Spectral Hole Burning in Dye Solutions

GERARD MOUROU

Abstract—**Using picopulses generated by a mode-locked ruby laser, we have measured the 3-8-Å bandwidth of a hole burned in the 0–0 transition of cryptocyanine in methanol and demonstrated the inhomogeneous character of this transition.**

The population-rate equations are written for an inhomogeneous transition with two and four energy levels interacting with continuous or pulsed excitation. Using the numerical solutions of this model together with the experimental result we determine a transverse relaxation time T_2 = 0.6–1 ps for cryptocyanine in methanol.

Introduction and Summary

In order to explain the spectral condensation of the Q-switched ruby-laser emission, some authors [1] introduced the concept of spectral hole burning in dye solutions and devised experiments to observe either directly [2], [3], [7], [8] or indirectly [4]–[6], [9], [10] the spectral behavior of the transition when the solutions were excited by the strong monochromatic light from a Q-switched laser. Very disparate results were obtained because, in our opinion, of the quasi-continuous[1] excitation used in all these experiments. In effect, as we will show in the theoretical model described in the following, the depth of the hole created by continuous excitation is small and not easily detected even for an extremely inhomogeneous line. Using short-test and excitation pulses one may improve considerably the detection of hole burning.

This paper presents an experimental and theoretical line-shape analysis of the absorption bands of dye solutions commonly used in the laser field. Experimental measurements of the hole-burning bandwidth of cryptocyanine dissolved in methanol were obtained using short pulses generated by a mode-locked ruby laser. The estimated 3-8-Å bandwidth is within the range of values of 30 and 0.5 Å given by Spaeth and Sooy [7] and Giuliano and Hess [5]. From this value a dephasing time $T_2 \approx 0.6$–1 ps is deduced for the solution. A similar time will be deduced from the line-shape analysis of the transition.

The inhomogeneous broadening of the dye transition is attributed to the different solvent cages, as well as the different configurations adopted by the solute molecule. This hypothesis is supported by the Gaussian shape of the absorption band.

A theoretical treatment will be presented where we will consider the population rate equations for an inhomogeneous transition with two-level and four-level models. From these equations we will find the solution of the hole burning for continuous monochromatic excitation and the spectral behavior of the absorption band during mode-locked excitation.

Manuscript received April 25, 1974; revised September 12, 1974. This work was supported by the Petroleum Research Fund.

The author was with the Laboratoire de Recherche en Optique et Laser, Laval University, P.Q., Canada. He is now with the Department of Chemistry, San Diego State University, San Diego, Calif. 92115.

[1] Quasi-continuous since the pulse duration T is greater than the fluorescence decay time T_1, typically $T \sim 50$ ns, $T_1 < 5$ ns.

Direct Measurement of Hole Burning in Cryptocyanine [8]

As shown schematically in Fig. 1, a train of pulses of 7-ps duration was used both to bleach the dye solution and to generate the spectrally broadened picopulses which probed the shape of the absorption band in the vicinity of the excitation wavelength. A beam splitter (B) divided the ruby-laser output in two parts. One part was focused into a 20-cm path length CS_2 cell. There the spectrum of the pulse was broadened by self-phase modulation. Immediately after the CS_2 cell a lens L_2 brought into focus the parallel light not trapped in filaments and this light was blocked by a small-diameter mask (M) at the focal point. The light trapped in filaments (and therefore strongly broadened) was collected by a lens L_3, passed through the 2-mm dye cell, and imaged on the slit of a spectrograph. The other beam (transmitted by B) passed through an adjustable delay line and bleached the dye. The low-intensity transmission of the dye T_0 is 10^{-3} for a concentration of 10^{-4} M. At this concentration there is no evidence for dimerization since the absorbance obeys the Beer–Lambert law. In addition, it is worth noting that, according to the work of Dempster *et al.* [11], no photoisomers have been found.

A diaphragm D with the same dimensions as the pump beam (7 mm) was set against the cell. The synchronization of the two beams was obtained by varying the delay line and observing the signal of a photomultiplier placed at the position of the spectrograph slit.

First, we checked that the film was not exposed by the probe beam when the exiting beam was blocked [Fig. 2(b)]. The Raman-scattered light did expose the film since this light is outside the 0–0 absorption band of cryptocyanine in methanol. Then we recorded the test beam spectrum when the exciting beam bleached the dye [Fig. 2(c)]. The input spectrum

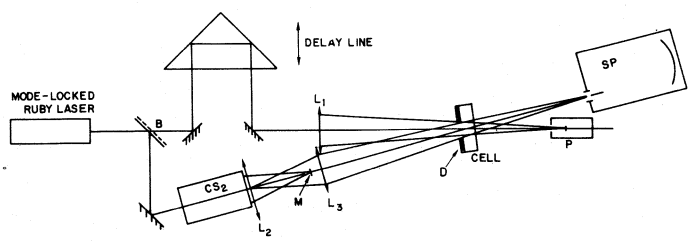

Fig. 1. The experimental arrangement which was used to demonstrate hole burning in the absorption band of cryptocyanine in methanol is shown. A beam splitter B divides the mode-locked ruby-laser output into a test pulse and a pump pulse. The test pulse is spectrally broadened by self-focusing in a cell of CS_2. A lens L_2 collects the light which is not trapped in filaments (and therefore not spectrally broadened) and brings it to a focus on a mask M. The lens L_3 images the light which was trapped in filaments in the CS_2 cell onto the slit of the spectrograph SP. The pump beam travels through an adjustable delay line and through the lens L_1 which focuses the beam into a light trap P. A diaphragm D is placed adjacent to the cell so that only that part of the test beam which overlaps with the pump beam in the 2-mm dye cell enters the spectrograph. The cell contains cryptocyanine in methanol and the transmission at 6963 Å is initially 0.001.

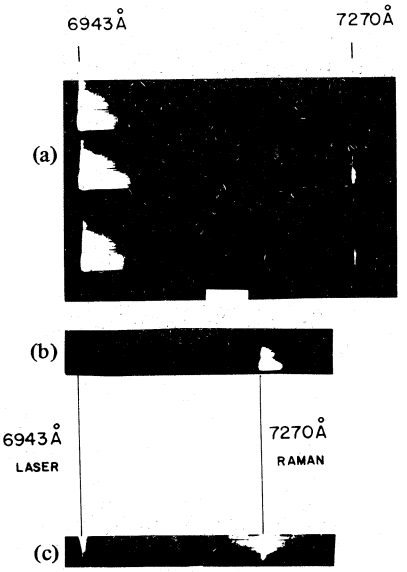

Fig. 2. (a) Spectrum of the incident test beam. The cryptocyanine has been removed and replaced by pure methanol. (b) Spectrum of the transmitted test beam when the cell contains the cryptocyanine (T_0 = 0.001) and the pump beam is off. The light at 6943 Å has been absorbed, while the CS_2 Raman-scattered light which is outside the absorption band is slightly attenuated. (c) Typical output spectrum obtained when the pump beam and the test beam are synchronous.

[Fig. 2(a)] was recorded by substituting pure methanol for the dye solution and setting a neutral density filter ($T = 0.50$) before the spectrograph slit in order to work in the same range of light intensity. From this we surmise that the transmission when the dye is bleached is in the range from 50 to 100 percent.

The densitograms of Fig. 2(a) and (c) (Fig. 3) show that a very narrow part of the probe beam, 5–10 Å wide, is transmitted when the dye is bleached. This observation leads us to conclude that there was a hole burned in the dye transition. On account of the spectral bandwidth of the laser, 2 Å, we estimate that the hole is 3–8 Å wide, and with the help of the theoretical treatment to be developed, we will determine that the dephasing time T_2 is between 0.6 and 1 ps.

Nature and Shape of the Dye Transition

Two mechanisms in dye solutions inhomogeneously broaden the transition. The first is related to the differences in the solvent cage surrounding each dye molecule, while the second is connected with the variation of the molecular configuration of the dye. For instance, for a polymethine cyanine dye such as cryptocyanine, formed by two heterocyclic nuclei linked by a conjugated chain, the transition frequency of these dyes should be very sensitive to the twisting of the heterocyclic nuclei with respect to the conjugated chain [15].

The variation of the solvent cages and molecular configurations are random quantities which exhibit Gaussian probability density. The numerical analysis of the absorption band for the cryptocyanine dye solutions shows that the long wavelength portion of the absorption band is approximately Gaussian, corroborating the hypothesis that the dye molecule's transition is inhomogeneous.

More precisely, Fig. 4 shows that the absorption curve can be fit with a convolution of a Gaussian 225 ± 5-Å full width at half maximum (FWHM) and a Lorentzian 15 ∓ 5-Å FWHM.

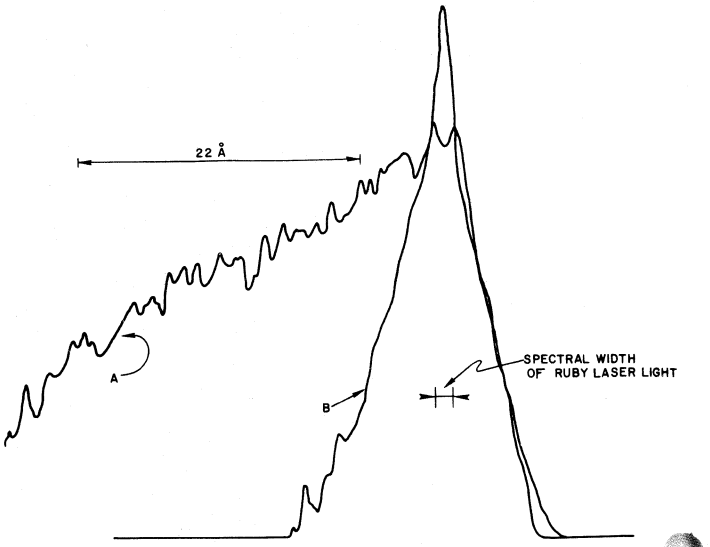

Fig. 3. Spectral selection carried out by the hole burning. Curve *A*: Input spectrum of the test beam. Curve *B*: Test-beam spectrum filtered by the hole burning.

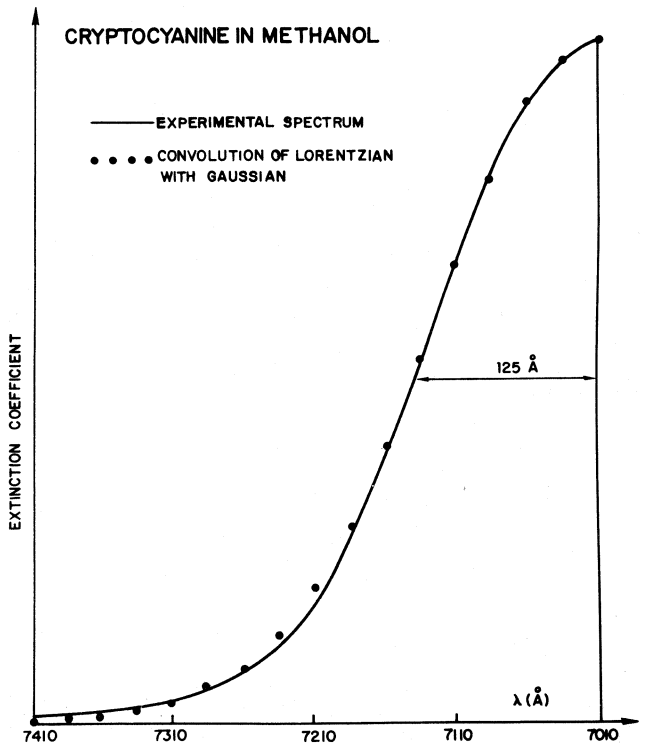

Fig. 4. Best fit of the experimental spectrum (–) of a cryptocyanine in methanol solution by the convolution (•) of a Gaussian (225-Å bandwidth) with a Lorentzian (15-Å bandwidth).

The Lorentzian bandwidth, which must be the homogeneous bandwidth of the solute molecule, is in good agreement with that deduced from the hole-burning experiment. Therefore, the line-shape analysis seems to be a convenient method to deduce the value of the homogeneous response of the solute molecule.

Inhomogeneous Transition Excited by Intense Monochromatic Field

Now, what is the behavior of the inhomogeneous transition when excited by an intense monochromatic light? Basically, since the super molecules (i.e., the dye molecules and their

solvent cage) making up the population are dissimilar, one needs to apply the population rate equations for all the different kinds of molecules at each frequency of the inhomogeneous line. However, all the frequencies ω will be coupled by spectral diffusion. The molecular agitation in the solution randomly forces each solvent cage and each solute molecule to adopt another configuration involving a different transition frequency for the super molecules. Let us call T_3 the time required to change the frequency. We will hypothesize that the probability for a molecule with a frequency ω' to adopt a frequency ω after a "collision" is proportional to $D(\omega)$, the molecular distribution. So we state that the probability rate per frequency of frequency change is

$$P(\omega' \to \omega) = \frac{1}{T_3} D(\omega) \tag{1}$$

with

$$\int_0^\infty D(\omega)\, d\omega = 1. \tag{2}$$

Now, let us write the population rate equations for a two-level and a four-level model.

Two-Level Model

Let us consider the energy diagram sketched in Fig. 5 and let us assume that the following is true.

1) The molecular distribution $D(\omega)$ is independent of the population of the ground 1 and excited state 2 so that

$$D(\omega) = n_1(\omega, t) + n_2(\omega, t) \tag{3}$$

where $n_1(\omega, t)$ and $n_2(\omega, t)$ are the number for the time t of molecules at the frequency ω in the states 1 and 2.

2) Since the halfwidth of the molecule distribution $D(\omega)$ is large compared to the homogeneous response of each super molecule, the extinction coefficient is proportional to the molecular distribution.

Let $I(\omega_L)$ and $\sigma(\omega)$ be the excitation intensity and the homogeneous cross section of the super molecule, respectively. On account of (1) and assumptions 1) and 2), the population rate equations for each frequency can be written

$$\frac{dn_1}{dt}(\omega, t) = -I(\omega_L)\, \sigma(\omega)\, n(\omega, t) + \frac{n_2(\omega, t)}{T_1} - \frac{n_1(\omega, t)}{T_3} + \frac{D(\omega)}{T_3} \int_0^\infty n_1(\omega', t)\, d\omega' \tag{4}$$

$$\frac{dn_2}{dt}(\omega, t) = +I(\omega_L) \cdot \sigma(\omega) \cdot n(\omega, t) - \frac{n_2(\omega, t)}{T_1} - \frac{n_2(\omega, t)}{T_3} + \frac{D(\omega)}{T_3} \int_0^\infty n_2(\omega, t)\, d\omega \tag{5}$$

with

$$\sigma(\omega) = \frac{T_2'}{T_1} \frac{\sigma_0}{1 + (2(\omega_L - \omega) T_2')^2} \tag{6}$$

$$n(\omega, t) = n_1(\omega, t) - n_2(\omega, t) \tag{7}$$

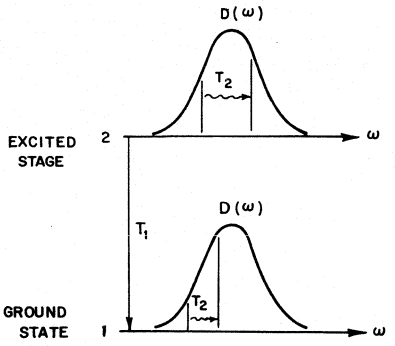

Fig. 5. Scheme of the two-level model with inhomogeneous population distribution adopted in the theoretical treatment.

where $1/T_2' = (1/T_1) + (2/T_2)$, and σ_0 is the maximum cross section when $T_2' = T_1$.

In (4) and (5) the first term is the number of stimulated transitions, the second relates spontaneous emission, while the third and the fourth are the terms associated with the spectral diffusion.

From (1)-(7) the expression of the population inversion for each frequency will be

$$\frac{dn}{dt}(\omega, t) = -2 \cdot I(\omega_L)\, \sigma(\omega)\, n(\omega, t) - \left(\frac{1}{T_3} + \frac{1}{T_1}\right) n(\omega) + \frac{D(\omega)}{T_1} + \frac{D(\omega)}{T_3} \int_0^\infty n(\omega, t)\, d\omega. \tag{8}$$

Equation (8) is expressed as a function of the homogeneous cross section $\sigma(\omega)$. Let us write this expression as a function of the classically measured[2] cross section $\sigma_M(\omega)$ and a parameter T_2' to be determined.

Assuming that $\sigma_M(\omega)$ is Gaussian, as shown previously, and since the oscillator strength is independent of the broadening mechanism, we can write

$$\int_0^\infty \sigma(\omega)\, d\omega = \int_0^\infty \sigma_M(\omega)\, d\omega. \tag{9}$$

Using (6) the homogeneous cross section can be expressed as

$$\sigma(\omega) = \frac{T_2' \cdot \Delta\omega_T}{\sqrt{\pi \cdot \ln 2}} \cdot \frac{\sigma_M(\omega_0)}{1 + (2(\omega - \omega_0) T_2')^2} \tag{10}$$

where $\Delta\omega_T$ is the Gaussian half-power bandwidth and ω_0 is the center frequency. If $I_S(\omega_0) = [(\sigma_M(\omega_0) \cdot T_1)/2]^{-1}$ is the saturation intensity, then (8) will take the form for $\omega_0 = \omega_L$

$$\frac{dn}{dt}(\omega, t) = \sqrt{\frac{1}{\pi \cdot \ln 2}} \cdot \Delta\omega_T \left(\frac{T_2'}{T_1}\right) \cdot \frac{B(\omega_L)\, n(\omega, t)}{1 + (2(\omega_L - \omega) T_2')^2} + n(\omega) \cdot \left(\frac{1}{T_2} + \frac{1}{T_1}\right) + \frac{D(\omega)}{T_1} + \frac{D(\omega)}{T_3} \int_0^\infty n(\omega, t)\, d\omega \tag{11}$$

where $B(\omega_L) = I(\omega_L)/I_S(\omega_0)$.

[2] $\sigma_M(\omega)$ is obtained by dividing the extinction coefficient by the number of molecules per unit volume.

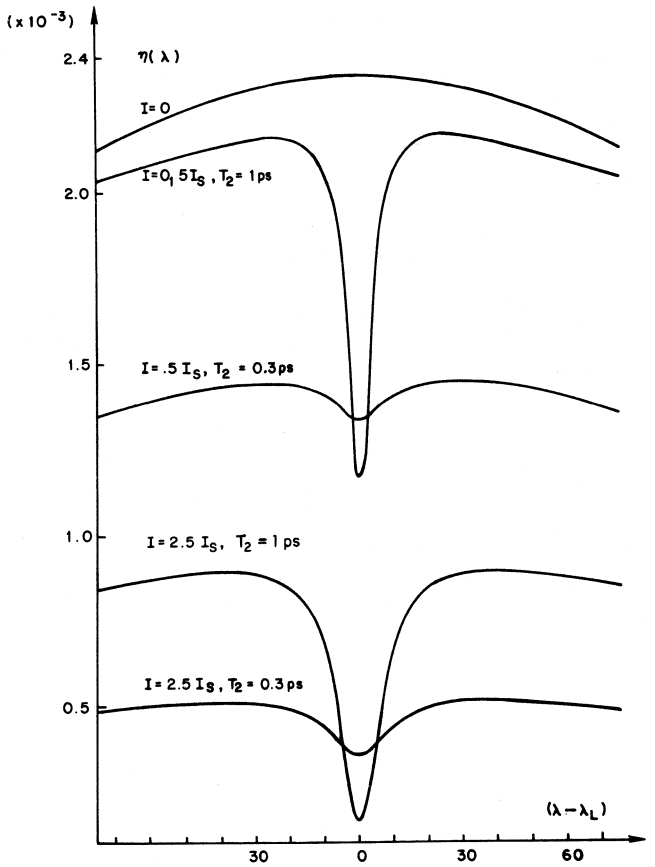

Fig. 6. Population inversion for a two-level inhomogeneous distribution when the solution is excited by continuous monochromatic light.

The steady-state solution for (11) is obtained numerically by applying a step function of amplitude B and assuming that each solvent collision alters the phase and the frequency of the molecule, in this case $T_2 = T_3$. After a time on the order of T_1 the solution of (11) does not change and may be considered steady state.

Fig. 6 shows the spectral distribution for two values of B and T_2, keeping $\Delta\omega_T = 1.54\ 10^{+14}$ rad/s and $T_1 = 50$ ps [12], [14] constant. $\Delta\omega_T$ and T_1 correspond approximately to the known parameters of cryptocyanine in methanol. The hole is narrower and deeper for larger values of T_2 because of the influence of molecular agitation both on the broadening of the homogeneous response and on the spectral diffusion. The excitation intensity also contributes to the width of the hole burned in the absorption band. The ratio between the minimum and the maximum absorption rapidly approaches unity when the spectral diffusion and dephasing times decrease. So we see that it is difficult to measure the hole-burning bandwidth with a continuous technique such as used by others [2]-[7]. The calculations made with pulse duration shorter than T_1 will show an improvement in the detection even for short T_2.

From (11) we can obtain the population inversion versus the intensity for homogeneously and inhomogeneously broadened lines with continuous excitation. Fig. 7 shows the variation of the population inversion at ω_L versus the excitation intensity for different values of T_2, keeping T_1 and $\Delta\omega_T$ constant. We notice significantly different behavior for each value, so that one may deduce T_2 from a study of optical saturation. However, this method supposes detailed knowledge of the specific parameters of the dye, such as the excited-singlet decay time, the solvent-solute relaxation time [12], and the anisotropic distribution of the excited oscillators, which makes the interpretation difficult.

Four-Level Model

Let us improve the previously developed theory by introducing the solvent cage and molecular-configuration effects which shift the ground and excited states after each transition. We will label these states 1, 2, 3, and 4 as shown in Fig. 8, for the stable ground state, the unstable excited state, the stable excited state, and the unstable ground state, respectively. We will assume that 1 and 2 are connected by T_1, while 2 and 3, like 4 and 1, will be connected by T_S, the solvent-solute relaxation time. Basically, the same treatment as for the two-level model will be used. Since it is not necessary to suppose any distribution for the states 3 and 4, the rate equations will be written

$$\frac{dn_1(\omega,t)}{dt} = -I(t)\,\sigma(\omega)\cdot n(\omega,t) - \frac{n_1(\omega,t)}{T_3} + \frac{D(\omega)}{T_3}\int_0^\infty n_1(\omega,t)\,d\omega + \frac{n_2(\omega,t)}{T_1} + \frac{n_4(t)\cdot D(\omega)}{T_S} \tag{12}$$

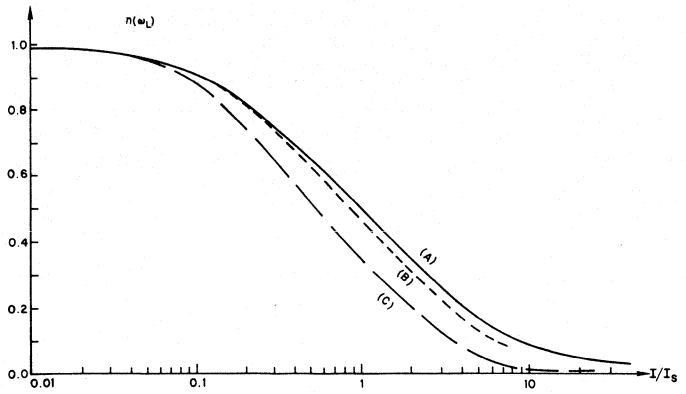

Fig. 7. Population inversion versus continuous monochromatic intensity shown by the following curves. *A:* for homogeneous broadening. *B:* for inhomogeneous broadening (T_2 = 0.3 ps). *C:* for inhomogeneous broadening (T_2 = 1 ps).

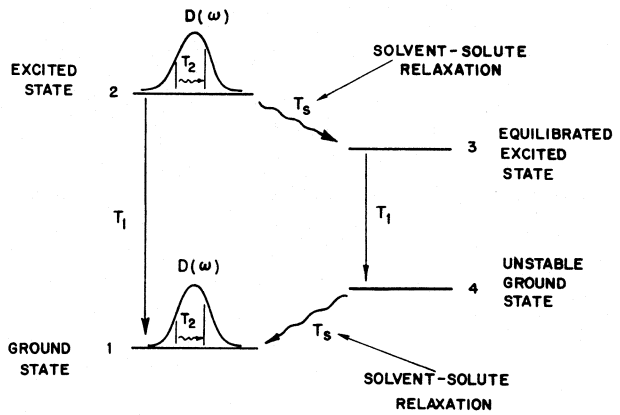

Fig. 8. Scheme of the four-level model with inhomogeneous population distribution adopted in the theoretical treatment. Stable ground state 1; unstable excited state 2; stable excited state 3; unstable ground state 4.

$$\frac{dn_2}{dt}(\omega,t) = +I(t)\cdot\sigma(\omega)\cdot n(\omega,t) - \frac{n_2(\omega,t)}{T_3} + \frac{D(\omega)}{T_3}\int_0^\infty n_2(\omega,t)\,d\omega - \frac{n_2(\omega,t)}{T_S} - \frac{n_2(\omega,t)}{T_1} \tag{13}$$

$$\frac{dn_3}{dt}(t) = \frac{1}{T_S}\int_0^\infty n_2(\omega,t)\,d\omega - \frac{n_3(t)}{T_1} \tag{14}$$

$$\frac{dn_4}{dt}(t) = \frac{n_3(t)}{T_1} - \frac{n_4(t)}{T_S} \tag{15}$$

$$n(\omega,t) = n_1(\omega,t) - n_2(\omega,t) \tag{16}$$

$$1 = \int_0^\infty n_1(\omega,t)\,d\omega + \int_0^\infty n_2(\omega,t)\,d\omega + n_3(t) + n_4(t). \tag{17}$$

With the help of (10) the system (12)–(17) is numerically resolved for a Gaussian pulse excitation, with 7-ps half-power duration. For T_1 = 50 ps and T_S = 10 ps [12], Fig. 9 shows the behavior of the spectral transition for the different times *A–F* during the excitation.

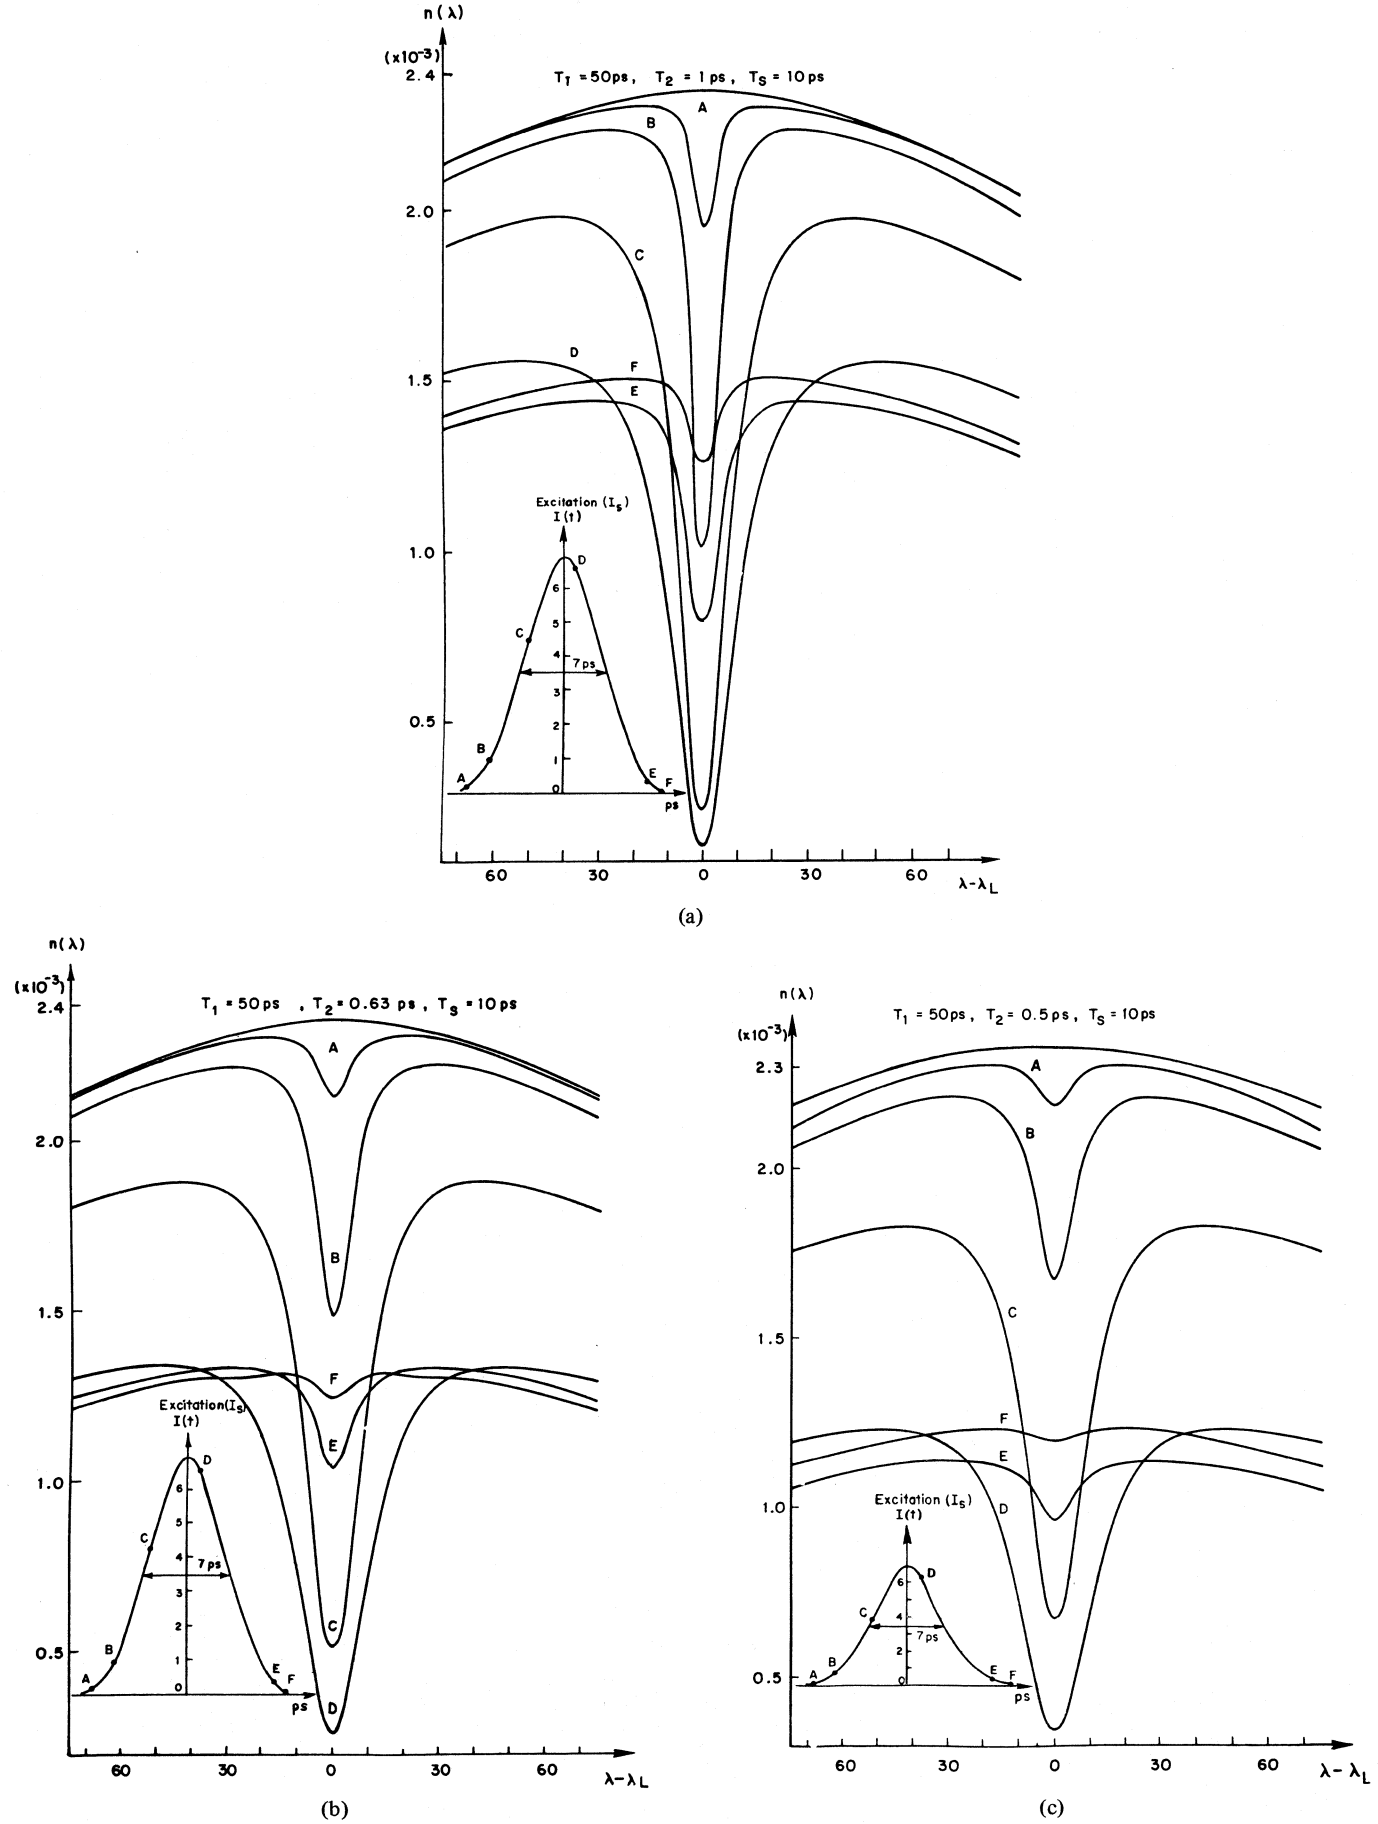
Now, in order to compare these curves with the experimental data, one must deal with the transmission versus wavelength which will be deduced using the simple expression

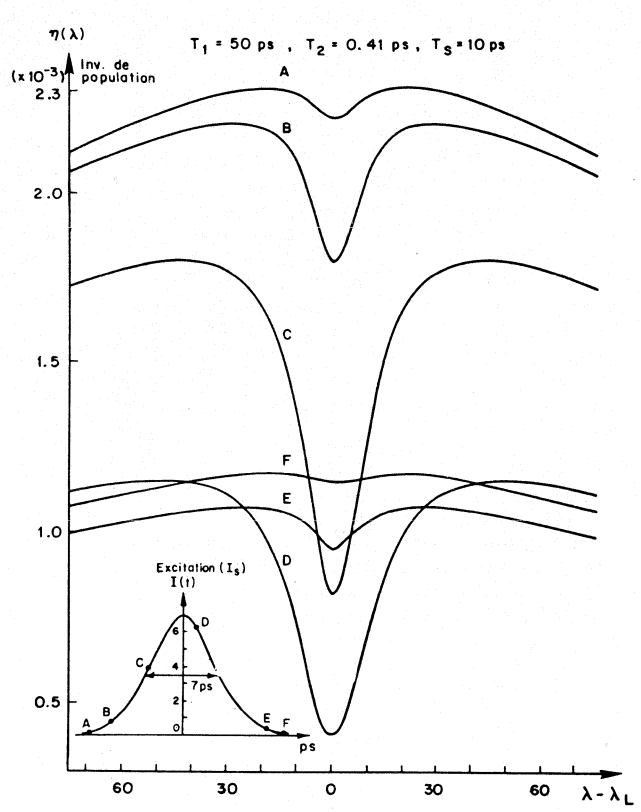
$$T(\lambda) = T_0^{n(\lambda)} \tag{18}$$

at the instant D, when the maximum of probe light goes through the cell. Fig. 10 shows that for T_1 = 50 ps and T_2 = 0.6–1 ps, a hole of 10-Å bandwidth is burned in the transition, as was observed experimentally.

Conclusion

By means of the ultrafast excitation and test pulses (pulse duration < excited-singlet lifetime) generated by a mode-locked ruby laser, we observed a 3–8-Å hole burned in the absorption band of cryptocyanine dissolved in methanol. The study of the line shape corroborated the experimental result and the idea of the inhomogeneous character of the dye transition. The population rate equations were written for the inhomogeneous case and resolved for two- and four-level models with the assumption that the spectral diffusion time T_3 is equal to the dephasing time T_2.





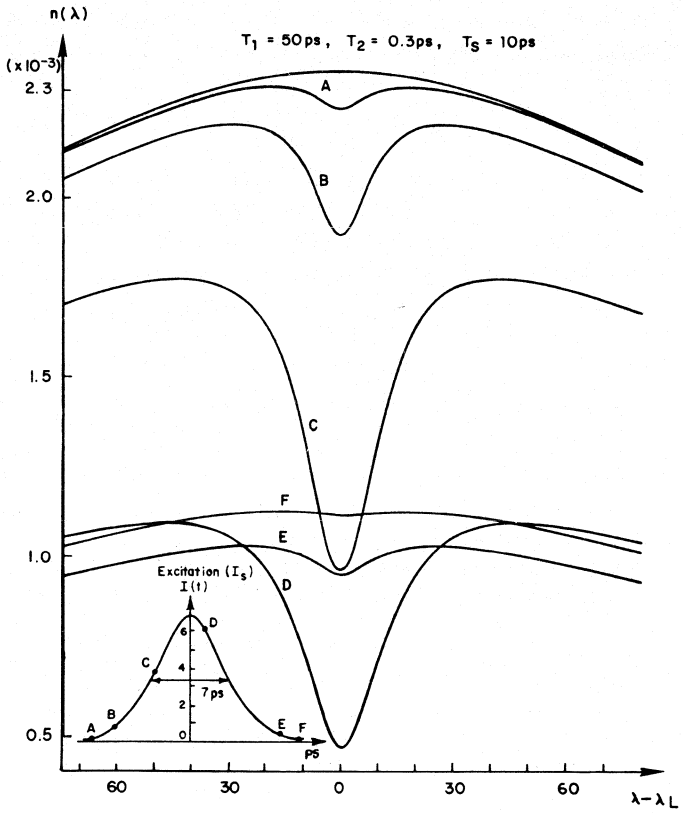


Fig. 9. Population inversion for an inhomogeneous distribution when excited by a strong monochromatic pulse at different times. $T_1 = 50$ ps, $T_S = 10$ ps. (a) $T_2 = 1$ ps. (b) $T_2 = 0.6$ ps. (c) $T_2 = 0.5$ ps.

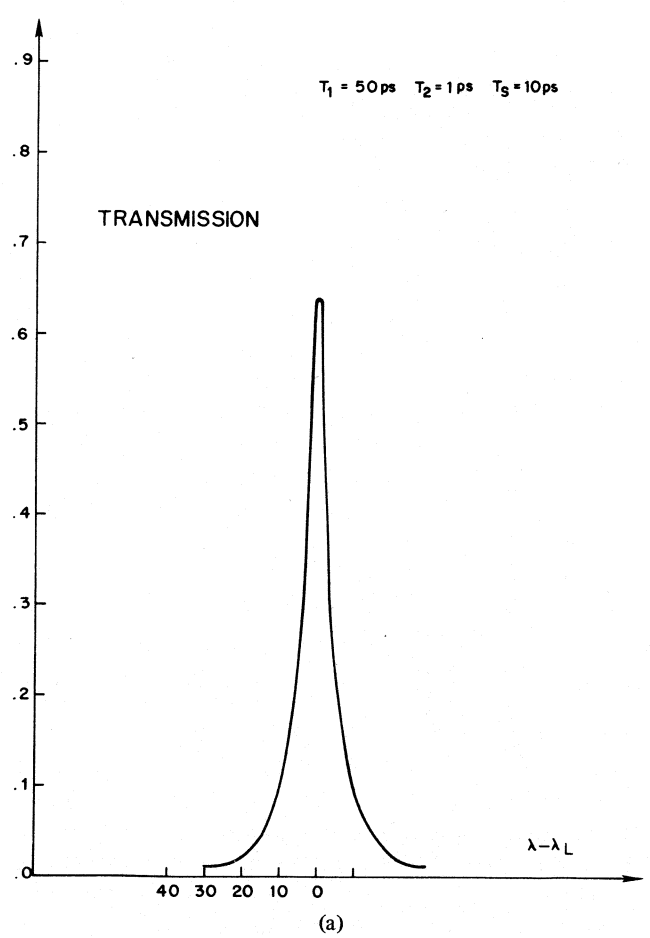
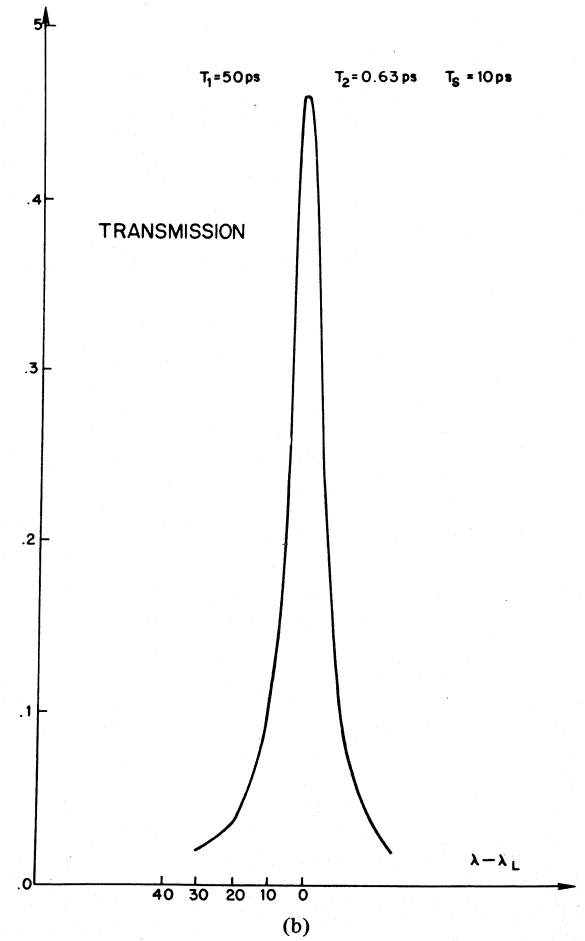


(d)



(e)

Fig. 9. (continued). (d) $T_2 = 0.4$ ps. (e) $T_2 = 0.3$ ps.

(a)

(b)

Fig. 10. Transmission across the wavelength deduced from the population inversion sketched on Fig. 9(a). (a) $T_2 = 1$ ps. (b) $T_2 = 0.6$ ps.

By using the experimental value for the bandwidth of the hole, we are able to estimate that the dephasing time is between 0.6 and 1 ps.

The Fluctuation Model of a Passively Mode-Locked Laser

WILLIAM H. GLENN, MEMBER, IEEE

Abstract—**The "Fluctuation Model" for the generation of ultrashort pulses by a saturable absorber has been discussed by a number of authors. This model has provided valuable insights into the mechanisms involved in passive mode locking; however, previous treatments have been incorrect in several important respects. These treatments have attempted to describe the behavior of the laser in terms of the evolution of a statistically independent set of fluctuations (pulses) circulating in the laser. It is shown here that such a description is impossible in principle. This paper discusses in detail the problem with the previous treatments and presents an alternate treatment of the evolution of the ultrashort pulses during the nonlinear phase of development. The model is capable of predicting the conditions under which good mode locking will occur, the probability of the appearance of secondary pulses and their relative intensities, the peak intensity of the output pulse train and its statistical variation, and the duration and time of appearance of the output pulse train. The analysis has also been formulated in such a way that the evolution of the signal can be followed by measurement of experimentally observable quantities.**

I. INTRODUCTION

THE "Fluctuation Model" of the passively mode-locked pulsed laser has been discussed by a number of authors [1]-[5]. The basic idea of this model is that the ultrashort pulse output from the laser results from the selection and temporal shaping of the fluctuations initially present in the spontaneous noise of the laser. When the flashlamp pumping begins, ions are excited to the upper laser level and produce spontaneous emission. The bandwidth of this emission is characteristic of the full inhomogeneous linewidth of the laser (~200 Å for Nd-glass) and the emission is noiselike. As the pumping continues, the laser gain builds up and the radiation in the cavity acquires a periodic structure with the cavity period $T = 2L/c$, while still retaining its noiselike structure within this period. With further increase in gain the radiation experiences a period of linear amplification resulting in a decrease in the bandwidth of the radiation. By the time the intensity reaches a point where the nonlinearity of the dye becomes important, the bandwidth of the radiation is such

that the time scale of the random variation of the intensity is a few picoseconds, and the radiation can be described by a collection of pulses of this duration and with random intensities. At this point the critical period for the development of mode locking takes place. Through the combined action of the nonlinearity of the dye, the laser gain saturation, and other possible nonlinearities, this random collection of pulses evolves to a condition where one of the pulses grows to an intensity that is much larger than any of the other pulses. This surviving pulse undergoes some narrowing in duration and spectral broadening in this process. Finally, it grows to such an intensity that electronic nonlinearities in the dye, solvent, and laser rod produce a further increase in the bandwidth to the observed output bandwidth. These nonlinearities can also impose complicated phase structures on the pulse. The analysis of this paper is concerned solely with the evolution of the radiation in the nonlinear period where the random fluctuations evolve into a single or multiple pulse train, and the description here is fundamentally different than previous treatments.

II. Formulation of the Model

A simple model of the behavior of the laser and bleachable dye will be used, and it is identical to previously described models. The dye cell will be treated as an inertialess bleachable absorber and the laser will be assumed to saturate on the total energy extracted. The transmission of the dye cell is determined by the dye transmission coefficient κ_0. The transmission is

$$\exp - \kappa = \exp - [\kappa_0/(1+I)]. \tag{1}$$

Here κ_0 is the unbleached absorption coefficient. A unit length is assumed. All intensities are normalized to the dye saturation intensity $I_s \sim 50$ MW/cm^2. The linear losses of the cavity are represented by a round-trip transmission of $\exp - \gamma$. The gain of the laser is given by $\exp \alpha$ where

$$\frac{d\alpha}{dt} = \frac{-2\sigma\alpha I}{h\cup} I_s + f. \tag{2}$$

Here σ is the cross section for stimulated emission and f is the rate of pumping due to the flashlamp.

We consider now a sample of the radiation field existing in the cavity at the kth pass. This intensity obeys the equation

$$\frac{dI_k}{dk} = I_k \left(\alpha_k - \gamma - \frac{\kappa_0}{1+I_k} \right) + \left(\frac{dI_k}{dk} \right)_{sp} \tag{3}$$

The last quantity represents the contribution of spontaneous emission. The gain coefficient α obeys the equation

$$\frac{d\alpha_k}{dk} = -\alpha_k \left(\frac{2\sigma}{h\cup} I_s T \right) I_k + fT \tag{4}$$

where T is the cavity transit time. It will be assumed that the flashlamp pumping is such that acting alone it produces a linearly increasing value of α.

The behavior of the laser is illustrated schematically in Fig. 1. The pumping begins at $t = 0$ and begins to excite the laser. In region I, the intensity is small and is dominated by the spontaneous emission term of (3). At the end of region I

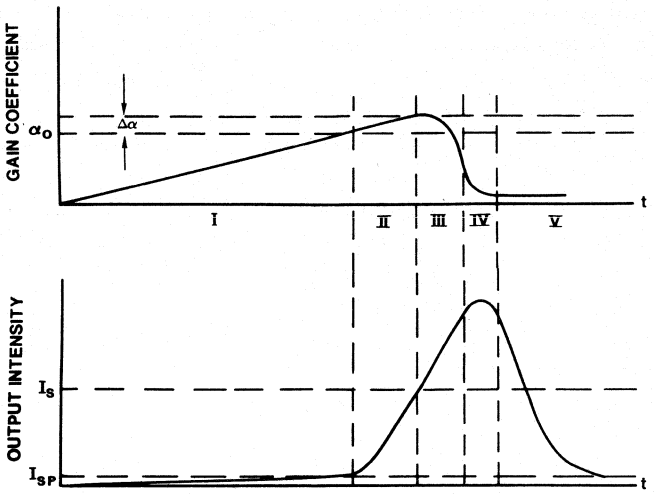

Fig. 1. Behavior of the gain and average intensity in a mode-locked laser.

the gain coefficient has increased to the threshold value

$$\alpha = \alpha_0 = \kappa_0 + \gamma. \tag{5}$$

In region II the intensity undergoes a linear period of amplification and acquires a periodic structure with period T. The bandwidth is reduced and the time scale of the random fluctuations is correspondingly increased. The increase in duration has been treated adequately elsewhere [1]. The end of region II occurs when the intensity has grown to such a point that nonlinearities in the dye become important. This represents the starting point for the mode-locking process. At this point, the radiaiton field in the cavity consists of a noiselike signal. It can be described by a collection of M pulses of duration T/M and with random intensities. The probability density of the intensities can be taken as

$$W_1(I) = \langle I \rangle^{-1} \exp - (I/\langle I \rangle) \tag{6}$$

characteristic of white noise. At the end of this period the gain has also increased from its threshold value α_0 to

$$\alpha_1 = \alpha_0 + \Delta\alpha. \tag{7}$$

It will be seen that this quantity $\Delta\alpha$ is of extreme importance in determining the behavior of the laser.

Region III is the critical period for mode locking. During this period, if the laser is to be well mode locked, the random ensemble of pulses evolves to a state where one pulse has an intensity that is much larger than any of the other pulses. During this period the pulses undergo some distortion and shortening in duration. This latter effect is of secondary importance and will not be treated here. It will be assumed that the pulses remain of constant duration, i.e., that they are effectively "square" pulses. The primary mechanism is one of pulse selection and discrimination.

III. Discussion of Previous Treatments

The behavior of the pulse intensities in region III is determined by

$$\frac{dI_{ki}}{dk} = I_{ki} \left(\alpha_{ki} - \gamma - \frac{\kappa_0}{1+I_{ki}} \right) \tag{8}$$

where the i subscript denotes the ith member of the set of M pulses circulating in the cavity. In general, the gain coefficient will depend on all previous pulses that have passed through the laser. Most previous treatments have assumed, however, that α is constant in region III and equal to $\alpha_0 + \Delta\alpha$, its value at the start of the period. This implies that the selection process is essentially complete before appreciable gain saturation sets in. The change in α during this period is quite small but small changes can be extremely important. We will return to this point in Section IV.

The basic approach used in previous treatments is to subject the starting ensemble of pulses to the nonlinear transformation of (8) and to calculate the statistical properties of the output set of pulses. This procedure assumes that the pulses are statistically independent, which in fact they would be if they were governed only by (8) with constant α. This approach, in spite of its apparent success, suffers from two fundamental errors.

1) It is impossible in principle to describe the output of a mode-locked laser in terms of a cavity containing a set of statistically independent pulses (fluctuations).

2) Even if the pulses were statistically independent, the statistics would be such that there would be no reason to expect that an ensemble average of any property of the pulses would correspond to a sample average as actually observed.

These difficulties may now be examined in detail.

If we assume that the pulses are statistically independent, then after passing through the dye and laser a number of times, the probability density given in (6) will be transformed into some new distribution $W_2(I)$. This may be calculated, but for the present purpose it may be allowed to be arbitrary. The implications of this may now be examined.

Let us take as a working definition of a "well mode-locked" laser, one that produces an output set of pulses in which one and only one is larger than some threshold value (say the triggering level of an oscilloscope), for a large percentage of the time. We now attempt to describe this situation by a set of M independent pulses with a probability density $W_2(I)$. The probability that one pulse exceeds the threshold I_t is

$$P_1 = Mpq^{M-1} \tag{9}$$

where

$$p = \int_{I_t}^{\infty} W_2(I)\, dI \tag{10}$$

$$q = \int_{0}^{I_t} W_2(I)\, dI. \tag{11}$$

Similarly, the probability that two and only two pulses exceed this threshold is

$$P_2 = \frac{M(M-1)}{2} p^2 q^{M-2} \tag{12}$$

and in general, for N pulses

$$P_N = \binom{M}{N} p^N q^{M-N}. \tag{13}$$

This is simply the binomial probability distribution. If many observations are made, the average number of pulses exceeding I_t will be Mp, and ideally $Mp = 1$. The case of large M and small p is the case where the Poisson approximation to the binomial distribution applies and we have

$$P_N \approx \frac{(Mp)^N}{N!} e^{-Mp} = \frac{\lambda^n e^{-\lambda}}{N!}$$

$$\lambda \equiv Mp. \tag{14}$$

P_1 has a maximum for $\lambda = 1$ and for this case $P_0 = 0.368$, $P_1 = 0.368$, and $P_2 = 0.184$. Thus the model predicts that a "single pulse" train can be achieved only 36.8 percent of the time. This is contrary to experimental observation. Note that this result is independent of the statistical distribution; it is a result only of the statistical independence.

From the previous discussion, it is clear that the pulses in the output cannot be statistically independent. Nevertheless, several authors [1], [3], [5] have calculated that the probability of the appearance of a single, large pulse is high. The basic argument is that the nonlinear transformation is so strong that initial pulses of very nearly the same intensity emerge after the transformation with much different intensities. The objection to this is that the nonlinear transformation is in fact so strong that it is not valid to expect that the statistical average will correspond to the actually observed average over a set of pulses. The situation is that the final probability density $W_2(I)$ calculated from the nonlinear transformation in (8) is so "spread out" that an enormous number of samples would be required for the sample average to approach the statistical average. We are considering a finite number M of samples and the number is simply not large enough to apply the statistical average. This statement may be proved by means of the Central Limit Theorem and a proof is given in Appendix I. There is no paradox involved in the fact that the statistically independent model predicts a high probability of a single isolated pulse for a fixed number of starting pulses. If a sufficient number of starting pulses were used to allow valid application of statistical averaging, then it would be found that in fact the probability of obtaining a single isolated large pulse would be small. A simple example of this is given in Appendix I.

IV. Formulation of the Alternate Approach

From the discussion of the previous section it is clear that the pulses cannot be treated as statistically independent. In more physical terms, it is necessary to invoke some mechanism by means of which one pulse can capture the stored energy of the laser at the expense of the other pulses. Only in this way can an output consisting of a single large pulse be obtained consistently. In terms of the statistics, the joint probability distribution must be such that the presence of a large-intensity pulse implies that the intensities of the other pulses are low. There are a number of mechanisms that could cause this. Perhaps the simplest is gain saturation. The net gain experienced by a pulse is a function of its intensity. The effective gain coefficient is

$$\alpha_{\text{net}} = \alpha - \gamma - \kappa_0/(1 + I_{ki}). \tag{15}$$

At the start of region III, this quantity is positive for all pulses, although it may be quite small. Only a minute amount of saturation is necessary, however, before this quantity can become negative for pulses of very low intensity while remaining positive for pulses of higher intensity. The higher intensity pulses continue to grow while the lower intensity pulses decay. This provides a powerful discriminant. It is convenient to think of a critical intensity I_c for which

$$\alpha - \gamma - \kappa_0/(1 + I_c) = 0 \tag{16}$$

$$I_c = \frac{\kappa_0}{\alpha - \gamma} - 1 = \frac{\kappa_0}{\kappa_0 + \Delta\alpha} - 1. \tag{17}$$

At the start of region III, $I_c < 0$, i.e., all pulses have gain. As the gain becomes depleted, $\Delta\alpha = \alpha - \gamma - \kappa_0$ goes to zero and becomes negative, and $I_c > 0$. Only pulses with greater intensity than this continue to grow. Clearly, the presence of a very large pulse will deplete the gain faster and will cause I_c to rise more rapidly. This results in more effective elimination of the smaller pulses. To achieve good mode locking, one wants to have the intensity of only the largest pulse "outrun" the rising value of I_c. This picture is borne out in detail in the results to be described below.

The treatment of a large number of statistically dependent variables is a formidable mathematical task. It was decided to resort to a simulation to verify the picture previously described. The simulation that was used started with an ensemble of pulses of low intensity. For each pass through the laser, the gain was assumed to be constant, but at the end of each pass, the total energy extracted from the laser was computed and the gain was recalculated for the next pass. The intensity of the pulses was assumed to obey (8), which in difference equation form is

$$\log I_{k+1,i} = \log I_{k,i} + \left(\alpha_k - \gamma - \frac{\kappa_0}{1 + I_{ki}}\right) \tag{18}$$

i.e., α was independent of i but a function of k. The dependence of α was

$$\alpha_{k+1} = \alpha_k - \frac{2\sigma\alpha_k}{h\upsilon} T \sum_{n=1}^{M} I_{ki}. \tag{19}$$

Before presenting the results of the simulation it is necessary to discuss the choice of the starting set of pulses. The starting set could simply be chosen by a computer-generated set of random intensities having the proper statistics (6). This was, in fact, how the fruitfulness of the present approach was initially discovered. Such an approach does not provide a good picture of the statistical variation that would be expected in the output without a large number of trials for each set of laser parameters. A better approach is to consider the statistics of all possible ensembles of M starting pulses (as opposed to the statistics of the individual pulses). For any given set of starting pulses the behavior is completely determined by (18) and (19). The problem is thus one of analyzing the properties of the starting set of pulses that are likely to lead to good mode locking, determining the statistical distribution of these properties, and running judiciously chosen sets of input pulses to determine the statistical behavior of the output.

We consider a set of M starting pulses having the probability density

$$W(I) = e^{-I} \tag{20}$$

and ask what is the probability density of the Nth largest pulse in the set. It may be shown (see Appendix II) that this is

$$U_N(I) = \frac{M!}{(N-1)!\,(M-N)!} e^{-NI} [1 - e^{-I}]^{M-N}. \tag{21}$$

The most probable intensity of the Nth largest pulse, I_{mp}, is determined by

$$\frac{d\,U_N(I)}{dI} = 0 \tag{22}$$

which gives

$$I_{mp} = \log (M/N). \tag{23}$$

A reasonable starting set of pulses is one in which the intensity of each pulse is assigned its most probable value, i.e., the largest is $\log M$, next $\log M/2$, next $\log M/3$, etc. The output from this set will thus represent the most probable output of the laser. For the case $M = 100$, the most probable amplitudes of the largest pulses are 4.6, 3.9, 3.5, and 3.2.

We must now consider what properties of the input set of pulses will lead to significant variations in the output. In this we may be guided by the picture presented earlier of a rising value of the critical intensity that gradually "eliminates" the pulses starting from the least intense pulse. For good mode locking only a few pulses will be able to outrun this critical intensity. Very close to the conditions for optimum mode locking the behavior will depend on the competition between the two largest pulses, i.e., whether their growth rate is such that they both survive or whether the rising critical intensity finally eliminates the second largest pulse, leaving only one pulse of large intensity. Thus one is led to the conclusion that for conditions close to those for optimum mode locking, the most important property of the starting set of pulses is the ratio between the intensities of the largest and the second largest pulse. The probability that the largest pulse is C times larger than the second largest pulse may be shown to be (see Appendix II)

$$V(M, C) = \frac{\Gamma(C+1)\,\Gamma(M+1)}{\Gamma(M+C)} \approx \frac{C}{(M+1)^{C-1}}. \tag{24}$$

The approximation is valid for C slightly greater than 1. The behavior of this function for $M = 100$ is shown in the following table:

C	1	1.01	1.02	1.04	1.10	1.20	1.50	2.0
V	1.0	0.96	0.93	0.86	0.69	0.48	0.15	0.02

If the pulses are assigned their most probable value, the ratio between the two largest pulses is ~1.18 and from (24) the ratio should be this large or larger approximately 50 percent of the time. Conditions could be found using this set of pulses

for which only the largest pulse survived to grow to an appreciable intensity. To further investigate the behavior, another starting set of pulses was chosen. In most cases, this was taken as a set in which all pulses had their most probable intensities except the second largest and the ratio of the largest to the second largest was taken as 1.02. The ratio would be expected to exceed this value 93 percent of the time. By varying the ratio of the two largest pulses, an excellent picture of the statistical behavior of the output near the conditions for good mode locking could be obtained. The results are discussed in the following sections.

V. Results of the Simulation

Equations (18) and (19) were simply computed for every pass and every pulse in the starting set. A flowchart for the simulation is shown in Fig. 2. The program was run on-line on a time-shared PDP-6 computer. The inputs to the program were the linear loss γ, the small-signal dye absorption κ_0, the laser cross section σ (taken as $\sigma/h\upsilon = 0.16$ cm^2/J characteristic of Owens Illinois ED-2 glass), the dye saturation intensity (taken as 50 MW/cm^2), the gain at the start of the calculation $\alpha = \alpha_0 + \Delta\alpha$, and the cavity transit time T (taken as 5 ns). The laser area is assumed to be 1 cm^2. The mean value of the starting set of pulses was taken as 0.002 (normalized to the dye saturation intensity), and all pulse intensities were assigned their most probable values with the exception of the second largest pulse. This intensity was also a variable input to the program. In all cases to be discussed, it was assumed that $M = 100$.

The output available consisted of a) the number of passes from the starting point, b) the intensity of any or all of the pulses at any pass (at the discretion of the operator), c) the average intensity of the M pulses at any pass, d) the ratio of the two largest pulses, e) the second-harmonic intensity that would be observed (i.e., the average of I^2 over the M pulses), f) the second-harmonic enhancement ratio (SHER) [i.e., the ratio of e) to the square of c)], g) the value of the gain and critical intensity, and the h) total energy extracted from the laser.

Of these quantities c), e), and f) are of particular significance since they are experimentally observable quantities. The intensities of the various pulses cannot be observed since detectors of sufficient speed, sensitivity, and dynamic range are not available.

The behavior of the laser was investigated for values of κ_0 of 0.1, 0.2, 0.3, and 0.4 and for a range of values of the gain α_0. The linear loss γ was usually taken as 0.1. For every case, it was found that a range of values of the gain α could be found for which excellent discrimination took place. The critical parameter is the "excess gain," $\alpha - \gamma - \kappa_0$ that is present at the start of the calculation. Space will not permit a complete presentation of all the results obtained, but several interesting cases will be discussed. Figs. 3-7 show the behavior for the case $\kappa_0 = 0.2$, $\gamma = 0.1$ for various values of the gain.

Fig. 3 shows the behavior of the intensity (within the cavity) of the largest pulse. As the excess gain is decreased, the peak output occurs later and later. For the value $\alpha - \gamma - \kappa_0 = 0.01$,

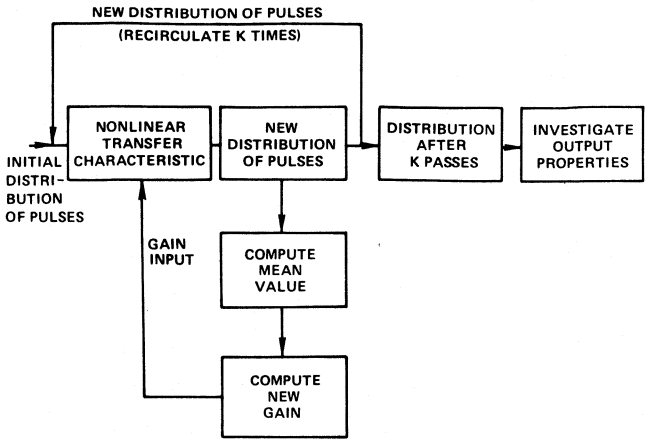

Fig. 2. Flowchart for the numerical simulation.

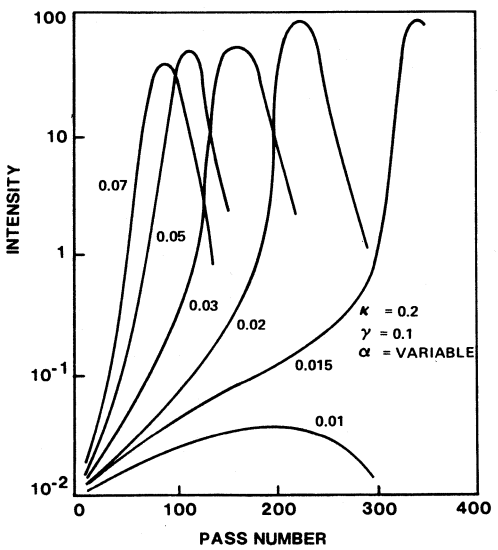

Fig. 3. Behavior of the intensity of the largest pulse. Conditions are $\kappa_0 = 0.2$, $\gamma = 0.1$, $\Delta\alpha$ is the parameter.

the output remains small throughout. In this case, the gain is depleted before any pulse saturates the dye. For values slightly greater than this, there is a long delay followed by a rapid increase in intensity. This, as we shall see, corresponds to the best mode locking.

Fig. 4 shows the behavior of the average intensity of all the pulses. These curves display, for $\Delta\alpha = 0.015$ and 0.02 a very interesting feature, namely a growth, followed by a dip and then a very rapid growth.

The reason for this is clear. In the region of the dip very strong discrimination of the pulse intensities is taking place. The largest pulses are growing while all the others are decaying. For a time this result in a decrease in the average intensity before the largest pulse reaches its peak.

Fig. 5 shows the behavior of the SHER. The positions of the peak output, from Fig. 3, are indicated by the arrows. The cases $\Delta\alpha = 0.015$ and $\Delta\alpha = 0.02$ represent essentially perfect mode locking as indicated by the enhancement ratio of 100 (the maximum possible value with $M = 100$ corresponding to 100 modes locked). For larger values of the excess gain, the

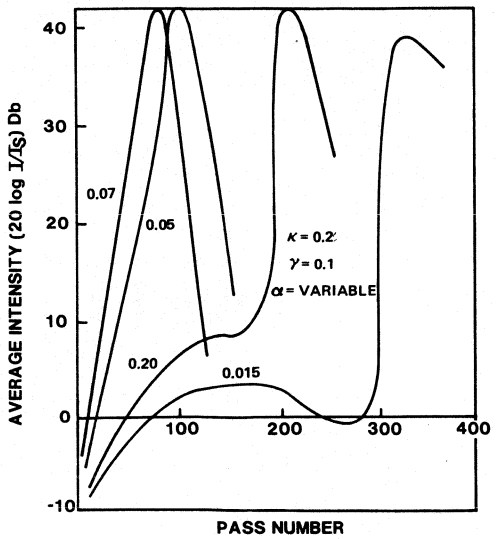

Fig. 4. Behavior of the average intensity. Same conditions as in Fig. 3.

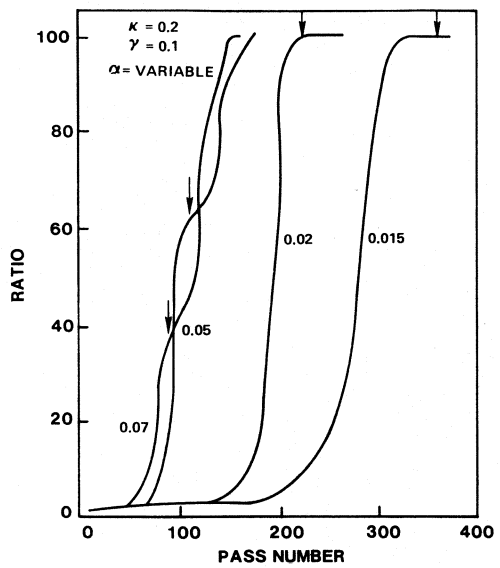

Fig. 5. Behavior of the SHER. Same conditions as in Fig. 3.

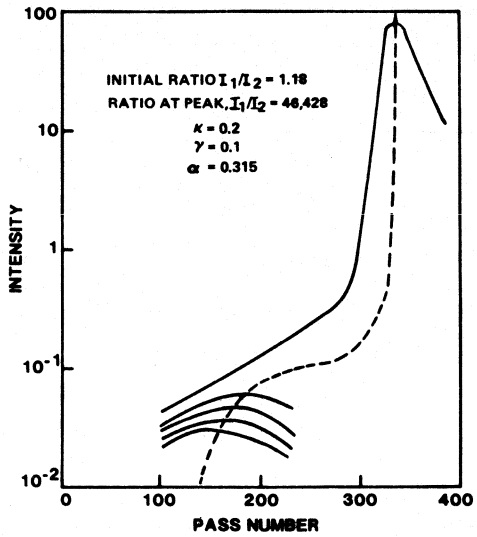

Fig. 6. Behavior of the five largest pulses for the most probable starting set. The initial ratio of the two largest pulses was 1.18. Conditions were $\kappa_0 = 0.2$, $\gamma = 0.1$, $\alpha = 0.315$ ($\Delta\alpha = 0.015$).

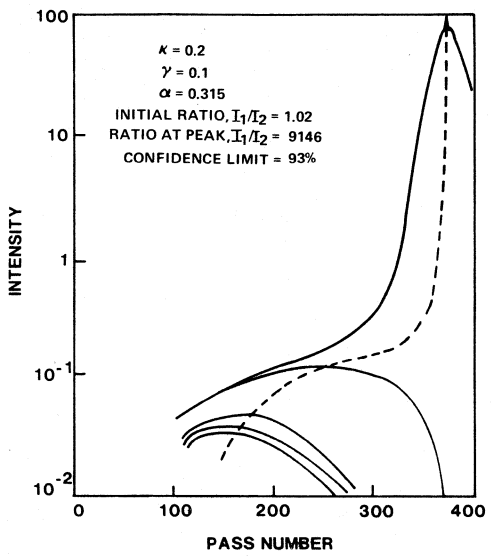

Fig. 7. Behavior of the five largest pulses for an initial ratio of 1.02 between two largest pulses. Other conditions as in Fig. 6.

mode locking is incomplete. The shoulder in the curves is easy to understand. Initially, the SHER grows as the pulse intensities pass through the nonlinear region of the dye characteristics. Finally, several pulses "break through" and grow to large values. At the peak, the dye is ineffective and the SHER slows its rate of growth. As the pulses decay they again pass through the nonlinear region and the SHER again grows and saturates at a value which may be less than 100 as all the pulses drop to low intensities.

Fig. 6 shows the behavior of the five largest pulses for $\Delta\alpha = 0.015$. In this case, all pulses were assigned their most probable value. The dotted line shows the behavior of the critical intensity defined earlier. The discrimination is dramatic. The initial intensity ratio of the two largest pulses was 1.18. At the peak, the ratio is in excess of 46 000. Fig. 7 shows the case where the initial ratio of the two pulses was taken as 1.02, which should be exceeded 93 percent of the time. The discrimination is still intense, with a final ratio in excess of 9000.

The critical role of the gain saturation may be readily seen. Fig. 8 shows the behavior of the five largest pulses for a case of good mode locking. The parameters were $\kappa_0 = 0.3$, $\Delta\alpha = 0.02$. Fig. 9 shows the behavior for the same parameters with the gain saturation removed. In this case, of course, the pulses continue to grow without limit; however, the discrimination is extremely weak.

The results of all the cases run can be combined to describe those conditions necessary for good mode locking. The SHER at the peak of the output may be taken as a measure of the quality of the mode locking. This is plotted in Fig. 10 as a function of the excess gain $\alpha - \gamma - \kappa_0$, with κ_0 as a parameter. As can be seen, there is a narrow window just above threshold for which mode locking will occur. For values that are too

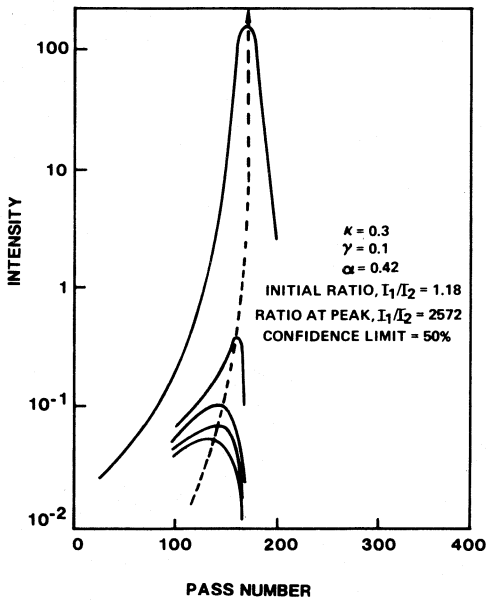

Fig. 8. Behavior of the five largest pulses for $\kappa_0 = 0.3$, $\gamma = 0.1$, $\alpha = 0.42$ ($\Delta\alpha = 0.02$).

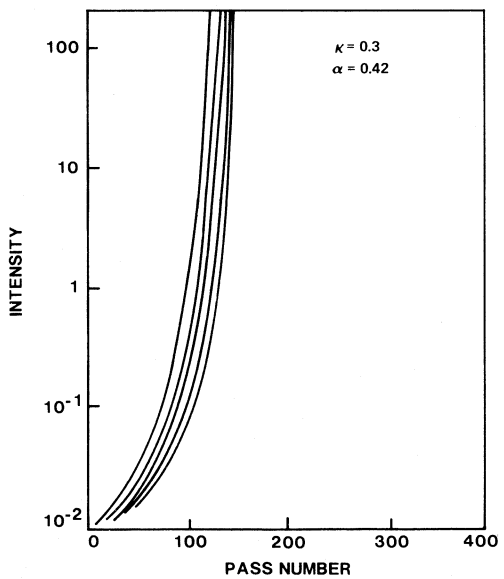

Fig. 9. Behavior of the five largest pulses in the absence of gain saturation. Conditions were the same as in Fig. 8.

low, the intensity never breaks through the dye. For values too high, the discrimination is poor. These curves were plotted for the 50-percent confidence level corresponding to the most probable set of starting pulses. Use of a higher confidence level would result in a narrowing of the window.

VI. Discussion

It has been shown that it is impossible to describe the the behavior of a mode-locked laser in terms of the evolution of a statistically independent set of fluctuations arising from spontaneous emission. It is necessary to invoke some mechanism to introduce a statistical dependence among the pulses. The simplest mechanism is the saturation of the laser gain. The introduction of the statistical dependence leads to formidable difficulties in the analytical description of the

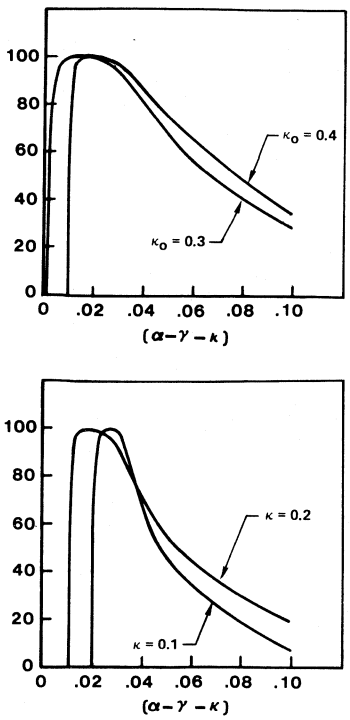

Fig. 10. SHER at peak output as a function of the excess gain.

evolution of the radiation field. A numerical simulation of the behavior, however, is straightforward. The results of the simulation provide a very clear picture of the mode-locking process. The most important parameter governing the behavior of the laser is the excess gain $\Delta\alpha = \alpha - \gamma - \kappa_0$ that exists at the start of the nonlinear phase of the process. For a small range of value of $\Delta\alpha > 0$, the combination of the dye nonlinearity and the laser saturation provides an extremely powerful discriminant that allows only the largest of the initial fluctuations to grow to a large intensity. The importance of this parameter has emerged from previous treatments of the problem. The present model, however, provides a much stronger discrimination of pulse intensities.

The present model is in excellent qualitative agreement with experimental observations. Quantitative agreement should not be expected since a number of effects have been neglected. The change in pulse duration during the nonlinear phase could be treated by an extension of the present approach which characterizes each pulse by an energy and duration rather than simply by an intensity as was done here. The present treatment has also tacitly assumed a undirectional ring-type geometry. In a linear laser, pulses traveling in opposite directions overlap in the dye cell leading to a further statistical dependence. This effect is somewhat more difficult to treat since it is sensitive to the time ordering of the starting set of pulses. The result of this effect is the development of satellite pulses, and it should be possible to estimate the statistical distribution of the intensity of these pulses. The introduction of a finite relaxation time of the saturable absorber can be readily incorporated into the simulation; however, this too introduces a dependence on the time ordering of the initial set of pulses and would require a large number of trials to determine the statistical behavior of the output.

It should be possible to verify the predictions of the model presented here experimentally. The average intensity and the average second-harmonic intensity can be observed experimentally by means of a reasonably slow detector, one with a response time of the order of the cavity transit time. The only problem is one of dynamic range in recording the signals. Logarithmic amplifiers may be used to compress the dynamic range required in the recording of the signals. The initial slope of the average intensity gives a measure of the excess gain while the behavior of the SHER gives a good indication of the amount of pulse-intensity discrimination taking place. Thus all parameters of the model can be determined.

Appendix I

In Section III it was stated that for a sufficiently severe nonlinear transformation, it is not reasonable to expect that the sample average and the statistical average should correspond. This may be shown rigorously by means of the Central Limit Theorem. As an example, suppose we wish to calculate the average intensity of a set of M statistically independent pulses each having a probability density $W(I)$. The sample average is

$$\langle I\rangle_{sa} = M^{-1}\sum_{i=0}^{M} I_i \tag{25}$$

while the statistical average is

$$\mu \equiv \langle I\rangle_{st} = \int_0^\infty IW(I)\,dI. \tag{26}$$

The Central Limit Theorem states that the sum of a number M of statistically independent random variables, each with a mean μ and a variance σ, is itself a random variable whose distribution approaches a normal distribution with a mean value $M\mu$ and a variance $M^{1/2}\sigma$. More precisely, for every fixed β [6]

$$P\left\{\frac{\Sigma_i I_i - M\mu}{\sigma M^{1/2}} < \beta\right\} \longrightarrow \Phi(\beta) \tag{27}$$

or

$$P\{M^{-1}\Sigma_i I_i - \mu < \sigma M^{1/2}\beta\} \longrightarrow \Phi(\beta) \tag{28}$$

where

$$\Phi = (2\pi)^{-1}\int_{-\infty}^{\beta} e^{-x^2/2}\,dx. \tag{29}$$

Let us now determine the probability that the sample mean and the statistical mean differ by no more than a fixed amount with a probability of 0.5. This is

$$P\{M^{-1}\Sigma_i I_i - \mu < \sigma M^{-1/2}\beta\} - P\{M^{-1}\Sigma_i I_i - \mu < -\sigma M^{-1/2}\beta\} = \Phi(\beta) - \Phi(-\beta). \tag{30}$$

The value of β for which $\Phi(\beta) - \Phi(-\beta) = 0.5$ is $\beta = 0.678$ so that

$$P\{|M^{-1}\Sigma_i I - \mu| < 0.678\sigma M^{-1/2}\} = 0.5. \tag{31}$$

That is, the sample average and the statistical average will differ by more than $0.678\sigma M^{-1/2}$ for 50 percent of the time.

Let us require that this deviation be no greater than $\frac{1}{2}\mu$. This implies

$$\tfrac{1}{2}\mu > 0.678\sigma M^{-1/2} \tag{32}$$

or

$$M > \left|\frac{1.356\sigma}{\mu}\right|^2$$

This provides an estimate of the sample size required for even a rather poor agreement between the sample average and the statistical average.

Let us now consider a strong nonlinear transformation of the type

$$I_k = I_0^n \tag{33}$$

where n is a reasonably large number (10–100). This transformation has been used by a number of authors. We may calculate the mean and variance of the transformed distribution where the distribution of I_0 is

$$W(I_0) = e^{-I_0}. \tag{34}$$

We find

$$\mu = \langle I_k\rangle = \int_0^\infty I_0^n\, e^{-I_0}\,dI_0 = n!$$

$$\langle I_k^2\rangle = \int_0^\infty I_0^{2n}\, e^{-I_0}\,dI_0 = (2n)!$$

$$\sigma^2 = [\langle I^2\rangle - \langle I^2\rangle] = (2n)! - n!. \tag{35}$$

Using the approximation

$$\log n! \approx n\log n \tag{36}$$

we have

$$\sigma \approx [e^{2n\log 2n} - e^{2n\log n}]^{1/2} \approx e^{n\log 2n} \tag{37}$$

and

$$\mu \approx e^{n\log n}. \tag{38}$$

Consequently,

$$\sigma/\mu \approx \frac{e^{n\log 2n}}{e^{n\log n}} = e^{n\log 2}. \tag{39}$$

Referring to (32), we have

$$M > 1.838e^{2n\log 2}.$$

For $n = 30$, this becomes $M > 1.838e^{41.6}$. This is an extremely large number of samples. M is the number of pulses in the cavity or, equivalently, the number of modes. It is at most a few thousand and this does not constitute a sufficiently large sample.

The hypothetical transformation in (33) does not, of course, correspond to the actual transformation that is produced by

(8). A similar situation occurs, however, if the actual transformation is used. Equation (8) has an exact solution for constant α; it was given by Kryukov and Letokhov [1] and is, in the present notation,

$$I_k^{-1}[(\alpha-\gamma-\kappa_0)+(\alpha-\gamma)I_k]^{\kappa_0/\alpha-\gamma} = I_0^{-1}[(\alpha-\gamma-\kappa_0)+(\alpha-\gamma)I_0]^{\kappa_0/\alpha-\gamma} \cdot \exp[-(\alpha-\gamma-\kappa_0)k]. \quad (40)$$

This is not an explicit solution for I_k in terms of I_0, but it may readily be solved numerically. If this is done, the mean and the variance of the new distribution may be computed. It is found that, as a function of k, the quantity σ/μ grows so rapidly that the sample size soon becomes too small for the valid application of statistical averaging.

A further point should be noted with regard to (40). One might be led to consider the case when I_0 is very small, $I_0 \ll (\alpha-\gamma-\kappa_0)/(\alpha-\gamma)$ and I_k very large, $I_k \gg (\alpha-\gamma-\kappa_0)/(\alpha-\gamma)$. If this approximation is made, (40) becomes

$$[(\alpha-\gamma)^{\kappa_0/\alpha-\gamma} I_k^{\kappa_0/(\alpha-\gamma)-1}] = (\alpha-\gamma-\kappa_0)^{\kappa_0/\alpha-\gamma} I_0^{-1} \exp[-(\alpha-\gamma-\kappa_0)k]. \quad (41)$$

Rearrangement gives

$$I_k^{(\kappa_0/\alpha-\gamma)-1} = I_k^{-(\alpha-\gamma-\kappa_0)/(\alpha-\gamma)} = \left(\frac{\alpha-\gamma-\kappa_0}{\alpha-\gamma}\right)^{\kappa_0/(\alpha-\gamma)} I_0^{-1} \exp-[(\alpha-\gamma-\kappa_0)k]. \quad (42)$$

Now let

$$n = \frac{\alpha-\gamma}{\alpha-\gamma-\kappa_0}. \quad (43)$$

Equation (43) becomes

$$I_k^{-1/n} = \left(\frac{1}{n}\right)^{(\kappa_0/\alpha-\gamma)} I_0^{-1} \exp-[(\alpha-\gamma-\kappa_0)k]$$

$$I_k = I_0^n (n)^{(\kappa_0 n)/(\alpha-\gamma)} \exp[(\alpha-\gamma)k] = DI_0^n$$

$$D = (n)^{(\kappa_0 n)/(\alpha-\gamma)} \exp[(\alpha-\gamma)k]. \quad (44)$$

We note

$$n = \frac{\alpha-\gamma}{\alpha-\gamma-\kappa_0} \approx \frac{\alpha_0-\gamma}{\Delta\alpha}. \quad (45)$$

This is simply the nonlinearity parameter μ introduced by Letokhov. This approximation results in the power-law dependence of the output intensity upon the input intensity, such as was used in (33). In fact, (44) constitutes a very poor approximation to (40) as may be verified by direct numerical computation.

As a final point on this topic, we may illustrate by an example the failure of the statistically independent model. According to [1], the probability of generating a double pulse train with an amplitude ratio not exceeding S is

$$\rho(2) = \frac{\log S \log \cdot M}{en}. \quad (46)$$

Here n (or μ in [1]) is the coefficient of the power law. In order for the statistical averaging to be valid we must have

$$M \gtrsim e^{2n \log 2}. \quad (47)$$

Thus

$$\rho(2) > \log S \frac{2 \log 2}{e}. \quad (48)$$

This is totally independent of the nonlinearity parameter and there is no way to make it small for any value of S that would represent good mode locking. For $S = 2$, $\rho(2) = 0.35$.

Appendix II

In Section IV, two probability densities were employed. The probability density for the intensity of the Nth largest pulse in a set of M pulses is

$$U_N(I)dI = KW(I)\left[\int_I^\infty W(I')dI'\right]^{N-1} \cdot \left[\int_0^I W(I')dI'\right]^{M-N} dI. \quad (49)$$

The $W(I)$ term is the probability density for the pulse in question. The first term in brackets is the probability that $N-1$ pulses are larger in intensity and the second term is the probability that the remaining $M-N$ pulses are smaller. The constant K can be determined by combinatorial analysis or by normalization. We require

$$\int_0^\infty U_N(I)dI = 1. \quad (50)$$

Let

$$x = \int_0^I W(I)dI \qquad dx = W(I)dI$$

then

$$\int_0^\infty U_N(I)\,dI = K\int_0^1 (1-x)^{N-1}x^{M-N}\,dx = KB(N, M-N+1) \quad (51)$$

$$= K\frac{\Gamma(N)\,\Gamma(M-N+1)}{\Gamma(M+1)} = 1. \quad (52)$$

Thus

$$K = \frac{\Gamma(M+1)}{\Gamma(N)\,\Gamma(M-N+1)} = \frac{M!}{(N-1)!\,(M-N)!}. \quad (53)$$

Here B and Γ are the beta and gamma functions as conventionally defined. Substituting the function $W(I)$ into (49) gives the result of (21).

The probability that the largest pulse is more than C times

larger than the second largest pulse is

$$V(M, C) = M \int_0^\infty W(I') \left(\int_0^{I'/C} W(I) dI \right)^{M-1} dI'. \quad (54)$$

The term $W(I')$ is just the probability density for the largest pulse. The term in parenthesis is the probability that the remaining $M-1$ pulses are at least C times smaller. The expression is integrated over all possible values of the largest pulse. The factor M arises because there are M ways to choose the largest pulse. Substituting $W(I)$ into this expression gives

$$V(M, C) = M \int_0^\infty e^{-I'} \left(\int_0^{I'/C} e^{-I} dI \right)^{M-1} dI'$$

$$= M \int_0^\infty e^{-I'} \left[1 - e^{-I'/C} \right]^{M-1} dI'$$

$$= MC \int_0^1 t^{C-1} \left[1 - t \right]^{M-1} dt (t = e^{-I'/C})$$

$$= MC\mathrm{B}(C, M)$$

$$V(M, C) = \frac{\Gamma(C+1)\,\Gamma(M+1)}{\Gamma(M+C)}. \quad (55)$$

It should be noted here that it is perfectly valid to apply statistical averages to the starting set of pulses. They are independent and there is an adequate number of samples.

Pulse Stretching and Shape Control by Compound Feedback in a Q-Switched Ruby Laser

R. V. LOVBERG, ERIC R. WOODING, AND MICHAEL L. YEOMAN

Abstract—**Feedback control is employed to stabilize the output of a Q-switched ruby laser. A computational model of the rate equations plus feedback terms is used to examine pulse shapes with changing feedback parameters. It is shown that a lengthened flat-top pulse cannot be obtained with negative feedback alone, a compound feedback arrangement is suggested to facilitate this. A practical laser system is constructed with an associated feedback loop, good agreement is found between theory and experiment. Pulses flat to within ±5 percent are obtained with durations up to 600 ns and are amplified with no apparent saturation. Output powers of 15 MW are achieved for hundreds of nanoseconds with a divergence of 7 mrad and a spectrum consisting of transform-limited lines separated by the axial mode spacing.**

Introduction

ULTRAHIGH-frequency drift waves in a plasma are expected to scatter laser light by acting as a diffraction grating. A preliminary study [1] showed the need for a rectangular pulse of light lasting about 200 ns. Long pulses have been obtained from Q-switched lasers by introducing nonlinear materials into the cavity [2]–[5], lengthening the cavity [1], or by use of a feedback loop to control the switching of an electrooptic shutter [6]–[8]. The first two methods produce light pulses whose time variation is either approximately Gaussian or asymmetric with a fast rise and a decay time of several hundred microseconds. The feedback technique with a Kerr cell has converted the random relaxation oscillations of a ruby laser to a steady flux which decays exponentially in several hundred microseconds [6], but the resulting output

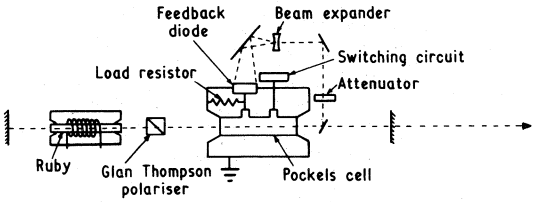

Fig. 1. Laser cavity with feedback elements.

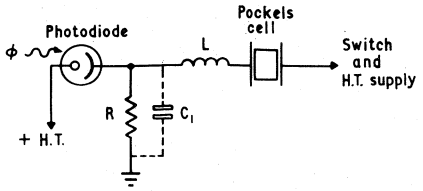

Fig. 2. Feedback control circuit with parasitic inductance and shunt capacitance.

power is low (<100 kW) and high-frequency oscillations occur [7].

The laser pulse for the proposed scattering experiment is required to have a power of at least 10 MW, a duration of about 200 ns, and rise and decay times less than 20 ns. Any ripple in the power should be less than 5 percent of the peak value and should occur at a frequency of less than 10 MHz.

The laser which produced the pulse is represented in Fig. 1 and contains a feedback loop consisting of a pellicle beam splitter and a photodiode which applies a negative feedback potential to a Pockels-cell shutter. Initially, the Pockels cell is biased for zero transmission by applying the quarter-wave voltage. As soon as this voltage is reduced the optical transmission rises and laser action begins. Five percent of the intercavity photon flux is used in the feedback loop.

After some preliminary experiments, a numerical analysis was carried out to determine which were the significant terms in the control equations governing the system. The mathematical model consists of a system of first-order linear differential equations with specific initial conditions. In these equations the terms corresponding to the circuit parameters may easily be varied, permitting a study of a wide range of operating conditions to be made in a short time. As a result of the computer experiments the system may be modified until the requisite pulse shape and duration are obtained.

Numerical Analysis

Previous calculations [4], [7] had shown that lengthened pulses could be generated by a Q-switched laser with the disadvantage that high-frequency oscillations occurred for an appreciable part of the pulse. The present analysis makes use of the rational extrapolation method of Burlisch and Stoer [9] through a software facility (ORDIFFS) for solving up to ten coupled first-order differential equations with Teletype printout.

Elementary Feedback System

The laser rate equations of Wagner and Lengyel [10] are used to describe the growth of photon flux which results from gain in the ruby and losses within the laser cavity. The rate of growth of photon density is given by

$$\frac{d\phi}{dt} = \frac{1}{t_1}(\alpha_0 nL - \gamma)\phi \tag{1}$$

and the rate of decay of the population inversion in the ruby is

$$\frac{dn}{dt} = -\frac{2\alpha_0 L}{t_1} \cdot n\phi \tag{2}$$

where $\phi = \Phi/N_0$ is the normalized photon density, Φ the total photon density (photons cm^{-3}), and N_0 is the chromium-ion density ($Cr^{+++}cm^{-3}$) in the ruby. The time taken for a photon to traverse the cavity is t_1, and the fraction of photons lost per traverse is γ. The fractional population inversion is $n = (N_2 - N_1)/N_0$. The absorption coefficient of the unexcited ruby is α_0 which becomes a gain parameter when n is greater than zero. L is the length of the ruby rod, N_2 the density of chromium ions excited to the upper level, and N_1 the density in the ground state.

These rate equations have been solved and yield giant pulses. However, in the present application γ is not constant but is made explicitly dependent upon ϕ by the feedback loop, i.e.,

$$\gamma = \gamma_c + \gamma(\phi) \tag{3}$$

where γ_c is the constant loss term, which is mainly attributable to the output mirror transmission T_1 and may be written $\gamma_c = -\ln(1 - T_1) = -\ln R_1$, while $\gamma(\phi)$ includes the transfer function of the feedback loop and shutter characteristics. It is assumed that the photodetector output current i is directly proportional to the input light flux so that $i = M\phi$. Then a voltage V may be produced by the load resistance R of Fig. 2 with

$$V = iR = MR\phi.$$

The transmission of the Pockels cell is

$$T = \cos^2\left(\frac{\pi}{2}\frac{V}{V_0}\right)$$

where V_0 is the quarter-wave bias-voltage. Then

$$\gamma(\phi) = -\ln\left[\cos^2\left(\frac{\pi}{2}\frac{V}{V_0}\right)\right]. \tag{4}$$

Before inserting (4) and (3) into (1) for solution, terms must be added to account for the stray series inductance and shunt capacitance of the feedback circuit. Since the photodiode is a pure current generator the voltage at its output is determined by the impedance of the circuit connected to it; with capacitance C_1 in shunt to earth, V cannot rise to the level iR until C_1 is charged in a time of the order $C_1 V/i$. Thus a time lag is introduced into the loop. It will be seen that values of C_1 of a few picofarads can produce destabilizing delays, whereas typical amounts of series wiring inductance do not seem significant.

The effect of shunt capacitance requires that the V in (4) be the solution of the circuit equation

$$C_1\frac{dV}{dt} = M\phi - \frac{V}{R}. \tag{5}$$

Computations

Equations (1), (2), (4), and (5) were integrated by the ORDIFFS routine which is capable of handling up to ten coupled first-order ordinary differential equations. No algebraic expressions may be used in addition to the differential equations so that parameters may be treated as time-dependent variables. The normalized photon density in the Pockels cell was assumed to be 10^{-4} at the instant of switching with t_1 = 4 ns, L = 10 cm, and $\alpha_0 = 0.4\ \text{cm}^{-1}$. The value of the load resistor R was chosen as 200 Ω after some experience; larger values produced instability because C_1 could not be less than a few picofarads, but smaller values required more current than the available photodiode could supply.

An initial computation was carried out with $M = 0$, corresponding to zero feedback and resulting in a conventional Q-switched pulse having a peak flux 400 times the initial value as shown in Fig. 3(a).

When negative feedback is introduced with $M = 10^3$ and the stray capacitance C_1 in parallel with the 200-Ω load resistor is 20 pF, the pulse shown in Fig. 3(b) is obtained. A small initial overshoot occurs as the capacitor charges making the feedback momentarily ineffective. Subsequently, the output falls almost exponentially with a decay time of 80 ns which is determined by C_1/M.

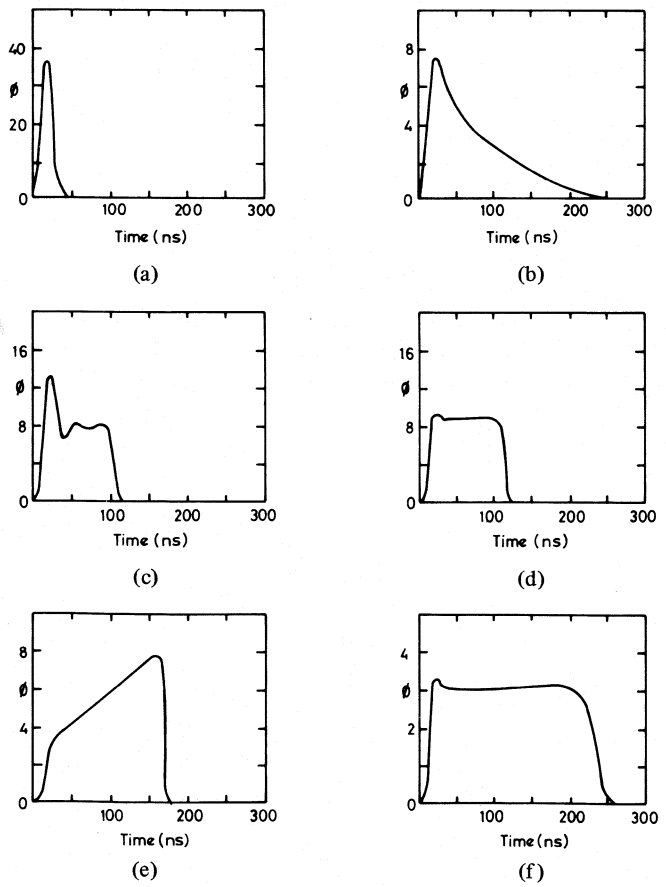

Fig. 3. Computed output for a controlled laser in units of 10^{-3} photons cm^{-3}/chromium-ion density. (a) No feedback. (b) Negative feedback only. (c) Compound feedback with $n = 0.5$. (d) Compound feedback with $n = 0.3$. (e) Increased feedback-loop gain, L_1 = 20 μH. (f) Increased feedback-loop gain, L_1 = 120 μH.

Compound Feedback

The purpose of introducing the feedback mechanism was to generate a rectangular pulse, but the circuit of Fig. 2 will always give a monotonic decay even with RC_1 made small enough to reduce the initial spike. To make the pulse rectangular the feedback must be reduced as time progresses. This is accompanied by adding an auxiliary positive-feedback loop consisting of an inductance L_1 in series with capacitor C_2 having a time-constant comparable with C_1/M.

The resulting feedback circuit is shown in Fig. 4. It is assumed that C_2 is initially uncharged but at a time approximately RC_1 after the laser pulse begins, a voltage appears on the Pockels cell and partially closes it. At the same time this voltage produces a current i_2 rising at a rate V/L_1, which charges the capacitor C_2 and reduces the net bias on the Pockels cell, tending to reopen it. For a constant input voltage the series circuit L_1C_2 produces a potential V_2 on C_2 which increases as $(1 - \cos 2\pi t/(L_1C_2)^{1/2})$ so that the shutter reopening does not become very rapid until about a quarter period after the pulse onset.

From Fig. 4 it is seen that the single-circuit equation (5) must be replaced by a set of three new equations given below, and that V in (4) must be replaced by $V_1 - V_2$.

$$C_1 \frac{dV_1}{dt} = i_1 = i_0 - i_2 - i_3$$

$$= M\phi - \frac{V_1}{R} - i_3$$

$$C_2 \frac{dV_2}{dt} = i_3$$

$$L_1 \frac{di_3}{dt} = V_1 - V_2.$$

Pulse shapes computed from these equations combined with (1)-(4) are given in Fig. 3(c)-(f). A value of 0.5 was assumed for the population inversion ratio, 20 μH for the inductor L_1, and 200 pF for C_1, the combined capacitances of the Pockels cell (6 pF), photodiode (6 pF), and circuit stray capacitance. This last value is slightly larger than the realizable minimum and results in a giant spike at the beginning of the output as shown in Fig. 3(c). This spike takes a large part of the available ruby energy from the rest of the pulse but is reduced if the pumping energy is lowered. The laser gain is then reduced, resulting in a lower pulse rise rate and a voltage rise of C_1 which

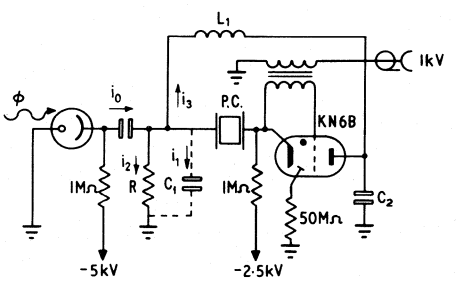

Fig. 4. Compound-feedback circuit with a Krytron switch.

follows the photon pulse more closely. In Fig. 3(d) the ruby is pumped to $n = 0.3$ which is more realistic than 0.5, and C_1 is made equal to 20 pF. The pulse overshoot is now seen to be negligible.

An increase in the pulse length must result in a decrease in pulse amplitude so that a longer pulse should be attained by increasing the feedback loop gain M. In Fig. 3(e) the gain M is increased from 10^3 to 3.10^3 resulting in a decrease in the initial pulse level but the amplitude rises steadily until its sudden collapse after about 150 ns. To recover a flat-topped pulse, the L_1C_2 product of the positive-feedback loop must be increased. In Fig. 3(f), L_1 has been increased to 120 μH and the resulting pulse is slightly longer than 200 ns, but over 150 ns the amplitude varies by less than 5 percent.

The abrupt turnoff of the pulses in Fig. 3 is obtained because the voltage V_2 rises quite rapidly in the later stages, exceeding V_1, causing momentary complete opening of the shutter. This sustains a high output, but V_2 continues to swing upwards and recloses the shutter. V_1 then drops, further increasing the value $V_1 - V_2$, and causes the final shutter closure to be very rapid. Some part of the population inversion remains and must be included in the final optimization of the system.

By solving the Frantz and Nodvik [11] equation for the gain of a laser amplifier it was shown that amplification of the laser pulse [Fig. 3(f)] causes a departure from the flat-topped structure of not greater than 10 percent when the pulse power at the amplifier input is as much as 15 MW.

A Q-Switched Long-Pulse Laser

A laser was constructed with a cavity 100 cm long and an output mirror of 50-percent reflectivity. The feedback loop consisted of an ITT FW114A photodiode and a KD*P Pockels cell, with the photodiode mounted so close to the Pockels cell that connections between terminals were only a few centimeters in length to minimize the stray capacitance. A 200-Ω load resistor R was employed as shown in Fig. 4. The Pockels cell was switched on initially by means of a Krytron switch type KN6B. The cavity flux was polarized with a Glan-Thompson prism and about 5 percent was diverted by a pellicle beam splitter into the feedback loop. All other optical surfaces were antireflection coated.

To operate the system the Pockels cell was initially biased to its quarter-wave voltage thereby preventing laser action. On firing the Krytron tube the Pockels cell bias falls to zero and light amplification begins. The switching time of about 1 ns determined by the load resistor and the Pockels cell capacitance, is insignificant compared with the pulse build-up time of about 200 ns. The megohm isolation resistor prevents C_2 charging from the power supply during the laser pulse duration but is low enough to keep the Krytron conducting.

It was shown that a conventional Q-switched pulse of 40-ns duration, as seen in Fig. 5(a), could be obtained by making the optical attenuator of Fig. 1 completely opaque to laser light and thereby eliminating all feedback. With simple feedback-omitting inductor L_1, the laser pulse and feedback voltage shown in Fig. 5(b) were obtained. It is apparent that control of the kind observed by Marshall and Roberts [6] has been effected since the fast rise and long decay is the same as the computed shape of Fig. 3(b). Compound feedback was achieved with the addition of a random-wound inductor of 75 μH together with a capacitor of 240 pF. An early result employing both positive and negative feedback is shown in Fig. 5(c), where the shunt capacitance to earth was high. The difference in shape between the feedback voltage and the laser pulse is due to ringing in the LC circuit. The initial spike and following hump of the laser pulse is the same as the computed shape of Fig. 3(c). On reducing the shunt capacitance the flat-topped pulse of 160-ns duration shown in Fig. 5(d) was obtained. When the feedback-loop gain M was increased without increasing the inductance, the laser pulse rose with time as in Fig. 5(e) until the surge in the positive-feedback voltage reduced it to zero. This figure compares with the computational shape of Fig. 3(e). Finally, in Fig. 5(f) we show the pulse shape obtained when the inductance was increased to 160 μH, the flat top in the computed curve of Fig. 3(f) is reproduced with a deviation from flatness of ±5 percent for 130 ns of the total pulse duration of 240 ns.

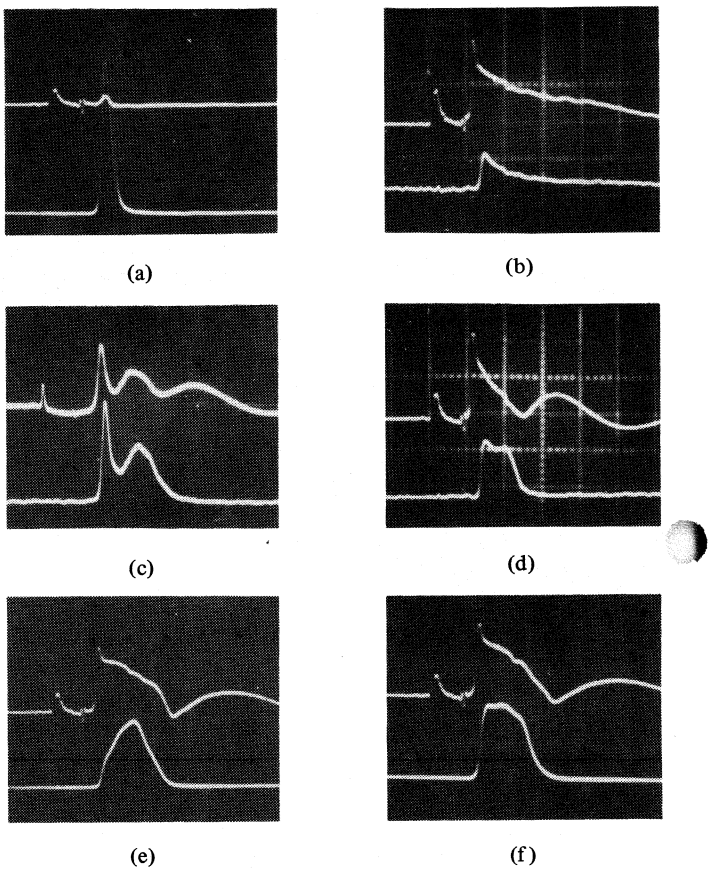

Fig. 5. The upper trace is the feedback voltage and the lower trace the laser pulse. 200 ns/major division. (a) No feedback. (b) Negative feedback only. (c) Compound-feedback large shunt capacitance. (d) Compound-feedback low shunt capacitance. (e) Increased feedback-loop gain, inductance 75 μH. (f) Increased feedback-loop gain, inductance increased to 160 μH.

Measurements of the output pulse made with a cone calorimeter showed that between 80 and 90 percent of the energy of the Q-spoiled pulse is retained in the extended pulse.

The spectrum of the laser pulse was determined in a photomixing experiment. An attenuated pulse was allowed to fall on a biplanar photodiode (ITL HCB2) with a 125-Ω load. The

output voltage was analyzed up to 30 MHz with a Heathkit RG52 communications receiver and up to 870 MHz with an Eddystone 990S UHF receiver. The spectrum was found to consist of lines having a transform-limited halfwidth of 2.5 MHz with subsidiary satellites, separated by the axial mode spacing of 125 MHz.

Conclusions

It has been shown that the shape of a ruby laser pulse can be controlled by the use of a Pockels cell whose transmission is governed by the intensity of light in the laser cavity. The latter is related to the potential difference across the Pockels cell by the use of a photodiode and a combination of negative and positive feedback.

Using the Wagner and Lengyel's giant-pulse equations coupled with the equations of the electric circuit, pulse shapes have been computed which bear a close resemblence to those actually measured in the laboratory.

A correct choice of feedback parameters permits the generation of approximately rectangular laser pulses whose length can be varied at will between 120 and 600 ns, and which, moreover, are free from high-frequency oscillations. 15-MW rectangular pulses have been amplified without distortion.

Acknowledgment

The authors wish to thank Dr. H. A. B. Bodin for inviting them to carry out this work as part of the Toroidal Pinch program at Culham, and are grateful to the UKAEA for the facilities provided. They also wish to thank P. Tripathi of the University of California for assistance in setting up the computational model, and R. Hamilton for experimental assistance.

A Theory of the Mode-Locked, Internally Frequency-Doubled Laser

JOEL FALK, MEMBER, IEEE

***Abstract*—An AM mode-locked laser with a frequency doubler internal to the laser cavity is analyzed. Mathematical expressions are derived for laser pulsewidth, saturated gain, and second-harmonic output power. It is shown that the maximum second-harmonic power output available from the mode-locked laser is a factor of $\sqrt{2}$ less than that available from an identical free-running laser.**

Numerical examples are given for an Nd:YAG laser with a $Ba_2NaNb_5O_{15}$ internal frequency doubler.

Manuscript received June 26, 1974; revised September 17, 1974. This work was partially supported by the Advanced Development Program 405B, Air Force Avionics Laboratory, Wright-Patterson AFB, Ohio, under a subcontract from the McDonnell Douglas Astronautics Company East.

The author is with the Electro-Optics Organization, GTE Sylvania Inc., Mountain View, Calif. 94042.

I. Introduction

A MODE-LOCKED LASER provides an attractive means of producing a stream of high repetition-rate pulses useful for optical communication. Frequency doubling of a mode-locked laser is often useful for shifting the output of a laser source from a wavelength of limited utility to a more useful region of the optical spectrum. Limited atmospheric transmission, poor detector, and modulator response at the fundamental wavelength are three possible reasons for considering frequency doubling of a mode-locked laser designed for optical communications applications. Frequency doubling may be accomplished internally or externally to the laser's optical cavity. The internally frequency-doubled laser, be-

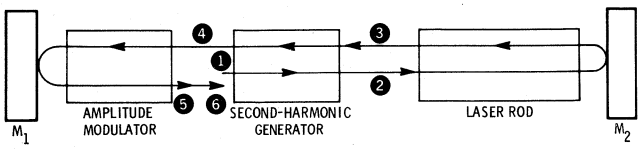

Fig. 1. The optical cavity.

cause of the higher fundamental fields available within the laser cavity, accomplishes the frequency doubling in a more efficient manner than if it is performed externally to the laser cavity. On the other hand, because the second-harmonic process provides a power-dependent loss to the mode-locked laser pulse, the laser's temporal width is increased by the doubling process [1]. This increase in pulsewidth at the fundamental wavelength is an important determinant of the pulse shape for the internally doubled laser.

This paper theoretically analyzes the mode-locked, *frequency-doubled*, homogeneously broadened laser. Mode locking produced by amplitude modulation is treated. The self-consistent approach introduced by Kuizenga and Siegman for describing a mode-locked homogeneously broadened laser is employed [2]. In the analysis that follows the propagation of a temporally Gaussian pulse is traced around the optical cavity shown schematically in Fig. 1. The effects of each component on the Gaussian pulse shape are considered, and it is required that the pulse envelope repeat itself after a round-trip traversal of the optical cavity. The principal extension of the Kuizenga-Siegman theory is the inclusion and analysis of a frequency doubler within the laser cavity.

Other authors have attempted to treat the mode-locked doubled laser analytically but analyses previously published [1], [3]:

1) have neglected the effects of laser fluorescent linewidth and hence present results which have only limited validity;
2) have not given an explicit expression for laser pulsewidth;
3) have not treated the effects of modulator detuning.

The analysis presented here leads to expressions for pulsewidth and laser power, and a prediction of laser performance when the modulator is detuned from its ideal driving frequency.

This paper first considers the component transforms of each of the elements in the cavity shown in Fig. 1. Self-consistent equations are then developed and simplified. Numerical examples relevant to the Nd:YAG laser are given.

II. Component Transforms

The effect of each of the intracavity components on a temporally Gaussian pulse is considered. The pulse is assumed to have a Gaussian spatial distribution with a $1/e$ beam size of w_0. The generalized electric-field pulse shape, including both time and radial variations, is

$$E_a(t,r) = A \exp(-r^2/w_0^2)\, E_a(t) \exp j\omega_a t + \text{c.c.} \tag{1}$$

where the function $E_a(t) = \exp - [\gamma(t+t_0)^2]$ describes the temporal variation of the envelope of $E_a(t,r)$. The parameters γ and t_0 determine the laser's pulsewidth and the time of the peak pulse amplitude. In the analysis that follows γ is assumed to be real, and any frequency chirping on the pulse is ignored.

The Fourier transform of $E_a(t,r)$, or a description of the propagating pulse in the frequency domain is

$$F[E_a(t,r)] = E_a(\omega,r) = A\sqrt{\pi/\gamma} \exp(-r^2/w_0^2) \cdot \exp[jt_0(\omega-\omega_a) - (\omega-\omega_a)^2/4\gamma]. \tag{2}$$

Thus the pulse's optical spectrum is centered at $\omega = \omega_a$.

A. The Laser Rod

The transfer function of the laser rod is best described in the frequency domain. For a homogeneously broadened medium, the amplifier single-pass field transfer characteristic $T_A(\omega)$ has a Lorentzian line shape [2]

$$T_A(\omega) = \exp[g/(1 + j2(\omega-\omega_a)/\Delta\omega_a)] \tag{3}$$

or

$$T_A(\omega) \cong \exp[g - (2jg(\omega-\omega_a)/\Delta\omega_a) - 4g(\omega-\omega_a)^2/\Delta\omega_a^2] \tag{4}$$

where g is the *saturated* single-pass field gain at line center ($\omega = \omega_a$), and $\Delta\omega_a$ is the homogeneous linewidth of the laser transition. The three-term Taylor-series expansion given in (4) for $T_A(\omega)$ is valid for $|\omega_a - \omega_a| << \Delta\omega_a$.

The temporal output field of the amplifier rod is given by

$$E_b(t,r) = F^{-1}[T_A(\omega)E_a(\omega,r)]$$

where F^{-1} indicates an inverse Fourier transform. Thus

$$E_b(t,r) = A' \exp(-r^2/w_0^2) \exp[-\gamma'(t+t_0')^2] \cdot \exp j\omega_a t + \text{c.c.} \tag{5}$$

and

$$A' \equiv A \exp(g)/\sqrt{G}, \quad \gamma' \equiv \gamma/G, \quad t_0' \equiv t_0 - 2g/\Delta\omega_0$$

where

$$G \equiv 1 + 16\gamma g/\Delta\omega_a^2.$$

Hence the output pulse from the laser amplifier remains Gaussian. The effects of the laser rod are to delay the pulse by $2g/\Delta\omega$, to lengthen it by decreasing γ to γ/G, and to increase the pulse amplitude. These effects have been previously reported by Kuizenga and Siegman and are repeated here only for completeness [2].

In writing (1)-(4) it was tacitly assumed that the center of the envelope of the optical spectrum of the Gaussian pulse lies exactly at the center of the amplifier's passband. In practice the centermost axial mode may be as far as one-half the longitudinal-mode spacing removed from line center. This small frequency displacement has no apparent practical consequence and is neglected in the remainder of this paper.

B. The Loss Modulator

The single-pass field transfer function of the loss modulator is [2]

$$a_L(t) = \exp[-\delta_L \sin^2(\omega_m t/2)] \tag{6a}$$

or

$$a_L(t) \cong \exp\left[-\delta_L\left[\sin^2(\omega_m t_0/2) - \frac{\omega_m(t+t_0)\sin(\omega_m t_0)}{2} + \frac{\omega_m^2(t+t_0)^2}{(2)(2!)}\cos\omega_m t_0)\right]\right] \quad (6b)$$

where $\exp(-\delta_L/2)$ is the time-average modulator amplitude transmission and $\omega_m/2$ is the modulator drive frequency. The loss seen by the laser varies with frequency ω_m, which is twice the modulator drive frequency. It is important to realize that the exact form of the modulator transfer function is dependent upon the physical means employed to loss modulate. Equation (6a) is only approximately correct for the two most common means of loss modulation, namely electrooptic or acoustooptic [4], [5]. However, (6b) is valid in the temporal region of interest, where $\delta_L \sin^2(\omega_m t/2) \ll 1$, i.e., when the optical pulse passes through the loss modulator with comparatively little loss.

C. The Second-Harmonic Generator

The frequency-doubling process has pronounced effects on both the spatial and the temporal shape of the Gaussian pulse. For this analysis the effects on the spatial variation can be treated in a conventional manner where coupling to the fundamental-field cavity mode is considered. Changes in the Gaussian temporal shape of the pulse, however, are not so easily treated. The investigation of the effect of second-harmonic generation on the temporal shape is facilitated by a physically reasonable approximation.

The analysis given is strictly valid only for small conversion efficiency to the second harmonic. As a practical matter this limitation is of little consequence because most internally frequency-doubled lasers produce the maximum output power with only a small conversion of the fundamental-wavelength circulating power to second-harmonic output power.

1) Spatial-Mode Considerations: In this section the effect of the second-harmonic generation process on the spatial variation of the generalized Gaussian pulse given by (1) is considered. For notational simplicity the time variation of every electric field is rewritten as a product of an optically varying phase and of an envelope that varies both in time and in space

$$E_a(t,r) = |E_a(t,r)| \exp -j\omega_a t + \text{c.c.} \quad (7)$$

where

$$|E_a(t,r)| \equiv AE_a(t)\exp(-r^2/w_0^2). \quad (8)$$

If second harmonic is generated with 90° phase matching, i.e., without Poynting-vector walkoff, the envelope of the second-harmonic field produced in the doubler crystal is

$$|E_{2\omega}(t,r)| = j|E_a(t,r)| \tanh[K|E_a(t,r)|] \quad (9)$$

where K is dependent solely upon crystal parameters [6]. Similarly, the envelope of the fundamental frequency field emerging from the crystal is

$$|E_b(t,r)| = |E_a(t,r)| \operatorname{sech}[K|E_a(t,r)|]. \quad (10)$$

If the conversion efficiency is small, i.e., if $K|E_a(t,r)| \ll 1$, (10) becomes

$$|E_b(t,r)| \cong E_a(t)A\exp(-r^2/w_0^2)[1-(K^2A^2/2)E_a^2(t)\cdot\exp(-2r^2/w_0^2)]. \quad (11)$$

For a laser operating in the TEM_{00} mode the only part of $|E_b(t,r)|$ which couples to the cavity mode is that which overlaps a Gaussian beam of radius w_0. In general, $|E_b(t,r)|$ can be expanded as a sum of products of Gaussian and higher order Hermite or Laguerre polynomials. The envelope of the TEM_{00} mode exiting from the crystal can then be calculated using the orthogonality properties of the Laguerre functions. Hence, if $|E_b'(t,r)|$ is the TEM_{00} component of $|E_b(t,r)|$,

$$|E_b'(t,r)| = \exp(-r^2/w_0^2)\frac{\int_0^\infty |E_b(t,r)|\exp(-r^2/w_0^2)\,2\pi r\,dr}{\int_0^\infty [\exp(-r^2/w_0^2)]^2\,2\pi r\,dr} \quad (12)$$

$$|E_b'(t,r)| = |E_a(t,r)|[1-(KA/2)^2 E_a^2(t)]. \quad (13)$$

Thus the time-varying loss seen by the Gaussian envelope $|E_a(t,r)|$ is $(KA/2)^2 E_a^2(t)$.

2) Temporal Considerations: An exact analysis of the temporal effects of the second-harmonic process within the framework of Gaussian pulses is impossible because the second-harmonic process does not maintain the envelope of Gaussian input pulse. That is, treatment of the second-harmonic generation process by use of the transfer function described in (13) destroys the Gaussian temporal pulse shape.

However, it has been noted that the experimentally observed pulse shape and optical spectrum observed from a mode-locked frequency-doubled laser are very nearly Gaussian [7]. The effect of many passes through the doubling crystal is to alter the Gaussian-pulse parameters γ and t_0 while essentially maintaining a Gaussian envelope.

Therefore, the temporal effect of the second-harmonic generation is treated as if it maintains the Gaussian envelope of an input pulse, and produces an output whose peak amplitude and curvature at the time of the peak pulse amplitude are the same as the actual TEM_{00} output pulse described by (13). Thus the output of the doubler crystal is approximated by

$$|E_b'(t,r)| \cong A\exp(-r^2/w_0^2)(\exp -a)\exp[-\gamma b(t+t_0)^2] \quad (14)$$

where a and b are the curve-fitting parameters that can be adjusted so that (13) and (14) yield identical 1) peak amplitudes,

$$|E_b'(t=-t_0,r)|$$

and 2) curvatures

$$\frac{\partial^2}{\partial t^2}|E_b'(t=-t_0,r)|.$$

We note that both expressions for $|E_b'(t,r)|$ yield equal (zero) slopes at $t=-t_0$. These three time derivatives, which are

identical if calculated from either (13) or (14), are the first three coefficients of a Taylor expansion for $|E_b'(t,r)|$. Thus, with parameters a and b appropriately chosen, (14) describes the nonlinear transmission of the doubler crystal correctly to second order in $t + t_0$. This is the same degree of accuracy used for the description of both the amplitude modulator (6b) and the amplifier rod (4).

Equating the three time derivatives, as outlined above, it is found that the parameters a and b are given by

$$a = -\ln [1 - (KA/2)^2], \quad a \cong (KA/2)^2 \tag{15}$$

$$b = [1 - 3(KA/2)^2] [1 - (KA/2)^2]^{-1},$$

$$b \cong 1 - (KA)^2/2 \tag{16}$$

where the approximate values hold for $(KA)^2 \ll 1$.

Equations (15) and (16) relate curve-fitting variables a and b to physical parameters K and A. Although, in principle, K and A are either measurable or calculable precise evaluation of either is difficult and furthermore is unnecessary because only the product KA appears in (13)-(16). It is more convenient and physically meaningful to relate KA, hence a and b, to the single-pass power loss associated with the second-harmonic process. This time-varying loss $\alpha(t) \equiv [P_2(t)]/[P_1(t)]$ = (second-harmonic power)/(fundamental power) can be calculated from (9), (14)-(16). The peak value of $\alpha(t)$, i.e., the peak conversion efficiency or peak single-pass power loss to the second harmonic, is the conversion efficiency at the peak of the fundamental pulse and is given by

$$\alpha_{\text{peak}} = \alpha(t = -t_0) = (KA)^2/2. \tag{17}$$

Similarly, it can be shown that the average single-pass power loss to the second harmonic,

$$\alpha_{\text{SHG}} = \frac{\int_{-\infty}^{\infty} P_2(t)\,dt}{\int_{-\infty}^{\infty} P_1(t)\,dt}$$

is related to KA via

$$\alpha_{\text{SHG}} = (KA)^2 \sqrt{2}/4. \tag{18}$$

Hence the peak loss to the second harmonic is $\sqrt{2}$ times the average power loss. It will later become apparent that the difference between peak and average second-harmonic losses leads to a unique power saturation behavior for the mode-locked frequency-doubled laser.

With values of α_{SHG}, the average single-pass power loss or second-harmonic conversion efficiency, determined by (18), the parameters a and b may be rewritten

$$a = (\sqrt{2}/2)\,\alpha_{\text{SHG}} \tag{19a}$$

$$b = 1 - \sqrt{2}\,\alpha_{\text{SHG}} \tag{19b}$$

for $\alpha_{\text{SHG}} \ll 1$.

III. Self-Consistency

It is required that after one round-trip traversal of the optical cavity, the pulse envelope repeat itself. With the required component transforms developed in the preceding sections of this paper the mathematical formalism necessary to follow a pulse around the optical cavity now exists.

Consider a pulse with electric-field envelope at point 1 (input to the doubler crystal) in Fig. 1 given by the generalized Gaussian

$$|E_1(t,r)| = A \exp(-r^2/w_0^2) \exp[-\gamma(t + t_0)^2]. \tag{20}$$

The TEM_{00} output pulse resulting from a single pass through the second-harmonic crystal and thus the pulse into the amplifier rod is determined from (14). The output resulting from two passes through the amplifier rod is found by two applications of (5). Hence the rod output is

$$|E_3(t,r)| = A'' \exp(-r^2/w_0^2) \exp[-\gamma''(t + t_0'')^2] \tag{21}$$

where

$$A'' \equiv \frac{A \exp(-a + 2g)}{\sqrt{G'}}, \quad \gamma'' = \gamma b/G',$$

$$t_0'' = t_0 - 4g/\Delta\omega_a \tag{22}$$

and

$$G' = 1 + 32\gamma b g/\Delta\omega_a^2. \tag{23}$$

Similarly, $|E_3(t,r)|$ is the input for the second pass through the doubler crystal, so that the output-field envelope $|E_4(t,r)|$ is

$$|E_4(t,r)| = (A/\sqrt{G'}) \exp(-r^2/w_0^2) \exp(-2a' + 2g) \cdot \exp[(-\gamma b'/G')(t + t_0 - 4g/\Delta\omega_a)^2] \tag{24}$$

where

$$2a' = \frac{\sqrt{2}}{2}[\alpha_{\text{SHG1}} + \alpha_{\text{SHG2}}] = \sqrt{2}\,\alpha_{\text{SHG}} \tag{25}$$

$$b' = 1 - \sqrt{2}(\alpha_{\text{SHG1}} + \alpha_{\text{SHG2}}) = 1 - 2\sqrt{2}\,\alpha_{\text{SHG}}. \tag{26}$$

Note that α_{SHG2}, the efficiency of conversion to the second-harmonic for the second pass through the doubler crystal, is not necessarily equal to α_{SHG1} (the first pass conversion efficiency) [8]. The parameter, $\alpha_{\text{SHG}} \equiv (\alpha_{\text{SHG1}} + \alpha_{\text{SHG2}})/2$, defines a measure of the effective single-pass losses to the second harmonic. Continuing the tracing of the optical pulse with two passes through the loss modulator

$$|E_5(t,r)| = |E_4(t,r)| \cdot a_L^2(t) \tag{27}$$

where $a_L(t)$, the loss modulator's amplitude transmission is given by (6b).

Finally, the round trip for the pulse is completed by including an additional time delay $2L_0/c$, and an effective loss α. The time delay allows for the time of round-trip propagation through the cavity of optical length L_0 and the effective loss α accounts for all linear cavity losses.

For self-consistency the envelope of the pulse at any point in the cavity must repeat itself after one period of the modulation cycle. Thus

$$E_1(t - T_m, r) = E_6(t, r) \exp(-j\theta) \tag{28}$$

where $T_M = 2\pi/\omega_m$ and θ allows for an optical phase precession [2].

Equation (28) may be rewritten by using (24)-(27) and by equating powers of t. This leads to three coupled complex equations which completely describe the behavior of the mode-locked frequency-doubled laser. These equations are

$$\gamma = \gamma b'/G' + (\delta_L \omega_m^2/2) \cos \omega_m t_0 \tag{29}$$

$$T_m - 2L_0/c = 4b'g/(G'\Delta\omega_a) + [\delta_L \omega_m/(2\gamma)] \sin \omega_m t_0 \tag{30}$$

and

$$\exp[-\gamma(T_M - 2L_0/c)^2] = (G')^{-1/2} \exp[2g - 2a' - \alpha + j\theta + j\omega_p(T_M - 2L_0/c) - 16g^2 \gamma b'/(\Delta\omega_a^2 G') - 2\delta_L \sin^2(\omega_m t_0/2)]. \tag{31}$$

In the absence of second-harmonic generation these equations, with minor notational changes, reduce to those given in [2].

Although (29)-(31) provide a complete description of the laser's performance, their complexity precludes any meaningful physical understanding without further simplification.

Fortunately, simplification is possible if a low-gain laser ($g \ll 1$), such as CW-pumped Nd:YAG is considered, and if note is taken of the usual magnitudes of the variables in (29)-(31). First, for internal frequency doubling, the conversion efficiency α_{SHG} must be much less than unity if overcoupling [9] of the laser is to be avoided. Further, the pulse spectral extent $\Delta\omega_p$, defined at its 10-percent power points, must be less than the laser fluorescent linewidth. Subject only to these two assumptions, (29) becomes

$$\gamma = -\frac{\sqrt{2}\,\alpha_{SHG}}{32g/\Delta\omega_a^2} + \frac{1}{2}\left[\frac{8\alpha_{SHG}^2}{(32g/\Delta\omega_a^2)^2} + \frac{2\delta_L \omega_m^2 \cos \omega t_0}{32g/\Delta\omega_a^2}\right]^{1/2}. \tag{32}$$

This equation essentially describes laser pulsewidth as a function of modulation depth (δ_L), second-harmonic conversion efficiency (α_{SHG}), and detuning. Pulsewidth (τ_p) is defined as the full pulsewidth of the second-harmonic output as measured as its 10-percent power points. This definition of pulsewidth is useful when dealing with optical communication systems because it represents the time which an optical shutter or modulator must be open in order to pass almost all (97 percent) of the energy in the second-harmonic output pulse [10]. Pulsewidth and γ are related by $\tau_p = [\ln 10/\gamma]^{1/2}$. Note that maximum γ, or minimum pulsewidth (τ_p), occurs with $\omega_m t_0 = 0$, i.e., when there is no phase shift between the optical pulse train and the loss modulation. Further note that minimum pulsewidth occurs at minimum value of α_{SHG}, i.e., where the effects of second-harmonic generation are least. It should be pointed out that although α_{SHG} is treated as an independent variable in (32) it is in fact an implicit function of pulsewidth (e.g., α_{SHG} increases for shorter pulsewidths) and hence cannot simply be varied at will.

It is interesting to evaluate the expression for pulsewidth in the region of large second-harmonic generation, i.e., where

$$\alpha_{SHG}^2 \gg 8g\delta_L(\omega_m^2/\Delta\omega_a^2) \cos \omega_m t_0. \tag{33}$$

In this case a Taylor expansion of (32) yields

$$\gamma = (\omega_m^2 \delta_L/4\sqrt{2})(\cos \omega_m t_0)/\alpha_{SHG} \tag{34}$$

and

$$\tau_p = 2[\sqrt{2} \ln 10]^{1/2} \frac{1}{\omega_m}\left[\frac{\alpha_{SHG}}{\delta_L \cos \omega_m t_0}\right]^{1/2}. \tag{35}$$

In this regime γ and τ_p are independent of g and $\Delta\omega_a$. That is, for high second-harmonic conversion efficiency, pulsewidth is independent of the characteristics of the laser amplifier medium and dependent only upon a competition between the doubler which favors long pulses and the modulator which prefers short pulses [1]. The simple explicit dependence of pulsewidth on ω_m and δ_L, given in (35), is markedly different from that which occurs for the mode-locked, nondoubled laser [2] where $\tau \sim (1/\omega_m)^{1/2}(1/\delta_L)^{1/4}$. It is interesting to note that the dependence of τ on α_{SHG}, ω_m, and δ_L given implicitly by Bernecker [3] (who neglects the effects of laser fluorescent linewidth) is identical to that predicted by (35).

The phase shift, described by (30), between the optical pulse train and modulator drive, may also be simplified using the small gain, small α_{SHG} approximation. Then

$$\Delta f = \omega_m^2/(4\pi^2)[4g/\Delta\omega_a + (\delta_L/2\gamma)\omega_m \sin \omega_m t_0] \tag{36}$$

where $\Delta f = c/2L_0 - \omega_m/2\pi$ is the deviation of twice the modulator drive frequency from the cavity axial mode spacing. In a practical laser system this phase-shift-detuning characteristic may be used as a discriminant in order to maintain mode locking with $\omega t_0 = 0$ over long periods of time [11].

Similarly, (31), which determines laser saturated gain and hence laser output power, may be written

$$2g = \sqrt{2}\,\alpha_{SHG} + \alpha + 2\delta_L \sin^2(\omega_m t_0/2) - 2(\ln 10)\delta_L^2(\omega_m/\Delta\omega_p)^2 \sin^2 \omega_m t_0 - 4g\delta_L(\omega_m/\Delta\omega_a) \sin \omega_m t_0 + (2g/\ln 10)(\Delta\omega_p/\Delta\omega_a)^2 \tag{37}$$

where $\Delta\omega_p$ is the pulse spectral width measured at its 10-percent power points. The terms on the right-hand side of (37) can be physically identified. The first three terms are due to the second-harmonic conversion, linear loss, and loss produced by the modulator if the pulse center does not pass through the modulator at a time of zero loss. The next three terms are a consequence of the finite amplifier linewidth and finite pulse spectral width. Typical values for an Nd:YAG mode-locked frequency-doubled laser are $\omega_m = 2\pi(250\ \text{MHz})$, $\Delta\omega_a = 2\pi(120\ \text{GHz})$, and $\Delta\omega_p = 2\pi(10\ \text{GHz})$. Hence $\omega_m/\Delta\omega_a \ll 1$,

$(\Delta\omega_p/\Delta\omega_a)^2 \ll 1$, and the last two terms are negligible. The fourth term, $-2(\ln 10)\delta_L^2 \cdot (\omega_m/\Delta\omega_p)^2 \sin^2 \omega_m t_0$ is maximum when $\Delta\omega_p$ is minimum. This occurs when the coupling to the second harmonic α_{SHG} is large. In that case $\Delta\omega_p$ can be determined from (35) and therefore an upper bound for the fourth term is given by $\sqrt{2}\,\delta_L\,\alpha_{SHG} \sin^2 \omega_m t_0/\cos \omega_m t_0$. In the usual frequency-doubled Nd:YAG laser, $\alpha_{SHG} \leqslant 0.01$, and therefore the fourth term of (37) is negligible compared to $+2\delta_L \sin^2 (\omega_m t_0/2)$ over nearly the entire detuning range.

Hence the saturated round-trip field gain is determined approximately by

$$2g = \sqrt{2}\,\alpha_{SHG} + \alpha + 2\delta_L \sin^2 (\omega_m t_0/2). \tag{38}$$

The form of this equation determines the power output from the mode-locked frequency-doubled laser discussed in the next section.

IV. Laser Saturation and Output Power

It has been noted previously [12] that the gain of a homogeneously broadened laser saturates according to

$$g = G_0/(1 + \beta P_c) \tag{39}$$

where G_0 is the unsaturated or small-signal single-pass electric-field amplitude gain, β is a saturation parameter which depends only upon laser-material parameters and the cross-sectional area of the oscillating mode, and P_c is the laser's average circulating power. Equations (38) and (39) thus serve to determine the circulating power that can be expected internal to a mode-locked frequency-doubled laser. Harmonic output power is given by $P_{out} = 2\alpha_{SHG} P_c$, and

$$P_{out} = \frac{2\alpha_{SHG}}{\beta}\left[\frac{2G_0}{\sqrt{2}\,\alpha_{SHG} + \alpha + 2\delta_L \sin^2 (\omega_m t_0/2)} - 1\right]. \tag{40}$$

Maximum power output occurs with $\omega_m t_0 = 0$ and

$$\alpha_{SHG} = (\sqrt{2}/2)\,[(2G_0)^{1/2}\,\alpha^{1/2} - \alpha] \tag{41}$$

and is given by

$$P_{max} = (\sqrt{2}/\beta)\,[(2G_0)^{1/2} - \alpha^{1/2}]^2. \tag{42}$$

These values of optimum output coupling and optimum output power are a factor of $\sqrt{2}$ less than those expected from either a frequency-doubled non-mode-locked laser or a mode-locked laser operating at its fundamental wavelength.

For either of these lasers, power gain saturates at a value equal to single-pass power loss. For the frequency-doubled free-running laser, this means that saturated gain is found from $2g = \alpha + \alpha_{SHG}$. Similarly, gain saturation in the mode-locked fundamental-wavelength laser reduces gain until $2g = \alpha + T/2$, where T is the power transmission of the output coupler. The maximum power available from either of these lasers is $2/\beta\,[(2G_0)^{1/2} - \alpha^{1/2}]^2$ and occurs with $\alpha_{SHG} = (2G_0)^{1/2} \cdot \alpha^{1/2} - \alpha$ for the doubled laser and with $T/2 = (2G_0)^{1/2}\,\alpha^{1/2} - \alpha$ for the mode-locked fundamental-wavelength laser [9].

The basic mathematical difference that distinguishes the mode-locked frequency-doubled laser from these lasers is that in the mode-locked frequency-doubled laser saturation is affected by $\sqrt{2}\,\alpha_{SHG}$, while only α_{SHG} contributes to the single-direction output power. For either a frequency-doubled free-running laser or for a mode-locked fundamental-wavelength laser, all loss terms which contribute to output power appear in an identical form in both output-power and laser-saturation equations.

There is one basic physically distinctive feature of the mode-locked frequency-doubled laser that accounts for a reduction in its available power output as compared to the free-running or fundamental-wavelength laser. In contrast to the latter two lasers, the loss encountered by the Gaussian pulse in passing through the amplitude modulator of a frequency-doubled laser is not negligible and is in fact proportional to α_{SHG}.

For the special case of a long pulsewidth, without detuning, a simple physical explanation exists which clarifies this result. In this case, the Gaussian pulse occupies a relatively narrow spectral width and the amplifier saturated gain may be considered a temporal constant g. In the steady state the sum of all single-pass cavity power-losses must be equal to $2g$ and thus must be time independent. Although second-harmonic loss and modulator losses each vary with time, their sum must be a constant if the total cavity loss is to be time invariant. At $t = 0$, i.e., at the peak of the Gaussian pulse, modulator loss is zero and second-harmonic loss is maximum and given by $\sqrt{2}\,\alpha_{SHG}$. As time increases from $t = 0$, doubling losses are reduced and modulator losses increase. Their sum nevertheless remains constant and may be calculated by its value at $t = 0$ and is thus given by $\sqrt{2}\,\alpha_{SHG}$.

In the case of no detuning and where the line shape of the amplifying medium is unimportant, the dependence of the sum of modulator and second-harmonic loss on α_{SHG} is mathematically easily demonstrated. Consider the field-amplitude transmission of a modulator as given by (6b). For a laser operating without detuning, i.e., for modulator-drive frequency adjusted such that $t_0 = 0$, this transmission may be written $a_L(t) = \exp[-\delta_L(\omega_m t)^2/4]$. The amplitude transmission through the second-harmonic generator is found from (7) and (14) and is given by

$$T_{SHG}(t) = (\exp - a) \exp[-\gamma t^2 (b - 1)] \tag{43}$$

where $a = (\sqrt{2}/2)\,\alpha_{SHG}$ and $b = 1 - \sqrt{2}\,\alpha_{SHG}$. Thus a single pass through the modulator, frequency-doubler combination results in a power-transmission function

$$T = [T_{SHG}(t)\,a_L(t)]^2 = \exp(-2a) \cdot \exp[-2t^2[\gamma(b - 1) + \delta_L \omega_m^2/4]]. \tag{44}$$

The pulse propagation constant γ is determined from (34) and hence the single-pass modulator, frequency-doubler power loss is

$$1 - T = 1 - \exp - 2a \cong \sqrt{2}\,\alpha_{SHG}. \tag{45}$$

Consequently, $\sqrt{2}\,\alpha_{SHG}$ accounts for the effect of both the modulator and the doubler in saturating the laser gain. On the other hand, only α_{SHG}, the time average losses to the second harmonic, is available as single-direction output coupling. The remaining loss is caused by the modulator and does not contribute to output power.

V. Some Numerical Examples

A. The Significance of α_{SHG}: Laser Performance as a Function of α_{SHG}

Before considering the analytical implications of the theory developed in this paper it is useful to examine further the physical significance of α_{SHG}, the second-harmonic conversion efficiency. Although in the theory herein α_{SHG} is treated as an independent variable and as a determinant of circulating power and pulsewidth, α_{SHG} actually changes both with circulating power and with pulsewidth.

The treatment of α_{SHG} as an independent, rather than dependent variable, has the advantage that it decouples the analysis of effects of laser saturation from the analysis of the effects of mode locking and frequency doubling. Hence it allows the characterization of the output mode-locked pulsewidth given in Section III without direct reference to laser saturation. This treatment permits the generation of generalized curves which describe the pulsewidth τ_p and phase shift $\omega_m t_0$ of the mode-locked pulse as a function of second-harmonic conversion efficiency α_{SHG}, and detuning parameter Δf. Figs. 2-4 present these curves for a internally frequency-doubled Nd:YAG laser. The laser parameters used to calculate the curves are $\Delta\omega_a = 2\pi(120\text{ GHz})$, $\omega_m = 2\pi(250\text{ MHz})$, and $2g = 0.05 + \sqrt{2}\,\alpha_{SHG}$.

Fig. 2 shows, for various modulation indices, δ_L the variation of pulsewidth τ_p with increasing second-harmonic conversion efficiency α_{SHG}. This curve is plotted from (32) for zero phase shift between the amplitude-modulation and the mode-locked pulse train ($\omega_m t_0 = 0$). Note that even for small α_{SHG} rather substantial broadening of the laser pulsewidth from its second-harmonic-free value occurs. It is interesting to note that for α_{SHG} greater than approximately 0.3 percent the pulsewidth follows a square-root dependency on α_{SHG}, as described by (35), and is consequently independent of the assumed value of saturated laser gain. That is, for $\alpha_{SHG} > 0.3$-percent pulsewidth is determined solely by the modulator and second-harmonic process and does not depend on the amplifier line shape.

Fig. 3 shows the variation of pulsewidth τ_p with detuning Δf. The detuning characteristic is approximately symmetric about a detuning $\Delta f = (\omega_m/2\pi)^2 (4g/\Delta\omega_a)$. A positive Δf corresponds to a modulation frequency lower than the axial mode spacing, $c/2L_0$. The occurrence of a minimum pulsewidth at a modulation period different from the round-trip cavity time is due to the time delay seen by the pulse passing through the Nd:YAG amplifier rod. Note also that as α_{SHG} is increased the effect of detuning is decreased.

The change in the mode-locked pulse phase shift $\omega_m t_0$ with detuning Δf is shown in Fig. 4. A positive value of $\omega_m t_0$ denotes that the laser pulse train leads the amplitude modulation. Here again note that detuning effects are less pronounced at high α_{SHG}. The reduced sensitivity of the phase shift $\omega_m t_0$ to detuning may be viewed as the cause of the insensitivity of pulsewidth to changes in modulation frequency when α_{SHG} is large. That is, from (32) it is seen that the primary way detuning affects pulsewidth is via a change in pulse position $\omega_m t_0$. Hence, if pulse position is insensitive to detuning, pulsewidth will also vary slowly with changes in modulation frequency.

Physically, the lessened sensitivity of pulse position to detuning at higher second-harmonic conversion efficiencies is due to the relatively long pulse durations associated with large values of α_{SHG}. This can be understood by examining the physical implications of modulator detuning. For any modulation period, the requirement that the pulse envelope repeat itself after a cavity round trip determines $\omega_m t_0$, the phase shift between the modulation and the output pulse train.

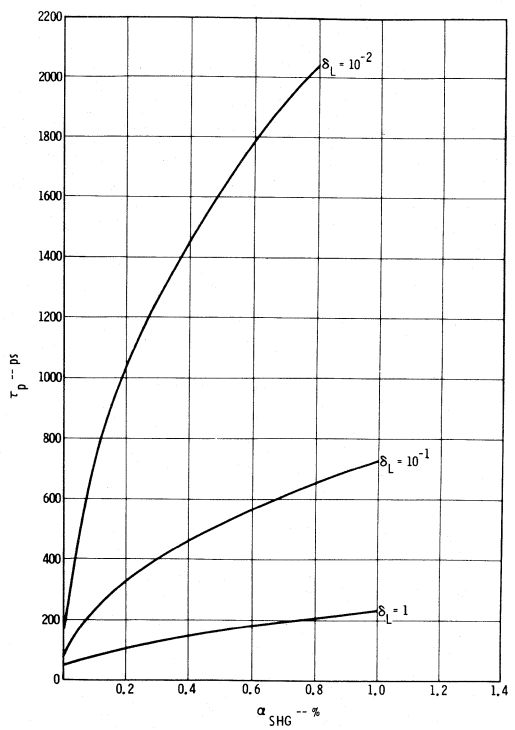

Fig. 2. Second-harmonic pulsewidth τ_p (10-percent power points) as a function of the second-harmonic conversion efficiency α_{SHG}.

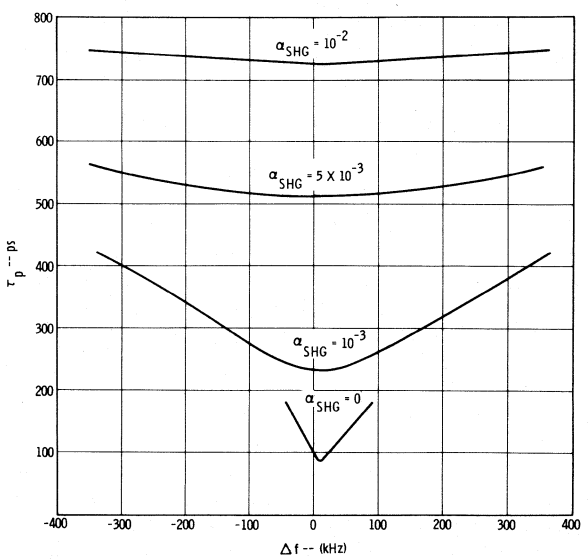

Fig. 3. Second-harmonic pulsewidth τ_p (10-percent power points) as a function of detuning Δf. The modulation depth δ_L is 0.1.

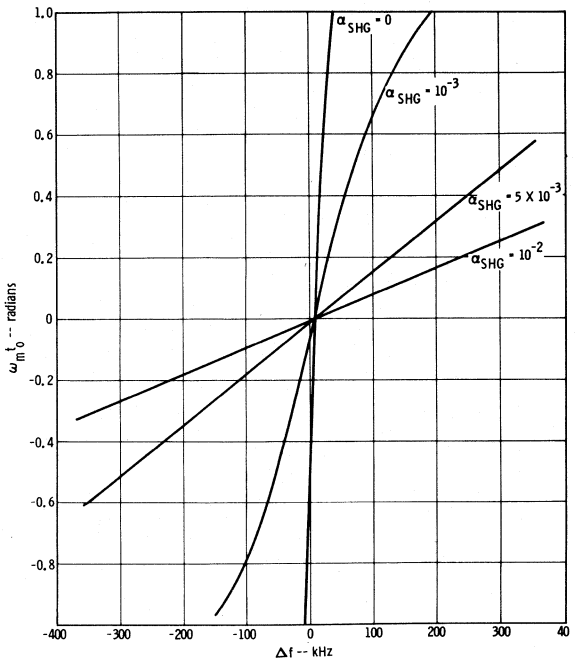

Fig. 4. Pulse position $\omega_m t_0$ relative to the amplitude modulation, as a function of detuning Δf. The modulation depth δ_L is 0.1.

If the drive frequency is chosen optimally, i.e., for minimum pulsewidth, then the pulse train will leave the modulator in phase with the modulation, complete a traversal through the optical cavity, and return in phase with the modulation waveform. A pulse thus propagating will suffer minimum loss in the modulator. In that case the modulation period T_M is the sum of the linear cavity propagation time and the two-pass amplifier delay time, i.e.,

$$T_M \text{ (optimum)} = 2L_0/c + 4g/\Delta\omega_a. \tag{46}$$

Now what happens if the modulation period is not chosen according to (46)? A pulse leaving the modulator in phase with the amplitude modulation will return to the modulator after a cavity round trip with a nonzero phase shift (ϕ) with respect to the amplitude modulation. First consider the case shown in Fig. 5 where the modulation period is slightly less than T_M (optimum) so that when the pulse reenters the modulator, $\phi > 0$. At $0 < \phi < \pi$ the modulator loss is increasing with increasing time and hence the pulse's trailing portion is attenuated more strongly than its leading edge. As seen in Fig. 5, this nonsymmetrical loss results in a negative delay of the pulse centroid. Steady-state operation of the detuned laser is achieved when the pulse leaving the modulator with phase ϕ returns to it with the same phase ϕ. Thus in the steady state the phase shift between the modulation and pulse train determines a delay in the modulator. This delay exactly compensates for the deviation of modulation period from T_M (optimum). The delay in the modulator is determined from the generalized Gaussian pulse shape given by (1) and the amplitude modulator transfer function given by (6b). From these equations it can be shown that the delay t_D, due to the amplitude modulator, is given by

$$t_D = (\delta_L \omega_m \sin \omega_m t_0)/(2\gamma) \tag{47}$$

or in terms of the pulsewidth

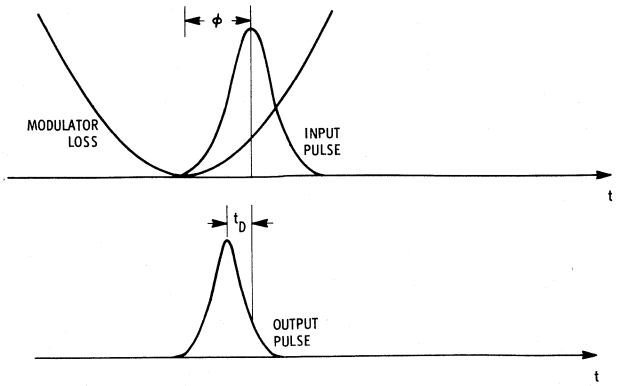

Fig. 5. Pulse delay in the amplitude modulator. If the pulse enters the modulator with a phase ϕ relative to the modulation it experiences an effective delay t_D.

$$t_D = (\delta_L \omega_m \sin \omega_m t_0)\, \tau_p^2/(2 \ln 10). \tag{48}$$

In Fig. 5 steady-state operation occurs with $\omega_m t_0 < 0$ so that t_D is negative.

On the other hand, if the modulation period is greater than T_M the pulse's leading edge sees more loss than its trailing portion and in the steady state the pulse position $\omega_m t_0 > 0$ so that a positive pulse delay results.

The delay t_D, required by the modulator, is determined solely by the deviation of the modulation period from T_M (optimum). From (48) it is seen that the phase shift $\omega_m t_0$ required for a particular delay t_D is least when the laser produces long pulses. Longest pulsewidth occurs when the conversion to the second harmonic is greatest and hence the sensitivity of pulse phase shift to detuning is least at highest conversion to the second harmonic.

B. Laser Performance as a Function of Beam Size in the Frequency-Doubler Crystal

Thus far this paper has analyzed the performance of modelocked internally frequency-doubled laser in terms of a single parameter, α_{SHG}, the second-harmonic conversion efficiency. Because of the dependent nature of α_{SHG}, a parametric analysis based only on α_{SHG} is necessarily incomplete and the variation of α_{SHG} with circulating power, laser beam size, and pulsewidth must be unraveled before a prediction of laser performance as a function of independent variables can be made. That is, a prediction of laser performance as a function of cavity mode sizes or pump-lamp input power requires an evaluation of α_{SHG} in terms of more basic laser parameters.

Recall that α_{SHG} is defined as the ratio of average single-direction second-harmonic power generated to the average circulating fundamental power, i.e.,

$$\alpha_{SHG} = \overline{P_2(t)}/P_c \tag{49}$$

where the overbar denotes a time average.

The average second-harmonic power produced can be found from the single-pulse second-harmonic shape, (9), by integrating over both the spatial and temporal pulse extent. Assuming the maximum instantaneous conversion efficiency is small the second-harmonic power may be written

$$\overline{P_2(t)} = [K^2 A^4 \pi w_0^2/(8 z_{2\omega})]\, (c/2L_0)\, [\pi/(4\gamma)]^{1/2} \tag{50}$$

where $z_{2\omega}$ is the crystalline impedance at the second harmonic, w_0 is the $1/e^2$ fundamental wavelength beam radius, and $c/2L_0$ is the pulse repetition frequency. Other quantities in (50) are defined in (1) and (9).

The average fundamental power, calculated from (1) in a similar manner, is given by

$$P_c = [A^2 \pi w_0^2/(4z_\omega)]\,(c/2L_0)\,[\pi/(2\gamma)]^{1/2} \tag{51}$$

where z_ω is the crystalline impedance of the fundamental wavelength. Thus the second-harmonic conversion efficiency can be described in terms of incavity beam sizes, fundamental circulating power, and second-harmonic pulsewidth as

$$\alpha_{SHG} = [2K^2/(\pi w_0^2)]\,[z_\omega^2/z_{2\omega}] \cdot P_c(2L_0/c)\sqrt{\ln 10}/(\sqrt{\pi}\,\tau_p). \tag{52}$$

In performing the temporal integrations necessary to evaluate P_c and $\overline{P_2(t)}$ it was implicitly assumed that $\tau_p \ll 2L_0/c$, so that temporal overlap of consecutive pulses is negligible.

It is instructive to compare the evaluation of α_{SHG} for the mode-locked laser to that of a identical single axial mode [6, p. 133] free-running laser. A similar calculation of the second-harmonic conversion efficiency for the free-running laser and a comparison with (52) shows that the factor

$$(2L_0/c)\,[\sqrt{(\ln 10)}/\sqrt{\pi}\,]\,(1/\tau_p) \simeq (2L_0/c)(0.85/\tau_p)$$

is the enhancement due to the mode locking.

Now with a mechanism established to relate α_{SHG} to basic cavity parameters, the results of this paper can be well illustrated by a numerical example. An Nd:YAG laser, AM mode locked and internally frequency doubled by a $Ba_2NaNb_5O_{15}$ crystal is considered. Where appropriate, parameters are taken equal to those analyzed in [2]. This choice of numerical values facilitates comparison with the mode-locked fundamental-wavelength laser.

A laser pumped by a single krypton lamp is considered, and the unsaturated power gain $2G_0$ is assumed to vary linearly with lamp input power and to be described by [13]

$$2G_0 = k[P_{lamp} - P_0]. \tag{53}$$

This linear approximation to unsaturated gain is approximately valid for $P_{lamp} \geqslant 2P_0$. The parameter k depends on the electrical efficiency of the pump lamp, on the efficiency of coupling into the Nd:YAG rod, and upon Nd:YAG material parameters. The parameter P_0 is the value of power input to the pump lamp at which the gain G_0 equals zero in the linear approximation. P_{lamp} is the input power to the pump lamp.

Assumed values for these parameters and other parameters are given in Table I. The values given are typical values for a laser consisting of a 3-mm-diam, 50-mm-long Nd:YAG laser crystal pumped by a 4-mm-bore krypton lamp.

Fig. 6 shows the predicted variation in second-harmonic output power as a function of lamp power for various beam sizes in the frequency-doubler crystal. For reference, the mode-locked second-harmonic power P_{max} available from the laser is also shown (42). The curve for a beam size of $w_0 = 100\ \mu$ is slightly under coupled over much of the range of pumping powers. Hence while decreasing the beam size in the doubler crystal to slightly below $100\ \mu$ would provide a small increase in output power, decreasing the beam size well below $100\ \mu$ would actually lead to a reduction of output power. A curve of second-harmonic output power for $w_0 = 50\ \mu$ falls nearly coincident with the 100-μ curve.

Fig. 7 shows predicted second-harmonic pulsewidths over the same range of pump powers and spot sizes. As lamp input

TABLE I
LASER PARAMETERS: FIGS. 6-10

k	pumping-efficiency constant = 2.2×10^{-4} $(W)^{-1}$
P_0	lamp-threshold parameter = 385 W
α	single-pass linear power loss = 0.05
$\frac{c}{2L_0}$	laser axial mode spacing = 250 MHz
L_0	laser-cavity optical length = 60 cm.
$\Delta\omega_a$	laser fluorescent linewidth (full width at half maximum) = 2π(120 GHz)
ω_m	AM frequency = $2x$ modulation drive frequency = 2π (250 MHz)
β	saturation parameter = 0.1 $(W)^{-1}$
K	second-harmonic nonlinearity[a] = 1.96×10^{-7} m/V

[a]The second-harmonic nonlinearity K (9) is calculated assuming a 90° phase-matched $Ba_2NaNb_5O_{15}$ of 5-mm length. The crystal parameters used in evaluation of K are from S. Singh, D. A. Draegert, and J. E. Geusic, "Optical and ferroelectric properties of barium sodium niobate," *Phys. Rev. B*, vol. 2, pp. 2709-2724, Oct. 1970.

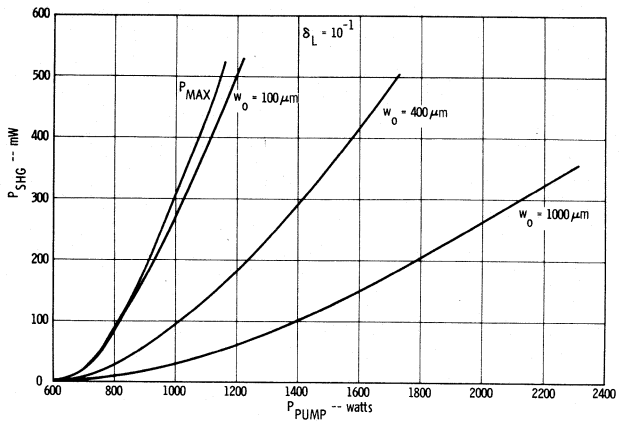

Fig. 6. Second-harmonic output power P_{SHG} as a function of the krypton-lamp input power P_{lamp}. The modulation depth δ_L is 0.1.

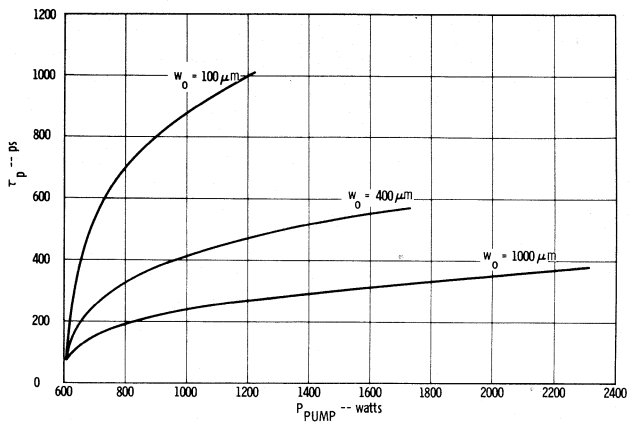

Fig. 7. Second-harmonic pulsewidth (10-percent power points) τ_p as a function of the krypton-lamp input power P_{lamp}. The modulation depth δ_L is 0.1.

power increases, pulses broaden due to the increase of second-harmonic conversion efficiency. Because pulsewidths increase monotonically with decreasing beam sizes (increasing α_{SHG}) a decrease in the beam size in the doubler crystal below 100 μ would result in a large increase in pulsewidth with only a small increase in power output.

Figs. 8–10 show the response of the frequency-doubled laser to detuning of the modulation drive frequency. As expected from Fig. 4, detuning effects are less pronounced for smaller beam sizes in the frequency doubler, i.e., at higher values of α_{SHG}. Figs. 8–10 show, respectively, the change in pulse position, output power, and pulsewidth with detuning. This large

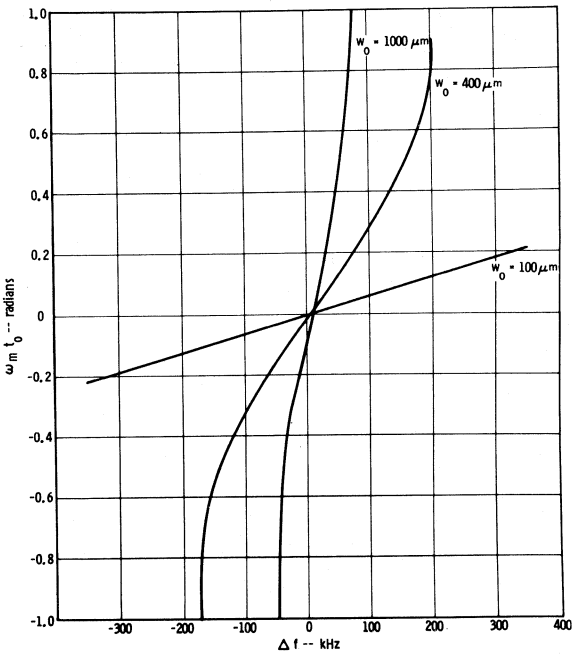

Fig. 8. Pulse position $\omega_m t_0$ relative to the amplitude modulation as a function of detuning Δf. The lamp input power P_{lamp} is 1000 W and the modulation depth δ_L is 0.1.

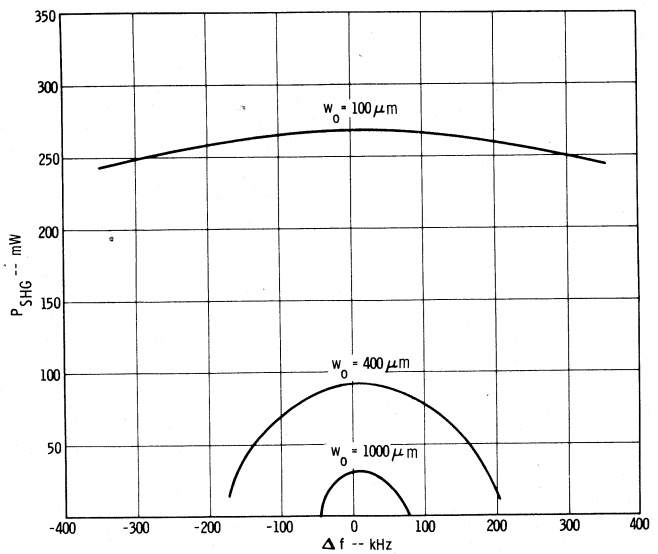

Fig. 9. Second-harmonic power P_{SHG} as a function of detuning Δf. P_{lamp} = 1000 W, δ_L = 0.1.

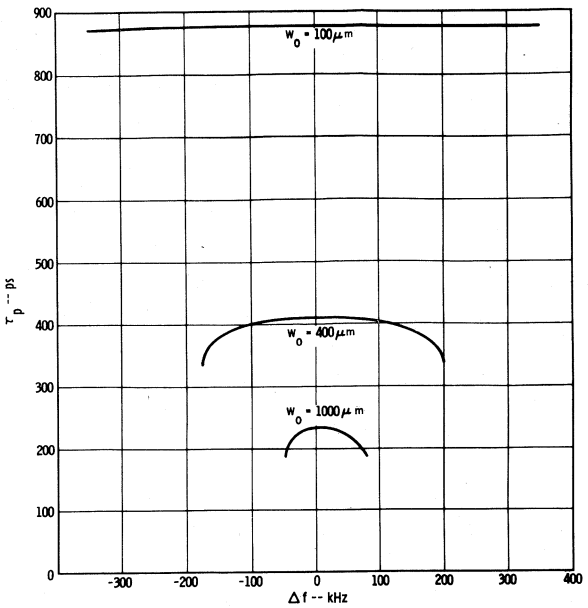

Fig. 10. Second-harmonic pulsewidth (10-percent power points) as a function of detuning Δf. P_{lamp} = 1000 W, δ_L = 0.1.

theoretical detuning range is not apt to be achieved in practice because the most common types of amplitude modulators, acoustooptic or electrooptic, do not usually present constant modulation depths over frequency ranges as large as the 700-kHz range shown in Figs. 8–10 [14].

The reduction in pulsewidth with detuning shown in Fig. 10 is caused by the reduction in circulating power due to modulator loss as the modulator is detuned from its optimal drive frequency (or as the cavity length is changed from optimum). As the detuning is increased the pulse position changes and the modulator presents an internal cavity loss that reduces P_c. This decrease in circulating power results in a decrease in α_{SHG} and hence reduction in the laser's pulsewidth.

VI. Experimental Results

A preliminary confirmation of this theory was made with a frequency-doubled Nd:YAG laser pumped by a K-Rb lamp. The frequency doubler was a barium sodium niobate crystal and relevant laser parameters were $g \cong 0.01$, $\delta_L = 0.03$, $c/2L = 5 \cdot 10^8$ Hz, and $\alpha_{SHG} \cong 0.005$. The theory developed here predicts a pulsewidth of 460 ps in rough agreement with the measured pulsewidth (corrected for detector response) of 390 ps.

VII. Summary

This paper has analyzed the performance of an internally frequency-doubled mode-locked laser. The results reported herein have been derived by considering the effects of each intracavity component upon a generalized Gaussian pulse shape. This technique was introduced by Kuizenga and Siegman [2] for the analysis of a mode-locked fundamental-wavelength laser. The effects of the internal frequency doubler are accounted for by a single parameter α_{SHG}, defined as the average power conversion efficiency to the second-harmonic wavelength. The second-harmonic process provides a power-

dependent loss to the intracavity propagating pulse, presenting more loss at its peak than at its extremities. This nonlinear loss leads to substantial broadening of the laser pulsewidth. The variation of pulsewidth, pulse position, and laser saturated gain with α_{SHG} has been predicted. The equations derived differ markedly from those describing the fundamental-wavelength laser. The pulse broadening caused by second-harmonic generation has been shown to be substantial even at small α_{SHG}.

In contrast to the fundamental-wavelength mode-locked laser, losses due to the amplitude modulator have been shown to be an important determinant of total laser losses and hence greatly affect the available second-harmonic output power. In fact, unavoidable modulator losses limit the output power theoretically extractable from the mode-locked frequency-doubled laser to a factor of $\sqrt{2}$ less than that available from an identical free-running laser. It has been further shown that, if the value of α_{SHG} necessary to extract the maximum available laser power is exceeded, the pulsewidth increases while the output power decreases with increasing α_{SHG}.

The response of the mode-locked frequency-doubled laser to detuning has been predicted. It has been shown that at higher values of α_{SHG} the laser is less affected by detuning of the modulator from its optimal frequency.

Numerical examples have been given for predicted laser performance for an Nd:YAG laser, internally frequency doubled by a $Ba_2NaNb_5O_{15}$ crystal.

Acknowledgment

The author wishes to thank A. E. Siegman for discussions regarding the treatment of second-harmonic generation used in Section II of this paper. He also wishes to thank J. D. Barry, C. B. Hitz, C. J. Kennedy, D. J. Kuizenga, N. Blackman, R. S. Reynolds, W. A. Specht, and P. J. Titterton for suggestions and comments on the manuscript. He especially wants to thank this JOURNAL's reviewers for valuable criticisms of the manuscript.

Mode Conversion in Planar-Dielectric Separating Waveguides

WILLIAM K. BURNS AND A. FENNER MILTON

Abstract—**The mode-conversion behavior of branching or separating planar-dielectric waveguides is studied theoretically as a function of branch asymmetry and taper slope. When the taper slope is large in a near-symmetric structure, considerable mode conversion will occur and the structure will act as a power divider. In an asymmetric structure with small taper slope, mode conversion is negligible and the structure will act as a mode splitter. A quantitative formula is presented which can be used to determine the behavior of a given separating structure.**

I. Introduction

IT IS ANTICIPATED that separating optical waveguides will become important in integrated optics. They will be encountered whenever a branching optical waveguide, as shown in Fig. 1(a), is used or whenever two parallel waveguides in close proximity are separated, as shown in Fig. 1(b). These structures are expected to find widespread use in electrooptical amplitude modulators and switches.

The distinguishing characteristics of optical separating waveguides in dielectric media are that the evanescent fields of the guided modes exist outside the boundaries of the guiding layers and power transfer between the individual waveguides or arms of the branching waveguide can occur due to the overlap of the evanescent fields. In this study we will confine our attention to planar-dielectric waveguides due to their mathematical simplicity, recognizing that the same mode-conversion considerations will apply to the separation of dielectric channel guides.

We use the term separating optical waveguide to apply to either of the structures in Fig. 1 since the separation of parallel waveguides is equivalent to a branching waveguide starting from a nonzero branch separation. The mode-conversion problem can be treated in the same way for each structure except for a different starting separation.

Yajima [1] showed experimentally that modes incident on an asymmetric planar-dielectric branching waveguide with a shallow taper propagate such that the mode power is transferred to one arm of the branch or the other. The principle was established that a mode would choose the arm in which it could propagate with an effective index closest to the effective index that characterized its propagation before the waveguide divided. An asymmetric branching waveguide with a shallow taper can thus be considered to act as a mode splitter [Fig. 2(a)]. Yajima recognized that branching waveguides with steeper tapers would not behave as ideal mode splitters due to mode conversion between the normal modes of the five-layer structure and power transfer to unguided radiation modes. Symmetry considerations lead us to believe that in extreme cases of steep tapers or near-symmetric branches the branching waveguide will act not as a mode splitter but rather as a power divider [Fig. 2(b)]. If the device acts as a power divider, incident power concentrated in the upper part of the structure will end up in the upper arm and incident power concentrated in the lower part of the structure will end up in the lower arm, independent of the modal evolution graphically described in Fig. 2(a).

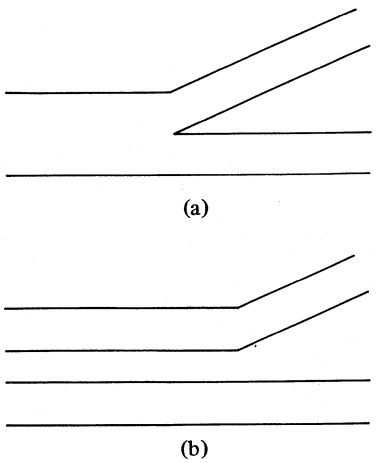

Fig. 1. Two types of separating optical waveguides. Propagation in both structures can be described in an equivalent manner if the parallel sections are sufficiently close in (b) for the normal modes to have power in both guiding regions.

Recently Yajima calculated many such cases of mode conversion [2], [3], starting with the approximate step theory of Marcuse [4]. We have extended the same step theory to include power transfer between two guided modes. By including a more rigorous treatment of the phase difference between the guided modes, we present results of more precise mode-conversion calculations for separating waveguides as a function of the rate of separation and mode synchronism, which is adjusted by the index asymmetry of the structure. The correct treatment of the phase difference between the two modes leads to a distinctly different dependence of mode conversion on taper slope for near-symmetric structures, and allows us to rigorously investigate the transition region between the two limiting modes of operation of a separating waveguide. We will thus explore the difference in behavior between separating

Manuscript received July 18, 1974; revised September 27, 1974. This research was partially supported by the Advanced Research Projects Agency and the Office of Naval Research.

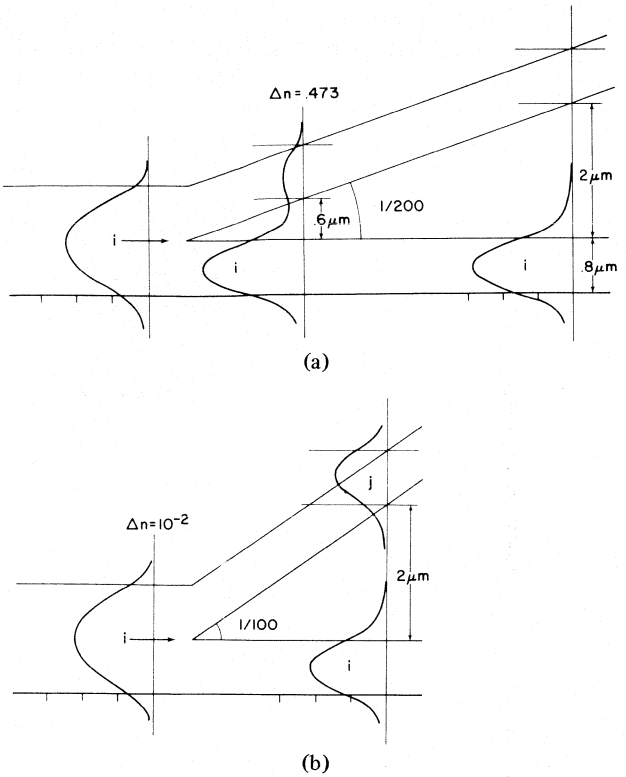

Fig. 2. Examples of a branching waveguide operated as a mode splitter (a) and as a power divider (b). Mode electric field is plotted for various waveguide cross sections, with indices as shown in Fig. 3. In (a) 98 percent of the input power remains in mode *i*. In (b) output powers are 55 percent for mode *i* and 36 percent for mode *j*.

asymmetric waveguides which separate slowly with a shallow taper and separating symmetric guides (where the two guides or branches are more nearly identical) which separate quickly with a steep taper.

II. Theory

We consider a planar, five-layer waveguide, which consists of two waveguiding layers and three regions of lower index boundary media that separate and clad the two waveguiding branches. Unless stated otherwise, use of the term "mode" will refer to the local normal modes of this five-layer waveguide for a given guide separation, which may be 0 or ∞. Thus propagation in the structures shown in Fig. 1(a) and (b) can be described by the same formulism with a different starting separation. With this approach the individual modes of a structure which consists of two guiding layers will evidence power in *both* layers if the guiding layers are in close enough proximity. Except in the case of exact symmetry (where the two guiding layers considered separately would have modes with exactly the same propagation constant), the modes of the five-layer structure with a large enough separation between guiding layers will concentrate power in one guiding layer or the other. Mode propagation is assumed in the z direction, the x direction is normal to the waveguiding layers, and fields and geometry are assumed unchanged in the y direction. The mode-dispersion equation can be obtained by solving the boundary value problem, and is given by Yajima [2], [3] for transverse electric modes

$$\{(\gamma_1+\gamma_3)\gamma_2+(\gamma_1\gamma_3-\gamma_2^2)\tan\gamma_2 d_2\}\cdot\{(\gamma_3+\gamma_5)\gamma_4+(\gamma_3\gamma_5-\gamma_4^2)\tan\gamma_4 d_4\}-\exp(-2\gamma_3 d_3)\{(\gamma_3-\gamma_1)\gamma_2+(\gamma_1\gamma_3+\gamma_2^2)\tan\gamma_2 d_2\}\cdot\{(\gamma_3-\gamma_5)\gamma_4+(\gamma_3\gamma_5+\gamma_4^2)\tan\gamma_4 d_4\}=0. \quad (1a)$$

Here γ_l is the transverse wave vector

$$\gamma_l=\sqrt{|n_l^2k^2-\beta^2|}, \quad l=1\text{-}5 \quad (1b)$$

and β is the mode wave vector in the direction of propagation, k is the free-space wave vector, and d_l and n_l are waveguide layer thicknesses and indices, as shown in Fig. 3. The roots of this equation yield mode wave vectors (β), which are then used to calculate the mode electric-field distributions. By plotting these mode electric-field distributions as a function of increasing branch separation, one can see how an individual mode transforms itself as the branch separation changes and which arm of the branch it chooses. All these considerations are calculations at a given position z and are independent of the rate at which the arms of the branch separate, or taper slope.

For a waveguide branch with an infinitely slow taper slope, we assume mode conversion to be negligible and mode power to be conserved for propagation through the branch. This corresponds to adiabatic passage. However, as taper slope is increased we expect that the adiabatic approximation will break down and power transfer will occur from an input mode to other guided and radiation modes, both transmitted and reflected. This problem is conveniently treated by the step approximation method of Marcuse [4]. The continuous-branch taper is approximated by a series of discontinuous, abrupt steps, separated by regions of parallel, five-layer waveguide (Fig. 3). We assume the waveguide modes of interest to be incident on a step and compute the transmitted mode amplitudes by requiring the transverse-field components to be continuous at the step. By breaking up the taper into a large number of small steps and repeating this process at each step, a reasonable approximation to the effect of a given taper slope is obtained.

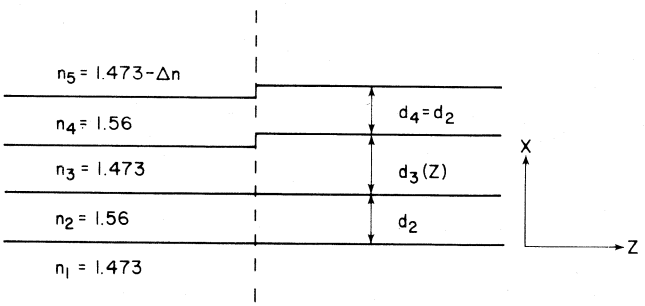

Fig. 3. Model of one of the steps used to approximate a continuous taper slope. The indices shown are used in most of the calculations in this paper. Note the geometric asymmetry assumed to approximate a planar geometry.

We restrict attention to two transverse electric guided modes, i and j. Guided-mode electric fields are written

$$e_y = E(z)\,\mathcal{E}(x,z)\exp(-i\alpha(z)) \tag{2a}$$

where

$$\alpha(z) = \beta z + \phi. \tag{2b}$$

$E(z)$ is the real amplitude at a point z, $\mathcal{E}(x,z)$ the real, x dependent field distribution, β the mode wave vector, and ϕ a phase constant. We will show that the effect of reflected radiation into unguided modes e^{ref} is small and can ultimately be neglected. Transmitted radiation into unguided modes e^{trans} is treated exactly. Boundary conditions for TE modes require e_y and h_x to be continuous across a step at z. We obtain the equations

$$\begin{aligned} e_y: {} & E_{i0}\mathcal{E}_{i0}\exp(-i\alpha_{i0}) + E_{j0}\mathcal{E}_{j0}\exp(-i\alpha_{j0}) \\ & + E^R_{i0}\mathcal{E}_{i0}\exp(i\alpha^R_{i0}) + E^R_{j0}\mathcal{E}_{j0}\exp(i\alpha^R_{j0}) + e^{\text{ref}} \\ & = E_{i1}\mathcal{E}_{i1}\exp(-i\alpha_{i1}) + E_{j1}\mathcal{E}_{j1}\exp(-i\alpha_{j1}) + e^{\text{trans}} \end{aligned} \tag{3a}$$

$$\begin{aligned} h_x: {} & \beta_{i0}E_{i0}\mathcal{E}_{i0}\exp(-i\alpha_{i0}) + \beta_{j0}E_{j0}\mathcal{E}_{j0}\exp(-i\alpha_{j0}) \\ & - \beta_{i0}E^R_{i0}\mathcal{E}_{i0}\exp(i\alpha^R_{i0}) - \beta_{j0}E^R_{j0}\mathcal{E}_{j0}\exp(i\alpha^R_{j0}) + h^{\text{ref}} \\ & = \beta_{i1}E_{i1}\mathcal{E}_{i1}\exp(-i\alpha_{i1}) + \beta_{j1}E_{j1}\mathcal{E}_{j1} \\ & \cdot \exp(-i\alpha_{j1}) + h^{\text{trans}} \end{aligned} \tag{3b}$$

where the subscripts 0 and 1 are used to denote the incident and transmitted fields across the step, and E^R is the amplitude of reflected guided modes. Multiplication by a transmitted mode field and integration over x eliminates the transmitted unguided radiation modes, because of orthogonality.

Our goal now is to obtain iterative equations for E_{j1} and α_{j1} from (3). If we consider cross reflection between modes i and j to be small, multiplication of (3) by $\int \mathcal{E}_{i1}\,dx$ gives an approximate equation for E^R_{i0}.

$$\begin{aligned} E^R_{i0}\exp(i\alpha^R_{i0}) \simeq {} & \left(\frac{\beta_{i0}-\beta_{i1}}{\beta_{i0}+\beta_{i1}}\right)E_{i0} \\ & \cdot \exp(-i\alpha_{i0}) + 0\left(E_{j0}\int \mathcal{E}_{j0}\mathcal{E}_{i1}\,dx\right). \end{aligned} \tag{4}$$

Now multiply (3) by $\int \mathcal{E}_{j1}\,dx$ and subtract out the term in E^R_{j0}. Using (4) in the resulting equation gives

$$\begin{aligned} & (\beta_{j0}+\beta_{j1})E_{j1}I_{j1,j1} \\ & \cdot \exp(-i\alpha_{j1}) = 2\beta_{i0}\left(\frac{\beta_{j0}+\beta_{i1}}{\beta_{i0}+\beta_{i1}}\right)E_{i0}I_{i0,j1} \\ & \cdot \exp(-i\alpha_{i0}) + 2\beta_{j0}E_{j0}I_{j0,j1} \\ & \cdot \exp(-i\alpha_{j0}) + 0(E_{j0}I_{j0,i1}I_{i0,j1}) \end{aligned} \tag{5a}$$

where

$$I_{\gamma,\delta} = \int \mathcal{E}_\gamma \mathcal{E}_\delta\,dx, \qquad \gamma,\delta = i,j. \tag{5b}$$

Equation (5a) is conveniently normalized by introducing a mode amplitude (E^s) which corresponds to a mode power of unity. At any point z, E^s is related to mode power (P) by

$$\sqrt{P_\gamma} = 1 = E^s_\gamma\sqrt{\frac{\beta_\gamma}{2k}I_{\gamma,\gamma}}, \qquad \gamma = i,j \tag{6}$$

where k is the free-space wave vector. By dividing the terms of (5a) by appropriate factors of the right-hand side of (6), and neglecting terms which contain the square of an overlap integral between different modes on opposite sides of the step, we obtain

$$A_{j1}\exp(-i\alpha_{j1}) = c_{ij}A_{i0}\exp(-i\alpha_{i0}) + c_{jj}A_{j0}\exp(-i\alpha_{j0}). \tag{7}$$

Here $A_\gamma = E_\gamma/E^s_\gamma$ is the ratio of mode amplitude in the presence of mode conversion to that mode amplitude which corresponds to unity power. The coefficient c_{ij} is given by

$$c_{ij} = \frac{2\sqrt{\beta_{i0}\beta_{j1}}}{(\beta_{j0}+\beta_{j1})}\left(\frac{\beta_{j0}+\beta_{i1}}{\beta_{i0}+\beta_{i1}}\right)\frac{I_{i0,j1}}{\sqrt{I_{i0,i0}I_{j1,j1}}} \tag{8}$$

and c_{jj} by substituting j for i in (8).

The real and imaginary parts of (7) then completely describe the transmitted mode j in terms of the input modes.

$$A_{j1} = c_{ij}A_{i0}\cos(\alpha_{i0}-\alpha_{j1}) + c_{jj}A_{j0}\cos(\alpha_{j0}-\alpha_{j1}) \tag{9a}$$

$$\tan\alpha_{j1} = \frac{c_{ij}A_{i0}\sin\alpha_{i0} + c_{jj}A_{j0}\sin\alpha_{j0}}{c_{ij}A_{i0}\cos\alpha_{i0} + c_{jj}A_{j0}\cos\alpha_{j0}}. \tag{9b}$$

Equation (9) plus its counterpart for mode i provide iterative, coupled-mode equations to calculate mode conversion and radiation loss due to a branch taper which is approximated by a large number of small steps. Since terms containing the square of an overlap integral between different modes on opposite sides of the step are neglected, we might expect poorer results for very steep tapers. Note that the phase of the output mode is coupled to the input mode parameters through (9b).

III. Discussion of Results

Using the theory developed in the last section we have studied mode conversion in a planar-dielectric waveguide branch as a function of taper slope and index asymmetry. The model waveguide, adapted from Yajima [2], [3], has dimensions $d_2 = d_4 = 0.8$ μm and indices as shown in Fig. 3. The free-space wavelength is 0.6328 μm and the first- and second-order modes are referred to as i and j, respectively. The geometry of the step model used to approximate the taper was deliberately chosen to reflect the experimental situation, where the lower branch lies flat on the substrate and the upper branch moves upward as the separation between the branches increases. Note that in this case we would expect modes with power primarily in the upper branch to suffer more radiation loss than modes in the lower branch. Computer programs were written to compute the mode wave vectors and electric fields between steps, evaluate the mode-

conversion coefficients, and to perform the iterations describing changes in mode amplitude at each step.

For a branching waveguide with indices as given in Fig. 3 and positive Δn, it was found that mode i propagated into the lower branch, while mode j went into the upper branch. It is mode j then which primarily sees the abrupt steps which form the taper. It was found that about 80 iterations were satisfactory to describe the mode-conversion effects of a waveguide branch within the limitations of computer time. Doubling the number of iterations caused amplitude changes of $\lesssim 5$ percent for mode j and $\lesssim 1$ percent for mode i. These small amplitude changes do make significant changes in estimates of power lost to radiation modes. To compensate for the larger error in A_j, we typically take mode i to be the input mode, and look at the buildup of power in mode j.

Plots of mode electric-field distributions versus increasing branch separation (Fig. 4) showed that initially mode power was equally divided between the branches, but that index asymmetry eventually caused the mode power to shift to one branch. The more asymmetric the branching waveguide, the faster this power shift occurs, as measured by amount of branch separation. This effect is shown in Fig. 5(a). Fig. 5(b) is a plot of c_{ij} and c_{ji} as given by (8) as a function of branch separation for various index asymmetries. We see that for each case the mode-conversion coefficient c_{ij} is large in the region of branch separation where mode power is being transferred from both branches to a single branch. This implies that mode conversion will also occur in this region. Although the branch separation at which the peak in c_{ij} occurs is a function of Δn, the width of this peak is approximately constant. We show in the Appendix that this width is a function of the index of the separating region between the branches. We also see that the coefficients c_{ij} and c_{ji} are related by $c_{ij} \simeq -c_{ji}$, as expected from power-conservation considerations in coupled-mode theory.

We can now be more precise in stating under what conditions the case of separating parallel guides is equivalent to a branching waveguide for the purpose of calculating mode conversion. They will behave in exactly the same manner if the initial branch separation of the separating parallel waveguide is less than or equal to the branch separation at which power transfer begins or the mode-conversion coefficient c_{ij} becomes appreciable. In this case, mode-conversion results will be directly transferrable from a branching-waveguide calculation. For initial branch separations in the region of power transfer, the mode-conversion calculations must be done with the appropriate initial conditions, and we can expect that mode conversion will be reduced. For initial branch separations beyond the region of power transfer there will be no mode conversion. In the calculations which follow we will assume a branching waveguide with zero initial branch separation.

Fig. 5(b) shows that c_{ij} tends to be finite for small branch separation and, for the smaller asymmetries, changes sign as the separation is increased. This effect is a consequence of the fundamentally asymmetric step geometry we have used to represent the experimental situation for a planar branching waveguide. The contribution to c_{ij} from the geometric asymmetry is of opposite sign to the contribution from modal evolution, and is dominant at small branch separation before power transfer takes place. We would expect that for a symmetric geometry, with displacement of both branches at a step, that c_{ij} would be zero at small branch separations and would exhibit no sign change as separation increased. Such a symmetric geometry for separating waveguides is more likely to be realized with channel guides. The initial behavior of c_{ij} does have important consequences on cumulative mode conversion, as will be shown.

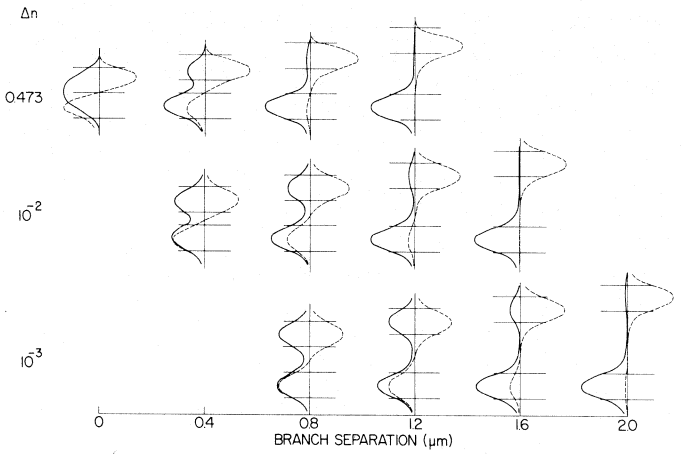

Fig. 4. Plots of adiabatic mode electric-field distributions in model waveguide versus branch separation for index asymmetry Δn of 0.473, 10^{-2}, and 10^{-3}. The solid curve is the first-order mode (i), and the dashed curve is the second-order mode (j). Each mode has unity power.

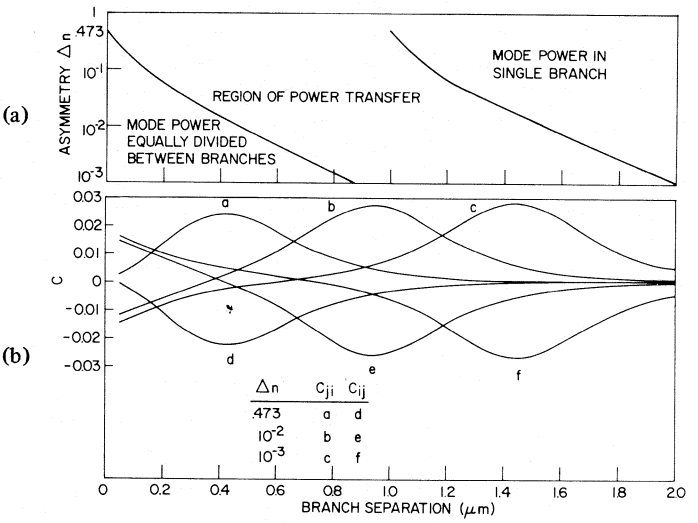

Fig. 5. (a) Branch separations at which power transfers from both branches to one as a function of branching waveguide index asymmetry for the model waveguide. (b) Plots of mode-conversion coefficients versus branch separation for various index asymmetries. The mode-conversion coefficients are large in the region of modal evolution.

The results of the mode-conversion calculations for the branching waveguides described by Fig. 3 with various index asymmetries and taper slopes are shown in Fig. 6. In each case, the input mode powers were 1 and 0 for modes i and j, respectively. The output mode amplitudes at branch separation $d_3 = 2$ μm ($d_3 = 2.4$ μm for the $\Delta n = 10^{-3}$ data) are plotted. Substantial mode conversion to mode j is observed

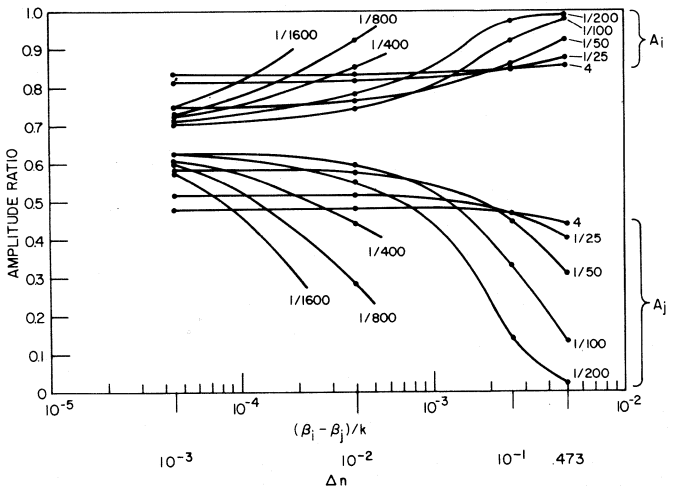

Fig. 6. Output-mode amplitude ratios illustrating mode conversion from mode i to mode j in the model branching waveguide with the indices given by Fig. 3 and $d_2 = d_4 = 0.8$ μm for various taper slopes. The abscissa shows both index asymmetry and difference in mode-effective indices at large branch separation ($\Delta\beta/k$).

in asymmetric branches (Δn large) as the slope increases. In the near-symmetric (Δn small) branches, substantial mode conversion occurs for nearly all slopes. This behavior can be understood by examining (7) when the condition

$$(\beta_{i0} - \beta_{j1})z \simeq 0 \tag{10a}$$

is satisfied over the length of the branch. For a small step $\beta_{j0} \approx \beta_{j1}$ so that we also have

$$(\beta_{j0} - \beta_{j1})z \simeq 0. \tag{10b}$$

Equation (10a) is obeyed for branches with steep slopes and for near-symmetric branches whose modes are nearly degenerate. Equation (7) can then be expressed in real form

$$A_{j1} = c_{ij}A_{i0}\cos(\phi_{i0} - \phi_{j1}) + c_{jj}A_{j0}\cos(\phi_{j0} - \phi_{j1}) \tag{11a}$$

$$0 = c_{ij}A_{i0}\sin(\phi_{i0} - \phi_{j1}) + c_{jj}A_{j0}\sin(\phi_{j0} - \phi_{j1}). \tag{11b}$$

If we assume a phase for mode i, $\phi_{i0} = 0$, and that the step is small enough so that the phase of mode j changes very little across a step, $\phi_{j0} - \phi_{j1} \simeq 0$, then (11) is satisfied by taking $\phi_{j1} = 0$ or π. A distinction can be made by expanding (11b) to give

$$\tan\phi_{j1} = \frac{c_{ij}A_{i0}\sin\phi_{i0} + c_{jj}A_{j0}\sin\phi_{j0}}{c_{ij}A_{i0}\cos\phi_{i0} + c_{jj}A_{j0}\cos\phi_{j0}}. \tag{12}$$

If c_{ij} were always negative, ϕ_{j1} would be locked at π and cumulative mode conversion would occur over the whole length of the taper. If c_{ij} is initially positive and then turns negative (asymmetric step displacement), $\phi_{j1} = 0$ until the denominator of (12) turns negative at

$$c_{ij} = -c_{jj}\frac{A_{j0}}{A_{i0}} \tag{13}$$

after which $\phi_{j1} = \pi$. After $\phi_{j1} = \pi$ cumulative mode conversion occurs.

Various cases of phase behavior are illustrated in Fig. 7. In

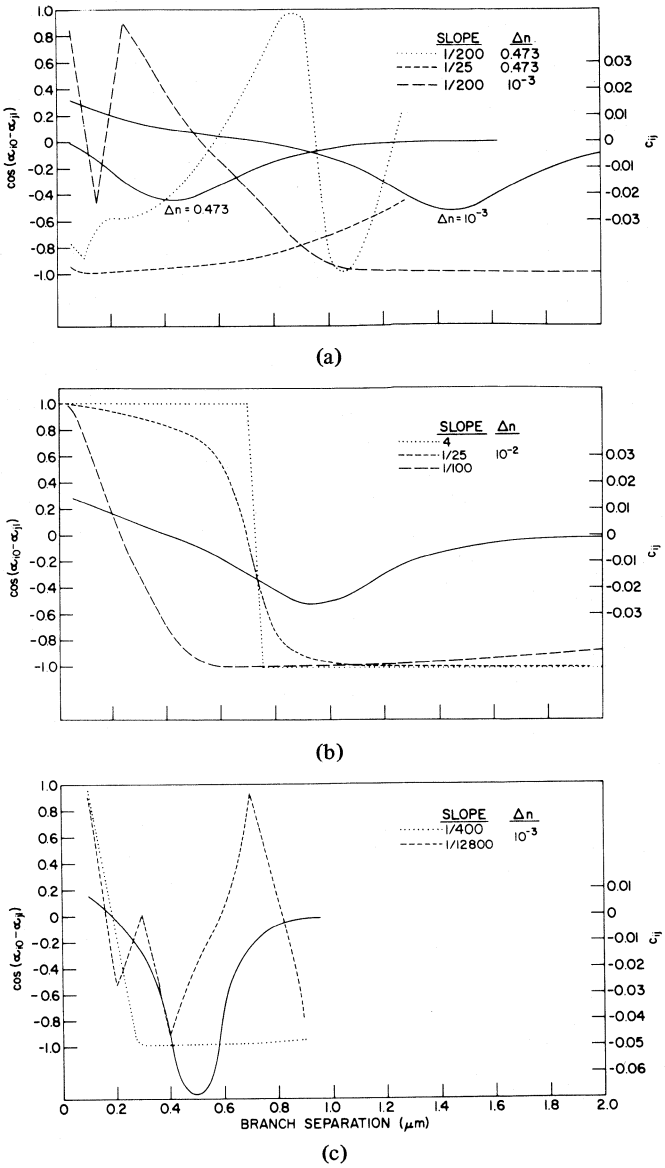

Fig. 7. Plots of the phase term and mode-conversion coefficient for various cases of slope, index asymmetry, and n_3 versus branch separation. (a) and (b): $d_2 = 0.8$ μm, $n_3 = 1.473$. (c): $d_2 = 0.6$ μm, $n_3 = 1.0$. In (b) an increase in slope reduces the range of mode-conversion coefficient over which the phase term has value −1. In (c) the slopes 1/400 and 1/12 800 correspond to converted mode amplitude of 62 and 7 percent, respectively.

Fig. 7(a) the terms c_{ij} and $\cos(\alpha_{i0} - \alpha_{j1})$ are plotted for waveguide branches with conditions of slope and Δn of 1/25, 0.473; 1/200, 0.473; and 1/200, 10^{-3}. For the first and last case the phase term is close to −1 when the overlap integral is large and negative, so that the converted mode amplitude builds up. In the case of large asymmetry and small slope, the phase term rapidly oscillates, and no accumulation of converted mode amplitude is possible. Plots of mode amplitude ratio (A_γ) versus branch separation for these 3 cases are shown in Fig. 8.

Fig. 6 shows that for near-symmetric branches mode conversion increases with increasing taper slope until it reaches a maximum value, after which it decreases. The phase behavior that causes this effect is shown in Fig. 7(b) for $\Delta n = 10^{-2}$. As the taper slope increases beyond 1/100, the phase term reaches

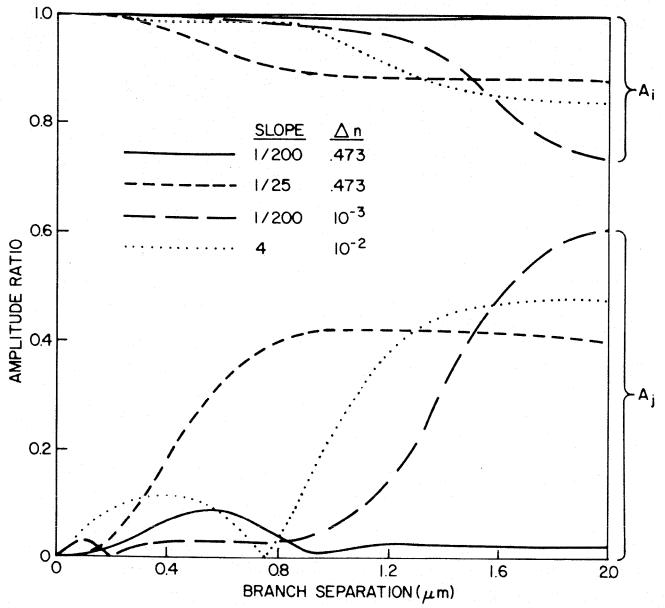

Fig. 8. Mode amplitude ratios versus branch separation for mode conversion from mode i to j in the model branching waveguide.

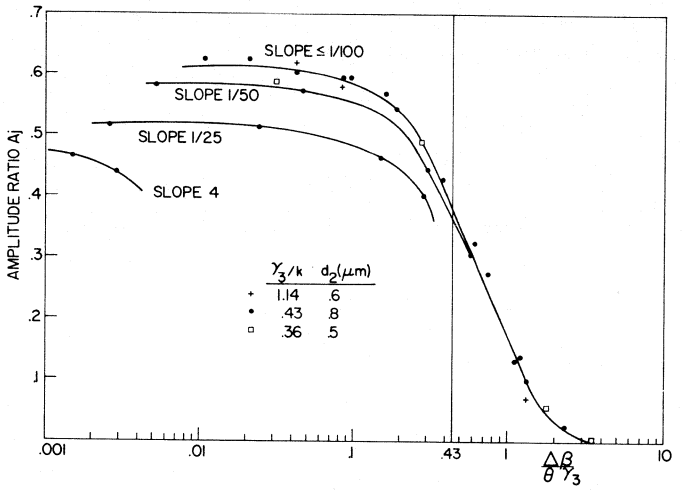

Fig. 9. Converted mode amplitude ratio A_j versus the calculated parameter $\Delta\beta/\theta\gamma_3$, which is indicative of mode-conversion magnitude. For abscissa values >0.43, the separating waveguide acts as a mode splitter; <0.43, as a power divider.

-1 more slowly and there is less cumulative mode conversion. The rate of development of the phase term to the -1 value depends in detail on the slope as defined by (2b) and (9b). The case of slope 4, $\Delta n = 10^{-2}$ in Fig. 8 shows the canceling effect of geometrical asymmetry at small branch separation for an abrupt taper. A physical interpretation is that with increasingly steep tapers the geometric asymmetry overrides the index symmetry due to small Δn, making the branches look asymmetric to the incoming modes. This asymmetry impedes the transfer of power between modes by causing a sign change in c_{ij} at small branch separations. In contrast we would expect a symmetrical step geometry to always show increasing mode conversion as the taper slope increased.

The important point is that for an asymmetrical taper geometry there is an optimum taper slope for maximum mode conversion for a given index asymmetry. This reduced mode conversion is limited by the data for slope 4 in Fig. 6, which is equivalent to an abrupt junction. No further changes were observed when this slope was increased by a factor of 100. We have also calculated mode conversion from mode j to i for the abrupt junction. In this case the mode-conversion coefficients and phase terms are mirror images of the case of i-j so that the converted amplitudes build up identically, except for slightly higher losses of mode j.

We have also calculated mode conversion for the case of thinner branches ($d_2 = d_4 = 0.5$ μm) where each branch can only support a single mode at large separation. These data are included in Fig. 9 and are similar to the data for $d_2 = d_4 = 0.8$ μm. We have assumed throughout this paper that any cumulative power transfer to higher order guided modes is small so that we can ignore any power transfer back from these modes. This assumption is justified by the large propagation-constant mismatch between the two modes of interest and the higher order guided modes, and is supported by the consistency of the data shown in Fig. 9.

An examination of the computer runs shows that the cumulative amount of mode conversion obtained depends critically on the behavior of the phase term $\cos(\alpha_{i0} - \alpha_{j1})$ in the region where c_{ij} is large. If the phase term oscillates rapidly in the region where c_{ij} peaks no cumulative mode conversion will occur and the device will act as a mode splitter; whereas, if the phase term is locked to ± 1 in that region, cumulative mode conversion will result and the device will act as a power divider. Quantitative examples of a branching waveguide acting as a mode splitter and a power divider are shown in Fig. 2. For the mode splitter of Fig. 2(a) (slope 1/200, $\Delta n = 0.473$) the corresponding phase and amplitude buildup is shown in Figs. 7(a) and 8. Mode conversion is essentially zero. The phase-term behavior for the power divider of Fig. 2(b) (slope 1/100, $\Delta n = 10^{-2}$) is shown in Fig. 7(b). This phase relationship between the output-mode amplitudes allows the power divider to operate as if the input mode is simply spatially divided between the branches.

Since negligible power conversion occurs until c_{ij} is appreciable, A_{j0} will remain small until the peak in c_{ij} is encountered. As long as A_{j0} is small the phases of the two modes are locked together by (9b). Thus the position of the peak in c_{ij} versus branch separation is not important to first order; only the behavior of the phase term over the width of the peak where the phase of A_{j0} is not locked is critical. Varying the index of the intermediate layer can cause a large shift in the position of the peak; however, under the conditions of near symmetry (small Δn) and a reasonable taper steepness considerable mode conversion will always occur.[1] This is illustrated in Fig. 7(c) where we show the phase-term behavior for a steep and very shallow slope when $n_3 = 1.0$.

The considerations used in the discussion of (10)–(12) lead us to conclude that as long as

$$(\beta_{i0} - \beta_{j1})\,\Delta z \ll \frac{\pi}{2} \tag{14a}$$

[1] This result is contrary to the initial suggestion by Yajima in [3] that the phase term does not depend on the position of the peak in c_{ij}.

considerable mode conversion will occur and the device will act as a power divider; whereas if

$$(\beta_{i0} - \beta_{j1})\,\Delta z \gg \frac{\pi}{2} \tag{14b}$$

cumulative mode conversion will not occur and the device will act as a mode splitter. Here Δz represents the width of the region where c_{ij} is appreciable. It is thus possible for the width of the peak in c_{ij} to influence the amount of cumulative mode conversion; however, the position of the peak will be unimportant. For a linear taper

$$\Delta z = \frac{\Delta d_3}{\theta} \tag{15}$$

where Δd_3 is the width of the peak in c_{ij} in units of branch separation (measured at the half-maximum points), and θ is the taper slope for the separating guides. Clearly, only the slope of the taper in the region of appreciable c_{ij} is important. It is also true, as is shown in the Appendix, that in the region of appreciable c_{ij} (where the coupling is caused by modal evolution, not geometric asymmetry)

$$\beta_{i0} - \beta_{j1} \approx \sqrt{2}\,\Delta\beta \tag{16}$$

where $\Delta\beta$ is the difference in propagation constant for infinite branch separation. In the Appendix we use an approximate coupled-mode formalism to show that the separation of the half-maximum points in c_{ij} versus d_3 is given by

$$\Delta d_3 \approx \frac{2.6}{\gamma_3}. \tag{17}$$

Here $\gamma_3 \simeq (\beta_0^2 - n_3^2k^2)^{1/2}$ is the decay constant of the field in the separating region, and β_0 is the average propagation constant for a large guide separation. Equation (17) indicates that Δd_3 reaches a minimum far from cutoff as β_j/k, $\beta_i/k \to n_2$. Near cutoff, if $n_3 \geqslant n_1, n_5$; β_i/k, $\beta_j/k \to n_3$, and Δd_3 can increase. This would tend to impede mode conversion in some circumstances, but here conclusions must be drawn with caution since the theory used in the Appendix breaks down for strong coupling between arms and significant coupling to radiation modes.

We can now describe the transition boundary between a mode splitter and a power divider approximately as

$$\frac{\Delta\beta}{\theta\sqrt{\beta_0^2 - n_3^2k^2}} \gtrless 0.43. \tag{18}$$

This equation can be used to predict the behavior of separating waveguides as well as a branching waveguide whenever the separating guides start out close enough together such that the normal modes of the five-layer structure contain appreciable power in both guiding regions at the starting separation. If this is the case as the guides separate they will pass through a region of appreciable c_{ij}. If the separating guides are initially further apart it will be impossible to distinguish between behavior as a mode splitter or behavior as a power divider since the normal modes will contain power only in a single guiding region. In Fig. 9 we plot the converted amplitude ratio A_j versus the quantity $\Delta\beta/\theta\gamma_3$ for all the cases previously discussed. We see that (18) is well obeyed with all the data lying near a single curve, except for those cases with slopes $\geqslant 1/50$ where the geometric asymmetry predominates.

IV. Summary

Paying careful attention to the phase relationship between the normal modes of a five-layer structure we have developed a theory of power transfer between two modes to use with the step transition model of Marcuse. This has allowed us to investigate branching and separating dielectric waveguides and to investigate in detail the transition region between the operation of these structures as mode splitters and as power dividers. We have developed approximate expressions which should be useful to the designers of integrated optical circuits. The amount of mode conversion can be described by a function of $\Delta\beta/\theta\gamma_3$.

We find that whenever the branches are symmetric ($\Delta\beta$ is small) and the taper slope θ is large the structure will act as a power divider; however, whenever the branches are asymmetric ($\Delta\beta$ is large) and the taper angle θ is small the structure will act as a mode splitter. The transition region is described by (18). It is expected that steeper tapers will evidence more loss to radiation modes so that a low-loss mode splitter will be easier to fabricate than a low-loss power divider. An evanescent coupler of the type envisioned for use in electro-optical amplitude modulators contains a region of separating waveguides which needs to act as a power divider. Unless the two separating guides are very similar a steep taper will be needed which will introduce losses into the device.

Appendix

In this section we will change representation to a more conventional coupled-mode theory appropriate for parallel waveguides with weak coupling to obtain approximation expressions for c_{ij} [5], [6]. The two coupled modes will now be considered to be the modes of each guiding layer taken separately, ϕ_a and ϕ_b, with mode amplitudes a and b and propagation constants β_a and β_b. With this representation the normal modes of the five-layer structure can be taken as linear combinations of these modes.

$$\psi_i = a\phi_a + b\phi_b \tag{A-1a}$$

$$\psi_j = b\phi_a - a\phi_b \tag{A-1b}$$

where $a^2 + b^2 = 1$; $\int_{-\infty}^{\infty} \phi_a\phi_a\,dx = 1$; $\int_{-\infty}^{\infty} \phi_b\phi_b\,dx = 1$; and b/a is constant as a function of z for a given guide separation. The ratio of b/a will depend upon guide separation d_3 (i.e., $b/a = f(d_3)$) approaching zero for large separation and one for small separation. If we consider a taper step there will be uncoupled modes ψ_{i0}, ψ_{j0} on one side with branch separation d_{30} and uncoupled modes ψ_{i1}, ψ_{j1} on the other with branch separation d_{31}. From the definition of c_{ij}:

$$c_{ij} \approx \int_{-\infty}^{\infty} \psi_{i0}\psi_{j1}\,dx \tag{A-2a}$$

$$= a_0 b_1 \int_{-\infty}^{\infty} \phi_{a0}\phi_{a1}\,dx - b_0 a_1 \int_{-\infty}^{\infty} \phi_{b0}\phi_{b1}\,dx + b_0 b_1 \int_{-\infty}^{\infty} \phi_{b0}\phi_{a1}\,dx - a_0 a_1 \int_{-\infty}^{\infty} \phi_{a0}\phi_{b1}\,dx. \tag{A-2b}$$

For a small symmetric step when the guides are far apart (weak coupling) we can approximate

$$\int_{-\infty}^{\infty} \phi_{a0}\phi_{a1}\,dx = 1; \quad \int_{-\infty}^{\infty} \phi_{b0}\phi_{a1}\,dx = 0$$

$$\int_{-\infty}^{\infty} \phi_{b0}\phi_{b1}\,dx = 1; \quad \int_{-\infty}^{\infty} \phi_{a0}\phi_{b1}\,dx = 0. \tag{A-3}$$

Using the above approximations

$$c_{ij} \approx a_0 b_1 - b_0 a_1 \tag{A-4a}$$

$$= a_0 a_1 \left(f(d_{31}) - f(d_{30})\right) \tag{A-4b}$$

$$= a_0 a_1 \frac{\partial f(d_3)}{\partial d_3}\delta d \tag{A-4c}$$

$$\approx \frac{1}{1 + (f(d_3))^2}\frac{\partial f(d_3)}{\partial d_3}\delta d \tag{A-4d}$$

where $\delta d = d_{31} - d_{30}$.

The conventional coupled-mode theory tells us that

$$b/a = -i\left[\frac{-(\beta_a - \beta_b) + \sqrt{(\beta_a - \beta_b)^2 + 4KK^*}}{2K}\right] \tag{A-5}$$

assuming $\beta_a - \beta_b$ is positive where K is the coupling coefficient. For the case of two parallel guides coupled-mode theory can be used to show that [7]

$$K = -iF\exp(-d_3\gamma_3) \tag{A-6}$$

where F is real and positive, $\gamma_3 \simeq (\beta_0^2 - n_3^2k^2)^{1/2}$, and $\beta_0 = (\beta_a + \beta_b)/2$. Then we can write expressions for $f(d_3)$ and its derivative by defining $\Delta\beta = \beta_a - \beta_b$ and $|K| = F\exp(-\gamma_3 d_3)$:

$$f(d_3) = \frac{-\Delta\beta + (\Delta\beta^2 + 4|K|^2)^{1/2}}{2|K|} \tag{A-7a}$$

$$\frac{\partial f(d_3)}{\partial d_3} = \frac{\gamma_3\Delta\beta}{2|K|}\left[\frac{\Delta\beta}{(\Delta\beta^2 + 4|K|^2)^{1/2}} - 1\right]. \tag{A-7b}$$

Substituting (A-7) into (A-4) then gives

$$c_{ij} \approx \frac{-\gamma_3\delta d\,|K|\Delta\beta}{(\Delta\beta^2 + 4|K|^2)}. \tag{A-8}$$

This function has a minimum value of $-\gamma_3\delta d/4$ for $|K| = 0.5\,\Delta\beta$ and has the half-minimum value $-\gamma_3\delta d/8$ for $|K| = 0.138\,\Delta\beta$ or $1.9\,\Delta\beta$. The minimum in c_{ij} will thus occur at

$$d_0 = -\frac{1}{\gamma_3}\ln\left(\frac{\Delta\beta}{2F}\right) \tag{A-9}$$

and the half width for c_{ij} will be

$$\Delta d_3 = \frac{\ln 1.9 - \ln 0.138}{\gamma_3} = \frac{2.6}{\gamma_3}. \tag{A-10}$$

Coupled-mode theory also tells us that

$$\beta_i - \beta_j = (\Delta\beta^2 + 4|K|^2)^{1/2} \tag{A-11a}$$

so that where c_{ij} is a minimum

$$\beta_i - \beta_j = \sqrt{2}\,\Delta\beta. \tag{A-11b}$$

This coupled-mode theory can only be rigorously defended when the peak in c_{ij} occurs in a region where K is small, i.e., for cases of small $\Delta\beta$. However, the exact computer-calculated results described in the main text are well described by the results of this approximate approach.

Bond-Orbital Model for Second-Order Susceptibilities

MICHAEL M. CHOY, SALIM CIRACI, AND ROBERT L. BYER

Abstract—**The bond-orbital model (BOM) for tetrahedral compounds is used self-consistently to calculate the second-order susceptibility. No adjustable parameters are used and agreement with experiment is good. The origin of the nonlinearity arises from a charge transfer as a result of the asymmetric polar energy between the anion and the cation. The model correctly predicts an optimum polarity to maximize second-order susceptibilities.**

I. Introduction

THE understanding of the origin of the nonlinear optical susceptibilities has been the subject of many investigations. This understanding is important in material assessment and prediction of new material characteristics in nonlinear optical devices such as harmonic generators, mixers, and parametric oscillators [1], [2]. In a more formal approach, quantum mechanical expressions are derived from perturbation expansion involving complex sums of matrix elements and energy denominators [3]-[5]. These fundamental expressions, even when simplified through the use of octupole moment of the ground-state charge distribution [6], or by employing ground-state wave functions [7], are still formidable to use in quantitative predictions. Exact wave functions in solids are often not known to high accuracy and the complete band structure is also required. Other complications from contributions to the nonlinearity from different points in the Brillouin zone can also arise [8], [9]. Another approach is to use simple phenomenological models such as the anharmonic oscillator model [10] and Miller's rule [11]. Included in this category are the universal semiconductor model [12], [13], the bond-charge model [14], the charge-transfer model [15], and the molecular-orbital model [16]. The latter three models all draw heavily from the results of Phillip's dielectric theory [17], [18].

In this paper we use an approach based on Harrison's bond-orbital model (BOM) [19], [20]. This is a more predictive model and only appeals to essentially two input factors, the dielectric constant and the $E_{2A}(X_4 - X_1)$ transition energy to calculate the model parameters. The model predicts useful properties related to valence electrons such as cohesive energy, band structure [21], etc. Using BOM parameters, we calculate the second-order susceptibility in the optical-transparency region of a crystal. The analysis clearly displays the physical origin of the nonlinearity. Perhaps more importantly, by expressing the nonlinearity in terms of the fundamental material parameters of polarity and the bond length, salient characteristics desirable for high optical nonlinearities are distinctly revealed.

II. Bond-Orbital Model

In this section, we outline the BOM so that we can discuss its extension to the calculation of the second-order susceptibility. For a more complete discussion of the model and the implications of the approximations involved refer to the original papers [19], [20].

The model is based on a tight-binding approximation of sp^3 hybrid orbitals for tetrahedral compounds. Denoting an sp^3 hybrid orbital on an anion (cation) by $|h^a>$ ($|h^c>$), a bonding orbital is constructed from a linear combination of nearest neighbor hybrids on the anion and its adjacent cation directed along the same bond,

$$|b> = u_a|h^a> + u_c|h^c>. \tag{1}$$

The minimization of the expectation value of the Hamiltonian by a standard variation on the u_a and u_c results in a (2 X 2) secular equation. The solution of the equations gives the eigenvalue and the eigenvectors. They are

$$\epsilon_{b,a} = V_2 <h^c|h^a> \mp \sqrt{V_2^2 + V_3^2} \tag{2}$$

and

$$u_a = \sqrt{\frac{1+\alpha_p}{2}}$$

$$u_c = \sqrt{\frac{1-\alpha_p}{2}} \tag{3}$$

where the polarity is defined by Harrison [19], [20] as

$$\alpha_p = \frac{V_3}{(V_2^2 + V_3^2)^{1/2}}. \tag{4}$$

Here V_2 and V_3 are the energy parameters defined as

$$V_2 = -\frac{<h^c|\mathcal{H}|h^a>}{1 - |<h^c|h^a>|^2} \tag{5}$$

for the covalent energy where $<h^c|\mathcal{H}|h^a>$ corresponds to hopping between an anion hybrid and a cation hybrid along the same bond,

$$V_3 = \frac{[<h^c|\mathcal{H}|h^c> - <h^a|\mathcal{H}|h^a>]}{2(1 - |<h^c|h^a>|^2)^{1/2}} \tag{6}$$

for the polar energy where $<h^c|\mathcal{H}|h^c>$ and $<h^a|\mathcal{H}|h^a>$

denote the coulomb integrals at the cation site and the anion site, respectively. In addition, there is one more energy parameter $V_1^{a,(c)}$, which is defined as a matrix element of Hamiltonian between adjacent anion (cation) hybrids. This is related physically to the atomic *s-p* splitting and does not come into play in most optical properties.

The dielectric constant, which is the parameter of interest in optical properties, is calculated by considering an isolated bond dipole with an applied electric field. The field perturbation is treated by adding to the polar energy V_3 the potential energy of the bond dipole in the electric field. Then in the ground-state wave-function approximation, calculation of the induced polarization by a change of polarity α_p through a change of the polar energy V_3 gives the dielectric constant

$$\epsilon_0 = 1 + \frac{N\pi\gamma^2 (ed)^2 V_2^2}{3(V_2^2 + V_3^2)^{3/2}} \tag{7}$$

where N is the density of electrons, d is the bond length, and γ is a parameter defined in the BOM formulation relating microscopic dipole moments to macroscopic linear susceptibilities and is taken to be constant along a row of the periodic table except for correction for carbon row atoms.

To determine the energy parameters Harrison and Ciraci [20] appeal to experimental parameters. The principal optical absorption peak E_{2A} is identified with the bonding and antibonding gap

$$\epsilon_a - \epsilon_b = 2\sqrt{V_2^2 + V_3^2}.$$

This identification has been shown to be consistent with experiments.

First, the E_{2A} gap of the group IV elemental compounds gives V_2 directly for each row of the periodic table, since $V_3 = 0$ in elemental compounds. The geometric mean is taken for compounds involving two rows. Then using (7) the dielectric constant gives γ for each row. A value for γ of 1.08 is found for diamond and 1.2 for silicon. When row three is reached, there are contributions from the polarizable d core electrons as noted by Phillips [17]. This is taken into account by introducing a correction factor θ in addition to γ. γ is taken at the silicon value and a value of $\theta = 1.18$ is obtained for germanium and $\theta = 1.41$ for the tin row. With these values of V_2 and γ, V_3 for any binary compound is derived from its dielectric constant using (7). This completes the summary of the BOM as originally stated by Harrison [19].

III. Calculation of $\chi^{(2)}$

The second-order susceptibility is defined by expanding the macroscopic polarization in a power series in the field

$$\boldsymbol{P}(\boldsymbol{E}) = \chi^{(1)}\boldsymbol{E} + \chi^{(2)}:\boldsymbol{EE} + \cdots \tag{8}$$

where $\chi^{(1)}$ and $\chi^{(2)}$ are the field-independent susceptibilities. In the independent bond formulation these macroscopic susceptibilities are related to their corresponding microscopic bond polarizabilities through geometrical factors as [21], [22]

$$\chi_{IJ}^{(1)} = \frac{1}{V}\sum_{s,i,j} a_{Ii}^{(s)} a_{Jj}^{(s)} \alpha_{ij} \tag{9}$$

$$\chi_{IJK}^{(2)} = \frac{1}{V}\sum_{s,i,j} a_{Ii}^{(s)} a_{Jj}^{(s)} a_{Kk}^{(s)} \beta_{ijk} \tag{10}$$

where a_{Ii} are the direction cosines between the macroscopic crystal axis I and the bond axis frame i. The index s identifies the different bonds in the periodic lattice structural unit whose volume is V. To apply the BOM, we confine ourselves to sp^3-bonded tetrahedral compounds with the zinc blende and wurtzite structures. In the former case, with crystal class point group $\bar{4}3$ m, (9) and (10) reduce to

$$\chi_{ii}^{(1)} = \frac{4n}{3}(\alpha_\parallel + 2\alpha_\perp) = \frac{4n}{3}\alpha_\parallel(1 + 2\kappa) \tag{11}$$

$$\chi_{14}^{(2)} = \frac{4n}{3\sqrt{3}}(\beta_\parallel - 3\beta_\perp) \tag{12}$$

where $\kappa = \alpha_\perp/\alpha_\parallel$ and $\alpha_\parallel$ and $\alpha_\perp$ are the parallel and perpendicular components of the bond polarizability.

Here $n = 3\sqrt{3}/16\, d^3$ is the number of tetrahedral unit cells per unit volume. In this case $\chi^{(1)}$ is a scalar, and $\chi_{14}^{(2)}$ is the only nonvanishing tensor component in Voigts notation. $E_\parallel$ is along the bond axis (111) and with axially symmetric $C_{\infty v}$ bonds, the independent nonvanishing components are $\alpha_\parallel = \alpha_{zz}$, $\alpha_\perp = \alpha_{xx} = \alpha_{yy}$, and $\beta_\parallel = \beta_{zzz}$, $\beta_\perp = \beta_{xzx} = \beta_{yzy}$. For the case of wurtzite structure the two inequivalent tetrahedra can be obtained from standard zinc-blende orientation by simple rotational matrices, the result is [23]

$$-\chi_{31}^{(2)} = -\chi_{15}^{(2)} = \chi_{33}^{(2)} = \frac{2}{\sqrt{3}}\chi_{14}^{(2)}.$$

It can be shown from an abinitio calculation that $\beta_\perp \ll \beta_\parallel$ [24]. In a bond-charge approach, $\beta_\perp = 0$ to first order [25]. Accordingly, we neglect $\beta_\perp$ relative to $\beta_\parallel$ in our formulation.

To calculate $\beta_\parallel$ we need to determine the variation of the linear polarizability α with an electric field. Physically, we expect a redistribution of charge density in the presence of the field. This manifests itself as an induced dipole as a result of an additional charge transfer. In the context of the BOM there is a change in the bond polarity α_p through a change in the bond-polar energy V_3. Harrison defines an effective charge on an anion (in units of $-e$) as

$$Z^* = 4\alpha_p - \Delta Z \tag{13}$$

where ΔZ is half of the nominal valence difference. Then the additional charge incurred by the applied field on a per-bond basis is

$$\Delta Z^* = \frac{\partial \alpha_p}{\partial V_3}\Delta V_3 = \frac{V_2^2}{(V_3^2 + V_2^2)^{3/2}}\Delta V_3 \tag{14}$$

where the main contribution is from the change in polar energy V_3. The covalent energy V_2 is constant since the bond length remains fairly undistorted. This is valid in the optical-transparency region above the phonon-lattice resonance frequencies, where the lattice and the bonds stay relatively stationary compared to the motion of the electronic-charge cloud. Here we have to stay below the interband electronic absorption, as the assumption of a bonding state of the hybrid orbitals implies that we are dealing with valence electrons

only. In the transparency region the optical response is fairly insensitive to frequency and hence our dispersionless approach should be adequate.

In the formulation of the BOM, when the macroscopic dielectric constant is used to calculate the microscopic bond parameters, the effects of charge-distribution scaling and the bond anisotropy are automatically included in the parameter γ. If we let γ^* be the charge-distribution scaling and $\kappa = \alpha_\parallel/\alpha_\perp$ be the anisotropy, then as in the derivation in BOM, the inclusion of the dipole potential energy in an electric field as a change in the polar energy gives in terms of γ^*

$$\alpha_\parallel = \frac{\gamma^{*2}\,(ed)^2\,V_2^2}{2(V_2^2 + V_3^2)^{3/2}}. \tag{15}$$

Putting this into (11) and comparing the result with (7) we find that $\gamma^2 = \gamma^{*2}(1 + 2\kappa)$, where $\epsilon = 1 + 4\pi\chi^{(1)}$ has been employed. There is no easy analytical calculation for the bond anisotropy. By simple extrapolation on values obtained from Kerr constants on diatomic molecules [26], we estimate $\kappa \approx 0.5$. Essentially the same estimate was employed previously [16]. With this value for the anisotropy factor and the BOM value of 1.2 for γ, γ^* is found to be 0.85.

To introduce the explicit field dependence we note that the induced bond dipole is

$$\Delta p = \gamma^* ed\,\Delta Z^* = \alpha_\parallel E_\parallel. \tag{16}$$

As explained earlier an electric field induces an additional charge transfer resulting in a change in the polar energy V_3. The second-order polarizability can be related to its linear counterpart by $\alpha_\parallel(E_\parallel) = \alpha_\parallel + \beta_\parallel E_\parallel + \cdots = \alpha_\parallel + \Delta\alpha_\parallel + \cdots$. Now $\Delta\alpha_\parallel = \beta_\parallel E_\parallel$ can be calculated from (15) through a change in polar energy ΔV_3. Elimination of ΔV_3 through (14) and (16) in terms of $E_\parallel$ gives

$$\beta_\parallel = \frac{3\alpha_p}{ed(1 - \alpha_p)^2}\,\alpha_\parallel^2. \tag{17}$$

To convert to experimental macroscopic quantities, (11) and (12) give

$$\chi_{14}^{(2)} = \frac{4d^2\,\alpha_p}{e\gamma^*(2\kappa + 1)^2\,(1 - \alpha_p^2)}\,|\chi^{(1)}|^2 \tag{18}$$

where the tetrahedral cell density ($n = 3\sqrt{3}/16d^3$) has been used. Since α_p can be calculated from the linear dielectric constant in BOM theory, (18) shows that $\chi^{(2)}$ can be estimated essentially from just the knowledge of the linear susceptibility alone. This is an important point. The independent bond formulation is only approximate in the sense that correlation effects between neighboring bonds do give rise to local-field corrections which are not subject to easy deductive analysis. By appealing to the macroscopic linear susceptibility as an input parameter, most of these local-field effects are accounted for in the BOM model.

To demonstrate the dependence of $\chi^{(2)}$ on polarity and to display some underlying physics, we transform (18) by casting $\chi^{(1)}$ in terms of polarity with the help of (7). Using the relation [20] $V_2 \propto 1/d^2$ we obtain

$$\chi_{14}^{(2)} \cong \text{constant}\;\alpha_p(1 - \alpha_p^2)^2\,d^4 \tag{19}$$

where the constant contains γ, and is constant for one row in the periodic table.

The dependence of $\chi^{(2)}$ on polarity is shown in Fig. 1, where $\chi_{14}^{(2)}/d^4$ is plotted against α_p. The upper boundary corresponds to the fifth row, and the lower one, the third row. Because of differences in geometric factors, we have only included the case of zinc blende. Note the interesting maximum at $\alpha_p \approx 0.44$, corresponding to an ionicity $f_i = 0.28$ in Phillip's model [$f_i = 1 - (1 - \alpha_p^2)^{3/2}$]. Tang [15] and Levine [14] have predicted an optimum value of $f_i \approx 0.17$. However, available experimental data seem to show a peak at around $\alpha_p = 0.45 (f_i \cong 0.3)$ in better agreement with our results. The physics of this maximum warrants some comment. In the complete polarity limit of $\alpha_p = 1$, i.e., full ionicity, all excess valence electrons from the cation are transferred to the anion. The anion in turn binds these electrons fairly tightly in its locality, resulting in a big forbidden energy gap characteristic of all ionic compounds. Actually, it can be shown that the energy gap of tetrahedral binary compounds scales linearly with ΔZ [18b]. Thus there is no more charge transfer ($\Delta Z^* \propto V_3^{-3}$) to respond to any applied field and hence the vanishing of $\chi^{(2)}$. In the covalent limit of $\alpha_p = 0$, we approach the transition of zinc blende into the elemental diamond structure and the center of inversion symmetry completely cancels all even order of nonlinearities. In a sense, the system overcompensates itself because the gain in the covalent "bond charge" is completely cancelled by the perfectly symmetric lattice environment. A minor word of caution seems to be appropriate here, since we must remember that in actual practice we have to stay within $f_i < 0.78$ for tetrahedral coordination. Any higher ionicity results in rock-salt structure, a hexacoordination typical of most ionic compounds.

To further test the accuracy of our analysis we choose materials of roughly equal polarity, i.e., ΔZ = constant, and plot $\log_{10}[\chi_{\text{expt}}^{(2)}\,10^7]$ against $\log_{10}[d]$ in Fig. 2. Lines of slope 4 are drawn and agreement is good with (18).

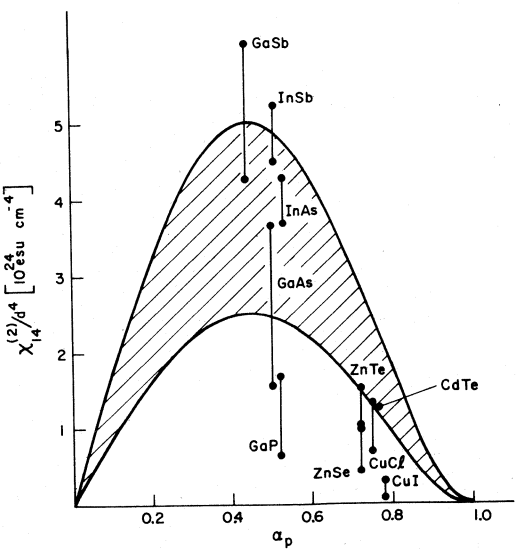

Fig. 1. The scaling of $\chi_{14}^{(2)}/d^4$ with α_p, the polarity. The upper boundary corresponds to materials from the fifth row and the lower one from the third row.

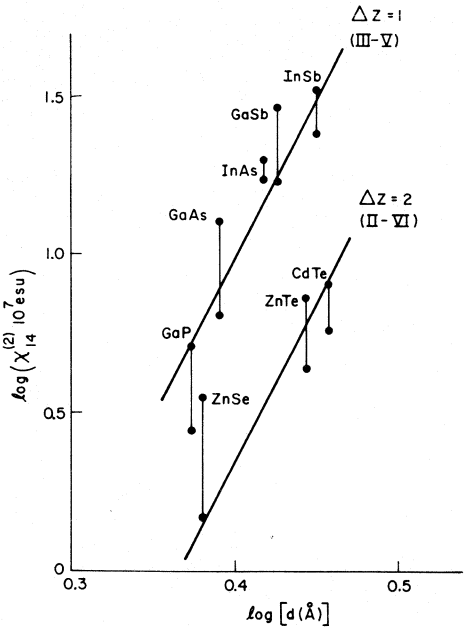

Fig. 2. The dependence of $\chi^{(2)}_{expt}$ on bond length d for materials of roughly constant polarity.

Thus, for large second-order nonlinearities, it is desirable to have a covalency high enough (α_p around 0.44) to give considerable polarizability from charge transfer but low enough such that inversion symmetry is not a detriment. We also want long bond lengths, which, from empirical evidence, means a high atomic number. As high covalency means proximity to group IV, the previous two criteria could be summarized in the context of the periodic table by saying that for high $\chi^{(2)}_{14}$ we want materials with small ΔZ and high atomic number.

These criteria are well borne out by experimental evidence. The III-V compounds are in general more nonlinear than the II-V, and among the III-V themselves the more metallic elements, InSb and InAs, which are from the fifth rows and fifth and fourth rows, respectively, are more nonlinear than GaAs and GaP, being compounds from the fourth rows and fourth and third rows. In Fig. 3 we plotted $\chi^{(2)}_{14}$ against the average quantum number $\bar{n}$ introduced first by Mooser and Pearson [27], verifying the above arguments.

However, for any device applications employing the second-order nonlinearity, the parameter of interest is the parametric gain coefficient [2] defined by

$$\Gamma^2 = \frac{9.10^8\,\omega_1\omega_2\,|\chi^{(2)}|^2 I_3}{8c^3 n_1 n_2 n_3}$$

where I_3 is the pump intensity and n_i are the refractive indices at ω_i.

From the device standpoint, besides the magnitude of $\chi^{(2)}$, there are also additional transparency factors in the frequency dependence of the gain coefficient. As one goes towards higher atomic numbers one loses ground in the transparency range as determined by the bandgap cutoff frequency. Experimentally, a material is chosen with the smallest bandgap consistent with transparency in the wavelength region of interest, as pointed out by Levine [14]. If half the bandgap frequency is taken for both ω_1 and ω_2 to avoid two-photon absorption,

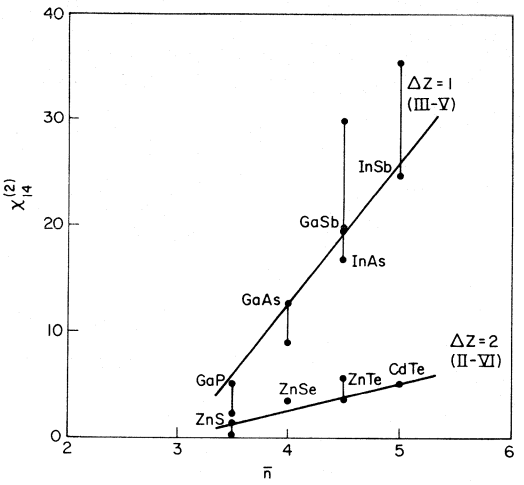

Fig. 3. A plot of $\chi^{(2)}_{14}$ versus $\bar{n}$, the average quantum number, showing the dependence within a vertical family in the periodic table.

it turns out that in some cases of high atomic numbers, e.g., InAb and InAs, the increase in $\chi^{(2)}$ is largely offset by frequency factors in the gain expression due to the narrow bandgap.

Another parameter which has proven to be very useful as a scale for nonlinearity is the Miller's delta, Δ_{ijk}, which is defined by

$$\frac{\chi^{2\omega}_{ijk}}{2} = \Delta_{ijk}\chi^{2\omega}_{ii}\,\chi^{\omega}_{jj}\,\chi^{\omega}_{kk}.$$

In the context of our model Miller's delta can be obtained by transforming (18) through use of $\chi^{(1)}$ expressed in polarity α_p and bond length d. We find that $\Delta_{ijk} \propto \alpha_p d/(1-\alpha_p)^{5/2}$. Thus we see that for materials of the same average quantum number $\bar{n}$, where the bond length is essentially constant and for materials of the same vertical family, i.e., of constant polarity, the Miller's delta should be constant. Essentially, a similar conclusion is reached by Tang and Flytzanis [15], though they employed slightly different parameters, namely the normalized-valence difference and the atomic-radii difference. In Miller's formulation, which is essentially an anharmonic oscillator model, Miller's delta is found to be a function of the asymmetric potential. Because polarity (charge transfer) is a direct result of the asymmetry between the cation and anion, and bond length also affects the potential, the dependence of Miller's delta on the previously given BOM parameters is not surprising.

The main results and parameters used are summarized in Table I. We have chosen the most recent data or that which we believe to be the most reliable. Correlation with experimental values is in general very good. It should be observed that there are two general classes of compounds where the relative discrepancy warrants some discussion. They are the narrow-bandgap materials; for example, InSb, InAs, GaSb, and the copper compounds.

As pointed out in the original formulation of BOM [20], the use of the E_{2A} peak for the bonding and antibonding gap works especially well for the large-bandgap materials. For narrow-bandgap materials, the minimum optical gap could be

almost an order of magnitude smaller than the E_{2A} gap. For example, in InAs $E_0 = 0.33$ eV and $E_{2A} = 3.9$ eV, so one might expect the Γ point in the Brillouin zone to modify the BOM energy parameters. As a result, the application of the BOM to these compounds is not as successful.

For the copper compounds, it is known that the *d* bands are strongly hybridized with the valence *s* and *p* bands. These delocalized *d* electrons at these noble-metal cations have been found experimentally to give an anomalous contribution to the second-order nonlinearity [28], [29]. This effect is discussed by Levine [14] in his bond-charge model and by Tang [16] in terms of a charge redistribution and a reversal of the direction of the bond dipole. Since the BOM deals with the sp^3 electrons, the *d* electrons are accounted for phenomenologically and the formulation overestimates the nonlinearity of these compounds. If we stay away from these noble-metal compounds and consider compounds where there is no appreciable hybridization of the *d* bands, then the BOM predictions agree well with experiment.

IV. Summary and Comments

Using a more predictive theory, the BOM, we have calculated the second-order susceptibility for tetrahedral compounds. Agreement with experiment is good, especially in light of the simplicity of the model. The approach is self-consistent, as the linear susceptibility is used to calculate the second-order susceptibility. Compared to other phenomenological models, our approach is more self-contained, as no adjustable parameter is used and all parameters are defined in the BOM.

The physical origin of the nonlinearity is seen to arise from the charge transfer as a result of the asymmetric polar energy between the anion and the cation. Chemical-trend considerations reveal an optimum value of polarity for a maximum second-order nonlinearity in zinc-blende and wurtzite structures. This, together with the bond-length dependence, gives a rule-of-thumb estimate on the choice of elements in the periodic table which will result in tetrahedral compounds of high second-order nonlinearity. It is found that for these tetrahedral structures, it is desirable to have high covalency and a high metallicity consistent with transparency region of interest. This means that one should stay close to group IV elements and high atomic numbers. We include the parametric gain parameter in our discussion showing that the bandgap is again important through the short wavelength frequency cutoff in the transparency range. The BOM is also quantitatively and qualitatively related to the Miller's rule through the concept of polarity.

Pulse Compression for More Efficient Operation of Solid-State Laser Amplifier Chains II

ROBERT A. FISHER AND WILLIAM K. BISCHEL

Abstract—**In a previous letter we proposed a compression scheme which reduces the intensity of a laser pulse in an Nd:glass amplifier chain and thereby allows more efficient energy extraction. In this scheme the nonlinear index of refraction (n_2) of the glass in the amplifier impresses a frequency sweep or "chirp" on the pulse. Further analysis is presented here. The stability to amplitude noise is demonstrated. We calculate that impressed periodic amplitude modulation is responsible for the growth of distinct spectral sidebands in the nonlinear host glass, and we find that the compressor converts these sidebands into temporal features which precede and follow the central compressed pulse. When a pulse with 10-percent peak-to-peak impressed periodic modulation passes through a sufficient length of glass so that the peak nonlinear phase is approximately 4π, these precursors are only about 1/20th the intensity of the main compressed pulse. RMS equivalent random noise has a flat sideband spectrum, and the precursors are found to be absent in the compressed pulses. The intensity averaging over possible transverse-mode structures is studied for some axially symmetric spatial mode shapes. This averaging somewhat reduces the compression ratio from the estimates in which the transverse modes were flat-topped. Finally, arguments are presented to explain why it is felt that a grating pair is not likely to be a suitable compressor for such intense nanosecond-duration pulses.**

I. Introduction

A COMPRESSION SCHEME for laser pulses was described in a previous letter [1]. The present paper primarily discusses that scheme's sensitivity to temporal and spatial pulse variations.

