 0$.

TB8. Vibrational Deactivation of CO Molecules by Atomic Oxygen, C. C. Davis and R. A. McFarlane, *Cornell University, Ithaca, N.Y. 14850.*

Measurements are being carried out on the rate at which atomic oxygen collisionally deactivates CO molecules in the $v = 1$ level of the electronic ground state. A grating tuned UV preionized $CO_2 : N_2 : He$ TEA laser which generates pulses of several hundred millijoules energy is operated at selectable rotational transitions in the $(001 \rightarrow 100)$ and $(001 \rightarrow 020)$ bonds of CO_2. Using a crystal of tellurium, phase-matched second-harmonic generation is obtained using the TEA laser as a driver and radiation at 4.6–5.4 μ is available for laser-induced fluorescence studies on molecules absorbing in this region.

The P(14) line of the CO fundamental at 2086 cm^{-1} is at twice the frequency of CO_2 P(24) of $(001 \rightarrow 020)$ at 1043 cm^{-1} and very substantial fractions of the second-harmonic energy can be absorbed in our fluorescence cell to populate the CO $v = 1$ level. Following illumination by the 300-ns second-harmonic pulse, the fluorescence on R-branch lines of CO $v = 1 \rightarrow v = 0$ is observed through a short wavelength pass filter by an InSb photovoltaic detector driving a Perry amplifier. The output is digitized using a Biomation Model 8100 Transient Digitizer and pulses are accumulated in a Northern Scientific Model 575 Signal Averager. Decay rates are determined by a least squares fit of the data to an appropriate exponential function.

The fluorescence cell is part of a flowing gas system and CO is injected upstream from the cell. At a point farther upstream from the CO injection molecular oxygen is introduced and passed through a microwave discharge to provide about 20% dissociation. Atomic oxygen concentration is measured using NO_2 titration at the plane of the cell. Absolute atomic concentrations will also be established with an X band E.P.R. system using molecular oxygen as a reference.

The contribution to the decay rate of CO ($v = 1$) due to atomic oxygen is determined from the increment in the observed decay rate as the microwave dissociation source is turned on. In addition to oxygen, measurements are planned using other atomic species and all data available at the time of the conference will be reported.

SESSION TC

Post-Deadline Papers
Tuesday, October 22, 2:00 P.M.

TC1. An Atomic Boron Laser—Pumping by Incomplete Autoionization or Ion-Electron Recombination, J. Stricker and S. H. Bauer, *Cornell University*.

Pulsed lasing was obtained from discharges in mixtures of He (≈10 torr) and a number of boron containing species (≈25 m torr). Discharge conditions for optimizing the output are briefly described. Lasing starts 20–50 μs after passage of the discharge pulse (≈1 μs halfwidth). By a suitable combination of filters that spanned the range 1 → 11 μm, we established that the radiation appeared only between 2 and 4 μm; a gold-doped germanium detector, cooled to liquid nitrogen, was used. We did not test for radiations outside the 1 to 11-μm range. With a calibrated 25 cm f.l. Spex grating monochromator fitted with 25-μm slits, a single line was found at 2777 ± 1.6 cm^{-1}; its width was less than or equal to the resolution of our instrument. *This frequency was unaffected by the reagents used* [B_2H_6, H_3BCO, B_5H_9, BBr_3]. The absence of any H/D

isotope shifts eliminated BH, BH_2, and BH_3 as emitters; this was later confirmed by the observed lasing from BBr_3/He mixtures. The possibility that the emitter is BHe^+ was eliminated by the absence of any $^{10}B/^{11}B$ isotope shift. We conclude that the emitter is atomic boron.

The appearance of a delay in the 20–50-μs range for an atomic laser is indicative of a multistep collisional mechanism. This was supported by our search for coincidence spacings among the term values for B I and B II. Reference to Moore's tables and the later work by Edlén *et al.* uncovered a single combination in the B I set which was close enough to be considered. The limiting ionization level for the doublet states is 66 928.10 ± 0.1 cm^{-1} [nf ^2F series], while $1s^2\ 2s^2\ 7s, {}^2S_{1/2}$ occurs at 64 156 ± ? cm^{-1}; i.e. 2772 ± ? cm^{-1} lower. The fact that two well-characterized states were observed above the ionization limit [$2s\ 2p^2, {}^2P_{3/2;1/2}$ at 72 547 and 72 535 cm^{-1}; $2p^3, {}^4S^0_{3/2}$ at 97 037 + x cm^{-1}] suggests that pumping may start by excitation to a metastable state above the ionization limit. Then, due to some perturbation, such as a distant collision, de-excitation to the ionization limit occurs but with the electron still captured (incomplete autoionization). Lasing occurs by induced transitions to the $1s^2\ 2s^2\ 7s, {}^2S_{1/2}$ state.

Dr. T. A. Cool called our attention to a second matching interval. Extrapolation *via* a linear Ritz formula indicates a term value of 61 381 cm^{-1} for the $1s^2\ 2s^2\ 5p, {}^2P_{3/2;1/2}$ state, which is 2775 cm^{-1} below 7s, $^2S_{1/2}$. Thus, the delay may be due to cascading from the incompletely autoionized states to $1s^2\ 2s^2\ 7s$, which is the upper lasing level, from which induced transitions are made to the 5p state. Finally, another possible route for populating states at the ionization limit is the capture of an electron by B^+ during a large impact-parameter encounter. The high sensitivity of lasing power to the pressure of B atom precursors suggests that populating the upper lasing level competes with other B atom or B^+ reactions.

TC2. Laser-Induced Photochemical Enrichment of Boron Isotopes, S. M. Freund, *Optical Physics Division, National Bureau of Standards, Washington, D.C.*, and J. J. Ritter, *Inorganic Materials Division, National Bureau of Standards, Washington, D.C.*

Mixtures of BCl_3 and H_2S are irradiated with 10.55-μm radiation (P(16) line of the 001-100 band of CO_2) from a TEA laser. This wavelength coincides with a strong B-Cl stretching transition in $^{11}BCl_3$. After several hours of irradiation it is found that the maximum ^{10}B to ^{11}B ratio of recovered gaseous boron containing material (primarily BCl_3) is 0.413 ± 0.004. The corresponding ratio of the BCl_3 starting material is 0.242 ± 0.002. The ^{10}B concentration has been increased from 19.5% to 29.2% by selectively exciting the $^{11}BCl_3$ with the laser radiation which causes it to react preferentially with the H_2S, forming a solid, and thereby increasing the ^{10}B concentration in the gas phase. Further, by irradiating a similar mixture with 10.18 μm (R(30) line of the 001-100 band of CO_2) it is found that the ratio changes to 0.1863 ± 0.002. This wavelength radiation coincides with a strong B-Cl stretching transition in $^{10}BCl_3$ which then reacts with the H_2S lowering its concentration to 15.7%. The thermal reaction between BCl_3 and H_2S, conducted under comparable conditions, proceeds very slowly yielding principally $HSBCl_2$. All laser experiments are performed in a small static system, and milligrams of enriched boron containing material are recovered. The principal products are a solid with negligible vapor pressure, the identification of which is not conclusive as yet, and HCl. Although the stoichiometry is somewhat uncertain at the moment, it is suspected that one mole of BCl_3 is consumed for every two moles of H_2S, liberating 2.5 moles of HCl.

TC3. Laser Induced Photochemical Enrichment of Chlorine Isotopes, M. Lamotte, H. J. Dewey, R. A. Keller, and J. J. Ritter, *National Bureau of Standards, Washington, D.C. 20234.*

Chlorine isotopic abundances were significantly altered by laser-induced selective excitation of particular isotopic species of thiophosgene followed by chemical reaction between electronically excited thiophosgene and diethoxyethylene. A CW argon ion laser was used to excite, primarily, the $CS^{37}Cl_2$ species while a tunable nitrogen pumped dye laser was used to excite the $CS^{35}Cl_2$ species. The extent of selective reaction was followed by analyzing the unreacted $CSCl_2$ mass spectrometrically. The intensities of the mass peaks of $CSCl^+$ at 79 and 81 were monitored as well as the parent peaks at masses 114, 116, and 118. The changes in the parent peaks are shown in Fig. 1. The percentage of ^{35}Cl in $CSCl_2$ was changed from the natural abundance value of 75% to either 64% or 80% in a single step. The extent of reaction required for various degrees of enrichment implies a loss in selectivity after the initial excitation.

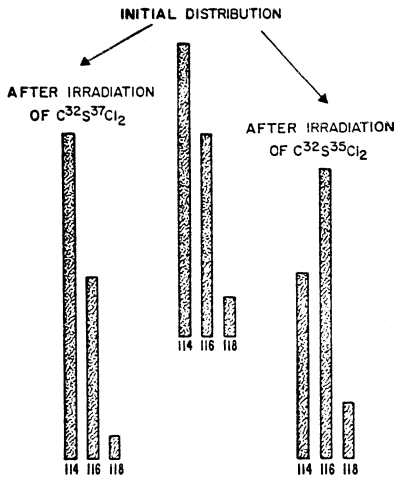

Fig. 1.

TC4. Laser Isotope Separation of Titanium-50 for Nuclear Reactor Applications, R. W. F. Gross, *The Aerospace Corporation, Los Angeles, Calif. 90009.*

The separation of titanium-50 by a two-step photodissociation with following chemical extraction process is proposed. It is suggested that titanium-50 could serve as a construction material for nuclear reactors, for instance, for cladding of reactor fuel elements. The laser separation process will be described in detail; it is based entirely on existing high-power laser sources. A preliminary cost estimate for the separation process indicates that titanium-50 could be economically competitive with zirconium, which is presently being used for such applications and at the same time be mechanically and structurally superior to zirconium.

TC5. Temperature Resolution of the Chemical Dynamics of the $O_3^\dagger$ + NO Reaction System, M. J. Kurylo, W. Braun, and C. Nguyen Xuan, *Physical Chemistry Division, National Bureau of Standards, Washington, D.C. 20234*, and A. Kaldor, *Corporate Research Laboratories, Exxon Research & Engineering Company, Linden, N.J. 07036.*

The rate constant for the decay of vibrationally excited ozone, $O_3^\dagger$, in the $O_3^\dagger$ + NO reaction system has been measured from 150 to 350 K. Vibrationally excited O_3 was produced in the asymmetric stretch normal mode by absorption of square-wave-modulated emission from a CO_2 laser tuned to the P(30) 9.6-μm transition. Under appropriate experimental conditions, a rapid V → V coupling process involving all three normal modes of O_3 is believed to set up a Boltzmann population distribution

between them. Reaction or relaxation of $O_3^\dagger$ out of this subset of normal modes is observed to proceed through a weighted average of rate constants. From the effects of temperature and buffer gas pressures it was determined that the predominant loss mechanism for the stretching mode(s) (ν_1 and/or ν_3) was via reaction with NO while the closely coupled ν_2 bending mode disappeared primarily via V → T deactivation by NO. The rate constant for the reaction channel (involving ν_1 and/or ν_3) is given by

$$k_{R2} = (2.0 \times 10^{-11}) \exp\left(\frac{-1107}{T}\right) \cdot \text{cm}^3 \text{ molec}^{-1} \text{ s}^{-1}$$

while that for V → T relaxation through ν_2 is

$$k_{R1} = (1.0 \times 10^{-13}) \exp\left(\frac{-39.2}{T}\right) \cdot \text{cm}^3 \text{ molec}^{-1} \text{ s}^{-1}.$$

The observations made in this study suggest the possibility of nonequilibrium among the vibrational modes under selected experimental conditions. This information is used in evaluating other measurements of this same reaction system and yield important conclusions suggestive of further research in chemical dynamics.

A comparison of the Arrhenius parameters for the above-mentioned reaction channel of $O_3^\dagger$ with parameters for the corresponding process involving thermal O_3 yields specific information about the effect of vibrational energy on the reaction dynamics.

TC6. High-Temperature Fast-Flow Reactor Studies of Metal Atom/N_2O Chemiluminescence,[1] W. Felder and A. Fontijn, *AeroChem Research Laboratories, Inc., Princeton, N.J. 08540.*

The AeroChem high-temperature (up to 2000 K) fast-flow reactor, previously used for reaction kinetic studies of metal atoms and metal monoxides with O_2, has been adapted for metal atom/N_2O chemiluminescence measurements. With this apparatus, spectroscopic and kinetic measurements are made under controlled and independently variable experimental conditions including reaction zone temperature, metal atom source temperature, total pressure, reagent partial pressure, and reaction time. Metal is evaporated from a suitable source in the upstream section of the flow tube, entrained in the bath gas and transported to the reaction zone, where N_2O is introduced in excess through a movable multiperforated ring. Measurements have been made on the reactions of N_2O with Sn, Ba, and Al.

Intense SnO chemiluminescence has been obtained from the Sn/N_2O reaction at 1000 K. A preliminary comparison of the total chemiluminescence intensity with the O/NO standard indicates a photon yield (branching ratio) for this reaction >20% from 300–750 nm. The spectrum exhibits transitions from the D, C, B, and A-X systems. The photon yields are $A > B > C \geqslant D$-X at all pressures studied, with the A-X (0, v'') bands accounting for ≈50% of the total light yield. The highest energy transition observed is the (5,0) $D^1\Pi$–$X^1\Sigma$ band at ≈310 nm, which agrees with $D_{\text{Sn-O}} \approx 5.7$ eV. Many band features especially for $\lambda > 550$ nm are not tabulated in the literature and have been shown to be A-X transitions. Initial kinetic and mechanistic studies indicate that the A and B-X photon yields and spectral distributions are pressure-independent from 3–50 torr. The yields of the C and D systems are enhanced by a factor of 2 as the pressure is increased over this range. The light producing reaction(s) have been shown to be first order in [Sn] and [N_2O]. The 1000 K value of the overall rate coefficient k for Sn + N_2O → all products, has been measured over a limited number of conditions (pressure, flow velocity, $[\text{Sn}]_{\text{initial}}$). The measurements indicate a $k \approx 10^{-12}$ ml molecule^{-1} s^{-1}, an usually low value suggesting the possibility of an electronic transition chemical laser system which is chemistry rather than mixing limited.

A test of the effect of temperature on the Ba/N_2O chemiluminescence was made by comparing the 350–750-nm spectra obtained under identical conditions at 500 and 1000 K at pressures from 0.7 to 20 torr. The comparisons show that the spectral distribution of the Ba/N_2O chemiluminescence at a given total density is temperature independent from 500–1000 K. Preliminary indications are that the total light yield also is independent of T over this range.

A search for 350–750 nm chemiluminescence from the Al/N_2O reaction was made. No chemiluminescence was observable at pressures of 0.7, 10, or 50 torr, T = 1000 K and reaction times from 0–10 ms. Simultaneous measurement of Al via atomic absorption verified that a rapid gas phase reaction with N_2O removes Al. From comparison with the Ba/N_2O chemiluminescence the photon yield is <0.05%. Thus this system does not appear to offer promise as a direct visible chemical laser pumping reaction.

TC7. Direct Determination of the Yield of Electronically Excited Iodine Atoms, I($5^2P_{1/2}$), in the Flash Photolysis of Alkyl Iodides, T. Donohue and J. R. Wiesenfeld, *Cornell University, Ithaca, N.Y.*

The flash photolysis of alkyl iodides has been utilized to produce population inversions in the optically metastable, excited spin-orbit level, I($5^2P_{1/2}$) [≡I*], of the lowest electronic state of iodine. This inversion may be exploited in the construction of a high-gain pulsed laser operating on the transition, I* → I(λ = 1315 nm). A variety of iodides may be photolyzed in this system; their efficiencies appear to be a function of the alkyl group structure. In particular, photolysis of n-propyl iodide results in lasing action while that of iso-propyl iodide does not. This phenomenon has been ascribed to differences in the initial yields of I* for these isomers, although no quantitative results have been obtained. Here we describe experiments which permit the direct measurement of the initial photochemical yields of I and I* as a function of alkyl group structure. These yields are important parameters in modeling the performance of the I* laser.

Following the flash photolysis of the molecule under study using a 100 J Kr-filled discharge lamp, the I and I* atoms formed are monitored using time-resolved atomic absorption analysis. In this technique, the attenuation of the resonance transition, I($6^2P_{3/2} \leftarrow 5^2P_{1/2}$) at 2062 Å is used to obtain the temporal profile of the I* concentration while the transition at 1783 Å, I($6^2P_{3/2} \leftarrow 5^2P_{3/2}$), permits the corresponding measurement to be made on the concentration of ground state atoms. Typical photolysis mixtures contain *ca.* 0.2–20 μ of alkyl iodide and 20 torr of argon which acts as a buffer gas to prevent adiabatic heating of the photolysis mixture or pyrolysis of the source material. In addition, small quantities of H_2 (*ca.* 20–300 μ) are added to enhance the rate of the relaxation of I* to I. By varying this rate, it is possible to observe the concentration of I atoms following their formation both in the initial photolysis and subsequent relaxation of I* by H_2 and the relative initial yields of I* and I may be determined.

A number of alkyl iodides and their perfluorinated derivatives have been studied. These were extensively degassed and purified, and fractionally distilled under vacuum to remove such efficient quenchers of I* as O_2 and I_2. The yields of I* and the second-order rate coefficients for quenching of I* by the alkyl iodides are presented below.

Source	$\frac{[I^*]_0}{[I^*]_0 + [I]_0}$	k_Q (torr^{-1} s^{-1})
CH_3I	0.92 ± 0.02	2.2 ± 0.5 × 10^4
C_2H_5I	0.67 ± 0.10	2.2 ± 0.5 × 10^4
n-C_3H_7I	0.60 ± 0.10	3.0 ± 0.6 × 10^4
i-C_3H_7I	<0.10	–
CF_3I	0.90 ± 0.04	1.2 ± 0.2 × 10^1
n-C_3F_7I	>0.98	–
i-C_3F_7I	0.89 ± 0.02	–

At present, theory does not provide an explanation for the dramatic effect of structure on I* yield. Some possible approaches to this problem will be discussed.

TC8. Quantum Yields of O(^{1}S) from N_2O and S(^{1}S) from OCS in the Vacuum Ultraviolet, G. Black, R. S. Sharpless, and D. C. Lorents, *Stanford Research Institute.*

For laser fusion requirements, the ^{1}S states of the Group VI elements are of interest as possible high-energy lasers. One of the major problems with these excited states is associated with their production. It is desirable to find source molecules which yield these excited states with high efficiency at the wavelengths of the rare gas dimer emission. We have measured efficient production of O(^{1}S) from N_2O in the vicinity of the Ar_2 emission at 1260 Å and a high yield of S(^{1}S) from OCS in the vicinity of the Kr_2 emission at 1460 Å. The results are shown in Figs. 1 and 2.

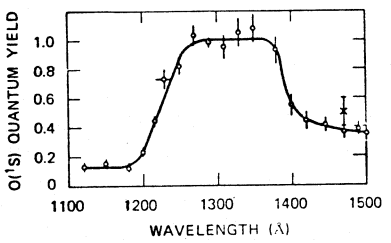

Fig. 1. Quantum yield of O(^{1}S) from N_2O.

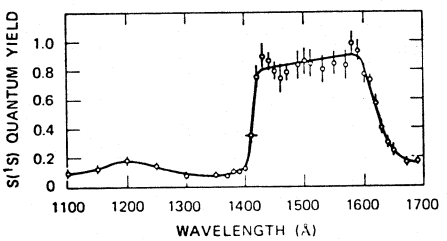

Fig. 2. Quantum yield of S(^{1}S) from OCS.

TC9. Xenon Oxide—The Kinetic Mechanism,[1] D. C. Lorents, D. L. Huestis, R. A. Gutcheck, R. M. Hill, and H. H. Nakano, *Stanford Research Institute.*

Laser action has recently been observed in the green band systems of XeO and KrO.[2] We report here our analysis of the reaction kinetics in e-beam pumped xenon–oxygen mixtures. The preliminary results of our experimental kinetic study were described previously.[3] Xe* and Xe_2^* have insufficient energy to produce O(^{1}S) from O_2 and must yield instead O(^{3}P) + O(^{1}D) or 2O(^{3}P). A second energy transfer from Xe_2^* to O(^{3}P) can then give O(^{1}S). The decay kinetics show mysterious features which are explained by the acceptance of this two-step excitation mechanism. Based on this mechanism various of the important rate coefficients have been determined from the kinetic data.

TC10. Measurement of Pressure-Broadened Infrared Linewidths with an Optical Parametric Oscillator,[1] J. Wormhoudt, L. Marabella,[2] and J. I. Steinfeld, *Massachusetts Institute of Technology, Cambridge, Mass.*

A tunable, narrow-band infrared source is being used to probe the density dependence of infrared absorption lineshapes. The source consists of a commercial optical parametric oscillator pumped by a Q-switched ND: YAG laser. An internal etalon is used to narrow the infrared output to a linewidth of 0.005 cm^{-1} or better. Reference and sample beam intensities are detected by matched InSb detectors, put through a gated amplifier-integrator, and averaged on a computer.

Data obtained in these experiments will be used to test theoretical predictions of the density dependence of the absorption coefficient. The absorption coefficient at the line center is predicted to have the form $k(\nu_0) = A/\rho + B + C\rho + D\rho^2 + D'\rho^2 \ln \rho$, where ρ is the total gas density. The coefficients in this expansion, as well as non-Lorentzian behavior in the wings of the line, will be determined.

Experiments are being carried out on HCl gas in the presence of 1 to 100 atm of Ar, and will be extended to DF in the near future.

SESSION TD

Post-Deadline Papers
Tuesday, October 22, 2:00 P.M.

TD1. HCl/H_2 Gas Dynamic Laser Calculations, C. P. Holmes, *AFWL/DYT.*

An HCl/H_2 gas dynamic laser has been investigated with a computer program which couples the quasi-one-dimensional gas dynamic equations with an anharmonic oscillator vibrational kinetics model. Starting at the plenum, the gas flow parameters and vibrational level populations are calculated through a laval nozzle into the laser cavity where a Fabry–Perot power extraction model is used to produce HCl multiline radiation in the 4.0 to 4.7-μ range. Typical initial conditions have a 1/9 mole fraction ratio mixture of HCl/H_2 in a plenum at 100 atm and 3000 K. After an expansion to A/A* of 100, exothermic pumping creates a nonequilibrium distribution in the anharmonic vibrational levels of HCl resulting in partial inversions in the first ten to twelve levels with small signal gains of up to 0.6% cm^{-1}. With a laser cavity, specific energies of up to 30 kJ/lb were extracted representing about 10% of the total HCl/H_2 vibrational energy at the nozzle exit plane and only 0.35% of the total plenum energy. Calculations on a screened nozzle mixing GDL, similar to the CO_2/N_2 MGDL modeled by Holmes and Graham,[1] were performed. However, due to the large HCl/H_2 molecular weight ratio and the high expansion ratios needed to reduce the H_2 gas temperature, large temperature rises due to dissimilar gas mixing would not allow any partial inversions causing the small signal gain to remain negative. It is suggested that a much more efficient system with less severe plenum and

[1] C. P. Holmes and D. C. Graham, *Laser Digest*, AFWL-TR-74-241, 243, 1974.

expansion conditions could be realized by using an electron beam sustained discharge. The roles of atomic hydrogen and chlorine arising from thermal and electron induced dissociation should be studied. More information on the vibration relaxation rates are needed, particularly the H_2 to HCl VV transfer rate for which there is no experimental data.

TD2. A New Electric Discharge Gas Dynamic Laser, J. A. Stregack and B. L. Wexler, *Naval Research Laboratory, Washington, D.C. 20375.*

An electric discharge gas dynamic laser facility has been constructed to study the potential of several CW laser systems. The primary motivation is the development of lasers utilizing energy transfer from a molecule easily excited in a discharge to another molecule whose vibrational excitation rate by electron impact is not as favorable. Plenum excitation of one gas species is obtained in a dc glow discharge. The excited gas present in the plenum is then accelerated through an array of supersonic nozzles where the laser species is injected and mixes with the primary flow. Energy transfer and lasing occur in the supersonic region of the flow. Brewster-angle windows which extend 10 cm downstream from the nozzle exit plane enable a laser cavity or diagnostic apparatus to be positioned at a variable distance from the injection point. The optics are mounted on a motor-driven translation table so that continuous scans of the region downstream of the nozzle exit plane may be conveniently made. The present facility is versatile in that it may easily be operated with a subsonic cavity, with an RF discharge in the cavity region to augment the plenum discharge, with all gases premixed, or with any combination of these configurations.

As a result of studies of D_2 electrical excitation a D_2-CO_2 transfer laser has been produced with an output power in excess of 50 W and measured peak small signal gains of 0.015/cm. These results compare very favorably with those for a N_2-CO_2 laser run on the same apparatus. A He and D_2 mixture is excited in the plenum with CO_2 injected in the supersonic nozzle. The supersonic cavity pressure was 10 torr and the mixture used for peak laser performance was 0.06 CO_2/0.32 D_2/0.62 He. Due to the gasdynamic cooling, the peak gain occurs on the P(14) transition of the 10 μ band. This new laser clearly demonstrates the vibrational energy storage capability of D_2 excited by an electric discharge.

Other potential laser systems are being investigated and fluorescence data have been taken. These systems include D_2-HCl and CO-CS_2. The fluorescence indicate that the number densities of vibrationally excited CS_2 and HCl are comparable to CO_2 densities.

TD3. Pulsed, Electrically-Initiated, HF Chemical Lasers at Atmospheric Pressure, J. A. Mangano, R. Limpaecher, J. D. Daugherty, H.-L. Chen, and F. Russell, *Avco Everett Research Laboratory, Inc.*

Two methods of electrically initiating pulsed HF chemical lasing action with total lasing mixture pressures of 1 atm will be described. In the first method, a cold cathode electron gun produces an electron beam (130 keV, 10 A/cm^2, 200 ns, 10 cm $\times$ 25 cm) which is used to initiate various slowly flowing nonstoichiometric mixtures of H_2:F_2:He:O_2. The highest laser energy density obtained is 51 J/l-atm for a mixture of $[H_2]:[F_2]:[He]:[O_2] = 0.08:0.30:0.61:0.01$ mole fractions at 1 atm total pressure in a total active volume of 0.125. The corresponding electrical efficiency based on the actual electron beam energy deposited in the lasing mixture is 900%. Consideration of the uniformity of electron beam energy deposition and beam window losses indicates that overall electrical efficiencies of 100 to 200% should be achievable in a scaled device. The lasing pulse duration under these conditions was 2 μs. Experimental results with other nonstoichiometric mixtures of H_2:F_2:He:O_2 will also be presented.

In the second method, laser action is initiated with an electron beam-stabilized discharge. The electron gun used was identical to that described above except that the beam pulse duration was shortened to 140 ns. A spark gap-switched, capacitive discharge circuit has been used to supply the discharge energy. For the lasing mixture studies ($[H_2]:[F_2]:[Ar]:[He]:[O_2] = 0.03:0.06:0.35:0.555:0.005$ mole fractions), the duration of the stable discharge pulse (140 ns) was probably shorter than the time for which the positive and negative ion current density of the discharge became equal to the discharge electron current density, a necessary condition for high-initiation efficiency. Under these conditions, approximately 6 times more energy was introduced into the lasing mixture with the discharge than with just the electron beam. A laser output energy density of 25 J/l-atm has been obtained corresponding to an electrical efficiency of 72% if just the energy deposited into the lasing mixture is counted. This result represents an enhancement of 2.5 over the output energy density achieved with the 140 ns electron beam alone. In this experiment the direction of the discharge was aligned with the electron beam direction. The beam electrons entered the lasing mixture through an 80% open stainless steel wire screen. This scalable discharge geometry is compatible with high-speed transverse lasing mixture flow. Methods of improving the electron beam-stabilized discharge results are being pursued. These methods include increasing the discharge E/P and varying the relative concentrations of the present lasing mixture.

TD4. Continuous-Wave HF Chain Reaction Laser,[1] T. J. Sadowski, C. E. Kepler, B. R. Bronfin, M. D. Krosney, and R. Roback, *United Aircraft Research Laboratories, East Hartford, Conn. 0618.*

A theoretical and experimental investigation was conducted at the United Aircraft Research Laboratories to evaluate the performance potential of the HF/DF chain reaction laser, i.e., a laser operating under conditions which favor the production of vibrationally excited HF (or DF) via the "cold–hot" chain reaction sequence

$$\text{cold } F + H_2 \longrightarrow HF^* + H$$

$$\text{hot } H + F_2 \longrightarrow HF^* + F$$

$$\Delta H = 31.5 \text{ Kcal, } 75\% \text{ vib}$$

$$\Delta H = 97.9 \text{ Kcal, } 53\% \text{ vib.}$$

The program consisted of: theoretical calculations to aid in the selection of design conditions and laser operating conditions, laser power and gain tests of an 8-in nozzle array, and chemiluminescence-emission tests of a 1-in nozzle segment. The experiments were conducted with a mass heater to preheat the primary flow to temperatures sufficient to dissociate only a small fraction of the fluorine molecules to F-atoms, thereby initiating the chain reaction while inhibiting lasing under "cold" reaction conditions. Heating the flow by this means also eliminated combustion contaminants from the primary flow. The lasing tests were conducted in a constant-pressure free-jet cavity with closed-cavity optics. The laser power extracted from the media was

[1] Sponsored by the U.S. Army Missle Command Contract DAAH01-73-C-0321.

absorbed by the mirrors and measured calorimetrically.

On the basis of the experimental results achieved under this program and reported herein, it was concluded that continuous-wave chain-reaction lasing was achieved. This conclusion is supported by the achievement of a specific laser power of 3.8 kJ/g of F-atoms on vibrational transitions up to the 5th level, at laser cavity pressures up to 16 torr, and over extraction lengths up to 23 cm. It was further substantiated by emission spectroscopy measurements performed on a segment of the above nozzle which indicated that the chain reaction had proceeded to a significant extent for the above-operating conditions. This is the first known demonstration of such power extraction. A maximum average laser power of 3.9 kW was achieved during these tests. These results give encouragement to the possible achievement of the predicted potential of this laser system.

TD5. Subsonic cw Chemical Laser Emission from the Reaction of H-Atoms with Cl_2 in a Transverse Flow Laser, J. Wanner, *Department of Chemistry, University of Toronto, Toronto, Canada.*

The reaction of $H + Cl_2 \rightarrow HCl + Cl$ $-\Delta H^\circ_2 = 45$ kcal mole^{-1} has been employed in a longitudinal-flow laser to yield a total CW output of 1 mW.[1] The $H + Cl_2$ system is attractive as a source of CW HCl emission in view of the low-cost and moderately corrosive nature of the reagents, as compared with Cl + HI. The drawback lies in the low output power. In this work the same system has been examined in a transverse flow laser, and has produced 190-mW CW output.

The aluminum water-cooled laser flow chamber was a slightly scaled-up version of that described.[2] This laser body was kindly made available by T. A. Cool. The flow cross section measured 6.3 X 70 mm. The molecular reagent was injected transverse to the primary flow by means of two opposing arrays of thirty-two 0.3 mm diam orifices, spaced 2 mm apart. The transverse optical axis was 8 mm downstream from the injection orifices—the optimal position for HF lasing in the SF_6/H_2 system (the total HF power obtained with this setup was 3.5 W). One CaF_2 Brewster window and one internally mounted mirror were employed. The optical cavity comprised a 10-m radius spherical mirror and a 2-m spherical dielectric mirror, spaced 45 cm apart. Atomic hydrogen was formed in a 1.5-kW 2450-MHz microwave discharge.[3] The inside of the 19-mm ID quartz discharge tube was coated with Teflon. The pumping system was capable of 630 1/s, through 100 1/s was found to give the same total output power.

The flow rates at maximum output were He 27-m moles s^{-1}, H_2 1.5-m mole s^{-1}, Cl_2, 1.4-m moles s^{-1}. The pressure in the cavity was 6 torr. The total output ranged from 75 mW using a 0.2% coupler, to 190 mW using a 3.5% coupler. In contrast to the earlier study which yielded emission in $v(1\text{-}0)$ only,[1] the output with the present arrangement was in $v(1\text{-}0)$ (70%) and $v(2\text{-}1)$ (30%). Lasing was recorded in $P_{1-0}(3)$ to $P_{1-0}(8)$, and $P_{2-1}(4)$ to $P_{2-1}(7)$.

TD6. Reaction Mechanism and Energy Distribution in a New Chemical Laser System: ClF_5-H_2, O. D. Krogh and G. C. Pimentel, *Chemistry Department, University of California, Berkeley, Calif. 94720.*

Stimulated vibration-rotation emission has been observed from both HF and HCl following flash photolysis of ClF_5-H_2-Ar mixtures. This new chemical laser is compared to the $ClF-H_2$ and ClF_3-H_2 chemical lasers to clarify the reaction mechanism. Applying tandem techniques we have put lower limits on the following population ratios for HCl, $N_1/N_0 > 1.8$, $N_2/N_1 > 1.5$, $N_3/N_2 > 0.76$, $N_4/N_3 > 0.61$ and for HF, $N_1/N_0 > 0.7$, $N_2/N_1 > 2.5$. The reaction:

$$H + ClF_4 \longrightarrow HCl^{\ddagger} + 2F_2,$$

$$\Delta H = -50 \text{ kcal/mole}$$

is probably contributing in the production of vibrationally excited HCl. This gives evidence for the existence of the radical ClF_4. Assuming that the above reaction is the only HCl producing reaction, the population ratios imply that more than 33% of the total energy available goes into vibrational excitation of HCl. Furthermore, the excitation of HCl to the $v = 4$ state would require that 62% of the total energy be channeled into vibration in a single reaction event. At least two and probably three different reactions produce vibrationally excited HF. One of these reactions (but not $F + H_2$) provides an unusual distribution of HF molecules over the rotational manifold as demonstrated by observation of $1 \rightarrow 0$ transitions up to $P_1(19)$, indicating rotational nonequilibrium.

TD7. Rotational Nonequilibrium in CW Chemical Lasers, L. H. Sentman, *University of Illinois and Bell Aerospace Company.*

By including the spontaneous emission term in the radiative transfer equation, an explicit expression for the radiation term in the species equation is obtained in terms of the fluid variables. With this description of the radiation field, the approach to saturation as well as the rapid decrease in α that occurs at cutoff is obtained. This formulation is used to study the role of rotational nonequilibrium in CW chemical lasers. A simplified chemical model in which the active species is a diatomic molecule with three vibrational levels that collide with an inert diluent is employed. The chemistry is described by an irreversible J-dependent pumping reaction, a set of J-dependent collisional deactivation reactions, and a set of J-dependent rotational relaxation reactions. The set of coupled nonlinear equations has been solved numerically for $J_{MAX} = 20$ (42 simultaneous equations). It is shown that the phenomena of J-shifting and the power being contained in the high J transitions are a consequence of the rotational equilibrium assumption. When rotational nonequilibrium is allowed to occur, several J transitions within a given vibrational band lase simultaneously, including R-branch transitions, which cut off when the initial total inversion is depleted. For the reference case (800 K), the transitions that contain most of the power are P6 to 12 with the strongest being 7, 8, and 9. The power is contained in those J transitions that are preferentially populated by the pumping reaction and the total power is decreased 20 to 30% from the rotational equilibrium value. As the ratio of the rate of rotational relaxation to the rate of collisional deactivation increases, the total power produced increases, the percent in the R branch decreases, the peak of the power distribution gradually shifts to higher J and eventually the phenomenon of J shifting occurs. As the temperature is decreased, the peak of the power distribution shifts to lower J. Comparison of these calculations for HF lasing on the $2 \rightarrow 1$ band with Hinchen's[1] and Kwok *et al.*[2] observations shows that the predicted

[1] J. J. Hinchen, *J. Appl. Phys.*, vol. 45, p. 1818, 1974.
[2] M. A. Kwok, R. R. Giedt, and R. W. F. Gross, *Appl. Phys. Lett.*, vol. 16, p. 386, 1970.

and observed peak power transitions are in agreement. The saturated R-branch transitions predicted by the present model agree with the observations of Green and Lin.[3] The agreement of these calculations with the observations of Chen *et al.*[4] who report lasing on P_3 through P_{16} for the $2 \rightarrow 1$ band in an atmospheric, pulsed HF laser supports their suggestion that rotational nonequilibrium is responsible for these observations.

TD8. Observation of Laser Action in CO Gas Excited Only with a Nuclear Reactor,[1] D. A. McArthur and P. B. Tollefsrud, *Sandia Labs.*

We report here what we believe is the first clear observation of lasing with only nuclear reaction product excitation. Lasing was observed on the vibrational bands of CO, when the CO was irradiated with an intense burst of fission fragments. No case of lasing under pure reactor excitation has been published, although reactor enhancement of electrically excited lasers has been observed. Since it appears possible to deposit at least ~1 mJ in a gas with a pulse ~100 μs wide using present fast burst reactors, it might now be possible to make very large lasers using only reactor excitation.

The laser apparatus for this experiment was mounted so that its axis was about 20 cm from the axis of the SPR-II reactor at Sandia Laboratories. This reactor produced a fast neutron flux $\sim 5 \times 10^{17}$ n/cm^2-s at the apparatus, in a pulse ~60 μs wide. The laser apparatus consisted of a vertically oriented cylinder divided into two chambers by a CaF_2 Brewster window. The lower chamber, immersed in liquid nitrogen, contained the laser gas (pure CO at ≈100 torr at 77 K), and a 20 cm long cylinder coated with enriched $^{235}U_3O_8$. The neutrons, partially moderated, caused fission fragments to emerge from the coating and excite the laser gas. A laser output mirror (reflectance = 96 or 98.5 percent) was mounted at the top of the upper chamber, while a totally reflecting mirror was mounted at the bottom of the lower chamber. The upper chamber was evacuated to provide insulation for the cold Brewster window. The laser output beam was focused by a mirror system onto a calorimeter and Ge:Au detector located about 15 m away, beyond the reactor shielding.

When the laser mirrors were aligned, a laser signal pulse about 1000 times larger than the background was observed in the Ge:Au detector. The signal peaked near the fast neutron pulse peak, and turned on and off rapidly as though a sharp threshold were being crossed. This signal disappeared if the CO was replaced by pure N_2, or if the output mirror was deliberately misaligned. The signal passed through a narrow-band interference filter centered at 5.24 μ, indicating lasing on the vibrational bands of CO. The measured laser pulse energy ($\sim 3 \times 10^{-4}$ J) was ten times larger than could possibly be explained by fluorescence from the gas.

Since the laser was operating near threshold, and since the calorimeter may not have intercepted the entire beam, the preliminary efficiency measurement (~0.2 percent) is believed to be a lower limit. Gain was also observed on ten CO laser transitions ranging in wavelength from 5.13 to 5.33 μ. Gain pulses ~80 μs wide were observed, with peak gains ~0.5%/cm. The relative gains on the 7-6, 9-8, and 10-9 bands are similar to those observed in low pressure, cooled CW CO lasers. To estimate the vibrational populations, we assumed a gas temperature and an approximate steady-state vibrational distribution to fit the gain data. For gas temperatures between 80 K and 150 K, gains of the observed magnitude were calculated, by assuming a vibrational excitation efficiency between 25 and 70 percent.

TD9. Time Dependent Kinetics of CO-EDL with Multi-Level Pumping,[1] J. L. Boulnois and R. B. Miles, *Department of Aerospace and Mechanical Sciences, Princeton University, Princeton, N.J.*

In the conventional description of the CO-electric discharge laser, the pumping mechanism is assumed to be a combination of a direct electron excitation of the lower CO vibrational states followed by a redistribution of vibrational energy through inelastic self collisions; the deactivation mechanism is assumed to be the loss of vibrational energy to the translational degree of freedom through inefficient V-V and V-T collisions.[2,3] The translation energy mode of the CO-He mixture and the rotational degrees of freedom of CO are assumed to be in equilibrium at the same temperature.

The present kinetic model consists of a set of vibrational rate equations featuring the previous assumptions plus multilevel electron pumping. The equations are numerically solved in a time-dependent analysis including achievement of steady state. The production terms for the kinetic equations include single quantum V-V exchange collisions and V-T transfer collisions, spontaneous emission of radiation, and excitation by electron impact.[4] The electron coupling to the vibration energy mode is not restricted to the ground state, but rather a pumping scheme involving the entire vibrational ladder is assumed here. The electron impact rate coefficients are derived from the solutions given by Nighan,[5] then an extrapolation for the excitation and de-excitation rates for the range $v > 10$ is made along with the conservative assumption $k_{0 \rightarrow v} = k_{n \rightarrow n+v}$ to complete knowledge of all possible rates. At high pressures, where radiation deactivation is negligible, and low temperatures where the V-T processes only deactivate the highly excited states, the electron deactivation mechanism is believed to play an essential role among the middle levels above $v = 10$ where the population distribution is achieved through a competition of V-V fluxes with forward and reverse superelastic electron impact fluxes.

The initial effect of this multilevel pumping is to significantly populate all the vibrational levels in an extremely short time before the exchange collision redistribution proceeds. The next phase, which corresponds to the raising of the vibrational plateau, is slowed by reverse pumping losses whereby superelastic CO-electron collisions substantially inhibit V-V exchanges. Comparison between a steady-state distribution obtained with a limited pumping ($0 \rightarrow 10$) and one obtained with multilevel pumping indicates that the "knee" of the latter extends to higher vibrational quantum numbers because it is then controlled by a balance between V-V, electron pumping, and V-T deactivation. Following pulse termination, vibrational inversion builds up very rapidly under the drive of the anharmonic pumping through exchange colli-

sions. Fig. 1 demonstrates that already 10 μs after pulse termination substantial total inversion has been achieved and persists with reasonable density for another few microseconds.

TD10. The Effects of Superelastic Collisions on Electron Energy Distributions in Vibrationally Excited CO Laser Mixtures, A. E. Greene, *Air Force Weapons Laboratory, Kirtland AFB, N. Mex. 87117.*

The dc Boltzmann equation, cast in a flux divergent form, has been solved to determine the electron energy distribution functions in vibrationally excited CO, CO-He, and CO-Ar mixtures. A brief explanation is given of the flux divergent Boltzmann equation formulation. Included in this formulation are ground state-to-excited state and excited-to-excited state inelastic and superelastic electron impact induced transitions among the first eight CO vibrational levels. The excited state populations used in this study were taken directly from predictions of e-beam sustained CO gas kinetic calculations. Once the electron energy distribution functions are determined, they are used to predict electron impact pumping rates and the partitioning of input energy between vibrational and electronic excitation, and ionization.

The results indicate that the effects of superelastic collisions are more pronounced in the CO-He and CO-Ar mixtures than in pure CO. Although the changes predicted for ground state-to-excited state electron impact pumping rates are, in some cases, quite significant, by far the most important effects are in the high-energy tail of the electron distributions. This can mean increases in the ionization rate of more than a factor of 20 implying that superelastic collisions may contribute significantly to ionization instabilities in CO lasers.

WA1. Quenching Studies of Ar($^3P_0$, $^3P_2$) Metastable Atoms by Chlorine Atoms, D. L. King and D. W. Setser, *Kansas State University.*

A mixture of chlorine and argon excited by dc discharge has been shown to produce chlorine atom laser emission.[1] This presumably is a two-step process, the first being dissociation of Cl_2, followed by transfer of energy from electronically excited argon to chlorine atoms. Although the postulated excited state of argon is 4s $^1P_1$, the metastable states 4s $^3P_0$ and 4s $^3P_2$ could also be involved. We will report some results from a study of the interaction between molecular and atomic chlorine and these metastable states of argon, as measured by the flowing afterglow technique. In addition to the possible importance as a laser system, this work is an extension of quenching studies of argon metastables by atoms[2] and is important to development of theories of electronic energy transfer. For the atomic studies a 1–2% mixture of chlorine in helium was passed through a microwave discharge, producing ~15–20% dissociation. The argon (purified by molecular sieve traps) was passed through a dc discharge, producing the metastables $^3P_0$(11.723 eV) and $^3P_2$(11.548 eV) in a ratio of ~1:6. The two species were mixed concentrically and the emission was measured by a 0.75 m Jarrel Ash, Czerny-Turner monochromator equipped with a SSR photon counter and EMI 9558QA phototube. The observed chlorine atom emission was compared with emission from Kr, which has a known Ar* quenching cross section.[2] Calculations were performed to correct for branching from the excited Cl states. For Ar($^3P_0$) the quenching cross section thus derived is ≥ 6.2 Å^2; three different Cl manifolds are populated: 5p $^4p^0$, 5p $^4D^0$, and $^4p'$ $^2P^0$ in a ratio of roughly 0.3:0.25:0.45, respectively. This ratio showed little variation with pressure in the 1-3 torr range, indicating collisional quenching by argon is probably not important. For the Ar $^3P_2$, the quenching cross section based upon *observed* emissions is at least 4.6 Å^2. The product states from quenching of Ar($^3P_2$) could not be observed directly, since they are presumably the 5s and 3d manifolds of Cl, which emit to the 4p manifolds at wavelengths $\geq$ 10,000 Å or to the 3p at wavelengths $\leq$ 1150 Å. Neither wavelength region is measurable by our current apparatus. We observe only emission from the 4p chlorine manifolds, which probably are populated by cascading from the 5s and 3d levels. These emissions were mainly from quartet states, to be expected since branching from doublet states favors emission to the ground state at short (vac UV) wavelengths. The previously measured[2] total quenching cross section of Ar($^3P_2$) by Cl_2 is 95 Å^2. The known exit channels are formation of Cl(4s ^4P and ^2P) + Cl and molecular emission (either Cl_2* or ArCl*) continua in the vac UV (with maxima at 1737, 1687 and 1649 Å) and in the UV (with maximum at 2560 Å). The latter is a known Cl_2 band and is estimated to have 10% of the total cross section. Since the lower states of the continua are likely to be repulsive, the major fraction of the quenching by Cl_2 gives atoms.

[2] L. G. Piper, D. W. Setser, and J. E. Velazco, *J. Chem. Phys.*, vol. 59, p. 3323, 1973.

WA2. Quenching Studies of Xe($^3P_2$) Metastable Atoms, J. E. Velazco and D. W. Setser, *Kansas State University.*

Continuing the work previously reported from this laboratory,[1,2] we have extended the measurement of total quenching cross sections (thermal) of rare-gas metastable atoms to include Xe*($^3P_2$) with some light hydrocarbons and with the four fluoromethanes. Xenon metastable atoms were produced in a hollow cathode discharge by the reaction:

$$Ar^*(^3P_{0,2}; 11.5\text{–}11.7 \text{ eV}) + Xe \rightarrow Xe^*(^3P_2; 8.32 \text{ eV}) + Ar$$

with an efficiency of ~50%. Quenching measurements were made at room temperature in a flowing afterglow apparatus which had a flow velocity of 70–80 m s^{-1}; the decay of Xe*($^3P_2$) was monitored by absorption spectroscopy. The concentration of Xe*($^3P_0$; 9.54 eV) was below the detectable limit of absorption spectroscopy. The results are listed below and for comparison pur-

poses the ratios of the quenching cross sections for Xe* to the cross sections for quenching of $Ar^*(^3P_2)$ are listed; the units of k_Q are cm^3 $molec^{-1}$ s^{-1}.

Reagent	$k_Q \times 10^{11}$	$\sigma_Q(Å^2)$	$\sigma_Q(Xe^*)/\sigma_Q(Ar^*)$
C_5H_{12}	71.8	192	
C_4H_{10}	67.6	170	1.14
C_3H_8	54.2	123	0.92
C_2H_6	63.5	125	1.15
C_2H_4	58.2	110	1.11
C_2H_2	69.0	130	1.44
CH_4	32.5	49	1.09
CH_3F	44.4	91	
CH_2F_2	40.9	99	
CHF_3	0.2	0.6	~0.01
CF_4	≤0.03	<0.1	~0.01

The hydrocarbons were selected in order to cover a wide range of polarizabilities, as well as photoabsorption cross sections and ionization potentials.[1] An upper limit to the quenching cross section of Hg was established as ≤0.001 Å². The decay of $Xe(^3P_2)$ in Ar was characterized; the diffusion coefficient for Xe* in argon was found to be 70 cm^3 $torr$ s^{-1} and the first- and second-order decay constants in Ar are 3.8×10^{-16} cm^3 $molec^{-1}$ s^{-1} and 2.8×10^{-23} cm^6 $molec^{-2}$ s^{-1}, respectively. For some of the systems studied earlier,[2] e.g., N_2, CO, NO, and Cl_2, the distribution of exit channels, as measured by fluorescence, was observed. Previous results[3] were confirmed for N_2 and CO. The major quenching channel for Cl_2 is direct chemical reaction with formation of XeCl* which subsequently radiates to Xe + Cl; the resulting bound-free continuum emission peaks at 304 nm. Emission from XeF* and XeBr* also has been identified from direct reaction of $Xe(^3P_2)$ with fluorine and bromine containing compounds.

WA3. Studies of the Deactivation of Electronically Excited Iodine Atoms, D. H. Burde, R. A. McFarlane, and J. R. Wiesenfeld, *Cornell University, Ithaca, N.Y. 14850.*

The transition in atomic iodine at 1.315 μ takes place between the spin-orbit split levels of the electronic ground configuration: $I(5\ ^2P_{1/2}) \rightarrow I(5\ ^2P_{3/2}) + h\nu(1.315\ \mu)$. The system is being widely studied because of the very high energy pulses which can be obtained from flash-lamp pumped lasers. In addition, CW operation appears to be possible using collisional transfer of electronic energy to iodine atoms from excited molecular species produced chemically or in an electrical discharge. Modeling of the kinetics of these systems requires information on the rates at which energy is transferred from excited species to $I(5\ ^2P_{3/2})$ and the quenching rates for $I(5\ ^2P_{1/2})$ due to any other species present in the laser.

In this paper we report measurements on the deactivation of $I(5\ ^2P_{1/2})$ by I_2 using a new technique which is 2 to 3 orders of magnitude faster in time resolution than previous methods. It is possible in fact to observe the time development of the *appearance* of excited iodine atoms following the excitation of molecular iodine both above and below the dissociation limit of the $B^3\Pi_{0_u^+}$ electronic state.

The iodine is excited in a multiple reflection cell by a nitrogen laser pumped tunable dye laser which produces 10 ns pulses at a rate of 20 pps. The population of $I(5\ ^2P_{1/2})$ is monitored by observing the time dependence of the absorption of atomic line emission which is passed through the cell from an iodine lamp and which is observed using a McPherson Model 225 Vacuum Ultraviolet Monochromator tuned to 2062 Å. The photomultiplier signal is digitized using a Biomation Model 8100 Transient Digitizer and for each measurement approximately 10^4 pulses are accumulated in a Northern Scientific Model 575 Signal Averager. A variety of computer programs are used to carry out a least squares fit of the data to derive both a decay rate for $I(5\ ^2P_{1/2})$ and information on the time development of its appearance following the laser pulse.

By varying the I_2 pressure we have measured the second-order quenching rate coefficient for $I(5\ ^2P_{1/2})$ by I_2 as $kI_2 = (3.6 \pm 0.4) \times 10^{-11}$ cm^3 $molecule^{-1}$ s^{-1} which is nine times faster than that reported by Husain and co-workers.[1] Measurements of $I(5\ ^2P_{1/2})$ deactivation by other species are being carried out and similar measurements are planned for $Br(4\ ^2P_{1/2})$. Data available at the time of the conference will be presented.

WA4. Kinetic Modeling of Photodissociation Iodine Laser Amplifiers,[1] C. E. Turner, Jr., and N. L. Rapagnani, *Lawrence Livermore Laboratory.*

A comprehensive kinetic model is described which predicts the time dependence of the inversion in iodine-laser energy-storage amplifiers over a wide range of helium diluent pressure. The high rare gas pressures (1–10 atm), which are required to control superfluorescence and produce bandwidths suitable for short pulse generation via collision broadening, significantly modify the chemical kinetics of the flash photolysis of fluorinated alkyl iodides (RI, e.g., CF_3I, C_3F_7I) because of lower temperature rise, fast thermalization of "hot" radicals and three-body effects. The model includes many of the typical two-body deactivation, recombination, and reaction mechanisms previously considered for low pressure analyses but it is appropriate to omit some uncertain reactions involving "hot" radicals. In addition, it is necessary to consider I_2 formation via three-body iodine atom recombination: (a) I + I + M, (b) I* + I + M, and (c) I* + I* + M, where the main catalysts (M) are He, I_2, and RI.

A major achievement of this modeling effort is the determination of a consistent set of rate equations and rate constants by critical examination of the experimental rate data coupled with an attempt to fit the detailed inversion history data of Hohla and Kompa[2] at P(He) = 0 and the inversion half-life data of Aldridge[3] at P(He) = 1 and 3 atm. An excellent fit to data is shown in Fig. 1. The agreement with Aldridge's data is also good. Since the various experimental conditions considered in the rate adjustment process emphasize different reactions, the overall confidence in the extrapolation capability is considerably enhanced.

Some important conclusions are: 1) it is unnecessary to invoke unknown chemical pumping processes[2] or diffu-

[3] F. T. Aldridge, to be published.