In [1] we proposed a scheme which reduces the intensity inside an Nd:glass amplifier chain by the injection of a longer duration and less intense pulse into the chain. By calculation the nonlinear index of refraction (n_2) of the glass host[1] was shown to impress upon the pulse a chirp which was suitable for subsequent temporal compression in a sequence of Gires–Tournois interferometers [2]. With this scheme energy extraction is far more efficient than if a pulse of the desired duration were amplified. This scheme is depicted in Fig. 1. It was shown in [1] that if a 1-ns (full $1/e$-duration) temporally Gaussian plane-wave pulse traveled 2 m through the glass chain with its peak intensity averaging 2 GW/cm^2 along the chain, the pulse could subsequently be compressed with high efficiency to 125 ps.[2] The Appendix presents the justification for averaging the intensity along the chain.

In [1] the influence of the dispersive-delay compressor was considered in terms of an expansion of the logarithm of the corresponding transfer function. The average phase shift and group delay do not affect pulse reshaping. The first term which is of influence is the group dispersion which is represented by the term quadratic in frequency offset [called $Q_2(\Delta\omega)^2$]. A pulse with a positive linear frequency sweep has a phase perturbation described by $\delta\phi = -\frac{1}{2}\beta t^2$ where $\beta > 0$. Such a pulse can be optimally compressed by a dispersive delay line adjusted so that $\beta Q_2 = -\frac{1}{2}$. This means that the low-frequency leading edge of the pulse is delayed half of the uncompressed pulse duration, and that the high-frequency trailing edge is correspondingly advanced. This assumes that higher terms in the logarithm of the transfer function ($\partial^3\Phi/\partial\omega^3$, $\partial^4\Phi/\partial\omega^4$, etc.) are of negligible consequence. A temporally Gaussian pulse in glass, for example, has a nonlinear phase given approximately by $\delta\phi = \delta\phi_{\max} \exp(-t^2/\tau^2)$ where 2τ is the full $1/e$ intensity duration of the uncompressed pulse. At the center time of the pulse, β is evaluated by taking the negative of the second derivative of $\delta\phi$ with respect to time; thus $\beta = (2\delta\phi_{\max}/\tau^2)$. From [1] the optimum compression ratio R can be written $R \simeq 1. + 0.65\delta\phi_{\max}$, from which β can be evaluated to find $\beta \simeq 2(R-1)/(0.65\tau^2)$. Therefore, for optimal compression in this scheme, only the initial and final pulse durations are sufficient to specify the necessary compressor dispersive delay. For the case of [1], ($\tau = 5 \times 10^{-10}$ s and $R = 8$) we estimate that $\beta = 8.6 \times 10^{19}$ s^{-2}. For optimal compression of this pulse ($\beta Q_2 = -\frac{1}{2}$), the required dispersive delay is given by $Q_2 = -5.8 \times 10^{-21}$ s^2. Although the compressor phase-shift terms through $Q_4(\Delta\omega)^4$ were analyzed for the case described in [1], the influence of terms above Q_2 can be made minimal. The new results we discuss in this paper are meaningful without consideration of the

[1] The first measurement of this quantity in glasses was performed by M. A. Duguay, J. W. Hansen, and S. L. Shapiro, "Study of the Nd:glass laser radiation," *IEEE J. Quantum Electron.*, vol. QE-6, pp. 725–743, Nov. 1970. We chose our coefficient for Owens-Illinois ED-2 glass from the recent work of A. Owyoung, "Ellipse rotation studies in laser host materials," *IEEE J. Quantum Electron.*, vol. QE-9, pp. 1064–1069, Nov. 1973. The more recent work of E. S. Bliss and R. D. Speck (private communication) indicates that this coefficient may be 15 percent lower than the value (1.7×10^{-13} ESU) which we use. Reference to a company name or a product name does not imply approval or recommendation of the product by the University of California or the U.S. Atomic Energy Commission to the exclusion of others that may be suitable.

[2] Since the value of n_2 for the glass we considered is only known to within 30 percent, the results presented here and in [1] may undergo some refinement as the value becomes better known.

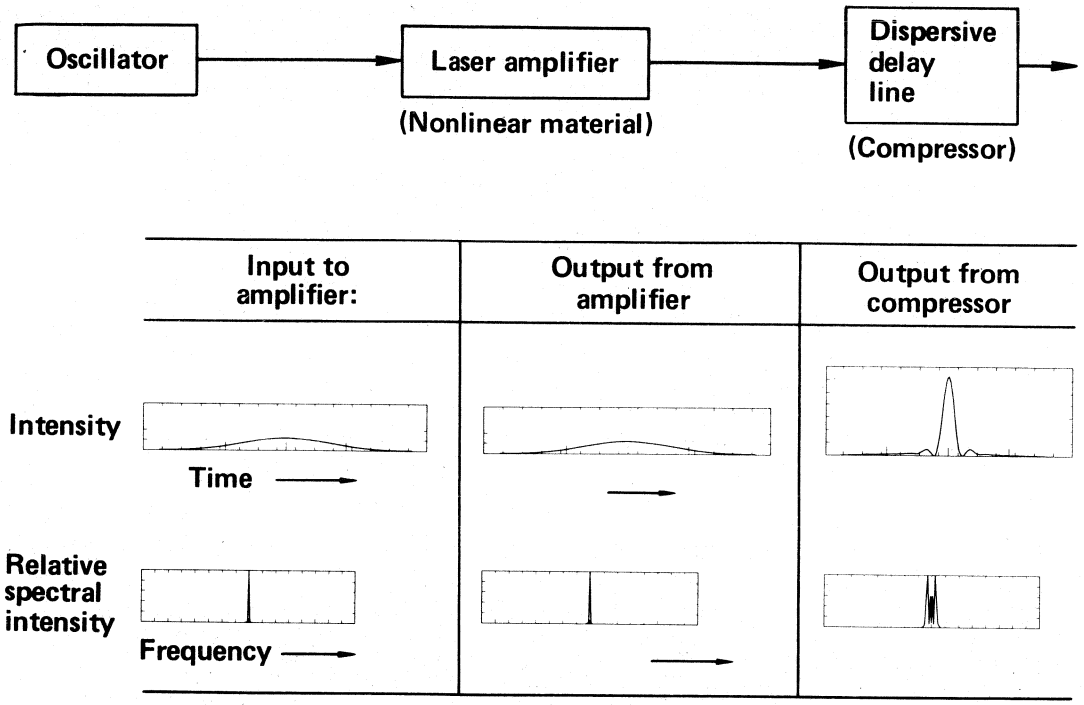

Fig. 1. A schematic of the pulse-compression proposal. The pulse spectrum is broadened due to the nonlinear effect of self-phase modulation in the laser amplifier. The pulse is then compressed by a dispersive delay line which takes advantage of the self-phase modulation "chirp." By this scheme it should be possible to get more energy out of a given amplifier system than if a short pulse were to be amplified.

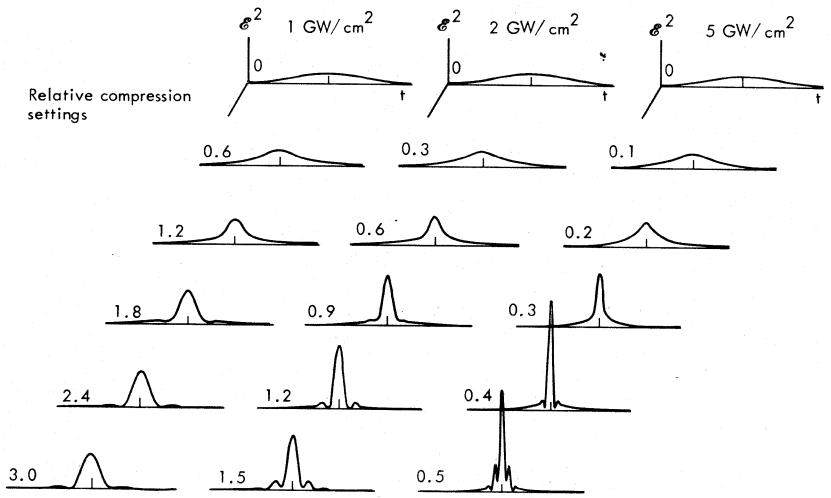

Fig. 2. Calculated dispersive compression of plane-wave pulses after they have traveled 2 m in an Nd:glass laser chain. Time is plotted horizontally and relative intensity is plotted vertically. Cases are shown for chain-averaged peak intensities of 1, 2, and 5 GW/cm^2. In each case, the initial full $1/e$ intensity duration is 1 ns. Spatial effects due to the radial intensity profile are not considered. Numbers associated with each graph are relative compression settings which are proportional to Q_2, with a setting of unity corresponding to $Q_2 = -6.4 \times 10^{-21}$ s^2. The optimally compressed pulse is next to the bottom in each column. The tic marks indicate where the center of the pulse would be if Q_2 were zero. The lateral displacement is of no consequence; it has been done in order that the 5-GW/cm^2 curves do not obscure each other. The intensity scales are different for each column so that the 3 cases may be readily seen on the figure.

higher order terms, and we therefore will restrict our attention to the calculations which only consider the influence of the Q_2 term.

In order that the more realistic cases we discuss in the remainder of the paper can be compared to the results for hypothetically perfect pulses, we have calculated (in the manner described in [1]) the dispersive temporal compression of various plane-wave 1-ns pulses. The results are shown in Fig. 2. In the calculation pulses traveled through 2 m of glass with their peak intensity averaging 1, 2, and 5 GW/cm^2 along the length of the chain. As one looks down any column of Fig. 2, dispersive delay is being increased. The relative com-

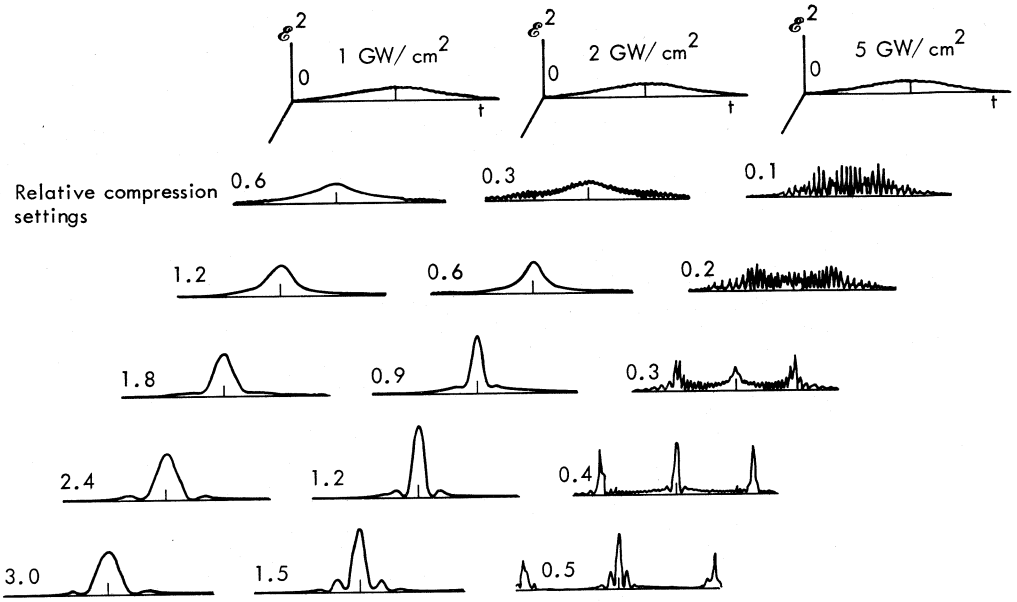

Fig. 3. A repeat of the calculation of Fig. 2 with the inclusion of 10-percent peak-to-peak amplitude ripple on the pulse which enters the laser chain. Note that compression of ripples occurs for far smaller compressor settings, so that the unwanted features are again temporally spread out at the optimally compressing dispersive delay setting. In the 5-GW/cm^2 case, the precursors (which are discussed in the text) are prominent features.

pression settings in the figure are proportional to the values of Q_2, and unity corresponds to $Q_2 = -6.4 \times 10^{-21}$ s^2. The relative compression setting of unity then should be fairly close to the optimally compressing setting for the 2-GW/cm^2 pulse of [1]. The optimally compressed pulse is next to the bottom in each column. Note that the less intense pulse develops less chirp, and therefore requires more dispersive delay for optimal compression. Note also that the more intense pulse can be compressed to a greater extent; this is because of the greater bandwidth expansion (i.e., greater chirp). The 2 GW/cm^2 case was the one considered in [1], and the other cases are shown for comparison.

II. Amplitude Noise Stability

Since the temporal shape of the input pulses may not be as smooth as in the calculated cases presented in [1], it is important that the pulse-compression scheme is not severely hampered by the presence of some temporal noise on the otherwise smooth input pulse. To study these stability considerations, we have repeated the plane-wave pulse-compression calculations shown in Fig. 2 with noise impressed upon the pulse which enters the chain. Terms in the compressor transfer function higher than Q_2 are neglected here. These calculations have been performed for 10-percent peak-to-peak periodic intensity modulation and for random amplitude modulation.

A. Periodic Amplitude Modulation

Fig. 3 shows the calculated attempt to compress the periodically modulated pulses. As $|Q_2|$ was increased from zero, the noise became accentuated because each feature had developed its own chirp. With further increase of $|Q_2|$ to the optimally compressing values, all amplitude fluctuations in the vicinity of the main pulses disappeared. This is because each ripple had generated a spectral content far richer than had the unmodulated pulses, and so each feature is quite smoothly dispersed (over-compressed) by the optimally compressing dispersive delay.

At optimum compression, the 10-percent modulated 2-GW/cm^2 case is indistinguishable from the smooth case (Fig. 2) in the time span we present. It is somewhat unfortunate, however, that during self-phase modulation the spectrum of the pulse develops sharp sidebands (at the modulation frequency) well separated from the smooth-pulse self-phase modulated spectrum. This can be seen in Fig. 4. These sidebands apparently have a spectral-intensity-dependent growth rate, and are ~1/20th the height of the spectral peak by the time the pulse exits the laser chain. At the optimally compressing dispersive delay (the setting 1.2 in Fig. 3), these "renegade" spectral components are delayed and advanced by approximately 2 ns with respect to the center of the compressed pulse. In the 5-GW/cm^2 case, the precursors are within the field of view because less dispersive delay is needed to optimally compress the pulse, and the precursors are prominent features. The precursor arrival time can be predicted by noting that the periodically modulated pulse develops spectral sidebands at the modulation frequency, which the compressor converts into temporal features. The anti-Stokes (Stokes) sideband is advanced (delayed) by $\sim 2Q_2$ times the modulation frequency. In the case presented here (50-ps ripple) these features for the 2-GW/cm^2 pulse precede and follow the central compressed pulse by ~2 ns. The difference in prominence of precursors in the 2- and 5-GW/cm^2 cases is because in the nonlinear chain, the sideband growth rate is spectral-intensity dependent. This can be seen in the relative heights of the spectral sidebands of the periodically modulated pulses in Fig. 4. Note in the same figure that nonlinear propagation in the 5-GW/cm^2 case has generated faint second spectral sidebands, and in the compressed pulse,

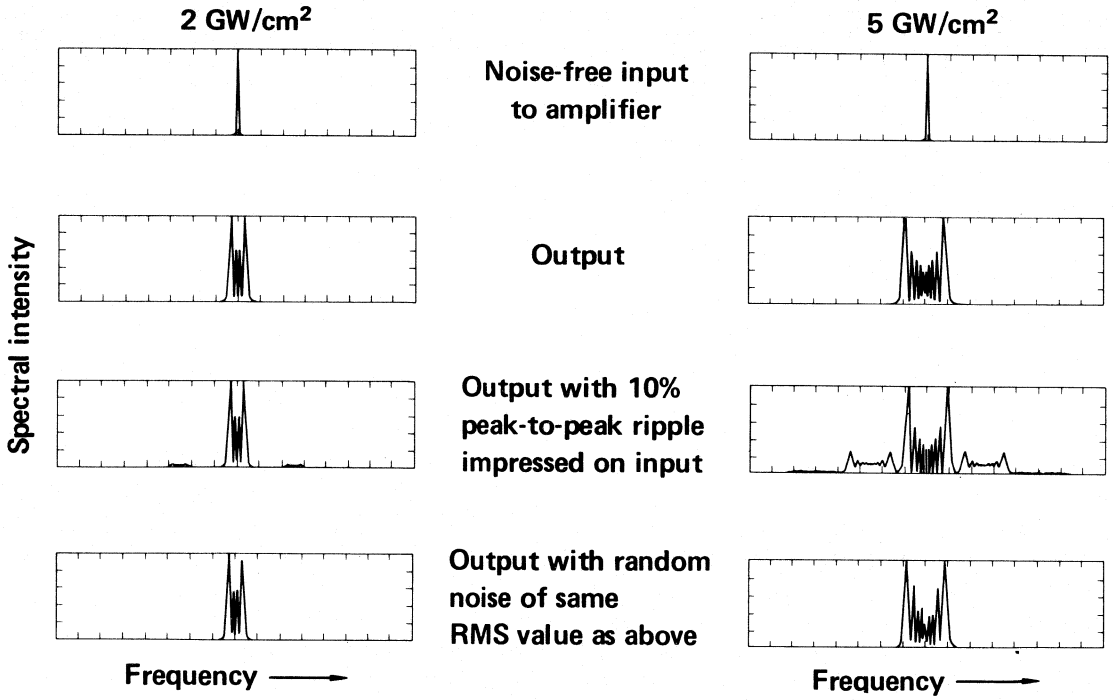

Fig. 4. Comparison of calculated spectra for pulses emanating from the laser amplifier chain. Cases of noise-free input, 10-percent peak-to-peak ripple, and random noise of the same rms deviation as in the 10-percent ripple are presented for 2-m propagation at chain-averaged peak intensities of 2 GW/cm^2 and 5 GW/cm^2.

they correspond to second precursors. These secondary features are 1/10th the height of the first precursor, and they are twice as far from the peak of the central compressed pulse.

B. Random Amplitude Modulation

The random modulation was generated by multiplication of of the original temporally Gaussian pulse-shape function at time N by the factor $[1 + \alpha A_N]$. Here α is an adjustable constant and $A_N = \sum_1^N R_i$, where $\{R_i\}$ is a set of random numbers distributed between the ranges +1 and −1. The value of α was adjusted so that after passing the calculated pulse through a 0.4-Å-bandwidth Lorentzian filter, the calculated rms deviation from the original Gaussian was equal to the calculated rms deviation for the 10-percent peak-to-peak periodic-ripple case previously discussed. The spectral filtering did not significantly reduce the rms deviation, yet it did remove the noise due to the finite temporal step size.

We have calculated the passage of the randomly modulated pulses through a 2-m laser chain, and have studied their compressibility. We find, as before, that for far less than the optimally compressing dispersive delay settings, the noise is accentuated, but at optimally compressing dispersive delay, the noise is not discernable. There is also no perceptible precursor, even in the 5-GW/cm^2 case, and it is because the spectrum as seen in Fig. 4 does not exhibit sidebands as had been observed in the periodic modulation case. Since the growth rate of a sideband is spectral-intensity dependent, the spectrally broader random noise did not have sufficient peak spectral amplitude to get significantly amplified during self-phase modulation in the laser chain.

From the comparison of the results just presented for periodic and random amplitude modulation, we conclude that although random amplitude modulation can be well tolerated, efforts must be made to limit periodic amplitude modulation in order to provide a pulse suitable for precursor-free dispersive compression.

III. Averages Over Spatial Profiles

In [1] the compression effect was intensity averaged over a Gaussian spatial profile. This neglects the influence of diffraction in the amplifier chain with the assumption that each radial zone in the amplifier chain acts independently and can therefore be treated in the plane-wave approximation. In the calculation, each radial zone is compressed and then the *intensities* are added to find the spatially averaged signal in the focal plane of a lens. In a laser fusion experiment, for example, this intensity averaging models the expected smoothing role of the electron thermal conductivity on the surface of the pellet. If the value of the conductivity proves to be insufficient, then spatially averaged quantities would not be meaningful, and one would have to consider the complicated time-dependent interference patterns produced by the laser pulse at the surface of the pellet. These interference effects have been studied by Campillo *et al.* [3].

Reference [1] presented the compression-effect intensity averaged over a spatially Gaussian pulse with a chain-averaged on-axis peak intensity of 2 GW/cm^2, and this was shown to be somewhat deleterious to the compression scheme. These intensity-averaging compression calculations have been extended here to include more typical spatial profiles. As a model of the various choices for spatial mode shapes which decrease monotonically with radius, consider the set of radial-intensity distributions given by the function $\exp\{-(R/R_0)^M\}$.

For $M = 2$, this is a Gaussian. In the design of a laser chain it is advantageous to run at higher M values. As M is increased, the central region becomes more flat-topped and the wings fall off faster. This means that higher M values allow R_0 to be chosen closer to R_A, the radius of the active medium which, in turn, results in more efficient extraction from the pumped laser amplifier. In addition, a higher M value gives more surface of relatively constant nonlinear phase, which brings compression results closer to the plane-wave case of [1]. The M value cannot be increased without limit, however, because of diffraction and self-focusing. The pulse-compression scheme presented here cannot improve the M-value limitations imposed by diffraction. If the M value is limited by self-focusing considerations, however, the reduction of the nonlinear-index change through this compression scheme can allow for an increased effective operating M value.

For temporally Gaussian 1-ns pulses we have repeated our spatial-intensity averaging calculations for M values from 2 through 6. In the calculation pulses traveled 2 m with their on-axis peak intensity kept at the chain-averaged value of 2 GW/cm^2. Fig. 5 shows the results of this spatial averaging for $M = 2$ (a Gaussian). For each M value the compression ratio R was estimated by measuring the $1/e$ intensity width of the compressed pulses, and the efficiency of compression ϵ was found by multiplying R times the ratio of the uncompressed maximum intensity to the maximum intensity of the compressed pulse. Results are shown in Table I. Since the cost of components for a constant energy subnanosecond Nd:glass laser system varies nearly inversely with pulse duration, we can estimate the potential savings if one were to convert from normal amplifier operation to this compression scheme. If the effective M value and output energy are not changed in the conversion, then we can define a figure of merit as $1 - 1/(\epsilon R)$. This denotes an estimate of the fractional-component cost savings which the compression scheme would provide if the compressor were free. The figure of merit is also shown in Table I. Note that the entries are only approximate because of our qualitative estimates of the optimally compressing conditions. The *additional* savings which can be achieved if, through its reduction of self-focusing problems, a compression scheme allows an increase in the operating M value can be estimated from the following. For a given M value, we assume that R_0 is chosen so that the intensity at R_A, the radius of the active medium, is approximately 10^{-3} of the intensity on-axis. This condition is written $\exp[-(R_A/R_0)^M] = 10^{-3}$. The mode-extraction efficiency is then estimated as $(R_0/R_A)^2$, which is approximately $7^{-(2/M)}$. This mode-extraction efficiency factor is also listed in Table I. As can be seen from Table I, there is an even greater benefit if the compression scheme can also allow the increase in effective operating M value.

TABLE I
COMPARISON OF CALCULATED RESULTS FOR INTENSITY AVERAGING OVER SPATIAL PROFILES

M-Value	Measured Compression Ratio:R	Efficiency ϵ	Figure of Merit $1-1/(\epsilon R)$	Mode Efficiency parameter $7^{-(2/M)}$
2	4.9	.56	.64	.14
3	5.5	.63	.71	.27
4	6.1	.64	.74	.37
5	6.3	.66	.76	.46
6	6.6	.68	.78	.52
∞ (plane-wave case)	7.8	.79	.84	1.0

Note: Temporal shape = $\exp\{-(t/\tau)^2\}$. Mode shape = $\exp\{-(R/R_0)^M\}$. Each pulse propagates 2 m through the chain with the peak intensity on axis averaging 2 GW/cm^2. The full $1/e$ intensity duration is given by $2\tau = 1$ ns.

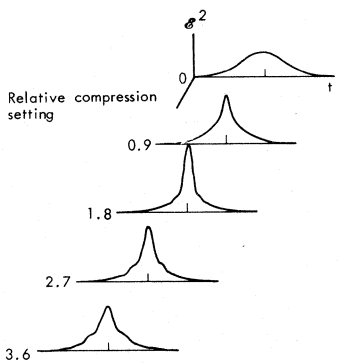

Fig. 5. Compression study of an intensity average over a Gaussian transverse mode with peak chain-averaged intensity on axis of 2 GW/cm^2. Time is plotted horizontally and intensity is plotted vertically. Note that ample compression can be achieved. As in Figs. 2 and 3, Q_3 and Q_4 terms were not included, and the numbers associated with each graph are relative compression settings which are proportional to Q_2, with a setting of unity corresponding to $Q_2 = -6.4 \times 10^{-21}$ s^2.

IV. Can a Grating Pair Compress Nanosecond Pulses?

There are two main candidates presently available for an anomalously dispersive compressor ($Q_2 < 0$). These are the Gires-Tournois interferometer and the grating pair. In [1] we considered only the Gires-Tournois interferometer because of the high damage threshold available from good coatings (approximately 5 J/cm^2 at 1.06 μm, 125-ps duration) and because of the low insertion loss. It is unfortunate, however, that there is only a narrow operating range over which the group delay depends linearly upon the center frequency, and hence sequential reflection from nine Gires-Tournois interferometers was required. The number of required interferometers might be reduced by designing more complex structures. Even though the proper alignment of as many as nine Gires-Tournois interferometers may be quite difficult, these interferometers most likely can be made the same diameter as the final output stage of the laser amplifier chain.

The second compressor candidate is the grating pair which has been studied by Treacy [4]. This device is very useful for compressing pulses from the 1-10-ps range, but we are not as confident that it can be used as a practical compressor for nanosecond-duration pulses. In general, we find that both required sizes of gratings and grating separation distances are

prohibitively large. For a single grating, the geometry of incident and diffracted rays is determined by the grating formula

$$N\frac{\lambda}{d} = \sin(\beta) + \sin(\gamma) \tag{1}$$

where N is the diffraction order, d^{-1} is the number of lines per centimeter, γ is the angle which the incident ray makes with the normal to the grating, and β is the angle between the diffracted beam and the normal to the grating. For a compressor phase-shift quadratic in frequency offset, we write $\Phi = Q_2(\Delta\omega)^2$. The quantity Q_2 has been derived for the grating pair [4], [5], and is written

$$Q_2 = -\left(\frac{\lambda}{4\pi c^2}\right)\left(\frac{N\lambda}{d}\right)^2 (b)\left(\frac{1}{\cos^3(\beta)}\right) \tag{2}$$

where b is the perpendicular distance between the two gratings. We find it quite difficult to make Q_2 sufficiently large. Note that increasing the order N or the grating constant d^{-1} will not significantly increase Q_2 because (1) limits the quantity $(N\lambda/d)^2$ to 4. Thus only the separation b and the geometric factor $[1/\cos^3(\beta)]$ can be adjusted to hopefully attain sufficiently large Q_2. The separation b could possibly be "folded" by a mirror system, but the increase of the geometric factor is accompanied by two distinct problems. First, high first-order blaze efficiency at these angles is not yet technologically possible for reflection gratings (transmission gratings may not be subject to this criticism). Second, if blaze efficiency could be kept high, operation would have to be near Littrow condition ($\beta \sim \gamma$), for which the size of the grating must be at least $D/\cos(\beta)$, where D is the beam diameter. For $D = 50$ cm and $\beta = 85°$, the grating would have to be 6 m across. This is exceedingly large.

As an example which could have high blaze efficiency, consider $\beta = 60°$, a grating spacing of 1200/mm and $\lambda = 1.06$ μm. Here only first-order diffraction can occur, and $(N\lambda/d)^2 = 1.6$. Equation (2) can be solved to find that under these circumstances, d must be 600 m in order to provide the Q_2 which was needed in [1]. Since d is the required *perpendicular* distance between gratings, their required physical separation will be 1200 m. Thus we see that at angles where the blaze will be efficient, the separation between gratings must be exceedingly large.

One must consider the additional difficulty that gratings may damage at much lower intensities than would the coatings of a Gires-Tournois interferometer. Although the damage susceptibility for gratings does not appear to be too well studied, one can surmise from the work of Bloembergen [6] that the preponderance of sharp corners could severely reduce the ability of a grating to tolerate high light fluxes. The possibility of standing waves with nodes at the periodically spaced sharp corners could further enhance the damage sensitivity. This damage consideration would probably require even larger surface gratings. If necessary, one might piece together several similar gratings, yet the accumulated list of design difficulties seems to rule out consideration of a grating pair for compressing nanosecond-duration pulses.

V. Concluding Remarks

Certain considerations have been described which are related to our previously presented pulse-compression scheme. The stability to amplitude noise was analyzed, and it was shown that a pulse could exit the compressor with precursors if it enters the chain with periodic amplitude modulation. For the case considered in [1], the addition of 10-percent peak-to-peak intensity ripple accounted for only a relatively small precursor, yet an increase of the operating intensity by a factor of $2\frac{1}{2}$ led to clearly unacceptable precursors. With the exception of causing these precursors, there is no other effect on the compressed pulse shapes. It was also shown that, unlike periodic modulation, random amplitude modulation (of the same rms value) did not produce the unwanted precursors. This was explained in terms of the nonlinear self-phase modulation effect, and is due to the broad spectral nature of the random modulation.

In order to help estimate the cost effectiveness of the pulse-compression scheme, the effects of intensity averaging the compression over reasonable spatial mode profiles were also tabulated. Our reasons were also stated for excluding consideration of the grating pair as a compressor.

Appendix

To justify the use of chain-averaged quantities, we consider a laser chain which consists of elements numbered from 1 through p. Each element is of length l_i, and the square of the maximum electric-field envelope is written $\mathcal{E}^2_{\max}(z_i)$, where z_i is the position in the ith element. The maximum nonlinear phase is written

$$\delta\phi_{\max} = \left(\frac{\omega_0}{c}\right)\left(\frac{n_2}{2}\right)\sum_{i=1}^{p}\int_0^{l_i} \mathcal{E}^2_{\max}(z_i)\,dz_i \tag{A1}$$

if both saturation of the transition and dispersion can be neglected. If we define the chain-averaged value of $\mathcal{E}^2_{\max}$ through the relationship

$$\overline{\mathcal{E}^2_{\max}} \equiv \left\{\sum_{i=1}^{p}\int_0^{l_i} \mathcal{E}^2_{\max}(z_i)\,dz_i\right\} \Big/ \left(\sum_{i=1}^{p} l_i\right) \tag{A2}$$

then the maximum nonlinear phase is written

$$\delta\phi_{\max} = \left(\frac{\omega_0}{c}\right) n_2 \frac{\overline{\mathcal{E}^2_{\max}}}{2}\left(\sum_{i=1}^{p} l_i\right). \tag{A3}$$

Thus we see that pulses can be treated as if they remained at their chain-averaged values. More precise calculations await the accurate specification of design parameters for a particular chain.

Radiation-Pressure Separation of Molecules and Atoms

JERRY GELBWACHS AND THOMAS S. HARTWICK

Abstract—**Radiation-pressure separation of molecules in a closed cylindrical geometry with radiation propagating along the axis has been analyzed. The degree of separation and separation efficiency are compared in the microwave, infrared, and visible-UV spectral regions for representative species.**

I. Introduction

The idea of using pressure induced by light to physically displace molecules is old [1]. Not until Ashkin and his colleagues [2]–[4] demonstrated vividly the utility of laser light did the use of radiation pressure merit serious consideration for applications. Since then, the old atomic-beam-deflection experiments have been repeated [5] and extended [6]. Due to the low density of atoms in an atomic beam, the yield of material separated by atomic-beam methods will be small. Our interest is to explore the usefulness of separation of isotopes by radiation pressure for a geometry that does not rely upon atomic beams and thus has potential for the separation of larger quantities of isotopes. A comparison of separation parameters in different spectral regions will be made.

II. Separation Parameters

Molecules are contained in a cylindrical tube of length L that is illuminated by radiation propagating along the axis of the cylinder. The molecular energy levels are modeled by a two manifold system with rotational line structure. The two levels describe electronic or vibrational transitions. Interaction between the radiation and the molecules changes the ground-state n_1 and excited-state n_2 populations. The spatial and temporal variation of the states is determined by the combination of stimulated absorption, radiative-momentum transfer, molecular diffusion, and relaxation of the upper state by spontaneous emission and collisional deactivation. The last process proceeds at a rate equal to $1/\tau$ and κp, respectively, where τ is the upper-state lifetime, κ is the collisional deactivation rate, and p is pressure. Assumptions are made to facilitate the calculation without significant loss of accuracy. These assumptions include: restricting the gas pressure to the regime where the mean free path is much less than the tube diameter; a constant gas temperature T; negligible radiation propagation losses; and uniform intensity I across the tube area. The stimulated absorption rate W is restricted to be less than the relaxation rate within the manifolds and the velocity cross-relaxation rate within the Doppler distribution. These restrictions eliminate hole-burning effects and permit the substitutions $f_{1,i}n = n_{1,i}$ and $f_{2,j}n_2 = n_{2,j}$, where the f's are Boltzmann coefficients.

Under the above constraints and assumptions, the time variations of the total population n and population difference δ is written as

$$dn/dt = -D\nabla^2 n + (Dhf/kT\lambda)\,\nabla \cdot W\delta\hat{z} \tag{1}$$

$$d\delta/dt = -D\nabla^2\delta - (Dhf/kT\lambda)\,\nabla \cdot Wn\hat{z} - 2Wf\delta + (n-\delta)(1/\tau + \kappa p) \tag{2}$$

where D is the diffusion coefficient, h is Planck's constant, k is Boltzmann's constant, λ is the excitation wavelength, and $\hat{z}$ is a unit vector in the longitudinal direction. For simplicity, the Boltzmann factors $f_{1,i}$, $f_{2,j}$ have been set equal to f.

The solutions to the coupled set of equations in the steady state are easily obtained by neglecting the slowly varying longitudinal drift and diffusion terms relative to the fast relaxation and stimulated absorption rates in (2). This produces

$$\delta = n[1 + 2Wf/(1/\tau + \kappa p)]^{-1}. \tag{3}$$

Substitution of (3) into (2) yields

$$0 = -D\nabla^2 n + \{hDfW/kT\lambda[1 + 2fW/(1/\tau + \kappa p)]\}\,\partial n/\partial z. \tag{4}$$

Only the longitudinal diffusion and drift terms remain.

The solution of (4) takes the form originally written by Ashkin [2]

$$n(z) = n(0)\exp \beta Z/L. \tag{5}$$

The exponential variation of the concentration with z fixes the degree of separation which is determined by the separation coefficient β. Solving (4) for β yields

$$\beta = \beta_s(I/I_s)[1 + (I/I_s)]^{-1} \tag{6}$$

TABLE I
LOW-INTENSITY SEPARATION COEFFICIENT AND EFFICIENCY FOR RADIATION-PRESSURE SEPARATION IN VARIOUS SPECTRAL REGIONS

Sprectral Region	Representative Molecule	Transition Wavelength	β^*/P (W^{-1})	η^* (Molecules/Joule)
Microwave	NH_3	12.6mm	2×10^{-4} [a]	1×10^{11}
Infrared	CO	4.7μm	5×10^{-3} [b]	1×10^{12}
uv-visible	NO	230nm	0.3 [b]	4×10^{13}
uv-visible	Na	589nm	10^{3} [b]	5×10^{17}

[a] Waveguide: $L = 100$ m; $A = \lambda^2$.
[b] $L/A = \lambda^{-1}$.

where

$$\beta_s = (h\nu L/2ckT)(1/\tau + \kappa p) \tag{7}$$

$$I_s = [4\pi h\nu/\lambda^2 f A_{ij} g(\nu)](1/\tau + \kappa p) \tag{8}$$

$$W = c^2 A_{ij} g(\nu) I/8\pi h\nu^3 \tag{9}$$

where c is the speed of light, A_{ij} is the spontaneous emission rate between the ith rotational state in the lower level and the jth rotational state in the upper level, $g(\nu)$ is the line-shape factor, and ν is the radiation frequency. This result demonstrates that saturation of the absorbing transition as measured by the saturation intensity I_s limits the amount of radiation pressure that can be exerted upon resonant molecules. The degree of separation that can be attained when maximum radiation pressure is exerted is β_s.

Until this point radiation pressure has been considered as a means to establish a concentration gradient of a resonant species along the length of a closed tube. For an open tube in which the initial mixture is continuously replenished at the input end and the separated species are removed at the output end, it is useful to define a separation efficiency η as the number of resonant molecules transported per incident radiant energy, i.e., the ratio of the drift current density to I. From (4) the drift current density is identified and it follows that

$$\eta = (nD\beta_s/LI_s)[1 + (I/I_s)]^{-1}. \tag{10}$$

III. CANDIDATE MOLECULES AND SPECTRAL COMPARISON

To determine the molecular species and spectral regime that are optimum for separation, it is useful to examine β and η at low-laser intensities (denoted by superscript *). Noting that the absorption coefficient in the absence of saturation is given by $\alpha = n_{1,i} c^2 A_{ij} g(\nu)/8\pi\nu^2$, (6) and (10) can be rewritten as

$$\beta^* = (\alpha/n)(LI/ckT) \tag{11}$$

$$\eta^* = D\alpha/ckT \tag{12}$$

where I_s has been eliminated in favor of α to facilitate computation of β^* and η^* from experimental parameters. The low-intensity value of β is a function of geometry through the dependence on length L. To compare values of β^* for different molecules in the optical region, a geometry is selected in which the focused laser radiation fills the area of the cylindrical tube A at its ends, i.e., $L/A \sim \lambda^{-1}$ for a single-mode Gaussian beam. Radiation pressure can be applied through the excitation of rotational, vibrational, and electronic transitions. In Table I values of β^*/P and η^* are compared in various spectral ranges for representative molecules. To avoid unduly penalizing the microwave spectral region, the L/A ratio has been calculated for a waveguide structure 100 m in length and $A = \lambda^2$ instead of $L/A = \lambda^{-1}$. In all spectral regions a sufficiently low pressure has been assumed so that the resonance lines are Doppler broadened. Values of β^*/P and η^* range over 7 orders of magnitude. For a given power P, atoms with strong resonance lines produce the largest separation coefficients and highest efficiencies in the absence of saturation.

IV. PRESSURE DEPENDENCE OF SEPARATION PARAMETERS

From (7) it is seen that maximum separation occurs when the excited state undergoes rapid deactivation. As discussed by Ashkin, the deactivation rate can be increased by introducing as the gas additive a collision partner with a large κ [2]. Three pressure regions are evident when the partial pressure of the resonant molecules is held constant and the variation of β_s and I_s with the pressure of the collision partner is considered. In the low-pressure region the absorption lines are Doppler broadened, and spontaneous emission relaxes the excited state so that β_s and I_s are independent of pressure. At higher pressure, collisions are mainly responsible for the decay of the excited state and both β_s and I_s vary directly as p. At still higher p, the line-shape factor $g(\nu)$ becomes Lorentzian and I_s varies as p^2. The lowest p region is characterized by small separation coefficients, low powers, and large separation efficiencies. At high p large separations are possible, but at the expense of a high-power requirement and, hence, reduced efficiency. In Fig. 1, β_s and saturation power $P_s (P_s = I_s A)$ are

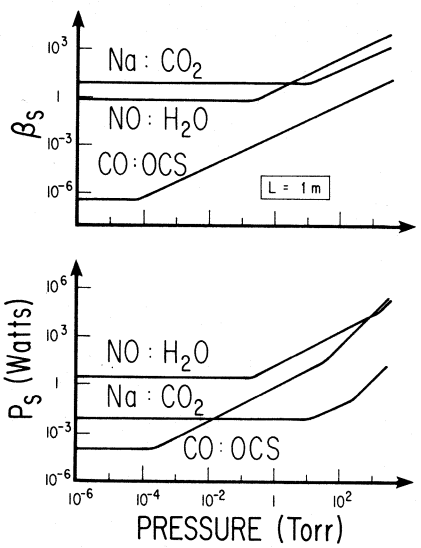

Fig. 1. Maximum degree of separation β_s and saturation power P_s versus the pressure of gas additive for various molecules and their collision partners.

plotted against the pressure of the gas additive for CO(4.7 μm), NO(0.23 μm), and Na(0.59 μm). A diffraction-limited geometry has been selected for which $L/A = \lambda^{-1}$ and $L = 1$ m. For example, consider that $\beta = 1.5$ is desired. When $\beta = \beta_s/2$ and $I = I_s$, good separation is achieved with only a slight reduction in separation efficiency due to saturation. These values for β and I are chosen in the examples. Under this condition, 30 kW of power and 1000 torr of OCS are necessary to separate CO isotopes. Isotopes of NO require 12 W and 1 torr of H_2O. Less than 10 mW is sufficient for the same separation of Na.

Atomic Laser Action in Rare Gas–SF_6 Mixtures

D. G. SUTTON, L. GALVAN, P. R. VALENZUELA, AND S. N. SUCHARD

Abstract—**Pulsed-laser action is described on a number of atomic transitions of ArI, one of which has not been reported previously. The addition of SF_6 to Ar shifts the laser action in the Ar from the $3d'(3/2)_1^0 - 4p'(1/2)_1$ transition to six ArI transitions originating from the three lowest states of the $3p^5 3d$ electron configuration. Significant enhancement of the intensity is observed over that resulting from a discharge in pure argon. In addition, when a small amount of SF_6 is added to a He discharge, laser oscillation results from FI at 0.7129 μm. Increased SF_6 pressure produces an unidentified oscillation at 2.639 μm. These last two transitions have been observed also in He–NF_3, He–CF_4, and He–PF_3 mixtures.**

I. Introduction

Dissociative-excitation transfer has previously resulted in a number of atomic lasers in both pulsed and CW longitudinal discharge devices [1]–[3]. Transverse excitation has also proven effective in exciting atomic lasers at pressures up to 1 atm [4]. In addition, enhancement of certain CW ArI laser oscillations has been accomplished by the addition of chlorine to a mixture of argon and helium [5].

We have observed a total of seven laser transitions in Ar, one of which has not been previously reported. In pure Ar, only one transition was observed; however, the other six transitions were observed to lase simultaneously upon the addition of SF_6 to the discharge in Ar. These six transitions form a highly coupled system between three upper ($3d$) and three lower ($4p$) levels of the Ar.

Manuscript received July 2, 1974. This research was supported by the Defense Advanced Research Projects Agency of the Department of Defense under U.S. Air Force Space and Missile Systems Organization (SAMSO) Contract F04701-73-C-0074.

The addition of less than 0.2 torr SF_6 to 49 torr He results in lasing on the FI($3p^2P^0_{1/2} \rightarrow 3s^2P_{1/2}$) transition at 0.7129 μm. However, the addition of several torr SF_6 to 49 torr He produces an unidentified oscillation at 2.639 μm. These last two transitions have also been observed to lase in He–NF_3, He–CF_4, and He–PF_3 mixtures.

II. Experimental Apparatus

The laser tube consists of a 3-m Lucite pipe fitted with a double helix of 470-Ω resistors. Each helix consists of 502 resistors with one wire lead penetrating the 1-in-ID tube at equally spaced intervals. The other lead is tied to a common bus line. One helix is connected via the bus to ground, and the other helix forms the anode of a pulsed power supply consisting of a 0.014-μF capacitor bank triggered at 1 Hz by a spark gap (EG&G GP-14B). The capacitor is connected to a dc supply (Universal Voltronics BAL 130-5.5) capable of delivering 130 kV. This configuration results in 502-pin-pair electrodes being opposed across a $\frac{3}{4}$-in gap. Actually, the tube is formed from two equal sections connected in the middle, where provision is made for evacuation by a mechanical pump, and the ends are sealed by CaF_2 windows at Brewster's angle. The gas mixture from a metered manifold flows into the tube from both ends. The cavity is formed by a 450-in focal-length silver-coated mirror and a silver-coated flat with a 1-mm-diam coupling hole. Both mirrors have a protective MgF_2 overcoat to prevent oxidation of the silver surface. These mirrors are spaced 6-in from the end windows, which yields a 3.2-m-long laser cavity. Output from the laser enters a screen room and is split into two beams by a sapphire flat at 45° to the beam. The beam reflected from the flat was monitored with an InSb photovoltaic detector at 77 K (Barnes Engineering). The transmitted portion of the laser beam was directed to a $\frac{1}{2}$-m McKee–Pedersen monochromator equipped with an infrared grating blazed at 3 μm. Output from the monochromator was focused onto an identical InSb detector by a gold-coated 8-in-radius of curvature mirror. Measured detector response was monitored by a Tektronix 7704 or 551 oscilloscope to be less than 20 ns.

III. Results

When the capacitor bank is charged to 25 kV and discharged through 5.0 torr or pure Ar, weak lasing occurs at 1.270 μm ($3d'(3/2)_1^0 \rightarrow 4p'(1/2)_1$). If the Ar pressure is maintained at 5 torr and 3 torr SF_6 is added, the peak laser intensity increases by two orders of magnitude. Spectral resolution of the laser output reveals six different laser oscillations occurring simultaneously between 1.652 and 2.397 μm from the Ar/SF_6 mixture. These transitions are cataloged in Table I. All transitions, except the first at 1.652 μm, have been observed previously, but under completely different conditions [6]. The temporal behavior of the six transitions resulting

TABLE I
Wavelengths of Observed Laser Transitions in Ar and Ar + SF_6 Mixtures

Transition	λ(μm)	Gas
$3d(3/2)^o_2 - 4p(3/2)_1$	1.652	Ar + SF_6
$3d(3/2)^o_2 - 4p(3/2)_2$	1.694	
$3d(1/2)^o_1 - 4p(3/2)_2$	1.791	
$3d(3/2)^o_2 - 4p'(1/2)_1$	2.153

$3d(1/2)^o_0 - 4p'(1/2)_1$	2.397	
$3d'(3/2)^o_1 - 4p'(1/2)_1$	1.270	Ar

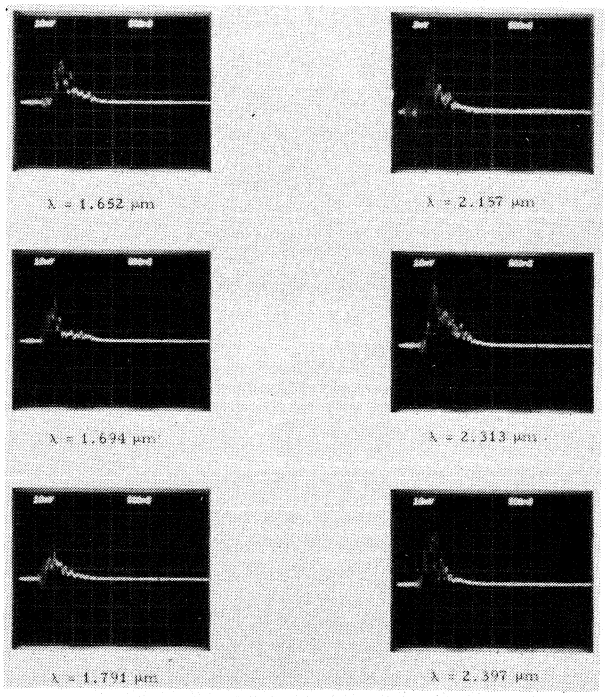

Fig. 1. Laser output at six wavelengths in ArI. (The signals at 1.791 and 2.397 μm were attenuated by a factor of 10 and 3.2, respectively. The time scale for all the oscilloscope traces is 500 ns/div.)

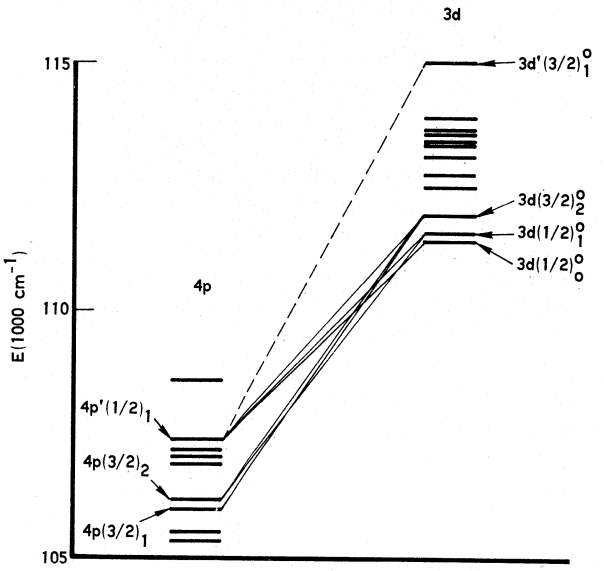

Fig. 2. Partial ArI energy-level diagram. (Dashed line shows weak laser transition occurring in pure Ar. Solid lines represent six strong transitions lasing simultaneously in Ar–SF_6 mixture.)

from the Ar/SF_6 mixture is shown in Fig. 1, and the relevant energy-level diagram of Ar is given in Fig. 2. It may be seen from Figs. 1 and 2 that the Ar/SF_6 mixture results in a highly coupled system of six transitions between six states, all lasing simultaneously.

When a mixture of 49 torr He and less than 0.2 torr SF_6 is discharged at 25 kV in the same device, lasing occurs at 0.7129 μm from FI atoms [7]. The laser pulse begins approximately 0.5 μs after initiation of the discharge and is 1 to 2 μs wide [full width at half maximum (FWHM)]. If the SF_6 pressure is increased to 18 torr, lasing occurs on an unidentified transition at 2.639 ± 0.002 μm. The output under these conditions (see Fig. 3) consists of a series of pulses beginning 10 μs after initiation and continuing for 50 μs. The pin discharge lasts no longer than 2 μs. Nearly identical results are obtained from He–CF_4 or He–PF_3 mixtures. A single 2-μs-wide pulse of laser light at 0.7129 μm is observed from a dilute (CF_4 or PF_3 = 0.2 torr, He = 49 torr) mixture. The laser output from a discharge in 25 torr CF_4 or PF_3 and 47 torr He occurs at 2.639 μm. The output consists of two or more pulses beginning 50 μs after initiation. In a mixture of NF_3 (0.2 torr) and He (47.8 torr), however, both the 0.7129- and 2.639-μm

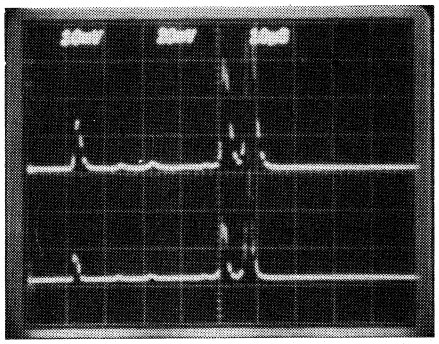

Fig. 3. Unidentified laser output at 2.639 μm in He–SF_6 gas mixture. (Top trace is the signal at the exit slits of the monochromator set at 2.639 μm. The bottom trace is the total laser output reflected from the front surface of the sapphire beam splitter. Reactant pressures are He = 49 torr and SF_6 = 18 torr. Time scale is 10 μs/div.)

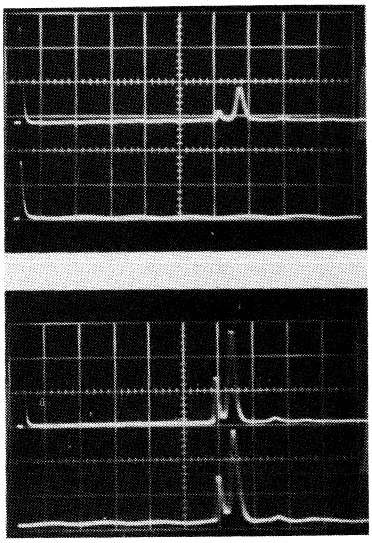

Fig. 4. Simultaneous laser oscillation on two lines from NF_3–He mixture. (The top trace in both photos is the total laser output. The bottom trace in the top photo is the output from the monochromator at 0.7129 μm. The bottom trace of second photo is from the monochromator set at 2.639 μm. Sweep time is 10 μs/cm. Sensitivity is 10 mV/cm. NF_3 = 0.2 torr and He = 47.8 torr.)

transitions lase simultaneously (Fig. 4). The time to threshold for the 2.639-μm line in this case is approximately 50 μs. Both of these laser oscillations are interpreted as arising from dissociative excitation transfer from metastable He to the F-atom bearing molecule.

In an attempt to identify the transition occurring at 2.639 μm, several additional experiments have been performed. The first of these was the interruption of the laser path, external to the optical cavity, by a cell with a path length of 2.0 cm containing HF at a pressure of 2 torr. Since a laser wavelength of 2.639 μm coincides with that of the $P_1(4)$ transition in the HF molecule, within the measurement accuracy of our spectral analysis apparatus, absorption of the laser radiation by the cell could be indicative of its source as HF radiation. Indeed, the laser radiation was greatly diminished in intensity by the HF cell. A possible source of H atoms for the production of the HF molecules could be an atmospheric water leak in our vacuum system. Test measurements made by adding water to the gaseous mixture did indeed demonstrate lasing from HF molecules, as has been reported previously by Florin and Jensen [8]; however, the laser action occurred from the $P_1(2)$–$P_1(10)$ transitions of the HF molecule. In our "pure" SF_6–He mixture, only laser radiation at the $P_1(4)$ wavelength was observed so, consequently, atmospheric water was not the H-atom source.

A second experiment in which the total gas pressure was increased to 300 torr was performed to ascertain if H-atom "contamination" was being formed by the discharge striking the laser-tube walls. As the gas pressure is increased, diffusion of vaporized Lucite into the laser zone should take longer, thereby increasing the time from the discharge to laser threshold. This increased threshold time was not observed; therefore, H-atom sources are not produced by laser-wall vaporization.

The results of the supporting experiments indicate that the laser oscillations at 2.639 μm do not originate from the HF molecule. Inspection of a table of atomic energy levels [9] indicates that this wavelength does not correspond to any known transitions in the neutral or ionized species possible in the gaseous mixture. Experiments are now under way to identify this laser-active species.

In addition to the FI transition at 0.7129 μm we have observed two additional laser oscillations that have been interpreted previously as arising from dissociative-excitation transfer from metastable He atoms [3]. The first of these occurs in a

mixture of 95 torr He with approximately 0.1 torr of N_2, N_2O, or NO discharged at 23 kV. The laser output is at 1.358 μm and is due to the $3p^2S^0_{1/2}$–$3s^2P_{3/2}$ transition of NI. The second oscillation is observed at 1.454 μm in mixtures of He (125 torr) and CO (0.1 torr). It has been assigned to the $3p^1P_1 - 3s^1P^0_1$ transition of CI. Both of these oscillations exhibit temporal behavior similar to the F-laser at 0.7129 μm.

In conclusion, we have observed laser action on seven transitions in ArI. Six of these are seen to lase simultaneously with enhanced output upon the addition of small amounts of SF_6. Oscillation in F, C, and N atoms in the near infrared occurs when small amounts of an appropriate compound are added to a He discharge. Discharging 18 torr SF_6 and 49 torr He results in an unidentified laser line at 2.639 μm that persists in multipulsing for >50 μs.

Acoustooptic Bragg Deflection in $LiNbO_3$ Ti-Diffused Waveguides

R. V. SCHMIDT AND I. P. KAMINOW

Abstract—**A $LiNbO_3$ acoustooptic Bragg deflector utilizing a Ti-diffused optical waveguide and acoustic surface waves, which requires only 50 mW of electrical drive power to obtain 70-percent deflection, has been demonstrated.**

Recently, high-performance acoustooptic deflectors have been demonstrated using TeO_2 which require electrical drive powers as low as 35 mW for several hundred resolvable spots and random access times on the order of 10 μs [1]. These deflectors require low drive power because TeO_2 has a high acoustooptic figure of merit and the anisotropic Bragg-diffraction regime can be used at practical acoustic frequencies [1], [2]. In this correspondence we report on an acoustooptic Bragg deflector using $LiNbO_3$, which has an acoustooptic figure of merit about 100 times smaller than TeO_2, but has electrical drive power requirements similar to TeO_2 deflectors. In particular, 70-percent deflection of the incident light beam is obtained over a 3-dB bandwidth of 30-MHz with only 50 mW of electrical drive power. This deflector requires low electrical drive power because guided optical waves and acoustic surface waves are utilized which allows for a much more efficient interaction geometry than is possible with bulk deflectors.

Acoustic surface waves and guided optical waves lend themselves to low drive power deflectors because both waves are closely confined to the surface allowing long interaction lengths which are not obtainable in bulk deflectors because of diffraction. By analogy to bulk acoustooptic Bragg deflectors the power required for 70-percent deflection P_0 is given by [3]

$$P_0 = \frac{2\lambda_0^2}{\pi^2}\frac{H}{L}\frac{1}{M_{2\text{eff}}} \tag{1}$$

where L is the length of interaction, H is the depth of the sound wave, and λ_0 is the optical wavelength. The quantity $M_{2\text{eff}}$ is the effective acoustooptic figure of merit analogous to M_2 for bulk deflectors, but in addition to material properties it must also include the overlap integral of the acoustic and optical fields [3], [4]. For an efficient interaction requiring low drive power one desires H to be as small as possible and L to be large.

Acoustic surface waves and guided optical waves provide an ideal means of satisfying these requirements. An acoustic surface wave is predominantly contained within an acoustic wavelength Λ of the surface. Thus $H \approx \Lambda$ is as small as can be obtained with focused bulk waves. But since the surface wave is trapped near the surface there is no difficulty which can arise from the sound-wave depth expanding due to diffraction when the optical beam is very wide.

Because guided optical waves are also trapped near the surface, typically within 1 μ of the surface, the light can be contained within a sound column of depth H for arbitrarily long lengths L. In the case of bulk devices a light beam can be focused to a spot of diameter H only for a short distance on the order of H^2/λ before diffraction expands the optical beam to a diameter larger than the sound-column depth. Since there are no diffraction limitations on a guided optical beam to keep it contained within the sound column, the interaction length for surface-wave deflectors is set by the bandwidth requirements of the deflector. For a 3-dB deflection bandwidth Δf the maximum interaction length over which the light and sound waves can be Bragg phase matched in the isotropic case is

$$L_{\max} = 1.8\frac{nV^2}{\lambda_0 f_0 \Delta f} \tag{2}$$

where V and f_0 are the acoustic velocity and center frequency, respectively, and n is the index of refraction of the acoustooptic medium [5]. The interaction length $L_{\max}$ can be much greater than the interaction length limited by optical diffraction in bulk deflectors. If acoustic beam-steering techniques [6], [7] are used, the interaction can be even longer than $L_{\max}$.

The acoustooptic deflector reported on in this correspondence is illustrated in Fig. 1. The crystal is a Y-cut slab of $LiNbO_3$ with the Z axis oriented along the propagation direction of the sound wave. The optical waveguide was formed by an in-diffusion technique [8] similar to that used to form Nb-diffused $LiTaO_3$ waveguides [9]. A 500-Å-thick Ti film was

Manuscript received August 19, 1974.

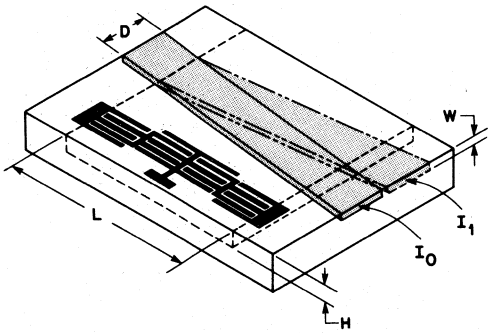

Fig. 1. Schematic of deflector illustrating optical beam of width D and sound beam of depth H and width L. Series-parallel connected transducer has center bonding pad wired to ground through inductor and outer two bonding pads wired together and connected to oscillator.

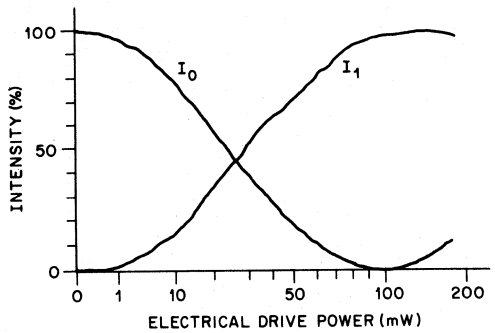

Fig. 2. Recorder trace of experimentally measured intensity of undeflected beam I_0 and deflected beam I_1 as a function of electrical drive power.

evaporated onto the Y-cut surface of a $LiNbO_3$ crystal and was heated for 6 h at 960°C in an argon atmosphere. However, no repoling was necessary since the diffusion took place below the Curie temperature. The waveguide whose losses were estimated to be approximately 1 dB/cm supported 4 TE modes and 1 TM mode. Each of the five modes could be excited independently with a prism coupler and there was insignificant scattering from one mode into the other modes. The waveguides were of good quality and confined the guided light to within 2 μ of the surface. The primary advantage of Ti-diffused waveguides for acoustooptic deflectors over out-diffused waveguides [10] is the tight surface confinement of the optical wave which allows the use of acoustic frequencies above 100 MHz.

A series-parallel connected interdigital transducer [11], illustrated in Fig. 1, was used in order to efficiently excite an acoustic surface wave over a long interaction length. This transducer consists of four 50-Ω, $4\frac{1}{2}$ finger-pair transducers which are series and parallel connected to give a transducer with 50-Ω input impedance, 175-MHz center frequency, and an active length L of 8.74 mm. This length corresponds to a 3-dB deflector bandwidth of 50-MHz as calculated from (2). The parameter $Q = 2\pi\lambda L/n\Lambda^2$ equals 40 indicating that the deflector is in the Bragg-deflection regime.

The efficiency of the deflector was measured by plotting the intensity of the undeflected and deflected optical beams as a function of electrical drive power. The results are presented in Fig. 2 for the TE_0 mode. Only 50 mW of electrical drive power are required for 70-percent deflection of the incident beam. The deflector had a measured 3-dB bandwidth of 30 MHz. This bandwidth is believed to be limited by the bandwidth of the transducer which had several broken electrodes. From measurements of the transducer input impedance the transduction loss was estimated to be greater than 7 dB indicating that less than 8 mW of acoustic power was necessary for 70-percent deflection. The higher order TE modes required slightly more drive power for a given deflection indicating a less efficient interaction geometry. When the TM_0 mode was launched, 140-mW electrical drive power gave 70-percent deflection. Presumably, this large increase in drive power is due to a smaller induced-index change in the ordinary index, which diffracts the TM mode, than in the extraordinary index which diffracts the TE modes.

The present deflector has ten resolvable spots with a 300-ns access time. The number of resolvable spots was limited by the width D over which a suitably uniform guided optical wave could be coupled into the waveguide with the available prism coupler arrangement, which was about 1 mm. However, the deflector has a time–bandwidth product which allows 300 resolvable spots with a 10-μs access time. Such performance would require an optical beamwidth of 35 mm. Such widths should be feasible if appropriate care is taken in coupling light into the deflector since Ti-diffused waveguides are extremely uniform and the guided light does not break up into filaments as is characteristic of many sputtered thin-film guides.

Optical damage may limit the optical power through the Ti-diffused $LiNbO_3$ deflector. For 6328-Å light, Ti-diffused waveguides normally show no signs of optical damage with power densities on the order of 5000 W/cm^2, but in some waveguides, similarly fabricated, rapid damage has been observed with power densities as low as 100 W/cm^2. The source of this optical damage is not understood and further work is necessary to determine the limitations on Ti-diffused $LiNbO_3$ waveguides set by optical damage.

In conclusion, an efficient acoustooptic deflector has been demonstrated on a $LiNbO_3$ crystal whose acoustooptic figure

of merit is approximately 100 times smaller than that of TeO_2. Such performance has been obtained by utilizing guided optical waves and acoustic surface waves which allow a more efficient interaction geometry than can be obtained in bulk deflectors. When optical waveguides become available on high acousto-optic figure-of-merit crystals such as TeO_2 one can expect even further reduction in electrical drive power.

Mode Locking the Nd:Glass Laser with BDN: Measurements of Dye Recovery Times and Laser Pulse Lengths

R. C. GREENHOW AND A. J. STREET

***Abstract*—The recovery times for transient bleaching of the *Q*-switch dye bis(4-dimethylaminodithiobenzil)nickel (BDN) in the solvents dichlorethane and iodoethane have been determined. The lengths of pulses from an Nd:glass laser mode locked with BDN have also been measured by means of the two-photon fluorescence technique.**

A new dye, bis(4-dimethylaminodithiobenzil)nickel (or BDN), has recently emerged for *Q* switching the Nd:glass laser [1], which has the advantage over Kodak dyes 9860 and 9470 of being extremely stable. Compared with the latter dyes, however, which have lifetimes of 7 ± 1 ps and 11 ± 1 ps, respectively [2], BDN has a much longer lifetime, which varies markedly with solvent. In chloroform it is 6.2 ± 1.6 ns and in carbon disulphide it is 1.5 ± 0.2 ns [3]. In these solvents, therefore, the dye is ineffective in mode locking, although strongly modulated emission is observed in a proportion of cases [3]. New solvents have now been found which reduce the recovery time to such an extent that clean mode-locked pulse trains may be recorded on an oscilloscope [4]. One class of solvent, exemplified by iodoethane, is effective on account of the heavy-atom substituent (iodine), while another class, exemplified by methyl sulfoxide, is effective because of non-bonding (n^-) electron pairs [4].

We have measured the length of pulses from an Nd:glass laser mode locked with BDN in iodoethane, using the two-photon fluorescence (TPF) method [5]. We have also determined the decay times of transient bleaching of BDN in dichlorethane and in iodoethane.

The laser consisted of a $4\frac{1}{2} \times \frac{3}{8}$-in Brewster-angled, helically pumped Nd:glass rod in a plane-parallel cavity incorporating a +4-m lens. A 1-mm flowing dye cell was in contact with the 70-percent reflectivity output mirror. Using Kodak 9860 dye this laser produced clean pulse trains with 95-percent reliability. Measurements of TPF tracks in rhodamine 6G indicated pulse lengths between 5 and 10 ps with contrast ratios up to 2.7. Typically, the linear transmission of the dye cell was 80 percent, and the pulse-train length was 200–300 ns with about 3 mJ in each pulse. With BDN in iodoethane the dye-cell transmission used was 50 percent, and the pulse trains were about 50 ns long with up to 10 mJ in each pulse.

The TPF patterns observed when mode locking with BDN varied considerably. Frequently, an apparently good pulse train as seen on an oscilloscope failed to yield a recognizable pulse in the TPF cell—presumably because the pulses were very long ($\gtrsim 150$ ps). Others showed clear evidence of close satellite pulses. A number showed the broad, smooth shoulder with narrow "coherence spike" expected for a non-transform-limited (noisy) pulse.

A pulse train consisting of bursts of noise with zero intensity between pulses would give a TPF pattern with peak-to-shoulder-to-background ratios of 3:2:1 [6]. Even though the the 3:1 ratio was not observed for experimental reasons, one would still expect 2:1 for the shoulder-to-background ratio. In practice we observe, typically, 2:1.6:1 from which we deduce that there must be substantial energy between the pulses.

Pulse lengths measured (full width at half shoulder height of the TPF trace) were between 25 and 70 ps, although much longer pulses occur. Gillman and Dewhurst have used BDN to mode lock an Nd:YAG laser, the resulting pulses being 50 ± 10 ps long, as measured by two-photon fluorescence [7].

Measurements of the recovery times of transiently bleached BDN were made using the Nd:glass laser mode locked with Kodak 9860. For BDN in dichlorethane the method of [8] was used, in which the integrated transmission of an entire pulse train was measured as a function of delay time between bleaching and sampling pulses. This yielded the recovery time of 2.2 ± 0.4 ns. For BDN in iodoethane the technique of [2] was employed, in which bleaching due to individual pulses, selected from the beginning of the pulse train and with intensities uniform to within 10 percent, was measured, again as a function of probe-pulse delay time. A recovery curve is shown in Fig. 1. Each point is an average of up to eight measurements, and the errors shown are standard deviations. The recovery time as determined from the curve by means of a Swinbourne plot [9] was found to be 90 ± 20 ps. These measurements correlate well with the observed mode-locking performance.

We conclude that BDN is of limited use in mode locking the Nd:glass laser. It does provide a means of generating ~50-ps pulses, but the occurrence of clean pulse trains is less reliable and the lengths of the pulses more erratic than with Kodak 9860. The situation could probably be improved by reducing the oscillating bandwidth. This would not only result in the possibility of smooth transform-limited pulses, but, according to [10], would greatly increase the reliability of generation.

Manuscript received August 26, 1974.
The authors are with the Department of Physics, University of York, Heslington, York, England.

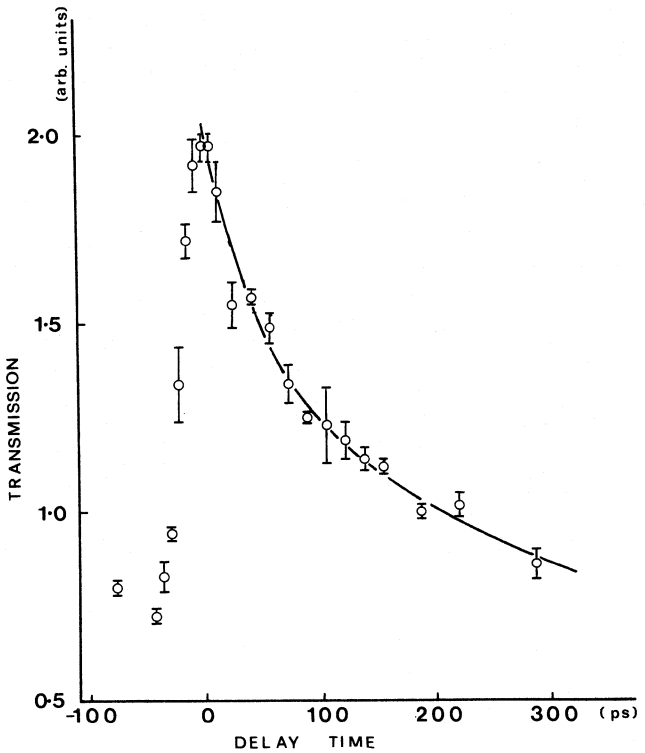

Fig. 1. Transmission of BDN in iodoethane as a function of delay time after bleaching pulse.

In this connection it is interesting to note that the Nd:YAG laser [7] with its smaller bandwidth, was much more reliable in its operation.

A disadvantage of BDN is that the pulses generated are much more destructive to the mirrors and the laser rod itself than the shorter pulses produced with Kodak 9860.

ACKNOWLEDGMENT

The authors wish to thank B. Knight of the Chemistry Department, University of York, for his synthesis of the BDN dye used in these experiments.

Near-Infrared Dye Laser Emission from Ultraviolet Nitrogen-Laser-Pumped Dye Solutions

CHINLON LIN

Abstract—**We report "superradiant" near-IR dye laser emission, with peak of emission in the 690–930-nm range, from nitrogen-laser (λ = 337-nm)-pumped dye solutions including aluminum phthalocyanine chloride and seven polymethine cyanine dyes.**

Recently, Hilderbrand [1] reported near-IR dye laser emission from several polymethine dyes directly pumped by UV nitrogen-laser radiation. With a 100-kW N_2 laser he was able to obtain stimulated emission for highly concentrated dye solutions (10^{-1} M) in a cavity. The peaks of emission were in the 43–928-nm range.

In this note we report the observation of "superradiant" emission from eight dyes, including six of those reported in [1], using direct UV pumping by a 400-kW nitrogen laser. As shown in Table I the emission peaks fall within the range 690–930 nm, and have bandwidths of 20 to 30 nm. It may be noted that for the six dyes [dyes 2)–7)] which were also reported in [1], the emission peaks all occur at shorter wavelengths than listed in [1]. This is no doubt due to the much lower concentrations used here (5×10^{-4} M versus 10^{-1} M) and to the different solvent (acetone versus methyl sulfoxide). Dyes 1) and 8) have not been previously reported with direct UV pumping.

TABLE I
LIST OF DYE SOLUTION AND PEAK WAVELENGTHS OF SUPERRADIANT EMISSION[a]

	Dye/Solvent	Concentration	λ Peak
1)	Aluminum Phthalocyanine Chloride/methanol	10^{-3}M	690 nm
2)	3,3'-Diethyl-2,2'-thiadicarbocyanine iodide/acetone	2.5×10^{-4}M	695 nm
3)	3,3'-Diethyl-10-chloro-2,2'-(5,6,5',6'-dibenzo) thiadicarbocyanine iodide/acetone	2.5×10^{-4}M	720 nm
4)	3,3'-Diethyl-2,2'-oxatricarbocyanine iodide/acetone	5×10^{-4}M	770 nm
5)	3,3'-Diethyl-2,2'-thiatricarbocyanine iodide/acetone (DTTC iodide)	5×10^{-4}M	820 nm
6)	1,3,3,1',3',3'-Hexamethyl-2,2'-indotricarbocyanine iodide/acetone	5×10^{-4}M	840 nm
7)	3,3'-Diethyl-2,2'-(4,5,4',5'-dibenzo) thiatricarbocyanine iodide/acetone	5×10^{-4}M	870 nm
8)	1,1'-Diethyl-4,4'-dicarbocyanine iodide/methyl sulfoxide	10^{-3}M	930 nm

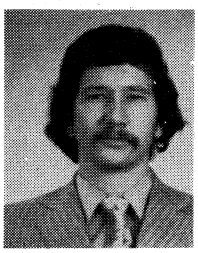
Gerard Mourou was born in Albertville, France, on June 22, 1944. He received the *licence de physique* degree from the University of Grenoble, Grenoble, France, in 1967, the *doctorat de 3ième cycle* and the *doctorat d'état* degrees from the University of Paris, Paris, France, in 1970 and 1973, respectively.

In 1968 he joined the Laboratoire Vignal de l'Ecole Polytechnique, France, where he did research on the frequency shift in Q-shifted ruby lasers. In 1970 he went to Laval University, where he was involved in measuring short fluorescence-decay time and nonlinear effects in saturable absorbers. In 1974 he joined the faculty at San Diego State University, San Diego, Calif.



Eric R. Wooding received the B.Sc. degree in 1948 and the Ph.D. degree in 1953, both from Imperial College, University of London, London, England.

From 1956 to 1960 he carried out research at the University of Sheffield, and then spent a year in the Engineering Science Laboratory at Oxford. From 1961 to 1966 he lectured in Electronic Physics at the University College of Wales, Aberystwyth. Since that time he has been Reader in Experimental Physics at Royal Holloway College, University of London. His main interest is in plasma physics, and he has collaborated with Culham Laboratory, UKAEA, on laser diagnostics for plasmas.

Dr. Wooding is a fellow of the Institute of Physics.

*

Michael L. Yeoman was born in the Principality of Wales on May 1, 1944. He received the B.S. degree in physics with honors from Swansea University, Swansea, Wales, in 1965. He then became a postgraduate student in Imperial College, University of London, London, England, where his masters degree was concerned with superconductivity and the science of materials, and his Ph.D. dissertation examined the effect of applied pressure and neutron irradiation on the electronic properties of the semimetal graphite.

On leaving Imperial College he joined the University of London as a Senior Research Fellow attached to the UKAEA Culham Laboratory for Plasma and Nuclear Fusion Research. His research work has included the use and development of novel laser diagnostic techniques for the observation of plasma parameters. He was involved in the development of a homodyne detection system for the study of laser light scattered by waves in a high-temperature plasma, and in tailoring the output of a Q-switched ruby laser in a controlled fashion. He is currently employed at AERE Harwell, Oxon., England.

Dr. Yeoman is an associate member of the Institute of Physics.

GaAs-Double-Heterostructure Lasers as Optical Amplifiers

D. SCHICKETANZ AND G. ZEIDLER

Abstract—**The results of measurements on a GaAs-double-heterostructure (DHS) laser used as an optical amplifier are reported. The laser's amplifying guide is coupled to an optical fiber with a rectangular core. The laser amplifier can be operated either in the traveling-wave or the resonator mode. The gain, noise, and performance of the amplifier when driven hard into saturation were measured as a function of various parameters.**

I. Introduction

MASER and laser amplifiers are, by accepted definition, simple configurations for the direct low-noise amplification of electromagnetic signals [1]. The intrinsic noise of such amplifiers when used to amplify optical signals may be so low as to be determined solely by fluctuations caused by the quantum nature of the optical power. Thus the recent development of low-loss optical fibers poses the question as to the possible use of laser amplifiers in fiber optic communications systems. Theoretical studies in [2] and [3] showed that even simple laser amplifiers can be meaningfully employed in fiber optic communications systems. First of all, they could be used in simple communications systems comprising only about 10–20 cascaded repeater sections with optical amplifiers, or in systems in which the pulse signal is regenerated 100 percent after passing through a few line sections with optical analog amplifiers in the baseband (hybrid-digital system).

Nonlinear laser amplifiers can be realized by, say, combining a laser amplifier with a saturable absorber. Such a configuration is capable of both amplifying pulses and regenerating them in their duration [4], so allowing the cascading of numerous optical repeater sections. Ultimately, it is to be expected that further work on integrated optics will result in the integration of laser amplifiers in a complex optical circuit configuration which directly performs all the functions of a regenerative baseband repeater also at optical frequencies.

These applications demand laser amplifiers of short structure which provide large gain accompanied by good pump efficiency. Of the amplifiers investigated so far, those with optically pumped solid-state lasers [5] and gas lasers [6] are too large, while the semiconductor laser amplifiers [7]–[9] satisfactorily meet the preceding demand. The amplifiers described in [7]–[9] were built with diffused GaAs laser diodes which were run cooled to the temperature of liquid nitrogen. For fiber optic systems [3], [10], on the other hand, double-heterostructure (DHS) diodes were used which can be run at room temperature [11] and whose optical amplification takes place in a dielectric guide that can be coupled to the guide of the fiber.

The present work will report the results of further measurements on this amplifier.

Manuscript received June 26, 1974; revised October 8, 1974. This work was supported by the Technological Program of the Federal Department of Research and Technology of the Federal Republic of Germany. The authors alone are responsible for the contents.

The authors are with Siemens Research Laboratories, Munich, Germany.

II. Experimental Configuration

Optical fibers usually have a core of circular cross section, whereas the amplifying guide in a GaAs-DHS laser diode has a flat rectangular cross section (e.g., 0.5 by 30 μm). In order to be able to use this laser diode as an amplifier in a fiber optic communications system, both guides have to be intercoupled. To avoid complicated optical systems (e.g., cylindrical lenses), we chose an optical fiber with a rectangular core as in [3], [10]. Fibers with this core cross section can be reliably fabricated by stretching appropriate preforms to fine fibers. Since the fibers used in the experiment were fabricated from commercial glass stock, the loss was rather high (about 500 dB/km) and we were only able to experiment with relatively short lengths of fiber. The coupling efficiency for intercoupling dielectric guides with a core of rectangular cross section was calculated in [12]. Relatively high efficiency (80 percent) is realized with a glass-to-GaAs interface if both guides have roughly the same core cross section. This simple possibility of coupling the fiber to the active guide of GaAs laser diodes (or to any other stripline in integrated optical systems) suggests two possible solutions, one being to use a fiber with a rectangular core cross section throughout the entire communications system and the other to splice lengths of fiber with a smooth tapered transition from a rectangular to a circular core to fibers with the conventional core cross section.

Fig. 1 shows the elementary configuration for this type of coupling and Fig. 2 the cross section of one of the fibers used. The fiber was scored and then broken. For coupling the fiber to the laser diodes, its ends were adjusted to within 0.1 μm with a piezoelectric drive. When coupling the fiber to the laser transmitter, the optical power in the fiber was measured with a photodetector and adjusted to maximum. When coupling the fiber to the amplifier, the amplifier output was observed through a microscope attached to a TV camera. Fig. 3 shows the coupling process. As the fiber is moved nearer to the laser diode, optical power is first coupled into all epitaxial layers of the laser diode (top photograph). When the fiber is almost touching the diode, the optical power enters only one guide. Given proper adjustment, this will be the amplifying guide (bottom photograph). During the adjustment of the optical fiber of both the laser and the amplifier, a droplet of immersion fluid or adhesive was added to improve the coupling efficiency. The coupling efficiency depends according to

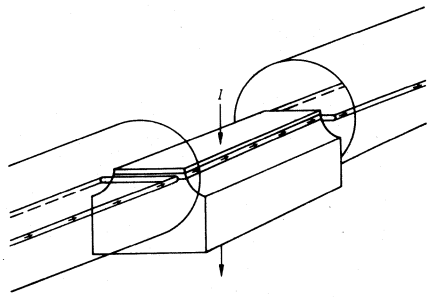

Fig. 1. Experimental configuration.

Fig. 2. Cross section of an optical fiber.

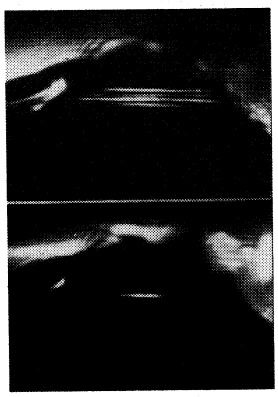

Fig. 3. Near-field of laser amplifier before and after it is coupled to the fiber. Top photograph: Fiber is still out of contact with the laser. Bottom photograph: Fiber is in contact with laser and properly adjusted.

[12] on the core dimensions of the two guides. After coupling the fiber shown in Fig. 2 (core dimensions about 2 by 30 μm) to a laser amplifier with a guide thickness of 0.5 μm, we obtained a coupling efficiency of only just under 10 percent. This value could certainly be improved by matching the two cross sections more closely.

The following measurements were obtained using laser diodes which were not mounted to a perfect heat sink. Therefore, the diodes could not be pumped continuously and they were pulsed in synchronism at a duty cycle of 10 percent, using different transmitter pulsewidths between 1 and 100 ns. Since the temperature of the active region rises during the applied pump pulse, all the following measurements were performed at the same relative phase of the pulse train. For that reason the results should also apply to CW diodes. The diodes used in the experiments were of the mesa type with a length of 150 μm and a width of 80 μm. The threshold current density was in the range of 1500 A/cm^2.

III. Some Measurements on a Nonresonant Amplifier

Subsequent to the experiments reported in [3] and [10] several gain and noise measurements were performed on simple GaAs-DHS laser amplifiers. Since the diodes were immersed in a fluid (monobromnaphthalene) with a refractive index of $n = 1.68$, the amplifier could only be run below its oscillation threshold. The laser transmitter was pumped so far above threshold as to cause the launching of a large number of axial modes in a broad frequency band. Since the length of the amplifier's cavity differed from that of the laser, no matching occurred between the launched modes and the gain resonances occurring just below the threshold of the amplifier [see (4)] and a gain averaged over the various modes was observed. The gain was measured by mapping the amplifier output by way of a grating monochromator onto a photodetector. The sensor's output signal was displayed on a CRT screen with and without the amplifier pump current i. For the power amplification factor G, the following relation with the pump current i is to be expected from theory [13], [14]:

$$10 \log G = g = \beta_1 \cdot i^{\delta_1} - \gamma. \tag{1}$$

γ denotes the loss of the amplifier waveguide and the exponent δ_1 should be in the range of 1-3. Fig. 4 shows the measurement obtained. The gain g (in decibels) increases with the current according to a power law (1). Fig. 4 gives about $\delta_1 = 2.5$ for the exponent. The amplifier is driven into saturation by increasing the amplitude of the input signal. The detectable gain is then lower, but increases with the pump current by roughly the same exponent (Fig. 4).

A large gain bandwidth is to be expected in GaAs. The gain was measured as a function of the wavelength by adjusting the wavelength of the laser by way of the temperature. Since the wavelength of the laser shifts by about 0.34 nm/K, the wavelength of the laser could be shifted by about 24 nm by varying the laser temperature from -35 to +35°C. Fig. 5 shows the measurement. The amplification factor G remains much the same at this large wavelength range. The shape of the amplification band is somewhat asymmetrical. The wavelength of maximum gain coincides with that of the laser emission of the amplifier (arrow). Fig. 5 also shows the spontaneous optical power emission of the laser amplifier as a function of wavelength for three different pump currents. It will be noted that the bandwidth decreases with rising pump current, i.e., with increasing gain [15], and that the maximum of the spontaneous emission shifts relative to the maximum of the gain (for the same pump current) [14]. Since the spontaneous emission is responsible for the noise of the laser amplifier, the emission was first measured as a function of the pump current (Fig. 6). Theory [1] indicates that the amplified spontaneous optical power emission P at the amplifier output will increase with the gain according to the following relation:

$$P = P_s \cdot \frac{e^{g'} - 1}{g'}. \tag{2}$$

P_s denotes the (unamplified) spontaneous emission in all of

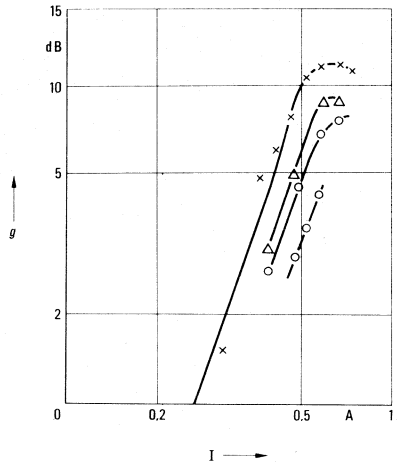

Fig. 4. Gain g as a function of the pump current i for input signals of various-size amplitude (saturation effect).

the modes covered by the measurements and g' the gain in Np ($g' = 0.1 \cdot g \cdot \ln 10$).

If the values calculated for g (or g') with (1) are substituted in (2) and compared with the measurement (Fig. 6) it will be noted that the abrupt rise in spontaneous emission is expressed well by the simple formulas (1) and (2). For small values of gain the relation (2) is reduced to $P \approx P_s$. For small amplifier pump currents it is accordingly possible to determine the dependence of P_s on the pump current i from Fig. 6. It may also be determined empirically from Fig. 6 that P_s likewise rises with the current according to a power law

$$P_s = \beta_2 \cdot i^{\delta_2}. \tag{3}$$

The measurements show the simple formulas (1)-(3) to describe with sufficient exactitude the performance of the amplifier as a function of the pump current. Since both power and exponential laws are effective, the pump current must be carefully regulated in order to assure stable parameters. Although the spontaneous emission is responsible for the amplifier noise, its mean value must not be confused with the noise power common to any communications system.

In a fiber optic communications system it is (especially with pulse code transmission) readily possible to slice off dc components at the photosensor so that the detector does not respond to the temporarily constant spontaneous emission. The noise added to the signal by the amplifier is then manifested by the increased amplitude fluctuations of the optical signal [3]. If the mean value is denoted n and the variance of the photon count during a scanning interval is denoted σ, the signal-to-noise ratio (SNR) will, assuming an ideal square-law photon counter, be given by

$$\frac{S}{N} = \left(\frac{n}{\sigma}\right)^2. \tag{4}$$

This relation can be measured with a real photon counter if the mean value and the variance of the signal are considerably larger than the intrinsic noise of the detector. For one measurement the laser was for this purpose run such that the generated optical pulses exhibited a fluctuating amplitude and lay considerably above the noise of the detector. By using a silicon photodiode it was possible to measure both the mean value and the amplitude fluctuation of these pulses. The results were used to determine the SNR with the amplifier on and off, and the noise figure was determined therefrom in the conventional manner. Fig. 7 shows the noise figure as a function of the gain. For the foregoing measurement the amplifier was driven harder towards saturation because, according to [16], a reduction in noise with nonlinear signal distortion is to be expected at saturation. This effect is clearly evident from the measurement curve. First the noise figure rises steadily with the gain [3], but falls off as saturation is reached. With this decreased noise figure, considerably more repeater sections can be cascaded as calculated in [2], [3] for a linear amplifier. Although the duration of the pulses used for this measurement was only of the order of nanoseconds, no serious pulse distortion was observed. The measurements show clearly that for pulse code modulation it is always recommendable to

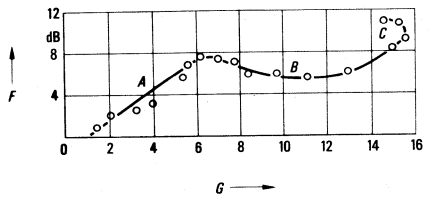

Fig. 7. Noise figure F as a function of the gain near to saturation. (a) Linear region. (b) Saturation. (c) Threshold.

drive the amplifier into saturation. The amplifier then exhibits, besides an improved noise figure, an overall efficiency which our measurements, as well as [7]-[9], show to approach that of the GaAs laser (about 0.2 W/A).

IV. Measurements on a Resonant Amplifier

When feedback is introduced into a laser amplifier, the traveling-wave amplifier becomes a resonant amplifier. Within the gain bandwidth of the laser material, the gain exhibits pronounced maxima and minima as a function of the frequency. The feedback can be produced by a periodic perturbation of the system [17] or by reflections at the unmatched end faces of the laser material [5]. In the latter case the power gain G_R of the resonant amplifier [18] is defined

$$G_R = \frac{T_1 \cdot T_2 \cdot G}{(1 - G \cdot \sqrt{R_1 R_2})^2 + 4G\sqrt{R_1 R_2} \cdot \sin^2 \phi} \tag{5}$$

where G denotes the amplification factor with which the optical power is amplified during a single passage through the laser material, R_1, R_2 denote the reflection coefficients, and T_1, T_2 denote the transmission factors for the optical power at the two end faces. $\phi = 2\pi L/\lambda = \omega L/c$ is the phase of a wave after passage through a laser material of the length L. The gain maxima are calculated with (5) for $\sin \phi = 0$, which may be ascribed to the known resonance condition of the Fabry-Perot cavity. The maximum gain approaches infinity when $G \cdot \sqrt{R_1 R_2}$ approaches unity, e.g., when the laser amplifier approaches its oscillation threshold. The periodic gain bands appearing due to (5) become steadily narrower.

A resonant amplifier offers the advantage that large gain is realized in what for optical frequencies is a narrow band (the noise filters added are of simpler design). It is, however, a drawback that even minor fluctuations may cause gain irregularities and that in a communication system the transmit frequency must coincide with one of the resonant frequencies of each amplifier.

For our measurements we brought the optical fibers close to the end faces of the GaAs laser material without immersion so that a thin layer of air provided sufficient reflectivity. Only laser and amplifier diodes of approximately equal length (and consequently approximately the same frequency separation between resonances) were chosen. The operating temperature was regulated such that the resonances in both the laser and the amplifier appeared at the same frequencies. This frequency matching was easily verifiable because the gain was at maximum. Fig. 8 shows the correspondingly adjusted maximum gain $G_{R\max}$ of the resonant amplifier as a function of the pump current. If the empirically determined gain for one

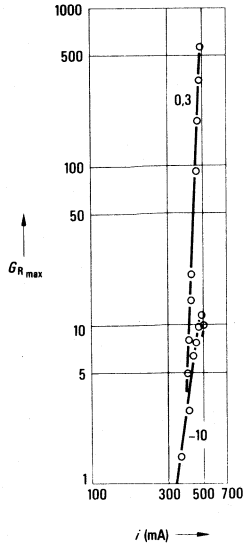

Fig. 8. Maximum amplification factor $G_{R\max}$ of resonant amplifier as a function of the pump current for 2 different input levels.

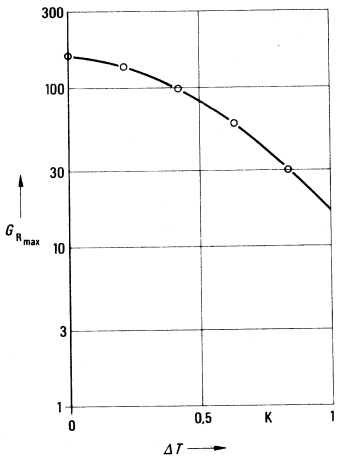

Fig. 9. Decrease in gain $G_{R\max}$ with temperature detuning T resonant amplifier.

passage through the amplifier is taken from Fig. 4 and substituted for G in (5), the maximum gain $G_{R\max}$ is found to agree well with the measurements in Fig. 8. Fig. 9 shows the described frequency matching by way of the temperature for a medium gain. If the temperature scale of Fig. 9 is converted with the aid of the length of the resonator into a frequency shift of the resonances, it is found that the frequency dependence so obtained approximately agrees with the shape of the amplification band which can be calculated with (5). It can further be determined from Fig. 9 that the temperature must be maintained constant at about ±0.4 K if the permissible fluctuation of the amplification factor is 30 percent. According to Fig. 7 the pump current must be maintained constant at ±0.4 percent for the same percentage fluctuation. Although it is essentially possible to realize amplification factors of over 1000 with a resonant amplifier, it is doubtless practical not to go beyond 100 in a communications system because the cost for the avoidance of instabilities would otherwise be excessive. Fig. 10 shows the performance of the resonant amplifier when

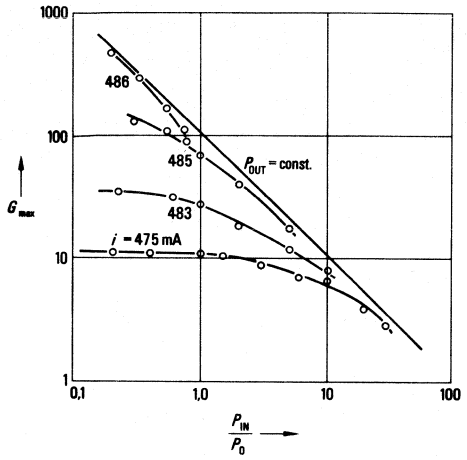

Fig. 10. Saturation of resonant amplifier. Gain G_{max} versus input power P_{in}/P_0 for various pump levels.

driven into saturation. The maximum gain is plotted as a function of the input power. The gain decreases at high input powers due to saturation. The limiting curve for various pump currents is shown as a curve of constant output power.

V. Conclusion

GaAs-DHS laser diodes can be used in fiber optic communications systems along with the coupling technique described. The laser diode can be run either in the traveling-wave or the resonant mode. In a communications system with pulse modulation techniques it is preferable to drive the laser line amplifier hard into saturation because of better noise performance and the higher efficiency. A combination of further accessories is required in order to allow the versatile use of this amplifier in fiber optic systems. Narrow-band filters, circulators, and nonlinear optical devices are here of special importance.

Amplification and Excited State Absorption in Longitudinally Pumped Laser Dyes

ROBERT F. LEHENY, MEMBER, IEEE, AND JAGDEEP SHAH

Abstract—**Direct measurements of optical gain using a probe laser beam for the laser dye cresyl violet perchlorate (CVP) in methanol solution using longitudinal pumping at two different wavelengths are described. An analysis of these longitudinal pumping experiments is developed and analytical expressions relating measured gain to the measured pump laser transmission are presented. This analysis is developed in terms of relevant optical cross sections including the influence of excited state absorption. The results demonstrate the influence of excited state absorption at the pump wavelength on pumping efficiency and on the gain per pass at the probe laser wavelength.**

I. Introduction

THERE has been continued interest in the direct measurement of optical gain in dye systems since the original measurements of Huth on flashlamp pumped rhodamine 6G [1]. Since then, gain measurements have been extended to a number of other dye systems by the use of laser pumping [2]. Gillard *et al.* [3] have demonstrated saturation of small signal gain at high pumping intensities. In general, the detailed analysis of such measurements is complicated by inhomogeneous pumping of the dye and the possible effects of excited singlet state absorption (ESA), an effect that has not been widely discussed for laser dyes [4]. In this paper we demonstrate that these factors can be accounted for by coupling measurements of the saturable absorption parameters at the pump laser wavelength with measurements of small signal amplification. To illustrate the analysis we report measurements for cresyl violet perchlorate (CVP) in methanol solution, a dye which has been shown to be efficient for use in the 6500-6800-Å region [5]. We have previously described measurements of the ESA spectrum in the range 2-2.7 eV for this dye and demonstrate here how this phenomenon influences the efficiency for pumping the dye [4]. We also determine that ESA significantly reduces the effective cross section for stimulated emission.

In Section II we describe the measurements. We consider saturable absorption of the dye solution at two pump wavelengths, first, at the absorption peak for ground state absorption in CVP [Fig. 1(a)], and second, at a shorter wavelength for which significant excited state absorption [Fig. 1(b)] occurs. For these cases we describe separate measurement of small signal amplification of a probe laser tuned to the CVP fluorescence peak. In the presence of excited state absorption there are alternative absorption processes corresponding to transitions between excited states and higher energy states [Fig. 1(c)]. The importance of these processes depends on

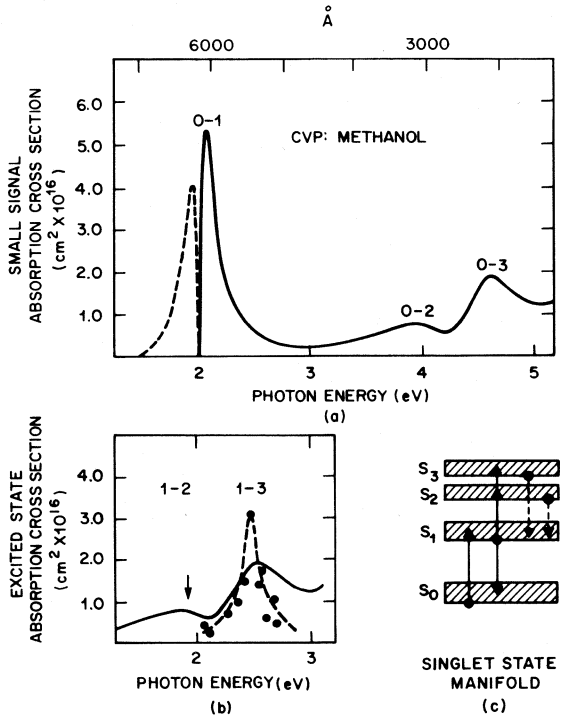

Fig. 1. (a) Low intensity absorption spectra for CVP in methanol solution. The dotted curve indicates the fluorescence spectra measured for the same solution. The index 0–*N* identifies initial and final singlet state electronic levels contributing to the observed absorption peak. (b) Excited state absorption spectra for CVP. The dotted curve indicates the measured variation in the range 2–2.7 eV while the solid curve was determined by assuming that the initial state for the ESA transitions corresponds to the peak of the 0–1 absorption of Fig. 1(a) and then translating the higher energy portion of that spectrum to lower energy. The arrow indicates the energy of the probe laser used to measure amplification. (c) Schematic representation of the assumed level structure for the singlet state manifold. Rapid internal conversion is assumed to leave the electron in the lowest vibrational level of the first singlet state, from which fluorescence occurs.

the wavelength dependent cross section for transitions between the excited states and the fraction of dye molecules that are excited. At the *pump* wavelength, excited state absorption competes with absorption from the ground state so as to reduce the effective pumping of the dye; at the *lasing* wavelength, excited state absorption competes directly with the stimulated emission process, reducing the effective cross section for stimulated emission.

At all pump levels the average small signal gain per pass through the pumped region is proportional to the number of molecules in the first excited state. For low input flux the dominant absorption process is described by Beer's law, for which the density of excited molecules varies exponentially along the pumping beam path. In this limit the calculation of net gain per pass $\bar{g} \equiv (1/L) \int_0^L g(x)\,dx$ is relatively straight-

forward. As the fraction of dye molecules in the excited state increases, deviations from Beer's law make determination of gain $g(x)$ at every point in the beam difficult. In Section III we demonstrate that, if only the net gain per pass $\bar{g}$ and not $g(x)$ is required, numerical computations can be avoided. The results of this analysis are general and we illustrate their utility by quantitatively determining the relevant absorption and stimulated emission cross sections for CVP.

II. Measurements

The CVP dye was obtained from Eastman Kodak and used without further purification. Fig. 1 summarizes the absorption spectrum for this dye. The gain measurements were made by exciting a 1-mm path of 2.5×10^{-4}-M/l methanol solution of CVP with a pump laser beam and probing this excited dye with a second collinear probe laser. Generation of these separately tunable lasers was accomplished using a single N_2 laser as illustrated in Fig. 2. With the 100-kW output of the N_2 laser divided evenly, ~ 5 kW was available from each dye laser in a > 5-ns pulse. Up to 10–15 kW was obtained when the entire 100-kW output of the N_2 laser was used to excite the pump beam laser.

We show in Section III that the amplification through a longitudinally pumped dye cell can be calculated analytically provided the variation in transmission of the pump beam through the dye is known. Therefore, in this section, we first describe the measurement of saturable transmission parameters for CVP. Typical results are shown in Fig. 3 for two pump wavelengths. At $\lambda = 5975$ Å the dye transmission exhibits typical response for a saturable absorber, the transmission through the cell increases with increasing pump intensity. However, for the pump laser set to $\lambda = 5145$ Å, a wavelength for which the ground state absorption cross section is approximately an order of magnitude smaller than at 5975 Å, we find the transmission decreases with increasing incident intensity. This decrease results directly from excited state absorption [4].

That the decrease in transmission does not contribute to an increase in the number of dye molecules in the first excited singlet state is dramatically demonstrated by observing the fluorescence from the S_1 level as the sample is moved through the focus of the input lens. The luminescence from the dye is observed to decrease by as much as an order of magnitude as the absorption *increases*. The additional absorption results from cycling the dye molecules between S_1 and higher levels with a net decrease in the number of molecules in the S_1 state [6].

We now consider the measurement of small signal amplification. The probe laser was generated by longitudinally pumping a separate CVP dye cell with the output of an untuned laser operated at $\lambda \sim 5700$ Å. In this way the available gain could be saturated so that the CVP laser operated close to the peak of the CVP fluorescence ($\lambda \sim 6375$ Å). The output of this laser was filtered and attenuated to a convenient level, then combined with the pump beam by means of a polarizing cube. The collinear beams were then focused onto the CVP sample cell and the transmitted light was collected with additional filtering to minimize the effect of fluorescence from the sample. The probe intensity was minimized to insure that saturation of the small signal amplification did not affect the measurements and care was taken to prevent the sample cell from lasing. The focused spot at the sample was ~ 50 μm in diameter for both beams and the intensity over this spot was relatively uniform. The output beams were apertured so that only the central overlapping portion was detected to minimize the possible effect of transverse intensity variations.

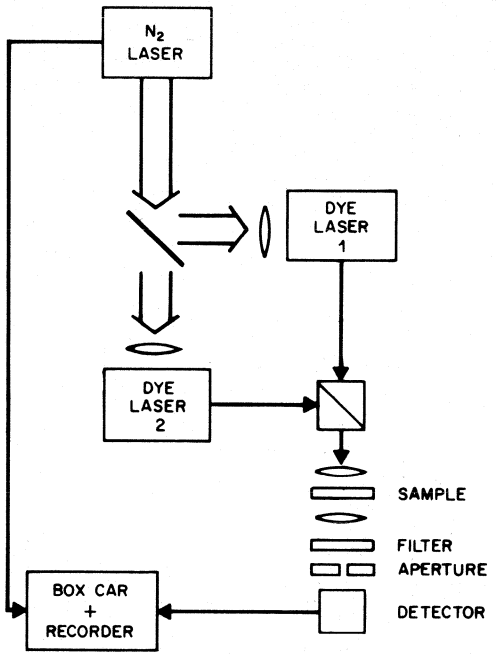

Fig. 2. Schematic of experiment. A polarizer in the pump laser cavity was set to polarize this laser's output to allow efficient beam combination in the polarizing cube. The output of the probe laser was filtered with a Kodak 2-60 filter, while the amplifier output was filtered with an Oriel f155 filter monochromator. A silicon cell detector was used.

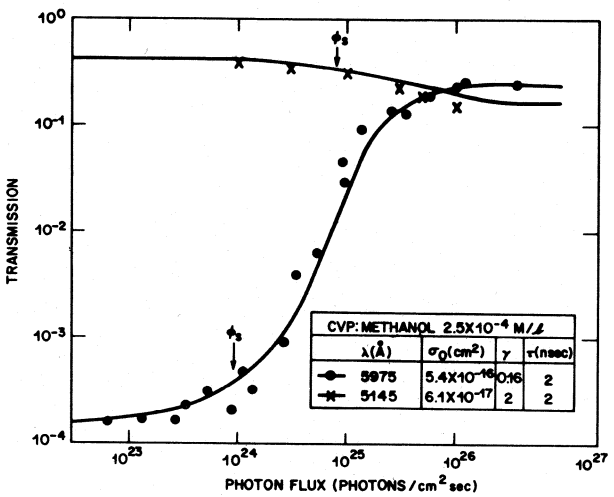

Fig. 3. Variation of transmission with input photon flux density through a 1-mm path length of 2.5×10^{-4}-M/l CVP for two wavelengths. The cross sections for small signal absorption were measured separately and are indicated on the figure. Values of γ and τ used in (4) of the text to compute the solid line are also indicated on the figure. The saturation photon flux density at each wavelength is indicated by an arrow.

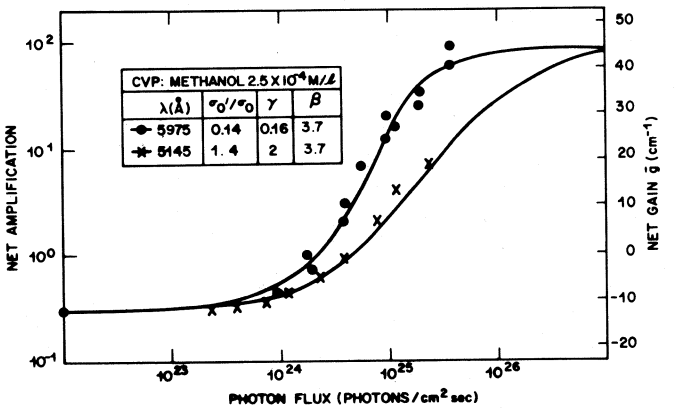

Fig. 4. Variation of net amplification with input photon flux density through a 1-mm path length of 2.5×10^{-4}-M/l CVP for a probe wavelength of 6357 Å and for two pump wavelengths. Values of β and σ_0'/σ_0 used in (8) of the text to compute the solid curves are indicated on the figure.

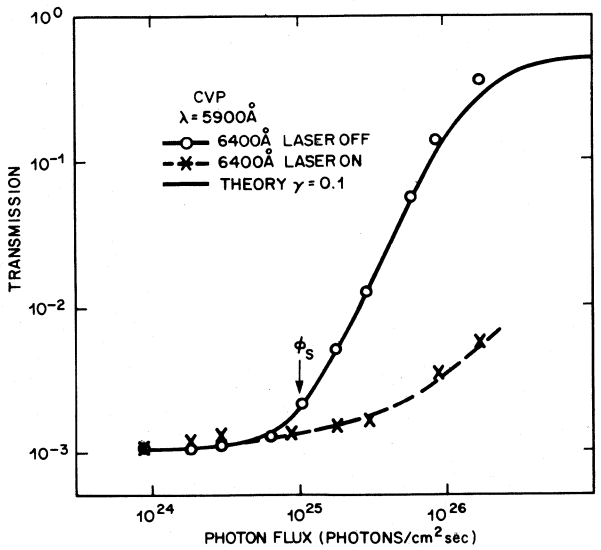

Fig. 5. Influence of an intense probe beam stimulating recombination on the saturation of transmission of a pump beam at 5900 Å. The solid line is a fit to the theory with $\tau = 2$ ns.

Typical results for the small signal amplification versus pump intensity are shown in Fig. 4. With a fraction of the N_2 laser diverted to pump the probe laser, the maximum available output from the pump beam was reduced somewhat over that available in the transmission measurement. The maximum net amplification measured for the 2.5×10^{-4}-M/l solution was $\sim 10^2$ ($\bar{g}l \sim 4.6$). Higher gains were observed for more highly concentrated solutions, but we experienced difficulty in maintaining linearity and in preventing the amplifier from oscillating.

The use of logarithmic scales in Fig. 4 tends to distort the apparent variation of gain with pump power. For low power the gain is found to increase linearly (a complete fit of the data to theory is described in Section III) reflecting the variation in absorbed power for small pump intensities. In this limit the small signal gain varies exponentially through the sample and this variation does not change with pump power. The principal effect of increasing pump power is a corresponding increase in the number of excited molecules. For the case of pumping at 5975 Å, saturation of the absorption at the input end of the cell results in more efficient pumping deeper into the sample with resultant continued increases of the gain until the entire sample is saturated. At 5145 Å, saturation of the input end results in less efficient pumping due to excited state absorption. While the presence of excited state absorption decreases the efficiency of pumping, it does not result in any net decrease in the S_1 population over the range of pump intensities available. The principal effect of excited state absorption is to reduce the differential efficiency for generating gain because of the additional absorption in the excited dye. For the conditions of our measurement we find at the highest pump intensity the available amplification at 5975 Å differs by an order of magnitude from that at 5145 Å, even though the absorbed powers are comparable.

As expected, increasing the probe laser intensity resulted in a decrease in the measured gain. This occurs when the signal flux is sufficient so that the rate of stimulated emission exceeds that of spontaneous emission. Then the relaxation of the excited state population is determined by the rate of stimulated emission, which results in a corresponding increase in the pump intensity required to saturate the absorption. The data shown in Fig. 5 for transmission versus pump intensity with and without the presence of a strong probe signal illustrate this effect.

III. Analysis and Discussion

In the limit of small signals the available amplification of a probe beam is proportional to the number of excited molecules it can interact with and the net cross section for stimulated emission. The analysis of amplification measurements therefore requires a determination of the distribution of excited molecules in the path of the probe laser beam which in turn is determined by the absorption of the pump beam. We analyze this interdependence by means of coupled equations governing the absorption of the pump beam and amplification of the probe beam.

Starting with the usual set of rate equations governing optical pumping for the level scheme illustrated in Fig. 1(c), and assuming the pump photon energy can excite an electron from S_1 to S_2, but that fast internal conversion occurs so that excitations from S_2 to higher states can be neglected, we have for the case of no transverse variation of the light beam:

$$\frac{dn_0}{dt} = \frac{n_1}{\tau} - n_0\sigma_0\phi$$

$$\frac{dn_1}{dt} = (n_0\sigma_0 - n_1\sigma_1)\phi - \frac{n_1}{\tau} + \frac{n_2}{\tau'}$$

$$\frac{dn_2}{dt} = -\frac{n_2}{\tau'} + n_1\sigma_1\phi, \qquad N = n_0 + n_1 + n_2 \tag{1}$$

with n_i the density of molecules in state i, N the total density, σ_i the cross section for absorption out of state i (at the pump wavelength), τ the time for relaxation between S_1 and S_0, and τ' the time for relaxation between S_2 and S_1. The incident

pump photon flux density is given by ϕ. For steady state,[1] and in the limit of $\tau' \ll \tau$ [7], these equations reduce to

$$n_1/n_0 = \phi/\phi_s$$
$$n_0/N = (1 + \phi/\phi_s)^{-1}. \quad (2)$$

For $\phi > \phi_s \equiv (\tau\sigma_0)^{-1}$, the saturation flux density, the number of molecules in the excited state, is greater than the number in the ground state, and absorption due to the ground state begins to decrease. The relative importance of excited state absorption depends on the magnitude of $n_1\sigma_1/n_0\sigma_0 \equiv \gamma\phi/\phi_s$ with $\gamma = \sigma_1/\sigma_0$. Writing for the pump beam absorption, $d\phi/dx = -(\sigma_0 n_0 + \sigma_1 n_1)\phi$ which from (2) can be written

$$\frac{dy}{dx} = -\alpha_0 y \frac{(1+\gamma y)}{1+y} \quad (3)$$

where $y = \phi/\phi_s$, $\alpha_0 = \sigma_0 N$, and x is distance into the cell. This relationship describes the saturable absorption in the dye as a function of the relative beam intensity y. For small y it reduces to the usual Beer's law expression $dy/dx = -\alpha_0 y$. At large y it again has this simple form with α_0 replaced by $N\sigma_1$, an absorption coefficient corresponding to the excited state absorption.

A number of investigators have discussed solutions to (3) with regard to saturable absorption in dyes [8]. The transmission (T) through a length of dye L, in terms of the normalized incident photon flux y_0, can be written

$$\left(\frac{1+\gamma y_0}{1+\gamma T y_0}\right)^{(1/\gamma)-1} = T/T_0 \quad (4)$$

with $T_0 = \exp -(N\sigma_0 L)$, the small signal transmission. This expression has been used to fit the data shown in Fig. 3 to obtain the solid curves shown in that figure. The data are fit with the choice of τ, γ indicated on the figure; σ_0 is determined from small signal absorption.

Analysis of the amplification measurement follows in a similar way. If we assume that Ψ, the probe beam photon flux, is small enough so that stimulated emission does not influence the relative population of excited and unexcited dye molecules, then (1)–(4) remain valid and the rate of increase of ψ with position is given by

$$\frac{d\psi}{dx} = (\sigma_s' n_1 - \sigma_0' n_0)\psi \equiv g(x)\psi(x) \quad (5)$$

with σ_s' the *net* cross section for stimulated emission ($\sigma_s' = \sigma_s - \sigma_1'$, the difference between the cross section for stimulated emission and that for excited state absorption at the *probe* wavelength) and σ_0' is the corresponding cross section for ground state absorption. Here n_1 and n_0 depend on the pump beam photon flux density according to (4). Expression (5) can be integrated to yield

$$\psi(L) = \psi(0) \exp \int_0^L g(x)\,dx = \psi(0) \exp \bar{g}L. \quad (6)$$

Direct evaluation of $\bar{g} = 1/L \int_0^L g(x)\,dx$ is quite complicated in general. Rewriting (5)

$$g(x) = \sigma_0'(\beta n_1 - n_0) = \sigma_0' N \left(\frac{\beta y - 1}{y+1}\right) \quad (7)$$

where $\beta = \sigma_s'/\sigma_0'$, and recognizing that the factor $(y+1)^{-1}$ also appears in (3), we can rewrite that expression to give

$$\frac{dy}{y}\left(\frac{1-\beta y}{1+\gamma y}\right) = \frac{\sigma_0}{\sigma_0'} g(x)\,dx. \quad (3')$$

Now this result can be directly integrated to give

$$\bar{g}L \equiv \int_0^L g(x)\,dx = \frac{\sigma_0'}{\sigma_0}\left[(1+\beta/\gamma)\ln\left(\frac{1+\gamma y_0}{1+T\gamma y_0}\right) + \ln T\right] \quad (8)$$

where T is given by (4). It is still necessary to solve (4) for T for each y_0 before $\bar{g}L$ can be determined from (8). However, the advantage of (8) is that it provides an analytic expression for the net amplification and eliminates the need for numerical integration of expression (5).

This result can be put in a more recognizable form if we assume $\gamma \to 0$ (no excited state absorption at the pump wavelength) then,

$$\bar{g}L = \frac{\sigma_s'}{\sigma_0}[(1-T)y_0 + (\ln T)/\beta] \quad (8a)$$

and in the limit that the pump beam absorption is not saturated, so that $T = \exp(-N\sigma_0 L)$.

$$\bar{g}L = \frac{\sigma_s'}{\sigma_0}(1-T)y_0 - \sigma_0' NL \quad (8b)$$

and finally, in the limit of small pump absorption, T becomes $1 - N\sigma_0 L$ giving

$$\bar{g}L = (\sigma_s' y_0 - \sigma_0')NL \quad (8c)$$

and the average gain is equal to the local gain.

The net amplification measurements shown in Fig. 4 were fitted to theory using (8) to obtain the solid curves shown on the figure. The procedure used was to first fit the transmission data shown in Fig. 3 to determine T versus ϕ and the parameters γ and ϕ_s. Using these parameters and T at each ϕ, (8) was used to determine $\bar{g}$. The only adjustable parameter in fitting the data in Fig. 4 is σ_s'. As indicated on the figure, the best fit is obtained with $\beta = 3.7$ which corresponds to a

[1] The principal conclusions concerning cross sections for various excited state processes obtained here result from determination of the properties of the dye when the density of excited molecules is saturated and do not depend on the details of how saturation is achieved. The rigorous use of steady state analysis in these pulsed experiments requires that the lifetime of the S_1 state be shorter than the pumping pulsewidth. We find our results can be fit with a 2-ns lifetime, while the laser pumping pulsewidth was > 5 ns. However, longer lifetimes (~ 4 ns) have been determined from fluorescence decay time measurements (E. P. Ippen, private communication). A detailed theory taking account of variations with time would be considerably more complicated than the analysis given here and we take the good agreement between our experimental results and the steady state theory in the range of pump intensities below saturation as evidence that the use of pumping pulsewidth comparable to the S_1 lifetime introduces no significant errors.

cross section $\sigma_s' \sim 2 \times 10^{-16}$ cm^2, a factor of 2 smaller than the cross section for absorption at 5975 Å.

Since the fluorescence spectrum mirrors the absorption spectrum for this dye, we expect that σ_s at the fluorescence peak should equal σ_0 at the absorption peak [9]. We attribute the measured difference to excited state absorption at the probe wavelength. Direct measurement of the ESA spectrum over the full range of photon energies for which stimulated emission can occur is not possible, since stimulated emission competes with this process [see (5)]. However, some estimate of excited state absorption in this energy range can be made from the high energy ground state absorption [Fig. 1(a)]; in particular, we can determine the energy difference between higher lying singlet states. In Fig. 1(a) we have labeled the various peaks in the absorption spectrum to indicate the index of the final electronic states involved. We have also previously described the measurement of the ESA spectrum in the range 2-2.7 eV, where we find a single peak at ~2.5 eV. If we take the peak of the 0-1 absorption as the initial energy for excited state absorption [10], then the peak at 2.5 eV in the ESA spectrum can be associated with transitions from the $n = 1 \rightarrow 3$ levels. With this assumption we have translated the high energy small signal absorption spectrum to lower energy and compared this translated spectrum to the measured ESA spectrum in Fig. 1(b). In this way we note that the contribution of the $n = 1 \rightarrow 2$ transitions should peak at ~1.9 eV or $\lambda = 6520$ Å (~600 meV below the $n = 1 \rightarrow 3$ peak) and therefore $n = 1 \rightarrow 2$ transitions can be expected to significantly reduce the net cross section for stimulated emission in CVP. While this procedure provides some information about the energies for which we expect ESA to be significant, our measurement of $\sigma's$ gives for the ESA cross section at 6375 Å, $\sigma' \sim 3 \times 10^{-16}$ cm^2 if we take $\sigma_s^{\text{theory}}(\lambda = 6375) = \sigma_0^{\text{mea}}(\lambda = 5975)$, and this value is a factor of 3 larger than the $n = 0 \rightarrow 2$ cross section. Since the initial states are different in each case some difference in absolute cross section is to be expected, and in fact we find the $n = 1 \rightarrow 3$ cross section is fifty percent larger than the $n = 0 \rightarrow 3$ [4]. More detailed measurements of the type described here would be required, over the entire gain spectrum, to provide complete data on the influence of ESA on the stimulated emission cross section.

IV. Summary and Conclusion

We have described the measurement and analysis of small signal gain measurements for the case of longitudinal pumping for the dye (CVP) in methanol solution. We have demonstrated that the influence of excited state absorption and absorption saturation effects can be accounted for by coupling measurements of saturable absorption parameters for the pump beam to the detailed measurements of optical gain. In this way we have demonstrated that excited state absorption at the pump can significantly influence the efficiency of stimulated emission. We have also shown how the influence of excited state absorption on stimulated emission can be determined from measurements of saturated gain. It is important to note that this last parameter affects not only the small signal gain coefficient, but also the losses in CW operation and thus the differential efficiency of the dye.

Acknowledgment

Analysis of Curved Optical Waveguides by Conformal Transformation

MORDEHAI HEIBLUM, STUDENT MEMBER, IEEE, AND JAY H. HARRIS, MEMBER, IEEE

Abstract—**The method of conformal transformations is applied to the analysis of waveguide bends. Equivalent structures are obtained that permit solution by traditional methods of optical waveguide analysis. Losses associated with both curvature and with the transition from straight to curved guides are discussed and simple first-order expressions that describe the dependence of the losses on waveguide parameters are derived.**

I. Introduction

CONFORMAL transformations provide a method for analyzing curved or otherwise varying waveguides that not only yields useful data concerning wave configurations and attenuation rates but also generates an equivalent structure whose properties may be readily appreciated on an intuitive level. Primary interest in this paper is centered on bend losses in curved waveguides. This determination is central to the design of integrated optical systems because switches and arrays of switches utilizing cylindrical waveguides require geometric displacements that are provided by bends.

The bend-loss problem has been previously investigated by Marcatili, Marcuse, and Lewin [1-a)-1-c)] using the established [2] technique of representing the field in the external region by a cylinder (Hankel) function of complex order and matching to fields in the guide that are assumed unperturbed from a straight guide. The transformations result in an analysis that differs from this previous work in that guides with a continuously varying refractive index such as diffused guides may be treated, in that radii of curvature need not be restricted to large values, and in that losses associated with a change in the direction of curvature required for a bend can be treated. Taylor [3] has also treated the bend problem using a computer-based analysis. Transformations not only provide an analytic approach but also avoid certain assumptions necessary for the efficient application of numerical methods.

Conformal transformations apply to solutions of the two-dimensional scalar wave equation

$$[\nabla_{x,y}^2 + k^2(x,y)]\psi = 0. \tag{1}$$

Solutions are obtained in a coordinate system u, v defined with respect to x and y by the relation

$$W = u + iv = f(Z) = f(x + iy) \tag{2}$$

where f is an analytic function. Expanding $\nabla_{x,y}^2$ in (1) with the aid of the Cauchy Riemann relations ($\partial u/\partial x = \partial v/\partial y$, $\partial u/\partial y = -\partial v/\partial x$), (1) may be expressed as

$$\left[\nabla_{u,v}^2 + \left|\frac{dZ}{dW}\right|^2 k^2(x(u,v), y(u,v))\right]\psi = 0 \tag{3}$$

where $|dW/dZ|^2 = (\partial u/\partial x)^2 + (\partial v/\partial x)^2$. Equation (3) is a well-known relation [4]. The objective of the transformation is to select an $f(Z)$ that converts curved boundaries in the x, y plane to straight ones in the u, v plane. Before discussing this matter further (see Section II) we wish to enumerate the kinds of integrated optical problems to which solutions to (1) are applicable.

1) TE mode on a planar guide. The guide is uniform in z with discrete or continuous index variation in x and y. The fields are constant in z and $\boldsymbol{E}$ has only a z component which we identify as ψ, i.e., $\boldsymbol{E} = \psi(x,y)\hat{z}$. Boundary conditions require continuity of ψ and $\nabla\psi$ and this continuity is maintained in the x, y plane if it is imposed in the u, v plane.

2) TM mode on a planar guide with discrete index variations and $\boldsymbol{H} = \psi(x,y)\hat{z}$. ψ is continuous and $(1/\epsilon)\nabla\psi$ is continuous.

3) TM mode on a planar guide with continuous index variation. In this case the wave equation for H_z is

$$[\nabla_{x,y}^2 + (\nabla_{x,y}\epsilon/\epsilon)\cdot\nabla_{x,y} + k^2(x,y)]H_z = 0 \tag{4}$$

and in the u, v coordinate system

$$[\nabla_{u,v}^2 + (\nabla_{u,v}\epsilon/\epsilon)\cdot\nabla_{u,v} + \left|\frac{dZ}{dW}\right|^2 k^2(x(u,v),y(u,v))]\psi = 0. \tag{5}$$

Although we concentrate on solutions to (1), the method of analysis is applicable to (4) or (5) as will be indicated.

4) Approximately applicable to cylindrical[1] waveguides that are uniform in the z direction. An example is a diffused waveguide [5] of rectangular cross section that undergoes a bend in the x, y plane. Using potential functions $A^{TE}(x,y,z)\hat{z}$ and $A^{TM}(x,y,z)\hat{z}$ that yield TE to z fields with $\boldsymbol{E} = \nabla \times A^{TE}\hat{z}$ and TM to z fields with $\boldsymbol{H} = \nabla \times A^{TM}\hat{z}$, approximate solutions to the wave equation can be expressed

$$A^{TM}(x,y,z) = g^{TM}(z)\psi(x,y). \tag{6}$$

For a guide centered about $y = 0$ and $z = 0$, $g(z)$ is a solution of

$$\left[\frac{\partial^2}{\partial z^2} + k^2(0,0,z)\right]g(z) = k_w^2 g(z) \tag{7}$$

where k_w is the wave-propagation constant for a planar guide. ψ is a solution of

[1] Also referred to as linear, two-dimensionally confined, and three-dimensional waveguides.

$$[\nabla^2_{x,y} + k^2(x, y, 0) - (k^2(0, 0, 0) - k_w^2)]\,\psi = 0. \quad (8)$$

We may identify (8) with (1) using a $k^2(x, y)$ in (1) that is modified by a constant. An equation of the form (5) results for A^{TE}. It is not our purpose to consider the approximation (6)–(8) in detail. This is a complex problem that has received only limited attention [6]. We wish merely to point out that within a customary approximation that derives from the field behavior in a rectangular waveguide with perfectly conducting walls, (1) may be employed to estimate the wave function in curved versions of such important integrated optical structures as diffused guides.

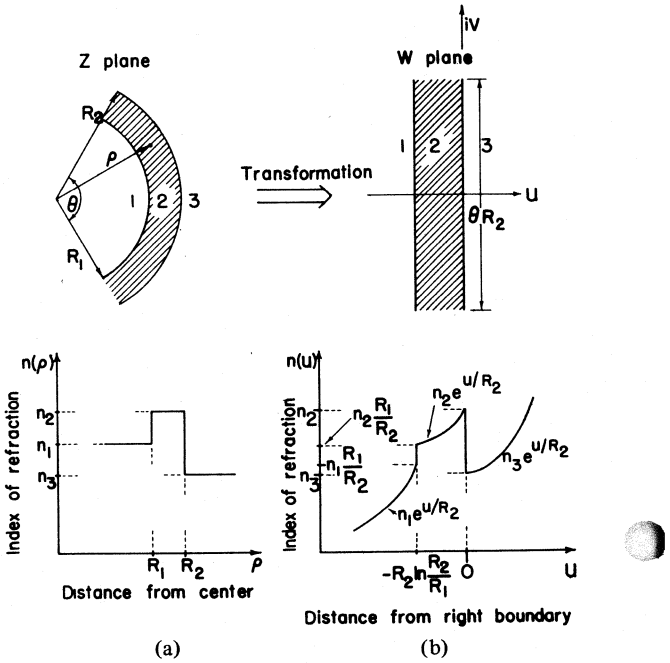
II. Equivalent Waveguide Structures

To illustrate the intuitive approach that conformal transformations provide, consider Fig. 1(a), which shows a circularly curved dielectric waveguide with a step discontinuity in refractive index at radii R_1 and R_2. Wave propagation along this structure is described by (1) in which $k^2(x, y)$ appears as a constant in each of the regions of the structure. Using the conformal transformation

$$W = R_2 \ln Z/R_2 \quad (9)$$

for which

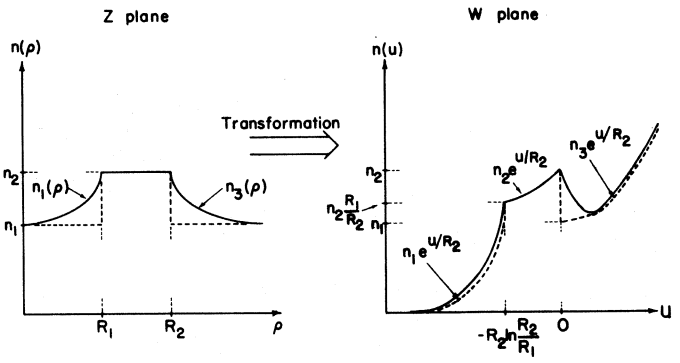
$$\left|\frac{dZ}{dW}\right| = \exp(u/R_2) \quad (10)$$



(3) is found to describe the waveguide shown in Fig. 1(b). In the W plane the walls are straight and lie between $u = 0$ and $u = -R_2 \ln R_2/R_1$. The refractive index in the structure is the product of (10) and the refractive index in the appropriate region of the curved guide. Those familiar with optical waveguides will note that the index profile of the equivalent structure resembles that in a prism coupler [9]. It is clear that all of the modes of the equivalent structure will radiate to the right where the refractive index exceeds the maximum refractive index in the guide.

If the waveguide in Fig. 1 were a diffused guide in a substrate, as an important practical example, the process of lateral diffusion would result in an index profile of the kind illustrated in Fig. 2(a). The modes on the equivalent guide in Fig. 2(b) are radiative as before. Furthermore, unless the decay rate $n_3(\rho)$ of the lateral diffusion is sufficiently rapid the minimum on the right side of the curve in Fig. 2(b) will cease to appear and there will be no confined modes. This "critical decay" condition is readily found by setting $n_3(\rho) = |dZ/dW|^{-1}$ and results in the requirement

$$n_3(\rho) < n_2 \cdot (R_2/\rho) \qquad R_2 < \rho < (n_2/n_1)R_2. \quad (11)$$



When the equality of (11) is met, the right side of Fig. 2(b) is constant at value n_2 in the manner depicted in Fig. 3. If there are no guided waves in the equivalent structure, neither will there be any in the curved waveguide.

The circular structure with one boundary illustrated in Fig. 4 will also support guided, albeit lossy waves [12]. This is made apparent by the equivalent guide of Fig. 4(b). We have $n_2 < n_1$ in this case. The guided waves on this structure will have wave refractive indices n_w that lie in the range $n_1 > n_w > n_2$ and the waves themselves will be confined to the range $0 > u > R \ln n_2/n_1$. The latter limit is indicated in Fig. 5(a) as u_0. In the original structure this boundary appears at $\rho_0 = R \cdot (n_2/n_1)$. As illustrated in Fig. 5(b), a ray tangent to the circle of radius ρ_0 will strike the tangent to the boundary of

he circular medium at the critical angle. Rays tangent to circles greater than ρ_0 are (nearly) totally reflected from the boundary while rays tangent to smaller circles are incident at angles less than the critical angle and pass through the boundary.

There are a number of transformations in addition to the logarithmic one (9) that are of potential interest in connection with integrated optics. One class of such transformations may be obtained from familiar equipotential surfaces and streamlines of electrostatics or laminar flow problems. Fig. 6, for example, shows the surfaces obtained when a conducting cylinder is placed in a uniform electric field. The transformation

$$W = Z + \frac{a^2}{Z} \tag{12}$$

applies to this situation with u equals constant defining the equipotential surfaces, and v equals constant defining the streamlines. If we have an optical waveguide with tapered walls (a horn-shaped structure [7] obtained by flaring a waveguide for coupling purposes, for example) that has the appearance of a segment of any two streamlines in Fig. 6, the transformation (12) will convert the waveguide into one with straight

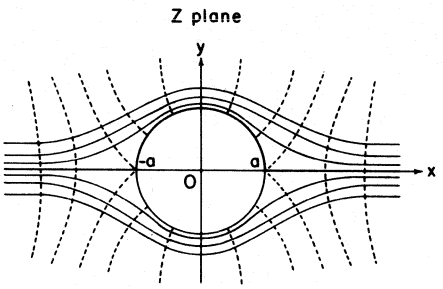

Fig. 6. Equipotential and streamlines of a conducting cylinder placed in a uniform electric field. The transformation $W = Z + a^2/Z$ converts curved guides whose shape is that of any two streamlines into waveguides with straight boundaries.

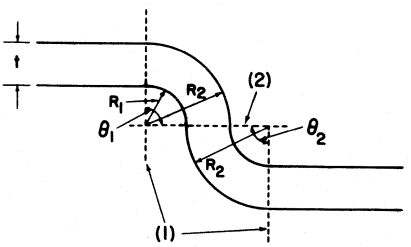

Fig. 7. Waveguide displacement produced by two circular bends. Dotted lines show transition regions.

walls. By varying a in (12), a wide variety of waveguide shapes can be generated. The refractive index in the equivalent structure varies along the guide as well as across it. This situation differs from the transformation (9) where the equivalent structure is uniform in the direction of propagation and necessitates a more complex analysis [8].

The waveguide bend illustrated in Fig. 7 represents an important passive integrated optical component. Under appropriate design the bend can consist of two sections of circular arcs connected to each other and to straight waveguide sections, as indicated by the dotted lines in Fig. 7. The arcs need not be 90° in length as in the figure. Loss mechanisms in this structure include the radiative loss due to modal attenuation along the bends and transition losses that occur between guides at the dotted lines. The remainder of the paper is devoted to an analysis of these effects that is based on the transformation (9).

III. Attenuation Along a Bend

Strictly speaking, the solution of (3) for structures with refractive index distributions of the kind shown in Figs. 1, 2, and 4 does not contain any guided waves because the refractive index at $u = \infty$ is greater than it is elsewhere. The region to the left of the minimum in refractive index can support a guided wave, however, and from a practical point of view, a field of the form

$$\psi(u, v) = F(u) \exp [i(\beta + i\alpha)v] = F(u) \exp [i(\beta + i\alpha)R_2\theta], \quad u < u_6 \tag{13}$$

can be used to represent the guided wave as in the prism coupler [9]. In this expression β and α are the respective propagation and attenuation constants of the wave, θ is the angular and $R_2\theta$ the actual length of the bend along the greater

arc, and $F(u)$ is the spatial characterization of the wave. Equation (13) can be used to the left of the turning point indicated as u_6 in Fig. 8 where $n(u_6) = \beta/k_0$.

$F(u)$, β, and α are functions of the radii of curvature of the bend. Characteristics of $F(u(x, y))$ determine transmission losses as the wave proceeds from one section to the next. This loss is discussed in Section IV. For the present we consider properties of β and α of a uniform bend. For the general structure shown in Fig. 8, β and α may be obtained as the solution of an eigenvalue equation that we express as

$$D_{1,6}(k_v)\big|_{k_v=\beta+i\alpha} = 0. \tag{14}$$

$D_{1,6}$, termed the "system function" for the structure, is a function of a wavenumber k_v. At certain values of k_v, $D_{1,6}$ is zero and these values are the complex propagation constants for waves on the structure.

The system function is the determinant obtained by matching boundary conditions for a multilayer structure when waves of arbitrary amplitude are assumed to exist in each layer. The system function for step index profiles is discussed in the Appendix. Our interest lies in the system function for continuously varying index profiles which can be obtained in the manner indicated in the Appendix. The method consists of subdividing the structure into thin slabs as indicated in Fig. 8, writing the expression for $D_{1,6}$ for a multilayer, and then taking the limit as the thickness of each slab reduces to differential dimensions. The limit procedure results in a series that must be expressed differently on each side of the turning points u_1, u_4, u_6 of Fig. 8 and in the vicinity of the turning points. The series expressions are presented in [11]. We will obtain approximate expressions by employing the first term of this series expression which involves Wentzel-Kramers-Brillouin (WKB) related approximations shown in the Appendix.

To present the equations to determine β and α we use the symbol k_u to represent the wavenumber

$$k_u(u) = [k_0^2 n^2(u) - k_v^2]^{1/2} \tag{15}$$

and define integrals over k_u as

$$h_{ij} = \int_{u_i}^{u_j} k_u(u)\, du. \tag{16}$$

The approximate eigenvalue equation for a wave propagating on the structure lying to the left of u_5 in Fig. 8 is found to be [see (A11)]

$$h_{2,3} + \left(h_{1^+,2} - \tan^{-1}\frac{K_{1^-}}{iK_{1^+}}\right) + \left(h_{3,4^-} - \tan^{-1}\frac{K_{4^+}}{iK_{4^-}}\right) = m\pi \tag{17}$$

where

$$K_{j^+,^-} = \begin{cases} k_u\big|_{u_{j^+,^-}}, & \text{for solutions of (3)} \\ \dfrac{k_u}{\epsilon}\Big|_{u_{j^+,^-}}, & \text{for solutions of (5).} \end{cases} \tag{18}$$

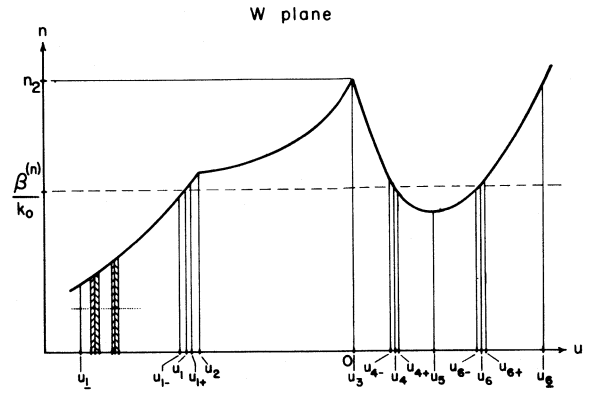

Fig. 8. Transformed index distribution of a bent guide with continuous index distribution. The turning points are u_1, u_4, and u_6. u_{1^+}, u_{1^-}, etc., define the positions at which the representation of the system function changes. The original straight guide has constant index between u_2 and u_3. u_1 and u_6 are arbitrary points beyond u_1 and u_6. To the right of u_1 some sublayers are shown that are used to reduce the system function for discrete layers to the system function of a continuously varying index distribution. (Characters with underbars in the figure appear boldface in text.)

Insight into (17) may be obtained by considering the simple uniform, straight-step index guide. For such a guide $n(u)$ is piecewise constant and the regions $u_{1^+} \rightarrow u_2$ and $u_3 \rightarrow u_{4^-}$ are of zero length. Equation (17) then reduces to

$$k_u t = m\pi + \tan^{-1}\frac{K_{1^-}}{iK_{1^+}} + \tan^{-1}\frac{K_{4^+}}{iK_{4^-}} \tag{19}$$

where t is the guide thickness and m is the mode order. This is the familiar eigenvalue equation for waveguides. The terms $\tan^{-1} K_j/iK_{j^+}$ are functions of k_v and take values between 0 and $\pi/2$ for a step discontinuity. At a continuous turning point, such as appears in Figs. 2 and 8, we may take $\tan^{-1} K_j/iK_{j^+}$ to be $\pi/4$ based on the assumption that u_{j^+} and u_{j^-} are selected to achieve this result. A more precise specification of the location of these points is discussed in Section IV. We will discuss examples of (17) for index distributions appropriate to waveguide bends following the discussion of α.

Using the same WKB-type approximation as is used to obtain (17), the change in propagation constant due to the presence of the high refractive index region on the right of Figs. 1, 2, 4 may be expressed

$$i\alpha = -\frac{1}{L}\left(\frac{K_{6^+} - K_{6^-}}{K_{6^+} + K_{6^-}}\right)\sin\left(2\tan^{-1}\frac{K_{4^-}}{iK_{4^+}}\right)\exp\left(2ih_{4^+,6^-}\right)$$
$$\simeq \frac{i}{L}\sin\left(2\tan^{-1}\frac{K_{4^-}}{iK_{4^+}}\right)\exp\left(2ih_{4^+,6^-}\right) \tag{20}$$

as obtained from (A12).

The terms in (20) are to be evaluated at β, the solution of (17). This renders $h_{4^+,6^-}$ positive imaginary in (20) and the exponential in (20), which may achieve small values, largely determines the behavior of α. The parameter L is the derivative of (17), viz.,

$$L = -\frac{\partial}{\partial k_v}\left[h_{2,3} + \left(h_{1^+,2} - \tan^{-1}\frac{K_{1^-}}{iK_{1^+}}\right) + \left(h_{3,4^-} - \tan^{-1}\frac{K_{4^+}}{iK_{4^-}}\right)\right]_{k_v=\beta} \tag{21}$$

and may be termed the *effective longitudinal ray length*. For TE modes in a uniform, straight guide ($h_{1^+,2} = h_{3,4^-} = 0$, $K_{i^\pm} = (k_u)_{u_{i^\pm}}$), for example, L is

$$L = \frac{\beta}{(k_u)_{u_3}}[t + 1/|k_u|_{u_{1^-}} + 1/|k_u|_{u_{4^+}}] = (\tan\phi)[t'] \tag{22}$$

where t' is the effective width of the waveguide, which includes the decay distances, and ϕ is the angle the wave normal in the guide makes with the surface of the guide (Fig. 9). The second equality in (20) follows from the assumption that u_{6^+} and u_{6^-} are selected so that $K_{6^+} = K_{6^-}/i$. For a continuous change in index at u_4 the sine function in (20) can be approximated by unity.

To further examine the equations for β and α we note that in regions in which the refractive index is constant in x, y, the equivalent index is $n(u) = n \exp u/R$. The resulting expression for $h_{i,j}$ can be integrated in closed form. As an example, for the single-boundary guide of Fig. 4, only $h_{1^+,2}$ of the h's is non-zero in (17). Taking $u_{1^+} = -R \ln (k_0 n_1/\beta)$ and $u_2 = 0$ we find the eigenvalue equation for β of a TE mode (3) to be

$$R\beta\left[\left(\frac{k_0^2 n_1^2}{\beta^2} - 1\right)^{1/2} - \cos^{-1}\frac{\beta}{k_0 n_1}\right] - \tan^{-1}\left(\frac{\beta^2 - k_0^2 n_2^2}{k_0^2 n_1^2 - \beta^2}\right)^{1/2} - \frac{\pi}{4} = m\pi. \tag{23}$$

Similarly, for the step index profile of Fig. 1, $u_2 = -R_2 \ln \cdot R_2/R_1$, $u_3 = 0$, $h_{1^+,2} = 0$, $h_{3,4^-} = 0$, and the eigenvalue equation is[2]

$$R_2\beta\left[\left(\frac{k_0^2 n_2^2}{\beta^2} - 1\right)^{1/2} - \left(\frac{k_0^2 n_2^2}{\beta^2}\frac{R_1^2}{R_2^2} - 1\right)^{1/2} - \cos^{-1}\left(\frac{\beta}{k_0 n_2}\right) + \cos^{-1}\left(\frac{\beta}{k_0 n_2}\frac{R_2}{R_1}\right)\right] - \tan^{-1}\left(\frac{\beta^2 - k_0^2 n_1^2\left(\frac{R_1}{R_2}\right)^2}{\left(\frac{R_1}{R_2}\right)^2 k_0^2 n_2^2 - \beta^2}\right)^{1/2} - \tan^{-1}\left(\frac{\beta^2 - k_0^2 n_3^2}{k_0^2 n_2^2 - \beta^2}\right)^{1/2} = m\pi. \tag{24}$$

For the diffused guide of Fig. 2, if the lateral diffusion results in an exponential-type decay of the form $n(\rho) = n_1 + (n_2 - n_1) \cdot \exp - [\zeta(\rho - R_2)/R_2]$ where ζ/R_2 is the decay rate of the index difference, the equivalent index profile is $n(u) = \exp \cdot [-\zeta \exp u/R_2 + \zeta + u/R_2]$. A closed form for $h_{3,4^-}$ is not known for such a profile. On the other hand, it is not difficult to generate approximations as is indicated in the next paragraph. Solutions of (23) and (24) can be obtained by graphical or numerical means.

The determination of α in closed form can be accomplished for index profiles exponential in the W plane. The results involve specification of $\sin(2\tan^{-1}K_{4^-}/iK_{4^+}), L$, and $\exp(2ih_{4^+,5})$. These results are presented in Table I. For the diffused guide of Fig. 2 with exponential lateral diffusion, we approximate $n(u) \sim n_1 \exp u/R_2 + (n_2 - n_1)\exp - bu/R_2$, where b/R_2 is the initial slope of $n(u)$ expressed in the previous paragraph; i.e., $b/R_2 = -[(1 - \zeta)/R_2] \exp \zeta$. An additional approximation for the diffused guide in Table I is made in the exponential term of α. We take

$$h_{4^+,6^-} \simeq 2[(\beta/k_0)^2 - n^2(u_5)]^{1/2}[u' - u_5] \tag{25}$$

where u_5 is the point at which $n(u)$ is a minimum (Fig. 8), viz., $u_5 = (R_2/1 + b) \ln [b(n_2 - n_1)/n_1]$, and u' is the point at which $k_u(u)$ decreases by $1/\sqrt{2}$, viz., $[(\beta/k_0)^2 - n^2(u')]^{1/2} = (2)^{-1/2} \cdot [(\beta/k_0)^2 - n^2(u_5)]^{1/2}$.

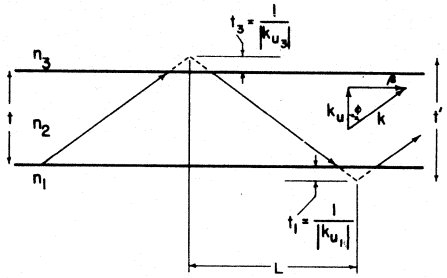

Fig. 9. The effective thickness t' and the effective longitudinal ray length L for a straight guide.

Turning to a consideration of the dependence of β and α on the radius of curvature, we note that as the radius of curvature decreases, the index profile of the guide is skewed increasingly upward on the right. Fig. 10 illustrates this point. The figure shows a waveguide of constant thickness at different radii of curvature. Note that when $n_2(R_1/R_2) < n_3$, the behavior of the step waveguide of Fig. 1 is similar to that of the single boundary guide of Fig. 4 since the inner boundary lies in the evanescent region of the wave. Furthermore, there is a minimum radius of curvature R below which the single-boundary and two-boundary guides cease to carry any mode. From (23), setting $\tan^{-1}$ and m to zero and $\beta = k_0 n_2$,

$$R_{\min} = (\lambda_0/8)/[((n_1^2/n_2^2) - 1)^{1/2} - \cos^{-1} n_2/n_1] \tag{26}$$

where λ_0 is the free-space wavelength. This same expression is obtained for the step index guide with n_1/n_2 replaced by n_2/n_3. When n_2 differs from n_1 by a small amount, $R_{\min}$ reduces to[3]

$$R_{\min} \simeq 0.1325\lambda_0/[(n_1 - n_2)/n_1]^{3/2}. \tag{27}$$

Using (26), $R_{\min} \simeq 0.45\lambda_0$ for $n_1/n_2 = 1.5$. Using (27), $R_{\min} \simeq 4200\lambda_0$ for $(n_1 - n_2)/n_1 = 10^{-3}$ and $R_{\min} \simeq 133\lambda_0$ for $(n_1 - n_2)/n_1 = 10^{-2}$.

When the radius of curvature is large compared to the wavelength, the value of β does not change radically from its value β_0 when the waveguide is straight. Using (24) to obtain a first-order expression for β in a step index guide, we find

$$\beta \simeq \beta_0 - \left(\frac{\partial[h_{1^+,4^-}]/\partial(1/R_2)}{-L}\right)\Bigg|_{1/R_2 = 0} \cdot 1/R_2 = \beta_0(1 - t/2R_2) \tag{28}$$

[2] For small t/R_2, (24) reduces to $[k_0^2 n_2^2 - (\beta R_2/R_1)^2]^{1/2} t - \psi_1 - \psi_2 = m\pi$.

[3] Defining $\cos^{-1} n_2/n_1 = y$ and $[(n_1/n_2)^2 - 1]^{1/2} = \tan y$, for small y $\tan y - y \simeq 1/3y^3$.

Two Boundaries (Fig. 1)	$\frac{2(k_2^2-\beta^2)^{1/2}(\beta^2-k_3^2)^{1/2}}{k_2^2-k_3^2}$	$\frac{\beta}{[\beta^2-k_3^2(\frac{R_1}{R_2})^2]^{1/2}[k_2^2(\frac{R_1}{R_2})^2-\beta^2]^{1/2}} + \frac{\beta}{(\beta^2-k_3^2)^{1/2}(k_2^2-\beta^2)^{1/2}} + R_2[\cos^{-1}\frac{\beta}{k_2} - \cos^{-1}(\frac{\beta}{k_2}\cdot\frac{R_2}{R_1})]$	$\exp\{2R_2(\beta^2-k_1^2)^{1/2}-2\beta R_2 \cdot \ln[\frac{\beta+(\beta^2-k_3^2)^{1/2}}{k_3}]\}$
Diffused Guide (Fig. 2)	$\simeq 1$	$\frac{R_2}{a}\cos^{-1}\frac{\beta}{k_2}(\frac{R_1}{R_2})^{\frac{a-2}{2}} + \frac{R_2}{b}\cos^{-1}\frac{\beta}{k_2} + R_2[\cos^{-1}\frac{\beta}{k_2} - \cos^{-1}(\frac{\beta}{k_2}\frac{R_2}{R_1})]$	$\simeq \exp\{-4[\beta^2-k^2(u_5)]^{1/2}(u'-u_5)\}$

Note: The attenuation along a bend is given by α as expressed in (20). The three parameters L, sin, and exp that are given in (20) are given for single-boundary, two-boundary, and diffused curved guides. For diffused guide parameters see the paragraph containing (25) and note that a and b are related to the initial slopes of the refractive index profile on the inner and outer boundary, respectively, of the guide. Note also that $k_j = k_0 n_j$.

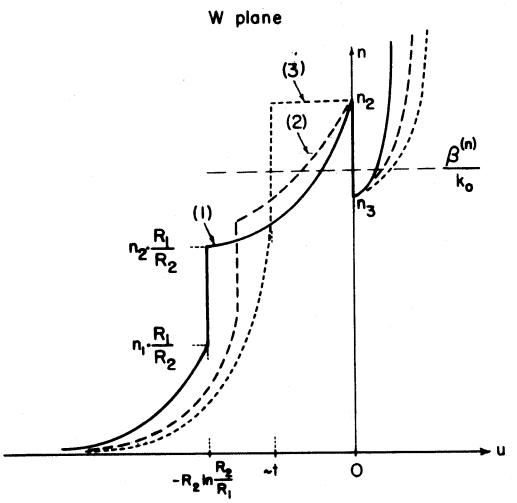

Fig. 10. Transformed index distribution of a step index guide of constant thickness at different radii of curvature. At small radius of curvature (1), i.e., when $R_1/R_2 < n_3/n_2$ the step index guide appears as a single-boundary guide. The dotted curve which corresponds to the largest radius of curvature should be labeled (3) and the dashed curve (2).

where $h_{1+,4-}$ is defined in (16), L is shown in (21), and t is the thickness of the guide $R_2 - R_1$. In (28) it is clear that a dramatic change in β occurs only when the radius of curvature approaches the guide thickness.

To consider the attenuation rate α expressed in (20), we note that the longitudinal ray path length has a simple geometric interpretation (Fig. 9) and is a number greater than the width of the equivalent guide. Unless $\exp(2ih_{4+,6-})$ is small, the attenuation is excessive. The exponential is small unless β approaches $k_0 n(u_5)$, where u_5 is the location of the index minimum (Fig. 8). For a prescribed αL we may specify a minimum β by solving equation (20) for β. Using the approximate expressions in Table I for a diffused waveguide and representing $n(u)$ near u_5 as $n(u_5) + (1/2)(\partial^2 n/\partial u^2)(u - u_5)^2$ we find

$$\beta_{\min} \simeq k_0 n(u_5) + \ln(\alpha L)^{-1}/8[n(u_5)/(\partial^2 n/\partial u^2)_{u_5}]^{1/2}$$

where

$$n(u_5) = n_1 b\left(\frac{n_2}{n_1} - 1\right)^{1/b+1} + (n_2 - n_1)b\left(\frac{n_2}{n_1} - 1\right)^{b/b+1}$$

$$[n(u_5)/\partial^2 n/\partial u^2]^{1/2} = R_2\left[\frac{1 + b(n_2 - n_1)}{1 + b^3(n_2 - n_1)}\right]^{1/2} \tag{29}$$

and b is related to the gradient of the lateral diffusion ζ/R_2 as discussed previous to (25). Using the value of L for a straight guide, (29) can provide a useful design relation for bends in diffused guides.

If we consider the attenuation rate of the step index guide (Fig. 1) for the situation in which $\beta = k_0 n_3(1 + \delta)$ differs by a small amount from the wavenumber of region 3, we find from Table I that the exponential term in α to first order in δ is

$$\alpha \propto \exp\left(-\frac{4\pi}{\lambda_0} R_2 n_3 \delta\right). \tag{30}$$

This simple expression shows that unless the radius of curvature approaches the value $\lambda_0/4\pi n_3\delta \sim \lambda_0/4\pi(n_2 - n_3)$ the attenuation will be small. Even when the index difference is 10^{-3}, a radius of curvature of several hundreds λ_0 can be tolerated.

It should be emphasized that the two-boundary guide (Fig. 1) behaves like a one-boundary guide (Fig. 4) not only when $n_2(R_1/R_2) < n_3$ (as was noted before) but also when $n_2(R_1/R_2) \geqslant n_3$ and $\beta > n_2(R_1/R_2)$. In both cases, the expressions for β and α for the one-boundary guide should be used.

As a point of reference, in the limit of large radii of curvature ($R_2 \gg \lambda_0, t$), the attenuation formula for a two-boundary guide (given in Table I) reduces to Marcuse's formula [2, eq. (32)] except for a factor of 2. This factor is the square of the transmission coefficient at the turning point and should be inserted in front of Marcuse's formula. The approximation for large radii can be shown easily by replacing the effective longitudinal ray length of the bend (L) by that of a straight guide (22) and by using $R_2 \gg t$.

IV. Transition Effects

The distortion in the index profile results in a displacement of the modes towards the outside of a bend and this effect results in transmission losses at the interfaces shown in Fig. 7. The WKB approximation of the spatial distribution of a mode in the region to the left of u_{6-} as obtained from (A6) is

$$F(u) = \begin{cases} (-1)^m [(|K_{4+}K_{4-}|)^{1/2}/|K_{4+} + K_{4-}|] (K_3/K)^{1/2} \exp i \displaystyle\int_{u_{4+}}^{u} k_u \, du, & u_{4+} < u < u_{6-} \\ (K_3/K)^{1/2} \cos \left(\displaystyle\int_{u_{1+}}^{u} k_u \, du - \tan^{-1} \frac{K_{1-}}{iK_{1+}} \right), & u_{1+} < u < u_{4-} \\ [(|K_{1+}K_{1-}|)^{1/2}/|K_{1+} + K_{1-}|](K_3/K)^{1/2} \exp i \displaystyle\int_{u}^{u_{1-}} k_u \, du, & u < u_{1-} \end{cases} \tag{31}$$

where K is the same as in (18) for an arbitrary point u. This expression holds outside the turning points. The positions u_{1-}, u_{1+}, etc., are determined by requiring

$$\left(\frac{\partial K/\partial u}{K} \frac{\pi}{k_u} \right)_{u_i^{\pm}} = \epsilon \tag{32}$$

where ϵ is a number much less than 1. Equation (32) is established by considering the second-order terms in the expansion of the system functions [11].[4]

Equation (31) indicates displacement of a mode because the argument of the cosine term contains an integral over $k_u = [k_0^2 n^2(u) - \beta^2]^{1/2}$ and the distortion in $n(u)$ results in a larger contribution from the right side of the guide than from the left. For the lowest order mode, the approximate peak occurs when the argument of the cosine is zero, i.e.,

$$\int_{u_{1+}}^{u} k_u \, du = \tan^{-1} \frac{K_{1-}}{iK_{1+}}. \tag{33}$$

Expressions for the integral in (33) may be obtained as in (23) and (24) using different representations in the regions $u_{1+} - u_2$, $u_2 - u_3$, $u_3 - u_{4-}$. The wave function within the guide region of a step index guide, for example, transformed back to the x, y plane is

$$F(\rho) = \left(\frac{k_2^2 - \beta^2}{k_2^2 \rho^2 / R_2^2 - \beta^2} \right)^{1/4} \cos \Big[(k_2^2 \rho^2 - \beta^2 R_2^2)^{1/2} - \beta R_2 \cos^{-1} (\beta R_2 / k_2 \rho) - (k_2^2 R_1^2 - \beta^2 R_2^2)^{1/2} + \beta R_2 \cos^{-1} (\beta R_2 / k_2 R_1) - \tan^{-1} \left(\frac{K_{1-}}{iK_{1+}} \right) \Big] \tag{34}$$

where $k_2 = k_0 n_2$ and

$$\tan^{-1} \frac{K_{1-}}{iK_{1+}} = \tan^{-1} \left[\frac{\beta^2 - k_0^2 n_1^2 (R_1/R_2)^2}{k_2^2 (R_1/R_2)^2 - \beta^2} \right]^{1/2}. \tag{35}$$

To provide a useful parameter we may determine the position of the peak ρ_0 of (34) in accordance with (33) to first order in $(\rho - R_1)/R_2$. The result is

$$\rho_0 \simeq R_1 + \left(\tan^{-1} \frac{K_{1-}}{iK_{1+}} \right) \Big/ [k_0^2 n_2^2 - (\beta R_2 / R_1)^2]^{1/2}. \tag{36}$$

Approximating β as in (28), with $\beta_0 = (1 - \delta') k_0 n_2$ where δ' is presumed small, and retaining first-order terms in $1/R_2$, ρ_0 reduces to

$$\rho_0 = \left(R_1 + \frac{t}{2} \right) + \frac{t}{2} \left\{ 1 - \frac{(2\delta')^{1/2} - 2t_3(\beta_0)/R_2}{[2\delta' + (t/R_2)^2]^{1/2}} \right\} \tag{37}$$

where $t = R_2 - R_1$ and $t_3(\beta_0)$ is the evanescent decay distance into region 3 of a straight guide (Fig. 9). The displacement ρ_0 is sensitive to the radius of curvature as presented by (t/R_2) only when β_0 differs from $k_0 n_2$ by an amount of the order $1/2(t/R_2)^2$.

The power transmitted at the transition between guides of different curvature, as appear in Fig. 7, can be estimated by the overlap integral

$$T^2 = 4 \frac{\left(\int F' F \, d\rho \right)^2 \Big/ \int F^2 \, d\rho \int F'^2 \, d\rho}{(1 + \beta'/\beta)^2} \tag{38}$$

where F' and F are the wave functions of connecting guides and β' and β are the propagation constants. T^2 can be evaluated numerically for any given configuration using (31), or as a specific example, (34). The overlap integral depends on the direction of the displacement (36). To provide an estimate of the power transmitted at intersection (2) of Fig. 7, consider the approximation $F(\rho) \sim \cos a(\rho - \rho_0)$ and $F'(\rho) \sim \cos \cdot$

[4] The second-order term in the expansion of the system function is

$$\frac{d}{du} \ln \frac{K(u_i)}{K(u)} \exp \left(i \int_u^{u_i} k_{u'} \, du' \right).$$

$a(\rho - \rho_0 + \Delta)$ where $a = \pi/2t$ and Δ represents the displacement between the two wave-function maxima in symmetric guides ($n_1 = n_3$), viz., $\Delta = 2(\rho_0 - R_1) - t$. We obtain

$$T^2 = \left(1 - \frac{\pi^2\Delta^2}{4t^2}\right)^2. \tag{39}$$

For small displacements the power loss is proportional to $(\Delta/t)^2$ and is a small percentage of the total. As Δ/t approaches unity there is, of course, substantial power loss. The overall power transmission of the structure shown in Fig. 7 may be approximated as a product of the form

$$T^2 = \left(1 - \frac{\pi^2\Delta_1^2}{4t^2}\right)^2 \cdot (1 - \exp(-2\alpha R_2\theta_1)) \cdot \left(1 - \frac{\pi^2\Delta^2}{4t^2}\right)^2 \cdot (1 - \exp(-2\alpha R_2\theta_2)) \cdot \left(1 - \frac{\pi^2\Delta_1^2}{4t^2}\right)^2 \tag{40}$$

where $\Delta_1 = \Delta/2$ is the displacement between guided-wave maxima at intersection (1) and θ_1 and θ_2 are the lengths of the arcs that make up a bend. Using (30) to approximate α and (37) to obtain Δ, (40) can provide a relatively simple approximation for the overall losses in a bend.

V. Conclusion

The method of conformal transformations has been shown to provide a useful qualitative as well as quantitative view of wave propagation in curved optical waveguides. The method requires no *a priori* limitations in radii of curvature or index differences. It has been shown how useful representations for the wave functions, eigenvalue equations, and attenuation constants can be obtained by analyzing equivalent structures in the transform plane. Using first-order approximations, simple expressions for the attenuation along a bend, the displacement of the wave from its position in a straight guide, the change in propagation constant due to bending of the guide, and the overall transmission loss in a practical bend have been presented.

Appendix

Solutions for the eigenfunctions and eigenvalue equations of continuously varying media may be obtained starting with solutions of a step discontinuous index profile containing constant index between steps. In such a profile, solutions to (3) or (5) are obtained by setting $\psi_j(u, v) = (1/K_j)(a_j^+ \exp ik_{u_j}u + a_j^- \exp -ik_{u_j}u) \exp ik_v v$ in layer j and matching boundary conditions at the interface between layers. The resulting equations in a_j^+ and a_j^- take the form

$$\left[\begin{array}{cc:cc} -K_1\exp(-ik_{u_1}u_1) & -K_2\exp(ik_{u_2}u_1) & K_2\exp(-ik_{u_2}u_1) & 0 \\ \exp(-ik_{u_1}u_1) & -\exp(ik_{u_2}u_1) & -\exp(-ik_{u_2}u_1) & 0 \\ \hdashline 0 & K_2\exp(ik_{u_2}u_2) & -K_2\exp(-ik_{u_2}u_2) & -K_3\exp(ik_{u_3}u_2) \\ 0 & \exp(ik_{u_2}u_2) & -\exp(-ik_{u_2}u_2) & -\exp(ik_{u_3}u_2) \end{array}\right] \left[\begin{array}{c} a_1^- \\ a_2^+ \\ a_2^- \\ a_3^+ \end{array}\right] = 0 \tag{A1}$$

where the k_u and K's are defined, respectively, in (15) and (18), the subscript refers to the layer, and u_1 and u_2 are two interfaces for a three-region problem.

The determinant of the matrix in (A1) is denoted $D_{1,3}$, while the determinants of the matrix within the dotted and dashed lines, respectively, are denoted $D_{1,2}$ and $D_{2,3}$. It is simple to show from (A1) that

$$D_{1,3} = D_{1,2}D_{2,3} - D'_{1,2}{}'D_{2,3} \tag{A2}$$

where the primes indicate

$$D'_{ij} = D_{ij}(k_{u_i}, \cdots, -k_{u_j}), \qquad {}'D_{ij} = D_{ij}(-k_{u_i}, \cdots, k_{u_j}). \tag{A3}$$

Furthermore, it may be shown that (A2) can be generalized to any number layers in the form

$$D_{1,N} = D_{1,p}D_{p,N} - D'_{1,p}{}'D_{p,N} \tag{A4}$$

where p is any layer between 1 and N.

The complex propagation constant for a guided wave is the value of k_v for which the determinant in (A1) is zero. The eigenvalue equation is thus

$$(D_{1,N})_{k_v=\beta+i\alpha} = 0. \tag{A5}$$

Furthermore, it may be shown that the eigenfunction can be expressed

$$F(u) = A\left[\frac{D_{1,p}}{2K_1 \cdots 2K_p}\exp(-ik_{u_p}u) - \frac{D'_{1,p}}{2K_1 \cdots 2K_p} \cdot \exp(ik_{u_p}u)\right], \qquad u_{p-1} < u < u_p \tag{A6}$$

where p refers to any layer in which (A6) is evaluated and A is a constant.

If the number of layers is permitted to become infinite and $n(u)$ becomes continuous, it is possible to represent the system functions in a series of the kind first described by Bremmer [10] and presented by Harris [11]. The first terms of the series are the WKB forms

$$D_{r,q}/(2K_r) \cdots (2K_{q-1}) \simeq (K_q/K_r)^{1/2}\exp\left[-i\int_{u_r}^{u_{q-1}} k_u\,du + i(k_{u_q}u_{q-1} - k_{u_r}u_r)\right]$$

$$'D'_{r,q}/(2K_r) \cdots (2K_{q-1}) \simeq -(K_q/K_r)^{1/2}\exp\left[i\int_{u_r}^{u_{q-1}} k_u\,du - i(k_{u_q}u_{q-1} - k_{u_r}u_r)\right]$$

$$D'_{r,q} = {}'D_{r,q} = 0. \tag{A7}$$

Near a turning point (A7) fails and we have

$$D_{r,q} \simeq (2K_r) \cdots (2K_{q-1})\left(\frac{K_r + K_q}{2K_q}\right)\exp i(k_{u_q}u_{q-1} - k_{u_r}u_r). \tag{A8}$$

The primes of (A8) are obtained as in (A3). The subscripts in (A7) and (A8) refer to sublayers as indicated in Fig. 8 and are described more fully in the next paragraph.

To express (A5) or (A6) for continuously varying media to the approximation (A7) and (A8) we employ (A4) sequentially stopping at each turning point (u_1, u_4, and u_6 of Fig. 8) and write, for example,

$$D_{1,6} = D_{1,1^-}\{[D_{1^-,1^+}D_{1^+,4^-}D_{4^-,4^+} + D'_{1^-,1^+}{}'D'_{1^+,4^-}{}'D_{4^-,4^+}] \cdot D_{4^+,6^-}D_{6^-,6^+} + [D_{1^-,1^+}D_{1^+,4^-}D'_{4^-,4^+} + D'_{1^-,1^+}{}'D'_{1^+,4^-}{}'D'_{4^-,4^+}] \cdot {}'D'_{4^+,6^-}{}'D_{6^-,6^+}\}D_{6^+,6}. \tag{A9}$$

The zero functions of the third equation in (A7) have been incorporated in (A9). Subscript **1** refers to the point u_1 located to the left of u_{1^-} as indicated in Fig. 8. Similarly, **6** refers to u_6 located to the right of u_{6^+}. Using the first equation in (A7) to describe the way the subscripts are used, we have

$$\frac{D_{1,1^-}}{2K_{u_1} \cdots 2K_{u_1}} = (K_{u_{1^-}}/K_{u_1})^{1/2} \exp\left\{-i\int_{u_1}^{u_{1^-}} k_u\, du + i[k_u(u_{1^-})u_{1^-} - k_u(u_1)u_1]\right\}. \tag{A10}$$

Note that to employ (A7) and (A8) conveniently, (A5) can also be written $D_{1,N}/2K_1 \cdots 2K_N = 0$.

The equation for β is obtained by neglecting the region to the right of u_{4^+} and can be expressed as

$$(D_{1,4^+}/2K_{u_1} \cdots 2K_{u_{4^+}})_{k_v=\beta} = 0. \tag{A11}$$

The equation for $i\alpha = (k_v - \beta)$ is obtained by setting $D_{1,6}$ to zero, expressing

$$(D_{1,4^+}/2K_{u_1} \cdots 2K_{u_{4^+}})_{k_v \simeq \beta} \simeq \left(\frac{\partial}{\partial k_v} D_{1,4^+}/2K_{u_1} \cdots 2K_{u_{4^+}}\right)_{\beta} \cdot (k_v - \beta)$$

and using (A4) with p at u_{4^+}. The result is

$$i\alpha = \left[\frac{(D'_{1,4^+}/2K_{u_1} \cdots 2K_{u_{4^+}})D_{4^+,6}}{\left(\frac{\partial}{\partial k_v} D_{1,4^+}/2K_{u_1} \cdots 2K_{u_{4^+}}\right)'D_{4^+,6}}\right]_{k_v=\beta}. \tag{A12}$$

In the text $K_{j^\pm}$ is used instead of $K_{u_j^\pm}$. Finally, the wave function is expressed using (A6) treating u_p as an arbitrary point u.

The POPOP Dye Vapor Laser

PETER W. SMITH, MEMBER, IEEE, PAUL F. LIAO, CHARLES V. SHANK, C. LIN, AND PATRICK J. MALONEY, MEMBER, IEEE

Abstract—**We report a comprehensive study of the operation of a laser using the organic scintillator dye POPOP in the vapor phase. Laser operating parameters have been determined, and we describe tuning experiments which demonstrate an oscillation range of 25 nm. Gain measurements as a function of wavelength and time are reported for transverse pumping with the 337.1-nm output of a pulsed N_2 laser. The quantum efficiency has been measured as a function of temperature and pump wavelength, and a preliminary study has been made of the effect of buffer gases on the quantum efficiency and the gain. Spectral condensation measurements show 90 percent of the broad-band laser output can be obtained in a 1-nm band—indicating that even in a dilute vapor, the thermalization time of the laser levels is $<<1$ ns. We conclude by discussing the implications of these results for the achievement of an electrically pumped dye vapor laser.**

I. Introduction

RECENTLY, three groups have independently reported laser action in a new class of laser media—an organic dye vapor [1]-[3]. These lasers are of interest for a number of reasons. They operate at dye molecule densities comparable to those of liquid dye lasers, but their performance is not degraded by thermally induced refractive index changes. They are useful systems for the study of the dye molecules themselves, and are a source of new laser wavelengths. Perhaps the most important aspect of dye vapor lasers is that they offer the possibility of efficient operation under electrical excitation. If problems of decomposition of the dye molecules can be overcome, dye vapor lasers offer the promise of a high efficiency, tunable, broad-band visible laser.

Although a number of organic dye vapors have been studied [4], [5], the lowest threshold operation under optical pumping has been obtained with the organic scintillator dye POPOP (2, 2′-*p*-phenylenebis [5 phenyloxazole]).

In this paper we report on our studies of the POPOP vapor dye laser. In Section II we describe the experimental apparatus including the oven used to heat the dye. Section III contains measurements of the optical properties of POPOP vapor including measurements of quantum efficiency of fluorescence as a function of temperature, pump wavelength, and buffer gas. Measurements of gain under optical pumping with a pulsed N_2 laser are described in Section IV. The gain is measured as a function of wavelength and time, and the effect of helium buffer gas is studied. In Section V we present data on the operating characteristics of the POPOP laser, and conclude with a discussion of the implications of these results for the development of an electrically pumped dye laser.

II. Apparatus

The apparatus used for these experiments is shown schematically in Fig. 1. The dye vapor cell shown in Fig. 1(b) was constructed from fused quartz. The length of the cell was 4 cm, and its cross section 1 cm × 1 cm. The faces were of optical quality, and the quartz pieces used to make the cell had their inside edges beveled so that when the cell was assembled, the inside corners of the cell would not have any material extending into the path of the dye fluorescence. Crystals of POPOP dye were introduced into a section of quartz tubing attached to the arm of a quartz sample cell, and the entire system was pumped down to a vacuum of $\sim 10^{-7}$ torr. The dye was then melted under gentle heat so that the liquid dye flowed down into the main body of the sample cell, and the system was again pumped down to $\sim 10^{-7}$ torr. In this way any adsorbed gases are removed from the system. The cell was then sealed off under vacuum, or with the appropriate pressure of buffer gas.

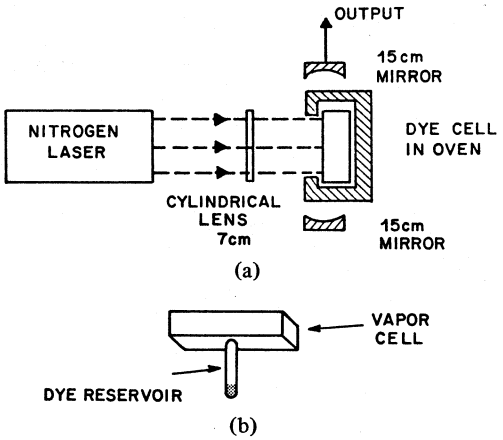

Fig. 1. Schematic view of dye vapor laser system. (a) As set up for laser experiments. (b) Sample cell.

The cell was placed in an oven, shown schematically in Fig. 1(a), which was designed to maintain the temperature of the dye reservoir at a lower temperature than the main body of the sample cell. This was accomplished by powering the two sections of the oven with two different temperature controllers. One governed the temperature of the dye reservoir (which determines the vapor pressure of the dye in the cell). The other was a differential controller which maintained the main body of the oven at a temperature somewhat higher than the dye reservoir (typically + 20°C). In this way "fogging" of the windows of the dye cell was avoided. The oven consisted of two aluminum chambers in which heating elements and temperature sensors were imbedded. The two chambers were separated by an insulator. Openings were made to permit entrance and exit of two light beams—one along the axis of the sample cell and the other perpendicular to it. It was verified that the temperature uniformity within the main body of the sample cell was within ∓5°C.

Optical pumping experiments were made using a pulsed N_2 laser giving output pulses of ~8-ns duration with a peak

intensity of 400 kW. The beam was focused with a 7-cm focal length cylindrical quartz lens onto the entrance face of the sample cell. The beam cross section in the focal plane was 4 cm × ~300 μm.

III. The Optical Properties of POPOP Vapor

The organic dye POPOP is a crystalline solid at room temperature. Its melting point is approximately 245°C. Above this temperature the dye readily vaporizes and at temperatures ~350°C dye vapor densities which correspond closely to dye concentrations commonly found in liquid solution dye lasers are achieved. No thermal degradation has been observed at temperatures up to 350°C over periods of several days.

POPOP vapor absorption and emission spectra were obtained for several vapor densities. A Cary 14 Spectrometer was used to obtain the absorption data and a Perkin Elmer Model MPF-2A Fluorescence Spectrometer to obtain emission data. Fig. 2 shows the absorption and emission spectra of POPOP vapor at a dye reservoir temperature of 300°C. For comparison, the corresponding spectra for a liquid solution of POPOP in cyclohexane are also shown. The emission spectra are corrected for the response of the detection system and represent photon flux. Both vapor emission and absorption curves are broad almost featureless bands showing no clearly resolved vibrational structure. The vapor emission and absorption curves show nearly perfect mirror symmetry and both are shifted to shorter wavelengths by ~30 nm from the typical spectra for POPOP dissolved in liquid solutions [6]. The absorption and emission spectra of both the vapor and dye solutions occur over nearly identical 500-nm bandwidths. The large Stokes shift makes the dye vapor an excellent candidate for a laser material.

In Fig. 3 we show the temperature dependence of the absorption length at 337 nm (the wavelength of the nitrogen laser). The approximate dye concentrations indicated in Fig. 3 were computed by assuming that the absorption cross section of the molecules in the vapor is the same as for those in liquid solutions. Concentrations comparable to those found in liquid solution lasers can be readily obtained.

Vibrational relaxation plays an important role in the four level laser scheme of liquid solution dye lasers, and it is the interactions between the dye molecules and the solvent molecules which are thought to induce the vibrational relaxation. In the vapor phase, however, the collision rate can be extremely low, and the mean time between collisions longer than the excited state lifetime. The vibration relaxation which is so important for laser action might be expected to be slow in low-pressure dye vapors.

Information about the relaxation process can be obtained from the emission spectra, and the data indicates that collisions are in fact not required for the vibrational relaxation of the first excited singlet state of POPOP vapor. In the absence of vibrational relaxation, or if the relaxation time is comparable to or larger than the fluorescence lifetime of the excited singlet, the emission spectrum would depend critically on which vibrational state is excited and therefore would depend on the excitation wavelength. No such behavior was observed in our experiments. The emission data in Fig. 2 was taken with 340-nm excitation; however, no change in the position or shape of the

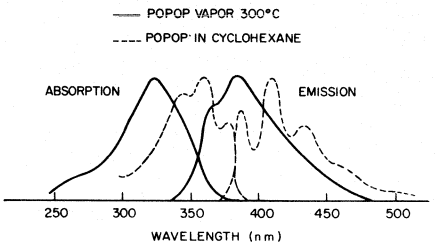

Fig. 2. Absorption and emission spectra for POPOP vapor at 300°C, and corresponding spectra for a liquid solution of POPOP in cyclohexane (from [6]).

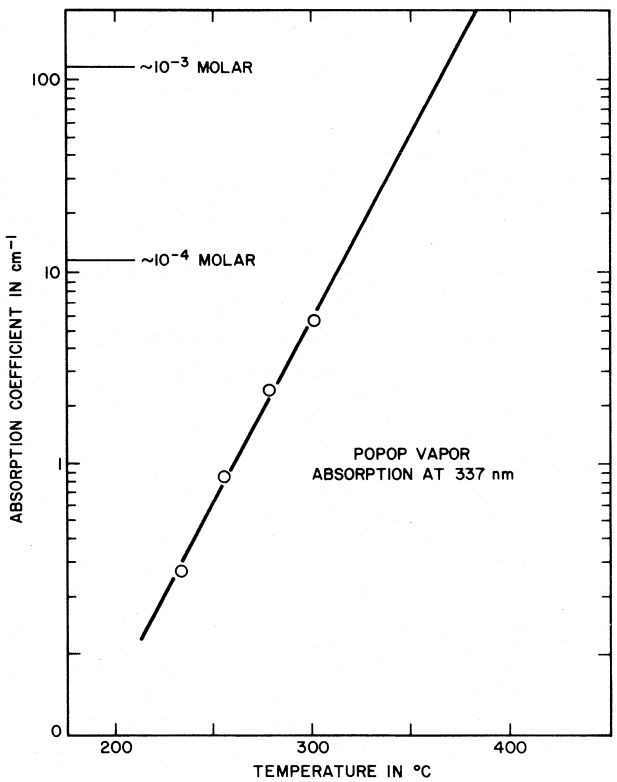

Fig. 3. POPOP vapor absorption at 337 nm as a function of dye reservoir temperature.

emission curve was found as the wavelength of the excitation was varied over the entire absorption band. This behavior was observed at all temperatures from 250°-325°C and is quite different from that which has been observed in rhodamine B (see [7]) where the vibrational relaxation rate appears to be small. The POPOP emission spectra also showed no dependence on collision frequency. Dye pressure (temperature) was varied and buffer gases were added (CO_2, He, SF_6) up to buffer gas pressures of 500 torr. The complete independence of the position and shape of the emission spectra on these two factors, excitation wavelength and collision frequency, implies an intramolecular relaxation process which is fast compared to the ~1.2 ns lifetime of the excited singlet state.

Fig. 4 shows a comparison of the excitation spectrum of POPOP vapor with the vapor's absorption spectrum. The excitation curve was obtained by monitoring the vapor fluorescence at a fixed wavelength, typically 380 nm, while sweeping the excitation wavelength and correcting for wavelength dependent variations in the excitation source intensity. If the fluorescence quantum efficiency of the vapor were con-

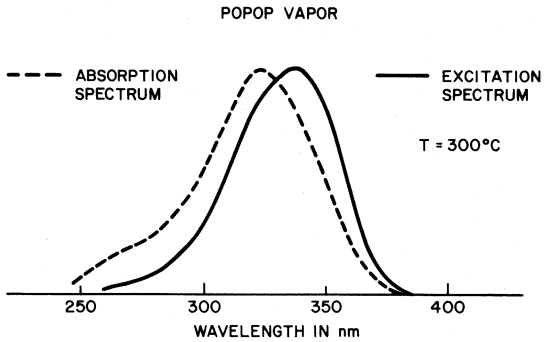

Fig. 4. A comparison of the absorption and excitation spectra for POPOP vapor at 300°C.

stant, the absorption and excitation curves would be identical. However, it is apparent from Fig. 4 that the quantum efficiency decreases with decreasing excitation wavelength (both curves are normalized at their peaks). Evidently, the higher energy photons have a greater probability of producing photodissociation, singlet-triplet conversion, or other photochemical processes. The effect of temperature on the excitation spectrum is shown in Fig. 5. Similar shifts of the absorption spectrum with temperature were not observed. The effect of higher temperatures is to decrease the quantum efficiency even more strongly at the shorter wavelengths.

Measurements of the absolute fluorescence quantum efficiency were made by comparing the peak fluorescence intensity of the vapor with the peak fluorescence intensity of POPOP dissolved in cyclohexane. In each case the fluorescence intensity was normalized to the number of absorbed photons as determined from absorption data. The quantum efficiency of the liquid solution was taken as unity.[1] With this technique we estimate an accuracy of 10 percent for relative values of the quantum efficiency and 20 percent for the absolute values. The results of these measurements are shown in Fig. 6. A falloff of quantum efficiency with temperature and decreasing pump wavelength is clearly shown.

Similar data were taken on the dye dimethyl POPOP. The main difference between the spectra of the two dyes is an approximately 10-nm shift of dimethyl POPOP vapor spectra to longer wavelengths. However, because of the dependence of the quantum efficiency on the location of the pump wavelength relative to the peak of the absorption curve, this shift results in a much lower quantum efficiency for excitation at 337 nm in dimethyl POPOP vapor than in POPOP (30 percent versus ~70 percent). Hence the laser threshold requirements of dimethyl POPOP for pumping with a pulsed nitrogen laser are significantly higher than for POPOP despite the fact that the 337-nm absorption of dimethyl POPOP vapor is stronger than that of POPOP vapor.

As a preliminary to the studies of the effects of buffer gases on gain reported in the next section, the effects of the buffer gases helium, CO_2, SF_6, and propane on the excitation and emission spectra of POPOP vapor were investigated. The buffer gas pressure in each case was 500 torr. As mentioned earlier, these buffer gases produced no marked changes in the fluorescence emission spectra. However, the fluorescence quantum efficiency was affected. These measurements are somewhat more uncertain than the quantum efficiency measurements made on POPOP vapor in a vacuum cell because the buffer gas slowed the approach of the POPOP vapor density to equilibrium and may have either enhanced the decomposition rate of the dye or chemically reacted with the dye. The preliminary results, however, showed that the addition of helium buffer gas had essentially no effect: the quantum efficiency was the same as that of the vacuum cell. The buffer gases CO_2, SF_6, and propane showed reduced fluorescence with estimated quantum efficiencies of 35 percent, 20 percent, and 5 percent, respectively. From this preliminary data we see that the quantum efficiency drops as the buffer gas molecule is made larger and more complex. Dye decomposition also appeared to be enhanced by the larger buffer gas molecules.

[1]The quantum efficiency of POPOP dissolved in cyclohexane is given as 0.93 by [1]. We have taken this to be unity for the purposes of this paper.

IV. Gain Data

The method that we used to measure the gain is a modification of the technique described by Silfvast and Deech [8] and later applied to dye lasers by Shank *et al.* [9]. The pumping configuration is as shown in Fig. 1(a), but no mirrors are used. Instead, the fluorescence along the axis of the pumped region is monitored by a detector. An aperture is placed in front of the detector to ensure that all of the collected light has passed through the pumped region, and the detector is placed far enough from the sample cell so that the detector-cell spacing is large compared to the length of the pumped region. A shutter arrangement between the pulsed N_2 laser and the sample

cell allows either one half, the other half, or the whole length of the sample cell to be pumped. Under these conditions we can determine both the gain coefficient α, and the ground state absorption coefficient β from measurements of the fluorescence intensity.

Let us define z as the coordinate along the axis of the pumped region and consider $z = 0$ as the end of the sample cell furthest from the detector. This geometry is illustrated in Fig. 7. If we consider the spontaneous fluorescence intensity from an elementary length dz to be Cdz, we can write I_1, the fluorescence intensity detected when the back 1/2 of the cell is pumped, as

$$I_1 = Ce^{-\beta l_2} \int_0^{l_1} \frac{e^{(\alpha-\beta)z}}{(d-z)^2}\, dz. \tag{1}$$

For our experiments $l_1 = l_2 = L/2$ where L is the length of the sample cell and we have $d >> L$. Under these conditions (1) becomes

$$I_1 = \frac{Ke^{-\beta L/2}}{\alpha - \beta}\left[e^{(\alpha-\beta)L/2} - 1\right] \tag{2}$$

where K is a constant proportional to the fluorescence power radiated per unit volume. We have assumed here that the gain is small enough so that the amplified spontaneous emission does not saturate the transition. This condition is well satisfied for the experiments reported in this paper. Similarly, the fluorescence intensity I_2 detected when the front 1/2 of the cell is pumped is given by

$$I_2 = \frac{K}{\alpha - \beta}\left[e^{(\alpha-\beta)L/2} - 1\right]. \tag{3}$$

When the entire cell is pumped

$$I_{1+2} = \frac{K}{\alpha - \beta}\left[e^{(\alpha-\beta)L} - 1\right]. \tag{4}$$

From (2) and (3), we find

$$\beta = \frac{2}{L}\ln\left(I_2/I_1\right) \tag{5}$$

and from (2), (3), and (4),

$$\alpha - \beta = \frac{2}{L}\ln\left[I_{1+2}/I_2 - 1\right]. \tag{6}$$

As shown in Fig. 7, a filter can be used in front of the detector in order to measure gain and absorption loss as a function of wavelength. For the experiments reported below, a monochromator with 3-nm bandwidth was used to select the wavelength of the detected fluorescence. The detector was a Sylvania Model 502 crossed field photomultiplier tube coupled to a Tektronix 7904 oscilloscope. The combined rise time of ~0.8 ns was fast enough to resolve the time dependence of the fluorescence. The pulsed N_2 laser pump pulse was also monitored and simultaneously displayed on the oscilloscope.

Fig. 8 shows the measured gain as a function of wavelength for POPOP vapor at 345°C in a vacuum. It can be seen that the gain (α) approximately follows the fluorescence curve

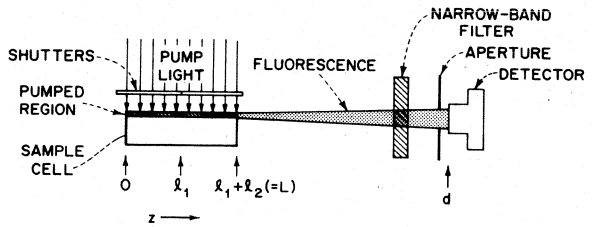

Fig. 7. Geometry of the apparatus used for gain measurements.

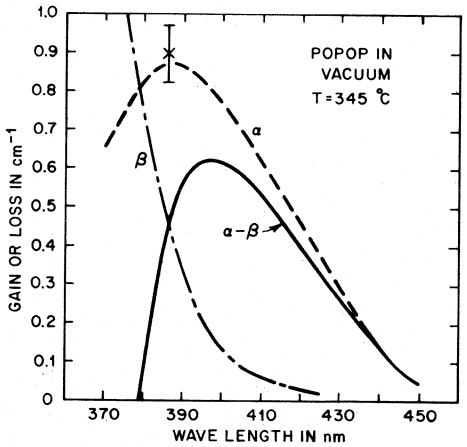

Fig. 8. Dependence of gain (α) and ground state absorption (β) on wavelength for POPOP vapor at 345°C in vacuum. For clarity only one experimental point has been shown with a bar to indicate the scatter of the data points.

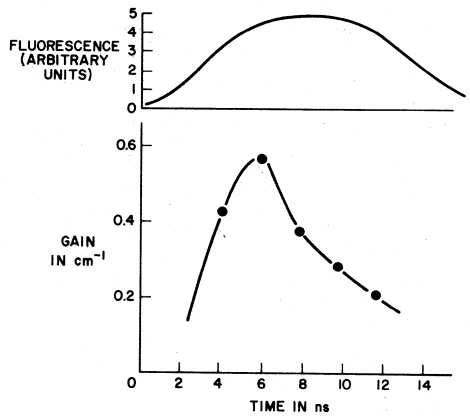

Fig. 9. The variation of POPOP vapor gain with time (no buffer gas). For comparison the off-axis fluorescence in arbitrary units is plotted on the same time scale. Data for $T = 330°C$ and $\lambda = 400$ nm.

(Fig. 2) while the net gain ($\alpha - \beta$) falls off rapidly at the shorter wavelengths due to the rapid increase in β.

The gain could be calculated as a function of time by using fluorescence data corresponding to given times after the initiation of the pump pulse. Fig. 9 shows the time variation of the POPOP vapor gain. For comparison, the off-axis fluorescence pulse in arbitrary units has been plotted on this figure with the same time scale. It can be seen that the gain falls off well before the end of the off-axis fluorescence pulse. This indicates that some mechanism such as triplet population buildup or poisoning by decomposition products is rapidly introducing loss.

We have investigated the effect of buffer gases on the time dependence of the gain. In the presence of a high pressure of He, the gain builds up more slowly, but does not fall off as

rapidly as the unbuffered POPOP vapor gain. A similar effect was observed with CO_2 buffer gas. A study of the effect of buffer gases on dye vapor gain and laser action is continuing and will be the subject of a subsequent publication.

V. Laser Experiments

By aligning laser mirrors at each end of the dye vapor cell as shown in Fig. 1, laser action could be obtained [3]. A well-collimated output beam could be seen using a fluorescent screen. Fig. 10 shows the relationship between the dye laser output power and the pump power, for POPOP vapor at 350°C in a vacuum. The slope efficiency is 10 percent.

A study was made of the spectral characteristics of the POPOP dye vapor laser with no buffer gas. Fig. 11 summarizes the results of these experiments. When broad-band laser mirrors were used, the laser output consisted of a broad featureless band of wavelengths of ~20 nm in width. When one of the laser mirrors was replaced with a diffraction grating, a ~1-nm-bandwidth output was obtained which could be tuned over a range of ~25 nm, as shown in Fig. 11. Fig. 12 shows a plot of laser output power versus wavelength for this experiment. It is not known why the output power drops off more rapidly at long wavelengths than we would expect from the gain measurements shown in Fig. 8.

Using a diffraction grating and an output mirror with 80-percent transmission, we found that the output power in a 1-nm band at the peak of the output versus frequency curve was 90 percent of the broad-band output power obtained by replacing the diffraction grating with a broad-band high reflectivity mirror. This high degree of spectral condensation implies an intraband thermalization time for the singlet ground state which is short compared to the upper state lifetime (~1 ns). If this relaxation time were long, a bottleneck would quickly occur in the lower laser level which would cause the laser to begin oscillating at another frequency or prematurely terminate the laser action. This is very direct evidence for rapid intraband thermalization in the absence of external influences (such as interactions with solvent molecules). Such behavior for the first excited singlet level was indicated by the study of the shape of the fluorescence spectrum as a function of pressure reported in Section III. A fast intraband relaxation for the first excited singlet level of dimethyl POPOP has recently been deduced from measurements of the onset of fluorescence after picosecond excitation pulses [10].

VI. Discussion and Conclusions

In Fig. 6, we show that the quantum efficiency of POPOP vapor increases at lower vapor pressures. This effect has also been observed with other dye vapors. In order to obtain a suitable pumping geometry for transverse pumped lasers, it is necessary to have the pump beam absorbed in a small distance—typically less than 1 mm—and thus high vapor densities corresponding to high temperatures must be used. If a longitudinal pumping geometry were used, however, much lower vapor densities, corresponding to absorption lengths of many centimeters, could be utilized. This would have the advantage of using the dye vapor in a regime where the quantum efficiency is close to unity, and result in more efficient laser operation. This would be particularly true for some dyes, such as the coumarins, that suffer severely from concentration quenching of fluorescence at vapor pressures above a few tenths of a torr.

Our experiments have shown that the optically pumped POPOP dye vapor laser has output power, efficiency, and tuning

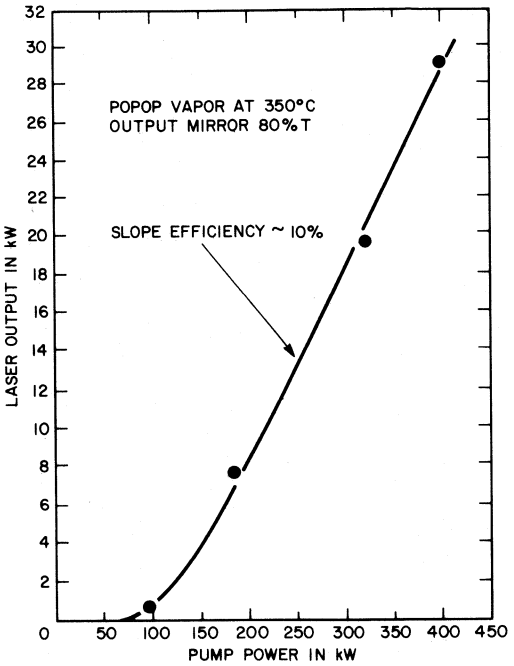

Fig. 10. Peak laser output power as a function of peak pump pulse power for POPOP vapor at 350°C using an 80-percent transmitting output mirror.

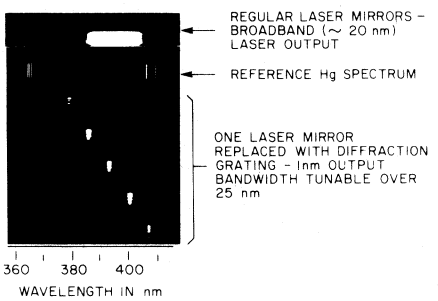

Fig. 11. POPOP vapor laser spectral output.

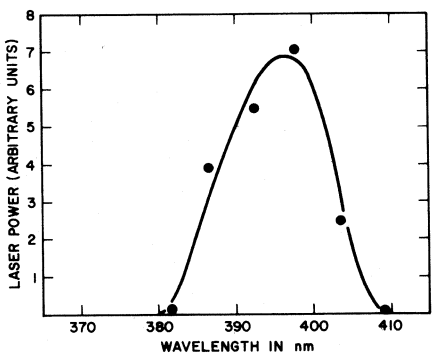

Fig. 12. POPOP vapor laser output power as a function of wavelength, when operated with one laser mirror replaced with a diffraction grating.

characteristics not too different from the average optically pumped liquid dye laser. What then is the interest in dye vapor systems? Some points have already been mentioned. A dye vapor laser provides freedom from pump-induced thermal gradient effects, a new range of laser wavelengths from a given dye, and a unique system in which to study the dye molecules themselves. Our main interest in the dye vapor laser, however, involves the development of an electrically excited dye vapor laser. In principle, such a laser could be an efficient, scalable source of tunable visible laser radiation. Even if efficient electronic excitation can be obtained, however, very high current densities will be required, and the problem of dye decomposition must be overcome. Our buffer gas studies show that relatively high helium buffer gas pressures have little effect on the quantum efficiency, but greatly increase the gain at times greater than ~5 ns after the initiation of the pump pulse. This may be due to the ability of the buffer gas to reduce dye decomposition by reducing the thermalization time for excited dye molecules. Further studies of the effects of buffer gases on dye vapor gain under both optical and discharge pumping are in progress.

In conclusion, we have reported a study of the operating characteristics of an optically pumped POPOP dye vapor laser, and have investigated in particular those properties of dye vapors whose understanding is important for the attainment of a discharge-excited dye vapor laser.

Acknowledgment

The authors wish to thank T. K. Gustafson and A. Dienes for several fruitful discussions relating to this work, and for their participation in some preliminary experimental studies.

Physical Interpretation of Bistable Unidirectional Ring-Laser Operation

J. B. HAMBENNE AND M. SARGENT III

Abstract—**Oppositely directed running waves in a ring laser saturate themselves and one another by population depletion. In addition, as the Doppler broadening decreases, they saturate one another by scattering off induced Bragg gratings in the medium, i.e., off spatial holes burned into the population difference. This increased coupling results in bistable operation near the atomic line center for Doppler-broadened media and for any equal tuning for stationary atoms.**

Considerable interest has developed concerning the obtaining [1], [2] (and suppressing [3], [4]) of unidirectional operation in ring lasers; that is, operation for which the running waves travel in only one direction. The origins of the interest stem from both theoretical considerations (unidirectional operation is simpler to treat theoretically since spatial dependences drop out [5]) and practical considerations; for examples, in achieving optical isolation and increased efficiency [6]. On the other hand, unidirectional operation is a nuisance in gyro applications where two running waves traveling in opposite directions are required [3]. Bistable unidirectional operation is that for which either of two oppositely directed running waves oscillates alone, and for which one depends on past history. It has been predicted theoretically for stationary atoms by White [6] and on the basis of Lamb theory by Zeiger and Fradkin [7]. Both references also show that for Doppler-limited media, the mode coupling is reduced sufficiently to obtain monostable operation, except for central tunings. The bistability results from cross saturation of one running wave on the other in excess of the self-saturation of a wave on itself. The bistable operation has been observed experimentally in the argon-ion laser by Rigrod and Bridges [8] and in He–Ne near central tuning by Moss *et al.* [9] and Aronowitz [3].

In the present correspondence we explain the increased cross saturation in terms of backscattering off induced population-inversion gratings (spatial holes burned into the population difference) and examine the dependence on the Doppler-width parameter Ku (K is the wavenumber and u the average atomic speed). The existence of such gratings has been mentioned before (see, for example, Menogozzi and Lamb [10]), but the fact that the Lamb theories actually include the effect is new here. Note that we are not concerned here with frequency locking of the two running waves, a phenomenon that also yields a zero beat frequency. The beat note vanishes for unidirectional operation since one of the running waves is suppressed. Furthermore, the backscattering by population-inversion gratings does not contain the relative phase angle between the waves, whereas that due to mirrors, dust, etc., does contain this angle and thereby contributes to mode locking [11].

We consider a ring laser that might support two oppositely directed running waves of the electromagnetic field. Self-saturation is caused only by population depletion. This depletion also results in cross saturation to the extent that the two running waves interact with similar groups of atoms. In particular, in the Doppler-broadened medium with the laser tuned to line center, the waves interact with the same group of atoms, causing the self-saturation to equal the cross saturation that results from population depletion. Although the wave with higher linear gain can often suppress the other when the self-saturation is only slightly greater than the total cross saturation, bistable operation does not occur (see [5, ch. 9] for a detailed explanation).

As the Doppler broadening is reduced, however, an additional cross saturation comes into play. Specifically, the two waves add in the medium yielding a standing wave (for equal mode tuning) and burn spatial holes in the population inversion. This corrugated inversion pattern acts like a Bragg grating to reflect one running wave back into the other. Unlike scattering by the "principal" grating in the distributed feedback laser [12], the scattering here produces a net reflected wave that subtracts from the similarly directed wave (for stationary atoms, the gain grating is precisely out of phase with the standing-wave pattern). Such a population-inversion grating should also occur in the distributed-feedback laser. In any event, an additional cross saturation occurs. When the total cross saturation exceeds the self-saturation, either mode may suppress the other; which wins depends on the linear gains and initial intensities. In particular, we find that for the stationary-atom medium (straight homogeneous broadening), the Bragg-like contribution to the cross saturation actually equals the population-depletion contribution for any tuning. This might be called the van der Pol limit, inasmuch as his double-tank circuit [13] had twice the cross saturation that it had self-saturation, a result caused by analogous phenomena (see, for example, [5, ch. 4]). For the special case of the two-mirror standing-wave laser, the increased coupling yields an increased saturation resulting in an output only two thirds as large as the corresponding unidirectional ring configuration [6]. Here the third results from the three sources of saturation: 1) self-saturation of the running waves comprising the standing wave; 2) cross saturation from population depletion; and 3) cross saturation from Bragg reflection. The Bragg term is an example of atomic coherence induced by mode interference that shows up in analogous ways in other laser configurations (see, for example, [5]), such as population pulsations in multimode laser operation and electric quadrupole moments in the Zeeman laser. In these examples, the coherence term leads to a Ramanlike scattering of one mode into another, although for the bidirectional ring and Zeeman cases, no frequency shift occurs for equal tuning of the modes.

Our physical interpretation is based on third-order Lamb theory (see, for example, [5, ch. 11]), although other calculations [14] reveal that much of the same qualitative conclusions persist to strong-signal operation. Specifically, we describe the laser electric field by the superposition of two oppositely directed running waves

$$E(s,t) = \tfrac{1}{2} E_+(t) \exp\left[-i(\nu_+ t + \phi_+ - K_+ s)\right] + \tfrac{1}{2} E_-(t) \exp\left[-i(\nu_- t + \phi_- + K_- s)\right] + \text{c.c.} \quad (1)$$

Here s is the laser axis, the amplitudes $E_\pm(t)$ and phases $\phi_\pm(t)$ vary little in an optical-frequency period, $\nu_\pm$ are the mode-oscillation frequencies, and K is the mode's wavenumber (which we assume is the same for both waves in our current development). The mode intensity $I_+ = E_+^2$ is found to obey the

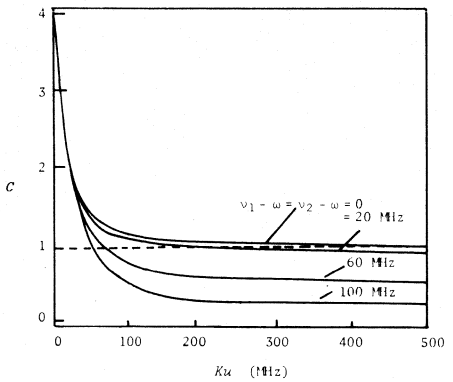

Fig. 1. Coupling parameter C of (3) plotted versus Doppler-width parameter Ku (in megahertz) for indicated detuning values. Upper and lower level decay rates are $2\pi \times 20.0$ and $2\pi \times 40.0$ MHz, respectively, and the dipole decay rate $(1/T_2)$ is $2\pi \times 100$ MHz. The dashed line gives $C = 1$, the dividing line between strong ($C > 1$) and weak coupling.

equation of motion

$$\dot{I}_+ = 2I_+(\alpha_+ - \beta_+ I_+ - \theta_{+-} I_-) \tag{2}$$

with a similar expression for I_-. Here α_+ is the net linear gain (that in excess of the loss) for I_+, β_+ is the self-saturation coefficient, and θ_{+-} is the cross-saturation coefficient. The phenomenon discussed above leads to values of θ_{+-} that are larger than those of β_+ (this result was noted in [4] and [10] for central tuning and Doppler-broadened media and in [7] and [10] for stationary atoms). In similar discussions in the past (see, for example, [15] or [5]), it has been convenient to use the coupling parameter defined by the ratio

$$C = \theta_{+-}\theta_{-+}/\beta_+\beta_-. \tag{3}$$

The bistable region is encountered for values of C greater than unity. For stationary atoms, the Bragg effect equals the population depletion yielding the value $C = 4$, considerably greater than unity. In the Doppler limit (the Doppler-width parameter Ku greatly exceeds the atomic decay rates), the coupling parameter has a squared Lorentzian dependence on detuning. The reduced coupling for nonzero detuning results from the fact that the running waves interact with different velocity ensembles, a phenomenon responsible for the Lamb dip in the standing-wave laser. In Fig. 1 we plot C as a function of Ku for several detuning values. We see that the coupling decreases as Ku increases. This is due to the facts that 1) moving atoms yield gain gratings reduced in peak-to-peak variation due to a tendency to see an average (i.e., not standing-wave) field, and 2) the gratings that do exist move out of phase with respect to one another leading to cancellation of the scattered waves. The decrease rate is characterized by the level decay rates (the Bragg contribution has Lorentzian dependence on these rates) inasmuch as the grating occurs in the population difference.

The dependence of grating shape on axial velocity is illustrated beautifully by [16, Fig. 8], a paper by Stenholm and Lamb, which treats the special case of the two-mirror standing-wave laser. In particular, that figure reveals that some velocity ensembles actually yield gratings that scatter in phase with the running waves (decrease the coupling). The grating effect vanishes completely in the Doppler limit due to combination of the cancellation and averaging. Other computations reveal that cavity rotation giving a symmetric tuning has little effect in the Doppler limit, but a pronounced effect for $Ku = 0$. Physically, this occurs since the Doppler-limit Bragg contribution is small and both waves interact with the same velocity ensemble (i.e., the population depletion contribution to the cross saturation is appreciable), while for small Ku, the grating contribution can be as large as that due to population depletion and has Lorentzian dependence on the splitting. The formulas that we have used for the coefficients are given (with appropriate specialization) by [15, eq. (61)], a paper by O'Bryan and Sargent (see also [7]).

We conclude that to achieve unidirectional operation, one should use stationary atoms with level decay rates exceeding any rotational splitting. Conversely, to obtain bidirectional operation, moving atoms with some detuning can be used. The standard mode of operation for ring gyros [3] involves two isotope media, for which this detuning condition is automatically satisfied. The coupling effects we have considered apply to any problem in which standing waves saturate the medium they interact with. In particular, lasers having two-mirror unstable-resonator configurations experience increased saturation of the nature discussed here to the extent that standing waves exist. Similarly, unstable ring resonators can be encouraged to oscillate in one direction through the use of homogeneously broadened media. Further discussion will be presented in a forthcoming paper [14] on strong-signal ring-laser operation.

New Laser Oscillation in the Oxygen Atom

D. G. SUTTON, L. GALVAN, AND S. N. SUCHARD

***Abstract*—A new laser oscillation has been observed in a pulsed discharge of He and O_2. This oscillation at 2.652 μm has been identified as belonging to the O(I) atom.**

A new laser oscillation in the O(I) atom has been observed. The laser emission was detected at a wavelength of 2.652 ± 0.003 μm. This wavelength can be assigned to the $4d\ ^5D^\circ \rightarrow 4p\ ^5P$ transition of the neutral O(I) atom when it is compared with the calculated wavelength obtained from known energy levels [1]. Other laser oscillations have previously been observed in the O(I) atom in the spectral region of 0.8–11.0 μm [2]: however, this is the first report of oscillation at this wavelength.

The laser apparatus used for these experiments has been described elsewhere [3]. Briefly, the laser tube consists of two 1.25-m (2.5-cm ID) Lucite pipes, which are fitted with 251 pairs of 470-Ω resistors in a double helical configuration coaxial with the optical axis. The gap between resistor pairs is 1.9 cm. One of these helices is connected to ground, which forms the cathode of the discharge circuit; the other is connected to a pulsed power supply triggered by a spark gap. The ends of the laser tube are sealed by CaF_2 windows at Brewster's angle. A stable optical cavity is formed about the laser tube by two silver-coated mirrors: a total reflector with a radius of curvature of 11.5 m and a flat output coupler with a 1-mm hole in its center. The entire length of the optical cavity is 3.2 m.

Manuscript received September 12, 1974. This work was supported by the Defense Advanced Research Projects Agency of the Department of Defense under U. S. Air Force Space and Missile Systems Organization (SAMSO) Contract F04701-74-C-0075.
The authors are with The Aerospace Corporation, El Segundo, Calif. 90245.

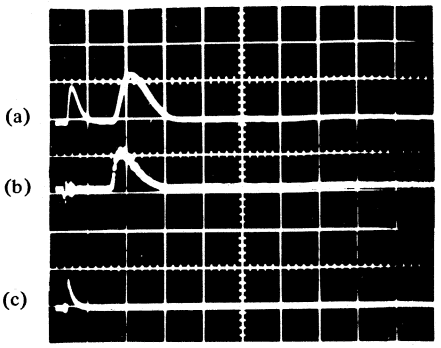

Fig. 1. Spectral output of the O(I) laser. (a) Total laser emission. (b) $^5D^\circ \rightarrow {}^5P$ emission at 2.652 μm. (c) Triplet emission at 0.8446 μm. (Time scale: 5 μs/div. Experimental conditions: 24-kV discharge through 80-torr He plus 2-torr O_2.)

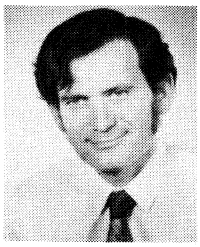
Laser output is directed into a screen room where the beam is split into two parts by a sapphire flat. One of these beams is directed to an InSb detector to monitor the total laser emission; the other is directed through a 0.5-m monochromator to an identical InSb detector to monitor the spectrally resolved emission. Detector response is monitored with a fast oscilloscope.



The laser results are displayed in Fig. 1. Total laser emission is presented on the top oscilloscope trace and the spectrally resolved emission on the lower two traces: 2.652-μm emission in the middle and 0.8446-μm emission on the bottom. The time scale for all the traces is 5 μs/div. For a gas mixture of 80 torr He and 2 torr O_2 and a discharge voltage of 24 kV, both the 0.8446-μm triplet and 2.652-μm oscillations are seen. As the discharge voltage is lowered to 18 kV, the intensity of the 2.652-μm emission decreases to zero, while, as the voltage is increased to 30 kV, the 0.8446-μm emission decreases to zero.

Since the upper laser level of the transition is a $^5D^\circ$ state and the lower level a ^5P state, many separate laser components are possible. The resolution of our monochromator, however, would not allow us to separate the total emission into its separate components.

Jay H. Harris (S'57–M'66) was born in Newark, N. J., in 1936. He received the B.E.E. degree from the Polytechnic Institute of Brooklyn, Brooklyn, N. Y., in 1958, the M.S. degree from the California Institute of Technology, Pasadena, in 1959, and the Ph.D. degree from the University of California at Los Angeles in 1965.

From 1958 to 1965 he was a member of the Technical Staff of the Hughes Aircraft Company. His work there was concerned with various aspects of antenna design and electromagnetic-wave propagation. The academic year 1965–1966 was spent as a Fulbright Hayes Fellow at the Laboratoire d'Electronic of the University of Paris where he was engaged in research dealing with wave propagation in linear accelerators. In 1966 he went to the University of Washington, Seattle, where he was a Professor in the Department of Electrical Engineering. He was a Traveling Lecturer of the Optical Society of America from 1971 to 1972 and a Visiting Associate Professor at the University of California at San Diego (La Jolla) from 1972 to 1973. His research at Seattle dealt with wave propagation in plasmas, ultrasonic measurement of biological flow systems, and integrated optics and optical communications. He is currently at the National Science Foundation, Washington, D.C.

Dr. Harris is a member of the American Physical Society.

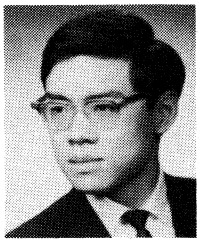
Mordehai Heiblum (S'74) was born in Holon, Israel, on May 25, 1947. He received the B.S. degree (honors) in electrical engineering from the Technion, Israel Institute of Technology, Haifa, in 1973, and the M.S. degree from Carnegie-Mellon University, Pittsburgh, Pa., in 1974. He spent the summer of 1974 in the Department of Electrical Engineering, University of Washington, Seattle. He is currently studying toward the Ph.D. degree in the Department of Electrical Engineering and Computer Sciences, University of California, Berkeley.

From 1967 to 1970 he served in the Israeli army. From 1970 to 1973 he was an Instructor in the Electronics Department at the Junior Technical High School, at the Technion.



Mr. Heiblum is a student member of the American Physical Society.

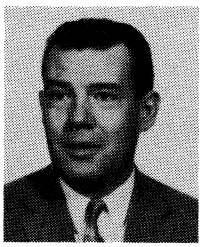
*

Robert F. Leheny (S'58–M'61) received the B.S. degree in electrical engineering from the University of Connecticut, Storrs, in 1960, and the Dr.Eng.Sc. in electrical engineering from Columbia University, New York, in 1967, where his dissertation topic was microwave interactions with plasmas.

From 1960 to 1961 he worked in the Systems Engineering Department of the Sperry Gyroscope Company. Between 1967 and 1968 he did postdoctoral work in the Plasma Laboratory at Columbia University. Since 1968 he has been a member of the Bell Laboratories, Holmdel, N.J. His current research interests are in semiconductor luminescence and laser physics.

Paul F. Liao was born in Philadelphia, Pa., on November 10, 1944. He received the B.S. degree in physics from the Massachusetts Institute of Technology, Cambridge, in 1966, and the Ph.D. degree in physics from Columbia University, New York, N.Y., in 1973.

During 1973 he was a Research Associate at the Columbia Radiation Laboratory, Columbia University, and joined Bell Laboratories, Holmdel, N.J., in September 1973, where his interests lie in laser physics.



Dr. Liao is a member of the American Physical Society and Sigma Xi.

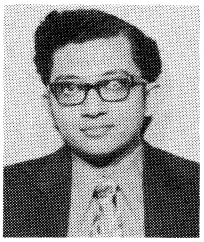
*

C. Lin was born in Taiwan, Republic of China, in 1945. He received the B.S.E.E. degree from the National Taiwan University, Taipei, Taiwan, in 1967, the M.S. degree in computer sciences from the University of Illinois, Urbana, in 1970, and the Ph.D. degree from the University of California, Berkeley, in 1973.

While at Berkeley he was a recipient of an IBM Graduate Fellowship and a Lankersheim Scholarship, as well as a Research Assistant in the Quantum Electronics Group of the Electronics Research Laboratory. He joined Bell Laboratories, Holmdel, N.J., in 1974. His current interest is in the field of picosecond pulses and dye lasers.

*

Patrick J. Maloney (S'71–M'71) was born in New York, N.Y., on November 11, 1925. He received the Associate degree in applied science (electrical technology) from New York Community College, New York, N.Y., in 1949.

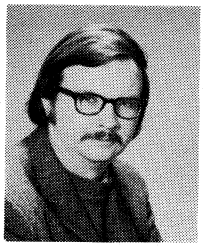


From 1950 to 1951 he was assigned to the cesium beam clock project in the Microwave Standards Section of the National Bureau of Standards, Washington, D.C. From 1951 to 1953 he was engaged in experimental research with traveling-wave magnetrons at the Thermionics Branch of the Fort Monmouth Signal Corps Laboratory. From 1953 to 1961 he was employed at the IBM Thomas J. Watson Research Laboratory, New York, N.Y., where he worked in the fields of cryogenics, superconductivity, and thin films. He assisted Prof. C. H. Townes in the Michaelson-Morley experiment conducted at the Watson Laboratory using two ammonia masers. Since 1961 he has been assigned to the Department of Coherent Wave Physics, Bell Laboratories, Holmdel, N. J. He has been principally engaged in laser research ranging from the early ruby to the present gaseous devices.

*

D. Schicketanz was born in Puerto Montt, Chile, on October 5, 1943. He received the degree Ingeniero Civil Electricista from the University of Chile, Santiago de Chile, Chile, in 1969.

From 1969 to 1970 he was employed by the Electrical Engineering Research Laboratory, University of Chile. Since 1971 he has been with the Siemens Research Laboratories, Munich, Germany. His present work is on fiber optics.

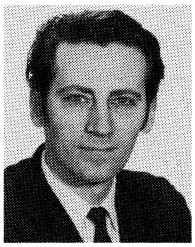


Jagdeep Shah was born in Surat, India. He received the B.Sc. degree in physics from Bombay University, Bombay, India, in 1962, and the Ph.D. degree in physics from the Massachusetts Institute of Technology, Cambridge, in 1967.

He has been with Bell Laboratories, Holmdel, N.J., since 1967, where he has been involved in studying optical properties of semiconductors, high-intensity effects in semiconductors, properties of organic dyes and dye lasers, and photoexcitation of superconductors.

Dr. Shah is a member of the American Physical Society.

*



Charles V. Shank received the B.S., M.S., and Ph.D. degrees from the University of California, Berkeley, in 1965, 1966, and 1969, respectively.

Since 1969 he has been a member of the Coherent Optics Research Department at Bell Laboratories, Holmdel, N. J., where his present interests include dye lasers and waveguide devices.

*

Peter W. Smith (M'68) was born in London, England, on November 3, 1937. He received the B.Sc. degree in mathematics and physics in 1958 and the M.Sc. and Ph.D. degrees in physics in 1961 and 1964, all from McGill University, Montreal, P.Q., Canada. His thesis work was on the paramagnetic relaxation of iron group ions in dilute single crystals.

From 1958 to 1959 he was an Engineer at the Canadian Marconi Company, Montreal, Canada, where he worked on transistor circuitry. After obtaining the Ph.D. degree he joined the Bell Laboratories, Holmdel, N. J., where he has conducted research on the fundamental properties of gas lasers. In 1970 he spent nine months at the University of California, Berkeley, as Visiting McKay Lecturer in the Department of Electrical Engineering. His current interests include waveguide gas lasers and dye vapor lasers.

Dr. Smith is a member of the American Physical Society and the Optical Society of America.

*

G. Zeidler was born in Rosshaupt, Germany, in 1940. He studied at the Technical University of Munich, Munich, Germany.

Since 1975 he has been with the Siemens Research Laboratories, Munich, Germany. After working on solid-state lasers, optical range finders, and organic dye lasers, he is currently working on fiber optics and integrated optics.

MEMBERSHIP APPLICATION

IEEE MICROWAVE THEORY AND TECHNIQUES SOCIETY

Membership in the IEEE MICROWAVE THEORY AND TECHNIQUES Society entitles you to receive, for the low Society fee, the monthly IEEE Transactions on Microwave Theory and Techniques, and the quarterly Microwave Theory and Techniques Society Newsletter. You are kept informed of latest developments, meetings and conferences in your areas of interest, and are entitled to purchase informative conference records and other helpful educational aides at greatly reduced rates for members.

Use the convenient coupon to become a member of the IEEE MICROWAVE THEORY AND TECHNIQUES Society. If you are not a member of the IEEE, but would like to join, please check the appropriate box on the coupon. Descriptive materials and an IEEE membership application form will be sent to you immediately upon receipt.

*Society Fee: $7.00 for IEEE members of all grades except Student. Student Fee: $2.00. These rates apply to payments received September 1 through February. On payments received March 1 through August 31 remit one-half of the above rates. (Payments received September 1 through December 31 apply through December 31 of the following year.)

Analysis of Laser Emission in Ho^{3+}-Doped Materials

JOHN A. CAIRD AND LARRY G. DESHAZER

Abstract—**The oscillator strengths, transition rates, and branching ratios associated with known and potential laser transitions in trivalent holmium are discussed. Recently reported laser transitions between the $^5F_5$ and $^5I_5$ energy manifolds are found to have an abnormally low average oscillator strength, and an alternative explanation of the laser observation is suggested.**

I. Introduction

INDUCED electric dipole oscillator strengths and transition rates between energy levels of rare-earth ions in crystals can be calculated using a theory developed by Judd [1] and Ofelt [2]. In recent years the Judd-Ofelt (JO) model has been used in the analysis of rare-earth laser materials [3]-[6], and its use led to the discovery of the four-level Tm:Cr:$YA1O_3$ laser at 2.35 μm [7]. This paper reports the results of an application of the JO model to known and potential laser transitions in trivalent holmium.

II. Theoretical Background

According to the JO model, the oscillator strength f and spontaneous emission rate A of crystal field induced electric dipole fluorescence in a rare-earth ion are given by [8]

$$f_{JJ'} = \frac{8\pi^2 mc}{3h\bar{\lambda}(2J+1)}\left[\frac{(n^2+2)^2}{9n}\right] \cdot \sum_{t=2,4,6} \Omega_t |\langle 4f^n [S,L] J \| U^t \| 4f^n [S',L'] J' \rangle|^2 \quad (1)$$

and

$$A_{JJ'} = \frac{8\pi^2 e^2 n^2}{mc\bar{\lambda}^2} \cdot f_{JJ'} \quad (2)$$

where $\bar{\lambda}$ is the mean wavelength associated with the transition, n is the crystal's index of refraction at the mean wavelength, and $2J+1$ is the number of levels in the upper J-manifold. In (1) the $\langle \| U^{(t)} \| \rangle$ are doubly reduced matrix elements of unit tensor operators calculated in the intermediate coupling approximation [1], and the Ω_t are three empirical parameters. These empirical parameters can generally be determined for each ion-host combination by a least squares fit between calculated and measured oscillator strengths in the absorption spectrum. Equation (1) may then be used to calculate oscillator strengths in the fluorescence spectrum. It should be noted that (1) gives the oscillator strength summed over the Stark split components of the final energy manifold J' and averaged over the components of the initial energy manifold J.

The cross section for stimulated emission integrated over all Stark split components of the upper and lower J-manifolds is given by [5]

$$\int_{J \to J'} \sigma(\nu)\, d\nu = \frac{\bar{\lambda}^2}{8\pi c n^2} A_{JJ'} \quad (3)$$

where $\nu = 1/\lambda$. Using (2) this reduces to

$$\int_{J \to J'} \sigma(\nu)\, d\nu = \frac{\pi e^2}{mc^2} f_{JJ'} \quad (4)$$

which shows the significance of the oscillator strength in laser analysis. Without detailed line shape information (4) cannot be used to predict peak cross sections, but it is evident that transitions with larger oscillator strengths will generally have larger peak cross sections.

In the $4f^n$ ground configuration of rare-earth ions, electric dipole transitions become allowed only when the ion feels a perturbing field lacking inversion symmetry so that parity restrictions are broken. Magnetic dipole (md) transitions between levels with $|\Delta J \leqslant 1|$ are always allowed, however, and can on occasion be comparable in strength to the crystal field induced electric dipole (ed) transitions. A definition of the md oscillator strength consistent with (2) and (4) is given by [9]

$$f_{JJ'}(\text{md}) = \frac{h}{6\bar{\lambda}(2J+1)mc} \cdot n\, |\langle 4f^n [S,L]\, J \| L + 2S \| 4f^n [S',L']\, J' \rangle|^2 \quad (5)$$

where the matrix elements of $L + 2S$ can be evaluated using standard formulas given elsewhere [10].

A computer program was developed capable of calculating the unit tensor operator matrix elements in (1) between all J-manifolds in all rare-earth ions using previously published intermediate coupling wave functions [6]. The program was then used to calculate ed and md oscillator strengths, transition rates, and radiative branching ratios for a large number of ion-host combinations for which intensity parameters Ω_t had been published. The branching ratio for a transition $i \to j$ is simply given by

$$\beta_{i \to j} = \frac{A(i \longrightarrow j)}{\sum_{j'} A(i \longrightarrow j')} \quad (6)$$

Manuscript received June 7, 1974; revised October 16, 1974. This work was supported in part by the Air Force Systems Command, Air Force Avionics Laboratory, Wright-Patterson Air Force Base, Ohio, and in part by the U.S. Army ECOM under Contract DAABO7-74-C-0104.

J. A. Caird is with the Department of Physics, University of Southern California, Los Angeles, Calif. 90007, and with Hughes Aircraft Company, Culver City, Calif. 90230.

L. G. DeShazer is with the Departments of Electrical Engineering, Physics, and Materials Science, University of Southern California, Los Angeles, Calif. 90007.

where the sum in the denominator is over all states of lower energy. In these calculations emphasis was placed on transitions for which laser action and/or fluorescence has been reported, and those for which the radiative transition rates were large enough to exceed multiphonon emission rates. It was found that the vast majority of laser lines had oscillator strengths greater than 10^{-6}. In a few notable exceptions although the oscillator strengths were somewhat lower than 10^{-6}, the branching ratio associated with the laser transition was particularly high, and the upper level lifetime was long, allowing for the buildup of a large inversion density. The only other exceptions were found in cases where a trivalent rare-earth ion was placed on a divalent ion site in the laser material.

III. Application to Holmium

Laser emission from Ho^{3+} ions has been observed in many hosts on transitions between the $^5I_7$ and $^5I_8$ energy manifolds at wavelengths near 2 μm. Laser action in the green near 0.55 μm has also been reported on $[^5S_2, {}^5F_4] \rightarrow {}^5I_8$ transitions in CaF_2 [11] and BaY_2F_8 [12]. Recently stimulated emission in $Ho:BaY_2F_8$ near 2.4 μm has been attributed to transitions within the $^5F_5 \rightarrow {}^5I_5$ group [13]. Fluorescence originating in the $^5I_6$ state has also been observed in a number of crystals [9], [13], [14], but emission from other levels is often quenched by nonradiative processes.

The intensity parameters in the JO model for $Ho:YAlO_3$ were determined by Weber *et al.* [9] to be 1.82, 2.38, and 1.53 ($\times 10^{-20}$ cm^2) for Ω_2, Ω_4, and Ω_6, respectively. The electric dipole oscillator strengths and transition rates for fluorescence from low lying energy levels of Ho^{+3} in $YAlO_3$ can be easily derived from data given in [9] along with the indices of refraction of $YAlO_3$ given in [15]. These are tabulated for transitions from the $^5I_7$, $^5I_6$, $^5F_5$, and $[^5S_2, {}^5F_4]$ states in Table I. Calculation of the md contributions in Table I required the use of intermediate coupling wave functions for Ho^{3+} which were obtained from the authors of [9]. The branching ratios are in close agreement with those reported in [9], with the exception of the $^5F_5 \rightarrow {}^5I_4$ transition for which the ratio is found to be much smaller than previously reported.

Examination of Table I shows that the laser transitions $^5I_7 \rightarrow {}^5I_8$ and $[^5S_2, {}^5F_4] \rightarrow {}^5I_8$ have oscillator strengths greater than 10^{-6}, consistent with most other rare-earth lasers [6]. It is interesting to note that $^5F_4 \rightarrow {}^5I_8$ transitions may be more important than $^5S_2 \rightarrow {}^5I_8$ transitions for green laser emission, and therefore the relative positions of the $^5S_2$ and $^5F_4$ energy levels may have a large effect on laser performance. The $^5S_2 \rightarrow {}^5I_7$ transition at 0.76 μm also appears to have sufficient strength to support laser oscillation, but the $^5I_7$ lifetime is longer than the $^5S_2$, so that quenching of the $^5I_7$ level may be required. Conditions also appear to be favorable for laser emission on both the $^5I_6 \rightarrow {}^5I_7$ line at 2.9 μm and the $^5I_6 \rightarrow {}^5I_8$ line at 1.2 μm, particularly since the fluorescence lifetime of the $^5I_6$ level is reasonably long. At least one attempt to achieve laser action on the $^5I_6 \rightarrow {}^5I_7$ transition, however, was unsuccessful [13] even though the $^5I_7$ lifetime was significantly shortened by addition of Pr^{3+} and Eu^{3+} ions.

The oscillator strength of the $^5F_5 \rightarrow {}^5I_5$ emission is seen to be very small in comparison to other rare-earth lasers, and to the other holmium lasers in particular. The transition does not have mitigating advantages either. The upper level lifetime is not long, the lower level lifetime is long (predicted), and the radiative branching ratio is very small. It would seem that stimulated emission from the $^5F_5$ level and terminating on the $^5I_6$, $^5I_7$, and $^5I_8$ levels should have been observed first. One might ask if the intensity parameters for BaY_2F_8 could be much larger than in $YAlO_3$. The predicted radiative lifetimes for the $^5I_6$ and $^5I_7$ levels in $YAlO_3$ are 3 and 6 ms, respectively, while the measured lifetimes in BaY_2F_8 are 5 and 16 ms, respectively [13], indicating that the intensity parameters for BaY_2F_8 must in fact be smaller than for $YAlO_3$. In addition, examination of the unit tensor operator matrix elements involved [9] shows that changing the relative magnitudes of the three intensity parameters could not change the branching ratio appreciably. It could be that the stimulated emission cross section for this transition is sharply peaked, while the integral (4) remains small. However, laser oscillation was reported on three different lines: 2.362 μm, 2.375 μm, and 2.377 μm.

Our own work on the $Tm:YAlO_3$ laser at 2.3 μm [16] leads us to suggest that the emission seen by Johnson and Guggenheim may have been due to impurity thulium ions in their laser rod. It should be noted at the outset, however, that the authors of [13] indicate that the $Ho:BaY_2F_8$ laser

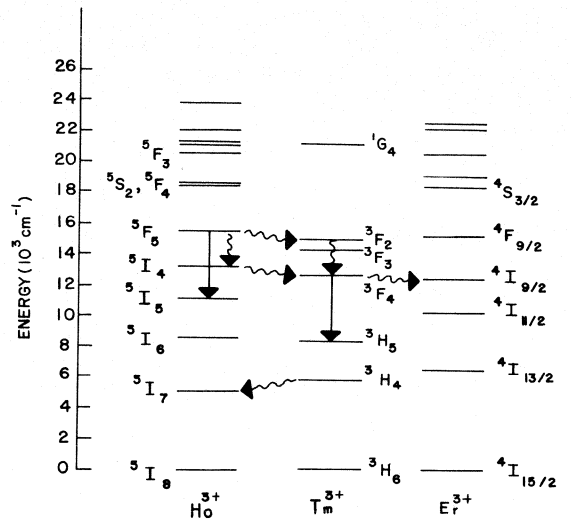

Fig. 1. Energy levels of Ho^{3+}, Tm^{3+}, and Er^{3+} indicating transitions in the 2.3–2.4-μm region.

material was of very high purity and that no fluorescence typical of thulium was observed [17].

Fig. 1 compares the energy levels and laser transitions of Ho^{3+} and Tm^{3+} in question. Er^{3+} is included for later discussion. The laser wavelengths which have been observed in $Tm:YAlO_3$ on $^3F_4 \rightarrow {}^3H_5$ transitions are 2.348 μm, 2.349 μm [18], and 2.272 μm [19], while the range of possible wavelengths in this group extends from 2.13 to 2.61 μm based on the energy levels given in [18]. Also indicated in Fig. 1 are possible mechanisms for nonradiative transfer from Ho^{3+} to Tm^{3+}. This excitation scheme is consistent with the observations of Johnson and Guggenheim since they indicate laser oscillation is initiated by pumping the $^5F_5$ level of Ho^{3+}. Nonradiative transfer from Ho^{3+} $^5I_4$ to Tm^{3+} $^3F_4$ is also possible, but direct excitation of the $^5I_4$ level of Ho^{3+} is ineffective because the absorption of the $^5I_4$ level is extremely weak. Cessation of oscillation early in the pump pulse attributed to terminal state population buildup was observed [13] and may be consistent with the Tm^{3+} $^3H_5$ level lifetime in BaY_2F_8 (though this is not observed in $YAlO_3$). The normal thulium $^3H_4 \rightarrow {}^3H_6$ fluorescence at 1.9 μm would be quenched by nonradiative energy transfer from the Tm^{3+} $^3H_4$ to the Ho^{3+} $^5I_7$ level, and would therefore be difficult to observe. Fluorescence from the $^3F_4 \rightarrow {}^3H_6$ transition at 0.8 μm might be expected, however, if thulium were responsible for the laser action. One might ask why the Tm^{3+} transition is not observed to lase in a large number of crystals in which Ho^{3+}, Er^{3+}, and Tm^{3+} are doped together to sensitize the 2-μm transition in holmium. Reference to Fig. 1 shows that the presence of erbium in these cases would quench fluorescence from the $^3F_4$ level of Tm^{3+} by nonradiative energy transfer to the $^4I_{9/2}$ level of Er^{3+}.

IV. Summary and Conclusion

An analysis of holmium laser transitions has been performed based primarily on the Judd-Ofelt theory of crystal field induced electric dipole oscillator strengths. The JO model appears to be useful in describing some of the actual and potential laser properties of Ho^{3+}, except in the case of the reported $^5F_5 \rightarrow {}^5I_5$ transitions. The observation of laser emission from holmium on these lines would not indicate a breakdown of the JO model, but would show that the applicability of the JO model to laser analysis is limited in its present form. If, however, the observed emission could be attributed to thulium impurities in the crystal, the JO model will have been a useful tool in the identification and prediction of the laser transitions.

Phase-Matched-Stimulated Four-Photon Mixing in Silica-Fiber Waveguides

ROGERS H. STOLEN

Abstract—**Stimulated four-photon mixing has been observed in silica-fiber waveguides. Phase matching is achieved by using the dispersion of the waveguide modes to compensate for bulk dispersion. The coherence lengths can be greater than 10 m and the gains more than double the usual Raman gain.**

I. Introduction

FIBER WAVEGUIDES provide a means for maintaining high optical intensities over long lengths. For self-phase-matched processes, such as stimulated Raman scattering in liquids and glasses, the interaction length is limited only by the linear absorption of the fiber which leads to a dramatic reduction of threshold power [1]. For processes such as four-photon mixing which are not automatically phase matched it is possible to use the dispersion of the waveguide modes to compensate for bulk dispersion in such a way as to achieve phase matching. This has been demonstrated by the observation of four-photon mixing (also called three-wave mixing) in a multimode fiber [2]. In that case, the effective coherence length was only 10 cm. This effective coherence length is reduced from the strictly infinite coherence length of perfect phase matching by imperfections in the guide. It will be shown here that for selected combinations of modes a relative insensitivity to imperfections will occur. Under these conditions effective coherence lengths increase from centimeters to meters in the same fiber and stimulated interactions are easily observed. The gain in this process is more than double the usual self-phase-matched Raman gain. The experimental results are presented first, followed by the explanation based on four-photon mixing.

II. Experimental Observations

The experimental arrangement is shown in Fig. 1. The output from a doubled Q-switched Nd:YAG laser is focused into a multimode guide. Peak powers were between 100 and 500 W. The output from the fiber is dispersed by a prism and displayed on a screen. The basic observation is that stimulated Stokes-anti-Stokes pairs are observed. This is in addition to the well-known stimulated Raman output which in fused silica occurs 460 cm^{-1} from the pump. The presence of the anti-Stokes shows that this is a four-photon process in which two pump photons are destroyed and Stokes and anti-Stokes photons created. Fig. 2 shows the results for two silica-core fibers [3]. A–C in Fig. 2 are from a 5-m fiber with a 5-μm core radius, and D is from 16 m of 2.5-μm core fiber. The pump at 532 nm is labeled P, and R is the self-phase-matched-stimulated Raman radiation. Stokes and anti-Stokes are designated S and A. A four-photon process requires phase matching and in all these cases this occurs with Stokes and anti-Stokes in different modes. The phase-matching frequency is different for different combinations of modes and for different fibers. The different pairs of modes were obtained by changing the coupling of the pump light into the fiber. Some of the pump propagates in the same mode as the Stokes and some in the same mode as the anti-Stokes: this doesn't show up in the photographs. The Stokes is always in the higher order mode. The anti-Stokes intensity is always less than the Stokes, with the strongest anti-Stokes observed close to the pump and no anti-Stokes seen at frequency shifts greater than 400 cm^{-1}. This is a consequence of the contribution of Raman gain to the four-photon intensities and will be discussed later. Neutral density filters were used to attenuate everything but the anti-Stokes in Fig. 2. From the photograph it is clear that the four-photon gain is larger than the Raman gain. This fact was used to estimate the coherence length. For a long fiber the self-phase-matched Raman process will dominate because the

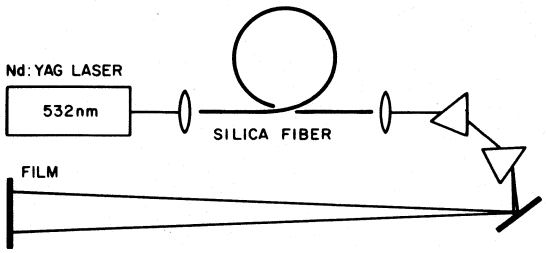

Fig. 1. Experimental arrangement.

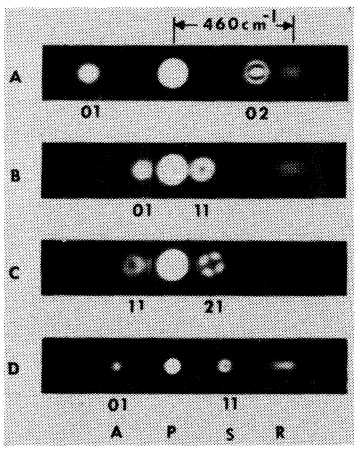

Fig. 2. Output from two silica fibers. A–C are from a 5-m length of 5-μm core radius fiber, and D is from 16 m of 2.5-μm core guide. Different Stokes (S) and anti-Stokes (A) pairs are obtained in A–C by adjusting the input coupling. P refers to the 532-nm pump and R is the non-phase-matched-stimulated Raman line. *ND* filters are used to attenuate everything but the anti-Stokes: 1.4 *ND* in A, 0.4 *ND* in B and C, and 1.0 *ND* in D. The modes are identified using the linearly polarized mode notation [5].

Manuscript received July 18, 1974.

coherence length for the four-photon process is less than the fiber length. Sections of fiber were then broken off until the four-photon process was the stronger. This length was taken to be the coherence length and was somewhere between 5 and 10 m. For shorter lengths of fiber the relative four-photon and Raman intensities remain about the same although more pump power is required to observe stimulated emission.

III. Phase Matching in Optical Fibers

It is precisely the fact that the pump is divided between two different modes and that Stokes appears in one of these modes while anti-Stokes appears in the other which leads to the long coherence lengths. In this section the method of calculating the phase-matching frequency for this process is illustrated. For comparison, the case where both pump photons are in the same mode is also treated. This latter type of process is characteristic of the phase-matched interactions observed in the previous mixing experiment [2]. These two cases will be referred to as "mixed-mode pump" and "single-mode pump" processes. The mixed-mode pump processes will have much longer coherence lengths than single-mode pump processes as will be shown in Section IV. The contribution of the guide modes to achieve phase matching can be understood by reference to Fig. 3 where the effective index of four fiber modes is plotted versus the characteristic number V which is proportional to frequency [5]. Linearly polarized mode [5] shapes are sketched alongside each branch. For the bulk material

$$k_A + k_S - 2k_P \equiv \Delta k(\Delta\bar{\nu}) > 0. \tag{1}$$

where k_A and k_S are the wave vectors of the high- and low-frequency waves and k_P refers to the pump. The bulk mismatch of the core material $\Delta k(\Delta\bar{\nu})$ is greater than zero. In Fig. 4, $\Delta k(\Delta\bar{\nu})$ is plotted versus $\Delta\bar{\nu}$ for fused silica [6]; $\Delta\bar{\nu}$ is the frequency shift in units of cm^{-1}. In the guide, each wave vector will be reduced slightly compared to the value in the bulk material. For example, the wave vector of the light in the 01 mode will be reduced by $2\pi(n_c - n)(1 - b_{01})\bar{\nu}$ where $\bar{\nu} = \nu/c$ and b is a normalized effective index which is defined in Fig. 3. In the approximation that the core-cladding index difference $(n_c - n)$ is independent of wavelength the result is to add to (1) another contribution to $k_A + k_S - 2k_P$ which we call $f(\Delta\bar{\nu})$

$$2\pi(n_c - n)(b_A\bar{\nu}_A + b_S\bar{\nu}_S - b_{P1}\bar{\nu}_P - b_{P2}\bar{\nu}_P) \equiv f(\Delta\bar{\nu}). \tag{2}$$

Consider the mixed-mode pump process illustrated in Fig. 3(a). Here the pump power is divided between the 01 and 02 modes. Stokes is in the 02 mode and anti-Stokes in the 01 which corresponds to observation. Expanding $b_A\bar{\nu}_A$ about $b_{P1}\bar{\nu}_P$ and $b_S\bar{\nu}_S$ about $b_{P2}\bar{\nu}_P$, using the definition of V in Fig. 3, and neglecting terms in $\Delta\bar{\nu}^2$, (2) reduces to

$$f(\Delta\bar{\nu}) = 2\pi(n_c - n)\left[\frac{d(b_{01}V)}{dV} - \frac{d(b_{02}V)}{dV}\right]\Delta\bar{\nu}. \tag{3}$$

The quantity $d(bV)/dV$ happens to be the normalized group delay and plots have been published for a simple waveguide structure [5]. At phase matching $f(\Delta\bar{\nu}) + \Delta k(\Delta\bar{\nu}) = 0$. In Fig. 4(a), $f(\Delta\bar{\nu})$ is plotted on the same scale as $\Delta k(\Delta\bar{\nu})$. The

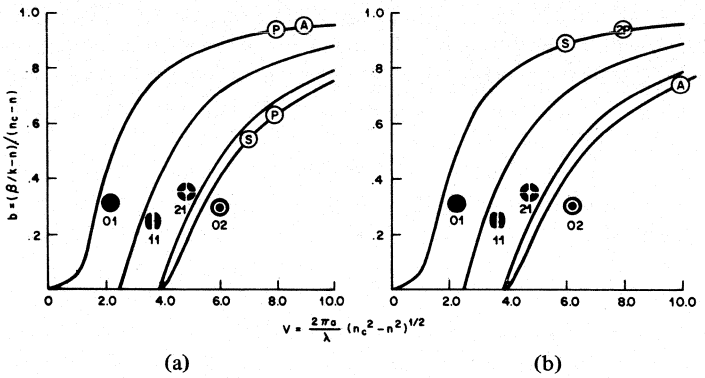

Fig. 3. Plots of the normalized effective index of refraction b for four-guide modes versus the characteristic number V. n_c and n are the core and cladding refractive indices, β is the propagation constant, k and λ the wave vector and wavelength in free space, and a is the core radius. Pump, Stokes, and anti-Stokes for a representative mixed-mode pump process is indicated in (a), and for a single-mode pump process in (b).

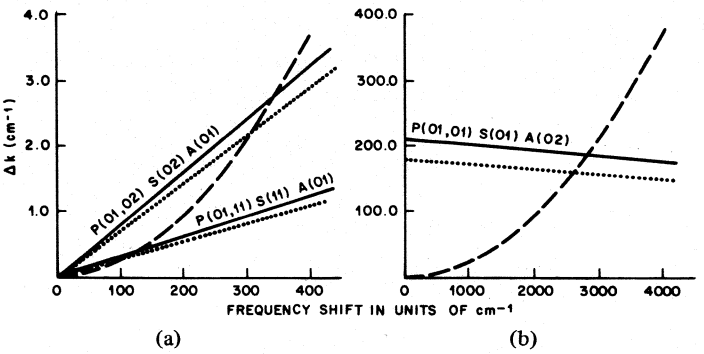

Fig. 4. Phase-matching diagrams for two mixed-mode pump processes (a), and a single-mode pump process (b). The dashed line is the bulk mismatch $\Delta k(\Delta\bar{\nu})$ plotted versus the frequency shift in units of cm^{-1}. The solid line is the contribution of the modes $f(\Delta\bar{\nu})$ for a guide with $a = 5.0$ μm and $n_c - n = 0.006$. The intersection of the curves is the phase-matching frequency. Note the difference in the horizontal axis. The dotted line illustrates the effect of an increase in core radius of 10 percent.

parameters used are taken from Fig. 3 which were calculated for a fiber of 5-μm core radius and $n_c - n = 0.006$. For comparison the similar process with Stokes 11, anti-Stokes 01 and pump 01 and 11, is also included. This process is phase matched at a smaller frequency shift. A single-mode pump process is illustrated in Fig. 3(b). Here pump light is only in the 01 mode, anti-Stokes in 02, and Stokes in 01. Symmetry considerations rule out combinations of 01 and 11 modes. Again using linear expansion

$$f(\Delta\bar{\nu}) = 2\pi(n_c - n) \cdot\left[(b_{02} - b_{01})\bar{\nu}_P + \left(\frac{d(b_{02}V)}{dV} - \frac{d(b_{01}V)}{dV}\right)\Delta\bar{\nu}\right]. \tag{4}$$

This curve is plotted in Fig. 4(b), again for the case of the 5-μm core fiber. For a fiber with several modes there will be many phase-matching combinations similar to those in Fig. 3. In general, single-mode pump processes will occur at much greater frequency shifts than mixed-mode pump processes. The mode labeled 11 in the photograph does not usually have the linearly polarized mode shape shown in Fig. 3. This mode is actually a combination of three almost degenerate modes,

each of which has a "doughnut" intensity profile [5]. Depending on the input coupling it seems to be possible to excite these in various combinations, and patterns have been observed ranging all the way from the two-lobe LP_{11} shape to a doughnut.

IV. Effective Coherence Length

The most interesting feature of the stimulated four-photon emission is the long coherence length. Previously, single-mode pump processes were studied in the 5-μm core fiber and a coherence length of only 10 cm was found [2]. This length depends on the fluctuations in diameter and $(n_c - n)$ which occur in any guide. Even if perfect phase matching were achieved at the beginning of a long guide there will be some point where conditions have changed. Changes in V will result in changes in $f(\Delta\bar{\nu})$ illustrated by the dotted line in Fig. 4. As a rough definition of the coherence length L_c we use the condition that

$$\delta k L_c \equiv \delta\,[f(\Delta\bar{\nu}) + \Delta k(\Delta\bar{\nu})]\,L_c \approx \pi. \tag{5}$$

The mixed-mode and single-mode pump processes described by (3) and (4) differ remarkably in their sensitivity to guide imperfections. If fluctuations in the core radius a are most important, then for the mixed-mode pump process

$$\delta k = 2\pi(n_c - n)\left[\frac{d^2(b_{01}V)}{dV^2} - \frac{d^2(b_{02}V)}{dV^2}\right]\Delta\bar{\nu}\,\frac{V}{a}\,\delta a \tag{6}$$

and for the single-mode pump process

$$\delta k = 2\pi(n_c - n)\left[\bar{\nu}_P\frac{d(b_{02} - b_{01})}{dV} + \Delta\bar{\nu}\left(\frac{d^2(b_{02}V)}{dV^2} - \frac{d^2(b_{01}V)}{dV^2}\right)\right]\frac{V}{a}\,\delta a. \tag{7}$$

Here $f(\Delta\bar{\nu})$ has been obtained from (3) and (4) and $(dV/da = V/a)$. The first term in (7) dominates primarily because of the difference between $\bar{\nu}_P$ and $\Delta\bar{\nu}$. The fiber used in [2] had $a = 5$ μm, $n_c - n = 0.006$, and $\delta a/a \simeq 0.2$ percent. The calculated coherence length for the single-mode pump process illustrated in Fig. 3(b) was 5 cm as compared to the measured 10 cm. In the mixed-mode pump processes the dominant term $\bar{\nu}_P d(b_{02} - b_{01})/dV$ drops out. For the same 5-μm core fiber the Stokes 02–anti-Stokes 01 combination should have $L_c = 5$ m and for S 11–A 01 $L_c = 29$ m. The long coherence length can be made even longer by a suitable choice of fiber parameters. From (6) it can be seen that if a phase-matched process occurs where $d[d(b_{01}V)/dV - d(b_{02}V)/dV]dV = 0$, then at least to first order this process would be insensitive to fluctuations in core diameter. In [5], $d(bV)dV$ is plotted versus V for different modes and it is apparent that this condition can be satisfied.

V. Comparison of Four-Photon and Raman Gain

The Stokes gain for the four-photon process is larger than the ordinary Raman gain, as is readily seen from the photographs in Fig. 2. The non-phase-matched Raman gain can be viewed as the imaginary part of a complex susceptibility, χ''. The real third-order susceptibility χ' makes possible the four-photon process. In the limits of pure real or pure imaginary susceptibilities Raman and four-photon gains are

$$g(\text{Raman}) = \alpha\,\frac{32\pi^2\omega_P}{n^2c^2}D_1\chi''\,\frac{P_p}{\pi\rho^2} \times 10^7\ \text{cm}^{-1} \tag{8a}$$

$$g(\text{four-photon}) = \beta\,\frac{32\pi^2\omega_p}{n^2c^2}D_2\chi'\,\frac{P_p}{\pi\rho^2} \times 10^7\ \text{cm}^{-1}. \tag{8b}$$

The intensity will increase as $\exp(gL)$, where L is the interaction length, P_p is pump power in watts, ω_p is the pump frequency, and n the refractive index. The effective radius ρ is to a good approximation the radius where the intensity of the lowest order fiber mode falls to $1/e$. The degeneracy factors D_1 and D_2 are 6 for Raman gain and 3 for four-photon gain for the case of a single-frequency pump [8]. The terms α and β appear because it is necessary to integrate over products of mode fields. For Raman gain with both pump and Stokes in the lowest order mode $\alpha \approx \frac{1}{2}$ [4]. With typical four-photon processes it can be shown that $\beta \approx \frac{1}{4}$. For fused silica the maximum value of χ'' at 460 cm^{-1}, as determined from the Raman-gain curve [4], is 0.5×10^{-15} ESU. The value of χ' has been reported to be about 5×10^{-15} ESU [7]. If these factors are combined, the four-photon gain is expected to be between two and three times the peak Raman gain for fused silica. This is consistent with the observations.

At frequencies less than 1000 cm^{-1} from the pump the four-photon gain is complicated somewhat by χ''. If χ'' were negligible, the Stokes and anti-Stokes intensities would be the same. The effect of χ'' is to increase the amplification of Stokes and to absorb anti-Stokes [9]. This explains the difference between the observed anti-Stokes and Stokes intensities. The real part of the susceptibility is also slightly frequency dependent in the frequency range of interest since χ' will be affected by χ'' through the Kramers–Kronig relations [9]. At low-frequency shifts χ' will be about 5 percent higher than the high-frequency value, while χ' will be depressed by about 5 percent around 500 cm^{-1}. In principle, the ratio of anti-Stokes and Stokes can be used to determine χ''/χ' at various frequency shifts. This is complicated by the need to calculate overlap integrals.

VI. Amplifier Gain and Bandwidth

To obtain some feeling for the amplification possible we choose a multimode fiber 10 m in length and with a 5-μm core radius. If we assume that the gain is 2.5 times the peak Raman gain, this means that a pump power of 50 W will result in a power amplification of e^3.

The amplifier bandwidth can be determined from the relative slopes of $f(\Delta\bar{\nu})$ and $\Delta k(\Delta\bar{\nu})$ in Fig. 4. We define the bandwidth $\delta\bar{\nu}$ by

$$\frac{d}{d(\Delta\bar{\nu})}[f(\Delta\bar{\nu}) + \Delta k(\Delta\bar{\nu})]\,\delta\bar{\nu}L = \pi. \tag{9}$$

For the single-mode pump processes the dominant term is $d(\Delta k)/d(\Delta\bar{\nu})$. For the mixed-mode pump processes the slopes of $f(\Delta\bar{\nu})$ and $\Delta k(\Delta\bar{\nu})$ are similar and the condition becomes

$$\frac{d(\Delta k)}{d(\Delta\bar{\nu})} - \frac{\Delta k}{\Delta\bar{\nu}}\,\delta\bar{\nu}L = \pi. \tag{10}$$

Again, using the index data for fused SiO_2 and choosing a length of 10 m, the bandwidth at a frequency 100 cm^{-1} from a 500-nm pump will be 1.4 cm^{-1}; at 500 cm^{-1} it will be 0.27 cm^{-1}. For a higher frequency shift process at 3000 cm^{-1}, $\delta\bar{\nu}$ is 2.2×10^{-3} cm^{-1}.

VII. Conclusion

In conclusion, the observation of stimulated four-photon mixing demonstrates that extremely long coherence lengths are possible for phase-matched nonlinear interactions in optical waveguides. The observed coherence lengths are two orders of magnitude larger than anything previously observed in solids. High amplification and broad bandwidths are possible using the four-photon interaction as an amplifier. The gain coefficient is more than double the self-phase-matched Raman gain. Other glasses might be expected to have even larger gains.

The Mechanism of Single-Frequency Operation of the Hybrid-CO_2 Laser

A. GONDHALEKAR, N. R. HECKENBERG, AND E. HOLZHAUER

***Abstract*—The mechanism of a new method of obtaining high-power single-frequency pulses from a TEA-CO_2 laser is discussed. Measurements of the shape and monochromaticity of pulses from the hybrid laser which has both a TEA and a low-pressure gain section inside one resonator are presented. The mechanism of single-frequency operation of the hybrid laser is discussed with reference to numerical solutions of simplified rate equations. The low-pressure section provides gain only over a narrow range of frequencies so that a mode lying in that bandwidth builds up faster than neighboring modes to give a single-frequency pulse resembling in overall shape the normal TEA laser pulse. If the system is already lasing when the TEA discharge begins, the single-mode radiation already present rapidly grows to give a single-frequency pulse lacking a gain-switched peak.**

Manuscript received August 9, 1974; revised November 11, 1974. This work was undertaken as part of a collaboration between the Institut für Plasmaforschung and the Max-Planck-Institut für Plasmaphysik.

N. R. Heckenberg is with the Max-Planck-Institut für Plasmaphysik, Euratom Association, 8046 Garching, Germany.

I. Introduction

THE output pulse of a high-pressure CO_2 laser exhibits strong modulation resulting from beats between different cavity modes. Such modulation, usually appearing in the range 10–100 MHz, is highly undesirable for many applications. A high degree of modulation is observed because the modes making up the output pulse grow at essentially equal rates from spontaneous emission, which supplies nearly equal power to each. This occurs because the gain width in a high-pressure discharge is very large (~3 GHz at atmospheric pressure) compared to the mode spacing ($\leqslant$75 MHz for a 200-cm-long cavity), and the laser gain is effectively constant over a number of modes, as is the spontaneous emission rate.

It is possible to ensure operation on the lowest order transverse mode by taking advantage of the higher losses suffered by high-order modes when an aperture is introduced into the laser cavity. Attempts at longitudinal mode selection have centered on similarly causing the cavity losses to vary rapidly

with frequency so that one mode will grow more rapidly than any other during the pulse development. These methods have drawbacks; additional elements such as a grating and a gas cell [1] in the laser cavity reduce the output. On the other hand, the alignment of multimirror systems [2] is difficult to maintain.

By incorporating a low-pressure (total pressure 10 torr) gain section in the same laser cavity as the high-pressure (TEA) section, we can ensure a substantial increase in gain for the one longitudinal mode lying inside the narrow (~60-MHz-wide) gain profile of the low-pressure section. If the low-pressure section is already lasing when the electrical discharge in the high-pressure section begins, the single longitudinal-mode radiation already present in the cavity builds up to give a single-frequency pulse lacking a gain-switched peak [3].

In Section II we describe the hybrid laser and present measurements of electrical and other parameters for the low-pressure gain section and the TEA section. We then present measurements of the laser pulse shape and monochromaticity, pulse power, and total energy for the four different modes of operation of the hybrid laser. In Section III we present a simplified rate-equation description of the hybrid-laser operation. A semiquantitive agreement between this description and the experimental results is achieved.

II. The Hybrid-CO_2 Laser

A schematic diagram of the hybrid laser is given in Fig. 1. The active medium was divided into two sections, a pulsed TEA gain section partitioned off by a Brewster-angle NaCl window from a pulsed low-pressure gain section. The laser cavity was made up of a 600-cm-radius-of-curvature gold-coated 100-percent-reflecting concave mirror at one end and a plane 65-percent-reflecting germanium output mirror at the other. A 7-mm-diam aperture at the plain mirror restricted laser oscillation to the TEM_{00} mode. The cavity was 210 cm long, giving a longitudinal mode separation of about 71 MHz.

The low-pressure section was 100 cm long and was filled with a 1:3:18 mixture of CO_2:N_2:He at a total pressure of 10 torr. Fig. 2 shows the current pulse and the output laser pulse when an 8-nF capacitor charged to 15 kV was discharged longitudinally through this section. The current pulse was about 4 μs long and had a peak value of about 120 A. The laser pulse, which came after about 60 μs, started with a gain-switched peak of 60 W followed by a long lower power tail lasting for many tens of microseconds. The energy in this pulse was measured to be about 20 mJ. Using a CO_2 spectrum analyzer, the laser output was ascertained always to be on the $P(20)$ transition at 10.59 μ. Measurements with a fast GeAu detector (~1-ns rise time) showed that the laser output was single longitudinal mode.

The TEA section was of the type utilizing UV preionization of the active gas before the main electrical discharge is initiated [4]. This section was 60 cm long and was filled with a 1:2:3 mixture of CO_2:N_2:He at a total pressure of 720 torr. The two 60-cm-long Rogowski-profiled electrodes were 34 mm apart. The electrical discharge across the electrodes excited a total of 940 cm^3 of gas but the TEM_{00} mode used only 20 cm^3 of this volume. The main electrical discharge was

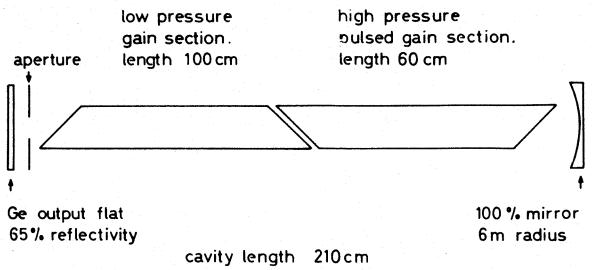

Fig. 1. Schematic diagram of the hybrid-CO_2 laser.

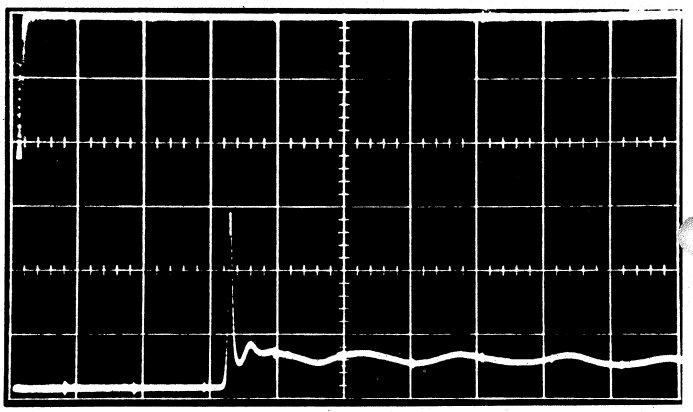

Fig. 2. Current pulse (upper trace: 50 A/div) and laser output (lower trace: 20 kW/div) for the low-pressure section. Time: 20 μs/div.

energized by the output of a two-stage Marx generator with total capacity of 37.5 nF and voltage of 64 kV. Fig. 3 shows the current through the discharge and the voltage across it. These two measurements show that the input power pulse to the laser gas has an approximately triangular shape of width (at half peak height) of about 350 ns. The peak electrical power dissipated in the gas was estimated to be 200 kW/cm^3. The output laser pulse obtained when this TEA section alone was excited is shown in Fig. 4(a), a pulse typical of TEA-CO_2 lasers. The oscilloscope was triggered at the start of the current pulse. The laser pulse came after a delay of abou 900 ns and had the familiar gain-switched peak followed by a long tail. The high-frequency modulation of the output is due to beating between several adjacent longitudinal modes. Again, the output was at 10.59 μ. The total energy in the pulse was approximately 140 mJ and the peak power about 300 kW.

When both sections were operated together, two different forms of behavior were observed, depending on the timing of the two pulses. In case 1 the electrical discharge in the TEA section was initiated 55 μs after the current pulse in the low-pressure section. At this time, the low-pressure section had an inverted population but the system was not yet lasing. The hybrid laser pulse is shown in Fig. 4(b). As before, the oscilloscope was triggered at the start of the current pulse in the TEA section. We notice that the output pulse resembles in overall shape the normal TEA laser pulse. However, the laser pulse started 200 ns earlier than the normal TEA laser pulse, and in addition no high-frequency modulation of the pulse occurred. The peak power in the laser pulse was about 250 kW and the total energy 140 mJ.

In case 2 the TEA section was energized 100 μs after the current pulse in the low-pressure section. At this time, the

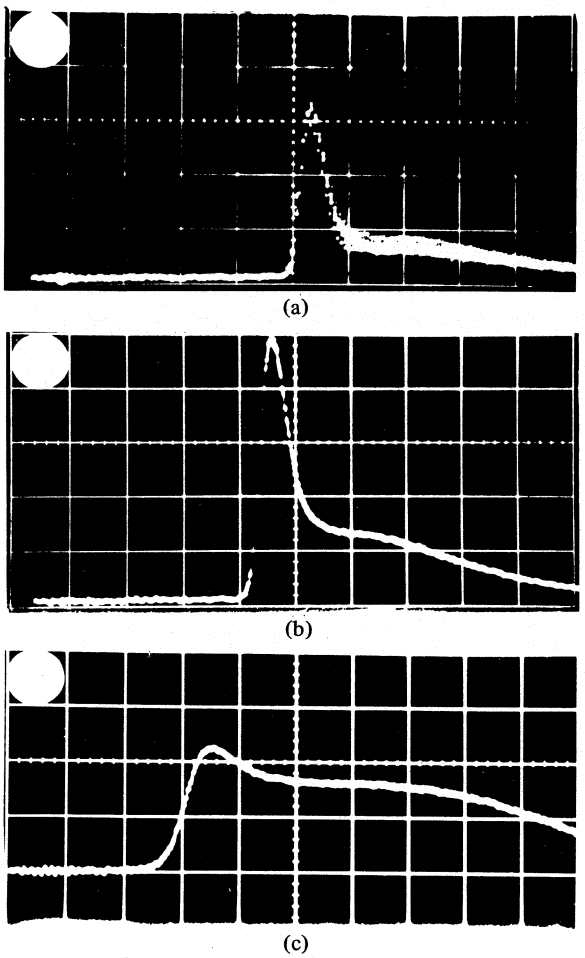

Fig. 4. Output pulses from the hybrid laser. Time: 200 ns/div. (a) Normal TEA-laser pulse (100 kW/div). (b) Hybrid-laser pulse with the low-pressure section operating below threshold (50 kW/div). (c) Hybrid-laser pulse with the low-pressure section operating above threshold (50 kW/div).

system was already lasing with an output power of 10–15 W. The type of hybrid laser pulse so obtained is shown in Fig. 4(c). The oscilloscope was triggered as before. The peak power in the laser pulse was now little more than 100 kW, and the total energy in the pulse remained unchanged at 140 mJ. We notice that unlike the normal TEA laser pulse, this one had no gain-switched peak, the pulse started about 400 ns earlier, and the mode beating was absent. The remaining modulation was measured to be smaller than 5×10^{-5} of the peak, the resolution being limited by detector noise. This represents a ratio of power in the main mode to the power in the unwanted neighboring modes of more than 10^9 [12].

III. Theory: A Rate-Equation Model

A simplified model of the hybrid laser has been developed which, since it produces many of the observed features of the system operation, throws light on the important operating mechanisms. The theoretical treatment is based on that used by Gilbert *et al.* [5] to describe the operation of a conventional TEA-CO_2 laser. They simplify the complicated level structure of the CO_2-N_2-He laser to a four-level structure, describing the time evolution of the population densities of the upper and lower laser levels and the excited nitrogen level (n_a, n_b, n_c, respectively) by the equations

$$\frac{dn_a}{dt} = I\sigma_e c(n_b - n_a) - \gamma_a n_a + \gamma_c(n_c - n_a) + W_a \tag{1}$$

$$\frac{dn_b}{dt} = I\sigma_e c(n_a - n_b) + \gamma_a n_a - \gamma_b n_b + W_b \tag{2}$$

$$\frac{dn_c}{dt} = \gamma_c(n_a - n_c) - \gamma_{c0} n_c + W_c \tag{3}$$

where I is the cavity radiation density, σ_e the cross section for stimulated emission, and c the velocity of light. γ_a, γ_b, and γ_{c0} are deactivation rate constants for the three levels while γ_c is the rate constant for transfer of energy from the excited nitrogen level to the upper CO_2 level. The rate equation for the density of radiation in the cavity is

$$\frac{dI}{dt} = -\gamma_0 I + I\sigma_e c(n_a - n_b) + n_a W_s \tag{4}$$

where γ_0 is the reciprocal of tne decay time of the photon density in the cavity and W_s is the rate of spontaneous emission into a mode. Having made estimates of the rate constants and pumping rates (W_a, W_b, W_c), they solve the differential equations numerically, obtaining reasonable agreement with measurements made on a small TEA laser.

In this treatment the radiation in the laser cavity is represented by a single radiation density integrated over all lasing modes so that no mode-beating structure appears in the calculated results.

We have used the same mathematical formalism and essentially the same rate constants, but have estimated the excitation rates for the upper laser level and the excited nitrogen from measurements of the discharge current and voltage [6]–[8]. According to these estimates, during the pumping pulse a peak power of some 120 kW/cm^3 goes into raising nitrogen molecules into the metastable state while some 16 kW/cm^3 of the total 200 kW/cm^3 dissipated in the discharge goes to raise CO_2 molecules to the upper lasing state. In the computer code the pumping pulse has been approximated by a triangular pulse of half-width 350 ns. The lower laser level is not pumped by electron collisions but is affected by the gas temperature which is difficult to estimate so that we have simply set this rate

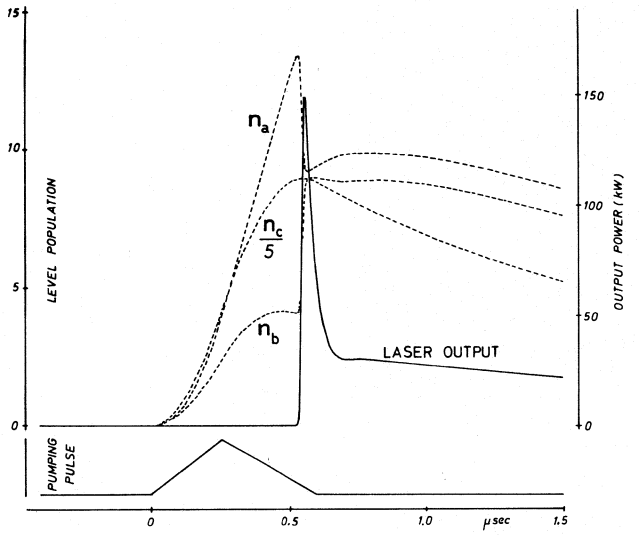

Fig. 5. Calculated output power and population densities for the normal TEA-laser pulse. The level population densities are expressed in units of the threshold inversion density ($\sim 1.5 \times 10^{16}/cm^3$).

equal to the electron collision excitation rate of the upper laser level [5].

With these parameters the model provides a substantially correct picture of the operation of the hybrid laser as a normal TEA laser, as can be seen from comparison of Fig. 4(a) and Fig. 5. The calculated output pulse energy of 70 mJ is within a factor of 2 of that observed; the calculated peak output power of 150 kW is to be compared with an observed value of 300 kW. Discrepancies such as the underestimation of the width of the gain-switched peak and pulse delay seem to be inherent deficiencies of the model [5]. Fig. 5 also shows that the population inversion in the TEA section grows rapidly to a value many times the threshold value before being suddenly depleted by the rapidly growing cavity radiation. During most of this rise, however, the population inversion is little affected by the modes present, which therefore grow with little competition. Several of the longitudinal modes near the center of the collision-broadened gain profile thus grow out of spontaneous emission with essentially equal rates to produce a heavily modulated pulse.

The low-pressure gain section of the hybrid laser has two effects on the pulse being built up by the TEA section. One is to considerably increase the round-trip cavity gain over a narrow-band of frequencies corresponding to the Doppler-broadened line profile. Since this width is about 60 MHz, whereas the longitudinal mode spacing of a 210-cm cavity is 71 MHz, only one longitudinal mode will experience substantial increase in gain. Secondly, when the low-pressure section is operated above threshold, there is, in addition, a substantial level of radiation of a single longitudinal mode present in the cavity before the TEA section is pulsed. The presence of this radiation can be handled directly in the computer code; the extra gain of the low-pressure section is simulated by adding small constant-excitation terms to the rate equations for the level populations, (1)–(3). Suitable values for these terms are determined empirically by seeking steady solutions of the equations which give either a continuous output of a few watts or a population inversion just below threshold.

The pulse shape calculated for the case where the gain of the low-pressure section is just below threshold (case 1) is shown in Fig. 6(a). Since threshold is reached much sooner after the pumping pulse than in the normal TEA laser [Fig. 6(b)], the pulse appears rather earlier in time but with essentially the same shape, i.e., a gain-switched peak followed by lower power "tail." Since the low-pressure section supplies gain but little energy, the peak power and total pulse energy are very little affected. All of these features agree with the experimental observations.

For the case where the low-pressure section is operated above threshold (case 2), a rather different pulse shape is obtained [Fig. 6(a)]. Fig. 6(b) shows how the presence of the high level of radiation in the cavity prevents the growth of a large population inversion, precluding the formation of a gain-switched peak. Thus the model predicts a longer pulse, lacking a pronounced gain-switched peak, and appearing earlier in time, just as is observed. The good qualitative agreement obtained in the two cases testifies to the importance of both of the two effects of the low-pressure section cited above.

In order to further examine the mechanism of the hybrid laser, another case was considered: the case where a continuous level of radiation is established in the cavity by external injection. Comparison with case 1 allows separation of the roles of the gain of the low-pressure section and the radiation in the cavity in case 2. In this case, the initial values for all of the population densities were taken as zero, as in the normal TEA case, but an additional steady source of radiation was included on the right-hand side of (4). This source rate was chosen so that an equilibrium intensity equal to that found in the cavity in case 2 was established before the TEA pump pulse was applied. Fig. 6(a) shows that the delay of the optical

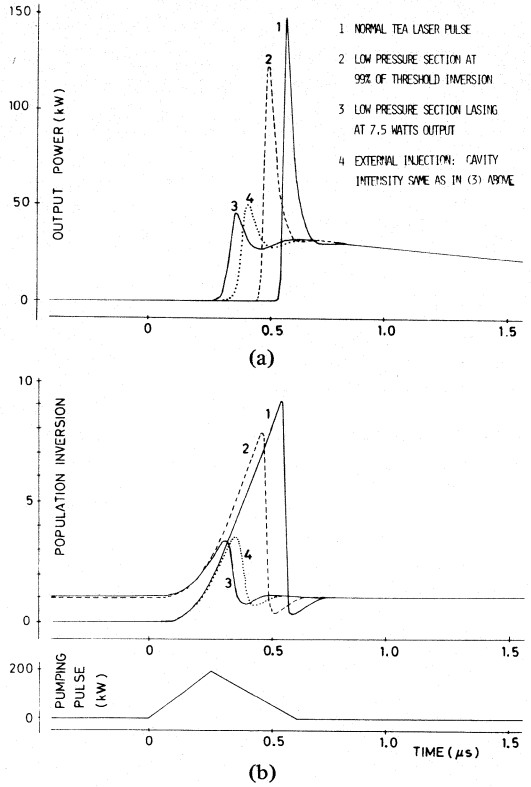

Fig. 6. Calculated output power and population densities for the hybrid laser. (a) Output laser pulses. (b) Population inversion in units of the threshold inversion density ($\sim 1.5 \times 10^{16}/cm^3$).

pulse was reduced compared to the normal TEA-laser case and the gain-switched peak greatly affected as in the above-threshold case (case 2). No comparable experiment could be performed because of the difficulty of matching the injected radiation to a mode of the TEA laser without the TEA laser affecting the injecting laser. The significance of the calculated result is, however, to indicate that the prior presence of radiation in the cavity has a significant effect on the laser pulse shape. Thus, when the low-pressure section of the hybrid laser is operated above threshold, both this factor and the increased gain due to the low-pressure section are important.

The early appearance of the pulse when the low-pressure section is excited is responsible for the observed lack of mode beating. The one mode inside the narrow-band gain profile builds up rather faster than others and can deplete the population inversion before other modes reach significant levels. As was pointed out earlier, until very shortly before the appearance of the gain-switched pulse, the various modes present grow independently so that comparison of the results shown in Fig. 6(a) can be used to make an estimate of the ratio of the dominant to other modes at the time of the gain-switched peak of the hybrid-laser pulse when the low-pressure section is operated just below threshold (case 1). This, in effect, makes the reasonable approximation that all modes experience the same gain in the high-pressure section, whereas only one is affected by the low-pressure section. In this case, a ratio of 10^7 in intensities is indicated. When the low-pressure section is operated above threshold (case 2) even better performance could be expected.

IV. Conclusion

We conclude that using the hybrid principle, very good frequency selection can be achieved without introducing losses in the TEA-CO_2 laser cavity. Such a laser could find application in plasma diagnostics [9], pulsed infrared radar, and optical pumping of submillimeter lasers which at present have low efficiencies due to the multimode output of the CO_2-laser pump pulse [10]. Pulses lacking a gain-switched peak may be useful in material studies. Study of nonlinear optical phenomena in gases and crystals (e.g., far-infrared generation by optical mixing), where interpretation is difficult due to fast modulation of the TEA-CO_2 laser pulse [2], may benefit from the availability of smooth high-power CO_2-laser pulses with well-defined power in the pulse. Further, a smooth high-power pulse is desirable for cutting and shaping a suitable short pulse for amplification and use in laser fusion research [11]. Lastly, the use of the hybrid configuration is not restricted to the CO_2 laser.

Mode-Dependent Retardation in (Ga,Al)P Waveguide Modulators

DAVID P. BORTFELD

Abstract—**Theoretically predicted mode-dependent modulation in (Ga,Al)P waveguide modulators for which the depletion region is small compared to the guide width is demonstrated experimentally. At 10 V the measured retardations of the three lowest order modes are 0.36, 0.78, and 1.13 rad, respectively.**

Manuscript received September 9, 1974; revised October 28, 1974.
The author was with the Laboratories RCA Ltd., Zurich, Switzerland. He is now with the David Sarnoff Research Center, Princeton, N.J. 08540.

In a recent theoretical treatment of p-n junction heterostructure waveguide modulators we discussed in detail the behavior of such devices when the depletion layer width t (corresponding to the modulated region) is less than the guide width [1]. If we assume that the waveguide is composed of three constant-index layers, then the intensity of the mth mode is proportional to $\cos^2(b_m X - \alpha_m)$ where b_m is the spatial frequency of the mth mode and x is the distance from one waveguide wall. Since it can be shown that the phase term α_m decreases with increasing mode number [1] the intensity for the higher order modes is higher at $x = 0$. If the p-n junction is highly asymmetric and located at $x = 0$ then the depletion layer penetrates only into the guide region. Assuming that the field is uniform over t we can write the change in the effective refractive index for the mth mode Δn_m as [1]

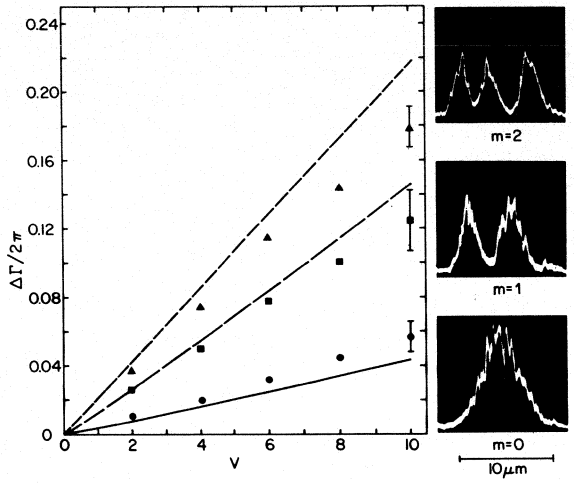

Fig. 1. Experimental points and theoretical curves for the modulation of the three lowest order modes. In order to eliminate strain effects we plot $\Delta\Gamma = \Gamma(V) - \Gamma(0)$. The photographs show the mode shapes. The scale is approximate.

$$\Delta n_m = \frac{\delta n}{b_m W} \left[b_m t + \sin b_m t \cos (b_m t - 2\alpha_m) \right] \tag{1}$$

where δn is the appropriate electrooptically induced index change and W is the effective guide width including the penetration into the cladding layers. The retardation Γ is then proportional to the difference between Δn_m for each TE, TM mode pair.

Note that for $b_m t \ll 1$, (1) becomes

$$\Delta n_m \approx \delta n \frac{t}{W} 2 \cos^2 \alpha_m \tag{2}$$

which clearly shows that the modulation is dependent upon the depletion layer width and the mode intensity at the waveguide wall. Thus, for very small t, higher order modes should be more strongly modulated.

In order to check the predictions of this simple model, we studied the performance of a number of (Ga,Al)P heterostructure modulators [2]. Laser light (6328 Å) polarized at 45° to the junction plane was focused on the input face of the guide using a 25X microscope objective. A high-power microscope was then used to project the image of the output face of the diode onto a vidicon which produced a picture on a monitor and an intensity profile on an oscilloscope. By carefully adjusting the input optics any one of the three lowest order modes could be generated in some single-heterostructure devices. The retardation was then measured by means of an Ehringhaus compensator and a photometric null detector. The averaged results for a number of measurements on one particular diode are shown as the points in Fig. 1. The error bars indicate the spread in the measurements which arise mainly from the difficulty in exciting pure modes by this technique. The accompanying photographs show the typical mode profiles obtained.

As a result of the difficulty in reproducing the mode profiles, consistent results could only be obtained on a few units. The mode-dependent behavior, however, was clearly seen on several devices so that the results are felt to be reasonably representative.

In order to apply (1) the exact layer width and refractive indices as well as the center-layer doping must be known. Since we lack detailed knowledge of these parameters we must develop a model on which to base our calculations. The model we use assumes a 7.5-μm GaP guiding layer ($n = 3.31$) doped n-type at about 10^{17} cm^{-3}. The lower waveguide wall is formed by the GaP–(Ga,Al)P heterojunction for which we estimate $n \approx 3.30$ on the basis of the expected Al concentration in the layer [2]. The upper waveguide boundary ($x = 0$) we take to be at the p-n junction. The diffused GaP p-layer is assumed to be 1.75 μm thick and with $n = 3.085$ and to be bounded on the upper side by air. (Because of the small index step and the proximity of the air–GaP interface, the thickness of the layer enters into the determination of b_m and α_m.)

Although the model appears to have several adjustable parameters, the choice was limited by requiring that the values be consistent with the measured layer thicknesses and the spatial frequencies of the modes. (No attempt was made to fit the mode shape *per se*.) The doping of the guiding n-region was directly measured by the capacitance–voltage method. The index step at the p-n junction was chosen to give the best match to the modulation data within the limits imposed in the preceding. The absolute magnitude $\Delta n = 0.0015$ lies considerably above the value predicted from a simple Drude model using the mid-10^{18}-cm^{-3} doping of the p-layer, but similar discrepancies have been found by other authors [3].

Note that, for 10^{17}-cm^{-3} doping, the maximum depletion layer thickness is about 0.6 μm at 10 V which is much smaller than the 7.5-μm guide width. Thus by (2), we would expect to see higher retardation for the higher order modes, which is clearly borne out in Fig. 1.

Since the junction is perpendicular to the [111] axis the appropriate values of δn needed for the application of (1) are

$$\delta n(\mathrm{TM}) \approx -2\,\delta n(\mathrm{TE}) = -n^3 r_{41} E/\sqrt{3} \tag{3}$$

where n is the refractive index (3.31 at 6328 Å) [4], r_{41} is the electrooptic constant (-0.98×10^{-10} cm/V) [4], and E is the average junction field. Using these values and assuming an abrupt, highly asymmetric junction together with (1) we obtain the continuous curves in Fig. 1. Considering the known limitations of the model [1], the agreement is excellent, which confirms the usefulness of (1) in predicting the behavior of such modulators on a semiquantitative basis.

NaCl Surface Reaction in Chemical-Laser Devices

ALAN B. PETERSEN AND CURT WITTIG

Abstract—**Pronounced absorptions in the 8–17-μm region are observed on surfaces of NaCl that are used as Brewster windows in chemical lasers that derive their excitation from the CS_2/O_2 reaction. Surface reaction involves species that are formed during the chemical and photochemical processes that are active in the system. Implications regarding other reactive systems (using either chemical or electrical excitation) are also discussed.**

In this correspondence, we wish to communicate several observations regarding the reactivity of NaCl which is used as window material in pulsed chemical lasers. The implications of these observations are far-reaching and the principles involved may be applied to other materials and to a variety of situations in which these materials are used as an interface between the normal atmosphere and some active nonequilibrium gaseous system. There have been numerous investigations into the losses that are present in various materials (single and polycrystalline) that are suitable for devices that operate at infrared frequencies [1]–[3]. Most of this effort has been directed toward determining the intrinsic losses of these materials and preparing samples that are sufficiently free from impurity absorptions so that intrinsic losses dominate. One of the widespread uses of these materials is with high-power IR lasers, and in this application it is imperative that the material be free of even the smallest amount of absorption in order to avoid either serious damage to the component or undesirable thermally induced distortion of the laser beam.

On the other hand, the gaseous environment that exists in most high-power IR gas lasers is in a state of pronounced nonequilibrium with a variety of atomic, free radical, and metastable species present. Thus the inside surface of any material that acts as an interface (internal mirror, Brewster window, etc.) between the active laser medium and the outside world will be subjected to a rather harsh test of its inertness. Since it is difficult to physically remove the interface region to the extent that surface reaction is *entirely* suppressed, it is not obvious that a material with low intrinsic losses will be sufficiently chemically inert for use in situations where active species are present. In general, the reactions that take place at the surface of any candidate material deserve prime consideration in the evaluation of the material as a suitable candidate for use in infrared devices.

In our own work with infrared chemical lasers, we have observed that NaCl Brewster windows [4] that are used in pulsed chemical lasers are seriously affected after only short-term use. Details of the laser systems employed have been described elsewhere [5]. Briefly, mixtures containing CS_2 and O_2 as the chemically active species are photolyzed in the presence of a large enough excess of He to maintain approximately isothermal conditions ($\Delta T \leqslant 100$ K). In some experiments, CO_2 or N_2O is also present in the gas mix.

A most graphic display of the phenomenon is shown in Fig. 1. The spectrophotometer trace shows the presence of prominent absorptions in the 8–17-μm region of the IR. The transmission of the NaCl at visible wavelengths is almost unaffected and a casual observation of the NaCl shows no surface change at all. When the surface is viewed at nearly grazing incidence a bit of interference is observed indicating a surface layer of roughly 10–100-nm thickness. The general effect of absorption in the 8–17-μm range is quite repeatable. The details of the spectra change from one set of conditions to the next, but the effect is easily measured under nearly all experimental conditions [6]. In many cases, laser emission from CO_2 or N_2O was completely quenched by these absorptions, since strong broad absorptions often occurred near the characteristic laser frequencies of these molecules. In no instance were absorptions observed in the region 2.5–8.0 μm, where many powerful molecular lasers operate.

The surface changes that are observed are due to the interaction of the surface with the active species that are generated, either directly or indirectly, by the flash photolysis. There is no detectable surface reaction when the gases are stored in the cell without photolyzing the mixture or when the cell is evacuated and the photolysis flash is fired repeatedly. All experiments are carried out under approximately isothermal conditions since the concentration of buffer gas far exceeds the concentration of the reactive components. The transient ac-

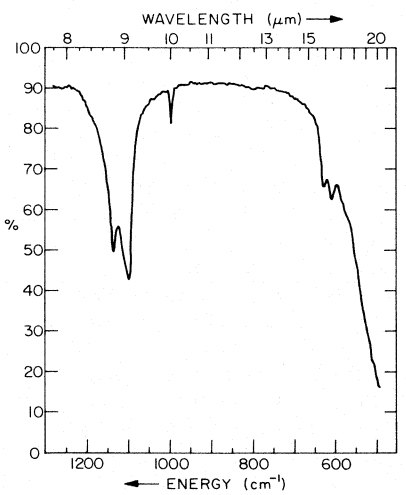

Fig. 1. IR spectrophotometer trace of a NaCl Brewster window taken from a pulsed chemical laser. The vertical scale represents percent transmission. The gas mix contained several torr of CS_2 and several tens of torr of O_2 + He. A photolysis pulse of nominally 10^3 J is used to initiate the chemical reaction. There are no detectable absorptions in the region: 2.5 μm $\leqslant \lambda \leqslant$ 8 μm.

tive species generated in these experiments are numerous and include O, S, SO, CS, S_2O, and many others. In addition, some of these species may be electronically and/or vibrationally excited. When one of the NaCl Brewster windows is replaced with BaF_2, we measure no change in the IR transmission of the BaF_2 window, although the NaCl window becomes badly contaminated in about two weeks time. Thus the surface change cannot be attributed to merely a deposit. No spontaneous cleanup is observed when samples are stored for several months in a dry atmosphere. If the absorbing species were physically adsorbed, some spontaneous cleanup should occur. We have made no attempt to heat the NaCl in vacuo to see if this restores its original transmission characteristics.

The observed spectra are in general rather complex and defy identification on the basis of the preliminary experiments that we have done to date. Various oxygen-containing cation impurities (CO_3, ClO_3, SO_4, etc.) are known to exist in alkali halide crystals and there are many reaction schemes that could satisfactorily account for the complex spectra that we have observed. Spectra obtained from samples that are doped even with only one impurity (e.g., CO_3) are often rather complex and the number, positions, and strengths of the characteristic absorptions change with concentration and other parameters [1]. The spectra shown in Fig. 1 are probably due to an anion of the form S_nO_m with SO_4 being the most likely suspect [7]. The possible superposition of absorptions due to several species and the complex conditions under which the surface reactions took place prevent us from making a positive identification of the absorbing species. Detailed kinetic experiments are currently underway in our laboratory aimed at sorting out some of the fundamental processes active in these systems. Many impurities such as carbon, alkaline earths, etc., that would not absorb radiation strongly of their own accord may be converted to cations via the introduction of atomic oxygen into the system (e.g., $C \rightarrow CO_3$). The large amount of atomic oxygen that is present in the chemical lasers under study in our laboratory is a prime suspect in this oxidation process. The large penetration depth manifest in our experiments is due either to the diffusion of atomic species into the bulk or the diffusion into the bulk of cations such as SO_4^{-2} which are formed initially at the surface. In two weeks time, the diffusion depth for SO_4^{-2} initially on the surface is 13 nm [9]. This rapid diffusion means that species introduced at the surface will quickly dissolve into the bulk leaving the surface free for further reaction.

Finally, we point out that this phenomenon is a general one and may be active and deserving of consideration in a variety of devices that are excited chemically and/or electrically. In the $CO^{\dagger}/CO_2$ [5] and $CO^{\dagger}/N_2O$ [8] chemical laser systems, absorptions are introduced that render NaCl useless as an interface material in these devices and the other alkali halides are expected to follow suit. Other IR materials and reactive systems deserve consideration in turn and experiments are currently underway toward this end in our laboratory.

ACKNOWLEDGMENT

The authors wish to thank Prof. D. A. Dows for the use of an infrared spectrophotometer during the course of this work.

Hollow-Cathode-Type CW White Light Laser

KAN-ICHI FUJII, TSUTOMU TAKAHASHI, AND YOSHIHIRO ASAMI

***Abstract*—A stable CW white laser light consisting of red (6360 Å, 6355 Å), green (5378 Å, 5338 Å), and blue (4416 Å) line spectra emitted from Cd ions has been obtained with an improved flute-type hollow-cathode He-Cd$^+$ laser tube and a broad-band optical cavity. The typical output-power level was about 10 mW, discharge conditions being 250 V and 0.6 A.**

Many visible as well as infrared laser line spectra have been obtained with the hollow-cathode-type He-Cd$^+$ laser tubes [1]–[4]. The authors have been trying to develop a single-gun CW white light laser due to the simultaneous oscillations of the three-color laser lines under fixed discharge conditions [5] because they have a special interest in visible laser lines for many engineering applications, such as color holography and color display [6]. Many studies on the improvements of the operating conditions as well as the tube structure have been made, and the ways to set the conditions for simultaneous oscillations have been clarified. A strong white laser light was successfully obtained with a pure dc power supply and two broad-band mirrors (made by Lambda Airton Company in the U.S.) which have a bandwidth of 2000 Å, a radius of 1 m, and a reflectivity of almost 100 percent.

A schematic diagram of the hollow-cathode-type He-Cd$^+$ laser tube used in our experiments is shown in Fig. 1. It is the characteristic of this laser tube to utilize the cathode region (consisting of a cathode dark space and a negative glow) of mixed He-Cd gases in the form of a hollow-cathode discharge. The hollow cathode was 4 mm in diameter and 80 cm in length, and was a perforated copper pipe covered with Pyrex glass. A thermocouple was made in contact with the hollow cathode to measure the cathode temperature. The partial pressure of the Cd vapor was estimated by the cathode temperature. A Cd metal was placed inside the cathode pipe. Ten anodes, made of tungsten rods 2 mm in diameter, were mounted with the intervals of 80 mm above each hole. The

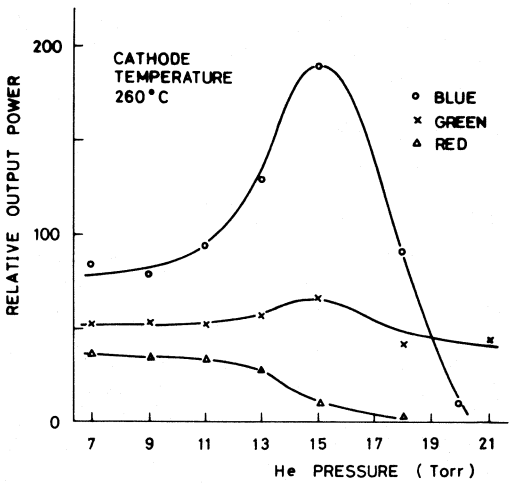

Fig. 3. Dependence of the laser output power on the He pressure.

distance of the anode from the cathode surface was 8 mm. Each anode was connected to the regulated dc power supply through a variable resistance of 1 kΩ. Mica spacers were inserted between the outer surface of the cathode and the inner surface of the glass envelope. A stable dc discharge was obtained at such a low pressure of He as 7 torr with these spacers. A liquid-nitrogen trap was set between the laser tube and the glass cock to eliminate the effect of impurities.

Fig. 2 shows the energy levels of a Cd ion and the laser transitions in the visible range which were obtained with our hollow-cathode-type He-Cd$^+$ laser tube. The red and the green laser line spectra have not been obtained with positive column-type He-Cd$^+$ laser tubes.

Fig. 3 shows the dependence of the laser output power on the He pressure for each of the three colors at a cathode temperature of 260°C. White laser light was obtained in the range of He pressure between 7 and 13 torr. At higher pressures above 13 torr it was difficult to obtain a balanced white laser light since the output power of red laser lines became weaker, while that of the blue laser line became much stronger. At lower pressures below 7 torr the discharge became unstable.

Fig. 4 shows the laser output power as a function of the

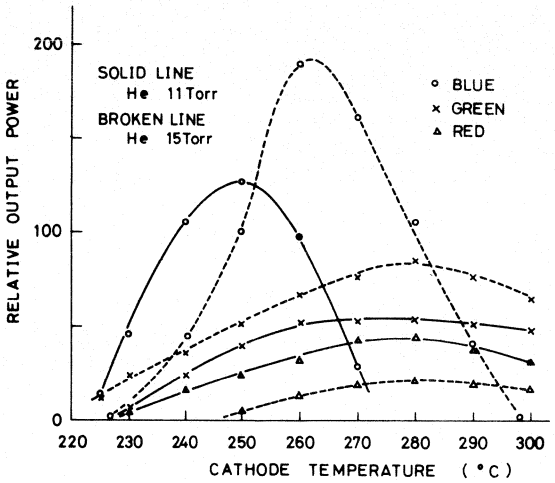

Fig. 4. Laser output power as a function of the cathode temperature (partial pressure of Cd vapor).

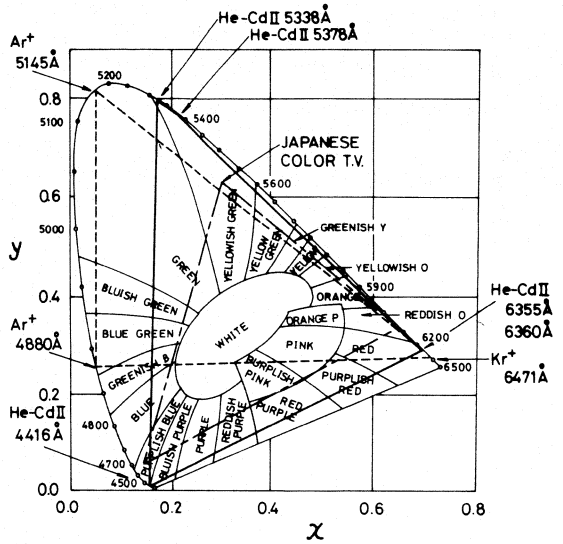

Fig. 5. CIE chromaticity diagram showing reproducing characteristics of He-Cd$^+$ laser (solid line), Ar-Kr$^+$ laser (broken line), and Japanese color TV (chain line).

cathode temperature (partial pressure of Cd vapor) at two different He pressures, 11 and 15 torr. A white laser light was obtained between 230 and 270°C at 11 torr (solid line), and between 250 and 290°C at 15 torr (broken line). The cathode temperature, which was adequate for an oscillation of the white laser light, slightly shifted toward higher regions with increasing He pressures. The laser outputs did not depend on the discharge currents since the laser tube operated on a constant current at steady-state conditions (the constant current value was about 0.6 A) [5].

Due to the characteristics of the cathode region, the hollow-cathode-type He-Cd$^+$ laser could result in three-color outputs with a single gun. In our experiments a flute-type He-Cd$^+$ laser tube was improved so as to operate at such a low pressure of He as to minimize the difference in laser outputs of the three colors.

Using the improved laser tube and a broad-band optical cavity, a pure and well-balanced CW white laser light was obtained. To show how close the dominant wavelengths of our He-Cd$^+$ laser are, the International Commission of Illumination (CIE) chromaticity diagram was drawn as in Fig. 5. It is clear from Fig. 5 that the He-Cd$^+$ laser has excellent characteristics in reproducing natural colors. In comparison, characteristics of the Ar-Kr$^+$ laser (broken line) and Japanese color TV (chain line) were also shown in Fig. 5. As may be seen, the characteristics of the He-Cd$^+$ laser are better than those of the Ar-Kr$^+$ laser and the color TV.

Since heavy atoms such as Cd are utilized, the Doppler width is narrower and therefore the axial mode numbers are fewer than other rare gas lasers [6]. Moreover, the angle of the polarization of the three colors was made coincident since a Brewster window having an almost constant refractive index in the range of the visible wavelength was used. The reason why the red and the green laser lines can be obtained only with the hollow-cathode-type He-Cd$^+$ laser tubes was reported a few years ago [5]. Other problems on the laser tube such as the discharge characteristic (constant-current characteristic [5]), the design principle [5], and the confining mechanism of the negative glow into the hollow cathode were also clarified [7].

In conclusion, we demonstrated that a stable CW single-gun

$He\text{-}Cd^+$ white light laser of the hollow-cathode type has excellent reproducing characteristics of the natural colors, as the contained wavelengths position properly in the chromaticity diagram. Stable CW oscillations are possible with low terminal voltages since the discharge may be sustained by the impressed voltage nearly equal to the cathode fall. These characteristics are considered to be very useful for practical applications.

Sixteen New IR Laser Dyes

J. PIERCE WEBB, F. GLENN WEBSTER, AND BERTRAND E. PLOURDE

Abstract—**Sixteen new IR laser dyes are reported. All lased successfully under excitation from a simple linear flashlamp of about 700-ns rise time. Untuned lasing wavelengths ranged from 810 to 972 nm. Laser output pulse energies from the four best of these dyes were 5–15 times greater than from diethylthiatricarbocyanine iodide (DTTC), with peak output of about 50 mJ obtained from 128-J excitation. Solvent effects with four selected laser dyes are also discussed.**

IR dye laser action under simple linear flashlamp excitation was obtained from 16 new laser dyes with untuned laser wavelengths spanning 810–972 nm. Whereas flashlamp-pumped dye lasers operating at wavelengths of up to 950 nm have been reported in the literature [1]–[4], these previous IR dye lasers have all been excited by ultrafast coaxial flashlamps with rise times of 80–150 ns. Our new dyes were all pumped with a flashlamp of ~700-ns rise time. Laser pulse durations (FWHM) from these new dyes ranged up to 800 ns. Output pulse energies from the four best of these new dyes were 5–15 times greater than from diethylthiatricarbocyanine iodide (DTTC). To our knowledge none of these 16 new dyes has been used in previous dye laser work.

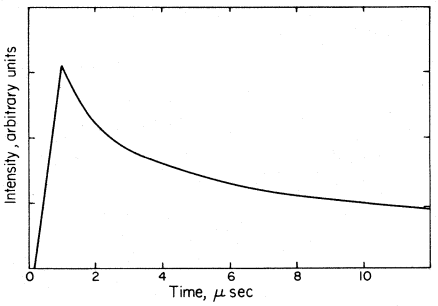

Fig. 1. Flashlamp excitation pulse shape. The curve is a drawing traced from an oscilloscope trace of the near-IR portion of our flashlamp output, measured by a fast silicon detector through a visible-blocking, IR-pass filter. Rise time of the infrared pumping pulse was approximately 700 ns.

Our source of excitation was a linear, air discharge flashlamp with a 3-mm bore and 15-cm arc length, located 1 mm from a 3-mm-bore dye cell of comparable length. The dye cell and flashlamp were enclosed in a 1.5-cm-diameter Plexiglas cylinder coated on the inside with high-reflectance white paint.

Prior to laser operation the flashlamp output was measured with a fast, small-area p-i-n photodiode after being filtered with an IR-passing filter that blocked wavelengths shorter than 700 nm. Rise time of the near IR pumping pulse from our air discharge flashlamp was about 700 ns, and the pulse-width was about 3.5 μs (FWHM), as shown in Fig. 1. Pumping bands of 5 of the best IR dyes are shown in Figs. 2–6.

We used a 36-cm-long, plane parallel resonant cavity with a 100-percent reflecting mirror and a 37-percent reflecting mirror both designed for uniform reflectance from 850–980 nm. Below 850 nm, the reflectance of the highly reflecting mirror dropped from 98-percent at 850 nm to 15-percent at 820 nm! Thus laser output from short wavelength dyes was discriminated against.

A 1-μF 20-kV capacitor is used for energy storage. The laser operates without any externally triggered electrical switch in the discharge circuit; it is actuated by evacuating the flashlamp to its breakdown pressure while full voltage is maintained across the lamp. An overdamped discharge current is observed with the air lamp in the circuit.

The laser output characteristics from 16 new near-IR dyes are shown in Table I. In these tests the dyes were dissolved to 10^{-4} M in dimethyl sulfoxide (DMSO), and the input energy to the lamp was 128 J. Recalling the low reflectance of the nominally high-reflectivity mirror at wavelengths shorter than 850 nm, the first four short wavelength dyes tagged with an (a) are certainly substantially better than this intercomparison indicates.

A 1.5-m grating spectrograph was used to record the laser wavelengths on KODAK High Speed Infrared Film 2481 (ESTAR Base). The absence of the two lasing wavelengths that are not reported results from our spectrograph having a cutoff at ~835 nm and from our not being able to borrow the instrument we used to measure IR-135 for IR-145 and 136. Their lasing wavelengths are certainly shorter than 835 nm, and we suspect based on dye structure that IR-145 is a little shorter than 810 nm and IR-136 a little longer than 810 nm.

Laser power was measured with a small-area p-i-n photodiode mounted 15 cm behind a 5-cm-diameter opal-glass diffuser. The fraction of light incident on the diffuser that reached the photodiode and the absolute spectral sensitivity of the

photodiode were measured separately. Our absolute power measurements should be correct to ±15 percent [5].

DTTC, a relatively well-known dye, is included in the table for comparison. One notes that the output pulse energy from IR-140 is about fifteen times greater than from DTTC, while IR-125, IR-137, and IR-144 are between five and ten times more energetic than DTTC. Pulse energies range up to ~50 mJ from IR-140.

The absolute laser pulse energies reported are characteristic of the laser configuration described in the preceding. We also tested dyes IR-125 and 144 in different laser configurations. In an Integrated Cell Resonant Cavity (ICRC) configuration, a cell with the same 37-percent R and 100-percent R mirrors coated directly on the outside of the cell windows was used with the air discharge lamp, and with a new laser head employing sealed linear flashlamps containing a variety of fill gases. Laser output from dyes IR-123, 125, 132, and 144 was also measured with a variety of output mirror reflectivities. Observations on results of these configuration changes are collected in Appendix II. Generally speaking, configuration-dependent results were completely consistent with well-understood principles of dye laser design. That is, results quoted in Tables I and II that appear to be configuration dependent can be generalized to other flashlamp-pumped laser systems so long as similarly fast rise time flashlamps are employed.

No tuning experiments employing a dispersive element in the cavity were performed. An attempt was made to optimize the dye concentration with four representative dyes: IR-123, 125, 132, and 144 [6]; measurements of lasing wavelength as a function of dye concentration provide some concentration tuning data. With mirrors that were spectrally flat from 850 nm to 980 nm, IR-125 lased from 924 nm (3×10^{-5} M in DMSO) to 952 nm (10^{-3} M in DMSO), IR-132 lased from 957 nm (3×10^{-5} M in DMSO) to 972 nm (10^{-4} M in DMSO), and IR-144 lased from 862 nm (10^{-5} M in DMSO) to 955 nm (10^{-3} M in DMSO). Untuned IR-144 solutions at 10^{-4} M in DMSO, tetrahydrothiophene oxide, 1-methyl-2-pyrrolidinone, and dimethylformamide all lased at 882 ± 8 nm and 950 ± 10 nm; frequently, both lasing wavelengths appeared during the same pulse. In this experimental configuration, incidentally, the optimum concentration was typically $1\text{–}2 \times 10^{-4}$ M in DMSO for these four dyes.

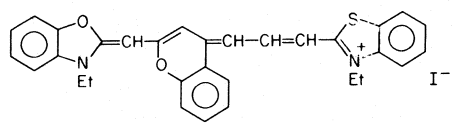
Our data show that no self-tuned laser output occurred between about 890 nm and 920 nm with any of the dyes and solvents used in our untuned laser configuration. We tentatively attribute this to a small solvent absorption peak from DMSO and other common solvents that occurs in this spectral region. DMSO and dichloromethane are hygroscopic solvents, of course, and the absorption observed in our spectro grade solvents could have resulted from water absorbed from the air rather than being intrinsic to the solvents. Tuning into this region with a dispersive tuning element in the cavity might be facilitated by careful dehydration of the solvent or by dye cells shorter than our 15-cm-long cuvettes.

Solvent effects are commonly important with dye lasers, and this is particularly true with IR laser dyes. We have investigated a variety of solvents for use with IR laser dyes. Lasability and laser output from four representative laser dyes dissolved in a variety of air-equilibrated solvents are listed in Table II.

The selection of solvents for the laser tests was based in part on a preliminary measurement of relative IR fluorescence yields from dye solutions excited by the air discharge flashlamp. These measurements were made on IR-107, 109, 116, 123, 125, 132, 134, and DTTC plus 25 other nonlasing IR dyes [7]. Although results varied somewhat from dye to dye, much higher fluorescence yields were consistently observed from highly polar solvents without OH groups such as dimethylformamide (DMF) and DMSO than from lower alcohols. Relative fluorescence yields from laser dyes dissolved in DMSO exceeded those from methanol solutions by 50–100 percent.

Hirth, Faure, and Lougnot [4] have shown that concentration of dissolved oxygen and the rate of collision between dye molecule and dissolved oxygen are important parameters influencing IR dye laser action in a system using fast (~100-ns rise time) excitation. Hirth *et al.* attribute their results to oxygen-enhanced intersystem crossing and triplet-state buildup, which would be more pronounced in methanol than in DMSO.

Our experiments all employed air-equilibrated solvents, and thus shed no light on the importance of dissolved oxygen in our long time (800-ns) domain. Our experiments do show that more is involved in these "solvent effects" in this long time domain than simple dissolved-oxygen effects. The most direct evidence for oxygen-independent effects in the host environment (solvent) came from substituting deuterated solvents for normal protonated solvents. The relative fluorescence yield of DTTC increased from 0.010 unit in CH_3OH to 0.020 unit in CD_3OD and from 0.019 in $(CH_3)_2SO$ to 0.023 in $(CD_3)_2SO$; the relative fluorescence of IR-132



increased from 4.9×10^{-3} in $(CH_3)_2SO$ to 8.2×10^{-3} unit in $(CD_3)_2SO$. (These relative fluorescence yields represent the peak fluorescence occurring at the flashlamp peak, not time-integrated fluorescence.) IR-144 did not lase at 10^{-4} M in CH_3OH, but did lase strongly at 10^{-4} M in CD_3OD in our flashlamp-pumped laser. These dramatic changes cannot be explained on the basis of oxygen effects, since oxygen solubility and solvent viscosity should be substantially independent of protonation versus deuteration of solvents.

These preliminary experiments with deuterated solvents were undertaken because we observed that the 800–950-nm (12 500 to 10 525 cm^{-1}) fluorescence region overlapped the third harmonic of the O–H stretch band and the fourth harmonic of the C–H stretch band. We speculated that this overlap might enhance nonradiative relaxation of excited-state dye molecules to the ground state. Since the deuteron is twice as heavy as the proton, the fundamental deuteron vibration frequencies are decreased by $\sim\sqrt{2}$, thus reducing the probability of resonant energy transfer from dye to solvent. At the very least, deuterated solvents provide alternative host solvents for IR laser dyes. These alternative solvents can be considered for IR laser dyes if the more common, highly polar, protonated solvents such as DMSO prove unsatisfactory for some reason, such as the small absorption peak around 900 nm, too high viscosity, etc.

In conclusion, we report 16 new IR laser dyes, all of which were successfully pumped with a simple linear flashlamp of 700-ns rise time. Untuned lasing wavelengths ranged from 810 nm to 972 nm. The four best of these dyes were from 5 to 15 times more energetic than DTTC.

Appendix II
Different Laser Configurations

While all of the data reported in this paper were taken with the specific laser configuration (air discharge lamp, 37-percent R output mirror, etc.) described previously, experiments with several of these dyes were performed with different configuration lasers. Some general observations about IR laser dye performance under these different conditions are collected here in Appendix II.

Output Mirror Reflectivity

Good laser dyes IR-123, 125, 132, and 144 were tested in the air discharge lamp laser configuration with 93-percent R and 76-percent R output mirrors in addition to the 37-percent R mirror [6]. At 128-J discharge energy, the 37-percent R output mirror configuration yielded between 3X and 4X higher peak power outputs than the 76-percent R output mirror, and the 76-percent R output mirror yielded more than twice the output power of the 93-percent R output mirror for all four dyes.

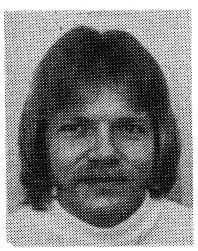
ICRC

The Integrated Cell Resonant Cavity plus air discharge flashlamp configuration produced ~30-percent more energetic laser pulses with IR-125 and 144 than the separate cell and mirror configuration.

Flashlamp Pumping

A more standard laser head using interchangeable capacitors, a triggered spark gap, and interchangeable, sealed flashlamps containing a variety of fill gases was constructed and evaluated with dyes IR-125 and 144 [5]. These lamps were of the 3D6 configuration (3-mm bore by 6-in arc length) from ILC, and were filled with argon (20, 50, 150, and 350 torr), krypton (150 torr), xenon (20 and 150 torr), neon (20 torr), and nitrogen (20 torr). Capacitors of 0.3 μF, 0.5 μF, 1.0 μF, and 2.0 μF were coupled to the lamps through a spark gap and short length of coaxial cable. Compared to the air discharge lamp laser, the sealed lamp head had longer leads and a somewhat slower rise time . . . at least for capacitors larger than 0.3 μF. Also optical coupling between the sealed lamps and dye cell was poorer than with the air discharge lamp, because the enlarged ballast chambers on the 3D6 lamps forced a larger separation between lamp and dye cell and a larger (diffuse white painted) energy coupling cavity enclosing lamp and cell. The two effects led to a reduced laser output in the sealed lamp configuration; output pulse energies with IR-144 dropped to ~70 percent of the air discharge energies and IR-125 energies decreased to ~50 percent of air discharge energies. (A similar increase in spacing between dye cell and air discharge flashlamp in the original screening laser produced a similar decrease in laser power with IR-125.) Generally speaking, nitrogen at 20 torr had the fastest rise time of any of the gases we tested and was generally most satisfactory, though differences in performance among all of the low-pressure lamps was small. Incidentally, the lifetime of the air discharge lamp was much better than that of the sealed lamps.

Acknowledgment



The authors wish to thank P. R. Manzo of NVL for many valuable conversations. They also wish to thank Dr. O. Peterson (formerly with Kodak Research Laboratories) for technical assistance with the flashlamp, and Dr. B. B. Snavely (formerly with Kodak Research Laboratories) for helpful

suggestions. Dr. Peterson and Dr. Snavely are now with the Lawrence Livermore Laboratory.

Since 1969 he has been a member of the Technical Staff in the Laser Division of the Hughes Aircraft Company, Culver City, Calif., and has continued his studies under the company's work-study fellowship program. He is currently working toward the Ph.D. degree in physics at the Center for Laser Studies, the University of Southern California, Los Angeles, where he was advanced to candidacy in December 1973.

Mr. Caird is a member of Eta Kappa Nu, Tau Beta Pi, and the Optical Society of America.

Larry G. DeShazer was born in Washington, D.C., on November 3, 1934. He received the B.S. degree in physics from the University of Maryland, College Park, in 1956 and the Ph.D. degree in physics from The Johns Hopkins University, Baltimore, Md., in 1963.

From 1963 to 1966 he was a Member of the Technical Staff of Hughes Aircraft Company, Culver City, Calif., engaged in research on energy transfer and fluorescence processes in solid-state laser materials, and later in studies of mode selection techniques for solid-state laser oscillators. In 1966 he joined the faculty of the Departments of Electrical Engineering and Materials Science at the University of Southern California, Los Angeles, Calif., as Assistant Professor. In addition, he joined the Department of Physics in 1970 and is currently Associate Professor. He has been mainly engaged in spectroscopy of rare-earth ions in laser glasses and

crystals, and saturated absorption of laser radiation by organic compounds. More recently he is studying laser-induced damage to thin-film coatings, and is concerned with generation and utilization of high-power optical beams. In 1973 he was appointed Director of the Center for Laser Studies at USC. He is consultant to Union Carbide Corporation, The Aerospace Corporation, and TRW Inc.

Dr. DeShazer is a member of the American Physical Society, the Optical Society of America, the American Association for the Advancement of Science, and Sigma Xi.

He has been with Bell Laboratories, Holmdel, N.J., since 1966. His present research interests are nonlinear optics in optical waveguides and Raman scattering in glass.

Third-Order Susceptibility of Alkali Metal Vapors

HERMANN EICHER

Abstract—**This paper presents calculations of the third-order susceptibility in the alkali metal vapors involving spin-orbit coupling in the energy spectrum of the alkali atoms and some power transfer between the atoms in the ensemble and their surroundings, including the radiation field. The results are plotted as a function of wavelength in the vicinity of the neodymium and iodine laser lines, and their second, third, and fourth harmonics for each of the alkalies; i.e., 10 520 Å < (λ, 2λ, 3λ, 4λ) < 10 720 Å, and 13 070 Å < (λ, 2λ, 3λ, 4λ) < 13 230 Å, respectively.**

I. Introduction

A POSSIBLE approach to generate coherent radiation in the vacuum ultraviolet and soft X-ray region of the electromagnetic spectrum is to use third-harmonic generation in alkali metal vapors, which may follow sequential second-harmonic generation in nonlinear crystals, or frequency tripling in gas mixtures, to convert the high peak power of the neodymium or iodine lasers to a much shorter wavelength. Third-harmonic generation in the inert gases and in alkali metal vapors has been studied by Ward and New [1] and Miles and Harris [2], respectively. Obviously, third-harmonic power is proportional to the cube of the fundamental power and to the square of the third-order susceptibility $X^{(3)}$. This susceptibility has been calculated as a function of wavelength for each of the alkalies, neglecting spin-orbit coupling and relaxation effects in the electronic structure of the alkali atoms [2]. For that reason, the calculations are of limited accuracy if the driving frequency lies in the vicinity of resonances. Moreover, only the lowest four s, p, and d states are taken into account which makes the calculation invalid for certain regions of the driving frequency.

To obtain theoretical data of higher accuracy, the third-order susceptibility of the alkalies was reevaluated within the concept of quantum statistics. All exact energies of the s, p, and d states [3], split by spin-orbit coupling, for which the oscillator strengths $ns \rightarrow mp$ and $np \rightarrow md$ are tabulated [4], [5], were included in our calculations. A weak interaction of the atoms with their surroundings and with the radiation field which would provide some damping effects in the case of resonant third-harmonic generation is taken into consideration by introducing relaxation rates of the density-matrix elements.

In Section II, values for the dipole-matrix elements are derived, and the reduced matrix elements between the electronic states for each of the alkalies are tabulated. In Section III, the third-order susceptibility of an ensemble of alkali atoms is calculated by means of the density-matrix formalism. Computer results of the real part of $|X^{(3)}|$ are plotted versus incident wavelength in the vicinity of the neodymium and iodine lasers and their second, third, and fourth harmonics.

II. Calculation of Dipole Matrix Elements

The bound eigenstates of the alkali atoms involving spin-orbit coupling are written in the form $|n, l, s = \frac{1}{2}, j, m\rangle$, where the radial part of the wave function depends only on the quantum numbers (n, l). The operator for the electric dipole moment $\boldsymbol{P} = -e \cdot \boldsymbol{r}$ is a tensor operator of rank one. Because of the spherical symmetry of our problem, we can assume the incident laser field to be linearly polarized in the z direction and thus take

$$\langle n, l, s, j, m | P_z | n', l', s, j', m' \rangle = -e \langle l, s, j, m, | T_0^{(1)} | l', s, j', m' \rangle \langle n, l \| r \| n', l' \rangle . \quad (1)$$

According to tensor techniques [6], the first factor is given in terms of 3-j and 6-j symbols [7]

$$\langle l, s, j, m | T_0^{(1)} | l', s, j', m' \rangle = (-1)^{j-m} \begin{pmatrix} j & 1 & j' \\ -m & 0 & m' \end{pmatrix} \cdot \langle l, s, j, \| T^{(1)} \| l', s, j' \rangle \quad (2a)$$

$$\langle l, s, j \| T^{(1)} \| l', s, j' \rangle = (-1)^{l+s+j'+1} (2j+1)^{1/2} \cdot (2j'+1)^{1/2} \cdot \begin{Bmatrix} j & 1 & j' \\ l' & s & l \end{Bmatrix} \cdot \langle l \| T^{(1)} \| l' \rangle \quad (2b)$$

$$\langle l \| T^{(1)} \| l' \rangle = (-1)^{l} (2l+1)^{1/2} (2l'+1)^{1/2} \cdot \begin{pmatrix} l & 1 & l' \\ 0 & 0 & 0 \end{pmatrix} . \quad (2c)$$

Table I gives the reduced matrix elements in (2b) between S, P, and D states of the alkalies. States with higher values of

the angular quantum numbers do not contribute to the third-order susceptibility because the ground state of the alkalies is a $^2S_{1/2}$ state, and it is assumed that this is the only populated level. The nonvanishing matrix elements in (2a) are therefore

$$\begin{aligned}
&\langle {}^2S_{1/2}, m=\pm\tfrac{1}{2}|T_0^{(1)}|{}^2P_{1/2}, m=\pm\tfrac{1}{2}\rangle = \mp\tfrac{1}{3}\\
&\langle {}^2S_{1/2}, m=\pm\tfrac{1}{2}|T_0^{(1)}|{}^2P_{3/2}, m=\pm\tfrac{1}{2}\rangle = (\tfrac{2}{9})^{1/2}\\
&\langle {}^2P_{1/2}, m=\pm\tfrac{1}{2}|T_0^{(1)}|{}^2D_{3/2}, m=\pm\tfrac{1}{2}\rangle = (\tfrac{2}{9})^{1/2}\\
&\langle {}^2P_{3/2}, m=\pm\tfrac{1}{2}|T_0^{(1)}|{}^2D_{3/2}, m=\pm\tfrac{1}{2}\rangle = \mp\tfrac{1}{15}\\
&\langle {}^2P_{3/2}, m=\pm\tfrac{1}{2}|T_0^{(1)}|{}^2D_{5/2}, m=\pm\tfrac{1}{2}\rangle = (\tfrac{6}{25})^{1/2}.
\end{aligned} \tag{3}$$

The absolute values of the radial-matrix elements in (1) are derived from oscillator strengths $f(n, l \to n', l+1)$ calculated by Anderson and Zilitis [4], [5]

$$\langle n, l\|r\|n', l+1\rangle^2 = f(n, l\to n', l+1) \cdot \frac{3(2l+1)}{2(l+1)\cdot|E_{n,l} - E_{n',l+1}|} \tag{4}$$

where the average energies $E_{n,l}$ are evaluated from the L–S split levels in Moore's tables [3]

$$\begin{aligned}
E_{n,p} &= \tfrac{1}{3}E(n\,{}^2P_{1/2}) + \tfrac{2}{3}E(n\,{}^2P_{3/2})\\
E_{n,d} &= \tfrac{2}{5}E(n\,{}^2D_{3/2}) + \tfrac{3}{5}E(n\,{}^2D_{5/2}).
\end{aligned} \tag{5}$$

In (4) and throughout the remainder of the paper all quantities are expressed in atomic units.

The sign of $\langle n, l\|r\|n', l+1\rangle$ may be found through the Bates and Damgaard [8] approach, corrected by Bebb [9],[1] which assumes a Coulombic radial potential field. Computer results of [9, eq. (A3)], giving the signs of the radial-matrix elements, are justified by yielding remarkably good agreement with (4). The dipole, radial-matrix elements for each of the alkalies are listed in Tables II-VI.[2]

III. THE THIRD-ORDER SUSCEPTIBILITY $X^{(3)}(3\omega)$

The coherent perturbation of the bound eigenstates $|E_n\rangle$ of the alkalies by an incident electric field

$$E(r,t) = \tfrac{1}{2}\,(E(r)e^{-i\omega t} + E^*(r)e^{i\omega t}) \tag{6}$$

is given by the Hamiltonian

$$H'(t) = e\,r\,E(r,t) = -\boldsymbol{P}\cdot E(r,t) \tag{7}$$

where the matrix elements of the dipole moment operator $\boldsymbol{P}$

[1] The correct expression of [9, eq. (A1d)] is given by $a_t = a_{t-1}(n^*/2t)\,[l(l+1) - (n^*-t)(n^*-t+1)]$.

[2] The definition of the radial-matrix elements differs from that of [2]. Note that the following $\langle z\rangle$ values in [2, table I] should be corrected to

Li $3s$–$4p$: $\langle z\rangle = +0.021$
K $7p$–$3d$: $\langle z\rangle = -0.209$
Cs $7s$–$8p$: $\langle z\rangle = -0.780$.

are defined in (1). Using the density matrix ρ, the expectation value of the polarization $\boldsymbol{P}(t)$ is

$$\langle \boldsymbol{P}(t) \rangle = N \cdot Tr(\rho(t) \cdot \boldsymbol{P}) = N \cdot \sum_{m,n} \rho_{mn}(t) \cdot \boldsymbol{P}_{nm} \tag{8}$$

where N is the number of atoms per unit volume, and the summation is carried over the bound eigenstates. The density-matrix elements ρ_{mn} as functions of time can be obtained from the well-known von Neumann equation

$$i\hbar \frac{\partial \rho_{mn}}{\partial t} = [H, \rho]_{mn} \tag{9}$$

modified by introducing relaxation rates to take care of the fact that the atoms are interacting weakly with their surroundings and with the radiation field, an interaction which would provide some damping effects [10]. Thus we shall remedy (9) as follows: for the off-diagonal term ($n \neq m$) and for the diagonal term, the ρ_{mn} must satisfy the equations

$$i\hbar \left(\frac{\partial}{\partial t} + \Gamma_{mn} \right) \rho_{mn} = [H^{(0)} + H'(t), \rho]_{mn} \tag{10}$$

$$i\hbar \left(\frac{\partial \rho_{nn}}{\partial t} + \sum_k (\rho_{nn} W_{nk} - \rho_{kk} W_{kn}) \right) = [H^{(0)} + H'(t), \rho]_{nn} \tag{10'}$$

where the Γ_{mn} and W_{ij} are called the transverse and longitudinal relaxation rates, respectively. Since we are interested only in induced transitions between eigenstates, and not in transitions resulting from relaxation processes, the appropriate equation of motion for the diagonal elements of the density operator is obtained by setting W_{ij} equal to zero. $H^{(0)}$ is the Hamiltonian of the atom when the radiation field is absent; its matrix elements $\langle m | H^{(0)} | n \rangle = E_m \delta_{mn}$ are the energy eigenstates of the alkalies, tabulated by Moore [3]. Because the interaction term $H'(t)$ is much smaller than the unperturbed Hamiltonian $H^{(0)}$ of the medium, each matrix element of the density operator may be expanded in terms of powers of the perturbation

$$\rho_{mn} = \sum_p \rho_{mn}^{(p)}. \tag{11}$$

With the notation

$$\hbar \omega_{mn} = E_m - E_n \tag{12}$$

we obtain from (10) and (10′)

$$i\hbar\left(\frac{\partial}{\partial t} + i\omega_{mn} + (1 - \delta_{mn})\,\Gamma_{mn}\right)\rho_{mn}^{(p)} = [H'(t), \rho^{(p-1)}]_{mn}. \tag{13}$$

It is assumed in our derivation that the spectral spread of the incident radiation is narrow compared to the transition linewidth $\hbar\Gamma_{mn}$ which must include contributions from the natural linewidth, pressure broadening, and self-broadening effects. This assumption would certainly be valid for a laser source. The effect of Γ_{mn} on the third-order susceptibility $X^{(3)}$ is significant only for the resonant case in which the driving frequency or its second or third harmonic lies in the vicinity of ω_{mn}

$$\omega, 2\omega, 3\omega \cong |\omega_{mn}|. \tag{14}$$

In that case, we can replace the relaxation rates Γ_{mn} in (13) by a single constant Γ, the transition linewidth of the two relevant eigenstates $|m\rangle$ and $|n\rangle$ in the resonant case. If the Hamiltonian $H^{(0)}$ of the medium is invariant under the parity transformation, the two eigenstates $|m\rangle$ and $|n\rangle$ must have opposite parity when resonant enhancement arises from odd harmonics of the incident frequency ω and vice versa. Assuming that the ground state $|g, {}^2S_{1/2}\rangle$ of the alkalies is the only populated level, the calculations which follow will give the resonance conditions for $X^{(3)}$:

$$\omega = \omega_{pg}$$

$$2\omega = \omega_{sg}, \omega_{dg}, \omega_{pp'}$$

$$3\omega = \omega_{pg}, \pm\omega_{sp}, \pm\omega_{pd} \tag{15}$$

where the energies of the ground state $|g\rangle$ and of the excited s, p, and d levels are indicated by indices. If the incident electric field is given by (6), then the third-order susceptibility $X^{(3)}(3\omega)$ is generally defined by the expectation value of the polarization at the third-harmonic frequency as

$$\langle P(3\omega t)\rangle = NX^{(3)}(3\omega)\cdot\left(\frac{E(r)}{2}\right)^3 e^{-3i\omega t} + \text{c.c.} \tag{16}$$

which can be evaluated from (8)

$$\langle \boldsymbol{P}(3\omega t)\rangle = N\sum_{mn}\rho_{mn}(3\omega t)\boldsymbol{P}_{nm}. \tag{17}$$

The required matrix elements of the density operator ρ are obtained in third-order perturbation theory by the method of successive approximation according to (13). Details of the calculation are given in the Appendix. Computer results of the real part of the third-order susceptibility for each of the alkalies are plotted in Figs. 1–10 as a function of wavelength in the vicinity of the neodymium and iodine laser lines, and their second, third, and fourth harmonics, respectively. Note that the wavelength scale corresponds to the fundamental laser frequency (curve *a*), and can be easily related to the incident second, third, or fourth harmonic of the laser radiation (curves *b*, *c*, and *d*). The calculated susceptibility for the 1.064-μm radiation in Rb vapor (1.072×10^{-32} ESU) agrees reasonably well with the reported generation of 0.3547-μm radiation by tripling the 1.064-μm radiation in a phase-matched mixture of

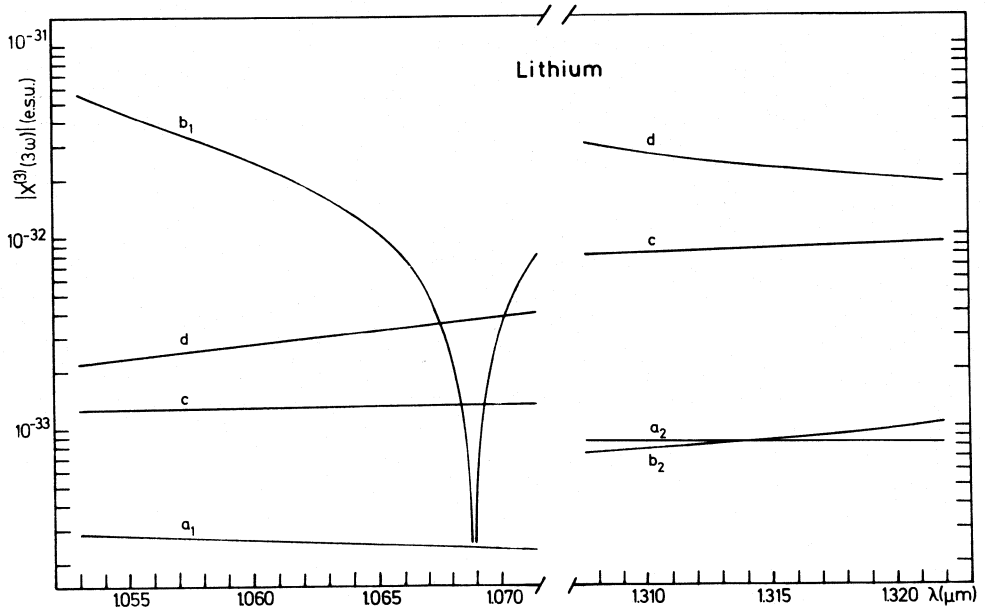

Fig. 1. Third-order susceptibility of lithium versus wavelength in the vicinity of the neodymium and iodine lasers. Curves a, b, c, and d are calculated for the first, second, third, and fourth harmonics of the incident laser radiation, respectively. For each curve, the logarithmic scale must be multiplied by a scaling factor: $a_1(1)$, $a_2(10^{-1})$, $b_1(10^{-3})$, $b_2(1)$, $c(10^{-3})$, and $d(10^{-4})$. The linewidth Γ is chosen to be 0.1 cm^{-1}.

Solid and dashed lines correspond to the linewidths $\Gamma = 0.1$ cm^{-1} and $\Gamma = 1$ cm^{-1}, respectively. The wavelengths of the three peaks ($\Gamma = 0.1$ cm^{-1}) are 0.655758 μm (B_1), and 0.660465 μm, 0.660498 μm (B_2).

rubidium and xenon [11], where the measured susceptibility is $X^{(3)}_{Rb}(\text{meas}) = 1.4 \times 10^{-32}$ ESU; the calculated value of Miles and Harris [2] is 6.15×10^{-33} ESU.[3]

Finally, it should be noticed that the resonances of $X^{(3)}$, seen in the figures, can be slightly shifted by an applied magnetic field according to the Zeeman-splittings of the atomic energy levels in order to enhance the susceptibility for a near-resonant laser radiation.

[3]Present calculations with the data of [2] yield the nonlinear susceptibility to be exactly a factor of 2 greater than that of Miles and Harris.

Appendix

In this Appendix, the third-order matrix elements of the density operator ρ are calculated by successive approximations according to (13). The starting point is the unperturbed system when the radiation field is absent. Therefore, if we consider that the unperturbed system is in the ground state $|g\rangle$, we get in the zeroth order

$$\rho^{(0)}_{mn} = \delta_{mg}\delta_{ng}. \tag{A1}$$

It is a systematic algebraic procedure to find the density-matrix elements as a power series in the perturbation $H'(t)$ of

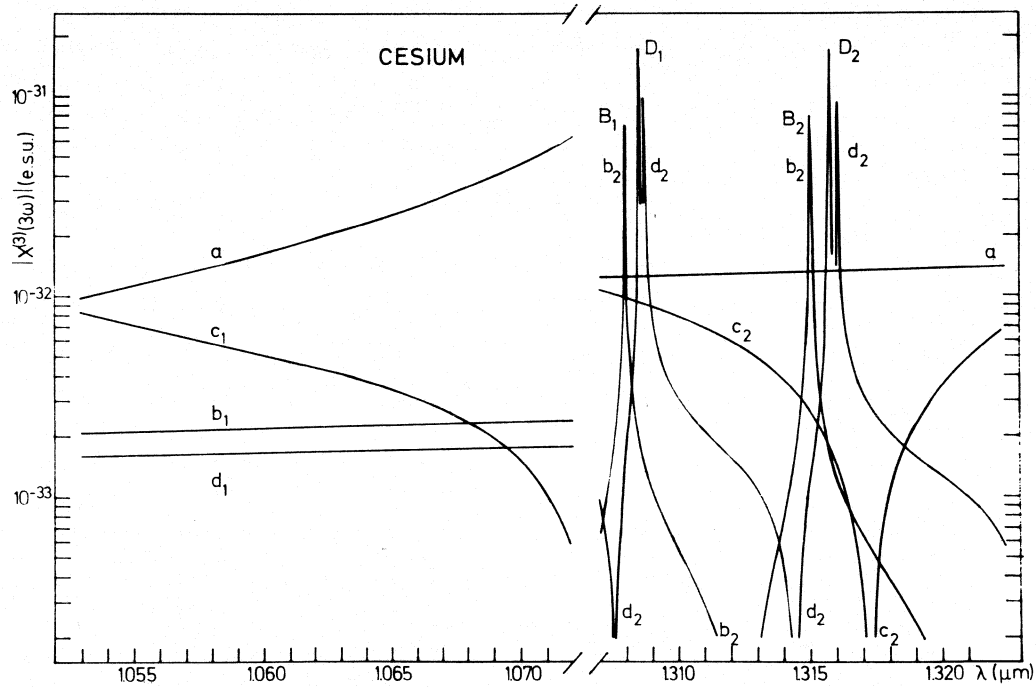

Fig. 8. Third-order susceptibility of cesium versus wavelength in the vicinity of the neodymium and iodine lasers. Curves a, b, c, and d are calculated for the first, second, third, and fourth harmonics of the incident laser radiation, respectively. For each curve, the logarithmic scale must be multiplied by a scaling factor: $a(1)$, $b_1(10^{-2})$, $b_2(1)$, $c_1(10^{-3})$, $c_2(10^{-4})$, $d_1(10^{-3})$, and $d_2(10^{-2})$. The linewidth Γ is chosen to be 0.1 cm^{-1}. The resonances B_1, B_2 and D_1, D_2 are enlarged in Figs. 9 and 10.

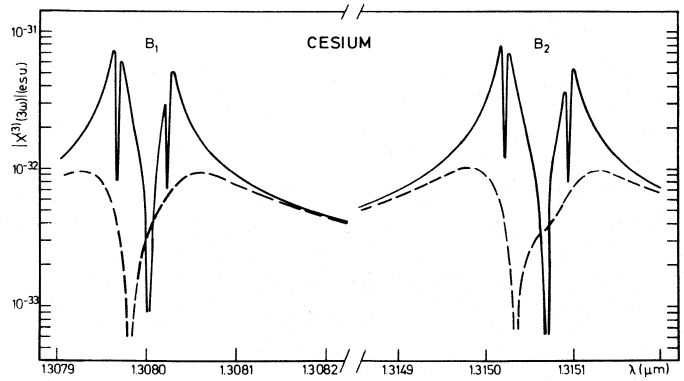

Fig. 9. Resonances of the third-order susceptibility of cesium for the second harmonic of the iodine laser, enlarged from Fig. 8. Solid and dashed lines correspond to the linewidths $\Gamma = 0.1$ cm^{-1} and $\Gamma = 1$ cm^{-1}, respectively. The wavelengths for the four peaks ($\Gamma = 0.1$ cm^{-1}) are 0.653984 μm, 0.654012 μm (B_1), and 0.657510 μm, 0.657547 μm (B_2).

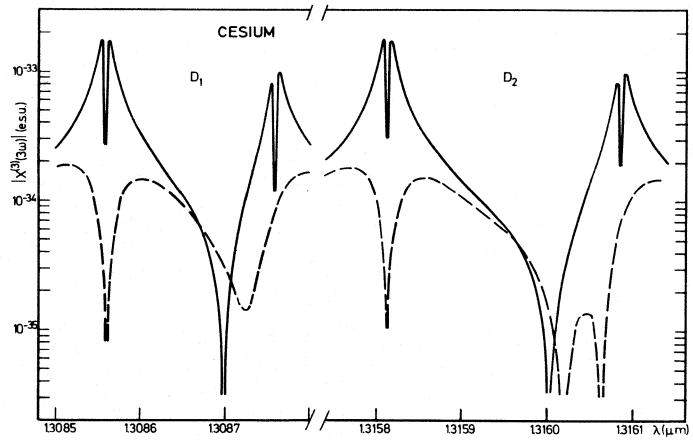

Fig. 10. Resonances of the third-order susceptibility of cesium for the fourth harmonic of the iodine laser, enlarged from Fig. 8. Solid and dashed lines correspond to the linewidths $\Gamma = 0.1$ cm^{-1} and $\Gamma = 1$ cm^{-1}, respectively. The wavelengths for the four peaks ($\Gamma = 0.1$ cm^{-1}) are 0.327140 μm, 0.327190 μm (D_1), and 0.328953 μm, 0.329021 μm (D_2).

(7). The terms will, in general, contain combination frequencies of the perturbation and may be written as

$$\rho_{mn}^{(1)} = A_{mn}^{(1)} e^{-i\omega t} + A_{nm}^{(1)*} e^{i\omega t}$$
$$\rho_{mn}^{(2)} = B_{mn}^{(2)} e^{-2i\omega t} + B_{mn}^{(0)} + B_{nm}^{(2)*} e^{2i\omega t}$$
$$\rho_{mn}^{(3)} = C_{mn}^{(3)} e^{-3i\omega t} + C_{mn}^{(1)} e^{-i\omega t} + C_{nm}^{(1)*} e^{i\omega t} + C_{nm}^{(3)*} e^{3i\omega t}. \quad \text{(A2)}$$

With the condition (A1) that the system is initially in state $|g\rangle$, we obtain from (13) the only nonvanishing coefficients

$$A_{pg}^{(1)} = -(E/2\hbar)P_{pg}/(\omega - \omega_{pg} + i\Gamma)$$
$$A_{gp}^{(1)} = (E/2\hbar)P_{pg}/(\omega + \omega_{pg} + i\Gamma) \quad \text{(A3)}$$

where the dipole-matrix elements and energy differences between the atomic eigenstates under consideration are indicated by the appropriate indices. Similarly, in second-order perturbation, we get

$$B_{pp}^{(2)} = (E/2\hbar)P_{pg}(A_{pg}^{(1)} - A_{gp}^{(1)})/2\omega$$

$$B_{gg}^{(2)} = -\sum_{p} B_{pp}^{(2)}$$

$$B_{pp'}^{(2)} = (E/2\hbar)(-P_{pg}A_{gp'}^{(1)} + P_{p'g}A_{pg}^{(1)})/(2\omega - \omega_{pp'} + i\Gamma)$$

$$B_{sg}^{(2)} = -(E/2\hbar)\sum_{p} P_{ps}A_{pg}^{(1)}/(2\omega - \omega_{sg} + i\Gamma)$$

$$B_{gs}^{(2)} = (E/2\hbar)\sum_{p} P_{ps}A_{gp}^{(1)}/(2\omega + \omega_{sg} + i\Gamma)$$

$$B_{dg}^{(2)} = -(E/2\hbar)\sum_{p} P_{dp}A_{pg}^{(1)}/(2\omega - \omega_{dg} + i\Gamma)$$

$$B_{gd}^{(2)} = (E/2\hbar)\sum_{p} P_{dp}A_{gp}^{(1)}/(2\omega + \omega_{dg} + i\Gamma). \quad \text{(A4)}$$

The coefficients $C_{mn}^{(3)}$ are obtained from the equation

$$C_{mn}^{(3)}(3\omega - \omega_{mn} + i\Gamma) = -(E/2\hbar)\sum_{k} \cdot (P_{mk}B_{kn}^{(2)} - P_{kn}B_{mk}^{(2)}) \quad \text{(A5)}$$

where the indices m and n are combinations of gp, pg, sp, ps, pd, and dp, respectively. Equation (17) may now be written as

$$\langle P(3\omega t)\rangle = N\sum_{mn} P_{nm}C_{mn}^{(3)}e^{-3i\omega t} + \text{c.c.} \quad \text{(A6)}$$

which determines directly the third-order susceptibility of (16).

Acknowledgment

The author wishes to thank Prof. W. Kaiser for stimulating this work, and Dr. H. Puell for discussions. The computational part of the work was carried out at the Leibniz-Rechenzentrum der Bayerischen Akademie der Wissenschaften.

Perturbation Theory of a Doubly Clad Optical Fiber with a Low-Index Inner Cladding

SHOJIRO KAWAKAMI, MEMBER, IEEE, AND SHIGEO NISHIDA, SENIOR MEMBER, IEEE

Abstract—**A doubly clad optical fiber which is composed of the core, inner cladding, and outer cladding is called a *W*-type fiber when the core has the largest index of refraction of the three and the inner cladding has the lowest. A *W*-type fiber is known to have several advantages over a conventional singly clad (SC) fiber. This paper presents simple, closed form approximations of a *W*-type fiber with respect to cutoff, the attenuation constant in the leaky wave region and a rapid change of the group velocity near cutoff, etc. In the approach to be described, a *W*-type fiber is thought of as a combined system of an SC fiber and an outer perturbing medium.**

Manuscript received September 9, 1974.
The authors are with the Research Institute of Electrical Communication, Tohoku University, Sendai, Japan.

I. Introduction

THIS paper presents a simple approximate theory of a doubly clad optical fiber shown in Fig. 1. The fiber consists of three portions: the core, inner cladding, and outer cladding. It is assumed that the outer cladding has a lower refractive index than the core, and the inner cladding has the lowest of the three. Such an optical fiber is referred to as a "*W*-type fiber" [1], [2]. It is known that a *W*-type fiber has several advantages over a conventional singly clad (hereafter abbreviated as SC) fiber: a *W*-type fiber has, as compared with an SC fiber, a tighter confinement property which minimizes the total waveguide dispersion and reduces absorption loss in

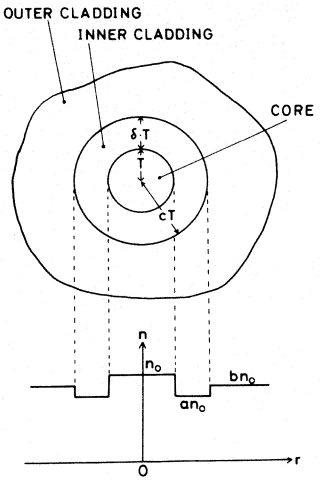

Fig. 1. Geometry and refractive index profile of a *W*-type fiber. The outer cladding is assumed to extend to infinity.

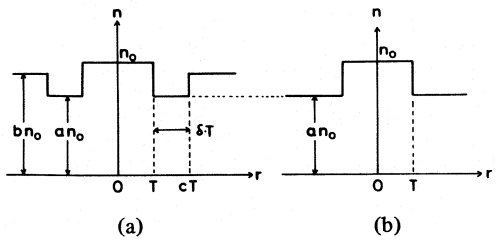

Fig. 2. Refractive index distribution of the following. (a) A *W*-type fiber. (b) The corresponding reference SC fiber. The reference SC fiber is obtained by letting $b = a$ in the *W*-type fiber.

the cladding. These characteristics have been predicted physically, and numerical solutions of the exact equations obtained are in excellent agreement with the prediction [2]. Though rigorous characteristic equations are derived in [2], they are very complicated. Numerical results are mainly presented concerning the propagating HE_{11} mode which is the lowest, and higher modes have not been investigated in detail. Numerical examples of general multimode doubly clad fibers have been reported [8].

This paper is intended to give a simple, though approximate, theory of a *W*-type fiber and to present formulas as a help for practical design work. The method of analysis is to regard a *W*-type fiber as a combined system of a reference SC fiber (the core and inner cladding) and a perturbing medium (the outer cladding) as shown in Fig. 2.

First, the characteristic equations are simplified for the case of weakly guiding fibers[1] and solved under the assumption of weak coupling: the latter approximation is valid when the inner cladding is sufficiently thick. Second, cutoff of each mode is approximately represented. Third, the attenuation constant of each mode below cutoff is derived through the perturbation theory. Finally, characteristics of each mode are treated in the frequency range above cutoff: the phase constant, group velocity, and power flow distribution among the three portions of the fiber are evaluated in a closed form.

[1]The words "weakly guiding" and "tightly confining" may sound contradictory. However, the former implies that the dielectric difference between the core and each surrounding medium is small, and the latter implies that a predominant portion of the electromagnetic power is confined within the core. Hence at a very high frequency, an optical fiber with a very small index difference is weakly guiding and tightly confining at the same time.

II. Derivation and Solution of the Characteristic Equations

The subject of this paper is a "*W*-type" optical fiber whose geometry and refractive index distribution are shown in Fig. 1. The core radius is denoted by T, and the thickness of the inner cladding is $\delta \cdot T$. The outer cladding is assumed to extend to infinity. All the three regions are assumed to be perfect insulators with the free-space permeability μ_0. Parameters a and b (see Fig. 1) are assumed to satisfy

$$1 > b > a. \tag{1}$$

The name of a *W*-type fiber comes from the shape of the index profile. In the following, we shall develop a theory of a weakly guiding *W*-type fiber: it is essential to assume

$$1 - b \ll 1, \quad 1 - a \ll 1. \tag{2}$$

At present, an index difference of the order of, or even significantly less than, 10^{-3} is common, and it is not difficult to have (2) satisfied. As in the case of an SC fiber [3], [4] the condition (2) makes the analysis much simpler. We further assume that

$$\delta \cdot T \gg \lambda/2\pi n_0 (b^2 - a^2)^{1/2} \tag{3}$$

where λ is the wavelength. This implies that the inner cladding should be "sufficiently" thick. The significance of the right-hand side will be clear later. The criterion (3) is, however, not rigorous. It should be replaced by (22) which requires $\hat{w}$ as a function of $\hat{v}$. In other words, the condition (3) is less rigorous but more convenient than (22). The two assumptions (weak guidance and sufficiently thick inner cladding) are fundamental ones of the following analysis.

We are interested in the electromagnetic field with the time and z dependence $\exp j(\omega t - \beta z)$. In order to have a guided mode, one must have

$$n_0 k_0 > \beta > b n_0 k_0 \tag{4}$$

where $k_0 = \omega(\epsilon_0 \mu_0)^{1/2}$. Guided modes are classified into hybrid modes (EH and HE modes), TE modes, and TM modes. First, we shall examine hybrid modes. It is assumed that the axial field components are expressed as

$$E_z = f(r) \cos n\theta \exp j(\omega t - \beta z) \tag{5}$$

$$H_z = \pm Y f(r) \sin n\theta \exp j(\omega t - \beta z) \tag{6}$$

where $Y = n_0(\epsilon_0/\mu_0)^{1/2}$ and $n \neq 0$. The hybrid modes are catalogued as HE_{nm} for the upper sign and EH_{nm} for the lower sign. Throughout this paper, when the double sign notation is used the upper sign is taken for the HE and the lower sign for EH modes [3], [5]. The radial function $f(r)$ is given by

$$f(r) = pJ_n(ur/T), \quad r < T$$

$$f(r) = qI_n(\hat{w}r/T) + sK_n(\hat{w}r/T), \qquad T < r < (\delta + 1)T$$
$$= hK_n(wr/T), \qquad T > (\delta + 1)T \tag{7}$$

where p, q, s, and h are constants to be determined. The quantities ju, $\hat{w}$, and w are normalized transverse propagation constants in the core, inner cladding, and outer cladding, respectively. They obey the relations

$$u^2 + \hat{w}^2 = (n_0k_0T)^2(1 - a^2) \equiv \hat{v}^2 \tag{8}$$

$$u^2 + w^2 = (n_0k_0T)^2(1 - b^2) \equiv v^2. \tag{9}$$

The quantities v and $\hat{v}$ are referred to as the normalized frequency of the W-type fiber and that of the reference SC fiber. When any one of u, $\hat{w}$, and w is known, the longitudinal phase constant β is given by

$$\beta^2 = (n_0k_0)^2 - (u/T)^2$$
$$= (an_0k_0)^2 + (\hat{w}/T)^2$$
$$= (bn_0k_0)^2 + (w/T)^2. \tag{10}$$

One can derive other field components from E_z and H_z using Maxwell's equations (see, for example, [2, (13)-(16)]). According to the assumption of weak guidance, $\epsilon(r)$ and β are approximated by $n_0^2\epsilon_0$ and n_0k_0 except where they appear in the combined form $\omega^2\epsilon\mu - \beta^2$. Equation (10) is used in the evaluation of $\omega^2\epsilon\mu - \beta^2$. Hence one obtains

$$\pm E_\theta = \mp H_r/Y = [jn_0k_0/(\omega^2\epsilon\mu - \beta^2)]$$
$$\cdot (f'(r) \pm nf(r)/r) \sin n\theta \exp j(\omega t - \beta z) \tag{11}$$

$$-E_r = -H_\theta/Y = [jn_0k_0/\omega^2\epsilon\mu - \beta^2)]$$
$$\cdot (f'(r) \pm nf(r)/r) \cos n\theta \exp j(\omega t - \beta z). \tag{12}$$

Using formulas of Bessel functions and modified Bessel functions, one can rewrite (11) and (12) as follows:

$$\begin{pmatrix} \pm E_\theta \\ -E_r \end{pmatrix} = \frac{1}{Y}\begin{pmatrix} \mp H_r \\ -H_\theta \end{pmatrix} = \begin{matrix} \sin n\theta \\ \cos n\theta \end{matrix} \exp j(\omega t - \beta z) \times \begin{cases} \pm(jn_0k_0T/u)pJ_{n\pm1}(ur/T), & r < T \\ (jn_0k_0T/\hat{w})(-qI_{n\mp1}(\hat{w}r/T) + sK_{n\mp1}(\hat{w}r/T)), & T < r < (\delta + 1)T \\ (jn_0k_0T/w) \cdot hK_{n\mp1}(wr/T), & r > (\delta + 1)T \end{cases} \tag{13}$$

where there are two choices, the upper ones go together and the lower ones go together. At dielectric discontinuities at $r = T$ or $r = (\delta + 1)T$, tangential field components must be continuous. One can easily represent p and h in terms of q and s from the continuity of E_z and H_z. Continuity of E_θ and H_θ leads to

$$\begin{bmatrix} K_n(\hat{w})\left(\frac{K_{n\mp1}}{\hat{w}K_n} \mp \frac{J_{n\mp1}}{uJ_n}\right) & I_n(\hat{w})\left(\frac{-I_{n\mp1}}{\hat{w}I_n} \mp \frac{J_{n\mp1}}{uJ_n}\right) \\ K_n(c\hat{w})\left(\frac{K_{n\mp1}}{c\hat{w}K_n} - \frac{K_{n\mp1}}{cwK_n}\right) & -I_n(c\hat{w})\left(\frac{I_{n\mp1}}{c\hat{w}I_n} + \frac{K_{n\mp1}}{cwK_n}\right) \end{bmatrix} \begin{pmatrix} s \\ q \end{pmatrix} = 0 \tag{14}$$

where $c = 1 + \delta$ and $K_{n\mp1}/c\hat{w}K_n$ is the abbreviation of $K_{n\mp1}(c\hat{w})/c\hat{w}K_n(c\hat{w})$, etc., throughout this paper. Existence of nontrivial solution to (14) leads to equating a second-order determinant to zero. Hence we have, for hybrid modes,

$$K_{n\mp1}/\hat{w}K_n \mp J_{n\mp1}/uJ_n = \frac{I_n(\hat{w})K_n(c\hat{w})}{K_n(\hat{w})I_n(c\hat{w})}$$
$$\cdot \left(\frac{I_{n\mp1}}{\hat{w}I_n} \pm \frac{J_{n\mp1}}{uJ_n}\right) \frac{K_{n\mp1}/c\hat{w}K_n - K_{n\mp1}/cwK_n}{I_{n\mp1}/c\hat{w}I_n + K_{n\mp1}/cwK_n}. \tag{15}$$

Simultaneous equations (8), (9), and (15) are the characteristic equations of a weakly guiding W-type fiber.

There are TE and TM mode families for $n = 0$, and the characteristic equation can be derived in a similar way. After some algebra, one finds that the TE_{0m} mode and TM_{0m} mode are degenerate. Their characteristic equations are the same as those of the HE_{2m} mode.

Similarly, there is some degeneracy relation between the HE and EH modes. We shall present the results without going into detail.

1) The $HE_{n+1,m}$ and $EH_{n-1,m}$ modes are degenerate for $n \geqq 2$.

2) The HE_{2m}, TE_{0m}, and TM_{0m} modes are degenerate.

Rigorously, the word "degenerate" used so far should be understood to imply "degenerate in the limit $a, b \to 1$." From the preceding degeneracy relations, we can concentrate on HE modes without loss of generality. We shall henceforth treat $HE_{n+1,m}$ mode ($n \geqq 0$). The characteristic equations for the $HE_{n+1,m}$ mode are listed again:

$$J_n/uJ_{n+1} - K_n/\hat{w}K_{n+1} = \frac{I_{n+1}(\hat{w})K_{n+1}(\hat{w})}{K_{n+1}(\hat{w})I_{n+1}(c\hat{w})}$$
$$\cdot \left(\frac{I_n}{\hat{w}I_{n+1}} + \frac{J_n}{uJ_{n+1}}\right) \frac{K_n/c\hat{w}K_{n+1} - K_n/cwK_{n+1}}{I_n/c\hat{w}I_{n+1} + K_n/cwK_{n+1}} \tag{16}$$

$$u^2 + \hat{w}^2 = (n_0k_0T)^2(1 - a^2) \equiv \hat{v}^2 \tag{17}$$

$$u^2 + w^2 = (n_0k_0T)^2(1 - b^2) \equiv v^2. \tag{18}$$

We shall hereafter denote by $F(u, \hat{w})$ and $\epsilon(u, \hat{w}, w)$ the left-hand side and right-hand side of (16), respectively.

We shall try to solve the preceding equations by regarding the W-type fiber as a combined system of the "reference SC fiber" surrounded by a perturbing outer medium. In Fig. 2 this interpretation is illustrated. This approach is justified when the following two conditions are satisfied.

1) The mode to be considered is above cutoff (i.e., propagating) along the reference SC fiber at the specified frequency.

2) The field strength at $r = (\delta + 1)T$ is much smaller than that at $r = T$.

When these two are satisfied, we proceed as follows: let the eigenvalue u and w of the reference SC fiber be denoted by U and $\hat{W}$. They are the solution of

$$J_n/UJ_{n+1} - K_n/\hat{W}K_{n+1} = 0 \tag{19}$$

$$U^2 + \hat{W}^2 = \hat{v}^2. \tag{20}$$

Equation (19) will be frequently utilized in the following analysis (e.g., in deriving (36), (40), (54), and (70)). These simultaneous equations are well known [3] and we assume that the eigenvalues U and $\hat{W}$ are already known. Substituting $u = U$ and $\hat{w} = \hat{W}$ into (17) and (18), one obtains

$$w^2 = \hat{W}^2(1 - b^2)/(1 - a^2) - U^2(b^2 - a^2)/(1 - a^2) \equiv W^2. \tag{21}$$

We look for the solution, close to U, $\hat{W}$, and W, of (16)-(18). The first factor $[I_{n+1}(\hat{w})K_{n+1}(c\hat{w})/I_{n+1}(c\hat{w})K_{n+1}(\hat{w})]$ in ϵ, given by (16), is of the order of $\exp(-2\delta\hat{W})$. From condition 2)

$$K_n((\delta + 1)\hat{W})/K_n(\hat{W}) \sim \exp(-\delta\hat{W}) \ll 1 \tag{22}$$

holds. Hence $\epsilon(u, \hat{w}, w)$ is very small. The solutions of (16)-(18) are expressed in the form

$$\begin{aligned} u &= U + \Delta u \\ \hat{w} &= \hat{W} + \Delta\hat{w} \\ w &= W + \Delta w. \end{aligned} \tag{23}$$

Substituting the preceding expressions into (16) and (17), and ignoring higher order terms, we obtain simultaneous linearized equations

$$\frac{d}{dU}\left(\frac{J_n}{UJ_{n+1}}\right)\Delta u - \frac{d}{d\hat{W}}\left(\frac{K_n}{\hat{W}K_{n+1}}\right)\Delta\hat{w} = \epsilon(U, \hat{W}, W) \tag{24}$$

$$U\Delta u + \hat{W}\Delta\hat{w} = 0. \tag{25}$$

Solving (24) and (25) for u, we have

$$U\Delta u = \frac{-\epsilon(U, \hat{W}, W)}{(1/U^2 + 1/\hat{W}^2)(1 - 2nK_n/\hat{W}K_{n+1})}. \tag{26}$$

Combining (10) and (26) leads to

$$\begin{aligned} \beta_0\Delta\beta &= -U\Delta u/T^2 \\ &= \frac{\epsilon(U, \hat{W}, W)/T^2}{(1/U^2 + 1/\hat{W}^2)(1 - 2nK_n/\hat{W}K_{n+1})} \end{aligned} \tag{27}$$

where $\beta_0^2 = (n_0k_0)^2 - (U/T)^2$. In (26) and (27), ϵ should be understood to represent

$$\epsilon = -\left(\frac{J_n}{UJ_{n+1}} + \frac{I_n}{\hat{W}I_{n+1}}\right)\frac{K_{n+1}(c\hat{W})I_{n+1}(\hat{W})}{K_{n+1}(\hat{W})I_{n+1}(c\hat{W})} \cdot \frac{K_n/c\hat{W}K_{n+1} - K_n/cWK_{n+1}}{I_n/c\hat{W}I_{n+1} + K_n/cWK_{n+1}}, \quad \text{for } W^2 > 0 \tag{28}$$

$$\epsilon = -\left(\frac{J_n}{UJ_{n+1}} + \frac{I_n}{\hat{W}I_{n+1}}\right)\frac{K_{n+1}(c\hat{W})I_{n+1}(\hat{W})}{K_{n+1}(\hat{W})I_{n+1}(c\hat{W})} \cdot \frac{K_n/c\hat{W}K_{n+1} - H_n^{(2)}/cBH_{n+1}^{(2)}}{I_n/c\hat{W}I_{n+1} + H_n^{(2)}/cBH_{n+1}^{(2)}}, \quad \text{for } W^2 = -B^2 < 0. \tag{29}$$

The nature of the solution depends on whether W^2 is positive or negative. When $W^2 > 0$, β_0 and $\Delta\beta$ are real, and one obtains a guided mode with the phase constant only slightly different from that of the reference SC fiber. When $W^2 < 0$, we have $\beta < bn_0k_0$ from (10). The perturbed mode has a larger phase velocity than the plane wave velocity in the outer medium and the mode loses its power in the form of radiation. Mathematically, $\Delta\beta$ becomes complex due to the presence of a Hankel function in (29). The perturbed mode is no longer a guided mode but a leaky wave which decays off exponentially as it propagates along the fiber.

III. Cutoff Characteristics

According to the results of Section II, the (first) approximation of the cutoff frequency $\hat{v}_{c1}$ is determined by the condition

$$F(U, \hat{W}) = 0 \tag{30}$$

$$U^2 + \hat{W}^2 = \hat{v}_{c1}^2 \tag{31}$$

and

$$U = v_{c1} = \hat{v}_{c1}[(1 - b^2)/(1 - a^2)]^{1/2} \tag{32}$$

which is equivalent to $W = 0$.

We shall examine the criterion of (3) for $\delta \cdot T$ being sufficiently large. Inequality (3) is equivalent to require that $\delta\hat{w} \gg 1$ at the first-order cutoff frequency: (8), (31), and (32) lead to (3).

Suppose that the simultaneous equations (19) and (20) are solved for U, and U is plotted versus $\hat{v}$ for each mode as in Fig. 3. The crossing of the $u - \hat{v}$ curve with the straight line $u = v$ corresponds to $\hat{v}_{c1}$. The portion between the $\hat{v}$ axis and

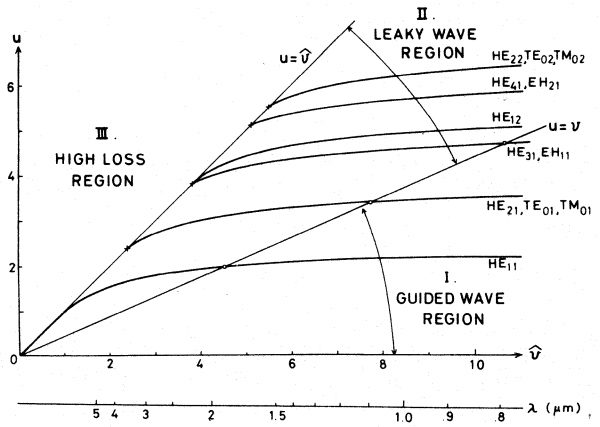

Fig. 3. Diagram indicating three regions of propagation. Each curve represents $u - \hat{v}$ characteristic of the specified mode of the reference SC fiber. In the W-type fiber, a specified mode is a guided mode in region I and leaky mode in region II. Region III is considered to be a high-loss region. A small circle on each curve denotes cutoff of the W-type fiber while a cross represents cutoff of the reference SC fiber.

the straight line $u = v$ corresponds to the guided wave region. In the portion between two straight lines $u = \hat{v}$ and $u = v$, each mode becomes a leaky wave. In the remaining part, namely between the u axis and the line $u = \hat{v}$, no mode propagates along the reference SC fiber and the perturbation theory is not applicable. An essentially the same situation is experienced in the analysis of a W-type slab waveguide. According to [6], this frequency region (denoted as region III in Fig. 3) corresponds to either a high-loss leaky mode or any low-loss improper mode which, however, it is not possible to excite efficiently.

The actual cutoff frequency of a W-type fiber is dependent on the value of δ. First-order cutoff defined by (30)-(32) does not, however, involve δ. To be more accurate, it is necessary to derive a second-order approximation for cutoff. Let us assume that we have the solution of the first-order cutoff conditions (30)-(32). The second-order cutoff frequency is denoted by $\hat{v}_{c2}$. The eigenvalues u and $\hat{w}$ for $\hat{v} = \hat{v}_{c2}$ are denoted by $U + \delta u$, $\hat{W} + \delta\hat{w}$. We have, from (16)-(18),

$$F(U + \delta u, \hat{W} + \delta\hat{w}) = \epsilon(U + \delta u, \hat{W} + \delta\hat{w}, W) \simeq \epsilon(U, \hat{W}, 0) \tag{33}$$

$$(U + \delta u)^2 + (\hat{W} + \delta\hat{w})^2 = \hat{v}_{c2}^2 \tag{34}$$

$$\delta u/U = \delta\hat{w}/\hat{W}. \tag{35}$$

The last equation results from

$$U + \delta u = [(1 - b^2)/(1 - a^2)]^{1/2}\hat{v}_{c2}.$$

Solving (33)-(35) for $\hat{v}_{c2}$, we have

$$\hat{v}_{c2} - \hat{v}_{c1} = (\hat{v}_{c1} \cdot \epsilon)/[U(\partial F/\partial U) + \hat{W}(\partial F/\partial\hat{W})] = -\frac{K_{n+1}(c\hat{W})I_{n+1}(\hat{W})}{K_{n+1}(\hat{W})I_{n+1}(c\hat{W})} \cdot \frac{(J_n/UJ_{n+1} + I_n/\hat{W}I_{n+1})\hat{v}_{c1}}{[(J_n(U)/J_{n+1}(U))^2 + (K_n(\hat{W})/K_{n+1}(\hat{W}))^2]}. \tag{36}$$

Example 1: We shall present a numerical example of a W-type fiber. In this example as well as throughout later examples, it is assumed that $a = 0.99821$, $b = 0.99966$, $n_0 = 1.5$, and $T = 15$ μm. However, the parameter δ is not fixed. In Fig. 3, the straight line $u = v = [(1 - b^2)/(1 - a^2)]^{1/2} \cdot \hat{v}$ is drawn for the case $a = 0.99821$, $b = 0.99966$. The first-order and second-order cutoff frequencies for the HE_{11} mode are

$$\hat{v}_{c1} = 4.4794 \tag{37}$$

$$\hat{v}_{c2} = 4.4411, \quad \text{for} \quad \delta = 0.5. \tag{38}$$

A computer program has been written by which the eigenvalue u of the exact equations for each mode is obtained when w is given [2]. It is found that the program operates normally when $w \geqq 10^{-4}$ but numerical errors begin to be observed when $w \leqq 10^{-5}$. We have determined cutoff (the value of u corresponding to $w = 0$) by the extrapolation procedure to be described in Section V as

$$\hat{v}_c = 4.4412 \tag{39}$$

with which (38) is in good agreement.

Let us consider the number of guided modes in a multimode W-type fiber, and assume that a number of modes propagate in the fiber. Roughly, a specified mode is above or below cutoff when v, defined by (9), is larger or smaller u_∞, where u_∞ represents the eigenvalue u in the limit $\hat{v} \to \infty$. Hence the number of guided modes mainly depends on b through the relation (9) but the number is not very sensitive to a. In other words, the number of guided modes depends mainly on the core and outer cladding while characteristics of guided modes are mainly determined by the core and inner cladding.

IV. Attenuation Constant of a Leaky Mode

The first-order attenuation constant of a leaky $HE_{n+1,m}$ mode is given by (-1) times the imaginary part of $\beta_0 + \Delta\beta$. By assumption β_0 is real, and we have, from (27)

$$\alpha = -\mathrm{Im}(\Delta\beta) = -\mathrm{Im}\left\{\frac{1}{\beta_0 T^2}\frac{\epsilon(U, \hat{W}, W)}{(1/U^2 + 1/\hat{W}^2)(1 - 2nK_n/\hat{W}K_{n+1})}\right\} \tag{40}$$

where ϵ is given by (29). When $\hat{W}$ and $B \gg 1$, we have

$$\alpha \sim \frac{1}{\beta_0 T^2}\frac{(2/\hat{W})\exp(-2\delta\hat{W})}{(1/U^2 + 1/\hat{W}^2)}\frac{2\hat{W}B}{\hat{W}^2 + B^2}. \tag{41}$$

The attenuation constant depends on the frequency and mode number. Consider a specified mode. As there is a guided mode when $\hat{v} > \hat{v}_{c1}$, the attenuation constant approaches zero as $\hat{v} \to \hat{v}_{c1} - 0$. Except very close to $\hat{v}_{c1}$ and the cutoff of the reference SC fiber, the dominant factor in (40) [where ϵ is given by (29)] is

$$I_{n+1}(\hat{W})K_{n+1}(c\hat{W})/I_{n+1}(c\hat{W})K_{n+1}(\hat{W}) \sim \exp(-2\delta\hat{W}).$$

Except close to the cutoff of the reference SC fiber, one obtains, roughly,

$$\hat{W} = (\hat{v}^2 - U^2)^{1/2} \sim \hat{v} - U^2/2\hat{v} \sim \hat{v} - u_\infty^2/2\hat{v} \tag{42}$$

where u_∞ is the mth zero of $J_n(u)$ for the $HE_{n+1,m}$ mode. Therefore, $\log \alpha$ is approximated by a linear expression with reference to $\hat{v}$ for the most part of region II in Fig. 3.

Example 2: The attenuation constants of a few lowest order modes in region II were calculated for parameters shown earlier, and plotted in Fig. 4. First, attenuation constants of a few modes for $\delta = 0.5$ ($\delta \cdot T = 7.5$ μm) are drawn in solid curves. The dashed ones correspond to $\delta = 0.9$ ($\delta \cdot T = 13.5$ μm). The leaky wave for $\delta = 0.9$ decays much more rapidly than that of the corresponding mode for $\delta = 0.5$. For example, at $v = 10$, the value of α for the HE_{31} mode is 3×10^{-4} dB/m for $\delta = 0.9$ and 3×10^{-1} dB/m for $\delta = 0.5$.

In the vicinity of cutoff of the reference SC fiber, the attenuation constant α becomes small when HE_{1m}, HE_{2m}, TE_{0m},

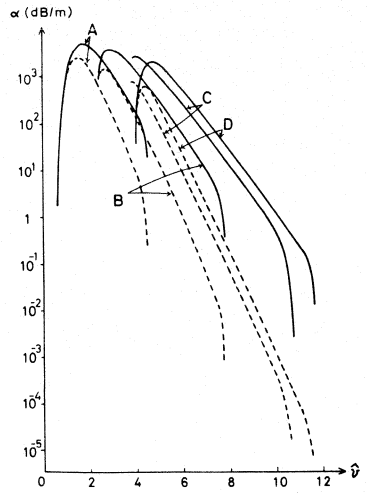

Fig. 4. Attenuation constant of each mode in the leaky wave region. Waveguide parameters are indicated in example 1. Solid lines are drawn for $\delta = 0.5$ and dashed ones for $\delta = 0.9$. Letters A, B, C, and D indicate HE_{11}, $HE_{21} + TE_{01} + TM_{01}$, $HE_{31} + EH_{11}$, and HE_{12}, respectively.

and TM_{0m} modes are considered. One can explain this behavior by considering the asymptotic form of the factor $(1 - 2nK_n/\hat{W}K_{n+1})$ in (40): when $\hat{W} \ll 1$, one obtains

$$1 - \frac{2nK_n}{\hat{W}K_{n+1}} = \begin{cases} 1, & n = 0 \\ -(\hat{W}^2/4)\ln(1.781\,\hat{W}/2), & n = 1 \\ \hat{W}^2/4n(n-1), & n \geqq 2. \end{cases} \quad (43)$$

Nevertheless, as stated earlier, the actual attenuation does not obey the first-order perturbation theory when $\hat{W}$ is small.

V. Group Velocity and Power Flow Distribution of a Propagating Mode

The phase constant of a propagating mode along a W-type fiber is given by (10) given any of the eigenvalues u, $\hat{w}$, and w. Usually, we have $\Delta\beta \ll \beta_0$. Above the cutoff frequency, the phase constant and field pattern are very close to those of the reference SC fiber. One must, however, examine the dependence of the phase constant on $\hat{v}$ at very close to the cutoff because in this region a large portion of the electromagnetic power of a certain mode is carried in the outer cladding.

A. Dispersion Relation Near the Cutoff Frequency

When we investigate the behavior of u, $\hat{w}$, and w at slightly higher than the cutoff frequency, we must use (15) instead of (26) because the presence of the outer cladding would significantly change the electromagnetic field of a certain mode. At the cutoff frequency $\hat{v}_c$ of the $HE_{n+1,m}$ mode, one obtains

$$F(u, \hat{w}) = \epsilon(u, \hat{w}, 0) \quad (44)$$

$$u^2 + \hat{w}^2 = \hat{v}_c^2 \quad (45)$$

$$u = [(1 - b^2)/(1 - a^2)]^{1/2}\,\hat{v}_c. \quad (46)$$

We shall obtain approximate functional dependence of w on $\Delta\hat{v} = \hat{v} - \hat{v}_c$. Let the value of eigenvalues be denoted by $u + \Delta u$, $\hat{w} + \Delta\hat{w}$, w at $v = v_c + \Delta\hat{v}$. We have

$$F(u + \Delta u, \hat{w} + \Delta\hat{w}) = \epsilon(u + \Delta u, \hat{w} + \Delta\hat{w}, w). \quad (47)$$

Subtracting (44) from (47), and ignoring higher order terms, we arrive at

$$\left(\frac{\partial F}{\partial u} - \frac{\partial \epsilon}{\partial u}\right)\Delta u + \left(\frac{\partial F}{\partial \hat{w}} - \frac{\partial \epsilon}{\partial \hat{w}}\right)\Delta\hat{w} = \epsilon(u, \hat{w}, w) - \epsilon(u, \hat{w}, 0). \quad (48)$$

We must adopt the difference expression in the right-hand side of (48) since in some cases $\partial\epsilon/\partial w$ does not exist in the limit $w \to 0$. We can approximate the left-hand side by $(\partial F/\partial u)\Delta u + (\partial F/\partial\hat{w})\Delta\hat{w}$ since $\epsilon/F = 0(\exp(-2\delta\hat{w}))$. We have, after some algebra,

$$(\partial F/\partial u)\Delta u + (\partial F/\partial\hat{w})\Delta\hat{w} = \left(\frac{J_n}{uJ_{n+1}} + \frac{I_n}{\hat{w}I_{n+1}}\right)\left(\frac{K_n}{c\hat{w}K_{n+1}} + \frac{I_n}{c\hat{w}I_n}\right)\frac{K_{n+1}(c\hat{w})I_{n+1}(\hat{w})}{K_{n+1}(\hat{w})I_{n+1}(c\hat{w})}$$
$$\times \begin{cases} 1/\ln(1.781\,cw/2), & n = 0 \\ (c^2w^2/4)\ln(1.781\,cw/2)/(1/2 + I_1/c\hat{w}I_2)^2, & n = 1 \\ -c^2w^2/[8n^2(n-1)(1/2n + I_n/c\hat{w}I_{n+1})^2], & n \geqq 2. \end{cases} \quad (49)$$

Similarly, we have

$$u\Delta u + \hat{w}\Delta\hat{w} = \hat{v}_c\Delta\hat{v} \quad (50)$$

$$2u\Delta u + w^2 = 2[(1 - b^2)/(1 - a^2)]\,\hat{v}_c\Delta\hat{v}. \quad (51)$$

The task is to solve simultaneous equations (49)–(51). When $n = 0$ or $n = 1$, we can show that $w^2/\Delta u$ and $w^2/\Delta\hat{w}$ approach zero in the limit $\Delta\hat{v} \to 0$. One obtains, then,

$$\Delta u = [(1 - b^2)/(1 - a^2)]^{1/2}\,\Delta\hat{v} \quad (52)$$

$$\Delta\hat{w} = [(b^2 - a^2)/(1 - a^2)]^{1/2}\,\Delta\hat{v} \quad (53)$$

from (50) and (51). Substituting these two into (49), one obtains

$$\ln\frac{1.781\,cw}{2} = -\frac{\hat{v}_c\left(\frac{J_0}{uJ_1} + \frac{K_0}{\hat{w}K_1}\right)\left(\frac{K_0}{c\hat{w}K_1} + \frac{I_0}{c\hat{w}I_1}\right)\frac{K_1(c\hat{w})I_1(\hat{w})}{K_1(\hat{w})I_1(c\hat{w})}}{\Delta\hat{v}\,[(J_0(u)/J_1(u))^2 + (K_0(\hat{w})/K_1(\hat{w}))^2]},$$

for $n = 0$

$$c^2w^2 \ln\frac{1.781\,cw}{2} - \left(1+\frac{2I_1}{c\hat{w}I_2}\right)^2 [(J_1(u)/J_2(u))^2 + (K_1(\hat{w})/K_2(\hat{w}))^2] = \frac{\left(\frac{J_1}{uJ_2}+\frac{K_1}{\hat{w}K_2}\right)\left(\frac{K_1}{c\hat{w}K_2}+\frac{I_1}{c\hat{w}I_2}\right)\frac{K_2(c\hat{w})I_2(\hat{w})}{K_2(\hat{w})I_2(c\hat{w})}}{\cdot\frac{\Delta\hat{v}}{\hat{v}_c}}, \quad \text{for } n=1. \tag{54}$$

When $n \geqq 2$, the expression (49) shows that the right-hand side of (49) is of the order w^2 in the limit $w \to 0$ and there is no singularity. We can accordingly ignore it since it is proportional to $\exp(-2\delta\hat{w})$. In other words, when $n \geqq 2$, the dependence of u and $\hat{w}$ on $\hat{v}$ is approximately the same as that of the reference SC fiber.

Example 3: The same parameters are assumed: $a = 0.99821$, $b = 0.99966$, $n_0 = 1.5$, and $T = 15$ μm. We further assume that $\delta = 0.5$. We wish to compare the approximation of (54) with the numerical solution of the exact equation. To calculate the right-hand side of (54), we substitute for u and $\hat{w}$ the first-order eigenvalues, given by (19) and (20), and obtain

$$w = (2/1.5 \times 1.781)\exp(-0.01276/\Delta\hat{v}). \tag{55}$$

Using the previously mentioned computer program, we calculated $\hat{v}$ versus w, where the minimum value of w is 10^{-4} as previously noted. Although explicit numerical evaluation of $\hat{v}_c$ is not feasible, it is expected from (54) and (55) that $1/\log(1.781\,cw/2)$ is approximated by a linear function of $\hat{v}$ for $w \to 0$. In Fig. 5, $1/\log(1.781 \times 1.5\,w/2) = 1/\log(1.3363\,w)$ is plotted versus $\hat{v}$. The straight line drawn in the figure has the tangent predicted by (55), and we find that (55) is a good approximation if Δv is appropriately redefined as $\Delta v = \hat{v} - \hat{v}_c$.

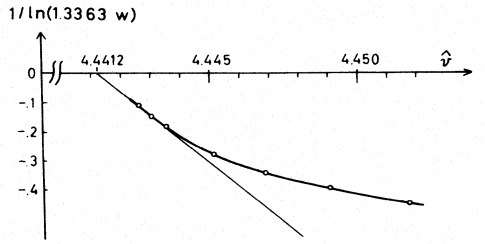

Fig. 5. Behavior of the eigenvalue w for the HE_{11} mode in the region close to the cutoff frequency. It should be observed that the quantity $1/\log(1.781\,cw/2)$ lies on a straight line when $w \to 0$. The cutoff frequency, obtained by extrapolation, is $v = 4.4412$. Small circles indicate sample points used.

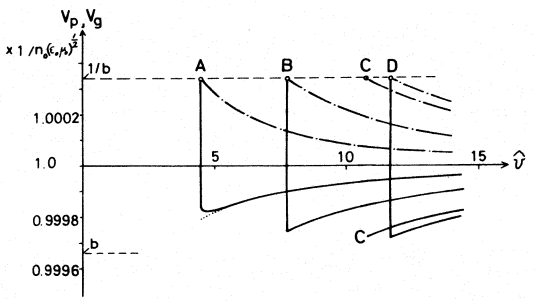

Fig. 6. Frequency dependence of the phase and group velocities of a few lowest modes. Letters A, B, C, and D represent HE_{11}, $HE_{21} + TE_{01} + TM_{01}$, $HE_{31} + EH_{11}$, and HE_{12}, respectively. The dotted-broken curves denote the phase velocities. The assumed parameters are: $a = 0.99821$, $b = 0.99966$, and $\delta = 0.5$. The dotted line is the plot of (57) for the HE_{11} mode. For other modes numerical solutions are in excellent agreement with (57).

B. Frequency Dependence of the Group Velocity

The frequency and mode number dependence of the group velocity plays an important role in the analysis of delay distortion. A general theory of a dielectric waveguide predicts, when applied to the analysis of a W-type fiber, that

$$\frac{1}{v_p v_g} = \frac{1}{n_0^2\epsilon_0\mu_0}\cdot\frac{P_{\text{core}} + a^2P_{ic} + b^2P_{oc}}{P_{\text{core}} + P_{ic} + P_{oc}} \tag{56}$$

where P_{core}, P_{ic}, and P_{oc} denote the power flow in the core, the inner cladding and in the outer cladding, respectively [7]. The phase and group velocities are denoted by v_p and v_g, respectively. The quantity v_p is equal to $1/bn_0(\epsilon_0\mu_0)^{1/2}$ at cutoff and decreases monotonically when the frequency increases. At $\omega = \infty$, v_p is equal to $1/n_0(\epsilon_0\mu_0)^{1/2}$. When any one of the HE_{1m}, HE_{2m}, TE_{0m}, and TM_{0m} modes is considered, nearly all the power flows in the outer cladding at very close to cutoff, and when the frequency becomes higher, the most part of power flows in the core. Using relation (56), one can predict the dependence of v_g of each mode on the frequency. The group velocity is equal to $1/bn_0(\epsilon_0\mu_0)^{1/2}$ at cutoff when any one of the HE_{1m}, HE_{2m}, TE_{0m}, and TM_{0m} modes is considered. Fig. 6 shows typical variation of v_g of each mode with the frequency. Note that

$$v_p = v_g = 1/bn_0(\epsilon_0\mu_0)^{1/2}$$

at cutoff for each of the HE_{11}, HE_{21}, TE_{01}, TM_{01}, and HE_{12} modes, and $v_g < 1/n_0(\epsilon_0\mu_0)^{1/2}$ at cutoff of the HE_{31} and EH_{11} modes. Far from cutoff, the group velocity of a mode along a W-type fiber is approximated by that of the reference SC fiber. In other words, one obtains

$$v_g n_0(\epsilon_0\mu_0)^{1/2} = 1 + (1 - 1/v_p^2)\cdot(1/2 - K_{n+1}(\hat{w})K_{n-1}(\hat{w})/K_n^2(w)) \tag{57}$$

for the $HE_{n+1,m}$ mode [3]. In order to analyze the rapid change of v_g, one should utilize (10) and (54). From (10) and (17), one derives

$$(\beta T)^2 = b^2\hat{v}^2/(1-a^2) + w^2 \tag{58}$$

and, after some algebra, one also obtains

$$\frac{1}{v_g} = n_0[(1-a^2)\epsilon_0\mu_0]^{1/2}\cdot\frac{b^2/(1-a^2) + (w/\hat{v})(dw/d\hat{v})}{[b^2/(1-a^2) + (w/\hat{v})^2]^{1/2}} \tag{59a}$$

$$\sim n_0(\epsilon_0\mu_0)^{1/2}b\{1 + (1-a^2)\cdot[(w/\hat{v})\,dw/d\hat{v} - (w/\hat{v})^2/2]/b^2\}. \tag{59b}$$

Combining (54) with (59a) or (59b), one obtains expressions for the group velocity of the HE_{1m} or HE_{2m} mode. For the HE_{11} mode, we may express (55) and (59a) in the form

$$w = A \exp(-B/\Delta\hat{v})$$

$$1/v_g \sim n_0(\epsilon_0\mu_0)^{1/2} b \{1 + [(1 - a^2)/b^2](A^2/\hat{v}_c) \cdot (B/\Delta\hat{v}^2 - 1/2\hat{v}_c) e^{-2B/\Delta\hat{v}}\}. \quad (60)$$

Example 4: The same parameters a, b, n_0, and T are assumed. The frequency response of the group velocity of the HE_{11} mode close to cutoff is plotted in Fig. 7(a). The dashed line shows the result of approximation (60) and the solid curve is based on the computer solutions of the exact equation. Observe that the two solutions are in good agreement when $\Delta\hat{v} < 3 \times 10^{-3}$.

In a multimode waveguide, a distortion of the signal is caused by the difference between the group delay of the fastest mode and that of the slowest mode. In the vicinity of cutoff of some higher mode (say the HE_{12} mode, see Fig. 6), the difference is large. It is advantageous not to use these frequency regions in order to have a low distortion. The same problem is known to exist also in the case of an SC fiber [4]. Comparing Fig. 6 with Fig. 4 of [4], one finds that the widths of the frequency regions to be avoided are much narrower when a *W*-type fiber is adopted. The widths have been found to be of the order $\Delta\hat{v} \lesssim \exp(-2\delta\hat{w})$ for the HE_{1m} mode and $\Delta\hat{v} \sim 1/\exp(\exp(2\delta\hat{w}))$ for the HE_{2m}, TE_{0m}, and TM_{0m} modes.

C. Power Flow Distribution Among the Three Portions

Usually, the most part of electromagnetic power is carried in the core. In the vicinity of cutoff, however, confinement becomes weaker. It is known [3] that, concerning an SC fiber, all the power is carried in the cladding at cutoff when the HE_{1m}, HE_{2m}, TE_{0m}, or TM_{0m} mode is considered. However, at cutoff of the $HE_{n+1,m}$ or $EH_{n-1,m}$ mode ($n \geqq 2$), $1/n$ times the total power of the mode is carried in the cladding. Likewise, in the case of a *W*-type fiber, at cutoff all the power is carried in the outer cladding when any one of the HE_{1m}, HE_{2m}, TE_{0m}, and TM_{0m} modes is considered. On the other hand, much less power than $1/n$ times the total power is carried in the outer cladding at cutoff of the $HE_{n+1,m}$ or $EH_{n-1,m}$ mode ($n \geqq 2$) due to the large transverse attenuation across the inner cladding. In this subsection, we shall derive closed form approximations of the power flow distribution. The electromagnetic power in the core, inner cladding, and outer cladding are, respectively, proportional to [see (7) and (13)]

$$P_{\text{core}} = (p/u)^2 \int_0^T J_n^2(ur/T)\, r\, dr \quad (61)$$

$$P_{ic} = (1/\hat{w})^2 \cdot \int_T^{cT} [qI_n(\hat{w}r/T) - sK_n(\hat{w}r/T)]^2\, r\, dr \quad (62)$$

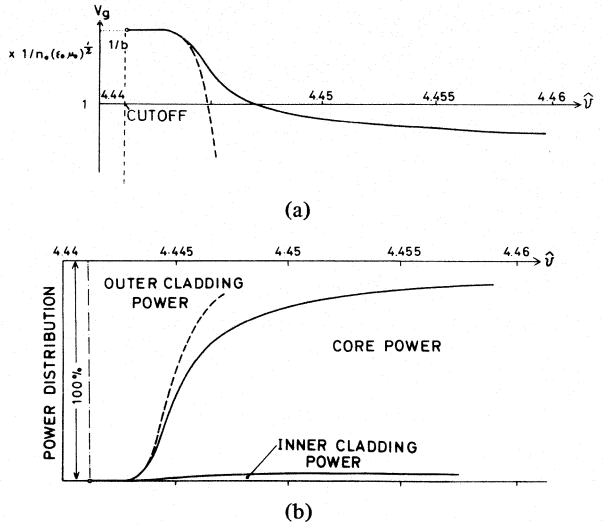

Fig. 7. (a) Frequency dependence of the group velocity of the HE_{11} mode near cutoff. (b) Power flow distribution among the core and the two claddings. In both figures solid curves and dashed lines correspond to computer solutions and closed form approximations based on (55), (59), (67)–(69).

$$P_{oc} = (h/w)^2 \int_{cT}^{\infty} K_n^2(wr/T)\, r\, dr \quad (63)$$

where the parameters p, q, s, and h satisfy

$$pJ_{n+1}(u) = qI_{n+1}(\hat{w}) + sK_{n+1}(\hat{w}) \quad (64)$$

$$hK_{n+1}(cw) = qI_{n+1}(\hat{w}) + sK_{n+1}(c\hat{w}) \quad (65)$$

$$sK_{n+1}(c\hat{w})\left(\frac{K_n}{c\hat{w}K_{n+1}} - \frac{K_n}{cwK_{n+1}}\right) = qI_{n+1}(c\hat{w})\left(\frac{I_n}{c\hat{w}I_{n+1}} - \frac{K_n}{cwK_{n+1}}\right). \quad (66)$$

Integrating (61)–(63), and ignoring insignificant terms of the order of $\exp(-2\delta\hat{w})$ with respect to unity, and eliminating a constant of proportionality, one arrives at

$$P_{\text{core}} \propto K_n^2(\hat{w})(J_n^2(u) - J_{n+1}(u)J_{n-1}(u)) \quad (67)$$

$$P_{ic} \propto K_n^2(\hat{w})(\xi_n(\hat{w}) - 1) - c^2K_n^2(c\hat{w})(\xi_n(c\hat{w}) - 1) \quad (68)$$

$$P_{oc} \propto c^2K_n^2(c\hat{w})(\xi_n(cw) - 1) \times \left[1 + \frac{I_n(c\hat{w})K_{n+1}(c\hat{w})}{I_{n+1}(c\hat{w})K_n(c\hat{w})} \cdot \frac{K_n/cwK_{n+1} - K_n/c\hat{w}K_{n+1}}{I_n/c\hat{w}I_{n+1} + K_n/cwK_{n+1}}\right]^2 \quad (69)$$

where $\xi_n(x)$ denotes $K_{n+1}(x)K_{n-1}(x)/K_n^2(x)$. P_{oc} should not be ignored near cutoff ($w \to 0$) when $n = 0$ or $n = 1$ because then $P_{oc} \to \infty$ in the limit $w \to 0$. For $n \geqq 2$, P_{oc} is of the order $\exp(-2\delta\hat{w})$ even at cutoff and can be ignored. Strictly, the second term in the right-hand side of (68) had better be omitted since it is of the order $\exp(-2\delta\hat{w})$ with respect to the first. However, we have retained the term in order to have exact formulas in the special case of $a = b$ and hence $w = \hat{w}$.

Far from cutoff ($w \gtrsim 1$), P_{oc} can be ignored when

$$\exp(-2\delta\hat{w}) \ll 1.$$

The fractional power in the core is given by

$$P_{\text{core}}/(P_{\text{core}} + P_{ic}) = (u/\hat{v})^2 [(\hat{w}/\hat{v})^2 + 1/\xi_n(\hat{w})] \quad (70a)$$

$$\sim 1 - u^2/\hat{v}^3 \quad (70b)$$

the last equation is valid when $\hat{v} \gg u$ and $\hat{w} \gg 1$.

Example 5: We assume the same parameters as before. In Fig. 7(b) are plotted the normalized power distribution near cutoff of the HE_{11} mode. Observe that the tendency of curves in Fig. 7(a) and 7(b) obeys the prediction of (56).

VI. Conclusion

A simple approximate method has been developed which is intended to analyze a *W*-type fiber. The method is based on the assumption of weak guidance and that of weak coupling between the outer cladding and the reference SC fiber.

The theory has been applied to the analysis of two remarkable properties of a *W*-type fiber: leaky mode characteristics below cutoff and the group velocity and power flow distribution anomalies at only slightly above cutoff. It is expected that the theory would be helpful in practical design work and in many cases the theory would eliminate the need for numerical solution of the exact equations.

High-Speed Electrooptic Waveguide Grating Modulator Using Epitaxial ZnO

JACOB M. HAMMER, SENIOR MEMBER, IEEE, D. J. CHANNIN, MICHAEL T. DUFFY, AND CLYDE C. NEIL

Abstract—**The results of a detailed study of electrooptic waveguide grating modulators are presented. Using low-loss epitaxial ZnO on sapphire waveguides with deposited interdigital electrodes diffraction percentages up to 80 percent at 80 V with rise times below 3 ns are observed. Capacitive power requirements on the order of 4 mW/MHz are predicted.**

A theoretical description which includes carrier and piezoelectric effects is given and is shown to be adequate for designing this type of modulator.

The grating waveguide modulator spatially separates the diffracted from the main beam and thus can be used for switching. In addition, the spatial separation allows a number of these to be cascaded on a common waveguide. These features make it probable that grating modulators will find a variety of uses in integrated optics.

Manuscript received September 9, 1974; revised November 21, 1974. This research was jointly sponsored by the Air Force Avionics Laboratory, Wright-Patterson AFB; the Office of Naval Research, Arlington, Va.; and the RCA Laboratories, Princeton, N.J.

The authors are with the RCA Laboratories, Princeton, N.J. 08540.

I. Introduction

In recent years, interest in the development of optical waveguides has been high. Optical waveguides have proved capable of being used to perform a variety of light-control functions analogous to those performed on electrons by integrated circuits. The advent of low-loss fiber optics as a promising transmission medium for light has heightened this interest.

Thus, in addition to the many papers on passive optical waveguides, there have been papers on switching [1], modulation [2], [10], [12], generation [3], frequency conversion [4], deflection [5], and electrically controlled guidance of light propagating in various optical waveguides [6]. In particular, bulk electrooptic grating modulators [2], [7], a Kerr liquid waveguide grating modulator [8], and an acoustooptic grating modulator have been reported earlier [5].

The electrooptic grating waveguide modulator described in

this report has the advantage of spatially separating the diffracted beam from the main beam and thus does not require a separate analyzer or strict control of the waveguide propagation characteristics as is required by the polarization and cutoff types of waveguide modulators [1], [9]. Also, because of the spatial separation, a number of grating modulators can be included on a single waveguide so that the output of one modulator can be used as the input to a second modulator. Thus it becomes possible to perform a variety of logic and switching functions on a single waveguide. The spatial separation also aids in obtaining high extinction ratios in the diffracted beam. Finally, our modulators are capable of extremely high-frequency response. As a result, the waveguide grating modulator promises to find a wide variety of uses in the field of integrated optics. A preliminary report on this work is given in [10]. Details of the growth and excellent waveguide properties of the single-crystal ZnO on Al_2O_3 films used in these experiments are described elsewhere [11]. The ZnO is grown by vapor phase deposition on $(01\bar{1}2)$-oriented Al_2O_3 so that the hexagonal c axis of the ZnO lies in the plane of the film. Waveguide losses, measured using a fiber-optic probe technique [11] below 1 dB/cm are observed in samples used for modulators. The as-grown single-crystal films are n-type with resistivities on the order of 1 $\Omega \cdot$ cm. These are polished after growth and Li compensated to resistivities greater than 10^5 $\Omega \cdot$ cm. The ZnO surface is then passivated by vapor depositing a 1000-Å-thick amorphous layer of Al_2O_3 which prevents long-term changes in surface resistivity.

An electrooptic waveguide grating modulator is based on the formation of an electrically induced phase diffraction grating in the guiding plane of an optical waveguide. For this purpose, the guide is made from material which exhibits the linear electrooptic (Pockels) effect.

Consider Fig. 1 in which interdigital metal electrodes are shown deposited on the surface of a transparent insulating layer (overlay) of amorphous Al_2O_3 on top of a single-crystal ZnO waveguide that has been epitaxially grown on a sapphire (Al_2O_3) substrate. When a voltage is applied between the interleaved fingers, electric fields fringe into the waveguide region. These fields vary periodically in the z direction.

The application of an electric field to a crystal such as ZnO, which exhibits the linear electrooptic effect, produces a change in index of refraction which is linearly proportional to the field and depends on the crystal orientation and light-polarization direction. In the particular case shown, an electric field parallel to the c-axis of the ZnO will change the index of refraction for either z- or y-polarized light traveling in the x direction.

Thus the z-component of the periodic electric field produced when a voltage is applied to the electrodes causes a periodic variation in index of refraction for light traveling as shown in the waveguide. The periodic index change acts as a diffraction grating and will cause some of the light to be diffracted through some angle in the waveguide plane.

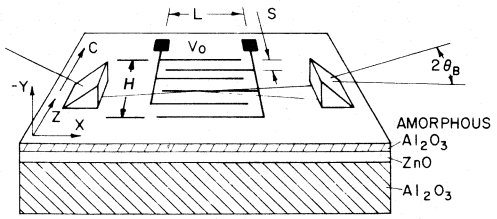

Fig. 1. Schematic diagram of electrooptic waveguide grating modulator.

II. Theory of Operation

In this section, theoretical relations which may be used to estimate the operating characteristics of the deflector modulator will be presented. We will first characterize the electrooptic effect in ZnO and give the relation between the electric field and the index of refraction. We then describe the rudiments of the operation of a thick (Bragg) periodic phase grating, relating the angles through which light is diffracted to the periodicity and relating the amount of light diffracted to the electrooptic index change. To make a quantitative estimate of the diffracted intensity, Engan's calculation of the fields produced by the electrodes is used. We then estimate power requirements. Finally, we consider some effects due to finite conductivity and piezoelectricity that may reduce the efficiency of the modulator.

A. Pockels Effect in ZnO

ZnO has 6-mm symmetry which implies that the electrooptic tensor has two important components, r_{13} and r_{33}. The subscripts 1, 2, and 3 are identified with the rectangular coordinates x, y, and z when z is taken parallel to the optic or c axis of the crystal. The following relations are obtained for the electrooptically induced index of refraction changes:

$$\Delta n_1 = -1/2\, r_{13} n_1^3 E_z$$
$$\Delta n_2 = -1/2\, r_{13} n_2^3 E_z$$
$$\Delta n_3 = -1/2\, r_{33} n_3^3 E_z \tag{1}$$

where n_1 and Δn_1 are the index and change in index, respectively, for x-polarized light traveling in the z or y direction; n_2 and Δn_2 designate y-polarized light traveling in the x or z direction; and n_3 and Δn_3 are for z-polarized light traveling in the x or y direction. E_z is the z component of the electric field in the crystal. For ZnO at $\lambda_0 = 6328$ Å, $n_1 = n_2 = 1.999$, and $n_3 = 2.015$, $r_{13} = -1.4 \times 10^{-12}$ m/V, and $r_{33} = +2.6 \times 10^{-12}$ m/V. Some of the physical constants of ZnO are listed in Table I.

For the geometry shown in Fig. 1, TE waveguide modes traveling in the x direction have z polarization, while TM modes traveling in the x direction have y polarization. Thus TE modes will experience an electrooptic effect characterized by r_{33}, the larger of the coefficients, while TM modes will see the smaller index changes characterized by r_{13}. The index changes shown in (1) will be used below to find the amplitude of the phase variation required to calculate the fraction of light diffracted by the electrooptic grating.

B. Bragg Phase Diffraction Gratings

We consider light traveling in the x direction through a medium with a z-periodic index of refraction variation. Expressing the index of refraction of the medium as the Fourier

series $n_i(z) = (n_i)_m \cos(m\pi z/s)$, $n_i(z)$ thus varies periodically in z and is constant in x and y. The fundamental spatial period is $2s$. $(\Delta n_i)_m$ is the amplitude of the $(m-1)$ harmonic for light of polarization i. If we consider Fig. 1, we see that $2s$ is just the period of the fundamental of the electric field when the center-to-center spacing of adjacent fingers is s.

For the $(m-1)$ spatial harmonic we define a grating vector k_m which is normal to the plane of constant index—in our geometry parallel to the z direction—and has magnitude

$$|k_m| = m\frac{2\pi}{(2s)} = \frac{m\pi}{s}. \tag{2}$$

The propagation vector for a waveguide mode with effective index n_w lies in the waveguide plane, points in the direction of power flow, and has magnitude

$$|k_w| = 2\pi n_w/\lambda_0. \tag{3}$$

If such a mode is scattered by a periodic index variation into a new direction, then conservation of momentum would imply that

$$k_w - k_s = k_m. \tag{4}$$

Here k_s is the propagation vector of the scattered wave.

The scattering of a plane wave from a periodic potential conserves momentum in precisely this form [28]. It has also been shown [29] that a similar conservation law can be used for the scattering of a waveguide mode which has a well-defined momentum into another waveguide mode or a plane wave (radiation mode) which also has well-defined propagation constants. Thus we can use (4) to describe the scattering of a waveguide mode with propagation vector k_w into a second mode in a new direction with propagation vector k_s.

The Bragg condition may be stated as

$$|k_w| = |k_s|. \tag{5}$$

This means that the phase velocity of the scattered wave is unchanged and the vectors are aligned as illustrated in Fig. 2. From (2) and (5) and by simple geometry

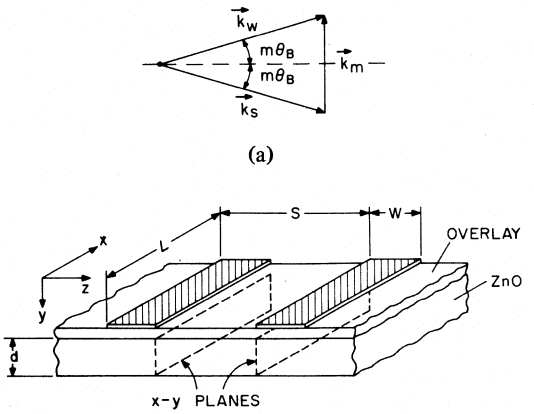

Fig. 2. (a) Vector diagram for calculation θ_B. (b) Section through waveguide and interdigital line showing x-y planes used in resistance calculation.

$$\sin(m\theta_B') = \frac{m\lambda_0}{2(2s)n_w} \tag{6}$$

where θ_B' is the Bragg angle for the fundamental period of the index variation and $m\theta_B'$ is the Bragg angle for the $(m-1)$ harmonic of the index variation. If, after scattering, the light passes from the medium of index n_w to a medium with index n_0, the Bragg angle measured in the medium n_0 is

$$\sin(m\theta_B) = \frac{m\lambda_0}{2(2s)n_0}. \tag{7}$$

Usually, the second medium is air or vacuum, $n_0 = 1$. In this case, θ_B is called the external Bragg angle and θ_B' is called the internal Bragg angle. Note that the angle between the undiffracted light and the diffracted light is $2\theta_B'$ internally and $2\theta_B$ externally.

The simple momentum conservation analysis assumes that the periodic medium extends an infinite distance along x so that the direction of k_m is precisely defined. In this case when θ is set to the Bragg angle, $(m\theta_B)$ for the $(m-1)$ harmonic, the ratio of the intensity of the diffracted light to the intensity of the light entering is given by [14]

$$\frac{I_m}{I_0} = \sin^2(\Delta\phi_m/2) \tag{8}$$

where I_m is the intensity diffracted at an angle $2m\theta_B$ to the direction of the entering light of intensity I_0, and $\Delta\phi_m$ is the amplitude of the phase change associated with the mth spatial period of the index variation. For infinite L the intensity of the diffracted light as θ departs from the Bragg angle is zero. Thus light is scattered into a solitary order at $m\theta_B$. When L is finite the direction of k_w is not precisely defined. Here, for angles θ other than $m\theta_B$, the intensity of the diffracted light is less than that given by (8). If a plot of I_m/I_0 is made as a function of $\theta - m\theta_B$, the width $\Delta\theta$ of the resulting "angular tuning" curve at I_m/I_0 equal to one-half its value at $\theta = \theta_B$ is given by [15]

$$\Delta\theta = \frac{n_w\lambda_0}{2L}\frac{\cos(m\theta_B')}{\sin(m\theta_B)\cos(m\theta_B)}.$$

For small values of $m\theta_B$ this becomes

$$\Delta\theta = \frac{2sn_w}{mL}. \tag{9}$$

As L approaches zero $\Delta\theta$ approaches infinity and momentum can be conserved for all values of θ giving rise to a thin grating type of diffraction in which multiple orders are observed as contrasted to the Bragg or "thick" case which allows only a single order. When $L >> (2s/m)^2/2\pi\lambda_0$, the diffraction is well characterized by (8) and only a single diffraction order need be considered [13].

To make use of (8) the amplitude of the phase change must be found as a function of the applied voltage and material properties. We now identify $(\Delta n_i)_m$ as the amplitude of the $m-1$ space harmonic of the electrooptic index change. $(\Delta n_i)_m$ will be found from (1) by setting E_z equal to $(E_z)_m$, the amplitude of the mth space harmonic of the field. The index $i = 1, 2, 3$ refers to the polarization direction which we have earlier identified with the TE and TM waveguide modes. We will drop this index and keep in mind that the calculation refers to a single polarization or waveguide mode.

The phase-change amplitude is related to the index-change amplitude by

$$(\Delta\phi)_m = \frac{2\pi(\Delta n)_m L}{\lambda_0}. \tag{10}$$

Using (1) and (10) we find

$$(\Delta\phi)_m = -\pi r_{33} n_3^3 \frac{L}{\lambda_0} (E_z)_m \tag{11}$$

for TE waveguide modes, and

$$(\Delta\phi)_m = -\pi r_{13} n_1^3 \frac{L}{\lambda_0} (E_z)_m \tag{12}$$

for TM waveguide modes.

Up to this point we have assumed both E_z and the light-intensity distribution to be constant in the y direction. Neither, however, is in fact constant. Thus, in order to make a rigorous calculation, we would have to average the applied field over the light-intensity distribution to find the correct value for use in (12).

The TE_0 and TM_0 modes of a symmetrical optical waveguide of the type we are studying has a symmetrical distribution of optical field centered in the waveguide film of form $\cos y$. (The origin of y is taken in the film center.) Engan [16] has analyzed the fields of interdigital surface electrodes and shows that $(E_z)_m$ falls off with distance from the surface as $\exp -(2m+1)(\pi/s)y$. For our waveguide thickness $y \sim 1$ μm and with $s \sim 8$ μm, the exponential may be expanded for $m = 0$ as $1 - (\pi/s)y$. Thus, with a roughly linear variation of E_z across the symmetric light distribution, a reasonable estimate might be considered to be obtained by using the value of E_z at the waveguide center in (12). This value of E_z may be expressed as a constant multiplied by the voltage applied between the electrodes by using Engan's calculation. Thus $(E_z)_m$ will be taken as equal to $A_m V_0$ and I_m/I_0 has the form $I_m/I_0 = \sin^2 BV_0$. For $m > 0$ the approximation will be much poorer than for $m = 0$.

Values of A_m for the two circuit geometries we consider are listed in Table I. Using these values in (11) the phase-change amplitudes as a function of V_0 for some of the space harmonics are also tabulated. With these amplitudes it is a simple matter to calculate the diffracted intensity ratio I_m/I_0 from (8). Values of V_0 required to obtain I_m/I_0 equal to 50 and 80 percent are included in Table I.

We note that I_m/I_0 increases almost as the square of V_0 and also as the square of the interaction length L.

C. Power Requirements

In general modulator applications it is conservative to assume that the power required to drive the modulator will be equal to the reactive power P_c. In our case, for a peak voltage V_0 this is given by [17]

$$P_c = \frac{\pi}{2} CV_0^2 \Delta f \tag{13}$$

where C is the capacitance of the interdigital circuit. Equation (13) is appropriate for pulse modulation.

For analog rather than pulse modulation the modulator will be biased with a dc voltage equal to $V_0/2$ so that as the applied signal swings positive and negative around the bias value direct frequency doubling due to the sine-squared response is not encountered. This also saves power. The bounding expression for the power here becomes

$$P_c = \frac{\pi}{8} CV_0^2 \Delta f. \tag{14}$$

In our experiments we measure V_0. The actual power dissipated in the modulator will, however, be given by

$$P = P_c \tan\delta \tag{15}$$

where $\tan\delta$ is the loss tangent associated with the materials which form the dielectric for the interdigital circuit. C may be found from a formula given by Engan [16]. Some typical values of C and of the capacitive power required in milliwatts per megahertz calculated from (13) and (14) are given in Table I.

Loss tangents of insulating crystals are in the range $1\text{-}2 \times 10^{-3}$. From Table I it can be seen that the power dissipated in the modulator is on the order 1-10 mW at frequencies in the gigahertz range.

We should observe that the frequency response of the electrooptic effect is in the region of 10^{14} Hz. The practical frequency limitation of electrooptic modulators is therefore set by circuit conditions. Since the interdigital line is basically a capacitive circuit we would expect that with simple connections the modulation rise times and frequency responses will be bounded by the RC time constant. Here R is the internal resistance of the supply, which will generally be 50 Ω and C is the capacitance of the interdigital line. For our values an RC time constant of about 0.5 ns is expected. Faster response than this can in principle be obtained by using appropriate networks.

D. Effects Due to Free Carriers

The resistivity of the epitaxial ZnO used in these experiments is controlled by compensation. It is of interest therefore to assess the effect that conductivity in the waveguide may have on the operation of the electrooptic grating.

There are two cases that may be distinguished and treated. These are a) electrodes in ohmic contact with the ZnO and b) electrodes fully insulated from the ZnO. Although the circuit in an actual modulator may be in poor contact or have slightly rectifying contacts, treatment of these two cases will provide bounds on the possible degradation that we would expect conductivity to cause in operating the modulator.

Case a) applies to gratings deposited directly on the ZnO. Case b) applies ideally to gratings deposited on a good insulating overlay. Finite conductivity can affect the operation either by carriers moving to alter or cancel the electric fields or by heating effects. In case a) we note that as long as ohmic contact is present the direct effect of free carriers on the electric field is zero. Current flows along the field lines which remain unaltered as long as V_0 is maintained. Here the heating effect will be the important one, and we will treat this case later.

In case b) the carriers will distribute on the insulating layer in a way that tends to cancel the electric field in the waveguide. We estimate the magnitude of the field cancellation as follows. The volume available in the ZnO to supply charge to each finger of the electrode structure is SLd where d is the waveguide thickness [see Fig. 2(b)]. The total available charge in this volume is

$$Q = SLd/\rho\mu \tag{16}$$

where ρ is the resistivity and μ the mobility. To get a worst case estimate imagine that Q is uniformly distributed on a plane surface of area dL (the waveguide thickness times the finger length), located midway between two adjacent fingers, and parallel to the x-y plane. The field of this "surface" charge will be parallel to E_z, of opposite sign, and will have magnitude

$$E = \frac{Q}{\epsilon\epsilon_0 Ld} = \frac{10^4 s}{\epsilon\epsilon_0 \rho d} \tag{17}$$

where s is in centimeters, ρ is in ohm centimeters, μ is in square centimeters per volt second, ϵ_0 is in farads per meter, and E is in volts per meter. The effective field $E_z' = E_z - E$. The mobility of epitaxial ZnO has been found to be on the order of 100 $cm^2/V \cdot s$. Using this value and taking the dielectric constant of ZnO to be 8, E_z' is plotted as a function of ρ with V_0 as a parameter in Fig. 3. As can be seen, for $\rho > 10^5\ \Omega \cdot$ cm, $E_z' \sim E_z$ for any appreciable V_0. For ρ below $10^3\ \Omega \cdot$ cm, the fields will be significantly reduced.

The calculation we have just made assumes that the only volume available to supply charge is that encompassed by the waveguide region under the interdigital circuit. Actually, the entire waveguide can act as a source of charge. The available waveguide volume is roughly 10^3 times larger than the volume under the circuit. Thus our calculation applies for times short compared to the time necessary for carriers to drift to regions under the circuit from remote waveguide regions. We may

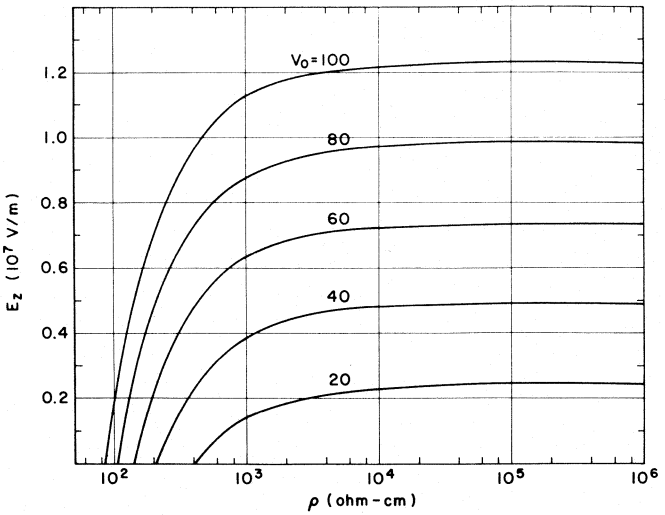

Fig. 3. Plot of z component of net electric field E_z' as a function of resistivity ρ. This plot shows how field is reduced by carriers when the electrodes are insulated from the waveguide.

crudely estimate this time as follows. Assume that a characteristic time is the time necessary for the carriers to drift from a median distance l_m in the waveguide to the circuit. The fields driving the carriers will be small and due to the fringing fields of the circuit edges. The edge field will be roughly in the ratio S/l_m to the fields in the circuit. Thus we can write the characteristic time as: $t_c = l_m/\mu E_{\text{fringing}}$, where $E_{\text{fringing}} = (S/l_m)E \sim (10^{-3} \times 10^3 V_0)$(V/cm). For $\mu = 100$ and $l_m = 1$ cm we have $t_c = 10^{-2}/V_0$. For $V_0 = 100$ V, $t_c = 10^{-4}$ s. Thus, very roughly, we can say that the calculation of field reduction can be used for frequencies well above 10 kHz or pulses much shorter than 10^{-4} s. At frequencies below these values we might expect much stronger reductions than predicted by (7) (see Fig. 3) and at dc we might expect almost complete cancellation for resistivities on the order of $10^5\ \Omega \cdot$ cm.

We now consider the effect finite resistivity will have because of ohmic heating and the resultant thermal changes in refractive index.

As an approximation assume that current flows uniformly in the z direction through the waveguide between x-y planes located at the near edges of two adjacent electrodes [see Fig. 2(b)]. In this approximation the resistance between two adjacent fingers is

$$R = \frac{\rho(s - w)}{Ld}. \tag{18}$$

Assuming the applied voltage is dropped across R, the ohmic power density P_0 is

$$P_0 = \frac{V_0^2}{\rho(s - w)^2}. \tag{19}$$

Mosekilde *et al.* [18] have calculated the temperature rise in an epitaxial layer with a uniformly distributed heat input. If we note that the main cooling takes place in the substrate and assume that heat flow parallel to the waveguide plane is negligible as compared with heat flow normal to the plane, we may

use their results. Doing this, the steady-state temperature rise ΔT is given by

$$(\Delta T)_{DC} = \frac{dbV_0^2}{K\rho(s-w)^2} \tag{20}$$

where K is the heat conductivity in watt centimeters per square centimeter in degrees Kelvin, b is the substrate thickness, 0.05 cm in our experiments, and all lengths are in centimeters. Equation (20) represents the temperature rise in the waveguide areas between adjacent fingers. In this approximation we assume that the waveguide area covered by a finger has no heat input and we also neglect heat flow into these regions.

The steady-state temperature will be reached in a time t_{DC} given by

$$t_{DC} = 2b^2/D \tag{21}$$

where $D = K/C_v$ and C_v is the heat capacity in joules per cubic centimeter in degrees Kelvin. For ZnO, $C_v = 2.75$, $K = 0.285$, $D = 0.103$, and for our experiment t_{DC} is approximately 50 ms.

We now briefly consider pulsed conditions. For pulses 50 ms or longer the dc temperature rise may be used. For pulses shorter than 50 ms the temperature rise will be less than $(\Delta T)_{DC}$ and may be found from a more complex formula given in [18]. We have plotted $\rho\Delta T/V_0^2$ as a function of pulse length t in Fig. 4. By use of this illustration the localized temperature rise can be found for any value of ρ, V_0, and t.

Our approximate calculation says that finite conductivity will result in localized heating between the finger pairs. This will occur when the electrodes are in ohmic contact with the ZnO. The temperature will be periodic with a spatial period equal to S.

Next we shall consider what this periodic temperature variation does to the index of refraction because a thermally induced index of refraction grating may interfere with the electrooptic grating.

A temperature change can affect the refractive index in three ways—by direct material expansion, through temperature dispersion of the index of refraction, and through the creation of stress birefringence. We expect the temperature dispersion to be the dominant effect and we will give an estimate of its magnitude.

Near room temperature the temperature dispersion in ZnO is approximated by [19]

$$(\Delta n)_T \sim 3 \times 10^{-7} T\Delta T. \tag{22}$$

By using (22) in conjunction with Fig. 4, $(\Delta n)_T$ can be found for a variety of voltages, resistivities, and pulse lengths.

For the purpose of evaluating the possible effect of $(\Delta n)_T$ on the operation of the electrooptic phase grating we make the arbitrary assumption that serious problems may arise when the thermal index change is 10 percent of the electrooptic index change or

$$(\Delta n)_T = 0.1(\Delta n) \text{ electrooptic.} \tag{23}$$

If we consider only the fundamental spatial frequency of the electrooptic effect, (23), in conjunction with (1) and the field

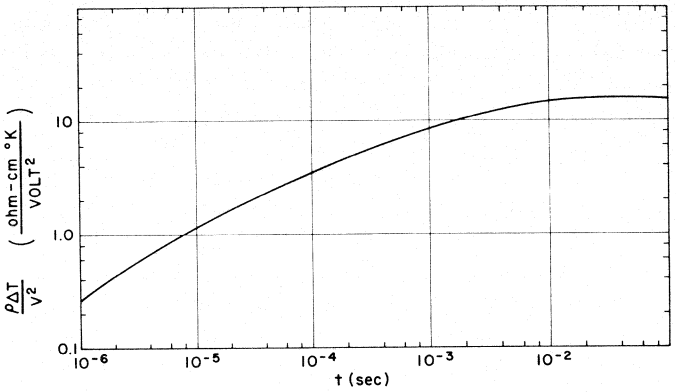

Fig. 4. Plot of $\rho\Delta T/V_0^2$ as a function of pulse length t. The space periodic-temperature rise ΔT can be found if the resistivity ρ and the pulse voltage V_0 are known.

harmonic values listed in Table I for the experimental circuit, gives

$$\Delta T = 0.14V_0 \tag{24}$$

as the limiting temperature rise. The constant is chosen so that with V_0 in volts ΔT is in degrees centigrade. In dc or long-pulse operation using (20), (24) will be satisfied when $\rho = 10^2 V_0$. The long-pulse heating effect is, of course, a problem only when the electrodes are in contact with the ZnO. For example, at $V_0 = 100$ V, ρ must be greater than $10^4\ \Omega \cdot$ cm. In the case of well-insulated contacts, the thermal effect will not be important.

We now may summarize our thoughts on the effect of finite conductivity on the operation of the electrooptic grating. In the case of electrodes in ohmic contact, carriers will cause localized heating which results in the production of a phase grating of period s (half the period of the electrooptic grating). The thermal grating will be seen at $\theta = 2v_B$ (first harmonic). We might also expect to see associated thermal lensing effects. This heating effect will be important if the resistivity is below about $10^4\ \Omega \cdot$ cm in long-pulse or CW operation.

In the case that electrodes are well insulated from the ZnO, the carriers will tend to cancel the fields. Here too it turns out that resistivities below $10^4\ \Omega \cdot$ cm will cause degradation.

We conclude, therefore, that it is important to ensure that material of the highest resistivity be used. Even with ρ on the order of $10^6\ \Omega \cdot$ cm we would expect low-frequency degradation although no high-frequency effects (frequency above 100 kHz) would be observed.

E. Acoustic Surface-Wave Generation

In general, linear electrooptic materials are also piezoelectric. The interdigital structure used to create the electrooptic phase grating is also capable of launching acoustic surface waves on piezoelectric materials at a resonant frequency determined by the electrode spacing and acoustic surface-wave velocity. We wish, therefore, to consider acoustic surface waves.

Coupling between the interdigital electrode structure and acoustic surface waves will take place at the resonant frequency

$$f_a = \frac{v_a}{2s} \tag{25}$$

where v_a is the surface acoustic-wave velocity. This has been determined empirically for the epitaxial ZnO on sapphire system by Pizzarello [20]. Using his results, for a nominal waveguide thickness of $d = 1$ μm and our spacing ($s = 7.6 \times 10^{-4}$ cm), $v_a = 5.4 \times 10^5$ cm/s and $f_a = 355$ MHz.

Pizzarello also gives the coupling factor k_a^2 as a function of the ZnO film thickness. For a 1-μm-thick layer, $k_a^2 = 2 \times 10^{-3}$. This value represents rather weak coupling. Thus, at frequencies near f_a, we would expect to couple energy into the acoustic surface wave but with rather low efficiency.

At frequencies below f_a the acoustic coupling would be expected to be negligible.

With very fast pulse rise times some of the energy will couple into the acoustic wave. The effect of this is uncertain.

III. Experimental Methods

A. Circuit Preparation

Several methods of forming the interdigital circuit on the waveguides were tried. The most successful was a photoresist lift-off technique. In this method the pattern is first contact-printed and developed onto a spun photoresist layer on the waveguide. Chromium films and then gold films are evaporated over the developed photoresist surface. Subsequent treatments in acetone removes the undeveloped photoresist along with its metal coating, leaving behind the pattern.

B. Measurement Procedures

A schematic diagram of the measuring setup is shown in Fig. 5. Laser light is focused on the input prism with a 20-cm lens. Provision is made to rotate the waveguide assembly around the z axis to reach the correct coupling angle for the mode to be studied. Small y- and z-translational motion of the lens allows the focused spot to be moved to optimize the coupling.

The waveguide is positioned so that the guided light passes beneath the modulator fingers. Provision is made to rotate the modulator around the y axis. Because the laser beam remains fixed in direction this rotation results in varying the angle between the guided light and the finger direction. This angle is

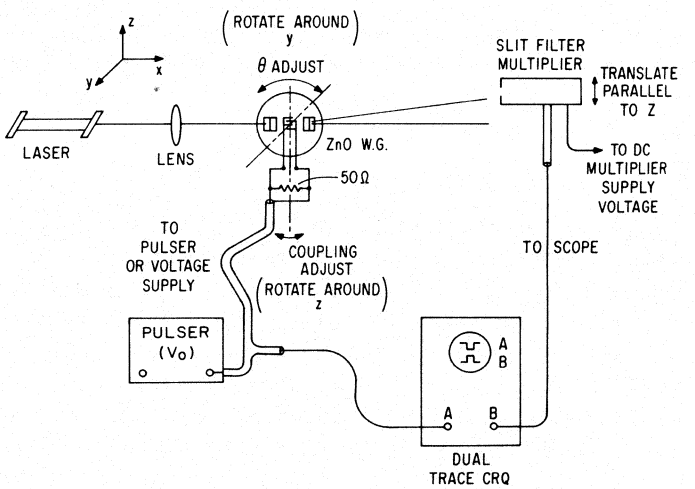

Fig. 5. Schematic diagram of experimental arrangement for measuring diffraction percentage and angular tuning range.

the θ of the theoretical description; it can be read to 30″ on the precision rotator used.

Light coupled out of the waveguide by the second prism passes through a slit and a filter into the window of an RCA 6199 photomultiplier. The slit-filter-multiplier assembly is located about 50 cm from the modulator and can be translated parallel to the z-direction. The motion allows the detector to be positioned to receive either the main beam or the diffracted beam.

With no voltage applied to the deflector it is possible to observe the Bragg diffraction due to the small increase in absorption for guided light traveling under a metal finger as compared with the guided light traveling under the gap between fingers. The effect is shown by the appearance of a second weak spot on a screen placed in front of the detector when θ is set at an angle which is twice θ_B for the electrooptic grating. This observation simplifies alignment. With θ set approximately to $m\theta_B$ for the desired harmonic, voltage from the pulser is applied and the signal produced by the modulated light can be seen on the scope when the detector is translated to the position of either the undiffracted or the diffracted beam. A 50-Ω matching termination is placed in parallel with the electrodes to avoid strong mismatch reflection and undue pulse distortion. The voltage measured is that across the termination. In an actual system a network or coaxial isolator would be employed to adsorb the reflected power. In the latter case, the power load on the source would be the capacitive power described earlier. The pulser is replaced by other voltage sources for certain measurements.

IV. Experimental Results and Discussion

In this section we will describe and discuss results of measurements made on three modulators. Samples A, B, and C have 1000-Å Al_2O_3 overlays and interdigital circuits deposited directly on the overlay. The samples are grown with different thicknesses such that sample A has seven TE and seven TM modes; sample B has five TE and five TM modes; and sample C has three TE and three TM modes.

A. Percentage Diffraction Measurements

Measurements of the percent output deflected as a function of voltage under a variety of operating conditions for the three samples are given in Figs. 6–8. Measurements on A and B are made under pulsed conditions with pulses approximately 0.5 μs long and pulse repetition rates of 20 kHz, giving a 1-percent duty cycle. Relatively short pulses are used to avoid arcing in the air above the interdigital circuits. The duty cycle is kept low to avoid overheating the 50-Ω load resistor at the higher pulse voltages. As mentioned earlier, proper isolation of source would be employed in systems use, and the duty cycle would not be restricted. Sample C was protected from arcing in the atmosphere by coating the top surface of the electrodes with a layer of polyester. The measurements on sample C were made under a variety of pulse lengths and frequency conditions and will be described in greater detail below. The data presented in Fig. 8 were, however, made under the same short-pulse conditions as the data presented for samples A and B.

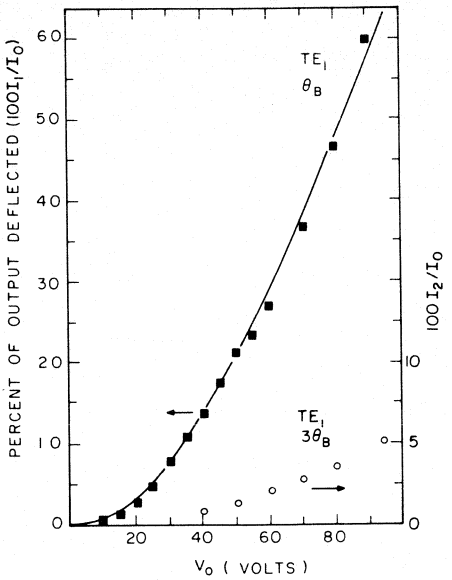

Fig. 6. Percent of light coupled out of the waveguide deflected (I/I_0) as a function of voltage for sample A. Squares are the data for the TE_1 mode with θ set to θ_B. Circles are for the TE_1 mode with θ set to $3\theta_B$ (second space harmonic). The scale factor is doubled for the $3\theta_B$ points. Solid curve is $\sin^2 BV_0$ normalized to θ_B data at V_0 = 50 V.

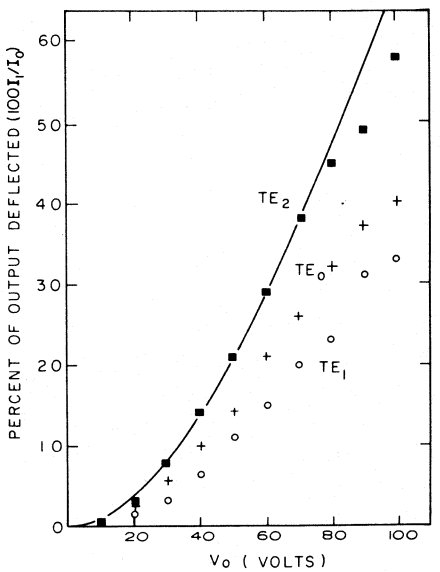

Fig. 7. Percent of light coupled out of the waveguide deflected (I/I_0 percent) as a function of voltage for sample B. All data taken with θ set to θ_B. Crosses TE_0, circles TE_1, squares TE_2. Solid curve is $\sin^2 BV_0$ normalized to TE_2 data at V_0 = 50 V.

The percent output ($100\, I_m/I_0$) deflected at the Bragg angle for the fundamental and for the second space harmonic of the grating in sample A is shown in Fig. 6. Here the TE_1 waveguide mode is used. The solid curve is a plot of $\sin^2 BV_0$, normalized to the data at V_0 = 50 V. The functional agreement is very good. The second space harmonic ($\theta = 3\theta_B$) data are plotted with a two times increase in scale factor. The second space harmonic results are in the expected ratio to the fundamental results.

In Fig. 7 the percentages deflected for the TE_0, TE_1, and TE_2 waveguide modes of sample B are plotted. All three sets of measurements are taken at $\theta = \theta_B$. As before, the solid curve $\sin^2 BV_0$ is normalized to the TE_2 result at V_0 = 50 V. We note that the TE_1 and TE_0 values are substantially less than the TE_2 values.

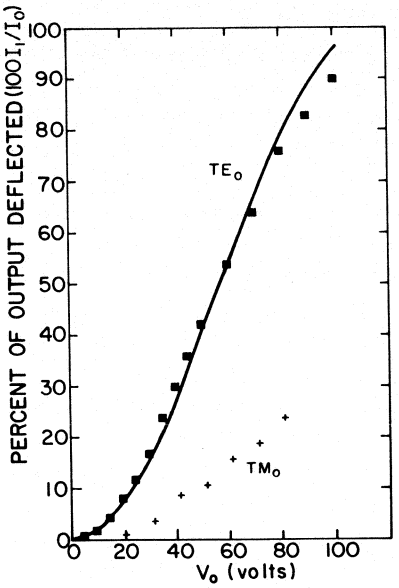

Fig. 8. Percent of light coupled out of the waveguide (I/I_0 percent) deflected for the TE_0 (squares) and TM_0 (crosses) waveguide modes of sample C as a function of voltage V_0. θ is set at θ_B. The solid curve is $\sin^2 BV_0$ normalized to TE_0 data at V_0 = 70 V.

In Fig. 8 the percent output deflected for the TE_0 and TM_0 waveguide modes of sample C is plotted. For these data θ is set to θ_B, the Bragg angle for the fundamental spatial period. The solid curve is a plot of $\sin^2 BV_0$ normalized to the TE_0 data at V_0 = 70 V. TE_0 data follow the sine-squared law reasonably well, showing some rolloff at the higher voltages. The ratio of TM_0 to TE_0 deflection percentage is in agreement with the theoretical expectation that this ratio should be as $(r_{13}/r_{33})^2$. The measured deflection is 80 percent at 80 V.

The data presented in Figs. 6-8 clearly show the correct functional form to be attributed to the action of an electrooptic phase grating of fundamental period $2s$.

The theoretical treatment accounts reasonably well for the observed differences between TE and TM waveguide modes and for the difference between the deflection at the fundamental spatial-frequency angle θ_B and that at the second-harmonic angle $3\theta_B$. The magnitude of the percentage deflection is less well accounted for. The theory predicts that 50-percent deflection should be obtained at V_0 = 41 V. Our best measured value (Fig. 8) is 50-percent deflection at 55 V. The mode-to-mode variation shown in Fig. 7 gives some indication of the sensitivity of the deflection to the exact field distribution and reinforces our recognition of the very approximate nature of the field and deflection-efficiency calculations. We observe no mode conversion in the modulated beams.

The total insertion loss including losses in the coupling prisms ranges between 85 and 95 percent. The variation apparently depends on the care with which the prisms are clamped in place.

B. Pulse Response and Carrier Effects

The high-frequency capabilities of the electrooptic waveguide grating modulators are illustrated by typical pulse-response measurements shown in Figs. 9 and 10.

Fig. 9 is a photograph of a dual oscilloscope trace of the pulse voltage and diffracted light. The light output follows the voltage with no apparent change in rise or fall time to within the 10-ns limitation of the Tektronix 547 oscilloscope and 1A1 dual-trace plug-in unit used. This pulse behavior, using longer pulses, however, is typical of the conditions observed when making the deflection percentage measurements described earlier.

To observe faster response times a delay-line pulser with 1-ns rise time was used. The multiplier output is observed with a 1S1 sampling plug-in unit installed in the 547 oscilloscope. The resultant oscilloscope trace of the diffracted light is shown in Fig. 10. Here we observe a rise time of less than 3 ns. This too is equipment-limited because the rise time of the RCA 6199 multiplier is on the order of 3 ns. Thus, to within our equipment limitations, we know that rise times of less than 3 ns are achieved. The actual limitation on the rise time, as has been pointed out earlier, is the RC time constant which is about 0.5 ns for the experimental circuit. At the other extreme we note that we cannot observe any diffraction with dc voltages applied.

At 60 Hz a fair amount of modulation is observed but is less than the short-pulse operation. This effect is shown in Fig. 11. Here the TE_0 data for sample C are plotted for two cases. The squares are for short-pulse operation, as in Fig. 8, while the crosses are for operation at 60 Hz. As might be expected at the higher voltages, where much charge is required for cancellation, little degradation is observed. At lower voltages a stronger degradation occurs. In general, this is in qualitative agreement with our analysis of the critical time.

To investigate the effect of free carriers further we make use

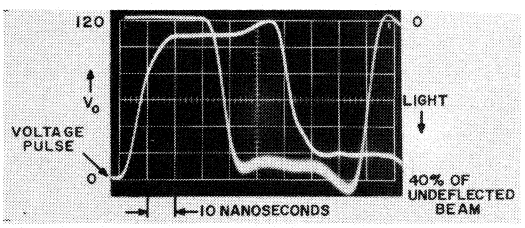

Fig. 9. Oscillogram of deflected output and applied voltage. Sample A. The delay between light and voltage pulse is due to the length of coaxial cable used. (10 ns/div.)

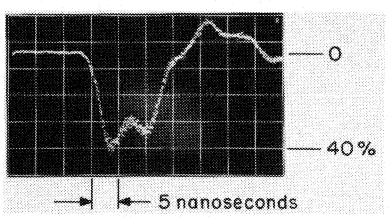

Fig. 10. Oscillogram of deflected output taken on sampling scope. The applied voltage from delay-line pulser has 1-ns rise time. The apparent response is limited by the 3-ns rise time of the photomultiplier. (5 ns/div.)

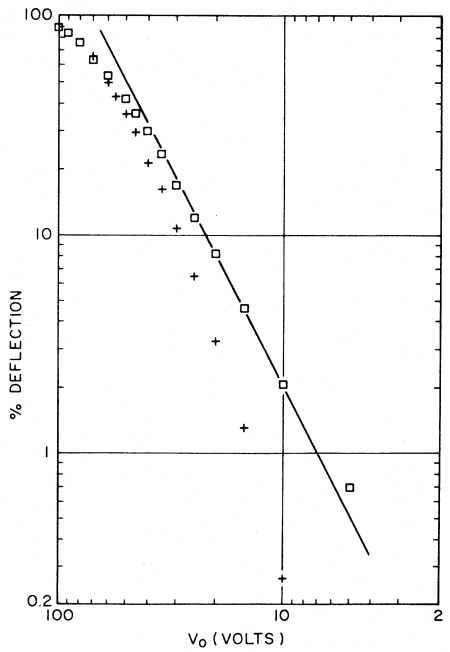

Fig. 11. Comparison between response to fast and slow voltage variation. Squares are deflected intensity for 0.5-μs pulses. Crosses are deflected intensity for 60 Hz.

of the photoconductive properties of the ZnO waveguide. We can create carriers by illuminating the waveguide with ultraviolet light and investigate how this affects the modulation. The relation between the density of carriers generated and the light intensity depends on the recombination mechanism. If we assume that radiative recombination between photoexcited electrons and holes dominates, then the carrier density will be proportional to the reciprocal square root of the light intensity [21].

The results of such a measurement on sample C are shown in Fig. 12. The closed circles are the experimental values at $V_0 = 60$ V. The intensity of the ultraviolet light is varied with a calibrated iris diaphragm and the observed reduction in the diffracted light is measured. The ordinate is the square root of the reduction in diffraction percentage which is proportional to the field. The abscissa is proportional to the resistivity which is lowered by increasing the incident ultraviolet radiation. Thus the theory (17) (see Fig. 3), may be used. The solid curve is the theoretical calculation normalized at high resistivity. There is some modest agreement. The practical implication of being able to control light with light in this type of waveguide should be noted.

C. Variation with θ

We note at this point that the average measured value of θ_B agrees to within our measurement error of $\pm 0.07^\circ$ (4′) with the theoretical value of 1.19°. To further demonstrate the thick-grating nature of these devices we measure the change in deflected output as θ is varied around θ_B. Results for sample B are given in Fig. 13.

The half-widths $\Delta\theta$ as measured from these curves show small variances around the calculated value. The calculation assumes a parallel beam. In the experiment the waveguided

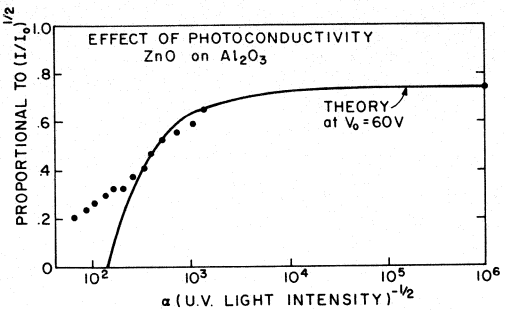

Fig. 12. Effect of photocarriers on deflected intensity. The ordinate is proportional to $(I/I_0)^{1/2}$ and hence is a measure of the net internal electric field. The abscissa is proportional to the density of photo-induced carriers.

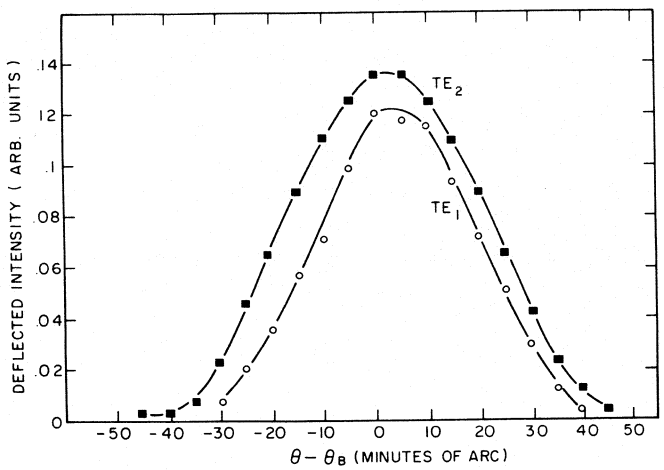

Fig. 13. Deflected intensity (arbitrary units) as θ is varied around θ_B. Sample *C*. Squares TE_2, $\Delta\theta = 0.73°$. Circles TE_1, $\Delta\theta = 0.60°$.

light has an angular spread that depends on the exact condition of focus and spatial position in the prism. These conditions are not closely controlled and will vary as one changes from mode to mode. Thus the measured spread is really a convolution of the spread of angles in the guided light with tuning of the Bragg effect.

The type of variation encountered is clearly shown in Fig. 13. The TE_2 data have $\Delta\theta = 0.73°$ while the TE_1 data have $\Delta\theta = 0.60°$ which is much closer to the theoretical value of 0.58°.

Despite these irregularities the general angular-tuning behavior of the modulators is in agreement with what would be expected for a Bragg phase grating and reinforces our identification of our observations as being due to electrooptically induced Bragg phase diffraction gratings.

D. Thermal Effects

The samples we have discussed thus far have had resistivities in the 10^6-$\Omega \cdot$ cm range. In this range we would not expect and indeed did not observe any thermal effects. In many early attempts we were unable to maintain the resistance of the ZnO layer and after circuit formation ended up with low-resistivity material. Under these conditions we measured ohmic resistances between the contacts on the order of 1000 Ω or less which indicated resistivities in the 10-100-$\Omega \cdot$ cm range. Here we did observe thermal-grating effects as would be expected from the analysis.

E. Use of Data and Theory to Design Interdigital Electrooptic Waveguide Modulators

On the basis of the measurements we have described in this section we may say with some confidence that the analysis in Section IV gives the correct functional relationships between the parameters of the interdigital electrooptic waveguide modulator. The analysis, however, underestimates the voltage required to obtain a given percentage deflection by 30 percent. This is not surprising and might even be considered gratifying in light of the rather coarse approximation made in taking the average value of the electric field produced by the grating. In general, the qualitative predictions of the theory as to pulse response and low-frequency operation are confirmed. We do not expect detailed quantitative predictions from this aspect of the analysis.

On the basis of our theoretical relations we have designed the parameters of an optimized interdigital modulator on ZnO. By increasing the interaction length to 0.5 cm and making the finger width equal to the finger separation ($w = s/2$), we find the parameters listed in Table I which may be compared with the experimental circuit. Voltages of around 25 V and powers on the order of a few milliwatts per megahertz would be expected.

Further improvement in this type of device can be achieved only by using superior materials such as the $LiNb_xTa_{1-x}O_3$ device recently reported [27].

V. Conclusion

Measurements on three epitaxial ZnO on Al_2O_3 waveguides with deposited interdigital electrode structures have been made. Behavior reasonably well characterized by the theory of electrooptic Bragg diffraction gratings is observed. Peak diffraction efficiencies as high as 80 percent at 80 V have been obtained. Diffraction by higher order space harmonics is observed and is in the ratio to the fundamental harmonic diffraction expected from theory. The ratio of diffraction between TE and TM modes is also in accord with the analysis. Our observations indicate that the theoretical description given here is adequate for design purposes.

We observe very high-frequency response and we predict even higher. We have little doubt that pulse response times of less than 1 ns can be achieved. Observations on low- and high-resistivity waveguides bear out our analysis of the thermal effects of carriers and indicate that this analysis can be used as a guide to resistivity requirements for the design of electrooptic grating modulators.

The research performed here confirms the feasibility of using electrooptical waveguides in a modulator-switching arrangement.

We have shown that our electrooptic grating waveguide modulator has the advantage of spatially separating the diffracted beam from the main beam and thus does not require a separate analyzer or strict control of the waveguide propagation characteristics as is the case for some other waveguide modulators. Furthermore, because of the spatial separation, a

number of grating modulators can be included on a single waveguide so that the output of one modulator can be used as the input to a second modulator, thus allowing a variety of logic and switching functions on a single waveguide. The spatial separation also aids in obtaining high extinction ratios in the diffracted beam. These features plus the extremely high-frequency response of our modulators leads us to conclude that they will find a wide variety of uses in the field of integrated optics.

Near-Field Emission from GaAs Double-Heterostructure Laser Mirrors

B. W. HAKKI, MEMBER, IEEE

Abstract—The near fields of GaAs double-heterostructure (DH) laser mirrors are studied both in photoluminescent (PL) excitation and in lasing emission. The various liquid-phase-epitaxial (LPE) layers of the laser diode are optically delineated, with ∓ 0.1-μm resolution, in a wavelength-selective PL detection system. The near fields of the transverse lasing modes are correlated with the LPE layers that constitute the optical waveguide. With special emphasis on the large-cavity fundamental-mode Ppn'N laser, it is found that small changes in refractive index within the waveguide have pronounced effects on the distribution of stimulated power within the LPE layers. The fundamental mode is found to be contained within the slightly higher refractive-index gain region. This explains the previously observed localization of catastrophic mirror damage and the anomalously large angles of beam divergence. High-order modes are also excited in the gain region when its thickness and refractive-index step within the waveguide exceed some prescribed limits.

I. Introduction

THE potential practical importance of GaAs double-heterostructure (DH) injection lasers has led to increased interest in both CW and pulsed devices [1]-[5]. In addition to the basic operating characteristics such as power output, efficiency, and emission spectrum, the near-field emission from the laser mirror is of central importance in some applications where coupling to the laser is accomplished with optical fibers [6], [7]. The distribution of the stimulated near field within the waveguide is also important in determining the limits of catastrophic mirror damage, as well as the angle of divergence of the emitted beam. This paper describes the diagnostic techniques and gives results of measurements of stimulated near-field emission from GaAs DH lasers. Special emphasis is put on the study of the fundamental-mode Ppn'N laser in which mode control in a large cavity (2-3 μm) is achieved by restricting the gain region to $\approx\frac{2}{3}$ of the waveguide thickness [5]. The individual liquid-phase-epitaxial (LPE) layers of the laser mirror are delineated optically by photoexcitation. When the stimulated near-field distribution within the waveguide is related to the LPE layers, it is found that the shape of the lasing mode transverse to the junction plane is sensitive to the dopants added to the layers within the waveguide. In particular, the addition of a small amount (3.6 ∓ 1 percent) of aluminum to one of the layers in the waveguide, to achieve separate optical and carrier confinement, is found to lead not only to confinement of the fundamental mode to the gain region, but also to excitation of high-order modes in the gain region under certain conditions that have been predicted analytically [5]. As a result of this investigation it is possible to understand previous observations of localized catastrophic mirror damage [4] and apparent discrepancies (unreported) in beam divergence. This also has led to more detailed calculations of mode-intensity distribution that are in general agreement with experiment [8].

II. Emission from Laser Mirror

A. Measurement Technique

A schematic of the apparatus is shown in Fig. 1. Individual lasers are mounted in a fixture which allows a bias (dc or pulse) to be applied to the diode. The fixture is attached to (*X-Y-Z*) piezoelectric micrometers (PZM) that allow distance adjustment and calibration in the micron range. The laser mirror is imaged on a Si target of a vidicon camera tube by using a 100X oil-immersion metallurgical microscope lens. The high sensitivity of the Si diode array to the IR radiation is advantageous in this application. A beam splitter directs a 7993-Å-wavelength beam from a krypton laser onto the laser mirror through the objective lens.[1] The resultant photoluminescent (PL) emission from the laser is filtered through a slice of single-crystal CdTe, optically polished and antireflection coated with Al_2O_3. The bandgap absorption edge of CdTe situated at 8500 Å passes the GaAs PL emission but rejects the 7993-Å laser excitation. This arrangement also provides excellent contrast between the PL emission of GaAs which is longer than 8500 Å, and PL emission from $Ga_{0.7}Al_{0.3}As$ which is peaked at 6900 Å. This contrast delineates the laser LPE layers. The electron beam in the camera tube has the facility for electronic magnification ("zoom") of the image. The video signal is amplified and fed into a video monitor for display. In addition, to get a plot of local light intensity (linear scale) as a function of distance, the video signal is fed into an adjustable time-delay scope which is triggered by the horizontal-scan output from the scanner. The adjustable time delay allows any horizontal scan on the video monitor to be displayed as light intensity versus distance. A feedback loop from the scope gate to the video monitor causes local intensification of the particular horizontal line on the monitor. This method correlates the scope display with the video monitor image.

When distance measurements derived from this system are compared with those from a scanning electron microscope, agreement is obtained to within ∓ 0.1 μm. The Rayleigh resolution limit of $\lambda/2NA$ is 0.34 μm for the present optics, where λ is the free-space wavelength and NA is the numerical aper-

[1] Not shown in the schematic of Fig. 1 are means of directing light from a tungsten source to the laser mirror for ordinary viewing, as well as a defocusing lens for the krypton laser beam.

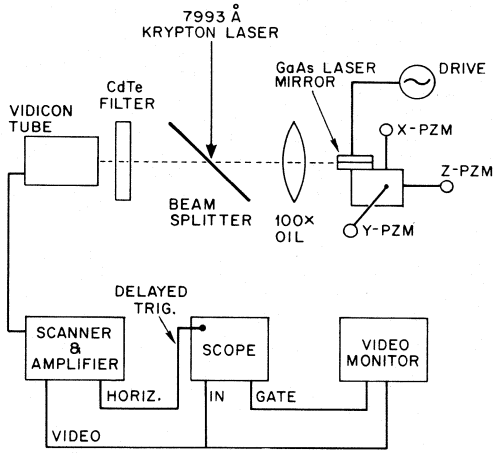

Fig. 1. Schematic of optical excitation and detection system used for studying the near-field emission from GaAs DH laser mirrors.

ture of the objective. The improved *distance* (not shape) resolution of 0.2 μm is due to two factors: 1) the increased contrast of photographic film; and 2) the use of well-defined inflection points in intensity scans to define boundaries between adjacent layers, as will be evident in later results.

To study the far-field radiation pattern of lasers, the IR laser beam is initially projected on the photosensitive surface of an image converter. The resulting visible image on the back surface is then focused on the camera tube. The use of the image converter is motivated by two reasons. First, the saturation level of the image converter at IR wavelengths is higher than that of the Si target. Second, the image converter eliminates the interference fringe lines seen in the Si target when the incident radiation is monochromatic.

B. Results

The Ppn'N lasers investigated are shown schematically in Fig. 2. Some devices have a final p-GaAs layer grown with heavy Ge doping to facilitate contacting, while others are terminated with the ternary P-$Ga_{0.7}Al_{0.3}As$ layer. Proton-beam bombardment is used to define stripes that are nominally 10 μm wide [9]. The main waveguide defined by the $Ga_{0.7}Al_{0.3}As$ layers is composed of a heavily Te-doped $Ga_{0.97}Al_{0.03}As$ layer which injects electrons into the Ge-doped GaAs layer. Hence the p-GaAs layer is the gain region, while the n'-$Ga_{0.97}Al_{0.02}As$ layer constitutes loss. When the thickness of the gain region is equal to or slightly larger than that of the loss region the electronic gain of the fundamental transverse mode is greater than that of higher order modes, and hence the fundamental mode is usually excited [5]. The choice of thicknesses for best mode discrimination depends on the degree of mode confinement within the gain region.

When such Ppn'N devices are studied in the system depicted in Fig. 1, the PL emission from the various LPE layers is shown in Fig. 3 for a particular laser diode. In this laser structure, a final 2.5-μm-thick p-GaAs layer is used for contacting, and the proton bombarded region in this layer has very low PL efficiency as evident from Fig. 3(a). This supports earlier measurements, in which proton bombardment had been shown to reduce the minority-carrier diffusion length as well as the radiative efficiency [10]. The stripe width, defined by

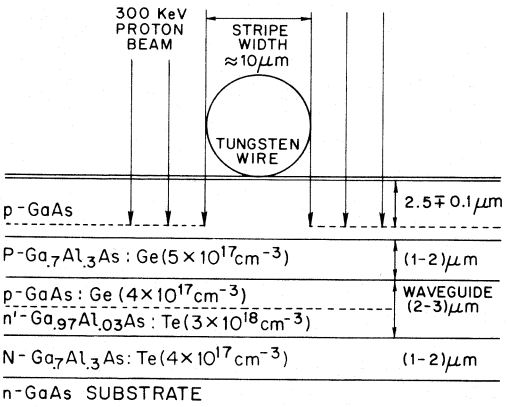

Fig. 2. The LPE layers that constitute the Ppn'N laser diode with a 10-μm-wide stripe geometry defined by proton bombardment.

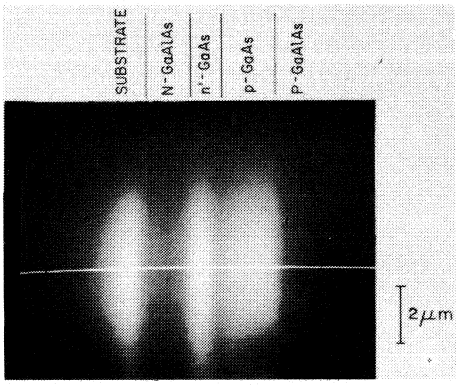
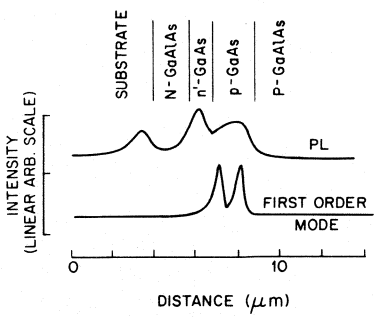
the unbombarded and hence bright region of the p-GaAs layer, is (9–12) μm wide. The boundary between the bombarded and unbombarded regions is tapered. The depth of penetration of the 300-keV proton beam in GaAs seems to be (2.5 ∓ 0.1) μm, as indicated by these PL measurements.

The waveguide region shown in PL emission in Fig. 3(a) contains a dark line separating the p-GaAs and n'-$Ga_{0.97}$-$Al_{0.03}As$ layers. This dark line is due to the space-charge region that exists in the unbiased diode. In this region photo-excited carriers are swept out by the field, and hence are unable to locally recombine radiatively.[2] Under conditions



[2]The level of PL intensity in the waveguide can be affected by whether the device is short circuited or open circuited. However, regardless of the circuit impedance, the space-charge region is always distinct as a dark line.

of PL excitation the influence of the space-charge region extends beyond its limited width due to the diffusion of the PL excited carriers. Hence the boundary between the n- and p-layers is difficult to locate with accuracy in this technique because of the width of the dark line in PL. If it is known *a priori* that the n-region is more heavily doped than the p-region, as is usually the case in Ppn′N structures, then most of the space-charge region occurs in the p-region. This can be checked experimentally by applying a reverse bias on the diode, and noting the direction of spread of the dark line.[3] Since the influence of the space-charge region on photo-excited carriers is greatest in the layer that contains the space-charge region, application of reverse bias usually provides an unambiguous determination of the p–n interface.



When a forward-bias pulse in excess of lasing threshold is applied to the diode, the resultant near field of the stimulated emission can be observed. For instance, Fig. 3(b) shows the stimulated fundamental mode excited in the same laser as that in Fig. 3(a). Here both PL and stimulated emission are depicted simultaneously. This method of observation provides a direct correlation between the near field of the stimulated emission and the various LPE layers. (The monochromatic emission gives rise to multiple reflections in the camera target and the resultant interference patterns associated with the stimulated emission make it easily distinguishable from the spontaneous PL emission.) It is evident, in Fig. 3(b), that the fundamental mode is well confined within the p-GaAs layer, which is the gain region. This is generally true of all Ppn′N laser structures operating in the fundamental transverse mode, and in which the Al concentrations in the P and N layers are the same.

When the same device of Fig. 3 is driven well above threshold, the first-order mode transverse to the junction plane is excited. In this case, the near field of the first-order mode is shown in Fig. 3(c), in relation to the various LPE layers. As in the case of the fundamental mode, the first-order mode is also confined within the gain region. This location of the first-order mode confirms theoretical predictions of excitation of a high-order mode within the gain region, in a structure with asymmetric refractive-index profile [5]. The conditions under which such a high-order mode is excited can be related to the width of the gain region relative to the refractive-index discontinuity at the p–n heteroboundary.

Although the results of Fig. 3 are qualitatively informative, insofar as the relative position of the stimulated near field with respect to the LPE layers, a quantitative evaluation is not simple. The difficulty in interpreting information contained in Fig. 3 is associated with the nonlinear sensitivity of photographic film. Hence the electronic scheme of Fig. 1 is employed to display on a scope the light intensity as a function of distance. An example of this is shown for another laser in Fig. 4. The PL emission from the laser mirror is given in Fig. 4(a), and the location of the intensity scan is marked by the intensified horizontal line. The various LPE layers of the Ppn′N laser are noted in Fig. 4(a). In Fig. 4(b), a plot is given of the PL emission intensity (on a linear scale) from the various layers as a function of distance. The low-intensity emission associated with the space-charge region is evident in Fig. 4(b). When the near field of the stimulated emission is displayed as a function of distance, without the PL emission, the result is given also in Fig. 4(b). This plot of the first-order-mode near field depicts several interesting features. In the first place, the null is quite deep, indicating good optical resolution. In the second place, the first-order mode is contained almost entirely in the gain region, as noted earlier. Finally, the depth of penetration into the P-$Ga_{0.7}Al_{0.3}As$ layer is very small ($\lesssim 0.3$ μm), whereas an appreciable tail in the intensity distribution extends into the passive n′-$Ga_{0.97}$-$Al_{0.03}As$ layer.

(a)

(b)

Fig. 4. Near-field emission from a Ppn′N laser. (a) PL emission from the laser mirror, with the white line designating the position of intensity scan in (b). The dark band in the N-layer is a spurious intensification in the video monitor. (b) PL intensity scan across laser mirror and scan of the near field of the lasing first-order mode.

Similar intensity scans show that the near fields of the fundamental and first-order modes subscribe to the same general behavior, namely, being predominantly confined to the P-GaAs gain region. In addition, the fundamental mode also has a tail in the intensity distribution that penetrates into the passive n′-region. However, the depth of penetration of the fundamental mode into the n′-region is less than that of the first-order mode.

Finally, it is found that the confinement of the high-order mode to the gain region is a strong indication of the presence of Al in the passive layer. Devices with no Al added to the n′-layer and operating in a high-order mode are distinguished by a near-field distribution which fills the whole waveguide,

[3] Application of reverse bias in excess of 10 V in an optical system utilizing 100× oil-immersion lenses is found to lead to gross optical distortion. This is suspected to be associated with the electrooptic coefficient of the oil. The use of 100× air lenses obviates this problem under high bias, but at a sacrifice in optical resolution.

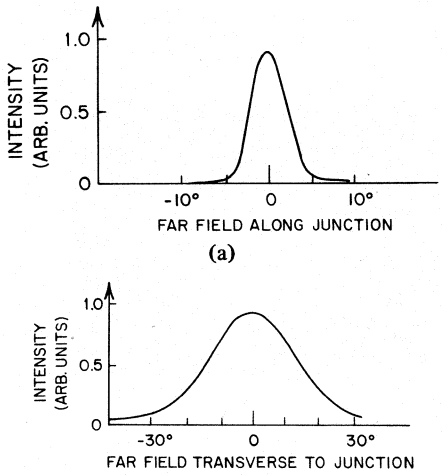


Fig. 5. Ppn'N stimulated emission projected on a planar surface. (a) Scan of intensity along junction plane. (b) Scan of intensity transverse to junction plane.

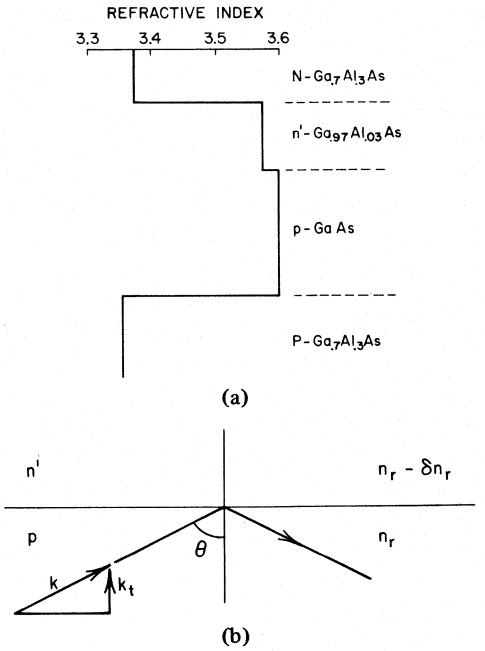

Fig. 6. Schematic representation of Ppn'N laser geometry. (a) Refractive-index variation across optical waveguide. (b) Reflection of rays at the p–n′ interface.

being nearly symmetric with respect to the center. Such devices may still operate in a fundamental mode very close to threshold, if the passive layer is doped with Te to a level of 3×10^{18} cm^{-3}. This Te doping level gives rise to an index discontinuity of $\approx 2 \times 10^{-2}$ at the p–n interface [11]. The near field of the fundamental mode shows some preference for the gain region. This may be attributable to the ease of confinement of the fundamental mode and its sensitivity to minor changes in refractive index caused either by doping or gain differences.

Fig. 5 shows the far-field radiation pattern of a laser in which the gain region is 1.2 μm thick and the unpumped n′-region is 0.9 μm, i.e., a total waveguide thickness of 2.1 μm. The full beamwidths, at the half-power points, transverse and along the junction plane are 34° and 6°, respectively. These angles are obtained after appropriate corrections are made on the intensity scans of Fig. 5 to account for the fact that the beam is being projected on a planar surface. (These corrections will be discussed in a later section.) It is evident that the results of Fig. 5 depict the far-field pattern of a laser operating in a fundamental mode both transverse and along the junction plane. The utility of this technique lies in the fact that even if the pattern were multifilamented, as is sometimes the case, the radiation pattern transverse to the junction plane can be measured for each filament separately by adjusting the scan position on the monitor.

III. Discussion

A qualitative understanding of the operation of the device can be acquired from the variation of the refractive index across the various layers shown schematically in Fig. 6(a). The refractive-index values of the layers that constitute the Ppn'N structure are consistent with recent measurements [12]. Therefore the optical containment characteristics of the transverse stimulated modes are a result of the small change in refractive index between the p- and n′-layers. Quantitatively, the degree of confinement within the gain region of a mode depends on whether its transverse propagation constant in the passive n′-region is real (propagation) or imaginary (attenuation). This, in turn, depends on whether the angle of incidence at the p–n′ heteroboundary, shown in Fig. 6(b), is less or greater than the critical angle [13], given by

$$\sin \theta_c = 1 - \delta n_r / n_r \tag{1}$$

where n_r and $n_r - \delta n_r$ are the refractive indices in the p- and n′-regions, respectively.

The angle of incidence at this heteroboundary of any mode is related to its transverse propagation constant by the relation

$$\sin \theta = (1 - k_t^2/k^2)^{1/2} \tag{2}$$

where k_t is the transverse propagation constant and k is propagation constant in the medium.

Suppose that a perturbation technique is applied to an initially symmetric GaAs/$Ga_{0.7}Al_{0.3}$As DH structure in which the active region is 2 μm thick. The unperturbed transverse propagation constants for the TE mode are obtained by solving the characteristic equation for the dielectric waveguide [14], [15]. For a lasing wavelength of 0.89 μm, the transverse propagation constants are 1.42×10^4, 2.84×10^4, and 4.26×10^4 cm^{-1} for the fundamental, first-, and second-order transverse modes, respectively. The structure is next perturbed by introducing a p–n′ heteroboundary within the 2-μm waveguide. For the doping levels shown in Fig. 2 and for 3-percent AlAs in the n′-region, the index discontinuity δn_r at the p–n′ heteroboundary is ≈ 0.03 [11]. Therefore, from (1), the sine of the critical angle is

$$\sin \theta_c = 1 - 8.3 \times 10^{-3}. \tag{3a}$$

Similarly, from (2) and the various propagation constants,

the angles of incidence of the modes are obtained from the relations

$$\sin \theta_0 = 1 - 1.5 \times 10^{-3} \tag{3b}$$

$$\sin \theta_1 = 1 - 6 \times 10^{-3} \tag{3c}$$

and

$$\sin \theta_2 = 1 - 14 \times 10^{-3}. \tag{3d}$$

It is obvious from (3a) to (3b) that the fundamental and first-order modes would be totally reflected at the p-n′ heteroboundary. Hence, in this perturbation approximation, the two lowest order modes would be confined to the gain region, and their fields in the unpumped n′-region would decay at an exponential rate k_t' given by

$$k_t' = k(\sin^2 \theta - \sin^2 \theta_c)^{1/2}. \tag{4}$$

Therefore, it is evident from (3b) to (4) that the first-order mode penetrates more deeply into the n′-region than the fundamental mode. These analytical deductions are entirely consistent with experimental observations, such as those given in Figs. 3 and 4, that show confinement of the low-order modes to the gain region.

The second-order mode, on the other hand, can propagate across the p-n′ heteroboundary with a real propagation constant in the n′-region. Such second-order modes are seldom observed experimentally in typical Ppn′N structures since their lasing thresholds are considerably higher than those of the fundamental and first-order modes. The confinement of the low-order modes to the gain region increases their coupling coefficient relative to the high-order modes, and at the same time reduces their mode loss. Hence the low-order modes tend to be the preferred modes.

The relevance of confinement of the fundamental mode within the gain region to far-field measurements of Fig. 6 is self-evident. But first, it should be appreciated that the projection of a divergent beam on a planar surface produces an intensity distribution which should be modified in order to get the angular distribution of the beam. Consider projection on the x-y plane and a source along the z axis at a distance D from the projection plane. If the surface intensity distribution along the x axis is $P(x)$, and the source has an angular distribution $I_s(\theta)$, where θ is measured in the x-z plane, then

$$\frac{P(x)}{P(0)} = \frac{I_s(\theta)}{I_s(0)} \cos^3 \theta \tag{5}$$

where $P(0)$ is the surface intensity at $x = 0$, and $I(0)$ is the source angular intensity along the z axis. Therefore the measured surface intensity distribution plots of Fig. 5 have to be corrected by the $\cos^3 \theta$ factor of (5) in order to get the angular distribution of the beam.

After having properly corrected the results of Fig. 5 to give the true beamwidth transverse to the junction plane, the results can be interpreted. If the fundamental mode were distributed symmetrically throughout the 2.1-μm waveguide, the beamwidth transverse to the junction plane would have been 28° [12]. On the other hand, if the fundamental mode were strongly confined to the 1.2-μm gain region, the beamwidth would have been 40° [12]. The measured beamwidth of 34° transverse to the junction plane therefore implies only partial confinement to the gain region, again consistent with the results of near-field measurements. There is evidently an appreciable contribution to the far field from that fraction of the field that penetrates into the unpumped n′-region.

The fact that the fundamental mode tends to be confined to the gain region more effectively than higher order modes changes the relative electronic gains of the various modes in the Ppn′N structure. If the index discontinuity at the p-n junction were absent, the fundamental mode would have the lowest relative threshold when the gain region is two-thirds of the waveguide thickness [4],[15]. In the Ppn′N structure, fundamental mode confinement to the gain region leads to best mode discrimination when the gain region is roughly half the waveguide width [8].

IV. Conclusion

The near-field emission from GaAs DH injection lasers is studied in an optical method that allows a correlation of the stimulated emission with the various LPE layers. The optical delineation of the LPE layers is accomplished by PL excitation of the laser mirror and the proper choice of optical filters. With a resolution of a few tenths of a micron, the location and shape of the stimulated near fields are related to the waveguide properties. It is found that in the Ppn′N laser where a heteroboundary is utilized to achieve separate optical and carrier confinement, the addition of aluminum in amounts as small as (1-3) percent has a marked influence on the distribution of power within the waveguide. It is found that the fundamental transverse mode is particularly sensitive to refractive-index variations within the waveguide, being contained preferentially in the higher refractive-index gain region.[4] The fringing field of the fundamental mode decays very rapidly in the large bandgap $Ga_{0.7}Al_{0.3}As$ layer, but penetrates more deeply into the passive n′-$Ga_{0.97}Al_{0.03}As$ layer. This containment of the fundamental mode within the gain region explains the experimental observation that catastrophic damage of Ppn′N laser mirrors tends to be most severe in the p-GaAs gain layer [4]. On the other hand, the higher order modes are more difficult to contain within the gain region, although the first-order mode can be excited in the gain region under some conditions that are consistent with analytical predictions. Qualitatively, the containment and symmetry of the high-order modes within the waveguide are used as a sensitive indication of the extent of refractive-index change within the waveguide.

Acknowledgment

The author wishes to thank D. C. Krupka for many useful discussions, and D. L. Van Haren and J. L. Statile for their able assistance in this work.

[4]The fundamental mode is the lowest threshold mode in Ppn′N structures with waveguide thicknesses of 2.5 μm, i.e., 1.5 and 1.0-μm-thick p- and n′-layers, respectively. This is a considerable improvement in fundamental-mode control over conventional symmetric DH lasers where the first-order mode tends to be excited when the thickness of the active region exceeds 0.5 μm.

Effect of External Reflectors on Longitudinal Modes of Distributed Feedback Lasers

WILLIAM STREIFER, SENIOR MEMBER, IEEE, ROBERT D. BURNHAM, AND DONALD R. SCIFRES

Abstract–**The effect of external reflectors on longitudinal modes of distributed feedback (DFB) lasers is analyzed. The general case of dissimilar reflectors arbitrarily located relative to the phase of the DFB structure is considered. An eigenvalue equation for the propagation constants is derived and solved numerically for a variety of practical cases. Longitudinal mode thresholds, wavelengths, separations, and field distributions are obtained for GaAs lasers and for DFB lasers with a single reflector. It is shown that these quantities are very sensitive not only to the relative strength of the discrete and DFB, but also to the relative phases. Quite asymmetric transmitted powers are shown to occur under a variety of circumstances.**

I. INTRODUCTION

LONGITUDINAL modes in a distributed feedback (DFB) laser with external reflectors are studied in this paper. In such devices, internal reflections are caused by a periodic DFB structure. External, as opposed to internal, reflectors may be purposely produced in GaAs diode lasers by cleaving along a crystallographic plane to produce flat parallel surfaces. External reflectors on other DFB lasers can be implemented in obvious ways. Among the reasons for studying such devices is that the combined action of the internal and external reflectors sometimes reduces the laser threshold. Often too, other optical elements, such as couplers, guides, or modulators, within an integrated optic circuit may produce reflections which interact with the DFB structure. Finally, it is frequently convenient to cleave one or both end faces of a DFB diode laser to facilitate the experimental study.

The periodic feedback itself may be effected by variations in refractive index and/or gain or by a physical corrugation in the vicinity of the gain region. Since the latter structure is equivalent to a periodic variation in index and/or gain for most purposes, it suffices to consider

$$n(z) = n + (\Delta n)\cos(2\pi z/\Lambda + \Omega) \tag{1a}$$

and

$$\alpha(z) = \alpha + (\Delta\alpha)\cos(2\pi z/\Lambda + \Omega) \tag{1b}$$

where $n(z)$ is the refractive index, $\alpha(z)$ is the gain, and z is measured along the laser from $-L/2$ to $L/2$. Furthermore, n and α are constants and Δn and $\Delta\alpha$ are the amplitude variations with spatial period Λ and phase Ω. For nonsinusoidal variations (1a) and (1b) include only the constant and fundamental terms of the Fourier expansion. Equations (1a) and (1b) are appropriate only for analyzing first-order Bragg scat-

tering in the DFB structure. Often third-order Bragg scattering is employed in which case

$$n(z) = n + (\Delta n)\cos(6\pi z/\Lambda + \Omega) \tag{2a}$$

and

$$\alpha(z) = \alpha + (\Delta\alpha)\cos(6\pi z/\Lambda + \Omega) \tag{2b}$$

where Δn and $\Delta\alpha$ are the third-harmonic coefficients.

Previous analyses have considered the DFB structure without external reflectors (see Kogelnik and Shank [1]) and with identical external reflectors located exactly symmetric with respect to the grating (see Chinn [2]). The latter analysis is not general in that it does not cover most cases. Specifically, both the following requirements must be met if Chinn's derivation is to apply.

1) The reflectors must have identical reflectivity.

2) The reflectors must be located relative to the grating, such that $\Omega = 0$.

As will be shown, reflector position relative to the peaks and troughs of the grating greatly influences the longitudinal mode structure. Since physical control of the relative reflector-grating position is very difficult (because of the small physical period Λ for visible and near IR lasers), the general case must be considered.

In Section II of this paper the eigenvalue equation for longitudinal modes in a DFB laser with external reflectors is derived. Although the equation is generally applicable, it is solved numerically to yield net threshold gains and wavelengths for some important special cases in Section III, viz., GaAs DFB lasers with two cleaves and DFB lasers with one reflector. Longitudinal mode separations are also calculated and the variation of mode fields along the length of the laser are also determined in Section III. The latter computation yields the ratios of radiated power from each end of the device.

II. Derivation of the Equation

Following [1], [2] we seek solutions of

$$[\nabla^2 + k^2(z)]E(z) = 0 \tag{3}$$

where the time dependence of the electric field $E(z)$ is $e^{i\omega t}$ and

$$k^2(z) \approx \beta^2 + 2i\alpha\beta + 4\kappa\beta\cos(2\beta_0 z + \Omega). \tag{4}$$

Here

$$\beta_0 \triangleq \pi/\Lambda \tag{5a}$$

for first-order Bragg scattering ($3\pi/\Lambda$ for third order)

$$\beta \triangleq n\omega/c \tag{5b}[1]$$

and κ is the coupling coefficient ($\kappa \ll \beta$) given by

$$\kappa = \left(\frac{\beta}{2}\right)\left(\frac{\Delta n}{n}\right) + \frac{i\Delta\alpha}{2}. \tag{5c}$$

The assumptions $\Delta n \ll n$, $\alpha \ll \beta$, and $\Delta\alpha \ll \beta$, were employed in deriving (4). Both β and α are determined by the analysis which follows. Values of α specify net gain at threshold for laser oscillation and those of β specify the allowable values of ω and thereby the free-space wavelength λ_0.

Without loss of generality we seek solutions in the form

$$E(z) = R(z)\,e^{-i\beta_0 z} + S(z)\,e^{i\beta_0 z} \tag{6}$$

where $R(z)$ and $S(z)$ are opposite going waves with $R(z)$ propagating in the direction of increasing z. These functions are assumed to change slowly so that $R''(z)$ and $S''(z)$ can be neglected compared with $\beta_0 R'(z)$ and $\beta_0 S'(z)$. Then upon substitution in (3) we obtain

$$\begin{aligned}&[-2\beta_0 R' - \beta_0^2 R + \beta^2 R + 2i\alpha\beta R]\,e^{-i\beta_0 z}\\ &\quad + [2\beta_0 S' - \beta_0^2 S + \beta^2 S + 2i\alpha\beta S]\,e^{i\beta_0 z}\\ &\quad + 2\kappa\beta\left(e^{i2\beta_0 z}\,e^{i\Omega} + e^{-i2\beta_0 z}\,e^{-i\Omega}\right)\\ &\quad \cdot \left(Re^{-i\beta_0 z} + Se^{i\beta_0 z}\right) = 0\end{aligned} \tag{7}$$

and after isolating expressions with similar z dependence

$$-R' + (\alpha - i\delta)R = i\kappa e^{-i\Omega}S \tag{8a}$$

and

$$S' + (\alpha - i\delta)S = i\kappa e^{i\Omega}R \tag{8b}$$

where

$$\delta \triangleq \beta - \beta_0 \tag{9}$$

$|\delta| \ll \beta$ has been assumed, and terms which propagate as $e^{\pm i3\beta_0 z}$ have been dropped. Since (8a) and (8b) are constant coefficient linear differential equations they admit exponential solutions in the form

$$R(z) = r_1 e^{\gamma z} + r_2 e^{-\gamma z} \tag{10a}$$

and

$$S(z) = s_1 e^{\gamma z} + s_2 e^{-\gamma z} \tag{10b}$$

where r_1, r_2, s_1, and s_2 are constants. Without loss of generality $\mathrm{Re}(\gamma) > 0$, so that r_1 and s_2 grow as they propagate. The combined effects of gain and coupling from opposite going waves ($s_1 \rightarrow r_1$ and $r_2 \rightarrow s_2$) cause the growth. Growing waves have propagation constants given by $\beta_0 - \mathrm{Im}(\gamma)$ [cf. (6)]. The waves multiplied by r_2 and s_1 decay as they propagate with constant given by $\beta_0 + \mathrm{Im}(\gamma)$.

The substitution of (10a) and (10b) in (8a) and (8b) results in four equations when terms with identical z dependence are collected

$$\hat{\Gamma} r_1 = i\kappa e^{-i\Omega} s_1 \tag{11a}$$

$$\Gamma r_2 = i\kappa e^{-i\Omega} s_2 \tag{11b}$$

$$\Gamma s_1 = i\kappa e^{i\Omega} r_1 \tag{11c}$$

$$\hat{\Gamma} s_2 = i\kappa e^{i\Omega} r_2 \tag{11d}$$

where

$$\hat{\Gamma} = -\gamma + \alpha - i\delta \tag{12a}$$

and

$$\Gamma = \gamma + \alpha - i\delta. \tag{12b}$$

[1] A more complicated relation applies for waveguiding structures. In that case an equivalent index n_{eq} should be used in (5b).

These equations have nontrivial solutions if and only if γ satisfies the dispersion relation

$$\gamma^2 = (\alpha - i\delta)^2 + \kappa^2 \tag{13}$$

which, as expected, is independent of Ω.

The actual determination of γ, and thereafter α and δ, is achieved only after imposing the reflection conditions at $z = \pm L/2$. If the reflection coefficient at $z = -L/2$ is denoted by $\hat{\rho}_l$ and that at $z = L/2$ by $\hat{\rho}_r$, we obtain

$$(r_1 e^{-\gamma L/2} + r_2 e^{\gamma L/2})\, e^{i\beta_0 L/2} = \hat{\rho}_l (s_1 e^{-\gamma L/2} + s_2 e^{\gamma L/2})\, e^{-i\beta_0 L/2} \tag{14a}$$

and

$$(s_1 e^{\gamma L/2} + s_2 e^{-\gamma L/2})\, e^{i\beta_0 L/2} = \hat{\rho}_r (r_1 e^{\gamma L/2} + r_2 e^{-\gamma L/2})\, e^{-i\beta_0 L/2}. \tag{14b}$$

Next (11a) and (11d) are employed to eliminate r_2 and s_1 from (14a) and (14b). The latter equations are homogeneous in r_1 and s_2, so that nontrivial solutions exist only if

$$\frac{(1 - \rho_l \hat{\Gamma}/i\kappa)\, e^{-\gamma L}}{(\rho_l - \hat{\Gamma}/i\kappa)} = \frac{(\rho_r - \hat{\Gamma}/i\kappa)\, e^{\gamma L}}{(1 - \rho_r \hat{\Gamma}/i\kappa)} \tag{15}$$

where

$$\rho_l = \hat{\rho}_l e^{-i\beta_0 L}\, e^{i\Omega} \tag{16a}$$

and

$$\rho_r = \hat{\rho}_r e^{-i\beta_0 L}\, e^{-i\Omega}. \tag{16b}$$

Equation (15) can also be derived by setting the coefficient determinant of (11a), (11d), (14a), and (14b) equal to zero.

The phase functions in (16a) and (16b) are just those of the DFB structure at $z = \pm L/2$, i.e., at $z = -L/2$, which is the location of the left reflector, the index variation from (1a) is $\cos(-\beta_0 L + \Omega)$, where as in the preceding $\beta_0 = \pi/\Lambda$. Similarly, at the right reflector $z = L/2$ so that the index variation is $\cos(\beta_0 L + \Omega)$. Values of $-\beta_0 L + \Omega$ and $-\beta_0 L - \Omega$ are shown in Fig. 1(a) and (b), respectively, for various positions of the left and right reflectors in the case of a nonsinusoidal corrugation grating and first-order Bragg scattering. It should be noted that ρ_l and ρ_r also depend on the phase of $\hat{\rho}_l$ and $\hat{\rho}_r$, which are commonly π. In that case all phases in Fig. 1(a) and (b) are shifted by π to obtain those of ρ_l and ρ_r.

By solving (15) for $\hat{\Gamma}/i\kappa$ and employing the relation

$$\gamma = \frac{-i\kappa}{2}\left(\frac{\hat{\Gamma}}{ik} - \frac{ik}{\hat{\Gamma}}\right) \tag{17}$$

which follows from (11a), (11c), (12a), and (12b), we obtain (after substantial manipulation) the eigenvalue equation

$$\gamma L = \frac{-i\kappa L \sinh(\gamma L)}{\mathfrak{D}} \{(\rho_l + \rho_r)(1 - \rho^2)\cosh(\gamma L) \pm (1 + \rho^2)[(\rho_l - \rho_r)^2 \sinh^2 \gamma L + (1 - \rho^2)^2]^{1/2}\} \tag{18}$$

where

$$\mathfrak{D} = (1 + \rho^2)^2 - 4\rho^2 \cosh^2(\gamma L) \tag{19}$$

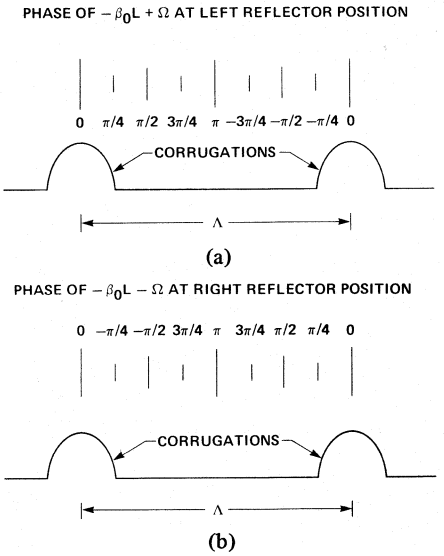

Fig. 1. Phases as a function of left- and right-reflector positions with first-order Bragg scattering.

and

$$\rho^2 = \rho_l \rho_r = \hat{\rho}_l \hat{\rho}_r e^{-2i\beta_0 L}. \tag{20}$$

Values of γ found by solving (18) determine the propagation constants for the longitudinal modes. For each γ, (13) is used to calculate α, which is the net gain required at threshold for that mode to lase and δ, which gives the laser frequency

$$\omega = \frac{c\beta}{n} = \frac{c}{n}(\beta_0 + \delta)$$

of that mode.

For the special case considered by Chinn [2], $\rho_l = \rho_r$, i.e., $\Omega = 0$, (18) reduces to (22). With $\rho_l = \rho_r = 0$ the equation derived by Kogelnik and Shank [1] is recovered.

Equation (18) is in an inconvenient form for solution since it contains a square root, two possible signs, and because the numerator and $\mathfrak{D}$ contain a common factor $\mathfrak{D}^{1/2}$. These difficulties are overcome by rewriting (18) in the form

$$\gamma L\, \mathfrak{D} + i\kappa L(\rho_l + \rho_r)(1 - \rho^2)\sinh(\gamma L)\cosh(\gamma L) = \mp i\kappa L(1 + \rho^2)\sinh(\gamma L)[(\rho_l - \rho_r)^2 \sinh^2(\gamma L) + (1 - \rho^2)^2]^{1/2} \tag{21}$$

squaring (21), and combining terms to obtain

$$(\gamma L)^2 \mathfrak{D} + (\kappa L)^2 \sinh^2(\gamma L)(1 - \rho_l^2)(1 - \rho_r^2) + 2i\kappa L(\rho_l + \rho_r)(1 - \rho^2)\gamma L \sinh(\gamma L)\cosh(\gamma L) = 0 \tag{22}$$

where the factor $\mathfrak{D}$ has been cancelled from the equation. No additional roots have been added by squaring (21) since both negative and positive signs precede the right-hand side.