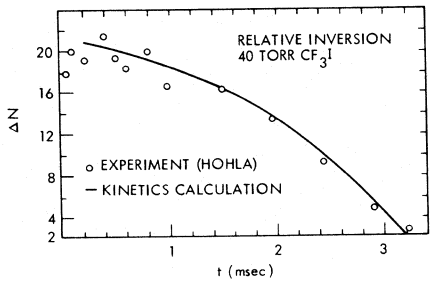

Fig. 1.

sion effects[4] to explain low pressure data; 2) the rate for reaction (b) with M = He may be only about a factor of five lower than that for (a); 3) reactions (c) can be neglected as expected theoretically; 4) for 10% dissociation of 10 torr C_3F_7I with a 10 μs FWHM pump pulse the model predicts a relatively weak dependence on the He diluent pressure, $T_{1/2}(\mu s) \sim 450/\sqrt{P(atm)}$, and 5) $T_{1/2}$ is principally determined by the formation rate of the main quencher, I_2.

WA6. Electronic-to-Vibrational Energy Transfer Reactions: X* + CO (X = 0, I and Br), M. C. Lin and R. G. Shortridge.[1]

The vibrational distribution of CO produced from the following two electronic energy quenching reactions:

$$O(^1D) + CO(X\,^1\Sigma^+, v = 0) \xrightarrow{I} O(^3P) + CO(X\,^1\Sigma^+, v \leqslant 7)$$

$$I(5\,^2P_{1/2}) + CO(X\,^1\Sigma^+, v = 0) \xrightarrow{II} I(5\,^2P_{3/2}) + CO(X\,^1\Sigma^+, v \leqslant 3)$$

have been determined by means of infrared resonance absorption measurements employing a CW CO laser. The electronically excited $O(^1D)$ and $I(5\,^2P_{1/2})$ atoms were generated from the photodissociation of O_3 and CF_3I, respectively, above 200 nm:

$$O_3 + h\nu(\lambda \geqslant 200\text{ nm}) \longrightarrow O(^1D) + O_2(^1\Delta, {}^1\Sigma_g^+)$$

$$CF_3I + h\nu(\lambda \geqslant 200\text{ nm}) \longrightarrow I(5\,^2P_{1/2}) + CF_3.$$

The populations of CO produced in reactions (I) and (II) are given in Table I. The CO molecules formed in both reactions were found to be vibrationally excited up to the limits of available electronic energies carried by the excited atoms. A similar result was also observed in the $Br(4\,^2P_{1/2}) + CO$ ($v = 0$) reaction, in which absorption occurred only in the 1 → 2 band. The Br* atom was produced by the photodissociation of CF_3Br in the UV region.

For the O* + CO reaction, the efficiency of E → V energy transfer was determined to be 17%. Our present results were found to be inconsistent with the impulsive (half-collision) model.

k_v(II)	–	1.0	0.094	0.043				

[a] Computed from the total quenching rate constant, determined by Heidner *et al.* (*J. C. S. Faraday Trans. II*, vol. 69, p. 927, 1973), and the extrapolated rate of formation of CO ($v = 0$) from the ln (N_v/N_1) versus [$G_0(v) - G_0(1)$] plot.

SESSION WB

$DF-CO_2$ Lasers
Wednesday, October 23, 8:30 A.M.

WB1. Electrically Initiated Pulse Chemical $DF-CO_2$ and DF Lasers,[1] T. O. Poehler and R. Turner, *Applied Physics Laboratory, Johns Hopkins U.*

While high energy outputs can be obtained from high-pressure pulsed $DF-CO_2$ chemical transfer lasers using optical initiation, the overall efficiency is low. Direct electrical initiation of the $D_2 + F_2$ reaction in a transverse discharge, with the potential advantage of much higher efficiency, has been studied for two excitation conditions: 1) a 150 ns wide current pulse; and 2) a 450 ns wide current pulse. The DF and $DF-CO_2$ lasers are nominally operated at 300–760 torr, static fill, with 2% D_2, 4.5% F_2, 6% O_2 (for stabilization), 6% CO_2 (when used) and 82–88% He.

In the $DF-CO_2$ laser, a 450-ns current pulse produces a 10.6-μm laser output beginning 7–12 μs after the start of current and usually consists of a series of spikes lasing 100–150 μs. The spikes are about 1 μs long, and occur at 3–4 μs intervals. The reaction pressure grows much less rapidly then in the flash initiated laser indicating a low initial F concentration or competing reactions with the chain reaction. There is no DF 3.8-μm laser output.

With 150-ns excitation, the laser output is completely different. With DF only, emission at 3.7–3.9 μm starts 0.3 μs after the current and the lines in order of occurrence are $P_3(4)$, $P_3(5)$, $P_3(6)$ (the strongest), and $P_3(7)$, followed by $P_4(5)$, $P_4(6)$, and $P_2(9)$. With CO_2 added, the initial output occurs 0.4 μs after the start of current and is at 10.6 μm—P(26), P(34), and P(42) of $00^\circ1\text{–}10^\circ0$. These are followed by 3.6-μm emission from $P_1(5)$ and $P_1(6)$. The main 10.6 μm follows at 4.8 μs from the P(20) and P(18) lines. If the laser is operated as a normal TEA laser, the 10.6-μm radiation occurs at 1.2 μs.

These results may be summarized as follows. With 450-ns excitation, the laser output is delayed as in flash initiation. With 150-ns excitation, DF alone lases first in the P branch from vibrational levels 3 to 2. The progressive transition to higher J's is probably the result of a temperature rise.[2] The 4 to 3 transitions occur after an inversion is produced by depletion of the lower level by the 3 to 2 transition. The $P_2(9)$ transition, which lases well after the peak of the 3-2 transitions, may be pumped by the 302 cascade. The pressure of inert gases has been observed to reduce the number of emission lines and reduce the equilibration time of the rotational temperature.[2]

The prompt 10.6-μm radiation in the case of the $DF-CO_2$ laser (in contrast to the delay with CO_2 only) is attributed to a collisional transfer of energy from DF to CO_2 with a rate constant of 6.0×10^5 s^{-1} $torr^{-1}$ with the result that the P_3 lines observed in DF only are missing. There is a significant difference in vibrational energy between the DF 3-2 transition and the CO_2 000-001 pump transition that may be taken up as rotational energy.[3] This energy transfer from DF in the V = 3 state will heavily populate the V = 2 states and produce the inversion responsible for the $P_2(1)$ and $P_2(2)$ lines. The P(18) and P(20) 10.6-μm lines observed later are presumably the result of excited DF formed as the chemical reaction proceeds.

WB2. Characteristics of a Supersonic DF-CO_2 Transfer Chemical Laser, J. A. Stregack and W. S. Watt, *Naval Research Laboratory.*

A CW supersonic DF-CO_2 transfer chemical laser has been developed which recovers to atmospheric pressure. The device is a modified combustion driven gas dynamic laser with added D_2-F_2 chemistry. A methane–oxygen pilot serves to catalyze the carbon monoxide–oxygen reaction which produces hot CO_2. Nitrogen and/or additional CO_2 are added to control the combustor conditions, and a mixture of fluorine and helium is injected downstream of the combustion zone. Plenum conditions range from 14–20 atm and 950–450 K which serve to partially dissociate the F_2 before the flow is accelerated to $M = 4.5$ through an array of supersonic nozzles. Two sets of nozzle arrays have been tested. The first injects the D_2 through a series of fine orifices immediately upstream of the nozzle throats. The mixing, chemical reaction, and energy transfer start near the throat and proceed through the nozzles and into the cavity region. The second nozzle configuration fully accelerates the flow prior to injection of D_2 at the nozzle exit plane. In this configuration, D_2-F_2 chemistry begins in the cavity. The cavity, a constant area flow channel, is connected at the downstream end to the converging section of a diffuser which enables the gas to recover to atmospheric pressure. Starting the diffuser is a prerequisite to laser operation.

The important chemistry is the D_2/F_2 chain reaction which produces vibrationally excited DF

$$F + D_2 \longrightarrow DF^* + D$$

$$D + F_2 \longrightarrow DF^* + F$$

the transfer of DF vibrational energy to CO_2

$$DF^* + CO_2(00^\circ 0) \longrightarrow DF + CO_2(00^\circ 1)$$

and the deactivation of the CO_2 upper laser level by species in the flow

$$CO_2(00^\circ 1) + M \longrightarrow CO_2(nm^l o) + M$$

$$M = HF, DF, \ldots .$$

Pumping of CO_2 by vibrational energy transfer from chemically produced DF has been observed but has been offset by deactivation due to by-products formed in the combustor.

For subsonic mixing of the D_2, the chemistry increases the laser power output over that during operation of the device as a gasdynamic laser. The enhancement is limited, however, by deactivation due to HF formed in the combustor as a by-product of methane combustion and prereaction in the injection and nozzle expansion region.

In the supersonic case the combustor conditions required to keep the diffuser started lead to incomplete CO oxidation prior to F_2 injection. The unburnt CO reacts with F_2 to form COF_2 and CF_4. This depletes the F_2 available for chemical pumping as well as introducing COF_2 which degrades CO_2 laser performance.

WB3. Supersonic Mixing DF-CO_2 Transfer Chemical Laser: Experiment, W. H. Evers, L. S. Forman, and J. J. Vieceli.

A multikilowatt, combustion driven, *supersonic mixing* transfer chemical laser has been operated efficiently (846 J/g available-fluorine, 40.1 kJ/1bm-total-flow) at high power levels (up to 2872 W) and moderate cavity pressures (up to 13 torr) in a small-scale laboratory device (1 in × 3 in nozzle-exit-area). The experimental apparatus is described in detail with emphasis on the unique method used for CO_2 injection. Performance variation with certain key-operating conditions (cavity pressure, CO_2 flow rate, available fluorine flow rate, and resonator configuration) is presented. In addition, performance variation over a narrow range of other variables (combustor temperature and laser cavity fuel (D_2) flow rate) is discussed. Comparisons are made between HF, DF, HF–CO_2, and DF–CO_2 lasing performance in the same device and conclusions are drawn about the operational characteristics of the four modes. Results obtained using alternate methods of CO_2 injection are also presented. The experimental data are discussed in terms of the physical bases for the observed trends; a more complete interpretation is presented in an accompanying paper on the theory of transfer chemical laser operation.

WB4. Supersonic Mixing DF-CO_2 Transfer Chemical Laser: Theory, J. J. Vieceli, W. H. Evers, and A. G. Negro.

A new analytical model, which represents both a significant conceptual improvement over previous models and a substantial reduction in computational requirements, has been developed for the DF-CO_2 transfer chemical laser and applied to evaluation of supersonic mixing device performance in light of recent data. Previous models for the DF-CO_2 transfer chemical laser have relied on a detailed state representation of the vibrational-level population densities of the species present (DF, CO_2, D_2). In the current model we assume that the population densities of each of the CO_2 vibrational modes can be described by a Boltzmann distribution vibrational temperature (an approach which has been demonstrated for the N_2-CO_2 gas dynamic laser). The existence of mode vibrational temperatures is both conceptually and quantitatively significant since, as would be expected physically, a mode vibrational temperature permits the population densities of each level within a particular vibrational mode to achieve a value representative of the total energy in that mode. This is clearly not the case with a detailed state model in which the $CO_2(001)$ is the highest vibrational level considered, while the effective vibrational temperature of the pumping species (DF) can easily be in excess of 5000 K. (The vibrational temperature of the pumping species (N_2) in the gas dynamic laser is typically only 1500 K.) Furthermore, inclusion of higher CO_2 vibrational levels into the detailed state model leads to an extremely unwieldy computation.

To apply the vibrational temperature concept, the kinetic rate equations are cast in an energy representation for which the dependent variables are the energies in $CO_2(\nu_1)$, $CO_2(\nu_2)$, $CO_2(\nu_3)$, $DF(v)$, and $D_2(v)$. Numerical solution of these equations in conjunction with mixing and power extraction represents a complete characterization of the lasing medium. The one-dimensional mixing model used is applicable to either laminar or turbulent mixing in either constant pressure or specified area flow fields. The interaction between the resonator and the lasing medium is considered using both geometric and physical optics.

Details of the model are presented and *results are compared* to experimental data for a supersonic mixing DF-CO_2 transfer chemical laser with a closed cavity stable resonator. In all cases, theoretical predictions compare favorably to the experimental data.

WB5. Kinetic Model and Computer Simulation of Continuous Wave DF-CO_2 Chemical Transfers Lasers, W. Baumann, J. A. Blauer, S. W. Zelazny, and W. C. Solomon, *Bell Aerospace Company Divison of Textron Inc., Buffalo, N.Y.*

Continuous wave DF-CO_2 chemical transfer has been investigated experimentally by Shirley, Falk *et al.*[1] and

[1] J. A. Shirley, R. N. Sileo, R. R. Stephens, and T. A. Cool, AIAA Paper 71-27, AIAA 9th Aerospace Sciences Meeting, N.Y., Jan. 1971; T. J. Falk, AF Tech. Rep. AFWL-TR-71-96, June 1973 and AFWL-72-169, June 1973.

more recently in our laboratory. Although all of these studies have employed the same chemical reagents, the experimental conditions used differ greatly. Thus, gaseous CO_2 and NO were added to a fluorine stream containing diluent (He or N_2) within a plenum chamber to provide, among other things, a source for atomic fluorine. The flow is directed past an array of deuterium injection ports into the optical cavity where lasing occurs. In order to better understand the available experimental results and use them to provide guidance to the designers of future devices, it is desirable to model such experiments analytically. Recent efforts of Kerber *et al.*[2] were confined to a consideration of pulsed devices. However, their success has encouraged us to attempt the mathematical description of the more complicated CW case with a consideration of the difficult subject of reagent mixing. We have successfully simulated much of the available experimental data for these devices. Our nonequilibrium model involves in excess of 150 individual chemical reactions and/or energy transfer processes and includes a simple description of mixing phenomena. The mixing model used is based upon the assumption that the fluid elements containing the oxidizer and fuel will mix through the eddy motion characteristic of a turbulent mixing layer. The process itself was characterized by two lengths the first being the distance required for a fluid lump to degrade in size to the point at which the transport properties and chemical reaction are significantly affecting the rate of the break-up; the second length scale represents the distance required for mixing to be complete. A direct comparison between the model and the available data demonstrates the chemical chain reaction mechanism chosen for input is quite adequate for most computational purposes. A moderate disagreement between experiment and theory can be shown to be primarily due to an inadequate description of the reagent mixing phenomena. The model developed reproduces in a quantitative way most of the salient features of the available data (e.g., the effect of cavity temperature, pressure, species mixture ratio, and flow Mach no.). Based upon the results of this study, it now appears that our present knowledge regarding the chemistry and physics of the DF-CO_2 transfer laser is adequate to allow for a reasonable mathematical description of a device which is based upon this system

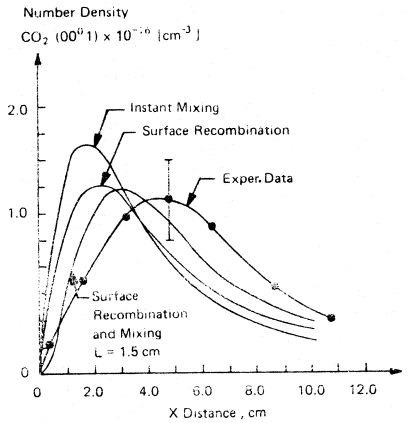

Fig. 1. Comparison of data by Shirley *et al.* with computed $CO_2(00^0 1)$ number densities.

and its operating in a continuous mode. In order to confirm the quantitative aspects discussed herein more data have been required. A more recent set of measurements for a chain reacting TCL have been conducted in our laboratory. These results have been obtained in a chain reacting device with a large mode volume and concomitant high output powers (15 kW). Power measurements and chemiluminescence data were compared to the newly developed model. The fit to the data from this large device confirms the validity of nonequilibrium models developed during the first part of the study. A typical comparison between observed and computed number densities in the upper laser level is shown in Fig. 1 for the data of Shirley *et al.*[1] Shown in this figure are the results computed not only for the case of instantaneous mixing but also the results to be expected when mixing phenomena as well as the effects of the recombination of atomic fluorine on the available surfaces are accounted for. We have estimated the losses due to surface recombination in line with the results of Ferrell *et al.*[3]

SESSION WC

cw HF/DF Chemical Lasers I
Wednesday, October 23, 8:30 A.M.

WC1. Investigation of a Supersonic cw HF-Chain Laser, J. C. Cummings and C. M. Dube.

The successful demonstration of HF-chain-reaction lasing in a supersonic CW device will be discussed. Closed-cavity power in excess of 100 W has been obtained. Spectral identification of the laser radiation showed contributions from vibrational levels as high as $v = 5$ (this provides unequivocable evidence of chain reaction rather than the "cold reaction" alone). Chemiluminescent spectra have been recorded and used to determine profiles of small-signal gain, HF vibrational-band number densities, and rotational temperatures. Comparison of the experimental data with those from a detailed computer model[1] indicates discrepancies in power output and rotational temperature. Fluid-mechanical disturbances and/or thermal blockage within the cavity may be inhibiting the CW chain reaction from producing higher laser power.

Several tests have been conducted on the "hot reaction" alone. An arc heater was used to fully dissociate molecular hydrogen. Lasing power was observed and chemiluminescent spectra were recorded. Concentrations of the upper vibrational levels of HF were larger than those observed under chain-reaction conditions.

Since the first successful operation of a pulsed H_2-F_2 system was reported in 1969,[2] many such devices have been built. Standard pulse-initiation techniques dissociate ~1% of the fluorine in a mixture of H_2, F_2, and diluent. Until recently,[3] the only successful demonstrations of CW chain-reaction lasing were in subsonic flow devices.[4,5] However, no laser emission was observed for vibrational levels above $v = 2$.

The goal of our investigation was to study the CW chain laser in a supersonic mixing device. It has been necessary to run tests under a variety of conditions and with a variety of hardware since the number of parameters which can affect the lasing performance is even greater than for the HF "cold-reaction" laser. Several different initiation techniques (production of atomic fluorine), diluent gases, nozzle arrays, and optical-resonator configurations have been used during the investigation. Diagnostics include flow visualization, closed-cavity power, outcoupled lasing spectra, and chemiluminescent spectra.

WC2. Spectroscopic Investigation of a Small-Scale cw HF Chain-Reaction Laser,[1] R. A. Meinzer and R. V. Steele, *United Aircraft Research Laboratories.*

[1] This work was supported by ARPA and was monitored by the U.S. Army Missile Command under Contract DAAH01-73-C-0321.

Investigation of the H_2-F_2 chain reaction demonstrated that it is effective as a method for efficiently generating vibrationally excited HF for a CW laser. These experiments were performed on a nozzle with an active area of 2 X 2 cm. Thermal dissociation of F_2 diluted in helium provided the small amount of F-atoms (1 mole %) needed to initiate the HF chain reaction downstream of a two-dimensional supersonic mixing nozzle. Chemiluminescent emission measurements were performed on the active medium and provided the HF vibrational population densities and rotational (static) temperatures. Interpretation of the emission data requires plotting the logarithm of the reduced emission intensity measured for each transition as a function of $J(J+1)$. A straight line plot is anticipated; after optical thickness effects were ruled out, the curvature that was experimentally observed was interpreted as indicating the presence of two temperatures within the flow field. One temperature corresponded to the rotational temperature that HF molecules would have if they had diffused into the unreacted primary gas stream and the second temperature corresponded to the anticipated temperature in the reaction zone. These conclusions are supported by the observation that the lower temperature (HF in unreacted, unmixed primary gas stream) remained constant with increasing distance downstream of the nozzle exit plane whereas the higher temperature (HF in reacting gas zone) increased. The associated vibrational population measurements provided a measurement of the degree of reaction that had occurred and the distribution of vibrational energy among the various vibrational levels. Vibrational levels up to $v = 6$ had significant populations ($\gtrsim 4 \times 10^{13}$ molecules/cc). The decrease in population with increasing vibrational level corresponded to the vibrational levels from $v = 2$ to $v = 6$ being in vibrational equilibrium at a temperature of approximately 5000 K. Use of optical thickness on the $v = 1 \rightarrow 0$ transitions allowed a measurement of ground state population to be made so that the total HF concentration could be determined. Comparison of the measured concentration with the amount of HF that would have been present if the chain reaction had gone to completion provided a quantitative estimate of the degree of reaction. At 10.6 cm downstream of the nozzle exit plane, the chain reaction had gone approximately 30% toward completion. Successful lasing tests were performed and the spectral content of the laser beam indicated that low J transitions were oscillating. This observation was consistent with gain calculations which had indicated that the gain arose from the HF that had diffused into the cool, unreacted primary gas stream.

WC3. Some Experimental Results with Stable Selected-Line Resonators in a Relatively High Gain cw HF Chemical Laser,[1] L. Boedeker, M. Foster, N. Nomiyama, L. Lynds, A. Angelbeck, and G. Wisner, *United Aircraft Research Laboratories.*

Fundamental transverse mode laser oscillations have been established in a CW HF chemical laser with stable single and multi selected-line resonators at power levels adequate for conducting subsequent saturation, cascade, selected-line power extraction and anomalous dispersion studies in separate CW chemical laser amplifiers. Good oscillator axial mode stability and control, amplitude stability, and near diffraction limited output were maintained, features of potential significance for the CW HF chemical laser. Requirements of power and gain for the selected line oscillator imply operation with a relatively high gain medium condition. Since the medium is predominantly Doppler broadened anomalous dispersion and frequency pulling effects are significant as discussed recently by Lynds.[2] The laser employs arc dissociation of SF_6, mixing of H_2 in a fine array nozzle, and supersonic expansion into the laser cavity. Stable single axial modes have been obtained for single vibration–rotation transitions in HF with a 37.5 cm PZT controlled Littrow grating cavity, and a 20 cm active optical path, at power levels near line center between 5 and 10 W per transition on P_2(2-8) and P_1(1-6). Mode widths, full width half power, were less than 80 MHz, however, the measurement may have been limited by the available finesse of the Fabry–Perot interferometer. Frequency stability was about ±15 MHz over 10 s. The full Doppler line width is about 300 MHz and the mode frequency was controllable over a range ±100 MHz about line center without significant introduction of a second axial mode. Amplitude stability was better than 3% rms over the frequency range investigated, 10 to 10^4 Hz. Long term drift (100 s) was less than 3%. Beam quality, as determined with focused integrated irradiance diagnostics was near diffraction limited for these single transitions. As the Littrow cavity was length tuned the laser power exhibited a Lamb dip near line center. Multi selected-line laser oscillator output was achieved using an intracavity grating, separate spherical total reflectors for each of up to three selected lines and a common flat dielectric output coupler. The three lines investigated were $P_2(3)$, $P_2(5)$, and $P_1(4)$. The extra length of this cavity relative to the Littrow for a 20 cm active path generally resulted in laser oscillation in HF on two simultaneous axial modes per transition. Selective simultaneous oscillation on combinations of two lines, including the cascade pair $P_2(3)$, $P_1(4)$, was observed with the Fabry–Perot scanning interferometer, which sets a lower limit to simultaneity here of ~100 MHz. Enhancement of laser output due to the cascade was not observed suggesting that significant saturation of the medium was not occurring.

WC4. High Field Saturation Phenomena in HF Chemical Amplifiers,[1] L. Lynds, M. C. Foster, and A. W. Angelbeck, *United Aircraft Research Laboratories.*

Amplification characteristics of five HF transitions: $P_2(3)$, $P_2(5)$, $P_2(6)$, $P_1(3)$, and $P_1(4)$ were investigated over three decades of intensity.[1] An arc-driven CW master oscillator with fine tuning capability provided the source of frequency-stable (±15 MHz) single line, single and double axial mode radiation with power outputs on the order of 5 W. Amplifier gain was generated by CW combustion driven supersonic flow devices utilizing the "cold" reaction, $F + H_2 \rightarrow HF(V, J) + H$. Two stages of amplification were used to obtain saturating power levels; measurements were performed relative to the second (final) stage. Small signal gains, $\langle g_0 \rangle$, and effective saturation parameters, I_s, measured at transition line centers with a single axial mode input were:

Transition	$\langle g_0 \rangle$ (cm^{-1})	I_s(W/cm^2)
$P_2(3)$	0.20	
$P_2(5)$	0.24	17-24
$P_2(6)$	0.16	8-12
$P_1(3)$	0.17	22-26
$P_1(4)$	0.17	

At sufficiently high intensity levels a single excitation line (double axial mode) induces superfluorescent radiation from the optically connected nonresonant

vibrational–rotational level. The induced emission exhibits the following unique properties. It is: 1) continuous, 2) coaxial with the exciting beam, 3) coherent, 4) unidirectional in the direction of the propagation vector, and 5) the process has a specific threshold intensity. Experiments were performed on HF transitions $P_1(4)$ and $P_2(3)$ having a double-axial mode structure. Using $P_1(4)$ as the exciting line, $P_2(3)$ is induced at approximately 1300 W/cm^2. Rate of stimulated emission at this intensity level suggests that T_2 relaxation processes are on the order of 8×10^{-8} s which is equivalent to about 8 collisions. A 2 W $P_1(4)$ beam was boosted to 99 W in two stages of amplification. Near field measurements in the final stage indicate a e^{-1} diameter of 1.4 mm and a corresponding total intensity of 6000–7000 W/cm^2. Spectral distribution of output power (watts) is $P_1(4)$, 36.5; $P_2(3)$, 36.5; $P_2(4)$, 18 and $P_2(5)$, 8. Adjacent lines connected to the mutual vibrational level are also induced as a consequence of rapid rotational draining. Similar experiments were performed with $P_2(3)$ as the exciting transition. A kinetic model has been developed to describe the cascade dynamics of optically connected levels. The theoretical implications of these experiments will be discussed and compared to recent theoretical treatments on cooperative spontaneous emission superradiance.

WC5. Temporal Characteristics of Multiline-Multimode CF HF Chemical Lasers,[1] M. C. Foster, L. Lynds, and A. W. Angelbeck, *United Aircraft Research Laboratories.*

The temporal characteristics of a multiline-multimode CW HF chemical laser using a linear unstable resonator configuration have been investigated over a range of parametric flow conditions. Decoupled energy was separated into its spectral components with a dispersive element such that up to three lines could be simultaneously subjected to a detailed spectral and temporal analysis. Fabry–Perot interferometry high-frequency spectrum analysis and fast-amplitude detection provided a wide frequency range of mode analysis. Results indicate that the two dominant power transitions $P_2(5)$ and $P_1(6)$ fluctuate violently and randomly between zero and total power levels with an effective duty cycle far less than 100 percent. Maximum modulation excursions on these transitions were 55 and 100 percent, respectively. Total decoupled power collected from all transitions showed similar variations but tended to be more constant as a consequence of averaging. Amplitude variations display a distinct spiking tendency without periodic structure. When the optically connected transitions fire simultaneously, their high-frequency components (1 MHz to 100 MHz) tend to be correlated and periodic suggesting that optical-kinetic interactions are operative. The RF amplitude is 10 to 20 percent of the peak power. Frequency modulation of the RF envelope occurs at much lower frequencies and appears to be random and uncorrelated between the two investigated transitions. Several theoretical models for intermittent and periodic behavior within the dynamic range of experimental observables will be discussed. Mechanical driving forces and second-order optical phenomena such as population pulsations predicted from the Lamb equations[2] will be included in these considerations.

SESSION WD

Laser-Controlled Chemistry
Wednesday, October 23, 8:30 A.M.

WD1. Laser Powered Homogeneous Pyrolysis,[1] W. H. Shaub and S. H. Bauer, *Cornell University.*

The large absorption cross sections for infrared radiation possessed by a few rather stable molecular species, their relatively fast vibration–translation relaxation times, and the availability of large laser fluxes at their characteristic frequencies can be effectively exploited to generate high bath temperatures for gas phase reactions under strictly homogeneous conditions. *Controlled* temperatures from 500–1500 K can be developed with a modest CO_2 laser. Rise times for heating are estimated to be in the millisecond range, with reaction times $\approx$10 s. Operating pressures [reagents, radiation absorber (generally, SF_6) and diluent] range from 10 to 100 torr. Thus, LPHP is complimentary to the single pulse-shock tube technique [rise time $\sim 10^{-8}$ s; reaction time $\sim 10^{-3}$ s] for obtaining product distributions in gas phase pyrolyses, and for measuring *relative* rates in the absence of hot walls, which may (and generally do) introduce catalytic effects. Further, LPHP is very simple and ideally suited for exploratory investigations of small amounts of reagent ($\approx 10^{-6}$ moles); also, sample cells may be heated externally to augment the vapor pressure of slightly volatile reagents. Conventional analytical procedures (gc, mass spec) are used to follow the course of pyrolysis.

The primary chemical kinetic parameters, the temperature and density of the reactants, have both spatial and temporal distributions. Computer programs were developed for $T(r, x; t)$, given the radial intensity distribution in the incident beam, the absorption coefficient of the SF_6 [as a function of density and the temperature for the anti-bleaching line, P(28)], as well as the mean heat capacity and thermal conductivity of the gas mixture. However, the computed profiles did not prove useful, since the effects of convection, which could not be included in the calculations, perturb the initial distribution significantly within a few milliseconds. Indeed, it proved practical to enhance convection so as to homogenize the sample composition. This was demonstrated experimentally by using a three-compartment cell with test mixtures irradiated in horizontal and vertical configurations. Chopping frequencies ranging from 100 Hz to 1 Hz gave the same product distributions. A practical procedure is to use a "chemical thermometer" to establish the mean *effective temperature* for a given experimental configuration. Examples showing how to measure relative rate constants for molecular conversions and the use of LPHP for qualitative determinations of product distributions as a function of temperature will be presented. For the former, the relative rates for $c \leftrightarrow t$ 2-butene; $c \leftrightarrow t$ 1,2-difluoro-ethene; $c \leftrightarrow t$ dichloro-ethene; cyclopropane; 1,4-cyclohexadiene were studied pairwise to demonstrate that the relative rates obtained by this technique are in agreement with literature values, as derived from single pulse-shock tube and conventional kinetic experiments. Finally, a number of high temperature conversions will be described to illustrate the utility of LPHP for flash thermolysis.

WD2. Infrared Laser Augmented Decomposition of H_3PBF_3, E. R. Lory and S. H. Bauer, *Cornell University*, and T. Manuccia, *Naval Research Laboratory.*

Consideration of v-v and v-T relaxation rates for polyatomic molecules subsequent to their vibrational excitation by currently available laser fluxes, led to a strategy for selecting reactants for which the possibility for successful

[1] Submitted by S. H. Bauer.

augmentation of reaction by infrared irradiation is optimized. Several criteria are listed. While these are shown to be useful guides, they do not constitute a sufficient set of conditions for predicting augmentation for reaction. The criteria were applied to the selection of a typical $2AB \rightarrow A_2 + 2B$ reaction; i.e., a self-scavenging system.

The thermochemistry, essential vibrational spectroscopy, and kinetic parameters for the H_3BPF_3 decomposition are briefly summarized. The experimental arrangement is described and the results of a series of runs with a CO_2 laser (10.6-μ band) are presented. That the augmented decomposition of H_3BPF_3 is due to specific vibrational excitation rather than to an overall temperature rise, or general vibrational excitation, such as developed through v-v transfer is demonstrated by the following: a) The extent of decomposition is dependent on the J value of the laser line used but not in proportion to its absorption coefficient; differences in energy between P(20), P(28), and P(30) are trivial, yet their relative chemical efficiencies differ by as much as a factor of 5. b) Collisional energy transfer to admixed H_3BCO does not appreciably raise the temperature of the latter, since there was no augmented decomposition of the carbonyl, which is as sensitive to rising temperatures as the phosphine adduct. Thus, the strategy of using low pressures to maintain the translational and rotational temperatures of the reactants at or near the wall temperature succeeded even though the radius of the cell was about four times the mean free path.

On the basis of the measured low-pressure absorption cross sections we concluded that under the high-flux conditions it is highly probable that most molecules which pass through the beam absorb at least one photon. However, the observation that the percent conversion depends on the laser power (as derived from log-log plots) indicates that for an H_3BPF_3 molecule to react at a translational temperature (25°C) it must carry at least two exciting quanta and that the absorption coefficient for the second photon must be at least an order of magnitude smaller than the first. Thus, the rate determining step is:

$$H_3B + H_3BPF_3^{(v \geqq 2)} = B_2H_6 + PF_3.$$

Similar studies with H_3BCO (9.6-μ band) showed no augmentation. No boron isotope effect (to within ±20%) was found for these self-scavenging systems.

WD3. Effects of Temperature and Buffer Gases on the Reactions of Nitric Oxide with Vibrationally Excited Ozone, R. J. Gordon[1] and M. C. Lin.

The reactions of nitric oxide and vibrationally excited ozone

$$NO + O_3(001) \xrightarrow{2a} NO_2^*(^2B_1) + O_2$$
$$\xrightarrow{2b} NO_2(^2A_1) + O_2$$

were studied in a rapidly flowing system. Ozone was excited with a pulsed CO_2 laser, and the enhanced NO_2^* emission was monitored with a photomultiplier.[2] The laser-induced signal had a double rise time followed by a slightly faster than exponential decay. The rapid rise rate is attributed to reactions (2a) and (2b), while the slower rise rate is attributed to the relaxation step,

$$O_3(001) + M \underset{-1}{\overset{1}{\rightleftharpoons}} O_3(010) + M$$

followed by the reactions

$$O_3(010) + M \xrightarrow{3a} NO_2^*(^2B_1) + O_2$$
$$\xrightarrow{3b} NO_2(^2A_1) + O_2.$$

The signal decay is due to consumption of excited ozone by chemical reaction and $V \rightarrow R/T$ relaxation. By changing the ozone concentration the gas temperature was varied from 300 to 450 K. The overall decay rate constant has a mean value of $1.1 \pm 0.2 \times 10^{11}$ cc/mole · s which appears to be independent of temperature (see Fig. 1). Most of the decay is due to the nonluminescence reaction, which has a rate constant of $9.6 \pm 1.2 \times 10^{10}$ cc/mole · s. From the analysis of the rise rates, we arrived at the conclusion that the rate constant $k_{2a} + k_{2b}$ is 60 ± 20% of $k_{3a} + k_{3b}$. The vibrational relaxation rates of ozone by various buffer gases (He, Ar, H_2, D_2, O_2, N_2, CO_2, N_2O, NO_2, and CH_4) were determined.

SESSION WE

Modeling and Theory
Wednesday, October 23, 2:00 P.M.

WE1. Quasi-Equilibrium Vibrational Population Distributions for Anharmonic Molecular Lasers,[1] S. H. Lam and N. Papageorgis, *Princeton University.*

Theoretical predictions of vibrational population distributions, N_i ($i = 0, 1, \cdots$), are conventionally obtained by direct numerical integration of the master kinetic equations. For every operating condition of interest, a separate computation must be performed. In the present paper, we shall show that N_i of anharmonic diatomic molecules (such as CO and N_2) can be approximately represented by a two-parameter family of universal quasi-equilibrium distributions $N_i^{QE}(e_v, T; \ldots)$ provided the operating conditions satisfy the quasi-equilibrium assumptions. The parameters e_v and T are the vibrational energy per molecule and the translational–rotational temperature of the gas, respectively. The significant point is that $N_i^{QE}(e_v, T)$ depends only on molecular parameters and the V-V and V-T collision probabilities and is independent of the details of the operating conditions; thus for a given gas (or gas mixtures) the family of $N_i^{QE}(e_v, T)$'s can be computed once and for all. The parameter e_v is shown to be governed by a nonlinear relaxation equation of the form $de_v/dt = P - D$ $(e_v, T; \ldots)$ where P is the net rate of external input of vibrational energy per molecule and $D(e_v, T)$ is again a two-parameter family of universal functions which also can be computed once and for all. Sample calculations of N_i^{QE} (e_v, T) and $D(e_v, T)$ for CO and N_2 have been performed and are presented.

The present theory differs from the classical work of Treanor, Rich, and Rehm in that the dominance of V-T collisions over V-V collisions at sufficiently high vibrational levels is recognized. While the Treanor distribution is independent of any collision probabilities, the present N_i^{QE} depends on all the V-V and the V-T collision probabilities. The calculated results show that N_i^{QE} is approximately Treanor at low vibrational levels and is approximately Boltzmann (at temperature T) at high vibrational levels. In the intermediate levels, N_i^{QE} depends on the details of the V-V and V-T collision probabilities, particularly on the level scaling law of the nearly resonant V-V collision probabilities. In classical harmonic oscillator theories, $D(e_v, T)$ is given by $[e_v - e_v(T;$ Boltzmann$)]/\tau(T)$ where $\tau(T)$ depends

[1] This research is supported by the Air Force Office of Scientific Research Contract F44620-73-C-0059.

only on the V-T probabilities. The present results show that whenever N_i^{QE} departs substantially from a Boltzmann distribution, $D(e_v, T)$ is a strongly nonlinear function of e_v and its value depends mainly on the nearly resonant V-V probabilities.

WE2. Theoretical Performance of a V → V Transfer Laser,[1] R. Naismith and R. Cavalleri, *Atlantic Research Corp.*, and R. L. Taylor, P. Lewis, and J. D. Teare, *Physical Sciences Inc.*

This paper presents the results of a theoretical analysis applicable to a general class of gas dynamic vibration–vibration (V-V) transfer lasers. The concept is as follows: A hot pumping gas is expanded through a nozzle freezing the vibrational mode. The lasing gas is either mixed with the pump gas prior to the expansion or after the expansion. V-V pumping, both intermolecular and intramolecular, occurs in the flowing gas under the expansion conditions of high-vibrational temperature and low-translational temperature producing a non-Boltzmann vibrational distribution sufficient for high gain and lasing.

Two necessary requirements for this type of laser are that: 1) the pump gas must have a larger characteristic vibrational temperature than the lasing gas; and 2) the vibrational kinetics must be such that the V-V rates are much larger than the total deactivation processes in the gas.[2]

The hot pumping gas or pump/lase gas mixture can be produced by a variety of techniques such as combustion, electric discharge, or solid propellant-fueled gas generators.

As an example of such a V-V transfer laser, calculations have been performed for the H_2/HCl molecular system. Based on gas generator research performed at ARC, we believe that it is feasible to consider solid propellant gas generators for producing H_2 or H_2/HCl mixtures at temperatures up to 3000 K and pressures to 100 atm. A review of pertinent kinetic rate data for the H_2/HCl molecular system including the effects of H and Cl atoms has been performed, and a complete kinetic mechanism and rate package for these molecules considered as multilevel anharmonic oscillators developed.

The results of two types of analyses will be presented: 1) a harmonic oscillator kinetic model using premixed gas or instantaneous mixing in the throat region of the nozzle; and 2) an anharmonic kinetic model assuming premixed gas. These calculations indicate available energies in the cavity region of the flow of 100 kJ/lb of gas mixture. It is also clear that certain kinetic rates such as the H_2/HCl V-V transfer rate and HCl V-T rate for H-atoms are critical for this laser concept.

Some of the advantages of the H_2/HCl V-V transfer laser compared to chemical lasers are: the lower toxicity and corrosiveness of HCl compared to F_2 and HF, storable and compact fuels, transmission in the 4μ window, and use of the already highly developed GDL technology.

WE3. Theoretical Modeling of Saturation Effects in Laser Amplifiers,[1] R. Tripodi and B. Burdick, *United Aircraft Research Laboratories.*

A theoretical model has been developed to simulate the amplification of a laser beam passing through a chemical laser medium. The model treats the relevant kinetics, and couples these iteratively with a wave-optics calculation describing the propagation of the optical field. The complete cavity gas-dynamic problem is solved once for a description of such parameters as temperature, pressure and velocity. The calculation is done under an assumed flux loading in the range expected in the actual solution. These gas-dynamic parameters, not being strongly dependent on the flux loading, are then treated as known for subsequent calculations. Only the number densities of relevant emitter states need be calculated explicitly as a function of flux loading. This approximation results in a considerable savings of computer time with little sacrifice in accuracy. The optical calculations are, for the time being, restricted to two-dimensional geometries. The model has been applied to experiments carried on at United Aircraft Research Laboratories to study saturation effects in HF media. A specific case was selected, applicable to the $P_1(3)$ transition. Conditions were selected for the initial complete gas-dynamic calculation that resulted in reasonable agreement of predicted gas temperatures and HF number densities with experimental measurements. These conditions were then used in calculations of the amplification of laser beams of various sizes and initial powers. Since the calculations are restricted to two dimensions whereas the actual experiments were three dimensional, exact agreement was not expected. However, the results of the calculations should be comparable with experiment along a plane parallel to the flow direction through the center of the beam. This turns out to be the case, with predictions within 50% of the measurements for amplification over a 20-cm path. The model was used to evaluate the effects of varying beam size and focusing. Such factors can have a significant effect on the amplification of a given input power. For example, at low powers narrower parallel beams are amplified more than wider beams whereas at higher powers the opposite is true. Similarly focused beams with a varying diameter through the medium can also demonstrate differing degrees of amplification, depending upon the input power, degree of focusing, and location of the focal point. These effects and their impact upon the interpretation of experimental data will be discussed.

[1] This work was sponsored in part by the Advanced Research Projects Agency (ARPA) and monitored by the Air Force Weapons Laboratory, Air Force Systems Command, The United States Air Force, Kirtland Air Force Base, N. Mex.

WE4. Vibrational Relaxation of HCl (v = 1, 2, 3, and 6) by H- and Cl-Atoms,[1] R. L. Wilkins, *The Aerospace Corporation, El Segundo, Calif. 90045.*

Rate coefficients have been calculated for the collisional de-excitation of vibrationally excited HCl molecules by H- and Cl-atoms. Three-dimensional classical trajectories of the collisional dynamics of these reactions have been calculated by means of London–Eyring–Polanyi–Sato (LEPS) potential energy surfaces. The results of this study indicate: a) the rapid deactivation of vibrationally excited HCl by H- and Cl-atoms can be explained provided that bound complexes are postulated for both ClH_2 and HCl_2; b) H- and Cl-atom exchange provide efficient mechanisms for relaxing vibrationally excited HCl by Cl- and H-atoms, respectively; c) multiple quantum-transitions are important in these de-excitation processes; d) the major energy transfer processes are vibration to translation in the deactivation of HCl by H- atoms and vibration to rotation in the deactivation of HCl by Cl-atoms. The vibrational relaxation of HCl by H-atoms is faster than vibrational relaxation of HCl by Cl-atoms. Room temperature overall relaxation rates for HCl(v) by H-atoms are as follows: $k_2/k_1 = 1.7$, $k_3/k_1 = 2.5$, and $k_6/k_1 = 3.0$ where $k_1 = 3.0 \times 10^{13}$ cm^3 mole^{-1} s^{-1}.

For deactivation of HCl(v) by Cl-atoms, the room temperature overall relaxation rates are as follows: $k_2/k_1 = 1.5$, $k_3/k_1 = 2.2$, and $k_6/k_1 = 8.4$ where $k_1 = 4.5 \times 10^{12}$ cm^3 mole^{-1} s^{-1}. For v = 1, 2, and 3, these overall rates show

[1] This work reflects research supported by the Air Force Weapons Laboratory (AFWL) under U.S. Air Force Space and Missile Systems Organization (SAMSO) Contract F04701-73-C-0074.

a linear dependence with v. The potential energy wells predicted for the ClH_2 surface of −3.0 kcal/mole and for the HCl_2 surface of −0.77 kcal/mole have an effect on the collision dynamics across these surfaces as vibrational energy in the reagent is increased. The collision dynamics on the surface with the deeper potential-energy well is such that the deactivation rate for the reaction H + HCl(v = 6) shows a much smaller enhancement than does the deactivation rate for the reaction Cl + HCl(v = 6) where the potential energy well is not as deep. Increased vibrational energy in the reagents does not necessarily enhance the overall reaction rates in reactions that occur mostly by formation of collision complexes instead of by direct interaction. The results of the calculations are compared to the rates which have been determined experimentally for the de-excitation of HCl (v = 1, 2, and 3) by Cl-atoms and of HCl(v = 1) by H-atoms. Rate coefficients are provided for many reactions that have not been measured experimentally.

WE6. Investigation of the Computation of V-T and V-V Intermolecular Potentials, N. M. Witriol and J. D. Stettler, *Redstone Arsenal*, and J. R. Sabin and S. B. Trickey, *U. of Florida.*

We report model calculations based on semiempirical computer codes that give V-T and V-V short-range intermolecular potentials strikingly different from those normally chosen in traditional theories of energy exchange. Knowledge of such intermolecular energy transfer processes is essential to the computer modeling of gaseous lasers. Despite the recent outpouring of experimental determinations of such rates, a clear need exists for a quantitative theoretical procedure for their calculation. Sharma and co-workers have shown how to do this for vibrational (V-V) energy transfer mediated by long range multipole–multipole forces for cases in which the vibrational energy mismatch is small. Two of us have recently shown that short range forces can also contribute significantly to such processes. Also, short range forces are the primary origin of vibration–translation (V-T) energy exchange. Typically, the functional form and magnitude of these forces have been determined by the traditional theoretical approach of SSH. A purely repulsive exponential form is assumed and its parameters are obtained from a fit to the repulsive region of the Lennard–Jones potential determined from experimental transport properties. Ab initio calculations of V-T and V-V potentials have not previously been attempted for complicated systems such as N_2-CO_2 because of prohibitive computer costs which arise from the extensive configuration interaction calculations needed to achieve chemical accuracy. However, qualitative chemical behavior is often adequately modeled by semiempirical calculational procedures such as CNDO. We have obtained the V-T and V-V potentials for N_2 and the asymmetric stretch of CO_2 in the N_2-CO_2 system by use of CNDO/2. The intermolecular potential $V(R_{cm}, \rho_1, \rho_2)$ was obtained as

$$\begin{aligned} V(R_{cm}, \rho_1, \rho_2) &= E(R_{cm}, \rho_1, \rho_2) \\ &\quad - E(\infty, \rho_1 \rho_2) \\ &\simeq A_1 + A_2\rho_1 + A_3\rho_2 \\ &\quad + A_4\rho_1^2 + A_5\rho_2^2 \\ &\quad + A_6\rho_1\rho_2 \end{aligned}$$

where $E(R_{cm}, \rho_1, \rho_2)$ is the total CNDO energy of the N_2-CO_2 complex with intermolecular distance R_{cm} and vibrational mode expansions ρ_1 and ρ_2 for CO_2 and N_2, respectively. Although the changes in E were small (less than 0.1%), they were systematic, so that 25 values of V at a given R_{cm} (V at that R_{cm} frequently varying over a factor of two) were fit by the six A's to within 5% for R_{cm}'s of interest. The variation of the A's differed strikingly from that of a simple repulsive exponential. For A_2 through A_6, a variation of at least an order of magnitude occurs as a function of relative molecular orientation in a physically reasonable manner. For a collinear orientation, all A's exhibit an attractive region. The location of the minimum differs among the A's. In particular, A_2, A_4, and A_6 are still attractive at the room temperature classical turning point of A_1, the term governing elastic scattering. (It should be noted that the minimum of A_1 is substantially deeper than the experimental value.) Thus the predominant V-V potential for N_2-CO_2 and V-T potential for CO_2 in a collinear collision would have the form of an attractive force. Computations of other collision orientations show that all the A's are strongly orientation dependent and that none of the A's are well approximated by any of the others.

SESSION WF

CW HF/DF Chemical Lasers II
Wednesday, October 23, 2:00 P.M.

WF1. Relative Performance of Arc and Combustor Driven C.W. HF Lasers, G. L. Grohs and G. Emanuel.

A theoretical model for the HF cold-reaction continuous-wave laser is outlined, which combines the analyses of Mirels *et al.*[1] and Broadwell.[2] Lasing with finite-rate chemistry is considered in the laminar or turbulent mixing layer between parallel uniform oxidizer and fuel jets of finite width. The physical significance of the dimensionless scaling parameters is discussed. Scaling laws predicted by this model are then used to correlate experimental laser performance data obtained with both arc[3] and combustor[4] plenums. In the first case, the oxidizer stream contains atomic fluorine and inert diluent, while in combustor operation it also carries DF from the $D_2 + F_2$ combustion which provides the energy for fluorine dissociation.

Good correlations are obtained when the dominant deactivators of vibrationally excited HF are assumed to be H, HF, or F in arc operation, but DF in the combustor case. The laminar and turbulent models correlate the data equally well. It is shown that in typical arc driven cavities lasing is terminated by merging of adjacent mixing layers at the center line of the oxidizer jet, i.e., by the end of fluorine entrainment. Under otherwise equivalent conditions, operation with a combustor plenum results in a shorter lasing zone, ending before the mixing layers merge. Fluorine entrained downstream of the lasing zone is then wasted, and accounts for the factor 2 or 3 lower efficiencies observed.[5] In addition, the correlations indicate effective ratios of pumping rate to deactivation rate of 0(10) for the combustor, and larger for arc operation.

These observations can be explained if, in agreement with recent hydrogen atom kinetic experiments,[6] the fastest deactivation rate in an arc driven cavity is an order of magnitude slower than HF deactivation by DF. If the measured rate coefficients for the latter are accepted, theoretical estimates[7] for deactivation by H appear to be too fast by an order of magnitude. The large effective ratios of pumping rate to deactivation rate may be attributable to cascading. It is concluded that the efficiency of HF lasers driven by $D_2 + F_2$ combustion can be improved with smaller nozzles. To achieve powers comparable to arc-driven lasers, the combustion reaction should be replaced by one whose products are less effective in deactivating vibrationally excited HF.

WF2. Spectroscopic and Infrared Measurements on the Mesa CW HF (DF) Chemical Laser,[1] M. A. Kwok, R. R. Giedt, and E. F. Cross, *The Aerospace Corporation, Los Angeles, Calif. 90009.*

Results from the spatially, spectrally scanning, remotely controlled spectrograph are described; observations from the IR vidicon system are also given. The behavior of the free supersonic jet HF/DF laser medium is examined in He-F_2/D_2 laser systems with two types of nozzle banks, slit and axisymmetric. The spectrograph monitors number density for HF(3) along the line-of-sight N_2L, and the rotational temperature T_R at a large number of spatial points (X, Z). The data can be classified into three types: 1) transverse spatial scans along Z, 2) spatial scans along X, and 3) data at fixed X_0, Z_0. Different types of interpretations can be developed for three types.

The spectrograph system was designed to acquire spectroscopic data in a field environment with limited test duration. The HF 3-0 P-branch is observed at 8800 A. For these lines, the cavity is optically thin without atmospheric effects on the path. The sensitivity and fast time constants of photomultiplier tubes (S-1) can be used. Each P-branch is observed in 20 ms with a frequency of 10 spectra per second. A mirror system and laser chamber movements provide the (X, Z) displacements.

The Z-scans in N_3L and T_R permit an evaluation of jet uniformity in the direction transverse to the flow. This examines plenum uniformity since $N_3L(Z)$ will reflect the initial F/F_2 distribution and T_R will strongly manifest the exothermity from pumping reactions in the free jet. (The fuel distributions in the nozzle banks will also affect pumping reactions, but the $H_2(D_2)$ is found to be uniform.)

The X-scans provide information on downstream jet properties, which are especially sensitive to nozzle configurations. In particular, the jet static temperature (equated to T_R) has been found; this is important in understanding the reaction kinetics. With pressure measurements, mass density can be evaluated in a manner previously reported.[2] With Mach number information, the amount of reaction for a given nozzle bank can be estimated using jet calorimetry. The efficiency of mixing and reaction in the slit and axisymmetric nozzle can be compared. By running a flow condition with zero-power and with full-power loading in closed cavity conditions, a localized cooling effect can be observed; it is believed, on this upstream cavity edge, that most of the vibrational energy in HF(v) is extracted as photons.

Data at fixed (X_0, Z_0) can provide correlations of $\bar{N}_3L$ and T_R with laser performance parameters. An example is shown of the effect of DF from a F_2-D_2 combustor on an HF laser.[3]

Infrared TV pictures of the laser reaction zones, along the same line-of-sight as the spectrograph, have been obtained. The DF emission between 3.2 and 4.2 μ has been successfully observed.

[3] An estimate of the HF(3) + DF relaxation rate constant can be given.

WF3. Power and Pressure Recovery Measurements in High Mach Number Supersonic Chemical Lasers, J. C. Hyde and R. Knight.

The DF supersonic chemical laser (SCL) provides high power and high efficiency at a radiation wavelength with good atmospheric propagation properties. These devices require low pressure in the optical cavity to obtain high efficiency. The subsystem required to pump the exhaust gases from the cavity dwarfs the rest of the system unless a supersonic diffuser is used to recover a large fraction of the velocity head in the exhaust products. Diffuser recovery pressure is related to the combustor total pressure. Therefore, high-combustor pressure and low-cavity pressure (high Mach cavity entrance numbers) are required for an efficient compact system.

This paper discusses an experimental program investigating laser efficiency and pressure recovery in a high Mach number SCL. A set of Mach 7 nozzles was designed and fabricated using methods that have been shown to be successful at Mach numbers of 4 to 5. The nozzles were designed for helium, fluorine, and deuterium in the combustor, and hydrogen as the cavity fuel. The reactant flow rate was 12 g/s. Flat plat shrouds were positioned above and below the nozzles to contain the expansion in the cavity.

Closed cavity power was measured calorically on each of the water cooled mirrors in the stable oscillator. A probe was used to measure pitot pressure profiles at various distances from the cavity entrance. Most of the tests used D_2 as the combustor fuel to heat and dissociate the excess F_2, and H_2 as the cavity fuel and H_2, C_2H_6, or H_2S as the combustor fuel. The primary variables were diluent ratio, β, cavity fuel ratio, R_L, F_2 dissociation fraction, α, cavity pressure, P_L, and shroud angle θ. Unshrouded performance was most affected by P_L and β. Maximum power was obtained at $\beta = 6$ to 7 with a sharp drop in power outside the range.