Clearly, (22) and its solutions are unaffected by interchanging ρ_l and ρ_r. If $\rho_l \to -\rho_l^*$, $\rho_r \to -\rho_r^*$, and $\kappa \to \kappa^*$, then (22) is conjugated except for all functions depending on γL. Thus the solutions are conjugated; α is unchanged, but $\delta \to -\delta$. Conjugating κ is equivalent to shifting the gain variation by π; of

course if $\Delta\alpha = 0$, $\kappa = \kappa^*$. An interesting special case occurs when one reflectance (say ρ_r) is zero. Then $\rho^2 = 0$, $\mathfrak{D} = 1$, and (22) becomes

$$(\gamma L)^2 + (\kappa L)^2 \sinh^2(\gamma L)(1 - \rho_l^2) + 2i\kappa L\rho_l \gamma L \sinh(\gamma L)\cosh(\gamma L) = 0. \quad (23)$$

With $\rho_l = \pm 1$

$$\gamma L \pm 2i\kappa L \sinh(\gamma L)\cosh(\gamma L) = 0 \quad (24)$$

and

$$(2\gamma L) \pm i(2\kappa L)\sinh(2\gamma L) = 0 \quad (25)$$

which is the eigenvalue equation for a DFB laser of length $2L$ without reflectors.

In the limit $\kappa L \to 0$, solutions of (22) are given by

$$\mathfrak{D} = (1 + \rho^2)^2 - 4\rho^2 \cosh^2(\gamma L) = 0 \quad (26)$$

from which it follows that

$$\rho^2 e^{2\gamma L} = \rho_l \rho_r e^{2\gamma L} = 1. \quad (27)$$

Equation (27) expresses the threshold and resonance conditions for a laser with conventional reflectors. For any fixed κL and large values of Im (δL) (far from the Bragg condition) solutions of (22) also approach those given by (26) since $(\gamma L)^2$ has the largest magnitude in (22).

To obtain numerical solutions for the eigenvalues we rewrite (22) symbolically

$$W(\gamma L) = U(\gamma L) + iV(\gamma L) = 0 \quad (28)$$

where U and V are, respectively, the real and imaginary parts of the analytic function $W(\gamma L)$ and

$$\gamma L = x + iy. \quad (29)$$

Thus

$$U(x, y) = 0 \quad (30a)$$

and

$$V(x, y) = 0 \quad (30b)$$

are to be solved simultaneously. Let (x_r, y_r) denote a solution of (30a) and (30b), which is to be determined. Then at any point (x, y) we have

$$U(x_r, y_r) = U(x, y) + \partial U/\partial x|_{x,y}(x_r - x) + \partial U/\partial y|_{x,y}(y_r - y) = 0 \quad (31a)$$

and

$$V(x_r, y_r) = V(x, y) + \partial V/\partial x|_{x,y}(x_r - x) + \partial V/\partial y|_{x,y}(y_r - y) = 0 \quad (31b)$$

where only first-order terms in the expansion about (x, y) have been retained. Equations (31a) and (31b) are now solved for (x_r, y_r), viz.,

$$x_r = x + \frac{V(x,y)\partial U/\partial y - U(x,y)\partial V/\partial y}{D} \quad (32a)$$

and

$$y_r = y + \frac{U(x,y)\partial V/\partial x - V(x,y)\partial U/\partial x}{D} \quad (32b)$$

where

$$D = \frac{\partial U}{\partial x}\frac{\partial V}{\partial y} - \frac{\partial U}{\partial y}\frac{\partial V}{\partial x}. \quad (33)$$

Since (31a) and (31b) are only approximations, so too are (32a) and (32b). The new estimates are then used as (x, y) in (31a) and (31b) and the procedure is continued until U and V are, simultaneously, less than a specified tolerance. In applying this method we also required that (x, y) change less than a tolerance for a point to be accepted as a root. All numerical results in this paper were obtained by the preceding procedure. Usually, depending on the initial values of (x, y), less than nine iterations were required to achieve accuracies of better than 10^{-5}. The calculation was facilitated by the analytic character of $W(\gamma L)$, i.e.,

$$\frac{dW}{d(\gamma L)} = \frac{\partial U}{\partial x} + \frac{i\partial V}{\partial x}$$

and

$$\frac{\partial U}{\partial x} = \frac{\partial V}{\partial y}, \quad \frac{\partial U}{\partial y} = -\frac{\partial V}{\partial x}$$

so that

$$D = \left(\frac{\partial U}{\partial x}\right)^2 + \left(\frac{\partial V}{\partial x}\right)^2.$$

The derivative itself is given by

$$\frac{dW}{d(\gamma L)} = 2\gamma L\,\mathfrak{D} - 8(\gamma L)^2\rho^2 \sinh(\gamma L)\cosh(\gamma L) + 2(\kappa L)^2(1 - \rho_l^2)(1 - \rho_r^2)\sinh(\gamma L)\cosh(\gamma L) + 2i\kappa L(\rho_l + \rho_r)(1 - \rho^2)[\cosh(\gamma L)\sinh(\gamma L) + \gamma L \sinh^2(\gamma L) + \gamma L \cosh^2(\gamma L)]. \quad (34)$$

Occasionally, in applying the preceding method several starting points would converge to the same solution [say $x_r^{(1)}, y_r^{(1)}$]. To overcome this inconvenience $W(\gamma L)$ was divided by $\gamma L - x_r^{(1)} - iy_r^{(1)}$ to remove that root. Equation (34) for $dW/d(\gamma L)$ was then modified in an obvious fashion.

III. Thresholds, Wavelengths, and Mode Fields

The following subsection III-A contains results for longitudinal mode thresholds and frequencies of GaAs DFB lasers with two cleaved ends. In subsection III-B the case $\rho_r = 0.0$ is treated. Zero reflectivity can be achieved (or at least closely approximated) by antireflection coating a laser end surface or by matching an integrated laser to a guide. Various values of ρ_l are studied. Subsection III-C deals with longitudinal mode separation and III-D with fields and power distribution within the laser and transmitted through the end reflectors.

A. GaAs Lasers with Two Cleaved Faces

Since the refractive index ratio at the GaAs:air interface is 3.6, the electric field reflection coefficients are $(\hat{\rho}_l, \hat{\rho}_r) = (-0.565, -0.565)$. Consideration of all possible values of κL, $\beta_0 L$, and Ω is a virtual impossibility and so the discussion is restricted to real κL and values of $\beta_0 L$ which are multiples of $\pi/4$ in the range $-\pi < \beta_0 L \leqslant \pi$. With $-\pi < \Omega \leqslant \pi$ and increments of $\pi/4$ there are 64 possible geometries, but because the results are unchanged for $\rho_l \rightleftharpoons \rho_r$ and the eigenvalues are conjugated either if $(\rho_l, \rho_r) \rightarrow (-\rho_l^*, -\rho_r^*)$ or $(\rho_l, \rho_r) \rightarrow (-\rho_r^*, -\rho_l^*)$ only 13 cases need be treated. These are listed in Table I with their various equivalencies. In Table I the symbols † and †† denote $(-\rho_l^*, -\rho_r^*) = (\rho_l, \rho_r)$ and $(-\rho_l^*, -\rho_r^*) = (\rho_r, \rho_l)$, respectively, for these cases plots of αL versus δL are symmetric about $\delta L = 0$. Plots for $(\rho_l, \rho_r) = (0.565\, e^{i\pi/4}, 0.565\, e^{i\pi/4})$ and $(0.565, 0.565\, e^{i\pi})$ were presented in our earlier paper [3]. Here in Fig. 2, αL (the total net threshold gain) versus δL (which determines laser frequency) with κL (the coupling) as a parameter is shown for $(\rho_l, \rho_r) = (0.565\, e^{i\pi/2}, 0.565\, e^{i\pi/2})$, which is one of the geometries included in [2]. Six longitudinal modes are presented; it should be noted that high-threshold longitudinal modes exist near $\delta L = 0$, which are not shown in Fig. 3 of [2]. This mode, i.e., with minimum, positive δL, is plotted in Fig. 3 with $\hat{\rho}_l = \hat{\rho}_r = -0.565 = 0.565\, e^{i\pi}$, and $e^{-i\beta_0 L} = e^{-i\pi/2}$ for various values of Ω with κL as a parameter along each curve. Setting $e^{-i\beta_0 L} = e^{-i\pi/2}$ (or any other value) fixes the laser length. Then with $\Omega = 0$, the grating is symmetrically located. For first-order Bragg coupling, $\beta_0 = \pi/\Lambda$, and with $\Omega = +\pi/4$ the grating is shifted to the left relative to the reflectors by $\Lambda/8$ [cf. Fig. 1(a) and (b)]; with $\Omega = -\pi/4$ the grating is shifted to the right. Similarly, with $\Omega = \pm\pi/2$ it is shifted by $\Lambda/4$, etc. Note that shifts of $\Omega > \pi$ correspond to shifts of $\Omega < \pi$ and the plot depends only on $|\Omega|$ because of the eigenvalue equation symmetry properties. For third-order Bragg scattering, the third-harmonic refractive index variation is employed, i.e., $\beta_0 L = 3\pi/\Lambda$, and Ω is the phase of that harmonic. The situation for the third harmonic is illustrated in Fig. 4(a) and (b). Fig. 3 also gives values of αL and δL for the mode nearest $\delta L = 0$ with $\delta L < 0$, if every phase shown is changed according to the symmetry conditions discussed previously and listed in Table I. A plot similar to Fig. 2 is shown in Fig. 5 for $(\rho_l, \rho_r) = (0.565, 0.565\, e^{i\pi/2})$. From both figures it is evident, as noted in the previous section, that the thresholds approach those of a conventional cleaved mirror laser without DFB as $|\delta L|$ becomes large. The rate at which this occurs depends on κL.

B. DFB Lasers with One Reflector ($\hat{\rho}_r = 0.0$)

Fig. 6 illustrates αL versus δL for $\delta L > 0$ near the Bragg condition $\delta L = 0$, with $\kappa L = 1.0$, $\rho_r \equiv 0.0$, and ρ_l taking on various values. Once again results for $\delta L < 0$ can be deduced from symmetry considerations. On the solid curves $|\rho_l| =$ constant, whereas phase $(\rho_l) =$ constant along the dashed curves. For $|\rho_l| = 0.0$, the phase is of no consequence and all dashed curves in Fig. 6 converge to $\alpha L = 1.75$, $\delta L = 2.67$, the point appropriate to a DFB laser without external reflectors [1]. For reflectivities $|\rho_l|$ greater than approximately 0.4 all thresholds regardless of phase are lower than $\alpha L = 1.75$. The phase (ρ_l), as noted after (16b), is just that of the grating structure at $z = -L/2$. For $\hat{\rho}_l = |\hat{\rho}_l|\, e^{i\pi}$ reflector positions relative to the grating are illustrated in Fig. 1(a) or Fig. 4(a) by adding π to the phases shown therein. Thus if $\rho_l = \pm 1.0$ the reflector images the grating such that it appears to be a DFB structure of length $2L$ without reflectors, a result which was derived analytically as (25) in the preceding. From Fig. 6, the solutions are $\alpha L = 0.429$, $\delta L = 1.69$ with $\rho_l = -1.0$ and $\alpha L = 0.885$, $\delta L = 3.15$ with $\rho_l = 1.0$. These values equal half those

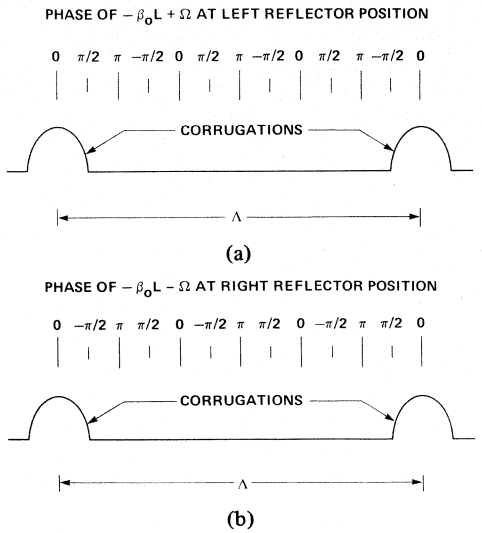

Fig. 4. Phases as a function of left- and right-reflector positions with third-order Bragg scattering.

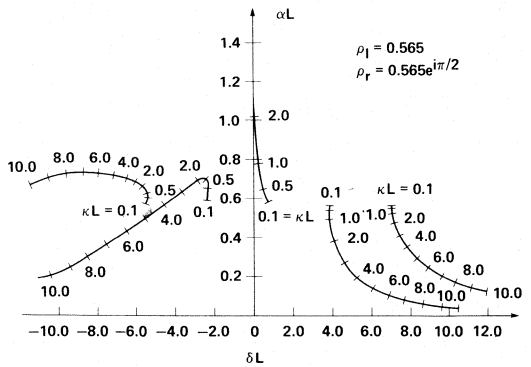

Fig. 5. Threshold and phase for longitudinal modes with κL as a parameter.

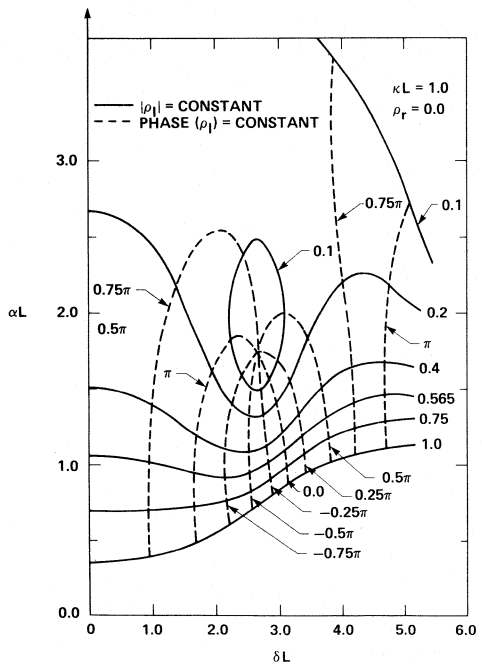

Fig. 6. Threshold and phase for longitudinal modes with $\rho_r = 0.0$ and $\kappa L = 1$. On the solid curves $|\rho_l|$ = constant and on the dashed curves phase (ρ_l) = constant.

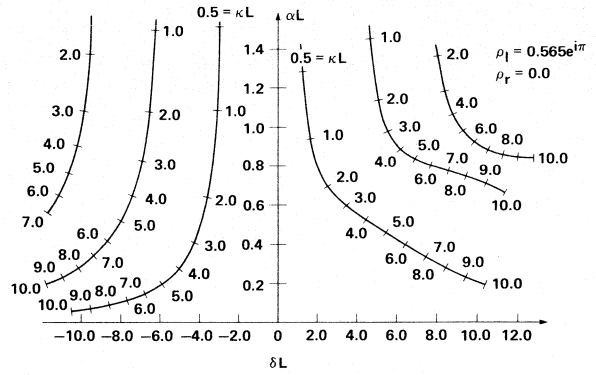

Fig. 7. Threshold and phase for longitudinal modes with κL as a parameter.

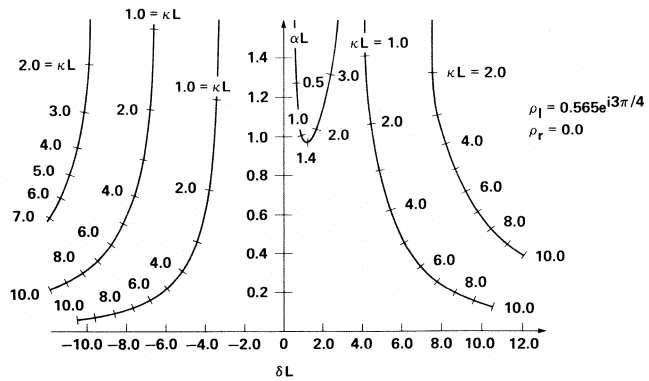

Fig. 8. Threshold and phase for longitudinal modes with κL as a parameter.

for the first and second longitudinal modes (numbering from $\delta L = 0$) of a DFB laser without reflectors and $\kappa L = 2.0$ (see [1]). The factor one-half occurs because (25) is for $2\gamma L$, whereas the equation for the single reflector geometry was solved for γL. Therefore κ, γ, α, and δ are identical in the two cases.

The minimum threshold as a function of phase occurs at $\pi/2$ for $|\rho_l|$ near 1.0 and quickly shifts to the vicinity of $-\pi/2$ as $|\rho_l|$ decreases. Perhaps this result is counterintuitive since placement at 0 or π may appear to optimally image the grating [see Fig. 1(a) and Fig. 4(a)]. It should be understood, however, that a grating length of $2L$ without reflectors and one of length L with one reflector are not identical even if $\rho_l = \pm 1.0$. This is the case because gratings continuously couple left and right going waves and the reflection interchanges directions and superimposes the wave differently. Furthermore, the threshold depends on the exact frequency of the waves (determined by δL) and their phases so that the preceding picture is overly simplistic.

Fig. 7 illustrates αL versus δL for six longitudinal modes with $\rho_r = 0.0$ and $\rho_l = 0.565\, e^{i\pi}$. For small κL, the reflector is relatively more important than the grating in determining device behavior, but as κL increases to overcoupled values the grating dominates. In fact, as shown in Fig. 8 for $\rho_l = 0.565\, e^{i3\pi/4}$, the mode with minimum $|\delta L|$, which does not exist in the pure DFB device, has an increasing threshold for $\kappa L \gtrsim 1.4$. For the other modes the threshold is generally lower with one reflector present rather than absent, although differences diminish with increasing κL.

C. Mode Separation

Longitudinal mode separation is obtained from differences in δL. If $\Delta(\delta L)$ is the difference between the ith and jth modes, then

$$\Delta(\delta L) = (\beta_i L - \beta_j L) = 2\pi L(n_{eq}^i/\lambda_i - n_{eq}^j/\lambda_j) \tag{35}$$

where λ_i, λ_j are the free-space wavelengths and n_{eq}^i, n_{eq}^j are the equivalent refractive indices, taking into account the laser waveguiding structure. As is customary we write

$$n_{eq}^j = n_{eq}^i + (dn_{eq}/d\lambda)_i(\lambda_j - \lambda_i)$$

substitute in (35) and solve for $\lambda_j - \lambda_i$ to obtain

$$\lambda_j - \lambda_i = \frac{\lambda_i\lambda_j\Delta(\delta L)}{2\pi n_{eq}^i L[1 - (dn_{eq}/d\lambda)_i(\lambda_i/n_{eq}^i)]}. \tag{36}$$

Often n_{eq} will approximate the active region index, $\lambda_i \approx \lambda_j$ (say λ), and $n_{eq}^i \approx n_{eq}^j$ (say n) so that

$$\lambda_j - \lambda_i = \frac{\lambda^2\Delta(\delta L)}{2\pi nL[1 - (dn/d\lambda)(\lambda/n)]}. \tag{37}$$

For $\Delta(\delta L) = \pi$, which is approximately correct for many of the longitudinal modes illustrated in this paper, this equation becomes

$$\lambda_j - \lambda_i = \frac{\lambda^2}{2nL[1 - (dn/d\lambda)(\lambda/n)]}. \tag{38}$$

This is the same result as for conventional lasers.

D. Mode Fields

Since saturation effects have not been considered the analysis applies only at threshold and absolute values of r_1, r_2, s_1, and s_2 in (10a) and (10b) cannot be determined. Instead, relative amplitudes, and thereby the energy distribution, within the DFB structure are computed as are the relative energies transmitted through the external reflectors.

From (11a) we have

$$r_1 = (i\kappa e^{-i\Omega}/\hat{\Gamma})s_1 \tag{39a}$$

and from (11d) and (14a)

$$r_2 = \frac{(1 - \rho_l\hat{\Gamma}/i\kappa)}{(\rho_l - \hat{\Gamma}/i\kappa)} e^{-i\Omega} e^{-\gamma L} s_1. \tag{39b}$$

In the special case $\rho_l = 0.0$

$$r_2 = -e^{-\gamma L} r_1 \tag{40}$$

so that

$$r_1 e^{\gamma z} + r_2 e^{-\gamma z} = 2r_1 e^{-\gamma L/2} \sinh[\gamma(z + L/2)] \tag{41}$$

in agreement with earlier results [1]. For $\rho_l = \pm 1.0$

$$r_2 = e^{-i\Omega} e^{-\gamma L} s_1. \tag{42}$$

From (39b) and (11d), we find

$$s_2 = \frac{i\kappa}{\hat{\Gamma}} \frac{(1 - \rho_l\hat{\Gamma}/i\kappa)}{(\rho_l - \hat{\Gamma}/i\kappa)} e^{-\gamma L} s_1 \tag{43}$$

which, by invoking (15), can be rewritten

$$s_2 = \frac{i\kappa}{\hat{\Gamma}} \frac{(\rho_r - \hat{\Gamma}/i\kappa)}{(1 - \rho_r\hat{\Gamma}/i\kappa)} e^{\gamma L} s_1. \tag{44}$$

Then with $\rho_r = 0.0$

$$s_2 = -e^{\gamma L} s_1 \tag{45}$$

so that

$$s_1 e^{\gamma z} + s_2 e^{-\gamma z} = 2s_1 e^{\gamma L/2} \sinh[\gamma(z - L/2)] \tag{46}$$

and with $\rho_r = \pm 1.0$

$$s_2 = \frac{i\kappa}{\hat{\Gamma}} e^{\gamma L} s_1 = e^{i\Omega} e^{\gamma L} r_1 \tag{47}$$

where (11a) has been employed.

The power in the wave $R(z)$ at any point in the DFB structure is

$$P_a(z) = c_1|r_1 e^{\gamma z} + r_2 e^{-\gamma z}|^2 \tag{48a}$$

that in $S(z)$ is

$$P_b(z) = c_1|s_1 e^{\gamma z} + s_2 e^{-\gamma z}|^2 \tag{48b}$$

where c_1 is a constant. The transmitted power through the right- and left-hand reflectors is

$$P_r = (1 - |\rho_r|^2)P_a(L/2) \tag{49a}$$

and

$$P_l = (1 - |\rho_l|^2)P_b(L/2) \tag{49b}$$

respectively. For $\rho_r = \rho_l$, $P_r = P_l$ for all modes as can be verified from the preceding formulas. Physically, this must be the case since the geometry is completely symmetric. However, if $\rho_l \neq \rho_r$, even if the magnitudes of the reflections are equal, $|\hat{\rho}_l| = |\hat{\rho}_r|$, P_r and P_l generally differ for each mode because of the phase difference. For the geometries marked † and †† in Table I, the modes and ratios P_r/P_l and P_l/P_r are symmetric about $\delta L = 0.0$. In Table II are listed values of αL, δL, and P_r/P_l for $(\rho_l, \rho_r) = (0.565, 0.565\, e^{i\pi/2})$ with $\kappa L = 1.0$. Note that the mode with maximum αL, i.e., minimum $|\delta L|$ also has the highest ratio $P_r/P_l = 5.0586$, all modes with $\delta L > 0$ have $P_r/P_l > 1.0$ and those with $\delta L < 0$ have $P_r/P_l < 1.0$. This is not a general characteristic, e.g., with $(\rho_l, \rho_r) = (0.565\, e^{-i\pi/4}, 0.565\, e^{i\pi/4})$, $P_r/P_l > 1.0$ for all modes. It is always true, however, that as $|\delta L|$ increases P_r/P_l approaches unity, since

TABLE II
VALUES OF αL, δL, AND P_r/P_l, THE RATIO OF TRANSMITTED POWER THROUGH THE LEFT REFLECTOR TO THAT TRANSMITTED THROUGH THE RIGHT REFLECTOR FOR NINE LONGITUDINAL MODES WITH $\rho_l = 0.565$, $\rho_r = 0.565e^{i\pi/2}$ AND $\kappa L = 1.0$

αL	δL	P_r/P_l
0.5969	-11.775	0.9023
0.6066	-8.632	0.8676
0.6278	-5.490	0.7956

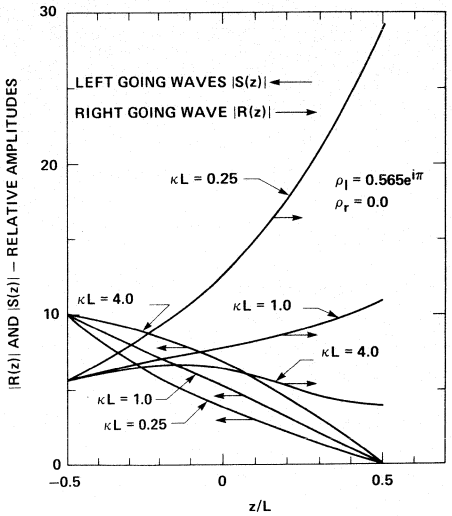

Fig. 9. Amplitudes of traveling waves for the first longitudinal mode (minimum $|\delta L|$) with $\delta L > 0$ and various κL.

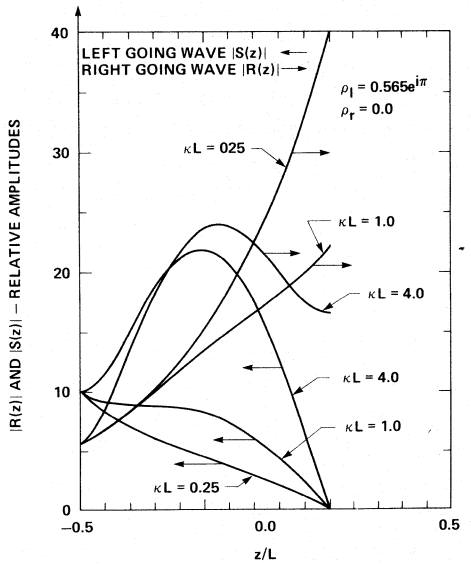

Fig. 10. Amplitudes of traveling waves for the first longitudinal mode (minimum $|\delta L|$) with $\delta L < 0$ and various κL.

then the longitudinal modes are primarily determined by the external reflectors and not the DFB structure.

In Figs. 9 and 10 are plotted $|R(z)|$ and $|S(z)|$ for the two longitudinal modes with minimum $|\delta L|$ and $\delta L > 0$, $\delta L < 0$, respectively. Here $(\rho_l, \rho_r) = (0.565\, e^{i\pi}, 0.0)$ and $\kappa L = 0.25$, 1.0, 4.0. In the undercoupled case ($\kappa L = 0.25$) the fields are approximately given by a single exponential, viz., $R(z) \sim r_1 e^{\gamma z}$, $S(z) \sim s_2 e^{-\gamma z}$. With increasing coupling ($\kappa L = 1.0$) both exponential terms in $R(z)$ and $S(z)$ are nonnegligible and in the overcoupled case Re (γL) is so small that the exponentials are more nearly oscillating functions. Power flows are proportional to the squares of the plotted fields and it is interesting to compute the ratio of transmitted power from (49a) and (49b). We find, for $\kappa L = 0.25$ and $\delta L > 0$, $P_r/P_l \approx 125$ whereas with $\delta L < 0$, $P_r/P_l \approx 245$.

IV. Remarks

The results presented in this paper provide insight into the longitudinal mode behavior of DFB lasers with external reflectors. We have shown that the relative positions of the reflectors and grating are of critical importance in determining laser thresholds, frequencies, and relative transmitted powers, which can differ markedly. The results were obtained under various assumptions, viz., the reflectors are aligned with the grating κ, the absorption, and the pumping are uniform along the laser length, all nonlinear effects of saturation, pumping, and spontaneous emission are neglected as is scattering from the grating other than into the desired Bragg order. No doubt these phenomena will affect comparisons with experimental results.

Light Scattering from Periodic Refractive-Index Fluctuations in Asymmetric Slab Waveguides

D. MARCUSE, FELLOW, IEEE

Abstract—**We consider scattering of light out of the guiding layer into the substrate and the airspace of an asymmetric slab waveguide caused by periodic refractive-index fluctuations. Also discussed is the effect of backscattering of a guided wave into itself. The periodic index fluctuations may be caused by an acoustic surface wave. For this reason, we assume that the intensity of the index fluctuations decreases exponentially with increasing depth below the surface of the guide. However, our discussion is general, and the acoustic surface wave is used only as an example. Numerical results and graphic examples are given.**

INTRODUCTION

ACOUSTOOPTIC light deflectors using a surface acoustic wave and an optical wave that is guided by a thin-film waveguide have been discussed in the literature [1], [2]. However, a theoretical analysis of the asymmetric slab waveguide with periodic refractive-index fluctuation does not seem to have been published.

In this paper we are considering an asymmetric slab waveguide defined by the refractive-index distribution

$$n_0(x) = \begin{cases} n_3, & \text{for } x > 0 \\ n_1, & \text{for } 0 \geqslant x \geqslant -d \\ n_2, & \text{for } -d \geqslant x > -\infty. \end{cases} \tag{1}$$

The waveguide, its index distribution, and the coordinate system used to describe it are shown schematically in Fig. 1. The guided and radiation modes of this structure are well known [3]. The example of an asymmetric slab guide serves as a model for more general diffused waveguides.

The acoustic surface wave influences the refractive-index distribution. We ignore its time variation so that frequency-modulation effects caused by the interaction between the acoustic wave and the light wave are neglected. In the presence of the acoustic wave, we describe the refractive-index distribution by the equation

$$n(x) = \begin{cases} n_0(x), & \text{for } x > 0 \\ n_0(x) + \dfrac{(\Delta n_1^2)}{2n_1} e^{x/D} \cos \theta z, & \text{for } 0 \geqslant x > -d \\ n_0(x) + \dfrac{(\Delta n_2^2)}{2n_2} e^{x/D} \cos \theta z, & \text{for } -d \geqslant x > -\infty \end{cases} \tag{2}$$

with $n_0(x)$ given by (1). The form of these equations shows that we assume that the acoustic wave does not reach into the region $x > 0$, which is the airspace above film and substrate, so that $n_3 = 1$ in most cases of interest.

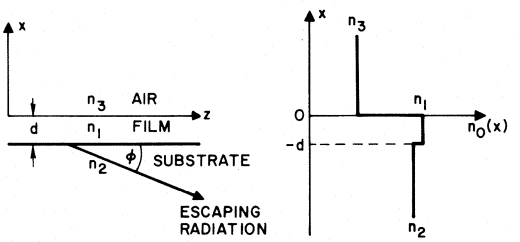

Fig. 1. Schematic of the asymmetric slab waveguide and its refractive-index distribution.

The acoustic wave decays in intensity with increasing distance below the surface of the asymmetric slab. Its intensity is assumed to have decayed to $1/e$ of its maximum value (at $x = 0$) at a depth of $x = D$. In the z direction, which coincides with the direction of propagation of the light wave, the acoustic wavelength is

$$\Lambda = \frac{2\pi}{\theta}. \tag{3}$$

The small factors (Δn_1^2) and (Δn_2^2) appearing in (2) depend on the power in the acoustic wave and on the acoustooptic coefficient of the materials. The form of (2) was chosen so that $n^2(x) \approx n_0^2(x) + (\Delta n^2)\, e^{x/D} \cos \theta$.

A general discussion of asymmetric slab waveguides with sinusoidal imperfections is given in [3]. It is well known that two light waves interact with each other via the acoustic wave, provided the phase-matching relation

$$|\beta_1 - \beta_2| = \theta \tag{4}$$

holds. The propagation constants β_1 and β_2 of the two optical modes may both belong to guided waves. In this case, the interaction converts power from one guided mode to another. In particular, it is possible to convert power from a given guided mode to its backward-traveling counterpart so that $\beta_2 = -\beta_1$. We shall discuss this case in detail. Another case of practical interest arises when β_2 is the z component of the propagation vector of a radiation mode. Of most interest is the case when the radiation escapes only into the substrate since it involves interaction with acoustic waves of relatively low frequency. The magnitude of the propagation vector of a plane wave in the substrate is $n_2 k$ ($k = 2\pi/\lambda$, free-space propagation constant). We thus have the relation

$$\beta_2 = n_2 k \cos \phi \tag{5}$$

where ϕ is the angle between the direction of the light beam and the film boundary. This angle is thus determined in terms of the propagation constant θ of the acoustic wave and the

propagation constant $\beta_1 = \beta_g$ of the guided optical mode by the relation

$$\phi = \arccos\left(\frac{\beta_g - \theta}{n_2 k}\right). \tag{6}$$

Since the frequency of the acoustic wave can be varied with a corresponding change of θ, the direction of the emerging optical beam can be changed, resulting in an optical-beam scanning device.

The efficiency of the beam scanner can be expressed in terms of the attenuation suffered by the guided wave. It is shown in [3] that light scattering by a sinusoidal imperfection of an optical waveguide causes the guided wave to decay exponentially in z direction according to the law

$$P(z) = P(0)\, e^{-2\alpha z}. \tag{7}$$

The form of the radiation field in the substrate of the guide is given by [3, eq. (4.2-39)]. The attenuation coefficient α appearing in (7) is sufficient to characterize the interaction between the guided mode and the acoustic wave, provided that the propagation constant of the acoustic wave is such that radiation, instead of coupling to other guided modes, results. In particular, we obtain only one radiated beam directed into the substrate if the relation

$$n_2 k > (\beta_g - \theta) > n_3 k \tag{8}$$

holds. For larger values of θ satisfying

$$n_3 k > (\beta_g - \theta) > -n_3 k \tag{9}$$

a second beam escapes into the airspace above the guiding layer. The total radiated power is now shared by the beam in the substrate and by the beam in air, but the attenuation coefficient α still indicates the total amount of power that is lost from the guided wave. This latter case is of less interest since it requires an acoustic wave of higher frequency which is highly attenuated in most materials.

As an example of guided-wave interaction, we limit ourselves to the case of scattering from a guided mode to its backward-traveling counterpart. This interaction takes place if

$$\theta = 2\beta_g. \tag{10}$$

This process requires very high acoustic frequencies, but it may be of practical interest because it is much more efficient than coupling from a guided mode to radiation. The interaction between two guided waves traveling in opposite directions is given by the equations [3]

$$c_1(z) = Ae^{-Rz} \tag{11}$$

and

$$c_2(z) = -Ae^{-Rz}. \tag{12}$$

The wave amplitude c_1 belongs to the wave traveling in the positive z direction, while c_2 is the amplitude of the wave traveling in the negative z direction. These equations apply to the special case that $c_1 = A$ at $z = 0$, and $c_2 = 0$ at $z = \infty$. It is apparent that wave 1 decays exponentially in its direction of propagation, while wave 2 grows as it advances in the guide.

The computation and discussion of the attenuation coefficient α and the coupling coefficient R will occupy the remainder of this paper.

Loss and Coupling Coefficient

Coupling between two modes (guided or radiation modes) is described by coupling coefficients of the approximate form [4], [3, p. 104, eq. (3.2-44), and p. 168, eq. (4.7-5)]

$$K_{\mu\nu} = \frac{\omega\epsilon_0}{4iP}\int_{-\infty}^{\infty} (n^2 - n_0^2)\, \mathfrak{E}_\mu^* \cdot \mathfrak{E}_\nu \, dx. \tag{13}$$

The radian frequency of the optical waves is designated as ω, and ϵ_0 is the dielectric permittivity of the vacuum. The expression is already simplified for the case of a slab waveguide by omitting integration in the y direction; consequently, P is the power-normalization coefficient of dimension watts/meter (unit length in the y direction, the direction in which no variation of any field quantities or waveguide irregularities occur). The refractive-index distribution $n = n(x)$ is given by (2), while $n_0 = n_0(x)$, the index distribution of the unperturbed waveguide, is given by (1). The script letters $\mathfrak{E}_\mu$ and $\mathfrak{E}_\nu$ indicate the electric-field vectors of the two coupled modes without their time and z variation. The asterisk stands for the complex conjugation. The subscripts μ and ν label the guided or radiation modes.

We substitute (1) and (2) into (13), neglect terms of the second order in (Δn^2), and omit the cosine factor obtaining

$$\hat{K}_{\mu\nu} = \frac{\omega\epsilon_0}{4iP}\int_{-\infty}^{0} (\Delta n^2)\, e^{x/D}\, \mathfrak{E}_\mu^* \cdot \mathfrak{E}_\nu \, dx. \tag{14}$$

The caret serves as a reminder that $\cos\theta z$ is absent from (14). The notation (Δn^2) indicates that either (Δn_1^2) or (Δn_2^2) must be used depending on whether the integration variable is in the range $0 \geqslant x \geqslant -d$ or $-d > x > -\infty$. The constant R appearing in (11) and (12) is related to $\hat{K}_{\mu\nu}$ by the equation [3]

$$R = \tfrac{1}{2}\,|\hat{K}_{\mu\nu}|. \tag{15}$$

Substitution of the fields for $\mathfrak{E}_\mu$ and $\mathfrak{E}_\nu$ results in the following explicit form of the coupling coefficient for a guided wave and its backward-traveling counterpart

$$R = \frac{k^2\kappa^2}{2\beta_g\left(d + \frac{1}{\gamma} + \frac{1}{\delta}\right)}\left\{(\Delta n_1^2)\left[\frac{D}{2\kappa^2}(1 - e^{-(d/D)}) + \frac{\left(\frac{1}{2D}\cos 2\psi + \kappa \sin 2\psi\right) - e^{-(d/D)}\left[\frac{1}{2D}\cos(2\kappa d - 2\psi) - \kappa \sin(2\kappa d - 2\psi)\right]}{\kappa^2\left(\frac{1}{D^2} + 4\kappa^2\right)}\right] + (\Delta n_2^2)\,\frac{e^{-(d/D)}}{(\kappa^2 + \gamma^2)\left(2\gamma + \frac{1}{D}\right)}\right\} \tag{16}$$

with

$$\tan \psi = \frac{\delta}{\kappa} \tag{17}$$

$$\kappa^2 = n_1^2 k^2 - \beta_g^2 \tag{18}$$

$$\gamma^2 = \beta_g^2 - n_2^2 k^2 \tag{19}$$

and

$$\delta^2 = \beta_g^2 - n_3^2 k^2. \tag{20}$$

$$\alpha = \frac{\pi}{4}\frac{\beta}{\rho}\sum_i |\hat{K}_{\mu\rho}^{(i)}|^2. \tag{25}$$

The form of the coefficient $\hat{K}_{\mu\rho}^{(i)}$ depends on the value of the propagation constant θ of the acoustic wave. If the inequality (8) applies, radiation is emitted only into the substrate because the guided mode interacts only with radiation modes that decay exponentially into the airspace of index n^3. This behavior is, of course, a consequence of total internal reflection at the air-film interface. In this case we obtain from (14), with the help of the guided and radiation modes listed in [3],

$$\hat{K}_{\mu\rho}^{(1)} = \frac{\kappa k^2}{\left[\pi\beta_g\left(d + \frac{1}{\gamma} + \frac{1}{\delta}\right)(\kappa^2 + \delta^2)\right]^{1/2}} \times \frac{\rho\sigma G_1}{\{\beta[\rho^2(\sigma\cos\sigma d + |\Delta|\sin\sigma d)^2 + \sigma^2(\sigma\sin\sigma d - |\Delta|\cos\sigma d)^2]\}^{1/2}} \tag{26}$$

Two special cases are of interest. For very small values of the penetration depth D of the acoustic wave, the index fluctuations are restricted to the immediate vicinity of the air-film interface so that the perturbation becomes equivalent to a sinusoidal distortion of that interface. The slab waveguide with sinusoidal interface distortion is described in [3]. If the interface distortion is given by the function

$$f(z) = b\cos\theta z \tag{21}$$

we find the equivalence

$$(\Delta n_1^2) = \frac{n_1^2 - n_2^2}{D} b \qquad \text{for } D \to 0 \tag{22}$$

and obtain from (16)

$$R = \frac{\kappa^2 b}{2\beta_g\left(d + \frac{1}{\gamma} + \frac{1}{\delta}\right)} \qquad \text{for } D \to 0 \tag{23}$$

in agreement with [3, eq. (4.2-3)] (specialized to the case of coupling between two waves traveling in opposite directions). In the other extreme, $D \to \infty$, we obtain from (16), for $(\Delta n_1^2) = (\Delta n_2^2) = (\Delta n^2)$,

$$R = \frac{(\Delta n^2) k^2}{4\beta_g\left(d + \frac{1}{\gamma} + \frac{1}{\delta}\right)}\left\{d + \frac{1}{\kappa^2 + \gamma^2} \times \left[\frac{\kappa^2}{\gamma} + \frac{(\gamma + \delta)(\kappa^2 + \gamma\delta)}{\kappa^2 + \delta^2}\right]\right\}. \tag{24}$$

The attenuation coefficient α, describing coupling between a guided mode and a very narrow band of radiation modes, is given by the expression[1]

with

$$G_1 = (\Delta n_1^2)\int_{-d}^{0} e^{x/D}\left(\cos\kappa x - \frac{\delta}{\kappa}\sin\kappa x\right) \times \left(\cos\sigma x - \frac{|\Delta|}{\sigma}\sin\sigma x\right) dx + (\Delta n_2^2)\left(\cos\kappa d + \frac{\delta}{\kappa}\sin\kappa d\right) e^{-(d/D)} \times \int_{-\infty}^{0}\left[\left(\cos\sigma d + \frac{|\Delta|}{\sigma}\sin\sigma d\right)\cos\rho x + \left(\frac{\sigma}{\rho}\sin\sigma d - \frac{|\Delta|}{\rho}\cos\sigma d\right)\sin\rho x\right] e^{[\gamma + (1/D)]x}\, dx. \tag{27}$$

In addition to the parameters that were already defined by (18)–(20), we have

$$\beta = \beta_g - \theta \tag{28}$$

$$\sigma^2 = n_1^2 k^2 - \beta^2 \tag{29}$$

$$\rho^2 = n_2^2 k^2 - \beta^2 \tag{30}$$

and

$$\Delta^2 = n_3^2 k^2 - \beta^2. \tag{31}$$

The integrals occurring in (27) have elementary solutions and can be found in [5]. We refrain from writing out their solutions to save space.

Finally, we need the coupling coefficient for the case (9). There are two types of radiation modes, and the sum in (25) must be extended over the contributions from both types of modes [3]. We indicate the two types with labels 2 and 3 and obtain ($i = 2, 3$)

[1] Equation (25) is obtained from [3, eqs. (3.4-19) and (4.2-24)].

$$\hat{K}_{\mu\rho}^{(i)} = \frac{\kappa k^2}{\left[\pi\beta_g\left(d + \frac{1}{\gamma} + \frac{1}{\delta}\right)(\kappa^2 + \delta^2)\right]^{1/2}} \times \frac{G_i}{\left\{\beta\left[(\cos \sigma d - F_i \sin \sigma d)^2 + \frac{\sigma^2}{\rho^2}(\sin \sigma d + F_i \cos \sigma d)^2 + \frac{\Delta}{\rho}\left(1 + \frac{\sigma^2}{\Delta^2} F_i^2\right)\right]\right\}^{1/2}} \tag{32}$$

with

$$F_i = \frac{1}{(\sigma^2 - \rho^2)\sin 2\sigma d}\left\{(\sigma^2 - \rho^2)\cos 2\sigma d + \frac{\rho}{\Delta}(\sigma^2 - \Delta^2) \pm \left[(\sigma^2 - \rho^2)^2 + 2\frac{\rho}{\Delta}(\sigma^2 - \rho^2)(\sigma^2 - \Delta^2)\cos 2\sigma d + \frac{\rho^2}{\Delta^2}(\sigma^2 - \Delta^2)^2\right]^{1/2}\right\} \tag{33}$$

and with

$$G_i = (\Delta n_1^2)\int_{-d}^{0}\left(\cos \kappa x - \frac{\delta}{\kappa}\sin \kappa x\right)(\cos \sigma x + F_i \sin \sigma x) \times e^{x/D}\, dx + (\Delta n_2^2)\left(\cos \kappa d + \frac{\delta}{\kappa}\sin \kappa d\right)e^{-(d/D)} \times \int_{-\infty}^{0}\left[(\cos \sigma d - F_i \sin \sigma d)\cos \rho x + \frac{\sigma}{\rho} \times (\sin \sigma d + F_i \cos \sigma d)\sin \rho x\right]e^{[\gamma + (1/D)]x}\, dx. \tag{34}$$

Discussion of Numerical Results

A natural application for an acoustooptic device of this type appears to be an asymmetric slab waveguide that consists of a thin guiding layer on top of a substrate of essentially the same material. The refractive index of the guiding layer may be increased by means of diffusion of a dopant or by outdiffusion of some component of the material. An example of the latter technique is given by the outdiffusion of Li from $LiNbO_3$ [6] or by the diffusion of metals into $LiNbO_3$ [7]. The advantage of this arrangement is the fact that $LiNbO_3$ is piezoelectric so that the acoustic wave can be excited simply by placing interdigital electrodes on the top of the material. Since the material of the guiding layer is practically identical with the material of the substrate, we use in this case

$$(\Delta n_1^2) = (\Delta n_2^2) = (\Delta n^2). \tag{35}$$

To calculate the effect of the wave interaction for this case we assume that the film thickness is $d = 1$ μm. For HeNe laser light with the wavelength of $\lambda = 0.6328$ μm, we have $kd = 9.9292$. The refractive index of the substrate is $n_2 = 2.2$, and for the film we use $n_1 = 2.21$. With $n_3 = 1$, we have, for the lowest order TE mode, $\kappa d = 1.899153$. Fig. 2 shows a plot of the attenuation constant that is obtained from (25)-(34). Instead of plotting α directly, we take the logarithm (to base 10) of the suitably normalized loss coefficient and divide it by 10. This method is necessary in order to plot the attenuation coefficient over a wide range of values of the independent variable θ/n_2k. Also shown is the angle ϕ of (6) at which the radiation escapes into the substrate. The curves extend symmetrically beyond $\phi = 90°$ so that $\alpha(180 - \phi) = \alpha(\phi)$. The various curves in Fig. 2 belong to different penetration depths D of the acoustic wave. Large values of D/d indicate that the acoustic wave reaches deep into the substrate; values of D/d less than unity indicate that the acoustic wave decreases in intensity even inside the guiding layer for the light wave.

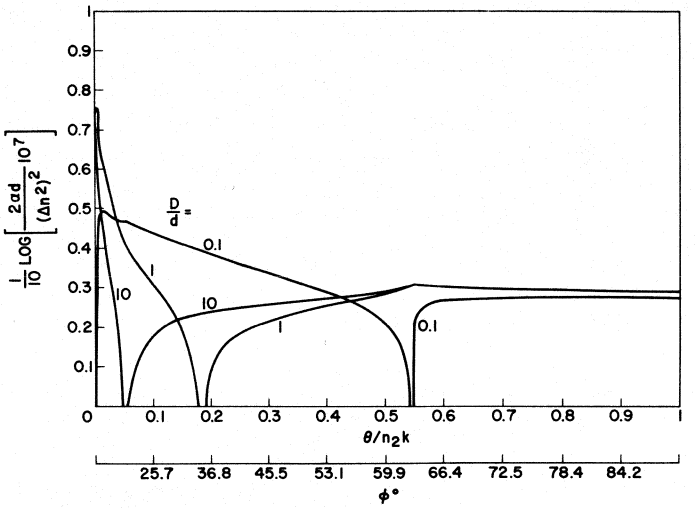

Fig. 2. Logarithmic plot of the normalized loss coefficient $2\alpha d/(\Delta n^2)^2$ as a function of the normalized propagation constant of the acoustic wave θ/n_2k or, equivalently, of the radiation angle ϕ in the substrate. Here, $n_1 = 2.21$, $n_2 = 2.2$, $n_3 = 1$, $kd = 9.9292$, and $\kappa d = 1.8992$.

The curves shown in Fig. 2 pass through zero at certain values of θ/n_2k or the corresponding angles ϕ. This vanishing of the coupling is an interference effect. According to Huygen's principle, we may assume that each element of the acoustic wave front acts as a point source of radiation. The magnitude of the resulting scattered light wave depends on the phase relationships of all the elementary waves to each other. At very small radiation angles, all contributions from one acoustic phase front add in phase, leading to the large peaks for small values of ϕ seen in Fig. 2. With increasing angle (the change in angle is accomplished by changing the propagation constant of the acoustic wave), the contributions from opposite ends of the acoustic phase front begin to cancel until, for certain radiation angles, complete cancellation results.

The slight kink in the curves at $\theta/n_2k = 0.545$ indicates the point at which radiation begins to escape, not only into the substrate, but also into the airspace above the guiding layer.

Since small radiation angles are of particular interest, the region $0 < \phi < 15°$ is shown stretched out in Fig. 3. The most striking features of these curves are the sharp peak values appearing at low radiation angles. The actual values of the radia-

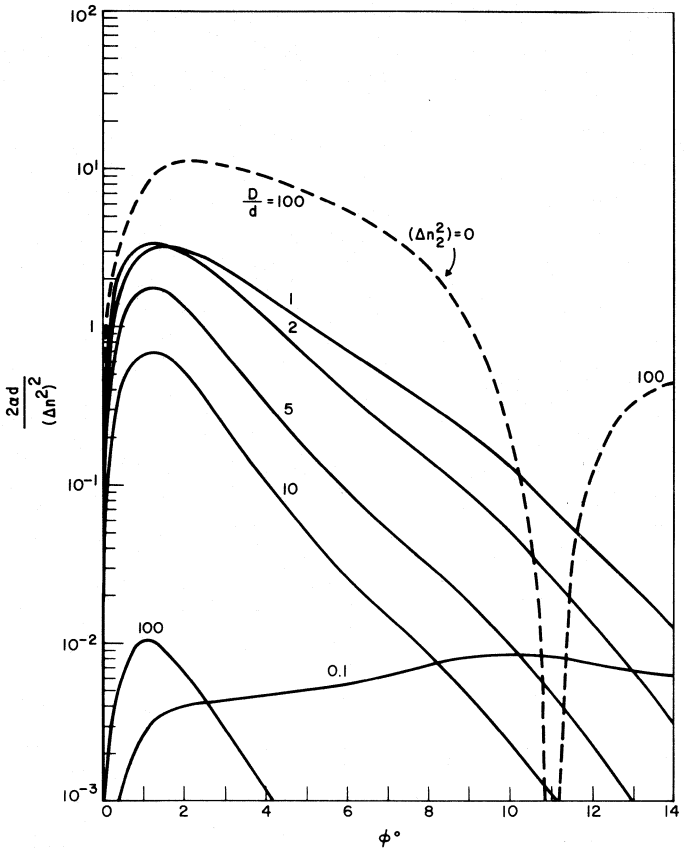

Fig. 3. An expansion of the loss coefficient shown in Fig. 2 for small angles ϕ.

tion peaks are determined by two competing effects. For a given value of (Δn^2) the volume of index fluctuations available for scattering increases with increasing penetration depth of the acoustic wave (increasing values of D/d). We would thus expect to see the radiation peak increase as D/d increases. This obvious effect is apparent only for the curve for $D/d = 0.1$ in comparison to the curves with $D/d = 1$ through 10. For all the other curves, the situation is reversed. This reversal is caused by mode orthogonality. If the acoustic wave would extend throughout all space with $D/d = \infty$, and the same value of (Δn^2) in all three regions, the integral in (14) would vanish because of mode orthogonality. The more uniform the acoustic wave becomes, the less contribution can be expected from the overlap integral in (14). In fact, it is because the acoustic wave does not extend into the airspace that we have a finite contribution to the scattering process even for $D/d = \infty$.

Mode orthogonality makes this type of acoustooptic coupler or beam scanner an inefficient device. It could work effectively only for small values of D/d. However, since the acoustic surface wave penetrates into the material to a depth that is comparable to its wavelength (which is much larger than that of the optical wave), small values of D/d cannot be obtained at low acoustical frequencies. The mode-orthogonality effect can be counteracted also by using materials for the guiding layer and substrate with different acoustooptic coefficients so that (Δn_1^2) and (Δn_2^2) become different. However, even in this case we may expect a poor coupling efficiency for large values of D/d and for tightly guided optical waves whose energy is contained almost exclusively inside the guiding layer. Good efficiency results only for waves close to cutoff that carry significant amounts of power in the substrate.

As an example, we consider the case of a slab waveguide whose acoustooptical coefficient is very small in the substrate by setting $(\Delta n_2^2) = 0$. Leaving the other waveguide parameters unchanged, we obtain the dotted curve shown in Fig. 3 for $D/d = 100$. Since mode orthogonality is less effective when the substrate no longer takes part in light scattering, the coupling efficiency is improved by three orders of magnitude. The same result is obtained with $(\Delta n_1^2) = 0$ and $(\Delta n_2^2) = (\Delta n^2)$. Even better results could be obtained for a wave that is closer to cutoff. In the present case we obtain from $n_1 = 2.21$, $n_2 = 2.2$, $n_3 = 1$, $kd = 9.9292$, and $\kappa d = 1.899153$, the value $\gamma d = 0.8608$. The parameter γ indicates the penetration depth of the light wave in the substrate. At a distance $1/\gamma$ the wave has decreased to $1/e$ of its field strength at the dielectric interface between the guiding layer and the substrate. In our example, the penetration depth is 1.16 times the width of the guiding layer. The wave is thus not very tightly bound to the guiding layer, but even weaker guidance would be possible.

In order to obtain a feeling for the required values of (Δn^2) let us consider specific numerical examples. In a typical case we may expect $D/d = 10$ so that we find from Fig. 3 the value

$$\frac{2\alpha d}{(\Delta n^2)^2} = 0.7 \tag{36}$$

at the peak of the loss curve at a substrate angle of $\phi = 1.2°$. To obtain a loss of $2\alpha L = 1$ Np = 4.34 dB in a waveguide of $L = 1$-cm length with a guide width of $d = 10^{-4}$ cm would require that $(\Delta n^2) = 1.2 \times 10^{-2}$. According to (2), we obtain the change of the refractive index from the equation

$$\Delta n = \frac{(\Delta n^2)}{2n} \tag{37}$$

so that $\Delta n = 2.7 \times 10^{-3}$. Such large values of Δn may be difficult to obtain by acoustical means. For a more realistic value of $\Delta n = 10^{-4}$ or $(\Delta n^2) = 4.4 \times 10^{-4}$, [8], we find instead

$$2\alpha L = 1.4 \times 10^{-3} \text{ Np} = 5.9 \times 10^{-3} \text{ dB}$$

for the conditions assumed earlier. Increasing the radiation angle from 1.2° to 10° reduces the coupling loss to $2\alpha L = 4.6 \times 10^{-6}$ Np $= 2 \times 10^{-5}$ dB. Figueroa [9] has measured values of $2\alpha L = 10^{-4}$ at a substrate angle of $\phi \approx 10°$. These values agree with our theory if we assume $D/d = 2$. These numbers show the inefficiency of an acoustical coupler whose guiding layer and substrate consist of essentially the same material. If the materials can be made substantially different so that either (Δn_1^2) or (Δn_2^2) is much larger than the index change in the rest of the waveguide structure, the conditions of the dotted curve in Fig. 3 prevail and we find

$$\frac{2\alpha d}{(\Delta n^2)^2} = 11$$

at the peak of the curve at $\phi = 2°$. For $\Delta n = 2.2 \times 10^{-4}$ we would have a coupling loss of $2\alpha L = 0.1$ Np = 0.43 dB. Coupling efficiencies of this order of magnitude have been re-

ported in the literature with a slab waveguide whose guiding layer and substrate consisted of different materials [2].

Fig. 4 corresponds to the same conditions that were assumed for Fig. 2, except that the value of kd is increased to $kd = 100$.

In order to include slabs with larger refractive-index differences between guiding layer and substrate we have drawn the coupling loss coefficient in Fig. 5 for the conditions $n_1 = 1.6$, $n_2 = 1.5$, $n_3 = 1$, and $kd = 12.572$ resulting in a value of $\kappa d = 2.59565$ for the lowest order TE mode. These conditions are similar to those used in [3, p. 139, fig. 4.2.2], except that there the next higher guided TE mode was considered. Fig. 5 shows pronounced maxima and minima. They are leaky wave resonances discussed in [3]. For small values of D/d, the curves of Fig. 5 are equivalent to scattering from a sinusoidally distorted air-film interface as was discussed earlier. For larger values of D/d, we see once more the deep minima of the loss curves caused by destructive interference of the wavelets originating along the acoustical phase front.

Finally, we turn to the case of backward scattering of a guided wave. Fig. 6 depicts three different cases labeled 1, 2, and 3. Case 1 corresponds to the conditions: $n_1 = 1.6$, $n_2 = 1.5$, $n_3 = 1$, $kd = 12.572371$, and $\kappa d = 2.59565$. Case 2 corresponds to $n_1 = 2.21$, $n_2 = 2.2$, $n_3 = 1$, $kd = 9.9292$, and $\kappa d = 1.899153$. Case 3 is similar to case 2 with the exception that $kd = 100$ and $\kappa d = 2.98388$. Backward scattering by means of an acoustic wave requires extremely high acoustic frequencies. However, our example is applicable to any kind of refractive-index fluctuation regardless of its cause. Backward scattering of a guided wave is not plagued by problems of mode orthogonality since a wave and its backward-traveling counterpart are not mutually orthogonal. It is thus advantageous to let the refractive-index disturbance extend as deeply into the substrate as possible. This trend is clearly apparent in Fig. 6 from the fact that all curves increase monotonically with increasing values of D/d reaching the asymptotic limit of (24). Consider again the example of $LiNbO_3$ with $n_1 = 2.21$ and $n_2 = 2.2$, case 2. We see from Fig. 6 that we obtain $RD/(\Delta n^2) = 1.1$ for large values of D/d. This gives $RL = 4.4$ for $L/d = 10^4$ and $(\Delta n^2) = 4.4 \times 10^4$. The incident wave is thus reduced in intensity to $e^{-8.8} = 1.5 \times 10^{-4}$ of its initial value. The slight index fluctuation of $\Delta n = 10^{-4}$ is thus very effective for backward scattering of a guided wave contrary to its ineffectiveness for coupling to radiation. This feature of backward scattering is useful for the design of distributed-feedback lasers [10], [11]. The other two cases depicted in Fig. 6 are even more efficient for the same value of (Δn^2).

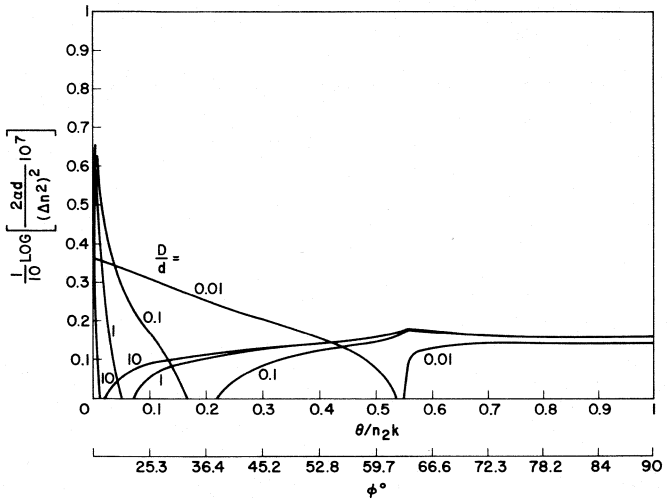

Fig. 4. This plot is similar to Fig. 2, except that $kd = 100$ and $\kappa d = 2.9839$.

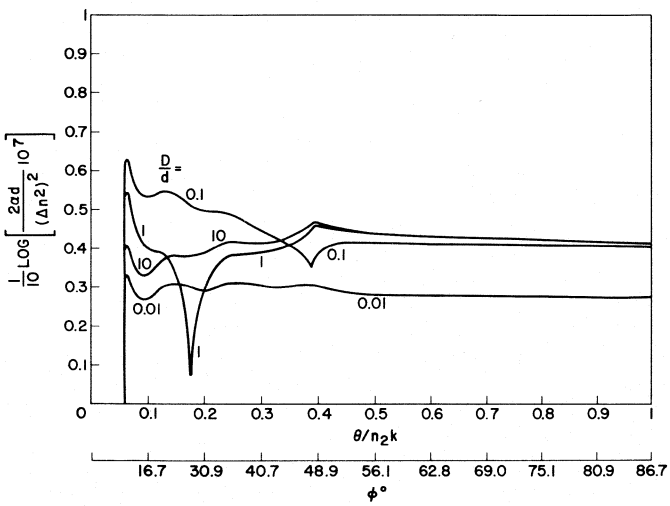

Fig. 5. This curve is similar to Fig. 2, except that $n_1 = 1.6$, $n_2 = 1.5$, $n_3 = 1$, $kd = 12.572$, and $\kappa d = 2.5956$. The curves show leaky wave resonances because of the large refractive-index difference between guiding region and substrate.

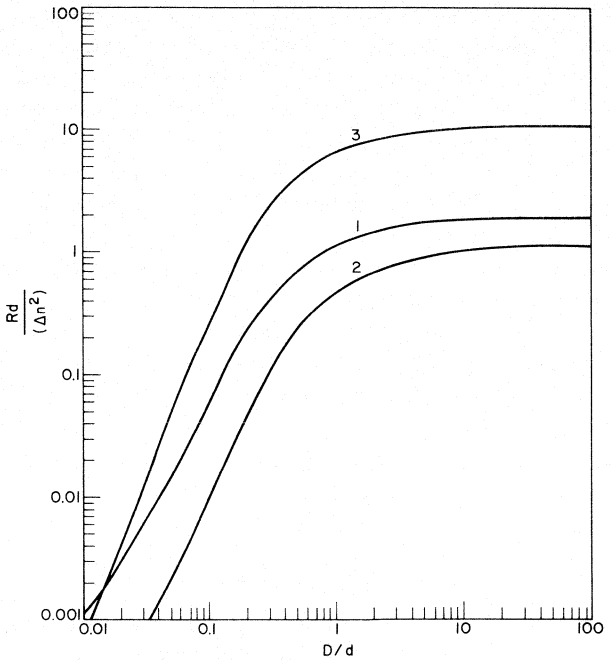

Fig. 6. Normalized coupling coefficient $Rd/(\Delta n^2)$ as a function of D/d. R describes coupling between a guided wave and its backward-traveling counterpart.

Conclusions

We have considered light scattering in asymmetric slab waveguides caused by periodic refractive-index perturbations whose intensity decreases exponentially with increasing depth in the substrate. Such an index fluctuation can be produced by an acoustical surface wave. We found that light scattering out of

the waveguide is very inefficient if the acoustical wave (or the index perturbation) reaches deep into the substrate, and if it affects the guiding region and the substrate in the same manner. This would happen if an acoustical wave were used in a waveguide formed by diffusion. Better efficiency can be achieved by several means. If the slab waveguide consists essentially of one single material, it would be necessary to restrict the penetration of the periodic index variations to a fraction of the guiding region so that mode orthogonality is prevented from cancelling the coupling effect. If the guide can be made of different materials, care should be taken to ensure that the acoustooptic coefficients of the guiding region and substrate are different. Very good results can be obtained for backward scattering of a guide wave into itself. In this case, mode orthogonality does not interfere with the coupling efficiency so that deep penetration of the periodic index fluctuations into the waveguide is desirable.

Realization of a Mode-Selective Three-Mirror Reflector

H. EICHLER, G. SCHICK, AND W. WIESEMANN

***Abstract*—A simple new mode-selective mirror configuration is realized for obtaining single-mode operation of a six-mode He/Ne laser. Stable single-mode operation could be maintained without active stabilization methods over periods of more than 5 min.**

I. Introduction

Numerous approaches to obtain mode-selective laser resonators have been reported [1]. For a great number of applications the Fox–Smith interferometer turned out to be the most suitable device. However, as has been investigated theoretically [2], a configuration consisting of three parallel mirrors should have likewise remarkable selective properties. This paper describes experimental results of longitudinal mode selection in a He/Ne laser with such a three-mirror reflector.

II. Apparatus

The laser resonator including the three-mirror reflector is shown schematically in Fig. 1. The He/Ne discharge tube was 680 mm long and 2 mm in diameter. The mirrors were separated by Invar and quartz rods. The power reflection coefficients of all the mirrors were about 0.99. The mirror configuration did not obey the mode matching conditions due to a lack of long-radius mirrors (r_1 = 2 m, $r_2 = r_3 = \infty$, r_4 = 6 m, L_L = 0.78 m, and L_R = 0.08 m). The distance between mirrors 3 and 4 could be tuned piezoelectrically.

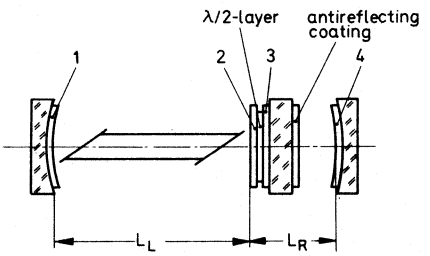

Fig. 1. He/Ne laser with three-mirror reflector consisting of mirrors 2, 3, and 4.

The reflection properties of the three-mirror reflector have been analyzed earlier. Fig. 2 shows the theoretical dependence of the power reflection coefficient R_{2*} of the three-mirror reflector on the phase shift between mirrors 3 and 4 for left-hand incidence. The parameters used for calculation are $R_1 = R_2 = R_3 = R_4 = 0.99$, $T_2 = T_3 = 7 \cdot 10^{-3}$ and $T_0 = 0.98$, where R_i, T_i are the power reflection and transmission coefficients of the ith mirror, respectively. T_0 is the power transmission of the λ/2-layer measured with a multiple reflection method [3]

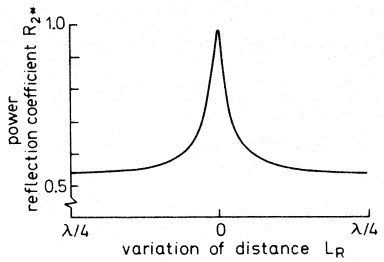

Fig. 2. Power reflection coefficient R_{2*} of the three-mirror reflector versus distance variation. Parameters are given in the text.

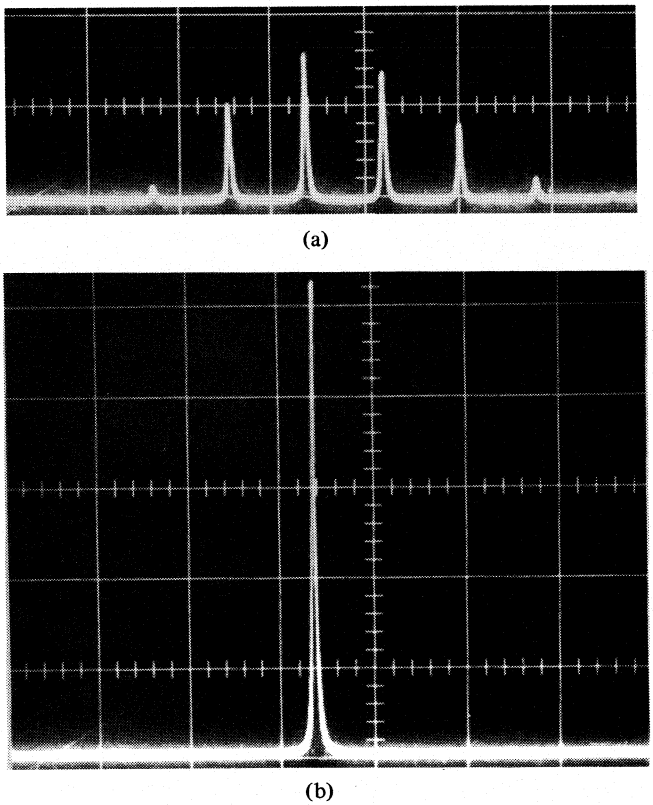

Fig. 3. Mode spectrum of the laser output as a function of frequency using (a) a flat mirror instead of the three-mirror reflector, and (b) the setup shown in Fig. 1.

using a test layer. The maximum power reflectivity of the three-mirror reflector amounts to 0.984. R_{2*} depends critically on the separation between mirrors 2 and 3. Therefore, mirrors 2 and 3 have been fabricated on a common substrate, separated by a λ/2-layer consisting of LaF_3. A power transmission coefficient of 0.1 and a halfwidth of 17 Å were measured for the interference filter consisting of mirrors 2 and 3 and the λ/2-layer (λ = 6328 Å).

III. Performance

In order to demonstrate the mode-selective properties of the three-mirror reflector the laser was first operated with a single flat mirror (R_2 = 0.99) instead of the three-mirror reflector. The mode spectrum [Fig. 3(a)] was monitored by a Spectra Physics scanning interferometer placed in front of mirror 1. Total power output (both sides) was 2.1 mW. After replacing the three-mirror reflector single-mode operation could be obtained [Fig. 3(b)] by tuning the distance L_R between mirrors 3 and 4 to an integer multiple of λ/2. Each of the six frequencies shown in Fig. 3(a) can be selected for single-mode operation by tuning the distance L_R. The total power of the single mode shown in Fig. 3(b) was 1 mW. No efforts were made for optimum output decoupling. Single-mode operation without mode jumping could be maintained without temperature stabilizing enclosures and servo loops for periods of 5–10 min after a warmup of half an hour.

The mirror configuration described here should be useful also for mode selection in other types of lasers.

Observations of Picosecond X-Ray Pulses

M. A. DUGUAY AND J. N. OLSEN

Abstract—**An upper limit on the duration of X-ray pulses emitted by a laser-produced plasma has been obtained using a picosecond optical-sampling system. When irradiating an iron target with 1-J 40-ps pulses from a Nd:glass laser, X-ray pulses were as short as 50 ps with a 0.5-percent conversion efficiency. The technique utilized direct excitation of a plastic scintillator and measurement of the scintillation light rise time. Time resolution was ≤50 ps.**

THE EXPERIMENT

Pulsed X-ray emissions in the nanosecond [1] and picosecond domains have many possible applications; pulsed radiography and X-ray laser excitation are two examples. In the laser-plasma context, picosecond-domain X-ray measurements are important diagnostics of the plasma time history. Recent advances in subnanosecond response X-ray detection have utilized fast vacuum photodiode [2] and ultrafast streak camera [3] techniques. In this work we report observation of 80-ps rise-time scintillation pulses excited by laser-plasma X-rays. Taking into account the scintillator characteristics, the X-ray pulse itself must be less than ~50 ps.

The apparatus used to create and observe ultrafast X-ray pulses is shown in Fig. 1. A 40-ps pulse of up to 1 J from a mode-locked Nd:YAG laser with glass amplifier [4] enters the system at a beam splitter; 75 percent of the energy is focused to an iron target. An NE 102 plastic scintillator,[1] placed 1 cm from the target behind a 10-μm-thick beryllium foil, converts the X-ray pulse into a fast-rising pulse of scintillation light which slowly decays. The subnanosecond rise time of the scintillation signal is monitored by a 5-channel optical sampler which is optically gated using the remaining 25 percent of the laser beam.

The optical-sampling technique has been described in detail previously [5], [6]. Briefly, optically induced birefringence in a CS_2 cell placed between crossed polarizers P_1 and P_2 provides signal transmission proportional to the square of the gating-beam intensity [7]. A 40-ps full width at half maximum (FWHM) infrared pulse thus allows transmission for 28 ps.

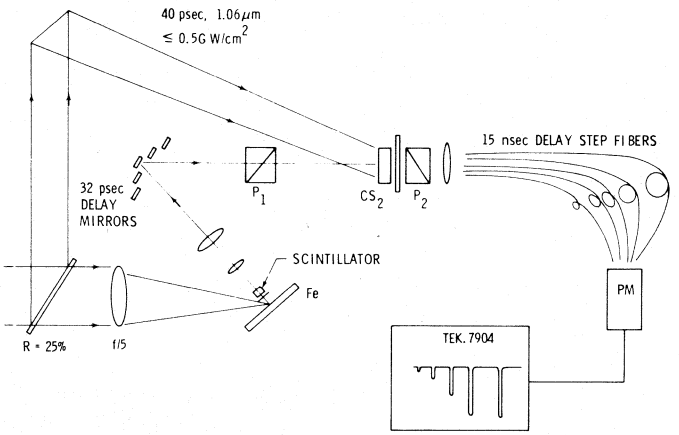

Fig. 1. Schematic of the picosecond X-ray apparatus. Not shown in the gating beam are a long focal-length lens and variable delay optics.

In the present application, the scintillation light is imaged from the scintillator surface onto an echelon array of mirrors. The five identical signals reflected from the mirrors enter the ultrafast gate at 33-ps intervals. When the gate opens for 28 ps, five samples are transmitted which span the scintillation rise time at 33-ps intervals for a total range of 132 ps. By varying the time at which the optical gate is opened on successive shots, a greater time range can be studied. The gated light in each of the five channels is imaged into an array of optical fibers, cut to delays of 5, 20, 35, 50, and 65 ns. Thus the samples can be conveniently detected and displayed at 15-ns intervals.

CALIBRATION AND RESULTS

The operation of the optical-gating array was tested as follows to assure picosecond gating and establish timing of the scintillation light relative to the laser input. A frequency-doubling crystal was inserted after the beam splitter and the foil was removed from the scintillator, thereby injecting a prompt 28-ps pulse of green light into the sampling array. Correct gating was demonstrated by single-channel response depending upon the gating-beam delay. Since the green signal is exactly synchronous with the infrared pulse, this enables one to establish an absolute time scale for the X-ray-induced scintillation light relative to the arrival time of the heating pulse. The relative sensitivities of the channels were obtained by removing the P_1 polarizer and displaying the green light in all channels.

A sampled display of the scintillation signal for 0.9 J on target is shown in Fig. 2(a). When the green-light calibration is used to normalize the observed samples, the sampled display of Fig. 2(b) is obtained. In this case, the scintillation is still rising in the fifth channel indicating a "long" X-ray pulse as discussed in the following. The X-ray yield is also monitored in a time-integrated mode using two p-i-n diodes behind beryllium foils (12 and 25 μm). Data from these detectors show $\langle h\nu \rangle \approx 1$ keV with up to 0.5-percent conversion efficiency for emission into 2π and correcting for absorption in the Be filters.

More reproducible and faster rise-time scintillation signals were obtained for slightly less energy on target, 0.5–0.7 J. In Fig. 3 a composite of several compatible shots with various gating delays is shown. The three middle time shots are normalized at their fourth channel; the earlier and later signals are normalized to agree with the middle shots. The longest delay measurements show that the scintillation does reach a

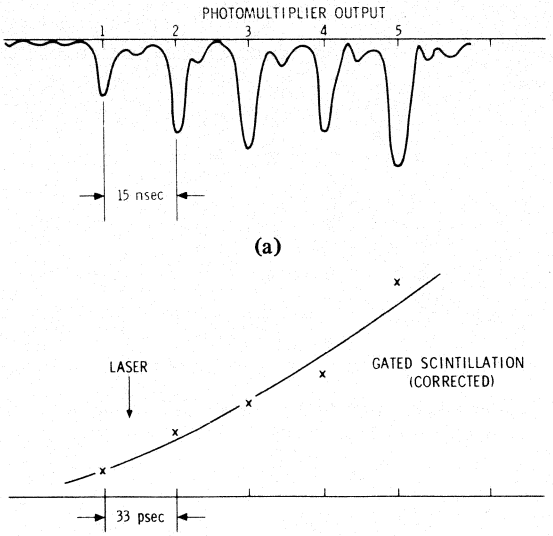

Fig. 2. Sampled scintillation signal for 0.9 J on target. The PM output is traced (a) from a 0.5-V/cm and 20-ns/cm oscilloscope display and corrected (b) for channel sensitivities.

plateau on the picosecond time scale, about 120 ps after the laser. The 10–90-percent rise time, $\tau_{10\text{-}90\%}$, is about 80 ps and the delay from the laser to 50-percent response, $\tau_{0\text{-}50\%}$, is 60–80 ps. Comparison of delay and rise time, as discussed below, set an upper limit of ~50 ps for the X-ray pulse duration.

The Scintillator Response

The role of the four-component plastic scintillator in detecting picosecond X-ray pulses is complicated by the absorption mechanism in the primary molecules and the several energy transfer times in converting absorbed energy to scintillation light [8]. In order to use a simple analytical model for the scintillator response, we assume a single time-independent excitation rate $1/\tau_R$, neglecting the time-dependent kinetics of intermolecular transfer mechanisms [9].

There are then four important times: τ_L, the Gaussian-laser half-width at the $1/e$ point (24 ps) which opens the CS_2 gate; τ_x, the X-ray pulse half-width; τ_R, the scintillator excitation time; and τ_D, the scintillator decay time (2.2 ns). Since τ_R has been reported to vary from less than 50 ps [10] to 900 ps [11], depending upon the exciting particle or wavelength, it appears that τ_R appropriate for excitation by 1-keV X-rays must be inferred from our data.

In a two-level model, the X-ray absorbing states decay to fluorescing states with $1/\tau_R$ rate and fluorescing states radiate with $1/\tau_D$ rate. Under these assumptions, the population of the fluorescing state N may be written as

$$N(t) \propto \int_{-\infty}^{t} dt' X(t') \left[\exp\left(-(t-t')/\tau_D\right) - \exp\left(-(t-t')/\tau_R\right)\right]$$

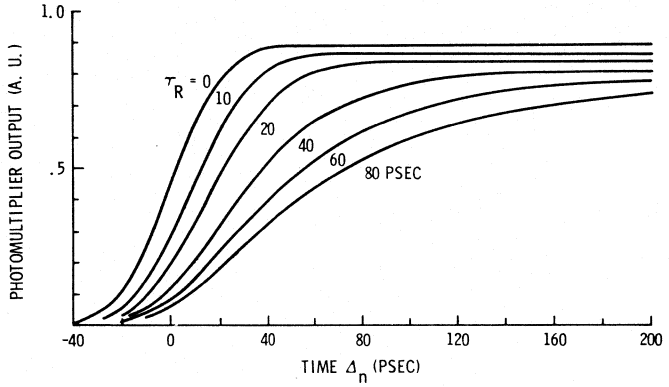

Fig. 4. Calculated photomultiplier output for various τ_R. Here both τ_X and τ_L have been chosen to be 24 ps, as an example.

where $X(t)$ is the X-ray pulse. The scintillation signal is simply $S(t) = N(t)/\tau_D$.

In the final measurement the fast photomultiplier records the integral of the scintillation light in each channel which was transmitted through the optical gate. Since the gate transmission depends upon the square of the gating intensity, the photomultiplier output in the nth channel, at time Δ_n, is

$$P(\Delta_n) \propto \int_{-\infty}^{\infty} dt \exp\left[-2(t - \Delta_n)^2/\tau_L^2\right] S(t).$$

For a Gaussian $X(t) = X_0 \exp\left[-t^2/\tau_X^2\right]$ the envelope of the $P(\Delta_n)$ is shown in Fig. 4 for various τ_R where τ_L, τ_X = 24 ps, as an example.

In the limit of $\tau_R \ll \tau_L, \tau_X$ the envelope of $P(\Delta_n)$ describes an error function with rise time $\tau_{10\text{-}90\%} \approx 2\,\tau_X$. For slower response times $\tau_{10\text{-}90\%} \approx \tau_R$ and the delay of the midpoint of the scintillator rise approaches $\tau_{50\%} = \tau_R \ln 2$. All three time scales τ_R, τ_X, and τ_L act to lengthen the rise time; however, only τ_R and any X-ray emission delay will cause a scintillation delay. Since X-ray emission delay is strongly limited by rapid plasma cooling, measurement of the scintillation delay allows an upper limit estimate of τ_R.

Discussion

By comparing the composite of results in Fig. 3 with the family of calculated responses in Fig. 4, we infer $\tau_R \leqslant 50$ ps from the observed 80-ps rise time after allowing for the effect of an assumed τ_X in the calculation. Such a τ_R is compatible with the observed delay time, within our accuracy, if the $X(t)$ is assumed to be somewhat delayed, say 10 ps. It is clear that for physically reasonable X-ray delays ($\leqslant \tau_L$) the observed combination of $\tau_{50\%}$ and $\tau_{10\text{-}90\%}$ can only be obtained for $2\tau_X \leqslant \tau_R \approx 50$ ps. We conclude that for modest energy inputs (0.5–0.7 J) the X-ray pulse duration was comparable or perhaps less than the scintillator response.

Acknowledgment

The authors wish to thank J. F. Cuderman for assistance in setting up the experiment and C. Martinex for highly competent technical support, particularly the operation of the laser. Special thanks are due to M. A. Palmer for lending laboratory space and equipment for this experiment. M. A. Duguay gratefully acknowledges discussions with P. J. Mallozzi of the Battelle Memorial Institute on the possibility of generating picosecond X-ray pulses.

A Discharge Heated Copper Vapor Laser

R. S. ANDERSON, L. SPRINGER, B. G. BRICKS, AND T. W. KARRAS

Abstract—**A simple, reliable copper vapor laser is described with vapor produced by discharge heating. Average output power of 1.3 W has resulted at 6.8 kHz and a specific energy of 39 μJ/cm^3. Copper vapor density as high as 3 × 10^{16} cm^{-3} was achieved.**

Manuscript received November 14, 1974; revised December 3, 1974.
The authors are with the General Electric Company Space Sciences Laboratory, Valley Forge, Pa.

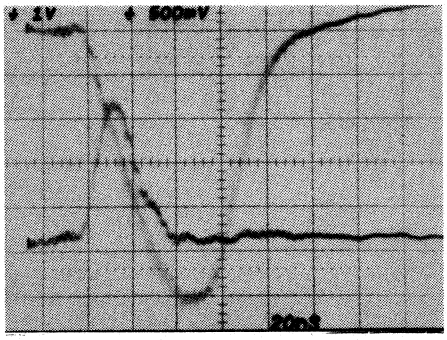

Fig. 1. Current and laser power. The laser discharge current as measured with a current transformer is shown on the upper trace and the laser power from a photodiode on the lower trace. Sweep was 20 ns/cm.

The copper vapor laser has shown potential as a high-power, high efficiency laser in the visible portion of the spectrum [1]-[3]. A key element in any such development must, of course, be the copper vapor source. Several different techniques for producing this vapor have been reported. As well as the original oven heated source [1], these have included heated expansion through a supersonic nozzle [4], explosion of copper wire and plasma gun acceleration [5], an evaporation-condensation cycle [6], and an efficient vaporizer producing a flowing medium [7]. Recently, low-temperature chemical production of copper vapor has also been reported [8], [9].

While several of these techniques promise high overall efficiency, at this time only Isaev *et al.* [2] have reported a practical copper vapor laser demonstrating both high power and high total system efficiency. In large part this was a result of the fact that no separate vapor source power was required. We report on the development of a self-heated copper laser similar in principle to that of Isaev and some preliminary results that were obtained.

In this laser the pulsed electrical discharge which pumps the inversion in the copper atom also serves to heat the tube and vaporize the copper. Thus no additional source of energy is required. The desired operating temperature is achieved through a proper balance of input power and radiation shielding. Normally, six minutes are required for the tube to heat up to a copper vapor pressure suitable for laser threshold; in nine minutes equilibrium and full power are reached.

The results from alumina tubes with two different gain regions are reported here, a small volume 0.28 $cm^2 \times 7$ cm and a larger volume 0.567 $cm^2 \times 8.5$ cm. In both cases long tantalum tube electrodes were inserted at each end, with a metal-ceramic seal at one end of each electrode and the discharge emerging from the other. As a result there was a hot bore region between the interior electrode ends and a cooler region external to them. This temperature gradient can produce diffusion of copper out of the hot zone. However, the discharge was carried by 10–30 torr of buffer gas (He, A, or Ne) which also limited the diffusion of copper.

During operation, the total input power was up to 1.5 kW as measured at the output of the power supply. The power supply inductively charged a 9-nF capacitor which was then discharged through the laser medium using an EG&G 1802 thyratron as a switch. Laser repetition rates between 1.8 and 10 kHz have been obtained with the thyratron and as high as 18 kHz using a quenching spark gap switch. Peak currents were the order of 10^3 A. Fig. 1 shows oscilloscope traces of the discharge current and the laser power.

Using the small gain region tube 0.27-W average power were obtained on both lines (5106 Å and 5782 Å) at a repetition rate of 4.2 kHz. This is equivalent to a specific energy of 33 $\mu J/cm^3$. With the large tube 1.3 W were obtained at a repetition rate of 6.8 kHz leading to a specific energy of 39 $\mu J/cm^3$.

All operation above about 0.100 W was strongly superradiant at both wavelengths. Optimum output mirror reflectivity was about 4 percent or lower. Removal of the output mirror entirely did not noticeably reduce the output power but did, of course, affect beam quality. Reduction of the rear mirror reflectivity from 99.9 percent to 50 percent and then to 4 percent, while holding the output mirror at 4 percent, also did not lead to substantial variation in the total output power.

These results are at least in part a result of the high copper vapor densities present. The tube temperature has been found to be as high as 1800°C–1850°C both by direct measurement with an optical pyrometer and observation of slight softening of the aluminum oxide. The copper vapor densities at this temperature are 3×10^{16} cm^{-3}, the highest thus far reported for a copper vapor laser.

With proper choice of materials, notwithstanding the slight softening of the aluminum oxide, the high temperatures within the device in no way limited operation. Lasing was maintained continuously for up to 12 h at a time without significant reductions in power. This demonstrates, as expected, that diffusion losses were greatly reduced by the presence of the buffer gas. The tube itself was generally valved off during operation implying negligible outgassing.

These results support the conclusions of Isaev [3] that the discharge heated copper vapor laser is a device of substantial practical significance.

ACKNOWLEDGMENT

The authors would like to thank B. Fox, T. E. Buczacki, and J. Nazar for their aid in laser construction and operation, and C. E. Anderson for useful technical discussions and his support.

Standing-Wave Effect in Laser-Saturation Experiments or When 2 is Less Than 1

H. J. GERRITSEN AND G. NIENHUIS

Abstract—**It is pointed out that, in order to obtain as large a population as possible in the upper state by laser pumping, the product of laser intensity and saturation parameter determines whether one gains or loses by reflecting the laser beam back into the saturated sample. Switching the polarization of the linearly polarized return beam by 90° eliminates this problem and is always advantageous.**

An amusing case of the previously stated paradox occurs when one attempts to saturate material by irradiating it with a resonant laser beam. Let the population of the ground-state level be denoted by N_1 and of the upper level by N_2, and let us consider the case that these levels are single and that they are the two lowest energy states.

Disregarding Doppler effects, either because the material is a solid, or because it is an atomic beam in which the atoms move perpendicularly to the laser beam, the rate equations for this case lead to the well-known stationary result

$$\frac{N_1 - N_2}{N_1 + N_2} = (1 + kI)^{-1} \tag{1}$$

where I is the laser intensity, and $k = \lambda^3(4\pi hc\Delta\nu)^{-1}$ is the saturation constant. Here λ is the wavelength of the radiation, h is Planck's constant, and $\Delta\nu$ is the linewidth of the absorption due to spontaneous decay. In many cases of practical interest, such as the pumping of a Na beam by a tunable CW dye laser, kI is of order unity. Furthermore, one often desires as large a value of N_2/N_1 as possible. Since usually the absorption experienced by the laser beam is not very large, one may be tempted to reflect the laser beam and have it traverse once more the volume to be pumped. The result is a standing wave, where some parts of space have a very large intensity which saturate easily, but where in the nodal planes saturation is not obtained at all. These nodal planes lay perpendicularly to the direction of the laser beams. The average population difference is then determined by

$$\frac{N_1 - N_2}{N_1 + N_2} = \frac{1}{\pi}\int_0^{\pi} dx\,(1 + 4kI\cos^2 x)^{-1} \tag{2}$$

where the integration is performed to obtain a volume average.

Manuscript received December 4, 1974.

H. J. Gerritsen is with the Department of Physics, Brown University, Providence, R.I. 02912. He is on leave at Fysisch Laboratorium, Rijksuniversiteit Utrecht, Utrecht, The Netherlands.

G. Nienhuis is with the Fysisch Laboratorium, Rijksuniversiteit Utrecht, Utrecht, The Netherlands.

The solution of (2) is

$$\frac{N_1 - N_2}{N_1 + N_2} = (1 + 4kI)^{-1/2}. \tag{3}$$

Comparison of (3) with (1) then leads to the intuitively acceptable result, that two-beam pumping is advantageous for low laser intensities. For if $kI < 2$, (3) is closer to zero than (1). At high intensities, one beam already pumps rather strongly, and the second beam does not add very much at the antinodal planes, since N_2/N_1 cannot exceed unity. But the two-beam situation suffers from the drop of intensity at the nodes. If $kI > 2$, (3) is farther from zero than (1). The break-even point occurs, as one sees, when $kI = 2$, in which case $N_2/N_1 = 0.5$. If the intensity of the laser is such that $kI > 2$, one better uses the beam once rather than twice.

A remedy to this situation is to switch the polarization of the reflected beam by 90° with a quarter-wave plate in front of the mirror. This generates a pattern of elliptical polarization without cancellation.

Photopreionization of the 3371-Å Pulsed N_2 Laser

N. A. KURNIT, S. J. TUBBS, K. BIDHICHAND, L. W. RYAN, JR., AND A. JAVAN

Abstract—**Photopreionization of the 3371-Å pulsed N_2 laser by use of a seed gas of low ionization threshold and flashlamp excitation is observed to result in increased laser output and reproducibility. Preionization also increases the range of permissible operating pressures, enabling operation with atmospheric-pressure mixtures of N_2 and He without reduced intensity.**

The 3371-Å pulsed N_2 laser [1] requires large current densities ($\gtrsim$1 kA/cm^2) and high electron temperature ($\gtrsim$5 eV) [2]. In order to operate with sufficiently high E/p to achieve these values, the N_2 laser is typically operated in a transverse discharge configuration with electric fields of ~10–30 kV/cm and pressure of 30–100 torr [3]. At higher pressures [4], where large amounts of energy could be stored and extracted, nonuniformities in the discharge leading to the formation of arcs tend to degrade the laser performance.

We have investigated the effect of volume photopreionization on the nitrogen-laser performance using a seed gas of low photoionization threshold and an external flashlamp [5]. The seed gas is used at sufficiently low partial pressure to ensure that the electron temperature is largely dominated by collisions with N_2 molecules. We observe significantly improved discharge uniformity and suppression of arcs over a wide pressure range, improved reproducibility of both the spatial distribution and intensity of the laser output, some increase in permissible operating pressures, including the ability to operate with atmospheric-pressure mixtures of N_2 and He, and an

increase in average laser power. The method also allows the use of a large-volume N_2 plasma (which requires excitation at correspondingly higher total current). This is of importance in possible realization of a high-energy N_2 laser.[1]

In the experiments, the nitrogen laser was similar to a design described by Small and Ashari [6] in which the current pulse is produced by a flat-plate Blumlein circuit consisting of two 25 X 25-cm capacitors etched on 18-mil-thick double-clad epoxy circuit board and charged to typically 16 kV. The electrodes are 10-mil-thick copper strips soldered along the length of the capacitors and edge opposed inside an evacuable lucite box. Electrode spacings of 1 cm and 0.2 cm have been tested. A single mirror was used at one end of the laser. Since the discharge is pressure confined in this laser, rather than confined by dielectric walls as in a number of designs, it is possible to place a standard Xe flashlamp inside the lucite box adjacent to the discharge region. We have utilized a 35-cm-long flashlamp placed 1.5 cm from the discharge and pulsed with typically 1.5 J (0.01 μF charged to 17 kV) in $\sim$5 μs. The volume preionization is produced by addition of trace amounts of triethylamine $[(C_2H_5)_3N]$ in a manner similar to that reported earlier for the production of large-volume high-density CO_2-laser plasmas [7]. The flashlamp current pulse is used to trigger a spark gap which initiates the laser discharge after a variable delay of 15–100 μs. The purpose of the photopreionization in this application is only to provide a sufficiently uniform initial electron distribution to ensure the creation of a uniform plasma when a voltage above avalanche breakdown is applied across the laser electrodes, and hence delay arc formation beyond the time during which laser oscillation occurs; thus only a small fraction of the total electron density need be supplied by the photoionization.

Before the introduction of triethylamine into the laser medium, it was observed that pulsing the flashlamp had little or no effect on the laser characteristics. For pure N_2 at low pressures ($\sim$100 torr), addition of small amounts of seedant by bubbling a small percentage of the laser gas through liquid triethylamine was, even without the flashlamp, sufficient to give a significant improvement in discharge uniformity and as much as a factor-of-2 increase in output power, to $\sim$50 kW in a 4-ns pulse.[2] The flashlamp gave a further small increase in laser power and reproducibility.[3] Fig. 1(a) shows a plot of relative laser output energy as a function of N_2 pressure both with and without preionization, for a 1-cm-wide discharge. The most significant visual differences occur on the high-pressure side of the curve, where the output without preionization becomes strongly arc limited.

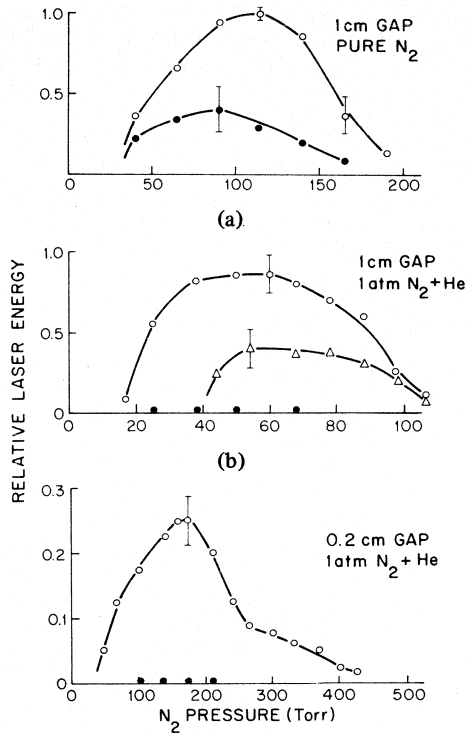

Fig. 1. Relative laser energy as a function of N_2 pressure for a) pure N_2 in 1-cm-gap laser, b) atmospheric-pressure mixture of N_2 and He with 1-cm gap, and c) atmospheric-pressure mixture of N_2 and He in 0.2-cm-gap laser. Open circles give output with flashlamp and optimized triethylamine flow; dots show output with no flashlamp and with triethylamine thoroughly purged from system. With atmospheric-pressure mixtures there is negligible output in the latter case. Triangles in (b) show output with triethylamine alone. Error bars indicate typical range of fluctuations during a series of 10 consecutive shots. (Magnitude of fluctuations is relatively constant along most curves, with corresponding decrease in percentage fluctuations near the peak of the curve; in the optimized curve in (a), a further decrease in fluctuations is observed near the peak of the curve.) Note the difference in pressure scales; in particular, (b) and (c) are scaled for the same ratio of field strength to nitrogen partial pressure.

A more dramatic behavior is illustrated in Fig. 1(b), which shows the laser output for an atmospheric-pressure mixture of N_2 and a He buffer[4] as a function of N_2 partial pressure, as determined from relative flow rates. Here, with no preionization the current is concentrated in a few arcs and there is negligible laser output, whereas with preionization the output is close to that obtained with pure N_2.

In this case again, triethylamine itself helps to produce a discharge which gives some laser action, but the laser performance is greatly improved when the flashlamp is fired shortly before the laser discharge. Delays of more than 50 μs between the flashlamp and laser reduce the effectiveness of the preionization. The discharge takes the form of a uniform distribution of closely spaced streamers as reported in [4], where atmospheric-pressure operation with pure N_2 was reported

[1] A publication which has just appeared in print discusses a different method in which a photostabilized discharge without the use of a seed gas is used to improve the performance of a UV N_2 laser; see V. Hasson, D. Preussler, J. Klimek, and H. M. von Bergmann, "Transverse double-discharge high-pressure glow excitation of UV lasing action in molecular nitrogen," *Appl. Phys. Lett.*, vol. 25, pp. 654–656, 1974.

[2] This effect may be attributable to the rapid rate of electron production from the low ionization threshold impurity. A similar effect has been reported in a CO_2–N_2–He laser mixture; see R. L. Schriever, "Uniform direct-current discharges in atmospheric-pressure He/N_2/CO_2 mixture using gas additives," *Appl. Phys. Lett.*, vol. 20, pp. 354–356, 1972. The laser power is strongly dependent on the fraction of volume utilized, the current density and rise time, and on whether the double-pass gain is high enough to saturate the transition.

[3] These experiments were performed at sufficiently low repetition rates ($\sim$2 pulses per second) so that the gas has time to be exchanged between shots. Some increase in reproducibility in such lasers can sometimes be observed at higher repetition rates, presumably due to some remaining background ionization, but for large energy deposition and high repetition rates arcing occurs if the gas is not exchanged quickly enough; see, for example, R. Targ, "Pulse nitrogen laser at high repetition rate," *IEEE J. Quantum Electron.* (Corresp.), vol. QE-8, pp. 726–728, Aug. 1972.

[4] T. Kobayasi, M. Takemura, H. Shimizu, and H. Inaba have reported such operation ("TEA UV nitrogen laser and its application to high sensitivity remote pulsed-Raman spectroscopy of atmospheric pollutants," presented at the IQEC 7th Int. Quantum Electronics Conf., Montreal, P. Q., Canada, May 1972, Paper M.9), but only at higher field strengths and with reduced intensity.

using higher field strengths and faster dielectric switches. It appears that photoionization should help to stabilize the discharge in such a TEA laser. The ability to operate at atmospheric-pressure mixtures of N_2 and He may in itself prove to be useful for some applications.

The maximum applied voltage of 16 kV was limited in these experiments by the breakdown potential of the epoxy board. In order to test the laser performance at higher E/p, a similar laser with a 2-mm gap was constructed. In this laser, with no photopreionization, the discharge was arc dominated at all but the lowest pressures, and laser performance was very poor. Photopreionization produces a discharge relatively free of arcs up to the highest pressure tested, and the laser gives an energy density comparable to that with the 1-cm gap, but in a smaller beam of smaller divergence (determined by the aspect ratio of the gap). Fig. 1(c) shows the pressure dependence of the output, again for an atmospheric-pressure mixture of N_2 and He. Some laser output was observed with as much as 400 torr of N_2. Since the discharge does not appear arc dominated even for high nitrogen pressure, the decrease of laser power at high pressure can presumably be attributed to the decrease of E/p.

We believe on the basis of these measurements that it should be possible by using preionization together with higher voltages and shaping of the electrodes to achieve atmospheric or higher pressure operation with pure N_2 or possibly with a mixture of N_2 and a buffer gas suitable for collisional quenching of the lower levels [8].

Generation of Second-Harmonic UV Radiation Using a Nonlinear Substrate Coated with a UV Absorbing Thin-Film Waveguide

BOR-UEI CHEN AND C. L. TANG

Abstract—**Second-harmonic Cerenkov radiation in the nonlinear substrate has been observed using a thin-film waveguide that is absorbing at the second harmonic but transparent at the fundamental wavelength.**

Second-harmonic generation using either a nonlinear thin-film waveguide or a thin-film waveguide deposited on a nonlinear substrate has been observed in the IR [1], [2], visible [3]–[6], and in the UV [7]. The second harmonic generated either propagates in the thin-film waveguide in the phase-matched case, or it is emitted in the nonlinear substrate in the form of Cerenkov radiation in the nonphase-matched case. In a previous publication [7], we reported on the observation of CW harmonic generation in the ultraviolet (λ_2 = 2850–3100 Å) using a thin-film waveguide on a nonlinear substrate. Both the phase-matched second harmonic in the thin-film and the nonlinear Cerenkov radiation in the substrate were observed. The thin-film structure consisted of an aluminum oxide waveguide deposited on a crystalline quartz substrate. Because of the difficulty in preparing good optical quality aluminum oxide film that was transparent in the UV region, the coherence length or the interaction length for the nonlinear process was relatively short (approximately 2 mm). The question that follows is whether the thin-film waveguide has to be transparent at the harmonic wavelength in the Cerenkov process in which the harmonic radiation propagates mainly in the nonlinear substrate. Since it is generally difficult to find high-index thin-film materials that are also transparent in the UV, if the latter requirement is not essential, a greater variety of materials that are easier to handle experimentally will also become usable in thin-film nonlinear optical experiments.

In this note, we report on an experiment in which a thin-film structure consisting of a Corning 7059 glass film on a nonlinear substrate was studied. The experimental setup is described in [7]. The CW dye laser was tunable from about 5650 Å to over 6100 Å with an output power on the order of 0.2 W. The laser light was coupled into the waveguide as a TE wave propagating along the z axis of the quartz substrate through a 14-cm focal length lens and a rutile prism. The Corning 7059 glass film was RF bias-sputtered onto the y-cut quartz substrate in an atmosphere of 3 μ oxygen and 7 μ argon. Both the refractive index and the thickness were measured by ellipsometry; the index at 6328 Å was found to be n(6328 Å) = 1.558 and the thickness 1.5 μ. The ordinary indices for the quartz substrate at the fundamental and the second-harmonic wavelengths were estimated to be n_0 (5900 Å) = 1.544, and n_0(2950 Å) = 1.580, respectively. The glass film was transparent at the fundamental wavelength but had an attenuation length shorter than 1 mm at the second-harmonic wavelength. Cerenkov radiation at the second-harmonic wavelength was observed in the substrate with an emission angle of ~11° relative to the film–substrate interface and found to vary linearly with the streak length far beyond 1 mm.

Fig. 1 shows the observed second-harmonic UV radiation as the streak length was varied from 3 mm to 15 mm at a fixed fundamental wavelength λ_1 = 5800 Å. The second-harmonic power detected varied approximately linearly with the streak length up to 10 mm. When the streak length was greater than 10 mm, part of the emitted Cerenkov radiation was intercepted by the quartz–air interface and was totally reflected internally at this surface due to the small Cerenkov angle. As a result, the second-harmonic light emerged at the end of the sample, became more divergent, and the collecting lens could not collect and focus all the signal into the monochromator; this accounted for the slight deviation from the straight line dependence shown in Fig. 1 for longer streak lengths. The measured absolute power of Cerenkov radiation was roughly 4×10^{-10} W at λ_1 = 5800 Å for a streak length of 15 mm, width of 60 μ, and a fundamental power of 0.2 W incident on the input focusing lens. This is comparable to the observed conversion efficiency when scaled to the same input power level reported in [7] for the aluminum oxide film.

Fig. 2 shows the typical spectral response of the second-harmonic output as the fundamental input wavelength was

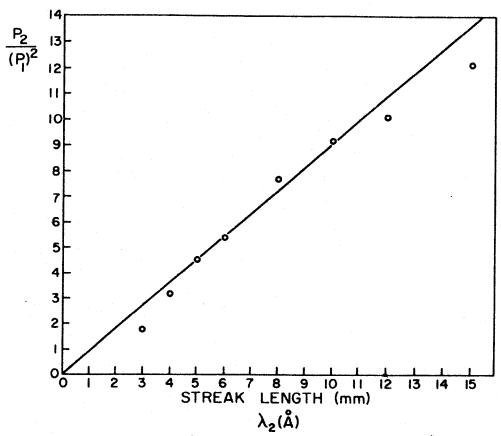

Fig. 1. Observed second-harmonic Cerenkov radiation versus streak length at λ_1 = 5800 Å. Each unit in the vertical scale corresponds to approximately 8×10^{-10} W^{-1}. P_2 is the emitted second-harmonic power collected by the collecting lens and P_1 is the total incident power on the focusing lens at the input.

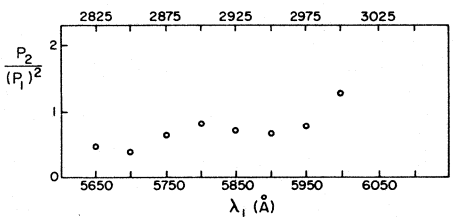

Fig. 2. Observed second-harmonic Cerenkov radiation versus input fundamental wavelength at streak length of L = 5 mm. The vertical scale is in relative units.

Manuscript received December 4, 1974. This work was supported in part by the National Science Foundation under Grant GK-33848 and in part by ARPA through the Materials Science Center of Cornell University.

scanned from 5650 Å to 6100 Å for a fixed streak length $L = 5$ mm. The Cerenkov radiation was found again to be broadly and continuously tunable.

We have, therefore, demonstrated the possibility of using films that are absorbing at the generated wavelength for some nonlinear optical experiments.

Controlled Timewise Redistribution of Laser Energy

EMILIO PANARELLA AND LORNE L. T. BRADLEY

Abstract—An electronic feedback circuit is described which has been used in a Nd:glass high-power laser system for converting the spiky light emission into a smooth near-rectangular output of adjustable intensity and duration. The feedback circuit is also capable of converting the laser emission into a stroboscopic output of frequency of several hundreds of kilohertz or into a Q-switched high-intensity output. The attractive feature of the system is that the change from one type of laser operation into the other does not require any modification to the circuit, but only a simple readjustment of a few control knobs.

The feedback system incorporates a high-current fast photodiode, a Pockels-cell shutter, and a pulser. The main innovation of the present electronic feedback circuit over previously proposed systems is the ability to set the Pockels cell at any point of its transmission curve. This feature will be demonstrated to be of decisive importance in smoothing out the laser emission and in converting the spiky light output into a series of periodic light pulses.

I. Introduction

CURRENTLY, one of the important problems in high-power laser technology is to be able to control the power output from a laser in a preassigned way. It is well known that solid-state lasers, in their normal mode of operation, emit a series of irregular spikes, the nonregularity appearing in the spike amplitude, duration, and their time separation. It would be desirable to be able to redistribute the laser energy in such a way that the emission follows a regular intensity pattern. One of the early successes along this line was obtained with the Q-switching technique whereby the available stored energy in the laser system was delivered in a symmetrical pulse of a few tens of nanoseconds duration and several megawatts intensity [1]. A second success was achieved with the technique of mode locking whereby the laser energy was redistributed in a series of megawatt-intensity pulses of picosecond duration emitted at constant frequency in the gigahertz range [2].

Unfortunately, these two clear advances in laser technology have not been followed by others to fill the gap that the many other possible laser-energy redistribution patterns have left open. For instance, no decisive progress has been made in the generation of rectangular light pulses of microsecond duration or in the production of repetitive pulses in the megahertz frequency range. Some attempts have been made to reduce the spiky output from the laser to a rectangular output of tens of microseconds duration, but the success along this line has always been rather limited.

Marshall and Roberts [3] were first to introduce the idea of an electronic feedback system able to resist the buildup of radiation energy inside the laser cavity. Statz *et al.* [4] expanded this idea by developing the theory behind it. Marshall and Roberts [3] and Statz *et al.* [4] actually performed an experiment which showed that indeed spiking had been eliminated and a reasonably smooth pulse had been achieved. Thomas and Price [5] went a step further. They controlled the duration of the light output by adding a pulser to the feedback system. In this way, lasing action was prevented until the laser rod was fully pumped and was stopped again after a few microseconds. Unfortunately, the light output obtained in this way was far from rectangular and the onset of a high-frequency instability further deteriorated the initial part of the laser pulse. Pantell and Warszawski [6] used a nonlinear absorber (a benzene cell) within the laser cavity to stabilize the laser output. They showed that power stabilization had indeed been achieved and that the resultant laser emission followed the flashlamp output. However, the technique is of limited use in that it allows neither the shaping of the light pulse into rectangular form, nor the control over the light intensity and duration. Balashov *et al.* [7] were first to achieve a very good rectangular light pulse of 10-μs duration but their technique is not easily adapted to conventional lasers. In fact, it requires a spherical resonator for the laser cavity and the control of the light duration is obtained by changing the speed of rotation of the Q-switching prism. The light duration then ranges from 4 to 10 μs and no further stretching is possible.

During the course of our work on the problem of power stabilization of a Nd:glass laser by means of an electronic feedback system, we realized that the ideas of Marshall and Roberts [3], Statz *et al.* [4], and Thomas and Price [5] had validity as initial steps in the solution of the light-emission control problem. The theoretical analysis of [4] had indicated that complete spike elimination could only be achieved in the ideal situation of zero time delay between the laser momentary power output and the corrective action of the feedback system. In practical cases the delay is never zero and the power output oscillates around an average value, the oscillation frequency increasing with decreasing time delay. We initially thought that an improvement could be obtained by the insertion within the laser cavity of a lossy element capable of absorbing part of the electromagnetic energy flowing within the cavity. In fact, we thought, the rate of variation of laser power would be reduced in this way and the delayed feedback signal would be facilitated in its corrective action. On the other hand, we realized that the power absorption of the lossy element really had to depend on the average power output of the laser, the absorption being greater when larger power outputs were delivered by the laser. Then it came to mind that an element, the Pockels cell, which was part of our feedback system, could perform both functions indicated above. In fact, the only thing that it was necessary to do was to set a

Manuscript received July 8, 1974; revised December 11, 1974.

The authors are with the National Research Council, Ottawa, Ont., Canada K1A OR6.

bias voltage on the cell and the amount of electromagnetic energy flowing within the laser cavity would be thus reduced. As a consequence, we designed the electronic feedback system in such a way that the Pockels-cell biasing could be easily achieved on any point of the cell's transmission curve. We then found that good laser-output stabilization was achieved in this way and, as an added advantage, this also proved instrumental for the conversion of the spiky laser emission into a regular pulsed output.

In the following sections, we shall first describe in detail the electronic feedback circuit used to control the light emission from our high-power Nd:glass laser. Then we shall present the experimental results. From these, it will be apparent that indeed the feedback system is able to control the laser emission so as to have either a rectangular pulse of variable intensity and duration, or a single light pulse of megawatt intensity and nanosecond duration, or a series of pulses of kilowatt intensity and submicrosecond duration. It will be shown that the conversion from one type of laser operation into the other does not require any modification of the apparatus but is accomplished through a simple adjustment of control knobs in the electronic feedback circuit. This feature is surely attractive and will prove useful, especially in those laser applications (e.g., in plasma diagnostic) where either a long constant-intensity light pulse for streak photography or a series of laser pulses for frame photography are required and have to be quickly obtained.

II. Description of the Laser and Electronic Feedback System

The laser used in the experimentation consists of an 8-in long, $\frac{5}{8}$-in-diam Brewster-ended Nd:glass rod pumped by two linear flashlamps type EG&G FX-47C (Fig. 1). The optical cavity is formed by two wedged dielectric mirrors having reflectivities of 99 and 75 percent at the laser wavelength, respectively. The electronic feedback system is made up of a Pockels cell inserted in the laser optical cavity, a polarizer, a delayed pulse generator, a pulser, and a fast high-current photodiode. A splitter, made out of a fully reflecting mirror with a $\frac{5}{16}$-in-diam central hole, reflects the peripheral part of the beam, thus allowing the uniform intensity central zone to proceed unimpeded for further use. The reflected part, which is ~15 percent of the total beam, is detected by a fast photodiode type ITT F4000-S1 which drives the Pockels cell, the load resistance being chosen according to the type of laser operation required (rectangular emission, pulsed, or Q-switched).

In operation, lasing is prevented by properly biasing the Pockels cell with a positive voltage (= 3 kV). A trigger pulse simultaneously fires the flashlamps and activates the delayed pulse generator. The delayed signal triggers the pulser, which in turn controls the open time and sets a new bias voltage on the Pockels-cell shutter. The photodiode converts the laser light into an electrical current which develops a negative voltage across the variable resistor, thus varying the Pockels-cell light transmission.

The electronic circuit of the pulser (Fig. 2) is composed of an integrated circuit monostable multivibrator 74121, a television horizontal-beam power tube 6BG6, and two 200-V dc power supplies for the screen and grid bias voltages of the 6BG6 tube.

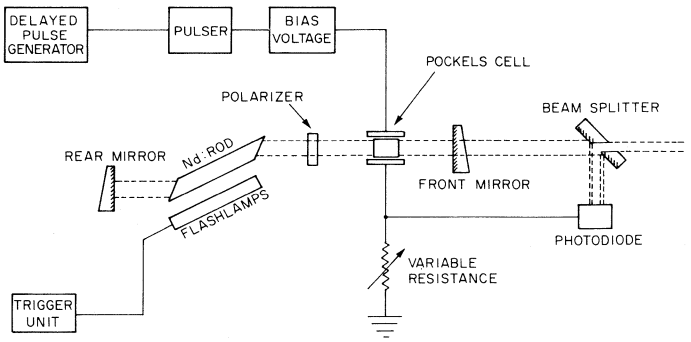

Fig. 1. Laser and electronic feedback system.

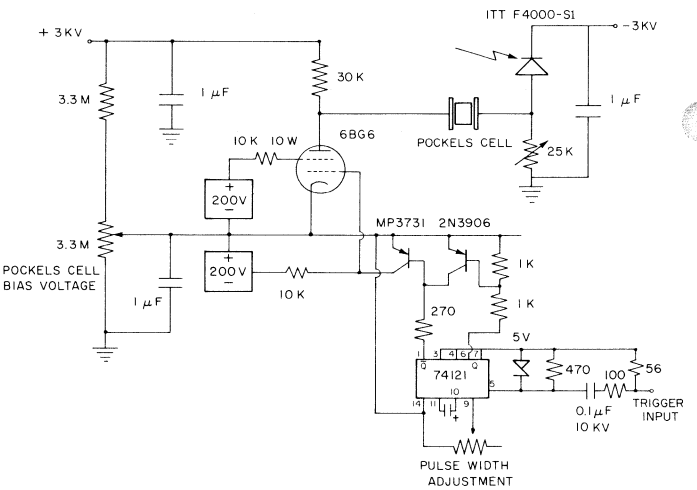

Fig. 2. Electronic circuit for control of intensity and duration of laser emission.

The trigger pulse from the delayed pulse generator turns the multivibrator 74121 on, which in turn switches on the tube 6BG6. Hence, the Pockels-cell voltage drops from +3 kV to a preset value at the cathode of the 6BG6 tube and the cell is then partially or fully open, according to the value of this bias voltage. After a period of time, which can be varied from 1 to 450 μs by means of a pulsewidth adjustment control, tube 6BG6 is turned off and the Pockels cell, restored to +3 kV, is effectively biased off.

The parameters of the feedback system that affect the laser operation are: 1) resistance across the photodiode; 2) Pockels-cell bias voltage; 3) Pockels-cell open time; and 4) delay time of the delay pulse generator.

In the following section we shall show the influence of these parameters on the laser operation.

III. Results

The familiar spiky output of the uncontrolled laser is shown in Fig. 3. The light emission begins after ≃240 μs from the initiation of the flashlamps discharge and proceeds undisturbed for ≃560 μs with large intensity fluctuations and spikes whose amplitude can reach the value of ≃315 kW.

We desire now to transform the irregular laser emission into

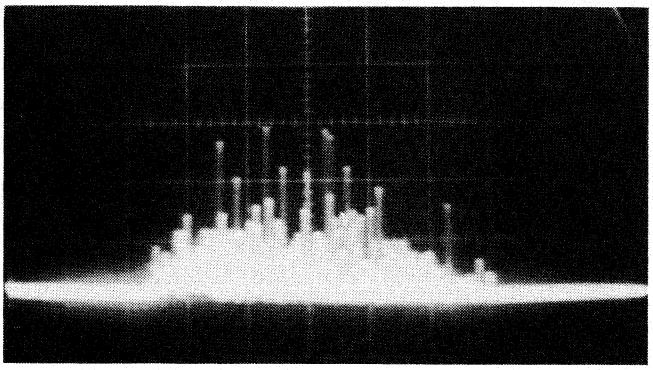

Fig. 3. Uncontrolled laser light output. Time: 100 μs/div. Intensity: 107 kW/div.

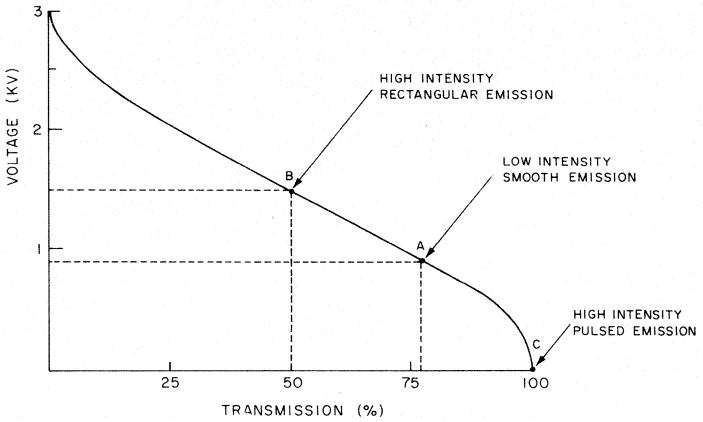

Fig. 4. Pockels-cell transmission curve.

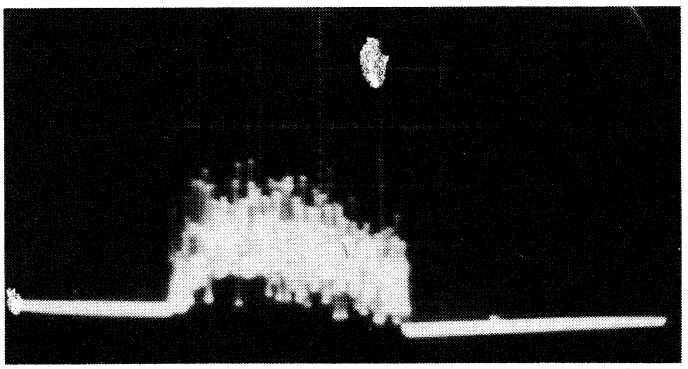
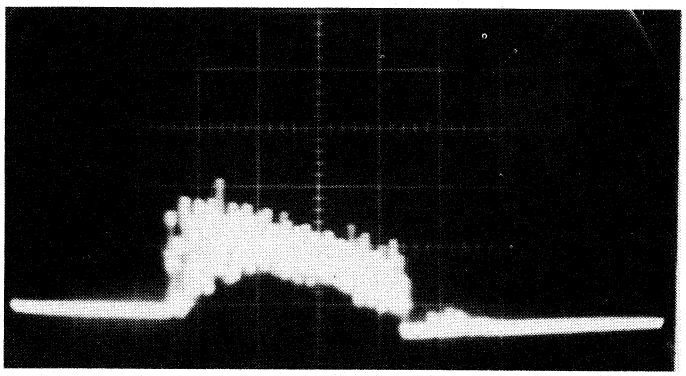


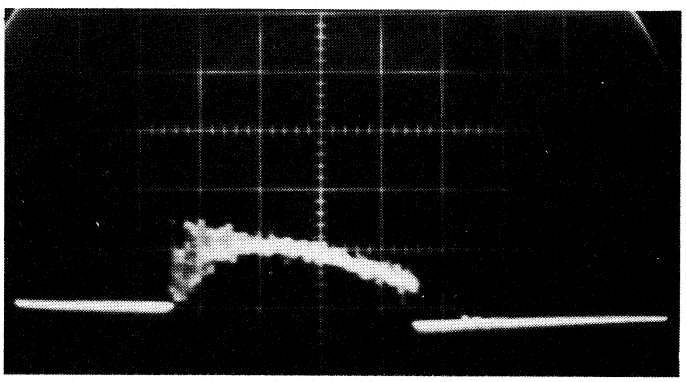
either: a) a long spikeless output, or b) a rectangular pulse of adjustable intensity and duration, or c) a Q-switched high-intensity pulse, or d) a stroboscopic output.

In the following it will be shown that any one of the above results can be achieved by a proper setting of the feedback parameters.



A. Long Spikeless Output

If we want to stabilize the laser-power output without controlling its time duration, we have available two parameters, the Pockels-cell bias voltage and the photodiode resistance. The choice of the bias voltage is obviously dictated by the power level in which the laser has to operate. When the power is high, the bias voltage has to be set so as to reduce the Pockels-cell transmission. When the power is low the bias voltage can be set for cell's full transmission. In the particular case we are considering, the laser power to be extracted is the lowest of all, being just the normal output simply stabilized in amplitude. As a consequence, one would be inclined to set the bias voltage for full transparency of the Pockels cell. However, examination of the Pockels-cell transmission curve (Fig. 4) reveals that the curve is linear only in its central portion and that, if the cell operates at the full transmission point, the photodiode feedback voltage is virtually ineffective for corrective action. Hence, the operating point will be chosen at A, where the cell has the largest transmission still in the linear part of the curve. As for the photodiode resistance, we shall select the lowest possible value still capable of inducing a feedback voltage sufficient to stabilize the laser output. Fig. 5 shows three typical laser outputs obtained with (a) 200 Ω, (b) 500 Ω, and (c) 1000 Ω photodiode resistance. It can readily be seen that, although the values of the (a) and (b) resistances are appropriate for attaining a low circuit delay time, resistance (c) is the one necessary in order to obtain a good laser-power stabilization for most part of the laser emission. The output then lasts ≃400 μs with an average power of ≃23 kW and the power fluctuation is ≃20 percent, except in the initial part of the pulse, where it is higher. The cutoff of laser emission on the right side of the display is due to our pulser, which is not able to provide a pulse longer than 450 μs.



Unfortunately, the foregoing experimental results do not lend themselves to an easy comparison with the predictions

(a)

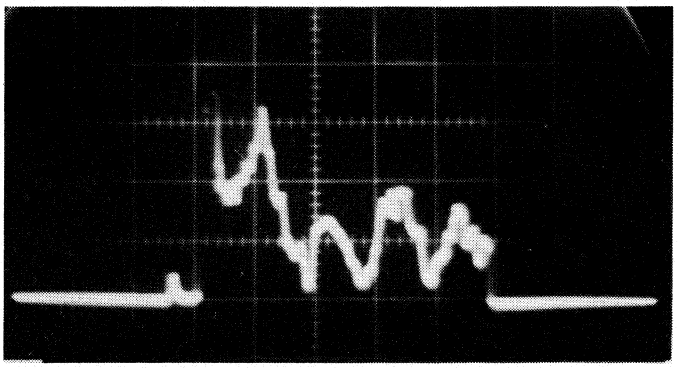
(b)

(c)

Fig. 5. Feedback-controlled light output. Pockels-cell bias voltage: 900 V. Undelayed lasing. Photodiode resistance: (a) 200 Ω; (b) 500 Ω; (c) 1000 Ω. Time: 100 μs/div. Intensity: 27 kW/div.

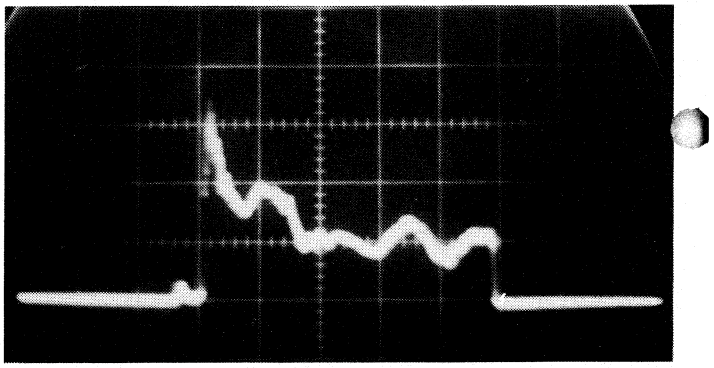
from the theoretical work of Statz *et al.* [4]. The reason is that the theory has been worked out for the particular case of insertion of a nonlinear absorber into the laser cavity, whereas in our case a Pockels cell has been inserted. The difference is that the calculations for the nonlinear absorber case have been done for constant losses in the system and variable time delays, whereas the Pockels-cell case involves simultaneous variation of time delays and system losses. However, we affirm that the loss term is more important than the time-delay parameter for a good stabilization of power output, as appears very clearly from the results of Fig. 5 and the results that will be shown in the next paragraph.

B. Rectangular Pulse of Adjustable Intensity and Duration



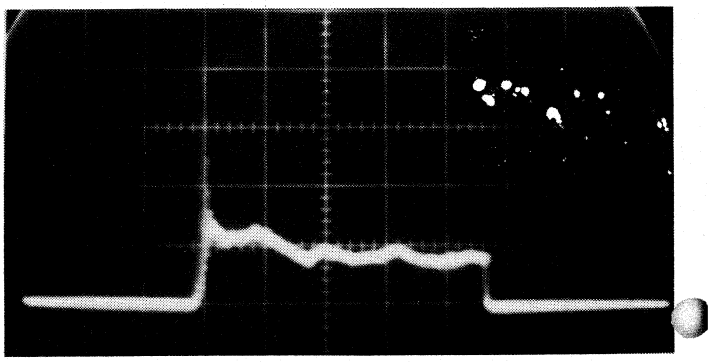
If it is required to control the time duration as well as the intensity of the light output, with the objective of obtaining rectangular emission, all four parameters in the system have to be adjusted. First, we shall set the pulse time duration for the value in which we are interested. Then, we shall delay lasing action until the stored energy is sufficient to yield a good rectangular output for the prescribed length of time. For instance, Fig. 6(c) shows the output when lasing action was started 300 μs after the initiation of the flashlamps discharge with the Pockels-cell bias voltage left at point *A* (Fig. 4) and the photodiode resistance set at 1000 Ω. It can be clearly seen that the light output, except for an initial overshoot, has near-rectangular form at power of $\simeq$27 kW for a time duration of $\simeq$50 μs. Fig. 6(a) and (b) show the effect of lower values photodiode resistances. It is readily seen that 200-Ω [Fig. 6(a)] and 500-Ω [Fig. 6(b)] resistances are insufficient for good power stabilization, which confirms what was found in the case of a long spikeless output.

If higher power for a shorter time is required, it is necessary to further delay lasing action and simultaneously reduce the duration of the light pulse. Clearly, now the Pockels-cell bias voltage has to be set for reduced cell's transmission. Fig. 7 shows the form of the laser emission when lasing has been delayed 650 μs after the initiation of the flashlamps discharge and the Pockels-cell bias voltage has been set at 1500 V (point *B* on the transmission curve, Fig. 4). The power stabilizing resistance has been found to be 2000 Ω in this case. As before, except for an initial overshoot, the laser emission is near-rectangular with intensity of $\simeq$150 kW for 14 μs.



If a much shorter light pulse at higher intensity is desired, it is simply necessary to reduce the photodiode resistance, in order to compensate for the light-intensity increase, leaving the Pockels-cell bias voltage at point *B* of Fig. 4. For instance, Fig. 8 shows the laser output when the photodiode resistance has been reduced to 100 Ω and lasing has been delayed 620 μs after the initiation of the flashlamps discharge. A pulse of $\simeq$2-MW intensity, 0.7-μs duration appears, as measured at half-power points.

C. Q-Switched High-Intensity Output



It is obvious that the feedback system used for the generation of rectangular light pulses does not impede the generation

(a)

(b)

(c)

Fig. 6. Feedback-controlled light output. Pockels-cell bias voltage: 900 V. Delayed lasing. Photodiode resistance: (a) 200 Ω; (b) 500 Ω; (c) 1000 Ω. Time: 10 μs/div. Intensity: 27 kW/div.

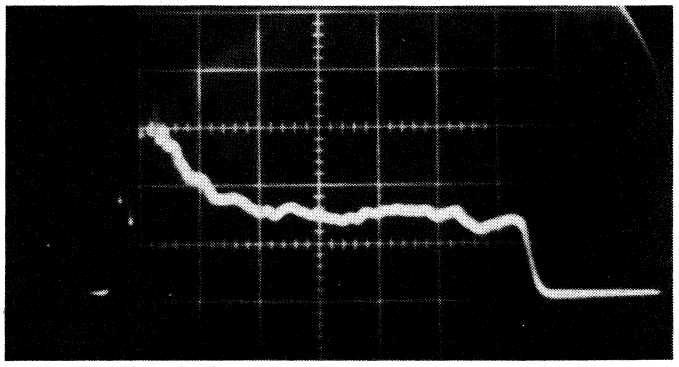


Fig. 7. Feedback-controlled light output. Pockels-cell bias voltage: 1500 V. Photodiode resistance: 2 kΩ. Delayed lasing. Time: 2 μs/div. Intensity: 107 kW/div.

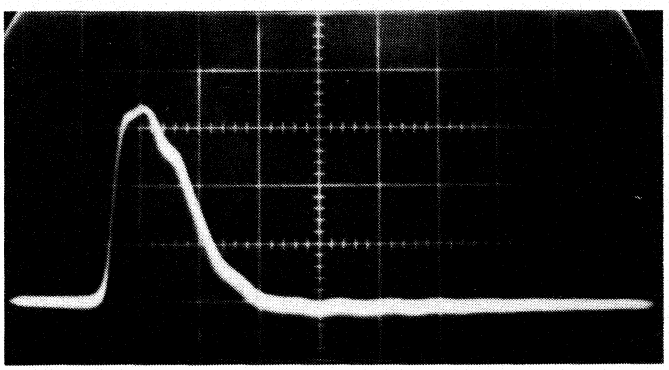

Fig. 8. Feedback-controlled light output. Pockels-cell bias voltage: 1500 V. Photodiode resistance: 100 Ω. Delayed lasing. Time: 0.5 μs/div. Intensity: 674 kW/div.

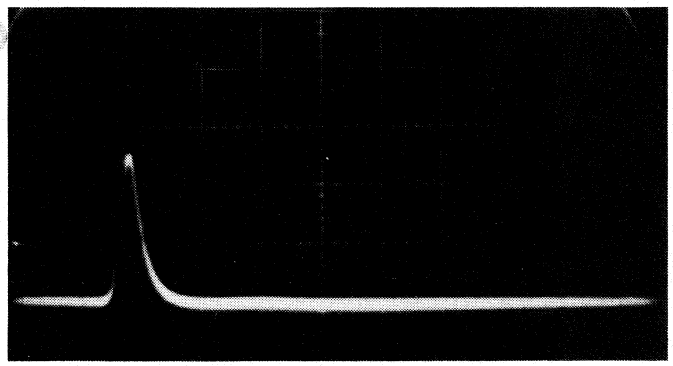

Fig. 9. *Q*-switched light output. Pockels-cell bias voltage: 0. Delayed lasing. Time: 0.5 μs/div. Intensity: 3.37 MW/div.

of *Q*-switched outputs. In fact, the only thing that is required to do is to set the Pockels cell for full transmission (point *C* of Fig. 4) and to eliminate the feedback light path. Then a *Q*-switched pulse will be obtained. Fig. 9 shows the laser emission when the Pockels cell is turned on 470 μs after the initiation of the flashlamps discharge. A 200-ns duration pulse appears with intensity of 8.5 MW.

D. Stroboscopic Output

Finally, if a series of light pulses are required, this can be obtained, as indicated in the work of [4], by providing a delay between the buildup of the electromagnetic energy within the laser cavity and the corrective action of the Pockels cell. In explicit terms, we simply need to increase the photodiode resistance. Fig. 10 shows the laser pulsed emission when the photodiode resistance has been increased to 15 kΩ, the Pockels cell set for full transmission, and lasing delayed 700 μs after the flashlamps discharge. Four pulses of submicrosecond duration and kilowatt intensity appear at a frequency of ≃1 MHz and many more pulses would be obtained by changing the duration of the Pockels-cell open time.

IV. Conclusions

In the present paper we have shown that the erratic emission from a high-power Nd:glass laser can be converted into a rectangular or pulsed emission of controlled intensity and duration. This result is achieved by the insertion into the laser cavity of a Pockels-cell shutter whose transmission is feedback controlled by a photodiode that monitors the laser output. An important feature of the present system is the ability to set the Pockels cell on any point of its transmission curve. This adjustment proved essential in obtaining either a rectangular emission of variable intensity and duration or a pulsed emission. We believe that the laser output in the rectangular mode can be smoothed further if a fraction larger than 15 percent of the available laser power (this is the value adopted by us) is deflected back to drive the Pockels cell. In fact, the photodiode resistance can have in this way a lower value, thus lowering the feedback delay time. Alternately, a nonlinear absorber can be added to the laser cavity, according to the ideas of Pantell and Warszawski [6] and Balashov *et al.* [7]. However, before proceeding along either one of these lines, it is important to consider very carefully if the advantage of obtaining a smoother pulse is offset by the disadvantage of a reduced light output.

Fluctuations in Mode-Locking Threshold Due to Statistics of Spontaneous Emission

ROBERT WILBRANDT AND HORST WEBER

Abstract—A passively mode-locked Nd:YAG oscillator operating in TEM_{00} mode is investigated theoretically and experimentally. It is shown that a mode-locking threshold well above the normal lasing threshold exists and that this second threshold is of a probabilistic nature. This means that mode locking at a given pump rate in the region of threshold occurs only with a certain probability due to the Gaussian statistics of spontaneous emission. Experiments agree qualitatively with theory. Furthermore, thermal effects in the liquid absorber are shown to play an important role in mode-locking systems; they introduce an additional time-dependent loss or gain, depending on the experimental setup. This can either lead to increase of mode-locking threshold or to the appearance of higher order transverse modes and possible damage of laser components.

I. Introduction

A NUMBER of theories on Q switching and passive mode locking have been published in the literature. Some of them are [1], [2] based on rate equations for the laser medium, the absorber, and the photon density averaged over the round-trip time of the resonator, thus neglecting the statistical nature of spontaneous emission; in others the analysis is made by looking at the development of one or several ultrashort fluctuation pulses in a cavity with nonlinear absorber [3]-[13]. Both analytical and numerical computations were made. For a pulsed Nd:YAG mode-locked oscillator we wish to present the following: 1) a comparison between two theoretical approaches, the first being a system of rate equations similar to those used by Erickson and Szabo [1], the second being a somewhat refined model used by Caruso *et al.* [13]; 2) a statistical consideration of the mode-locking threshold; 3) a comparison of theory and experiments with respect to 1) and 2), which demonstrates the importance of considering the statistics of spontaneous emission in the theory; 4) experimental results of the influence of thermal blooming in the saturable absorber on mode-locking characteristics.

II. Theory

The two different systems of rate equations used to compute numerically the peak intensity (or energy, respectively) of a passively mode-locked laser as a function of pump rate are the following:

$$\frac{dn}{dk} = W \cdot t_L - (W+A) \cdot t_L \cdot n - \frac{\sigma_L \cdot t_L}{2\sigma_A \cdot t_A} \cdot n \cdot \varphi \qquad (1a)$$

$$\frac{d\varphi}{dk} = \left(\sigma_L \cdot l \cdot N_0 \cdot n - \gamma - \frac{\kappa_0}{1+\delta \cdot \varphi}\right) \cdot \varphi \qquad (1b)$$

and

$$\frac{dn}{dk} = W \cdot t_L - (W+A) \cdot t_L \cdot n - \frac{1}{\sigma_A \cdot l \cdot N_0} \left\{ \frac{1}{\delta} \ln \cdot [1 + T_0(e^{\delta \cdot E} - 1)] + M \cdot \langle E \rangle \cdot T_0 \right\} \cdot (G-1) \qquad (2a)$$

$$\frac{dE}{dk} = \frac{1}{\delta} \cdot \ln [1 + T_0(e^{\delta \cdot E} - 1)] \cdot R \cdot G - E \qquad (2b)$$

$$\frac{d\langle E \rangle}{dk} = (T_0 \cdot R \cdot G - 1) \cdot \langle E \rangle \qquad (2c)$$

where

- N_0 concentration of active Nd: atoms;
- n population in the upper laser level normalized to N_0;
- φ intensity (photons/square centimeter second) normalized to saturation intensity of the saturable dye;
- t_L round-trip time;
- k time normalized to round-trip time t_L;
- W pump rate;
- A Einstein coefficient of spontaneous emission;
- σ_L cross section for stimulated emission in the laser medium;
- l length of the laser medium;
- σ_A absorption cross section of the absorber at $\lambda = 1.06\ \mu$;
- t_A relaxation time of the absorber;
- δ ratio of beam cross section in the laser medium to beam cross section in the absorber;
- T_0 low-intensity transmission of the dye;
- κ_0 $= -\ln T_0$;
- R loss factor;
- γ $= -\ln R$;
- E energy density of the largest noise pulse within a round-trip time normalized to saturation energy density E_s of the absorber;
- $\langle E \rangle$ mean energy density of a noise pulse within a round-trip time normalized to saturation energy density E_s of the absorber;
- M number of oscillating longitudinal modes equal to number of noise pulses per round trip;
- G $= e^{\sigma_L \cdot l \cdot N_0 \cdot n}$ = single-pass gain in the laser rod;
- W_{th} $= A \cdot (\gamma + \kappa_0)/\sigma_L \cdot l \cdot N_0$ = threshold pump rate for stationary case.

The first set of equations is essentially the single-mode approach of Erickson and Szabo [1] with two modifications.

Manuscript received July 7, 1974; revised December 18, 1974. This work was sponsored by the Swiss National Foundation.

R. Wilbrandt is with the Atomic Energy Commission Risø Research Establishment, Roskilde, Denmark.

H. Weber is with the Institute of Applied Physics, University of Berne, Berne, Switzerland.

1) A pump term is included, which allows comparison with experiments.

2) Focusing of the beam into the absorber is considered by the introduction of the cross-section ratio δ.

The relaxation of the absorber is regarded as very fast compared to changes in intensity and intensity fluctuations are not taken into account.

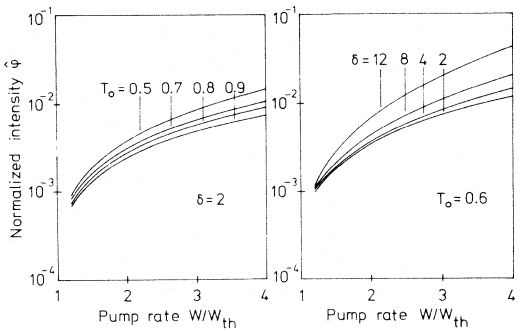
The second set of equations is that used by Caruso *et al.* [13], where a single noise pulse with energy density E and short duration compared to the dye relaxation time propagates through the resonator. The model is somewhat refined compared to that of Caruso and somewhat simplified with respect to that of Fleck [10] in that background fluctuations are taken into account by a number M of noise pulses of mean energy $\langle E\rangle$. Thus (2a) describes the depletion of inversion by two terms: the energy E of the highest pulse and the energy $M \cdot \langle E\rangle$ of the M noise pulses. Equation (2b) characterizes the temporal behavior of the highest pulse which passes the nonlinear absorber and (2c) that of the background, where it is assumed that the mean energy $\langle E\rangle$ remains in the domain of linear absorption of the dye throughout the calculations. This approximation is confirmed by the numerical results.

We shall show that the single-mode approach does (as expected) not give a satisfying description of Q switching and mode-locking threshold, whereas the inclusion of background results is in much better correspondence with experiments.

Consider now the statistics of spontaneous emission in order to draw conclusions about the probabilistic nature of mode-locking threshold. If in the region of linear absorption the probability of a particular pulse having an energy greater than E is given by

$$f(E) = \frac{1}{\langle E\rangle}\int_E^\infty e^{-E/\langle E\rangle}\,dE \tag{3}$$

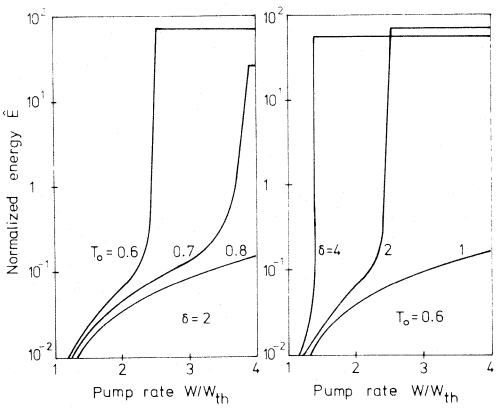
then the probability $p(E)$ of finding at least one such pulse among the number M of pulses per round trip is



$$p(E) = f(E)\sum_{n=0}^{M-1}[1-f(E)]^n = 1-[1-f(E)]^M. \tag{4}$$

With integration of (3) this results in

$$p(E) = 1-[1-e^{-E/\langle E\rangle}]^M. \tag{5}$$



In the following numerical integration of (2) $p(E)$ is varied by variation of the starting ratio $E/\langle E\rangle$. It should be noted that the background $M \cdot \langle E\rangle$ plays an important role in the depletion of inversion since it contains a considerable amount of energy. For example, with $M = 200$ and $p(E) = 0.6$ the ratio of background energy to maximum pulse energy is $M \cdot \langle E\rangle/E = 37$. We first show results for constant $p(E) = 0.63$ and compare the two sets of equations.

The integration was carried out starting at threshold with the following numerical values for Nd:YAG as laser medium and the absorber 9860 from Eastman Kodak: $E_s = 0.016$ J/cm^2 [13], $t_L = 10$ ns, $A = 5 \cdot 10^3$ s^{-1} [14], $\sigma_L = 3.5 \cdot 10^{-19}$ cm^2 [15], $l = 7.5$ cm, $\sigma_A = 3.7 \cdot 10^{-16}$ cm^2, $t_A = 9$ ps, $R = 0.5$, $M = 200$, $N_0 = 1.38 \cdot 10^{20}$ cm^{-3}, $E(0) = 10^{-14}$, $\varphi(0) = 10^{-14}$ (starting values at threshold). The resulting peak intensities and energies as a function of pump rate above threshold are shown for (1) in Fig. 1 and for (2) in Fig. 2. A comparison shows that without consideration of a fluctuation mechanism (Fig. 1) the "second threshold" W'_{th} [1], [13] lies above the considered pump rates even with focusing by a factor of 12 into the absorber. (We define as W'_{th} the value W at which the maximum values $\hat{\varphi}$ or $\hat{E} = 1$.) On the other hand, in the second model a mode-locking threshold is seen which depends on absorber transmission T_0 and focusing parameter δ. The time behavior of the largest pulse, the average pulse, and total gain in this latter case are shown in Fig. 3 at different pump rates for $T_0 = 0.6$, $p(E) = 0.6$, $\delta = 2$, whereby the maximum of E in this figure corresponds to $\hat{E}$ in Fig. 2. It is seen that the maximum of the pulse train is reached earlier at higher pump rates, but the height of the maximum pulse does not change considerably. Instead the higher inversion is mainly depleted into the background. Thus the system stabilizes itself. The importance of the background is also shown by the fact that its amount does not change significantly from a pump value ($W/W_{th} = 2.43$) just below mode-locking threshold to one ($W/W_{th} = 2.45$) just above.

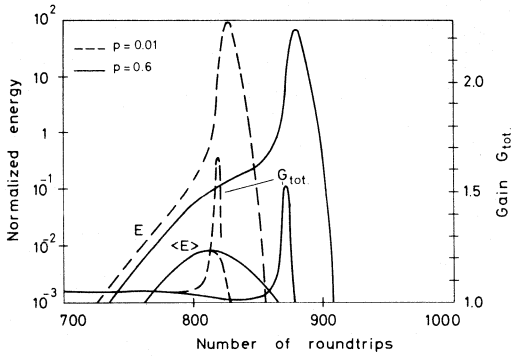

Fig. 4. Energy E of maximum pulse, energy $\langle E \rangle$ of mean pulse, and total single-pass gain G_{tot} as a function of number of round trips for different probabilities.

Very similar curves occur with Nd:glass instead of Nd:YAG, the difference being mainly that intensities in Nd:glass are generally higher by about a factor of 10 than in Nd:YAG, which leads to lower mode-locking threshold.

Next we show the influence of $p(E)$ on the calculations. In Fig. 4 the time behavior of the maximum pulse E, the mean pulse $\langle E \rangle$, and the total single-pass gain G_{tot} is shown for $p(E) = 0.6$ (solid lines) and $p(E) = 0.01$ (dashed lines) for $W/W_{th} = 2.45$, $T_0 = 0.6$, $\delta = 2$. It can be seen that for the smaller value of $p(E)$ the absorber is bleached earlier. Therefore, at the end of the linear phase the population is less depleted by the background, which leads to a higher gain. Correspondingly, the mode-locking threshold W'_{th} is decreased. The $p(E)$ corresponding to a certain W'_{th} can be regarded directly as the probability $p(W = W'_{th})$ to find this mode-locking threshold. Thus the probability $p(W = W'_{th})$ for bleaching the dye with pump rate W can be found as, for example, in Fig. 5 for $\delta = 2$.

III. Experiments

To compare the theoretical results with experiments, a resonator was set up, which exhibits very regular and reproducible spiking emission [16], [18] in the TEM_{00} mode. The reproducibility was the same as shown in [18]. The setup is seen in Fig. 6. It consisted of a 280-cm-long ring resonator with one curved mirror (radius of curvature 2 m). The laser

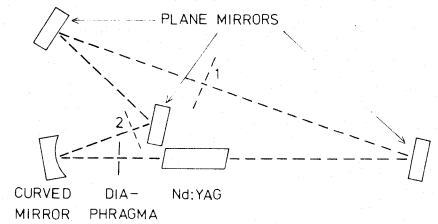

Fig. 6. Experimental setup of the mode-locking ring oscillator with the dye either in position 1 (beam waist) or position 2.

rod was a 3 in × 1/4 in Nd:YAG with ends cut at 6°. The TEM_{00} mode was selected by a diaphragm with 3.0-mm diameter. A 10-percent change in focal length of the thick lens produced by inhomogeneous heating of the laser rod leads only to a change of 10^{-3} in beam diameter. The largest beam diameter of the cavity is on the curved mirror, while the beam waist is found at position 1, which leads to a maximum value of $\delta = 4$. The experimentally resulting peak energies with the Kodak 9860 dye in position 2 are shown in Fig. 7. The pump rate W was obtained both by computer calculations and by a method described in [20]. From Fig. 7 it is seen that the experiments qualitatively follow the theory in that a "second threshold" W'_{th} is found, which depends on T_0 as predicted. However, mode locking occurs already for $\delta = 1$ which is not the case in the theory. One possible explanation for this discrepancy is thermal effects in the liquid, which shall be discussed in the following; another one is that while the pulse shortens in time, it is narrowed in space by the dye leading to higher energy densities and possibly to smaller losses at the diaphragm.

To obtain some statistics on the mode-locking threshold a series of 50 shots was investigated for each given pump rate and the number of mode-locking pulses counted. When no mode locking occurred, a spiking emission was found. The results are given in Fig. 8, where the probability for bleaching is plotted versus pump rate. They agree qualitatively with the theory. Again the experiments were carried out with $\delta = 1$. The mode-locking emission was quite reproducible as shown in Fig. 9. However, our experiments showed that while the qualitative behavior of the probability for mode locking is always of the indicated form in Fig. 8, the quantitative results depend on experimental conditions as, e.g., the size of the diaphragm. Closing the diaphragm by 10 percent led to considerably higher W'_{th} which supports the argument that beam

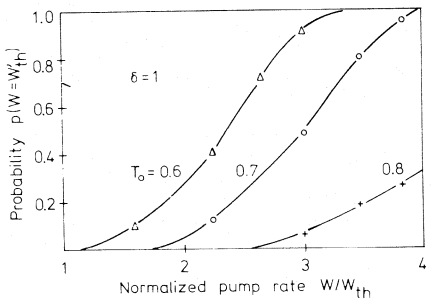

Fig. 8. Experimental results for the probability $p(W = W'_{th})$ that at a given pump rate W mode locking occurs as a function of normalized pump rate for a beam cross-section ratio 1.

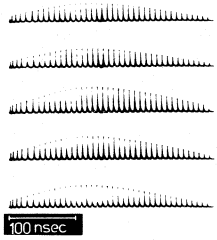

Fig. 9. Five subsequent mode-locking pulse trains.

narrowing effects as mentioned in the preceding are of considerable importance.

Regarding the influence of thermal effects in the absorber, it has been stated previously [19] that the liquid can be regarded as a time-dependent negative lens due to heating by a Gaussian intensity profile, which leads either to an additional time-dependent loss or gain mechanism. The position 2 (see Fig. 5) for the absorber is chosen such as to minimize the influence of a corresponding negative lens on the beam size at the diaphragm and in the laser rod. Putting the dye closer to the diaphragm leads to the appearance of higher order transverse modes, which can clearly be seen by the resulting mode patterns, and to damage of the mirror nearest to the beam

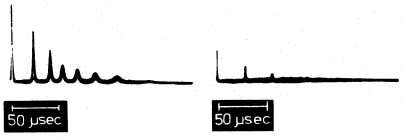

Fig. 10. Spiking emission with dye cell in position 1 (see Fig. 4) at $W/W_{th} = 2$. (a) With pure solvent (left). (b) With absorber of transmission $T_0 = 0.6$ (right).

waist. On the other hand, focusing into the absorber cell, as considered in the theory, by setting the dye in the beam waist at position 1 (corresponding to $\delta = 4$) augments time-dependent cutoff losses at the diaphragm due to thermal effects. Thus the intensity does not increase as expected from theory, but a reduction takes place. A picture of the emission with solvent and with absorber below mode-locking threshold ($T_0 = 0.6$) at position 1 for $W/W_{th} = 2$ is shown in Fig. 10. Thus it is clearly demonstrated that thermal effects play an important role in passive mode-locking systems. One reason that mode locking is much more reproducible with Nd:YAG than with Nd:glass is the higher cross section for stimulated emission in Nd:YAG, which leads to a lower spiking intensity [18] and reduces thermal effects compared to Nd:glass. Embedding the absorber in polymethylmetacrylate (PMMA) did not lead to significantly different behavior at least with Nd:glass, probably because the thermal gradient of index of refraction in PMMA is one of the highest of all solids. However, no experiments with PMMA were made with Nd:YAG.

IV. Conclusion

The theoretical and experimental investigation of a Nd:YAG mode-locking system has shown the following.

1) A distinct "second threshold" exists for mode locking above the normal lasing threshold.

2) This second threshold is characterized by a probability distribution, which means that mode locking in the region of threshold (which is the region of high selectivity [13] and therefore of interest) can only be expressed with a certain probability, the most favorable case being obtained with high absorber concentrations.

3) Thermal effects in the liquid absorber influence the mode-locking characteristics considerably and can as well lead to damage of the components of the laser as to a substantial increase or even suppression of mode-locking threshold.

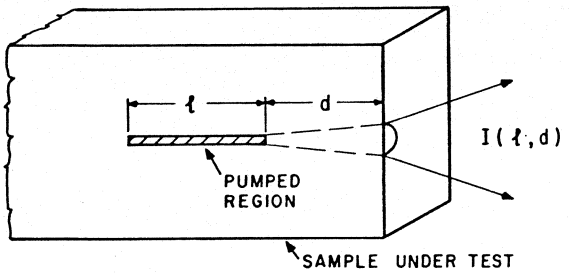
Theory of Optical-Gain Measurements

PETER S. CROSS AND WILLIAM G. OLDHAM, MEMBER, IEEE

Abstract—**The widely used technique for determining optical gain and absorption from single-pass, amplified spontaneous emission (ASE) is analyzed with particular attention given to active-volume saturation and three-dimensional effects. The results for homogeneously broadened media show that the population inversion and hence the gain in the active region is diminished by high levels of spontaneous and ASE. The externally measured gain is further reduced for large output collection apertures that admit incompletely amplified off-axis rays. Criteria are given for the excitation and detection geometries required to ensure accurate (~10-percent) gain measurement. The simultaneous measurement of the equilibrium absorption coefficient can be made under less restrictive conditions.**

I. INTRODUCTION



THERE HAS BEEN considerable interest in recent years in the direct measurement of optical gain in various active media. In the usual technique using a pulsed-gas laser pump, the gain is found from the variation of the intensity of amplified spontaneous emission (ASE) with excitation geometry [1], [2]. Recently, Cross and Oldham have extended this technique to allow the measurement of the absorption coefficient of an umpumped region as well [3]. The combined measurement technique is illustrated in Fig. 1(a). The pumped region is a narrow stripe of length l translated a distance d from the sample edge with the output $I(l, d)$ collected along the stripe axis as shown. The ideal dependence of $I(l, d)$ is shown in Fig. 1(b). The optical gain is found from the variation of $I(l, d)$ with l, and the absorption coefficient is determined from the dependence of $I(l, d)$ on d. However, in order to accurately determine the optical gain or absorption from $I(l, d)$, the effects of active-region saturation and incomplete amplification of collected rays must be properly included.

This paper presents a detailed theoretical analysis of the gain-absorption measurement technique that explicitly investigates gain saturation and the effects of a nonzero collection aperture on the interpretation of experimental data. In Section II, the emission equations are derived that relate stimulated and spontaneous emission in homogeneously broadened media and include saturation. In Section III, the active-volume gain saturation is investigated for the geometry that is typically used in an ASE measurement. The effects of a nonzero collection aperture on the detected output are analyzed in Section IV. In Section V, the results are discussed and criteria are given for the measurement conditions necessary to accurately measure gain and absorption.

II. Emission Equations with Saturation

An excited, optically active medium can be characterized by two parameters, r_{spon}, the spontaneous-emission rate per unit volume per unit energy, and g, the optical-gain coefficient. Both r_{spon} and g are functions of many parameters including excitation level, electromagnetic radiation intensity, absolute temperature T, and photon energy E. Under steady-state excitation, the total downward-transition rate must equal the pumping rate $\mathcal{P}$ as expressed by

$$\mathcal{P} = \mathcal{R}_{spon} + \mathcal{R}_{stim} + \mathcal{R}_{nr} \tag{1a}$$

$$\mathcal{P} = \int r_{spon}(E)\,dE + \int \Phi(E)\,g(E)\,dE + \mathcal{R}_{nr} \tag{1b}$$

where

$\Phi(E)\,dE$ the flux of photons with energy between E and $E + dE$;
$\mathcal{R}_{nr}$ the nonradiative transition rate;
$\mathcal{R}_{spon}$ the total spontaneous-emission rate per unit volume;
$\mathcal{R}_{stim}$ the total stimulated-emission rate per unit volume.

Equations (1a) and (1b) can often be applied as well to pulsed experiments, as discussed in Appendix I.

For many optical media used in laser applications, $\mathcal{R}_{spon}$ can be characterized by a lifetime τ_{spon}

$$\mathcal{R}_{spon} = n/\tau_{spon} \tag{2}$$

where n is the density of the excited species. Similarly, the nonradiative transition rate is given by

$$\mathcal{R}_{nr} = n/\tau_{nr} \tag{3}$$

where τ_{nr} is the nonradiative lifetime. Thus, (1a) can be written

$$\mathcal{P} = \mathcal{R}_{stim} + \mathcal{R}_{spon}(1 + \tau_{spon}/\tau_{nr}). \tag{4}$$

However, the relationship between $\mathcal{R}_{stim}$ and $\mathcal{R}_{spon}$ cannot, in general, be expressed in closed form. The amplitude and shape of the photon flux $\Phi(E)$ depend on the excitation level everywhere in the active volume, and therefore must be calculated from transcendental integral equations. In the present work, in order to reduce the computational complexity at minimum sacrifice, the photon-energy dependence is eliminated by approximating the emission characteristics with rectangular spectra of width ΔE. Thus the transition probabilities (spontaneous and stimulated) are independent of photon energy within the bandwidth ΔE, which tacitly requires very short energy-relaxation times (i.e., homogeneous broadening).[1]

In determining the onset of saturation in an ASE measurement, the use of the rectangular approximation is equivalent to assuming that the emission properties (r_{spon} and g) can be described by effective average values (over energy). In Appendix II it is verified for the illustrative cases of parabolic and triangular spectra that the effective average-gain coefficient is nearly constant for the conditions of interest in this analysis. The concomitant assumption that the spontaneous and stimulated spectra have the same width does in fact lead to an overestimation of the degree of saturation. In general, some portion of the spontaneous spectrum lies outside the gain spectrum and is consequently not amplified. Thus the results based on the rectangular approximation represent an upper bound on the degree of saturation. Carrying out the integral for $\mathcal{R}_{stim}$ in (1b)

$$\mathcal{R}_{stim} = \Phi \cdot g \cdot \Delta E = (I \cdot g)/E \tag{5}$$

which is expressed in terms of the integrated radiation intensity I. Following the usual Einstein treatment of induced transitions, $\mathcal{R}_{stim}$ is proportional to the product nI, where $\mathcal{R}_{spon}$ is proportional to n only. To find the proportionality constant relating $\mathcal{R}_{stim}$ to $\mathcal{R}_{spon}$ for the case of rectangular spectra, we define I_{sat} as the radiation intensity at which g (and consequently n and $\mathcal{R}_{spon}$) has dropped to one half its low-intensity value. Thus when I equals I_{sat}, from (4) and (5)

$$(\mathcal{R}_{spon,0}/2)(1 + \tau_{spon}/\tau_{nr}) = I_{sat}g_0/2E = \mathcal{P}/2 \tag{6}$$

where the subscript 0 denotes the low intensity value. Since g and $\mathcal{R}_{spon}$ are both proportional to n only and do not explicitly depend on I, the subscript 0 can be dropped in general, and for arbitrary intensity I, (6) is rearranged to give

$$g = [(E \cdot \mathcal{R}_{spon})/I_{sat}]\,(1 + \tau_{spon}/\tau_{nr}). \tag{7}$$

[1] To extend the analysis to provide spectral information and include inhomogeneously broadened systems would require specific density-of-states functions and accurate data or assumptions about energy-relaxation times. The additional scope of the results would not justify the greatly increased complexity.

For an interesting optical system in which the rectangular approximation is useful, I_{sat} is a constant of the system and independent of the excitation level. Examples include homogeneously broadened two- and three-level systems [4] and degenerate semiconductors [5]. Further, since g and $\mathcal{R}_{spon}$ depend only on radiative transitions, the proportionality constant in (7) $(1 + \tau_{spon}/\tau_{nr})/I_{sat}$ must be independent of τ_{nr}. Thus decreasing the nonradiative lifetime correspondingly increases the intensity at which gain saturation becomes important (I_{sat}).

From (4), (5), and (7), at arbitrary radiation intensity

$$\mathcal{G} = g\, I/E + g \cdot I_{sat}/E \tag{8}$$

and substituting for $\mathcal{G}$ from (6)

$$g = g_0/[1 + (I/I_{sat})]\,. \tag{9}$$

Equations (7) and (9), coupled with appropriate geometrical considerations, are used in Section III to calculate the gain and intensity everywhere in the active region.

III. Active-Volume Gain Saturation

To properly predict the manner in which gain saturation will manifest itself in an ASE experiment, a three-dimensional analysis is undertaken. Referring to Fig. 2, for the purposes of these calculations the active region is modeled as follows.

1) The cross section is approximated by a rectangle of dimensions $2t \times 2w$. The depth is a function of the combined effect of the nonzero absorption length of the pumping source and of the subsequent diffusion of the excited species. The effective width depends on the width of the stripe focused on the lateral diffusion.

2) To account for three-dimensional effects, the active volume is assumed to contain a collection of point sources emitting spontaneously, isotropically, and with random phases. The computed intensity at any point is the proper summation of spherical waves.

3) The stripe is assumed to be narrow (i.e., $l >> w, t$).

4) The quantities $\mathcal{R}_{spon}$ and g do not vary in the y and z directions.

5) In order to minimize the number of parameters in the computations which follow, τ_{nr} is taken as large compared to τ_{spon}. As a result, the effective saturation intensity I_{sat} is a minimum, and the computations represent the worst case for gain saturation. The crucial results involving active-region saturation are subsequently reexamined to include the effects of scaling due to nonradiative processes.

The manner in which the three-dimensional effects are handled is also illustrated in Fig. 2. The emitting element $dxdydz$ at position x emits a total power $E \cdot \mathcal{R}_{spon}(x)\, dxdydz$ into 4π sr. The receiving area at position x' presents a solid angle $\Omega(x - x')$ to the emitting volume, and as a result, only a fraction $\Omega(x - x')/4\pi$ of the rays emitted at x are collected at x'.[2] In addition, the rays that are collected at x' have experienced an amplification of $\exp\left(\int_{x'}^{x} g'(\xi)d\xi\right)$, where $g'(\xi)$ is the net gain $g - \alpha_e$, and α_e is the excess absorption due to parasitic processes such as free-carrier absorption and scattering. The amplification is expressed as an integral to allow for the variation of gain with position, owing to saturation. Thus the intensity at x' due to spontaneous emission at x, $I(x, x')$ is

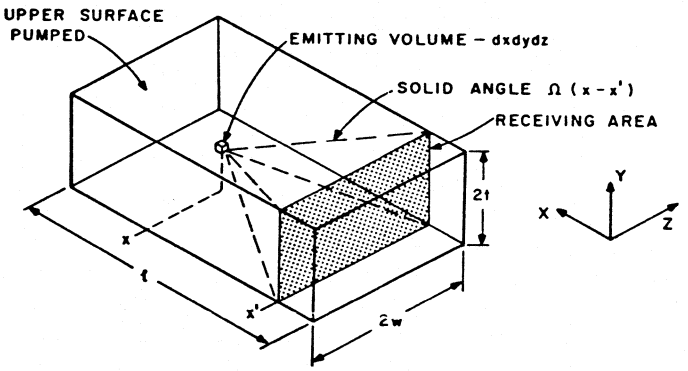

Fig. 2. Schematic diagram of the active volume illustrating the solid angle $\Omega(x - x')$.

$$I(x, x') = I_{spon}(x) \cdot \frac{\Omega(x - x')}{4\pi} \cdot \exp\left[\int_{x}^{x'} g'(\xi)\, d\xi\right] \tag{10}$$

where $I_{spon}(x) = E \cdot \mathcal{R}_{spon}(x)$. The complete solution at x' is the summation of all terms like (10). In deriving (10), the various waveguiding effects due to induced refractive-index variations have been neglected because of the following.

1) The temperature-induced change can be either positive or negative depending on the medium, but can usually be made negligible in the experiment.

2) The injected excess free-carrier concentration makes a negative contribution to the index that inhibits waveguiding.

3) The gain-induced index variation has an N-shaped dispersion [6] that can give a significant positive contribution for large gains, but only over a small fraction of the gain linewidth.[3]

Since the excited region is located near a sample edge, the intensity distribution in the active volume is in general asymmetric. Radiation incident on the sample edge undergoes a partial reflection due to the dielectric discontinuity, causing a fraction to make a second transit of the active region and be further amplified. Referring to Fig. 3(a), there are three components to the intensity at any point x'. The forward wave (FWD) is the cumulative effect of all emitting elements between l and x'; the reverse wave (REV) is the summation of the effects of the elements between x' and 0; and the reflected wave (REFL) is the contribution from those rays that have been generated in the active region, propagated to the front surface, and have been reflected back into the active region.

Integrating terms similar to (10), the following expressions are obtained:

$$I_{FWD}(x') = \frac{1}{4\pi}\int_{x'}^{l} I_{spon}(x) \cdot \Omega(x - x') \cdot \exp\left[\int_{x'}^{x} g'(\xi)\, d\xi\right] dx \tag{11}$$

[2] Due to the total internal reflection at the top surface, the effective receiving area is actually twice that shown in Fig. 2. The expression for $\Omega(x)$, derived in [5], is given by

$$\Omega(x) = 2\pi\left\{1 - \frac{2}{\pi}\cos^{-1}\left[\frac{2wt}{\sqrt{x^2 + w^2}\sqrt{x^2 + 4t^2}}\right]\right\}.$$

[3] Item 3 could become more significant in spectral, as opposed to wavelength-averaged measurements.

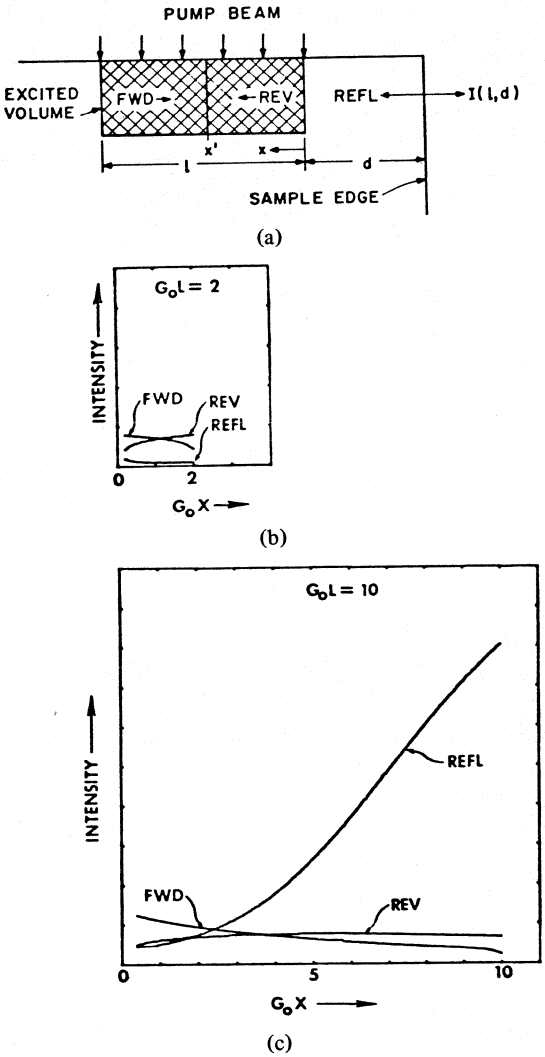

Fig. 3. (a) Cross-sectional view of the active region showing the three waves (forward, reverse, reflected) traveling in the sample. (b) The calculated variation of the intensity of the three waves with normalized position in the stripe for $G_0L = 2$. (c) The calculated variation of the intensity of the three waves for $G_0L = 10$. $G_0 = 0.03$: $R = 0.5$: $K = 0.025$: $D = 0$: $\rho = 6$.

$$I_{\mathrm{REV}}(x') = \frac{1}{4\pi}\int_0^{x'} I_{\mathrm{spon}}(x)\cdot\Omega(x'-x)\cdot\exp\left[\int_x^{x'} g'(\xi)\,d\xi\right]dx \tag{12}$$

$$I_{\mathrm{REFL}}(x') = \frac{1}{4\pi}R\cdot\exp(-2\alpha d)\cdot\exp\left[\int_0^{x'} g'(\xi)\,d\xi\right]\cdot\int_0^{l} I_{\mathrm{spon}}(x)\cdot\Omega(x+x'+2d)\cdot\exp\left[\int_0^{x} g'(\xi)\,d\xi\right]dx \tag{13}$$

where R equals the reflection coefficient at the front surface.

As a result of the intensity dependence of the gain in (9), equations (11)-(13) comprise a set of nonlinear integral equations that must be solved numerically. The parameters used in the numerical calculations are normalized to t, the half-depth of the active region, as shown in Table I.

TABLE I
PARAMETER NORMALIZATIONS

Parameter	Normalized Parameter	Value
Net Gain	G	$g'\cdot t$
Unsaturated Gain	G_o	$g_o'\cdot t$
Excess Absorption	K	$\alpha_e\cdot t$
Position	X	x/t
Stripe length	L	ℓ/t
Stripe width (aspect ratio)	ρ	w/t
Absorption path length	D	d/t
Collection half angle	θ	θ
Reflection coefficient	R	R

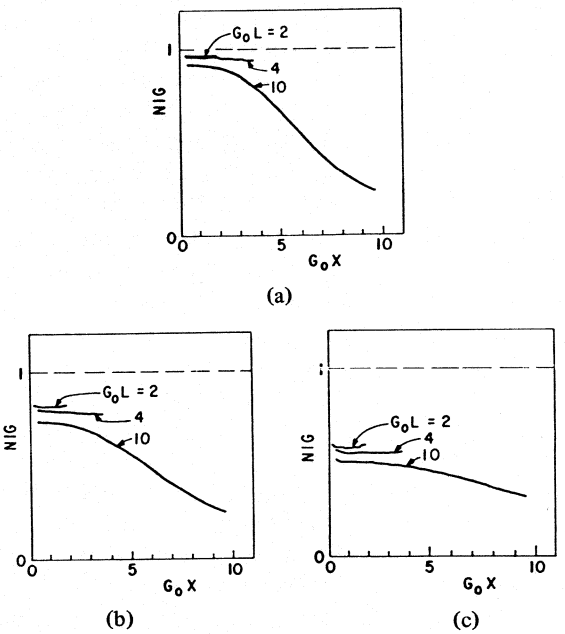

Fig. 4. The calculated variation of the NIG with normalized position in the stripe for three values of G_0L illustrating the saturation due to increasing ρ. $G_0 = 0.03$: $R = 0.5$: $K = 0.025$: $D = 0$. (a) $\rho = 1$. (b) $\rho = 6$. (c) $\rho = 20$.

Fig. 3(b) and (c) shows the calculated spatial variation of the three intensity components under laboratory conditions typical for a semiconductor medium at two values of the product G_0L. The reflected wave clearly dominates for large values of G_0L while the forward and reverse waves change relatively little with stripe length. The magnitude of the reflected wave can be significantly reduced by minimizing the reflection at the sample edge or translating the pumped region away from the sample edge.

A useful quantity for examining active-region saturation is the ratio G/G_0 defined as the normalized internal gain (NIG). Ideally, NIG equals 1 everywhere in the active volume, but nonzero values of radiation intensity cause NIG to be always less than 1. To further illustrate how saturation is manifested in an ASE experiment, Fig. 4 shows the NIG versus position for various values of G_0L, and explicitly demonstrates the effect of the aspect ratio ρ on the saturation: there is a higher degree of saturation for larger aspect ratios. Physically, the

ρ-dependence can be thought of as a purely geometrical effect where (referring to Fig. 2) each element of the receiving area at x' collects radiation from a source at x whose volume is proportional to ρ. Thus the intensity at x', and therefore the degree of saturation, rises as ρ is increased.

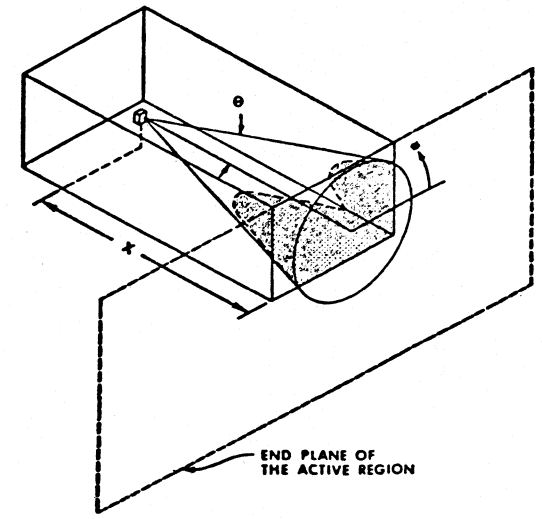
IV. Effects of a Nonzero Collection Aperture

In general, experimental conditions in an ASE measurement are such that the output is collected within a specific aperture. It is therefore desirable to be able to predict the angular dependence of the output. The calculations involved are best explained by referring to Fig. 5(a).

The fraction of the photons emitted by the indicated volume element that is collected by the external optics is the fraction within the cone of half-angle θ, where θ is related to the external collection angle by Snell's Law. In the example shown in Fig. 5(a), a significant fraction of the rays within the cone pass out of the active region (in the shaded area) before reaching the edge of the sample. Thus some of the rays within the cone are amplified over the entire distance from the emitting volume to the sample edge and some are not. The calculation is further complicated when the emitting element is positioned so that the cone intersects the top surface, where total internal reflection can occur due to dielectric discontinuity.

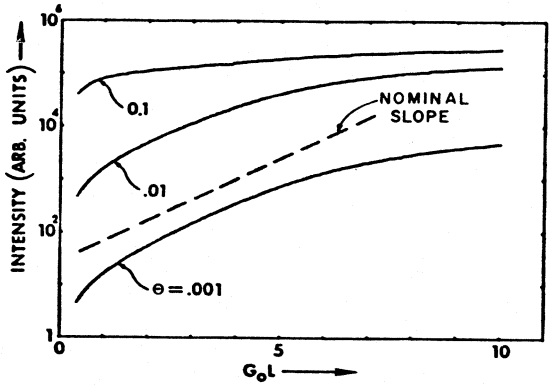
The complete solution involves numerical integrations over the five coordinates X, Y, Z, θ, and ϕ, and therefore converges exceedingly slowly. Thus suitable approximations are made here to simplify the computations.

To first order, the total intensity collected within half-angle θ can be approximated by the summation of only those rays that remain in the active region for the maximum distance. However, in reality, rays that leave the active region prematurely can contribute significantly to the total collected intensity, and a better estimate should be used. An improved approximation is made in the present work by counting as "effectively amplified" all those rays that receive at least $1/e$ of the available amplification and ignoring the remaining rays. In this approximation, the contribution $I(X, \theta)dX$ of the cross section at X to the total light in aperture θ can be expressed by



$$I(X,\theta)dX = \frac{\theta^2}{4} \cdot F(X,\theta) \cdot I_{\text{spon}}(X) \cdot \exp\left[\int_0^X G(\xi)\,d\xi\right] dX \tag{14}$$

where $F(X, \theta)$ is the fraction of the cone of rays of half-angle θ, emitted at position X, that is effectively amplified. The quantities $I_{\text{spon}}(x)$ and $G(X)$ are known from the saturation calculations in Section III, making the angular distribution calculation a straightforward numerical integration.



The calculations described in (14) are used to predict the detected output intensity as a function of the parameters L, θ, G_0, K, ρ, R, and D. Some typical results are presented below.

The variation of the collected output power is plotted versus excitation length in Fig. 5(b) for various values of collection angle. It can be seen that the deviation from the desired nominal slope becomes severe at large collection angles.

The slope of the log intensity versus the G_0L graph should be equal to unity in the ideal measurement. The actual slope,

(a)

(b)

Fig. 5. (a) Diagram of the active volume showing the cone rays of the half-angle emitted by an element at position X. (b) The calculated variation of the output intensity for various collection half-angles θ. $G_0 = 0.03$: $R = 0.5$: $K = 0.025$; $D = 0$: $\rho = 6$.

defined as the normalized differential gain (NDG) is therefore a useful measure of gain saturation and other sources of error. Analytically, NDG is expressed by

$$\text{NDG} = \frac{1}{G_0}\frac{d\ln(I)}{dL} = \frac{1}{g_0'}\frac{d\ln(I)}{dl}. \tag{15}$$

Fig. 6 shows the dependence of NDG on the cross-sectional aspect ratio ρ (a) and on the nominal gain (b). The suppression of the curves below the nominal value does not have a monotonic variation with gain, and there seems to be an optimum condition, as will be discussed further in the next section.

Fig. 7 shows the calculated variation of the output intensity with translation distance D. The slope of all curves for large values of D is constant and exactly equal to the absorption coefficient in the unpumped region. Thus very accurate measurements of the equilibrium absorption coefficient can be made, as discussed in [3].

An interesting phenomenon that is encountered experimentally is observed in the theoretical results of Fig. 7. In absorption measurements where G_0L is large, as the excited region is translated away from the sample edge, the measured intensity remains nearly constant or actually increases for a distance, before falling into an exponential decay. The non-

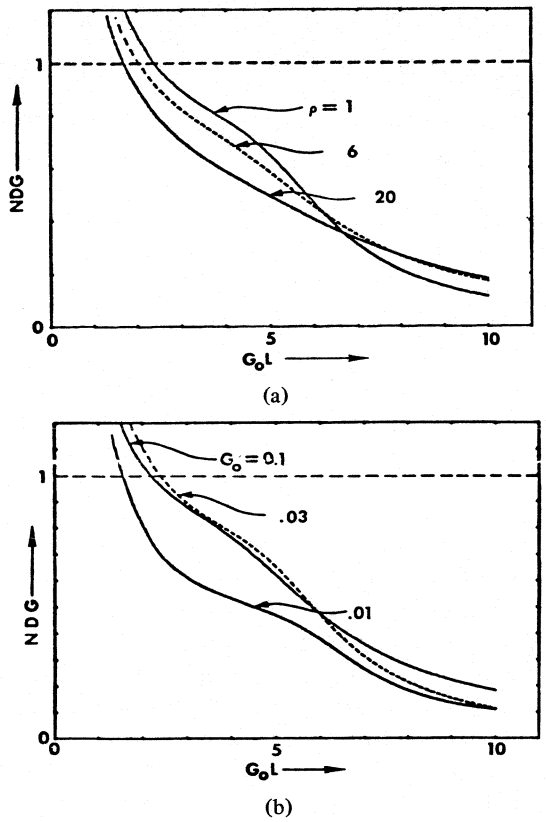


Fig. 6. The calculated NDG versus stripe length for various values of (a) cross-sectional aspect ratio ρ ($G_0 = 0.03$: $R = 0.5$: $K = 0.025$: $D = 0$: $\theta = 0.01$) and (b) low light-level gain G_0. $\rho = 1$.

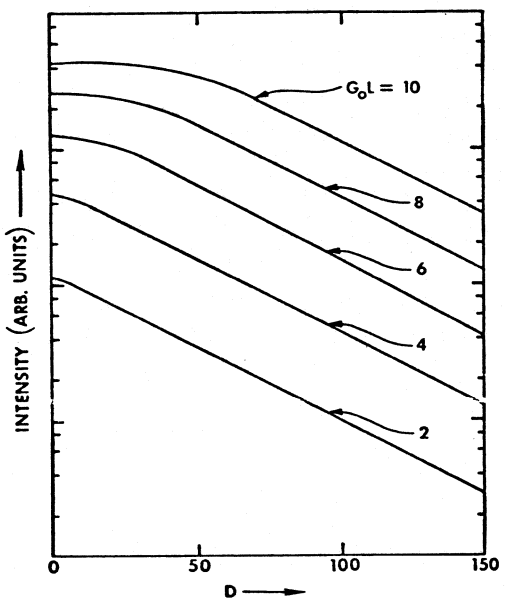

Fig. 7. The output intensity versus D (the normalized distance from the active region to the sample edge) for various values of the gain-length product. $G_0 = 0.1$: $\theta = 0.01$: $R = 0.5$: $\rho = 6$: $K = 0.025$.

exponential behavior for small D is a manifestation of the gain saturation exacerbated by the presence of the reflected wave. The output intensity leaving the active region increases due to the decreasing level of saturation as the active region is translated away from the sample edge. The increase is greater than the attenuation suffered while propagating through the unpumped region. When the reflected wave has been sufficiently attenuated, there is no further increase in emission to compensate the absorption, and the detected output then falls off exponentially. Although this appears to be a major source of error, the effect is easily discernable in the experiment, and the errors can therefore be avoided. It should be noted that saturation of the absorbing path near the excited volume due to high radiation intensity would cause further variations from the desired exponential behavior for small values of D. However, for large D the radiation intensity in the incremental absorption path (near the sample edge) becomes small.

V. Discussion

Figs. 6 and 7 illustrate that measured values of gain can be substantially below the true values, whereas the absorption coefficient can be very accurately determined. The errors in measured gain (NDG) stem from two major sources: 1) internal-gain saturation caused both by high levels of spontaneous emission and by stimulated emission primarily from the reflected wave; and 2) large collection apertures which allow undesired radiation to fall on the detector.

Errors in NDG can be minimized under the following "ideal" conditions.

1) The aspect ratio ρ approximately equals 1 to minimize the geometrical effect on saturation (see Fig. 4).

2) The reflection coefficient is small to minimize the contribution of the reflected wave to saturation. An alternative is to move the active region a long distance from the edge, but this has the attendant disadvantage that the collected output will be significantly attenuated.

3) The collection aperture is small so that only those rays that have traveled the maximum distance in the active region are detected.

The calculated results of an ideal gain measurement are shown in Fig. 8 for various values of G_0 and K. In Fig. 8(a), there is a low excess absorption, while in Fig. 8(b) the excess absorption is large. In both figures, there is an optimum range of G_0 over which the true gain is accurately measured. For gains that are too high, the corresponding high level of spontaneous emission causes internal-gain saturation, even in the absence of a reflection from the front surface. For gains too small, the stripe length becomes so long in the interesting region ($2 \lesssim G_0L \lesssim 6$) that the output collection aperture must be reduced.

Upon examination of a wide range of parameter values in the theoretical model, the limits of G_0 for accurate gain measurement are found to be

$$5\theta \lesssim G_0 \lesssim 0.06 - 2K. \tag{16}$$

The lower limit requires that a photon emitted at angle θ from the center of the active region at $X = L$ will remain in the active region for $G_0L = 5$. Thus (16) quantifies the requirement that all detected rays are effectively amplified. The physical origin of the upper limit in (16) is the high level of spontaneous emission that exists simultaneously with high gain (see Appendix III). The upper limit on measurable gain in (16) represents the worst case value (long nonradiative lifetime). For systems with short τ_{nr}, the gain-saturation limit is increased as discussed in Appendix III.

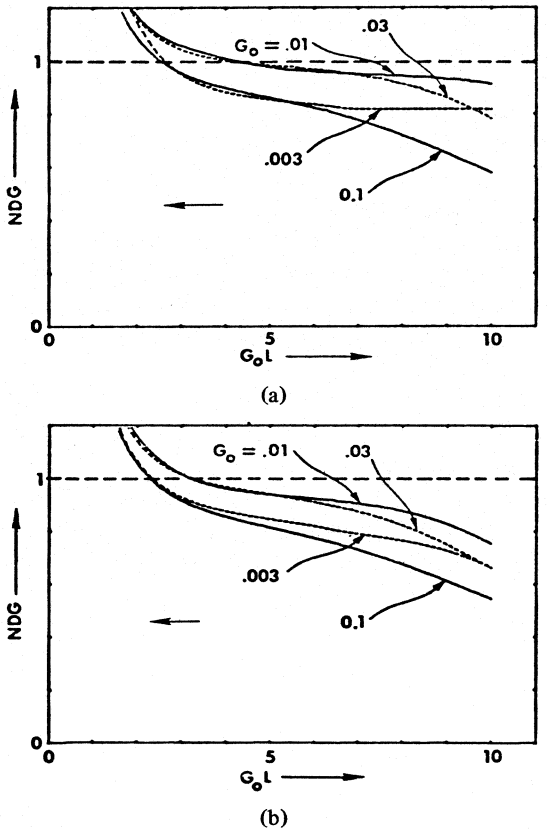

Fig. 8. (a) NDG versus excitation length under ideal conditions for various values of gain G_0. $R = 0$: $K = 0.0025$: $\theta = 0.001$: $\rho = 1$. (b) NDG versus excitation length under ideal conditions with large background absorption. $R = 0$: $K = 0.025$: $\theta = 0.001$: $\rho = 1$.

The major impact of (16) is that the dimensions of the experiment must be chosen according to the gain to be measured. As an example, using parameters typical of a semiconductor measurement, for $t = 2.5\ \mu$, $\alpha = 50\ \text{cm}^{-1}$, and $\theta = 0.001$, the ideal range of measurable gains is from 20 to 140 cm^{-1}.

In summary, for 10-percent accuracy (including the scaling due to nonradiative processes) the measurement conditions imposed are: R small, ρ near unity, and $5\theta \lesssim G_0 \lesssim 0.06\,(1 + \tau_{\text{spon}}/\tau_{\text{nr}}) - 2K$.

Due to low detector sensitivity or lack of dimensional control over the excited region, the conditions necessary for the ideal ASE experiment often cannot be met. As a result, the gain cannot be determined by the simple slope-measuring technique because there is no region of constant slope [see Fig. 5(b)]; a modification of the data-reduction process is required.

To first order, the cumulative effects of active-volume saturation and collection aperture can be included by approximating the NDG by

$$\text{NDG} = G_0 - aL + \text{higher order terms} \tag{17}$$

where the form of the first-order term is derived by noting that all effects tend to reduce the measured gain (hence the minus sign) and all effects reduce to zero at $L = 0$. In principle, G_0 can be determined from a plot of NDG versus L that is extrapolated back to $L = 0$.

For a wide range of parameter values (including large values of the reflection coefficient R), it is found that this method extends the measurement range with ~15-percent accuracy to

$$2\theta \lesssim G_0 \lesssim 0.1\,[1 + (4/\rho^2)]^{1/2} \cdot (1 + I_{\text{spon}}/\tau_{\text{nr}}) - 2K. \tag{18}$$

Outside these limits the first-order approximation fails and the error in the measurement becomes excessive.

Appendix I
Transient Pumping Effects

The theoretical results of Sections III, IV, and V are derived assuming a steady-state excitation, while most measurements of this type are made with pulsed sources [1], [2]. For example, with semiconductors and dyes, typical stripe lengths are $\lesssim$5 cm and double-pass photon transit times are therefore $\lesssim$200 ps. As a result, for pumping pulses longer than the excited-carrier lifetimes (a few nanoseconds) the system can be considered to be in an instantaneous equilibrium at all times. Hence the steady-state theory can be directly applied, even for an arbitrary pulse shape.

Experimentally, if the detector's frequency response is insufficient, the detected signal is actually the integral over the pulse duration and therefore depends on the pulse shape. Further analysis is required to extract the proper gain coefficient from the data of a pulsed measurement.

The mathematics of this computation are identical to that in Appendix II with the integration variable being time instead of photon energy. Thus only the results are discussed here. Fig. 9 displays the ratio of the differential gain g_{diff} for the specified pulse shapes to the differential gain for a rectangular pulse g_{rect} plotted versus the gain-length product. The curves are plotted with $Q = g_0'/\alpha_e$ as a parameter.

As examples, Fig. 9(a) shows the results for a parabolic pulse shape, and Fig. 9(b) shows the results for a triangular pulse shape. In general, the slope of the curves is small enough that a correction factor dependent only on pulse shape can be found.

Appendix II
Justification of the Rectangular-Spectrum Approximation

The assumption that the radiation in the sample has a rectangular spectrum is equivalent to assuming that the spontaneous and stimulated emission can be described by constant, average values. To verify the validity of the assumption, consider a cone of rays narrow enough to be essentially one-dimensional. From [2] we know that the intensity $I_E(l)$ at a particular photon energy E and stripe length l is given by

$$I_E(l) = K\,[I_{\text{spon}}(E)/g'(E)]\,\{\exp\,[g'(E)\,l] - 1\} \tag{19}$$

where K is a geometrical constant. The total intensity $I(l)$ is the integral of (19) with respect to E, and the differential gain g_{diff} is

$$g_{\text{diff}} = (d \ln\,[I(l)])/dl. \tag{20}$$

In the limit of high inversion in the active medium, the spontaneous and stimulated (gain) spectra have the same shape, thereby allowing the following simplification:

$$I_{\text{spon}}(E) = K'[g'(E) + \alpha_e] = K' \cdot g(E) \tag{21}$$

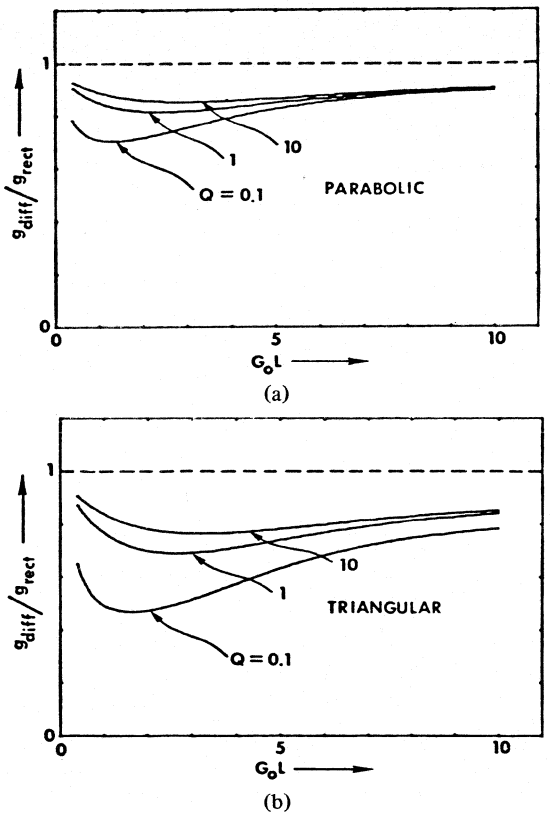

Fig. 9. The effect on the differential gain of a nonrectangular pumping pulse or nonrectangular gain line for (a) parabolic and (b) triangular shapes.

where K' is independent of photon energy. The absorption coefficient α_e is included to allow for any wavelength-independent absorption that must be overcome before net gain can be achieved. Thus the net internal gain $g'(E)$ varies from $-\alpha_e$ to g_0 as E is varied over the linewidth, and $I(l)$ is given by

$$I(l) = K'' \int_{\Delta E} \left[1 + \frac{\alpha_e}{g'(E)}\right] \cdot \{\exp [g'(E)l] - 1\}\, dE \qquad (22)$$

where ΔE is the emission linewidth and $K'' = K \cdot K'$.

Using (20) and (22), a comparison can be made between the case of a rectangular spectrum and the more physically appropriate case of a smoothly varying distribution. Specifically, parabolic[4] and triangular distributions are assumed here.

In Fig. 9(a), the ratio of g_{diff}, for a parabolic distribution, to g_{rect}, the differential gain for a rectangular distribution, is plotted versus $g_0 \cdot l$ with $Q(Q = g_0'/\alpha_e)$ as a parameter. The results for a triangular spectrum are shown in Fig. 9(b). The anticipated line-narrowing effects are evidenced by the slow variation of g_{diff} with gain-length product. However, in the region of primary interest in an ASE experiment ($2 < g_0'l < 6$), g_{diff} is fairly constant, especially for the frequently encountered situation where $Q > 1$. Thus the gain spectrum can be reasonably approximated by the constant, average value of 85 percent of the peak gain for the parabolic case, and 75 percent for the triangular.

[4]The results are not significantly different for other smoothly varying functions such as Gaussian or Lorentzian.

Appendix III

Saturation Due to Spontaneous Emission

The upper limit on G_0 is due to the high level of spontaneous emission that leads to high-intensity isotropic (undetected) stimulated emission. The upper limit in (16) is derived intuitively by finding the intensity that would exist in the active volume due to spontaneous emission alone, ignoring amplification (i.e., finding the lower limit on radiation intensity that can exist in the active volume under given excitation). Summing (11)–(13) for zero reflection coefficient

$$I(x')|_{g'=0} \simeq 2 \cdot I_{spon} \cdot \int_{\Delta l} \frac{\Omega(x)}{4\pi}\, dx \qquad (23)$$

where, for simplicity, $I_{spon}(x)$ is taken as constant. In [5] it is shown that the integral rapidly converges ($\Delta l \gtrsim 4t$) to $1.8\rho/(4 + \rho^2)^{1/2}$. Using (5) and (7) we get

$$\frac{I(x')|_{g'=0}}{I_{sat}} \simeq 3.6 \sqrt{\frac{\rho^2}{4 + \rho^2}} \cdot (G_0 + K)/(1 + \tau_{spon}/\tau_{nr}) \qquad (24)$$

when (9) is approximated in the limit $I \ll I_{sat}$

$$g'/g_0' \simeq 1 - (I/I_{sat})/(G_0 + K/G_0) \cong 1 - \epsilon \qquad (25)$$

where ϵ is the error in g' due to saturation. Finally, the upper limit on G_0 is

$$G_0 \lesssim 0.28\epsilon\, [(4 + \rho^2)^{1/2}/\rho^2]\, (1 + \tau_{spon}/\tau_{nr}) - 2K. \qquad (26)$$

Equation (16) follows for $\rho = 1$, $\epsilon = 10$ percent, and $\tau_{nr} \gg \tau_{spon}$.

On the Saturation Effects and Start Jump of Gaussian Modes in Oscillators

W. J. WITTEMAN AND G. J. ERNST

Abstract—**The present paper deals with the interaction of a Gaussian mode with a homogeneous and an inhomogeneous laser transition. The interaction of the beam with the medium in a laser is treated by taking into account the spatial distribution of both radiation and gain. The intensity characteristics are very different from those obtained for a one-dimensional interaction of a plane wave with a saturating medium. In the presence of a small-signal gain profile the threshold condition requires much higher inversion densities along the optic axis than by ignoring this profile. For gas lasers, for instance, having a small-signal gain profile that is approximately described by a zero-order Bessel function, the threshold inversion density can be about 50 percent higher. For high-power systems the saturation of the medium by the Gaussian intensity distribution results in a considerable amount of radial radiation transport. For homogeneous transitions this amount is about equal to the stimulated emission and for inhomogeneous transitions it is about half of it, independent of the beamwidth. Further, it is found that if one slowly passes the threshold condition for laser action, the intensity jumps from zero to a certain value and vice versa. This effect has also been verified experimentally.**

I. Introduction

THE radiation intensities produced by steady-state lasers have been computed in the past by using one-dimensional interaction of a plane wave with a saturating medium [1], [2]. As far as the interaction is concerned, the resonator has been assumed to support plane electromagnetic waves with its outcoupling loss concentrated near the mirrors. By using this approximation, one calculates the intensity characteristics, maximum output flux densities, etc., as a function of gain and outcoupling loss for lines with homogeneous and inhomogeneous broadening. However, in any interaction phenomenon of an electromagnetic beam and an amplifying medium there is no plane wave and no uniform gain of the field due to the finite aperture, to the inhomogeneity of the medium, and/or to the intensity-induced saturation of the medium. This nonuniformity depends not only on the coordinate of the direction of propagation, but also on the coordinates perpendicular to the direction of propagation, i.e., the gain profile.

In search of maximum radiation production from an efficiently pumped optical system, it seems advisable to extend the intensity computations by removing the restrictions of only one-dimensional interaction. Usually, the spatial distribution of the radiation intensity is also computed without taking into account a nonuniform gain profile. But this turns out to be very reasonable, because as far as the radiation distribution is concerned it is found [3] that, at least for small laser systems, the geometry of the beam is practically unaltered by the inhomogeneity of the gain, so that the optical beam parameters such as beamwidth can be reasonably well predicted by neglecting the gain profile. This is found for a positive as well as a negative gain profile, because in both cases a change in amplitude distribution, which is expected by neglecting phase changes, is nearly canceled by the effect of phase changes. Therefore, it is found and in agreement with observations, that under normal experimental conditions of laser systems the effect of a gain profile, caused either by the small-signal gain or by the saturation, will leave the beam size practically unchanged. Thus there is no focusing or defocusing by the gain profile. However, we cannot neglect the gain profile for radiation-intensity studies. Here the gain profile, as we shall see, is an important parameter, even for small systems having low output power.

The analysis here treats homogeneous and inhomogeneous laser transitions. We restrict ourselves to a commonly used system of a single-mode Gaussian beam in a radially symmetric excited medium. The advantage of treating this system is its simplicity. The physics involved can be easily appreciated and the effects of various processes on the radiation intensity can be compared. It is found that the three-dimensional character of the gain has for any optimized laser system—high or low power, homogeneous or inhomogeneous transitions—a large bearing on the intensity characteristics and output powers. Furthermore, from the computation of the intensity characteristics a remarkable effect can be predicted: i.e., when a laser builds up the inversion and passes (slowly) the threshold condition for the Gaussian mode, the laser output does not start from zero, but jumps to a finite value. We verified this jump experimentally, which gives a direct proof of the so-called "radial radiation transport." Although the analysis is primarily set up to describe saturation effects and to compute laser characteristics, it is also seen that the threshold conditions are changed drastically by a small-signal gain profile.

II. The Incremental Gain

Since in the present analysis we are dealing with the propagation of a Gaussian beam in a normal resonator, the nonuniformity of the medium must be lenslike in order to preserve the Gaussian nature. This means that the medium is described by a quadratic profile. In fact, the appearance of high-power Gaussian laser beams supports the assumption that a quadratic description can be adequate. In practice, of course, no profile is quadratic, but it should be noted that for media having axial symmetry a series expansion of the propagation constant in terms of the radial distance from the axis

Manuscript received September 21, 1974; revised January 15, 1975.
The authors are with the Department of Physics, Twente University of Technology, Enschede, The Netherlands.

shows that the main terms near the axis (where the field is strongest) are the constant and quadratic ones.

The derivation [4] of the propagation laws for Gaussian beams in quite general lenslike media starts with the scalar wave equation

$$\nabla E + k^2 E = 0 \tag{1}$$

where the quadratic dependence of k^2 near the optic axis is given by

$$k^2(r,z) = k_0^2(z) + k_0(z)\, k_2(z)\, r^2 . \tag{2}$$

These medium constants are generally complex to allow for loss or gain. k_0 is the part of the propagation constant that does not depend on r, whereas k_2 describes the variation of the propagation constant with r and includes thermal effects, gain variations, and also the associated dispersive effects of the gain profile.

In solving (1), the main interest is in waves bouncing back and forth between two mirrors that propagate primarily in the z direction, or almost-plane waves. It can be shown that such waves with a Gaussian radial dependence satisfy (1). Accordingly, one writes

$$E(r,z) = E_1 \exp\{-i(\phi + T + \tfrac{1}{2} r^2 k_0/q)\} \tag{3}$$

in which the time-dependent part has been dropped, $d\phi/dz = k_0(z)$ is the complex propagation constant on the axis, T is a complex phase parameter, q is the complex beam parameter defined by

$$\frac{1}{q} = \frac{1}{R(z)} - i\,\frac{\lambda}{\pi\omega^2(z)} \tag{4}$$

where $R(z)$ is the radius of curvature of the wavefront, λ is the wavelength, and $\omega(z)$ is the beam waist. Substitution of (3) into (1) gives, after comparison of terms of equal powers of r, the following two differential equations:

$$T' = -i\left(\frac{1}{q} + \frac{k_0'}{2k_0}\right) \tag{5}$$

$$\frac{1}{q^2} + \left(\frac{1}{q}\right)' + \frac{k_0'}{k_0}\frac{1}{q} - \frac{k_2}{k_0} = 0 \tag{6}$$

where the prime means differentiation with respect to z. For laser systems, (2) can be approximated by

$$k = k_0 + \tfrac{1}{2} k_2 r^2 . \tag{7}$$

By separating real and imaginary parts, we write

$$k_0 = \beta_0 + i\alpha_0 \tag{8}$$

$$k_2 = \beta_2 + i\alpha_2 . \tag{9}$$

By differentiating (3) with respect to z and using (5), we find for E on the axis ($r = 0$)

$$\frac{1}{E}\frac{dE}{dz} = -i\left(k_0 - \frac{i}{q} - \frac{ik_0'}{2k_0}\right). \tag{10}$$

By adding the complex conjugates to both sides of (10), using (4), and assuming that the wavelength is constant along the axis, the incremental gain along the axis is found to be

$$\frac{1}{I}\frac{dI}{dz} = 2\left(\alpha_0 - \frac{1}{R(z)}\right). \tag{11}$$

By substituting (4), (8), and (9) into (6) and taking the imaginary part, we get

$$\frac{2}{R(z)} = \frac{d\ln\omega^2}{dz} - \tfrac{1}{2}\alpha_2\omega^2 . \tag{12}$$

By substituting (12) into (11), we finally get for the incremental gain on the optic axis

$$\frac{1}{I}\frac{dI}{dz} = 2\alpha_0 - \frac{d\ln\omega^2}{dz} + \tfrac{1}{2}\alpha_2\omega^2 . \tag{13}$$

The first term on the right-hand side of (13) describes the local conversion of inverted states into stimulating emission. This is the same term as found for a one-dimensional treatment with plane waves [5]. The last two terms on the right-hand side of (13), equal to $2/R(z)$, describe the part of the incremental gain due to convergence or divergence of the wavefront of a propagating wave [6]. One part of it, the second term of (13), is related to the continuity of propagating electromagnetic energy; in the absence of any interaction, the product of beam cross section and intensity at the optic axis of a Gaussian beam ($\omega^2 I$) is constant along the axis. Therefore this term simply describes focusing or defocusing of the beam. The last term on the right-hand side of (13) describes a contribution of the radial radiation transport to the incremental gain related to the parabolic gain profile. From (13) we obtain for the increase of energy flux

$$\frac{d\ln(I\omega^2)}{dz} = 2\alpha_0 + \tfrac{1}{2}\alpha\omega^2 . \tag{14}$$

It is seen that only the imaginary parts of the propagation constants, i.e., the gain and its profile, determine the increase of energy flux. Thermal and dispersive effects contribute in so far as they influence the beamwidth of the Gaussian mode [3]. But normally, the fractional change of beamwidth by thermal and dispersive effects is relatively small so that the incremental energy flux is practically given by the gain parameters.

In a laser system, the standing wave consists of a running wave in the $+z$ direction and one in the $-z$ direction. Although the beamwidths of the two running waves are not exactly equal, it turns out that in practice they can be taken equal at any place along the axis. If we write down (14) for both running waves, we then find because of bidirectional gain

$$\frac{d\ln(I\omega^2)_+}{dz} = -\frac{d\ln(I\omega^2)_-}{dz} \tag{15}$$

and we see that

$$(I\omega^2)_+ (I\omega^2)_- = \text{constant}. \tag{16}$$

Thus the product of the energy flux of the two running waves is constant along the axis.

III. Homogeneous Line Broadening

For homogeneous line broadening, the saturated amplitude gain coefficient α is related to the unsaturated or small-signal gain coefficient G, which depends on the line shape of the transition by

$$\alpha(r) = \frac{\frac{1}{2}G(r)}{1 + I_t(r)/I_0} \tag{17}$$

where I_0 is the saturation parameter and I_t the total intensity of the two running waves. Since we are interested in the constant and quadratic term of the gain profile, we substitute into (17) for the unsaturated gain profile

$$G(r) = G(1 + \tfrac{1}{2}\gamma r^2) \tag{18}$$

and for intensity

$$I_t(r) = I_t \exp(-2r^2/\omega^2). \tag{19}$$

For the constant term of the amplitude gain we obtain

$$\alpha_0 = \frac{\frac{1}{2}G}{1 + I_t/I_0}. \tag{20}$$

For the quadratic term we get

$$\alpha_2 = \frac{\frac{1}{2}G}{1 + I_t/I_0}\left(\gamma + \frac{4}{\omega^2}\frac{I_t/I_0}{1 + I_t/I_0}\right). \tag{21}$$

By substituting (20) and (21) into (14), we find for the incremental gain

$$\frac{d \ln (I\omega^2)}{dz} = \frac{G}{1 + I_t/I_0}\left(1 + \tfrac{1}{4}\gamma\omega^2 + \frac{I_t/I_0}{1 + I_t/I_0}\right). \tag{22}$$

It is seen that the contribution of radial radiation transport to the incremental gain comes from both the small-signal gain profile and the gain induced saturation. In general, the small-signal gain decreases with the distance from the axis (γ is negative). Such a profile broadens the wavefront and radiation energy is radially transported out of the center. This means that the threshold condition to start oscillations requires higher inversion densities along the axis than that predicted on the basis of one-dimensional plane-wave interaction.

This conclusion can also be reached more simply by stating that the integrated gain over the mode volume must be equal to the losses. Then one finds that the inversion along the axis is much higher than the average inversion needed to reach threshold. It is assumed, however, that the geometry of the beam is unchanged by the gain profile. In other words, it is assumed that if the effective diameter of the gain region has become smaller, the effective beam diameter does not become smaller. Only a more comprehensive analysis will show that the beamwidth is indeed practically unchanged by the gain profile [3].

In order to estimate the threshold condition, let us consider a small-signal gain profile proportional to the electron density of the discharge. In dealing with a positive column discharge, this gain profile can then be described by a zero-order Bessel function. The quadratic term of such a gain profile is

$$\gamma = -\frac{2.88}{\rho^2} \tag{23}$$

where ρ is the radius of the tube diameter.

The second term of (22) becomes $-0.72\ \omega^2/\rho^2$. In many single-mode oscillators the value of ω^2/ρ^2 is about $\frac{1}{2}$. Substituting this value into (23) makes the incremental gain for starting oscillations about 36 percent smaller than in the case where the small-signal gain profile is ignored.

The last term on the right-hand side of (22) describes the part of the radial radiation transport that comes from the change of the saturated gain profile by the Gaussian intensity distribution. For optimized laser systems, when $I_t/I_0 \gg 1$ the last term of (22) approaches one. Thus at high intensities the intensity profile itself leads to a radial radiation transport that contributes as much to the incremental gain as the stimulated emission from the local medium. It is interesting to note that the latter conclusion is independent of the beamwidth.

In order to find the intensity characteristics of an oscillator, we have to integrate (22) over a round trip through the resonator. In general, the beamwidth may vary considerably along the tube, so that the integration of (22) with the aid of (16) has to be worked out numerically. The integration becomes complicated because one also has to know the beamwidth at any place along the tube. The beamwidth in turn depends on α_2 and, in fact, on I_t. However, the general behavior of the obtained characteristics is similar to what will be obtained for the case where $\lambda L/\pi\omega^2 \ll 1$ (L is the length of the system), so that the beamwidth varies very little along the axis, and the outcoupling is not too large. In that case we find from (16) that the product of the intensities of the two running waves is constant. Let us consider a system having one totally reflecting mirror and one outcoupling mirror with reflectivity R. The maximum relative variation of the sum of the two intensities is equal to $\frac{1}{2}\sqrt{R}(1 + 1/R)$. It is seen that even for $R = 50$ percent the sum of the two intensities is constant to within 5 percent.

By integrating (22) over a round trip through the resonator and taking I_t as constant, we find

$$-\frac{\ln R}{2GL} = \frac{1}{1 + I_t/I_0}\left(1 + 0.25\ \gamma\omega^2 + \frac{I_t/I_0}{1 + I_t/I_0}\right). \tag{24}$$

The outcoupled intensity I_{out} is related to the total intensity within the laser by

$$I_{out} = \frac{1 - R}{1 + R} I_t. \tag{25}$$

Normalized values of the output intensity are plotted in Fig. 1 as a function of $-GL/\ln R$ for various values of $\epsilon = 1 + 0.25\ \gamma\omega^2$. In Fig. 2 we plotted the normalized output as a function of the reflectivity R for various values of GL and ϵ. It is seen that the threshold condition depends on the small-signal gain profile given by ϵ.

Furthermore, it can be seen that there are nonzero fields with smaller gain over loss ratios than at threshold. These

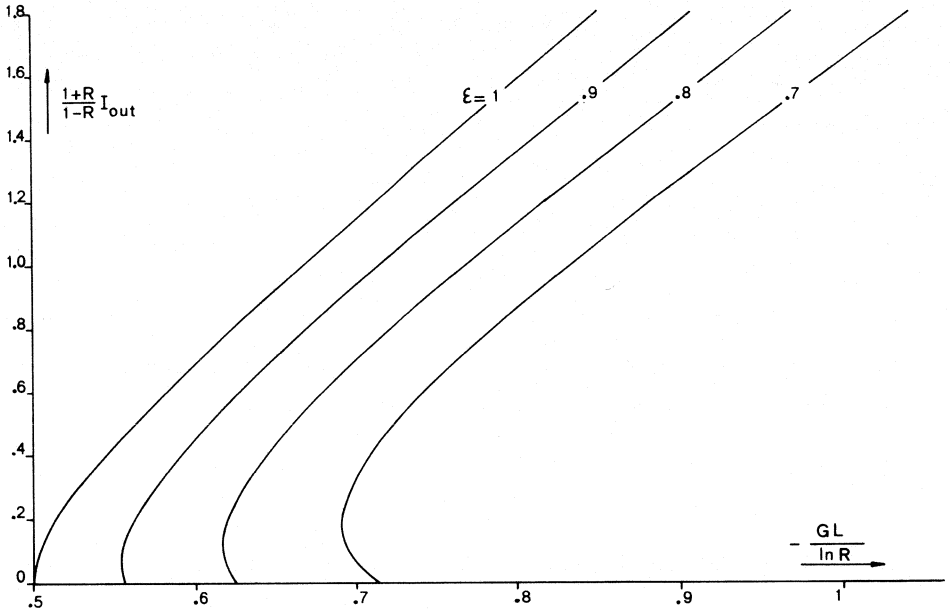

Fig. 1. The outcoupled intensity of homogeneous line broadening divided by the saturation-intensity parameter I_S is plotted versus the gain over loss ratio. The small-signal gain profile is indicated by $\epsilon = 1 + 0.25\,\gamma\omega^2$.

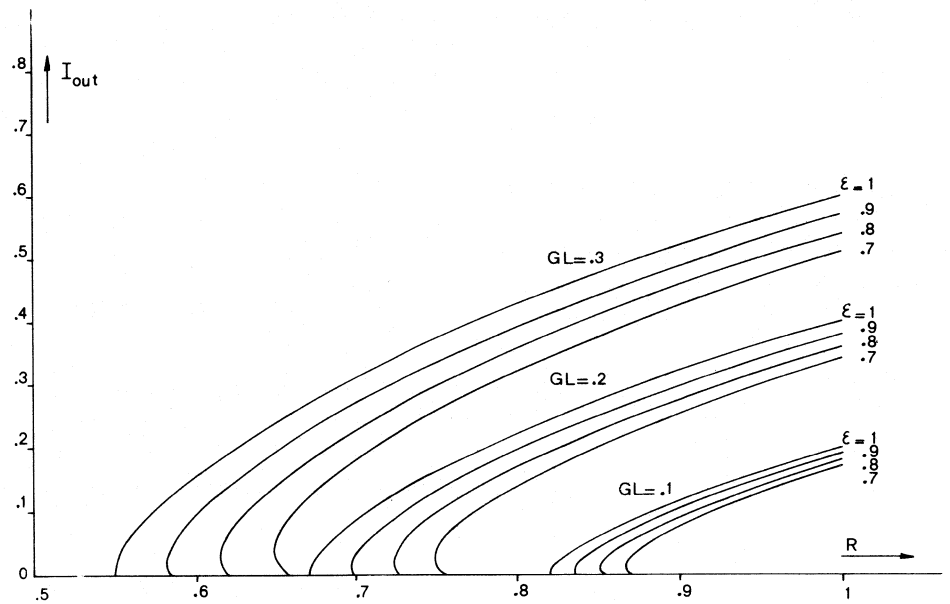

Fig. 2. The outcoupled intensity divided by I_S is plotted as a function of R for homogeneous line broadening. The characteristics indicate that near threshold the intensity is not continuously changeable, but jumps.

nonzero-field conditions can only be reached by a field that has already been built up within the resonator and therefore one first has to pass the zero-field threshold condition. By passing this point, the induced saturation levels the gain profile and, consequently, the divergence of the wavefront decreases, which means that less radiation is transported radially out of the center. Thus the apparent "loss factor" induced by the small-signal gain profile is reduced by the field itself and therefore, if for a Gaussian beam system the gain over loss ratio is slowly increased from below threshold, the intensity does not increase continuously from zero as one passes threshold but jumps to a certain value.

The jump depends on the small-signal gain profile. The stronger this profile, i.e., the smaller γ, the larger the start jump. For values of γ larger than or equal to zero there is no jump.

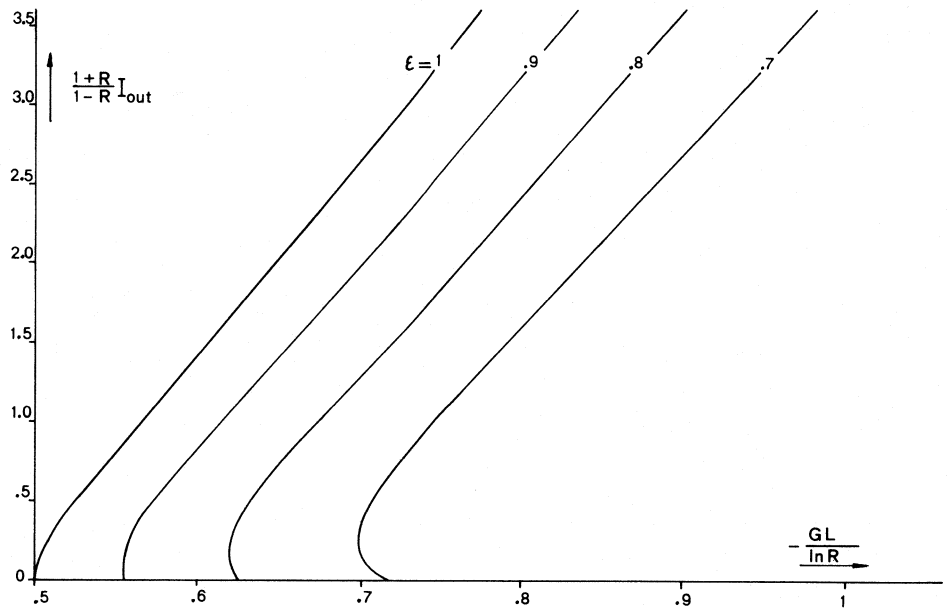

Fig. 3. The outcoupled intensity for inhomogeneous line broadening divided by the saturation parameter I_s is plotted versus the gain over loss ratio.

IV. Inhomogeneous Line Broadening

For inhomogeneous line broadening the saturated amplitude gain coefficient is known as

$$\alpha(r) = \frac{\frac{1}{2}G(r)}{\{1 + I_t(r)/I_0\}^{1/2}} \tag{26}$$

where $G(r)$ is again the small-signal intensity gain which depends on the line shape of the oscillating transition. Let us consider again that the small-signal gain profile and intensity distribution are given by (18) and (19), respectively. For the constant and quadratic term of the amplitude gain we find

$$\alpha_0 = \frac{\frac{1}{2}G}{\{1 + I_t/I_0\}^{1/2}} \tag{27}$$

$$\alpha_2 = \frac{\frac{1}{2}G}{\{1 + I_t/I_0\}^{1/2}} \left(\gamma + \frac{2}{\omega^2} \frac{I_t/I_0}{1 + I_t/I_0}\right). \tag{28}$$

By substituting (27) and (28) into (14), the incremental gain of an inhomogeneous transition becomes

$$\frac{d \ln (I\omega^2)}{dz} = \frac{G}{\{1 + I_t/I_0\}^{1/2}} \left(1 + \tfrac{1}{4}\gamma\omega^2 + \tfrac{1}{2} \frac{I_t/I_0}{1 + I_t/I_0}\right). \tag{29}$$

If the small-signal gain profile of gas lasers is again proportional to the electron density and therefore approximated by a zero-order Bessel function, we find, similar to the homogeneous case, that the threshold condition to start oscillation requires much higher inversion densities along the axis than by ignoring this gain profile. With ω^2/ρ^2 about 0.5, the threshold inversion density is about 50 percent higher. Further, we see that for $I_t/I_0 >> 1$ the contribution of radial radiation transport to the incremental gain due to the Gaussian intensity distribution is about equal to half the amount of stimulated emission given by the first term on the right-hand side of (29).

In order to find the intensity characteristics, we integrate (29) over a round trip through the resonator and consider again the case where the beamwidth varies little within the resonator, so that it can be approximated as constant. We find, similar to the homogeneous case,

$$-\frac{\ln R}{2GL} = \frac{1}{\{1 + I_t/I_0\}^{1/2}} \left(1 + 0.25\,\gamma\omega_+^2 \frac{0.5\, I_t/I_0}{1 + I_t/I_0}\right). \tag{30}$$

The normalized output intensities are plotted in Figs. 3 and 4. It is seen that the obtained characteristics also predict a start jump as one slowly increases the gain over loss ratio and passes threshold. Again, the jump only exists for negative values of γ and increases with decreasing γ. By comparing this result with the numerical evaluation of gain saturation as given by Fox and Li [8], it is seen that they did not find a start jump. The reason may be that they consider a homogeneous small-signal gain coefficient ($\gamma = 0$), which according to our results will indeed not lead to a start jump.

V. Start Jump of a Gaussian Mode

The aforementioned predicted start effect can be demonstrated experimentally. It can be found either by increasing the pumping power or by decreasing the outcoupling losses from below threshold. For continuously variable outcoupling losses we chose a Gaussian-mode CO_2 laser with an outcoupling cavity. The experimental setup is indicated in Fig. 5. The cavity has a length of 150 cm and an internal diameter of 9 mm. There is a totally reflecting gold mirror with a radius

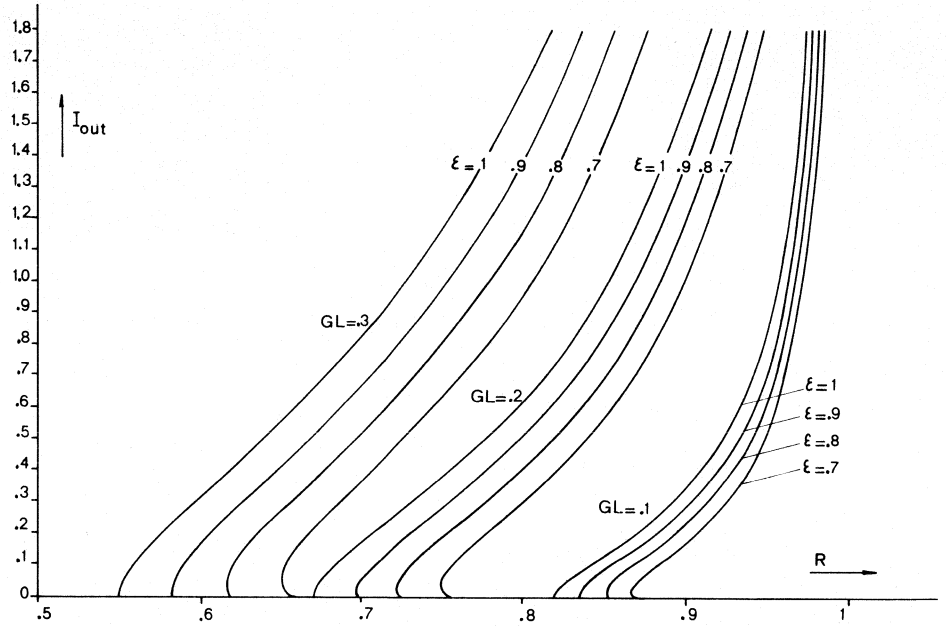

Fig. 4. The outcoupled intensity for inhomogeneous transitions is plotted versus reflectivity for various values of the small-signal gain and its profile parameter ϵ.

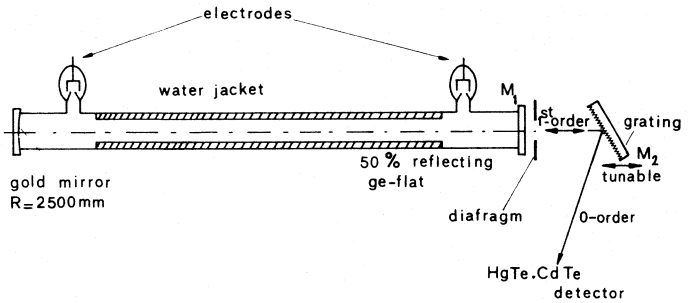

Fig. 5. Experimental arrangement of a Gaussian-mode laser with transition selective outcoupling cavity. The outcoupling is continuously variable. The grating is mounted on a tunable piezoelectric translator.

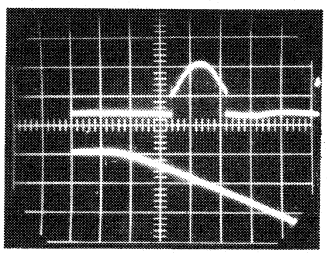

Fig. 6. The outcoupled intensity as a function of the position scanning of the piezoelectric translator. The reflectivity of the coupling cavity first increases and further on decreases with the translated position of the grating. The lower part shows the ramp voltage. The time scale is 5 ms/cm.

of curvature of 2500 mm on one side and a 50-percent reflecting germanium flat on the other side. The length of the discharge is about 130 cm. With a mixture of about 8 torr CO_2 and 6 torr He, the cavity is overcoupled and will not lase with a dc discharge current of about 10 mA. By placing a wavelength selective grating in front of the germanium flat, we use the first-order reflection on the grating for intracavity reflection and the zero-order reflection for outcoupling. The grating, mounted on a tunable piezoelectric translator for position scanning, together with the germanium flat, forms a Fabry-Perot (FP). This FP as an outcoupling cavity offers a variable narrow-band reflection [7]. In order to suppress higher order modes, a 4.2-mm diaphragm is placed between the grating and the germanium flat. The diffraction grating is gold coated, has 75 lines/mm, and is blazed for 10.6 μ. The outcoupled radiation is detected with a fast HgTe:CdTe photo diode having a time constant of a few nanoseconds.

Fig. 6 shows the output intensity as a function of the position scanning of the piezoelectric translator. The lower part shows the ramp voltage applied to the translator and the upper part shows the output as a function of time with 5 ms/division. The reflectivity is continuously varied by the applied ramp voltage from below threshold. At threshold the intensity does not increase continuously but clearly jumps. It also falls suddenly back to zero as the reflectivity is decreased by further scanning.

By using the laser system without the grating, varying gain is obtained by increasing the current suddenly from 1 to 40 mA. (In a dc experiment it will not lase at 40 mA.) After this change the inversion density grows and passes threshold and after some time the inversion drops again, probably due to thermal effects. The upper trace of Fig. 7 shows the change of current and the lower trace shows the radiation output. The time scale is 50 μs/division. Apparently, it takes some

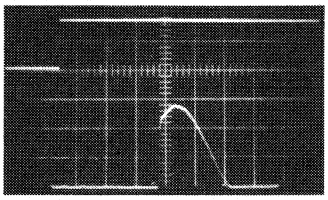

Fig. 7. The dc discharge current of about 1 mA is suddenly changed to 40 mA, as shown by the upper trace. The output of the laser without grating and diaphragm is shown by the lower trace. The time scale is 50 μs/cm.

time before the threshold inversion is built up, and then the oscillation jumps to a certain intensity. The extinction of the laser action is not sudden. It may be that, for the steady state of 40 mA due to thermal effects, the small-signal gain profile becomes flat or even reversed. If the same experiment is done by suddenly increasing the current from about 5 mA, where the steady-state oscillations exist, to 40 mA, it is found that the oscillating field increases continuously and finally drops to zero. This is shown in Fig. 8, where the time scale is 100 μs/division.

VI. Conclusions

A three-dimensional treatment of the interaction of a Gaussian mode and a saturated medium leads to conclusions that differ much from one-dimensional treatment. We wish to stress again that the gain parameters have practically no influence on the intensity distribution, i.e., there is no focusing owing to the gain parameters, but they have a large influence on the energy flux and output power. For both homogeneous and inhomogeneous transitions, the effect of the Gaussian distribution of the intensity on the saturation of the medium is a considerable increase of output power. Finally, it is found

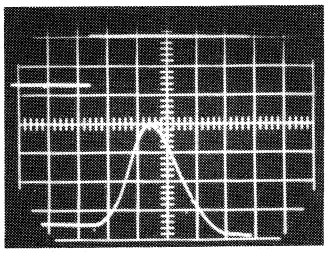

Fig. 8. A dc discharge of about 5 mA producing a weak laser field is suddenly changed to 40 mA, as shown by the upper trace. The Gaussian radiation intensity is shown to be continuous, and it finally goes to zero. The time scale is 100 μs/cm.

that near threshold the intensity is not continuously variable but jumps.

High-Resolution Spectral Measurements of SO_2 from 1176.0 to 1265.8 cm^{-1} Using a Single PbSe Laser with Magnetic and Current Tuning

FRANK ALLARIO, CLAYTON H. BAIR, AND JACK F. BUTLER, MEMBER, IEEE

Abstract—**A single magnetic- and current-tuned PbSe diode laser was used to measure completely resolved spectra of SO_2 at low pressures over a major portion (1176.0–1265.8 cm^{-1}) of the R branch of the ν_1 band for the first time. It is shown that the combination of magnetic and current tuning allows *complete* coverage of this 89.8-cm^{-1}-wide spectral region. Results generally show excellent agreement with theoretically generated spectra. Magnetic-tuning rates and, with magnetic field applied, current-tuning rates were observed to be significantly nonlinear. Precise spectroscopic data could be obtained with these nonlinearities taken into account. The current-tuning rate in zero magnetic field was essentially constant over the range investigated.**

I. Introduction

As a result of their narrow linewidths ($\leqslant 10^{-5}$ cm^{-1}) and wavelength tunability, Pb-salt semiconductor lasers have been used for ultrahigh-resolution spectral measurements in a variety of molecular gases, and have found application in atmospheric-pollution monitoring [1]. Semiconductor lasers also appear promising as high-resolution sensors of atmospheric pollutants from satellite or aircraft platforms [2]. Using several current-tuned $Pb_{1-x}Sn_xTe$ diode lasers of differing compositions, line intensities and positions in the ν_1 band of SO_2 have previously been measured in the P branch, from 1114.5 to 1167.8 cm^{-1} [3], [4]. Current-tunable semiconductor lasers of $Pb_{1-x}Sn_xTe$ have also been used to investigate the infrared spectrum of SO_2 at high resolution near 1130 cm^{-1} up to pressures of 1 atm [5]. In this paper we report on the use of a single magnetic- and current-tuned PbSe laser to generate individual absorption lines over a major portion (1176.0–1265.8 cm^{-1}) of the R branch of the ν_1 band of SO_2, a common atmospheric pollutant. The use of two separate tuning mechanisms allowed complete coverage of this region to be achieved. Pronounced tuning-rate nonlinearities were observed, and it is shown that precise spectroscopic information can be obtained in spite of such nonlinearities.

II. Experimental Apparatus

The diode laser used in this study was fabricated from single-crystalline PbSe grown by a method of recrystallization through the vapor phase. The growth temperature was approximately 800°C, with the temperature gradient maintained at a small value through the use of a Na heat-pipe furnace liner. Carrier concentration and type were controlled by adjustment of stoichiometry deviation without impurity doping. The homojunction diode was fabricated with a p-type skin on an n-type bulk and had cleaved end faces.

The diode was mounted on the cold finger of a liquid-helium Dewar and in the 1-in-diam bore of a superconducting solenoid. The temperature of the cold finger was not monitored but was believed to be below 10 K. The magnetic field was impressed parallel to the current flow along a ⟨100⟩ crystallographic axis and was variable to 50 kG. The output laser beam from the liquid-helium Dewar was collected by an $f/2$ spherical mirror and focused onto the entrance slit of an E-14 spectrograph whose bandpass was never larger than 0.14 cm^{-1}. The spectrograph provided mode isolation and gross frequency calibration. The laser beam was modulated at 520 Hz by a mechanical chopper and detected with a Cu:Ge detector. The electrical signal from the detector was processed by a lock-in amplifier and displayed on a strip-chart recorder. A current-regulated dc power supply with adjustable sweep capability (A. D. Little, Model SCPS-II) was used to excite the lasers. Oscilloscope displays of SO_2 absorption lines were also obtained by superimposing a small periodic-current ramp on the dc current. The absorption cell used for most of this work was 45.0 cm long and employed CaF_2 windows slightly wedged with respect to each other to eliminate interference fringes.

III. Tuning Mechanisms

The mechanism of magnetic tuning of PbSe semiconductor lasers has been described by Butler and Calawa [6], and Butler [7]. Shifting of the spontaneous-emission spectrum of PbSe lasers to wavelengths shorter than 8.5 μm is due to the magnetic-field dependence of the spin-split zero-order Landau levels of PbSe. Continuous tuning of individual laser modes with magnetic field is produced by the dependence of the index of refraction on the magnetic field given in [6]. Fig. 1 illustrates the frequency dependence of individual laser modes on magnetic field for the PbSe diode used in the present work, operated at a constant current of 0.750 A. This behavior is typical of other PbSe diodes we have studied. The inset in Fig. 1 is a schematic representation of the Landau-level structure; a discussion of these energy levels and transitions is

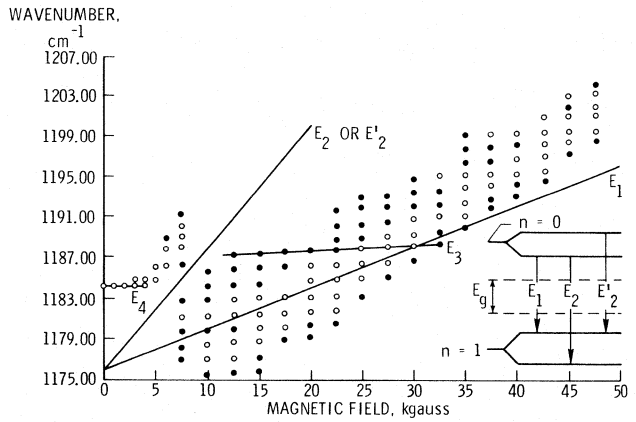

Fig. 1. Dependence of laser emission modes with magnetic field for 0.750 A. Inset is a schematic representation of zero-order spin-split Landau levels at band edges of PbSe. Curves E_2 and E_1 indicate theoretical mode shifting of energy levels due to Landau-level dependence of B from [6]. E_3 and E_4 are lines drawn through continuous laser modes as measured on the spectrograph, and indicate continuous mode tuning due to dependence of the index of refraction on B. PbSe: (TDL-11142-4); current: 0.750 A; bandpass: 0.14 cm^{-1}; ○ strong modes; • weak modes; $\Delta\nu = \pm 0.10$ cm^{-1}.

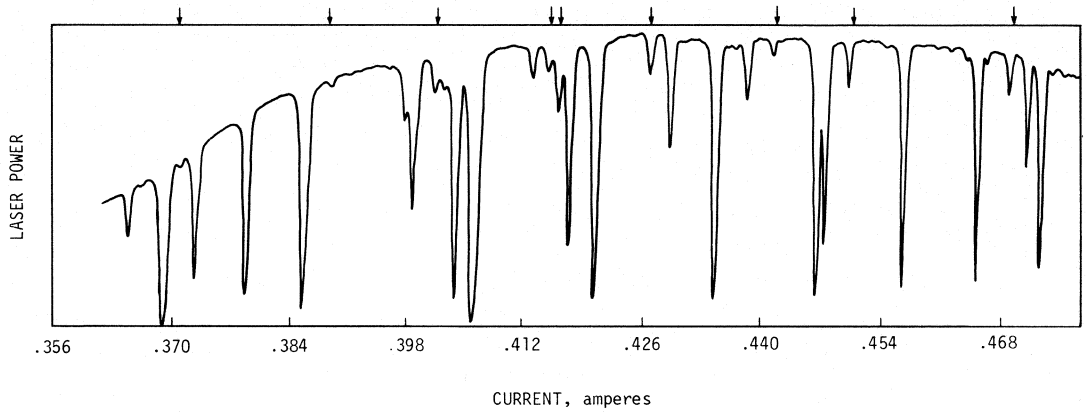
given in [7]. In the present work we were interested in exploiting magnetic tuning of PbSe to extend its useful tuning range for high-resolution spectral measurements on the SO_2 molecule in the region above 1176 cm^{-1}.

In Fig. 1, two regions of frequency tuning are observed: above and below 7.5 kG. For $B > 7.5$ kG, the modes are regularly spaced ($\Delta\nu = 1.4$ cm^{-1}) and numerous. Individual modes tune, on the average, approximately 0.1 cm^{-1} at an average tuning rate of approximately 4×10^{-5} cm^{-1}/G for a current of 0.750 A as indicated by curve E_3 in Fig. 1. Shifting of the emission wavelength with magnetic field as shown in Fig. 1 allowed the spectral range of PbSe to extend as high as 1205.0 cm^{-1} with a current of 0.750 A. At higher currents (1.2 A), laser modes at 50 kG had a wavenumber as high as 1266.0 cm^{-1}. The rated damage threshold for CW operation of the diode was 1.8 A, which should extend the frequency even higher, but in our work currents were maintained at values ≤ 1.2 A. To date, it has been estimated that this particular semiconductor laser has operated over 800 h without noticeable degradation in performance. The maximum power of individual laser modes was estimated to be > 75 μW/mode.

Current tuning of individual modes at constant magnetic field was also measured with the spectrograph to obtain approximate values of tuning rates and tuning ranges. Typically, tuning rates measured with the spectrograph appeared constant for currents below 0.800 A (due to low resolution), but with magnetic field applied, the tuning rates showed nonlinear behavior above 0.800 A. At $B = 20$ kG and $I = 0.750$ A, the tuning rate was estimated to be 4.0 cm^{-1}/A, and individual laser modes for these conditions were observed to tune as far as 2 cm^{-1}. This value is larger than the spacing between individual laser modes in Fig. 1, which shows that complete coverage of a broad spectral region can be achieved with the combination of current and magnetic tuning. In fact, complete coverage of the spectral region between 1175.0 and 1265.8 cm^{-1} was found to be possible with one PbSe diode.

For magnetic fields below 7.5 kG, the diode was not as well behaved in that it emitted fewer modes, with less maximum power per mode ($\simeq 25$ μW/mode). In general, operation below 7.5 kG was avoided since the smaller number of modes limited the spectral coverage, and the reduced power per mode limited the available signal. A more accurate measurement of tuning rates, using high spectral-resolution numerical results, is provided in the following sections.



IV. Spectral Measurements on SO_2

The high-purity sample gas was maintained at a pressure of 1 torr in the 45-cm cell, and was at room temperature. The general procedure was to hold the magnetic field fixed, while varying the diode current. The spectrograph setting was varied synchronously with diode current to continuously isolate a single mode as it was tuned over its range. For frequency calibration, a computer-generated spectrum from an SO_2 line compilation of R. F. Calfee[1] was used as reference. As will be discussed in the next section, significant tuning-rate nonlinearities were observed with magnetic field applied.

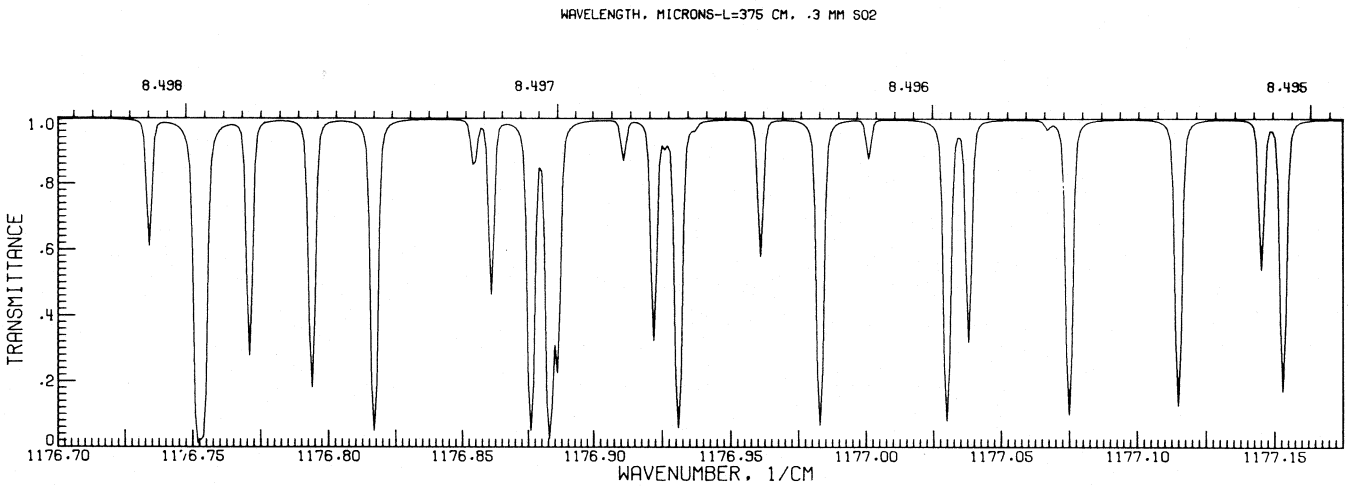


Fig. 2(a) is an example of raw data taken with a PbSe diode laser in the wavelength interval from 1176.70 to 1177.15 cm^{-1} using a magnetic field of 13.5 kG and a current ranging from 0.356 to 0.483 A. The length of the absorption cell was 375 cm, and the SO_2 pressure was 0.3 torr. The spectrometer bandpass was 0.14 cm^{-1}. Fig. 2(b) is a computer-generated spectrum of SO_2 over the same region. The spectrum was computed for $T = 300$ K, $p = 0.3$ torr, and $l = 375$ cm with a Voight profile assumed for the line shape. All lines on the computer-generated plot appear on the raw data. Weak lines not identified in the computer-generated scan are indicated with arrows on the scan of the raw data. These weak lines which appear frequently when long cell lengths are used are attributed to transitions of hot bands of SO_2. From knowledge of the spectrometer settings of wavelength and bandpass, and by visually comparing the raw data with computer-generated data, we were able to assign absolute wavelengths to absorption lines of the laser-generated scans. The complex spectra of the SO_2 molecule allowed unambiguous identification of SO_2 absorption lines throughout the region from 1176.0 to 1265.8 cm^{-1}. With the absolute wavelengths assigned, a tuning rate was then determined with knowledge of the current needed to generate individual portions of the scan. In this case, because the current is relatively low, the tuning rate is fairly linear; however, at higher currents, the nonlinearity can be observed on the scans of raw data.

Fig. 3(a) and (b) shows typical results of a comparison between a laser-generated absorption spectrum and a computer-generated spectrum over a wider region, from 1176.00 to 1178.00 cm^{-1}, for a shorter cell length (45.0 cm) and an SO_2 pressure of 1 torr. In this case, the laser-generated spectrum has been normalized to laser power variations and utilizes experimentally determined line intensities. Comparisons

[1] Theoretical absorption profiles for the ν_1 band of SO_2 were generated from a magnetic tape containing line-absorption parameters for SO_2. This work was performed at NOAA by R. F. Calfee. The magnetic tape is available at NASA Langley Research Center.

similar to this were performed over the spectral region from 1176.0 to 1265.8 cm^{-1}, and complete coverage obtained [2], [8]. Again, it was observed that more lines appear on the experimental scan than on the computer-generated scan, although fewer lines appear here because of the shorter cell length (e.g., 1176.33 cm^{-1}, 1176.65 cm^{-1}, 1176.71 cm^{-1}, 1177.38 cm^{-1}). The additional weak lines are attributed to SO_2 hot bands, and the strong line at 1177.38 cm^{-1} is

attributed as an impurity NH_3 line. Absolute line intensities agreed to better than 10 percent.

V. Observations of Nonlinear Tuning Rates

This section describes an investigation into tuning-rate variations observed with PbSe diode lasers in magnetic fields. We have determined that magnetic-tuning rates and current-tuning rates (with magnetic field applied) for the PbSe laser used in our study are significantly nonlinear; tests with other PbSe diode lasers have confirmed this finding. Current tuning in zero magnetic field, on the other hand, was essentially constant over the range of currents investigated (0–1.2 A).