Two tests were run using combustor fuels that produced significantly reduced concentrations of HF in the combustor products. Ethane produced slower mixing but less deactivation for a net longer lasing zone. Ethane combustion showed less decrease in power at high β and a 10% higher maximum power than H_2 combustion. H_2S combustion produced a 35% increase in power and produced high power at high β.

WF4. Experimental Comparison of CW Chemical Laser Gas Heaters and Nozzle Arrays,[1] R. R. Giedt, *The Aerospace Corporation, Los Angeles, Calif. 90009.*

Two important components of an HF/DF supersonic diffusion chemical laser configuration are the gas heater, traditionally an electric arc or a combustor, and the nozzle bank for accelerating the flow into the optical cavity, usually variations of a slit or axisymmetric array. Recent experiments at the MESA facility have been conducted with several combinations of an arc or combustor heater configured with one of four nozzles, two slit and two axisymmetric types. The discussion is limited to a comparison of specific experimental results for selected gas conditions and closed cavity lasing.

The performance of the two gas heaters, measured during tests with the same nozzle, an 18:1 expansion ratio axisymmetric array, was: maximum power 11.8 and 7.3 kW and at comparable high power levels, maximum chemical efficiency 7.0 and 4.6%, maximum specific power 120 and 45 kJ/lb., and maximum power peak at an optical axis position of 4.6 and 4.1 cm, for the arc and combustor, respectively. These data are part of a larger body of experimental and analytical evidence that DF combustion product is one of the few important deactivators of HF* in laser flows. In a previous arc versus combustor comparison, this deactivation factor was listed together with a nonuniformity of temperature detected in that combustor flow. The present advanced combustor has regenerative gas cooling so less energy is lost and thus there need be less DF in the flow (now uniform).

The four nozzles are compared in two steps. First, HF laser results from an axisymmetric versus a slit array, both coupled to the same arc, were 11.8 and 12.4 kW, respectively, closed cavity laser power for similar mass flows. Power profiles were sensitive to the faster mixing and therefore faster reac-

tion of the axisymmetric design. The slit nozzle-arc combination with longer mirrors produced 15 kW, HF, and DF. Second, higher expansion ratio slit and axisymmetric nozzle banks were matched in HF and DF lasing against the original axisymmetric nozzle, all tested with the combustor and the longer mirrors. These higher expansion ratio nozzles did not improve laser performance. One explanation for this, supported by some static temperature data, is that the $F + H_2$ reaction occurs mainly in the boundary layer and therefore the reaction zone does not see the core flow from the higher expansion. Another possible reason, supported by some pitot pressure data, is that the plenum (upstream of nozzle) pressure varies inversely as the throat area, and the increased expansion ratio was not able (because of boundary layer) to compensate for the higher plenum pressures used with the higher expansion ratio nozzles, thus causing higher static pressures in the lasing jet. However, the higher expansion ratio nozzles do show some evidence of a more extended lasing gain zone, and also a tolerance of high or "matched" optical cavity pressures with less degradation of DF power.

WF5. CW HF/DF Chemical Laser Spectral Diagnostics,[1] R. L. Varwig and M. A. Kwok, *The Aerospace Corporation, Los Angeles, Calif. 90009.*

Two spectrographic systems have been developed and applied to a number of diagnostic experiments on several CW HF/DF supersonic diffusion lasers. The experiments include spectroscopic determination of plenum temperature, and spatial mapping of HF(v)/DF(v) number densities and static temperatures in the lasing region. One system, using phase-lock techniques, has been designed for laboratory applications with high signal sensitivity at high spatial resolution commensurate with the spatial variations in the reaction zones of jets from the small supersonic nozzles employed in CW chemical lasers. It has been applied to the plenum temperature and jet mapping experiments. The second system is rapid spectrally, spatially scanning spectrograph intended for mapping flame zones in field applications where test duration is limited. Accordingly, signal sensitivity and spatial resolution are reduced. The spectrographic systems are described, experimental results are given and the two systems are compared.

The plenum temperature is important, because the degree of dissociation of fluorine containing compounds in the plenum and, hence, the free F atoms available for the HF reaction is dependent on temperature. The measurement is made by observing the rotational temperature of excited HF molecules formed in the hot plenum gas when it is seeded with trace amounts of H_2. The temperatures observed are generally higher than those predicted from the plenum pressure change when a fixed mass flow is heated. This may be expected since the latter value is actually a "throat estimate" back-computed to the plenum. Significant cooling can take place between plenum and throat; therefore, the measured values should be higher than the values predicted from the plenum pressure change associated with heating.

The laboratory spectrographic measurements made in the HF laser cavity have been aimed at getting the spreading rate of the reaction products, the temperature (from rotational temperature) and relative number density in each HF vibrational level. SF_6, heated by mixing with hot He diluent, provides the fluorine for the HF reaction. Data for both H_2 and D_2 fuel are reported and the spreading rates compared for similar flow conditions. From these data total inversion of HF is observed to occur at the nozzle exit plane close to the point where mixing between F and H_2 begins. Further downstream and further into the H_2 flow, the total inversion vanishes as a result of deactivation by HF and H_2. Rotational temperature measurements from the nozzle exit plane to two inches downstream (essentially the extent of the radiating cavity) are obtained as well as spreading rate over the same range. Spatial resolution obtained in these tests is about half mm which is adequate for observing the details of the flow including the differences in spreading rate for H_2 and D_2 fuel.

The spectrograph employed in field operation studies is also described. A special feature is the total remote control of the system. Complete spatial and spectral surveys of the flow field can be obtained in one short sequence. The overall uniformity of the medium is thus evaluated.

WF6. Analysis of Small-Scale DF Cold-Reaction CW Lasers,[1] R. V. Steele, R. A. Meinzer, and R. Roback, *United Aircraft Research Lab.*

Chemiluminescent emission spectroscopy and laser beam spectral content measurements performed with two different nozzle configurations have been used to characterize the resulting differences in the chemical laser media generated by the reaction of an F-atom with D_2 to form vibrationally excited DF. One nozzle design, which utilizes strips of conical nozzle elements, provided a relatively coarse grid of mixing elements while the other, which utilizes fine-scale nozzle elements with small base area, provided a fine grid; the former nozzle had a width of 4.0 cm and the latter a width of 1.7 cm. The long run times achievable with these nozzle segments facilitated making spectral diagnostic measurements. Vibrational populations and rotational temperatures were determined via emission spectroscopy as a function of the distance downstream of the nozzle for various gas compositions and static pressures. Comparison of the measured vibrational population distributions with the primitive vibrational distribution of the DF cold reaction provided an estimate of the degree of vibrational relaxation occurring in the laser medium. From this population and rotational temperature information, the small-signal gain profiles for the two nozzle configurations were also computed. In the case of the coarse grid mixing nozzle, the gains calculated on the basis of emission measurements showed good agreement with the results of gain probe measurements that were made on a larger version of the same nozzle design. Spectral content measurements were used in combination with the emission data to provide information on saturation and cascading in the presence of laser radiation. Spectral content measurements made with a high Q resonator gave evidence for cascading; the $4 \rightarrow 3$ transitions were observed to lase, whereas, the corresponding small-signal gain determined via emission spectroscopy was always below threshold. Estimates of the degree of saturation of optically connected levels can be obtained in part from the intensity distribution of lines observed in the laser output. For example, in one experiment the vibrational population ratio N_2/N_1 was observed to be 1.5 in the absence of lasing; whereas, with the laser operating, this ratio was estimated to be 0.6 from the observed lasing transitions. In addition, the small-signal gain calculations were combined with measurements of the extracted laser power to provide an estimate of the saturation intensity (200 W/cm^2). The measured spatial variation in vibrational population downstream of the nozzle exit plane has also been compared with calculations performed with the UARL one-dimensional chemical laser code and the exponential mixing length associated with the coarse-grid nozzle was estimated to be 10 cm. Furthermore, comparisons of the measured vibrational distributions with those predicted by the computer code provide a unique test of various V-V rate packages which have been proposed for the relaxation of the higher vibrational levels.

Jack D. Daugherty was born in Ottumwa, Iowa, on February 4, 1935. He received the B.S. degree in electrical engineering from Iowa State University, Ames, in 1957, and the M.S. and Ph.D. degrees from Purdue University, Lafayette, Ind., in 1963 and 1966, respectively. While at Purdue, he studied under a National Science Foundation Graduate Fellowship. He also attended the 1964 Princeton University Plasma Physics Summer Institute sponsored by a National Science Foundation Grant.

From 1957 to 1961 he was attached to Naval Reactors, U.S. Atomic Energy Commission, where he worked on the structural, electrical, and nuclear engineering of naval nuclear propulsion reactors. He joined AVCO Everett Research Laboratories, Everett, Mass., where he is currently Vice President for Laser Research, in 1966. As a Principal Research Scientist at AVCO Everett he conducted theoretical and experimental research in various areas of plasma physics, high-voltage electron devices, gas-discharge physics, and lasers. Since the invention of the E-beam sustained laser in 1969, he has concentrated his technical efforts on the development of high-power laser technology.

Dr. Daugherty is a member of the American Physical Society and several physics, engineering, and scholastic honor societies.

W. Q. Jeffers (M'73) was born in Aurora, Nebr., on November 1, 1939. He received the S.B. degree in electrical engineering from the Massachusetts Institute of Technology, Cambridge, and the M.S. and Ph.D. degrees in electrical engineering from the University of Illinois, Urbana, in 1961, 1964, and 1967, respectively.

From 1961 to 1963 he was employed in the Research Division of McDonnell Aircraft Company, where he worked on microwave masers. He was in the Department of Electrical Engineering of the University of Illinois from 1963 through 1968 as a Research Assistant, Research Associate, and Assistant Professor. His thesis research at the University of Illinois was concerned with the water-vapor laser. He was associated with Hughes Research Laboratories, Malibu, Calif., in 1968, and rejoined McDonnell Douglas Research Laboratories, St. Louis, Mo., in 1969. His research interests have since been in the field of molecular and chemical lasers. He has been active in organizing the Conference on Chemical and Molecular Lasers in St. Louis in 1969, 1972, and 1974.

Dr. Jeffers is a member of Sigma Xi and the Optical Society of America.

*

J. D. Kelley was born in Chicago, Ill., on July 30, 1937. He received the B.S. degree in chemistry from St. Louis University, St. Louis, Mo., and the Ph.D. degree in chemistry from Georgetown University, Washington, D.C., in 1959 and 1964, respectively.

From 1964 to 1967 he was with Brookhaven National Laboratory. In 1967 he joined the McDonnell Douglas Research Laboratories, where he is presently a Senior Scientist in the Radiation Sciences Laboratories, St. Louis, Mo. His research interests include molecular collision phenomena, chemical kinetics, and chemical lasers.

Dr. Kelley is a member of the American Chemical Society, Sigma Xi, and the American Association for the Advancement of Science.

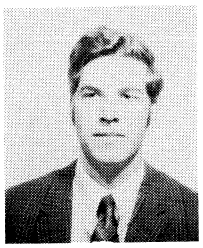
H. K. Shin was born in Korea. He came to the United States in 1957, where he received the B.A. and Ph.D. degrees in chemistry in 1959 and 1961, respectively, from the University of Utah, Salt Lake City.

From 1961 to 1962 he was a Research Chemist at the National Bureau of Standards, Washington, D.C. For the next two years he was a postdoctoral Research Fellow at Cornell University. Since 1965 he has been a member of the Faculty at the University of Nevada, Reno. His fields of research are the theory of molecular collisions, theory of collision-induced light scattering, and nonequilibrium rate processes.

Dr. Shin is a member of the American Chemical Society, the American Physical Society, the Korean Chemical Society, and Sigma Xi.

*

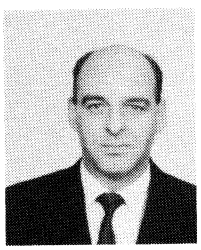


G. W. Tregay was born in Oak Ridge, Tenn., in 1945. He received the B.S. degree from the Massachusetts Institute of Technology, Cambridge and the Ph.D. degree in physical chemistry from Boston College, Boston, Mass., upon completing a spectroscopic investigation of low-pressure H_2/F_2 flames, in 1967 and 1972, respectively.

Since 1973 he has been employed at Bell Aerospace Company, Division of Textron Inc., Buffalo, N.Y., and is currently involved in both experimental and analytical studies of chemical laser systems.

Dr. Tregay is a member of the Combustion Institute and the American Chemical Society.

*



R. F. Webbink was born in Hutchison, Kans., on September 21, 1945. He received the B.S. degree in physics from the Massachusetts Institute of Technology, Cambridge, in 1967, and is presently completing work on the Ph.D. degree in theoretical astronomy at Cambridge University, Cambridge, England.

He worked at the McDonnell Douglas Research Laboratories immediately prior to, and following, service in the U.S. Navy from 1969 to 1972. He resumed a Marshall Scholarship at the Institute of Astronomy, Cambridge University, in October 1972. His current research includes calculations of the structure and evolution of close binary stars. He has been appointed Research Fellow in Astronomy and Astrophysics at the University of Illinois, Urbana, from August 1975.

Mr. Webbink is an associate member of Sigma Xi.

L. M. Wood was born in Evanston, Ill., in 1930. He received the B.S. degree from the University of Missouri at Rolla, Rolla, in 1956.

He has been with Bell Aerospace Company, Division of Textron Inc., Buffalo, N.Y., since 1959. He is currently working on optical cavity diagnostics for CW chemical lasers.

A Simplified Method for Predicting Unstable Resonator Mode Profiles

WILLIAM H. STEIER, SENIOR MEMBER, IEEE, AND GARY L. McALLISTER

Abstract—The qualitative features of the lowest order mode profile of an unstable resonator can be predicted by a simple technique based on Fresnel zone theory. The number of rings in the pattern and the occurrence of a local minimum or a local maximum on-axis can be predicted by computing the number of Fresnel zones subtended at the observation plane by the cavity aperture uniformly illuminated by a point source at the virtual focus. This technique has been verified by computer calculations of mode profiles both inside and external to the cavity for moderate Fresnel numbers. The results were also confirmed by experimentally measured mode profiles on an unstable cavity He-Xe laser. The predicted cyclic nature of the mode loss with cavity aperture diameter was also confirmed experimentally.

I. Introduction

NUMEROUS computer studies [1] of unstable resonators have shown complex mode patterns for even the lowest order modes. These patterns change rapidly as the cavity aperture size is changed, and prediction of the mode has, in general, required computer calculations. Any change in aperture size, or mirror spacing, or curvature has required another complete computer analysis to predict the mode shapes. In this paper we demonstrate a simple technique based on Fresnel zone theory [2] to predict the qualitative features of the mode profile and give experimental examples for moderately low equivalent Fresnel numbers.

The geometrical picture of unstable modes is that of spherical waves emanating from the virtual foci. This picture provides a first-order value for the cavity loss or mode eigenvalue and predicts a spherical phase front for the modes. Using this geometrical picture as a starting point, we have found that the number of rings in the pattern and the occurrence of a local minimum or local maximum in the on-axis intensity of the lowest order mode can be simply predicted by assuming the cavity aperture (generally the resonator mirror) to be uniformly illuminated by a spherical wave emanating from the virtual focus. By computing the number of Fresnel zones subtended by this aperture from any observation point inside or outside the cavity, these general features of the lowest order mode can be predicted at that point. In particular, if the observation point chosen is the opposite mirror, then the features of the resonator mode profile that would be calculated numerically can be predicted. This technique is demonstrated to work quite well when $2N_{eq}$ is odd, that is, away from a cavity loss degeneracy point [3]. Near a degeneracy point ($2N_{eq}$ even) the general mode features can be predicted in the same manner by assuming an additional corrective phase-front curvature to the aperture illumination.

Manuscript received August 15, 1974; revised April 22, 1975. This work was done at the Northrop Research and Technology Center, was supported in part by the Advanced Research Projects Agency, Department of Defense, and was monitored by the Office of Naval Research under Contract N00014-72-C-0043.

W. H. Steier is with the Department of Electrical Engineering, University of Southern California, Los Angeles, Calif. 90007.

G. L. McAllister was with the High Power Laser Program, Northrop Research and Technology Center, Hawthorne, Calif. 90250. He is now with the Exxon Nuclear Company, Richland, Wash. 99352.

II. Numerical Calculations

Diffraction calculations for near-field patterns of a uniformly illuminated circular aperture show series of concentric rings where the number of relative peaks in intensity in a scan taken along any diameter of the pattern is equal to the Fresnel number [4]. Furthermore, when the Fresnel number is even, there is a local minimum on-axis, and when it is odd, there is a local maximum on-axis. If the lowest order resonator mode has a phase profile which is approximately equal to that predicted by geometrical optics, and if the intensity profile varies slowly over the width of a Fresnel zone, then the general features of the mode profiles should show the same behavior as a uniformly illuminated aperture. That is, when the effective Fresnel number (which includes the spherical curvature of the illuminating wave) is even, there will be an on-axis dip in the intensity, and when it is odd, there will be peak. Also there will be a number of intensity peaks along a diameter equal to the effective Fresnel number. To demonstrate this, the mode patterns for the lowest loss mode of a symmetrical unstable resonator shown in Fig. 1 were computed using the Prony method described by Siegman and Miller [3]. The details of this computer code have been described in a previous paper [5]. Circular mirrors (with spherical surfaces) and cylindrical symmetry are assumed throughout. The modes were computed at an observation plane which can be inside or outside the cavity for the wave traveling from left to right. These computer results are compared to our simplified theory which is based on the effective Fresnel number N_{eff} at the observation plane for the mirror on the left when it is uniformly illuminated by a spherical wave from the virtual focus on the left. N_{eff} and N_{eq} are therefore defined by

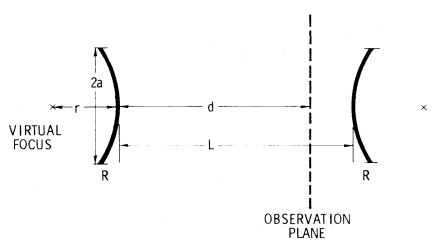

Fig. 1. Schematic diagram indicating the observation plane for calculating the intensity profile of a symmetric unstable resonator.

$$2N_{eq} = N(M - 1/M)$$

$$N_{eff} = N(L/r + L/d)$$

where

$N = a^2/L\lambda$	cavity Fresnel number;
a	radius of the cavity aperture;
L	mirror spacing;
R	mirror radius of curvature;
λ	wavelength;
g	$= 1 - L/R$;
$M = g + (g^2 - 1)^{1/2}$	cavity magnification;
$r = L/(M - 1)$	distance from the mirror to the virtual focus.

Fig. 2 illustrates the computed mode patterns at the plane of the mirrors with $N_{eq} = 1.5$ which is a minimum loss point for the lowest order mode and hence not near a mode degeneracy point as predicted by Siegman and Miller [3]. Modes for $N_{eff} = 4$ and 5 are shown. Since the modes are being calculated at the mirror, $d = L$ is used in calculating N_{eff}, and therefore $N_{eff} = NM$. It should be noted there that M is different for each example and they are therefore not normalized to the same radius. The tick mark on each curve denotes the respective mirror edge for each example, and the point where the normalized radius is 1.0 corresponds to a radius equal to the true cavity radius times the geometrical magnification. Fig. 3 shows similar mode profiles calculated for $N_{eq} = 0.5$. These results show that, at least for these low values of N_{eq}, the number of intensity peaks along a diameter of the pattern is equal to N_{eff} (the mode is symmetric about the center and hence the figures show $N_{eff}/2$ intensity peaks). Also the mode has a local minimum on-axis if N_{eff} is even and a local maximum on-axis if N_{eff} is odd. This is qualitatively the same as a simple diffraction calculation would have predicted for a point source at the virtual focus uniformly illuminating the mirror aperture.

Near a loss degeneracy point ($2N_{eq}$ is even) we have found that there are two distinct mode eigenfunctions with nearly the same mode loss (magnitude of the eigenvalue) but with different phase angles of the eigenvalue. This is in contrast to earlier published work with square apertures and slightly larger N_{eq} in which the mode eigenfunctions were also found to be degenerate. Numerous calculations have shown that the two modes have different intensity profiles and different phase-front radii; one is more concave than the geometrical wave and one is more convex in approximately equal amounts. We have found that near degeneracy our method is still applicable and that the mode features can be predicted by allowing the first-order-mode phase profile to be 90° advanced at the mirror edge relative to the geometric wave and by allowing the second-order-mode phase profile to be 90° retarded. This ±90° phase deviation would modify N_{eff} by ∓0.5 and would be expected to affect the number of rings observed in the intensity profile. Figs. 4 and 5 are the computed intensity and phase profiles

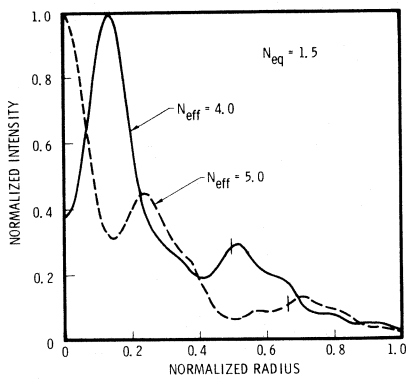

Fig. 2. Normalized mode intensity profile for a symmetric unstable resonator with $N_{eq} = 1.5$.

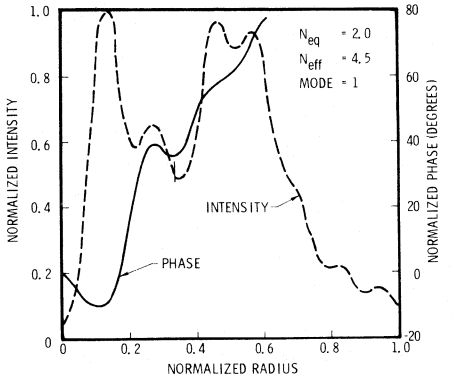

Fig. 4. Intensity and phase profiles for mode 1 of a symmetric unstable resonator at the loss degeneracy point $N_{eq} = 2.0$.

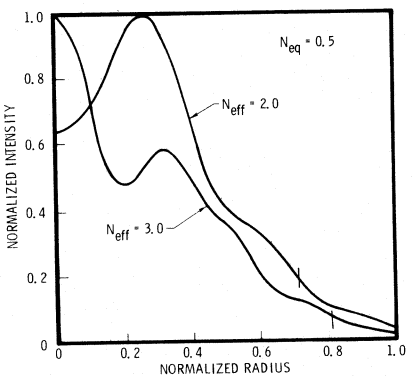

Fig. 3. Normalized mode intensity profiles for a symmetric unstable resonator with $N_{eq} = 0.5$.

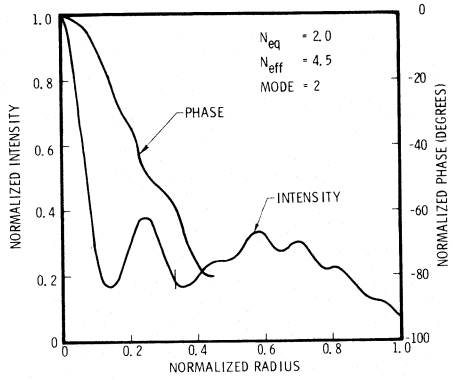

Fig. 5. Intensity and phase profiles for mode 2 of a symmetric unstable resonator at the loss degeneracy point $N_{eq} = 2.0$.

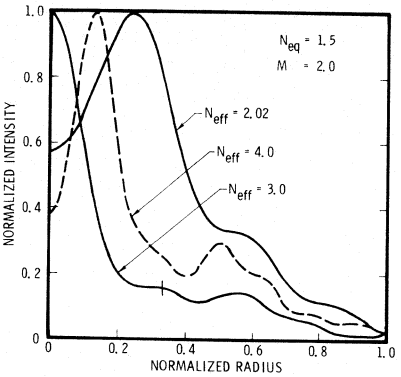

Fig. 6. Normalized intensity profiles for a symmetric unstable resonator at the mirror (N_{eff} = 4.0) and external to the cavity at the virtual focus (N_{eff} = 3.0) and at a distance far from the mirror (N_{eff} = 2.02).

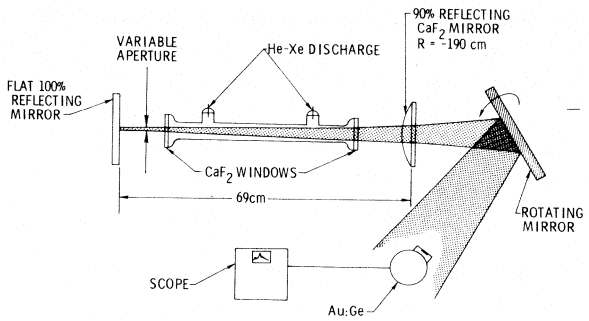

Fig. 7. Schematic diagram of the experimental configuration for measuring mode intensity profiles.

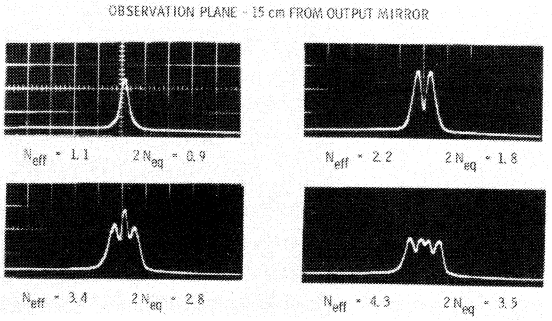

Fig. 8. Experimentally observed mode intensity profiles.

for, respectively, the first and second modes for N_{eq} = 2.0 and N_{eff} = 4.5, which is very near a mode crossing. As expected, the number of relative maxima along a diameter in the first mode is 4.5 - 0.5 = 4 and 4.5 + 0.5 = 5 in the second mode. The modes exhibited a smooth transition through the degeneracy point with the lowest mode phase front gradually assuming this additional curvature as $2N_{eq}$ increases from odd to even.

It is also possible to predict the mode profiles at other observation planes, and calculations have been made for the mode propagating outside the cavity. Fig. 6 shows examples for a symmetric resonator with N_{eq} = 1.5 and M = 2.0. The mode profile is shown at the plane of the opposite mirror (N_{eff} = 4), at the virtual focus (N_{eff} = 3), and far from the mirror (N_{eff} = 2.02). As expected, these profiles also follow the predicted shapes. These external calculations are particularly interesting at the virtual focus where $N_{eff} = 2N_{eq}$. A minimum in cavity loss occurs when $2N_{eq}$ is odd and hence corresponds to a relative peak in intensity at the virtual focus when the mode is extended outside the cavity. Likewise a maximum in cavity loss ($2N_{eq}$ even) corresponds to a minimum intensity at the virtual focus. Several papers [5], [6] have pointed out the importance of the virtual focus and this is another indication of the possible significance that a source at the virtual focus may play in acting as an equivalent source for the modes. Additional understanding of the importance of the virtual focus may yield further insight on unstable modes and increase our ability to make simplified predictions of their properties.

III. Experimental Results

An experimental study of the mode profiles was made using a longitudinal-discharge 3.5-μm He-Xe laser as shown in Fig. 7. This discharge tube was 25 cm long and 1 cm in diameter with sufficient gain to allow the use of an unstable resonator with a reasonably large magnification. One of the resonator mirrors was CaF_2 with -190-cm radius of curvature and coated for 90-percent reflectivity on its entire surface; the other mirror was flat and coated for 100-percent reflectivity. The mirrors were spaced at 69 cm to give a left to right cavity magnification of about 1.5 and a right to left cavity magnification of about 2.0. A variable-diameter leaf aperture was placed near the flat mirror and was the cavity-limiting aperture. Thus an equivalent symmetric unstable resonator (M = 3) can be defined as described by Siegman and Miller [3], and an N_{eq} can be calculated. The 10-percent transmission through the curved mirror was used to observe the mode pattern. The output was swept past a small Ge:Au detector by a rotating flat. The intensity profile was thus displayed in time on the oscilloscope trace.

The mode profiles were first observed in a plane 15 cm from the output mirror. The tube bore and the cavity axis were first carefully aligned with a He-Ne laser. With the xenon laser well above threshold, the cavity aperture was adjusted until a single bright spot with maximum intensity was obtained and the aperture diameter was measured. The aperture was then opened until the mode profile with the deepest minimum in the center was found, and again the aperture diameter was measured. This was continued up to a pattern having four intensity peaks in the scan. Typical observed mode profiles are shown in Fig. 8 with the calculated N_{eff} and cavity N_{eq}. The mode profiles were easily repeatable and in all cases exhibited a smooth transition between the patterns.

It is not possible with our experimental setup to obtain various combinations of integer values of $2N_{eq}$ and N_{eff} which would correspond to the computer results presented earlier. This would have required changing the cavity magnification by various combinations of mirror radii and spacings.

The detector was then moved to the virtual focus and the measurements repeated. The observed modes were very similar to Fig. 8, but to obtain the single peaked mode the aperture was adjusted for N_{eff} = 1.3; for two peaks, N_{eff} = 2.1, for three peaks, N_{eff} = 3.0, and for four peaks, N_{eff} = 4.1.

These results demonstrate that the general features of the

mode profiles can be predicted from N_{eff} both at the cavity mirror and at the virtual focus. In all cases the number of maxima in the pattern corresponds approximately to N_{eff}.

When the laser discharge current was reduced so that the laser was operating near threshold, the variation of the mode eigenvalue with N_{eq} as predicted by Siegman could be clearly demonstrated. As the cavity aperture was slowly opened, it was found that there were ranges of aperture diameters over which lasing occurred separated by ranges of diameters where no lasing was observed. As the discharge current was reduced still further, these ranges of diameters around which lasing occurred became narrower until the laser was below threshold for all aperture sizes. This is demonstrated in Fig. 9 in which the shaded areas correspond to ranges of N_{eq} where lasing did not occur. N_{eq} was calculated from the measured aperture diameters. Also shown in Fig. 9 are the mode losses calculated by the Prony method for the equivalent symmetric resonator ($M = 3.2$, $g = 1.76$). The lasing ranges clearly correspond to the ranges of N_{eq} where the losses are minimum, and the alternate lasing and nonlasing ranges demonstrate the cyclic nature of the loss of the lowest order mode.

Freiberg *et al.* [7] have reported mode profile measurements at a plane inside a CO_2 unstable resonator laser and in the far field. They also observed the cyclic nature of the eigenvalue.

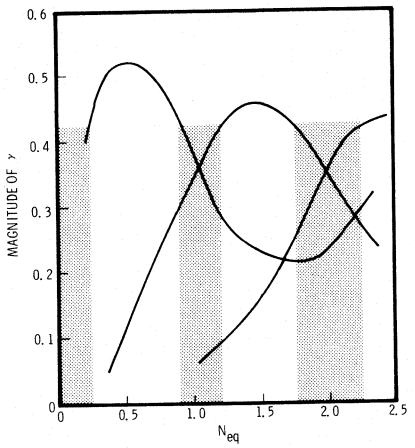

Fig. 9. Calculated magnitude of the mode eigenvalue γ for the experimental resonator used. The shaded zones indicate the regions below lasing threshold.

IV. Conclusions

It is concluded from these studies that the qualitative features of the fundamental mode for unstable resonators with reasonably low Fresnel numbers can be predicted on the basis of simple Fresnel zone theory. Both the mode shape within the cavity and the profile which would exist outside the cavity in the absence of the second mirror appear similar to the shape expected for a uniform spherical wave emanating from the virtual focus and illuminating the resonator aperture. The experimental loss also reaches a maximum when the equivalent Fresnel number is an integer in agreement with the calculations of Siegman and Miller [3]. This corresponds to the point where the effective Fresnel number computed at the virtual focus ($N_{eff} = 2N_{eq}$) is even and the on-axis intensity is minimum. Thus the resonator loss cycles with the same period as the relative intensity at the virtual focus giving further evidence to support the significance of the virtual foci. In a previous paper [5] it was pointed out that the fundamental mode could be optimized by minimizing the edge-wave diffraction at this point. It thus appears somewhat anomalous that the virtual foci, whose locations are given by geometrical optics, should be so significant in determining results based on diffraction theory. It is hoped that better understanding of these phenomena will make it possible to preempt with geometrical optics analyses many lengthy numerical calculations.

Characteristics of Optical Guided Modes in Multilayer Metal-Clad Planar Optical Guide with Low-Index Dielectric Buffer Layer

YOSHIHISA YAMAMOTO, STUDENT MEMBER, IEEE, TAKESHI KAMIYA, AND HISAYOSHI YANAI, SENIOR MEMBER, IEEE

Abstract—**The attenuation characteristics of a multilayer metal-clad optical guide, which is suitable for a mode filter or electrooptic devices, is investigated by the exact theory and the analytical approximation based on a perturbation technique. By using this approximation the dependences of the ohmic loss on the various waveguide parameters and the condition for the absorption peak of the TM mode are derived in closed form. Some remarks concerning the waveguide material and dimension for the design of the mode filter are also presented. The insertion loss at the abrupt junction between a normal (dielectric-clad) optical guide region and a metal-clad optical guide region is treated. Also the transformation of optical guided modes in the two kinds of tapered structures between the above two regions is examined.**

I. Introduction

A METAL-CLAD optical guide is suitable for electrooptic [1]-[3] or magnetooptic [4] devices because the metal cladding can be used for a part of electric circuits. This guide is also suitable for a mode filter because the ohmic loss of a TM guided mode is much larger than that of its TE counterpart [5]-[8].

In the former case of electrooptic or magnetooptic devices, it is important for the guided light to interact with the induced electric field effectively and not to be attenuated seriously due to the metal cladding. In the latter case of the mode filter, it is necessary to obtain a sufficient extinction ratio without introducing a significant loss in the transmitted light. Recently, Polky *et al.* pointed out that a TM guided mode exhibits an absorption peak as a function of the thickness of the low-index buffer layer in the multilayer structure shown in Fig. 1, and that this absorption peak is caused by the resonant coupling to the lossy surface mode [9], [20]. It is expected that a TE_0 mode filter having a high extinction ratio is obtained by utilizing this phenomenon. This multilayer structure was also proposed as one of the methods to decrease the ohmic loss for electrooptic devices [1], [10].

However, the dependences of the ohmic loss of each mode on the various waveguide parameters and the condition for the absorption peak of a TM guided mode, which are essential to the design of this guide, have not been sufficiently investigated yet. The first purpose of this paper is to investigate attenuation characteristics of the multilayer metal-clad optical guide by the analytical approximation based on a perturbation technique. The dependences of the attenuation constant on core-layer thickness, buffer-layer thickness, mode number, and refractive index difference between core and buffer layers are presented in closed form. By using these results, some remarks for the design of the mode filter are also presented. The exact solution of the eigenvalue equation by numerical analysis is used as a guide to assess the validity of this approximate solution.

Manuscript received December 27, 1974; revised April 22, 1975. This work was supported in part by the Oki Electric Company, and in part by the Toray Science Foundation.

The authors are with the Department of Electronic Engineering, Faculty of Engineering, University of Tokyo, 7-3-1, Hongo, Bunkyo-ku, Tokyo 113, Japan.

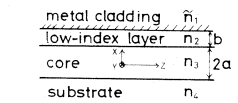

Fig. 1. A multilayer metal-clad planar optical guide with low-index dielectric buffer layer.

The insertion loss at the abrupt junction between a normal (dielectric-clad) optical guide region and a metal-clad optical guide region would also be an important problem for the two applications of this guide [11] previously mentioned. The tapered structure between two regions is needed for the reduction of this insertion loss. The second purpose of this paper is to examine this insertion loss at the abrupt junction and the transformation of optical guided modes in the tapered structures.

II. An Approximate Analysis of the Attenuation Characteristics

The guided mode in the multilayer metal-clad optical guide shown in Fig. 1 is assumed to propagate in the Z direction with a phase term $\exp[j(\omega t - k_z \cdot Z)]$, where k_z is the complex propagation constant. The mode characteristics are determined by applying the usual boundary-value technique, and k_z is expressed as solutions of the eigenvalue equation [10]

$$2au_3 = m\pi + \tan^{-1}\left(\gamma_{34}\frac{u_4}{-ju_3}\right) + \tan^{-1}\left[\gamma_{32}\frac{u_2}{u_3}\tan\left\{\tan^{-1}\left(\gamma_{21}\frac{u_1}{-ju_2}\right) - u_2 b\right\}\right] \quad (1)$$

where

$$\gamma_{pq} = \begin{cases} 1 & \text{TE mode} \\ \left(\dfrac{n_p}{n_q}\right)^2 & \text{TM mode} \end{cases} \quad (2)$$

$$u_l = k_0(n_l^2 - n^2)^{1/2}, \qquad l = 1 \sim 4 \quad (3)$$

$$n = \frac{k_z}{k_0} \equiv \frac{\beta - j\alpha}{k_0} \quad (4)$$

$$k_0 = \frac{2\pi}{\lambda} \quad (5)$$

where

$2a$ thickness of core layer;
b thickness of buffer layer;
u_l transverse wavenumber in each region;
n mode effective index;
m mode number.

The phase constant β and the attenuation constant α of each mode are obtained by the numerical analysis of the preceding transcendental equation concerning the complex propagation constant k_z, where the imaginary part of u_l is negative, and the real part of $\tan^{-1}$ ranges from 0 to π.

Figs. 2 and 3 show the attenuation constants of several modes versus the thickness of the core layer and the buffer layer, respectively. The solid line shows the exact solution by the numerical analysis of the eigenvalue, (1). Fig. 4 shows the change of the field distribution of TM guided modes at the various values of the buffer-layer thickness. The second lowest order TM guided mode (TM_1) in the multilayer structure exhibits the absorption peak and transforms continuously to the TM_0 mode in the single-layer structure [10]. The lowest order TM guided mode (TM_0) does not exhibit the absorption peak and transforms continuously to the surface mode [12] in the single-layer structure.

The second and the third terms of the right-hand side (RHS) of (1), which are the halves of the phase shifts of total internal reflection at both boundaries approach to $\pi/2$ for the well-guided TE modes, and the transverse wavenumber in the core layer, and the mode effective index are given in zeroth-order approximation by

$$u_3^{(0)} = \frac{(m+1)}{2a}\pi \tag{6}$$

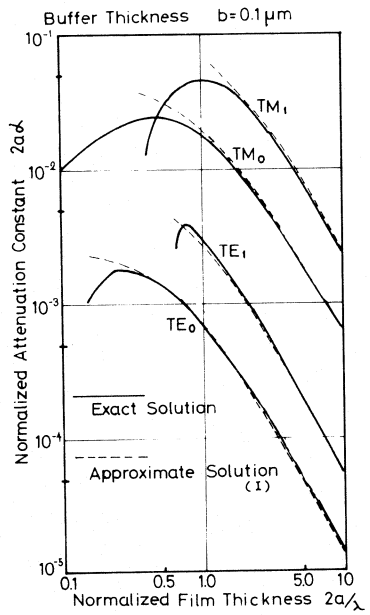

Fig. 2. The attenuation constants of several modes versus the core-layer thickness: —— indicates exact solution of the eigenvalue equation (1); ---- indicates approximate solution by (18). $n_1 = 1.2 - j7.0$ (for Al); $n_2 = 1.544$ (for Corning 7059 glass); $n_3 = 1.758$ (for Al_2O_3); $n_4 = 1.457$ (for SiO_2); and $\lambda = 0.633$ μm.

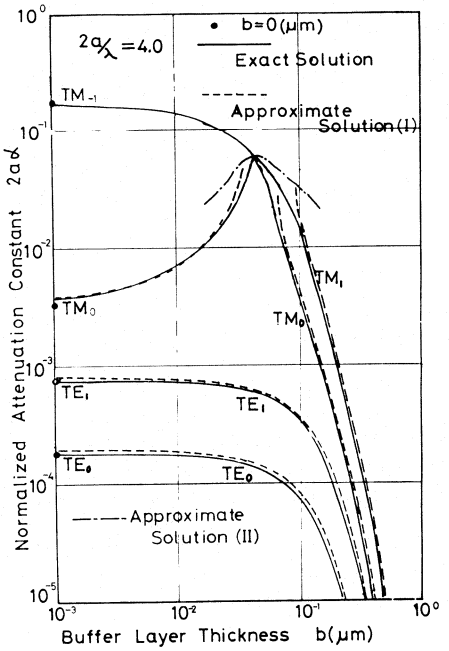

Fig. 3. The attenuation constants of several modes versus the buffer-layer thickness: —— indicates exact solution of the eigenvalue equation (1); ---- indicates approximate solution by (18); —·—· indicates approximate solution by (21). The numerical parameters are the same as those used in Fig. 2.

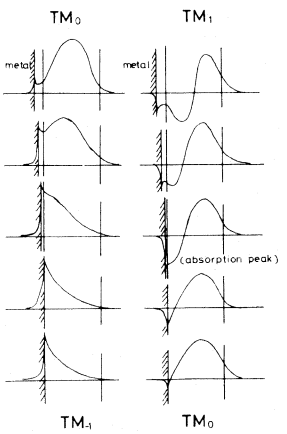

Fig. 4. The change of the transverse magnetic field distributions of the TM modes calculated by the exact solution of the eigenvalue equation (1). The numerical parameters are the same as those used in Fig. 3.

and

$$n^{(0)} = \left\{ n_3^2 - \frac{(m+1)^2}{4a^2k_0^2}\pi^2 \right\}^{1/2}. \tag{7}$$

Fig. 4 shows that this approximation is also valid for the well-guided TM modes except for the region just near the absorption peak. At the absorption peak, half of the phase shift of internal reflection at the buffer boundary is not $\pi/2$ but zero. The transverse wavenumber in other regions is given by

$$u_l^{(0)} = -jk_0\left\{ n_3^2 - \frac{(m+1)^2}{4a^2k_0^2}\pi^2 - n_l^2 \right\}^{1/2} = -ju_1^{(0)\prime}, \quad l = 2, 4 \tag{8}$$

and

$$u_1^{(0)} = k_0 \left\{ n_1^2 - n_3^2 + \frac{(m+1)^2}{4a^2 k_0^2} \pi^2 \right\}^{1/2} = u_1^{(0)\prime} - j u_1^{(0)\prime\prime} \quad (8a)$$

where $u_l^{(0)\prime}$, $u_1^{(0)\prime}$, and $u_1^{(0)\prime\prime}$ are real and positive. Substituting (8) and (8a) into (1), u_3 is given approximately by

$$u_3^{(1)} = (m+1)\pi \left[2a + \frac{1}{\gamma_{34} u_4^{(0)\prime}} + \frac{j}{\gamma_{32} u_2^{(0)\prime} \tan\left\{ \tan^{-1}\left(\gamma_{21} \frac{u_1^{(0)\prime} - j u_1^{(0)\prime\prime}}{-u_2^{(0)\prime}} \right) + j u_2^{(0)\prime} b \right\}} \right]^{-1}$$

$$\approx \frac{(m+1)\pi}{2a} \left[1 - \frac{\gamma_3}{2aU_4} - \frac{j\gamma_3}{2aU_2 \tan\left\{ \tan^{-1}\left(-\frac{U_1' + jU_1''}{U_2} \right) + jU_2^{(0)\prime} b \right\}} \right]$$

$$= \frac{(m+1)\pi}{2a} \left[1 - \frac{\gamma_3}{2aU_4} - \frac{\gamma_3 \{ \zeta_1 \exp(2u_2^{(0)\prime} b) - \zeta_2 \exp(-2u_2^{(0)\prime} b) - j4U_1' U_2 \}}{2aU_2 \{ \zeta_1 \exp(2u_2^{(0)\prime} b) + \zeta_2 \exp(-2u_2^{(0)\prime} b) + \zeta_3 \}} \right] \quad (9)$$

where

$$U_1 = U_1' + jU_1'' = \begin{cases} u_1^{(0)\prime} - j u_1^{(0)\prime\prime} & \text{TE mode} \\ \dfrac{u_1^{(0)\prime} - j u_1^{(0)\prime\prime}}{n_1^2} & \text{TM mode,} \end{cases}$$

U_1' and U_1'' are real (10)

$$U_l = \begin{cases} u_l^{(0)\prime} & \text{TE mode} \\ \dfrac{u_l^{(0)\prime}}{n_l^2} & \text{TM mode,} \quad l = 2, 4 \end{cases} \quad (11)$$

$$\gamma_3 = \begin{cases} 1 & \text{TE mode} \\ \dfrac{1}{n_3^2} & \text{TM mode} \end{cases} \quad (12)$$

$$\zeta_1 = U_1'^2 + U_1''^2 + U_2^2 - 2U_1'' U_2 \quad (13)$$

$$\zeta_2 = U_1'^2 + U_1''^2 + U_2^2 + 2U_1'' U_2 \quad (14)$$

$$\zeta_3 = 2(U_1'^2 + U_1''^2 - U_2^2). \quad (15)$$

The complex propagation constant k_z is given by

$$k_z \equiv \beta - j\alpha = k_0 \left\{ n_3^2 - \frac{u_3^{(1)2}}{k_0^2} \right\}^{1/2} \approx k_0 n_3 - \frac{u_3^{(1)2}}{2k_0 n_3}. \quad (16)$$

Using (9) and (10), the phase constant and the attenuation constant are given by

$$\beta = k_0 n_3 \left[1 - \frac{(m+1)^2 \pi^2}{8k_0^2 n_3^2 a^2} \left\{ 1 - \frac{(U_2 + U_4)\zeta_1 \exp(2u_2^{(0)\prime} b) + (U_2 - U_4)\zeta_2 \exp(-2u_2^{(0)\prime} b) + U_2 \zeta_3}{aU_2 U_4 (\zeta_1 \exp(2u_2^{(0)\prime} b) + \zeta_2 \exp(-2u_2^{(0)\prime} b) + \zeta_3)} \gamma_3 \right\} \right] \quad (17)$$

$$\alpha = \frac{(m+1)^2 \pi^2}{k_0 n_3 (2a)^3} \left\{ \frac{4U_1' \gamma_3}{\zeta_1 \exp(2u_2^{(0)\prime} b) + \zeta_2 \exp(-2u_2^{(0)\prime} b) + \zeta_3} \right\}. \quad (18)$$

On the other hand, Fig. 4 shows that the third term of the RHS of (1) is about zero for the TM guided mode near the absorption peak. So the transverse wavenumber in core layer and the mode effective index are given in zeroth-order approximation by

$$u_3^{(0)} = \frac{\left(m + \frac{1}{2}\right)\pi}{2a} \quad (19)$$

and

$$n^{(0)} = \left\{ n_3^2 - \frac{\left(m + \frac{1}{2}\right)^2}{4a^2 k_0^2} \pi^2 \right\}^{1/2}. \quad (20)$$

According to the procedure used in the former approximation, the attenuation constants of TM guided modes near the absorption peak are given by

$$\alpha = \frac{n_3}{k_0 \cdot 2a} \cdot \left\{ \frac{4U_1' U_2^2}{\zeta_1 \exp(2u_2^{(0)\prime} b) + \zeta_2 \exp(-2u_2^{(0)\prime} b) + \zeta_3} \right\} \quad (21)$$

where each parameter is given by replacing $(m+1)$ with $(m + \frac{1}{2})$ in (8), (8a), (10), (11), and (13)–(15).

The attenuation characteristics calculated by these two approximations are shown in Figs. 2 and 3. They show that the approximate solution by (18) is valid for the well-guided TE modes and the well-guided TM modes except for the region just near the absorption peak, and that the approximate solution by (21) is valid only for the well-guided TM modes just near the absorption peak. The attenuation characteristics of the second lowest order TM mode ($TM_0 \rightarrow TM_1$) is obtained by linking these two approximations to each other.

For the well-guided TE and TM modes in the multilayer

structure with the thick buffer layer, the dependence of the attenuation constant on the waveguide parameters is derived by (18)

$$\alpha \propto \frac{(m+1)^2}{(2a)^3}\lambda^2 \exp(-2u_2^{(0)\prime}b). \tag{22}$$

The $(m+1)^2$ and $(2a)^{-3}$ dependence of the attenuation constant is in agreement with the results which Reisinger showed theoretically and experimentally for the single-layer metal-clad optical guide [13]. The thickness of the buffer layer b_m at which the TM_m mode exhibits an absorption peak is given by equating the differential coefficient of (21) with respect to the buffer-layer thickness to zero and expressed as

$$b_m = \frac{1}{4u_2^{(0)\prime}} \ln\left(\frac{\xi_2}{\xi_1}\right). \tag{23}$$

This buffer layer thickness b_m is in agreement with that derived from the condition that the real part of the third term of the RHS of (1) is just zero (see Fig. 4).

III. Some Remarks for the Design of the Mode Filter

By using the results of Section II, the dependences of the extinction ratio of the mode filter on various waveguide materials and dimensions are investigated. Fig. 5(a)–(d) shows the attenuation constants of TE_0 mode and the second lowest order TM mode ($TM_0 \rightarrow TM_1$) versus the buffer-layer thickness for the various conducting materials. Optical constants of the conducting materials are presented in Table I. In Fig. 5(a), the approximate solutions are also presented. Fig. 6 shows the buffer-layer thickness b_m at which the second lowest order TM mode exhibits an absorption peak versus the refractive index difference between core and buffer layer for the various conducting materials. The approximate solution by (23) is in good agreement with the exact theory. Fig. 7 shows the extinction ratio of the TE_0 and TM_0 modes $\alpha_{TM_0}/\alpha_{TE_0}$ at the buffer-layer thickness b_m given in Fig. 6 versus the refractive index difference between core and buffer layer for the various conducting materials. In the case of the single-layer metal-clad mode filter, it was pointed out that a high extinction ratio can be obtained by using Ni or Al as the conducting material [14], but in the case of the multilayer metal-clad mode filter silver and gold are promising materials. In the single-layer structure of 1.0-μm core-layer thickness, the extinction ratio $\alpha_{TM_0}/\alpha_{TE_0}$ is about 2×10 for Ni, but in the multilayer structure of the same core-layer thickness, the extinction ratio is raised to 5×10^2 by using silver as the conducting material (see Fig. 7). Fig. 8 shows the attenuation constant of the second lowest order TM mode versus the refractive index difference. For the absorption modulator mentioned in [9], utilizing the attenuation characteristics of TM mode, the buffer layer consisting of the electrooptic material should be thick, and its refractive index should be nearly equal to that of the core layer in order to obtain a sufficient extinction ratio by the small change of the refractive index difference.