For accurate tuning-rate measurements, SO_2 absorption spectra were obtained by scanning the B-field or current, and calculating tuning rates from the theoretical line positions. These were substantiated by using a Fabry-Perot etalon to directly measure the tuning rates. The results are in excellent agreement, but the technique of measuring tuning rates with calculated absorption is believed to give higher precision.

Fig. 4 shows the dependence of the magnetic-tuning rate on the magnetic-field intensity with diode current maintained at 0.890 A. This figure was constructed by a curve fit of the form ae^{bx} to 21 data points. For 0.890 A, the tuning rate varied from 0.45 MHz/G at 11.0 kG, to approximately 3.4 MHz/G at 21.0 kG (1 MHz corresponds to 3.3×10^{-5} cm^{-1}).

Tuning rates were also observed to depend on current for a constant magnetic field. In Fig. 5, the measured dependence of tuning rate is shown as a function of current for three values of magnetic field. Again these curves were generated using theoretical separations of SO_2 absorption lines, measuring the current required to scan across them, and curve-fitting a function of the form ae^{bx} to the data points. For 35.0 kG, approximately 40 data points were generated. In this case, the current-tuning rate varied from 60 MHz/mA at 0.40 A, to a value greater than 700 MHz/mA at 1.0 A, representing more than an order-of-magnitude increase in tuning rate over this current range. For 15.0 kG, the tuning rate varied less, changing from 60 MHz/mA at 0.60 A to 450 MHz/mA at 1.0 A. At zero magnetic field, the current tuning was approximately 30 MHz/mA, and within the limits of a spectrograph measurement, was constant over the range of 0–1.2 A. It was observed for both magnetic and current tuning that adjacent modes shifted at the same rate, i.e., the mode spacings remained constant as mode positions were varied.

Tuning rates shown in Figs. 4 and 5 were obtained over a period of several days and the scatter in the tuning-rate data was approximately 10 percent. A check on the reproducibility of the tuning rates was performed by measuring the full width at half maximum (FWHM) of SO_2 absorption lines for self- and N_2 broadening with the same PbSe diode laser. The magnetic field was maintained constant at 20.0 kG, and the current scanned across six closely lying SO_2 absorption lines. The tuning rate was obtained from Fig. 5. Results are shown in Fig. 6 and are in excellent agreement with the earlier measurements made with PbSnTe diode lasers [3], [4].

Preliminary results in our laboratories obtained with several PbSSe diode lasers indicate that these ternary materials also

exhibit nonlinear tuning characteristics in the presence of a magnetic field. Nonlinear magnetic-field tuning rates in PbSSe have been previously observed [9], although a dependence of current-tuning rate on magnetic field was not reported.

Tuning of laser modes in semiconductor lasers is due to the dependence of the refractive index on the tuning parameter (current or magnetic field in this case). The observed constancy of mode spacing suggests that there is no significant mode pulling in our PbSe laser and hence the tuning rate is given simply by [6]

$$\frac{d\nu}{dX} = -\frac{\nu}{n}\left(\frac{\partial n}{\partial X}\right)_\nu \tag{1}$$

which may also be expressed as

$$\frac{d\nu}{dX} = -2\,l\nu\Delta\nu\left(\frac{\partial n}{\partial X}\right)_\nu.$$

In (1), ν is the emission frequency in wavenumbers, $\Delta\nu$ is the laser-mode spacing, l is the laser-cavity length, n is the laser refractive index, and X is the tuning parameter (B or I). Equation (1) may be used with tuning-rate data to obtain the dependence of the quantity $(\partial n/\partial X)_\nu$ on X. As an example, from (1) and Fig. 4, $(\partial n/\partial B)_\nu$ was found to have the values -0.85×10^{-7} $(G)^{-1}$ at 11 kG, and -6.8×10^{-7} $(G)^{-1}$ at 21 kG, at a current of 0.890 A. For comparison, [6] gives $(\partial n/\partial B)_\nu = -13 \times 10^{-7}$ $(G)^{-1}$ at a field of 20 kG and a current of approximately 0.4 A. A rapid change in refractive index with magnetic field is qualitatively expected from the sharply peaked nature of the density-of-states function of the spin-split Landau levels [10]. The details of the process would be expected to depend strongly on temperature, injection level, p-n-junction concentration profile, and other factors. Thus, on this basis, nonlinear tuning rates for both magnetic tuning and current tuning (in the presence of a magnetic field) can be qualitatively understood. We are presently investigating the theoretical aspects of these phenomena in greater detail.

VI. Summary

In this work, it has been shown that by using a combination of magnetic and current tuning with a single PbSe laser, it is possible to perform ultrahigh-resolution-absorption measurements with complete coverage from 1176.0 to 1265.8 cm^{-1}. Using this method, a major fraction of the R branch of the ν_1 band of SO_2 has been investigated, thus supplementing earlier measurements of the P branch made with several current-tuned PbSnTe lasers of differing compositions. In performing these measurements it was found necessary to account for pronounced tuning-rate nonlinearities to obtain quantitative spectroscopic information from laser-produced absorption spectra.

Spatial Hole Burning and Oligo-Mode Distance Control in CW Dye Lasers

INGOLF V. HERTEL AND ALEKSANDAR S. STAMATOVIĆ

Abstract—**Spatial hole burning at the position of the dye cell is identified to be responsible for stable double-, triple-, and higher oligo-mode action in a narrow-band CW dye laser. This may be exploited systematically to control the mode distances by arranging the positions of both resonator end mirrors. A total output power up to over 100 mW is obtainable for double- or triple-mode action. Special conditions are described to obtain stable double-mode action with 1772-MHz mode spacing, as needed for simultaneous optical pumping of the two sodium hyperfine ground states.**

I. Introduction

BY THE USE of dispersive elements and etalons, stable single-mode action may be achieved in CW dye lasers (see, e.g., [1], [2]).

However, when operating high above threshold as necessary for optical-pumping applications [3], stable oscillation on two modes, simultaneously, is frequently observed. This may be attributed to spatial hole burning [4], [5]. The spacing $\Delta\nu$ between these modes was usually a few times the FSR of the laser resonator $\Delta\nu_R$ as shown in Fig. 1, where a piezo-scanned Fabry-Perot interferometer (FPI 2) of 8-GHz FSR was used to display the mode structure. Pike [5] has avoided this effect by placing the dye cell in the center of the resonator.

One can systematically make use of the spatial hole burning in order to vary the mode distance and produce a well-defined double-mode distance. This can be of importance for optical pumping with dye lasers, when more than one hyperfine component is involved, as usual.

For example, with such a device the two hyperfine-structure ground states of sodium having a distance of 1772 MHz could be pumped simultaneously, allowing a higher equilibrium population of the excited states and pumping to any of the upper hyperfine levels, which was hitherto impossible [3]. Thus a systematic investigation will be presented here.

II. Experiment

The laser and analyzing system is shown in Fig. 2, and the data of the Fabry-Perot components used are given in Table I. We use essentially the folded cavity described by Kogelnik *et al.* [6] and Dienes *et al.* [7] in a modification recommended by Johnston and Runge [8].

In Fig. 2, two Brewster prisms 5 and 6 are used as dispersive elements. A 1-mm plane parallel, coated glass flat 7, is used as an FP etalon to limit the laser bandwidth. It can be tilted to change the frequency transmitted.

FPI 1 glas flat	0.01	95	1000	50		20
FPI 2 spherical piezoscanned	3.75		8	150		0.05

An aperture stop 9, or, alternatively, a 10-mm glass flat 8, is used to prevent lasing at frequencies ±1 FSR of the 1-mm etalon.

The slit causes fewer losses but is more difficult to adjust. The angle Θ for compensation of the astigmatism is found to be not too critical and is chosen to be approximately $2\Theta \approx 12°$.

The two end mirrors are movable independently. The rela-

tively high (4-percent) transmission of the output mirror optimizes mirror losses to intracavity losses. The rhodamine 6-G solution in water is pumped with the 514.5-mm argon-ion laser line. The threshold pump power is less than 400 mW without and 525 mW with etalon and slit. The typical double-mode structure is observed with an FPI 2 on an oscilloscope screen. The mode distance $\Delta\nu$ is measured by comparing it to the FSR of FPI 2 (see Fig. 1). Alternatively, the number n of resonator FSR's $\Delta\nu_R$ between the two modes may be counted by twisting etalon 7 slowly. The mode distance is then $\Delta\nu = n \cdot \Delta\nu_R$, where $\Delta\nu_R$ is given by the resonator length. The $\Delta\nu$ values obtained in either way agree well. This is demonstrated in Fig. 3, where both modes can be seen before and after a mode hop on an expanded scale.

To make sure that really only near-neighboring laser modes occur, the 0.01-mm etalon FPI 1 was used to display the interference fringes which allow mode distances of >20 GHz to be distinguished. We have systematically varied the positions of the two laser end mirrors with respect to the dye cell for different combinations of etalons and slit. The mode distance and stability, as well as the output power, were measured for each mirror position.

III. Results and Interpretation

Let us denote by a and b the distances from the dye cell of end mirrors 1 and 2, respectively. Spatial hole burning of a mode with wavelength λ_1 affects a mode with λ_2 least, when

$$b = \beta \cdot (\lambda_1/2), \quad \text{with } \beta \text{ any large rational number}$$

and

$$b = \beta \cdot (\lambda_2/2) + m(\lambda_2/4), \quad \text{with } m = 1, 3, 5, \cdots, \text{odd}.$$

It follows that the conflict between two modes due to local hole burning is at a minimum when the mode distance is

$$\Delta\nu = (m/2) \cdot (c/2b), \quad m = 1, 3, 5, \cdots \tag{1}$$

where c is the velocity of light.

Of course, all mode spacings must be a multiple n of the resonator FSR

$$\Delta\nu = n \cdot \Delta\nu_R = n \cdot [c/2(a+b)], \quad n = 1, 2, 3, \cdots. \tag{2}$$

We may rewrite (1) and (2) dimensionless, measuring $\Delta\nu$ in units of $c/2a$

$$[\Delta\nu/(c/2a)] = (m/2)\,(a/b) \tag{1a}$$

$$[\Delta\nu/(c/2a)] = [n/(1 + b/a)]. \tag{2a}$$

While (2a) is a necessary condition for all mode distances in the laser resonator, (1a) gives desirable points for neighboring modes.

In Fig. 4, we plot, for convenience, the reciprocal equations that describe straight lines as a function of $x = b/a$

$$y = [(c/2a)/\Delta\nu] = (2/m)\,(b/a), \quad m = 1, 3, 5, \cdots \tag{1b}$$

$$y = [(c/2a)/\Delta\nu] = (1/n) + (1/n) \cdot (b/a), \quad n = 1, 2, 3, \cdots. \tag{2b}$$

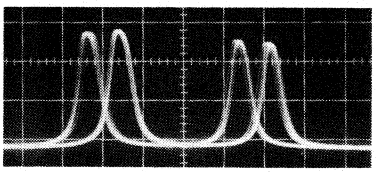

Fig. 3. FPI 2 trace; double exposure of double-mode action before and after one mode hop. Scale is 133 MHz/div; mode-hop distance, $\Delta\nu_R \approx 110$ MHz; mode distance $\Delta\nu = 5 \times \Delta\nu_R$.

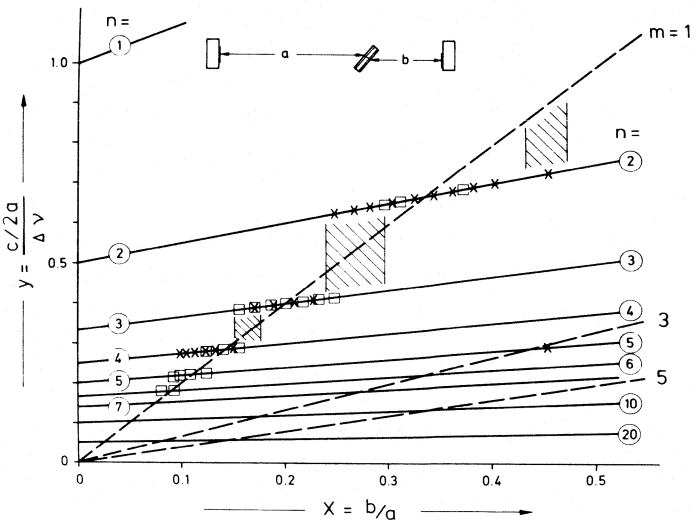

Fig. 4. Neighboring-mode conditions (1b) and (2b). All modes have to lie on the full n-lines, n being the mode distance, in units, of the resonator FSR. Antinodes coincide with nodes of the neighbor modes on the dashed m-lines, when m is the path difference in units of $\lambda/4$. Experimental points: × a = 105 cm, a = 129 cm. Shaded area represents unstable and difficult to adjust regions. Measurements were made with etalon 7a and slit or 7a and 8a (see Fig. 2).

Obviously, all observed modes have to fall on the full n-lines, and crossings between them and the dashed m-lines should be preferred, if spatial hole burning is responsible for double-mode action.

The experimental points are given for a = 105 cm, a = 129 cm, and varying b. The crossing points are definitely preferred; most stable actions usually are obtained at these points, and instability and difficulties in adjusting the laser occur where no crossing is near. Note the point near the $m = 3$, $n = 5$ crossing for large b, which is in competition with the more unstable modes on the $n = 2$ line for the same b/a.

A slight deviation from the preceding statement is occasionally found, especially in the region $n = 4$, $b/a \approx 0.1$, and a = 105 cm. The preferential $n = 5$ mode distance is obviously suppressed by etalon 7a (Fig. 2), limiting the bandwidth.

One important and somewhat surprising fact is that for larger b/a (fixed a), i.e., for smaller resonator FSR, triple- or multiple-mode action is observed with equal spacings, as shown in Fig. 5. The points in Fig. 3 always give the distance between next neighbors.

The pumping power in these experiments was 1.35 W, and up to 110-mW total output power was obtained with stable triple- or double-mode action, corresponding to 75 percent of the power obtained without etalon and slit.

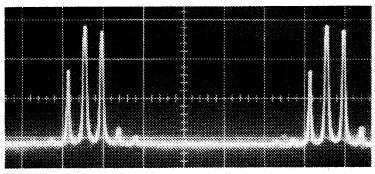

Fig. 5. FPI trace for triple-mode action: 1.33 GHz/div. Etalon 7*b* and slit were used.

The transit from double- to triple-mode action depends on the resonator losses and on the gain curve. Triple mode starts when the losses for the extreme modes become tolerable; e.g., the extreme-mode distance $2 \cdot \Delta\nu$ in Fig. 5 is $\approx$1 GHz. Etalon 7*b* (Fig. 2) (1 mm, $R = 40$ percent) was used here, while for the 7*a* (1 mm, $R = 60$ percent) etalon, triple modes appeared only, when $2 \cdot \Delta\nu \lesssim 600 \cdots 800$ MHz.

Still, the crossing rule for next neighbors holds. However, for the extreme mode's distance then, of course, node is on node in the cell.

Without a detailed study of the laser dynamics, this fact cannot be explained with the present knowledge about the homogeneous linewidth.

The stability of the mode structure near the *n–m* crossings is excellent, which means less than one or two mode hops per minute. The bandwidth of a single mode is better than 50 MHz, which is enough for all pumping applications, where saturation broadening determines the overall linewidth. The magnitude of the jitter is indicated in Fig. 3 (1-s exposure). Stability, bandwidth, and jitter could be greatly improved by avoiding thermal fluctuations, and using dust pipes, electronic stabilization, and great care.

Obviously, within the limits of the etalon bandwidth any mode distance $\Delta\nu$ can be chosen for stable double-, triple-, or higher oligo-mode action just by choosing the appropriate *a* and *b* according to (1) and (2). However, the number of modes occurring is not readily to be selected in the manner previously described. Especially for large mode spacing $\Delta\nu$ (e.g., 1772 MHz), it is not possible to obtain double-mode action without additional measures.

One may, however, insert another Fabry-Perot etalon in the cavity, having a free spectral range $\Delta\nu_{et}$ equal to the desired frequency difference, which would suppress intermediate modes. In addition to (1) and (2) the condition

$$\Delta\nu = \Delta\nu_{et} \tag{3}$$

must also hold. This, together with (1) and (2) leads finally to

$$a = n \cdot [c/(2 \cdot \Delta\nu_{et})] - b, \qquad n = 1, 2, 3, \cdots \tag{4}$$

$$b = (m/2)\,[c/(2 \cdot \Delta\nu_{et})], \qquad m = 1, 3, 5, \cdots. \tag{5}$$

Thus, for given n and m, the positions of *a* and *b* are fixed by the desired mode spacing $\Delta\nu_{et}$; n and m have to be chosen such that *a* and *b* are geometrically accessible.

We have used etalon 8*b* (5.5-cm glass flat, 1772-MHz FSR) to obtain two stable modes in 1772-MHz distance in the range of the Na-D lines.

Preselection was made with etalon 7*b* and the slit 9 (Fig. 2). Stable two-mode action is obtainable at a number of positions and has been investigated for $m = 3$, $n = 16$ corresponding to $a = 122.8$ cm and $b = 7.7$ cm; at $m = 4$, $n = 18$ ($a = 131.3$, $b = 21.2$); and finally, $m = 4$, $n = 17$ ($a = 122.8$, $b = 21.2$).

The adjustment of both *a* and *b* is not too critical; ±2 cm for *a* and ±1 cm for *b* may be tolerated without loss of stability. Care must be taken when adjusting the slit 9 (Fig. 2) and the tilt of the preselecting etalon 7 (Fig. 2).

The total output power for stable double modes spaced at 1772 MHz was up to 55 mW at 1.35-W pumping power, which is a fair result considering the high losses due to the long glass etalon. This could be improved by using an air-spaced etalon and a preselecting device with a higher FSR and flatter transmission curve (e.g., 0.5-mm 40-percent glass flat).

IV. Conclusion

Stable double-mode action with choosable mode distance is proved to be possible in CW dye lasers making use of spatial hole burning at the dye cell.

This allows simultaneous excitation from, or to, two different hyperfine states. More efficient optical pumping is thus possible on the one hand, and special hyperfine states become accessible to stationary pumping, which were hitherto emptied during the course of pumping.

Sodium-atom preparation in one of the $3^2P_{1/2}$ states for scattering processes may be one application, and in the growing field of laser-induced chemical reactions, and especially isotope separation (see, e.g., [9], [10]), new possibilities may emerge, especially when further improvement on the output power is obtained. Even spectroscopic applications of double-mode action may be thought of, e.g., in connection with light-beating techniques.

New CW Lines from a Submillimeter Waveguide Laser

HARRISON E. RADFORD

Abstract—**Sixty-one new CW laser lines with wavelengths between 0.1 and 1.5 mm have been observed with a waveguide laser optically pumped by a CO_2 laser.**

THE submillimeter optically pumped waveguide laser [1] is much smaller than its Fabry-Perot predecessor and holds promise as a compact, stable local oscillator for spectroscopy and radio astronomy. The pencil-thin waveguide resonator also offers a better match to the beam of a typical CO_2 pump laser than does the Fabry-Perot resonator, and thus allows more efficient excitation of the laser gas. To the extent that the number of available laser lines is increased, the frequency coverage of the waveguide laser, and hence its usefulness as a local oscillator, will increase as well. Using known laser gases, I have made an inventory of the CW oscillation wavelengths of a waveguide laser fabricated from half-inch copper tube, and find about 100, of which 61 are new.

The waveguide laser was patterned on that of Hodges and Hartwick [1], with minor changes dictated by convenience. The waveguide resonator was a 90-cm length of hard copper refrigeration tubing, 11 mm ID, internally polished with a carborundum-loaded swab. The mirrors were gold-coated Pyrex, one flat and one spherical (R = 10 m), positioned close to, but not in contact with, the ends of the waveguide. The grating-tuned CO_2 pump laser generated CW power in the lines $R(4)$ through $R(42)$ and $P(6)$ through $P(46)$ of both the 9.6 μm and 10.6 μm bands; the maximum output power, in lines near the middles of the R branches, was 25 W. The pump beam was focused into the waveguide resonator, through a 1-mm-diameter hole in the flat mirror, with 80 percent efficiency. The submillimeter power emerged from a 2-mm-diameter hole in the spherical mirror, and was focused by a polyethylene lens onto a quartz-windowed Golay detector, sensitive at wavelengths longer than 40 μm. Wavelengths were measured from voltage versus time recordings of the Golay detector output during linear translations of the spherical mirror.

CW laser emission was found in nine known laser gases: methanol (CH_3OH) [2]-[5], methyl fluoride (CH_3F) [2], vinyl chloride (CH_2CHCl) [2], vinyl cyanide (CH_2CHCN) [6], methylamine (CH_3NH_2) [5], [6], 1, 1 difluoroethylene ($C_2H_2F_2$) [3], [6], formic acid (HCOOH) [4], [5], [7], methyl cyanide (CH_3CN) [8], and ethyl fluoride (CH_3CH_2F) [4]. The last two gases have been studied previously only with pulsed CO_2 laser excitation, but were included in the search after several new high-threshold lines were found with the CW-pumped laser gases. Other pulse-pumped laser gases, ammonia [4], ethylene glycol [5], and methyl acetylene [8], failed to yield CW emission, as also did one CW-pumped laser gas, difluoroethane [3]. The line searches were carried out by first setting the gas pressure for maximum submillimeter signal on a known high-threshold line, and then testing each of the 82

CO_2 pump wavelengths in turn for new submillimeter lines. This exhaustive search was not performed on the four gases mentioned above, which failed the initial tests on known lines.

Table I gives the inventory of new CW lines, arranged by molecule and submillimeter wavelength. The experimental uncertainty in these wavelengths, judged from measurements of standard lines that have been measured more precisely by others, is ±2 percent. Also tabulated are the threshold pump power and gas pressure for each line, and the submillimeter output power registered by the Golay detector at the highest power available in the pump line. Pump powers were measured with a calorimetric beam probe and corrected for the 80-percent transmission of the coupling optics. The Golay power readings are based on the manufacturer's calibration and are subject to an unknown wavelength-dependent error; they are tabulated for rough comparison purposes. Gas pressures were measured with thermocouple gauges, which were calibrated for air and located at the two ends of the waveguide resonator tube. The tabulated values are averages of the two pressure readings.

By judging from the pump power threshold values of Table I, a large number of the 61 new laser lines, perhaps as many as 40, can be credited to the improved pump efficiency of the waveguide laser. The remainder are low-threshold lines that should also oscillate in a CW-pumped Fabry-Perot resonator. Some are known pulse-pumped lines that have apparently not been tried until now in a CW-pumped laser; some are lines that appear to have slipped through the nets of previous searches.

Except for the strong lines of methanol and formic acid, the submillimeter output power in most of the new lines is low, a few microwatts being a typical value. This is enough for many applications of the waveguide laser to spectroscopy, but not for applications to heterodyne radiometry, where, typically, milliwatts of local oscillator drive are required to reach conditions of minimum mixer noise. Some increase in output power, particularly at long wavelengths, can be expected from waveguide resonators that are completely gold plated, have internal end mirrors [9], and are designed for critical output coupling and optimum pumping efficiency. With these improvements, a CW local oscillator for heterodyne radiometry could probably operate on at least the wavelengths listed in Table II, which are already at or near the milliwatt level of output.

Stimulated-Emission Cross Section and Inversion Lifetime in a Three-Atmosphere Iodine Photodissociation Laser

F. T. ALDRIDGE

Abstract—**An iodine photodissociation laser has been operated at three atmospheres by adding an inert gas to the laser medium. With three atmospheres of helium added a stimulated-emission cross section of 2×10^{-19} cm^2 and an inversion half-life of 110 μs was observed.**

The iodine photodissociation laser uses the photodissociation of CF_3I or C_3F_7I to generate excited iodine atoms which can then give laser action by stimulated emission at 1.315 μ [1]

$$CF_3I + h\nu\,(2700\ \text{Å}) \rightarrow CF_3 + I^*\,(^2P_{1/2})$$

$$I^*\,(^2P_{1/2}) \rightarrow I\,(^2P_{3/2}) + h\nu\,(1.315\ \mu)\,.$$

The stimulated-emission cross section of I^* at low pressure is about 5×10^{-18} cm^2, too large for use in a large laser amplifier [2]. For this system to be useful as a high-energy short-pulse amplifier medium, the peak stimulated-emission cross section must be lowered without shortening the I^* lifetime excessively. One method of doing this is the addition of an inert gas to the system to pressure broaden the emission line, and this has been experimentally demonstrated at pressures up to 600 torr [3], [4]. In this work, the results are extended to three atmospheres and it is shown that under these conditions cross sections and lifetimes appropriate for large-pulsed laser systems are attained.

The laser setup is shown in Fig. 1. The quartz laser tube had an inside diameter of 4 mm and an illuminated length of 45 cm. The total cavity length was 1.7 m. Two rows of three flashlamps were mounted above and below the laser tube in an aluminum reflector. Each lamp had a 15-cm arc length, a 7-mm inside diameter, and was filled with 30 torr of xenon. A 1-μF capacitor, charged to 30 kV, was discharged through each row of flashlamps, giving a flash with a full-width half-maximum time of 5 μs. In order to keep all the pumped parts of the laser tube as evenly pumped as possible, the tube was covered with aluminum foil in sections where it was not next to a flashlamp arc. The Pockel's cell and glan prism were removed except when the laser was being Q switched. The laser output beam was split with an uncoated glass plate, with 92 percent of the beam going to a Hadron cone-type thermopile calorimeter and 8 percent to either an InSb detector or an S-1 photodiode detector for display on an oscilloscope. Argon and helium (Mathieson ultrahigh purity, 99.999 percent) were used without purification. n-C_3F_7I (Peninsular Chemresearch) was purified by distillation under vacuum from dry-ice–acetone temperature (−78°C) to liquid-nitrogen temperature (−190°C) with the middle 70 percent being used. The system was evacuated and filled with a fresh charge of gas mixture for each run.

At threshold, the following relation is true:

$$\frac{1}{\sqrt{R_1R_2}\,(1-L)} = \exp(\sigma \Delta N l) = G \qquad (1)$$

where σ is the stimulated-emission cross section, ΔN is the inversion population per unit volume, l is the length of the pumped laser medium, R_1 and R_2 are the reflectivities of the mirrors, and L is nonmirror cavity losses. Due to the differing multiplicities of excited- and ground-state iodine atoms, ΔN is equal to $(N_{I^*} - \frac{1}{2} N_I)$ and the total energy available from the inversion is equal to $\frac{2}{3} h\nu \Delta N$. R_1, R_2, and l are easily measured. If L and ΔN are determined, then σ can be calculated from threshold measurements. They were determined in the following way.

The laser tube was designed with a small diameter so that the laser medium was almost transparent to pumping radiation at all of the C_3F_7I concentrations used. Thus, since the pumping radiation is the same for each firing, the fraction of the C_3F_7I photolyzed is a constant. It was assumed that the ratio of excited- to ground-state iodine atoms formed was also a constant. It is known that photodissociation of C_3H_7I gives only excited iodine atoms [5]. When no inert gas was used threshold pressures of C_3F_7I ranged from 0.2 to 0.7 torr depending on the exit mirrors used. Thus, at pressures of 5–10 torr, the energy remaining in the inversion after laser action stopped was a small fraction of the energy originally available in I^* atoms. For a given set of mirror and other cavity losses, the laser output energy should thus be proportional to the total inversion or, in this case, to the C_3F_7I pressure. By measuring the output energy of the laser with several different exit mirrors, both the total energy stored in the inversion and the total cavity losses were determined.

Four series of runs were made with exit mirrors from 30- to 90-percent reflectivity to determine output energy as a function of C_3F_7I pressure. The results are shown in Fig. 2. Within experimental error the energy observed from the laser was proportional to the C_3F_7I pressure, showing that the assumptions made earlier are valid.

The total energy in the inversion and the nonmirror losses were calculated at C_3F_7I pressures of 5 and 10 torr using the data from Fig. 2. ΔN was calculated by dividing the total energy by $\frac{2}{3} h\nu$ and found to be 13.9 percent of $N_{C_3F_7I}$ at 5 torr and 13.8 percent at 10 torr. $N_{C_3F_7I}$ was calculated by assuming it to be a perfect gas.

The threshold pressure of C_3F_7I was then determined with up to three atmospheres of argon or helium added to the system. Threshold was determined for a given set of experimental conditions by reducing the concentration of C_3F_7I atoms until laser action was just detectable. Threshold pulses occurred about 20 μs after the flashlamps were triggered, when the flash intensity had fallen to 1 or 2 percent of maximum. Since the gain reached threshold while being pumped at only a few percent of the maximum rate, the rate of deactivation of I^* was

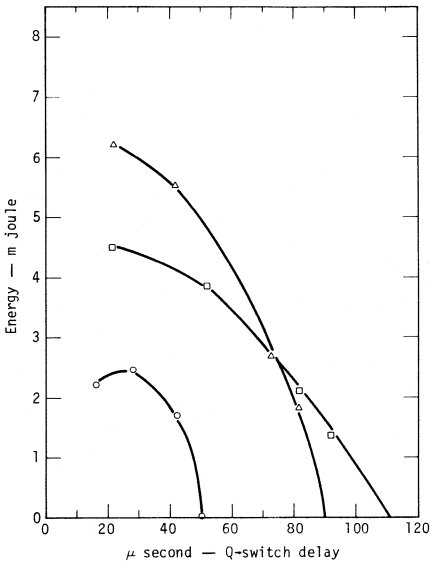

Fig. 4. Effect of Q-switch delay at three atmospheres. △—3-atm He at 29.5-torr C_3F_7I; □—3-atm He at 22.1-torr C_3F_7I; ○—3-atm Ar at 29.5-torr C_3F_7I.

low when threshold was reached. The stimulated-emission cross section of I^* was calculated with (1) using a ΔN value of 13.9 percent of $N_{C_3F_7I}$. The results are shown in Fig. 3, which shows the expected linear relationship between the cross section and the reciprocal of pressure. Argon is more effective as a pressure-broadening gas than helium.

The inversion lifetime at high pressure was measured using a Pockel's-cell Q switch. With the Q switch installed in the system and opened at the same time as the pumping flash, the threshold C_3F_7I pressure was determined for each set of operating conditions. The C_3F_7I pressure was then increased to twice the threshold value and laser action delayed by opening the Q switch after the flash.

The Q-switch delay time was lengthened until laser action was just detectable when it was opened. Since the peak inversion was initially twice the threshold level, it should have then fallen to half of its initial value, and this delay time was the inversion half-life. This method is approximate, but does show that the inversion lifetime is long enough at three atmospheres for the system to be useful.

The results are shown in Fig. 4. The 22.1-torr C_3F_7I data are twice threshold with three atmospheres of helium. The 29.5-torr C_3F_7I data with helium were run to show that the shorter lifetime with argon was not due to the higher C_3F_7I pressure needed to reach twice threshold with argon. It is clear that argon is a more effective deactivator of I^* than helium, and helium is probably a better choice for a pressurizing gas despite its lower efficiency as a line broadener.

The stimulated-emission cross section of 2.2×10^{-19} cm^2 and inversion half-life of 110 μs observed with three atmospheres of helium are both satisfactory for a large iodine laser system.

ACKNOWLEDGMENT

"Buried Modes" in Planar Media with Nonmonotonically Varying Index of Refraction

ESTHER M. CONWELL

Abstract—**When guiding is due to a continuously varying, rather than discontinuous, index of refraction, $n(z)$, and $n(z)$ peaks at some point inside the propagation medium, there may result "buried modes," i.e., modes whose exponential decay takes place inside the guiding medium rather than, as is usual, in an adjacent medium. The conditions for obtaining these modes are discussed in the Wentzel-Kramer-Brillouin (WKB) approximation and the mode equations given for both these modes and the usual ones for an illustrative case.**

Waveguiding in planar media with nonmonotonically varying index of refraction $n(z)$ has been reported by a number of researchers. The peaked index has been created by ion migration [1], [2] or impurity diffusion [3], [4]. Schematically, we may represent the resulting dielectric constant variation, $n^2(z)$, by the solid line in Fig. 1. This is similar to what was observed in [1], for example, in glass that had undergone electrically induced migration of Tl ions. For specificity we take $\epsilon = 1$ for $z < 0$. The guided modes will be assumed to propagate in the x-direction with propagation vector for the mth mode, $k_x^{(m)} \equiv (\omega/c)(\epsilon_{\text{eff}}^{(m)})^{1/2}$. For the situation of Fig. 1

$$\epsilon_b < \epsilon_{\text{eff}} < \epsilon_p. \tag{1}$$

It is readily seen that there is a difference between modes with $\epsilon_s < \epsilon_{\text{eff}} < \epsilon_p$, exemplified by $\epsilon_{\text{eff}}^{(1)}$, and those with $\epsilon_b < \epsilon_{\text{eff}} < \epsilon_s$, exemplified by $\epsilon_{\text{eff}}^{(2)}$. As can be deduced from the wave equation (see [5, (3)–(5)]) the E and H fields are oscillatory in character where $\epsilon(z) > \epsilon_{\text{eff}}$ and exponentially decaying where $\epsilon(z) < \epsilon_{\text{eff}}$. Thus the mode corresponding to $\epsilon_{\text{eff}}^{(2)}$ is oscillatory from the surface at $z = 0$ to $b^{(2)}$, while that corresponding to $\epsilon_{\text{eff}}^{(1)}$ is oscillatory only between $a^{(1)}$ and $b^{(1)}$. The latter therefore constitutes a buried mode. Evidence for such modes has been presented in [1] and [2], although the authors did not make a detailed comparison with theory. As pointed out in those references, the buried modes should have the advantage of lower attenuation since they are not subject to surface scattering.

Modes in a situation such as shown in Fig. 1 are most easily studied by the Wentzel–Kramer–Brillouin (WKB) approximation. The equation for determining the propagation vectors or ϵ_{eff}'s is conveniently stated [6], [7]

$$k_z = k[\epsilon(z) - \epsilon_{\text{eff}}]^{1/2} \tag{3}$$

k being ω/c, and a and b representing the extremes of the range in z for which the fields are oscillatory or, equivalently, for which k_z is real. (a and b are the WKB turning points.) The Φ's are related to the phase changes on reflection [6]. For reflection at the $z = 0$ interface, Φ is determined in the usual way for total internal reflection [8]. When the changes in $\epsilon(z)$ are small, i.e., $(\epsilon_p - \epsilon_b) \ll \epsilon_b$, as is generally the case, $\Phi \simeq \pi/2$ since k_z is quite small and the decay in air is rapid [6]. For reflection at points such as $a^{(1)}$, $b^{(1)}$, and $b^{(2)}$, $\Phi = \pi/4$, [6]. It is clear then that the equation for determining the modes is different for the buried ones and the ones oscillatory to the surface. Specifically, for the mth buried mode the mode equation is

$$\int_{a^{(m)}}^{b^{(m)}} k_z^{(m)}(z)\,dz = (m + \tfrac{1}{2})\pi, \qquad \epsilon_s < \epsilon_{\text{eff}}^{(m)} < \epsilon_p \tag{4}$$

while for modes that extend to the surface it is

$$\int_0^{b^{(m)}} k_z^{(m)}(z)\,dz = (m + \tfrac{3}{4})\pi, \qquad \epsilon_b < \epsilon_{\text{eff}}^{(m)} < \epsilon_s. \tag{5}$$

It should be noted that (4) will not describe the buried modes accurately unless $a^{(m)}$ is far enough from $z = 0$ so that the exponential decay is essentially complete there. If that is not the case, the additional boundary conditions at $z = 0$ will affect the modes substantially.

Although detailed experimental data with which to compare theory are not available, we present the results of a calculation for the two types of modes to illustrate the dependence on the relevant parameters. To simplify the integration we represent $\epsilon(z)$ by a straight line to the left of z_p, an exponential to the right. Specifically, we choose

$$\epsilon(z) = \epsilon_s + [(\epsilon_p - \epsilon_s)/z_p]z, \quad 0 \leqslant z \leqslant z_p \tag{6}$$

and

$$\epsilon(z) = \epsilon_b + (\epsilon_p - \epsilon_b)e^{(z_p - z)/d}, \quad z_p \leqslant z \leqslant \infty \tag{7}$$

where d is a constant determined by the diffusion or migration process. With (6) and (7) we obtain the mode equation for the buried modes

$$A(\epsilon_{\text{eff}}) = (m + \tfrac{1}{2})\pi, \quad \epsilon_s < \epsilon_{\text{eff}} < \epsilon_p \tag{8}$$

where

$$A(\epsilon_{\text{eff}}) = \frac{2kz_p}{3}\frac{(\epsilon_p - \epsilon_{\text{eff}})^{3/2}}{\epsilon_p - \epsilon_s} + 2kd\left\{(\epsilon_p - \epsilon_{\text{eff}})^{1/2} - (\epsilon_{\text{eff}} - \epsilon_b)^{1/2}\tan^{-1}\left(\frac{\epsilon_p - \epsilon_{\text{eff}}}{\epsilon_{\text{eff}} - \epsilon_b}\right)^{1/2}\right\}. \tag{9}$$

Accuracy of (8) requires, for the reason given earlier, that ϵ_{eff} not be too close to ϵ_s. For the other modes we find

$$A(\epsilon_{\text{eff}}) - \frac{2kz_p}{3}\frac{(\epsilon_s - \epsilon_{\text{eff}})^{3/2}}{\epsilon_p - \epsilon_s} = (m + \tfrac{3}{4})\pi, \quad \epsilon_b < \epsilon_{\text{eff}} < \epsilon_s. \tag{10}$$

We note that the possible number of buried modes may be increased by increasing z_p, d, or $(\epsilon_p - \epsilon_s)$. If ϵ_s were smaller than ϵ_b, all existing modes of the system would be buried ones.

On Saturation Mechanisms in PC He-Cd$^+$ Lasers

JERZY K. MIZERACZYK

Abstract—**The results of experimental studies on the saturation mechanisms in He-Cd laser discharge are presented. It is concluded that the saturation effects may be explained in terms of the influence of the discharge parameters on the helium triplet metastable density.**

Manuscript received November 27, 1974. This work was sponsored in part by the Institute of Quantum Electronics, WAT, Warsaw, Poland.

The author is with the Institute of Fluid-Flow Machines, Polish Academy of Sciences, Gdańsk, Poland. He is on leave at the Department of Electronics, Nagoya University, Nagoya, Japan.

Since the proposal of the He–Cd$^+$ laser [1] many papers have appeared which discuss the excitation mechanisms responsible for the population inversion on the $5s^2{}^2D_{5/2} - 5p^2{}^2P_{3/2}$ 4416-Å and $5s^2{}^2D_{3/2} - 5p^2{}^2P_{1/2}$ 3250-Å transitions of the Cd ion [2]–[8].

It is now accepted that Penning collisions between helium triplet metastable and cadmium ground-state atoms have importance as the process of population of the preceding upper Cd-ion levels in the positive column He–Cd laser discharge. But according to this excitation mechanism there are some troubles in explaining the effects of saturation of the He–Cd$^+$ laser power output, especially when at constant cadmium vapor pressure the discharge current is increased. A very interesting explanation of the behavior of He–Cd$^+$ laser output is given in [8] on the basis of the behavior of the He metastable densities measured in the He–Cd discharge.

This correspondence shows that the saturation mechanisms of the He–Cd$^+$ laser power output can be explained qualitatively in terms of the behavior of plasma parameters of the discharge and their influence on the He triplet metastable density in whole region of interest.

The cataphoresis-type discharge tube used in these studies was 3 mm in diameter and about 40 cm in active length. Cadmium of natural isotopic abundance was supplied from the side arm placed at $\frac{2}{3}$ of the active length, closer to the anode. The side-arm temperature was stabilized to better than $\pm\frac{1}{2}$°C. All parts of the tube except the small region of cadmium condensation were put in the oven at a temperature of 350 ± 7.5°C. The experiments were made over the following range of parameters: the discharge current, 15–155 mA; helium pressure, 1.5–6 torr; cadmium vapor pressure, 10^{-5}–$2 \cdot 10^{-3}$ torr. The cadmium pressure in the discharge was estimated from the temperature of the side arm. The plasma parameters: electric field, electron temperature, and density were obtained using the double-probe technique modified [9] to avoid the difficulty in getting the electron density in the He–Cd discharge from the conventional double-probe method [10].

Because of using the probes in the active region of the tube the behavior of the 4416-Å spontaneous-emission sidelight was observed instead of the laser power output. But fortunately, it is known from our experiments and those of the others [8], [11] that the spontaneous-emission sidelight at 4416 Å follows the same behavior as the laser output. It seems that the He–Cd$^+$ laser output depends on the pumping of the upper laser level rather than on the excitation and trapping effects of the lower laser level. This allows an explanation of the behavior of the He–Cd$^+$ laser power output at 4416 Å in terms of the spontaneous-emission sidelight following the power.

Typical results of the experiments are presented in Figs. 1 and 2. Fig. 1 shows the influence of increasing cadmium vapor density on the intensities of the spontaneous-emission sidelight of the Cd$^+$ at 4416 Å, Cd at 4799 Å, and He at 3889 Å and on the reduced electric field E/p, electron temperature V_e, and density n. These results were obtained for the fixed He pressure and discharge current optimal in the sense of the maximum of intensity of the 4416-Å laser line. The broken lines in Figs. 1 and 2 illustrate the variations of the He triplet metastable density M and normalized product of MN_{Cd}, where N_{Cd} is the density of the neutral cadmium atoms in the discharge. The plots of M and MN_{Cd} were obtained from the calculations based on the data of these experiments and on the rate equation for the He triplet metastable population in pure He discharge [8], modified by taking into account the destruction of the triplet metastables by Penning process in the He–Cd laser discharge. The final shape of the equation describing the He triplet metastable density in the He–Cd

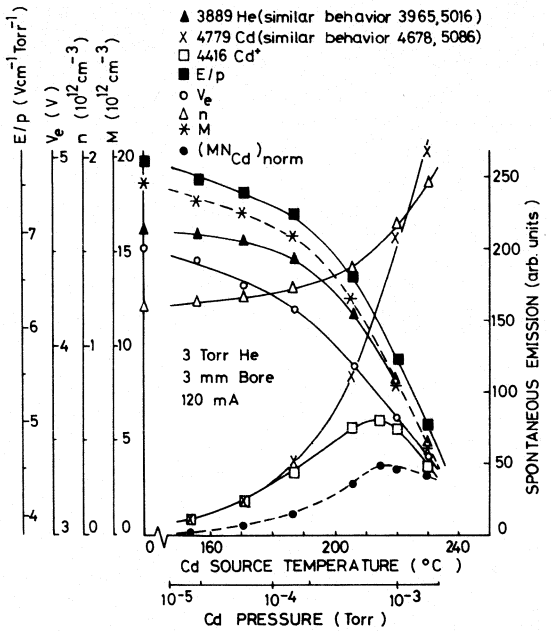

Fig. 1. Spontaneous emission of 3889-Å He, 4799-Å Cd, and 4416-Å Cd^+ lines, reduced electric field (E/p), electron temperature (V_e), and density (n), helium triplet metastable density (M), and normalized product MN_{Cd} (N_{Cd}-cadmium density) as functions of cadmium pressure in He–Cd laser discharge for fixed He pressure and discharge current. The broken lines show the results calculated.

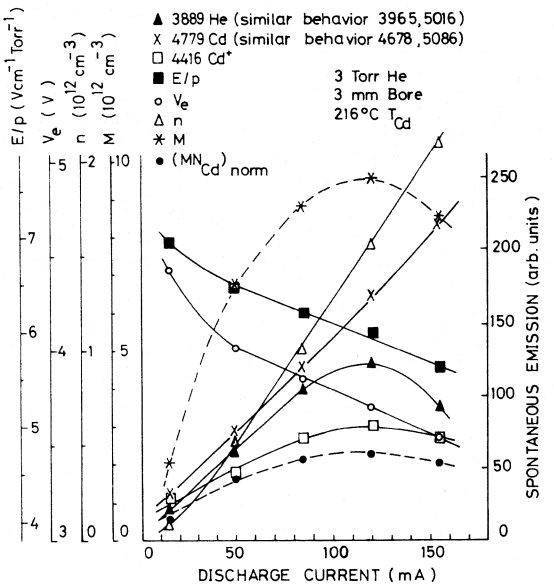

Fig. 2. Spontaneous emission of 3889-Å He, 4799-Å Cd, and 4416-Å Cd^+ lines, reduced electric field (E/p), electron temperature (V_e), and density (n), helium triplet metastable density (M), and normalized product MN_{Cd} (N_{Cd}-cadmium density) as functions of discharge current in He–Cd laser discharge for fixed He and Cd pressures. The broken lines show the results calculated.

discharge is as follows [12]

$$M = \frac{540n}{70n + N_{Cd} + 47}(E/p - 4) \quad (1)$$

where M and n are expressed in 10^{12} cm^{-3} and E/p in Vcm^{-1} $torr^{-1}$.

It is seen from Fig. 1 that the electron temperature and reduced electric field decrease with increasing cadmium density, contrary to the electron density. These are due to the inelastic collisions between electrons and neutral cadmium atoms. Also the metastable density decreases as cadmium density increases. It can be easily shown from (1) that the

decreasing of the metastable density is essentially determined by decreasing the reduced electric field rather than through the destruction of Penning process and electronic-collision effects in the region of interest. It is interesting to notice that the spontaneous emission of the 3889-Å line terminating on the triplet metastable level follows the metastable density plot. Spontaneous emission of the 4799-Å Cd indicates the increasing density of neutral cadmium atoms in the discharge.

According to the assumption that Penning collisions are the dominant source of the excitation of the upper level state the intensity of the 4416-Å emission sidelight would be proportional to the product of MN_{Cd} [2]. This was confirmed by these experiments. As is seen from Fig. 1 the normalized plot of MN_{Cd} follows the same behavior as the experimental values of sidelight intensity for the 4416-Å transition of Cd^+. Both these quantities saturate for the same value of cadmium vapor pressure of about $0.9 \cdot 10^{-3}$ torr. This means that the dependance of the spontaneous-emission sidelight at 4416 Å (and laser power output) on cadmium pressure can be understood in terms of the importance of Penning ionization in pumping processes of PC He–Cd^+ lasers.

Fig. 2 shows the behavior of the preceding quantities as the functions of discharge current for fixed He and Cd vapor pressures optimal in the sense of the maximum of the 4416-Å emission sidelight. According to (1), despite rapidly increasing electron density the He triplet metastable density saturates for the current of about 120 mA because of the decreasing reduced electric field when the discharge current increases. It means that the reducing of the mean electron energy and the E/p or V_e corresponding to it, due to the inelastic collisions of electrons in the He–Cd discharge, is important in the saturation mechanisms of the He triplet metastable density. As may be seen from Fig. 2 the 4416-Å emission sidelight follows the behavior of the metastable density and the plot of the product MN_{Cd}, and this is consistent with the generally accepted assumption that Penning ionization is important in the excitation mechanisms in the PC He–Cd^+ lasers.

It is worthwhile to notice that the plots of the triplet metastable density calculated herein is in a good agreement with those of measured values presented in [8].

It can be concluded that the saturation mechanisms in the PC He–Cd^+ lasers may be explained qualitatively by the behavior of the He triplet metastable density saturated due to the influence of the plasma parameters of the He–Cd discharge, the reduced electric field mainly.

ACKNOWLEDGMENT

The author wishes to thank Dr. Z. Zakrzewski, Prof. S. Hattori, and Dr. T. Goto of Nagoya University for helpful discussions, and J. Ziemann for technical assistance.

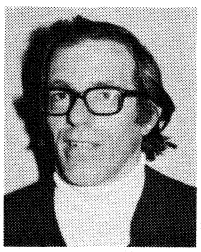
G. J. Ernst was born in Castricum, The Netherlands, on December 30, 1941. He received the doctor's degree from the University of Amsterdam, Amsterdam, The Netherlands, in 1966, where he participated in relaxation phenomena in silicon-iron alloys.

From 1966 to 1970 he was with Philips Research Laboratories, Eindhoven, The Netherlands, where he was engaged in technological applications of high-power laser systems. In 1970 he joined the Twente University of Technology, Enschede, The Netherlands, where he is now working in the field of nonlinear optics and high-power laser systems.

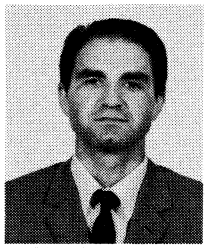


*

Ingolf V. Hertel was born in Dresden, Germany, on June 9, 1941. He graduated as Engineer for Technical Physics in Lübeck, Germany, in 1963. He received the Diplom in Physics from the University of Freiburg, Freiburg, Germany, in 1967. During 1967 and 1968 he worked as an Experimental Officer at the University of Southampton, Southampton, England, and received the Dr. rer.nat. from the University of Freiburg in 1969.

In 1969 and 1970 he was an Assistant in the Physics Department at the University of Mainz, Germany, and joined the University of Trier-Kaiserslautern, Kaiserslautern, Germany, in 1970 as a Professor of Physics. His main research interests are in atomic collision processes and lasers.

*



William G. Oldham (M'65) was born in Detroit, Mich., on May 5, 1938. He received the B.S. and Ph.D. degrees in electrical engineering from Carnegie Institute of Technology, Pittsburgh, Pa., in 1960 and 1963, respectively.

From 1963 to 1964 he worked for Siemens-Schuckertwerke, Erlangen, Germany, on vapor growth of III–V compounds. Since 1964 he has been on the faculty of the University of California, Berkeley. He is currently a Professor of Electrical Engineering and Computer Sciences,

and a member of the Electronics Research Laboratory. He spent a sabbatical year, 1970–1971, with the Technische Universität, Munich, Germany as an NSF Senior Postdoctoral Fellow, and is currently on an industrial leave (1974–1975) at Intel Corporation, Santa Clara, Calif.

*

Emilio Panarella was born in Ferrandina, Italy, on January 3, 1933. He received the Doctoral Degree in navigational sciences from the University of Navigation, Naples, Italy, in 1956, presenting a thesis on the physics of polar aurorae.

In 1961 he was awarded a Postdoctorate Fellowship and went to the Polytechnic Institute of Brooklyn, N.Y., where he worked on microwave techniques for plasma diagnostics for one year. He then returned to Italy and worked on electron spin resonance with the Microwave Institute of the National Research Council of Italy, located in Florence. In 1964 he joined the Gas Dynamics Section, Division of Mechanical Engineering, National Research Council of Canada, Ottawa, and since then has been involved in the production, diagnosis, and theoretical analysis of hot plasmas, such as implosive and explosive discharges and laser-induced sparks.

Dr. Panarella is a member of the American Physical Society, the European Physical Society, and the Italian Physical Society.

*

Harrison E. Radford was born in Peterboro, N.H., on July 26, 1927. He received the B.S. degree in physics (*summa cum laude*) from the University of New Hampshire, Durham, in 1954, and the M.S. and Ph.D. degrees, both in physics, from Yale University, New Haven, Conn., in 1955 and 1959, respectively.

From October 1958 to May 1967 he was Project Leader in the Cryogenics Section of the Heat Division at the National Bureau of Standards. In May 1967 he became Project Leader in the High Voltage Section of the Electricity Division, also at the National Bureau of Standards, a position he held until July 1969. In August 1969 he went to the Smithsonian Astrophysical Observatory, Cambridge, Mass., where he is a Physicist (Microwave Spectroscopy) in the Radio Astronomy Laboratory. In September of that same year he became an Associate of the Harvard College Observatory, Harvard University, Cambridge, Mass.

Dr. Radford was awarded the Department of Commerce Silver Medal for Meritorious Service in 1963, and the Distinguished Alumni Award from the College of Technology, University of New Hampshire, in 1971.

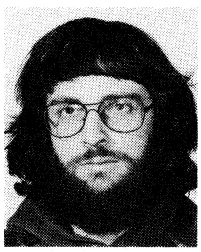
*

Aleksandar S. Stamatović was born in Šabac, Yugoslavia, on December 26, 1940. He received the B.S. degree in physical chemistry, and the

M.S. and Ph.D. degrees in physics, all from the University of Belgrade, Belgrade, Yugoslavia, in 1963, 1966, and 1969, respectively.

In 1967 he joined the Department of Engineering and Applied Science at Yale University, New Haven, Conn., where he was involved in research on low-energy electron-molecule collisions. He is now at the University of Trier-Kaiserslautern, Kaiserslautern, Germany, on a leave of absence from the Institute of Physics, Belgrade, Yugoslavia. His research interests include electron-collision phenomena and lasers.

Dr. Stamatović is a member of the European Physical Society.



*

Horst Weber was born in Berlin, Germany, on March 28, 1935. He received the M.S. and Ph.D. degrees, both in physics, from the Technical University of Berlin, Berlin, in 1961 and 1965, respectively.

In 1967 he became an Assistant Professor at the Technical University of Berlin. In 1969 he joined the Institute of Applied Physics, University of Berne, Berne, Switzerland, and is now a Professor of Applied Physics and Head of the Laser Group. His research is related to ultrashort pulses, dye lasers, interaction of intense laser light with matter, and laser-induced plasmas.

*

Robert Wilbrandt was born in Berne, Switzerland, on April 22, 1945. He received the M.S. degree in physics and the Ph.D. degree, both from the University of Berne, Berne, in 1971 and 1974, respectively.

He is now a Postdoctoral Fellow at the Atomic Energy Commission Risø Research Establishment, Roskilde, Denmark, where he is working on laser absorption and Raman spectroscopy.

*

W. J. Witteman was born in Monster, The Netherlands, on December 12, 1933. He received the degree of mechanical engineer from the Technical University of Delft, Delft, The Netherlands, in 1958, and the Ph.D. degree in physics from the Technical University of Eindhoven, Eindhoven, The Netherlands, in 1963.

He was a Postdoctoral Fellow from 1958 to 1959 and a Research Associate from 1959 to 1960 at the Institute for Fluid Dynamics and Applied Mathematics, University of Maryland, College Park, where he was engaged in shock tube work and molecular

relaxation phenomena. From 1961 until 1969 he was with Philips Research Laboratories, Eindhoven, The Netherlands, and participated from 1961 to 1963 in development work on high-pressure apparatus. Since 1963 he has been doing laser research and has published on continuous water-vapor lasers, mode competition in gas lasers, sealed-off high-power carbon-dioxide lasers, the behavior of water vapor added to a CO_2-laser mixture, and on relaxation phenomena in a CO_2 laser. Since September 1969 he has been a Professor at Twente University of Technology, Enschede, The Netherlands, where he is engaged in high-power systems and nonlinear optics.

ADVICE TO AUTHORS[1]

Abstract—**Suggestions are made about the preparation of papers to be submitted to IEEE Journals and Transactions including directions for writing equations compactly and some remarks about the form of references and about style.**

I. Preparation of Manuscripts

For general instructions about preparing manuscripts for this and other IEEE journals, see "Information for IEEE Authors," *IEEE Spectrum*, pp. 111–115, August 1965, and the inside back cover of this Transactions. In particular, the following points should be noted.

1) Manuscripts should be typed, and *everything* should be double-spaced.

2) The title page should carry the author's name, address, and zip code. There should be an abstract of no more than 200 words for a paper, no more than 50 for correspondence. Abstracts should contain only the simplest, one-line equations, and they should not refer to footnotes or to references.

3) It is preferred that references be given in footnotes, but they may be collected at the end if the author desires. Footnotes should be assembled on a separate page after the main text and any appendices.

4) Figure captions should be typed on a separate page at the end.

5) Glossy prints or india-ink copies of figures, suitable for engraving, must be supplied before publication.

6) Send three legible copies of your paper to the appropriate editor. See the inside back cover for the names of the editors and their areas of responsibility.

II. Writing of Equations

Every effort, consistent with clarity, must be made to write equations so that they take up as little space as possible. Some specific directions are the following.

1) Write equations as much on a single line of type as you can.

2) Use the diagonal (/) and negative exponents to avoid cumbersome fractional expressions. Use case fractions ($\frac{1}{2}$, $\frac{1}{4}$) for common fractions.

3) Although a bar, caret, tilde, or single dot can be set above a single letter, nothing should appear below a letter or above more than one letter, nor should a letter have more than one symbol above it. Use $\underset{\sim}{E}$ or angular brackets $\langle\rangle$ for expected values, not an overline.

4) Use fractional exponents instead of radical signs ($\sqrt{\ }$).

5) Use "exp" for the exponential function whenever the exponent takes more than a single line of type.

6) Matrices that have any simple symmetries should not be written out in full; they take too much space. Use a subscript notation instead, e.g., $\underset{\sim}{A} = ||a_{ij}||$.

7) Do not write out a column vector; display the transposed row vector instead.

8) Use boldface type, indicated by a wavy underline $\underset{\sim}{A}$, for vectors and matrices.

9) Introduce a new symbol for a complicated expression that is often repeated.

10) All mathematical symbols should be clearly identified, particularly if they are handwritten. Be sure that subscripts and superscripts are clearly designated.

11) Equations should be numbered consecutively throughout the text and referred to simply by number. The word "equation" should be used only at the beginning of a sentence.

"Equation (23) enables us to write (32) in the form ···."

12) Do not put complicated expressions in the limits of integrals or sums.

III. References

Use the standard IEEE form in references. For journal articles give names of all authors, full title, full name of journal, volume number, inclusive page numbers, month, and year. For books give the name of the publisher, his city, and the year of publication. References to books should always include page numbers. Reports and memoranda of limited circulation may be cited only by permission of the editor who is handling your paper.

IV. Usage

It is most important that your paper be correct, concise, and crystal clear. Attention to grammar fosters clarity. Here are some suggestions about usage.

1) Avoid jargon. Introduce new terminology only when it is indispensable.

2) Hyphenate complex modifiers to help the reader sort them out:
"capacity-equalized frequency-modulation channel."

3) Shun dangling participles.

4) Use "that" for defining relative clauses, "which" for nondefining relative clauses.
"The theorem that has just been proved permits us ···"
"This theorem, which was proved by Brown, permits us ···"

5) Avoid parenthetical expressions that interrupt the thought of a sentence or paragraph.

6) Avoid coy parentheses.
NO: "This (unique) solution of the (Fredholm) integral equation ···."
YES: "This unique solution of the Fredholm integral equation···"

7) Break up overlong paragraphs. Check whether a series of one-sentence paragraphs can be combined.

8) Do not overuse the word "case."
NO: "In the white-noise case···"
YES: "When the noise is white, ···"

9) Distinguish "can" and "may."
"According to (15), this expression can be written as ···"
"Interested readers may request copies of the report ···"

10) Do not use "too" to mean "very."
(What does "I cannot recommend this book too strongly" really mean?)

11) Do not use "essentially" to mean "approximately" or "effectively."
"Signal detection is essentially hypothesis testing."
"Outside the band the signal spectrum is nearly zero."
(*not* "essentially zero!")
"Under these conditions the noise is effectively white."
(*not* "essentially white!")

12) Use possessives.
"Jones's theorem" *not* "the theorem of Jones."

13) Distinguish "alternate" and "alternative."
"An alternative proof has been given by Smith."
"Alternate rows of the matrix contain only zeros."

14) "Based on" is adjectival; the adverbial phrase is "on the basis of."
"On the basis of these experiments we predict ···"
"Our prediction, based on incomplete data, was incorrect."

15) Capitalize adjectives and nouns derived from proper names, excepting names of units of measure, which are uncapitalized.
"Gaussian noise," "Cartesian coordinates,"
"The Hamiltonian of the system is ···"
"The inductance is 1 henry."

If you have difficulty in writing, a good book to study is *The Elements of Style*, by William Strunk, Jr. and E. B. White (New York: Macmillan 1959). It is now available in paperback. Reminiscing about his old teacher, E. B. White says in his introduction,

> "Will [Strunk] felt that the reader was in serious trouble most of the time, a man floundering in a swamp, and that it was the duty of anyone attempting to write English to drain this swamp quickly and get his man up on dry ground, or at least throw him a rope."

The reader is in trouble all of the time, the difficulties of the subject matter being what they are, and authors should strive to give him all the help they can.

Effect of Refractive-Index Nonlinearity on the Optical Quality of High-Power Laser Beams

B. R. SUYDAM, MEMBER, IEEE

Abstract—**Both small-scale and large-scale partial self-focusing produce phase distortions which result in loss of optical quality of the beam. Both effects are herein studied and both can result in significant power loss. Incipient fine-scale self-focusing losses can be mitigated by spatial filtering. Nonlinear lensing, i.e., partial large-scale self-focusing, is more or less serious depending on the size of the target onto which the beam is to be focused.**

I. Introduction

SELF-FOCUSING sets an upper limit [1] on the achievable intensity from a laser employing an optically dense host material such as glass or ruby. But even if very high intensity were achieved, the laser may well be useless unless the beam is of adequate optical quality. For example, for laser fusion experiments the light must be focused on a target of 100-μm radius, more or less. The question therefore arises whether the phase distortions introduced by the nonlinearity of the refractive index, which eventually would lead to self-focusing, may not spoil the optical quality of the beam long before self-focusing actually occurs. It is the purpose of this paper to investigate this question.

Self-focusing can occur in two quite distinct ways depending on the power level. At low power the beam tends to collapse more or less as a whole [2], [3]. At high-power levels there is also a tendency to collapse as a whole, but before this can proceed very far, the beam breaks up and self-focuses in a myriad of filaments [1], [4]. As we are interested primarily in very powerful beams we shall in this paper adopt the nomenclature that *self-focusing* means the unstable breakup of the beam into many filaments; for the general collapse of the beam as a whole we shall adopt the term *nonlinear lensing*. Both processes lead to optical loss.

Our analysis will be based on the quasi-optical equation

$$\frac{2i\omega}{v}\frac{\partial E}{\partial z} = \nabla^2 E + \gamma |E|^2 E \tag{1}$$

in which γ is proportional to n_2 and represents the nonlinear part of the refractive index, and v is phase velocity in the medium $v = c/n_0$. If we work in variables (x, y, z, τ) rather than (x, y, z, t), where

$$\tau = t - v/c \tag{2}$$

then (1) can represent the propagation of a pulse. In this case $\partial/\partial z$ is calculated with τ = const, i.e., in a frame moving with the pulse, and E depends on τ as a parameter only. In our work it will generally be more convenient to work in the real amplitude A and phase ϕ, given by

$$E = A \exp(i\phi) \tag{3}$$

rather than in E. We shall not, however, need to rewrite (1) in terms of A and ϕ.

We have been concerned mainly with the laser-induced fusion problem of focusing a very powerful laser beam onto a small target. It therefore seemed most natural to think of beam quality in terms of the smallest focal spot one can produce with an ideal lens. Accordingly, in this paper we measure beam quality in terms of achievable focal spot size.

II. Effect of Incipient Self-Focusing

At very high power levels small-scale perturbations grow to what are ultimately disastrous proportions. During this process, perturbations of the initially plane-wave front grow larger and progressively degrade the beam. To study the early phases of this growth it is sufficient to study initial perturbations of the amplitude and phase of the form [1], [4]

$$(\delta A)_{\text{initial}} = -A_0 \delta_A \sin(k_x x)\cos(k_y y)$$
$$(\delta\phi)_{\text{initial}} = \delta_\phi \sin(k_x x)\cos(k_y y). \tag{4}$$

Because it will soon outstrip all others, we confine our attention to the fastest growing mode; this grows as

$$(\delta A)_z = -A_0[\delta_A \cosh \alpha z + \delta_\phi \sinh \alpha z]\sin(k_x x)\cos(k_y y)$$
$$(\delta\phi)_z = [\delta_A \sinh \alpha z + \delta_\phi \cosh \alpha z]\sin(k_x x)\cos(k_y y). \tag{5}$$

Moreover, we may set $k_x = k_y$ as this mode ultimately grows fastest [1]. Thus after a few generations of growth the electric-field envelope will be

$$E = E_0[1 - \beta \sin kx \cos ky]\exp[i\beta \sin kx \cos ky] \tag{6}$$

where we have dropped indices on the k and have written $\beta = \frac{1}{2}(\delta_A + \delta_\phi)\exp(\alpha z)$ for short. In order for (6) to be a good approximation to the true perturbed field β should be small. We shall, however, wish to say something about finite perturbations and therefore shall *not* so restrict β, with the understanding that the use of our final formula with β not small requires justification.

The effect of incipient self-focusing is calculated by illuminating an aperture with the perturbed field (6) and examining the resultant Fraunhofer diffraction pattern. This simply amounts to a cross-ruled grating problem of the type discussed, for example, by Goodman [5]. The extra set of rulings and the amplitude modulation add nothing to the difficulty. At

Manuscript received May 20, 1974; revised October 14, 1974. This work was performed under the auspices of the U.S. Atomic Energy Commission.

The author is with the Los Alamos Scientific Laboratory, Los Alamos, N. Mex. 87544.

high-power levels $1/k$ is much smaller than the aperture, so the grating has many rulings each way. This has the result that the grating orders do not overlap. Thus the central spot has precisely the intensity and phase distribution which would have been produced by plane-wave illuminated aperture. Owing to diffraction into higher order spots, however, power is lost from the central spot; its intensity is reduced by the degradation factor

$$D = J_0^2(\beta/2)\,[J_0^2(\beta/2) + \beta^2 J_1^2(\beta/2)]\,/(1 + \beta^2/4). \tag{7}$$

The calculation of this result is outlined in the Appendix. Had there been an amplitude perturbation alone, it is clear that the degradation factor would have been

$$D^* = (1 + \beta^2/4)^{-1} \tag{8}$$

rather than (7). Table I gives numerical values of D^* and of D versus β. It is seen that, over the range of β tabulated, the amplitude and the phase perturbations account for approximately equal loss factors, that is to say D roughly equals $(D^*)^2$.

Actually, well before $\beta = 1$, higher harmonics of the normal mode (5) will develop [1], owing to nonlinear self-interaction of the perturbation. This results in a sharpening of the peaks and a broadening of the valleys of both δA and $\delta\phi$. When this happens, all of the energy in the amplitude perturbation is lost, as before, but as the phase peaks sharpen, the relative loss factor owing to phase modulation diminishes. In fact, it is easy to see that for a phase modulation, which is of the form of flat valleys and narrow spikes, the diffraction loss goes to zero as the spike width goes to zero *regardless* of spike height. Now it has been shown [6] that precisely one critical power goes into a self-focal spot. As each cell of our normal mode pattern contains 3.3735 critical powers [1], the quantity D^* goes to the asymptotic limit $1 - 1/3.3735 = 0.7036$. This corresponds with the last value $\beta = 1.298$ in Table I. It follows from our preceding discussion that the corresponding value of D, namely 0.5467, *is an overestimate of power loss at the self-focal limit*, because it does not allow for sharpening of the phase spikes.

TABLE I
DEGRADATION FACTORS D AND D^*

β	D, from Eq. (7)	D* from Eq. (8)
0.0	1.000	1.0000
0.1	0.9951	0.9975
0.2	0.9803	0.9901
0.3	0.9568	0.9780
0.4	0.9251	0.9615
0.5	0.8873	0.9412
0.6	0.8449	0.9174
0.7	0.7996	0.8909
0.8	0.7530	0.8621
0.9	0.7066	0.8316
1.0	0.6620	0.8000
1.298	0.5467	0.7036

Owing to the lack of a satisfactory mathematical theory of the later stages of self-focusing, we cannot compute the power loss as self-focus is approached. We have, however, shown that incipient self-focusing does not lead to enlargement of the main focal spot, but does lead to power loss in this (diffraction-limited) spot. As self-focus is approached the power-degradation factor monotonically approaches a limit lying somewhere between 0.55 and 0.70.

It follows that power on target (into the focus) increases monotonically as the amplifier output is raised, right up to the limit of self-focusing. Beyond the self-focusing limit all bets are off. If self-focusing occurs well inside the amplifier, scattered and diffracted light from the foci will interact nonlinearly with the remaining light. This automodulation of the beam will further degrade its optical quality in a way the author sees no way to estimate.

III. Nonlinear Lensing

Incipient self-focusing leads to diffraction of power out of the main focal spot, but to no loss of quality of the spot itself. Nonlinear lensing on the other hand leads to large-scale aberrations which smear the focal spot. Vlasov *et al.* [3] have developed a moment theory of (1) which seems particularly well suited to the problem of estimating focal spot size. The theory treats certain integrals evaluated over the full beam cross section Σ, namely

$$\begin{cases} W = \displaystyle\int_\Sigma A^2\, d\sigma \quad \rho^2 = \frac{1}{W}\int_\Sigma r^2 A^2 d\sigma \\ B = -\dfrac{v}{\omega W}\displaystyle\int_\Sigma A^2 \tilde{r}\cdot\nabla\phi\, d\sigma \\ C = \dfrac{v^2}{\omega^2 W}\displaystyle\int_\Sigma \left[(\nabla A)^2 + A^2(\nabla\phi)^2 - \frac{1}{2}\gamma A^4\right] d\sigma. \end{cases} \tag{9}$$

Clearly, they are all functions of z alone; the moment theory specifies the z dependence as

$$\begin{cases} W, C \text{ are constants} \\ B(z) = Cz + B_0 \\ [\rho(z)]^2 = Cz^2 + 2B_0 z + \rho_0^2 \end{cases} \tag{10}$$

where B_0 and ρ_0^2 are, respectively, B and ρ^2 evaluated at $z = 0$. From its definition it is apparent that ρ is the root-mean-square (rms) beam radius. Further noting that

$$\rho\frac{d\rho}{dz} = Cz + B_0 = B(z) \tag{11}$$

it is apparent that B measures the mean divergence of the

beam; precisely, B/ρ is the tangent of the mean divergence angle. From (10) we see that ρ^2 is a minimum when $z = z_m$

$$z_m = -B_0/C \tag{12}$$

and at this point $\rho = \rho_m$

$$\rho_m^2 = (\rho_0^2 C - B_0^2)/C. \tag{13}$$

The quantity z_m we shall call the focal distance, as modified by diffraction and by aberration and shall use ρ_m as our estimate of the aberrated focal spot size.

To make our computations we must know how the moments (9) transform on passage through a thin lens of focal length R. At the entrance to the lens let the moments and the field have the values

$$\rho = \rho_e \quad B = B_e \quad C = C_e \quad E = A \exp(i\phi_e). \tag{14}$$

At the exit ρ and A will not have changed, but the phase will be modified to

$$\phi = \phi_e + \omega r^2/(2cR). \tag{15}$$

Setting (15) into (9) we readily see that at the lens exit

$$\begin{cases} W = W_e \quad \rho^2 = \rho_e^2 \\ B = B_e - \rho_e^2/R \\ C = C_e - 2B_e/R + (\rho_e/R)^2. \end{cases} \tag{16}$$

By combining the lens transformation (16) with the translation transformation (10) we can compute the result of passing the beam through such an optical device as a telescope. In making such transformations it is useful to note that the quantity

$$\rho^2 C - B^2 \text{ is invariant both under translation (10) and under the lens transformation (16).} \tag{17}$$

As our first example, let us consider a beam which at $z = 0$ has a Gaussian profile and diverges with a radius of curvature R, so that

$$A = A_e \exp[-r^2/2a_e^2] \quad \phi = -\omega r^2/(2vR). \tag{18}$$

This beam is to be propagated a distance z through a nonlinear passive medium. We readily calculate

$$\begin{cases} W = \pi a_e^2 A_e^2 \quad \rho_0^2 = a_e^2 \\ B_0 = a_e^2/R \\ C = (v/\omega a_e)^2 [1 - \frac{1}{4}\gamma a_e^2 A_e^2 + (\omega a_e^2/vR)^2] \end{cases} \tag{19}$$

whence by (10) we have

$$[\rho(z)]^2 = a_e^2 [(1 + z/R)^2 - (N - 1)(vz/\omega a_e^2)^2], \qquad N \equiv \tfrac{1}{4}\gamma a_e^2 A_e^2. \tag{20}$$

For a parallel beam ($R = \infty$) ρ is constant if $N = 1$; for this reason we shall call N as defined in the preceding the number of critical powers in the beam. To be precise, because we used a Gaussian profile rather than a minimum critical power profile [3], N is 1.074 times the true number of critical powers as defined by Chiao *et al.* [7].

For a beam of many critical powers, self-focusing will occur in a distance z_f given by [1]

$$z_f = \frac{2\omega}{v\gamma A_e^2} \log(3/\delta) = \frac{\omega a_e^2}{2vN} \log(3/\delta) \tag{21}$$

where δ measures the initial perturbation. At $z = z_f$ (20) gives

$$[\rho(z_f)]^2 = a_e^2 \left\{ (1 + z_f/R)^2 - \frac{N - 1}{4N^2} [\log(3/\delta)]^2 \right\}. \tag{22}$$

Clearly, for any z in $0 \leqslant z \leqslant z_f$, $\rho^2 = a_e^2 (1 + z/R)^2$ is a very good approximation provided N is large. As we are interested only in $z \leqslant z_f$, propagation of a beam through a nonlinear medium can be treated by the simplest ray optics; the only effect of the nonlinear refractive index is a phase shift at the exit.

To show how we use the preceding ideas let us consider the divergent beam of Gaussian profile given by (18). Now, however, we pass it through an amplifying nonlinear medium of linear gain g Np/cm. The amplifier ends are at $z = 0$ and $z = l$. According to our preceding results, deduced from (22), the amplitude inside the amplifier can be expressed as

$$A(z) = (A_e/\zeta) \exp\left\{ -\frac{r^2}{2a_e^2\zeta^2} + \frac{1}{2} gz \right\}, \qquad \zeta \equiv 1 + z/R \tag{23}$$

provided only N is large. At the amplifier output the phase will consist of two parts, the term

$$\phi_L = -\omega r^2/(2vR\zeta_0), \qquad \zeta_0 \equiv 1 + l/R \tag{24}$$

which arises from the beam divergence, plus a nonlinear phase shift

$$\phi_{NL} = -\int_0^l \frac{v\gamma}{2\omega} [A(z)]^2 \, dz = -\frac{v\gamma}{2\omega} l_{\text{eff}} A_0^2 \exp(-r^2/a_0^2),$$

$$A_0 \equiv A_e/(1 + l/R) \quad a_0^2 \equiv a_e^2 (1 + l/R)^2 \tag{25}$$

where l_{eff} is an effective length. The integral is taken along the geometric optic rays on which $r/(a_e\zeta)$ is constant. Thus

$$l_{\text{eff}} = \exp(-gl) \int_0^l (\zeta_0/\zeta)^2 \exp(gz) \, dz. \tag{26}$$

At the exit we first collimate the beam as well as possible, i.e., reduce B_{exit} to zero, by means of a lens of focal length R_c. After this collimation we have

$$A = A_0 \exp(-r^2/2a_0^2) \quad \phi = \phi_L + \phi_{NL} + \omega r^2/2cR_c). \tag{27}$$

Setting these into (9) we first obtain

$$\rho_0^2 = a_0^2$$

$$B_0 = -\frac{ca_0^2}{\omega} \left\{ \frac{\omega}{c} \left(\frac{1}{R_c} - \frac{n_0}{R\zeta_0} \right) + \frac{vl_{\text{eff}}}{\omega a_0^4} N \right\} = 0$$

or

$$\frac{1}{R_c} = \frac{n_0}{R\zeta_0} - \left(\frac{v}{\omega a_0^2} \right)^2 n_0 l_{\text{eff}} N. \tag{28}$$

With this value of $1/R_c$ we calculate

$$C_0 = \frac{c^2}{\omega a_0^2}\left\{1 + \frac{7}{9}\left(\frac{vl_{\text{eff}}}{\omega a_0^2}N\right)^2\right\}. \tag{29}$$

In the last two equations N is the number of critical powers *in the exit* beam.

We now pass the beam through an ideal lens of focal length F. Under this transformation the quantity

$$\rho_0^2 C_0 - B_0^2 = \frac{c^2}{\omega^2}\left[1 + \frac{7}{9}\left(\frac{vl_{\text{eff}}}{\omega a_0^2}N\right)^2\right] \tag{30}$$

remains invariant, but C transforms to

$$C_F = \frac{a_0}{F}^2\left\{1 + \left(\frac{cF}{\omega a_0^2}\right)^2\left[1 + \frac{7}{9}\left(\frac{vl_{\text{eff}}}{\omega a_0^2}N\right)^2\right]\right\}. \tag{31}$$

Setting these values into (12) and (13), we obtain for the focal distance z_M and focal spot size ρ_M^2

$$z_m = F\Big/\left\{1 + \left(\frac{cF}{\omega a_0^2}\right)^2\left[1 + \frac{7}{9}\left(\frac{vl_{\text{eff}}}{\omega a_0^2}N\right)^2\right]\right\}$$

$$\rho_m^2 = \left(\frac{cF}{\omega a_0^2}\right)^2\left\{\frac{1 + \frac{7}{9}\left(\frac{vl_{\text{eff}}}{\omega a_0^2}N\right)^2}{1 + \left(\frac{cF}{\omega a_0^2}\right)^2\left[1 + \frac{7}{9}\left(\frac{vl_{\text{eff}}}{\omega a_0^2}N\right)^2\right]}\right\}. \tag{32}$$

Normally, the second term in the denominators of (32) will be much smaller than 1. If instead this term were unity, we would have $(\rho_m)^2 = a_0^2/2$. Thus, unless F is inordinately large, the beam quality becomes catastrophically bad long before the denominators differ appreciably from unity. Clearly, $(cF/\omega a_0)^2$, or more precisely, $(cF/\omega a_0)^2/[1 + (cF/\omega a_0^2)^2]$, is the mean-square radius of an ideal ($N = 0$) diffraction-limited spot. Thus we can define a degradation factor D by

$$\frac{1}{D} = \frac{(\rho_m)^2}{(\rho_{\text{ideal}})^2} = \frac{1 + \frac{7}{9}\left(\frac{vl_{\text{eff}}}{\omega a_0^2}N\right)^2}{1 + \left(\frac{cF}{\omega a_0^2}\right)^2\left[1 + \frac{7}{9}\left(\frac{vl_{\text{eff}}}{\omega a_0^2}N\right)^2\right]}$$

$$\doteq 1 + \frac{7}{9}\left(\frac{vl_{\text{eff}}}{\omega a_0^2}N\right)^2. \tag{33}$$

Everything has now been calculated except for l_{eff}. This quantity can be expressed exactly in terms of exponential integral functions, but it is more instructive to examine two limiting cases. First let us set $g = 0$. Then (26) gives

$$l_{\text{eff}} = l(1 + l/R), \quad \text{if } g = 0. \tag{34}$$

In the other limit consider an amplifier of sufficiently high gain and a beam of sufficiently weak divergence that $Rg \gg 1$. Then integrating (26) by parts gives

$$l_{\text{eff}} = \zeta_0^2 \exp(-g^l)\left\{\left[\frac{\exp(gz)}{g\zeta^2}\right]_0^l + \frac{2}{gR}\int_0^l \frac{1}{\zeta^3}\exp(gz)\,dz\right\}. \tag{35}$$

Continuing this process gives the asymptotic expansion

$$l_{\text{eff}} = \frac{1}{g}\left\{\left[1 + \frac{2}{g(R+l)} + \frac{2.3}{[g(R+l)]^2} + \cdots\right] - \zeta_0^2 \exp(-gl)\left[1 + \frac{2}{gR} + \frac{2.3}{(gR)^2} + \cdots\right]\right\}. \tag{36}$$

For a high-gain amplifier $\exp(-gl) \ll 1$ and

$$l_{\text{eff}} \doteq \frac{1}{g}\left\{1 + \frac{2}{g(R+l)}\right\}. \tag{37}$$

Clearly, the aberration is least when g is large and $R = \infty$.

For a parallel beam propagating through an amplifier of linear gain g it has been shown [1] that the critical intensity I_c, which just self-focuses at the exit, is given by

$$I_c = \frac{10^{-7} c\epsilon_0}{3\pi\epsilon_2}\left(\frac{gc/\omega}{4\Phi_M}\right)\log\left(\frac{3}{\delta}\right). \tag{38}$$

Rewriting this as the number of critical powers in the beam gives

$$N_c = \frac{\omega a_0^2 g n_0}{2c(4\Phi_M)}\log(3/\delta). \tag{39}$$

For an amplifier of power gain exceeding 6.43, $4\Phi_M = 0.7246$. Thus at the self-focusing limit the degradation factor owing to nonlinear lensing is

$$(1/D)_{\text{lim}} = 1 + 0.37\,[\log(3/\delta)]^2. \tag{40}$$

As $\log(3/\delta)$ could conceivably exceed 10 for an initially clean beam, ρ_m might be as large as five to ten times the ideal diffraction limit. For $\lambda = 1.06$ μm and $F/a_0 = 30$ the diffraction-limited rms radius is 5 μm. In this case the power loss starts to become serious for targets of 25–50-μm radius. For larger targets the nonlinear aberration will alter the intensity distribution over the target area, but will not lead to a serious loss of total power on target. It is easy to see from (33) that if ρ_m exceeds the target radius, power on target will be maximized by reducing the total output to the point where ρ_m matches the target size.

In the foregoing analysis we have tacitly assumed a steady beam, whereas normally the very high laser powers of which we have been thinking come as short pulses. But (1) describes pulses as well as continuous beams if we simply allow E to depend on the retarded time τ as a parameter. This in no way alters the moment theory; the only effect is that A, and hence N, in all our foregoing formulas now depend on τ. If we are interested only in peak power, we simply set this peak value of N into the appropriate formula, e.g., (32).

If instead we are interested in total energy on target, some sort of time averaging is required. As we wish to avoid a time-dependent collimating lens, the logical place to do this averaging is early in the problem. Hence we do our time averaging at the very beginning, that is we define time-averaged moments by simply extending the range of integration in (9) to cover all τ as well as the full beam cross section. This in no way modifies the basic equations (10) and (16). To illustrate let us return to our first example (18), but now we

allow A_e to depend on τ as

$$A_e = A_{e0} \exp(-\tau^2/2b^2). \tag{41}$$

The time-averaged quantities, which we write with a bar, become

$$\overline{W} = \tfrac{1}{2}\pi^{3/2} a_e^2 b A_{e0}^2 \quad \overline{\rho_0^2} = a_e^2$$
$$\overline{B}_0 = a_e^2/R$$
$$\overline{C} = (v/\omega a_e)^2 [1 - \gamma a_e^2 A_{e0}^2/(4\sqrt{2}) + (\omega a_e^2/vR)^2]. \tag{42}$$

Comparing with (19) we see that the sole result of this averaging is to replace N by $\overline{N}$, given by

$$\overline{N} = N_{\text{peak}}/\sqrt{2}. \tag{43}$$

With this simple substitution all our instantaneous results are transformed to time-averaged results.

IV. Conclusions

The most important result of Section II is intuitively obvious, namely that under the influence of incipient self-focusing alone, the central part of the far-field pattern is of high optical quality and the junk is all diffracted at large angle. Thus if incipient self-focusing were the only problem it could be solved by spatial filtering. An aperture in the focal plane of a lens could be several times the diffraction-limited spot size and yet filter the beam effectively. Moreover, from (7) it is very easily seen that such filtering would discard negligible total energy provided only it is done often enough.

The really serious problem is nonlinear lensing. In Section III we give a theory of this phenomenon which is mathematically sound, but it is based on the assumption that the rms spot radius is a good measure of optical quality. Fortunately, there is some experimental evidence on this point. Campillo *et al.* have recently measured the effect of nonlinear lensing in glass [8]. They report an experimental value of $2vlN/(\omega a_0^2)$ as 3.9. Thus from (33) $1/D = 13$ instantaneous peak and $1/\overline{D} = 7.0$ time averaged. Their optical system would have produced a diffraction-limited spot of 0.034-cm radius. Thus (32) predicts $\rho_m = 0.12$ cm, whereas they measured 0.10-cm peak value in their streak-camera record. We can make another comparison. Reference [8, fig. 1(a) and (b)] show, respectively, unaberrated and aberrated burn patterns. Measurement of these gives the aberrated to unaberrated radius ratio as approximately 2.1. Our theoretical prediction would be $(1/\overline{D})^{1/2} = 2.6$. Within experimental error our rms radius, both instantaneous peak and time averaged, seems to agree with what the eye aided by photography judges to be the focal-spot radius.

Appendix

The Far-Field Diffraction Pattern Produced by Incipient Self-Focusing

We wish to consider an aperture Σ, which for convenience we take to be a square $a \times a$, illuminated by the field (7). The far-field diffraction pattern is computed simply by following the prescription given by Goodman [5]. We expand the incident field (7) as a Fourier series and substitute the result as $E_0(\overline{x}, \overline{y})$ into the right-hand side of

$$E(x,y,z) = \frac{i\omega}{2\pi cz} \exp\left\{-\frac{i\omega}{2cz}(x^2+y^2)\right\} \cdot \int_\Sigma E_0(\overline{x},\overline{y}) \exp\left\{\frac{i\omega}{cz}(x\overline{x}+y\overline{y})\right\} d\overline{x}\,d\overline{y}. \tag{A1}$$

The expansion is perfectly straightforward and the series can be integrated term by term to give

$$E(x,y,z) = \frac{2i\omega E_0}{\pi cz} \exp\left[-\frac{i\omega}{2cz}(x^2+y^2)\right] \cdot [\Sigma_0 + \Sigma'] \tag{A2}$$

where Σ_0 is the zero-order term

$$\Sigma_0 = \frac{c^2z^2}{\omega^2 xy} J_{00}\left(\frac{\beta}{2}\right) \sin\left(\frac{\omega x a}{2cz}\right) \sin\left(\frac{\omega y a}{2cz}\right) \tag{A3}$$

and Σ' is the rest of the series, which we write as

$$\Sigma' = \frac{1}{a^2k^2} \sum_{m,n=-\infty}^{\infty}{}' a^2 J_{mn} \cdot \frac{\sin\frac{a}{2}\left[(m+n)k + \frac{\omega z}{cz}\right] \sin\frac{a}{2}\left[(m-n)k + \frac{\omega z}{cz}\right]}{[m+n+\omega x/kcz]\,[m-n+\omega y/kcz]}. \tag{A4}$$

The double sum $\Sigma\,\Sigma'$ extends over all m, n *except* $m = n = 0$. The coefficients J_{mn} are given by

$$J_{mn}\left(\frac{\beta}{2}\right) = J_m J_n + (i\beta/4) \cdot [J_m(J_{n-1} - J_{n+1}) + J_n(J_{m-1} - J_{m+1})] \tag{A5}$$

and every Bessel function has the argument $\beta/2$. Our equations (A3)–(A5) are an obvious generalization of Goodman's [5, eq. 4.23]. The double sum and product $J_m J_n$ arise because our phase modulation is two dimensional, and the terms in (A5) multiplied by $i\beta/4$ arise from the amplitude modulation.

As is well known, the grating orders all separate when the number of rulings, i.e., when $(ak)^2$, is large; thus the central (zero-order) spot pattern is given to good precision by (A2) with the term Σ' omitted. This is just the diffraction pattern of an $a \times a$ aperture illuminated by an initial field of intensity

$$I = |E_0|^2 |J_{00}|^2 = |E_0|^2 J_0^2 [J_0^2 + \beta^2 J_1^2] \tag{A6}$$

whereas our actual field had a mean intensity

$$\overline{I} = |E_0|^2 (1 + \beta^2/4) \tag{A7}$$

when averaged over the aperture. From this follows (7) of the main text.

Photon-Echo Behavior in the Presence of Extreme Inhomogeneous Broadening

NOBUO TAKEUCHI

Abstract—**Analysis of photon-echo behavior using single-mode excitation is given. It is shown that in the presence of extreme inhomogeneous broadening, the excitation with long pulses may display a complicated echo shape. Two typical cases are treated, one in which the pulses have equal length, and the other in which the pulses have equal electric-field strength. These show a large difference in echo behavior, especially for large excitation pulse areas.**

I. INTRODUCTION

COHERENT PHENOMENA in an inhomogeneously broadened system have recently attracted attention in optical transitions. In particular, the theory of superradiance has been closely investigated [1], [2]. The photon echo [3], [4] is a typical example of coherent phenomena and is developing as a powerful method of measuring the relaxation [5] and the interaction with the neighboring atoms in a system [6]. The inhomogeneous broadening must be much larger than the homogeneous broadening in order to avoid free induction decay; this is satisfied under usual conditions. Most photon-echo experiments have been done in systems where the inhomogeneous line broadening is much wider than the reciprocal of excitation pulsewidth [3]–[8] (we shall call this situation "long-pulse excitation"). However, these experiments have been analyzed on the assumption that the inhomogeneous width is much narrower than the reciprocal of pulsewidth; i.e., "short-pulse excitation." This assumption was enough to explain the echo behavior because the existence of many modes in the excitation pulses averaged out the fine structure in the echo shape generated by each mode.

With the advance of laser technology, a stable and single-frequency excitation source has been possible. Liao and Hartmann [7] demonstrated some of the peculiar features of photon echoes in ruby using single-frequency ruby-laser excitation. In electron spin echoes, Mims [9] has already demonstrated the existence of this peculiar behavior for the limited case of two equal excitation pulses. Yajima [10] calculated another limiting case (field strengths $E_1 = E_2$, pulsewidth $\tau_{p1} = \tau_{p2}/2$) in the photon echo in a semiconductor. In this paper we treat the more general case of two arbitrary square-wave excitation pulses. In the case of long-pulse excitation, off-resonant atoms also contribute to the echo formation. The rotation axis and angle for their pseudodipole moments (i.e., the Bloch vectors) [11] are different for a different combination of the excitation-field strength E and the pulsewidth τ_p even for a given pulse area θ, which leads to a different echo behavior. We treat two typical cases: 1) the excitation pulsewidth the same for both pulses (we shall call this "equal τ_p excitation"); and 2) the electric-field strength the same for both pulses ("equal E excitation").

II. FORMULA

We concentrate interest on an ordinary two-pulse echo and consider the simplest system consisting of atoms with two levels in the presence of extreme inhomogeneous broadening. The two relaxation times are taken equal ($T_1 = T_2 = T$). The

system is optically thin and is irradiated by a circularly polarized plane wave with a frequency ω_0 coinciding with the center of the atomic distribution.

We express the state of a two-level atom by a pseudodipole moment [3] (i.e., the Bloch vector [11]) and follow Jaynes' semiclassical treatment of nuclear induction [12] and its application to spin echo by Bloom [13], taking into consideration the spatial distribution of atoms [3], [14]. When the time of travel of light through a sample is much shorter than the echo width, which is a usual situation, we can ignore the spatial distribution of atoms in a shape factor for the jth atom $S_j(\tau - \tau_j)$ [see (2)], which reduces $S_j(\tau - \tau_j)$ to $S(\tau - \tau_s)$ (where τ is the time after the second pulse and τ_s is the pulse separation). In the case of a large Fresnel number of the irradiated volume, the summation of a phase factor exp $[i(\boldsymbol{k} - 2\boldsymbol{k}_2 + \boldsymbol{k}_1)(\boldsymbol{R}_j - \boldsymbol{R}_{j'})]$ over all excited atoms yields an effective aperture of $\lambda^2/\epsilon A$ [3]. Then the echo intensity is given by

$$I(\boldsymbol{k}) = (N^2/4)(\lambda^2/\epsilon A) I_0(\boldsymbol{k}) \exp(-2t/T) S(\tau - \tau_s)^2 \quad (1)$$

with

$$S(\tau - \tau_s) = \theta_1 \theta_2^2/2 \int_{-\infty}^{\infty} d(\Delta\omega) g(\Delta\omega) [\cos(\Delta\omega(\tau - \tau_s)) \times \sin\phi_1/\phi_1 + \Delta\omega\tau_{p1} \sin(\Delta\omega(\tau - \tau_s)) \times (1 - \cos\phi_1)/\phi_1^2] (1 - \cos\phi_2)/\phi_2^2. \quad (2)$$

Here N is the total number of echo atoms, $I_0(\boldsymbol{k})$ is the spontaneous-emission intensity rate per unit time per mode from an individual atom, t is the time from the beginning of the first pulse, $\Delta\omega$ is the off-resonance frequency, $g(\Delta\omega)$ is the normalized atomic distribution function, ϕ_i is the rotation angle of the Bloch vector by the ith excitation pulse $(= \{(\gamma E_i)^2 + (\Delta\omega)^2\}^{1/2} \tau_{pi})$, and τ_{pi} is the width of the ith excitation pulse. The pulse separation τ_s is long enough compared with τ_{p1} to get rid of the overlapping with the induced free-induction decay [7].

As will be mentioned later, the echo shows a complicated shape for some situations. Hence the integrated echo energy $I_\tau(\boldsymbol{k})$ is more convenient to compare different experimental conditions, and is obtained integrating over τ

$$I_\tau(\boldsymbol{k}) = (N^2/4)(\lambda^2/\epsilon A) I_0(\boldsymbol{k}) \sqrt{2} \times \pi^{1/2} T_2^* F(E_1, \tau_{p1}; E_2, \tau_{p2}) \quad (3)$$

with

$$F(E_1, \tau_{p1}; E_2, \tau_{p2}) = \pi^{1/2} \theta_1^2 \theta_2^4/2\sqrt{2}\, T_2^* \times \int_{-\infty}^{\infty} d(\Delta\omega) [g(\Delta\omega)(1 - \cos\phi_2)/\phi_2^2]^2 \times [\sin^2\phi_1/\phi_1^2 + (\Delta\omega\tau_{p1})^2 (1 - \cos\phi_1)^2/\phi_1^4]. \quad (4)$$

III. Short-Pulse Excitation

In the case of short-pulse excitation, (2) is easily integrated and gives a Gaussian echo shape with the full width at half maximum (FWHM) of $2T_2^*(2 \ln 2)^{1/2}$. The echo peak position is determined only by the first pulse and for a small value of θ_1, it takes place at $\tau_s + \tau_{p1}/2$, [3], [13] after the termination of the second pulse, and for $\theta_1 = \pi/2$, it does so at $\tau_s + 2\tau_{p1}/\pi$.

IV. Short to Long-Pulse Excitation

It is necessary to investigate the transitional behavior from short-pulse to long-pulse excitation and to determine the range of the excitation parameter $\eta(= \tau_p/T_2^*)$ appropriate to each type of excitation. We select the case of equal pulsewidths, and the 90°-180° pulse sequence as typical values of θ_1 and θ_2.

The calculated echo shape $S(\tau - \tau_s)^2$ is plotted in Fig. 1 as a function of $(\tau - \tau_s)/T_2^*$ for a range of τ_p/T_2^* from 0.01 to 20. It is seen that as τ_p/T_2^* increases beyond unity, the echo intensity decreases, the width gradually increases, and the echo peak position shifts to the positive side. However, if we consider the peak position as a function of $(\tau - \tau_s)/\tau_p$ instead of $(\tau - \tau_s)/T_2^*$, as shown in Fig. 2(a), the echo peak stays very nearly at the position $(\tau - \tau_s)/\tau_p = 2/\pi$ for $\tau_p/T_2^* < 1$ and changes position for the region of $\tau_p/T_2^* > 1$. The situation of a stable feature for $\tau_p/T_2^* < 1$ and of a varying feature for $\tau_p/T_2^* > 1$ is seen also in the echo width, the integrated echo energy, and the ratio of the emitted energy to the absorbed energy [Fig. 2(b)]. The echo width stays constant at $2\Delta\tau(\text{FWHM}) = 2(2 \ln 2)^{1/2} T_2^* = 2.36\, T_2^*$ for $\tau_p/T_2^* \leqslant 0.7$ and gradually increases with τ_p/T_2^*, approaching $2\Delta\tau = \tau_p$ for $\tau_p/T_2^* \geqslant 5$. The normalized echo energy $F(\theta_1 = \pi/2, \theta_2 = \pi)$ takes the value of almost unity for $\tau_p/T_2^* \leqslant 0.7$ and gradually approaches $F(\theta_1 = \pi/2, \theta_2 = \pi) = 2.85\, T_2^*/\tau_p$ as τ_p/T_2^* in-

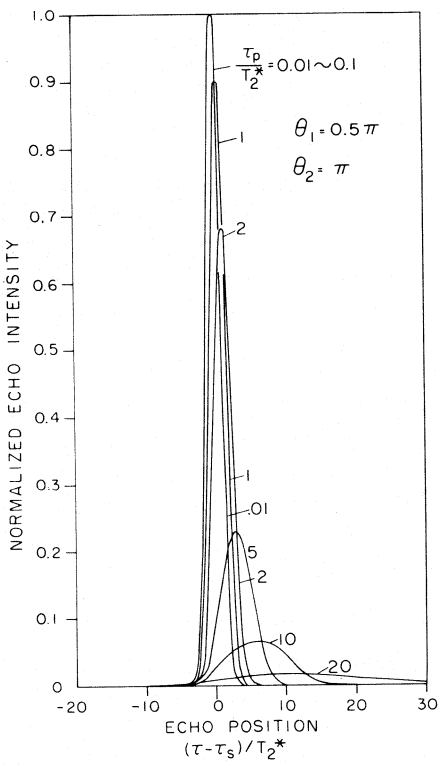

Fig. 1. The echo shape for excitation areas $\theta_1 = \pi/2$ and $\theta_2 = \pi$ with various values for the excitation parameter τ_p/T_2^*. The normalized echo intensity $(S(\tau - \tau_s))^2$ [see (2)] is shown on the vertical axis. The echo position on the horizontal axis is shown in the form $(\tau - \tau_s)/T_2^*$.

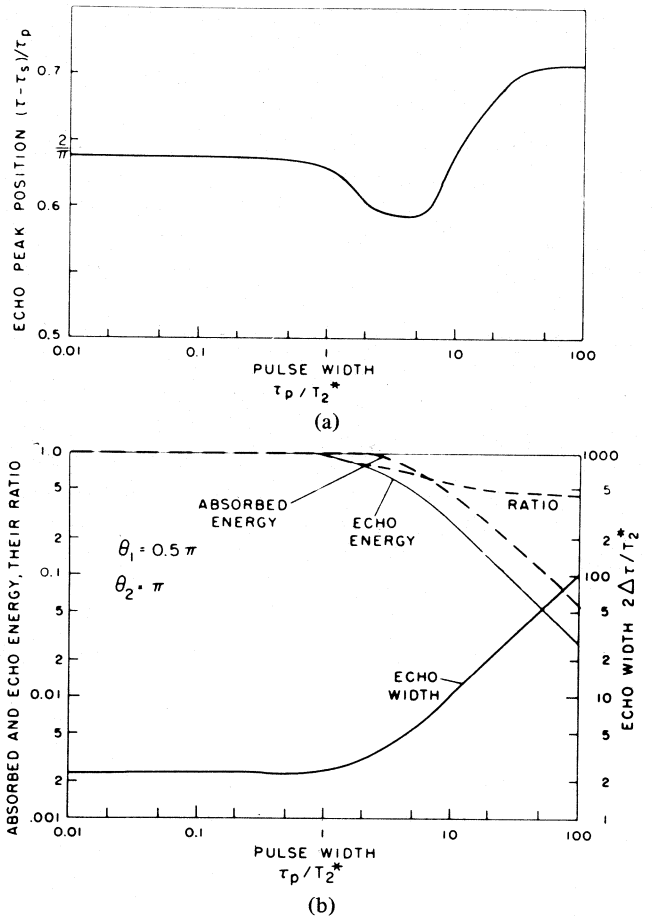

Fig. 2. Behavior of (a) the peak position in units of $\tau_p(=\tau_{p1}=\tau_{p2})$, and (b) the echo width (FWHM) in units of T_2^*. (b) Also shows the echo energy, the absorbed energy by a system, and their ratio, all of which are normalized to unity in the limit of short-pulse excitation. The calculation is done for $\theta_1 = \pi/2$ and $\theta_2 = \pi$ as a function of τ_p/T_2^*.

creases, which means that off-resonant atoms within the range of several times the resonant region $(1/\pi\tau_p)$ contribute to the echo formation. The ratio of the emitted energy in the photon echo to the absorbed energy in the system is also shown in Fig. 2(b), where the ratio at short-pulse excitation is normalized to be unity.

From the inspection of the case of 90°-180° sequence, it is found that the echo behavior is different on both sides of $\tau_p/T_2^* = 1$. In the range $0.2 \leqslant \tau_p/T_2^* \leqslant 5$, the transitional behavior can be seen, while outside this region the echo behavior is typical of short-pulse or long-pulse excitation. Similar features can be seen for different combinations of θ_1 and θ_2.

V. Long-Pulse Excitation with Equal Pulsewidth

We first treat the long-pulse excitation with an equal pulsewidth $(\tau_{p1} = \tau_{p2} = \tau_p)$. We choose the value of 100 as an excitation parameter $(\eta = \tau_p/T_2^*)$ because it corresponds to a parameter determined by a typical excitation pulsewidth of 30 ns [3] and the inhomogeneous broadening of 1.8 GHz (FWHM) in ruby.

The echo intensity was calculated as a function of $t_p = (\tau - \tau_s)/\tau_p$. Nonnegligible echo intensity ($>10^{-3}$ times the maximum) takes place in the range of $|(\tau - \tau_s)/\tau_p| \leqslant 2$. Since the second pulse has a function as a time-reversal pulse and a 180° pulse is typical in the short-pulse excitation, we first study the echo shape for a fixed $\theta_2(=\gamma E_2 \tau_p) = \pi$ while changing $\theta_1(=\gamma E_1 \tau_p)$ from 0.1π to 2π in 0.1π steps. The echo shapes are drawn in Fig. 3(a)-(d). We should notice that the maximum echo intensity expressed by $(S(\tau - \tau_s))^2$, which appears at $\theta_1 \approx 0.6\pi$, not at $\theta_1 = 0.5\pi$, is about 8×10^{-4}, and that this value is much smaller than unity (for the short-pulse excitation) but one order of magnitude larger than the square of the reciprocal excitation parameter $(T_2^*/\tau_p)^2$ of 10^{-4}, which roughly describes the square of the fraction of resonant atoms. The oscillatory shape for $\theta_1 > 1.5\pi$ partially depends on the

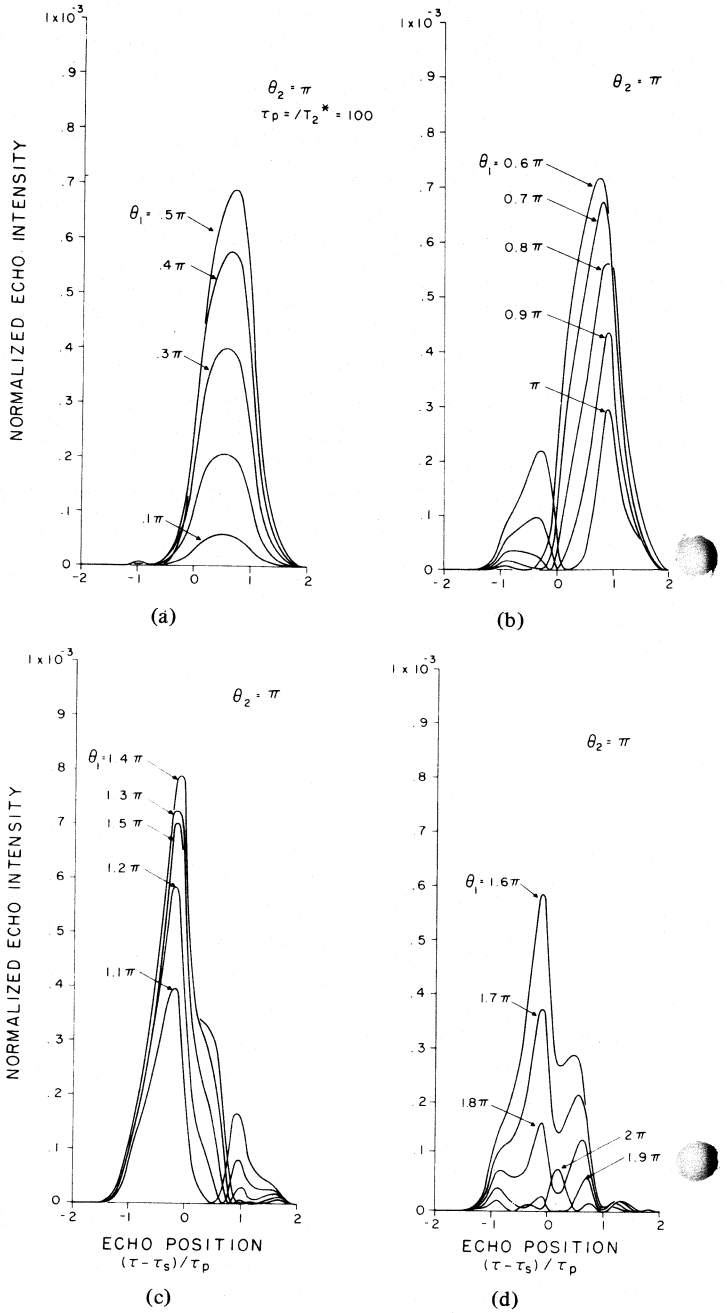

Fig. 3. The echo intensity $(S(\tau - \tau_s))^2$ in equal pulsewidth excitation as a function of the echo position $(\tau - \tau_s)/\tau_p$ for $\theta_2 = \pi$. (a) $\theta_1 = 0.1\pi$ to 0.5π. (b) 0.6π to π. (c) 1.1π to 1.5π. (d) 1.6π to 2π.

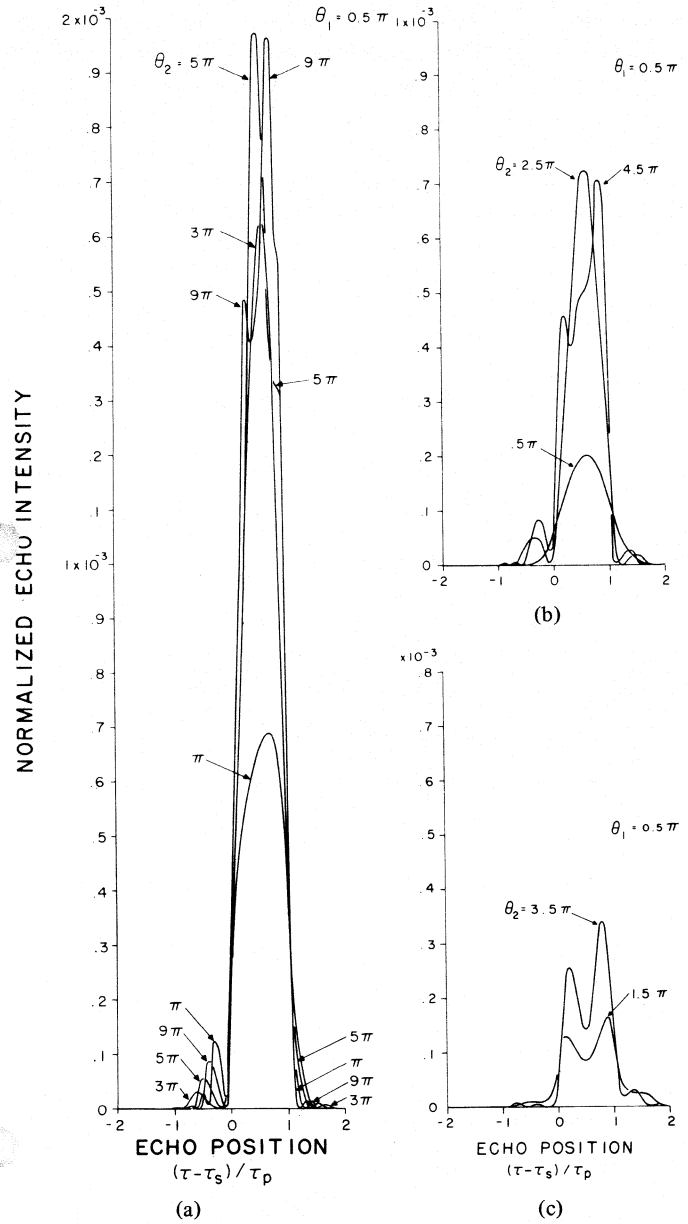

Fig. 4. The echo intensity $(S(\tau - \tau_s))^2$ in equal pulsewidth excitation for $\theta_1 = \pi/2$ and a large θ_2. (a) $\theta_2 = (2p + 1)\pi$. (b) $\theta_2 = (2p + \frac{1}{2})\pi$. (c) $\theta_2 = (2p + \frac{3}{2})\pi$ (p is an integer). It should be noticed that a shallow "notch" is seen in (c).

fact that the condition $\theta_2 > \theta_1$,[1] which gives an efficient time-reversal effect, is not satisfied. Further calculations for $\theta_2 = \pi$ with larger values of θ_1 show only slight enhancement of the peak intensity since θ_2 is smaller than θ_1. The (main) peak is on the positive side of $\tau - \tau_s$ for $\theta_1 = (2p + \frac{1}{2})\pi$ and on the negative side for $\theta_1 = (2p + \frac{3}{2})\pi$. For $\theta_1 = (2p + 1)\pi$, we can see the notched echo where the minimum is centered on the echo signal.

The echo shapes for $\theta_1 = \pi/2$ are shown in Fig. 4(a)-(c). For $\theta_1 = \pi/2$ the echo peak is always located on the positive side of $\tau - \tau_s$. Since θ_2 is larger than $\theta_1 = \pi/2$, the echo intensity is enhanced with an increase in θ_2.

In equal τ_p excitation, the periodicity in θ_1 and θ_2, which is seen in short-pulse excitation, still remains. The extremum of echo intensity takes place around a multiple of $\pi/2$ in θ_1 and $\theta_2/2$. The echo with θ_1 and $\theta_2/2$ off from the multiple of $\pi/2$ shows an intermediate behavior of neighboring multiples of $\pi/2$.

VI. Long-Pulse Excitation with Equal Field Strength

In long-pulse excitation with equal field strength E, we also choose a value 100 as the excitation parameter $\eta = 1/\gamma E T_2^*$ referring to Liao and Hartmann's paper [7], ($\theta = \pi/2$ for τ_p = 80 ns). The change of the echo shape for $\theta_1 (0.1\pi \sim 2\pi)$ with a fixed $\theta_2 = \pi$ is shown in Fig. 5(a)-(d). General features seen in equal τ_p excitation can also be seen here. We should notice that the echo width is determined by the excitation pulsewidth.

A "notched echo" with $\theta_1 = 3\pi$ and $\theta_2 = 0.5\pi$ in [7] is reproduced in Fig. 6, also with $\theta_1 = 2\pi$ and $\theta_2 = 0.5\pi$.

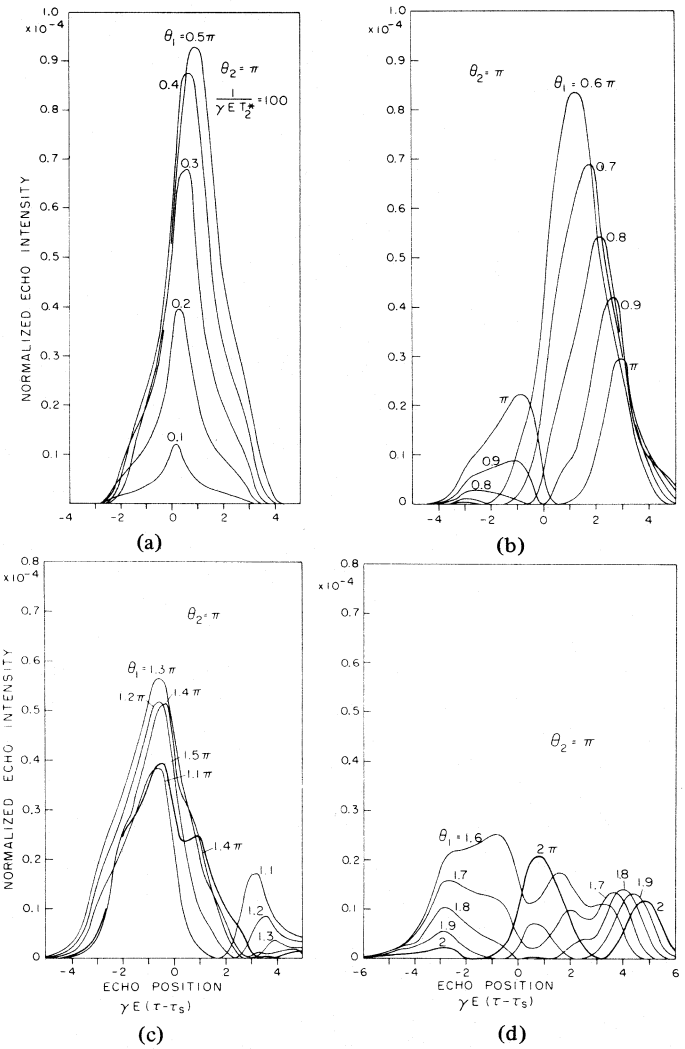

Fig. 5. The echo intensity $(S(\tau - \tau_s))^2$ in equal electric-field excitation as a function of the echo position $\gamma E(\tau - \tau_s)$ for $\theta_2 = \pi$. (a) $\theta_1 = 0.1\pi$ to 0.5π. (b) 0.6π to π. (c) 1.1π to 1.5π. (d) 1.6π to 2π.

[1] For equal τ_p excitation, a larger area θ, i.e., a larger field strength E, orients the rotation axis of each Bloch vector nearer to the applied electric-field direction. This leads to more efficient time reversal by the second pulse for $\theta_2 > \theta_1$ under long-pulse excitation.

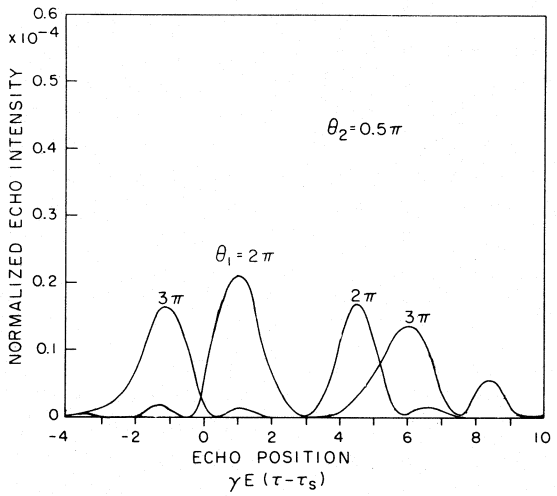

Fig. 6. The echo intensity $(S(\tau - \tau_s))^2$ in equal electric-field excitation for $\theta_2 = 0.5\pi$ and $\theta_1 = 2\pi$ and 3π with respect to the echo position $\gamma E(\tau - \tau_s)$.

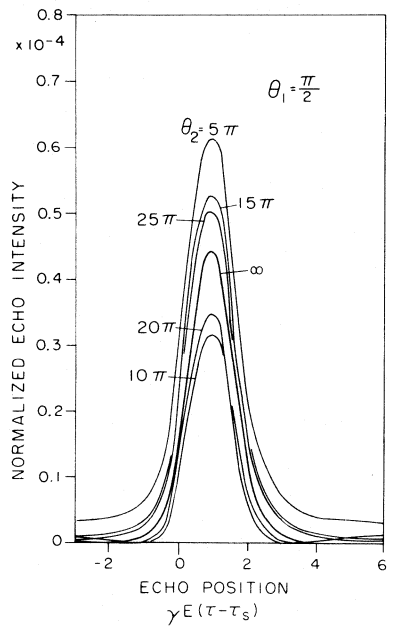

Fig. 7. The echo intensity $(S(\tau - \tau_s))^2$ in equal electric-field excitation for $\theta_1 = \pi/2$ and a large θ_2. The echo intensity gradually converges to an asymptotic shape.

For a large value of θ_2, the averaging effect of the second pulse can be seen. With an increase of θ_2 the Bloch vectors excited by the first pulse are averaged and the contribution from off-resonant atoms is washed away. The echo shape tends to take an asymptotic shape determined by θ_1 without the enhancement of echo intensity. In Fig. 7, an example for $\theta_1 = \pi/2$ is shown. This explains the stable echo at $\theta_1 = \pi/2$ and $\theta_2 = 25\pi$ mentioned in [7]. The averaging effect is different from the narrow spectrum excitation by the long second pulse, which should show a longer echo pulsewidth.

VII. Discussion

We now discuss the relation of the resonance frequency region with the excitation condition. When the echo is excited by two pulses with $\theta_1, \theta_2 \leqslant \pi$, and with $\tau_{p1} \approx \tau_{p2}$, the atom with $\Delta\omega \leqslant 2\pi/\tau_{p1}$ mainly contributes to the echo formation. In equal τ_p excitation, the resonant frequency region is fixed to $1/\pi\tau_p$ because of a fixed (arbitrary) value of excitation parameter $\eta = \tau_p/T_2^*$. With an increase of θ_2 (i.e., an increase of E_2) from $\theta_2 \simeq \pi$ to a large value, the frequency region of atoms contributing to echo formation is widened several times. Consequently, the echo intensity for θ_2 with $(2p + 1)\pi$ (p is an integer) is also enhanced several times. When θ_1 increases in addition to θ_2, the frequency region approaches the whole inhomogeneous broadening as in short-pulse excitation. On the contrary, in equal E excitation, the constant electric field determined by a given parameter $\eta = 1/\gamma E T_2^*$ does not expand the frequency region contributing to echo formation. With an increase of θ_2 (i.e., an increase of τ_{p2}), the averaging of the rapidly oscillating Bloch vector for an off-resonant atom leads to a stable width of echo, instead of widening the echo width (i.e., narrowing the resonance frequency region), and does not bring an enhancement of echo intensity.

In this paper the complex echo behavior in long-pulse excitation was analyzed, based on the simplest model of a two-level atomic system excited by two square-wave pulses. For a case of Gaussian pulse excitation with an amplitude $E_i \exp[-(t - t_i)^2/\tau_{gi}^2]/\pi^{1/2}$, which is nearer to an actual situation by pulse laser excitation, the treatment in this paper gives a good approximation by substituting the pulse area $\theta_i = \gamma E_i \tau_{pi}$ by $\theta_i = \gamma E_i \tau_{gi}$.

Scaling Generalizations for a CO Electric Laser

WILLIAM B. LACINA AND GARY L. McALLISTER

Abstract—**Several scaling generalizations for a high-pressure CO electric-discharge laser (EDL) are presented and compared with experimental data from a pulsed e^--beam-stabilized device. It is shown that the transient evolution of the CO laser medium is mainly dependent only upon the total energy deposition per CO molecule as a function of time. Results of theoretical calculations for CO/Ar mixtures are presented which show that, for temperatures 100-300 K, laser threshold occurs after $E/p_{CO} \sim 0.5 - 1.0$ J/l/torr (CO) has been deposited, and that steady state is attained after $E/p_{CO} \sim 1.7 - 2.6$ J/l/torr (CO) has been deposited. Experimental results for a variety of CO/Ar and CO/N_2 mixtures confirm these predictions for a range of excitation rates. These generalizations make it possible to predict the temporal power characteristics of a large class of both pulsed and flowing CW CO lasers without resort to extensive computer calculations. Characterization of the gain saturation as a function of total radiation intensity was also investigated. Results indicate that, after attainment of steady state, the CO EDL saturates with threshold level like a simple two-level system, with a scaled saturation intensity of $I_{sat}\xi/p_{CO}^2 \sim 0.6 = 6.4$ W/cm^2/torr^2 (CO) over the range of temperatures from 60 to 300 K (ξ is the fraction of CO self-broadening to total broadening).**

I. Introduction

A MOLECULAR-KINETIC model for an electrically excited (CO, N_2, Ar, He, $\cdots$) gas mixture has been constructed for the calculation of the radiative characteristics of a CO laser oscillator or amplifier. A computer program for the numerical solution of the steady state or transient master equation for the diatomic species has been developed to predict vibrational population distributions, gain and saturation parameters, energy transfer and extraction rates, conversion efficiencies, output intensities, and spectral distributions. The radiative calculations are self-consistent with the saturated gain on all oscillating transitions equal to the losses. The plasma kinetics are described by a Boltzmann energy distribution, with electron density and temperature adjusted self-consistently in the calculation as a function of time to produce a specified temporal input power. A more complete discussion of the assumptions upon which this model is based has been given elsewhere [1], [2], where numerical results for a variety of operating conditions were presented and compared with experimental data from a pulsed high-pressure e^--beam-stabilized CO electric-discharge laser (EDL) oscillator. Similar analytical work on the CO EDL has been presented by numerous other authors [3]-[8].

It is possible to make several reasonable approximations that allow certain general scaling laws for a CO EDL to be formulated [9]. These generalizations, which depend only upon a few basic parameters, make it possible to predict the temporal output characteristics of a large class of both pulsed and flowing CW CO laser systems. Although the present theoretical results are limited to gas mixtures containing CO and monatomic diluents only, comparisons with experimental data for both CO/Ar and CO/N_2 are included. It is found experimentally that the excitation times required to attain threshold and steady state agree with the scaling results predicted for CO/Ar. Uncertainties in the CO-N_2 and N_2-N_2 VV rates make theoretical analysis for CO/N_2 mixtures less reliable. However, the experimental results indicate that CO/N_2 systems can be scaled similarly. Except for the spectral details,

it is possible to design general CO/X systems to a very good approximation without resort to extensive computer calculations.

II. Theoretical Model

The present theoretical model consists of four basic systems of equations that couple the CO vibrational-state population densities, the radiation intensities, the gas kinetic temperature, and the plasma-kinetic parameters (electron density and temperature) as a function of time. Since the general formulation of these equations and the assumptions made have been described previously [2], they will be summarized only briefly here. Certain approximations (most of which are not required for the complete computer analysis) make it possible to obtain a variety of general results in terms of a very small set of scale parameters [8], [9]. In fact, one basic parameter related to pumping is all that is required to present a reasonably simple description of the CO EDL under the set of approximations to be discussed later.

The molecular-kinetic processes are described by the master equation for the vibrational population densities n_v of the CO molecule

$$dn_v/dt = R_v^e + \sum_X R_v^{\mathrm{VT}}(\mathrm{CO}, X) + R_v^{\mathrm{VVT}}(\mathrm{CO}, \mathrm{CO}) + R_v^{\mathrm{VVT}}(\mathrm{CO}, \mathrm{N_2}) + R_v^{\mathrm{spon}} + R_v^{\mathrm{stim}} \quad (1)$$

with pumping and relaxation processes which include: 1) electron-impact excitation of the vibrational states; 2) vibration-to-translation (VT) deactivation processes; 3) near-resonant vibration-to-vibration (VVT) single-quantum-exchange collisions; 4) spontaneous radiative decay; and 5) stimulated-emission and absorption processes. Sources for rates have been summarized previously [2].

Radiation intensities are calculated by requiring that the gain coefficients for all oscillating transitions be equal to the loss coefficient at all times. The rotational levels are assumed to be in thermal equilibrium with the molecular-kinetic temperature, and rotational cross relaxation is assumed to be sufficiently fast that only one rotational line can oscillate in any given vibrational band. Losses such as mirror absorption, output coupling, window losses, or intracavity line-selection losses are all assumed to be uniformly distributed throughout the laser gain medium. These cavity losses are assumed to be small enough that the approximation of a spatially uniform intensity distribution over the length of the active medium is adequate for describing the molecular and radiative characteristics of the medium. The optical resonator is assumed to be formed by two plane-parallel mirrors (one totally reflecting, the other with reflectivity R) separated by a distance L. From the oscillator gain conditions, $R \exp[2(\alpha - \beta)L] = 1$, the gain coefficient α for an oscillating line (for $R \sim 1$) must be equal to the threshold loss $\gamma = \beta + (1 - R)/2L$, where β is the loss coefficient for the cavity exclusive of the output coupling.

The analysis assumes that the plasma kinetics can be treated with a Boltzmann electron energy distribution, with a self-consistent adjustment of the electron density and effective temperature as a function of time to produce a prescribed temporal input excitation power characterized by a rise and fall time. Physically, the choice of that form for the electrical-excitation power is appropriate for an e^--beam-sustained CO device with the rise time related to the approach to steady state of the electron density and the fall time to the decay of the sustainer voltage due to the discharge of a capacitor bank. Calculations have shown that, for a specified electrical input power, the molecular-kinetics predictions are quite insensitive to the detailed plasma parameters chosen to produce that power (e.g., trading off n_e and T_e, or modifying the assumed Boltzmann distribution).

It is, of course, important that reverse ("superelastic") electron-molecule collisions be included in the molecular kinetics. Then the analysis will reflect the physical phenomenon that, as the vibrational levels become excited, the effective electron temperature T_e rises to maintain the specified input power. A tacit assumption is made that for low values of E/N, all of the electrical power is transferred directly to vibrational excitation.

Effects of gas heating from VV and VT kinetic processes, as well as from rotational equilibration accompanying stimulated emission, are included in the analysis.

In order to derive a useful set of generalized results that can easily be scaled, it is first necessary to simplify the equations by introducing approximations that will reduce the number of scale parameters required to a reasonable minimum value. Although the additional approximations to be discussed here are neither required nor invoked in the complete computer analysis, they will be useful for summarizing the results of the computer calculations in a coherent way. The objective here is to show that a rather general class of pulsed CO oscillators can be described quite accurately in terms of only one basic scale parameter that defines the electrical pumping per CO molecule.

For a high-pressure oscillator operating at temperatures in the range 60–300 K, the spontaneous radiative and VT decay terms in the master equation can be neglected. (Spontaneous terms contribute typically $\lesssim 0.1$ percent to total power balance at CO pressures $\lesssim 10$ torr, and (CO, X) VT deactivation $\sim 10^{-2} - 10^{-6}$ percent for $X = \mathrm{CO}$, Ar, He, $\mathrm{N_2}$.) It is convenient to classify the results of calculations to be presented here by referring to initial values of the temperature T_{mol} and the pressures p_{CO}, p_X. A theoretical prediction that only a small percentage of electrical power is converted to kinetic heating (typically <10 percent), even after steady state has been attained, has been experimentally verified [10]. Thus, for reasonably dilute CO gas mixtures, it is a good approximation to neglect the temperature rise for pulse times that are comparable to the time required to reach steady state (although heating effects have been retained in the analysis). The calculations correspond to fixed-number densities, and because of the small temperature rises, the pressures will change from their initial values by only a small fraction during that time scale. All of the calculations to be presented here correspond to cases for which the electrical excitation was

kept constant as a function of time during the pulse, with temporal evolution of the electron temperature T_e to maintain the given power loading.

The coupled set of equations of [2] with the approximation discussed previously can be written in dimensionless form by introducing the following quantities:

$$\begin{aligned} x_v &= n_v/N_{CO} \\ x_e &= n_e/N_{CO} \\ \tau &= p_{CO}t \\ f &= 1 + (3/2)p_{tot}/p_{CO} \\ \xi &= \Delta\nu_{CO}/\Delta\nu_{tot} \\ &= \frac{p_{CO} < v_{rel}(CO, CO) > \sigma^{opt}(CO, CO)}{\sum_X p_X < v_{rel}(CO, X) > \sigma^{opt}(CO, X)} \\ \tilde{\gamma} &= \gamma/\xi \\ \tilde{W}_e &= W_e/p_{CO}^2 \\ \tilde{I} &= I\xi/p_{CO}^2 \\ \tilde{E} &= E/p_{CO} \end{aligned} \tag{2}$$

where x_v are the relative populations, x_e is a measure of the degree of ionization, f is related to the number of thermal degrees of freedom, and ξ is the fractional percentage of total optical line broadening caused by CO. $\tilde{\gamma}$, $\tilde{W}_e$, $\tilde{I}$, and $\tilde{E}$ are scaled threshold loss (cm^{-1}), power density (watts/cubic centimeter/torr squared (CO)), intensity (watts/square centimeter/torr squared (CO)), and energy density (joules/cubic centimeter/torr (CO)). The definition of the parameter ξ given here applies to a situation in which pressures are high enough ($\gtrsim 20$ torr) that optical lines are predominantly pressure broadened.

If these scale parameters are introduced, the master equation expresses the evolution of the relative populations x_v as a function of scale time $\tau = p_{CO}t$. This is to be expected, since the electrical excitation is kept constant, and the dominant kinetic processes are (two-body) VV collisions. Thus the physics of the molecular vibration states depends explicitly only upon the kinetic temperature and the scaled electrical excitation $\tilde{W}_e = W_e/p_{CO}^2$. Implicitly, however, it depends also upon the scaled threshold-loss coefficient $\tilde{\gamma}$ for the cavity due to the oscillation condition, and upon the parameter f due to the kinetic heating.

It is apparent that the set of parameters (T_{mol}, $\tilde{W}_e$, $\tilde{\gamma}$, f) completely characterizes the CO EDL under these approximations; all other inputs to the mathematical model consist only of fundamental physical constants. In the following section, a variety of numerical results based on the complete computer analysis for this model will be presented and discussed to show the relative sensitivity of these parameters.

III. Theoretical Results

Computer calculations were carried out for a fixed value $f = 16$ (corresponding to a dilute, 10-percent CO mixture). The kinetic temperatures T_{mol} included (60, 100, 150, 200, 300) K, the scaled electrical pumping rates (0.2, 0.5, 1.0, 2.0, 5.0, 10, 20, 50, 100, 200) $W/cm^3/torr^2$, and the scaled threshold-loss coefficients (0.1, 0.2, 0.5, 1.0, 3.0, 7.0, 10, 20) percent/cm. From the results of any given case specified completely by the set of four parameters (T_{mol}, $\tilde{W}_e$, $\tilde{\gamma}$, f), the general class of problems that can be scaled exactly from those results is quite restrictive; it allows only the variation of the CO partial pressure, provided that the electrical excitation W_e is scaled by p_{CO}^2, and that the threshold level and gas-mixture ratio are held constant. However, except for the scaled excitation power $\tilde{W}_e$, most of these parameters do not have a sensitive effect on the power response of the system as a function of time (although detailed spectral predictions may have a more critical dependence). Thus the class of problems that can be analyzed from a given case is often more extensive than that just described. The reasons for this are the following. 1) The most important parameter, the scaled excitation $\tilde{W}_e$, is a measure of the electrical pumping per molecule relative to the rate of VV cross relaxation, and thus specifies the ratio of the two dominant kinetic processes in the CO EDL. 2) A pulsed high-pressure CO EDL typically operates in a regime where oscillation is high above threshold, and thus results for optical power extraction will usually be insensitive to the scaled cavity-loss coefficient $\tilde{\gamma}$. Unless the ratio $\tilde{W}_e/\tilde{\gamma}$ becomes very small the medium intensity will be high above the saturation intensity, and the optical output will be independent of $\tilde{\gamma}$. 3) The temperature rise for pulse times comparable to the time required to reach steady state is small, so the results do not depend critically upon f, providing it is large. This parameter is mainly important for detailed predictions of spectral distribution. 4) Results of calculations for systems operating with parameters in the ranges previously noted do not show a significant sensitivity to dependence on T_{mol}.

Fig. 1 shows plots of the quantum power efficiency (for the total optical conversion of electrical input) for a variety of different values of $\tilde{W}_e$ as a function of $p_{CO}t$, for $T_{mol} = 100$ K. Results of calculations show that the most important parameter for small values of $\tilde{\gamma}$ is the scaled excitation power $\tilde{W}_e$, and that the optical output is relatively insensitive to $\tilde{\gamma}$ for small values of $\tilde{\gamma}$. It is apparent from Fig. 1 (and from similar results for other values of $\tilde{\gamma}$ and T_{mol}) that the optical output efficiency displays a remarkably similar behavior over a wide range of the parameter $\tilde{W}_e$. In fact, these results can be used

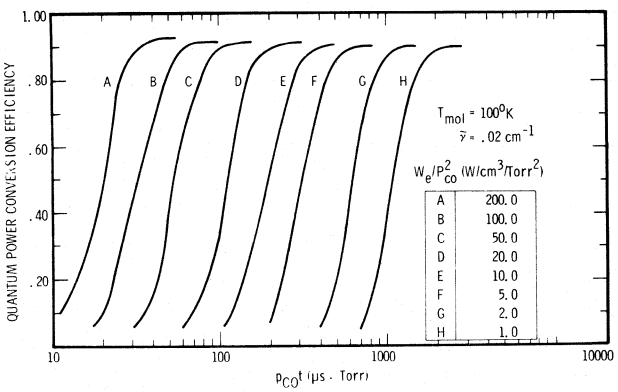

Fig. 1. Quantum power-conversion efficiency versus a function of scale time $p_{CO}t$, for several values of scaled excitation power W_e/p_{CO}^2, at 100 K.

to show that, for a given temperature T_{mol} and a fixed value of quantum efficiency η/η_∞ (where η_∞ is the steady-state value), a log-log plot of $p_{CO}t$ versus the scaled power $\tilde{W}_e$ is approximately linear. For example, Fig. 2 shows such a plot for the turn-on time $p_{CO}t_0$ (obtained by tangentially extrapolating the curves of Fig. 1 to the origin and neglecting a small initial bump that often occurs in the calculations) versus $\tilde{W}_e$. The slope of the linear curves of Fig. 2 is approximately $-\frac{5}{6}$ and was found to be independent of T_{mol} and $\tilde{\gamma}$; the variation in the magnitude of the curves is less than a factor of 2 within the range of temperatures chosen. The turn-on time corresponds to the point where $\eta = 0$; however, it is apparent that the curves of Fig. 1 remain similar as time evolves. Thus, for a fixed temperature T_{mol}, the time t required to attain any specified value η/η_∞ for the optical extraction efficiency satisifies

$$\tilde{e} = p_{CO}t\tilde{W}_e^{5/6} = \text{constant} \tag{3}$$

which implies that, within a range of values for $\tilde{\gamma}$, which are suitably small, a "universal" plot of efficiency versus the parameter $\tilde{e} = p_{CO}t\tilde{W}_e^{5/6}$ can be constructed. As an example, all of the plots for the conditions of Fig. 1 can be summarized as shown in Fig. 3. (The value of the steady-state efficiency η_∞ depends only slightly upon $\tilde{W}_e$, T_{mol}, and $\tilde{\gamma}$.) The significance of the parameter $\tilde{e}$ can be seen by noting that if the exponent of $\tilde{W}_e$ in (3) were unity instead of $\frac{5}{6}$, $\tilde{e}$ would represent the total electrical energy $\tilde{E} = W_e t/p_{CO}$ (J/l/torr(CO)) which has been deposited into CO vibrational energy up to time t. Therefore, the response of the system is approximately a function only of the specific input energy $\tilde{E}$ (which is, of course, a function of time and the excitation rate). The power efficiency can be integrated to give a universal curve for the energy efficiency ϵ/η_∞ as a function of the parameter $\tilde{e}$, and this result is also presented in Fig. 3.

Among the important conclusions to be drawn from the previous remarks are the following. Characteristic times required to attain any specified efficiency satisfy a condition given by (3); a special case of this relation, which has been discussed by Rockwood and Hunter [11], is that the time required to attain threshold (i.e., $\eta = 0^+$) requires a fixed energy deposition into CO. For the range of temperatures (100–300 K) and for the reasonably small values of $\tilde{\gamma}$ discussed here, turn-on occurs after a specific electrical energy $E_0 \sim 0.5 - 1.0$ J/l/torr (CO) has been deposited, and steady state is attained after an energy $E_{ss} \sim 1.7 - 2.6$ J/l/torr (CO) has been deposited. (These numbers correspond to a specific pumping rate $\tilde{W}_e = 1.0$ W/cm^3/torr (CO)^2; for other values of $\tilde{W}_e$, (3) shows that these deposition energies increase as $\tilde{W}_e^{1/6}$.) The typical range of values for $\tilde{W}_e$ in the data to be presented later is sufficiently small that the $\tilde{W}_e^{1/6}$ variation is not significant, and thus experimental results will be plotted in terms of the more physically significant quantity $\tilde{E} = W_e t/p_{CO}$. However, the theoretical results correspond to a range of values for $\tilde{W}_e$ that vary by a factor ~200, and $\tilde{W}_e^{1/6}$ can therefore vary by a factor ~2.5, showing that the exponent 5/6 can be significant for higher pumping.

It is interesting to characterize the CO medium by a saturation intensity. Although the full kinetic model contains

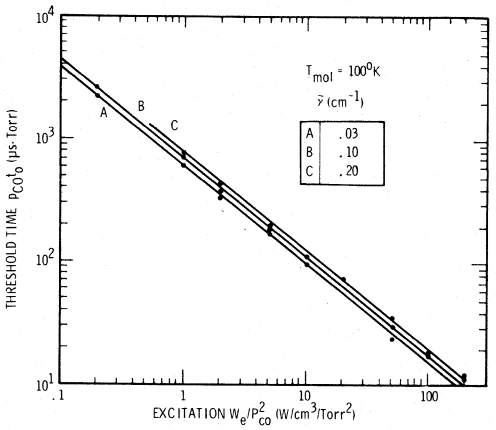

Fig. 2. Scaled threshold time $p_{CO}t_0$ as a function of scaled excitation W_e/p_{CO}^2 for several values of loss $\tilde{\gamma}$ at 100 K.

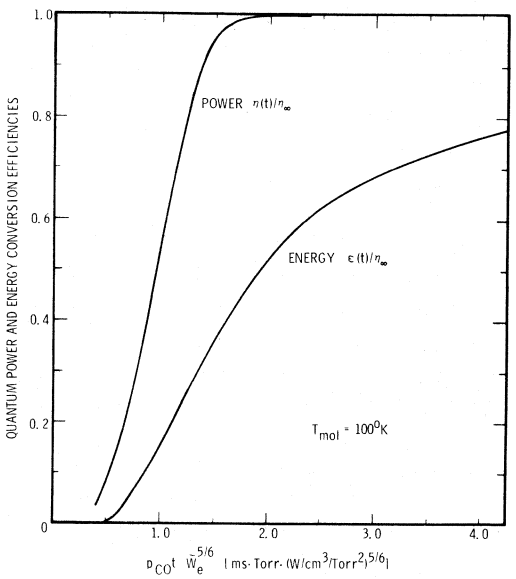

Fig. 3. Generalized power and energy-conversion efficiencies as a function of $p_{CO}t(W_e/p_{CO}^2)^{5/6}$ at 100 K. (Note that without the 5/6 exponent the units of the horizontal axis would correspond to energy deposition in joules/liter/torr (CO).)

simultaneous oscillation on several lines, we now neglect this feature and investigate how the gain saturates as a function of threshold level and total intensity in the medium. From the analysis of a simple two-level model, it can be shown that the saturated gain $\alpha(I)$ satisfies

$$\alpha(I) = \alpha_0(1 + I/I_s)^{-1} \tag{4}$$

where the saturation intensity I_s is independent of the electrical pumping. We shall show that, at steady state, the CO EDL follows a simple dependence of this form, and an estimate of the scaled saturation intensity as a function of T_{mol} will be derived. In terms of scaled quantities, (4) becomes, upon setting $\alpha(I) = \gamma$,

$$\tilde{\gamma} + \eta_\infty \tilde{W}_e/\tilde{I}_s = \tilde{\alpha}_0 \tag{5}$$

where the steady-state condition $\tilde{\gamma}\tilde{I} = \eta_\infty \tilde{W}_e$ has been used. Thus, for a fixed value $\tilde{W}_e$, the steady-state oscillator power efficiency η_∞ and the cavity threshold $\tilde{\gamma}$ are linearly related

if the laser gain medium saturates according to the relation of (4). That is, if $\eta_\infty(0)$ is the limiting value of the steady-state efficiency for $\tilde{\gamma} \to 0$ (lossless cavity), then

$$\tilde{\gamma} = -[\eta_\infty - \eta_\infty(0)]\, \tilde{W}_e/\tilde{I}_s. \tag{6}$$

Fig. 4 shows η_∞ plotted versus $\tilde{\gamma}$ for $T_{mol} = 100$ K for two different values of $\tilde{W}_e$, and as (6) shows, the slope $|d\tilde{\gamma}/d\eta_\infty|$ of these curves is proportional to $\tilde{W}_e$. Furthermore, the proportionality constant determines the scaled saturation intensity, which is determined from Fig. 4 to be $\tilde{I}_s \sim 0.8$ W/cm^2/torr^2. Similar plots for a fixed value of $\tilde{W}_e$ and variable temperature T_{mol} are shown in Fig. 5. All of these curves are linear to a very good approximation, and the saturation intensities obtained from their slopes are summarized in the following table. During the transient evolution, the relation between the quantum efficiency and the cavity threshold does not seem to follow a linear relationship:

T_{mol}(K)	60	100	150	200	300
I_s(W/cm^2/torr^2)	0.6	0.8	1.6	2.5	6.4

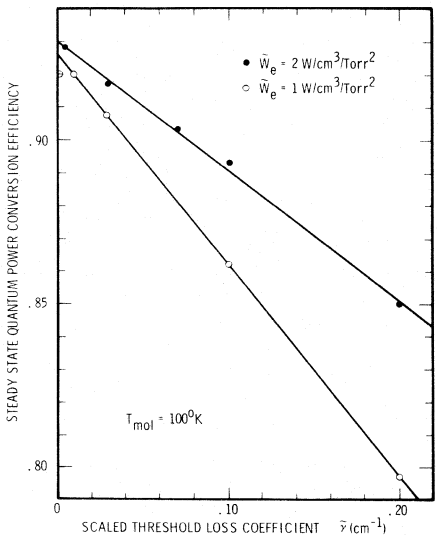

Fig. 4. Steady-state power efficiency as a function of scaled threshold loss coefficient $\tilde{\gamma}$ for an oscillator, for two values of scaled excitation $\tilde{W}_e = We/p_{CO}^2$. Note that the slopes of these curves are proportional to $\tilde{I}_s/\tilde{W}_e$, where $\tilde{I}_s$ is the scaled saturation intensity.

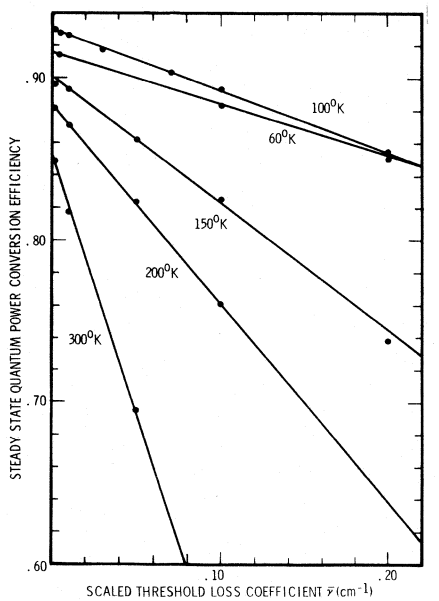

Fig. 5. Steady-state power efficiency as a function of scaled threshold loss coefficient $\tilde{\gamma}$ for several different temperatures, for $\tilde{W}_e$ = 2 W/cm^3/torr(CO)^2.

Small-signal gain characteristics can be obtained from (5) with $\tilde{\gamma} = 0$. For values of pumping and cavity threshold considered here, it is apparent that the small-signal gain is proportional to $\tilde{W}_e$

$$\tilde{\alpha}_0 = \eta_\infty(0)\, \tilde{W}_e/\tilde{I}_s. \tag{7}$$

For efficient operation of the oscillator (high above threshold), the necessary condition is $\tilde{\alpha}_0 >> \tilde{\gamma}$, and therefore (since $\eta_\infty \sim 1$)

$$\tilde{W}_e/\tilde{\gamma} >> \tilde{I}_s. \tag{8}$$

IV. Experimental Comparisons and Conclusions

The electrical-excitation times required to reach laser threshold and steady state have been measured for CO/Ar and CO/N_2 gas mixtures and are compared in the following to the scaling generalizations described in Section III. The laser used for these measurements was an e^--beam-stabilized electric-discharge CO laser with a 10 × 10 × 100-cm discharge region. The operating temperature was 80 K with gas pressures typically in the range from 50 to 200 torr. The nominal operating parameters were $E/N = 1.1 \times 10^{-16}$ V · cm^2, sustainer current density $I_s = 2$ A/cm^2, and e^--beam current density $I_b = 25$ mA/cm^2. Output energies exceeding 500 J/pulse have been obtained. The electrical-excitation pulse length was 75 μs and the optical pulse length varied between 20–100 μs depending on the electrical-excitation rate and the gas mixture used.

The laser output energy was measured with a ballistic thermopile calorimeter (Hadron Series 117) and the temporal pulse shape was monitored with a Ge:Au detector. Fig. 6 illustrates a typical pulse shape for CO/N_2 with a nearly constant electrical-excitation rate for 75 μs. In this example, laser threshold is reached 38 μs after the electrical excitation

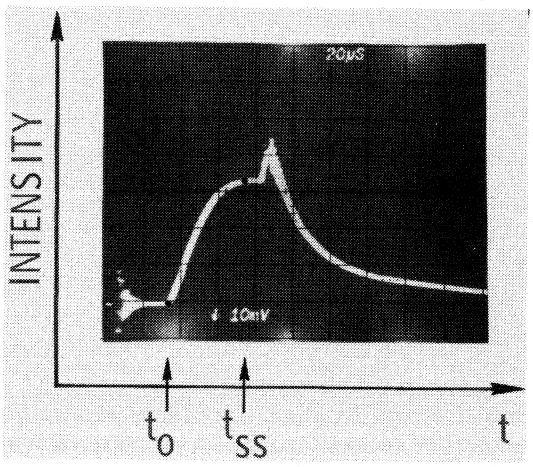

Fig. 6. Scope trace of total optical output power as a function of time for a typical e^--beam laser pulse.

is initiated and the output lasts considerably longer than the excitation pulse length. This long decay is typical of CO/N_2 gas mixes due to the time required for energy stored in the vibrational levels of nitrogen to be transferred back to the CO molecules. The pulse shapes for CO/Ar mixtures look similar except that the pulse decay time is shorter, since no energy is stored in the argon.

The laser threshold time t_0 is taken to be that time from initiation of the sustainer current to the point where the laser intensity is about 3-5 percent of the maximum intensity as indicated by the arrow in Fig. 6. This threshold is generally sharp and the time is therefore well defined. The steady-state time t_{ss} is defined as the time required to reach ~95 percent of the maximum value, also indicated by an arrow in Fig. 6. This value is not as sharply defined as t_0 and considerable spread in the data may occur for the determination of steady state.

It was shown in Section III that the inverse of the threshold and steady-state times for CO/Ar laser-gas mixtures should scale as $p_{CO}\tilde{W}_e^{5/6}$, where $\tilde{W}_e$ is the electrical-excitation rate (watts/cubic centimeter/torr squared (CO)). For the range of experimental variables considered ($\tilde{W}_e \sim 1$), the exponent $(\frac{5}{6})$ can be taken to be unity with the resulting physical interpretation that, regardless of the excitation rate, fixed specific energies (joules/liter/torr (CO)) must be deposited to attain threshold and steady state. Experimental values of threshold and steady-state times were measured for CO/Ar gas mixtures from 75 to 150 torr. The inverse times are plotted in Fig. 7 and, as predicted by the scaling generalizations, are proportional to W_e/p_{CO}. From Fig. 7 it is concluded that approximately 0.9 J/l/torr (CO) must be deposited in order to reach threshold, which is in good agreement with the scaling generalizations which predict that 0.5 - 1.0 J/l/torr (CO) is necessary. The experimental value for the deposited energy required to attain steady state, ~2.0 J/l/torr (CO), is also in good agreement with the scaling predictions of 1.7 - 2.6 J/l/torr (CO).

The calculations discussed in Section III are valid only for gas mixtures of CO and monatomic diluents. However, the scaling generalizations appear to be valid for CO/diatomic systems, provided that only the fractional energy into the CO system is used for scaling. Experimental measurements of the threshold and steady-state times for a fixed CO/N_2 (1:6) mixture are shown in Fig. 8. It is apparent from this graph that the inverses of these times scale with W_e just as they do for CO/Ar mixtures although the required total energy deposited is different. This is to be expected because the deposited energy is split between the CO and N_2. It would seem, in fact, that the required energy deposited in the CO vibrational system should be the same regardless of the diluent and that the fractional amount deposited into nitrogen can be determined from the experimental data; i.e., a specific energy $E(CO)/p_{CO}$ must be deposited into vibrational excitation of CO in order to attain any given efficiency.

Additional evidence is provided for the previous supposition by measurements of the threshold time dependence on the fractional content of CO, $f_{CO} = p_{CO}/p_{tot}$. These data, shown in Fig. 9, indicate that the total specific energy required to achieve threshold increases linearly with f_{CO} which, when

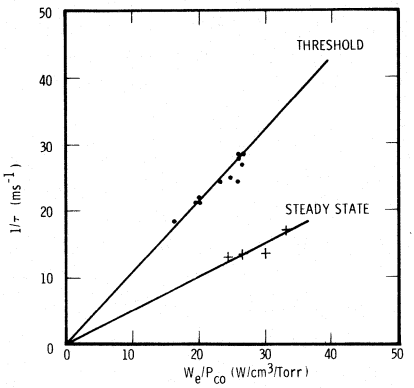

Fig. 7. Inverse of experimentally observed times required for attainment of threshold and steady state for a CO/Ar gas mixture, as a function of W_e/p_{CO}.

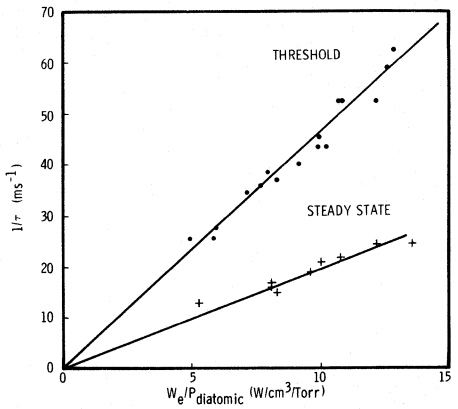

Fig. 8. Inverse of experimentally observed times required for attainment of threshold and steady state for a 1:6 CO/N_2 gas mixture.

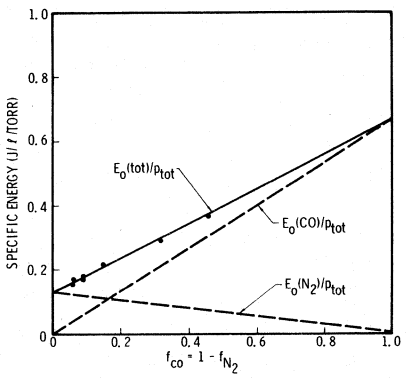

Fig. 9. Experimental specific energies as a function of fractional CO content required for attainment of laser threshold for CO/N_2 gas mixtures.

extrapolated to $f_{CO} = 1$, gives ~0.7 J/l/torr (CO), which agrees approximately with the previous results for CO/Ar mixtures. If it is assumed that the required threshold energy deposited in CO is always 0.7 J/l/torr (CO), the remaining fraction into nitrogen increases linearly with $f_{N_2} = 1 - f_{CO}$, as is also shown in Fig. 9. That is

$$E_0(\text{tot})/p_{\text{tot}} = f_{CO}E_0(CO)/p_{CO} + f_{N_2}E_0(N_2)/p_{N_2}. \quad (9)$$

From the experimental value for $E_0(CO)/p_{CO}$, it is determined that $E_0(N_2)/p_{N_2} = 0.13$ J/l/torr(N_2). The physical

interpretation of the experimental data presented in Fig. 9 is that the energy deposition per molecule is six times higher than CO than for N_2. Thus it appears that the scaling generalizations derived for CO/Ar mixtures can also be applied to systems with diatomic diluents, and that accurate knowledge of the large number of kinetic rates required for a complete analysis of the CO/N_2 system is not essential for prediction of approximate laser performance.

Experiments and Theory on Energy Extraction in an Atmospheric-Pressure CO_2 Amplifier with 60 ns-1 μs Pulses

G. GIRARD, J. C. FARCY, M. MICHON, AND P. VINCENT

Abstract—**We measured the energy extraction for 60-ns pulses and compared our experimental and theoretical results. The theoretical curve is in agreement with the experimental results. We plotted the theoretical evolution of α, N_{001}/N_A, N_{100}/N_A, and T in an amplifying stage. We finally compared the different energy extraction versus the pulse duration.**

I. Introduction

THE ability of a CO_2 laser pulse with 60 ns-1 μs duration to extract energy from an atmospheric-pressure CO_2 amplifier was studied. We have measured the energy extraction from an amplifying stage for 60-ns pulses by varying the input energy, and have compared these results with a rate equation theory. The theory presented here is an extension of a method employed by Schwartz *et al.* [1]. Basov *et al.* [2] and Brunet [3] have obtained similar equations for CO_2 mixtures. Experimental results are in good agreement with the theoretical ones. We also deduced the theoretical evolution of the gain, the translational temperature, and the population of the upper and lower levels in an amplifying stage. A comparison is made between the maximum extractable energies for 1.5-ns (single and multiline), 60-ns, 100-μs, 0.5-μs, and 1-μs pulses.

Manuscript received September 19, 1974; revised January 22, 1975. This work was supported by the Commissariat à l'Energie Atomique, Centre d'Etude de Limeil, Limeil, France.

II. Experiment

The experimental apparatus was arranged as shown in Fig. 1. Single-longitudinal and transversal-mode operation of a pulsed atmospheric-pressure CO_2 laser is obtained through the use of an intracavity SF_6 cell [4], [5]. The cavity is about 2 m long and is composed of a grating and a germanium reflector. A diaphragm, 8 mm in diameter, is used to restrict oscillations to a single transverse mode. The absorber cell is 1 cm thick with parallel Brewster-angle windows. Operation on a single longitudinal mode is obtained with about 2 torr of SF_6 in the cell. The output pulses are 60-ns full width at half maxi-

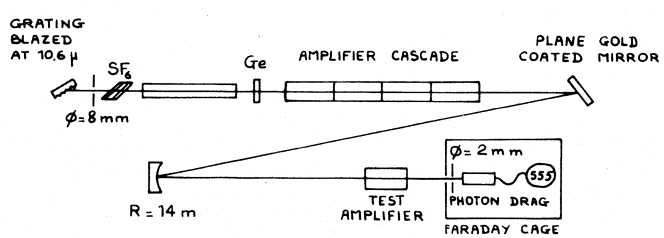

Fig. 1. Experimental setup for measuring energy gain.

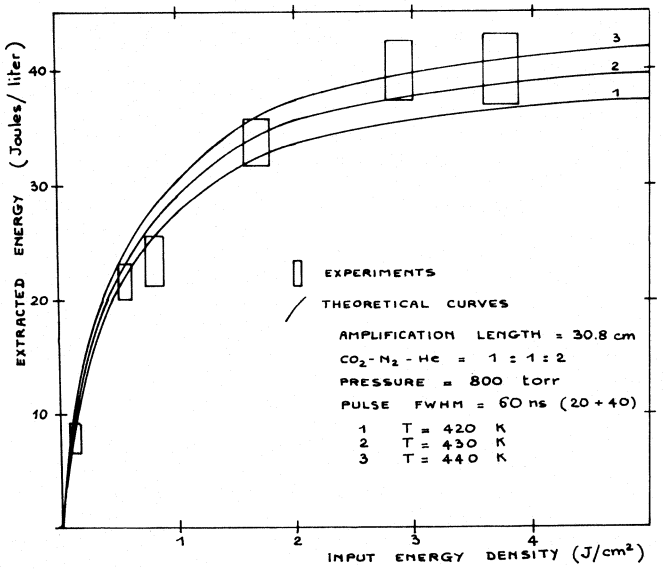

Fig. 2. Comparison between experimental and computed energy extractions for a medium of length 30 cm with small-signal gain $\alpha_0 = 0.0435\ \text{cm}^{-1}$.

mum (FWHM) (20-ns rise time and 40-ns decay time). This oscillator is followed by 4 m of amplification with an overall small-signal gain of about 10^4. At the output of the amplifier chain the beam is focused into the test amplifier to reach a high level of energy density. The test amplifier, 30 cm long, has been described elsewhere [6]. Eventually, the beam reaches the photon-drag detector. Attenuators are set in front of the photon drag in order to be in its linear response range [7]. Because of radial intensity variations, a Gaussian-shaped beam does not experience the same degree of saturation over its cross section. In order to overcome this effect, a diaphragm 2 mm in diameter is set in front of the detector so that the photon drag intercepts a small but radially uniform portion of the beam.

The experiment is performed as follows. Various levels of energy density at the output of the chain are obtained by firing an appropriate number of amplifiers and by adjusting the pump energy. For all these levels of energy, the shape of the pulse was not modified. The photon-drag detector output is displayed on an oscilloscope. Photographic records are taken with the test amplifier alternately on and off. We have operated our test amplifier with a CO_2-N_2-He mixture of 1:1:2, for an input energy corresponding to $\alpha_0 = 0.0435\ \text{cm}^{-1}$, $T = 430$ K, and $T_3 = 2550$ K, where T is the translational temperature of the mixture and T_3 is the vibrational temperature of the ν_3 mode. The results of the energy-gain measurements are shown in Fig. 2. Each datum point is the average of ten measures. Rectangles represent the magnitude of the experimental error.

III. Theory

At atmospheric pressure the transfer times between vibrational levels of a mode are of the order of 10 ns and the transfer times between rotational levels are of the order of 0.1 ns [8]. As a consequence, whenever the laser pulse duration is long compared to these transfer times, a Boltzmann distribution is maintained during the pulse between the vibrational levels of a mode and between rotational levels. The vibrational temperature of the ν_1 and ν_2 modes of the CO_2 molecule and the rotational temperature are equal to the temperature of translation T.

The variables introduced in the rate equations are the photon density ϕ and the mean numbers A of quanta per vibrational mode. We have to consider three sets of equations: 1) the relaxation equations; 2) the relations between the populations of the levels 001, 100, and the mean numbers of quanta per mode; and 3) the rate equations.

A. Relaxation Equations [3]

1) The relaxation of the vibrational energy of N_2 occurs via the following process:

$$N_2(v=1) + N_2(v=0) \xrightarrow{k_{10}(B,B)} 2N_2(v=0) \tag{1a}$$

$$N_2(v=1) + CO_2(00^\circ 0) \xrightarrow{k_{10}(B,A)} N_2(v=0) + CO_2(00^\circ 0) \tag{1b}$$

$$N_2(v=1) + M \xrightarrow{k_{10}(B,C)} N_2(v=0) + M \tag{1c}$$

$$N_2(v=1) + CO_2(00^\circ 0) \xrightarrow{k_{10}^{01}(B,A)} N_2(v=0) + CO_2(00^\circ 1). \tag{1d}$$

$k_{10}(B,B)$, $k_{10}(B,A)$, $k_{10}(B,C)$ are the constants of vibration-translation (VT) deexcitation (A for CO_2, B for nitrogen, C for helium). $k_{10}^{01}(B,A)$ is a constant of vibration-vibration (VV) transfer.

2) The relaxation of the vibrational energy of the ν_1 mode of the CO_2 is due to VV transfers between the ν_1 and ν_2 modes.

$$CO_2(10^\circ 0) + CO_2(00^\circ 0) \xrightarrow{k_{02}^{10}} \begin{bmatrix} CO_2(01^1 0) + CO_2(01^1 0) \\ CO_2(02^\circ 0) + CO_2(00^\circ 0). \end{bmatrix} \tag{2}$$

3) The relaxation of the vibrational energy of the ν_2 mode is due to the following VT process:

$$CO_2(01^1 0) + CO_2(00^\circ 0) \xrightarrow{k^{10}(A,A)} 2CO_2(00^\circ 0) \tag{3a}$$

$$CO_2(01^1 0) + N_2(v=0) \xrightarrow{k^{10}(A,B)} CO_2(00^\circ 0) + N_2(v=0) \tag{3b}$$

$$CO_2(01^1 0) + M \xrightarrow{k^{10}(A,C)} CO_2(00^\circ 0) + M. \tag{3c}$$

4) The relaxation of the vibrational energy of the ν_3 mode is due to VV transfers to the ν_1 and ν_2 modes.

$$CO_2(00^\circ 1) + CO_2(00^\circ 0) \xrightarrow{k_{03}^{10}(A,A)} \begin{bmatrix} CO_2(3\nu_2) + CO_2(00^\circ 0) \\ CO_2(2\nu_2) + CO_2(\nu_2) \end{bmatrix} \tag{4a}$$

$$CO_2(00^\circ 1) + N_2(v=0) \xrightarrow{k_{03}^{10}(A,B)} CO_2(3\nu_2) + N_2(v=0) \tag{4b}$$

$$CO_2(00°1) + M \xrightarrow{k_{03}^{10}(A,C)} CO_2(3\nu_2) + M. \quad (4c)$$

The rate constants k are taken principally from Taylor and Bitterman [9]. The actual rate constants employed are tabulated in Table I for $T = 430$ K [10].

5) In the following relaxation equations, a, b, and c are the molar concentrations of CO_2, N_2, and He; N_A, N_B are the numbers of CO_2 and N_2 molecules and

$$A_1 = \frac{E_1}{N_A h\nu_1} \quad A_2 = \frac{E_2}{N_A h\nu_2} \quad A_3 = \frac{E_3}{N_A h\nu_3} \quad B = \frac{E_B}{N_B h\nu_B}$$

are the average number of quanta per vibrational mode.

$$\frac{dA_1}{dt} = -k_{02}^{10}(A,A)\,[A_1(A_2+1)^2 - \epsilon_{12}(A_1+1)A_2^2] \quad (5a)$$

where

$$\epsilon_{12} = \exp\,[-h(\nu_1 - 2\nu_2)/kT] \quad (5b)$$

$$\frac{dA_2}{dt} = k_{02}^{10}(A,A)\,[A_1(A_2+1)^2 - \epsilon_{12}(A_1+1)A_2^2] + \tfrac{3}{2}[ak_{03}^{10}(A,A) + bk_{03}^{10}(A,B) + ck_{03}^{10}(A,C)] \cdot [A_3(A_2+1)^3 - \epsilon_{32}(A_3+1)A_2^3] - [ak^{10}(A,A) + bk^{10}(A,B) + ck^{10}(A,C)] \cdot [A_2 - A_2(T)] \quad (6a)$$

where

$$\epsilon_{32} = \exp\,[-h(\nu_3 - 2\nu_2)/kT] \quad (6b)$$

$$A_2(T) = 1/[\exp(h\nu_2/kT) - 1] \quad (6c)$$

$$\frac{dA_3}{dt} = -[ak_{03}^{10}(A,A) + bk_{03}^{10}(A,B) + ck_{03}^{10}(A,C)] \cdot [1 + A_2(T)]^3\,[A_3 - A_3(T)] - bk_{01}^{10}(A,B)\,[B(T)+1]\left[A_3 - \frac{A_3(T)}{B(T)}B\right] \quad (7a)$$

where

$$A_3(T) = 1/[\exp(h\nu_3/kT) - 1] \quad (7b)$$

$$\frac{dB}{dt} = -ak_{01}^{10}(A,B)\,[\epsilon_{3B}B(A_3+1) - A_3(B+1)] - [ak_{10}(B,A) + bk_{10}(B,B) + ck_{10}(B,C)]\,[B - B(T)] \quad (8a)$$

where

$$\epsilon_{3B} = \exp\,[-h(\nu_3 - \nu_B)/kT] \quad (8b)$$

$$B(T) = 1/[\exp(h\nu_B/kT) - 1]. \quad (8c)$$

B. Relations Between the Populations of the Levels 001, 100, and the Mean Numbers of Quanta per Mode

The populations of the upper and lower levels of the laser transition are, respectively,

TABLE I
DIFFERENT RATE CONSTANTS FOR $T = 430$ K

Rate Constants	$cm^3\ s^{-1}$ ($T = 430$ K)
$k_{10}(B,B)/N$	5.46×10^{-18}
$k_{10}(B,A)/N$	5.46×10^{-18}
$k_{10}(B,C)/N$	1.43×10^{-15}
k_{02}^{10}/N	4.68×10^{-13}
$k^{10}(A,A)/N$	1.65×10^{-14}
$k^{10}(A,B)/N$	2.82×10^{-15}
$k^{10}(A,C)/N$	2.03×10^{-13}
$k_{03}^{10}(A,A)/N$	1.53×10^{-14}
$k_{03}^{10}(A,B)/N$	5.74×10^{-15}
$k_{03}^{10}(A,C)/N$	4.15×10^{-15}

$$N_{100} = N_A \exp\left(-\frac{h\nu_1}{kT}\right) Q_v^{-1} \quad (9a)$$

$$N_{001} = N_A \exp\left(-\frac{h\nu_3}{kT_3}\right) Q_v^{-1} \quad (9b)$$

where

$$Q_v^{-1} = \left[1 - \exp\left(-\frac{h\nu_1}{kT}\right)\right]\left[1 - \exp\left(-\frac{h\nu_2}{kT}\right)\right]^2 \cdot \left[1 - \exp\left(-\frac{h\nu_3}{kT_3}\right)\right]. \quad (9c)$$

The mean numbers of quanta per vibrational mode are

$$A_1 = \frac{\exp\left(-\frac{h\nu_1}{kT}\right)}{1 - \exp\left(-\frac{h\nu_1}{kT}\right)} \quad (10a)$$

$$A_2 = \frac{\exp\left(-\frac{h\nu_2}{kT}\right)}{1 - \exp\left(-\frac{h\nu_2}{kT}\right)} \quad (10b)$$

$$A_3 = \frac{\exp\left(-\frac{h\nu_3}{kT_3}\right)}{1 - \exp\left(-\frac{h\nu_3}{kT_3}\right)}. \quad (10c)$$

The following relations are deduced from (9) and (10):

$$N_{100} = N_A \frac{A_1}{(1+A_1)^2\left(1+\frac{A_2}{2}\right)^2(1+A_3)} \quad (11a)$$

$$N_{001} = N_A \frac{A_3}{(1+A_1)\left(1+\frac{A_2}{2}\right)^2(1+A_3)^2}. \quad (11b)$$

C. Rate Equations

Equation (11) is introduced into the classical equation

$$\frac{\partial \phi}{\partial t} + c\frac{\partial \phi}{\partial x} = \phi \frac{8\pi^2 \nu}{3h\delta\nu} |\mu_{vv'}|^2 \frac{J}{2J+1} \cdot \left(N_{001} f_{J-1} \frac{2J+1}{2J-1} - N_{100} f_J\right) \tag{12a}$$

and the rate equations are

$$\frac{\partial \phi}{\partial t} + c\frac{\partial \phi}{\partial x} = \phi \frac{8\pi^2 \nu}{3h\delta\nu} |\mu_{vv'}|^2 \frac{J}{2J+1} N_A \cdot \left[f_{J-1} \frac{2J+1}{2J-1} \frac{A_3}{(1+A_1)\left(1+\frac{A_2}{2}\right)^2 (1+A_3)^2} - f_J \frac{A_1}{(1+A_1)^2\left(1+\frac{A_2}{2}\right)^2 (1+A_3)}\right] \tag{12b}$$

$$\frac{\partial A_3}{\partial t} = -\phi \frac{8\pi^2 \nu}{3h\delta\nu} |\mu_{vv'}|^2 \frac{J}{2J+1} \left[f_{J-1} \frac{2J+1}{2J-1} \cdot \frac{A_3}{(1+A_1)\left(1+\frac{A_2}{2}\right)^2 (1+A_3)^2} - f_J \frac{A_1}{(1+A_1)^2\left(1+\frac{A_2}{2}\right)^2 (1+A_3)}\right] - [ak_{03}^{10}(A,A) + bk_{03}^{10}(A,B) + ck_{03}^{10}(A,C)] \cdot [1+A_2(T)]^3 [A_3 - A_3(T)] - bk_{01}^{10} \cdot [B(T)+1]\left[A_3 - \frac{A_3(T)}{B(T)} B\right] \tag{13}$$

$$\frac{\partial A_1}{\partial t} = \phi \frac{8\pi^2 \nu}{3h\delta\nu} |\mu_{vv'}|^2 \frac{J}{2J+1} \left[f_{J-1} \frac{2J+1}{2J-1} \cdot \frac{A_3}{(1+A_1)\left(1+\frac{A_2}{2}\right)^2 (1+A_3)^2} - f_J \frac{A_1}{(1+A_1)^2\left(1+\frac{A_2}{2}\right)^2 (1+A_3)}\right] - k_{02}^{10}[A_1(A_2+1)^2 - \epsilon_{12} A_2^2 (A_1+1)]. \tag{14}$$

Equations (13), (14), (6a), and (8a) describe the amplification process.

The initial conditions are determined by T_{3i} and T_i (initial values of T and T_3). The initial vibrational temperature of N_2 is assumed to be equal to T_{3i} (see Section V).

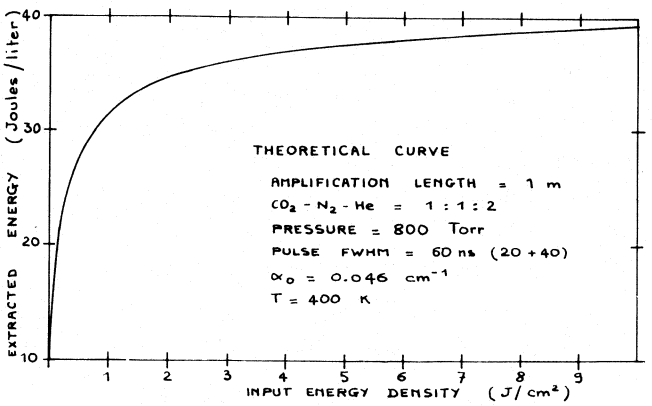

Fig. 3. Theoretical energy extraction versus incident-pulse energy density for a 60-ns FWHM pulse (20 + 40 ns) from an amplifier state 1 m long with a small-signal gain $\alpha_0 = 0.046$ cm^{-1}.

D. Comparison between Experimental Results and Theoretical Ones

The pulse shape is represented for convenience by the function $\phi(t) = \phi_0/\cosh^3(a(t - t_0))$ which corresponds to an exponential function during the buildup time and during the decay time; t_0 is the time of the pulse peak intensity. However, the a value is different for $t < t_0$ and $t > t_0$. The calculations were carried out for an N_2-CO_2-He mixture of 1:1:2, $T = 430$ K, a small-signal gain $\alpha_0 = 0.0435$ cm^{-1} corresponding to $T_3 = 2550$ K, an input-pulse 60-ns FWHM (20-ns rise time, 40-ns decay time), an amplification length 1 = 30 cm, and a pressure $p = 800$ torr. The initial vibrational temperature of N_2 is assumed to be equal to the vibrational temperature T_3. The experimental and theoretical curves are in good agreement (Fig. 2).

In Fig. 3 the same type of curve for a 1-m amplifier is plotted. The small-signal gain is $\alpha_0 = 0.046$ cm^{-1} (value for α_0 usually appearing in the literature). The CO_2-N_2-He mixture is 1:1:2 and the pressure is 800 torr. The pulse FWHM is 60 ns (20 + 40 ns).

IV. Theoretical Evolution of the Pulse Shape Versus Power and of the Functions $\alpha, N_{001}/N_A, N_{110}/N_A$, and T Versus Time

In Fig. 4 the theoretical evolution versus power of the FWHM of a pulse in an amplifier cascade is plotted. The characteristics of the pulse entering the amplifier cascade are the following. Its FWHM is 60 ns (20 + 40 ns) and its peak power is 10^6 W/cm^2. Each amplifier of the cascade is identical to the one previously described. The theoretical evolution of the pulse FWHM versus power is negligible until an input power density is equal to 5×10^7 W/cm^2. This was previously verified in the experiment described in Section II.

In Fig. 5 the evolution of the functions α, N_{001}/N_A, N_{100}/N_A, and T versus time in such an amplifier is plotted. The increase of N_{001} after the pulse is due to the $N_2 \rightarrow CO_2$ energy transfer. During the pulse, the energy transfer $N_2 \rightarrow CO_2$ is weak and the maximum available energy is equal to about 35 percent of the initial energy of the ν_3 mode (i.e.,

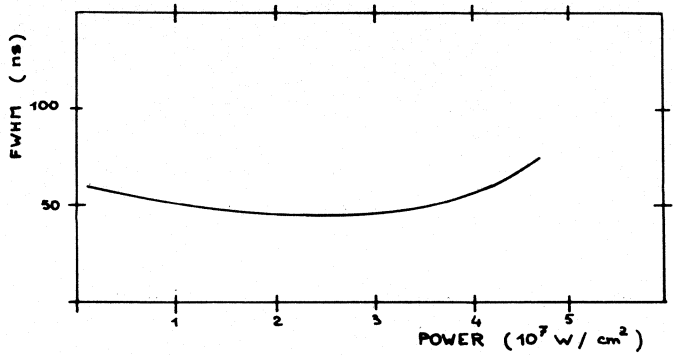

Fig. 4. Theoretical evolution versus power of the FWHM of a 60-ns (20 + 40) pulse in an amplifier cascade. The original peak power of the pulse is 10^6 W/cm^2. Each amplifier of the cascade is identical to the one described in Fig. 3.

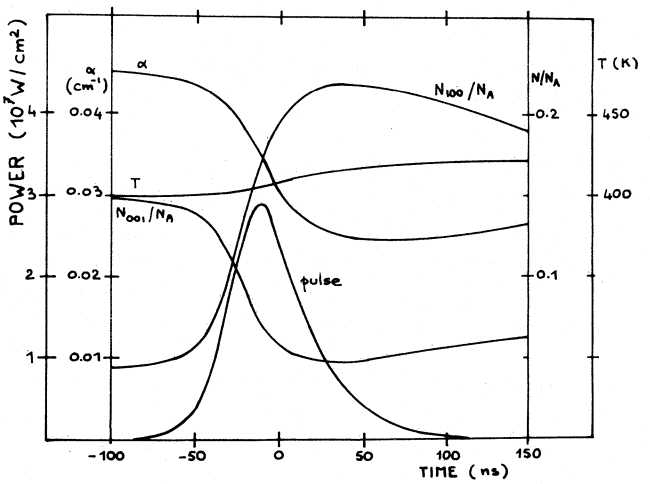

Fig. 5. Theoretical evolution of α, N_{001}/N_A, N_{100}/N_A, and T versus time in an amplifying stage.

taking account of the quantum efficiency of the laser emission of 0.41, only 90 percent of the extractable energy of the ν_3 mode can be extracted). The temperature of translation increases during and after the pulse. This is due to an increase of the ν_1 mode energy followed by a transfer to the translation via the ν_2 mode.

V. Theoretical Evolution of the Energy Extraction versus the Pulse Duration: 1.5 ns-60 ns-100 ns-0.5 μs-1 μs

In Fig. 6 the energy extraction versus input energy from an amplifier stage for input pulses with different FWHM is plotted. The calculations were carried out for a CO_2-N_2-He mixture of 1:1:2, p = 800 torr, T = 400 K, α_0 = 0.046 cm^{-1} corresponding to T_3 = 2370 K, and for input-pulse FWHM of 60 ns ②, 100 ns ③, 0.5 μs ④, and 1 μs ⑤ with a 20-ns rise time. We have added the results of energy extraction, as obtained previously [11], for a 1.5-ns FWHM pulse, ①. In Fig. 7 are plotted typical energies versus T_3, the vibrational temperature ν_3 mode, and the corresponding small-signal gain for a CO_2-N_2-He mixture 1:1:2, at p = 800 torr and

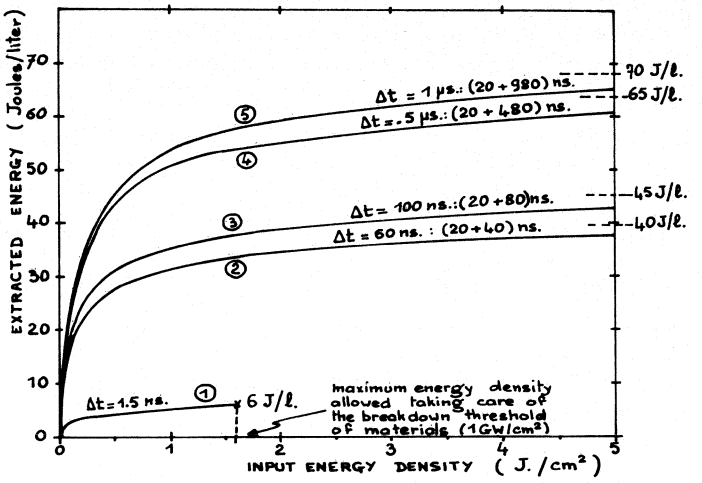

Fig. 6. Theoretical energy extraction versus incident-pulse energy density for different FWHM pulse: 1.5 ns, 60 ns, 100 ns, 0.5 μs, and 1 μs. The values given by the asymptotes are the energies extracted by a 10-J/cm^2 input-pulse energy density.

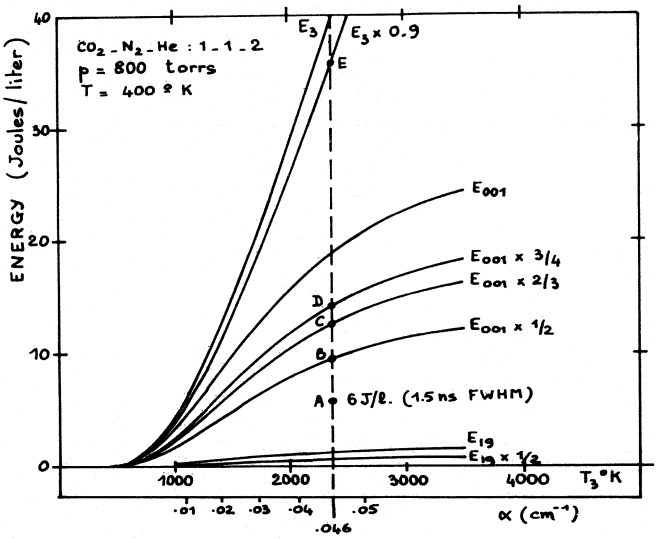

Fig. 7. Typical energies in CO_2 molecules versus T_3.

T = 400 K. E_3 is the energy stored on the ν_3 vibrational mode and E_{001} is the energy stored on the rotational level J' = 19. These energies are multiplied by the factor 0.41 corresponding to the quantum efficiency, i.e.,

$$E_3 = 0.41\,\mathfrak{N}(CO_2)\,k\theta_3\,\frac{\exp(-\theta_3/T_3)}{1-\exp(-\theta_3/T_3)} \tag{15}$$

$$E_{001} = 0.41\,\mathfrak{N}(CO_2)\,k\theta_3\exp\left(-\frac{\theta_3}{T_3}\right)\left[1-\exp\left(-\frac{\theta_1}{T}\right)\right] \cdot\left[1-\exp\left(-\frac{\theta_2}{T}\right)\right]^2\left[1-\exp\left(-\frac{\theta_3}{T_3}\right)\right] \tag{16}$$

$$E_{19} = E_{001}\,\frac{2hB'}{kT}(2J-1)\exp\left[-\frac{hB'}{kT}J(J-1)\right]. \tag{17}$$

A 1.5-ns pulse consisting of a single vibrational-rotational

TABLE II
EXTRACTABLE ENERGY AS A FUNCTION OF THE PULSE LENGTH

Pulse Length	Index	Maximum Extractable Energy for $\alpha_0 = 0.046$ cm^{-1}
1.5 ns (single line)	A	6 J/l
1.5 ns (multiline at 10.6 μ)	B	9.5 J/l
1.5 ns (multiline at 9.6 and 10.6 μ)	C D	12.5 J/l 14 J/l
60 ns (→ the whole energy stored in CO_2)	E	40 J/l
100 ns (→ the whole energy stored in CO_2 + a part of the energy stored in N_2)		45 J/l
0.5 μs (→ nearly the whole energy stored in $CO_2 + N_2$)		65 J/l
1 μ (→ the whole energy stored in $CO_2 + N_2$)		70 J/l

transition will extract 6 J/l for α_0 equal to 0.046 cm^{-1}. The maximum energy density extractable by a 1.5-ns pulse consisting of multiline transitions within the 10.6-μ band will be $1/2\,E_{001}$ [12]; the factor 1/2 is due to the bottleneck of the lower level. If the 1.5-ns pulse consists of multiline transitions within the 9.6- and 10.6-μ bands, the maximum energy density extractable will be $2/3\,E_{001}$; the factor 2/3 is due to the fact that there are now two lower levels, 100 and 020. If the transitions between the two sublevels $02^{0}0$ and $02^{2}0$ are fast enough, the maximum energy density extractable will be $3/4\,E_{001}$. The values corresponding to $\alpha_0 = 0.046$ cm^{-1} (T_3 = 2370 K) are indicated by a vertical line in Fig. 7. Taking into account the theoretical results, the energy extractable from the ν_3 mode by a 60-ns pulse is about 90-percent E_3. The energy extractable by a 1-μs pulse is about double than the energy extractable by a 60-ns pulse. In fact, for the same number of N_2 and CO_2 molecules, nearly the same amount of energy is extractable from N_2 as from CO_2. We summarize in Table II the different extractable energy as a function of the pulse length.

VI. CONCLUSIONS

To describe the gain saturation in a CO_2 atmospheric-pressure amplifier, we used a theoretical model taking account of the various vibrational energy exchange mechanisms between species, between vibrational modes, and between levels of a mode. This model was confirmed experimentally with 60-ns pulse durations. It appears that at atmospheric pressure, nearly all the extractable energy of the medium will be extracted in a 0.5-μs pulse with 20 MW/cm^2 pulse power density.

APPENDIX
DETERMINATION OF T AND T_3

The method used to determine T and T_3 has been described elsewhere [6]. We would like to describe some improvements on our method and purpose some corrections. Once the peak small-signal gain α_0 is plotted versus the quantum number of the line (Fig. 8), it is somewhat inaccurate to determine T by combining the experimental values of α_0 in groups of two by two, because of the fluctuations of α_0 due to other transitions than those considered (001 → 100). It is more appropriate to determine T and T_3 simultaneously by comparing all the experimental values of α_0 to a set of theoretical curves. This is what we did in Fig. 8. These curves were plotted for a CO_2-N_2-He mixture of 1:1:2, a pressure of 800 torr, and different pairs of values for T and T_3. In Fig. 9 there is a set of extreme theoretical curves, and in Fig. 8 is the set of the average theoretical curves. From these curves we can deduce the values of α_0, T, and T_3 in this experiment: $\alpha_0 = 0.0435$ cm^{-1} ± 10 percent; T = 430 K ± 10 percent; T_3 = 2550 K ± 20 percent.

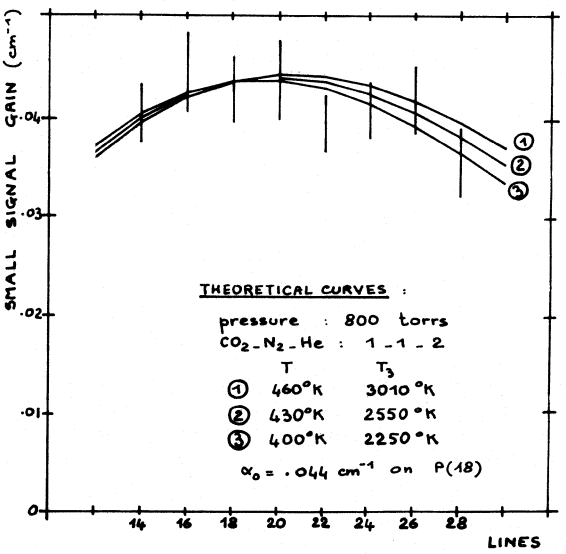

Fig. 8. Comparison between experimental and theoretical gain variations versus the quantum number of the line.

The errors are rather significant, especially for T_3; this error is inherent to the method for high values of the small-signal gain.

The dependence of the small-signal gain on T_3 is not linear. In our experiments, α_0 may come close to its maximum value. Near this maximum the error on T_3 is high. A small variation of α_0 corresponds to a high variation of T_3. These errors are now evaluated.

For a given T and a given mixture

$$\alpha = Ax(1 - x) \tag{A1}$$

where

$$x = \exp(-\theta_3/T_3) \tag{A2}$$

and A is a constant.

$$\frac{d\alpha}{dx} = A(1 - 2x)$$

$$\frac{d\alpha}{\alpha} = \frac{1 - 2x}{1 - x}\,\frac{dx}{x}. \tag{A3}$$

The gain is maximum for $x = \frac{1}{2}$

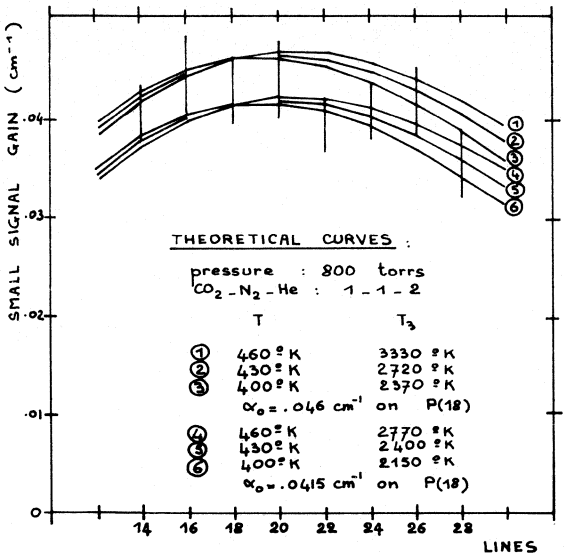

Fig. 9. Comparison between experimental and theoretical gain variations versus the quantum number of the line.

$$\alpha_M = A/4.$$

From (A1) we obtain

$$\alpha = 4\alpha_M x(1 - x)$$

$$4\alpha_M x^2 - 4\alpha_M x + \alpha = 0$$

$$x = 1/2 - 1/2(1 - \alpha/\alpha_M)^{1/2}. \tag{A4}$$

From (A2) we obtain

$$\left|\frac{dx}{x}\right| = \frac{dT_3}{T_3}\,\frac{\theta_3}{T_3}. \tag{A5}$$

Adding (A5) and (A3), we obtain

$$\frac{dT_3}{T_3} = \frac{1 - x}{1 - 2x}\,\frac{d\alpha}{\alpha}. \tag{A6}$$

Adding (A5) and (A4), we obtain

$$\frac{dT_3/T_3}{d\alpha/\alpha} = \frac{1}{2(1 - \alpha/\alpha_M)^{1/2}} + \frac{1}{2}. \tag{A7}$$

In Fig. 10 we have plotted the function (A7). The value corresponding to our experiment is indicated by point E. The error on T_3 is nearly twice the error on α as suggested in the preceding.

Thus this method to determine T and T_3 is valid only for low excitation of the mixture. But, as indicated in this paper, the determination of T_3 is considerably more accurate if one studies long-pulse amplification.

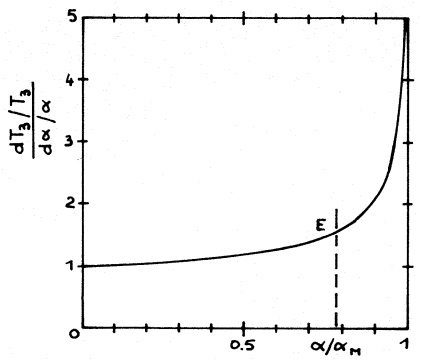

Fig. 10. Evolution of dT_3/T_3 versus $d\alpha/\alpha$.

ACKNOWLEDGMENT

The authors wish to thank H. Brunet for helpful discussions and P. Cottin and M. Huguet for technical assistance. They also wish to thank A. Fertal for his help in the determination of T and T_3.

The Optically Pumped Far-Infrared Laser: Rate Equations and Diagnostic Experiments

J. O. HENNINGSEN AND H. G. JENSEN

Abstract—A four-level rate-equation model for an optically pumped far-infrared (FIR) laser is presented, and an expression is derived for the output power as a function of pump power and gas pressure. The theory is compared with measurements on the 570.5-μm line of CH_3OH, pumped by a CO_2 laser. The width of the gain curve is measured and is shown to go below the Doppler width of the laser transition at low pressure. This indicates that the use of a monochromatic pump source leads to a velocity selective pumping process.

I. Introduction

IN THE SEARCH for stable monochromatic radiation sources bridging the gap between the infrared (IR) range and the millimeter-wave range, the optically pumped far-infrared (FIR) lasers attract considerable interest. The first observation of laser action in the FIR by optical pumping was reported in 1970 by Chang and Bridges [1], and an extensive survey of the subsequent rapid development of this field is found in a review article by Chang [2].

Until now, the interest has been mainly focused on increasing the number of lines and extending the spectral coverage. In contrast, with a few exceptions [3]-[5], relatively little attention has been paid to the study of the laser as such. The aim of this paper is to present a four-level rate-equation model and to correlate this model with experiments. Section II contains the theory and leads up to an expression giving the FIR output power as a function of pump power and gas pressure. We compare this expression with measurements on the 570.5-μm line emitted when CH_3OH is pumped by the 9.52-μm $P(16)$ line of a CO_2 laser [6] and Section III contains the experimental details together with some observations concerning this particular line. The analysis of the results follows in Section IV, and we show that by studying the gain width as a function of pressure, information can be obtained concerning the particular nature of monochromatic pumping.

II. Theoretical Model

Rate Equations

We describe the laser by a four-level system as shown in Fig. 1 where 0 is some rotational level in the vibrational ground state, 1 and 2 are adjacent rotational levels in a low-lying excited vibrational state, sufficiently above the ground state to be thermally unpopulated, and 3 represents the lumped effect of those rotational levels in the upper vibrational manifold, which are not directly involved in the laser transition $2 \rightarrow 1$.

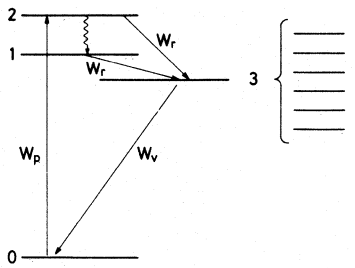

Fig. 1. Four-level model for the optically pumped FIR laser.

In the pumping process, which is assumed to take place uniformly over the mode volume of the laser, molecules are excited from 0 to 2 at a rate w_p by a CO_2 laser tuned to the $0 \rightarrow 2$ absorption line. Collisions between the molecules, occurring at a rate w_r, are very efficient in establishing thermal equilibrium among the rotational levels of a given vibrational state. w_r can therefore be assumed to be much larger than the rate w_v of relaxation back to the vibrational ground state. To be precise, the return back to 0 takes place via other rotational levels in the vibrational ground state. In addition, as will be demonstrated in Section IV, the pumping is effective for molecules inside a narrow velocity range only, and a complete cycle for the molecules will therefore also involve relaxation across the velocity profile inside a given rotational level. The quantity w_v represents the combined effect of all of these processes, and it must therefore be regarded as a phenomenological quantity.

In equilibrium, the net production of photons by stimulated emission from 2 to 1 must equal the losses, and neglecting spatial variations, the rate equations governing the total occupation numbers per unit volume N_i of the various molecular levels, and the number n of FIR photons, are the following:

$$\frac{dN_0}{dt} = w_v N_3 - w_p N_0 \tag{1}$$

$$\frac{dN_1}{dt} = B_{21} n \left(N_2 - \frac{g_2}{g_1} N_1 \right) - w_r N_1 \tag{2}$$

$$\frac{dN_2}{dt} = w_p N_0 - w_r N_2 - B_{21} n \left(N_2 - \frac{g_2}{g_1} N_1 \right) \tag{3}$$

$$N = N_0 + N_1 + N_2 + N_3 \tag{4}$$

Manuscript received September 20, 1974; revised January 27, 1975. This work was supported by Statens Naturvidenskabelige Forskningsråd. A preliminary version of this work was presented at the International Conference on Submillimeter Waves and Their Applications, Atlanta, Ga., June 5-7, 1974.

The authors are with the H. C. Ørsted Institute, the University of Copenhagen, Copenhagen, Denmark.

$$\frac{dn}{dt} = -2\pi\gamma n + B_{21} n \left(N_2 - \frac{g_2}{g_1} N_1\right) \tag{5}$$

where N is the total number of molecules in the 0 state in the absence of pumping, g_1 and g_2 denote the degeneracy of the levels 1 and 2, γ is the cavity half-width [full width at half maximum (FWHM)] and measures the FIR losses, including coupling losses, and B_{21} is the Einstein coefficient for stimulated emission.

In the rate equations we have neglected terms arising from spontaneous emission since the spontaneous lifetime at FIR frequencies is of the order of seconds. Further, we have assumed that w_v, albeit smaller than the rotational relaxation rate w_r, is still so large that we can neglect the collisional population of 1 and 2. In quantitative terms this corresponds to the requirement $w_v >> (w_r/\mu)$, where μ is the effective number of levels represented by the level 3. Presumably, this assumption is too restrictive, since collisions will to a first approximation populate 1 and 2 equally, and hence leave the inversion unchanged. However, it does lead to a substantial simplification of the model.

Solving (1)-(5) for the equilibrium situation, where all time derivatives are zero, we arrive at an equilibrium FIR photon density

$$n = \frac{g_1}{g_1 + g_2} \frac{w_r}{B_{21}} \left(\frac{N B_{21} w_p}{2\pi\gamma w_r (1 + w_p/w_v)} - 1\right) \tag{6}$$

and the FIR output power is given by

$$P_{\mathrm{FIR}} = \tfrac{1}{2} ncAh\nu \tag{7}$$

where A is the effective area of the coupling hole, c is the velocity of light, and ν the FIR frequency. This result may be written in the form

$$P_{\mathrm{FIR}} = \frac{1}{2} t P_s \left(\frac{2Lg}{t + a} - 1\right) \tag{8}$$

where t is the relative coupling loss per double pass, a is the loss from other mechanisms, g is the small signal gain per unit length, L is the active length of the laser, and P_s is the saturation power [7]. Relating the losses to the cavity half-width and introducing the active volume V of the laser, we can then make the identifications

$$g = \frac{B_{21}}{c w_r} \frac{N w_p}{1 + w_p/w_v} \tag{9}$$

$$P_s = h\nu \frac{Vc}{L} \frac{g_1}{g_1 + g_2} \frac{w_r}{B_{21}} . \tag{10}$$

Pressure and Pump-Power Dependence

The step needed in order to make contact with experiments, is to derive the dependence of the various quantities in (6) on pressure p and pump power U. Assuming homogeneous broadening, the Einstein coefficient $B_{21}(\nu)$ is given by

$$B_{21}(\nu) = \frac{c^3}{4\pi^2 \nu^2 t_{\mathrm{sp}} \Delta\nu_N} f(\nu) \tag{11}$$

where ν is the frequency, t_{sp} is the spontaneous lifetime of the 2 state, $\Delta\nu_N$ is the homogeneous linewidth (FWHM) of the $1 \rightarrow 2$ transition, and $f(\nu)$ is a normalized Lorentzian of width $\Delta\nu_N$. The rotational relaxation rate w_r is related to the homogeneous linewidth, so that we have

$$w_r = \pi \Delta\nu_N = \pi C p \tag{12}$$

where C is a constant.

The loss parameter a contains a constant contribution from diffraction losses, scattering losses at the mirrors, etc. In addition, self-absorption of the FIR radiation may give rise to pressure-dependent terms, varying as p if the laser line is coincident with the FIR absorption line, and as p^2 if this is not the case, the width of the absorption line then accounting for the second factor of p.

The pump rate w_p depends on pressure and pump power in a fairly complicated way. It is proportional to the intensity I of pump radiation in the cavity, but I in turn depends on the power absorbed in the gas, and therefore on w_p. A further complication is added by the fact that the absorption must be allowed to saturate. Denoting the power absorbed in the gas by U_{abs}, and assuming that a fraction ξ of this power goes into the $0 \rightarrow 2$ transition, we have

$$\xi U_{\mathrm{abs}} = h\nu_p V \frac{N w_p}{1 + w_p/w_v} \tag{13}$$

where ν_p is the pump frequency. The rate equation for the pump intensity in the cavity is

$$\frac{dI}{dt} = U - 2\pi\Gamma I - U_{\mathrm{abs}} \tag{14}$$

where Γ measures the loss rate of the pump radiation at zero pressure. w_p is obtained by solving (13), (14) for $dI/dt = 0$, and for the expression entering in (6) we then find

$$\frac{N w_p}{1 + w_p/w_v} = \frac{\xi}{V h\nu_p} \frac{p/p_s}{1 + p/p_s} \frac{U}{1 + U/U_s} \tag{15}$$

where

$$p_s = 2\pi k T \xi\Gamma / h\nu_p f_0 \zeta V \tag{16}$$

$$\zeta = w_p / I \tag{17}$$

$$U_s = (1 + p/p_s) \cdot 2\pi\Gamma w_v / \zeta \tag{18}$$

and where k is the Boltzmann constant and f_0 the fraction of the total number of molecules being in the 0 state in the absence of pumping. U_s is a parameter determining the saturation of the pump transition with increasing pump power, and in the limit $U << U_s$, p_s is the pressure at which the absorption in the gas equals the pressure-independent losses. The expression (15) is valid provided just one of the conditions

$$p << p_s, \quad U << U_s, \quad U >> U_s \tag{19}$$

is satisfied. We have not introduced any explicit pressure dependence of w_v since the precise nature of the rate-limiting process in the decay back to the 0 state is not known.

The qualitative behavior of g, P_s, and P_{FIR} is found by com-

bining (8)–(10) with (11), (12), (15)

$$g(\nu) = \frac{G}{2Lp^2} \frac{p/p_s}{1+p/p_s} \frac{U}{1+U/U_s} \tag{20}$$

$$P_s = \frac{2Q}{G} \frac{\nu}{\nu_p} p^2 \tag{21}$$

$$P_{\mathrm{FIR}} = tQ \frac{\nu}{\nu_p} \left(\frac{1}{t+a} \frac{p/p_s}{1+p/p_s} \frac{U}{1+U/U_s} - \frac{p^2}{G} \right) \tag{22}$$

where

$$G = \frac{Lc^2 \xi}{2\pi^3 \nu^2 t_{\mathrm{sp}} C^2 V h \nu_p} f(\nu) \tag{23}$$

$$Q = \xi \frac{g_1}{g_1 + g_2}. \tag{24}$$

Inspection of (22) shows that P_{FIR} increases linearly with U for $U \ll U_s$, and saturates for $U \gg U_s$. When the pressure is increased at constant U, P_{FIR} will start out proportional to p, go through a maximum, and eventually go to zero again. Neglecting FIR self-absorption and assuming $U \ll U_s$, all the p dependence is explicit in (22), and for the optimum pressure we then find

$$p_{\mathrm{opt}} \propto U, \qquad p \ll p_s \tag{25}$$

$$p_{\mathrm{opt}} \propto U^{1/3}, \qquad p \gg p_s. \tag{26}$$

III. Experiments

To check the theoretical results derived in the preceding section, we studied the 570.5-μm line of CH_3OH, using the experimental arrangement shown in Fig. 2. The resonator and beamsplitter construction is in principle similar to that described by Chang [1]. The resonator length is 110 cm and its diameter 10 cm. One mirror is flat; the other is concave, with a 3.5-m radius of curvature, and is provided with a central 5-mm coupling hole. The length of the resonator is stabilized by 3 Invar rods. This is very important since at low pressure the gain width may drop to about 0.3 MHz, corresponding to less than 1-μm variation in resonator length.

The single mode CO_2 radiation is focused at a 1-mm hole in the beamsplitter by a 58-cm focal-length NaCl lens, and it enters the FIR cavity with a divergence half-angle of 10 mrad. A tungsten bolometer, constructed from the filament of a small light bulb, can be inserted in the cavity as shown in Fig. 2 and is used for checking the pump intensity. The CO_2 power level is adjusted by a gas attenuator of length 10 cm, based on CH_3OH. An axial blower circulates the gas in order to prevent distortion of the beam profile due to local heating. The power level is monitored by a disk calorimeter which can be inserted after the attenuator. It is calibrated against a cone calorimeter onto which the beam could be directed by an auxiliary mirror placed immediately in front of the entrance window of the FIR cavity. A separate measurement ascertained that by proper focusing all the power could be passed through the beamsplitter.

The FIR signal is chopped at 10 Hz and detected by a He-cooled Ge bolometer. The pressure in the FIR cell is measured by a Pirani gauge which has an appropriate sensitivity down to a few meter torr. Since its response is different for different gases, we calibrated it for CH_3OH against an absolute gauge of the Bourdon type, manufactured by Texas Instruments. Measurements were made by adjusting the pressure, sealing off the FIR cell, closing all pumps to avoid vibrations, and then scanning the cavity length slowly at a number of different CO_2 power levels. At regular intervals the setting of the CO_2 laser was checked, but very little adjustment was usually needed.

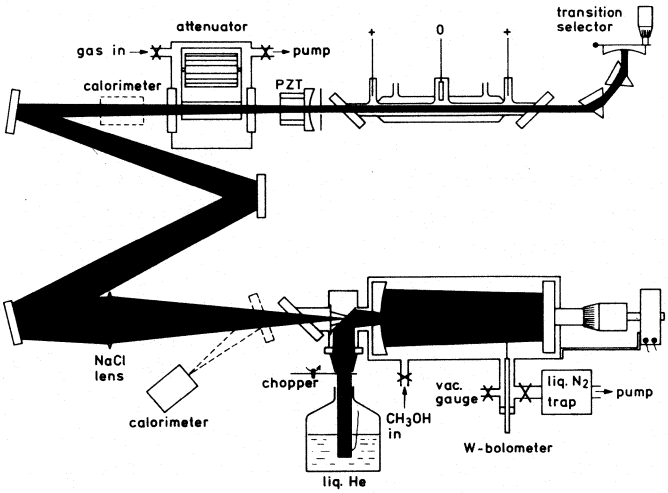

Fig. 2. Schematic diagram of the experimental arrangement.

Although the 570.5-μm line is listed in the literature as a single line [4], [6], [8], our experiments show that it consists of three components. The two strongest ones are of about equal strength, and separated by 1.3 MHz. The third, situated 0.4 MHz outside the doublet, is much weaker and could only be observed at a pressure of 6.5 mtorr. FIR output was observed over a CO_2 tuning range of about ±20 MHz, centered at an offset of +25 MHz relative to the CO_2 line center. Inside this range, the frequency separation between the two components as well as their relative amplitude, was essentially independent of pump frequency, pump power, and gas pressure, and also unaffected by various asymmetric perturbations of the cavity. We therefore conclude that the doublet arises from transitions between two sets of nearly degenerate molecular energy levels, the degeneracy presumably being produced by the internal rotation of the molecule.

The cavity scans indicate that usually only one transition will oscillate at a time if the cavity is tuned to the corresponding line center. However, both transitions are pumped, and the main effect of the degeneracy is therefore to introduce a source of dissipation for the pump power. This can be accounted for through the factor ξ [see (13)], while the p and U dependences are left unchanged. At the highest values of pressure and pump power the overlap of the lines is substantial, and they tend to be pulled together. For this reason the measurement of gain width could not be extended beyond 50 mtorr.

Saturation Effects

The variation of P_{FIR} with pump power at different pressures is shown in Fig. 3. The nonlinear behavior below 20 mtorr shows that in this range saturation effects are impor-

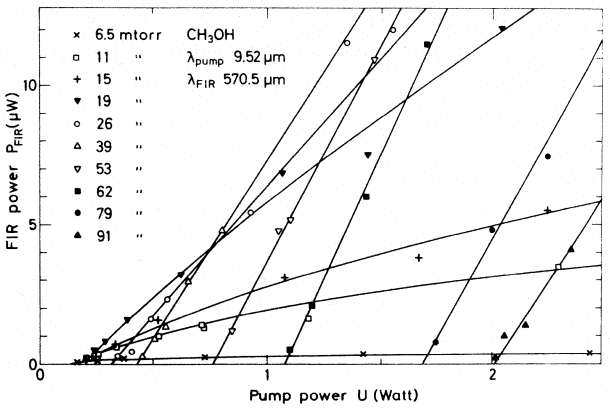

Fig. 3. FIR output as a function of pump power for various pressures. Solid lines are fitted to the theoretical expression.

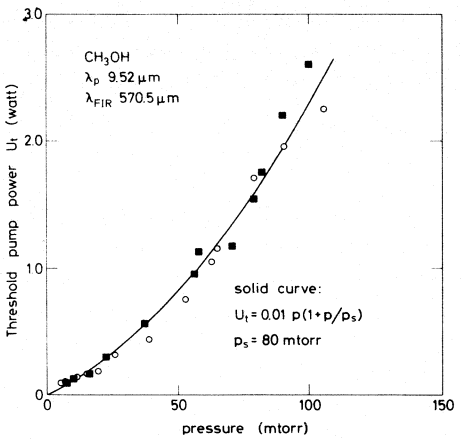

Fig. 4. Threshold pump power U_t as a function of pressure, different symbols denoting different runs. Solid curve is the theoretical prediction.

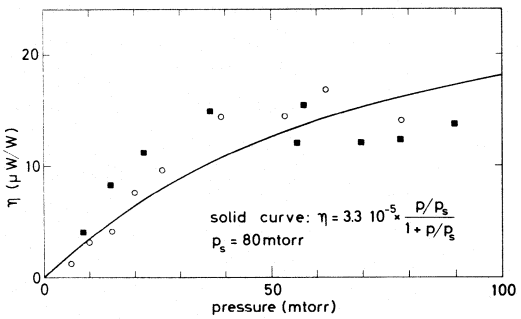

Fig. 5. Experimental values for conversion efficiency, different symbols denoting different runs. Solid curve is the theoretical prediction.

tant. Such effects have not previously been observed in this type of laser. A fit to (22) results in the solid lines of Fig. 3, yielding U_s values ranging from about 0.5 W at the lowest pressures to more than 5 W at 19 mtorr. These values are associated with a quite large uncertainty, particularly at the higher pressures where the deviation from linear behavior of P_{FIR} is small. From (18) it follows that the variation of U_s reflects that of w_v since, as will be shown in the following, we are in the limit $p \ll p_s$. The increase of U_s with pressure therefore indicates that w_v is determined by collisions, even though the large uncertainty precludes a reliable determination of its functional dependence on p.

Threshold Pump Power

A quantity of practical importance is the threshold pump power U_t, whose experimentally determined variation with pressure is shown in Fig. 4. Disregarding an insignificant correction from saturation effects at the lowest pressures, we find from (22)

$$U_t = \frac{p_s\, p}{G}(1 + p/p_s)\,(t + a). \tag{27}$$

In order to determine the possible pressure dependence of the loss parameter a, the absorption of FIR radiation in CH_3OH was measured in an external cell. It was found to have a weak p^2 dependence, the loss at 100 mtorr corresponding to only 0.01 percent per double pass of the cavity. This experiment would not give information about losses due to absorption of the FIR radiation by molecules in those levels, which are nearly degenerate with the lower laser level, since these are only populated under pumping conditions. However, such a loss term would depend on the pump power and hence change the U dependence of (22), and there is no experimental evidence for such a term. We may consequently take a to be independent of pressure.

The solid line in Fig. 4 represents the expression (27), using the parameters p_s = 80 mtorr and $p_s(t + a)/G$ = 0.01 W/mtorr. The overall agreement is good, but considering the two sets of data points independently, there are discrepancies which appear to be of a systematic nature. Due to the nonuniform pumping the pressure dependence of the pump intensity will vary from point to point in the resonator. A change in pressure then leads not only to a change in the total power absorbed, but also to a redistribution, and consequently the exact pressure dependence of U_t may be more complicated than predicted by (27).

According to (27) U_t should tend to zero in the limit $p \to 0$, but this is true only as long as the homogeneous linewidth $\Delta\nu_N$ is proportional to p [see (12)]. As p is reduced, $\Delta\nu_N$ will eventually reach a constant value, and this will lead to a finite lower limit for U_t. Our lowest measured threshold power is 0.1 W but the data are not sufficiently precise to decide whether this represents the limiting value.

Differential Conversion Efficiency

The differential conversion efficienty η is defined as the slope of $P_{\mathrm{FIR}}(U)$ in the unsaturated limit. We find from (22)

$$\eta = Q\frac{\nu}{\nu_p}\cdot\frac{t}{a+t}\cdot\frac{p/p_s}{1+p/p_s}. \tag{28}$$

Fig. 5 shows the measured values for η compared with the expression (28), using p_s = 80 mtorr as before, and adjusting the constant factor to yield a reasonable overall agreement. As for U_t, we expect the main source of the deviations to be the nonuniform pumping.

Frequency Dependence of the Small Signal Gain

Experimentally, we can determine the variation of the small signal gain with frequency by making use of its known dependence on pump power. At the threshold for oscillation the small signal gain always equals the total losses. Thus compar-

ing the two threshold pump-power levels U_t and $U > U_t$, corresponding to the center frequency ν_0 and a detuned frequency ν, respectively, we find by using (20)

$$\frac{g(\nu(U))}{g(\nu_0)} = \frac{U_t}{U}\frac{1 + U/U_s}{1 + U_t/U_s}. \tag{29}$$

The desired variation can be derived from this expression by measuring, as a function of pump power, the range of cavity tuning over which oscillations can be sustained. Fig. 6 shows the result of such a procedure, plotted so as to reveal Lorentzians as straight lines. The gain width (FWHM) is shown as a function of pressure in Fig. 7, and it follows the expression (12) with C = 38 MHz/torr, down to about 20 mtorr. This confirms our *ab initio* assumption of homogeneous broadening of the $1 \rightarrow 2$ transition.

The Doppler width of the transition is 1.15 MHz, using a temperature of 300 K. Fig. 7 clearly shows that the gain width goes below this value at low pressure, and the excited molecules can therefore not have a Maxwellian velocity distribution. We see this as a consequence of the monochromatic pumping. The Doppler width of the $0 \rightarrow 2$ transition is of the order of 70 MHz, so that the pump radiation interacts with molecules inside a very narrow velocity range only. Consequently, the Doppler width of the $2 \rightarrow 1$ transition will be suppressed. Two effects counteract this velocity selective pumping. Power broadening may lead to a broader velocity distribution if the pump transition is saturated [9]. However, since all the data points of Fig. 7, possibly excluding the one at 6.5 mtorr, can be derived by considering the unsaturated limit $U \ll U_s$, this appears to play a minor role. Further, velocity cross relaxation inside the excited level will tend to restore the Maxwellian velocity distribution [10]. The rate at which this takes place in CH_3OH is not known, but we may take as a guideline the value 12 MHz/torr obtained for CO_2 in [10]. From (7), (11) the rate $B_{21}n$ of stimulated emission is estimated to be about 20 MHz at a FIR output of 10 μW, and this indicates that the Doppler profile cannot be restored before the molecules have left the 2 level.

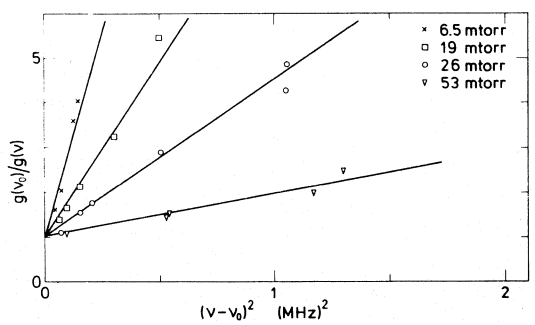

Fig. 6. Determination of the gain-curve line shape, straight lines corresponding to Lorentzians.

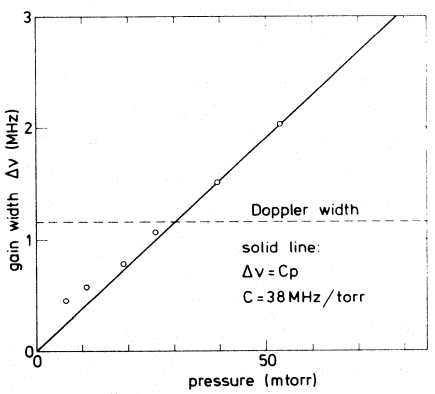

Fig. 7. Gain width (FWHM) as a function of pressure.

Below 20 mtorr the gain width levels off and approaches a constant value of 0.4 MHz. An estimate shows that time-of-flight effects lead to a much smaller linewidth, but the effect could be caused by velocity cross relaxation. Most likely, however, it arises from the finite cavity half-width which is estimated to be about 0.3 MHz, and which limits the experimental resolution.

IV. Conclusion

The four-level model described in this paper accounts reasonably well for pressure and pump-power dependences observed in a study of the 570.5-μm line of CH_3OH, the main discrepancies being attributed to nonuniform pumping. By studying the pressure dependence of the gain width, it is shown that the laser is homogeneously broadened down to at least 20 mtorr. In this range the gain width is smaller than the Doppler width of the laser transition due to the monochromatic pumping process.

Near Single-Line Operation of a Free-Burning $CS_2/O_2/N_2O$ Flame Laser with a Nondispersive Optical Cavity

KENNETH D. FOSTER, GEORGE H. KIMBELL, AND DAVID R. SNELLING

Abstract—The $CS_2/O_2/N_2O$ flame laser has been operated for the first time under conditions in which the spectral output is nearly single line. This transition is the $P_{10\text{-}9}(17)$ of CO at 5.4265 μm, the same transition which was observed to oscillate in single-line fashion by Hirose *et al.* in an electrically initiated CO chemical laser. It is suggested that the unique behavior of this line may be due to its close proximity to a P branch transition in an adjacent band, namely the $P_{9\text{-}8}(23)$ line, such that the gain profiles of the two lines overlap. Calculations suggest that at the conditions of these experiments, the separation of the line centers for this pair is about 0.3 Å or less.

The $P_{10\text{-}9}(17)$ transition was also found to be totally absent under certain conditions of high multiline power, particulary at low O_2 and N_2O flows. This may be due to absorption by a high-band R branch transition at 5.4266 μm, namely the $R_{15\text{-}16}(32)$ line.

I. Introduction

INTEREST in the efficient conversion of chemical energy into laser energy led to a great deal of research into the hydrogen halide, hydrogen halide-CO_2 transfer, and CO chemical lasers. Most of these lasers rely on initiation of the important chemical reactions by injection of electrical energy into the system.

The first purely chemical continuous-wave (CW) laser was the DF-CO_2 transfer laser [1], where the F atoms required for initiation were formed by the reaction of NO with F_2.

A particularly interesting avenue of research for a chemical CW laser is the study of flame excitation processes. In 1970 Foster and Kimbell [2] reported intense infrared radiation (IR) from flames of carbon disulfide and oxygen. This radiation was identified as emission from vibrationally excited CO formed in the flame. The observation of radiation from high vibrational levels of CO indicated that the vibrational temperature of the CO far exceeded the flame temperature. Under certain conditions vibrational population inversions were found to exist in the flame.

Later studies of the electrically assisted CS_2/O_2 chemical laser [3], [4] (the O atoms were produced in an electrical discharge) showed that the chemical mechanism responsible for the laser action near 5 μm was the following:

$$O + CS_2 \longrightarrow CS + SO \tag{1}$$

$$S + O_2 \longrightarrow SO + O \tag{2}$$

$$O + CS \longrightarrow CO^{\dagger} + S. \tag{3}$$

The pumping reaction (3) was shown to produce vibrationally excited CO with almost 90 percent of the reaction exothermicity going into CO vibration [5]-[8]. This rather simple mechanism is obviously not adequate at the elevated temperatures present in a free-burning flame of CS_2 and O_2. At temperatures of about 1000 K reactions such as

$$SO + O_2 \longrightarrow SO_2 + O \tag{4}$$

$$SO + SO \longrightarrow SO_2 + S$$

$$\longrightarrow S_2O_2 \longrightarrow S_2O + O \tag{5}$$

become important.

Pilloff *et al.* measured gain [9] and later achieved laser action [10] in CS_2/O_2 flames. Addition of N_2O was found to increase the output power up to 0.6 W [11].

Improvement of the efficiency and total power of the $CS_2/O_2/N_2O$ laser has been reported by Linevsky and Carabetta [12]. These authors found N_2O to have an even more striking effect than did Searles and Djeu [11]. A thirty-fifty-fold increase in output power was observed when N_2O was added. In electrically assisted CS_2/O_2 chemical lasers, the role of N_2O is believed to be principally one of depopulating the lower vibrational levels of CO due to vibrational-vibrational (V-V) energy transfer [13]. At the elevated temperatures present in flames, it has also been suggested [12] that N_2O may participate in the flame chemistry. In a footnote of [12] the authors report output powers of some 25 W and chemical efficiencies of 2.5 percent. Spectroscopic studies of the laser output spectrum showed lasing to occur from the $v = 12 \longrightarrow 11$ band near 1790 cm^{-1} to $v = 5 \longrightarrow 4$ band near 1980 cm^{-1}.

We describe here what is believed to be the first observation of a nearly single-line operation in the $CS_2/O_2/N_2O$ flame laser under certain conditions of gas mix. No dispersive elements were used in the optical cavity. Laser output spectra having somewhat higher resolution than those reported previously [12] are also given.

II. Experimental

The burner which was used in this study was 43 cm long and was constructed primarily of aluminum. A schematic representation of the essential features of the burner is shown in Fig. 1. The O_2 and N_2O flows were premixed and liquid carbon disulfide was injected into a vaporizer by using a suction feed through a fine control needle valve. The vaporizer consisted of an aluminum cylinder about 15 cm long and 10-cm radius half-filled with solid copper chunks. The outside of the cylinder was wrapped with heating tape. A 12-l ballast volume was inserted immediately downstream of the vaporizer to

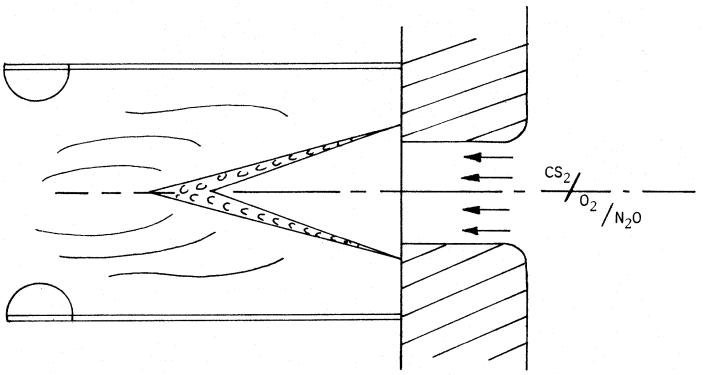

Fig. 1. $CS_2/O_2/N_2O$ flame and burner shows unburned-gas, flame-front, and burned-gas regions. The laser axis is just upstream from the apex of the flame front.

minimize pressure fluctuations. The CS_2 vapor then passed through a sonic orifice of known dimensions into the premixed O_2/N_2O stream at a pressure of about 70 torr. After allowing enough flow time to ensure complete mixing this $CS_2/O_2/N_2O$ stream was spread the length of the burner and underwent a pressure drop across some 200 small channels down to the ambient pressure in the flame region of about 30 torr. At the exit of these channels, the flow was allowed to "settle" through a 3-cm × 40-cm channel extending some 10 cm in the flow direction. Finally, the flow was narrowed to a 1-cm × 40-cm slot giving a linear velocity of 10–15 ms^{-1} to the unburned gas as it entered the flame region. The flame shape relative to the burner is shown as the shaded area in Fig. 1. The side walls were found to render the flame more stable. A small auxiliary flow of N_2 was added through the window supports to prevent sulfur deposition and a larger flow (about five to ten times the total combustible flow) of ballast N_2 which was added downstream of the combustion chamber in order to dilute and cool the hot product gases.

Representative flows for the experiments described here were $CS_2 \sim 2.5$ mmoles/s; $O_2 \sim 30$ mmoles/s; $N_2O \sim 7$ mmoles/s. The total pressure in the combustion chamber was kept between 25 and 35 torr for most experiments.

The optical cavity consisted of a 10-m radius of curvature total reflector of the protected metal type and a 98-percent reflectivity germanium partial reflector of 10-m radius of curvature. The optical axis was centered slightly upstream of the apex of the flame front.

Total power measurements were performed with a coherent radiation power meter.

Some spectroscopic measurements were conducted with a CO spectrum analyzer (Optical Engineering Inc.) having a nominal resolution of 0.0024 μm, determined largely by the thermosensitive display screen. For these experiments the laser beam was focused on the entrance slit. The slit was then used to control the radiant flux on the display screen. The display screen was photographed using a Polaroid camera mounted on the instrument.

For higher resolution measurements, a 1-m McPherson instrument (Model 2051) was used with 50-μm slits and a 150-1/mm grating blazed for 4 μm. The laser beam was chopped at 680 Hz and detected with a Mullard Labyrinth InSb detector whose output was connected to a lock-in amplifier (PAR-HR8). Rapid recording (2000 A/min) was accomplished by use of a visicorder (Honeywell Model 906B). The wavelength was calibrated with a HeNe laser in the 8th, 9th, and 10th orders.

III. Results

The maximum output power that has been observed in the present flame laser is 15.5 W at a CS_2 flow rate of 2.5 mmoles/s. The flows of N_2O and O_2 were 6.3 mmoles/s and 31.5 mmoles/s, respectively, and the total pressure was 31.5 torr. This corresponds to a chemical efficiency based on the reaction $O + CS \longrightarrow CO + S + 80$ kcal/mole, of about 2 percent.

Thermocouple measurements of the flame temperature, under conditions of lower CS_2 flow rates than those used in the preceding, indicated the temperature reached a maximum of about 1000 K. Linevsky and Carabetta [12] have measured maximum temperatures of approximately 1300 K for flow rate and total pressure conditions similar to those described here. They have found that the gain region is slightly upstream of the flame in the front in the unburned gas region and estimate the temperature in this region to be (800 ± 200)K.

Preliminary laser output spectra were taken using a CO spectrum analyzer. This proved to be a very convenient instrument since the whole spectrum was displayed at one time on a thermosensitive screen having wavelength and frequency scales. Experiments involving the effects of gas mix on the laser output spectrum could be performed in a short period of time. The effect of N_2O on the laser output spectrum was as follows. With a flow of N_2O of 6.31 mmoles $\cdot s^{-1}$ there were approximately 32 lasing lines. An increase in N_2O flow to 11.1 mmoles $\cdot s^{-1}$ resulted in the appearance of only about 20 lines. Of these lines the most dominant appeared at 5.423 μm. This line was absent from the spectrum at the lower N_2O flow. A further increase of the N_2O flow to 12.7 mmoles $\cdot s^{-1}$ showed approximately ten weak lines and one intense line again at 5.423 μm.

The dependence of the laser output spectrum on O_2 flow was found to behave in a manner similar to that of N_2O. With an oxygen flow of 32 mmoles/s and 13.2 mmoles/s of N_2O the spectrum was nearly single line. As the O_2 flow was reduced to 25 mmoles/s more lines appeared and the 5.423-μm line became very weak. With a further reduction in oxygen to 20 mmoles/s the spectrum was multiline but again with no line at 5.423 μm. This line, at 5.423 μm on the display screen, corresponds to the $P_{10\text{-}9}$ (17) line.

On the basis of the preceding results, it was decided to examine the CO flame laser output spectrum at higher resolution.

The 1-m McPherson was used with both entrance and exit slits set at 50 μm. Measurements of a single line indicated that the resolution of the instrument (by the Rayleigh criterion) was approximately 0.16 cm^{-1}. Linevsky and Carabetta's [12] flame-laser spectra using an interferometer have a stated resolution of approximately 0.5 cm^{-1}.

The output spectra are shown in Fig. 2. The upper multiline spectrum was taken under the following flow conditions $CS_2 = 2.15$ mmoles/s, $O_2 = 28.6$ mmoles/s, $N_2O = 5.41$ mmoles/s. The total pressure was 35.8 torr and the total multiline laser power was about 11 W. Even with the present resolution some lines are not resolved so that assignment is somewhat ambiguous. However, certain closely spaced lines

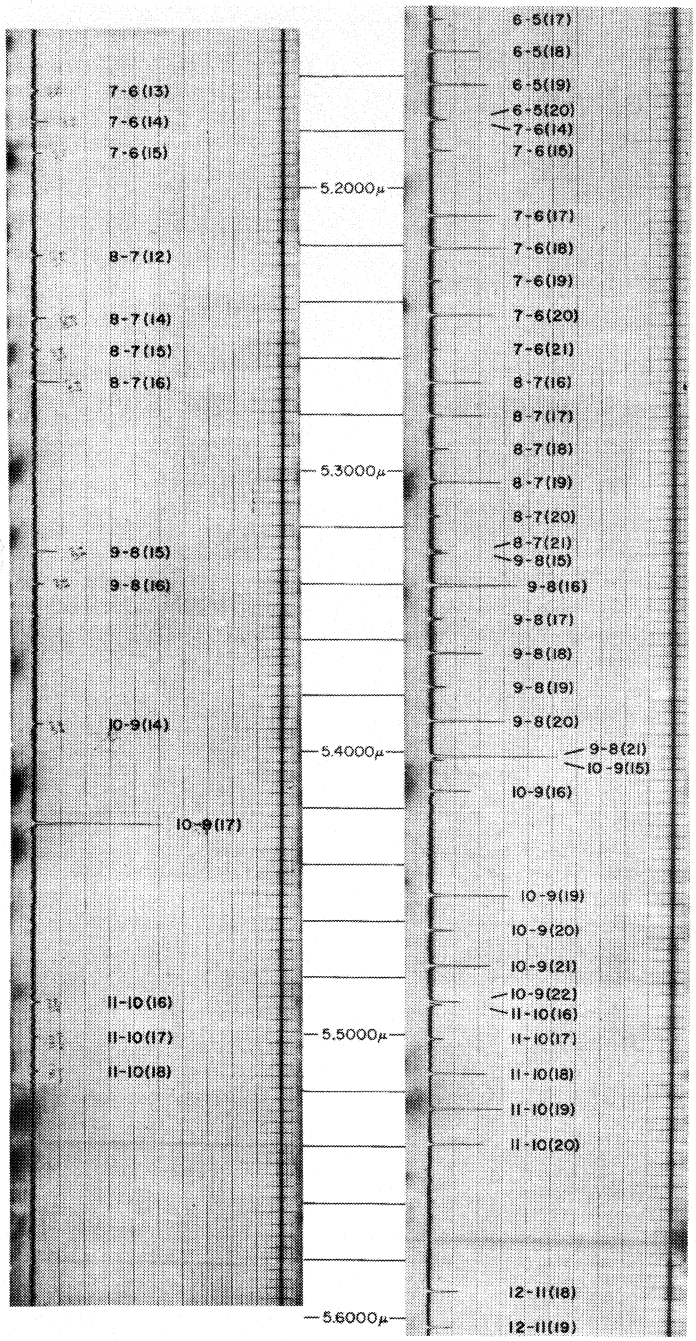

Fig. 2. Photos of high resolution spectra (RN 0.16 cm^{-1}) for multiline and near single-line conditions. $P_{v-v^1}(J^1) \equiv v\text{-}v^1(J^1)$.

are resolved which were not resolved with the CO spectrum analyzer. Three lines are notable by their absence: $P_{7\text{-}6}$ (16), $P_{10\text{-}9}$ (17), and $P_{10\text{-}9}$ (18). The $P_{10\text{-}9}$ (17) line is the line which was found to behave in a peculiar fashion during the experiments using the spectrum analyzer so that its absence under these conditions was not unexpected. The other two lines, however, i.e., $P_{7\text{-}6}$ (16) and $P_{10\text{-}9}$ (18), were seldom observed in any of our spectra. It should be pointed out that these two lines were also absent from Linevsky and Carabetta's spectra.

The lower spectrum shown in Fig. 2 was obtained under conditions which were previously shown to give a near single-line output, i.e., at higher N_2O and O_2 flows than for the multiline spectrum. The $P_{10\text{-}9}$ (17) line indeed predominates and represents about 65 percent of the output power at these conditions. The following flows were used for the near single-line operation: $CS_2 = 2.2$ mmoles/s, $O_2 = 32.6$ mmoles/s, $N_2O = 10.1$ mmoles/s. The total pressure was 31.8 torr and the laser output power was 1-1.5 W.

IV. Discussion

Single-line operation of an electrically excited CS_2/O_2 chemical laser has been observed previously [14]. This was a longitudinal flow system employing a diluent helium flow and a total pressure of 10.5 torr. Single-line output was observed on the $P_{10\text{-}9}$ (17) line at 5.426 μm, the same line which was found to dominate in the present flame laser. This single-line operation was attributed [14] to V-V coupling sufficiently rapid that CO vibrational level populations equilibrate faster than the stimulated emission rate. Laser oscillation was then supposed to occur on only the highest gain line with the other lines kept below threshold. It was suggested that the conditions of temperature and pressure employed in their experiment thus resulted in single-line operation.

The fact that near single-line operation on the same line has been obtained in the present $CS_2/O_2/N_2O$ flame laser, which operates at very different conditions than the preceding longitudinal laser, suggests that the preceding explanation of rapid V-V coupling may not be sufficient to explain the preceding effect. The question which may be raised then is: "Why should the $P_{10\text{-}9}$ (17) line have the highest gain in both systems?"

It is therefore suggested that besides the previously mentioned rapid V-V coupling, the tendency for single-line operation is due to something unique about the $P_{10\text{-}9}$ (17) line itself. Tabulated values of the various wavelengths for CO fundamental transitions reveal a near coincidence between the $P_{10\text{-}9}$ (17) line (1842.818 cm^{-1}) and the $P_{9\text{-}8}$ (23) line (1842.824 cm^{-1}). The CO line positions were calculated from a recent determination of the molecular constants given by Roh and Rao [15].

These molecular constants reproduce most of the observed CO line positions within ±0.005 cm^{-1} for CO P branch lines. If the separation of the $P_{10\text{-}9}$ (17) and $P_{9\text{-}8}$ (23) line centers is of the same order as the isolated linewidth, then the gain profiles for the two lines will overlap, i.e., a photon emitted in the process $v = 10, J = 16 \longrightarrow v = 9, J = 17$ can be amplified in part by the inversion between $v = 9, J = 22$ and $v = 8, J = 23$. Unfortunately, sufficiently accurate wavelengths of these transitions are not available.

One experiment which would help explain the behavior of this line would be to scan the cavity length with one mirror mounted on a piezoelectric translator. This would entail operation on the axial transverse mode and a cavity length such that the longitudinal mode separation was greater than the linewidth. For geometrical reasons, such an experiment was not performed with the apparatus described herein.

In order to examine the effect of the line center separation on the gain profile, approximate CO linewidths have been calculated using an empirical expression for the Voight profile [16]. For the purposes of this calculation, the gas in the active region of the flame laser was assumed to consist of CO, O_2, and N_2O. The mole fractions of the components were set

at 0.053, 0.631, and 0.316, respectively, and the total pressure was put at 30 torr. These conditions coincide approximately with the near single-line conditions which were observed. The self-broadening cross section for CO was computed from data by Williams *et al.* [17]. The broadening cross section for N_2O was assumed to equal that for CO_2 which was obtained from the same source. The broadening cross section for O_2 was estimated from the formula

$$\sigma_{opt}(CO\text{-}O_2) = \sigma_{opt}(CO\text{-}X) \cdot \frac{\sigma_{coll}(CO\text{-}O_2)}{\sigma_{coll}(CO\text{-}X)}$$

where

$\sigma_{opt}(CO\text{-}O_2) \equiv$ broadening cross section of O_2

$\sigma_{opt}(CO\text{-}X) \equiv$ broadening cross section of species X

$\sigma_{coll}(CO\text{-}O_2)$, $\sigma_{coll}(CO\text{-}X) \equiv$ hard sphere collision cross sections for $CO\text{-}O_2$ and $CO\text{-}X$ collisions, respectively.

Values of $\sigma_{opt}(CO\text{-}X)$ were taken from the data of Williams *et al.* for $X \equiv$ Ar, N_2, and H_2. The resultant values of $\sigma_{opt} \cdot (CO\text{-}O_2)$ were 55.2 A^2, 59.1 A^2, and 55.3 A^2, respectively. The average value of 56.5 A^2 was then used in subsequent calculations. In view of the slight J dependence of the cross section [16], the preceding cross sections were computed for $J = 20$ to be

$$\sigma_{opt}(CO\text{-}CO) \simeq 70.3\ A^2$$

$$\sigma_{opt}(CO\text{-}N_2O) \simeq 65\ A^2$$

$$\sigma_{opt}(CO\text{-}O_2) \simeq 56.5\ A^2.$$

The Doppler width was taken to correspond to a temperature of 800 K.

Lorentzian and Doppler widths, determined from the preceding data to be 64 MHz and 211 MHz, respectively, were then employed in the empirical approximation to the Voight profile of Whiting [16] in order to obtain a normalized gain profile. Fig. 3 shows the extent of overlap for two equally intense lines at various line center separations. It will be noted, for instance, that at a line center separation of three Voight widths (i.e., 0.723 Å for the conditions used here) and a Lorentzian to Voight width ratio of 0.261 the central valley is about 5 percent of the two isolated peak heights. The fractional increase in peak gain as a function of line center separation is shown in Fig. 4, again assuming equally intense lines. The peak gain is seen to be 10 percent greater than that for the isolated lines at a line center separation of about 1.2 Voight widths or about 0.29 Å. If the proposed explanation for the tendency to operate on a single line is correct, and the peak gain for the line at 5.4265 μm is augmented because of an overlap between the $P_{10\text{-}9}$ (17) and $P_{9\text{-}8}$ (23) profiles, then the line centers must be within about 0.3 Å (or 0.01 cm^{-1}) of each other.

The absence of the line at 5.4265 μm under conditions where the overall multiline power is high is difficult to explain by the preceding argument. In view of the dependence of the gain on J as shown in [18], it is difficult to envisage a situation where gain on $P_{10\text{-}9}$ (17) would be offset by a loss on

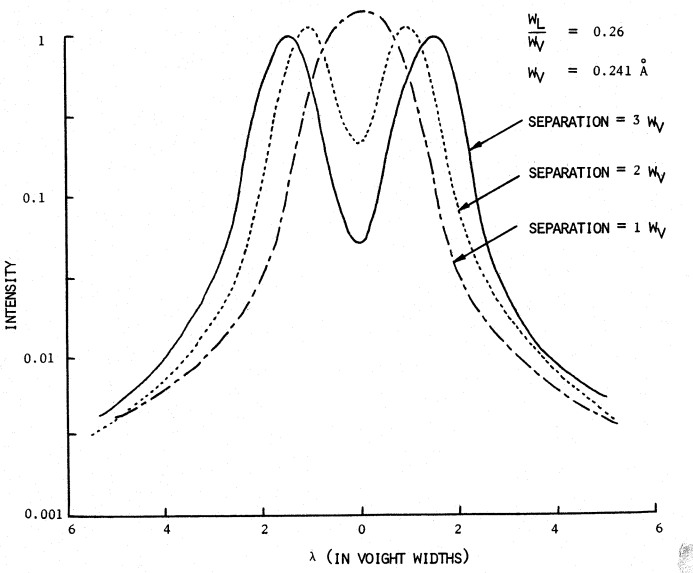

Fig. 3. Dependence of the extent of overlap on the line center separation assuming equal intensities for isolated lines, $W_1 \equiv$ Lorentzian width full width at half maximum (FWHM), $W_v \equiv$ Voight width (FWHM).

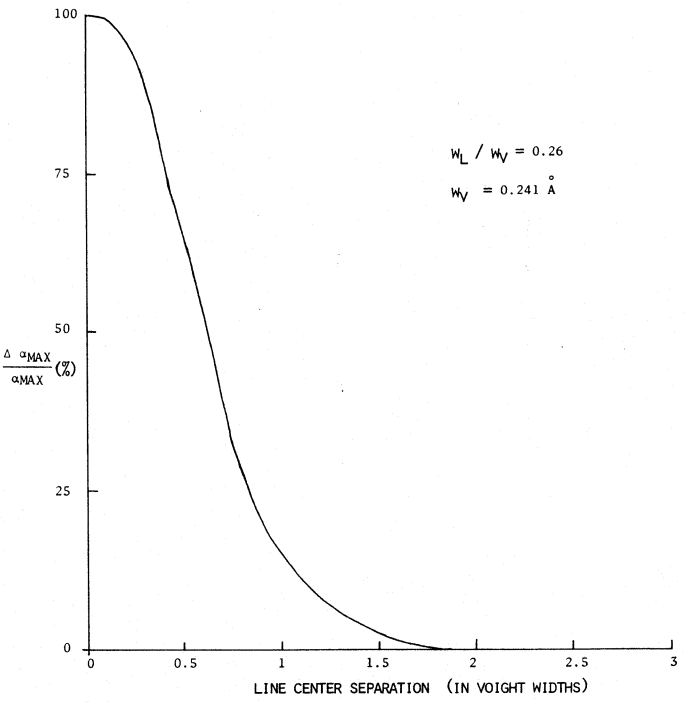

Fig. 4. Fractional increase in peak gain coefficient as a function of line center separation.

$P_{9\text{-}8}$ (23) or vice versa such that the line did not lase since they are both P branch lines of adjacent bands. Only if there was a sharp difference in the N_{10}/N_9 and N_9/N_8 inversion ratios could this circumstance prevail. It is possible, however, that if an R branch line of high J number overlapped with $P_{10\text{-}9}$ (17), then $P_{10\text{-}9}$ (17) radiation would tend to be absorbed. Examination of the wavelengths of the CO R branch transitions indicates the existence of a line at 1842.819 cm^{-1} in the 16-15 band, namely, the $R_{15\text{-}16}$ (32) transition. Although the existence of these high v CO molecules was not confirmed directly in the present experiments, they have been

found to be present in previous CS_2/O_2 experiments (see, for example, [8]).