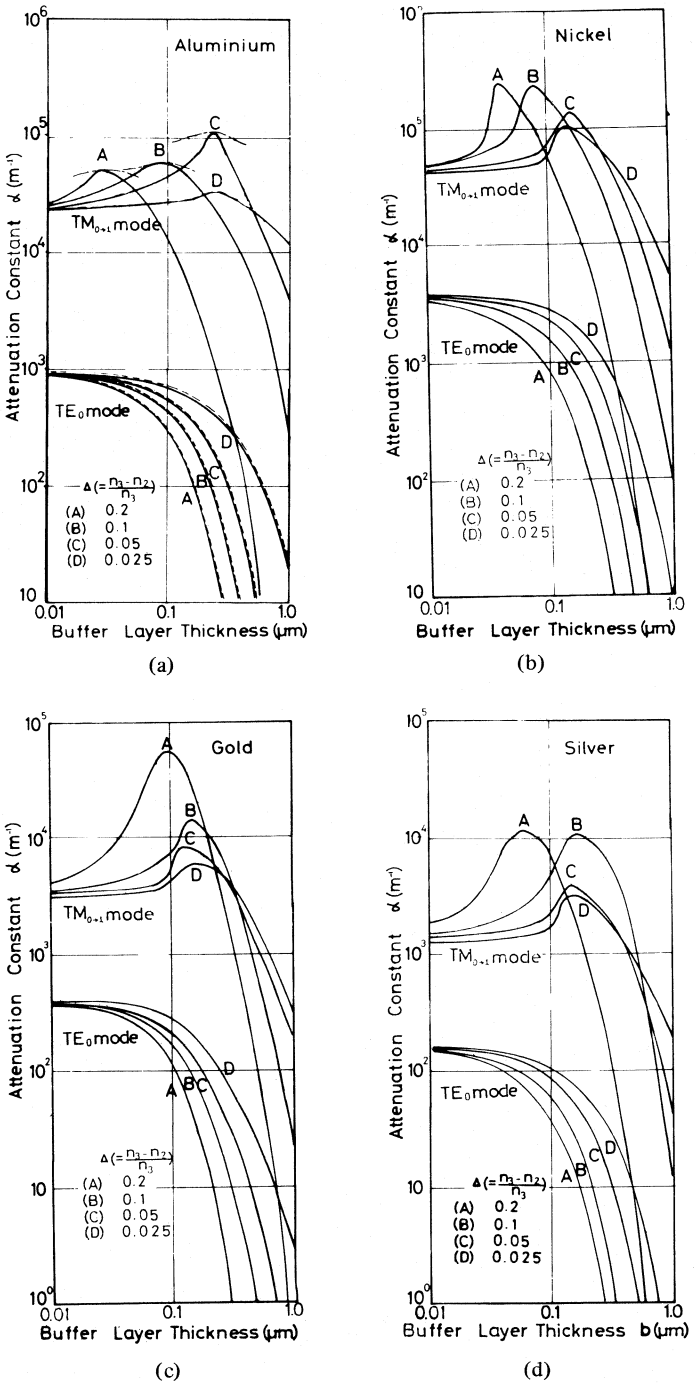

Fig. 5. The attenuation constants of TE_0 mode and the second lowest order TM mode ($TM_0 \rightarrow TM_1$) versus the buffer-layer thickness for the various conducting materials. $n_3 = 1.758$ (for Al_2O_3); $n_4 = 1.457$ (for fused quartz); and $2a = 1.0$ μm. IV. An Insertion Loss at the Abrupt Junction and a Transformation of Guided Modes in the Tapered Structure

The insertion loss at the abrupt junction between a normal (dielectric-clad) optical guide region and a metal-clad optical guide region shown in Fig. 9 is in general undesirable for the application to electrooptic devices or a mode filter. The coupling constants to the reflected guided mode, the transmitted guided mode, and the radiation modes are given by the boundary condition at the abrupt junction [15]. The boundary condition for the incident TE_0 mode is

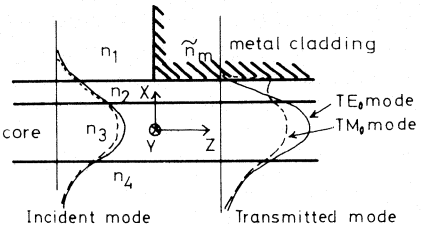

Fig. 9. The abrupt junction between a normal optical guide region and a metal-clad optical guide region.

$$E_y^{(i)} + a_r E_y^{(r)} + \int_{-k_0 n_4}^{0} q_r(\beta)\, E_y^{(r)}(\beta)\, d\beta = c_t E_y^{(t)} + \int_{0}^{k_0 n_4} q_t(\beta')\, E_y^{(t)}(\beta')\, d\beta' \tag{24}$$

$$H_x^{(i)} + a_r H_x^{(r)} + \int_{-k_0 n_4}^{0} q_r(\beta)\, H_x^{(r)}(\beta)\, d\beta = c_t H_x^{(t)} + \int_{0}^{k_0 n_4} q_t(\beta')\, H_x^{(t)}(\beta')\, d\beta' \tag{25}$$

where β and β' are the phase constants of the continuous radiation modes in the normal optical guide region and the metal-clad optical guide region, respectively. The superscripts i, r, and t indicate incident, reflected, and transmitted waves. The field components whose β and β' dependences are explicitly shown are radiation modes, and the other components belong to TE_0 guided mode. The TE higher mode is assumed to be cut off in both regions. The normalized condition for E_y is given by

$$-\frac{1}{2}\int_{-\infty}^{\infty} E_y H_x^*\, dx = \frac{\beta_0}{2\omega\mu_0}\int_{-\infty}^{\infty} |E_y|^2\, dx = 1 \tag{26}$$

$$-\frac{1}{2}\int_{-\infty}^{\infty} E_y(\beta_1) H_x(\beta_2)^*\, dx = \frac{\beta_2}{2\omega\mu_0}\int_{-\infty}^{\infty} \cdot E_y(\beta_1) E_y(\beta_2)^*\, dx = \delta(\beta_1 - \beta_2) \tag{27}$$

where β_0, β_1, and β_2 are the phase constants of each mode. If the coupling constant c_t which satisfies (24) and (25) is obtained, the insertion loss at the abrupt junction is given by

$$\frac{\Delta P}{P} = 1 - |c_t|^2 \tag{28}$$

where P is the power carried by the incident TE_0 mode. However, (24) and (25) are not solved exactly. We obtain the approximate solutions of c_t and a_r by neglecting the coupling coefficient q_r [15] and using the orthogonality of the modes

of the same waveguide. From (24) and (25)

$$c_t = \frac{\beta_i \beta_t}{\beta_i + \beta_t} \cdot \frac{1}{\omega \mu_0} \int_{-\infty}^{\infty} E_y^{(i)} E_y^{(t)*} \, dx \tag{29}$$

$$a_r = \frac{\beta_i - \beta_t}{\beta_i + \beta_t} \tag{30}$$

where β_i and β_t are the phase constants of the incident guided mode and the transmitted guided mode, respectively.

The coupling coefficients c_t and a_r for the TM_0 incident mode are in the same procedure given by

$$c_t = \frac{\beta_i \beta_t PQ}{\omega(\beta_i Q + \beta_2 P)} \tag{31}$$

$$a_r = \frac{(\beta_i - \beta_t)Q}{\beta_i Q + \beta_t P} \tag{32}$$

where

$$P = \int_{-\infty}^{\infty} \frac{1}{\epsilon^{(t)}(x)} H_y^{(i)} H_y^{(t)*} \, dx \tag{33}$$

$$Q = \int_{-\infty}^{\infty} \frac{1}{\epsilon^{(i)}(x)} H_y^{(i)} H_y^{(t)*} \, dx \tag{34}$$

where $\epsilon^{(i)}(x)$ and $\epsilon^{(t)}(x)$ are the dielectric constants of the normal optical guide region and the metal-clad optical guide region, respectively.

Fig. 10 shows the power-coupling coefficients of the TE_0 and TM_0 modes versus the buffer-layer thickness. The insertion loss of the TM_0 mode is larger than that of the TE_0 mode, which is attributed to the larger difference of the field distributions of the TM_0 mode between two regions compared with the TE_0 mode. The insertion losses of the TE_0 and TM_0 modes are decreased by increasing the thickness of the low-index buffer layer, which is well explained by the fact that the difference of the field distributions between two regions becomes small by increasing the thickness of the low-index buffer layer. However, the selection of buffer-layer thickness of the multilayer metal-clad optical guide regions should be determined by consideration for the performance of the devices. In the case of the electrooptic devices of multilayer structure, both the induced electric field strength and the ohmic loss of the guided modes are decreased by increasing the low-index buffer-layer thickness, and the optimum thickness exists. In the case of the mode filter, the buffer-layer thickness should be b_m given by (23), so that the other method to decrease the insertion loss is needed.

Two kinds of tapered structures to decrease the insertion loss at an abrupt junction are shown in Fig. 11. In the case of decreasing the thickness of the low-index buffer layer gradually as shown in Fig. 11(a), the TM_0 mode of the normal optical guide region transforms continuously to the TM_{-1} mode (surface mode) of the metal-clad optical guide region as discussed in Section II (see Fig. 4), and the maximum attenuation of this mode is caused in the single-layer structure ($b = 0$). In the case of increasing the metal-layer thickness

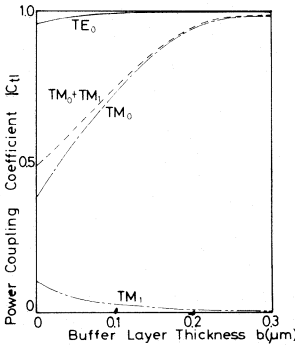

Fig. 10. The power coupling coefficient $|C_t|^2$ versus the buffer-layer thickness. The thickness of core layer is 0.4 μm. $n_1 = 1.0$; $n_2 = 1.480$; $n_3 = 1.680$; $n_4 = 1.480$; $n_m = 1.2 - j7.0$; and $\lambda = 0.633$ μm. The metal-clad optical guide of this dimension guides both the TM_0 and the TM_1 modes.

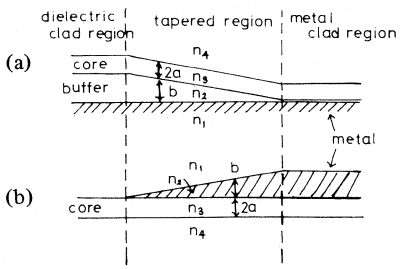

Fig. 11. Two kinds of tapered structure to decrease the insertion loss at the abrupt junction.

gradually shown in Fig. 11(b), the TM_0 mode of the normal optical guide region transforms continuously to the TM_0 mode of the metal-clad optical guide region as shown in Fig. 12, and the maximum attenuation of this mode is given in the multilayer structure ($b = b_m$). The changes of the mode effective index in these two kinds of tapered structures are shown in Fig. 13(a), (b). In the tapered structure shown in Fig. 11(a), the change of the mode effective index of the TM_0 mode is contrary to that of the TE_0 mode.

If the transverse boundary of the metal-clad optical stripline (MCOSL) [16], [17] is made by the tapered structure as shown in Fig. 14, the MCOSL of this structure guides only the TE mode, because the mode effective index of the metal-unclad region is lower than that of the metal-clad region for the TM mode; that is, this guide is a leaky waveguide for the TM mode. Fig. 15(a) shows the mode order converter only for TM modes. Fig. 14(b) shows the TE_0 mode selector of very high extinction ratio because the attenuation constant of the TM surface mode is very large.

V. Conclusion

The attenuation characteristics of the multilayer metal-clad optical guide are examined by the analytical approximation based on the perturbation technique, and the transformation of the guided mode in the tapered structures is also investigated. The main results presented in this paper follow.

1) The attenuation constants of the well-guided TM modes except for the region just near the absorption peak and the well-guided TE modes are expressed approximately by (18),

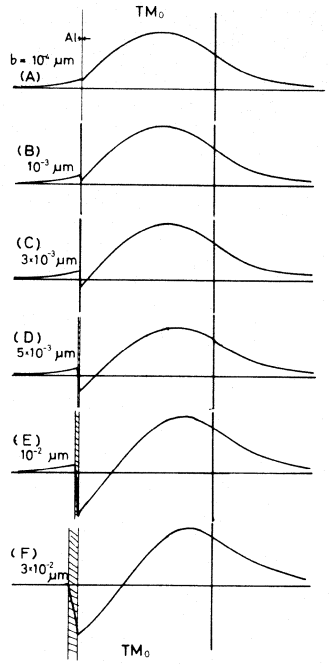

Fig. 12. The change of the transverse magnetic field distribution of the TM_0 mode for the gradual increase of the metal-layer thickness as shown in Fig. 11(b); (b = 0 μm).

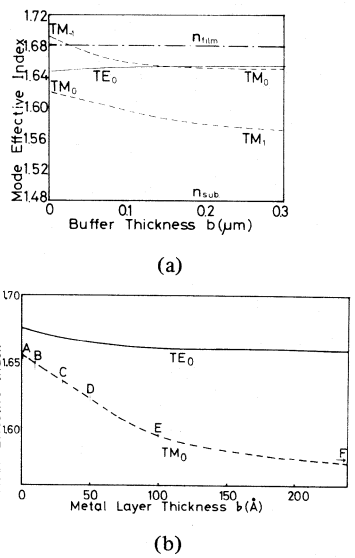

Fig. 13. (a) The mode effective index versus the buffer-layer thickness in the tapered structure shown in Fig. 11(a). $n_1 = 1.2 - j7.0$ (for Al); $n_2 = 1.48$; $n_3 = 1.68$; $n_4 = 1.48$; and $2a = 1.0$ μm. (b) The mode effective index versus the metal-layer thickness in the tapered structure shown in Fig. 11(b). $n_1 = 1.0$; $n_2 = 1.2 - j7.0$ (for Al); $n_3 = 1.68$; $n_4 = 1.48$; and $2a = 1.0$ μm.

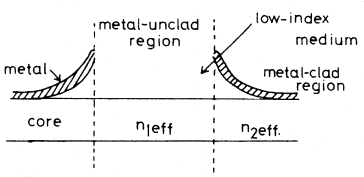

Fig. 14. MCOSL with the transverse boundary of the tapered structure. Only the E_{pq}^{y} (TE polarized) mode is confined in the metal-unclad region because of the effective index difference between the metal-unclad region and the metal-clad region.

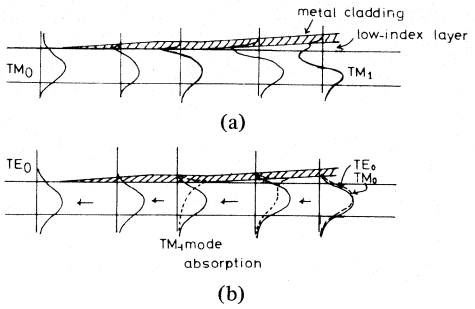

Fig. 15. (a) The mode order converter only for TM modes. (b) TE_0 mode filter having the high extinction ratio.

and the attenuation constants of the well-guided TM modes just near the absorption peak are expressed approximately by (21).

2) The attenuation constants of the well-guided TE and TM modes in the multilayer metal-clad optical guide with large buffer-layer thickness have the $(m+1)^2$, $(2a)^{-3}$, and $\exp(-2u_2^{(0)\prime}b)$ dependences for the mode number m, core-layer thickness $2a$, and buffer-layer thickness b, respectively.

3) The buffer-layer thickness b_m at which the TM_m mode exhibits an absorption peak is given by (23).

4) The extinction ratio between the TE and TM modes is increased by inserting the proper buffer layer between the metal cladding and the core layer. Silver and gold are promising materials for this multilayer mode filter.

5) The insertion loss at the abrupt junction between a normal optical guide region and a metal-clad optical guide region of the TM_0 mode is larger than that of the TE_0 mode because the difference of field distributions of the TM_0 mode between two regions is larger than that of the TE_0 mode.

6) In the tapered structure, decreasing the thickness of the low-index buffer layer gradually, the TM_0 mode of the normal optical guide region transforms continuously to the TM_{-1} mode (surface mode) in the metal-clad optical guide region, and the TM_1 mode of the normal optical guide region transforms continuously to the TM_0 mode in the metal-clad optical guide region. However, in the tapered structure, increasing the thickness of the metal layer gradually, the TM_0 mode in the normal optical guide region transforms continuously to the TM_0 mode in the metal-clad optical guide region.

Very recently, the waveguide polarizer using a birefringent material as a cladding was reported [18] in which the transmitted TE_0 mode is theoretically lossless. However, from the viewpoint of the integration with other waveguide components, the multilayer metal-clad optical guide polarizer investigated here seems to be superior. The mode filter of this structure cutting the higher modes by utilizing the $(m+1)^2$ dependence of the ohmic loss can be applied to the mode filter of the multimode optical fiber. The approximate analysis presented in this paper can be applied to the analysis of the multilayer lossy waveguide having a high-index semiconductor cladding such as Si or GaAs. Also in these structures, the attenuation constant of the TM mode is about ten times larger than that of its TE counterpart. This theoretical result shows that the mode-selecting photodetector which absorbs and

detects only the TM mode is constructed in the semiconductor substrate.

Theory of Mode Locking with a Slow Saturable Absorber

HERMANN A. HAUS, FELLOW, IEEE

***Abstract*—A closed-form solution is presented for the pulses of a homogeneously broadened laser mode locked by a saturable absorber of relaxation time much longer than the pulsewidth. With suitable approximations, the pulse shape is a secant hyperbolic. The system is described in terms of the linewidth ω_C of the system, the saturation energies of the saturable absorber and the laser medium, the ratio of saturable-absorber loss to resonator loss, and the ratio of cavity round-trip time and laser-medium relaxation time. The energy and width of the pulse are obtained as functions of these parameters. Graphs are presented for the operating regimes as bounded by the choice of the preceding parameters. The theoretical predictions are compared with second-harmonic-generation (SHG) autocorrelation traces of mode-locked dye-laser pulses.**

Manuscript received January 13, 1975.

I. INTRODUCTION

EVEN THOUGH the literature on the theory of saturable absorber mode locking is extensive [1]-[14], no closed-form solution has been obtained for the mode-locked pulses ([11] gives a closed-form solution, but does not include the absorber modulation self-consistent with the temporal pulse shape). Of all publications only New's [14] addressed itself to the case when the saturable absorber has a long relaxation time compared with the pulse duration (slow absorber). This is the case of interest for subpicosecond pulse generation in dye lasers [15], [16]. New does not obtain a closed-form solution for the pulse shape. Here we present such a solution and explore the dependence of the pulse upon the system parameters. We also find conditions that have to be satisfied by the laser medium and the saturable absorber if stable mode locking is to be achieved.

In another paper [17] we have obtained a closed-form solution for a passively mode-locked system containing an absorber of fast relaxation time compared with the pulse duration. With solutions for the slow absorber as well as the fast absorber, one has covered two limiting cases which then in turn shed light on the general case for which no closed-form solution has been found as yet. It is true, though, that the most interesting case is the one when the mode-locked pulse is short compared with the relaxation time of the absorber, and this is the case covered in this paper.

The analysis makes the following assumptions and approximations.

1) The laser medium is homogeneously broadened.

2) A pulse passing through any one of the elements of the system, saturable absorber, gain medium, etc., is modified only slightly (say, 20-percent gain or loss) on one single pass. This assumption enables one to expand exponentials to first order in their argument.

3) The saturable-absorber and laser-medium gain coefficients, as functions of energy, may be expanded to second order in their (pulse-) energy dependence.

4) The dispersion of the system as a function of frequency may be expanded to second order in frequency (this assumption is legitimate if the laser pulse spectrum is narrow compared with the bandwidth of the system).

These assumptions enable one to get analytic solutions. Some conclusions reached by the present analysis will be shown to be independent of some of the assumptions.

Conditions necessary to achieve mode locking via a saturable absorber of long relaxation time have already been explored by New [14]. Our conditions are similar to his, but not precisely the same. The reasons for this are twofold.

1) New did not include the effect of bandwidth limitation upon the gain requirements. Bandwidth limitation "disperses" the pulse in the time domain, broadens it, and in so doing calls for adjustment of the gain conditions away from those that would have been obtained by disregarding the effect entirely.

2) In order to obtain the closed-form solution, we expand the exponential dependence of gain and absorption upon pulse energy up to second order. This introduces some approximation in our analysis which New did not need to make because he was not looking for closed-form solutions for the pulse shape.

In Section II we develop the basic equation, introducing explicit approximations. In Sections III and IV we establish the constitutive laws for the laser medium and saturable absorber starting with the rate equations. In Section V we solve the nonlinear integro-differential equation by expanding to second order the exponential dependence upon pulse energy of laser gain and absorber loss (parabolic approximation). We obtain two equations for the pulsewidth and pulse energy in terms of the system parameters. The best description of the operation of the system proves to be using the parameters of the net-gain parabola as carried out in Section VI. Section VII is devoted to a comparison between New's result and our analysis. Sections VIII and IX study the pulse shapes resulting from a nonparabolic dependence of net gain upon pulse energy. Finally, in Section X we discuss the relevance of the present theory to the dye-laser system.

II. The Fundamental Equation

The literature on mode locking analyzes the phenomenon either in the frequency domain, treating mode locking as injection locking of the axial cavity modes, or in the time domain. Passive mode locking is most conveniently analyzed in the time domain. The action on the mode-locked pulse within the laser cavity by any one of the components of the system is analyzed, and then the net modification of the pulse upon return to the starting reference plane is set equal to zero. This is the approach used here to arrive at the fundamental equation.

Consider an optical cavity with the laser medium near one end mirror and a saturable absorber near the other end mirror (Fig. 1). The absorber and laser medium are assumed to be "thin," i.e., the transit times through the laser medium and the saturable absorber are assumed to be short compared to the pulse duration. The pulse duration τ_p, in turn, is assumed to be short compared with the transit time through the cavity. We shall assume that the laser-medium and saturable-absorber bandwidths are broad compared to the pulse spectrum. Bandwidth limitation is provided by a linear passive element in the cavity (e.g., etalon). Also this assumption can be modified (within limits) as explained further on in this paper. At the start we assume a uniform intensity profile over the optical beam cross section. Later we show the generalization for treating nonuniform (Gaussian) beam profiles.

The positive-frequency part of the time-dependent electric field at the reference plane next to the laser medium is denoted by $v(t) \exp j\omega_0 t$, where $v(t)$ is the pulse envelope which is slowly time varying compared to $\exp j\omega_0 t$; ω_0 is a frequency near the center of the band, to be made more precise later. The Fourier transform is $v(\omega_k - \omega_0)$. The Fourier transform has a discrete spectrum with components spaced at $2\pi/T$, where T is the period of the mode-locked pulse train.

After passage through the laser medium, the pulse envelope is (see Fig. 1)

$$v_1(t) = e^{A(t)} v(t - T_1) \tag{1}$$

where $A(t)$, the gain coefficient for double passage through the laser medium, is a function of the integrated pulse power

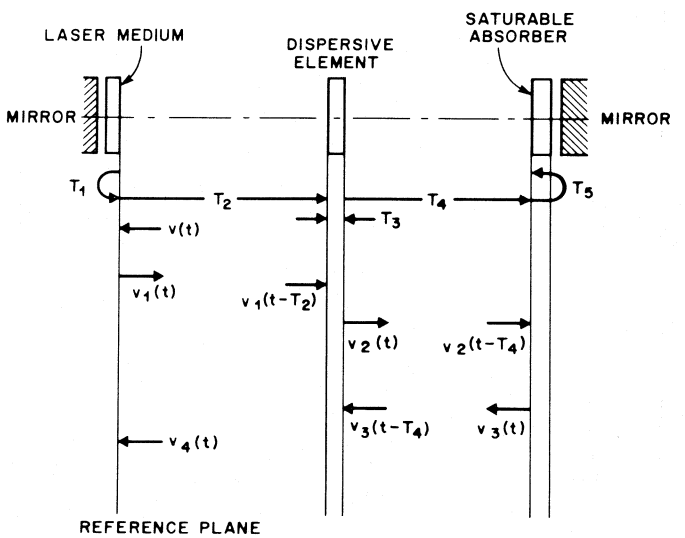

Fig. 1. Schematic of the laser cavity.

(time-dependent pulse energy) at the time t; T_1 is the time of travel through the absorber. The laser gain is assumed to be nondispersive but dependent upon the energy of the passing pulse. This is a necessary assumption if we want to obtain stable mode-locked solutions with a slow saturable absorber, an absorber whose relaxation time is slow compared to the pulse duration τ_p. After passage of a pulse the absorber has no chance of relaxing back to full absorption in a time corresponding to several pulsewidths. If the absorber remains "open," and the laser-medium gain itself is assumed to be time independent, there remains a net positive gain after passage of the pulse for a time corresponding to several pulsewidths. Now the response of the system to a perturbation is, in general, an operation in the time domain involving time derivatives, and hence growth or decay of a perturbation cannot be determined simply from the net-gain coefficient. However, if the perturbation is slow, i.e., has a narrow bandwidth compared to the system bandwidth, the response of the system is described by the net-gain coefficient of the system. With the saturable absorber open for a time corresponding to several pulsewidths, and the laser-medium gain unchanged, there is a net positive gain for a slow disturbance after the passage of the pulse. A steady-state solution found under such circumstances (and one does find such solutions) is unstable. Perturbations of the tail end of the pulse grow, and the pulse broadens, until its duration is limited by the relaxation of the absorber itself.

In order to obtain stable solutions, one must require that the net gain of the system be negative after passage of the pulse [14]. If the pulse is to be short compared with the absorber relaxation time, the gain can be shut off only through the action of the laser medium itself.

Next, the pulse passes through the bandwidth-limiting element (see Fig. 1). The spectrum of the pulse after passage is

$$v_2(\omega_k - \omega_0) = \exp\left[-j(\omega_k - \omega_0)(T_2 + T_3)\right] \cdot H(\omega_k)\, v_1(\omega_k - \omega_0) \tag{2}$$

where $H(\omega_k)$ is the Fourier transform of the transfer function of the element; T_2 is the time of travel between the laser medium and bandwidth-limiting element; T_3 is the delay in the element. The linear loss is included in $H(\omega_k)$ applied twice which, therefore, contains the factor $\exp - \omega_0 T_R/4Q$; T_R is the net round-trip time; Q is the optical cavity Q; and ω_0 is the center frequency of the cavity-mode spectrum. We shall assume that the loss goes up with deviation of frequency from the center frequency ω_0 of the cavity-mode spectrum which will be identified with ω_0 defined previously. The explicit frequency dependence of the loss factor is assumed to be

$$H(\omega_k) = \exp\left[-(\omega_0 T_R/4Q)\left(1 + \left(\frac{\omega_k - \omega_0}{\omega_C}\right)^2\right)\right] \tag{3}$$

where ω_C is the width of the loss "well" plotted versus frequency. Multiplication of $v(\omega_k - \omega_0)$ by $j(\omega_k - \omega_0)$ corresponds to operation by $d/dt - j\omega_0$ on $v(t) \exp j\omega_0 t$. The operation (2), using (4) gives in the time domain

$$v_2(t) = \exp\left(\left(-\frac{\omega_0 T_R}{4Q}\right)\left(1 - \frac{1}{\omega_C^2}\frac{d^2}{dt^2}\right)\right) v_1(t - T_2 - T_3). \tag{4}$$

When the pulse passes the saturable absorber, the envelope function becomes

$$v_3(t) = e^{-B(t)}\, v_2(t - T_4 - T_5) \tag{5}$$

where B is the loss coefficient, a function of the integrated power in the pulse, the time-dependent energy of the pulse; the delays T_4 and T_5 are shown in Fig. 1. Finally, after the pulse passes once more through the bandwidth-limiting element and returns to the reference plane it becomes

$$v_4(t) = \exp\left(\left(-\frac{\omega_0 T_R}{4Q}\right)\left(1 - \frac{1}{\omega_C^2}\frac{d^2}{dt^2}\right)\right) \cdot v_3(t - T_4 - T_3 - T_2). \tag{6}$$

We shall make some further approximations. We shall assume that the bandwidth of the pulse is sufficiently narrow, so that the exponential operators in (3) and (4) may be expanded to first order in $(\omega_k - \omega_0/\omega_C)^2$ or $-(1/\omega_C^2)\, d^2/dt^2$. Further, we shall assume that the modifications of the pulse in one pass through absorber or amplifier are sufficiently small so that all exponentials may be expanded to first order, and, also, in the functional dependence of B upon $v_3(t)$ this function may be replaced by $v(t - \Sigma_{i=1}^{5} T_i)$.

Introducing these approximations, we obtain for the change in the envelope $v(t)$ after one round trip

$$v_4(t) = \left[1 - \frac{\omega_0}{2Q} T_R \left(1 - \frac{1}{\omega_C^2}\frac{d^2}{dt^2}\right) + A(t) - B(t)\right] v(t - T_R) \tag{7}$$

where T_R is the cavity round-trip time, $T_R = T_1 + T_5 + 2(T_2 + T_3 + T_4)$. Now $v_4(t)$ need not be equal to $v(t)$ shifted by T_R, because some pulse shaping may lead to delays or advances of the pulse. Setting $v_4(t) = v(t - T_R + \delta T)$, and expanding to first order in δT, one finally obtains

$$\delta T \frac{dv}{dt} = -\frac{\omega_0}{2Q} T_R \left(1 - \frac{1}{\omega_C^2}\frac{d^2}{dt^2} - \left(\frac{2A(t)Q}{\omega_0 T_R}\right) + \left(\frac{2B(t)Q}{\omega_0 T_R}\right)\right) v. \tag{8}$$

This is the starting equation for our analysis. We shall introduce normalized parameters

$$\frac{2\omega_C \delta T}{\omega_0 T_R} Q \equiv \delta \tag{9}$$

$$g(t) \equiv \frac{2A(t)Q}{\omega_0 T_R} \tag{10}$$

$$\frac{Q}{Q_A(t)} \equiv \frac{2B(t)Q}{\omega_0 T_R} \tag{11}$$

where g may be interpreted as the gain coefficient of the laser medium normalized to the linear loss coefficient, δ is a time delay (or advance) parameter indicating whether the pulse repetition period deviates from the free-space round-trip time T_R, and Q_A is the Q of the saturable absorber.

Rewriting (8) one has

$$\left(1 + \frac{Q}{Q_A(t)} - g(t) - \frac{1}{\omega_C^2}\frac{d^2}{dt^2} + \frac{\delta}{\omega_C}\frac{d}{dt}\right)v = 0. \tag{12}$$

Note that

$$g_T(t) \equiv -\left(1 + \frac{Q}{Q_A(t)}\right) + g(t) \tag{13}$$

is the net-gain parameter, as determined from the combined loss and gain of the cavity (without dispersion), laser medium, and saturable absorber. This parameter plays a very important role in the mode-locking problem. We shall call it the net-gain function or the modulation function. In terms of g_T, (12) can be written

$$\left(g_T(t) + \frac{1}{\omega_C^2}\frac{d^2}{dt^2} - \frac{\delta}{\omega_C}\frac{d}{dt}\right)v = 0. \tag{14}$$

The same result can be obtained from a cavity-mode expansion, making the assumption of high Q (large growth and decay times of mode amplitudes due to the media in cavity). One advantage of the cavity-mode expansion approach [18] is that it permits the analysis of Gaussian modes (in the high-Q approximation). If only axial modes are present in the cavity, a situation assured by the use of mode-suppressing irises, and therefore the mode pattern is known to be Gaussian, then the nonlinear gain and loss parameters may be evaluated as integrals of the susceptibilities of the media in the cavity weighted by the mode patterns.

Note that the bandwidth-limiting element has introduced the operator $-(1/\omega_C^2)\,d^2/dt^2$ which is a diffusion operator (in time-"space"). This operator causes spreading of the pulse which, upon each transit, is compensated by the modulation function to restore the original pulsewidth. Because pulse diffusion or spreading can be caused by many different physical processes, we surmise that the final equation is relatively model independent.

III. The Saturable Absorber

Here we derive an expression for the time-dependent loss coefficient B (or inverse Q) of the absorber. This is proportional to the population difference n of the absorber

$$\frac{\partial n}{\partial t} = -\frac{n - n_e}{T_A} - \frac{\sigma_A}{\hbar\omega_0 A_A}|v(t)|^2\, n \tag{15}$$

where T_A is the relaxation time of the absorber; $|v(t)|^2$ is the square of the amplitude of the electric field within the absorber (normalized so that its square is equal to the sum of the powers in the counter-traveling waves); σ_A is the optical cross section; A_A is the beam cross section in the saturable absorber. In (15) a three-level system has been assumed with a fast relaxation of the upper level.

If the time dependence of the process to be considered is fast compared with T_A, then (15) can be replaced by

$$\frac{\partial n}{\partial t} = -\frac{\sigma_A|v(t)|^2}{\hbar\omega_0 A_A}\, n \tag{16}$$

with the integral

$$n = n^{(i)} e^{-\frac{E(t)}{E_A}} \tag{17}$$

where

$$E(t) \equiv \int^t |v(t)|^2\, dt \tag{18}$$

is the cumulative energy in the pulse

$$\frac{1}{E_A} \equiv \frac{\sigma_A}{\hbar\omega_0 A_A} \tag{19}$$

is the inverse saturation energy, and $n^{(i)}$ is the starting population difference. We shall assume that the saturable absorber relaxes completely *between pulses*, i.e., $T_A \ll T_R$, where T_R is the pulse repetition time. Then $n^{(i)} = n_e$.

The time-dependent inverse Q, as caused by the absorber, is proportional to the time-dependent population difference

$$\frac{Q}{Q_A(t)} = \frac{Q}{Q_A^0} e^{-\frac{E(t)}{E_A}} \tag{20}$$

where Q/Q_A^0 is the measure of the small-signal loading of the saturable absorber.

IV. The Laser Medium

The laser medium must possess a time-dependent gain in order to obtain stable pulses as explained previously. We shall assume that the bandwidth of the medium is much wider than the pulse bandwidth and that the relaxation time T_L of the laser medium is much longer than T_A, an assumption that is usually met in practice.

By a completely analogous argument as the one used for the saturable absorber, we find for the laser gain parameter g

$$g(t) = g^{(i)} e^{-\frac{E(t)}{E_L}} \tag{21}$$

where

$$\frac{1}{E_L} = \frac{\sigma_L}{\hbar\omega_0 A_L} \tag{22}$$

and $g^{(i)}$ is the gain before arrival of the pulse.

With (20) and (21) we have completed the description of the system. For any given $g^{(i)}$, Q/Q_A^0, E_A, and E_L one may plot g_T of (14) versus energy. This is an instructive plot which must be investigated before proceeding with the solution of (14). Fig. 2 shows $1 + (Q/Q_A)$ and $-g$ plotted versus energy. The net gain $g_T(E)$ is obtained by taking the difference between $1 + (Q/Q_A)(E)$ and $g(E)$. The figure shows an initial negative g_T. This is required because if gain preceded the pulse, the pulse would not be stable with respect to perturbations preceding it and would tend to "spread forward." The laser medium is assumed to be hard to saturate, $E_L \gg E_A$, so that over the energy range over which the saturable absorber is fully saturated, the laser-medium gain still decreases approximately linearly with energy.

One conclusion can be drawn immediately. Stability requires that

$$g^{(i)} < 1 + \frac{Q}{Q_A^0}. \tag{23}$$

If the medium relaxed fully between the pulses, $g^{(i)} = g_0$, the

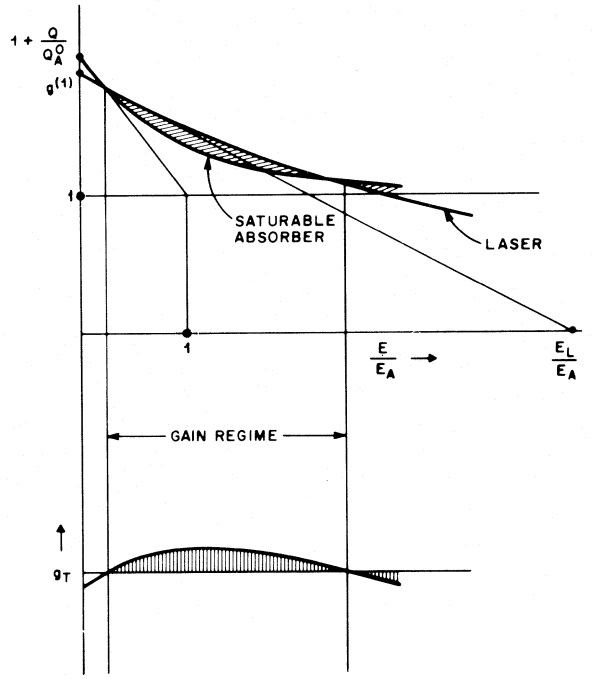

Fig. 2. (a) The saturable-absorber parameter Q/Q_A and laser gain as functions of energy. (b) The net gain g_T as a function of energy.

small-signal gain. But then $g_0 < 1 + (Q/Q_A^0)$, and the system could not get started. Therefore, one requires that $g_0 > 1 + (Q/Q_A^0) > g^{(i)}$, and hence the laser must not fully relax. This means that T_L must not be much shorter than T_R.

In order to relate $g^{(i)}$ to g_0, we note that $g^{(i)}$ decreases during the pulse to $g^{(i)} \exp -(E_0/E_L)$, where E_0 is the total pulse energy, and then relaxes back exponentially to $g^{(i)}$ within one cavity round-trip time T_R. The steady-state consistency requirements give

$$\left[g_0 - g^{(i)} \exp -\frac{E_0}{E_L}\right] e^{-\frac{T_R}{T_L}} = g_0 - g^{(i)}.$$

Solving for g_0 one has

$$g_0 = g^{(i)} \left(1 + \frac{E_0/E_L}{\exp (T_R/T_L) - 1}\right) \tag{24}$$

where we have expanded the exponential $\exp - E_0/E_L$ to first order in E_0/E_L, in anticipation of, and consistent with, the approximations made further on in this paper. If the laser medium is in the middle of the cavity, the round-trip time $T_R = 2L/c$ has to be replaced by L/c, as long as single pulsing occurs. Instead of the sum of the counter-traveling powers, one uses only one traveling component. Everything else is left unchanged.

V. The Solution

We are now ready to reenter (12) and write out all the terms. Using (20) and (21) we obtain

$$-\frac{Q}{Q_A^0} e^{-\frac{E}{E_A}} v = \left(1 - g^{(i)} e^{-\frac{E}{E_L}}\right) v + \frac{\delta}{\omega_C} \frac{d}{dt} v - \frac{1}{\omega_C^2} \frac{d^2}{dt^2} v \tag{25}$$

where E is defined by (18). This is a nonlinear integro-differential equation which looks quite complicated. A simple solution of the equation is obtained if we expand the exponentials into power series and break them off with second-order terms. This corresponds to representing the *net-gain curve* as shown in Fig. 2 by a parabola. Because $E_L \gg E_A$, one may break off the expansion of $\exp(-E/E_L)$ with the first-order term so that one obtains

$$0 = \left(\left(1 + \frac{Q}{Q_A^0} - g^{(i)}\right) - \left(\frac{Q}{Q_A^0} - g^{(i)} \frac{E_A}{E_L}\right) \frac{E}{E_A} + \frac{1}{2} \frac{Q}{Q_A^0} \left(\frac{E}{E_A}\right)^2\right) v + \frac{\delta}{\omega_C} \frac{dv}{dt} - \frac{1}{\omega_C^2} \frac{d^2}{dt^2} v. \tag{26}$$

A solution of this equation is

$$v = \frac{(V_0 E_A/2\tau_p)^{1/2}}{\cosh \frac{t}{\tau_p}} \tag{27}$$

where V_0 and τ_p are constants to be determined by substitution of (27) into (26), using the fact that

$$\frac{E}{E_A} = \frac{V_0}{2} \left(1 + \tanh \frac{t}{\tau_p}\right). \tag{28}$$

Note that V_0 is the normalized energy of the pulse, $V_0 = E_0/E_A$. Substituting (27) in (26), and setting the coefficients of the three hyperbolic functions equal to zero, we obtain three equations. To simplify notation we introduce two parameters, New's s parameter [14]

$$s \equiv \frac{E_L}{E_A} \tag{29}$$

and the saturable-absorber "loading" parameter

$$q \equiv \frac{Q}{Q_A^0}. \tag{30}$$

In terms of these parameters, the three characteristic equations become

$$(1 + q - g^{(i)}) - \frac{1}{2}\left(q - \frac{g^{(i)}}{s}\right) V_0 + \frac{1}{4} q V_0^2 - \frac{1}{\omega_C^2 \tau_p^2} = 0 \tag{31}$$

$$-\frac{1}{2}\left(q - \frac{g^{(i)}}{s}\right) V_0 + \frac{1}{4} q V_0^2 - \frac{\delta}{\omega_C \tau_p} = 0 \tag{32}$$

$$-\frac{1}{8} q V_0^2 + \frac{2}{\omega_C^2 \tau_p^2} = 0. \tag{33}$$

Equation (32) determines the detuning, once the pulse duration τ_p and pulse energy V_0 are determined from (31) and (33).

The net gain g_T as a function of normalized energy $U \equiv E/E_A$ has the dependence

$$g_T(U) = -(1 + q - g^{(i)}) + \left(q - \frac{g^{(i)}}{s}\right) U - \frac{1}{2} q U^2. \tag{34}$$

The pulse energy must satisfy the stability criterion that the net gain be negative after passage of the pulse

$$g_T(V_0) < 0. \tag{35}$$

Eliminating $1/\omega_C^2\tau_p^2$ from (31) and (33), one has

$$-(1+q-g^{(i)})+\left(q-\frac{g^{(i)}}{s}\right)\frac{V_0}{2}-\frac{3}{16}qV_0^2=0. \tag{36}$$

Equation (36) gives two solutions for V_0 for any choice of q, $g^{(i)}$, and s. The smaller of these two can be shown never to satisfy (35) and hence can be discarded.

Some constraints on the parameters may be gleaned directly from (34). In order to have loss before the pulse comes along, we must have

$$1+q-g^{(i)}>0. \tag{37}$$

The loss must be converted into gain with rising pulse energy, i.e., the coefficient $q-g^{(i)}/s$ must be positive

$$g^{(i)}<sq. \tag{38}$$

Fig. 3 shows pulsewidths versus small-signal gain computed for different saturable-absorber loadings $Q/Q_A^0=q$, at fixed s. For each value of q there are two limits on $g^{(i)}$ and V_0, as determined from (35) and (37). Hence there are two limiting values of g_0 obtained from (24). In between, the pulsewidth varies by not more than a factor of the order of 5/3, as explained further on in this paper.

VI. The Gain Parabola

It is convenient to analyze the problem in terms of parameters that are a direct measure of the net-gain parabola (34). We use the height H of the parabola at its maximum which is given by

$$H=\frac{1}{2}\left(1-\frac{g^{(i)}}{sq}\right)^2-\left(1+\frac{1}{q}-\frac{g^{(i)}}{q}\right). \tag{39}$$

Further, we use the curvature parameter (second derivative) of the parabola which is equal to q, and the displacement U_0 of the peak of the parabola from the origin of the energy scale

$$U_0=1-\frac{g^{(i)}}{sq}. \tag{40}$$

Note that U_0 is a weak function of $g^{(i)}$, whereas H is generally a strong function of $g^{(i)}$, because $g^{(i)}$ will generally lie close to $1+q$. This can be seen from the graph of Fig. 4. If $Q/Q_A^0=q\ll 1$, then the laser characteristic hinges around the "distant" point E_L/E_A on the abscissa, and its rotation as a function of $g^{(i)}$ is effectively a translation in the upper left-hand corner of the graph. This is the limit when U_0 is practically $g^{(i)}$ independent.

In terms of these parameters, we obtain for the pulse energy V_0, from (36)

$$-\tfrac{3}{8}V_0^2+U_0V_0-U_0^2+2H=0. \tag{41}$$

The equation for the net gain is

$$g_T(U)=-U^2+2U_0U-U_0^2+2H. \tag{42}$$

Note that the height of the parabola is limited on one hand by the fact that the net gain must be negative when $U=0$. This condition gives the maximum height H_0

$$H_0=\tfrac{1}{2}U_0^2.$$

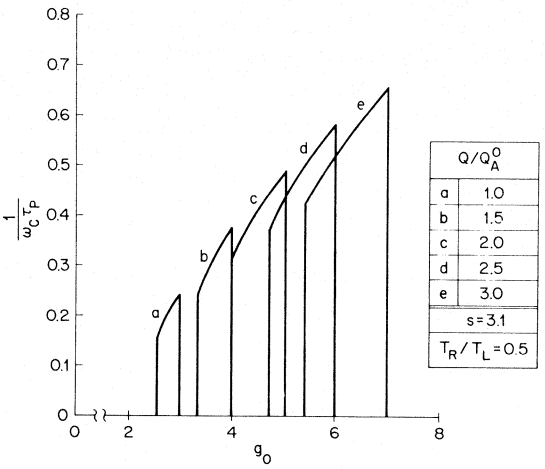

Fig. 3. Inverse pulsewidth versus g_0 with Q/Q_A^0 as parameter.

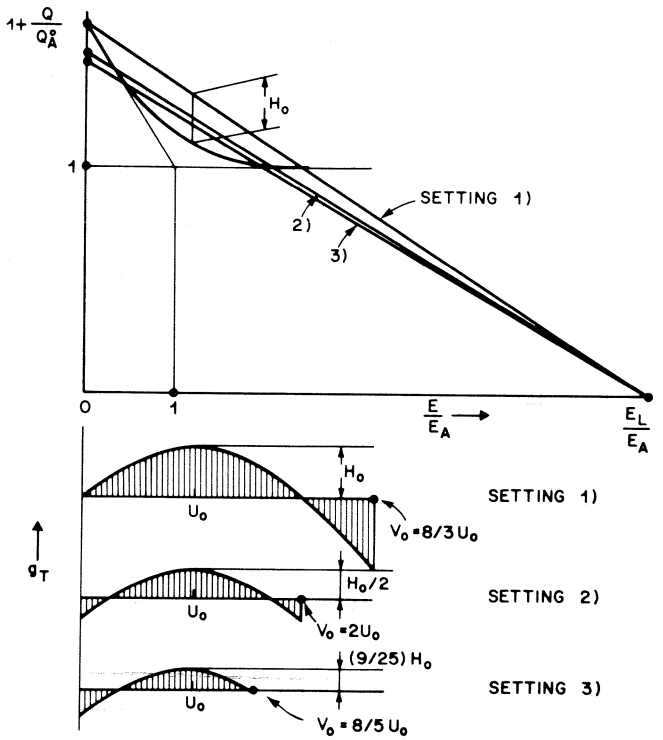

Fig. 4. Various settings of $g^{(i)}$.

TABLE I

Setting	Height H	Normalized Pulse Energy V_0	Normalized Inverse Pulse Width $\frac{1}{\omega_C\tau_p}$
1)	$H=\frac{1}{2}V_0^2=H_0$	$\frac{8}{3}U_0$	$\frac{2}{3}\sqrt{q}\,U_0$
2)	$H=\frac{1}{2}H_0$	$2U_0$	$\frac{1}{2}\sqrt{q}\,U_0$
3)	$H=\frac{9}{25}H_0$	$\frac{8}{5}U_0$	$\frac{2}{5}\sqrt{q}\,U_0$

The minimum height H is not zero, but rather has a positive value imposed by the fact that the pulse energy V_0, as obtained from (41), must satisfy the stability criterion (35). Table I summarizes the more important roots of (41). Case

1) has the largest energy and shortest pulsewidth. Case 2) is the case of symmetry, when the net gain g_T after passage of the pulse is equal to the net gain preceding the pulse. Case 3) is the case of minimum energy, smallest H, when the gain after the passage of the pulse just barely satisfies the stability requirement (35). The three settings for $g^{(i)}$ corresponding to these three cases are shown in Fig. 4.

Case 2) with $H = \frac{1}{2} H_0$ is one in which the loss before arrival of the pulse is equal to the loss after passage of the pulse and hence is a case of high symmetry. From (32), (40), and (41) we find that the detuning δ is zero for this case. We illustrate the conditions in Fig. 5. We show the secant hyperbolic pulse, its energy as a function of time, and the net gain g_T as a function of energy converted into a function of time. It is clear from the graph, and from a perusal of (14) with $\delta = 0$, that $g_T(t)$ plays a role of modulation function which enhances the pulse at its center and suppresses the wings of the pulse. The function $g_T(t)$ time modulates v just so as to compensate for the dispersive effect of the system. Note that the peak g_T at the time of maximum gain is equal and opposite to the g_T at the times before and after passage of the pulse.

Note from (33) and from Table I that the inverse pulsewidth is proportional to the pulse energy. The largest pulse energy equal to $2H_0$ is achieved in setting 1), with H_0 equal to the height of the gain parabola. Hence the largest achievable inverse pulsewidth, for given $g^{(i)}$, is proportional to the height H_0 of the gain parabola of setting 1). This gives a useful criterion for choice of laser medium and saturable-absorber parameters.

Further, we note from Table I that the largest pulse energy is $\frac{4}{3}$ times the distance (on the energy scale) between the zeros of the $g_T(U)$ curve. The smallest energy is $\frac{3}{5}$ times smaller than the largest energy.

To illustrate how the analysis may be applied to predict experimental variation of pulsewidth, we consider the case when q is varied at fixed s. This means that the absorber dye concentration is varied. Concurrently, the gain has to be readjusted by varying the pumping. Suppose that for each dye concentration the gain is adjusted for maximum pulse energy. Then $g^{(i)}$ is set equal to $1 + q$ [setting 1), Fig. 4]. From (40), with $g^{(i)} = 1 + q$, one may solve for q in terms of s and U_0. Using the value $V_0 = \frac{8}{3} U_0$ for setting 1) of Table I we may write for the pulsewidth

$$\omega_C \tau_p = \frac{4}{V_0} [s(1 - \tfrac{3}{8} V_0) - 1]^{1/2}. \tag{43}$$

The equation predicts zero pulsewidth when $\frac{3}{8} V_0 = s - 1$; however, this value corresponds to $q \to \infty$, and clearly the analysis breaks down in this unattainable limit. When $\frac{3}{8} V_0 \ll s - 1$, and thus $q \ll \infty$ we can approximate (43) by

$$\omega_C \tau_p = \frac{4(s-1)^{1/2}}{V_0}. \tag{44}$$

The pulsewidth varies inversely with the pulse energy. This finding should be compared with the prediction of Garmire and Yariv [12] who discussed the case of a relatively fast absorber, neglecting laser-medium dispersion.

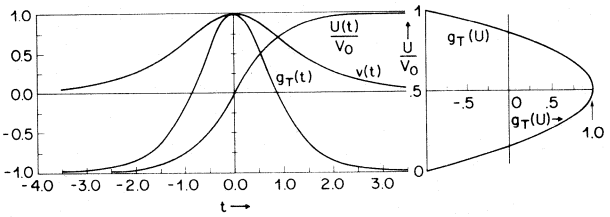

Fig. 5. Pulse amplitude, modulation function, and energy versus time, and g_T versus energy for the symmetric case; g_T is in units of $1/(\omega_C \tau_p)^2$; U and t are in units of τ_p.

Another experimental procedure may consist of varying the beam diameter in the absorber dye, followed by an adjustment of the laser pump to attain maximum energy and minimum pulsewidth. A beam cross-section change by a factor of x leads to a change of the s parameter by $1/x$, and the saturable-absorber loading parameter by x. Setting $s = s_0/x$ and $q = q_0 x$, one may again express x in terms of V_0 [setting 1)] and then write $\omega_C \tau_p$ in terms of V_0. The result is

$$\omega_C \tau_p = \frac{4}{V_0 [s_0 q_0 (1 - \frac{3}{8} V_0) - 1]^{1/2}}.$$

As long as $\frac{3}{8} V_0 \ll 1$, one finds again a variation of $\omega_C \tau_p$ proportional to the inverse pulse energy. When $\frac{3}{8} V_0 = 1 - 1/(s_0 q_0)$, one finds an infinite pulsewidth. This happens at $x = 0$, i.e., at zero beam diameter. This corresponds to the limit of no saturable-absorber action because of oversaturation.

VII. Correspondence with New's Results

To establish correspondence with New we have made the identifications displayed in Table II. Since we used New's notation in Section II, the entries are self-explanatory. Our Fig. 6 is a reevaluation of New's Fig. 2 in terms of the present theory. New put the laser medium at the center of the cavity, and for this reason we use (24) with T_R/T_L replaced by $T_R/2T_L$. Qualitatively, the two figures correspond to each other, whereas quantitatively there are discrepancies.

The discrepancies are accounted for by two facts.

1) We used an expansion for all exponentials.

2) In order to find the limiting regime of g_0, one must know the energy in the pulse. New computed the energy on the basis of the assumption that the net energy gain of the pulse be zero, disregarding medium dispersion. We took dispersion into account. Dispersion introduces an additional loss, and therefore the energy gained by the pulse, computed from $\int g_T(t) v^2 dt$ must be greater than zero. This criterion calls for a pulse energy different from that of New.

In order to show the difference in predicted energies in the pulse, using New's criterion on one hand, and our criterion (36) on the other hand, we plot Fig. 7. The figure shows the two limiting values of pulse energy obtained from New's criterion (as expressed in our notation, with expansion of the exponentials implied)

TABLE II

TABLE OF CORRESPONDENCE

New's Notation	Our Notation
$\beta_0 = \exp - 2B_0$	$\exp - \frac{\omega_0}{Q} q T_R$
$\gamma = \exp - 2\Gamma$	$\exp - \frac{\omega_0}{Q} T_R$
$g_0 = \alpha_0\beta_0\gamma$	$\exp \frac{\omega_0}{Q} T_R(g_0 - 1 - q)$
$\frac{\ln\beta_0}{\ln\gamma}$	q

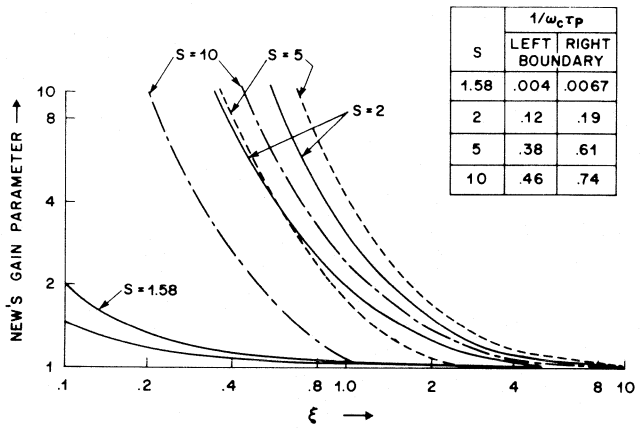

Fig. 6. Boundaries of allowed regimes of gain versus T_R/T_L. Plot corresponds to New's Fig. 2. In order to relate with New's case of a laser medium in cavity center, we multiply T_R/T_L in (24) by 0.5; Q/Q_A^0 = 1.76.

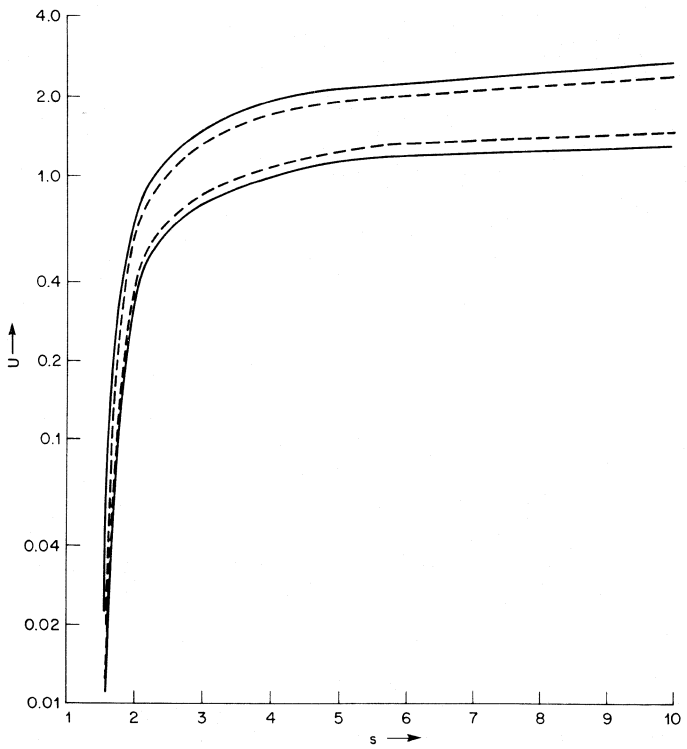

Fig. 7. The limiting energies computed on the basis of the two criteria (45) and (46), the latter is shown by a dashed line; Q/Q_A^0 = 1.76.

$$\int g_T(U)\, dU = 0 \tag{45}$$

and from our criterion (14)

$$\int g_T dU = \frac{1}{\omega_C^2 E_L} \int \left(\frac{dv}{dt}\right)^2 dt \tag{46}$$

which is automatically satisfied by (36).