The molecular constants for CO (15) give the following line positions: $P_{10\text{-}9}$ (17) 1842.818 cm^{-1}, $P_{9\text{-}8}$ (23) 1842.824 cm^{-1}, and $R_{15\text{-}16}$ (32) 1842.819 cm^{-1} [14]. It can be seen that, within the experimental error of ± 0.005 cm^{-1}, the three lines are coincident.

The absence of $P_{10\text{-}9}$ (17) under conditions of low O_2 and N_2O flows, as well as the predominance of $P_{10\text{-}9}$ (17) with high O_2 and N_2O flows does lend some support to this explanation of R branch absorption. If the absence of $P_{10\text{-}9}$ (17) is indeed due to R branch absorption in the 16-15 band then the addition of O_2 will preferentially lower the populations in high v levels and hence remove absorbers from the system by the V-V transfer process

$$CO_{v=15} + O_2 \longrightarrow CO_{v=14} + O_{2\,v=1} + 222\ cm^{-1}.$$

The peak at $P_{10\text{-}9}$ (17) will therefore increase in intensity with increasing O_2. The rate constant increases, for example, from 2.1×10^{-14} $cm^3 s^{-1}$ for $CO_{v=12}$ to 4.4×10^{-14} $cm^3 s^{-1}$ for $v = 13$ [19].

It is noteworthy that this unique behavior of the $P_{10\text{-}9}$ (17) line has manifested itself in pulsed chemical CO lasers. In the first report by Pollack [20] of chemical laser action in the CS_2/O_2 system using a flash, the highest J number P branch line for any of the bands was P (14) except for the 10-9 band which showed lasing lines at $P(10)$, $P(11)$, $P(12)$, $P(13)$, and $P(17)$. Jacobson and Kimbell [21] observed a similar effect in their TEA-style CS_2/O_2 laser, i.e., the anomalous presence of the $P_{10\text{-}9}$ (17) line.

The possibility of vibrational-rotational cascades caused by the radiation field should be considered. The fact that it is possible to achieve a condition of near single-line operation indicates that cascade pumping of other lines by the $P_{10\text{-}9}$ (17) line apparently does not occur. Cascade pumping of vibrational-rotational lines should be most important under conditions where the rate of stimulated emission exceeds the rate of rotational relaxation, thereby allowing individual rotational levels to have nonequilibrium populations. In the present system, the $P_{10\text{-}9}$ (17) line would cascade pump the $P_{9\text{-}8}$ (18) line only if the population of the $v = 9, J = 17$ level were significantly increased by the $P_{10\text{-}9}$ (17) radiation. Similar considerations apply to cascade pumping of the $P_{11\text{-}10}$ (16) line. Calculations by Coleman *et al.* [14] suggest that the rate of V-V coupling may exceed the rate of stimulated emission in the longitudinal flow system. This would likely apply to the present flame system as well which operated at a higher temperature and pressure than the longitudinal system. Hence the rate of rotational relaxation will also exceed the stimulated emission rate. Under these conditions radiation from the $P_{10\text{-}9}$ (17) line should have the effect of slightly raising the populations of all accessible J levels in the $v = 9$ level. Also one would expect a concomitant decrease of populations of J levels in the $v = 10$ level. As pointed out in [14], however, vibrational relaxation itself is very rapid. This will greatly reduce the buildup in population in $v = 9$. To sum up, the absence of cascade pumping by the $P_{10\text{-}9}$ (17) transition is probably a reflection of the very rapid rotational and vibrational relaxation processes in relation to the rate of stimulated emission. Perturbations in populations caused by the $P_{10\text{-}9}$ (17) line are rapidly spread over many rotational and vibrational levels. Moreover, other potential transitions do not have the benefit of an augmented gain due to overlap of the gain profiles. Apparently, the resultant change in any single v, J level population is insufficient to result in cascade pumping.

In view of the possible importance of overlap of line profiles a search was made of CO transitions to determine whether other overlaps occurred. Vibrational levels up to 20 and J values up to 35 were considered. Since the molecular constants in [15] are believed to predict the frequencies to ± 0.005 cm^{-1}, coincident transition pairs whose line positions differ by ± 0.01 cm^{-1} or less were found.

In the P branch, of 350 pairs of transitions considered, there were seven coincidences found within the limits indicated in the preceding. Of these, only one pair involved a transition within the lasing region in the present system (i.e., $v \sim 5$-12 and $J \sim 12$-25). This coincidence was between $P_{10\text{-}9}$ (17) and $P_{9\text{-}8}$ (23) with frequency difference of 0.006 cm^{-1}.

To examine possible absorption effects, a search was made for coincidences between P and R branch lines. Some 16 coincidences between line pairs were found according to the preceding limit of 0.01 cm^{-1}. Of these, six involved a P branch transition within the lasting region of the present system. Both the P-P and P-R coincidences are shown in Table I. Two of the P-R pairs reflect the three-way coincidence namely, $P_{10\text{-}9}$ (17), $P_{9\text{-}8}$ (23), and $R_{15\text{-}16}$ (32). The adjacent

line P_{10-9} (18) is noted with its coincidence with R_{14-15} (19). The absence of the lines P_{12-11} (21), P_{12-11} (16), and P_{11-10} (21) from the laser output spectrum may also be partly attributable to R branch absorption through the coincidences indicated in Table I. However, the absence of one other line, the P_{7-6} (16) is not explainable by R branch absorption.

V. Summary and Conclusions

Laser output spectra for the $CS_2/O_2/N_2O$ flame laser revealed that the laser line at 5.4265 μm, namely, the P_{10-9} (17) line was very sensitive to the O_2 and N_2O flow rates in the system. Under conditions of high O_2 and N_2O flow a nearly single-line condition was found where the line at P_{10-9} (17) accounted for about 65 percent of the total laser power.

It is suggested that the behavior of this line can be explained by invoking an overlapping line profile argument. The proximity of a nearby line, the P_{9-8} (23), may be such as to permit significant overlap of their gain profiles. Linewidth calculations suggest that for the conditions of these experiments the line centers would have to be within about 0.3 Å (0.01 cm^{-1}) of each other to significantly affect the peak gain of this line pair.

The absence of the P_{10-9} (17) line under certain high multiline power conditions and the dependence of this line intensity on the O_2 partial pressures may be due to absorption by the R branch line R_{15-16} (32). Similarly, the absence of other P branch lines under most conditions may be attributable to R branch absorption.

Interferometric Measurements of the Nonlinear Refractive-Index Coefficient Relative to CS_2 in Laser-System-Related Materials

MICHAEL J. MORAN, CHIAO-YAO SHE, MEMBER, IEEE, AND ROBERT L. CARMAN

Abstract—**Using time-resolved interferometry, we have compared the nonlinear wavefront distortion induced by the simultaneous propagation of an intense light beam in pertinent sample materials relative to the known reference material. Utilizing several normalization techniques, these measurements have led to precise values for the nonlinear coefficient n_2 good to 10 percent.**

I. Introduction

BEAM PROPAGATION effects associated with an intensity-dependent index of refraction

$$n = n_0 + n_2 \langle E^2 \rangle \equiv n_0 + \Delta n \tag{1}$$

where $E(t) = \epsilon(t) \cos \{\omega_0 t - k_0 z - \delta\phi(z, t)\}$, have been an important consideration in the development of short-pulse high-peak-intensity laser systems. This is especially true for solid-state lasers. The radial dependence of the laser-beam intensity distribution leads to both gross spatial beam distortions [1] and small-scale fluctuation instabilities [2], while the time dependence of the intensity distribution leads to self-phase modulation [3] and optical shocks [4] (particularly when linear chromatic dispersion is important) [5]. For pulse durations near T_2 (the transition dephasing time) of the system, the presence of an intensity-dependent refractive index can further complicate the coherent pulse-propagation problem [6].

Because the small-signal or perturbation analysis of these effects involves exponentially growing Fourier components, the magnitude of n_2 must be accurately determined in order to characterize the propagation problem. Furthermore, the illumination of the mechanisms responsible for n_2 may provide avenues for further optimization of the laser materials.

Many methods [7] have been employed to measure n_2 or, more generally, the full tensor [8] $\chi^{(3)}_{ijkl}(-\omega, \omega, \omega, -\omega)$. A particularly attractive technique for performing this class of measurements is to use a Mach-Zehnder interferometer. The interferometric technique was first proposed [9] in 1968 in a form where the output fringe pattern was time integrated. The time-resolved output fringe pattern yields both much more information and better precision [10], [11] than previously used methods. However, elimination of systematic errors and the establishment of the actual peak laser intensity still limit the experimental accuracy of [10] and [11]. In this paper we describe some experiments performed with time-resolved interferometry and a 1-ns pulsed laser system. The experiments used a Mach-Zehnder interferometer, where one arm of the interferometer contained the sample of unknown nonlinearity and the reference arm contained a compensating CS_2 cell with the same linear optical path length and a known nonlinear response [12]. Thus n_2 was measured relative to CS_2 under conditions where systematic errors were removed and high precision was possible. Relative numbers were believed to be good to ±10-percent absolute accuracy.

Manuscript received October 30, 1974; revised February 10, 1975. This work was performed under the auspices of the U.S. Atomic Energy Commission.

II. Discussion of Experiment

In Fig. 1 we present a schematic of the basic experiment. The output beams from the interferometer were carefully overlapped spatially and temporally at the slit of an LLL ultrafast streak camera [13] (resolution ~10 ps). The camera was used to establish that the two interferometer arms had an equal path length to within 1.5 mm. This was further checked by obtaining interferometer fringes with a simple image-converter camera when a 20-ps-duration ruby-laser pulse was used to illuminate the interferometer. The interferometer beam splitters were uncoated and wedged glass substrates while the reflectors were 50-percent reflectivity mirrors, thus necessitating the preceding technique for linear path-length adjustment. Although the n_2 of CS_2 was typically 10–100 times that of the samples, the nonlinear phase delay was approximately the same in the reference and sample because of the different intensities in the two arms. By varying the relative

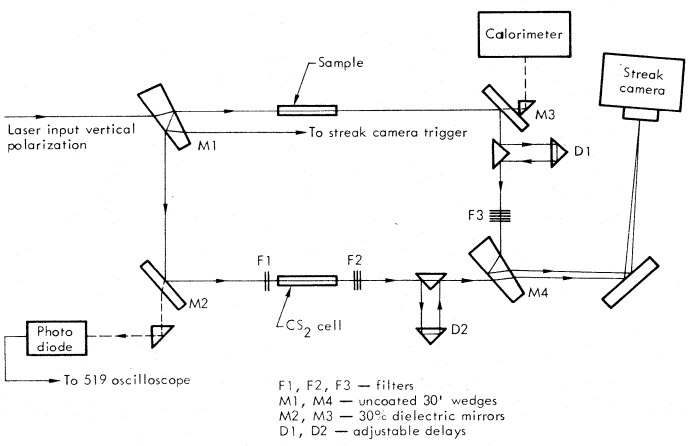

Fig. 1. Schematic of experimental arrangement.

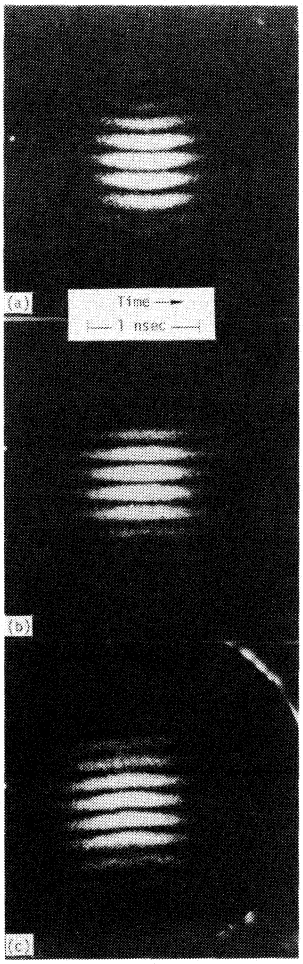

Fig. 2. Time-resolved fringe patterns. (a) Nonlinear delay greatest in ED-2 arm. (b) Nonlinear delay same in both arms. (c) Nonlinear delay greatest in CS_2 arm.

intensity between the two arms (using identical filters before the sample and after the CS_2 or vice versa), the relative phase delay in the arms was similarly varied. This was established using the streak camera to determine the interferometer fringe distortion as a function of time (and, consequently, intensity). When the fringe pattern is independent of intensity, both the nonlinear path length increases and the linear path lengths are the same for both arms. Under these conditions, the intensity ratio between the two arms is inversely proportional to the n_2 ratio of the samples. Fig. 2(a)-(c) illustrates the time-resolved fringe patterns used to determine the n_2 ratio.

For our measurements we used a Nd:YAG-Nd:glass laser system [14] capable of output energies as high as 1 J. The output pulse was spectrally bandwidth limited and spatially within 50 percent of the minimum uncertainty angle for our finite beam. The beam quality was important because amplitude or phase-modulated beams would have caused numerous experimental difficulties.

The experimental operating conditions were designed to allow the maximum possible phase delay in the samples without the presence of small-scale instabilities. The onset of self-focusing in the samples was accompanied by a "washing out" of the Mach-Zehnder fringes, as shown in Fig. 3. In order to obtain the required intensities for the experiment, but at the same time avoid nonlinear processes in the final laser amplifiers, the laser output beam was telescoped down to an approximate 2-mm full width at half maximum (FWHM) intensity diameter. The washing out of the interferometer fringes, together with the 2-mm beam diameter, limited the useful nonlinear optional path delay to $\frac{1}{2}$ wavelength. When no sample was present we further checked that a thin-lens analysis of the phase distortion in the CS_2 approximately predicted the magnitude of the time-resolved interference patterns. Here

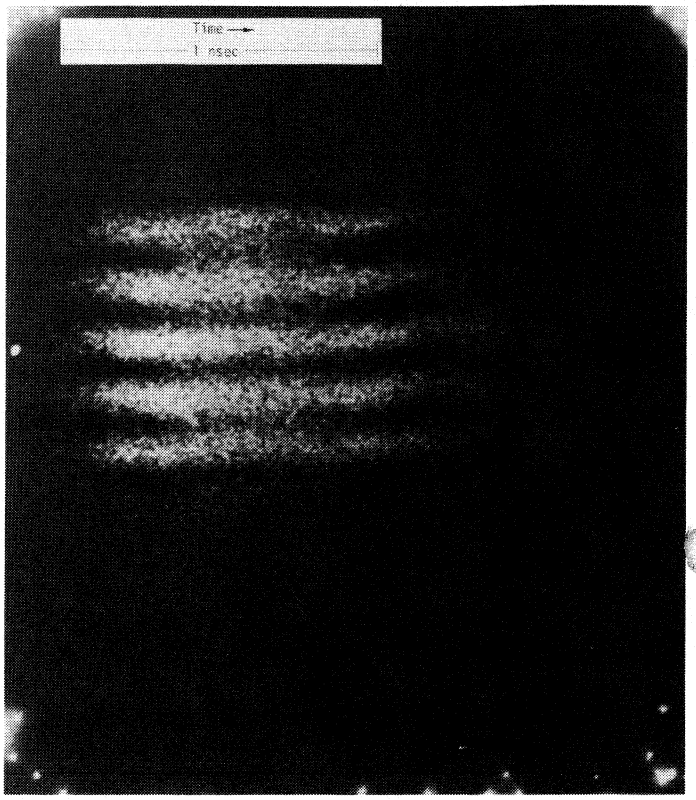

Fig. 3. Fringe pattern at self-focusing threshold intensity.

$$f_{\text{equivalent}} \approx \frac{a^2}{4\Delta n l} \simeq \frac{Z_{sf}^2}{n_0 l} \tag{2}$$

where a is the beam radius, l the cell length, Δn the nonlinear path increase, and Z_{sf} the self-focusing length for a semi-infinite medium.

Under certain experimental conditions the onset of this lensing was accompanied by a temporal breakup of the laser pulse. This effect was different from the washing out of fringes previously mentioned. It was most often observed when the beam waist was at or in front of the CS_2-cell entrance window. Fig. 4(a) shows streak pictures of the input and output laser pulses from a CS_2 cell. The output shows a mild lensing during the intense portion of the pulse with a random time structure imposed on the pulse envelope. The missing energy in this case was reflected back toward the laser with no dramatic frequency change. At roughly ten times the input energy, as in the previous case, the output beam self-focuses, and Fig. 4(b) shows the input and output pulses from the CS_2 cell under these conditions. The relative filtering be-

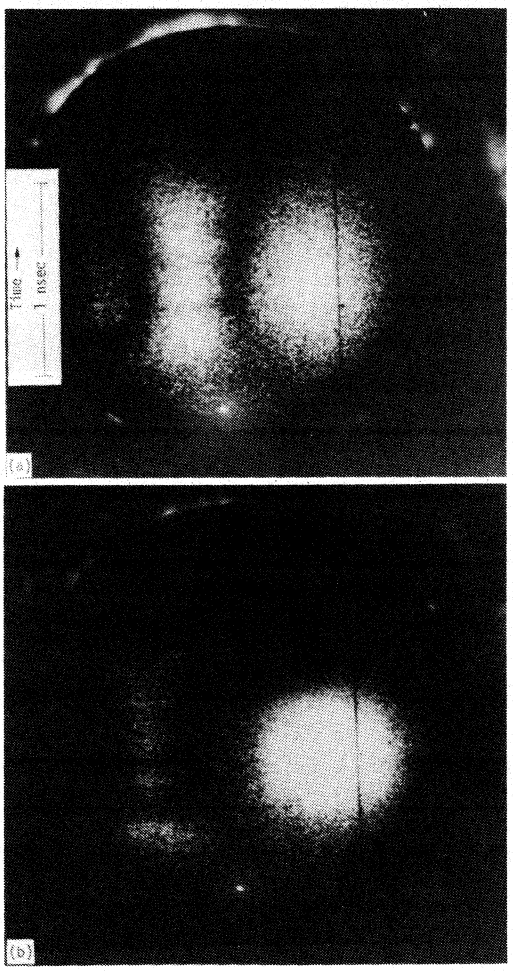

Fig. 4. Pulse time breakup. (a) Pulse intensity below self-focusing threshold. (b) Pulse intensity above self-focusing threshold. The dark line in these photographs is a small wire on the camera slit used to determine the streak direction.

tween the two output beams of Fig. 4(a) and (b) was the same, and it is interesting that roughly the same laser intensity was transmitted through the CS_2 cell in both situations. The unexpected temporal breakup was also observed with an SF_6 Schott glass rod at an intensity higher roughly by the ratio of the n_2. The mechanism for reflecting the light just prior to self-focusing has not been unequivocally established in our situation, but Owyoung [15] has attributed similar behavior to Brillouin scattering. When n_2 data were being taken we always avoided the conditions shown in Fig. 4(a) and (b). This was possible because the laser intensity was routinely reproducible to 20 percent.

By plotting and least squares fitting the relative fringe shift versus the relative pulse intensity, it was possible to obtain precise values for the ratio of the index change Δn for the sample to that for CS_2. It was not necessary to measure the absolute laser intensity to determine n_2 since the time history of the laser pulse in both arms of the interferometer is always the same, and both nonlinear elements have an instantaneous response. Therefore, only the relative pulse energies need be determined. The pulse energy ratios were determined using two LLL Gunn-type calorimeters [16] (good to ±1 percent) and previously calibrated neutral density filters (good to ~5

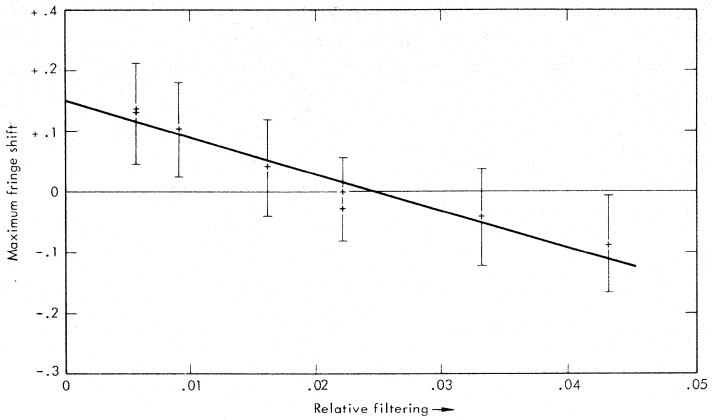

Fig. 5. Fringe shift versus relative filtering.

percent). The filters were calibrated at 1.06 mm with a Cary spectrophotometer[1] and were used at a position in the laser beam where they responded as linear attenuators, as was verified with calorimetry. A typical plot of the fringe distortion versus relative intensity including error bars is shown in Fig. 5. In order to compare data on different laser shots, as in Fig. 5, it was necessary to normalize all the plotted data to the same relative peak laser intensity, since the fringe shift is a function of both the relative and absolute laser intensity. We found that Tektronix 519 oscillograms[1] (system response 0.4 ns) were sufficiently accurate for this purpose.

III. Results

The results of the data taken on numerous materials are summarized in Table I. Since our data are in the form of a ratio, column 4 represents our output. In the absence of an absolute measurement of n_2 for CS_2 at 1.06 μm, we have used an absolute measure of n_2 in ED-2 by Speck and Bliss [11] together with our relative measurement of n_2 $(CS_2)/n_2$ (ED-2) to provide the absolute numbers quoted in column 5. This procedure allows estimation of absolute n_2 values with ±30-percent accuracy. For n_2 ratios measured here, the ~10-percent precision quoted is due to the normalization to the same laser peak intensity and the spatial resolution of the streak camera. With ~5-lines/mm resolution, a 25-mm slit, and six fringes on the slit, we are limited to ~25 resolution points between fringes. Using microdensitometry, we are able to measure $\frac{1}{30}$ of a fringe shift (with a total of $\frac{1}{3}$ fringe distortion) by enhancing the signal to noise somewhat through scanning several neighboring positions along the slit and taking advantage of the expected fringe symmetry. Another source of error was the absolute calibration of our filters. These errors can be reduced somewhat by performing the least squares fit to the data, as in Fig. 5, in the determination of the null condition from which n_2 is established. Practical limitations on alignment accuracy at the camera slit provided further limits on the overall accuracy of determinating n_2, but was not an important contribution here.

[e] Measurement performed with beam propagating along (111) axis with optical electric-field vector 45 from (01-1) axis.
[f] Manufactured by Schott Optical.

The data in Table I are not raw data, but have been corrected for several effects. We have taken into account Fresnel losses and beam cross-sectional changes associated with the tilted end faces of the sample rods. Furthermore, in relating the nonlinear phase change to the increase in the refractive index, we have used the k vector and optical field internal to the materials leading to the usual definition of n_2 internal $= n_0 n_2^{\text{vac}}$. For the Lucite measurement we have also corrected for the linear absorption at 1.06 μm.

The full third-order nonlinear susceptibility in question is, in general, a fourth-rank tensor, but for isotropic materials such as CS_2 or glass, there are only three independent elements of this tensor [15], [17]. When we further assume a monochromatic laser there are only two independent terms. It has been shown [15], [18] that n_2 for circularly polarized light versus linearly polarized light, a ratio of 2/3 for an electronic response is expected, while other ratios are to be expected when nuclear contributions are present. Table I shows for Nd:YAG and Schott SF_6 glass, where the two polarization measurements were made, the ratio is 2/3 to well within experimental error for SF_6 glass, while the ratio is 13 percent higher than 2/3 for Nd:YAG which is still within experimental error. Using a simple Stark-effect model including local field effects and only one judiciously chosen ultraviolet absorption (harmonic oscillator) frequency [19], the magnitudes and ratios of n_2 for the solids listed in Table I can be fairly well predicted. Also we note, as expected, that changing the Nd concentration for a given host-glass composition does not produce a measurable change in n_2, while changing the host glass can lead to significant differences in n_2. Our measurement found the n_2 of ED-2 to be lower than the n_2 of the American Optical glasses, but other measurements at 6943 Å [15], [20] have found the opposite result for similar glass compositions. This difference probably indicates that n_2 is a function of excitation frequency, as expected from the Stark-effect model [19].

IV. CONCLUSIONS

In rating materials as candidates for lasers or laser systems, it is important to recognize that the absolute magnitude of n_2 is not the only important consideration. Inhomogenieties in the linear refractive properties of the materials will broaden the spatial Fourier spectrum, enhancing the growth of small-scale instabilities and ultimate beam breakup [2]. When considering the third-order nonlinear refractive-index effects, the significant parameter is the minimization of the nonlinear phase change, which is an integral over the optical path length to be propagated. In unsaturated gain but amplifying media, a more meaningful comparison of materials is obtained if values of n_2/g are used, where l/g is referred to as the gain length obtained in the amplifier in question.

There are other kinds of materials used in laser amplifier chains in addition to amplifiers, and they have nonlinear figures of merit which also are not generally just the magnitude of n_2. It is important to include the expected length l required of Faraday rotator glass, for example, leading to $n_2 l$ as the nonlinear figure of merit for candidate materials for this application. In the case of electrooptic materials, we must integrate the polarization decomposition effects over the path length, properly taking account of the difference in n_2 for linear and circular polarized light, leading to an even more complicated relationship.

As a final comment, with this interferometric method of determining n_2, assessment of the magnitude of higher order terms in the expansion of the refractive index with optical electric-field strength is possible [21]. If, for example, the $n_4 E^4$ term were comparable to the magnitude of the minimum fringe distortion in our experiments, in either the CS_2 or any of the samples, the plot of fringe shift versus relative intensity would not have been linear. There would also appear to be a bulge in the high-intensity fringes near the maximum-intensity part of the fringe pattern, due to the $n_4 E^4$ term. The lack of any evidence for such effects establishes an upper limit for the magnitude of n_4 which, for example, in ED-2 glass was $n_4 \sim 6 \times 10^{-21}$ (ESU^4), [21].

ACKNOWLEDGMENT

The authors wish to thank E. Snitzer of the American Optical Company for his cooperation in supplying some of the glass samples used in this set of experiments. They also wish to thank L. Coleman, S. Thomas, and G. Tripp for their assistance with the LLL ultrafast streak cameras used, and D. Speck for the loan of one of the same.

Studies of the Inversion and Lower Level Relaxation in Pulsed TE CO_2 Discharges

BRIAN K. GARSIDE, JOHN REID, AND EDWARD A. BALLIK, MEMBER, IEEE

Abstract—**It has generally been supposed that the rise and fall times of the gain in pulsed CO_2 laser discharges reflect the effective lifetimes of the lower and upper laser levels. Consequently, the ratio of the upper to lower level populations N_u/N_l should change during the evolution of the gain, and should be a relatively large number at the gain peak. The problems associated with the determination of this ratio using conventional direct gain measurements are discussed, and a new in-cavity technique is described that has sufficient precision to determine the ratio N_u/N_l as a function of time. The results obtained unambiguously demonstrate that the lower laser level empties rapidly during the rise time of the gain. This conclusion is further reinforced by some measurements concerning the time variation of the gain in the hot band ($01^11 \rightarrow 11^10$).**

I. Introduction

IT HAS generally been supposed that the rise and fall times of the gain in pulsed CO_2 laser discharges reflect the effective lifetimes of the lower and upper laser levels [1]. Furthermore, the symmetric stretching vibrational mode of CO_2 (including the lower laser level, 10^00) is thought to be very strongly coupled to the bending mode. Consequently, the relaxation of the lower laser level is controlled by the energy decay in the bending mode, in particular the vibration-translation (V-T) relaxation of the 01^10 level. As thermal equilibrium is very rapidly established between the bending and symmetric stretching vibrational modes, they can be assumed to have a common temperature (T_1) [2]. This temperature rises during the discharge current pulse, but relaxes quickly at the V-T rate after the current pulse. Therefore, T_1 attains a value close to the gas translational temperature within a few V-T decay times. As a particular consequence of this model, no more than 5 percent of the total CO_2 molecules can be excited into the lower laser level, whatever the value of T_1, and this population will have fallen to less than 1 percent after a few V-T decay times. The inversion in pulsed CO_2 lasers is typically several percent of the available CO_2 molecules. In both double-discharge and resistive-pin systems, the gain peak occurs several V-T decay times after the current pulse. Consequently, in these lasers, the ratio of the upper (N_u) to lower (N_l) laser level populations should be a relatively large number (>6) at the gain peak.

Manuscript received November 13, 1974; revised January 29, 1975. This work was supported in part by the National Research Council and in part by the Defence Research Board of Canada.

Several measurements have been reported recently which cast doubt on the above interpretation of the gain dynamics. In the first place, some measurements of the lower level relaxation indicate that the coupling between the Fermi-resonance levels (10^00, 02^00) and the rest of the bending mode may be much weaker than hitherto supposed [3], [4]. Secondly, measurements of the gain on different rotational lines for the ($00^01 \rightarrow 10^00$) transition in pulsed discharges have been employed to show that the population in the lower laser level exceeds 10 percent of the total number of CO_2 molecules [5]. Several investigators have reported low values for the ratio of the upper to the lower laser level populations at the peak of the gain [5], [6]. These results are clearly not consistent with the conventional model of the pulsed gain dynamics, but they can be accounted for if the following alternate model is postulated. Suppose that, at the end of the current pulse, an inversion is produced between the laser levels, and considerable energy is stored in the bending mode. The rise time of the gain now simply corresponds to the emptying of the energy from the bending mode and the consequent decrease in the value of the partition function. During this time, the lower laser level is supposed to be more or less decoupled from the bending mode, and so suffers little decay. The fall time of the gain corresponds, as before, to the decay of the upper laser level, but there may now also be a contribution from the lower level (presumably somewhat similar) decay time.

It is important to establish which of these two models correctly describes the laser gain dynamics. The pumping efficiencies into the upper level and the associated laser dynamical calculations are very different in the two models. Consequently, the approach to the problem of extracting more output energy/unit volume from CO_2 lasers depends greatly on which model is correct. The work described in this paper is aimed at discriminating unambiguously between these two possible dynamical models. The strategy employed is described briefly in what follows.

Gain measurements of the conventional type allow the difference between N_u and N_l to be monitored. This alone cannot distinguish between the two models. What is required is a means of measuring the *ratio* of the upper to the lower laser level populations during the dynamical changes in the gain. This can be done, in principle, by measuring the gain as a function of time on many lines in the P and R branches of the 10.4-μ band. The ratio of the maximum gain obtained in the R branch to the maximum gain in the P branch (R/P hereafter) is a measure of the ratio N_u/N_l at the instant of time chosen, provided that the rotational temperature is known [7]-[9]. Measurements of gain, made in the conventional fashion employing a CW probe laser, are reported in Section II. These

results are analyzed to determine a rotational temperature, and the accuracy with which a value for N_u/N_l can be extracted is studied. It is concluded that this technique lacks sufficient precision for the task at hand. A new technique, having a much higher precision, is described in Section III. This method employs an improved version of a previously reported [10] in-cavity laser technique for measuring gain, using observations of the time delay between the peak of the excitation current pulse and the onset of lasing action. This approach permits the ratio N_u/N_l to be monitored from the end of the current pulse to the peak of the gain. The decay of the lower laser level during this time is clearly demonstrated. This behavior is consistent with the model in which the bending and symmetric stretching modes are in thermal equilibrium, and the energy decay is controlled by the V-T relaxation of the 01^10 level. The alternate model, in which the 10^00 population decays much more slowly than the rise time of the gain, is ruled out. Finally, in Section IV, this issue is settled beyond doubt by some studies of the dynamics of lasing action on the hot-band transition ($01^11 \rightarrow 11^10$) at 11 μ.

II. Direct Laser Amplifier Gain Measurements

A. Experimental Arrangement

Fig. 1 is a schematic diagram of the apparatus used for small-signal gain measurements. A stable CW CO_2 laser was operated in the fundamental TEM_{00} mode. An internal grating allowed the output to be tuned over several lines in the P and R branches of the 10.4-μ band. The output beam had a power of approximately 1 W, and an amplitude stability of 2 percent. This beam was chopped by a spinning disk at the common focus of two Ge lenses, passed through the test amplifier, and then focused onto a Ge:Au detector (rise time 300 ns). The effective beam diameter in the discharge region was kept as small as possible, and the maximum spot size was generally less than 2 mm ($1/e$ intensity) throughout the discharge region. The amplifier [11] employs a resistor-pin discharge to excite the gas mixture. Although this type of discharge has been superceded by double-discharge and electron-beam systems in most applications, it is nevertheless an effective method of obtaining stable discharges in small volumes. Measured gains remained constant when the probe signal was reduced by a factor of 10, confirming that the gain was measured in the small-signal region.

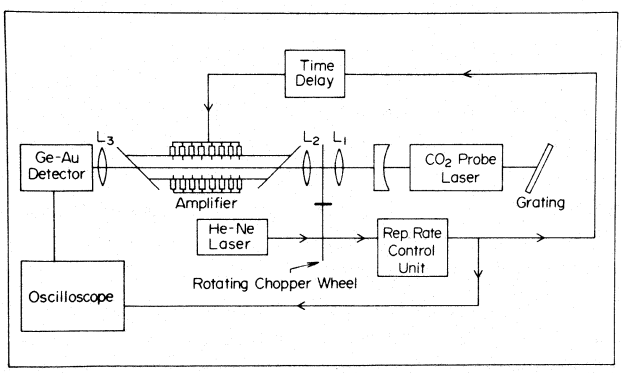

Fig. 1. Schematic diagram of apparatus used for direct measurements of gain.

The method used to trigger the amplifier discharge circuit is similar to the one employed by Jacobs [12], modified to permit electronic control of the repetition rate of the amplifier. The rotating chopper wheel periodically admits both the 10.6-μ CW probe beam and a 6328-Å He-Ne laser "trigger" beam through two small slots located 180° apart. The "trigger" beam falls upon a photodiode and the resulting train of pulses is fed to a repetition rate control unit. This reduces the pulse repetition rate to 2 or 3 pulses per second (pps) while maintaining the time synchronization. These pulses, with a suitable time delay, are used to trigger both the discharge and the monitoring oscilloscope. This scheme yields a single oscilloscope trace of the probe beam amplitude prior to, during, and after amplification. The time delay to the amplifier can be adjusted to locate the gain pulse anywhere on the probe signal. This enables the time base to be expanded to determine rise times, or compressed to examine the absorption after the amplifier pulse. Further advantages of this technique are described by Jacobs [12].

B. Results

Fig. 2 shows the measured peak gains obtained on the P and R branches of the 10.4-μ band for all the wavelengths at which the CW laser probe could be operated. A moderately low total gas pressure of 80 torr was employed in the laser amplifier to ensure excellent stability and repeatability of the discharge. This is reflected in the small errors shown for the gain measurements. The gas mixture was 10 percent CO_2, 6 percent N_2, and 84 percent He, and the energy input to the discharge was approximately 100 J/l · atm. The measured gain on $P(18)$ was 2 percent/cm. It is well known that the J dependence of the gain on the P branch is given, in the case of pressure broadening, by [6]-[8]

$$\alpha_P = \frac{(\text{const}) N_l B_l \cdot J F_J}{\Delta\nu(J)\lambda(J)} \cdot \left[\frac{N_u B_u}{N_l B_l} \exp\left(-\frac{E_u(J-1)}{kT}\right) - \exp\left(-\frac{E_l(J)}{kT}\right)\right]. \quad (1)$$

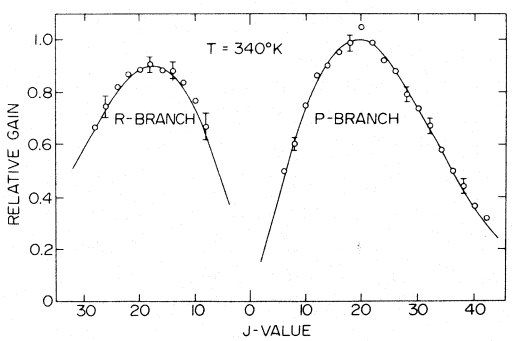

Fig. 2. Measured peak gain for several R- and P-branch transitions in the 10.4-μ band. The fitted curve [using (1) and (2)] corresponds to $T = 340$ K and $N_u/N_l = 10$. A 10 percent CO_2: 6 percent N_2: 84 percent He mixture at 80-torr total pressure was used, with an input energy of ~100 J/l · atm. The $P(18)$ peak gain was 2 percent/cm. Some typical error bars are also indicated.

A similar expression holds for the R branch, viz.,

$$\alpha_R = \frac{(\text{const})N_l B_l \cdot (J+1)F_J}{\lambda(J)\Delta\nu(J)} \cdot \left[\frac{N_u B_u}{N_l B_l}\exp\left(-\frac{E_u(J+1)}{kT}\right) - \exp\left(-\frac{E_l(J)}{kT}\right)\right] \cdot \quad (2)$$

In these two expressions, the constant contains all the factors which are not J dependent (J is the rotational number of the lower laser level). F_J accounts for the interaction between vibration and rotation, giving a small J dependence to the total transition moment [13]. B_u and B_l are the rotational constants for the upper and lower vibrational levels, and $E_u(J)$ and $E_l(J)$ are the respective rotational energies of the Jth level. $\lambda(J)$ is the wavelength of the transition, and $\Delta\nu(J)$ is the linewidth. In the work described here, we are only interested in relative values of gain on different transitions. Hence, it is not necessary to separate the line strength into contributions from the transition moment and linewidth. The absorption data of Cousin *et al.* [13] is used in a self-consistent fashion, and rotational constants and wavelengths are taken from [14].

Careful examination of (1) and (2) shows that the variation of gain with J depends strongly upon the value of the rotational temperature T. Observe that in Fig. 2 the measured ratio of the gain maximum of the R branch to that on the P branch is 0.90. As we shall see, for a value as high as this, the variation in gain with J is insensitive to N_u/N_l, and depends almost entirely on the rotational temperature. The lines fitted to the experimental points correspond to a value for T of 340 K to within a precision of ±15 K. This rather moderate increase above room temperature is in agreement with measurements reported elsewhere [7]. Observe that the gain on the $P(20)$ line is anomalously high. Such an effect has been reported previously, and ascribed to the presence of a hot-band gain line which overlaps $P(20)$ [15], [16]. Fig. 3 shows results obtained with the same gas mixture and total pressure as employed previously, but with a considerably larger discharge input energy (~250 J/l · atm). The rotational temperature which best fits the observations in this case is 410 K with an estimated precision of ±20 K. Observe that, once again, the gain on the $P(20)$ line is anomalously high. In this figure, we have only shown the P branch for convenience. The maximum gain on the R branch, on the same arbitrary scale as the P branch, is 0.90 ± 0.02.

The fit obtained between theory and experiment for the J dependence of the gain in the above experiments is excellent, and the precision of the data points is very high. The question now is, given this precision, how well can we determine N_u/N_l? Fig. 4 displays the results of a calculation of the ratio (R/P) as a function of N_u/N_l, for two rather different rotational temperatures. Evidently, R/P is extremely insensitive to the value of N_u/N_l when $R/P \gtrsim 0.85$.

It should be emphasized that when considering relative gains, the value of (R/P) is the only factor which is sensitive to N_u/N_l. Patel [8] gives a further demonstration of this for values of N_u/N_l very close to 1.0.

The experimental implications of this behavior are illustrated by the error bar shown in the figure, which represents a precision of ±5 percent in the ratio (R/P). Evidently, either the precision of the gain measurements must be made much better than 5 percent, or this method of determining N_u/N_l must be abandoned for values greater than two. A precision of 5 percent is typical of results obtained with direct gain measurements and so the only recourse is to find a more accurate method. It is fortunate that it is only the ratio of the gains on the P and R branches, not the absolute values, which is required. In this case, a high-precision technique for comparing the relative gains will do the trick. One approach to this problem is described in the next section.

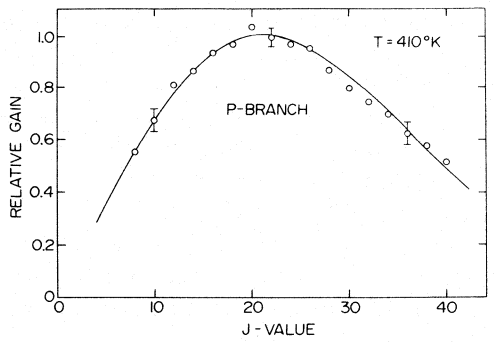

Fig. 3. Measured peak gain for several P-branch transitions in the 10.4-μ band. The fitted curve corresponds to $T = 410$ K and $N_u/N_l = 10$. Gas mixture and pressure were the same as for Fig. 2, but the discharge energy was increased to ~250 J/l · atm. This gave a peak gain of 1.5 percent/cm on $P(18)$.

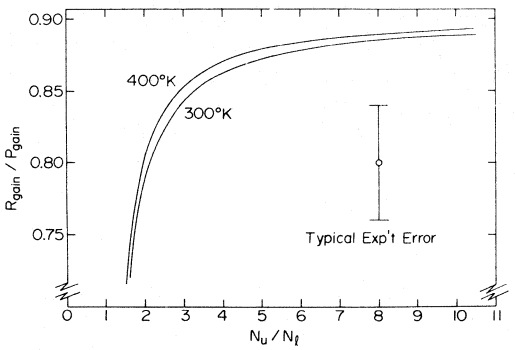

Fig. 4. The ratio of the maximum gain in the R branch to the maximum gain in the P branch (R/P) plotted as a function of N_u/N_l, for two different rotational temperatures. Also displayed is a typical experimental error bar of ±5 percent in the value of R/P.

III. In-Cavity Laser Gain Measurements

We have previously reported an experimental method for studying the time-dependent gain in TEA CO_2 lasers [10]. The technique involves an investigation of the time delay from the current pulse to the onset of lasing. In the present work, investigations of a similar type are made, but the measurements obtained are treated in a somewhat different fashion. The use of a diffraction grating within the laser cavity permits operation on a wide variety of P- and R-branch lines in the 10.4-μ band. It is this expanded capability that is the key to a new method of data analysis. The raw data required for subsequent analysis are acquired in the following way. At a given discharge input energy, the time delay to the onset of lasing is measured over a wide range of P- and R-

branch gain lines. Now, the relative variation of the gain over the P- and R-branch lines is well known [see (1) and (2)]; it depends on the rotational temperature and the J value for the particular line. Consequently, for an *assumed* value of the rotational temperature, the gain on each rotational line relative to that on $P(18)$ can be predicted. The time delay data are now treated as follows. Assume a value for the rotational temperature, and calculate the gains on all the relevant P- and R-branch lines relative to $P(18)$, which is assigned an arbitrary value of 1.0. For each rotational line, plot the *calculated* relative gain against the *observed* time delay. Now, increasing the rotational temperature has the effect of increasing the relative gain on high J-value lines and reducing that on the low J-value lines (see Fig. 5). Accordingly, only if we made the correct choice of initial temperature will the high J and low J-value points lie on the same curve. This is illustrated in Fig. 6. The high and low J-value points are indicated by crosses and circles, respectively. The anomalous point indicated by a square corresponds to the $P(20)$ line. (It is of interest to note that anomalous gain is found on $P(20)$ at discharge pressures as low as 25 torr. This suggests either a very close coincidence between $P(20)$ in the $00^01 \rightarrow 10^00$ band and $P(23)$ in the $01^11 \rightarrow 11^10$ band, or an unexpectedly narrow linewidth for the $P(20)$ transition [14], [15].) Two choices of rotational temperature are shown. The value of 360 K is obviously a wrong choice in that the low and high J-value points are clearly separated. A reduction of only 30 K is sufficient to bring the two sets of points into agreement. This serves to indicate the precision with which the rotational temperature can be determined. The gas mixture and other relevant experimental parameters are given in the figure caption. There is a complication which has been ignored thus far. From Section II it is known that the relative gain variation among the rotational levels depends on N_u/N_l. Consequently, it follows that to fit a rotational temperature requires a value for N_u/N_l. Although this is certainly true, the value chosen is of little consequence provided that it is greater than four. Furthermore, the values of T and N_u/N_l can, if necessary, be simultaneously determined. Variations in N_u/N_l serve mainly to change the ratio of the peak gain in the R branch to that in the P branch. The following strategy can now be applied. Select a value of N_u/N_l and separately fit a rotational temperature to the P-branch and R-branch data, employing the method indicated in Fig. 6. Repeat for different values of N_u/N_l. In general, the rotational temperatures obtained for the P and R branches will be different. Only when N_u/N_l has the right value will the two temperatures agree. Typical results are displayed in Fig. 7. Evidently, for the experimental situation analyzed (which is the same as for Fig. 6) the value of $N_u/N_l \gtrsim 6$ and T is 330 K. As indicated earlier, it is actually only necessary to carry out this procedure when N_u/N_l is less than four. In making measurements over the wide wavelength range required for this method, it is important to take precautions that the resonator loss is not significantly wavelength dependent.

When an appropriate determination of the values of T and N_u/N_l has been made according to the above prescription, the resulting time delay curve is an accurate plot of laser pulse time delay against *relative gain*. This is all we need to compare the gain on the P and R branches of the 10.4-μ band. It is of interest to observe that we can employ the technique described in [10] to determine the temporal variation of the gain once the plot of relative gain against time delay is known. Furthermore, if the cavity loss is known to fair precision, the actual magnitude of the peak gain (on $P(18)$ say) can be determined. Reference should be made to the original paper for details. Fig. 8 shows the time variation and magnitude of the gain in $P(18)$ deduced in this way for a 10 percent CO_2:90 percent He gas mixture at 75-torr total pressure.

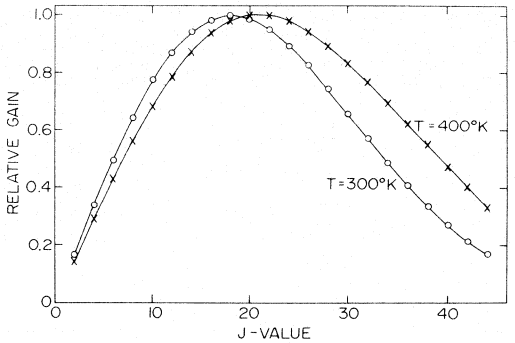

Fig. 5. Relative gains on the P-branch transitions of the 10.4-μ band for two different rotational temperatures calculated using (1).

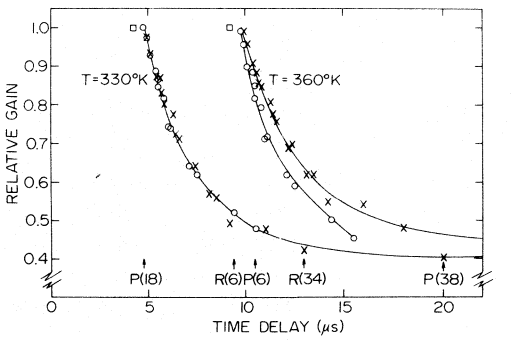

Fig. 6. Time delay to lasing as a function of relative gain for transitions $P(6)$ to $P(38)$ and $R(6)$ to $R(34)$. Transitions with J values greater than 20 are represented by X, those with J values less than 20 by 0. $P(20)$ is represented by □. The time delay curve is plotted for two different rotational temperatures, 330 K and 360 K. (N_u/N_l was taken as 10 in each case.) The data for 360 K have been shifted 5 μs to the right. Discharge mixture is 10 percent CO_2: 90 percent He at 75-torr total pressure, with an input energy ~90 J/l · atm.

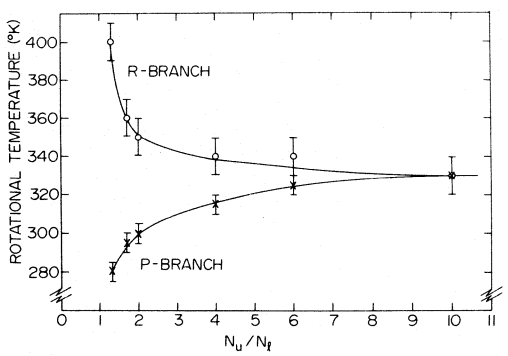

Fig. 7. Determination of N_u/N_l using the data of Fig. 6. As N_u/N_l is varied, the P- and R-branch temperatures are fitted separately, using (1) and (2). The error bars represent fitting errors.

Also shown is the result of a direct measurement of the gain on the same line using a probe laser. The small discrepancies between the two curves are well within the range of experimental error.

A method has now been established for determining an accurate plot of relative gain against observed time delay in the laser resonator. Clearly, the maximum gain on the R branch will correspond to that line which lases with the shortest time delay. It is only necessary to locate this time delay on the curve of relative gain against time delay in order to establish the R/P ratio. This technique can be employed to measure the R/P ratio as a function of time, by changing either the laser cavity loss or gain on $P(18)$. As a matter of fact, this R/P ratio is an average over the time to the onset of lasing from the instant the gain exceeds the loss. Operation at relatively low pressure ensures that this time is short compared with the rise time of the gain. Fig. 9 shows the results of such an experiment carried out with a 10 percent CO_2 : 90 percent He gas mixture at a total pressure of 35 torr. The different curves were generated by changing the gain and loss in the laser resonator. The horizontal error bar displayed on each curve represents the maximum variation in the time delay of that R-branch line with the highest gain. As a measure of the precision of the technique, the data points employed in obtaining one of the time delay curves are also displayed. The values of the N_u/N_l ratios appropriate to each of the error bars are shown in the figure. Since the value of N_u is falling during this time, these observations can only be accounted for if the lower laser level itself is emptying during the rise time of the gain. In the next section, we present further independent evidence that this indeed must be the case.

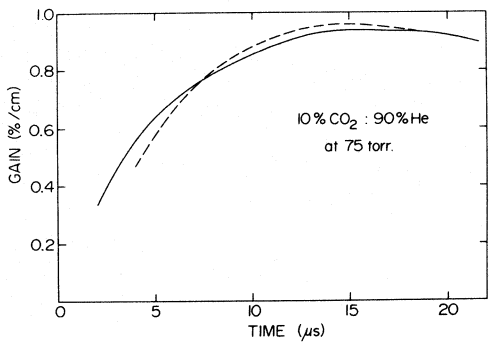

Fig. 8. Time variation of the gain on $P(18)$ as measured directly with a CW probe laser (solid line) and as deduced from the time delay data of Fig. 6 (dashed line). Discharge conditions are given in the caption of Fig. 6. Zero time corresponds to the peak of the discharge current pulse.

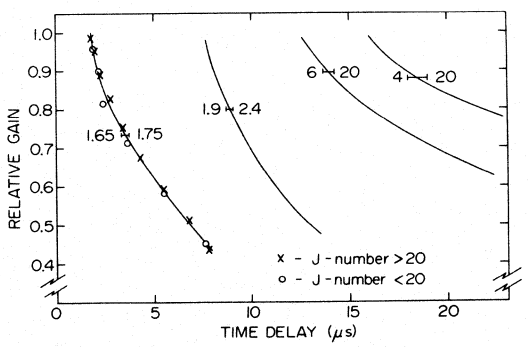

Fig. 9. Variation of the ratio N_u/N_l during the rise time of the gain. The four time delay curves are generated by varying the excitation conditions and cavity loss for a 10 percent CO_2:90 percent He mixture at 35-torr total pressure. The horizontal bars on each curve represent the maximum variation in the time delay of the R-branch line with the highest gain. Also indicated is the corresponding range of N_u/N_l. The gain peak occurs approximately 27 μs after the peak of the current pulse (0 μs).

IV. Hot-Band Lasing Observations

It is known that there is a hot-band transition ($01^1 1 \rightarrow 11^1 0$) which has maximum gain in the region of 11 μ [17]. The inversion which is obtained for this band is related to that of the 10.4-μ band by the ratio of the $01^1 0$ to the $00^0 0$ populations. Evidently, the ratio of the gain in the hot band to that of $P(18)$ in the 10.4-μ band is a measure of the bending mode temperature. Consequently, provided that the relative line strengths are known [13], time delay measurements of the type described in Section III can be employed to determine the bending mode temperature. Fig. 10 shows plots of relative gain against time delay obtained in the fashion described in Section III. The gas mixture was 10 percent CO_2: 90 percent He at a total pressure of 35 torr. The limits of the time delay obtained for the peak of the hot band is indicated by the horizontal error bars on the time delay curves. The two different curves were obtained by varying the resonator loss. By this method, it was determined that the gain on the hot band was 26 percent of that on $P(18)$ during the initial portion of the gain rise time. This determination was checked by measuring the time delay obtained on $P(18)$ for one fourth of the gain (see arrow in the figure). The measured gain ratio corresponds to a bending mode temperature of 700 K. At the later time, the measured gain ratio of 0.155 corresponds to a bending mode temperature of 515 K. This confirms that the bending mode does not attain very high vibrational temperatures (~1300 K) such as would be required if the rise of the gain corresponded only to the change in partition function as the bending mode cools. The time delay measurements on

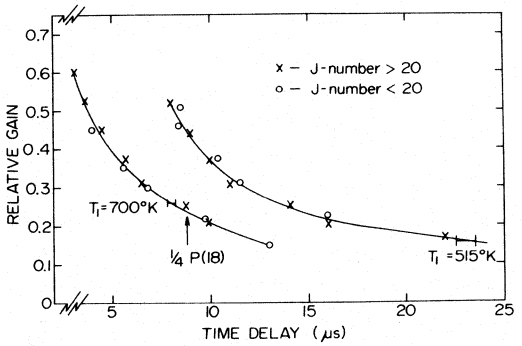

Fig. 10. Variation of the bending mode temperature T_1 during the rise time of the gain. The two time delay curves are generated by varying the cavity loss for a 10 percent CO_2: 90 percent He mixture at 35-torr total pressure. The horizontal bars on each curve represent the maximum variation in the time delay of the $P(20)$ transition of the hot band. The arrow indicates the time delay obtained on $P(18)$ of the 10.4-μ band when the total gain in the amplifier has been reduced by a factor of 4. The gain peak occurs approximately 27 μs after the peak of the current pulse (0 μs).

the hot band were made using the $P(20)$ line at 10.99 μ. There is a stronger transition at 11.02 μ, corresponding to the overlap of the $P(56)$ line in the 10.4-μ band with the $P(23)$ line in the hot band [18]. This transition was avoided in the present work.

V. Discussion and Conclusions

In the Introduction, two models are presented that can account for the gross features of the gain evolution in pulsed CO_2 lasers. In one model, the rise time of the gain is a reflection of the decay of the population of the lower laser level. This is the generally accepted model of CO_2 laser gain dynamics. However, several measurements have been reported recently which cast doubt on this interpretation. To account for these measurements, we have postulated an alternative model in which the gain rise time corresponds only to the cooling of the bending mode, and both upper and lower laser level populations remain relatively unchanged. The key difference between these two models from an observational point of view lies in the behavior of the ratio N_u/N_l. For the former model, this ratio will be large at the gain peak, regardless of initial conditions, and will be monotonically increasing in value during the buildup of the gain. For the latter model, however, the ratio will be constant during the evolution of the gain. In this paper, we have reported experiments aimed at the determination of N_u/N_l at the peak of the gain, and for selected times during the gain buildup.

The conclusion reached as a result of these measurements, namely that the lower laser level undoubtedly empties during the rise time of the gain, is reinforced by some measurements concerning the gain on the hot band ($01^1 1 \rightarrow 11^1 0$).

In Section II, results are reported of the direct measurement of the peak gain on a number of rotational lines in the P and R branches of the 10.4-μ band. It is shown that these results can be analyzed to obtain values for both the rotational temperature and the ratio N_u/N_l. This ratio is found to be large at the peak of the gain for several discharge input energies. The precision with which values of N_u/N_l can be obtained from experimental data is analyzed.

It is shown that, although some indication of the size of N_u/N_l can be obtained, it is too inaccurate in general to be employed for a study of changes in this ratio as the gain evolves. Accordingly, we have devised an alternative scheme which has the necessary accuracy.

A technique is described in Section III for *comparing* the gains on the P and R branches of the 10.4-μ band to a high precision. This is basically all that is required to obtain a value for N_u/N_l. This method involves a comparison of the time delays to the onset of lasing from the current pulse for a number of P- and R-branch gain lines. This approach is used to determine the value of N_u/N_l and the rotational temperature for selected times during the onset of the gain. It is clearly demonstrated that N_u/N_l changes from a value less than two at a time shortly after the end of the current pulse to a value greater than six near the peak of the gain pulse. This constitutes clear evidence that the model of the gain dynamics in which the bending and symmetric stretching vibrational modes of CO_2 are strongly coupled is correct. The energy in these modes decays at a rate equal to the V-T relaxation rate of the $01^1 0$ level. The coupling between the bending and symmetric stretching modes must be faster than this rate, which is determined by the partial pressure of the He in the gas mixture. For sufficiently high CO_2 content mixtures, the coupling between the $10^\circ 0$ level and the bending mode is determined by the effectiveness of CO_2-CO_2 collisions [19]. In the particular case of a 10-percent CO_2: 90-percent He mixture, it follows that the relaxation rate of the $10^\circ 0$ level into the bending mode must be greater than 3×10^4 torr^{-1}s^{-1}. This value is in good agreement with the calculations of Seeber [20] and Sharma [21], and the experimental results of Stark [19]. However, it exceeds the rate deduced in [4] by an order of magnitude, and is significantly faster than that observed in [3].

Section IV gives a brief account of some measurements made on the lasing behavior of the hot-band transition ($01^1 1 \rightarrow 11^1 0$). The important characteristic of this transition is that the ratio of the hot-band gain to the gain in the 10.4-μ band is a measure of the $01^1 0$ population. We have applied this, using an experimental method much like that employed in Section III, to show that the bending mode temperatures during the rise time of the gain are much too small to permit the gain increase after the current pulse to be accounted for in terms of a decrease in the partition function of the bending mode. This provides an independent confirmation of the above conclusions concerning the two postulated models of the gain dynamics.

All the data presented in this report were taken at gas pressures below 100 torr. However, relaxation rates in CO_2 lasers are collisionally controlled, and the results can be scaled directly to higher pressures. The duration of the gain pulse will, of course, be inversely proportional to the gas pressure. Even at atmospheric pressure, the lower laser level will be almost empty at the time of the gain peak, providing that short excitation current pulses are used.

It is also pertinent to observe that, although the conditions in low-pressure dc-excited CO_2 lasers are very different from those existing in pulsed lasers, several recent measurements [22] have determined that the population of the lower laser level is close to equilibrium with the gas temperature. Once again, this confirms the existence of very strong coupling between the bending and symmetric stretching modes.

Modes in Diffused Optical Waveguides of Arbitrary Index Profile

G. BENJAMIN HOCKER, MEMBER, IEEE, AND WILLIAM K. BURNS

Abstract—**A method is presented for numerical calculation of the phase constants of the modes of diffused optical waveguides of arbitrary index profile. For a given bulk and surface index, the phase constants can be plotted against diffusion depth. Graphs giving the number of modes supported by a guide with a particular diffusion depth and index change can also be calculated. Examples are given for complementary error function, Gaussian, and exponential profiles, with indices representative of metal-diffused $LiNbO_3$ guides. It is also shown that, by making certain approximations, the modes of a diffused waveguide may be described by just two quantities, a normalized diffusion depth and a normalized mode index. A single universal chart of these two quantities can be made for any diffusion shape, and all diffused guides with this diffusion shape are described by this chart. Charts are given for complementary error function, Gaussian, and exponential shapes. Careful measurement of effective mode indices of Ni-diffused $LiNbO_3$ guides fit the universal chart for a complementary error-function shape. A second type of universal chart for each shape relates the number of modes to the diffusion depth and indices of refraction.**

Manuscript received December 2, 1974. The work of G. B. Hocker was supported in part by the University of Minnesota Graduate School and the University Computer Center. The work of W. K. Burns was supported by the Advanced Research Projects Agency.

I. Introduction

Optical waveguides having a graded index have been formed in lithium niobate by outdiffusion [1] and by indiffusion [2], by diffusion in II-VI semiconductors [3], in glass [4], and in other materials [5]. In such waveguides the index of refraction is a smoothly varying function of depth and is higher at or near the surface than in the bulk material. The variation in index with depth may be of the form of a complementary error function, a Gaussian, a simple exponential, or may be of a shape not described by any simple mathematical function [1], [2], [4], [6].

To use such waveguides in integrated optics devices, it is useful to know the number of modes and their phase constants for any given diffusion profile. Calculations have been made analytically for only two possible profiles: one in which the dielectric constant is assumed to vary exponentially with depth [7] and one where the dielectric constant varies linearly with depth [8]. In both cases, exact solutions involving Bessel functions are obtained, but only for TE modes.

In Section II we describe a simple numerical method for calculating the phase constants of the modes of diffused waveguides of arbitrary index of refraction profile using a digital

computer. The method is based on wave optics considerations, and includes the phase shifts on reflection from the waveguide surfaces. Sample calculations are given plotting the effective indices of the various waveguide modes versus diffusion depth for exponential, Gaussian, and complementary error-function index profiles representative of diffused lithium niobate waveguides. Also given are plots for each of these three index profiles showing the diffusion depths and index changes necessary to produce a given number of waveguide modes in lithium niobate.

In Section III it is shown that, by making certain approximations, the diffused waveguide modes may be described by just two quantities, a normalized diffusion depth and a normalized mode index. A single universal chart of these two quantities can be made for any diffusion shape. Such a chart describes any guide having this diffusion shape, and examples are given for complementary error function, Gaussian, and exponential. Another universal chart is given for each of these shapes relating the number of modes supported by the waveguide to the diffusion depth and indices of refraction.

II. Numerical Calculations

Let the dielectric waveguide material occupy the half-space $y > 0$. The index of refraction profile may be written as

$$n(y) = n_b + \Delta n\, f(y/D) \tag{1}$$

where the maximum value of $n(y)$ is denoted $n_s = n_b + \Delta n$. The function $f(y/D)$ describes the variation in the index due to diffusion and takes on values between 0 and 1. For example, $f(x) = \text{erfc}\,(x)$ or $\exp(-x^2)$ or $\exp(-x)$. $f(x)$ will be referred to as the diffusion shape, and D as the diffusion depth. When the diffusion depth is given in units of the free-space wavelength, it is denoted $Y_0 = D/\lambda$. We shall assume here that $f(x)$ has its maximum value at $x = 0$ and decreases with increasing x, although the method is easily adapted to other situations. Thus n_b represents the index in the bulk undiffused material, while n_s is the index at the surface after diffusion.

With each allowed waveguide mode is associated a phase constant β. The limits on β are

$$n_s k_0 > \beta > n_b k_0 \tag{2}$$

where $k_0 = 2\pi/\lambda$ is the free-space phase constant. An effective index of refraction n_{eff} can be defined for each mode by

$$\beta = n_{\text{eff}} k_0 \tag{3}$$

where the limits on n_{eff} are

$$n_s > n_{\text{eff}} > n_b. \tag{2'}$$

As shown in Fig. 1(a) for a mode propagating in the x direction with a propagation vector $\beta(\hat{x}) = n_{\text{eff}} k_0 \hat{x}$, a wave at a depth y_i has a propagation vector $n(y_i) k_0 \hat{r}$, where $\hat{r}$ makes an angle θ_i with the x axis. θ_i is given by

$$\theta_i = \cos^{-1}\left(\frac{n_{\text{eff}}}{n(y_i)}\right). \tag{4}$$

At this depth y_i, the y component of the propagation vector of the wave is $n(y_i) k_0 \sin\theta_i$. For an incremental propagation distance Δx along x, the wave penetrates a depth Δy_i as in

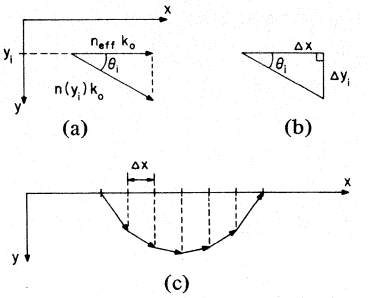

Fig. 1. (a) Wave-vector diagram for a mode with phase constant $n_{\text{eff}} k_0$ and a wave depth y_i with phase constant $n(y_i) k_0$. (b) Incremental propagation of mode by Δx increases depth of wave by $\Delta y_i = \Delta x \tan\theta_i$. (c) Piecewise-linear path of wave corresponding to waveguide mode as used in computer calculations.

Fig. 1(b)

$$\Delta y_i = \Delta x \tan\theta_i. \tag{5}$$

Across Δy_i the incremental transverse phase variation is

$$\phi_i = n(y_i) k_0 \sin\theta_i \Delta y_i. \tag{6}$$

Beginning at the surface with a given n_{eff}, then θ_i, Δy_i, and ϕ_i can be calculated by computer for each small increment Δx, following the wave as it dips into the diffused waveguide and returns to the surface as shown in Fig. 1(c). Typically, several hundred straight-line segments are used to approximate the wave's path.

When a wave in a material of index n_a undergoes total internal reflection at an interface with material of index n_b ($n_b < n_a$), then there is a phase shift on reflection given by [9]

$$2\Phi_{ab} = -2\tan^{-1}\left[(n_a^2 \sin^2\alpha - n_b^2)^{1/2}/n_a \cos\alpha\right] \tag{7a}$$

for a wave polarized perpendicular to the plane of incidence and

$$2\Phi_{ab} = -2\tan^{-1}\left[n_a^2(n_a^2 \sin^2\alpha - n_b^2)^{1/2}/n_b^2 n_a \cos\alpha\right] \tag{7b}$$

for a wave polarized in the plane of incidence. α is the angle between the incident wave vector and the normal to the interface.

Such a reflection takes place at the top surface of the diffused waveguide, at the interface between the diffused guide material and air. For this reflection $n_a = n_s$, $n_b = 1$, $\alpha = (\pi/2) - \theta_0$, and $n_a \sin\alpha = n_s \cos\theta_0 = n_{\text{eff}}$. Hence the phase shift at this surface is given by

$$2\Phi_1 = -2\tan^{-1}\left[(n_{\text{eff}}^2 - 1)^{1/2}/(n_s^2 - n_{\text{eff}}^2)^{1/2}\right] \tag{8a}$$

for TE modes, and by

$$2\Phi_1 = -2\tan^{-1}\left[n_s^2(n_{\text{eff}}^2 - 1)^{1/2}/(n_s^2 - n_{\text{eff}}^2)^{1/2}\right] \tag{8b}$$

for TM modes. Since for diffused guides produced to date $\Delta n \ll n_b$, then n_{eff}^2 is close to n_s^2 and both are $\gg 1$. Thus $2\Phi_1$ is close to $-\pi$, typically, between -0.8π and -0.95π for guide parameters so far reported in the literature.

The wave which dips into the diffused guide also undergoes a phase shift at the point of maximum penetration y_t where it turns back toward the surface. This point is defined by $n(y_t) = n_{\text{eff}}$. The phase shift at this reflection is a limiting case of (7) with a wave approaching grazing incidence and an

index discontinuity approaching zero. To show that the phase shift has a limiting value, let the wave traveling in the x direction with effective index n_{eff} be incident on an interface at $y = y_t$ between material for index $n(y_t - \delta)$ and $n(y_t + \delta)$. The slope of the index profile at $y = y_t$ is $(dn/dy)(y_t)$, so

$$n(y_t - \delta) = n(y_t) - \delta \frac{dn}{dy}(y_t) = n_{\text{eff}} - \delta \frac{dn}{dy}(y_t) \tag{9a}$$

$$n(y_t + \delta) = n_{\text{eff}} + \delta \frac{dn}{dy}(y_t). \tag{9b}$$

Substituting (9a) and (9b) into (7) and taking the limit as $\delta \to 0$, gives

$$2\Phi_2 = -2 \lim_{\delta \to 0} \tan^{-1} \cdot [(n_{\text{eff}}^2 - n(y_t + \delta)^2)^{1/2}/(n(y_t - \delta)^2 - n_{\text{eff}}^2)^{1/2}]$$

$$= -2 \tan^{-1}(1) = -\frac{\pi}{2} \tag{10a}$$

for TE modes [10]. Similarly, for TM modes

$$2\Phi_2 = -\frac{\pi}{2}. \tag{10b}$$

The fundamental requirements for the existence of a waveguide mode is that the total transverse phase shift for one round trip across the guide must be an integral multiple of 2π. This is expressed in the eigenvalue or mode dispersion equation

$$\sum \phi_i + 2\Phi_1 + 2\Phi_2 = 2m\pi \tag{11}$$

with $m = 0, 1, 2, \cdots$ and where the summation can be carried out numerically as previously described. A computer routine can easily search out the value of n_{eff} satisfying (11) for each m and for any given diffusion profile $n(y)$. The diffusion shape $f(x)$ can be a mathematical function, or could be numerically defined by experimental measurements.

Calculations have been made using $n_b = 2.20$ and $\Delta n = 0.010$. This is typical for extraordinary polarized modes in metal-diffused lithium niobate waveguides. Choices for $f(x)$ include a complementary error function, a Gaussian function, and a simple exponential. The complementary error function is expected to best describe metal-diffused $LiNbO_3$, at least up to the time when all of the metal has just been diffused into the substrate [2]. A Gaussian profile would be expected for diffusion times much longer than this. Fig. 2(a)-(c) gives the allowed values of n_{eff} for TE modes versus diffusion depth $Y_0 = D/\lambda$ in units of the free-space wavelength, for these three choices of $f(x)$. Calculations were also made for TM modes, but these are not shown here since they are very close to the corresponding TE modes. Calculations have also been made for $n_b = 2.29$ and $\Delta n = 0.010$, representing ordinary polarized waves in $LiNbO_3$. The resulting curves are virtually indistinguishable from Fig. 2(a)-(c) if the ordinates of Fig. 2(a)-(c) are simply relabeled to run from 2.29 to 2.30 (n_b to n_s) with the scale remaining the same. With suitable relabeling of the ordinates, Fig. 2(a)-(c) can be used as good representations of any guides with $\Delta n = 0.010$ and n_b in the range of 2.1-2.3.

To check the accuracy of our method, we have compared our

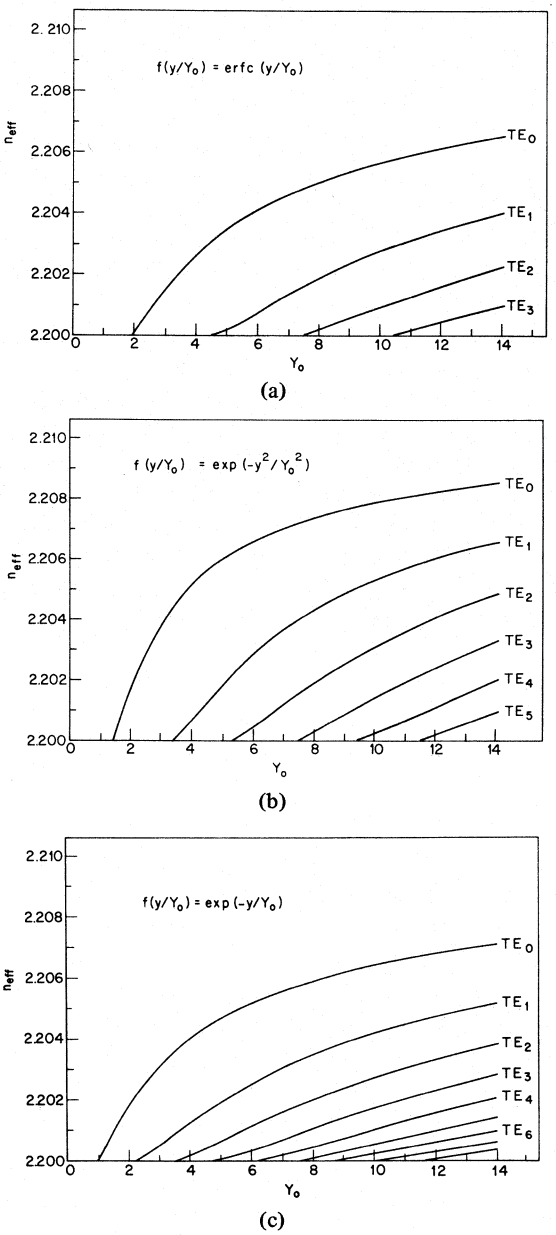

Fig. 2. Allowed values of n_{eff} for TE modes in diffused waveguide plotted against diffusion depth $Y_0 = D/\lambda$ in units of free-space wavelength, with indices typical of metal-diffused $LiNbO_3$. The index profile is as follows. (a) A complementary error function. (b) A Gaussian. (c) An exponential.

calculations with the exact solutions obtained by Conwell for an exponential dielectric constant profile [7]. For a dielectric constant of 6.1 in the bulk material and 6.4 at the surface, we choose the diffusion depth to give $\xi = 27.0$ and solve [7, eq. (8)]. The values of n_{eff} obtained agree to 10^{-4} in n or 0.17 percent of Δn as shown in Table I. This accuracy is believed to be maintained in calculations for other $f(x)$, and confirms our calculations of $\Sigma \phi_i$, $2\Phi_1$, and $2\Phi_2$.

Curves such as Fig. 2(a)-(c) have several uses. If the diffusion shape is already known, Y_0 can be determined from the set of n_{eff} observed experimentally or the diffusion depth and/or index change needed to produce a given set of n_{eff} can be obtained. Sets of curves such as these should also be useful for determining what diffusion shape best describes an observed set of n_{eff}. However, these applications may require

TABLE I
n_{eff} FOR EXPONENTIAL DIELECTRIC CONSTANT

m	Our Calculations	Exact Solution of [7]
0	2.5083	2.5082
1	2.4952	2.4951
2	2.4865	2.4866
3	2.4804	2.4805
4	2.4761	2.4760
5	2.4731	2.4731
6	2.4711	2.4711
7	2.4701	2.4701

Note: $\epsilon_b = 6.1$, $\epsilon_s = 6.4$ ($n_b = \sqrt{6.1}$, $n_s = \sqrt{6.4}$, $Y_0 = 3.949447$).

that many such curves be plotted for various n_b and Δn. In Section III, several approximations will be made which allow all diffused guides having the same diffusion shape to be described by a single universal chart relating a normalized mode index to a normalized diffusion depth.

It is desirable to know for a given diffusion shape $f(x)$, what combinations of diffusion depth and index change Δn produce waveguides which support a given number of modes. For a particular n_b and Δn, the values of $Y_0 = D/\lambda$ corresponding to cutoff for the various modes can be found from (11) by a simple computer search routine. To restrict the penetration of the wave to a finite depth, we define cutoff as $n_{eff} = n_b + 10^{-3}\Delta n$. Using $n_b = 2.20$, we plot the values of Δn and Y_0 obtained in this way for $f(x)$ given by a complementary error function, a Gaussian, and an exponential, shown here as Fig. 3(a)-(c), respectively. The curves for cutoff of the various modes divide each of these figures into regions of Δn and Y_0 where waveguides would support no modes, one mode, two modes, etc., and so should be particularly useful when designing single-mode waveguides. The bottom two curves in Fig. 3(c) agree with the analytical expressions given by Conwell [13]. Calculations for n_b from about 2.1 to 2.3 give nearly identical curves, so Fig. 3(a)-(c) are applicable to a number of materials with bulk index in this range.

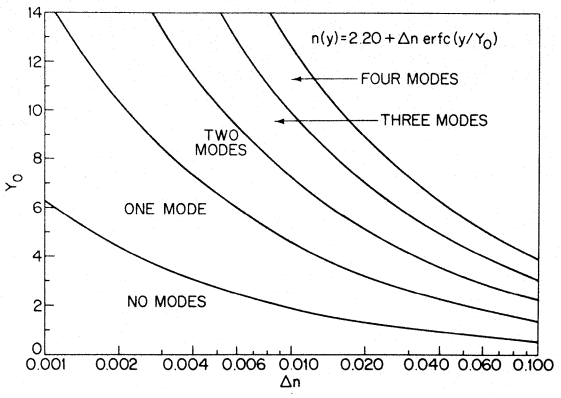

Fig. 3. Index change $\Delta n = n_s - n_b$ versus diffusion depth $Y_0 = D/\lambda$ in units of free-space wavelength, showing the number of waveguide modes. $n_b = 2.20$, and the index profile is as follows. (a) A complementary error function. (b) A Gaussian. (c) An exponential.

III. UNIVERSAL CURVES FOR DIFFUSED WAVEGUIDE MODES

Kogelnik and Ramaswamy have recently shown that, by defining a set of three normalized parameters describing thin-film optical waveguides, the modes of any thin-film waveguide can be determined from a universal chart [12]. The parameters include: a normalized film thickness V; a normalized effective mode index b; and a measure of the asymmetry between substrate and superstrate indices a. The mode dispersion equation normally gives β or n_{eff} for each mode in terms of five independent quantities: the index of refraction of guide, substrate, and superstrate; the guide width; and optical wavelength. This can be reduced to an equation for the normalized guide index b, in terms of only the two normalized parameters V and a. A universal chart of b versus V is obtained, with a as a parameter, which describes any thin-film waveguide. Since b is weakly dependent on a, curves of b versus V for only a few values of a are sufficient. In this section, we show that (11) can, with certain approximations, be written in a normalized form, giving a universal chart of normalized mode index versus normalized diffusion depth for each diffusion shape.

From the definition of θ_i in (4), $\sin\theta_i$ can be written as

$$\sin\theta_i = (1 - \cos^2\theta_i)^{1/2} = \left[\frac{n(y_i)^2 - n_{eff}^2}{n(y_i)^2}\right]^{1/2} \tag{12}$$

so that (6) becomes

$$\sum \phi_i = k_0 (n(y_i)^2 - n_{eff}^2)^{1/2} \Delta y_i. \tag{13}$$

As $\Delta y_i \to 0$, this becomes an integral

$$\sum \phi_i \to 2k_0 \int_0^{y_t} (n(y)^2 - n_{\text{eff}}^2)^{1/2}\, dy \tag{14}$$

where

$$n(y_t) = n_{\text{eff}}.$$

Equation (11) can therefore be written as

$$2k_0 \int_0^{y_t} (n(y)^2 - n_{\text{eff}}^2)^{1/2}\, dy + 2\Phi_1 + 2\Phi_2 = 2m\pi. \tag{15}$$

Let us now make the approximation

$$n(y)^2 \cong n_b^2 + (n_s^2 - n_b^2) f(y/D). \tag{16'}$$

We can now introduce the normalized diffusion depth V

$$V = k_0 D(n_s^2 - n_b^2)^{1/2} \tag{17}$$

and normalized mode index b

$$b = \frac{n_{\text{eff}}^2 - n_b^2}{n_s^2 - n_b^2} \tag{18}$$

where D is the diffusion depth given in the same system of units as k_0. V and b are the same parameters used in [12], with diffusion depth D replacing the guide width.

Using the approximation of (16) along with the definitions of (17) and (18), the integral in (15) becomes

$$2k_0 \int_0^{y_t} (n(y)^2 - n_{\text{eff}}^2)^{1/2}\, dy = 2V \int_0^{x_t} (f(x) - b)^{1/2}\, dx \tag{19}$$

where $x = y/D$ and $f(x_t) = b$. Since we are considering diffused waveguides bounded above by air, and since n_s is appreciably larger than 1 and $\Delta n \ll n_s$, calculations are simplified and the introduction of a third parameter is avoided by approximating

$$2\Phi_1 \cong -\pi. \tag{20}$$

Note that this removes the distinction between TE and TM modes in isotropic materials. In anisotropic materials they will of course see different n_b and Δn depending on crystal orientation. The mode dispersion (11) becomes

$$2V \int_0^{x_t} (f(x) - b)^{1/2}\, dx = (2m + \tfrac{3}{2})\pi \tag{21}$$

for $m = 0, 1, 2, \cdots$. Equation (21) is a more general form of the equation obtained in [11] by use of the Wentzel-Kramers-Brillouin (WKB) approximation.

For a particular diffusion shape $f(x)$, the values of V satisfying (21) for a given value of b are easily obtained. Universal charts of b versus V for $f(x)$ given by a complementary error function, a Gaussian function, and an exponential are given as Fig. 4(a)-(c). Each of these universal charts describes *all* diffused waveguides having the specified $f(x)$ shape, within the approximations of (16) and (20). While they are not as accurate as the type of calculation shown in Fig. 2, these universal charts should be much more useful, since repeated calculations for each specific case are not necessary. Instead, a single universal chart may be used to find the values of n_s and diffusion depth which best fit an experimentally observed n_b and set of n_{eff} for a given $f(x)$. As a check on the accuracy of these results, we use the values of n_{eff} for $Y_0 = 12.0$ from Fig. 2(a)-(c) to calculate the corresponding b and V. Comparing these with Fig. 4(a)-(c), they agree to within 2 percent of b, indicating that the approximations we have made do not introduce any serious errors.

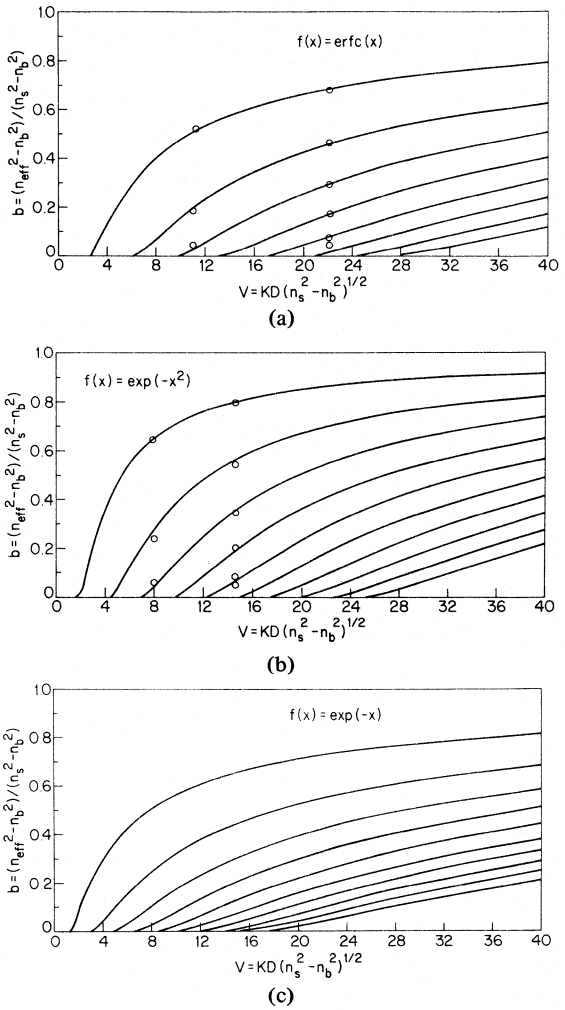

Fig. 4. Universal chart of normalized mode index $b = (n_{\text{eff}}^2 - n_b^2)/(n_s^2 - n_b^2)$ versus normalized diffusion depth $V = k_0 D(n_s^2 - n_b^2)^{1/2}$ for a diffusion shape of the following. (a) A complementary error function. (b) A Gaussian. (c) An exponential. Experimental measurements of TM-mode effective indices in two Ni-diffused $LiNbO_3$ guides are fitted to charts (a) and (b). Measurement uncertainties are indicated by the size of the data points, except for the sixth mode of the six-mode guide, which was detectable but not resolvable. The better fit to theory in (a) indicates that the experimental diffusion profiles are nearly complementary error function.

As an example of the use of the universal charts in Fig. 4, we have plotted the experimental results of mode effective index measurements of two metal-diffused $LiNbO_3$ guides. The waveguides were made by diffusing 500 Å of Ni into Y-X $LiNbO_3$ plates at temperatures near 900°C, as reported in

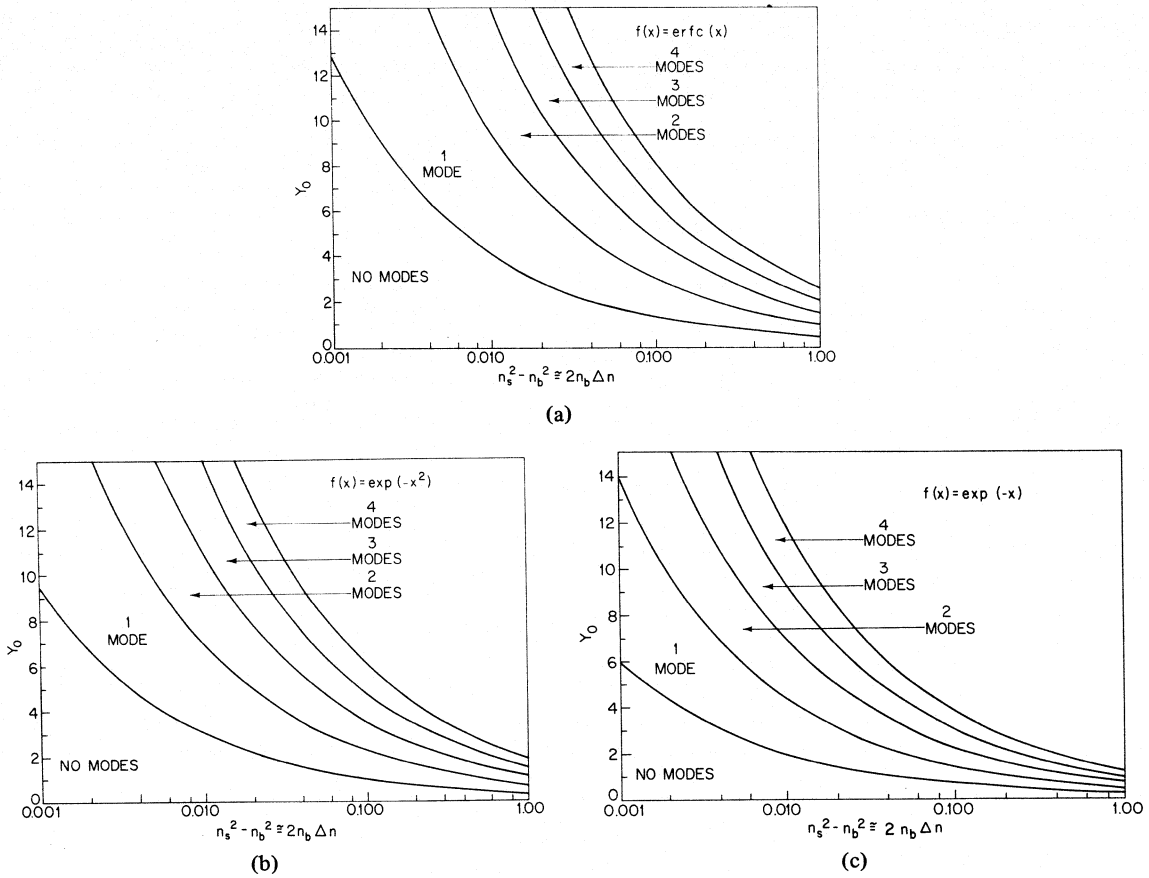

Fig. 5. Universal chart of diffusion depth $Y_0 = D/\lambda$ versus $n_s^2 - n_b^2 \cong 2n_b\,\Delta n$ showing the number of waveguide modes for a diffusion shape of the following. (a) A complementary error function. (b) A Gaussian. (c) An exponential.

[2]. Measurements of TM coupling angles were made on a Gaertner L123 Precision Spectrometer which allowed angular readings to 5″. Resetability errors then predominate and correspond to experimental uncertainties in effective index of $\pm 2\text{-}3 \times 10^{-3}$ percent. A best fit of the experimental data is plotted on both the Gaussian and complementary error function universal charts in Fig. 4 [2]. Comparison of these plots implies that diffusion profiles which closely approximate a complementary error function were obtained, particularly so for the six-mode waveguide. The three- and six-mode waveguides had values for Δn and D of 0.016 and 4.24 μm, and 0.0051 and 14.9 μm, respectively, based on the complementary error-function profile [14].[1]

The cutoff of the mth mode is easily found from (21), since for cutoff $b \to 0$ and $x_t \to \infty$. Thus cutoff of the mth mode is given by

$$V \int_0^\infty \sqrt{f(x)}\,dx = (m + \tfrac{3}{4})\,\pi \tag{22}$$

or, in terms of the (unnormalized) diffusion depth and indices of refraction

$$Y_0 = D/\lambda = \frac{(m + 3/4)}{2\sqrt{n_s^2 - n_b^2}\displaystyle\int_0^\infty \sqrt{f(x)}\,dx}. \tag{23}$$

Curves of Y_0 versus the parameter $(n_s^2 - n_b^2)$ $(\cong 2n_b\,\Delta n)$ for cutoff of the first five modes are shown in Fig. 5(a)-(c) for $f(x)$ given by a complementary error function, a Gaussian, and an exponential, respectively. These are universal charts similar to the form of Fig. 3, relating the diffusion depth and parameter $(n_s^2 - n_b^2)$ to the number of modes supported by the guide.

IV. Conclusions

Both the numerical method of Section II and the generalized method of Section III can be used to describe the modes of diffused optical waveguides of a variety of index profiles. The calculations of Section II are capable of high accuracy in finding the allowed set of n_{eff} from n_b, Δn, and Y_0 for a given shape $f(x)$. However, these calculations must be repeated for each change in the parameters. The methods of Section III are a less accurate but more practical alternative. The charts given in that section suffice, within the approximations made to describe all diffused waveguides having complementary error function, Gaussian, and exponential profiles.

[1] *Note Added in Proof:* Better data have improved the fit to the erfc profile for the sixth mode of the six-mode guide.

Noise Characteristics of Stripe-Geometry Double-Heterostructure Junction Lasers Operating Continuously—I. Intensity Noise at Room Temperature

THOMAS L. PAOLI, MEMBER, IEEE

Abstract—**Measurements of the noise fluctuations present in the output intensity from stripe-geometry double-heterostructure junction lasers operating continuously at room temperature are reported. In some but not all the lasers studied, the low-frequency (50-MHz) fluctuations exhibit the quieting expected of an amplitude-stabilized oscillator operating above threshold. The intensity noise in these lasers becomes shot noise limited at currents about 10 percent above threshold, even when many longitudinal modes are oscillating. Additional measurements demonstrate explicitly the effective elimination of the wave-interaction, or excess, noise during the transit of the threshold region. However, in other lasers which are nominally similar, only a partial reduction of the excess noise occurs above threshold, resulting in a noise level which can be more than ten times the shot-noise limit. In addition, we find in all lasers studied thus far no quieting at high frequencies (4 GHz), in apparent contradiction to the behavior expected of a well-stabilized oscillator.**

Manuscript received December 2, 1974. Preliminary results of this paper were presented at the 8th International Quantum Electronics Conference, San Francisco, Calif., June 10–13, 1974.

The author is with Bell Laboratories, Murray Hill, N.J. 07974.

I. INTRODUCTION

SINCE the pioneering work of Armstrong and Smith [1] in 1964, the statistical properties of the light emitted by a junction laser have received very little attention. However, the utilization of this laser as a source in an optical communication system necessitates a thorough evaluation of its noise characteristics. Furthermore, a detailed investigation of the statistical fluctuations of its emission and junction current can provide much information about the fundamental properties of this laser.

Intrinsic fluctuations in the output intensity of junction lasers were theoretically studied first by McCumber [2], then by Haug and Haken [3], [4], and most recently by Morgan and Adams [5]. In addition to the early experimental work of [1], the fluctuations in the neighborhood of the spiking resonance were observed by Paoli and Ripper [6], while the intensity noise in multifilament lasers has been

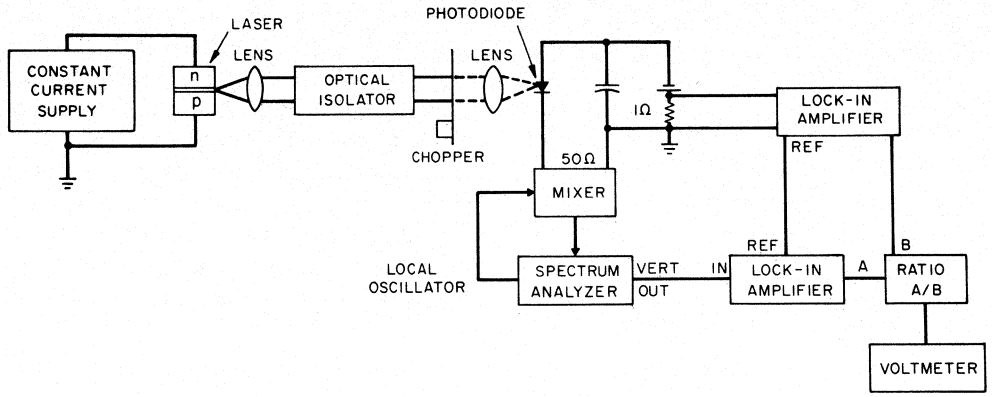

Fig. 1. Schematic diagram of the system used to measure the relative noise fluctuations of the light intensity from stripe-geometry double-heterostructure junction lasers.

studied by Guekos and Strutt [7]. The latter work indicates the complications inherent in attempting to measure the intrinsic intensity fluctuations in the presence of random filaments.

In this paper, we present experimental observations of the intensity-noise characteristics of present-day stripe-geometry junction lasers operating continuously at room temperature. Some initial results of this work were briefly reported previously [8]. In general, we find that some but not all of our lasers exhibit the quieting expected of an amplitude-stabilized oscillator operating above threshold. Low-frequency (50-MHz) intensity fluctuations in these lasers are shot-noise limited at currents greater than about 10 percent above threshold, even when many longitudinal modes are oscillating. However, other lasers which are nominally similar exhibit intensity noise which is many times higher than the shot-noise limit. In addition, we find in all lasers studied thus far no quieting at frequencies above the spiking resonance.

II. Experimental Details

A. Measurement System

Fluctuations in the light intensity from CW junction lasers were measured with the single-detector system shown schematically in Fig. 1. Because of the low level of the signal generated by the intensity fluctuations, phase-sensitive detection was utilized to improve the overall signal-to-noise ratio. Consequently, the laser light was collected and chopped before being focused onto a coaxially mounted Si p-n avalanche photodiode or a Si p-i-n photodiode. An optical isolator, consisting of a polarizer and a quarter-wave plate, was inserted between the laser and the photodiode to avoid interaction of the laser with reflections from the detector. The photodiode was biased at constant voltage with a coaxial capacitive coupling.

The ac output of the photodiode was coupled through the capacitor to a double-balanced mixer (Relcom M1F) which was used[1] in place of the internal input mixer of a conventional spectrum analyzer (Hewlett-Packard, 851B/8551B). In this way, the sensitivity of the receiver was increased by more than 10 dB. With this improvement plus the gain provided by the avalanching photodiode, the sensitivity of the system was more than 20 dB greater than that of the receiver used previously [6]. Consequently, the shot-noise level was within the system sensitivity, even at laser currents well below threshold.

The vertical output of the analyzer was directed to a lock-in amplifier whose output provided the A input for a ratio unit (PAR model 230). The B input was obtained from the output of a second lock-in whose input was the average photocurrent as measured by the chopped voltage produced across a 1-Ω standard resistor located at the output of the bias supply. The output of the second lock-in was also taken as indicative of the average light intensity.

The output at frequency $f = \omega/2\pi$ of the system described previously is [2]

$$S_{\mathrm{REL}}(f) = \frac{2\Delta f|b(\omega)|^2}{|b(0)|} \cdot \frac{[\eta\langle N\rangle_t F + \eta^2 P(\omega)]}{\eta\langle N\rangle_t} \tag{1}$$

where $\langle N\rangle_t$ is the time-average light intensity in photons/second, η is the quantum efficiency of the detector, F is the noise factor for the photodiode [9], $b(\omega)$ is the frequency-response function for the complete system including the gain and carrier-transport factors for the photodiode [9], Δf is the analyzer bandwidth, and $P(\omega)$ is the power spectrum of the fluctuating intensity. We call $S_{\mathrm{REL}}(f)$ the relative noise power since it is a measure of the intensity noise relative to the shot noise expected for the same average photocurrent. The first term on the right of (1) arises from shot-noise fluctuations of the signal. The factor F accounts for the enhancement of the shot noise by the gain process within the photodiode and increases with the carrier multiplication [9]. The second term, which is called the excess noise, arises from the time variation of the intensity. The power spectrum $P(\omega)$ is directly related to the intensity-correlation function of the incident light. For the later discussion, we rewrite (1) in normalized form as

$$S_{\mathrm{REL}}(f) = \alpha F + \eta\alpha \frac{P(\omega)}{\langle N\rangle_t} \tag{2}$$

where $\alpha \equiv 2\Delta f|b(\omega)|^2/|b(0)|$. For comparison, we note that the relative noise power $S_{\mathrm{REL}}(f)$ is αF times the factor

[1] Spectrum-analyzer modification kit A (Relcom p/n 7001-0689).

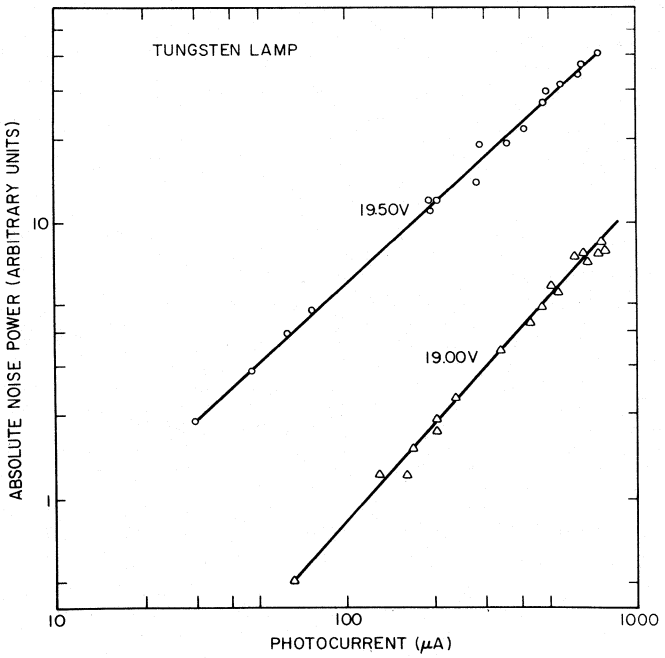

Fig. 2. The absolute noise power at 50 MHz produced by a tungsten lamp as a function of the photocurrent. The photocurrent is varied by attenuating the lamp intensity with neutral-density filters. Note the substantial gain in signal, i.e., absolute noise power, obtained by increasing the bias voltage on the avalanching photodiode from 19.00 to 19.50 V.

$(1 + S_e/S_s)$ used by Freed and Haus [10] to characterize the noise of He-Ne lasers.

For a broad-band optical source, such as an incandescent lamp, the spectral brightness is too low to produce detectable excess noise in comparison with the shot noise. Consequently, the sensitivity and linearity of the system were determined by measuring the noise produced by a tungsten lamp as a function of the photocurrent. The photocurrent produced by the lamp was varied over the same range as that obtained with the lasers by attenuating the lamp output with neutral-density filters. The experimental results shown in Fig. 2 indicate that the system response is reasonably linear and that a substantial gain in signal, i.e., the absolute noise, is obtained with the avalanching photodiode. Since the noise level of the overall receiver is determined primarily by noise intrinsic to the spectrum analyzer, the signal gain obtained from the photodiode leads directly to improvement of the signal-to-noise ratio of the system. For the measurements described in the following, the bias voltage was held constant at 19.50 V.

B. Lasers

Lasers used in the present work were fabricated from conventional double-heterostructure material grown by liquid-phase epitaxy [11] under near-equilibrium conditions [12]. The four-layered wafers were composed of a thin layer of p-type GaAs (the active layer) sandwiched between p- and n-type layers of $Al_xGa_{1-x}As$. The $Al_xGa_{1-x}As$ layers contained between 24 and 36-percent Al, depending on the wafer. The active layers were 0.2–0.3 μm thick and doped with Ge to provide a hole concentration in the low 10^{17}-cm^{-3} range.

Stripe-geometry lasers were fabricated from the epitaxial wafers by proton bombardment [13]. The use of the stripe-geometry eliminates the complications inherent in broadly contacted diodes which oscillate in random filaments. All lasers had stripe widths nominally equal to 13 μm. In most cases, thick Au pads were plated on the p-side before cleaving. For efficient heatsinking, each laser was bonded to a metallized high-thermal-conductivity diamond mounted on a copper stud.

Laser current was provided either by a 6-V storage battery or by a commercial constant-current source. Within the experimental accuracy, both sources gave identical results.

III. Experimental Results

A. Amplitude-Stabilized Lasers

As reported previously [8], the frequency spectrum of the fluctuating light intensity from a GaAs junction laser operating above threshold contains a pronounced peak due to the excitation of the "spiking" resonance of the laser by quantum shot noise. At currents just above threshold, the frequency of this resonance is typically 200–500 MHz for 380-μm-long lasers. At frequencies below about 100 MHz, the spectrum has been observed [8] to be essentially flat, as expected theoretically [2], [4], [5]. Consequently, we can take measurements of the noise at a convenient frequency, such as 50 MHz, to be indicative of the behavior of the low-frequency plateau.

In some GaAs double-heterostructure lasers, a pronounced reduction in the low-frequency intensity noise occurs above threshold as predicted [2], [4], [5]. Such behavior was reported previously [8] for Si-doped lasers and is shown in Fig. 3 for one of the Ge-doped lasers studied in the present work. At currents below 75 mA, the relative intensity noise in the light polarized parallel to the junction plane (TE) is essentially independent of the current, or equivalently, the light intensity. This behavior indicates that the intensity fluctuations have the character of pure shot noise in this current range. As the current is increased above 75 mA, stimulated emission becomes an appreciable fraction of the TE intensity as indicated by the superlinear increase of the intensity shown in Fig. 3. Consequently, the relative noise increases abruptly with current until the threshold (91 mA) for amplitude-stabilized oscillation is reached. Further increases in current produce a rapid decrease of the relative noise back to its low-current value as the dynamic saturation of the gain effectively stabilizes the intensity fluctuations. The existence of regenerative oscillations in this diode was also confirmed by the existence of a sharp "knee" (at 88.5 mA) in the variation of the TE intensity with current (also shown in Fig. 3) and by observation of the longitudinal-mode spectrum. The spectrum of the total emission at a current well above threshold, as shown in Fig. 4, indicates that regenerative oscillation occurs in many longitudinal modes. As reported previously [8], the spectral observations do not define a precise value for the threshold current, since on the scale of 1-mA changes in the current there is no abrupt change in the spectrum.

On the other hand, over the entire current range, the relative noise in the intensity of the light polarized perpendicular to the junction plane (TM) remained approximately constant and

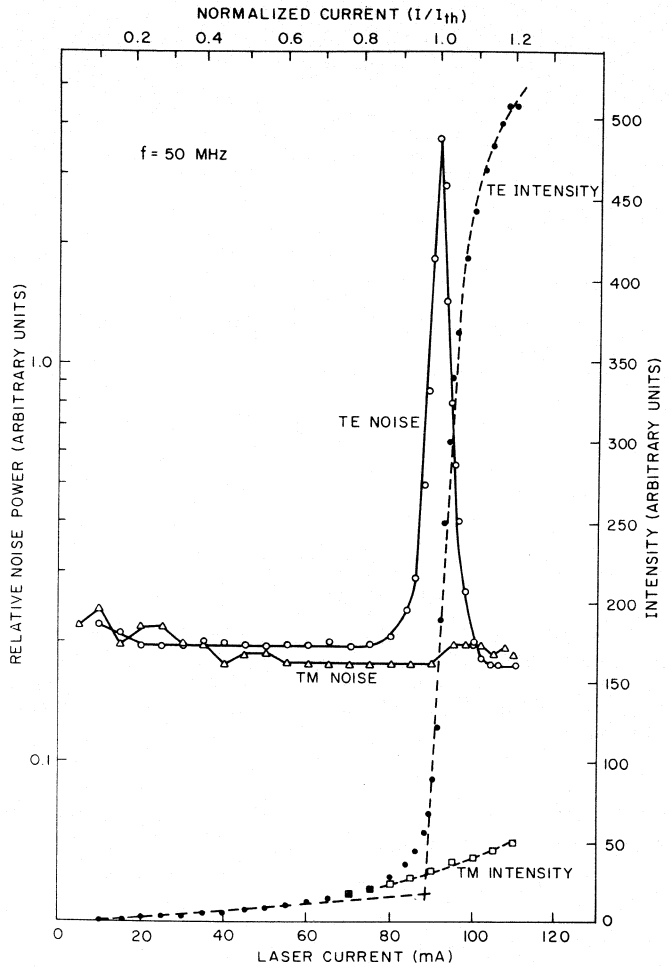

Fig. 3. Variation of the relative intensity noise for both TE and TM polarized light as a function of laser current. The noise power is measured in a 1-MHz interval centered at 50 MHz. Also shown are the variation of the intensities of the TE and TM light as a function of laser current.

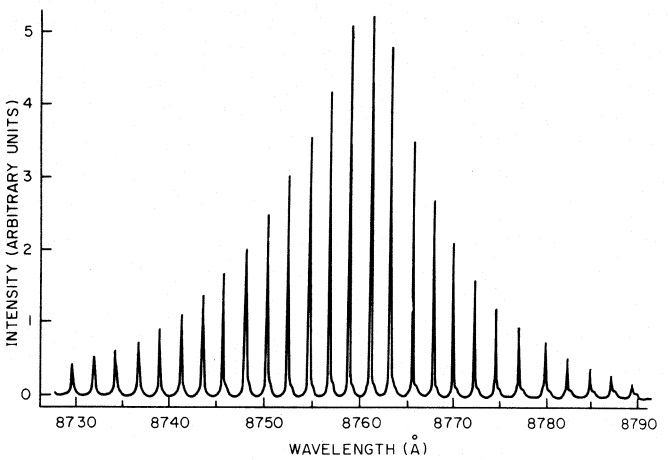

Fig. 4. The spectra of the total light intensity emitted by the same laser as used in Fig. 3. The operating current is 110 mA and corresponds to a point 20 percent above threshold where there is no observable excess noise in the TE intensity.

equal to the noise in the TE emission at low currents. This behavior indicates that the TM modes do not oscillate and, in fact, experience little gain narrowing of their linewidth. The subthreshold nature of these modes was confirmed by 1) the

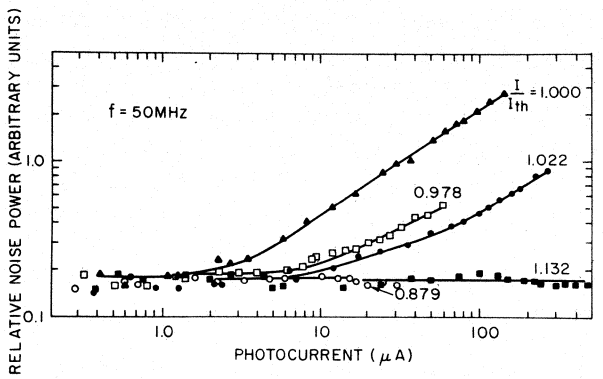

Fig. 5. Variation of the relative intensity noise at 50 MHz for TE polarized light as a function of laser intensity incident on the photodiode. For each curve the laser current is maintained constant equal to the value indicated by the respective label. The threshold current is taken as the current at which the relative noise is maximum in Fig. 3.

absence of a knee in the variation of their intensity with current, as shown in Fig. 3, and 2) the absence of deep nulls in their spectrum.

In the vicinity of threshold, the pronounced change in the character of the noise is readily observed in the variation of the relative noise power with photocurrent for different laser currents. By attenuating the laser intensity with neutral density filters, the experimental results shown in Fig. 5 were obtained for the laser of Fig. 3. At laser currents well below ($0.879\ I_{th}$) and well above ($1.132\ I_{th}$) threshold, the relative noise at 50 MHz is independent of the average light intensity which is incident on the detector. This behavior indicates that the intensity fluctuations at this frequency are pure shot noise. On the other hand, at threshold, just below ($0.978\ I_{th}$), and just above ($1.022\ I_{th}$), the relative noise decreases with decreasing incident intensity, indicating the presence of appreciable intensity-dependent excess noise. However, as the intensity is decreased to values where the excess noise becomes negligible, the relative noise becomes independent of photocurrent and equal to the value $(\alpha F)_{50\ \mathrm{MHz}} = 0.175 \pm 0.025$ established by the system response to pure shot noise. In principle, the shot-noise level αF can also be determined from the measurements made with the tungsten lamp as described in Section II-A. However, in practice the value obtained with the lamp was only about 65 percent of the value obtained with the lasers. This difference may be due to the larger detector area seen by the focused image of the lamp as compared to the laser. This conclusion is suggested by the agreement of the values for αF found with the junction lasers, spontaneously emitting diodes, and a He-Ne laser.

At laser currents where the excess noise is appreciable, the linearity of the behavior at high photocurrents shown in Fig. 5 suggests that the power spectrum of the intensity fluctuations is proportional to a power of the average intensity. The value of this exponent is obtained from the slope of a log-log plot of the excess noise, i.e., $S_{\mathrm{REL}}(f) - \alpha F = \eta\alpha P(\omega)/\langle N\rangle_t$ versus photocurrent. For the measurements at $I = 0.978\ I_{th}$, we find that $P(\omega)$ varies very nearly as $\langle N\rangle_{t,cc}^2$,[2] in agreement with

[2]The subscript *cc* indicates laser current is held constant.

the behavior expected for a noise amplifier operating with fixed gain [1]. For $I = 1.000\ I_{th}$, i.e., the current at which $S_{REL}(f)$ reaches its maximum value in Fig. 3, we find $P(\omega) \sim \langle N \rangle_{t,cc}^{1.85}$ which is close to the expected quadratic behavior.

A similar analysis of the excess noise as a function of increasing laser current indicates that below threshold $P(\omega)$ in this laser varies as $\langle N \rangle_t^{5.5}$.[3] However, at currents in the vicinity but below threshold where many identical modes are excited, $P(\omega)$ is expected [2] to increase as $\langle N \rangle_t^3$. This discrepancy suggests that the linearized theory as applied to many identical modes may not adequately describe the detailed variation of the noise in the subthreshold region. Above threshold, we find that the dependence of $P(\omega)$ on $\langle N \rangle_t$ cannot even be represented by a simple power, indicating clearly that quantitatively a single-mode theory of the intensity noise does not apply to the multimode laser intensity. However, a detailed comparison with the multimode theory [2] has not been undertaken due to our lack of knowledge of the modal parameters.

Although the intensity noise at 50 MHz shows the pronounced reduction expected of an amplitude-stabilized oscillator above threshold, the excess noise at frequencies above the resonance exhibits no such quieting. For example, Fig. 6 shows the variation of the relative noise $S_{REL}(f)$ in a 1-MHz bandwidth centered 200 MHz above and below 4 GHz[4] (a convenient frequency) as a function of laser current. At currents below threshold the behavior of the noise in the TE light near 4 GHz is similar to that at 50 MHz, i.e., the relative noise remains constant for currents up to 75 mA and then increases rapidly as the pump current approaches threshold. However, in marked contrast to the low-frequency fluctuations, the 4-GHz noise shows only a very small reduction as the current is increased just above threshold before continuing to increase anomalously with further increases in current. This anomalous increase in the high-frequency noise is qualitatively similar to that observed previously [8] with Si-doped double-heterostructure lasers. However, in the latter case, no evidence of any reduction was observed at threshold.

As shown in Fig. 6, the relative noise in the TM modes, which do not experience appreciable gain, remains approximately constant over the entire range of currents. The value of this constant 5.5 ± 0.5 coincides within the experimental accuracy with the value for the noise in the TE emission at low pumping. Additional measurements described in the next paragraph and others performed with LED's and a He-Ne laser indicate that the constant 5.5 ± 0.5 is the response of the detection system to shot noise, i.e., $(\alpha F)_{4\ GHz}$. However, as with the measurements at 50 MHz, $(\alpha F)_{4\ GHz}$ obtained this way is slightly greater than the value obtained with a tungsten lamp.

The characteristics of the noise near 4 GHz were also studied by varying with neutral-density filters the intensity of the TE emission incident on the detector. The resulting dependence

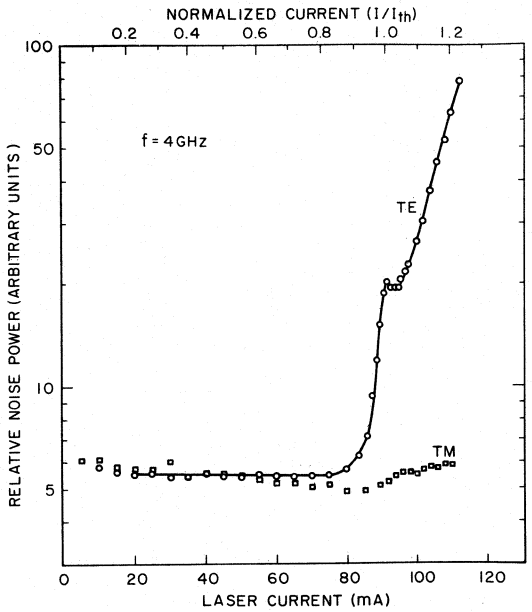

Fig. 6. Variation of the relative intensity noise in 1-MHz intervals centered 200 MHz above and below 4 GHz as a function of the laser current for the same laser as Figs. 3 and 4. For current normalization, threshold is taken as the current at which the relative noise is maximum in Fig. 3.

of the relative noise power on the photocurrent $\propto \langle N \rangle_{t,cc}$ is shown in Fig. 7 for several laser currents. At a current well below threshold ($0.879\ I_{th}$), the relative noise at 4 GHz remains constant $(\alpha F)_{4\ GHz} = 5.5 \pm 0.5$ with changes in the photocurrent, indicating pure shot noise. At higher laser currents, the relative noise decreases with decreasing incident intensity, indicating the presence of appreciable intensity-dependent excess noise. At low intensities where the excess noise is negligible, the relative noise again approaches the shot-noise value $(\alpha F)_{4\ GHz} = 5.5 \pm 0.5$ for each laser current.

Analysis of the excess noise at 4 GHz as a function of the incident intensity indicates that at constant laser current $P(\omega)$ varies as $\langle N \rangle_{t,cc}^m$. The exponent m is 1.90, 1.91, 1.93, and 1.84 at I/I_{th} equal to 1.000, 1.044, 1.132, and 1.209, respectively. The proximity of the values for m to 2 suggests that the excess noise even at a laser current where it is anomalously high is not substantially different from the noise obtained with an amplifier operating with unsaturated gain.

Further analysis of the excess noise as a function of increasing laser current suggests that $P(\omega)$ at 4 GHz in this laser varies as $\langle N \rangle_t^{4.85}$ over a limited range of currents below threshold. Above threshold, and especially in the range of anomalous excess noise, no simple dependence on $\langle N \rangle_t$ could be found for $P(\omega)$.

B. Unstabilized Lasers

Not all of the double-heterostructure lasers studied in this work show the characteristic quieting described in the previous section. In some lasers, the excess intensity noise at low frequencies is only partially reduced above threshold, as shown in Fig. 8. At best, the light intensity from this device is nearly twice as noisy when oscillating regeneratively as when operated as a purely spontaneous emitter. As indicated in

[3] Note that laser current is varied to obtain this dependence, hence the absence of the subscript *cc*.

[4] Signals at both 3.8 and 4.2 GHz are detected simultaneously when the local oscillator frequency is 4 GHz, since the IF frequency is 200 MHz.

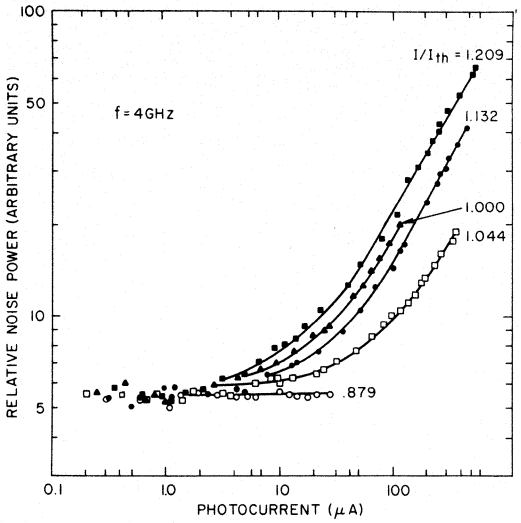

Fig. 7. Variation of the relative intensity noise near 4 GHz for TE polarized light as a function of laser intensity incident on the photodiode. For each curve the laser current is maintained constant.

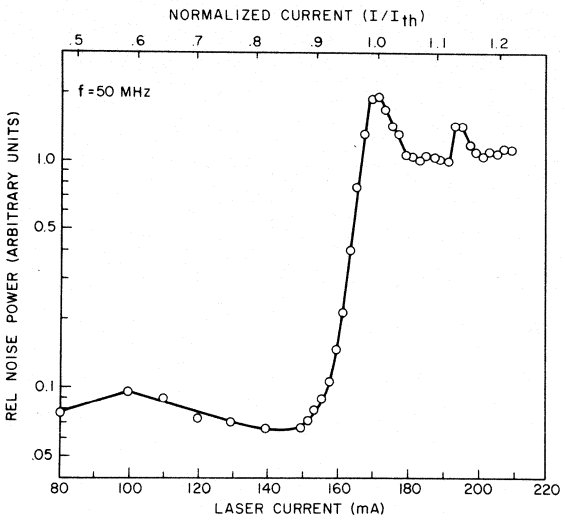

Fig. 9. Variation of the relative noise at 50 MHz for the TE emission as a function of laser current for another unstabilized laser.

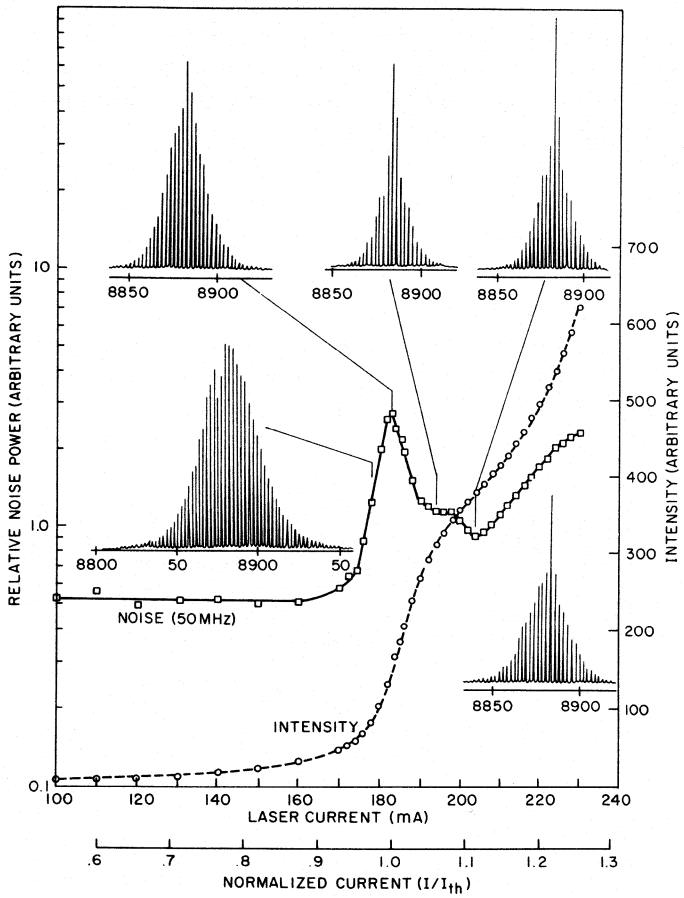

Fig. 8. Variation of the relative intensity noise at 50 MHz and the total intensity of the TE emission as a function of laser current for an unstabilized laser. The longitudinal mode spectra obtained at selected currents are also shown.

Fig. 8, the total intensity also departs from a linear dependence on pump current at the current where the relative noise stops decreasing. Similar "kinks" in the intensity-current relation have been reported previously [14], especially for lasers with stripe widths greater than 20 μm. At the present time, the exact cause of this nonlinear behavior is not known for certain and the number of diodes studied thus far is insufficient to determine whether it is always accompanied by incomplete stabilization of the intensity fluctuations.

In addition, as the current in this laser is increased more than 11 percent above threshold, the relative intensity noise also increases. This increase in the noise seems to be accompanied by a slight broadening of the overall spectrum on the short wavelength side, as indicated by the spectra shown in Fig. 8. Furthermore, high-resolution scans of each longitudinal mode show a loss of the fine structure associated with transverse modes of different spatial distribution along the junction plane [15]. The disappearance of the spectral fine structure on each longitudinal mode may indicate either a spectral broadening of the linewidth of the fundamental transverse mode or a decrease of the frequency interval between the transverse modes. The high-resolution spectra as well as visual observation of the far field also show no evidence for the onset of oscillation in a second filament.

The behavior of another laser for which only a partial reduction of the excess noise occurs is shown in Fig. 9. The fluctuations in the emission from this laser are of particular interest since regenerative oscillation occurred primarily in a single longitudinal mode, as indicated by the spectra of Fig. 10. Although single-mode lasers might be expected from earlier work [16] done at 4.2 K to be at least as quiet as multimode devices, this particular device is more than 10 times noisier above threshold than below. However, the high level of noise in this case is probably not a result of oscillation in a single mode. Another laser from the same wafer also showed a high level of excess noise above threshold but oscillated in many (7-10) longitudinal modes. Unfortunately, the small number of lasers available for testing has precluded determining whether this type of instability is symptomatic of a wafer or only of individual lasers. In addition, both lasers were about 8 mils long and the dependence of stabilization on laser length, if any, has not been determined. Finally, it is interesting to note that the slight perturbation in the noise level which

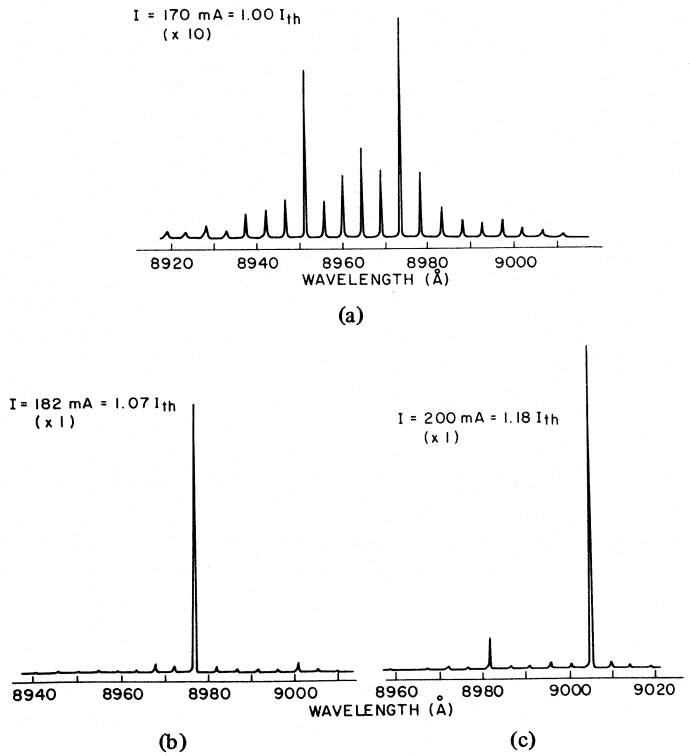

Fig. 10. Longitudinal mode spectra for the same laser as Fig. 9.

occurs between 190 mA and 200 mA was accompanied by a change in the oscillating longitudinal mode as shown in parts (b) and (c) of Fig. 10. However, further study is required to determine if this relation is significant or only coincidental.

IV. Conclusion

In this work we have investigated the noise fluctuations present in the total intensity of stripe-geometry GaAs-$Al_xGa_{1-x}As$ double-heterostructure junction lasers operating continuously at room temperature. The experimental results show that in some lasers stabilization of the low-frequency (50-MHz) fluctuations occurs at threshold. As predicted by McCumber [2], this stabilization of the total intensity occurs even when many longitudinal modes are oscillating regeneratively. In a well-stabilized laser, we have shown that the intensity fluctuations can be reduced to pure shot noise at pump levels as low as 10 percent above threshold. With additional measurements we have also demonstrated the effective elimination of the intensity-dependent excess noise during the transit of the threshold region.

In the same lasers, however, stabilization of high-frequency (4-GHz) fluctuations does not accompany the quieting observed at low frequencies. Although a slight reduction of the excess noise at 4 GHz is observed to occur at threshold, further increases in the level of the laser current above threshold cause the high-frequency noise to increase anomalously. At 20 percent above threshold, the noise level can be more than an order of magnitude greater than pure shot noise. At present, the precise source of this high noise level is not known. However, it is clear that such noise does not originate in a high-frequency disturbance of the population inversion, since nonlasing emission in the orthogonal polarization shows no increased noise. The lack of stabilization may indicate that for times shorter than about 0.5 ns the population inversion does not respond to the fluctuating intensity rapidly enough to provide effective quieting. Such an ineffective response could result from an unexpectedly long energy or spatial relaxation time. In addition, interactions between the fundamental and first-order transverse modes (along the junction plane) with the same longitudinal mode number may be important in determining the observed noise at 4 GHz, since the intermode spacing is about 5.5-6 GHz in these lasers. However, these and other possibilities require further study for clarification.

This initial investigation of the noise characteristics of room-temperature junction lasers has also demonstrated that many stripe-geometry lasers exhibit only a partial reduction of the low-frequency excess noise above threshold, resulting in a noise level which can be more than 10 times pure shot noise. Lasers with this behavior have been observed to oscillate in either many or primarily one longitudinal mode. No evidence was found to indicate that this type of instability was a result of competitive interactions between filaments. The exact cause of the ineffective stabilization has not been determined but is presently under investigation. In particular, the possibility that this instability is symptomatic of certain laser batches needs to be given serious consideration. The reproducibility of low-noise lasers remains an open but important question.

Acknowledgment

The author wishes to thank H. Melchior for useful discussions, C. J. Hwang, J. C. Dyment, and R. L. Hartman for providing the lasers, and B. C. De Loach, Jr., and L. A. D'Asaro for helpful comments on the manuscript.

Microwave Switching by Picosecond Photoconductivity

A. M. JOHNSON AND D. H. AUSTON

Abstract—**Bulk photoconductivity produced by the absorption of picosecond optical pulses in silicon transmission-line structures has been used to switch and gate microwave signals. The technique permits the generation of microwave and millimeter-wave pulses as short as a single cycle, and requires only a few microjoules of optical energy. The basic features of the device are illustrated with switching experiments at 1 GHz and 10 GHz, and the results are discussed with reference to the physical properties of the high-density plasma responsible for the switching.**

I. Introduction

IN MANY CASES, both for experimental purposes and for applications, it is desirable to have a capability for generating very short bursts of microwave and millimeter-wave signals of relatively high power. The current state of the art, however, is limited to switching speeds of approximately 1 ns [1]. Furthermore, at these speeds, the semiconductor p-i-n diodes which are used for this purpose are limited to powers of a few tens of watts. In this paper, we describe a simple optical technique for switching microwave signals which offers a significant improvement of both speed and power handling.

Although bulk semiconductor plasmas have received considerable attention as microwave switching devices [2], the use of high-density, optically generated plasmas has not been given serious consideration. Aside from the obvious speed capability, picosecond optical pulses have the additional advantage of enabling the generation of extremely high-density plasmas without damaging the material. Longer optical pulses are less efficient since they tend to produce more heating, and consequently are more likely to cause damage. It has recently been demonstrated [3] that plasma densities in excess of 10^{20} cm^{-3} can be readily generated by the absorption of single-picosecond optical pulses in semiconductors. Plasmas such as these are highly degenerate and have quasi-metallic properties. Their high conductivities make them ideal for bulk switching applications. The research reported in this paper is an extension of related work [4] in which switching and gating of dc signals was achieved with solid-state plasmas produced by picosecond pulses.

II. Optoelectronic Microwave Switching

An example of a microwave switch which utilizes the photoconductivity produced by picosecond optical pulses is illustrated in Fig. 1. It consists of a 50-Ω microstrip transmission-line [5] structure fabricated on a high-resistivity silicon substrate. The microstrip line consists of a uniform aluminum ground plane on the bottom and a narrow strip for an upper conductor in which there is a gap. Input and output microwave signals are coupled to the silicon chip by 3-mm coaxial-to-microstrip launchers. In a typical application, one side of the device would be connected to a microwave-signal source and the other to a load or test instrument. The switching action is produced by two optical pulses; one in the green region of the spectrum at $\lambda = 0.53$ μm, which is used to turn on the switch, and the other in the infrared at $\lambda = 1.06$ μm, which turns it off. The absorption constant at $\lambda = 0.53$ μm in silicon is 8×10^3 cm^{-1}, and consequently the effect of absorbing a green pulse in the microstrip gap is to produce a thin surface

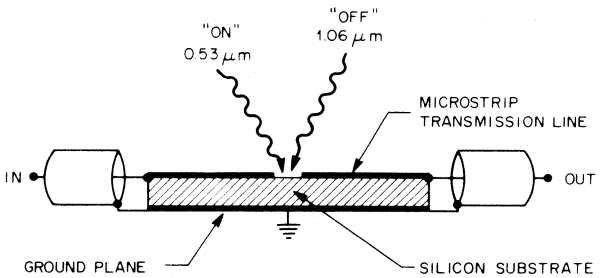

Fig. 1. An optoelectronic switch. The transmission of the switch is turned on by a surface layer of photoconductivity produced by the green pulse, and is turned off by volume photoconductivity produced by the infrared pulse, which shorts the device.

layer of conductivity across the gap. If it is sufficiently intense, the green pulse can close the gap by producing a net resistance which is much less than the characteristic impedance of the microstrip line, thus permitting efficient transmission of the microwave signal across the device.

To turn off the switch the infrared pulse is absorbed at the gap. In this case, however, the absorption depth is 1.4 mm, and consequently the pulse penetrates through the substrate to the ground plane, producing a region of high conductivity between the upper and lower conductors. This shorts the transmission line, preventing further transmission by totally reflecting the incident microwave signal. Unlike conventional semiconductor junction devices, this switch does not depend on recombination or carrier sweepout to turn off. The optically generated electrons and holes remain; the volume conductivity of the second pulse has merely annulled the effect of the surface layer of conductivity produced by the first pulse. Consequently, the switching speed can be extremely fast, being primarily limited by the durations of the optical pulses. Also the device is capable of handling moderately high microwave powers unlike conventional semiconductor switches which are limited by junction breakdown and thermal dissipation. Since the controlling signals are optical pulses, near-perfect isolation exists between the gated microwave signals and the gating signals. A disadvantage of this technique is the repetition rate, since carriers must recombine or be swept out before the switch can be used again. This aspect of the device is discussed in detail in Section VI.

The specific device illustrated in Fig. 1 consisted of a silicon slab of resistivity, $\rho = 10^4\ \Omega \cdot$ cm, measuring 1.5 X 1.5 X 0.043 cm, which was syton polished on both faces. The microstrip conductors were formed by evaporating 5000 Å of aluminum through a shadow mask, followed by a heat treatment of 10 min at 550°C in flowing N_2. The strip width was chosen to be 0.034 cm for a characteristic impedance Z_0 of 50 Ω. The size of the gap in a typical case was equal to the strip width.

The microstrip geometry is particularly suitable for the device since it is capable of supporting a quasi-TEM mode of low dispersion over very large bandwidths. This feature permits a single device to be used over a wide range of carrier frequencies and, more important, it enables it to handle extremely fast transients which may have bandwidths almost as large as the carrier frequency (e.g., when gating a single cycle, $\Delta f \simeq f_0$).

The optical pulse at 1.06 μm was generated by extracting a single pulse with a laser-triggered spark gap and Kerr cell from a train produced by a mode-locked Nd:glass laser (see Fig. 2). The 0.53-μm pulse was produced by second-harmonic generation in a 1-cm KDP crystal. These two pulses were then separated in a dichroic beamsplitter, the infrared pulse was delayed relative to the green pulse, and both pulses were focused onto the microstrip gap. From previous measurements the widths of the infrared and green pulses were estimated to be approximately 8 and 5 ps, respectively.

III. Experimental Results

To evaluate the performance of the switch, measurements were made at two microwave frequencies, 1 GHz and 10 GHz. The reason for using the low 1-GHz carrier frequency was simply to permit the direct observation of the gated waveshape on a high-speed oscilloscope without using a microwave detector. The low repetition rate of 3 pulses per minute of the Nd:glass laser prevented the use of a sampling oscilloscope. The input cable was connected directly to a 1-GHz oscillator of approximately 100-mW output power, and the gated output was connected directly to a fast oscilloscope of 1-GHz bandwidth (rise time was 0.3 ns). Green and infrared pulses of approximately 10 μJ each were used for switching. Typical results are shown in Fig. 3. In Fig. 3(a) a burst of approximately 8 cycles was generated by first turning on the switch with a green pulse and then turning it off with an infrared pulse delayed 8 ns. In Fig. 3(b), a delay of only 1 ns was used to produce a microwave pulse of a single cycle. The peak transmission through the gate was at least 95 percent, and no appreciable signal level was observed on the oscilloscope when the switch was in the off state both before and after the gating pulses.

To measure the response at 10 GHz a high-speed back-diode microwave detector in a 3-mm coaxial mount was used to rectify the output signal. The detector output was amplified in a pulse amplifier with a gain of 35 and displayed on the oscilloscope. The overall system time response of the detector-amplifier-oscilloscope combination was estimated to be 2.0 ns. Typical results are illustrated in Fig. 4. In Fig. 4(a) the effect of the green pulse is observed (the detector output signal was negative), showing a clean step with a rise time limited by the detection system. Fig. 4(b) shows the effect of the infrared pulse, which terminates the signal transmission in an equally

(b)

Fig. 4. Optoelectronic gating of a 10-GHz signal. The transmitted microwave signal was detected, amplified, and displayed on a fast oscilloscope (negative signal). In (a) the effect of the green pulse is seen to turn on the transmission, and in (b) the infrared turns it off. (10 ns/div.)

fast time. In this case, the delay between the infrared and green pulses was approximately 6 ns. The peak microwave power was approximately 25mW. These results are very reproducible, and no damage was observed to either the metallization or the silicon after many hundreds of shots.

At the time these experiments were performed, a high-power source of microwaves was not available, and consequently it was not possible to make a complete evaluation of the power-handling capabilities of the switch. The extreme broad-band feature of the device, however, permits us to obtain an estimate from dc power ratings. Constant voltages as large as 100 V have been applied without breakdown or excess heating. For a 50-Ω characteristic impedance this is equivalent to a microwave rating of 200-W CW. If the input signal is pulsed rather than continuous, even greater power ratings should be possible, perhaps as large as 1 kW.

While these preliminary results do not demonstrate the full speed capability of the switch, they do serve to adequately illustrate the basic features of the device. Related measurements [4] in which the switch was used to gate a dc signal clearly demonstrate that the ultimate switching speed can be comparable to the durations of the optical pulses, i.e., as short as 10 ps.

IV. Picosecond Photoconductivity

The response of the switch to the two optical pulses can be analyzed in the following straightforward manner. If recombination and trapping are neglected, the total number of electrons and holes produced in the crystal are each simply equal to the number of absorbed photons. For the case of the surface layer of conductivity produced by the green pulse, we find that the total conductance G_1 across a gap of length l is

$$G_1 = \frac{4n_r}{(n_r+1)^2}\left(\frac{e}{\hbar\omega}\right)(\mu_n+\mu_p)\frac{\mathcal{E}_1}{l^2} \tag{1}$$

where

n_r refractive index of the substrate;
$\hbar\omega/e$ photon energy in volts;
$\mu_n+\mu_p$ sum of electron and hole mobilities;
$\mathcal{E}_1$ energy of green pulse incident on the gap.

Expression (1) was obtained by integrating the conductivity over the exponential profile induced by the absorbed optical intensity. Typical plasma densities and conductivities can be as large as 10^{19}-10^{20} cm^{-3} and a few thousand $(\Omega\cdot\text{cm})^{-1}$, respectively. Collision frequencies of the degenerate solid-state plasma are typically in excess of 10^{12} Hz, and consequently the plasma is highly damped even in the millimeter-wave region. In spite of the high conductivities, the skin depth is greater than the thickness of the plasma layer in most cases of interest.

As an example, we consider a typical case, with the following choice of parameters: $n_r = 3.6$, $\hbar\omega/e = 2.34$ V, $(\mu_n+\mu_p) = 2000$ cm^{2}V^{-1}s^{-1}, $l = 0.034$ cm, and $Z_0 = 50\ \Omega$. The total conductance normalized to the characteristic admittance Z_0^{-1} of the transmission line is

$$G_1 Z_0 = 24/\mu\text{J}. \tag{2}$$

Hence 1 μJ or less should be adequate to provide efficient switching. Notice that the required optical energy for a fixed $G_1 Z_0$ varies as the square of the gap length.

The effect of the infrared pulse can be similarly analyzed. In this case, however, the longer absorption depth necessitates the inclusion of multiple optical reflections between the substrate surfaces. Summing these and integrating over the substrate thickness, the conductance G_2 connecting upper and lower conductors is

$$G_2 = \frac{2\alpha_2^2 n_r}{(n_r+1)^2}\,\frac{e^{-\alpha_2 h}}{\tan^{-1}(\sin h\alpha_2 h)}\left[1-\left(\frac{n_r-1}{n_r+1}\right)^2 e^{-2\alpha_2 h}\right]^{-1} \cdot \frac{e}{\hbar\omega}(\mu_n+\mu_p)\mathcal{E}_2 \tag{3}$$

where

α_2 absorption constant of the infrared pulse;
h substrate thickness;
$\mathcal{E}_2$ infrared pulse energy incident on the gap.

If the absorption depth is considerably larger than the substrate thickness, (3) reduces to the following simpler form:

$$G_2 \simeq \frac{2\alpha_2}{h}\frac{e}{\hbar\omega}(\mu_n+\mu_p)\mathcal{E}_2, \qquad \alpha_2 h \ll 1. \tag{4}$$

For example, with $\alpha_2 = 7$ cm^{-1}, $h = 0.043$ cm, and $\hbar\omega/e = 1.17$ V we find

$$GZ_0 = 8.7/\mu\text{J}. \tag{5}$$

Since the photoconductivity produced by the infrared pulse occupies a larger volume, the plasma density and conductivity are usually considerably less than in the case of the green pulse. Typical densities are 10^{16}-10^{17} cm^{-3} and conductivities 1-10 $(\Omega\cdot\text{cm})^{-1}$. At frequencies up to 10 GHz the skin depth corresponding to the conductivities is still greater than a fraction of a millimeter, and consequently the use of a lumped conductance to describe the infrared photoconductivity is justified. At higher frequencies and larger gap lengths, the detailed transmission properties of the plasma must be

considered. In both the infrared and green-produced plasmas, the conductivities are sufficiently large that the dielectric relaxation time, ϵ/σ, is 1 ps or less, and consequently does not affect the switching speed. Although the infrared pulse is somewhat less efficient than the green pulse in this specific example, it is clear that a few microjoules of infrared should produce an adequate shorting conductance.

The results of the experiments are generally in fair agreement with the theoretical estimates of the photoconductivity. Expressions (1) and (3) tend to underestimate the energy requirements somewhat, particularly in the case of the green pulses. The reason for this may in part be due to a reduction in carrier mobilities at high densities by degeneracy and electron-hole scattering. A more detailed study of photoconductivity at high excitation levels is in progress to determine the importance of these effects.

V. Microwave Transmission

The overall transmission coefficient of the device can be estimated by a simple model which characterizes the photoconductivity by series and parallel lumped-circuit elements in the microstrip transmission line. In addition to the conductances G_1 and G_2, derived in Section IV, it is necessary to account for the small displacement current across the gap due to the finite capacitance of the gap C_g, [6]. The following expressions determine the power-transmission coefficients in the three separate states of the switch:

$$\text{OFF: } T_0 = \frac{4[(G_g Z_0)^2 + (\omega Z_0 C_g)^2]}{(1 + 2Z_0 G_g)^2 + (2\omega Z_0 C_g)^2}, \qquad t < t_1 \quad (6)$$

$$\text{ON: } T_1 = \left| \frac{2G_1 Z_0}{1 + 2G_1 Z_0} \right|^2, \qquad t_1 < t < t_2 \quad (7)$$

$$\text{OFF: } T_2 = \left| \frac{2G_1 Z_0}{1 + 2G_1 Z_0 + G_2 Z_0 + G_1 G_2 Z_0^2} \right|^2, \qquad t_2 < t \quad (8)$$

where t_1 and t_2 are the times at which the green and infrared pulses are absorbed in the microstrip gap and G_g is the conductance of the gap in the absence of any optical pulses. For simplicity, we have assumed that the durations of the optical pulses are negligible compared to the gating period. As an example, we consider a typical case with $\mathcal{E}_1 = \mathcal{E}_2 = 10\ \mu\text{J}$, $C_g = 1.5 \times 10^{-14}$ F, $G_g = 10^{-5}\ \Omega^{-1}$. Using (2), (5), and (6)-(8), we find

$$\text{OFF: } T_0 = 8.9 \times 10^{-3} \text{ @ } 10 \text{ GHz } (-21 \text{ dB}), \qquad t < t_1$$

$$\text{ON: } T_1 = 0.996\ (-0.02 \text{ dB}), \qquad t_1 < t < t_2$$

$$\text{OFF: } T_2 = 5 \times 10^{-4}\ (-33 \text{ dB}), \qquad t_2 < t\,.$$

The use of a larger infrared energy would clearly further reduce the transmission T_2. To improve T_0, it is necessary to either reduce the overall geometry of the switch or increase the gap length, or both. The latter case, of course, will increase the optical-energy requirements.

VI. Recombination

Recombination of the optically generated electrons and holes is clearly an important feature of the device, since the photoconductivity must decay before the device can be used again. Preliminary measurements indicate that the principal recombination mechanism is band-to-band Auger [7] recombination. This is a nonradiative process whereby an electron and a hole recombine and give their energy to a third particle, which can be either an electron or a hole, instead of emitting a photon. In an intrinsic plasma the Auger recombination rate is proportional to the cube of the density, and consequently is expected to be dominant in high-density plasmas such as those produced by picosecond pulses. Radiative recombination in silicon is insignificant. For the case of the surface photoconductivity produced by the green pulse, integration of the Auger rate equation, neglecting diffusion, predicts the following time decay of the conductance G_1:

$$G_1(t) = G_1(0) \frac{1}{\sqrt{t/\tau}} \log\left[\sqrt{t/\tau} + \sqrt{1 + t/\tau}\right] \quad (9)$$

where $\tau = (2n_0^2 \gamma_3)^{-1}$, n_0 is the initial plasma density, and γ_3 is the rate constant in the Auger equation $\partial n/\partial t = -\gamma_3 n^3$. Preliminary measurements of the decay of G_1 show reasonably good agreement with the general features of (9), particularly in the initial stages of the decay. Depending on the excitation level, the conductance decayed to one-half its initial value in anywhere from 10 to 100 ns, in typical cases, depending on the excitation level. At longer times, however, recombination appeared to proceed somewhat faster than (9) would predict, probably due to the influence of traps which were too few in number to appreciably affect the decay at higher densities. Diffusion and sweepout can also affect the decay rate. The overall time for the transmission due to G_2 alone to decay to a percent was approximately 1 μs.

The repetition rate imposed by the rather slow recombination is a distinct disadvantage for a practical device. Fortunately, there are a number of relatively straightforward measures that can be taken to greatly improve the rate. For example, the addition of gold to silicon is known [8] to reduce carrier lifetimes to a few nanoseconds. Also the use of other substrate materials, such as GaAs, which have much faster intrinsic recombination rates could potentially increase the repetition rate to 1 GHz.

VII. Summary

We have described a simple optoelectronic switch for microwave applications in which the switching action is controlled by picosecond optical pulses. The device has a potential for switching relatively high-power microwave and millimeter signals with an ultimate time precision limited by the optical pulse durations. The basic features of the device were illustrated by switching 1-GHz and 10-GHz signals. In both cases, the observed response times were limited by the resolution of available microwave detection techniques. The physical properties of the plasma generation and recombination are reason-

ably well understood, although further study is needed to elucidate the details of the conduction process at very high carrier densities, and the dynamics of the recombination.

Effects of Focusing on Third-Order Nonlinear Processes in Isotropic Media

GARY C. BJORKLUND, MEMBER, IEEE

Abstract—**A theoretical analysis of third-order nonlinear interactions of focused laser beams is performed for the processes $\omega_1 + \omega_2 + \omega_3 \rightarrow \omega_4$, $\omega_1 + \omega_2 - \omega_3 \rightarrow \omega_4$, and $\omega_1 - \omega_2 - \omega_3 \rightarrow \omega_4$. The total power and far-field beam profile of the generated radiation is related to the total powers of the fundamental beams, to the tightness and location of the focus, and to the value of the difference between the wave vectors of the generated radiation and driving polarization. The optimum degree of wave-vector mismatch as a function of tightness and location of focus is determined for each of the three processes. The process $\omega_1 + \omega_2 - \omega_3 \rightarrow \omega_4$ is found to be unique in that it is always optimized by focusing as tightly as possible. Experimental results, which verify the theory for the processes $\omega_1 + \omega_2 + \omega_3 \rightarrow \omega_4$ and $\omega_1 + \omega_2 - \omega_3 \rightarrow \omega_4$, are presented.**

I. INTRODUCTION

THIRD-ORDER nonlinear processes in isotropic media have recently been utilized for efficient frequency tripling of high-power laser radiation [1], [2], for the production of tunable [3], [4] and fixed-frequency [5], [6] coherent vacuum ultraviolet (VUV) radiation, for up-conversion of infrared (IR) radiation [7], [8], for the production of tunable IR radiation [9], and for coherent anti-Stokes Raman spectroscopy [10]–[13]. These processes involve frequency sum and/or difference mixing between as many as three different fundamental frequencies. In order to achieve the high-power densities required by these processes without damaging the windows of the cell containing the nonlinear medium, it is often necessary to focus the fundamental beams tightly enough to produce a depth of focus small in comparison to the cell length. Focusing in this manner dramatically alters the form of the functional dependence of the efficiencies on the mismatch between the wave vectors of the generated radiation and driving polarization.

This paper presents a theoretical and experimental investigation of the effects of focusing on the processes $\omega_1 + \omega_2 + \omega_3 \rightarrow \omega_4$, $\omega_1 + \omega_2 - \omega_3 \rightarrow \omega_4$, and $\omega_1 - \omega_2 - \omega_3 \rightarrow \omega_4$. The optimum values of the wave-vector mismatch Δk (defined as the wave vector of the generated radiation minus the wave vector of the driving polarization) are found to depend on the tightness and location of the focus. In the case of very tight focusing with the fundamental beam-waist region entirely contained within the cell, efficient generation can be achieved only for restricted values of Δk. It is shown that Δk must be nonzero and negative for the process $\omega_1 + \omega_2 + \omega_3 \rightarrow \omega_4$ and that Δk must be nonzero and positive for the process $\omega_1 - \omega_2 - \omega_3 \rightarrow \omega_4$. Given a nonlinear medium with dispersion characteristics proper to produce the correct sign for Δk, each of these processes can be optimized by varying the tightness of focus. The process $\omega_1 + \omega_2 - \omega_3 \rightarrow \omega_4$ is found to be unique in that it can always be optimized by varying the tightness of

focus, regardless of the dispersion characteristics of the nonlinear medium.

These focusing effects arise from the well-known phase shift of π rad which occurs as a beam traverses the region of the focus. This phase shift also affects the driving polarization and, except for the process $\omega_1 + \omega_2 - \omega_3 \rightarrow \omega_4$, introduces a slip in phase between the driving polarization and the generated radiation. Destructive interference between portions of the generated radiation arising from different locations in the cell will result unless this slip in phase is compensated by a wave-vector mismatch of the proper sign.

In the following sections, a rigorous theoretical analysis is used to derive expressions which relate the total power and far-field beam profile of the generated radiation to the total powers of the fundamental beams, to the tightness and location of focus of these beams relative to the dimensions of the cell, and to the value of the wave-vector mismatch. Numerical evaluations of these expressions are presented for a wide variety of cases. Procedures for the optimization of the total generated power are discussed. Experimental results, which verify some aspects of the theory, are presented.

It should be noted that the effects of focusing in the case of third-harmonic generation in isotropic media have been previously considered by Miles and Harris [1] and by Ward and New [14]. The rigorous theoretical analysis of this paper is an extension of the work of Ward and New and of Kleinman *et al.* [15].

II. Theory

In this section expressions are developed for the total output power and beam shape of the generated radiation produced by the four-wave mixing processes $\omega_1 + \omega_2 + \omega_3 \rightarrow \omega_4$, $\omega_1 + \omega_2 - \omega_3 \rightarrow \omega_4$, and $\omega_1 - \omega_2 - \omega_3 \rightarrow \omega_4$. The basic approach is to specify the spatial variation of the driving polarization, perform a Fourier decomposition of the driving polarization into plane-wave components, calculate the generated radiation field arising from each such component, and then to determine the total generated field by summing the contributions of all of these components.

The fundamental beams at ω_1, ω_2, and ω_3 are assumed to be lowest order Gaussian modes which propagate concentrically along the z axis with identical waist locations and identical confocal beam parameters. If the wave vectors of these beams in the nonlinear medium are taken as k_1, k_2, and k_3, respectively, and if the electric-field amplitudes are taken as $\boldsymbol{E}_{10}$, $\boldsymbol{E}_{20}$, and $\boldsymbol{E}_{30}$, respectively, then the fundamental electric field is given by

$$\boldsymbol{E}(r, t) = \text{Re}\,[\boldsymbol{E}_1(r)\exp(-i\omega_1 t) + \boldsymbol{E}_2(r)\exp(-i\omega_2 t) + \boldsymbol{E}_3(r)\exp(-i\omega_3 t)] \quad (1)$$

with $\boldsymbol{E}_n$, where $n = 1, 2$, or 3, given by the theory of Boyd and Gordon [16] as

$$\boldsymbol{E}_n(r) = \boldsymbol{E}_{n0}\exp(ik_n z)(1 + i\&)^{-1} \cdot \exp[-k_n(x^2 + y^2)/b(1 + i\&)]. \quad (2)$$

In (2), b is the confocal parameter, defined by

$$b = \frac{2\pi\omega_0^2}{\lambda} = \frac{2\pi\omega_0^2 n}{\lambda_0} = \frac{2\lambda_0}{n\theta^2} = k\omega_0^2 \quad (3)$$

where ω_0 is the beam-waist radius, n is the index of refraction, λ_0 is the vacuum wavelength, and θ is the far-field diffraction half-angle. & is a normalized coordinate along the z axis, defined as

$$\& = \frac{2(z - f)}{b} \quad (4)$$

where f is the position of the focus (beam waist) along the z axis.

If the fundamental and generated beams are all assumed to be linearly polarized in the same direction, the vector nature of the electric fields as well as the tensor nature of the nonlinear susceptibility may be neglected, and the driving polarization at ω_4 is given by

$$P_4(r, t) = \text{Re}\,[P_4(r)\exp(-i\omega_4 t)] \quad (5)$$

where

$$P_4(r) = \begin{cases} \frac{3}{2}N\chi(-\omega_4;\omega_1,\omega_2,\omega_3)E_1(r)E_2(r)E_3(r), \\ \qquad (\text{for } \omega_1 + \omega_2 + \omega_3 \rightarrow \omega_4) \\ \frac{3}{2}N\chi(-\omega_4;\omega_1,\omega_2,-\omega_3)E_1(r)E_2(r)E_3^*(r), \\ \qquad (\text{for } \omega_1 + \omega_2 - \omega_3 \rightarrow \omega_4) \\ \frac{3}{2}N\chi(-\omega_4;\omega_1,-\omega_2,-\omega_3)E_1(r)E_2^*(r)E_3^*(r), \\ \qquad (\text{for } \omega_1 - \omega_2 - \omega_3 \rightarrow \omega_4) \end{cases} \quad (6)$$

with χ the nonlinear susceptibility per atom and N the number density of atoms of the nonlinear medium. (When two or three of the input frequencies are degenerate, the factor of $\frac{3}{2}$ in (6) must be changed to $\frac{3}{4}$ or $\frac{1}{4}$, respectively.)

The nonlinear medium is considered to occupy the semi-infinite space $z > 0$, with the space $z < 0$ considered to be a vacuum. Then from (2) and (6), for the process $\omega_1 + \omega_2 + \omega_3 \rightarrow \omega_4$, the driving polarization at ω_4 is given by

$$P_4(r) = \frac{3}{2}N\chi(-\omega_4;\omega_1,\omega_2,\omega_3)E_{10}E_{20}E_{30} \times \exp(ik'z)(1 + i\&)^{-3}\exp\left[\frac{-k'(x^2 + y^2)}{b(1 + i\&)}\right]B(z) \quad (7)$$

where k', the wave vector of the driving polarization, is given by

$$k' = k_1 + k_2 + k_3 = k'' \quad (8)$$

and where

$$B(z) = \begin{cases} 1, & z > 0 \\ 0, & z < 0. \end{cases} \quad (9)$$

Similarly, for the process $\omega_1 + \omega_2 - \omega_3 \rightarrow \omega_4$,

$$P_4(r) = \frac{3}{2} N\chi(-\omega_4; \omega_1, \omega_2, -\omega_3) E_{10} E_{20} E_{30} B(z) \times \exp(ik'z)(1 + i\xi)^{-2}(1 - i\xi)^{-1} \times \exp\left[\frac{(-k'' + i\xi k')(x^2 + y^2)}{b(1 + \xi^2)}\right] \quad (10)$$

where k' is now defined as

$$k' = k_1 + k_2 - k_3 \quad (11)$$

and k'' is defined as before.

Finally, for the process $\omega_1 - \omega_2 - \omega_3 \rightarrow \omega_4$

$$P_4(r) = \frac{3}{2} N\chi(-\omega_4; \omega_1, -\omega_2, -\omega_3) E_{10} E_{20} E_{30} B(z) \times \exp(ik'z)(1 + i\xi)^{-1}(1 - i\xi)^{-2} \times \exp\left[\frac{(-k'' + i\xi k')(x^2 + y^2)}{b(1 + \xi^2)}\right] \quad (12)$$

where k' is now defined as

$$k' = k_1 - k_2 - k_3 \quad (13)$$

and k'' is defined as before.

The next step is to perform a Fourier decomposition of $P_4(r)$ to determine the amplitudes of the plane-wave components of the driving polarization. $P_{4(K)}$, the amplitude of the plane-wave component with wave vector K, is defined by

$$P_{4(K)} = (2\pi)^{-3} \int_{-\infty}^{\infty} dx'' \int_{-\infty}^{\infty} dy'' \int_{-\infty}^{\infty} dz'' P_4(r'') \times \exp(-iK \cdot r''). \quad (14)$$

$E_{4(K)}(r)$ the generated radiation field arising from the plane-wave component of the driving polarization with wave vector K, and $P_{4(K)}$ can be shown by Maxwell's equations to be related by

$$\nabla \times \nabla \times E_{4(K)}(r) - k_4^2 E_{(K)}(r) = 4\pi k_0^2 P_{4(K)} \exp(iK \cdot r) \quad (15)$$

where k_4 and k_0 are the wave vectors of the generated radiation in the nonlinear medium and in vacuum, respectively. Equation (15) may be solved subject to the boundary condition that the tangential component of $E_{4(K)}$ vanish at the vacuum-medium interface. For $K_x, K_y \ll K_z$ and $|K| - k_4 \ll |K|, k_4$ Kleinman [17] has shown that

$$E_{4(K)}(r) = i[2\pi k_0^2 z/k_4]\, g(U_K) \exp(iK \cdot r) P_{4(K)} \quad (16)$$

with

$$U_K = iz[K_z - k_4 + (K_x^2 + K_y^2)/2k_4] \quad (17)$$

and

$$g(x) = [1 - \exp(-x)]/x = \int_0^1 \exp(-xp)\, dp. \quad (18)$$

The wave-vector mismatch Δk is defined by the relation

$$\Delta k = k_4 - k'. \quad (19)$$

This choice of sign for Δk is opposite from that of Ward and New [14] but consistent with Miles and Harris [1].

The substitutions $k_4 = k' + \Delta k$ and $p = -\frac{1}{2} b(\xi' - \xi)/z$ may be performed in (17) and (18) to yield (assuming $\Delta k \ll k_4, k'$)

$$g(U_K) = \left(\frac{b}{2z}\right) \int_{-\zeta}^{\xi} d\xi' \times \exp\{ib[K_z - k' + (K_x^2 + K_y^2)/2k' - \Delta k] \times (\xi' - \xi)/2\} \quad (20)$$

where $\xi = 2(z - f)/b$ and $\zeta = 2f/b$.

The total generated electric field $E_4(r)$ is derived by combining the $E_{4(K)}(r)$

$$E_4(r) = \int_{-\infty}^{\infty} dK_x \int_{-\infty}^{\infty} dK_y \int_{-\infty}^{\infty} dK_z E_{4(K)}(r) \quad (21)$$

where $E_{4(K)}(r)$ is defined by (16), (20), and (14).

These integrals may be evaluated by first integrating over K_z to yield the factor $\delta(z'' - z)$, then integrating over z'', and finally integrating over x'', y'', K_x, and K_y by means of the formula [15]

$$\int_{-\infty}^{\infty} \exp[-iqx - isx^2]\, dx = (\pi/is)^{1/2} \exp(iq^2/4s), \quad \mathrm{Im}(s) < 0. \quad (22)$$

For $\omega_1 + \omega_2 + \omega_3 \rightarrow \omega_4$, the result is

$$E_4(r) = i\frac{3N}{2k_4} \pi k_0^2 b\chi(-\omega_4; \omega_1, \omega_2, \omega_3) E_{10} E_{20} E_{30} \times \exp(ik'z)(1 + i\xi)^{-1} \times \exp\left[\frac{-k'(x^2 + y^2)}{b(1 + i\xi)}\right] \times \int_{-\zeta}^{\xi} \frac{\exp[-(ib/2)\Delta k(\xi' - \xi)]}{(1 + i\xi')^2} d\xi' \quad (23)$$

while for $\omega_1 + \omega_2 - \omega_3 \rightarrow \omega_4$

$$E_4(r) = i\frac{3N}{2k_4} \pi k_0^2 b\chi(-\omega_4; \omega_1, \omega_2, -\omega_3) E_{10} E_{20} E_{30} \times \exp(ik'z) \times \int_{-\zeta}^{\xi} d\xi' \times \frac{\exp[-(ib/2)\Delta k(\xi' - \xi)]}{(1 + i\xi')(k'' - ik'\xi')H} \exp\left[\frac{-(x^2 + y^2)}{bH}\right] \quad (24)$$

and for $\omega_1 - \omega_2 - \omega_3 \rightarrow \omega_4$

$$E_4(r) = i\frac{3N}{2k_4}\pi k_0^2 b\chi(-\omega_4;\omega_1,-\omega_2,-\omega_3)E_{10}E_{20}E_{30} \times \exp(ik'z) \times \int_{-\xi}^{\xi} d\xi' \times \frac{\exp[-(ib/2)\Delta k(\xi'-\xi)]}{(1-i\xi')(k''-ik'\xi')H} \exp\left[\frac{-(x^2+y^2)}{bH}\right]. \quad (25)$$

k' is defined by (8), (11), and (13) in (23)-(25), respectively. k'' is always given by (8) and the function H is defined by

$$H = H(\xi,\xi') = \frac{(1+\xi'^2)}{(k''-ik'\xi')} - i\frac{(\xi'-\xi)}{k'}. \quad (26)$$

If the nonlinear medium is contained in a cell of length L with input window located at $z = 0$ and with the location of the focus at $z = f$, then (23)-(25), with $\xi = 2(L-f)/b$, $z = L$, and $\zeta = 2f/b$, completely describe the amplitude of the generated field at the plane of the output window. The functional dependence of the field distribution upon the transverse coordinates x and y scales with the value of k', b, and ξ.

It can be seen from (23) that for the process $\omega_1 + \omega_2 + \omega_3 \rightarrow \omega_4$, $E_4(r)$ is always a lowest order Gaussian mode with the same confocal parameter and waist location as the input beams. However, (24) and (25) show that for the processes $\omega_1 + \omega_2 - \omega_3 \rightarrow \omega_4$ and $\omega_1 - \omega_2 - \omega_3 \rightarrow \omega_4$, $E_4(r)$ is not in general a single Gaussian mode except when $k'' = k'$. The multimode output of the difference-mixing processes may be explained as resulting from a mismatch between the size of the driving polarization beam waist and the size of the generated radiation beam waist which would correspond to the confocal parameter of the input beams. This mismatch may be represented by the ratio k''/k'. When $k''/k' = 1$, these beam waists are of the same size, and a lowest order Gaussian beam with the same confocal parameter and waist location as the input beams can be produced. The sum-mixing process $\omega_1 + \omega_2 + \omega_3 \rightarrow \omega_4$ always has $k''/k' = 1$ and thus always produces a lowest order Gaussian beam output.

For all three mixing processes it may be seen that $E_4(r)$ is circularly symmetrical about the z axis and that the total generated power at ω_4 is thus obtained by performing integrals of the form

$$\int_0^\infty 2\pi R\,|E_4(R)|^2\,dR \quad (27)$$

where $R = (x^2+y^2)^{1/2}$ and $z = L$. It is convenient to define the dimensionless functions $F_j(b\Delta k, b/L, f/L, k''/k')$ by the relations

$$F_j\left(b\Delta k, \frac{b}{L}, \frac{f}{L}, \frac{k''}{k'}\right) = \frac{8}{9}\frac{k_4^2 k'}{\pi^3 k_0^4}\frac{1}{b^3\chi^2|E_{10}E_{20}E_{30}|^2} \times \int 2\pi R|E_4(R)|^2\,dR \quad (28)$$

where $j = 1$, 2, or 3 implies $\omega_1 + \omega_2 + \omega_3 \rightarrow \omega_4$, $\omega_1 + \omega_2 - \omega_3 \rightarrow \omega_4$, or $\omega_1 - \omega_2 - \omega_3 \rightarrow \omega_4$. Although the spatial distribution of $E_4(r)$ depends upon the value and units of k' and b, the integrated intensity represented by the F_j depends only on the dimensionless parameters $b\Delta k$, b/L, f/L, and k''/k'.

With all wave vectors expressed in units of cm^{-1}, b in centimeters, N in atoms/cubic centimeters, χ in ESU per atom, and with total power in watts, the total generated power $\mathcal{P}_4$ is given by

$$\mathcal{P}_4 = (6.318\times10^{-4})\frac{k_0^4 k_1 k_2 k_3}{k_4^2 k'}N^2\chi^2\,\mathcal{P}_1\,\mathcal{P}_2\,\mathcal{P}_3 \times F_j\left(b\Delta k, \frac{b}{L}, \frac{f}{L}, \frac{k''}{k'}\right) \quad (29)$$

where $\mathcal{P}_1$, $\mathcal{P}_2$, and $\mathcal{P}_3$ are the total powers of each of the fundamental beams. (When two or three of the input frequencies are degenerate, the factor of 6.318×10^{-4} in (29) must be changed to 1.580×10^{-4} or 1.755×10^{-5}, respectively.)

For the process $\omega_1 + \omega_2 + \omega_3 \rightarrow \omega_4$

$$F_1\left(b\Delta k, \frac{b}{L}, \frac{f}{L}, \frac{k''}{k'}\right) = \left|\int_{-\xi}^{\xi} d\xi \frac{\exp[-(ib/2)\Delta k\xi']}{(1+i\xi')^2}\right|^2. \quad (30)$$

Thus $F_1(b\Delta k, b/L, f/L, 1)$ is equivalent to the quantity $|I(3,\Delta k,\xi,\zeta)|^2$ as defined by Ward and New [14] (who define Δk with the opposite sign). In the tight-focusing limit where b is short compared to the cell, and the entire focal region is contained within the cell ($\xi, \zeta \rightarrow \infty$), the integral may be solved in closed form to yield

$$F_1(b\Delta k, 0, 0.5, 1) = \begin{cases} \pi^2(b\Delta k)^2\exp[b\Delta k/2), & \text{for } \Delta k < 0 \\ 0, & \text{for } \Delta k \geqslant 0. \end{cases} \quad (31)$$

For the process $\omega_1 + \omega_2 - \omega_3 \rightarrow \omega_4$

$$F_2\left(b\Delta k, \frac{b}{L}, \frac{f}{L}, \frac{k''}{k'}\right) = \frac{2k'}{\pi b}\int_0^\infty 2\pi R\,dR \times \left|\int_{-\xi}^{\xi} d\xi' \frac{\exp[-(ib/2)\Delta k\xi']}{(1+i\xi')(k''-ik'\xi')H} \times \exp\left[\frac{-R^2}{bH}\right]\right|^2 \quad (32)$$

with H defined by (26) and k' and k'' defined by (8) and (11). In the tight-focusing limit and in the case $k'' = k'$

$$F_2(b\Delta k, 0, 0.5, 1) = \pi^2\exp[-b|\Delta k|]. \quad (33)$$

For the process $\omega_1 - \omega_2 - \omega_3 \rightarrow \omega_4$

$$F_3\left(b\Delta k, \frac{b}{L}, \frac{f}{L}, \frac{k''}{k'}\right) = \frac{2k'}{\pi b}\int_0^\infty 2\pi R\, dR \times \left|\int_{-\xi}^{\xi} d\xi' \frac{\exp\left[-(ib/2)\,\Delta k\xi'\right]}{(1 - i\xi')(k'' - ik'\xi')H} \times \exp\left[\frac{-R^2}{bH}\right]\right|^2 \quad (34)$$

with H defined by (26) and k' and k'' defined by (8) and (13). In the tight-focusing limit and in the case $k'' = k'$

$$F_3(b\Delta k, 0, 0.5, 1) = \begin{cases} 0, & \text{for } \Delta k \leq 0 \\ \pi^2(b\Delta k)^2 \exp\left[b\Delta k/2\right], & \text{for } \Delta k > 0. \end{cases} \quad (35)$$

III. Evaluation of the F_j

The functions F_j were numerically evaluated as continuous functions of $b\Delta k$ for various sets of discrete values of b/L, f/L, and k''/k'. From (30), (32), and (34) it is evident that the evaluation of each F_j involves an integration over ξ' which may be put in the form of a Fourier transformation. An efficient discrete fast Fourier transform (FFT) routine [18] was employed to numerically evaluate the F_j on an IBM computer. This routine is capable of performing a 4096-element complex discrete Fourier transform in less than 4 s of computer time. One such transformation is sufficient to completely specify F_1 as a function of $b\Delta k$ for one set of values of b/L and f/L, or to evaluate $|E_4(R)|^2$ as a function of $b\Delta k$ for one set of values of $b/L, f/L, k''/k'$, and R. F_2 and F_3 were calculated as functions of $b\Delta k$ for one set of values of $b/L, f/L$, and k''/k' by evaluating $|E_4(R)|^2$ for 40 discrete values of R and then integrating over R by means of the trapezoidal rule. Thus the determination of F_2 or F_3 as a function of $b\Delta k$ for a single set of values of $b/L, f/L$, and k''/k' required the FFT routine to be run 40 times and required approximately 3 min of computer time.

The behavior of the F_j near the tight-focusing limit was studied in detail. It was determined that, when $b/L \leq 0.1$ and when $b \leq f \leq L - b$, the F_j as functions of $b\Delta k$ may, to a good approximation, be represented by the curve for F_j versus $b\Delta k$ corresponding to the infinitely tight-focusing limit where $b/L = 0.0$ and $f/L = 0.5$. For instance, the maximum deviation of the numerically computed $F_1(b\Delta k, 0.1, 0.5, 1)$ from the analytically derived $F_1(b\Delta k, 0, 0.5, 1)$ of (31) is less than 0.1 for all values of $b\Delta k$.

F_1 for $b/L \leq 0.1$ and $f/L = 0.5$ are plotted in Fig. 1; F_2 for $b/L \leq 0.1$, $f/L = 0.5$, and $k''/k' = 1$, 1.1, 1.5, 2.0, and 3.0 are plotted in Fig. 2; and F_3 for $b/L \leq 0.1$, $f/L = 0.5$, and $k''/k' = 1$, 1.1, 1.5, 2.0, and 3.0 are plotted in Fig. 3. The analytical results of (31), (33), and (35) were used to supply the curves for $b/L = 0$, while the numerical results were used for $b/L \neq 0$.

In the case of tight focusing, the F_j, when viewed as functions of $b\Delta k$, have the mutual characteristic of possessing a single large peak. As the value of $b\Delta k$ departs from the optimum value, the F_j approach zero in a nearly asymptotic manner. In the case of b/L slightly more than zero, some sidelobe structure appears far in the wings. However, as long as the fundamental beam-waist region is contained entirely in the cell, these sidelobes are always less than 0.1 percent of the magnitude of the peak value of F_j. (This is in distinct contrast to the plane-wave case, where sidelobes to the main peak occur with magnitudes as high as 4 percent of the maximum value.)

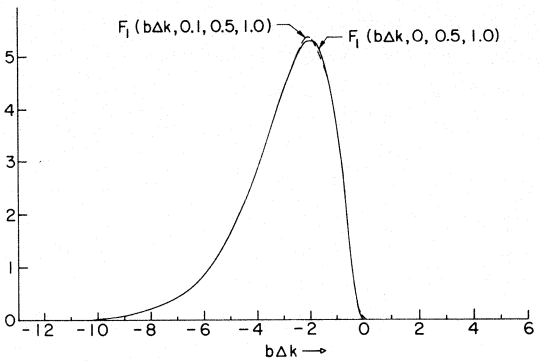

Fig. 1. F_1 versus $b\Delta k$ for $b/L \leq 0.1$ and $f/L = 0.5$.

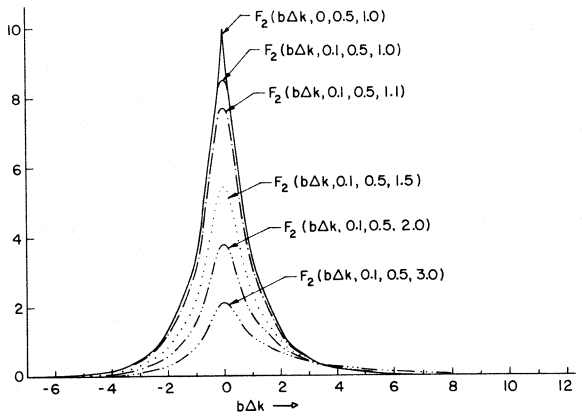

Fig. 2. F_2 versus $b\Delta k$ for $b/L \leq 0.1$; $f/L = 0.5$; and $k''/k' = 1.0$, 1.1, 1.5, 2.0, and 3.0.

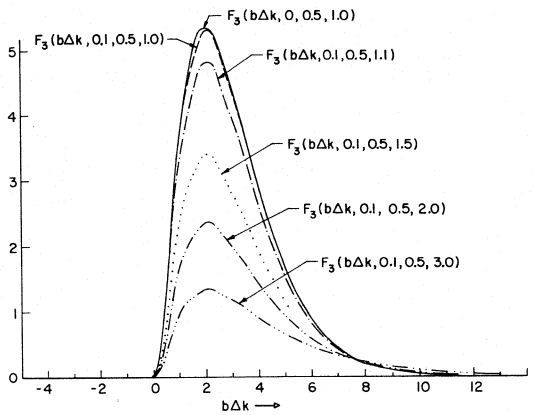

Fig. 3. F_3 versus $b\Delta k$ for $b/L \leq 0.1$; $f/L = 0.5$; and $k''/k' = 1.0$, 1.1, 1.5, 2.0, and 3.0.

In the case of very loose focusing, the F_j approach the plane-wave limit, as given by Miles and Harris [1], of

$$\lim_{b/L \to \infty} F_j\left(b\Delta k, \frac{b}{L}, 0.5, \frac{k''}{k'}\right) = \frac{4L^2}{b^2}\,\mathrm{sinc}^2\left(\frac{\Delta kL}{2}\right). \tag{36}$$

The value of k''/k' is irrelevant to the behavior of the F_j in the plane-wave case. The peak of this sinc^2 function is offset from zero by $\Delta k = -4/b$ for F_1 and by $\Delta k = 4/b$ for F_3, while for F_2 the peak is always at zero.

The complete evolution of the form of the F_j from the tight focusing limit to the plane-wave limit is demonstrated in Figs. 4 and 5 for the case of F_1. Families of curves of F_1 versus $b\Delta k$ for various locations of the focus (various values of f/L) are plotted in Figs. 6–10, where each figure corresponds to a different, constant value of b/L. Fig. 6 shows that, for tight focusing, F_j versus $b\Delta k$ is relatively unchanged as long as the fundamental beam-waist region is entirely contained within the cell. Fig. 10 illustrates that, for b much larger than L, F_j versus $b\Delta k$ is relatively unchanged as long as the cell is located close to the beam-waist location. Figs. 7–9 show the more complicated behavior of the intermediate cases. In every case, however, when the beam-waist location is far outside of the cell, the location of the peak of the F_j lies very near to $b\Delta k = 0$.

The dependence of the mode structure of the generated radiation upon $b\Delta k$ may be determined by monitoring $|E_4(R)|^2$ as a function of the transverse coordinate R for each value of $b\Delta k$. For the processes $\omega_1 + \omega_2 - \omega_3 \rightarrow \omega_4$ and $\omega_1 - \omega_2 - \omega_3 \rightarrow \omega_4$, when $k''/k' \neq 1$, the far-field intensity distribution evolves from a nearly Gaussian shape for $b\Delta k \leqslant 0$, to a circularly symmetric ring pattern as $b\Delta k$ becomes large and positive. This nearly Gaussian shape is in close agreement with the far-field intensity distribution which would arise from a lowest order Gaussian mode with the same wavelength as the generated radiation and with the same confocal parameter and waist location as the fundamental beams. The circularly symmetric ring pattern is of the type which has been observed by Terhune [19] and others for anti-Stokes radiation produced by three-wave mixing. The results of this section thus indicate that this ring pattern will appear only when $b\Delta k$ is positive. A typical evolution of the far-field pattern as Δk is changed is presented in Fig. 11 for the process $\omega_1 + \omega_2 - \omega_3 \rightarrow \omega_4$ with $k''/k' = 3$.

IV. A Physical Basis for the Behavior of the F_j

Several aspects of the behavior of the F_j, including the optimum values of $b\Delta k$ and the invariance with respect to the exact location of the focus in the tight-focusing case, may be explained by a simple model which takes into account the additional phase shift caused by focusing.

From (2) and (6), it can be seen that the amplitude of the driving polarization strongly peaks in the region of the fundamental beam waists. A region of significant generation may somewhat arbitrarily be defined as bounded by the z values at which the driving polarization falls to 10 percent of its peak value. In the case of tight focusing, when b is much less than L and the fundamental beam-waist region is located entirely within the cell, the boundaries of the generating region are

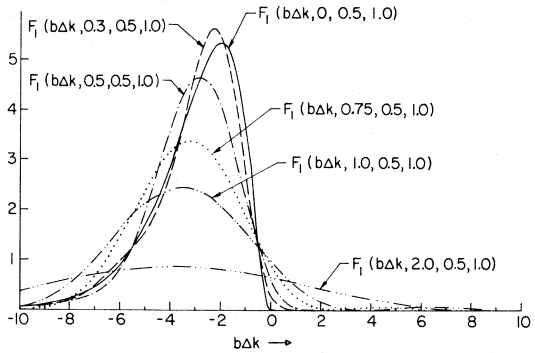

Fig. 4. F_1 versus $b\Delta k$ for f/L = 0.5 and b/L = 0, 0.3, 0.5, 0.75, 1.0, and 2.0.

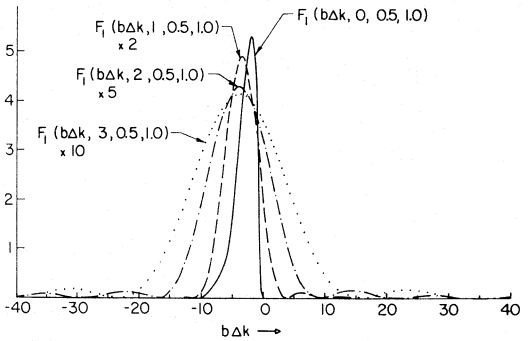

Fig. 5. F_1 versus $b\Delta k$ for f/L = 0.5 and b/L = 0, 1, 2, and 3.

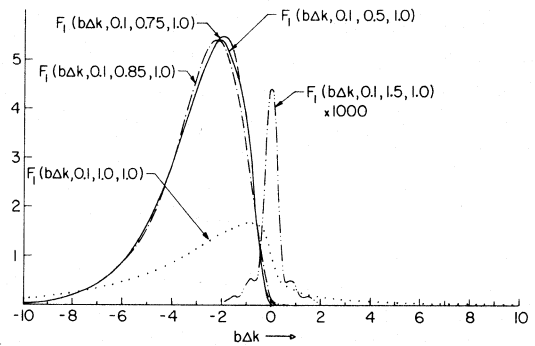

Fig. 6. F_1 versus $b\Delta k$ for b/L = 0.1 and f/L = 0.5, 0.75, 0.85, 1.0, and 1.5.

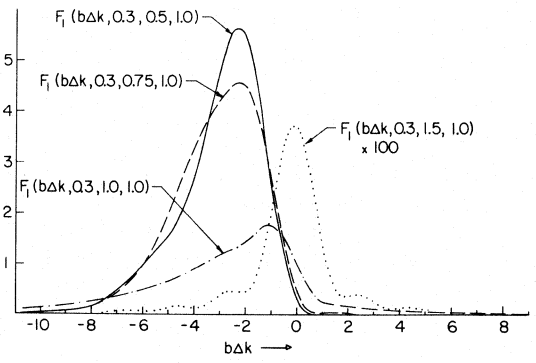

Fig. 7. F_1 versus $b\Delta k$ for b/L = 0.3 and f/L = 0.5, 0.75, 1.0, and 1.5.

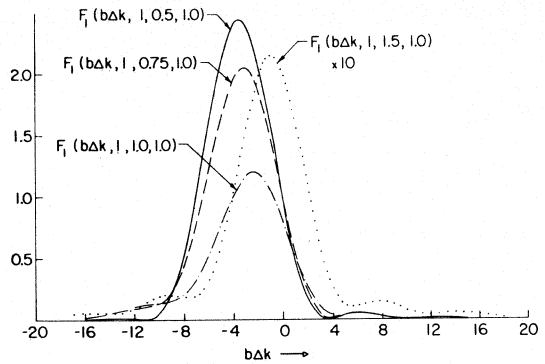

Fig. 8. F_1 versus $b\Delta k$ for $b/L = 1$ and $f/L = 0.5$, 0.75, 1.0, and 1.5.

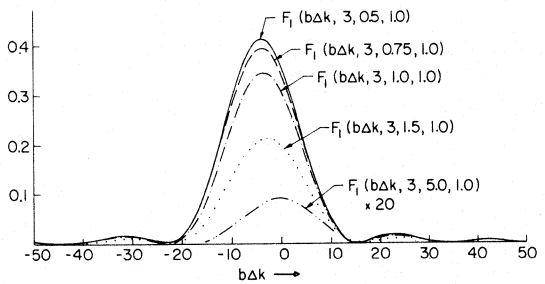

Fig. 9. F_1 versus $b\Delta k$ for $b/L = 3$ and $f/L = 0.5$, 0.75, 1.0, 1.5, and 5.0.

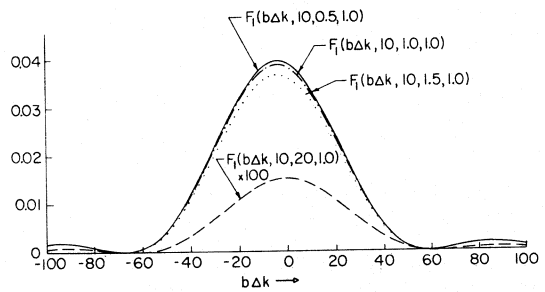

Fig. 10. F_1 versus $b\Delta k$ for $b/L = 10$ and $f/L = 0.5$, 1.0, 1.5, and 20.0.

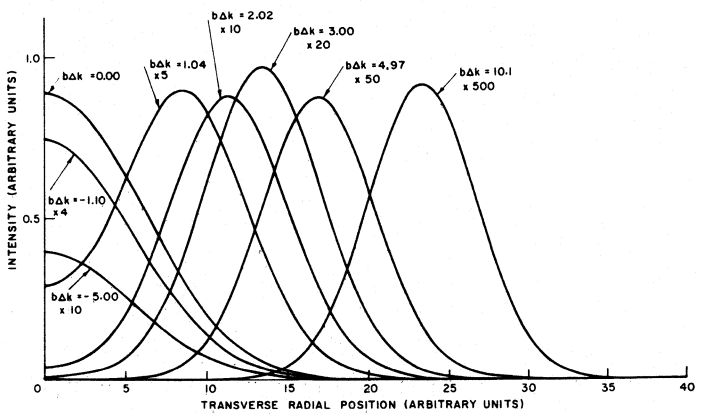

Fig. 11. Far-field intensity distribution for several values of $b\Delta k$ for the process $\omega_1 + \omega_2 - \omega_3 \rightarrow \omega_4$ with $k''/k' = 3.0$. The distribution in each case is calculated at the position of the output window of a cell with $b/L = 0.1$ and $f/L = 0.5$.

located at $\xi = -2$ and $\xi = +2$ (or $z = f - b$ and $z = f + b$). In the case of loose focusing, when b is much larger than L, the boundaries are located at the input and output windows of the cell.

From (2), it can be seen from the term

$$(1 + i\xi)^{-1} = (1 + \xi^2)^{-1/2} \exp(-i \tan^{-1} \xi)$$

that a focused lowest order Gaussian beam undergoes a shift in phase given by $\tan^{-1} \xi$ as it propagates through the waist region. The driving polarization given by (6) then experiences a phase shift of $3 \tan^{-1} \xi$ for $\omega_1 + \omega_2 + \omega_3 \rightarrow \omega_4$, $\tan^{-1} \xi$ for $\omega_1 + \omega_2 - \omega_3 \rightarrow \omega_4$, and $-\tan^{-1} \xi$ for $\omega_1 - \omega_2 - \omega_3 \rightarrow \omega_4$. If it is assumed that the optimum conversion efficiency occurs when the generated radiation is nearly a lowest order Gaussian mode with the same confocal parameter as the fundamental beams, then the generated radiation may be considered to experience a phase shift of $\tan^{-1} \xi$. Thus a slip in phase between the driving polarization and the generated radiation of $2 \tan^{-1} \xi$ for $\omega_1 + \omega_2 + \omega_3 \rightarrow \omega_4$ and of $-2 \tan^{-1} \xi$ for $\omega_1 - \omega_2 - \omega_3 \rightarrow \omega_4$ occurs, while no slip in phase occurs for $\omega_1 + \omega_2 - \omega_3 \rightarrow \omega_4$. This slip in phase causes destructive interference between radiation generated in different portions of the generating region.

The slip in phase due to focusing may be compensated to some degree by the wave-vector mismatch Δk introduced by the dispersion of the nonlinear medium. The optimum value of Δk, Δk_{opt}, is that value which exactly cancels the total slip in phase which occurs as the generating region is traversed.

In the case of tight focusing, when the entire generating region is contained within the cell, this requirement yields

$$\Delta k_{opt} \cong \begin{cases} -2.2/b, & \text{for } \omega_1 + \omega_2 + \omega_3 \rightarrow \omega_4 \\ 0, & \text{for } \omega_1 + \omega_2 - \omega_3 \rightarrow \omega_4 \\ +2.2/b, & \text{for } \omega_1 - \omega_2 - \omega_3 \rightarrow \omega_4 \end{cases} \tag{37}$$

in good agreement with the exact results. Since significant generation occurs only in the generating region, it follows that this behavior should be independent of the exact location of the focus so long as the entire generating region is contained within the cell.

In the case of loose focusing, when the entire cell is located in the beam waist, these arguments yield

$$\Delta k_{opt} = \begin{cases} -\dfrac{4}{b}, & \text{for } \omega_1 + \omega_2 + \omega_3 \rightarrow \omega_4 \\ 0, & \text{for } \omega_1 + \omega_2 - \omega_3 \rightarrow \omega_4 \\ \dfrac{4}{b}, & \text{for } \omega_1 - \omega_2 - \omega_3 \rightarrow \omega_4 \end{cases} \tag{38}$$

again in good agreement with the exact results.

V. Optimization of the Tight-Focusing Case

In this section, procedures for the optimization of the total generated power are developed for the case of tight focusing ($b/L \leqslant 0.1$) with the fundamental beam-waist region entirely contained within the cell. If limiting processes [1] such as

pump depletion, absorption, breakdown, saturation, thermal defocusing, and the quadratic Kerr effect are neglected, then the total generated power at ω_4 is always given by (29) and thus obeys the proportionality relation

$$\mathcal{P}_4 \propto \mathcal{P}_1 \mathcal{P}_2 \mathcal{P}_3 N^2 \chi^2 F_j(b\Delta k, b/L, f/L, k''/k'). \tag{39}$$

The parameters $\mathcal{P}_1 \mathcal{P}_2 \mathcal{P}_3$, χ, and k''/k' are considered to be constant and thus the optimization procedure reduces to maximizing the quantity $N^2 F_j(b\Delta k, b/L, f/L, k''/k')$ by varying the parameters N, $b\Delta k$, b/L, and f/L.

When N is a parameter which is independent of $b\Delta k$, b/L, and f/L, the optimization procedure further simplifies to increasing N to the highest possible value while independently maximizing F_j. By the results of Section III, the maximization conditions for the F_j under these tight-focusing conditions are then simply to set $b\Delta k$ to $b\Delta k_{\text{opt}}$ given by

$$b\Delta k_{\text{opt}} = \begin{cases} -2, & \text{for } \omega_1 + \omega_2 + \omega_3 \rightarrow \omega_4 \\ 0, & \text{for } \omega_1 + \omega_2 - \omega_3 \rightarrow \omega_4 \\ +2, & \text{for } \omega_1 - \omega_2 - \omega_3 \rightarrow \omega_4 \end{cases} \tag{40}$$

regardless of the exact values of b/L and f/L (so long as $b/L \leqslant 0.1$ and $b \leqslant f \leqslant L - b$).

The parameter $b\Delta k$ may be adjusted to its optimum value by means of altering b or by altering Δk. The value of b may be straightforwardly altered by varying the tightness of focus, but in order for the tight-focusing approximation of this section to remain valid, b/L must remain less than 0.1. In order to make Δk a parameter which is independent of N, another medium with negligible nonlinearity but appreciable dispersion may be mixed with the nonlinear medium [1]. Δk could then be controlled by varying the concentration of the added medium. The process $\omega_1 + \omega_2 - \omega_3 \rightarrow \omega_4$ is unique in that the optimum value of b is always zero, regardless of the value of Δk. It should be noted that the procedure of optimizing by adjusting b is valid only if the nonlinear medium can tolerate the high-power densities introduced by very tight focusing. If this is not possible, the best compromise is to reduce b to the smallest permissible value and then to adjust Δk to reach $b\Delta k_{\text{opt}}$.

The value of F_j is severely reduced if $b\Delta k$ deviates from its optimum value. The tolerances on the value of $b\Delta k$ which correspond to F_j maintaining a desired fraction of its peak value may be determined from Fig. 1, Fig. 2, or Fig. 3. It is particularly important to note that the process $\omega_1 + \omega_2 + \omega_3 \rightarrow \omega_4$ requires that $b\Delta k$ be nonzero and positive while the process $\omega_1 - \omega_2 - \omega_3 \rightarrow \omega_4$ requires that $b\Delta k$ be nonzero and negative. The generated total power at ω_4 under these optimized conditions is given by (29) with F_j set to its peak value from Fig. 1, Fig. 2, or Fig. 3.

Different optimization procedures are required when N is a parameter which is not independent of $b\Delta k$. One particularly important case occurs when Δk is constrained to be proportional to N while b is constrained to be constant and N is a free parameter. In this case, the quantity which must be maximized in the optimization procedure is $\Delta k^2 F_j(b\Delta k, b/L, f/L, k''/k')$. This quantity is not dimensionless, and depends on the absolute value of b. Therefore it is appropriate to define the dimensionless quantity

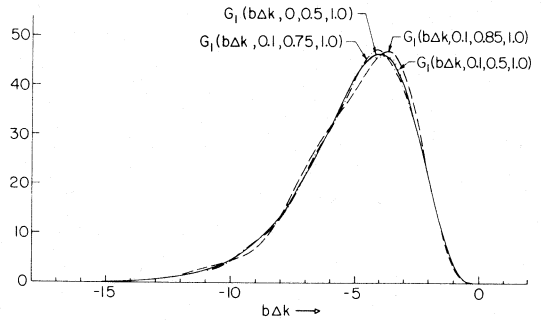

Fig. 12. G_1 versus $b\Delta k$ for $b/L \leqslant 0.1$ and $f/L = 0.5$, 0.75, and 0.85.

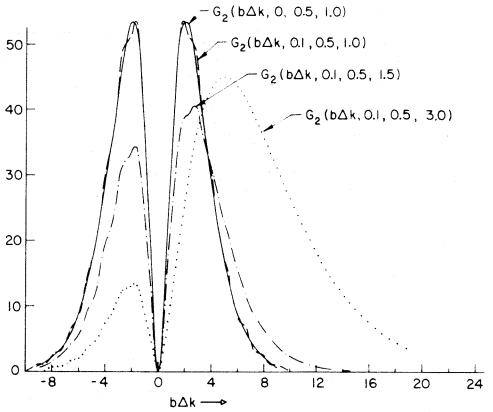

Fig. 13. G_2 versus $b\Delta k$ for $b/L \leqslant 0.1$; $f/L = 0.5$; and $k''/k' = 1.0$, 1.5, and 3.0.

$$G_j(b\Delta k, b/L, f/L, k''/k') = (\Delta k b)^2 F_j(b\Delta k, b/L, f/L, k''/k') \tag{41}$$

and to realize that the quantity which must be maximized is then $(1/b)^2 G_j(b\Delta k, b/L, f/L, k''/k')$.

G_1 is plotted for $b/L = 0$ and $b/L = 1$ with $f/L = 0.5$, 0.75, and 0.85 in Fig. 12. Here it is apparent that, as in the case of the F_j, the value of b/L in the G_j may to a good approximation be replaced by zero for b/L less than 0.1. In addition, for tight focusing, the G_j are independent of the value of f/L as long as the entire input beam-waist region is contained within the cell. G_2 is plotted for $f/L = 0.5$, $b/L = 0.1$ in Figs. 13 and 14. G_3 is plotted for $f/L = 0.5$, $b/L = 0.1$ in Fig. 15.

Since N is the only free parameter, the optimization procedure is to adjust $b\Delta k$ to maximize G_j by adjusting N. Let $(b\Delta k)_{\text{opt}}$ be the value of $b\Delta k$ which corresponds to the peak of G_j. Define the coefficient of proportionality α by the relation $\Delta k = \alpha N$. Then the optimization procedure reduces to adjusting N to the value $N_{\text{opt}} = (b\Delta k)_{\text{opt}}/\alpha b$.

From (29) and (41), the total generated power in this optimized case is

$$\mathcal{P}_4 = (6.318 \times 10^{-4}) \frac{k_0^4 k_1 k_2 k_3}{k_4^2 k'} \frac{\chi^2 \mathcal{P}_1 \mathcal{P}_2 \mathcal{P}_3 G_j}{\alpha^2 b^2} \tag{42}$$

where G_j is given its peak value from Fig. 12, Fig. 13, Fig. 14, or Fig. 15.

It may be noted that in order to reach this optimized condition, α must be negative for the process $\omega_1 + \omega_2 + \omega_3 \rightarrow \omega_4$, while α must be positive for the process $\omega_1 - \omega_2 - \omega_3 \rightarrow \omega_4$. The process $\omega_1 + \omega_2 - \omega_3 \rightarrow \omega_4$ is unique in that G_2 possesses

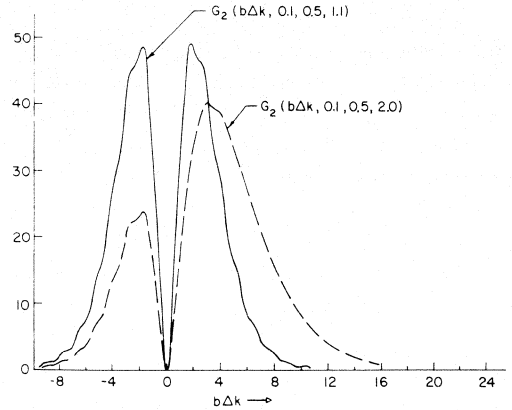

Fig. 14. G_2 versus $b\Delta k$ for $b/L \leqslant 0.1$; $f/L = 0.5$; and $k''/k' = 1.1$ and 2.0.

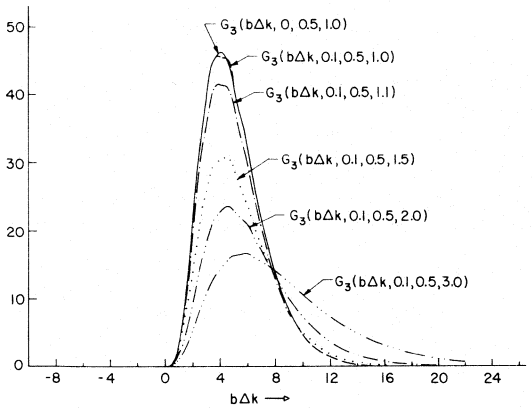

Fig. 15. G_3 versus $b\Delta k$ for $b/L \leqslant 0.1$; $f/L = 0.5$; and $k''/k' = 1.0$, 1.1, 1.5, 2.0, and 3.0.

peaks for positive and negative $b\Delta k$ and thus α may be either negative or positive.

VI. Experimental Results

An experiment has been conducted which verifies the theory of this paper for the process $\omega_1 + \omega_1 + \omega_1 \rightarrow 3\omega_1$ (third-harmonic generation) in the case of very tight focusing near the center of the cell. In these experiments the nonlinear medium was Xe gas, the fundamental beam had a wavelength of 3547 Å, and the generated radiation had a wavelength of 1182 Å. For this process, Xe possesses both a high nonlinear susceptibility and the proper dispersion characteristics to produce a negative value for Δk.

The experimental setup was identical with that of Kung *et al.* [6], except that the 3547-Å beam was passed through a lens-diamond pinhole-shearing aperture spatial filter in order to produce a very high-quality diffraction-limited beam with well-known parameters.

In this experiment, approximately 0.1 percent of the 3547-Å radiation was converted to 1182-Å radiation. The fundamental beam was focused at the center of the cell and b/L was 0.025. Fig. 16 shows the relative power output at 1182 Å versus Xe pressure with no Ar in the cell. The agreement of the triangular data points to the theoretical function $G_1(b\Delta k, 0, 0.5, 1)$ is excellent. The departure of the circular data points from theory is caused by the multimode character of the fundamental beam which results from an incorrect shearing aperture diameter. The process of fitting G_1 to the data

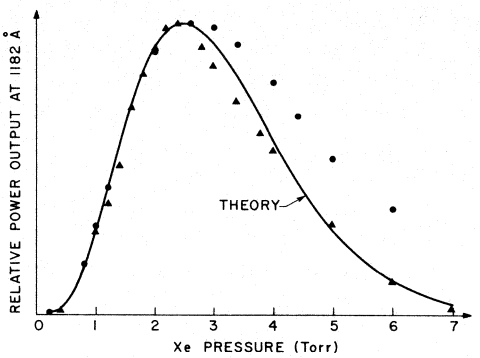

Fig. 16. Relative power output at 1182 Å versus Xe pressure. (The triangular points represent data from a run in which the shearing aperture was set to the proper diameter. The circular points represent data from a run in which the shearing aperture was open too far. The solid curve represents the best fit to the function $G_1(b\Delta k, 0, 0.5, 1)$ to the triangular points.)

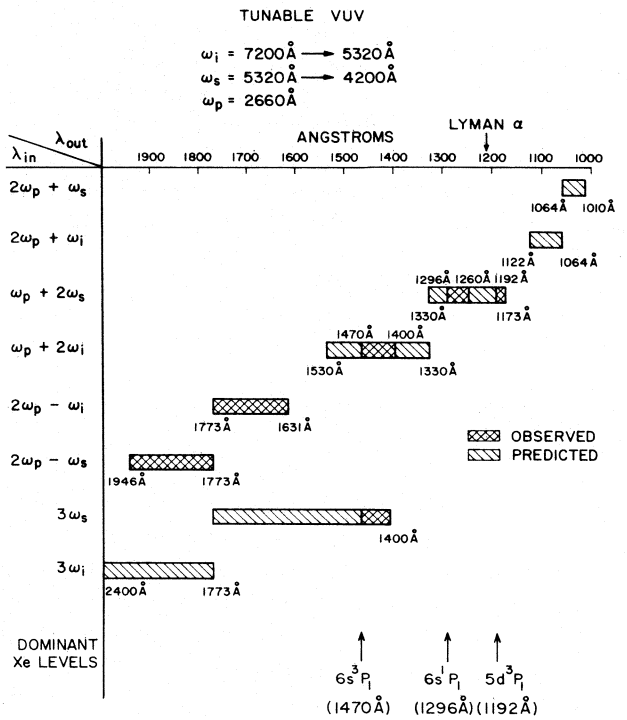

Fig. 17. Summary of the tunable VUV output achieved by Kung [4]. ω_p is pump frequency at 2660 Å, ω_s is signal frequency tunable from 5320 Å to 4200 Å, and ω_i is idler frequency tunable from 7200 Å to 5320 Å.

yields the coefficient of proportionality between Δk and the atomic-number density of the nonlinear medium, and thus provides an alternative method of determining the dispersion between the fundamental and generated wavelengths. The fit in Fig. 16 yielded $\Delta k = (-5.99 \times 10^{-17}) N_{Xe}$ (CGS units).

Some aspects of the theory of this paper for the processes $\omega_1 + \omega_1 - \omega_3 \rightarrow \omega_4$ and $\omega_1 + \omega_1 + \omega_3 \rightarrow \omega_4$ have been verified in a series of experiments performed by Kung [4]. These experiments concerned the mixing of a fixed-frequency pump at 2660 Å ($\omega_p = \omega_1$) with a variable-frequency signal or idler ($\omega_s, \omega_i = \omega_3$) in Xe gas to produce tunable coherent VUV radiation. Kung's experimental configuration involved very tight focusing of the fundamental beams. Fig. 17 shows the maximum possible spectral range which would be predicted for each process on the basis of simple addition or subtraction of the available fundamental photon energies. Fig.

17 also shows the range of tunable VUV output actually observed by Kung. The process $\omega_1 + \omega_1 + \omega_3 \rightarrow \omega_4$ produced a detectable signal at ω_4 only when ω_4 was near to, and on the short wavelength side of a strong Xe line. This is a necessary condition to produce anomalous dispersion and thus the negative values for Δk necessary to optimize G_1. The process $\omega_1 + \omega_1 - \omega_3 \rightarrow \omega_4$, however, produced a detectable signal over the entire maximum possible spectral range. This result would be expected since G_2 may be optimized for either negative or positive Δk. Thus the theory qualitatively explains the results of these experiments.

VII. Conclusions

This paper has presented a theoretical and experimental investigation of the effects of focusing on third-order nonlinear processes in isotropic media. A rigorous theory which relates the total power and far-field beam profile of the generated radiation to the various parameters of the fundamental beams and to the wave-vector mismatch has been developed. In the case of tight focusing with the fundamental beam-waist region entirely contained within the cell, it has been shown that the process $\omega_1 + \omega_2 + \omega_3 \rightarrow \omega_4$ can be efficient only in media whose dispersion characteristics produce a negative wave-vector mismatch and that the process $\omega_1 - \omega_2 - \omega_3 \rightarrow \omega_4$ can be efficient only in media whose dispersion characteristics produce a positive wave-vector mismatch. The process $\omega_1 + \omega_2 - \omega_3 \rightarrow \omega_4$ can be efficient in media with all types of dispersion characteristics and is always optimized by focusing as tightly as possible.

The improved understanding contributed by this paper of the far-field beam profile of the generated radiation for the process $\omega_1 + \omega_2 - \omega_3 \rightarrow \omega_4$ has important applications for coherent anti-Stokes Raman spectroscopy. By controlling the value of $b\Delta k$, the mode of the output radiation may be varied from near Gaussian to a ring-shaped pattern of variable cone angle. The cone angle of this ring pattern may be increased to the point where the generated radiation and the Gaussian fundamental beams become completely spatially separated in the far field. The advantages in detectivity which accrue from spatial separation between the generated radiation and fundamental beams may thus be secured for geometries which involve collinear propagation of the fundamental beams.

In the VUV and soft X-ray spectral regions, index of refraction data are often completely lacking and even the sign of the wave-vector mismatch produced by various media may be unknown. In this case, if Δk is of the wrong sign and/or if b is of the wrong value, the efficiencies of the processes $\omega_1 + \omega_2 + \omega_3 \rightarrow \omega_4$ and $\omega_1 - \omega_2 - \omega_3 \rightarrow \omega_4$ may be reduced by several orders of magnitude. Thus the process $\omega_1 + \omega_2 - \omega_3 \rightarrow \omega_4$ with very tight focusing has the highest probability of successfully producing a sufficient output for detection.

Effects of Near-Resonance Self-Absorption on CO Laser Kinetic Modeling

WILLIAM B. LACINA

Abstract—**Resonance self-absorption from overlapping lines is an important pressure-dependent mechanism for theoretical analysis of a high-pressure CO laser. Although the effect on total optical output efficiency, kinetic heating rate, and transient time scales is small, predicted output spectral distributions can change significantly. Results of calculations will be presented which show that output power is redistributed to higher vibrational bands with more unique $P(J)$ characteristics. Previous analytical work on CO laser kinetics produced distributions that lay one or two v bands lower than what is observed, and was incapable of explaining anomalous spectra which often show certain transitions missing. Qualitative comparisons with experiment indicate that these effects occur at much lower pressures than theoretically predicted by this analysis. This suggests that further work will be required to correctly describe the mechanism of optical broadening in a CO laser medium.**

Introduction

In recent years, several theoretical analyses of CO laser kinetics have been reported [1]-[8]. In general, the results of calculations have agreed reasonably well with experimental comparisons at cryogenic temperatures, although there remain certain theoretical discrepancies that still need to be resolved to obtain a realistic and reliable model. These include, for example, 1) anomalies in output spectral distribution, 2) differences in predicted time scales, 3) degraded optical extraction efficiency with kinetic heating, and 4) sensitive dependence on molecular temperature. With varying levels of approximation and differences of approach, present theoretical models for a CO electric-discharge laser (EDL) consist of numerical computer solutions to the coupled set of equations that describe the molecular kinetics, plasma kinetics, gas dynamics, and optical fields (with gain equal to loss) in a simple plane parallel resonator. In addition to the approximations and simplifying assumptions, the model predictions are subject to uncertainties in the knowledge of various rate constants and to the possibility of the omission of important fundamental physical mechanisms. In regard to the latter possibility, we have proposed [9] that resonance self-absorption in the CO medium itself can be an important pressure-dependent effect that must be included for correct theoretical modeling of the CO laser.

At total pressures approaching atmospheric, line broadening in the CO laser is dominated by collisions, with a half-width ~0.05-0.1 cm^{-1}. (Doppler broadening is much less, and is important only at low temperatures, with total pressures $\lesssim$ 20 torr.) Therefore, at high pressures, the collision broadening of lines results in several significant spectral overlaps for almost every CO transition, so that laser oscillation on one vibrational-rotational line can be absorbed (or have enhanced gain) due to near-resonant transitions of other bands. Of particular importance is the fact that the $P(J)$ transitions (which are the ones which oscillate) most frequently have overlaps with $R(J)$ transitions of *higher* vibrational bands, and thus absorptive pumping to higher v levels results.

Results of calculations to be reported here show that, for high pressures, this mechanism can produce output spectral distributions that are significantly different from those predicted on the basis of previous theoretical models. A variety of experimental evidence is available which indicates the presence of this effect. For example, some transitions are never observed in high-pressure laser devices, and spectral distributions generally lie in vibrational bands higher than predicted. Results of transient small-signal gain measurements recently reported by Boness and Center [10] also show anomalous holes for certain transitions. They find that, in a CO/N_2 ~ 20/80-torr mixture at 130 K, the gains for $6 \rightarrow 5$ $P(10)$ and $7 \rightarrow 6$ $P(10)$ are degraded by overlaps with $8 \rightarrow 7$ $R(3)$ and $9 \rightarrow 8$ $R(3)$, respectively, and that coincidence of the $5 \rightarrow 4$ $P(13)$ transition with the $8 \rightarrow 7$ $R(7)$ line results in total absence of gain. Their kinetic calculations of small-signal gain with the inclusion of resonance absorption produce a reasonable qualitative explanation of their experimental data. Fig. 1 shows experimental data [11] of integrated spectral output energy from a CO/Ar = 50/150-torr pulsed CO laser oscillator, pumped at 20 kW/cm^3 for 50 μs at 80 K. The spectrum is not time resolved, and thus contains several $P(J)$ components which probably occur as the pulse evolves in time; note, however, that the $6 \rightarrow 5$ $P(10)$, $7 \rightarrow 6$ $P(10)$, and $8 \rightarrow 7$ $P(11)$ transitions never appear. Although definitive comparisons of the theory with experimental spectra are not yet available, it will be shown

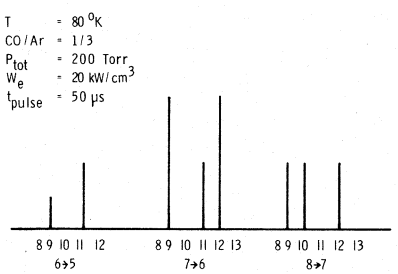

Fig. 1. Experimental integrated output spectrum from an e^--beam-sustained pulsed CO laser oscillator, with a CO/Ar = 50/150-torr gas mixture at 80 K, pumped at 20 kW/cm^3 for 50 μs, showing spectral anomalies.

that the mechanism of near-resonant absorption based on currently accepted optical-broadening constants alters the analytical predictions at high pressures. Based upon this fact and the strong qualitative experimental evidence available that supports it, resonance absorption must be included in the theoretical model for high-pressure CO lasers. However, as the calculations to be presented show, further work is required to improve the understanding of optical wing broadening to correctly describe its pressure dependence quantitatively.

The existence of resonances can lead to either of two possibilities: 1) the absorptions are so strong that laser oscillation is permanently inhibited from certain transitions; or 2) oscillation occurs, but relative spectral output as a function of vibrational band shifts upward because higher v levels are absorptively pumped. Both of these effects can have important consequences for line selection. It is possible that certain lines with favorable atmospheric transmission may never be attainable from high-pressure devices. (For example, $6 \rightarrow 5$ $P(10)$ has never been observed from the pulsed e^--beam-sustained CO EDL even at total pressures ~ 85 torr at 100 K with an intracavity water-vapor line-selection cell.) Furthermore, the upward shift of the spectrum makes it more difficult to obtain output in vibrational bands $6 \rightarrow 5$ and below, where almost all of the good atmospheric lines ($>$ 10-km e-folding range) are found. Finally, there is a small frequency shift from line center for oscillating transitions that is associated with the frequency dependence of the gains when resonance absorption is included. These shifts, which will be discussed in the following, are not expected to favorably alter any of the atmospheric transmission properties predicted for the CO laser.

Basic Theory

In this section, the theoretical formulation of the radiation calculations for a self-consistent oscillator analysis with resonance absorption will be outlined. It will be shown how this set of equations simplifies considerably when the mechanism of resonance absorption is neglected. For the optical analysis of the CO laser, stimulated emission processes are described by requiring that radiation intensities be instantaneously adjusted to maintain the (saturated) gain coefficients for all oscillating transitions equal to the threshold loss. Without resonance absorption the threshold condition is determined from the line-center gain on the laser transition alone.

However, with the inclusion of near-resonance absorption (or enhanced gain), the optical output intensities for all of the levels become coupled. The threshold condition must then be defined by the *net* gain coefficient for an oscillating transition, determined from line-center gain offset by wing absorption of all the near-resonant transitions of other bands. Furthermore, the calculations must be consistent kinetically, with all of the resulting optical emissions and absorptions included in the master equation for the population densities of the vibrational levels. Basically, these are the only generalizations required for extension of the previous analysis, and all of the prior assumptions can be retained. For example, we shall continue to assume a simple oscillator model with gain equal to loss in a spatially uniform plane parallel resonator. Furthermore, rotational levels are assumed to be in thermal equilibrium with the molecular temperature, with rotational cross relaxation taken to be sufficiently fast that only one rotational line can oscillate in any given vibrational band. Optical losses such as mirror absorption, output coupling, internal windows, or intracavity line selection are assumed to be uniformly distributed throughout the laser gain medium.

Emission and absorption for all transitions will be described by homogeneous collision broadening, with a normalized Lorentzian line shape

$$S(\tilde{\nu}, \tilde{\nu}_0) = (\Delta\tilde{\nu}/\pi c)\,[(\tilde{\nu} - \tilde{\nu}_0 - \delta\tilde{\nu})^2 + \Delta\tilde{\nu}^2\,]^{-1} \tag{1}$$

where frequencies $\tilde{\nu} = \nu/c$ are expressed in cm^{-1}. $\delta\tilde{\nu}$ is a pressure-induced shift of the center frequency $\tilde{\nu}_0$ of the transition, and will be neglected, although it is likely to be important at very high pressures ($>$ several atmospheres). The optical-broadened half-width is taken to be

$$\Delta\tilde{\nu} = \sum_X N_X \langle v(\text{CO}, X)\rangle\, \sigma^{\text{opt}}(\text{CO}, X)/(2\pi c) \tag{2}$$

where the sum is over the components X of the gas mixture. N_X are the total population densities, $\langle v(\text{CO}, X)\rangle$ are relative thermal velocities, and $\sigma^{\text{opt}}(\text{CO}, X)$ are the optical-broadening cross sections for the (CO, X) dephasing collisions. For the calculations to be reported here, we have taken average cross sections reported by Williams *et al.* [12] for the $1 \rightarrow 0$ CO fundamental band: $\sigma^{\text{opt}}(\text{CO}, \text{CO}) = 80 \times 10^{-16}$ cm^2 and $\sigma^{\text{opt}}(\text{CO}, \text{Ar}) = 60 \times 10^{-16}$ cm^2. The line-broadening assumptions will be discussed further in the following.

It is most convenient to label the complete set of vibrational-rotational transitions by (v, J, K), where $K = 1$ corresponds to $v \rightarrow v - 1$ $P(J)$ and $K = -1$ to $v \rightarrow v - 1$ $R(J - 1)$. (Then both P and R transitions appear symetrically in sums over $J = 1$ to $J = J_{\max}$, which is here taken to be 25.) With infinitely fast rotational cross relaxation, the frequency-dependent gain or absorption coefficients for all transitions are given by

$$\alpha_{vJK}(\tilde{\nu}) = n_v(t)\sigma^{21}_{vJK}(\tilde{\nu}) - n_{v-1}(t)\sigma^{12}_{vJK}(\tilde{\nu}) \tag{3}$$

in terms of the vibrational level population densities $n_v(t)$ and the stimulated emission cross sections, which are defined by

$$\begin{aligned}
\sigma^{21}_{vJK}(\tilde{\nu}) &= C_{vJK}\, B_v \exp\,[-B_v J(J - K)/kT] \\
\sigma^{12}_{vJK}(\tilde{\nu}) &= C_{vJK}\, B_{v-1} \exp\,[-B_{v-1} J(J + K)/kT] \\
C_{vJK} &= S(\tilde{\nu}, \tilde{\nu}_{vJK})\,\tilde{\nu}_{vJK} J \\
&\quad \cdot A_{10} |R_{v,v-1}/R_{10}|^2/(8\pi k T \tilde{\nu}^{\,3}_{10}).
\end{aligned} \tag{4}$$

Here, $A_{10} = 30.3$ s^{-1} is the $1 \rightarrow 0$ spontaneous radiative rate, $\tilde{\nu}_{10} = 2143$ cm^{-1} is the fundamental $1 \rightarrow 0$ frequency, $k = 0.69$ cm^{-1}/K is the Boltzmann constant, $|R_{v,v-1}/R_{10}|^2$ is the ratio of dipole moments, B_v is the rotational constant for level v, and T is the molecular temperature. The ratio of dipole moments $|R_{v,v-1}/R_{10}|^2$ is taken to be that given by Penner [13] for a Morse oscillator, and is approximately $|R_{v,v-1}/R_{10}|^2 \approx v$. (Note that C_{vJK} contains the factor J which applies for either $P(J)$ or $R(J - 1)$ transitions.) The gains α_{vJK} are a function of time, and because of kinetic heating, so are the stimulated emission cross sections σ^{21}_{vJK} and σ^{12}_{vJK} as a result of their dependence on T. However, for simplicity of notation the t dependence has been suppressed.

In general, the total gain coefficient for any frequency $\tilde{\nu}$ can be expressed as a sum of gains and absorptions over all of the transitions of the medium

$$\alpha(\tilde{\nu}) = \sum_{vJK} \alpha_{vJK}(\tilde{\nu}). \tag{5}$$

For a self-consistent oscillator analysis, the spectrum at time t is defined by the condition that $\alpha_L(t) \equiv \alpha(\tilde{\nu}_L) = \gamma_L$, where γ_L are the loss coefficients and $\tilde{\nu}_L$ are the frequencies for the set of lasing transitions $(v_L, J_L, 1)$, $L = 1, 2, \cdots, N$. (Except for calculations involving intracavity line selection, the loss coefficients γ_L are constant, independent of L.) The set of transitions L is restricted to one $P(J)$ line for any given v band, and as the transient evolution proceeds, this set can change. The intensities $I_L(t)$ of the set of N transitions which have attained threshold at time t satisfy a linear set of N equations of the form $d\alpha_L(t)/dt = 0$

$$(d/dt) \sum_{vJK} [n_v(t)\sigma^{21}_{vJK}(\tilde{\nu}_L) - n_{v-1}(t)\sigma^{12}_{vJK}(\tilde{\nu}_L)] = 0 \tag{6}$$

which become

$$\sum_{vJK} [\dot{n}_v(t)\sigma^{21}_{vJK}(\tilde{\nu}_L) - \dot{n}_{v-1}(t)\sigma^{12}_{vJK}(\tilde{\nu}_L)]$$

$$= - \sum_{vJK} [n_v(t) d\sigma^{21}_{vJK}/dT - n_{v-1}(t) d\sigma^{12}_{vJK}/dT]\, \dot{T} \tag{7}$$

for $L = 1, 2, \cdots, N$. $\dot{T}$ is determined by the instantaneous heating rate as a function of time. The time derivatives of the population densities are defined by the molecular kinetics master equation

$$\dot{n}_v(t) = R_v(t) + \sum_{JKL} [\beta_{v+1,JK}(\tilde{\nu}_L) - \beta_{vJK}(\tilde{\nu}_L)]\, I_L(t) \tag{8}$$

which is shown here explicitly separated into the kinetic terms $R_v(t)$ (e.g., electrical excitation, VV and VT relaxation, spontaneous emission, etc.) and the stimulated emission and absorption terms

$$I_L(t)\beta_{vJK}(\tilde{\nu}_L) = \alpha_{vJK}(\tilde{\nu}_L)\, I_L(t)/hc\tilde{\nu}_{vJK}. \tag{9}$$

Thus the set of linear equations for the intensities $I_L(t)$ becomes

$$\sum_{L'} \Phi_{LL'}(t)\, I_{L'}(t) = \phi_L(t) \tag{10}$$

where

$$\Phi_{LL'}(t) = \sum_{\substack{vJK \\ J'K'}} \{\sigma^{21}_{vJK}(\tilde{\nu}_L)\, [\beta_{v+1,J'K'}(\tilde{\nu}_{L'}) - \beta_{vJ'K'}(\tilde{\nu}_{L'})]$$

$$+ \sigma^{12}_{vJK}(\tilde{\nu}_L)\, [\beta_{v-1,J'K'}(\tilde{\nu}_{L'}) - \beta_{vJ'K'}(\tilde{\nu}_{L'})]\,\} \tag{11}$$

and

$$\phi_L(t) = - \sum_{vJK} [\sigma^{21}_{vJK}(\tilde{\nu}_L)\, R_v(t) - \sigma^{12}_{vJK}(\tilde{\nu}_L)\, R_{v-1}(t)]$$

$$- \sum_{vJK} [n_v(t)\, d\sigma^{21}_{vJK}/dT - n_{v-1}(t)\, d\sigma^{12}_{vJK}/dT]\, \dot{T}. \tag{12}$$

Thus all of the vibrational levels of the medium become optically coupled whenever there are resonant transitions with sufficient overlap. Without the mechanism of resonance self-absorption, the set of linear equations for the intensities $I_L(t)$ is considerably simplified; in that case, it reduces to a tridiagonal system since only line-center terms occur. If perfect resonance is implicitly assumed, it is convenient to suppress the frequency dependence and to simplify the subscript notation; without resonance absorption, all of the sums collapse, and (11) becomes

$$\Phi_{L,L+1} = \sigma^{21}(v_L, J_L)\, \beta(v_L + 1, J_{L+1})\, \delta(v_L + 1, v_{L+1})$$

$$\Phi_{L,L} = - \beta(v_L, J_L)\, [\sigma^{21}(v_L, J_L) + \sigma^{12}(v_L, J_L)]$$

$$\Phi_{L,L-1} = \sigma^{12}(v_L, J_L)\, \beta(v_L - 1, J_{L-1})\, \delta(v_L - 1, v_{L-1}) \tag{13}$$

where $K = 1$, specifying that all terms in (13) correspond to $P(J)$ transitions, has been suppressed for simplicity. It is also tacitly assumed in (13) that the upper laser vibrational levels v_L increase monotonically with the index L (i.e., that the transitions are labeled sequentially).

Equation (13) forms the basis of the radiation calculations reported previously [7]. The more general formulation expressed by (11) consists of sums which couple any two transitions L, L' for which there exist overlapping wings. In the numerical calculations based on (11) to be reported here, the sums are truncated beyond a specified number of collision half-widths $\Delta\tilde{\nu}$, which is taken to be a variable input parameter. After the radiation intensities $I_L(t)$ have been determined by inversion of (10), the resulting stimulated emission and absorption terms that occur in the master equation (8) can be obtained and the integration continued.

Numerical Results and Conclusions

Calculations based on the old and new radiation models were compared for a variety of pressures, electrical pumping rates, and molecular temperature. Contrary to some of the initial speculations [9], the results indicate that resonance absorption does not have a significant effect on predictions of total optical output efficiency, kinetic heating rates, or transient evolution. Changes are typically less than 10 percent, and therefore the parameter scaling generalizations reported recently [14] are not immediately invalidated. However, the predicted output spectral distribution does change significantly, with the output power redistributed to the higher vibrational bands.

Previous calculations produced distributions that lay about one or two v bands lower than what is observed, and were incapable of explaining anomalous experimental spectra which often show certain transitions always missing. The envelope of intensities calculated on the basis of (13) is usually peaked at the lowest vibrational band (or next to it) with a monotonic decrease for increasing v, while calculations with resonance absorption based on (11) produce more distinctive distributions. Furthermore, the predicted $P(J)$ characteristics become more unique, both as a function of time for any given v band, and relative to each other for several v bands at any fixed time.

To assess the sensitivity to resonance, the distance (in frequency) from line center, beyond which terms in the sums of

(11) were truncated, was treated as a variable input parameter. This parameter was increased until further terms made no significant contribution to the accuracy of the final results, and it was found that resonances as far away as 50–100 $\times \Delta\tilde{\nu}$ had to be included. Thus the assumption of Lorentzian wing absorption itself becomes important and must be examined and evaluated. Furthermore, there are open questions that remain about the optical-broadening cross sections σ^{opt} (CO, X; v, J, T). The dependence on rotational level [12] and molecular temperature [15] for different species X has been the object of limited experimental investigations for the $1 \rightarrow 0$ infrared absorption band. However, since the mechanism of optical broadening for CO probably originates from dipole-dipole collisional interactions, the possibility also exists that the cross sections for all the levels may not be constant, but an increasing function of the vibrational level v. Further experimental work to determine the vibrational-level dependence (if any) for these cross sections would be important, since there are presently no available data.

Although definitive time-resolved spectral data are not presently available, semiquantitative comparisons with experiment indicate that the important spectral effects occur at much lower pressures (~0.1 atm) than predicted by this analysis ($\lesssim$0.5 atm). This suggests the possibility of uncertainty in present knowledge of the CO optical pressure-broadening mechanism, since an increase in wing absorption (either by non-Lorentzian wings or increased broadening cross sections) would cause the predicted effects to appear at correspondingly lower pressures.

Comparison of calculations with and without absorption for CO/Ar = 20/80 torr at 80 K, pumped at 500 W/cm^3, showed no significant changes in either spectral distribution or magnitude of predicted intensities (< 1-percent change). Further calculations were carried out for CO/Ar mixtures of 100/200 and 100/600 torr at 100 and 300 K, with (constant) electrical pumping rates of 10, 20, and 50 kW/cm^3. (The optical resonator was assumed to be formed by two plane parallel mirrors with 80- and 100-percent reflectivities, separated by 50 cm, with a 6-percent/pass intracavity optical loss.) Fig. 2 shows a comparison of the predicted transient evolution of the optical output for CO/Ar = 100/600 torr at 300 K, pumped at a constant rate of 20 kW/cm^3 for 20 μs. Fig. 3 shows the predicted intensity distribution near the end of the pulse (18 μs) with and without resonance effects, and Fig. 4 shows a comparison of the $P(J)$ spectral designations as a function of time. Note that the intensity envelope, as well as the $P(J)$ characteristics, are considerably different. The significant differences originate completely from the resonance absorption mechanism, and not from differences in heating (temperature rise was ~40 K, with a change less than 1 percent for the two calculations). Fig. 5 shows predicted intensity distributions at the end of the pulse (20 μs) for the same case, but with initial temperature T = 100 K. Similar results were obtained for the other cases analyzed, and thus the presentation of further spectral plots would neither be necessary nor useful here. The intention has been to demonstrate that this mechanism is important for theoretical modeling of a high-pressure CO laser.

However, to show the effects of pressure and pumping in a

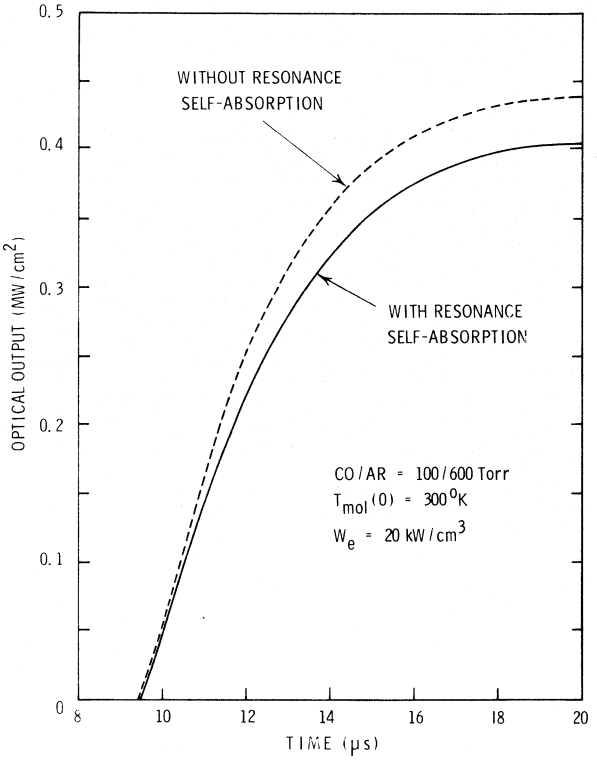

Fig. 2. Total optical output intensity as a function of time, with (solid) and without (dashed) resonance self-absorption included.

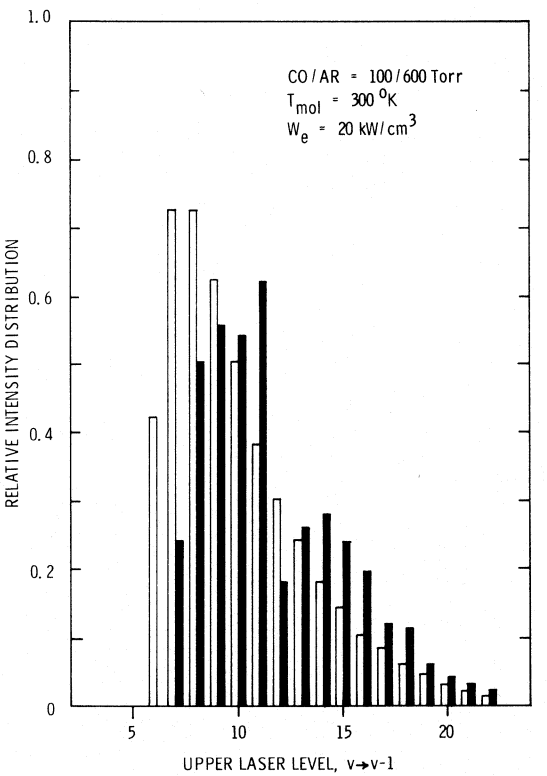

Fig. 3. Relative intensity distribution (full scale = 100 kW/cm^2) predicted at pulse end, with (solid) and without (open) resonance absorption.

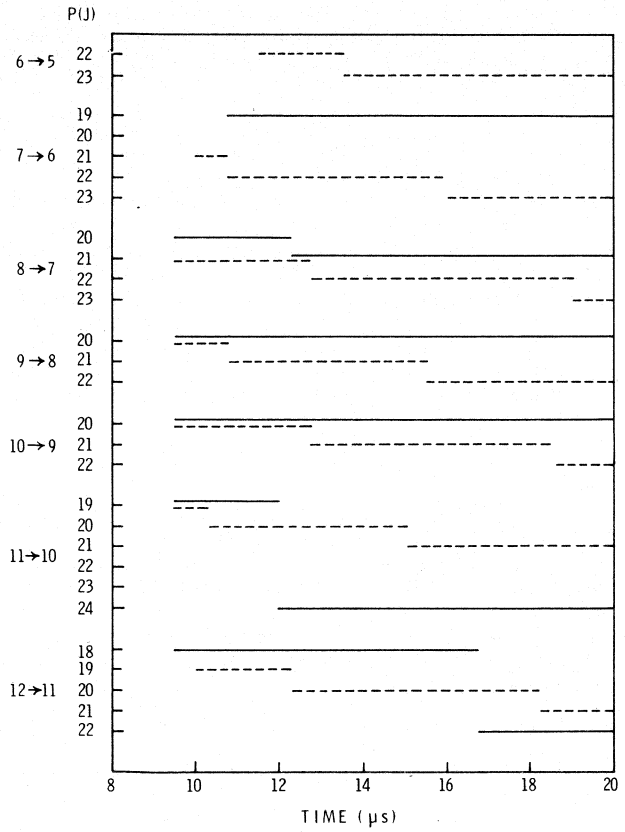

Fig. 4. $P(J)$ spectral characteristics as a function of time, with (solid) and without (dashed) resonance self-absorption.

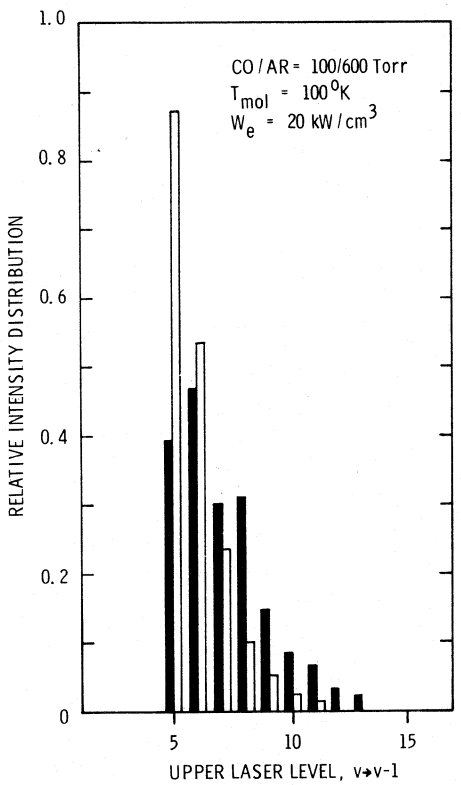

Fig. 5. Relative intensity distribution (full scale = 300 kW/cm^2) predicted at pulse end, with (solid) and without (open) resonance absorption.

brief quantitative way, it is convenient to summarize for several cases the percentage η of electrical power W_e (W/cm^3) that is distributed to different bands by the absorption mechanism (at steady state, for example). This is defined by

$$\eta = \sum_L [\alpha(v_L, J_L) - \gamma_L] I_L / W_e \tag{14}$$

where $\alpha(v_L, J_L)$ denotes the line-center gain for transition L as in (13). Results are presented in Table I. It was found that, for the case presented in Figs. 2-4, $\eta \sim 0.13$, and that resonances as far as $\sim 50 \times \Delta\tilde{\nu}$ (corresponding to ~ 2.4 cm^{-1}) were required for the calculation. (Typically, the net gain for each oscillating transition contained contributions from ~ 10 overlapping lines.)

The gain coefficient for any CO transition is a sum of Lorentzians (5) over all of the resonant lines, and thus the frequency dependence will be distorted. Therefore, oscillation frequencies will be shifted slightly from the line centers. Calculations show that the magnitude of these shifts is not significant; predicted changes for the frequencies of the lines of Fig. 4 were < 0.005 cm^{-1}, which is comparable to typical cavity mode separations. Frequency shifts of this magnitude do not result in significantly improved atmospheric transmission predictions. Calculations for atmospheric transmission, based on molecular absorption through a horizontal path at sea level in a midlatitude winter model using McClatchey AFCRL atmospheric constituent data, were carried out for all the CO lines in the first ten vibrational bands with the line-center frequencies shifted by as much as ± 0.02 cm^{-1}. This did not produce any significant changes, so frequency shifts anticipated from resonance absorption should not be considered important.

It is clear from this analysis that, if present values for optical cross sections and assumptions of Lorentzian broadening are valid, then resonance absorption is important for theoretical modeling of CO lasers at pressures approaching atmospheric. However, experimental evidence strongly suggests that the effects occur at much lower pressures ($\lesssim 0.1$ atm). This may be explained if wing absorptions are a factor of ~ 10 greater than assumed. It has been the purpose of this paper to assess quantitatively the effect of resonance absorption as a function of gas pressures, temperature, and pumping rates, and to show that it is *necessary* (although perhaps not sufficient) to modify

TABLE I
PERCENTAGE η OF ELECTRICAL INPUT POWER W_e THAT IS REDISTRIBUTED TO DIFFERENT VIBRATIONAL LEVELS BY ABSORPTIVE PUMPING FOR SEVERAL DIFFERENT CASES AT STEADY STATE

Case W_e (kW/cm^3)	10	20	50
CO/Ar = 100/600 T(0) = 100 K	.20	.30	.49
CO/Ar = 100/200 T(0) = 100 K	.15	.17	.34
CO/Ar = 100/600 T(0) = 300 K		.14	

Note: Results correspond to $t = 20$ μs except for $W_e = 10$ kW/cm^3, for which $t = 40$ μs.

contemporary theoretical models of CO-laser kinetics to include this mechanism. It will be necessary in future work to resolve this as well as remaining discrepancies (such as rotational equilibration) to achieve a more complete understanding of the CO laser.

On the Mechanism of the $N(^4S) + CS_2$ Reaction: N_2–CO_2 Laser Pumping from the Products of the $N(^4S) + CS_2$ Reaction

T. J. McGEE AND F. X. POWELL

Abstract—**The reaction of N atoms with CS_2 has been studied and a mechanism for the reaction proposed. It has been demonstrated that the N + NS reaction produces vibrationally excited N_2. Evidence has been presented which indicates that the rate of the N + CS_2 reaction is substantially slower than first indicated. The analogous reaction N + OCS ⟶ NS + CO has also been studied and a mechanism proposed.**

Introduction

In 1973 Hirose *et al.* [1] reported the achievement of a CO laser from the reaction of discharged nitrogen with O_2 and CS_2. The authors presented evidence leading to the following proposed mechanism:

$$N + CS_2 \longrightarrow CS + NS \quad (1)$$

Manuscript received February 25, 1975. This research was supported by the Office of Naval Research.

T. J. McGee was with the Department of Chemistry, The Catholic University of America, Washington, D.C. 20017. He is now with the Department of Chemistry, the University of Maryland, College Park, Md. 20742.

F. X. Powell is with the Department of Chemistry, The Catholic University of America, Washington, D.C. 20017.

$$N + NS \longrightarrow N_2 + S \quad (2)$$

$$S + O_2 \longrightarrow SO + O \quad (3)$$

$$O + CS_2 \longrightarrow CS + SO \quad (4)$$

$$O + CS \longrightarrow CO^* + S. \quad (5)$$

In their work Hirose *et al.* assumed rate constants on the order of 10^{14} $cm^3/mole \cdot s$ for reactions (1) and (2), largely because the power levels achieved by this reaction were very close to those achieved when O_2 was discharged and reacted directly with CS_2. The work reported herein confirms that the reaction of N + CS_2 reaction is rapid enough to participate in the laser-pumping mechanism but it does not appear to be as rapid as suggested by Hirose.

In a previous paper [2] we have reported the technique of CO_2 laser pumping by species born of a chemical reaction, notably vibrationally excited N_2. Using this technique with the N + CS_2 system has shown that the N + NS reaction, like the analogous N + NO reaction, produces vibrationally excited N_2.

Experimental

The apparatus has been previously described in [2] and only slight modifications were made for these experiments. The reaction zone/optical path was increased to 2 m which resulted in a more stable laser system for the reactions studied, and laser power was measured from reflection off the Brewster's angle rather than by hole coupling. 10 torr of nitrogen was discharged using a condensed discharge of 5 kV and

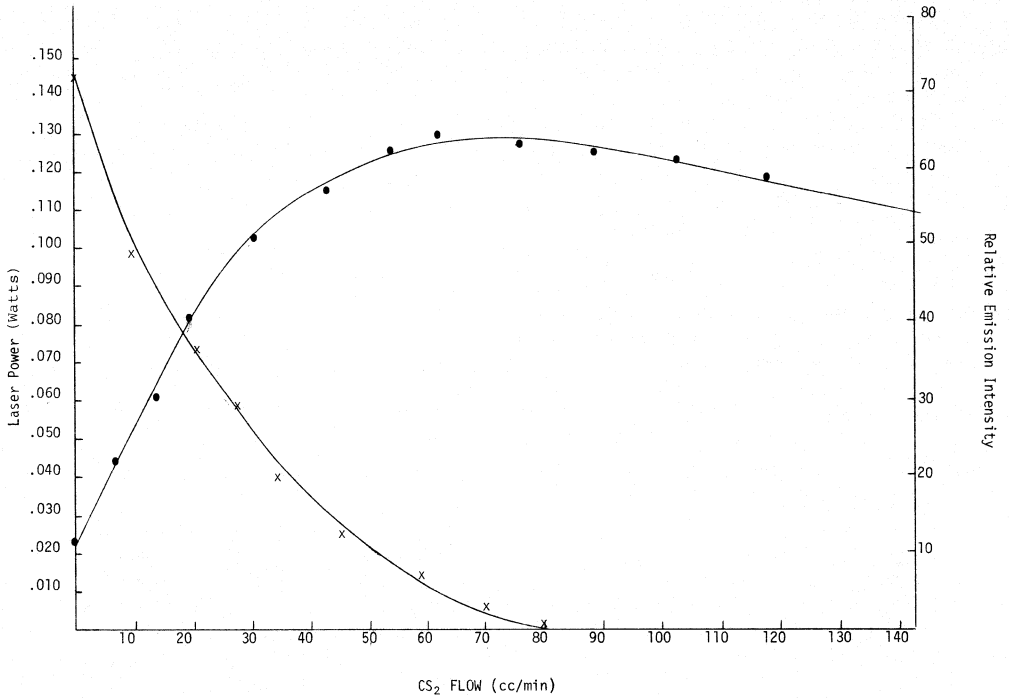

Fig. 1. Titration of N atoms with CS_2. X–N_2 first positive series versus CS_2 flow. •–Laser power versus CS_2 flow.

200 mA, yielding approximately 0.4-percent N atoms. The pressure of CO_2 was kept constant in the experiments at 1.5 torr. Both a chemical trap and a liquid-N_2 trap were used to prevent explosions from CS and unreacted CS_2.

Results and Discussion

When CO_2 was introduced to the flowing nitrogen afterglow, a low-power CO_2 laser was generated from the near-resonant transfer of energy from vibrationally excited N_2. The addition of CS_2 resulted in a linear increase in laser power, as shown in Fig. 1. As in the work with NO this curved into a maximum and decreased beyond the endpoint due to collisional deactivation of the CO_2 by the excess of CS_2. Spectral analysis of the lasing radiation on a Perkin-Elmer 112 G IR spectrophotometer showed that all lasing occurred at 10.6 μ. Radiation at 11.5 μ, corresponding to the CS_2 transitions observed by Patel [3], was not observed in any of the experiments described herein.