The discrepancy is of the order of 10 percent, not a large effect. Hence, the major reason for discrepancies in the plots is our expansion of the exponentials. Note, however, that New's values for the losses and gain per pass are high compared with those occurring in the system of [16]. Hence the approximations made in this paper are better suited for the analysis of this experimental system than for a quantitative comparison with New's results.

It should be noted that Fig. 6 also gives a measure of pulsewidth versus the ξ parameter for a given g_0. A choice of g_0 chooses a horizontal line which intersects the s = const boundaries at two points. The rightmost boundary corresponds to a shorter pulsewidth than the leftmost. In between, the pulsewidth increases monotonically; the range of variation is of the order of 5/3.

VIII. Other Symmetric Pulse Shapes

We have concentrated on solutions for pulse shapes resulting from a parabolic g_T versus U-dependence. Experimentally, one finds shapes other than secant hyperbolics [16]. It behooves us, therefore, to look into the reasons for generating pulse shapes that are not secant hyperbolics. One could proceed by changing the $g_T(U)$ function to a dependence other than parabolic. Because the equation to be solved is a nonlinear integro-differential equation, with easy solution only if one guesses it, this route seems less desirable than the alternate one: one assumes a pulse shape and asks for the U-dependence of the modulation function g_T. We pursue here this second alternative. We use functional dependences that give us closed-form solutions while approximating the pulse shapes we are looking for.

In particular, we are interested in pulse shapes that have sharp peaks. We set

$$v = \frac{E_A^{1/2}}{(\cosh^2 u - a)^{1/2}} \tag{47}$$

where u is related to the time variable t by

$$\frac{t}{\tau} = u - a \tanh u \tag{48}$$

where τ is a time-scale parameter, and the a parameter lies in the range $0 < a < 1$. The pulse shape is a secant hyperbolic when $a = 0$, and becomes sharper at the time origin as $a \to 1$. Such a pulse shape has a dependence of energy upon time

$$U = \frac{1}{E_A} \int_{-\infty}^{t} v^2 dt = \tau[1 + \tanh u]. \tag{49}$$

One computes

$$-\frac{\tau^2}{v}\frac{d^2v}{dt^2} = \omega_C^2\tau^2 g_T(t)$$

$$= -\frac{\cosh^8 u - 2\cosh^6 u - a(3\cosh^4 u - 4\cosh^6 u)}{(\cosh^2 u - a)^4}. \quad (50)$$

Fig. 8 shows plots of v, U, and g_T versus time for different values of the a parameter and the corresponding plots of $g_T(U)$. We find that "sharp" pulses are generated by $g_T(U)$ dependences that have sharper peaks than parabolic. Now when a cavity is loaded heavily by the saturable absorber ($Q/Q_A^0 > 1$, compare Fig. 2), the $g_T(U)$ curve, aside from tending to become asymmetric, does acquire a peak that is sharper than the peak of a parabolic function. Hence heavy loading by the saturable absorber in an attempt to produce short pulses will also tend to produce pulses with sharp peaks. These pulses will have more energy content in their "tails" than secant hyperbolic pulses of comparable full width at half-intensity. This may be undesirable for some applications. One way of preventing the formation of pulses with sharp peaks, while maintaining strong saturable-absorber loading, is to use a combination of absorbing media. Through proper choice of saturation energies and small-signal loading factors (q) of the absorbers one may synthesize a more parabolic dependence of g_T upon U.

IX. Asymmetric Pulse Shapes

So far we have studied only symmetric mode-locked pulses resulting from (basically) symmetric $g_T(U)$ curves. To be sure, the parabolic $g_T(U)$ curve was not necessarily centered at the peak of the parabola. When this happened, detuning occurred, but the pulse was still symmetric. We shall now inquire into the reasons for the occurrence of asymmetric pulses.

We follow the procedure used in the preceding section. We postulate an asymmetric pulse shape and then explore what $g_T(U)$ curves are required to give these shapes.

We start by setting

$$v = \frac{E_A^{1/2}}{(\cosh^2 u + b\sinh u\cosh u + bu)^{1/2}} \quad (51)$$

and relate u to t by

$$\frac{t}{\tau} = u(1 + b\tanh u). \quad (52)$$

This "Ansatz" corresponds to asymmetric pulses with an energy

$$U = \frac{1}{E_A}\int_{-\infty}^{t} v^2 dt = \tau[1 + \tanh u]. \quad (53)$$

The modulation function $g_T(t)$ is obtained by straightforward algebra.

Fig. 9 shows a set of curves of $v(t)$, $g_T(t)$, and $U(t)$ for different b parameters, and the $g_T(U)$ curves. Note that all $g_T(U)$ curves are normalized to unity peak amplitude. Fig. 10 shows the half-power width of the pulses versus asymmetry parameter for constant peak amplitude of $g_T(U)$. We find that the width is not a very rapid function of asymmetry, indicating that the height of the asymmetric $g_T(U)$ curve is still a reasonable indication of pulsewidth.

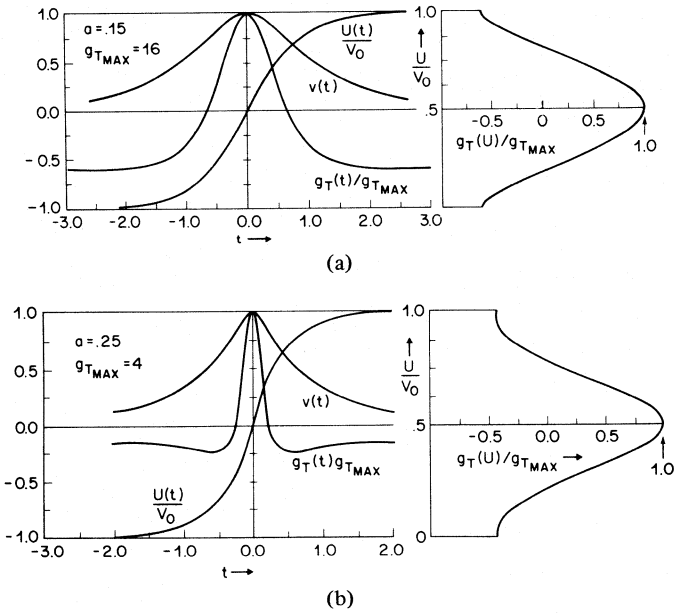

Fig. 8. Plots of pulse amplitude, modulation function $g_T(t)$, and energy versus time, and g_T versus energy for two values of parameter a. g_T is in units of $1/(\omega_C\tau)^2$; U and t are in units of τ.

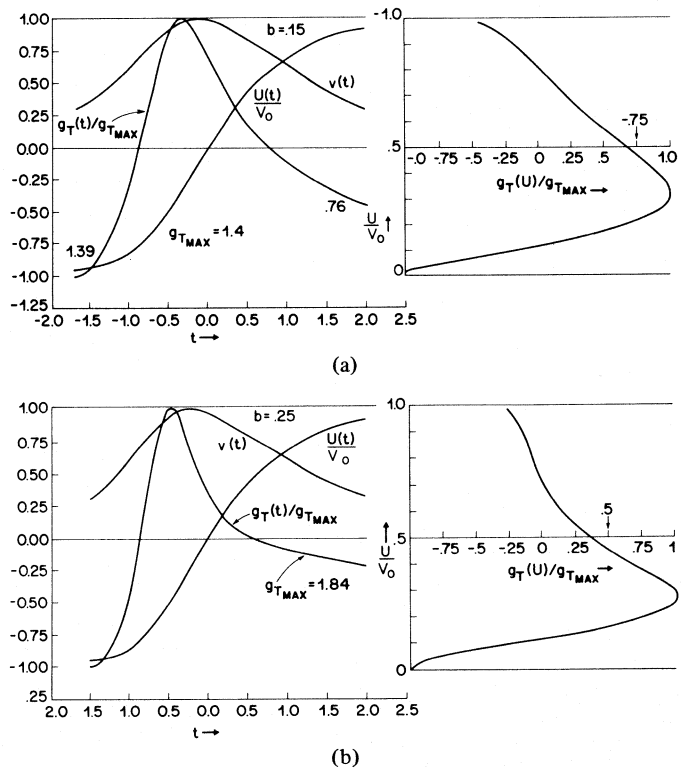

Fig. 9. Plots of pulse amplitude, modulation function $g_T(t)$, and energy versus time, and g_T versus energy for two values of parameter b. The maxima of $g_T(t)$ are in units of $1/(\omega_C\tau)^2$, U and t are in units of τ.

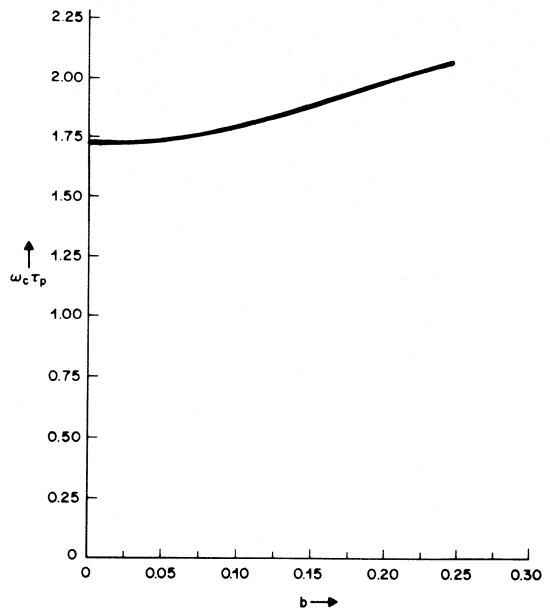

Fig. 10. Half-power widths versus b parameter for fixed peak modulation function, $g_{T\max} = 1$.

X. Relevance to Dye-Laser System

We have dealt here with a rather idealized model which, hopefully, can give us insight into the mode locking of CW dye lasers. Some of the assumptions we made were necessary to obtain a closed-form solution, but, if dropped, do not change the qualitative conclusions.

Consider the assumption that Q/Q_A and g may be expanded in E/E_A. If this assumption is dropped, then the gain (or modulation) function $g_T(U)$ has a shape other than parabolic as a function of normalized energy U. We have seen that pulses result which may be peaked, or asymmetric depending upon the shape of $g_T(U)$. Yet, regardless of the detailed pulse shape, the leading and trailing edges of the pulse must be exponentials. This follows directly from (14), rewritten here for convenience

$$g_T[U(t)]\, v = \left(\frac{\delta}{\omega_C}\frac{d}{dt} - \frac{1}{\omega_C^2}\frac{d^2}{dt^2}\right) v. \tag{54}$$

Suppose we found the solution to this equation. Then a certain $g_T(U(t))$ would have been found. But for a known $g_T(U(t))$, (54) may be reduced by substitution of

$$v = V(t) \exp(\delta\omega_C t/2) \tag{55}$$

to a quantum problem of a particle of displacement $V(t)$ in a well

$$-g_T[U(t)] + \frac{\delta^2}{4}.$$

This well must be open on both sides, because $U(t)$ approaches constants for $t \to -\infty$ and $t \to +\infty$. Thus $V(t)$ must have exponential leading and lagging edges. This conclusion depends solely on the assumption that the operator $(1/\omega_C^2)d^2/dt^2$ represents satisfactorily the dispersion of the system.

In analyzing a mode-locked pulse train one makes the implicit assumption that mode locking is successful and all axial modes are in phase coherence with each other. This is not always the case as evidenced by the second-harmonic-generation (SHG) trace of Fig. 11 which was kindly supplied to the author by Dr. C. V. Shank and Dr. E. P. Ippen. The trace was taken under operating conditions such that only partial mode locking occurred. The SHG trace indicates that the pulse consists of a deterministic envelope $V(t)$ with a stochastic substructure $a(t)$

$$v(t) = V(t)a(t). \tag{56}$$

Can this pulse shape be explained by the theory presented here, or by a minor modification thereof?

When the pulse behaves as represented by (56), clusters of modes are locked, with random phases between clusters. The width of the envelope $V(t)$ is of the order of the average inverse bandwidth of the clusters. The saturable absorber and laser media relax slowly and hence are acted upon by the deterministic intensity envelope only. The time dependences of absorption and gain are, therefore, adequately described by the present analysis. The spreading mechanism, i.e., the diffusion term in (25), has to be reconsidered, however. Modes locked in clusters (in frequency space) spread in time if there are temporal shifts of the time envelopes of the clusters. Such temporal shifts are produced when the locking-range boundaries of the clusters fluctuate. When a diffusion term is introduced into the equation for $V^2(t)$, one finds again that the solution is a secant hyperbolic squared for $V^2(t)$.

The experimentally observed SHG trace for partial mode locking shows a pedestal and a coherence spike (Fig. 11). The pedestal is described very well by the correlation function of $1/\cosh^2(t/\tau_p)$ shown by the points in Fig. 11, with τ_p adjusted for a best match.

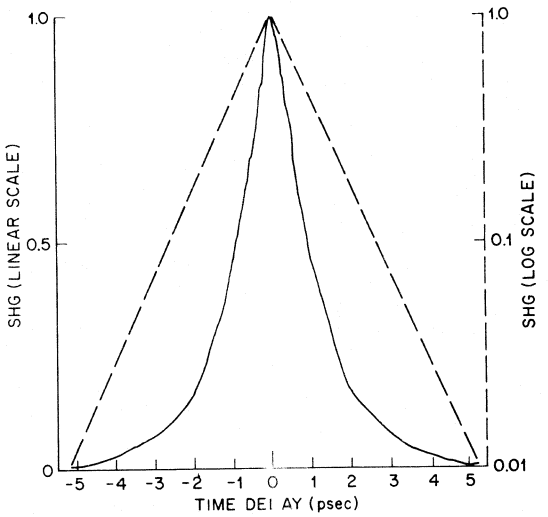

Fig. 12. Experimental correlation function for short pulse. Dashed curve is plotted on logarithmic scale.

When the mode locking is complete so that no coherence spike is visible, and much shorter pulse duration is achieved, the SHG traces assume the shape shown in Fig. 12 also supplied by Dr. Shank and Dr. Ippen. This correlation function cannot be fitted by the correlation function of a secant hyperbolic squared; it is too sharply peaked at the origin. The tails can be seen to be exponentials as predicted by theory. There are at least three different explanations for the deviation of the shape of the correlation function from that of a squared secant hyperbolic.

1) The pulse may not be Fourier-transform limited. The trace in Fig. 12 may be the merger of a coherence spike with the pedestal. The trace can be matched quite well under such an assumption, taking the spectrum of the substructure $a(t)$ of (56) to be that of a secant hyperbolic as well.

2) Deviation of the $g_T(U)$ function from a parabola may lead to asymmetric pulse shapes as explained in Section IX. The correlation function of a one-sided exponential can be fitted well to the trace of Fig. 12.

3) The short pulse may be affected by the nonnegligible time response of the upper and lower levels of the saturable absorber.

XI. Conclusions

By approximating the excess-gain curve versus energy by a parabola, we have obtained closed-form solutions for the problem of mode locking by a slow saturable absorber. The pulse shape is a hyperbolic secant. The analysis led to the following conclusions which hold for parabolic shapes of the $g_T(U)$ curve.

1) Inverse pulsewidths are porportional to the square root of the height above zero of the $g_T(U)$ curve. The widths are smallest when $g^{(i)} = 1 + Q/Q_A^0$, but are only $\frac{5}{3}$ times larger for the lowest allowed value of $g^{(i)}$.

2) The energy in the pulse is roughly $\frac{4}{3}$ times the distance (on the energy scale) between the zeros of the $g_T(U)$ curve.

For nonparabolic shapes of the $g_T(U)$ curve these conclusions follow.

3) Deviations from symmetry of the $g_T(U)$ curve do not affect the form of the solution of the pulsewidth drastically, but do lead to asymmetric pulse shapes.

4) "Peaking" of the $g_T(U)$ curve leads to sharply peaked pulses.

Acknowledgment

The author wishes to thank his students C. P. Ausschnitt and P. Hagelstein with whom many of the basic ideas presented in this paper have been worked out at M.I.T. However, theory did not make contact with physical reality until the author had the privilege of working closely with Dr. C. V. Shank and Dr. E. P. Ippen. Helpful suggestions by Dr. H. Kogelnik on changes in the manuscript are gratefully acknowledged. The careful reading of the manuscript by Dr. Shank and Dr. Ippen is greatly appreciated.

Low-Threshold, Transversely Excited NdP_5O_{14} Laser

STEPHEN R. CHINN, MEMBER, IEEE, JAMES W. PIERCE, AND HELMUT HECKSCHER

Abstract—We have measured the room-temperature lasing behavior of NdP_5O_{14} (NdPP) transversely pumped at 0.58-μm wavelength by a CW dye laser in an excitation geometry simulating that of an LED or laser diode. For a crystal 760 μm long, the lowest transverse threshold was 4 mW. From this threshold and a theoretical relationship between excitation efficiency and pump wavelength, we predict that a threshold of approximately 8.5 mW should be possible for excitation by an edge-emitting 0.8-μm wavelength LED. Using thin NdPP samples with reflecting back surfaces for better excitation efficiency should lower this threshold by ~60 percent, and give minimum optical-to-optical conversion efficiencies of ~3.5 percent.

I. Introduction

NEODYMIUM pentaphosphate (NdP_5O_{14}, abbreviated as NdPP), which has also been called Nd ultraphosphate, is a potentially useful laser material containing a high concentration of Nd^{3+} ions (4×10^{21} cm^{-3}) [1], [2]. Its Nd^{3+} emission cross sections, linewidths, and spontaneous lifetimes [3]-[6] are roughly comparable to those in 1-3 atomic percent Nd:YAG (Nd^{3+} concentration ~$1.4\text{-}4.2 \times 10^{20}$ cm^{-3}) [7]-[9]. Therefore the 10-30-fold increase in Nd^{3+} concentration in NdPP allows much shorter samples to yield useful gain-length products, and also results in much shorter absorption lengths, permitting efficient optical excitation of very small volumes.

Small efficient lasers emitting at 1.05 μm could have many applications as substitutes for low-power Nd:YAG lasers at this wavelength. In particular, miniature NdPP lasers would be well suited as sources for fiber-optic transmission systems, which have minimum absorption and scattering losses above 1 μm [10], [11]. Also NdPP lasers offer a possible solution to problems presently found with most semiconductor diode lasers, such as short operating lifetimes, poor mode aspect-ratios, and large beam divergence.

Excitation of Nd:YAG lasers by light-emitting diodes (LED's) or laser diodes results in lower thresholds and power consumption than excitation by the more conventional incandescent or discharge lamps. This paper reports on room-temperature lasing behavior of NdPP excited by a tunable CW dye laser in a transverse geometry that simulates a useful laser diode or LED excitation scheme. Using a simple model for the mode excitation appropriate to this configuration, we have computed a theoretical fit to our experimental data for threshold power versus excitation wavelength near 0.58 μm. From this model, we have calculated the threshold powers required for excitation in the 0.80-μm absorption region, which is of more practical interest because direct-gap, efficient 0.80-μm laser diodes and LED's are better developed than those emitting at 0.58 μm. Also the 0.80-μm band is the strongest Nd^{3+} absorption band in the visible and near infrared.

II. Experimental Procedure and Results

The experimental apparatus, shown schematically in Fig. 1, was similar to those described by Weber *et al.* [1] and Danielmeyer *et al.* [2], except that we used a CW tunable dye laser as the excitation source. The dye was rhodamine 6G, whose output range includes the strong NdPP absorption band near 0.58 μm. The dye laser was excited by a CW argon-ion laser. The dye laser output was either interrupted by a tuning-fork chopper or used directly for CW pumping. The pump beam was expanded, passed through a 1-cm aperture, and focused on the NdPP sample at the center of a nearly spherical optical cavity having 5-cm radius input and output mirrors with reflectivities at 1.05 μm of nominally 100 percent and ~99.7 percent, respectively.

Two alternate excitation schemes were used. The first was collinear excitation [1], [2], with the pump beam focused on one end of the sample by a 10-cm focal length lens through the input mirror (transmitting at 0.58 μm). This configuration gave the lowest thresholds and was used for the initial alignment of the sample and cavity. For transverse excitation, a deflecting mirror diverted the pump beam to two other mirrors and then through two crossed cylindrical lenses to form a narrow-line image on one side of the sample. An enlarged sketch of the resulting excitation at the sample is shown in Fig. 2(a). The cylindrical lenses were first adjusted so that the horizontal length of the focused beam matched the sample length L in the lasing direction, and the beamwidth was as narrow as possible. This initial adjustment was performed

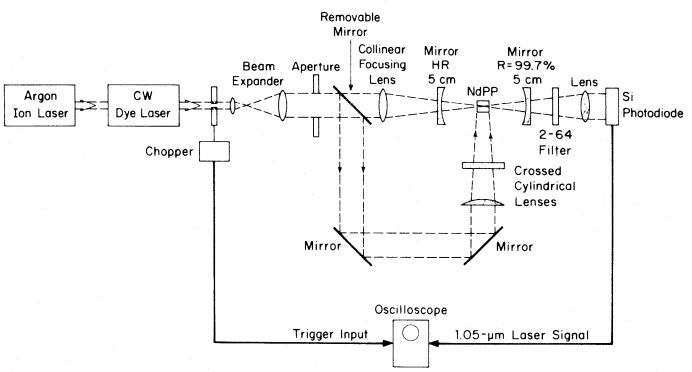

Fig. 1. Schematic diagram of experimental apparatus for optical excitation of a NdPP laser.

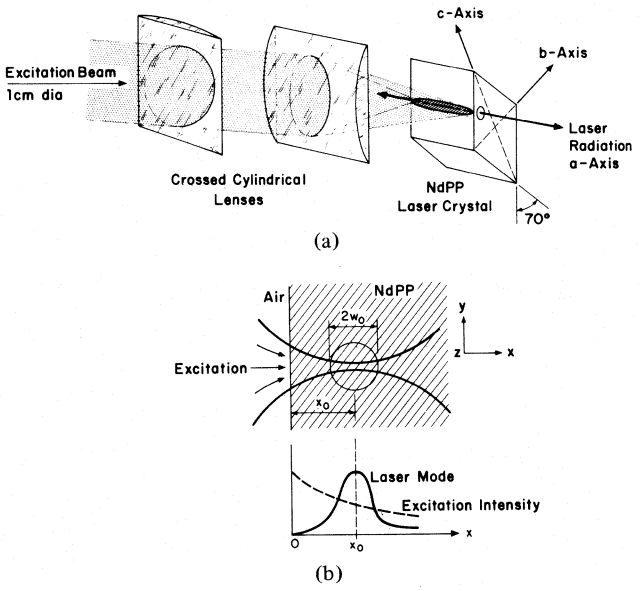

Fig. 2. (a) Enlarged view of transverse excitation at the NdPP laser crystal. (b) Diagram of the laser mode and transverse excitation intensity in the NdPP crystal.

visually by using a microscope with an infrared (IR) image converter to view the spontaneous emission at the beam focus. Fine angular adjustment of the output mirror was then performed by piezoelectric tuning of the mirror-mount micrometers. The mirror spacing and, consequently, the laser mode parameters were not changed from the collinear geometry. Both the excitation focus and transverse sample position were adjusted for minimum threshold. Then the threshold was measured as a function of pump wavelength, using a Si photodiode inserted in the beam outside the cavity to monitor the excitation power. In order to correct for losses due to the input optics, for both collinear and transverse cases the external photodiode was first calibrated against a calibrated detector placed at the sample position. In the data presented below the threshold powers refer to these measured incident powers. For the collinear geometry, the laser samples were long enough so that no significant amount of pump power was transmitted. Therefore, the absorbed power can be estimated by reducing the incident power by 5 percent, the Fresnel reflectivity of NdPP. Of course, for the transverse excitation case the most useful information is the amount of power absorbed in the region of the laser mode, which is discussed in the calculation below. Again, the data for transversely directed powers are the measured incident powers. Another Si photodiode, placed after the output mirror and preceded by an IR-transmitting visible-blocking Corning 2-64 glass filter, measured the 1.05-μm NdPP laser output.

The natural growth habit of the rhombohedral-prism-shaped NdPP crystals [Fig. 2(a)] made their use extremely convenient. Since both end *a* faces and the side excitation face were of very high optical quality, no sample preparation was necessary except for cleaning and cementing to a mounting pin. However, in an attempt to increase the transverse excitation efficiency by reflecting the transmitted pump light, we polished one sample to a thickness (t) of 78 μm, and placed the polished face against a small mirror. The mirror, fabricated from 100-μm-thick aluminized glass, had a length of 500 μm, slightly less than the sample length (565 μm) so as not to intercept the diverging laser mode. An as-grown platelet only 36 μm thick was also mounted in this fashion. This platelet had *a* faces parallel to the mirror surface, and the laser facets were cleaved normal to the *b* axis.

The general method used for growing NdPP crystals has been described by Danielmeyer *et al.* [12] and Hong [13], but we have found that there is some variation in crystal habit depending on specific growth conditions. To obtain the rhombohedral-prism-shaped samples, we used the following procedure. A 5-*g* charge of Nd_2O_3 was weighed into a 250-cm^3 Au crucible, and 200 cm^3 of 85-percent phosphoric acid was added slowly. The uncovered crucible was heated in a muffle furnace. The temperature was first raised to 250°C and held there for 50 h, then raised to 550°C in less than an hour and held there for 7 days. The excess liquid was poured off as quickly as possible (in about 1 min), and the crucible was returned to the hot furnace, which was shut off and cooled to room temperature in about 5 h. Any remaining polyphosphoric acid was removed by soaking the crucible in a beaker of cold, distilled water for about 24 h. Most of the cyrstals could then be washed from the crucible without applying any mechanical stress. The crystals obtained were rinsed several times with acetone and allowed to dry. After selection of the best crystals, followed by final cleaning with detergent, trichlorethylene, acetone, and methanol, the laser samples were cemented to pins for mounting on a goniometer in the optical cavity. These samples, typically about 0.5 × 0.5 × 0.5 mm^3, showed some internal growth striations under a microscope. Generally, however, these were faint enough and far enough apart so as not to degrade the laser operation significantly. The platelet 36 μm thick was selected from crystals grown by the same method as in the preceding, but using a 15-*g* charge of Nd_2O_3. It had no visible optical flaws.

The experimental data for transverse threshold $P_T(\lambda)$ versus pump wavelength λ for sample 1 (L = 760 μm) and sample 2 (L = 940 μm) are shown in Figs. 3 and 4, respectively. For sample 1 the collinear threshold P_C was 600 μW, and the minimum value of $P_T(\lambda)$ (found at λ = 0.58 μm), was 3.9 mW. Corresponding values for sample 2 were P_C = 720 μW and minimum $P_T(\lambda)$ = 4.8 mW.

The effects of reducing the thickness and reflecting the transmitted pump radiation are shown by the data for sample 3 (L = 565 μm, t = 78 μm) plotted in Fig. 5. Although P_C, 625 μW, was slightly higher than that of sample 1, the minimum $P_T(\lambda)$ = 2.7 mW was significantly lower. The output power, P_{out} (at 1.05 μm), as a function of optical input power, P_{in} (at 0.58 μm), was measured with 1.6-ms excitation pulses and 20-percent duty cycle. Sample 3 had a more efficient excitation geometry resulting in generally higher output power and power conversion efficiency than sample 1. With transverse excitation the best conversion efficiencies were 8.5 percent (sample 3) and 8 percent (sample 1) compared with 30-percent efficiency which we typically obtain with collinear pumping (and the same 99.7-percent reflector). Continuous lasing with up to 1-mW output power (3.5-percent efficiency) was also obtained, but thermal limitations made stable higher

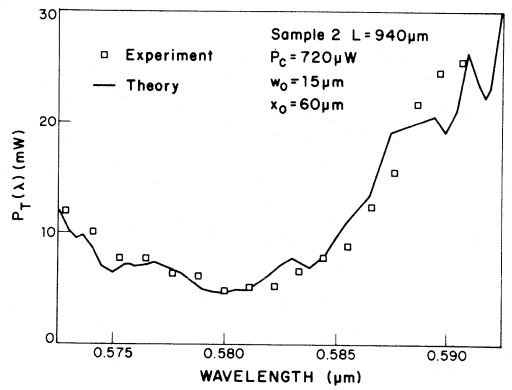

Fig. 4. Experimental and theoretical transverse pump threshold $P_T(\lambda)$ as a function of wavelength near 0.58 μm for NdPP sample 2, 940 μm long.

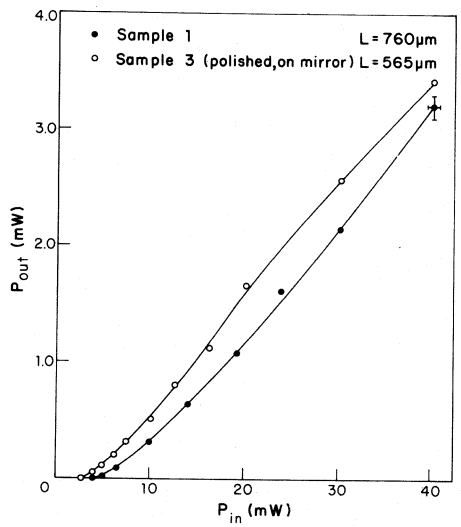

Fig. 5. Output power at 1.05 μm, P_{out}, as a function of transverse input power at 0.58 μm, P_{in}, for sample 1 (760 μm long) and for sample 3 (565 μm long) with reflecting back.

output powers difficult to achieve. The laser output for samples 1-3 was linearly polarized with the electric field parallel to the *b* axis, the orientation with highest stimulated emission cross section [5], [6].

To see whether an even thinner sample might be lased in the transverse configuration, we made measurements on sample 4,

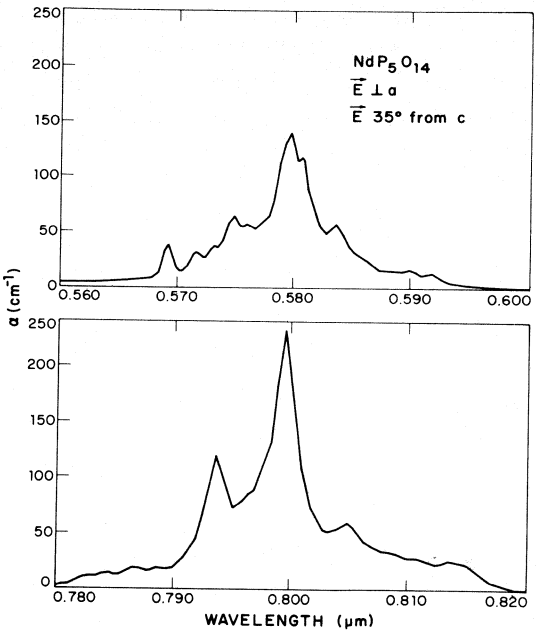

Fig. 6. Absorption coefficient α of NdPP as a function of wavelength near 0.58 and 0.80 μm. The electric field is polarized in the *y* direction of Fig. 2.

described in the preceding, with t = 36 μm and L = 290 μm. Like sample 3, this was mounted on a 500-μm-wide mirror, which may have partially vignetted the laser mode. Threshold values of P_C = 1.41 mW and minimum $P_T(\lambda)$ = 5.8 mW were found, with the laser output polarization parallel to the *c* axis, i.e., in the plane of the platelet. Singh *et al.* [5] and Huber *et al.* [6] have shown that the *c* polarization has approximately 50-percent smaller emission cross section and gain than the *b* polarization obtained with samples 1-3. This fact, along with vignetting of the laser mode, may explain the somewhat higher thresholds found for sample 4. However, the thickness of 36 μm seemed to be sufficient to give efficient absorption of the transverse pump radiation when the back-surface reflector was used.

Polarized optical transmission measurements were performed near 0.58 μm and 0.80 μm to obtain values of the absorption coefficient α for use in the theoretical calculations discussed below. These data were obtained with a double-beam spectrophotometer provided with a beam condenser to focus the transmitted light on the very small NdPP samples used. These samples were thin, as-grown platelets with the *a* axis normal to their broad faces. The transmission measurements were performed with the same electric field polarization as in the transverse excitation of the thicker laser samples, namely, E perpendicular to the *a* axis and rotated 35° from the *c* direction. The absorption coefficients computed from the measured transmission data are plotted in Fig. 6. (For convenience, α was evaluated at a limited number of wavelengths, and the resulting data points are connected by straight lines in the figure.)

III. Theoretical Calculations

A simplified model has been used to compute $P_T(\lambda)$. We assume that the width of the focused pump beam is sufficiently narrow compared to the NdPP laser mode diameter that no ex-

citation is lost in that dimension. Also we assume that both the mode and excitation are uniform along the axial direction. For these approximations, a simple one-dimensional integral gives the overlap, or effective gain, of the mode, as schematically indicated in Fig. 2(b). We define the additional parameters.

w_0 Gaussian laser mode radius;
x_0 depth of mode center from excitation face;
c_1 $= x_0/w_0$, $\rho = \alpha w_0/2$;
r radial coordinate for collinear geometry;
w_p collinear Gaussian pump beam radius at focus.

By computing the overlap of the excitation density and mode intensity for the transverse and collinear configurations (assuming complete absorption of the pump radiation in the collinear geometry) we find

$$P_T(\lambda) = P_C \left\{ \int_0^\infty \frac{4r \exp\left[-2r^2(1/w_p^2 + 1/w_0^2)\right]}{w_p^2}\, dr \right\} \cdot \left\{ \alpha \int_0^\infty \exp\left[-\alpha x - 2(x - x_0)^2/w_0^2\right] dx \right\}^{-1}$$

$$= P_C \left\{ (1 + w_p^2/w_0^2)\, \rho \exp\left[-\rho(2c_1 - \rho/2)\right] \sqrt{\pi/2} \cdot \left[\operatorname{erf}\left(\frac{2c_1 - \rho}{\sqrt{2}} \right) + 1 \right] \right\}^{-1}. \quad (1)$$

The pump radius, $w_p = 9 \pm 2$ μm, was determined experimentally by measuring the transmission through pinhole apertures of various diameters, assuming a Gaussian mode intensity. Equation (1) was used with the measured values of α, w_p, and P_C to calculate $P_T(\lambda)$ for samples 1 and 2. For sample 1, the mode parameters x_0 and w_0 were adjusted to give the curve best fitting the experimental data of Fig. 3 for λ near 0.58 μm. This curve, which was obtained with x_0 = 60 μm and w_0 = 15 μm, is shown in Fig. 3. We then used the same values of x_0 and w_0 to calculate $P_T(\lambda)$ for sample 2, again obtaining a good fit to the data, as shown in Fig. 4. This agreement is not surprising since the theoretical curves were found to be only moderately sensitive to the mode parameters over the physically reasonable range 50 μm $< x_0 <$ 75 μm and 10 μm $< w_0 <$ 20 μm. Note that P_C is an experimentally measured quantity (later, estimated for the 0.8-μm excitation), determined at a wavelength for total absorption of the pump radiation, and is not a function of λ.

The same values of x_0 and w_0 were also adopted in using (1) to predict $P_T(\lambda)$ for the Nd^{3+} absorption band peaking near 0.80 μm. The calculated curve for sample 1 is shown in Fig. 7. To obtain the value of P_C used in the calculations, 540 μW, the experimental value of 600 μW found at 0.58 μm was multiplied by 1.24 to allow for the increase in w_p [the first factor in (1)] and divided by 1.38 to allow for the decrease in energy per pump photon. For pumping at 0.80 μm, as at 0.58 μm, $P_T(\lambda)$ is relatively insensitive to the choice of laser mode parameters.

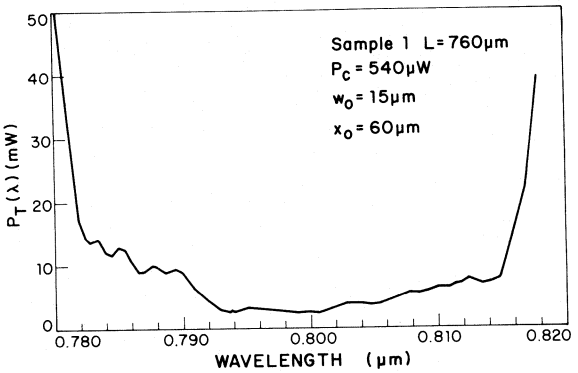

Fig. 7. Predicted transverse pump threshold $P_T(\lambda)$ versus excitation wavelength near 0.8 μm for a narrow-band source with a tightly focused beam (using sample 1).

The preceding calculations were made for a narrow-band pump. We now consider the case of wide-bandwidth pump radiation characterized by a spectral power density $\rho(\lambda)$. In a small wavelength interval $\delta\lambda$ the fraction of threshold attained will be $[\rho(\lambda)\, \delta\lambda/P_T(\lambda)]$. Therefore, the threshold condition is

$$\int \frac{\rho(\lambda)}{P_T(\lambda)}\, d\lambda = 1.$$

For simplicity we assume the pump radiation to have the normal distribution

$$\rho(\lambda) = \frac{P_\Sigma}{\Delta\lambda\sqrt{\pi}} \exp\left[-(\lambda - \lambda_0)^2/(\Delta\lambda)^2\right]$$

where

P_Σ total pump power;
λ_0 center wavelength of pump band.

The parameter $\Delta\lambda = \Delta\lambda_{1/2}/2\sqrt{\ln 2}$, where $\Delta\lambda_{1/2}$ is the full-width half-maximum (FWHM) interval. From this distribution, we find the wide-band pump power at threshold

$$P_\Sigma = \left\{ \int d\lambda \exp\left[-(\lambda - \lambda_0)^2/(\Delta\lambda)^2\right] / \left[\Delta\lambda\sqrt{\pi}\, P_T(\lambda)\right] \right\}^{-1}. \quad (2)$$

Numerical integration of (2) over the wavelength range 0.78–0.82 μm was used to compute P_Σ as a function of $\Delta\lambda_{1/2}$ as shown in Fig. 8 along with similar results for the 0.58-μm band. This plot shows that using wide-band LED's or laser diodes should not require an inordinate increase in pump power compared with a narrow-band source.

The threshold calculations in the preceding assume that the imaging geometry for the wide-band pump beam is the same as that of the dye laser. By suitable collection, collimation, and focusing optics it should be possible to achieve this type of beam geometry with narrow-junction edge-emitting laser diodes or LED's. However, it would be much simpler to place the narrow emitting junction region of the diode immediately next to or in contact with the NdPP crystal. The increase in power necessary in this configuration because of the pump beam diver-

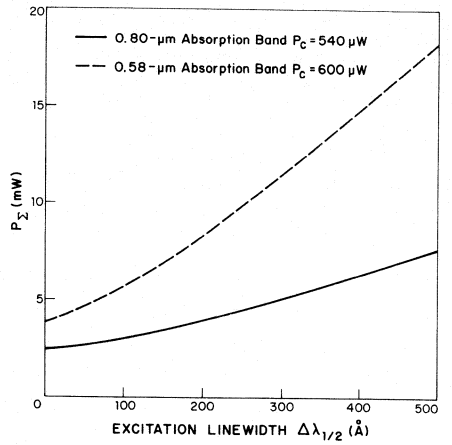

Fig. 8. Predicted transverse pump threshold P_Σ at 0.58 and 0.8 μm versus FWHM excitation bandwidth $\Delta\lambda_{1/2}$ for a tightly focused beam (using sample 1).

gence can be easily estimated by using an integration scheme [similar to the one used in deriving (1)] to evaluate the overlap along the y direction at $x = x_0$. The divergence is found to increase the threshold by the factor

$$\beta = \sqrt{1 + w_t^2(x = x_0)/w_0^2} \tag{3}$$

where $w_t(x = x_0)$ is the transverse pump beam radius along the y coordinate at the center of the NdPP laser mode. This expression confirms our earlier assumption that $\beta \simeq 1$ for diffraction-limited focusing of the dye laser beam along the y direction. For diode pumping, we take some typical parameters to estimate $w_t(x = x_0) \simeq [\lambda x_0/\pi w_t(x = 0)]$. For $\lambda = (0.8/n)$ μm = 0.5 μm (where the refractive index $n = 1.6$) and $w_t(x = 0) = 0.5$ μm, $w_t(x = x_0) \simeq x_0/3$. This calculation is approximate in that it uses simple diffraction theory to calculate the divergence from a source with height $2w_t \sim 1$ μm. This dimension is not an unreasonable estimate, either for high-radiance double-heterostructure (AlGa)As light-emitting diodes [14] (active region thickness ~2 μm, output power 3 mW for 50-μm-wide device) or for CW double-heterostructure (AlGa)As laser diodes [15] (active region thickness ~0.3 μm, output power 10 mW for 13-μm-wide device). In both cases, the output power densities should be sufficient for a small array of such narrow devices to exceed by several times our calculated thresholds. For the previous values $x_0 = 60$ μm and $w_0 = 15$ μm, (3) gives $\beta = 1.67$, a quite moderate price to pay for the convenience of this pumping configuration.

IV. Discussion

Certain refinements in the theory might give better agreement with experimental data.

1) We have implicitly assumed that the Gaussian laser mode is not truncated at the sample edge. Although this is probably a good approximation for $x_0 > 2w_0$, a condition satisfied in the present case, the truncation effect could be considered in a more exact model.

2) We have also neglected the variation of the laser mode in the z direction. Typical confocal parameter values, $(\pi w_0^2 n/\lambda) \simeq 1.2$ mm, are longer than the samples used, so that this is a good approximation, but the z variation could be taken into account.

3) Another factor which we have neglected is diffusion of the Nd^{3+} excitation. Theoretical analysis [16] shows that diffusion should be highest along the a axis; diffusion in this direction would not affect our results.

One reason for not attempting these refinements is that our experimental data are not sufficiently accurate to justify the additional mathematical complexity that would be required. Another reason is that our model may be only qualitatively correct to begin with, since it assumes excitation of the fundamental TEM_{00} mode. However, we did not observe a uniform symmetric mode unless apertures were introduced into the optical cavity. We believe that the output of this nearly unstable, almost spherical cavity is probably composed of several independent fundamental modes which are nearly collinear. Evidence for this is provided by the incoherent, rapidly fluctuating nature of the output relaxation oscillations observed with chopped excitation; in other NdPP collinearly pumped lasers, the relaxation oscillations are quite coherent and stable when care is taken to obtain a few well-defined modes. In any event, the simple model seems to provide a good, if phenomenological, fit to the data, and further sophistication in the theory is probably not warranted at present.

The results obtained for sample 3 mounted on a reflector are quite promising (Fig. 5). This sample shows a 60-percent reduction in the ratio of transverse to collinear thresholds over the thicker nonreflecting samples 1 and 2. The improved geometry also gives higher efficiency but seems to suffer more from thermal limitations on the output power at high levels. Presumably, this arises from the smaller sample volume and poorer heat dissipation, and should be reduced by establishing better thermal contact to a back reflector with increased thermal conductivity. The optical power conversion efficiency of sample 3 for excitation by a 300-Å bandwidth, 0.8-μm wavelength LED can be estimated from the efficiency of 8.5 percent measured with dye laser excitation. Dividing by a bandwidth factor of 2 (found from Fig. 8) and by the beam divergence factor $\beta = 1.67$, and multiplying by the photon energy factor 0.80 μm/0.58 μm = 1.38, we predict an efficiency ~3.5 percent.

In recent theoretical calculations, Singh *et al.* [5] claim that NdPP has no advantage over Nd:YAG for miniaturized lasers. This conclusion is reached on the basis of several factors, including the larger emission cross section [5]-[7], [9], longer fluorescent lifetime [5], [8], and smaller "resonant" loss (absorption from the thermally populated $^4I_{11/2}$ levels) in Nd:YAG. We do not disagree with their conclusion that an end- (collinearly) pumped Nd:YAG laser should have lower threshold than NdPP, although at the cost of a much longer crystal to insure efficient absorption of the pump radiation. However, we strongly disagree with their conclusions concerning side-pumped lasers. First, their own calculations [5, fig. 6] show that for "nonresonant" loss, L_0 (output coupling, scattering, etc.) exceeding 0.3 percent, NdPP has a lower threshold power density than 3-percent Nd:YAG. The differential output efficiency of the laser is inversely proportional to $[1 + L_i/$

$(\ln 1/R)]$, where L_i represents the internal part of the nonresonant loss, and R is the output mirror reflectivity (the other mirror is assumed to have $R \simeq 1$). Since in most lasers the internal loss exceeds a few tenths of a percent, one would generally desire an output transmission exceeding this loss to optimize the output power [17], and consequently would nearly always be in a regime where L_0 exceeded 0.3 percent, making NdPP the lower threshold material. Second, and perhaps more important, are the practical considerations of device size and total threshold powers (not power densities), which have been neglected by Singh *et al* [5]. The calculation in [5] for side-pumped lasers compares cases in which the excitation depth is an effective absorption length $1/\tilde{\alpha}_p$. Their value of $\tilde{\alpha}_p = 1.1$ cm^{-1} for Nd:YAG would give a laser 1 cm thick, hardly a miniaturized laser compared to 0.01-cm thickness, typical of NdPP. To be more specific, we have repeated our previous procedure, and measured the absorption coefficient of the 1-percent Nd:YAG for use in (1). After multiplying the measured α by three to apply to the case of 3-percent Nd:YAG we have calculated the ratio of transverse to collinear thresholds. Even after doubling the laser mode radius to 30 μm (compared to the NdPP results with $w_0 = 15$ μm) and placing the mode right at the edge of the crystal ($x_0 = 30$ μm) the *minimum* narrow-bandwidth threshold is 14 times higher than the collinear threshold. Increasing the bandwidth of the pump to 300 Å increases this value to 48 times the minimum narrow-band collinear threshold. The same factor for NdPP with a mode half the diameter, located 60 μm from the pump face, is only 9. Assuming that nonresonant losses dominate, one would expect nearly equal minimum collinear thresholds since the threshold power density is ~4 times lower for Nd:YAG (a factor of 2 from longer lifetime, and a factor of 2 from larger cross section), but the mode area is 4 times larger. With this choice of modes giving the same normalization factor, we find that the side-pumped NdPP threshold should be at least 5-6 times lower than for 3-percent Nd:YAG, and also enables use of a thinner device.

To verify that present NdPP crystal quality is good enough (scattering and extraneous loss much less than mirror-coupling losses) to allow a meaningful comparison with Nd:YAG for practical device applications, we have measured the differential quantum efficiency of a 1-mm-thick NdPP crystal using different output reflectors with transmission 0.3, 1.2, 2.2, and 5.7 percent. With collinear excitation, we have obtained *overall* power conversion efficiencies of 50 percent with the highest transmission mirror, and a value (corrected for sample reflectivity) of *differential* quantum efficiency $\eta \sim 95$ percent (within experimental error). Our data for η as a function of R show that $L_i \lesssim 0.3$ percent. This value is also consistent with estimates obtained from analysis of relaxation oscillations in the laser output, using chopped excitation.

A direct correspondence between our NdPP results and previous experimental work on diode-pumped Nd:YAG lasers is difficult because of the differences in laser geometries, modes, reflectivities, etc. Nevertheless, it should be useful to examine the device parameters of various diode-pumped Nd:YAG lasers to give some idea of the progress achieved in this area, and to serve as comparisons with the type of device we are considering in this paper. In Table I we summarize our experimental and predicted results along with some of the diode-pumped Nd:YAG results [18]-[24],[1] listed in approximately chronological order. These published results show the relative advantages of diode-pumped NdPP and Nd:YAG in different types of applications, which we have noted in the preceding. The most recent larger-scale (1.5-mm diameter × 30-50 mm long) Nd:YAG devices designed for maximum output power, such as those in items 9 and 10 (improved over similar, earlier versions in items 4-6) perform well in terms of power conversion efficiencies (even with a nonoptimum pump wavelength of 8680 Å for item 10). However, even after allowance for the different output couplers (i.e., 3 percent in item 10), the long absorption lengths and large volumes in these devices lead to high threshold powers. Reducing the device size would lower the threshold, but also the output power and efficiency. Such a trend is shown by the end-pumped devices of items 7 and 8. Here much smaller Nd:YAG rods (0.5-mm diameter × 6 mm long) are used, in an end-pumped geometry to allow greater pump absorption. The threshold powers are low, but the output is limited by the single end-pumping LED. Comparable thresholds should be obtainable with yet smaller, transversely pumped NdPP crystals, which would have the additional advantages of higher efficiency and larger output power obtained by using several diodes in a transverse pumping array. From our data, NdPP appears to offer the potential of performance superior to Nd:YAG for diode-pumped *miniature low-power* lasers, while for larger higher power ($\gtrsim$100-mW) devices, Nd:YAG probably will remain the better choice.

Low-threshold operation has also been demonstrated in an ion-laser excited Nd-doped silica fiber laser [25]. With a 1-cm-long 40-μm-core-diameter fiber end-pumped by an argon-ion laser emitting at 0.51 μm, a threshold of 1-2-mW absorbed power was obtained with 3-percent duty cycle. This system, like the end-pumped Nd:YAG lasers of [21] and [22], has the advantage of nearly complete absorption of the pump radiation, but requires moderately long lasers (several millimeters) and high-brightness excitation at the laser end face with area comparable to the cross section of the fiber core. Similar lasers using Nd-doped single-crystal YAG fibers have also been demonstrated [26]. The lasing parameters were close to those of the Nd:silica fiber lasers, and the same advantages and disadvantages mentioned in the preceding apply.

In order to make a more compact NdPP device the present input and output mirrors could be replaced by reflective coatings applied directly to the crystal lasing faces. A miniature cavity with smaller mode volume and better stability could be made using reflectors fabricated from coated, plane-polished

[1] We calculated the optical powers and efficiencies of [23] in Table I from the reported electrical input power by assuming 1-percent efficiency for the LED's, a conservative estimate. The actual thresholds were probably higher, and the efficiencies lower, than those listed.

TABLE I
COMPARISON OF NDPP LASERS AND DIODE-PUMPED ND:YAG LASERS

Laser Material	Ref.	Configuration	Pump	Temperature (K)	Duty Cycle and/or Pulse Duration	Optical Threshold Power (mW)	Optical Power Conversion Efficiency (%)
(1) NdPP	a	Side-pumped, nearly spherical external cavity; 0.3% output mirror	0.58 μm cw dye laser	300	20% (1 ms) cw	4 4	8.0 3.5
(2) NdPP	a	Same as (1), but with added pump reflector	Same as (1)	300	20%	2.7	8.5
(3) NdPP (calculated)	a	Same as (1)	Single 0.8 μm, 300Å bandwidth, edge-emitting LED	300	~20%	8.5 (calculated)	3.5 (calculated)
(4) Nd:YAG (1.5%)	18	Side-pumped cylindrical rod; external mirrors, 0.5% output; pump reflector	$GaAs_{1-x}P_x$ LED array	77	cw	~30	5
(5) Nd:YAG (1.5%)	19	Side-pumped cylindrical rod; polished mirrors, 0.4% output; elliptical pump reflector	$GaAs_{1-x}P_x$ LED array	270 150	cw cw	300 75	-- --
(6) Nd:YAG (1%)	20	Same as (5)	$GaAs_{0.85}P_{0.15}$ LED array	273 293	1 ms 1 ms	550 650	3.5 0.95
(7) Nd:YAG (1%)	21	End-pumped cylindrical rod; polished mirrors, HR output reflector	Single dome $GaAs_{1-x}P_x$ LED	300	2% (2 ms)	19	--
(8) Nd:YAG (1%)	22	Same as (7)	Same as (7)	88 300	2% (2ms) 98% (98ms)	6.2 6.2 19 (calculated)	0.2 0.09
(9) Nd:YAG (1%)	23	Side-pumped cylindrical rod; polished mirrors, 0.2% output; pump reflector with index-matching cylinder	$Ga_xAl_{1-x}As$ LED array	273	1% (500 μs) cw	~200 ~150	~7.5 ~5.5
(10) Nd:YAG	24	Side-pumped cylindrical rod; polished mirrors, 3% output; pump reflector	GaAs laser diode array	175	1.75% (500 ns)	1000	5.5

[a]Present work.

graded-index rods which simulate spherical mirrors [27]. Using a semiconfocal resonator should give optimum mode volume, stability, and ease of alignment. Since we have demonstrated the feasibility of efficient transverse pumping of NdPP platelets 36 μm thick, resembling thin-film or waveguide lasers, techniques such as distributed feedback might be considered for making an optical resonator compatible with planar, integrated optical circuits. The problems of NdPP crystal growth and device fabrication techniques still deserve much attention, but in view of the short time that this material has been studied for laser applications, present results are quite promising. Our present growth technique has yielded striation-free single domain perfect crystals up to 1 mm × 1 mm × 4 mm in size (this sample was used for the efficiency and loss measurements described in the preceding. The only polishing we have carried out has been for reducing the sample thickness in a side-pumped sample, with no degradation of the perpendicular lasing facets. Introduction of differently oriented domains [6], [28] can be a problem in polishing, but if no permanent defects are introduced, the domain walls should be removable by application of stress and/or heating above the monoclinic-orthorhombic phase transition temperature, 115°C [29]. Epitaxial growth of NdPP will probably be quite difficult, since few materials (except other pentaphosphates) can withstand the hot phosphoric acid growth melt. Nevertheless, NdPP lasers may still find applications in integrated optical circuits as thin hybrid elements added to a monolithic circuit containing other components, including diode excitation sources. Whether integrated or not, such small, efficient lasers should be useful as sources in fiber-optic communication systems and other areas requiring low-power lasers having mode quality and spectral output better than presently available semiconductor lasers. As past work has demonstrated [5], [30], (NdLa)PP may also offer many of the advantages of pure NdPP. With (NdLa)PP, a compromise between improved lifetime and lower resonant loss versus larger device size could be reached, depending on the particular desired properties and intended application.

In summary, we have obtained low-threshold operation of NdPP lasers transversely pumped at 0.58-μm wavelength with a CW dye laser. From a theoretical analysis of the data for threshold as a function of wavelength, we conclude that low-threshold operation at room temperature should also be possible with 0.8-μm excitation. For our example, a crystal 760 μm long (using 0.3-percent output mirror transmission), we predict quasi-CW transverse excitation thresholds at 0.8 μm of 4.4 mW and 8.5 mW, respectively, for 30-Å bandwidth (laser diode) and 300-Å bandwidth (LED) pumps in a very convenient, contact configuration. If quasi-CW sources are not available, short-pulsed sources having these average powers

should also be suitable. Using thin samples with back reflectors should lower these thresholds by ~60 percent. For designs with good heat-sinking, CW optical conversion efficiencies better than 3.5 percent should be possible with 0.8-μm 300-Å bandwidth excitation.

Acknowledgment

The authors wish to thank E. J. Delaney for assisting with the NdPP crystal growth, P. Moulton for help with the optical absorption measurements, and T. Lind for expert sample polishing. They also wish to thank A. J. Strauss for helpful comments and suggestions in preparing this paper.

Critically Index-Matched Second-Harmonic Generation in Multiple Crystals

F. M. LIBRECHT, STUDENT MEMBER, IEEE, AND G. E. FRANÇOIS

Abstract—A new method is presented for reducing the conversion-limiting effects of crystal anisotropy in critically index-matched second-harmonic generation (SHG). A number of crystals are put in series; adjacent crystals are oriented in such a way that their walkoff effects are opposite one another. The harmonic field and the harmonic power of a compensated two-crystal generator are calculated. Numerically computed curves show the dependence of the SH power on the mismatching of the crystals and on the focusing of a TEM_{00} laser beam. Theoretically predicted results are confirmed by experiment. As a typical result, the conversion efficiency of a compensated ADP generator (2 crystals, 1 cm each, in series) at optimum focusing is about twice the efficiency obtained with a single crystal of the same total length (2 cm, single crystal).

I. Introduction

THE second-harmonic generation (SHG) of coherent light in uniaxial nonlinear crystals has been studied extensively. Boyd and Kleinman [1] pointed out that the maximum conversion efficiency occurs when the angle of double refraction is zero. This condition is met by temperature tuning and occurs when the harmonic beam index matches the fundamental beam at 90° to the optic axis [2]. Commonly referred to as noncritical index matching, this type of matching is generally preferred to the critical index matching (angle tuning) for its higher harmonic conversion efficiency. Due to the thermal properties of the nonlinear material, there is for each type of harmonic generator a limited range of wavelengths that can be covered by temperature tuning. Outside of this range a critical matching technique with its lower conversion efficiency is required.

In this paper we show that the limitation of the conversion efficiency in critical index matching can be reduced by putting a number of crystals in series. Each crystal is critically index matched; any two adjacent crystals are oriented in such a way that their walkoff effects are opposite one another. Crystals in series were used in previous SHG studies [3]-[6], but never for the purpose of compensating for the walkoff effect at critical index matching.

In the following paragraphs we calculate the harmonic field and the harmonic power of a two-crystal harmonic generator put in the focus of a TEM_{00} laser beam. The crystals are assumed to belong to the XDP group; the calculations, however, can be adapted easily for other crystal classes. Theoretically predicted results on the effects of mismatching in the crystals and on the effects of focusing of the laser beam are confirmed by experiment.

II. Harmonic Field and Harmonic Power of a Two-Crystal Harmonic Generator

Consider two ADP crystals of length $l/2$ in the focus of a Gaussian laser beam in the TEM_{00} mode (Fig. 1). The fundamental beam diameter at the beam waist is $2w_0$ ($1/e^2$ surface). The fundamental beam at frequency ω (wavelength = 632.8 nm) is introduced in each crystal as an ordinary wave index matched to the extraordinary second-harmonic wave (Type 1 index matching [7]). The input and output faces of each crystal are parallel. They are cut so that at approximately normal incidence the laser beam passes through the crystal in the critical index-matching direction z at an angle θ_m to the optic axis. The optic axis lies in the xz-plane. ρ is the angle of double refraction. The crystals are oriented in such a way that their walkoff effects are opposite one another. The origin $x = y = z = 0$ of the right-hand xyz-reference system is in the center of the nonlinear material. The medium surrounding the crystals is supposed to have the same refractive index as the crystal index at critical matching. Throughout the calculations we neglect the weak absorption at the fundamental and harmonic frequencies. We also neglect the depletion of the fundamental beam by the doubling process.

The description of the laser beam focused inside the harmonic generator is a straightforward problem since the beam is an ordinary wave and the crystal appears to it as an isotropic medium. We use Fourier analysis to decompose the fundamental beam into a sum of plane waves. The harmonic field generated in the first crystal is obtained from a well-known formal approach outlined by Boyd *et al.* [8] and applied by Bjorkholm [9]. This field propagates in the second crystal as an extraordinary wave. We assume that this extraordinary wave does not affect the harmonic generating process in the second crystal. So once more we use the formal theory of [9] to calculate the harmonic field generated in this second crystal.

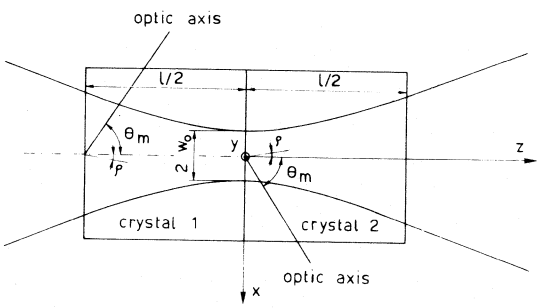

Fig. 1. Orientation of the ADP crystals of a compensated two-crystal harmonic generator in the focus of a TEM_{00} laser beam (wavelength = 632.8 nm). θ_m is the index-matching angle; ρ is the angle of double refraction.

The total harmonic field of the two-crystal generator is obtained by summing the harmonic contributions of the two crystals at the exit face of the second crystal. These harmonic contributions are individually described by an expression similar to [9, eq. (27)]. When the two crystals are tilted away from the index-matching direction by an angle Φ, Φ', respectively, we account for this by introducing additional mismatch terms (as defined in [9, eq. (54)]). Eventually, the total harmonic field at the exit face of the second crystal is written as follows:

$$E_{2\omega}(x, y, z = l/2) = E_{2\omega} \exp(ikl) \frac{\xi}{1 + i\xi} (I_p + I_q) \tag{1}$$

where

$$\xi = \frac{l}{b} \tag{2}$$

with b the confocal parameter ($b = kw_0^2$). The constant $E_{2\omega}$ has been defined by Bjorkholm [9]. It depends on the parameters of both the crystal and the laser beam. k is the propagation constant of the fundamental beam. I_p and I_q are integral expressions related to [9, eq. (27)]. They give the harmonic contributions at $z = l/2$ of the first and the second crystal, respectively.

$$I_p = \exp(-ik\rho\Phi' l) \cdot \int_0^1 \frac{\exp(-ipk\rho\Phi l) \exp\left[\dfrac{-2k[y^2 + (x - p\rho l/2 + \rho l/2)^2]}{b(1 + i\xi)}\right]}{-ipl/2 + b/2} dp \tag{3}$$

$$I_q = \int_0^1 \frac{\exp(-iqk\rho\Phi' l) \exp\left[\dfrac{-2k[y^2 + (x + q\rho l/2)^2]}{b(1 + i\xi)}\right]}{-iql/2 + b/2 + il/2} dq. \tag{4}$$

The difference between (3) and (4) arises from the fact that the harmonic contribution of the first crystal propagates in the second one as an extraordinary wave. The signs in front of the terms $pp l/2$ and $q\rho l/2$ in the second exponent of the integrands of (3) and (4), respectively, are determined by the orientation of the crystal optic axis with respect to the reference system. As the crystals are oriented in such a way that their walkoff effects are opposite (Fig. 1), the signs in front of the terms $pp l/2$ and $q\rho l/2$ are opposite too. The phase factor in front of the integral in (3) is a result of the mismatch Φ' in the second crystal.

Evaluating the harmonic field (1) in the far field outside the harmonic generator, greatly simplifies the calculation of the SH power $P_{2\omega}$, [1]. According to [1, eq. (2.13)], we transform the x- and y-coordinates into the variables s and s', and we define a parameter β. The SH power then reads

$$P_{2\omega} = KP_\omega^2 \frac{l^2\pi^2}{w_0^2\xi^2} F(\Phi, \Phi', \beta, \xi) \tag{5}$$

where

$$F(\Phi, \Phi', \beta, \xi) = \frac{2}{\pi^{1/2}} \int_{-\infty}^{+\infty} \exp(-4s^2) |H(s, \Phi, \Phi', \beta, \xi)|^2 \, ds \tag{6}$$

and

$$H(s, \Phi, \Phi', \beta, \xi) = \frac{\xi}{2\pi}\left[\int_0^1 \frac{\exp(-ik\rho\Phi lp) \exp(-4i\beta s\xi p)}{1 - i\xi p} dp + \int_0^1 \frac{\exp[-ik\rho\Phi' l(1 - q)] \exp[-4i\beta s\xi(1 - q)]}{1 + i\xi(1 - q)} dq\right]. \tag{7}$$

The definitions of H, K, and F are essentially the same as those given by [1, eqs. (2.16), (2.20), and (2.24)]. P_ω is the power at the fundamental frequency. From (5)-(7), and after integration with respect to s, the harmonic power can be written as a sum of four double integrations, each of them in a form like [9, eq. (32)] or [1, eq. (2.25)].

III. Theoretical and Experimental Study of the Harmonic Power as a Function of the Mismatching in the Crystals

In the weak focusing limit ($\xi << 1$), we have calculated $\pi^2 F(\Phi, \Phi', \beta, \xi)/\xi^2$ from (5) numerically as a function of the mismatch X_2 ($X_2 = k\rho l\Phi'$) in the second crystal at different values of the mismatch X_1 ($X_1 = k\rho l\Phi$) in the first crystal.

We have used Gaussian-Hermite quadrature formulas [10]. The results for $X_1 = 0$ and $X_1 = 1$ are given in Fig. 2. The maximum conversion efficiency occurs at nominal index matching ($X_1 = X_2 = 0$) in both crystals. The curve for $X_1 = 0$ is fully symmetric. A mismatch ($X_1 = 1$) in the first crystal

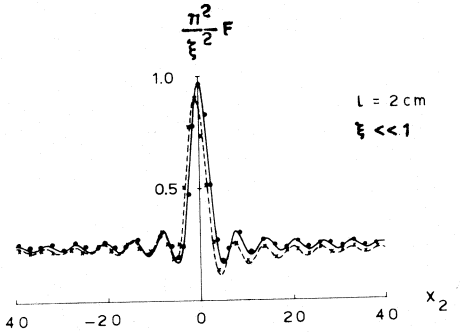

Fig. 2. Theoretical curves and experimental values of the SHG factor $\pi^2 F/\xi^2$, (5) in the weak focusing limit ($\xi << 1$, (2)) as a function of the mismatch X_2 in the second crystal at a given value of the mismatch X_1 in the first crystal: $X_1 = 0$, (solid line, dots); $X_1 = 1$, (dashed line, crosses). Total length l of nonlinear material: 2 cm.

results in an asymmetric curve and in a decrease of the maximum conversion efficiency.

In the experimental setup the first crystal is mounted in a gimbal; the second sits on a motor-driven rotating disk. An adjustable air gap remains between the crystals. Each crystal can be angle-tuned independently. Moreover, both crystals are provided with gold electrodes to fine tune the index-matching condition by means of the electrooptic effect.

The reflection and refraction effects at the crystal surfaces and the dispersion in the air gap between the crystals affect the expressions (5)-(7). Due to the air dispersion, a phase shift builds up between the harmonic wave and the square of the fundamental wave giving rise to a phase factor in front of the first integration of (7). In the weak focusing limit ($\xi \ll 1$), we have mounted the crystals at about 26 mm of each other to obtain a 2π phase shift, as can be derived from air refractive-index data [11]. On the other hand, tedious but straightforward calculations reveal that the reflection and refraction effects at the crystal surfaces do not affect the shape of the harmonic curve. Fig. 2 shows a close agreement between the experimental results and the theoretically predicted curves. The peak power in the experiment was arbitrarily taken to coincide with the theoretical peak.

At the point $\xi = 1$ (nearly optimal focusing) we have calculated the same curve: $\pi^2 F(\Phi, \Phi', \beta, \xi)/\xi^2$ as a function of the mismatch X_2 ($X_2 = k\rho l\Phi'$) in the second crystal. We have used an algorithm for automatic integration, based on the Gaussian and Kronrod quadrature formulas [12]. The results are given in Fig. 3. At nominal matching in the first crystal ($X_1 = 0$), the maximum efficiency occurs at a slight mismatch in the second crystal. A mismatch in the first crystal ($X_1 = 1$) shifts the maximum to other X_2 values. The amplitude of this maximum, however, does not change.

In the experimental setup the separation between the crystals is about 1 mm, resulting in a phase shift of $\pi/12$ between the harmonic wave and the square of the fundamental wave. As can be calculated from (5)-(7) this phase shift gives rise to a negligible additional asymmetry in the harmonic curve. The experimental results for $X_1 = 0$ are also shown in Fig. 3. Some quantitatively measurable features such as the peak width at half height and the ratio of the peak value to the value at X_2 values in excess of 30 are in good agreement. The overall agreement in the structure of the side maxima, however, is rather poor.

IV. Theoretical and Experimental Study of the Harmonic Power as a Function of the Focusing of the Laser Beam

We have calculated asymptotic and exact values of the harmonic power as a function of the focusing of the laser beam. The asymptotic values are listed in Table I. For comparison, the asymptotic values of a single crystal are listed in the same table.

In Fig. 4 the asymptotic solutions for a compensated two-crystal generator (2 ADP crystals, 1 cm each, in series) and for a single crystal (ADP, 2 cm) are shown on a log-log plot. This same figure also shows exact curves of the relative harmonic power $P_{2\omega}/KP_\omega^2$ calculated by Gaussian-Kronrod quadrature formulas [12]. At nearly optimal focusing, the conversion efficiency of a compensated two-crystal generator is about

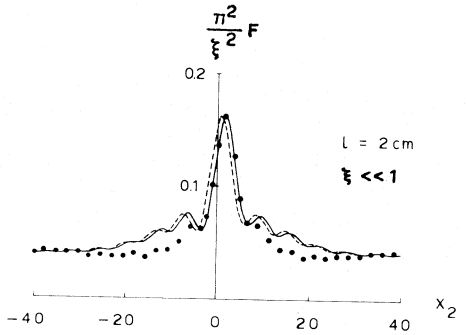

Fig. 3. Theoretical curves of the SHG factor $\pi^2 F/\xi^2$, (5) at nearly optimal focusing ($\xi = 1$, (2)) as a function of the mismatch X_2 in the second crystal at a given value of the mismatch X_1 in the first crystal: $X_1 = 0$, (solid line); $X_1 = 1$, (dashed line). Experimental results for $X_1 = 0$ are given by dots. Total length l of nonlinear material: 2 cm.

Harmonic Power of a Compensated Two-Crystal Harmonic Generator and of a Single Crystal of the Same Total Length

	Compensated Two-Crystal Generator	Single Crystal [1], [9]
$\xi \ll 1$ $\beta\xi \ll 1$	$P_{2\omega} = KP_\omega^2 (l^2/w_0^2)$	$P_{2\omega} = KP_\omega^2 (l^2/w_0^2)$
$\xi \ll 1$ $\beta\xi \gg 1$	$P_{2\omega} = KP_\omega^2 (l^2\pi^{1/2}/w_0^2\beta\xi)$	$P_{2\omega} = KP_\omega^2 (l^2\pi^{1/2}/2w_0^2\beta\xi)$
$\xi \gg 1$ $\beta \gg 1$	$P_{2\omega} = KP_\omega^2 [(1 + 2e^{-1}) l^2\pi^{3/2}/4w_0^2\beta\xi^2]$	$P_{2\omega} = KP_\omega^2 (l^2\pi^{3/2}/4w_0^2\beta\xi^2)$

Note: Asymptotic values.

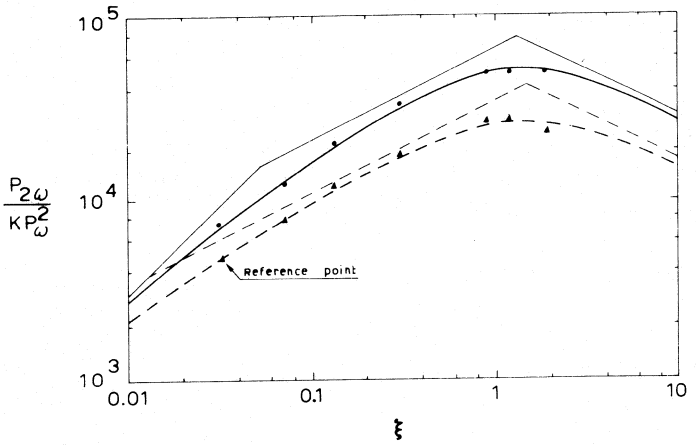

Fig. 4. Harmonic power as a function of focusing. Asymptotic and exact curves. Solid lines: 2 ADP crystals of 1 cm each in a compensated setup. Dashed lines: single ADP crystal of 2 cm. Dots: experimental values for a compensated, two-crystal generator (2 × 1 cm). Triangles: experimental values for a single crystal (1 × 2 cm). The reference point shown was chosen to coincide with the corresponding theoretical curve.

twice the efficiency obtained with a single crystal of the same total length.

The experimental results shown in Fig. 4 were obtained with an air gap in between the crystals of only 0.5 mm. The resulting phase shift of the harmonic wave with respect to the square of the fundamental wave was neglected. We have used a set of achromatic compound lenses ranging in focal length from 80 to 600 mm to vary the focusing parameter ξ. The power level at weak focusing ($\xi = 0.032$) in a single crystal was taken as a reference.

V. Multiple-Crystal Harmonic Generator

Increasing the number of crystals in a compensated arrangement, while keeping the total length of the harmonic generator constant, will further increase the peak doubling efficiency, as long as each crystal exceeds greatly the critical double-refraction length l_b, defined in [9, eq. (48)]. When the number of crystals increases to the point where each individual crystal is equal to or shorter than l_b, the doubling efficiency reaches a limit. This limit will take on the same value as for the noncritical index matching.

VI. Summary

In this paper, we have proposed a new method for reducing the conversion-limiting effects of crystal anisotropy in critically index-matched SHG by putting a number of crystals in series. Adjacent crystals have been oriented in such a way that their walkoff effects were opposite one another. The theoretically predicted doubling properties of a compensated two-crystal generator have been confirmed by experiment.

Electrooptic Coupling Between TE and TM Modes in Anisotropic Slabs

D. MARCUSE, FELLOW, IEEE

Abstract—**In an electrooptic crystal TE and TM modes can be coupled by application of a modulation voltage. Two types of modulators using anisotropic crystals are discussed. In the first type a voltage that is constant along the direction of wave propagation couples a guided mode to a radiation mode of the orthogonal polarization so that the radiation loss of the guided mode can be controlled by the applied voltage. The modulator of the second type uses voltage-controlled coupling between guided TE and TM modes. The computation of the coupling coefficients is outlined and numerical examples are plotted for $LiNbO_3$ and $LiTaO_3$ crystals.**

Introduction

CERTAIN electrooptic crystals are suitable for the fabrication of thin-film waveguides by diffusion methods [1]-[3]. Thin-film waveguides have been made by out-diffusion [1] as well as by in-diffusion [2], [3] of metal ions in $LiNbO_3$ and $LiTaO_3$. These crystals do not only have large electrooptic coefficients but they also are anisotropic. This anisotropy can be utilized to achieve phase matching between two modes coupled by the electrooptic effect without the need for imposing a periodicity on the coupling process. For example, it is possible to couple a guided TM mode to a TE radiation mode in $LiNbO_3$. The refractive indices of this material are for the ordinary index at $\lambda = 0.6328\ \mu m$ [4]

$$n_{o2} = 2.28 \tag{1}$$

and for the extraordinary index

$$n_{e2} = 2.17. \tag{2}$$

It has been demonstrated that doping may increase these indices to the following larger values in the guiding layer [1]:

$$n_{o1} = 2.29 \tag{3}$$

and

$$n_{e1} = 2.21. \tag{4}$$

Fig. 1 shows the possible values of the propagation constants β of the guided and radiation modes if the optical axis of the crystal is directed normal to its surface. The guided modes, one of which is indicated schematically in Fig. 1, have propagation constants whose values are bracketed by the plane-wave propagation constant $n_2 k$ of the substrate and the plane-wave propagation constant $n_1 k$ of the guiding layer. The radiation modes have propagation constants that are less than $n_2 k$ [5], [6]. If the guided TM mode is coupled to TE modes without the use of a periodic structure, phase matching requires that

Manuscript received February 4, 1975.
The author is with Bell Laboratories, Crawford Hill Laboratory, Holmdel, N.J. 07733.

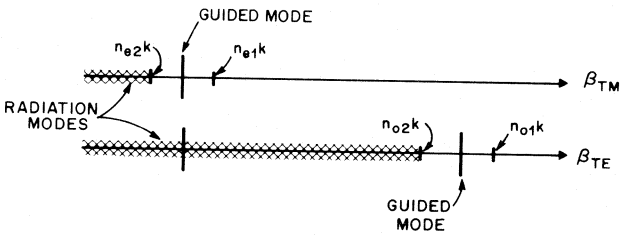

Fig. 1. This diagram shows the ranges of guided and radiation modes for TE and TM polarization for the case of $LiNbO_3$.

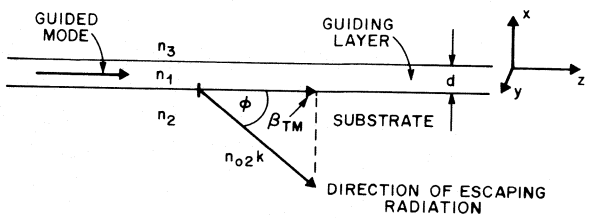

Fig. 2. Schematic of the asymmetric slab waveguide showing the angle at which radiation escapes into the substrate.

such coupling can occur only to a TE radiation mode whose propagation constant equals that of the guided TM mode. The angle at which the resulting radiation escapes into the substrate is given by [5], [6]

$$\cos\phi = \frac{\beta}{n_{o2}k} \tag{5}$$

with $\beta = \beta_{TM}$ as shown in Fig. 2. Coupling between the guided TM and TE radiation modes is caused by a change in the refractive index tensor induced by a dc electric field.

Coupling between a guided TM and guided TE mode is possible if the coupling coefficient is a periodic function whose periodicity, with spatial frequency θ, satisfies the relation [5], [6]

$$\theta = \beta_{TE} - \beta_{TM}. \tag{6}$$

In $LiTaO_3$ the situation is reversed because in this crystal the extraordinary refractive index n_e is larger than the ordinary index n_o

$$n_{o2} = 2.183$$

and

$$n_{e2} = 2.188. \tag{7a}$$

Doping may increase these indices to the following values in the guiding layer:

$$n_{o1} = 2.193$$

and

$$n_{e1} = 2.198. \tag{7b}$$

Fig. 3 shows a schematic diagram for this case. It is again assumed that the optical axis of the crystal is directed normal to its surface. Because the TE mode "senses" the ordinary refractive index the propagation constant of a guided TE mode can be matched to a TM radiation mode if

$$\beta_{TE} < n_{e2}k. \tag{8}$$

The radiation angle in the substrate is determined by the direction of power flow

$$\cos\phi = \frac{\beta}{(n_{e2}/n_{o2})\{n_{e2}^2k^2 + [(n_{o2}^2/n_{e2}^2) - 1]\,\beta^2\}^{1/2}} \tag{9}$$

with $\beta = \beta_{TE}$. The direction of power flow is not exactly perpendicular to the phase fronts for TM modes in this anisotropic crystal. The angle of escaping radiation is much smaller for the $LiTaO_3$ case. Coupling between guided TE and guided TM modes requires a periodic coupling process since an accidental overlap of a TE mode and a TM mode would involve modes of different symmetry whose coupling efficiency would be small. However, the period of the periodic coupling process can be much larger than in $LiNbO_3$ which is advantageous for the fabrication of electrodes.

The principal objective of this paper is the derivation of coupling coefficients for electrooptic coupling between TE and TM modes of anisotropic slab waveguides. These coupling coefficients are used to estimate the coupling efficiency for guided mode coupling to radiation into the substrate of the crystal and for the power exchange between guided modes. The field expressions for TE modes are the same as those of isotropic waveguides if the optical axis of the crystal is oriented perpendicular to the surface of the crystal. However, TM modes are different from those of isotropic guides. Expressions for the guided and radiation modes of TM polarization are presented.

Modes of the Anisotropic Slab

We consider a slab waveguide consisting of a thin film on a substrate. This waveguide is used as a model for integrated optics guides produced by diffusion of dopants into anisotropic crystals. The refractive index distributions of diffused guides do not have the step profile assumed here for simplicity. However, the asymmetric slab guide with piecewise constant discontinuous index distribution may be regarded as a reasonable first approximation to the more complicated graded index slabs.

Further, we assume throughout this paper that the optical axis of the uniaxial anisotropic crystal is oriented perpendicular to the guiding layer. The ordinary refractive index is "sensed" by electric-field components perpendicular to the optical axis. This means that electric-field components in the plane of the film are affected by the ordinary refractive index. The extraordinary refractive index, on the other hand, affects electric-field components parallel to the optical axis or, in our case, perpendicular to the plane of the film. TE modes in slab waveguides have only one electric-field component in the plane of the film perpendicular to their direction of propagation. TE modes are thus only affected by the ordinary refractive index and have the same field expressions as TE modes in isotropic slab waveguides. TM modes have electric-field components in the plane of the film and perpendicular to it. These fields are affected by the ordinary as well as the extraordinary refractive indices and are thus different from TM modes in isotropic slabs.

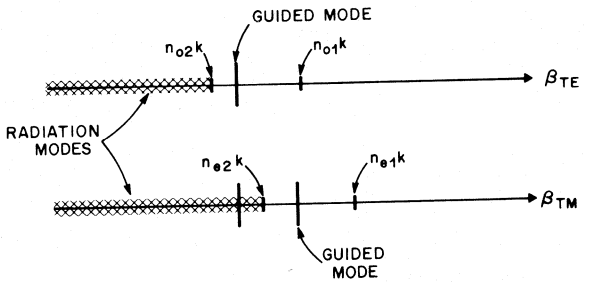

Fig. 3. This figure is similar to Fig. 1 but applies to the $LiTaO_3$ case.

The TE modes of the slab waveguide are well known [6]. Their H_x and H_z components are obtained from the E_y component by differentiation (the orientation of the coordinate system is shown in Fig. 2)

$$H_x = \frac{-i}{\omega\mu_0}\frac{\partial E_y}{\partial z} = \frac{-\beta}{\omega\mu_0}E_y \tag{10}$$

and

$$H_z = \frac{i}{\omega\mu_0}\frac{\partial E_y}{\partial x}. \tag{11}$$

The time dependence of the fields is assumed to be given by the function

$$\exp(i\omega t) \tag{12}$$

and μ_0 is the magnetic permeability of vacuum.

The E_y component of guided TE modes has the form

$$E_y = \begin{cases} A_g \exp(-\delta_e x), & \text{for } x \geqslant 0 \\ A_g\left(\cos\kappa_e x - \dfrac{\delta_e}{\kappa_e}\sin\kappa_e x\right), & \text{for } 0 \geqslant x \geqslant -d \\ A_g\left(\cos\kappa_e d + \dfrac{\delta_e}{\kappa_e}\sin\kappa_e d\right)\exp[\gamma_e(x+d)], & \text{for } x \leqslant -d. \end{cases} \tag{13}$$

The factor

$$\exp[i(\omega t - \beta z)] \tag{14}$$

($\beta = \beta_g$ for guided modes) is omitted from all the field equations for simplicity. The parameters appearing in (13) are defined as follows:

$$\kappa_e = (n_{o1}^2k^2 - \beta_{ge}^2)^{1/2} \tag{15}$$

$$\gamma_e = (\beta_{ge}^2 - n_{o2}^2k^2)^{1/2} \tag{16}$$

and

$$\delta_e = (\beta_{ge}^2 - n_{o3}^2k^2)^{1/2} \tag{17}$$

with

$$k = \omega\sqrt{\epsilon_0\mu_0} \tag{18}$$

(ϵ_0 is the dielectric permittivity of vacuum). The parameters (15)-(17) are not independent but must obey the eigenvalue equation

$$\tan \kappa_e d = \frac{\kappa_e(\gamma_e + \delta_e)}{\kappa_e^2 - \gamma_e\delta_e} \tag{19}$$

(d = film thickness). The mode fields are normalized with respect to a power parameter P that is chosen to be the same for all modes

$$A_g = \left\{\frac{4\omega\mu_0\kappa_e^2 P}{|\beta_{ge}|\left(d + \frac{1}{\gamma_e} + \frac{1}{\delta_e}\right)(\kappa_e^2 + \delta_e^2)}\right\}^{1/2}. \tag{20}$$

There are two types of radiation modes [6]. Modes of the first type show a standing-wave pattern in the substrate but have an exponential field decay in the region above the film provided we assume

$$n_{o1} > n_{o2} > n_{o3}. \tag{21}$$

These are the radiation modes of interest to us. There are modes of the second kind that have standing-wave patterns in the substrate as well as in the space above the film. The propagation constants of the modes of the second type obey the inequality

$$|\beta| < n_{o3}k. \tag{22}$$

These modes cannot be excited by constant electrooptic coupling since the phase-matching condition (6) requires a periodicity of the coupling process to couple guided modes to radiation modes in the range (22). Consequently, we limit our attention to radiation modes of the first kind whose propagation constants form a continuum in the range

$$n_3k < \beta < n_2k. \tag{23}$$

The E_y component of these radiation modes is given by

$$E_y = \begin{cases} A_r \exp(-\Delta_e x), & \text{for } x \geq 0 \\ A_r\left(\cos\sigma_e x - \frac{\Delta_e}{\sigma_e}\sin\sigma_e x\right), & \text{for } 0 \geq x \geq -d \\ A_r\left[\left(\cos\sigma_e d + \frac{\Delta_e}{\sigma_e}\sin\sigma_e d\right)\cos\rho_e(x+d)\right. & \\ \left. + \frac{\sigma_e}{\rho_e}\left(\sin\sigma_e d - \frac{\Delta_e}{\sigma_e}\cos\sigma_e d\right)\sin\rho_e(x+d)\right], & \\ \text{for } x \leq -d. & \end{cases} \tag{24}$$

The parameters are defined as follows:

$$\sigma_e = (n_{o1}^2k^2 - \beta^2)^{1/2} \tag{25}$$

$$\rho_e = (n_{o2}^2k^2 - \beta^2)^{1/2} \tag{26}$$

$$\Delta_e = (\beta^2 - n_{o3}^2k^2)^{1/2}. \tag{27}$$

There is no restriction on the allowed values of β except for the inequality (23). The amplitude coefficient is related to the power normalizing factor by the equation

$$A_r = \left\{\frac{4\omega\mu_0\rho_e^2\sigma_e^2 P}{\pi\beta[\rho_e^2(\sigma_e\cos\sigma_e d + \Delta_e\sin\sigma_e d)^2 + \sigma_e^2(\sigma_e\sin\sigma_e d - \Delta_e\cos\sigma_e d)^2]}\right\}^{1/2} \tag{28}$$

The power normalization factor P has a different physical interpretation for guided and for radiation modes. For guided modes P represents the power actually carried by the mode (24). The power carried by one individual radiation mode is infinite. For radiation modes P is a factor (with the dimension of power) that multiplies the δ-function in the orthogonality relation of these modes [6].

As already mentioned, the field expressions for TM modes of anisotropic slabs are different from those of isotropic waveguides [7], [8]. The derivation is straightforward and leads to the results quoted in the following. Assuming, as always in the case of slabs, that there is no variation in the y direction we obtain the field components E_x and E_z from

$$E_x = \frac{\beta}{n_e^2\omega\epsilon_0}H_y \tag{29}$$

and

$$E_z = \frac{i}{n_o^2\omega\epsilon_0}\frac{\partial H_y}{\partial x}. \tag{30}$$

The H_y component must be a solution of the reduced wave equation

$$\frac{\partial^2 H_y}{\partial x^2} + \frac{n_o^2}{n_e^2}(n_e^2k^2 - \beta^2)H_y = 0. \tag{31}$$

The guided TM modes are now obtained from the following solution for the H_y component:

$$H_y = \begin{cases} B_g\exp(-\delta_m x), & \text{for } x \geq 0 \\ B_g\left(\cos\kappa_m x - n_{o1}^2\frac{\delta_m}{\kappa_m}\sin\kappa_m x\right), & \\ & \text{for } 0 \geq x \geq -d \\ B_g\left(\cos\kappa_m d + n_{o1}^2\frac{\delta_m}{\kappa_m}\sin\kappa_m d\right)\exp[\gamma_m(x+d)], & \\ & \text{for } x \leq -d \end{cases} \tag{32}$$

with

$$\kappa_m = \frac{n_{o1}}{n_{e1}}(n_{e1}^2k^2 - \beta_{gm}^2)^{1/2} \tag{33}$$

$$\gamma_m = \frac{n_{o2}}{n_{e2}}(\beta_{gm}^2 - n_{e2}^2k^2)^{1/2} \tag{34}$$

and

$$\delta_m = (\beta_{gm}^2 - k^2)^{1/2}. \tag{35}$$

It was assumed that the region above the film is air with $n_{o3} = n_{e3} = 1$. In the case where the region above the film is not air we can easily obtain the generalization for an isotropic medium by replacing k with $n_3 k$ and by replacing all refractive indices by the ratios n/n_3.

The tangential field components H_y and E_z must remain continuous at the dielectric interfaces at $x = 0$ and $x = -d$. These boundary conditions lead to the eigenvalue equation

$$\tan \kappa_m d = \frac{n_{o1}^2 \kappa_m (\gamma_m + n_{o2}^2 \delta_m)}{n_{o2}^2 \kappa^2 - n_{o1}^4 \gamma_m \delta_m}. \tag{36}$$

The power carried by the mode (per unit length in y direction) is given by the general expression

$$P = \frac{1}{2} \operatorname{Re} \int_{-\infty}^{\infty} (\boldsymbol{E} \times \boldsymbol{H}^*)_z \, dx = \frac{1}{2} \frac{\beta_{gm}}{\omega \epsilon_0} \int_{-\infty}^{\infty} \frac{1}{n_e^2} |H_y|^2 \, dx. \tag{37}$$

This equation is used to express the mode amplitude B_g in terms of P

$$B_g = \left\{ \frac{4\omega\epsilon_0 P}{\beta_{gm}} \frac{n_{e1}^2 \kappa_m^2}{\kappa_m^2 + n_{o1}^4 \delta_m^2} \cdot \left[d + \frac{n_{o2}^2}{\gamma_m} \frac{n_{o2}^2 (n_{e1}^2/n_{e2}^2) \kappa_m^2 + n_{o1}^2 \gamma_m^2}{n_{o2}^4 \kappa_m^2 + n_{o1}^4 \gamma_m^2} + \frac{1}{\delta_m} \frac{n_{e1}^2 \kappa_m^2 + n_{o1}^2 \delta_m^2}{\kappa_m^2 + n_{o1}^4 \delta_m^2} \right]^{-1} \right\}^{1/2}. \tag{38}$$

For the reasons explained in the preceding we need only the TM radiation modes of the first kind. Their electric-field components are derived from (29), (30), and from the H_y component

$$H_y = \begin{cases} B_r \exp(-\Delta_m x), & \text{for } x \geq 0 \\ B_r \left(\cos \sigma_m x - n_{o1}^2 \frac{\Delta_m}{\sigma_m} \sin \sigma_m x \right), & \text{for } 0 \geq x \geq -d \\ B_r \left[\left(\cos \sigma d + n_{o1}^2 \frac{\Delta_m}{\sigma_m} \sin \sigma_m d \right) \cos \rho_m (x + d) \right. & \\ \left. + \frac{n_{o2}^2}{n_{o1}^2} \frac{\sigma_m}{\rho_m} \left(\sin \sigma_m d - n_{o1}^2 \frac{\Delta_m}{\sigma_m} \cos \sigma_m d \right) \right. & \\ \left. \cdot \sin \rho_m (x + d) \right], & \text{for } x \leq -d \end{cases} \tag{39}$$

with

$$\sigma_m = \frac{n_{o1}}{n_{e1}} (n_{e1}^2 k^2 - \beta^2)^{1/2} \tag{40}$$

$$\rho_m = \frac{n_{o2}}{n_{e2}} (n_{e2}^2 k^2 - \beta^2)^{1/2} \tag{41}$$

and

$$\Delta_m = (\beta^2 - k^2)^{1/2}. \tag{42}$$

The amplitude coefficient is expressed as

$$B_r = \left\{ \frac{4 n_{e2}^2 \omega \epsilon_0 \sigma_m^2 \rho_m^2 P}{\pi \beta} \cdot \left[\sigma_m^2 \left(\frac{n_{o2}^2}{n_{o1}^2} \sigma_m \sin \sigma_m d - n_{o2}^2 \Delta_m \cos \sigma_m d \right)^2 + \rho_m^2 (\sigma_m \cos \sigma_m d + n_{o1}^2 \Delta_m \sin \sigma_m d)^2 \right]^{-1} \right\}^{1/2}. \tag{43}$$

Mode Coupling

Coupling between the modes of an anisotropic dielectric optical waveguide is described by coupled-mode theory. The coupling coefficients can be approximated in the following way [9]-[11]:

$$K_{\mu\nu} = \frac{\omega}{4iP} \int_{-\infty}^{\infty} \boldsymbol{E}_\mu^* \cdot (\epsilon - \bar{\epsilon}) \cdot \boldsymbol{E}_\nu \, dx \tag{44}$$

provided that the dielectric tensors ϵ and $\bar{\epsilon}$ deviate only slightly from the unit tensor (times the isotropic dielectric constant) and that the dielectric tensor ϵ of the actual waveguide is very nearly the same as the z independent dielectric tensor $\bar{\epsilon}$ of an ideal guide whose modes are $\boldsymbol{E}_\nu$.

If we apply to the $LiNbO_3$ or $LiTaO_3$ crystal a dc electric-field E_{dc} in y direction simultaneously with a light field polarized in x direction, we obtain an electric polarization P_y of the anisotropic material in y direction. Similarly, we obtain an electric polarization P_x in x direction from the combination of the dc field in y direction and a light field in y direction. These polarizations can be expressed as [4, p. 56, eq. (2)]

$$P_y = -n_o^2 n_e^2 \epsilon_0 r_{51} E_{dc} E_x \tag{45}$$

$$P_x = -n_o^2 n_e^2 \epsilon_0 r_{51} E_{dc} E_y. \tag{46}$$

The relation

$$\epsilon \cdot \boldsymbol{E} = \bar{\epsilon} \cdot \boldsymbol{E} + \boldsymbol{P} \tag{47}$$

allows us to define the tensor

$$\epsilon - \bar{\epsilon} = \begin{pmatrix} 0 & \Delta\epsilon & 0 \\ \Delta\epsilon & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \tag{48}$$

with

$$\Delta\epsilon = -n_o^2 n_e^2 \epsilon_0 r_{51} E_{dc}. \tag{49}$$

The coupling coefficient (44) can now be written in the form

$$K_{\mu\nu} = \frac{i\omega n_{o2}^2 n_{e2}^2 \epsilon_0 r_{51}}{4P} \int_{-\infty}^{0} E_{dc} (E_{\mu x}^* E_{\nu y} + E_{\mu y}^* E_{\nu x}) \, dx. \tag{50}$$

We have ignored the small differences between n_{o1} and n_{o2} and between n_{e1} and n_{e2}.

The dc electric field may be a function of x and z. In the simplest case shown in Fig. 4(a) it is generated by two parallel electrodes on the surface of the slab. In this case we approximate its x dependence by the expression

$$E_{dc} = E_0 \exp(x/D) \tag{51}$$

so that the dc field decays exponentially in the negative x direction. If the dc field is generated by opposing contact fingers shown in Fig. 4(b), we may write the fundamental spatial Fourier component of the field as

$$E_{dc} = E_0 \exp(x/D) \cos \theta z. \tag{52}$$

The y dependence of the fields is ignored. The amplitude factor E_0 must be regarded as a suitable average. The light wave is assumed to propagate in the space between the two metal electrodes in Fig. 4(a) and, correspondingly, also in the gap between the two rows of periodic electrodes in Fig. 4(b). Diffraction spreading tends to broaden the beam in the plane of the film so that additional guidance must be provided to form a rectangular strip guide that confines the light not only to the plane of the film but also to the narrow region between the metal electrodes. The dielectric waveguide is thus not truly a slab but a rectangular guide. However, the analysis is based on slab waveguide modes which are considered to be adequate approximations of the modes of the rectangular guide particularly if the beam confinement perpendicular to the slab is much narrower than in the plane of the slab. The device configurations shown in Fig. 4 were proposed by Schmidt and Kaminow [13].

The device sketched in Fig. 4(a) generates a dc electric field that is independent of the z coordinate. Coupling can thus only occur between two modes with equal propagation constants such as between a guided TM mode and a TE radiation mode according to Fig. 1 (in $LiNbO_3$). If the voltage is applied to the two electrodes power is converted from the guided TM mode to the TE radiation mode so that a light beam emerges in the substrate. The coupling efficiency of this device is best expressed in terms of the attenuation coefficient α of the guided mode. The attenuation is caused by power loss from the guided mode μ to the radiation modes ρ. High attenuation indicates good conversion efficiency. The power attenuation coefficient 2α is related to the coupling coefficient by the formula

$$2\alpha = 2\pi e(\theta) \frac{\beta}{\rho} |K_{\mu\rho}|^2 \tag{53}$$

with

$$e(\theta) = \begin{cases} 1 & \text{for } \theta = 0 \\ \frac{1}{4} & \text{for } \theta > 0. \end{cases}$$

Equation (53) is, of course, also applicable to the device of Fig. 4(b). The parameter ρ is defined by (26) for TE modes and by (41) for TM modes. The propagation constant β is

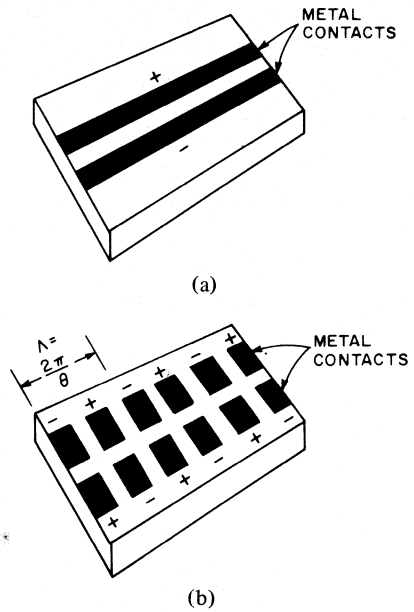

Fig. 4. Electrode configurations for electrooptic modulators. (a) Two continuous strips supply the voltage for a device that couples a guided mode to radiation. (b) Periodic electrodes are required for mode matching a guided TE and a guided TM mode.

given by

$$\beta = \beta_g \tag{54}$$

for the modulating field (51) and by

$$\beta = \beta_g - \theta \tag{55}$$

for the modulating field (52). These values for β must be used to compute the parameters of the radiation modes (25)-(27) and (40)-(42).

The electrode configuration in Fig. 4(b) can be used to convert a guided TE mode to a guided TM mode or vice versa or also for conversion from guided modes to radiation modes. The efficiency for conversion between guided modes is best expressed by the conversion length L that is required to couple all the power from one mode to the other. Defining

$$K_{\mu\nu} = 2\hat{K}_{\mu\nu} \cos \theta z \tag{56}$$

we obtain the total conversion length from the equation [6, p. 135, eq. (4.2-12)]

$$L = \frac{\pi}{2|\hat{K}_{\mu\nu}|}. \tag{57}$$

A useful approximation for L may be obtained by assuming that the field penetration depth D occurring in (52) is infinite and approximating the guided modes by plane waves. A straightforward analysis yields

$$L = \frac{2\pi}{(n_o n_e)^{3/2} k(r_{51} E_0)} \tag{58}$$

the approximation (58) is convenient for order of magnitude estimates of the total conversion length.

Substitution of the mode field expressions into (50) leads to

integrals that can be solved analytically. However, the resulting expressions are so long and unwieldy that they are omitted from this paper. All the relevant information is given in the preceding so that the evaluation of (50) is a simple matter of algebra.

The DC Electric Field

An idealized electrode configuration of Fig. 4(a) used to apply the dc electric field to the crystal is shown in Fig. 5. We have reversed the customary coordinate labels to obtain agreement with the coordinates used in Fig. 2. The metal electrodes are assumed to be infinitely thin and extend from $y = -\infty$ to $y = -a$ and from $y = a$ to $y = \infty$. The potential generated by these electrodes is given by the function $u(x, y)$ according to the formula [12] (the anisotropy of the material is ignored)

$$u + iv = \frac{V}{\pi} \arccos\left(\frac{y}{a} + i\frac{x}{a}\right). \tag{59}$$

The electric field follows from this potential equation

$$E_y = -\frac{\partial u}{\partial y} = \frac{V}{\pi\sqrt{2}} \frac{\{(a^2 + x^2 - y^2) + [a^4 + x^4 + y^4 + 2x^2y^2 + 2a^2(x^2 - y^2)]^{1/2}\}^{1/2}}{[a^4 + x^4 + y^4 + 2x^2y^2 + 2a^2(x^2 - y^2)]^{1/2}} \tag{60}$$

and

$$E_x = -\frac{\partial u}{\partial x} = \frac{V}{\pi\sqrt{2}} \frac{\{-(a^2 + x^2 - y^2) + [a^4 + x^4 + y^4 + 2x^2y^2 + a^2(x^2 - y^2)]^{1/2}\}^{1/2}}{[a^4 + x^4 + y^4 + 2x^2y^2 + a^2(x^2 - y^2)]^{1/2}}. \tag{61}$$

V is the potential difference between the electrodes. These field expressions apply to the region $-a < x < a$. For $|x| > a$ the sign of the inner square root in the numerator of (60) and (61) must be reversed.

The complicated field expressions (60) and (61) simplify substantially in the planes $x = 0$ and $y = 0$. We obtain for the plane of the electrodes $x = 0$

$$E_x = 0 \tag{62}$$

and

$$E_y = \frac{V}{\pi(a^2 - y^2)^{1/2}}. \tag{63}$$

In the vertical plane halfway between the two electrodes at $y = 0$ we have

$$E_x = 0 \tag{64}$$

and

$$E_y = \frac{V}{\pi(a^2 + x^2)^{1/2}}. \tag{65}$$

Fig. 6 shows a comparison between the function $(1 + x^2)^{-1/2}$ and the exponential function $\exp(-0.4x)$. It is apparent that the exponential function is a reasonable approximation to the electric-field distribution (65) over the entire range shown in Fig. 6. Therefore, we may approximate (65) in the form

$$E_y = \frac{V}{\pi a} \exp\left(-0.4\frac{|x|}{a}\right). \tag{66}$$

The field penetration depth D defined by (51) and (52) is thus expressed in terms of the electrode separation $2a$ as follows:

$$D = 2.5a \tag{67}$$

and the amplitude coefficient of the field can be expressed in terms of the applied voltage

$$E_0 = \frac{V}{\pi a}. \tag{68}$$

We use the field expression (66) as an approximation for the electrode field of Fig. 4(a) and

$$E_y = \frac{V}{\pi a} \exp\left(-0.4\frac{|x|}{a}\right)\cos\theta z \tag{69}$$

as an approximation for the field of the electrode configuration shown in Fig. 4(b).

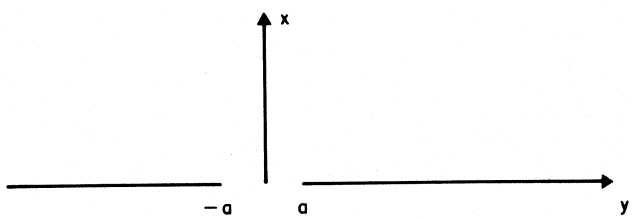

Fig. 5. Idealized geometry for establishing the field distribution generated by the electrodes shown in Fig. 4.

Numerical Examples

The electrooptic coefficient is [4, p. 113]

$$r_{51} = \begin{cases} 28 \times 10^{-12}\ \text{m/V}, & \text{for } LiNbO_3 \\ 20 \times 10^{-12}\ \text{m/V}, & \text{for } LiTaO_3 \end{cases} \tag{70}$$

at the helium-neon laser wavelength of 0.633 μm.

The power loss coefficient 2α is shown in normalized form in Fig. 7 as a function of $kd = 2\pi d/\lambda$. The solid curves of Fig. 7 represent the loss for different values of the field penetration depth D/λ. The dotted line in the figure shows the angle at which the radiation escapes into the substrate. The figure is drawn for the case of the lowest order guided TM mode losing power to a TE radiation mode due to electrooptic coupling in $LiNbO_3$.

In order to keep the modulating voltage low it is desirable to maintain close electrode spacing. For this reason we consider the case $D/\lambda = 1$. The peak of the curve with $D/\lambda = 1$ occurs at $kd = 5.52$, with $\lambda = 0.633$ μm. Thus we need a slab guide with a thickness $d = 0.56$ μm. Using (67) and $D/\lambda = 1$ we obtain the electrode spacing $2a = 0.51$ μm. This small spacing cannot be realized with present-day fabrication methods.

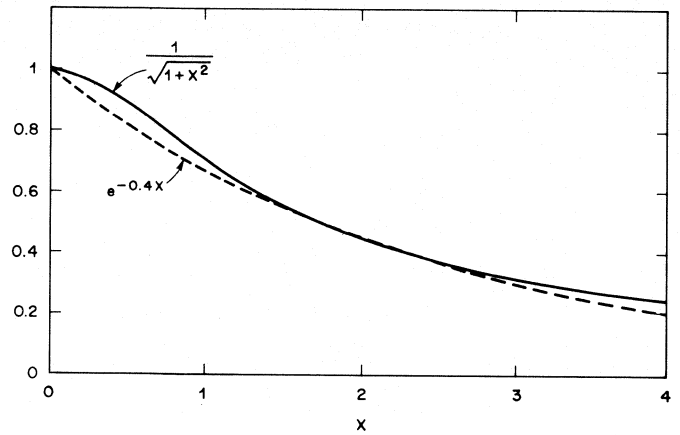

Fig. 6. Comparison between the electric field in the midway plane of the electrode of Fig. 4(a) and an exponential function.

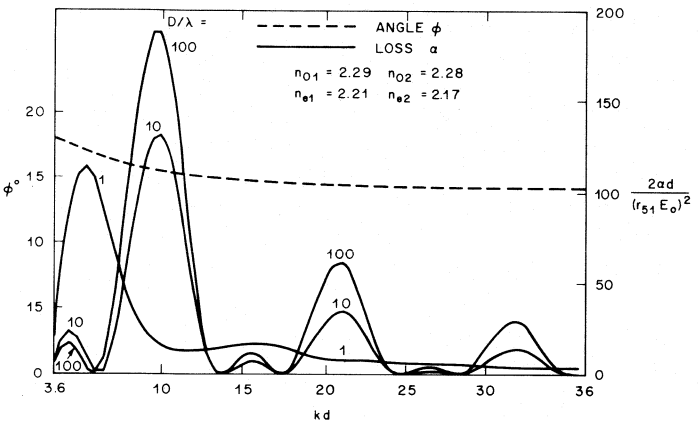

Fig. 7. Normalized loss coefficient as a function of $kd = 2\pi d/\lambda$. The solid curves apply to the loss coefficient and are labeled by different values of the normalized field penetration depth D/λ. The dotted curve represents the angle at which radiation escapes into the substrate. The figure applies to the $LiNbO_3$ case with $n_{o1} = 2.29$, $n_{o2} = 2.28$, $n_{e1} = 2.21$, and $n_{e2} = 2.17$.

Next we consider the amount of attenuation that we may achieve for the guided TM mode. A voltage of $E_a = 30\,000$ V/cm causes breakdown in dry air. Equation (68) yields for this value and the preceding electrode spacing the electrode voltage $V = 2.4$ V. For $LiNbO_3$ we obtain from (70) $r_{51}E_0 = 8.4 \times 10^{-5}$. Using a path length of $L = 1$ cm we have $L/d = 1.8 \times 10^4$. At the peak of the $D/\lambda = 1$ curve of Fig. 7 we have $2\alpha d/(r_{51}E_0)^2 = 114$ so that we obtain for the attenuation caused by electrooptic coupling to radiation, $2\alpha L = 0.014$ Np = 0.063 dB. This example shows that a modulator based on electrooptic radiation loss in $LiNbO_3$ is not efficient even for an idealized design. If it were possible to increase the modulation voltage the modulator could be improved because the attenuation is proportional to the square of the applied modulating voltage.