Fig. 1 also shows a plot of the decay of the N_2 first-positive series measured at 5804 Å. It can be seen that the laser-power maximum and the endpoint of the N + CS_2 reaction as measured by zero intensity of the N_2 first-positive emission closely coincide, indicating that the N atoms were directly responsible for producing the species pumping the CO_2 laser. It is also possible that a small fraction of the CO_2 inversion is due to vibrational energy transfer from the NS and CS produced in reaction (1). Transfer of any vibrational energy released into NS or CS to CO_2 would necessarily be slow compared to the near-resonant transfer from N_2^*, (ω_e for NS and CS are 1220 and 1285 wavenumbers, respectively [4]).

Although equipment for the determination of accurate kinetic data was not available, it was possible to make a rough estimate of the reaction rate by comparison of the reaction with the N + NO reaction. The N + NO reaction has been well studied and has a reported rate constant of 1.8×10^{13} cm^3/mole · s [5]. In our previous work, this reaction was studied using a 16-in optical path which was sufficiently long for the reaction to proceed while still in the optical path. Experiments with CS_2 using the 16-in optical path resulted in a laser-power maximum long before the first-positive bands went to zero. In order to react all the N atoms in the 16-in zone, it was necessary to add such a large excess of CS_2 that the CO_2 was collisionally deactivated and no laser power was observed. Increasing the length of the reaction zone/optical path to 2 m, which increased the residence time in the optical path from 5 to 27 ms, enabled the N atoms and CS_2 to react in more nearly stoichiometric concentrations and the laser-power maximum then agreed with zero intensity of the N_2 first-positive series. This necessary increase in residence time thus indicates that the N + CS_2 reaction is substantially slower than the N + NO reaction, perhaps by as much as an order of magnitude.

This estimate of a rate constant on the order of 10^{12} cm^3/mole · s, is approximately equal to the rate constant reported for the O + CS_2 reaction [6] and thus would be sufficiently rapid to produce the relatively high laser-power levels reported by Hirose.

The reaction mechanism does not appear to be as simple as indicated by reactions (1) and (2). Evidence has been presented [7]–[9] indicating that the CS formed in the reaction is in the singlet state which makes reaction (1) doubly spin-forbidden. We therefore suggest the following mechanism, using the reaction intermediate advanced by Westbury and Winkler [7], which takes into account the spin-forbidden nature of the reaction:

$$N(^4S) + CS_2 \longrightarrow N \cdot CS_2(111) \quad (6)$$

$$N \cdot CS_2(111) \longrightarrow N \cdot CS_2(1\downarrow 1) \quad (7)$$

$$N \cdot CS_2(1) \longrightarrow NS(1) + CS \quad (8)$$

$$N + NS \longrightarrow N_2^* + S. \quad (9)$$

This mechanism proposes a rapid equilibrium with the intermediate being formed in a quartet state. The second step of the reaction would appear to be the rate-determining step as it involves a radiationless isomerization to the doublet state. The increase in exothermicity from this step can then cause the decomposition of the intermediate to doublet NS and singlet CS, whereupon the NS further reacts with an N atom to yield vibrationally excited N_2 and the S necessary to

Hirose's laser-pumping mechanism. Reactions (6)–(9) followed by reactions (3)–(5) would then appear to be the mechanism for Hirose's laser. It can be seen that in this sequence of reactions, CS molecules have two sources: The N + CS_2 reaction scheme and the O + CS_2 mechanism. This fact doubtless contributes to the relatively high laser-power levels observed.

Because of its chemical similarities, OCS was also reacted with N atoms. In spite of the fact that the N + OCS reaction is thermodynamically more favorable than the N + CS reaction, it is apparently much slower. It was possible to generate a slight increase in laser power followed by a deactivation of the laser by excess OCS long before the reaction consumed the available N atoms. Extension of the reaction zone to 10 ft (the maximum length at our disposal) failed to alter these experimental results appreciably, indicating that the reaction is considerably slower than the N + CS_2 reaction. The slight increase in laser power did, however, show that this reaction as well ultimately results in vibrationally excited N_2. Thus a mechanism similar to that for the N + CS reaction can be proposed

$$N(^4S) + OCS \longrightarrow N \cdot OCS(111) \quad (10)$$

$$N \cdot OCS(111) \longrightarrow NOCS(1\downarrow 1) \quad (11)$$

$$NOCS(1) \longrightarrow NS + CO \quad (12)$$

$$N + NS \longrightarrow N_2^* + S. \quad (13)$$

Conclusion

In this work, we have reported the achievement of a CO_2 laser by means of the reaction of N atoms with CS_2 to form, after a series of subsequent steps, vibrationally excited N_2 which can transfer energy by a near-resonant V–V transfer with CO_2. It has been demonstrated that the N + CS_2 reaction sequence is sufficiently rapid to be involved in the laser-pumping mechanism proposed by Hirose *et al.*, although it appears that the reaction is not as fast as they had assumed in their work. A more detailed mechanism for the reaction of N atoms with CS_2 has been advanced, utilizing the reaction intermediate first proposed by Westbury and Winkler [7]. This mechanism takes into account the spin-forbidden nature of reaction (1).

Additionally, the apparently slow reaction of N + OCS ⟶ NS + CO has been studied. The increase in laser power at low flow rates of OCS gives further evidence that the reaction

$$N + NS \longrightarrow N_2 + S$$

produces N_2 in a vibrationally excited state. A mechanism similar to that of the N + CS_2 reaction has been proposed.

Multimode Bragg Diffractions in an Ion-Exchanged Optical Waveguide with a Sputter-Etched Periodic Surface Corrugation

K. ASAKAWA, M. KONDO, Y. OHTA, F. SAITO, AND T. YAMAZAKI

Abstract—**An optical diffraction phenomenon in an ion-exchanged planar optical waveguide with a sputter-etched periodic surface corrugation was experimentally investigated in detail. A single-mode incident beam simultaneously gave rise to several diffracted beams of different mode indices in different directions. This phenomenon was interpreted on the basis of the phase-matching diagram for the multimode Bragg diffraction by using measured wave vectors of the propagation modes and of the surface corrugation.**

In recent years, work on several planar optical waveguides with periodic structures for integrated optics has been reported [1], [2]. The collinear Bragg diffraction for the phase-grating structure in the deposited thin-film optical waveguide have been both experimentally and theoretically investigated to a great extent, in connection with grating couplers [3] and DFB lasers [4]. Very little was mentioned, however, about noncollinear Bragg diffractions in the multimode optical waveguide [2].

An ion-exchanged planar optical waveguide on a glass substrate has been reported to have many advantages, such as extremely low propagation loss and easy fabrication of buried or undulating waveguide structures by electromigration technique [5]. Such a waveguide can propagate many modes, since its high refractive index layer is generally thicker than the deposited thin-film optical waveguide.

This correspondence reports experimental results on the noncollinear Bragg diffraction phenomenon in the above-mentioned ion-exchanged planar optical waveguide, whose surface is periodically corrugated by sputter-etching technique.

A planar optical waveguide was formed on the surface of an approximately 30- by 10- by 3-mm F-2 glass substrate by ion-exchange technique. The refractive index profile normal to the surface was measured by the interference microscope and was found to be nearly parabolic. The waveguide is 50 μm thick and optical propagation loss is less than 0.1 dB/cm.

A periodic surface corrugation was fabricated on the waveguide by an RF sputter-etching technique. Prior to the sputtering, a 12-μm pitch grating pattern was formed with AZ-1350 photoresist in a 3- by 3-mm area on the waveguide surface. The surface grating obtained in this way had a 12-μm pitch with 250 grooves in the 3- by 3-mm area. Its depth was about 0.5 μm.

Configuration of the optical diffraction experiment is shown in Fig. 1. An He–Ne laser beam (6328 Å) was coupled into

and out of the planar optical waveguide through prism couplers. Excitation of a particular TE mode was accomplished by adjusting the angle incident to the input prism coupler.

When a single-mode incident beam in the waveguide (hereinafter referred to simply as an incident beam) impinged on the grating, many diffracted beam spots appeared simultaneously on both sides of the transmitted beam spot on the screen behind the output prism coupler. A diffracted beam spot always lay on one of the m lines, as shown in Fig. 1.

Fig. 2 shows photographs of typical diffraction patterns. The m lines mentioned above are too faint to be recorded in the photographs. In Fig. 2, the diffraction order is indicated by n and the incident and the diffracted mode indices are indicated by m_{in} and m_{dif}, respectively. Incident angle θ_{in} is the angle between the incident beam and the grating groove direction. Diffraction patterns changed definitely, even for small incident angle change, say, 0.15°.

The typical relationship between n and m_{dif} for $m_{in} = 11$ is diagramed in Fig. 3. In this diagram, filled circles show observed diffracted beam spots. Dashed line curves were obtained by connecting the circles corresponding to the simultaneously observed diffracted beam spots for given θ_{in} values. It is noted that the maximum mode index change from the incident mode to the diffracted mode becomes as high as 11 and a diffracted beam of as high as the sixth order is observed at $\theta_{in} = -8.43°$.

Diffracted beam intensity incident angle dependence is measured for $m_{in} = 11$ and the results are shown in Fig. 4. The diffracted mode index m_{dif} is indicated at the top of each

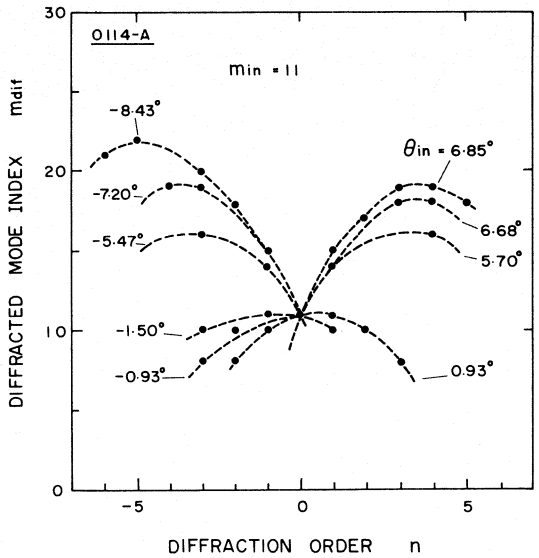

Fig. 3. Relationship between the diffracted mode index m_{dif} and the diffraction order n for $m_{in} = 11$.

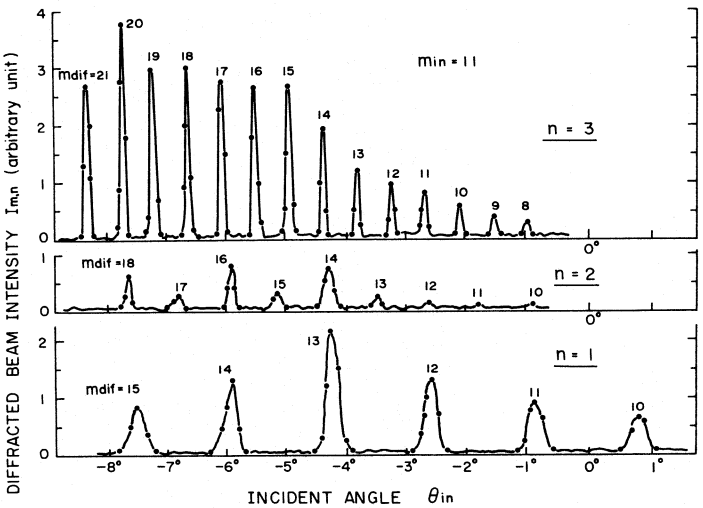

Fig. 4. Measurement of diffracted beam intensity versus incident angle θ_{in} for $m_{in} = 11$.

peak. For $n = 1$, angular width $\delta\phi_{in}$ of each peak is about 0.3°, which is nearly one-fifth of the angular interval $\Delta\theta_{in}$ between two adjacent peaks. Even if n increases, the ratio $\delta\theta_{in}/\Delta\theta_{in}$ is almost invariant. For $\theta_{in} = 2.6°$ and 4.3°, diffractions of several orders were simultaneously observed. Since vertical scales for different n's in Fig. 4 are the same, it is of interest that the maximum diffracted beam intensity for $n = 3$ is larger than that for $n = 1$.

These experimental results can be interpreted in terms of a multimode Bragg diffraction phase-matching diagram by using the measured relationship between wavenumbers, β's for the propagation mode, and mode indices. Fig. 5 shows effective refractive index β/k values for the TE mode, measured by the conventional prism-coupler technique. Here, $k = 2\pi/\lambda_0$ and λ_0 is vacuum light wavelength.

Fig. 6 shows translation of the observed relationships between n, m_{dif}, and θ_{in} given in Fig. 4, into a phase-matching diagram with the aid of measured β/k values. Magnitudes of concentric circle radii indicate β/k's for $m_{in} = 8$ to 14, shown in Fig. 5. Here, the abscissa is parallel to the grating grooves and the arrows show grating wave vectors. Solid, dotted, and

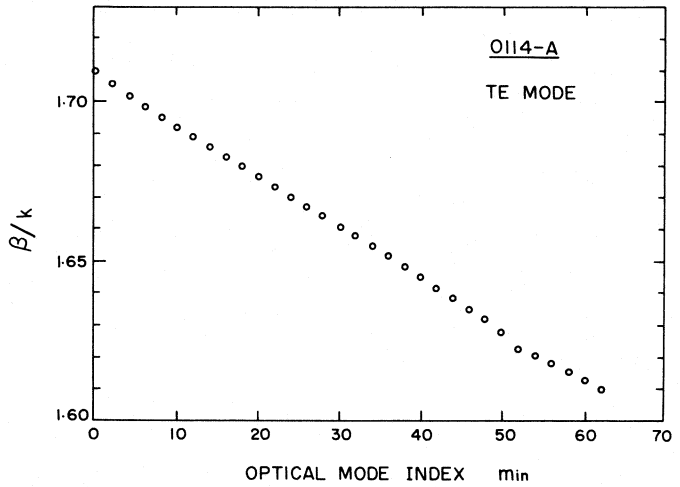

Fig. 5. Effective refractive index β/k for propagation mode in optical waveguide used in the experiment.

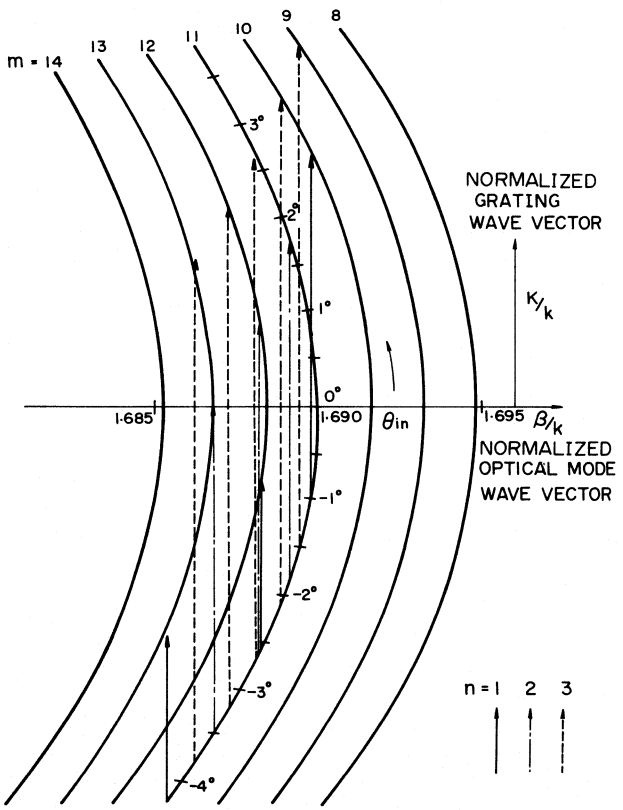

Fig. 6. Translation of observed n, m_{dif}, and θ_{in} relationships into the phase-matching diagram for multimode Bragg diffraction. Concentric circle radii β_m/k's were derived from the values in Fig. 5. The value of K/k is calculated from a 12-μm grating pitch. Solid, dotted, and dashed arrows represent diffractions of n = 1, 2, and 3, respectively.

dashed line arrows, whose lengths are equal to K/k, $2K/k$, and $3K/k$, respectively, distinguish diffractions of n = 1, 2, and 3 in Fig. 4, respectively. Since the 11th mode is excited in the experiment, incident angle θ_{in} is indicated on the circumference where m_{in} = 11, and each arrow starts from a point corresponding to θ_{in} giving the diffracted beam-intensity peak shown in Fig. 4.

As a result of such translation, most of the arrow vertices always come close to, or appear on some one of the circumferences, as shown in Fig. 6. Those circumferences give mode indices of the diffracted beams, which exactly agree with the mode indices obtained in the experiment. Thus, the phase-matching diagram for the multimode Bragg diffraction successfully explains the observed behavior of the diffracted beams in the experiment.

Nd:$LiNbO_3$ Laser

I. P. KAMINOW AND L. W. STULZ

Abstract—**Laser action at 1.0845 μm is demonstrated in a neodymium-doped $LiNbO_3$ crystal pumped by 0.7525-μm krypton laser, which happens to coincide with a Nd absorption line. Although $LiNbO_3$ is a good laser host, with good electrooptic and acoustooptic properties, laser damage limits its applicability at present unless one is willing to maintain the crystal at 165°C.**

INTRODUCTION

Laser action in Nd-doped $LiNbO_3$ has been studied on several occasions [1] with the object of employing the excellent piezoelectric, electrooptic, acoustooptic, or nonlinear optic properties of the crystal within the laser medium. Laser emission at 1.0845 μm was first reported in 1967 [2] and 1969 [3] in flashlamp-pumped crystals of relatively poor quality.

At room temperature, strong pumping bands, containing sharp peaks, were noted [3] in the near infrared at 0.75, 0.81, and 0.88 μm, where semiconductor diode lasers or light-emitting diodes might serve as pump sources. We have found a close coincidence between the 0.7525-μm krypton laser line and one of these absorption peaks. With this pump, laser action was observed in a high-quality crystal placed inside a resonator formed by external mirrors. It was found, however, that even with the long wavelengths involved, optical index damage limits the laser life to a few minutes. Past experience indicates that this problem can be alleviated by warming the crystal or by reducing the Fe content in the $LiNbO_3$ crystal [4]. Our ultimate objective was to fabricate optical waveguide laser devices in these crystals.

EXPERIMENTAL

An a-axis boule of Nd:$LiNbO_3$ was pulled from a melt containing 0.5 percent of Nd_2O_3 by weight by Crystal Technology, Inc. The optical quality of the crystal was excellent.

Manuscript received February 10, 1975.
The authors are with Bell Laboratories, Crawford Hill Laboratory, Holmdel, N.J. 07733.

The measured absorption coefficients for the 0.7525-μm Kr laser line were $\alpha_{\parallel} = 1.2\ cm^{-1}$ (5.4 dB/cm) and $\alpha_{\perp} = 2.0\ cm^{-1}$ (8.7 dB/cm) for polarizations parallel and perpendicular to the c axis, respectively. The peak of the absorption line is within 0.5 Å of 0.7525 μm and the linewidth (full width at half maximum [FWHM]) is 25 Å for both polarizations. The fluorescent decay time τ was found to be 100±5 μs for either polarization when excited by chopped 0.7525-μm radiation.

A polished rod having dimensions 10 mm × 3 mm × 3 mm in the a, b, and c directions, respectively, was inserted in the resonator illustrated schematically in Fig. 1(a). Matching liquids with negligible absorption loss at 0.75 and 1.08 μm were employed to reduce the Fresnel reflection losses at the crystal faces. For CCl_4 ($n = 1.46$ at 1 μm) and $LiNbO_3$ ($n_{\perp} = 2.24$, $n_{\parallel} = 2.16$), the reflection coefficients are $r_{\perp} = 4.4$ percent and $r_{\parallel} = 3.7$ percent. The coatings on the flat and 2-cm-radius mirrors are identical and transmit 82 percent at 0.7525 μm and ~0.3 percent at 1.08 μm in air.

The resonator is designed so that the crystal length L is half the confocal length $b = (2\pi w_0^2 n)/\lambda$ at the laser wavelength where n is the appropriate refractive index and w_0 is the Gaussian beam-waist radius at the flat mirror. Then the mirror spacing d is 2.05 cm. The confocal requirement ensures minimum beam divergence over the crystal length; the beam diameter at the far end of the crystal is $\sqrt{2}$ times the value at the waist. At 1.08 μm, $w_0 = 40$ μm; at 0.75 μm, $w_0 = 33$ μm. A 14.6-cm focal-length lens was employed to match the pump and laser mode volumes, approximately, as indicated in Fig. 1(b); the pump-waist radius is estimated to be 40 μm. The pump beam is chopped at a 60-Hz rate with a duty cycle of $\frac{1}{34}$ (0.5-ms pulses) in order to inhibit laser damage.

Laser oscillation is observed with input pump powers as low as 280 mW. The Nd:$LiNbO_3$ laser power is detected with a silicon pin photodetector and oscilloscope. Pump laser damage causes the 1.08-μm output power to decrease as soon as it is observed; laser output disappears completely after about 10 min for 300 mW of 0.75-μm input. Taking the input mirror transmission and the absorption coefficient of the crystal into account gives an absorbed pump power that is 0.6 times the input power for parallel polarization and 0.7 times the input power for perpendicular polarization. Thus, with a duty cycle of $\frac{1}{34}$, approximately 3 J of absorbed pump energy over an effective cross-sectional area $\pi w_0^2 = 5 \times 10^{-5}\ cm^2$ terminates laser action due to damage effects.

The laser output is polarized parallel to the c axis irrespective of pump polarization. Plotting laser output versus pump input for parallel input polarization yields an incident pump threshold of 250 mW, or an absorbed power threshold of 150 mW, or an absorbed intensity at threshold of $3 \times 10^3\ W/cm^2$. The uncertainity in threshold measurements is estimated to be about ±20 percent because of the damage problem. For perpendicular input polarization, the incident threshold power is somewhat higher (about 275 mW) than for parallel input polarization.

Laser damage was studied as a function of temperature in an undoped and a Nd-doped $LiNbO_3$ crystal for 0.7525-μm light polarized parallel or perpendicular to the c axis. The 14.6-cm lens was used to focus the light into the crystals. The transmitted spot was observed on a screen. At room temperature, the spot became distorted and, after a time, reached an equilibrium shape which was elongated parallel to the c axis. Above a critical temperature, the equilibrium spot became identical with the unperturbed spot. This critical temperature was about the same for both crystals and for both polarizations. Moreover, the critical temperature was a weak function of input power, varying between 130°C at 60 mW and 160°C at 370 mW. Thus, if the Nd:$LiNbO_3$ crystal were maintained at 165°C, we would expect that laser action would not be limited by damage. These temperatures are close to those found [4] for annealing damage in $LiNbO_3$ at 0.5145 μm. Crystals damaged in the present laser experiments were routinely rehabilitated by heating them in an oven at about 200°C for a few hours.

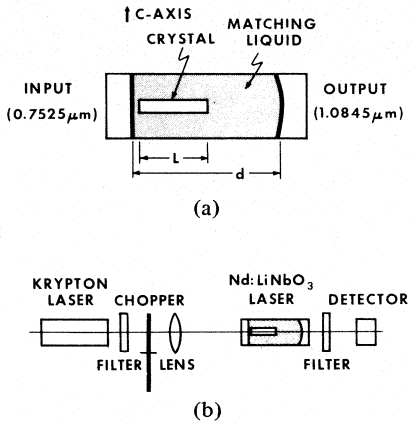

Fig. 1. (a) Nd:$LiNbO_3$ laser resonator. (b) Experimental arrangement.

CALCULATIONS

The cross section for laser emission in Nd:$LiNbO_3$ cannot be estimated without measurements of the Nd concentration in the crystal and of certain other spectroscopic quantities. However, the laser gain, which is an important parameter for laser-device design, can be estimated from the observed threshold power.

The threshold-power measurements given previously should be regarded only as upper limits because the rapid optical damage does not allow optimization of pump and cavity orientations. Further, the pump-beam volume probably does not match the laser resonator-mode volume very well. Thus we obtain only a *lower limit* on the laser gain using the measured quantities. The pump intensity varies exponentially as

$$I(z) = I_0 \exp(-\alpha_{\parallel} z) \tag{1}$$

along the crystal length z, for parallel polarization. Here I_0 is the pump power per unit area, $A \approx \pi w_0^2$, of the Gaussian beam at threshold. The overall gain, exp (gL), is obtained by integrating the gain per unit length $\gamma I(z)$ along the crystal length

$$gL = \int_0^L \gamma I(z)\, dz = \gamma I_0 (1 - \exp(-\alpha_{\parallel} L))\alpha_{\parallel}^{-1}\ \text{Np}. \tag{2}$$

Then equating the gain to the sum of the Fresnel reflection losses, the mirror loss, and an estimated 0.03-dB/cm bulk crystal loss, we find the gain per unit pump intensity

$$\gamma = 4.3 \times 10^{-5}\ cm/W. \tag{3}$$

If γ is calculated (rather than measured) for Nd:YAG using known values of cross section and other parameters [5] one obtains an *upper limiting* value which is about seven times this measured Nd:$LiNbO_3$ value.

Consider now a Nd:$LiNbO_3$ waveguide laser of length $L = 1$ cm and 4 × 4-μm cross section with dielectric mirrors coated on the ends. Such a waveguide might be formed by etching a ridge in a planar guide [6] or by diffusing metal through a mask [7]. Assume that the mirrors pass the pump completely and that the output mirror reflects 99 percent (10^{-2} Np, 4×10^{-2} dB) while the input mirror reflects 100 percent (0 Np, 0 dB) at 1.08 μm. Typical waveguide loss (scattering and absorption) for a good guide at 1.08 μm might be 20 percent (0.22 Np, 1 dB). Then the pump power required

at 0.7525 μm would be 1.5 mW. The power required in the 0.81- or 0.88-μm bands, where a GaAlAs semiconductor laser might serve as the pump, should be comparable.

Conclusions

Lithium niobate is a reasonably good host for a Nd laser; i.e., the gain is not markedly smaller than for Nd:YAG. However, optical index damage limits its utility at present. Heating the crystal to 165°C, though inconvenient, should eliminate the damage problem. Since $LiTaO_3$ is ordinarily less susceptible to damage than $LiNbO_3$, it might prove to be a better host.

The combination of laser gain and electrooptic or acousto-optic effect in the same medium offer some interesting device possibilities, particularly in optical waveguide configurations. A threshold pump power as low as 1.5 mW may be expected when the laser mode is confined within a 4-μm × 4-μm guide by a ridge or diffused strip guide. The resonator can be formed by mirrors on the ends of the guide or by a distributed feedback grating on the guide. The laser can be quenched or the power can be dumped from the cavity by an acoustic wave.

Alternatively, an electric field applied to the guide will change the phase length of the cavity electrooptically. Then if the resonator is sufficiently short that only one longitudinal mode receives gain, that mode can be shifted from the peak to the wings of the gain curve in order to switch the laser on or off. The required resonator length and modulating voltage are approximately 1 mm and 10 V, respectively. If a distributed feedback grating is used instead of mirrors, its resonant wavelength can be tuned electrooptically to turn the laser on or off.

10.6-μm FM-Chirp Radar Using Narrow-Band Correlation Detection

W. E. BICKNELL, L. R. TOMASETTA, AND R. H. KINGSTON

Abstract–**We report the demonstration of high-resolution 10.6-μm radar-range resolution using a broad-band FM-chirp signal, but requiring only narrow-band performance in a heterodyne detector.**

Manuscript received February 17, 1975. This work was sponsored by the Advanced Research Projects Agency of the Department of Defense.

The authors are with the Massachusetts Institute of Technology Lincoln Laboratory, Lexington, Mass. 02173.

Introduction

Pulse-compression or FM-chirp waveforms have been utilized extensively for range-Doppler radar systems at microwave frequencies [1], [2]. Previously reported work on the use of FM waveforms at 10.6 μm has been concerned with short pulses having a relatively low time–bandwidth product and with a CW technique [3]–[5]. We wish to report the demonstration of high-resolution radar ranging using a broad-band chirped signal but requiring only narrow-band performance in the heterodyne photodetector. The waveform, a 500-MHz linear FM pulse of 10-μs duration, is generated as an optical sideband of the main laser frequency in a broad-band traveling-wave electrooptic modulator. By performing correlation detection at the optical frequency, using a chirped local oscillator, the required detector output bandwidth is markedly reduced and is determined by the desired range interval rather than the waveform bandwidth.

Experimental Setup

A diagram of the experimental arrangement is shown in Fig. 1. The FM-chirp generator employed to drive a traveling-wave electrooptic modulator had a total excursion of 500 MHz, a center frequency of 14.85 GHz, and a PRF of 10 kHz. A *Ku*-band traveling-wave tube amplified the peak-chirp drive power to 150 W. A stable, single-mode CO_2 laser provided 15 W in a beam that was focused through the modulator [6]. The modulator employed a 12-cm-length section of reduced-height waveguide containing two 6-cm-long AR-coated GaAs rods placed in tandem [7], [8]. To achieve phase-velocity matching, the rods only partially filled the waveguide in the transverse *H*-plane dimension [9]. Microwave impedance matching was achieved by use of waveguide input and output irises [10]. The crystal orientation of the rods was chosen to provide polarization modulation of the output beam. A polarizer comprised of a pair of Brewster-angle Ge plates was used following the modulator to extinguish the carrier component of the modulator output while transmitting the orthogonally polarized sideband components. The carrier power was further suppressed by a Fabry–Perot interference filter that was tuned to a single FM-chirped sideband center frequency. Just prior to entering the Fabry–Perot, the beam was transformed into a 0.5-cm-diam collimated mode.

The measured 10.6-μm throughput loss of the modulator was 2.7 dB. This was primarily attributed to the diffraction losses at the entrance and exit ports of the modulator, the small safety factor exhibited by the crystal cross section, and the end-face reflections of the two GaAs rods employed. The microwave throughput loss of approximately 3 dB was found to be primarily due to wall and metal-to-metal contact losses in the brass waveguide structure. The structure was water cooled. The beam exiting from the polarizer was com-

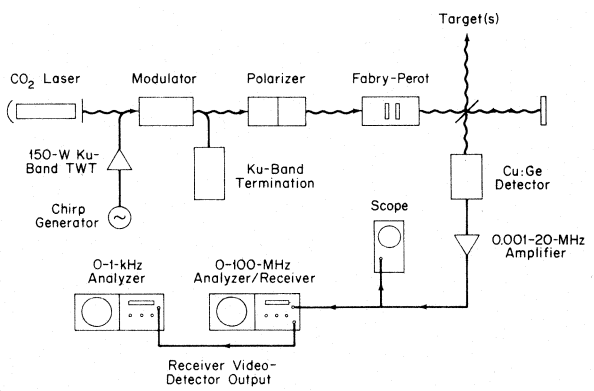

Fig. 1. Schematic of experimental apparatus.

prised of about 212 mW of unsuppressed carrier power along with 6.3 mW of power in each sideband. Throughput loss of the polarizer was 1.3 dB. The Fabry–Perot had a finesse of 30 and a FSR slightly in excess of 30 GHz. Its peak transmission throughput loss was measured to be 3.2 dB. The beam exiting from the Fabry–Perot was comprised of a single FM-chirped sideband of 3 mW and a residual unsuppressed carrier of 2 mW.

A Michelson interferometer transceiver system employing a nominal 3-dB beam splitter and a Cu:Ge detector was utilized. A 10X beam expander was used in the transmit/receive path to facilitate illumination of two retroreflector targets. The detector has an F60 FOV and a 4.2 K, 10-percent bandwidth filter centered at 10.6 μm. With the approximately 0.5-mW local-oscillator power incident upon the detector from the reference arm of the interferometer, its noise performance was determined by the noise figure of the post-detector video amplifier [11]. Use of HgCdTe detectors offers the possibility of a g–r noise-limited sensitivity with this local-oscillator power [12].

Stationary Targets

Fig. 2 shows the amplitude-versus-time and the frequency-versus-time characteristics of a transmit and receive waveform. The received wave was delayed by Δt due to the round trip to and from the target. Here Δt was less than or equal to 0.267 μs, which accrued from using a maximum range of 40 m. When the transmit and receive waveforms were correlated with the Cu:Ge detector, a difference frequency Δf appeared at the output of the detector. It is seen from Fig. 2 that for the case here

$$\Delta f\,(\text{MHz}) = 50 \cdot \Delta t\,(\mu\text{s}) = \tfrac{1}{3} R\,(\text{m})$$

where R is the range in meters.

Fig. 3 shows the return from a mirror spaced 1.7 m further from the detector than the reference or local-oscillator-arm mirror of Fig. 1. The 570-kHz difference frequency is evident. The oscillation is superimposed on a dc pulse that is due to the local-oscillator signal.

Fig. 4 shows the spectrum of a pulse train due to a retroreflector target at 40 m. This was observed on the 0–100-MHz spectrum analyzer of Fig. 1. The center frequency of the spectrum was 13.3 MHz, and the spectrum's amplitude envelope exhibits close to the expected sinc-function dependence on frequency.

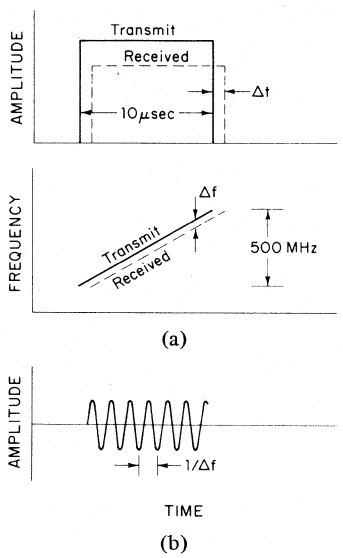

Fig. 2. (a) Amplitude versus time and frequency versus time of the transmit and receive waveforms. (b) Amplitude versus time of the correlated waveform.

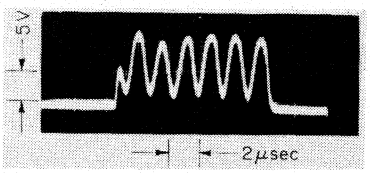

Fig. 3. Correlated return from a mirror with a 1.7-m path-length difference.

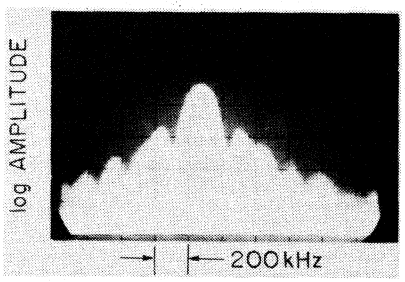

Fig. 4. Power spectrum of a retroreflector at a 40-m range.

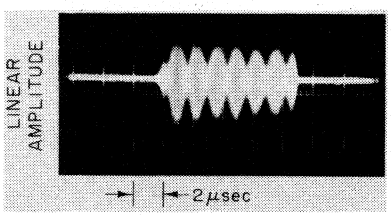

Fig. 5. Correlated return from two retroreflectors at 40-m range, separated by 2 m.

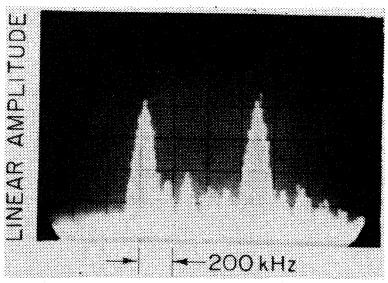

Fig. 6. Power spectrum of the correlated return shown in Fig. 5.

Figs. 5 and 6 show the time and frequency-domain display of the correlated return from two retroflectors at a nominal 40-m range, but separated by 2 m. The time-domain oscilloscope display of Fig. 5 shows the envelope-modulated waveform of the sum of two individual 13-MHz bursts separated in frequency by 333 kHz. The envelope modulation frequency f_m is given by

$$f_m\,(\text{MHz}) = \tfrac{1}{6} \Delta R\,(\text{m})$$

where ΔR is the target's separation. In the frequency domain two distinct spectral peaks are evident in Fig. 6. Resolution of two returns could be readily discerned on the 0–100-MHz analyzer for separations as close as 0.6 m. Below about 0.6-m separation, the spectral peaks observed on the analyzer became separated less than the reciprocal of the correlation-waveform duration, and the ability to distinguish the separate spectral peaks tended to diminish.

By use of an FM-chirp waveform and correlation-detection

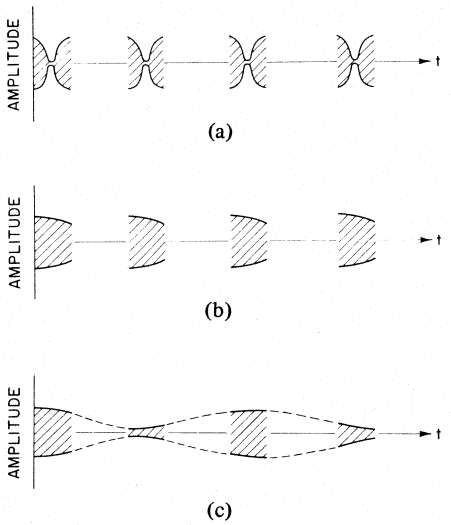

Fig. 7. Envelope of the correlated waveforms for the following. (a) Two targets that are marginally resolved in range. (b) Two stationary targets that cannot be resolved in range. (c) Two targets that cannot be resolved in range but one target moving with respect to the other.

range resolution appropriate for a 500-MHz bandwidth waveform can clearly be obtained with a detector and analyzing system that has a considerably smaller bandwidth.

Moving Targets

The waveform employed could be used to distinguish moving targets from stationary targets within a range-resolution cell. In radar terminology this is known as moving-target-indicator (MTI) capability [1]. This capability results from the effect of target motion on the detected, correlation waveform shown in Fig. 2(b). Target motion causes the phase of the correlation beat signal to change from pulse to pulse. The effect of target motion could thus be discerned by monitoring the phase of the correlation pulse that passes through a given spectrum-range window. Such monitoring was not possible with the instrumentation at hand, and therefore a method utilizing the effect of target motion on the envelope of the return from two targets was utilized instead. The utilized technique is analogous with "non-coherent MTI" [1].

Fig. 7(a) shows the envelope of the correlated waveform for two targets that are marginally resolvable in range. The difference frequency of the returns causes approximately one cycle of envelope modulation. As the targets are moved closer together their correlated return frequencies become sufficiently close such that only a small fraction of an envelope cycle occurs over the duration of a correlation pulse. Because of the targets' stationary position the envelope is repeated for each pulse. This case is illustrated in Fig. 7(b). If one target moves with respect to the other, however, the phase of the envelope modulation progresses from pulse to pulse, as shown in Fig. 7(c). The progressing envelope of the pulses then gives, in effect, a sampling of the Doppler beat.

To verify this MTI capability the 0–100-MHz analyzer was tuned to the nominal 13-MHz-range frequency for two retroreflector targets placed at 40 m but separated by a few centimeters. One retroreflector was moved to give a 500-Hz Doppler. The output of the tuned analyzer was, after being envelope detected and low-pass filtered, fed into a second 0–1-kHz spectrum analyzer. Fig. 8 shows the output spectrum of the 0–1-kHz analyzer. The 500-Hz peak vanished when

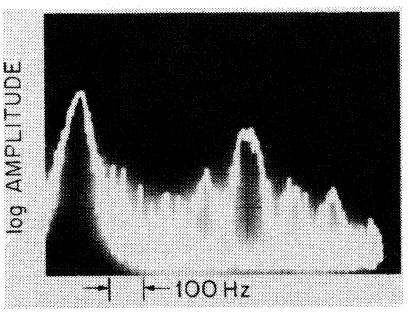

Fig. 8. Power spectrum of envelope waveform showing the relative Doppler of two targets unresolved in range.

the return from either the moving or stationary retro was blocked.

The performance of large time–bandwidth exchange waveforms can be realized at laser-carrier frequencies because of the phase coherence of the microwave FM-chirp generator and the use of correlation detection. With this technique range resolution is limited by only the bandwidth of the transmit waveform, and not by the bandwidth of the detector.

Acknowledgment

Correction to "Experiments and Theory of Nanosecond Pulse Extraction in an Atmospheric Pressure CO_2 Amplifier"

G. GIRARD

In the above correspondence,[1] the last sentence in the second paragraph of Section III which reads: "Experimental results are expected to fall between these curves." should be deleted.

The experimental results do fall between the two curves of Fig. 4 (as shown when comparing Figs. 2 and 4). The two curves on Fig. 4 should not, however, be considered as upper and lower limits for experimental values as could be inferred from the last sentence as given in the second paragraph of Section III in the original correspondence.

Manuscript received February 15, 1975.

The author is with the Section Sources d'Ondes Cohérentes, Département Recherches Physiques de Base, Laboratoires de Marcoussis, Centre de Recherches de la Compagnie Générale d'Electricité (CGE), Marcoussis, France.

Notes and Lines

Two-Electron Laser Transition in SN(I)?

D. G. SUTTON, L. GALVAN, AND S. N. SUCHARD

Abstract—**A new laser oscillation has been observed in a pulsed discharge of He and $SnCl_4$. This oscillation at 1.061 μm corresponds to the $5s5p^3\ {}^3D_1^\circ \longrightarrow 5s^2 5p6p\ {}^3P_2$ transition in Sn(I).**

The purpose of this note is to report a new laser transition obtained in mixtures of $SnCl_4$ and He. The discharge tube and cavity are identical to those described in earlier publications [1], [2]. The laser tube consists of two 1.25-m (2.5-cm ID) Lucite pipes, each fitted with 251 pin-pairs of 470-Ω resistors mounted transverse to the optical axis in a double-helical configuration. The gap between resistor pairs is 1.9 cm. One of these helices is connected to ground, which forms the cathode of the discharge circuit; the other is connected to a pulsed power supply triggered by a spark gap. The resultant discharge has a duration of 2 μs. The ends of the laser tube are sealed by suprasil windows at Brewster's angle. A stable optical cavity is formed about the laser tube by two silver-coated mirrors: a total reflector with a radius of curvature of 11.5 m and a flat output coupler with a 1-mm hole in its center. The entire length of the optical cavity is 3.2 m.

Laser output is directed into a screen room where the beam is split into two parts by a sapphire flat. One of these beams is directed to an InSb detector to monitor the total laser emission; the other is directed through a 0.5-m monochromator to an identical InSb detector to monitor the spectrally resolved emission. Detector response is monitored with a fast oscilloscope.

Manuscript received January 3, 1975. This work reflects research supported by the Defense Advanced Research Projects Agency of the Department of Defense under USAF Space and Missile Systems Organization (SAMSO) Contract F04701-74-C-0075.

The authors are with The Aerospace Corporation, El Segundo, Calif. 90245.

When small amounts of $SnCl_4$ (0.05–3 torr) are discharged in a bath of He (85–250 torr) at 65 kV, a single pulse of 1.061-μm laser radiation is detected. The pulse initiates 3 μs after the termination of the discharge, has a 3 μs half-width [full width at half maximum (FWHM)], and has a total duration of 8 μs.

When Moore's tables [3] are gleaned for transitions that occur at this wavelength, the only possibility that satisfies the electronic dipole selection rules is the $5s5p^3\ {}^3D_1^\circ \longrightarrow 5s^2 5p6p\ {}^3P_2$ transition in the Sn(I) spectrum. Helium, chlorine, and their positive ions have no dipole-allowed transitions at this wavelength.

In Meggers' 1940 analysis of the Sn(I) spectrum [4], the upper laser state with a term value of 56658 cm^{-1} was designated as the ${}^1P_1^\circ$ state of the $5p({}^2P_{3/2})6d$ configuration. In Shenstone's reinterpretation, which appears in Moore [3, vol. III, pp. 74–79], the state at 56658 cm^{-1} is reassigned to be $5s5p^3\ {}^3D_1^\circ$. If Shenstone's analysis is correct, the 1.061-μm laser oscillation arises from stimulated emission on a two-electron transition.

It may be noted that the energy required for the atomization of $SnCl_4$ plus the term value of $Sn({}^3D_1^\circ)$

$$SnCl_4 \longrightarrow Sn({}^3D_1^\circ) + 4Cl$$

is 446 kcal, nearly equal to the 455 kcal carried by the $He({}^3S_1)$ metastable. This may indicate that metastable helium plays an important role in the excitation mechanism, especially since the laser action occurs in the afterglow of the discharge.

Robert L. Carman was born in Bay Shore, N.Y., on January 15, 1941. He received the A.B. degree in physics, mathematics, and chemistry from Adelphi University, Garden City, N.Y., and the Ph.D. degree in physics from Harvard University, Cambridge, Mass., in 1958 and 1968, respectively.

In 1957 he was a National Science Foundation Research Fellow working in solid-state physics. From 1958 through 1964 he worked in high-energy physics at the Brookhaven National Laboratories cosmotron and sychrotron, as well as at the Cambridge Electron Accelerator as a Member of the Cambridge Bubble Chamber Group. From 1964 to 1968 he was a Staff Member of the Lincoln Laboratory, Massachusetts Institute of Technology, where his work on lasers and high-intensity light propagation began. During this period he consulted for the National Aeronautics and Space Administration, the Institute for Defense Analysis, and several commercial firms. From 1968 through 1970 he was a Postdoctorate Research Fellow with the Department of Engineering and Applied Physics, Harvard University, where work was begun on ultrahigh brightness lasers and nonlinear optics utilizing picosecond pulses. During this period he remained a consultant at the Lincoln Laboratory and carried out some joint work with United Aircraft's Research Laboratory. From 1970 to 1974 he was employed by the Lawrence Livermore Laboratory, University of California, Livermore, where for the latter three years he was a Group Leader in charge of the development of advanced solid-state laser oscillators, advanced research in solid-state laser-system design and diagnostics, and basic research in nonlinear optics. In 1974 he transferred to the Staff of the Los Alamos Scientific Laboratory, University of California, Los Alamos, N. Mex., where he is currently concerned with experimental aspects of high-energy lasers, the nonlinear optics of laser-produced plasmas, and advanced concepts in high-energy laser systems.

J. O. Henningsen was born in Sønderborg, Denmark, on February 11, 1939. He received the M.S. degree in electrical engineering and the technical licentiate degree, both from the Technical University of Denmark, Lyngby, in 1963 and 1967, respectively. His dissertation was on cyclotron resonance in metals.

He was a staff member at Physics Laboratory I, at the Technical University of Denmark until 1970, working with resonances and electromagnetic-wave propagation in solids at microwave frequencies. He continued this work at far-infrared frequencies at the University of Maryland, College Park, until 1972. Since then he has been a member of Physics Laboratory I, H. C. Ørsted Institute, University of Copenhagen, Copenhagen, Denmark, working with far-infrared lasers and their application in solid-state physics.

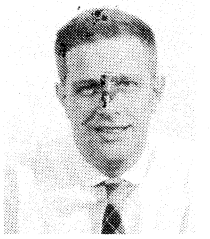
*

G. Benjamin Hocker (S'69–M'69) was born in Harrisburg, Pa., in September 1942. He received the B.E.P degree and the Ph.D. degree in applied physics, both from Cornell University, Ithaca, N.Y., in 1965 and 1970, respectively.

Since 1970 he has been an Assistant Professor in the Department of Electrical Engineering at the University of Minnesota, Minneapolis. He has done research on mass-spectroscopic studies of molecular-gas lasers, and on materials and devices for integrated optics.

Dr. Hocker is a member of the Optical Society of America and the American Society for Engineering Education.

*



H. G. Jensen was born in Vojens, Denmark, on August 7, 1926. He received the B.Sc. degree from the Technical University of Denmark, Copenhagen, in 1948, and the Ph.D. degree from Copenhagen University, Copenhagen, in 1951.

He joined the H. C. Ørsted Institute, University of Copenhagen, in 1963. During 1965 and 1966 he was a Visiting Scientist at the Center for Materials Science, Cambridge, Mass., working with nonlinear optics. His research interests include electromagnetic-field theory, quantum optics, and laser physics.

Dr. Jensen is a member of the Danish Physical Society and the European Physical Society.

George H. Kimbell received the B.A. (Hons.), M.A., and Ph.D. degrees in physical chemistry from the University of Toronto, Toronto, Ont., Canada, in 1961.

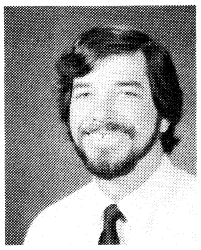
For two years he worked as a Research Assistant at the Imperial College of Science and Technology, London, England, and in 1963 he joined the Canadian Defence Research Estabment Valcartier (DREV), Valcartier, P.Q., Canada. As leader of the Combustion Group since 1967, he became Head of the Chemistry Section, Propulsion Division in 1971.

*

William B. Lacina received the B.S. degree in 1962 from Rensselaer Polytechnic Institute, Troy, N.Y., where he was a Union Carbide Scholar. He received the M.S. and Ph.D. degrees in physics from Harvard University, Cambridge, Mass., in 1963 and 1969, respectively, where he held a National Science Foundation Predoctoral Fellowship. His doctoral research involved an experimental and theoretical study of the effects of disordering on the phonon optical properties of mixed crystal systems.

He has held summer research appointments at the Oak Ridge National Laboratory, Oak Ridge, Tenn., and the Lawrence Radiation Laboratory, Livermore, Calif. In 1969 he joined the Northrop Research and Technology Center, Hawthorne, Calif., where he has been involved with the study of molecular gas lasers, nonlinear optical effects in the infrared, and pulsing and modulation techniques for the CO_2 laser. Current work is directed toward an understanding of the molecular and plasma kinetic processes in the electrically excited CO laser, with emphasis on design of high-power and high-efficiency pulsed and CW laser systems.

*



Gary L. McAllister was born in Quincy, Ill., on November 4, 1939. He received the B.S. degree in electrical engineering from Iowa State University, Ames, in 1961, the M.S. degree in electrical engineering from Purdue University, West Lafayette, Ind., in 1965, and the Ph.D. degree in electrical engineering from the University of Southern California, Los Angeles, in 1969.

From 1961 to 1963 he served as Instructor in the U.S. Army Signal School, Fort Monmouth, N.J. From 1965 to 1966 he was a member of the Technical Staff of Hughes Aircraft Company, Culver City, Calif., engaged in research on saturated absorption of laser radiation and solid-state laser amplifiers. From 1969 to 1971 he was an Assistant Professor in the Department of Electrical Engineering, Colorado State University, Fort Collins. In 1971 he joined the Northrop Research and Technology Center, Hawthorne, Calif., where he was involved with the study of high-power molecular gas lasers. In 1974 he joined the Exxon Corporation in Richland, Wash., where he is now working on laser techniques for isotope separation.

Michael J. Moran was born in Oakland, Calif., on June 4, 1946. He received the B.S. degree in engineering physics from the University of California at Berkeley, and the M.S. degree in physics from the University of New Hampshire, Durham, in 1968 and 1970, respectively.

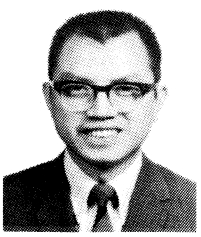
He is currently employed at the Lawrence Livermore Laboratory, University of California, Livermore, and is a doctoral candidate at the University of California at Davis.

*

Thomas L. Paoli (S'59-M'73) was born in Springfield, Ill., on May 27, 1940. He received the B.S. degree in electrical engineering and the B.A. degree (magna cum laude), both from Brown University, Providence, R. I., in 1962, and the Ph.D. degree in applied physics from Stanford Univeristy, Stanford, Calif., in 1967. During the summer of 1964 he attended the Summer School of Theoretical Physics of the University of Grenoble, Les Houches, France.

He was a Research Assistant and a National Science Foundation Fellow (1962-1967) at Stanford University, working on optical coherence theory. He has also held summer positions with the Applied Research Laboratory of Sylvania Electronic Systems, where he worked on communication theory, and with the Electronic Defense Laboratory of Sylvania, where he worked on laser theory. In 1967 he joined Bell Telephone Laboratories, Inc., Murray Hill, N.J., where his research has been concentrated on GaAs injection lasers.

Dr. Paoli is a member of Phi Beta Kappa, Tau Beta Pi, Sigma Xi, and the American Physical Society.



*

John Reid was born in Littleborough, Lancs., England, on December 14, 1948. He received the B.A. degree in physics from the University of Oxford, Oxford, England, in 1970, and the M.Sc. and Ph.D. degrees from McMaster University, Hamilton, Ont., Canada, in 1972 and 1975, respectively.

From 1970 to 1974 he was engaged in the investigation of CO_2 lasers. He is currently working on laser spectroscopy in the Division of Physics of the National Research Council of Canada, Ottawa, Ont., Canada.

*

Chiao-Yao She (S'61-M'65) was born in Fukien, China, on August 4, 1936. He received the B.S. degree from the National Taiwan University, Taipei, Taiwan, the M.S. degree from the North Dakota State University of Agriculture and Applied Sciences, Fargo, and the Ph.D. degree from Stanford University, Stanford, Calif., all in electrical engineering, in 1957, 1961, and 1964, respectively.

He was a Research Assistant from 1961 to 1964 and then a Research Associate for the following summer at the Stanford Electronics Laboratories. From 1964 to 1968 he was an Assistant Professor of Electrical Engineering at the University of Minnesota, Minneapolis. He joined the Colorado State University, Fort Collins, in September 1968 where he is now an Associate Professor of Physics. His research interests include both theoretical and experimental aspects of light-scattering spectroscopy and quantum electronics.

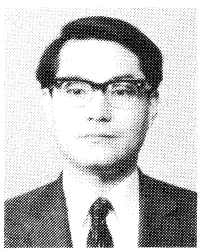
Dr. She is a member of the American Physical Society, the Optical Society of America, Eta Kappa Nu, and Sigma Xi.

*

David R. Snelling was born in Bognor Regis, England, on September 14, 1937. He received the B.Sc. and Ph.D. degrees in chemistry, both from Birmingham University, Birmingham, England, in 1959 and 1962, respectively.

From 1962 to 1964 he was engaged in postdoctoral studies at the University of Toronto, Toronto, Ont., Canada, with Dr. J. C. Polanyi, and from 1964 to 1966 he worked with Dr. E. J. Bair at Indiana University, Bloomington. On joining the Defence Research Establishment Valcartier (DREV), Valcartier, P.Q., Canada, in 1966, he was engaged in research into upper atmospheric photochemistry. Since 1971 he has headed a Chemical Laser Research Group at DREV.

*



B. R. Suydam (M'72) was born in New Jersey on October 12, 1916. He received the B.S. degree from Pennsylvania State University, University Park, and the Sc.D. degree in physics from the Massachusetts Institute of Technology, Cambridge, in 1937 and 1940, respectively.

From 1940 to 1947 he worked on design of electronic instruments for the U.S. Naval Proving Ground, Dahlren, Va. Since 1947 he has been a Staff Member at the Los Alamos Scientific Laboratory, Los Alamos, N. Mex., where he has worked first on effects of nuclear weapons, and later in theoretical plasma physics as applied to the controlled thermonuclear reaction research. Recently, remaining in the broad field of CTR research, he has switched to the field of nonlinear optics.

Dr. Suydam is a fellow of the American Physical Society.

*

Nobuo Takeuchi was born in Tokyo, Japan, in 1941. He received the B.Sc., M.Sc., and Ph.D. degrees, all from the University of Tokyo, Tokyo, in 1963, 1965, and 1969, respectively.

His research fields are laser spectroscopy, nonlinear optics, and atomic coherent phenomena. He joined the Institute for Solid State Physics at the University of Tokyo in 1968, was at Columbia University from 1971 to 1973, and received a postdoctoral fellowship from the National Research Council of Canada, where he was from 1973 to 1975. In 1975 he joined the National Institute for Environment, Ibaraki, Japan, as a Senior Research Staff member.

Dr. Takeuchi is a member of the American Physical Society, the Physical Society of Japan, and the Japan Society of Applied Physics.

SECOND SUMMER COLLOQUIUM on ELECTRONIC TRANSITION LASERS

Marine Biology Laboratory Conference Center
Woods Hole, Mass.

SEPT. 17-19, 1975

Contributed papers are solicited on the following subjects:

- Chemically pumped, electronic transition lasers
- Electrically, collision, or optically pumped electronic transition lasers
- Branching ratios and quantum yields for chemiluminescent systems
- Deactivation and quenching rates for electronically excited systems
- Spectroscopic analysis and potential curves for laser candidate molecules

Proceedings to be published by M.I.T. Press

For Information & Applications Write to:
J. Steinfeld, 2-221 M.I.T., Cambridge, Massachusetts 02139
Applications Due June 1st / Summaries of Papers Due August 1st

Sponsored by:
Chemistry Department
and Spectroscopy Laboratory, M.I.T.
Air Force Weapons Laboratory
Aerospace Corporation
Joint Council on Quantum Electronics

Financial Support Provided by
Air Force Office of Scientific Research

Influence of Contaminants on the CO_2 Electric-Discharge Laser

PETER BLETZINGER, SENIOR MEMBER, IEEE, DAVID A. LABORDE, WILLIAM F. BAILEY, WILLIAM H. LONG, JR., PETER D. TANNEN, AND ALAN GARSCADDEN, SENIOR MEMBER, IEEE

Abstract—In CO_2-N_2-He electric-discharge lasers, small concentrations of impurities may be present in the original gases, or new species may be generated by the discharge. In order to determine the effects of such impurities, controlled amounts of possible contaminants were introduced into the amplifier of a CO_2 probe-amplifier system. Small-signal gain was reduced in all cases when CO, O_2, NO, N_2O, or NO_2 molecules were added. It was found that less than 0.1 percent of NO_2 or N_2O markedly reduces the laser gain and alters the discharge impedance. A discharge model which describes a three-component positive-column plasma (electrons, positive ions, and negative ions) yields results consistent with the observations. The influence of attachment and detachment rates on molecular gas discharge characteristics and stability are studied.

INTRODUCTION

THE CO_2 dc discharge laser operates at high efficiency in the glow discharge mode with an optimum mixture of CO_2, N_2, and He which depends on the total pressure, flow rate, current density, and discharge geometry [1]. The operating conditions for a given geometry of this weakly ionized plasma ($n^+/N = 10^{-7}$) are determined by a self-consistent balance of charged-particle production and loss. The discharge properties are controlled by collisional kinetics, plasma chemistry, laser operation, and boundary conditions.

In those papers dealing with mass-spectrometric measurements of CO_2 laser discharges [2]-[6] the main emphasis has been on the rate of dissociation of CO_2 into CO and O_2 and how this dissociation is changed by operating conditions or gas additives. However, the possible effects on laser performance of the other minor species that are known to exist [7] have not been measured. Therefore, the purpose of the present study was to determine the influence of nitrogen oxides and other candidate dissociation products on the discharge properties and optical gain characteristics of a CO_2 laser.

EXPERIMENT

Calibrated amounts of contaminant gases were added to an open-cycle flowing CO_2-N_2-He laser discharge. Discharge voltage and small-signal gain were monitored as functions of current. The discharges studied were at total pressures of 5, 10, and 15 torr. The amplifier-tube active length was approximately 57 cm between hollow Kovar electrodes in a water-cooled Pyrex tube, with a 22-mm internal diameter (ID). The gas flow rates of CO_2-N_2-He were in the ratio 5:10:85, and the gas residence time in the discharge was approximately 20 ms.

A frequency stable laser,[1] operating on the $P20$ line of the 10.6-μ transitions, was used to measure small-signal gain. The intensities of the reference and amplified beam were measured simultaneously using thermocouples with digital readouts. To compensate for any fluctuations in the probe oscillator output power, the ratio of these two intensities was evaluated. The discharge current was swept linearly from 5 to 75 mA in a period of approximately 5 min. The probe beam from the oscillator was 1.57-mm diameter at its 6-dB points at the input window and 4.6-mm diameter at the exit window, the distance between windows being 110 cm. The total power in the probe beam was typically 100 mW.

RESULTS

The principal results are shown in Figs. 1-5. The upper half of each figure shows the amplifier gain as a function of the discharge current for selected amounts of added contaminant. The lower half shows the discharge voltage (measured simultaneously with the gain data) as a function of the same parameters. The abrupt transition in the discharge characteristics, apparent on some of the diagrams, corresponds to the glow-to-arc transition. Extremely noisy current-voltage curves correspond to the presence of large-amplitude low-frequency striations. For comparison with theoretical modeling, our primary interest will be in the glow regime at low currents with small amounts of contaminants.

Figs. 1 and 2 show the effects of adding CO and O_2, respectively, to a discharge operating at 15-torr pressure in CO_2-N_2-He. Similar results were obtained at 10 and 5 torr. The discharge impedance and the amplifier gain were relatively insensitive to the presence of added CO or O_2. The impedance was increased by CO but decreased by O_2.

Fig. 3 shows the results of adding NO to a discharge at 15 torr. The discharge impedance increases at low current and decreases at high current, while the small-signal gain decreases at all currents. Significant effects were observable at less than

0.1-percent addition (relative to the total gas flow rate) of NO. At higher currents the gain was extinguished by NO concentrations of approximately 1.5 percent. With 120 Standard cubic centimeters per minute of NO added, the discharge was unstable between high-voltage and low-voltage modes and the laser gain was essentially zero above 30 mA. Similar effects were recorded at pressures of 10 and 5 torr. The discharges at higher total pressures, however, were more sensitive to the presence of NO.

Nitrogen dioxide, NO_2, was very effective in modifying the laser plasma properties at 10 torr (Fig. 4). At the lowest current, there was an increased impedance of about 50 percent with 0.3-percent NO_2. The discharge became unstable at approximately 18 mA for addition of NO_2 of only 0.04 percent. Constriction occurred at lower currents as the contaminant level was increased. Even in the constricted mode, the impedance of the discharge with NO_2 was slightly higher than without contaminants. At 15 torr the addition of only 0.1 percent caused the plasma to become violently unstable with almost complete loss of gain.

Nitrous oxide, N_2O gave results that are very similar to those for NO_2. However, the amounts required to cause the equivalent loss of gain were about a factor of 2 higher. At 10-torr pressure (Fig. 5) the discharge impedance increased about 30 percent at low currents. The amplifier gain was significantly reduced at N_2O levels above about 0.05 percent. There was zero gain at higher current densities and N_2O concentrations above approximately 0.5 percent. The N_2O will dissociate into other compounds including NO. However, the effects of added N_2O were found to be more severe at higher flow velocities and to be more serious than an equivalent concentration of NO.

Discussion

The addition of contaminants to the CO_2 electric-discharge laser alters the discharge impedance, affects plasma stability, and degrades the small-signal gain. These parameters are all interrelated and dependent on the microscopic processes taking place in the plasma. The discharge impedance is determined by the balance achieved between charged-particle production and loss. The neutral-gas temperature is determined by the power input to the discharge and is therefore a function of discharge impedance. The small-signal gain has been shown to be extremely sensitive to changes in the gas temperature [8]. Introduction of gases with large attachment or detachment rates modifies the positive-negative ion balance. A large negative ion concentration and the presence of species with attachment rates which vary rapidly with E/N (the ratio of applied electric field to neutral number density) can seriously affect discharge stability [10].

To interpret the observations presented here, a theoretical model has been constructed employing a three-component plasma (positive ions, negative ions, and electrons) in a background neutral-gas mixture. The relationships between discharge current, impedance, gas pressure, and gas composition are considered using the particle-conservation equations for the charged species

$$zn_e - \frac{D_a^+}{\Lambda_+^2} - r_i n_- n_+ - r_e n_e n_+ = 0 \tag{1}$$

$$an_e - \frac{D_a^-}{\Lambda_-^2} - r_i n_- n_+ - dn_- = 0 \tag{2}$$

and

$$n_e = n_+ - n_- \tag{3}$$

where the ion densities are evaluated on axis. The conservation equation for electrons has been replaced by the assumption of quasi-neutrality. The positive- and negative-ion temperatures are equal to the neutral-gas temperature which is assumed to be independent of radial position.

In the preceding equations, z is the rate for electron impact ionization in the mixture, including processes such as $CO_2 + e^- \rightarrow CO_2^+ + 2e^-$, and a is the rate for dissociative attachment, e.g., $O_2 + e^- \rightarrow O + O^-$. These rates and the electron mean energy and drift velocity were evaluated using a numerical solution of the collisional Boltzmann equation with the cross sections of Phelps *et al.* for momentum transfer and vibrational excitation, and the cross sections of Rapp *et al.* [12] for ionization and attachment (Figs. 6 and 7). The rate constants for ion-ion recombination r_i and electron-ion recombination r_e were taken to be constant. The rate for associative detachment d for the reaction $X + O^- \rightarrow XO + e^-$ is proportional to the density of detaching gas X, where X is either CO or NO.

The ambipolar diffusion coefficients D_a^+ and D_a^- were evaluated by Thompson [11] in a three-component plasma and are functions only of n_-/n_e when $T_e/T_g \gg 1$ (Fig. 8). The diffu-

sion lengths for positive and negative ions defined by

$$\Lambda_\pm = \left[\frac{1}{rn_\pm}\frac{\partial}{\partial r}\left(r\frac{\partial n_\pm}{\partial r}\right)\right]^{-1/2}$$

are approximately equal to $R/2.4$. The loss of negative ions to diffusion is in general negligible compared to that for positive ions, because the ambipolar field retards the radial flow of negative charges. The diffusion of electrons, with their higher temperature and mobility, is sufficient to balance the positive-ion loss. The transition to free diffusion, when the radial field goes to zero, occurs for n_-/n_e greater than 100.

Using (1) and (3), we can express the ionization rate z required to balance positive-ion loss as a function of n_-/n_e for a given neutral-gas density. This function is plotted in Fig. 9, with the corresponding E/N on the right ordinate, for a CO_2–N_2–He mixture in the ratio 5:10:85, at 300 K and 10 torr. The steady-state operating point of the discharge is then defined by the intersection of this curve with the curve representing (2). At low currents, where recombination is negligible, this point is given by $n_-/n_e = a/d$. Movement along this steady-state curve can be achieved by varying either the attachment or detachment rate. As will be seen later, the region to the right of the dashed line in Fig. 9 is unstable, and the parameters E/N and n_-/n_e are no longer confined to the solid curve.

With no contaminants added except those naturally occurring in the discharge, the operating point occurs at $n_-/n_e = 0.3$, near the minimum value of E/N. Adding small quantities of CO, which has a large cross section for electron detachment from O^- [23], moves the operating point to the left, resulting in a small increase in impedance. Adding quantities of CO sufficient to reduce the ionization rate by lowering the tail of the electron energy distribution further increases the imped-

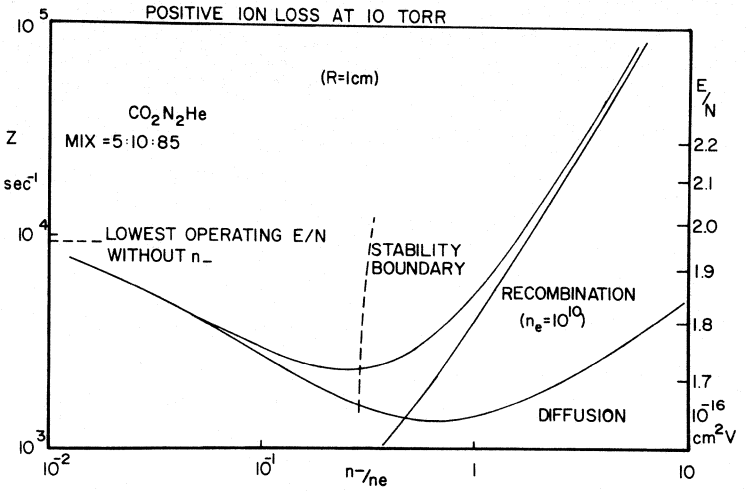

Fig. 9. E/N, ionization rate, diffusion, and recombination losses in a low-pressure CO_2–N_2–He (5:10:85) discharge as a function of negative-ion density and electron density (total pressure 10 torr, discharge current 10 mA).

ance. A gas with a large attachment cross section, such as NO_2 or N_2O (Fig. 7), moves the steady-state point to the right and results in a higher electric field if the discharge remains stable.

The addition of NO has competing effects on impedance. Its low ionization potential provides an easy source of electrons which allows the discharge to operate at a lower E/N. This effect is most evident at high currents where the fields are lower and the electron energy distribution is falling more rapidly in the vicinity of the ionization thresholds. At low currents, the more important process is detachment by NO, which tends to increase the discharge impedance, moving the operating point in Fig. 9 to the left of the minimum.

Changes in impedance and small-signal gain may also be brought about by plasma instabilities, which manifest themselves in two forms. The first form involves moving striations in the positive column, which do not alter the glow character of the discharge, but cause fluctuations in the sidelight emmission. These fluctuations were not observed in the small-signal gain due to spatial and temporal averaging. The striations have the effect of allowing the discharge to operate at a lower average electric field than in their absence [14]. The second form of instability is the sudden constriction of the glow into a bright filament. This is accompanied experimentally by a drop in impedance and degradation of the small-signal gain.

In order to explain these effects in the context of the foregoing model, the stability of the solution was analyzed by examining the time development of a small-amplitude plane-wave perturbation, keeping the gas temperature constant. This technique predicts the onset condition and early growth of moving striations, but cannot follow large deviations from the steady state. Due to the constant-temperature assumption, the model does not include the transition to a constricted discharge, which is believed to be a thermal instability [21]. Following a procedure similar to that used in [10], the criterion for the growth of long wavelength fluctuations in the plasma is found to be

$$z(K(z, v_d)-1)-a(K(a, v_d)-1)+\frac{D_a^+}{\Lambda_+^2}+d+r_i(n_-+n_+)<0 \tag{4}$$

where $K(x,y)=(x/y)(\partial y/\partial x)$ and v_d is the electron drift velocity. The rates and number densities occurring in this expression are evaluated at steady-state conditions. Since $K(z, v_d)$ is generally greater than 1, the only term which can give rise to moving striations is the attachment rate when $K(a, v_d)$ is greater than 1. All the other terms tend to damp the oscillations.

As we can see in Fig. 7, O_2 has a large attachment rate which exhibits a strong E/N dependence. The value of $K(a, v_d)$ for O_2 is approximately 4. Hence moving striations can be induced by the addition of O_2. They can be quenched by the addition of a sufficient amount of a detaching gas, such as CO. Both of these results have been confirmed experimentally [14]. Although NO_2 and N_2O have large attachment rates, they do not give rise to moving striations because of the weak dependence of those rates on E/N (Fig. 7). In fact, since $K(a, v_d)$ is less than 1 for these gases, they can also be used to quench moving striations.

We now consider the behavior of the small-signal gain at low currents before the onset of constriction. It has been shown [22] that the gain in a CO_2 laser amplifier is an increasing function of n_e and a strongly decreasing function of T_g. In the present device, the higher electric fields caused by contaminants increase the electron drift velocity. To maintain a constant total current, then, the average electron density must be reduced. In addition, at these elevated E/N values the efficiency of pumping the vibrational levels is diminished. Both of these effects reduce the population inversion of the CO_2 (001) level and hence the small-signal gain. An even more important process is thought to be thermal bottlenecking brought on by increased gas temperature. Once again the higher electric fields increase the ohmic heating, which is

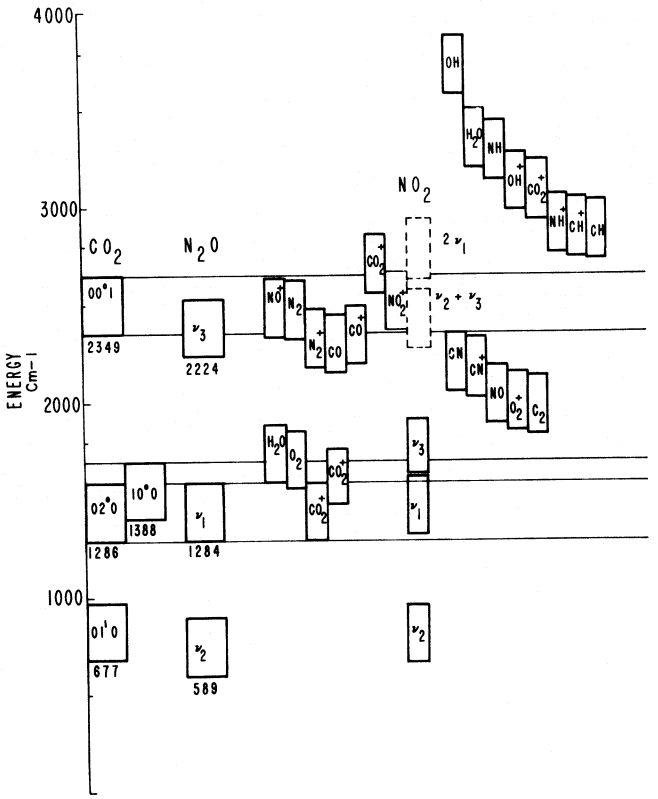

Fig. 10. Energy resonance between vibrational levels of molecular species in CO_2-N_2-He discharge lasers. Each level is broadened by about 300 cm^{-1}, equivalent to a gas temperature of approximately 400 K. This figure is adapted from [9].

coupled into the gas through elastic collisions with electrons and VT relaxation. The hot gas is then more efficient in exciting the lower laser level through the CO_2 bending mode.

The addition or creation of vibrational species nearly resonant with the upper laser level provides new channels for energy transfer which can also degrade the small-signal gain characteristics [9] (Fig. 10). This effect, however, is believed to be negligible in the present experiment. The VV rates between $N_2(v = 1)$ and the contaminants considered in the preceding are less than the resonant energy exchange rate between $N_2(v = 1)$ and $CO_2(000)$. Therefore, the quantities of contaminant required to compete with CO_2 would have to be comparable to the CO_2 concentration. For the small quantities of nitrogen oxides added in the present experiment, this process is insignificant.

Conclusions

The observed variations of discharge and laser properties can be explained adequately by a three-component modeling of the discharge operation. The impedance variations are due principally to alteration of the negative-ion density due to contaminant addition. Instabilities generated by contaminant addition arise from the strong E/N dependence of their attachment rates. Gas temperature increases, resulting from the increase in discharge impedance, reduce the normalized laser gain. The influence of the additives, especially NO_2, on the laser output and discharge stability becomes more severe at higher pressures and current densities.

In a previous paper [7], we reported the mass-spectrometric measurement of the buildup of nitrogen oxides in CO_2-N_2-He sealed-off positive-column discharges at pressures of a few torr. Under these conditions the preceding results show that the contaminant most adverse to laser efficiency is NO_2. The mass-spectrometer investigation showed that at 80 mA in a 1:2:5 mix at 5 torr, NO_2 attains an equilibrium concentration of 0.23 percent. Our results show that this will quench laser operation. At lower currents, e.g., 10 mA, the NO_2 equilibrium concentration is 0.04 percent. The contaminant concentration versus gain studies show that this will reduce the gain of the laser by approximately one-half. These characteristics have been observed in sealed-off lasers. Thus the generation of nitrogen oxides, especially NO_2, is considered to be the reason that efficient sealed-off high-power CO_2 lasers require the methods outlined in the following.

If one flows the laser gases sufficiently fast, it is possible to avoid the effects of contaminants and postpone the onset of the discharge instability if the gases are exhausted. This is not always feasible or economical. The results of this study can be applied to nonflowing or recycled gas laser systems. However, operation of nonflowing and recycled CO_2 gas laser systems will suffer some degradation due to the self-generation of impurities. Methods to overcome the loss in laser gain are as follows: 1) devising a method of selective scrubbing of the nitrogen oxides; 2) avoiding their generation by the use of a low ionization potential gas; 3) utilizing catalysts to change the chemical kinetics; or 4) eliminating nitrogen from the discharge. This last method seems to be the most practical for sealed-off lasers. When nitrogen is replaced by an approximately equal quantity of CO, it has been shown to pump the $CO_2(001)$ level in both sealed-off and gas-mixing lasers [16]. Earlier papers [17], [18], on the influence of xenon on CO_2 lasers showed not only the benefits of the xenon additive, but also that it was possible to run the laser without nitrogen. Improved long-life performance at reasonable output powers resulted. This success can be attributed to the stabilizing effects of the CO detachment, and the minimization of the nitrogen oxides. Efficient resonant energy transfer from CO to CO_2 establishes the population inversion [19], [20].

A Theory of Forced Mode Locking

HERMANN A. HAUS, FELLOW, IEEE

Abstract—**Differential equations are derived for forced mode locking of a homogeneously broadened laser in the frequency domain and time domain. Simple methods are presented for the analysis of pulse shapes for other than sinusoidal modulation. The higher order Hermite-Gaussian solutions of the synchronous sinusoidal modulation are shown to be unstable and hence unrealizable in the steady state.**

I. Introduction

THE THEORETICAL investigations of mode locking may be roughly divided into two groups (see [1] for a large list of references): 1) those which treat the mode-locking process in the time domain, e.g., the paper by Kuizenga and Siegman [2]; and 2) those which treat the phenomenon in the frequency domain as injection locking of cavity modes (notably the paper by McDuff and Harris [3]). In this paper we unify these two approaches and show when one or the other is preferable.

The introduction of yet another theory of mode locking needs justification. The presentation here serves the following purposes.

1) Some problems of mode locking are more conveniently analyzed in terms of injection locking of cavity modes, others in terms of the propagation of pulses through the laser cavity. A unified theory which establishes a simple correspondence between the two approaches facilitates the proper choice of description.

2) As an example of the injection-locking approach, a stability analysis of the mode-locked supermodes is carried out. The stability analysis of injection locking recently discussed lucidly by Kurokawa [4] can be adapted easily for this purpose.

3) The differential equations of mode locking in the time domain derived here are shown to be in one-to-one correspondence with the one-dimensional Schroedinger equation of a particle in a potential well. Hence known solutions of the Schroedinger equation can be applied to the mode-locking problem.

In Section II we give a brief derivation of the equation governing the spectrum of mode-locked pulses. The approach is in close correspondence with that of [5]. In Section III we apply the equation to the case of strong sinusoidal mode locking of the homogeneously broadened laser and obtain the well-known Hermite-Gaussian solutions. In Section IV we Fourier transform the fundamental equation and show how the result may be interpreted in terms of pulse propagation through the system. New results are presented in the remaining sections. In Section V we derive a quantum mechanical analog for the solution of the mode-locking problem with other than sinusoidal modulation. This analog facilitates the

solution of mode locking by a general periodic modulation. In Section VI we present the stability analysis of the steady-state solutions. It is shown that, for synchronous sinusoidal modulation, all Hermite-Gaussian solutions, except the lowest order one, are unstable.

II. Mode Locking as Injection Locking

In this section we develop an equation for the Fourier components of the optical-field amplitude in a cavity containing a mode-locking element. This equation can be reduced to a difference equation when the modulation is sinusoidal. We use as the starting point the injection-locking model of high-Q resonators containing an active medium. The analysis will use equivalent admittances, which can be related to the geometry and the parameters of the media inside the cavity in the usual way [5]. Identification of the admittances with the gain per pass, loss per pass, etc., is made in Section IV, where we rederive the basic equations in the time domain.

Injection locking of a single mode of a cavity containing an active medium may be analyzed with the aid of the equivalent circuit of Fig. 1. Here the admittance $Y_L(|V|)$ represents the admittance produced by the active medium; it is, in general, complex and a function of the "voltage" V, and Y_C is the cavity admittance, a function of ω. If a current source I_S of frequency ω is applied across the circuit as indicated, then the equation for this injection-locked oscillator is given by [4]

$$I_S = [Y_C(\omega) + Y_L(\omega, |V|)]\, V. \tag{1}$$

Equation (1) can be adapted to the case of a mode-locked optical cavity involving the interaction among many axial modes. The identification of equivalent-circuit elements of each resonance circuit (representing one axial laser mode) with laser and optical cavity parameters has been treated in the literature [5].

The electric field in the cavity is expanded in the set of axial modes $\bar{e}_k(\bar{r})$ of the lossless cavity. The mode patterns $\bar{e}_k(\bar{r})$ are standing waves with nodes at the mirrors, and with transverse dependences that are functions of the geometry and the parameters of the media within the cavity. Within a distance z_0 from the end mirrors, the $\bar{e}_k$ are approximately equal over a band of k values obeying the inequality $\Delta k \ll L/z_0$, where L is the cavity length.

One assumes at the outset that mode locking is successful and that the Fourier components of the electric field have frequencies that are spaced evenly, separated by the modulation frequency of the mode-locking element ω_M. In general, any mode $\bar{e}_k(\bar{r})$ has a time dependence with many Fourier components. If the Q of the cavity modes is high, then only the Fourier component nearest to the cavity-mode resonance frequency is appreciably excited. In this case, the expansion of the time-dependent electric-field distribution in the cavity

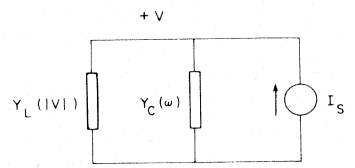

Fig. 1. Equivalent circuit for single-mode injection-locked oscillator.

$\bar{E}(\bar{r}, t)$ is

$$\bar{E}(\bar{r}, t) = \exp(j\omega_0 t) \sum_k V_k \exp(jk\omega_M t)\, \bar{e}_k(\bar{r}) + \text{c.c.} \tag{2}$$

where the kth mode has the frequency

$$\omega_k = k\omega_M + \omega_0. \tag{3}$$

The fast time dependence $\exp j\omega_0 t$ has been explicitly extracted where ω_0 is to be identified with the frequency of oscillation of the central mode ($k = 0$), the mode nearest to the peak of the laser gain profile (peak of the negative conductance Re Y_L).

Each complex amplitude V_k obeys a set of equations that can be represented by a parallel resonant circuit [5]. The equivalent circuits describing different modes are coupled by the sideband generation of the mode-locking element, i.e., the driving current for the kth cavity mode I_{Sk} contains contributions of $V_i (i \neq k)$. We shall disregard couplings as caused by other effects. Thus, in particular, we shall assume that the gain of the laser medium (represented by Y_L) is time independent and therefore no sidebands are produced on frequency components amplified by the laser medium. This in turn implies that the relaxation time of the population inversion is long compared with the cavity transit time so that the laser medium, while affected by the time average optical power in the cavity, does not respond to instantaneous power variations. (This assumption was also made in [2] and [6].) Generalizing (1) to the kth cavity mode with amplitude V_k one has

$$[Y_{Ck}(\omega_k) + Y_L(\omega_k)]\, V_k = I_{Sk}. \tag{4}$$

Consider first the dependence of $Y_{Ck}(\omega_k)$ upon ω_k. The kth cavity mode has a quality factor Q (assumed to be the same for all modes) and a resonance frequency

$$\omega_{k0} = k\Delta\omega + \omega_0 - \delta\omega_0 \tag{5}$$

where $\Delta\omega$ is the separation between the resonances of the (empty-axial) cavity modes and $\delta\omega_0$ is the detuning of the oscillation frequency of the central mode. Since the frequency of excitation is given by (3), one has

$$Y_{Ck} = G_C \left[1 + jb + kj2Q \frac{\omega_M - \Delta\omega}{\omega_0}\right] \tag{6}$$

where $G_C(1 + jb)$ is the admittance of the mode with $k = 0$; $b = (2Q/\omega_0)\,\delta\omega_0$. Next consider I_{Sk} of (4). If the cavity is mode locked by the time-dependent loss of a mode-locking element, then

$$I_{Sk} = -G_C \left[m(t) \sum_l V_l \exp(jl\omega_M t)\right]_{k\text{th Fourier component}} \tag{7}$$

where $m(t)$ has the time dependence of the loss modulation with period $2\pi/\omega_M$ and its magnitude is a measure of the "loading" of the cavity by the mode-locking element.[1] In (7) all modes l affect the mode k equally ($m(t)$ is l and k

[1] A time-modulated loss element causes a time dependence of the inverse Q. If the contribution to the inverse Q of the time-dependent loss element is denoted by $1/Q_M(t)$, then $m(t) = Q/Q_M(t)$.

independent), an assumption justified if the mode-locking element is near one of the mirrors.

Finally, consider the equivalent admittance $Y_L(\omega_k)$ of the laser medium. The laser gain is frequency dependent, and a Lorentzian line shape will be assumed. The admittance may be normalized to G_C so that

$$Y_L(\omega_k) = -G_C \frac{g}{1 + j\dfrac{\omega_k - \omega_0}{\omega_L}} \tag{8}$$

where ω_L is the laser medium linewidth, and g is the magnitude of the negative conductance at line center normalized to G_C.[2] We have assumed that the center frequency of the laser line coincides with the oscillation frequency of the cavity mode $k = 0$. We shall show later that this approximation is always a satisfactory one.

Next we assume [6] that (8) can be expanded in $(\omega_k - \omega_0)/\omega_L$ and only terms up to second order are retained

$$Y_L(\omega_k) \simeq -G_C g \left\{1 - \left(\frac{\omega_k - \omega_0}{\omega_L}\right)^2 - j\frac{\omega_k - \omega_0}{\omega_L}\right\}. \tag{9}$$

This assumption implies that the pulsewidths predicted by the ensuing analysis must be long compared with $1/\omega_L$, a situation usually encountered in practice. A further consequence of this assumption is the disregard of nonuniformity of mode spacing in the wings of the mode-locked spectrum.

Combining (4) and (6)-(8) one obtains the basic equation of mode locking expressed in the frequency domain.

$$\left\{1 + jb + \frac{jk\omega_M}{\omega_L}(\delta + g) - g\left[1 - \left(\frac{k\omega_M}{\omega_L}\right)^2\right]\right\} V_k = -\left[m(t)\sum_l V_l \exp(jl\omega_M t)\right]_{k\text{th Fourier component}} \tag{10}$$

where the "detuning" parameter δ is

$$\delta \equiv \frac{\omega_M - \Delta\omega}{\omega_M} 2Q \frac{\omega_L}{\omega_0}. \tag{11}$$

The equivalent negative conductance g decreases monotonically with increasing laser intensity. If the laser medium is near one of the end mirrors, and the $\bar{e}_k$ of all modes of interest are approximately the same, the saturation is a function of the sum of the intensities $\Sigma_k |V_k|^2$. Through proper normalization of the $\bar{e}_k$ in (2), the summation of the field intensities can be made equal to the net power P traveling towards the end mirror, $\Sigma_k |V_k|^2 = P$. If the equivalent negative conductance g is produced by inversion of a two-level medium of relaxation time T_L, then g obeys the following differential equation:

$$\dot{g} = -\frac{g - g_0}{T_L} - g\frac{P}{T_L P_L} \tag{12}$$

where g_0 is the small signal value of g and P_L is the saturation power. For the steady state one obtains

$$g = \frac{g_0}{1 + \dfrac{P}{P_L}} \tag{13}$$

where the assumption is made that $T_L >> T_R$, the round-trip time of the pulses, so that g does not possess an appreciable time-varying component [2]. Further, (13) assumes that all axial modes have the same saturation power, i.e., $1/P_L$ is a constant in the time domain, not an operator. This assumption is valid if the spectrum of the pulse solutions is narrow compared with the laser linewidth. Finally, (13) disregards spatial hole-burning effects. This is rigorous if the laser medium is short and near one of the mirrors but is an approximation otherwise.

III. Solution for Sinusoidal Modulation

In this section we shall solve the basic equation (10) for the special case of sinusoidal modulation. This is done, in part, to relate the present formalism to the literature, and, in part, to obtain the relations necessary for the stability analysis of the solutions carried out in Section VI.

For a (co-)sinusoidal modulation

$$m(t) = 2M(1 - \cos \omega_M t). \tag{14}$$

The injection current of (7) is

$$I_{Sk} = G_C M(V_{k-1} - 2V_k + V_{k+1}). \tag{15}$$

Introducing (15) into (10) we obtain the second-order difference equation

$$\left\{1 + jb - g\left[1 - \left(\frac{k\omega_M}{\omega_L}\right)^2\right] + j\frac{k\omega_M}{\omega_L}(\delta + g)\right\} V_k = M[V_{k-1} - 2V_k + V_{k+1}]. \tag{16}$$

If many modes are to be locked, and if the variation of the gain over a frequency range corresponding to the mode spacing is small, then the difference equation can be replaced by a second-order differential equation [6], [7].[3] One has

$$[V_{k+1} - 2V_k + V_{k-1}] \longrightarrow \omega_M^2 \frac{d^2V}{d\omega^2}$$

where V_k is now replaced by a continuous function of the variable ω, the frequency deviation from ω_0, and ω_M is the frequency separation of the spectral lines. The modes are identified by the continuous variable

$$\omega = \lim_{\substack{k\to\infty \\ \omega_M \to 0}} k\omega_M$$

where k is the mode number, which assumes both positive and negative values. One obtains for (16), [6]

$$\left[1 + jb - g\left(1 - \frac{\omega^2}{\omega_L^2}\right) + j\frac{\omega}{\omega_L}(\delta + g)\right] V = M\omega_M^2 \frac{d^2V}{d\omega^2}. \tag{17}$$

$\delta + g$ is identical to the detuning parameter d of [8]. Equation

[2] The normalized negative conductance g may be expressed in terms of the (negative) Q_L of the laser medium and the cavity mode Q, $g = Q/|Q_L|$.

[3] Letokhov has replaced the discrete frequency spectrum of the cavity modes by a continuum. He did not take into account the laser gain profile and hence did not get the same steady-state solutions.

(14) is particularly simple, if we require that

$$\delta + g = 0. \tag{18}$$

This implies that the modulation frequency is adjusted to equal the cavity-mode frequency separation as modified by the laser medium. With (18) satisfied, (17) is identical with the harmonic oscillator equation of quantum mechanics, where V plays the role of the wave function and ω the role of the spatial variable.

$$M\omega_M^2 \frac{d^2V}{d\omega^2} - g\frac{\omega^2}{\omega_L^2} V = (1 + jb - g)V. \tag{19}$$

The solutions are the well-known Hermite-Gaussians [6]

$$V(\omega) = H_n(\omega/\omega_P) \exp - \tfrac{1}{2}(\omega/\omega_P)^2 \tag{20}$$

where [2], [6]

$$\omega_P = \sqrt[4]{(M/g)}\,\sqrt{\omega_L\,\omega_M}. \tag{21}$$

Equation (20) defines "supermodes" or "mode-locking modes" of the mode-locked oscillator. The lowest order supermode was obtained by Kuizenga and Siegman [2], and the higher order supermodes by Haken and Pauthier [6] and others [9], [10]. We shall show in Section VI that all higher order supermodes ($n > 0$) cannot be excited in the steady state because they are unstable.

The role of the energy eigenvalues E_n of the harmonic oscillator is played by the parameter $g - (1 + jb)$ in (20). We find for the quantization of this parameter

$$E_n = g - 1 = \frac{2\sqrt{Mg}\;\omega_M(n + 1/2)}{\omega_L} \tag{22}$$

and

$$b = 0. \tag{23}$$

The central mode is found to oscillate at line center.

Equation (22) determines the power in the mode-locked cavity. Indeed, by using the dependence of g upon power P, (13), we find the following relationship for P:

$$\frac{P}{P_L} = \frac{g_0}{1 + \mu + \sqrt{2\mu + \mu^2}} - 1 \tag{24}$$

where $\mu = \frac{1}{2}(2n + 1)^2\, M(\omega_M/\omega_L)^2$. If a saturation formula different from (13) is assumed, the power is still determined from (22) and still decreases monotonically with μ.

Let us now return to an interpretation of the present solution in terms of the physical model used as a starting point of the investigation, the injection-locking model. We must remember that the differential equation was used as a mathematical approximation to the difference equation, and that the solution obtained must be interpreted as an approximate solution of the difference equation if the replacement is made: $V(\omega) \to V_k$ and the solution (20) are assigned values only at discrete frequencies ω_k. Mode locking has led to simultaneous oscillation of many modes in a homogeneously broadened system, even though the unmodulated system would have oscillated only in a single mode. The simultaneous oscillation in many modes is allowed because of injection locking. The

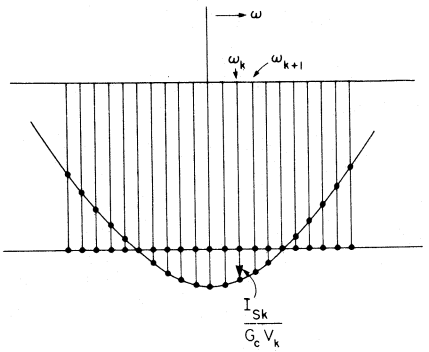

Fig. 2. The balancing of admittance discrepancy by injected currents produced by mode-locking modulation.

injection currents are given by (15). Fig. 2 shows a plot of the real part of the two sides of (16) versus ω_k (the imaginary part vanishes because of assumed synchronous modulation), showing explicitly the discrepancies $\mathrm{Re}[Y_C(\omega_k) + Y_L(\omega_k)]$ which are balanced by the modulation-produced "source" current normalized to the oscillation voltage I_{Sk}/V_k.

Suppose, now, we had not made the assumption that the center frequency of the laser line coincides with the oscillation frequency ω_0 of the mode $k = 0$. The actual deviation cannot be greater than $\omega_M/2$. The laser medium contributes a susceptance to this mode of magnitude equal to or less than

$$\frac{\omega_M}{2}\,\mathrm{Im}\left.\frac{dY_L}{d\omega}\right|_{\omega=0} = \frac{\omega_M}{2\omega_L}\, gG_C.$$

The mode then oscillates not at its (empty-cavity) resonance frequency, but a frequency away from it

$$|\delta\omega| = \frac{1}{4}\,\frac{\omega_M}{\omega_L}\, g\Delta\omega_C$$

where $\Delta\omega_C = \omega_0/Q$ is the cavity-mode bandwidth. Along with it, all other oscillation frequencies are shifted by this same amount, which is very small because $\omega_M g/\omega_L \ll 1$.

The results obtained thus far are well known. They have been checked experimentally by Kuizenga and Siegman [11], and Smith *et al.* [12]. One can extend the analysis to cover phase (reactive) rather than loss (resistive) modulation by replacing M by an imaginary quantity, again arriving at results derived previously [2], [8]. We shall not go into details, but concentrate instead on problems that have not received adequate treatment.

IV. The Mode-Locking Equation in the Time Domain

Forced mode locking with a modulation function $m(t)$ of arbitrary (periodic) time dependence is analyzed most conveniently in the time domain. Also the time-domain description permits an alternate interpretation of the mode-locking equation and of the assumptions that were made in its derivation. For this purpose, we study the Fourier transform of (10). We define the time function $v(t)$ as the Fourier transform of V_k

$$v(t) = \sum_k V_k \exp(j\omega_k t). \tag{25}$$

Since the mode amplitudes $\bar{e}_k(\bar{r})$ are equal to each other at one of the end mirrors, where all $\bar{e}_k$ have a common node, (25) may be interpreted as the time-dependent amplitude of the standing-wave field near one of the mirrors. Alternately, it is proportional to the time-dependent amplitude of the electric-field pulse traveling towards the end mirror.

With the definition (25), the Fourier transform of (10) is

$$\left\{1 + jb - g\left[1 + \frac{1}{\omega_L^2}\frac{d^2}{dt^2}\right] + \frac{g+\delta}{\omega_L}\frac{d}{dt}\right\} v(t) = -m(t)v(t). \tag{26}$$

Equation (25) may be interpreted in terms of the time-domain approach of mode locking. A pulse of electric field, $E(t) = v(t) \exp j\omega_0 t$ of complex time-dependent amplitude $v(t)$, experiences changes in one round-trip time T_R due to each of the components of the system. The cavity causes a decay and also a phase shift of the amplitude $v(t)$ if all frequency components of $E(t)$ are shifted by a constant $\delta\omega_0$ from the cavity resonance frequencies

$$v(t) \longrightarrow v(t) \exp - \frac{\omega_0 T_R}{2Q} \exp - j\delta\omega_0 T_R. \tag{27}$$

The laser medium amplifies and disperses the pulse. If an expansion like (9) is made of the frequency-dependent gain $G(\omega)$, then

$$v(t) \longrightarrow \exp\left\{G(\omega_0)\left[1 + \frac{1}{\omega_L^2}\frac{d^2}{dt^2} - \frac{1}{\omega_L}\frac{d}{dt}\right]\right\} v(t). \tag{28}$$

Here the exponential operator is to be interpreted in terms of its Taylor expansion. Finally, the passage through the mode-locking element of time-dependent loss $L(t)$ changes the pulse by

$$v(t) \longrightarrow v(t) \exp - L(t). \tag{29}$$

The existence of a steady state requires that the pulse experience no more than a time advance δT (or delay, $\delta T < 0$) upon one round trip. Expanding all exponentials to first order, a step that is legitimate if the changes wrought on the pulse on one passage by the elements of the system are small, one obtains

$$v(t - T_R) - \frac{\omega_0 T_R}{2Q}\left\{1 + jb - g\left[1 + \frac{1}{\omega_L^2}\frac{d^2}{dt^2} - \frac{1}{\omega_L}\frac{d}{dt}\right] + m(t)\right\} v(t - T_R) = v(t - T_R + \delta T) \tag{30}$$

where we have introduced the parameters b, g, and $m(t)$ which may be expressed in terms of $\delta\omega_0, L(t)$, and $G(\omega_0)$

$$b = 2Q\frac{\delta\omega_0}{\omega_0} \tag{31}$$

$$m(t) = \frac{2Q}{\omega_0 T_R} L(t) \tag{32}$$

$$g = \frac{2Q}{\omega_0 T_R} G(\omega_0). \tag{33}$$

An expansion of $v(t - T_R + \delta T)$ to first order in δT reproduces (26) with δ identified with

$$\delta = \frac{2Q\omega_L \delta T}{\omega_0 T_R}. \tag{34}$$

Thus we have fully interpreted the Fourier transform of (10) in terms of the steady-state requirement upon a pulse shaped by the components of the laser system.

V. General Time-Dependent Loss Modulation

With the aid of the mode-locking equation in the time domain, (26), it is possible to study mode locking by an arbitrary periodic loss modulation $m(t)$. Equation (26) can be reduced to a standard equation of quantum mechanics by the change of variable

$$v(t) = V(t) \exp\left[\tfrac{1}{2}(g + \delta)\omega_L t/g\right]. \tag{35}$$

Introducing (35) into (26), one obtains the differential equation for $V(t)$

$$\frac{g}{\omega_L^2}\frac{d^2V}{dt^2} - m(t)V(t) = -EV(t) \tag{36}$$

with

$$E = g\left[1 - \left(\frac{g+\delta}{2g}\right)^2\right] - (1 + jb). \tag{37}$$

This is a well-known equation of quantum mechanics. A particle with the mass $2m/\hbar^2 = \omega_L^2/g$ moves in the potential well $m(t)$ where the role of the spatial variable x of quantum mechanics is now played by the *time*.

Because the eigenvalues E of this problem are real, we find $b = 0$, the mode at laser line center oscillates at its resonance frequency also for this form of modulation.

The sinusoidal modulation problem of the homogeneously broadened laser could have been solved in the time domain, with $1 - \cos\omega_M t \to \frac{1}{2}(\omega_M t)^2$ and the Hermite-Gaussian solutions would have been obtained, another way of observing the invariance of Hermite-Gaussians with regard to Fourier transformation. Consider as another example a very deep modulation of the mode-locking crystal which shuts off transmission entirely outside an interval of length τ. This is shown in Fig. 3. Equation (32) for the square potential well is the quantum mechanical problem of an electron in a perfectly reflecting box. The eigenfunctions and eigenvalues of

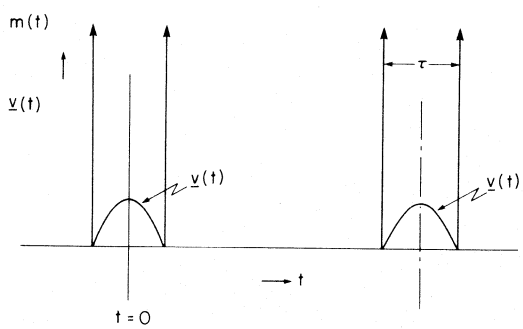

Fig. 3. "Deep" modulation and the quantum mechanical wave function analog.

this problem are [13]

$$V(t) = \cos \frac{n\pi}{\tau} t \tag{38}$$

in the time domain. The eigenvalue equation yields

$$g\left[1 - \left(\frac{g+\delta}{2g}\right)^2\right] - 1 = \frac{g}{\omega_L^2}\left(\frac{n\pi}{\tau}\right)^2. \tag{39}$$

In the time domain the mode-locked pulse is confined to the time interval τ. Equation (39) shows that excessive detuning of the modulation quenches the laser; no solution is found for $g + \delta > 2\sqrt{g(g-1)}$.

If the square-wave modulation is modified to one of lesser depth, one has the problem of a particle in an open-square well with well-known eigenfunctions [13].

One may think of other modulation functions $m(t)$ for which either quantum mechanical solutions exist, or for which one may arrive at qualitative conclusions as to the shape of the mode-locking pulse. Consider, for example, the approximations made when the discrete spectrum of the cavity-mode oscillations was replaced by a continuum, and the modulation of loss was represented by the operator $d^2/d\omega^2$. In the time domain, this operator is replaced by the multiplier $-\frac{1}{2}t^2$. The analog of the full cosinusoidal modulator is the particle in a cosinusoidal potential. When the modulation is strong enough so that the eigenvalue levels are near the bottoms of the wells, one obtains a set of solutions in each of the well bottoms, which are the Hermite-Gaussians. When the modulation is decreased, the height of the wells is decreased and solutions are found with overlap between the (wave) functions within each of the periodic wells. The mode locking is not strong enough to suppress the field amplitude between the pulses.

VI. Stability of Solutions

The existence of a solution of the mode-locking equation does not imply physical realizability. In particular, a whole set of Hermite-Gaussian solutions is found in the case of sinusoidal modulation. Which of these solutions is realized in the steady state? In order to answer this question one must resort to a stability analysis.

In this section we study the stability of the supermodes with respect to arbitrary perturbations for synchronous modulation. We shall follow the analysis of stability of injection locking of a single oscillator of Kurokawa [4]. In this analysis, the assumed steady state is perturbed, and the perturbation is taken to be a slow function of time (compared with the time variation of the unperturbed oscillation). An instantaneous frequency and growth or decay rate is obtained for the perturbation. If it can be shown that there is no net growth the injection locking is stable. We shall extend this analysis to the study of the stability of "steady-state" mode-locking solutions. Here all oscillations are coupled to each other through the mode-locking process. Study of transients implies the replacement of the frequencies ω_k of the modes by $\omega_k + \Omega_k$ where Ω_k is complex: $-\text{Im}(\Omega_k) > 0$ implies growth of excitation. Further the "instantaneous" perturbation frequency Ω_k itself is a function of time. Thus even temporary growth may be offset by eventual decay.

The objective then is to obtain an equation for a complex perturbation δV_k of the steady state V_k of the kth axial mode. The frequency Ω_k of the perturbation is, in general, a function of the phase ϕ_k between δV_k and V_k. The perturbation obeys the same difference equation (16) as V_k, except that ω_k must be replaced everywhere by $\omega_k + \Omega_k$ and g may be perturbed because an amplitude perturbation changes P and thus changes g. All ω_k dependent parameters may be expanded to first order in the Ω_k if the Ω_k are assumed small (small growth or decay and phase deviations within one transit time T_R). We shall disregard all derivatives of the parameters of (4) with respect to Ω_k, except that of $\text{Im}\, Y_{Ck}(\omega_k)$. This is an approximation which disregards energy storages other than the electromagnetic energy storage of the cavity modes. If the oscillation of the perturbation δV_k of the kth axial mode occurs with the frequency $\omega_k + \Omega_k$, then the admittance to be associated with δV_k is

$$Y_{Ck}(\omega_k + \Omega_k) = Y_{Ck}(\omega_k) + j\Omega_k \frac{2Q}{\omega_k}$$

or in the continuum limit

$$Y_C(\omega + \Omega) \cong Y_C(\omega) + j\Omega \frac{2Q}{\omega_0}. \tag{40}$$

If we assume that the unperturbed solution is the nth supermode $V_n(\omega)$ excited at synchronism (i.e., $g + \delta = 0$) expand the difference equation as indicated and go to the continuum limit, we obtain the equation [compare (17)]

$$\left[M\omega_M^2 \frac{d^2}{d\omega^2} + g\left(1 - \frac{\omega^2}{\omega_L^2}\right) - 1\right]\delta V + (\delta g)\left(1 - \frac{\omega^2}{\omega_L^2} - j\frac{\omega}{\omega_L}\right)V_n = \frac{2Q}{\omega_0} j\Omega\, \delta V. \tag{41}$$

Because the change of the pulse per transit time T_R has been assumed small, $j\Omega T_R \delta V$ is the change of δV within one transit time T_R

$$j\Omega\, T_R \delta V = \Delta \delta V.$$

One may define the slow-time variable $T = NT_R$, where N is the number of transits. In terms of T, the rate of change of the pulse spectrum as a function of the time parameter T is

$$j\Omega \delta V = \frac{\Delta \delta V}{T_R} = \frac{\Delta \delta V}{\Delta T} = \frac{\partial \delta V}{\partial T} \tag{42}$$

where we use a partial derivative to emphasize that δV is a function of T and ω.

Next consider the perturbation δg. In general, δg obeys a differential equation in time. Thus if one adheres to the two-level model of (12), then δg obeys the differential function

$$\frac{\partial}{\partial T}\delta g = -\frac{\delta g}{\tau} - \frac{g}{T_L}\frac{\delta P}{T_L} \tag{43}$$

where

$$\frac{1}{\tau} = \frac{1}{T_L}\left(1 + \frac{P}{P_L}\right). \tag{44}$$

Suppose that the mode spectrum $V_n(\omega)$ is so normalized that $\int |V_n(\omega)|^2 d\omega$ is equal to the power P. Then

$$\delta P = 2 \int V_n(\omega) \operatorname{Re} \delta V \, d\omega \tag{45}$$

where the phase of the perturbation is measured with respect to the steady state. Equation (45) suggests the expediency of an expansion of the perturbation δV in terms of orthonormal eigenfunctions which, except for one, are orthogonal to V_n. The obvious set is the one defined by the differential equation

$$M\omega_M^2 \frac{d^2}{d\omega^2} u_p - g \frac{\omega^2}{\omega_L^2} u_p = -E_p u_p \tag{46}$$

with eigenvalues E_p given by (22). The steady-state solution V_n is a member of the set. We put

$$V_n = A_n u_n(\omega). \tag{47}$$

The perturbation is expanded in terms of the complete set

$$\delta V(T, \omega) = \sum_p a_p(T) u_p(\omega). \tag{48}$$

Introducing (48) in (41), with $j\Omega$ replaced by d/dT, multiplying the result by $u_q(\omega)$, and integrating over all m, we obtain

$$\frac{2Q}{\omega_0} \frac{da_q}{dT} = -(E_q - E_n) a_q + \delta g \, A_n C_{qn} \tag{49}$$

where

$$C_{qn} = \int_{-\infty}^{\infty} \left[1 - \frac{\omega^2}{\omega_L^2} - j \frac{\omega}{\omega_L} \right] u_q u_n \, d\omega. \tag{50}$$

Equation (43) for the gain perturbation becomes

$$\frac{d}{dT} \delta g = -\frac{\delta g}{\tau} - \frac{2g}{T_L} \frac{A_n \operatorname{Re} a_n}{P_L}. \tag{51}$$

For $n \neq q$ the perturbation of gain δg vanishes and one finds

$$\frac{2Q}{\omega_0} \frac{d}{dT} a_q = -(E_q - E_n) a_q. \tag{52}$$

The amplitude a_q is uncoupled from all the others. Growth of a_q occurs for $q < n$. This finding is the consequence of the fact that a mode $q < n$ requires less gain in the steady state, according to (22), than the mode n. If the two modes are orthogonal, then the power does not change to first order due to addition of a perturbation $a_q u_q$ to the steady-state $A_n u_n(\omega)$. Hence no gain change occurs. As the gain is higher already than the one required for the steady state of the qth mode, the perturbation grows.

Next consider the equations for the perturbation of the lowest order mode $n = 0$. The equations for a_0 are uncoupled from all the other amplitudes $a_q, q \neq 0$. Separating a_0 into phase and amplitude

$$a_0 = r \exp(j\phi_0)$$

introducing this expresison into (49) and (51), eliminating the gain variation δg, one obtains a second-order differential equation. Dividing by the phase factor $\exp j\phi_0$ and separating the equation into its real and imaginary parts, one obtains

$$\ddot{r} - \dot{\phi}_0^2 r + \frac{1}{\tau} \dot{r} = -\left(\frac{\omega_0}{2Q} \frac{g}{T_L} \frac{P}{P_L} \right) C_{00} r (1 + \cos 2\phi_0) \tag{53}$$

$$r\ddot{\phi}_0 + 2\dot{r}\dot{\phi}_0 + \frac{1}{\tau} r\dot{\phi} = \left(\frac{\omega_0}{2Q} \frac{g}{T_L} \frac{P}{P_L} \right) C_{00} r \sin 2\phi_0. \tag{54}$$

The coefficient C_{00} is equal to

$$C_{00} = 1 - \frac{1}{2} \frac{\omega_P^2}{\omega_L}.$$

Note that C_{00} is positive for all values of ω_P permitted by our original assumption of narrow pulse-bandwidth. Equations (53) and (54) are the equations of motion of a particle of inverse mass equal to $C_{00}\omega_0 gP/(2QT_L P_L)$ in a force field

$$f_r = -(1 + \cos 2\phi_0) r$$

$$f_\phi = \sin 2\phi_0 \, r.$$

This force field is conservative (its curl vanishes) and hence is properly represented by a potential $\Phi(r, \phi_0)$ which is found to be

$$\Phi = \frac{r^2}{2} (1 + \cos 2\phi_0).$$

This potential is a parabolic trough, with the bottom of the trough aligned along the $\phi_0 = (\pi/2)$ axis. A particle launched at any point with a certain velocity (the analog of a perturbation of given initial phase, amplitude, and time rate of change) will experience a damped oscillatory motion until finally it lands at the bottom of the trough, in general, at a finite distance from the origin. Translated into the language of the perturbation evolution, we find that an arbitrary initial perturbation of given initial phase, amplitude, and time rate of change experiences damped oscillations running through various phases, but always ending up with $\phi_0 = \pm 90°$, in quadrature with the steady state. This final phase indicates a quadrature component to the steady state, or a phase change of the factor $\exp j\omega_0 t$. The behavior is analogous with that of the simple van der Pol oscillator for which one also finds that random noise perturbations cause a random walk of the phase of the oscillation [16].

Next consider the equations obtained for the perturbation amplitudes a_1 and a_2 from (49). The amplitudes a_q for $q > 2$ are all uncoupled because $C_{q0} = 0$ for $q > 2$ and they all decay. On the other hand, $\operatorname{Re} a_0$ acts as a source of a_1 and a_2. Since the natural "frequencies" of a_1 and a_2 have positive imaginary parts, the amplitudes a_1 and a_2 in turn vanish along with $\operatorname{Re} a_0$. Hence we have shown that for synchronous modulation the $n = 0$ supermode is stable with respect to arbitrary perturbations.

VII. Conclusions

An analysis of forced mode locking has been presented in both the time domain and the frequency domain. For deep sinusoidal modulation, the well-known Hermite-Gaussian supermode solutions have been obtained. Transformation

of the equations into the time domain for a general periodic modulation led to a simple quantum analog of a particle in a periodic potential well. This analog permitted the observation that a shallow sinusoidal modulation was the analog of a particle motion in a sinusoidally spatially varying potential. When the modulation is deep, and the pulses (wave functions) are well separated, the potential can be approximated by a parabola within the range occupied by any one of the wave functions. In this limit the Hermite-Gaussian solutions are obtained.

Maybe the most important new result of this paper is the conclusion that all Hermite-Gaussian steady-state solutions for synchronous modulation are unstable except the lowest order one. We have determined the response of the fundamental (Gaussian) mode to an initial perturbation and found, in general, that all such perturbations die down, resulting in a phase perturbation of the carrier.

ACKNOWLEDGMENT

The author wishes to thank C. P. Ausschnitt for many useful discussions.

Spectroscopy and Laser Oscillation Properties of Lithium Neodymium Tetraphosphate

KENJU OTSUKA, ASSOCIATE MEMBER, IEEE, TOMOAKI YAMADA, MASATOSHI SARUWATARI, AND TATSUYA KIMURA, MEMBER, IEEE

Abstract–**Optical absorption, fluorescence, and laser characteristics of lithium neodymium tetraphosphate ($LiNdP_4O_{12}$, abbreviated as LNP) were examined. The crystal belongs to the monoclinic system (pseudoorthorhombic system) and the Nd content is $4.37 \times 10^{21}\,cm^{-3}$. The lifetime of the $^4F_{3/2}$ level is 120 μs, which is one-half of 230 μs observed in Nd:YAG. The largest effective emission cross section at the line peak (1.047$_7$ μm) was spectroscopically determined as $3.2 \times 10^{-19}\,cm^2$ for the electric vector parallel to the pseudoorthorhombic c axis and quantum efficiency was estimated as 0.48.**

Quasi-continuous laser oscillation pumped by a chopped Ar-ion laser was achieved with a 1.85-mm-long crystal. The output light was linearly polarized along the pseudoorthorhombic c axis of the crystal, which does not depend on the polarization direction of the pump light.

The measured threshold and round-trip loss yield the value of $3.1 \times 10^{-19}\,cm^2$ for the effective emission cross section of LNP, which is in good agreement with the value obtained from the spectroscopic data.

I. INTRODUCTION

AS AN EFFICIENT laser material, in which active ions are an essential component of the chemical compound, neodymium pentaphosphate (NdP_5O_{14}) was proposed by Danielmeyer and Weber [1]. Although the Nd content of $4 \times 10^{21}\,cm^{-3}$ is about 30 times higher than that of Nd:YAG, the crystal has little concentration quenching and the lifetime of $^4F_{3/2}$ state is 66 μs. Moreover, the lifetime of NdPP was recently reported to increase up to 120 μs by annealing

the crystal [2]. Quasi-continuous and continuous laser oscillations with very low threshold were also reported in (Nd, La) and (Nd, Sc) pentaphosphate, respectively [3], [4].

Recently, we reported the fluorescence in lithium neodymium tetraphosphate ($LiNdP_4O_{12}$, abbreviated as LNP) as another material with little concentration quenching [5]. Single crystals of LNP up to about 3 X 3 X 3 mm in size were obtained by the top-seeded Kyropoulos method from a melt of composition different from LNP. Fundamental crystallographic properties of LNP are summarized.

Stoichiometry	$LiNdP_4O_{12}$.
System	Monoclinic (pseudoorthorhombic).
Space group	$C2/c - C_{2h}^6$.
Lattice constants	a = 16.45 Å, b = 7.07 Å, c = 13.25 Å, $\beta = 143°37'$ (a = 9.76 Å, b = 13.25 Å, c = 7.07 Å).
Density (calculated)	3.39 g/cm^3.
Z	4 molecules/unit cell.
Nd concentration	4.37×10^{21} cm^{-3}.
Refractive index (6328 Å)	1.58.

The present paper reports the spectroscopic properties such as absorption, fluorescence, and laser transition cross section, and the examination of quasi-continuous oscillation of LNP laser.

II. Spectroscopy and Laser Transition Cross Sections

Several plates normal to the crystallographic axes cut out from the boules of LNP were polished to a uniform thickness and their absorption spectra were examined, using a Cary 14R recording spectrometer. The absorption spectra of an a plate which correspond to the most intense absorption band ($^4I_{9/2} \rightarrow {}^4F_{5/2}, {}^2H_{9/2}$) are shown in Fig. 1. The peak absorption cross section of the line at 8009 Å ($^4I_{9/2}(2) \rightarrow {}^4F_{5/2}(2)$) was $\sigma_a = 1.25 \times 10^{-19}$ cm^2. This is very much in line with the cross section for Nd:YAG at 8100 Å (1.20×10^{-19} cm^2) [6]. Since the Nd concentration is about 30 times higher in LNP than in Nd:YAG and the absorption cross sections are nearly the same for both materials, the absorption coefficient of LNP is about 30 times larger than that of Nd:YAG at the most intense absorption band.

The room-temperature lifetime of the $^4F_{3/2}$ state was determined by measuring the spontaneous decay on an oscilloscope. The sample was excited by Xe flashlamp of 0.6-μs pulse duration or a dye laser (5965 Å) of 1-μs pulse duration. The decay was exponential with a $1/e$ lifetime τ_f of 120 μs.

The emission cross sections were determined at room temperature, using the method reported by Neeland and Evtuhov [7] and recently refined by Singh *et al.* [8] in the case of Nd:YAG. The method consists of the following two processes: 1) the direct determination of the transition cross sections from the ground-state manifold ($^4I_{9/2}$) to the laser state manifold ($^4F_{3/2}$) by the absorption measurement; and 2) the comparison of fluorescence-emission intensities from the laser state manifold to the lower manifold with those of $^4F_{3/2} \rightarrow {}^4I_{9/2}$.

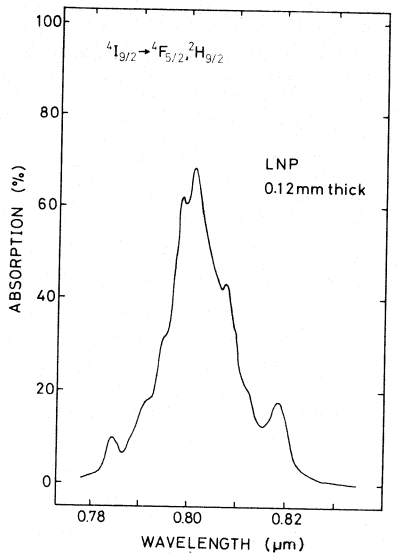

Fig. 1. Absorption spectra of an a plate LNP of 0.12-mm thickness at the most intense absorption band.

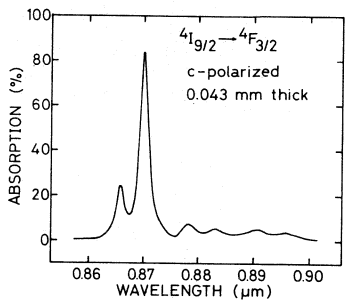

Fig. 2. Absorption spectra of LNP 43 μm thick, which correspond to the transitions from the ground state to the $^4F_{3/2}$ state for the light polarized along the pseudoorthorhombic c axis of the crystal.

Since the laser emission is linearly polarized along the pseudoorthorhombic c axis, as described in the next section, the measurements were made for the electric vector parallel to the c axis.

Fig. 2 shows the absorption spectra of the $^4I_{9/2} \rightarrow {}^4F_{3/2}$ transitions measured on a 43-μm-thick plate of LNP. From the absorption coefficients determined by the figure, the peak absorption cross sections $\sigma_{R_1} = 2.3 \times 10^{-19}$ cm^2 and $\sigma_{R_2} = 0.31 \times 10^{-19}$ cm^2 were obtained for the R_1 (0.870_8 μm) and R_2 (0.866_6 μm) lines which correspond to the transitions from the ground state $^4I_{9/2}(1)$ to the lower and upper levels of the $^4F_{3/2}$ state, respectively. The population of the $^4I_{9/2}(1)$ level is $0.40N_0$ at room temperature, where N_0 is the total Nd-ion density.

The fluorescence spectra were examined as follows. The sample was excited by a high-pressure Hg lamp and the fluorescence from LNP was detected with a cooled S-1 photomultiplier and a lock-in amplifier after it had been passed through a polarizer. The relative spectral sensitivity of the detection system was calibrated with a NBS standard lamp.

The Nd^{3+} ion has four fluorescence groups that originate from the two $^4F_{3/2}$ levels. The transitions into the $^4I_{15/2}$ levels around 1.9 μm and the $^4I_{13/2}$ levels around 1.3 μm were weak in LNP. The shortest wavelength transitions near 0.9 μm

which terminate in the five $^4I_{9/2}$ levels are shown in Fig. 3. The sample thickness was 25 μm to make corrections due to reabsorption small; however, the peak value of the R_1 line was corrected to be consistent with the absorption spectra and the relative population between the two $^4F_{3/2}$ levels. The fluorescence from the $^4F_{3/2} \rightarrow {}^4I_{11/2}$ levels was shown in Fig. 4, which was measured in exactly the same experimental arrangement. The intensity scale in Fig. 4 is the same as in Fig. 3. The splitting of the two $^4F_{3/2}$ levels could be found by looking for pairs with equal spacing in the spectra. The I-level energies could be determined by ordering the pairs according to their wavenumber, where spectra measured for the electric vector parallel to the pseudoorthorhombic a and b axes were also taken into consideration. The results of this procedure are shown in Fig. 5.

As seen in Fig. 6, the 1.0647-μm laser line of LNP consists of two Lorentzian lines at room temperature. The l_1 line located at 1.0647 μm has a peak value of about 0.88 times the total peak value with 17-Å full width between half-intensity points. The l_2 line located at about 13 Å longer from the l_1 line has a peak value of about 0.24 times the peak value of the l_1 line with 25-Å full width. We shall define the effective emission cross section for the ion in the $^4F_{3/2}$ manifold as follows:

$$\sigma_l = \frac{\sigma_{l_1} + \sigma_{l_2} a}{1 + a} \tag{1}$$

where σ_{l_1} and σ_{l_2} are the cross sections of the two transitions at the laser line peak (1.0647 μm), and a is the Boltzmann factor between the R_1 and R_2 levels at room temperature (0.76).

If we assume that the peak emission cross sections of the R_1 ($^4F_{3/2}(1) \rightarrow {}^4I_{9/2}(1)$) and R_2 ($^4F_{3/2}(2) \rightarrow {}^4I_{9/2}(1)$) lines are equal to the peak absorption cross sections σ_{R_1} and σ_{R_2}, respectively, the ratio of the peak emission intensities to the R_1 and R_2 lines to those of the laser lines are given as

$$(dI_{R_1}/d\lambda)/(dI_{l_1}/d\lambda) = (\nu_{R_1}/\nu_{l_1})^5 (\sigma_{R_1}/\sigma_{l_1})$$
$$(dI_{R_2}/d\lambda)/(dI_{l_2 p}/d\lambda) = (\nu_{R_2}/\nu_{l_2})^5 (\sigma_{R_2}/\sigma_{l_2 p}) \tag{2}$$

where $\sigma_{l_2 p}$ is the emission cross section at the l_2-line peak and ν represents the transition frequency. From Figs. 3, 4, and 6 $\sigma_{l_1}/\sigma_{R_1} = 2.2$ and $\sigma_{l_2 p}/\sigma_{R_2} = 5.1$ were obtained. Using the values for σ_{R_1} and σ_{R_2}, determined by the absorption measurement and (1), we obtained the laser transition cross section $\sigma_l = 3.2 \times 10^{-19}\,\mathrm{cm}^2$ ($\sigma_{l_1} = 5.1 \times 10^{-19}\,\mathrm{cm}^2$, $\sigma_{l_2 p} = 1.6 \times 10^{-19}\,\mathrm{cm}^2$, $\sigma_{l_2} = 0.8 \times 10^{-19}\,\mathrm{cm}^2$ at 1.0647 μm).

Integrating the curves of Figs. 3 and 4 and then converting from intensity into number of photons, the branching ratios were obtained as $\beta_{9/2} = 0.36$ and $\beta_{11/2} = 0.64$, where $\beta_{13/2}$ and $\beta_{15/2}$ were assumed to be negligibly small. The branching ratio of the l_1 line was calculated as 0.20.

The same measurements were made for the electric vector parallel to the a and b axes. The results are summarized in Table I.

The total radiative lifetime τ_r could be calculated by using

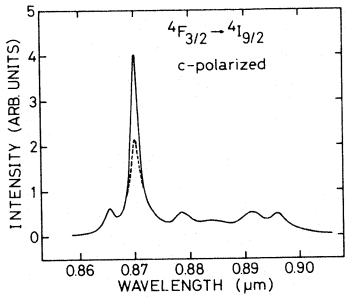

Fig. 3. Fluorescence of the shortest wavelength band of LNP 25 μm thick for the electric vector parallel to the c axis. The dashed curve shows the measured fluorescence spectra and the solid curve shows the corrected one, taking into account reabsorption.

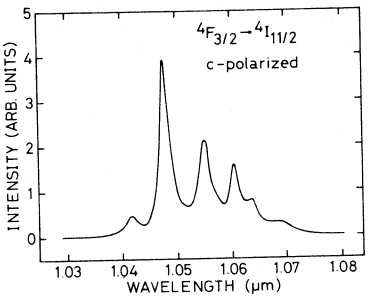

Fig. 4. Fluorescence of the strongest band of LNP 25 μm thick for the electric vector parallel to the c axis. The intensity scale in Fig. 4 is the same as Fig. 3.

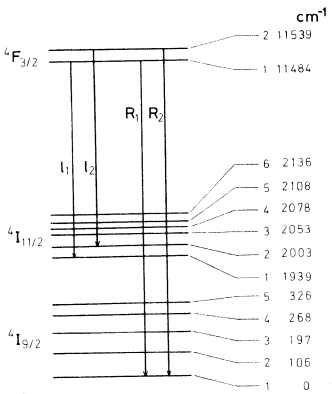

Fig. 5. Energy levels and main transitions in LNP at 300 K. R_1 and R_2 lines are also presented.

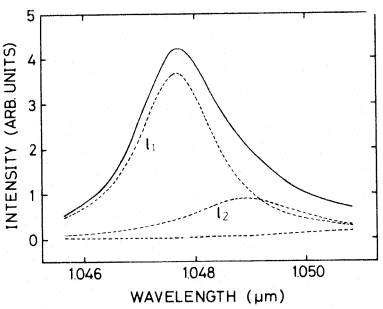

Fig. 6. Emission spectrum of the 1.0647-μm laser lines at 300 K. Two Lorentzian lines contributing to the laser transition are shown by dashed curves.

TABLE I

	β_{l_1}	$\Delta\lambda_{l_1}$	σ_{l_1}	β_{l_2}	$\Delta\lambda_{l_2}$	σ_{l_2}	σ_l
a	0.19	20Å	2.1×10^{-19}cm^2	0.12	24Å	1.5×10^{-19}cm^2	1.5×10^{-19}cm^2
b	0.16	19	1.7	0.11	23	1.3	1.3
c	0.20	17	5.1	0.07	25	1.6	3.2

Note: Branching ratios, linewidths, and peak emission cross sections for the two transitions in the 1.047_7-μm laser line in LNP for the electric vectors parallel to the pseudoorthorhombic *a*, *b*, and *c* axes. The effective emission cross sections at the laser line are also shown.

the relation

$$\tau_r^{-1} = (4\pi^2 cn^2 F_{l_1}/\lambda_{l_1}^4)\left(\sum\sigma_{l_1}\Delta\lambda_{l_1}/\beta_{l_1}\right)\Big/3 \qquad (3)$$

where c is the velocity of light, n is the refractive index, F_{l_1} is the fraction of ions in the $^4F_{3/2}(1)$ level (0.57) and the summation was made over the values for the electric vector along the *a*, *b*, and *c* axes. From the values listed in Table I, τ_r was obtained as 250 μs. This total radiative lifetime is much longer than the measured fluorescent lifetime τ_f of 120 μs, and therefore the radiative quantum efficiency is estimated as $\eta = \tau_f/\tau_r = 0.48$. For a comparison, the fluorescent lifetime in the limit of zero concentration was measured. In $Li(Nd_xR_{1-x})P$ (R = Y, La, Gd) the lifetime increases from 120-320 μs with the concentration (N) dependence of $\tau_f = \tau_0(1 + QN^2)^{-1}$, where the cross relaxation rate Q was obtained as about 0.5×10^{-43}cm^6. Although LNP has a little concentration quenching, the quenching is much less than other host materials, i.e., the value of Q is about 20 times smaller than that of Nd:YAG [9].

III. Laser Characteristics

We report in this section quasi-continuous laser action in LNP. The experimental arrangement is shown in Fig. 7. A chopped Ar-ion laser (5145 Å) served as a pump. The Ar-ion laser pulses had a duration of 300 μs-2 ms, a duty factor of 2-50 percent, and was linearly polarized. The following results were obtained with a crystal 1.85 mm long (pseudo-orthorhombic *a* axis) and 1 mm wide (*c* axis) cemented on a copper heat sink. The thickness of the crystal was 0.7 mm (*b* axis). The resonator is of a nearly semiconcentric type with mirrors M_1 (radius of curvature R_1 = 9 cm, transmittance at 1.047_7 μm, T_1 = 0.1, 1.2, 2, 3 percent) and M_2 ($R_2 = \infty$, T_2 = 0.1 percent) separated by about 9 cm. The crystal was placed just in front of M_2. The focal length of the lens L focusing the pump beam was 5 cm and adjusted to minimize the pumped volume in the crystal.

The power absorbed by the crystal was measured with a silicon photocell as the difference between input and output power. The absorption coefficient depends on the polarization direction of the pump light. The maximum absorption was obtained when the polarization direction of the pump light was adjusted along the *c* axis of the LNP, and the crystal of 1.85-mm length absorbed about 100 percent of the pump light.

The output power through the mirror M_1 is shown in Fig. 8

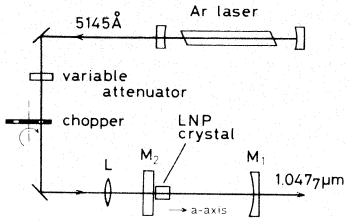

Fig. 7. Experimental arrangement of the quasi-continuous LNP laser.

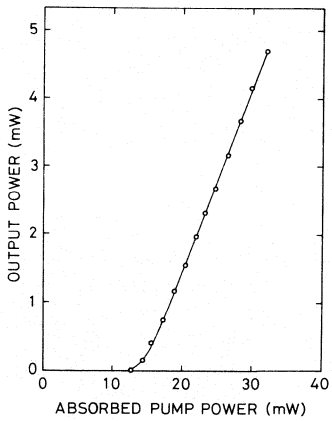

Fig. 8. The output power through the mirror M_1 (T_1 = 1.2 percent) as a function of the absorbed pump power at 5145 Å.

as a function of the absorbed pump power at 5145 Å, where T_1 and T_2 were fixed as 1.2 and 0.1 percent, respectively. The threshold was P_{th} = 12.7 mW and the slope efficiency was 27 percent.

The LNP laser emission was linearly polarized along the *c* axis of the crystal, which does not depend on the polarization direction of the pump light.

The output waveform shows the relaxation oscillation in the onset of laser oscillation, as shown in Fig. 9.

The round-trip loss of the resonator L_c was directly measured by the change of threshold with $\ln(r_1 r_2)$, where r_1 and r_2 were the mirror reflectivities. The measured threshold was plotted as a function of $-\ln(r_1 r_2)$ in Fig. 10. From Fig. 10, the round-trip loss, except the transmission losses of the mirrors, is found to be 0.03.

The output-beam spot size of the LNP-laser radiation was measured as a function of the distance from the mirror M_1, as shown in Fig. 11(a), and we estimated the spot size at the mirror M_1 as w_m = 2.2 mm. With w_m = 2.2 mm and R_1 = 9 cm, the oscillating beam spot size in the 1.85-mm-long LNP crystal was calculated in Fig. 11(b), using the propagation laws for the fundamental mode [10, eqs. (20) and (23)], and considering the effect of refractive index. From Fig. 11(b), the beam spot size averaged over the crystal length is found to be w_a = 43 μm.

The effective emission cross section for the ion in the $^4F_{3/2}$ manifold can be calculated from

$$\sigma_l = \frac{L_c h\nu\pi w_a^2}{2P_{th}\tau_f} \qquad (4)$$

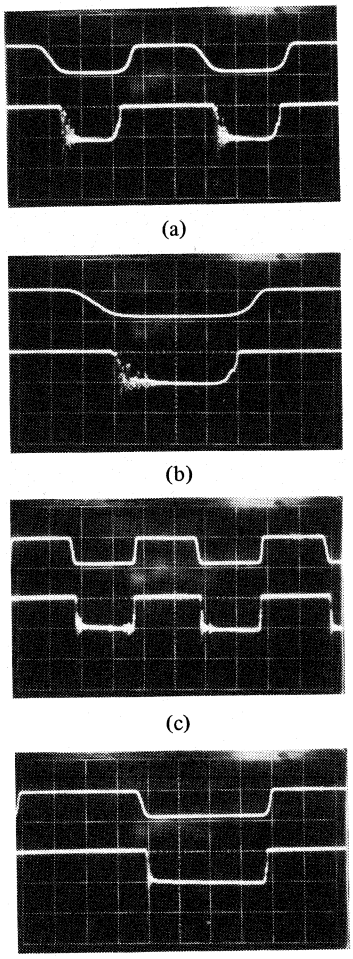

Fig. 9. Quasi-continuous output observed with an S-1 photomultiplier. The upper and lower traces represent the pump light and the output of the LNP laser, respectively. Absorbed pump power: 32 mW. (a) 200 μs/div. (b) 100 μs/div. (c) 1 ms/div. (d) 500 μs/div.

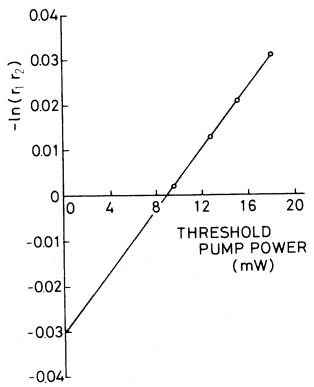

Fig. 10. The laser threshold as a function of $-\ln(r_1 r_2)$, where r_1 and r_2 are the mirror reflectivities.

where ν is the pump frequency. With $\nu = 5.83 \times 10^{14}$ Hz, $w_a = 43$ μm, and $\tau_f = 120$ μs, the effective emission cross section σ_l is determined as 3.1×10^{-19} cm^2 assuming $L_c = 0.043$ and $P_{th} = 12.7$ mW from Figs. 8 and 10. This is in good agreement with the value of 3.2×10^{-19} cm^2 obtained from the spectroscopic data.

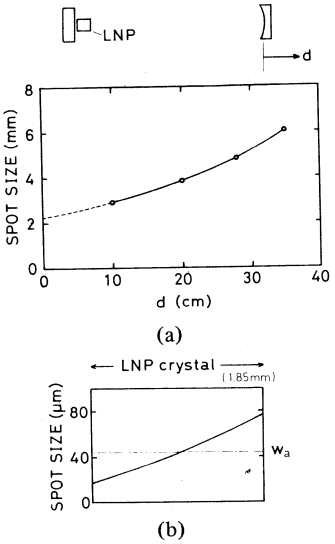

Fig. 11. The oscillating beam spot size of the LNP laser. (a) The output-beam spot size as a function of the distance from the mirror M_1 ($R_1 = 9$ cm). (b) The oscillating beam spot size in the LNP crystal. The mirror spacing is about 9 cm and the crystal is located about 0.2 mm apart from the mirror M_2.

The output spectra of the laser were analyzed with a JASCO single grating monochrometer with a resolution of 0.1 Å. The output spectrum was 2 Å wide for TEM_{00} mode.

IV. Conclusion

Optical absorption, fluorescence, and laser characteristics of $LiNdP_4O_{12}$ were examined. The laser transition cross section of 3.2×10^{-19} cm^2 obtained from the spectroscopic data was in good agreement with that obtained from the measured threshold, round-trip loss, and beam spot size of quasi-continuous laser operation.

With 5145-Å pump, observed threshold was 12.7 mW and the slope efficiency was 27 percent when the spot size of the cavity mode was 43 μm.

Since the largest laser transition cross section, for the electric vector parallel to the pseudoorthorhombic c axis, is 1.8 times that of Nd:YAG [8], the ground-state population density of 4.37×10^{21} cm^{-3} is 33 times higher than 1-percent doped Nd:YAG and the lifetime of $^4F_{3/2}$ state is as long as 120 μs despite the high Nd concentration, LNP may be useful as a high gain material especially for transverse pumping by luminescent diodes if large crystals with high quality could be grown.

Acknowledgment

The authors wish to thank J. Nakano for support in growing the LNP laser crystal. They also wish to thank Miss H. Suzuki for her excellent technical assistance, and Dr. N. Niizeki and Dr. Y. Furukawa for encouraging this work and offering valuable criticism.

The Effects of Gas Additives on TEA CO_2 Lasers

A. L. S. SMITH, T. H. BETT, AND P. G. BROWNE

Abstract—**The effects of the selective addition of the gases H_2, CO, O_2, NO, NO_2, and N_2O on the output peak power and stability of a flowing-gas TEA laser operating with a basic mixture of CO_2, N_2, and He are examined. These additive gases are possible products of reactions which occur in the discharge region of the laser and have considerable bearing on the operation of a sealed TEA laser.**

The power output is increased with the limited addition of H_2 (~5 percent) or NO (~0.2 percent), whereas N_2O, NO_2, O_2, and CO reduce the power output when present in any amount; 50-percent reduction being obtained with ~0.23-percent N_2O, ~0.15-percent NO_2, ~4-percent O_2, and ~22-percent CO.

H_2 (and possible NO) limits the transition from a diffuse glow to arc discharge by allowing a larger range of operating conditions, whereas CO reduces the range of operating conditions for stable operation. O_2 does not affect the discharge, whereas N_2O and NO_2 both encourage the transition to arcing.

I. INTRODUCTION

In a typical flowing-gas TEA laser the gas is completely replaced between discharge pulses. Thus the plasma chemistry is dependent on the species introduced by the gas flow and any species produced by the electrical-discharge pulse which can affect the discharge characteristics within the discharge period (~0.1 μs), or can collisionally affect the molecular species in the time up to the appearance of the infrared (IR) laser-emission pulse (0.5–1.5 μs). These will include electrons, primary positive ions, and other ions formed by very rapid charged-particle reactions such as charge transfer and electron attachment. The quantities of neutral particles, atomic or molecular, formed on this time scale will be too small to affect the laser excitation or relaxation.

In a sealed TEA laser, however, the reaction products of many discharge pulses may build up considerable concentrations of other molecular species, which lead to changes in the operating characteristics and possible device failure. The possible effects of these reaction products on a preionized TEA laser can be categorized under five headings.

A. Photon Production and Absorption

If the preionization is produced by a photon flux from a subsidiary discharge between a trigger wire and the anode [1] or by trigger sparks [2], then the reaction products may affect these preliminary discharges and hence the photon emission and resonant absorption processes. The photon flux is necessary to produce an initial electron density (by photoionization or photoelectric emission from the electrodes) sufficient to prevent the main diffuse discharge constricting into an arclike channel, by ensuring that the individual avalanches in the main discharge are sufficiently close together that the local electric field is not affected by the presence of individual streamers [3]. This condition is apparently met if there is sufficient bulk photoionization in the discharge region to produce an electron density $\geq 10^4$ cm^{-3}.

It has also been observed [4] that the breakdown potential

Manuscript received October 1, 1974; revised March 3, 1975.

A. L. S. Smith is with the Department of Physics, University of St. Andrews, St. Andrews, Fife, Scotland.

T. H. Bett was with the University of St. Andrews, St. Andrews, Fife, Scotland. He is now with AWRE, Aldermaston, England.

P. G. Browne was with the University of St. Andrews, St. Andrews, Fife, Scotland. He is now with the Department of Electrical Engineering and Electronics, University of Liverpool, Liverpool, England.

V_s of the main discharge decreases considerably with an increase in the preionization photon flux.

B. Main Discharge Equilibrium

The main discharge reduced field, E/N (electric field E, particle number density N) for atmospheric-pressure discharges with current densities less than 1000 A cm^{-2} is controlled by a balance between the following bulk processes: ionization (rate coefficient k_i), attachment (rate coefficient k_a), recombination (rate coefficient k_r), and detachment (rate coefficient k_d). Thus the balance equation for electrons may be written as

$$n_e n k_i + n_n n k_d = n_e n_p k_r + n_e n k_a \quad (1)$$

where n, n_e, n_p, n_n are the number densities of neutrals, electrons, positive ions, and negative ions, respectively, and all the rate coefficients are appropriately weighted for the gas mixture [5]-[7]. The reaction products can affect some or all of these bulk processes, so that a change in the E/N value of the discharge results.

C. Main Discharge Stability

Although an initial electron density of $\sim 10^4$ cm^{-3} is adequate to ensure uniformity of the main pulsed discharge it is not adequate to sustain this main discharge, which requires an electron density of 10^{10}-10^{12} cm^{-3}. To achieve this electron density necessitates a main discharge E/N value which is so great that the diffuse discharge can rapidly undergo a transition into a single arclike channel. This is more likely to happen either when the main discharge pulse is long and the arc formative time lag is small [over voltage $(V - V_s)$ large, where V is the applied potential] [8] or when it is possible for all the stored energy to be guided into the one arc channel or when the attachment coefficient exceeds the ionization coefficient and has a positive dependence on the electron temperature [9].

D. Electron Excitation

If the breakdown potential V_s and running reduced field E/N are changed, for instance, by Sections I-A and B in the preceding, then the energy distribution and density of the electrons will change and the excitation rates to the upper and lower laser levels will be altered. Likewise, the rate of gas heating will vary, and changes in the optical gain will result.

E. Vibrational Excitation and Deexcitation

The lifetimes of the laser levels are controlled by collisional processes. The maximum rate constants for such processes are about 10^5 $torr^{-1}s^{-1}$, so that any gas species must have a partial pressure of at least 10 torr for effective collisional interaction within ~ 1 μs; i.e., the concentration of any reaction species must be at least ~ 1 percent of an atmospheric-pressure mixture to have an effect on the lifetimes of excited states in the discharge.

In a sealed-device dissociation products of CO_2, such as CO,O, and O_2, are found together with oxides of nitrogen and various positive and negative ions. There are also small amounts of H_2 and H_2O desorbed from the laser walls and electrodes. Since so many species are present it is not easy to identify their individual effects in a sealed device, but if they are selectively added to a flowing gas device, then their individual effects can be isolated.

We report here on the effects of the addition of the gases H_2, CO, O_2, N_2O, NO, and NO_2 on the output power and discharge stability of a flowing-gas TEA laser operating with a basic mixture of CO_2, N_2, and He. These additive gases can be expected to have considerable bearing on the operation of a sealed TEA laser in view of the previously mentioned effects, Sections I-A-E.

We have used a TEA laser similar to that described by Pearson and Lamberton [1]. The Rogowski profile electrodes are 20 cm long, 2 cm wide, and 1 cm apart. Electrical pulses were obtained from a 7.5-nF low-inductance capacitor discharged at about 1 pulse per second (pps) through a spark gap. The main discharge was initiated by photon emission from a predischarge between two trigger wires and the anode, the energy being supplied by two 180-pF capacitors charged to the same potential as the main capacitor. The flow rate of the $CO_2/N_2/He$-additive-gas mixture through the device was sufficient to completely change the gas between consecutive pulses. The individual gas flow rates were measured with calibrated flow meters. The resonant cavity consisted of a 100-percent plane reflector and a 20-percent transmitting germanium plane reflector separated by 30 cm. The output power was measured with a photon drag monitor together with a 100-MHz oscilloscope and camera. The pulse output was found to have a shape very similar to that obtained by Pearson and Lamberton [1], with a sharp initial spike followed by a long tail. The maximum peak power observed was 1.6 MW and the pulse energy was found to be linearly proportional to the peak power. The results in the following should be directly scalable to devices with larger excitation volumes.

II. Addition of Hydrogen

Both hydrogen and helium are known to be desirable additive gases in CO_2 lasers. In CW low-pressure devices (10-30 torr) helium lowers the gas temperature and relaxes the lower laser level, while in atmospheric-pressure devices the helium is found to be essential to stop the discharge developing in the arc mode. Normally, $CO_2/N_2/He$ TEA devices are operated with the minimum amount of helium necessary to avoid arc formation since this gives maximum power output, as the amount of CO_2 and N_2 is then a maximum. As mentioned in Section I-C, too large a discharge potential leads to arc formation. Deutsch [10] found that a TE laser at 50-250 torr can be operated at higher discharge potentials (and hence higher output powers) without the formation of arcs if 3-10 percent of hydrogen is added to the gas mixture.

We have studied the effects on the peak laser power output (W) of adding hydrogen to several different $CO_2/N_2/He$ mixtures (Fig. 1). The hydrogen has little effect when present up to 9 percent of the total gas pressure, but with greater amounts the output power drops. These results are replotted in Fig. 2 with the power output W, normalized to the power output with no added hydrogen W_0 and the added hydrogen expressed

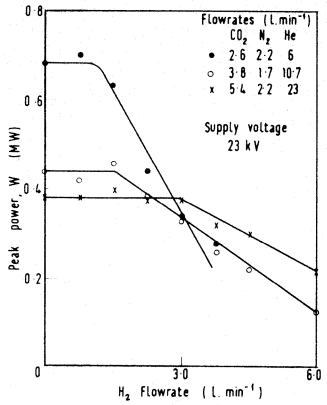

Fig. 1. Variation of laser peak power with flow rate of added hydrogen for three $CO_2/N_2/He$ mixtures.

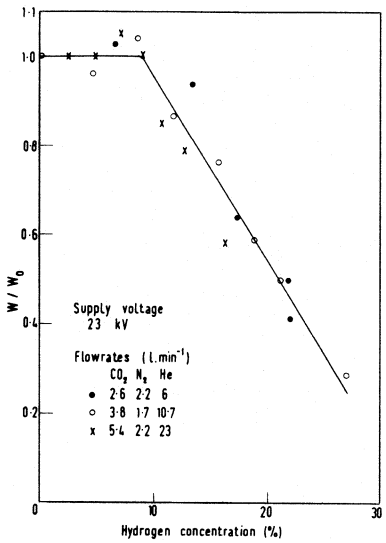

Fig. 2. Effect of addition of hydrogen on the normalized power output W/W_0 of a TEA laser.

as a percentage of the total gas mixture. One curve is seen to describe all three sets of results.

The total gas pressure in the laser was kept at 1 atm at all times and the flow rates of the CO_2, N_2, and He kept constant as the hydrogen was added. So as the hydrogen was added the other gases passed through the laser cavity faster and their partial pressures decreased. This could become significant for the carbon dioxide and nitrogen when a considerable quantity of the additive was used, but the composition change was small compared with that between the three sets of results of Figs. 1 and 2.

The general form of the curve can be understood in the following way. The ν_3 mode of CO_2 is collisionally excited by the $\nu = 1$ vibration of nitrogen with a time constant τ_1 of 400-700 ns (this is the major parameter causing the delay between the current pulse and the laser pulse). The ν_3 mode of CO_2 is deexcited by collisions with hydrogen. When the deexcitation time constant for the process is less than τ_1 the population of the ν_3 mode is significantly reduced, i.e., the laser power is reduced when

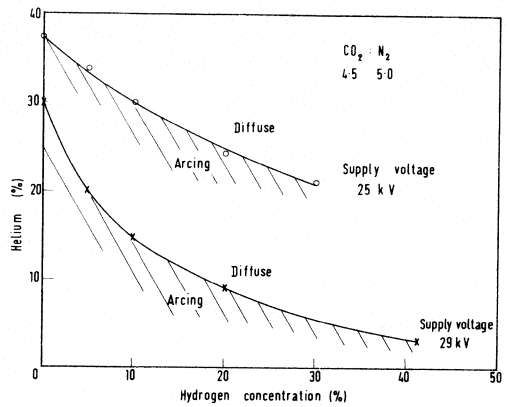

Fig. 3. Dependence of arcing limit in a $CO_2/N_2/He/H_2$ mixture at 25 and 29 kV on concentrations of He and H_2.

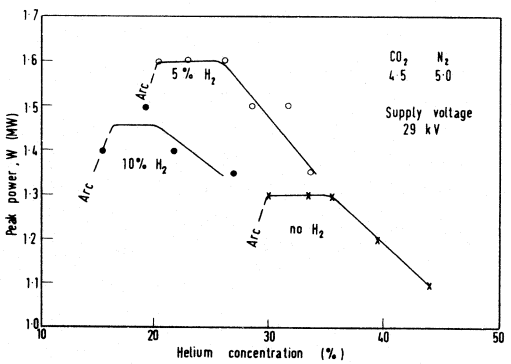

Fig. 4. Effect of the addition of hydrogen on the peak power output of a $CO_2/N_2/He$ TEA laser with varying amounts of helium.

$$\frac{1}{k_{H_2} P_{H_2}} \leqslant \tau_1$$

where k_{H_2} is the deexcitation rate constant of the ν_3 mode by collisions with molecular hydrogen [11] and P_{H_2} is the partial pressure of hydrogen. Taking the values $\tau_1 = 600 \times 10^{-9}$ s and $k_{H_2} = 5 \times 10^3$ torr^{-1} s^{-1} shows that the laser power should be reduced for $P_{H_2} \geqslant 300$ torr. This compares reasonably well with the experimental range of 70 torr for initial observation of power falloff and 250 torr for cessation of oscillation.

It is seen that up to 70 torr of hydrogen (9 percent) may be added without any loss of peak power. This allows the laser to be operated at higher voltages [10] (and hence higher energy input) and also allows the helium content in the gas mixture to be reduced. Fig. 3 shows this latter point for potentials of 25 and 29 kV. As the hydrogen percentage is increased, the helium percentage can be reduced without arcing. Further, Fig. 4 shows the peak power plotted against the percentage of added helium, for no added hydrogen, for 5-percent added hydrogen, and for 10-percent added hydrogen. With about 5-percent added hydrogen the peak power output can be at least 20 percent greater than without the hydrogen.

One of the functions of the hydrogen is to suppress the onset of the arc discharge, probably by enhancing the initial preionization, rather than altering the main discharge E/N. If the latter was so, one would expect a power increase with an other-

wise constant mixture as the hydrogen was added (see Section IV).

III. Addition of Oxygen and Carbon Monoxide

The carbon dioxide in a Pearson-type TEA laser is dissociated by 0.1-0.3 percent per discharge pulse [12]. The dissociation products are carbon monoxide and atomic oxygen. At atmospheric pressure the atomic oxygen is converted to molecular oxygen within a few milliseconds [13] by three-body collision processes and within this time it will have negligible effect on the vibrational excitation or relaxation of the carbon dioxide [14], [15].

We have selectively added molecular oxygen to several different $CO_2/N_2/He$ laser mixtures, and typical results are shown in Fig. 5. There is a slow decrease in power output with increasing amounts of oxygen added, the rate of decrease is the same for the different $CO_2/N_2/He$ mixtures at a given discharge voltage V, but varies with the value of V. No arcing was observed under any conditions.

The molecular oxygen is not present in sufficient quantity to alter the collisional lifetimes of the upper or lower laser states [16]-[18], nor is there any reason to think that oxygen will alter the photon preexcitation. Thus the most likely cause of the power decrease with added oxygen is that it has altered the E/N of the main discharge slightly, which in turn affects the laser excitation rate. The variation in E/N is brought about as follows. Oxygen has a similar rate of ionization in the discharge to carbon dioxide, but its electron attachment rate is an order of magnitude higher than that of CO_2 [9]. Consequently, to overcome this additional electron loss mechanism, the E/N value of the discharge must increase.

The effect on the laser power of the addition of carbon monoxide to several different $CO_2/N_2/He$ mixtures is shown in Fig. 6. As for oxygen there is a slow decrease in power output with an increasing amount of the additive gas, but in this case the rate of decrease depends slightly on the gas mixture. Arcing was easily obtained, occurring more readily at low values of $V - V_s$ and with mixtures low in helium content.

There is no reason to expect the carbon monoxide to affect the preionization, and in the quantities involved it will not significantly alter the lifetimes of the upper and lower laser levels [11]. However, the carbon monoxide may be expected to alter considerably the discharge E/N for the following reasons. As was discussed in Section I-B the E/N of the discharge is determined by a balance of the bulk charge collision processes. In the $CO_2/N_2/He$ laser the major dissociation process is via a neutral excited-state path [19] described by the reaction

$$CO_2 + e \longrightarrow CO_2^* + e \longrightarrow CO + O + e \tag{2}$$

but there will also be a small amount of dissociative attachment [20] according to the reaction

$$CO_2 + e \xrightarrow{k_a} CO + O^-. \tag{3}$$

The oxygen ion will rapidly form clusters with the carbon dioxide [21] rather than detach by collisions with other heavy particles. The resulting CO_3^- ions are relatively stable and it

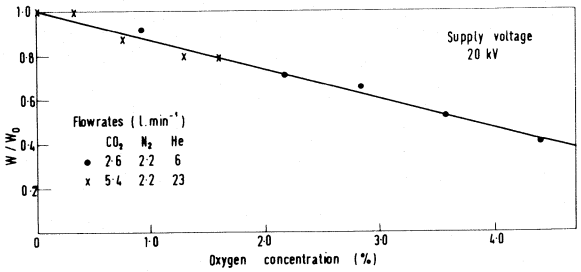

Fig. 5. Effect of the addition of oxygen on the normalized power output W/W_0 of a TEA laser.

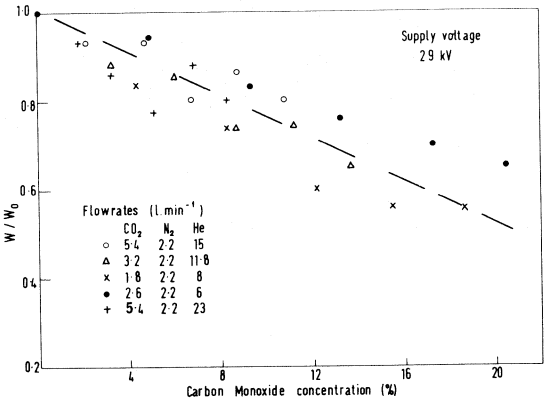

Fig. 6. Effect of the addition of carbon monoxide on the normalized power output W/W_0 of a TEA laser.

has been shown that [9] when the detachment rate is small (1) reduces to $k_i \approx k_a$. However, if carbon monoxide is present the extra detaching reaction

$$CO_3^- + CO \xrightarrow{k_d} 2CO_2 + e \tag{4}$$

occurs with a rate constant [21] (k_d) of 5×10^{-13} $cm^3 s^{-1}$. Although this is fairly slow, if sufficient carbon monoxide is added the effect is the same as if there were no negative-ion processes involved and the discharge can run at a lower value of E/N. The rate limiting process in the formation of the CO_3^- is the attachment reaction (3), so that in equilibrium this must balance the detachment reaction (4), i.e.,

$$n_e k_a [CO_2] = k_d [CO] [CO_3^-].$$

The ratio of concentration of negative ions to electrons is given by

$$\frac{[CO_3^-]}{n_e} = \frac{[CO_2]}{[CO]} \frac{k_a}{k_d} \tag{5}$$

assuming that the dominant negative ion is CO_3^-.

The value of k_a will of course depend on the gas mixture and exact discharge conditions, but in the TEA laser it will be $\sim 10^{-12}$ $cm^3 s^{-1}$, so that the negative-ion population is small compared with the electron population only when the carbon monoxide concentration is the same or greater than the carbon dioxide concentration. In our case the CO_2 concentration is 15-25 percent and the power decrease is ~20 percent with 9-percent added CO and 50 percent with 22-percent added

CO. The power is falling when the amount of added CO would be expected to lower the discharge E/N and hence increase the power output. Even if the reverse of reaction (3) is faster than expected this discrepancy would not be explained. An alternate hypothesis is that the added carbon monoxide used came from iron cylinders and may have formed iron carbonyls, which form negative ions and hence as the "carbon monoxide" is added so the discharge E/N would be raised [22].

IV. Addition of Oxides of Nitrogen

Tannen *et al.* [23] have measured both neutral species and positive ions in a dc electrical discharge in flowing $CO_2/N_2/He$ mixtures at low pressures (1-5 torr) and have found a considerable amount (100-1000 ppm) of the oxides of nitrogen. Bletzinger *et al.* [24] have suggested that the oxides of nitrogen, especially NO_2 and N_2O, may affect the discharge stability because of their high attachment rates. We have failed (using low-sensitivity mass spectrometry) to find any oxides of nitrogen (detection limit ~100 ppm) in atmospheric pressure TEA devices, but we have found some evidence at lower pressures (1-20 torr). Recently, NO and NO_2 have been observed [25] in concentrations of the order of parts per million in a flowing-gas TEA laser.

To determine the effects of NO, NO_2, and N_2O on the power output and discharge stability of the TEA laser we have added these gases to different $CO_2/N_2/He$ mixtures. Fig. 7 shows the effect on the peak power output of increasing the amount of N_2O and NO_2 in the gas mixture. The output power decreases by 50 percent with the addition of 0.23-percent N_2O or 0.15-percent NO_2. At a discharge potential of 20 kV arcing occurs with 0.42-percent N_2O or 0.26-percent NO_2, but at higher voltages arcing occurs with less of the additive gas.

Since such small amounts of NO_2 and N_2O cause a decrease in power output the effect cannot be due to any alteration of the lifetimes of the laser vibrational levels, nor is there any reason to expect that these gases alter the preexcitation photon processes. However, both N_2O and NO_2 are known to strongly attach electrons with attachment rates one to two orders of magnitude greater than CO_2 [9], [20], [26]. The ionization rate of N_2O is similar to that of CO_2 and that of NO_2 is probably also similar since its ionization potential is nearly the same. Thus the effect of adding both gases should be to raise the E/N of the discharge.

Fig. 8 shows the effect on the laser power of adding NO to three different $CO_2/N_2/He$ mixtures. There is a small increase (~15 percent in peak power output with about 0.2-percent added NO, and then a decrease with 50 percent of the original power being reached with about 2-percent added NO (but varying with the different $CO_2/N_2/He$ mixtures). No arcing was observed when adding these amounts of NO.

The initial power increase with added NO can be explained by its low ionization potential (9.2 eV) compared with CO_2 (13.79 eV). This gives NO an ionization-rate constant in a typical laser system nearly an order of magnitude greater than CO_2 or any of the other species, whereas its attachment rate is very similar to that of CO_2 [9]. Alternatively, it has been

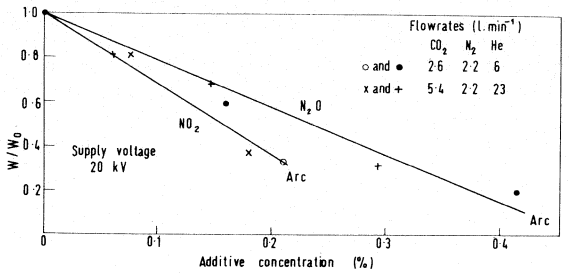

Fig. 7. Effects of the addition of nitrous oxide and nitrogen dioxide on the normalized power output W/W_0 of a TEA laser.

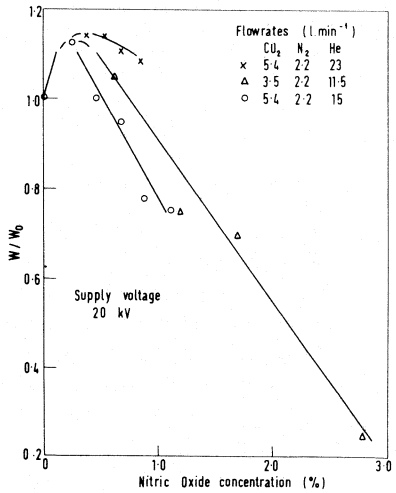

Fig. 8. Effect of the addition of nitric oxide on the normalized power output W/W_0 of a TEA laser for three $CO_2/N_2/He$ mixtures.

suggested that NO might increase the preionization because its ionization potential is low enough (9.25 eV corresponds to a photon of wavelength of 1340 Å) for the ~1200-Å photons thought to be responsible for the preionization to ionize it [27]. In either case the E/N value necessary to sustain the discharge is lower. The subsequent decrease in power is more difficult to explain: the collisional relaxation of the 001 laser level is not fast enough [28].

V. Conclusions

The method of selectively adding individual gases to the flowing-gas TEA laser has shown that the different gases have widely different effects on the laser power. Carbon monoxide and hydrogen have little effect until they are present in concentrations similar to those of the original gas constituents, whereas NO_2 and N_2O affect the laser power when present with a concentration about two orders of magnitude smaller.

N_2O, NO_2, O_2, and CO when present in any amount reduce the peak power output of the laser. However, small amounts of H_2 (~5 percent) and NO (~0.2 percent) can increase the peak output power, but larger amounts decrease it. H_2 (and possibly NO) limit the transition to arcing while O_2 does not seem to affect it. On the other hand, N_2O and NO_2 encourage the transition to arcing, but only after the power has been very greatly reduced. Carbon monoxide seems to affect the arcing in a more complicated manner. It limits the range of operation of the TEA laser, but within that range does not

affect the glow to arc transition until the power has been greatly reduced.

The increase in power output with the limited addition of hydrogen appears to be due to the ability of the laser to operate under better excitation conditions without arcing due to a change in the preionization process. Likewise, the initial increase in laser power with NO may be due to enhanced preexcitation. The only significant collisional effect with the laser vibrational levels is that of hydrogen in large concentrations when the upper laser level is deexcited. All the other effects appear to be due to changes in the main discharge processes which give rise to variations in the E/N value of the discharge and hence to variations in the rate of excitation of the upper laser level. It is clear from (1) that for a full analysis of the main discharge one needs a knowledge of all the ionization, recombination, attachment and detachment rates for each species, and how these rates vary with electron energy. Much of this information is not available. Both Nighan and Wiegand [9] and Bletzinger *et al.* [24] have attempted to determine theoretically the effects of additive gases on the discharge of a low-pressure gas laser by mainly considering the effects of the additives on the ionization and attachment rates. From this one would expect a lowering of the discharge E/N value with the addition of NO, large increases with the addition of N_2O and NO_2, a small increase with the addition of oxygen, and little effect with the addition of CO. If a lowering of the E/N value of the discharge is linked with improved laser excitation and an increase with poorer excitation, then the relative behavior of the power output with the addition of NO, NO_2, N_2O, and O_2, which we have observed, is clear. As we have seen and as Nighan and Wiegand [9] pointed out the situation with carbon monoxide may be more complicated because of the formation of fairly stable cluster ions. Also in the case of carbon monoxide such a large quantity of the gas is being added that it is not adequate to just consider a modification of the E/N of the discharge, the value of the optimum E/N for laser excitation may change [29].

The theoretical analyses should be extended to cover the potentially useful additive gases H_2 and NO and also CO because of its complicated effects. It would seem less necessary to investigate NO_2 and N_2O further because they do not become harmful until they reach a concentration of greater than 100 ppm, whereas they are almost certainly generated in sealed devices in concentrations considerably less than this.

Pulsed Operation of an Optically Pumped Far-Infrared Molecular Laser

H. J. A. BLUYSSEN, ROBERT E. McINTOSH, SENIOR MEMBER, IEEE, A. F. VAN ETTEGER, AND PETER WYDER

Abstract—**An investigation of the far-infrared (FIR) response of an optically pumped molecular laser to an infrared (IR) pulse source is presented. It is shown that a three-level laser model explains the observed amplitude and delay of FIR output pulses when a reduction factor for participating molecules is included in the model. A discussion of those physical mechanisms that might be responsible for the reduction factor is given along with a description of how the FIR laser's performance depends on various physical parameters.**

I. INTRODUCTION

SINCE Chang and Bridges reported the first optically pumped far-infrared (FIR) molecular laser in 1970 [1], this promising method of generating submillimeter waves has been studied extensively. Investigators have discovered over 250 lasing transitions at wavelengths ranging between 40 and 2000 μm using at least 18 different molecules. Although CW operation is possible for approximately 25 percent of these transitions, most experimental studies have utilized pulsed infrared (IR) pump sources owing to the large amounts of FIR output which can be achieved. TEA lasers have been used, for example, to generate FIR pulses of several kilowatts [2]. An excellent review of FIR molecular laser development has been recently given by Chang [3].

In their first paper, Chang and Bridges described the pressure dependence of the peak amplitude of a 496-μm FIR pulse which was generated in CH_3F by a 1.5-kW CO_2 laser pulse. They measured this amplitude to increase with pressure up to approximately 0.08 torr and, after being constant to approximately 0.400 torr, to drop off rapidly to zero at 1 torr. They observed the pulse duration to be approximately one-half of a microsecond. More interestingly, they observed a noticeable delay between the start of their Q-switch CO_2 pump pulse and the peak of the FIR output. This delay increases with decreasing pressure to 1.5 μs at a few millitorr.

Although the qualitative behavior of a molecular laser has also been discussed by other authors, we are unaware of literature in which the dynamics of the FIR lasing mechanism during transient pumping is analyzed. In particular, it is felt that there is a strong need to develop appropriate models that adequately predict the dependence of FIR output pulse characteristics from the IR pump excitation and the physical properties of the lasing molecules. In addition to giving a better understanding of the physical mechanisms themselves, such models are essential to the further development of these devices for application. The results reported in this paper follow from our effort to contribute to these objectives.

In this paper we present experimental measurements of FIR pulses generated in an optically pumped molecular laser similar to that described by Chang and Bridges and we compare these results with calculations made using the three-level maser model of Bloembergen [4].

In Section II we describe the experimental apparatus which is used to measure those FIR pulse parameters indicated in Fig. 1 as follows: 1) peak amplitude; 2) delay between start of pump pulse and peak of FIR pulse; and 3) pulse half-width. Details are given related to the test apparatus and measurement procedure. Of particular interest are the precautions used to eliminate the effect of the fluctuations of the pump source on the measurements. We complete this section by presenting typical amplitude and delay measurements of FIR pulses generated in $C_2H_2F_2$.

The time-dependent three-level maser model of Bloembergen [4] is used in Section III to describe the transient behavior of the molecular laser. Rate equations for the population of the participating laser levels are given along with the equation governing FIR radiation resulting from the stimulated emission occurring in the cavity. The coefficients for these nonlinear

equations can be specified for the case of a CH_3F laser because the rotational-vibrational laser transitions for 496-μm FIR radiation have been completely specified [1]. Consequently, we have been able to numerically compute the temporal behavior of the population levels and the FIR output as a function of pressure. Comparing calculations of FIR pulse amplitude and delay with measurements, we obtain qualitative agreement over the entire pressure range. However, in order to achieve quantitative agreement, we must introduce a phenomenological pressure-dependent factor in our model. The pressure dependence of this factor suggests that collisional-dependent effects play a role in FIR molecular lasers at lower operational pressures.

The dependence of our solution on parameters such as the cavity decay time, the frequency of collisional deexcitation, and pulse pump power and shape are also discussed in Section IV. This discussion is of interest because it sheds light on the performance of optically pumped FIR laser systems (including those where the precise levels of the lasing transitions have not been identified) which are to be designed.

II. Pulse Measurements

The experimental test system used to measure the FIR pulse characteristics is shown in Fig. 2. The major components of this system include: 1) the FIR molecular laser; 2) the Q-switched IR pump laser; 3) the IR and FIR detection systems; and 4) the video recording system (to facilitate the data gathering). Each of these subsystems is described briefly.

FIR Molecular Laser

The FIR laser under test is similar to that originally described by Chang and Bridges [1]. The laser cavity is formed from one concave (2.5-m radius of curvature) gold-coated aluminum mirror located approximately 1 m from a gold-coated flat mirror. Both mirrors are 10 cm in diameter and the spherical mirror is mounted on a micrometer stage for tuning purposes. A 1.6-mm hole is located at the center of the flat mirror in order to allow the transmission of the pump and FIR radiation in and out of the cavity. The FIR output is deflected by a 45° gold-coated mirror and leaves the vacuum vessel through a TPX lens as a parallel beam. Absolute pressure measurements of the test gas were provided by a McLeod manometer.

IR Pump Laser

The pump radiation is provided by a CO_2 laser consisting of a gold-coated (4.0-m radius of curvature) spherical mirror and a gold-coated grating having 72 lines per millimeter. The grating is mounted on a piezoelectric translator so that each CO_2 laser transition may be tuned over approximately 100 MHz. Q switching is achieved by means of an air-driven rotating mirror which is situated within the laser cavity. The CO_2 laser beam is focused into the FIR cavity by means of a Ge lens after reflecting off of a beam splitter (80-percent reflecting Ge plate). We have determined that the CO_2 pulses entering the FIR cavity region have peak powers of several hundred watts and durations ranging from 300 to 400 ns when the Q switch is rotating between 40 and 100 Hz.

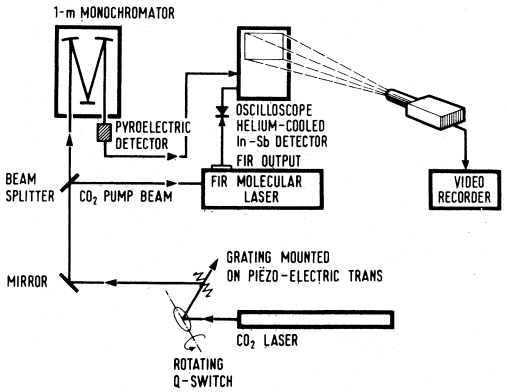

Fig. 2. The experimental test system used to measure FIR pulse characteristics.

IR and FIR Detection Systems

The beam splitter transmits approximately 20 percent of the CO_2 pulse to a 1-m monochromator which has a pyroelectric detector at its output. With the entrance and exit slits nearly closed, this system is used to resolve the CO_2 pump transition to well within the desired accuracy. With the slits wide open, the system is a sensitive detector having a rise time of approximately 5 ns. The FIR radiation pulse is detected by means of a helium-cooled InSb element placed in an external magnetic field. The sensitivity of this device is specified as 200 V/W and the rise time is less than 100 ns at 500-μm wavelengths. The outputs of the IR and FIR are both fed to a double-beam oscilloscope having 20-MHz bandwidth. Both channels of this oscilloscope are triggered by the output of a photodetector that monitors a He-Ne laser beam reflected off the rotating mirror which Q switches the CO_2 laser.

Video Recording System

As the Q switching of the CO_2 laser results in some fluctuations in the pump pulse amplitude and frequency, it is useful to obtain records of the pulse shape of each FIR output pulse and its corresponding excitation pulse. Since the output pulses are observed to depend on peak pump power, these records are used to insure that data presented in our experimental curves represent a constant pump power. (This precaution is particularly important near the high- and low-pressure cutoffs where the FIR signal is strongly affected by small pump fluctuations.) We have recorded the shapes of the CO_2 pump pulse and the FIR output pulse using a television camera and a video recording unit during the performance of the experiment. Consequently, the experimental data presented in this paper were obtained by viewing each pair of pulse images when replaying the tape afterwards. Although each pair of images represents an average of three consecutive pulses (due to the finite scan time of the camera), this technique is successful in removing fluctuations having a frequency of less than 20 Hz.

Measurements of the pump and FIR pulse were obtained for pressures of the test gas inside the molecular laser between 0.004 and 0.3 torr. A video tape of these measurements at each pressure was made over a 1-min interval with the result

that each ensemble contained approximately 3000 pairs of pulse images. In playing back the tapes, we used those ensemble images which corresponded to the larger FIR pulses in obtaining measured values of the signal characteristics shown in Fig. 1. This was done to eliminate effects due to frequency variations that may occur in the pump signal. By choosing the maximum output signals corresponding to a given CO_2 pump power, we maintain that all measurements presented were obtained while the pump frequency was optimally tuned to the FIR transition. Although these precautions seem unnecessary in the case of the CH_3F laser, which is discussed in detail in the next section, they are clearly necessary in the case of the $C_2H_2F_2$ laser. In the latter case, we found fluctuations in the pump signal to cause standard deviations in the FIR pulse amplitude, delay, and half-width of up to 10 percent of the mean values.

We note here that experimental errors in determining the peak CO_2 and FIR pulse amplitudes and the pressure of the molecular test gas are estimated to be less than 10 percent for most of our measurements. The errors in our pressure measurements may be greater than 10 percent at pressures below 10 mtorr, but only one experimental data point is presented in this paper (see Fig. 6) in this pressure range.

Typical experimental results are shown in Fig. 3 that show the peak amplitude and time delay for the $C_2H_2F_2$ molecule as a function of pressure. Shown is the 554-μm wavelength which is pumped by the 10.53-μm CO_2 laser line. Since the nature of the lasing transitions is not known for $C_2H_2F_2$ as far as we know, we were unable to calculate theoretical curves for comparison with these measurements. However, it is useful to examine these results before proceeding because such an examination is helpful in understanding the theoretical results given for the CH_3F molecule in the next section.

The behavior of the peak amplitude and delay for $C_2H_2F_2$ are similar to that for CH_3F as previously described by Chang and Bridges. The most significant differences are that $C_2H_2F_2$ exhibits a larger low-pressure cutoff than CH_3F and the flat portion of the peak amplitude-pressure curve which is so noticeable for CH_3F is absent in the case of $C_2H_2F_2$. A comparison of the high-pressure cutoff is not meaningful because our measurements were performed using a lower pump field. We also observe that the delay between the excitation and FIR response pulses is minimum at the maximum of the peak amplitude curve. In addition to observing the increase of delay with decreasing pressures noted earlier at low pressures in CH_3F [1], we measure the pulse delay to increase at high pressures in $C_2H_2F_2$. This last effect has also been observed by us in other gases at other frequencies but we, like Chang and Bridges, have not observed this behavior in CH_3F.

Summarizing, we state that in those cases measured by us, substantial delays are always observed at low pressures when the peak amplitude is small. We have also observed increased delay at higher pressures when the peak amplitude begins to drop off in various gases. We show that the observed relationship between amplitude and delay results directly from the role which the number of participating molecules plays in the rate equations given in the next section.

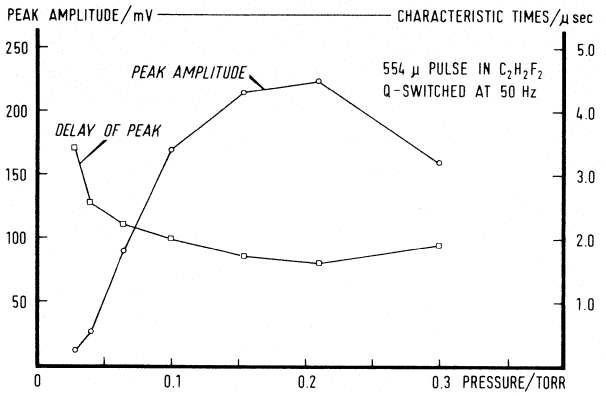

Fig. 3. Experimental results showing the peak amplitude and time delay for the $C_2H_2F_2$ molecule as a function of pressure. A 10.53-μm CO_2 laser line was used as a pump to generate a 554-μm FIR output.

III. Solution of Three-Level Model

To better understand the generation of FIR pulses in CH_3F we have used a three-level system for our theoretical model similar to that proposed by Bloembergen [4] for an RF pumped solid-state maser. Although the system of energy levels for methyl fluoride is known to be more complicated than the system assumed here, we justify the use of a simplified model as a first approximation by the following remarks.

1) Pumping may occur simultaneously for two transitions (see Fig. 4(a)), while six transitions may give rise to laser action. In the three-level model shown in Fig. 4(b) we consider only the pumping transition $(\nu, J, K) = (0, 12, 1) \rightarrow (1, 12, 1)$ and the laser transition $(1, 12, 1) \rightarrow (1, 11, 1)$. In our experiments, we tune the FIR cavity so that only the $(1, 12, 1) \rightarrow (1, 11, 1)$ transition lases. In that case, the stimulated emission rate for the $(0, 13, 1) \rightarrow (0, 12, 1)$ transition must be small during the pump pulse owing to the long delay times observed for this transition [1]. The replenishment of the $J = 12$ level by this transition can be neglected, therefore, during the pump pulse. The effect of the stimulated emission of the cascade transition $(1, 11, 1) \rightarrow (1, 10, 1)$ on the population level of the $J = 11$ level may be included in the rate equations and does not influence the total number of molecules in our three-level model.

2) The $\nu = 0$ state has a number of rotational levels which have energies that differ from the lower pump level (0, 12, 1) by less than κT. Participation of these levels in the pump dynamics is limited below pressures of 0.1 torr, because the duration of the pump pulse (approximately 0.3 μs) is equal to or less than the characteristic time for reaching thermal equilibrium by collisional relaxation (greater than about 0.3 μs at pressures below 0.1 torr).

3) CO_2 power simultaneously pumps the desired pump transition and the $(0, 12, 2) \rightarrow (1, 12, 2)$ transition. However, we estimate that only 10-15 percent of the CO_2 power pumps the $K = 2$-band transition when the pump power is tuned such that optimum output power from the $(1, 12, 1) \rightarrow (1, 11, 1)$ lasing transition occurs. This is within the experimental error of our pump power measurements.

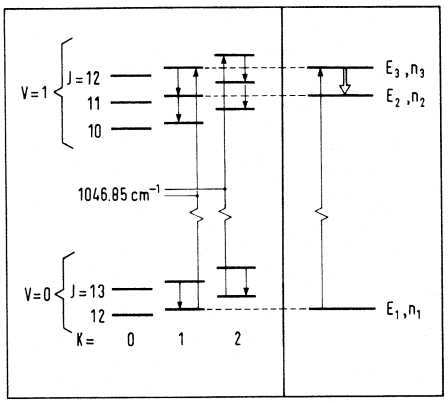

Fig. 4. Energy-level diagrams for CH_3F. (a) Laser transitions observed by Chang and Bridges [1]. (b) Three-level model used in present calculations.

4) Finally, energy transfer between the pumped levels of the $K = 1$ and $K = 2$ bands may have an effect on the number of molecules assumed in our three-level model. This effect is neglected in our initial calculations but we later acknowledge that the transfer of energy between K levels may provide some of the justification needed to introduce a phenomenological factor into subsequent calculations. This factor modifies the number of molecules in the system that participate in FIR lasing.

A three-level model yields the following set of rate equations which relate n_3 and n_2, the populations of the upper and lower laser levels, to the FIR laser radiation $\rho_1(t)$, which builds up in the cavity due to stimulated emission.

$$\begin{aligned}\partial n_3/\partial t = {} & n_3[-(g_3/g_1+1)B_{31}\rho_p(t) - w(1.008+A)] \\ & + n_2[-(g_3/g_1)B_{31}\rho_p(t) - w(0.008-0.91A)] \\ & + B_{32}\rho_1(t)[(g_3/g_2)n_2 - n_3] \\ & + n_0[(g_3/g_1)B_{31}\rho_p(t) + 0.008w] \qquad (1)\end{aligned}$$

$$\begin{aligned}\partial n_2/\partial t = {} & n_3[A-0.008]w - n_2[0.91A+1.008]w \\ & + B_{32}\rho_1(t)[n_3 - (g_3/g_2)n_2] + 0.008n_0w \qquad (2)\end{aligned}$$

$$\begin{aligned}\partial\rho_1/\partial t &= B_{32}h\nu_{32}[n_3 - (g_3/g_2)n_2]\rho_1 - \rho_1(t)/\tau \\ &= G_T\rho_1(t) - \rho_1(t)/\tau. \qquad (3)\end{aligned}$$

The statistical weights for the various rotational levels involved are given by $g_i = 2J_i + 1$, and n_0 is the total number of molecules present in the three levels. In our model we assume that the collisional deexcitations from the two lasing levels to the ground state are the same; i.e., the deexcitation rates w_{31} and w_{21} are expressed by the quantity w, which is given by $w = \pi\Delta\nu_p$, where $\Delta\nu_p$ is the pressure-broadened linewidth. The collisional deexcitation rate from the upper level to the intermediate level is, in general, not the same as w and we take account of this by defining the ratio $A = w_{32}/w$. The constant τ accounts for FIR cavity losses and is given by $(L/c\gamma)$ where L is the cavity length, c is the speed of light, and γ is the cavity attenuation factor. Furthermore, the numerical constants in (1) and (2) follow from the evaluation of the quantities; $\exp[-h\nu_{13}/\kappa T]$, $\exp[-h\nu_{12}/\kappa T]$, and $\exp[-h\nu_{23}/\kappa T]$ at room temperature and the respective transition frequencies.

In the preceding equation, $B_{31}\rho_p(t)$ and $B_{32}\rho_p(t)$ are the induced transition rates for the pump and laser transitions, respectively. Their theoretical values are computed from

$$B_{3j} = 2\pi_2|\mu_{3j}|^2 g(0)/3h^2\epsilon_0 \qquad (4)$$

at resonance where $|\mu_{31}|^2$ and $|\mu_{32}|^2$ are the electric dipole moment matrix elements. In the case of the pump transitions the linewidth $\Delta\nu_D$ is Doppler broadened[1] and $g_D(0) = 0.939/\Delta\nu_D$. The FIR laser transition is assumed to be partly pressure broadened and in this case we take $g(0) = [(\Delta\nu_D/0.939)^2 + (\Delta\nu_p/0.637)^2]^{-1/2}$. Thus, at high pressures, $g(0) = 0.637/\Delta\nu_p = g_p(0)$ and at low pressure, $g(0) = g_D(0)$.

It is widely known that the theoretical FIR radiation gain of optically pumped molecular lasers [$G_T = B_{32}h\nu_{23}[n_3 - (g_3/g_2)n_2]$ in (3)] is greater than that achieved in practice. This discrepancy may be caused by a host of physical mechanisms; however, our present thinking is that one of the two mechanisms given in the following is responsible for the output power limits of the FIR laser.

1) Hole-Burning: The linewidth of the pump transition is Doppler broadened and is much larger than that of the pump radiation (30 MHz versus 3 MHz). The pump radiation therefore excites only a portion of the molecules occupying the lower pump level (1). Collisions tend to restore the equilibrium velocity distribution within that pumped rotational sublevel and the rate of this velocity cross relaxation depends on pressure. Consequently, the number of molecules assumed to participate in the lasing process is both high and pressure dependent.

2) Population Diffusion to Other States: Above 0.25 torr some of the molecules may be pumped to levels other than the upper level of the assumed three-level model. Also some mole-

[1] In Section IV we note that pressure-broadening effects might also play a role in FIR generation.

TABLE I
PHYSICAL PARAMETERS FOR CH_3F FIR LASER

Physical parameter	Symbol	Value	Units
1. Electric dipole moments	μ	6.17×10^{-30}	Coul.m
	$\lvert\mu_{31}\rvert^2 = \frac{\mu^2 K^2}{J(J+1)}$	2.44×10^{-61}	$[\text{Coul.m}]^2$
	$\lvert\mu_{32}\rvert^2 = \frac{\mu^2(J^2-K^2)}{J(2J+1)}$	1.815×10^{-59}	$[\text{Coul.m}]^2$
2. Doppler line-widths	$\Delta\nu_D$	1.3×10^6 (for $\nu_{32}=6\times10^{11}$ sec^{-1})	sec^{-1}
		6.8×10^7 (for $\nu_{31}=3\times10^{13}$ sec^{-1})	
3. Pressure broadened line width FIR line.	$\Delta\nu_p$	$5. \times 10^6$ (at .1 Torr)	sec^{-1}
4. Total number of molecules per meter^3	n_0	1.6794×10^{19} (at .1 Torr)	m^{-3}
5. Initial number of molecules in upper levels	$n_3(0)$	$.00730\ n_0$	m^{-3}
	$n_2(0)$	$.00868\ n_0$	
6. Initial FIR energy [note: solution nearly independent of this quantity]	$\rho_1(0)$	3.182×10^{-25}	Watt.sec.m^{-3}
7. FIR cavity decay constant	τ	$7. \times 10^{-8}$	sec
8. Deexcitation ratio	A	1	dimensionless

cules on the upper level may be transferred by means of collisions to levels not included in our model. An indication of the levels involved has been given by Weitz *et al.* [6], [7], who have made fluorescence measurements. These effects should also cause the effective number of molecules in our model to be lower and pressure dependent.

To account for these effects in our model, we introduce a pressure-dependent reduction factor $F(P)$, such that the population n_j at each level is replaced by an effective population $F(P)n_j$. Replacing n_j by $F(P)n_j$ in (1)-(3), we obtain three new system equations. The first two equations are identical to (1) and (2) after they have been divided by $F(P)$, but the third equation takes the form

$$\partial\rho_1/\partial t = F(P)G_T\rho_1 - \rho_1/\tau. \tag{5}$$

From the resulting equations, we note that the reduction factor $F(P)$ has the effect of modifying the gain G_T in (5).

For reference purposes, the values of the various physical parameters used in this paper are summarized in Table I. In this table $n_2(0)$, $n_3(0)$, and $\rho_1(0)$ are the initial values of the three independent variables.

Computed Results

Equations (1)-(3) have been solved on an IBM 370/158 computer using Hamming's modified predictor-corrector method for the pump transitions $(\nu, J, K) = (0, 12, 1) \rightarrow (1, 12, 1)$ and the lasing transition $(1, 12, 1) \rightarrow (1, 11, 1)$ in CH_3F. Here the usual symbols ν, J, and K are used to indicate the vibrational (ν) and rotational (J and K) quantum numbers of the symmetric top molecule under study. The time dependence of the pump energy in our program was chosen to be

$$\begin{aligned}
\rho_p(t) &= 0, && t < 0.4 \\
&= \rho_{p0} \exp\left[-(t-1)^2/\sigma_1^2\right], && 0.4 < t < 1 \\
&= \rho_{p0}\left[(1-K)\exp\left[-(t-1)^2/\sigma_2^2\right] - K(t-3)/2\right], && 1 < t\ 3 \\
&= 0, && 3 < t
\end{aligned} \tag{6}$$

where t is given in microseconds. By varying the peak pump energy ρ_{p0}, the variances σ_1 and σ_2, and the parameter K (which accounts for the tail which is occasionally observed on the excitation pulse), the IR pump signal can be simulated rather accurately for various Q-switch repetition rates. For the calculations presented here we use the values: $\rho_{p0} = 1.5 \times 10^{-4}$ W · s/m^3; $\sigma_1 = 0.1$ μs; $\sigma_2 = 0.25$ μs; and $K = 0.001$ to represent the CO_2 pulse Q switched at 100 Hz. In the fourth section we discuss the effects that alterations in the pump pulse shape have on FIR pulses.

Fig. 5 shows the solution of the rate equations for the CH_3F molecule lasing at 496 μm at pressures of 0.125 and 0.3 torr. These curves correspond to a pump pulse (see hashed curve) having 300-W peak power and a duration of 320 ns. In both cases, the population inversion reaches its maximum value at the peak of the pumping pulse. At 0.125 torr, a rapid increase in FIR stimulated emission quickly depletes the population inversion level to about 18 percent of its maximum value. This rapid switching may account for the steepened front edge of the FIR response which is observed experimentally. At the 0.3-torr pressure, this switching phenomenon is no longer present and the FIR peak output is delayed more than at 0.125 torr. Although this last result is consistent with

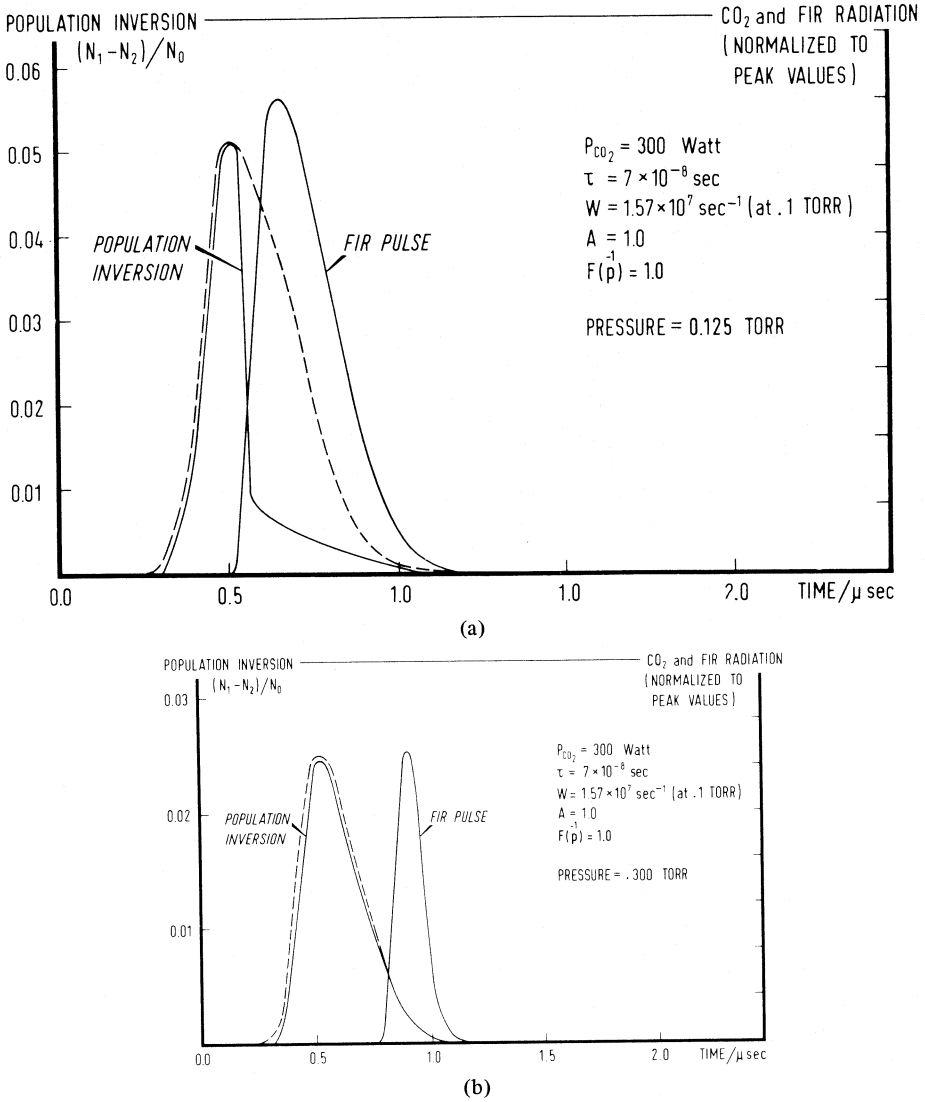

Fig. 5. Solution of the rate equations for the CH_3F molecule lasing at 496 μm at a pressure of 0.125 and 0.3 torr. These curves correspond to a pump pulse of the 9.55-μm CO_2 line (hashed curves) having 300-W peak power and a duration of 320 ns.

measurements made in other gases, it does not agree with experimental measurements of CH_3F radiation at 496 μm.

The experimentally and theoretically determined values of the peak pulse power and delay between the start of the pump pulse and the peak of the FIR pulse are shown in Fig. 6(a) as a function of pressure. Although these results are in qualitative agreement, there are quantitative disagreements which need resolution. The salient difference between the theoretically computed results and the measurements lies in the magnitude of the computed gain in the pressure range of maximum output. Besides yielding peak amplitudes which are larger than those experimentally observed, the calculated amplitude response with pressure is not flat in the 0.05–0.19-torr pressure range. Further, the measured increase in delay that occurs at pressures below 0.04 starts at pressures below 0.01 in our model.

Both of these differences have been traced to the strong dependence that the peak amplitude and delay of the FIR pulse have on the number of molecules in our three-level system. Consequently, we have carried out a numerical search for the phenomenological function $F(P)$ in (5) which causes the experimental and computed amplitude curves to agree. We found that the values of $F(P)$, which give agreement between measured and computed amplitudes, also result in agreement between measured and calculated pulse delays [see Fig. 6(b)]. It is our feeling that the computation of a single function $F(P)$, which causes both signal characteristics to agree with measurement over the entire pressure range, is evidence that the observed amplitude and delay behavior results from the effective reduction of participating molecules. A plot of the obtained phenomenological factor $F(P)$ is shown in Fig. 7. It is seen that this function increases nearly linearly with pressure.

Computed responses of the population inversion and FIR output after inclusion of the factor $F(P)$ are shown in Fig. 8 for two pressures. We observe larger FIR pulse rise times than for our previous calculations. The calculated pulse half-widths for both sets of calculations do not vary significantly with pressure. However, the computed pulse durations are less (ap-

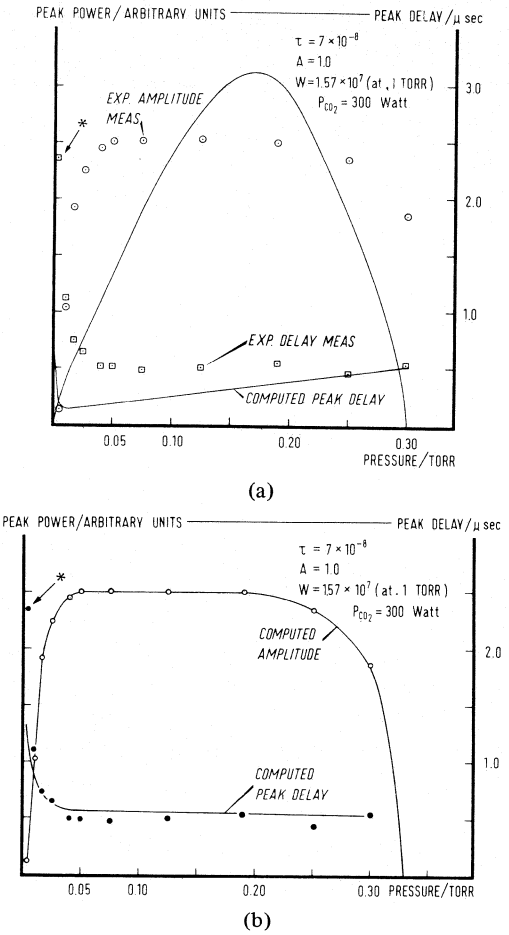

Fig. 6. Experimentally and theoretically determined values of the FIR pulse power and delay between start of the pump pulse and peak of the FIR pulse as a function of pressure for the CH_3F molecule lasing at 496 μm and pumped by the 9.55-μm CO_2 line. (a) The calculations made with the theoretical FIR radiation gain G_T. (b) The calculations made with the phenomenological value $G_p = F(P)G_T$. proximately 0.3 μs) than those observed experimentally by us and Chang and Bridges (approximately 0.500 μs). We believe that this inconsistency may be explained by the rise time of the InSb detector (less than 0.100 μs) which was used to obtain the measurements.

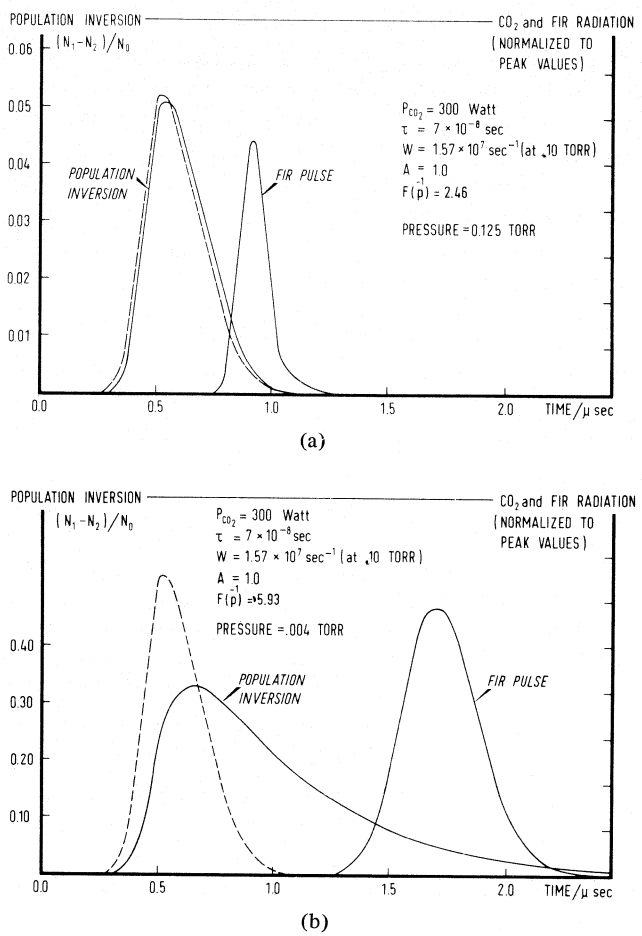

Fig. 8. Solutions of the rate equations for the CH_3F molecule lasing at 496 μm at a pressure of 0.125 and 0.004 torr. These curves correspond to a pump pulse (hashed curves) of the 9.55-μm CO_2 line having 300-W peak power and a duration of 320 ns. Calculations were made using the phenomenological FIR radiation gain $G_p = F(P)\,G_T$ shown in Fig. 6.

IV. Discussion

The results of the previous section indicate that the observed pressure-dependent time delays are explained by the effective number of molecules participating in lasing in the optically pumped medium. In the following, we elaborate on how the pressure dependence of $F(P)$ may be caused by the CO_2 pump radiation "burning a hole" in the Doppler distribution of the molecular transitions. We then note the effects that other physical parameters may have on the pulsed operation of the optically pumped FIR laser.

The dependence of the gain factor for FIR radiation [G_T in (3)] is proportional to both the population inversion density Δn and the line-shape factor at resonance $g_D(0)$. In addition to depending on the intensity of the pump radiation, Δn is directly proportional to the number of molecules in the gas that actually participate in the lasing process. We have already noted that the linewidth of the pump transition (approximately 30 MHz owing to Doppler broadening) is much larger than the linewidth of the pump radiation (approximately 3 MHz for a CO_2 pump pulse of 320-ns duration). Consequently, the pump radiation excites only those molecules occupying a 3-MHz portion of the pump transition distribution. This means that the number of molecules assumed to

participate in the lasing process in our calculations [where $F(P) = 1$] is high, and therefore the observed gain should be less than the theoretical gain. In fact, a reasonable first estimate of the reduction factor $F(P)$ from this mechanism might be to take the ratio of the CO_2 radiation linewidth to the IR pump transition linewidth. However, at high enough power the CO_2 beam will "burn a hole" into the distribution of the pump transition. In this case the width of the hole, and therefore $F(P)$, may be related to the pressure-broadened component of the pump transition and to velocity cross relaxation [5] in addition to the half-width of the pump radiation. The former two factors are of interest because they indicate the rate at which molecules having transition energies outside the hole region can contribute to the supply of molecules participating in the FIR lasing process. This rate of contribution should be greater for high pressures than for low pressures owing to collision effects. It may be expected, therefore, that the effective value of n_0 increases with pressure in agreement with the computed results shown in Fig. 7.

It is reasonable to expect that in addition to the mechanism described in the preceding, there may be other effects which decrease the actual number of molecules taking part in the FIR laser action. We have already mentioned that some of the molecules may be pumped to levels other than the upper level of the three-level model assumed. Also some molecules in the upper level may be transferred to levels not included in our model. We have not conjectured how these mechanisms yield the observed pressure dependence of $F(P)$, however, because the transfer process is not clearly understood at this time.

Gain reduction through changes in the line-shape factor at low pressures implies that the laser transition linewidth does not increase with pressure as rapidly as assumed in our model. Diffusion effects may account for some of this discrepancy in a qualitative way. However, it can be shown quantitatively that this mechanism only accounts for a small fraction of the gain modification needed to explain the observed amplitude and delay curves.

In comparing theory with measurements for CH_3F, we have used known physical quantities in the calculation of the three-level model. In addition, we have varied these parameters in our computations to gain insight into the relationship that these quantities have with the peak pulse amplitude and delay of the FIR pulse. We summarize our conclusions in the following.

1) Dependence on Pump Power Radiation Level ρ_p: The peak FIR pulse energy is dependent on the level of pump radiation. Although this dependence is less important at low pressures, owing to saturation effects, we find the upper pressure limit (where lasing ceases) to be strongly dependent on the pump level. Thus our theoretical model predicts the experimentally known fact that increased output is achieved when both the CO_2 pump radiation and molecular gas pressure are increased. Our model also suggests that the delay is related to the level of pump radiation.

2) Dependence on CO_2 Pump Pulse Shape: We have varied the pulse-shape parameters appearing in (6) and have determined that the FIR pulse characteristics depend primarily on the integrated pump radiation (i.e., $\int \rho_p(t)\,dt$) in our model. Thus we predict that the shape of the pump pulse is of little importance in designing pulsed optically pumped molecular lasers.

3) Dependence on Collisional Deexcitation Rates w and Aw: Collisional deexcitation is unimportant at low pressures, according to our calculations. However, we find the pressure range over which lasing occurs to depend strongly on w. This range is extended considerably, for example, when the collisional deexcitation rate is reduced. By reducing w, we find that the computed peak pulse amplitude is substantially increased, whereas the delay is hardly affected. The dependence of pulse characteristics on A has been found to be small, confirming that the choice of this parameter is not critical in calculations.

4) Dependence of Cavity Decay Time τ: We find that increasing τ leads to enhanced FIR output power levels but has no appreciable effect on pulse delay. For example, an increase in τ from 70 to 100 ns results in approximately twice as much peak FIR pulse energy. Further increases in τ, however, will not result in additional power out for a practical system because these increases can be achieved only by reducing the size of the hole through which FIR radiation is coupled out of the laser.

Acknowledgment

The authors wish to thank H. Fetterman and T. Y. Chang for useful discussions related to this work. They also wish to thank P. Groen for his assistance with the computer program and H. Salemink for his assistance with the experimental measurements.

Effect of Rotational and Intramode Vibrational Coupling on Short-Pulse Amplification in CO_2

ROBERT J. HARRACH

Abstract—**The extraction of stored energy from a CO_2-laser amplifier by a short-duration input pulse is described using a rate-equation theory. The influence of rotational and intramode vibrational energy-transfer processes is studied as a function of the energy density E_{in} and width τ_p of the input pulse. By a suitable choice of normalized variables δ and E_{in}/E_{sat} for the extracted-energy and input-energy density, it is found that the results for different values of τ_p are interrelated by simple translations in a δ versus E_{in}/E_{sat} diagram. The characteristic curves in this diagram are nearly independent of the amplifier gain factor exp ($\alpha_0 L$) for high-gain systems. A comparison of the theory with experimental results of Figueira *et al.* shows satisfactory agreement and leads to an estimate of (1.0-3.5) 10^6 $s^{-1}torr^{-1}$ for the rate of intramode vibrational-vibrational (VV) energy transfer in CO_2.**

I. Introduction

PREVIOUS STUDIES have shown that the saturation characteristics of high-pressure molecular-laser amplifiers are significantly affected by rotational energy transfer [1]-[6]. In particular, the rotational relaxation rate [4] of about 10^7 s · torr in carbon dioxide gas accounts for a substantial increase in the energy gain experienced by a nanosecond-duration pulse in an atmospheric-pressure CO_2 amplifier [1]. Beyond this, we show that intramode vibrational-vibrational (VV) energy transfer is rapid enough to influence amplification on a time scale of about 50 ns. The analysis is based on a reservoir model [1] to describe rotational coupling and a vibrational-temperature model [7], [8] to calculate the effect of vibrational relaxation. The theory is applied to interpret some recent experiments by Figueira *et al.* [5] on energy extraction by short-duration pulses in a heavily saturated CO_2 amplifier.

The range of effects one can expect is gauged by the parameters τ_p/τ_r, τ_p/τ_{vv}, and E_{in}/E_{sat}, where τ_p is the duration of the input pulse and E_{in} is its energy density. τ_r and τ_{vv} represent characteristic times for rotational and intramode VV energy transfer. E_{sat}, which is inversely proportional to the product of the absorption cross section σ and the energy gain factor exp ($\alpha_0 L$) of the amplifier, is a characteristic saturation level for the input-energy density. By including the influence of intramode VV as well as rotational interactions, we are able to analyze the properties of pulse amplification over a wide range of these parameter values, covering four orders of magnitude variation in τ_p/τ_r and six orders in E_{in}/E_{sat}.

When the pulse duration is so short that $\tau_p/\tau_r \ll 1$, the rotational and vibrational energy transfers do not have time to occur during the pulse-molecule interaction. The amplifying medium then acts like a two-level system, as described in the rate-equation approximation[1] by Frantz and Nodvik [9]. The amount of energy the pulse can extract from the medium in this case is governed by the initial value of the population-inversion density $(n^u - n^l)$ of the upper (u) and lower (l) vibrational-rotational levels directly involved in the laser transition.

In the opposite extreme, when the input pulse duration is quite large relative to τ_r, the field-induced changes in n^u and n^l can be countered by rotational and vibrational energy exchange. We find that the extractable energy in this limit is determined by the appreciably larger population-inversion density $\gamma(M+1)[n^u(0) - n^l(0)]$. The factor M arises from rotational energy transfer while the factor γ is contributed by the intramode VV process (slower types of vibrational relaxation are neglected). In a typical case, M is about 15 and γ about 3.

The effect of rotational coupling in the case of arbitrary τ_p/τ_r value is analyzed in Section II and Appendix A; intramode VV coupling is described in Section III and Appendix B. A comparison of the theory with published experimental results [5] is made in Section IV, where it is shown that the inclusion of vibrational energy transfer is essential to the interpretation of the data. A fit of the theory to the data leads to an estimate of (1.0-3.5) $10^6 P_{CO_2}$ s^{-1} for the rate of intramode VV energy transfer, where P_{CO_2} is the partial pressure of CO_2 in torr.

II. Effect of Rotational Coupling

We consider a homogeneously broadened laser transition between a pair of molecular-energy levels u and l, each of which is part of a band of rotational levels strongly coupled by collisional interactions (Fig. 1). Since the quantum mechanical selection rules for collision-induced transitions among the various rotational levels of most molecules are not well understood [3], [10], we will use a reservoir model. In this model the particular laser level u (or l) in the rotational band is singled out, while the rest of the levels in the band are treated collectively. The totality of these other rotational levels constitute the rotational reservoir for level u (or l).

The details of the model are developed in Appendix A, where it is shown that the basic equations relating the flux

Manuscript received November 21, 1974; revised February 24, 1975. This work was performed under the auspices of the U.S. Energy Research and Development Administration.

[1] A semiclassical (rather than rate-equation) theory is needed to treat most aspects of electromagnetic-pulse amplification in the very short pulse regime where $\tau_p/\tau_r \lesssim 1$. However, as noted in [1b)], the amount of energy extracted from the medium by the pulse in this regime is apparently satisfactorily described using rate equations.

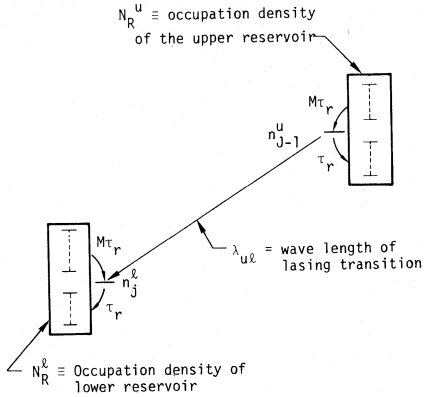

Fig. 1. Rotational reservoir model.

density I of the radiation pulse and the population densities n^u and n^l of the laser levels and N_R^u and N_R^l of the rotational reservoirs are (A-11)-(A-15). This rotational-reservoir (RR) model is essentially the same as the model first analyzed by Schappert [1].

In Appendix A the RR model is solved analytically in the two limiting cases where the input pulse duration τ_p is either very long or very short compared to the rotational relaxation time τ_r. Despite the limitations of the RR model, stemming from the neglect of vibrational energy transfer when $\tau_p \gg \tau_r$ and the neglect of phase-dependent effects[1] when $\tau_p \lesssim \tau_r$, these analytical solutions provide useful benchmarks for the amount of rotational-band energy extractable from the amplifier as a function of the ratio τ_p/τ_r. In the remainder of this section we introduce convenient normalization factors for the extracted-energy and input-energy density and discuss the RR model results for arbitrary τ_p/τ_r value. The role of vibrational energy transfer is explored later in Section III.

Extracted Energy and Energy Gain

The major focus of our attention is the energy gain G_E of the amplifier, defined as the ratio of the output-energy density (in, say, joules/square centimeters) to the input-energy density

$$G_E \equiv E_{out}/E_{in} = \int_{-\infty}^{\infty} I(x = L, t')\, dt' \Big/ \int_{-\infty}^{\infty} I(x = 0, t')\, dt'. \tag{1}$$

The extracted-energy density, or amount of energy per unit area extracted from the amplifier by the pulse, is given in terms of G_E by $(E_{out} - E_{in}) = (G_E - 1)E_{in}$.

In the limiting cases $\tau_p/\tau_r \gg 1$ and $\tau_p/\tau_r \ll 1$ the RR-model energy-gain relation can be integrated analytically for an arbitrary input pulse shape to give G_E as a function of the input-energy density

$$E_{in} = h\nu_{ul} \int_{-\infty}^{\infty} I_0(t')\, dt'.$$

For relatively long-duration pulses the energy gain is, using (A-21)-(A-25),

$$\lim_{\tau_p/\tau_r \gg 1} G_E = [(M+1)E_{sat} \exp(\alpha_0 L)/E_{in}] \cdot \ln\{1 + \exp(\alpha_0 L)[\exp(E_{in}/(M+1)E_{sat} \cdot \exp(\alpha_0 L)) - 1]\}. \tag{2}$$

Similarly, when the input pulse duration is very short, the energy gain is given by this same equation with M set equal to zero

$$\lim_{\tau_p/\tau_r \ll 1} G_E = (E_{sat} \exp(\alpha_0 L)/E_{in}) \ln \cdot \{1 + \exp(\alpha_0 L)[\exp(E_{in}/E_{sat} \exp(\alpha_0 L)) - 1]\}. \tag{3}$$

Here E_{sat} is a characteristic saturation level for E_{in} defined by

$$E_{sat} \equiv (h\nu_{ul}/2\sigma) \exp(-\alpha_0 L). \tag{4}$$

Inspection of (3) shows that for very short-duration pulses the regime of linear amplification (i.e., where E_{out} is linearly proportional to E_{in}) occurs for $E_{in} \ll E_{sat}$. The extracted-energy density in this case is

$$(E_{out} - E_{in}) = (G_E - 1)E_{in} = (\exp(\alpha_0 L) - 1)E_{in}. \tag{5}$$

Nonlinear (saturation) effects are significant whenever E_{in} is comparable to or greater than E_{sat}. Similarly, in the limit of large τ_p/τ_r value the regime of linear amplification is given by $E_{in} \ll (M+1)E_{sat}$, and, in general, the input-energy density required to produce a given degree of saturation in this limit is larger by a factor $(M+1)$.

The parameter E_{sat} and the extracted-energy density given by (5) provide very convenient reference values for E_{in} and $(E_{out} - E_{in})$ in the general case of arbitrary τ_p/τ_r. Throughout the remainder of this paper the energy saturation characteristics will be discussed in terms of the variation with E_{in}/E_{sat} of the normalized extracted energy δ defined by

$$\delta = (E_{out} - E_{in})/E_{in}(\exp(\alpha_0 L) - 1) = (G_E - 1)/(\exp(\alpha_0 L) - 1). \tag{6}$$

Results for Arbitrary τ_p/τ_r

The reservoir-model equations (A-11)-(A-15) or (A-15)-(A-17) require numerical solution when the duration τ_p of the input pulse is neither very large nor very small compared to the rotational relaxation time τ_r. This entails that specific numerical values be assigned for the amplifier parameters σ, M^u, M^l, τ_r, $n_{j-1}^u(0)$, $n_j^l(0)$, $N_R^u(0)$, and $N_R^l(0)$. Once the time- and space-dependent population densities and radiation flux density are found for a given problem, the normalized extracted energy δ can be calculated as a function of E_{in}/E_{sat} by means of (A-25), (1), (4), and (6).

Fig. 2, obtained by solving (A-11)-(A-15) on a CDC 7600 computer, illustrates the variation of δ versus E_{in}/E_{sat} for the case of a Gaussian input pulse. Each curve in the figure corresponds to a given value of the ratio $\tau_p/\tau_r = 0.1, 1.0, 10, 100$, or 1000. (Recall that τ_p refers to the duration of the *input* pulse; as the pulse propagates through the amplifier its shape

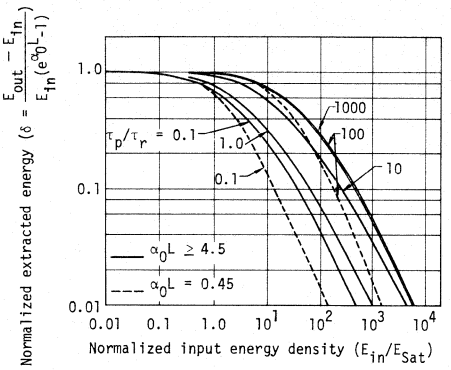

Fig. 2. Curves of normalized extracted-energy versus normalized input-energy density for Gaussian input pulses. Solid lines correspond to ratios of pulsewidth to rotational relaxation time τ_p/τ_r = 0.1, 1.0, 10, 100, and 1000 for $\alpha_0 L \gtrsim 4.5$ Dashed lines correspond to τ_p/τ_r = 0.1 and 100 for $\alpha_0 L$ = 0.45.

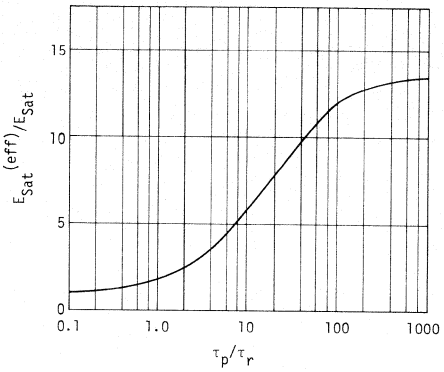

Fig. 3. Effective saturation-energy density for a multilevel system, relative to saturation-energy density for a two-level system, versus τ_p/τ_r.

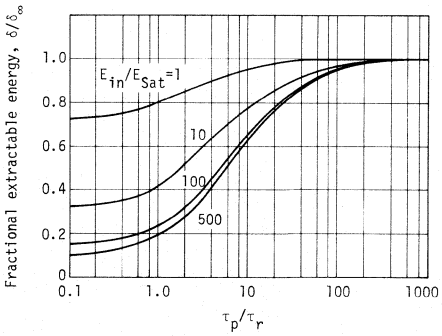

Fig. 4. Fractional extracted energy versus τ_p/τ_r for Gaussian input pulses and E_{in}/E_{sat} = 1, 10, 100, and 500. The fractional extracted energy is defined as $\delta/\delta_\infty = (E_{out} - E_{in}) / \lim_{\tau_p/\tau_r \to \infty} (E_{out} - E_{in})$.

and effective duration can change.) Owing to the choice of normalization factors for the plotted variables, the results are practically independent of the gain-length product $\alpha_0 L$ so long as it is above a value of about 4.5. The solid lines in Fig. 2 apply for this high-gain regime $\alpha_0 L \gtrsim 4.5$; the dashed lines represent the smaller value $\alpha_0 L = 0.45$. A corresponding set of curves constructed for the case of rectangular input pulses is only slightly different from Fig. 2, indicating that the extracted energy for arbitrary τ_p/τ_r value is not very sensitive to the input pulse shape.

The particular numerical problem on which Fig. 2 is based corresponds to pulse amplification on a $P(16)$ transition in a $He/N_2/CO_2$ = 3/1/1 laser gas mixture at temperature T = 325 K and pressure P = 0.85 atm. The small-signal gain of the system is $\alpha_0 = 0.045$ cm^{-1} and other relevant parameters are [8] $\sigma = (1.97)\ 10^{-18}$ cm^2, $n^u_{J-1}(0) = n^u_{15}(0) = (2.33)\ 10^{16}$ cm^{-3}, $n^l_J(0) = n^l_{16}(0) = (7.68)\ 10^{14}$ cm^{-3}, $N^u_R(0) = (3.06)\ 10^{17}$ cm^{-3}, $N^l_R(0) = (1.00)\ 10^{16}$ cm^{-3}, and $\tau_r = (1.72)\ 10^{-10}$ s. The amplifier length was taken to be L = 10 cm for the small-gain results, and $L \geq 100$ cm for the high-gain examples.

The curve labeled $\tau_p/\tau_r = 0.1$ is indistinguishable from the analytical result given by (3). Likewise, the curve labeled $\tau_p/\tau_r = 1000$ is virtually indistinguishable from the analytical result using the value $M \cong M^l \cong M^u = N^u_R(0)/n^u_{15}(0) \cong 13$ in (2).

To a good approximation any pair of curves labeled by different τ_p/τ_r values in Fig. 2 are related to one another by a simple translation property. This property is exact for the extreme cases $\tau_p/\tau_r << 1$ and $\tau_p/\tau_r >> 1$ as seen by comparing (2) and (3): If the abscissa value $E_{in}/E_{sat} = a$ corresponds to the ordinate value $\delta = b$ for $\tau_p/\tau_r << 1$, then the abscissa value $E_{in}/E_{sat} = (M+1)a$ corresponds to $\delta = b$ for the $\tau_p/\tau_r >> 1$ curve. This feature can be used to define an effective saturation-energy density $E^{(eff)}_{sat}$ for arbitrary τ_p/τ_r value. We define $E^{(eff)}_{sat}$ as the E_{in} value that gives rise to the same degree of saturation (same δ value) for a given ratio τ_p/τ_r as does the value $E_{in} = E_{sat}$ for $\tau_p/\tau_r << 1$. Fig. 3, which is derived from Fig. 2, shows $E^{(eff)}_{sat}/E_{sat}$ as a function of τ_p/τ_r. As τ_p/τ_r tends to infinity, $E^{(eff)}_{sat}/E_{sat}$ asymptotically approaches the value $(M+1) \cong 14$. As stated earlier, vibrational energy transfer becomes important when $\tau_p/\tau_r >> 1$, so this asymptotic limit would never be realized in practice.

A second quantity of interest that we can obtain from Fig. 2 is the dependence of the extracted energy on input pulse duration for a given input energy density E_{in}. As shown in Fig. 4, the reservoir model predicts that the extracted energy is monotonically increased by increasing τ_p and correspondingly decreasing I_{in} (to maintain fixed E_{in}). The ordinate in this figure is the ratio of extracted energy for a given τ_p/τ_r value to the maximum extracted energy as τ_p/τ_r is made very large while keeping E_{in} fixed

$$\delta/\delta_\infty = (E_{out} - E_{in}) \Big/ \lim_{\tau_p/\tau_r >> 1} (E_{out} - E_{in}).$$

Fig. 4 shows that the effects of varying τ_p are considerably more pronounced for larger input-energy densities.

III. Effect of Vibrational Energy Transfer

When the input pulse duration is long compared to the rotational relaxation time, it may be inadequate to consider only the influence of the rotational energy reservoirs. Other secondary reservoirs of stored energy can come into play on this longer time scale. In this section we estimate the effect of the most rapid type of vibrational energy transfer for the important example of a CO_2 amplifier. The basis of the cal-

culation is a vibrational-temperature model [7], [8] and the relevant process is intramode VV energy transfer. The basic physics of the model and necessary preliminaries to the calculation are discussed in Appendix B.

We begin with the expression [(B-4) in the Appendix] for the total vibrational energy $\mathcal{E}_T^{(\mathrm{vib})}$ per unit volume in the excited CO_2 gas mixture. Just before the pulse enters the amplifier the initial value of this quantity is

$$\mathcal{E}_T^{(\mathrm{vib})}(r_0, s_0) = N_c\left\{\hbar\omega_{\nu 1}\left[\frac{s_0}{(1-s_0)} + \frac{s_0^2}{(1-s_0)^2}\right] + \hbar\omega_{\nu 3}\frac{r_0}{(1-r_0)}\right\}. \tag{7}$$

The symbols in this equation are explained in Appendix B. The initial values r_0, s_0 for the Boltzmann factors are determined by the particular method used to pump the amplifier and by the relatively slow gas kinetic processes [8]. The connection of the Boltzmann factors to quantities we have used up to this point is that they determine the initial population densities $n_{J-1}^u(0)$, $N_R^u(0)$, etc., for a CO_2 problem. In particular, the factors n_T^u and n_T^l in (A-2) and (A-3) are given by $n_T^u = N_c r_0/Q(r_0, s_0)$ and $n_T^l = N_c s_0^2/Q(r_0, s_0)$, where Q is the partition function defined in (B-3). The initial population-inversion density on the u-l transition is then, from (A-3) with $(J \pm 1)$, approximated by J

$$\Delta n(0) \cong (2J/J_{\mathrm{opt}}^2)\exp\left[-J^2/2J_{\mathrm{opt}}^2\right] N_c(r_0 - s_0^2)/Q(r_0, s_0) \tag{8}$$

with J_{opt} given by (A-4). The numerical example treated earlier in Section II corresponds to the values $r_0 = 0.11$, $s_0 = 0.06$, $N_c \cong (3.8)\ 10^{18}\ \mathrm{cm}^{-3}$, $J = 16$, and $J_{\mathrm{opt}} \cong 17$.

Now in order to get an upper bound on the reservoir-model results for energy extraction, we suppose that the amplifier input pulse has a duration τ_p that is long compared to both the rotational relaxation time τ_r and the intramode VV relaxation time τ_{vv}, but short compared to any other vibrational relaxation times. The pulse causes energy to be transferred from the $\nu 3$ mode of a CO_2 molecule to the $\nu 1$ mode via stimulated emission between the energy levels $u = (J-1; 0, 0, 1)$ and $l = (J; 1, 0, 0)$. This occurs gradually enough that the intramode VV relaxation process adjusts the equilibrium population distributions in the modes (i.e., adjusts the values of r and s). Immediately following the passage of the pulse through the amplifier, the modes are characterized by final Boltzmann-factor values r_f, s_f. The total vibrational energy per unit volume in this post-pulse state is given by (7) with r_f and s_f replacing r_0 and s_0.

We can determine r_f and s_f in the following way. First it is noted that the driving force of stimulated emission can only change the Boltzmann factors to the point where

$$r_f = s_f^2 \tag{9}$$

since upon reaching this value the population-inversion density on the transition is zero by (8). Secondly, by conservation of energy the decrease in vibrational energy per unit volume must equal the energy $(\Delta\mathcal{E})_{\mathrm{VV}}$ per unit volume added to the radiation pulse

$$\mathcal{E}_T^{(\mathrm{vib})}(r_0, s_0) - \mathcal{E}_T^{(\mathrm{vib})}(r_f, s_f) = (\Delta\mathcal{E})_{\mathrm{VV}}. \tag{10}$$

The energy added to the pulse is itself a fraction $(\omega_{\nu 3} - \omega_{\nu 1})/\omega_{\nu 3}$ of the energy lost from the $\nu 3$ mode

$$(\Delta\mathcal{E})_{\mathrm{VV}} = (\omega_{\nu 3} - \omega_{\nu 1})\,\Delta\mathcal{E}_{\nu 3}/\omega_{\nu 3} = \frac{(\omega_{\nu 3} - \omega_{\nu 1})}{\omega_{\nu 3}}\left\{\frac{r_0}{1-r_0} - \frac{r_f}{1-r_f}\right\}\hbar\omega_{\nu 3} N_c. \tag{11}$$

By solving (10) and (11) simultaneously and using (9) to eliminate r_f, we find that s_f satisfies a quadratic equation. The solution is

$$\sqrt{r_f} = s_f = \{[4(c_0+3)c_0 + 1]^{1/2} - 1\}/2(c_0+3) \tag{12}$$

with

$$c_0 = \frac{s_0}{(1-s_0)}\left[1 + \frac{s_0}{1+s_0}\right] + \frac{r_0}{(1-r_0)}. \tag{13}$$

The maximum amount of energy that can be extracted by the pulse when the intramode VV processes have time to occur is then given by $(\Delta\mathcal{E})_{\mathrm{VV}}$ in (11) using the r_f value from (12). This can be compared to the maximum extractable energy per unit volume due to rotational relaxation alone, namely $(\Delta\mathcal{E})_{\mathrm{RR}} = h\nu_{ul} \cdot \Delta N/2 = (h\nu_{ul}/2) N_c(r_0 - s_0^2)/Q(r_0, s_0)$.

This comparison gives

$$(\Delta\mathcal{E})_{\mathrm{VV}}/(\Delta\mathcal{E})_{\mathrm{RR}} = \gamma \tag{14}$$

where the constant γ is

$$\gamma = [2Q(r_0, s_0)(\omega_{\nu 3} - \omega_{\nu 1})/2\pi\nu_{ul}] \cdot \left\{\frac{r_0}{(1-r_0)} - \frac{r_f}{(1-r_f)}\right\}\Big/(r_0 - s_0^2). \tag{15}$$

Thus the effect of intramode VV processes is to enlarge the size of the reservoir population-inversion density from the value $\Delta N = (\Delta N_R + \Delta n)$ to a value γ times greater. For the numerical example treated in Section II we find that $r_f = 0.0179 = s_f^2$, which gives $\gamma = 2.72$ for this problem. The result for the normalized extracted energy δ is shown in Fig. 5. The curve labeled 2LS in the figure refers to the $\tau_p/\tau_r \ll 1$ limit, and is accurately given by (3) for any single-peaked input pulse shape. The curve RR represents the $\tau_p/\tau_r \gg 1$ limit with only rotational relaxation taken into account. The RR curve can be constructed using (2), which amounts to simply translating the 2LS curve to the right by a factor $(M+1) \cong 14$. The curve labeled VV applies when τ_p is large compared to the intramode VV relaxation time. It can be constructed by translating the 2LS curve to the right by a factor $(M+1)\gamma \cong 38$, or by solving the detailed pulse-propagation problem using a computer code based on a vibrational-temperature model [8]. We have made computer runs of this type and find precise agreement with the result using the translation factor $(M+1)\gamma$.

The three curves 2LS, RR, and VV in Fig. 5 can readily be drawn for any given CO_2 laser amplifier since they are determined by an analytical expression (3) and two translation factors involving easily calculable quantities M and γ [from

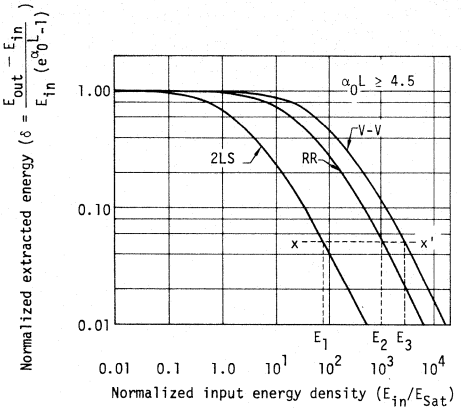

Fig. 5. Limiting curves for a CO_2 amplifier. The curves 2LS, RR, and VV refer, respectively, to the limits $\tau_p/\tau_r \ll 1$, $\tau_p/\tau_r \gg 1$ with only rotational coupling included, and $\tau_p/\tau_r \gg 1$ with both rotational and intramode VV energy transfer included. The indicated abscissa points have values in the ratio $E_3:E_2:E_1 = \gamma(M+1):(M+1):1$, as explained in the text.

(A-10) and (15), respectively]. The curves for intermediate τ_p/τ_r values can be interpolated reasonably accurately by using the same relative positions as shown in Fig. 2.

IV. Comparison with Experiment

The amplification of nanosecond-duration CO_2 pulses in the heavily saturated regime has been studied experimentally by Figueira *et al.* [5]. Using a two-stage electron-beam-controlled amplifier, they obtained data on output energy q_{out} as a function of input energy q_{in} for three different pulse durations corresponding to the values $\tau_p/\tau_r \cong 25$, 100, and 350.

The foregoing theory deals with energy densities E rather than energies q. To compare the experimental results to the theory we will transform all data points q_{out} versus q_{in} to a δ versus E_{in}/E_{sat} diagram by using

$$\delta = \left(\frac{q_{out}A_{in}}{q_{in}A_{out}} - 1\right) \Big/ (\exp(\alpha_0 L) - 1) \tag{16}$$

and

$$E_{in}/E_{sat} = (q_{in} 2\sigma / h\nu_{ul} A_{in}) \exp(\alpha_0 L) \tag{17}$$

in which A_{in} and A_{out} are the effective cross-sectional areas of the input pulse and the output pulse, respectively.

In calculating the effective areas it is necessary to take into account that the input pulse used by Figueira *et al.* is a diverging Gaussian beam and that A_{out} exceeds A_{in} due to the effects of both diffraction and saturation. The transverse spot size of the input pulse is specified by w_0, the radius from the pulse center to the point where the intensity has declined by a factor $1/e$. By diffraction the corresponding spot size of the output pulse is $w = w_0 + \theta L$, where θ is the divergence angle and L is the propagation distance through the amplifier. Thus diffraction effects alone give

$$(A_{out}/A_{in})_{diffr} = (w/w_0)^2. \tag{18}$$

Using the quoted [5] values $w_0 = 0.89$ cm, $\theta = 0.7$ mrad, and $L = 200$ cm we get $(w/w_0)^2 \cong 1.3$.

The effect of saturation is to increase the off-axis energy relative to the on-axis energy. The Gaussian transverse distribution of intensity in the input plane is converted into a more nearly uniform distribution over the spot size in the output plane. The compound effect of saturation and diffraction acting simultaneously is thus to give an area ratio

$$(A_{out}/A_{in}) \cong \int_0^w 2\pi r\, dr \Big/ \int_0^{w_0} \exp(-r^2/w_0^2)\, 2\pi r\, dr$$

$$= (w/w_0)^2/[1 - \exp(-1)]. \tag{19}$$

This gives the estimate $(A_{out}/A_{in}) \cong 2$ to be used in (16).

The cross section $\sigma = \lambda_{ul}^2/(4\pi^2 \tau_{ul} \Delta\nu)$ in (17) is evaluated using $\lambda_{ul} = 10.6$ μm, $\tau_{ul} = 4.2$ s, and the expression [8] for the pressure-broadened linewidth in a $He/N_2/CO_2$ gas mixture

$$\Delta\nu(\text{Hz}) = (1.29)\, 10^{-11} N T^{1/2} [(0.695)\, \psi_{He} + (0.755)\, \psi_{N_2} + \psi_{CO_2}] \tag{20}$$

where N is the total number of molecules per unit volume and the ψ's represent the mole fractions of different species. For the $He/N_2/CO_2 = 3/(1/4)/1$ system at 450 K used by Figueira *et al.*, we find

$$\sigma = (1.67)\, 10^{-18}\ \text{cm}^2. \tag{21}$$

Combining this result with the quoted gain-length factor $\alpha_0 L = (0.051\ \text{cm}^{-1})\ (200\ \text{cm}) = 10.2$, we have the saturation-energy density

$$E_{sat} = (h\nu_{ul}/2\sigma) \exp(-\alpha_0 L) = (5.62\ \text{mJ/cm}^2) \exp(-10.2) \tag{22}$$

or $E_{sat} = (2.09)\, 10^{-4}\ \text{mJ/cm}^2$.

The remaining quantities needed for the theory-experiment comparison can be inferred from the small-signal gain value α_0 and the system temperature and pressure. In particular, the translation factors $(M+1)$ and γ in (A-10) and (15) are found to be

$$(M^u + 1) \cong (M^l + 1) \cong \Delta N(0)/\Delta n(0) = 16.5 \tag{23}$$

and

$$\gamma \cong 3.49 \tag{24}$$

Fig. 6 shows the distribution of data points for the three cases $\tau_p/\tau_r = 25$, 100, and 350 relative to the theoretical curves. It is seen that the data for $\tau_p/\tau_r = 100$ are closely approximated by the corresponding RR curve. This indicates that transfer of vibrational energy is fairly negligible on this time scale of $\tau_p \cong 20$ ns at about one-quarter atmosphere partial pressure of CO_2.

The significant role played by the intramode VV process is clearly evident, however, in the data for $\tau_p/\tau_r = 350$. As the depth of saturation is increased the experimental data points increasingly deviate from the RR 350 curve until they closely approach the upper bound VV curve representing full extraction of energy from both the RR's and the intramode vibrational reservoirs. The RR's alone can account for less

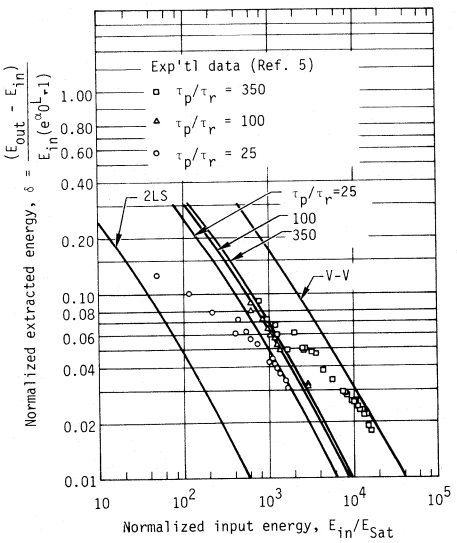

Fig. 6. Comparison of theory with experimental data adapted from [5].

than half of the observed extracted energy at high E_{in}/E_{sat} values for this case.

These results allow us to estimate the imprecisely known rate of intramode VV transfer in CO_2. The fact that the influence of this process is fairly negligible at $\tau_p = 100\tau_r$ but is very pronounced at $350\tau_r$ implies that the intramode VV relaxation time τ_{vv} lies in the range $10\tau_r < \tau_{vv} < 35\tau_r$ for this system. Since the partial pressure of CO_2 in this case is $P_{CO_2} = \psi_{CO_2} P = (0.235)P$ and the rate of rotational energy transfer is [4]

$$(1/\tau_r P) \cong [(1.1)\,\psi_{CO_2} + (0.7)\,\psi_{He} + (1.0)\,\psi_{N_2}] \cdot 10^7\ s^{-1}torr^{-1} \cong (0.81)\ 10^7\ s^{-1}torr^{-1} \quad (25)$$

we obtain the result [11][2]

$$(1/\tau_{vv}P_{CO_2}) \cong (1.0\text{-}3.5)\ 10^6\ s^{-1}torr^{-1}. \quad (26)$$

The data points for $\tau_p/\tau_r = 25$ agree with the expectations based on the RR model for E_{in}/E_{sat} values greater than about 10^3, but fall significantly below these expectations for lower input-energy densities. We have not satisfactorily accounted for this discrepancy. It may be due in part to the double-peaked input pulse used in the experiments [5], which would make the effective input pulse duration an increasing function of the degree of saturation for low to moderate E_{in}/E_{sat} values.

In summary, a relatively simple rate-equation theory has been used to describe the complicated effects of rotational and vibrational coupling on the energy-saturation characteristics of a short-pulse CO_2-laser amplifier. By analyzing the problem in terms of suitably normalized variables, the theoretical results for different pulse durations were found to be interrelated by simple translations in a δ versus E_{in}/E_{sat} diagram. Over a very broad range of E_{in}/E_{sat} values the curves in this diagram are practically independent of the amplifier gain factor $\exp(\alpha_0 L)$, so long as $\exp(\alpha_0 L) \gtrsim 90$. Since vibrational as well as rotational coupling is taken into account, the theory can be usefully applied to situations where the pulse duration is up to several thousand times longer than the rotational relaxation time in a CO_2 system. For still longer pulse durations, extending into the domain of microseconds or more, a vibrational-temperature model, such as that in [8], can be used to describe the amplification process. Finally, a comparison of the short-pulse theory to published experimental results has led to an estimate of the imprecisely known rate of intramode VV transfer in CO_2.

Appendix A
Rotational-Reservoir Model

In a gas comprised of linear polyatomic molecules the number density $\bar{n}_J$ of molecules occupying the Jth rotational level of a given vibrational state in thermal equilibrium is approximately given by [12]

$$\bar{n}_J = (2J+1)\,(Bhc/kT)\,(1/\kappa_0)\,n_T \exp[-(Bhc/kT)J(J+1)] \quad (A\text{-}1)$$

where T is the gas temperature in degrees Kelvin, $B = h/8\pi^2 c\,\mathcal{I}$ is the rotational constant in cm^{-1}, $\mathcal{I}$ is the moment of inertia of the molecule, and h, c, and k are Planck's constant, the speed of light in vacuum, and Boltzmann's constant, respectively. The parameter κ_0 takes the value one or one-half, depending on the symmetry of the molecules; e.g., for a gas of $CO^{16}O^{16}$ molecules $\kappa_0 = \frac{1}{2}$, while for $CO^{16}O^{18}$ $\kappa_0 = 1$. The rotational quantum number J assumes any integer value from 0 to ∞ when $\kappa_0 = 1$, but every other J value is missing when $\kappa_0 = \frac{1}{2}$. The quantity n_T is the total number of molecules per cubic centimeter in all rotational levels corresponding to a given vibrational state

$$n_T = \sum_J^{\infty} \bar{n}_J \cong \kappa_0 \int_0^{\infty} \bar{n}_J\, dJ. \quad (A\text{-}2)$$

Now, if $\bar{n}_J^u$ and $\bar{n}_J^l$ represent the number density of molecules in the Jth rotational levels of the upper and lower vibrational states between which a laser transition occurs, then the initial population-inversion density for the transition is

$$\Delta n(0) = \bar{n}_{J+\Delta J}^u - \bar{n}_J^l = (2J-1)\,(\beta/\kappa_0)\,n_T^u \exp[-\beta J(J-1)] - (2J+1)\,(\beta/\kappa_0)\,n_T^l \exp[-\beta J(J+1)] \quad (A\text{-}3)$$

[2]This result (26) represents an average rate that is influenced by all types of intramode VV processes for the $\nu 1$, $\nu 2$, and $\nu 3$ modes [see the discussion accompanying (B-1) in Appendix B]. The value (26) is consistent with the only measured CO_2 intramode VV rates of which we are aware. These are the rate $(5.3 \pm 1)\ 10^6\ s^{-1}torr^{-1}$ for the process

$$CO_2(01^11) + CO_2(00^00) \rightleftarrows CO_2(01^10) + CO_2(00^01)$$

determined by Burak *et al.* in [11a)], and the rates $(1.6 \pm 0.2)\ 10^6\ s^{-1}torr^{-1}$ and $(4 \pm 0.4)\ 10^6\ s^{-1}torr^{-1}$ for the processes

$$CO_2(00^01) + C^{13}O_2(00^00) \rightleftarrows CO_2(00^00) + C^{13}O_2(00^01)$$

and

$$CO_2(00^01) + CO^{18}O^{16}(00^00) \rightleftarrows CO_2(00^00) + CO^{18}O^{16}(00^01)$$

respectively, determined by Stephenson *et al.* in [11b)].

where $\beta \equiv Bhc/kT$, and we have taken $\Delta J = -1$ for a P-branch vibrational-rotational transition.