The situation is more hopeful for a device based on $LiTaO_3$. Fig. 8 applies to this case. The peak of the $D/\lambda = 1$ curve appears at $kd = 9.2$ requiring a slab thickness $d = 0.93$ μm ($\lambda = 0.633$ μm). The electrode spacing is unchanged, $2a = 0.51$ μm. However, the normalized value of the attenuation constant is much higher for this case because the attenuation escapes into the substrate at a much smaller angle, $2\alpha d/(r_{51}E_0)^2 = 3800$. From (70) we have for $LiTaO_3$ with

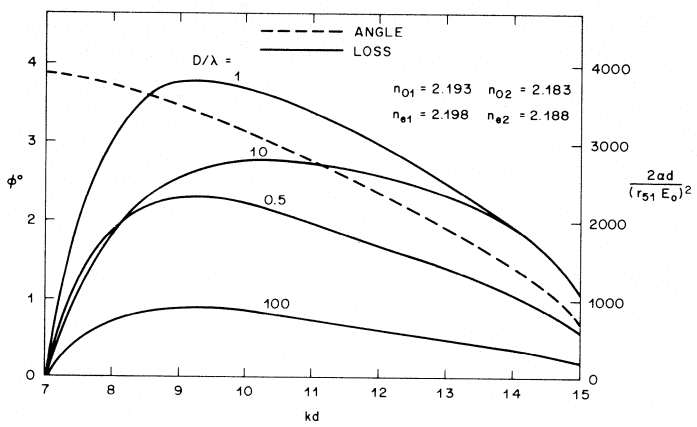

Fig. 8. Similar to Fig. 7, this figure applies to the $LiTaO_3$ case, $n_{o1} = 2.193$, $n_{o2} = 2.183$, $n_{e1} = 2.198$, and $n_{e2} = 2.188$.

$E_0 = 30\,000$ V/cm the value $r_{51}E_0 = 6 \times 10^{-5}$ so that the peak value of the attenuation for $L = 1$ cm is in this case $2\alpha L = 0.15$ Np = 0.65 dB. This value is far more favorable than the corresponding figure for the $LiNbO_3$ case. If it were possible to double the applied voltage, a value of $2\alpha L = 0.6$ Np would be obtained so that approximately 50 percent of the guided mode power could be radiated into the substrate.

Figs. 9 and 10 apply to electrooptic mode conversion from a guided TE mode to a guided TM mode or vice versa. The figures show the normalized total exchange length L (required for complete exchange of power from one mode to the other) as a function of kd. The parameter D/λ (normalized field penetration depth) is again used to label the curves. The dotted line shown in the figures gives the period length Λ of the periodic electrodes shown in Fig. 4(b). Fig. 9 applies to $LiNbO_3$ and Fig. 10 to $LiTaO_3$. It is immediately apparent that the coupling efficiency is comparable in both cases. A small value of L is desired for an efficient modulator. More important than the coupling efficiency is the required electrode spacing $\Lambda = 2\pi/\theta$ that follows from (6). (It must be remembered that the values of Λ—as all other values—were calculated from a slab waveguide model. A diffused guide has different dispersion characteristics and, therefore, different values of Λ.) The $LiTaO_3$ case, Fig. 10, leads to much larger, more easily manageable electrode spacings so that we concentrate on this case. The curves in Figs. 9 and 10 labeled $D/\lambda = \infty$ were calculated from the plane-wave model that leads to (58). It is apparent that the curves for large values of D/λ, that were calculated from the coupled-mode theory, asymptotically assume the same values predicted by the plane-wave model. Only for small values of kd does the plane-wave model yield inaccurate results since the rapid increase caused by the cutoff behavior of the guided modes is not included in the plane-wave analysis.

A modulator based on mode coupling between guided waves is more efficient for large values of D/λ. This is not surprising since the modulating field penetrates deeper into the waveguide if D/λ is large. The fluctuations in the radiation loss curves of Figs. 7 and 8 are caused by interference effects that are absent for guided mode interaction. Large values of D/λ are obtained by large electrode spacings. However, it is advantageous to keep the electrode spacing small in order to reduce the required modulating voltage.

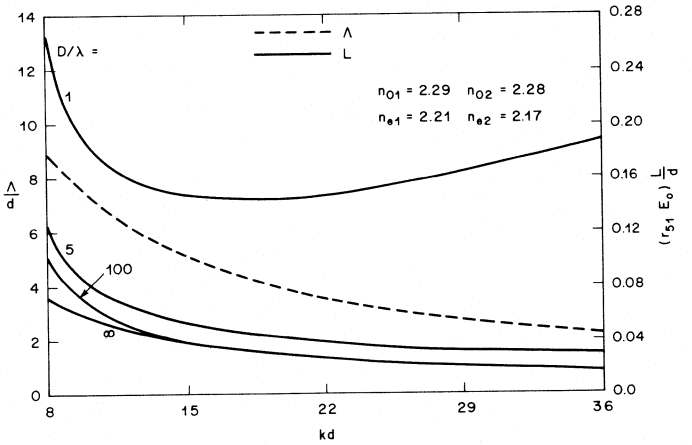

Fig. 9. Normalized power exchange length L as a function of kd for different values of the normalized field penetration depth D/λ, solid curves. The dotted curve gives the normalized length Λ/d of the electrode period. This figure applies to $LiNbO_3$ with $n_{o1} = 2.29$, $n_{o2} = 2.28$, $n_{e1} = 2.21$, and $n_{e2} = 2.17$.

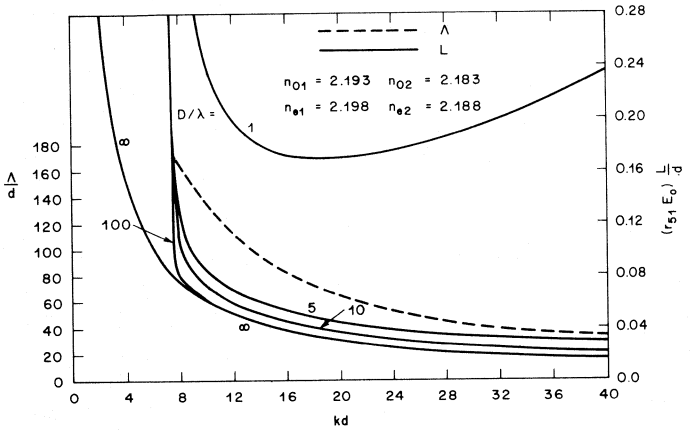

Fig. 10. Same as Fig. 9 for $LiTaO_3$ with $n_{o1} = 2.193$, $n_{o2} = 2.183$, $n_{e1} = 2.198$, and $n_{e2} = 2.188$.

Table I shows numerical values for the required gap spacing $2a$ between the modulating electrodes, the modulating voltage V (provided that $E_0 = 30\,000$ V/cm), and the length L required for total power exchange between the lowest order guided TE and TM modes for several values of D/λ. The values in Table I are taken from Fig. 10 and are based on a slab width of $d = 2$ μm and $\lambda = 0.633$ μm. The length for one period of the periodic electrode spacing is $\Lambda = 130$ μm.

Table I shows that complete conversion of power is easily obtainable over short distances. A modulator based on power conversion between guided modes is thus far more attractive than the modulator based on radiative power loss discussed in the preceding.

Conclusions

We have discussed the performance of two different types of electrooptic modulators. The modulator of the first type couples a guided TE or TM mode to radiation modes that are polarized orthogonally to the polarization of the guided wave. This type of modulator requires a modulating voltage that need not be periodic in the direction of wave propagation.

TABLE I

$\frac{D}{\lambda}$	2a(μm)	V(volts)	L(cm)
1	0.51	2.4	0.57
5	2.53	11.9	0.15
10	5.06	23.84	0.12
100	50.6	238.5	0.10

Note: This table shows the spacing $2a$ between contact pairs and the required modulating voltage to achieve complete conversion from a guided TE to a guided TM mode (or vice versa) over a distance L for a $LiTaO_3$ crystal for preselected values of D/λ. It is assumed that the electric-field strength is $E_0 = 30\,000$ V/cm, that the slab thickness is $d = 2$ μm corresponding to $kd = 19.85$. The length of the fundamental period of the periodic electrodes is $\Lambda = 130$ μm.

Numerical examples for $LiNbO_3$ and $LiTaO_3$ show that the efficiency of this type of modulator is marginal. In $LiTaO_3$ approximately 14 percent of the guided wave power may be coupled out of the guide by a dc field of $E_0 = 30\,000$ V/cm applied via two contact strips that are 1 cm long. If the voltage could be increased by a factor of 2 about 50 percent of the power could be coupled out. For $LiNbO_3$ the situation is even less favorable.

The modulator of the second type uses a (spatially) periodically varying applied voltage whose period (of approximately 100 μm for $LiTaO_3$) is adjusted to match the phases of the two guided waves. Complete conversion of power from a TE to a TM mode (or vice versa) is possible over distances ranging from 0.1 cm to about 0.6 cm. This type of modulator is capable of 100-percent modulation with an applied voltage of a few volts. To achieve amplitude modulation one of the two guided modes must be suppressed before reaching the detector. This can be done in several ways. For example, it is possible to taper the width of the guiding film to such a thickness that one of the modes exceeds its cutoff condition while the other mode remains guided. The cutoff mode would radiate out of the film in a very short distance. A metal layer on top of the guiding film introduces more loss to the TM mode than to the TE mode so that suppression of the TM mode is possible in this way [14]. An efficient method of mode suppression consists of a periodic grating deposited on top of the guiding film. This grating can be adjusted to couple one of the two guided modes to radiation resulting in very high radiation losses without appreciably affecting the other mode.

Gain Characteristics of a Multiatmosphere UV-Preionized CO_2 Laser

A. J. ALCOCK, MEMBER, IEEE, ROBERT FEDOSEJEVS, AND ANDREW C. WALKER

Abstract—**The small-signal gain of a transverse-discharge UV-preionized CO_2 laser has been investigated at pressures in the 1–15-atm range. Measurements were carried out on the $P(18)$ and $R(16)$ lines of both the 10.4- and 9.4-μm bands, and data on the pressure dependence of the peak gain and gain rise time are presented. The results demonstrate that small-signal gains in excess of 5-percent cm^{-1} are readily obtained at pressures of $\sim$ 12 atm and confirm that the relaxation times of the energy levels relevant to laser action scale inversely with pressure. In addition, it is found that the gain of both R branches increases more rapidly with pressure than that of the P branches, while there are indications that the 9.4- and 10.4-μm gain values become comparable at pressures of $\sim$ 15 atm. The experimental results have been compared with the dependence of gain on pressure predicted by a relatively simple theoretical model. On the basis of this model it is found that the experimentally determined gain rises more rapidly with pressure than one would expect and a number of possible reasons for this discrepancy are discussed.**

I. Introduction

SINCE the inherent advantages of operating molecular lasers at extremely high pressures were first pointed out [1]–[3], a number of experimental approaches have successfully demonstrated CO_2-laser action at pressures well in excess of 1 atm. The excitation techniques employed include fast, ultrahigh-voltage discharges [4], electron-beam-sustained discharges [5], optical pumping [6], and UV preionized [7] and "double-discharge" configurations [8]. However, only three of these methods [5]–[7] have so far permitted operation at pressures higher than 10 atm, with the highest reported operating pressure (50 atm) being attained by means of an electron-beam-sustained discharge [5]. An interesting feature of molecular lasers at such high pressures is the overlapping of the individual rotational lines caused by pressure broadening. In the case of CO_2, significant overlap occurs at pressures of the order of 10 atm and the individual vibrational-rotational lines merge into a single continuous gain spectrum. As a result the gain at any particular wavelength is the sum of contributions from several nearby rotational lines and thus it is pressure dependent even though the pump energy per unit-volume pressure is maintained constant. This is in contrast to the low-pressure (20 torr–2 atm) situation where pressure broadening of the individual rotational lines maintains a constant ratio of bandwidth to molecular density, and hence results in the gain being almost independent of pressure.

Although a number of authors have discussed the effects of line broadening [9] and calculations of the high-pressure gain spectrum have been published [10], there has been little effort to compare the predicted behavior with experimental data. Recently, gain measurements for a 15-atm electron-beam-controlled device were reported by Harris *et al.* [11]; however, the only study which has dealt specifically with the effect of pressure on gain has been that of Basov *et al.* [12]. In the case of an electron-beam-sustained device, these authors were able to show that the gain is proportional to the pump energy density per atmosphere and that the gain lifetime is inversely proportional to pressure for pressures up to 20 atm. In the present paper we wish to describe an experimental study of a transverse-discharge UV-preionized CO_2 laser capable of operation at pressures as high as 15 atm. Small-signal gain measure-

ments have been carried out on the $P(18)$ and $R(16)$ lines of both the 10.4- and 9.4-μm bands at pressures ranging from 1 to 15 atm, and the results compared with the dependence of pressure on gain predicted by a simple theoretical model.

II. Experimental Details

Aside from a minor modification to the preionization system, the main features of the multiatmosphere CO_2 laser have been described in an earlier publication [7]. UV radiation is provided by a series of small (~2 mm long) arcs formed between tungsten electrodes running parallel to the 26-cm-long main discharge electrodes; however, unlike the device described in [7], a second preionizer array has been added to permit illumination from both sides of the main discharge volume. Although no additional energy is required for the larger number of arcs, this symmetrical illumination scheme has resulted in a significant improvement in the laser's performance. The main discharge is energized by a five-stage Marx Bank operating at charging voltages ranging from 30 to 80 kV. Thus, for the 0.7-cm interelectrode gap, the nominal E/p values cover the range 14.3 kV/cm · atm to ~70 kV/cm · atm and correspond to pump energy densities between 30 and 500 J/l · atm. Over this range stable operation, with a gas-mixture composition of 1:1:8, $CO_2:N_2:He$, is achieved at pressures anywhere between 1 and 15 atm.

Gain measurements were made by operating the laser with Brewster-angled NaCl windows and probing the active region with radiation from a grating-tuned CW CO_2 laser having an output power of ~2 W. The experimental setup is shown in Fig. 1. After checking the wavelength of the CW laser output the probe beam was chopped and directed through the gain medium. It was then focused onto a liquid-N_2-cooled, photoconductive, Ge:Au detector. The latter had a measured rise time of ~50 ns, when suitably matched into both channels of a Tektronix 556, dual-beam oscilloscope, and allowed full temporal resolution of the gain pulses. The chopped signal was displayed on a slow sweep while the other oscilloscope beam was triggered from this sweep after an appropriate delay. The start of the second sweep triggered the CO_2-laser discharge and the delay was set so that this coincided with an "on" period of the chopped probe beam. In this manner a value for the power of the probe beam could be recorded while at the same time displaying the gain pulse on a fast sweep. Fig. 2 shows an example of a typical gain measurement. It should be noted that the diameter of the probe beam corresponded approximately to the 0.7-cm laser aperture and hence the results obtained are average gain values for the whole active area.

III. Experimental Results

The gain of the laser was measured on the $P(18)$ and $R(16)$ lines of both the 9.4- and 10.4-μm transitions over the pressure range of 1-15 atm and at various pump energies. The gas mixture was kept constant with a composition of 1:1:8, $CO_2:N_2:He$. Each gain measurement was made by averaging six shots of the laser, the greatest shot-to-shot variations being observed at the extremes of the ranges covered; e.g., near 15 atm and at maximum energy input.

Fig. 3 shows one set of peak gain measurements for the

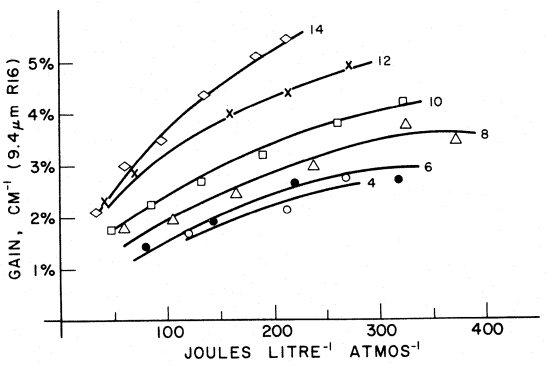

Fig. 3. Peak gain measurements for the 9.4-μm $R(16)$ line showing dependence on laser gas pressure and pump energy density.

9.4-μm $R(16)$ line. This shows that the peak gain increases with pressure, above 1 atm, and that gain values of more than 5-percent cm^{-1} can be readily obtained at pressures over 12 atm. Maximum gain occurs at pump energy densities of approximately 300 J/l · atm. A similar set of data was obtained for the other laser lines investigated.

Fig. 4 is a summary of the experimentally measured gain for the four laser lines studied, given a constant energy input of 200 J/l · atm.

As expected from the closer spacing of the rotational lines, the R-branch gain increases relatively more with increasing pressure than that of the P-branch lines. Fig. 4 also shows that the 10.4- and 9.4-μm gain values approach one another at the higher pressures. The measurement accuracy of these relative effects is estimated to be within a 5-percent error margin; however, it should be noted that the absolute measurement accuracy of the peak gain values is of the order of ± 0.005 cm^{-1}.

A study was also made of the pressure dependence of the rise time of the gain pulse [Fig. 2(b)]. The result is shown in Fig. 5 and indicates a linear relationship between pressure and the reciprocal rise time. The limit of this proportionality is reached when the rise time of the gain becomes comparable to the pumping time. In our laser this occurs at a pressure of ~15 atm where the gain was observed to rise to its peak value in only 80 ns. The duration of the gain pulse [full width at half maximum (FWHM)] also varies inversely with pressure and is usually about ten times larger than the pulse rise time. These observations show that, as expected, the relaxation times of the energy levels relevant to laser action scale inversely with pressure. This agrees with the results of Basov *et al.* [12] who showed, using an electron-beam-controlled CO_2 laser, that the product of inversion lifetime and pressure remains constant over the pressure range from 3 to 20 atm.

IV. Theoretical Model

As mentioned previously (Section I) the high-pressure gain at any particular wavelength consists of contributions from a number of adjacent vibrational-rotational transitions. In the case of the 10.4- and 9.4-μm CO_2-laser bands, these transitions occur between rotational sublevels of the $(00^\circ 1)$ upper vibrational level and the $(10^\circ 0)$ and $(02^\circ 0)$ lower vibrational levels, respectively. Within each laser band the P branch and R branch correspond to transitions from upper states with rotational quantum numbers of $J-1$ and $J+1$, respectively, to a lower state with a rotational quantum number of J; however, due to the symmetry of CO_2, there are no antisymmetric rotational levels [13], and thus all of the laser transitions occur between an upper level with odd J and a lower level with even J. For the individual vibrational-rotational transitions the gain coefficient at a frequency ν is given by

$$\alpha_J(\nu) = \frac{c^2}{8\pi\nu_J^2} A_{21} \left(n_2 - \frac{g_2}{g_1} n_1\right) g(\nu - \nu_J) \tag{1}$$

where ν_J is the frequency at the line center; A_{21} is the spontaneous transition probability; n_2 and n_1 are the populations of the upper and lower states, respectively; g_2 and g_1 are the degeneracies of the upper and lower levels; and $g(\nu - \nu_J)$ is the line-shape function. The number densities of the upper and lower levels are related to the total population densities N_2 and N_1 of the upper and lower vibrational levels by

$$n_i = N_i \left(\frac{2hcB_i}{kT}\right) g_i \exp\left[-B_i J_i (J_i + 1)\frac{hc}{kT}\right]_{i=1,2} \tag{2}$$

where J_2 and J_1 are the rotational quantum numbers for the upper and lower levels, respectively; B_2 and B_1 are the rotational constants for the upper and lower levels, respectively; and T is the rotational temperature. The line shape at high pressures is assumed to be a collision-broadened Lorentzian with a FWHM of $\Delta\nu_L$, and thus

$$g(\nu - \nu_J) = \frac{2\Delta\nu_L}{\pi} \frac{1}{4(\nu - \nu_J)^2 + \Delta\nu_L^2}. \tag{3}$$

The spontaneous-transition probability is given by

$$A_{21} = \frac{64\pi^4 \nu_J^3}{3hc^3 g_2} |R_{12}|^2 S_J \tag{4}$$

where $|R_{12}|^2$ is the vibrational contribution to the matrix element, and S_J is the rotational contribution to the matrix element equal to J for the P branch and $J+1$ for the R branch.

Thus the gain coefficient of transition J is given, for the P branch, by

$$\alpha_J(\nu) = A\nu_J J \left\{R \exp\left[-B_2 J(J-1)\frac{hc}{kT}\right] - \exp\left[-B_1 J(J+1)\frac{hc}{kT}\right]\right\} g(\nu - \nu_J) \tag{5}$$

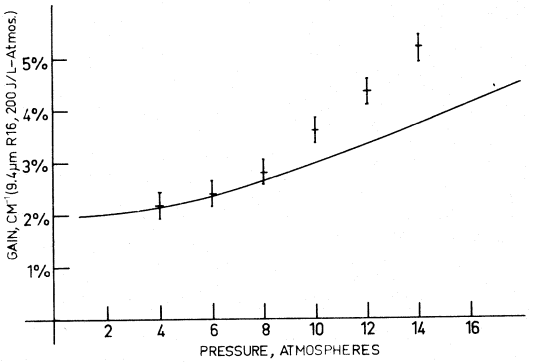

Fig. 6. Experimentally determined pressure dependence of gain for the 9.4-μm $R(16)$ transition at a constant energy input of 200 J/l · atm. The continuous line shows the calculated pressure dependence based on a collision-broadening coefficient of 3.5 GHz/atm.

and for the R branch, by

$$\alpha_J(\nu) = A\nu_J [J+1] \left\{ R \exp\left[- B_2 (J+1)(J+2) \frac{hc}{kT} \right] - \exp\left[- B_1 J(J+1) \frac{hc}{kT} \right] \right\} g(\nu - \nu_J) \quad (6)$$

where $R = (N_2 B_2 / N_1 B_1)$ is almost equal to the inversion ratio and

$$A = \frac{16\pi^3}{3kT} |R_{12}|^2 N_1 B_1 .$$

Taking line overlap effects into account, the total gain at any frequency is given by

$$\alpha(\nu) = \sum_J \alpha_J(\nu). \quad (7)$$

Substituting measured values for the rotational constants [14] and line frequencies [15], (5)-(7) were used to compute the CO_2 gain spectra and, in the case of no line overlap, the results were normalized to give $\alpha = 1$ on the peak of the 10.4-μm $P(20)$ transition and $\alpha = 0.74$ on the peak of the 9.4-μm $P(20)$ transition. The factor of 0.74 was calculated from (5) assuming equal linewidths for both bands and using values for the vibrational matrix elements given by Cousin *et al.* [16].

The small-signal gain of atmospheric-pressure transverse-discharge lasers has been investigated experimentally by Robinson [17], Girard *et al.* [18], and Singer [19] and their measurements yield inversion-ratio values between 16 and 30 and rotational temperatures ranging from 325 to 435 K. However, measurements carried out with electron-beam-sustained amplifiers [20], [21] indicate considerably lower values (2.5-10) for the inversion ratio, and for the computed spectra presented in this paper a rotational temperature of 325 K was used together with an inversion ratio of 4.0 for the 10.4-μm band. Assuming thermodynamic equilibrium for the (10°0) and (02°0) levels at 325 K, the inversion ratio for the 9.4-μm band becomes 2.54. Although the assumed values are quite low, the shape of the gain spectrum is not highly dependent on this ratio and the chosen value gives a gain maximum between $P(18)$ and $P(20)$ on the 10.4-μm band.

The linewidths can be determined from the collision-broadening coefficients (GHz [FWHM]/atm) and partial pressures P(atm), of the gases present in the laser discharge, by using

$$\Delta\nu_L = \beta_{CO_2} P_{CO_2} + \beta_{N_2} P_{N_2} + \beta_{He} P_{He} = \beta_{eff} P_{tot}. \quad (8)$$

However, the collision-broadening coefficients are temperature dependent ($\Delta\nu \propto PT^{-1/2}$) and their values must be corrected for the gas temperature in the discharge.

V. Comparison of Experimental Data and Theoretical Predictions

A critical parameter in the calculation of the pressure dependence of the laser gain is clearly the value taken for the line-broadening coefficient (β_{eff}). Many values have been published and by taking a weighted average of 12 of these results a value of 5.4 GHz/atm is obtained for pure CO_2. A similar review of the published data by Judd [22] yielded a value in agreement with this figure. In the case of mixtures of CO_2 and other gases, fewer data are available; however, relative broadening coefficients for N_2 and He have been measured by Patty *et al.* [23] and reduce β_{eff} by a factor of ~0.65 for our laser gas mixture (10-percent CO_2, 10-percent N_2, 80-percent He), giving a value of 3.5 GHz/atm (FWHM). This figure used with the theory described in Section IV allows calculation of the variation with pressure of the laser gain at a particular wavelength. Fig. 6 shows the experimentally determined gain values for the 9.4-μm $R(16)$ transition at a number of pressures. The calculated pressure dependence is shown as a continuous line and has been normalized to agree with the low-pressure experimental values where the effect of line overlap is not significant. This implies an assumption that the population-inversion ratio remains constant provided the energy input per unit-volume-pressure does not change. Such an assumption is compatible with the observed proportionality between pressure and molecular relaxation rates, and seems particularly appropriate for the 8-14-atm pressure range where the nominal value of E/p does not vary significantly (37-49 kV/cm · atm). As can be seen from Fig. 6, a serious discrepancy exists between theory and experiment. A similar disagreement is found to occur at the other three wavelengths investigated, and in all cases the

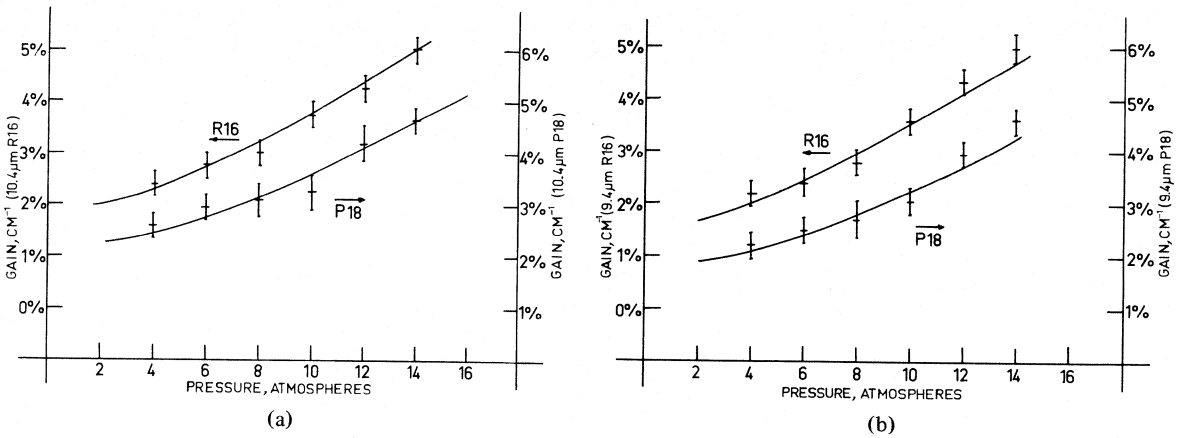

Fig. 7. (a) Measured pressure dependence of gain for the 10.4-μm, $P(18)$, and $R(16)$ lines. (Pump energy density is 200 J/l · atm.) The continuous line shows the calculated pressure dependence for a collision-broadening coefficient of 5.3 GHz/atm. (b) Measured pressure dependence of gain for the 9.4-μm, $P(18)$, and $R(16)$ lines. (Pump energy density is 200 J/l · atm.) The continuous line shows the calculated pressure dependence for a collision-broadening coefficient of 6.1 GHz/atm.

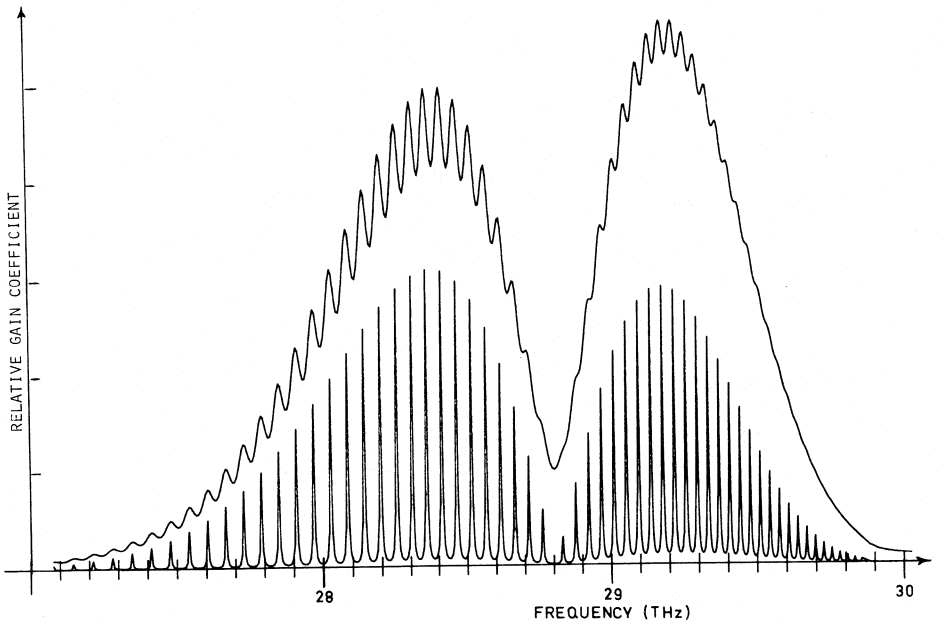
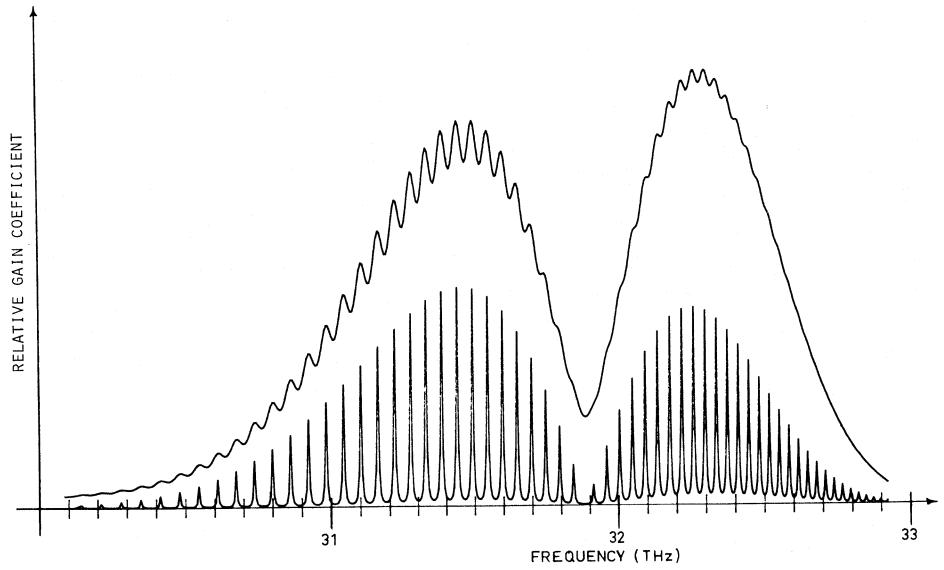
gain increases more rapidly with pressure than the theory predicts.



The failure of our theoretical model to agree with experiment may be attributable to the use of an incorrect value for the line-broadening coefficient as there is a large spread in the data on which the average is based (~40 percent). However, those values published more recently and obtained by more accurate techniques [24] are all close to the value we have used and imply that our choice of broadening coefficient is not unreasonable. In spite of this, an attempt was made to obtain a fit between theory and experiment by taking β_{eff} to be an adjustable parameter. The closest fit is shown in Fig. 7(a) for the $R(16)$ and $P(18)$ lines of the 10.4-μm transition and corresponds to an assumed value of β_{eff} of 5.3 GHz/atm. Similarly, Fig. 7(b) shows the best fit to experimental data taken for the 9.4-μm transitions using $\beta_{eff} = 6.1$ GHz/atm. Coincidentally, both of these latter values correspond to some preliminary results of CO_2 linewidth measurements made available to us by Meyer and Rhodes [25]; however, these values are exceptionally high and in a published account of this work have been revised downwards [26]. Although they no longer explain our results, Meyer's data do indicate that the collision-broadening coefficient is larger for the 9.4-μm transitions than for the 10.4-μm transitions, and therefore agree qualitatively with our experimental observations. Nevertheless, noting that the experimental fit of Fig. 7(a) and (b) is far from perfect and considering the large number of publications giving β_{eff} values of approximately 3.5 GHz/atm, we feel it is unlikely that this value is significantly in error.

Although they are not in agreement with the majority of measured values, the high values for β_{eff} previously mentioned do permit our theoretical model to approximate the experimentally measured pressure dependence of the laser gain. Thus, in calculating the gain spectrum at high pressures, it would seem appropriate to use these values for β_{eff}. The resulting computer calculation yielded the spectrum shown in Fig. 8(a) and (b). As can be seen, considerable smoothing of the rotational bands occurs as one changes from a pressure of 1-10 atm. It should further be noted that, unlike the results of a similar calculation by Chang and Tavis [10], a more realistic estimation of the population inversion ($N_2/N_1 = 4$) results in a higher gain on the R branches than on the P branches at pressures of the order of 10 atm. This result is confirmed experimentally by the observation that the laser always oscillates on an R-branch transition when operated at pressures over 8 atm. Furthermore, when operated as a simple oscillator [7] the laser has a strong tendency to generate 9.3-μm radiation, an effect which is compatible with the effective β value being higher for the 9.4-μm transitions than the 10.4-μm transitions.



VI. Discussion

A similar discrepancy between calculated and observed optical properties of high-pressure CO_2 has been reported by Christiansen *et al.* [27]. Studying the transmission of 10.6-μm radiation through CO_2 at pressures up to 18 atm, these authors found that the absorption increased faster with pressure than predicted by theory. As possible explanations for this result they proposed: 1) an incorrect choice for the broadening coefficient; 2) that the rotational line shape may not be Lorentzian; and 3) the existence of collisionally induced absorption effects. All of these explanations could be applied to our gain measurements, but there is little evidence to determine the validity of any particular one.

The atmospheric-pressure gain measurements reported recently by Singer [19] have particular relevance since they have revealed that the gain on certain lines (e.g., $P(20)$ of the 10.4-μm band) is ~10 percent higher than that predicted by the theoretical population distribution. The explanation for this effect is based on the coincidence in wavelength between

(a)

(b)

Fig. 8. (a) Upper curve–Computed 10.4-μm gain spectrum for $p \sim 10$ atm. Values of 4.0 and 53 GHz were used for the inversion ratio and collision-broadened linewidth, respectively. Lower curve–Low-pressure gain spectrum ($p \sim 1$ atm). (b) Upper curve–Computed 9.4-μm gain spectrum for $p \sim 10$ atm. Values of 2.54 and 61 GHz were used for the inversion ratio and collision-broadened linewidth, respectively. Lower curve–Low-pressure gain spectrum ($p \sim 1$ atm).

this particular line and a corresponding transition among the higher CO_2 energy levels. Thus some of the energy stored in these "hot bands" becomes available and leads to an enhancement of the gain for this individual line. Clearly, at higher pressures the probability of such a coincidence increases when all the lines are broadened and will lead to an increasing contribution to the gain from overlapping hot-band transitions.

This effect could account for the observation that the gain at 14 atm is ~40 percent higher than the value predicted by theory and might also explain the discrepancy between our observations and the 15-atm data of Harris *et al.* [11] who found that maximum gain occurred for the $R(16)$ line of the 10.4-μm band. Indeed, assuming an appreciable population inversion among the upper CO_2 levels, such an effect must occur. A numerical calculation, including the contribution from hot-band transitions, would follow closely that described in Section IV with the final summation including the terms due to all relevant transitions. However, a detailed determination of the relative population inversion between the various upper levels requires a fairly sophisticated model for the excitation process. For this reason we have not attempted to confirm this explanation theoretically. Futhermore, it should be noted that this cannot be the explanation for the anomalous pressure dependence obtained from the CO_2 absorption studies [27] as these were performed at room temperature, and hence with a negligible population of the upper energy levels. A

similar argument would also apply to an explanation based on a pressure-dependent population-inversion ratio, and thus there is little reason to doubt the assumption mentioned in Section V.

In conclusion, therefore, it is clear that more detailed investigations, capable of determining the true linewidth and line shape at high pressures, coupled with a knowledge of the direct effect of collisions on the stimulated-emission cross section will be required before a complete explanation for our experimental observations can be given.

Note Added in Proof: An investigation of the gain spectrum of a 14-atm CO_2 laser has been reported recently (J. L. Miller, A. H. M. Ross, and E. V. George, "Gain spectrum of a high pressure CO_2 laser," *Appl. Phys. Lett.*, vol. 26, pp. 523-526, 1975). The data presented indicate that the high-pressure gain spectrum is modified significantly by overlapping higher lying vibrational bands.

A Compact Sealed Pulsed CO_2 TEA Laser

DONALD S. STARK, PETER H. CROSS, AND HARRY FOSTER

Abstract—A compact sealed pulsed CO_2 TEA laser with an operational life exceeding 10^6 pulses has been developed. It provides single-mode output pulses of 1.0-MW peak power in 50-ns full width at half maximum (FWHM) and total energy 110 mJ in 2 μs. The output beam emerges from an 8.5-mm-diam aperture with a full-angle divergence of 3.5 mrad, which is less than 1.5 times the diffraction limited value. With a different optical resonator system, the corresponding multimode output exceeds 1.4 MW in 80 ns with a total energy of 300-500 mJ delivered in 4 μs and with a beam divergence of about 10 mrad. These output levels, corresponding to 15-25 J/l, are obtained for a pulse repetition frequency of 2 Hz and are maintained after initial conditioning, even in lasers tested to 2×10^6 pulses. Hitherto, prolonged sealed operation was not possible because the glow discharge degraded into arcs. This has been overcome in the present device by the addition of small quantities of carbon monoxide and hydrogen to the basic CO_2-N_2-He-laser gas mixture before seal-off.

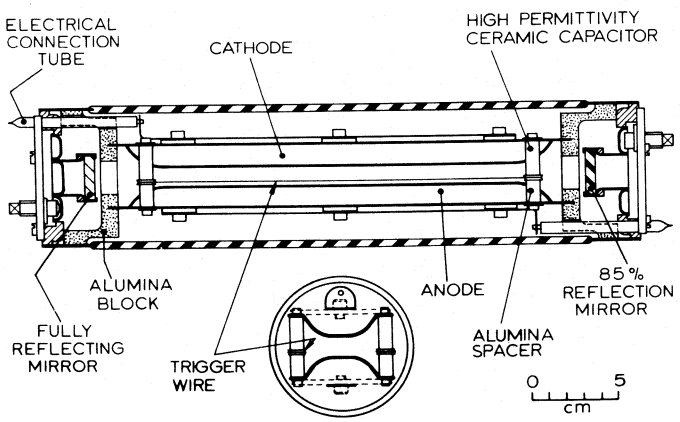

Fig. 1. Sealed pulsed CO_2 TEA laser.

Introduction

THE generation of high-power pulses by TEA CO_2 lasers using flowing-gas mixtures (CO_2-N_2-He) has been extensively described in the literature [1]-[5], but thus far there have been no published reports of the successful operation of sealed devices of this type. The major obstacle has been the early onset of arcing between the electrodes, due to the accumulation of gaseous reaction products of the electrical discharge. In a flowing-gas system these are swept out of the discharge region. This paper describes the development of a compact sealed TEA CO_2 laser in which the peak power output exceeds 1 MW and operational lives greater than 10^6 pulses are reliably obtained. The design is outlined in the following, together with a description of the techniques which have made the development possible. The compactness and portability of this device greatly widen the range of possible applications compared with those of previous TEA lasers requiring bulky and immobile gas handling equipment.

Description of the Laser

The sealed laser is derived from the double-discharge laser described by Pearson and Lamberton [4], [5], in which a uniform pulsed electrical discharge is produced in a flowing gas at atmospheric pressure between two parallel Rogowski-profiled electrodes. The natural tendency to arc is countered by the use of subsidiary discharges between "trigger" wires and the anode. These cause ultraviolet irradiation of the cathode surface, so producing the diffuse photoemission of electrons necessary for the creation of a uniform discharge at high pressures.

Manuscript received February 25, 1975; revised May 22, 1975. This paper was reprinted with permission of the Controller, HMSO, London, England, 1975.

The authors are with the Ministry of Defence, Procurement Executive, Services Electronics Research Laboratory, Baldock, Herts. SG7 6NG, England.

The design of the sealed laser is shown in Fig. 1. Two pressed nickel electrodes are spaced so as to form a discharge volume of cross section 10×10 mm and of length 200 mm. Two trigger wires are placed close to the anode and are supported on ceramic posts separating the electrodes. The insulators between the wires and the cathode are made of a high-permittivity ceramic while those spacing the wires from the anode are of alumina. In this way, capacitative coupling of the trigger wires to the cathode is achieved inside the laser envelope. This eliminates the additional electrical lead-through seals which are normally needed for the connection of external capacitors, thus reducing the size of the device. Energy for the discharge is provided by a 12-nF condenser, charged to about 25 kV and connected across the main electrodes via a triggered sparkgap. The energy in the auxiliary discharges between the trigger wires and the anode is maintained at an optimized low level by limiting the capacity between each wire and the cathode to 45 pF.

The envelope of the laser is made of glass and expansion-matched NiFeCo alloy, and is designed so that the principal joints are argon-arc welds. Low-inductance electrical connections to the main electrodes are made at opposite ends of the envelope via copper tubes which also serve to flow gas through the laser during initial testing. The laser is ultimately sealed by squeezing off these tubes. The principal dimensions of the laser and typical operating parameters are summarized in Table I.

Development

Each laser went through a processing schedule which commenced with a period of outgassing on a high-vacuum pumping system. This was followed by operation as a laser using a flowing-gas mixture at atmospheric pressure for at least 10^4 pulses in order to stabilize the uniformity of the discharge before seal-off.

TABLE I
DIMENSIONS AND TYPICAL OPERATING CONDITIONS OF SEALED TEA LASERS

Length of laser (mm)	380
Diameter of laser (mm)	81
Discharge dimensions (mm)	200 × 10 × 10
Optical-cavity length (mm)	281
Reflectivity of output window (percent)	85
Main storage capacitance (nF)	12
Charging voltage (kV)	20–27
Input energy (J)	2.4–4.4
Proportions of principal gases (CO_2–N_2–He)	1:1:5

During operation, either sealed or with a flowing gas, the output energy was continuously monitored using a calibrated thermopile and the output waveform was measured using a photon-drag detector. At intervals, samples of gas were transferred to a mass spectrometer for analysis.

Initial Experiments

In the development of the sealed laser, several different electrode materials were assessed experimentally. Lasers containing stainless-steel electrodes operated well with flowing gases (a 1:1:5, CO_2–N_2–He mixture being used, typically) but arcing between the main electrodes commenced soon after seal-off and became persistent after 10^3–10^4 pulses. It was not possible to significantly prolong the life of the device by varying the proportions of gas mixture. In the hope of increasing the photoemission of electrons from the cathode and hence preventing arcing, several lasers containing electrodes with varying degrees of controlled surface oxidation were assessed. These produced no significant improvement in life, however.

After the onset of arcing, analyses of the residual free gas in several sealed lasers showed that significant amounts of carbon monoxide and oxygen had accumulated. These were presumably produced by the dissociation of carbon dioxide according to the reversible equation

$$CO_2 \rightleftharpoons CO + O.$$

In general, between 0.1 and 0.4 percent of oxygen and 1–2 percent of carbon monoxide were found. Neither ozone nor oxides of nitrogen were observed to the detection sensitivity limits of 100 parts per million (ppm) for NO and NO_2 and 0.2 percent for N_2O. This does not rule out the possibility that concentrations of these gases below the detection limit are important. Moreover, little is known about the lifetime of ozone in the laser environment and it is possible that some was present originally.

To determine whether oxygen or carbon monoxide was associated with arcing, lasers were operated with flowing gases and various proportions of oxygen and carbon monoxide were added separately and in combination. It was found that more than 5 percent of carbon monoxide could be flowed before arcing commenced, whereas the levels of oxygen which led to arcing were 0.1–0.5 percent, i.e., similar to those found in degraded sealed lasers. Moreover, if these concentrations of oxygen were present, the addition of carbon monoxide did not prevent arcing. It therefore appeared desirable to minimize the presence of oxygen.

The stainless-steel electrodes used in the initial experiments were replaced by nickel pressings in the hope of catalyzing the recombination of carbon monoxide and oxygen back to carbon dioxide at the electrode surfaces. This change led to a significant improvement, and operational lives of 4×10^3–1×10^5 pulses were obtained (though mostly at the lower end of this range). This was not necessarily the result of catalytic action since there are other differences between the nickel and stainless-steel electrodes; for example, in the nature of inclusions in the metal surface. The best discharges and the longest lives were achieved when the distance between the electrodes varied by less than 0.02 mm. All subsequent lasers were therefore made with this degree of precision.

Gaseous Additives

In order to limit the generation of oxygen, three basic approaches were considered. The first was to introduce some mechanism for the selective removal of oxygen; for example, by diffusion through a heated silver tube. The second was to seal the laser with added carbon monoxide in order to bias the reaction equation in the backward direction and thus to discourage the dissociation of carbon dioxide. The third approach was to use a form of gaseous catalysis. The aim of this would be to cause each oxygen atom to recombine with a carbon monoxide molecule preferably before it could combine with another oxygen atom to form a stable oxygen molecule. It was thought that in a sealed device operating at atmospheric pressure a gaseous catalyst would be more effective than a solid surface, since the mean free path for collisions between gas molecules is very small ($\simeq 5 \times 10^{-5}$ mm) compared with the interelectrode distance.

The first of these three approaches (the selective removal of oxygen) was rejected since this would probably encourage the dissociation of carbon dioxide by inhibiting the reverse reaction. The second was assessed in a series of experiments in which lasers were sealed after the addition of carbon monoxide in various proportions between 1.25 and 6.6 percent. The best concentration was found to be 4.6 percent, and even this produced only a tenfold increase in life. Failure of the device again came through arcing rather than a reduction of output.

For the third approach (the addition of a gaseous catalyst) it was felt that hydrogen might be suitable since it had been shown by Carbone [6] and Wittemann [7] to be effective in producing long lives in sealed CW lasers operating at pressures up to 2.7 kPa. Although the mechanisms limiting the life of

low-pressure lasers are very different (for example, there is no arcing problem due to the generation of oxygen), they share the requirement that the dissociation of carbon dioxide should be limited.

The reactions proposed by Wittemann for the possible effect of hydrogen are as follows. There would always be present some oxygen atoms derived from the basic dissociation equation

$$CO_2 \rightleftharpoons CO + O.$$

Hence OH radicals would be formed thus

$$O + H \rightleftharpoons OH.$$

This would be followed by reactions which could be summarized as follows:

$$CO + OH \rightleftharpoons CO_2 + H.$$

Hence, in effect, the oxygen and carbon monoxide would be recombined to form carbon dioxide and the hydrogen would be available to repeat the cycle.

It was not known whether such a catalytic effect would be appreciable at atmospheric pressure. To assess this approach, a series of experiments were performed in which a laser was sealed off with varied proportions of hydrogen between 0.19 and 2.5 percent. The results showed that the addition of hydrogen in suitable proportions prolonged life by a factor exceeding 10 but that, though arcing was prevented, the output dropped rapidly. It was interesting to note that even when the proportion of oxygen had risen as high as 1.2 percent, there was no arcing in the presence of a suitable concentration of hydrogen. On the other hand, if the proportion of hydrogen exceeded about 0.6 percent, not only was the steady decline in output even more rapid but there was a tendency to arc towards the end. Higher concentrations of hydrogen resulted in arcing even though the proportion of oxygen was much lower than normal.

It appeared, then, that though carbon monoxide and hydrogen each prolonged life, hydrogen in appropriate concentrations inhibited arcing but allowed the output to fall to very low levels, whereas carbon monoxide maintained the output but ultimately permitted arcing. The possibility that the simultaneous addition of both gases would combine the benefits of each was assessed experimentally by sealing the laser successively with mixtures of both gases in varied proportions. This was successful in that a suitable mixture gave a very great increase in life. The output remained constant at a high level and there was virtually no arcing.

Operational Life

To establish the effectiveness of the mixture of hydrogen and carbon monoxide, life tests were performed at a pulse-repetition frequency (PRF) of 2 Hz on a first batch of seven substantially identical lasers, initially without the additives. All of these became very difficult to operate within about 10^4 pulses, since the operational voltage range became extremely narrow and variable. It was possible by careful control of the voltage, PRF, etc., to process only two lasers through this very difficult initial period and these ultimately provided more than 2×10^6 consecutive satisfactory pulses. The remaining five failed, however, due to persistent arcing within about 10^4 pulses. These were opened and resealed with the H_2-CO additives. All then operated satisfactorily from the outset and showed no deterioration after 1×10^6-2×10^6 pulses each. Thus the effectiveness of the H_2-CO mixture in promoting long lives was established and all subsequent lasers were therefore sealed off with its prior addition. Fourteen sealed lasers have now each operated for 4×10^5-2.5×10^6 pulses. Some of these were pulsed continuously while others were deliberately interrupted for periods of up to a month. Optical stability was good; retuning of the mirrors was seldom needed, even after transportation. In all cases, the performance was unchanged at the termination of the test.

Fig. 2 is a graph of output peak power as a function of the number of pulses of sealed operation for one multimode laser. The scale on the pulse-number axis is divided into two parts, that nearest the origin being on an expanded scale to show the details of the initial fall in output following seal-off, while later the scale is compressed to demonstrate the long-term stability of the output. The first point on the graph is for flowing gas (with H_2-CO additive) and subsequent points are after seal-off. The immediate initial fall is partly due to the fact that the laser was sealed off at atmospheric pressure, while in flowing conditions the pressure in the laser was slightly above atmospheric because of the impedance of pipes and taps. The output peak power measurements were made at 2 Hz throughout. At this PRF the output power and energy were the same as for single-shot pulses. All the points on the graph relate to measurements made at the same instantaneous voltage ($\simeq$21 kV) in order to give a valid comparison of the output at different times. However, in between these spot measurements the laser was operated at voltages up to 27 kV and output levels around 1.5 MW as indicated. After a rapid drop during the initial 5×10^3 pulses following seal-off, the peak power output efficiency was substantially constant over the next 2×10^6 pulses.

Tests were also performed on the pulse-to-pulse repeatability of the output by photographing a large number of successive output-power traces displayed on an oscilloscope, using a single exposure. Fig. 3 is a typical photograph of one hundred consecutive traces from a sealed laser after 5×10^5 pulses, and shows that the output peak power was constant within ± 10 percent.

During prolonged sealed operation, a dark grayish film developed upon the surface of the anode but not on the cathode. An analysis of the film from a laser which was still operating satisfactorily after 2.4×10^6 pulses showed that it consisted almost entirely of oxygen and nickel in roughly equal atomic proportions. The thickness was approximately 1 $\mu g/mm^2$ ($\simeq$200 nm). These results suggest the presence of a high concentration of negative oxygen-bearing ions within the discharge. The possible significance of this is discussed later.

The shelf life of sealed lasers exceeds one year. Thus far

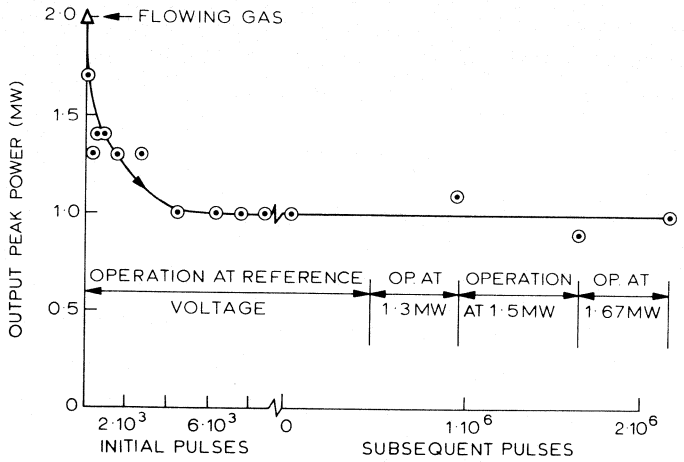

Fig. 2. Peak power output (multimode) as a function of the number of pulses of sealed operation.

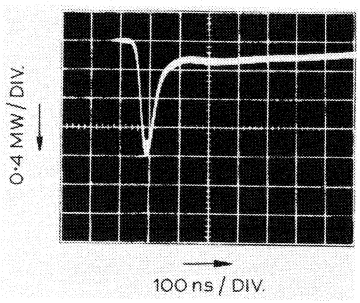

Fig. 3. Power output waveform of 100 superimposed pulses for a multimode laser after 5×10^5 pulses.

no laser has failed on the shelf, so that the upper limit is not known.