The particular J value for which $\Delta n(0)$ is maximum is the nearest allowed integer to the value

$$J_{\text{opt}} = (kT/2Bhc)^{1/2}. \tag{A-4}$$

This result follows most simply by making the approximations $J - 1$ and $J + 1 \cong J$ in (A-3) and then solving for the J value that makes $\partial \Delta n(0)/\partial J = 0$.

For a given $P(J)$ transition between the levels u and l, neighboring rotational levels provide a fairly tightly coupled reservoir of stored energy. To describe this coupling it is convenient to separate out the particular laser level u (or l) in the rotational band, and treat the rest of the levels in each band collectively as indicated in Fig. 1. To find the effective relaxation times for transfer of rotational energy between the laser levels and the reservoirs, we invoke the principle of overall microscopic reversibility for population exchanges between levels in a rotational band. Denoting the thermal-equilibrium population densities of any pair of levels by $\bar{n}_J$ and $\bar{n}_k$, and denoting the transition-rate probabilities (number of transitions per second) for $J \to k$ and $k \to J$ processes by w_{Jk} and w_{kJ}, respectively, this principle is expressed as

$$\bar{n}_J \sum_{k=0}^{\infty}{}' w_{Jk} = \sum_{k=0}^{\infty}{}' \bar{n}_k w_{kJ}. \tag{A-5}$$

The sum in (A-5) goes over all levels in the band except $k = J$, and the prime on the sum is a reminder that $k \neq J$. The overall rotational relaxation time τ_r for transfer out of level J to all other rotational levels in the band is defined by

$$1/\tau_r = \sum_{k=0}^{\infty}{}' w_{Jk}. \tag{A-6}$$

We define a collective relaxation time $M \cdot \tau_r$ for transitions from all levels of the reservoir to the level J by the relation

$$\bar{N}_R/(M\tau_r) = \sum_{k=0}^{\infty}{}' \bar{n}_k w_{kJ} \tag{A-7}$$

where

$$\bar{N}_R = \sum_{k=0}^{\infty}{}' \bar{n}_k \tag{A-8}$$

is the thermal-equilibrium population density of the reservoir. Using the definitions (A-6)-(A-8) in (A-5), we find that M is the thermal-equilibrium ratio of the reservoir and level J populations

$$M = \bar{N}_R/\bar{n}_J = \left(\sum_{k=0}^{\infty} \bar{n}_k - \bar{n}_J \right) \Big/ \bar{n}_J. \tag{A-9}$$

Using (A-1) for $\bar{n}_k$, and approximating the sum by integral, as in (A-2), it follows easily that

$$M = M(J) = (kT/Bhc)\,[\kappa_0/(2J+1)] \cdot \exp\,[(Bhc/kT)\,J(J+1)] - 1. \tag{A-10}$$

Rate Equations

From the foregoing discussion and definitions, we can immediately write down the rate equations for the reservoir model indicated schematically in Fig. 1. The variation in time of the population densities n^u_{J-1} and n^l_J of the laser levels and of the collective population densities N^u_R and N^l_R of the other levels in the two rotational bands is described by

$$\partial n^u_{J-1}/\partial t = -\sigma I(x,t)\,(n^u_{J-1} - n^l_J) - n^u_{J-1}/\tau_r + N^u_R/(\tau_r \cdot M^u) \tag{A-11}$$

$$\partial N^u_R/\partial t = -N^u_R/(\tau_r M^u) + n^u_{J-1}/\tau_r \tag{A-12}$$

$$\partial n^l_J/\partial t = \sigma I(x,t)\,(n^u_{J-1} - n^l_J) - n^l_J/\tau_r + N^l_R/(\tau_r \cdot M^l) \tag{A-13}$$

$$\partial N^l_R/\partial t = -N^l_R/(\tau_r M^l) + n^l_J/\tau_r \tag{A-14}$$

where M^l is given directly by (A-10), and M^u is given by the same expression with $(J - 1)$ replacing J. The space- and time-dependent radiation flux density I (photons/s $\cdot$ cm^2) is assumed to satisfy the familiar transport equation

$$\partial I/\partial t + c\partial I/\partial x = c\sigma(n^u_{J-1} - n^l_J) \cdot I \tag{A-15}$$

where $\sigma = \lambda^2_{ul}/(4\pi^2 \tau_{ul} \Delta\nu)$ is the cross section for stimulated emission and λ_{ul}, τ_{ul}, and $\Delta\nu$ are, respectively, the wavelength, spontaneous lifetime, and linewidth of the u to l transition.

In the event that $M^u \cong M^l$ (i.e., $\bar{N}^u_R/\bar{n}^u_{J-1} \cong \bar{N}^l_R/\bar{n}^l_J$) the four population-density equations (A-11)-(A-14) can be reduced to a pair of equations [1] for the population-inversion densities $\Delta n = (n^u_{J-1} - n^l_J)$ and $\Delta N_R = (N^u_R - N^l_R)$

$$\partial(\Delta n)/\partial t = -2\sigma I \cdot \Delta n - \Delta n/\tau_r + \Delta N_R/(\tau_r M) \tag{A-16}$$

$$\partial(\Delta N_R)/\partial t = \Delta n/\tau_r - \Delta N_R/(\tau_r \cdot M). \tag{A-17}$$

The problem is completely determined by specifying the initial conditions on the population densities, e.g., $\Delta n(0)$ and $\Delta N_R(0)$ for (A-16) and (A-17), and by specifying the boundary condition $I(0,t)$ and initial condition $I(x,0)$ for the incident pulse. Whether the set of (A-11)-(A-15) or (A-15)-(A-17) is used, the solution is expedited by the customary transformation to independent variables $\tau = t - x/c$ and $\zeta = x/c$, which gives the simple operator relationships $\partial/\partial t + c\partial/\partial x = \partial/\partial\zeta$ and $\partial/\partial t = \partial/\partial\tau$.

Limiting Cases

A very useful feature of the reservoir model is that it admits analytical solutions [1] in both the limits $\tau_p/\tau_r \ll 1$ and $\tau_p/\tau_r \gg 1$. To demonstrate this we will consider the slightly simplified set of (A-15)-(A-17), which apply when the population-density ratios $N^l_R(0)/n^l_J(0)$ and $N^u_R(0)/n^u_{J-1}(0)$ for the lower and upper rotational bands are approximately equal.

$\tau_p/\tau_r \gg 1$: When the envelope of the input radiation pulse changes slowly compared to the rotational relaxation time, the population of the reservoirs can continually adjust to any changes in n^u_{J-1} and n^l_J caused by the pulse. Mathematically,

this situation is expressed in (A-17) by writing

$$\partial \Delta N_R/\partial t = (\Delta n(t) - \Delta N_R(t)/M)/\tau_r \cong 0$$

for all t. Thus the population-inversion density of the reservoirs remains continuously in steady state[3] with the population-inversion density of the laser levels

$$\Delta N_R(t) = M\Delta n(t), \quad (\tau_p/\tau_r \gg 1). \tag{A-18}$$

If we now add together (A-16) and (A-17) and use this result we have

$$\partial(\Delta N_R + \Delta n)/\partial t = (M+1)\,\partial(\Delta n)/\partial t = -2\sigma I \Delta n.$$

The reservoir-model equations in the limit $\tau_p/\tau_r \gg 1$ therefore reduce to the pair

$$\partial(\Delta n)/\partial t = -2\sigma I \Delta n/(M+1) \tag{A-19}$$

$$\partial I/\partial t + c\partial I/\partial x = c\sigma I \Delta n. \tag{A-20}$$

Apart from the factor $(M+1)$ in (A-19), this is the pair of coupled equations solved by Frantz and Nodvik [9]. The general solution obtained by their method is

$$\Delta n(x,t) = \Delta n(x,0)/\{1 + \exp[C_1(x)] \cdot [\exp[C_2(x,t)] - 1]\} \tag{A-21}$$

$$I(x,t) = I_0(t - x/c)/\{1 + \exp[-C_2(x,t)] \cdot [\exp[-C_1(x)] - 1]\} \tag{A-22}$$

in which

$$C_1(x) = \sigma \int_0^x \Delta n(x',0)\,dx' \tag{A-23}$$

and

$$C_2(x,t) = [2\sigma/(M+1)] \int_{-\infty}^{t-x/c} I_0(\tau')\,d\tau'. \tag{A-24}$$

The function $\Delta n(x,0)$ is the initial population-inversion density and $I_0(t) = I(x = -\infty, t)$ is the input pulse shape. Specifically, we will deal with cases where the initial inversion density is spatially uniform: $\Delta n(x,0) = \Delta n(0)$ for $0 \leqslant x \leqslant L$, so that $C_1(x) = \alpha_0 x$, where α_0 is the small-signal incremental gain given by

$$\alpha_0 = \sigma \Delta n(0). \tag{A-25}$$

Also the input pulse shapes we will consider are the rectangular: $I_0(t - x/c) = I_0 =$ constant for $0 \leqslant (t - x/c) \leqslant \tau_p$, and the Gaussian: $I_0(t - x/c) = I_0 \exp[-(t - x/c)^2/(\tau_p/2\sqrt{\ln 2})^2]$ for $-\infty \leqslant (t - x/c) \leqslant \infty$.

$\tau_p/\tau_r \ll 1$: There is insufficient time for the reservoirs to influence pulse amplification if the pulse duration is short[1] in comparison with τ_r. In this limit we put $(1/\tau_r) = 0$ in the reservoir-model rate equations (A-11)-(A-14) or (A-16)-(A-17) and obtain a pair of equations like (A-19) and (A-20), but with $M = 0$. The general solution in this case is obtained from (A-21)-(A-24) by setting $M = 0$ wherever it occurs.

[3] This steady-state relation cannot be maintained if the field is too intense, however. By examining the implicit steady-state condition $|\Delta N_R/M\tau_r| \gg |\partial \Delta N_R/\partial t|$, it is found that the flux density I must satisfy $I \ll (1/(2\sigma M\tau_r))$. In terms of energy density this translates to $(E_{in}/E_{sat}) \ll (\tau_p/M\tau_r) \exp(\alpha_0 L)$, where E_{sat} is defined by (4) in the text.

Appendix B

Vibrational-Temperature Concept for CO_2

Detailed descriptions of the vibrational and rotational energy levels of the carbon dioxide molecule are readily available [12]. In this appendix we briefly review some of this information, and sketch the vibrational-temperature concept [7], [8] that is used in Section III of the text to derive upper bound results on our reservoir model.

The linear triatomic CO_2 molecule can vibrate in three linearly independent normal modes designated as $\nu 1$ (symmetric stretching), $\nu 2$ (bending), and $\nu 3$ (asymmetric stretching). The vibrational energy state of a given CO_2 molecule can be expressed by giving the number of excitation quanta in each of these modes. The number of CO_2 molecules per cubic centimeter which have i quanta each of size $\hbar\omega_{\nu 1}$ in the $\nu 1$ mode, and $(j + j')$ quanta of size $\hbar\omega_{\nu 2}$ in the doubly degenerate $\nu 2$ mode, and k quanta of size $\hbar\omega_{\nu 3}$ in $\nu 3$ is written $N_c(i, j + j', k)$. Each of the quantum numbers i, j, j', k can take any integer value from 0 to ∞, and the spacings of adjacent levels in the modes are approximately given by $\hbar\omega_{\nu 1} \cong (2.76)10^{-13}$ ergs, $\hbar\omega_{\nu 2} \cong (1.33)10^{-13}$, and $\hbar\omega_{\nu 3} \cong (4.67)10^{-13}$.

An infinite set of rotational energy levels is associated with each vibrational level. The rotational energy is approximately $BhcJ(J+1)$, where B is the rotational constant (inversely proportional to the molecule's moment of inertia) and J is the integer rotational quantum number. A given vibrational-rotational energy level of the CO_2 molecule is then determined by the values of J, i, $(j + j')$, and k. For example, the familiar 10.6-μm band of CO_2 transitions occurs between the lower level $(J; 1, 0, 0)$ and the upper level $(J \pm 1; 0, 0, 1)$.

Transfers of vibrational, rotational, and translational energy occur in collisions between a CO_2 molecule and a molecule A, which may be another CO_2 molecule or a molecule of some other species present in the gaseous mixture. The vibrational-temperature concept exploits the wide disparity in the rates of different types of these elementary energy-transfer processes. The two most rapid and efficient processes are those between the rotational and translational degrees of freedom (i.e., the RT processes proceeding at a rate $1/\tau_r \cong 10^7 P\ s^{-1}$ where P is the total pressure in torr) and the intermolecular vibrational energy exchanges within a given vibrational normal mode (intramode VV processes with an imprecisely known rate which we estimate in Section IV to be $1.0\text{-}3.5\ 10^6 P_{CO_2}\ s^{-1}$ where P_{CO_2} is the partial pressure of CO_2 in torr). An example of an intramode VV process is

$$CO_2[\nu 3(k)] + CO_2[\nu 3(k')] \rightleftarrows CO_2[\nu 3(k-1)] + CO_2[\nu 3(k'+1)]. \tag{B-1}$$

The notation $CO_2[\nu 3(k)]$ refers to a CO_2 molecule with k quanta in the $\nu 3$ mode and arbitrary numbers of quanta in modes $\nu 1$ and $\nu 2$. The process (B-1), and its counterparts for

the $\nu 1$ and $\nu 2$ modes, involves an almost lossless redistribution of vibrational energy in the mode.

The basic assumption of a vibrational-temperature model is that the RT and intramode VV processes occur so rapidly on the time scale of interest that the population distributions they lead to are continually in equilibrium. Thus the population distribution of the rotational levels associated with any vibrational level v is a Boltzmann distribution at the gas translational temperature T; i.e., $n(J; v)$ is proportional to $(2J+1)$ $\exp[-hcBJ(J+1)/kT]$ as in (A-1). Similarly, the population distribution in each of the vibrational normal modes is continuously a Boltzmann distribution at a (vibrational) temperature θ_α, where $\alpha = \nu 1$, $\nu 2$, or $\nu 3$. For example, the number density of CO_2 molecules which have $(n+1)$ quanta in the $\nu 3$ mode is smaller than the number density with n quanta in this mode by the Boltzmann factor $r \equiv \exp[-\hbar\omega_{\nu 3}/k\theta_{\nu 3}]$. The occupation of the $\nu 2$ mode is similarly characterized by a Boltzmann factor $s \equiv \exp[-\hbar\omega_{\nu 2}/k\theta_{\nu 2}]$, where $\theta_{\nu 2}$ can be made to differ greatly from $\theta_{\nu 3}$ under a selective excitation (pumping) process. The $\nu 1$-mode Boltzmann factor is approximately given by $\exp[-\hbar\omega_{\nu 1}/k\theta_{\nu 1}] \cong s^2$ since $\omega_{\nu 1} \cong 2\omega_{\nu 2}$ and $\theta_{\nu 1} \cong \theta_{\nu 2}$ due to a strong (Fermi resonance) coupling between the $\nu 1$ and $\nu 2$ modes. The population density of CO_2 molecules in the mixed vibrational state $(i, j+j', k)$ is then expressible [8] as

$$N_c(i, j+j', k) = N_c r^k s^{2i+j+j'}/Q(r, s) \tag{B-2}$$

where N_c is the total number of CO_2 molecules per unit volume and Q is the partition function given by

$$1/Q(r, s) = (1-r)(1-s^2)(1-s)^2. \tag{B-3}$$

The total vibrational energy $\mathcal{E}_T^{(\mathrm{vib})}$ per unit volume in a CO_2 gas laser mixture is simply given in terms of the Boltzmann factors

$$\begin{aligned}\mathcal{E}_T^{(\mathrm{vib})} &= \sum_{i,j,j',k=0}^{\infty} N_c(i, j+j', k) \\ &\quad \cdot (i\hbar\omega_{\nu 1} + (j+j')\hbar\omega_{\nu 2} + k\hbar\omega_{\nu 3}) \\ &= N_c \left\{ \hbar\omega_{\nu 1} \left[\frac{s}{(1-s)} + \frac{s^2}{(1-s^2)} \right] + \hbar\omega_{\nu 3} \frac{r}{(1-r)} \right\}.\end{aligned} \tag{B-4}$$

Thus $\mathcal{E}_T^{(\mathrm{vib})}$ is the sum of the energies per unit volume $(\mathcal{E}_{\nu 1} + \mathcal{E}_{\nu 2} + \mathcal{E}_{\nu 3})$ in each of the vibrational normal modes, where $\mathcal{E}_{\nu 3} = N_c\hbar\omega_{\nu 3} r/(1-r)$, etc.

The kinetic equations of the vibrational-temperature model [8] describe the evolution of T and the θ_α (or r and s) in time, taking explicit account of slower energy-transfer processes. These include vibrational-translational (VT) and VV types (other than intramode VV) as well as electron-molecule collisions, etc. This sort of model is appropriate to describe gain generation in a high-pressure ($\sim$ 1-atm) CO_2 laser on a microsecond time scale and can be used to study the amplification of moderate-intensity pulses with durations $\gtrsim 1$ μs.

Acknowledgment

The author wishes to thank D. K. Miller for the significant contributions he made to this paper through his efforts in computer programming, running of problems, and analysis of the results.

The Optically Gated Dye Cell—A High-Speed Shutter and Pulse Shaper

G. A. MASSEY, MEMBER, IEEE, AND R. A. ELLIOTT

Abstract—This paper discusses characteristics of a class of devices that use a saturable absorber irradiated by an optical control pulse, or gating pulse, to alter the shape of a transmitted optical signal. We consider two device geometries: a longitudinally gated cell, in which signal and gate beams are nearly parallel, and a transverse cell, in which the medium is bleached by a gating pulse applied at right angles to the signal beam. The longitudinal device permits synthesis of rising exponential signal pulses with arbitrary, subnanosecond time constants. The transverse geometry can provide pulses of complex shape and permits independent optimization of several device parameters. The dynamics of the saturable absorber (with particular emphasis on liquid dye systems) is analyzed in detail, and a pulse-shape synthesis procedure is outlined. Spurious nonlinear effects are considered, and an example of pulse shaping for laser-driven fusion is given.

INTRODUCTION

IN APPLICATIONS that require shuttering or shaping of light pulses with time constants and synchronism well below 1 ns, increasing difficulty in generating the electronic-gating signal is encountered if electrooptic or magnetooptic devices are used, and acoustooptic devices suffer from transit-time limitations that become severe in this time regime. For these reasons optically grated Kerr cells [1] have been used for this purpose. The principal advantage of the Kerr cell is that it can be gated by picosecond optical pulses generated by mode-locked lasers. This paper presents an analysis of a type of device which shares this advantage and offers additional versatility for pulse shaping.

Saturable absorbers have been used extensively to mode lock lasers [2] and as an optical shutter in a type of streak camera [3], but they have not yet been widely exploited in their possible role as a modulating element which allows one optical signal to interact with another. The relaxation times of these materials, particularly the bleachable dye solutions, can be widely varied and offer interesting possibilities for modulating optical pulses over time intervals from picoseconds to nanoseconds. In the devices we are considering, a cell filled with saturable absorber is irradiated with a strong "gating" pulse at the absorption frequency. Depending on the shape, intensity, and polarization of the gating pulse (which may, in fact, consist of several optical pulses) the transmission of the cell for an incident "signal" pulse will be altered. The exponential dependence of the cell transmission on such factors as cell length and population difference between the ground state and excited state of the absorber permits a wide range of transmission functions to be synthesized using only a few gating pulse shapes. In this paper we restrict our attention to liquid solutions of bleachable dyes, although many of the considerations apply to gaseous or solid media as well. In the following sections we describe two types of cell geometry that offer particular advantages in specific pulse-shaping applications and present an analysis of the absorption dynamics that applies even when the ground-state population is substantially depleted. We also estimate the magnitude of spurious nonlinear effects such as phase modulation, beam steering, and focusing, and finally we apply the previously stated theory to the shaping of 1.06-μm pulses for laser-induced fusion.

CELL GEOMETRY

We have considered two different types of dye cell configurations in the course of this work. The first type, the longitudinal cell or cell array, can produce signal pulse shapes that are exponentially rising functions of time. The exponential time constants that can be achieved in this way are shorter than can be obtained using conventional pulsed laser oscillator techniques. By combining several cells of different absorber concentrations and lengths in a longitudinal array, as in Fig. 1, a variety of rising pulse shapes can be generated. In these systems a very short, intense gating pulse is applied to one end of a sequence of dye cells of different lengths and concentrations. A signal pulse to be shaped is applied to the opposite end. By selecting a dye with relaxation long compared to the time required for light to propagate through the cell and by utilizing a gating energy density high enough to produce substantial bleaching with the leading edge of the gating pulse, one can achieve the effect of an attenuator cell whose length shortens linearly with time. The gating energy required for this case is

$$E_g > -\frac{Ah\nu \ln T_0}{2\sigma} \tag{1}$$

where $h\nu$ is the photon energy, A is the beam cross-sectional area, T_0 is the unbleached cell transmission for the signal, and σ is the absorption cross section per molecule of the dye. As an example, if we consider a value of T_0 of 10 percent and a dye for which $\sigma \approx 10^{-16}$ cm^2 at 1.06 μm, we find that E_g/A must be greater than 2.2 mJ/cm^2 which, for a 50-ps pulse, corresponds to about 43 MW/cm^2.

The signal envelope observed at the output of a cell of length L with N_0 dye molecules per unit volume is easily shown to be approximated by

$$P_s(t) \approx P_{so}\left(t - \frac{nL}{c}\right) \exp\left(-\sigma N_0 L\right) \exp\left(\frac{\sigma N_0 ct}{2n}\right) \tag{2}$$

where c/n is the pulse velocity in the dye cell and $P_{so}(t)$ is the envelope of the signal applied to the cell input. Clearly, if P_{so} has exponential form, one can alter the growth coefficient

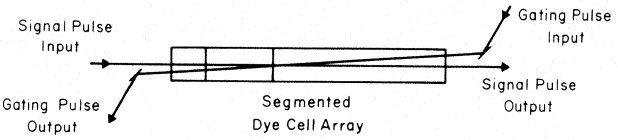

Fig. 1. Longitudinal dye cell configuration. Dye concentration and cell length are different for each segment, with higher concentrations in the shorter cells.

in the exponent by the additive constant ($\sigma N_0 c/2n$), which may be different for each cell in the array through selection of the concentration N_0. Each cell produces its effect during a time segment $2nL/c$ in duration.

Because the intensities required for this system are considerable and the optical paths traversed by the signal can be many centimeters for shaping long pulses, undesirable, nonlinear effects may be present in this geometry; however, it still may be a very convenient way to generate synchronized *gating* pulses with the correct shape for use with the transversely gated cell geometry discussed below.

The second type of dye cell system is the transverse geometry, which we have considered as a means of overcoming the long optical path (for signal) and high gating intensities inherent in the longitudinal system. In the transverse system, shown schematically in Fig. 2, the gating pulse is introduced approximately at right angles to the signal beam. The length of the cell along the signal axis is a short length (e.g., of the order of a centimeter) for which the signal-beam diameter is to be optimized to achieve the least possible depletion of the gating pulse across the aperture. We start our analysis by letting L_s be the signal length and L_g be the gate length (cell width) through the dye. For a dye concentration of N_0 molecules per unit volume, the unsaturated transmissions for signal (T_s) and gate (T_g) are

$$T_s = \exp(-\sigma N_0 L_s) \tag{3}$$

and

$$T_g = \exp(-\sigma N_0 L_g). \tag{4}$$

Taking the ratio of the logarithms of the previous equations we obtain

$$L_s/L_g = \ln T_s/\ln T_g. \tag{5}$$

Now it is desirable to have the most uniform possible gating intensity across L_g subject to the constraint that L_s be reasonably small. We therefore must specify the values of T_g and T_s allowable in our system, thus determining L_s/L_g from (5), and then we seek the minimum L_s and L_g which satisfy this aspect ratio. For a Gaussian signal beam with an intensity profile versus radius r of the form

$$I(r) = I_0 \exp\left(-\frac{2r^2}{w^2}\right) \tag{6}$$

propagating along the Z axis ($Z = 0$ at the center of the system), the spot radius $w(Z)$ varies according to the relation [4]

$$w^2(Z) = w_0^2\left[1 + \left(\frac{\lambda_0 Z}{\pi n w_0^2}\right)^2\right] \tag{7}$$

where λ_0 is the signal wavelength in air, n is the refractive index of the dye solvent, and w_0 is the spot radius at the beam waist, which we take to be centered in the cell. In this case, the largest aspect ratio for any central spot radius w_0 is obtained when L_s is set equal to the confocal parameter $b = (2\pi n w_0^2/\lambda_0)$. A reasonable choice for L_g is four times the spot radius at the ends of the system; thus we take

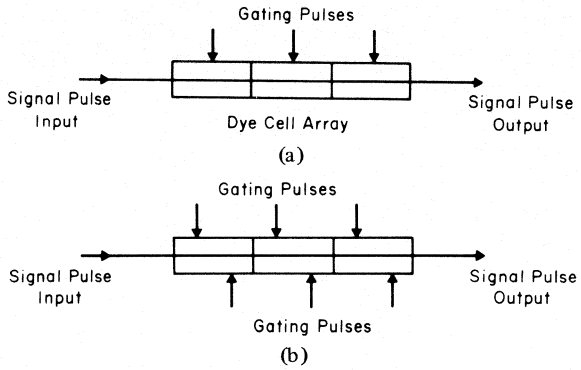

Fig. 2. Transverse dye cell configurations. Gating pulses of different durations are applied to each cell segment, either from one side (a), or symmetrically (b) to avoid a gradient of bleaching across the signal aperture. (a) Single-sided gating configuration. (b) Symmetrical gating.

$$L_g = 4\sqrt{2}\, w_0 \tag{8}$$

or

$$L_s/L_g = \frac{\pi n w_0}{2\sqrt{2}\,\lambda_0}. \tag{9}$$

This choice directly yields the desired results

$$w_0 = \frac{2\sqrt{2}\,\lambda_0}{\pi n}\frac{\ln T_s}{\ln T_g} \tag{10}$$

$$L_g = \frac{16\lambda_0}{\pi n}\frac{\ln T_s}{\ln T_g} \tag{11}$$

$$L_s = \frac{16\lambda_0}{\pi n}\left(\frac{\ln T_s}{\ln T_g}\right)^2. \tag{12}$$

From (3) we also obtain the concentration

$$N_0 = \frac{1}{\sigma L_s}\ln(1/T_s). \tag{13}$$

The previous equations completely specify the static characteristics of the optimized transverse system. As an indication of the results forthcoming from this analysis, consider a complete cell system for which $\lambda_0 = 1.064\ \mu$m, $n = 1.4$, $T_g = 0.9$ (90-percent transverse uniformity with the gating pulse incident from one side only), and $T_s = 10^{-4}$ (providing at least 10^3 of dynamic range for signal shaping). In this case

$$w_0 = 59.8\ \mu\text{m}$$

$$L_g = 0.338\ \text{mm}$$

$$L_s = 2.958\ \text{cm}$$

and

$$N_0 = 3.114 \times 10^{16}\ \text{cm}^{-3}$$

for $\sigma = 10^{-16}$ cm^2. The beam area in this case would be about πw_0^2, or 1.12×10^{-4} cm^2, which is sufficiently small to imply the use of signal powers less than about 1 kW to avoid signal-induced interactions.

It is immediately apparent that the tolerance of T_g can be reduced somewhat from the previous example if the gating pulse is reflected back through the dye cell by a mirror, or if the pulse is split and applied to opposite sides of the cell simultaneously, so that the first-order gradient of gating intensity over the signal aperture is nulled out. Such a geometry would have to be designed very carefully to avoid problems of standing waves and spatial inhomogeneities which might affect the bleaching dynamics and might even diffract a portion of the signal beam.

We now discuss the temporal behavior of the transverse dye cells under bleaching excitation and present a synthesis procedure for pulse shaping.

Dynamics of Saturable Absorber Dyes

We consider a system of dye molecules which can be approximated by a randomly oriented array of absorbing dipoles. The action of linearly polarized light on such a system is to create anisotropies in both the ground- and excited-state populations. The degree of anistropy varies with time depending on the intensity of the exciting light pulse, the excited-state lifetime, and rotational Brownian motion [5], if the orientation of the molecules is not fixed. Earlier studies of such systems have either neglected molecular reorientation [6], considered relaxation from a prepared initial distribution without subsequent excitation [7], [8], or ignored the depletion of the ground-state population by the exciting light pulse [9]. If the system is to be considered as an ultrafast modulator, none of these effects can be ignored in general. The analysis presented here takes account of each of these effects, but is somewhat simplified in that the molecules are assumed to be spherically symmetric rotors with a single relaxation time, τ_{0r}, rather than asymmetric rotors which may have as many as six relaxation times [7], [8]. In addition we consider only thin dye cells so that attenuation of the gating pulse can be ignored.

We define $n_1(\theta, \phi; t)$ to be the population of ground-state molecules whose absorption dipoles are oriented in the direction (θ, ϕ) at time t and $n_2(\theta, \phi; t)$ to be the same quantity for the excited state. The rate equations controlling these populations are more conveniently written in terms of the sum and difference of n_1 and n_2, i.e.,

$$n(\theta, \phi; t) = n_1(\theta, \phi; t) - n_2(\theta, \phi; t)$$

and

$$N(\theta, \phi; t) = n_1(\theta, \phi; t) + n_2(\theta, \phi; t).$$

The exciting light pulse is taken to be linearly polarized and the direction of polarization defines the polar axis $\theta = 0$. The excitation rate for molecules in the ground state whose absorption dipoles lie at an angle θ to this direction is proportional to $3\sigma \cos^2 \theta$ with σ being the usual absorption cross section for random dipole orientation. Using these definitions, we obtain for the rate equations

$$\frac{dn}{dt} = -6\sigma \cos^2 \theta I_g(t)\, n(\theta, \phi; t) + \frac{1}{\tau}\,[N(\theta, \phi; t) - n(\theta, \phi; t)] + \frac{1}{6\tau_{0r} \sin \theta} \frac{\partial}{\partial \theta}\left[\sin \theta \frac{\partial n(\theta, \phi; t)}{\partial \theta}\right] \tag{14}$$

$$\frac{dN}{dt} = \frac{1}{6\tau_{0r} \sin \theta} \frac{\partial}{\partial \theta}\left[\sin \theta \frac{\partial N(\theta, \phi; t)}{\partial \theta}\right] \tag{15}$$

with $I_g(t)$ being the light intensity and τ the natural lifetime of the excited state. Assuming that at $t = 0$ all are in the ground state and isotropically distributed, i.e., $N(\theta, \phi; 0) = n(\theta, \phi; 0) = (N_0/4\pi)$, then solution of the second equation is trivial

$$N(\theta, \phi; t) = N(\theta, \phi; 0) = \frac{N_0}{4\pi}. \tag{16}$$

Noting that there is no ϕ dependence in the rate equations we drop it from the arguments and expand $n(\theta, t)$ in Legendre polynomials

$$n(\theta, t) = \frac{N_0}{4\pi} \sum_{k=0}^{\infty} a_k(t) P_k(\cos \theta). \tag{17}$$

Substituting in the rate equation and using the orthogonality of the P_k we get

$$\frac{da_k}{dt} = -3\sigma(2k+1) I_g(t) \sum_{k'=0}^{\infty} a_{k'}(t) \cdot \int_0^{\pi} P_{k'}(\cos \theta) P_k(\cos \theta) \cos^2 \theta \sin \theta \, d\theta + \frac{1}{\tau} \delta_{k,0} - \frac{a_k(t)}{\tau} - \frac{k(k+1)}{6\tau_{0r}} a_k(t). \tag{18}$$

The first term in (18) couples the coefficients of different orders, resulting in two hierarchies of equations, one for the odd orders and one for the even orders. The coefficients of the odd-order polynomials are identically zero because of the initial condition $n(\theta, 0) = (N_0/4\pi)$. The even-order equations are

$$\frac{da_0}{dt} = \frac{1}{\tau} - \frac{1}{\tau} a_0(t) - 2\sigma I_g(t)\left[a_0(t) + \frac{2}{5} a_2(t)\right] \tag{19a}$$

and

$$\frac{da_{2k}}{dt} = -\left(\frac{1}{\tau} + \frac{k(2k+1)}{3\tau_{0r}}\right) a_{2k}(t) - 6\sigma I_g(t) \cdot \left[\frac{4k^2 + 6k + 2}{16k^2 + 32k + 15} a_{2k+2}(t) + \frac{8k^2 + 4k - 1}{16k^2 + 8k - 3} a_{2k}(t) + \frac{2k(2k-1)}{16k^2 - 16k + 3} a_{2k-2}(t)\right] \tag{19b}$$

for $k \geq 1$.

These equations present some difficulty: they are coupled, the coefficients in the differential equations are not constant,

and the system is infinite. However, the first term in (19b) is $0(k^2)$ while all the other terms are 0(1). This indicates that for a given set of parameters the system can be truncated at an order M which makes

$$6\sigma(I_g)_{\max} \ll \frac{1}{\tau} + \frac{M(2M+1)}{3\tau_{0r}}. \tag{20}$$

The resulting finite system of equations can then be solved numerically.

Let us assume that the system of equations has been solved and we have an expression for the difference in the population of the ground and excited states

$$n(\theta) = \frac{N_0}{4\pi}\left[a_0 + a_2 P_2(\cos\theta) + a_4 P_4(\cos\theta) + \cdots\right]. \tag{21}$$

What then is the effect of this collection of dye molecules on the intensity of an independent light beam (we assume it to be too weak to perturb the system) propagating at any arbitrary direction and with arbitrary linear polarization? In traversing a distance Δx the intensity will be diminished by

$$\Delta I_s = -3\sigma\Delta x \int_0^{2\pi}\int_0^{\pi} n(\theta)\cos^2\gamma \sin\theta\, d\theta\, d\phi \tag{22}$$

where γ is the angle between the direction of polarization of the light and the direction defined by (θ, ϕ). If θ_0 is the angle between the direction of polarization and the polar axis of the distribution of molecular orientations, then

$$\cos\gamma = \cos\theta\cos\theta_0 + \sin\theta\sin\theta_0\cos\phi. \tag{23}$$

When (21) and (23) are substituted into (22), and use is made of the orthogonality properties of the Legendre polynomials, we find that

$$\frac{\Delta I_s}{\Delta x} = -3\sigma\frac{N_0}{4\pi}\left[\frac{4\pi}{3}a_0 + \frac{8\pi}{15}a_2 P_2(\cos\theta_0)\right]. \tag{24}$$

For simplicity consider $\theta_0 = 0$ and assume that $n(\theta)$ does not vary along the path of light. The transmittance of the dye as a function of time is then

$$T_s(t) = \frac{I_s(t)}{I_0} = \exp\left\{-N_0\sigma L_s\left[a_0(t) + \frac{2}{5}a_2(t)\right]\right\} \tag{25}$$

with L_s being the length of the path, and $a_0(t)$ and $a_2(t)$ being obtained by solving (19).

The problem is now to determine if it is possible to produce a reasonable approximation to the desired signal-pulse intensity using a system of dye cells bleached by a few pulses which can be readily produced. The parameters of the system which must be specified are: the absorption cross section σ; the dye concentration N_0; the length of the dye cells L_s; the natural lifetime of the excited state τ; and the rotational relaxation time τ_{0r}. For the recently developed nickel-complex dyes useful at 1.06 μm, and assuming a solvent such as chloroform, $\tau \approx 5$ ns and $\sigma \approx 10^{-16}$ cm^2 [10]-[13]. Much shorter τ values are obtained with the same dye in solvents such as iodoethane.

The rotational relaxation time can be estimated from the Debye-Stokes-Einstein hydrodynamic model [5]: $\tau_{0r} = (3\eta V/kT)$, where η is the shear viscosity of the solvent and V is the "volume" of the molecule. The volume to be used can be found by estimating the molecular radius a from the bond lengths in the complex and setting $V = (4\pi/3)a^3$. Alternatively, one might take the measured value of τ_{0r} for a molecule such as rhodamine 6G in the same solvent and scale this value according to the ratio of the molecular weights of the two dyes. Since viscosity is strongly temperature dependent, it is not unreasonable to consider τ_{0r} a parameter which can be controlled almost arbitrarily in any real system. As a limiting case τ_{0r} might be infinite if the dye is suspended in a transparent solid.

The dye concentration N_0 and cell length L_s are constrained by requirements on the unbleached transmittance T_s and the cell-geometry considerations as discussed previously. T_s for an individual cell is in turn determined by the total dynamic range required and the number of cells and gating pulses needed to obtain the desired light-intensity curve $I_s(t)$ with the desired accuracy.

Given an input signal $I_{s0}(t)$, the synthesis problem is to determine what gating-pulse intensity $I_g(t)$ must be inserted into (19) to produce the required $a_0(t)$ and $a_2(t)$ to be used in (25) to give the transmission $T(t)$ for a particular cell in the array. This problem cannot be solved in closed form. However, an approximate expression for $I_g(t)$ which may be used as a starting point for the trial and error solution of (19) and (25) can be obtained if it is assumed that $a_2 \ll a_0$ and that terms in $1/\tau_{0r}$ can be neglected in (19). This procedure yields

$$\frac{d}{dt}\left(a_0 + \frac{2}{5}a_2\right) \approx \frac{1}{\tau} - \frac{1}{\tau}\left(a_0 + \frac{2}{5}a_2\right) - \frac{18\sigma}{5}I_g\left(a_0 + \frac{2}{5}a_2\right)$$

or using (25)

$$I_g = \frac{5}{18\sigma \ln T}\left(\frac{\sigma N_0 L_s}{\tau} - \frac{1}{\tau}\ln T - \frac{1}{T}\frac{dT}{dt}\right). \tag{26}$$

The numerical solution of (19) truncated at some convenient order, say $k = 3$, can be effected for the trial gating pulse $I_g(t)$ obtained from (26). The values of $a_0(t)$ and $a_2(t)$ so obtained are used in (25) to determine the transmittance $T_1(t)$ of the first dye cell. This is compared with the desired $T(t)$ and $I_g(t)$ is modified in a way intended to improve the agreement. Once the optimum conditions for the first dye cell have been effected and the time interval over which a good fit is obtained is determined, the procedure is repeated for the next dye cell in the array. Equation (26) can again be used with $T_i(t)$ instead of $T(t)$ to obtain an approximate gating pulse for the ith cell in the array.

Nonlinear Optical Effects

If the intensities and optical path lengths are sufficiently large, nonlinear changes in refractive index of the dye solutions under exposure to the intense gating pulses (or possibly even the signal pulses) used in these systems can produce beam focusing and steering as well as spurious phase modulation

which might ultimately distort the spatial and temporal form of the transmitted signal. We have separated these effects into refractive-index changes induced in the solvent and index changes which accompany bleaching of the dye molecules. Since the signal-beam intensity can be independently adjusted to any reasonable value in the systems we are considering, it is principally the gating-pulse powers and power densities which are of concern here. At high optical electrical-field strengths E, the change in refractive index of the solvent is simply n_2E^2, where n_2 is the effective nonlinear coefficient for the particular liquid used and E^2 is the mean square value of the field. Hellwarth [14] has listed n_2 values for a large number of useful common solvents; the values vary from 1.1×10^{-19} $(m/V)^2$ for CS_2 to 7.5×10^{-21} $(m/V)^2$ for acetone.

The differential phase shift induced on a signal of free-space wavelength λ_0 in passing through a path length L_s in a nonlinear solvent of refractive index n_0 is

$$\Delta\phi = \frac{2\pi}{\lambda_0}\Delta n L_s = \frac{2\pi}{\lambda_0} n_2 E^2 L_s = \frac{2\pi n_2}{\lambda_0 n_0}\sqrt{\mu_0/\epsilon_0}\, I L_s \tag{27}$$

where $\sqrt{\mu_0/\epsilon_0} \approx 377\ \Omega$ and I is the gating intensity. A typical maximum value of I in a gated dye cell should be of the order of 10 MW/cm^2, and the total length for a system of three cells might be $L_s \approx 3$ cm. For a solvent such as chloroform, with $n_2 = 2.11 \times 10^{-20}$ $(m/V)^2$ and $n_0 = 1.4$ at 1.06 μm, we obtain $\Delta\phi = 0.101$ rad, or $\Delta\phi/L_s = 33.7$ mrad/cm of path. Because this $\Delta\phi$ is small compared to a radian, we see that beam steering of the signal due to the largest possible monotonic gradient in I across the aperture will be small compared to the diffraction spread of the signal beam. In addition, the result implies that temporal variations in I will not phase modulate the signal by an amount comparable to the Fourier transform spectral spread inherent in the signal-envelope variations, since $\Delta\phi/\Delta t < 1/\Delta t$, while $\Delta\omega\Delta t \approx 2\pi$ for a transform-limited pulse.

Another effect to be considered is self-focusing of the gating signal, which might result in the breakup of the gating beam into self-trapped filaments if the gating power and path length are large enough and if there are significant gradients in the gating-beam intensity across the cell. From the paraxial theory for self-trapping of Gaussian beams [15], the critical power P_c to produce self-focusing is

$$P_c = \frac{\lambda_0^2}{8\pi n_2\sqrt{\mu_0/\epsilon_0}}. \tag{28}$$

Evaluating this expression for chloroform at 1.06 μm we obtain a value of 5.6 kW for P_c. Since the dye cell geometry we are considering requires a gating beam area L_sL_g of roughly 0.1 cm^2, and an intensity as high as 10 MW/cm^2 might be needed, a total power as high as about 1 MW may be present, exceeding the previous critical power by a factor of nearly 200. To determine how serious the problem of gating-beam self-focusing will be in a thin dye cell ($L_g \approx 3 \times 10^{-4}$ m) we evaluated the paraxial wavefront curvature $1/R$ that would result when a Gaussian plane-wave beam of average intensity I and spot radius w_0 refracts through a thin cell of nonlinear liquid of thickness δ. If we then approximate, as a worst case, a geometry for which $w_0 \approx \delta \approx L_g$, and evaluate the induced parabolic phase shift, we obtain the curvature

$$\frac{1}{R} \approx \frac{4n_2}{n_0^2}\sqrt{\frac{\mu_0}{\epsilon_0}}\frac{I}{L_g}. \tag{29}$$

From this we find that an I of 10 MW/cm^2, $L_g = 3 \times 10^{-4}$ m, $n_2 = 2 \times 10^{-20}$ $(m/V)^2$, and $n_0^2 = 2$ give us $R \approx 200$ m. We therefore conclude that if reasonably uniform gating intensity is maintained over the cell area, significant gating-beam breakup can be avoided along the very short path L_g, since it will be much less than R. This should permit the use of gating-pulse powers much higher than the corresponding critical power indicated by (28).

Changes in refractive index due to dye bleaching are also present because of the Kronig–Kramers relation connecting the real and imaginary parts of the dielectric constant of the dye. If we write the total dielectric constant of the dye molecules in a loss-free solvent as

$$\epsilon = \epsilon_0(\epsilon_r' - i\epsilon_r'') \tag{30}$$

it is readily shown that for cases of practical interest here that $\epsilon_r''/\epsilon_r' \ll 1$. Under this approximation we obtain

$$\alpha \approx \frac{2\pi\epsilon_r''}{n\lambda} \tag{31}$$

for the exponential attenuation coefficient for intensity, where n is the solvent refractive index. We note that ϵ_r'' results from the dye molecules alone and not from the solvent. The loss ϵ_r'' of α is accompanied by a reactive susceptibility of the dye alone which we designate as $\epsilon_{rd}' - 1$. Since this is much smaller than the susceptibility of the solvent, we obtain an approximate refractive-index contribution from the dye

$$\Delta n \approx \frac{\epsilon_{rd}' - 1}{2n}. \tag{32}$$

Finally, we have the Kronig–Kramers relation [16]

$$\epsilon_{rd}'(\omega) - 1 = \frac{2}{\pi}\int_0^\infty \frac{x\epsilon_r''(x)\,dx}{x^2 - \omega^2}. \tag{33}$$

By substitution of (31) and (32) we obtain

$$\Delta n(\lambda) = \frac{\lambda}{2\pi^2}\int_{y=0}^\infty \frac{\alpha(y)\,dy}{1 - y^2} \tag{34}$$

in which the loss exponent $\alpha(y)$ is evaluated at a wavelength λ' such that $\lambda'/\lambda = y$. Equation (34) can be written in a more useful form by evaluating the signal phase shift $\Delta\phi(\lambda)$ corresponding to $\Delta n(\lambda)$

TABLE I
GATING PULSE INTENSITIES FOR THREE-CELL SYSTEMS

Cell Number	$I_i(t)$ (τ_{or} = 1/3 nsec)	$I_i(t)$ (τ_{or} = 2 nsec)	$I_i(t)$ (τ_{or} = ∞)
i = 1	$2.44 \times 10^{-4} \exp(1.08\,t)$	$1.74 \times 10^{-4} \exp(1.1\,t)$	$1.71 \times 10^{-4} \exp(1.08\,t)$
i = 2	$0.0253 \exp[4.43(t - 8)]$	$0.0241 \exp[4.37(t - 8)]$	$0.0268 \exp[4.2(t - 8)]$
i = 3	$13.1 \exp\left(\frac{t - 9.542}{.170}\right)^2$	$12.46 \exp\left[\left(\frac{t - 9.544}{.173}\right)^2\right]$	$12.15 \exp\left[\left(\frac{t - 9.548}{.178}\right)^2\right]$
$I_i(t)$ in MW/cm^2; t in nanoseconds			

$$\Delta\phi_s(\lambda) = \frac{2\pi\Delta n(\lambda) L_s}{\lambda}$$

$$= \frac{L_s}{\pi}\int_{y=0}^{\infty} \frac{\alpha(y)\,dy}{1 - y^2}. \tag{35}$$

Since at any wavelength $\alpha L_s = \ln(1/T_s)$, we actually require only the total cell transmission at some wavelength and the relative spectral distribution of α to evaluate (35) for a cell of any length.

We obtained numerical data for the α values of the nickel-complex dye from [11] over the spectral range 0.8–1.3 μm and evaluated (34) and (35) for the special case $T_s = 10^{-4}$ at 1.064 μm. This work yielded

$$\Delta n(1.064\ \mu\text{m}) = 8.57 \times 10^{-6} \quad (L_s = 1 \text{ cm is assumed})$$

and $\Delta\phi_s$ (1.064 μm) = 0.506 rad (any length cell). These numbers of course imply that a change of dye transmission from 10^{-4} to unity could result in a phase change of about $\frac{1}{2}$ rad at 1.064 μm. If this change occurs over a time Δt the corresponding frequency spread would be

$$\Delta\omega \approx |\Delta\phi/\Delta t|$$

and we see that for these numbers the signal should remain essentially transform limited. However, since $\Delta\phi_s$ is comparable to 1 rad, beam steering and nonlinear focusing can approach the diffraction limit for this effect if there are significant variations in gating-beam intensity over the cell. This is the justification for our constraints on signal-beam diameter and dye concentration discussed earlier.

APPLICATION TO LASER FUSION

A possible application of the pulse-shaping techniques we have been describing is to the creation of pulses with the proper time behavior for use in laser-fusion experiments. One intensity function that has been considered for this application is the expression [17]

$$I(t) = I_0(1 - t/T)^{-15/8} \tag{36}$$

where $I(t)$ is of interest over the time interval $0 \leqslant t \leqslant 9.4$ ns and T is 9.45 ns. This function increases faster than an exponential and does not seem to be approximated by any "naturally produced" laser-pulse envelope. For this reason some type of active shaping is necessary.

We have applied our shaping synthesis procedure to approximate the $I(t)$ of (36). We selected as a signal input a growing exponential of the form $\exp(t/4)$ with t in nanoseconds, and considered an array of three transversely gated dye cells filled with a dye of cross section 10^{-16} cm^2 and an excited-state lifetime of 5 ns. The three gating pulses were assumed to be either exponential or Gaussian because it was expected that these could be readily produced. The entire calculation was carried out for three different orientational relaxation times τ_{0r}: $\frac{1}{3}$ ns, 2 ns, and infinity. In each case τ_{0r} was assumed to be the same in all of the cells. The unbleached transmissions of the three cells were taken to be 0.1, 0.05, and 0.01. The best fit to (36) was found for a slower exponential gating pulse applied to the first cell, a faster exponential to the second, and a subnanosecond Gaussian pulse to the third.

Computer runs were made for the three values of the orientational relaxation time, with (19) truncated at various orders to ensure that negligible errors were being introduced by truncating the hierarchy. This was particularly important for infinite τ_{0r} because the criterion given in (20) does not hold. It was found that it was necessary to include up to the 6th-order Legendre coefficients for $\tau_{0r} = \frac{1}{3}$ and 2 ns and up to the 10th-order for infinite τ_{0r}.

Table I gives the gating pulses calculated for the three cells for these values of τ_{0r}. The transmittance of the array varies from 5×10^{-5} at the beginning to ≈ 0.084 at the end of the 9.4-ns interval. In each case, the calculated transmittance was made to fit $I(t)$ in (36) within 10 percent over a range of output-signal intensity covering about four orders of magnitude. The agreement between the 3-cell transmission and the ideal function, for τ_{0r} = 2 ns, is shown in Fig. 3. Clearly, this system is capable of generating a rather complicated pulse waveform with an accuracy that probably exceeds that of the input signal and gating pulses that could be realized in practice.

CONCLUSION

We have presented a preliminary analysis of the characteristics of saturable absorber systems in which a signal pulse is intensity modulated by one or more gating pulses. A synthesis procedure useful for numerical calculation of the necessary

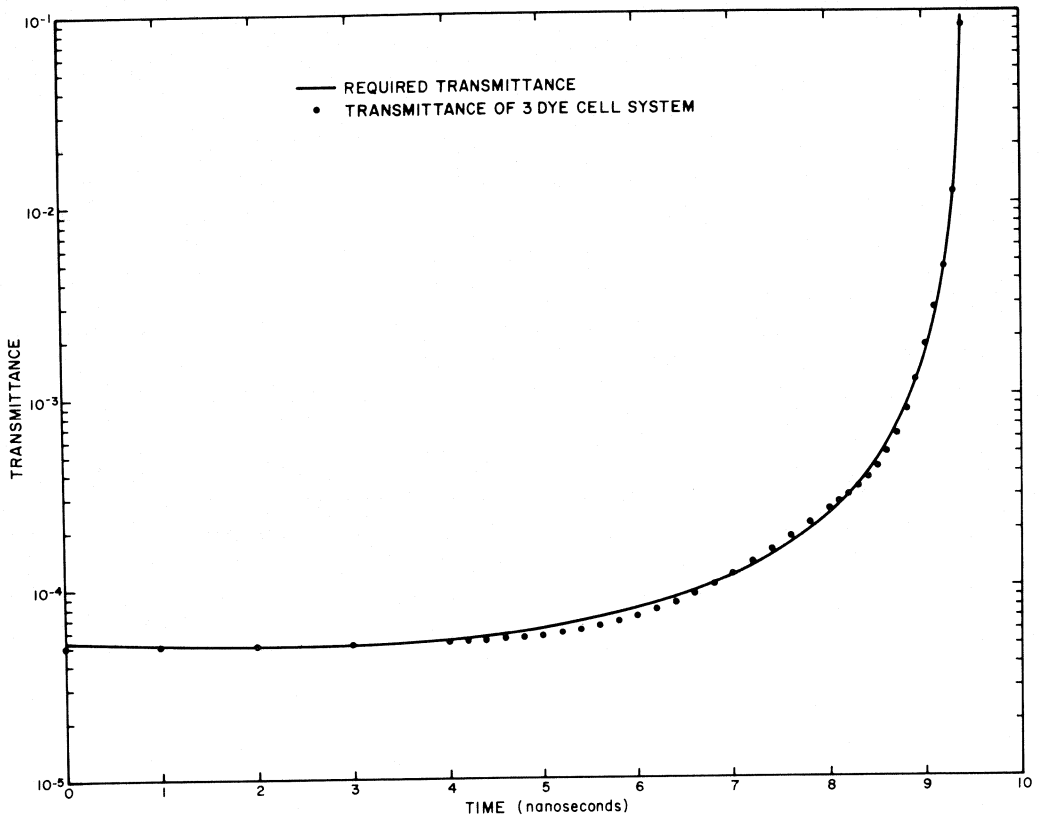

Fig. 3. Synthesized transmittance function for a 3-cell transversely gated system. Required transmittance corresponds to generation of a pulse for laser fusion.

gating intensities has been discussed. Limitations imposed by undesirable nonlinear properties of liquid dye systems have been estimated, and the performance of a 3-cell dye system of potential use in shaping master oscillator pulses for laser-fusion experiments has been calculated to illustrate the possibilities offered by this technique. We believe devices of this type may also prove useful in optical radar and in a variety of experiments in which short laser pulses are made to interact with physical systems.

Pulsewidth of the Mode-Locked, Internally Frequency-Doubled Laser

JOEL FALK, MEMBER, IEEE, AND C. BRECK HITZ, MEMBER, IEEE

Abstract—**The variation in the output pulse duration of a mode-locked internally frequency-doubled (MLFD) laser was experimentally studied. The dependence of pulse duration on second-harmonic conversion rate and modulation index in a Nd:YAG laser is reported. The laser was frequency doubled by a barium sodium niobate crystal located inside the laser cavity and was mode locked by a quartz acousto-optic loss modulator.**

The observed variation of pulse duration with modulation depth and second-harmonic conversion rate is in good agreement with theory. The techniques reported should allow continuous variation of 1.06-μm pulse duration from about 50 ps to greater than 900 ps to be obtained.

THE MODE-LOCKED, internally frequency-doubled (MLFD) Nd:YAG laser is an attractive source for optical communications systems. Its wavelength, 532 nm, falls near the optimum response of many optical detectors. The laser is capable of a high pulse-repetition-rate short-pulse output that is useful for pulse-code modulation formats. The large fundamental-wavelength optical fields available within the Nd:YAG optical cavity make efficient conversion to the second harmonic possible and permit generation of useful output powers at relatively high system efficiency.

The primary difficulty encountered in the use of the MLFD Nd:YAG laser as a high-data-rate communications transmitter occurs because of the difficulty of maintaining the short-pulse duration available from a fundamental-wavelength Nd:YAG laser during the second-harmonic generation (SHG) process. This difficulty arises because the intracavity SHG tends to increase the fundamental-wavelength laser pulse duration which in turn increases the pulse duration of the harmonic pulse. Losses caused by SHG are directly proportional to the instantaneous power present at the fundamental wavelength and hence are greatest at the peak of the pulse and smallest at its extremes. This greater loss inflicted on the center of the pulse increases the measured pulse duration [1].

Although these increased pulse durations are detrimental to optical communications the variable-pulse-duration output that is achievable by changing the rate of conversion of fundamental-wavelength power to second harmonic is useful for other applications. The operation of a subnanosecond, variable-pulse-duration optical source has uses in laser fusion and nonlinear optics experiments [2], [3]. Other authors have used internal frequency doubling in a similar manner to that reported here to control the durations of the submicrosecond pulses available from Q-switched lasers [3], [4].

Falk [5] has theoretically analyzed the AM mode-locked, internally doubled laser and has found that the laser's pulse duration is determined by a competition among three mechanisms. These are the following: 1) the amplitude modulation which imposes a loss on the pulse, 2) the gain of the active laser medium, and 3) the frequency-doubling process. The amplitude modulator shortens the pulse duration, and the frequency-doubling process increases it. Because the gain medium has a finite bandwidth, it increases the pulse duration and places a lower limit on the pulse duration achievable.

The purposes of the present paper are the following: 1) to present results that substantiate some of the theoretical predictions of the earlier paper, and 2) to demonstrate the operation of a mode-locked laser whose pulse duration is easily controllable.

Falk has shown that the effect of SHG on the pulsewidth of a MLFD laser is describable in terms of a parameter α_{SHG} defined as the average single-pass power loss due to the frequency-doubling process [5], that is

$$\alpha_{SHG} = \frac{1}{2}\frac{P_{SHG}}{P_c} \tag{1}$$

where P_{SHG} is the total (two-direction), time-average, second-harmonic power produced if P_c is the average fundamental power passing through the nonlinear crystal in each direction. He showed that if the effect of the gain medium's linewidth is negligible, and if the modulator drive frequency is chosen so that the pulse suffers minimum loss in the modulator, then pulse duration is given by

$$\tau = 2[\sqrt{2}\ln 10]^{1/2}\frac{1}{\omega_m}\left[\frac{\alpha_{SHG}}{\delta_L}\right]^{1/2}. \tag{2}$$

The strength of the amplitude modulation is measured by the value of δ_L. This modulation index is defined so that the time-average single-pass modulator power transmission is $(\exp - \delta_L)$. The other parameters in (2) are defined as follows: ω_m is the circular frequency of the amplitude modulation; and τ is the laser pulse duration measured between the 10-percent points of the second-harmonic output. Equation (2) applies when the pulse duration is determined only by the amplitude modulator and frequency doubler and is not influenced by the laser gain linewidth. This occurs for sufficiently large values of single-pass second-harmonic power loss so that [5]

$$\alpha_{SHG}^2 >> 8g\delta_L(\omega_m^2/\Delta\omega_a^2) \tag{3}$$

where

$\Delta\omega_a$ the laser fluorescent linewidth;
g single-pass *saturated* electric-field laser gain.

The pulse duration predicted by (2) is radically different from that expected from a fundamental-wavelength mode-locked laser where [6]

$$\tau \sim (\omega_m)^{-1/2}(\delta_L)^{-1/4}. \quad (4)$$

The present paper reports the results of an experimental effort designed to verify the accuracy of the functional dependence given in (2). Fig. 1 is a diagram of the laser investigated. The active laser medium is Nd:YAG and frequency doubling is accomplished using a 5-mm cube of barium sodium niobate. The laser is limited by an aperture to fundamental transverse mode (TEM_{00}) operation. The optical resonator, which consists of three mirrors, is designed so that the second-harmonic power generated in each direction can be measured separately. Since mirror M_3 is partially reflecting at the harmonic wavelength, there are interference effects between the two beams which, in general, prevent them from containing equal power [7]. Mirror M_3 has a calibrated transmission at 1.06-μm of 0.5 percent so that the average fundamental circulating power can be determined from a measurement of the power output through M_3.

The laser was mode locked by a quartz loss modulator driven at 250 MHz, approximately one-half of the axial mode spacing of the 30-cm optical-length cavity. This modulator was a low-Q, acoustically resonant device whose modulation index varied with both the temperature of the quartz substrate and the RF drive frequency to the $LiNbO_3$ transducer [8]. Fig. 2 shows the measured variation in modulation index caused by a change in temperature of the quartz substrate. The variation of modulation index with change in modulator drive frequency follows a curve similar in shape to Fig. 2 and has a frequency spacing between acoustic resonances of ~250 kHz.

Thus, if the modulation index is to be maintained at a constant level during mode-locking experiments, accurate control of both the temperature of the quartz substrate and of the drive frequency to the modulator must be maintained. In the experiments reported here the quartz block was maintained at a constant temperature to within ±0.2°C by a thermistor-control-feedback circuit and the modulator drive frequency was manually held constant to within ±3 kHz. In addition, heating of the modulator substrate due to RF and acoustic losses in the modulator resulted in a frequency shift of the acoustic resonance of 110 kHz/W of RF input power to the modulator. This required that the average power input to the modulator be held nearly constant (±5 percent) to avoid changes in modulation index.

The approximate modulation depth δ_L at 1.06 μm was inferred from a measurement of the modulator's time-average diffraction efficiency at 632.8 nm [9]. The values of δ_L at 1.06 μm used in the experimental results shown in Fig. 3 were several times 10^{-3} so that the inequality given by (3) was well satisfied. Variation in the value of δ_L was accomplished by varying the duty cycle of the pulsed input drive to the modulator, while maintaining an average power input of 0.5 W. In a typical experimental run the modulator duty cycle was 0.18 and the modulator "on" time was 10 ms. Constant input power was necessary to avoid shifting the frequency of the acoustic resonance and thereby changing the diffraction ef-

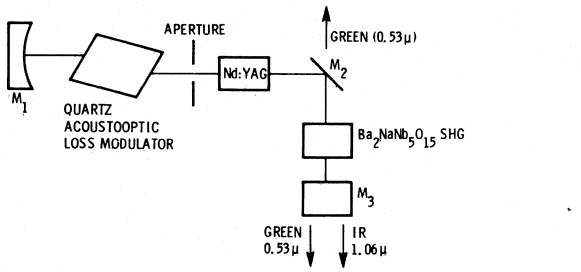

Fig. 1. Diagram of experimental laser. Mirror M_1 has a radius of curvature of 27 cm. Mirrors M_2 and M_3 are flat. Thermal focusing in the Nd:YAG rod makes the optical cavity stable.

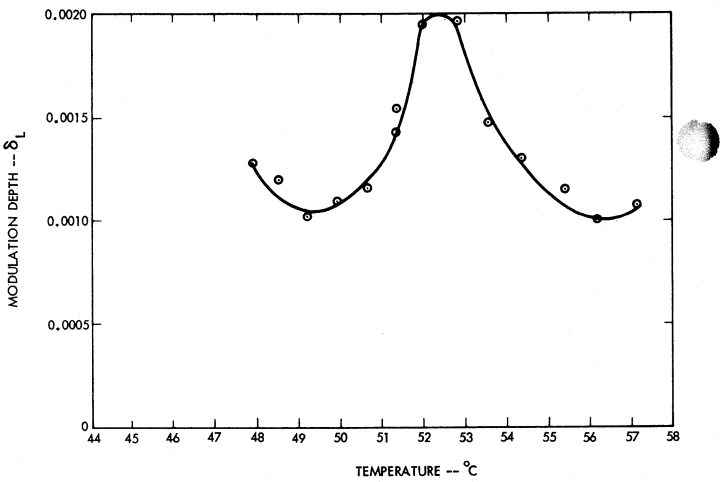

Fig. 2. Modulation depth of modulator as a function of the substrate temperature.

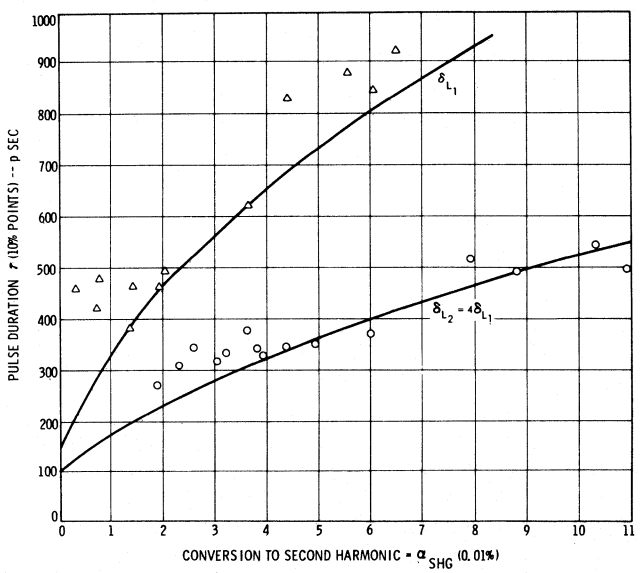

Fig. 3. Experimental data for two different modulation depths. The modulation depth (δ_L) used for the lower data points is four times as large as those used for the upper data points. The solid lines are drawn to show the theoretical $(\alpha_{SHG})^{1/2}$ dependence of pulse duration on second-harmonic conversion rate.

ficiency. An observed linear variation of modulation depth at 632.8 nm with drive power allowed a calibration of the relative modulation index in terms of the modulator duty cycle.

Operation of the modulator in a pulsed mode also permitted an indirect measurement of the laser's pulsewidth without requiring the use of fast photodiodes [10] or sophisticated beam overlap techniques [11]. Pulsewidth was inferred from the enhancement in green output power and decrease in infrared (IR) circulating power which were observed when the drive power was switched "on" to the loss modulator. Since the harmonic output from the laser is proportional to the square of the fundamental-wavelength circulating power and inversely proportional to the pulse duration [12] the enhancement E of the second-harmonic output power due to mode locking can be written

$$E = \frac{K}{\tau}\left(\frac{P_{c1}}{P_{c2}}\right)^2. \tag{5}$$

In (5) P_{c1} is the fundamental-wavelength circulating power with the modulator on and P_{c2} is its value with the modulator off. This method of determining pulse duration requires one direct measurement of pulse duration in order to determine the constant of proportionality K. A pulse duration of 1000 ps (10-percent power points) was measured directly along with the corresponding values of P_{c1}, P_{c2}, and E. The pulsewidths reported in this paper were then calculated from (5).

The value of the laser's saturated gain, determined from an independent measurement of total cavity losses, was 0.02.

Fig. 3 shows the principal result of this paper, the experimentally observed variation of laser pulse duration as a function of α_{SHG}. The efficiency of the SHG process (i.e., α_{SHG} itself) was controlled by selecting various temperatures for the nonlinear crystal in the vicinity of the phase-matching temperature [13]. The numerical values of α_{SHG} were determined from (1).

Several difficulties were encountered in performing the experiments described in the preceding.

1) At low-α_{SHG} severe relaxation oscillations were often observed when the laser was mode locked. This made precise evaluation of the low-α_{SHG} pulse duration difficult. When the loss modulation was removed, the relaxation oscillations usually disappeared. The appearance of relaxation oscillations in a loss-modulated laser has been previously noted and briefly discussed by Kinsel [14].

2) At modulation depths greater than about 0.05 the modulator introduced a noticeable CW loss. This loss is probably caused by the presence of an acoustic traveling wave in addition to the acoustic standing wave responsible for the laser mode locking. This traveling wave would result from any effect which makes the oppositely directed acoustic waves in the quartz substrate of unequal amplitude or not completely overlapping. Effects that might be responsible for the CW modulator loss thus include acoustic attenuation in quartz, acoustic diffraction, and the use of a substrate with nonparallel ends. The observed CW loss for the modulator used cannot be completely explained in terms of any of these three mechanisms.

In spite of the difficulties outlined in the preceding, the agreement between theory and experiment in Fig. 3 is good (especially at higher values of α_{SHG}), i.e., the pulse durations experimentally observed agree with the $(\alpha_{SHG})^{1/2}$ and the $(\delta_L)^{-1/2}$ dependence predicted by (2) [15].[1] Unfortunately, verification of the theory in the low-conversion-efficiency short-pulse region was hampered by the difficulties outlined previously.

Thus the technique of intracavity SHG has been shown to be useful in generating an optical pulse train with pulses whose duration can be changed in a predictable way. In a Nd:YAG laser pulse durations from 50 ps [6] to at least as long as the 900-ps durations reported here should be possible.

Heating in a CW Nd-Pentaphosphate Laser

HEINZ P. WEBER, MEMBER, IEEE, AND B. C. TOFIELD

Abstract—**In a Kr-laser pumped CW Nd-pentaphosphate (NdP_5O_{14}) laser, with a threshold of 1.6 mW, an internal quantum efficiency of 63 percent is measured using a novel method. Bistable operation between oscillating and nonoscillating regimes is observed, resulting from the thermal lens created in the pumped zone. If stimulated emission is initially absent, this lensing effect is strong, making the resonator unstable and stimulated emission cannot build up. With stimulated emission initially present, heat development is reduced by the stimulated process itself and the resonator remains in the stable regime. For both situations, temperatures in the pumped area are determined using Raman spectroscopy. For the nonlasing situation, a fluorescence quenching rate of 68 percent, originating from Nd-Nd interactions is deduced, in close agreement with an earlier finding.**

A TEMPERATURE RISE in a Nd laser material increases the pump threshold owing to linewidth broadening and also because of the greater reabsorption of laser radiation resulting from the increased thermal population of the terminal laser state. Heat is developed by the optical pumping process itself, and the undesired rise in temperature can be kept at a minimum by adequate heatsinking and by pumping at the longest possible wavelength.

We report here measurements of the temperature rise due to pumping in a CW NdP_5O_{14} (NdPP) laser [1]. In a laser with 63-percent internal quantum efficiency heat development results in thermal lensing, leading to a reproducible bistable laser operation. Temperature in the pumped area is measured using Raman spectroscopy. The results provide quantitative agreement with previous measurements of the degree of fluorescence quenching caused by Nd-Nd interactions, based on lifetime investigations.

Crystals of NdP_5O_{14} were grown [2] in a H_2O-saturated N_2 atmosphere at a temperature of 550°C. Twin free crystals [3], with fluorescent lifetime [2] $\tau = 120$ μs and 1-mm length, were clamped on a brass block. A thin film of contact grease ensured good heat transfer. The laser resonator (see Fig. 1) consisted of two mirrors with reflectivities $R \approx 99.8$ percent at 1.05 μm and radii of curvature of 2.5 cm, arranged in close to concentric resonator configuration with the crystal at the center of the cavity. A Kr^+-ion-laser pump beam was focused to a spot of approximately 20-μm diameter in the crystal, and CW laser action was achieved using any of the three IR pump wavelengths 676.4 nm, 752.5 nm, and 799.3 nm. The threshold was similar with the resonator axis along either the [100] or [011] crystal directions, and the lowest threshold was 1.6-mW absorbed pump power at 752.5 nm, which is close to the value achieved elsewhere [4]. Above threshold, output increased linearly with input up to the maximum available pump power of 80 mW. Significant internal scattering of laser light could be easily detected with an infrared-sensitive phosphor card.

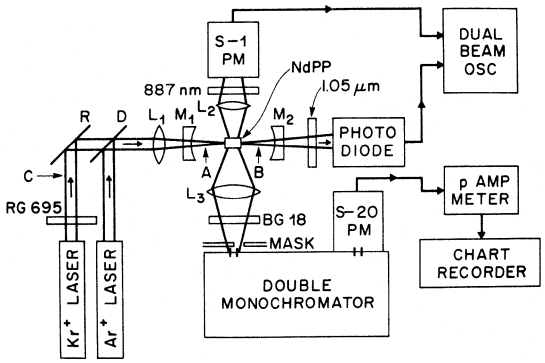

Fig. 1. Experimental arrangement. The Kr^+-ion-laser beam, redirected by reflector R, and focused with lens L_1 onto the NdPP crystal, longitudinally pumps the Nd laser. Mirrors M_1, M_2 with radii of curvature 2.5 cm and reflectivities of 99.8 percent at 1.05 μm form a close to concentric resonator. The laser output passes through a 1.05-μm transmitting filter and is detected by a Si photodiode. The spontaneous fluorescence is collected by lens L_2, passes through an 887-nm transmitting filter ($\Delta\lambda = 10$ nm), and is detected with a dry-ice-cooled S-1 photomultiplier and recorded on the lower traces of the oscilloscope. The Ar^+-ion-laser beam at 488.0 nm is made collinear with the pump beam by the dichroic beamsplitter D and generates the Raman spectrum. The IR transmitting filter RG 695 eliminates blue fluorescence from the Kr discharge. Raman-scattered light is collected by lens L_3 and imaged onto the entrance slit of the double monochromator. The mask shadows light from the second half of the NdPP crystal. Filter BG 18 blocks IR light from entering the monochromator. The gratings, blazed at 1 μm, are used in second order. Gas from boiling liquid N_2 cools the S-20 photomultiplier at the exit slit of the spectrometer. The output signal is processed by a p-Amp meter and recorded with a chart recorder.

The measured external quantum efficiency of the laser of 5 percent is of marginal value because mirror transmission was not optimized for optimum efficiency. A meaningful and precise value for the internal efficiency of the laser, however, is gained by using a novel method employing monitoring of the intensity of the fluorescence light into the Nd ground manifold. In Fig. 2 the complete optical cycle is shown. The pump light of 752.5 nm pumps the $^4S_{3/2}$ and $^4F_{7/2}$ manifolds that decay nonradiatively (with thermalization energy D_1) into the $^4F_{3/2}$ manifold. This thermalization efficiency is approximately unity, as will be verified later on. The $^4F_{3/2}$ manifold has three decay routes: a) fluorescence quenching Q; b) laser emission L into the $^4I_{11/2}$ manifold; and c) spontaneous fluorescence F into any of the ^4I manifolds. We denote the branching ratio for these decays as q, l, and f. The distribution of fluorescence F into the four manifolds are for Nd systems such that the average photon energy is almost equivalent to that of the F_2 decay. For the energy considerations in the later part of this paper we will simplify our analysis by assuming that all the fluorescence F is of energy F_2.

The decay of the $^4F_{3/2}$ levels for the nonlasing (N) and lasing

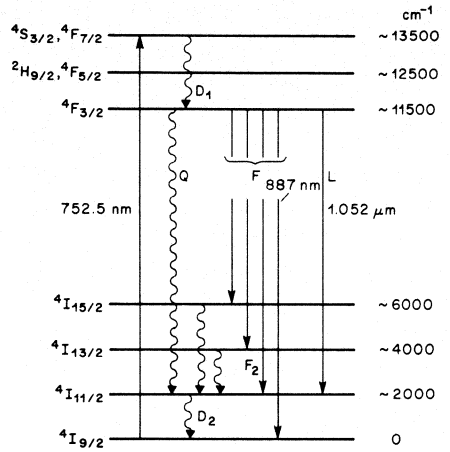

Fig. 2. Energy-level diagram of NdPP. Level assignments and energies are given at the left- and right-hand sides, respectively. Straight vertical lines represent radiative and wavy vertical lines nonradiative transitions. The 752.5-nm pump light populates the $^4S_{3/2}$ and $^4F_{7/2}$ manifolds which decay nonradiatively with thermalization energy D_1 into the $^4F_{3/2}$ manifold with efficiency ≈ 1. The three decay routes from $^4F_{3/2}$ are a) fluorescence quenching Q, b) laser emission L, and c) spontaneous fluorescence F, into any of the ^4I manifolds. The average energy of a fluorescence photon is F_2. The thermalization energy from $^4I_{11/2}$-$^4I_{9/2}$ is denoted by D_2.

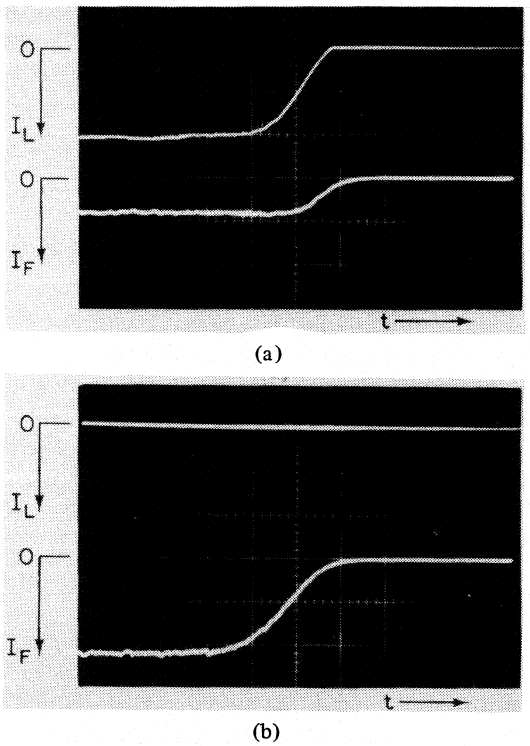

Fig. 3. Light intensities of NdPP laser. Laser output intensity I_L recorded by the photodiode (upper trace) and $^4F_{3/2}$-$^4I_{9/2}$ fluorescence light intensity I_F at 887 nm monitored by an S-1 photomultiplier (lower trace). The time scale is 0.5 ms/cm. For the second half of the time periods the pump beam is blocked. (a) For ideal mirror alignment. (b) Same conditions as for (a) but with mirror M_2 (Fig. 1) slightly misaligned, to curtain laser action.

(L) situation is described by (1a) and (1b), respectively

$$1 = q_N + f_N \tag{1a}$$

$$1 = l + q_L + f_L = l + p(q_N + f_N) \tag{1b}$$

where p is the directly measurable reduction of fluorescence intensity if laser action takes place. The internal quantum efficiency for stimulated emission from the $^4F_{3/2}$ manifold is given by $r = (1 - p)$. (Note that the measurement of r is independent of the degree of quenching q.) By monitoring the reduction in fluorescence intensity into any of the ^4I manifolds after onset of laser action, p may be measured. It is experimentally convenient to measure the fluorescence intensity into the ground $^4I_{9/2}$ manifold at 887 nm. In Fig. 3 the intensity of the laser output at 1.052 μm measured with a Si photodiode is shown together with the fluorescence monitored at 887 nm with a dry-ice-cooled S-1 photomultiplier. Fig. 3(a) shows the intensities for ideally aligned mirrors, and Fig. 3(b) shows them for a slightly misaligned mirror M_2. For the second half of the time period the pump beam was blocked. A reduction factor $p = 0.37$ for the fluorescence was observed corresponding to an internal quantum efficiency for laser action of $r = 63 \pm 2$ percent.

Upon pumping at 752.5 nm (see Fig. 2) the thermalization decay paths D_1 and D_2 convert 30 percent of the pump energy into heat. The nonradiative quenching process Q produces additional heat. Due to the temperature increase in the absorbing focal spot a thermal lens is formed, converting the nearly concentric resonator into an unstable resonator. A stable resonator can be obtained again by slightly shortening the mirror spacing. Observable modifications of the resonator characteristics will be used in the following to directly demonstrate that a sizable fraction of the population of the $^4F_{3/2}$ manifold decays via the quenching process Q.

When the NdPP laser was oscillating, pumped with 80 mW of pump power, and a mirror separation close to critical, we blocked feedback at position B with a cardboard. After removal of the cardboard, oscillation did not build up again. After inserting and removing the cardboard at position A laser oscillation always restarted. A reproducible, truly bistable operation was observed. The insertion time found necessary at A or B to switch from one mode to the other was found to be $\sim\frac{1}{10}$ s. By adjusting mirror M_2 we were also able to switch between two finite, well-defined intensity levels. This behavior results from the generation of a thermal lens. Different amounts of heat are developed for the two situations. By blocking feedback at B (Fig. 1) the crystal was allowed to heat in a nonlasing condition. The thermal lens formed converted the previously concentric resonator into an unstable resonator and lasing did not recommence after removal of the screen. By blocking at A (Fig. 1), on the other hand, heating could not occur and laser oscillation always recommenced after the screen was removed. The difference in contribution of heat generation for the two situations is $r \cdot q_N \cdot F_2$ per excited ion. The stimulated emission effectively carries heat out of the laser and thus has a cooling effect. Obviously, this effect can only be strong if q_N is large and the internal efficiency $r = (1 - p)$ is high. It is practically impossible, however, to obtain precise results about the temperature in the lasing area from a difference of resonator adjustments.

A quantitative measure of the temperature rises under lasing and nonlasing conditions, and hence of the quenching efficiency q may be obtained by monitoring the pumped area of the crystal by Raman spectroscopy. The intensity of an anti-Stokes Raman line with energy shift E is directly proportional

to the occupation number $\bar{n}$ of the phonon state with energy E, and

$$\bar{n} = 1/[\exp(E/kT) - 1] \tag{2}$$

is strongly dependent on temperature T, especially for $E >> kT$. Due to an overlap with a weak Nd fluorescence, the Kr^+-ion-laser pump beam itself could not be used as the Raman source. Instead we used the 488.0-nm line of an Ar^+-ion laser, and with the dichroic beamsplitter D the Ar laser beam was made collinear with the Kr-laser pump beam, in order to occupy the same focal spot. The light-scattering area was imaged onto the entrance slit of a double monochromator, with a mask used to block all but the image of the more strongly pumped front half of the NdPP crystal. The grating, blazed at 1 μm, was used in second order and a Schott BG 18 filter blocked any IR light from the spectrometer. An S-20 photomultiplier, cooled with gas from boiling liquid N_2, served as detector. Spectra were recorded covering the whole Stokes and anti-Stokes range of the 488.0-nm Ar line. The Raman spectra look all very similar to the spectrum published elsewhere [2], and no superimposed structure due to excited-state absorption seemed to be present when Kr and Ar laser beams were simultaneously present in the crystal. The highest energy anti-Stokes line observable corresponds to an energy $E = 672$ cm^{-1}, and the wavelength selector of the double monochromator was locked onto this line (at 472.5 nm). We measured the scattered intensity when the Kr^+-laser beam pumped the NdPP crystal and when it was blocked (at position C in Fig. 1). With an aligned resonator (lasing condition) we measured a ratio $V_L = 1.14:1$, and for a misaligned resonator (nonlasing condition) we measured a ratio $V_N = 1.23:1$.

The ratios correspond to temperature increases of $\Delta T_L = (11 \pm 1)^\circ$C and $\Delta T_N = (18 \pm 1)^\circ$C above the temperature when the nonabsorbed-Ar-laser beam alone transversed the crystal. These temperatures are averages over the spot size, which was not necessarily perfectly overlapping with that of the pump beam, so that the absolute temperature increases may have been higher. From their ratio significant conclusions with respect to the amount of quenching can be drawn. The observed temperature increases ΔT_L and ΔT_N are directly proportional to the amounts of heat H_L and H_N, generated per absorbed pump photon, in the lasing and nonlasing condition, respectively. From Fig. 2 we obtain, for the two situations, the relations

$$H_N = D_1 + D_2 + q_N \cdot F_2 \tag{3a}$$

$$H_L = D_1 + D_2 + p \cdot q_N \cdot F_2. \tag{3b}$$

With $H_N:H_L = 18:11$, $p = 0.37$, and $D_1 + D_2 = 4000$ cm^{-1}, we find $q_N = 0.68 \pm 0.1$. This quenching rate q_N of the $^4F_{3/2}$ level can also be obtained by comparing lifetimes for different x in $Nd_xLa_{1-x}P_5O_{14}$ [2], [5], [6]. With $\tau(x = 1) = 120$ μs and $\tau(x = 0.01) = 320$ μs, a quenching ratio

$$q_N = 1 - \tau(x = 1)/\tau(x = 0.01) \tag{4}$$

of 0.625 is obtained, in close agreement with the value previously found. The agreement supports the result that the emission cross section is independent of Nd concentration [6]. The suggestion that the lifetime shortening for higher Nd concentration is the result of a larger emission cross section at a high concentration [4] cannot explain our observed temperature effects. The agreement between the two values of q_N also supports the result [5] that for dilute crystals the fluorescence efficiency is unity and the efficiency for multiphonon decay of the $^4F_{3/2}$ levels is negligibly small. A significant multiphonon decay would result in a far smaller value of q_N determined by the lifetime measurement, and the same would hold if the efficiency of the nonradiative decay D_1 (Fig. 2) were far smaller than unity.

In conclusion, we have found, in a CW NdPP laser with a 1.6-mW threshold, an internal quantum efficiency of 63 percent. Due to heat developed by the optical pumping, thermal lensing in the laser crystal was found which led, under critical adjustment, to a bistable mode of laser operation. By measuring the intensities of a Raman anti-Stokes line, the temperature of the laser medium was measured for an aligned and misaligned resonator. The "cooling" effect of stimulated emission was clearly observed. Qualitative analysis shows that under the nonlasing condition the fluorescence is quenched by $\frac{2}{3}$ as a result of nearest neighbor Nd–Nd interactions. Although the temperature increase due to CW pumping is in the range of 20°C in our experimental arrangement, this does not severely modify the laser properties, but does demonstrate the need for adequate heatsinking. Use of $Nd_{0.5}La_{0.5}P_5O_{14}$ instead of NdP_5O_{14} would reduce the heat generated per unit volume by $\frac{2}{3}$, due to the reduced Nd^{3+} concentration and the 50-percent reduction in q, which will also result in an expected lower threshold [6]. The suggested [7] advantageous rapid electronic-energy migration in NdP_5O_{14} was recently shown to be far too small to influence the laser properties [8]. These results, therefore, render the less concentrated material more attractive for device applications than undiluted NdP_5O_{14}.

Amplification of the 1.32-μm Line in Nd:YAG

T. R. LOREE, L. M. SHERMAN, AND J. M. THORNE

Abstract—**Single-pass amplifier gains at 1.32 μm have been measured in an 80-mm Nd:YAG rod, achieving a saturated gain of 3.1. Small-signal gain comparisons imply a stimulated-emission cross-section ratio (1.32/1.06 μm) of 0.19.**

In addition to the normal 1.06-μm wavelength, the Nd:YAG laser can produce a number of other lines ranging from 0.95 to 1.84 μm [1]–[4]. The 1.32-μm line has application in optical parametric oscillators (OPO's). When doubled to 0.66 μm, this line is a pumping wavelength for a 90°-cut temperature-tuned $LiNbO_3$ OPO. Pumping with 0.66 μm allows tuning of the OPO crystal through the degeneracy wavelength within the temperature range in which the $LiNbO_3$ is chemically stable [5].

The desire to scale up such an OPO system led us to investigate the problem of amplifying the 1.32-μm line in Nd:YAG. The amplifier units used 9.5-mm-diam 80-mm-long Nd:YAG rods with uncoated 12°-cut ends. About 70 mm of the rod was pumped by two linear flashlamps in a double elliptical cavity filled with circulating water.

As these amplifiers produce a maximum energy gain of about 30 for 1.06-μm radiation, it was expected that a saturated gain of 2–4 could be obtained at 1.32 μm. These rough predictions were made on the assumption that the ratio of the cross sections for these two transitions would be the same as the ratio of the natural logarithms of the saturated gains. Cross-section values were obtained from two sources.

1) Deserno *et al.* [3] measured the single-pass gains for a number of lines in an oscillator. Gain slopes taken from their data imply the ratio

$$\sigma_{1.32}/\sigma_{1.06} = 0.4$$

giving a predicted saturated gain of 3.9 for 1.32 μm.

2) Stimulated-emission cross sections for Nd:YAG have been most recently measured by Singh *et al.* [6]. Assuming that the "1.06" line is a combination of $R_2 \rightarrow Y_3$ and $R_1 \rightarrow Y_2$ and that the "1.32" line is both $R_2 \rightarrow X_1$ and $R_2 \rightarrow X_2$, one obtains a cross-section ratio of 0.2. This value gives a saturated-gain prediction of 2.0 for the 1.32-μm radiation.

The experimental gain measurements were made in a straightforward manner by ratioing the signals from reference and signal calorimeters. The original beam of about 1 mJ was generated by a tunable Chromatrix 1000 Nd:YAG oscillator, split to provide the reference signal, amplified, and detected by a calorimeter. The measured single-pass gains for both 1.06 and 1.32 μm are plotted in Fig. 1 as a function of total flashlamp pumping energy. The maximum gain at 1.06 μm was not quite 30 at saturation, and the saturated gain for the 1.32-μm line was about 3.

A number of experimental strategies were employed to lend credence to this result. The input beam was apertured, spatially filtered, and carefully matched to the rod diameter. The timing of the input pulse relative to the firing of the amplifier flashlamps was varied. The temperature of the amplifier rod was varied throughout the range 5–30°C. No combination of variables resulted in appreciably different results.

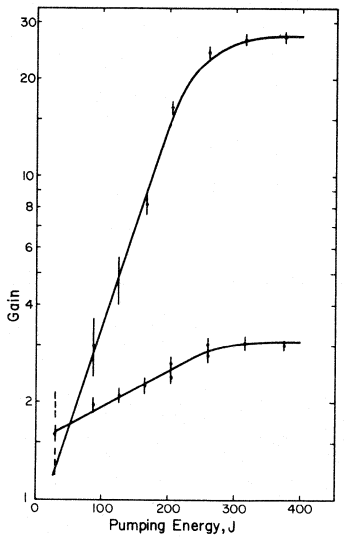

Fig. 1. Experimental single-pass gains for millijoule-level pulses in an 80-mm Nd:YAG rod for 1.06 and 1.32-μm wavelengths.

The low-energy portions of the exponential gain curves may be reasonably fit with straight lines, as shown in Fig. 1. The failure of either curve to intersect the origin is indicative of the imperfections in the rod (residual losses) and/or experimental procedures. The most valid method of estimating the 1.32/1.06 cross-section ratio from these data is to compare the slopes of the straight-line sections of the experimental curves. The single-pass unsaturated gain is given by

$$G_i = \exp(N\sigma_i L)$$

where N is the population inversion density, σ_i is the stimulated-emission cross section for wavelength i, and L is the pumped length of the rod. As both transitions of interest share a common upper $^4F_{3/2}$ state, one may approximate that N is proportional to the flashlamp energy and the same for both transitions at a given lamp input energy. It follows that a ratio of the straight-line slopes will also be the ratio of the cross sections. In this way we obtain

$$\sigma_{1.32}/\sigma_{1.06} = 0.19 \pm 0.05$$

where the limits are determined by the extremes of straight-line fits to the data. This result is in excellent agreement with the ratio obtained from the data of Singh *et al.*

Pumping of Red Continuous-Wave Laser Dyes

F. A. BEISSER AND D. J. EILENBERGER

Abstract—**Two methods of operating red CW dye lasers are examined. A single laser with a mixture of rhodamine 6G and cresyl violet perchlorate (CVP) is compared with a tandem system in which a rhodamine 6G laser is used to pump a CVP laser. At high pumping levels the tandem system is shown to be superior.**

The wavelength range of CW dye lasers has recently been extended to cover the spectrum from 4150 to 7900 Å [1]. Over most of this range, excitation of the dyes is achieved by optical pumping with one or more lines from a CW argon laser. When using dyes in the far-red portion of the spectrum the absorption of available wavelengths is small and excitation becomes inefficient. In this correspondence, we compare two possible ways of surmounting this problem. The first is to utilize a mixture of dyes and use energy transfer between the dye molecules to excite a laser dye. In particular, we have investigated the cresyl violet laser using a mixture of rhodamine 6G with cresyl violet to provide excitation energy transfer [1], [2]. Secondly, we have constructed a separate rhodamine 6G laser as an optical pump for a cresyl violet laser.

The optical configuration used in the experiments to be discussed here was a folded three-mirror cavity described previously [3]. In the first set of experiments dye mixtures were investigated. Rhodamine 6G was added to the ethylene glycol solvent until approximately 90 percent of the 5145-Å pump power was absorbed. Cresyl violet perchlorate (CVP) was then added to the solution and measurements of power and gain were made for different concentrations of CVP. The gain was measured by observing threshold with a calibrated variable-loss device internal to the laser resonator. The measured gain is therefore gain in excess of dye and resonator losses. All three mirrors were high reflectivity.

The results of the gain versus input pump power for the optimum CVP concentration are plotted in Fig. 1. Note that the gain increases linearly up to about 3-W input power at which point it begins to roll off. Above 3 W thermal effects begin to induce loss, which is apparently responsible for the curve rolling off.

In order to compare the efficiency of energy transfer with direct excitation, the rhodamine 6G laser (without CVP) was used for direct optical pumping of a CVP laser with the same cavity configuration. The concentration of CVP was adjusted to absorb 85 percent of the 5825-Å pumping power from the rhodamine 6G laser. Again the measurements of the CVP laser were taken as a function of 5145-Å pump power into the rhodamine 6G laser. These results are also plotted in Fig. 1. Note that the gain increased linearly with 5145-Å power over the range of measurement. A maximum output power of 585 mW at $\lambda = 6900$ Å was achieved. With the tandem pumping system one would expect reduced thermal effects since the heating is distributed into two streams.

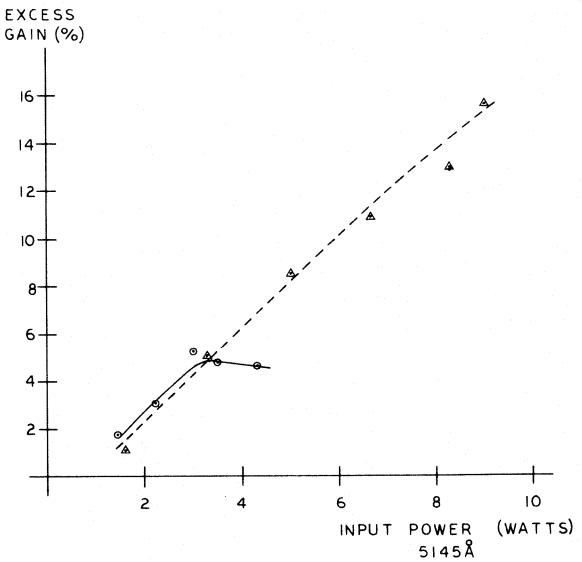

Fig. 1. Excess gain for CVP laser versus argon laser input power. Circles indicate data for the dye mixture. Triangles are data for tandem system.

It was noted that a decrease in overall gain and output power occurred over a period of several days due to a deterioration of the CVP. The CVP was observed to recover somewhat by bubbling nitrogen through the solution for a period of about 16 h. The decay of the CVP occurred in both systems. Operating in a nitrogen atmosphere may help to stabilize the CVP laser output in either system.

Nile blue perchlorate (NBP) was also investigated. A peak output of 200 mW at 7200 Å was observed using a rhodamine 6G pump with 9 W of 5145-Å pumping power. The output of the NBP was also observed to deteriorate over a period of days. Nitrogen had no apparent effect on this system.

In conclusion we have compared a dye mixture system and a tandem pumping arrangement for the CVP laser. At pumping powers below 3 W both the mixture and the tandem scheme produced nearly equal results. Since the rhodamine 6G laser operated with an efficiency of about 30 percent one deduces an approximately equal efficiency for energy transfer in the mixed solution. The basic limitation of the mixture scheme appears to be large thermal effects from the combined Stokes loss of both dyes.

3547-Å Pumped High-Power Dye Laser in the Blue and Violet

K. KATO

Abstract—**Efficient generation of high-power dye-laser radiation in the blue and violet has been achieved by pumping longitudinally with the third harmonic of a Nd:YAG laser. A peak power as high as 2.4 MW at 4890 Å and peak powers in excess of 1.3 MW from 4300 to 5100 Å have been obtained.**

With the development of a high-power Nd:YAG laser system, it has been possible to obtain a high-repetition-rate high-power visible dye laser using the second-harmonic radiation as a pump source [1]. However, an optical pump by the 5321-Å radiation does not allow lasing of dyes at wavelengths shorter than approximately 5400 Å. The third-harmonic radiation of a Nd:YAG laser could be an attractive pump source to extend this wavelength limit, and can offer the important advantage of higher repetition rates than the dyes pumped by the second harmonic of a ruby laser. In this correspondence we wish to report the efficient generation of a 3547-Å pumped high-power dye laser that is capable of high average power in the blue and violet region of the spectrum. A high-repetition-rate visible dye laser pumped by the third harmonic of a Nd:YAG laser has previously been reported by Okada *et al.* [2], but they have used very low pump powers and have consequently obtained much lower output powers and conversion efficiencies than the values reported in this correspondence. The dye laser reported here has produced a peak power as high as 2.4 MW with an average power of 390 mW at 4890 Å at a pulse repetition rate of 20 pulses per second (pps) and peak powers in excess of 1.3 MW from 4300 to 5100 Å.

Fig. 1 is a schematic diagram of the experimental setup. The basic pump source was a repetitively Q-switched Nd:YAG oscillator–amplifier system working in the TEM_{00} transverse mode and in 2–4 axial modes with a peak power of 50 MW and 12-ns pulse duration. The 10-ns 22-MW second-harmonic radiation at 5321 Å generated from a temperature-tuned deuterated cesium dihydrogen arsenate (CD*A) crystal [3] was frequency mixed with the transmitted fundamental radiation in a phase-matched rubidium dihydrogen phosphate (RDP) crystal [4]. The third-harmonic radiation at 3547 Å was characterized by a peak power of 10.5 MW and 8-ns pulse duration. The measured angular divergence of the 5-mm-diam third-harmonic beam was 0.95 mrad. As shown in Fig. 1, the third-harmonic beam was physically separated from the fundamental and second harmonic by a high-quality Glan polarizer, and was used to pump a dye laser in an on-axis longitudinal configuration. The 40-cm-long dye-laser cavity was a folded three-mirror configuration consisting of a flat dichroic mirror, a 50-percent-reflectivity broad-band flat output mirror, and a 1200-lines/mm diffraction grating for wavelength tuning. By inserting a telescope having an angular magnification of 5 between the dichroic mirror and the diffraction grating, the linewidth of the dye-laser spectrum was reduced to less than 2 Å with a corresponding decrease in the output power by a factor of 1.2. The dichroic mirror had approximately 92-percent transmission at 3547 Å and 98–99-percent reflectivity from 4300 to 5250 Å. The 1-cm-thick dye cell consisted of two 2.5-cm-diam uncoated fused silica windows wedged by approximately 8° to prevent internal coupling. The dye flow was transverse to the optical axis of the dye-laser cavity. All the dye compounds used in this experiment were purchased from Eastman Kodak and New England Nuclear Company in dye-laser quality and used without further recrystallization, though the solutions were purified through 0.7-μ filters. The dye concentration was approximately 7×10^{-4} mole/l with some adjustment made to minimize the threshold.

Manuscript received February 4, 1975; revised March 5, 1975.

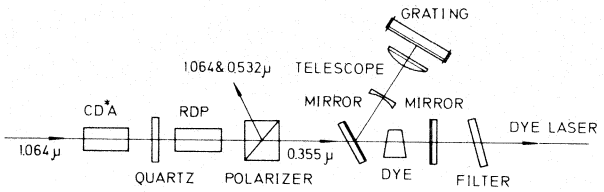

Fig. 1. Schematic diagram of experimental setup.

TABLE I
DYE-LASER PERFORMANCE PUMPED BY THIRD HARMONIC OF ND:YAG LASER

dye compound	solvent	central lasing wavelength	average output power
dimethyl POPOP	p-dioxane	4320 Å	250 mW
coumarin 120	ethanol	4410	220
coumarin 2	methanol	4540	330
7-diethylamino-4-methylcoumarin	ethanol	4570	380
coumarin 102	methanol	4850	270
7-diethylamino-4-trifluoromethylcoumarin	p-dioxane	4890	390

Note: The pump power at 3547 Å is 10.5 MW at a pulse repetition rate of 20 pps.

The detection of the dye-laser pulses was made through an UV cutoff glass filter and a high-speed photodiode–oscilloscope system having an overall rise time of less than 1 ns. With this system we have observed that the pulse shape and pulse duration of the dye laser closely followed the pump pulse in the high-gain region of the tunability range. For the low-gain region near the limits of the tunability range the pulse duration dropped to 50–60 percent of the pump pulse. The spectral linewidth of the dye-laser output analyzed with a 1-m grating spectrograph was well under 2 Å, but a frequency jitter of up to 5 Å was often observed. This instability is probably due to the mechanical vibrations of the dye-laser cavity.

Table I represents the central lasing wavelength and the average output power achieved with different combinations of dye compounds and solvents. The tunability range of the dye-laser output for individual dye solutions was around 500 Å, which could probably be somewhat extended by optimizing the output-mirror reflectivity. We note that in excess of 20-percent energy conversion efficiency from the 3547-Å pump power to the dye-laser output has been obtained with three different dyes. The best conversion efficiency obtained was 23 percent for a p-dioxane solution of 7-diethylamino-4-trifluoromethylcoumarin [5]. The excellent conversion efficiencies observed were due to the near optimum matching of the pump wavelength to the absorption bands of the dye compounds utilized, and to the perfect overlap between the dye-laser mode and the pump beam in the on-axis longitudinal pumping scheme. With a p-dioxane solution of 7-diethylamino-4-trifluoromethylcoumarin, we have obtained a peak output power of 2.4 MW with an average power of 390 mW around 4890 Å at a pump power of 10.5 MW and a pulse rep-

etition rate of 20 pps. The short wavelength limit for which the dyes could be lased was determined by the rapid fall in the reflectivity of the dichroic mirror rather than by the relatively low quantum efficiency of the organic scintillators. For instance, BBE dissolved in p-dioxane lased very efficiently around 4000 Å in an off-axis longitudinal pumping scheme.

The fine adjustment of the intracavity telescope for a minimum angular divergence of the dye-laser beam was made by observation of the far-field pattern with a high-magnification camera, and the result obtained was 1.15 ± 0.15 mrad irrespective of the wavelength. The spatial profile of the 5-mm-diam dye-laser beam was close to Gaussian and no inhomogeneous structure was observed.

The system described in the preceding has been operated many hours without noticeable deterioration in the dye-laser output power, although the dichroic mirror exhibited some surface damage after 1 h of operation due to the UV pump power.

When the dye-laser output was focused by a 3.5-cm-long focal-length lens, breakdown in air was observed with all the dye solutions listed in Table I. A preliminary measurement of the breakdown threshold in air at atmospheric pressure showed a monotonic increase of breakdown threshold with increasing wavelength from 4300 to 5100 Å, in qualitative agreement with previous measurements [6] made with a similar dye-laser system pumped by a frequency-doubled single-mode ruby laser [7].

In summary, we have reported the efficient operation of a high peak power and high average power dye-laser system in the blue and violet using the third harmonic of a Nd:YAG laser as a pump source.

Five-Year Operation of a He-Ne Laser

W. P. KOLB

Abstract—**A metal ceramic He-Ne laser has been operating on lifetest for over five years (> 47 000 h). During this period there has been no appreciable change in either the output power or the voltage-current characteristics of the unit. These results indicate the possibility of extremely long-life He-Ne lasers.**

Manuscript received March 14, 1975; revised March 24, 1975.

The author is with the Electron Dynamics Division, Hughes Aircraft Company, Torrance, Calif. 90509.

Some of the many possible life-limiting mechanisms in He-Ne lasers have been discussed by several different authors [1]-[5]. This correspondence reports the construction and continuous operation of a cold-cathode metal-ceramic He-Ne laser for over five years (> 47 000 h). The operating characteristics for this laser have remained essentially unchanged over this period, and the lifetest is continuing.

Background

The laser being lifetested was built around the basic design that Bridges and Kolb described in previous articles [6]-[8]. The device was built in June 1969 and placed on lifetest in September of that year.

Construction

The construction details of the laser are shown in Fig. 1. The laser package, not including the output window, is a cylinder 13.5 in long and 2.5 in in diameter. The plasma tube envelope is made of stainless steel, Kovar, and alumina ceramic. The alumina ceramic bore is 8.5 in long with a 1.5-mm inside diameter. The mirrors, a 2-m radius output and total reflecting flat, are supported by the outer cylinder which is made of aluminum. The cold cathode is made of 2024 aluminum alloy and the snout on the stainless-steel mirror/window holder serves as the anode. The gas volume is 350 cm^3. The dielectric mirrors, which are coated on fused silica substrates, are internal to the vacuum envelope. The output beam is transmitted through a Corning 7056 glass window which is sealed to the vacuum jacket using a P.R. Mallory electrostatic sealing technique. No organic materials were used anywhere in the vacuum tube.

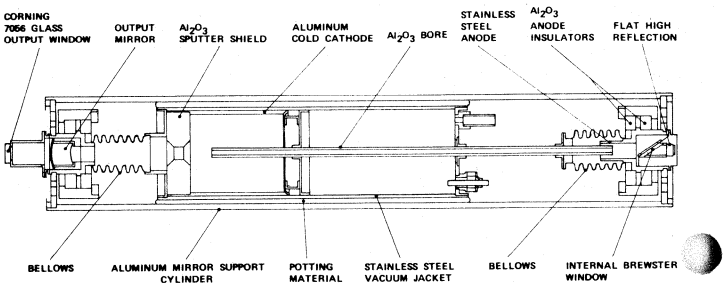

Fig. 1. A section view of the laser showing the construction details.

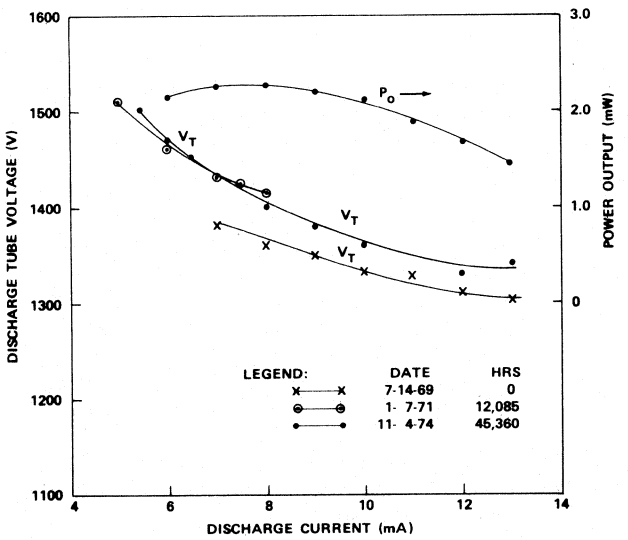

Fig. 2. The voltage-current characteristics of the discharge tube taken at different times during test. The power-output-current characteristics after 45 360 h of operation.

Processing and Packaging

The discharge tube was assembled using high-temperature brazing and heli-arc welding techniques. It was given a normal vacuum bakeout at 325°C for 20 h. The cathode was then oxidized in 3 torr of O_2 using a discharge current of ≈50 mA. The tube was filled to 2.0 torr with a 6:1 ratio of He to Ne. The maximum power output seen prior to pinchoff was 3.25 mW.

The laser discharge tube was then packaged in the aluminum mirror support cylinder. The maximum power obtained in the final package configuration was 2.25 mW.

Lifetesting

The lifetest started September 2, 1969. The laser has been operating continuously at a discharge current of 7.5 mA since that time except for infrequent shutdown when data were taken. Fig. 2 is a plot of the voltage-current characteristic taken initially and at subsequent times during test. A plot of the output power versus discharge current after the five-year period is also shown. Although no initial power data were taken at various currents, the initial pressure was selected to optimize the power in the 7–8-mA region.

Conclusions

The results obtained to date indicate the possibility of building He–Ne lasers with operating lifetimes in excess of five years. The relative importance of the many unique construction features of the metal ceramic discharge tube is not totally understood. However, large gas volume, low cathode current density, cathode geometry, large area anode design, high sputter-resistant ceramic bore, electrostatically shielded mirrors, ultraclean construction, high-temperature bakeout, and low activity of getter, especially with regard to oxygen, are all important. The ranking of importance of these design considerations would require considerable investigation. It is, however, safe to say that the results of this lifetest prove the possibility of building He–Ne lasers with lifetimes in excess of five years when all of the preceding factors are considered.

Correction to "Theory of Optical Gain and Threshold Properties of Semiconductor Lasers"

A. G. ALEKSANIAN

In the above paper,[1] on page 299, formula (9) should read

$$g(\omega) = 4\pi e^2 \Delta \bar{f} m^{3/2} \delta (\epsilon_e^v)^{3/2} / m_0 c \epsilon_0^{1/2} \hbar^3 \gamma \times \frac{[X(\beta) + 2\beta]^{3/2} \sinh(\Gamma_0 - \beta/\theta) \exp\{-X^2(\beta)/4\delta^2\}}{[\delta^2 + (X(\beta) + 2\beta)^2]^{3/2} \left[\cosh\frac{\Gamma_0 - \beta}{\theta} + \cosh\left(\frac{X(\beta) - \beta}{\theta} - Z_0\right)\right]}. \quad (9)$$

Formula (11), on page 300, should read

$$g(\omega) = B_0 \frac{\gamma^{3/2}\pi^{1/2}}{2^{11/4}} \cdot \frac{\exp\{-X_0^2/2\} \sinh[(F - \hbar\omega)/2kT] D_{-3/2}(-2^{1/2}X_0)}{\sinh^2[(F - \hbar\omega)/4kT] + \cosh^2[\zeta(X^m - X_m)]} \quad (11)$$

where

$$B_0 = 32 e^2 m_e^{1/2} \Delta_0 \pi^{1/2} N_A a_v^3 / 3\epsilon_0^{1/2} c\hbar^3 \omega\gamma (1 + a_v^2 K_e^2)^4.$$

Manuscript received March 21, 1975.

The author is with the Radio Physics and Electronics Institute, Academy of Science of Armenian SSR, Ashtarek, USSR.

Contributors

William F. Bailey was born in Cleveland, Ohio, in 1942. He received the B.S. degree from the United States Military Academy, West Point, N.Y., and the M.S. degree in physics from Ohio State University, Columbus, in 1964 and 1966, respectively.

From 1966 to 1970 he was assigned as a Theoretical Physicist to the Air Force Weapons Laboratory, Kirtland Air Force Base, N. Mex. In 1970 he was reassigned to the Aerospace Research Laboratories, Wright-Patterson Air Force Base, Ohio, where he headed a theoretical group analyzing nonequilibrium laser discharges. He is currently enrolled in the doctoral program at the Air Force Institute of Technology, Wright-Patterson Air Force Base.

*

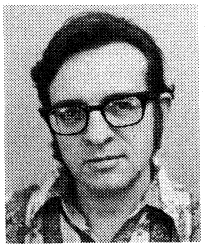
Peter Bletzinger (M'58-SM'71) was born in Stuttgart, Germany, on September 3, 1929. He received the Dipl. Ing. degree and the Dr. Ing. degree, the latter in 1966, both from the Technical University of Stuttgart, Stuttgart.

In 1955 he joined the Standard Electronic Division of International Telephone and Telegraph, Stuttgard, and in 1956 he went to the Communications and Navigation Laboratory, Wright-Patterson Air Force Base, Ohio, where he worked on navigational systems. In 1961 he joined the Aerospace Research Laboratories, where he has been working in the fields of high-speed photography, electrooptics, plasma diagnostics, and gas lasers.

*



H. J. A. Bluyssen received the doctorandus degree in physics and mathematics from the University of Utrecht, Utrecht, The Netherlands, in 1962. He joined the Physics Department of the University of Nijmegen, Nijmegen, The Netherlands, where he worked under Prof. A. Dymanus on molecular-beam microwave spectroscopy and received the doctorate degree in physics in 1968.

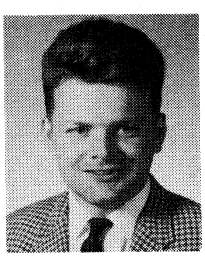
He is currently working on far-infrared lasers and is interested in their application to solid-state physics.

Dr. Bluyssen is a member of the American Physical Society.

P. G. Browne, photograph and biography not available at the time of publication.

*

R. A. Elliott was born in Canada in 1937. He received the B.A. degree in 1960, the B.Sc. degree in physics in 1961, and the M.Sc. degree in physics in 1963, all from Queen's University Kingston, Ont., Canada. He received the Ph.D. degree in 1966 from the University of British Columbia, Vancouver, where he specialized in kinetic theory and nonequilibrium statistical mechanics.



He was a research associate of Prof. E. W. Montroll at the Institute for Fundamental Studies, University of Rochester, from 1966 to 1969. While there he worked on random-walk theory and its application to exciton conduction in macromolecules and molecular crystals. Since 1969 he has been at the Oregon Graduate Center, Beaverton. His research interests have expanded to include laser propagation through turbulent media, statistical models of small-scale turbulence, high-gain optical-parametric interactions, and laser pulse shaping.

Dr. Elliott is a member of the Canadian Association of Physicists.

*

Joel Falk (S'64-M'70), for a photograph and biography please see page 62 of the January 1975 issue of this JOURNAL.

*

Alan Garscadden (M'69-SM'71) was born in Glasgow, Scotland, on June 10, 1937. He received the B.Sc. (Hons.) and Ph.D. degrees from Queen's University, Belfast, Northern Ireland, in 1958 and 1962, respectively.

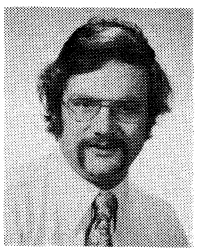
In 1962 he joined the Aerospace Research Laboratories, Wright-Patterson Air Force Base, Ohio, where he is currently working on instabilities in plasmas and on discharge processes in gas lasers. In 1972 he was appointed Director of the Plasma Research Laboratory.

Dr. Garscadden is a member of the American Physical Society.

Robert J. Harrach was born in Colorado on March 30, 1937. He received the A.B. degree in physics from Dartmouth College, Hanover, N.H., in 1960, and the M.S. and Ph.D. degrees in physics from the University of Colorado, Boulder, in 1962 and 1965, respectively.

As a graduate student and one year thereafter he worked in the Atomic Frequency and Quantum Electronics Sections of the National Bureau of Standards, Boulder. In 1966 he joined the University of California, Lawrence Livermore Laboratory, Livermore, Calif., where he is currently a member of the Theoretical Division. His research has dealt primarily with high-power lasers and nonlinear optics. Since 1970 he has concurrently held a position as Lecturer in the Department of Applied Science, University of California, Davis-Livermore.

*



Hermann A. Haus (S'50–A'55–SM'58–F'62) attended the Technische Hochschule, Graz, Austria, from 1946 to 1948, and the Technische Hochschule, Vienna, Austria, in 1948. He received the B.S. degree from Union College, Schenectady, N.Y., the M.S. degree from Rensselaer Polytechnic Institute, Troy, N.Y., and the Sc.D. degree from Massachusetts Institute of Technology, Cambridge, Mass., all in electrical engineering, in 1949, 1951, and 1954, respectively.

He is Elihu J. Thomson Professor of Electrical Engineering and a Research Staff Member of the Research Laboratory of Electronics, Massachusetts Institute of Technology. He also serves as a Consultant to the Raytheon Company. From 1959 to 1960 he was a Visiting Professor and Guggenheim Fellow at the Technische Hochschule, Vienna. He is coeditor of the recent book *Noise in Electron Devices*, coauthor of the monographs *Circuit Theory of Linear Noise Networks* and *Electrodynamics of Moving Media*, and coauthor of the book *Case Studies in Electromagnetism*. He is currently on leave at Bell Laboratories, Holmdel, N.J.

Dr. Haus is a member of Sigma Xi.

*

C. Breck Hitz (M'70) was born in Palm Springs, Calif., on January 1, 1944. He received the B.S. degree in physics from the Pennsylvania State University, University Park, and the M.S. degree in physics from the University of Massachusetts, Amherst, where he was an N.D.E.A. Fellow in 1966 and 1969, respectively.

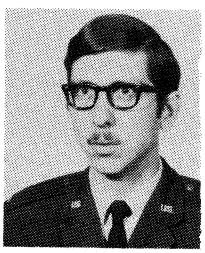
After joining GTE Sylvania Inc., Mountain View, Calif., in 1969 he was involved in optical communication system components and nonlinear optics development. He has been active in several nonlinear optics projects including a study of the techniques of frequency doubling the CO_2 laser, and has assisted in the development of a mode-locked space-qualified Nd:YAG laser. His present interests include novel modulation techniques and vapor-phase nonlinear optics. He is now with the General Photonics Corporation, Santa Clara, Calif.

Mr. Hitz is a member of the American Physical Society.

Tatsuya Kimura (S'66–M'71) was born in Osaka, Japan, on February 20, 1940. He received the B.S. degree in electrical engineering, the M.S. degree in electronic engineering, and the Ph.D. degree in the field of quantum electronics, all from the University of Tokyo, Tokyo, Japan, in 1962, 1964, and 1967, respectively.

In 1967 he joined the Musashino Electrical Communication Laboratories, Nippon Telegraph and Telephone Public Corporation, Tokyo, Japan. He has been engaged in work on equipment for optical communications, such as light modulators, detectors, PM–AM converters, optical FDM filters and laser oscillators, and guided millimeter-wave transmission systems and equipment.

Dr. Kimura is a member of the Institute of Electronics and Communication Engineers of Japan, the Japan Society of Applied Physics, the Physical Society of Japan, and the American Physical Society.



*

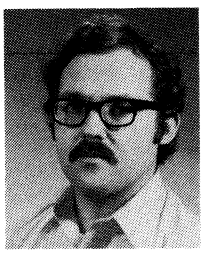
David A. LaBorde received the B.S. degree from Northeast Louisiana State University, Monroe, and the M.S. degree in engineering physics from the Air Force Institute of Technology, Wright-Patterson Air Force Base, Ohio, in 1960 and 1972, respectively. He attended the Armed Forces Staff College in 1974.

He entered the Air Force in 1960 and after attending Officer Training School, he received a commission in the United States Air Force in 1961. Upon completion of flying schools, he served as an Electronic Warfare Officer in the Strategic Air Command until 1970. He served four tours in Southeast Asia as a crew member on B-52 and AC-130 aircraft between the years 1965 and 1973. He is currently assigned to the Aeronautical Systems Division (AFSC), Wright-Patterson Air Force Base, as an Electronic Warfare Engineer.

*

William H. Long, Jr., was born in San Francisco, Calif., on May 11, 1947. He received the B.S. degree in physics from the California Institute of Technology, Pasadena, and the M.S. degree in plasma physics from the University of Wisconsin at Madison in 1969 and 1970, respectively.

Since joining the Air Force in May 1971, he has been assigned to the Aerospace Research Laboratories, Wright-Patterson Air Force Base, Ohio. His research has included theoretical and experimental studies of the electric-discharge laser, low-energy electron kinetics, and positive-column modeling in molecular gases.

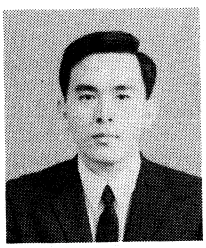


G. A. Massey (M'67) received the B.S.E.E. degree from the California Institute of Technology, Pasadena, in 1959, and the M.S. and Ph.D. degrees from Stanford University, Stanford, Calif., in 1967 and 1970, respectively.

From 1959 to 1963 he was a member of the Engineering Staff of the Raytheon Company, Santa Barbara, Calif., where he worked in the areas of optical communications, modulator device development, and laser range-finders. In 1963 he joined the Electro-Optics Group of GTE Sylvania, Mountain View, Calif., where, as Senior Engineering Specialist, his activities included development of laser vibration sensors and acoustooptical devices, research in acoustical holography and acoustical imaging systems, laser mode locking, and development of high-power lasers, new materials for solid-state lasers, and nonlinear optical devices. He joined the Faculty of the Oregon Graduate Center, Beaverton, in 1972, and currently holds the position of Professor in the Applied Physics Department. His current research activities include nonlinear optical devices, dye lasers, and laser remote-sensing techniques.

Dr. Massey is a member of the Optical Society of America and the Acoustical Society of America.

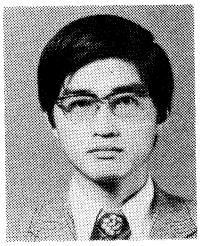
*



Robert E. McIntosh (S'66-M'67-SM'72) was born in Hartford, Conn., on January 19, 1940. He received the B.S. degree in electrical engineering from Worcester Polytechnic Institute, Worcester, Mass., in 1962, the S.M. degree in applied physics from Harvard University, Cambridge, Mass., in 1964, and the Ph.D. degree from the University of Iowa, Iowa City, in 1967. His Ph.D. dissertation was in the area of nonlinear behavior of plasmas.

He was a member of the Technical Staff at Bell Laboratories, North Andover, Mass., from 1962 until 1965, where he worked in a microwave networks group. In 1967 he joined the Department of Electrical and Computer Engineering, University of Massachusetts, Amherst, where he is now a Professor. He spent the 1973-1974 academic year as Guest Professor of Physics at the Fysisch Laboratorium Katholieke Universiteit, The Netherlands. His teaching and research interests are in electromagnetic field theory, microwaves, plasmas, and communication engineering.

Dr. McIntosh is a member of the International Scientific Radio Union, the American Physical Society, Sigma Xi, Tau Beta Pi, Phi Kappa Phi, and Eta Kappa Nu. He is a Past Chairman of the Springfield section of the IEEE, and was a member of the National Membership and Transfers Committee of the IEEE. He is also the Chairman of the Steering Committee of the IEEE International Symposium on Antennas and Propagation, which is to be held at the University of Massachusetts in 1976.



*

Kenju Otsuka (A'73) was born in Anto, Manchuria, on January 2, 1946. He received the B.S. degree in communication engineering from Tohoku University, Sendai, Japan, in 1968.

In 1968 he joined the Musashino Electrical Communication Laboratories, Nippon Telegraph and Telephone Public Corporation, Tokyo, Japan. He has been engaged in the research of the technique of mode locking in solid-state lasers and more recently in the investigation of Nd-ultraphosphate lasers for high bit-rate optical transmission systems.

Mr. Otsuka is a member of the Institute of Electronics and Communication Engineers of Japan and the Japan Society of Applied Physics.

Masatoshi Saruwatari was born in Miyazaki, Japan, on April 3, 1945. He received the B.S. degree in pure and applied science, and the M.S. degree in coordinated sciences, both from the University of Tokyo, Tokyo, Japan, in 1968 and 1970, respectively.

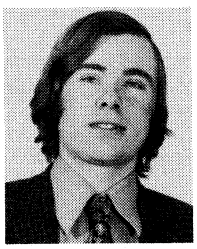
In 1970 he joined the Musashino Electrical Communication Laboratories, Nippon Telegraph and Telephone Public Corporation, Tokyo. He has been engaged in research on optical communication equipment such as optical frequency multiplexers and solid-state laser oscillators.

Mr. Saruwatari is a member of the Institute of Electronics and Communication Engineers of Japan and the Japan Society of Applied Physics.

*

A. L. S. Smith, photograph and biography not available at the time of publication.

*



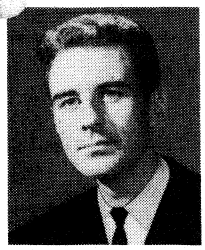
Peter D. Tannen was born in the Bronx, N.Y., on February 17, 1936. He received the B. Aero. Engr. degree from Rensselaer Polytechnic Institute, Troy, N.Y., and the M.S. degree in astronautical engineering from the Air Force Institute of Technology, Wright-Patterson Air Force Base, Ohio, in 1957 and 1962, respectively. He is a doctoral candidate for the Ph.D. degree from the Air Force Institute of Technology.

From 1962 to 1967 he was a Project Engineer at the Air Force Special Weapons Center, Kirtland Air Force Base, N. Mex. From 1969 to 1973 he was a Research Physicist with the Plasma Physics Laboratory, Aerospace Research Laboratories, Wright-Patterson Air Force Base. He is currently at the Air Force Weapons Laboratory, Kirtland Air Force Base.

Major Tannen is an associate fellow of the American Institute of Aeronautics and Astronautics, and a member of the American Association for the Advancement of Science, Tau Beta Pi, and Sigma Gamma Tau.

*

B. C. Tofield received the B.A. degree in chemistry and the D.Phil. degree in inorganic chemistry, both from Oxford University, Oxford, England, in 1966 and 1969, respectively.



From 1969 to 1972 he was a Turner and Newall Research Fellow at the Inorganic Chemistry Laboratory, Oxford University. While there, he worked on the preparation and magnetic and structural properties of high-oxidation-state rare-earth and transition-metal oxides, structural details of nonstoichiometry in oxide perovskites by neutron and electron diffraction, and bonding in rare-earth and transition metal systems by neutron scattering. He was with Bell Laboratories, Holmdel, N.J., from 1972, where he has been involved in the development and conception of new rare-earth laser crystals and nonlinear optical properties of inorganic crystals. He is currently with the Materials Physics Division, Atomic Energy Research Establishment, Harwell Didcot, Oxon., England.

A. F. van Etteger was born in Nijmegen, The Netherlands, in 1943. He completed his engineering training in 1965.

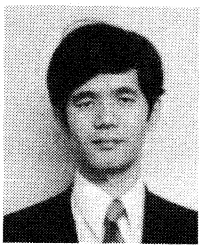
In 1965 he joined the Instrumentation Group of the Faculty of Science at the University of Nijmegen. After a period of six years he accepted the position of Research Associate in the Physics Department at the same University, where, ever since, he has actively participated in the development, design, and other problematics in relation to molecular lasers operating in the far-infrared region of the electromagnetic spectrum.

*

Heinz P. Weber (M'72) was born in Winterthur, Switzerland, on April 18, 1939. He received the Diploma in physics from the Swiss Federal Institute of Technology, Zürich, Switzerland, in 1964, and the Ph.D. degree from the University of Berne, Berne, Switzerland, in 1968.

From 1964 he has been a Graduate Research Assistant at the Institute of Applied Physics, University of Berne, engaged in problems in the field of nonlinear optics and the generation and measurement of ultrashort light pulses. Since joining Bell Laboratories, Holmdel, N.J., in 1969, he has been involved in research on integrated optics. He has explored ways to form optical waveguides and integrated-optics structures using photosensitive organic compounds. He has also investigated new rare-earth laser crystals with high Nd concentration and small concentration quenching, as well as concepts for miniaturized lasers using such materials.

Dr. Weber is a member of the American Optical Society.



*

Peter Wyder was born in Burgdorf, Switzerland, in 1934. He received the diploma in physics and the Dr. sc. nat. degree from the Swiss Federal Institute of Technology, Zurich, Switzerland.

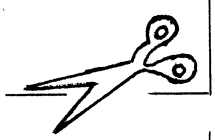
His main research interest is experimental solid-state physics. From 1964 to 1966 he was a Fellow of the Miller Institute for Basic Research in Science at the University of California at Berkeley, and from 1966 to 1967 he was a Research Fellow at Harvard University. Since 1967 he has been a Professor of Physics at the University of Nijmegen, Nijmegen, The Netherlands.

*

Tomoaki Yamada was born in Tokyo, Japan, on November 1, 1942. He received the B.S. degree from the University of Tokyo, Tokyo, in 1965.

He joined the Musashino Electrical Communication Laboratories, Nippon Telegraph and Telephone Public Corporation, Tokyo, in 1965 where he is currently a Deputy Director of the Sixth Section. He has been working on ferroelectrics and solid-state laser crystals.

He is a member of the Physical Society of Japan and the Japan Society of Applied Physics.



MEMBERSHIP APPLICATION

IEEE ELECTRON DEVICES GROUP

Membership in the IEEE ELECTRON DEVICES Group entitles you to receive, for the low Group fee, the monthly IEEE Transactions on Electron Devices, and the bimonthly Electron Devices Group Newsletter. You are kept informed of latest developments, meetings and conferences in your areas of interest, and are entitled to purchase informative conference records and other helpful educational aids at greatly reduced rates for members.

Use the convenient coupon to become a member of the IEEE ELECTRON DEVICES Group or a Group Affiliate. If you are not a member of the IEEE, but would like to join, please check the appropriate box on the coupon. Descriptive materials and an IEEE membership application form will be sent to you immediately upon receipt.

*Group Fee: $7.00 for IEEE members of all grades except Student. Student Fee: $2.00. These rates apply to payments received September 1 through February. On payments received March 1 through August 31, remit one-half of the above rates. (Payments received September 1 through December 31 apply through December 31 of the following year.)

Membership Application/IEEE ELECTRON DEVICES GROUP
Send to: IEEE Service Center, 445 Hoes Lane, Piscataway, NJ 00854

☐ I am a _____ (Grade) member of IEEE and hereby apply for membership in the ELECTRON DEVICES Group. I enclose a check for the Group fee* (made payable to IEEE).

☐ I am not now a member of the IEEE but would like to join. Please send information.

☐ I am interested in becoming an ELECTRON DEVICES Group Affiliate. Please send information.

Introduction

Semiconductor Lasers—1975

THIS ISSUE of the IEEE JOURNAL OF QUANTUM ELECTRONICS marks the fourth special issue of this journal devoted to semiconductor lasers. It comes at a time when the active effort on semiconductor lasers around the world is the largest it has ever been. For the increasing number of specialists in this field, this issue provides a convenient collection of current papers for future reference. For interested workers in other fields, this volume presents a snapshot view of topics under current investigation by researchers in the field.

The issue is sponsored by the 1974 IEEE International Semiconductor Laser Conference, which was held on November 18–20, 1974, in Atlanta, Ga. The conference was attended by 160 specialists from the United States, Japan, England, Germany, Canada, France, The Netherlands, the Soviet Union, Switzerland, Brazil, and Italy. This record number of participants clearly demonstrated the high level of attention which semiconductor lasers presently enjoy.

Although the program committee led by A. R. Calawa was faced with many more papers than could possibly be accommodated, they successfully arranged 46 papers into 6 formal sessions and 2 evening sessions. In spite of the full and taxing program, there was ample time and energy for lively discussion during and after each session. Topics of discussion ranged over most aspects of semiconductor lasers from the very practical problem of device reliability to the exciting possibilities of distributed-feedback structures. Corrugations in the laser waveguide were used as an output coupler to obtain a well-collimated beam or as a mode selector to achieve tunable single-frequency operation, while theoretical and experimental studies of degradation by dark-line formation were presented in attempts to understand more clearly the nature and origin of this perverse mechanism. Although the reliability of junction lasers remained a primary concern of most workers, the nervous fear that such devices might be limited to relatively short CW lives was somewhat alleviated by the informal report by Bell Laboratories of a continuous lifetime in excess of 14 000 h for at least one junction laser.[1] Reproducibility remains the most vexing problem. Hopefully, by the time of the next semiconductor laser conference, solution of this problem will have led to the commercial availability of CW junction lasers.

Theoretical and experimental characteristics of $Ga_xAl_{1-x}As$ double-heterostructure lasers with thin active regions received considerable attention, with discussions centering on waveguide modes, optical-scattering loss, depolarization of the lasing emission, and saturation effects. Heterostructures in other materials were not neglected with current interest focused on lead-salt and $GaAs_{1-y}P_y$ lasers. New laser structures as well as new methods of making old structures were examined. Notable were the use of a two-dimensional waveguide to obtain lasing in a small active region at a low input current and the monolithic integration of a junction laser phase coupled to a passive waveguide as a means for directly obtaining a guided output beam. Other attractive coupling schemes are also described in this issue. Oxygen implantation and selective heterojunction growth were presented as two new ways to form stripe-geometry lasers. With the second technique, continuous lasing at wavelengths as short as 7610 Å was obtained. Continuous operation at temperatures as high as 9°C was also reported for stripe-geometry lasers fabricated from material growth by molecular-beam epitaxy.

Mode interactions, always a popular subject for discussion, encompassed stimulated scattering at high power levels, longitudinal mode locking, and self-induced intensity pulsations. Externally imposed diffractive coupling was used to induce coherence of separate lasers, while an optical fiber was incorporated into a laser cavity to achieve transverse mode control.

The eternal subjects of time delays, Q switching, and related transient effects still provided ground for active debate. Hopefully, a final chapter in this elusive story is emerging with the recognition of the role played by a loss of the optical confinement. Other topics included another persistent phenomenon in semiconductor lasers, namely filament formation, as well as semiconductors excited by electron beams and electric fields.

In conclusion, I hope that this issue will be not only a useful reference and stimulus for those actively working on semiconductor lasers but also interesting to those engaged in other fields of quantum electronics. I thank the authors and referees without whose contributions this issue would not exist. In addition, all of us who profited by attending the conference or by reading the papers of this issue are grateful to J. E. Ripper for his enthusiastic initiation of the 1974 Conference and to N. Holonyak, Jr., for accepting the responsibility for its success. A very special note of thanks goes to J. A. Rossi for his persistent attention to the myriad arrangements so necessary to a smoothly running conference and to the JOURNAL OF QUANTUM ELECTRONICS, the IEEE Group on Electron Devices, IBM, and Bell Laboratories for their financial support of this issue.

The program of the IV IEEE International Semiconductor Laser Conference was as follows.

[1] See R. L. Hartman and R. W. Dixon, *Appl. Phys. Lett.*, vol. 26, pp. 239–242, Mar. 1, 1975.

SESSION I: Theory and Device Physics
M. J. Adams, *Chairman*

1) "Self-consistent calculations of the electrical and optical characteristics of the double heterostructure GaAs laser," *K. A. Shore and M. J. Adams.*
2) *"The analysis of optical scattering loss in double-heterostructure injection lasers with narrow active layers," *G. H. B. Thompson, J. E. A. Whiteaway, and P. A. Kirkby.*
3) *"Modal properties of very thin heterojunction structures," *J. K. Butler, I. Ladany, and H. Kressel.*
4) *"DH lasers in the limit of thin active regions," *W. P. Dumke.*
5) "Transverse modes in semiconductor injection lasers with thin active layer," *K. Kurokawa.*
6) "Energy-dependent rate equations for semiconductor lasers," *B. A. Rogers.*

SESSION II: Mode Properties of Lasers
M. Balkanski, *Chairman*

1) "Pressure induced mode conversion in homostructure GaAs junction lasers," *N. B. Patel, T. J. B. Serra, and M. B. Zakias.*
2) *"Transverse mode control of stripe-geometry large-cavity GaAs lasers optically coupled to single-mode fibers," *D. C. Krupka and T. L. Paoli.*
3) "Critical power in narrow stripe and wide sawed lasers," *H. S. Sommers, Jr.*
4) "Formation of spatially coherent beam from a GaAs laser diode array," *E. M. Phillip-Rutz.*
5) *"GaAs-GaAlAs double heterostructure injection lasers with distributed feedback," *M. Nakamura, K. Aiki, J. Umeda, A. Katzir, A. Yariv, and H. W. Yen.*
6) *"Coupling coefficients, thresholds, and propagation constants for modes in distributed feedback laser diodes," *D. R. Scifres, W. Streifer, and R. D. Burnham.*
7) "Electron beam excited distributed feedback laser in CdS," *Y. Aoyagi and S. Namba.*

SESSION III: New Laser Structures and Processes
M. Pilkuhn, *Chairman*

1) *"Optical and thermal properties of buried-heterostructure injection lasers," *T. Tsukada and Y. Shima.*
2) *"Integrated twin-guide AlGaAs laser with multi-hetero structure," *Y. Suematsu, M. Yamada, K. Hayashi, K. Furuya, and S. Ibukuro.*

Lead–Tin Telluride Double-Heterojunction Laser Diodes: Theory and Experiment

L. R. TOMASETTA AND C. G. FONSTAD, MEMBER, IEEE

Abstract—Calculations of threshold current densities for lead-tin telluride double-heterojunction (DH) laser diodes are presented, in which the spatial distribution of the injected minority carriers and the critical level of minority carrier injection necessary for population inversion are considered. Excellent agreement between the predictions of this model and experimental data is obtained, which suggests that credible predictions of high-temperature performance can be made. The need to inject a critical level of minority carriers is shown to be the principal contribution to the threshold current density except at very low temperature and to lead to a rapid increase in threshold with increasing temperature. It is found experimentally that below 40 K the threshold no longer decreases with temperature; two possible explanations for this behavior are suggested.

INTRODUCTION

THE IMPORTANCE of the double-heterojunction (DH) device geometry, see Fig. 1, in reducing semiconductor diode laser threshold current densities has been well documented in the (Ga, Al)As alloy system [1]. Heterojunction geometries have also very recently been used in Pb-salt diode lasers, specifically in the Pb(S, Se) [2] and (Pb, Sn)Te [3]-[5] alloy systems. Significant systematic reduction of threshold current densities in DH (Pb, Sn)Te laser diodes has recently been demonstrated by Tomasetta and Fonstad [3] and continuous operation of (Pb, Sn)Te laser diodes at 77 K has been achieved by Groves *et al.* with the aid of the DH geometry and careful heat sinking [5].

While experimental progress in Pb-salt laser diodes has been dramatic, theoretical calculations of threshold currents have been less successful. Published calculations [6] predict threshold current densities much lower than those observed, and furthermore predict a much more gradual increase of threshold with temperature than one in fact observes. These discrepancies are important to resolve because without a credible model it is impossible to understand the limiting device and materials parameters, or to predict ultimate device performance, i.e., threshold current density and efficiency.

In this paper we will first look at the limitations of the simple model and point out where it is invalid for DH (Pb, Sn)Te laser diodes. We will then present a more detailed model which is in agreement with the experimental results measured in this program [3] and by others [4], [5]. From this model we can begin to identify the parameters that will be important to further reduce threshold current densities, and can make more realistic predictions concerning high-temperature operation of $Pb_{1-x}Sn_xTe$ laser diodes.

Manuscript received December 19, 1974; revised February 3, 1975. This work was supported in part by the National Science Foundation. This paper is based in part on a dissertation submitted to the Department of Electrical Engineering, Massachusetts Institute of Technology, by L. R. Tomasetta, in partial fulfillment of the requirements for the Ph.D. degree.

L. R. Tomasetta was with the Department of Electrical Engineering and Center for Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Mass. 02139. He is now with the Massachusetts Institute of Technology Lincoln Laboratory, Lexington, Mass. 02173.

C. G. Fonstad is with the Department of Electrical Engineering and Center for Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Mass. 02139.

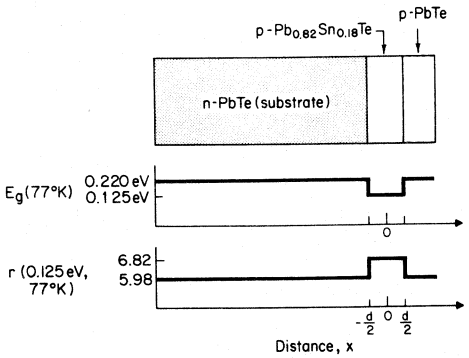

Fig. 1. An ideal, symmetrical DH lead-tin telluride laser diode and the variation of energy gap and refractive index perpendicular to the junction plane. The numbers indicated are for 77 K and typical of those used in this work. The improvement in performance of the DH geometry in comparison with the simple p-n junction device is a result of optical and minority carrier confinement that occurs at the heterojunctions. The three-layer dielectric waveguide structure helps to keep the optical field confined to the higher index active region where the optical field aids stimulated emission. The p-p heterojunction creates an electrical barrier to minority carriers thereby requiring their recombination in the center higher index active region where the optical field and minority carrier concentration are greatest, rather than in the passive regions where their recombination does not aid stimulated emission.

GAIN IN SEMICONDUCTOR LASERS, $T = 0$ MODEL

Lasher and Stern [7] have shown that the net gain in the active region of a semiconductor laser is

$$G = \frac{\int_{-d/2}^{d/2} g[n_p(x)]\, E^2(x)\, dx}{\int_{-d/2}^{d/2} E^2(x)\, dx} \tag{1}$$

where $g[n_p(x)]$ is the gain distribution across the active region as a function of the injected minority carrier concentration, and $E(x)$ is the optical field. At $T = 0$, for the case where the minority carrier diffusion length L_D is much greater than the width of the active region d, the following approximations are valid [6]:

$$g[n_p(x)] = An_p(x) \tag{2a}$$

$$n_p(x) = n_p(-d/2). \tag{2b}$$

By relating G in the active region to the internal losses α, and the end face losses $(1/L)\ln(1/R)$, the threshold current density J_T of the laser diode is found to be [7]

$$J_T = \frac{8\pi q d r^2 \Delta\nu(\alpha + 1/L \ln 1/R)}{\eta_{\text{int}} \lambda_0^2} \tag{3}$$

where λ_0 is the free-space wavelength, η_{int} is the internal quantum efficiency, $\Delta\lambda$ is the spontaneous linewidth, d is the active region width, r is the index of refraction in the active region, L is the length of the cavity, and R is the mirror reflectivity. The absorption coefficient α is the sum of two terms, α_0 the absorption loss in the high-index region, and α_D the diffraction loss [8].

Because the end losses $(1/L)\ln(1/R)$ typically dominate the loss mechanisms until

$$d < \frac{\lambda_0}{2r} \tag{4}$$

when diffraction losses become significant, decreasing d results in a nearly linear decrease in J_T. Fig. 2 shows results of threshold current calculations for (Pb, Sn)Te DH laser diodes at 8, 77, and 195 K based on the $T = 0$ model given by (3) and the analysis of the optical fields provided by Anderson [8]. They are identical to results obtained using the technique of Sleger *et al.* [6].

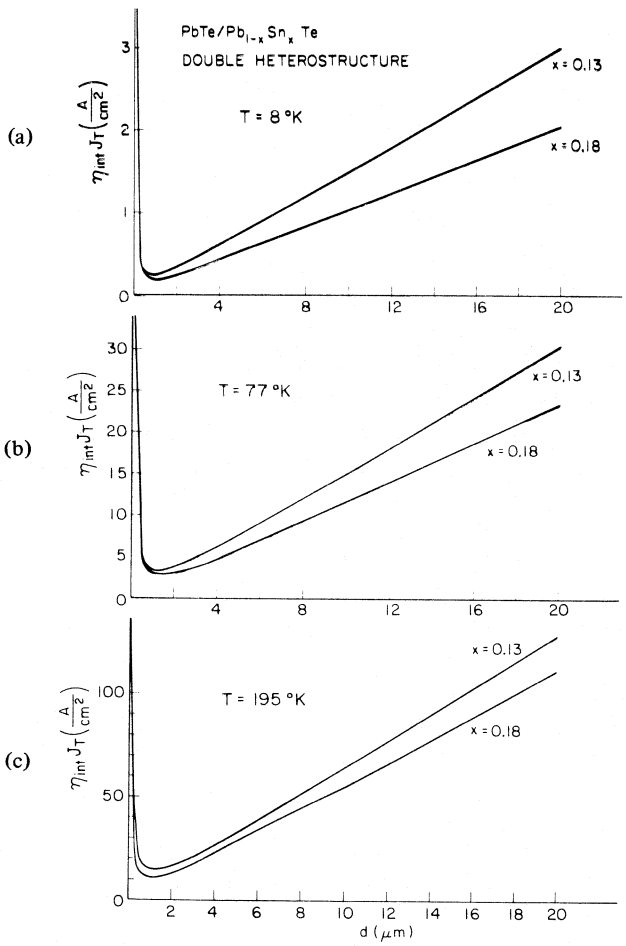

Fig. 2. (a) Threshold current density of $Pb_{1-x}Sn_xTe$ DH laser diodes at 8 K calculated using the $T = 0$ constant gain model. The horizontal scale is the active region, i.e., $Pb_{1-x}Sn_xTe$ layer, width. Two alloy compositions, $x = 0.13$ and $x = 0.18$, are presented. $L = 0.05$ cm. (b) Same with $T = 77$ K. (c) Same with $T = 195$ K.

Limitations of $T = 0$ Model

A closer examination of the two assumptions implicit in deriving (3) clearly indicates that great care must be exercised when using it to predict threshold currents of semiconductor lasers. The first assumption (2a) is valid only at $T = 0$. For any other temperature the well-known condition for internal optical gain must be used [9]

$$|\psi_n - \psi_p| \geq h\nu \tag{5}$$

where ψ_n, ψ_p are the quasi-Fermi levels of the electrons and holes, respectively, and $h\nu$ is the lasing energy.

The significant implication of (5) is that there is a certain minority carrier density that must be built up before there is any gain at all. The gain variation with injected minority carriers is given by [10]

$$g[n_p(x)] = A(n_p(x) - n_t) \tag{6}$$

where n_t is the threshold value of injected minority carriers needed to satisfy the equality condition in (5). Of course, if n_t is very much less than $n_p(x)$, then (6) is only an insignificant variation of (2a). This is what occurs at $T = 0$ where $n_t = 1\ \text{cm}^{-3}$ if the majority carrier population is degenerate. But if the required gain is a result of the small difference between two large quantities $n_p(x)$ and n_t, then the effect of the minimum injection level for gain n_t is significant and must be considered.

The behavior of the quasi-Fermi levels with doping, temperature, and injection level for an ideal semiconductor is provided by Blakemore [11]. Details of the band structure and quasi-Fermi-level movement peculiar to $Pb_{1-x}Sn_xTe$ are provided by Adler *et al.* [12]. The results of this calculation are illustrated in Fig. 3. From this figure we find that for a majority carrier concentration of $5 \times 10^{17}\ \text{cm}^{-3}$, n_t is $1.6 \times 10^{16}\ \text{cm}^{-3}$ at 77 K and increases to $8 \times 10^{17}\ \text{cm}^{-3}$ at 195 K. If the majority carrier concentration is increased to $1 \times 10^{18}\ \text{cm}^{-3}$, n_t decreases to $3 \times 10^{15}\ \text{cm}^{-3}$ at 77 K and $4 \times 10^{17}\ \text{cm}^{-3}$ at 195 K. Note that the decrease in n_t for a doubling of the majority carrier concentration is fivefold at 77 K, but is only twofold at 195 K.

The second assumption that the minority carrier distribution is constant across the active region and equal to the value at the point of injection, (2b), is valid only when the diffusion

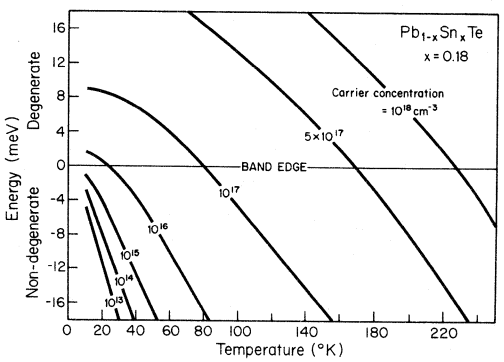

Fig. 3. Position of quasi-Fermi level in $Pb_{0.82}Sn_{0.18}Te$ for various carrier concentrations as a function of temperature. Because the bands are symmetrical, these curves can be used for both electrons and holes (after [12]).

length of the injected minority carriers L_D is much greater than the active region width d. When L_D is not much greater than d this assumption has the effect of overestimating the optical gain of the laser. The seriousness of the miscalculation depends on the magnitudes of L_D, d, and n_t. Another result of assuming a constant gain across the active region is that the zeroth-order mode is always the highest gain mode. The validity of this result will be discussed shortly.

$T \neq 0$ Model

We now proceed to recalculate threshold current densities for DH lasers in a more general way than (3), accounting for both the minimum injection level for gain and the spatial distribution of the injected minority carriers. The carrier distribution in the active region of a DH laser like that shown in Fig. 1 can be approximated by the solution to

$$\frac{\partial^2 n_p}{\partial x^2} - \frac{n_p - n_{p0}}{D_n \tau_n} = 0 \tag{7}$$

where n_p is the total minority carrier density; n_{p0} is the equilibrium minority carrier density; and D_n and τ_n are the minority carrier diffusion coefficient and lifetime, respectively. The diffusion length L_D is

$$L_D = \sqrt{D_n \tau_n}. \tag{8}$$

We are assuming that the minority carrier lifetime τ_n is not a function of position. In fact, the lifetime depends on the amount of stimulated recombination at each point which is in turn proportional to $E^2(x)$. Hakki [13] has considered this problem for GaAs heterostructure lasers. The difference between his more complex result and our simpler result is significant only well above threshold, and should therefore not be important for our calculations of threshold current density. The boundary conditions on the DH laser are: 1) one-way injection of minority carriers from the n-PbTe into the p-$Pb_{1-x}Sn_xTe$; and 2) no electron flow from the p-$Pb_{1-x}Sn_xTe$ to the p-PbTe, i.e., $(\partial n_p/\partial x)_{d/2} = 0$.

Solution of (7) with these boundary conditions yields

$$n_p(x) = \frac{n_p(-d/2)\cosh\left[(d - 2x)/2L_D\right]}{\cosh\left(\frac{d}{L_D}\right)}. \tag{9}$$

The gain coefficient A in (6) can be determined from Pilkuhn [14]

$$g[n_p(x)] = \frac{\eta_{\text{int}} c^2}{8\pi r^2 \nu^2 \Delta\nu \tau_n}(n_p(x) - n_t). \tag{10}$$

The net gain in the active region can then be calculated using (1), (9), and (10), and optical-field results from Anderson [8]

$$G = \frac{\eta_{\text{int}} c^2}{8\pi r^2 \nu^2 \Delta\nu \tau_n}\left[f(a, d, L_D) n_p(-d/2) - n_t\right] \tag{11}$$

where

$$f(a, d, L_D) = \left\{\frac{2}{L_D} \cdot \cos^2(ad/2)\sinh(d/L_D) + 4L_D a^2 \sinh(d/L_D) + 4a \sin(ad/2) \cdot \cos(ad/2) \cdot [1 + \cosh(d/L_D)]\right\} \Big/ \cdot [(d/2) + (1/2a)\sin(ad)] \cdot [8a^2 + (2/L_D^2)] \cdot \cosh(d/L_D)$$

where a is the transverse propagation constant of the optical field in the active region.

The threshold current is found by equating (11) with the total losses of laser. The gain at threshold G_T is

$$G_T = \alpha_D + \alpha_0 + \frac{1}{L}\ln\frac{1}{R}. \tag{12}$$

The diffraction losses α_D were calculated using the technique of Anderson [8], [16]. The absorption losses are dominated by free-carrier absorption, and are given by

$$\alpha_0 \simeq \alpha_{fc} = \frac{p_p q^3 \lambda_0^2}{4\pi^2 r c^3 \epsilon_0 \mu_h m_c^{*2}} \tag{13}$$

where p_p is the majority carrier (hole) concentration, c is the speed of light, ϵ_0 is the permittivity of free space, μ_h is the hole mobility, and m_c^* is the valence band conductivity effective mass.

Threshold Current Density Calculations

Using (11) and (12), and

$$J = qD_n\left(\frac{\partial n_p}{\partial x}\right)\Big|_{-d/2} \tag{14}$$

we can calculate the threshold current density for DH (Pb, Sn)Te lasers like those shown in Fig. 1.

$$J_T = \frac{qD_n}{L_D}\frac{\tanh(d/L_D)}{f(a, d, L_D)}\left[\frac{8\pi r^2 \nu^2 \Delta\nu \tau_n}{\eta_{\text{int}} c^2} G_T + n_t\right]. \tag{15}$$

Figs. 4–7 present the results of such calculations for p-PbTe/p-$Pb_{0.82}Sn_{0.18}Te$/n-PbTe devices. Figs. 4, 5, and 7 correspond to an active region majority carrier concentration N_A of 5×10^{17} cm^{-3} at 8, 77, and 195 K, respectively. Fig. 6 repeats the 77 K calculation with $N_A = 1 \times 10^{18}$ cm^{-3}. The vertical scale in these figures is J_{th}, while the horizontal scale is the active region width. In each figure a set of curves is presented with minority carrier diffusion length as the parameter; it is varied from 2–20 μm. The spontaneous emission linewidth was taken at 2 kT. To calculate τ_n from L_n (8), D_n was taken to be 100 cm^2/s at 77 K and to vary inversely with temperature [16]. η_{int} was set equal to 1 (this point is discussed further in the following).

At 8 K, Fig. 4, the results are nearly identical to those of the $T = 0$ model, but at 77 K, Figs. 5 and 6, the threshold currents are nearly two orders of magnitude higher. At 195 K the results differ by more than three orders of magnitude.

Looking at Figs. 4–7, and the previous discussions, we can

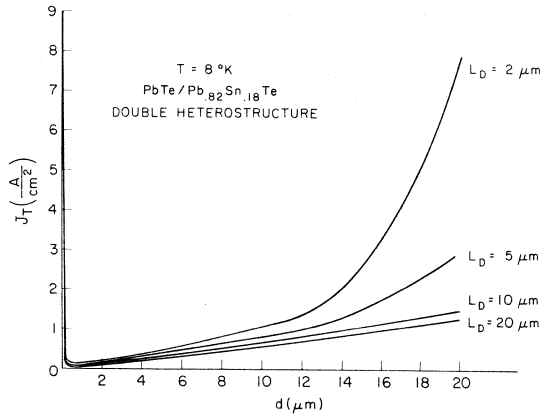

Fig. 4. Threshold current density for $Pb_{0.82}Sn_{0.18}Te$ DH laser diodes at 8 K calculated using the $T \neq 0$ model presented in this work. Minority carrier diffusion length is used as a parameter and the horizontal scale is the active region, i.e., (Pb, Sn)Te layer, width. The vertical scale is J_T. The active region doping is 5×10^{17} cm^{-3}, p-type. η_{int} was taken to be 1 (see text). $L = 0.05$ cm.

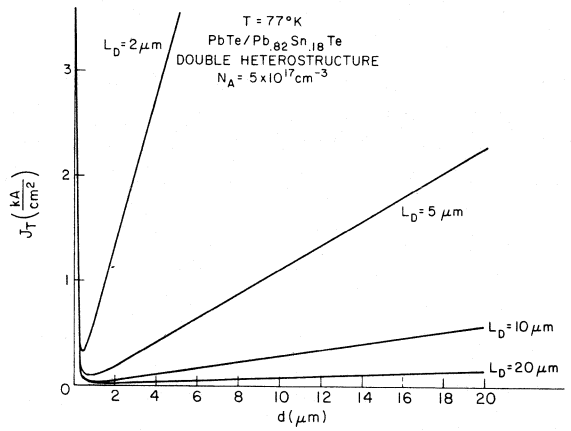

Fig. 5. Same as Fig. 4 for 77 K.

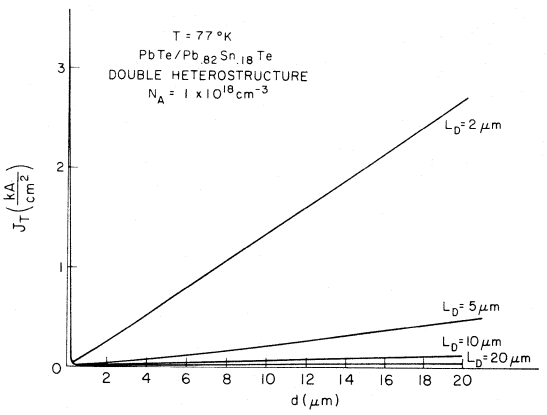

Fig. 6. Same as Fig. 5 with an active region doping of 10^{18} cm^{-3}, p-type.

point out some important features and results of these calculations as follows.

A. Temperature

The main variation of threshold with temperature is not a variation in the coefficients of (15), but rather the change in n_t. At $T = 8$ K, n_t is essentially zero because the majority quasi-Fermi level is so far into the band that a small current will move the minority carrier quasi-Fermi level close enough to the band edge to satisfy (5) for gain. At 77 K the majority quasi-Fermi level is not as far into the band and an injection level of 1.6×10^{16} cm^{-3} is needed for gain to occur. This already represents a substantial current and, in fact, represents the dominant contribution to threshold current. As temperature is increased, the majority carrier quasi-Fermi level becomes less degenerate and finally nondegenerate, and the bandgap increases. As a result, n_t increases rapidly with temperature and the current needed to provide a specific gain increases with n_t.

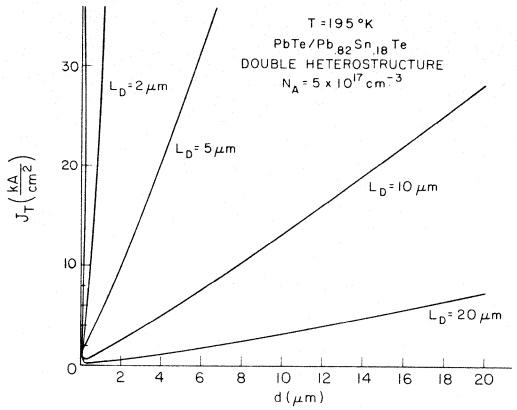

Fig. 7. Same as Fig. 4 for 195 K.

B. Carrier Concentration

As the majority carrier concentration increases, n_t decreases, reducing the current needed for a given value of gain. Thus the threshold can be reduced by increasing the active region doping until end face and free-carrier absorption losses become dominant. For example, as the majority carrier concentration is increased from 5×10^{17}–10^{18} cm^{-3}, the increased free-carrier absorption losses are still insignificant and at 77 K the threshold is reduced by a factor of 5, Figs. 5 and 6. The effect is smaller at higher temperatures, however, and the same change in doping level only leads to a twofold reduction in J_T at 195 K.

C. Optical Mode

One result of the spatial variation of the gain and the asymmetry of the minority carrier injection with respect to the active region is that maximum gain occurs at $x = -d/2$ rather than $x = 0$, the center of the optical-field pattern. Consequently, greater gain is possible for higher order optical modes than for the $m = 0$ mode under certain circumstances. Consider the case where $L_D \ll d$. The gain coefficient $g(x)$ is a maximum at $x = -d/2$ and rapidly decays as x increases. Since the net gain G is a result of the integration of $g(x)E^2(x)$, it is desirable to have $E(x)$ large where $g(x)$ is large. The $m = 1$ and $m = 2$ modes have large optical-field densities near $x = -d/2$ and can have significantly higher gain. For the case $d \leqslant L_D$, however,

the case corresponding to thin DH, which is the one of most interest, the difference in gain for different modes is insignificant. The diffraction losses for higher order modes are larger and thus threshold current densities for these modes are larger. We have restricted ourselves to consideration of only the lowest order mode in Figs. 4-7; inclusion of higher order modes would keep the predicted threshold current from increasing indefinitely with increasing d.

D. Spontaneous Lifetime and Efficiency

In the calculations we have assumed 100-percent internal efficiency, $\eta_{int} = 1$. This, of course, can only be true for the one situation for which the minority carrier lifetime τ_n is equal to the spontaneous radiative recombination lifetime τ_r. The other curves should be adjusted for the proper $\eta_{int} = \tau_n/\tau_r = L_D^2/\tau_r D_n$ by increasing the contribution to J_T from the term in (15) involving G_T by a factor of η_{int}^{-1}. This contribution is essentially the J_T obtained in the $T = 0$ model, so making the adjustment is straightforward. In many cases where the n_t term is the dominant factor in J_T, this correction is small and can be neglected, particularly in light of the uncertainties in the parameter values used in the calculations. This is the situation in the 77 and 195 K cases considered here, Figs. 5-7. In all cases neglecting the adjustment will lead to conservative (lower limit) estimates of L_D, τ_n, and ultimately η_{int} when the calculated threshold current densities are compared to experimental results.

Recent calculations [17][1] indicate that at 77 K τ_r is approximately 20 ns. Using this value at 77 K, η_{int} ranges from 2 percent for the $L_D = 2$ μm, $\tau_n = 0.4$-ns curve, to >100 percent for the $L_D = 20$ μm, $\tau_n = 40$-ns curve (which, of course, simply means that for the values of D and τ_r used, L_D is never as large as 20 μm at 77 K). For $\tau_n = \tau_r$, i.e., $\eta_{int} = 100$ percent at 77 K, $L_D \simeq 14$ μm. At 8 K the diffusion length corresponding to $\tau_n = 20$ ns is 45 μm; at 195 K it is 9 μm.

Experimental Results

To examine the effects of active region thickness and temperature on threshold current in (Pb, Sn)Te DH laser diodes, a series of heterostructure laser diodes was fabricated which were identical in all controllable respects except that the active region thickness varied from 4-20 μm. Growth, fabrication, and testing details as well as threshold current density dependence on active region thickness have previously been reported [3] for these devices without an attempt to compare the experimental results with theory.

In Fig. 8 experimental threshold data [3] have been plotted on the same graph with the curves from Fig. 5 which were theoretical calculations for a similar device. A minority carrier diffusion length $L_D \simeq 3$ μm, a minority carrier lifetime $\tau_n \simeq 1$ ns, and a $\eta_{int} \simeq 5$ percent are indicated. We point out that

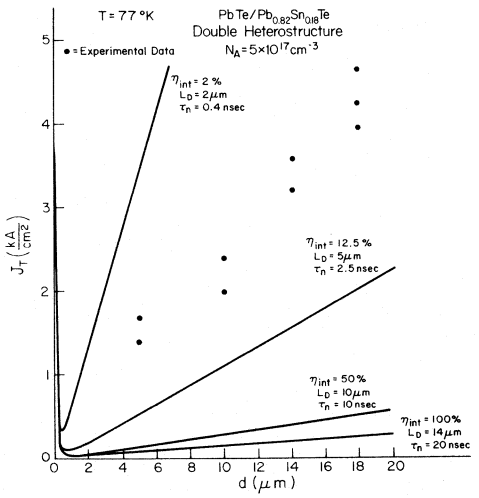

Fig. 8. Comparison of experimental pulsed threshold current densities with theoretical curves: $T = 77$ K. The solid curves are the same as those in Fig. 5 except that η_{int} has been calculated for each curve assuming $\tau_r = 20$ ns and $D = 100$ cm^2/s; the vertical scale is J_T.

many parameter values are assumed in arriving at these quantitative conclusions; experiments are currently in progress to obtain direct measurement of L_D, τ_n, and η_{int}, and to carefully confirm the theoretical predictions. It is felt, however, that the parameter values used in the calculations are reasonable and that the conclusions will be substantially unchanged once more exact values for each device are known.

There is experimental evidence that a minority carrier lifetime of 1 ns and an efficiency of 5 percent are not unreasonable. In particular, Asbeck [17] has recently measured a lifetime of 2.3 ns in PbSe laser diodes at 77 K and he infers an efficiency of 10 percent. Walpole *et al.* [4] see evidence of large internal quantum efficiencies in some of their diodes. These results had been irreconcilable with the earlier $T = 0$ theory which predicts very low thresholds for efficient devices.

Further support for the model can be obtained by comparing the experimentally observed temperature variation of threshold with the predicted variation. This is done for a 10-μm, $Pb_{0.82}Sn_{0.18}Te$/PbTe DH laser in Fig. 9. The theoretical curves correspond to $\tau_r = 20$ ns and $\eta_{int} = 5$ percent and 100 percent, respectively. (The η_{int} adjustment has been made in the $\eta_{int} = 5$ percent curve.) For contrast, the $T = 0$ model prediction, $\eta_{int} = 100$ percent is plotted also. The much more rapid increase of threshold with temperature predicted by the present model is dramatically evident. Good agreement in this respect with the data is also seen above 40 K.

Below 40 K neither model predicts the observed threshold plateau. The existence of such a plateau is not unusual and similar plateaus have been seen in GaAs laser diodes[2] and in

[1] Asbeck shows that the spontaneous lifetime is inversely proportional to the bandgap, the index of refraction, and an interband matrix element, and calculates a spontaneous lifetime for degenerate PbSe of 9.3 ns at 77 K. Using this value, and the bandgap and index of refraction of (Pb, Sn)Te, the lifetime of $Pb_{0.82}Sn_{0.18}Te$ is found to be 16.5 ns at 77 K if the value of the matrix element is assumed to be the same.

[2] With this reference to GaAs laser diode work it is appropriate to mention that the shortcomings of a $T = 0$ model and the importance of a critical minority carrier injection level n_t have been appreciated in GaAs DH laser research for some time. It is interesting to note that because of the larger density of states effective masses and narrower bandgap in $Pb_{1-x}Sn_xTe$, n_t is an even more important factor in $Pb_{1-x}Sn_xTe$ than in GaAs.

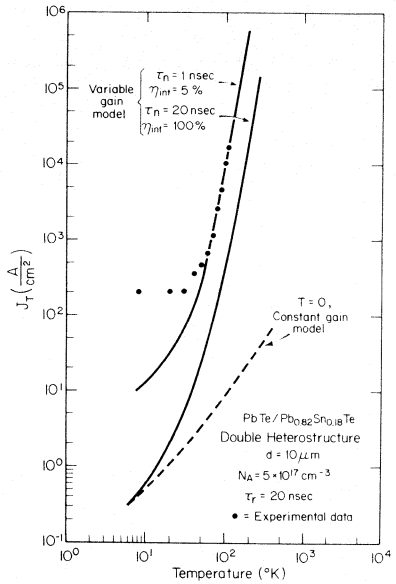

Fig. 9. Comparison of the temperature variation of J_T measured experimentally for a $Pb_{0.82}Sn_{0.18}Te$ DH diode with active region width 10 μm, and the theoretical prediction. τ_r was again taken to be 20 ns and D was assumed to vary inversely with temperature.

other IV-VI laser diodes [4], [5], [18]. The important point, however, is that only now that we have a model which accurately predicts the threshold current densities above 40 K can we identify this as an anomalous region in DH (Pb, Sn)Te laser diodes. Two possible explanations for this plateau might be the following.

1) The spontaneous linewidth will not continue to decrease indefinitely with temperature and will ultimately be limited by scattering mechanisms to some finite value. This might contribute a factor of 2 or 3 to the threshold but does not seem sufficient to make up the entire difference.

2) There may be a leakage current across the junction due to one or more of a number of sources such as surface leakage, traps, or interface states (caused perhaps by the heterojunction lattice mismatch). This current would have to be of the order of 100-200 A/cm^2 in this device.

Summary and Conclusions

From the experimental and theoretical threshold results presented and the comparisons made between them we can draw the following important general conclusions.

1) The $T = 0$ threshold model is inappropriate at temperatures much above 10 K and leads to ever increasing errors as temperature increases. It cannot be used to make predictions concerning high-temperature operation.

2) A model which accounts for the spatial variation of the gain and for the critical injection level necessary for inversion is seen to work very well for temperatures greater than 40 K. As temperature increases, the critical minority carrier injection level n_t becomes the dominant factor determining threshold current density and causing its rapid increase with increasing temperature.

3) It appears from the model that the reductions in threshold current density achievable by using the DH structure will ultimately allow routine continuous wave (CW) operation at 77 K; but at higher temperatures, greater than 150 K, for example, the increasing critical minority carrier injection level and the decreasing diffusion length indicate that CW operation will be difficult to achieve even in DH lasers.

4) Some improvement in threshold at high temperatures can be obtained by increasing the majority carrier density in the active region. Above 5×10^{18} cm^{-3} it is likely that increased free-carrier absorption losses will negate the gains from reducing the critical injection level.

5) The plateau in the threshold-temperature relation for $T < 40$ K is not explained by either model. Two possible explanations for it in these DH lasers have been proposed but the exact mechanism is unknown.

Acknowledgment

The authors wish to thank A. Colozzi for his technical assistance in the experimental portion of this work. Dr. J. N. Walpole's contributions through discussions of the theoretical threshold predictions, the low-temperature plateau, and his experimental observations are gratefully acknowledged. We also would like to acknowledge many helpful discussions with Dr. P. Asbeck and Dr. J. R. Lowney and with Prof. S. D. Senturia and Prof. A. L. McWhorter.

Selection of Modes Perpendicular to the Junction Plane in GaAs Large-Cavity Double-Heterostructure Lasers

D. C. KRUPKA, MEMBER, IEEE

Abstract—**The gains and reflectivities of the transverse-electric (TE) modes of GaAs large-cavity double-heterostructure (DH) (P-p-n′-N) lasers have been calculated in order to study mode selection perpendicular to the junction plane. The GaAs laser is modeled as a passive dielectric-slab waveguide composed of four layers whose optical constants are taken from recent literature. In lasers having a cavity thickness of a few microns, a small difference in refractive index between the p- and n′-region leads to the fundamental mode being confined to the p-region. Discrimination in favor of this mode without significant penalty in threshold gain may be achieved by utilizing the mode-dependent loss in the n′-layer. It is found that optimum mode discrimination in favor of the fundamental mode is governed by a suitable combination of the p-layer thickness, loss in the n′-region, and the difference of refractive indices of the p- and n′-layers. This analysis contrasts with an earlier analysis of the case of uniform refractive index in which it was found that the p-layer should be twice as thick as the n-layer for optimum mode discrimination. The calculated mode shapes in P-p-n′-N lasers are found to be in qualitative agreement with those observed recently by Hakki, and also with earlier observations that catastrophic mirror damage in P-p-n′-N lasers is confined to the p-region. Contrary to experimental observation, the model predicts that lasers having cavity thicknesses as large as 3 μm should operate stably in the fundamental mode. Possible reasons for this discrepancy are advanced. A simplification of the P-p-n′-N laser, which consists of omitting the N-layer thus yielding an asymmetric double-heterostructure laser, is suggested, and the merits and drawbacks of such a design are discussed.**

I. Introduction

THE possibility of obtaining pulsed powers of the order of 0.5 W from a GaAs stripe geometry laser, coupled with the ease of modulation and prospects for low ultimate cost, make this device an attractive candidate for a variety of applications. For many of these, it is required that the laser operate in the fundamental transverse mode, with its inherent beam ellipticity minimized. Reduction of beam ellipticity is particularly important in systems which employ a single-mode optical fiber to act either as a mode filter for the GaAs radiation or as a mode-selecting element [1]. Although ellipticity may be reduced by recourse to some narrow mesa structure, such a technique would entail reducing the mirror area to the point of risking mirror damage. It is important, therefore, to investigate laser designs which lead to stable operation in a fundamental transverse mode having low ellipticity and which provide output powers of at least 40 W/mm of stripe width.

One answer to the present problem has been to fabricate lasers with provision for the separate confinement of carriers and of the optical field [2], [3]. Another approach is the P-p-n-N or P-p-n′-N laser, shown in Fig. 1, with a cavity thickness of about 2 μm. This second class of structures is capable of supporting several transverse modes perpendicular to the junction plane which are typically transverse electric (TE) [5]. Since the effective angle of incidence at the mirror facets increases for higher order modes [5], these will possess a lower lasing threshold by virtue of their lower mirror transmission loss unless means are found for discriminating against them. This discrimination has been achieved by confining the gain to a selected portion of the cavity [4]. Calculations by Ripper[1] had shown that optimum mode discrimination favoring the fundamental mode in a laser with a uniform refractive index across the cavity would be achieved by inverting the population over a region extending from one side over approximately two-thirds of the optical waveguide. Successful operation of a thick-cavity zero-order-mode laser utilizing these ideas was first reported by Paoli *et al.* [4].

In order to appreciate the need for position selective inversion, it is helpful to consult Fig. 2, showing the fundamental and first-order TE modes perpendicular to the junction plane (TE_0 and TE_1) of a P-p-n-N laser with a cavity width of 2 μm and an index discontinuity between the ternary and binary regions of 0.14. The electronic gain of the mth-order TE mode

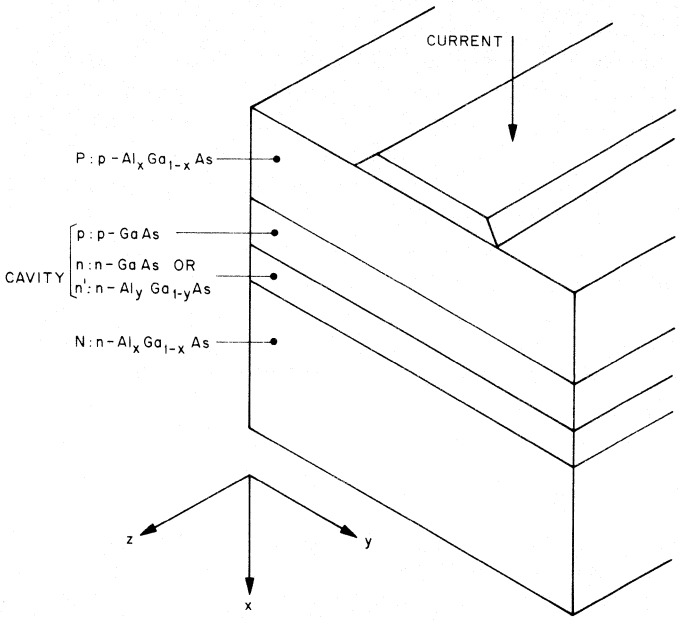

Fig. 1. Physical structure of a P-p-n-N or P-p-n'-N laser. The distinction between the two types lies in the introduction of a small amount of Al to the n-GaAs to produce a P-p-n'-N laser. The stripe contact which is 12 μm wide and the coordinate system employed in the present work are also shown. The two inner layers are referred to as the cavity.

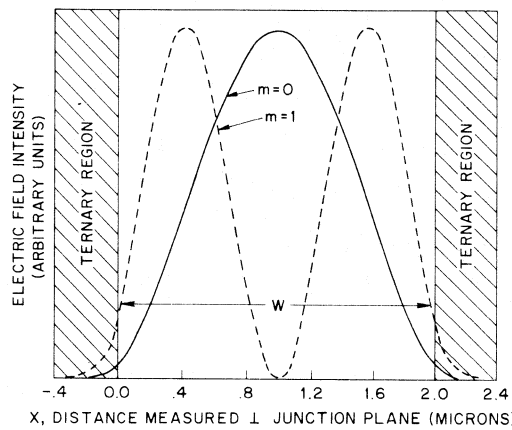

Fig. 2. The fundamental ($m = 0$) and first-order ($m = 1$) mode intensities (not normalized) or a P-p-n-N laser with a cavity width of 2 μm and a symmetric index profile with refractive indices of 3.48 and 3.62 are shown.

G_m is given by [6], [7]

$$G_m = \frac{k_0}{\beta} \int_{-\infty}^{\infty} n(x) g(x) \mathcal{E}_m^2(x)\, dx \tag{1}$$

where $\mathcal{E}_m(x)$ is the normalized electric field of the mth mode, $g(x)$ is the spatial distribution of gain or loss, $n(x)$ is the refractive index profile, and β/k_0 is the effective refractive index seen by the mode. If $g(x)$ is uniform over the cavity region ($0 \leqslant x \leqslant W$), the electronic gains of the two modes are almost identical, and the first-order mode may oscillate by virtue of its lower mirror loss [5], [8]. Inverting the population over exactly half of the guide, say, from $x = 0$ to $x = W/2$, would likewise provide little mode discrimination. On the other hand, confining the gain to two-thirds of the cavity from $x = 0$ to $x = \frac{2}{3}W$ clearly does result in mode discrimination since the inversion now exists over about 70 percent of the fundamental mode and over 55 percent of the first-order mode volume. This simple intuitive idea is stressed here since it will be important in understanding much of the material to follow.

While theory and experiment [4] indicated that mode discrimination could be achieved by appropriate definition of the region of inverted population, it remained for Hakki and Hwang [9] to explain and demonstrate improved control of the dimensions of the gain region. They concluded that in order to restrict gain to the p-region, hole injection from that region to the n-region had to be eliminated or greatly reduced. As the laser approaches threshold, the electron concentration in the p-region is estimated to be 1.8×10^{18} cm^{-3} [10], and this causes the electron quasi-Fermi level to rise into the conduction band by an amount approximately given by

$$\Delta E = \frac{\hbar^2}{2m_e} (3\pi^2 n_e)^{2/3} \approx 70 \text{ meV}. \tag{2}$$

In the above expression n_e is the electron concentration and the other symbols have their usual meaning with $m_e/m_0 = 0.068$ for GaAs. As pointed out in [9], (2) neglects a number of possible complicating effects such as nonparabolicity of the bands and band shrinkage at high concentration. For a lightly doped n-region, it is found that a potential drop of about 25 meV from the p- to the n-region, favorable for hole flow, will result [11]. Thus, unless appropriate steps are taken, gain will not be confined to the p-layer. Doping of the n-region by an amount in excess of 2×10^{18} cm^{-3} will produce a barrier for hole flow as will the addition of Al. (For low Al concentrations the shift is approximately 12.5 meV/mole percent [12].) It was recognized [9] that the presence of Al would modify the refractive index profile of the laser, and could lead to excitation of higher order modes effectively confined to the gain region when sufficiently large cavity thicknesses were employed. In such extreme cases, mode discrimination favoring the fundamental mode could be lost.

It is the purpose of this work to examine in more detail how the addition of the n-dopant and Al to the unpumped region, essential to the proper operation of this laser, affects the transverse-mode structure and mode selection in GaAs P-p-n'-N lasers. The change in the refractive index profile caused by these additions alters the mode structure sufficiently to force one to reexamine design parameters based on the assumption that the refractive index is uniform across the optical cavity. This work further suggests modifications of the laser design which result in a simpler structure.

It should be pointed out that calculations of the type to be described here have been carried out by Anderson [6] and by Butler and Kressel [13], [14]. The present analysis differs in that it includes calculations of mode reflectivities and considers specific geometries and doping levels. The work has been greatly aided by recent measurements [15]-[17] of the optical properties of GaAs and $Ga_xAl_{1-x}As$ over a useful range of energies and for a variety of doping levels.

Section II contains a description of the model to be used in the calculations and outlines the method. It also includes a summary of the optical properties of the various layers deemed

useful for this discussion. In Section III the results of numerical calculations of mode shapes, gains, and reflectivities are presented for a number of possible laser designs. These calculations demonstrate the importance of accurately taking into account the refractive index profile when calculating mode gains. In Section IV the calculations are compared with experimental data and conclusions are drawn concerning the factors governing mode selection. These lead directly to a suggested modification of the P-p-n′-N structure. A summary of the findings is given in Section V.

II. Calculations

A. Waveguide Modes

The GaAs laser is modeled as a dielectric slab, infinite in the plane of the junction and composed of the following four layers: ternary P; binary p of width W_p; an n′ or "unpumped" region of width W_n; and ternary N (c.f. Fig. 3). The ternary layers are assumed to be infinitely thick. Doping leads to a difference between the refractive indices n_p and $n_{n'}$ of the binary p- and the n′-regions, and the difference $n_p - n_{n'}$ is defined as δn. It is assumed that the modes propagate along the z direction and that the fields are independent of the y coordinate, taken to be in the plane of the junction, so that one may speak of TE_m and TM_m modes. Only TE modes will be considered here, since when lasing occurs in higher order modes, they are generally observed to be TE [14].

In this geometry only E_y, H_x, and H_z components are nonvanishing, and the magnetic components may be obtained from a knowledge of E_y which, in regions under consideration, takes the form

$$E_y = \mathcal{E}(x)\, e^{i(\omega t - \beta z)}$$

$\mathcal{E}(x)$ being the normalized field distribution along the x axis. The four-layer slab has been treated by Smith [18].

It will be assumed that the solutions for the modes are determined from the knowledge of the waveguide dimensions and the real part of the dielectric constant. For the absorption losses encountered in the devices to be discussed, it is entirely reasonable to neglect the imaginary part of the dielectric constant when discussing guidance perpendicular to the junction plane [8].

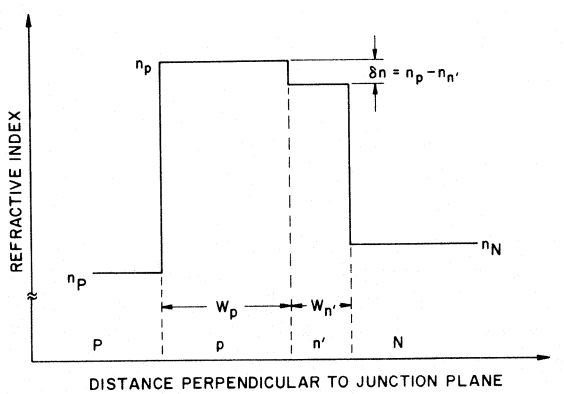

Fig. 3. Refractive index profile employed in the calculations. The refractive indices have subscripts which identify them as belonging to the ternary p-region; n_p, etc. The quantity δn is defined as $n_p - n_{n'}$, and the widths of the p- and n′-regions are W_p and $W_{n'}$.

B. Mode Gains

The chief aim of this work is to determine the electronic gain at threshold of all the modes for a given laser geometry and to determine parameters which optimize mode discrimination in favor of the fundamental mode at threshold. No attempt has been made to consider the influence of the presence of a lasing mode upon the gain profile.

Fig. 4 shows the gain profile which will be used throughout. Absorption and interface scattering give rise to the loss. Strictly speaking, the gain is not uniform over the p-region as indicated, but the departure from that assumption may not be sufficiently large for the majority of the designs to be considered if one assumes a typical diffusion length for electrons in the p-layer of 4–5 μm [19], [20].

C. Device Parameters

For the sake of consistency, all parameters necessary for mode-gain calculations have been taken from [15]–[17]. All data are based on a wavelength of 0.8875 μm (1.397 eV) since this corresponds to a typical lasing energy observed for this type of laser [21]. The refractive index data are summarized in Tables I and II, while Table III contains relevant information on absorption coefficients. The absorption coefficients for $Al_xGa_{1-x}As$ were estimated from the GaAs data at an energy of $1.4 - \Delta(x)$ eV, where $\Delta(x)$ is the change in the bandgap for a fraction x of Al [12]. Since the values of x do not exceed 0.05, such a procedure should give reasonable values.

To determine the refractive index of the active region at threshold, the following approach was adopted. The lasers currently fabricated have a p-doping in the active layer of approximately 4×10^{17} cm^{-3} which, using Table II, yields a refractive index of 3.62. At threshold, this refractive index will be altered by the increase in free carrier concentration and also as a result of inversion. In order to estimate these effects

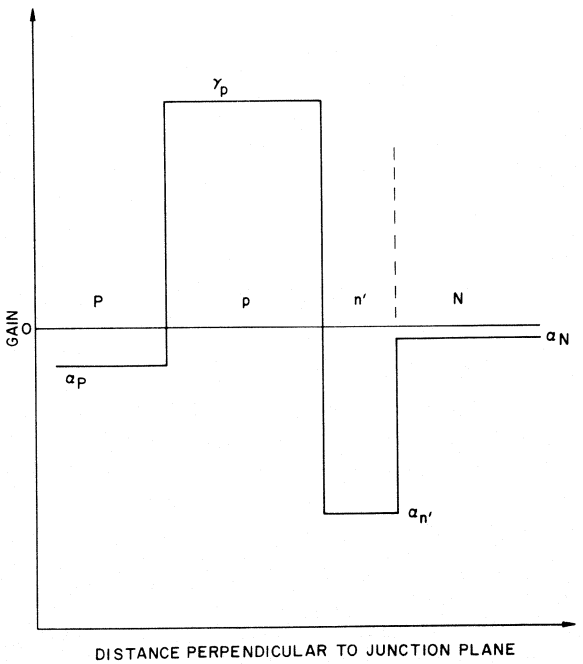

Fig. 4. Assumed gain profile perpendicular to the junction plane. The absorption coefficients α are subscripted in an obvious manner. The gain in the p-region necessary to attain fundamental mode threshold is designated γ_p.

for the present analysis, use will be made of the results of Selway *et al.* [22] on single-heterostructure (SH) lasers. These authors give

$$\Delta n \approx -(5\text{-}11)\times 10^{-21}\, n_{inj} \qquad (3)$$

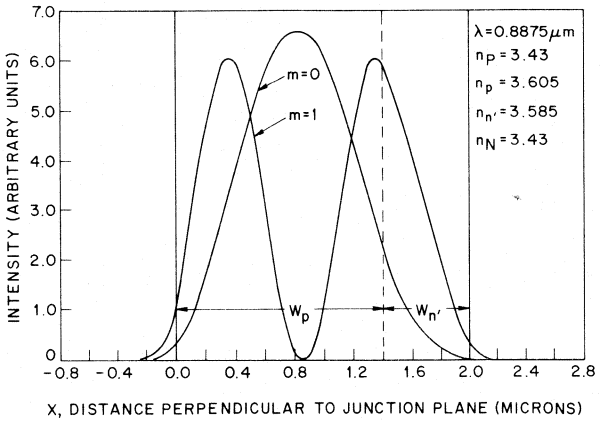
where n_{inj} is the injected carrier concentration at threshold. Equation (3) is not expected to represent accurately the refractive index shift for our lasers, which, in contrast to the SH devices, have a lightly doped active region, and, consequently, a different "inversion" contribution to the change in refractive index. In the absence of more appropriate data, however, we shall assume the validity of (3). Thus, using $n_{inj} = 2\times10^{18}$ cm^{-3} [10],

$$-0.02 \lesssim \Delta n \leqslant -0.01$$

and we shall take $\Delta n = -0.015$, making $n_p = 3.605$.

In the calculations that follow, the most important material parameters are actually $\delta n = n_p - n_{n'}$, and, to a somewhat lesser extent, $\alpha_{n'}$, the loss in the n'-region (cf. Fig. 4). Thus, even if the absolute value chosen for n_p is not quite accurate, the results plotted in Figs. 6 and 7 will remain useful since one can adjust the doping levels in the n'-region, and thus the value of $n_{n'}$, to keep δ_n at the value used in these figures while also maintaining $\alpha_{n'}$ sufficiently close to the values used in the plots.

III. RESULTS



A. Mode Shapes

Before launching into a discussion of mode discrimination, it will be helpful to consider the appearance of some low-order modes in order to obtain further physical understanding of the effects of mode shape on discrimination. Fig. 5(a) shows the $m = 0$ and the $m = 1$ modes for a laser with a 2-μm cavity having the p-n junction located to yield $W_p/W_n = 2.3$. The refractive index step, δn of 0.02, is sufficiently large to confine over 90 percent of the $m = 0$ mode to the p-region while confining about 70 percent of the $m = 1$ mode. Fig. 5(b) shows the effect of reducing the width of the p-region for the same value of δn. The fundamental mode spills out of the gain region with only about 70 percent of the power now being carried in that region. However, the $m = 1$ mode has but 20 percent of its power in the p-layer, with the bulk concentrated in the n-region. Clearly, mode discrimination favoring the fundamental mode is improved in the situation shown in Fig. 5(b) at the price of increased threshold gain.

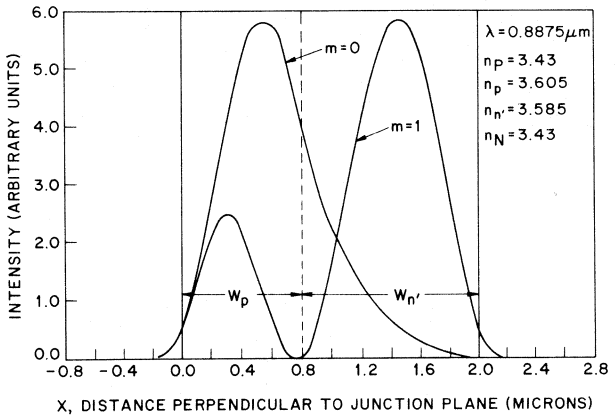


Fig. 5(c) illustrates yet another effect to be encountered. The sole difference between Fig. 5(a) and (c) is the doubling of δn in the profile shown in Fig. 5(c). Increasing the refractive index step results in compression of the $m = 1$ mode into the active region with a resulting loss in discrimination. For the case shown in Fig. 5(c), there are 96 and 83 percent of the $m = 0$ and $m = 1$ modes, respectively, in the active region.

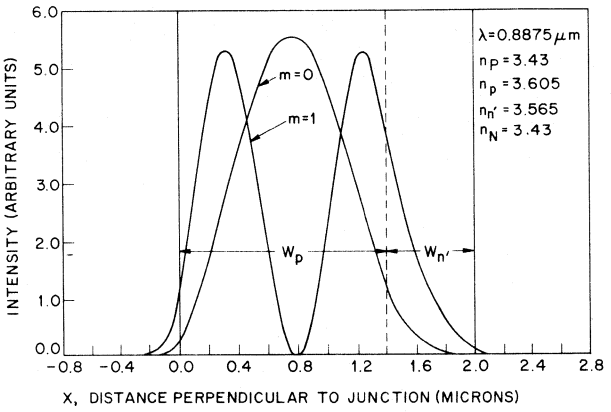
B. Mode Gains



The calculation of mode gain is carried out as follows. The index profile shown in Fig. 3 is used to calculate the modes $\mathcal{E}_m(x)$, using Smith's expressions [18], and these in turn are employed in determining mode reflectivities as described in the Appendix. For a laser whose length L is 375 μm, which is the standard used in these calculations, and for cavity thicknesses in excess of 2 μm, the fundamental mode reflectivity is such as to yield a total mirror loss α_0 of approximately 30 cm^{-1} when the mirrors are merely cleaved surfaces. (The mirror loss for the mth mode is obtained from the relation

(a)

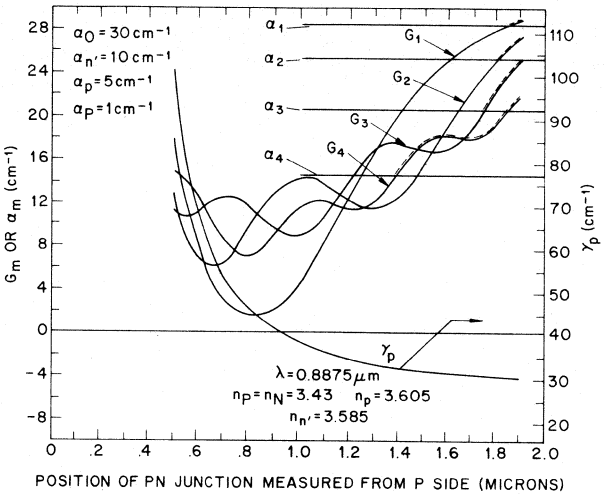
(b)

(c)

Fig. 5. Illustrating the effects of layer thickness and index profile on the shapes of the fundamental and first-order modes (not normalized for power). In all cases $n_p = n_N = 3.43$ and $n_p = 3.605$. (a) 2-μm cavity with $W_p = 1.4$ μm and $n_{n'} = 3.585$. (b) Same as (a) except that $W_p = 0.8$ μm. (c) Same as (a) except that $n_{n'} = 3.565$.

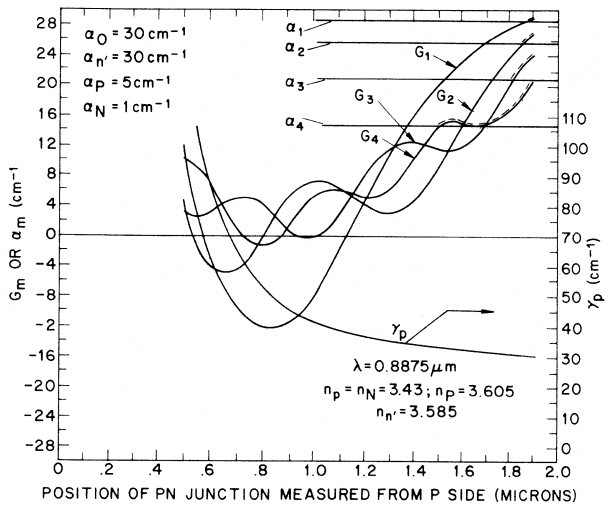
$\alpha_m = -(1/L) \ln R_m$, where R_m is the mode reflectivity of the mth mode.) For these lasers to attain fundamental mode threshold it is required that

$$\alpha_0 = G_0 = \frac{k_0}{\beta}\left(-n_P\alpha_P \int_{\text{P-region}} \mathcal{E}_0^2(x)\,dx + n_p\gamma_p \int_{\text{p-region}} \mathcal{E}_0^2(x)\,dx - n_{n'}\alpha_{n'} \int_{\text{n'-region}} \mathcal{E}_0^2(x)\,dx - n_N\alpha_N \int_{\text{N-region}} \mathcal{E}_0^2(x)\,dx\right). \quad (4)$$



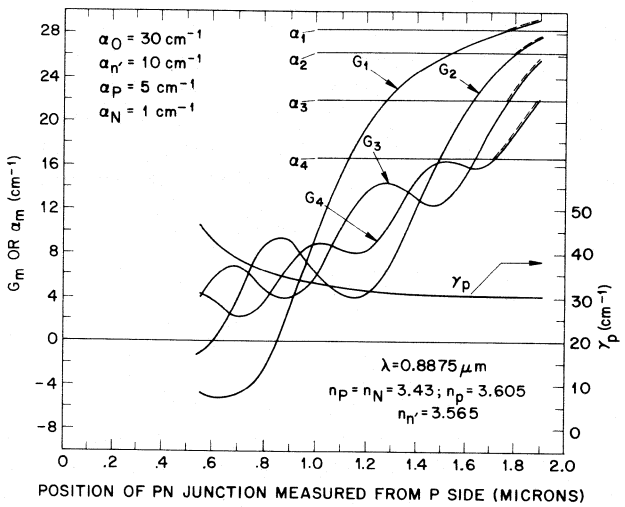
Equation (4) is used to solve for the quantity γ_p (cf. Fig. 4) which is the gain in the p-region required to attain fundamental mode threshold. Knowledge of γ_p together with the absorption coefficients now determines the gain profile $g(x)$ as in Fig. 4 and permits calculation of the gains G_m of all higher order modes. Thus the present calculations determine the gains for all higher order modes *given that there exists sufficient gain for the fundamental mode* to oscillate.

C. Specific Examples



1) 2-μm Cavity: In Fig. 6(a)–(c) are plots of mode gain G_m, mirror loss α_m, and γ_p, the gain in the p-region required to attain fundamental mode threshold as a function of the position of the p-n junction in a 2-μm cavity which supports a total of five modes. The left-hand scale refers to G_m and α_m, while the scale on the right applies to γ_p. All the data presented have been calculated for the case of ternary layers possessing 24-mole percent of AlAs.

Since the plot of γ_p is simpler to treat, it is considered first. The physical reasons underlying its appearance have been presented in Section III-A. The increase of γ_p as the width of the active region is reduced reflects the fact that a smaller fraction of the fundamental mode volume occupies the active layer and thus gain must be increased to attain threshold. When the gain region is wide, the fundamental mode is contained almost entirely within the gain region and suffers little loss. Under such conditions $\gamma_p \approx \alpha_0$.



The mirror losses α_m have been drawn as straight lines although these quantities change as the position of the p-n junction is varied. For the 2-μm cavity the difference between the α_m values for the case when the junction is at the midpoint of the cavity and the case when the entire cavity is made of p-material is less than 5 percent. For present purposes this difference is considered negligible. Naturally, the lower order modes which are more tightly bound will be less sensitive to changes in the index profile than the highest order modes. For a given position of the p-n junction, the curves of α_m and G_m

(a)

(b)

(c)

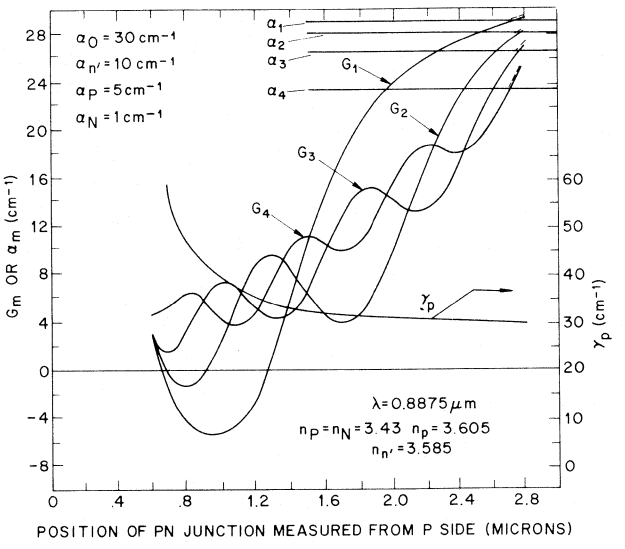
Fig. 6. Mode properties of a 2-μm cavity. The following quantities are plotted as a function of the position of the p-n junction measured from the p-P boundary: G_m—the mode gain of the mth mode; α_m—effective mirror loss for the mth mode. If $G_m > \alpha_m$, the fundamental mode will not reach threshold before the mth mode, and G_m is shown with broken lines. γ_p—gain in the gain region required to attain fundamental ($m = 0$) mode threshold assuming an effective mirror loss, $\alpha_0 = 30\ cm^{-1}$. It is assumed that operation is at 0.8875 μm with the following properties held constant: $\alpha_P = 5\ cm^{-1}$; $\alpha_N = 1\ cm^{-1}$; $n_N = n_P = 3.43$; $n_p = 3.605$. (a) $\alpha_{n'} = 10\ cm^{-1}$, $n_{n'} = 3.585$. (b) $\alpha_{n'} = 30\ cm^{-1}$, $n_{n'} = 3.585$. (c) $\alpha_{n'} = 10\ cm^{-1}$, $n_{n'} = 3.565$.

may be used to determine whether or not the mode will attain threshold before the fundamental. As long as $\alpha_m > G_m$ for $m > 0$, the fundamental has the lowest threshold. Note that there are, of course, no curves for α_0 and G_0. The reason for this is that both α_0 and G_0 are taken to be equal to 30 cm^{-1} for all positions of the p-n junction and the value of γ_p is adjusted to satisfy (4).

As the p-region is broadened, the electronic gain G_m tends to increase in an oscillatory fashion that results from the detailed shapes of the modes and the distribution of mode volume between the two regions. When the p-region is made very narrow, the curves of G_m begin to rise again, reflecting the rise in γ_p due to the reduced coupling of the fundamental mode to the gain region.

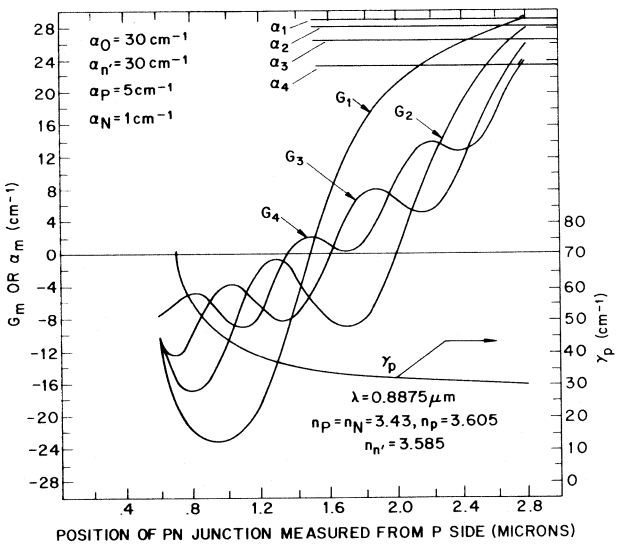
The chief aim of Fig. 6(a)-(c) is to demonstrate how mode discrimination as measured by the difference ($\alpha_m - G_m$) is affected by loss in the n'-region and by the size of the refractive index step δn. It must be kept in mind that the two effects are *not* separable in general. The effects of loss are considered first. Fig. 6(a) and (b) shows the mode gains for structures having $\delta n = 0.02$ and differing only in loss in the n'-region. From Tables I-III it may be seen that Fig. 6(a) with an absorption coefficient in the n'-region, $\alpha_{n'} = 10\ cm^{-1}$, would correspond to a structure with 3.5-percent Al and an electron concentration somewhat in excess of $3.3 \times 10^{18}\ cm^{-3}$. The parameters in Fig. 6(b) are appropriate for a laser with an unpumped region with no Al and $n \approx 4.5 \times 10^{18}\ cm^{-3}$. The key point is illustrated by considering the gain curves for a gain-region thickness of approximately 1.2 μm. In the case of $\alpha_{n'} = 10\ cm^{-1}$, the mode gains for all higher order modes lie

between 12 and 16 cm^{-1}. For $\alpha_{n'} = 30\ cm^{-1}$, mode gains are between 4 and 8 cm^{-1}, and γ_p is not greatly increased thereby. Thus, in this case, higher loss in the n'-region considerably improves mode selection without significantly raising the threshold gain.



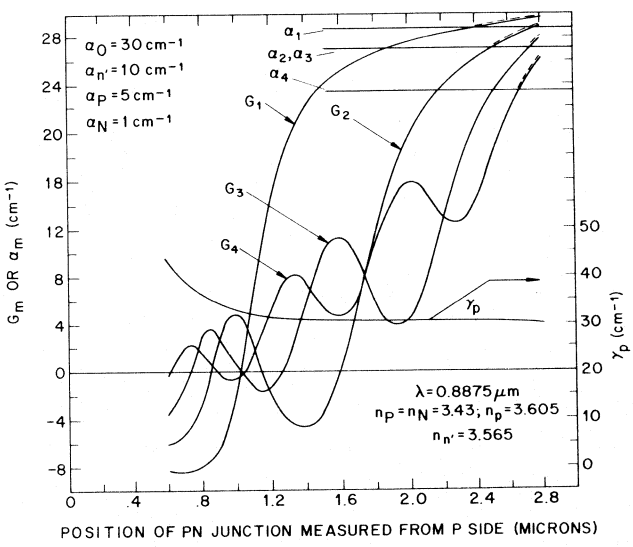
For a 2-μm cavity, the effects of changes in δn at fixed loss are shown in Fig. 6(a) and (c). The parameters given in Fig. 6(c) are representative of a laser with a 3.5-percent Al concentration in the n'-layer and an electron concentration of about 4×10^{18} cm^{-3}, producing $\delta n = 0.04$. Qualitatively, the effect of a larger δn is to degrade the mode discrimination between the $m = 0$ and the $m = 1$ modes if one restricts one's attention to the practical region where $W_p/W_{n'} \geq 1$. The physical explanation for this effect was discussed earlier in connection with Fig. 5(c). The larger value of δn leads, however, to an improved discrimination between the $m = 0$ and $m = 4$ modes. With $W_p/W_{n'} = 2$, the laser in Fig. 6(c) would have a stable fundamental mode, whereas the laser in Fig. 6(a) would have both fundamental and fourth-order modes. The best approach for a 2-μm cavity P-p-n'-N laser thus appears to be to dope heavily the unpumped region to an electron concentration between 4.5×10^{18} and 5.5×10^{18} cm^{-3} to provide both loss as well as δn. Using the ideas of [11], such designs give rise to potential barriers against hole flow of 110 and 130 meV, respectively.

It remains to determine the location of the p-n junction which will lead to oscillation in a fundamental mode having the greatest width. If one arbitrarily stipulates that $\alpha_m - G_m \geq 4\ cm^{-1}$ for $m \neq 0$, then one finds from Fig. 6(b) that a gain region in a 2-μm cavity can be about 1.4 μm wide. Further reduction of the p-layer width gives better mode discrimination but leads to an undesirably smaller mode width. Optimum mode discrimination, as measured by a maximum in $(\alpha_m - G_m)$ for $m > 0$, appears to be attained at a W_p of about 0.9 μm. This conclusion differs considerably from Ripper's[1] simple model where a uniform index across the cavity was assumed. His model, applied to a 2-μm cavity, would predict optimum mode discrimination for a p-layer 1.3 μm thick.



2) 3-μm Cavity: The results for the 3-μm cavity are shown in Fig. 7(a)-(c). In each case the structure will support a total of eight modes but only four are plotted for clarity's sake, and also because the highest order modes are very rarely observed. As with Fig. 6(a)-(c), the local gain γ_p is adjusted to give a fundamental mode gain G_0 of 30 cm^{-1}.

The improved mode discrimination realized by loss in the n'-region is once again apparent by comparing the mode gains for structures differing only in $\alpha_{n'}$ [e.g., Fig. 7(a) and (b)]. Increasing δn from 0.02 to 0.04 [Fig. 7(a) and (c)] has a strong effect on mode discrimination between the $m = 0$ and $m = 1$ modes. For the larger δn, both modes are essentially confined to the gain region, and there is very little discrimination for values of W_p/W_n, of interest.



Since Fig. 7(a)-(c) shows only four curves rather than the full seven supported by these 3-μm cavities, Table IV has been prepared to show the effects of δn and loss for all modes in 3-μm cavities having $W_p/W_{n'} = 2$. This ratio has been chosen as it leads to reasonable mode discrimination as well as a fundamental mode whose width is not too much smaller than

(a)

(b)

(c)

Fig. 7. Mode properties of a 3-μm cavity. Only four of seven possible modes are shown for clarity. For quantities plotted as a function of the position of the p-n junction measured from the p-P boundary, see caption of Fig. 6.

TABLE IV
MODE GAINS AND REFLECTIVITIES FOR THREE DIFFERENT DESIGNS FOR A 3-μm CAVITY P-p-n′-N LASER OPERATING AT 0.8875 μm

	Mode No. (m)	Mirror Loss, α_m (cm^{-1})	Mode Gain, G_m (cm^{-1}) With $\alpha_{n'}$ = 30 cm^{-1}	Mode Gain, G_m (cm^{-1}) With $\alpha_{n'}$ = 10 cm^{-1}
(a) $n_{n'}$ = 3.585				
	1	29.0	21.2	24.1
	2	28.1	0.56	10.3
	3	26.4	6.8	14.3
δn = 0.02	4	23.6	9.3	15.8
	5	20.2	6.2	13.5
	6	14.6	10.1	15.5
	7	11.9	6.0	11.2
(b) $n_{n'}$ = 3.565				
	1	28.7		27.7
	2	27.2	At 0.8875 μm the combination of $n_{n'}$ = 3.565 and $\alpha_{n'}$ = 30 cm^{-1} is not physically realizable.	20.2
	3	27.1		4.6
δn = 0.04	4	23.5		15.9
	5	20.4		11.4
	6	15.2		13.3
	7	14.4		9.2

Note: α_P = 5 cm^{-1}; α_N = 1 cm^{-1}; α_0 = 30 cm^{-1}. (Laser length = 375 μm.) $n_P = n_N$ = 3.43; n_p = 3.605; $W_p/W_{n'}$ = 2 in all cases.

the cavity width. The important quantity to consider is $\alpha_m - G_m$, and it is seen that the design with $\delta n = 0.02$ and $\alpha_{n'} = 30$ cm^{-1} leads to better mode discrimination than the other two designs listed. For a 3-μm cavity of this general design, however, optimum mode discrimination in favor of the fundamental occurs when $W_p \approx 1$ μm ($W_p/W_{n'} \approx \frac{1}{2}$) but this leads to a fundamental mode with a width so much smaller than the cavity that it is not considered to be a useful design for high-power lasers.

Throughout this section, results have been presented for a model in which there is 24-percent Al in the ternary layers. Some calculations have been carried out for the case of 18-percent Al. It was found that with the exception of the highest order modes, where small differences appear, the results differ negligibly from those presented here.

IV. DISCUSSION

The aforementioned calculations are based on a simple threshold model and emphasize two aspects of P-p-n′-N laser design important for good mode discrimination: 1) a relatively small value for δn, one sufficient to confine primarily the fundamental mode to the gain region; and 2) loss outside the gain region to ensure lower gain for higher order modes. It has been shown that a model which includes a nonzero δn predicts values of W_p which optimize mode discrimination very different from those predicted for $\delta n = 0$.

Our lasers are currently designed with p = 4×10^{17} cm^{-3} for the gain region and n = 4×10^{18} cm^{-3} and approximately 3.5-percent Al in the n′-region. Based on the figures summarized in Tables I–III, such designs lead to a δn of approximately 0.04. Thus lasers having cavities about 2 μm thick would be expected to display a pronounced shift of the $m = 0$ and $m = 1$ modes into the gain region. This has been observed recently by Hakki [23], who studied the near field emission of P-p-n′-N lasers superposed on the photoluminescence of the laser mirrors excited by a krypton laser. In other studies, Paoli *et al.* [4] have noted that when mirrors failed catastrophically in their P-p-n′-N lasers, operating in the fundamental mode, damage was confined essentially to the p-layer. Although no Al was deliberately introduced into the n-region of these lasers, it was deduced from other observations that there was some inadvertent "drag-over" of Al from the N-layer during growth. A gradient in Al concentration from the ternary region towards the p-P boundary would be expected to yield effects on mode shape qualitatively similar to those produced by a step in index.

While there exists qualitative agreement between the present calculations and the observed mode shapes, no P-p-n′-N lasers have been fabricated which have a 3-μm cavity with a 2-μm active region and operate at threshold in the $m = 0$ mode [24]. For the current design parameters, however, the model does predict fundamental mode operation. In light of this discrepancy, there must be other factors affecting operation that have not been fully accounted for in the analysis. As stated previously, such lasers have been designed with doping profiles leading to $\delta n = 0.04$ and $\alpha_{n'} \approx 10$ cm^{-1}. According to Fig. 7(c), there is thus very little discrimination in favor of the fundamental mode expected for 3-μm cavity lasers at the design value of $W_p/W_{n'} = 2$, and it is possible that rather small departures from the model assumptions can account for the observations. One possibility is discussed in the following.

Shurtz [25] has recently carried out self-consistent calculations of the lasing behavior of the modes perpendicular to the junction plane and finds that for lasers of the type discussed here, with a 1-μm active region, the carrier profile in this region is fairly uniform at threshold, but becomes peaked at the P-p heteroboundary above threshold. For wider active regions these effects, due to finite diffusion lengths, are expected to be more pronounced and will be reflected in a gain profile more favorable for the $m = 1$ mode than that assumed. The effect of such a mode profile on higher order modes is more difficult to assess.

A notable result of the present calculations is that there is really no optimum ratio of $W_p/W_{n'}$ for P-p-n′-N lasers in general; the mode-selection behavior is governed largely by W_p and δn. The relation of W_p and δn in determining the Al doping in the n′-region had been considered earlier by Hakki and Hwang [9]. Such considerations lead one, therefore, to a simplification of the laser structure in which the N-layer is simply omitted, producing an asymmetric double-heterostructure (ADH) laser. It is clear from Fig. 5(a)–(c) that the fundamental mode in P-p-n′-N lasers with typical values of δn should be little affected by the presence of the ternary N-region since the optical field virtually vanishes at the n′-N heteroboundary. The main effect on the mode properties resulting from the omission of the N-layer will be a reduction of the mode content, and a tendency for the modes to penetrate a little more deeply into the lossy unpumped region, leading to mode discrimination in favor of the fundamental mode. The absence of high-order modes would be particularly helpful in designing antireflective layers in a system such as discussed in [1].

Table V is a summary of calculated mode gains and mode reflectivities of ADH lasers with gain regions 1.4 and 2.0 μm thick. For comparison, the results on related P-p-n′-N structures have been included. The refractive indices and absorption coefficients used are the same as those employed in calculating

TABLE V

7	"	9.2	14.4				

Note: The following parameters are assumed: $n_P = 3.430$; $n_p = 3.605$; $n_{n'} = 3.565$; $n_N = 3.430$; $\alpha_P = 5$ cm^{-1}; $\alpha_{n'} = 10$ cm^{-1}; $\alpha_N = 1$ cm^{-1}; $\alpha_0 = 30$ cm^{-1}. (Laser length = 375 μm.)

the data contained in Figs. 6(c) and 7(c). As anticipated in the preceding, these ADH lasers support fewer modes and possess threshold gains γ_p equal to or only marginally greater than those of P-p-n′-N lasers. Furthermore, mode discrimination in favor of the fundamental mode is at least as good as that in P-p-n′-N lasers. Thus, since the fabrication of ADH lasers is simpler than that of P-p-n′-N lasers, they would appear to be an attractive approach to large-optical-activity high-power lasers. Although these lasers are related to SH lasers, which are known in some cases to exhibit Q-switching behavior, this is not expected to be a problem for values of δn of interest [26].

While these lasers appear to have useful mode properties, they have no n′-N heteroboundary and thus lack a high barrier to hole flow. An excess hole current density, J'_p, may, therefore, result. This point is considered in the following. For the ADH lasers, the upper limit for the excess hole current density $(J'_p)_{max}$, is proportional to the product of hole concentration in the n′-region and the thermal velocity [11]. For the lasers considered in Table V, one finds $(J'_p)_{max} \approx 36$ kA/cm^2. This is clearly a large overestimate since SH lasers possess lower thresholds than this. Some estimate of the factor by which $(J'_p)_{max}$ should be reduced to provide a more realistic estimate of J'_p may be obtained by considering results on SH lasers.

For SH lasers we may express the threshold current density J_{th} as

$$J_{th} = (J_{th})_0 + J'_p \tag{5}$$

where $(J_{th})_0$ is the threshold current density which would be observed for a double-heterostructure (DH) laser having the same active layer width d and a doping level in the ternary layers leading to full confinement of optical field and charge carriers. For such DH lasers $(J_{th})_0/d \approx 5$ kA/cm^2 μm [27].

Selway *et al.* [22] report on SH lasers having $d = 2$ μm, with room-temperature thresholds estimated[2] to be 17 kA/cm^2, $\delta n = 0.01$, and a doping in the n substrate of $3 - 4 \times 10^{18}$ cm^{-3}. Using (5) and a carrier concentration at threshold of 2×10^{18} cm^{-3}, one estimates $J'_p \approx 7$ kA/cm^2. Using the same data as the preceding, one obtains, following [11], $(J'_p)_{max} \approx 180$ kA/cm^2. This suggests that a reduction factor no greater than 0.04 be used in estimating the real excess hole current density from the upper limit calculated. Reduction factors ranging between 0.01 and 0.08 have been determined in an analogous manner using data on SH lasers reported by Hayashi and Panish [28] and Minden and Premo [29]. With a reduction factor of 0.04, one obtains $J'_p \approx 1.5$ kA/cm^2 for the ADH lasers considered in Table V. This represents a 15-percent increase in threshold current density for the laser having a 2-μm-wide active layer.

Provided the excess hole current density can be kept to the levels estimated here, appropriately designed ADH lasers may represent a useful simplification of the P-p-n′-N design.

V. SUMMARY

Using recent data on the optical properties of GaAs and $Al_xGa_{1-x}As$, calculations have been made of the mode-selection properties perpendicular to the junction plane of P-p-n′-N lasers. These calculations lead to the design principle of confining the fundamental mode to the gain region and letting the higher order modes spill out into the unpumped n′-region. It has been demonstrated that loss in the n′-region is important in mode selection and that in appropriately designed structures such loss does not significantly raise the threshold of the fundamental mode. Earlier design rules for the ratio $W_p/W_{n'}$ which were based on the assumption of a uniform refractive index across the cavity, break down for practical doping levels in the n′-region, and the governing parameters become instead W_p and δn. These findings have led to the suggestion that P-p-n′-N lasers be simplified by omitting the N-layer to produce an ADH laser. The potential usefulness of such a laser hinges on the ability to achieve low excess hole currents while maintaining a stable fundamental mode with low ellipticity.

APPENDIX
CALCULATION OF MODE REFLECTIVITY

A method suggested by McKenna[3] and employed by Reinhart *et al.* [8] and Gordon [30] is outlined in order to show more directly what approximations are being made.

For a region characterized by a real refractive index n, the reduced wave equation [31] for TE modes is written

$$\frac{\partial^2 E_y}{\partial z^2} + \frac{\partial^2 E_y}{\partial x^2} + k^2 n^2 E_y = 0 \tag{A1}$$

where k is the propagation constant in free space. Solutions for the modes are assumed to take the form $E_y = \mathcal{E}(x)e^{-i\beta z}$ and the modes for the four-layer slab are obtained by solving (A1) in each region and matching at the boundaries.

For a uniform dielectric medium with refractive index n, there exists a complete set of plane-wave solutions of (A1), which takes the form

[2] This was done by linearly interpolating the threshold values between 20 and 40°C.

[3] J. McKenna, quoted in [8]. The author is grateful to him for explaining the method outlined here.

$$\Psi = Ae^{-ikn(z\cos\theta + x\sin\theta)}.$$

Here A is a normalization constant and θ is the angle which the propagation vector k makes with the z axis. For calculation of mode reflectivity, it would be convenient to expand the guided modes in terms of the plane waves since the reflectivity of the latter may be calculated readily. Strictly speaking, this method is permissible if the mode is contained entirely within a single medium. This is never exactly true, but since the fractional difference between refractive indices of interest is small ($\leqslant$5 percent), the approximation may be a reasonable one, especially for the lower order modes when a large number of modes is present. Thus one may write for the mth mode when it reaches the mirror at $z = 0$

$$\mathcal{E}_m(x) = \int_{-\infty}^{\infty} F_m(l)e^{-iknlx}\,dl \tag{A2}$$

where $l = \sin\theta$, and $F_m(l)$ is the Fourier coefficient at l for the mth mode. An appropriate choice for the value of the refractive index n will be discussed in the following. When the mth mode is reflected at the mirror ($z = 0$) a reflected *wave* $\mathcal{E}(x)$ results which may be expressed as

$$\mathcal{E}(x) = \int_{-\infty}^{\infty} R(l)F_m(l)e^{-iknlx}\,dl \tag{A3}$$

where $R(l)$ is the Fresnel (field strength) reflection coefficient. One may expand $\mathcal{E}(x)$ in terms of the complete set of guided and continuum modes of the laser, the mth coefficient of this expansion being identified as the reflection amplitude of the mth mode. The guided TE modes have the normalization condition [31, p. 324]

$$\int_{-\infty}^{\infty} \mathcal{E}_m \mathcal{E}_k^*\,dx = \frac{2P\omega\mu}{\beta_m}\delta_{mk} \tag{A4}$$

where P is the power carried by the mode, ω is the angular frequency, μ is the permeability of the medium, and β_m is the propagation constant of the mth mode. The subscripts m and k label the modes. Using orthogonality of the slab modes, one finds that the coefficient of the mth mode is given by

$$C_m = \frac{\beta_m}{2P\omega\mu}\int_{-\infty}^{\infty} \mathcal{E}_m^* \int_{-\infty}^{\infty} F_m(l)R(l)e^{-iknlx}\,dl\,dx$$

$$= \frac{\beta_m}{4\pi P\omega\mu}\int_{-\infty}^{\infty} |F_m(l)|^2 R(l)\,dl. \tag{A5}$$

The second step in the preceding equation follows from interchange of the order of integration and the definition of the inverse Fourier transform. The mode reflectivity is simply

$$R_m = |C_m|^2. \tag{A6}$$

The problem of the choice of n in (A5) has been resolved by replacing n by β_m/k for all modes. This is in keeping with the spirit of the picture of a wave traveling in a medium of effective index β_m/k. Since the equivalent mirror loss α_m has a logarithmic dependence on mode reflectivity, viz.

$$\alpha_m = -\frac{1}{L}\ln R_m$$

α_m will not depend critically on the details of the approximation. For a symmetric three-layer slab 2 μm thick with refractive indices of 3.43 and 3.565, the aforementioned method for determining mirror reflectivity has been checked against Ikegami's [5] more elaborate calculation. The results are shown in the following table:

	$\ln(1/R_m)$	
Mode Number m	Present Method	Ikegami
0	1.16	1.14
1	1.08	1.07
2	0.97	0.97
3	0.84	0.78
4	0.71	0.66

As expected, good agreement is obtained for low-order modes, and the agreement is better than 8 percent for the higher order ones. Apart from its simplicity, the present method has the virtue of being capable of treating cases where antireflection layers are evaporated on the mirror surfaces.

Acknowledgment

The author wishes to thank B. W. Hakki for stimulating discussions during the course of this work, particularly concerning aspects of P-p-n-N laser design and performance, and for his careful reading of an early version of the manuscript. He also wishes to thank H. C. Casey, Jr., who has been most helpful with advice concerning the optical properties of GaAs and $Al_xGa_{1-x}As$, and D. Cook, L. A. D'Asaro, J. McKenna, R. C. Miller, T. L. Paoli, M. B. Panish, F. K. Reinhart, and D. L. Rode for fruitful discussions.

The Angular Beam Divergence in Double-Heterojunction Lasers with Very Thin Active Regions

W. P. DUMKE

Abstract—**An analytical expression is found for the angular beam divergence from a double-heterojunction (DH) laser in the limit of an infinitely thin active region. In this limit the beam divergence is proportional to the thickness of the active region and to the index of refraction difference between the active and confining layers. A simple expression combining the limiting expressions for thin and thick active regions gives a very accurate fit to the numerical calculations of the beam divergence for intermediate active region thicknesses.**

IT HAS BEEN SHOWN by Kressel *et al.* [1] and by Selway and Goodwin [2] that double-heterojunction (DH) GaAs injection lasers may be made with thin active regions without having a large angular spread of the coherent light in the plane perpendicular to the active region. Besides having thin active regions, such lasers also had a smaller index of refraction step at the interface between the active and confining layers which allowed the light to penetrate some distance into the $Ga_{1-X}Al_XAs$ layers. In spite of this penetration and because of the superlinear dependence of gain with current in room-temperature injection lasers, the current thresholds were low, reflecting the thinness of the active layers.

Casey *et al.* [3] have numerically calculated the beam divergence at half-intensity $\theta_\perp$ as a function of active region thickness d for several values of X ($Ga_{1-X}Al_XAs$ composition). In this paper we wish to show that there is a simple expression for $\theta_\perp$ in the limit as $d \to 0$ which yields the values of $\theta_\perp$ attainable for small d and X. In calculating the limiting value of $\theta_\perp$ we will use the latest data on index of refraction for $Ga_{1-X}Al_XAs$. For intermediate values of d we shall present an expression for $\theta_\perp$ having the correct limiting behavior for thin or very thick active regions and which agrees extremely well with the detailed numerical calculations of Casey *et al.* [3].

In a symmetrical three-layer optical waveguide, the solution for the vector potential of the lowest order confined TE mode

Manuscript received December 6, 1974; revised January 30, 1975.
The author is with the IBM Thomas J. Watson Research Center, Yorktown Heights, N.Y. 10598.

is of the form [4] $A_0 \cos qx$ in the active region $|x| < d/2$ with index of refraction N_1, and $A_0 \cos(qd/2) \exp(-p|x|)$ in the confining layers $|x| > d/2$ where the index of refraction is $N_2 < N_1$. The requirements on the continuity of the tangential electric- and magnetic-field components at $x = \pm d/2$ yield a matching condition [4]

$$\tan qd = \frac{2p/q}{1 - (p/q)^2}$$

which is further constrained by the wave equation that

$$q^2 + p^2 = \frac{(N_1^2 - N_2^2)\omega^2}{c^2}.$$

As $d \to 0$, $\tan qd \to qd$ and $p/q \to 0$. The matching condition simplifies to

$$p \cong \frac{dq^2}{2} \cong \frac{d(N_1^2 - N_2^2)\omega^2}{2c^2}.$$

The far-field pattern as $d \to 0$ is due to a source field at the end face of the form

$$E(x) = E_0 \exp(-p|x|).$$

If θ is the angle between the active region plane and a line from the end face to a point a distance R from the laser (R large compared to laser dimensions) and $k_0 = 2\pi/\lambda$, then we may approximately write the field at R as

$$E(\theta) = \frac{\exp(ik_0R)}{R} \int_{-\infty}^{\infty} E(x) \exp(-ik_0 x \sin\theta)\, dx.$$

If we substitute the preceding form for $E(x)$, we obtain

$$E(\theta) = \frac{E_0 \exp(ik_0R)}{R} \frac{2p}{p^2 + k_0^2 \sin^2\theta}$$

which yields a far-field dependence of intensity on θ of

$$I(\theta) \propto |E(\theta)|^2 \propto \frac{p^2}{(p^2 + k_0^2 \sin^2\theta)^2}.$$

The half-intensity angle is determined by the condition

$$\frac{I(\theta_{1/2})}{I(0)} = \frac{p^4}{(p^2 + k_0^2 \sin^2\theta)^2} = \frac{1}{[1 + (k_0/p)^2 \sin^2\theta]^2} = \frac{1}{2}$$

which requires $\sin\theta_{1/2} = (\sqrt{2} - 1)^{1/2} p/k_0$. If $\theta_{1/2}$ is small, we may write

$$\theta_\perp = 2\theta_{1/2} \cong \frac{(\sqrt{2} - 1)^{1/2}}{\pi} p\lambda = 0.205 p\lambda.$$

In a laser with a thick active region the transverse dependence for the lowest order mode is approximately $E \propto \cos(\pi x/d)$, which can be shown to yield $\theta_\perp = 1.2\,\lambda/d$. If in the case of a penetrating mode we relate the total energy in the mode $\mathscr{E}_t$, to the average energy density in the active region $\mathscr{E}_d$, we may introduce an effective width $d^* = (\mathscr{E}_t/\mathscr{E}_d)d$ characterizing the width of the photon distribution. In the notation of Casey *et al.* [3], $d^* = d/\Gamma$. For lasers with very thin active regions it is easy to show that $d^* = 1/p$. Therefore we may write

$$\theta_\perp = 0.205\,\lambda/d^*.$$

This is to be compared with the preceding expression $\theta_\perp = 1.2\,\lambda/d = 1.2\,\lambda/d^*$ for the limit $d \to \infty$, that is for a mode which is perfectly confined. Obviously, the smooth variation of the exponential components of the mode in the confining layers contributes less to the beam divergence than if the energy were contained in an active region of width $d = 1/p$.

From the expression for p we may relate $\theta_\perp$ to the layer properties

$$\theta_\perp = 0.41\,\pi^2(N_1^2 - N_2^2)d/\lambda.$$

For $Ga_{1-X}Al_XAs$ the variation of N_2 with X is fairly linear for $X < 0.3$. For small X we may write $N_1^2 - N_2^2 \cong -2N_1 (\partial N_2/\partial X)_0 X$.

From the measurements of Casey *et al.* [5], we obtain $-N_1(\partial N_2/\partial X)_0 \cong 2.5$. Substituting this value gives a limiting beam divergence in radians for GaAs-$Ga_{1-X}Al_XAs$ injection lasers as $d \to 0$ of

$$\theta_\perp = 20 \frac{dX}{\lambda}.$$

For $d = 0.1\ \mu$m, $X = 0.1$, and $\lambda = 0.88\ \mu$m, we obtain

$$\theta_\perp = 13°.$$

Thus by having a thin active region and a small compositional difference (small $N_1 - N_2$), both of which result in a mode which penetrates deep into the confining layers, we are able to obtain a small beam divergence. The difference between the preceding value of $\theta_\perp$ and that calculated by Casey *et al.* of $\sim 11°$ for the $d = 0.1\ \mu$m and $X = 0.1$ case reflects the fact that even for these parameters we are not quite close enough to the limiting case for the preceding expression for the divergence to be perfectly accurate.

We may combine the expressions for $\theta_\perp$ in the two limits $d \to 0$ and $d \to \infty$ in a single expression of the form

$$\theta_\perp = \frac{a\,d/\lambda}{1 + a(d/\lambda)^2/1.2}$$

where $a = 0.41\,\pi^2(N_1^2 - N_2^2) = 20X$.

This expression yields the correct values for $\theta_\perp$ in the two limits, but it is a somewhat arbitrary choice of those functions having the proper limiting behavior. For intermediate values of d, however, this expression yields reasonably good agreement with the values calculated by Casey *et al.* [3], and provides a convenient formula for predicting the divergence of a given DH laser.

Having a simple expression to describe $\theta_\perp(d, X)$ we may perform some elementary analysis to see at what values of d, $\theta_\perp$ will be maximum and how this maximum varies with X. Setting $(d\theta_\perp/dd) = 0$ yields a maximum value of $\theta_{\perp\max} = \frac{1}{2}\sqrt{1.2a}$ at a value of $d = \lambda\sqrt{1.2/a}$. For a "typical" GaAs-$Ga_{1-X}Al_XAs$ DH laser with $X = 0.3$ and $\lambda = 0.88\ \mu$m, $\theta_{\perp\max} = 1.33$ rad $= 76°$ at $d = 0.39\ \mu$m. From these results, as from the earlier calculations of Casey *et al.* [3], it can be seen that many of our DH injection lasers are actually made having values of d and X close to the values which result in the largest amount of beam di-

vergence. By using a lower Al composition and active region thickness the divergence can be significantly reduced.

There is one precaution one must take, however, if reduced values of X and d are to be used. If the mode penetrates far into the confining layers, it is important that these layers be thick enough so that the intensity is sufficiently attenuated through the thickness of the layers. If the layers are too thin some of the light will leak through resulting in an increased loss and higher thresholds. From calculations which will be published elsewhere [6] this required thickness may exceed that commonly used for the top $Ga_{1-X}Al_XAs$ layer when X and d are small. For a laser with $X = 0.1$ and $d = 0.1$ μm, a confining layer thickness of ~ 3 μm is needed to prevent such leakage.

Internal Optical Losses in Very Thin CW Heterojunction Laser Diodes

J. K. BUTLER, MEMBER, IEEE, H. KRESSEL, FELLOW, IEEE, AND I. LADANY, MEMBER, IEEE

Abstract—**Theoretical calculations are presented showing the relationship between the internal laser absorption and structural parameters appropriate for CW room-temperature lasers. These diodes have submicron-thick recombination regions, and very small spacings between the heat sink and the recombination region to minimize the thermal resistance. The optical loss is shown to be strongly dependent on the degree of radiation confinement to the active region. In particular, absorption in the surface GaAs layer providing the ohmic contact becomes very significant when the intermediate (AlGa)As layer is reduced below about 1 μm. It is further shown that excessive penetration into the GaAs regions gives rise to anomalies in the far-field radiation profiles in the direction perpendicular to the junction plane. Proper design of the internal structure of the laser avoids large increases of the threshold current density as well as large decreases in the external differential quantum efficiency from interaction with the contact layer. The design curves presented can be used to predict the gain required at threshold for a broad range of structural parameters of interest in low-threshold laser design.**

Introduction

LASER DIODES designed for CW operation require the recombination region to be located in the proximity of the heat sink in order to minimize their thermal and electrical resistance. Previous work [1]–[3] has shown that an optimum combination of low threshold current density and moderate radiation-pattern beamwidth is best obtained from double-heterojunction lasers with submicron-wide active regions with strong electron-hole pair confinement but weak field confinement to the recombination region. Because the optical field may extend outside the recombination region into high-loss regions, the diode geometry and material parameters must be selected for optimum distance between the active region and the heat sink. Extreme reduction in certain layer dimensions increases the threshold current density, while excessive thickness increases the thermal resistance. This paper presents the results of theoretical calculations on the effect of structural parameters on the laser threshold. We also show both theoretically and experimentally that anomalies in the far-field radiation patterns result from complex interactions between the radiation field and highly absorbing regions in the vicinity of the recombination region.

Device Model and Radiation Distribution

The diodes selected for the present analysis are (AlGa)As double-heterojunction diodes emitting at ~8000 Å of the type which has demonstrated long-term reliability [4]. The schematic cross section of the double-heterojunction diode is shown in Fig. 1(a). Beginning at the mounting surface of the diode, region 1 is a GaAs surface layer ($p \approx 10^{19}$ cm^{-3}) about 1 μm thick for ohmic contact; region 2 is of p-type $Al_xGa_{1-x}As$ ($\sim 10^{18}$ cm^{-3}); region 3 is the $Al_yGa_{1-y}As$ recombination region ($y < x$); region 4 is the n-type ($\sim 10^{18}$ cm^{-3}) $Al_zGa_{1-z}As$ ($z > x$); region 5 is the n-type ($\sim 10^{18}$ cm^{-3}) GaAs substrate. Fig. 1(b) shows the refractive-index distribution at the lasing wavelength. Other relevant numerical parameters used in the numerical calculations presented will be discussed later. Such structures are prepared by liquid-phase epitaxy. The recombination region, not deliberately doped, has an electron concentration of 5×10^{16} cm^{-3}.

For low thermal and electrical resistance of the diode it is essential to keep regions 1 and 2 thin. Region 2 is a particularly strong contributor to the thermal resistance because of the low thermal conductivity of (AlGa)As compared to that of GaAs [5]. However, because of the spread of the optical field outside the recombination region into the surrounding ones, the structural design must be chosen to prevent excessive optical loss.

The solution of Maxwell's equations in a five-layer laser structure has been effected previously [6], [7]; we applied the results to the five-layer geometry in Fig. 2. The computer program used for the calculations uses the complex dielectric constant $\kappa = \kappa' - j\kappa''$ of each region. The real part $\kappa' = n^2$, where n is the index of refraction, while $\kappa'' = n\alpha/k_0$, where α is the absorption coefficient and k_0 is the free-space wavenumber. The structure studied here has indices of refraction n_1, n_5 (in regions 1 and 5, respectively), which are larger than the index n_3 of the optical cavity, while for the structure in [6], $n_1, n_5 < n_3$. However, the mathematical solution of the fields for both structures is identical. The reason for the similarity is due to the condition placed on the fields in regions 1 and 5, i.e., the fields must decay exponentially to zero as $|x| \to \infty$. This condition is satisfied here because the material is lossy. (The field exponential decay factor in regions 1 and 5 is strongly related to the absorption constants α_1 and α_5, as will be illustrated.) On the other hand, if regions 1 and 5 are reactive, the fields would not tend to zero as $|x| \to \infty$.

A simple intuitive understanding of the transverse-field distribution can be obtained from knowledge of the value of the complex propagation constant. Aside from their x-dependence, the propagating fields have the form $\exp(j\omega t - \gamma z)$, where $\gamma = \alpha + j\beta$; $-\alpha$ represents the modal gain; and β determines the wave characteristics along z. In normalized form, we write $\beta = k_0 B$, where B must satisfy the condition that $n_2, n_4 < B < n_3$ for energy trapped predominately in region 3. In region 3 the field has largely a sinusoidal dependence which can be represented to a good approximation by two plane waves propagating at angles $\pm\theta_1$, with respect to the z axis. These two waves combine to give a wave component along the z direction carrying a majority of the optical energy (see Fig. 2). However, since the material in all regions is lossy, a characteristic associated with the complex dielectric constant, there is an additional wave component in the $\pm x$ directions which supplies power to regions 1, 2, 4, and 5. In regions 2 and 4 the field distributions have a predominant exponential or hyperbolic dependence along the x direction because the normalized propagation constant $B > n_2, n_4$. The propagating components of the fields in regions 2 and 4 carry a majority of the energy along the z direction as indicated in Fig. 2. However, we stress the fact that since the material is lossy there will be a wave component in regions 2 and 4 supplying power to regions 1 and 5. The magnitude of the x component of the Poynting vector P_x, compared to its z component P_z, is a function of the optical properties and widths of the various regions of the five-layer structure; however, for the geometries discussed in this paper the ratio $P_x/P_z \ll 1$. In regions 1 and 5, where $B < n_1, n_5$, the transverse-field dependence consists of damped traveling waves propagating away from the active region; i.e., positive x direction in region 1 and the negative x direction in

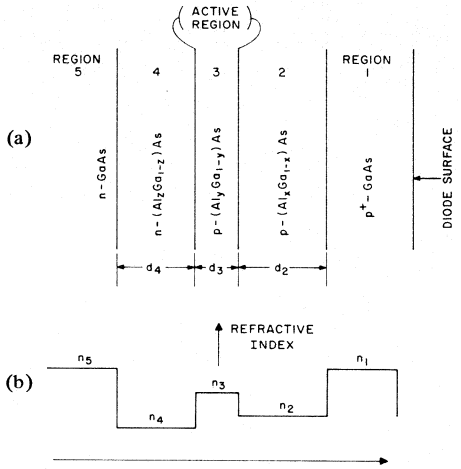

Fig. 1. Schematic of double-heterojunction diode showing the five regions relevant to the present work and the distribution of the refractive index at the lasing photon energy.

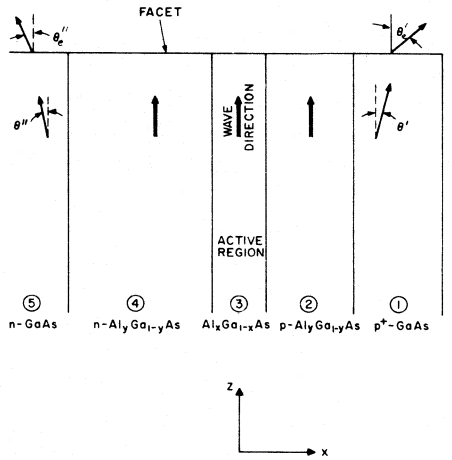

Fig. 2. Wave propagation in the five layers of the diode showing the effect of transmission through the highly absorbing GaAs regions 1 and 5 on the radiation emitted at the facet at those regions. (Not shown are the relatively small wave components in the transverse direction which carry energy from the active region into the lossy passive regions.)

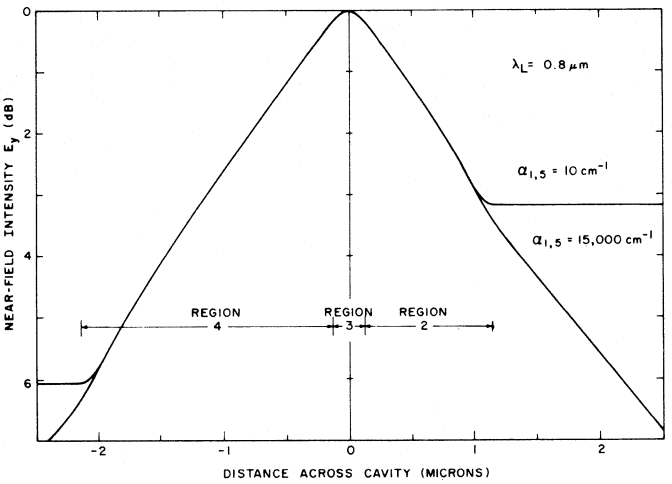
region 5. Consequently, the fields in regions 1 and 5 are composed of plane waves propagating in both the x and z directions with a resultant wave propagating at angles θ' and θ'' with respect to the z axis as shown in Fig. 2.

The decrease of the fields along the x direction in the two outer GaAs regions is dependent upon the absorption coefficient of these layers. To illustrate this effect, we show in Fig. 3(a) the near-field intensity pattern for a symmetrical structure ($n_2 = n_4$ in Fig. 1) with the parameters given in Table I and two different values for the absorption coefficient in regions 1 and 5; Case 1, $\alpha_1 = \alpha_5 = 10\ \text{cm}^{-1}$; and Case 2, $\alpha_1 = \alpha_5 = 15\,000\ \text{cm}^{-1}$, which is appropriate to above-bandgap energy radiation [8].

Case 1: The optical field penetrates through the 1-μm-thick (AlGa)As layer (region 2) and deep into the GaAs region 1. Since $n_1 > n_2$, the field does not "see" an optical barrier and propagates in region 1, and has little dependence on x because α_1 is small.

Case 2: The penetration depth within layer 1 is small because of large α_1. The higher the absorption coefficient, the shallower the penetration in a manner analogous to the "skin-depth" effect in metallic layers.



A particularly interesting fact is that the strong attenuation of the radiation by the surface layer affects the far-field radiation pattern in the direction perpencidular to the junction. This is illustrated in Fig. 3(b) which shows the far field calculated [7] for the near-field distribution of Fig. 3(a). Note the extra peak at $\theta = 60°$, the magnitude of which depends on the fraction of the power propagating in region 1. The plane wave inside the GaAs region 1, propagating at the slight angle θ' with respect to the z axis, exits the laser facet at an angle $\theta_e' = \sin^{-1}(n_1 \sin\theta')$. Fig. 3(b) shows no similar peak due to field propagating through the n-type GaAs region, because, as shown in Fig. 3(a), only an insignificant fraction of the power is now propagating in the n-type GaAs region. A strong penetration to region 5 would have resulted in an additional peak on the left-hand side of the far-field radiation pattern of Fig. 3(b).