Output Mode Properties

Nine out of the fourteen life-tested sealed lasers contained a concave fully reflecting mirror and a plane output window, so that the output was multimode. Typically, at the end of 2×10^6 pulses the output peak power exceeded 1.5 MW. This was contained within a "spike" of duration 80-ns full width at half maximum (FWHM), followed by a "tail" of 3–4 μs. The total output energy was 300–500 mJ/pulse depending upon the operating voltage, corresponding to an energy per unit volume of 15–25 J/l and an optical conversion efficiency of about 10 percent. The beam divergence, defined as the full angular width at $1/e^2$ of the peak intensity, was measured as about 10 mrad.

Five of the sealed lasers contained two plane mirrors and an 8.5-mm-diam aperture, thus giving a single-mode (TEM_{00}) output. After 10^6 pulses at 2 Hz, the output peak power was still 1.0 MW contained in a 50-ns spike (FWHM), followed by a tail of about 2 μs. The beam divergence was 3.0 mrad, which is less than 1.3 times the diffraction-limited value. Fig. 4 shows a typical plot of beam energy density against radial distance in the optical far field, and shows that the distribution is approximately Gaussian, as expected for single-mode operation. The corresponding total energy was 100 mJ/pulse, which

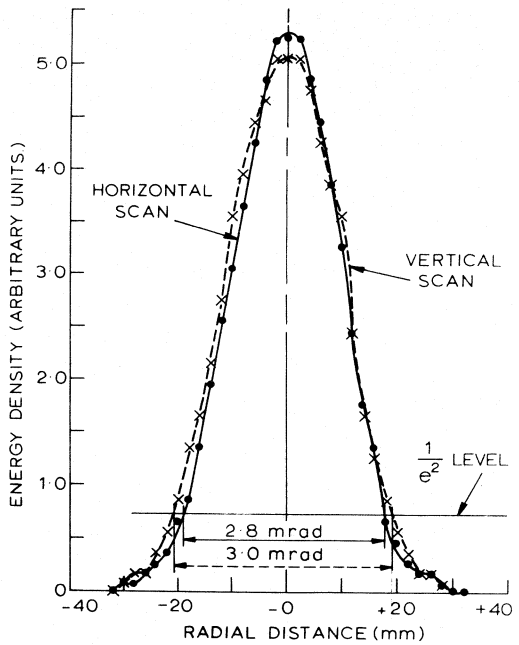

Fig. 4. Beam energy density of a single-mode laser as a function of radial distance in the optical far field. (Output peak power = 1 MW. Measurement distance = 13.35 m.)

was about one third of that from similar multimode lasers. Thus the output energy reduction in a single-mode laser is considerably greater than the peak power reduction. This is because of the sharper output spike and shorter tail as expected in single-mode operation.

Discussion

The development of arcing in sealed lasers may be explained in terms of the work of Nighan *et al.* [8] who have made a theoretical study of the discharge stability conditions for CO_2-N_2-He gas mixtures at low pressures ($\simeq$2.7 kPa). Their work shows that a high proportion of negative ions (predominantly O^- and CO_3^-) is present, and that the discharge becomes unstable if the ratio Nn/Ne between the negative ion and the electron concentrations (Nn and Ne, respectively) lies within a certain range of values. The presence of carbon monoxide influences this ratio; for example, by the associative detachment reaction

$$O^- + CO \longrightarrow CO_2 + e.$$

It is probable that hydrogen has a similar effect. Deutsch [9] has reported that the addition of hydrogen to a double-Rogowski TE laser operating with flowing gas led to a more uniform discharge and suppressed the formation of arcs.

Assuming that these principles are applicable at atmospheric pressure (and the analysis of the oxide surface film on the sealed laser anode is consistent with the presence of oxygen-bearing negative ions), it is probable that one role of the hydrogen and carbon monoxide is to control the Nn/Ne ratio right from the outset, thereby maintaining conditions for arc-free operation. The last statement is validated by analyses of the residual gases at the end of the life tests in the two

lasers which had operated for 10^6 pulses without the additives. These analyses showed that the residual hydrogen and carbon monoxide levels were similar to those found in life-tested lasers which had been sealed off with the H_2-CO mixture. In other words, the proper levels of carbon monoxide and hydrogen in the two lasers had been accidentally obtained early in the tests. Presumably, the carbon monoxide was produced by dissociation of carbon dioxide while the hydrogen was derived from water vapor and outgassing of the electrodes, etc.

In general, the concentrations of the carbon monoxide, oxygen, and hydrogen in lasers which had survived 10^4 pulses without arcing were very similar to those in lasers surviving 10^6 pulses and more. This was true whether or not hydrogen and carbon monoxide were added initially. It appears, therefore, that in satisfactory lasers an equilibrium composition is established within about 10^4 pulses. This is consistent with the fact that the laser output remains substantially constant between 10^4 and 10^6 pulses.

Optimization of a Laser Communications System Using Electrooptic Modulation

ARMAND L. WAKSBERG, SENIOR MEMBER, IEEE

Abstract—**An analysis is made of the optimum carrier-to-noise ratio (CNR) that can be obtained from a laser communications system using external polarization electrooptic modulation and avalanche diode detection. The analysis is not restricted to low-modulation index but covers the range up to the maximum possible modulation. Alternate definitions of modulation index are given in terms of communication concepts. Finally, some practical uses of the results are discussed.**

I. Introduction

In a previous publication [1] a study was made of the maximum signal power that can be obtained from electrooptic modulation of lasers using internal and external polarization modulation. In this paper, we shall consider the optimum carrier-to-noise ratio (CNR) that could be obtained from a laser communications system using external polarization, electrooptic modulation, and avalanche diode detection. The analysis is not restricted to low-modulation index but covers the range up to the maximum possible modulation. Alternate definitions of modulation index are given in terms of communication concepts. Finally, some practical uses of the results are discussed.

Manuscript received March 7, 1975; revised April 28, 1975. This work was supported in part by the Canadian Government under Defense Industrial Research Grant 9751-11.

The author is with RCA Research Laboratories, Ste-Anne de Bellevue, P. Q., Canada.

II. System Analysis

The type of system that is being considered is shown in Fig. 1. It consists, on the transmitter side, of a laser producing a polarized beam of power P_l, an electrooptic modulator properly oriented, a phase shifter, an analyzer, and a telescope. The receiver includes a telescope, an avalanche-type diode, and a preamplifier. It is assumed that maximum modulation of the laser beam is permissible even though strong nonlinearity will be produced. This is because the resulting intensity modulation can be used to generate a subcarrier which can itself be modulated by any convenient modulation scheme such as FM,

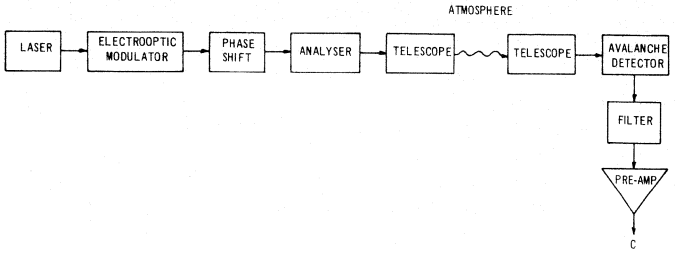

Fig. 1. Schematic diagram of a laser communication system.

PM, or PCM. Nonlinear effects would then become inconsequential. In our subsequent derivations, CNR will refer to that subcarrier which modulates the laser beam.

A. Modulation System

The type of modulation envisaged is a standard external polarization modulation using an electrooptic crystal as modulator. The output power P_0 in this case is given by [2]

$$P_0 = P_l \sin^2 \Gamma/2 \tag{1}$$

where P_l is the laser output power and Γ is the phase difference between the two electrooptic axes of the crystal.

A modulation voltage $V_m(\omega) = V_m \cos \omega_m t$ applied to such a crystal would produce a modulation in the power of the laser beam given by

$$P_0 = CP_l \{\tfrac{1}{2}[1 - \cos(\Gamma_b)J_0(\Gamma_m)] + \sin(\Gamma_b)J_1(\Gamma_m)\cos \omega_m t + \cdots\} \tag{2}$$

where the series is expanded only to the fundamental frequency. Other terms are eliminated by proper filtering. J_n is the Bessel function of order n. $\Gamma = \Gamma_b + \Gamma_m \cos \omega_m t$ is the total phase difference along the two electrooptic axes of the crystal made up of a constant bias term Γ_b and a modulated term of amplitude Γ_m and circular frequency ω_m. The constant term can be the result of natural birefringence or a dc voltage applied to the crystal, while the modulated term is produced by the modulating voltage $V_m \cos \omega_m t$ through the relation $\Gamma_m = KV_m$ with K a constant. Finally, C is the coupling coefficient of the polarization coupler which extracts the cross polarized part of the beam ($\leqslant 1$).

B. Modulation Indices

In order to relate our results to the magnitude of the modulation impressed on the carrier, possible definitions of modulation indices have to be given explicitly. Also the functional relation between these indices and the phase modulation (Γ_m) should be obtained. The power output versus phase shift relation is shown in Fig. 2.

If an optical bias Γ_b is chosen and a drive modulation Γ_m is applied, the output light modulation would fluctuate between $P_{\max}$ and $P_{\min}$ in a manner similar to that depicted in the figure. This is what would be observed on a scope if the light is detected by a typical square law detector. The modulation is obviously not sinusoidal but is given by (2). Three modulation indices suggest themselves and will now be defined.

Peak-to-Peak Modulation Index m_p: This is probably the simplest modulation index as it can be obtained directly from

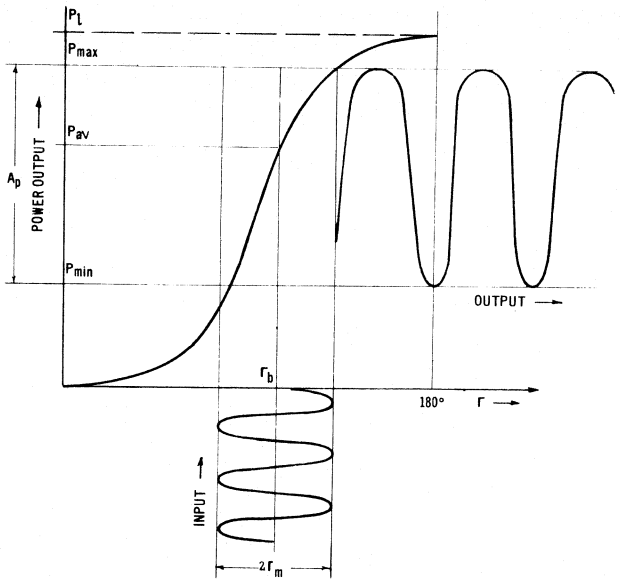

Fig. 2. Electrooptic modulation.

the scope output. We thus define the peak-to-peak modulation index as

$$m_p = \frac{P_{\max} - P_{\min}}{P_{\max}} = \frac{A_p}{P_{\max}} = \frac{2 \sin \Gamma_p \sin \Gamma_m}{1 - \cos(\Gamma_b + \Gamma_m)}. \tag{3}$$

Amplitude Modulation Index m_a: It is possible to define an amplitude modulation index m_a such that

$$m_a = \frac{P_{\max} - P_{\min}}{2/P_a} = \frac{\sin \Gamma_b \sin \Gamma_m}{1 - \cos \Gamma_b}, \quad \text{for } \Gamma_m \leqslant \frac{\pi}{2} \tag{4}$$

where P_a is that output power that would be obtained when Γ_m is reduced to zero.

Efficiency Factor ξ: A third modulation index, here called the efficiency factor ξ, is defined as the ratio of the total laser power which is being modulated at the signal frequency ω to the average nonmodulated part of the laser power, i.e.,

$$\xi = \frac{2 \sin(\Gamma_b)J_1(\Gamma_m)}{1 - \cos(\Gamma_b)J_0(\Gamma_m)}. \tag{5}$$

It can be shown that this term is directly related to the efficiency of the modulation being used.

Comparison Between the Indices: Probably the best way to compare the three indices is by means of a graph as shown in Fig. 3. Measurement of one modulation index thus permits the determination of the other two and the corresponding phase drive.

C. Detection

For detection, it is assumed that a standard avalanche detector is used. It is shown in [3] that the carrier power, noise power, and power CNR for these devices is given by

$$C = (P_R(\omega_m)R_0M)^2 \frac{R_L}{2} \tag{6}$$

$$N = \{2q(I_{ds} + (\bar{P}_R R_0 F_s + I_{db}F_d)M^2 + i_{na}^2(\omega_m)\}BR_L \tag{7}$$

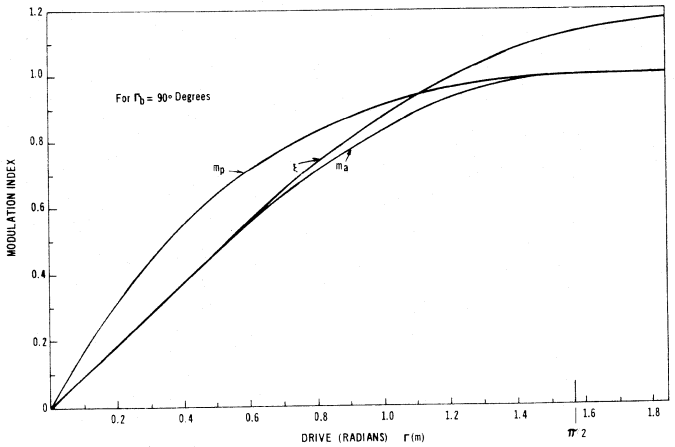

Fig. 3. Modulation indices versus phase angle drive.

$$\frac{C}{N} = \frac{(P_R(\omega_m)R_0M)^2/2}{\{2q[I_{ds} + (\bar{P}_R R_0 F_s + I_{db}F_d)M^2] + i_{na}^2(\omega_m)\}B} \tag{8}$$

where $P_R(\omega_m)$ is the received amplitude of the modulated power of the laser beam at the carrier frequency (at the detector), $\bar{P}_R$ is the received average dc component of laser power at the detector where

- R_0 unity-gain responsivity;
- M gain ($M = 1$ in the case of nonmultiplying photodiode);
- q electronic charge;
- I_{ds} that component of the dark current (usually the surface component) which is not multiplied, typically, $I_{ds} \approx 10^{-7}$ A for an RCA #C30817 diode;
- I_{db} that component of the dark current (usually the bulk-generated dark current) which undergoes multiplication, $I_{db} = 10^{-10}$ A for this diode;
- B noise bandwidth;
- i_{na}^2 equivalent mean-square noise current of the amplifier and biasing circuit;
- F_d detector effective excess noise factor appropriate to the multiplication of the dark current I_{db};
- F_s detector effective excess noise factor appropriate to the multiplication of the photocurrent (we assume that the radiation due to background and signals are at the same wavelength);
- R_L load resistance.

In the case of typical reach-through avalanche diodes [4]

$$F_s \approx F_d = k_e M + \left(2 - \frac{1}{M}\right)(1 - K_e) \tag{9}$$

where K_e is an effective weighted ionization rate ratio and depends on the particular diode. It is equal to 0.02 for the RCA #C30817

$$R_0 = \frac{q\eta}{h\nu}$$

where η is the efficiency of the diode and is about 70 percent for this diode.

- h Planck's constant.
- ν Laser frequency.

It shall be assumed here that the system under consideration has a gain bandwidth wide enough that it does not need to be taken into account in the calculation.

A bandpass filter introduced at the output of the detector, centered at the frequency of interest (ω_m), will produce a power signal [from (2)] of

$$P_R(\omega_m) = P_R \sin(\Gamma_b) J_1(\Gamma_m) \tag{10}$$

while the dc component is

$$\bar{P}_R = \frac{P_R}{2}(1 - \cos(\Gamma_b) J_0(\Gamma_m)) \tag{11}$$

where $P_R = TCP_l$ is the received power at the detector when $\Gamma_b = 180°$, $\Gamma_m = 0$. T is the transmission loss coefficient going from the modulator output to the detector. It includes all optical and atmospheric losses. By making the proper substitutions, the CNR becomes

$$\frac{C}{N} = \frac{(P_R \sin(\Gamma_b) J_1(\Gamma_m) R_0 M)^2/2}{\left\{2q\left\{I_{ds} + \left(\frac{P_R}{2}[1 - \cos(\Gamma_b)J_0(\Gamma_m)]R_0 + I_{db}\right)\left[k_e M + \left(2 - \frac{1}{M}\right)(1 - k_e)\right]M^2\right\} + \frac{4KT}{R_L}\right\}B}. \tag{12}$$

D. Optimization Carrier-to-Noise Ratio

It is evident that for best systems performance, one should strive to maximize the CNR at the receiving end. An examination of (12) will reveal that for high CNR, the laser power and coupling coefficient should be a maximum. Usually, the driving voltage limitation sets a limit on the driving phase Γ_m. In a real situation, the laser beam power will be attenuated by the intervening optics and atmosphere between laser and detector. In the calculation of CNR, we shall therefore set the received power P_R and the driving phase Γ_m as the independent variables. Optimization will then result by choosing the dc bias Γ_b and gain M so as to make the CNR a maximum.

Because of the complexity of (12) optimization has to be carried out using a computer. The avalanche diode considered here is a well-proven "reach-through" diode of a type such as an RCA #C30817. The standard load of $R_L = 50\ \Omega$ is used for the computation and a bandwidth of 30 MHz is assumed. The results of the optimization calculations are plotted in Figs. 4-7.

In Fig. 4 the optimum CNR is plotted as a function of the received power P_R for various modulation drive Γ_m. It can be seen that the amount of drive can have a marked effect on the CNR. In fact, a factor of about 9 in Γ_m (which is equivalent to the same factor in drive voltage) will produce a ratio of about 30 in CNR.

To obtain the optimum CNR for any other bandwidth than 30 MHz, simply multiply the CNR by 30 MHz and divide by the required bandwidth B. Fig. 5 is a plot of carrier signal and output noise as a function of received power. This is done for various Γ_m. The values are those obtained under maximum

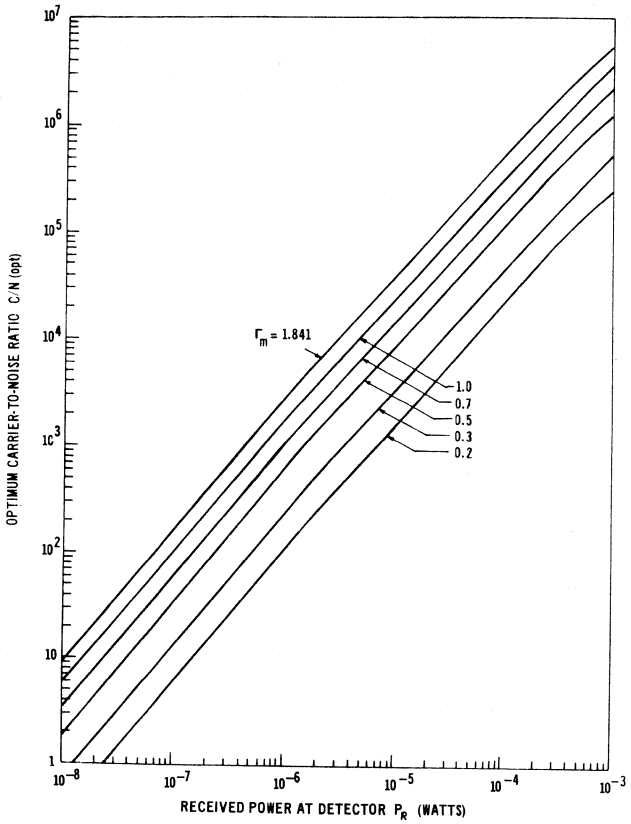

Fig. 4. Optimum CNR as a function of received power P_R for various signal drive Γ_m.

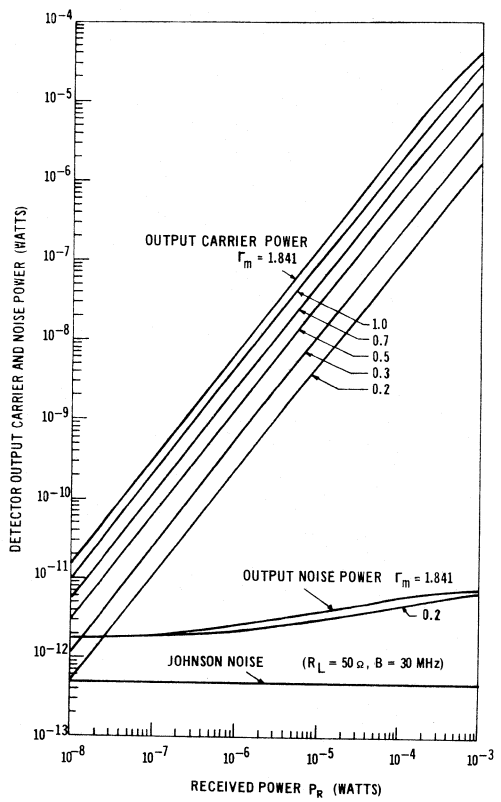

Fig. 5. Carrier and noise levels at detector output as a function of received power P_R and various signal drives Γ_m.

CNR. For reference purposes, the Johnson noise reference level is also put on the same graph.

In Fig. 6 the optimum avalanche diode gain M is plotted against the received power. As before, this is done for various Γ_m.

Fig. 7 is a plot of the optimum optical bias Γ_b as a function of P_R for various Γ_m.

Finally, Fig. 8 gives the maximum CNR as a function of Γ_m for various P_R.

III. Discussion of Results

Calculations using the curves in Fig. 4 result in a CNR which is approximately proportional to $P_R^{1.3}$ for $0.4 < \Gamma_m < 1.3$. The effect of drive (Γ_m) is important and Fig. 8 shows that the optimum CNR varies linearly with Γ_m in the interval $0.4 < \Gamma_m < 1.3$. Within some narrow limits it is possible to trade P_R for larger Γ_m although the former has a larger effect and is not limited in magnitude as is Γ_m. It is also observed that once Γ_m reaches about 1.4, 90 percent of the maximum attainable CNR has been achieved. Trying to obtain greater CNR by driving the modulator harder becomes a venture of diminishing return. For example, to go from $\Gamma_m = 1.4$ to its maximum value of 1.841 means an increase in voltage requirement of about 30 percent, i.e., an increase

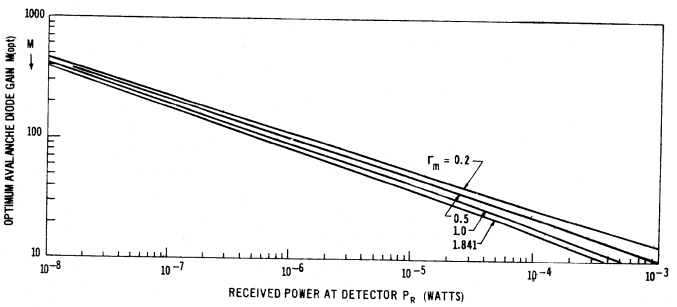

Fig. 6. Optimum avalanche detector gain (M) as a function of received power (P_R) for various signal drives (Γ_m).

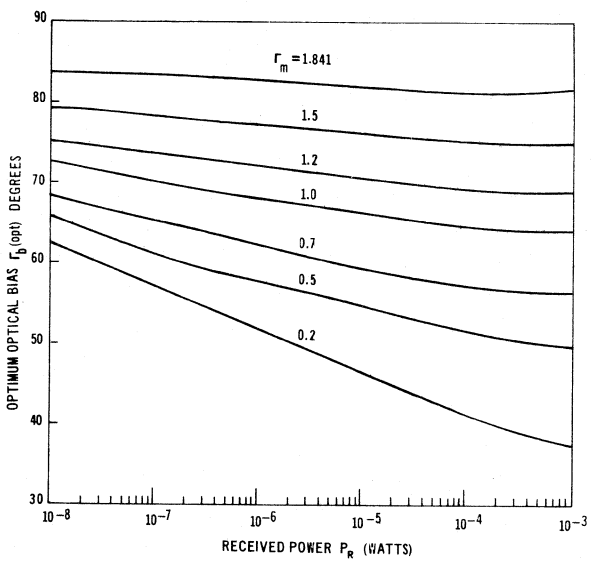

Fig. 7. Optimum optical bias (Γ_b) as a function of received power (P_R) for various signal drives (Γ_m).

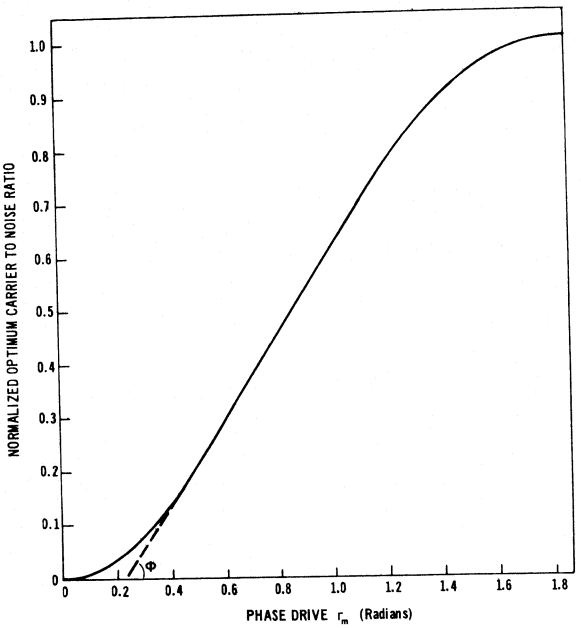

Fig. 8. Normalized CNR as a function of drive Γ_m.

drive power requirement of 70 percent. The benefit in CNR is only about 10 percent.

The optical bias required for optimum CNR is seen from Fig. 7 to be always below 90°. In fact, for small drive, the optical bias should be well below that point. The reason for this can be understood qualitatively if it is realized that although the maximum modulated power would occur for $\Gamma_b = 90°$, the average (dc) radiation component is very high at this point—specifically, it is equal to $P_R/2$ (see Fig. 2). The values of Γ_b given in Fig. 7 are thus a compromise between the size of the signal and the noise level produced by the dc component of the signal which results in the maximum possible CNR.

Consequently, in a practical situation, it is important to know the drive Γ_m and the expected received power in order to control the optical bias for optimum operation.

A. Practical Use of Results

In the design of a practical system it is most important to be able to predict its performance. For example, knowing the power output of a laser, the modulation index, and the loss through the atmosphere, it is possible to predict the absolute signal strength at the detector (P_R). The optimum CNR to be expected can then be obtained from Fig. 4.

In another example, let us suppose a communication system has been built and prediction of its performance under various conditions is required. This can be obtained by first measuring the laser power received by the avalanche detector using a power meter or a calibrated diode at the place of the detector. The power reading when the modulator phase is adjusted for maximum output (no RF modulation) gives the value of P_R. Knowing the drive Γ_m, it is now possible to determine the optimum CNR for this situation (using Fig. 4).

If a certain CNR is required, it is possible to obtain through Figs. 4 or 8 the required modulation drive Γ_m (or modulation index from Fig. 2). If the effect of the link distance or the weather can be evaluated, new values for P_R can be calculated and optimum CNR obtained using Fig. 4.

Acknowledgment

The author wishes to thank Dr. McIntyre and Dr. J. Conradi for their helpful discussions concerning the avalanche diodes as well as Dr. Bachynski for his kind support.

Interferometric Studies of Mode-Locked Nd^{3+}:Glass Lasers

RAJIV R. SHAH, STUDENT MEMBER, IEEE, THOMAS A. RABSON, MEMBER, IEEE, AND DAE M. KIM

Abstract—**A general technique for measuring the electric-field vector of the ultrashort pulses from mode-locked laser systems is described. The technique is applied to perhaps the most difficult laser to analyze, the dye mode-locked Nd^{3+}:glass laser whose pulses change rapidly in bandwidth and amplitude, are chirped, and can occur in quite short pulse trains. The results of these measurements indicate a rather rapid change in the phases between modes, and a plot of the phase change as a function of mode frequency has been obtained.**

I. Introduction

NUMEROUS TECHNIQUES have been developed for analysis of the output of mode-locked lasers [1]. The technique to be reported here is unusual in its inherent simplicity and the fact that its basic concepts are rooted in classical optics modified to take into account the transient nature of the output of mode-locked Nd^{3+}:glass lasers. The methods used so far are two- and three-photon fluorescence [2]-[4], second- and third-harmonic generation [5]-[7], time-resolved spectroscopy [8], [9], and photographing with ultrafast streak cameras with picosecond time resolution [10], [11]. The information obtained from all but the time-resolved spectroscopy method is limited mainly to the spectral- or temporal-intensity profiles of the picosecond pulses. However, the phase of the mode-locked field is equally important since the typical mode-locked output from pulsed lasers does not usually reach a steady state and such phenomena as chirping, partial mode locking, and substantial change of pulse characteristics from pulse to pulse even within a single firing of the laser are known to exist in mode-locked Nd:glass lasers. Cross-correlation measurements between two different lasers have been used to measure the time duration of one of the mode-locked HeNe lasers, and it was suggested that the technique be applied to mode-locked Nd^{3+}:glass lasers [12]. The necessity of having one unchirped laser was also mentioned in [12], whereas our technique only requires the cross correlation of two pulses in the pulse train of a single laser in order to obtain relative phase information.

One can measure the amplitude and frequency of the cavity modes which are present in the output pulse of a mode-locked laser by various well-known spectroscopic methods including the use of a Michelson interferometer (MI), which essentially gives the autocorrelation of the pulse. However, to determine completely the nature of the pulse, one must also determine the relative phase of the different modes in the pulse. These phases do not change appreciably throughout the duration of the pulse (usually less than 10 ps). It is shown in this paper how one can obtain by numerical techniques the relative phase change from one pulse to another from the experimentally determined cross correlation of the two pulses. If the form of one of the pulses in the train is known, then by forming the cross correlation of it with other pulses, the form of the other pulses can be determined. In addition to the cross correlation, the bandwidth and mode amplitude of the unknown pulses must be measured. The theory and experimental results of techniques involving time-resolved linear interferometry are presented herein. Specifically, it is pointed out that the measurements of fringe visibilities of auto- and cross correlations of Nd^{3+}:glass lasers can lead to information regarding: 1) the pulse bandwidth as well as the fraction and nature of the noise present; 2) the change of bandwidth between two successive pulses; and, finally, 3) the evolution of the relative phase of modes in any region of the pulse train. An interferometric technique of this kind, performed in different regions of the pulse train, combined with the fact that the pulses in the rising edge of the train are usually bandwidth limited [2], [9], can ultimately lead to the calculation of the time-dependent phase dispersion which occurs throughout the pulse train.

In Section II we present an outline of the theory of auto- and cross correlation of short pulses. The experimental procedures for measuring these functions are described in Section III. The numerical analysis of the experimental data and the final results are presented in Section IV.

II. Theory

The fringe visibility (FV) as measured by the MI (sketched in Fig. 1) is given by

$$\mathrm{FV} = \frac{I_{\max} - I_{\min}}{I_{\max} + I_{\min}} \tag{1}$$

where the total registered intensity

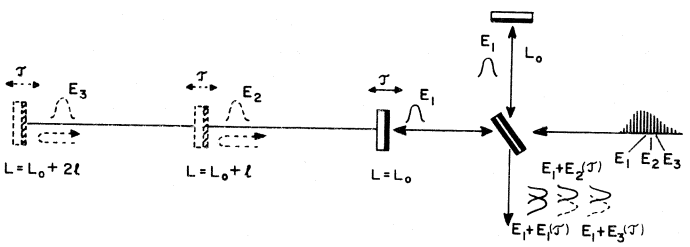

Fig. 1. Schematic representation of the MI as used for measuring auto- and cross correlations. L_0 is the distance of the fixed mirror from the beamsplitter and l is the optical length of the laser cavity. E_1, E_2, E_3 are any three consecutive pulses in the pulse train. τ is the differential displacement of the movable mirror.

The authors are with the Department of Electrical Engineering, Rice University, Houston, Tex. 77001.

$$I = \int_{-\infty}^{\infty} dt \langle |E_i(t) + E_j(t+\tau)|^2 \rangle \quad (2)$$

consists of the linear superposition of the time-delayed electric field of the same ($i = j$) or different pulses ($i \neq j$).

A. Autocorrelation

For the case of autocorrelation, for which $i = j$, the net registered intensity can be expressed in terms of the power spectrum of the electric field as

$$I(\tau) = 2\,\mathrm{Re} \int d\omega [\,|\langle \mathcal{E}(\omega) \rangle|^2 + \langle |\epsilon(\omega)|^2 \rangle]\ [1 + e^{-i\omega\tau}]. \quad (3)$$

Here we have partitioned the field power spectrum into the mode-locked signal $|\langle \mathcal{E}(\omega) \rangle|^2$ and random noise $|\epsilon(\omega)|^2$ to include the effect of noise on fringe visibility since the output pulse is generally accompanied by noise due to imperfect mode-locking. Upon inserting (3) into (1), we obtain

$$\mathrm{FV} = \frac{\left| \int dw [\,|\langle \mathcal{E}(\omega) \rangle|^2 + \langle |\epsilon(\omega)|^2 \rangle]\ e^{-i(\omega - \omega_0)\tau} \right|}{\int dw [\,|\langle \mathcal{E}(\omega) \rangle|^2 + \langle |\epsilon(\omega)|^2 \rangle]} \quad (4)$$

where ω_0 is the central frequency of the emission.

From (4) note that by measuring the FV of the field autocorrelation one can distinguish the nature of noise present in the mode-locked pulses. For instance, for the case of white noise, the FV will go to zero for large delay time τ. The same is true if the bandwidth of the noise is of the same order of magnitude as that of the mode-locked signal within the broad gain profile. If, on the other hand, the bandwidth of the noise is much less than that of the signal, the FV will not go to zero even for large T. Additionally, one can also obtain the fraction of power present in the noise and the ratio of bandwidths of two successive pulses. These points will be pursued further in the following sections.

B. Cross Correlation

For the case of cross correlation between two pulses in the same pulse train, the FV can be analyzed in the same way as in the autocorrelation. In this case, however, there exist two important differences: a) the two pulses can have different power spectra, i.e., bandwidths, which can be measured separately by autocorrelation techniques (see Section IV); and b), more importantly, the relative phase difference existing between the modes of the two pulses under consideration can significantly modify the FV profile. Because the FV curves for cross correlation are quite sensitive to relative mode phase, they can be used to measure these phases.

Thus we may write in this case

$$\mathrm{FV} = \frac{\left| \mathcal{S}(\tau) + \int \{\langle |\epsilon(\omega)|^2 \rangle\}_{\mathrm{av}}\, e^{-i(\omega - \omega_0)\tau}\, d\omega \right|}{\int d\omega [\{|\langle \mathcal{E}(\omega) \rangle|^2\}_{\mathrm{av}} + \{\langle |\epsilon(\omega)|^2 \rangle\}_{\mathrm{av}}]}. \quad (5)$$

Here $\{|\langle \mathcal{E}(\omega) \rangle|^2\}_{\mathrm{av}}$, $\{\langle |\epsilon(\omega)|^2 \rangle\}_{\mathrm{av}}$ represent, respectively, the powers in the mode-locked signal and noise averaged over the two interfering pulses, and the signal portion of FV

$$\mathcal{S}(\tau) \equiv \int |\langle \mathcal{E}_1(\omega) \rangle|\, |\langle \mathcal{E}_2(\omega) \rangle|\, e^{i\Delta\chi(\omega)}\, e^{-i(\omega - \omega_0)\tau}\, d\omega \quad (6)$$

contains explicitly the relative phase between the two pulses

$$\Delta\chi(\omega) = \chi_1(\omega) - \chi_2(\omega). \quad (7)$$

III. Auto- and Cross-Correlation Measurements

A. Experimental Setup

The experimental systems for generation and measurement of picosecond pulses are depicted schematically in Fig. 2. The setup consists of 1) a mode-locked Nd^{3+}:glass laser; 2) a triangular two-photon-fluorescence (TPF) monitoring arrangement; 3) a diffraction spectrometer; and 4) a photodiode-oscilloscope detection system. In addition, the arrangement necessary for time-resolved interferometry includes: 1) a Michelson interferometer (MI); 2) an image-converter camera (ICC); 3) a laser-triggered spark gap (LTSG); and 4) a 17-m optical delay path.

The laser cavity consists of two plane-wedge mirrors with 99- and 65-percent reflectivities. The active medium is an Owens Illinois Type ED2 Nd:glass rod 20.5 cm long, 1 cm in diameter, and cut at Brewster angles at both ends. The rod was pumped by an ILC helical xenon flashlamp. The cavity was made to oscillate in the TEM_{00} mode by inserting a 3-5-mm spatial filter into the cavity. Mode locking was achieved using Eastman Kodak dyes A-9860 in 1,2-dichloroethane or A-9740 in chlorobenzene.

Small fractions of the laser output were sampled to monitor: a) the TPF in a 10^{-2}-M solution of rhodamine-6 G in ethanol using a triangular arrangement; b) the spectra of the pulse trains on Kodak 1Z plates at the output of a Jarrel Ash Series 70-000 3.4-m Ebert grating spectrograph with a first-order reciprocal linear dispersion of 5.0 Å/mm; and c) the intensity profiles of pulse trains using an ITT F-4000 biplanar vacuum photo-diode detector displayed on a Tektronix 7904 oscilloscope.

The rest of the beam was allowed to reach the MI after traveling a distance of 17 m in air (effective delay ≈ 55 ns). The movable arm of the interferometer could be moved through a distance $L = L_0 + 2l$, where l is the optical length of the cavity and L_0 is the distance of the fixed mirror from the beamsplitter. The movable mirror was mounted on a translation stage provided with a micrometer gauge to allow small, accurately measured dispalcements. The output of the MI was viewed through a TRW Instruments STL Model 1D ICC with an S-1 spectral response tube and fitted with a Model 7B high-speed streak unit. Fast and efficient triggering of the ICC was achieved by using an LTSG. A small fraction of the beam focused with a short focal-length lens was used to trigger the spark gap. The LTSG delays were typically less than 40 ns.

The experimental setup described previously allowed simultaneous recording of the TPF, the spectrum, the intensity profile, and streaked interference fringes of the mode-locked laser output.

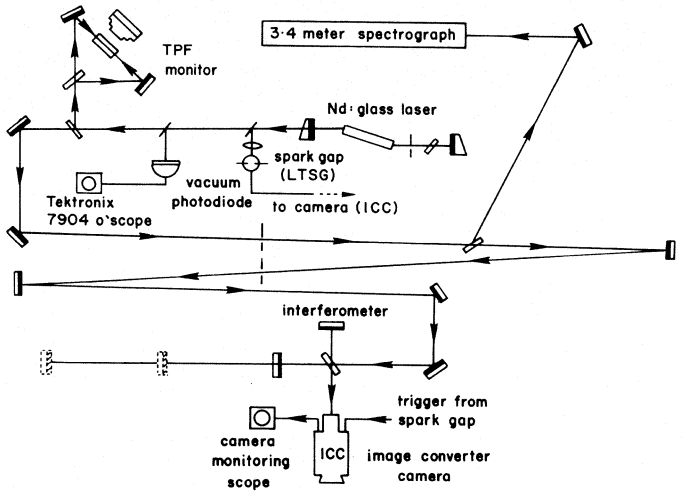

Fig. 2. Experimental arrangement for generation and measurement of picosecond pulses. In addition to the MI and ICC necessary for measuring time-resolved correlations, the experimental setup includes a TPF monitor and a 3.4-m spectrograph.

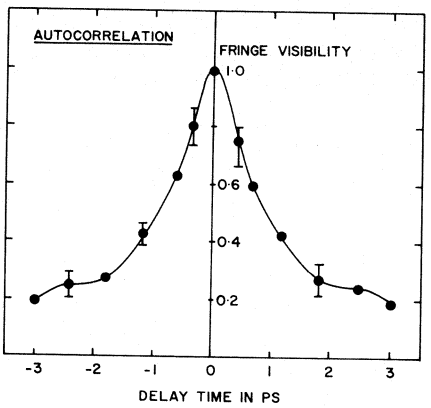

Fig. 3. Measured FV as a function of delay time τ for autocorrelation.

B. Techniques

Reproducible regular pulse trains were obtained under carefully controlled conditions. High peak power, short pulse trains were generated using a concentrated mode-locking dye solution and pumping voltages approximately 20 percent above threshold. The optical length of the cavity as determined by adjacent-pulse cross correlation TPF was 74.8 cm. Pulse trains generated under these conditions were typically of 100–150-ns duration. Spectral widths were determined from the microdensitometer records of the processed photographic plates. Photographs of the TPF taken with an $f = 5.6$ cm, 1:1.3 camera were similarly analyzed with a microdensitometer.

Since the interference patterns were obtained for pulses with durations $\sim 10^{-12}$ s, the arms of the interferometer had to be equal to within a fraction of a millimeter. The ICC was triggered by a high-voltage pulse (~ 600 V) obtained from the LTSG. For pulse trains of 100–150-ns duration and a triggering accuracy $\leqslant 40$ ns of the spark gap, exposures could be obtained only on some shots of the laser for a 2-m delay path. This indicated that the region of observation was close to the tail of the pulse train. Introducing a 17-m delay path shifted the region of observation further up in the pulse train. The ICC was operated without the objective lens and with a slit in front of the photocathode. The streaking rate of the ICC was 50 mm/20 ns and the direction of sweeping was parallel to that of the fringes.

Time-resolved interference patterns were recorded on Kodak Royal X-Pan film. The film was developed using Acufine developer. Under conditions of operation and processing identical to that in the actual experiment, the characteristic curve for the film was plotted using density steps from the Kodak photographic step tablet. From the microdensitometer traces of the interference fringes and the characteristic curve of the film, the values of intensity maxima, minima, and hence of FV were obtained. For each setting of the interferometer arm (zero, one, or two cavity transit-time delays) values of FV were obtained for various values of the differential delay τ between the interferometer arms. Simultaneously, the TPF, the spectrum, and the intensity profile were recorded for each value of τ.

C. Results

The pulse trains were of 100–150-ns duration, consisting of 20–30 pulses. Typical widths for the time-integrated spectra ranged between 9 and 15 cm^{-1} and the time-integrated TPF widths were between 2 and 5 ps. In each interference pattern from the ICC, four sets of interference fringes were obtained corresponding to four consecutive pulses in the same pulse train as in [13]. From these pictures one can obtain the difference in sharpness of the sets of fringes for different delay times.

In Fig. 3 the measured autocorrelation fringe visibility as a function of differential delay time τ in the arms of the interferometer is plotted. The pulses in a streaked picture are any four consecutive pulses in the region of the pulse train being probed limited by the accuracy of the triggering system. Note in particular that the FV does not fall off to zero for large delay time. From this curve one can determine the bandwidth of the mode-locked signal and can also infer the nature as well as the power fraction of noise, as will be explicitly presented in the next section. In addition, by comparing the FV for any two successive sets of fringes in a streaked interference pattern one can obtain the change of bandwidth between two successive pulses.

In Fig. 4 we present the FV curves for cross correlation between two consecutive pulses. The substantial difference in the general shape of this curve as compared to that of autocorrelation clearly demonstrates the relative phase dispersion existing between two consecutive pulses. This will be elaborated upon in Section IV. Experimentally measured values of FV for the correlation of pulses separated by two cavity transit times are given in Fig. 5. For this case, due to the rapid variation of the FV values within the delay-time intervals used (which are the same as in Figs. 3 and 4) one should take the curve with data points connected qualitatively. However, the significance of this curve will be explained later.

IV. Analysis and Conclusions

In interpreting the autocorrelation fringe visibility, we approximate the actual power spectrum of the mode-locked signal and nosie with, in general, different bandwidths. Inas-

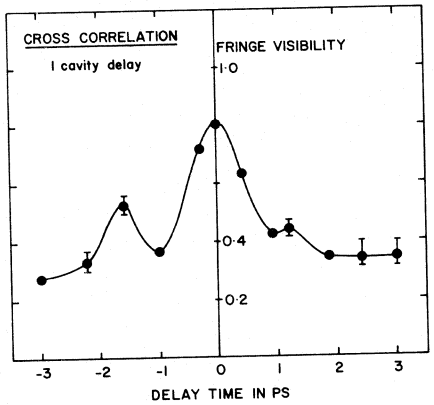

Fig. 4. Measured FV as a function of differential delay time τ for 1 cavity-delay cross correlation.

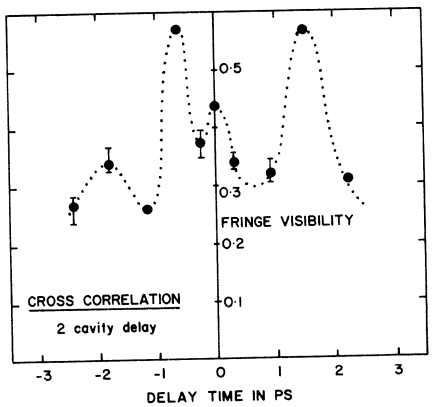

Fig. 5. Measured values of FV as a function of differential delay time τ for 2 cavity-delay cross correlation. The dotted curve represents the experimental values connected only qualitatively, due to rapid variation of FV within the delay-time intervals used.

much as the main information contained in this FV is the bandwidth, our Gaussian approximation with the corresponding bandwidth determined to fit the data optimally is a reasonable assumption. Needless to say, this approximation is not essential. However, any improvement in actual data fitting does not lead to substantial change in the information to be obtained. Hence (4) can now be written as

$$\mathrm{FV} = [e^{-\beta\tau_p^2} + f]\ [1+f]^{-1} \tag{8}$$

where the dimensionless time parameter τ_p is scaled with respect to picosecond unit ($\tau_p = \Delta\Omega t$, $\Delta\Omega = 10^{12}$) and β is the correspondingly scaled bandwidth of the signal. In view of the fact that the autocorrelation curve (Fig. 3) does not fall off to zero but reaches a constant value for a large delay time, it is clear that the bandwidth of the noise is much less than that of the signal. Thus we may, to a good approximation, take the time dependence of noise to be essentially constant f in the τ_p scale, in which case f represents the power fraction of noise with respect to signal power.

By optimally fitting (8) to our autocorrelation data we find that $f = 0.25$ and $\beta = 1.125$. This means that about 75 percent of the laser output power goes into the mode-locked optical pulses whose spectral bandwidth is approximately 10 cm^{-1}. These values for f and β fit the data to within 3-percent error (Fig. 6).

We next consider the cross correlation, first between two pulses separated by one cavity transit time. In so doing, we

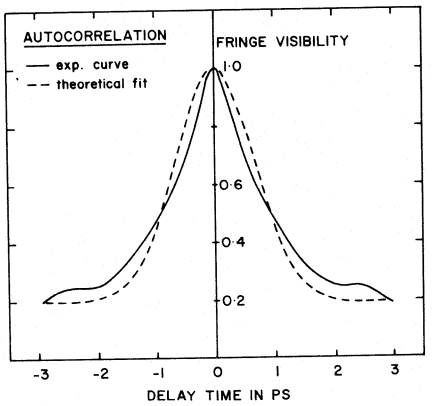

Fig. 6. Comparison of experimental and theoretical plots of autocorrelation FV as a function of differential delay time τ. Fit to data within 3.2 percent.

take the total power and fraction of noise in these two pulses to be the same. This is a good approximation considering the fact that the pulses are two consecutive pulses in a single pulse train. We point out, however, that the bandwidths of these two pulses are substantially different from each other. Their ratio is to be estimated by measuring the autocorrelation FV for two consecutive sets of fringes for a given delay time in a single streaked autocorrelation interference pattern. Bandwidth modulation of this kind has also been previously observed by Duguay *et al.* with a different technique [2].

As mentioned earlier, the relative phase dispersion existing between these two pulses can affect significantly the FV curve for cross correlation. In order to obtain this phase dispersion, we first represent the relative phase as

$$\Delta\chi(\omega) = a \sin K\left(\frac{\omega-\omega_0}{\Delta\Omega}\right) + b \cos K\left(\frac{\omega-\omega_0}{\Delta\Omega}\right). \tag{9}$$

Here, the parameters a, b, and K (scaled with respect to picosecond units) will be determined in such a way that the ensuing theoretical expression fits optimally the experimental data. The fit to data will undoubtedly improve if we increase the number of available parameters by adding more terms in (9) such as the harmonic terms. But as will become clear later, (9) is adequate for the analysis of our data.

Upon inserting (9) into (5) and (6), with the identity

$$e^{iz\sin\theta} = \sum_{n=-\infty}^{\infty} J_n(z)\, e^{in\theta}$$

with J_n representing nth-order Bessel function, we find, as in the case of autocorrelation,

$$\mathrm{FV} = \left(\frac{2r}{1+r^2}\right)^{1/2} [1+f]^{-1}\ [f + |\delta(\tau_p)|] \tag{10}$$

with

$$\delta(\tau_p) = \sum_{\pm} \{[A_0 e^{-\gamma\tau_p^2} + A_{\pm 1} e^{-\gamma(\tau_p \pm K)^2} + A_{\pm 2} e^{-\gamma(\tau_p \pm 2K)^2}] + i[B_{\pm 1} e^{-\gamma(\tau_p \pm K)^2} + B_{\pm 2} e^{-\gamma(\tau_p \pm 2K)^2}]\} \tag{11}$$

$$\gamma = 2r^2\beta/[1+r^2] \tag{12}$$

and

$$A_0 = J_0(a)\,J_0(b)$$
$$A_{\pm 1} = \pm J_0(b)J_1(a)$$
$$A_{\pm 2} = J_0(b)\,J_2(a) - J_0(a)\,J_2(b)$$
$$B_{\pm 1} = J_0(a)\,J_1(b)$$
$$B_{\pm 2} = \pm J_1(a)\,J_1(b). \tag{13}$$

Here r denotes the ratio of bandwidth of these pulses.

We take the values $f = 0.25$ and $r = 1.74$ appearing in (10) as obtained from the autocorrelation data to fit the theoretical expression to the cross-correlation curve. Numerical analysis of one cavity delay cross correlation was performed by varying the parameters a, b, and K. The best fit is obtained for $a = -0.23$, $b = 0.77$, and $K = 1.555$, in which case the error is 2.5 percent (see Fig. 7). In Fig. 8 we show the relative phase dispersion corresponding to this best fit. The shape of this phase curve shows explicitly that there exist both positive- and negative-frequency chirping as well as a substantial degree of nonlinear phase dispersion occurring within the bandwidth of the mode-locked signal. This rapid change in phase and bandwidth is understandable considering the fact that the pulses investigated here lie near the peak amplitude region of short high-power pulse trains.

We also applied our analysis to previously reported data obtained under different conditions [13]. The auto- and one cavity-delay cross correlation FV's reported therein were measured for the case of 1) long pulse trains of durations 400–500 ns, and 2) the region of investigation long after the start of the pulse train. The results of the analysis are shown in Figs. 9–11. The bandwidth of the pulse is 23 cm^{-1}, the fraction of noise power $f = 28$ percent, and the ratio of bandwidths of two successive pulses, $r = 1.2$. The main difference lies in the cross correlation, and hence the phase-dispersion curve. Note that in this case there is essentially no relative

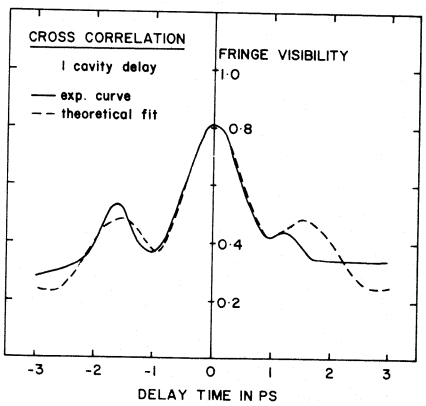

Fig. 7. Comparison of experimental and theoretical plots of 1 cavity-delay cross correlation FV as a function of differential delay time τ. Fit to data within 2.5 percent.

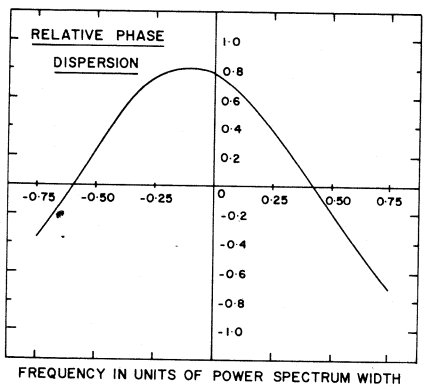

Fig. 8. Relative phase dispersion plotted in frequency units of power-spectrum bandwidth. The shape of the curve demonstrates the existence of positive- and negative-frequency chirping as well as substantial degree of nonlinear phase dispersion in the peak amplitude region of short high-power pulse trains. The region of the curve near $\Delta\omega = 0$ is most important because the amplitude of the modes is largest there.

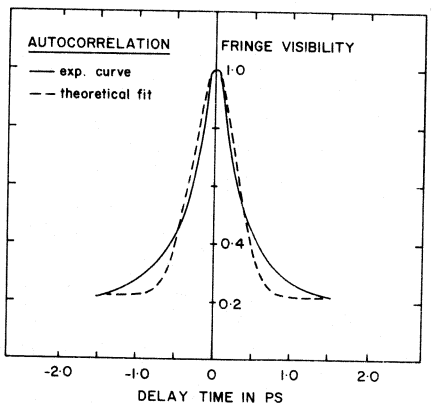

Fig. 9. Comparison of experimental and theoretical plots of autocorrelation FV as a function of differential delay time τ for the data reported in [13]. Fit to data within 2.5 percent.
